DEDICATION: TO ORTHODONTIC EDUCATORS AND RESIDENTS

Every text that is conceived, written and published starts with a purpose. Although this is the sixth edition of Orthodontics: Current Principles and Techniques, the concept of this multi-authored graduate level textbook started in the late 1960's with work that culminated in the 1969 publication of *Current Orthodontic Concepts and Techniques*. Why do a graduate level textbook? The answer was very simple: The principal editor and author Tom Graber, when interviewed later in life said it best—"There was a need." "The need" was defined by a widely held perception that there was a lack of supportive materials for clinicians teaching in orthodontic specialty education programs. Indeed, many of those who served as instructors and lecturers were private practice clinicians with little or no background in professional education.

The authors sought to provide a vehicle for educators to meld the then existing scientific basis of orthodontics with clinical practices in a manner that could be universally used. Course outlines that followed the textbook chapters as well as supportive slides were made available to help good clinicians become better teachers. A secondary but no less important goal for the textbook was to provide an organized platform by which practicing orthodontists could be updated on current concepts within the specialty. Tom Graber championed the need for continuing professional education and often cited G.V. Black, the father of modern dentistry, who had stated, "The professional person has no right to be other than a continuous student." The focus of the authors and editors who participated in the 1969 orthodontic text—and those who now do so in what is the eight iteration[1] has remained the same. We want to support orthodontic educators, the residents they teach and the "continuous students" orthodontic specialists must become.

With these thoughts as a background, it is to the educators and the orthodontic residents of the past, present and future we wish to dedicate the sixth edition. They embody the purpose of this text, because it is from their efforts our supportive science and clinical practice has grown and on their shoulders that rides the future development of our dental specialty.

[1]This is the sixth edition of the current series, with the title of the textbook and publisher changed in 1985. The first edition of the current series was the third for the text and included a change in title and publisher.

Behrents).

LIST OF CONTRIBUTORS

Adrian Becker, BDS, LDS, DDO
Clinical Associate Professor Emeritus
Orthodontics
Hebrew University-Hadassah School of Dental Medicine
Jerusalem, Israel

Erika Benavides, DDS, PhD
Clinical Associate Professor
Periodontics and Oral Medicine
University of Michigan
Ann Arbor, Michigan

Philip Edward Benson, PhD FDS (Orth)
Professor of Orthodontics
Academic Unit of Oral Health and Development, School of Clinical Dentistry
University of Sheffield
Sheffield, United Kingdom

Ignacio Blasi, Jr., DDS, MS
Diplomate, American Board of Orthodontics
Private practice
Tysons Corner, Virginia

Charles J. Burstone, DMD, MS, PhD†
Professor, Emeritus
Orthodontics
University of Connecticut Health Center
Farmington, Connecticut

Peter H. Buschang, PhD
Regents Professor & Director of Orthodontic Research
Orthodontics
Texas A&M University Baylor College of Dentistry
Dallas, Texas

Tamer Büyükyilmaz, DDS, MSD, PhD
Private practice
Adana, Turkey

David S. Carlson, PhD
Regents Professor
Biomedical Sciences
Texas A&M University Baylor College of Dentistry
Dallas, Texas

Lucia Cevidanes, DDS, MS, PhD
Assistant Professor
Orthodontics and Pediatric Dentistry
University of Michigan
Ann Arbor, Michigan

Stella Chaushu, DMD, PhD
Professor and Chair
Orthodontics
Hebrew University-Hadassah School of Dental Medicine
Jerusalem, Israel

Peter D. Chemello, DDS
Private practice, Northwest Oral and Maxillofacial Surgery
Arlington Heights, Illinois

Clark D. Colville, DDS, MS
Assistant Clinical Professor
Orthodontics
University of Texas School of Dentistry
Houston, Texas
Clinical Advisory Board
Invisalign
Santa Clara, California

Hali Dale, HON.B.Sc, DDS
Diplomate, American Board of Orthodontics
Private Practice
Toronto, Ontario

Jack G. Dale†, BA, DDS

Oslo, Norway

PREFACE

This is the eighth re-writing of a textbook that has remained the most widely used graduate orthodontic textbook in the world and has now been translated in to multiple languages. Tom Graber was the initial editor in the late 1960s. He was encouraged by colleagues within the orthodontic educational community to fill what they saw as a void within orthodontic specialty programs. They perceived that although there were many excellent graduate programs, there was significant variance in the educational assets these programs provided for their residents. In bringing together the thoughts of excellent clinicians and related scientists in a text specifically meant for the advanced study of orthodontics, concepts and techniques could be shared with all benefitting.

An additional thought, shared at the time in both academic and professional association circles, was the need for a means to provide better continuing education to those already in practice. Today we take for granted that technologies and concepts change very quickly, and we must keep ourselves current. Forty-five plus years ago, the need was not as self-evident. Thus, in developing a textbook with recognized and vetted authorities on a wide array of subjects impacting clinical practice, the editors could provide a critical resource to those who had completed their formal education and were subsequently in primarily solo practices offices. The concept was that the text would be a basis for continued learning—a foundation on which these clinicians could better judge new material seen in their journals and professional lectures. By the very nature of this concept, there was an inherent demand that the text itself be updated to reflect the current basis on which the orthodontic specialty was being practiced. This demanded that it be updated on a regular basis, reducing emphasis in some areas, adding in others as both basic science concepts and clinical techniques further matured.

The task of "keeping current" is not an easy one and has become more difficult with the explosion of orthodontic-related research and technical development. Additionally, in the early years of the text, chapters were developed primarily by North American-educated authors. Today's world of orthodontics is significantly expanded with great work being done globally, as is seen in the variety of locations listed by authors in our most prestigious journals. Tom Graber was often heard saying, "Science has no borders!" and as the initial editor of the text sought the best and the brightest to contribute, a tradition we are proud to uphold to this day. Tom was the solo editor for the first two editions published by Saunders and was joined by Brainard Swain when C.V. Mosby became the publisher of what was then the first edition of the current Mosby (now Elsevier) series. Subsequently Tom, seeking a broader expertise to aid in the development of the text, was joined in the editorial role by Robert Vanarsdall in the second edition and then Katherine Vig in the third edition followed by Lee Graber and now Greg Huang in this sixth edition. As the scope of the orthodontic specialty has grown, so has the need for added editorial background and expertise.

We write this text with the presumption that those using it will have had a basic exposure to orthodontic principles provided in dental school education both within their undergraduate dental courses and from basic orthodontic texts used in the DDS/DMD curricula. The purpose of this graduate orthodontic textbook remains the same—to provide a compendium of information from authors who are experts in specific topics that are considered important to the education of orthodontic specialists. This was the vision of Tom Graber when he wrote the first edition which met with much acclaim from educators who used it as the assigned readings for their residents. It is to these educators and the orthodontic residents of the past, present and future that we have dedicated the sixth edition.

In the writing of this text, we are acutely aware of an added need within orthodontic education. That call is to encourage current residents as well as clinicians to become part of the orthodontic specialty teaching and/or research corps for the future. This text demonstrates the broad scope of orthodontics, from basic science concepts to intricate clinical techniques as well as patient management considerations. With such breadth, the specialty provides opportunities for motivated individuals to consider becoming part- or full-time educators or research scientists (or both). We can all remember the teachers we have had who made special impact on our lives. They shared their passion for their subject, the excitement over their research and their interest in mentoring a following generation. There is much within the chapters of this text about which to have excitement and passion—as well as provide motivation for answering still vexing problems through clinical and basic science research.

What is new in the presentation of this sixth edition? The most notable changes are in how the textbook may be used. The advent of computers and advances in technology for transmitting information have resulted in transforming the methods with which we share information and teach students. These technology changes have been matched by research in education that demonstrates that there is broad variability on how individuals learn. By the fifth edition we had started to put part of the text online. This sixth edition expands that effort and the ease with which the electronic version of the text may be used by way of the Expert Consult, a feature rich eBook format for medical and dental education. The ability to have added material online also increases the opportunity for more content as discussed below. Downloading sections and chapters on to your computer, laptop or tablet—or even your phone—is now possible and widely used. Using Expert Consult, readers can access and work with the text on any platform and even communicate on material with colleagues through social media. Indeed, with the inherent convenience of an electronic format, and the opportunities for editors and authors to update material without waiting for a "new edition", the investment one makes in the purchase of the text has the potential to last long after the printed publication date. These considerations coupled with the high cost of physically printing a textbook, could result in the sixth edition being the last one offered in a printed format.

What has changed in terms of content? A lot! Fully one third of the material in this edition is completely new. In addition, chapter authors from prior editions have been joined with co-authors to further update their own material. Improvements range from the organization of the chapters and the subject material to the new chapter authors who have joined us to provide the best background for orthodontists possible within the confines of a broad-based textbook. Additional information on the science that supports orthodontics, diagnostics and therapeutic interventions has been developed. New chapters on adjunctive treatments as well as management of the potential adverse sequelae from orthodontics have been added. We also have selected several chapters from prior editions and placed them online as “classic chapters”. These represent clinical topics that had to be incorporated into other chapters to maintain the already “heavy” book in a manageable size. The material in these online-only chapters further expands the scope of the textbook, better matching the increased scope of material with which a practicing orthodontist must be knowledgeable.

Finally, the chapters within the text have been reorganized to better match the progression of subjects addressed in an orthodontic specialty residency program. Section heads provide a means by which educators and residents can better identify subject material as they move through the material. Equally important, the re-organization provides the practicing clinician with a logical grouping of subjects that can be efficiently referenced. As editors, we hope that the challenge of presenting added material to residents and practitioners is made easier by way of the improved organization of material within the text.

PART ONE

Foundations of Orthodontics

Chapter 1: Craniofacial Growth and Development: Developing a Perspective. In the opening chapter of the text, authors David Carlson and Peter Buschang provide an up-to-date discussion of craniofacial growth and development. They review the basic anatomical and functional structures within the craniofacial complex, and starting with pre-natal development, describe the complex interrelationships influencing form and function. In describing the importance of the subject material, they aptly state, “…knowledge of how the craniofacial complex develops and grows provides the foundation for understanding the etiology of the various dental and skeletal malocclusions, the best of all possible treatment approaches, and how patients might be expected to respond after treatment.”

Chapter 2: Genetics and Orthodontics. James Hartsfield, joined in this edition by Lori Ann Morford, has further developed basic principles of genetics while focusing on aspects that directly affect orthodontic clinicians. Clinical concerns including aberrant facial growth and development, tooth agenesis and size variability, dental eruption problems and tissue response to orthodontic forces all are impacted by genetic factors. The interaction between environmental factors and genetic expression determine an individual’s response to treatment interventions. The authors complete their chapter with a look to the future and the general movement toward “personalized” medical and dental treatment.

Chapter 3: The Biologic Basis of Orthodontics: Tissue Reactions in Orthodontics. Birgit Thilander builds on the contributions of prior authors of this chapter, Kaare Reitan and Per Rygh. There is a review of the tissue components involved in tooth movement followed by a detailed discussion of the response of those tissues to various forces. The local tissue consequence of various types of tooth movement are discussed and illustrated as well as the long-term tissue changes that take place during “retention.” A review of the temporomandibular joint underscores the importance of considering tissue reactions in locations distant from orthodontic force application.

In Tooth Movement at the Cellular and Molecular Level, Zongyang Sun and Nan Hatch provide a new chapter segment that focuses on the most current understanding of the control of tooth movement, that is, cellular and molecular changes in response to physiologic as well as orthodontic forces. The means by which external forces are “seen” by cells in order to stimulate tooth movement are discussed in terms of the biologic signaling mechanisms involved. The tissue changes outlined in the first section of this chapter are further described here in terms of components of mechanobiology. There is also a discussion on how biomedicine is opening doors to future patient-specific treatment alternatives.

Chapter 4: Bone Physiology, Metabolism, and Biomechanics in Orthodontic Practice. Eugene Roberts has now been joined by Sarandeep Huja to rewrite this chapter focusing on craniofacial osteology, the dynamics of bone physiology and the impact on orthodontic treatment. In addition, there is detailed discussion on osteoblast histogenesis (bone formation), osteoclast recruitment (bone resorption), and how this interplay affects tissue response to tooth-moving forces. Bone adaptations to temporary anchorage devices are reviewed as well as those aspects that play in favor of retention of mini- screws versus early loss. Finally, the authors address how it is possible to increase the rates of tooth movement by altering the local environment.

Chapter 5: Application of Bioengineering to Clinical Orthodontics. The late Charles Burstone completed the rewrite of this chapter shortly before he died. The recognized preeminent author on orthodontic biomechanics, Dr. Burstone brings together physics, mathematics and engineering to provide the theoretical background for orthodontic appliance construction and manipulation. Specific topics include discussions of the biomechanics of tooth movement (centers of rotation, force magnitude, optimal force and stress), orthodontic appliance components, mechanical properties of wires, selection of proper wires, influence of wire size-length-cross-section, archwire design and the role of friction. No matter what appliance the orthodontic clinician decides to use, it is these shared physical principles that affect the biomechanical success and efficiency of treatment.

Chapter 6: Clinically Relevant Aspects of Dental Materials Science in Orthodontics. Theodore Eliades is joined in this edition by Iosif Sifakakis to discuss the important considerations for the everyday materials in use by the clinical orthodontist. What are the characteristics of different brackets and wire materials, and how do they influence orthodontic mechanotherapy? What are the important clinical concerns with bracket bonding materials, and what might prove adverse to the patient if not properly managed by the orthodontist? What are the considerations in longterm fixed retainer wear, and what wire should a clinician use? These questions and other practical issues are answered within this chapter.

Chapter 7: The Role of Evidence in Orthodontics. One cannot attend a dental or medical meeting without some reference to “evidence-based” practice. The early years of orthodontics were characterized by “gurus” espousing one concept or another without much call for support. “Expert opinion” determined what clinicians in private practice would use for patient care. Today’s clinicians are faced with the imperative to use a balanced approach to clinical decision making. Matching findings from respected research with the one’s experience and patient goals is a challenge to all practitioners. We all have hopes of providing “the best of care” and also need to respect potential medicolegal issues as we treat patients. David Turpin and Greg Huang discuss how today's clinicians can evaluate the broad range of relevant information from multiple sources and be biased to make better decisions by way of the best evidence available.

PART TWO

Diagnosis and Treatment Planning

Chapter 8: The Decision Making Process in Orthodontics. William Proffit and Tung Nguyen have restructured this chapter to better fit with the background of entering orthodontic residents and seasoned clinicians in orthodontic specialty practice. The focus is on the process of diagnosis and treatment planning, providing a method to systematically evaluate patient information and organize it in a way that helps to avoid errors of omission. Using a problem oriented approach, the authors demonstrate how (1) excellent diagnostic records, (2) a thorough case evaluation and (3) a priority-based listing of findings form the basis of an appropriate therapeutic plan.

Chapter 9: Special Considerations in Diagnosis and Treatment Planning. We are all aware of parent and patient expectations for improved cosmetics after orthodontics. Indeed, very few patients have an appreciation for functional considerations, but they are able to point to a specific tooth out of alignment or an uneven smile. David Sarver dissects the esthetic evaluation of the face and provides a broader context for patient evaluation than what has historically been considered "orthodontic diagnosis". His protocols for the evaluation of facial proportions (macroesthetics), evaluation of the smile (miniesthetics), and evaluation of the teeth and surrounding gingiva (microesthetics) are detailed within this chapter. Societal pressures create the desire for optimal dentofacial esthetics and it falls to the orthodontist to make a thorough evaluation of these characteristics on behalf of each patient.

Chapter 10: Psychological Aspects of Diagnosis and Treatment. This chapter by Leslie Will provides information on the psychological assessment of patients and how it can be accomplished within the context of an orthodontic evaluation. It describes psychological disorders and how clinicians can best manage affected patients. Patients with craniofacial anomalies present a subset of those seen in most clinical practices, but these "special needs" patients require more than an understanding of their physical challenges. The chapter has been expanded to include important psychological considerations for orthognathic surgery patients and the effect of abrupt facial change.

Chapter 11: Orthodontic Diagnosis and Treatment Planning with Cone Beam Computed Tomography (CBCT) Imaging. This is a new chapter and reflects the increasing use of CBCT in orthodontics. CBCT has been available for quite a while, with increased utilization in routine orthodontics over the past 10 years related to improved availability and reduced patient radiation dosages. Our patients see and all of us work in a three dimensional world. One can readily understand the appeal of 3D imaging to patients and clinicians alike. Authors Lucia Cevidanes, Erika Benavides, John Ludlow and Antonia Ruellas have internationally recognized craniofacial imaging expertise. They have joined to provide an outstanding discussion on how CBCT may be used to enhance orthodontic diagnosis and treatment.

Chapter 12: Upper Airway, Cranial Morphology, and Sleep Apnea. As an additional new chapter we have added information in regards to evaluating patients for morphologic and functional traits that may predispose to disturbed sleep syndromes. Juan Martin Palomo, Hakan El, Leena Palomo, and Kingman P. Strohl provide an in-depth discussion on identifying airway problems, and a thorough review of sleep disordered breathing and the classification of associated clinical problems. They discuss how an orthodontist might influence airway patency through various treatment modalities. The authors underscore how the orthodontist fits in to a multi-disciplinary team to best manage these multifactored patients.

Chapter 13: Orthodontic Therapy and the Patient with Temporomandibular Disorder. Jeffrey Okeson is the internationally recognized authority on TMD disorders and especially how these disorders potentially impact orthodontic patients before, during and after treatment. In this updated chapter he reviews the basic concepts of orthopedic stability, how to perform a complete TMD evaluation, and how to develop a treatment plan. His discussion of a stepwise approach for TMD problems that may arise during treatment is a must read for residents and practitioners.

Chapter 14: The Orthodontist's Role in a Cleft Palate–Craniofacial Team. Katherine Vig and Ana Mercado review the important considerations for orthodontists who are treating craniofacial anomalies as part of craniofacial teams. The emphasis is on an orthodontist as a component of "the team" and the appropriate timing for various interventions for the cleft patient. New to this edition is an excellent discussion of the clinically vexing issue of how to approach the missing maxillary lateral incisor in patients with cleft palate. The authors do an excellent job of emphasizing the long term relationship with craniofacial patients and how the clinician must recognize the multi-stage needs of these patients.

PART THREE

Mixed Dentition Diagnosis and Treatment

Chapter 15: Patient Management and Motivation for the Child and Adolescent Patient. How does one create an office environment that has patients who are happy and appreciate the services provided? Patrick and Patricia Turley bring information from the pediatric dental literature as well as patient management sphere to develop this new chapter for the sixth edition. The theme of the chapter is how to best guide young patients to comply with instructions both in the office setting and at home. The Achilles heel for orthodontic treatment is most often patient cooperation. These authors present guidance on how best to communicate to patients at different ages and how to encourage compliance with home care responsibilities for hygiene as well as appliance wear. They point out that clinicians need to have a systematic approach for monitoring patient cooperation as well as routine measures to intervene when compliance is lacking.

Chapter 16: Optimizing Orthodontics and Dentofacial Orthopedics: Treatment Timing and Mixed Dentition Therapy. For an orthodontist, the opportunity to intervene and reduce the severity of a developing malocclusion needs to be recognized. Additionally, guidance that can improve the maxilla–mandibular relationships and space for erupting permanent teeth can provide significant benefit to growing patients. The questions for the clinician revolve around when and how one should intervene in a growing child. In this chapter, authors James McNamara, Laurie McNamara McClatchey, and Lee Graber provide an organized approach to mixed dentition diagnosis and treatment. With the broad spectrum of malocclusions that present to the practitioner, there are an equally varied considerations for treatment timing and approach. There is a brief discussion of serial extraction technique within this chapter, but readers are encouraged to see Chapter 34, Interceptive Guidance of Occlusion with Emphasis on Diagnosis (online only) for further information. Chapter 16 provides information on the proper age for dentofacial orthopedic–orthodontic intervention, appliance construction and management. The appliance types and treatment protocols presented in the chapter are evidence based, but it is understood that there are many types of orthodontic appliances that can be selected as long as the underlying principles of diagnosis, appropriate timing and orthopedic–orthodontic therapy are maintained.

PART FOUR

Orthodontic Treatment

Chapter 17: Contemporary Straightwire Biomechanics. Since the straightwire appliance was introduced in the 1970s its use has grown to where it is now the most popular fixed orthodontic appliance design available today. In this chapter, Antonino Secchi and Jorge Ayala provide (1) the historical basis of the appliance, (2) the principles of precise bracket placement and (3) the three separate phases of straightwire mechanics. With excellent clinical cases and explanations, they detail the specific wire sequences, anchorage considerations, and finishing mechanics designed to optimize the benefits of the straightwire bracket system.

Chapter 18: Nonextraction Treatment. Orthodontists are faced everyday with decisions of whether or not they need to remove permanent teeth as part of a comprehensive treatment program. Our journals have documented the trends to more extraction or fewer extractions with a reduced rate of extractions currently in vogue. Realistically, these extraction decisions should be made on the basis of a solid diagnosis and evidence-based treatment planning. With this as a given, what techniques can be used to maximize the success of a non-extraction approach in a borderline patient? This chapter authored by Robert Vanarsdall and Raffaele Spena details an approach that can provide needed dental arch space in a predictable fashion and provides case examples.

Chapter 19: Standard Edgewise: Tweed-Merrifield Philosophy, Diagnosis, Treatment Planning and Force Systems. For many years, orthodontic residents and clinicians have traveled to Tuscon, Arizona to take the "Tweed Course," the oldest dental continuing education program in the world. This chapter is written by James Vaden and Herbert Klontz, co-directors of the Tweed Foundation, along with the late Jack Dale. It provides an historical perspective on the development of the Tweed technique, presents diagnostic and treatment concepts, and describes the Tweed-Merrifield edgewise appliance. The authors review the steps of the Tweed technique as currently practiced and present excellent illustrative case material.

Chapter 20: Biomechanical Considerations with Temporary Anchorage Devices (TADs). The use of temporary anchorage devices has greatly increased the ability of the clinical orthodontist to move teeth efficiently without the side effects of reciprocal undesired moments of force. "Absolute anchorage" as provided by these adjuncts provides a platform from which the clinician can better move teeth in all three planes of space. They have literally increased the range of orthodontic mechanotherapy. Authors Jong Suk Lee, Jung Kook Kim and Young-Chel Park have combined their internationally recognized expertise to provide a discussion of the biomechanical considerations when using TADs.

Chapter 21: Adult Interdisciplinary Therapy: Diagnosis and Treatment. Adult orthodontic treatment has continued to increase as a percentage of the patients seen by orthodontic specialists. There are many reasons including the ability to use "esthetic" treatment appliances, the increased interest in adults in their long term dental health, and the improved understanding within the general dental community that orthodontics can be an integral part of an overall restorative plan. Robert Vanarsdall and David Musich discuss the added considerations when treating adult patients. Treatment criteria differ, and there is concern for adverse tissue response especially where compromised tissue relationships are present before the start of orthodontics. This chapter reviews adult orthodontic diagnostic and treatment regimens, limitations in adult care, and compromises that must be made as well as the special demands for long term retention. Case reports provide excellent reference material for the subject.

Chapter 22: Periodontal-Orthodontic Interrelationships. As we see more adults entering comprehensive orthodontic treatment, we must be more attuned to the implications of periodontal issues. In this updated chapter, Robert Vanarsdall, Ignacio Blasi and Antonino Secchi review periodontal issues that impact orthodontic tooth movement. They describe periodontal "high risk" factors, mucogingival considerations, and problems with ectopic as well as ankylosed teeth. A new section on alveolar decortication and augmentation grafting has been added to address the increased use of these procedures designed to develop the alveolar housing and potentially increase the speed of tooth movement. Excellent clinical examples are pictured throughout the chapter.

Chapter 23: Orthodontic Aspects of Orthognathic Surgery. David Musich and Peter Chemello discuss the added considerations for patients who present with treatment needs that exceed the potential for orthodontic mechanotherapy alone. Diagnostic considerations and a systematic protocol are presented as a guide for orthodontists and oral and maxillofacial surgeons teaming up to provide coordinated surgical care. What are the potentials of surgical orthodontics? What are the problems and pitfalls that must be addressed? What are the timing issues when considering jaw surgery? What are the risks of treatment, and of course, how can the clinician help to stabilize results with long term retention? These questions and more are addressed within this chapter.

Chapter 24: Self-Ligating Bracket Biomechanics. The increased use of self-ligating brackets has brought forth many discussions at orthodontic meetings, articles both for and against their use, and direct-to-consumer marketing that has resulted in more questions from patients as they interact with their orthodontists. This chapter authored by Nigel Harradine provides an historical perspective on self-ligating techniques and proceeds to review the advantages and disadvantages of these appliances. Although some of the advertised claims for reduced treatment times may not have been demonstrated in systematic reviews of the technique, there do appear to be positive indications for clinicians. This chapter provides an unbiased view of current findings and makes specific recommendations for the use of these brackets.

Chapter 25: Lingual Appliance Treatment. Lingual appliance treatment has had more popularity in Europe and Asia than in North America. That may change as increasingly more clinicians adopt partial or full fixed lingual appliance treatment in their offices. This trend has been greatly aided by the integration of three dimensional modeling, the development of custom braces and/or robotically bent archwires, and increased call of "invisible" treatment by adult and adolescent patients. In addition, there is an added benefit of minimal risk of labial surface decalcification—scars seen from labial therapy— with lingual bracket treatment. This chapter has been completely re-written and is co-authored by Dirk Weichmann and Dan Grauer. Although the authors focus on their own lingual appliance type, the principles they discuss can be generalized to a number of lingual treatment systems.

Chapter 26: Clear Aligner Treatment. This chapter has been re-written by three of the most knowledgeable clinicians in the use of clear aligners, David Paquette, Clark Colville and Timothy Wheeler. The chapter focuses on the Invisalign system, the most researched and used clear aligner system in the world. The authors discuss the unique aspects of diagnosis and treatment planning for clear aligners. The continuing development of adjuncts within the aligner system has increased the type and range of tooth movement that can be accomplished. Significant research has been reported and provides a basis for discussion of what movements can be accomplished more easily—and what becomes more difficult with aligners. This comprehensive chapter provides critical considerations that distinguish treatment provided by an orthodontic specialist from the clinician who has less of a background.

Chapter 27: Bonding in Orthodontics. The premier authority on orthodontic bonding, Bjorn Zachrisson is joined in this updated chapter by Serdar Usumez and Tamer Büyükyilmaz. Adhesive dentistry is the norm for restorative clinicians, but direct and indirect bonding of brackets to enamel and restorative materials for orthodontics is equally important. This detailed chapter reviews patient preparation for bonding, techniques for the application of brackets to teeth and artificial surfaces, indirect bonding protocols, re-bonding considerations and the use of bonded lingual retainers. Additionally there is a discussion of the use of microabrasion and resin infiltration to repair decalcified enamel areas. The technical procedures are well documented with clinical pictures.

PART FIVE

Specialized Treatment Considerations

Chapter 28: Management of Impactions. This is a totally new chapter designed to aid clinicians in developing a diagnostic and therapeutic protocol for impacted teeth. Adrian Becker and Stella Chaushu are the internationally respected leaders in this important area of orthodontic diagnosis and treatment. The chapter reviews the etiology of impactions, the prevalence of impactions of specific teeth, the assessment of impactions and finally the therapeutic interventions that are required of the clinician. The authors discuss areas for potential failure in management of impactions and provide clinical suggestions to improve success. The chapter is well illustrated in support of the recommended clinical procedures.

Chapter 29: Management of Dental Luxation and Avulsion Injuries in the Permanent Dentition. Patrick Turley has provided a new chapter to cover an aspect of practice that gets little attention in orthodontics, the management of dental trauma. An orthodontists is often the first to see a youngster who has had teeth displaced by way of accident—often because this is the dental office the family has seen most often during the adolescent years. The addition of this chapter fills a prior void by addressing the sequelae of trauma to the teeth, acute management of injuries to the teeth and alveolar structures, and treatment of avulsed teeth. The author also provides information on the importance of treatment of overly procumbent teeth to reduce the risk of incisal fractures. This is information that parents in addition to clinicians need to know!

Chapter 30: Iatrogenic Effects of Orthodontic Treatment: Prevention and Management of Demineralized White Lesions. This is another new subject area addressed in an added chapter for the sixth edition. Well known clinical researchers and authors Philip Benson and Norah Flannigan review the potential for adverse effects of orthodontic appliance wear on labial surfaces that have bonded attachments. The most common adverse effect is the development of white spot lesions. The authors review the prevalence of the problem, means by which it may be diagnosed and most importantly, how these lesions can often be prevented.

In Root Resorption, Glenn Sameshima and M. Ali Darendeliler look at the problem of reduced root length during tooth movement. What are patient and mechanotherapeutic predisposing factors for root resorption? What should the clinician do when root resorption is expected or detected? What is the long term prognosis for teeth with foreshortened roots? All clinicians see these problems in daily practice, and this chapter provides an excellent summary of clinical considerations.

Chapter 31: Minimally and Noninvasive Approaches to Accelerate Tooth Movement: Micro-osteoperforations. Patients are always attracted to decreasing the time it takes to complete orthodontic treatment. Recent advances in the understating of bone biology have been applied to a number of adjunctive techniques that in certain situations may reduce the time for orthodontics. In this new chapter, Ignacio Blasi looks at the use of micro-osteoperforations and the ability of these perforations to increase bone turnover rates, providing for increased speed of tooth movement. Studies have been done that demonstrate a localized positive effect on the speed of tooth movement.

In Low-Level Mechanical Vibrations, Dubravko Pavlin presents information on the influence of low level mechanical vibration on orthodontic treatment, a technique borrowed from orthopedic colleagues. Some of the animal and human studies have reported increased rates of tooth movement and an ability to reduce pain perception when low level vibration therapy is used. Still other studies report no clinical effectiveness. Although the jury is still out on this technique, clinical and basic science research into adjuncts that can influence biologic factors, are likely to bear fruit in the future.

Chapter 32: Biodigital Orthodontics: Integrating Technology with Diagnosis, Treatment Planning and Targeted Therapeutics. Rohit Sachdeva presents a discussion of how clinical decision making should be accomplished, with enhanced integration of digital technologies. Although this chapter focuses on just one of the technology systems available to orthodontists, the thought process that underlies the use of these technologies is shared. These technologies are tools and only serve to enhance the principles of sound diagnosis and treatment planning. They can make good clinicians better, but their sophistication precludes the ability for poorly educated dental practitioners to use them properly. Benefits to dental specialists can be significant with improved abilities at both diagnostic evaluation and treatment planning as well as, in some instances, the fabrication of appliances. These technologies gain their benefit in reducing the "error of the method" of conventional orthodontics.

PART SIX

Orthodontic Retention and Post-Treatment Changes

Chapter 33: Stability, Retention, and Relapse. Don Joondeph is joined in this updated chapter by colleagues Greg Huang and Bob Little, all respected clinicians with a wealth of research material on post-orthodontic treatment changes, developed over many years at the University of Washington. The authors outline a series of problems routinely addressed by orthodontic treatment. With evidenced-based suggestions, they provide important clinical recommendations to reduce adverse post-active treatment changes that take place over time. "Maturational change" to varying degrees is the norm, but patients often have an unrealistic expectation that their teeth will "stay perfect" after orthodontics. Perfection remains a goal, but the structural and functional environment within which the dentition exists over time makes excellent retention planning a "must" to preserve treatment accomplishments and long term patient satisfaction. The authors provide information gleaned from the UW retention studies as a basis for their clinical recommendations.

PART SEVEN

Classic Chapters (online only)

Chapter 34: Interceptive Guidance of Occlusion with Emphasis on Diagnosis. Although the general topic has been reviewed within Chapter 16, this classic chapter from Jack and Hali Dale provides more in depth background on the diagnosis of space problems in the mixed dentition and associated interceptive treatment modalities. Diagrams representing the stages of tooth eruption are coordinated with photographic case documentation of a variety of malocclusions secondary to space problems. Interception of crowding through a series of staged clinical decisions is demonstrated. Guided tooth removal is presented as an option for interceptive orthodontics, with goals for decreased time in fixed orthodontic mechanotherapy.

Chapter 35: Functional Appliances. The use of functional appliances remains high world-wide and the material herein provides background important to orthodontic specialist clinicians. This chapter was authored by the late Tom Graber, the original author and editor of the textbook. The goal of the chapter (originally published in the 4th edition) is to provide a basic understanding of how functional appliances work as well as a discuss the attributes of the most widely used designs. Although the topic is briefly addressed in Chapter 16, this specific chapter focuses more in detail on functional appliance construction and clinical management. The author reviews the mechanism of Class II correction with functional jaw orthopedics, compares fixed with removable functional appliance designs and relates how clinicians may concurrently use functional jaw orthopedics with fixed bracket treatment. The chapter is well illustrated with clinical case material and diagrammatic representations of expected treatment results. Orthodontic residents and experienced clinicians alike will gain much from this thorough review of functional jaw orthopedics.

Chapter 36: Treatment of the Face with Biocompatible Orthodontics. This "classic chapter" by Dwight Damon reviews diagnosis and treatment planning protocols used with one of the most popular fixed appliance clinical techniques in use today. Chapter 24 appropriately discusses the general topic of self-ligation brackets, but this chapter on the specific use of the Damon technique has been one of the most requested since its original publication in the fourth edition. The author uses a series of case studies to demonstrate diagnostic considerations and treatment of a variety of malocclusion types. Although the bracket design has improved since the original publication of this chapter, the principles behind the treatment remain the same and are applicable to the self-ligating bracket systems currently available.

In re-writing and presenting this sixth edition of *Orthodontics: Current Principles and Techniques* we are well aware that an undertaking of this sort requires help from many sources. We are thankful for the great work of our authors, those who have been with us before and the outstanding colleagues who have joined them. Our authors have been pressed by us as well as our publisher to succinctly provide their best material. They have done so admirably with the result that we have succeeded in giving our educators and residents a broad based textbook that provides the foundational knowledge for an orthodontic specialist. We have dedicated this sixth edition of the text to them and to the degree that we have made their teaching and learning efforts easier, we are very happy!

This text revision would never have been completed without an outstanding editorial team at Elsevier. Thanks go to Kathy Falk, Laura Klein, Anne Schook, Srividhya Vidhyashankar and all of their supporting staff. As in any large project of this type, problems arise. It is these folks who went above and beyond their normal work hours and assignments to overcome challenging issues and keep us on track. The quality of production was enhanced over prior editions in part because of improved editing and printing technologies, but most of all because of the diligence of the Elsevier personnel.

In this edition of the text, we added a new editor, Greg Huang, chair of the orthodontic department at the University of Washington. His strong contributions were important in many seen and unseen ways. All of us as editors have shared an excitement for the educational mission of the text, one that carries over from the first volume edited by Tom Graber more than 45 years ago. We are thrilled that we can share the expertise of our authors with our colleagues. We remain personally positive and passionate about the orthodontic specialty. Our hope is that the enthusiasm that we share for orthodontics comes through the pages of the text and helps to motivate a new generation of educators, residents and practitioners.

Craniofacial Growth and Development: Developing a Perspective

David S. Carlson and Peter H. Buschang

OUTLINE

This chapter is enhanced with the following electronic assets at www.expertconsult.com: 2 tables.

INTRODUCTION

An appreciation of the biological principles associated with growth and development, especially of the structures composing the craniofacial complex, is essential for attaining competency within the field of orthodontics. Particular emphasis for the advanced practice of orthodontics is placed on the hard tissues comprising the craniofacial regions, i.e., the skeletal structures and the teeth, because these are the primary components of the craniofacial complex that the orthodontist addresses during treatment. Development, growth, and function of other craniofacial structures and tissues, such as muscles, neural tissues, and pharyngeal structures, as well as spaces such as the airway, are also of major interest to orthodontists. However, those elements are important primarily in terms of their influence—structurally, functionally, and developmentally—on the growth, size, and form of the skeletal elements of the face and jaws.

This chapter emphasizes postnatal growth, principally of the skeletal structures of the craniofacial complex, because of its importance in orthodontic treatment. Considerable attention is also given to prenatal development of craniofacial tissues and structures because it is critical for understanding postnatal growth. The reader is referred to a number of excellent references on developmental biology and human embryology for comprehensive reviews of early craniofacial development.[1,2]

SOMATIC GROWTH

The size and form of the craniofacial complex are major components of an individual's overall body structure. Moreover, the growth and maturation of the body as a whole, referred to generally as *somatic growth*, are highly correlated with those of the craniofacial complex. Therefore, clinical evaluation of the status and potential for craniofacial growth, and thus of treatment planning in orthodontic patients, is highly dependent on an understanding of the somatic growth process.[3]

Differential Development and Maturation

In his classic work during the 1930s, Scammon[4] drew attention to the fact that the rate and timing of postnatal maturation, measured as a proportion of total adult size, vary widely among major systems of the human body (Fig. 1-1). In what has become known as "Scammon's curve," for example, maturation of the central nervous system is shown to be completed primarily during the last trimester of gestation through age 3 to 6 years. As a result, the cranial vault, which houses the precociously developing and enlarging brain, is disproportionately large in the infant relative to the rest of the craniofacial region (Fig. 1-2). In contrast, the reproductive organs become mature a decade later, during adolescence.

The rate of general somatic growth and development, which includes the skeletal and muscular systems, is characterized by an S-shaped curve. The relative rate of growth is very high prenatally but then decreases during infancy and becomes even slower during childhood. The rate then accelerates greatly with the initiation of adolescence through the point of peak growth velocity, after which it slows once again and effectively stops altogether in adulthood. Development and growth of the craniofacial complex is intergraded between neural and somatic maturity patterns. The gradient moves from the cranium, which is the most mature, through the anterior cranial base, posterior cranial base and maxillary length, upper face height, corpus length, to ramus height, which is the least mature and most closely approximates the general S-shaped pattern of general somatic maturation.[5]

Overall somatic growth, including the onset and end of puberty, is coordinated throughout the body by sex hormones and growth factors that are expressed differentially during the first two decades of postnatal life. However, the timing, rate, and amount of secretion of endocrine factors vary significantly between males and females and within each sex relative to chronologic age.

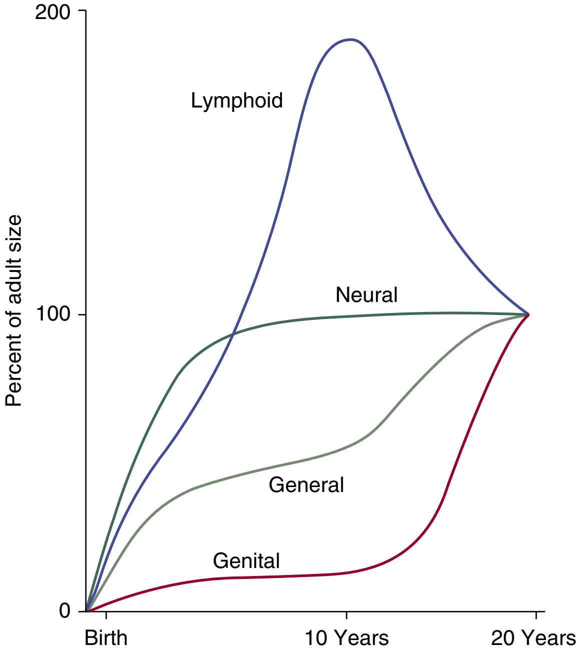

FIGURE 1-1 *Scammon's curve* illustrating the fact that different systems of the body have different rates of development and come to maturity at different ages.

Variation in Rates of Growth during Maturation

Two episodes of relatively rapid growth, or growth spurts, have been documented for both general somatic and craniofacial growth. The lesser of these, the mid-childhood spurt, takes place in approximately 50% of children between 6.5 and 8.5 years of age. The mid–growth spurt tends to occur more frequently and approximately 1 year later for boys than girls.[6] The more prominent adolescent growth spurt begins with the onset of puberty, at approximately 9 to 10 years of age in females and 11 to 12 years in males (Fig. 1-3). Female and male peak height velocities (PHV) are attained on average at 12 and 14 years of age, respectively, for North Americans and Europeans.[7] Females complete adolescence approximately 2 or more years ahead of males. The extra years of childhood growth prior to adolescence in males, as well as the slightly greater rates of adolescent growth and the slightly lengthier adolescent period, explain most of the sex differences in overall body size as well as in craniofacial dimensions.

Because growth of craniofacial structures is correlated with general somatic growth, the timing of peak height velocity (PHV), which occurs at the pinnacle of the adolescent growth spurt, is especially useful for estimating peak maxillary and mandibular growth velocity. It has been shown that maxillary growth attains its maximum rate slightly before PHV, while the maximum rate of mandibular growth occurs just after PHV.[8,9]

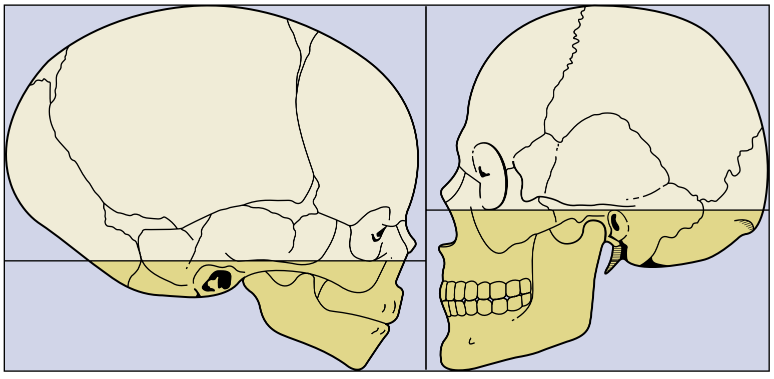

FIGURE 1-2 Disproportions of the head and face in infant and adult. The neurocranium, which houses the brain and eyes is precocious in its development and growth and therefore is proportionately larger than the face during infancy and early childhood. (Adapted from Lowry GH. *Growth and Development of Children.* 6th ed. Chicago: Year Book Medical Publishers; 1973.)

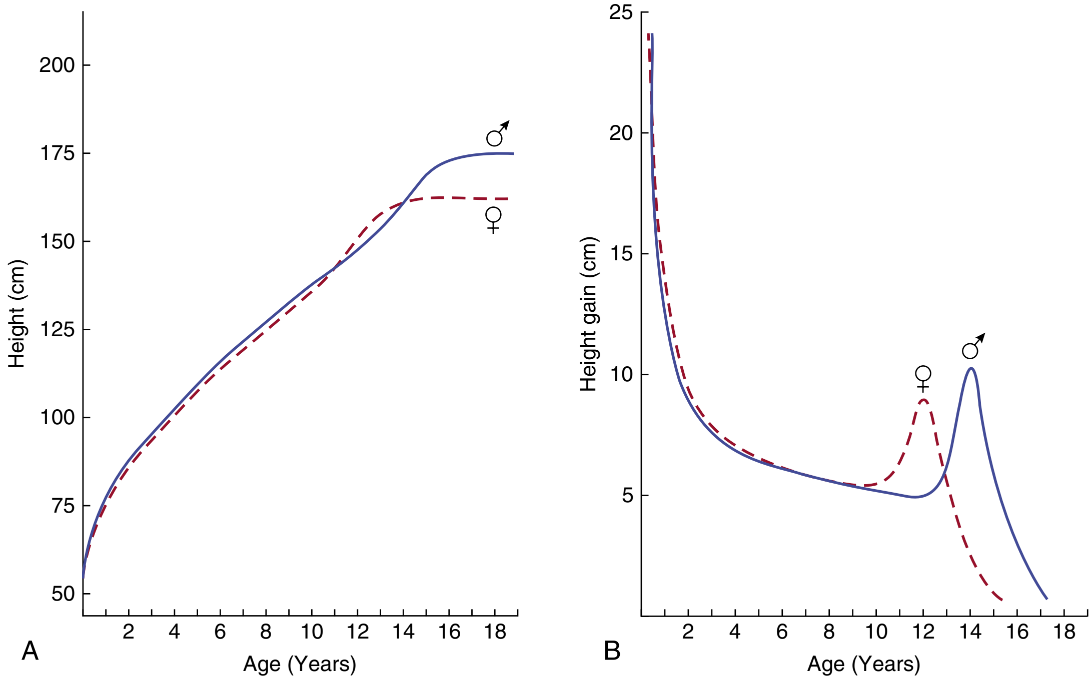

FIGURE 1-3 Growth velocity curve (growth per unit of time) for skeletal growth as general measure of human ontogeny. Velocity of growth is characterized by decrease in growth rate beginning in the last trimester of prenatal development through maturation in the adult. During adolescence, hormonally mediated growth typically occurs to bring about a spurt in skeletal growth (PHV, peak height velocity). Pubertal growth spurt is characterized by considerable variability in onset and duration among individuals and according to gender. Onset of the pubertal growth spurt typically begins about age 10 in girls and lasts approximately 2 years. Boys have later onset (12 years); the entire pubertal period can last 4 to 6 years. (Adapted from Tanner JM, Whitehouse RH, and Takaishi M: Standards from birth to maturity for height, weight, height velocity and weight velocity: British children, 1965. *Arch Dis Childh* 41:454-471, 1966.)

The timing, rate, and amount of somatic growth are best determined by changes in overall height. As such, height provides an important adjunct for cephalometric evaluations, especially during periods of rapid growth. Population-specific height percentiles make it possible to individualize craniofacial assessments. For example, if an individual's rate of somatic growth is particularly high or low, it is likely that his or her rate of craniofacial growth will be similarly high or low. Height measurements are recommended because they are noninvasive, highly accurate, and simple to obtain at multiple occasions. Reference data for height are also typically based on larger samples of defined populations than are craniofacial reference data, which makes them more precise at the extreme percentiles.[10]

Assessments of maturation also provide critical information about the likelihood that the growth of craniofacial structures will continue and for how long or that growth has been completed. This is important because patients' maturational and chronologic ages should be expected to differ, often by more than 1 to 2 years, which confounds growth assessments necessary for orthodontic diagnosis and treatment planning. For this reason, it is always better to use the patient's skeletal age based on radiologic assessments of hand/wrist ossification to determine skeletal maturity, especially for determining whether the patient has entered adolescence, attained peak velocity, is past peak growth, or is near the end of clinically meaningful growth.[11,12] Cervical vertebrae maturation provides another, albeit less precise, method to determine skeletal maturity.[13] Molecular assays are now being developed to provide more sensitive assessments to determine maturational status of skeletal growth.[14]

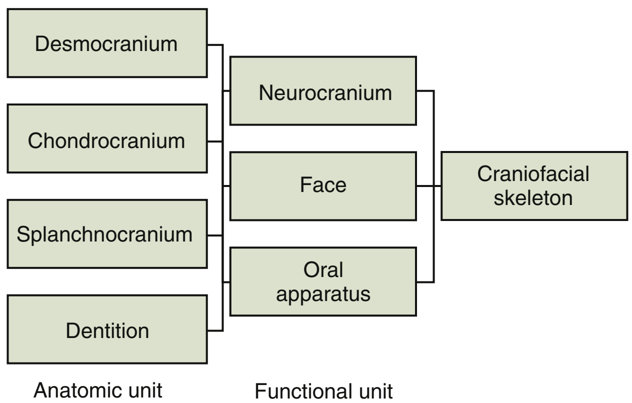

FIGURE 1-4 Schematic of organization of the craniofacial skeleton into anatomic regions and overlapping functional regions.

CRANIOFACIAL COMPLEX

The craniofacial complex is comprised of 22 separate bones that can be organized for heuristic purposes into relatively discrete anatomic and functional regions. Each of these regions has distinct mechanisms of development and growth, as well as different capacities for adaptation during growth (Fig. 1-4).

Structural Units

Desmocranium

The term *desmocranium* refers to the portion of the craniofacial skeleton that arises from a membrane of ectodermal, mesodermal, and neural crest origin that surrounds the proximal end of the notochord very early in development. As the brain develops and expands in utero, the desmocranium develops initially as a fibrous membrane covering of the brain that eventually will give rise to the bones of the cranial vault and fibrous joints, or sutures, as well as the dura mater over the brain and the periosteum overlying the bones of the cranial vault. In fact, in the absence of a brain, as with anencephaly, the desmocranial bones will fail to develop at all. Because the skeletal derivatives of the desmocranium have exclusively a membranous precursor, initial morphogenesis and subsequent bone growth take place completely via intramembranous ossification.

Chondrocranium

The *chondrocranium* forms initially as part of the embryonic anlagen of primary cartilage that will become the cranial base, nasal septum, and nasal capsule. Like the desmocranium, the chondrocranium is also a derivative of the embryonic membrane surrounding the developing central nervous structures. However, the chondrocranium is significantly less dependent on the presence of the brain for its initial formation and subsequent development. Growth associated with the derivative bones of the cranial base occurs by means of endochondral ossification.

Viscerocranium

The *viscerocranium*, also referred to as the *splanchnocranium*, is composed of all those elements of the craniofacial complex that are derived from the first branchial arch and thus is of neural crest origin. These elements primarily include the bones of the midfacial complex and the mandible. Because the skeletal elements of the viscerocranium have no primary cartilaginous precursors, development and growth of its skeletal derivatives take place via intramembranous ossification that is also characterized by the presence of sutures and a specialized form of membrane-derived (secondary) cartilage at the mandibular condyles.

Dentition

The deciduous and permanent teeth are specialized anatomic components of the craniofacial complex that are composed of unique tissues and undergo a unique mechanism of development characterized by the interaction between ectodermal and mesenchymal tissues.

Functional Units

These four anatomic components can be combined organizationally into three overlapping and very broad functional units comprising the craniofacial complex (Fig. 1-5).

Neurocranium

The *neurocranium* houses the brain and other elements of the central nervous system, such as the olfactory apparatus and auditory apparatus. As the brain rests on the cranial base and is covered by the cranial vault, development and growth of the neurocranium are characterized by a combination of membranous (desmocranium) and cartilaginous (chondrocranium) bone growth.

Face

The upper face may be defined as the region of the orbits of the eye. The midface, comprised primarily of the maxillae and zygomatic bones, is the region between the orbits and the upper dentition. Ectocranially, the bones of the face are composed externally of the intramembranously formed bones of the viscerocranium. However, the face also receives contributions from the chondrocranium as the cartilaginous nasal capsule and nasal septum. The lower face, comprised of the mandible, develops entirely from the first branchial arch and thus is derived entirely as part of the viscerocranium. The mandible develops and grows via a specialized form of intramembranous formation of both bone and secondary cartilage.

Oral Apparatus

The oral apparatus is composed of the dentition and supporting structures within the upper and lower jaws. Thus, the oral apparatus also is characterized by a unique morphogenesis of the teeth as well as a specialized form of intramembranous bone growth of the alveolar processes of the maxilla and mandible (viscerocranium). Development and growth of the skeletal structures comprising the oral apparatus are greatly influenced by the muscles of mastication and other soft tissues associated with mastication.

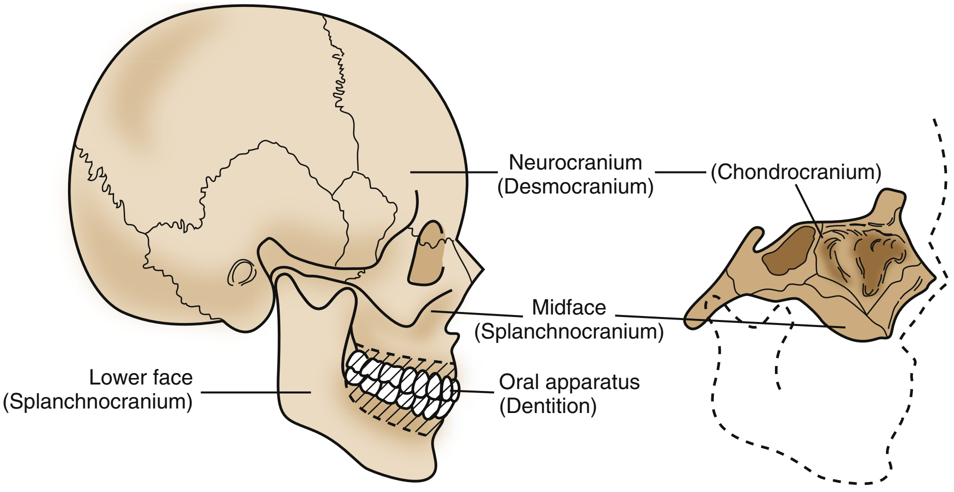

FIGURE 1-5 Major components of the craniofacial skeletal complex.

MOLECULAR BASIS OF CRANIOFACIAL DEVELOPMENT AND GROWTH

Patterning and subsequent formation of craniofacial tissues and structures have a complex, polygenic basis. For example, it has been shown that there are over 90 specific genes in which mutations will result in major disruptions of development leading to severe craniofacial malformations.[15] Moreover, variations in craniofacial development and growth, from dysmorphologies to malocclusions, are multifactorial as a result of epigenetic mechanisms.[16,17] No genes are unique to the craniofacial complex. However, certain genes, especially those associated with developmental patterning of the head region and growth of cartilage, bone, and teeth, are of particular relevance for craniofacial development and growth and thus are of special importance for orthodontics. In addition, a number of genes of interest include those responsible for specific craniofacial deformities, such as craniosynostosis and facial clefts. The reader is referred to Hartsfield and Morford (see Chapter 2) for a comprehensive review of genetic mechanisms in the craniofacial region that are most important to orthodontics. A summary of the key genes associated with the patterning, development, and growth of the craniofacial region can be found in E-Table 1-1.

The key genes associated with craniofacial development may be organized informally into two broad yet overlapping groups based on their timing and patterns of expression and also their primary target tissues. First are those highly conserved genes, such as homeobox genes and transcriptions factors, that are responsible primarily for early pattern formation and differentiation of primary embryonic tissues and structures, including neural crest cells and head mesoderm. Mutation of those genes typically has a profound role in craniofacial dysmorphogenesis. The second group is comprised of genes such as growth factors and signaling molecules that are also responsible for mediating development, growth, and maintenance of the tissues and structures associated with the craniofacial complex both during embryogenesis and throughout postnatal development. While mutations in this latter group of genes also are associated with craniofacial malformation syndromes, minor variants appear to be more common and may play a role in the development of more minor variations in growth. In addition, genes from both groups may be expressed reiteratively during development and growth, producing a highly complex matrix of interactions required for normal craniofacial morphogenesis. Adding to the complexity are the issues of wound healing, tissue regeneration, and repair—all processes important during orthodontic treatment—that can reinitiate the expression of genes required for early morphogenesis as well as postnatal growth.

Molecular research historically has focused on the role of specific genes critical for craniofacial morphogenesis during embryogenesis. The initial focus in that research typically has been on three areas: (1) naturally occurring genetic mutations associated with craniofacial dysmorphogenesis in humans; (2) development of genetically engineered animal models, typically the mouse, to produce loss of function of selected genes; and (3) mapping of gene expression in experimental animals through in situ hybridization and other biomarker approaches. More recently, significant progress has been made in the identification of gene variants (polymorphisms) that may be important for the origin of minor variations in craniofacial growth of potential relevance to orthodontic diagnosis and treatment. These genes and their variants could be significant for diagnosis and response to treatment of dentofacial deformities and minor malocclusions.[18] Significant advances in the genetic and epigenetic basis of craniofacial development, including the role of key genes in normal growth and orthodontic treatment, are expected to continue at a rapid pace.[19,20]

CRANIAL VAULT

Development of the Cranial Vault

The most prominent feature of the embryonic cephalic region at 6 to 7 weeks' gestation is the frontonasal prominence. The frontonasal prominence is a nonpaired structure that forms a dense desmocranial membrane, which covers the entire forebrain and extends laterally and inferiorly on each side of the developing head to meet the developing maxillary processes. The inner portion of the membrane contains neural crest cells and gives rise to the dura mater covering the brain. The outer portion of the desmocranial membrane, the *ectomeninx*, is comprised of surface ectoderm deep to which is the paraxial mesoderm. Patterning of the frontonasal prominence to form the cranial vault and elements of the nasal region is induced by expression of sonic hedgehog (Shh) and FGF-8.

By 8 weeks' gestation, initial blastemas of bone become apparent within the ectomeninx, first for the frontal bone and the squamous temporal bone and subsequently for the parietal bones and squamous portion of the occipital bone (Fig. 1-6).

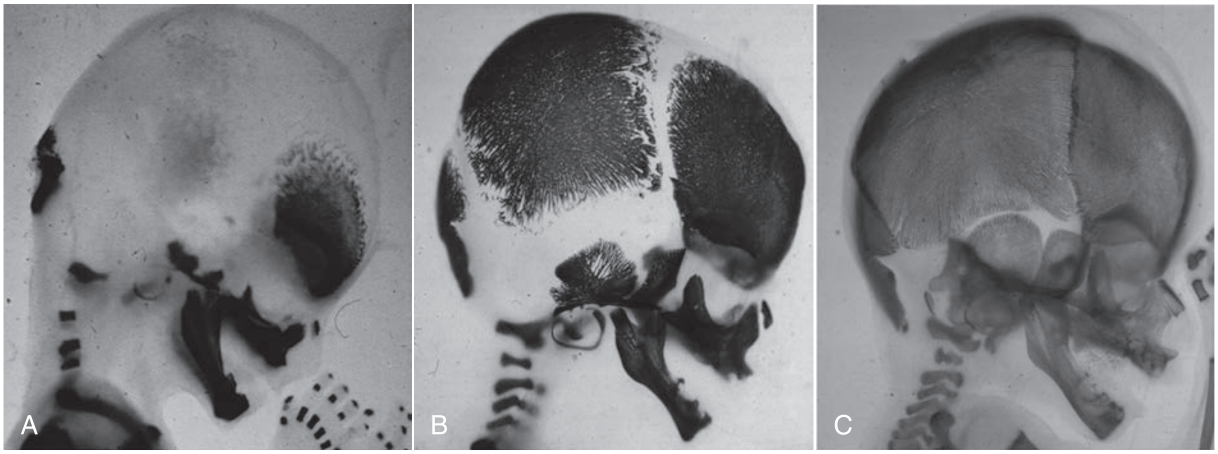

FIGURE 1-6 Cleared and stained human fetuses indicating craniofacial skeletal structures at approximately 8 weeks' gestation (A), 15 weeks' gestation (B), and 18 weeks' gestation (C).

TABLE 1-1 Summary of Key Genes Associated with the Development and Growth of the Tissues and Structures Comprising the Craniofacial Complex

Gene/Protein		General Role and Function	Significance for Craniofacial Development and Growth	References
Bmp-1 to Bmp-9	Bone morphogenetic protein 1-9	*Signaling molecule:* Skeletal differentiation, growth, repair	NCC and CF mesenchyme patterning; suture development; odontogenesis; nsCL/P	1-6
Dlx-1 to Dlx-6	Distal-less 1-6	*Homeobox:* Limb development; chondrogenesis; osteogenesis	Orofacial clefting	7-9
Efnb1	Ephrin B1	*Protein coding:* Cell division, adhesion	Craniofrontonasal syndrome; candidate for role in class III malocclusion	1, 10-12
Fgf-1 to Fgf-18	Fibroblast growth factor 1-18	*Growth factors*: Differentiation and growth of multiple tissues and structures	CF ectoderm, NCC patterning; suture development; MCC growth; tooth induction; CL/P	1, 3, 4, 13-15
Fgfr-1 to Fgfr-3	Fibroblast growth factor receptor 1-3	*Transmembrane receptors*: Fgf receptor	Anterior cranial base growth; MCC growth; syndromic, nonsyndromic C-SYN; MX hypoplasia; CL/P	1, 3, 4, 15, 16, 17
Gh	Growth hormone	*Peptide hormone-mitogen*: Cell growth and tissue regeneration	Growth of multiple CF tissues, structures; variations in MD growth, dentofacial treatment	13, 18
Ghr	Growth hormone receptor	*Transmembrane receptor*: Receptor for GH	Polymorphisms associated with MD growth and MCC response to dentofacial treatment	19-21
Gli2 to Gli3	Zinc finger protein Gli2-3	*Transcription factor*: Regulates Ihh and Shh signaling	C-SYN; Greig cephalopolysyndactyly syndrome	1, 10, 22
Gsc	Goosecoid	*Transcription factor*: Dorsal–ventral patterning of NCC, head formation; rib fusion	Inner ear, cranial base, MX/MD anomalies	1, 8, 13, 23, 24
Hoxa1 to Hoxa3	Homeobox A1, A2, A3	*Homeobox*: Patterning of hindbrain rhombomeres and pharyngeal arches	Neural tube closure, 1st-2nd arch deformities	25, 26
Igf-1	Insulin-like growth factor 1	*Growth factor*: Mediator of Gh; muscle, cartilage, and bone growth	MX/MD growth; suture development/growth; mediation of MCC to dentofacial treatment	3, 8, 13, 27-30
Ihh	Indian hedgehog	*Signaling molecule*: Endochondral and intramembranous ossification	Cranial base development; mediation of MCC growth during dentofacial treatment	31-33
L-Sox5	Long-form of Sox5	*Transcription factor*: Neurogenesis; chondrogenesis; type II collagen	Mediation of MCC growth during dentofacial treatment	34
Msx1 to Msx2	Muscle segment homeobox 1-2	*Homeobox*: Limb development; ectodermal organs	NCC proliferation, migration; odontogenesis; MD development; nsCL/P; Boston-type C-SYN	1, 3, 4, 8, 10, 35
Myo1H and-Myo1C	Myosin 1H, Myosin 1C	*Protein coding*: Cell motility, phagocytosis, vesicle transport	Polymorphisms associated with MD prognathism	36, 37
Nog	Noggin	*Signaling molecule*: Patterning of the neural tube and somites	Head formation; neural tube fusion	4, 25, 26
Notch		*Transmembrane receptor*: Neuronal development; cardiac development; osteogenesis	MCC development	38
Osx	Osterix	*Transcription factor*: Osteoblast differentiation, mineralization; chondrogenesis	MCC differentiation, endochondral ossification; mediation of MCC growth during dentofacial treatment	39
Pitx1-2	Paired-like homeodomain 1-2	*Homeobox*: Left–right axis; left lateral mesoderm; skeletal development; myogenesis	MD development; role in Treacher-Collins syndrome; CL/P; odontogenesis	8, 13
Prx-1Prx-2		*Homeobox*: Epithelial development in limbs and face	NCC patterning; malformations of 1st-2nd arch structures	8, 40, 41
PTHrP	Parathyroid-related protein	*Protein coding*: Endochondral bone formation	Development/growth of cranial base, MD, dental arches	42, 43
Runx2	Runt-related transcription factor	*Transcription factor*: Osteoblast differentiation; intramembranous and endochondral bone growth	Closure of fontanelles and sutures; ossification of cranial base, MX, and MCC; cleidocranial dysplasia	32, 43-46
Shh	Sonic hedgehog	*Transcription factor*: Development of limbs, midline brain, neural tube; osteoblastic differentiation; skeletal morphogenesis	Induction of frontonasal ectoderm; cranial base; fusion of facial processes; palatogenesis; odontogenesis; holoprosencephaly	1, 9, 33
Sho2		*Signaling molecule*: Development of digits; organization of brain, CF mesenchyme	Palatogenesis; TMJ development	6, 9, 38

TABLE 1-1 **Summary of Key Genes Associated with the Development and Growth of the Tissues and Structures Comprising the Craniofacial Complex—cont'd**

Gene/Protein		General Role and Function	Significance for Craniofacial Development and Growth	References
Sox9		*Transcription factors*: Chondrogenesis; type II collagen; male sexual development	Cranial base; MCC growth; CL/P; Pierre-Robin sequence	38, 46-48
Spry 1-2	Sprouty	*Protein coding*: Mediates FGF signaling	MD/TMJ development	38, 48
Tcof1	Treacle	*Protein coding*: Early embryonic nucleolar-cytoplasmic transport	NCC proliferation, migration, survival; Treacher-Collins syndrome	38, 49
Tgf-ß1 to Tgf-ß3	Transforming growth factor-beta 1-3	*Growth factor*: Proliferation, differentiation, growth, function of multiple tissues	Palatogenesis; MD growth; suture development, maintenance, fusion; sCL/P	3, 24
Twist-1	Twist-related protein 1	*Transcription factor*: Skeletal development; syndactyly	MCC development; suture fusion; Saethre-Chotzen syndrome; facial asymmetry	9, 35, 38, 50, 51
Vegf	Vascular endothelial growth factor	*Growth factor*: Ingrowth of blood vessels	Chondrogenesis in cranial base, MCC	38, 45, 52
Wnt-1	Proto-oncogene protein Wnt 1	*Signaling molecule*: Cell fate, patterning during embryogenesis	MCC development/growth; MCC growth during dentofacial treatment	6, 32, 38, 53

CF, Craniofacial; *CPO*, cleft palate only; *CL/P*, cleft lip and palate; *C-SYN*, craniosynostosis; *MCC*, mandibular condylar cartilage; *MD*, mandible; *MX*, maxilla; *NCC*, neural crest cells; *nsCL/P*, non-syndromal cleft lip and palate; *sCL/P*, syndromal cleft lip and palate; *TMJ*, temporomandibular joint.

Over the ensuing 4 weeks, these condensations of bone steadily increase in size by radial expansion of newly differentiated skeletal tissue within the ectomeninx. As the development of new bone exceeds the rate of growth of the brain, the peripheral bone fronts become located closer and closer to each other, until they approximate each other as single-thickness plates of flat bones by about 12 weeks' gestation. At this point, the intervening fibrous tissue becomes highly cellular, and fibrous articulations, or *sutures*, are formed between the individual bone elements (Fig. 1-7).

Growth of the cranial vault bones represents a specialized form of intramembranous ossification that begins prenatally as blastemas of bone tissue that arise de novo within the middle layer of the desmocranial membrane covering of the brain. Once the skeletal elements as plates of bone become located close to each other, their fibrous connections become reorganized with the periosteum and the dura mater derived from the outer and inner layers of the desmocranial membrane, respectively, extending into the sutural articulations. The sutures then continue to support growth of the cranial vault through another specialized form of intramembranous osteogenesis similar to periosteal bone formation.[21–23]

Mechanisms of Suture Growth

Sutural bone growth can best be considered as a specialized form of intramembranous periosteal bone growth. Once formed, the bones of the cranial vault are enveloped, like all bones, in a skeletogenic membrane. On the external surface, this membrane is the periosteum. On the intracranial surface, the membrane is the dura mater, which is also derived from the embryonic ectomeninx and is skeletogenic. Viewed in cross section, the outer fibrous layer of periosteum (uniting layer) spans over the cranial suture and provides structural support to the suture and its two or more skeletal elements. The inner osteogenic layers of

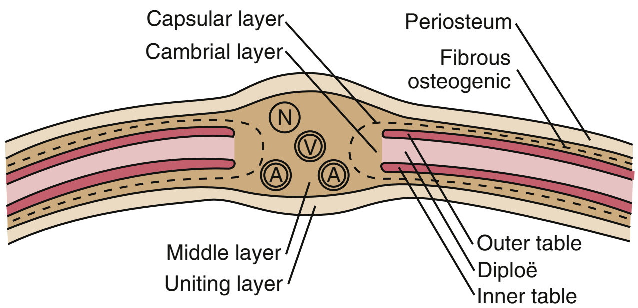

FIGURE 1-8 Schematic representation indicating the relationship between the periosteum and dura mater as a mechanism for a specialized of intramembranous growth within the sutures of cranial vault bones. (Adapted from Pritchard JJ, Scott JH, Girgis FG. The structure and development of cranial and facial sutures. *J Anat.* 1956;90:73–86.)

the periosteum and the dura reflect into the space between the two cranial vault bones and provide a source of new osteogenic cells (Fig. 1-8). As the bones of the cranial vault become separated because of expansion of the brain and intracranial contents, the osteogenic cells form skeletal tissue and thus provide a mechanism for maintaining relatively close contact through the intervening suture.

The molecular basis of the development and growth of the sutures of the cranial vault has received considerable attention, principally because of the number of naturally occurring and engineered genetic mutations characterized by craniosynostosis (see Wilkie and Morriss-Kay,[15] Rice,[24] and Chai and Maxson[25] for comprehensive reviews). Studies have shown a complex pattern of gene expression within the sutural blastema associated with the periosteal reflection as well as the intracranial dura mater. Secretion of soluble factors by the

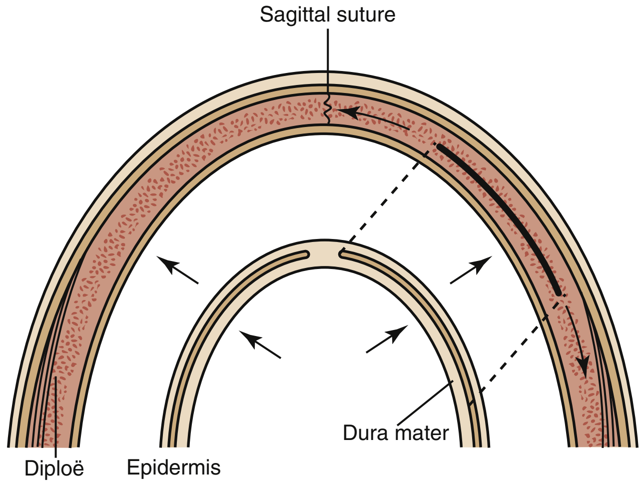

FIGURE 1-10 Schematic diagram indicating the relationship between expansile growth of the brain as a stimulus for compensatory growth of sutures of the cranial vault. (Adapted from Moss ML. The functional matrix. In: Kraus B, Reidel R, eds. *Vistas Orthod*. Philadelphia: Lea & Febiger; 1962;85–98.)

dura mater in response to growth signals from the expanding, underlying brain is essential for normal cranial suture morphogenesis as well as for the maintenance of cranial sutures as patent bone- growth sites through complex tissue interactions and feedback between dura mater, bone fronts, and sutures. Both sutures and the dura mater also contain growth factors, such as several members of the family of transforming growth factor beta (TGF-β1, TGF-β2, TGF-β3), bone morphogenetic protein (BMP2, BMP7), fibroblast growth factor 4 (FGF-4), insulin-like growth factor 1 (IGF-1), and sonic hedgehog (SHH) (Fig. 1-9).[26,27] Overexpression of transcription factors Runx2 and Msx2 and haploinsufficiency of Twist[28] and Noggin[29] are also associated with suture obliteration, while loss of function of *Gli3* results in premature synostosis.[30] Genetic analysis of naturally occurring craniosynostosis in humans has shown that mutations of genes for fibroblast growth factor receptors 1, 2, and 3 (*FGFR-1*, *FGFR-2*, and *FGFR-3*) and in *MSX2*[31] and *TWIST*[32,33] genes are also associated with premature suture fusion.

Development and growth of the cranial vault as a whole, and development and growth of bone at the sutural articulations, are primarily dependent on the expansion of the brain and other intracranial contents.[34] Furthermore, it has been clearly demonstrated that sutures are secondary, compensatory, and adaptive sites of bone growth that normally respond to biomechanical forces. As the brain expands during prenatal development and during the first decade of life postnatally, forces are created within the neurocranium that cause the bones of the cranial vault to expand outward, which tends to separate them from each other at the sutural boundaries (Fig. 1-10). Under normal conditions, the cellular and molecular substrate associated with the dura mater, the periosteum, and the suture respond to this biomechanical displacement in the same manner in which periosteum throughout the skeletal system responds—by initiating and maintaining osteogenesis within the sutures to maintain the proximity of the adjoining skeletal structures. When the biological substrate of the suture is abnormal, however, as in the case of many genetic syndromes such as Crouzon syndrome, Apert syndrome, and Jackson-Weiss syndrome, for example, each of which is associated with mutations of *FGFR-2*, premature craniosynostosis may result.[35,36] The opposite condition, reduced suture growth, and prolonged patency, as seen in cleidocranial dysostosis, may occur with abnormalities associated with growth factors, including in particular Runx2, which are necessary for normal suture fusion.

Postnatal Growth of the Cranial Vault

Due to the very precocious nature of prenatal and early postnatal human brain development, the cranial vault is disproportionately large relative to the rest of the face and body. At birth, the cranial vault is initially characterized by the presence of all of the cranial vault bones. At that time, all the major sutural fibrous articulations between the bones of the cranial vault are present, including the metopic suture between the right and left frontal bone. In addition, there typically are four larger remnants, known as *fontanels*, of the desmocranial membrane in areas where the pace of bone growth has not been sufficient to approximate the bones of the cranial vault to form a suture (Fig. 1-11).

During the first 24 months after birth, growth of the cranial vault bones proceeds rapidly enough to close the fontanels as each complex of cranial vault bones becomes organized through interlocking sutures. The metopic suture normally fuses to form a single frontal bone within the first year of life, although the suture may appear to persist for up to 8 years of age or even throughout life in a small percentage of individuals. The cranial vault will continue to enlarge primarily as a result of compensatory growth of the sutural bone fronts stimulated by expansion of the brain. By 4 years of age, the brain and the associated cranial vault will have achieved approximately 80% of adult size; by age 10, the brain and cranial vault have attained 95% of their adult size. Throughout this time of very rapid expansion, the remaining sutures of the cranial vault normally remain patent and actively growing to keep pace with the brain as it expands in size.

Osteogenesis at cranial sutural bone fronts may continue for the first two decades of life. However, by the end of the second decade of life, bone growth at cranial sutures has slowed and the potential for growth of cranial sutures has greatly diminished. Also at that time, the sutures will begin the normal process

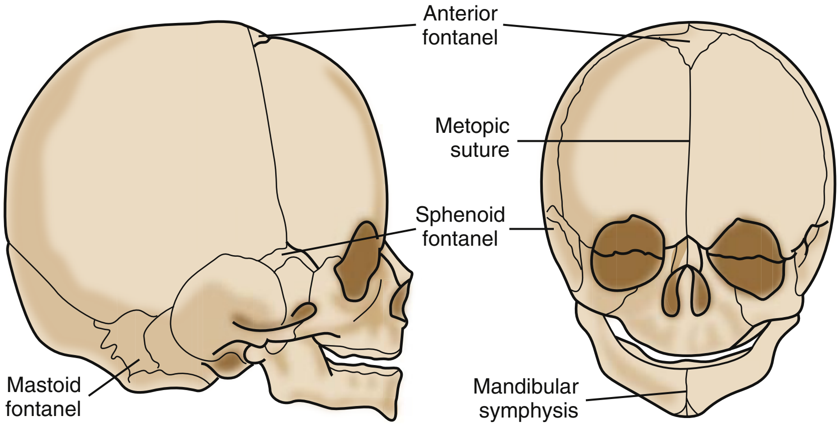

FIGURE 1-11 Lateral and frontal views of the neonate skull indicating the location of sutures and fontanels. (Adapted from Sicher H, DuBrul EL. *Oral Anatomy*. 5th ed. St. Louis: Mosby; 1970.)

of bony closure, or *synostosis*, when the potential for sutural growth ceases altogether.

The cranial sutures normally lose the capacity for growth by the end of the second decade of life, and virtually all become synostosed during the life span. Normal suture closure is initiated along the endocranial surface. Initially, this is characterized by bridging of bone across the suture and eventually through modeling of bone, leading to complete obliteration of the suture. Cessation of growth at cranial sutures typically begins around age 25 for the sagittal suture and may be extended for 2 to 3 additional years for the coronal suture.

Despite the fact that the major cranial sutures stop growing by the third decade of life, some enlargement of the cranial vault overall typically occurs throughout the lifespan as a result of periosteal deposition along the ectocranial surface. Certain specific areas of the cranial vault, such as the glabellar and nuchal regions, may exhibit slightly greater periosteal growth as a secondary sex characteristic in males.

CRANIAL BASE

Development of the Cranial Base

The ectomeningeal membrane that surrounds the developing brain in the cranial base region gives rise to a number of paired cartilaginous elements that form the embryonic chondrocranium. The first of the cartilage anlagen to form arises from neural crest cells at about 6 weeks' gestation as the parachordal cartilages, which surround the proximal end of the notochord and give rise to the anterior cranial base. The posterior component of the cranial base is derived primarily from mesoderm to form the basioccipital bone.[37] Development of the chondrocranium then progresses rostrally to the otic capsule, which will form the petrous portion of the temporal bone; the postsphenoid, presphenoid, alisphenoid, and orbitosphenoid cartilages of the sphenoid bone; and the nasal capsule and mesethmoid, which will form the ethmoid bone, inferior turbinate, and nasal septum. By 8 weeks' gestation, the separate cartilage elements have merged to form a single plate of primary hyaline cartilage, the *basal plate*, extending from the foramen magnum rostrally to the tip of the nasal cavity (Fig. 1-12).

More than 110 separate centers of ossification form in the basal plate, beginning with the parachordal cartilages and continuing rostrally through the sphenoid complex around 9 to 16 weeks, to the ethmoid region as late as 36 weeks. As

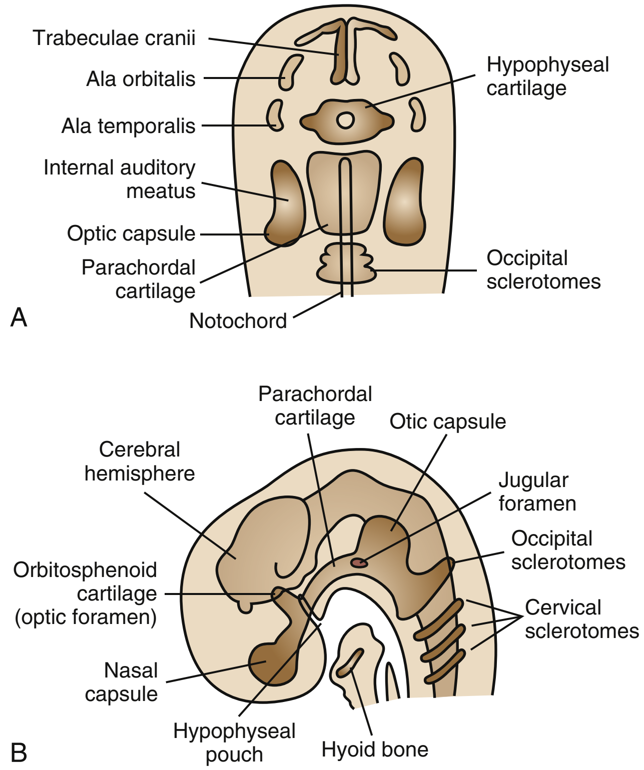

FIGURE 1-12 Schematic representation of the cartilaginous basal plate comprising the embryonic chondrocranium. **A**, Dorsoventral view; **B**, Lateral view.

these centers of ossification arise within the chondrocranium, segments of intervening cartilage form *synchondroses* (Fig. 1-13). The principal cranial base synchondroses that are most relevant for understanding craniofacial growth are the spheno-occipital synchondrosis, between the body of the sphenoid and the basioccipital bone, and the spheno-ethmoidal synchondrosis, between the sphenoid and ethmoid bones. The greater wing of the sphenoid bone and the squamous portion of the occipital bone develop and grow via intramembranous ossification.

Mechanism of Synchondrosal Growth

Cranial base synchondroses are temporary cartilaginous joints located between bones of endochondral origin and growth.

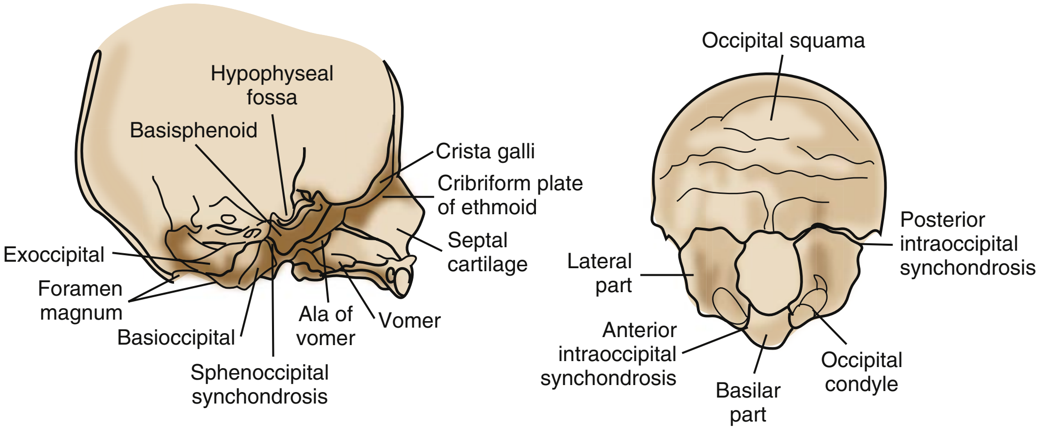

FIGURE 1-13 Drawing of sagittal and basal views of the neonatal skull indicating spheno-occipital synchondrosis and intraoccipital synchondroses. The sphenoethmoidal synchondrosis will arise between the sphenoid and ethmoid bones. (Adapted from Bosma JF. Introduction to the symposium. In: Bosma JF, ed. *Development of the Basicranium*. Synchondroses can best be considered as homologous to the epiphyseal growth plates of long bones. Functionally, both provide a mechanism for rapid endochondral growth of bone in a manner that is capable of overcoming biomechanical loads, thus exhibiting tissue-separating capabilities. Developmentally, cranial base synchondroses and epiphyseal plates of long bones synostose and become obliterated when the skeletal element achieves its mature size and shape. This typically occurs at the end of puberty for epiphyseal growth plates but varies from the end of the juvenile period through the end of puberty for the major cranial base synchondroses.

Cranial base synchondroses and epiphyseal growth plates are both derived from the primary hyaline cartilage that arises as part of the embryonic cartilaginous anlagen. Like endochondral bones and growth plates throughout the body, growth of synchondroses is controlled principally by expression of Indian hedgehog gene (Ihh) and sonic hedgehog (Shh).[38,39] The significance of *FGFR-3* for growth of the anterior cranial base is also indicated by mutations associated with achondroplasia.

Histomorphologically, both cranial base synchondroses and epiphyseal growth plates, are characterized by primary chondrocytes that are distributed into zones that are highly typical for growth plate cartilage (Fig. 1-14). However, a major difference between epiphyseal growth plates in long bones and cranial base synchondroses is that synchondroses are "bidirectional." Thus, each cranial base synchondrosis effectively has two back-to-back growth plates with a shared region of newly forming cartilage in the center and bone at each end. Growth plates are "unidirectional."

The primary hyaline cartilage of the cranial base is the same as that found throughout the embryonic cartilaginous anlage that characterizes all the other cartilaginous bones throughout the body. It is well known that growth of tissues derived from the primary embryonic cartilaginous anlagen tends to be relatively resistant to all but very extreme external influences. Growth of cartilage-derived skeletal elements throughout the body tends to be relatively resistant to environmental and other factors and instead is regulated to a large extent by intrinsic, genetically regulated growth factors and cell-signaling molecules.[40] The same is true for the cranial base synchondroses.

However, it is important to note that the growth of both epiphyses and synchondroses can be significantly affected by such epigenetic factors as disease, malnutrition, and undernutrition, as well as other conditions that affect production and expression of endocrine factors responsible for bone growth.

The cartilage cells within both epiphyseal growth plates and cranial base synchondroses are characterized by extensive amounts of extracellular matrix that are secreted by and separate the cartilage cells. This matrix makes the cartilage very dense and strong but also flexible relative to bone and thus better able to absorb mechanical forces without directly affecting the cells and potentially altering growth. Because there are no vessels within cartilage extracellular matrix, all nutrients, growth factors, and cell-signaling molecules must diffuse through the matrix to reach the chondrocytes. The matrix thus “buffers” the chondrocytes from extrinsic mechanical forces and many soluble molecules that might provide information about the external environment.[41] As a result, cartilage growth in general, and endochondral ossification from primary hyaline cartilage in particular, tend to be more rigidly programmed genetically than intramembranous bone growth associated with periosteum, such as occurs in the desmocranium and viscerocranium.

This difference in the mechanisms of growth between bone formed by means of intramembranous ossification and bone derived from endochondral ossification can be summarized through the concepts of skeletal *growth centers* versus skeletal *growth sites*.[42] Development and growth of the skeletal tissues derived from primary cartilage are significantly more intrinsically regulated and less dependent for their expression on epigenetic factors. In particular, *growth centers* have what has been described as “tissue-separating capabilities,” emphasizing the capacity to grow and expand despite the presence of mechanical forces that would seem to be capable of inhibiting or restricting skeletal growth. Thus, epiphyseal and synchondrosal cartilage are referred to as growth centers. In contrast, a *growth site* is an area of skeletal growth that occurs secondarily and grows in compensatory fashion to growth and function in a separate but proximate location. Growth sites have no tissue-separating capabilities but rather respond more readily to factors extrinsic to their specific area. Periosteal bone growth associated with muscle function is one obvious example of a growth site. Sutural bone growth is another example of a class of growth sites because of its association with bones of intramembranous origin and its clear connection to periosteal bone growth.

Postnatal Growth of the Cranial Base

Late prenatal and overall postnatal growth of the cranial base is related directly to growth of the synchondroses. There are three principal growth-related cranial base synchondroses that separate the bones of the cranial base at birth. The intersphenoid synchondrosis, between the presphenoid and basisphenoid, fuses around the time of birth in humans and thus does not contribute to postnatal growth. The sphenoethmoidal synchondrosis, which lies between the sphenoid and the ethmoid bones, is most active with respect to growth of the cranial base through approximately 7 to 8 years of age in humans. At that time, the sphenoethmoidal synchondrosis loses its cartilage phenotype and becomes a suture. Once that transition occurs, growth of the anterior cranial base is essentially complete. As a result, the anterior wall of the sella turcica, which is located on the body of the sphenoid; the greater wing of the sphenoid; the cribriform plate; and the foramen cecum are commonly used after age 7 as stable reference structures for analyses of serial lateral radiographic cephalograms.

The spheno-occipital synchondrosis, between the body of the sphenoid and occipital bones, is most prominent throughout the period of active craniofacial growth and fuses shortly after puberty (Fig. 1-15). Once synostosis occurs, growth of the cranial base, especially in the anteroposterior direction, is essentially over. Subsequent changes in the form of the cranial base, such as in the angulation of the basioccipital bone relative to the anterior cranial base, for example, must come about as a result of bone modeling.

During the early postnatal years, the cranial base undergoes a dramatic shift in its growth pattern (Fig. 1-16). Anterior (nasion–sella) and posterior (sella–basion) cranial base lengths, as well as cranial base angulation (nasion–sella–basion), exhibit greater growth changes during the first 2 to 3 postnatal years than any time thereafter. For example, cranial base angulation decreases more than twice as much during the first 2 postnatal years than between 2 and 17 years of age, primarily due to differential growth of the spheno-occipital synchondrosis. Growth continues after 2 years of age, but the changes are smaller and steadier.

Between birth and 17 years of age, the anterior cranial base grows approximately 36% (males) to 53% (females) more than the posterior cranial base, with most of the differences occurring during the first few years.[43] It is important to understand that the anterior cranial base grows more and is also more mature (i.e., closer to its adult size) than the posterior cranial base throughout the postnatal growth. Longitudinal analyses have shown that the anterior cranial base has already attained approximately nearly 90% of its adult size by 4.5 years of age, while the posterior cranial base has attained only about 80% of its adult size (Fig. 1-17). The relative maturity differences between the anterior and posterior cranial base lengths are maintained throughout postnatal growth.

Anterior and posterior cranial base lengths increase because of bony deposition, as well as growth at the spheno-occipital and sphenoethmoidal synchondroses. Postnatally, the posterior cranial base becomes longer primarily due to growth at the spheno-occipital synchondrosis. Histologic studies have shown that the spheno-occipital synchondrosis fuses at approximately 16 to 17 years in females and 18 to 19 years in males.[44] Radiographically, the spheno-occipital synchondrosis shows active growth until approximately 10 to 13 years of age, at which time closure starts superiorly and continues inferiorly around 11 to 14 years in females and 13 to 16 years in males.[45,46]

Because both landmarks are commonly used to describe the growth of the anterior cranial base, it is important to distinguish the changes that occur at nasion from those that occur at foramen cecum. After fusion of the sphenoethmoidal synchondrosis, which occurs at approximately 7 to 8 years of age, increases in the distance between sella and foramen cecum are due primarily to the posterior and inferior drift of the sella turcica. The distance sella–nasion, on the other hand, continues to increase primarily due to bony apposition on the outer surface of the frontal bone associated with the development of the frontal sinus (the earliest pneumatization of the frontal sinus occurs around 2 years of age). The anterior cranial fossa continues to expand slightly, and the frontal sinus becomes more prominent. As a result, the frontal bone and root of the nose become

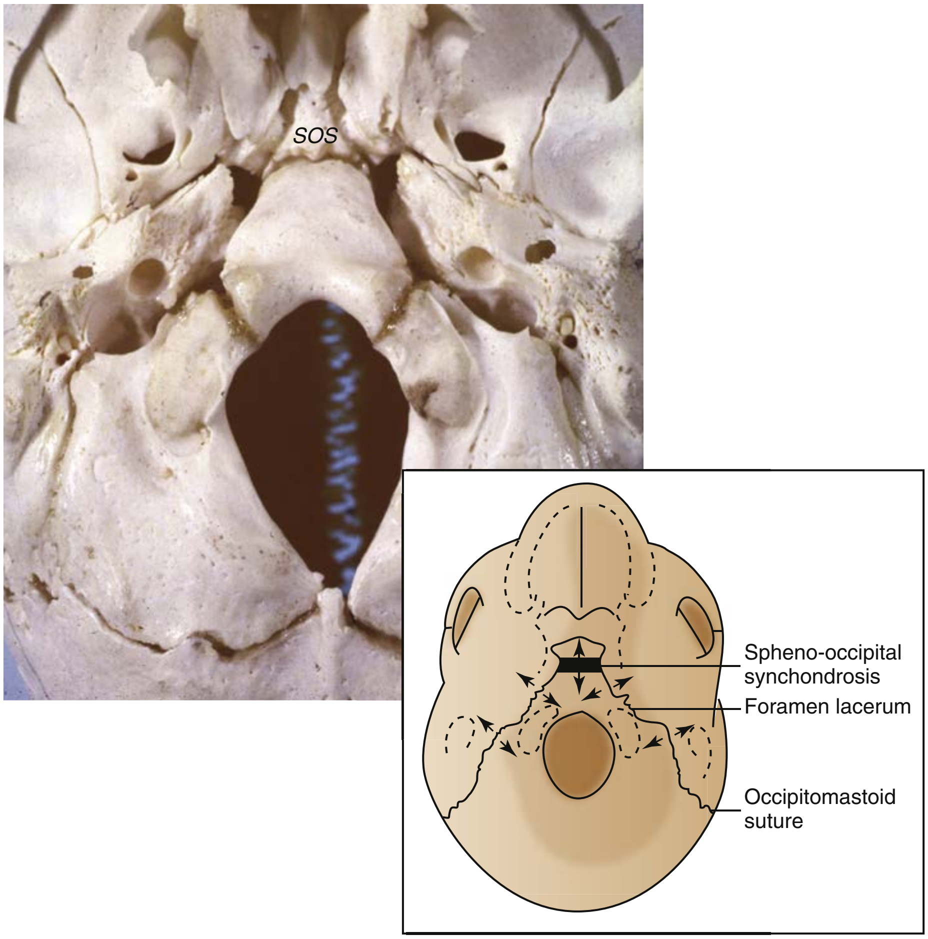

FIGURE 1-15 Basal view of a juvenile human indicating the spheno-occipital synchondrosis (*SOS*).

more anteriorly located. Ford[47] estimated that the frontal bone drifts anteriorly approximately 7 mm between the time that the sphenoethmoidal synchondrosis fuses and adulthood.

MIDFACE/NASOMAXILLARY COMPLEX

The midface, or nasomaxillary complex, is composed of the paired maxillae, nasal bones, zygomatic bones, lacrimal bones, palatine bones, and, within the nasal cavity, the turbinates and vomer. Prenatally, human fetuses also have left and right premaxillary bones; however, these normally fuse with the maxillae within 3 to 5 years after birth (Fig. 1-18).

The midface is connected to the neurocranium by a circummaxillary suture system and, toward the midline, by the cartilaginous nasal capsule, nasal septum, and vomer (Fig. 1-19). There is also an intermaxillary suture system composed of the midpalatal, transpalatal, intermaxillary, and internasal sutures. With the exception of the inferior turbinates, all the bones composing the midface are formed intramembranously from a connective tissue mass.

Development of the Midface

The midface has both viscerocranial and chondrocranial components. The chondrocranial component is comprised principally of parasagittal extensions of the cartilaginous anterior cranial base as the nasal septum and cartilaginous nasal capsule into the nasal region. The viscerocranial component is derived from two embryonic structures. The first is an inferior extension of the frontonasal prominence, which extends toward the oral opening, or stomodeum, to form nasal structures and the philtrum of the upper lip. The second is the paired maxillary processes of the first branchial arch. Differential growth of the right and left maxillary processes results in their apparent migration medially until they come into contact with the medial nasal process of the frontonasal prominence.

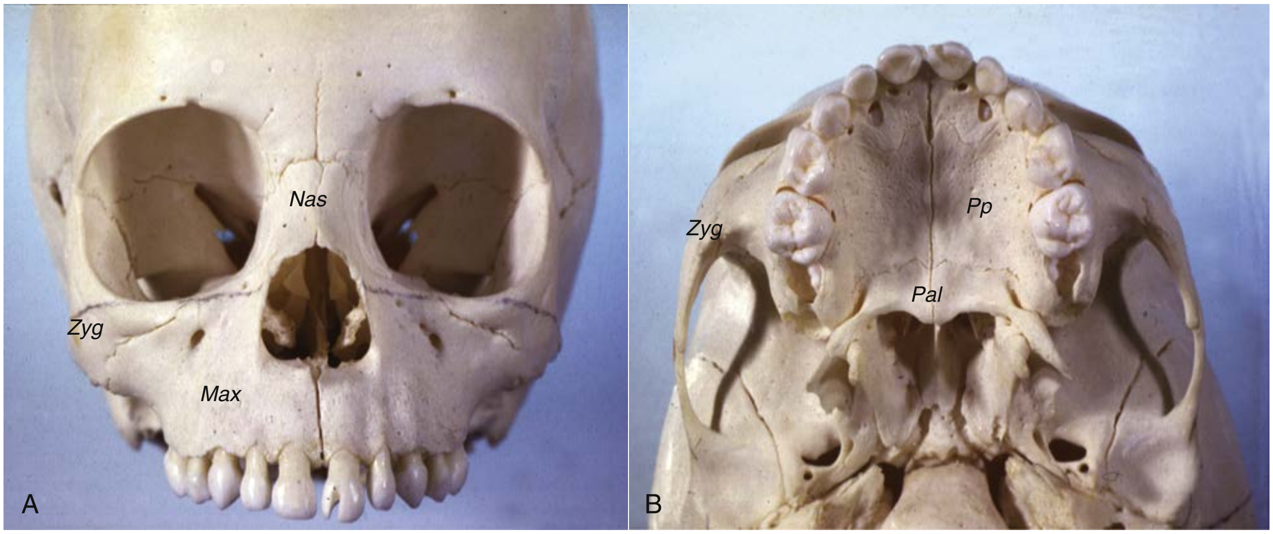

FIGURE 1-18 (A) Frontal and (B) basal views of a juvenile human indicating the bones comprising the midface. *Max*, maxilla; *Nas*, nasal bones; *Zyg*, zygomatic bones; *Pal*, palatine bones; *Pp*, palatal processes of the maxillary bones.

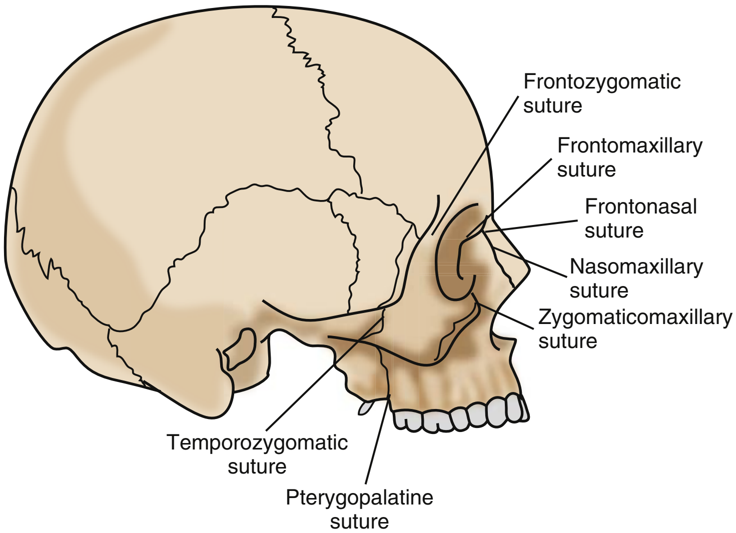

FIGURE 1-19 Location of the circummaxillary suture system articulating the midface with the neurocranium.

The skeletal elements comprising the midfacial complex arise almost exclusively from neural crest cells within the maxillary process of the first branchial arch. The primary palate, which gives rise to the four maxillary incisors, is derived from the frontonasal prominence. Only the facial ethmoid and inferior turbinate are derived from the cartilaginous component of the midface. Like the bones of the cranial vault, since the bones comprising the nasomaxillary complex have no cartilaginous precursors, they rely on intramembranous ossification for their development. However, the exact process by which initial bone formation occurs differs from that of the cranial vault bones. While the bones of the cranial vault arise within a desmocranial membrane, centers of ossification for the nasomaxillary bones develop as blastemas directly within the mesenchyme of the first branchial arch. These blastemas of bone are then surrounded by a periosteum that provides the source of new osteoblastic cells and thus for enlargement of the skeletal element. Molecular signaling mechanisms associated with the development, growth, and maintenance of the facial sutures are dependent on the presence of the nasal capsular cartilage, which appears to play a role similar to the dura mater in sutures of the cranial vault in the expression of TGF-β1, TGF-β2, TGF-β3, and Msx2.[48] It has also been shown that *Fgf8* plays a significant role in the integration and coordination of the frontonasal prominence with the nasal and optic regions.[49]

Virtually all of the major centers of ossification within the midface can be seen at approximately 7 to 8 weeks' gestation. At 6 weeks' gestation, the palatal shelves, which are mesenchymal tissue extensions of the embryonic maxillary processes of the first branchial arches, elevate within the oral cavity, where they will give rise to the hard and soft palates. The palatal shelves begin to ossify at 7 to 8 weeks' gestation, with the two bone fronts of the palatal processes each extending medially to form the secondary palate, composed of processes from the maxillary bones and from the palatine bones, as they meet in the midline where they form the midpalatal suture.

The molecular mechanisms associated with the development of the palate are among the most studied in all of craniofacial growth and development because of the obvious problem of cleft lip and palate, which is the most common craniofacial deformity (approximately 1:1000 for children of European descent).[50,51] Genes that have been identified specifically for a significant role in the genesis of cleft lip and palate now include isoforms of BMP, Dlx, Fgf-8, Msx, Pitx, Sho2, Shh, Sox9, and TGF-β, among others. It is also well documented that epigenetic factors, such as anoxia due to cigarette smoking and alcohol, have a major impact on nonsyndromal cleft lip and palate.

Development of the nasomaxillary complex proceeds laterally and anteroposteriorly with expansion of the brain and cranial cavity and expansion of the oral cavity and oronasal pharynx. Also throughout the fetal period, anterior and inferior growth of the nasal septal cartilage, which is an extension of the anterior cranial base, is most prominent. The cartilaginous nasal capsule, which envelops the nasal cavity laterally, is primarily structural and contributes little to the overall growth of the nasomaxillary complex other than possible expression of growth factors that support the facial sutures (Fig. 1-20). Thus, the primary factors influencing the growth of the nasomaxillary complex from the late embryonic period and throughout the fetal period and the juvenile period postnatally are an expansion of the brain and cranial vault and growth of the anterior cranial base, including in particular anterior and inferior growth of the nasal septum, as well as expansion of the nasal cavity and oronasal pharynx.

Postnatal Growth of the Midface

At the time of birth, the midface is well developed but diminutive relative to the neurocranium. The circummaxillary and intermaxillary sutures are all present and active as sites of bone growth. The nasal capsule and midline nasal septum are still primarily cartilaginous and continuous with the rest of the

FIGURE 1-20 Frontal histologic sections of human fetuses at approximate ages of 5 weeks' gestation (**A**) and 11 weeks' gestation (**B**) (hematoxylin and eosin–stained). *NS*, Nasal septal cartilage; *NC*, nasal capsular cartilage; *V*, vomer; *PS*, palatal shelves.

chondrocranium from the anterior cranial base. The septum is also very actively growing by means of interstitial cartilaginous growth, leading to significant anterior and vertical growth of the midface, especially during the first 3 to 4 years of life.

With the exception of the nasal septum, postnatal development of the nasomaxillary complex occurs via intramembranous ossification. Growth at the circummaxillary and intermaxillary sutures occurs in response to midfacial displacements due principally to growth of the anterior cranial base and nasal septum. Inferior, anterior, and lateral displacements of the midface result in concomitant compensatory sutural growth to account for the majority of vertical, anteroposterior, and transverse changes that occur during both childhood and adolescence (Fig. 1-21). Along with displacements, extensive surface modeling takes place over the entire nasomaxillary complex, especially along its posterior and superior aspects.

As long as the midface undergoes displacement, sutural growth occurs, with the amounts of bony apposition being related directly to amounts of sutural separation. Growth continues until the sutures are no longer separating. The premaxillary/maxillary suture fuses at approximately 3 to 5 years of age.[52] The midpalatal and transpalatal maxillary sutures, which are the major intermaxillary growth sites associated with transverse and anteroposterior maxillary growth, have been reported to close between 15 and 18 years of age[53] and 20 to 25 years of age,[54] depending on the criteria on which closure is based. More recent studies suggest only limited amounts of sutural obliteration (i.e., the development of bony bridges, or spicules, running across the suture after growth has ceased) in adult midpalatal sutures.[55,56] The increasing complexity that characterized sutures during childhood and adolescence appears to be functionally, rather than age, related.[57] Although data are limited, it appears that closure of the circummaxillary sutures occurs somewhat later than closure of the intermaxillary sutures.

The midface undergoes a complex modeling pattern throughout childhood and adolescence (Fig. 1-22).[58] As the midface is displaced anteriorly, compensatory bony deposition occurs

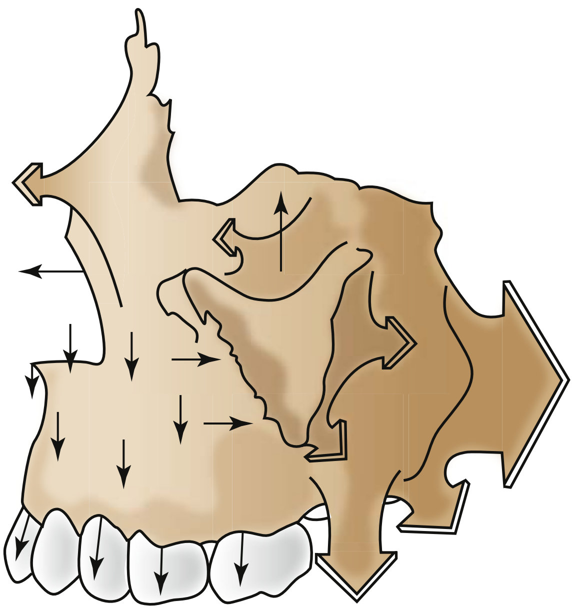

FIGURE 1-22 Maxillary remodeling, with the sizes of the arrows indicating relative amounts of change and with *dark* and *light arrows* indicating resorption and apposition, respectively. (Redrawn from Enlow DH, Bang S. Growth and remodeling of the human maxilla. *Am J Orthod.* 1965;51:446–464.)

along the posterior margin of the maxillary tuberosity, resulting in an increase in the length of the entire maxilla and of the dental arches.[59] The posterior maxilla is a major modeling site that accounts for most of the increases in maxillary length. The anterior periosteal surface of the maxilla is slightly resorptive, while the buccal surfaces undergo substantial bony deposition. From the sagittal perspective, the area of the anterior nasal spine drifts inferiorly; the A-point also drifts inferiorly and slightly posteriorly. For every 4 mm that the posterior nasal spine drifts posteriorly, it drifts approximately 3 mm inferiorly. Associated with inferior displacement of the midfacial complex, bony resorption occurs along the floor of the nasal cavity, whereas apposition occurs on the roof of the oral cavity (i.e., palate) and orbital floor. Implant studies suggest that for every 11 mm of inferior midfacial displacement, the orbital floor drifts superiorly 6 mm and the nasal floor drifts inferiorly 5 mm.[60] Thus, midfacial height increases due to the combined effects of inferior cortical drift and inferior displacement (see Fig. 1-19). The height of the midface is further increased by continued development of the dentition and alveolar bone. The lack of naturally stable structures on the surface of the midfacial complex makes superimposition difficult.

The width of the midface at the time of birth is proportionately large due to the precocious development of the eyes, which are the central features of the neonatal midface. Growth in width during the first 2 to 3 years after birth is associated with expansion of the brain laterally and anteroposteriorly, which brings the eyes laterally with it. As this occurs, the sutures separating the two halves of the frontal bone (metopic suture), the two nasal bones (internasal suture), the two maxillae (intermaxillary suture), and the two palatine bones (midpalatal suture) are positioned to respond by secondary, compensatory bone formation. It has been estimated that the midalveolar and bijugale widths of the maxilla increase approximately 5 mm and 6 mm, respectively, between 7.6 and 16.5 years of age; rates of growth in width diminish slightly with increasing age.[61]

At the same time that the midface is increasing in width, it is increasing even more dramatically in depth (anteriorly) and height (vertically). The midface increases most in height, next in depth, and least in width. As the brain and eyes grow anteriorly relative to the middle cranial base, the orbits increase in depth and the anterior cranial base lengthens, primarily as a result of growth at the sphenoethmoidal synchondrosis. Concomitantly, the nasal septum grows vertically as the midface is displaced inferiorly relative to the anterior cranial base. The combination of these two growth processes—growth in a vertical direction associated with interstitial cartilaginous growth within the nasal septum and growth in an anterior direction associated with interstitial cartilage growth within both the nasal septum and synchondroses of the cranial base—results in the typical downward and forward growth of the entire midface relative to the anterior cranial base. Surface deposition cannot account for the downward and forward midfacial growth that occurs during childhood and adolescence.

The age of approximately 7 years is something of a benchmark for growth of the midface. Growth of the central nervous system—the brain and eyes—is essentially complete at about 7 years of age. Concomitantly, the cartilage of the sphenoethmoidal synchondrosis ossifies and a suture is formed between the sphenoid and ethmoid bones at about that time. As a result, a relatively stable anterior cranial base is established extending from the sella turcica to the foramen cecum. Also at about 7 years of age, the growth of the cartilages of the nasal capsule and nasal septum changes significantly. The cartilaginous nasal capsule becomes ossified, and the nasal septum, which remains cartilaginous throughout life in humans, decreases significantly in growth activity. Despite these important developmental changes in the growth processes of the midface, downward and forward skeletal growth continues to be significant over the next decade or so, particularly in males during adolescence.

Growth of the nasomaxillary complex continues throughout childhood and adolescence, with substantially greater vertical than anteroposterior growth potential (Fig. 1-23). By 4.5 years of age, palatal length (anterior nasal spine–posterior nasal spine) and anterior facial height (nasion–anterior nasal spine) have attained approximately 80% and 73% of their adult size, respectively (see Fig. 1-18). In terms of absolute growth, midfacial heights should be expected to increase 10 to 12 mm in females and 12 to 14 mm in males between 4 and 17 years of age. Palatal length should be expected to increase 8 to 10 mm over the same time period. Because nasion drifts anteriorly at approximately the same rate as the midface is displaced anteriorly, the sella–nasion–anterior (SNA) nasal spine angle shows little or no change during childhood or adolescence. Although vertical maxillary growth rates peak during adolescence, at approximately the same time as stature, anteroposterior maxillary growth remains more or less constant, with no distinct adolescent spurt.

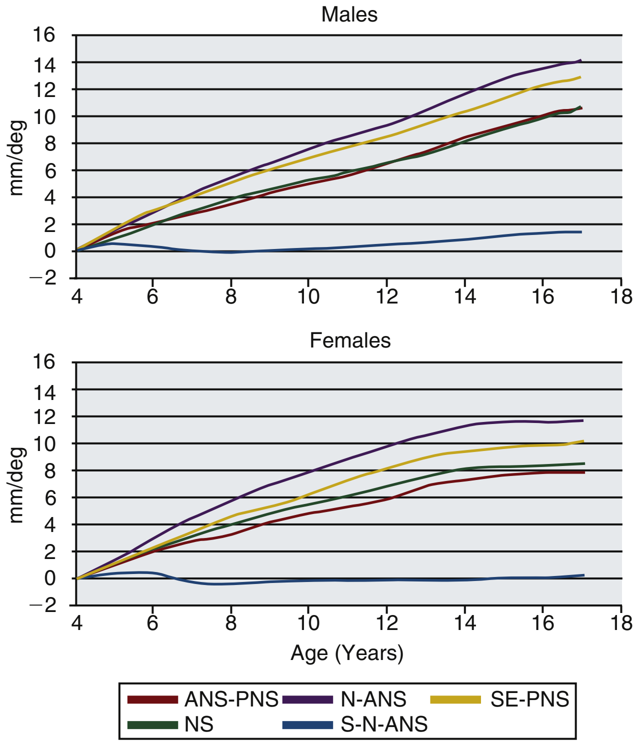

FIGURE 1-23 Maxillary growth changes between 4 and 17 years of age of males and females. (Adapted from data provided by Bhatia SN, Leighton BC. *A Manual of Facial Growth: a Computer Analysis of Longitudinal Cephalometric Growth Data.* New York: Oxford University Press; 1993.)

Because the displacements are not parallel, the midface undergoes varying amounts of vertical and transverse true rotation. True rotation is independent of surface modeling and refers to changes that occur over time in the positions of basal bone; it is commonly assessed with metallic implants placed into the mandibles and maxillae of growing children.[62] From the sagittal perspective, most children undergo true forward or counterclockwise (subject facing to the right) rotation of the midface, due to greater inferior displacement of the posterior than anterior maxilla. The true rotation that occurs tends to be covered up or hidden by the resorption that occurs on the nasal floor. For example, true forward rotation is associated with greater resorption in the anterior than posterior aspect of the nasal floor. Due to greater transverse displacements

posteriorly than anteriorly, the midfacial complex also exhibits transverse rotation around the midpalatal suture (Fig. 1-24). As a result, there is greater sutural growth in the posterior than anterior aspect of the midpalatal suture. Cephalometric analyses using metallic implants have shown that the posterior maxilla expands approximately 0.27 to 0.43 mm/yr, with greater expansion occurring during childhood than during adolescence.[60]

There are definite sex differences in maxillary postnatal growth (Fig. 1-25), with males being larger and growing more than females. Size differences, averaging between 1 mm and 1.5 mm, are small but consistent during infancy and childhood. Sexual dimorphism increases substantially throughout the midfacial complex during adolescence, with differences of approximately 4 mm in maxillary length (anterior nasal spine to posterior nasal spine [ANS-PNS]) and upper facial height (nasion to anterior nasal spine [N-ANS]) at 17 years of age. Males also have significantly wider midfaces than females, with differences approximating 5 to 7 mm during late adolescence.[63] The primary reason that adult males are larger than adult females is the 2 extra years of childhood growth that males have; males enter the adolescence phase of growth at approximately 12 years of age, while females enter around 10 years. Males are also larger than females because they experience a more intense adolescent spurt, but this contributes less to the sex differences observed.

MANDIBLE

Development of the Mandible

The mandible develops bilaterally within the mandibular processes of the first branchial arch. Each embryonic mandibular process contains a rod-like cartilaginous core, Meckel's cartilage, which is an extension of the chondrocranium into the viscerocranium. Throughout its course, distally Meckel's cartilage is accompanied by the mandibular division of the trigeminal nerve (CN V), as well as the inferior alveolar artery and vein. Proximally, Meckel's cartilage articulates with the cartilaginous cranial base in the petrous region of the temporal bone, where it gives rise to the malleus and incus bones of the inner ear.

By 6 weeks' gestation, a center of ossification appears in the perichondrial membrane lateral to Meckel's cartilage. It is critical to note that ossification of the mandible takes place in membrane *lateral and adjacent* to Meckel's cartilage, and *not within* Meckel's cartilage itself (Fig. 1-26). Therefore, it is clear that the mandible develops and subsequently grows by means of intramembranous ossification and not through endochondral ossification and replacement of Meckel's cartilage. The only portion of the developing lower jaw that appears to be derived from endochondral ossification of Meckel's cartilage is the mental ossicles, which are two very small sesamoid bones that are formed in the inferior aspect of the mandibular symphysis.[65] These bones are no longer present at the time of birth.

Intramembranous ossification of the body of the mandible proceeds distally toward the mental symphysis and proximally up to the region of the mandibular foramen. As it does so, Meckel's cartilage begins to degenerate and involute as the inferoalveolar neurovascular bundle becomes progressively enveloped by the intramembranously developing mandibular bone. Meckel's cartilage completely disappears by approximately 24 weeks' gestation, remaining in remnant form as the dense sphenomandibular ligament and giving rise to the malleus and incus ear ossicles.

Initial evidence of the formation of the temporomandibular joint (TMJ) is seen upon expression of the Barx-1 homeobox gene. By approximately 8 weeks' gestation, the condylar process appears as a separate carrot-shaped blastema of cartilage extending from the ramus proximal to the mandibular foramen and extending up to articulate with the squamous (membranous) portion of the developing temporal bone. Formation of

the joint cavity between the condylar process and the squamous portion of the temporal bone is essentially completed as the TMJ by about 12 weeks' gestation (Fig. 1-27).

As the cartilage comprising the mandibular condyle arises "secondarily" within a skeletogenic membrane and apart from the primary embryonic cartilaginous anlagen, it is referred to as a *secondary cartilage* (Fig. 1-28). Secondary cartilage is a unique type of skeletal tissue that has the characteristics of both intramembranous bone and certain histologic and functional features of hyaline growth cartilage. Secondary cartilage is formed in areas of precocious stresses and strains within intramembranous bones, as well as in areas of rapid development and growth of bone.[65,66] Within the craniofacial complex, the angular and the coronoid processes of the mandible also may exhibit the presence of secondary cartilage because these are sites of very

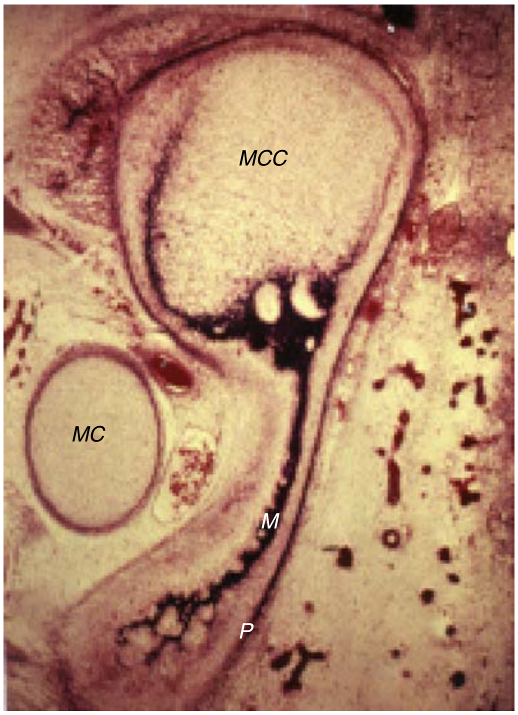

FIGURE 1-28 Frontal histologic section of a human fetus (approximately 8 weeks' gestation) (hematoxylin and eosin–stained). The bone comprising the body and ramus of the mandible (*M*) originates in the membrane lateral to Meckel's cartilage (*MC*). The periosteal membrane enveloping the mandible gives rise secondarily to the mandibular condylar cartilage (*MCC*).

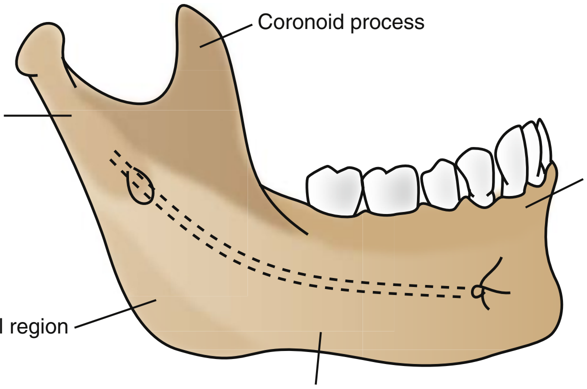

FIGURE 1-29 Major functional units of the mandible.

rapid bone growth associated with the function of the muscles of mastication. In addition, secondary cartilage may be found in areas of sutures that are characterized by rapid intramembranous bone growth and biomechanical load associated with separation and bending at the articular surfaces.

At birth, the two halves of the mandible are separated in the midline by a fibrous articulation, the mental symphysis, which will fuse by the end of the first year of life. Each half of the mandible is characterized anatomically by (1) a *condyle* and *condylar process*, which articulates with the temporal bone to make up the TMJ; (2) a *ramus*, which extends roughly vertically–inferiorly from the condylar process and provides insertions for the muscles of mastication; and (3) a *corpus*, or body, which extends roughly horizontally–anteriorly to provide a base for the mandibular dental arch and house the inferior alveolar–neurovascular bundle. Each of these anatomic structures can also be considered in terms of overlapping functional units (Fig. 1-29). The mandibular condyle and condylar processes obviously are essential for normal articular function of the TMJ and movements of the mandible, while at the same time playing a significant role in mandibular growth for most of the first two decades of life.[67] Variation in the function of the TMJ, such as might occur in association with differences in mastication, jaw movements, and jaw position, for example, is highly likely to affect its growth and form. The gonial region of the mandible, at the inferior aspect of the ramus, is related to the function of the masseter and medial pterygoid complex of muscles, while the coronoid process is primarily related to the temporalis muscle. Variation in the growth and form of each of these regions is due in large part to variation in the function of the muscles of mastication. The alveolar process of the mandible functions to provide support for the dentition. Finally, the body of the mandible, extending from the mandibular foramen to the mental process, provides support and structural connection between the various functional components of the mandible.

Growth of the Mandibular Condyle

Just as a suture can be considered to be a specialization of an osteogenic membrane (i.e., periosteum and dura mater), the condylar cartilage can also best be considered to be a specialization of periosteum. As with sutures, growth of the mandibular condyle tends to be relatively highly responsive to mechanical, functional, and hormonal stimuli both at the time of development and throughout the growth period, similar to intramembranous bone development elsewhere.

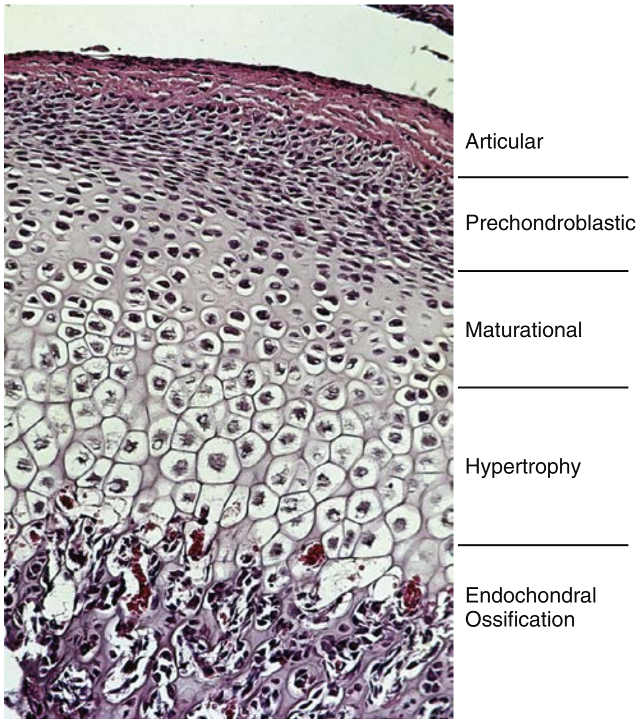

FIGURE 1-30 Histologic section indicating the various layers of the secondary cartilage in a growing mandibular condyle (hematoxylin and eosin–stained).

Histomorphology of the Growing Condyle

A number of similar but somewhat different terms have been used to describe the histomorphology of the growing mandibular condyle.[68] These are summarized according to their equivalencies in E-Table 1-2.

The secondary cartilage composing the condyle during growth can be divided into two general layers: an articular layer and a growth layer. The more superficial *articular layer* is continuous with the outer fibrous layer of the bilaminar periosteum encapsulating the condylar neck and temporal bone, respectively. Deep to the articular layer is a subarticular *growth layer*. The growth layer of the condylar cartilage is organized into an additional series of layers or zones typical of growing cartilage that blend into each other (Fig. 1-30). Each of these zones is present in the neonate and remains in the condyle through

maturity. However, their absolute and relative size as well as their growth-related activity may vary considerably, depending on the overall rate and amount of condylar growth and on the functional requirements placed on the condyle and TMJ.[69,70]

Articular layer. The articular layer of the joint surface of the mandibular condyle and temporal portion of the TMJ consist of an avascular dense fibroelastic connective tissue whose collagen fibers are oriented parallel to the articular surface. The articular layer varies in thickness along the condylar head and temporal joint surface, increasing in thickness in the superior aspect of the condyle and on the articular eminence of the glenoid fossa, where compressive forces associated with mastication are greatest.[71] The fibrous articular layer of the mandibular condyle and that found in the glenoid fossa and articular eminence are identical functionally to the articular cartilage found in the diarthroideal joints of the postcranial long bones, but their origin and histologic composition are completely different. Articular cartilage is derived from the primary cartilaginous anlagen at the ends of long bones; the articular tissue of the TMJ is a specialization of the fibrous layer of periosteum that covers the mandible and temporal bone.

Growth layer. The growth layer immediately deep to the articular layer is comprised of a series of cellular zones representing the various stages of chondrogenesis in secondary cartilage. The *proliferative*, or *prechondroblastic*, *zone* immediately deep to the articular layer is continuous with the osteogenic layer of the periosteal membrane along the condylar neck.[72,73] Its outer portion is composed of undifferentiated mesenchymal cells that differentiate into skeletoblastic stem cells or prechondroblasts. Morphologically, this zone appears as densely packed with spindle-shaped cells that increase in size and become increasingly separated due to production of intercellular matrix within the inner region of the proliferative zone. The newly formed cartilage cells in the proliferative zone express type I collagen, which is characteristic of bone and underscores the fact that the source of these cells is a periosteal-like membrane. Recent studies of gene expression in the proliferative zone demonstrate that the prechondroblastic layer is also characterized by high expression of FGF-13, FGF-18, TGF-β2, Igf-1, and VEGF.[74,75]

The *zone of maturation* contains larger, spherical, maturing chondrocytes arranged in an apparently random fashion. These cartilage cells undergo very few mitoses, which is atypical for cartilage cells found in a growing epiphyseal plate. In addition, there is significantly less extracellular matrix in the mandibular condylar cartilage than is found in the growth plates of developing long bones, which are comprised of primary cartilage. Cartilage cells within the zone of maturation are capable of switching their phenotype to express type II collagen, which is typically expressed by primary cartilage in growing epiphyses in response to biomechanical load.

Cartilage cells in the *zone of hypertrophy* become progressively larger through osmotic activity and absorption of water. Their nuclei become pyknotic and their cytoplasm is increasingly evacuated as the cells are about to be encroached upon by the osteoblasts from the endosteal region of the condyle. Genes for procollagen, aggrecan, Sox9, and Ihh are highly expressed in the chondroblastic layer.[74]

The *zone of endochondral ossification* is characterized by the initiation of mineralization of the intercellular matrix within the distal-most three to five layers of hypertrophying cells. This matrix is subsequently eroded away by osteoclastic activity and replaced by bone. The process of endochondral ossification associated with the condylar cartilage is identical to the process that takes place in the primary cartilage of long bone epiphyses.

Age-Related Changes in the Mandibular Condyle

Detailed histologic analysis of human autopsy specimens of the human TMJ has demonstrated progressive changes in the thickness and presumed growth activity of the condyle cartilage throughout development.[76–79] These changes appear to be coordinated with functional changes associated with occlusal development.[80,81] In general, the combined growth-related layers of the condylar cartilage begin as a relatively thick structure in the neonate (1.25 to 1.5 mm thick) but become much thinner (0.3 mm) by the mixed dentition stage. The cartilage remains generally thin but well defined and actively growing in the permanent dentition stage until, by age 20 to 30 years, the cartilage essentially disappears and the condyle is capped by a bony plate. Even in adults, however, it is not unusual to see areas of hyaline cartilage ("cartilage islands") deep to the articular layer in the condyle.

The subarticular region of the temporal component of the TMJ has the same tissue layers as the condyle; however, they are substantially less prominent. Morphologically, the temporal component of the TMJ in the neonate is essentially flat, and the articular disc interposed between the condyle and temporal bone is highly vascular. During the period of the primary dentition, at approximately 3 years of age, the temporal surface takes on its characteristic S-shaped contour, and the articular disc becomes avascular in its central region. Thereafter, the temporal surface of the TMJ grows more slowly, with the mandibular fossa becoming deeper as the articular eminence becomes steeper; this happens primarily through the process of bone deposition on the articular eminence and, to a lesser extent, by resorption of bone in the posterosuperior region of the fossa, as well as endosteal deposition in the superior aspect of the fossa. This increase in the contour of the temporal component of the TMJ normally continues until the fourth decade of life.

In summary, the mandibular condylar cartilage is a secondary cartilage that in subadult individuals serves both as a site of growth and as a place of articulation. As such, it displays functional characteristics of both a growth plate and an articular cartilage, but it differs from both in fundamental aspects of its development and structure throughout ontogeny. Its most superficial layers are not cartilaginous in phenotype but rather are perichondrial in origin. Importantly, the chondrocytes of the mandibular condylar cartilage are derived via mitosis in cells that are themselves not chondrocytes, similar to embryonic cartilage but not to the growth plate in which the cells that proliferate are chondrocytes. Finally, the prechondrogenic phenotype of these dividing cells in the mandibular condylar cartilage can be readily modulated to a preosteogenic phenotype by changes in the periarticular environment. Taken together, these features define a tissue with structural and growth characteristics that are consistent with the concept of an adaptive, compensatory growth site and set it apart from primary cartilaginous growth centers.

Mechanisms of Condylar Growth

The mandibular–condylar cartilage was initially considered to be a growth center with an intrinsic capacity for tissue-separating growth. However, it is now generally understood that growth of the mandibular–condylar cartilage is highly adaptive and responsive to growth in adjacent regions, particularly the maxilla. Numerous experimental studies were conducted over the past several decades to assess the role that function and jaw position, in particular, might play in influencing the postnatal growth of the mandibular condyle. For example, in a number of studies involving anterior postural change of the mandible using rats[82,83] and primates[84] as experimental animals demonstrated significant increases in the overall length of the mandible. From these experiments, Petrovic and colleagues developed a "cybernetic" model of mandibular growth regulation referred to as the "servosystem hypothesis of mandibular growth" (Fig. 1-31).[85,86]

There has been a significant expansion of knowledge concerning the molecular biology and cellular dynamics associated with growth of the condylar cartilage. It has been shown, for example, that fibroblast growth factor (FGF) and insulin-like growth factor (IGF) are present in the matrix and cell surfaces of the condylar cartilage and that they vary according to their specific location, much like in sutures. Less is known of the presence or importance of transforming growth factor-beta (TGF-β) or other growth factors, and knowledge of hormonal influences on growth of the condylar cartilage is even more rudimentary and somewhat contradictory.[87–89]

Several studies have begun to explore the molecular basis for the effect of mandibular function and position on mandibular growth by using appliances that replicate the effects (e.g., increased mitotic activity, cartilage thickness) reported previously.[90–93] Fuentes and coworkers[94] used a novel incisor-borne appliance that prompted a crossbite in growing rats and produced a differential change in proliferation and cartilage thickness between the crossbite and noncrossbite sides. In animals wearing the appliance, gene expression for *IGF-1* and *FGF-2* and their receptors in condylar cartilage was altered from that in control rats. The changes in gene expression, which typically preceded the changes in mitotic activity and cartilage thickness, were in most instances opposite in direction between the crossbite and noncrossbite sides. Using a similar design, Hajjar and associates[95] found that rats fitted with an incisor-borne appliance that prompted anterior displacement of the mandible exhibited increased expression of both IGF-I and IGF-II mRNA and protein in the MCC. Rabie and colleagues[90,96,97] demonstrated that the expression of Sox9, type II collagen, and Indian hedgehog (Ihh) was increased in the condylar cartilage and glenoid fossa of rats wearing the appliance for 1 to 2 weeks.

In general, these findings parallel the findings discussed previously for development of the sutures of the cranial vault. These similarities between the condylar cartilage and sutures should not be surprising given the periosteal origin of both suture mesenchyme and the secondary cartilage of the mandibular condyle.

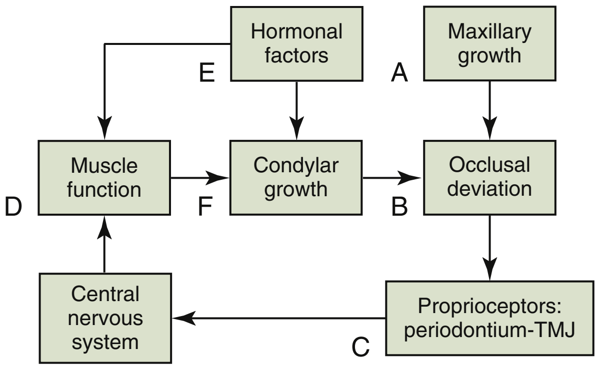

FIGURE 1-31 Simplified explanation of Petrovic's "servosystem hypothesis of mandibular growth." Independent growth of the maxilla (A) creates a minor occlusal deviation between the upper and lower dentition (B). This occlusal deviation is perceived by proprioceptors (C), which provide a signal to the muscles responsible for jaw protrusion to be tonically more active (D), which causes the mandibular condyle to become slightly more anteriorly located within the temporomandibular joint, thus stimulating condylar growth (F). Muscle function and the adaptive capacity of the condyle for growth are enhanced by expression of hormonal factors (E), and thus condylar growth may vary depending on the maturational and hormonal status of the individual. (Adapted from Carlson DS. Theories of craniofacial growth in the postgenomic era. *Semin Orthod.* 2005;11(4):172–183.)

Postnatal Growth of the Mandible

At birth, the ramus of the mandible is quite short, both in absolute terms and in proportion to the mandibular corpus. During postnatal development, the ramus becomes much more prominent, particularly in height but also in width. At the same time, the corpus increases in length, providing the necessary space for development and eruption of the mandibular dentition. Associated with these early postnatal changes in the absolute and relative sizes of the mandible are decreases in the gonial angle between the ramus and corpus and increases in the angle between the two corpora.

The mandible has the greatest postnatal growth potential of any component of the craniofacial complex. Growth changes that occur are closely associated with the functional processes that comprise the mandible, including the gonial process, coronoid process, alveolar process, and bony attachments of the suprahyoid muscles, which are all major sites of postnatal modeling. Although condylar growth is often assumed to be the mandible's primary growth site, it is important to note that the entire superior aspect of the ramus displays approximately the same amount of growth.

Viewed in its lateral projection, the posteroinferior and superior border of the ramus, including the condyle, and the posterosuperior aspect of the coronoid process are depository throughout the period of active growth. The anterior and lower borders (extending approximately to the first molars) of the ramus of the mandible are resorptive. Resorption of bone continues to occur along the anterior border of the ramus, resulting in a longer corpus and increased space for the development and eruption of the mandibular dentition (Fig. 1-32).[98] Within the corpus, the greatest growth changes are appositional growth of the alveolar bone associated with dental development and eruption. The symphysis, especially the superior aspect, becomes wider due to superior and posterior drift of its posterior aspect (Fig. 1-33).[99] There is resorption on the anterior aspect of the symphysis above the bony chin. The cortical region at or just above the chin is the only place on the entire surface of the mandible that remains stable (i.e., does not model) during postnatal growth, which is why it serves as an important site for superimposing successive radiographs. The inferior aspect of the anterior corpus tends to be depository, but the amounts of bone added are limited and variable.

Widening of the body of the mandible occurs through deposition of bone along the buccal surface and transverse rotation of the right and left corpii. The mandible also widens due to bony deposition along its posterior surface, which, due to its posterolateral orientation, produces a longer and wider body. Growth in width of the superior aspect of the ramus is somewhat more complex due to the substantial increases in height that occur. Viewed in a coronal projection, the superior aspect of the ramus and coronoid process are canted somewhat mediolaterally. As the mandibular corpus and inferior aspect of the ramus increase in width by deposition along the buccal surface, the buccal surface of bone on the superior aspect of the ramus is resorptive, while the lingual and superior surfaces of bone are depository.

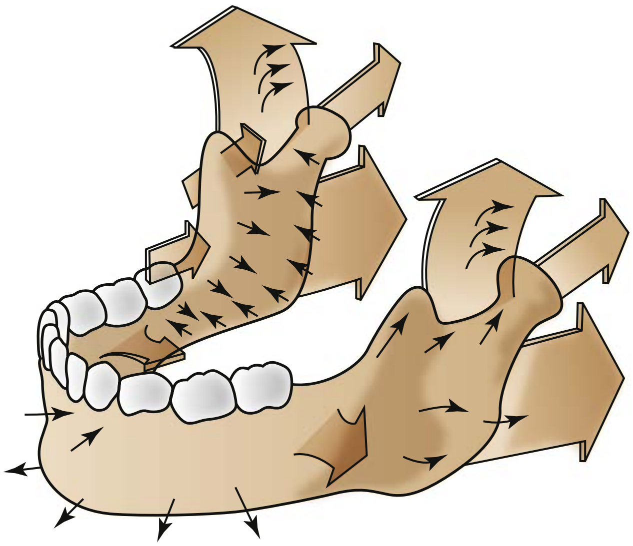

FIGURE 1-32 Mandibular remodeling, with the sizes of the arrows indicating relative amounts of change and with dark and light arrows indicating resorption and apposition, respectively. (Adapted from Enlow DH, Harris DB. A study of the postnatal growth of the human mandible. *Am J Orthod*. 1964;50:25.)

The greatest postnatal changes in mandibular growth also occur during infancy, with overall length (condylion to gnathion [Co–Gn]) increasing 15 to 18 mm during the first year, 8 to 9 mm during the second year, and then slowing down to increase approximately 5 mm during the third year. During these early years, condylar growth and modeling of the superior aspects of the ramus are directed posteriorly and superiorly, with roughly equal amounts of growth in each direction. This orientation is important because it rapidly increases corpus length to make room for the rapidly developing dentition. After the first few postnatal years, growth of the condyle and superior ramus slows down dramatically and changes orientation toward a predominant superior direction.

By 4.5 years of age, ramus height has attained approximately 64% and 70% of its adult size for males and females, respectively (see Fig. 1-18). Corpus length (Go–Gn) closely approximates the maturity pattern of midfacial height; it remains more mature than ramus height throughout postnatal growth. This supports the general principle that the vertical aspects of craniofacial growth are less mature and have greater postnatal growth potential than the anteroposterior aspects. Total mandibular length (condylion to menton [Co–Me]) undergoes the greatest increases in length (approximately 25 mm and 30 mm for females and males, respectively) between 4 and 17 years of age, followed by corpus length (gonion to pogonion [Go–Pg]; approximately 18 and 22 mm for females and males, respectively) and ramus height (condylion to gonion [Co–Go]; approximately 14 and 17 mm for females and males,

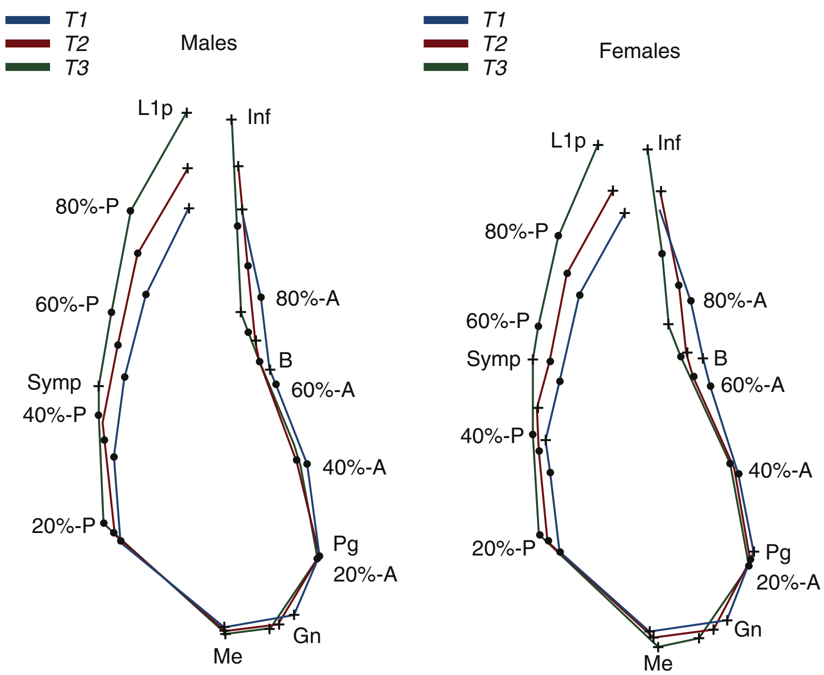

FIGURE 1-33 Remodeling changes of the symphysis between 6 (*T1*), 10 (*T2*), and 15 (*T3*) years of age. (Adapted from Buschang PH, Julien K, Sachdeva R, et al. Childhood and pubertal growth changes of the human symphysis. *Angle Orthod*. 1992;62:203–210.)

respectively) (Fig. 1-34). During later childhood and adolescence, the condyle shows substantially greater amounts of superior than posterior growth. For every 1 mm of posterior growth, there is 8 to 9 mm of superior growth. It has been estimated that the condyles of females and males grow 2 to 2.5 and 2.5 to 3.0 mm/yr, respectively, during childhood and adolescence, with the greatest rates occurring during the adolescent spurt (Fig. 1-35). The coronoid process and sigmoid notch follow similar growth patterns. Due to the resorption of bone that normally occurs in the gonial region, ramus height (measured from gonion to condylion) substantially underestimates the actual amount of growth that occurs at the condyle. There is approximately 1 mm of resorption at gonion for every 3 mm of superior condylar growth.[100] Between 7 and 15 years of age, biantegonial and bigonial widths increase approximately 10 mm and 12 mm, respectively.[61,63] Importantly, mandibular width continues to increase throughout childhood and adolescence. While an adolescent spurt in vertical mandibular growth certainly occurs, a pronounced spurt for the anteroposterior and transverse growth has not been established.

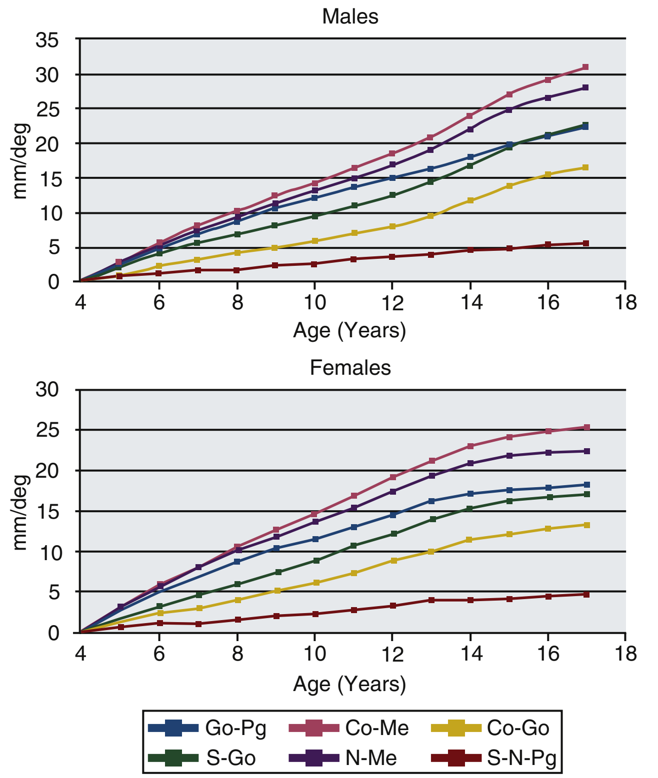

FIGURE 1-34 Mandibular growth changes between 4 and 17 years of age of males and females. (Adapted from data provided by Bhatia SN, Leighton BC. *A Manual of Facial Growth: a Computer Analysis of Longitudinal Cephalometric Growth Data.* New York: Oxford University Press; 1993.)

The mandible undergoes substantial amounts of true vertical rotation and more limited, but definite, transverse rotation. While the maxilla exhibits more transverse rotation, the mandible exhibits more vertical rotation than the maxilla. The typical pattern of vertical rotation is forward (counterclockwise with the subject facing to the right), due to greater inferior displacements of the posterior than anterior aspects of the mandible.[101] Rates of vertical mandibular rotation have been estimated to range between 0.4 and 1.3°/yr, with significantly greater rates of rotation during childhood than adolescence (Fig. 1-36). Although relatively few (<10%) children are "true" posterior rotators, up to 25% of adolescents have been reported to be posterior rotators.[80] Greater amounts of true mandibular rotation occur during the transition to the early mixed dentition than at any time thereafter.[102,103]

The mandible also rotates transversely due to greater expansion of the posterior than of the anterior aspects of the two corpii. This type of rotation has been demonstrated repeatedly in subjects with metallic implants and represents expansion of basal bone. It has also been shown that, when viewed from frontal projects, the right and left mandibular nerves are displaced laterally throughout growth. Transverse rotation is also age related, with greater amounts occurring during childhood than adolescence. The posterior aspect of the mandible expands approximately 65% to 70% as much as the posterior maxilla expands at the posterior aspect of the midpalatal suture (see Fig. 1-20).

As in the rest of the craniofacial complex, sex differences in mandibular growth are evident at the earliest ages and become pronounced during adolescence. At birth, males have significantly larger mandibles than do females. Sex differences, which are greatest for overall length, followed by corpus length and ramus height, respectively, range from 0 to 2 mm between 1 and 12 years of age, when males initiate their adolescent phase of

growth. Mandibular dimorphism increases to 4 to 8 mm by the end of the adolescent growth phase (Fig. 1-37). There are no sex differences in vertical rotation during childhood or adolescence.

In summary, the mandible increases in size as a result of the combined processes of proliferation of secondary cartilage at the condyle and differential formation and modeling of bone along the entire surface of the mandible, particularly along its superior and posterior aspects. Growth of the mandible is expressed in a downward and forward direction relative to the cranium and cranial base. The mandible is typically displaced downward more than the maxilla, with the resulting space being taken up by the erupting dentition. Due to the geometry of the craniofacial complex, normal, coordinated growth of the jaws and a normal relationship of the associated occlusal arches require that the relative rate and amount of growth of the maxilla and mandible differ.

ARCH DEVELOPMENT, TOOTH MIGRATION, AND ERUPTION

The oral apparatus is the region of the craniofacial complex that holds the greatest potential for adaptive changes. Dental arch width and perimeter change dramatically, especially during the transitions to the early mixed and permanent dentitions.[104] Maxillary intercanine width increases approximately 3 mm during the transition to the early mixed dentition and an additional 2 mm with the emergence of permanent canines (Fig. 1-38).[105] Mandibular intercanine width increases approximately 3 mm during initial transition but shows little or no change with the eruption of the permanent canines. Intermolar widths progressively increase during childhood and adolescence, approximately 4 to 5 mm for the maxilla and 2 to 3 mm for the mandible between 6 and 16 years of age (Fig. 1-39). Maxillary arch depth (incisors to molars) decreases slightly during the transition to the early mixed dentition, increases 1 to 2 mm with the emergence of permanent incisors, and then decreases approximately 2 mm with loss of the deciduous first and second molars. Mandibular arch depth decreases slightly during the transition to mixed dentition, maintains its dimension during most of the mixed dentition, and then decreases 2 to 3 mm with the loss of the deciduous first and second molars. Maxillary arch perimeter from first molars to first molars increases 4 to 5 mm during early mixed dentition and then decreases approximately 4 mm during late mixed dentition, resulting in only a slight overall increase between 5 and 18 years of age (Fig. 1-40). Mandibular arch perimeter, from first molar to first molar, on the other hand, increases approximately 2 mm during early mixed dentition and decreases 4 to 6 mm during late mixed dentition, resulting in overall decreases of 3.5 and 4.5 mm in males and females, respectively.

Perhaps most important from a clinical perspective, the teeth continue to migrate and erupt throughout childhood and adolescence, even after they have attained functional occlusion. The posteruptive movements of teeth are directly related to the spaces created by growth displacements and movements of other teeth. Dentoalveolar compensation is the mechanism that coordinates their eruption and migration relative to their jaw bases; it maintains the relationships of teeth within and between the upper and lower dental arches. Dentoalveolar compensation depends on a normal eruptive system, dental equilibrium, and influences of neighboring teeth.[105] During childhood, the maxillary incisor drifts anteriorly at a greater rate than the maxillary molar (0.8 versus 0.6 mm/yr, respectively), which accounts for the arch-depth increases evident with the eruption of the incisors (Fig. 1-41). In contrast, the mandibular molars drift anteriorly at a slightly greater rate than the incisors. Between 10 and

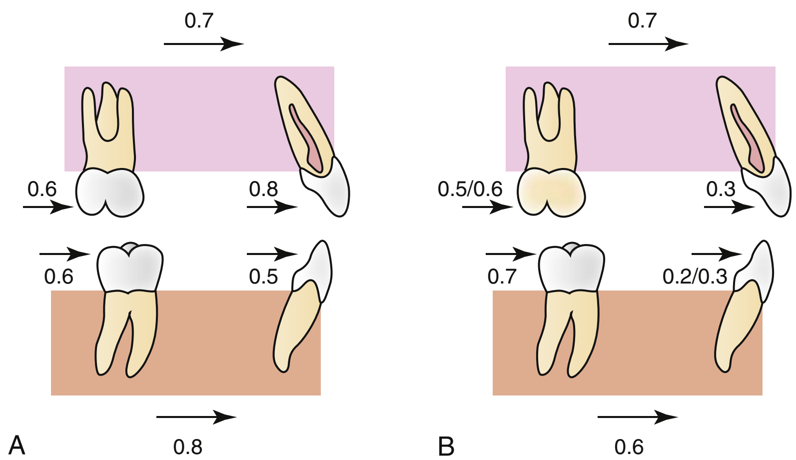

FIGURE 1-41 Approximate maxillary and mandibular AP displacements and tooth migration (mm/yr) during (**A**) childhood and (**B**) adolescence (female/male).

15 years of age, the molars (0.5 to 0.7 mm/yr) show significantly greater amounts of anterior drift than the incisors (0.3 mm/yr).

Substantial amounts of eruption occur throughout growth. During childhood, the maxillary first molars and incisors erupt at a rate of approximately 1.0 mm/yr, while their mandibular counterparts erupt at a rate of approximately 0.5 mm/yr (Fig. 1-42). During adolescence, the maxillary molars and incisors erupt at rates of 1.2 to 1.4 mm/yr and 0.9 mm/yr, respectively. The mandibular molars and incisors erupt at a rate of 0.5 to 0.9 mm/yr, with little or no differences between incisor and molar eruption. The amounts of eruption that occur are associated closely with the inferior displacements of the midface and, especially, the mandible.

During childhood, there is little or no evidence of sexual dimorphism in the migration and eruption of teeth. In contrast, there is a relatively high degree of dimorphism during adolescence in mandibular eruption, with boys showing almost twice as much eruption as girls. The maxillary teeth show only limited sex differences, pertaining primarily to the molars.

ADULT CHANGES IN CRANIOFACIAL FORM

The size and shape of the craniofacial complex continue to change throughout a considerable part of adulthood. Over 90% of the 70 cephalometric distances and 70% of the 69 angles evaluated by Behrents[106] showed changes after 17 years of age; 61% of the distances and 28% of the angles showed changes after 35 years of age. In particular, the mandibular plane angle increases in adult females and decreases in adult males, which explains why males 25 to 46 years of age exhibit greater chin projection than females, who undergo increases in NSGn.[107]

Adult soft tissues undergo the more pronounced changes than the skeletal structures. The nose grows substantially during adulthood, with the tip moving down and forward approximately 3 mm after 17 years of age. Males exhibit significantly more nasal growth than females. Upper lip length increases (approximately 2 to 3 mm) in both males and females after 17 years of age, resulting in decreases in upper incisor display over time. Lower lip length also increases, but less than upper lip length. The lips straighten and flatten during adulthood, but the most pronounced changes occur after 50 years of age. The soft tissue profile angle increases over time, with smaller increases when the nose is included than when it is excluded. Adult profile changes are limited to 2 to 3° and 4 to 6° when the nose is included and excluded, respectively.

POSTNATAL INTERRELATIONSHIPS DURING CRANIOFACIAL GROWTH

Postnatal craniofacial growth follows a gradient of relative growth that ranges between the neural and general somatic patterns. Vertical growth and modeling of the viscerocranium, as well as dental eruption, exhibit midchildhood and pubertal growth spurts. Anteroposterior growth and tooth migration, which do not exhibit midchildhood or pubertal growth spurts, change more or less regularly—except for the accelerated migration associated with the loss of teeth—throughout childhood and adolescence.

Generally, most displacements and rotations of the maxillo–mandibular complex are controlled epigenetically through growth of the chondrocranium, soft tissue growth, and expansion of the oronasal capsule. The cartilaginous growth centers play a particularly important role in the primary displacement of the chondrocranium, as well as in the secondary displacement of the viscerocranium. The anterior displacement of the midface has been associated with growth of the anterior cranial base and expansion of the anterior cranial fossa; mandibular displacements are more closely associated with growth of the posterior cranial base and middle cranial fossa. Anteroposterior length changes of the anterior cranial base, measured from sella to foramen cecum, coincide closely with expansion of the frontal lobes and growth at the sphenoethmoidal synchondrosis. Angular changes of the cranial base have been associated with growth gradients within the synchondroses, complex interactions with the growth of the brain, as well as facial growth. The cranial base angle decreases due to greater chondrogenesis in the superior than in the inferior aspects of the sphenoethmoidal and, especially, spheno-occipital synchondroses. Changes in cranial base angulation also appear to be related to changes in brain size, especially to the dramatic changes that occur during the first 2 postnatal years.

Cranial base growth influences the displacement and rotation of the viscerocranium. Growth of the posterior cranial base (i.e., spheno-occipital synchondrosis) is directly related to inferior and posterior displacements of the glenoid fossa; growth of the anterior cranial base is associated with midfacial displacement. Consequently, cranial base growth changes partially

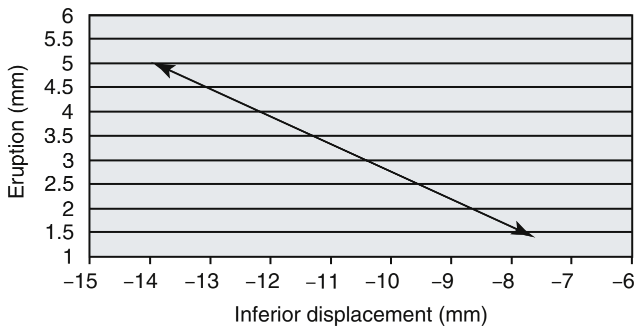

FIGURE 1-45 Relationship between the eruption of the mandibular molars and inferior displacement of the mandible.

explain individual and population differences in anteroposterior skeletal relationships. Most studies show that individuals with larger cranial base angles and/or larger anterior and posterior cranial base lengths tend to be retrognathic (i.e., Class II), whereas those with the smaller lengths and angles tend to be prognathic (i.e., Class III).

Structures within the midfacial complex also affect its displacement and rotation. Growth of the eyeball is associated with both the anterior and lateral displacements of the midface, which explains why enucleation of the eyeball results in anterior and lateral growth deficiencies of the midface.[108] The nasal septum also plays important roles in nasomaxillary growth, displacement, and rotation. However, while the anterior cranial fossa, cranial base, eyeball, and nasal septum play important roles in the early displacement and rotation of the midface, their growth potentials are limited after 7 to 8 years of age. Soft tissue growth and other factors leading to the expansion of the oronasal capsule are relatively more important in explaining the midfacial rotation and displacement during later childhood and adolescence.

In turn, mandibular displacement and rotation are greatly influenced by midfacial displacement and rotation, growth of the posterior cranial base, soft tissue growth, expansion of the oronasal capsule, and development of occlusion. Posture appears to have a profound effect on mandibular growth and remodeling. There is also a direct relationship between the true rotation of the maxilla and mandible. Both jaws usually rotate forward; individuals showing greater amount of forward rotation of the maxillary also tend to show greater forward rotation of the mandible (Fig. 1-43). Midfacial growth and the associated changes in the position of the maxillary dentition are also thought to play an important role in mandibular growth displacements. Major insults to maxillary growth can inhibit mandibular growth. Cranial growth disturbances can also influence mandibular growth indirectly through their effects on the midface, as well as on the positional changes of the glenoid fossa, especially during infancy and early childhood. For example, it has been shown that craniosynostosis, if left untreated for a sufficiently long period of time, can produce significant asymmetry of the mandible.

The anterior and, especially, inferior displacements of the maxilla and mandible have direct effects on the growth at the sutures, condylar growth, modeling patterns, dental eruption, and dental migration. Although there is an upper threshold, the amount of bony apposition that occurs at sutures is directly related to the amount of sutural separation. Larger expansion forces produce greater sutural separation, which in turn results in greater sutural bone formation (Fig. 1-44). Such growth potential is essential during periods of greater sutural separation, which require concomitantly greater bone formation. The condyle also undergoes a growth spurt that closely coincides with the increased rates of inferior displacement of the mandible that occur during adolescence.[109] Because the mandible's modeling patterns are directly related to the amounts of vertical and horizontal displacement that take place,[110] individuals with greater inferior displacement show greater superior drift of bone along the entire surface of the ramus (i.e., greater apposition superiorly and greater resorption along the lower border) than do individuals who undergo less inferior displacement. Due to the close association between mandibular displacement and rotation, individuals showing greater or lesser amounts of anterior displacement of the mandible tend to exhibit lesser or greater amounts of posterior drift of the superior aspect of the ramus, respectively. The amounts of inferior displacement of the mandible that occur are also positively related to the amount of eruption that occurs, especially of the posterior teeth (Fig. 1-45). Importantly, it is the displacement that determines the amounts of eruption that occur during growth, rather than vice versa. Displacements of the mandible also influence the anteroposterior compensations of the teeth. Individuals showing relatively greater anterior displacement of the mandible than maxilla tend to exhibit greater mesial displacement of the maxillary molars and counterclockwise rotation of the occlusal

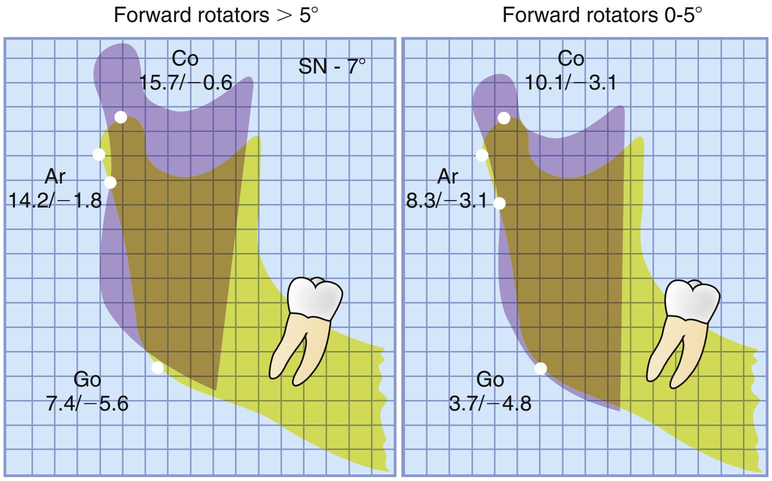

FIGURE 1-46 Vertical/horizontal (mm) remodeling changes of individuals showing greater than 5 degrees of true forward rotation, compared with those showing 0- to 5-mm true forward rotation.

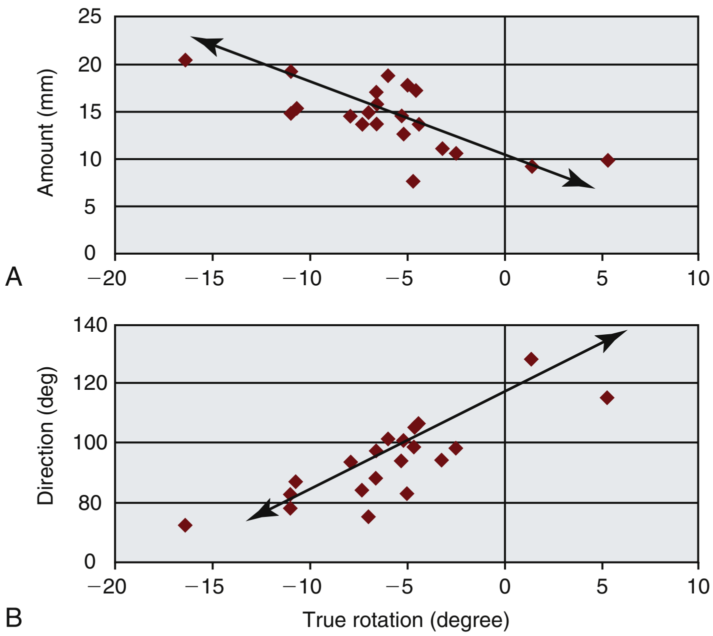

FIGURE 1-47 Relationships of true mandibular rotation and (**A**) the amount of condylar growth and (**B**) the direction of condylar growth. (Data from Björk A, Skieller V. Facial development and tooth eruption. An implant study at the age of puberty. *Am J Orthod*. 1972;62:339–383.)

plane; those who undergo relatively greater anterior maxillary displacements display greater mesial displacement of the mandibular molars and minimal mesial displacement of maxillary molars.

The morphologic correlates with true rotation are numerous and hold important clinical implications.[111] Vertical rotation has been directly related to changes in tooth position, with true forward rotators showing greater amounts of lower incisor proclination during eruption; backward rotators show retroclination of the incisors and loss of arch space. Rotation is also related to the modeling pattern that occurs on the lower mandibular border; subjects who undergo the greatest amounts of true forward rotation also exhibit the greatest amounts of posterior resorption and anterior bony deposition (Fig. 1-46). Ramus modeling in general depends on the rotational pattern of the mandible. Individuals who undergo greater amounts of true forward rotation also exhibit greater amounts of condylar growth, oriented in a more superior–anterior direction (Fig. 1-47). Perhaps the most important clinical correlate is the relationship between true rotation and chin position. True rotation of the mandible explains more of the individual variation in chin position than condylar growth or changes in glenoid fossa position.

SIGNIFICANCE OF UNDERSTANDING CRANIOFACIAL GROWTH FOR ORTHODONTICS

To be most effective as clinicians, it is essential that orthodontists understand the development, growth, and adaptive potentials of the craniofacial structures. Along with orthodontic biomechanics, knowledge of how the craniofacial complex develops and grows provides the foundation for understanding the etiology of the various dental and skeletal malocclusions, the best of all possible treatment approaches, and how patients might be expected to respond after treatment. A thorough understanding of growth provides the basis for knowing which craniofacial components might be expected to respond to a stress and how great the response might be expected to be. Because a structure's response potential to stress is directly related to its relative growth potential, and the vertical aspects of the mandible have the greatest relative growth potential, it follows that skeletal malocclusions might be expected to relate to vertical mandibular growth. Class II malocclusion, which is the predominant form of skeletal malocclusion, pertains primarily to the mandible.[112,113] These individuals are often retrognathic due to limited true forward rotation of the mandible, which is in turn related to deficient inferior growth displacement of the posterior mandible and/or excessive inferior displacement of the anterior aspect of the mandible.

Knowledge of growth is also important because, whenever possible, orthodontists should try to mimic growth when planning treatment. An understanding of growth provides the biological limits within which treatments can be performed. As previously indicated, the viscerocranium is made up almost entirely of intramembranous bone and is predominantly under epigenetic and environmental control. It is programmed to adapt, and adaptation should be expected whenever it is stressed. The biological system cannot distinguish between stresses imposed by the orthodontist and those imposed during normal growth; it simply responds depending on its growth potential. Continuing with the previous example, individuals who exhibit good growth patterns tend to be true forward rotators with condyles that grow in a more anterior direction. Based on this knowledge, hyperdivergent retrognathnic patients would best be served by treatments that focus on rotating the mandible rather than stimulating or redirecting condylar growth in a posterior direction.[114]

Finally, an understanding of growth makes it possible to estimate morphologic changes that might be expected to occur during and after orthodontic treatment. Unless it is intentionally disrupted, an individual's growth path before treatment might be expected to continue during and after treatment. Knowing how the maxilla and mandible have been rotated and/or displaced during treatment provides an understanding of the modeling and consequent shape changes that might be expected to occur. Vertical growth after treatment might be problematic in terms of posttreatment crowding, due to its relationship with tooth eruption. It has been shown that the best predictors of crowding of the mandibular incisors, both after treatment and without treatment, are the inferior displacement of the mandible and superior eruption of the incisors.[86]

As understanding of craniofacial development, growth, and adaptation continues to improve in the future, orthodontists can look forward to even more therapeutic advances that can be used to influence growth and posttreatment stability. This understanding will facilitate greater clinical control of changes in the craniofacial complex due to the normal growth process and in compensatory adaptation of tissues after treatment. Understanding normal craniofacial growth and especially that of the complex network of underlying molecular factors responsible for craniofacial growth and treatment will also be of immeasurable benefit in assisting the orthodontist in understanding what may or may not be possible, not only with respect to diagnosing a patient's underlying abnormality but also in determining the best treatment approach for its correction.[17,18,115]

Genetics and Orthodontics

James Kennedy Hartsfield, Jr., and Lorri Ann Morford

OUTLINE

Malocclusion arises from the combined interactions of genetic and environmental factors on the developmental pathway(s) involved in the formation of the orofacial region. Orthodontists who gain a solid foundational understanding of genetics are best equipped to understand why some patients develop certain occlusions. The consideration of family history and known genetic factors in the diagnosis and treatment planning of malocclusion is essential, especially since there are genetic influences on virtually all aspects of dental/facial growth and development. Therefore, to maximize the chance of successful treatment outcomes, there are two key considerations: (1) properly identify the cause of the problem before attempting treatment, (2) identify the factors that will influence the treatment outcome, or both. The factors involved in the cause may not be the same factors that would influence the treatment outcome. Knowing whether the cause of the problem is "genetic" has been cited as a factor in eventual outcome; that is, if the problem is genetic, then orthodontists may be limited in what they can do (or change).[1-3] However, this concept has often been misapplied. For example, in the orthodontic literature, there are many inappropriate uses of heritability estimates as a proxy for evaluating whether a malocclusion or some anatomic morphology is of "genetic origin." As will be explained in this chapter, heritability estimates have no relevance to the question of the genetic influence on a specific malocclusion in a particular patient. How specific genetic factors will influence a patient's responsiveness to environmental factors (including orthodontic treatment and the long-term stability of its outcome) as determined by studies of genetic markers, or gene sequences, and their impact on the proteins that they encode or influence, should be the greatest concern for the clinician.[4,5]

ETIOLOGY

Consideration of the potential cause(s) of a malocclusion requires careful contemplation of the following:

1. Most problems in orthodontics (or any outcome of growth and development), unless acquired by trauma, are not strictly the result of only genetic or only environmental factors.[6] Growth is the result of the interaction of genetic and environmental factors over time.[7,8]
2. Many studies examining the genetics of craniofacial growth are analyses of heritability. Heritability studies estimate the proportion of the total phenotypic variation, for a quantitative trait, that can be attributed to genetic differences among individuals within the specific population being examined up to the time of the analysis. Heritability studies *do not* determine the types of genetic influences or their mode of inheritance—that is, whether the trait is a single gene (monogenic) trait or a complex trait[5] with the effects of multiple genetic and environmental factors.
3. Even if a patient's craniofacial growth is influenced heavily by one gene (i.e., monogenic in familial skeletal Class III) as opposed to multiple genetic factors, there is no guarantee

that future growth will necessarily or absolutely be predetermined. Nor does it mean that growth will proceed on a particular immutable track, although traits with a monogenic influence may be less amenable to environmental (treatment) intervention than traits influenced by multiple genes. Orthodontic treatment itself is an environmental factor that can move the teeth within the hard and soft tissue envelope, but to what extent it can influence growth is difficult to determine. This is because it is impossible to really know exactly how much growth would have happened in the individual without treatment, even if compared to an untreated identical twin.

4. A patient's biological responsiveness to a particular environmental factor (e.g., orthodontic treatment) does not necessarily depend on any prior interactions of genetic and environmental factors but rather on the individual's biological responsiveness to the orthodontic treatment. The final outcome of orthodontic treatment will be a function of the overall interactions between the gene products generated from genetic factors that are expressed (or not expressed) during the treatment time, combined with any other environmental factors present during the treatment time, against the backdrop of the developmental maturity of the individual.[9-12] The most important and practical questions regarding orthodontics and genetics, however, lay in the determination of whether different patients respond to a specific type of orthodontic treatment in dissimilar ways due to the influence of their "unique" genetic makeups.

BACKGROUND AND BASIC DEFINITIONS

Before proceeding, a few basic genetic definitions and concept descriptions are required. An organism's *genome* is defined as the complete set of genetic instructions for that organism. The Human Genome Project (HGP), completed in April of 2003, was instrumental in helping us understand more about the overall size and complexity of the human genome. We learned that the human genome is made up of a double helix of deoxyribonucleic acid (DNA) comprised of ~3.2 billion chemical nucleotide base pairs.[13] The genetic instructions, or DNA code(s), are created by the linear pattern, order, and number of adenine (A), thymine (T), cytosine (C), and guanine (G) bases along the paired double helix, where A base pairs with T in the double helical structure and C base pairs with G. This genetic information is normally organized into smaller units (ranging in length from ~50 to 250 million base pairs each) called *chromosomes*.[13] A chromosome is made up of a continuous stretch of the double helical DNA that is wrapped around proteins that are called *histones*. Histones enable the DNA units to be tightly packed into the nucleus of our cells and also play an important role in regulating when and where our cells will use portions of the genetic information contained in the genome.[14] Altogether, we each inherit a total of 46 chromosomes; 22 *homologous pairs* of chromosomes called *autosomes* that are numbered by size and other characteristics, along with one pair of *sex chromosomes* that are homologous (X,X) in females and only partly homologous (X,Y) in males (Fig. 2-1). *Homologous chromosomes* are units of genetic material that are similar in

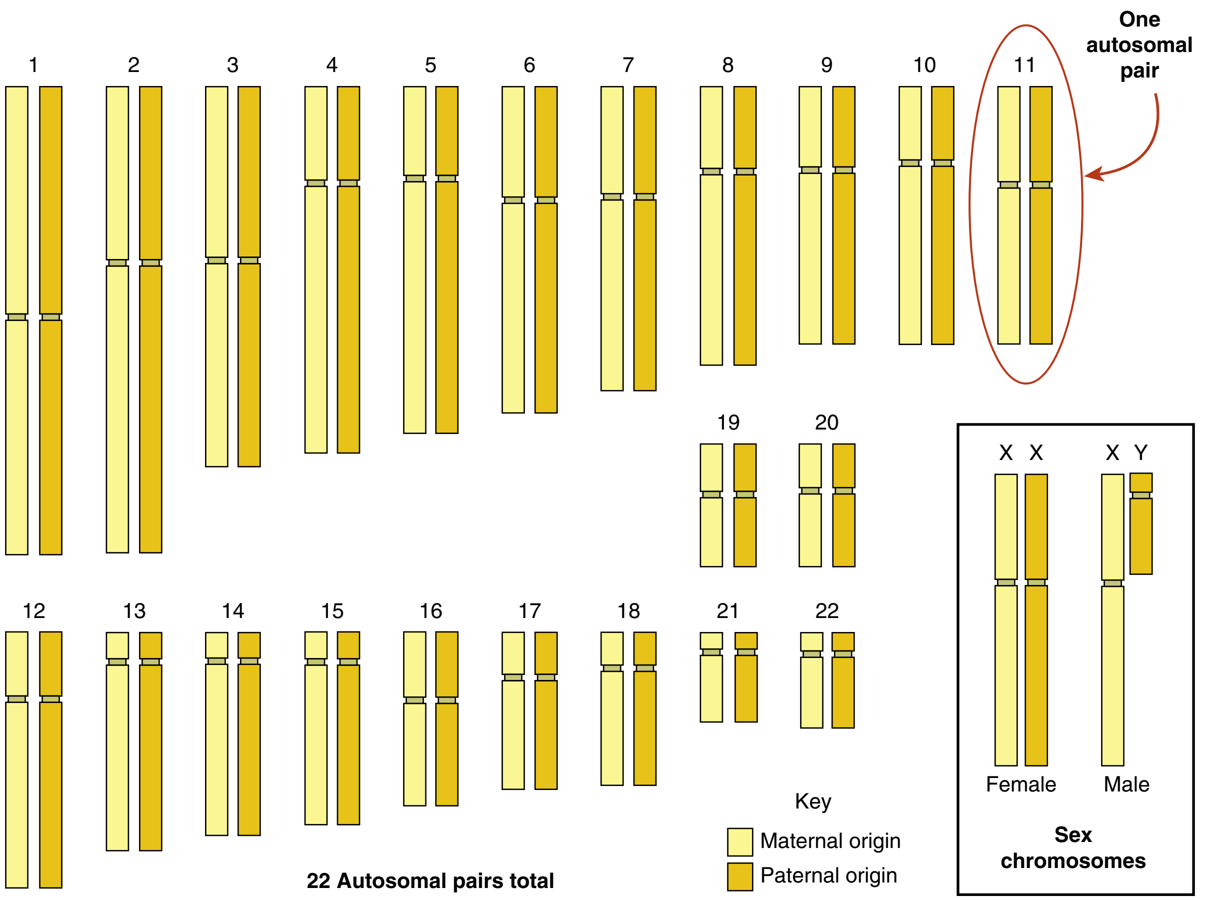

FIGURE 2-1 Diagram of human chromosomes.

size and structural features. Upon conception, a person inherits all 46 chromosomes (22 autosomal pairs total and one pair of sex chromosomes) that make them a unique individual; one chromosome for each autosomal pair is contributed by each parent, and one sex chromosome originates from each parent. Chromosomes in all subsequent cells are copies of the original maternal or paternal chromosomes.

Looking closer at the chromosomes, they are further organized into smaller units called *genes*, which represent the smallest physical and functional unit of inheritance. A gene can be defined as the complete DNA sequence that codes for the synthesis of a specific polypeptide via a messenger RNA intermediate (mRNA) (Fig. 2-2) or the synthesis of a specific RNA molecule (e.g., transfer RNA, ribosomal RNA, and noncoding regulatory RNA molecules such as microRNA or long noncoding RNA).[15] Each person normally inherits two copies of every gene within the genome: one gene copy on the autosome or sex chromosome of maternal origin and the other gene copy on the autosome or sex chromosome of paternal origin, although the X chromosome has more genes than the Y chromosome (Fig. 2-3). Based on the findings of the HGP, we have learned that (1) there are an estimated 25,000 genes in the human genome; (2) our genes only make up 2% of the whole genome; and (3) the average gene is 3000 nucleotide base pairs in length.[13]

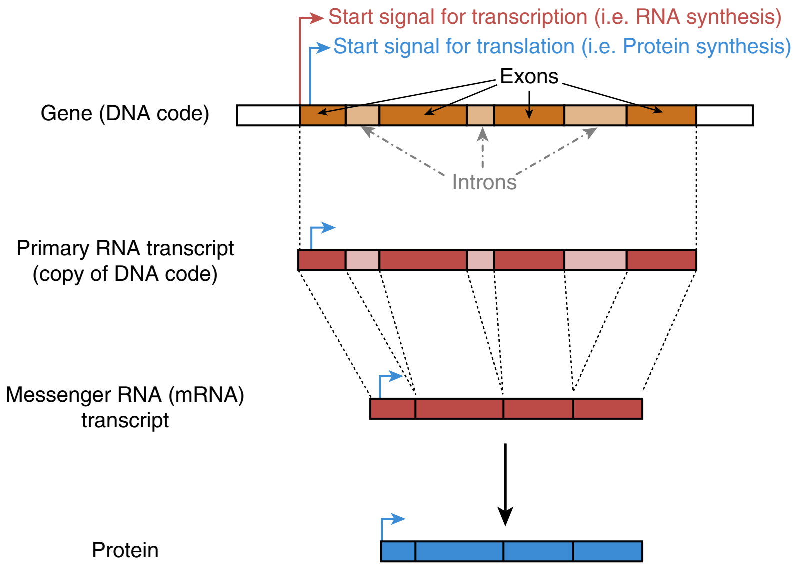

FIGURE 2-2 An illustration of how protein is synthesized from DNA. A gene contains all of the instructions in the DNA code to make a protein. Within our cells, the DNA instructions are transcribed (copied) into a primary RNA transcript by an enzyme called RNA polymerase II. The RNA transcript is processed to form a messenger RNA (mRNA) template that contains only the information that was originally coded in the genes' exon sequences (i.e., removal of the intron information). Then the code for the mRNA template is read (translated) by ribosome complexes in our cells, and protein is synthesized out of amino acids based on the information found in the mRNA.

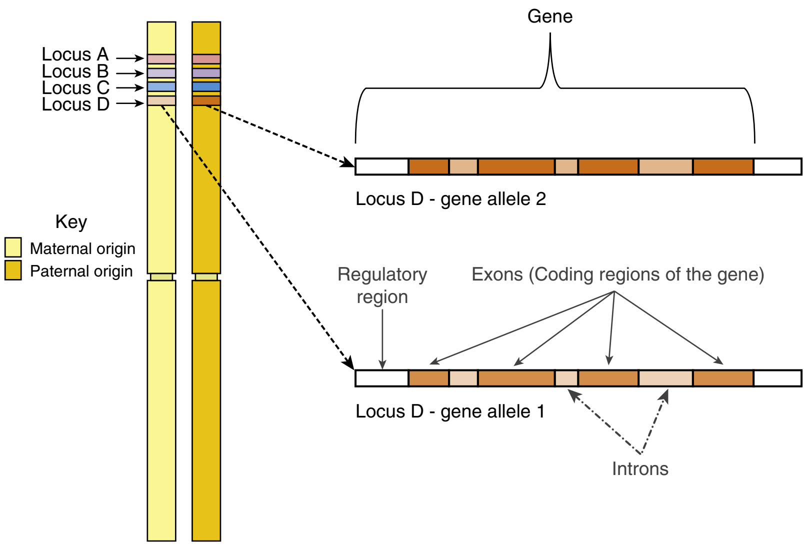

FIGURE 2-3 One autosomal pair of chromosomes illustrating the concepts of four unique gene loci contained on the autosomal pair, multiple alleles, and the general structure of a gene.

Within the human genome, every gene resides in a specific location referred to as a locus. The term *locus* is used when describing a single genetic region or location, and *loci* is plural. Genes at the same locus on a pair of homologous chromosomes are called *alleles.* One allele would be a copy of the maternal allele and the other a copy of the paternal allele. If these alleles are not identical, they can produce different polypeptide sequences and possibly diverse effects. When a pair of alleles are identical in DNA sequence (e.g., allele *A* and allele *A*), the individual is said to be *homozygous* for that locus. However, when the two alleles have one or more differences in the DNA sequence (e.g., allele *A* and allele *a*), the individual is said to be *heterozygous* for that locus. A *genotype* generally refers to the combination of alleles at a given locus within the genome (e.g., *AA*, *Aa*, or *aa*). A person's *genotype* cannot be seen with our eyes but must be determined with the use of a genetic test or analysis.

According to the information gained in the HGP, we now know that the human genome is ~99.9% identical from one person to another.[13] Thus, there is only an estimated 0.1% variation within the entire DNA code between two people that makes each individual unique. So how does this translate to the level of the gene or individual nucleotide? Homologous genes that exhibit more than one allele will vary from one another at the DNA sequence level due to either normal inherited variations or sporadic mutations. The most common inherited variation or sporadic mutation in the human genome is called a *single nucleotide polymorphism* (SNP; pronounced "snip") (Fig. 2-4). SNP describes the occasion when more than one nucleotide base (A, G, T, or C) can be inherited at a specific location in the DNA code upon comparing the DNA codes at that same position among many individuals. There are over 10 million SNPs that have been identified in the human genome to date; ~1 SNP occurs every 300 nucleotides.[13,16] Three basic categories of SNPs exist: (1) intergenic SNPs located in between genes; (2) intragenic SNPs located within the intron regions of a gene; and (3) gene coding region SNPs, which lie within an amino acid coding (exon) region of a gene. Coding region SNPs are further divided into (a) synonymous SNPs in which the variation does not lead to an amino acid change in the protein encoded by the gene and (b) nonsynonymous SNPs in which the variation does result in an amino acid change. Information pertaining to genes and such things as SNP location, the SNP minor allele frequency by ethnic group, and the biological impact of gene variations is available online at the National Center for Biotechnology Information (NCBI) Website (http://www.ncbi.nlm.nih.gov/gene/) and the 1000Genomes Browser (http://browser.1000genomes.org/index.html). Different types of sporadic or inherited variations in the DNA code can also arise from variable number tandem repeats (VNTRs; i.e., microsatellites, simple sequence repeats, short tandem repeats), gene or region duplications, insertions or deletions of a small segment of DNA sequence, inversions of the DNA sequence, translocation of a segment of the DNA sequence, or base-pair changes.

DNA variations are examined and analyzed using numerous methodologies. Large abnormalities in chromosome structure can be studied via karyotyping or genomic hybridization, which are methods that can detect insertions, deletions, translocations, and whole chromosome deletion or duplication. Smaller-scale variations can be studied: (1) within families by linkage analysis or association analysis (i.e., trios of mother, father, and child), and (2) within large populations of unrelated individuals of the same ethnic background by association analysis. These types of studies may specifically test (a) a limited number of genetic markers within a candidate gene/loci; (b) millions of genetic markers (i.e., SNPs or VNTRs) in a genome-wide association study (GWAS); or involve (c) targeted DNA sequencing, whole exome sequencing, or whole genome sequencing.[17]

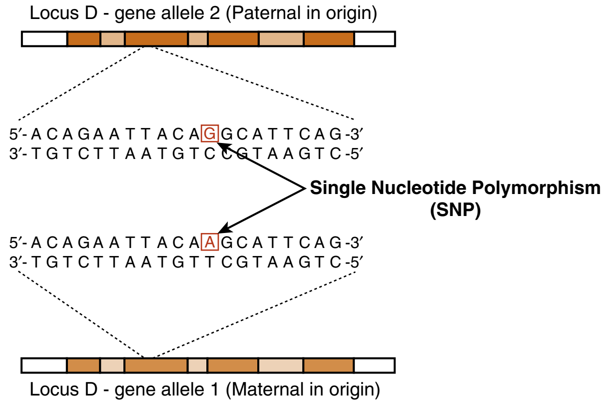

FIGURE 2-4 An example of a single nucleotide polymorphism (SNP).

In contrast to genotypes, *phenotypes* are the observable properties, measurable features, and physical characteristics of an individual.[18] A phenotype is generated by the summation of the effects arising from an individual's genotype and the environment in which the individual develops over a period of time. A *trait* is a particular aspect or characteristic of the phenotype. Examples of traits include eye color, hair color, mandibular jaw size, and stature. When considering genetic influences on traits, it is convenient to think of two types of influences: monogenic (predominantely single gene with the possibility of other smaller genetic and environmental factors), and complex (many genetic and environmental factors). Information from a numbered database/catalog of human traits, syndromes, and genetic disorders associated with monogenic influence is available at the Online Mendelian Inheritance in Man (OMIM) Website (http://omim.org/). Complex traits that are visibly expressed or not, and are not associated with a monogenic syndrome (e.g., nonsyndromic cleft lip/palate, neural tube defects such as spina bifida and anencephaly, or congenital hip dislocation), are also referred to as multifactorial traits where the combination of genetic and environmental factors have to reach a threshold for the trait to be present in that individual (Fig. 2-5).[19] For further information, the reader is referred to the reviews by Mossey,[2,20] Abass and Hartsfield,[21] Lidral et al.,[19] or Hartsfield and Bixler.[22]

TYPES OF GENETIC EFFECTS AND MODES OF INHERITANCE

It is important to understand that it is the *trait*, and *not the gene*, that influences the trait, which can be described as having a specific mode of inheritance (e.g., dominant or recessive). Why is this so? A gene is simply a set of instructions for making something. Hence, a single gene could be "turned on" (i.e., "expressed") to produce a protein that affects the development of one trait in a given tissue or area of the body. The same gene could also be "turned on" to produce the exact same protein, in a different area of the body, which affects the development of a very different trait in another tissue. Any one gene or a specific gene allele, therefore, is technically not dominant or recessive; it is simply a set of instructions. The same gene allele in

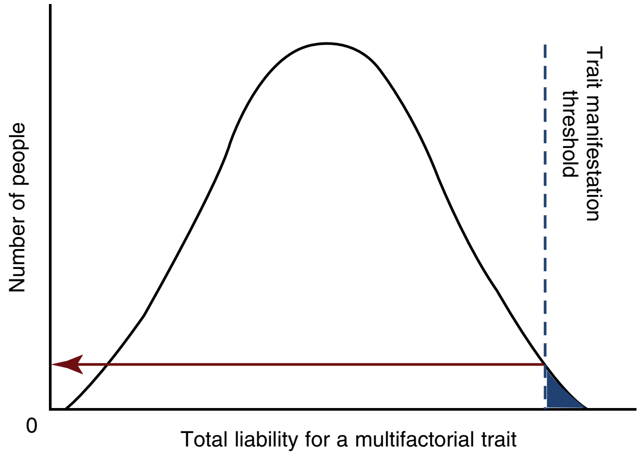

FIGURE 2-5 The liability to have a multifactorial trait is influenced by multiple genes and environmental factors that are distributed throughout a population. However, if some of the population members do not have the trait and some do, then there is a threshold on which a member of the population who has a particular susceptibility to the trait will manifest it. If the genetic liability, environmental liability, or both increase, then the liability distribution curve shifts to the right, increasing the number of persons who are affected.

an individual can influence more than one trait in that person, and each trait may have a different mode by which it is inherited. For example, the melanocortin 1 receptor gene (*MC1R*, OMIM *155555) produces a protein that is involved in the pigmentation of our skin, hair, and eyes. This gene is known to play an important role in the development of two different traits: freckles and red hair. Freckles (ephelides) are inherited as a dominant trait because a person only needs to have one causative copy of the *MC1R* gene to develop them.[23] Red hair, on the other hand, can be inherited as an autosomal recessive trait, where you have two causative copies of the *MC1R* gene to develop red hair,[23] or as a compound heterozygous trait that acts similarly to a recessive trait.[24]

Monogenic Traits

As already noted, traits that develop primarily due to the influence of a single gene locus are termed *monogenic* traits. The traits associated within the peas that Mendel described in his inheritance studies happened to be monogenic; thus, monogenic traits sometimes are called *mendelian traits.* They can have autosomal recessive or dominant, or X-linked recessive or dominant, inheritance. These types of traits also tend to be described as discrete or qualitative (dichotomous or yes/no) in occurrence. However, if they are present, these traits still may be variable and quantifiable in some cases.

Autosomal Dominant Traits and Penetrance

When a trait is present as the result of only one copy of a particular allele (e.g., *A*) in a heterozygous allele pair (e.g., *Aa*), then the trait has an *autosomal dominant* inheritance. If the trait is only present when *both* alleles at the locus are the same (e.g., *aa*; in other words, the individual is homozygous for *a*), then the trait has an *autosomal recessive* inheritance. Although it is actually the phenotype that is actually dominant or recessive and not the gene itself, the terms *dominant gene/dominant allele* and *recessive gene/recessive allele* are used commonly to describe the genes associated with these types of inherited traits in families.

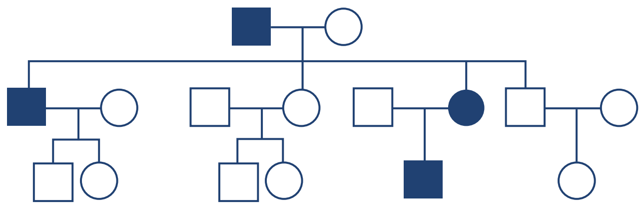

FIGURE 2-6 Three-generation pedigree of a family with an autosomal dominant trait, with the younger generations below the older generations. Square symbols are male and round symbols are female. Affected members are denoted by filling in their individual symbol.

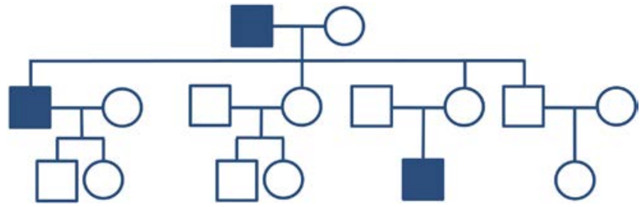

FIGURE 2-7 Three-generation pedigree of a family with an autosomal dominant trait showing incomplete penetrance. Square symbols are male and round symbols are female. Family members who are affected (the phenotype is observable) are denoted by filling in their individual symbol. An individual who does not outwardly show the trait but is able to have offspring with the trait is called a *carrier* of the genetic information that can influence trait formation.

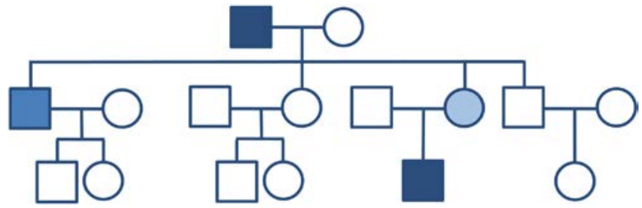

FIGURE 2-8 Three-generation pedigree of a family with an autosomal dominant trait showing variable expressivity. Square symbols are male and round symbols are female. Family members who are affected (the phenotype is observable) are denoted by filling in their individual symbol. Darker symbol filling colors are indicative of a more severe phenotype.

The nature of these family-based (familial) traits can be studied by constructing family trees called *pedigrees* in which males are denoted by squares and females by circles, noting who in the family has the trait and who does not. Constructing a pedigree as a part of the patient's medical history is indicated when more than one member of the immediate family is affected. The practitioner should solicit and record the family history in first-degree relatives of the patient (siblings and parents), second-degree relatives (half-siblings, aunts, uncles, grandparents), and third-degree relatives (first cousins). From this information, a pedigree similar to those in Figures 2-6 to 2-8, 2-10, and 2-11 may be drawn. This can be used to help understand the approximate likelihood that the patient or a sibling may also develop the same trait. This can be particularly useful for monogenic traits including Class III malocclusion, hypodontia, primary failure of eruption (PFE), and developmental dental dysplasias such as types of dentinogenesis and amelogenesis imperfecta. A family history may also be useful for complex traits such as Class II/division 2, external apical root resorption

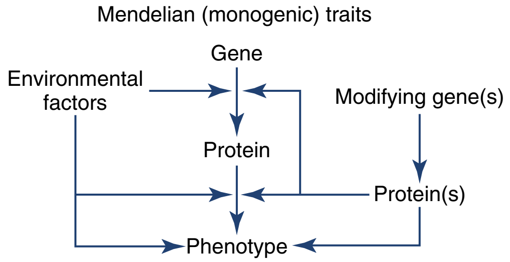

FIGURE 2-9 Mendelian (monogenic) traits or diseases result because a single gene polymorphism or mutation usually results in a recognizable phenotype. Environmental factors and other genes may modify the clinical expression of the disease or other type of trait but are not of crucial importance for its development. (From Abass SK, Hartsfield JKJ. Investigation of genetic factors affecting complex traits using external apical root resorption as a model. *Semin Orthod*. 2008;14:115–124.)

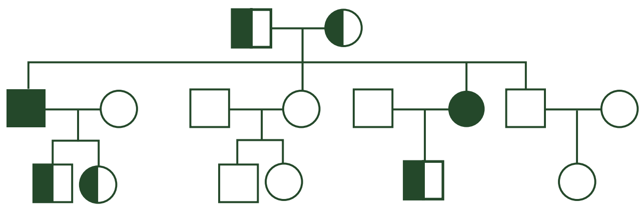

FIGURE 2-10 Three-generation pedigree of a family with an autosomal recessive trait. The symbols for presumed carriers (heterozygotes) of the autosomal recessive gene are filled in halfway. Some other family members also may be carriers but cannot be determined strictly from the pedigree.

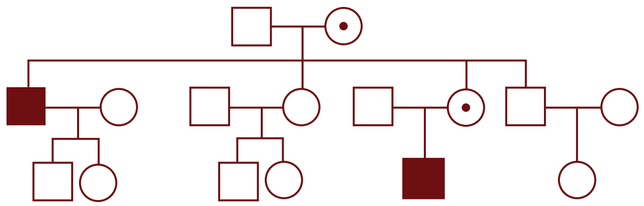

FIGURE 2-11 Three-generation pedigree of a family with an X-linked recessive trait. The symbols for presumed female carriers (heterozygotes) of the X-linked recessive gene have a dot in the middle of the circle. Some other female family members also may be carriers but cannot be determined strictly from the pedigree.

(EARR), palatally displaced canines (PDC),[25] or any trait that occurs in more than one member of the family.

The findings in the patient, combined with possible findings in other family members, may help to diagnose the presence of a syndrome or trait that may not have been previously diagnosed. For example, the presence of a single primary and permanent maxillary incisor at first may appear to be a product of dental fusion. However, if the single tooth is in the midline and symmetric with normal crown and root shape and size, then it may reflect an isolated phenotypic finding, or it could be part of the solitary median maxillary central incisor syndrome.[26] Other findings that may be syndromic in nature or of medical interest because they can be an indication for referral to a physician and/or clinical/medical geneticist include (1) dental agenesis with features of an ectodermal dysplasia, taurodontism, and/or other radiographic findings; (2) midface/malar hypoplasia, especially in the patient with any medical findings even if they seem unrelated to their craniofacial/oral findings; and (3) developmental delay. A comprehensive summary of craniofacial/oral findings along with possible syndromes that they may be a part of can be found in a resource created by Hartsfield.[27] This resource includes brief discussions and references addressing the orthodontic management of these types of cases, in addition to information on how to find and refer your patients to a clinical/medical geneticist.

If the mode of inheritance is autosomal dominant, the following characteristics may be present in a pedigree: (1) the trait occurs in successive generations (Fig. 2-6); (2) on average, 50% of the offspring of each parent who has the trait will also have the trait; (3) if an individual has the gene allele that results in the trait, each of his or her children has a 50% chance of inheriting the gene allele that leads to the expression of the trait; (4) males and females are equally likely to inherit the trait; and (5) parents who do not have the trait have offspring who do not have the trait. An exception to this occurs when the trait shows nonpenetrance in a particular offspring.

When a person inherits a gene allele or genotype that characteristically is associated with a specific trait, yet the trait is not evident in that person, then the trait is said to show *nonpenetrance* in that individual and *incomplete penetrance* (Fig. 2-7) in any group of individuals who have the genotype. The trait is present or not (nonpenetrant) in an individual. If some of the individuals do not manifest the trait in a sample of individuals with the trait-associated genotype, then the trait is said to have a penetrance of whatever percentage of the trait-associated genotype that the group actually manifests. Incomplete penetrance is a condition most commonly observed with dominant traits such as hypodontia, Class III malocclusion, and Treacher Collins syndrome, to name a few. Exceptions to this may include (1) when a new (sporadic) mutation is introduced into the DNA of the sperm or egg that will form the offspring or (2) when a germinal mosaicism arises because one of the parents was *mosaic* at the germ cell level (i.e., the sperm or eggs generated by the affected parent arise from two unique germ cell lines—one germ cell line carries a mutation and one germ cell line does not). Thus, *mosaic* is a term that describes an individual who has two of more cell populations in their body, with different genotypes, that originally came from a single fertilized egg but genetically diverged from each other during some stage of growth and development.[28] Chance usually determines which sperm cell line will be passed on. The other obvious exception is nonpaternity. Although this is not strictly a genetic problem, the illegitimacy rate in the U.S. population is high enough to make this a possible explanation for a couple without the trait to have a child with a completely penetrant dominant trait.

Variable Expressivity

Although the trait in each individual may either be present or not when discussing penetrance, if the trait is present, it may vary in its severity or degree of expression. Thus, not all individuals with the trait may have it to the same extent and they may express varying degrees of effect or severity (Fig. 2-8). Variable expressivity also may apply to the pleiotropic effect of a particular genotype; that is, the expression of the same gene may result in seemingly disparate traits in an individual. The occurrence of two or more traits appearing together, more often than what would be expected by simple chance, defines a *syndrome*. Although the term *genetic syndrome* often is used, not all syndromes necessarily have a strong genetic basis, e.g., fetal alcohol syndrome.

Variable expressivity, even in the same family with presumably the same segregating primary genetic determinant, may be observed with a large number of dominantly inherited traits, syndromes, and conditions, including Class III malocclusion,[29] hypodontia,[30] osteogenesis imperfecta involving type I collagen abnormalities,[31,32] and craniosynostosis syndromes.[33-35]

This phenomenon is presumably due to the variable interaction(s) of different proteins encoded by modifying genes plus environmental/epigenetic factors occurring in each individual (Fig. 2-9). These examples give a clear message: even an extreme phenotype that is typically associated with an autosomal dominant mutation can display some degree of variability. Simply discovering the likely causal gene mutation may indicate a future effect on craniofacial growth and development, but it will not necessarily predict the precise effect. This should be borne in mind when hoping for a precise prediction of phenotype based on genetic analysis of a complex trait, with many and not just one main genetic factor to consider.

Autosomal Recessive Traits

As previously stated, an autosomal recessive trait requires the inheritance of two causal allele copies to see an observable phenotype (i.e., homozygous *aa*). The concept of having a "gene carrier" is used regularly with autosomal recessive traits. Both parents of a child with the autosomal recessive trait are typically heterozygous for the gene allele that causes the recessive trait (i.e., they are a carrier of only one copy of the "causal" allele) and most often have a normal phenotype. Sometimes, however, the carrier status can be detected, greatly improving the precision of genetic counseling, even before a child is born with the recessive trait. The rarer the recessive gene allele, the more likely it is that the unaffected parents who have an affected child will be blood relatives—that is, a *consanguineous mating*. Still, it is highly probable that each of us carries a number of recessive-trait gene alleles, making it possible for biologically unrelated couples also to have a child with an autosomal recessive trait, condition, or syndrome. A study on inbreeding in Japan by Schull and Neel that was cited by Niswander[36] found that malocclusion occurred 6% to 23% more often (depending on the sample and the sex) in children of first cousins compared with children of nonrelated parents, indicating the potential for the effect of recessive genes when homozygous. Given that both parents who produce a child with an autosomal recessive trait are presumed to be heterozygotes, only one of the four possible gene combinations from the parents will result in the homozygous genotype associated with the autosomal recessive trait. Hence, the recurrence risk for an affected child in this case is 25% (i.e., $Aa \times A^{*}a^{*}$ would yield offspring with an approximately equal distribution of the genotypes: AA^{*}, Aa^{*}, aA^{*}, or aa^{*}, where only the aa^{*} genotype can manifest the recessive trait). Transmission of the phenotype in a pedigree is horizontal (typically present only in siblings) and not vertical, as with a dominant trait (Fig. 2-10).

X-Linked Traits and Lyonization (X Inactivation)

Most genes located on the X and Y chromosomes are not homologous and are unequally distributed between males and females. This inequality occurs because males inherit only one copy of the X chromosome along with one copy of the Y chromosome, compared to females who inherit two X chromosomes. Many of the unique genes found only on the Y chromosome influence the development of the male reproductive system. Since females inherit two X chromosomes, it is possible for them to be either homozygous or heterozygous at each X-linked gene locus, in a similar fashion to loci located on autosomal chromosomes. By comparison, however, males only inherit one X chromosome normally, and while some loci on the males' X chromosome do have a homologous locus on the Y chromosome, most loci on the males' X chromosome do not have a homologous locus in the males' genome. The term *hemizygous* is used to describe the fact that men inherit only half of the number of X-linked genes (one copy) that females inherit, a condition that can lead to interesting genetic phenotypes that are possible only in men. Accordingly, since a normally functioning homologous allele is not present on any other chromosome for some of the X-linked gene alleles in males, recessive genes located on the one male X chromosome express themselves phenotypically as if they were dominant genes. In females, both X-linked recessive genes must be present at a homologous locus to express the recessive phenotype. Consequently, full expression of rare X-linked recessive phenotypes is almost entirely restricted to males, e.g., in X-linked hypohidrotic ectodermal dysplasia (HED), although occasionally it is seen with variable severity in females (Fig. 2-11). Females who are heterozygous for the gene associated with the X-linked recessive phenotype may show some expression of the phenotype because most of the genes on one of the X chromosomes in the female will normally be inactivated by a process called *lyonization.*

Complex Traits

The predominant role of genetics in the clinic has focused on the study of chromosomal and monogenic phenotypes that are clearly associated with specific changes (mutations) in the genome of the individual. New knowledge and techniques, however, have enabled the study of various conditions and traits that "run in families" but do not adhere to patterns of mendelian inheritance. These conditions are referred to as *complex* or *common* diseases, phenotypes, or traits, reflecting their complex etiologic interaction among genes from more than one locus and environmental factors (Fig. 2-12), as well as their greater incidence/more common occurrence when compared with monogenic phenotypes.

The genetic influence on a complex trait takes place through many gene loci collectively asserting their influence on the trait. Historically, each gene involved in creating the trait was thought to have a minimal effect by itself but that the effect of all genes involved was additive. The associated phenotype is rarely discrete and is most commonly continuous or quantitative. Because these traits show a quantitative distribution of their phenotypes in a population, they do not show mendelian (monogenic) inheritance patterns. Environmental factors can play a variable and generally greater role in complex traits than in monogenic traits. A change in phenotype depends on the result of the genetic and environmental factors present at a given time. Thus, one may expect that compared with monogenic traits, complex traits will be more amenable to change (or a greater change) following environmental/treatment modification.

Another important aspect to consider, especially with complex traits, is the fourth dimension of development—time. Although an environmental/treatment modification may alter the development of the phenotype at a particular moment, gross structural morphology, already present, may not change readily unless the environmental modification is sufficient to alter preexisting structure or function.[12] This reinforces the possibility that understanding or even changing the genetic factors influencing the malocclusion may not be the same genetic factors that would influence the treatment outcome.

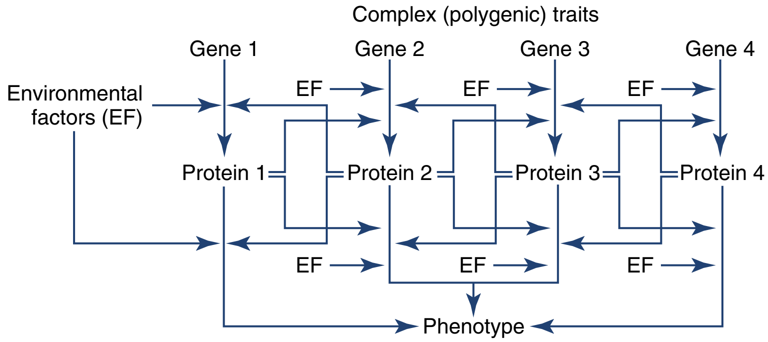

FIGURE 2-12 Unlike mendelian traits, environmental factors and multiple genes are critical to the development of complex (polygenic) traits. These types of physical traits are continuous rather than discrete (although diseases of this type can still be present or not). Such traits are referred to as quantitative traits or multifactorial because they are caused by some number of genes in combination with environmental factors. (From Abass SK, Hartsfield JKJ. Investigation of genetic factors affecting complex traits using external apical root resorption as a model. *Semin Orthod.* 2008;14:115–124.)

NATURE VERSUS NURTURE

Consideration of which factors influence, determine, or even drive growth and development has often led to discussion, if not debate, regarding the influence of nature versus nurture; as though there could only be the influence from one or the other. Growth and development, however, are not simply the results of genetic (nature) or environment (nurture) working in complete absence or independence of other. Genetic factors refer to the actual DNA code that is inherited. Environmental factors, in contrast, can include such things as diet, living conditions, stress, and learned behaviors that may influence a person's mindset, perception, and/or epigenetic landscape.

The term *epigenetic* is used to describe heritable changes to the structure of chromatin (DNA packaged around histones) that directly influence how genes are turned on and off. This type of regulation occurs in the absence of any code changes within the actual DNA sequence and can be reversible. While our DNA code provides the necessary instructions for how to make a polypeptide, a person's epigenetic landscape helps to determine what polypeptides will be made, when they will be made, and where they will be made. An *epigenetic landscape* refers to the specific pattern of modifications present on the DNA double helix backbone and/or the histone protein tails that individuals acquire from their parents and over their own lifetime. Modification of the DNA double-helix backbone by methylation, combined with various amino acid modifications on histone proteins (i.e., methylation, acetylation, phosphorylation, ubiquitination, and/or sumylation) specifically acts to "open" or "close" the regional chromosome structure to enhance or shut down gene expression. While MZ twins are identical at the level of their actual DNA code, differences in their epigenetic landscapes can still generate phenotypic differences between them. Thus, environmental factors may not only cause a change in the DNA sequence through mutations, but they may also alter gene expression (short term and long term) through epigenetic regulation. Genetic mutations, as well as epigenetic patterns located on the DNA backbone and histone protein complexes, can be inherited.[14,37]

Full siblings share, on average, half of their genes, and studies have shown that siblings can have similar occlusions. Developing similar occlusions, however, is influenced in some part by environmental factors (e.g., influenced by having dietary and respiratory factors in common) and in some part by genetic factors that influence development.[38-40] For example, malocclusion is less frequent and less severe in populations that have not been industrialized (i.e., nonurbanized) and that tend to be isolated. Typically, an increase in the occurrence of malocclusion has been noted as these populations become more "civilized" or increasingly urbanized. This has been attributed to the interbreeding of populations with different physical characteristics, presumably resulting in a synergistic disharmony of tooth and jaw relationships. This idea was supported by the crossbreeding experiments of Stockard and Anderson,[41] utilizing inbred strains of dogs that showed an increased incidence of malocclusion, typically caused by a sagittal mismatch of the jaws. The craniofacial anomalies that were produced in these experiments, however, have been attributed largely to the influence of a major gene, or collection of genes, that have been selectively bred to be part of specific canine breeds. Considering the polygenic nature of most craniofacial traits, it seems improbable that racial crossbreeding in human beings could resemble the condition of these experiments and thereby result in a synergistic increase of oral-facial malrelations.[6,36,42]

In a study of individuals from disparate ethnic groups that have interbred in Hawaii, it was discovered that children of racial crosses are at no increased risk of malocclusion beyond what would have been expected from the usual parental influence. In addition, the increase in malocclusion within populations that have moved recently into an industrialized lifestyle occurred too quickly to be attributed to genetic change caused by evolutionary fitness pressure.[42] The most likely explanation for the observed increase in the occurrence of malocclusion in "civilization" is environmental change, such as the types of foods being consumed and airway effects.[43]

Not to be lost in this discussion is the understanding that how the individual responds to environmental changes is influenced by genetic factors. Moss[8] concluded that both are necessary in a revisitation of the functional matrix hypothesis and resolving synthesis of the relative roles of genomic and epigenetic processes and mechanisms that cause and control craniofacial growth and development. Neither genetic nor epigenetic factors alone are sufficient, and only their integrated (interactive) activities provide the necessary and sufficient causes of growth and development. Moss considered genetic factors as intrinsic, while prior causes and epigenetic causes were extrinsic and proximate. The phrase *form follows function* has been used to explain that skeletal development is secondary to muscle function, airway requirements, and other causes extrinsic to the bone. However, what about genetic and epigenetic effects on muscle that then affect skeletal development? Recent research by Sciote and collaborators has shown that variations in masseter muscle fiber type, gene expression in masseter muscle, and epigenetic changes are associated with anterior open versus deep bites, mandibular retrognathism versus prognathism, and mandibular asymmetry.[44-47]

Skeletal muscle cells produce many proteins that, when in combination, define the unique characteristics and function of the muscle fiber tissue. These proteins include myosin heavy chain (MHC) protein isoforms such as (MYH7 (I), MYH2 (IIA), and MYH7 (IIX)) and cytoskeletal muscle proteins such as α-actinin-2 and -3. While α-actinin-2 appears to be found in all types of skeletal muscle fibers, α-actinin-3 is restricted to fast-contracting type II muscle fibers[48] where it enhances muscle force.[49] The proportions of muscle fiber type may be varied during growth through interactions of α-actinin-3 and calcineurin to influence variation in muscle function. In studies of muscle composition, at least four unique muscle fiber types can be described, including type I MHC-protein containing muscle fibers (termed *type I*), type IIA and/or type IIX MHC protein containing muscle fibers (termed *type II*), hybrid type I/II muscle fibers containing a mixture of both type I and II MHC proteins, and neonatal/atrial type muscle fiber containing neonatal or α-cardiac muscle isoforms combined with some type I and II MHC isoforms. Interestingly, differences in muscle fiber composition have been noted in masseter muscle tissue obtained from patients with a mandibular asymmetry. Significant increases in type II muscle fiber area and frequency on the same side as the deviation were discovered when compared to muscle fibers on the side opposite the deviation. Moreover, no significant differences were noted when comparing the muscle composition on the right and left sides of symmetrical patients.[45] Additional studies have shown that greater human facial height (i.e., vertical dimension) is inversely related to the size and proportion of masseter muscle fast, type II muscle fibers. Accordingly, short-faced, deep bite phenotypes correlated with increased type II fiber area and frequency, while long faced, open bite phenotypes showed increased type I fiber area and frequency.[44,46,47]

In contrast to the muscle fiber variations observed in vertical dimension malocclusions, muscle fiber compositions varied to a lesser degree in malocclusions affecting the sagittal dimension, although type IIA and IIX MHC proteins were expressed in the masseter muscle of individuals with mandibular prognathism (MP).[46,50] This may help to explain the relative difficulty in maintaining an overbite correction, particularly of a deep bite. Among Class III cases, differences were observed in the average fiber area when comparing normal, open bite and deep bite cases. Class III deep bite cases showed an increased amount of type I and hybrid type I/II muscle fiber areas in the masseter muscle, compared to normal and open bite cases. Sex differences have also been observed between masseter muscle fiber type and size, along with muscle growth factor–related gene expression levels.[46] Interestingly, when the *α-actinin-3* gene (*ACTN3*) alleles were homozygous for the polypeptide to stop being made at the 577th amino acid (577Stop/Stop), the patient was more likely to have a Class II malocclusion, while this genetic variation was less likely to be found in patients with a deep bite.[49]

Epigenetic factors may also influence muscle fiber types, vertical and/or sagittal dimension variations, and malocclusion types. Masseter muscle from patients with deep bite malocclusions had a higher level of gene expression (i.e., greater mRNA production) for both histone deacetylase 4 (*HDAC4*) and lysine acetyltransferase 6B (*KAT6B;* OMIM 605880) compared to masseter muscle from patients with an open bite phenotype. Since the enzymes encoded by these two genes play an important role in regulating histone acetylation patterns, it has been suggested that masseter muscle fiber variations may be influenced via an increased acetylation of histones resulting in an opening of chromatin (DNA wrapped around histone proteins) and upregulated gene expression for fast (type II) MHC genes combined with an increased deacetylation of histones and the closing of DNA containing the slow-contracting (type I) MHC gene.

In support of this hypothesis, increased gene expression of *HDAC4* was associated with increased gene expression of the fast type IIX MHC (*MYH1*) and decreased gene expression of slow type I MHC (*MYH7*) in subjects diagnosed with Class II. Increased gene expression from the *KAT6B locus*, in contrast, correlated negatively with type IIX MHC (*MYH1*) gene expression in Class III malocclusions.[44] Overall, gene expression at both *KAT6B* and *HDAC4* loci were elevated in masseter muscle from patients with Class III malocclusions compared to individuals diagnosed with Class II.[44,51] It has been proposed that the KAT6B protein could play a potential role in MP through its ability to activate the runt-related transcription factor 2 gene (*RUNX2*), which encodes an osteogenic transcription factor.[51] Finally, the genetic variation located near the *myosin 1H gene* (*MYO1H* rs10850110; OMIM 614636), which encodes an unconventional class I myosin protein, has been associated with MP.[52] The significance of this is yet to be determined, as expression levels of *MYO1H* are extremely low in masseter muscle biopsies.[51] Clearly, this new muscle-related research field will continue to add much to the understanding of the variations that result in different malocclusions, especially since the described correlations do not explain all of the phenotypic variation observed. It is likely that additional muscle, cartilage, growth factors and their receptors, and transcription factors and other genes and proteins may influence skeletal growth.

Heritability and Its Estimation

Heritability estimates can range from 0 to 1. A trait with a heritability estimate of 1 would be expressed with complete positive correlation to genotypic factors theoretically, as measured by comparing the concordance of the phenotype to the percentage of genes in common—for example, among twins or other siblings. By comparison, a trait with a heritability of 0.5 would have half its variability of concordance (from individual to individual) positively correlated with the percentage of genes in common. One must remember some important aspects of heritability studies when reviewing them in the literature. First, hereditary estimates are just that, estimates of genetic and environmental contributions that may have been affected by not accounting for a common environmental effect and ascertainment bias. They only include additive genetic influences and do not take into account genetic and environmental interactions.[39,53] In addition, heritability estimates refer to a specific sample and do not necessarily pertain to the situation of a given individual, even from within the sample. Thus, they do not allow one to tell to what degree a particular trait was determined by genetic or environmental factors in a single individual. Finally, heritability estimates are descriptive of variances within a sample at a given time; they are not predictive.[54]

Although the mode of inheritance (e.g., autosomal dominant or polygenic) of a trait is a fixed property in a given individual, heritability is not.[55] It is important to understand that heritability estimates can change with age. This was demonstrated in a longitudinal analysis of 30 sets of siblings, none of whom had undergone orthodontic treatment, which showed a significant increase overall in median heritability estimates between the ages of 4 and 14 years for 29 craniofacial skeletal variables. The affected variables included increases for total anterior face height, upper anterior face height, total posterior face height, and upper posterior face height. Still, despite the general increasing trend in heritability estimates for the craniofacial skeletal variables, a decrease was noted for lower posterior face height. The median estimates of heritability for craniofacial skeletal variables increased from 0.6 at age 4 years of age to 0.9 at age 14 and 20 years of age. This is in contrast to the heritability estimates of arch and occlusal variables that decreased from 0.5 at age 4 years to 0.2 and 0.1 at ages 14 and 20, respectively.[56]

Numerous studies have examined through heritability estimates how genetic variation in a sense correlates with either or both occlusal and skeletal variation among family members.[1,6,53,56-76] In most studies (particularly those that try to account for bias from the effect of shared environmental factors, unequal means, and unequal variances in monozygotic (MZ) and dizygotic (DZ) twin samples),[10] variations in cephalometric skeletal dimensions are associated in general with a moderate to high degree of genetic variation, whereas variation of occlusal relationships has generally little or no association with genetic variation.[5]

Although the heritability estimates are low, most of the studies that looked at occlusal traits found that genetic variation has more to do with phenotypic variation for arch width and arch length than for overjet, overbite, and molar relationships. Still, arch size and shape are associated more with environmental variation than with genetic variation.[61] Even so, recent preliminary GWAS data suggest relationships of the protein kinase D1 (*PRKD1*) gene with anteroposterior (AP) discrepancies between the maxillary and mandibular arch, the *Caenorhabditis elegans* homolog of the RNA-binding protein FOX1 (*RBFOX1*) gene with arch width variation, and the homolog of the drosophila dachshund 1 (*DACH1*) gene with AP discrepancies with variation in the curve of Spee.[77] Although these findings are among the first to identify variation in dental arch shape and position that may be related to variants in these genes, the mechanisms by which they affect these phenotypes are unknown.

The heritability of a trait cannot necessarily be extrapolated from one sample and set of environmental conditions to another.[9] For example, heritability estimates of lower anterior face heights change more than upper anterior face heights in a group of subjects who have a change in their breathing pattern.[78] Therefore, a high heritability cannot measure if a trait can be influenced substantially by subsequent changes in environmental/treatment conditions.[5,9] Still, confirming a certain degree of genetic influence on a trait for a particular sample in a particular environment at a particular time is a preliminary step to further specific genetic studies to determine areas of the genome that appear to be associated with the characteristics of a given trait.[54]

Use of Family Data to Predict Growth

Siblings have been noted as often showing similar types of malocclusions. Examination of parents and older siblings has been suggested as a way to gain information regarding the treatment need for a child, including early treatment of malocclusion.[36,74,79,80] Niswander[36] noted that the frequency of malocclusion is decreased among siblings of index cases with normal occlusion, whereas the siblings of index cases with malocclusion tend to have the same type of malocclusion more often. Harris and colleagues[68] showed that the craniofacial skeletal patterns of children with Class II malocclusions are heritable and that a high resemblance to the skeletal patterns occurs in their siblings with normal occlusion. From this it was concluded that the genetic basis for this resemblance was probably due to multiple genetic factors, and family skeletal patterns were used as predictors for the treatment prognosis of the child with a Class II malocclusion, although it was acknowledged that the current morphology of the patient is the primary source of information about future growth.[80]

Although each child receives half of his or her genes from each parent, they are not likely the same combination of genes in each sibling, unless the children are MZ twins. When looking at parents with a differing skeletal morphology, it is difficult to know which of the genes, in what combination from each parent are present in the child until the child's phenotype matures under the continuing influence of environmental factors. As Hunter[81] pointed out with polygenic traits, the highest phenotypic correlation that can be expected based on genes in common by inheritance from one parent to a child, or between siblings, is 0.5. Because the child's phenotype is likely to be influenced by the interaction of genes from both parents, the "mid-parent" value may increase the correlation with their children to 0.7 because of the regression to the mean of parental dimensions in their children.

Squaring the correlation between the two variables derives the amount of variation predicted for one variable in correlation with another variable. Therefore, at best, using mid-parent values, only 49% of the variability of any facial dimension in a child can be predicted by consideration of the average of the same dimension in the parents. Only 25% of the variability of any facial dimension in a child can be predicted, at best, by considering the same dimension in a sibling or one parent. Because varying effects of environmental factors interact with the multiple genetic factors, the usual correlation for facial dimensions between parents and their children is about 30%, yielding even less predictive power.[81]

Unfortunately, orthodontists usually do not have sufficient information to make precise and accurate predictions about the complex development of occlusion simply by studying the frequency of its occurrence in parents or even siblings. Still, family patterns of resemblance are frequently obvious and are ignored at our risk. The taking of a family history as already mentioned, especially for traits that have or can have a monogenic inheritance, can alert practitioners to the increased likelihood of the same trait developing in their patient.

FACIAL GROWTH

Growth Differences during Puberty

Approximate facial growth predictions based upon expected growth curves may be useful for the average patient, but a more precise and valid prediction must incorporate and account for the variation associated with individual genetic factors, including those that are highly pertinent to the pubertal growth spurt. The pubertal growth spurt response is mediated by the combination of sex steroids, growth hormone, insulin-like growth factor, and other endocrine, paracrine, and autocrine factors. The administration of low doses of testosterone in boys with delayed puberty not only accelerates their statural growth rate but their craniofacial growth rate as well.[82]

In addition to testosterone, estrogens are also a group of hormones involved in growth and development.[83] Aromatase (also known as estrogen synthetase) is a key cytochrome P450 enzyme involved in estrogen biosynthesis by catalyzing the final rate limiting step of converting testosterone and androstenedione to estradiol and estrone, respectively.[84] *CYP19A1* is the gene that encodes aromatase; therefore, regulation of this gene's transcription is critical for the testosterone/estrogen (T/E) ratio in the body. Some studies have shown that the T/E ratio is critical in the development of sex-indexed facial characteristics such as the growth of cheekbones, the mandible and chin, the prominence of eyebrow ridges, and the lengthening of the lower face.[85,86]

A significant difference in the average sagittal jaw growth was observed between the groups of Caucasian males examined who inherited different *CYP19A1* alleles/genotypes (rs2470144-T/T versus C/T or C/C, and rs2445761-T/T versus C/T or C/C); with the greatest differences in growth per year just over 1.5 mm per year during treatment for the maxilla, and 2.5 mm per year for the mandible. There was no statistical difference for the particular *CYP19A1* alleles in females. This is particularly impressive since at the beginning of treatment there was no significant difference among the males based upon the *CYP19A1* genotype. The significant difference only expressed itself over the time of treatment during the cervical vertebral stage associated with increased growth velocity.[87]

Interestingly, the same result was found in a group of Chinese males and females, strongly suggesting that this variation in the *CYP19A1* gene may be a multiethnic marker for sagittal facial growth.[88] Although the differences in average annualized sagittal mandibular and maxillary growth based upon the *CYP19A1* genotypes were significant, i.e., associated with the complex trait of sagittal jaw growth, they accounted for only part of the variation seen, and therefore by themselves have little predictive power. Further investigation of this and other genetic factors and their interactions with each other and with environmental factors will help to explain what has up to now been an unknown component of individual variations in pubertal facial growth.

Mandibular Prognathism/Class III Malocclusion

Searching for the term *malocclusion* in OMIM (http://omim.org/) reveals more than 100 entries for a variety of syndromes and traits that may include malocclusion as one of their features. Perhaps the best known example is the familial "MP" (OMIM *176700) referred to as the *Hapsburg jaw*. Although MP has been said to be a polygenic[79] or multifactorial trait (i.e., influenced by the interaction of many genes with environmental factors), in the majority of cases, there are families in which the trait (and possibly some other associated findings) appears to have autosomal dominant inheritance, such as in the European noble families. Analysis of a pedigree comprising 13 European noble families with 409 members in 23 generations determined that the MP trait was inherited in an autosomal dominant manner, with a penetrance of 0.95 (i.e., 95% of the time that someone was believed to have the gene for the MP trait in his or her pedigree, the trait itself also was expressed). Although the penetrance is high, considerable variation exists in the clinical expression of the trait, as already mentioned.[89]

Additional studies have supported the autosomal dominant mode of inheritance with variable expressivity and incomplete penetrance,[90] which may also have a major gene and multifactorial influence.[29]

Also noted was that some of the members of the European noble families had, in addition to varying degrees of MP, other facial characteristics such as a thickened lower lip, prominent nose, flat malar areas, and mildly everted lower eyelids (which may be associated with a hypoplasia of the infraorbital rims), as also were reported in three generations of a family by Thompson and Winter.[91] Apparent maxillary hypoplasia, as well as malar flattening and downward eversion of the lower eyelids, may indicate that although the trait is referred to as MP, the overall clinical effect may be at least in part due to hypoplasia of the maxilla.

Clinically, we observe a variety of anatomic changes in the cranial base, maxilla, and mandible that may be associated with "MP" or a Class III malocclusion.[92,93] Understanding the concept of phenotypic and genetic heterogeneity is critical to understanding the genetic influences on all types of phenotypes.[94] For example, although orthodontists often first classify a malocclusion as Angle Class I, II, or III, we also know that a number of different subtypes of occlusions have varying genetic and environmental influences. The concept of further delineating the Angle classification has clinically been done for the Class II division 1 and 2 phenotypes. A rationale for further subtypes is based on statistical cluster analysis of cephalometric variables that may or may not have undergone a Procrustes transformation to standardize for size, leaving differences in relative size and shape to undergo morphometric analysis. Most of the studies have sought to delineate Class III subtypes, finding either five or seven of them as separate clusters.[95] Other studies have done the same with Class II subjects.[96,97] Since they analyze different populations with sometimes different methods, it is not surprising that they do not all conclude with the same number of clusters or subtypes. Still, the clustering effect based on cephalometric morphology could have clinical importance as the subtypes may be treated differently, or have different outcomes, or retention concerns. We already do this to some degree based on observation of subtypes based on open bite versus deep bite, etc. In addition, the subtypes may be more homogeneous endpoints to explore the genetic and environmental factors that produce them and how they respond to different treatment and retention modalities.

The prevalence of Class III malocclusion varies and can show different anatomic characteristics among different ethnic groups. Considering this heterogeneity and possible epistasis (the interaction between or among gene products on gene expression), it is not surprising that genetic linkage studies to date have indicated the possible location of genetic loci influencing this trait in several chromosomal locations.[95,98] In studies of Asians, genetic linkage and association studies have identified multiple loci and candidate genes connected to the Class III phenotype, including 1p22.3, 1q32.2, 1p35-36 (matrillin-1, *MANT1;* erythrocyte membrane protein band 4.1, *EPB4.1*; heparin sulfate proteoglycan 2, *HSPG2*; alkaline phosphatase, *ALPL*), 3q31.2, 4p16.1, 6q25, 12q13 (collagen, type II, alpha 1, *COL2A1*), 14p24.3, and 19p13.2.[99-105] By comparison, several unique loci were identified in linkage analysis of the Class III phenotype in multiple South American families including 1p22.1-22.2, 3q26.2, 7p21, 11q22.2-q22.3, 12q13.13, and 12q23.[106,107] In an association analysis of Class III malocclusion cases with a U.S.-based population compared to Class I and comprised of multiple ethnic backgrounds (European, African, Hispanic, and Asian), the SNP rs10850110 within the *MYO1H* on chromosome 12q24.11 was found to be associated with Class III, as already mentioned in the discussion of the effects of muscle variation.[52] While numerous genetic loci have been associated with Class III, so far only four causal genetic mutations have been identified in familial Class III malocclusions within the following genes: (1) dual specificity phosphatase 6 (*DUSP6*) gene (c. 3361G>A; p.Ser182Phe; rs139318648) in a family from Estonia[108], (2) Rho GTPase activating protein 21 (*ARHGAP21*) gene (c. 3361G>A; p.Gly1121Ser; rs111419738) in an Italian family:[109], (3) a mutation in the fibroblast growth factor 23 (*FGF23*) gene (c.35C>A; p. Ala12Asp; no assigned rs number) in a family from the Henan Province of China new[110], and (4) a mutation in the ADAM Metallopeptidase with Thrombospondin Type1, motif 1 (*ADAMTS1*) gene (c.2225T>C; p.Ile742Thr; rs200052788) in a Chinese family new[111].

Class II Division 2 (II/2) Malocclusion

The Class II division 2 (II/2) malocclusion is a relatively rare type of malocclusion, representing between 2.3% and 5% of all malocclusions in the western Caucasians.[110a,111a] There is evidence that Class II/2 can have a genetic component based upon a twin study in which all 20 MZ twin pairs were concordant for Class II/2, while only 10.7% of 28 DZ twin pairs were concordant.[112] The much lower concordance for DZ twins suggests that more than one genetic factor contributes to Class II/2. Further evidence for Class II/2 to have a polygenic complex etiology was found in a study of 68 Class II/2 patients, with a relative risk (RR) of first-degree relatives of the patients to have a Class II/2 of 3.3 to 7.3. The 95th percentile confidence interval was 1.1 to 10.3 if the RR was 3.3 and 1.7 to 31.6 if the RR was 7.3.[113]

There is a strong association of Class II/2 with dental developmental anomalies, more so than for other Angle malocclusion classes. Dental agenesis excluding third molars was at least three times more common in Class II/2 subjects than in the general population.[114,115] In addition, there is a statistically significant reduction in permanent maxillary incisor mesial-distal width associated with Class II/2,[116] which could influence anterior Bolton discrepancies.

TOOTH SIZE AND AGNESIS

Dental Crown Morphology

Investigation of the genetic and environmental factors that affect dental crown morphology, especially mesial-distal dimensions, is important since tooth size variation may more often play a role in skeletal Class I crowding than skeletal growth variation.[117-120] Additive genetic variation for mesial-distal and buccal-lingual crown dimensions of the permanent 28 teeth (excluding third molars) ranged from 56% to 92% of phenotypic variation, with most over 80%.[121] Estimates of heritability for a number of variables measuring overall crown size of the primary second molars and permanent first molars were moderate to high. Yet, less genetic variation was associated with distances between the cusps on each tooth, implying that phenotypic variation for overall crown size was associated more with genetic variation than was the morphology of the occlusal surfaces.[122] Based on studies of epithelial–mesenchymal interactions during tooth generation, cell proliferation in a specific spatiotemporal pattern along with *sonic hedgehog* (*SHH*) gene expression appears to have a major influence on crown width and cusp number.[123] Thus, *SHH* may be a candidate gene for Class I malocclusion with dental crowding. SNPs in the ectodysplasin-A (*EDA*; OMIM 300451) gene and the gene for its receptor, ectodysplasin A2 receptor (EDA2R/XEDAR) were found to be associated with dental crowding greater than 5 mm in a Hong Kong Chinese Class I malocclusion sample. It was thought that this may at least be due in part to variation in tooth size as the protein product of *EDA* is involved in tooth development, and mutations in *EDA* cause X-linked HED. Although these genes are located on the X chromosome, the associations remained after adjustment for sex.[120]

Dental Agenesis

Dental agenesis may occur within the context of having a family history of dental agenesis (familial) or due to a newly introduced mutation (sporadic), although it is most often familial in origin and usually observed as an “isolated” trait (i.e., nonsyndromic). Dental agenesis, however, may also occur as part of a syndrome, especially in one of the many types of ectodermal dysplasias. Genetic factors are believed to play a major role in most of these cases with autosomal dominant, autosomal recessive, X-linked, and multifactorial inheritance reported;[124] however, epigenetics and environment can also be involved in the etiology.[125]

A general trend in patients with dental agenesis is to have the mesial-distal size crowns of the teeth present to be relatively small (especially if more teeth are missing). The mesial-distal size of the permanent maxillary incisor and canine crowns tends to be large in cases with supernumerary teeth.[126] Relatives who do not have dental agenesis may still manifest teeth that are smaller than normal in size. This suggests a polygenic influence on the size and patterning of the dentition, with a multifactorial threshold for actual hypodontia in some families.

One of the most common patterns of hypodontia (excluding the third molars) involves the maxillary lateral incisors. This can be an autosomal dominant trait with incomplete penetrance and variable expressivity as evidenced by the phenotype sometimes “skipping” generations, sometimes being a peg-shaped lateral instead of agenesis, and sometimes involving one or the other or both sides.[127] A polygenic mode of inheritance also has been proposed.[128] Currently unidentified, the gene mutation that primarily influences this phenotype has been suggested, in the homozygous state, to influence agenesis of the succedaneous teeth or all or almost all of the permanent dentition.[129,130] In addition, an associated increase in the agenesis of premolars occurs,[131] as well as the appearance of PDCs.[132]

Numerous mutations in transcription factor and growth factor–related genes involved in dental development have been shown to have roles in human dental agenesis, including paired box 9 (*PAX9*; OMIM 167416) and muscle segment homeobox 1(*MSX1*; OMIM 142983). Mutations in *PAX9* typically show a nonsyndromic autosomal dominant mode of inheritance for oligodontia with variable expressivity within families.[133-137] The characteristic pattern of dental agenesis caused by *PAX9* mutations largely affects molars in both dental arches and second premolars most often in the maxilla arch than the mandibular arch,[137,138] occasionally presenting with missing or peg-shaped mandibular central incisors and/or maxillary lateral incisors.[134-139] Agenesis of maxillary first premolars[136,138,140] and/or canines can occur with a low frequency among *PAX9* mutations,[138,140,141] while the *PAX9* Ala240Pro (c. G718C) mutation may be unique in that it leads uniquely to third molar agenesis with or without affected incisors.[142-145] *MSX1* gene mutations can lead to hypodontia or oligodontia,[138,146-155] as well as variations in the downstream signaling gene *BMP4*.[156] Mutations in the Axis inhibitor 2 gene (*AXIN2*; OMIM 604025) have also been linked to oligodontia, often exhibiting a similar pattern of affected teeth as *PAX9* mutations (i.e., molars, premolars, mandibular incisors > maxillary lateral incisors > canines).[138,157] The AXIN2 protein is a regulator of WNT and β-catenin signaling, so it is not surprising that mutations in the wingless-type MMTV integration site family, member 10A (*WNT10A*; OMIM 606268) gene have also been linked to hypodontia and oligodontia.[158-163] Other chromosomal locations and/or candidate genes thought to be involved in nonsyndromic hypodontia and/or oligodontia include,[164-171] EDA receptor–associated death domain gene (*EDARADD*),[138] transforming growth factor–alpha gene (*TNFA*),[172,173] interferon regulatory factor 6 (*IRF6*),[174,175] fibroblast growth factor receptor 1 (*FGFR1*),[174] transforming growth factor-β3 (*TGFβ3*),[156] C2H2 zinc finger transcription factor 22 (*KROX-26/ZNF22*), and 10q11.2 (OMIM 610926).[124,176,177] Many nonsyndromic EDA mutations affect incisor, canine, and premolar development.[164-171] The latent transforming growth factor beta binding protein 3 (*LTBP3*; OMIM 602090) gene, which may also influence traits of short stature and increased bone density, plays a role in autosomal recessive hypodontia.[150,178,179] An increased understanding of the various morphogenetic signaling pathways regulating tooth development should allow for induction of tooth development in areas of tooth agenesis.[180]

With the push for more personalized medicine, we are now learning more about how phenotypes and/or disease in the oral cavity can serve as a diagnostic marker or indicator of susceptibility to other health issues outside of the oral cavity. In addition to the association of dental agenesis with many syndromes, mutations in tooth development genes have been associated with other medical conditions, such as cancer. In 2004, Lammi et al.[157] reported on a Finnish family with multiple members who manifested oligodontia early in life and colon cancer later in life. These two traits segregated in an autosomal dominant pattern of inheritance with a rare nonsense mutation in the *AXIN2* DNA sequence (1966C > T) that leads to an amino acid change (p. Arg656STOP).[157] *AXIN2* mutations may also be involved with dental agenesis in combination with a variety of other phenotypes, including early onset colon and breast cancers, prostate cancer risk, mild ectodermal dysplasia, colonic polyposis, gastric polyps, and gastric cancer.[181-183] While some studies have begun to examine connections between dental tooth agenesis and epithelial ovarian cancer,[184-186] other studies have connected dental agenesis with a self-reported family history of cancer;[187] however, the causal genes are yet to be determined. Although these associations are interesting because of the possibility of the orthodontist or other dental practitioner referring an individual or family for cancer susceptibility testing or clinical screening someday, it must be emphasized that the actual risk of an increased likelihood of developing cancer associated with dental agenesis is unknown and may be very small in the general public. Further investigation is needed into this area, particularly for biomarkers that may help to determine if there is a greater risk and, if so, who has that risk.

DENTAL ERUPTION PROBLEMS

Canine Impaction and/or Displacement

Maxillary canine impaction or displacement is labial/buccal to the arch in 15% of the cases of maxillary canine impaction and often is associated with dental crowding. The canine impacted or displaced palatally occurs in 85% of the cases and typically is not associated with dental crowding.[188] PDCs frequently, but not always, are found in dentitions with various anomalies. These include small, peg-shaped, or missing maxillary lateral incisors, hypodontia involving other teeth, dentition spacing, and dentitions with delayed development.[189] Because of varying degrees of genetic influence on these anomalies, there has been some discussion about PDCs themselves also being influenced by genetic factors to some degree. In addition, the occurrence of PDCs does occur in a higher percentage within families than in the general population.[190]

A greater likelihood exists of a PDC on the same side of a missing or small maxillary lateral incisor, emphasizing a local environmental effect.[191] Also, in some cases, a canine is displaced palatally without an apparent anomaly of the maxillary lateral incisors; in some other cases, lateral incisors are missing without palatal displacement of a canine. Adding to the complexity is the heterogeneity found in studies of cases of buccally displaced canines[192] and PDCs.[189] Although the canine eruption theory of guidance by the lateral incisor root cannot explain all instances of PDCs, it does seem to play some role in some cases.[193]

With apparent genetic and environmental factors playing some variable role in these cases, the cause appears to be multifactorial.[194] The phenotype is the result of some genetic influences (directly, indirectly, or both, for example, although a primary effect on development of some or all of the rest of the dentition) interacting with environmental factors. Some of these cases may be examples of how primary genetic influences (which still interact with other genes and environmental factors) affect a phenotypic expression that is a variation in a local environment, such as the physical structure of the lateral incisor in relation to the developing canine. Candidate genes that are proposed possibly to influence the occurrence of PDCs and hypodontia in developmental fields include *MSX1* and *PAX9*.[195]

Primary Failure of Eruption

In addition to hypodontia and its primary or secondary relationship to maxillary canine eruption, there are emerging data regarding the influence of genetics on dental eruption. Presently, this is clearest in cases of PFE, in which all teeth distal to the most mesially involved tooth do not erupt or respond to orthodontic force. The familial occurrence of this phenomenon in approximately one-quarter of cases facilitated the investigation and discovery that the parathyroid hormone 1 receptor (*PTHR1*) gene is involved.[196,197] Advancements in this area could not only help to define patients who are likely to develop or have PFE but also potentially result in the molecular manipulation of selective tooth eruption rates to enhance treatment protocols on an individual basis.[198]

ENVIRONMENTAL AND GENETIC INFLUENCES ON BILATERAL SYMMETRY

Unlike structures that have directional asymmetry when development of one side is different from that of the other during normal development, facial and dental structures lateral to the midline are essentially mirror images of each other, with the same genetic influences affecting both sides. The conditions are theoretically identical for the trait on both sides of the body because they are developing simultaneously and therefore should develop identically.

There is not one group of genes for the permanent maxillary right first molar and another group of genes for the permanent maxillary left first molar. Fluctuating asymmetry occurs randomly when a difference exists between right and left sides. This reflects the inability of the individual to develop identical, bilaterally homologous structures.[61]

Fluctuating asymmetry has been observed in the primary and permanent dentitions,[199,200] as well as in the craniofacies.[61] The greater amount of fluctuating asymmetry for the distance between cusps on each tooth than for the overall crown size of primary second molars and permanent first molars indicates that the occlusal morphology of these teeth is influenced more by environmental factors than the overall crown size.[122] In addition, an association between decreased developmental stability (evident in increased fluctuating asymmetry), arch form discrepancies, and anterior maxillary dental crowding has been reported,[201] suggesting that a variable component of occlusal variation may be the individual's relative ability to develop right and left mirror images. This clinically could be an indication for selective interproximal reduction in specific areas to maximize intercuspation.

GENETIC FACTORS AND EXTERNAL APICAL ROOT RESORPTION

Analysis of the genetic basis for variable response to treatment has been applied to the specific adverse outcome sometimes associated with orthodontic treatment called EARR. The degree and severity of EARR associated with orthodontic treatment are complex, involving host and environmental factors. An association of EARR exists in those who have not received orthodontic treatment, with missing teeth, increased periodontal probing depths, and reduced crestal bone heights.[202] Individuals with bruxism, chronic nail biting, and anterior open bites with concomitant tongue thrust also may show an increased extent of EARR before orthodontic treatment.[203]

EARR is also increased as a pathologic consequence of orthodontic mechanical loading in some patients.[204,205] The amount of orthodontic movement is positively associated with the resulting extent of EARR.[206-208] Orthodontic tooth movement, or "biomechanics," has been found to account for approximately one-tenth to one-third of the total variation in EARR.[209-211] Owman-Moll and coworkers[212] showed that individual variation overshadowed the force magnitude and the force type in defining the susceptibility to histologic root resorption associated with orthodontic force. Individual variations were considerable regarding both extension and depth of histologic root resorption within individuals, and these were not correlated to the magnitude of tooth movement achieved.[213]

There is considerable individual variation in EARR associated with orthodontic treatment, indicating an individual predisposition and multifactorial (complex) etiology.[214-219] Heritability estimates have shown that approximately half of EARR variation concurrent with orthodontia, and almost two-thirds of maxillary central incisor EARR specifically, can be attributed to genetic variation.[219,220] A retrospective twin study on EARR found evidence for both genetic and environmental factors influencing EARR.[221] In addition, studies in a panel of different inbred mice supported a genetic component involving multiple genes in histologic root resorption.[222,223]

While there is a relationship between orthodontic force and root resorption, it is against the backdrop of other treatment factors and individual susceptibility. Because mechanical forces do not adequately explain the variation seen among individual expressions of EARR, interest has increased on genetic and other factors influencing the susceptibility to EARR. The reaction to orthodontic force, including rate of tooth movement, can differ depending on the individual's genetic background.[219,220,224,225]

Since the initial investigation into genetic factors associated with EARR concurrent with orthodontics were published in 2003, there have been a number of candidate gene studies in various populations (Fig. 2-13).[226-236] Even though heritability studies, with all of their caveats, indicated the total genetic influence on EARR concurrent with orthodontics was associated with most of the variation in the phenotype, the separate contributions of the genes investigated appear to be relatively small and inconsistent, as would be expected with a complex trait.

More recently studies are including multiple treatment and genetic factors in models to explain the occurrence of EARR concurrent with orthodontics. For example, 30% of the EARR variability in one study were explained by variation in or the presence of treatment duration, a Hyrax appliance, premolar extractions, sex, and the *P2RX7* gene rs1718119 SNP, while age, overjet, tongue thrust, skeletal Class II, and other genetic polymorphisms made minor contributions.[237] Likewise in another study looking at the relative influence of multiple parameters on the occurrence of EARR including treatment duration, extraction of maxillary premolars, and numerous cephalometric measurements (pretreatment values and post-treatment change in values), as well as genotypes for multiple DNA polymorphisms, found that a longer length of treatment and specific genotypes for *P2RX7* SNP rs208294 together explained 25% of the total variation associated with EARR concurrent with orthodontics in the sample tested.[236] These studies are interesting in that they (1) emphasize the possible effect of longer treatment times on EARR concurrent with orthodontics and (2) support the involvement of a biological pathway since the P2RX7 protein is an upstream regulator of the activation of IL1B that was a focus of initial

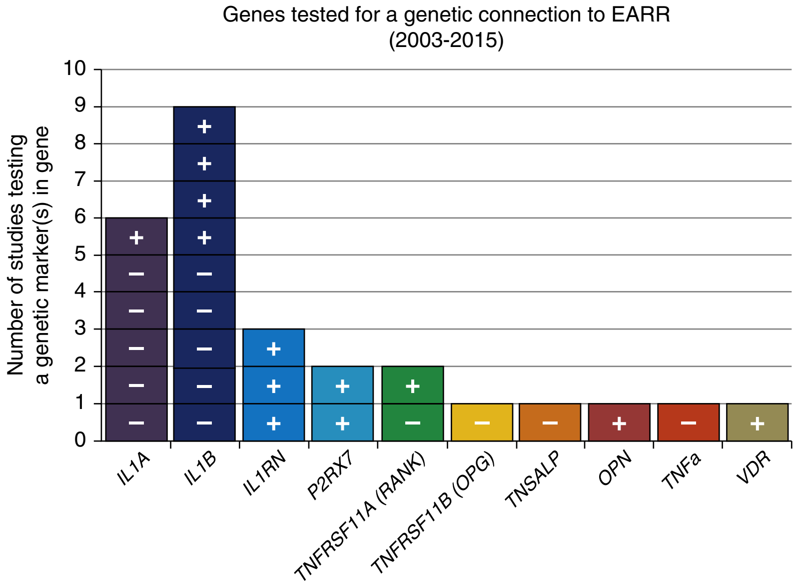

FIGURE 2-13 Several genetic variants have been investigated in association with the presence of external apical root resorption (EARR) concurrent with orthodontia, in a number of populations and using various methods of EARR assessment. Each plus sign in a box above a gene indicates that at least one genetic marker in that gene was found to be significantly associated with EARR in a published study, while a minus sign indicates that marker(s) in that gene were not significantly associated with EARR. Markers in some of the genes have been evaluated in more than one study. The references and discussion are in the text.

studies,[238] and an inbred mouse model with the mouse version of the *P2RX7* gene knocked out showed an increase in histological root resorption with orthodontic force,[239] as did a previous inbred mouse model with the mouse version of the *IL1B* gene knocked out.[240]

While these more recent studies are helping us to investigate the complexity of EARR occurring with orthodontics, they are insufficient for clinically useful prediction. The use of a nonbiased whole exome or whole genome sequencing approach when possible instead of the current candidate gene models could aid in identifying additional genetic factors that may be involved in orthodontic patient EARR. Even if all the factors were known, their number and complexity may only yield a general high, medium, or low risk of EARR concurrent with orthodontics.

PERSONALIZED-PRECISION ORTHODONTICS

The President's Council of Advisors on Science and Technology noted that personalized medicine "refers to the tailoring of medical treatment to the individual characteristics of each patient. It does not literally mean the creation of drugs or medical devices that are unique to a patient but rather the ability to classify individuals into subpopulations that differ in their susceptibility to a particular disease or their response to a specific treatment. Preventive or therapeutic interventions can then be concentrated on those who will benefit, sparing expense and side effects for those who will not."[241] Personalized medicine has garnered a tremendous amount of attention and yet has not even approached its potential in the provision of healthcare. Thus, it remains to be seen how much this will really affect daily medical practice. The same may be projected for the future of orthodontics. What would personalized orthodontics be based upon, and how would the studies be undertaken and then validated in practice? How will this be funded? The understanding of the combination and interaction of genetic and environmental (including treatment) factors (nature and nurture together) that influence the treatment response of our patients is fundamental to the evidence-based practice of orthodontics.[17]

SUMMARY

Multiple factors and processes contribute to the response to orthodontic treatment. Some patients will exhibit unusual outcomes linked to or associated with polymorphic genes. Analysis of overall treatment response requires a systems analysis using informatics for integration of all relevant information. The influence of genetic factors on treatment outcome must be studied and understood in quantitative terms. Conclusions from retrospective studies must be evaluated by prospective testing to truly evaluate their value in practice. Next Generation Sequencing and other types of genetic studies, and their careful assessment in clinical trials for their relevance to diagnosis and treatment outcomes, are necessary to further the evidence base for the practice of orthodontics. Only then will we begin to truly understand how nature (genetic factors) and nurture (environmental factors, including treatment) together affect our treatment of our patients in a truly evidence-based manner.[17]

The Biologic Basis of Orthodontics

Birgit Thilander, Nan Hatch, and Zongyang Sun

OUTLINE

TISSUE REACTIONS IN ORTHODONTICS*

Orthodontic treatment today comprises a wealth of removable and fixed appliances, sometimes in combination with extraoral ones. Despite differences in design, they all involve the use and control of forces acting on the teeth and adjacent structures. The principal changes from such forces are seen within the dentoalveolar system, resulting in *tooth movements*. Other structures, such as sutures and the temporomandibular joint (TMJ) area, can also be influenced by means of *dentofacial orthopedics*. An optimal orthodontic force intends to induce a maximal cellular response and to establish stability of the tissue, whereas an unfavorable force does not result in a precise biological response and may initiate adverse tissue reactions.

Although a considerable number of studies based on human material illustrate the *quantitative* changes occurring during orthodontic treatment (e.g., cephalometry), the main evidence for the *qualitative* histologic responses to orthodontic treatment comes from experimental studies on animals. Human material has been used to study orthodontically

*Birgit Thilander

induced reactions in the supporting structures of teeth intended for extraction, but animal material must be used to study basal changes. However, conclusions based on such results should be viewed with caution because species may differ in terms of basic morphology, growth pattern, turnover rate, and speed of tissue reaction. Moreover, animal experiments involve the alteration of normal structures, whereas dentofacial orthopedic measures are aimed at correcting already existing anomalies.

The main purpose of this chapter is not to discuss appliances but instead to focus on tissue reactions in the periodontium, sutures, and the TMJ region during the active phase of treatment as well as during the retention and postretention periods.

TOOTH-SUPPORTING TISSUES

During tooth movement, changes in the periodontium occur, depending on magnitude, direction, and duration of the force applied, as well as the age of the orthodontically treated patient. Tooth movement is a complicated process, requiring changes in the gingiva, periodontal ligament, root cementum, and alveolar bone with their differences in cell population and remodeling capacity. This chapter, therefore, includes a brief description of the normal periodontium.[1]

Gingiva

The gingiva is differentiated into the free and attached gingiva (Fig. 3-1). In a clinically healthy condition, the *free gingiva* is in close contact with the enamel surface, and its margin is located 0.5 to 2 mm coronal to the cementoenamel junction after completed tooth eruption. The *attached gingiva* is firmly attached to the underlying alveolar bone and cementum by connective tissue fibers and is therefore comparatively immobile in relation to the underlying tissue.

The predominant component of the gingiva is the connective tissue, which consists of collagen fibers, fibroblasts, vessels, nerves, and matrix. The *fibroblast* is engaged in the production of various types of fibers but is also instrumental in the synthesis of the connective tissue matrix. The *collagen fibers* are bundles of collagen fibrils with a distinct orientation. They provide the resilience and tone necessary for maintaining its architectural form and the integrity of the dentogingival attachment. They are usually divided into the following groups (Fig. 3-2):

- *Circular fibers* run in the free gingiva and encircle the tooth.
- *Dentogingival fibers* are embedded in the cementum of the supraalveolar portion of the root and project from the cementum in a fanlike configuration into the free gingival tissue.
- *Dentoperiosteal fibers* are embedded in the same portion of the cementum as the dentogingival fibers but terminate in the tissue of the attached gingiva.
- *Transseptal fibers* run straight across the interdental septum and are embedded in the cementum of adjacent teeth (Fig. 3-3).

Periodontal Ligament

The periodontal ligament (PDL), about 0.25 mm wide, is the soft, richly vascular and cellular connective tissue that surrounds the roots of the teeth and joins the root cementum with the lamina dura or the alveolar bone proper. In the coronal direction, the PDL is continuous with the lamina propria of the gingiva and is separated from the gingiva by the collagen fiber bundles, which connect the alveolar bone crest with the root (the alveolar crest fibers).

The PDL and the root cementum develop from the follicle, which surrounds the tooth bud. The true periodontal fibers, *the principal fibers*, develop along with the eruption of the tooth. First, fine fibrils arise from the root cementum and the bone surface and fuse as they contact. Later on, the number and thickness of fibers increase. The orientation of the collagen fiber bundles alters continuously during tooth eruption. When the tooth has reached contact in occlusion and is functioning properly, they associate with the following well-oriented groups: *alveolar crest fibers* and *horizontal*, *oblique*, *apical*, *and interradicular fibers* (Fig. 3-4). The individual bundles have a slightly wavy course, which allows the tooth to move within its socket (physiologic mobility). The presence of a PDL makes it possible to distribute and resorb the forces elicited during mastication and is essential for movement of the teeth in orthodontic treatment.

The fibrils of the PDL are embedded in a ground substance with connective tissue polysaccharides (glycosaminoglycans),

which vary with age. The tissue response to orthodontic forces, including cell mobilization and conversion of collagen fibers, is considerably slower in older individuals than in children and adolescents. The ground substance has a more rapid turnover than the collagen fibers.

During physiologic conditions, collagen turnover in the PDL is much higher than that in most other tissues (e.g., twice as high as that of the gingiva). The high turnover has been attributed to the fact that forces on the PDL are multidirectional, having vertical and horizontal components. The lower collagen turnover in the gingiva may result from the lowered functional stress as the transseptal fibers function in a manner similar to tendons, providing firm anchorage of the tooth.

Root Cementum

The root cementum is a specialized mineralized tissue covering the root surface and has many features in common with bone tissue. However, the cementum contains no blood vessels, has no innervation, does not undergo physiologic resorption or remodeling, and is characterized by continuing deposition throughout life. The cementum attaches the PDL fibers to the root and contributes to the process of repair after damage to the root surface (e.g., during orthodontic treatment).

During root formation, a *primary cementum* is formed. After tooth eruption and in response to functional demands, a *secondary cementum* is formed that, in contrast to the primary cementum, contains cells. During the continuous formation of the primary cementum, portions of the principal fibers in the PDL adjacent to the root become embedded and mineralized (Fig. 3-5). The Sharpey fibers in the cementum should be regarded as a direct continuation of the collagen fibers in the PDL.

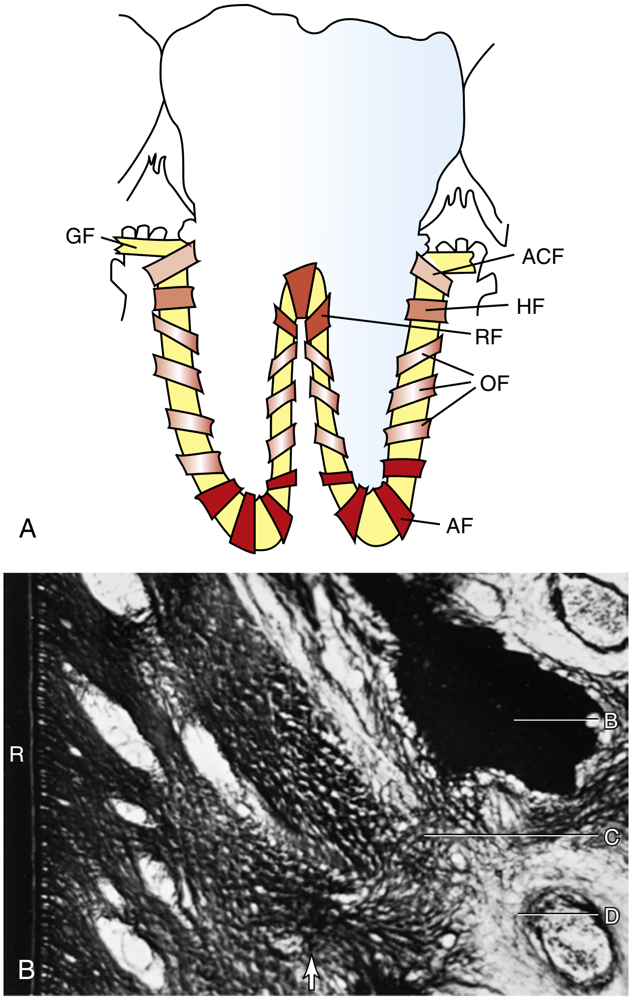

FIGURE 3-4 **A,** The PDL fibers: Alveolar-crest fibers (*ACF*), apical fibers (*AF*), gingival fibers (*GF*), horizontal fibers (*HF*), oblique fibers (*OF*), and interradicular fibers (*RF*). **B,** The periodontal fibers interlace with the fibrous matrix of the bone, forming a fibrous system. In a physiologic state this system appears relaxed. *R*, Root surface; *B*, Remaining calcified bone in which the fiber arrangement cannot be seen; *C*, Sharpey's fibers interlacing with fibers of the bone; *D*, Loose fibrous tissue around a capillary (*arrow*).

Alveolar Bone

The alveolar bone is covered with the *periosteum*, which is differentiated from the surrounding connective tissue (Fig. 3-6). The contiguous mesenchymal cells acquire the character of osteoblasts. The matrix-producing and proliferating cells in the cambium layer, as well as osteocytes inside the bone matrix, are subject to mechanical influence. Whenever the pressure exceeds a certain threshold, reducing the blood supply to osteoblasts at PDL and alveolar bone interfaces, osteogenesis ceases. However, if the periosteum is exposed to tension, it responds with bone deposition. Therefore, the periosteum continues to function as an osteogenic zone throughout life, although its regenerative capacity is extremely high in the young child.

The alveolar process forms and supports the sockets of the teeth. It consists of dense outer *cortical bone* plates with varying amounts of spongy or *cancellous bone* between them. The thickness of the cortical laminae varies in different locations (Fig. 3-7). The cancellous bone contains bone trabeculae, the architecture of which is partly genetically determined and partly the result of forces to which teeth are exposed during function or orthodontic treatment.

The alveolar bone is renewed constantly in response to functional demands. Bone-forming *osteoblasts* and *osteoclasts*, cells involved in resorption (Fig. 3-8), are responsible for this remodeling process. These cells are present on the socket walls toward the periodontal membrane, on the inside of the cortical bone toward the marrow spaces, and on the surface of the bone trabeculae in cancellous bone. The osteoblasts produce *osteoid*, consisting of collagen fibers and a matrix that contains mainly proteoglycans and glycoproteins. Osteoid is found on all bone surfaces where new bone is deposited (Fig. 3-9, *A*), and unlike calcified bone is not attacked by osteoclasts. When this bone matrix undergoes mineralization by deposition of minerals, such as calcium and phosphate, it converts into *bundle bone*. Cells and fiber bundles are incorporated in bundle bone during its life cycle. When bundle bone has reached a certain thickness and maturity, parts of it are reorganized into *lamellated bone* (Fig. 3-9, *B*).

The type of bone through which the tooth is displaced must be considered in the orthodontic treatment plan. Tooth movements in a mesial or distal direction displace the roots through the spongiosa of the alveolar bone. When a tooth is moved into the reorganizing alveolus of a newly extracted tooth, remodeling is rapid because of the many differentiating cells present and the limited amount of bone to be resorbed. On the contrary, movement of a tooth labially or lingually into the thin cortical plates should be undertaken with a high degree of caution, especially in adult patients, to avoid iatrogenic responses.

PHYSIOLOGIC TOOTH MIGRATION

Tissue reactions in the tooth-supporting tissues are connected not only with orthodontic treatment but also with eruption of the teeth and development of the occlusion. The development of the dentition is a complex process and depends on many variables, which by no means always combine harmoniously.

The *eruption of teeth* to occlusal contact is an event that covers only a short period in life. However, the teeth and their supporting tissues have a lifelong ability to adapt to functional demands and hence drift through the alveolar process, a phenomenon called *physiologic tooth migration*. Also well known clinically is that any change in the equilibrium of occlusal pressure, such as loss of a neighboring or antagonistic tooth, may induce further tooth movement.

The tissue reaction that occurs during physiologic tooth migration is a normal function of the supporting structures. This was pointed out for the first time by Stein and Weinmann,[2] who observed that the molars in adults gradually migrate in a mesial direction. When the teeth migrate, they bring the supraalveolar fiber system with them. Such movement implies remodeling of the PDL and alveolar bone. The turnover rate of the PDL is not uniform throughout the ligament, the cells being more active on the bone side than near the root cementum.

The modeling processes that occur during the physiologic migration are illustrated in Figures 3-10 and 3-11. Osteoclasts are seen in scattered lacunae associated with the *resorptive surface* along the alveolar bone wall, toward which the tooth is moving; the number of cells is higher when tooth migration is rapid. The alveolar bone wall from which the

tooth is moving away (*depository side*) is characterized by osteoblasts depositing nonmineralized osteoid, which later mineralizes in the deeper layer. Specific staining techniques reveal how the older fibers of the PDL are surrounded by newly deposited bone matrix and become embedded in bone. Simultaneously, new collagen fibrils are produced on the bone surface.

A slow apposition occurs on the cementum surface throughout life, a fact that is of great importance for the resorptive mechanism in the bone and cementum. The nonmineralized precementum layer has special importance as a resorption-resistant "coating" layer, thus protecting the root surface during the physiologic migration.

Because considerable changes in tooth position occur without any orthodontic invention, knowledge of periodontal remodeling during physiologic tooth migration is of utmost importance during the postretention period.

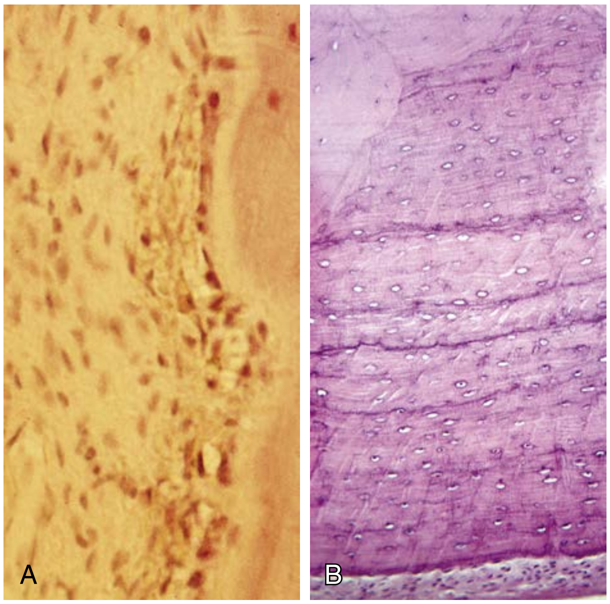

FIGURE 3-9 **A,** Osteoid is found on all bone surfaces, where new bone is deposited. **B,** Bundle bone reorganized into lamellated bone.

ORTHODONTIC TOOTH MOVEMENTS

Basically, tissue reactions observed in orthodontic tooth movement to some extent resemble that observed in physiologic tooth migration. Because the teeth are moved more rapidly during treatment, the tissue changes elicited by orthodontic forces are more significant and extensive.[3] The knowledge of the reactions of the supporting structures in orthodontic treatment is still incomplete because histologic techniques used today can provide only limited information on the behavior of the ground substance, blood, and tissue fluids. However, application of a force on the crown of the tooth leads to a biological response in its surrounding tissues, resulting in an orthodontic tooth movement, which depends on type, magnitude, and duration of the force. Thus, knowledge of several fundamental biological and mechanical concepts is necessary for a complete understanding of clinical orthodontics, and this is discussed in greater detail in Chapters 4 and 5. Hence, only a brief survey of biomechanical principles is given here, which is a factor of importance for understanding the tissue reaction in supporting tissues.

The initial phase of orthodontic root resorption incident to local compression of the periodontal ligament. *Eur J Orthod.* 1993;15(249).)

Orthodontic Forces and Tissue Reaction

Orthodontic forces comprise those that are meant to act on the PDL and alveolar process, whereas orthopedic forces are more powerful and act on the basal parts of the jaws. The decisive variables regarding these forces at the cellular level are application, magnitude, duration, and direction of force.[4]

Two different types of applied forces exist: *continuous* and *intermittent* (Fig. 3-12). Modern fixed appliance systems are based on light continuous forces from the archwire. However, a continuous force may be interrupted after a limited period. An example of such an *interrupted continuous* force is when it is no longer acting and hence has to be reactivated. In clinical orthodontics, an interrupted tooth movement may have certain advantages as the tissues are given ample time for reorganization, which is favorable for further tissue changes when the force is again activated. An *intermittent* force acts during a short period and is induced primarily by removable appliances, especially functional appliances.

The *magnitude* and duration of forces are important for the tissue response. Reactions in PDL to heavy, continuous loads (50 centiNewtons [cN]) in experimental tipping of first molars in rats[5] indicated that (1) up to a certain level of stress or duration, the reactions occur mainly in the periodontal membrane with increasing vascularization, cell proliferation, fiber

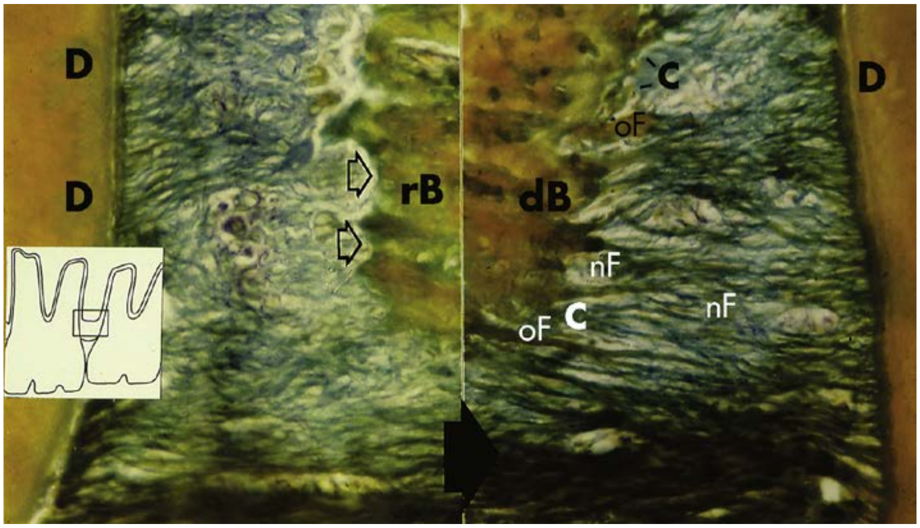

FIGURE 3-11 Physiologic migration in the rat in the interdental area in direction of *black arrow*. *rB,* Resorptive alveolar bone surface (*open arrows*); *dB,* depository alveolar bone surface; *oF,* older fibers included in the new bone formation by osteoclasts; *nF,* new fibrils near the bone surface and in the middle of the PDL; *C,* osteoblasts; *D,* dentin.

formation, and osteoid application on the bone surfaces and (2) beyond a certain level of stress or duration, decreased vascular supply in the PDL and destruction of cells between stretched fibers occur. The reactions become more significant within the alveolar bone, with removal and undermining resorption of Sharpey fibers from the rear (Fig. 3-13), subsequently permitting vascular invasion of cells into the periodontal membrane from the alveolar bone.

A light force over a certain distance moves a tooth more rapidly and with fewer injuries to the supporting tissues than a heavy one. The purpose of applying a light force is to increase cellular activity without causing undue tissue compression and to prepare the tissues for further changes. Another reason for applying light forces is that it results in less discomfort and pain to the patient. Unmyelinated nerve endings persist in the hyalinized tissue, and they are more or less compressed during the initial stage.

The *duration* of force, equivalent to treatment time, is considered to be a more crucial factor than the magnitude of the force regarding adverse tissue reactions, especially in connection with long treatment periods and in cases with high density of the alveolar bone.

Direction of forces will result in different kinds of tooth movements. All tooth movements can be described in terms of rotation and translation. This discussion addresses only the small, initial tooth movements that occur within the periodontal space. Clearly, the larger long-term movements are the result of a succession of such minor movements, depending on the pattern of socket remodeling. For the purposes of illustration, forces and movements are often presented in terms of *tipping*, *torquing*, *bodily*, *intrusion*, *extrusion*, *and rotation*. The different types of tooth movements will be discussed next.

Note the proliferation of blood vessels (*BV*) in the alveolar bone, detaching periodontal membrane fibers from the bone surface from the rear. Blood vessels have infiltrated the alveolar bone plate (*B*) from the rear. Sharpey fibers and parts of the alveolar bone have disappeared. *C,* Undermining resorption; *H,* hyalinization; *Oxf,* oxytalan fibrils. (From Rygh P, et al. Activation of the vascular system: a main mediator of periodontal fiber remodeling in orthodontic tooth movement. *Am J Orthod.* 1986;89:453.)

TISSUE RESPONSE IN PERIODONTIUM

In 1905, Carl Sandstedt's studies[6] in dogs convincingly demonstrated that tooth movement is a process of resorption and apposition. He gave the first description of the glasslike appearance of the compressed tissue, termed *hyalinization*, which has been associated with a standstill of the tooth movement. It was not until the 1950s that tooth movements attracted wider attention with Kaare Reitan's classic study, *The initial tissue reaction incident to orthodontic tooth movement as related to the influence of function.*[7] Reitan used the dog as his experimental model but also extracted teeth from humans. Histology was his means to address the questions of clinical importance, such as the identity of the factors that control and regulate the pattern of tooth movement in different individuals. In this way, he explored age, sex, the type of alveolar bone, the kinds of forces, and the matrix of cells of the gingival and periodontal ligament. He pointed out differences in the tissue response between animals and humans. Per Rygh continued Reitan's research to explain why orthodontic tooth movements might cause damage to the tooth, possibly as a sequela of the hyalinization process.

Reitan and Rygh, dear friends and scientific colleagues, were my coauthors in "Tissue Reactions" in the third and fourth editions of *Orthodontics: Current Principles and Techniques.* They are remembered with gratitude even in this sixth edition.

Initial Period of Tooth Movement

Application of a continuous force on the crown of the tooth leads to tooth movement within the alveolus that is marked initially by narrowing of the periodontal membrane, particularly in the marginal area. After a certain period, osteoclasts differentiate along the alveolar bone wall, as occurs in young humans after 30 to 40 hours.[8] All permanent alterations depend on cellular activity. When conditions are favorable, the cells increase in number and differentiate into osteoclasts and fibroblasts. The width of the membrane is increased by osteoclastic removal of bone, and the orientation of the fibers in the periodontal membrane changes, as does the arrangement of the ground substance (Fig. 3-14). Experimental studies indicate that fibroblasts not only are capable of synthesizing fibrous tissue and ground substance but also play an important role in the breakdown of connective tissue. These processes occur simultaneously.[9]

Hyalinization Phase

During the crucial stage of the *initial application of force*, compression in limited areas of the membrane frequently impedes vascular circulation and cell differentiation, causing degradation of the cells and vascular structures rather than proliferation and differentiation. The tissue reveals a glasslike appearance in light microscopy, which is termed *hyalinization* (Fig. 3-15). It is caused partly by anatomic and partly by mechanical factors

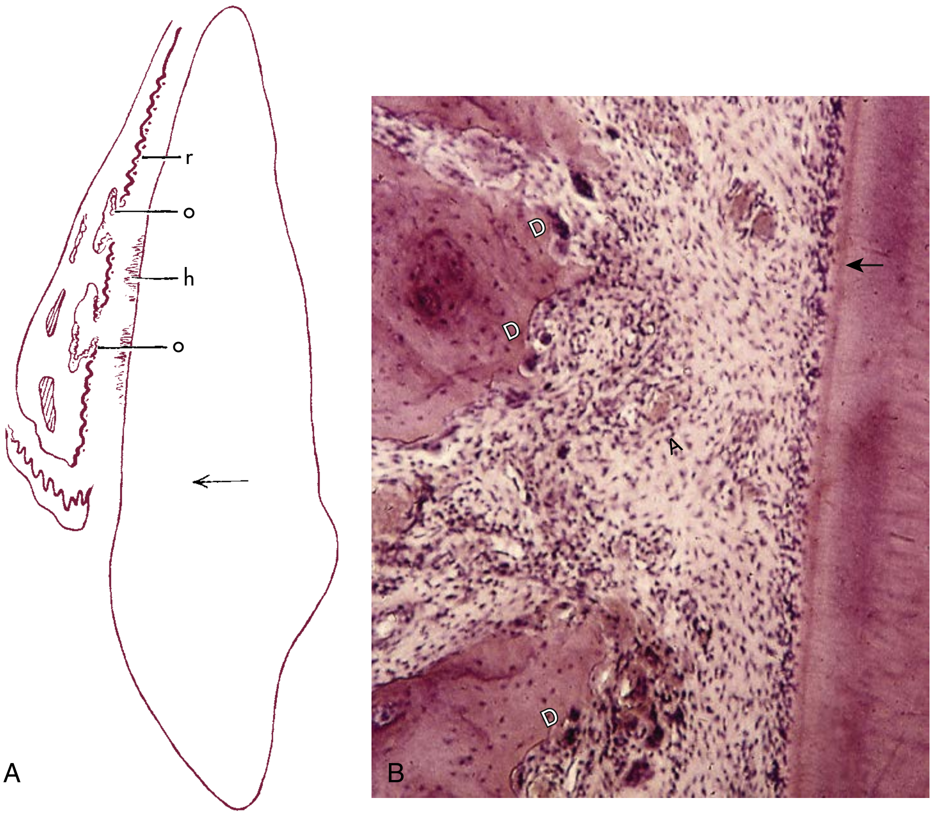

FIGURE 3-14 **A,** Location of bone resorption adjacent to the apical third of an upper canine in a 39-year-old patient. The tooth was moved continuously for 3 weeks. *O,* Compensatory formation of osteoid in open marrow spaces; *h*, Remnants of hyalinized tissue adhering to the root surface; *r,* direct bone resorption adjacent to the apical third of the root. **B,** Direct bone resorption with osteoclasts along the bone surface (*D*) (area marked *r* in A). *A,* Absence of epithelial remnants in adjacent periodontal tissue, center of the formerly cell-free zone; note the widening of the periodontal space; *D,* direct bone resorption with osteoclasts.

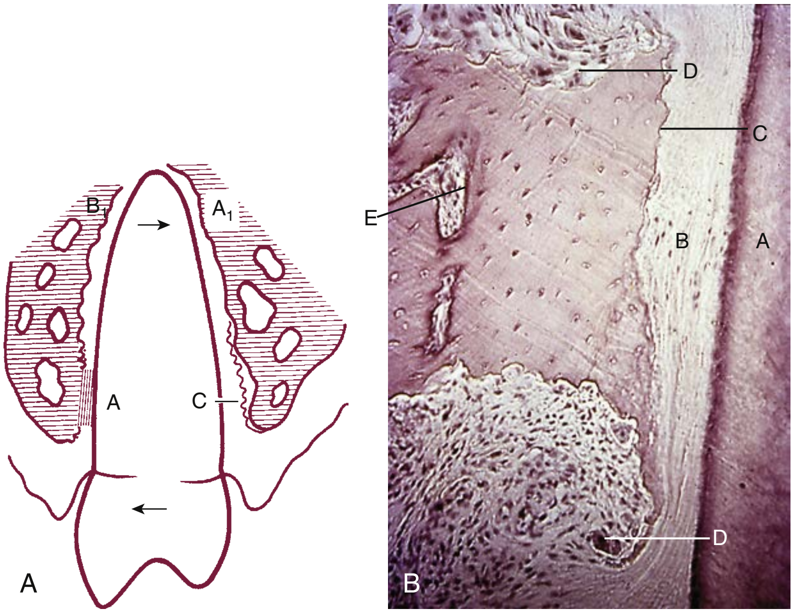

FIGURE 3-15 **A,** In most cases, tooth movement is initiated by formation of a cell-free area at *A* and new osteoid formed at *C*. No osteoclasts have been formed in the marrow spaces. *A,* Root surface; *B,* remaining pyknotic cell nuclei in hyalinized tissue; *C,* reversal line; *D,* direct bone resorption with osteoclasts; *E,* marrow space.

and is almost unavoidable in the initial period of tooth movement in clinical orthodontics. Hyalinization represents a sterile necrotic area, characterized by three main stages: degeneration, elimination of destroyed tissue, and establishment of a new tooth attachment.

Degeneration starts where the pressure is highest and the narrowing of the membrane is most pronounced, that is, around bone spicules. Degeneration may be limited to parts of the membrane or extend from the root surface to the alveolar bone. Electron microscopy[10-13] has shown that advanced cellular and vascular changes may occur within a few hours of the application of the force. Retardation of the blood flow is followed by disintegration of the vessel walls and degradation of blood elements, all occurring by mechanisms different from those seen during physiologic breakdown (Fig. 3-16). The cells undergo a series of changes, starting with a swelling of the mitochondria and the endoplasmic reticulum and continuing with rupture and dissolution of the cytoplastic membrane. This leaves only isolated nuclei between compressed fibrous elements (pyknosis) and is the first indication of hyalinization.

In hyalinized zones, no osteoclast progenitor cells can be recruited and subsequently differentiated into mature osteoclasts; thus no bone resorption can take place from the periodontal membrane. Tooth movement stops until the adjacent alveolar bone has been resorbed, the hyalinized structures are removed, and the area is repopulated by cells. A limited hyalinized area occurring during the application of light forces may be expected to persist from 2 to 4 weeks in a young patient (Fig. 3-17). When bone density is high, the duration is longer.

The peripheral areas of the hyalinized compressed tissue are *eliminated* by an invasion of cells and blood vessels from the adjacent undamaged PDL. The hyalinized materials are ingested by the phagocytic activity of macrophages and are removed completely[14] (Fig. 3-18, *A*). The adjacent alveolar bone is removed by indirect resorption by cells that have differentiated into osteoclasts on the surfaces of adjacent marrow spaces or, if the alveolar wall and the outer cortical bone are fused, on the surface of the alveolar process (Fig. 3-18, *B*).

Reestablishment of the tooth attachment in the hyalinized areas starts by synthesis of new tissue elements as soon as the adjacent bone and degenerated membrane tissue have been removed. The ligament space is now wider than before treatment started, and the membranous tissue under repair is rich in cells.[3]

Hyalinized Zone and Root Resorption

A side effect of the cellular activity during the removal of the necrotic hyalinized tissue is that the cementoid layer of the root and the bone are left with raw, unprotected surfaces in certain areas that can readily be attacked by resorptive cells (Fig. 3-19, *A*).[15,16] Root resorption then occurs around this cell-free tissue, starting at the border of the hyalinized zone (Fig. 3-19, *B*).

Some of these small resorption lacunae are visible only by the scanning microscope. According to Kvam,[17] organic tissue tends to remain in the resorbed area, which can be exposed more clearly by removing the organic components (Fig. 3-20). These initial injuries are small and insignificant.

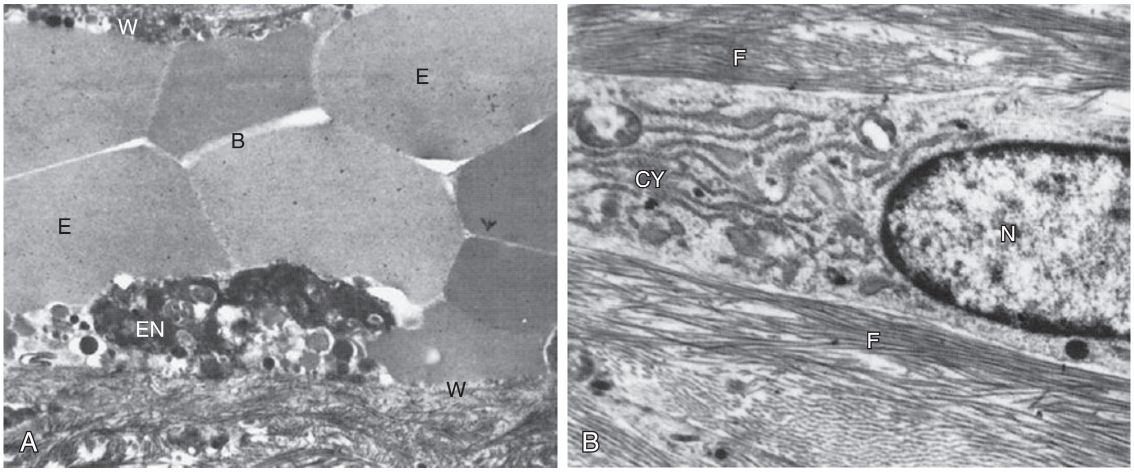

FIGURE 3-16 **A,** Early capillary changes in the hyalinized zone (human tissue) as seen with the electron microscope; findings usually not visible by light microscopy (force, 70 cN; duration, 2 days [×6000]). *E,* Stasis with packing of erythrocytes; *B,* borderline between red blood cells; *W,* disappearance of the capillary wall; *EN,* endothelial cell undergoing disintegration. **B,** Principal fibers on the tension side in the rat (force, 10 cN; duration, 28 days [×9000]). *F,* Fibrils subjected to moderate tension and located on both sides of the fibroblast; *N,* nucleus; *CY,* cytoplasm with well-developed endoplasmic reticulum. Prolonged stretching of supraalveolar fibers may cause disappearance of similarly located cellular elements as a result of compression. (From Rygh P. Ultrastructural vascular changes in pressure zones of rat molar periodontium incident to orthodontic tooth movement. *Scand J Dent Res.* 1972;80:307.)

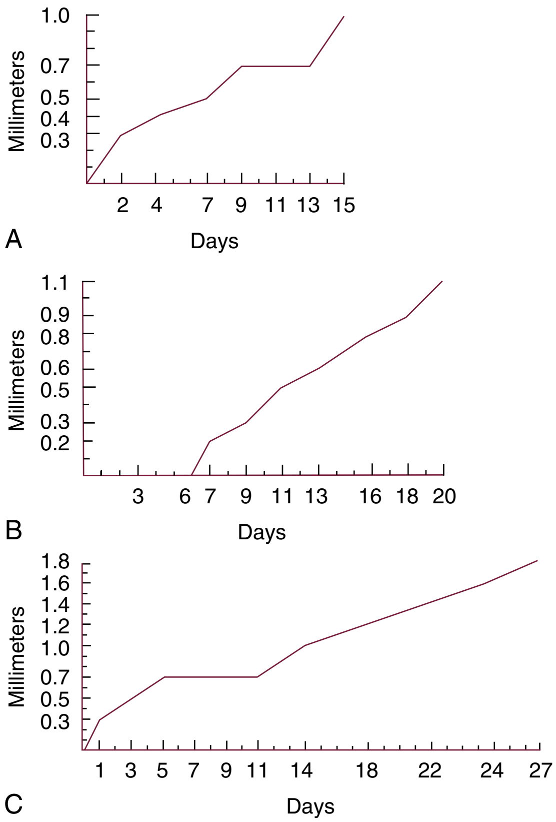

FIGURE 3-17 Movement of upper premolars with Bimler's removable appliances (force, 70 to 100 cN). Note the short hyalinization periods. **A,** A cell-free zone lasted for about 4 days. **B,** The appliance remained passive during the first 6 days. Tooth movement amounted to 1.1 mm during 14 days started after a layer of gutta-percha had been added. **C,** A cell-free area existed from the fifth to the eleventh day.

Light and transmission electron microscopy have shown that root resorption occurs near the hyalinized zone in close proximity to a rich vascular network.[10] This has been verified by Brudvik and Rygh,[18,19] who showed occurrence of small lacunae in the cementum at the coronal and apical peripheries of the hyalinized zone (Fig. 3-21). Their results indicated an association between root resorption and active removal of the hyalinized necrotic tissue. The first sign of root resorption (*initial phase*) was defined as a penetration of cells from the periphery of the necrotic tissue where mononucleated fibroblast-like cells, stained negatively by tartrate-resistant acid phosphatase (TRAP), started removing the precementum/cementum surface. Root resorption beneath the main hyalinized zone occurred in a *later phase* during which multinucleated TRAP-positive cells were involved in removing the main mass of necrotic PDL tissue and resorbing the outer layer of the root cementum. Further studies indicated that after the multinucleated TRAP-positive cells reached the subjacent contaminated and damaged root surface and removed the necrotic periodontal tissue, they continued to remove the cementum surface.

When the movement is discontinued, *repair* of the resorbed lacunae occurs, starting from the periphery (Fig. 3-22). After the force has terminated, active root resorption by TRAP-positive cells in the resorption lacunae still was observed in areas where hyalinized tissue existed (Fig. 3-23).[20,21] After the hyalinized tissue was eliminated, fibroblast-like cells invaded the active resorption site. After termination of force and in the absence of hyalinized necrotic tissue in the PDL, repair on the resorption lacunae occurred. The first sign was synthesis of collagenous fibrillar material by fibroblast- and cementoblast-like cells, followed by reestablishment of the new PDL. Further studies are needed, however, to fully clarify the factors leading to transition of an active process of resorption into one of repair.

A reduction of root resorption is likely provided by minor trauma and can be repaired during periods of no force or possibly during periods of extremely low force application (Fig. 3-24). Chapter 30 further discusses root resorption.

Secondary Period of Tooth Movement

In this period (Fig. 3-25), the PDL is considerably widened. The osteoclasts attack the bone surface over a much wider area. As long as the force is kept within certain limits or gentle reactivation of the force is undertaken, further *bone resorption* is predominantly direct (Fig. 3-26). The fibrous attachment apparatus is reorganized by the production of new periodontal fibrils. When the application of a force is favorable, a large number of osteoclasts appear along the bone surface on the pressure side and tooth movement is rapid. Modern histologic techniques reveal that complete reorganization of the fibrous system takes place throughout the membrane.

The main feature is the *deposition of new bone* on the alveolar surface from which the tooth is moving away (tension side). Cell proliferation usually occurs after 30 to 40 hours in young human beings. The newly formed cells, osteoblasts with darkly stained nuclei, have a characteristic appearance (Fig. 3-27). Osteoblasts may be observed along stretched fiber bundles. Shortly after cell proliferation has started, osteoid tissue is deposited on the tension side. The formation of this new osteoid depends to some extent on the form and thickness of the fiber bundles. The original periodontal fibers become embedded in the new layers of prebone, or osteoid, which mineralizes in the deeper parts.[3]

New bone is deposited until the width of the membrane has returned to normal limits, and simultaneously the fibrous system is remodeled. The original stretched fibers are not broken down to the same extent as is the case on the pressure side, and the remodeling involves resorption and replacement of collagen, leading to a lengthening of the fibers, the mechanism of which is largely unknown.

Concomitantly with bone apposition on the periodontal surface on the tension side, an accompanying resorption process occurs on the spongiosa surface of the alveolar bone that tends to maintain the dimension of the supporting bone tissue (Fig. 3-28). Correspondingly, during the resorption of the alveolar bone on the pressure side, maintenance of the alveolar lamina thickness is ensured by apposition on the spongiosa surface. These processes are mediated by the cells of the endosteum, which cover all the internal bone surfaces and dental alveoli. Extensive remodeling takes place in the deeper, cell-rich layers of the periosteum, incident to the orthodontic forces, a reaction that tends to restore the thickness of the supporting bone.

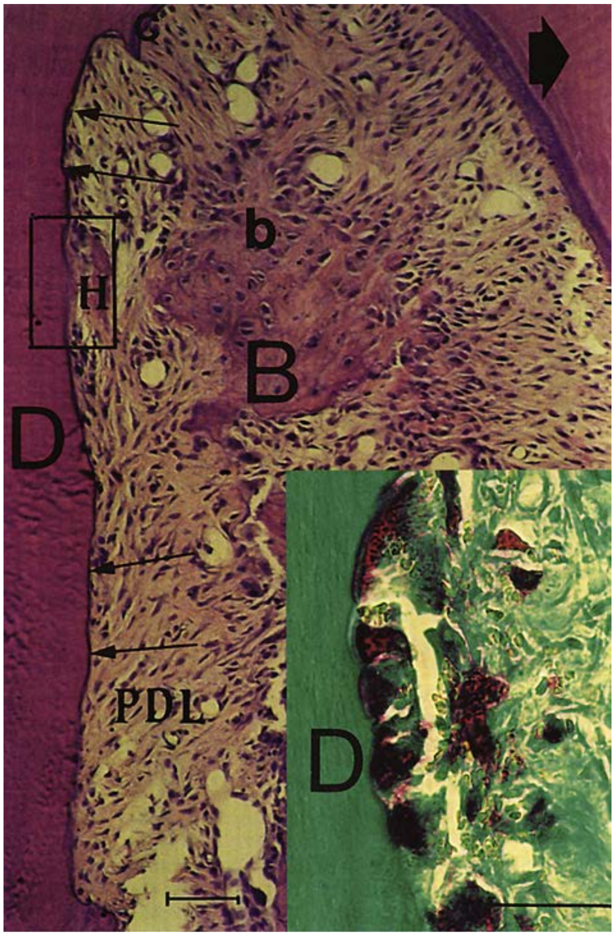

FIGURE 3-23 Repair of lacuna by cementum deposition in the periphery (*arrows*). Small amounts of hyalinized tissue (*H*) persist in boxed area, which shows active root resorption indicated by TRAP-positive cells in the lacuna (*bars* are 50 μm). The heavy arrow (*upper right*) indicates direction of force. (Adapted from Brudvik P, Rygh P. Transition and determinants of orthodontic root resorption-repair sequence. *Eur J Orthod.* 1995;17:177.)

The observation that orthodontic tooth movement involves many *inflammation-like* reactions is important in that this, in turn, has enhanced an understanding that the whole cascade of factors involved in inflammation may be part of the reactions to orthodontic forces in the tooth-supporting tissues: that is, extracellular breakdown of collagen by collagenases, produced by leukocyte–fibroblast interaction. The term *inflammation* should not be confused with the term *infection*, as is often the case in popular use. In orthodontics, inflammation is a process occurring in a local environment when a rapid response is needed for a stress that is felt transiently by the cells as being too heavy.

Types of Tooth Movements

The tissue response in different parts of the PDL is dependent on the type of tooth movement, which briefly will be exemplified.

Tipping

Tipping of a tooth leads to a concentration of pressure in limited areas of the PDL (Fig. 3-29, *A*). A fulcrum is formed, which enhances root movement in the opposite direction. A tipping movement, in general, results in the formation of a hyalinized zone slightly below the alveolar crest, particularly when the tooth has a short, undeveloped root. If the root is fully developed, the hyalinized zone is located a short distance from the alveolar crest (Fig. 3-29, *B*). Tipping of a tooth by light, continuous forces results in a greater movement within a shorter time than that obtained by any other method. In most young orthodontic patients, bone resorption resulting from a moderate tipping movement usually is followed by compensatory bone formation. The degree of such compensation varies individually and depends primarily on the presence of bone-forming osteoblasts in the periosteum. Compensatory periosteal bone apposition in the apical region is also subject to some variation, according to whether osteoblasts are present or absent in the periosteum (Fig. 3-30).

Torque

A torquing movement of a tooth involves tipping of the apex (Fig. 3-31, *A*). During the initial movement of torque, the

If the force is light, the hyalinization period will be short and the coronal portion will move quite readily. *A,* Supra-alveolar fibers; *B,* hyalinized zone on the pressure side. **B,** A prolonged tipping movement may result in formation of a secondary hyalinized zone (*A*) after the first hyalinized zone has been eliminated. Compression of the PDL is maintained in the apical region (*B*). *X,* Fulcrum.

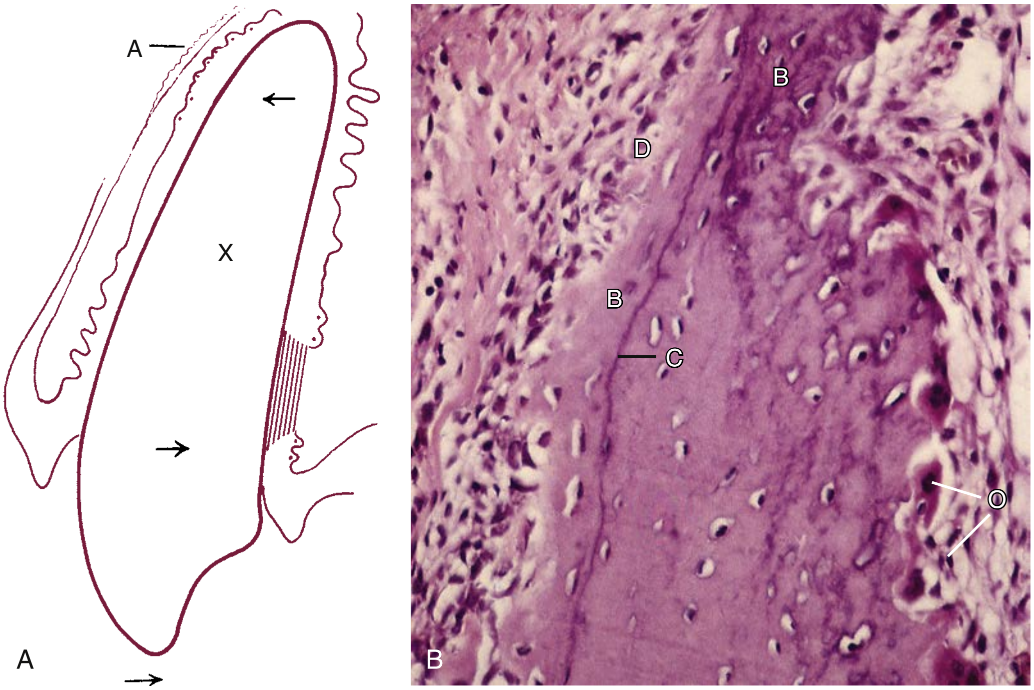

FIGURE 3-30 **A,** Compensatory bone formation on the periosteal side after tipping of an upper second incisor in the dog. *X,* Fulcrum. **B,** Corresponds to area *A*. *B,* Bone formation in formerly resorbed lacunae; *C,* resting line indicating thickness of the compensatory bone layer; *D,* osteoblast chain of the periosteum covering new partly calcified bone layer; *O,* osteoclasts on the bone surface.

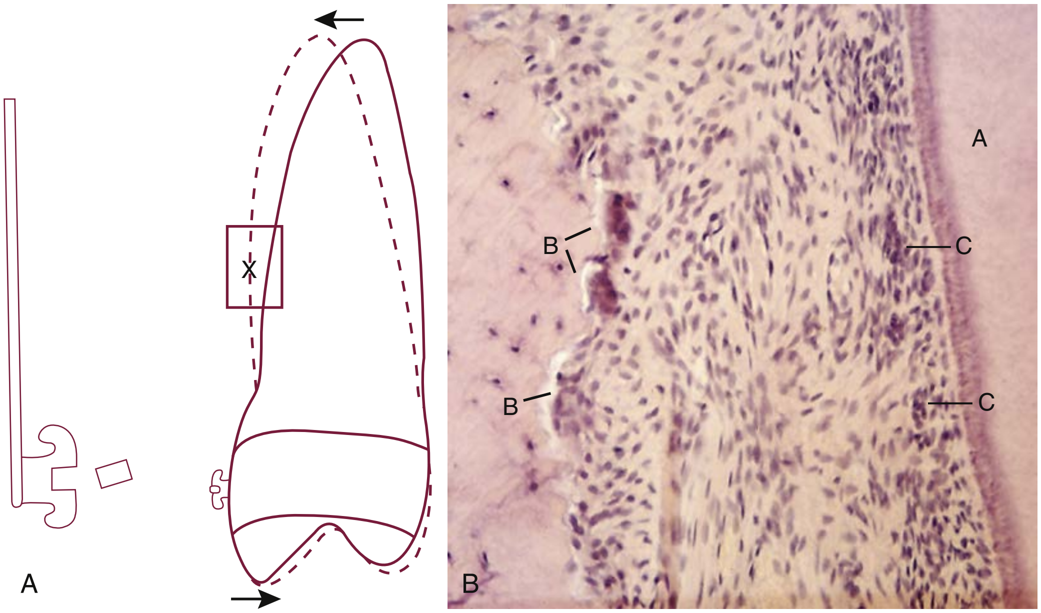

FIGURE 3-31 **A,** Torquing of an upper premolar. **B,** Pressure side in a 12-year-old patient after buccal root torquing movement performed in the apical region with a 0.021- × 0.025-inch edgewise arch (area *X* in **A**) (force, 120 to 130 cN; duration, 2 weeks). As indicated by the presence of epithelial remnants, no hyalinization of the PDL has occurred. *A,* Root surface; *B,* osteoclasts along the bone surface; *C,* epithelial remnants.

pressure area usually is located close to the middle region of the root. This occurs because the PDL is normally wider in the apical third than in the middle third. After resorption of bone areas corresponding to the middle third, the apical surface of the root gradually begins to compress adjacent periodontal fibers, and a wider pressure area is established (Fig. 3-31, *B*). However, if more torque is incorporated in the archwire, the force will increase and may result in resorption and fenestration of the buccal bone plate (Fig. 3-32).

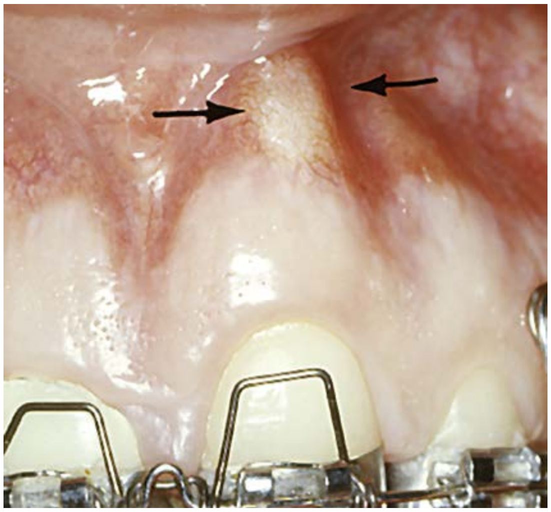

FIGURE 3-32 Bone fenestration at the left central and lateral incisors (*arrows*) after labial root torque movements.

Bodily Movement

Bodily tooth movement is obtained by establishing force couples acting along parallel lines and distributing the force over the whole alveolar bone surface. This is a favorable method of displacement, provided that the magnitude of force does not exceed a certain limit.[22]

Application of a light, continuous force on premolars in a dog resulted in small compressed areas shortly after the movement began, with a hyalinized zone of short duration usually located as seen in Figure 3-33, *A*. No bodily movement of the tooth in a mechanical sense is observed during this period; instead, a slight tipping is noticed. The degree of initial tipping varies according to the size of the arch and the width of the brackets.

The short duration of the hyalinization results from an increased bone resorption on both sides of the hyalinized tissue, especially in the apical region of the pressure side. This leads to rapid elimination of the hyalinized zone. This favorable reaction on the pressure side is caused partly by gradually increased stretching of fiber bundles on the tension side, which tends to prevent the tooth from further tipping (Fig. 3-33, *B*). New bone layers are formed on the tension side along these fiber bundles (Fig. 3-33, *C*).

Rotation

Rotation of a tooth creates two pressure sides and two tension sides (Fig. 3-34, *A*) and may cause certain variations in the type of tissue response observed on the pressure sides. Hyalinization and undermining bone resorption take place in one pressure zone, while direct bone resorption occurs in the other. These variations are caused chiefly by the anatomy of the tooth and the magnitude of the force. As in other types of tooth movements, applying a

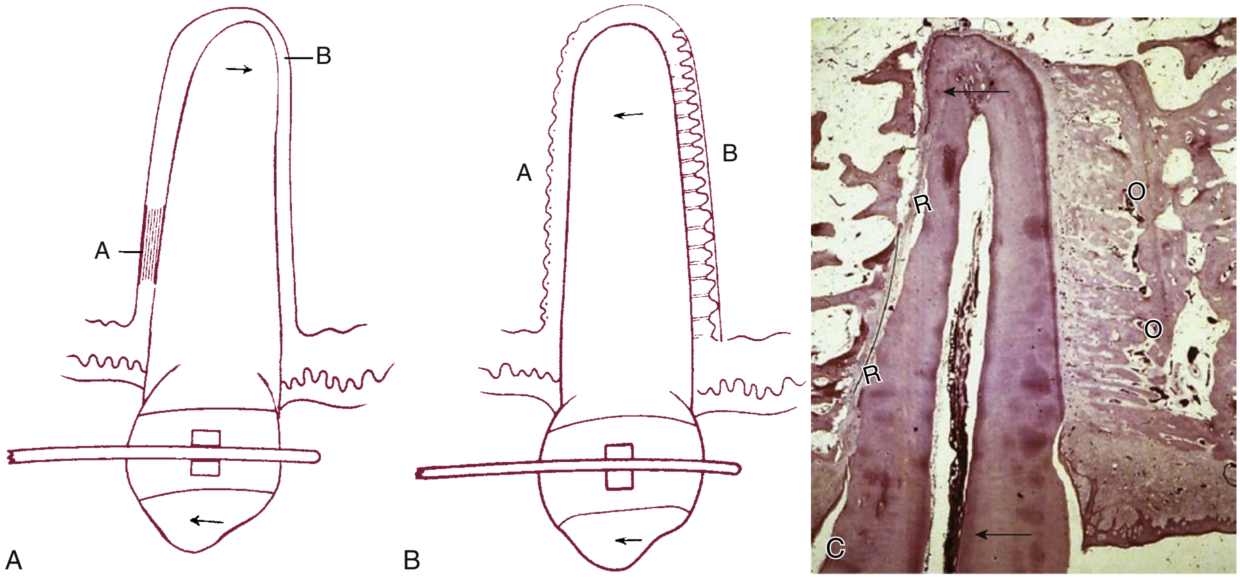

FIGURE 3-33 Two stages of bodily tooth movement. **A,** Effect observed during the initial stage of a continuous bodily tooth movement. *A,* Hyalinized tissue; *B,* slight initial compression as a result of tipping of the tooth. **B,** Undermining bone resorption terminated. Gradual upright positioning of the tooth caused increased bone resorption adjacent to the middle and apical thirds of the root. Further movement is largely controlled by stretched fiber bundles. *A,* Bone resorption on the pressure side; *B,* Bone deposition along the stretched fiber bundles. The arrows denote direction of tooth movements. **C,** Bodily movement(*arrow*) of a premolar in a dog during a period of 6 months. New bone layers on the tension side with osteoblasts (*O*); root resorption on the pressure side (*R*).

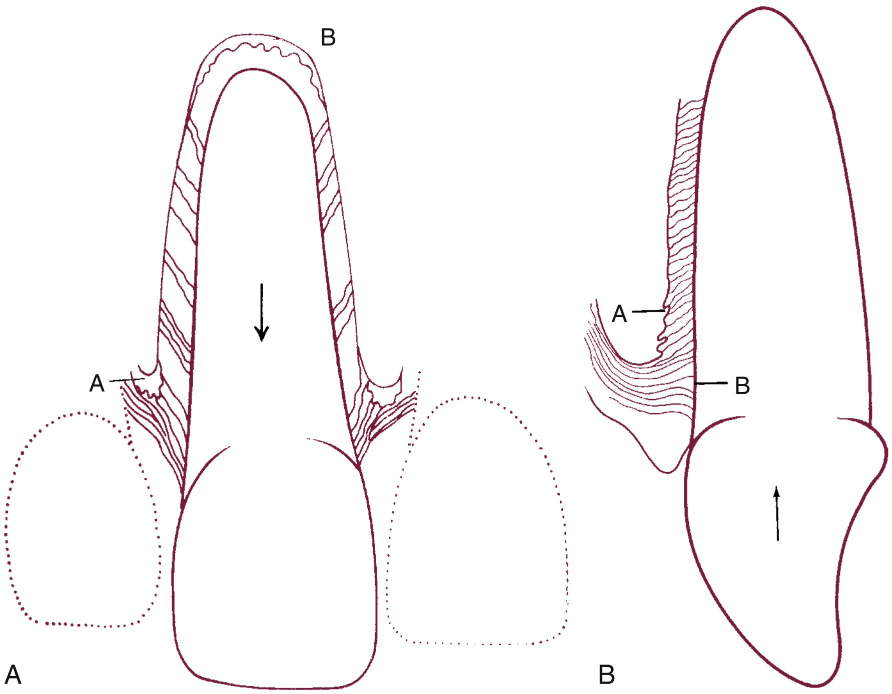

FIGURE 3-35 A, Arrangement of fiber bundles during or after *extrusion* of an upper central incisor (*arrow*). *A,* Extrusive tension results in added bone at alveolar crest. *B,* New bone layers at the alveolar fundus. **B,** Relaxation of the free gingival fibers during *intrusion* (*arrow*). *A,* Bone spicules laid down according to the direction of the fiber tension; *B,* relaxed supraalveolar tissue.

light force during the initial period is favorable. On the tension side, new bone spicules are formed along stretched fiber bundles arranged more or less obliquely. In the marginal region, rotation usually causes considerable displacement of fibrous structures. The free gingival fiber groups are arranged obliquely from the root surface. Because these fiber bundles interlace with the periosteal structures and the whole supraalveolar fibrous system, rotation also causes displacement of the fibrous tissue located some distance from the rotated tooth (Fig. 3-34, *B*).

Extrusion

Extrusive movements ideally produce no areas of compression within the PDL, only tension. Even if compressed areas could be avoided, heavy forces risk "extraction" of the tooth. Light forces, however, move the alveolar bone with the tooth.

Varying with the individual tissue reaction, the periodontal fiber bundles elongate and new bone is deposited in areas of alveolar crest as a result of the tension exerted by these stretched fiber bundles (Fig. 3-35, *A*). In young individuals, extrusion of

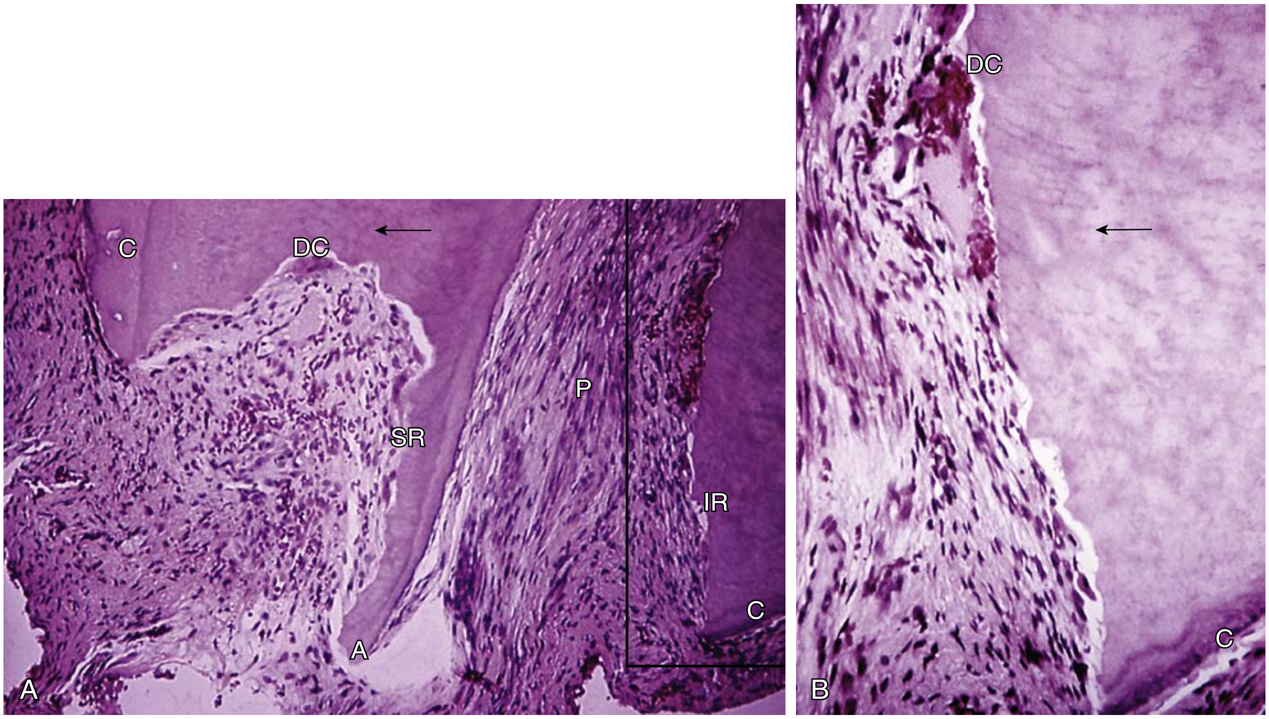

FIGURE 3-36 Apical portion of a lower first premolar tipped and intruded by a force of 100 cN for 35 days. **A,** *C,* Well-calcified cementum; *SR,* apical side resorption; *DC,* dentinoclast; *A,* remaining area of the apex, a detail of importance during reconstruction; *IR,* internal apical resorption; *P,* pulp tissue. **B,** Boxed area in **A.** *Arrows* indicate direction of applied force.

a tooth involves a more prolonged stretch and displacement of the supraalveolar fiber bundles than of the principal fibers of the middle and apical thirds. Some of the fibers may be subjected to stretch for a certain time during the tooth movement, but they will be rearranged after a fairly short retention period. Only the supraalveolar fiber bundles remain stretched for a longer time.

Intrusion

Unlike extruded teeth, intruded teeth in young patients undergo only minor positional changes after treatment. Relapse usually does not occur, partly because the free gingival fiber bundles become slightly relaxed (Fig. 3-35, *B*). Stretch is exerted primarily on the principal fibers. An intruding movement may therefore cause formation of new bone spicules in the marginal region. These new bone layers occasionally become slightly curved as a result of the tension exerted by stretched fiber bundles. Such tension also occurs in the middle third of the roots. Rearrangement of the principal fibers occurs after a retention period of a few months.

Intrusion requires careful control of force magnitude. Light force is required because the force is concentrated in a small area at the tooth apex. A light continuous force, such as that obtained in the light wire technique, has proved favorable for intrusion in young patients. In other cases the alveolar bone may be closer to the apex, increasing the risk for apical root resorption (Fig. 3-36). If the bone of the apical region is fairly compact, as it is in some adults, a light interrupted force may be preferable to provide time for cell proliferation to start, and direct bone resorption may prevail when the arch is reactivated after the rest period. Intrusion may also cause changes in the pulp tissue such as vascularization of the odontoblast and pulpal edema.[23,24]

Movements in the Labial/Buccal Direction

Heavy forces in the labial and buccal direction may result in alveolar bone dehiscence. Experiments in monkeys and beagle dogs have shown that "predisposing" alveolar bone dehiscences may be induced by uncontrolled labial expansion of teeth through the cortical plate, thereby rendering the teeth liable to the development of soft tissue recession (Fig. 3-37).[25-28] Of interest to note from those studies is that labial bone reforms in the area of dehiscence with intact epithelial junction (JE) when the tooth is retracted toward a proper positioning of the root within the alveolar process (Fig. 3-38).[27,28]

An experimental study in monkeys[29] in which teeth were moved orthodontically in a labial direction into areas with varying thickness and quality of the marginal soft tissue showed that a thin gingiva may serve as a locus minoris resistentiae to developing soft tissue defects in the presence of plaque-induced inflammation or toothbrushing trauma (Fig. 3-39).

The *clinical implication* of the results from the studies discussed is that careful examination of the dimensions of the tissues covering the facial aspect of the teeth to be moved should precede labial tooth movement. As long as the tooth can be moved within the envelope of the alveolar process, the risk of harmful side effects in the marginal tissue is minimal, regardless of the dimensions and quality of the soft tissue.

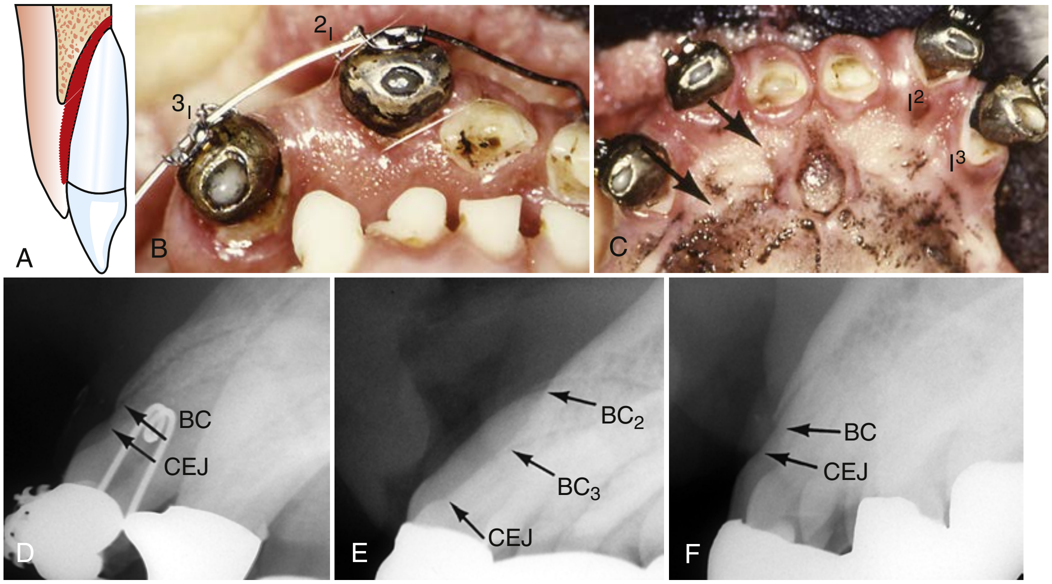

FIGURE 3-37 Bone dehiscences related to orthodontic tooth movement in a dog. **B,** The incisors 2_I and 3_I have been displaced through the alveolar bone plate to the level shown in **A**. **C,** The incisors I^2 and I^3 have been moved back to their original position; simultaneously I^2 and I^3 are displaced labially (days 150–300). Movements into Reduced Alveolar Bone Height

In patients with *partially edentulous dentitions* due to congenital absence or extraction of teeth, orthodontic treatment often is necessary. By positioning the teeth toward or into the edentulous area, improved aesthetics and functional results may be gained. Many of these individuals experience a *reduced alveolar bone* height.

Do tissue changes on the pressure side allow the tooth to move into such an area? An experimental study in the beagle[30] (Fig. 3-40) has shown that a tooth with normal periodontal support can be moved orthodontically into an area of reduced bone height with maintained height of the supporting apparatus. On the pressure side, supporting alveolar bone was also present, extending far coronal to the surrounding, experimentally created bone level (Fig. 3-41). The histologic picture of the bone tissue in the coronal portion of the root showed a large number of cells in contrast to the compact appearance of the more apically located bone, as in the unmoved tooth.

An interesting finding was that the newly formed bone on the pressure side showed resorption on the surface near the root and apposition on the opposite side of the thin bone plate (see Fig. 3-41, *C*), which was interpreted as a piezoelectric effect through strain-generated potentials, arising as a result of mechanically induced deformation of collagen or hydroxyapatite crystals.[31]

This experimental model has been tested in partially edentulous patients with normal periodontal tissue support located adjacent to an area with reduced bone volume.[32] Teeth have been moved orthodontically between 5 and 8 mm into such an area with maintained support and used as an abutment for a fixed prosthetic denture (Fig. 3-42). A dental implant placed in the created space showed excellent bone integration (Fig. 3-43). The results of these clinical follow-up studies are encouraging, as long as bodily tooth movements with light orthodontic forces are used. How far a tooth can be displaced into such an area can only be speculated.

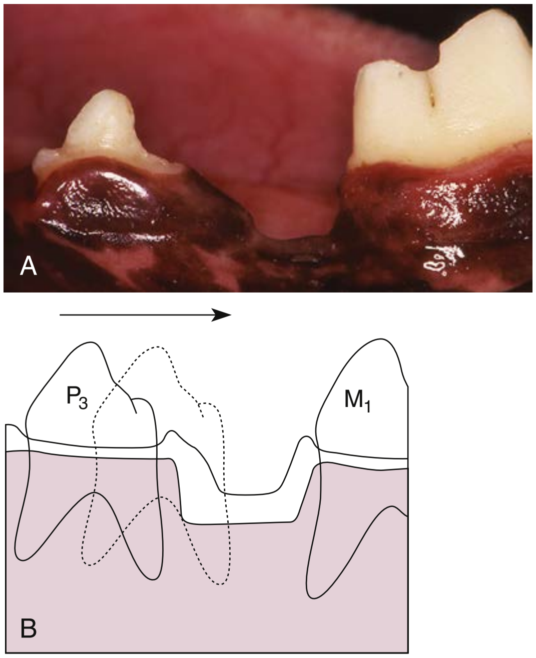

FIGURE 3-40 Clinical photograph **(A)** and schematic drawing **(B)** illustrating the bodily movement of the third premolar in the dog into an area with reduced alveolar bone height. (From Lindskog-Stokland B, et al. Orthodontic tooth movement into edentulous areas with reduced bone height. An experimental study in the dog. *Eur J Orthod.* 1993;15:89.)

Transmission of Orthodontic Forces into a Cellular Reaction

The old observation by Reitan illustrates well one of nature's wonders (Fig. 3-44).[7] The tooth is being moved in the direction of the arrow. Resorption of the alveolar bone wall has occurred. Fatty bone marrow has been changed into red bone marrow. At a little distance behind the alveolar bone wall, a new bony lamella is laid. How do the different cells know that they should react and in a special way? Tooth movement involves cell signaling leading to remodeling of the periodontal tissues,[31-39] which is described in detail in the next section of this chapter and begins on page 85.

TISSUE RESPONSE IN SUTURES

The effect of mechanical forces on the craniofacial sutures has been well described in the literature. Controlled forces generated by various types of headgear and appliances for palatal expansion have shown measurable changes of the craniofacial morphology. The changes are, however, of different degrees, and contradictory findings regarding long-term stability have been reported. One explanation of these different opinions is that the position, orientation, and even numbers of facial sutures seem to be closely oriented with respect to various forces (Fig. 3-45).

The possibility of influencing the basal parts of the nasomaxillary complex is an open suture before any bony union (synostosis) has been established. However, different opinions about the age of human suture closure are prevalent, and the mechanism of physiologic fusion of sutures is still obscure. Histologic studies

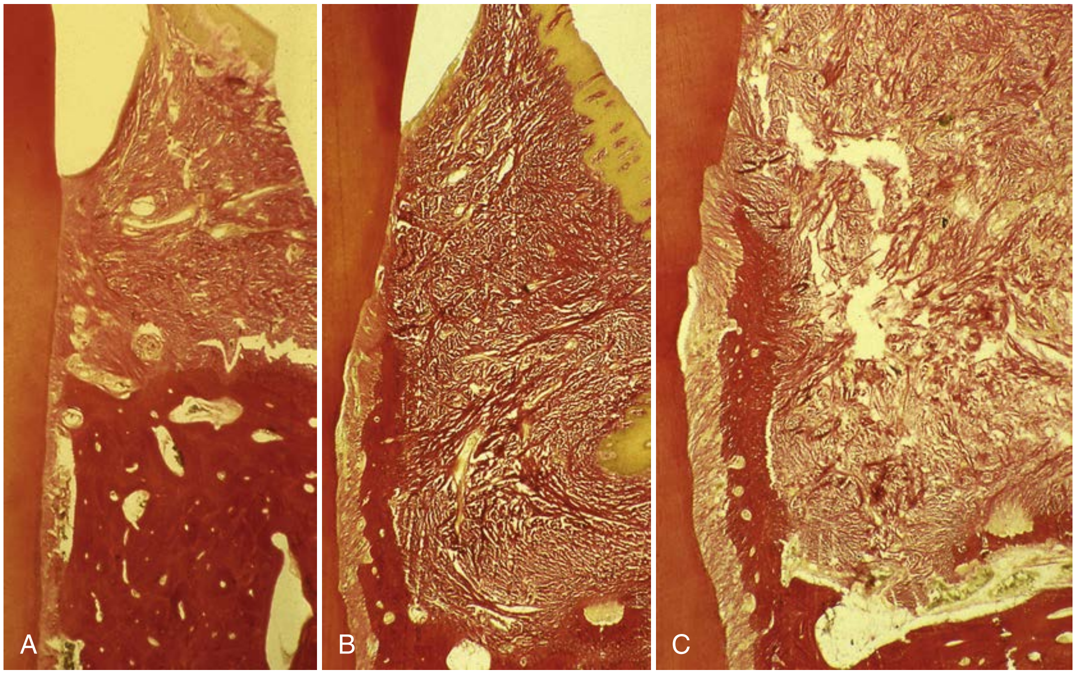

FIGURE 3-41 Specimens from a control (unmoved tooth) **(A)** and a tooth moved as shown in Figure 3-40 **(B)**. **C,** The bone tissue in the coronal part of the root showed a large number of cells in contrast to the compact appearance of the more apically located bone. (From Lindskog-Stokland B, et al. Orthodontic tooth movement into edentulous areas with reduced bone height. An experimental study in the dog. *Eur J Orthod.* 1993;15:89.)

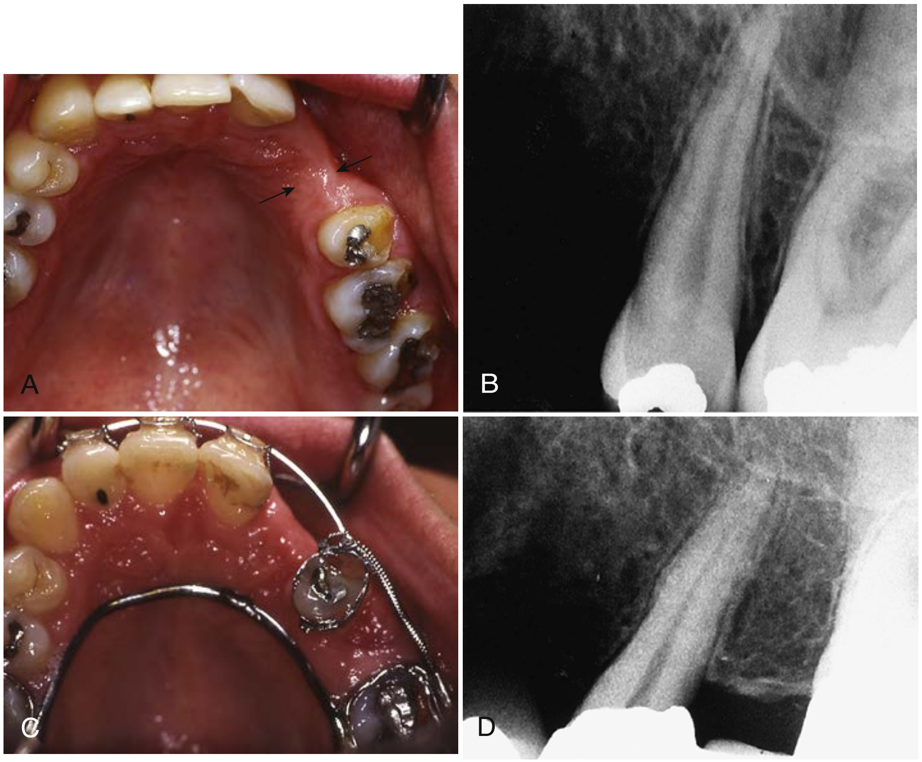

FIGURE 3-42 A 25-year-old man who is partially edentulous because of trauma. **A, B,** Marked bone loss (*arrows*) in the left maxillary alveolar process. **C,** The second premolar was moved bodily one cusp width into the area with reduced bone support. **D,** After a treatment period of 12 months, a prosthetic bridge was constructed. Note the regaining of alveolar bone. (From Thilander B. Infrabony pockets and reduced alveolar bone height in relation to orthodontic treatment, *Semin Orthod.* 1996;2:55.)

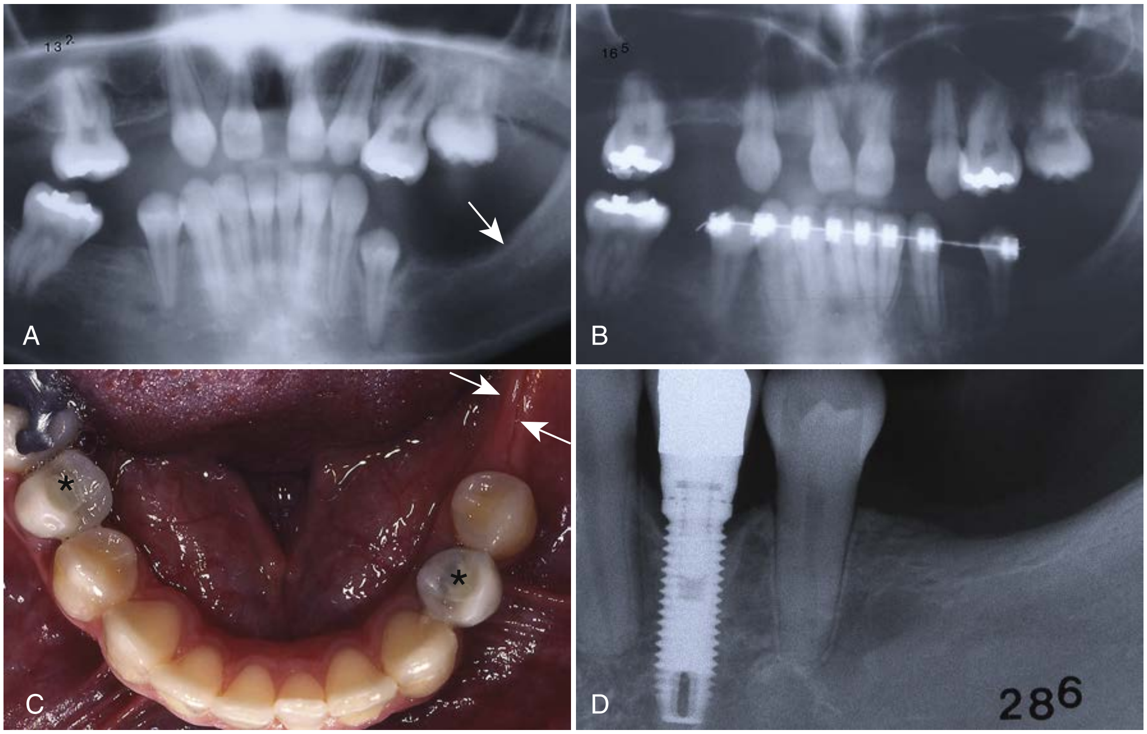

FIGURE 3-43 **A,** Radiograph of a 13-year-old girl with 12 congenitally missing teeth. In the mandible, it was decided to align the dental arch and to place an implant in the right premolar region. On the left side, implant placement was contraindicated because of thin bone volume in the buccolingual direction. **B,** Instead, the first premolar was moved one cusp width distally, and an implant was placed in the created space at age 17 years. **C,** Note the thin buccolingual bone volume in the lower left side (*arrows*) posterior to the distalized premolar. The implant-supported crowns are indicated by asterisks. **D,** At the last observation, a good result was registered with excellent bone integration of the implants. (From Thilander B, et al. Orthodontic aspects on the use of oral implants in adolescents: a 10-year follow-up study. *Eur J Orthod.* 2001;23:715.)

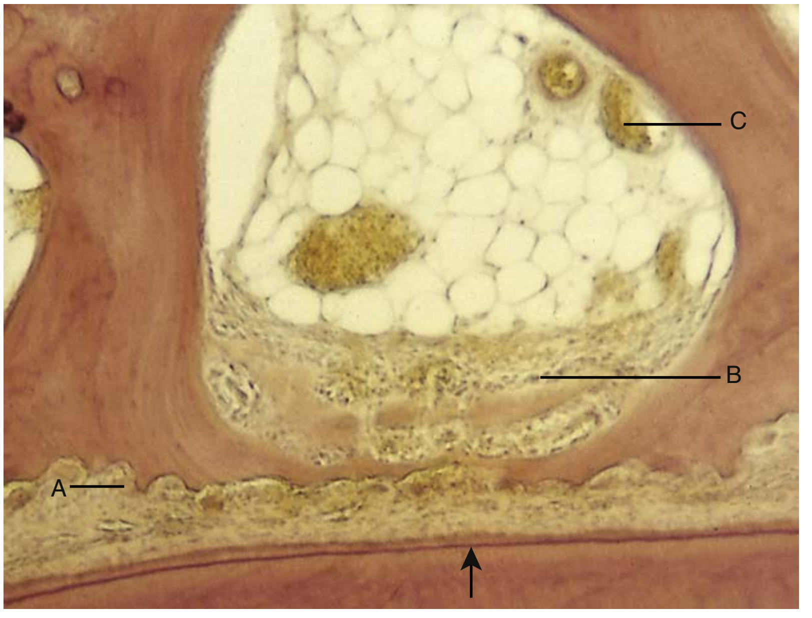

FIGURE 3-44 Bodily movement of an upper second incisor in a dog. The *arrow* indicates the tooth and direction of movement. The root was moved against a space containing fatty marrow, which was transformed into loose, fibrous tissue in advance of the movement. The periodontal space is narrower in this area because the uncalcified bone layer along the inside of the marrow space is less readily resorbed by osteoclasts. *A,* Direct bone resorption, one of the many Howship lacunae with osteoclasts; *B,* compensatory bone formation; osteoid layer bordered by osteoblasts; *C,* capillary surrounded by fatty marrow.

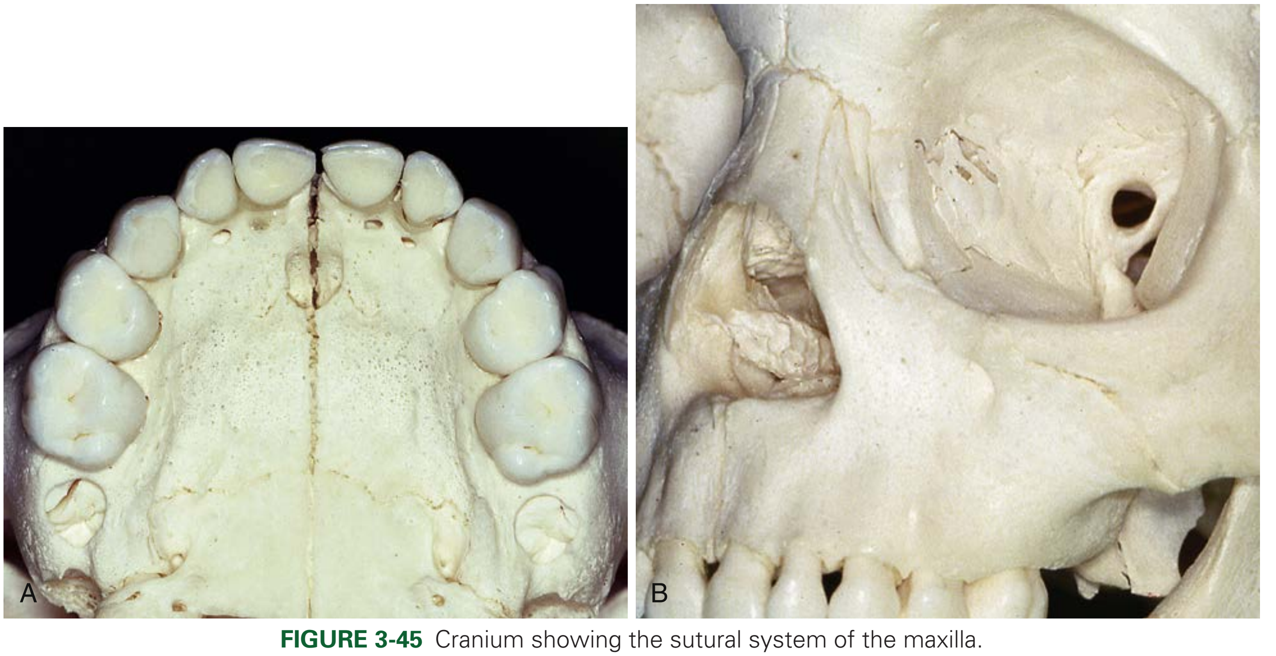

FIGURE 3-45 Cranium showing the sutural system of the maxilla.

on human maxillary sutures[40,41] have shown that palatal suture closure usually starts during the third decade of life, although with large individual variations. After adolescence, closure was observed in most specimens, indicating a rapid increase in fusion during the third decade. Based on microradiograms of the frontozygomatic suture in humans, Kokich[42] concluded that most facial sutures remain visible until the eighth decade of life.

Structure of the Suture

Sutures consist of a fibrous tissue with osteogenic layers on both surfaces (Fig. 3-46). Sutures therefore represent an extension of the periosteal layer of the bone and participate in the design of the bone by their remodeling capacity. The fiber system is mainly collagenous with a rapid synthesis and turnover. Elastic fibers are more frequent in sutures than in the PDL.

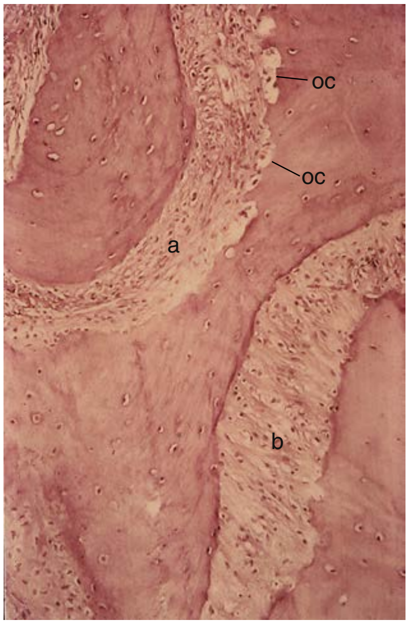

FIGURE 3-46 Photomicrograph of the intermaxillary suture of a 12-year-old boy. Variation in the fiber structure is evident; cells and fibers parallel (*a*) and perpendicular (*b*) to the bony surface. Note the osteoclasts (*oc*). (From Persson M, Magnusson B, Thilander B. Suture closure in rabbit and man: a morphological and histochemical study. *J Anat.* 1978;125:313.)

The maturing suture tissue in the growing individual demonstrates changes with age that eventually end with a bony obliteration of the sutural space (Fig. 3-47). The density and thickness of the fibrous component increase with age, and when growth ceases, bundles of fibers can be seen running transversely across the suture, increasing the mechanical strength of the joint. Osteogenesis tends to be restricted to areas of transversely densely arranged collagen bundles, a preliminary stage to bony bridgings.[43] Because of the serpentine course of the suture, areas of tension and compression develop in the tissue (Fig. 3-48).

Concomitant with a general advance of obliteration with age in a single suture, more of the palatal suture area is involved. Besides variations in the degree of closure between sutures, variations also exist between different parts of the same suture. Closure progresses more rapidly in the oral than in the nasal part of the palatal vault, and the intermaxillary suture starts to close more often in the posterior than in the anterior part.[41] Because of the increased inclusion and bone locking (interdigitation), the possibility for influencing the suture area by orthopedic treatment gradually decreases with age.

Suture Response to Orthodontic/Orthopedic Forces

The attempt to move an incisor orthodontically *through the midpalatal suture* in dogs was shown to be unsuccessful.[44] The histologic analysis revealed that the suture had been dislocated

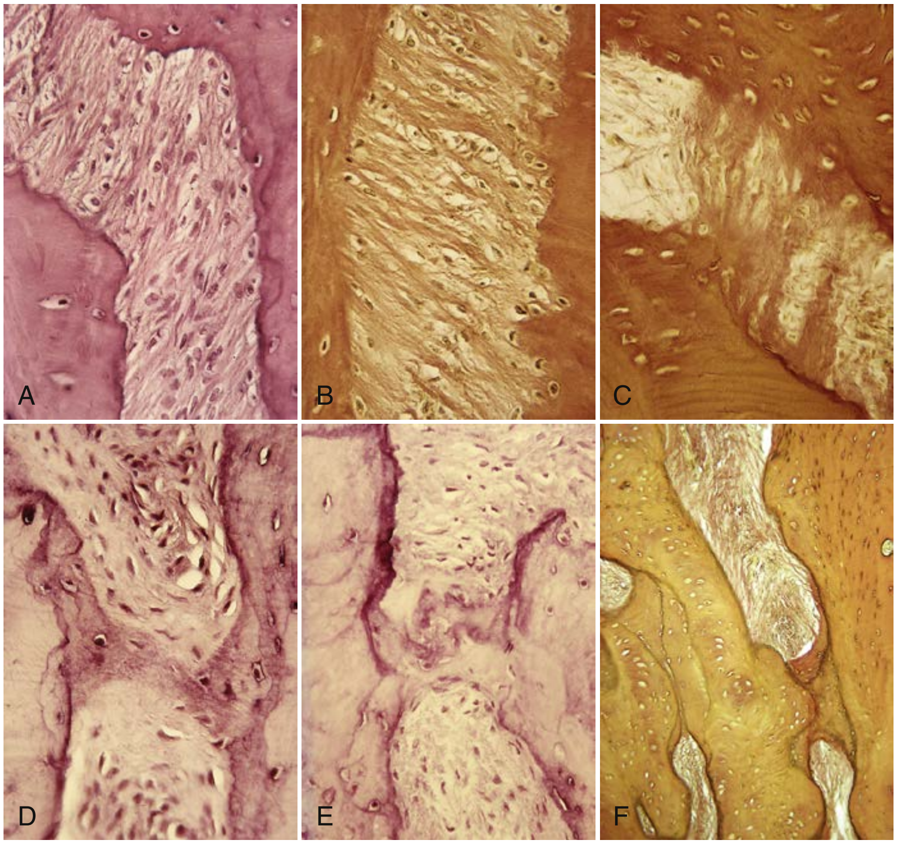

FIGURE 3-47 Photomicrographs from the human intermaxillary suture at different ages (14 to 25 years) showing various stages of fusion. The collagen fibers perpendicular to the bony surface (A) increase in thickness (B) and density (C) with age. A slender bridge of uncalcified tissue in the area of tightly packed fibers (D and E) is a preliminary stage to bony obliteration (F) of the suture. (Adapted from Persson M, Magnusson B, Thilander B. Suture closure in rabbit and man: a morphological and histochemical study. *J Anat.* 1978;125:313.)

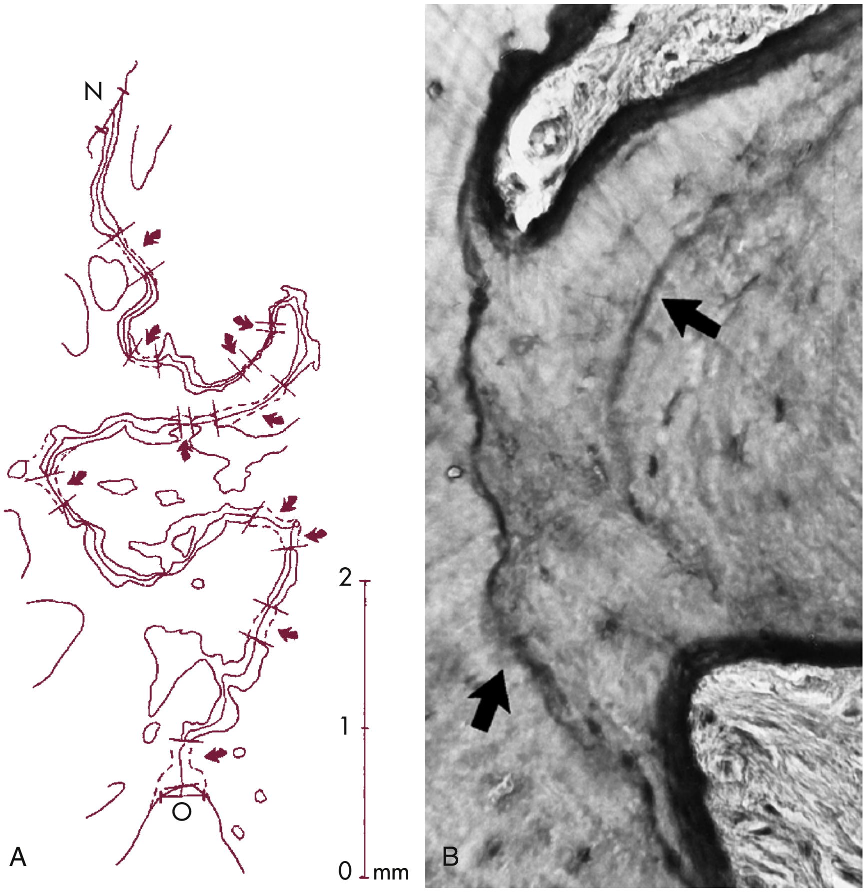

FIGURE 3-48 **A,** Tracing of a section in the frontal plane from the posterior part of the intermaxillary suture of a 31-year-old man. Nasal (*N*) and oral (*O*) sides are presented. Bony bridges occur at the arrows. **B,** An ossified part of the suture. Note the basophilic staining at the site of the earlier resting-suture margin (*arrows*). (From Persson M, Thilander B. Palatal suture closure in man from 15 to 35 years of age. *Am J Orthod.* 1977;72:42.)

in front of the orthodontically moved incisor (Fig. 3-49). Eventually, the PDL and suture tissue became merged, demonstrating an apparently close similarity between the tissues of the two joint types. However, in dogs with a closed suture, the incisor could pass the sutural area without any impediment.

Traction generated by *orthopedic forces* has long been claimed to stimulate sutural growth, and widening of the midpalatal suture is a clinically well-documented procedure in orthodontics (Fig. 3-50) (for a review, see Timms[45]). The tissue response has been reported in histologic studies in animals. The mechanical response to traction includes a widening of the suture and changes in the orientation of fiber bundles.[46] A considerable increase of osteoblasts and an osteoid zone on both sutural bone surfaces indicate bone formation (Fig. 3-51). The bone deposition accompanies traction, allowing the suture to recover a normal histologic picture. A positive correlation exists between the magnitude of the tensile force and osteogenic response.[47,48] Experiments in vitro verify that mechanical tensile forces stimulate synthesis of structural proteins.[49] *Healing* of a suture after rapid expansion may entail formation of bony bridges across the suture. Low-power laser irradiation has been shown to accelerate bone regeneration in the midpalatal suture during rapid palatal expansion in the rat.[50]

The *transduction of a mechanical force* into bone production may involve an intracellular influx of calcium and/or sodium ions, which decreases cAMP and triggers DNA synthesis and cellular proliferation.[34] Ten Cate et al.[51] used heavy forces to expand cranial sutures and showed that fibroblasts must proliferate and repair sutural connective tissue before osteogenesis and remodeling of the suture take place.

Rapid maxillary expansion is an orthopedic procedure that has been shown to influence not only the midpalatal suture but also the *circumaxillary sutural system*. In such a palatal splitting, most of the resistance to separation results from the circumaxillary structures. Because posterior and anterior *displacements of the maxilla* (*protraction*) involve more sutures than displacements caused by palatal expansion, the resistance to separation consequently increases (see Fig. 3-47).

TISSUE RESPONSE IN THE TEMPOROMANDIBULAR JOINT

The response in the TMJ region to functional and orthopedic appliances has been a subject of discussion for many years. So, it is necessary to understand the nature of the tissues that make up the TMJ, their relation to the normal growth process, and the manner in which they express themselves during maturation.

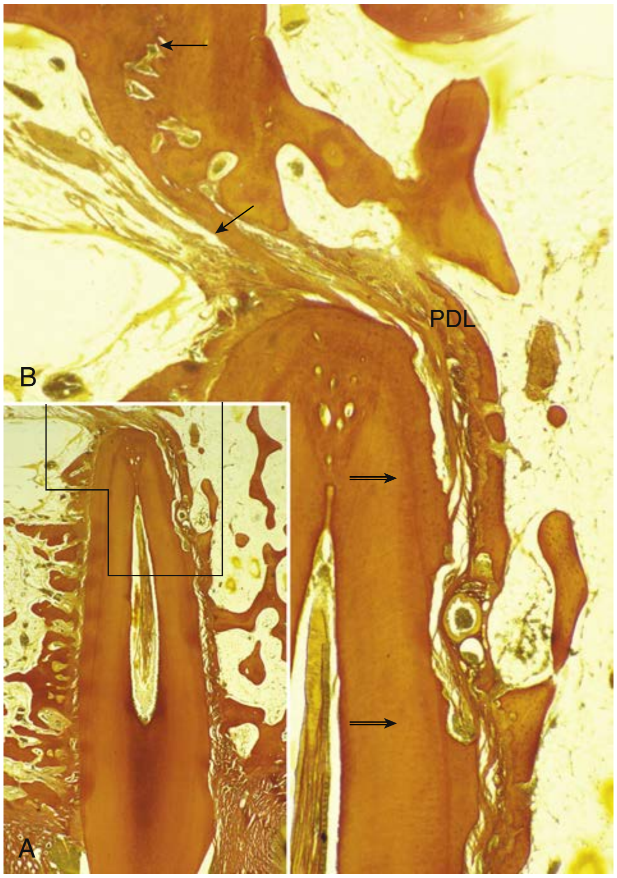

FIGURE 3-49 Photomicrographs of the intermaxillary suture of a young dog in which an attempt to orthodontically move an incisor through the suture was shown to be unsuccessful. **A,** The suture fibers are stretched around the apex and seem to continue in the periodontal ligament (*PDL*). **B,** Magnification of boxed area in **A**. *Closed arrows* indicate the intermaxillary suture; open arrows indicate the direction of movement with root resorption. (From Follin M, Ericsson I, Thilander B. Orthodontic tooth movement of maxillary incisors through the midpalatal suture area. An experimental study in dogs. *Eur J Orthod.* 1984;6:237.)

The TMJ provides the essential functional connection between the cranium and the upper and lower jaw (Fig. 3-52). However, the primary functions of the TMJ in general and the mandibular condyle in particular are not simple, and they change during development. Furthermore, striking differences exist in the extent of mineralization between the condyle and the temporal component (Fig. 3-53).

Structure of the Temporomandibular Joint

Several investigations of the anatomy and development of the TMJ in various experimental animals are available. However, there are only a few comprehensive systematic investigations of human postnatal TMJ development.[52-54]

Condylar Cartilage

The condylar cartilage varies in appearance from one part of the condyle to another, and its histomorphologic picture varies from birth to childhood, but the following four layers usually can be seen (Fig. 3-54): a fibrous connective tissue layer (surface articular zone); a highly cellular intermediate layer containing proliferating cells (proliferative zone); a cartilage layer with irregularly arranged chondrocytes (hypertrophic zone); and a zone with endochondral bone ossification (bone formative zone).

During the juvenile period, the condyle becomes progressively less vascularized, and the entire growth cartilage layer becomes significantly thinner, primarily because of reduction in the hypertrophic zone. At the age of 10 years, the mandibular condyle is characterized by a relatively thick articular tissue layer, progressive reduction in the size of the entire growth cartilage layer, and evidence of increased mineralization in the deeper portion of the hypertrophic zone. After 13 to 15 years, the cartilage layer decreases further in thickness. By the age of 19 to 22 years, only islands of cartilage cells remain in the superior and anterior regions.

Mandibular Neck

The fibrous layer of the condylar cartilage is continuous with the periosteum of the ramus, and remodeling processes are seen in all regions of the mandibular neck (Fig. 3-55). The term *condylar growth* is therefore misleading, and the term *ramus and condylar growth* is more correct, as expressed by Enlow.[55]

Temporal Component

The S-shaped curve that characterizes the temporal component of the TMJ becomes evident during the first 6 months of life. The articular surface is lined with a fibrous connective tissue resembling the surface articular zone of the condyle (Fig. 3-56, *A*), with an increase in thickness during early and mixed dentitions through puberty. The proliferating zone is seen up to the age of 17 to 18 years (Fig. 3-56, *B*). In the fossa, remodeling is observed from early childhood to adulthood[53] (Fig. 3-56, *C* and *D*).

Temporomandibular Joint Response to Orthopedic Forces

Because remodeling processes are seen in all components of the joint, most obviously in young ages, it has been speculated whether the TMJ would respond to orthodontic stimuli and influence the growth of the mandible.[56] McNamara[57] has shown that the TMJ in monkeys is capable of functional adaptation when the mandible is displaced in a *forward direction*. Hypertrophy and hyperplasia of the prechondroblastic and chondroblastic layers of the condylar cartilage were seen, particularly along the posterior border of the condyle, with rapid bone formation in the condylar head. After about 10 weeks, the generalized proliferation of the condylar cartilage was, however, no longer evident, indicating that the essential remodeling had been completed. Furthermore, an increased activity of the superior head of the lateral pterygoid muscle was recorded. A progressive modification of the neuromuscular pattern thus was observed with the skeletal adaptation to the forward displacement of the mandible. Moreover, the subperiosteal growth rate increases at the posterior border of the ramus. In addition, the bone turnover rate and mineralization in the mandible as a whole are significantly influenced.

Petrovic and coworkers have shown in a number of experiments in rats, with anterior displacement of the mandible, that a functional appliance primarily induces an amplification in skeletoblast and prechondroblast mitotic activity, an acceleration in differentiation of skeletoblasts into prechondroblasts, an increase in transformation of prechondroblasts into

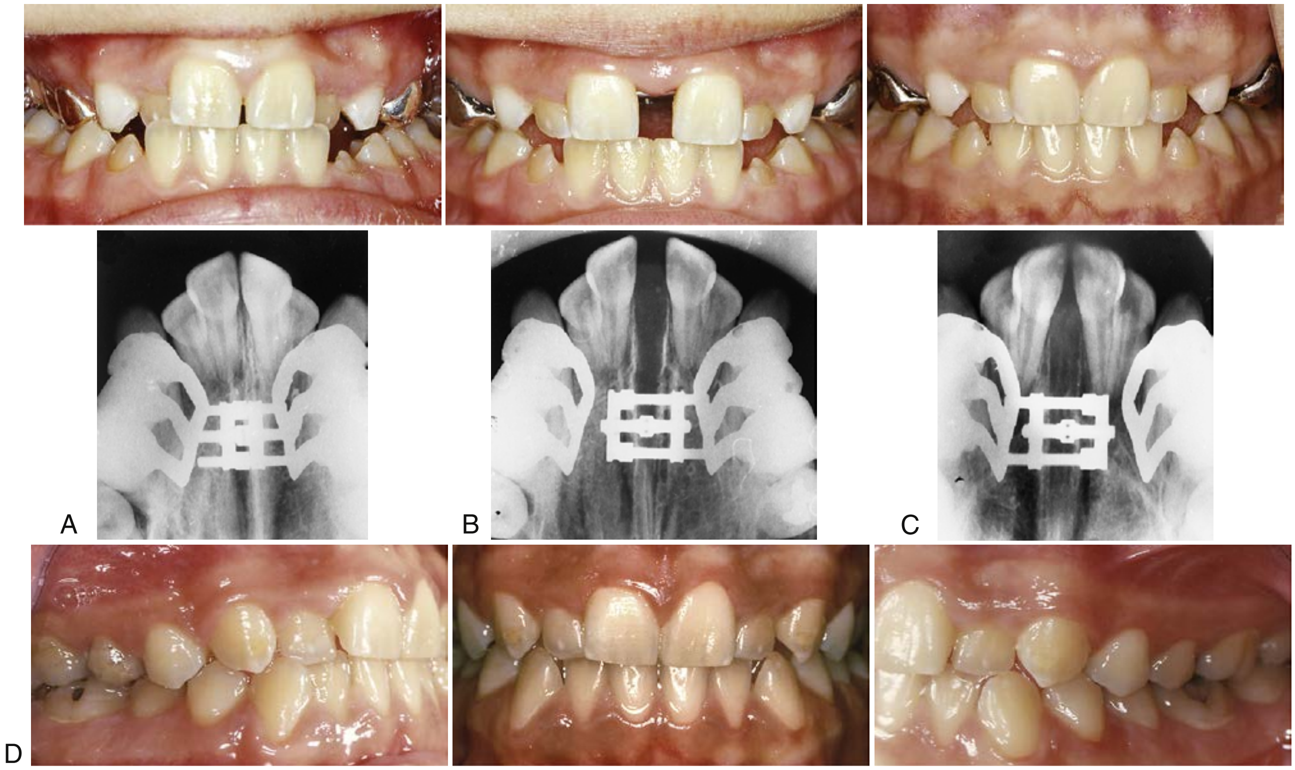

FIGURE 3-50 Widening of the midpalatal suture in a 12-year-old girl. **A,** Before maxillary expansion. **B,** After 21 days of rapid maxillary expansion. **C,** Spontaneous closure at day 60, when the appliance was removed. **D,** 5 years postretention.

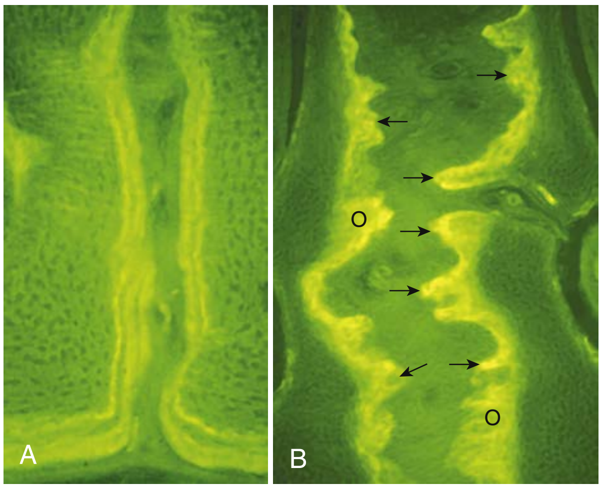

FIGURE 3-51 Photomicrographs of the intermaxillary suture in the rat. **A,** Before expansion. **B,** After sutural expansion for 7 days. Increased cellular activity is evident along the total bone surfaces (*arrows*). *O,* Osteoid layer in the yellow areas (tetracycline administration). (From Engström C, Thilander B. functional chondroblasts, and an acceleration in chondroblast hypertrophy and endochondral bone growth (for a review, see Petrovic et al.[58]).

A *mandibular retrusion* by chin cap therapy in the rat revealed a reduced thickness of the prechondroblastic zone and a decrease in the number of dividing cells.[59] A reduced length of the mandible indicated that chin cap treatment had a retarding effect on mandibular growth, contrary to the increased length in the experiments with anterior displacement of the mandible.

How does this experimentally induced stimulation or retardation of condylar growth relate to *clinical orthodontics*? Some researchers maintain that mandibular growth in children can be altered and that this change can be detected through well-designed clinical procedures. However, several researchers consider that the therapeutic effect of a functional appliance on the lengthening of the mandible is not clinically relevant, for the individual's growth potential during the treatment period also is included in this effect.

These conflicting observations made in clinical studies over many years suggest that alterations in condylar growth in human patients are difficult to document. One reason for this is that the controlled design in animal experiments is hardly attainable in humans. Moreover, the growth rate in the rat and monkey is much faster than that in humans, factors that make appearance and quantification of the adaptive changes difficult. In addition, the clinician is aiming at changing an abnormal growth pattern into a normal one, which is different from alterations that start from normal growth pattern, as in animal experiments. Thus, the question of whether the growth of the human mandible may be altered by orthopedic and functional appliances remains partly unanswered (See also Chapter 35). However, research shows that the orthopedic change apparently is a combined change of mandibular and temporal components (i.e., condylar and remodeling processes).

POSTTREATMENT STABILITY

Not all orthodontically achieved changes remain stable. If an undesirable growth pattern is treated partly by influencing growth and partly by compensations in the dentoalveolar system, subsequent posttreatment growth may upset a result that looks good when the patient is young. It is well known that many patients experience changes some years after treatment, which is often described as relapse (i.e., a return toward pretreatment conditions). We have, however, to distinguish the "rapid relapse" occurring during the period of remodeling of periodontal structures from the "slow relapse" that is due to the late changes during the postretention period.

Tissue Reactions Seen in Orthodontic Retention and Relapse

Experimental studies have shown that if orthodontic movement is not followed by remodeling of the supporting tissues, the tooth will return to its former position.[59-61] The most persistent relapse tendency is caused by the structures related to the marginal third of the root, whereas little relapse tendency exists in the area adjacent to the middle and apical thirds. The effect caused by contraction of the principal and supraalveolar fibers is shown in Figure 3-57. The crown of an experimentally moved tooth in a dog was moved 2 mm by tipping over during a period of 40 days. After the tooth was released, the degree of relapse movement was recorded graphically. Some relapse was noticed to have already occurred after 2 hours, partly caused by the tooth's regaining a more upright position within the periodontal space. Still more relapse occurred on the following days for a total of about 0.5 mm during 4 days. After this, the tooth came to a standstill. Histologic examination revealed that this was caused by a hyalinized area on the tension side.[61] Therefore, fiber contraction is strong enough to produce hyalinization. Similar hyalinized zones may be observed after tipping human teeth without subsequent retention (Fig. 3-58).

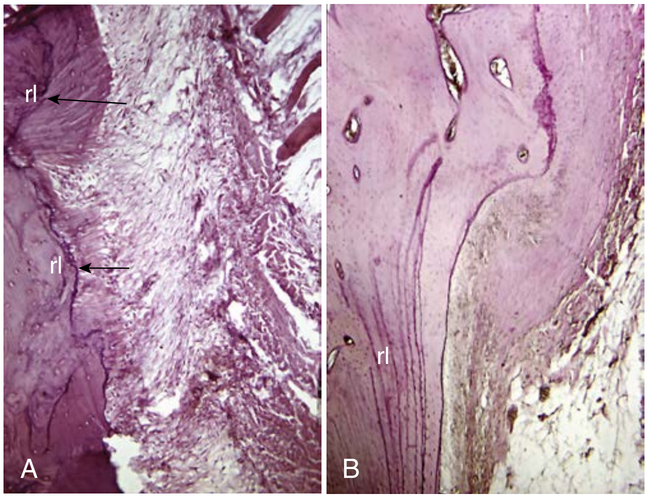

FIGURE 3-55 Photomicrographs from the mandibular neck (transversal plane) illustrating the remodeling processes (×40). **A,** A 7-year-old girl. **B,** A 23-year-old woman. *rl,* Resting lines. Apposition starts medially to *rl* (*arrows*). (Adapted from Thilander B, Carlsson GE, Ingervall B. Postnatal development of the human temporomandibular joint. I. A histologic study. *Acta Odont Scand.* 1976;34:117.)

The tissue reactions in the gingiva differ from those in the PDL and are of different importance for the stability of an acquired tooth position (see Figs. 3-2 through 3-4). The various fiber groups also respond differently to the remodeling process. Furthermore, the supporting fibrous systems, both supraalveolar and periodontal, develop during the eruption of teeth according to increasing functional demands. This explains the greater stability of teeth that are guided passively into position during the eruptive period, compared with teeth that are moved after having reached occlusal stability.

Several factors are essential for the reestablishment of an adequate supporting apparatus during and after tooth movements. The main remodeling of the PDL takes place near the alveolar bone; the remodeling of the fibrous system on the tension side is related to the direction of pull on the tooth, resulting in production of new fibers only in that direction.

Unlike the PDL, the supraalveolar fibers are not anchored in a bone wall that is readily remodeled, and therefore they have less chance of being reconstructed. Furthermore, the remodeling of gingival connective tissue is not as rapid as that of the PDL, and the slower turnover of the gingival collagen fibers[34] easily explains why such fibers are seen stretched and unremodeled as long as 232 days after experimental tooth rotation[60] (Fig. 3-59). The stretched fiber bundles on the tension side tend to become relaxed and rearranged according to the

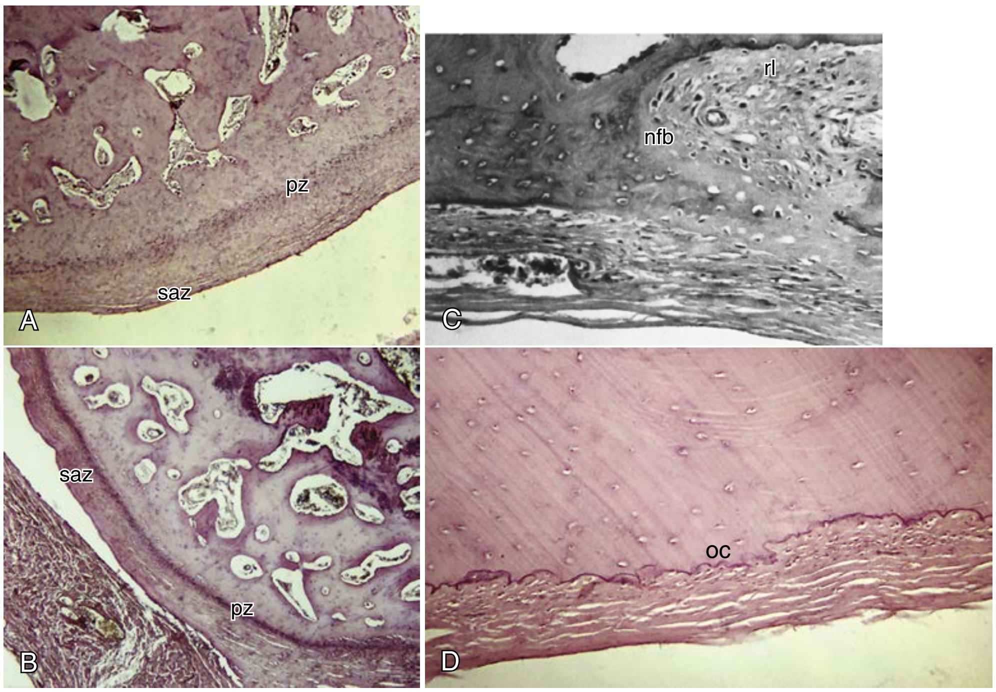

FIGURE 3-56 **A, B,** Photomicrographs from the temporal part (central section, sagittal plane) (×40) articular tubercle of **A,** 9-year-old boy and, **B,** a 14-year-old boy. *saz,* Surface articular zone; *pz,* proliferation zone. **C, D,** Articular fossa illustrating remodeling processes in **C,** a 7-year-old boy and, **D,** a 16-year-old boy. *rl,* Resting line; *nfb,* Newly formed bone; *oc,* Osteoclastic activity. FIGURE 3-57 **A,** Formation of hyalinized areas during tooth movement of an upper second incisor in a dog (duration 40 days). **B,** Formation of hyalinized areas during the relapse period. The tooth was not retained after movement. **C,** Relapse movement during a period of 8 days (as seen in tooth **B**). Hyalinization occurred after 4 days.

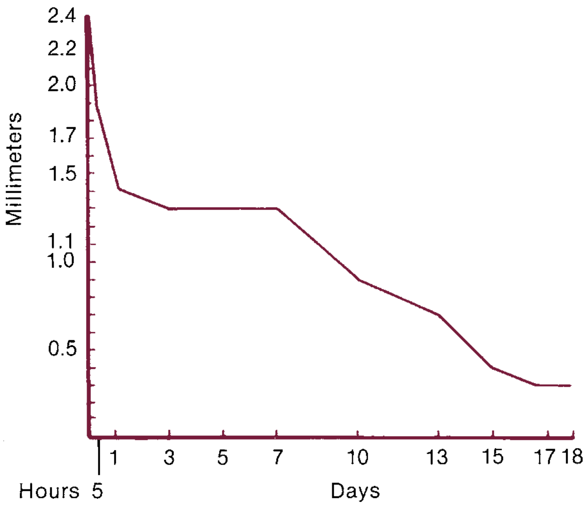

FIGURE 3-58 Degree of movement after labial tipping and the subsequent relapse movement after the tooth had released. Upper lateral incisor of a 12-year-old patient (force, 40 cN). Most of the relapse movement occurred during the first 5 hours. A hyalinized zone existed from the third to the seventh day.

physiologic movement of the tooth. During retention, new bone fills in the space between the bone spicules. This rearrangement and calcification of the new bone spicules result in a fairly dense bone tissue.[3] Therefore, to avoid relapse, a tooth should be retained until total rearrangement of the structures involved has occurred.

Slower remodeling also explains why supracrestal fiberotomy surgery prevents or reduces relapse after the experimental rotation of teeth (see Fig. 3-37, *B*). The reason for the slow remodeling of the supraalveolar tissues after experimental tooth movement probably is related to the quality of particular fiber groups, whose main function is to maintain tooth position and interproximal contact.

A clinical experience is that cases after orthodontic space closure of extraction gaps have a tendency to reopen. The orthodontic force creates a compressed gingival tissue in the extraction site (Fig. 3-60, *A*). Excision of this hyperplastic area showed a long-lasting epithelial fold (invagiation) with loss of collagen but an increased amount of glycosaminoglycans (Fig. 3-60, *B*).[62] Such "elastic" tissue together with the compression of the transseptal fibers may be responsible for relapse after closure of the extraction gap.

Changes during the Postretention Period

The length of the retention period to avoid relapse is controversial. Some recommend 2 to 5 years, whereas others have suggested a minimum of 10 years or longer. Analysis of not only orthodontically treated cases but also of nontreated cases in follow-up studies is of importance to learn more about postretention development versus relapse.

A longitudinal study of individuals, not orthodontically treated, with well-shaped dental arches and normal occlusion ("ideal cases")[63,64] clearly showed the dentofacial changes from early childhood into adolescence, young adulthood, and late adulthood, changes that are a gradual process that has to be taken into consideration in orthodontic treatment. The circumference of the dental arches increased during eruption of the incisors and canines but thereafter continuously decreased, especially in the mandible (Fig. 3-61). This will explain why 12 of the 30 subjects, examined at 31 years of age, showed incisor crowding of different degree, even in cases with congenitally missing third molars (Fig. 3-62). Width and depth of the dental arches also showed slow continuous changes of importance for postretention stability (See Chapter 33 for further discussion).

One interesting finding in that longitudinal study was the development of the palatal height. A continuous slow increase in this distance seems to indicate an important role in the tooth eruption mechanism (Fig. 3-63). This knowledge is of importance in explaining the infraposition of an implant-supported crown as a continuous eruption of its adjacent teeth[65] (Fig. 3-64).

The continuous dentoalveolar change, known as *physiologic tooth migration*, thus has to be distinguished from orthodontic relapse. The occlusion hence is to be regarded as a dynamic rather than as a static interrelation between facial structures.

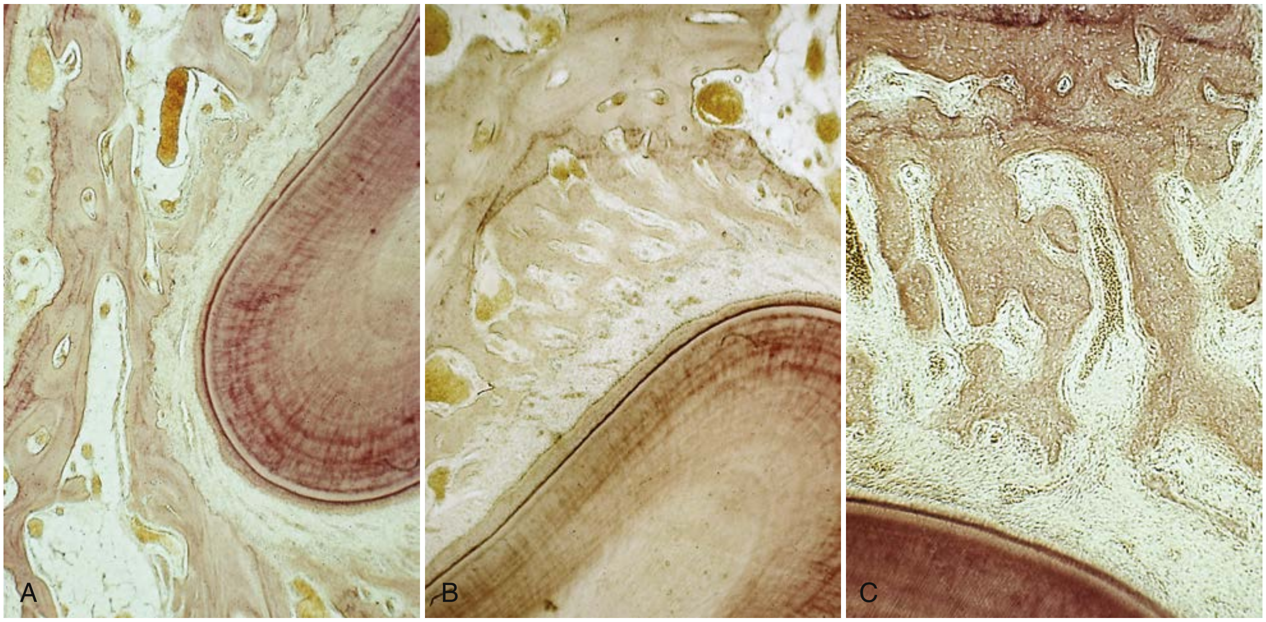

FIGURE 3-59 Tissue response after rotation of a tooth. **A,** Pressure side with direct bone resorption. **B,** Arrangement of new bone layers formed on the tension side along stretched fiber bundles after rotation. **C,** Same area after a retention period of 3 to 4 months. The bone and the principal fibers are rearranged much sooner than the displaced supraalveolar structures.

Gingival tissue reactions to orthodontic closure of extraction sites: histologic and histochemical studies. *Am J Orthod.* 1980;77:620.)

SUMMARY

This chapter represents a discussion of the principal tissue changes resulting from orthodontic forces acting on teeth and supporting structures, sutures, and the TMJ region. Unfavorable forces may initiate adverse tissue reactions. After orthodontic treatment, a rapid-to-slow relapse occurs during the period of remodeling of the periodontal structures. The tissue reactions in the gingiva differ from those in the periodontal ligament and are of different importance to maintain the stability of the tooth in its new position. *Late changes occurring during the postretention period generally cannot be distinguished from normal aging processes that occur regardless of whether a person has been treated orthodontically*. Even though the knowledge of tissue reaction in orthodontics is well documented by numerous experimental and clinical studies, many basic questions still are unanswered.

TOOTH MOVEMENT AT THE CELLULAR AND MOLECULAR LEVELS*

INTRODUCTION

Orthodontic tooth movement beyond the constraints of the original tooth socket requires the conversion of mechanical forces into biological signals by mechanosensitive cells. This mechanotransduction of signals promotes intracellular communication and allows for the coordinated cellular response of alveolar bone modeling that occurs in response to orthodontic force. Orthodontic forces are likely perceived by cells as changes in substrate strain, fluid flow shear induced stress, and/or oxygen tension. Osteoprogenitor cells, bone lining cells, and osteocytes sense orthodontic forces and initiate a number of signaling pathways through mediators such as Wnt, BMP, TNFα, IL1β, CSF-1, VEGF, and PGE2, etc. These factors subsequently lead to the recruitment, differentiation, and activation of osteoblasts and osteoclasts to conduct the bone formative and resorptive activities, respectively, needed for orthodontic tooth movement.

*Nan Hatch, Zongyang Sun

ORTHODONTIC FORCES STIMULATE BIOLOGICAL RESPONSES

The orthodontic profession has long been aware that changes in the supporting tissues of teeth are necessary for tooth movement beyond the constraints of the original tooth socket upon application of an orthodontic force. Theories regarding the biological response to orthodontic forces

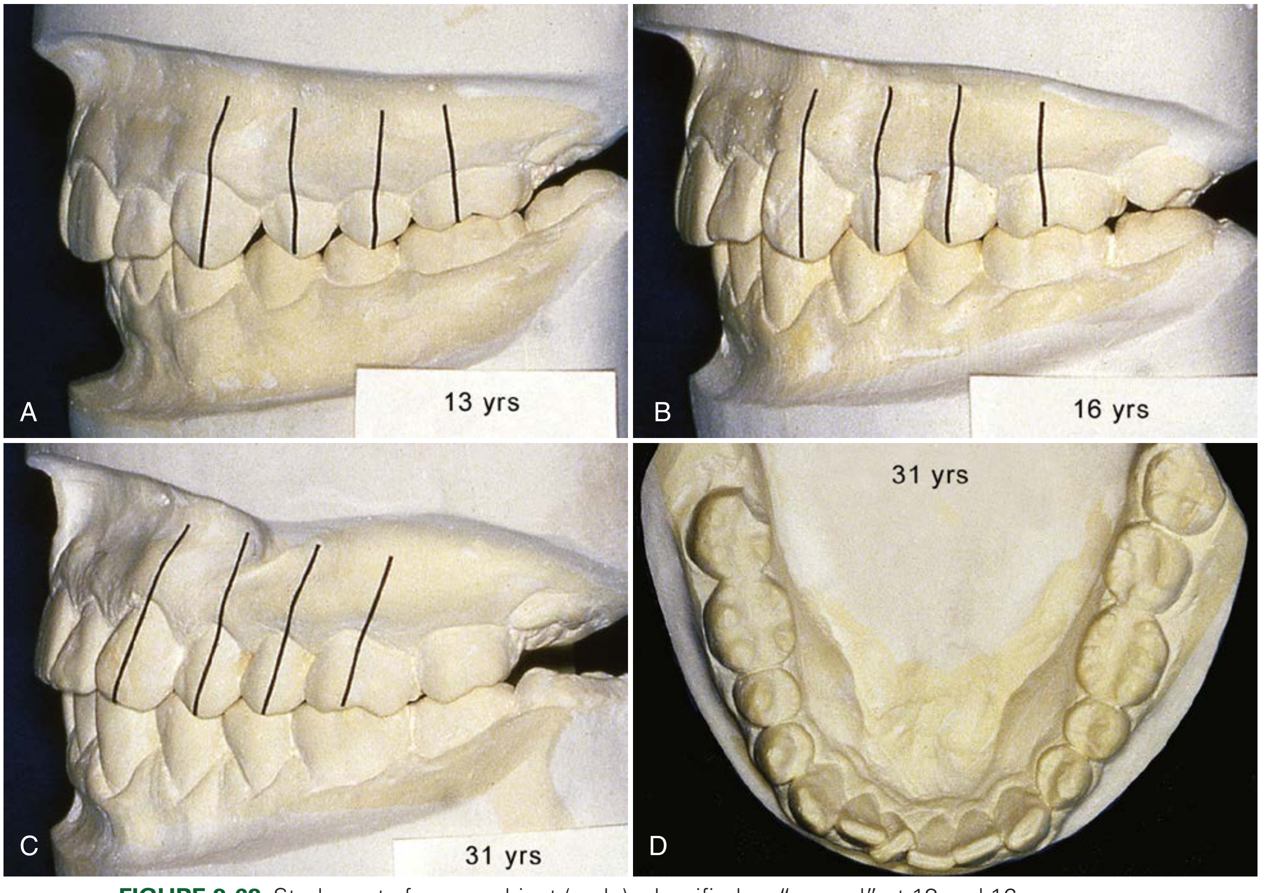

FIGURE 3-62 Study casts from a subject (male), classified as "normal" at 13 and 16 years, even at 31 years. Note the negative effect of physiologic migration, resulting in 41 in a crowded position in spite of a congenital absence of 48 in contrast to fully erupted 38.

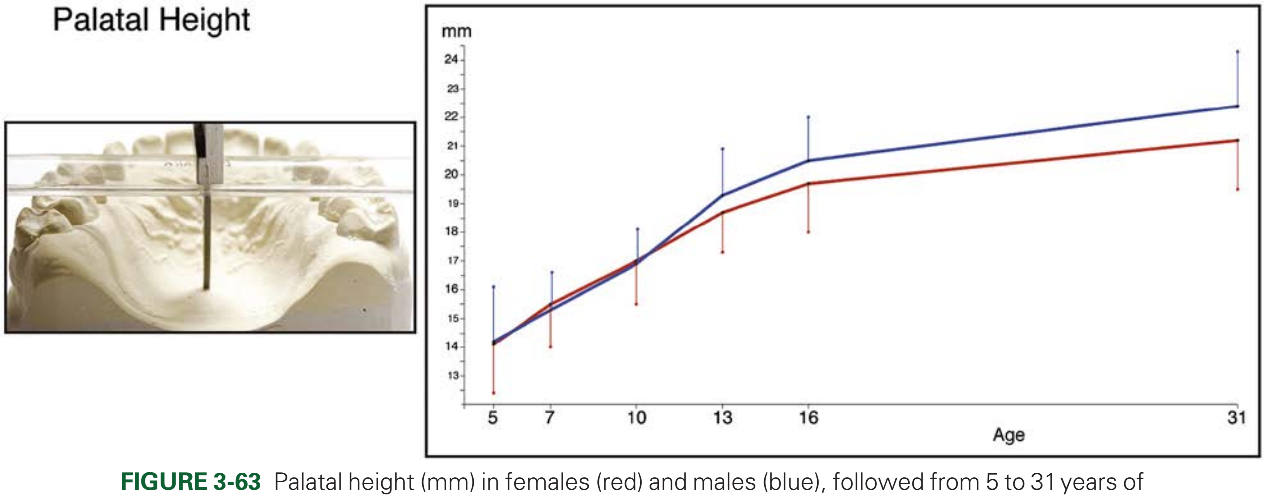

FIGURE 3-63 Palatal height (mm) in females (red) and males (blue), followed from 5 to 31 years of age; mean and standard deviation for each recording. (From Thilander B. FIGURE 3-64 A, A patient with an implant-supported crown (*arrow*) replacing the congenitally missing upper right lateral incisor. B, Continuous eruption of the teeth adjacent to the implant from 16 to 24 years resulted in 1.6 mm of infraocclusion of the implant-supported crown (*arrow*). (Adapted from Thilander B, et al. Orthodontic aspects of the use of oral implants in adolescents: a 10-year follow-up study. *Eur J Orthod.* 2001;23:715.)

resulting in tooth movement were initially proposed over a century ago. Based upon their clinical observations, Kingsley and Walkhoff theorized that tooth movement depends upon the elasticity, compressibility and extensibility of bone while Schwalbe and Flouren theorized that bone resorption occurs in areas of pressure, and bone deposition occurs in areas of tension, following the application of orthodontic force.[66] The first systematic experimentation investigating local tissue responses to orthodontic force application was performed by Carl Standstedt in the early 1900s. His light microscopic studies following incisor retraction in dogs confirmed the theory of Schwalbe and Flouren and showed for the first time that bone deposition occurs in areas of tension and bone resorption occurs in areas of pressure following the application of orthodontic force.[66] Significantly, Standstedt was the first to show that lighter orthodontic compressive forces lead to rapid bone resorption along the alveolar wall while heavier compressive orthodontic forces lead to tissue necrosis within the PDL space along the alveolar wall (defined as hyalinized tissue) (see Figs. 3-15 to 3-23). He also noted that tooth movement in these hyalinized areas occurred only after bone resorption in underlying bone marrow spaces was sufficient to undermine the supporting alveolar bone (defined as undermining resorption). Schwartz extended the findings of Standstedt by correlating the tissue response to compressive orthodontic forces with PDL capillary blood pressure. He stated that lighter orthodontic forces leading to rapid alveolar bone resorption and tooth movement are those that are below the pressure of PDL blood capillaries and that heavier orthodontic forces lead to "suffocation of the peridental membrane" that leads to tissue necrosis and a delay in orthodontic tooth movement.[67] These findings, in combination with numerous other studies, suggested that orthodontic forces move teeth by stimulating a biological response involving bone modeling activity. Importantly, these results also indicated that occlusion of PDL blood vessels with resulting ischemia and necrosis is not required for bone resorption to occur along the alveolar wall on the pressure side of orthodontic force application. In other words, light compressive forces can stimulate alveolar bone resorption that allows for tooth movement beyond the original constraints of the tooth socket.

We now know that bone modeling requires the differential activity of bone-forming cells (osteoblasts) and bone-resorbing cells (osteoclasts). A study conducted in the early 1990s by King et al. confirmed that orthodontic force application induces differential osteoclastic and osteoblastic activity. Results of this study showed that orthodontic appliance activation leads to primarily osteoclastic activity along the alveolar bone in the compressed regions of the PDL space and primarily osteoblastic activity along the alveolar bone in the tensed regions of the PDL space. For osteoclastic activity to occur, osteoclast precursor cells must be recruited to the PDL space from the circulatory system and bone marrow, as these cells are hematopoietic in origin. For tooth movement to occur, recruited osteoclastic precursor cells must also then be stimulated to fuse, differentiate, and develop into multinucleated, fully functional, mature osteoclasts. Similarly to obtain bone formative activity along the alveolar wall of the tooth socket, PDL mesenchymal stem cells, osteoblast precursor cells and/or bone lining cells must be stimulated to differentiate into osteoblasts. Overall, the work of King et al.[68] therefore showed that mechanical orthodontic forces stimulate biological responses involving the recruitment and activation of osteoblasts and osteoclasts.

MECHANOTRANSDUCTION MEDIATES THE BONE MODELING RESPONSE TO ORTHODONTIC FORCE

In the years since these studies were completed, significant progress has been made in understanding how mechanical signals can initiate biological cellular responses. This process is generally known as *mechanotransduction*. Mechanotransduction requires the application of a mechanical load to tissue, conversion of that load into a mechanical signal that can be sensed at the cellular level, and cellular transformation of the mechanical signal into a biochemical signal that is then communicated to other cells to elicit a coordinated cellular response. In the context of orthodontic tooth movement, mechanotransduction very likely involves alveolar bone osteocytes, bone lining cells, and PDL mesenchymal precursor cells. Orthodontic forces move a tooth initially within the PDL space. This tooth movement likely results in mechanical strain changes in PDL fibers and in underlying alveolar bone, as well as changes in fluid flow within the lacunar–canalicular alveolar bone network and within the PDL space. Tooth movement can also compress PDL blood capillaries resulting in localized hypoxia. Once initiated, mechanotransduction leads to the activation of downstream cell signaling pathways and cellular responses that lead to bone resorptive and formative activities (Fig. 3-65).

Recent advances in bone mechanotransduction are well detailed in several excellent reviews.[69-71] Briefly, it is now recognized that the primary bone cell type responsible for sensing mechanical load is the osteocyte rather than the osteoblast. Osteocytes are terminally differentiated osteoblasts. After osteoblasts lay down bone matrix, they either undergo apoptosis (cell death) or undergo terminal differentiation and become osteocytes embedded within the matrix. Accounting for 90% to 95% of total bone cells, osteocytes reside in a complex lacunae–canaliculi network inside the bone matrix, with numerous dendritic processes extending into the canaliculi. Through gap junctions at the end of the processes, osteocytes form direct connections with each other and with osteoblasts and bone lining cells at the bone surfaces.

When mechanical loads are applied to tissue, shear stress or strains are produced around cells. Significant evidence exists that mechanical forces applied to bone lead to interstitial fluid flow within the lacunar–canalicular network (a network of intersecting channels within the bone, in which osteocytes and their long dendritic cellular processes reside).[72] Fluid flow is sensed by osteocytes as shear stress. More specifically, a number of studies indicate that shear stress stimulates cellular responses that correspond well to *in vivo* bony responses to applied forces in terms of their frequency and magnitude. Mechanical loads applied to tissues can also be sensed by cells as strain (cell compression, stretch, or deformation of shape). While earlier studies indicated that at the cellular level, physiologic mechanical loads cannot elicit strains of a great enough magnitude to initiate a cellular response,[73,74] more recent studies have indicated that osteocytes experience significantly amplified strain upon mechanical loading of bone, due to the structural properties of bone lacunae and/or the close and regular attachment of the lengthy osteocytic cellular processes to the canalicular bone in which they reside.[75-77]

At present, the precise molecular mechanisms involved in mechanically induced osteocyte excitation are not completely clear, but abundant evidence has suggested that multiple factors and pathways are involved, such as integrins (cell to extracellular matrix adhesion molecules), cytoskeletal structural proteins, purinergic receptors, connexin 43 hemichannels, stretch-sensitive ion channels, voltage-sensitive ion channels, and/or primary cilia (microtubular structures extending from the basal body through the cell membrane into the extracellular space).[76,78-82] Soluble factors released by osteocytes may also play a role in this process known as autocrine stimuli.[83,84]

After sensing the mechanical load, osteocytes send signals to other cells to regulate osteogenesis and osteoclastogenesis. Complex molecular mechanisms are involved in these mechanotransduction processes, which researchers are just beginning to understand. Recent findings have indicated that osteocyte-mediated mechanotransduction is induced by the Wnt signaling pathway but inhibited by the sclerostin (SOST) pathway through gap-junction intercellular communications and/or extracellular cytokines,[85-87] or through soluble factors such as prostaglandins released by osteocytes in a paracrine fashion.[83,84]

In addition to the osteocyte-mediated mechanism, mechanical force can also directly stimulate osteoblasts and their progenitor cells by producing strain (deformation) within the tissues where these cells reside. As detailed in a recent review,[88] mesenchymal stem cells can sense mechanical strain through their cytoskeleton, focal adhesions, and primary cilia. Tissue strain-induced cell stretching can induce the osteoblastic differentiation of preosteoblasts via integrin/focal adhesion kinase signaling and mechanosensitive calcium channels.[89,90] A number of studies have found that cyclic tension stimulates osteogenic lineage commitment and differentiation of mesenchymal stem cells, resulting in enhanced expression of Runx2 and other matrix proteins produced by osteoblasts.[91,92] At the molecular level, mechanotransduction by mesenchymal stem cells may involve several pathways, including mitogen-activated protein kinase (MAPK), Wnt, and RhoA/Rho kinase signaling pathways.

The PDL space is also fluid filled, such that the application of orthodontic force leads to fluid-flow changes within the PDL space. Shear stress from fluid flow can stimulate mesenchymal precursor cell (such as PDL cells) Ca^{2+} signaling, which in turn promotes ATP release, the production of prostaglandin E2 (PGE2), and the proliferation of precursor cells.[72,81] Notably, studies indicate that NO synthase (the enzyme that synthesizes NO) and IL1β are also critical mediators of orthodontic tooth movement.[93-95] These mechanisms could potentially explain the differentiation of PDL preosteoblasts into osteoblasts and initial mineralization along stretched PDL fibers following orthodontic tooth movement.[66]

LOCAL BIOLOGICAL MEDIATORS OF ORTHODONTIC TOOTH MOVEMENT

Despite this gap in our knowledge of the mechanotransduction of orthodontic force, much progress has been made in identifying downstream critical biochemical mediators of orthodontic tooth movement. During quiescence, osteocytes secrete sclerostin, which inhibits Wnt cell signaling, preosteoblastic differentiation, and bone formation.[96] Upon tooth movement, PDL cells, bone lining cells, and/or alveolar bone osteocytes secrete inflammatory cytokines such as TNFα and IL1β, which function to stimulate autocrine (same cell) and paracrine (neighboring cell) cell changes, including the production of additional biological mediators (CSF-1, VEGF, and PGE2). PGE2 release is also stimulated directly by fluid flow–induced shear stress.[80,81] Each of these factors in turn elicits multiple cellular reactions. IL1β acts to propagate the opening of connexin hemichannels in response to mechanical signals.[87] In this manner IL1β may act to amplify the cellular response to mechanical load. IL1β, TNFα, and VEGF stimulate angiogenesis, which increases local vascularity. TNFα, CSF-1, and PGE2 stimulate osteoclastogenesis and bone resorption. Of note, PGE2 also stimulates osteoblastogenesis and bone formation. Together, these local biological mediators elicit changes in cell behavior resulting in increased blood vessel dilation and permeability, mononuclear osteoclastic precursor cell recruitment, and differentiation in regions of compression, as well as preosteoblastic proliferation and differentiation in regions of tension (Fig. 3-66). Evidence for the early local release of these factors following application of an orthodontic force is provided by the fact that gingival crevicular fluid levels of TNFα, IL1β, CSF-1, VEGF, and PGE2

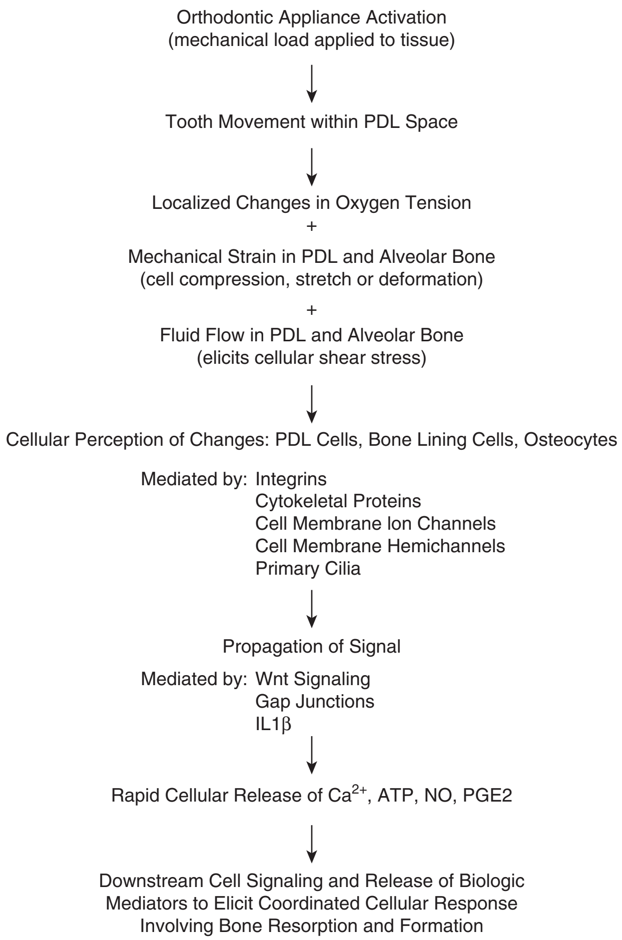

FIGURE 3-65 Mechanotransduction in orthodontic tooth movement. (Hatch NE. The biology of orthodontic tooth movement: current concepts on and applications to clinical practice. In: *Proceedings of the 37th Annual Moyers Symposium*, February, 2010, Ann Arbor, MI. Volume 48, Craniofacial Growth Series. Ann Arbor, MI: Needham Press, Inc., 2011.)

all rise significantly following orthodontic tooth movement in humans.[97-100] Each of these mediators has also previously been shown to be essential for orthodontic tooth movement (Table 3-1).

NEUROPEPTIDES AND ORTHODONTIC TOOTH MOVEMENT

PDL and pulpal nociceptors respond to orthodontic tooth movement by secreting neuropeptides such as Substance P and CGRP (calcitonin gene–related peptide).[101-105] These neuropeptides act to enhance the cellular secretion of inflammatory cytokines and to increase vasodilation and vasopermeability of blood vessels.[106,107] That sensory nerve responses are critical for orthodontic tooth movement is evidenced by studies showing that transection of the inferior alveolar nerve in rats inhibits vascular and tooth movement responses to applied loads.[108-110] While it is tempting to consider utilizing local delivery of neuropeptides to enhance orthodontic tooth movement in humans, the fact that neuropeptides also mediate pain makes this proposition less promising.

RANK/RANKL/OPG SYSTEM FOR CONTROL OF OSTEOCLASTOGENESIS AND TOOTH MOVEMENT

The regulation of osteoclastogenesis by osteoblasts is mediated in large part by the nuclear factor kappa B ligand (RANKL)/nuclear factor kappa B (RANK)/osteoprotegerin (OPG) ligand–receptor complex. RANKL is found on the surface of osteoblast lineage cells where it stimulates osteoclastogenesis by binding to receptor nuclear factor kappa B (RANK), a transmembrane protein located on osteoclast progenitors and osteoclasts. The binding of RANKL to RANK is essential for stimulating osteoclast formation and activity and for promoting osteoclast survival.[111] The interaction of RANKL with RANK is regulated by the soluble decoy receptor OPG, which is secreted by cells of the osteoblastic lineage and functions as a competitive inhibitor of RANKL.[112-114] OPG competes with RANKL for RANK and therefore acts to inhibit osteoclast differentiation, activity, and survival, hence diminishing osteoclastogenesis.

Importantly, several prior studies have demonstrated that the ratio of RANKL to OPG controls osteoclastogenesis and that inhibition of the RANKL/RANK interaction can inhibit bone resorptive activity. Transgenic overexpression of OPG in mice leads to osteopetrosis due to inadequate osteoclasts,[114-116] while a lack of OPG in mice is accompanied by decreased bone density with severely increased trabecular and cortical bone porosity.[117] Rodents administered recombinant OPG protein (OPG-Fc) show a rapid and sustained decrease in bone surface osteoclasts in combination with increased bone mineral density.[118] In humans, subcutaneous injection with OPG-Fc or a monoclonal antibody to RANKL that also functions to inhibit RANKL binding to RANK, contributes to significantly diminished serum markers of bone resorption,[119,120] reduced fracture incidence, and increased bone mineral density in postmenopausal adults.[121-125] In addition, *in vivo* evidence also supports a role for RANKL and OPG in control of mechanically induced bone resorption. For example, OPG administration in rodents inhibits bone loss resulting from mechanical unloading by reducing bone resorptive activity. Together, these studies demonstrate that RANKL and OPG are essential for regulating osteoclast activity and that inhibitors of RANKL can be used to systemically improve bone quality and reduce bone resorption induced by biological or mechanical perturbations of bone.

The RANKL/RANK/OPG system is also an essential component of orthodontic force-induced tooth movement and relapse after orthodontic appliance removal. Previous studies indicate that manipulation of this system can be utilized to control tooth movement and relapse after movement.[126] OPG expression increases in tensed regions of the PDL and alveolar bone while RANKL expression increases in compressed regions of the PDL and alveolar bone following orthodontic tooth movement.[127-132] Alveolar bone resorption is dramatically enhanced following orthodontic tooth movement in OPG null mice.[133] Delivery of OPG through gene transfer or injection of a recombinant protein to alveolar tissues inhibits osteoclastogenesis and orthodontic tooth movement while delivery of RANKL enhances osteoclastogenesis and tooth movement in rats.[134-137] Injection of recombinant OPG protein (OPG-Fc) also inhibits relapse tooth movement after appliance removal.[138] A single local injection of OPG-Fc can prevent relapse of tooth movement beyond the constraints of the tooth socket for up to 1 month after appliance removal compared to a 70% relapse in control animals, with minimal systemic effects. Additional

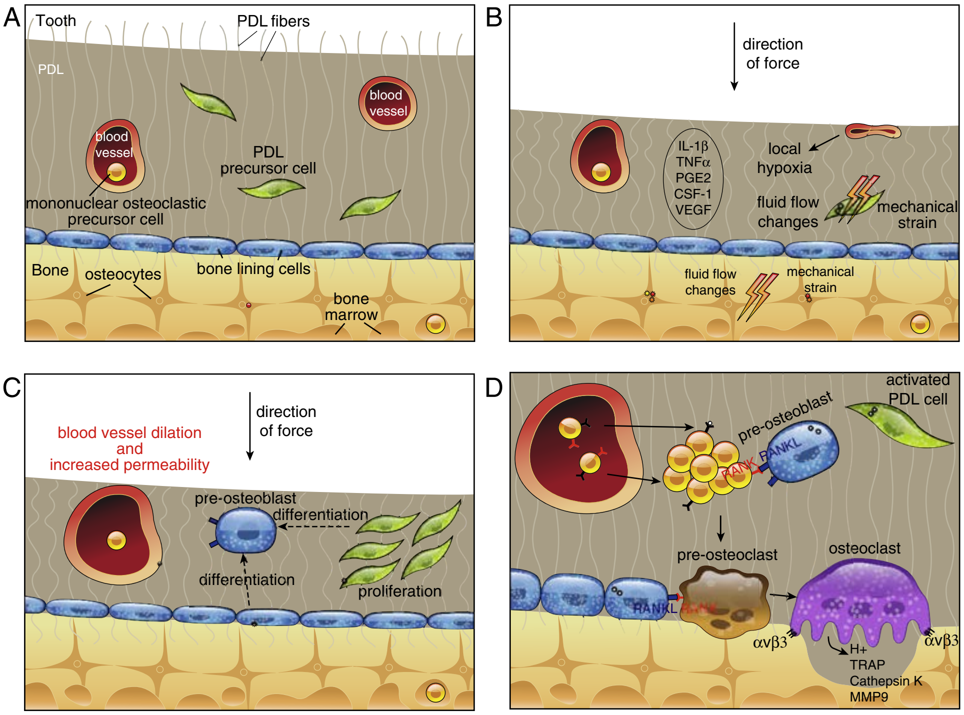

FIGURE 3-66 A, **Tooth, PDL space and supporting alveolar bone environment during quiescence.** Blood vessels exist in PDL space and is contiguous with bone marrow. Bone marrow exists in alveolar bone. Osteoclast precursor cells are located in bone marrow and circulating through blood vessels. Bone lining cells reside along socket wall/alveolar bone surface. PDL cells (mesenchymal precursor cells) are located within PDL space. During quiescence, osteocytes express and secrete sclerostin, which inhibits pre-osteoblastic (PDL cell and bone lining cell) activity. **B, Cellular mechanotransduction of applied orthodontic force.** Upon application of an orthodontic force, the tooth moves within the PDL space. This tooth movement results in compression of blood vessels leading to localized hypoxia (diminished oxygen tension). Tooth movement within the PDL space also results in mechanical strain (cell compression, stretch or deformation) and fluid flow changes within the PDL and underlying alveolar bone (which induces cellular shear stress). In response to perception of these changes in the physical environment, PDL cell, bone lining cells and/or alveolar bone osteocytes rapidly express and secrete local biologic mediators including IL1b, TNFa, PGE2, CSF-1 and VEGF. **C, Extracellular biologic mediators induce cellular changes.** In response to the secreted factors (small yellow, orange and red stars), cells within the PDL space undergo changes. Endothelial cells that line the blood vessels respond by proliferating and differentiating, leading to increased blood vessel dilation and increased blood vessel permeability. Mesenchymal precursor cells within the PDL space respond by proliferating and differentiating into pre-osteoblasts. Bone lining cells can also respond by proliferating and differentiating into osteoblast precursor cells. Pre-osteoblastic cells express RANK. **D, Recruitment, differentiation and activation of osteoclast precursor cells leads to alveolar bone resorption and tooth movement.** Endothelial cells, osteoblastic precursor cells, bone lining cells and/or osteocytes that have been activated by changes in oxygen tension, mechanical strain and/or shear stress produce and release biologic factors such as TNFa, CSF-1, VEGF and PGE2. Once released, these factors act to recruit mononuclear osteoclastic precursors cells (yellow/orange cells) from the adjacent bone marrow via local permeabilized blood vessels. These osteoclastic precursor cells express receptors for the secreted extracellular factors and, once recruited, are further stimulated by these factors. This stimulation leads to cellular changes including expression of the transmembrane protein, RANK. RANK binds RANKL, a transmembrane protein that is expressed on pre-osteoblasts (blue cell). Binding of RANK with RANKL, in addition to continued stimulation by the other secreted factors, leads to fusion of the mononuclear osteoclastic precursor cells into a multinucleated pre-osteoclast (brown cell). Stimulation of this pre-osteoclast via the RANK/RANKL interaction promotes differentiation of the pre-osteoclast into a mature osteoclast (purple cell). The mature osteoclast adheres tightly to bone via the integrin avb3. Once adherent, the osteoclast secretes acid and enzymes that demineralize the bone and degrade the bone matrix (bone resorption). (Hatch NE. The biology of orthodontic tooth movement: current concepts on and applications to clinical practice. In: *Proceedings of the 37th Annual Moyers Symposium*, February, 2010, Ann Arbor, MI. Volume 48, Craniofacial Growth Series. Ann Arbor, MI: Needham Press, Inc., 2011.)

TABLE 3-1 **Local Biological Mediators of Orthodontic Tooth Movement**

This table includes information on inflammatory cytokines, growth factors, and prostaglandins that are expressed early following orthodontic appliance application and established as essential for orthodontic tooth movement. Additional mediators of tooth movement exist and include but are not limited to neuropeptides, leukotrienes, and chemokines.

Extracellular Biological Mediator	GCF Expression	Function in Bone Modeling/Remodeling	Role in Orthodontic Tooth Movement
IL1β	Within 1-hour postappliance activation.	Propagate initial response to mechanical signal. Stimulate angiogenesis.	Higher IL1β and lower IL-RA (IL1 receptor antagonist) levels in GCF are associated with faster orthodontic tooth movement in humans.
		Stimulate production/secretion of additional biological factors.	Homozygosity for IL1β polymorphism (A1, A1 at position +3954) is associated with faster orthodontic tooth movement in humans.
TNFα	Within 24-hour postappliance activation.	Stimulate angiogenesis. Stimulate production/secretion of additional biological factors. Stimulates osteoclastogenesis.	TNF receptor knockout mice exhibit diminished osteoclastogenesis and tooth movement.
PGE2	Within 24-hour postappliance activation.	Stimulates inflammatory cytokine expression.	Prostaglandin receptor EP4 agonist enhances tooth movement in rats.
		Bimodal function: important for bone resorption and bone formation.	PGE2 but not PGE1 enhances tooth movement in monkeys.
		Stimulates RANKL expression and inhibits OPG expression by preosteoblasts and osteoblasts.	NSAIDs (inhibit COX2 activity) inhibit osteoclastogenesis and orthodontic tooth movement in rodents.
		Stimulates RANK expression by preosteoclasts and osteoclasts.	
VEGF	Within 24-hour postappliance activation.	Stimulate angiogenesis. Promote recruitment of mononuclear osteoclastic precursor cells from bone marrow.	Neutralizing antibodies against VEGF inhibit osteoclastogenesis and tooth movement.
		Promote differentiation of osteoclastic precursor cells. Promote osteoclast survival.	Local delivery of VEGF enhances osteoclastogenesis and tooth movement.
CSF-1	Within 24-hour postappliance activation.	Stimulate angiogenesis. Promote recruitment of mononuclear osteoclastic precursor cells from bone marrow. Promote differentiation of osteoclastic precursor cells. Promote osteoclast survival.	Neutralizing antibodies against CSF-1 receptor inhibit osteoclastogenesis and tooth movement.

studies are required to establish dose levels required for local orthodontic anchorage, inhibition of orthodontic relapse utilizing OPG-Fc in humans, as well as whether pharmacologic inhibition of orthodontic relapse requires sustained or transient inhibition of osteoclasts during a critical time-limited period after orthodontic appliance removal. From a clinical perspective, controlled local inhibition of osteoclast activity could allow for enhanced control of individual teeth during orthodontic treatment and for spatially restricted effects in the prevention of relapse after orthodontic treatment. Yet, because osteoclast activity is essential for normal bone physiology, use of osteoclast inhibitors for local control of bone resorption in otherwise healthy humans will be limited if the delivered protein yields undesirable systemic effects.

BIOLOGICAL CONTROL OF OSTEOGENESIS INVOLVED IN ORTHODONTIC TOOTH MOVEMENT

As the primary cell type in charge of osteogenesis involved in alveolar bone modeling and remodeling, most active osteoblasts at the PDL–bone interface derive from progenitor cells stimulated to differentiate and deposit bone upon the application of orthodontic force (Table 3-2; see also Fig. 4-61). Histologically, osteoblasts are cuboidal-shaped, mononucleated cells with strongly basophilic cytoplasm that appear clustered along bone surfaces. During tooth development, osteoblasts that form the primary alveolar bone largely arise from the neural crest–derived ectomesenchymal stem cells in the first branchial arch.[139] While it remains unknown whether these stem cells remain in the mature periodontium as a postnatal source of progenitor cells for osteoblasts, it is clear that even in adults, the PDL and alveolar bone still possess a steady source of progenitor cells for osteoblasts.[140]

That a main source of osteoprogenitor cells derives from perivascular stem cells (including those around PDL and alveolar bone blood vessels) is well evidenced by several findings. By administering 3H-thymidine into mouse peridontium, which labels dividing cells, McCulloch demonstrated that within 10 μm of blood vessels there is a slowly dividing population of progenitor cells.[141] Subsequently, Roberts et al. found that an osteogenic gradient radiating from blood vessels is present in

the PDL surrounding rat molars. Less differentiated precursor cells were predominantly localized within 20 µm of the nearest major blood vessel, while cells 30 µm from the vessel wall were undergoing proliferation, differentiation, and migration to the bone surface, where they became osteoblasts.[142] Simultaneously, McCulloch et al. reported that paravascular tissues in endosteal spaces of alveolar bone are enriched with progenitor cells, whose progeny can rapidly migrate into the PDL.[143] More recently, researchers have successfully isolated a cell population from the PDL that expresses numerous cell surface markers indicative of mesenchymal stem cells, including STRO-1, CD146, CD90, CD44, CD105, etc.[144,145]

Another likely source of osteoblasts comes from bone lining cells located at the alveolar bone surface. Bone lining cells are thin, elongated cells with flat or slightly ovoid nuclei that line inactive bone surfaces. They connect with each other via gap junctions and send cell processes to canaliculi at bone surfaces,[146] where they can form connections with cytoplasmic processes of neighboring osteocytes. While it is commonly accepted that bone lining cells are quiet remnants of osteoblasts after they complete bone formation, some evidence has shown that these lining cells may differentiate into osteoblasts upon certain stimulation such as parathyroid hormone (PTH)[147] or mechanical loading.[148]

The differentiation of mesenchymal stem cells into mature osteoblasts is a multistage process, with each stage characterized by specific features of cell morphology, production of extracellular matrices, and gene expression. For a comprehensive understanding of osteoblast differentiation, the readers are referred to these review articles.[149-152] One particularly important aspect about the regulation of osteoblast differentiation is the expression of several key transcription factors. The runt-related transcription factor 2 (Runx2) is indispensable for the commitment of mesenchymal stem cells to the osteogenic lineage. Runx2 also regulates all the early stages of osteoblast differentiation and serves as an upstream regulator for another essential osteoblastic transcription factor, Osterix (Osx). Osx, through both Runx2-dependent and Runx2-independent pathways, promotes differentiation of osteoprogenitor cells into immature osteoblasts. The third important transcription factor is activating transcription factor (ATF4), which through interacting with Runx2, regulates the transcriptional activities of mature osteoblasts. Combined, these transcription factors not only serve as markers of osteoblast differentiation but also play critical roles in regulating osteoblast differentiation and function. By changing the expression of these transcription factors, a number of molecular pathways are involved in regulating osteoblast differentiation. The canonical Wnt signaling pathway, transforming growth factors (TGFs), bone morphogenic proteins (BMPs), fibroblast growth factors (FGFs), gap junction protein connexin 43 (Cx43), and calcium ion (Ca^{2+}) mediated noncanonical Wnt pathways are all likely regulators of osteoblast differentiation.[69,152]

Mature osteoblasts are very versatile cells. In addition to forming bone, they act to regulate osteoclasts and hematopoietic stem cells and also function as endocrine cells.[152] To form bone, osteoblasts first produce a highly collagenous extracellular matrix. This nonmineralized layer of tissue (osteoid) includes many structural and regulatory proteins such as type I collagen, osteopontin, osteocalcin, and bone sialoprotein. Osteoblasts then mineralize the osteoid through a tightly controlled process involving the production of matrix vesicles and a number of enzymes and proteins that function to increase local concentrations of inorganic phosphate. At the surface of osteoblasts and osteoblast-derived matrix vesicles, ectonucleotide pyrophosphatase/phosphodiesterase 1 (Enpp1) generates inorganic pyrophosphate from nucleotides (ATP), which is subsequently converted to inorganic phosphate by the enzyme tissue nonspecific alkaline phosphatase (TNAP/ALP/*Alpl*). Phospho1 (a phosphatase) and the pyrophosphate transporter known as ankylosis protein (Ank), also contribute to this process. These events lead to the precipitation of hydroxyapatite crystals (the mineral component of bone) and the mineralization of bone.

During orthodontic treatment, mechanical forces applied to teeth are transmitted to the PDL and the alveolar bone. Compared to long bones, the tooth–PDL–alveolar bone complex presents a unique environment. Mechanosensing in this environment that subsequently precipitates osteogenesis, especially on the orthodontic tension side, has been a subject of extensive discussion and review recently.[153-156] Briefly, thanks to the great advances of basic research, especially on bone mechanobiology as summarized above, it has become clear that cells in the alveolar bone and the PDL are both playing critical roles in sensing mechanical loading, and in activating osteoblast differentiation and function. Based on current understanding, a schematic drawing was made to depict major cellular events and molecular interactions involved in osteogenesis at the orthodontic tension side (Fig. 3-67). Briefly, within the PDL and surrounding alveolar bone, mesenchymal stem cells, osteoprogenitors, and bone lining cells can sense the strain of extracellular matrix caused by orthodontic tension and subsequently contribute to osteoblast differentiation and function. Both osteoprogenitors and bone lining cells can directly differentiate into osteoblasts to deposit bone along the bone surface. Inside the alveolar bone, osteocytes sense the fluid flow caused by the tensile strain (stretch of the Sharpey's fibers) and subsequently send signals to stimulate bone lining cells and osteoblasts at the surfaces.

At the molecular level, multiple factors and signaling pathways are likely involved in these processes. One of the most important of these is the Wnt pathway. In humans, mutations of the Wnt coreceptors LRP 5/6 are associated with bone loss, osteoporosis (loss-of-function),[157] or bone mass increase

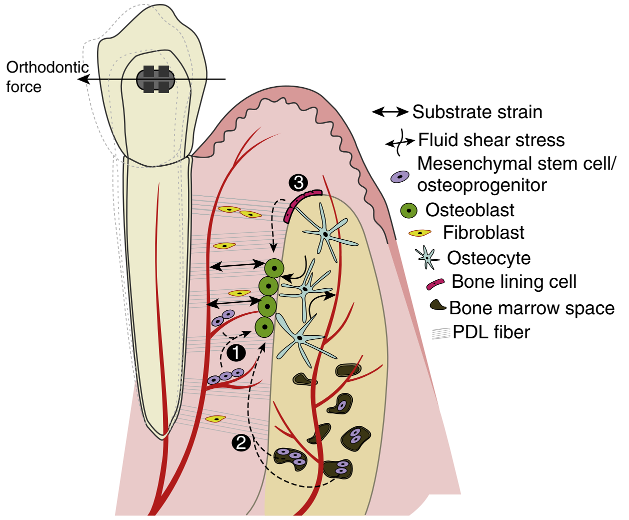

FIGURE 3-67 Osteogenesis at the tension side. Upon receiving mechanical loading, perivascular osteoprogenitor cells in the periodontal ligament and bone marrow, as well as some bone lining cells, can differentiate into osteoblasts and migrate to the bone surface to start forming new bone. Osteocytes inside the bone matrix also sense loading and subsequently regulate the differentiation and function of bone surface cells.

(gain-of-function).[158] Abundant evidence has shown that Wnt signals stimulate the differentiation of osteoblast progenitors[69,152] and periodontal cells.[159] Mechanotransduction from osteocytes to osteoblasts is also thought to be mediated, at least in part, through the Wnt pathway. More specifically, during unloading, osteocytes produce sclerostin, which binds to Wnt coreceptor LRP5/6 on osteoblasts and subsequently through a cascade of signal transduction, prevents translocation of β-catenin into the nucleus, hence inhibiting the gene expression needed for osteoblast function and osteogenesis. Upon sensing mechanical load, osteocytes produce less sclerostin, resulting in relieving the inhibition on osteoblasts and bone formation. Another important molecule is connexin 43, the principal molecular component of mechanosensitive hemichannels and gap junctions. Recent studies have demonstrated that orthodontic force leads to increased connexin 43 expression in alveolar bone osteocytes and bone lining cells,[160,161] suggesting enhanced intercellular communication resulted from orthodontic force.

PHYSICAL METHODS THAT STIMULATE THE BIOLOGY OF ORTHODONTIC TOOTH MOVEMENT

Efforts to enhance orthodontic tooth movement and decrease overall treatment time also include mechanics and/or physical insults to stimulate the cell biologic activity underlying orthodontic tooth movement.

Injury-Facilitated Acceleration of Tooth Movement

The biology underlying injury-facilitated acceleration of tooth movement is generally attributed to the regional acceleratory phenomenon (RAP), a nonspecific, dynamic healing process of bone after sustaining trauma, and this process is generally characterized by upregulated bone remodeling.[162] In support of this notion, evidence from rat studies has confirmed that decortication of the alveolar bone leads to escalated demineralization–remineralization dynamics[163] and transient upregulated expression of multiple cytokines relating bone remodeling.[164]

The concept of using local bone injuries to accelerate tooth movement was initially raised in the 1890s. In the 1950s, Kole further advanced the idea by introducing a surgical procedure that involved vertical cuts of the buccal and lingual alveolar cortical plates (corticotomy) combined with subapical horizontal cuts penetrating the entire alveolus (osteotomy).[165] Due to invasiveness, however, this technique was never popularized. A few decades later, Wilcko et al. revised this surgical procedure by adding bone grafting to the corticotomies. This procedure is now termed *periodontally accelerated osteogenic orthodontics* (PAOO).[166,167] To further reduce surgical invasiveness, cortical bone injuries without reflecting flaps characterized by small and local incisional cuts (called *corticision* or *piezocision*) were subsequently proposed.[168,169] As reviewed by Hoogeveen et al.,[170] to date, a body of clinical studies exists that has attempted to verify the effectiveness of corticotomy-facilitated orthodontic treatment. These studies indicate that surgical corticotomies are safe and possibly effective for shortening the duration of orthodontic treatment. Notably, however, well-conducted prospective clinical studies are still lacking.[170] Similarly, the effectiveness of the more recently proposed corticision or piezocision procedures also needs to be confirmed by high-quality clinical trials.

Vibration-Induced Acceleration of Tooth Movement

In recent years, appliances delivering vibrational forces, such as Acceledent® and Tooth Masseuse, have been introduced to the orthodontic profession as methods to accelerate tooth movement. The biological mechanisms and clinical effectiveness of these vibrational appliances, however, remain largely uncertain. First, data obtained from animal studies are inconsistent and preliminary. On one hand, high-frequency cyclic forces were found to stimulate bone formation and reduce osteoclast density in rabbit craniofacial sutures[171] and to upregulate rat alveolar bone osteogenesis.[172] On the other hand, high-frequency vibrations were also found to accelerate tooth movement in rats[173,174] by upregulating RANKL expression and enhancing bone resorption.[174] To date, only a few clinical studies have been conducted to investigate the effectiveness of vibrational appliances. Although a retrospective study found that an AcceleDent Type I appliance led to faster tooth movement, the comparison was against published norms rather than measurements from a control group without using vibration appliances.[175] More recently, prospective randomized clinical trials of the high-frequency Tooth Masseuse and AcceleDent devices did not accelerate tooth movement.[176,177]

Laser Irradiation-Induced Acceleration of Tooth Movement

Another physical modality that has been proposed for acceleration of tooth movement is low-energy laser irradiation. The last decade has seen a large body of animal studies that investigated the impact of low-energy radiation of orthodontic tooth movement. While many studies found stimulatory effects,[178] several others reported inhibitory effects.[179,180] Similarly, the findings from three clinical studies conducted so far are inconsistent, with acceleration of tooth movement found in two[181,182] but no acceleration of tooth movement in the third study.[183] To date, no randomized clinical trials have been conducted to address the efficacy of laser irradiation for enhancing tooth movement. Nevertheless, several animal studies have attempted to examine the potential biology underlying the impact of low-energy laser irradiation on orthodontic tooth movement. Data from these animal studies indicate that mechanisms such as stimulation of alveolar bone remodeling,[184] upregulation of matrix metalloproteinase-9, cathepsin K and integrin expression,[178] activation of the RANK/RANKL system,[185] and stimulation of fibronectin and type I collagen expression[186] may mediate the effect of low-energy laser irradiation.

TRANSLATION OF BIOLOGICAL TECHNIQUES INTO ORTHODONTIC PRACTICE: THE FUTURE OF OUR PROFESSION?

Throughout the past century, many orthodontic academics have advocated theories that include an individualized tissue response to orthodontic force application. With more recent advances in biomedicine we may soon see an incorporation of new technologies into private practice that allow for enhanced prediction of a given patient's response to orthodontic force application. In understanding the true potential for translation of this knowledge into clinical practice, it is important to remember that each individual patient is likely to have subtle differences in expression levels and/or function of these mediators. Because the biological mediators of orthodontic tooth movement are encoded by genes and because the sequence of each gene differs among individuals (existence of polymorphisms or normal variations in the genetic code that result in subtle differences in protein expression and/or function), it is very likely that the individual variation seen upon orthodontic appliance activation is due at least in part to these differences. Gingival crevicular fluid expression of biological mediators following orthodontic appliance activation can also diminish with age.[187] Bone modeling, as mediated by osteoblastic and osteoclastic cell function, can also be influenced by hormones, medications, and diet. Significant advances in protein bone biomarkers of osteoclast and osteoblast activity have been accomplished within this past decade. Proteomic analysis of known orthodontic biological mediators and/or bone biomarkers could therefore also provide novel and relevant information for all of our patients. Given the dramatic advances that have been made in the fields of genetic testing and proteomics, it is now possible that the orthodontic records for a given patient could include genetic polymorphic testing (DNA accessed via a buccal swab) and gingival crevicular fluid proteomic analysis. With this information we could better predict tooth movement and relapse for each patient and subsequently provide individualized orthodontic treatment recommendations for each patient. While this may seem far-fetched to some, we will conclude by reminding you that recent studies demonstrate that genetic and proteomic testing for IL1β predicts the speed of orthodontic tooth movement.[95,188] Future work is required to determine if similar tests can be utilized for other known mediators of orthodontic tooth movement and to translate these tests into every orthodontic practice.

Bone Physiology, Metabolism, and Biomechanics in Orthodontic Practice

Wilbur Eugene Roberts and Sarandeep Singh Huja

OUTLINE

The physiologic mediators of orthodontic therapy are the facial sutures, the temporomandibular joint (TMJ), the alveolar bone, and the periodontal ligament (PDL). The PDL is the osteogenic bone–tooth interface; it is a modified periosteum with remarkable bone resorptive and formative capabilities. By means of the teeth, alveolar bone can be loaded in a noninvasive and relatively atraumatic manner. Clinical therapy is a combination of orthodontics (tooth movement) and orthopedics (relative repositioning of bones). The biomechanical response depends on the magnitude, direction, and frequency of applied load. Cell kinetic and multiple fluorochrome bone-labeling studies have helped define the fundamental mechanisms of orthodontic and dentofacial orthopedic responses. This chapter explores the determinants of craniofacial bone morphology, mechanically mediated osteogenesis, and physiologic mechanisms for therapeutic correction of malocclusion.

Bones have fascinated human beings since the dawn of time. Much of what is known about the evolution of vertebrates is based on the ordered recovery of bones and teeth from the soil. Over the millennia, these "relatively inert" structures tended to be well preserved. Compared with living bone, teeth are relatively inert structures. Accretion capability at the dentin–pulp interface (secondary dentin) is limited, and some turnover of the cementum occurs because of root resorption and cementum repair processes. The enamel is a hard and inert structure. However, bone is a dynamic structure that is adapting constantly to its environment. As a reservoir of calcium, bone remodeling (physiologic turnover) performs a critical life-support role in mineral metabolism (Fig. 4-1). In addition, the skeleton is the structural scaffold of the body. Collectively bones are essential elements for locomotion, antigravity support, and life-sustaining functions such as mastication. Mechanical adaptation of bone is the physiologic basis of orthodontics and dentofacial orthopedics. A detailed

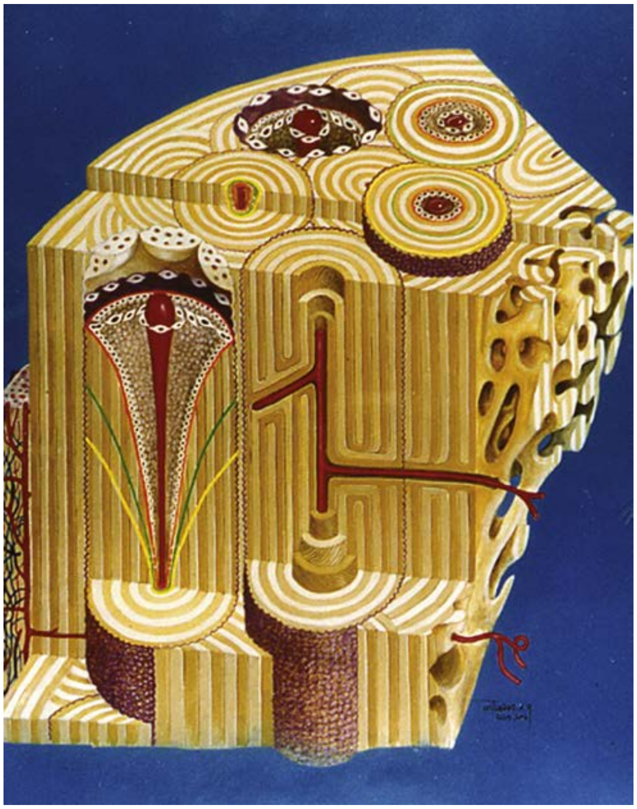

FIGURE 4-1 This artist's rendition of the dynamic principles of cortical bone remodeling was produced by the renowned dental illustrator Rolando De Castro. Remodeling is a vascularly mediated process of bone turnover that maintains the integrity of structural support and is a source of metabolic calcium. Osteoblasts are derived from preosteoblasts circulating in the blood, and perivascular mesenchymal cells give rise to osteoblasts. Note the three colored chevrons (*yellow*, *green*, and *orange*) progressively marking the mineralization front of the evolving second osteon that is moving superiorly on the left. (From Roberts WE, Arbuckle GR, Simmons KE. What are the risk factors of osteoporosis? Assessing bone health. *J Am Dent Assoc*. 1991;122(2):59–61.)

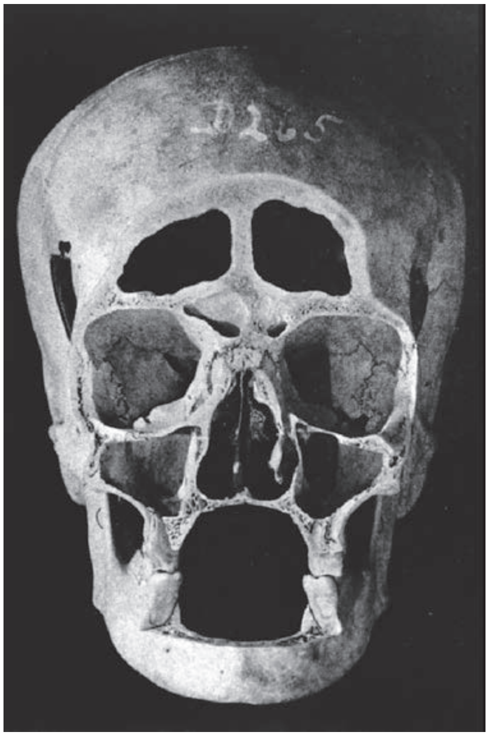

FIGURE 4-2 Frontal section of a human skull in the plane of the first molars. (From Atkinson SR. Balance: the magic word. *Am J Orthod*. 1964;50:189.)

knowledge of the dynamic nature of bone physiology and biomechanics is essential for modern clinical practice.

OSTEOLOGY

In defining the physiologic basis of orthodontics, it is important to initially consider the bone morphology (osteology) of the craniofacial complex. Through systematic study of a personal collection of more than 1000 human skulls, Spencer Atkinson provided the modern basis of craniofacial osseous morphology as it relates to the biomechanics of stomatognathic function. A frontal section of an adult skull shows the bilateral symmetry of bone morphology and functional loading (Figs. 4-2 and 4-3). Because the human genome contains genes to pattern the structure of only half of the body, the contralateral side is a mirror image. Consequently, normal development of the head is symmetric; that is, unilateral structures are on the midline, and bilateral structures are equidistant from it. As shown in Figure 4-3, the vertical components of the cranium tend to be loaded in compression (negative stress), and the horizontal components are loaded in tension (positive stress). From an engineering perspective, the internal skeletal structure of the midface is similar to that of a ladder: vertical rails loaded in compression connected by rungs loaded in tension. This is one of the most efficient structures for achieving maximal compressive strength with minimal mass in a composite material.

Note in Figure 4-3 that there is no net tension across the palate in an adult. During the prenatal and early postnatal period, the palate grows in width via the posterior palatal synchondrosis (primary growth center).[1] When the first deciduous molars establish a functional occlusion, the midpalatal suture evolves into a secondary growth site that responds to occlusal loading. A soft diet decreases the rate of palatal expansion during the growing years.[2] Because growth in width of the maxilla reflects the magnitude of occlusal function,[3] inadequate functional loading may result in functional aberrations such as posterior crossbite.

Differential Osteology of the Maxilla and Mandible

Although equal and opposite functional loads are delivered to the maxilla and mandible, the maxilla transfers stress to the entire cranium, whereas the mandible must absorb the entire load. Consequently, the mandible is much stronger and stiffer than the maxilla. A midsagittal section through the incisors (Fig. 4-4) and a frontal section through the molar region (Fig. 4-5) show the distinct differences in the osseous morphology of the maxilla and mandible. The maxilla has relatively thin cortices that are interconnected by a network of trabeculae (see Figs. 4-2, 4-4, and 4-5). Because it is loaded primarily in compression, the maxilla is structurally similar to the body of a vertebra.

The mandible, however, has thick cortices and more radially oriented trabeculae (see Figs. 4-4 and 4-5). The structural array is similar to the shaft of a long bone and indicates that the mandible is loaded predominantly in bending and torsion. This

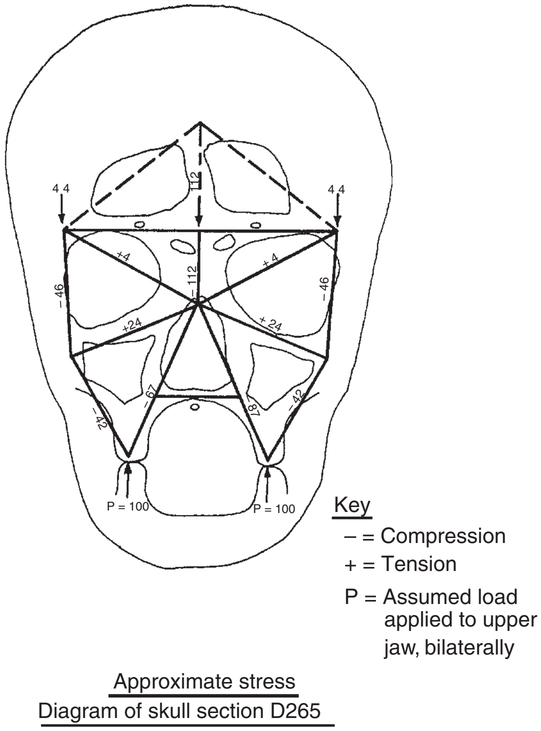

FIGURE 4-3 Two-dimensional vector analysis of stress in the frontal section of the human skull depicted in Figure 4-2. Relative to a bilateral biting force of 100 arbitrary units, the load is distributed to the vertical components of the midface as compressive (negative) stress. The horizontal structural components are loaded in tension. In a nongrowing individual, the stress across the midpalatal suture is 0. When masticating, loads increase and the midpalatal suture is subjected to a tensile load, resulting in an increase in maxillary width. (From Atkinson SR. Balance: the magic word. *Am J Orthod.* 1964;50:189.)

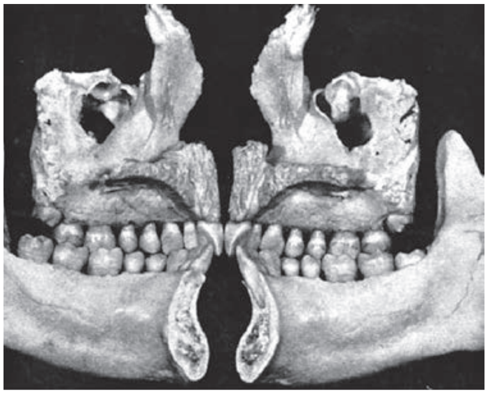

FIGURE 4-4 Midsagittal section of a human skull shows that the maxilla is composed primarily of trabecular (spongy) bone. The opposing mandible has thick cortices connected by relatively coarse trabeculae. (From Atkinson SR. Balance: the magic word. *Am J Orthod.* 1964;50:189.)

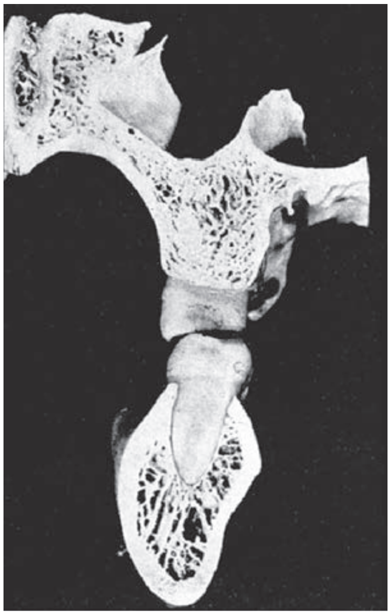

FIGURE 4-5 Frontal section of the maxilla and mandible in the plane of the first molars. Because it transmits masticatory loads to the entire cranium, the maxilla has thin cortices connected by relatively fine trabeculae. The mandible, however, is loaded in bending and torsion; it therefore is composed of thick cortical bone connected by coarse, oriented trabeculae. (From Atkinson SR. Balance: the magic word. *Am J Orthod.* 1964;50:189.)

biomechanical impression based on osteology is confirmed by in vivo strain-gauge studies in monkeys. Hylander[4,5] demonstrated substantial bending and torsion in the body of the mandible associated with normal masticatory function (Fig. 4-6). A clinical correlation consistent with this pattern of surface strain is the tendency of some human beings to form tori in the areas of maximal bending and torsion (Fig. 4-7). The largest tori are on the side on which the individual habitually chews (preferential working side).

Temporomandibular Articulation

The TMJ is the principal adaptive center for determining the intermaxillary relationship in all three planes of space. Figure 4-8 shows optimal skeletal development consistent with normal morphology of the TMJ. Biomechanics studies have demonstrated that the TMJ eminence develops a shape that minimizes joint loads.[6] Figure 4-9 shows aberrant skeletal and dental relationships consistent with degeneration of the fossa and mandibular condyle (i.e., the enlarged mushroom shape of the condylar process, the roughened topography of the articulating surfaces, and the loss of articular cartilage and subchondral plate). Progressive degeneration or hyperplasia of one or both mandibular condyles may result in substantial intermaxillary discrepancies in the sagittal, vertical, and frontal dimensions. The growth and development of the TMJ in response to facial growth are well known. During childhood and adolescence, the face grows several centimeters anteriorly and inferiorly. Adaptation of the TMJ allows this substantial change to occur without disturbing the intermaxillary relationship of the dentition (e.g., Class I occlusion remains Class I). In the adult years, the intermaxillary relationship continues to change but at a slower rate. The face lengthens and may rotate anteriorly as much as 10 mm over the adult lifetime.[7] The mandible adapts to this change by lengthening and maintaining the intermaxillary dental relationship (Fig. 4-10). However, if the TMJs of an adult undergo bilateral degenerative change, whether or not symptomatic, the mandible can decrease in length, resulting in a shorter, more convex face (Fig. 4-11). Cone-beam computed tomography (CBCT) has revealed intraosseous changes in the metaphysis of a degenerating mandibular condyle

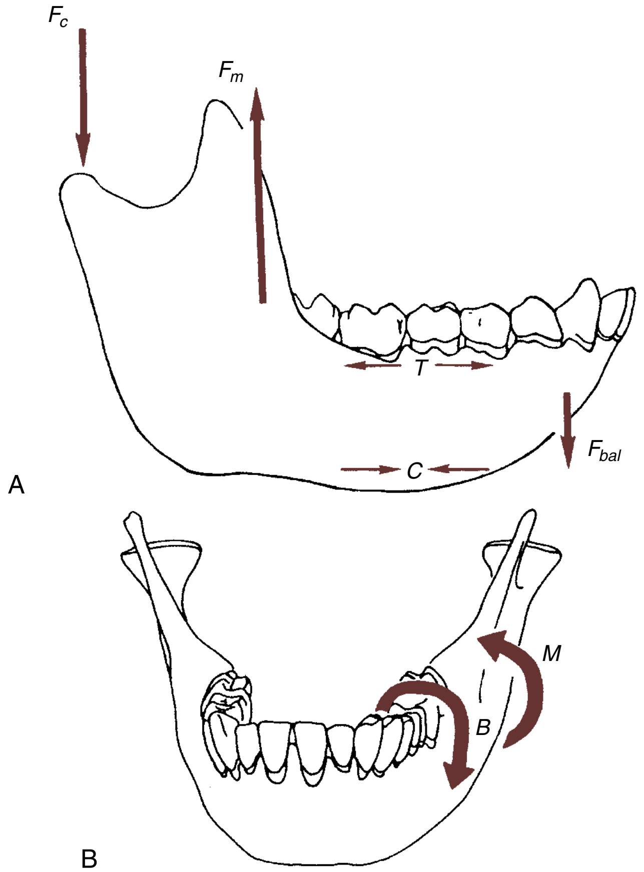

FIGURE 4-6 Stress patterns in the primate mandible during unilateral mastication. F_c and F_m are the condylar reaction and the resultant muscle forces on the balancing side, respectively. F_{bal} is the force transmitted through the symphysis from the balancing to the working side. *T* and *C* indicate the location of tensile stress and compressive stress, respectively. **A,** During the power stroke, the mandibular corpus on the balancing side is bent primarily in the sagittal plane, resulting in tensile stress along the alveolar process and compressive stress along the lower border of the mandible. **B,** On the working side, the corpus is twisted primarily about its long axis (it also experiences direct shear and is slightly bent). The muscle force on this side tends to evert the lower border of the mandible and invert the alveolar process (*curved arrow M*). The twisting movement associated with the bite force has the opposite effect (*curved arrow B*). The portion of the corpus between these two twisting movements experiences maximal twisting stress. (From Hylander WL. Patterns of stress and strain in the macaque mandible. In: Carlson DS, ed. *Craniofacial Biology*. Ann Arbor, MI: Center for Human Growth and Development; 1981.)

(Fig. 4-12). Compared with the normal left side, there are trabecular sclerosis and subcondylar osteolytic lesions on the degenerating side. The picture is consistent with a mechanical overload of the TMJ. Animal studies have described the molecular mechanism of TMJ degeneration due to mechanical overload: (1) expression of vascular endothelial growth factor (VEGF), (2) hypoxia-inducible factor-1α (Hif-1α) is activated, and (3) osteoclastogenesis via repression of osteoprotegerin (Opg) expression results in osteolytic lesions.[8]

Within physiologic limits, the TMJ has remarkable regenerative and adaptive capabilities. The TMJ can recover spontaneously

FIGURE 4-7 Occlusal view of the mandibular dentition of a male patient with extensive buccal and lingual tori. Note that the exostoses are most extensive in the area of the second premolar and first molar, the area of maximal torsion in the posterior segment of the mandible.

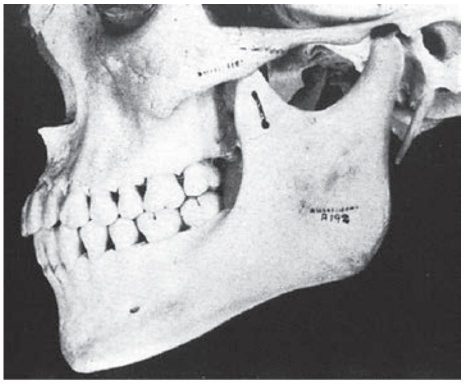

FIGURE 4-8 Adult human skull with ideal occlusion and osseous form of the maxilla and mandible. Note the ideal anatomic form of the condyle and articular fossa of the temporomandibular joint. (From Atkinson SR. Balance: the magic word. *Am J Orthod*. 1964;50:189.)

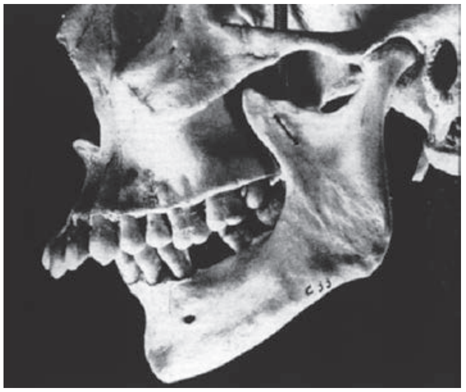

FIGURE 4-9 Adult human skull with a severe Class II malocclusion. Note the degeneration of the temporomandibular joint (i.e., the large, mushroom-shaped condyle and the enlarged, roughened articular fossa). (From Atkinson SR. Balance: the magic word. *Am J Orthod*. 1964;50:189.)

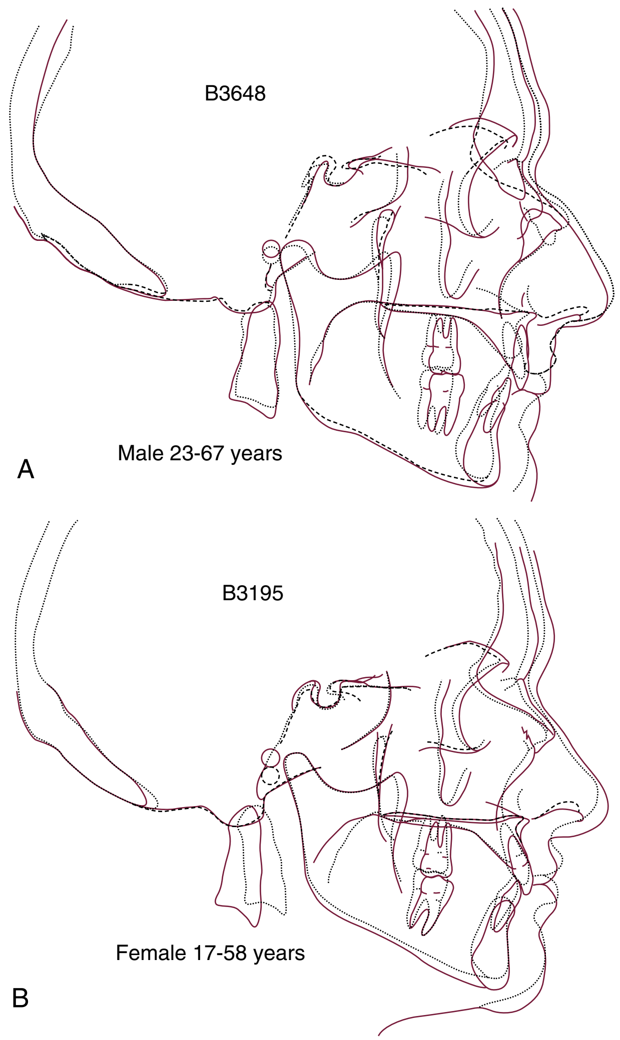

FIGURE 4-10 A, Superimposed cephalometric tracings of a male patient at ages 23 and 67 years (*black* and *red* tracings, respectively). Note the downward and forward growth of the mandible and the substantial increase in the length of the face. The nasal form was altered by a rhinoplasty in the intervening years. B, Superimposed cephalometric tracings of an adult female at ages 17 and 58 years (*black* and *red* tracings, respectively). Note the downward growth of the mandible and the substantial increase in the length of the face. (From Behrents RG. Adult facial growth. In: Enlow DH, ed. *Facial Growth*. 3rd ed., Philadelphia: WB Saunders; 1990.)

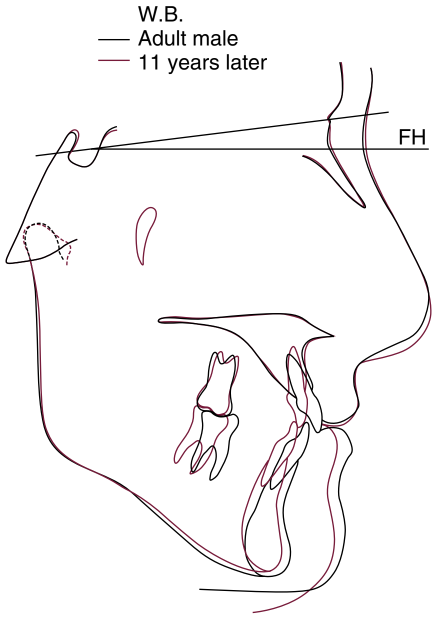

FIGURE 4-11 Superimposed cephalometric tracings of a middle-aged man over an 11-year period. Although the soft tissue changes are similar to those seen in other adult males (see Fig. 4-10, *B*), the less prominent mandible and more convex skeletal profile are consistent with a shortened mandible. This man had a history of bilateral temporomandibular internal derangement that progressed to crepitus. However, despite the substantial change in facial form and occlusal compensation, no appreciable pain was reported.

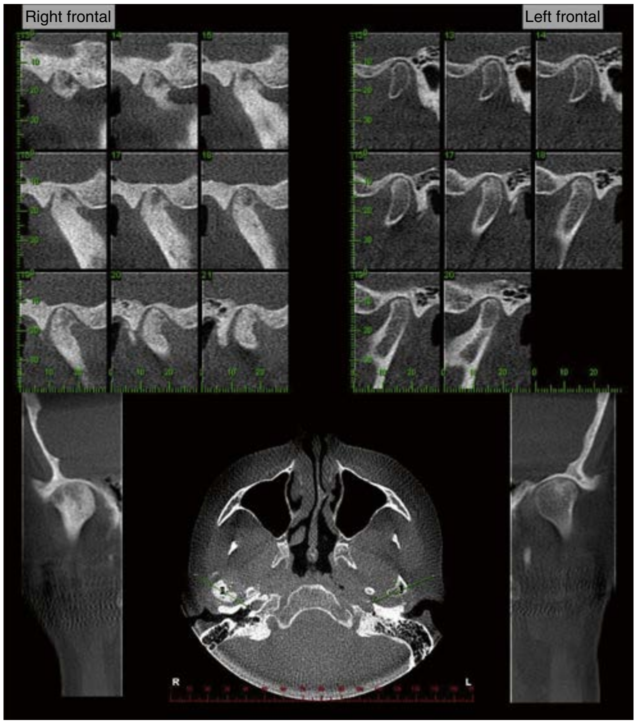

FIGURE 4-12 A CBCT image reveals osseous degeneration of the right mandibular condyle in a 65-year-old female. In both the frontal and sagittal cuts, note the lack of joint space between the condyle and the fossa, as well as the subcortical plate radiolucent erosions in the trabecular bone of the condylar metaphysis.

from degenerative episodes (Fig. 4-13). However, more advanced degeneration associated with abnormal occlusal loading requires distraction of the degenerating condyle with a removable orthotic, orthodontic alignment, and occlusal reconstruction to create a balance occlusal load bilaterally (Figs. 4-14 and 4-15). Unlike other joints in the body, the TMJ has a remarkable ability to adapt to altered jaw structure and function. After a subcondylar fracture, the condylar head is pulled medially by the superior pterygoid muscle and resorbs. If the interocclusal relationship is maintained, a new condyle forms and assumes normal function. Unilateral subcondylar fractures usually result in regeneration of a new functional condyle with no significant deviation of the mandible.[9] However, about one-fourth of subcondylar fractures result in a mandibular deviation toward the injured side, resulting in an asymmetric Class II malocclusion with a midline deviation.

Another sequela of mandibular trauma is internal derangement such as a unilateral closed lock (a condyle distally displaced relative to the disc). If the range of motion is reduced in a growing patient, the compromised function may inhibit mandibular growth, resulting in a cant of the occlusal plane. Progressive dysfunction and pain may ensue, particularly when associated with occlusal trauma. Reestablishing normal bilateral function allows the compromised condyle or condyles to adapt favorably.

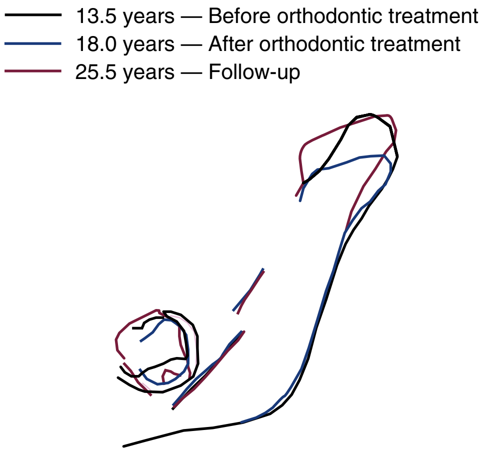

FIGURE 4-13 Superimposed tracings of a series of panoramic radiographs documenting the degeneration of a mandibular condyle between 13.5 and 18 years of age. Between the ages of 18 and 25.5 years, the degenerative condyle grew, restoring the original length of the mandible. (From Peltola JS, Kononen M, Nystrom M. A follow-up study of radiographic findings in the mandibular condyles of orthodontically treated patients and associations with TMD. *J Dent Res*. 1995;74(9):1571.)

BONE PHYSIOLOGY

The morphology of bone has been well described, but its physiology is elusive because of the technical limitations inherent in the study of mineralized tissues. Accurate assessment of the orthodontic or orthopedic response to applied loads requires time markers (bone labels) and physiologic indexes (DNA labels, histochemistry, and in situ hybridization) of bone cell function. Systematic investigation with these advanced methods has defined new concepts of clinically relevant bone physiology.

Specific Assessment Methodology

Physiologic interpretation of the response to applied loads requires the use of specially adapted methods:

- Mineralized sections are an effective means of accurately preserving structure and function relationships.[10]
- Polarized light birefringence detects the preferential orientation of collagen fibers in the bone matrix.[11]
- Fluorescent labels (e.g., tetracycline) permanently mark all sites of bone mineralization at a specific point in time (anabolic markers).[11,12]
- Microradiography assesses mineral density patterns in the same sections.[13]
- Autoradiography detects radioactively tagged precursors (e.g., nucleotides and amino acids) used to mark physiologic activity.[14-16]

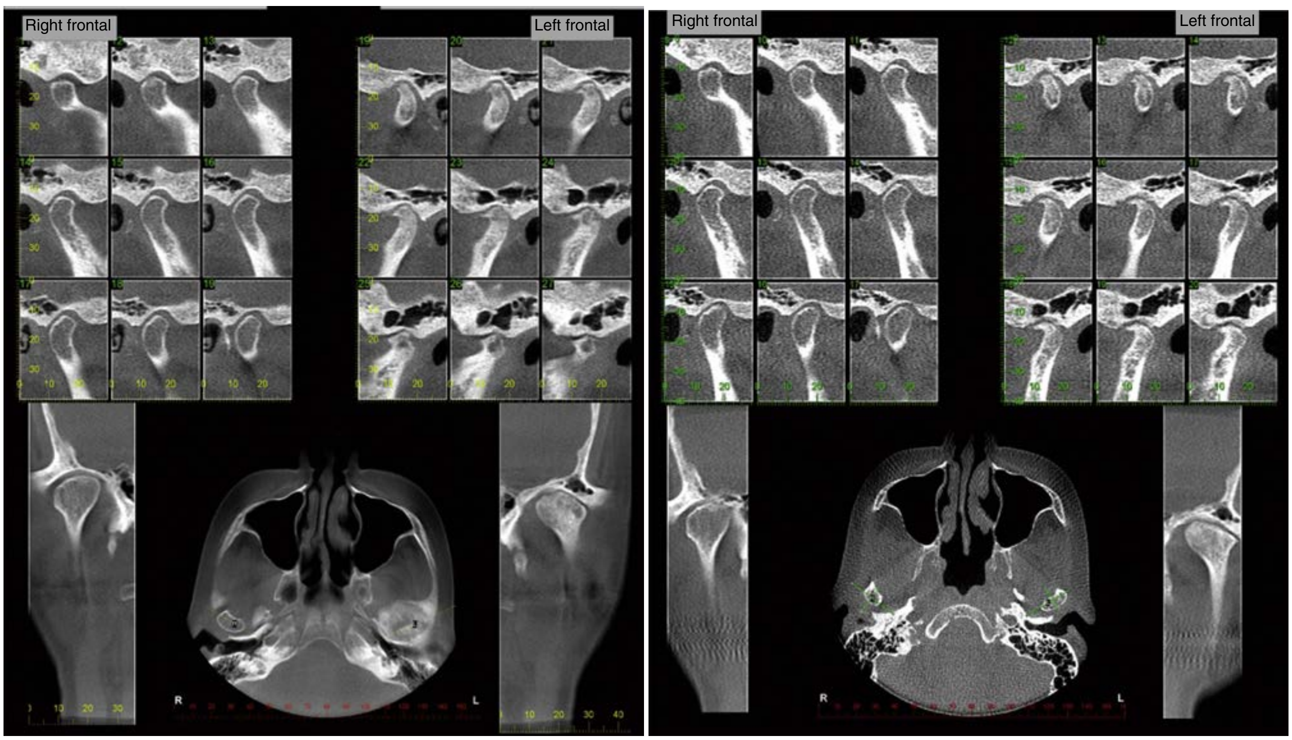

FIGURE 4-14 Pretreatment CBCT imaging of a 72-year-old female shows osseous degeneration of the left mandidular condyle, characterized by subcortical radiolucent lesions that are noted in both the frontal and sagittal cuts. A well-defined osteophyte is noted on the anterior surface of the left mandibular condyle.

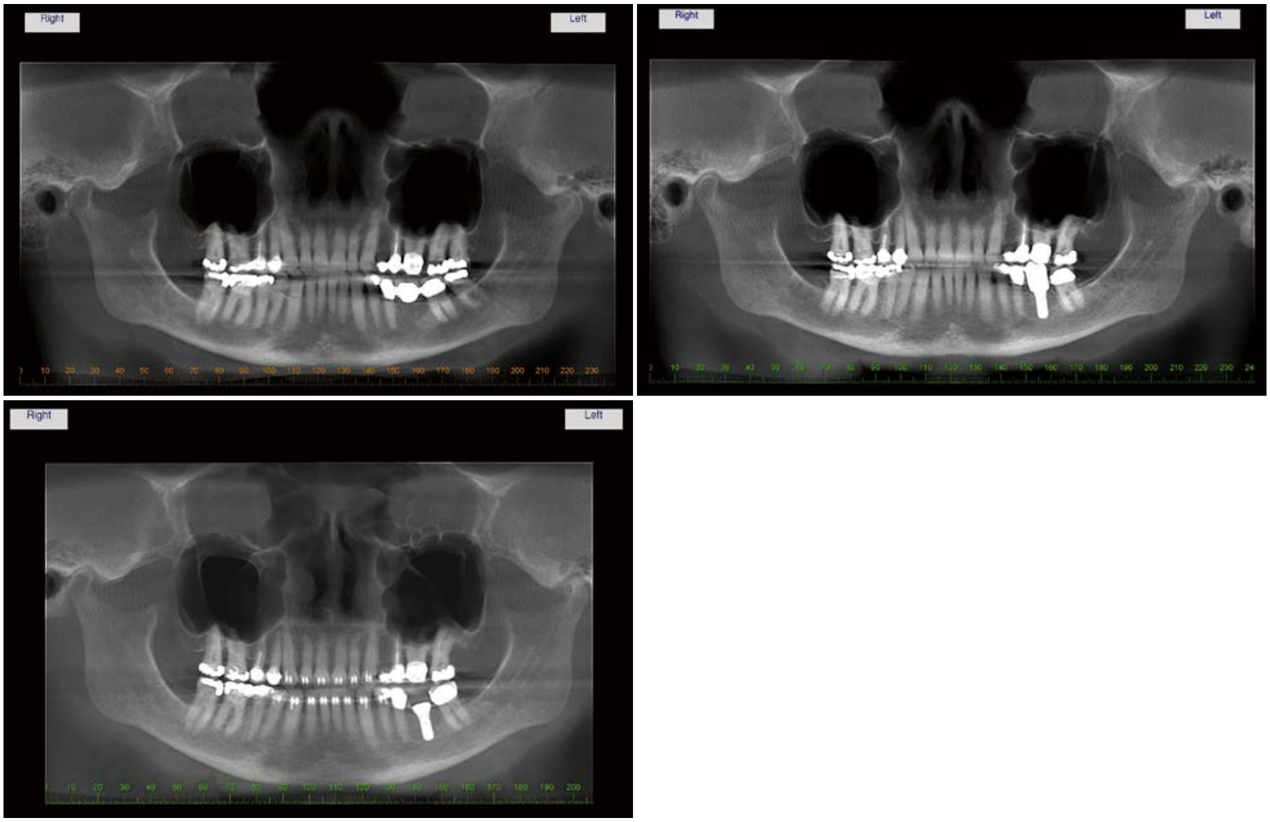

FIGURE 4-15 A posttreatment CBCT scan was performed on the patient imaged in Figure 4-14. Condylar distraction of the left mandibular condyle, producing a left-posterior open bite of about 2 mm, resulted in resolution of the subcortical osteolytic lesions, but the osteophyte on the anterior surface persisted. The patient subsequently received coordinated orthodontics and restorative treatment to correct the posterior open bite by increasing the vertical dimension of occlusion.

CASE STUDY 4-1 TEMPOROMANDIBULAR DISCREPENCIES

A 52-year-old man sought treatment for a long history of facial pain, occlusal dysfunction, and an internal derangement of the right mandibular condyle (Figs. 4-16 and 4-17). Intracapsular surgery was performed on the right TMJ to repair the internal derangement. After transient postoperative improvement, degeneration of the TMJ accelerated, the pain increased, and a progressive anterior open bite malocclusion developed. Masticatory function deteriorated, and an internal derangement of the left TMJ was noted. Bilateral intracapsular surgery was performed to restore "normal jaw function." After the second surgical procedure, the patient suffered for 10 years with chronic pain and progressive bilateral degeneration of both TMJs. Orthodontic and orthotic (splint) therapy failed to relieve the pain and functional debilitation. The patient declined further treatment and is being managed with pain medication. From a physiologic perspective, intracapsular surgery usually is contraindicated because it inhibits the natural ability of the joint to adapt to changing biomechanical demands. The TMJ is a remarkably regenerative and adaptive joint if its physiologic limits are respected.

W. Eugene Roberts

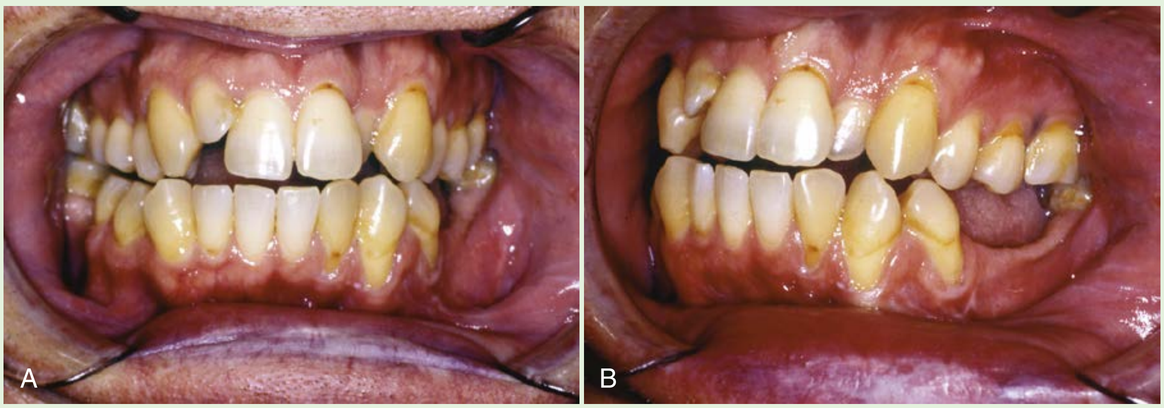

FIGURE 4-16 Frontal view (A), lateral view (B), maxillary occlusal view

CASE STUDY 4-1 TEMPOROMANDIBULAR DISCREPENCIES—cont'd

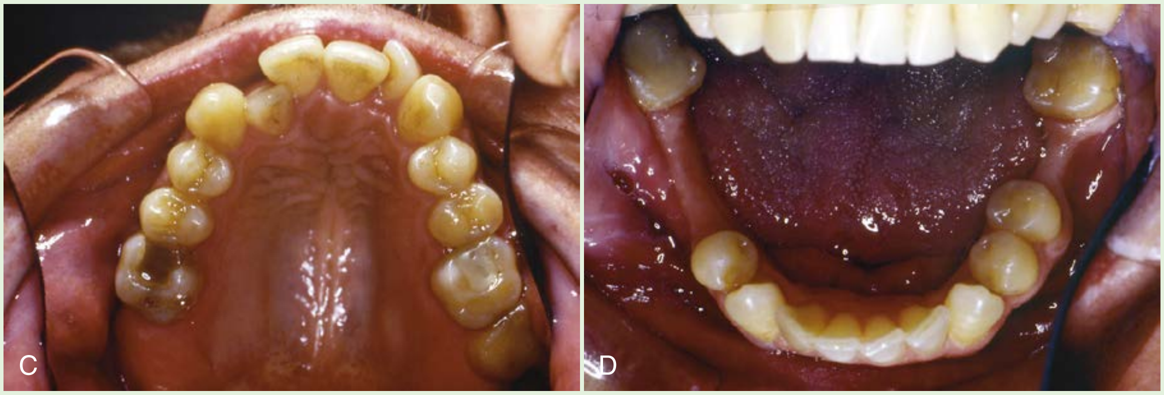

FIGURE 4-16 cont'd (**C**), and mandibular occlusal view (**D**) of the dentition of a 52-year-old man with a partly edentulous open bite malocclusion. Note the atrophic extraction sites and gingival recession. (From Roberts WE, et al. Adjunctive orthodontic therapy in adults over 50 years of age. *J Ind Dent Assoc*. 1997;76(2):33.)

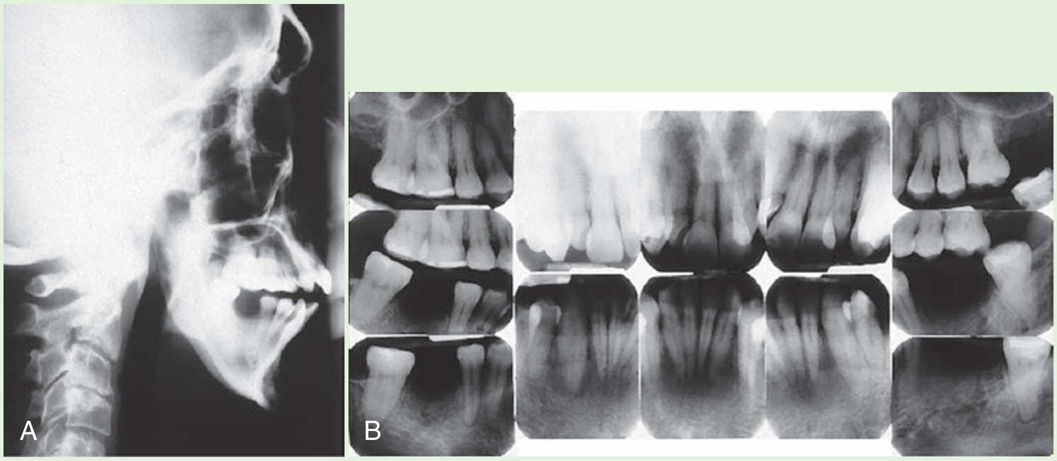

FIGURE 4-17 **A,** Cephalometric radiograph of the patient shown in Figure 4-16 shows a skeletal open bite with a steep mandibular plane and a relatively short ramus. The thin symphyseal cortex is consistent with a systemic osteopenia. **B,** A full-mouth radiographic survey shows a generalized lack of cortical bone at the alveolar crest and a pattern of indistinct lamina dura and trabeculae. This generalized ground-glass appearance of the alveolar bone is consistent with high-turnover metabolic bone disease. (From Roberts WE, et al. Adjunctive orthodontic therapy in adults over 50 years of age. *J Ind Dent Assoc*. 1997;76(2):33.)

- Nuclear volume morphometry differentially assesses osteoblast precursors in a variety of osteogenic tissues.[17]
- Cell kinetics is a quantitative analysis of cell physiology based on morphologically distinguishable events in the cell cycle (i.e., DNA synthesis [S] phase, mitosis, and differentiation-specific change in nuclear volume).[17,18]
- Finite element modeling is an engineering method of calculating stresses and strains in all materials, including living tissue.[19-22]
- Microelectrodes inserted in living tissue, such as the PDLs, can detect electrical potential changes associated with mechanical loading.[18,23]
- Backscatter emission is a variation of electron microscopy that assesses relative mineral density at the microscopic level in a block specimen.[24]
- Microcomputed tomography is an in vitro imaging method for determining the relative mineral density of osseous tissue down to a resolution of about 5 μm (about the size of an osteoblast nucleus).[25]
- Microindentation testing is a method for determining the mechanical properties of bone at the microscopic level.[26-29]

For a detailed discussion and illustration of the methods used to investigate the inherent bone physiologic mechanisms of bone, refer to the 4th edition of this text and to two issues of *Seminars in Orthodontics* (June 2004, December 2006). The first issue focuses on bone development and its inherent modeling mechanism, applied to tooth movement and dentoalveolar adaptation. The second issue is an advanced discussion of the bone remodeling mechanism, osteogenesis imperfecta, retromolar implant anchorage, and the use of stainless steel miniscrews in the zygomatic crest.

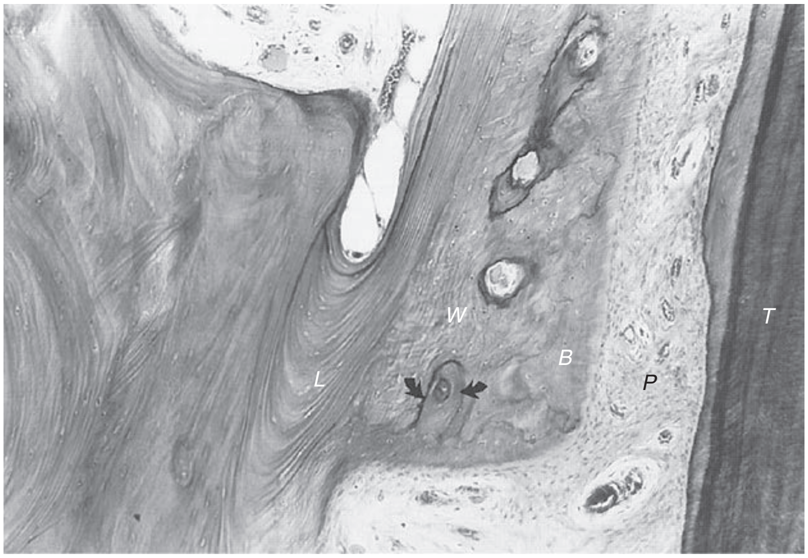

FIGURE 4-18 A section of human periodontium from the lower first molar region shows a typical histologic response to orthodontic tooth movement. With respect to the mature lamellar bone (*L*) on the left, the tooth (*T*) is being moved to the right. The first bone formed adjacent to the periodontal ligament (*P*) is of the woven type (*W*). Subsequent lamellar compaction forms primary osteons of composite bone (*arrows*). Bundle bone (*B*) is formed where ligaments such as the periodontal ligament are attached. (From Roberts WE, et al. Implants: bone physiology and metabolism. *Calif Dent Assoc J*. 1987;15(10):58.)

Classification of Bone Tissue

Orthodontic tooth movement results in rapid formation of relatively immature new bone (Fig. 4-18). During the retention period, the newly formed bone remodels and matures. To appreciate the biological mechanism of orthodontic therapy, the practitioner must have a knowledge of bone types.

Woven Bone

Woven bone varies considerably in structure. However, it is relatively weak, disorganized, and poorly mineralized. Woven bone serves a crucial role in wound healing by (1) rapidly filling osseous defects, (2) providing initial continuity for fractures and osteotomy segments, and (3) strengthening a bone weakened by surgery or trauma. The first bone formed in response to orthodontic loading usually is the woven type. Woven bone is not found in the adult skeleton under normal, steady-state conditions; rather, it is compacted to form composite bone, remodeled to lamellar bone, or rapidly resorbed if prematurely loaded.[13,30] The functional limitations of woven bone are an important aspect of orthodontic retention (Fig. 4-19) and of the healing period following orthognathic surgery.[31]

Lamellar Bone

In contrast to woven bone, lamellar bone, a strong, highly organized, well-mineralized tissue, makes up more than 99% of the adult human skeleton. When new lamellar bone is formed, a portion of the mineral component (hydroxyapatite) is deposited by osteoblasts during primary mineralization (Fig. 4-20, *D*). Secondary mineralization, which completes the mineral component, is a physical process (crystal growth) that requires many months. Within physiologic limits, the strength of bone is related directly to its mineral content.[32,33] The relative strengths of different histologic types of osseous tissues can be stated thus:

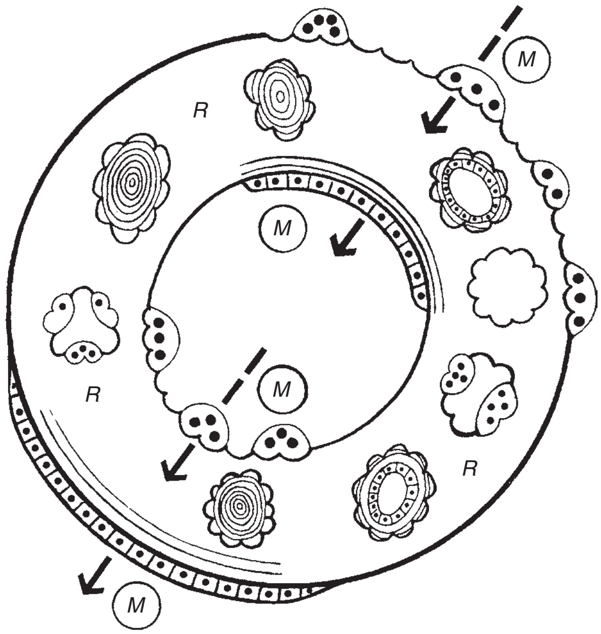

FIGURE 4-19 A schematic cross section of cortical bone shows surface modeling (*M*), which is the process of uncoupled resorption and formation. Remodeling (*R*) is the turnover of existing bone. (From Roberts WE, et al. Remodeling of devitalized bone threatens periosteal margin integrity of endosseous titanium implants. *Ind Dent Assoc J*. 1989;68:19.)

woven bone is weaker than new lamellar bone, which is weaker than mature lamellar bone.[31] Adult human bone is almost entirely of the remodeled variety: secondary osteons and spongiosa.[11,33,34] The full strength of lamellar bone that supports an orthodontically moved tooth is not achieved until about 1 year after completion of active treatment. This is an important

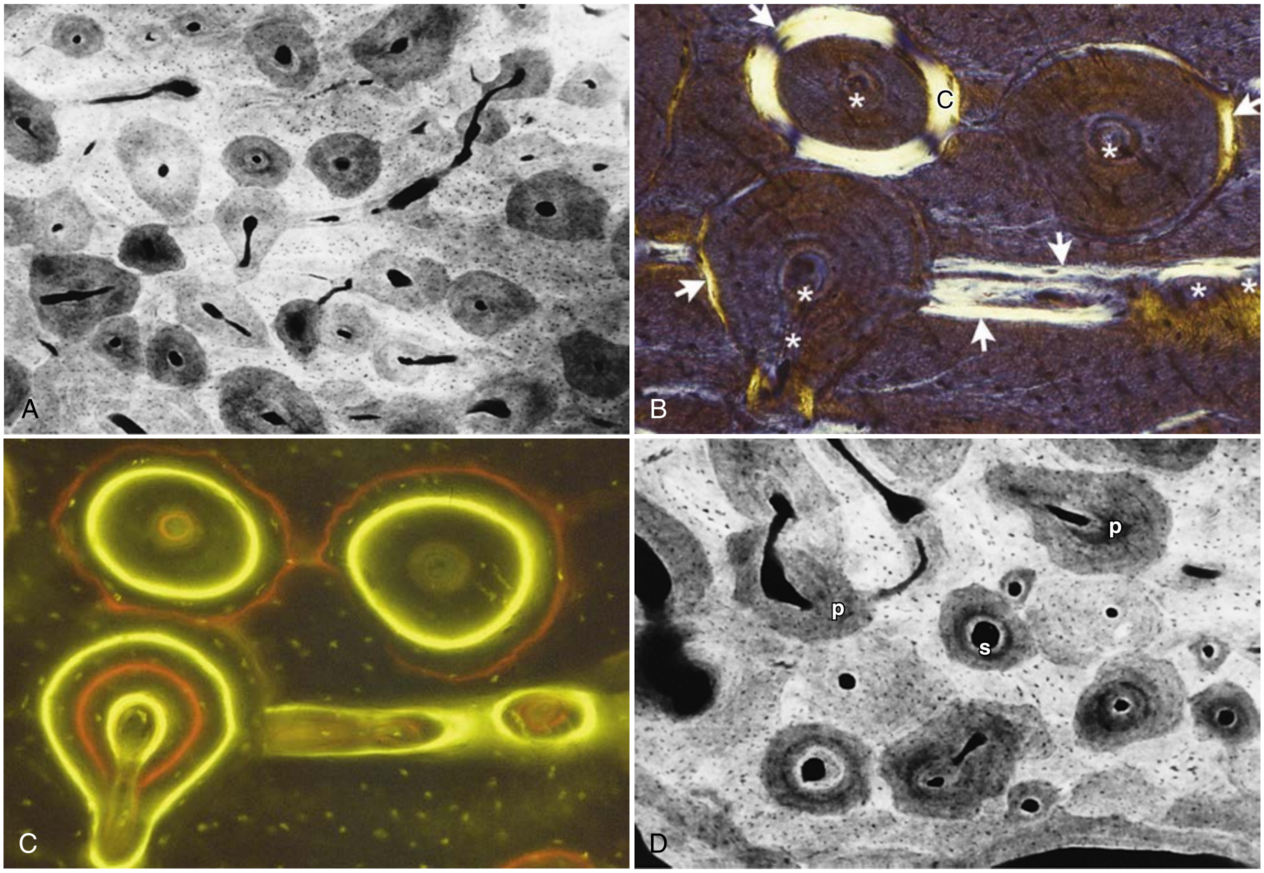

FIGURE 4-20 A, Microradiograph provides a physiologic index of bone turnover and relative stiffness. The more radiolucent (*dark*) osteons are the youngest, the least mineralized, and the most compliant. Radiodense (*white*) areas are the oldest, most mineralized, and rigid portions of the bone. B, Polarized light microscopy shows the collagen fiber orientation in bone matrix. Lamellae with a longitudinally oriented matrix (*C*) are particularly strong in tension, whereas a horizontally oriented matrix (*dark*) has preferential strength in compression (*arrows* mark resorption arrest lines, and *asterisks* mark vascular channels). C, Multiple fluorochrome labels administered at 2-week intervals demonstrate the incidence and rates of bone formation. D, This microradiograph shows an array of concentric secondary osteons (haversian systems) characteristic of rapidly remodeling cortical bone. Primary (*p*) and beginning secondary (*s*) mineralization are more radiolucent and radiodense, respectively. (D, From Roberts WE, Garotto LP, Katona TR: Principle of orthodontic biomechanics: metabolic and mechanical control mechanisms. In Carlson DS, Goldstein SA, editors: Bone biodynamics in orthodontic and orthopedic treatment, Ann Arbor, 1992, University of Michigan Press)

consideration in planning orthodontic retention (Fig. 4-21) and in the postoperative maturation period that follows orthognathic surgery.

Composite Bone

Composite bone is an osseous tissue formed by the deposition of lamellar bone within a woven bone lattice, a process called *cancellous compaction*.[10,35] This process is the quickest means of producing relatively strong bone.[36] Composite bone is an important intermediary type of bone in the physiologic response to orthodontic loading (see Fig. 4-18), and it usually is the predominant osseous tissue for stabilization during the early process of retention or postoperative healing. When the bone is formed in the fine compaction configuration, the resulting composite of woven and lamellar bone forms structures known as *primary osteons*. Although composite bone may be high-quality, load-bearing osseous tissue, it eventually is remodeled into secondary osteons.[11,31]

Bundle Bone

Bundle bone is a functional adaptation of lamellar structure to allow attachment of tendons and ligaments. Perpendicular striations, called *Sharpey fibers*, are the major distinguishing characteristics of bundle bone. Distinct layers of bundle bone usually are seen adjacent to the PDL (see Fig. 4-18) along physiologic bone-forming surfaces.[37] Bundle bone is the mechanism of ligament and tendon attachment throughout the body.

SKELETAL ADAPTATION: REMODELING AND MODELING

Bone Remodeling

Bone remodeling is a *coupled sequential* process of bone resorption followed by bone formation (Fig. 4-20, *A* to *D*). Bone remodeling occurs both in cortical (Fig. 4-20) and trabecular bone (Fig. 4-22) compartments of the skeletal system. However,

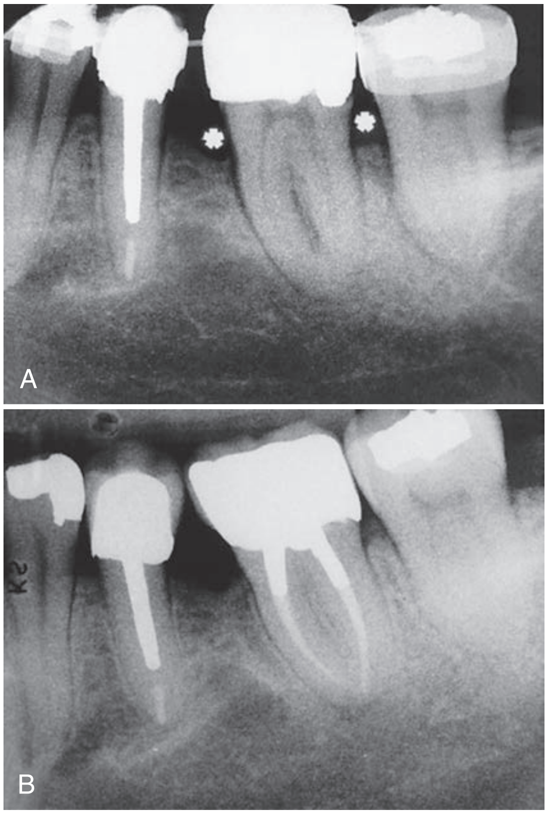

FIGURE 4-21 Periapical radiographs comparing bone maturation at the end of active orthodontic treatment and 2 years later. **A,** At the end of treatment, large amorphous areas of relatively immature bone can be seen. **B,** After retention and restorative treatment, including endodontics, distinct definition of cortices and trabeculae is evident. (From Roberts WE, Garotto LP, Katona TR: Principle of orthodontic biomechanics: metabolic and mechanical control mechanisms. In Carlson DS, Goldstein SA, editors: Bone biodynamics in orthodontic and orthopedic treatment, Ann Arbor, 1992, University of Michigan Press.)

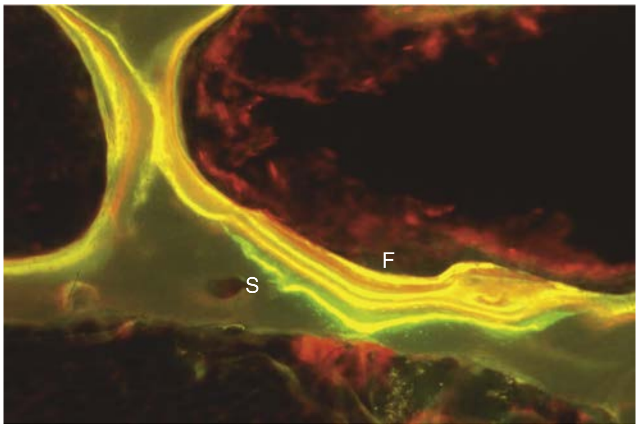

FIGURE 4-22 Trabecular bone remodeling in the vertebrae in a rat: multiple fluorochrome labels demonstrate bone formation (*F*) over a scalloped resorption arrest line (*S*). (From Roberts WE, Roberts JA, Epker BN, et al. Remodeling of mineralized tissues, part I: the Frost legacy. *Semin Orthod*. 2006;12(4):216–237.)

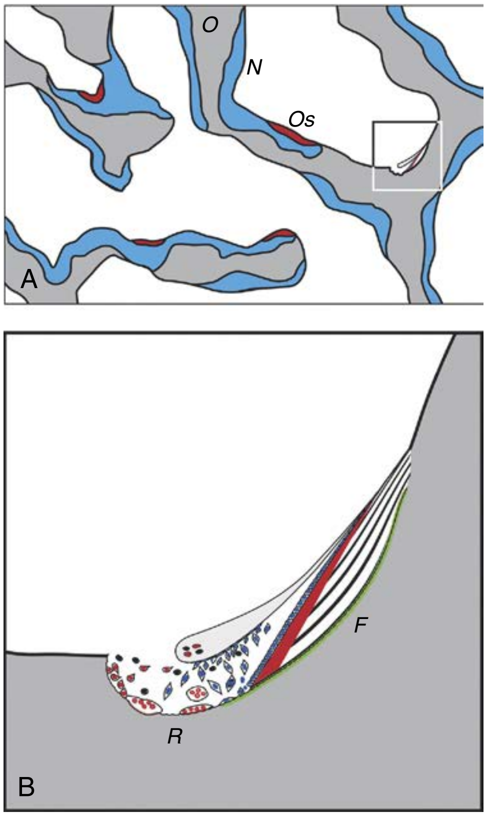

FIGURE 4-23 A, A schematic drawing of trabecular bone remodeling over a 1-year interval shows the pattern of new bone formation (*N*) relative to old bone (*O*) and osteoid seams (*Os*). The *box* marks an area of active trabecular resorption, which is magnified in the accompanying figure. **B,** A detailed drawing of an active remodeling site (magnified from **A**) shows a hemicutting/filling cone with a similar perivascular array of resorptive (*R*) and formative (*F*) cells as shown for cortical bone remodeling. The osteoclastic and osteoblastic cell lines are *red* and *blue*, respectively. A nonmineralized osteoid seam (*solid red line*) marks the bone-forming surface. (From Roberts WE, Roberts JA, Epker BN, et al. Remodeling of mineralized tissues, part I: the Frost legacy. *Semin Orthod*. 2006;12(4):216–237.)

there are important differences between bone remodeling in the cortical versus trabecular bone that are reflected at a tissue level and revealed by histologic studies. Histologically, when viewed in transverse sections of long bones, the end result of bone remodeling in cortical bone is the production of a new, circular (typically 200- to 300-μm diameter) shaped osteon (Fig. 4-20, *C*). This type of cortical bone remodeling can also be described as *intracortical secondary osteonal* bone remodeling. Thus, the remodeling that occurs in cortical bone occurs within the substance of the cortical bone (in the *intracortical* compartment) and away from the periosteal and endosteal surfaces. In addition, the osteons that result from the bone remodeling process result in the formation of *secondary* osteons.[38] These osteons have a reversal line and are in contrast to primary osteons,[39] which histologically resemble secondary osteons but lack the reversal line because no bone resorption occurs in the development of a primary osteon. In essence, primary osteons are produced by bone formation and thus not by a coupled process of bone resorption and bone formation. In trabecular bone, the bone tissue structure is frequently not wide enough to accommodate 200- to 300-μm sized

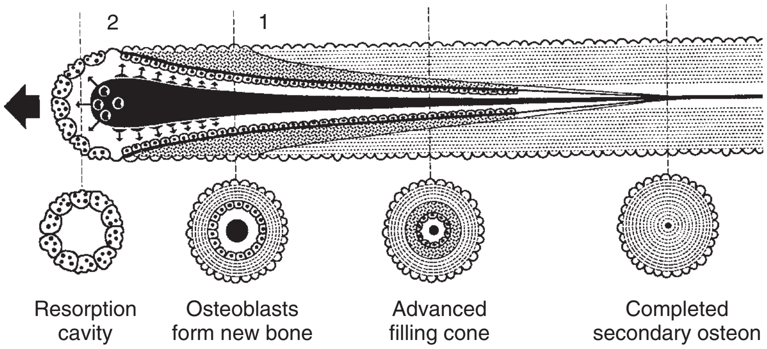

FIGURE 4-24 The cutting/filling cone has a head of osteoclasts that cut through the bone and a tail of osteoblasts that form a new secondary osteon. The velocity through bone is determined by measuring between two tetracycline labels (*1* and *2*) administered 1 week apart. (Adapted from Roberts WE, et al. Osseous adaptation to continuous loading of rigid endosseous implants. *Am J Orthod*. 1984;86:95–111.)

osteons. Thus, only "hemi-osteonal" *surface* bone remodeling (Fig. 4-23, *A* and *B*) occurs in trabecular bone.[40] However, the bone remodeling is identical to that of cortical bone as it follows the same, coupled, resorption and formation process. For a detailed discussion of calcium homeostasis and trabecular bone remodeling, refer to Roberts.[41] A schematic drawing (see Fig. 4-23, *A*) of adult trabecular bone illustrates the pattern of turnover associated with continuous remodeling to support calcium homeostasis. An individual remodeling site is shown in Figure 4-23, *B*. The A→R→F process is similar to the cutting/filling cones of cortical bone remodeling (Fig. 4-24). The trabecular bone remodeling mechanism is essentially a hemicutting/filling cone.[41] At a cellular level, though very complex interactions exist, the resorption is carried out by osteoclasts, and the formation is effected by the osteoblasts.[42] To restate, bone remodeling in both cortical and trabecular bone involves the coordinated, coupled activity of osteoclasts and osteoblasts.

Bone remodeling is a homeostatic process. It results in the rejuvenation and replacement of old bone that has served its purpose. It is unique to bone and does not occur within the substance of other mineralized tissues such as enamel, dentin and cementum. This provides a distinct advantage to bone and makes it a tissue that is capable of regeneration. The bone remodeling also underlies the immense adaptive potential of this mineralized and hard tissue, both terms otherwise potentially implying limited adaptability.[43] From a functional standpoint, bone remodeling provides for calcium and thus helps in precisely regulating calcium levels in the body.[38] From an evolutionary perspective, bone acts as a calcium reservoir, allowing life-forms to move away from the sea. Without such a reservoir and a method for mobilization of calcium stores, calcium in the immediate environment (e.g., seawater) was essential for various cellular functions.

There are two terms used to further describe the types of bone remodeling, *stochastic* and *targeted*.[44] Stochastic remodeling occurs somewhat uniformly throughout the body—that is, the continuous repair and regeneration process. There are multiple sites (e.g., ~1 million by some estimates) in both trabecular and cortical bone at which stochastic bone remodeling is occurring at any one time. These remodeling sites also provide for metabolic calcium. During calcium deprivation[45] bone remodeling is enhanced and the bone remodeling rate is increased with more "cutting/filling cones" or osteons being produced (see Fig. 4-24). Targeted remodeling occurs at a specific site of injury and not throughout the entire body. A relevant and easily understandable example for orthodontists is the bone–implant interface. In placing a miniscrew, microdamage (small linear cracks) are created within the bone by the insertion of the screw.[46] The microdamage, a manifestation of tissue injury in a mineralized tissue, is repaired by bone remodeling.[47] Thus microdamage production stimulates bone remodeling at the site of damage (e.g., close to the interface) and repairs the damaged bone. Another form of bone injury is manifestation of diffuse damage.[48] This damage is not as clearly visible in histologic sections as microdamage. Corticotomies and tissue injury of both hard and soft tissue produce a localized injury, and repair is *targeted* to that specific area. This targeted remodeling is probably important for expedited orthodontic tooth movement as most therapies (vibration, corticotomies, etc.) work at some level through the local insult and subsequent healing.

Bone Modeling

Bone modeling is a distinct and a different process from bone remodeling. These two processes are frequently confused even though they can be readily distinguished at a histologic level. Histologic sections, labeled with intravital dyes, can clearly distinguish bone remodeling and modeling.[49,50] This contrast is not trivial, and the underlying process and controls of bone remodeling and modeling are different. It is not uncommon to find bone modeling being measured in studies and being mistaken for bone remodeling. This then leads to confusion in the literature and, more unfortunately, to incorrect interpretations.

Bone modeling is a surface-specific activity and results in a change in shape and size.[38] It is an *uncoupled* process, and the bone resorption and formation are not linked or coupled in a sequential manner (Figs. 4-19 and 4-25). The bone formation and resorption mediated by the osteoblasts and osteoclasts, respectively, do not occur on the same bone surface and occur independent of each other on different bone surfaces. One example of the end result of bone modeling that can occur over a duration of years is the difference in the diameter of the dominant arm of a tennis player from the contralateral nondominant arm.[51] The bone of the dominant arm has a diameter about 1.6-fold greater than the nondominant arm. The change in size occurs over a period of years and due to modeling events on the periosteal surface (and endosteal surface) of the arm. This does not mean that bone remodeling cannot occur *within* the cortical bone (intracortical compartment) independently or simultaneously; however, they are two different processes, each having different control mechanisms.[52] There are numerous other

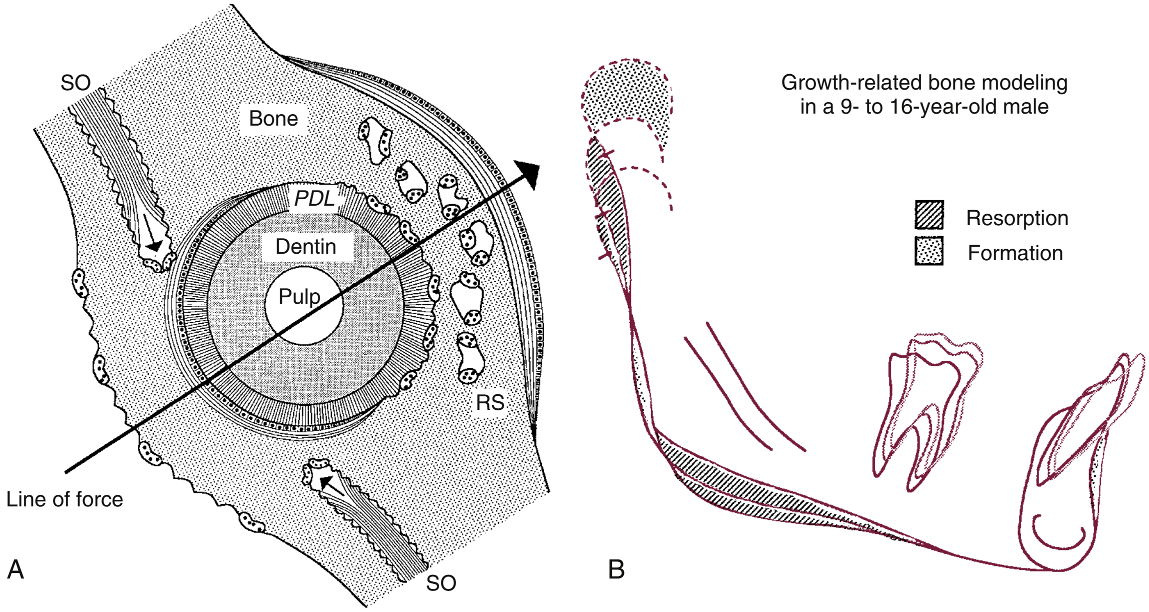

FIGURE 4-25 **A,** Orthodontic bone modeling, or site-specific formation and resorption, occurs along the periodontal ligament (*PDL*) and periosteal surfaces. Remodeling, or turnover, occurs within alveolar bone along the line of force on both sides of the tooth. **B,** Orthopedic bone modeling related to growth in an adolescent male involves several site-specific areas of bone formation and resorption. Although extensive bone remodeling (i.e., internal turnover) also is under way, it is not evident in cephalometric radiographs superimposed on stable mandibular structures.

examples of bone modeling. The formation of a callus after fracture of a bone (and insertion of an endosseous implant) and changes seen on the surfaces of bone (changes in shape and size) are readily apparent in cephalometric superimposition in a growing patient (Fig. 4-25, *B*). The surface changes are modeling; however, there is no doubt that remodeling is concurrently occurring within the bone. In fact modeling occurs primarily during growth (on periosteal and endosteal bone surfaces) and then decreases after maturity. It is activated again during healing and other pathologic biological processes (e.g., bony cyst-producing expansion).

From an orthodontic perspective, the biomechanical response to tooth movement involves an integrated array of bone modeling and remodeling events (see Fig. 4-25, *A*). Bone modeling is the dominant process of facial growth and adaptation to applied loads such as headgear, rapid palatal expansion, and functional appliances. Modeling changes can be seen on cephalometric tracings (see Fig. 4-25, *B*), but remodeling events, which usually occur at the same time, are apparent only at the tissue level. True remodeling usually is not imaged on clinical radiographs.[53] For a detailed discussion of the modeling mechanisms of tooth movement and alveolar bone adaptation, refer to Roberts et al.[43,54] The remodeling (bone turnover) aspect of tooth movement is reviewed in Roberts et al.[54] Constant remodeling (internal turnover) mobilizes and redeposits calcium by means of coupled resorption and formation: bone is resorbed and redeposited at the same site. Osteoblasts, osteoclasts, and possibly their precursors are thought to communicate by chemical messages known as *coupling factors*. Transforming growth factor β is released from bone during the resorption process; this cytokine helps stimulate subsequent bone formation to fill resorption cavities.[55] It is currently thought that growth factors released from bone mediate the coupling process via a genetic mechanism for activating and suppressing osteoclasts. Thus, *RANK*, *RANKL*, and *OPG* are gene products that control the remodeling sequence of bone resorption followed by formation. This ubiquitous genetic mechanism appears to be involved in the inflammatory induction of bone resorption and the coupling of bone formation at the same site (Fig. 4-26).[56,57]

CORTICAL BONE GROWTH AND MATURATION

Enlow[35] sectioned human skulls and histologically identified areas of surface apposition and resorption. The overall patterns of bone modeling ("external remodeling") helped define the mechanisms of facial growth. Although the method could not distinguish between active and inactive modeling sites, it was adequate for determining the overall direction of regional activity in the maxilla and mandible. This method of osseous topography was a considerable advance in the understanding of surface modeling of facial bones.

Melsen[58] used microradiographic images of mineralized sections to extend the capability of the osseous topography method. Patterns of primary and secondary mineralization (as described in Fig. 4-20) identified active appositional sites and provided a crude index of bone formation rates. Through the systematic study of autopsy specimens of 126 normal males and females from birth to 20 years of age, the most stable osseous structures in the anterior cranial base of growing children and adolescents were defined anatomically (Fig. 4-27, *A*). This research established that the three most stable osseous landmarks for superimposition of cephalometric radiographs are (1) the anterior curvature of the sella turcica, (2) the cribriform plate, and (3) the internal curvature of the frontal bone (Fig. 4-27, *B*). In effect, this research established the gold standard for reliable superimposition on the anterior cranial base.

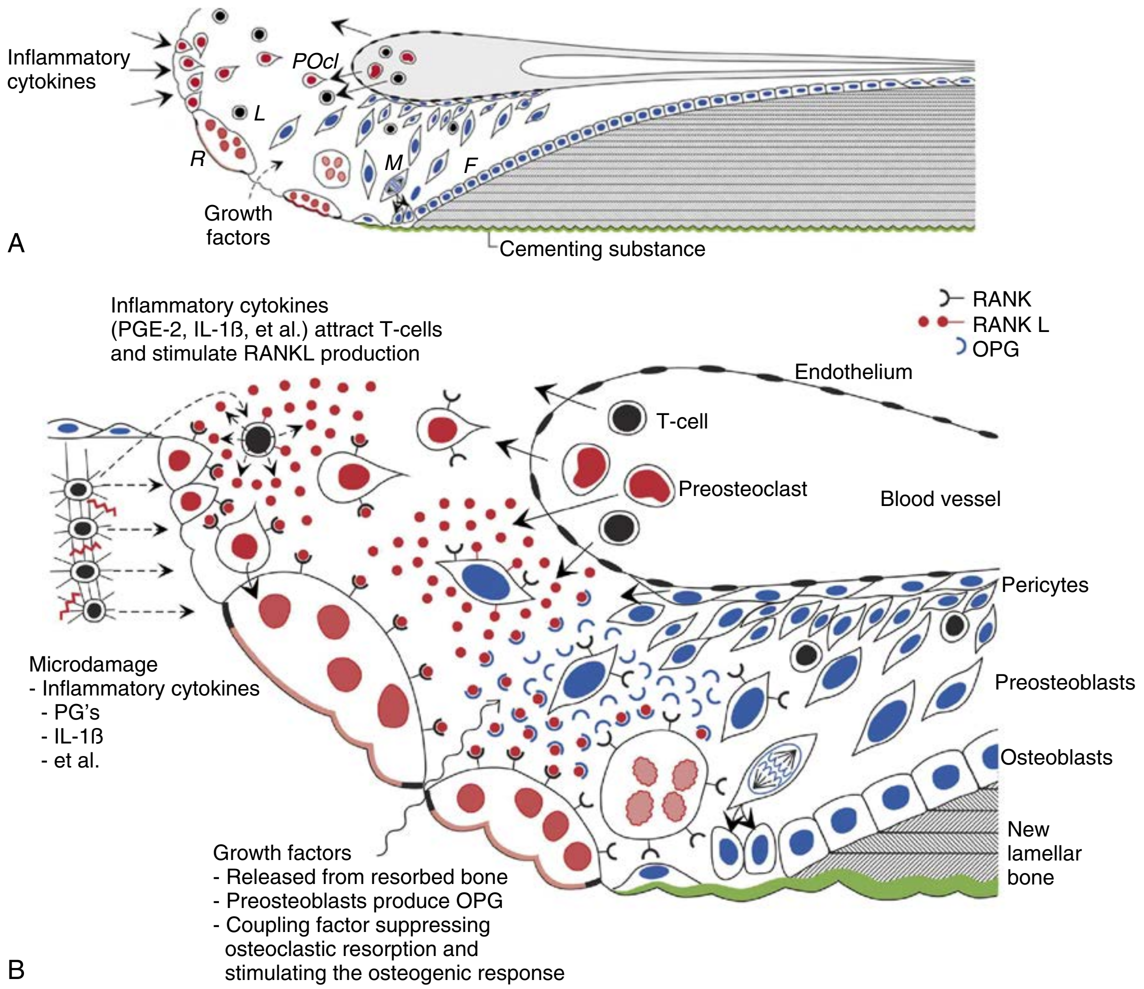

FIGURE 4-26 A, A hemisection of a cutting/filling cone moving to the left demonstrates the intravascular and perivascular mechanisms for coupling bone resorption (*R*) to formation (*F*) during the remodeling process. Lymphocytes (*L*) are attracted from the circulation by inflammatory cytokines. They help recruit preosteoclasts (*POcl*) from the circulation. See text for details. B, A magnified view of the head of a hemicutting/filling cone illustrates the proposed mechanism for coupling bone resorption to formation via the genetic *RANK/RANKL/OPG* mechanism. The cutting head is stimulated by inflammatory cytokines produced by osteocytes in damaged bone (*left*). Preosteoclasts have RANK receptors that are bound and activated by RANKL, probably produced or mediated by T cells (lymphocytes) near the resorption front. Growth factors from resorbed bone (*bottom*) stimulate production of preosteoblasts, which then produce OPG to block the RANK receptors on osteoclasts; the latter then withdraw from the scalloped surface and degenerate. Relatively flat mononuclear cells (*bottom center*) form cementing substance to form a resorption arrest line. Osteoblasts (*bottom right*) produce new lamellar bone to fill the resorption cavity. (From Roberts WE, et al. Remodeling of mineralized tissues, part II: control and pathophysiology. *Semin Orthod*. 2006;12:238–253.)

Roberts et al.[10,11,59] introduced simultaneous use of multiple fluorochrome labels and microradiography to assess modeling and remodeling patterns over extended periods of time. Noorda[60] applied these methods for a three-dimensional assessment of subcondylar growth of the mandible of adolescent rabbits. Rabbits 20 weeks of age (early adolescents) were labeled every 2 weeks with a rotating series of six different multifluorochrome labels for 18 weeks. Cross sections of the subcondylar region (Fig. 4-28, *A*) were superimposed on original, oldest labeled, and newest labeled bone according to fluorescent time markers (Fig. 4-28, *B*). Because all three sections were at the same relative level at a point in time, superimposition on original (unlabeled) bone and the oldest labeled bone (Fig. 4-28, *C*) provided an index of the relative amounts of bone resorbed and formed as the mandible grew superiorly (Fig. 4-28, *D*). This method provided the most accurate assessment to date of cortical bone drift over time. The major mechanism of the increase in interramal width during adolescent growth in rabbits is lateral drift of the entire subchondral region.

The Noorda study also produced important quantitative data on the rates of surface modeling (apposition and resorption) of primary bone (Fig. 4-29). During the last 18 weeks of growth to adult stature, the surface apposition rate decreased from more than 25 μm/day to less than 5 μm/day (Fig. 4-30, *A*). The secondary osteon census peaked at about 8 to 10 weeks

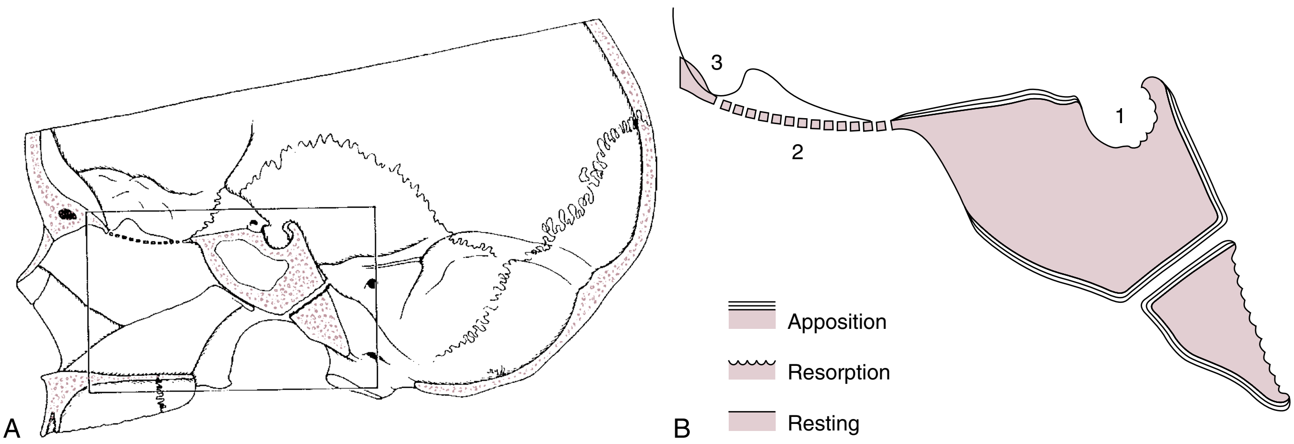

FIGURE 4-27 **A,** Schematic drawing of a skull showing the tissue block removed at autopsy from a series of growing children and adolescents from birth to 20 years of age. **B,** Diagrammatic representation of the bone modeling patterns of the cranial base in growing children. Histologic and microradiographic analysis established that the three most stable anatomic landmarks are (1) the anterior curvature of the sella turcica, (2) the cribriform plate, and (3) the internal curvature of the frontal bone. (From Melsen B. The cranial base. *Acta Odontol Scand.* 1974;32(suppl 62):103.)

(Fig. 4-30, *B*). Thus, under conditions of relatively rapid growth, primary cortical bone is remodeled to secondary osteons in about 2 months. Remodeling therefore is a time-dependent maturation of primary cortical bone.[10,11]

Cutting and Filling Cones

The rate at which cutting and filling cones progress through compact bone is an important determinant of turnover. The progression is calculated by measuring the distance between initiation of labeled bone formation sites along the resorption arrest line in longitudinal sections.[10] Using two fluorescent labels administered 2 weeks apart in adult dogs, the velocity was 27.7 ± 1.9 μm/day (mean ± SEM [standard error of the mean], $n = 4$ dogs, 10 cutting and filling cones sampled from each). At this speed, evolving secondary osteons travel about 1 mm in 36 days. Newly remodeled secondary osteons (formed within the experimental period of the dog study) contained an average of 4.5 labels (administered 2 weeks apart); the incidence of resorption cavities is about one-third the incidence of labeled osteons.[59] These data are consistent with a remodeling cycle of about 12 weeks in dogs[59] compared with 6 weeks in rabbits[10] and 17 weeks in human beings.[10,34] This relationship is useful for extrapolating animal data to human applications. More recent experimental studies have shown that new secondary osteons may continue to fix bone labels for up to 6 months, indicating that terminal filling of the lumen is slow.[61]

Traumatic or surgical wounding usually results in intense but localized modeling and remodeling responses. After an osteotomy or placement of an endosseous implant, callus formation and resorption of necrotic osseous margins are modeling processes; however, internal replacement of the devitalized cortical bone surrounding these sites is a remodeling activity. In addition, a gradient of localized remodeling disseminates through the bone adjacent to any invasive bone procedure. This process, called the *regional acceleratory phenomenon*, is an important aspect of postoperative healing.[34,62] Orthodontists can take advantage of the intense postoperative modeling and remodeling activity (1) to position a maxilla orthopedically with headgear, occlusal bite plates, or cervical support within a few weeks after a LeFort osteotomy and (2) to finish orthodontic alignment of the dentition rapidly after orthognathic surgery.[21,63]

Modeling and remodeling are controlled by an interaction of metabolic and mechanical signals. Bone modeling is largely under the integrated biomechanical control of functional applied loads. Hormones and other metabolic agents have a strong secondary influence, particularly during periods of growth and advanced aging. Paracrine and autocrine mechanisms, such as local growth factors and prostaglandins, can override the mechanical control mechanism temporarily during wound healing.[64] Remodeling responds to metabolic mediators such as PTH and estrogen primarily by varying the rate of bone turnover. Bone scans with ^{130}Te-bisphosphate, a marker of bone activity, indicate that the alveolar processes, but not the basilar mandible, have a high remodeling rate.[65,66] Uptake of the marker in alveolar bone is similar to uptake in trabecular bone of the vertebral column. The latter is known to remodel at a rate of about 20% to 30% per year compared with most cortical bone, which turns over at a rate of 2% to 10% per year.[50] Metabolic mediation of continual bone turnover provides a controllable flow of calcium to and from the skeleton.

Structural and Metabolic Fractions

The structural fraction of cortical bone is the relatively stable outer portion of the cortex; the metabolic fraction is the highly reactive inner aspect (Fig. 4-31, *A*). The primary metabolic calcium reserves of the body are found in trabecular bone and the endosteal half of the cortices, and thus these regions constitute the metabolic fraction. Analogous to orthodontic wires, the stiffness and strength of a bone are related directly to its cross-sectional area. Diaphyseal rigidity quickly is enhanced by adding a circumferential lamella at the periosteal surface. Even a thin layer of new osseous tissue at the periosteal surface greatly enhances bone stiffness because it increases the diameter of the bone. In engineering terms, cross-sectional rigidity is related to the second moment of the area. The same general relationship of round wire diameter and stiffness (strength) is well known to orthodontists. The rigidity of a wire increases as the fourth power of diameter.[67] Thus, when a relatively rigid material (bone or wire) is doubled in diameter, the stiffness increases 16 times.

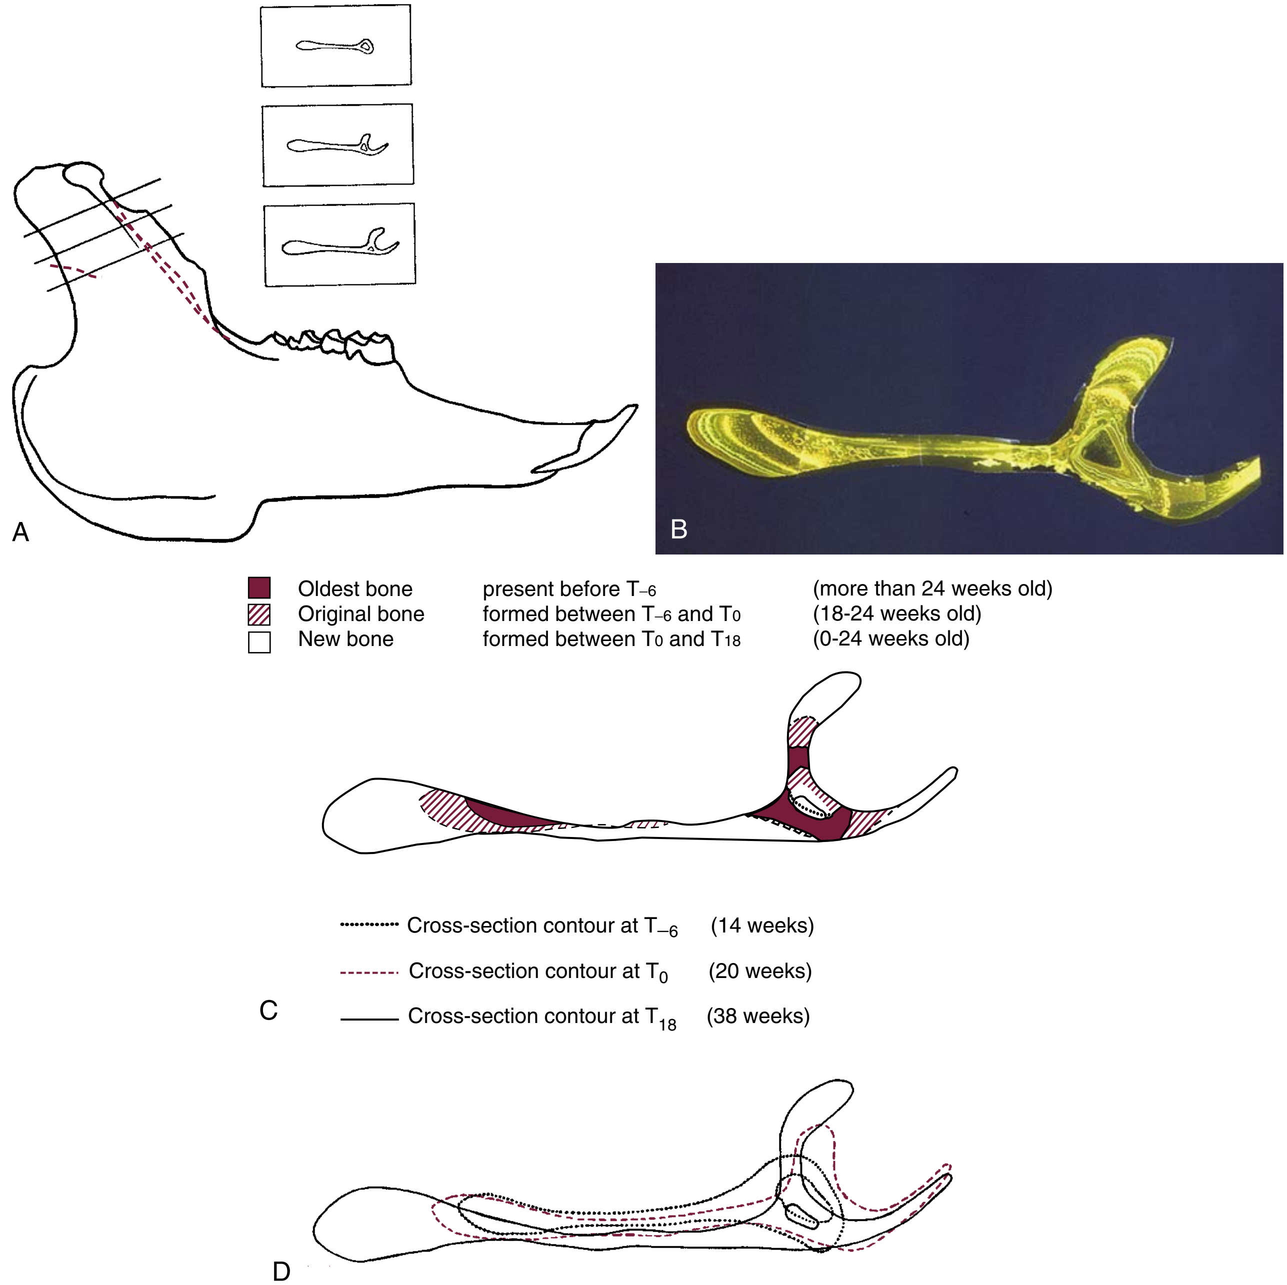

FIGURE 4-28 **A,** Schematic drawing of a rabbit mandible showing the plane of sectioning in the subcondylar region of the ramus. **B,** Fluorescent light photomicrographs of the most inferior section are arranged in a composite. The weekly deposition of bone labels over 4 months shows the patterns of bone modeling and remodeling associated with the growth and development of the subcondylar region. **C,** Based on the uptake of bone labels, the age of specific areas in a given cross section can be determined accurately. **D,** Because the subcondylar region of the ramus is growing superiorly, superimposition of the three sections on the oldest bone gives an estimation of the patterns of bone resorption (catabolic modeling) associated with growth of the mandibular ramus. (From Noorda CB. *Modeling and Remodeling in the Cortical Bone of Both Growing and Mature Rabbits*. [Master's thesis]. San Francisco: University of the Pacific; 1986.)

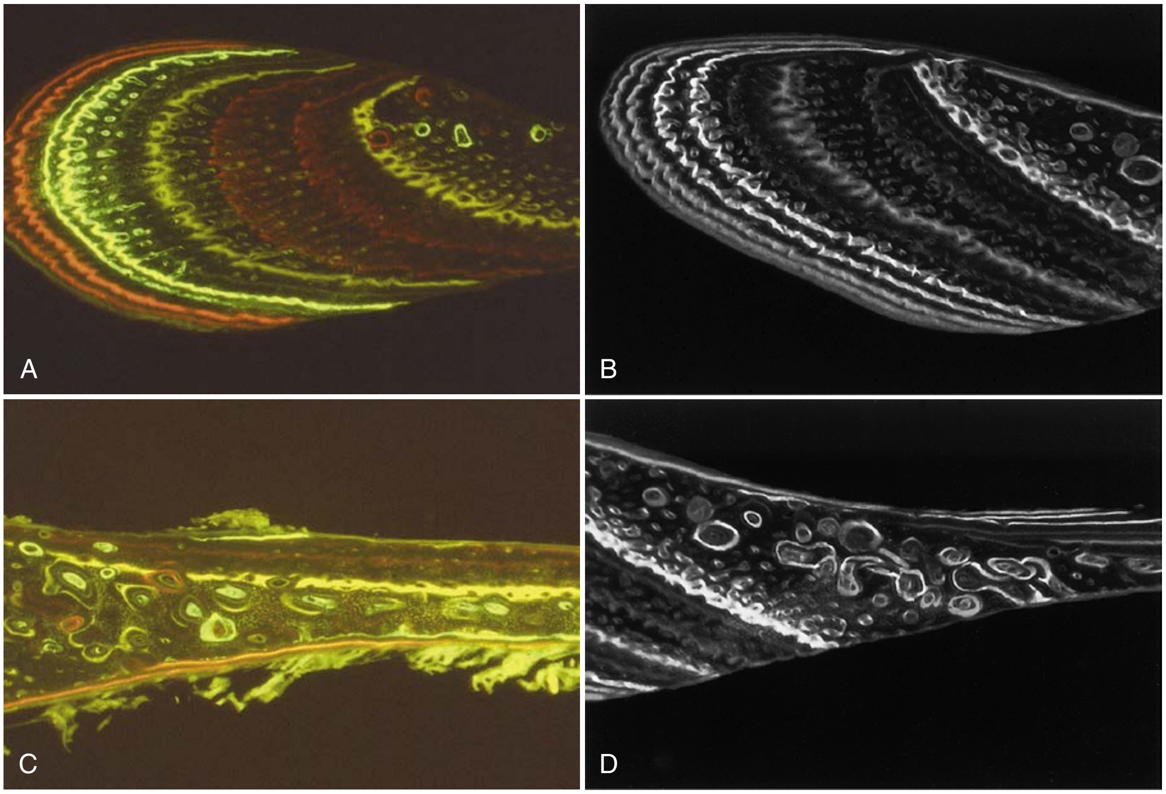

FIGURE 4-29 A, Fluorescent microscopy of weekly bone labels shows the patterns of anabolic modeling (bone apposition) in a rabbit. Note the diminishing space between the labels as growth slows and the animal achieves an adult skeletal form. B, A similar section from another rabbit in the same study shows the consistency of the growth pattern. C, In the first rabbit, the adjacent microscopic field shows several sites of bone remodeling in primary cortical bone formed about 6 to 12 weeks earlier. D, In the second rabbit, the adjacent microscopic field shows a consistent pattern of remodeling of new cortical bone at about 6 to 12 weeks after formation. (From Noorda CB. *Modeling and Remodeling in the Cortical Bone of Both Growing and Mature Rabbits*. [Master's thesis]. San Francisco: University of the Pacific; 1986.)

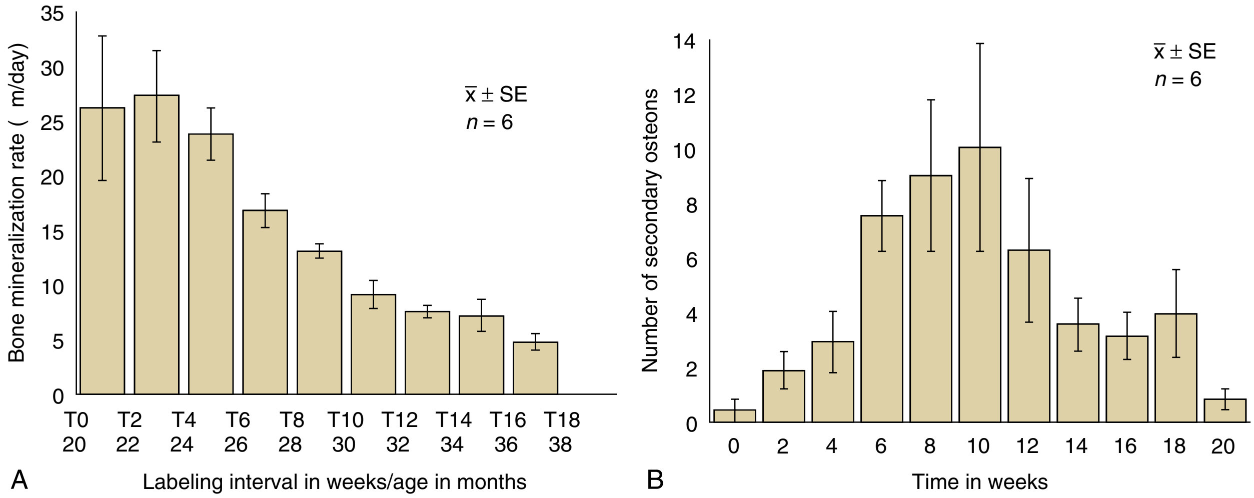

FIGURE 4-30 A, Age-related changes in the rate of periosteal apposition that occur in the posterior border of the mandibular ramus of the rabbit. Note the progressive decrease in the rate of periosteal bone apposition as the adolescent animals mature. B, Remodeling of new cortical bone. The highest incidence of remodeling to secondary osteons occurs when new cortical bone is 6 to 12 weeks old. (From Noorda CB. *Modeling and Remodeling in the Cortical Bone of Both Growing and Mature Rabbits*. [Master's thesis]. San Francisco: University of the Pacific; 1986.)

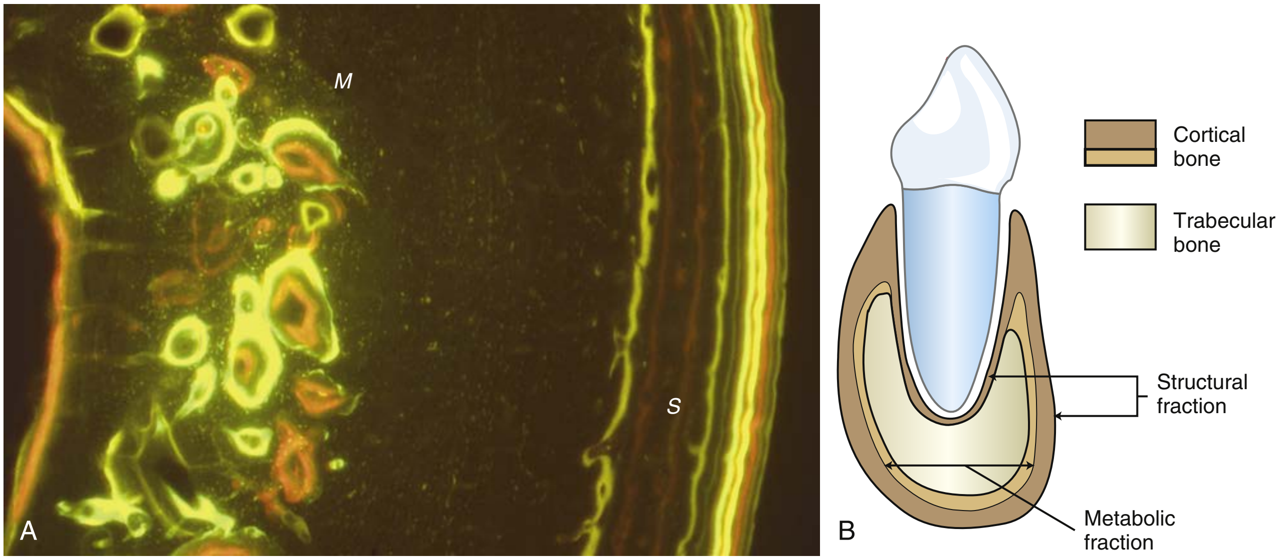

FIGURE 4-31 A, The structural (*S*) and metabolic (*M*) fractions of cortical bone are revealed by multiple fluorochrome labeling of a rabbit femur during the late growth and early adult periods. Continuing periosteal bone formation (*right*) contributes to structural strength, and high remodeling of the endosteal half of the compacta provides a continual supply of metabolic calcium. **B**, Structural and metabolic fractions of bone in the mandible. (Adapted from Roberts WE, et al. *Bone Dynamics in Orthodontic and Orthopedic Treatment: Craniofacial Growth Series*. Vol. 27. Ann Arbor: University of Michigan Press; 1991.)

The addition of new osseous tissue at the endosteal (inner) surface has little effect on overall bone strength. Structurally, the long bones and mandible are modified tubes—an optimal design for achieving maximal strength with minimal mass.[32] Within limits, loss of bone at the endosteal surface or within the inner third of the compacta has little effect on bone rigidity. The inner cortex can be mobilized to meet metabolic needs without severely compromising bone strength (Fig. 4-31, *B*); this is the reason patients with osteoporosis have bones with a normal diameter but thin cortices. Even under severe metabolic stress, the body follows a cardinal principle of bone physiology: maximal strength with minimal mass.[68]

BONE METABOLISM

Orthodontists and dentofacial orthopedists manipulate bone. The biomechanical response to altered function and applied loads depends on the metabolic status of the patient. Bone metabolism is an important aspect of clinical medicine that is directly applicable to orthodontics and orthopedics. This section discusses the fundamentals of bone metabolism with respect to clinical practice.

The skeletal system is composed of highly specialized mineralized tissues that have structural and metabolic functions. Structurally, lamellar, woven, composite, and bundle bone are unique types of osseous tissues adapted to specific functions. Bone modeling and remodeling are distinct physiologic responses to integrated mechanical and metabolic demands. Biomechanical manipulation of bone is the physiologic basis of orthodontics and facial orthopedics. Before addressing dentofacial considerations, an orthodontist must assess the patient's overall health status. Orthodontics is bone manipulative therapy, and favorable calcium metabolism is an important consideration. Because of the interaction of structure and metabolism, a thorough understanding of osseous structure and function is fundamental to patient selection, risk assessment, treatment planning, and retention of desired dentofacial relationships.[68,69]

Bone is the primary calcium reservoir in the body (Fig. 4-32). About 99% of the calcium in the body is stored in the skeleton. The continual flux of bone mineral responds to a complex interaction of endocrine, biomechanical, and cell-level control factors that maintain the serum calcium level at about 10 mg/dL.

Calcium homeostasis is the process by which mineral equilibrium is maintained. Maintenance of serum calcium levels at about 10 mg/d is an essential life support function. Life is thought to have evolved in the sea; calcium homeostasis is the mechanism of the body for maintaining the primordial mineral environment in which cellular processes evolved.[45] Calcium metabolism is one of the fundamental physiologic processes of life support. When substantial calcium is needed to maintain the critical serum calcium level, bone structure is sacrificed (see Fig. 4-30). The alveolar processes and basilar bone of the jaws also are subject to metabolic bone loss.[70] Even in cases of severe skeletal atrophy, the outer cortex of the alveolar process and the lamina dura around the teeth are preserved. This preservation is analogous to the thin cortices characteristic of osteoporosis.

Calcium homeostasis is supported by three temporally related mechanisms: (1) rapid (instantaneous) flux of calcium from bone fluid (which occurs in seconds); (2) short-term response by osteoclasts and osteoblasts (which extends from minutes to days); and (3) long-term control of bone turnover (over weeks to months). Precise regulation of serum calcium levels at about 10 mg/dL is essential for nerve conductivity and muscle function. A low serum calcium level can result in tetany and death. A sustained, high serum calcium level often is a manifestation of hyperthyroidism and some malignancies. Hypercalcemia may lead to kidney stones

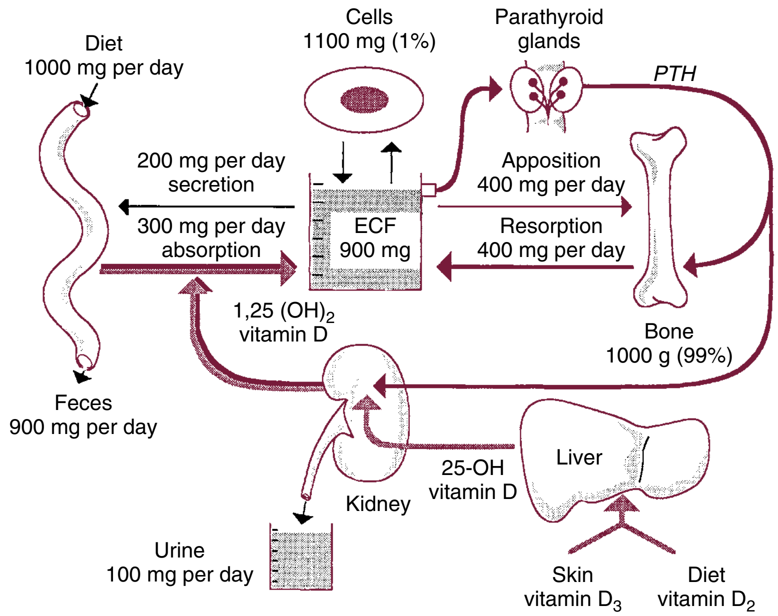

FIGURE 4-32 Calcium metabolism is a complex physiologic process. Maintaining zero calcium balance requires optimal function of the gut, parathyroid glands, bone, liver, and kidneys. Parathyroid hormone (*PTH*) and the active metabolite of vitamin D, 1,25-dihydroxycholecalciferol, are the major hormones involved. (Adapted from Roberts WE, et al. *Bone Dynamics in Orthodontic and Orthopedic Treatment: Craniofacial Growth Series*. Vol. 27. Ann Arbor: University of Michigan Press; 1991.)

and dystrophic calcification of soft tissue. Normal physiology demands precise control of the serum calcium level.[45,69,70]

CALCIUM CONSERVATION

Calcium conservation is the aspect of bone metabolism that involves preservation of skeletal mass. A failure in calcium conservation because of one problem or a combination of metabolic and biomechanical problems may leave a patient with inadequate bone mass for reconstructive dentistry, including orthodontics and orthognathic surgery. The kidney is the primary calcium conservation organ in the body (see Fig. 4-30). Positive calcium balance normally occurs during the growing period and for about 10 years thereafter. Peak skeletal mass is attained between 25 and 30 years. Zero calcium balance (see Fig. 4-30) is the ideal metabolic state for maintaining skeletal mass. Preservation of bone requires a favorable diet, endocrine balance, and adequate exercise.[68,69]

Endocrinology

Peptide hormones (e.g., PTH, growth hormone, insulin, and calcitonin) bind receptors at the cell surface and may be internalized with the receptor complex. Steroid hormones (e.g., vitamin D, androgens, and estrogens) are lipid soluble and pass through the plasma membrane to bind receptors in the nucleus.[68,69] PTH increases serum calcium by direct and indirect vitamin D–mediated effects. Clinically, a major effect of 1,25-DHCC is induction of active absorption of calcium from the gut. Sex hormones have profound effects on bone. Androgens (testosterone and other anabolic steroids) build and maintain musculoskeletal mass. The primary hypertrophic effect of androgens is to increase muscle mass. The anabolic effect on bone is a secondary biomechanical response to increase loads generated by the enhanced muscle mass. Estrogen, however, has a direct effect on bone; it conserves skeletal calcium by suppressing the activation frequency of bone remodeling.[71] At menopause, enhanced remodeling activation increases turnover.[72] Because a slightly negative calcium balance is associated with each remodeling event, a substantial increase in the turnover rate can result in rapid bone loss, leading to symptomatic osteoporosis. Even young women are susceptible to significant bone loss if the menstrual cycle (menses) stops.[36] Bone loss is a common problem in women who have low body fat and who exercise intensely (e.g., running or gymnastics), and in women who are anorexic.[73]

Estrogen replacement therapy (ERT) was widely recommended for calcium conservation and the prevention of osteoporosis in postmenopausal women.[74,75] However, the increased incidence and progression of breast cancer have greatly decreased the use of ERT.[76] The antiestrogen tamoxifen is used to treat some forms of breast cancers. Fortunately, in postmenopausal women, tamoxifen has a beneficial effect on bone similar to that of estrogen.[77] Raloxifene (Evista) has been shown to reduce the risk of osteoporosis and heart disease without increasing the risk of breast cancer. Some studies have even shown a substantial anticancer protective effect.[78] The reader is referred to the 5th edition of the textbook for additional details.

METABOLIC BONE DISEASE

Osteoporosis is a generic term for very low bone mass (osteopenia). The most important risk factor for the development of osteoporosis is age: after the third decade, osteopenia is related directly to longevity. Other high-risk factors are (1) a history of long-term glucocorticoid treatment, (2) slight stature, (3) smoking, (4) menopause or dysmenorrhea, (5) lack of or little physical activity, (6) low-calcium diet, (7) excessive consumption of alcohol, (8) vitamin D deficiency, (9) kidney failure, (10) liver disease (cirrhosis), and (11) a history of fractures. These risk factors are effective in identifying 78% of those with the potential for osteopenia.[79,80] This is a good screening method for skeletally deficient dental patients. However, one must realize that more than 20% of individuals who eventually develop osteoporosis have a negative history for known risk factors. Any clinical signs or symptoms of low bone mass (e.g., low radiographic density of the jaws, thin cortices, or excessive bone resorption) are grounds for referral. A thorough medical workup, including a bone mineral density measurement, usually is necessary to establish the diagnosis of osteopenia. The term *osteoporosis* usually is reserved for patients with evidence of fracture or other osteoporotic symptoms. The treatment of metabolic bone diseases such as osteoporosis depends on the causative factors. Medical management of these often complex disorders is best handled by physicians specifically trained in bone metabolism.[68,69]

An increasing number of adults are seeking orthodontic treatment. Because all orthodontic and facial orthopedic therapy requires bone manipulation, orthodontists should have a detailed knowledge of bone physiology. All healthcare practitioners can play an important role in screening patients with high-risk lifestyles. Arresting the progression of metabolic bone disease is preferable to treating the condition after debilitating symptoms appear. A carefully collected history is the best screening method for determining which patients should be referred for a thorough metabolic workup. No age limit is specified for orthodontic treatment; however, clinicians must assess carefully the probability of metabolic bone disease.[68,69]

In addition to osteoporosis, orthodontists should be particularly vigilant for osteomalacia, a disease of poor bone mineralization associated with vitamin D deficiency,[50] and for renal osteodystrophy, a related condition in patients with compromised kidney function.[81]

Orthodontics usually is contraindicated in patients with active metabolic bone disease because of excessive resorption and poor rates of bone formation. If the metabolic problems (particularly negative calcium balance) are resolved with medical treatment, these patients can be treated orthodontically, assuming that sufficient skeletal structure remains. In fact, some individuals with osteoporosis retain near-normal jaw and alveolar bone, probably because they have healthy oral structures that are loaded normally. Apparently, under these circumstances, the disease preferentially attacks bone and other parts of the body with a less optimal mechanical environment.[68,69,82] A study of all adult female dental patients at Indiana University School of Dentistry showed that about 65% were at high risk for developing osteoporosis (these women were estrogen deficient or had at least two other risk factors).[83]

Osteoporosis is the most common metabolic bone disease, but orthodontic patients can be affected by many other osseous pathologies, such as renal osteodystrophy, hyperparathyroidism, hypoparathyroidism, hyperthyroidism, and osteomalacia osteogenesis imperfecta. In addition, bone can be compromised by a number of other systemic diseases. See Roberts et al.[23] for an orthodontically oriented review.

With the use of more potent bisphosphonates to treat osteoporotic patients, including Reclast, the question has arisen whether tooth movement is retarded, or even more important, will osteonecrosis of the jaw (ONJ)[84] develop after tooth extractions for orthodontics or miniscrew placement? Animal studies suggest that while potent bisphosphonates such as zoledronic acid greatly suppress bone remodeling,[85,86] they do not abolish the formation of new osteons at a site of injury. In other words, bone remodeling at a tissue level does occur in response to injury in an animal model that has received potent and high-dose bisphosphonates.

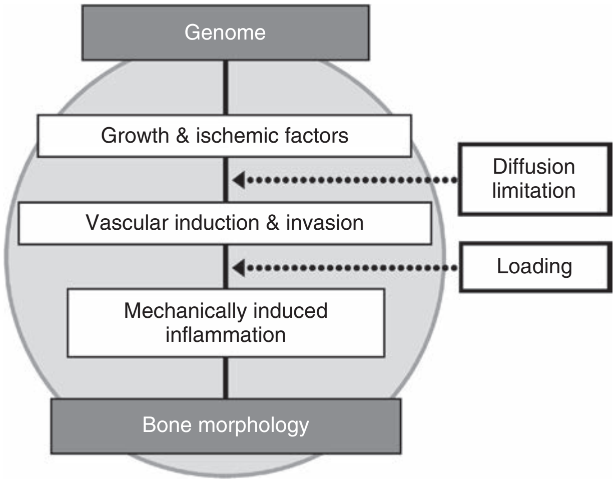

FIGURE 4-33 The genome dictates bone morphology by a sequence of three genetic mechanisms: (1) growth and ischemic factors, (2) vascular induction and invasion, and (3) mechanically induced inflammation. The latter two are influenced by two major physical influences: (1) diffusion limitation for maintaining viable osteocytes and (2) mechanical loading history. (From Roberts WE, Hartsfield JK. Bone development and function: genetic and environmental mechanisms. *Semin Orthod.* 2004;10(2):102.)

BIOMECHANICS

Mechanical loading is critical for skeletal health. An essential element of bone biomechanics is the inflammatory control of bone development, the adaptation to applied loads, and the response to pathologic challenges. The physiologic mechanism for controlling bone morphology involves inherent (genetic) and environmental (epigenetic) factors. There are three genetic mechanisms: (1) growth and ischemic factors, (2) vascular induction and invasion, and (3) mechanically induced inflammation. The latter two are influenced by two major physical influences: (1) diffusion limitation for maintaining viable osteocytes and (2) mechanical loading history (Fig. 4-33).[1]

Both bone formation and resorption are controlled at the cellular level by inflammatory mechanisms.[87] Thus, inflammation is an important factor in the mediation of bone physiology and pathology. Normal bone modeling and remodeling are controlled by inflammatory processes, both from a direct and indirect perspective. The P2X7 receptor is an important genetic mechanism for the production of inflammatory cytokines. It plays a crucial role in bone biology and inflammation, but it has no significant effect on teeth or alveolar bone morphology.[88] Thus, P2X7 knockout mice (animals with a deactivated gene) are a good model for defining the role of inflammatory cytokines in the tooth movement and alveolar adaptation to orthodontics loads. Skeletal adaptations, such as the orthodontic response, are related to the principal stress patterns in the periodontal ligament, and the P2X7 receptor plays a significant role in their mechanotransduction.[89]

Experiments in mice with deactivated *P2X7* genes have demonstrated that a principal function of the gene is the promotion of necrotic tissue metabolism, by ensuring a normal acute-phase inflammatory response. An increased pattern of functional loading generates damage in affected musculoskeletal tissue, and there is a subsequent pain response that limits function during the initial healing stage. All forms of musculoskeletal adaptation to functional and applied loads involves an interaction of inflammatory mechanisms to stimulate bone cell activity, heal tissue damage, and limit function during the adaptive process. However, it is important to remember that the genetic mechanisms active in bone have interactive functions throughout the body. The receptor–activator system of NF-κB ligand (TNFSF11, also known as RANKL, OPGL, TRANCE, and ODF), as well as the tumor necrosis factor (TNF)-family receptor RANK, are essential regulators of bone remodeling. Recently, RANKL and RANK were found to have an essential role in the brain in initiating fever,[90] another important inflammatory mechanism. Thus, genetic inflammatory mechanisms controlling bone physiology are just beginning to be understood at the systemic level. Control of most bone modeling and some remodeling processes are related to strain history, which usually is defined in microstrain (με) (deformation per unit length $\times 10^{-6}$).[91] Repetitive loading generates a specific response, which is determined by the peak strain.[92-96] In an attempt to simplify the often conflicting data, Frost[97] proposed the mechanostat theory. Reviewing the theoretic basis of this theory, Martin and Burr[33] proposed that (1) subthreshold loading of less than 200 με results in disuse atrophy, manifested as a decrease in modeling and an increase in remodeling; (2) physiologic loading of about 200 to 2500 με is associated with normal, steady-state activities; (3) loads exceeding the minimal effective strain (about 2500 με) result in a hypertrophic increase in modeling and a concomitant decrease in remodeling; (4) after peak strains exceed about 4000 με, the structural integrity of bone is threatened, resulting in pathologic overload. Figure 4-34 is a representation of the mechanostat. Many of the concepts and microstrain levels are based on experimental data.[33,98] The strain range for each given response probably varies among species and may be site-specific in the same individual.[21,33,93-96] However, the mechanostat provides a useful clinical reference for the hierarchy of biomechanical responses to applied loads.

Normal function helps build and maintain bone mass. Suboptimally loaded bones atrophy as a result of increased remodeling frequency and inhibition of osteoblast formation.[99] Under these conditions, trabecular connections are lost and cortices are thinned from the endosteal surface. Eventually the skeleton is weakened until it cannot sustain normal function. An increasing number of adults with a history of osteopenia caused by metabolic bone disease are seeking orthodontic treatment for routine malocclusions. Assuming that the negative calcium balance is corrected and adequate bone structure remains, patients with a history of osteoporosis or other metabolic bone disease are viable candidates for routine orthodontic therapy. The crucial factor is the residual bone mass in the area of interest after the disease process has been arrested (Fig. 4-35).

When flexure (strain) exceeds the normal physiologic range, bones compensate by adding new mineralized tissue at the periosteal surface. Adding bone is an essential compensating mechanism because of the inverse relationship between load (strain magnitude) and the fatigue resistance of bone.[100] When loads are less than 2000 με, lamellar bone can withstand millions of loading cycles, more than a lifetime of normal function. However, increasing the cyclic load to 5000 με, about 20% of the ultimate strength of cortical bone, can produce fatigue failure in 1000 cycles, which is achieved easily in only a few weeks of normal activity. Repetitive overload at less than one-fifth of the ultimate strength of lamellar bone (25,000 με, or 2.5% deformation) can lead to skeletal failure, stress fractures, and shin splints.

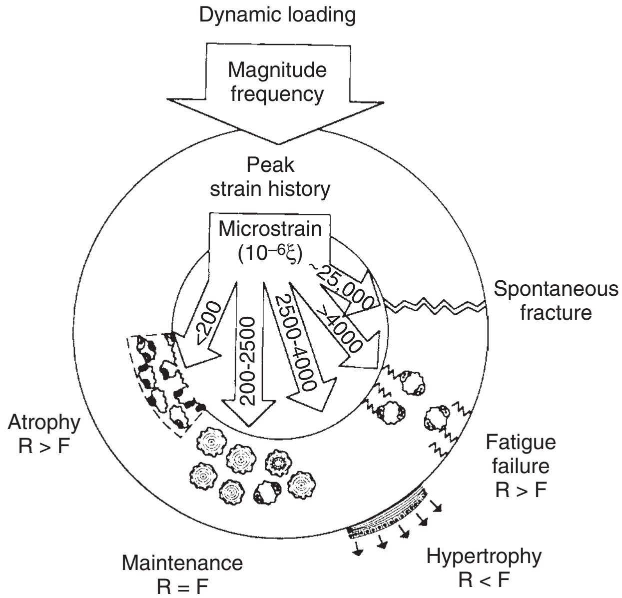

FIGURE 4-34 The mechanostat concept of Frost as defined by Martin and Burr. Bone formation (*F*) and resorption (*R*) are the modeling phenomena that change the shape or form (or both) of a bone. The peak strain history determines whether atrophy, maintenance, hypertrophy, or fatigue failure occurs. Note that the normal physiologic range of loading (Maintenance R + F) is only at less than 10% of maximal bone strength (spontaneous fracture). Fatigue damage can accumulate rapidly at greater than 4000 ∝ε.

From a dental perspective, occlusal prematurities or parafunction may lead to compromise of periodontal bone support. Localized fatigue failure may be a factor in periodontal clefting, alveolar recession, tooth oblation (cervical ditching), or TMJ arthrosis. Guarding against occlusal prematurities and excessive tooth mobility, while achieving an optimal distribution of occlusal loads, are important objectives for orthodontic treatment. The human masticatory apparatus can achieve a biting strength of more than 2200 N, or more than 500 lb of force.[101,102] Because of the high magnitude and frequency of oral loads, functional prematurities used during orthodontic treatment could contribute to isolated incidences of alveolar clefting (Fig. 4-36, *A*) and root resorption (Fig. 4-36, *B*). Excessive tooth mobility should be monitored carefully during active orthodontic treatment and retention. Prevention of occlusal prematurities is a particular concern in treating periodontally compromised teeth.

SUTURES

The facial sutures are important mediators of skeletal adaptation to craniofacial growth and biomechanical therapy.[103] Mechanical forces, both functional and therapeutic, regulate sutural growth by inducing sutural mechanical strain.[104] Expansion of the midpalatal suture often is a key objective in

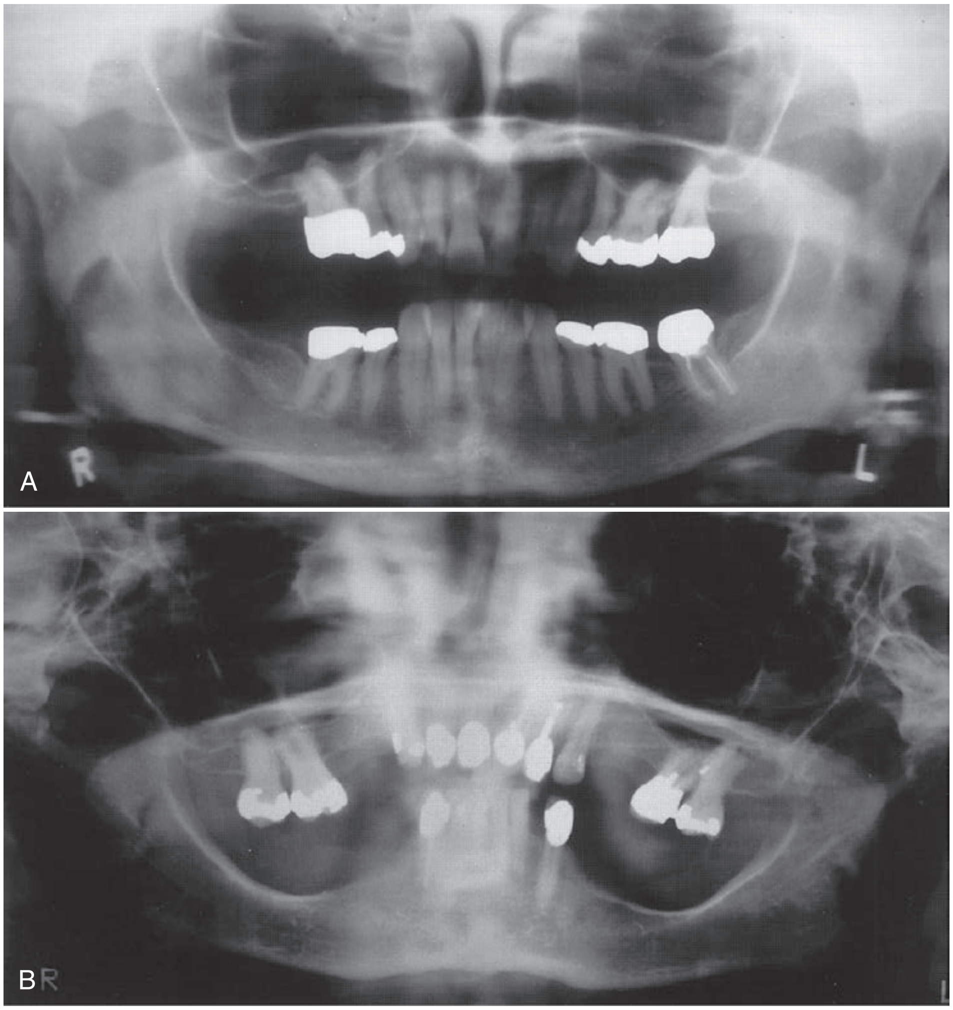

FIGURE 4-35 Two postmenopausal women with systemic osteopenia present widely varying patterns of lower posterior bone loss. **A,** Alveolar bone in the buccal segments is well preserved by functional loading of natural teeth. **B,** Severe resorption of the alveolar process and basilar mandible has occurred in the absence of adequate functional loading. (From Roberts WE. Fundamental principles of bone physiology, metabolism and loading. In: Naert I, et al., eds. *Osseointegration in Oral Rehabilitation.* London: Quintessence; 1993.)

dentofacial orthopedic treatment. Although the potential for sutural expansion has been appreciated since the middle of the nineteenth century, Andrew Haas[105] introduced the modern clinical concepts of rapid palatal expansion (RPE) in the last half of the twentieth century. RPE is very effective in growing children, but the skeletal response of the craniofacial sutures of adults is questionable. The nonsurgical RPE of young adult females was documented with a bone scintigraphy study, demonstrating a bone metabolic pattern consistent with both dental and skeletal effects.[7] Biomechanics studies using finite element models have helped explain the highly variable clinical reactions in adults, depending on if sutures are patent or fused.[106] Despite the long history of palatal expansion, little was known of the cell kinetics of osteogenesis and the bone remodeling response associated with it. Sutures and the PDL were widely assumed to have similar mechanisms of osseous adaptation. Chang et al.[107,108] compared the osteogenic reaction in the expanded midpalatal suture with orthodontically induced osteogenesis in the PDL of adjacent incisors (Figs. 4-37 to 4-40). The widened PDL resulted in direct osteogenic induction of new bone, whereas the adjacent expanded suture experienced hemorrhage, necrosis, and a wound-healing response. Vascular invasion of the blood clot in the expanded suture was a prerequisite for new bone formation. Chang et al.[108] also defined the angiogenic capillary budding process associated with the propagation of perivascular osteogenic cells (Fig. 4-41). After its vascularity had been reestablished, the expanded midpalatal suture and adjacent widened PDL produced new osteoblasts by the same mechanism. Pericytes, the osteogenic cells that are perivascular to the venules (Fig. 4-42), are the cells of origin for preosteoblasts. This vascularly mediated osteogenic mechanism for producing osteoblasts was described earlier in this chapter. (For the detailed cell-kinetic analysis that established this important mechanism, see Chang et al.)[107,108]

The role of perivascular cells in the origin of PDL osteoblasts first was reported in 1987.[109] Over the past decade, a number of investigators have reported the same mechanism for the production of osteoblasts throughout the body. Doherty

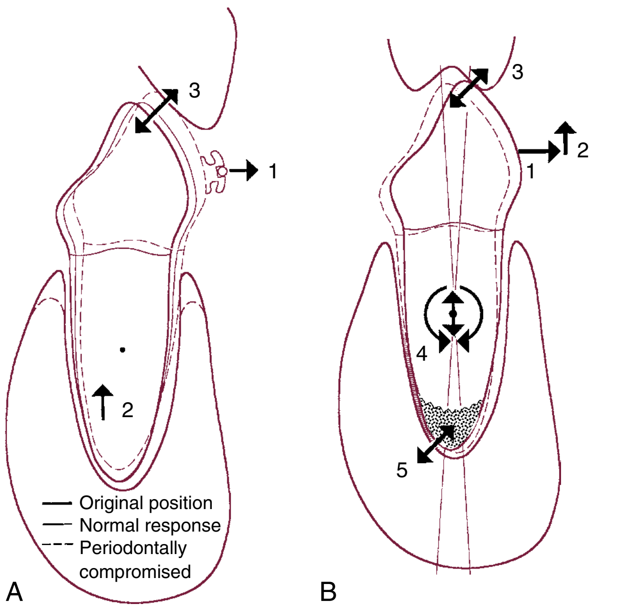

FIGURE 4-36 **A,** A moderate load in the buccal direction (1) results in tipping displacement of the crown. In the absence of vertical constraint, a normal healthy tooth would be expected to extrude slightly because of the inclined plane effect of the root engaging the tapered alveolus (2). As a result of diminished bone support and destruction of restraining collagen fibers at the alveolar crest, a periodontally compromised tooth may tip and extrude considerably more. Depending on the occlusion, this displacement may cause an occlusal prematurity (3). **B,** Orthodontic tipping (1) with an extrusive component (2) may produce an occlusal prematurity (3) and mobility (4). An individual tooth in chronic occlusal trauma is expected to fatigue the root apex continuously. This combination of physical failure in a catabolic environment may lead to progressive root resorption (5).

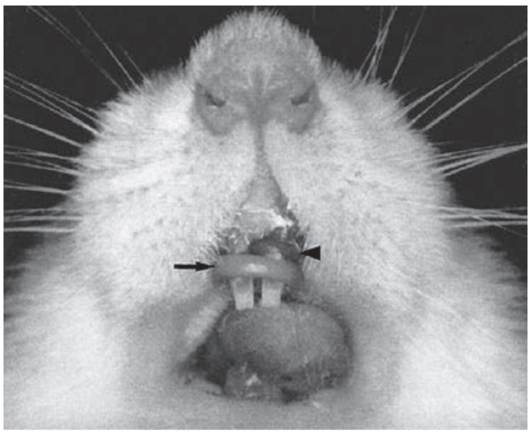

FIGURE 4-37 An expansion appliance is placed on the maxillary incisors of a rat. A 1-mm-diameter elastomeric ring (*arrowhead*) was fitted into the left incisor; a 2-mm-diameter elastomeric ring (*arrow*) encircled both incisors, 2 mm from cutting edges. The 2-mm ring constricts the incisors while the interproximal elastic elicits a parallel separation of the interpremaxillary suture. (From Chang H-N, et al. Angiogenesis and osteogenesis in an orthopedically expanded suture. *Am J Orthod Dentofac Orthop*. 1997;111(4):382-90.)

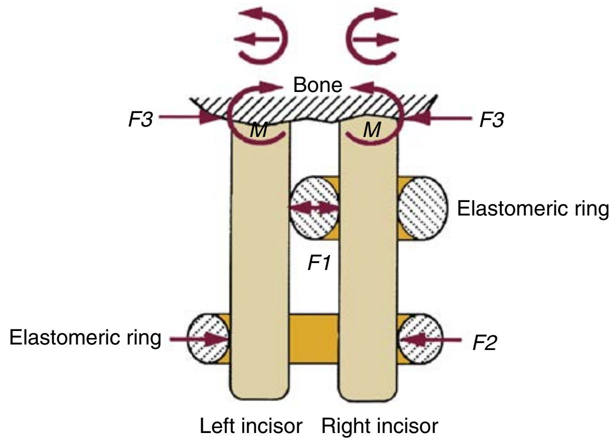

FIGURE 4-38 Forces (*F*) and moments (*M*) on a tooth. *F1* and *F2* were produced by inner and outer elastomeric rings, respectively. This illustration of the device demonstrates the formation of a couple that resulted in parallel separation of the interpremaxillary suture. As measured in a pilot study using a Dontrix tension gauge, the outer elastomeric ring exerted about 200 *g* of initial separation force (*F2*), of which 90 *g* remained at the end of day 3. This force level (90 *g*) is suitable for premaxillary expansion in rats. (From Chang H-N, et al. Angiogenesis and osteogenesis in an orthopedically expanded suture. *Am J Orthod Dentofac Orthop*. 1997:111(4):382-90.)

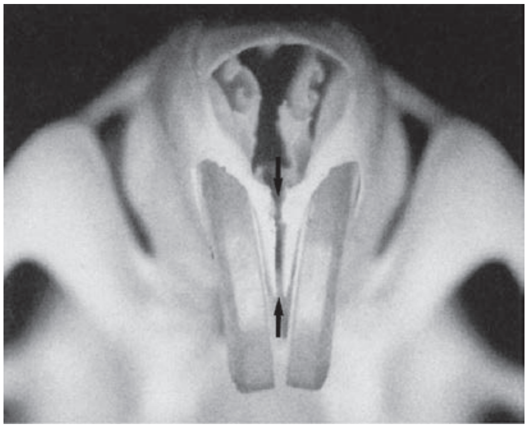

FIGURE 4-39 A dry skull expanded as illustrated in Figure 4-36 shows parallel separation of the interpremaxillary suture (*arrow*). (From Chang H-N, et al. Angiogenesis and osteogenesis in an orthopedically expanded suture. *Am J Orthod Dentofac Orthop*. 1997;111(4):382-90.)

et al.[110] recently reviewed the literature and provided evidence that vascular pericytes express osteogenic potential in vivo and in vitro. What is now clear is that perivascular osteogenesis is not a mechanism unique to the PDL and sutures, but rather it is the source of osteoblasts all over the body under a variety of osteogenic conditions.

Parr et al.[111] used an innovative endosseous implant mechanism to expand the nasal bones in young adult rabbits with forces from 1 to 3 N. Injection of multiple fluorochrome bone labels documented the bone modeling and remodeling reactions that occurred not only adjacent to the suture but also throughout the nasal bones. Expansion of a suture results in

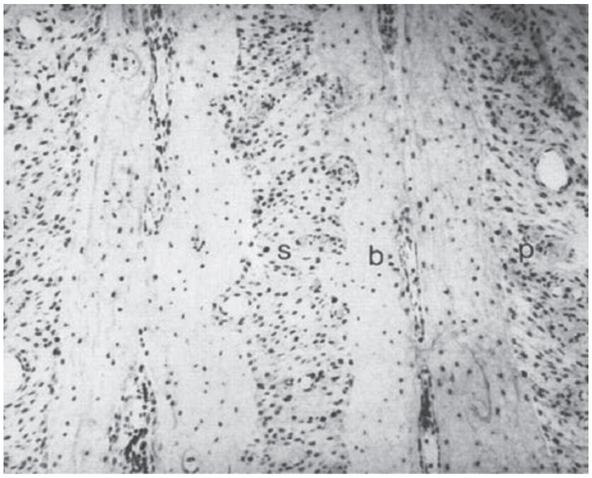

FIGURE 4-40 Photomicrograph of a sagittal section of the interpremaxillary suture, showing the relationship of expanded suture (*s*), alveolar bone (*b*), and periodontal ligament (*p*). (Stained with hematoxylin and eosin; original magnification ×40.) (From Chang H-N, et al. Angiogenesis and osteogenesis in an orthopedically expanded suture. *Am J Orthod Dentofac Orthop*. 1997;111(4):382-90.)

a regional adaptation of adjacent bones similar to the postoperative regional acceleratory phenomenon that is characteristic of bone wound healing.[33] Parr et al.[111] described the bone formation rate and mineral apposition rate for new bone formed in the suture (Figs. 4-43 to 4-45). Sutural expansion, relative to load decay, is shown for repeatedly reactivated 1- to 3-N loads (Fig. 4-46). Osseointegrated implants were excellent abutments for sutural expansion mediated by loads as large as 3 N.

Overall, expanded sutures are less efficient at initiating osteogenesis because of postactivation necrosis.[107] After a wound-healing response has occurred to reestablish sutural vitality, the vascularly mediated origin of osteoblasts is the same as for the PDL and other skeletal sites. Expansion of a suture results in a regional acceleration of bone adaptive activity, which allows for extensive adaptation of the affected bones to new biomechanical conditions. These results indicate that sutural expansion within physiologic limits is a clinically viable means of repositioning the bones of the craniofacial complex to improve aesthetics and function. With respect to fundamental bone physiology, sutural expansion is similar to surgically mediated distraction osteogenesis. Using sequential labels of ^{3}H-thymidine and bromodeoxyuridine in rabbits, Sim[112] demonstrated that the osteoblast histogenesis sequence for evolving secondary osteons was a perivascular process (Fig. 4-47) similar to that previously demonstrated for the PDL[109] and the intermaxillary suture.[107,108] The Sim data confirmed the hypothesis that the perivascular connective tissue cells proliferate and migrate along the surface of the invading capillaries or venules. Figure 4-48 is a three-dimensional perspective of a remodeling focus (cutting/filling cone) in cortical bone, which demonstrates that perivascular cells, near the head of the proliferating blood vessel, are the source of osteoblasts for the filling cone. Confirmation of a perivascular origin of osteoblasts in PDL, sutures, and cortical bone remodeling foci strongly suggests that all osteoblasts, at least in the peripheral skeleton, are derived from perivascular precursors. These data suggest that less differentiated osteogenic cells grow along the surface of bone-related blood vessels (capillaries and venules) as they invade blood clots or other connective tissue spaces in preparation for osteogenesis. From a clinical perspective, the perivascular origin of osteoblasts confirms an important surgical principle: preservation of the blood supply is essential for optimal healing of bone.

Maxillary protraction in skeletal Class III patients is particularly effective in the mixed dentition,[113] but bone biomechanics studies have failed to demonstrate the advantage of expanding the palate at the same time to enhance the sagittal response.[114] Determining bone age from hand-wrist films radiographic analysis is effective for screening patients most likely to have a positive response to maxillary protraction.[115] Recently, miniplates for anchorage of intermaxillary elastics have proven to be very effective for changing detrimental growth patterns.[116,117]

DISTRACTION OSTEOGENESIS

Distraction osteogenesis (DO) is a surgical procedure for reconstructing skeletal deformities of the skeleton, jaws, and alveolar processes. A corticotomy (osteotomy) divides the bone into segments, or if there is an intervening suture or PDL, the bone that is resisting movement is removed. A surgically assisted RPE is the most common distraction procedure used in orthodontics. Distraction of the PDL is a method for achieving rapid tooth movement,[118] but the method is too invasive for routine clinical procedures.

For DO of the maxilla, mandible, and alveolar process, the osseous segments are progressively moved apart, generating new bone in the defect. The desired position of the segments is achieved in the distraction phase. The segments are then retained, allowing the gap to fuse, and the newly generated bone remodels into a more mature structure (consolidation phase). A particular advantage of distraction osteogenesis is the simultaneous increase in length and volume of the investing soft tissues. This variation of the bone-lengthening procedure, introduced to orthopedic surgery by Ilizerov to lengthen limbs,[119] is now used extensively by reconstructive plastic and maxillofacial surgeons for the correction of micrognathia, midface deficiencies, and orbital anomalies in patients with craniofacial deformities. Although the procedure has been used effectively for some mandibular problems,[120] it has been problematic in some patients.[121] DO is widely used for maxillary deficiencies, for which favorable follow-up has been reported.[122] Surgically assisted protraction of the maxilla is an effective procedure, particularly in patients with craniofacial anomalies.[123] When all the bony attachments are cut for a structure such as the maxilla, it is free to move in any direction dictated by the applied biomechanics.[124] Much like a suture, the osseous margins can resorb if exposed to compression or become bone-forming surfaces when exposed to tension. Rigid external distraction has evolved as superior to a face mask for controlling the protraction and vertical position of the maxilla.[125] Miniimplants and miniscrews have proved to be effective for controlling osteotomy segments under some circumstances.[126] New bone can be generated in the alveolar process, and teeth can be moved into it.[127] This method can be used for rapid retraction of canines or correction of tooth size–to–arch length discrepancies.[128]

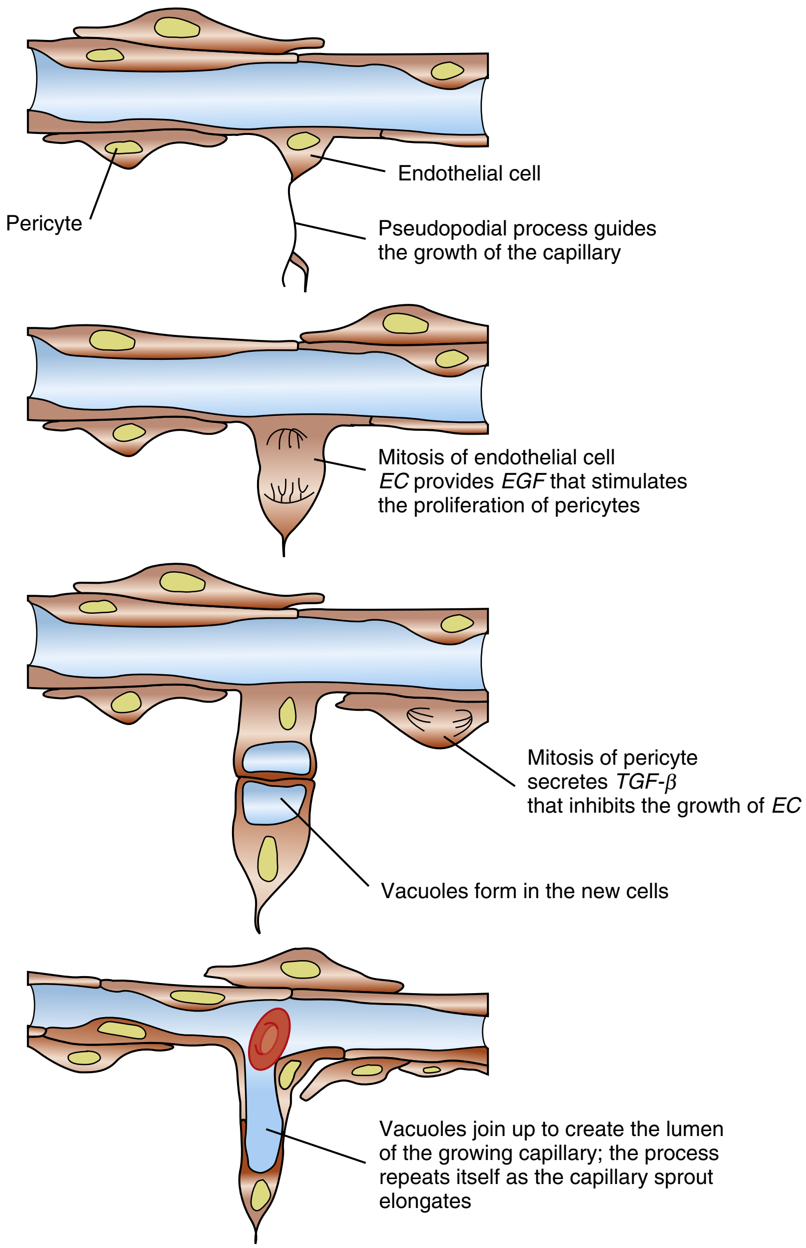

FIGURE 4-41 Angiogenesis involves a well-defined sequence of capillary budding followed by an extension of the perivascular network of pericytes, which are the source of osteoprogenitor cells. *EC*, Endothelial cell; *EGF*, epidermal growth factor; *TGF-β*, transforming growth factor β. ORTHODONTIC TOOTH MOVEMENT

Figure 4-49 illustrates a typical tooth movement response after application of a moderate, continuous load (0.2 to 0.5 N, or about 20 to 50 g). The orthodontic response is divided into three elements of tooth displacement: initial strain, lag phase, and progressive tooth movement. Initial strain of 0.4 to 0.9 mm occurs in about 1 week[21,129,130] because of PDL displacement (strain), bone strain, and extrusion (Fig. 4-50). The initial deformation response varies according to the width of the PDL, root length, anatomic configuration, force magnitude, occlusion, and periodontal health. Initial tooth displacement occurs within seconds,[131,132] but actual compression of the PDL requires 1 to 3 hours (see Fig. 4-50).

Unfortunately, no studies have used a broad range of invasive and noninvasive techniques to define completely the fluid and solid mechanics associated with initiating and sustaining tooth movement. Figure 4-47 is an attempt to unify a broad range of data. The fluid mechanics of root displacement in the PDL probably accounts for about 0.3 mm of crown movement.[133] Assuming an average anatomic configuration and bone strain of 1% (about 40% of ultimate strength) or less,[33] distortion of mineralized tissue caused by bending and creep[33,134] probably

accounts for about another 0.3 mm of the initial movement (see Chapters 2 and 13).[133]

Occlusal Trauma and Root Resorption

Extrusion in response to a horizontal load may be a component of initial displacement,[131] depending on the direction of the force, the point of application, and the axial inclination of the root. However, varying amounts of extrusion can be expected because of the inclined-plane effect of the root apex being compressed against the alveolus (see Fig. 4-50). The tendency toward extrusion and enhanced horizontal displacement during tooth movement varies directly with force magnitude and periodontal compromise of the dentoalveolar fibers at the

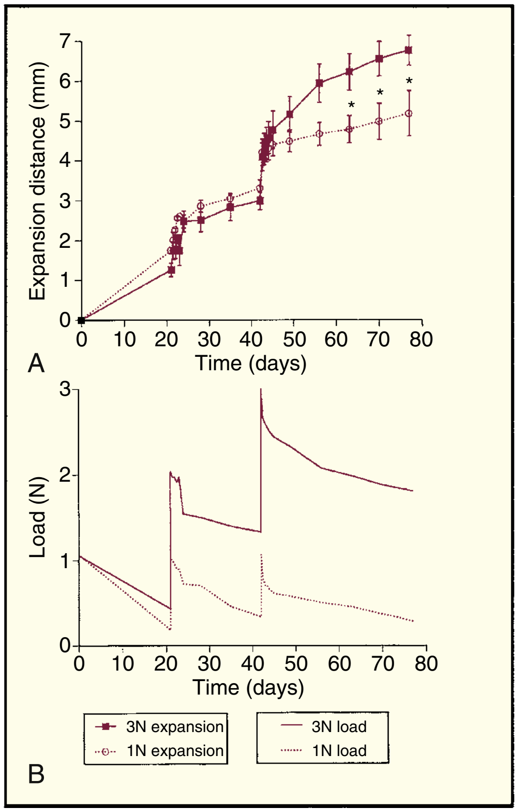

FIGURE 4-46 **A,** Sutural expansion measured as an increase in the distance between implants. The slope of this curve is the rate of sutural expansion; 3 N is significantly greater than 1 N at these time points ($p < 0.05$). **B,** Load on the suture as a function of time. Load was calculated using the formula $F = kx$, where k is the spring constant and x is the distance between implants. As sutural expansion occurs, force decays. Loads were placed at day 0 and adjusted at days 21 and 42. (From Parr JA, et al. Sutural expansion using rigidly integrated endosseous implants: an experimental study in rabbits. *Angle Orthod*. 1987;67(4):287.)

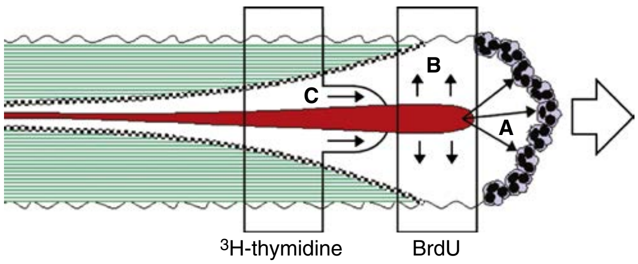

FIGURE 4-47 A cutting/filling cone in rabbit cortical bone shows the intravascular origin of osteoclasts **(A)**. The perivascular proliferation and migration away from the perivascular surface **(B)** are demonstrated by bromodeoxyuridine (BrdU) labeling and nuclear volume morphometry. A sequence of ^{3}H-thymidine labels from 2 to 72 hours before sacrifice and nuclear morphometric analysis revealed migration of proliferating perivascular cells in the direction of vascular invasion **(C)**. These data demonstrate the perivascular origin of osteoblasts in evolving secondary osteons. (From Sim Y. *Cell Kinetics of Osteoblast Histogenesis in Evolving Rabbit Secondary Haversian Systems Using a Double Labeling Technique with ^{3}H-Thymidine, and Bromodeoxyuridine*. [PhD thesis]. Indianapolis: Indiana University, School of Dentistry; 1995.)

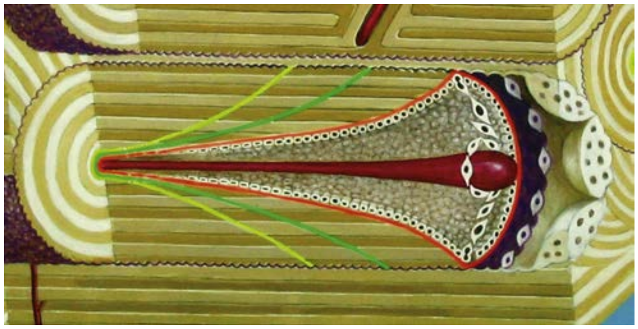

FIGURE 4-48 An evolving secondary osteon, moving to the right, shows a head of multinucleated osteoclasts (*right*), followed by a layer of mononuclear cells secreting cement substance (*blue*) to cover the scalloped resorption arrest line. The perivascular osteogenic cells proliferate and differentiate to osteoblasts, which form the new secondary osteon. Three sequential colored bone labels (*yellow*, *green*, and *orange*) allow the calculation of the velocity of the cutting/filling cone through cortical bone.

alveolar crest. Extrusion and occlusal prematurities are distinct possibilities, particularly for periodontally compromised teeth, and these conditions depend on the vertical constraint of a clinically applied load (see Fig. 4-36, *A*). If occlusal prematurity is a chronic periodontal trauma, root resorption may result because of catabolic cytokines in the PDL[135] or because of fatigue failure (see Fig. 4-36, *B*).

Remodeling/Repair of Root

Remodeling is the physiologic term for internal turnover of a mineralized tissue, without a change in its overall form. Pioneer histologic studies by Dr. Kaare Reitan (Fig. 4-51) in humans and in multiple species have demonstrated that root-resorption cavities are usually repaired (filled) with secondary cementum. In effect, this is "repair" of the root of a tooth. While cementum repair is very similar, it is not identical to remodeling of trabecular bone. The similarities between bone remodeling and root resorption are striking: Kimura and coworkers[136] concluded that the "odontoclasts" of root resorption have an intravascular origin similar to the osteoclasts of bone remodeling. Considering all available evidence, it appears that root resorption is a portion of the turnover process to replace damaged root structure. From a clinical perspective, it is important for orthodontists to consider mechanics and retention procedures that provide for adequate periods of atraumatic rest to allow resorbing sites to refill with cellular cementum.[137] Continuous forces, particularly if they are associated with traumatic occlusion, may result in permanent loss of root structure[41] if multiple sites of root resorption communicate before the initiation of their respective cementum repair phases. The reader is referred to the 5th edition of the textbook for additional details.

Induction of the Tooth Movement Response

Progressive displacement of the tooth relative to its osseous support stops in about 1 week (see Fig. 4-49), apparently because of areas of PDL necrosis (hyalinization). This lag phase varies considerably; it usually lasts 2 to 3 weeks but may be as long as 10 weeks.[129] Clinical experience and histologic studies[129,133] suggest that the duration of the lag phase is related directly to the patient's age, the density of the alveolar bone, and the extent

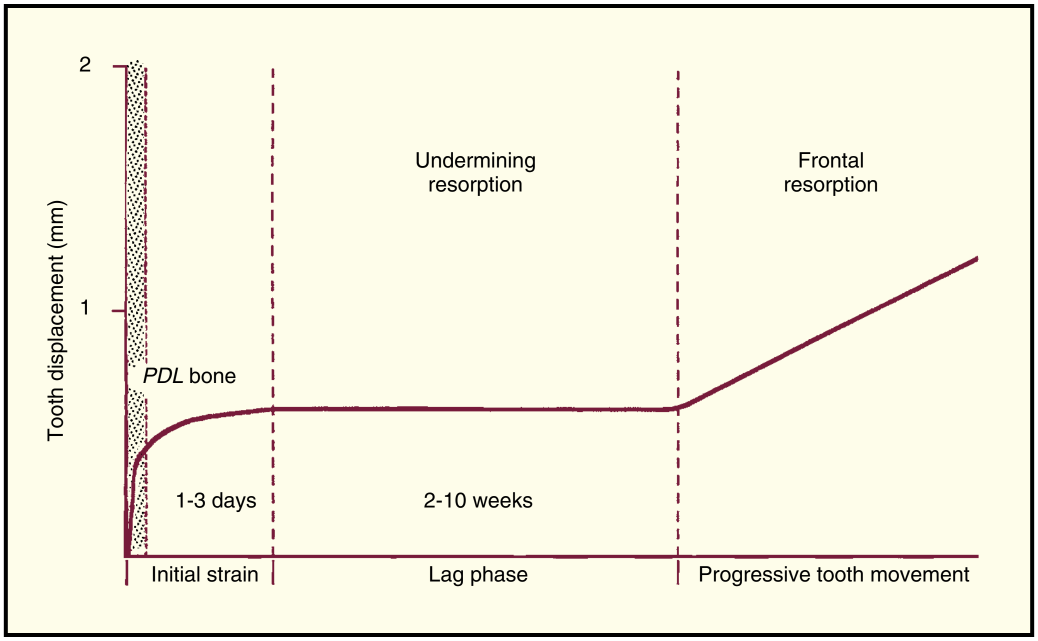

FIGURE 4-49 After application of a moderate orthodontic load (0.2 to 0.5 N, or about 20 to 50 g), tooth displacement is divided into three phases: (*1*) initial strain for 1 to 3 days in the periodontal ligament (*PDL*) and supporting bone; (*2*) a variable lag phase, in which undermining resorption removes bone adjacent to crushed areas in the PDL; and (*3*) progressive tooth movement when frontal resorption in the PDL limits the rate of orthodontic correction.

of PDL necrotic zones. After undermining resorption restores vitality to the necrotic areas of the PDL, tooth movement enters the secondary,[129,130] or progressive, tooth movement phase (see Fig. 4-49). Frontal resorption (modeling) in the PDL and initial remodeling events (resorption cavities) in cortical bone ahead of the advancing tooth (see Fig. 4-25, *A*) allow for progressive tooth movement at a relatively rapid rate. Gene expression during the initiation of tooth movement has recently been reviewed.[138] Low-energy laser irradiation enhances the initiation and velocity of tooth movement by increasing the expressions of matrix metalloproteinase-9, cathepsin K, and $\alpha_v\beta_3$ integrin.[139]

The mechanism of sustained tooth movement is a coordinated array of bone resorption and formation events (see Fig. 4-25, *A*). Both fundamental mechanisms of osseous adaptation, modeling, and remodeling, are involved.[140] A modeling response is noted in the alveolus; bone resorption occurs where the PDL is compressed (in the direction of movement), and bone formation maintains the normal width of the trailing PDL. By means of this coordinated series of surface modeling events, the alveolus drifts in the direction of tooth movement. The modeling events of tooth movement commonly are referred to as areas of compression and tension within the PDL.[129,130] For small amounts of tooth movement (less than 1 mm) over 1 or 2 months, PDL modeling probably is the predominant mechanism of tooth movement. However, when teeth are moved greater distances over longer periods, the PDL response is supplemented by alveolar bone remodeling and periosteal modeling (Figs. 4-52 and 4-53).

Remodeling of dense alveolar bone (see Fig. 4-52) may enhance the rate of tooth movement[133] and replace the less mature osseous tissue formed by rapid PDL osteogenesis (see Fig. 4-53). Resorption cavities ahead of the moving tooth reduce the density of cortical bone (see Fig. 4-52). These intraosseous cavities are the initial remodeling events that occur during the first month of the remodeling cycle (see Fig. 4-20). With progressive tooth movement, it appears that these resorption cavities are truncated remodeling events.[133]

Continuous force[141,142] or reactivation at about 1-month intervals is expected to yield the maximal rate of tooth movement through cortical bone. The remodeling-dependent concept of long-range tooth movement has important clinical implications. Efficient mechanics and regular reactivations at about 4-week intervals long have been associated with optimal rates of tooth movement.[133] However, breakage, distortion of appliances, and appointment failures substantially increase treatment time. One reason for slow tooth movement in uncooperative patients may be the tendency for resorption cavities initiated by orthodontic activation to complete the remodeling cycle by refilling with new bone if appropriate mechanics are not maintained. Repeatedly reinitiating force after periods of periodontal recovery requires one startup period after the other (see Fig. 4-47) to reestablish the modeling and remodeling mechanisms to move a tooth through dense cortical bone.

Secondary osteons are formed in new cortical bone trailing a moving tooth (Fig. 4-55). The major modeling and remodeling events associated with sustained buccal movement (controlled tipping) of a lower premolar are summarized in Figure 4-54. The efficiency of bone resorption is the rate-limiting factor in tooth movement. Bone is removed ahead of the moving tooth by two mechanisms: frontal resorption at the PDL interface and initial remodeling events (resorption cavities) in the cortical plate. In addition to PDL modeling of the alveolus (bone resorption in the area of pressure and bone formation in the area of tension), Figure 4-56 shows surface modeling on periosteal and endosteal surfaces. These coordinated modeling events

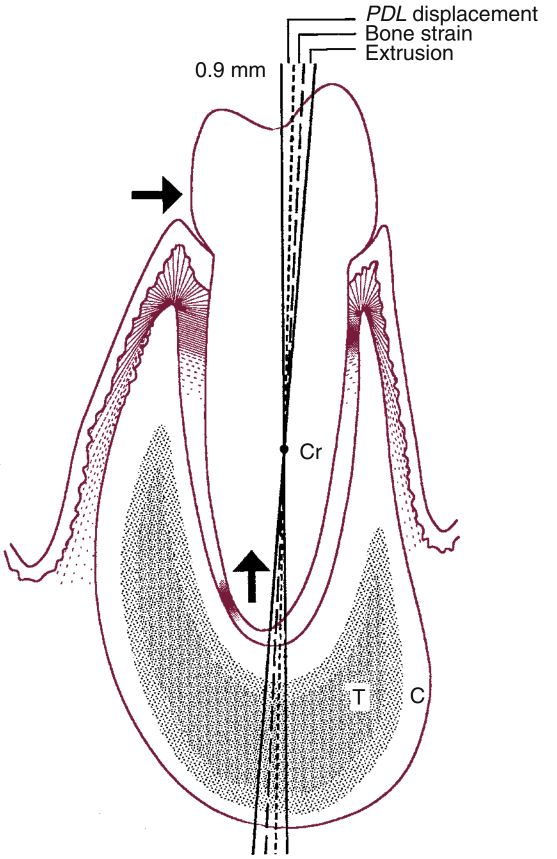

FIGURE 4-50 Initial displacement (1 to 3 days) of a tooth exposed to a tipping (horizontal) load usually is about 0.5 mm but may be as much as 0.9 mm for teeth that are slightly mobile, periodontally compromised, or heavily loaded. The three components are (1) displacement of the root in the periodontal ligament (*PDL*), (2) bone strain caused by bending and creep, and (3) extrusion caused by the inclined plane effect of the tooth root pressing against a tapered alveolus. FIGURE 4-52 Demineralized histologic section of human periodontium reveals the modeling and remodeling mechanisms of progressive tooth movement through dense cortical bone (*B*). A tooth (*T*) is moving in the direction of the *large arrow*. The rate of translation is enhanced by frontal resorption in the periodontal ligament communicating with the extensive resorption cavities (*) created by initial remodeling events (cutting cones). By this mechanism, teeth move through dense cortical bone at a rate of about 0.3 mm a month (×25). (From Roberts WE, Garotto LP, Katona TR: Principle of orthodontic biomechanics: metabolic and mechanical control mechanisms. In Carlson DS, Goldstein SA, editors: Bone biodynamics in orthodontic and orthopedic treatment, Ann Arbor, 1992, University of Michigan Press.)

maintain the structural relationship of the alveolar process as the tooth moves.[74]

PERIODONTAL LIGAMENT RESPONSE

Within 1 min after application of a continuous orthodontic load to a rat maxillary first molar, a more negative electrical potential is noted where the PDL is widened and a more positive signal where it is compressed (see Fig. 4-55). These bioelectric changes are not piezoelectric signals but are probably streaming potentials.[23] Changes in electrical potential may drive the PDL osteogenic and osteoclastic responses or may be merely physical manifestations of the intense cellular activities (ion flux across cell membranes) triggered by orthodontic stimuli.[18] Coordination of cellular reactions in the PDL to changes in electrical potential is a prime area for future investigation.

Application of orthodontic force initiates a cascade of cellular proliferation and differentiation events in the PDL. Maximal compression of the PDL occurs in 1 to 3 hours (see Fig. 4-56), a time frame consistent with most clinical

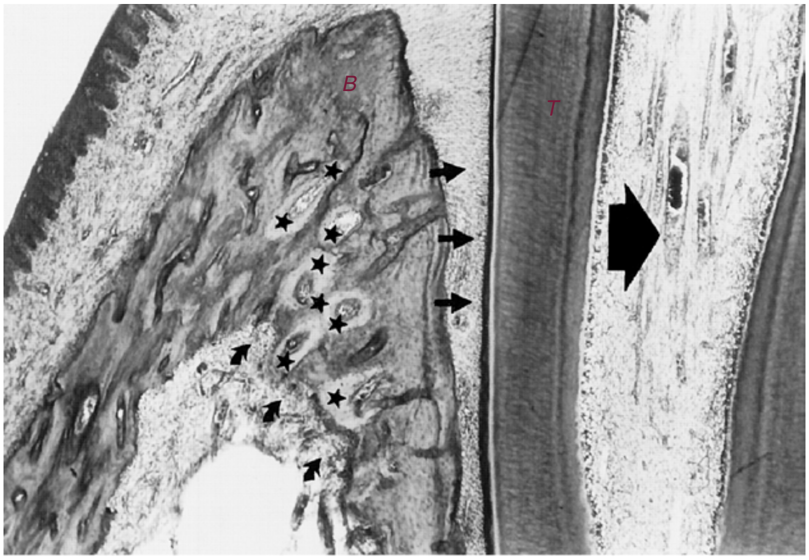

FIGURE 4-53 A demineralized histologic section of human periodontium documents the bone modeling and remodeling aspects of alveolar bone (*B*) drift in the direction of tooth (*T*) movement (*large black arrow*). Three major aspects of bone modeling are noted: (1) new bone formation in the periodontal ligament (*small horizontal arrows*), (2) periosteal resorption on the lingual alveolar bone surface (*left*), and (3) endosteal resorption (in the direction of the curved arrows) to maintain the cortical thickness of the alveolar crest as it drifts to the right. Bone remodeling replaces relatively immature bone with new secondary osteons (*stars*) (×25). (From Roberts WE, Garotto LP, Katona TR: Principle of orthodontic biomechanics: metabolic and mechanical control mechanisms. In Carlson DS, Goldstein SA, editors: Bone biodynamics in orthodontic and orthopedic treatment, Ann Arbor, 1992, University of Michigan Press.)

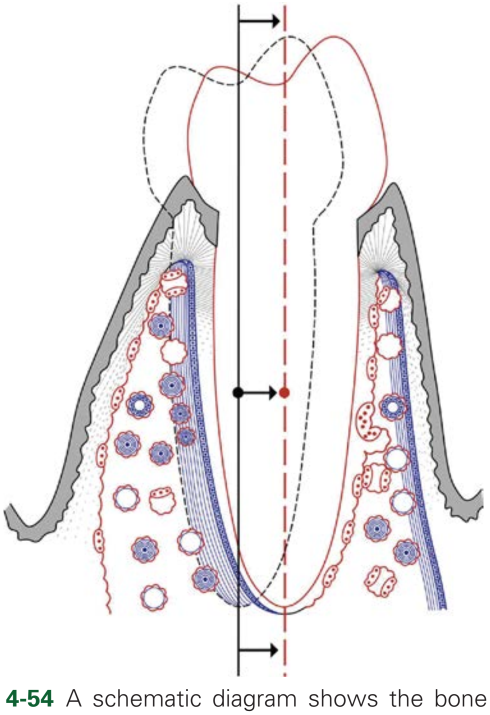

FIGURE 4-54 A schematic diagram shows the bone physiology associated with translation of a tooth. Note that there is a coordinated bone modeling and remodeling response leading and trailing the moving tooth. This mechanism allows a tooth to move relative to basilar bone while maintaining a normal functional relationship with its periodontium. Osteoclastic and osteoblastic activities are shown in *red* and *blue*, respectively. (From Roberts WE, Roberts JA, Epker BN, et al. Remodeling of mineralized tissues, part I: the Frost legacy. *Semin Orthod*. 2006;12(4):216–237.)

estimates for initial displacement after application of an orthodontic load (see Fig. 4-49). The postactivation sequence of about 6 hours for the initiation of tooth movement has been confirmed with a nitric oxide synthetase assessment in rat PDL.[143]

A variety of nervous, immune, and endocrine system responses, as well as local cytokines and intracellular messages, have been implicated in the osseous adaptive reaction as the root of the tooth is displaced.[144] These localized agents probably are mediators of the often painful transient inflammatory events noted during the initiation of the orthodontic reaction. The role of local cytokines in the sustained bone modeling and remodeling events of tooth movement are yet to be clearly outlined. However, prostaglandins are thought to be important factors in the control of mechanically mediated bone adaptation.[111,135,145,146]

Comparing control rat PDL (Fig. 4-57, *A*) with orthodontically stimulated PDL (Fig. 4-57, *B*) helps define the biological mechanisms for mechanically induced bone formation and resorption. The specificity of bone resorbing and forming sites is dictated by the physics of the applied force system.[141] Although the PDL histologic changes and cell kinetics associated with orthodontically induced osteoclasis and osteogenesis are well defined,[16,21,129,130,133,136,147-150] the cellular mechanisms controlling tooth movement are less clear. An interaction of metabolic, biomechanical, bioelectric, and biochemical factors has been implicated.[18,21,133,135,151] The challenge is to determine the sequence of cybernetic events.[133]

Minimal proliferative activity is noted in areas of the PDL where bone resorption predominates. An intense proliferative response is noted in the PDL where new bone is destined to form.[15,16,149,150,152] For the first 12 hours after initiation of

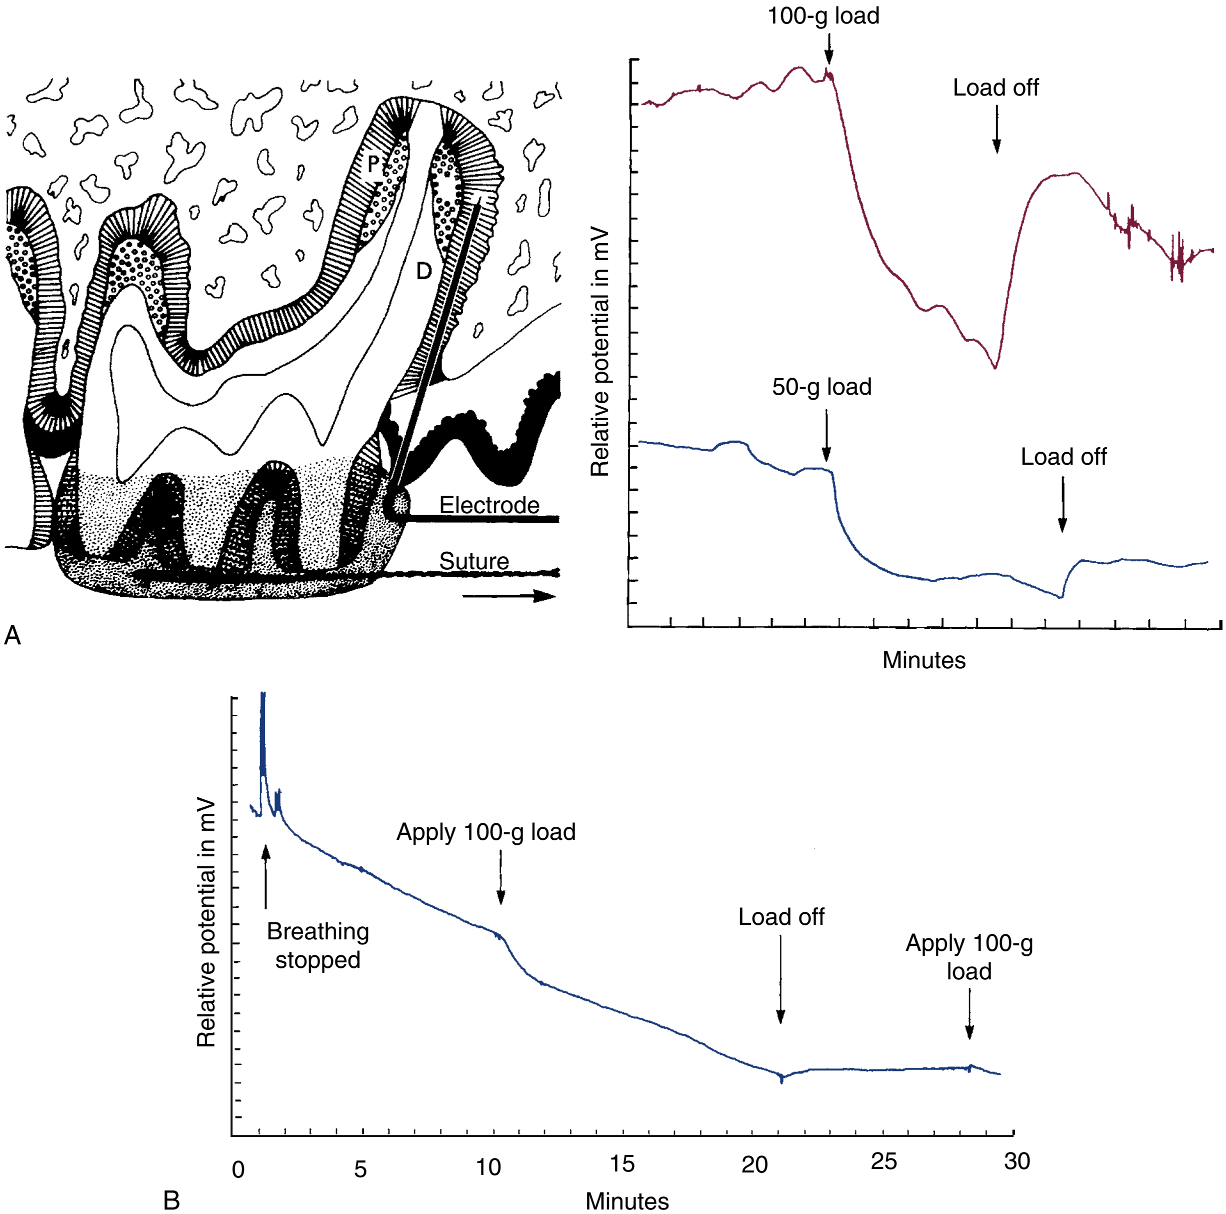

FIGURE 4-55 **A,** A tungsten microelectrode is inserted on the mesial aspect of a rat maxillary first molar and stabilized to the tooth with composite resin. An orthodontic load of 50 to 100 g (about 0.5-1 N) applied with a traction suture results in a more negative electrical potential in the periodontal ligament, where new bone formation occurs. **B,** Similar measurements of electrical potential were performed in orthodontically stimulated periodontal ligament of a rat terminated with an overdose of anesthetic. The electrical response was lost 20 min after breathing stopped. (Top left image and top right image, From Roberts WE, et al. Change in electrical potential within periodontal ligament of a tooth subjected to osteogenic loading. In: Dixon A, Sarnat B, eds. *Factors and Mechanisms Influencing Bone Growth*. New York: Allan R Liss; 1982.)

orthodontic stimulus, a modest, nonspecific increase of cells into mitotic and DNA S-phases occurs throughout the PDL (Fig. 4-58, *A*). After 16 hours, a specific osteogenic response is noted in the area of the PDL where new bone formation will begin (Fig. 4-58, *B*). More than half of the fibroblast-like PDL cells in the widened area of the PDL enter the DNA S-phase of the cell cycle[153] and subsequently divide.[133,154] Preosteoblasts then migrate from throughout the PDL to the alveolar bone surface (Fig. 4-59),[13] form osteoblasts, and initiate new bone formation in about 40 to 48 hours.[15,133]

The orthodontic response in the PDL is an effective experimental model for determining the physiologic mechanisms of mechanically induced bone modeling. Orthodontic stimulation of rat maxillary molars has been particularly useful for initiating a defined osteogenic reaction within the PDL on the mesial aspect of the mesial root (Fig. 4-59, *B*). Using the finite element modeling method, one can calculate stresses in the tissue down to the cellular level. Tissue complexity and the diverse range of mechanical properties make orthodontically stressed periodontium a relatively

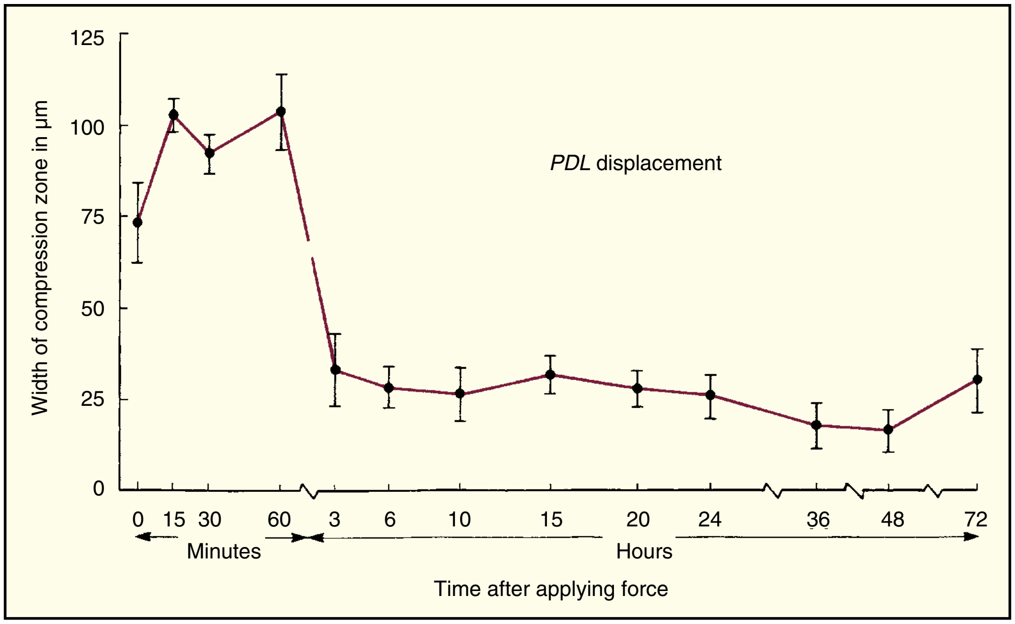

FIGURE 4-56 Initial displacement of the mesial root of rat maxillary first molars in the periodontal ligament (*PDL*) space is assessed by measuring the width of the maximal compression zone. This method is an index of periodontal ligament displacement that is relatively independent of bone deformation. Note the resistance to compression during the first hour, followed by maximal compression at 3 h, creating necrotic areas where undermining resorption will occur.

challenging application of the finite element modeling method. The model simulates the experimental tipping of a rat maxillary first molar (Fig. 4-60, *A*). Osteogenesis was concluded to occur where maximal principal stress was elevated in the PDL (Fig. 4-60, *B*). Bone resorption began where peaks in minimal principal stress, maximal shear, and strain energy density developed.[19]

OSTEOBLAST HISTOGENESIS AND BONE FORMATION

Osteoblasts are derived from paravascular connective tissue cells (Fig. 4-61). The less differentiated precursor and committed osteoprogenitor cells are associated closely with blood vessels. Their progeny (preosteoblasts) migrate away from the blood vessels. The major rate-limiting step in the histogenesis sequence occurs as the cells move through an area of low cell density about 30 μm from the nearest blood vessel.[109] The osteoblast histogenesis sequence (Fig. 4-62) was determined by in situ morphologic assessment of three distinct events in cell physiology: (1) DNA S phase, (2) mitosis, and (3) the increase in nuclear volume (A′→C shift) that accomplishes differentiation to a preosteoblast.[140]

Careful cell-kinetic analysis of orthodontically induced osteogenesis[17] demonstrated that the initial, mechanically mediated step in osteoblast histogenesis is differentiation of preosteoblasts from less differentiated precursor cells (Fig. 4-63). Subsequent studies further classified the less differentiated precursor cells into committed osteoprogenitor (A′) cells and self-perpetuating precursor (A) cells.[154] The morphologic marker for this key step in osteoblast differentiation (change in genomic expression) is an increase in nuclear volume—preosteoblasts have larger nuclei than their precursors. Orthodontically induced osteogenesis is associated with elevated stress in the PDL. The reader is referred to the 5th edition of the text-book for additional details.

OSTEOCLAST RECRUITMENT AND BONE RESORPTION

Bone resorption is the limiting factor that determines the rate of tooth movement.[18,133] The removal of osseous tissue during progressive tooth movement is related directly to (1) bone porosity, (2) the remodeling rate, (3) the resorption rate, and (4) osteoclast recruitment. Porous cortical and trabecular bone allows improved access for osteoclasts. The remodeling rate is related directly to resorption cavities and the number of osteoclasts present at any time in resisting bone. The osteoclast resorption rate largely is controlled by metabolic factors, particularly PTH.[155,156] No direct evidence exists to suggest that osteoclasts are produced in the PDL or at any other bone surface. Preosteoclasts derived from the marrow enter the PDL and adjacent bone through the blood circulation.[18,133,157]

Roberts and Ferguson[18] compared the cell kinetics of metabolic and mechanical induction of PDL resorption. As shown in Figure 4-64, the number of osteoclasts per millimeter of bone surface is maximal about 9 hours after a single injection of parathyroid extract. Mechanical stimulation produces a slow but more sustained response that requires almost 50 hours to reach the same osteoclast density. Preosteoclasts are derived from the marrow by circulating.

Because osteoclasts originate in the marrow, production of osteoclast precursor cells is under systemic (metabolic) and local (hematopoietic) control. The reservoir of circulating osteoclast precursors is controlled systemically. However, the localization

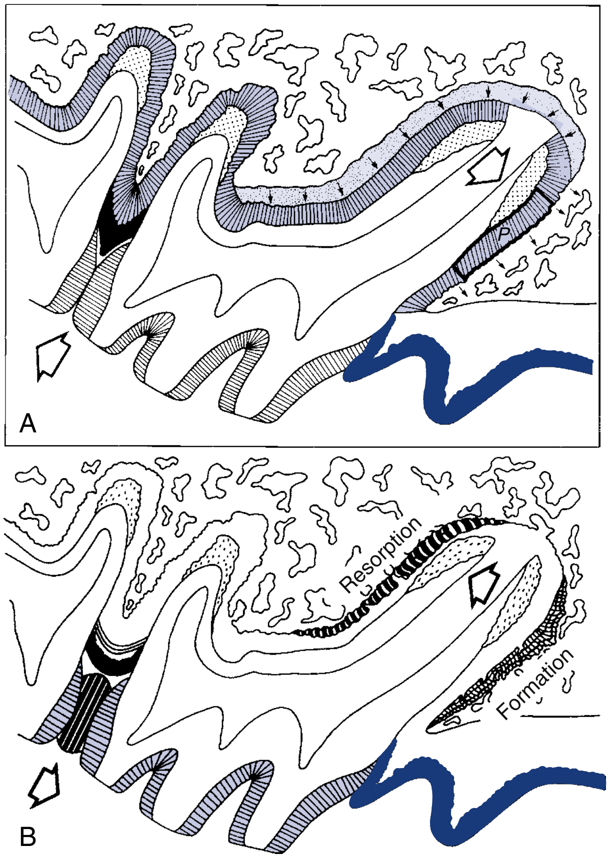

FIGURE 4-57 **A,** Physiologic drift for the mesial root of a rat maxillary first molar involves a relative tipping of the tooth in the direction of the large arrows. Net resorption occurs adjacent to the area of the periodontal ligament (*P*) marked with the *bold outline*. Bone formation is noted along the periodontal ligament adjacent to the stippled area. **B,** Inserting a Latex elastic between the first and second molars reverses the direction of tooth movement, resulting in resorption on a previously bone-forming surface (*above*) and vice versa (*below*). (**A,** From Roberts WE, Morey ER. Proliferation and differentiation sequence of osteoblast histogenesis under physiological conditions in rat periodontal ligament. *Am J Anat*. 1985;174:105; **B,** from Roberts WE. Advanced techniques for quantitative bone cell kinetics and cell population dynamics. In: Jaworski KFG, ed. *Proceedings of the First Workshop on Bone Morphometry*. Ottawa: University of Ottawa Press; 1976.)

of resorptive sites in the PDL is regulated mechanically. Metabolic stimuli such as PTH produce a relatively nonspecific resorption response along previously resorbing surfaces.[158] Mechanical induction is a specific response that occurs only in the direction of tooth movement. The current challenge is to understand the mechanical and biological components of the resorptive mechanism.

Because osteoblasts and their precursors have a more complete complement of bone-related receptors (i.e., PTH, growth hormone, and estrogen), they may play a role in controlling osteoclasts.[18,153,159] The intricate bone modeling and remodeling responses that characterize orthodontic tooth movement require close coordination of osteoblastic and osteoclastic function.[160]

Intermittent versus Continuous Mechanics

The rate of tooth movement is determined by initiating and sustaining a coordinated bone-resorptive response.[133] The kinetics of continuous mechanics are well known; the response to intermittent loads, such as headgear and removable appliances, is less clear. In general, tooth movement is related directly to the number of hours each day that force is applied. However, even when motivation and cooperation are optimal, the effectiveness of similar therapy among patients is inconsistent. This is a physiologic indication that additional variables are involved.

Reitan[129] reports that a short-duration force (12 to 14 hours per day for 15 to 27 days) delivered by a functional appliance triggers a resorptive reaction that lasts a week or more. Apparently this experience with functional appliances does not apply to cyclic intermittent mechanics such the wearing of nighttime headgear. Otherwise, headgear worn at night would be as effective as 24-hour wear. In the absence of specific experiments, interpolation from continuous-force studies appears to be the best explanation available. A 3-hour period of continuous loading is necessary to achieve maximal displacement of a tooth root in the periodontium (see Fig. 4-54). If one assumes that at least 3 hours are needed for PDL activation or recovery,[18] continuous wearing of the headgear for 12 hours per day is expected to be more effective than a longer period of wearing the headgear with frequent release of force. The recommendation is that the headgear is not removed during the day. Removing the device for meals or sports compromises the biomechanical activation of the periodontium. The complex biological response associated with irregular force application probably is the main factor in the unpredictable response to headgear or removable appliances.

Another possible variable in the response to intermittent force is the circadian rhythm of PDL proliferation and differentiation (Figs. 4-65 and 4-66). Maximal cell proliferation in the PDL occurs during the resting hours :[161,162] daytime for rats and nighttime for human beings. Differentiation to preosteoblasts, the key rate-limiting step in osteoblast differentiation, occurs during the late resting and early arousal periods.[154] These data suggest that wearing headgear or a removable appliance at night is more effective than wearing the same appliance for an equal period during the day.[162]

Differential Anchorage

The density of the alveolar bone and the cross-sectional area of the roots in the plane perpendicular to the direction of tooth movement are the primary considerations for assessing anchorage potential. The volume of osseous tissue that must be resorbed for a tooth to move a given distance is its anchorage value. If all bone offered the same resistance to tooth movement, the anchorage potential of maxillary and mandibular molars would be about the same. Clinical experience shows that maxillary molars usually have less anchorage value than mandibular molars in the same patient. A common example is space closure in a Class I four premolar extraction case; it often is necessary to use headgear on the maxillary first molars to maintain the Class I relationship. The relative resistance of mandibular molars to mesial movement is a well-known principle of differential mechanics.

Why are mandibular molars usually more difficult to move mesially than maxillary molars? At least two physiologic factors

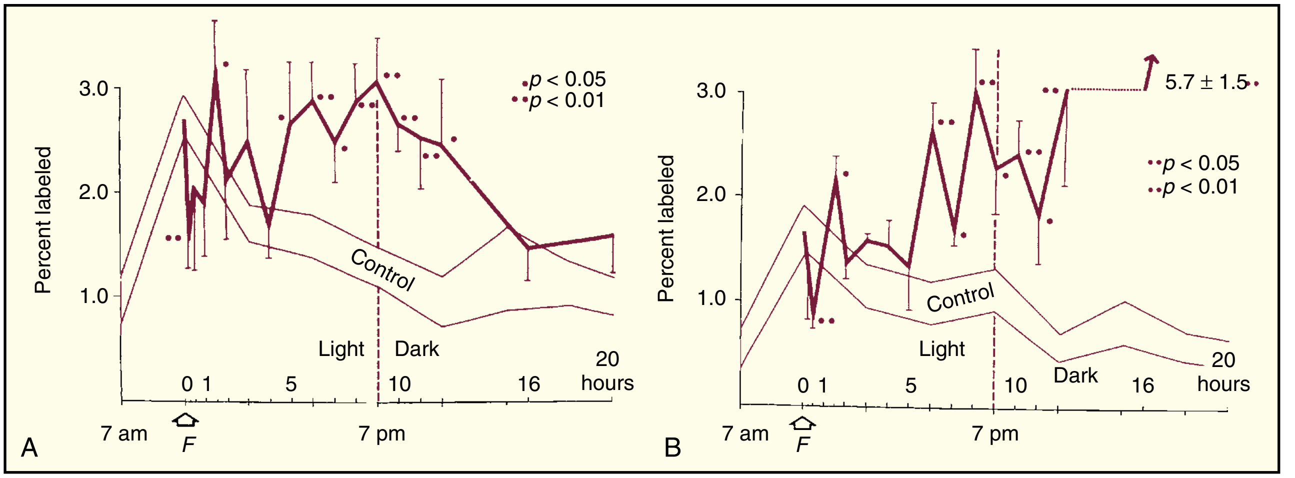

FIGURE 4-58 **A,** Compared with the normal circadian range of DNA S phase cells, orthodontic stimulus (*F*) results in a modest, nonspecific increase in S phase cells throughout the periodontal ligament. This is a mechanically induced release of G_1-blocked cells. These data are from the alveolar crest area, where no new bone formation occurs. **B,** In the midroot area, where new bone formation is induced, a similar nonspecific response is followed by a large proliferative reaction that specifically supports orthodontically induced osteogenesis. (From Smith RK, Roberts WE. Cell kinetics of the initial response to orthodontically induced osteogenesis in rat molar periodontal ligament. *Calcif Tissue Int.* 1980;30:51.)

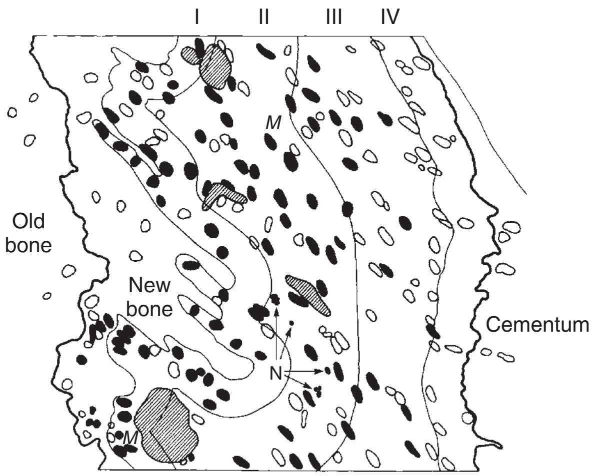

FIGURE 4-59 During the first 70 hours of orthodontically induced osteogenesis, periodontal ligament osteogenic cells migrate toward the bone surface from throughout the ligament. Cell migration patterns are tracked by repeated injection of the DNA precursor ^{3}H-thymidine. Labeled cells have black nuclei. (From Roberts WE, Chase DC. Kinetics of cell proliferation and migration associated with orthodontically induced osteogenesis. *J Dent Res.* 1981;60(2):174.)

can be considered: (1) the thin cortices and trabecular bone of the maxilla (see Figs. 4-2, 4-3, and 4-5) offer less resistance to resorption than the thick cortices and coarser trabeculae of the mandible (see Figs. 4-4 and 4-5), and (2) the leading root of mandibular molars being translated mesially forms bone that is far denser than the bone formed by translating maxillary molars mesially (Fig. 4-67).[144] The reason mandibular molars form denser bone than maxillary molars is unclear; it may be that new bone formed in the maxilla is remodeled more rapidly. In general, bones composed primarily of trabeculae remodel more rapidly than those composed primarily of cortical bone.[50,162]

Why is the alveolar process that supports the mandibular molars denser than maxillary molars? Functional loading dictates the osseous anatomy for the opposing jaws: the maxilla is predominantly trabecular bone with thin cortices, similar to a vertebral body or an epiphysis (see Figs. 4-2, 4-4, and 4-5); the mandible has thick cortices, similar to the diaphysis of a major long bone (see Figs. 4-4 and 4-5). Although the forces of occlusion are distributed equally to the maxilla and mandible, the maxilla transfers a major fraction of functional loads to the rest of the cranium.

The loads (compression, tension, and torsion) to which the maxilla and the mandible are exposed are different. The mandible is subjected to substantial torsion and flexure caused by muscle pull and masticatory function.[5,163] Thick mandibular cortices are needed to resist the torsional and bending strain (see Figs. 4-5 and 4-6). The maxilla, however, is loaded predominantly in compression, has no major muscle attachments, and transfers much of its load to the rest of the cranium. Because of its entirely different functional role, the maxilla is predominantly trabecular bone with thin cortices (see Figs. 4-2 to 4-4). This anatomic configuration is similar to that of other bones loaded primarily in compression (e.g., proximal tibia and vertebral bodies of the spine).

Rate of Tooth Movement

A histomorphometric evaluation of alveolar bone turnover between the maxilla and the mandible during experimental

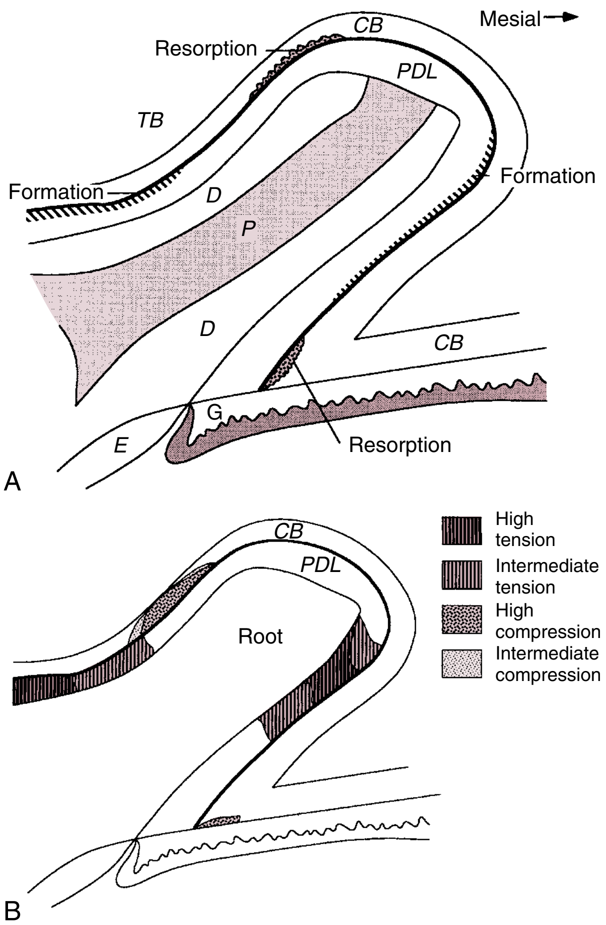

FIGURE 4-60 **A,** The mesial tipping of the rat maxillary first molar results in a typical pattern of bone resorption and formation that produces tooth movement. *G*, Gingiva; *E*, enamel; *D*, dentin; *TB*, trabecular bone; *CB*, cortical bone; *P*, pulp; *PDL*, periodontal ligament. **B,** Finite element model stress analysis of orthodontic tipping indicates that areas of elevated maximal principal stress (tension) in the periodontal ligament and minimal principal stress (compression) in the cortical bone of the lamina dura are associated with areas of bone formation and resorption, respectively. (Redrawn from Roberts WE, Garotto LP, Katona TR. Principle of orthodontic biomechanics: metabolic and mechanical control mechanisms. In: Carlson DS, Goldstein SA, eds. *Bone Biodynamics in Orthodontic and Orthopedic Treatment*. Ann Arbor: University of Michigan Press; 1992.)

tooth movement in dogs has defined the differential response of the jaws to tooth movement.[164] A similar miniscrew anchored force system of 200 to 250 *g* was applied to premolars in the maxillary and mandibular arches for 4 or 12 weeks. The tooth movement response was monitored with radiographs and fluorescent bone labels. Significantly more orthodontic tooth movement was observed for maxillary than for mandibular teeth. The primary histomorphometric analysis indicated that, after 4 weeks of tooth movement, a marginal increase in resorptive parameters. On the other hand, after 12 weeks of tooth movement, secondary histomorphometric analysis indicated an increase in the bone formation rate, resulting in increased woven bone formation, especially at the tension sites. These results indicate that tooth movement is a regional acceleratory phenomenon (RAP), manifested as increased bone turnover in the alveolar process as the teeth move through it. The RAP of resisting bone can be enhanced by corticotomies.[165]

From a clinical perspective, maxillary bone is more responsive to orthodontics because it is primarily composed of trabecular bone.[140] The rate of tooth movement is the inverse of anchorage potential; the same physiologic principles apply. Clinical studies using endosseous implants for anchorage[118] have provided excellent opportunities to assess the rate of tooth movement through dense cortical bone in the posterior mandible (see Fig. 4-73, *A*) compared with the less dense trabecular bone of the posterior maxilla (see Fig. 4-73, *B*). The enhanced anchorage value of mandibular molars is related to the high-density bone formed as the leading roots are moved mesially. After a few months of mesial translation, the trailing roots engage the high-density bone formed by the leading root and the rate of tooth movement declines (Fig. 4-68).

Overall, the maximal rate of translation of the midroot area through dense cortical bone is about 0.5 mm per month for the first few months; the rate then declines to less than 0.3 mm per month until the first molar extraction site is closed (see Fig. 4-68). A composite analysis of four similar cases of molar translation in adults showed that teeth moved out at a rate of about 0.6 mm per month for about 8 months; the rate decreased to 0.33 mm per month as the trailing (distal) root engaged the dense bone formed by the leading (mesial) root (Fig. 4-69).

When teeth are moved continuously in the same direction, the remodeling rate increases in compact bone immediately ahead of the moving tooth (see Figs. 4-52 and 4-53). This enhanced remodeling process probably is related to the regional acceleratory phenomenon commonly noted in osseous wound healing. Cutting/filling cones are the means of osteoclast access to the inner portion of dense compacta (see Fig. 4-24). This remodeling mechanism appears to be particularly important for resorbing the dense cortical bone formed by the leading root during mesial movement of lower molars (see Fig. 4-67). Note the radiolucent areas in the dense compact bone.

Figure 4-70 is a summary of the relative rates of molar translation in the upper and lower jaws of growing children and adults. A maximal rate approaching 2 mm per month is possible with space-closure mechanics or 24-h-per-day headgear wear by a rapidly growing child (Child Mx). Similar mechanics in a nongrowing adult can translate upper molars about 1 mm per month (Adult Mx). Mesial translation of lower molars in a child occurs at a rate of about 0.7 mm per month (Child Md). The slowest molar translation (0.3 mm per month) is in the lower arch of adults (Adult Md). Overall, the same teeth in growing children move about twice as fast as they move in adults. Certainly histologic factors, such as less dense alveolar bone and more cellular PDL,[30] are relevant factors; growth-related extrusion is the principal reason that space closure is almost twice as rapid in children. Figure 4-71 shows the considerably smaller volume of bone that is resorbed during space closure in a child compared with that in an adult. In general, the rate of tooth movement is inversely related to bone density and the volume of bone resorbed.

Rates for orthodontic tipping movements usually are higher but are more variable than for translation. No well-controlled studies of tipping in various intraoral sites of children and adults are available; however, some interesting theoretical considerations have been offered. When teeth are moved rapidly, immature new bone can form at a rate of 100 μm/day or more

(more than 3 mm per month). This rate of tooth movement probably is never achieved during routine treatment. Premolar and canine tipping of about 2 mm per month may be achieved with removable appliances in the maxillary arch of growing children.

Three principal variables determine the rate of tooth movement: (1) growth, (2) bone density, and (3) type of tooth movement. Alveolar bone of the maxilla is less dense than that of the mandible because it has a higher ratio of cancellous bone to cortical bone. Bone in children generally is less dense (more porous or cancellous) than bone in adults. Cancellous or trabecular bone has more surface area available for resorption, which is important because bone that impedes tooth movement can be resorbed from all sides. Cortical bone is restricted largely to frontal and undermining resorption mechanisms in the PDL. In general, children have a higher rate of bone remodeling than adults. In simple terms, more osteoclasts are present in the bone that can help with the task of removing the osseous tissue impeding tooth movement.

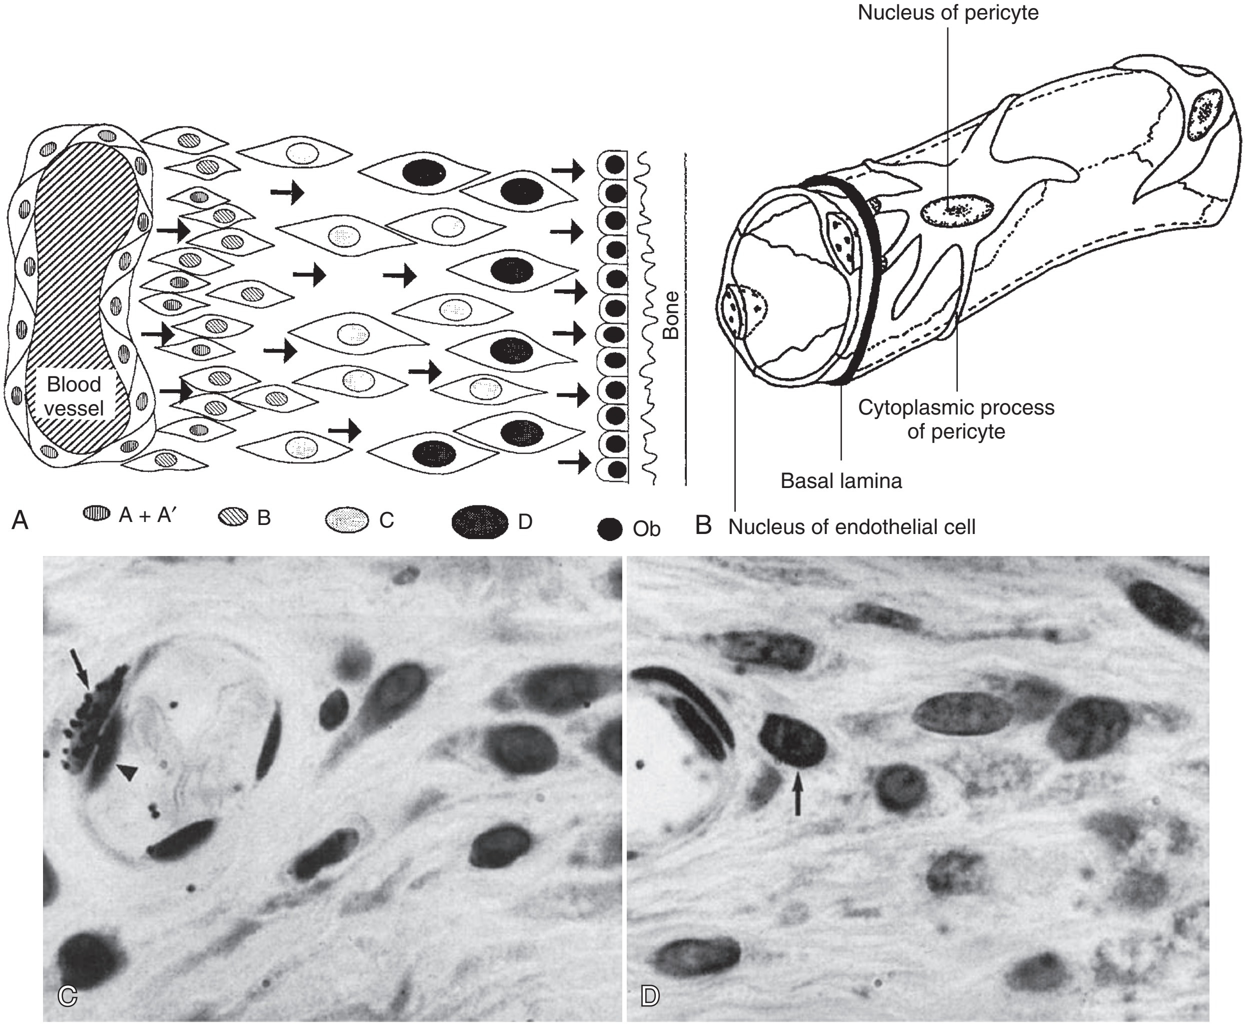

FIGURE 4-61 **A,** Less differentiated precursor cells (A cells) are a paravascular population. They differentiate to committed osteoprogenitor cells (A′ cells), which migrate away from the blood vessel. Traversing the low-cell density zone, the A′ cells differentiate to G_1-stage preosteoblasts (C cells), which synthesize DNA and become G_2-stage preosteoblasts (D cells). **B,** A pericyte, a distinct polymorphic cell of mesenchymal origin, partly encircles a microvessel and shares a common basal lamina with an endothelial cell. **C,** Photomicrograph of autoradiography of an expanded interpremaxillary suture, showing labeled pericyte (*arrow*) and unlabeled endothelial cell (*arrowhead*). (Stained with hematoxylin and eosin; original magnification ×1000 under oil immersion.) **D,** Photomicrograph of autoradiography of an expanded interpremaxillary suture, showing an activated pericyte (*arrow*) that has partly separated from the basal lamina of the blood vessel. The nuclear pattern of the activated pericyte shows that it is in the prophase of mitosis. (Stained with hematoxylin and eosin; original magnification ×1000 under oil immersion.) (From Chang H-N, et al. Angiogenesis and osteogenesis in an orthopedically expanded suture. *Am J Orthod Dentofac Orthop*. 1997;111:382.)

The teeth of growing children extrude as they move through bone. One must remember that for the basilar bone of the jaws to separate 1 to 2 cm during 2 years of orthodontic treatment is not uncommon. This means that the teeth of children move as much by differential apposition (guided eruption) as by resorption (see Fig. 4-71). Tipping the teeth requires less resorption of bone adjacent to the middle of the root. This bone, which is farthest from bone surfaces, probably is the most difficult for the osteoclasts to access. Eliminating the most difficult part of the resorptive process probably is the reason teeth move faster by tipping than by translation. Considering all the variables of age, arch, and type of tooth movement, maxillary buccal segments in children move as much as four times faster than posterior mandibular segments in adults (see Fig. 4-70).

To date almost all studies of the rate of tooth movement have used two-dimensional methods of analysis. Tooth movement is a three-dimensional phenomenon, and more advanced methods of analysis are needed.

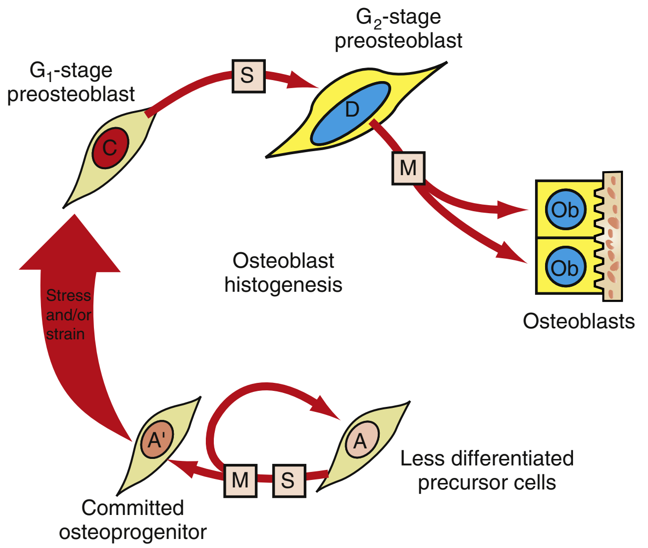

FIGURE 4-62 Frequency distribution of nuclear volume for fibroblast-like cells in unstimulated rat periodontal ligament. A, A′, C, and D cells are a morphologic classification based on peaks in the distribution curve. The osteoblast histogenesis sequence is a progression of five morphologically and kinetically distinguishable cells. The process involves two DNA S phases and two mitotic (M) events. (Redrawn from Roberts WE, Morey ER. Proliferation and differentiation sequence of osteoblast histogenesis under physiological conditions in rat periodontal ligament. *Am J Anat*. 1985;174:105.)

Periodontitis and Orthodontics

Osteoclasts are hardy cells that thrive in a pathologic environment. Osteoblasts, however, are vascularly dependent cells, and their histogenesis is disrupted easily.[18,154] Therefore, most skeletal deficits probably are errors in bone formation rather than resorption. A good example of the fragility of bone formation is suppression of osteoblast differentiation by inflammatory disease processes.[109] Orthodontics often is a useful adjunct for enhancing periodontal health, although moving teeth when progressive periodontal disease is present invites disaster.[109] Tooth movement in the alveolar process stimulates resorption and formation. Osteoclasts thrive in an inflammatory environment because they originate in the marrow, a protective site removed from the localized lesion. Preosteoclasts are attracted to the inflammatory site by cytokine mediators.[135] Vascularly mediated osteoblast histogenesis, is suppressed strongly by inflammatory disease. Therefore, when teeth are moved in the presence of active periodontal disease, resorption is normal or even enhanced and bone formation is inhibited. In a patient who has periodontitis, orthodontics may exacerbate the disease process, resulting in a rapid loss of supporting bone (Fig. 4-72). A thorough, full-mouth periodontal examination, evaluating

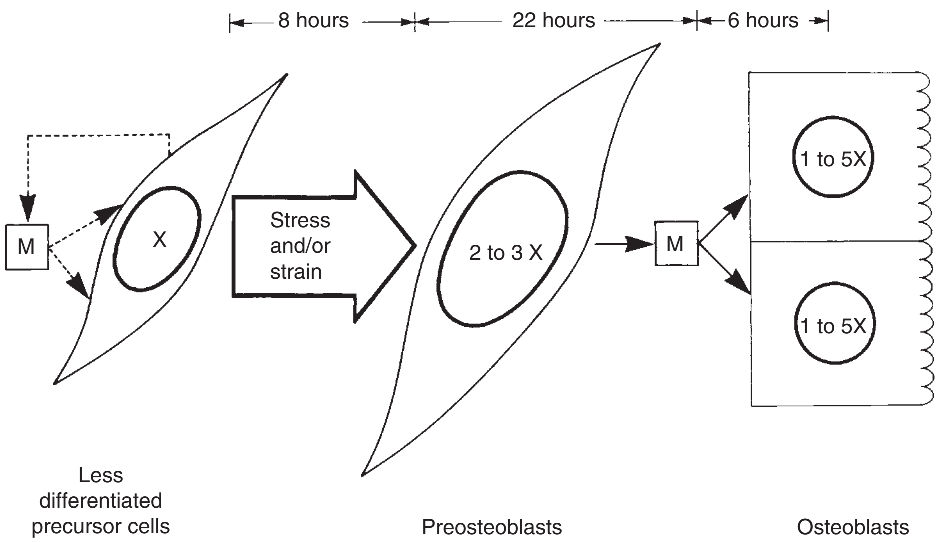

FIGURE 4-63 Differentiation of less differentiated precursor cells to preosteoblasts involves an increase in nuclear volume mediated by stress, strain, or both. The increase in nuclear size is a morphologic manifestation of change in genomic expression (differentiation). (From Roberts WE, Mozsary PG, Klingler E. Nuclear size as a cell kinetic marker for osteoblast differentiation. *Am J Anat*. 1982;165:373.)

for presence of deep periodontal pockets, recession, bleeding on probing, tooth mobility, and furcation involvement should be conducted on adult patients. For patients who demonstrate signs of periodontal disease and inflammation, the disease must be brought under control prior to commencing orthodontic treatment.

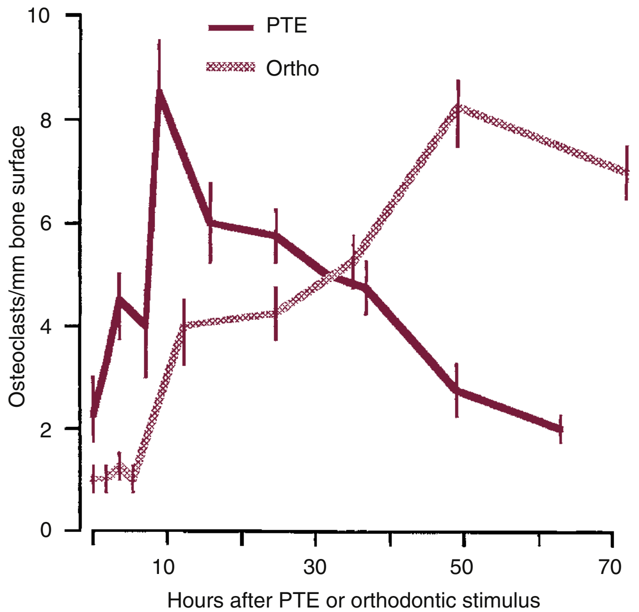

FIGURE 4-64 Metabolic (parathyroid extract [PTE]) versus mechanical (orthodontic) stimulation of periodontal ligament osteoclastic activity. (From Roberts WE, Ferguson DJ. Cell kinetics of the periodontal ligament. In: Norton L, Burstone CB, eds. *The Biology of Tooth Movement*. Boca Raton, FL: CRC Press; 1989.)

Endosseous Implants

A major problem in orthodontics and facial orthopedics is anchorage control.[31] Undesirable movement of the anchorage units is a common problem that limits the therapeutic range of biomechanics.[166] An important application of the basic principles of bone physiology is the use of rigid endosseous implants for orthodontic and orthopedic anchorage. Animal studies[59] and clinical trials of custom orthodontic devices[53] have established that rigidly integrated implants do not move in response to conventional orthodontic and orthopedic forces. These devices are opening new horizons in the management of asymmetry, mutilated dentition, severe malocclusion, and craniofacial deformity.[167]

A preclinical study in dogs tested the anchorage potential of two prosthetic-type titanium implants: (1) a prototype of an endosseous device with a cervical post, asymmetric threads, and an acid-etched surface and (2) a commercially available implant with symmetric threads (Fig. 4-73). Based on label incidence (Fig. 4-74, *A*) and the relative number of new osteons in microradiographs (Fig. 4-74, *B*), the rate of bone remodeling near the implant was higher compared with the basilar mandible only a few millimeters away.[168] Compared with titanium implants with a smooth surface, the degree of remodeling at the interface is greater for threaded implants placed in a tapped bone preparation.[31] This may be related to the increased resistance of threaded implants to torsional loads over time.[169]

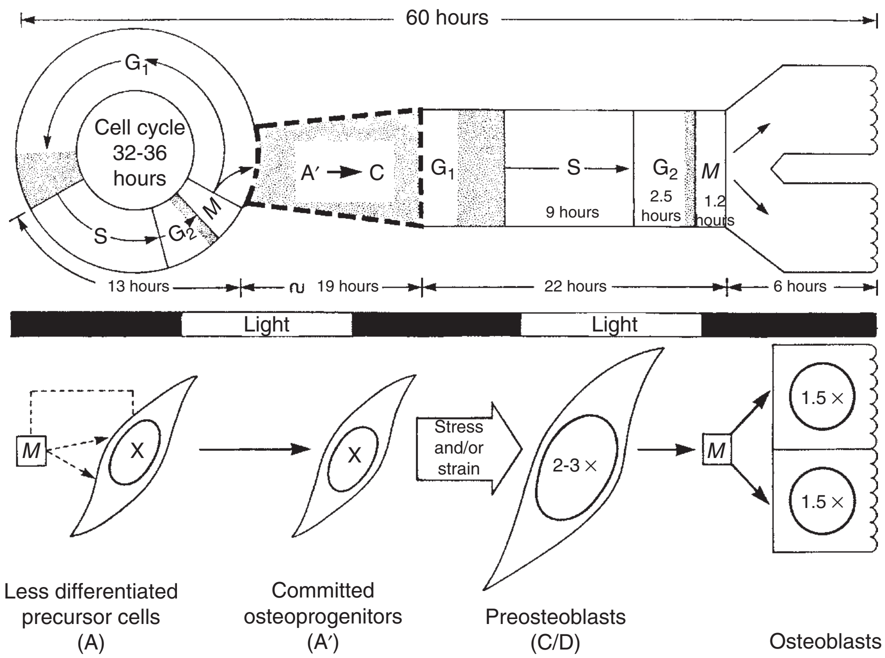

FIGURE 4-65 Photoperiod (circadian rhythm) influence on physiologic osteoblast histogenesis in rat periodontal ligament. Note that the A′→C increase in nuclear size occurs during the late resting and early arousal phases. The overall osteoblast differentiation sequence is 60 hours, five alternating dark/light cycles of 12 hours each. (From Roberts WE, Morey ER. Proliferation and differentiation sequence of osteoblast histogenesis under physiological conditions in rat periodontal ligament. *Am J Anat*. 1985;174:105.)

Direct bone apposition at the endosseous interface results in rigid fixation (osseointegration).[170] From an anchorage perspective, a rigid endosseous implant is the functional equivalent of an ankylosed tooth. Complete bony encapsulation is not necessary for an implant to serve as a rigid anchorage unit. The crucial feature is indefinite maintenance of rigidity despite continuous orthodontic loads. Over time, orthodontically loaded implants achieve a greater fraction of direct osseous interface.[161,169] From an orthodontic and orthopedic perspective, titanium implants can resist substantial continuous loads (1 to 3 N superimposed on function) indefinitely. Histologic analysis with multiple fluorochrome labels and microradiography confirm that rigidly integrated implants do not move relative to adjacent bone (see Fig. 4-74).[59] By definition, maintaining a fixed relationship with supporting bone is true osseous anchorage. Endosseous (osseointegrated) implants are well suited to many demanding orthodontic applications.[53]

Routine use of rigid implants for prosthetic or orthodontic applications requires that fixtures be placed between or near the roots of teeth. Inadvertent impingement on the PDL and the root of an adjacent tooth still may provide an acceptable result (Fig. 4-75). Cementum repair occurs where the root is cut, the PDL reorganizes, and the implant surface is integrated

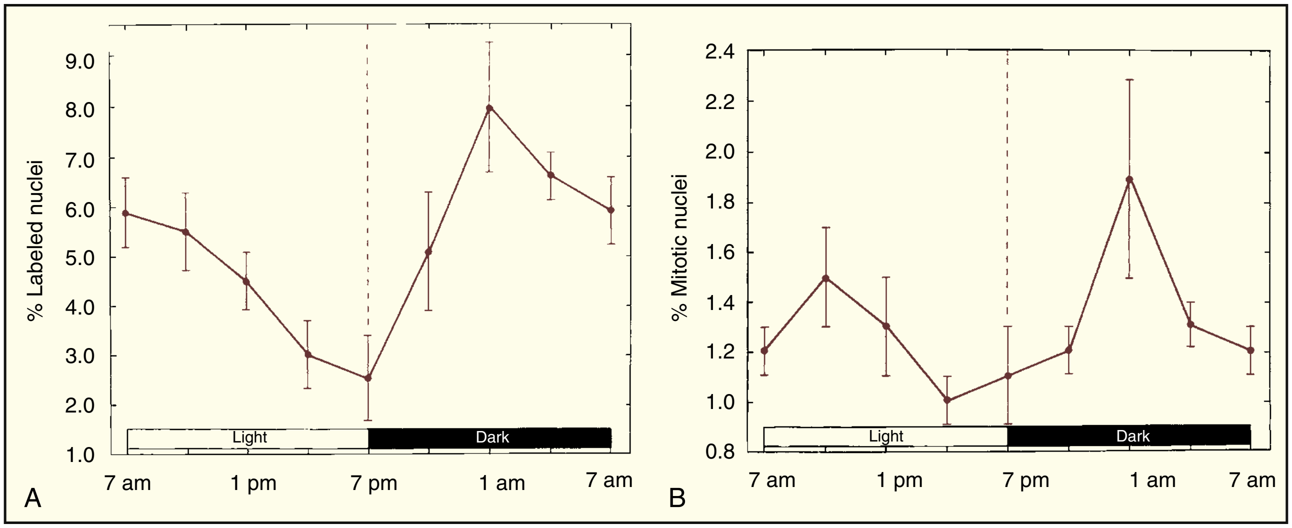

FIGURE 4-66 **A,** Circadian rhythm (photoperiod) of S phase cells in unstimulated rat periodontal ligament along a natural bone-forming surface. **B,** Circadian rhythm (photoperiod) of mitotic cells in unstimulated rat periodontal ligament along a natural bone-forming surface. FIGURE 4-68 Overall tooth movement curve for lower second and third molars demonstrates mesial root movement and translation of 8 to 10 mm in about 2 years. Note that the rapid movement of the first 3.5 months (as much as 0.86 mm a month) slows to about 0.3 mm a month for the duration of space closure.

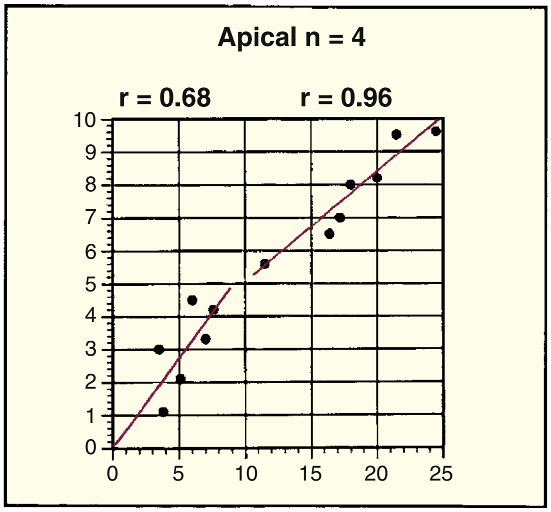

FIGURE 4-69 Separate linear regressions plotted for tooth movement during the first 8 months compared with regression seen after about 12 months in four patients in whom mesial root movement was initiated at the start of treatment. (From Roberts WE, Arbuckle GR, Analoui M. Rate of mesial translation of mandibular molars using implant-anchored mechanics. *Angle Orthod.* 1996;66(5):335.)

rigidly with osseous tissue. No evidence exists of ankylosis of the tooth.[59]

Retromolar Implant Anchorage

The isolated loss of a lower first molar with a retained third molar is a common problem. Rather than extract the third molar and replace the first molar with a three-unit bridge, mesial translation of second and third molars to close the edentulous spaces often is preferable (Fig. 4-76). The first case with long-term follow-up has been published.[53] Because of the increasing incidence of progressive bone loss and fatigue fracture associated with single tooth implants in lower first- and

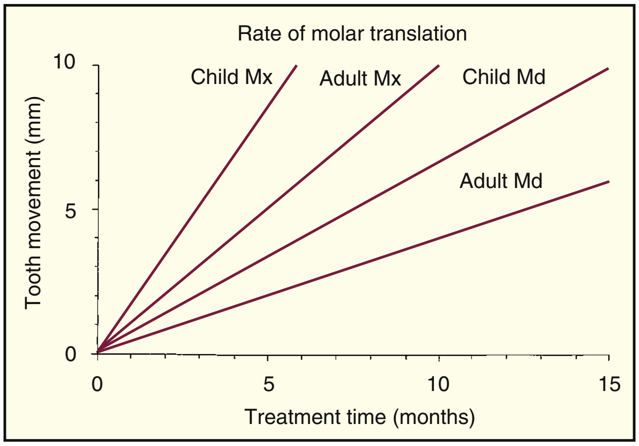

FIGURE 4-70 Relative rates of molar translation in both jaws of rapidly growing children compared with the rates in adults.

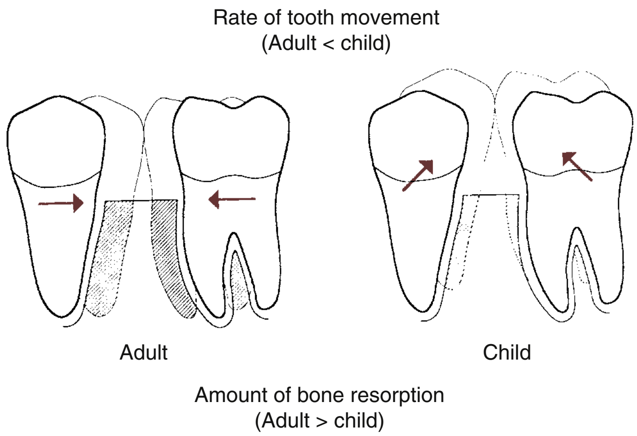

FIGURE 4-71 The rate of molar translation is related directly to the amount and density of bone that must be resorbed. Because extrusion is associated with growth, relatively less bone must be resorbed in translation of children's molars.

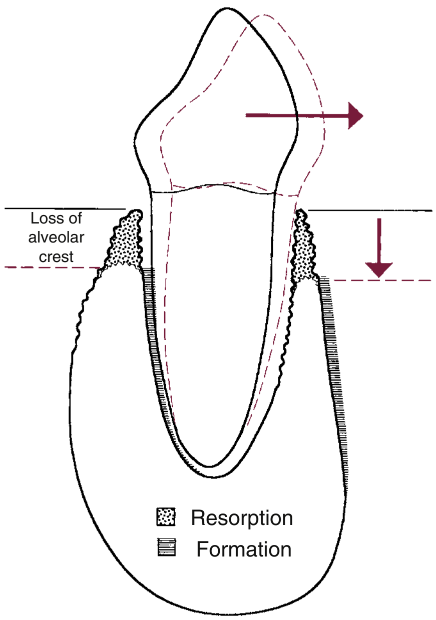

FIGURE 4-72 Because active periodontitis enhances resorption and inhibits apposition, orthodontics in patients with this condition often results in a severe loss of alveolar bone support.

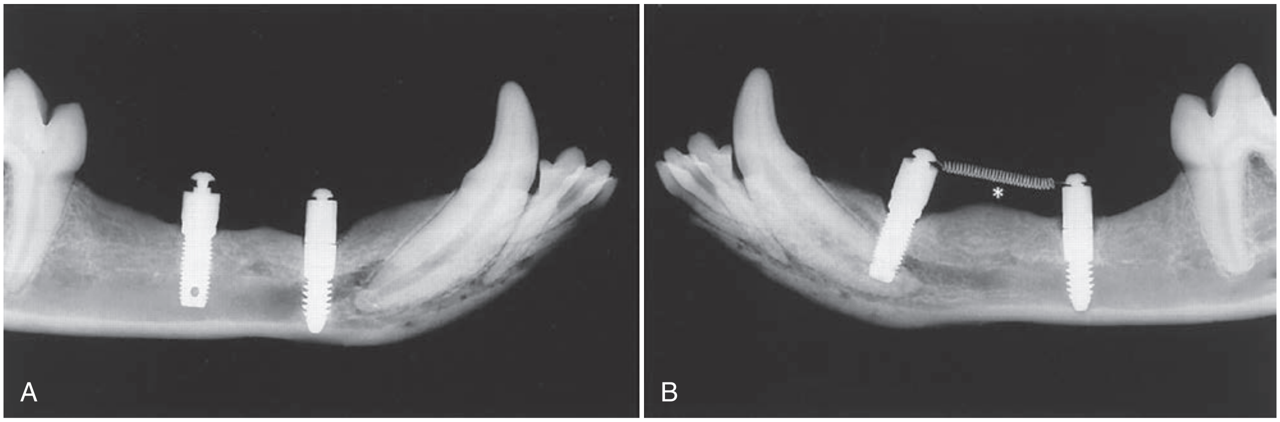

FIGURE 4-73 **A,** Two titanium implants of different design were placed in the partly edentulous mandibles of young adult dogs. **B,** After 2 months of unloaded healing, a 3-N compressive load was applied between the implants for 4 months. Increased periosteal apposition (*) was noted between the implants of some dogs. None of the rigidly integrated fixtures was loosened by the continuous load superimposed on function. (From Roberts WE, et al. Rigid endosseous implants for orthodontic and orthopedic anchorage. *Angle Orthod*. 1989;59:247.)

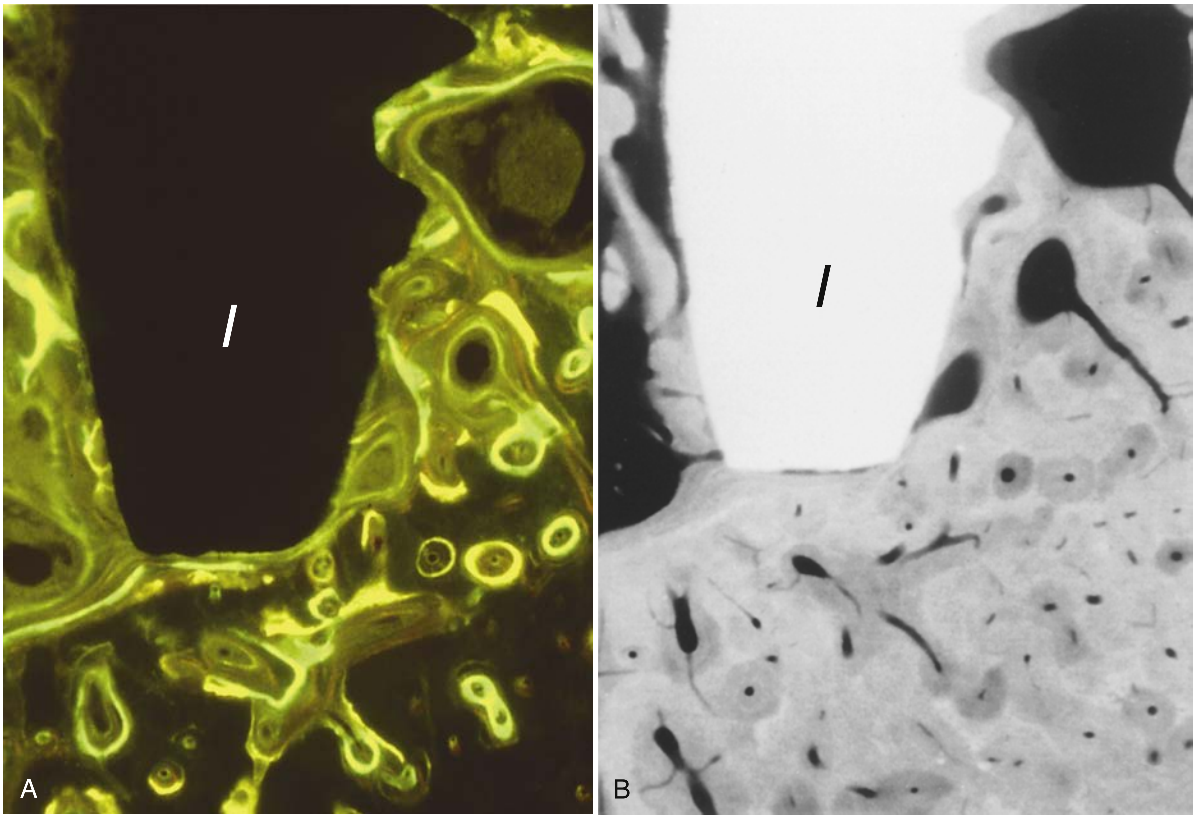

FIGURE 4-74 **A,** Multiple fluorochrome labels in bone adjacent to an implant (*I*) show a high rate of remodeling at the bone–implant surface. **B,** Microradiographic image of the same section shows direct bone contact on the surface of the implant. FIGURE 4-76 **A,** The mechanics of using a retromolar implant with an external abutment as anchorage to stabilize the premolar anterior to an extraction site. **B,** Using buccal and lingual mechanics to balance the load and shield the periosteum in the extraction site, the atrophic extraction site is closed without periodontal compromise of any of the adjacent teeth. (From Roberts WE, Garotto LP, Katona TR. Principle of orthodontic biomechanics: metabolic and mechanical control mechanisms. In: Carlson DS, Goldstein SA, eds. *Bone Biodynamics in Orthodontic and Orthopedic Treatment*. Ann Arbor: University of Michigan Press; 1992.)

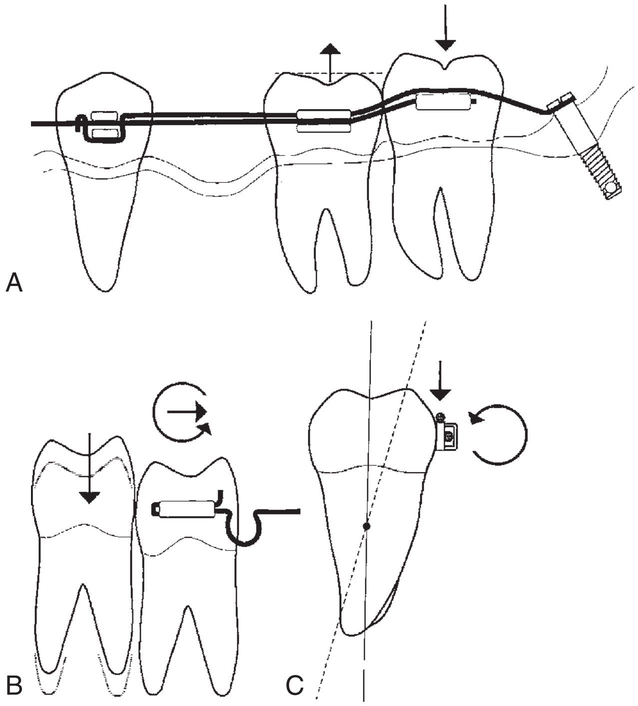

FIGURE 4-77 **A,** The mechanics of intruding a third molar with implant anchorage before space closure. **B,** A removable lingual arch prevents extrusion of the second molar. **C,** Because the intrusive force on the third molar is buccal to the center of resistance, the tooth tends to tip buccally. This problem is controlled by placing lingual crown torque in the rectangular wire inserted in the tube. (From Roberts WE, Garotto LP, Katona TR. Principle of orthodontic biomechanics: metabolic and mechanical control mechanisms. In: Carlson DS, Goldstein SA, eds. *Bone Biodynamics in Orthodontic and Orthopedic Treatment*. Ann Arbor: University of Michigan Press; 1992.)

second-molar areas, the orthodontic option for mesially translating the molars to close the space is increasing in popularity. The ingenious mechanics (Fig. 4-77) used with retromolar implant anchorage served to highlight anchorage requirements of molar protraction, and biomechanical resolution of forces and moments allows for translation of molars. Extraalveolar location of retromolar implants allows for great versatility and anchorage potential, and such locations are now being favored to intraradicular and intraalveolar sites at which miniscrews are placed. Clinical details have been published.[53] Rigid endosseous implants show great promise for considerably extending the therapeutic possibilities of orthodontics and dentofacial orthopedics.

CURRENT STATUS OF MINISCREW IMPLANTS

The utility of skeletal anchorage in orthodontics continues to evolve, with many new designs and emerging clinical applications. The term *temporary anchorage devices* (TAD) has gained popularity in the orthodontic literature[171] and refers to a broad group of devices, which includes, for example, miniscrew implants (MSI), palatal implants, and retromolar implants. MSI are clearly the most popular TAD in current use, and the term *MSI* is specifically used to describe small (typically 1.5 to 2 mm in diameter and 6 to 10 mm in length) machined

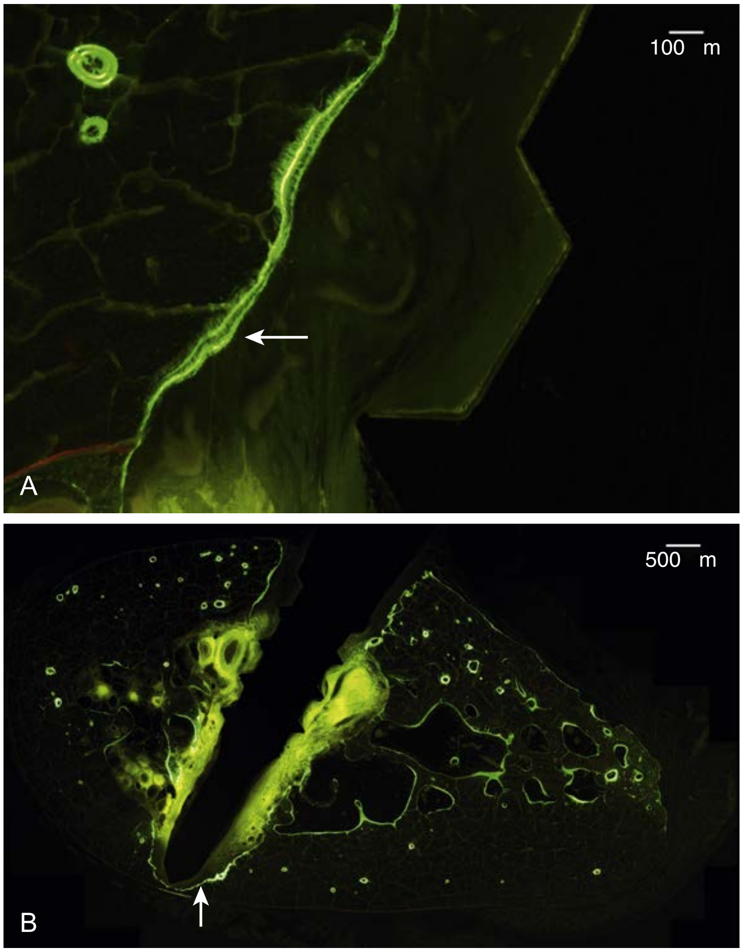

FIGURE 4-78 Failed implant with fibrous tissue interface. **A,** Bone is seen on left side and fibrous tissue between (arrow) the implant and toward the bone surface. **B,** Failed implant encapsulated with fibrous tissue in a canine model. There is no bone contact. The implant has nearly perforated the opposite cortex (*arrow*). (From Huja SS. Bone anchors – can you hitch up your wagon? *Orthod Craniofac Res*. 2015;18(suppl 1):109–16).

devices. Another less popular but possibly a more accurate collective term for these types of devices that are borne by the bone would be *skeletal anchors*. There is a large vocabulary of terms that have been introduced into the literature to describe these anchorage devices, their design, and other features associated with their use, and a description of such terms can be found in the literature.[171]

MSI are placed within the alveolar process, typically in an interradicular location. As MSI are placed in the close vicinity of the anchorage requirement, they eliminate the need for complex biomechanics and strategies that are typically seen, for example, with retromolar implants.[144] This versatility of placement is considered to be the major advantage for these anchors. The literature is replete with numerous case reports and studies on the potential and possibilities of enhancing anchorage with MSI.[172] However, one of the major issues with MSI are the persistently high failure rates.[173] Orthodontists are also interested in other skeletal anchorage options such as miniplates[174] and other extraalveolar sites for MSI placement, such as the palate.[175] The salient difference between many of these TAD is that MSI currently cannot routinely support larger forces (e.g., 10 N) over a prolonged duration (1 to 2 years) and are typically used for movement of few teeth over a period of 6 to 8 months.[172]

One of the assumptions made by researchers and clinicians alike is that MSI would serve in an identical manner to endosseous implants. Endosseous implants have been demonstrated, beyond a doubt, to be rigid and capable of withstanding high orthodontic forces and prolonged loads.[176] They osseointegrate to the bone, and no movement of implant device has been observed after load application.[10] Unfortunately, the term *absolute anchorage* has crept into the orthodontics literature and suggests that MSI are identical to endosseous implants and are entirely rigid. While it was desired that MSI would not fully osseointegrate and could be removed upon completion of their use, some of the other sequelae such as high[177] failure rate (10% to 30%) and displacement[178] were not anticipated.

Osseointegration

A major challenge for researchers in developing a more successful implant device is to determine how a "successfully osseointegrated" implant should appear on histologic examination in vivo. These histologic studies are conducted in animals or from retrieval specimens from humans. The definition and mechanism of a successful implantation historically has been described by the term *osseointegration* at a histologic level.[179] Osseointegration is the presence of vital load-bearing bone directly in contact with the implant. The term *osseointegration* is defined at a tissue level in animals, and thus most of the implant studies examine bone sections and quantify histologicic outcome variables that are suggestive of a favorable response at the interface. For others, osseointegration may refer to the lack of ability to remove the implant and break the bone–implant interface. Percent bone to implant contact (%BIC) is frequently measured in various studies. However, there is no clear, quantifiable metrics of what constitutes a successful implant on a histologic section. In addition, one cannot evaluate a successful implant solely from a histologic section as other mechanical factors (e.g., primary and secondary stability) cannot be measured on histologic sections. Also, there is disagreement on the question of whether an MSI osseointegrates. These devices are biocompatible and can be removed easily even after 1 to 2 years after insertion. Dental implants cannot typically be removed without the aid of a trephine. Thus, the level of osseointegration or strength of the interface between the bone and implant surface must be different for an endosseous implant and MSI.

A failed or failing implant can be ascertained from histologic sections (Fig. 4-78, *A* and *B*). The presence of fibrous tissue and woven bone[180] instead of load-bearing lamellar bone at the implant interface is indicative of overload and augurs to future failure. Another major challenge in animal studies is the inability to carry out these implant studies to long durations (e.g., greater than 9 to 12 months), thus mimicking their clinical use. While many studies examine the early time points (weeks and months after implantation), longer time points after bone healing has occurred are difficult to conduct in experimental designs, and costs can be prohibitive. Finally, selection of an appropriate animal model interpretation and extrapolation of results to humans have to be attempted with caution.[181] Within the framework of implant research, in vitro studies have contributed to the understanding of the cellular and molecular responses and gene expression, which may be predictors for the success of various implant-surface modifications.[182]

Bone Contact

Bone to implant contact, frequently referred as BIC, is measured in most histologic studies. The measurement is relatively straightforward but requires an intact bone–implant interface with the implant and the bone being sectioned together, which itself is challenging. Bone contact as measured in studies is a static measurement of a dynamic variable. The presence of bone remodeling at the implant interface is evidence that bone contact is dynamic—that is, it may increase or decrease and different areas of the implant may contact bone at different times.[24] Given that the remodeling rate is elevated and high at the implant interface,[183] it is likely that bone contact does change.

A question that intrigues researchers and clinicians alike is the relationship, if any, between bone contact with implant and implant success. It is unknown if an implant with 80% of bone contact will fail, while an implant with 30% bone contact will be successful or vice versa. Bone contact alone is not a predictor for implant success. Retrieval analyses of dental implants that were in function for many years point to 50% to 60% bone contact.[184]

Bone Remodeling

Presence of viable bone is key to success at an implant interface. One method to measure the metabolic activity at an implant interface is by estimation of bone remodeling in supporting cortical and trabecular compartments. One study examined retrieval specimens from various animal species,[183] and it was observed that even after accounting for periods of time for typical bone healing, a persistent, elevated remodeling rate is observed in implant adjacent bone in the long term (e.g., 1 to 2 years after implantation). This led one group to conclude that an elevated rate of bone remodeling in the direct vicinity of the implant (0 to 1 mm from the interface) was critical to the long-term success of implants.[183] However, similar to bone implant contact, it is unclear what the magnitude of the bone turnover should be for it to be beneficial. In other words, can excessively high or low turnover rates be counterproductive at the implant interface?[185]

More recently, μCT has been used to study bone healing and adaptation. These μCT images provide 3D reconstructions of the region of interest. However, μCT still has not replaced dynamic histomorphometry but seems to have promise when measuring static histologic measurement. These subtleties may have been overlooked and confound study designs in animal experiments.[186] A major limitation of destructive examination by histology is that only a select number of 2D sections can be examined and do not reveal the true 3D nature of the implant interface.

Failure of Miniscrew Implants—Design or Unique Biological Constraints?

A major difference between MSI and endosseous implants is the need to remove the MSI after clinical use without a trephine. The ability to torque the MSI out without fracturing the implant or loss of bone in the alveolar process is critical. With this in mind, most MSI are smooth-surface machined implants. More recently, displacement of MSI, with migration of the device toward the point of force application, has been observed.[187] In addition, the MSI can be displaced (creep) within the bone without being extruded or "pulled out."[188] One key question is whether this migration of the MSI can be prevented. The nature and mechanism of MSI displacement within alveolar bone are unknown.

There is evidence to suggest that the alveolar process provides a unique milieu for implantation. It is well known that the volume of bone is small in the interradicular locations and placement of a screw close to the periodontal ligament results in increased probability that it will loosen and fail.[189] It is likely that bone within the alveolar process experiences greater strains than basal bone in the jaw and such strains may result in overloading of the implant interface or even predispose the MSI to failure in this hostile environment.[190]

Initial reports of displacement of MSI when subjected to orthodontic load were presented from 2D cephalometric data as early as 2004.[187] Subsequent reports with 3D cone beam studies suggest that MSI could be displaced by ~1 mm with a maximum value in one device of 4 mm.[191] Others indicated that MSI used in the maxilla had an average displacement of 0.78 mm; however, some of the MSI had a displacement close to 2 mm.[178] The current designs of MSI may not be able to withstand orthopedic loads. A clinical study reports that surface modification results in no difference in the survival rates of MSI used for orthodontic anchorage in the mandible and maxilla over a ~5-month period.[192] However, the CBCT data from a 9-month study of a larger C implant (SLA-coated and 1.8-mm diameter) in the maxilla for en masse canine retraction indicates that the MSI remain stationary.[193] It is not common practice currently to use surface-modified MSI. However, it seems that an implant with surface modification of an appropriate diameter may provide more rigidity.

Rigidity of Miniscrew Implants

Initially, when skeletal anchorage was introduced to orthodontics, the anchors were used in an extraalveolar location (e.g., retromolar implants, zygomatic wires). It was only with the introduction of smaller (1.5- vs. 3.75-mm-diameter) miniimplants that interradicular placement was attempted.[194] In addition, a major advantage of MSI is the ease by which they can be placed by the orthodontist accurately at the desired site from which load could be applied.[195] This overcomes the need for patient referral, the additional cost and time for device placement by a surgeon.

One of the questions that have not been systematically addressed is the ideal diameter of MSI. The diameter has been determined primarily by the site of placement. For example, when MSI are placed between roots of maxillary molars for intrusion of maxillary posterior segment, a device with a diameter of 1.3 mm will allow for adequate bone for placement/retention and prevent impingement on adjacent roots.[196] As bone volume and vital structures are not a consideration in some extraalveolar sites, it should be possible to use wider diameter implants, should they provide greater rigidity and service. Systematic studies will be needed to address these questions. Other methods to test for a successful implant such as insertion torque, removal torque, pull-out testing, fatigue loading, and other standard tests have not been discussed but are acknowledged.

There are a large number of studies conducted in a variety of animal models. Animal models serve as one step toward translation of discovery to humans, and there are limitations and advantages to each animal model.[181] The typical histomorphometric variables that should be measured to provide relevant and useable information to the reader and for preventing repetition of studies especially on larger animal models[197] are briefly discussed below, and the reader is referred to a recent review for additional details.[198]

A novel non-anchorage related application of miniscrew implants has recently been proposed. Alveolar bone loss after extraction, loss of primary teeth or absence of permanent teeth, can compromise the vertical alveolar height for subsequent implants. An animal experiment based on clinical observations[199] suggests that vertical bone loss can be prevented by horizontal insertion of a miniscrew transcortically below the alveolar crest (Fig. 4-79). This is in contrast to insertion of a miniscrew vertically through the alveolar crest.[200] Clinical applications, such as placing a miniscrew in the palate below the alveolar crest to support a pontic for a missing lateral or at the site of second primary molars, may preserve bone for future endosseous implants.

ANIMAL MODELS FOR STUDYING BONE ADAPTATION, REMODELING, AND MODELING

Rodents (mice and rats), Lagomorpha (rabbits), canines (dogs), and porcine (pigs) serve as models for study of orthodontic tooth movement and craniofacial biology. Each of these animal models has been extensively studied. However, it is important to understand differences among these models. While selecting an animal model, it is important to ask the question or test

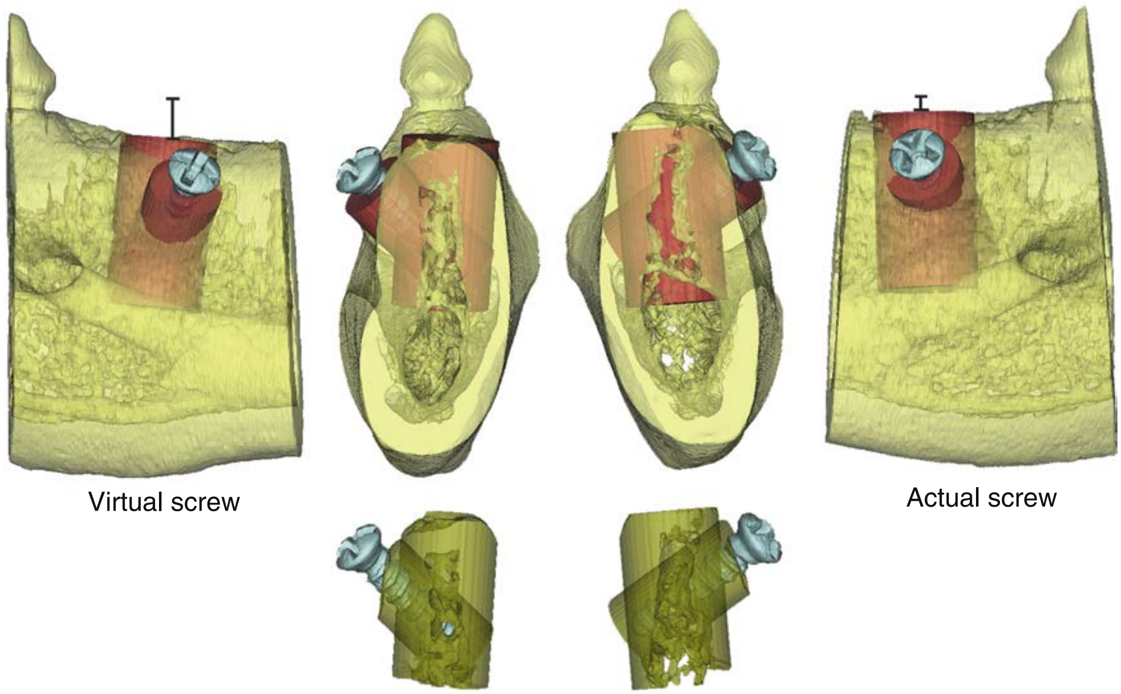

FIGURE 4-79 Surface models of a transmucosal screw placed at an extraction site versus contralateral side where no screw was placed but a virtual screw was simulated. Placement of a miniscrew below the alveolar crest prevented further bone loss as compared to the control (*virtual*) side. This bone loss will potentially allow for vertical bone height preservation. (From Melsen B, et al. Alveolar bone preservation subsequent to miniscrew implant placement in a canine model. *Orthod Craniofac Res*. 2015;18(2):77–85).

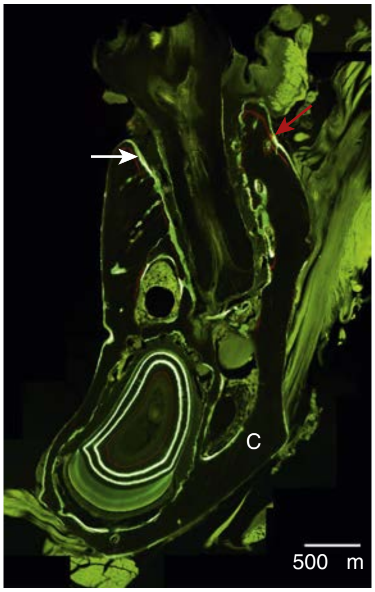

FIGURE 4-80 Epifluorescent image from an ~13-month-old rice rat mandible containing a mandibular molar and surrounding bone. Note that modeling occurs on the periosteal (*red arrow*) and periodontal surface (*white arrow*). The cortical compartment (*C*) is devoid of secondary osteons, indicating no physiologic bone remodeling.

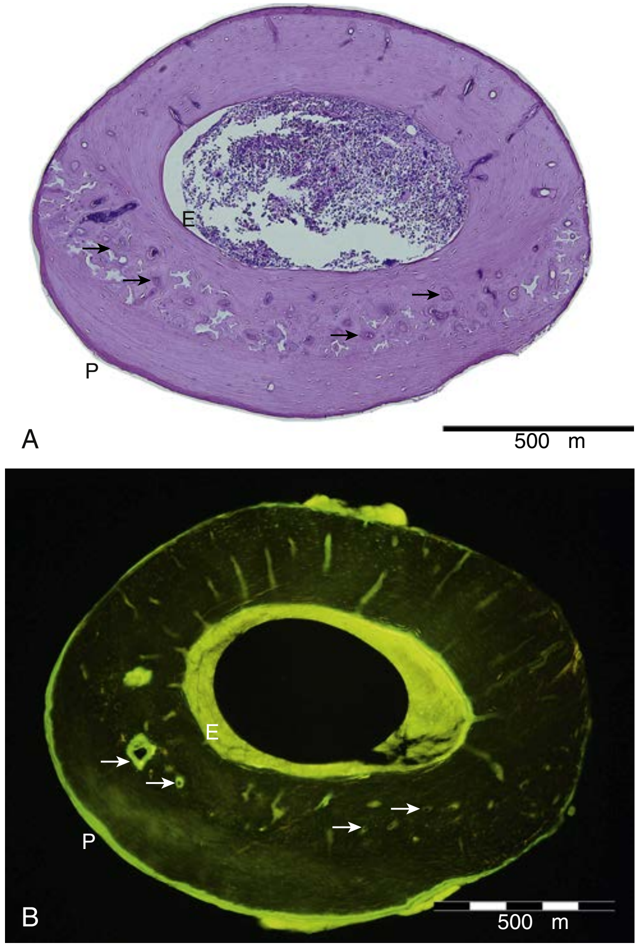

FIGURE 4-81 Hematoxylin and eosin (A) and epifluorescent (B) sections from a transverse section of a C3H mouse femur. The C3H is an inbred mouse with thick bones. When the bone dimension increases, vascular invasion with osteonal-like structures (*white and black arrows*) become apparent in the cortical compartment away from the periosteal (*P*) and endosteal (*E*) surfaces.

a hypothesis that can be answered in the particular and suitable animal model. Thus, it is critical that the bone physiology of the model be understood. For example, rodents possess thin[201] cortical plates (<0.2 to 4 mm), and vascular invasion to produce an osteonal system is not required. The vascular supply from the periosteal and endosteal surfaces suffices to provide nutrients to the bone cells within the cortical plates. Thus, typically in the jaw bone of rodents only modeling is observed (Fig. 4-80) on the periodontal and periosteal surfaces of the bone. Inbred mice such as the C3H mice have thickened cortical plates (Fig. 4-81, *A* and *B*) and do demonstrate evidence of cortical bone remodeling in the femur.[201] In addition, in response to injury, ovarioectomy and possible microdamage accumulation, targeted remodeling with appearance of osteons, may occur in rodents[202] within the cortical plate. This remodeling is not physiologic but experimentally produced. When studying bone remodeling at a tissue level the rodent model will not possess the typical intracortical osteonal remodeling in the jaw bones (Fig. 4-82, *A* and *B*). However, the cell and molecular events[203] in the bone of the rodent more closely reflect the changes that are observed in larger animals. Thus, rodents possess many advantages in studying tooth movement, and many cellular, molecular pathways can be interrogated, with probes being available for a large number of molecules. In addition, transgenics offer new insights into bone biology and mechanisms of bone adaptation and can be exploited in rodent models.[204]

In contrast to the cortical bone, the trabecular bone[205] of the distal femur and proximal tibia (Fig. 4-83) are standard sites to evaluate by alterations in bone remodeling using histomorphometric methods in mice and rats, respectively. These trabecular bone sites allow researchers to examine the effects of drug interventions, experimental procedures, or transgenes on bone remodeling in a rodent model. In other words, rodents remodel in the trabecular bone but not typically in the intracortical compartment.

Rabbits are also used to study craniofacial biology such as sutural growth[111] implant biology.[206] The jaw bone of the rabbit is lamellar on the periosteal and endosteal surfaces with numerous osteons in the intracortical compartment (Fig. 4-84, *A* and *B*). Figure 4-85 shows the root structure and bone distribution in a rabbit model, which are vastly different from those in the canine model and humans. Thus studies, for example, on tooth movement have to be carefully planned and interpreted from data obtained from rabbits. The rate of osteonal bone turnover is low and is estimated to be 2%/yr in the jaw bones of 4-month-old female New Zealand rabbits (see Fig. 4-84, *A* and *B*). Thus rabbits, in a scaling order of size, are the first animal model to routinely demonstrate physiologic intracortical osteonal secondary remodeling in the jaw bone, but the remodeling remains to be at a much lower level than other larger animal models.

In the canine model, physiologic intracortical secondary osteonal remodeling (Fig. 4-86) occurs throughout the skeleton, in both the trabecular[85] and cortical bone compartments.[12,207] Animal husbandry in larger animal models can be very expensive. However, the dental structures and bone distribution are

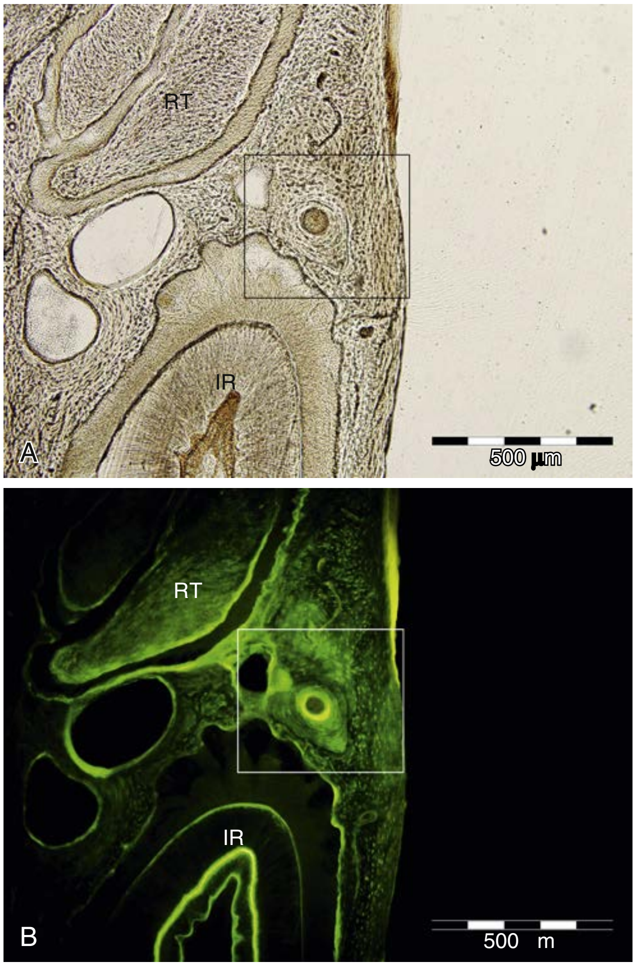

FIGURE 4-82 Brightfield (A) and epifluorescent (B) images of a buccolingual section from a B6 mouse mandible. Within the box an osteonal structure is observed just above the incisor root (*IR*) and below the root tip (*RT*). These structures are rare, indicating that mice to do have physiologic secondary intracortical osteonal bone remodeling in the mandibular bone. (From Meta IF, et al. Alveolar process anabolic activity in C3H/HeJ and C57BL/6J inbred mice. *J Periodontol.* 2008;79(7):1255–1262. Reproduced with permission from the American Academy of Periodontology).

FIGURE 4-83 Epifluorescent image from an ~13-month-old rice rat proximal tibia demonstrating trabecular bone remodeling (*white arrow*) in the metaphyseal bone. Alizarin bone seeking label is seen in red (*red arrow*). This is the typical site for measuring bone remodeling activity in a rat model, in contrast to the mandibular cortical bone (see Figure 4-80) that does not demonstrate cortical bone remodeling.

similar to those in humans. Histomorphometric dynamics in the canine model have been studied extensively.[208,209] It is also possible to place implants and devices that are used in humans without scaling the size of the device.

Porcine models also demonstrate intracortical and trabecular bone remodeling and continuous growth (Fig. 4-87). However, the ability to obtain older animals for experimental studies remains a challenge. These animal models (such as minipigs) have been used to study distraction osteogenesis, biology of bone adaption to functional forces,[190] and occlusion. In a study of four ~2-year-old domestic female pigs the mean rate of bone turnover in the bone of the alveolar process of the mandible was 31.2%/yr and 17.9%/yr in the basal region of the mandible. The rate of bone turnover in the femur was 54%/yr.

EXPEDITED TOOTH MOVEMENT

Currently there are increasing numbers of case reports that demonstrate that substantial reductions in orthodontic treatment times are achievable. Corticotomies, vibration, laser, electric current, and controlled localized injury have been suggested to increase the bone metabolic rate that is considered to be the "mechanism" that reduces treatment time in orthodontic patients. Altering bone remodeling, a tissue-level histologic event, to expedite tooth movement has not been fully explored and substantiated by research studies. The treatment duration for comprehensive orthodontic therapy is estimated to be 24 to 30 months. Predictable reduction in treatment time to approximately 12 months would be a significant advance that would benefit orthodontic patients. Reduction in treatment time would also have the additional benefit of potentially decreasing the major sequelae of orthodontic therapy, such as root resorption and white spot lesions. Treatment duration has probably remained largely unchanged for the past century. With the synergy of rapid advances in technology and understanding the biology of tooth movement, opportunities for expediting tooth movement seem to be poised on the horizon. There are a number of clinical case reports that suggest treatment time can be reduced for orthodontic patients.[210,211] A number of hurdles remain before such claims can be substantiated and become evidence based. For example, does a reduction in treatment time during the initial phases (initial leveling/alignment or space closure) of orthodontics translate to overall reduced treatment time? Is it possible that the finishing phase of treatment would actually be prolonged? Also the cost-benefit ratio of a 4- to 6-month reduction in treatment time and the quality of the final result should be compared to cases with traditional treatment times.

In the literature a number of "mechanisms" have been suggested as a/the reason responsible for the accelerated tooth movement. These include:

1. Cortical plates are an impediment to orthodontic tooth movement[212]

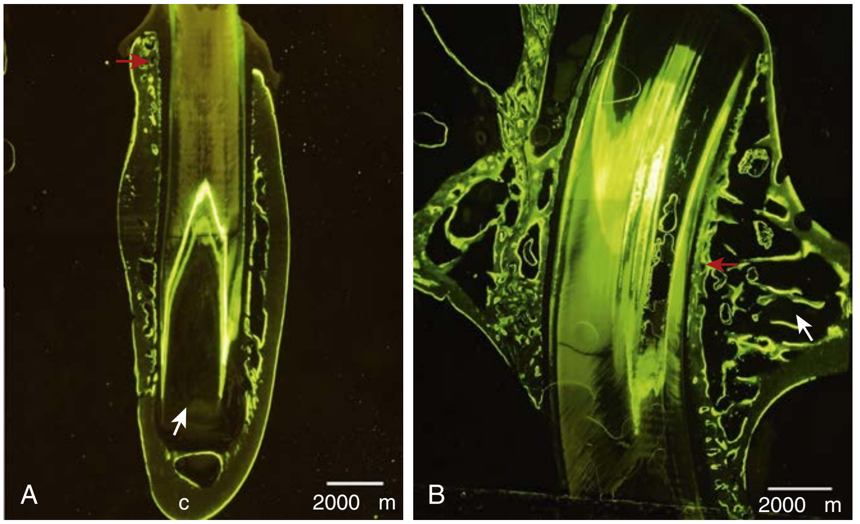

FIGURE 4-84 **A,** Epifluorescent buccolingual section of a rabbit mandibular molar. Note open apices of root (*white arrow*) and a thin plate of cortical bone (*C*). Only a few labeled osteons are apparent in the alveolar bone toward the crest (*red arrow*). **B,** Epifluorescent buccolingual section of a rabbit maxillary molar. The cortical bone supporting the tooth is very thin (*red arrow*) with large trabecular spaces (*white arrow*).

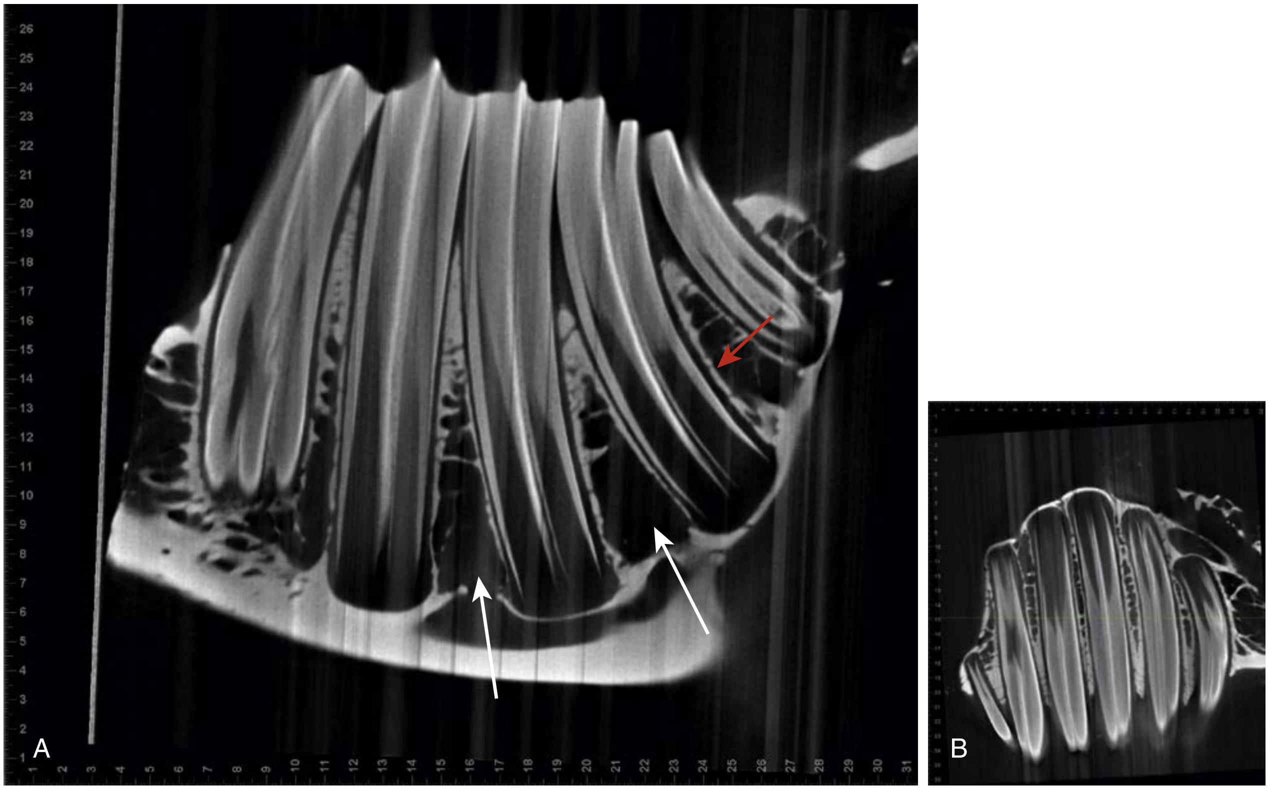

FIGURE 4-85 Sagittal view of mandibular (**A**) and maxillary (**B**) molars reconstructed from a high-resolution microCT of an ~4-month-old New Zealand female rabbits. Note the open apices of the roots of the teeth, and very thin alveolar bone (*red arrow*) with large marrow spaces (*white arrows*). The anatomy of the supporting bone is very different from a canine model and human bone.

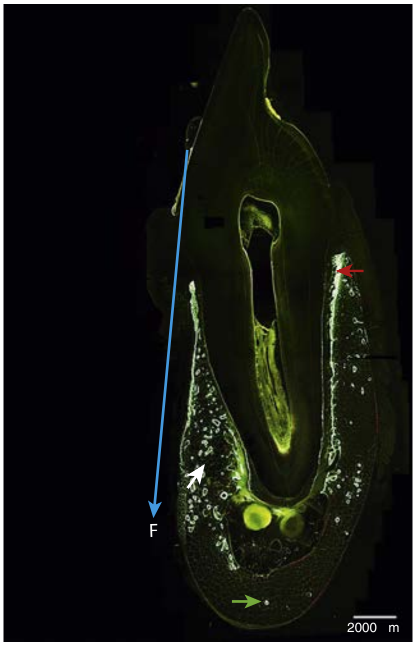

FIGURE 4-86 Epifluorescent buccolingual section from a dog molar root. An intrusive force (*F*) was applied from a miniscrew inserted between the interradicular area. Bone apposition (*red arrow*) is seen adjacent to the periodontal ligament, and secondary osteons are readily apparent and numerous in the cortical alveolar compartment (*white arrow*). The basal bone (*green arrow*) demonstrates a lower rate of bone turnover.

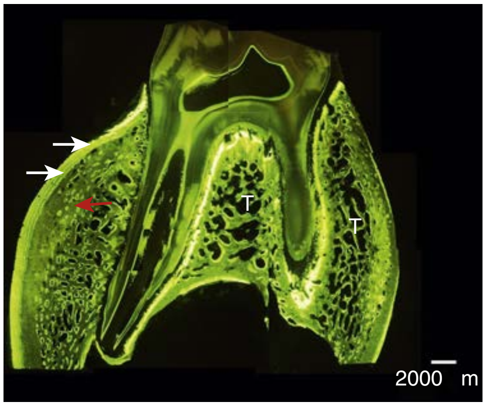

FIGURE 4-87 Epifluorescent section from a domestic pig jaw molar region. Even in this 24-month-old animal, modeling (*white arrows*) events are apparent on the periosteal surface. Below the modeling surface intracortical osteonal remodeling (*red arrow*) is observed. There is an intervening layer of trabecular bone (*T*) adjacent to the cortical bone lining the periodontal ligament.

2. Regional acceleratory phenomena and associated tissue remodeling[213]
3. High rates of bone turnover[213]
4. Demineralization/remineralization process[214]
5. Increase in cortical bone porosity, transient osteopenia, and osteopenia-facilitated rapid tooth movement[213]
6. Dramatic increase in trabecular bone turnover[213]
7. Bone matrix transportation[214]

The basis of some of these statements lies in beliefs, observations, and interpretations from clinical and animal data. All of the above listed “mechanisms” refer to tissue-level histologic events and should be explained by a thorough understanding of bone remodeling[215] and modeling[97] processes. These two processes are well described in the bone literature. However, they are frequently misunderstood and are clarified in the earlier part of this chapter.

Regional Acceleratory Phenomena

Regional acceleratory phenomena (RAP) are most exclusively and frequently cited in the literature as the basis of accelerated tooth movement. RAP was first described by Dr. Harold Frost.[62] He described RAP as a complex reaction to diverse noxious stimuli. He indicated that it is an “SOS” mechanism and acceleration of normal vital tissue processes. In humans, it lasts 4 months in bone and somewhat less in soft tissues. Importantly, RAP is a process of intermediary organization of tissues and organs *and not revealed in isolated cells*. This statement is very important as concluding from isolated cells that RAP is occurring in an experimental system is incorrect as originally defined. Initially RAP was described in cortical tissues and later in trabecular bone. RAP is *not* typically accompanied by osteopenia in the cortical[216] and trabecular[217] bone compartments as has been described in the orthodontic literature. The osteopenia associated with orthodontic tooth movement in some rodent animal models may be unique to the model in which it is being described and may not be related directly to the RAP per se. The contribution of a large rigid structure (the tooth) within the bone with and without superimposed force application may modify the response to tissue injury.

Another term that has been introduced in the orthodontic literature in terms of mechanisms of accelerated tooth movement is *demineralization* (which implies loss of mineral to some extent). New bone has less mineral content. The two phases of deposition of mineral in bone have been well described earlier in this chapter. It is not surprising that the new bone that is deposited is less rigid and more compliant and has less mineral.[29] It seems that in the orthodontic literature on expedited tooth movement, it is implied that the mineral is removed from the bone; however, the bone matrix remains intact and the tooth is transported through the matrix without the typical resistance experienced in a mineralized tissue. It is unclear how the bone mineral is exclusively removed rapidly without bone resorption by osteoclasts, which would also remove the matrix of bone. A decrease in bone volume rather than a decrease in mineral per se seems more plausible. Bone volume can be altered by osteoclastic resorption or by bone formation rather than by a mechanism for sole and rapid removal of the mineral.

Bone Remodeling Rate

In order to understand if increases in bone remodeling (bone turnover) rate are responsible for increased rate of tooth movement, it will be important to quantify the alterations (increases or decreases) in the rate of bone remodeling. It is well known that cortical bone remodels at 2 to 10%/year, and the rate of turnover in the trabecular bone is 30 to 35%/year.[40,44] Trabecular bone is metabolically active and is the source of serum calcium. Interestingly in the alveolar bone that supports the tooth, the physiologic rate of cortical bone turnover can be as high as 35%/year, this being 3- to 10-fold higher than cortical bone elsewhere (e.g., in the long bones) in the body.[12,218] In implant adjacent bone the rate of bone turnover can be as high as 100 to 500%/year, suggesting intense cortical bone remodeling in implant adjacent bone.[219] It is likely that this elevated turnover is required to maintain a compliant zone of bone and to buffer for the modulus mismatch between the implant and bone. This elevated rate of bone turnover is seen both in miniimplant and implant adjacent bone. During tooth movement,[140] the rate of cortical bone turnover is estimate to be 100 to 200%/year—again, a 3- to 6-fold increase over the physiologic rate in the alveolar process. Currently there is no quantification of intracortical bone remodeling in the alveolar process after corticotomies. Thus, we do not know if the rate of turnover increases, for example, to 1000%/year or to any such level. Without these data from cortical and trabecular bone, it is difficult to confirm that RAP or increased bone turnover is responsible or accompanies expedited tooth movement and even the sole mechanism that allows for more rapid tooth movement.

Current Evidence of Expedited Tooth Movement from Experimental Studies on Rodents and Canines

While a multitude of animal models have been used to study orthodontic tooth movement and specifically expedited tooth movement, it behooves us to understand and interpret the results from the literature as translation to our patients must be attempted with caution.

A rat model has frequently been exploited to study the biology of expedited tooth movement in response to injury (corticotomy, piezocision, etc.) Bone changes subsequent to injury have been demonstrated[213] using a rodent/rat model. An indentation with a dental burr onto the cortical bone of the maxilla was used to represent the decortication injury common in the “Wilkodontic” procedure. Sebaoun et al.[213] demonstrated that the injury results in “disappearance” of bone in the 3-week surgery group, between the roots of the 1st molar, and at 11 weeks, the bone was restored between the roots similar to that of the 3-week control group. They conclude their histomorphometric data (intravital bone labels and TRAP staining for osteoclasts) suggests that modeling of the trabecular bone occurs and bone turnover after corticotomy *does not* involve a linear/sequential series of events. In other words, remodeling (coupled bone formation/resorption) in the rat model is not responsible for the bone response after decortication under their specific experimental conditions. In this particular study, there is no explanation of how mineralized tissue returns to its original state. Typically bone resorption by osteoclasts results in the loss of both the mineralized tissue and the organic matrix. Once bone loss occurs (e.g., in trabecular bone of the spine during osteoporosis), reversal of the bone loss and new bone formation do not occur, as no matrix exists for new bone formation to occur within. Baloul et al.[220] studied the corticotomy-facilitated tooth movement with the aid of microCT and the expression of selective osteoclast and osteoblast genes in their rodent model. They demonstrate in the split-mouth study design that the rate of tooth movement initially peaks at 7 days in the decortication side as compared to 14 days on the control side. In their mCT data, they demonstrate that apparently greater values of BV, BV/TV, BMC, and BMD occur in their corticotomy-only group compared to the tooth movement-only group or tooth movement plus corticotomy group. They also demonstrate that key osteoblastic and osteoclastic genes are elevated temporally, suggesting increased bone activity. However, due to the method of collection of the tissue sample for this gene analysis, it is not possible to analyze on which surface the bone formation or bone resorption is occurring. As Frost indicated, RAP does not occur in isolated cells but at a tissue level of organization. The field of molecular biology did not exist at the time of Dr. Frost’s publication. Dibart et al.[221] used piezocision to facilitate the orthodontic tooth movement in rats. Their histologic images demonstrate aggressive/extensive bone loss that extends beyond the initial piezocision site, and the injury results in changes in both the cortical and trabecular bone. Dibart et al.[221] demonstrated reduction in percent bone from 60% to virtually 0% to 20% in all their three groups. The question remains if in a human, such reductions would result in the devastation of the bone strength and structure. Also, it is questionable if tooth movement could occur in bone that has been so severely compromised. This may be a limitation of the model and may not entirely detract from other parts of the data. Also, in the presence of such severe bone loss, it is unknown whether a matrix for regaining the bone would exist. In the study, however, bone recovery occurred primarily between the 40- and 60-day period.[222]

The dog/canine animal model also offers valuable insights into understanding of expedited tooth movement. The concept of cortical bone resistance impeding tooth movement was tested by undermining the septal bone in a canine model.[212] This work demonstrated that the cortical bone structure has to be resorbed during tooth movement, and surgical removal of this localized bone will result in more rapid tooth movement. Doubling in the rate of tooth movement over a period of 6 weeks was demonstrated in a split-mouth study in a canine model. Mostafa et al.[223] demonstrated that the injury (corticotomy) has only a transient effect, and a short window of opportunity exists to effect the tooth movement. Major differences were seen in the first 2 weeks between the groups, and the authors suggest that based on histology there was decreased hyalinization in the experimental groups. Their histologic images are quite different from the rodent model, with no rapid declines in mineral content of bone being apparent.[223] This leads to the question whether what is seen in the rodents would really be observed in humans. In a similar split-mouth study, it was observed that a higher rate of tooth movement occurred in the experimental group, with the rate of tooth movement in a canine model being higher in the maxilla than in the mandible.[224] Similar to other studies, there are greater differences between the control and experimental groups, in the first 2 to 3 weeks after which in these animal models the differences diminish. The transient nature of the effect reinforces the need for the tooth movement to begin immediately after the corticotomy. In humans, if the effect is primarily seen for 6 weeks, only a small portion of a phase of treatment, e.g., canine retraction, would be complete, and the question remains if a second invasive surgery would be warranted.

Based on the current literature, there are inconsistencies and vast differences in histology and interpretation of the histology between rodent and canine animal models. This poses a problem, and it is unclear as are the mechanism(s) of expedited tooth movement. The rate-limiting step in tooth movement is resorption of bone by osteoclasts. However, in rodents, the bone mineral “disappears” by a method other than osteoclastic resorption, and transport of the tooth occurs within the compliant bone matrix. In larger animal models, the corticotomies do not seem to “devastate” the bone—that is, the BV/TV does not drop from 60% to 20% in a matter of weeks.

Molar protraction even when using contemporary methods of anchorage can take approximately 20 to 24 months. This type of tooth movement would lend itself to investigation into procedures that expedite the rate of tooth movement. In contrast to animals, in humans, the two-rooted mandibular molar moves mesially, and the rate of tooth movement[144] is diminished. Other nonultrainvasive methods such as vibration (Acceledent type of device), and microperforations (Propel-type devices), also are believed to alter the rate of bone turnover, but animal studies do not clearly demonstrate an altered, secondary osteonal-bone remodeling.

SUMMARY

Bone physiologic, metabolic, and cell-kinetic concepts have important clinical applications in orthodontics and dentofacial orthopedics. The application of fundamental concepts is limited only by the knowledge and imagination of the clinician. Modern clinical practice is characterized by a continual evolution of methods based on fundamental and applied research.

Application of Bioengineering to Clinical Orthodontics

Charles J. Burstone

OUTLINE

An important aspect of the scientific revolution that has taken place in biology over the past decade is the broad application of the physical sciences to living tissues. Physics, engineering, and mathematics can be applied similarly, with great profit to the field of orthodontics. Of all the possible applications, this chapter concerns itself with only one, the biophysics of the orthodontic appliance. The chapter covers whether theoretic mechanics can help in the design and clinical manipulation of an orthodontic appliance.

Theoretic mechanics offers potential benefit in orthodontics in three primary ways:

- Basic principles of engineering and physics can point the way toward improved design of orthodontic appliances. If the orthodontic specialty relies only on trial-and-error procedures for the development of new appliances, the developmental horizons become sharply limited. Empiricism in orthodontic design must give way to a new discipline of orderly appliance development using concepts from the physical sciences. In a less ambitious way, theoretic mechanics may help in the design of a new appliance by enabling clinicians to apply knowledge that has been gained from some of the older appliances. For example, if an existing appliance works well for a given type of tooth movement, clinicians can use the force system developed by that appliance as a basis for designing a new one. Although the trial-and-error method has proven valuable in the past, presumably the application of biophysical principles will give rise to a more orderly development of orthodontic appliances.
- Study of the biophysics of tooth movement can yield important information. If researchers and clinicians can quantify the force systems applied to teeth, they can understand clinical, tissue, and cellular responses better. To make valid judgments about the response of teeth to orthodontic forces, clinicians first must define fully the force system acting on the tooth. Theoretic mechanics also can be helpful in formulating useful concepts of stress distribution in the periodontal ligament (PDL) as it relates to bone remodeling.
- A knowledge of physics can enable better treatment results. Each time clinicians adjust an archwire or any other orthodontic appliance, they make certain assumptions about the relationship between the appliance and the biology of tooth movement. As these assumptions about the relationship between forces and tooth movement come closer to reality, the quality of orthodontic treatment will improve. For instance, many of the undesirable side effects that occur during orthodontic treatment can be attributed directly to a lack of understanding of the physics involved in a given adjustment. Many variables in orthodontic treatment cannot be controlled fully, such as growth and tissue response to appliances; however, the force placed on the tooth is a

controllable variable. In a sense, clinicians have the duty to understand the physics of these forces so they can better control the one variable they are in a position to affect so strongly.[1,2]

SIGN CONVENTIONS

A universal sign convention is available for forces and moments in dentistry and orthodontics. The convention is as follows: Anterior forces are positive (+), and posterior forces are negative (−); lateral forces are positive (+), and medial forces are negative (−) (Fig. 5-1). Forces acting in a mesial direction are positive (+), and forces acting in a distal direction are negative (−). Buccal forces are positive (+), and lingual forces are negative (−) (Fig. 5-2).

Moments (couples) that tend to produce mesial, buccal, or labial crown movement are positive (+), and moments that tend to produce distal or lingual crown movement are negative (−) (see Fig. 5-2 and *B, C*). The same convention is used for groups of teeth (a segment or an entire arch) and for establishing signs for orthopedic effects on the maxilla and mandible. However; any sign convention is acceptable, such as the right hand rule of thumb, if it is made clear to the reader by diagram.

BIOMECHANICS OF TOOTH MOVEMENT

From a clinical viewpoint, two major problems related to tooth movement can be considered: (1) the type of force system required to produce a given center of rotation and (2) the optimal force magnitudes for tooth movement. Solving these problems requires a thorough understanding of the forces and moments that may act on the teeth and also detailed documentation of tooth movement and the response in the PDL.

The forces delivered by an orthodontic appliance can be determined by direct measurement with suitable instruments or, partly, by mathematical calculation.[3-6] The load-deflection rates of orthodontic springs or wires can be measured with electronic strain gauges or mechanical gauges. Most orthodontic appliances deliver a complicated set of forces and moments. In clinical studies, therefore, appliances of simple construction, in which forces are determined more easily and accurately, are useful. For the same reason, a clinical study in which force variables are controlled is likely to yield more information than are data taken from patients in a routine orthodontic practice.

The problems inherent in studying the response of a tooth subjected to a force system are much more complex and difficult to solve than those of simple measurement of the forces. Observations can be made on three levels to describe the response of a tooth to forces: the clinical level, the cellular and biochemical levels, and the stress–strain level. The clinical level allows the study of phenomena such as the rate of tooth movement, pain response, tooth mobility, alveolar bone loss, and root resorption. The cellular and biochemical levels give insight into the dynamics of bone and connective tissue changes in the PDL.[7,8]

Perhaps the most important and least understood level is the stress–strain level of activity in the PDL. The ability to determine accurately the level of stress (the force per unit area) in different areas of the PDL may well offer the best means of correlating the application of force on a tooth with the response of the tooth. Currently, to place strain gauges in

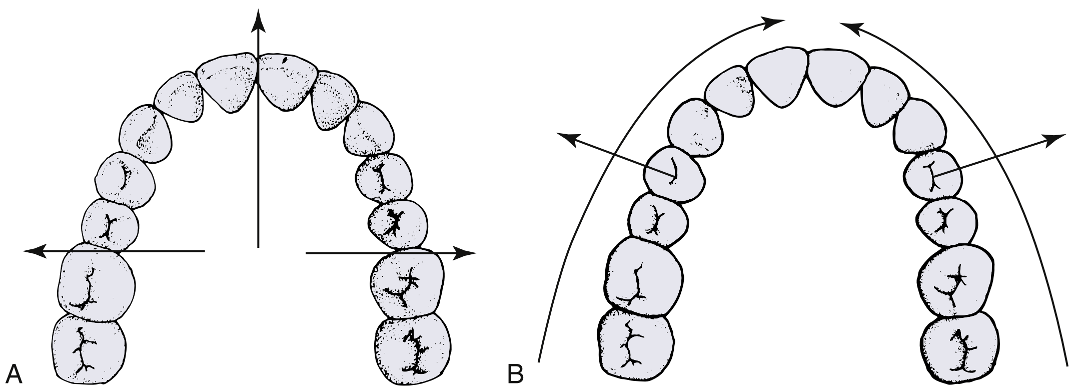

FIGURE 5-1 Sign conventions. **A,** Lateral and anterior forces are positive. **B,** Buccal, labial, and mesial forces are positive. (From Burstone CJ, Koenig HA. *Am J Orthod*. 1974;65:270. With permission from the American Association of Orthodontists.)

the PDL to measure stress distributions is impossible; therefore, knowledge of stress phenomena must depend on another approach. For example, a mathematic model of the tooth and surrounding structures can be constructed based on certain assumptions, and theoretic stress levels can be calculated from these models if the forces applied to the teeth are known. Unfortunately, these mathematic models are no better than the assumptions on which they are based. All such calculations, therefore, should be verified by clinical or animal experimentation whenever possible.

Centers of Rotation

Tooth movement often is described in general terms: tipping, bodily movement, and root movement. More specific descriptions can be devised by locating a center of rotation relative to three mutually perpendicular planes, which are (1) a buccolingual or labiolingual plane oriented through the long axis of the tooth, (2) a mesiodistal plane also oriented through the long axis of the tooth, and (3) a transverse plane that intersects the buccolingual or labiolingual and mesiodistal planes at right angles. To define fully the changes in the position of a tooth, one must use all three planes of reference. For simplicity's sake, the following discussion considers two-dimensional representations of teeth, and therefore only one plane of space is described. If certain simple assumptions are made about stress distributions (e.g., a uniformly varying distribution for pure rotation and a uniform distribution for pure translation), if a linear stress–strain relationship is postulated, and if axial loading is ignored, to mathematically predict the force system required for various centers of rotation is possible. These calculations will err because the realities of tooth and PDL differ from idealized assumptions. A typical central incisor is used to represent the application of this theory to centers of rotation. For purposes of presentation, actual force values are not used.

As a tooth translates (bodily movement), a relatively uniform stress distribution along the root is found. In terms of a center of rotation, the center of rotation for translation is at infinity (Fig. 5-3, *A*). A single force acting through the center of resistance of a root affects pure translation of a tooth. The center of resistance in a single-rooted tooth with a parabolic shape is calculated by multiplying the distance from the alveolar crest to the apex by 0.33. The center of resistance coincides with the centroid, which in this case is the geometric center of the part of the root between the alveolar crest and the apex. A force placed near the center of the root therefore should produce pure translation.[9,10]

If a pure moment (a couple) is placed anywhere on a tooth, a center of rotation is created near the center of resistance of the tooth. In Figure 5-3, *B*, the clockwise moment tends to displace the crown in a lingual direction and the root in a labial direction, with a center of rotation near the middle of the root. Unlike pure translation, pure rotation does not produce a uniform stress distribution in the PDL but rather a uniformly varying distribution, with the highest stress at the apex and the next highest at the alveolar crest. No stress is found at the center of resistance. The center of rotation is located at the level of the root where the stress is zero.

Pure translation (center of rotation at infinity) and pure rotation (center of rotation near the center of resistance) can be considered the two basic types of tooth displacements. Other centers are a combination of pure rotation and pure translation; that is, any center of rotation can be produced by combining a single force through the center of resistance of a root and a pure moment if the proper force-to-couple ratio is used.[11]

In Figure 5-4, *A*, a lingual force is acting through the center of resistance of the tooth. If a couple is added in a clockwise direction, the center of rotation moves from infinity toward the center of resistance. If the magnitude of the couple is small (relative to the force at the center of resistance), the center of rotation lies at the apex of the root. As the magnitude of the couple increases, the center of rotation shifts from the apex toward the center of resistance; finally, as the couple continues to increase, the center approaches the center of resistance of the tooth. The relative magnitude of the couple and force acting through the center of resistance determines the specific type of lingual tipping of the tooth if the direction of the moment is clockwise.

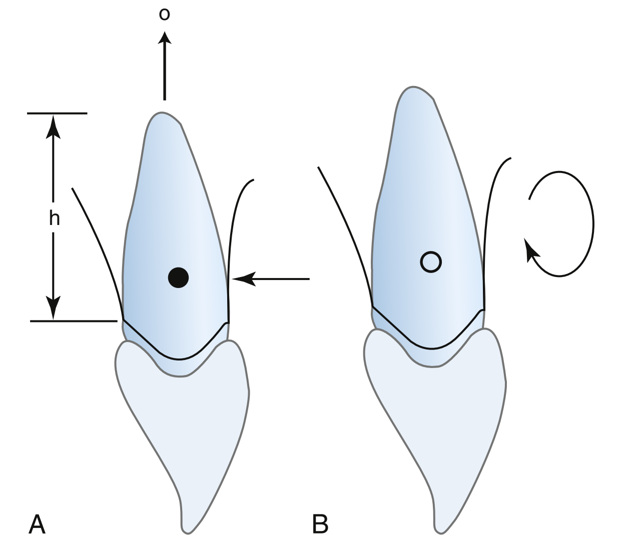

FIGURE 5-3 Basic tooth movements. **A,** A force acting through the center of resistance of a tooth produces a translation center of rotation at infinity. **B,** A couple acting on the tooth produces a center of rotation at the center of resistance.

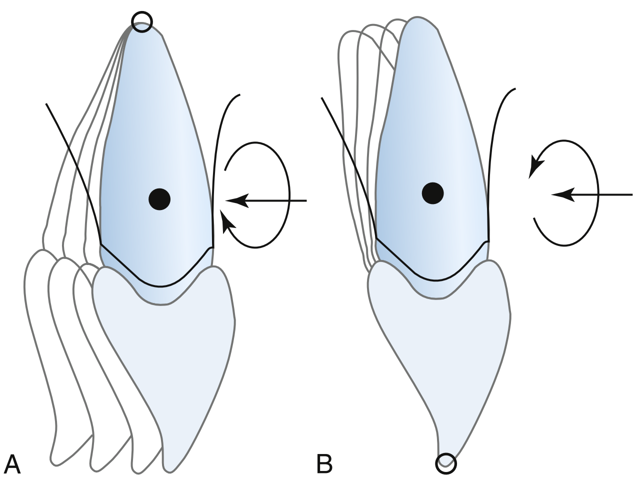

FIGURE 5-4 A couple and a force acting through the center of resistance. **A,** A negative couple produces lingual tipping of the incisor crown. **B,** A positive couple produces incisor lingual root movement.

However, a counterclockwise moment plus a force acting through the center of resistance places the center of rotation somewhere between the center of resistance and infinity (Fig. 5-4, *B*). More specifically, as the couple-to-force ratio increases, the center of rotation moves from the incisal edge to the level of the bracket and finally approaches the center of resistance. Control of the center of rotation during tooth movement then is based on two components: placement of a single force through the center of resistance of the tooth and use of a couple of proper direction and magnitude.[12]

In most instances, however, anatomic limitations in the oral cavity make placing a force through the center of resistance impractical. Therefore, a force system must be placed on the crown of the tooth (at a bracket or tube) equivalent to the required couple and force acting through the center of resistance. The two force systems are equivalent if the sums of their individual forces (F_x, F_y, and F_z) are equal and the sums of their moments around any axis of rotation are equal.

The following equivalent force systems, acting on a bracket of an incisor, are typical effects of changing the couple-to-force ratio:

- A lingually directed single force placed on the crown of a tooth produces a center of rotation somewhere between the center of resistance and the apex (Fig. 5-5, *A*).
- If a counterclockwise moment (lingual root torque) of sufficient magnitude is added, the center of rotation moves to the apex (Fig. 5-5, *B*).
- If an additional moment in the same direction is placed on the tooth, the center of rotation moves toward infinity, and at this instance the tooth is translating, or moving bodily (Fig. 5-5, *C*).
- Further increases in the magnitude of the couple place the center of rotation incisal to the crown of the tooth (Fig. 5-5, *D*), then at the incisal edge, and finally at the bracket.
- Any further increase in the moment tends to move the center of rotation toward the center of resistance.

In Figure 5-6 the moment-to-force (M/F) ratio is plotted against the center of rotation for incisor roots of 7, 10, and 15 mm. The moment and force are applied at the bracket. In all cases, the distance of the bracket is 6 mm from the alveolar crest. The direction of the force applied to the incisor is lingual (−), and the sense of the moment is lingual root torque (+). As the M/F ratio approaches zero in the three examples, the center of rotation approaches the center of resistance. As the ratio increases, the center of rotation is found at the apex of the root, at infinity, at the incisal edge, at the bracket, and at the alveolar crest. As the ratio becomes infinitely large, the center of rotation approaches the center of resistance. A slight variation in the M/F ratio can make a significant difference in the positioning of the center of rotation, except with ratios that produce centers of rotation near the center of resistance. Furthermore, the same M/F ratio produces different centers of rotation, depending on the length of the root.

Nägerl et al.[13-15] developed a general theory of tooth movement based on assumptions about three-dimensional linear elasticity. The general theory states that in any given plane, the distance from the applied force to the center of resistance (a) multiplied by the distance from the center of resistance to the center of rotation, equals a constant (s^2), which represents the distribution of the restraining forces in the PDL. As shown in Figure 5-7, regardless of where the force is applied in a given plane, s^2 remains the same. Experimental determination of s^2 offers the possibility of determining centers of rotation for given teeth with similar morphologic characteristics, which should minimize the number of recordings required experimentally.

The preceding analyses have a number of clinical implications:

1. The location of the center of rotation depends on the ratio between the moment and the force applied to the tooth (M/F ratio) and not on the absolute value of either. For example, if a single force is placed on the crown of a tooth, the center of rotation should be the same, regardless of the magnitude of the force. A light or a heavy force tends equally to move the crown in one direction and the root in the other. This is in sharp contrast to the oft-repeated idea that lighter forces do not displace root apices as much as heavy forces. This statement would be accurate only if a properly directed moment, as well as a force, were applied to the tooth in question. If the moments were identical, the tooth with the lower force would possibly have minimal root displacement.[16] Research suggests that if identical M/F ratios are delivered to a tooth, the center of rotation may not be exactly identical. Heavier single forces on the crown

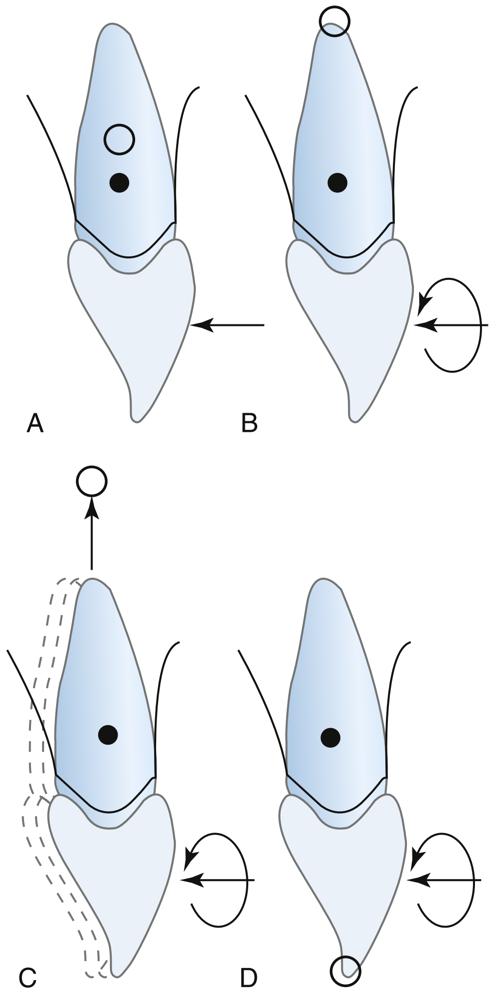

FIGURE 5-5 A single force acting on the crown of a tooth produces a center of rotation (*open circle*) slightly below the center of resistance. **A,** If increasingly larger couples are added to the force in the direction shown in **B** to **D,** the center of rotation will be found at the apex (**B**), the infinity (**C**), or the incisal edge (**D**).

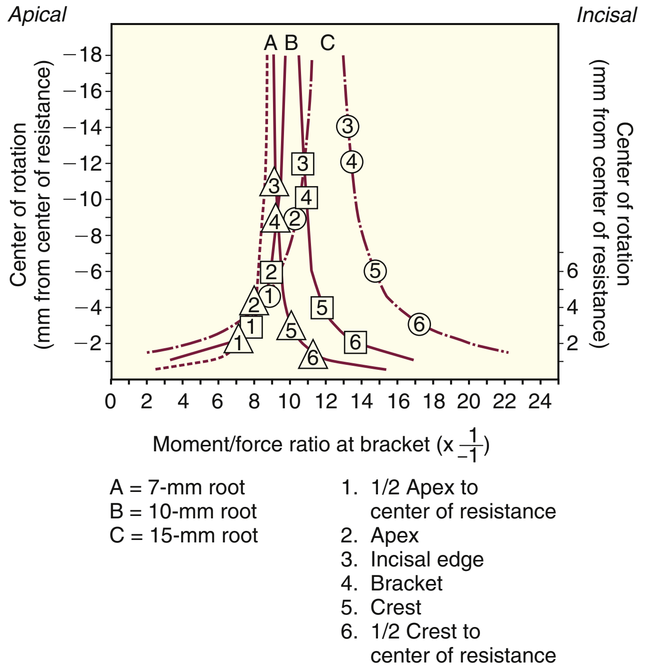

FIGURE 5-6 Moment-to-force ratio plotted against the center of rotation for three incisor root lengths. Note that identical moment/force values produce different centers of rotation if the root length varies.

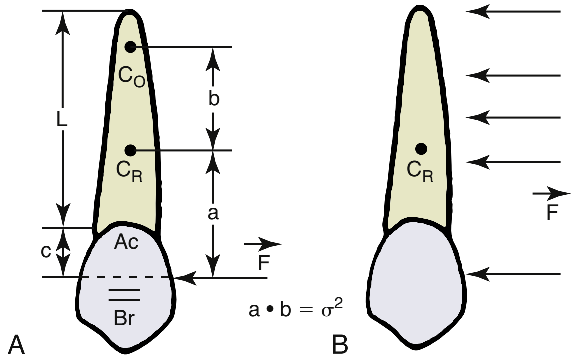

FIGURE 5-7 **A,** A general theory of tooth movement states that the product of the distance a times b equals s^2. **B,** s^2 is a constant provided the single forces are parallel and act in the same plane. Any of the individual forces shown in B produces the same s^2. (Redrawn from Nägerl H, Burstone CJ, et al. *Am J Orthod.* 1991;49:337.)

tend to move the center of rotation slightly apically rather than occlusally.

2. The M/F ratio is crucial to the establishment of a center of rotation. Small miscalculations in this ratio can change the type of tooth movement affected. Because stress distributions in the PDL are altered as well, the ease of tooth movement also may be affected.
3. The load deflection rate of the force acting on the crown and the torque deflection (angular) rate of the moment often may be different. For example, if a lingual force dissipates faster than the moment (torque), the center of rotation changes. In this case, the center of rotation shifts, rather than remaining constant, because of the change in the M/F ratio.

Laser holography is a new, noninvasive technique for studying tooth movement in closer detail.[9,10,17,18] In Figure 5-8, the location of the center of rotation is plotted against the M/F ratio for a typical maxillary central incisor. The experimental curves are similar to those derived from previously discussed theory.

In addition to analytic methodology and laser holography, numeric techniques have been used to determine centers of rotation under different loading conditions and estimate stress in the PDL. These techniques use a three-dimensional finite element method. The tooth and the alveolar process are broken down into elements (Fig. 5-9) by accurately determining the shape of the elements and the constitutive mechanical behavior of each element. Centers of rotation are determined using assumed forces on the teeth.[19-22]

As researchers become more knowledgeable, refinements in mathematic models will provide the clinician with good estimates of the M/F ratios needed to produce required centers of rotation for teeth of different geometric configurations and periodontal supports and for groups of teeth or segments.

The lack of knowledge about the variation in tooth morphology and support should not deter clinicians from making their best estimates of the relationship between the forces exerted by an appliance and the centers of rotation produced. An understanding of basic theory can guide the clinician in adjusting appliances when undesirable centers of rotation result.

Nägerl et al.[13,14] developed a concept of tooth motion that is not as limiting in three-dimensional space as the center of rotation concept. Tooth movement is envisioned as a screw oriented in a coordinate system. The screw forms an axis around which the tooth rotates, and translation may occur in or out along that axis.

Bracket Path and the Required Force System

The clinician, by tradition, has been taught to place brackets in a correct and standardized manner and then to reason what a straight wire will do when a discrepancy exists. In Figure 5-10, *A*, the flared upper incisor (brown) must be brought lingually (green). The center of rotation is the solid blue circle and the center of resistance is the open purple circle. The bracket path from the beginning to the final position is shown by the dotted gray arrows and line. The bracket translates lingually and occlusally and also rotates in a counterclockwise direction. Some orthodontists may think that the bracket path (gray arrows) shows the force and moment direction and that should be the correct force system for achieving the depicted goal. This interpretation is not correct.

In Figure 5-10, *B*, only the enlarged brackets are shown; a straight edgewise wire is inserted. What is the force system delivered to the incisor? For simplicity, let us assume the discrepancy is between two central incisors and the incisors are in the same plane. The gray arrows are in the same direction as the bracket path and unfortunately are not correct in both force and moment direction. The actual force system depends on wire-deflection properties that are better described by beam theory (complicated involving large deflections and friction). Thus, the clinician cannot just look at the bracket discrepancy and assume that a straight wire will give the proper force system.

The correct direction of the force system to tip the tooth around a point near the root apex is shown in Figure 5-10, *C*. Note that the direction of the moment should be counterclockwise (lingual root torque) and not clockwise like the bracket path. Also, the direction of force parallels the displacement of

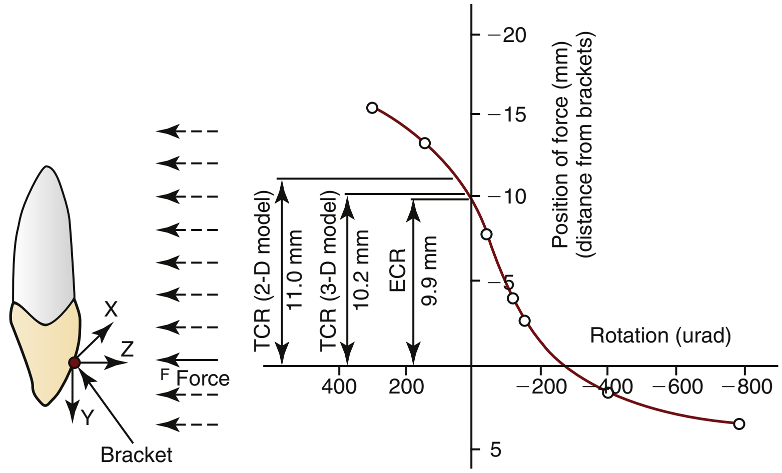

FIGURE 5-8 Center of rotation measured from the centroid of the paraboloid of revolution (h/3) as a function of the moment-to-force ratio at the bracket. The center of rotation approaches infinity as the line of action of the applied force approaches the centroid. *TCR*, Theoretic center of resistance; *ECR*, experimental center of resistance.

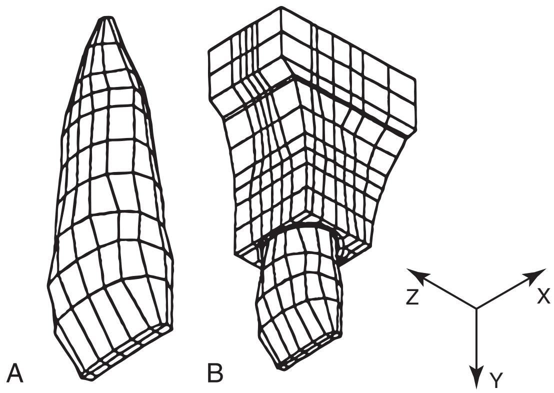

FIGURE 5-9 Three-dimensional model for tooth **A** and tooth-periodontal ligament-alveolar bone system **B**. (Redrawn from Tanne K, Koenig HA, Burstone CJ. Moment to force ratios and the center of rotation. *Am J Orthod Dentofac Orthop*. 1988;94(5)426–431.)

the purple center of resistance circles. A line connecting the center of resistance from the start to the final is a better indicator of the force direction than a line connecting the brackets (bracket path).

Since the initial force system when the archwire is placed into the bracket and the subsequent force systems when the archwire works out may be incorrect, there is no assurance that the straight wire as used here gives the best force system. On the other hand, if teeth eventually are in full or almost full alignment, the straight wire shape is correct. The straight wire works best as a final finishing arch.

Force Magnitude and the Rate of Tooth Movement

Considerable debate in orthodontics has centered on the relationship of force magnitude and the rate of tooth movement.[23-27] Attempts at correlations of this type are more likely to succeed if the rate of tooth displacement is used rather than the total displacement (absolute displacement) value. The rate of tooth movement is defined as the displacement of a tooth per unit time, and it usually is measured in millimeters per hour, per day, or per week. As the increments of time become shorter, the dynamics of tooth movement become clearer, and thus daily rather than weekly or monthly recordings are preferred.

The average daily rate can be established by dividing the absolute displacement by the number of days when measurements are made at less frequent intervals than daily. Such methods tend to smooth out rate curves and eliminate much of the rate fluctuation that can be observed each day. For practical purposes, if daily increments of movement cannot be measured (which is the case in many clinical studies), average rates of tooth movement must be used. However, when average rates are used, their limitations should always be kept in mind.

Two possible force–rate relationships can be studied. One approach relates force magnitude and tooth displacement. The other approach, which perhaps is more logical, attempts to relate stress–strain phenomena in the PDL (force per unit area and displacement per unit length) with tooth displacement. Until better experimental methods are devised, the latter method is limited by the fact that the stress–strain values must be calculated from mathematic models rather than by experimentation in the living.

The difficulty of correlating forces and tooth movement is compounded by the large number of variables that can influence the recorded rate of tooth displacement. Connective tissue forces operating through gingival and transseptal fibers or forces from the tongue, perioral musculature, and muscles of mastication may alter the force system acting on the tooth. For these reasons, the clinician should be aware of certain limitations in predicting tooth movement. If a relatively constant force is placed on a tooth, a typical type of graph is obtained when the rate of tooth movement is plotted against time (Fig. 5-11). Tooth movement can be differentiated into three phases: initial phase, lag phase, and postlag phase. The initial phase, which is characterized by a period of rapid tooth movement, normally lasts a few days. The onset of displacement immediately after application of a force and its rapidity suggest that tooth movement in the initial phase largely represents displacement of the tooth in the periodontal space. The initial phase is followed immediately by the lag phase, during which the tooth does not move or shows a relatively low rate of

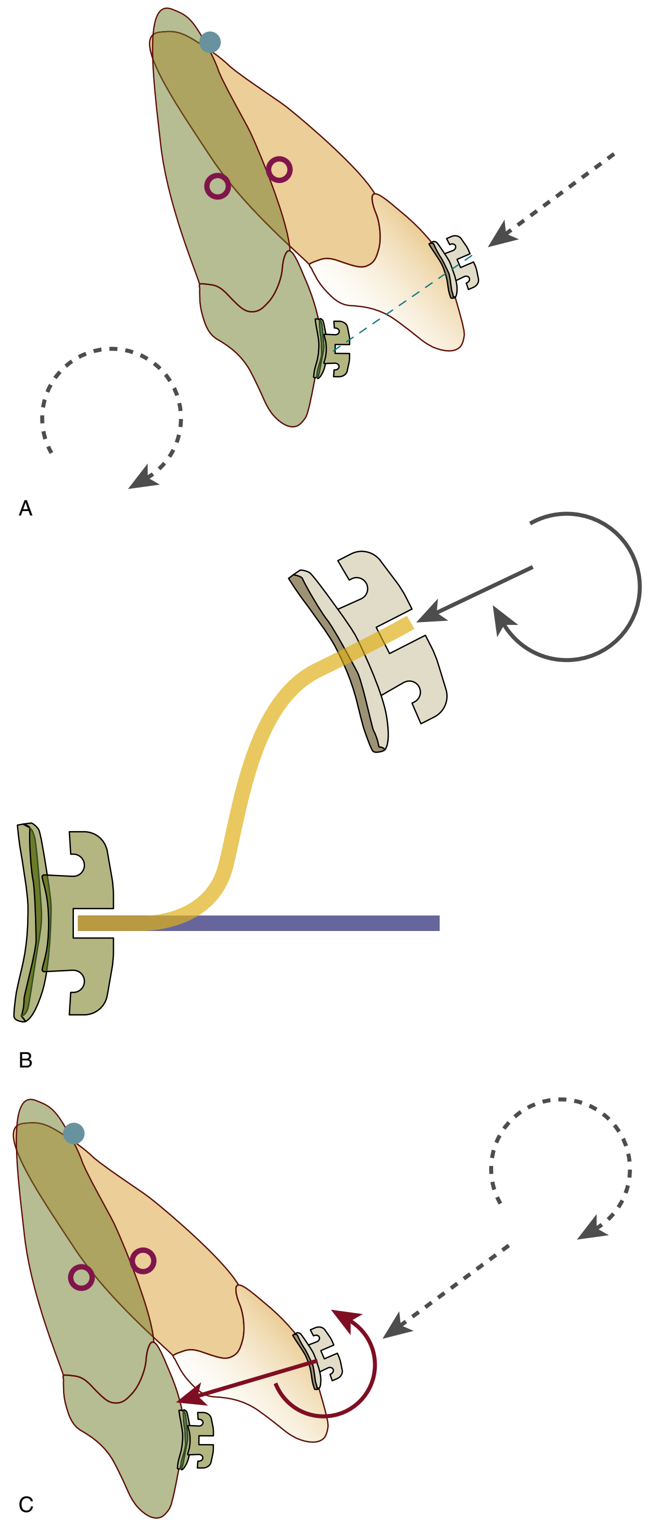

FIGURE 5-10 Flared upper incisor (*brown*) requires retraction. **A,** Center of rotation, solid blue circle. Center of resistance, purple circles. Dotted gray arrows, bracket path direction. **B,** Enlarged view of brackets only. Gray force arrows based on bracket path are not what is produced. The force system is also incorrect to achieve treatment goal. A straight wire if inserted into the bracket will deliver the wrong force system initially. **C,** Red arrows, correct force system to produce desired tooth movement. Compare to arrows based on bracket path (*gray arrows*) where moment is opposite and force direction is in error.

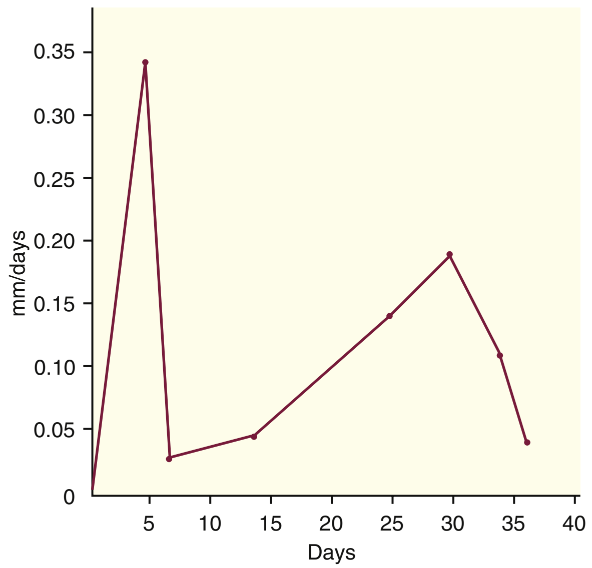

FIGURE 5-11 Typical tooth movement graph in which the rate of movement is plotted against the number of days after application of a continuous force (125 *g*). Rates are given for the reciprocal closure of a diastema between two central incisors.

displacement. A number of explanations have been postulated for the presence of a lag period. Some have suggested that the lag is caused by nonvitalization (hyalinization) of the PDL in areas of maximal stress and that no tooth movement can occur until the area of nonvitalization has been removed by cellular processes.[25,28,29] Others believe that the lag period may represent the interval required for absorption of the thicker compact bone of the lamina dura; hence the rate of tooth movement is reduced. The third phase of tooth movement, the postlag phase, occurs when the rate of tooth movement gradually or suddenly increases (see Chapters 3 and 4).

The great variation of response in tooth movement to relatively identical force systems is impressive. However, this is not surprising because the force applied to a tooth is but one of many variables that determine its displacement. If constant force were applied to a tooth, the tooth might be expected to move at a constant rate through the alveolar process. Nevertheless, clinical measurements show a lack of constancy in rate not only during the initial and lag phases but also during subsequent tooth movement.

The crucial issue in orthodontic therapy is the relationship between force magnitude and the rate of tooth movement. The most obvious and appealing relationship is a linear one, in which more force implies greater tooth movement. Nevertheless, appealing as the simplicity of this assumption might be, it does not correspond to the facts observed histologically and clinically in all phases of tooth movement.

During the first part of the initial phase, when the tooth is deflected through the periodontal space, something approaching a linear relationship may exist. As the stress levels in the PDL increase, a faster rate of tooth movement is expected. Thus, a light force may take days to move a tooth through the width of the PDL, whereas a heavy force, such as a dental separator, can accomplish the same result in seconds. The responses to light and to heavy forces show no gross difference if the absolute displacement is measured after 2 or 3 days or if the average rate is calculated for a similar period.

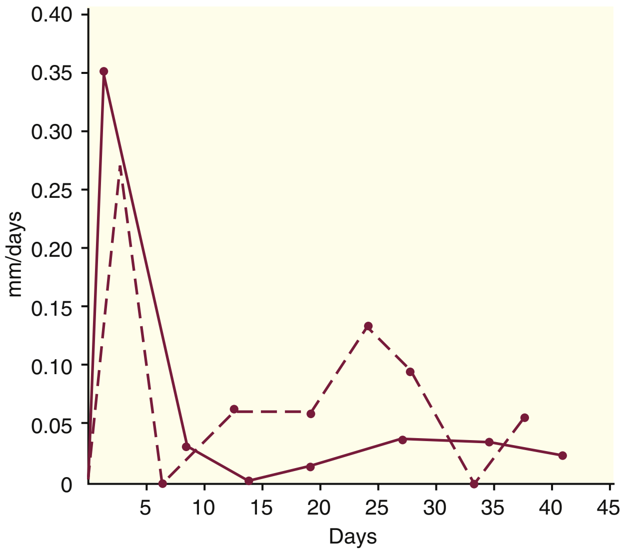

FIGURE 5-12 Rates of tooth movement with different force applications (*dotted line*, 200 *g*; *solid line*, 10 *g*). The rates given are for reciprocal closure of a diastema between two central incisors.

In Figure 5-12, the average rates of tooth movement are plotted against the number of days after insertion of a continuous-force appliance. Application of 10 and 200 *g* of force on a central incisor produces a similar initial response. Fairly light forces apparently can move a tooth through a greater part of the width of the PDL. After this has been accomplished, higher forces may be expected to produce additional compression of the ligament. This additional compression is of lesser magnitude than the initial tooth movement and therefore is not evident in gross measurements of tooth movement. Variables such as the width of the PDL are much more important than force magnitude in determining the initial absolute displacement of a tooth.

During the lag phase of tooth movement, two processes can be observed in areas of pressure: direct resorption may occur on the bone surface facing the root, or indirect (undermining) resorption may start in the medullary spaces and work toward the tooth.[28,29] Currently, the best that can be hoped for is the development of a working hypothesis to explain and relate these bony changes to stress levels in the PDL. Until data are available to correlate measured or calculated stress levels with histologically observed bony resorption, assumptions of this type must be considered tentative. Theoretically, if low-level stress is introduced into the PDL, no bony transformation will occur. If the stress level is increased, a point will be reached at which bone resorption can begin (i.e., a threshold stress level). Nothing is known about the level of stress that can initiate bone resorption and apposition. Clinically, however, relatively small force magnitudes (e.g., 10 *g* or less on the maxillary incisors) can tip teeth.[30] If it even exists, the threshold force (the lowest possible force that will move a tooth) has a low magnitude, at least for simple tipping movements. Stress in the PDL above the threshold level can be expected to increase the amount of frontal resorption on the alveolar process. As the stress value increases, cellular activity can be expected to decline because areas of maximal stress undergo further compression of blood vessels and cellular elements. Histologically, these areas appear hyalinized and may be described as at least partly nonvital. Logically, then, bone resorption also declines because direct bone resorption requires vital connective tissue. Undermining resorption, however, is associated with high stress on the PDL and is a response to a compressed, nonvital area of connective tissue.

At a low stress level, little indirect resorption occurs; in fact, bone apposition can occur in the medullary spaces. As the stress increases, the magnitude of cellular response also increases; however, here, too, a limiting factor comes into play. A force can be only great enough to displace a tooth against the alveolar process; when this occurs, the stress level is limited, and for that particular interval, no greater stimulus for indirect resorption may be expected.

Under most clinical conditions, tooth displacement after the lag phase is caused by a combination of direct and indirect resorption. Concomitant bony and connective tissue changes in the areas of tension most likely occur following resorption of bone in the existing pressure regions.

What, then, is the relationship between force magnitude and the rate of tooth movement? At lower force magnitudes, most increases in force enhance the rate of tooth movement. At higher magnitudes, increases in force are partly responsible for hyalinization of the PDL and result in a longer lag phase. Eventually, undermining resorption removes the area of hyalinization, and the tooth moves rapidly into the newly created space. For these reasons, a wide range of forces, from light to heavy, can move teeth rapidly, provided that the force is continuous.

Lighter forces are more likely to move teeth gradually; heavy forces produce a considerable lag phase followed by a period of rapid movement. Over a long interval, the average rate of movement for heavy continuous force may be greater than that seen with light, continuous force. The complexity of the tissue changes and the large number of variables suggests that postulation of any simple relationship between force magnitude and the rate of tooth movement is plagued by inherent difficulties.

One of the variables to be considered in evaluating force magnitude and rate of movement is the type of tooth movement (center of rotation). For identical forces applied on the crown of a tooth, different centers of rotation can be obtained by altering the applied couple. Although the force remains the same, the change in the moment modifies the stress distribution in the PDL. Imagine a simple model of the tooth in its alveolus (a linear stress–strain relationship in the PDL is assumed). For simplicity's sake, the model has a uniformly thick PDL and smooth alveolar walls. This oversimplifies the nature of the tooth and its surrounding structures; the PDL is not uniformly thick, and the lamina dura is an irregular cribriform plate pierced by many holes. Nonetheless, the tooth model, despite all its difficulties, may prove most useful in comparing stress distribution for different types of tooth movements.

In pure translation (bodily tooth movement), a relatively uniform stress distribution is found in the PDL (actually, variations in the thickness of the PDL alter the stress distribution). Figure 5-13 shows an imaginary stress distribution for a force system causing translation of a central incisor in a lingual direction. If movement of the crown is reduced, the center of rotation shifts from infinity toward the apex of the root. Although the lingual force is identical with that used for bodily movement, the stress distribution is greatly changed. In tipping with a center of rotation at the apex, the maximal stress is found at the alveolar crest, and it is of considerably greater magnitude than that seen in translation. If the moment is increased beyond the amount required for translation, the center of rotation

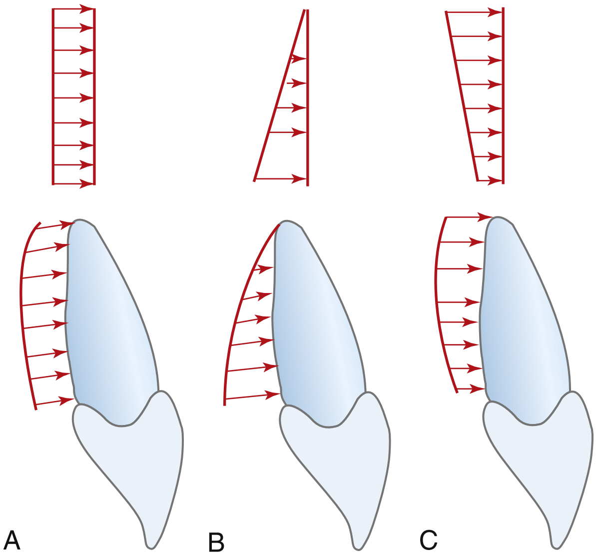

FIGURE 5-13 Theoretic stress distributions in the periodontal ligament. **A**, Translation. **B**, Center of rotation at the apex. **C**, Center of rotation at the incisal edge. The force magnitude is identical in the three situations.

shifts from infinity toward the incisal edge. With the center of rotation at the incisal edge, a nonuniform stress distribution once again is observed. In this case, the maximal stress is at the apex, and it is of greater magnitude than the stress found in translation. One should emphasize that in the three processes (translation, tipping at the apex, and rotation around the incisal edge), the lingual force is identical.

To develop the same maximal stress level of bodily tooth movement as that seen in rotation around the apex and the incisal edge, the lingual force and moment applied to the crown of the tooth must be increased. The center of rotation is an important factor that determines stress distribution in the PDL, and hence the degree and type of cellular reaction. Therefore, in any attempt to relate force magnitude and the rate of tooth movement, the force system must be well defined. This requires knowledge not only of the magnitude but also of the constancy of all forces and moments acting on a tooth crown.

Figure 5-14 shows a tooth in which stress was studied using the finite element method. If a force is placed to produce translation, as shown in Figure 5-15, it is apparent that the stress is not as uniform as that described in the simplistic explanations given previously.[20,31-34] The simplistic explanations may aid in developing an understanding of the ways in which stress distributions vary with the same magnitude of force. One should remember, however, that a tooth is a three-dimensional irregular body that has a most complicated stress distribution, even during translation.

Not all variables that influence the rate of movement involve stress levels in the PDL. Some involve the structure of the supporting bone of the alveolar process. Clinical observation also suggests a great variation in connective tissue response to the stress of orthodontic tooth movement. The response of tissues to mechanical stress is as yet obscure. However, the biochemical mechanisms by which stress and strain cause bone resorption and apposition are beginning to be better understood. Strain, working through biochemical mediators, such as prostaglandins and piezoelectric effects, could be responsible for the biologic response to orthodontic forces.

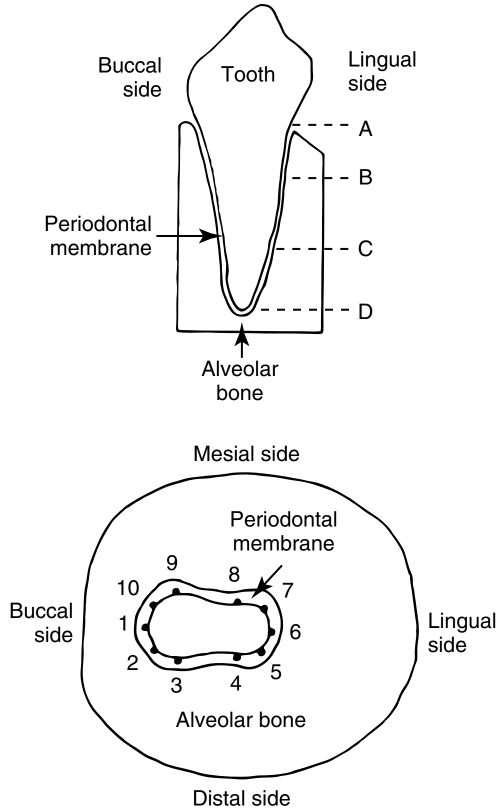

FIGURE 5-14 Occlusogingival levels (**A** to **D**) and horizontal points (*1 to 10*) where the principal stresses were determined. (Redrawn from Tanne K, Sakuda M, Burstone CJ. *Am J Orthod Dentofac Orthop.* 1987;92:499.)

Relationship of Force Magnitude to Pain and Tooth Mobility

After an active orthodontic appliance has been inserted, pain or discomfort may develop. Objective evaluation of pain is difficult because the pain response is determined by the central nervous system and local tissue changes. Not surprisingly, however, one finds a wide range of pain reactions among individuals in whom similar forces have been placed on the teeth.

To evaluate the relationship of force to pain, a classification of pain response is helpful. Three degrees of pain responses may be described. First-degree pain is caused only by heavy pressure placed on the tooth with an instrument such as a band pusher or a force gauge. A first-degree response usually is elicited most easily by placing a force in the same direction as the force produced by the appliance. The patient is not aware of first-degree pain unless the teeth being moved with the orthodontic appliance happen to be manipulated. A second-degree pain response is characterized by pain or discomfort during clenching of the teeth or heavy biting. The patient still is able to masticate a normal diet without difficulty. If spontaneous pain is present or the patient is unable to masticate food of normal consistency, a third-degree response exists. Proper interpretation of pain data requires testing of the patient's response to heavy forces placed on the teeth before orthodontic treatment is begun. In this way, the patient influences and even controls future pain and discomfort.

The two types of pain based on time of onset are immediate pain and delayed pain. Immediate pain responses are associated

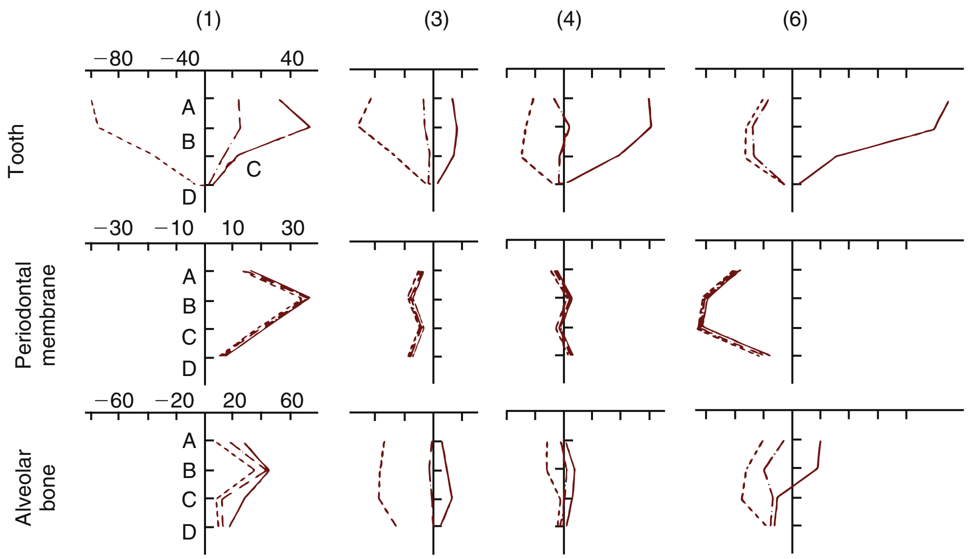

FIGURE 5-15 Stress distribution (g-cm^2) in loading condition for a lingual force of 100 g and a buccal crown couple of 858.5 g-mm (L_2). Three principal stresses—maximal (—), intermediate (-··-), and minimal (–)—are shown for four significant points (1, 3, 4, and 6) at various occlusogingival levels (*A to D*). (Redrawn from Tanne K, Sakuda M, Burstone CJ. *Am J Orthod Dentofac Orthop.* 1987;92:499.)

with sudden placement of heavy forces on a tooth. For example, a hard figure-eight tie between spaced incisors usually causes an acute pain reaction that gradually subsides. Some hours after an orthodontic adjustment, a delayed response may become evident. Delayed pain responses are caused by a variety of force values, from light to heavy, and represent hyperalgesia of the PDL. The degree of response usually lessens with time. A decreasing gradient is observed when, for instance, the pain reaction passes from a third-degree to a second-degree response and finally to a first-degree or zero-degree response. Although a gradient of this type usually is observed, situations arise in which the pain reaction suddenly increases, for no apparent reason, several days after a continuous force was applied.

Generally, the magnitude of force applied to a tooth has a definite correlation to the patient's experience of pain. Clinical studies have shown that the incidence of second- and third-degree pain is greater with application of heavier forces to the teeth. Not only is a greater degree of pain evident with a heavy force, but also the total number of days in which an abnormal pain response can be elicited is higher. This is not to imply, however, that a linear relationship exists.

The generalization that greater forces produce greater degrees of pain for longer periods is an oversimplification. As with the rate of tooth movement, force magnitude is only one of the factors determining the patient's final response.

An understanding of pain that occurs during orthodontic treatment also is obscured by a lack of knowledge about the reason pain is produced. This difficulty is aggravated by the fact that the PDL has no pain fibers. When the mechanisms of pain production during tooth movement become known, orthodontists will understand better the relationship of force and pain response.

Optimal Force and Stress

The effect of the couple-to-force ratio on the center of rotation of a moving tooth has been considered. Another question of great clinical significance concerns the appropriate magnitude of force and couple to achieve the most desirable response. In other words, what force magnitudes are optimal for tooth movement?[35-37]

From a clinical standpoint, an optimal force is one that produces a rapid rate of tooth movement without discomfort or ensuing tissue damage (particularly alveolar bone loss and root resorption) to the patient. From a histologic viewpoint, an optimal force is one that produces a stress level in the PDL that basically maintains the vitality of the tissue throughout its length and initiates a maximal cellular response (apposition and resorption). Optimal forces, therefore, produce direct resorption of the alveolar process. Because optimal forces require no period for repair, such forces apparently can be made to act continuously.

Histologic studies that correlate forces on the crown or stress in the PDL with tissue responses are most helpful in establishing the levels of optimal force for different situations. Unfortunately, the difficulty involved in obtaining human material is a limiting factor in this type of investigation. At the clinical level, where a greater wealth of material is available, the orthodontist is limited to gross tooth and bone changes or the patient's symptoms. This is not to imply that careful clinical observation is not helpful in determining optimal forces. Lack of pain, minimal mobility, and the absence of a considerable lag period immediately after appliance adjustment are clinical responses that suggest desirable stress levels in the PDL. To use the rate of tooth movement alone as an indicator of optimal force is dangerous, however. Rate is deceptive because heavy and light continuous forces can move teeth rapidly. It does not necessarily follow that because the teeth move rapidly, the forces used are optimal. Long-term histologic and clinical studies are needed to define further the nature of optimal force.

Although study of the biomechanics of tooth movement shows great promise, use of mathematic formulations to describe biologic phenomena is risky because mathematic oversimplification of highly dynamic, variable vital structures and reactions can mislead as well as inform. Biomechanical assumptions, therefore, must be checked against observations made on the clinical and histologic levels. This type of multidisciplinary approach offers the best hope for solving orthodontic problems involving force systems and tooth movement.

THE ORTHODONTIC APPLIANCE

In designing any orthodontic appliance, the orthodontist starts by subscribing to certain assumptions about the nature of an optimal force system to move teeth. An optimal force system is one that (1) accurately controls the center of rotation of the tooth during tooth movement, (2) produces optimal stress levels in the PDL, and (3) maintains a relatively constant level of stress as the tooth moves from one position to the next. For the sake of argument, assume that these objectives for the orthodontic appliance are correct; one then must decide what is needed to design an appliance to deliver this type of force system.

Active and Reactive Members

An orthodontic appliance can be considered to have active and reactive members. The active member is the part involved in tooth movement; the reactive member serves as anchorage and involves the teeth that will not be displaced. A member sometimes can play an active and a reactive role simultaneously. For example, this is clearly the case when reciprocal anchorage is used.

On the subclinical level, the three primary objectives are to control the center of rotation of the tooth, produce desirable stress levels in the PDL, and maintain a relatively constant level of stress. At the clinical level of observation, the focus becomes the forces and moments produced by an orthodontic appliance. Specifically of interest are three important characteristics involving active and reactive members: (1) the M/F ratio, (2) the load-deflection rate, and (3) the maximal force or moment of any component of the appliance.

Moment-to-Force Ratio

To produce different types of tooth movements, the ratio between the applied moment and the force on the crown must be changed. As the M/F ratio is altered, the center of rotation changes. Crown tipping, translation, and root movement are examples of different types of tooth movements that can be produced with the proper M/F ratio. The important thing for the orthodontist to remember is that in few cases can desirable tooth movement be produced by applying a single force to the crown. If a modern orthodontic appliance is under consideration, an active member must be capable of producing the desired moment and force.

The M/F ratio is equally significant in the reactive member of the appliance. For example, if the practitioner is considering preserving anchorage of the posterior segments in an extraction case, to introduce a moment that tends to move roots forward and crowns back is desirable so that, combined with the mesial forces acting on the posterior segment, a more uniform distribution of stress is achieved in the PDL. A more uniform distribution of stress in the posterior segment minimizes forward displacement. The tip-back bend is one example in which a moment of this type is added to the posterior segment to enhance anchorage. In short, the M/F ratio determines the control that the orthodontic appliance has over the active and reactive units; specifically, it controls the center of rotation of the tooth or a group of teeth.

Load-Deflection Rate

The second characteristic of an orthodontic appliance, the load-deflection (or torque-twist) rate, is a factor in the delivery of a relatively constant force.[38] By definition, the load-deflection rate gives the force produced per unit activation. As the load-deflection rate declines for a tooth that is moving under a continuous force, the change in force value is reduced. For active members, a low load-deflection rate is desirable for two important reasons: (1) a mechanism with a low load-deflection rate maintains a more desirable stress level in the PDL because the force on a tooth does not radically change magnitude every time the tooth has been displaced, and (2) a member with a low load-deflection rate offers greater accuracy in controlling force magnitude. For example, if a high load-deflection spring is used (e.g., an edgewise vertical loop), the load-deflection rate might be 1000 *g*/mm; this means that an error in adjustment of 1 mm could produce an error in force value of about 1000 *g*. However, if a low load-deflection spring is used, such as one with a rate of 10 *g*/mm, an error of 1 mm in activation affects the force value by only 10 *g*. Flexible members with low load-deflection rates require long ranges of activation to build up to optimal force values; hence, they give the orthodontist greater control over the magnitude of force used.

If a low load-deflection rate is desirable for the active member of the appliance, the opposite is true for the reactive member. The reactive member should be relatively rigid; that is, it should have a high load-deflection rate. The anchorage potential of a group of teeth can be enhanced if the teeth displace as a unit. If individual teeth in the reactive unit tend to rotate around separate centers of rotation, higher stress distributions are produced in the PDL and the teeth can be more easily displaced. Another factor to consider is that the equal and opposite forces produced by the active members usually are distributed to localized areas, with just one or a few teeth involved. Localized tooth changes in these areas can be minimized if the reactive members of the appliance are sufficiently rigid. In short, the load-deflection rate is an indicator of the force required per unit deflection. In the reactive part of the appliance, a high load-deflection rate is needed when the orthodontist is dealing with a relatively rigid member.

Maximal Elastic Moment

The last characteristic of an orthodontic appliance that must be evaluated is the maximal elastic load or moment, which is the greatest force or moment that can be applied to a member without causing permanent deformation. Active and reactive members must be designed so they do not deform if activations are made that allow optimal force levels to be reached. In designing an appliance, a good idea is to go beyond required force needs and create a safety factor. Thus, permanent deformation or breakage will not occur from accidental overloading, which can be caused by abnormal activation of an appliance or by abnormal forces during mastication.

All three of the important characteristics of an orthodontic appliance—the M/F ratio, the load-deflection rate, and the maximal elastic load or moment—are found within the elastic range of an orthodontic wire and therefore may be called spring characteristics. Beyond this range are the plastic changes that can occur in a wire up to the point of fracture. Although plastic changes are important in the design of an orthodontic appliance, they are not considered in detail in this discussion.

The designer controls a number of variables that influence spring characteristics; these variables are discussed individually in the following sections. The orthodontist always should keep in mind the relationship between these variables and the three important characteristics previously examined.

Manner of Loading

If an active member is to deliver continuous force for tooth movement, it must be able to absorb and release energy. Energy absorption in a flexible member results from the elastic deformations that occur during application of a force or load. Elastic deformations are changes in form or configuration that are reversible when the load is removed.

To understand the different types of loading and their significance, one must visualize a structural axis centrally positioned along a round wire (Fig. 5-16). A force acting along the structural axis of the wire may produce compression or tension, shortening or elongating the wire. Thus, in tension and compression, the axial load may increase or decrease the length of the structural axis. This change is produced by force acting along the structural axis and therefore is called an axial load. If a moment operates around the structural axis (i.e., at right angles to the lines of the structural axis), torsion is produced (Fig. 5-17, *A*). In torsion, the wire rotates around the structural axis, with the greatest elastic deformation occurring at the periphery of the wire. Bending, or flexure, is produced when the structural axis changes its configuration transversely or at right angles to its original structural axis. Bending can be produced by moments acting at right angles to the cross section of the wire (Fig. 5-17, *B*) or by a transverse force acting on the wire (Fig. 5-17, *C*).

The typical orthodontic appliance usually is not loaded in a simple manner. Tension, compression, torsion, and bending commonly are combined into a more complicated type of loading pattern referred to as *compound loading*. Figure 5-18, *A*, shows two vertical loops in a round wire that can be used clinically to move a tooth buccally or lingually by displacing the central section at right angles to the surface of the paper. In reality, a compound deformation takes place, with bending occurring at point B and torsion or twisting at point A. During activation of this particular member, bending or torsion occurs. Figure 5-18, *B*, shows a vertical loop that can be used as a retraction spring. In a loop of this type, if the horizontal arms are kept parallel during activation, the loading pattern is fairly complicated. Not only are horizontal forces required, but also two equal and opposite couples must be used to keep the horizontal arms parallel. Even though the loading pattern is more complicated in this example, the vertical loop undergoes only bending.

Certain types of loads, whether forces or moments, can produce certain changes in the structural axis of a wire. These changes are referred to as *compression, tension, torsion*, and *flexure*. A more sophisticated system of categorizing changes in a wire is to describe such changes in terms of the stress distribution throughout the length of the wire. This approach is not included in this discussion because a knowledge of stress–strain phenomena is required of the reader. One should remember, however, that resisting forces act throughout the wire during loading, resulting in certain internal factors of stress and strain. Reference is made to stress and strain only when absolutely necessary to develop a point.

Axial loads that produce compression or tension are not useful for spring design because the load-deflection rate is high. An axial pull on a wire often is observed not to produce much elastic deformation, even with a heavy force, because the force is distributed uniformly as stress over each cross section of the wire. However, when nonuniform stress is distributed over various cross sections of wire (as in torsion and bending), the load-deflection rate may be low. For this reason, loading that leads to torsion and flexure is useful in the design of active or flexible members of an appliance.

If the maximal load or maximal torque were maintained as a constant, the load-deflection rate would be lowest in two particular types of loading: torsion and bending produced by moments alone. Such a low load-deflection rate might exist for a given maximal load because each cross section of the wire, from one end to the other, undergoes the same amount of torsion

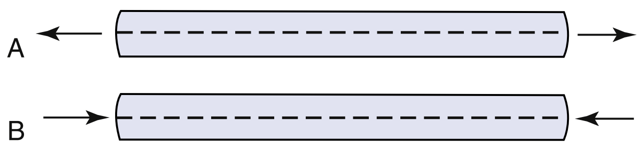

FIGURE 5-16 Axial loading. **A,** Tension. **B,** Compression. The force acts along the structural axis (*dotted line*).

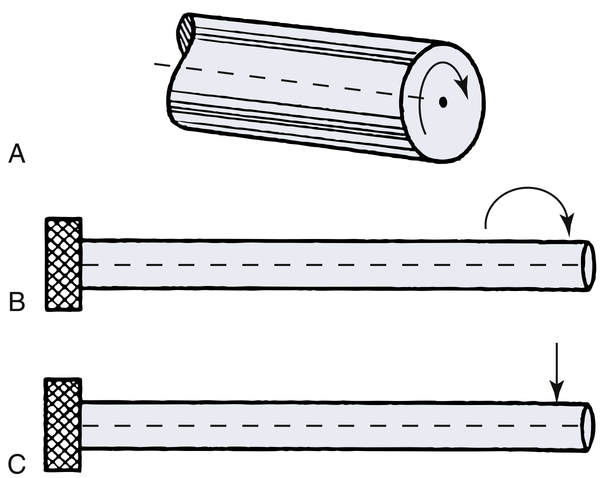

FIGURE 5-17 Torsion and bending. **A,** Torsion is produced by a couple acting around the structural axis. **B,** Pure bending is produced by the application of a couple. **C,** Bending is produced by a transverse force.

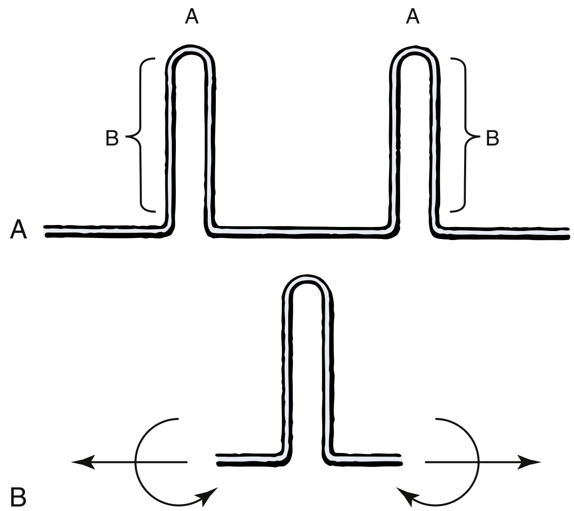

FIGURE 5-18 **A,** Displacement of the central portion of a loop at right angles to the page requires a force and a moment. Bending occurs at B and torsion at A. **B,** Opening a vertical loop requires a force and a moment to keep the horizontal arms parallel.

or bending. Loading of this type is ideal for spring design, but unfortunately in most instances more than a moment must be delivered to a tooth. Transverse loads therefore must be introduced, and these do not produce uniform changes along a wire unless the diameter of the wire differs along its length (i.e., a tapering wire).

In designing an orthodontic appliance, when should the orthodontist take advantage of tension, compression, torsion, and bending? A number of factors determine the manner of loading that should be used on a given member. For example, one configuration may be superior to another based on simplicity of design, general space available, or comfort in the mouth. Also, the M/F ratio needed to control the teeth partly determines the configuration to be used. For example, if equal and opposite moments are required, pure torsion or bending in a wire may be used. However, if moments and forces are required, primarily bending properties most likely will be used. In considering a reactive member, the forces should be distributed as axial loads whenever possible. For example, a transpalatal lingual arch can preserve widths of the posterior segments better than can a horseshoe lingual arch because the horseshoe-type arch bends more easily in this plane of space. Therefore, one of the early steps in the design of an orthodontic member is to decide on its basic configuration, keeping in mind the objectives listed.

Of the variables that influence the spring characteristics of load-deflection rate (torque-twist rate), maximal elastic load or maximal elastic torque, and M/F ratio, only bending is considered in the following sections. Because most orthodontic configurations take advantage of bending as a major type of elastic deformation, many of the concepts (if not the exact formulations) also apply to torsion and axial loading.

Mechanical Properties of Metals

The mechanical properties of an alloy to be used in an orthodontic wire can be described on at least three levels. The most superficial is the observational level, on which the clinician operates. On this level, forces and deflection can be noted and measured. In other words, a certain amount of force in grams can be applied, and the wire will deflect by a certain number of millimeters. On the observational level, the orthodontist is limited in how much can be understood and predicted about the nature of appliances.

The second level of description is the stress–strain level. On this level the orthodontist is dealing with pounds per square inch and deflection per unit length. These values cannot be measured directly, but they can be calculated from measurements made on the observational level. Most of the engineering formulations that can be used to predict changes in bodies subject to loads are based on stress–strain phenomena.

The third level of description is the atomic and molecular levels. An understanding of events at the atomic and molecular levels enhances the ability to predict responses and design new structures.

Basic Behavior of Alloys

Figure 5-19 is a theoretic diagram that plots load against deflection. It might represent, for instance, the load-deflection characteristics of an open coil spring. Deflection can be seen that from O to P_{max} (maximal elastic load) on the graph, a linear relationship exists between load and deflection. As the force increases, the deflection increases proportionately; this proportionality is referred to as *Hooke's law*. Load divided by deflection is a constant through this range and already has been defined as the load-deflection rate. At P_{max} a point is reached where load and deflection are no longer proportionate. Near P_{max}, permanent deformation is being produced in the spring, which will not return to its original shape. P_{max} represents the highest load that can be placed on the spring without permanent deformation; that is, the maximal elastic load. All the behavior found to the left of P_{max} on the graph lies in the elastic range, and behavior to the right lies in the plastic range. Elastic behavior is the ability of a configuration to return to its original shape after unloading; plastic behavior is the occurrence of permanent deformation in a configuration during loading. Finally, at the extreme right of the graph, the ultimate load (P_{ult}) is reached, at which point the spring will break. The diagram is a schematic one, and loads and deflections may not be so regular in commonly used orthodontic springs.

Load-deflection diagrams of the type shown have a limited application because a separate diagram is required for every orthodontic member. However, if the stress–strain level is studied, one can make generalizations about orthodontic alloys that apply to any given alloy regardless of the configuration. The graph shown in Figure 5-20 plots stress against

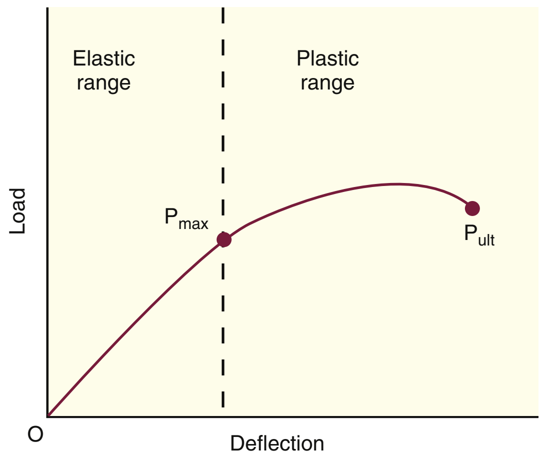

FIGURE 5-19 Load deflection. Note the linear relationship between load and deflection in the elastic range. P_{max}, Maximal elastic load; P_{ult}, maximal load before fracture.

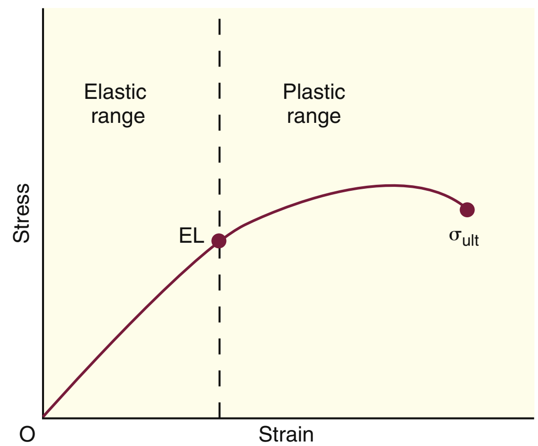

FIGURE 5-20 Stress–strain relationship. Note the linear relationship between load and deflection in the elastic range. *EL*, Elastic limit; σ_{ult}, tensile strength.

strain.* A diagram of this type corrects for the dimensions of the wire. The graph is identical in form to that of the load-deflection rate, except that the units are different. From O to EL (the elastic limit) is a straight line, denoting a linear relationship between stress and strain. This relationship is comparable to the relationship seen on the observational level between load and deflection. The ratio of stress to strain is referred to as the *modulus of elasticity* (E). As might be expected, this mechanical property determines the load-deflection rate of a spring.[39] The EL is the greatest stress that can be applied to the alloy without permanent deformation. The EL is analogous to the maximal elastic load and therefore is the mechanical property that determines the ability of a member to withstand permanent deformation. A number of other terms describe this general part of the curve, such as yield point, yield strength, and proportional limit; these points are close to the EL, although they differ by definition. Finally, at the ultimate stress (tensile strength), the wire will fracture. As with loads and deflections, most actual alloys do not present such a regular and definitive pattern.

An explanation of elastic and plastic behavior would not be complete without a brief mention of atomic and molecular events. Fundamentally, elastic behavior involves interatomic bonding. Because atoms are pulled apart, a fairly definite relationship exists between stress and strain. However, plastic behavior involves displacement along slip planes, which are molecular, not atomic. Plastic behavior, therefore, is not as linear as elastic behavior.

Elastic Limit

The EL determines the maximal elastic load of a configuration. With respect only to the mechanical properties of the wire, the maximal elastic load varies directly and linearly with the EL. Manufacturers' data usually include the yield point or the tensile strength. The yield point is close to the elastic limit, but the tensile strength is higher.*

In a given alloy (e.g., 18-8 stainless steel), a number of factors determine the elastic limit. The amount of work hardening produced during cold drawing of the wire sharply influences the EL.† Wires that have been considerably cold worked have a hard temper and therefore a high EL.[40] Small, round wires may have particularly high ELs because the percentage of reduction by cold working is high. Also, the cold-worked outer core becomes proportionately greater in a wire of smaller cross section. Too much work hardening, however, produces a structurally undesirable wire that becomes highly brittle and may fracture during normal use in the mouth. Far better is to have a slightly lower EL so that an orthodontic member can deform permanently rather than break under accidental loading. Because the work hardening required to reduce the diameter of a wire increases the EL, anodic reduction is a poor method for reducing the size of the wire. Anodic reduction does not cold work a metal; therefore, the wire produced by that method has a lower EL than a work-hardened one, a circumstance that could lead to permanent deformation.

Many orthodontic alloys, such as Elgiloy and gold, can be heat treated to raise the EL, but the most commonly used alloy, 18-8 stainless steel, cannot. However, a stress relief process at 8508°F for 3 minutes or longer raises the apparent elastic limit of 18-8 stainless steel. Stress relief removes undesirable residual stress introduced during manufacturing and during fabrication by the orthodontist. If a single stress release is used, the optimal time to perform it is after all required bends and twists have been placed in the wire.

Modulus of Elasticity

The mechanical property that determines the load-deflection rate of an orthodontic member is the modulus of elasticity (E).† Load-deflection varies directly and linearly with E (in torsion, linearly, and directly as the modulus of rigidity). Steel has an E approximately 1.8 times greater than that of gold. A reactive member made of stainless steel is 1.8 times as resistant to deflection as one made of gold. With edgewise brackets and a 0.022-inch × 0.028-inch archwire, for example, a steel wire gives greater control over the anchorage unit. However, activations made in a steel wire for tooth movement, if identical to the ones made in a gold wire of similar configuration, produce a load-deflection rate almost twice as high. For this reason, steel and gold are not directly interchangeable in the design of an orthodontic appliance.[39,42]

Steel alloys are the alloys most commonly used for orthodontic wires. The E of most steel alloys is almost identical. Unlike the EL, the E is constant for a given alloy and is not influenced by work hardening or heat treatment.* Therefore, hard-temper wires do not have higher load-deflection rates than soft-temper wires. When changing the E of a piece of stainless steel, a new alloy must be chosen because nothing can be done to a steel alloy that will alter its E greatly.

Shape-Memory Alloys

Within recent years, two new alloys have been introduced in orthodontics: nickel titanium and beta-titanium (TMA).

Nickel titanium (nitinol) was developed by William F. Buehler in the early 1960s. The original alloy contained 55% nickel and 45% titanium, which resulted in a 1:1 stoichiometric ratio of these elements. The unique feature of this bimetallic (NiTi) compound is its memory, which is a result of temperature-induced crystallographic transformations. Andreasen and Hilleman[43] and Andreasen and Morrow[44] suggested that the orthodontist use these shape changes to apply forces. The shape-memory principle is not used clinically. Instead, nitinol is used for its low force and high springback. The low E of nitinol, only 0.26 that of stainless steel, means that a 0.018-inch wire has the approximate stiffness of a 0.013-inch stainless-steel wire. The most dramatic characteristic of nitinol, however, is its resistance to permanent deformation. NiTi wires can be activated over twice the distance of stainless steel, with minimal permanent deformation. Because permanent deformation is time dependent, though, additional small deformation occurs between adjustments. After bends or twists are placed, if the wire is activated in a direction opposite that used in forming the configuration, it easily deforms permanently.[45] Nitinol, therefore, is most useful when low forces and large deflections are needed in relatively straight wires. Nitinol is more brittle than stainless steel and cannot be joined by soldering or welding.[43]

A new generation of shape-memory alloys has been introduced into orthodontics and is referred to as *superelastic*.[46-50] Unlike nitinol, these alloys have a much lower transition temperature—either slightly below or slightly higher than mouth

* Stress in a wire is force per unit area applied to a cross section. Strain is deflection per unit length of the wire.

† Residual stress or other mechanisms can give an E that is slightly lower after work hardening.[17,41]

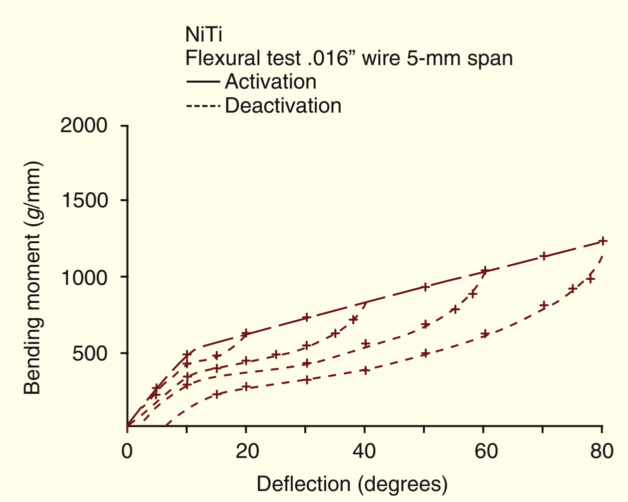

FIGURE 5-21 Activation and deactivation curves for NiTi wire. Unlike with stainless steel and nitinol wires, the unloading curves for NiTi wire change at different activations. (Redrawn from Tanne K, Sakuda M, Burstone CJ. *Am J Orthod Dentofac Orthop*. 1987;92:499.)

temperature. Generally speaking, the austenitic form of these alloys has a slightly higher springback than nitinol and may be less brittle. Figure 5-21 shows a loading and unloading curve for a superelastic NiTi wire at various activations. At the larger activations, part of the unloading curve is relatively flat. The clinical significance of this finding is that more constant forces are delivered to the teeth during the deactivation. Another interesting finding is that the stiffness is greater for small activations than for large activations. The typical orthodontic wire, however, is different because it has a relatively constant load-deflection rate, and it delivers increasing force, depending on the amount of activation.

The superelastic NiTi wires are available in different degrees of stiffness. A true comparison of stiffness should be made at mouth temperature because some wires may appear to have lower forces, due to the fact that they are partly martensitic at room temperature.[51] Forces increase as a phase transformation occurs with mouth temperature. Although the final transition temperature of some superelastic NiTi wires is below mouth temperature, others are not activated fully until they reach 37°C or higher. These wires have both superelastic and shape-memory properties. Generally, the heat treatment process performed during manufacture to raise the transition temperature allows for wires that deliver lower forces at mouth temperature; hence, the orthodontist may be able to achieve full bracket engagement with larger wires earlier in treatment.

The superelastic NiTi wires and nitinol are limited in that they are not formed easily; also, through permanent deformation, they lose bends that are placed unless a heat treatment process is carried out. NiTi wires are brittle, and they usually are used in procedures that call for relatively straight wires and large deflections without permanent deformation.

TMA has a modulus of elasticity between that of steel and nitinol (approximately 0.4 times that of stainless steel).[52,53] TMA can be deflected up to two times as much as steel without permanent deformation. Unlike nitinol, TMA is not significantly altered by the placement of bends and twists and has good ductility, equivalent to or slightly better than that of stainless steel, and can be welded without significant reduction in yield strength. Finger springs and hooks can be welded directly without solder reinforcement[54,55] (Fig. 5-22).

Another new alloy introduced into orthodontics is titanium niobium. The alloy has low springback (equivalent to stainless steel) and is much less stiff than TMA. The alloy is useful when a highly formable wire with low forces in small activations is required.

Ideal Orthodontic Alloys

The ideal orthodontic wire for an active member is one that gives a high maximal elastic load and a low load-deflection rate. The mechanical properties that determine these characteristics are the EL and E. The ratio between the EL and E determines the desirability of the alloy: the higher the ratio, the better the spring properties of the wire. In the commercial development of new wires, the orthodontist should look for alloys that have a high EL and a low E. Small differences in the EL or E do not appreciably alter the ratio. For an alloy to be considerably superior in spring properties, it must possess a significantly higher ratio.

In the reactive member of an appliance, however, not only is a sufficiently high EL required, but also a high E is desirable. Because common practice is to use the same size slot or tube opening throughout a hookup, different alloys can be combined in the same appliance to serve the needs of active and reactive members.

Four other properties of wire should be considered when evaluating an orthodontic wire: (1) the alloy should be reasonably resistant to corrosion caused by the fluids of the mouth, (2) the wire should be sufficiently ductile so that it does not fracture under accidental loading in the mouth or during fabrication of an appliance, (3) the wire should be able to be fabricated in a soft state and later heat-treated to hard temper, and (4) the alloy should allow easy soldering of attachments.

A thorough knowledge of the mechanical and physical properties of an alloy is important in the design of an orthodontic appliance. However, these are but two of the many variables that determine the final form of an orthodontic mechanism.

Wire Cross Section

One of the crucial factors in the design of an orthodontic appliance is the cross section of the wire to be used. Small changes in cross section can influence the maximal elastic load and the load-deflection rate greatly.[38,56]

The maximal elastic load varies directly as the third power of the diameter of round wire, and the load-deflection rate varies directly as the fourth power of the diameter. The most obvious means of reducing the load-deflection rate of an active member may seem to be to reduce the size of the wire. However, the fallacy in reducing the size of the cross section is that the maximal elastic load also is reduced at an alarmingly high rate (as d^3). When designing active members, a good policy is to use as small a cross section as is consistent with a safety factor so that undue permanent deformation does not occur. Beyond this, any attempt to reduce the size of the cross section to improve spring properties may well lead to undesirable permanent deformation.

The fact that the load-deflection rate varies as the fourth power of the diameter in round wires suggests the crucial importance of selecting a proper cross section. For example, 0.018-inch wire is not interchangeable with 0.020-inch

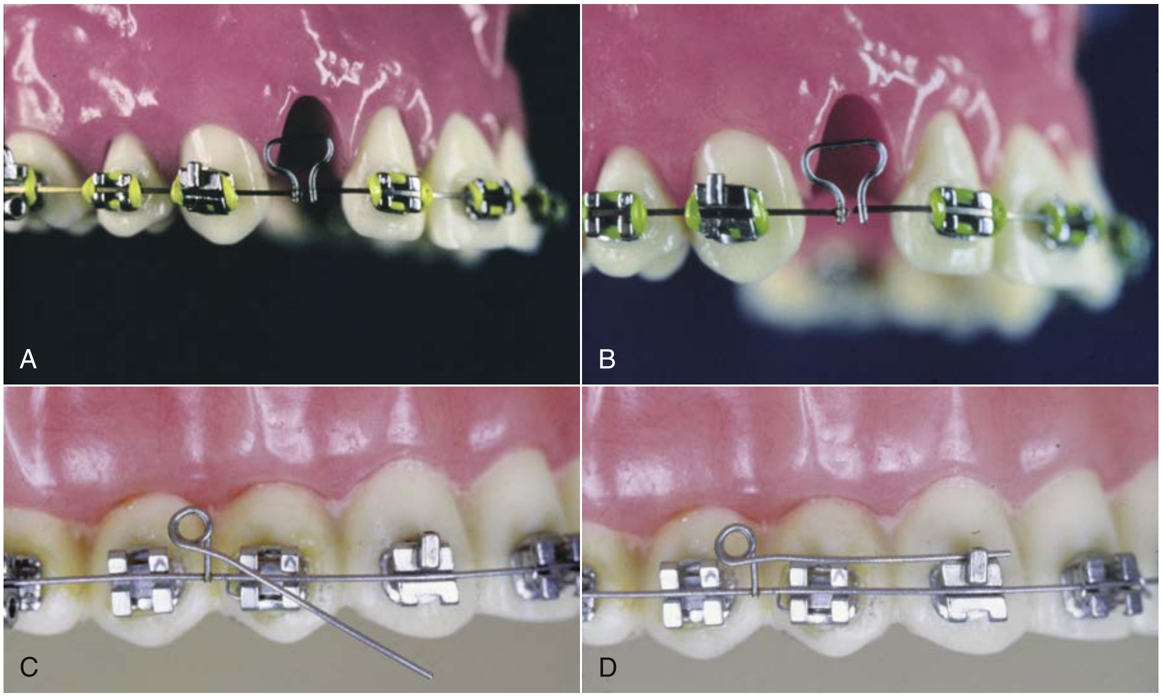

FIGURE 5-22 A, A vertical loop is welded to a continuous arch. B, The arch is cut between the loop forming a vertical loop arch. C, D, Welded helical spring used to erupt a high cuspid. The cuspid is now erupted and engaged in the arch wire. TMA wires can be welded directly together without significantly affecting the mechanical properties.

wire because with a similar activation (forgetting about play in the bracket), the 0.020-inch wire delivers almost twice as much force. The dramatic difference between wire sizes can be demonstrated further by comparing two similar activations in a 0.020-inch and a 0.010-inch round wire. The 0.020-inch wire delivers not twice as much force but rather 16 times as much force, the load-deflection rate varying as the fourth power of the diameter.

In selecting a proper cross section for the rigid reactive members of an appliance, the load-deflection rate, rather than the maximal elastic load, is the prime consideration. Normal circumstances require a large enough wire cross section to give sufficient rigidity so that a sufficiently high load-deflection rate is ensured.

What is the optimal cross section for a flexible member? Generally, for multidirectional activations in which the structural axis is bent in more than one plane, a circular cross section is the structure of choice. Furthermore, because round wire is so widely available for commercial purposes, the mechanical properties of the wire and the cross-sectional tolerances are far superior to those of other cross sections. One of the drawbacks to round wire is that it must be properly oriented or activations may not operate in the intended plane. Moreover, round wire may rotate in the bracket, and if certain loops are incorporated into the configuration, these can roll into the gingiva or the cheek. Many orthodontic wire configurations undergo unidirectional bending. For example, an edgewise vertical loop used for anterior retraction has a structural axis that bends in only one plane. For unidirectional bending, flat wire is the cross section of choice; more energy can be absorbed into a spring made of a flat wire than with any other cross section. This principle has been used for years in watch springs and other commercial designs. Hence, flat (ribbon) wire can deliver lower load-deflection rates without permanent deformation more successfully than any other type of cross section. Another advantage of flat wire is that the problem of orientation is much easier to solve than with a round cross section. Flat wire can be anchored definitely into a tube or bracket so that it will not spin during deactivation of a given spring. Flat wire also can be used in certain situations when considerable tooth movement is required in one plane but limited tooth movement is needed in the other. For instance, if continuous ribbon wires are used (long-axis oriented occlusogingivally), positive leveling can be achieved occlusogingivally over a limited range, and buccolingual and labiolingual tooth alignment can be effected over a long range of action. A configuration of this type is useful when most of the problems are in the horizontal rather than the vertical plane.

For the reactive member, square or rectangular wire is superior to round wire because of the ease of orientation and greater multidirectional rigidity of the former, which leads to more definite control of the anchorage units. In the edgewise mechanism, the assumption may be made that greater rigidity is needed buccolingually or labiolingually than occlusogingivally because an edgewise wire is used. This may or may not be true, depending on the intended use of the edgewise mechanism.

Selection of the Proper Wire (Alloy and Cross Section)

Selection of the proper size wire should be based primarily on the load-deflection rate required and secondarily on the magnitude of the forces and moments needed. Many orthodontists select a cross section of wire based on two other factors, which, although valid, are not as significant:

1. Some clinicians believe that increasingly heavy wires are needed in a replacement technique to eliminate the play between wire and bracket. In an edgewise appliance, however,

TABLE 5-1 Factors Influencing Load-Deflection Rate, Maximal Load, and Maximal Deflection

Design Factor	Load-Deflection Rate	Maximal Load	Maximal Deflection
Addition of wire without changing length	Decreases	No change	Increases
Activation in direction of original bending		Increases	Increases
Material properties of wire	Increases as E	Increases as Sp	Increases as Sp/E
Wire cross section (d) (round)	d^4	d^3	1/d
Wire cross section (b, h) (rectangular)	bh^3	bh^2	1/h
Length (L) (cantilever)	$1/L^3$	1/L	L^2

d, Diameter; *h*, diameter in the direction of bending; *b*, direction at right angle to h; *E*, modulus of elasticity; *Sp*, proportional limit.

the ligature wire minimizes much of the play in a first-order direction because it can fully seat within the brackets. Therefore, the clinician does not select a 0.018-inch over a 0.016-inch wire primarily because of the difference in play.

2. A wire also may be selected because it is believed that the smaller the wire, the greater the maximum elastic deflection possible; in other words, the smaller the wire, the more it can be deflected without permanent deformation. This is true, but maximal elastic deflection varies inversely with the diameter of the wire. A 0.016-inch wire has only 1.15 times as much maximal elastic deflection as a 0.018-inch wire; therefore, the difference is negligible from a clinical standpoint. If the difference is 2:1 (as in 0.010-inch versus 0.020-inch wire), this factor becomes clinically significant.

The primary reason for selecting a particular wire size is the stiffness of the wire (i.e., its load-deflection rate). In a replacement technique, for example, the orthodontist might begin with a 0.014-inch wire that, deflected over 2 mm, gives the desired force. After the tooth had moved 1 mm, the wire can be replaced with a 0.018-inch wire, which gives almost the same force with 1 mm of activation.

Small differences in cross section produce big changes in load-deflection rates because in round wires, the load-deflection rate varies as the fourth power of the diameter (Table 5-1). In bending, the stiffness, or load-deflection rate, is determined by the moment of inertia of the cross section of the wire with respect to the neutral axis. Clinicians are interested in the relative stiffness of the wire they use, but they have neither the time nor the inclination to use engineering formulas to determine these degrees of stiffness. Therefore, a simple numbering system has been developed, based on engineering theory, which gives the relative stiffness of wires of different cross sections if the material composition of the wire is the same.[56] The cross-sectional stiffness number (C_s) uses 0.1-mm (0.004-inch) round wire as a base of 1.

A 0.006-inch wire has a C_s of 5.0, which means that for the same activation, five times as much force is delivered. Tables 5-2 and 5-3 list, under the C_s column, stiffness numbers based on nominal cross sections. Manufacturing variation or mislabeling of wires obviously can change the actual C_s significantly.

TABLE 5-2 Cross-sectional Stiffness Numbers (Cs) of Round Wires

CROSS SECTION (in)	(mm)	Cs
0.004	0.102	1.00
0.010	0.254	39.06
0.014	0.356	150.06
0.016	0.406	256.00
0.018	0.457	410.06
0.020	0.508	625.00
0.022	0.559	915.06
0.030	0.762	3164.06
0.036	0.914	6561.00

Two C_s numbers are given for rectangular wires—one for the first-order direction and one for the second-order direction.

The C_s of wire with a cross section of 0.016 inch is 256; this means that for an identical activation, it delivers 256 times as much force as a 0.004-inch round wire. The C_s of 0.018-×0.025-inch wire in a first-order direction is 1865. Because the C_s for 0.016-inch wire is 256, a 0.018-×0.025-inch wire in a first-order direction delivers 7.3 times as much force for the same activation. The assumption, for purposes of comparison, is that the wire configuration and the alloy are identical and only the cross section varies. Any two sections of wire can be compared for stiffness simply by dividing the C_s number of one into the other.

Figure 5-23 presents a graph of the C_s numbers for 0.014- to 0.018-×0.025-inch wires. Although the full spectrum of available wire cross sections is not shown, it is apparent that load-deflection rates can vary by a factor of 10 or more if different sized wires of a constant material (e.g., stainless steel) are used.

In the past, the cross section of wires has been varied to produce different degrees of stiffness. The overall stiffness of

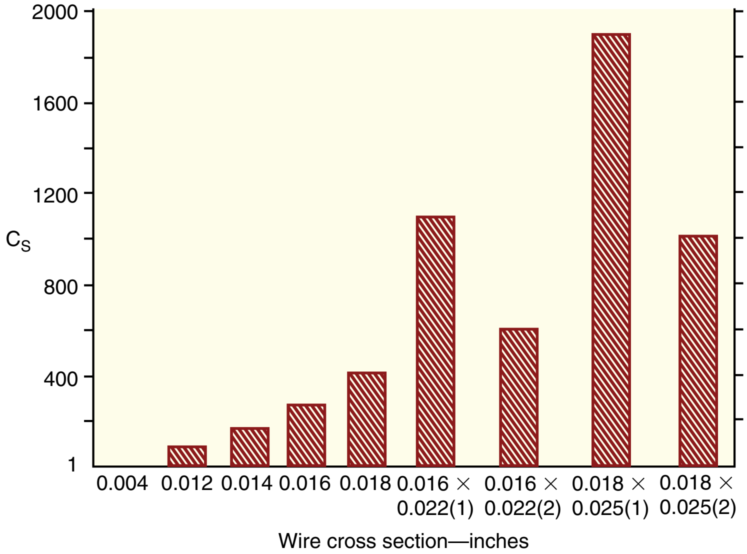

FIGURE 5-23 Cross-section stiffness (C_S) numbers of orthodontic wires. Forces for any given activation are proportionate to the number. With varying cross sections, stiffness can vary by a factor of 10 or more.

an appliance (S) is determined by two factors: one relates to the wire itself (W_s), and the other is the design of the appliance (A_s):

$$S = W_S \times A_S$$

where S is the appliance load-deflection rate; W_s, the wire stiffness; and A_s, the design stiffness factor. In general terms

$$\text{Appliance stiffness} = \text{wire stiffness} \times \text{design stiffness}$$

As the appliance design is changed by increasing wire between the brackets or by adding loops, the stiffness can be reduced as the design stiffness factor changes; however, the orthodontist is not concerned only with ways in which wire stiffness can be altered. Wire stiffness is determined by the cross section and the material of the wires:

$$W_S = M_S \times C_S$$

where W_s is the wire stiffness number; M_s, the material stiffness number; and C_s, the cross-sectional stiffness number. In general terms

$$\text{Wire stiffness} = \text{material stiffness} \times \text{cross-sectional stiffness}$$

Wire stiffness is determined by a cross-sectional property (e.g., moment of inertia) and a materials property (the E). In the past, because most orthodontists used only stainless steel with almost identical Es, only the size of the wire was varied and no concern was expended on the material property, which determines wire stiffness. With the availability of new materials, one can use the same cross section of wire but with different materials with differing degrees of stiffness to produce the wide range of forces and load-deflection rates required for comprehensive orthodontics.

Just as a simple numbering system proved useful for describing the relative stiffness of wires based on cross section, a similar numbering system can be used to compare relative stiffness based on the material. The material stiffness number (M_s) is based on the E of the material. Because steel currently is the most commonly used alloy in orthodontics, its M_s has been arbitrarily set at 1.0. Table 5-4 shows typical stiffness numbers for other alloys. Although the E is considered a constant, the history of the wire (particularly the drawing process) may have some influence on the modulus. Furthermore, differences in chemistry may make small changes in the recorded modulus. For practical clinical purposes, however, the M_s can be used to determine the relative amount of force a wire gives per unit activation. Note that TMA has an M_s of 0.42, which means that for the same appliance and wire cross section, a given activation delivers approximately 0.4 as much force as steel. Elgiloy wires deliver slightly more force than comparable wires of stainless steel, but for all practical purposes this increase is negligible.

In addition to new alloys, braided wires have been introduced into orthodontics. Braids take advantage of smaller cross sections, which have higher maximal elastic deflections and in the process produce wires that have a relatively low stiffness. If the reader were to pretend that a braid was a solid wire and if nominal cross sections were used, it would be possible to establish an apparent E. Based on an apparent modulus, the material stiffness numbers are given for representative braided wires in Table 5-4. For instance, a 0.018-inch Respond wire braid has an M_s of 0.07 and delivers only 0.07 times the force of a 0.018-inch steel wire. The variation in M_s is depicted in a graph in Figure 5-24.

The load-deflection rate can be changed by keeping the wire size constant but varying the load-deflection rate significantly by altering the cross section. Maintaining a cross section of 0.018- × 0.025-inch wire, the wire stiffness (W_s) can be changed by using different materials. To obtain the Ws, the M_s must be multiplied by the C_s. For example, in a second-order direction for TMA,

$$W_S = M_S \times C_S \quad W_S = 0.42 \times 967$$
$$W_S = 406.1$$

TABLE 5-4 Material Stiffness Numbers (Ms) of Orthodontic Alloys and Braided Steel Wires*

Material	M_s
Alloys	
Stainless steel (ss)	1.00

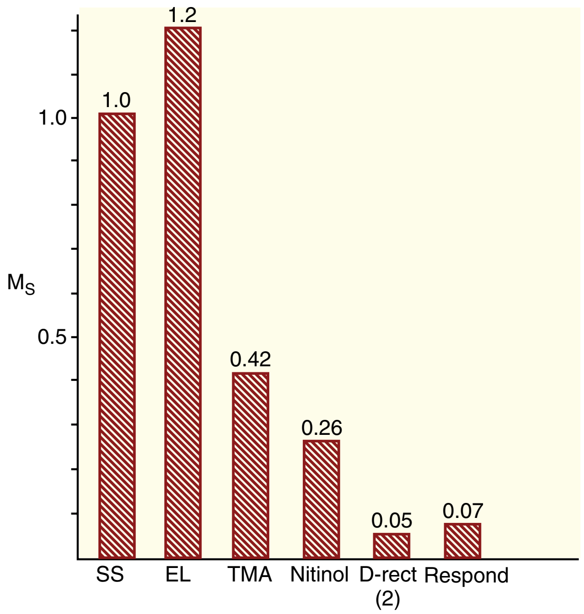

FIGURE 5-24 Material stiffness (M_S) numbers. Stainless steel has a base number of 1.0. The numbers for the other alloys and braids denote their stiffness in comparison with stainless steel. With variations in material, a range of stiffness is available equivalent to that for cross sections.

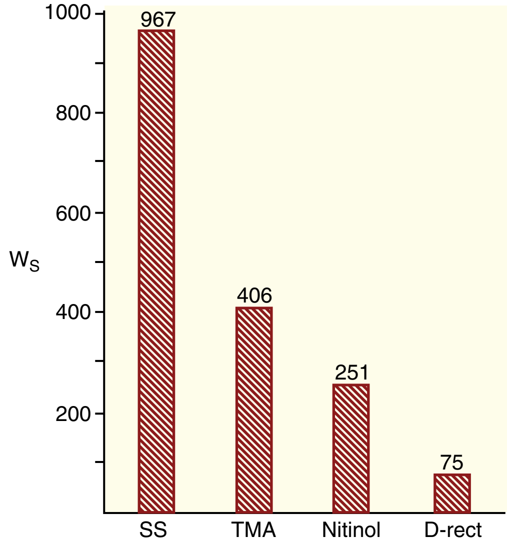

FIGURE 5-25 Wire stiffness (W_S) numbers of 0.018- × 0.025-inch wires in second-order direction. Forces for the same activations are proportionate to the W_S numbers. A full range of forces can be obtained by keeping a constant cross section (e.g., 0.018 × 0.025 inch) but using different materials.

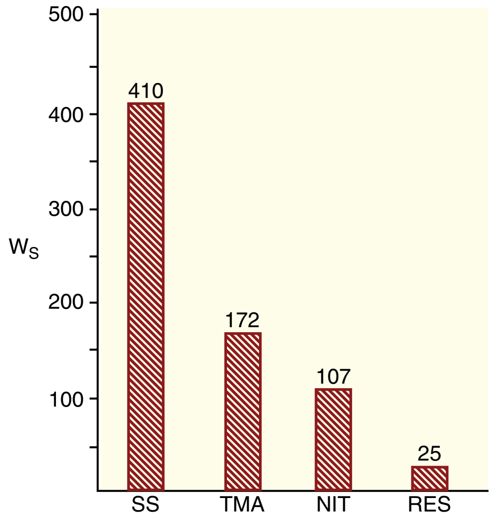

FIGURE 5-26 W_S numbers for 0.018-inch round wires. Figures 5-27 and 5-28 show wide stiffness ranges when the occlusogingival wire dimension is kept constant at 0.018 inch.

A 0.018- × 0.025-inch TMA wire has a W_s of 406.1, which is equivalent to a 0.018-inch round steel wire. Nitinol wire has a W_s of 251.4, which is similar to that of 0.016-inch steel wire. Braided wire (0.018 × 0.025 inch) with a W_s of 75.4 is similar to 0.012-inch steel wire. A full range of forces can be obtained by varying the material of the wire while keeping the cross-section the same (Fig. 5-25). The W_s numbers for 0.018-inch round wire of different materials are shown in Figure 5-26.

Using the principle of variable cross-sectional orthodontics, the amount of play between the attachments and the wire can be varied, depending on the stiffness required. With small, low-stiffness wires, excessive play may lead to lack of control over tooth movement. However, if the principle of variable-modulus orthodontics is used, the clinician determines the amount of play required before selecting the wire. In some instances, more play is needed to allow the brackets freedom of movement along the archwire. In other situations, minimal play is allowed to ensure good orientation and effective third-order movement. After the desired amount of play has been established, the correct wire stiffness can be produced by using a material with a proper M_s. In this way, the play between the wire and the attachment is not dictated by the stiffness required but rather is under the full control of the operator.

The variable-modulus principle allows the orthodontist to use oriented rectangular wires or square wires in light force and heavy force applications and stabilization. A rectangular wire orients in the bracket and thus offers greater control in delivering the desired force system; it is easier to bend because the orientation of the wire can be checked carefully. More importantly, when placed in the brackets, the wire does not turn or twist, allowing the forces to be dissipated in improper directions.

Wire Length

The length of a member may influence the maximal elastic load and the load deflection in a number of ways, depending on the configuration and loading of the spring. The cantilever has been chosen to demonstrate the effect of length because the cantilever principle is widely used in orthodontic mechanisms. A finger spring may be visualized for the following discussion.

Figure 5-27 shows a cantilever attached at *B* with a vertical force applied at *A*. The distance *L* represents the length of the cantilever measured parallel to its structural axis. In this type of loading, the load-deflection rate varies inversely as the third power of the length; in other words, the longer the cantilever, the lower is the load-deflection rate. The maximal elastic load varies inversely as the length of the cantilever. Again, the longer the cantilever, the lower is the maximal elastic load.

Increasing the length of the cantilever is a better way to reduce the load-deflection rate than is reducing the cross section. Increasing the length of the cantilever greatly reduces the load-deflection rate, yet the maximal elastic load is not changed radically because it varies linearly with the length. Adding length within the practical confines of the oral cavity is an excellent way to improve spring properties.

Another way of loading the cantilever is shown in Figure 5-28, this time by means of a couple or moment applied to the free end. With a couple applied at the free end, the moment-deflection rate varies inversely as the second power of the length. Interestingly, the maximal elastic moment is not affected at all by changes in length. The length may be doubled or tripled, but the maximal elastic moment remains the same. This is a most desirable type of loading because additional length can reduce the moment-deflection rate, but the maximal elastic moment is not reduced. However, the principle can be applied only if moments alone are required for a given tooth movement.

Increasing the length of a wire with vertical loops is one of the more effective means of reducing load-deflection rates for flexible members and at the same time only minimally altering their maximal elastic loads. However, limitations exist on how much the length can be increased. The distance between brackets in a continuous arch is predetermined by tooth and bracket width. Vertical segments in the wire are limited by occlusion and the extension of the mucobuccal fold. An application that shows the way in which added length in a wire achieves more constant force delivery without radically sacrificing maximal elastic load is the use of a 0.018- × 0.025-inch TMA intrusion arch (Fig. 5-29). The arch is used to depress maxillary anterior teeth in the correction of deep overbite.[57-59] The long distance from an auxiliary tube on the buccal stabilizing segment to the midline of the incisor is responsible for a more constantly delivered depressive force on the anterior teeth.[60,61]

Amount of Wire

Additional length of wire may be incorporated in the form of loops or helices or some other configuration. This tends to lower the load-deflection rate and increase the range of action of the flexible member. The maximal elastic load may or may not be affected.

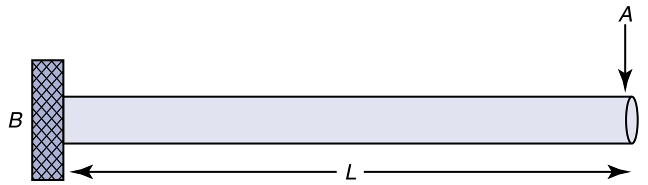

FIGURE 5-27 Cantilever (*B*) with load (*L*) applied at the free end (*A*).

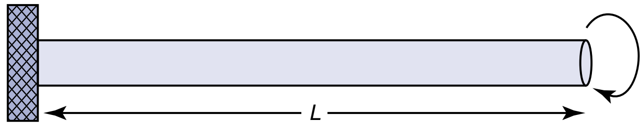

FIGURE 5-28 Cantilever with an applied couple; the effect is uniform bending along the wire.

When a member is to incorporate additional wire, the parts of the configuration where additional wire should be placed must be located properly, and the form the additional wire should take must be determined. If location and formation are done properly, lowering the load-deflection rate without changing the maximal elastic load should be possible merely by adding the least amount of wire that will achieve these ends.

Consider the problem of the cantilever in relation to the placement of the additional wire. In Figure 5-30 a cantilever is shown with the vertical force of 100 *g* at the free end. Imaginary vertical sections can be cut along the length of the wire, and at each of these sections a bending can be calculated. The bending moment is found by multiplying the load at the end of the cantilever by the perpendicular distance to the section in question; therefore, the bending moment at the point of force application at the free end of the wire is zero. Approximately 1 mm closer to the point of support, it is 100 *g*/mm. At 2 mm closer, it is 200 *g*/mm. Finally, at the point of support, the bending moment is 1000 *g*/mm. The bending moment represents an internal moment resisting the 100-*g* force applied to the free end of the cantilever. The significance of the bending moment is that the amount of bending at each cross section of the wire is directly proportionate to the magnitude of the bending moment; in other words, the greater the bending moment at any particular cross section, the more the wire is going to bend at that point.

The optimal place for additional wire is at cross sections where the bending moment is greatest. In the case of the cantilever, the position for additional wire is at the point of support because the bending moment is greatest there: 1000 *g*/mm. Helical coils can be used to reduce the load-deflection rate. Figure 5-31 illustrates the proper positioning of a helical coil for this purpose. The load-deflection rate is maximally lowered for the amount of wire used if the helix is placed at the point of support.

Placement of additional coils at the point of support in a cantilever does not change the maximal elastic load. A straight wire of a given length and a wire with numerous coils at the point of support have identical maximal elastic loads, provided they have the same length measured from the force to the point of support. This should not be surprising because the maximal elastic load is a function of this length of the configuration rather than of the amount of wire incorporated into it. This is true of many other configurations as well: the load-deflection rate can be lowered without changing the maximal elastic load

FIGURE 5-29 Intrusion arches deliver relatively constant force because of the sizable distance between the molar tube and incisor tie. **A,** An intrusion arch showing a canine bypass. **B,** A patient with deep overbite requiring intrusion; 11 mm (60 *g*) of activation. **C,** After intrusion.

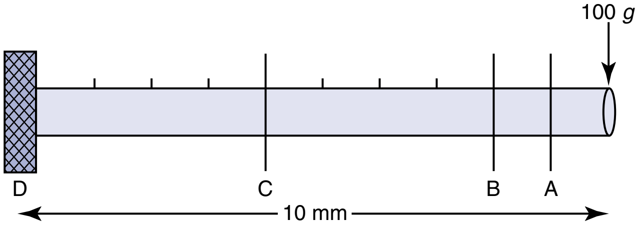

FIGURE 5-30 Cantilever with load applied at the free end. **A** to **C,** Imaginary perpendicular sections. **D,** Point of support.

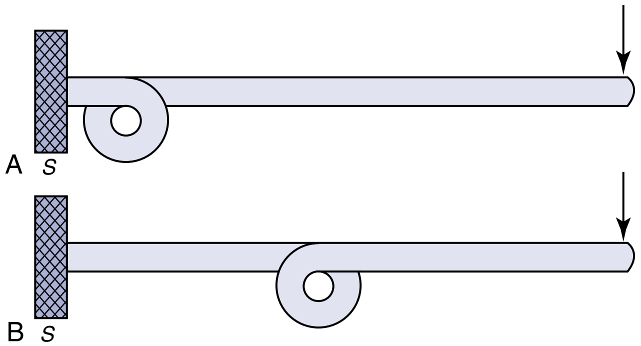

FIGURE 5-31 Placement of a helical coil in a cantilever. **A,** Correct. **B,** Incorrect. *S,* Point of support.

if additional wire is incorporated properly. This is important from a design standpoint because it provides a method of lowering the load-deflection rate without subsequently reducing the maximal elastic load.

As mentioned previously, to achieve this objective using the minimal amount of wire, the best placement of additional wire is at cross sections where the bending moment is greatest. A practical way of deciding where these parts of a wire might be is to activate a configuration and see where most of the bending or torsion occurs. The sections where the bending or torsional moments are greatest are the cross sections with the greatest stress. The configuration of the additional wire should be such that maximal advantage can be taken of the bending and torsional properties of the wire. In short, the amount of wire used is not what is important in achieving a desirably flexible member but rather the placement of the additional wire and its form.

Although additional wire is helpful in the design of flexible members, it should not be used in reactive or rigid members. Loops and other types of configurations diminish the rigidity of the wire and thus may be responsible for some loss of control over the anchor units.

Stress Raisers

From a theoretical point of view, the force or stress required to deform a wire permanently can be calculated; however, in many

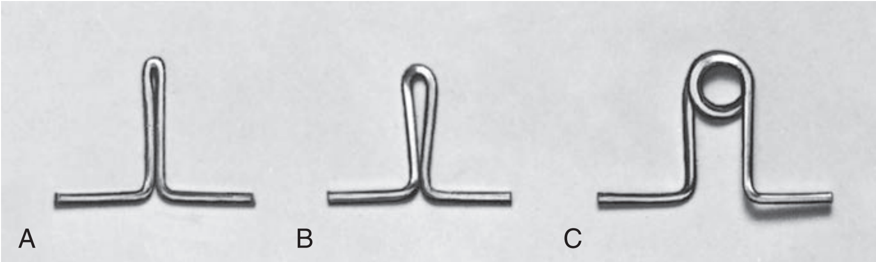

FIGURE 5-32 Vertical loops. **A,** Squashed loop. **B,** Plain loop. **C,** Loop with a helical coil.

cases the wire deforms at values much lower than the predicted one because local stress raisers increase the stress values in a wire far beyond what might be predictable by commonly used engineering formulas.

Two common stress raisers are sudden changes in cross section and sharp bends. Any nick in a wire tends to raise the stress at that cross section and hence may be responsible for permanent deformation or fracture at that point. For this reason, one should not use a file to mark a wire, particularly the small cross-sectional wires used in the flexible member of an appliance.

A sharp bend in a wire also may result in higher stress than that which might be predicted for a cross section of wire. A sudden, sharp bend deforms far more easily than a more rounded or gradual bend. Unfortunately, with a continuous archwire, the orthodontist is limited in space between brackets, and many times must make sharp bends because of this limitation. Flexible members should be designed with gradual bends so that they are less troubled by permanent deformation than comparable members with sharp or sudden bends.

For example, three vertical loops might be compared: a squashed one, a plain one, and one with a helical coil (Fig. 5-32). In terms of permanent deformation, the poorest design is loop A, which because of its squashed state has a sharp bend at its apex. The plain vertical loop (B) is slightly superior because the bending is more gradual; nevertheless, a fairly sharp bend occurs at its apex. The configuration with the most gradual bending is the loop with a helical coil (C). Not only does the helical coil enhance the flexible properties of the spring because of its additional wire, but also the lack of sharp bends further increases its range of action without permanent deformation. (Proper direction of activation is discussed later.)

Sections of Maximal Stress

Certain sections along a wire are points of maximal stress; these sections may be called *critical sections*. As discussed previously, sections in which the bending moments are greatest are areas of high stress. These critical sections are important from a design viewpoint because they are the locations where permanent deformation is most likely to occur.

A number of precautions should be observed at a critical section. First, stress raisers should be avoided in these sections at all costs. A nick in a wire, for instance, might not be so disastrous if the stress is low but might well lead to deformation or fracture where the stress level is high. Second, the EL of the wire should be watched carefully at a critical section. Operations such as soldering may overheat the wire, reducing its EL. Lowering the EL at another place in the wire where stress is low may not be too undesirable but could be responsible for failure at a critical section. Therefore, in high-stress areas an auxiliary

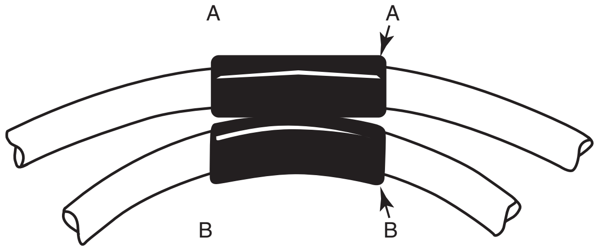

FIGURE 5-33 Face-bow: the anterior portion of the inner and the outer bow. **A,** The juncture of the solder and the outer bow is a stress point. **B,** Another stress point is found at the juncture of the solder and the inner bow.

should be attached by some means other than soldering; if soldering is used, it should be done with considerable care.

An example of permanent deformation or fracture produced by a sudden change in cross section and a lowering of the EL can be seen in the face-bow in Figure 5-33.[62,63] A stress point is found at the juncture of the solder and the outer bow (A) and secondarily at the juncture of the solder and the inner bow (B). At A, the wire may be structurally weak for two reasons: the stress point associated with the sudden change of cross section and a lowering of the EL because of the soldering operation. A also happens to be a critical section where stress is high; therefore, it is a predictable area of fracture in a face-bow of this design.

If the orthodontist is in doubt about which parts of an appliance have critical sections, the appliance can be activated in a typical manner and the parts that exhibit the most bending or torsion noted. These generally have high stress along their cross sections.

One must keep in mind three rules in the design of critical sections: (1) all stress raisers should be eliminated as much as possible, (2) a larger cross section can be used to strengthen this part of the appliance, and (3) the appliance may be so designed that it elastically rather than permanently deforms under normal loading. Many times, a highly flexible member is more serviceable than a rigid one because the flexible member can deflect out of the way of the oncoming load. A light, flexible spring can withstand occlusal trauma far better than a more rigidly constructed one because it can displace elastically away from an occlusal force. Because the wings of airplanes are flexible, they are less apt to fracture under normal flying conditions. Similarly, increasing the flexibility of a member may be a way of preserving the integrity of the appliance.

Direction of Loading

Not only is the manner of loading important, but also the direction in which a member is loaded can influence its elastic properties greatly. If a straight piece of wire is bent so that permanent deformation occurs and an attempt is made to increase the magnitude of the bend, bending in the same direction as had originally been done, the wire is more resistant to permanent deformation than if an attempt had been made to bend in the opposite direction. The wire is more resistant to permanent deformation because a certain residual stress remains in it after placement of the first bend. A flexible member will not deform as easily if it is activated in the same direction as the original bends were made to form the configuration. If a bend is made in an orthodontic appliance, the maximal elastic load is not the same in all directions; it is greatest in the direction identical to the original direction of bending or twisting. The phenomenon responsible for this difference is known as the Bauschinger effect.

Figure 5-34 shows a vertical loop with a coil at the apex and a number of turns in the coil under different directions of loading. The type of loading in A tends to wind the coil, increasing the number of turns in the helix and shortening the length. The type of loading in B tends to unwind the helix, reducing the number of coils and lengthening the spring. The loading in Figure 5-34, *A*, tends to activate the spring in the same direction as it originally was wound and thus is the correct method of activation. In many configurations in which residual stress is high, such as a vertical loop that uses a number of coils at the apex, the range of action can vary 100% or more between correct and incorrect loading. Obviously this is a much more significant factor in design than are small differences in the mechanical properties of the wire.

The same principles can be applied to less complicated configurations, such as a continuous archwire. The orthodontist should be sure that the last bend in an archwire is made in the same direction as the bending produced during its activation. For example, if a reverse curve of Spee is to be placed in an archwire, the curve first should be overbent and then partly removed; only then will activation of the archwire occur in the same direction as the last bend (Fig. 5-35). The same is true of a series of tip-back bends. The tip-back bend should be increased beyond the amount required, and then some of it should be removed. In this way, bending during activation of the tip-back bend when it is placed in the brackets occurs in the same direction as the last bend.

Attachment

If forces and moments are to be delivered to a tooth, some means of attachment are necessary. If forces alone were sufficient without the use of moments, the attachment could be relatively simple; however, this usually is not the case. Most orthodontic movements require moments and forces. Moments and forces can be produced if a noncircular wire is oriented in a noncircular bracket. The edgewise bracket and tube are excellent examples of the use of a noncircular cross section for wire and attachment. However, loops can be used to obtain an orientation of round wire that allows moments and forces to be delivered.

What are the optimal dimensions for a bracket or tube? This question has no definitive answer unless the objectives and design of an orthodontic appliance are specified fully. However, some of the factors involved in making this decision can be discussed.[64]

The starting point in the design of a bracket is determining the width of the bracket (mesiodistal dimension). From a theoretic viewpoint, a system of forces and moments can be produced regardless of the mesiodistal width of the brackets. However, width becomes important for two reasons. First, wider brackets minimize the amount of play between the arch wire and attachments. A certain amount of leeway must exist between the archwire and the bracket, or easy bracket engagement becomes impossible. However, if a bracket is too narrow, considerable play may exist in all planes between wire and bracket. If the bracket is wider, the archwire has a much more positive purchase. Second, the greater the distance between the brackets, the lower the load-deflection rate. Because at least part of the movement required to treat a patient is produced by adjustments between brackets, it is desirable that the distance between attachments be as great as possible. One of the problems of the continuous arch is the sharp limitation of space between brackets, no matter how narrow the brackets might be.

The decision on proper bracket width lies between two extremes. At one end, a bracket might be as wide as the tooth. In this instance, however, the interbracket distance is not enough to produce sufficient flexibility for adjustment. At the other end, a knife-edge bracket offers the greatest interbracket distance and thus the most desirable load-deflection rates. With a knife-edge bracket, however, delivering the necessary moments and forces to achieve full control over tooth movement is impossible.[65] Generally speaking, the ideal bracket width is one that is as narrow as possible, yet still capable of obtaining positive purchase on an archwire so that moments can be delivered to teeth.

Optimal occlusogingival slot dimensions are determined by the maximal elastic loads required from the active and reactive members. A safe rule is to design based on the reactive members, ensuring that the bracket and tube slots are large enough for rigid control of anchor units. Designing primarily based on the active members is a mistake that may lead to the use of slots that are too small to control the anchor teeth and withstand the forces of mastication.

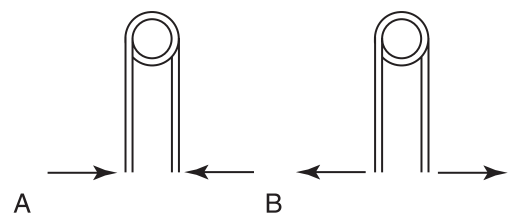

FIGURE 5-34 Activation of a loop with a helical coil. **A,** Correct. **B,** Incorrect.

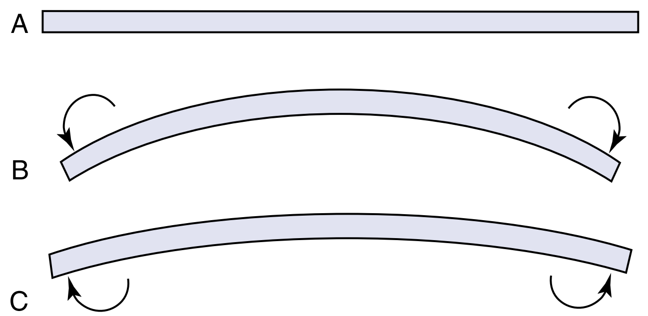

FIGURE 5-35 Placing a reverse curve of Spee in a lower arch.* **A,** Original straight wire. **B,** Wire overbent. **C,** Final configuration. Note that the last bends are in the same direction as the activation in the mouth.

A vexing problem in orthodontic treatment arises when appliance requirements change between stages of treatment. Teeth that at one time are being moved actively may later become reactive units. For convenience, in the typical strap-up, the same dimensions are used in all slots throughout the arch; yet the active and reactive requirements are not the same throughout the arch. One objective in the design of an appliance is to ensure a positive fit between different cross sections of wire, depending on the needs of the case. An edgewise bracket can become adjustable in a buccolingual or labiolingual direction by means of a ligature tie, but it is not adjustable occlusogingivally. Thus, no definite answer can be given to the question of optimal occlusogingival slot dimension.

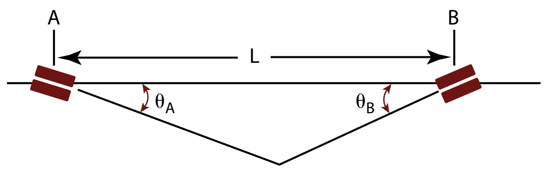

FIGURE 5-36 The geometry of the wire to an edgewise bracket is defined by the interbracket distance (L) from the angles of the brackets with respect to the interbracket axis. (From Burstone CJ, Koenig HA. *Am J Orthod.* 1974;65:270. With permission from the American Association of Orthodontists.)

The decision depends on many factors, including the general concept of treatment and the basic design of an orthodontic appliance.

Forces from a Continuous Arch

A multibanded appliance, such as that used in edgewise mechanics, produces a complicated set of forces and moments. For example, a straight (ideal) arch placed between irregular brackets on malaligned teeth may deliver desirable and undesirable forces. An analysis of two-tooth segments (two teeth connected by a straight wire) can demonstrate some of the problems encountered when adjacent brackets are connected by a continuous wire or arch.[4,6,66-70]

The force system produced in a two-tooth segment is determined by the angle of the bracket (θ_A and θ_B) with respect to the straight wire and the interbracket distance (Fig. 5-36). Based on the ratio θ_A/θ_B, six classes of force systems can be described (Fig. 5-37). The force system for each class is given in Table 5-5. Note that the ratio of the moments at bracket A with respect to bracket B is constant for each class. Lines 2 and 3 of Table 5-5 give the force systems acting on the wire; line 5 reverses the direction, showing the forces acting on the teeth. What is apparent is that forces, moments, and their ratios may not be correct to produce the desired changes in a malocclusion without side effects.[71,72]

For example, Figure 5-38, *A*, shows a Class I geometry in which the second premolar is supererupted in relation to the first molar. A straight wire placed on the premolar produces a desirable intrusive force; unfortunately, however, the moment produced on the premolar is undesirable, displacing the root mesially. This can be avoided by using a noncontinuous configuration, the rectangular loop. Figure 5-38, *B*, shows the force system from the rectangular loop, which can be designed to produce an intrusive single force and no moment on the premolar. Figure 5-39 shows a rectangular loop used to rotate and extrude a premolar. Rectangular loops and other loop designs offer the potential for delivering desired force systems with

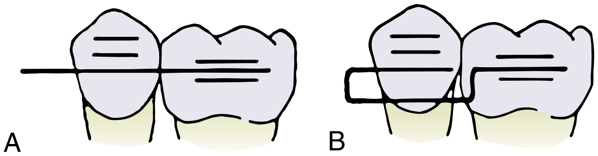

FIGURE 5-38 A, A straight wire (ideal arch) between the first molar and premolar produces an undesirable positive movement that displaces the premolar root mesially. B, A rectangular loop used for the same bracket malalignment produces no side effects on the premolar because only an intrusive force is delivered.

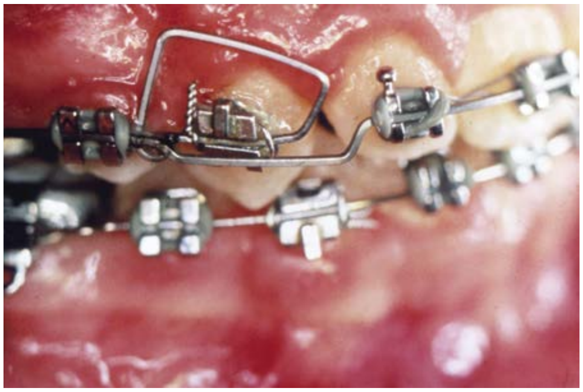

FIGURE 5-39 A rectangular loop is used to rotate and extrude the upper cuspid without a side effect. Note bypass arch for added anchorage.

minimal side effects, which is not usually possible with the continuous arch.[57,58] Loops are not used only to lower forces; they change the entire force system.

Straight wires may reduce desirable or undesirable force systems. The undesirable components of the forces can produce unwanted tooth movement during the leveling process. These side effects can be eliminated by the placement of suitable bends, use of bypass arches, and selection of anchorage teeth not adjacent to malaligned teeth.[60,61,73-75] In addition, forming properly designed loops can change a force system from the straight wire.

Figure 5-40, *A*, shows a canine with its root apex forward. A straight wire, as it moves the root distally, also erupts the incisors, producing deep overbite. To prevent this side effect, a bypass arch was constructed. In Figure 5-40, *B*, the continuous 0.018-inch stainless-steel arch steps occlusally bypass the canine. The axial inclinations have been corrected by a 0.017- × 0.025-inch TMA cantilever root-spring. The reactive forces have been distributed to the whole arch rather than to the incisors. Final leveling can be carried out safely with a straight wire (Fig. 5-40, *C*).

With a high canine, as in Figure 5-41, *A*, a straight wire tends to tip the buccal segment toward the canine. To avoid this effect, a bypass arch was formed so that the entire arch was an anchorage unit. A separate NiTi arch from auxiliary tubes on the first molars brought the canine into alignment (Fig. 5-41, *B*). Instead of the NiTi secondary arch, a cantilever can be used from the molar auxiliary tube (Fig. 5-42).

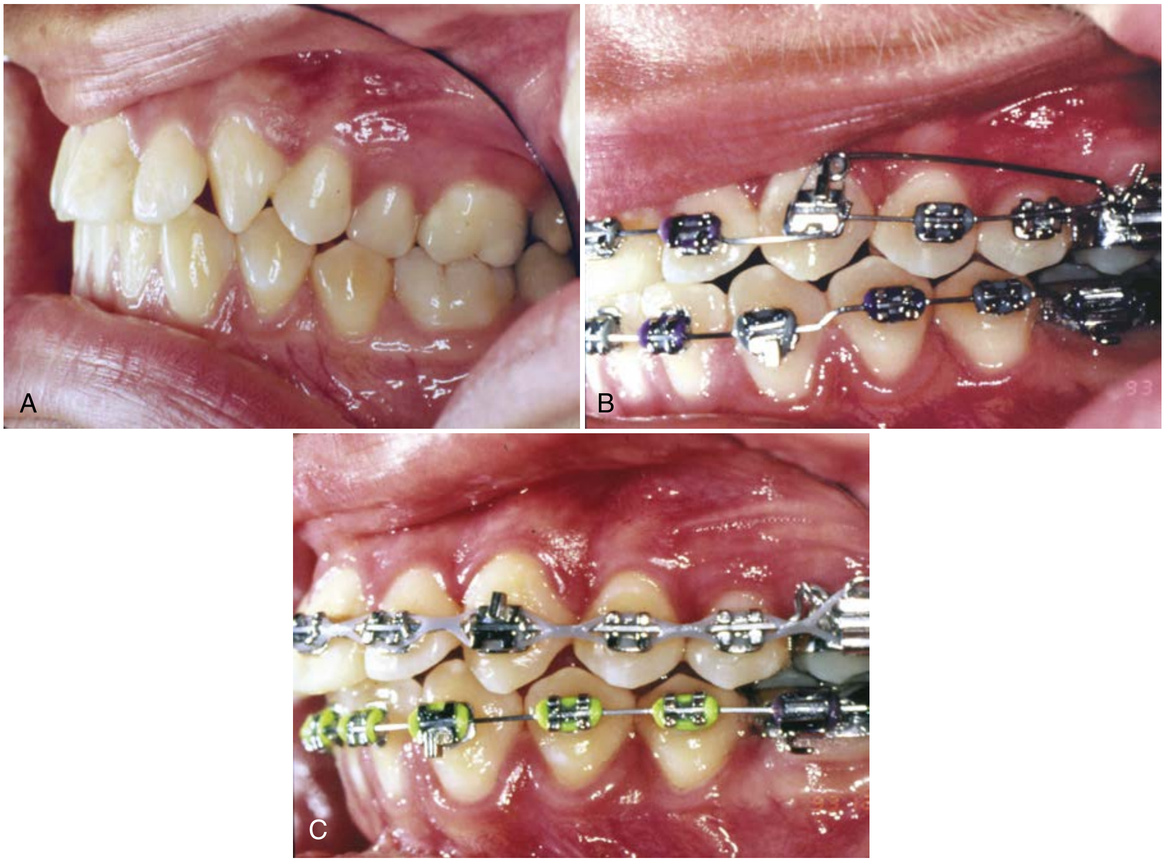

FIGURE 5-40 A 0.017- × 0.025-inch TMA root spring is used to move the canine root distally before final leveling. A, Before treatment. B, After root correction. C, After final leveling.

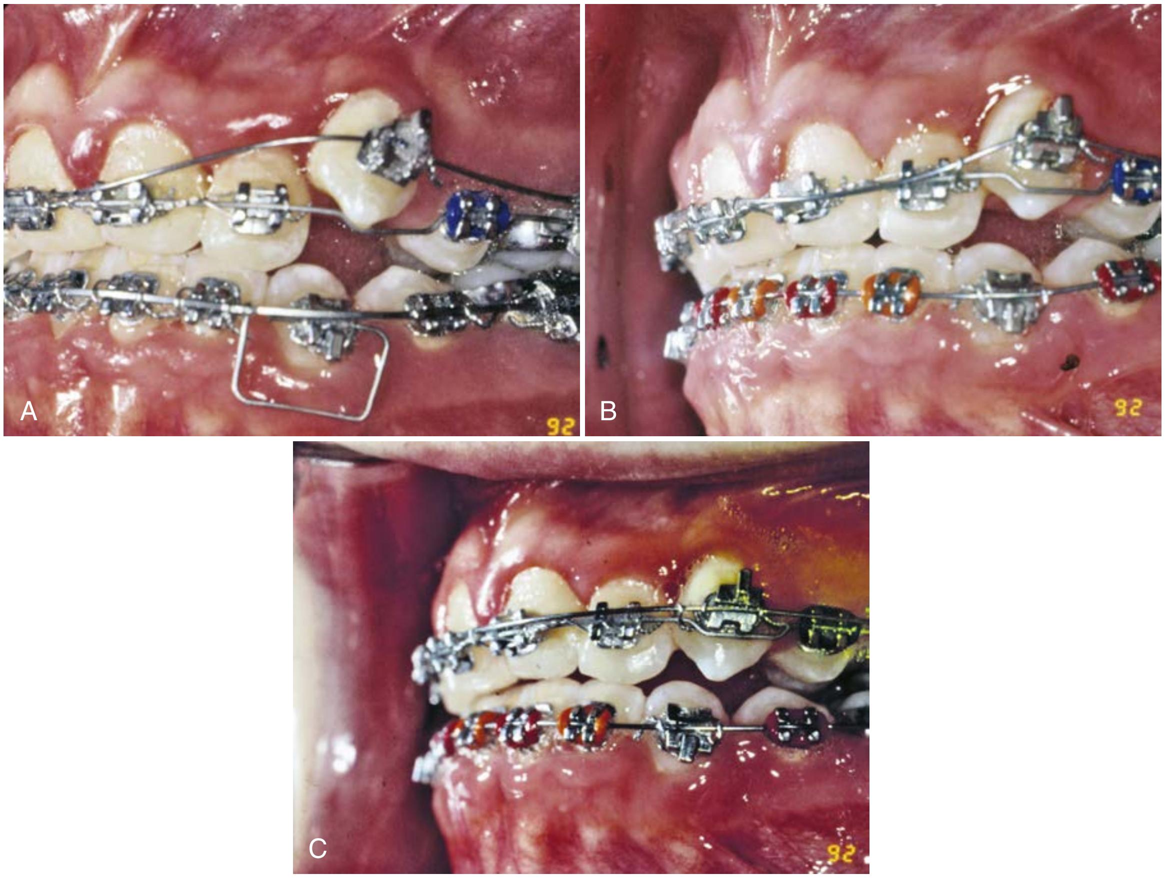

FIGURE 5-41 A cuspid bypass arch prevents side effects. A separate, secondary NiTi wire erupted the cuspid. **A,** Before. **B,** Intermediate. **C,** After.

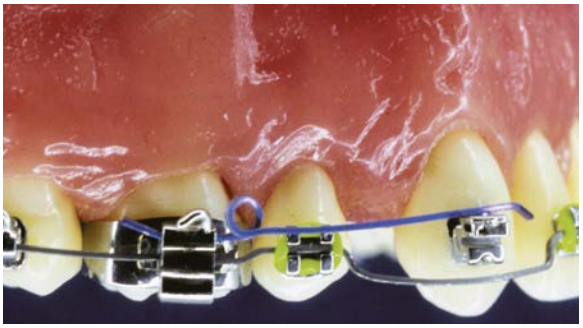

FIGURE 5-42 Canine bypass arch. A cantilever from the molar tube erupts the canine.

FIGURE 5-43 Canine bypass arch made of 0.016- × 0.022-inch TMA wire torques the canine root lingually. The wire is placed ribbonwise in the canine bracket.

A 0.018- × 0.025-inch TMA wire connects auxiliary tubes on the canine and first molars to torque the root of the canine lingually (Fig. 5-43). The long span reduces the torque-twist rate, increasing the range of action and delivering more constant torque. The bypass arch gives full anchorage control.

Teeth other than the canine can be bypassed. With the high central incisor, a straight wire tends to tip the adjacent teeth toward the high incisor (Fig. 5-44). A continuous bypass arch with a secondary NiTi wire is used to extrude the incisor without distributing forces to the adjacent teeth.

If a straight wire is used with first molars that are rotated mesially, the side effects can include molar expansion, arch form changes, and prevention of molar distalization. A lingual or transpalatal arch that delivers equal and opposite couples uses reciprocal anchorage and thus more efficiently rotates molars without side effects. This is an example of selecting teeth for anchorage and not relying on a continuous wire that connects adjacent teeth. Connecting only two teeth improves the accuracy of activation. Figure 5-45 shows a 0.032-inch, round, TMA transpalatal arch that attaches to a precision hinge-cap lingual attachment.[76] Equal rotation bends produce equal and opposite couples with no horizontal forces.

Principles of Spring Design

An understanding of the relationships between bioengineering parameters and force systems can offer a rational basis for the design of orthodontic appliances. To achieve an optimal force system, not only must the force magnitude be correct, but also the force must be delivered constantly, and the required M/F ratio must be produced to control the center of rotation. In this section, these factors are considered together, using the example of an anterior or canine retraction spring.[57,58,77,78]

For a canine that needs translation, or bodily movement, a force must be applied through the center of resistance of the tooth (Fig. 5-46). If the force is 200 *g*, 200 *g* must be delivered at the bracket, as well as a moment of 2000 *g*/mm (provided the distance between the bracket and the center of resistance is 10 mm). In other words, a 10:1 M/F ratio is produced. If a simple vertical loop is used for space closure, a moment that encourages the root to move distally is provided during activation. For a loop 6 mm long, the M/F ratio typically is low, about 2.2:1.24. This ratio is too low to control the root and prevent it from being displaced mesially. A number of strategies can be used to increase the M/F ratio during activation.[75,79] The loop can be made as long as possible in an apical direction. Increasing the length of the loop to 11 mm approximately doubles the M/F ratio. However, a loop can be extended apically only so far before it causes irritation in the mucobuccal fold. Another strategy involves increasing the amount of wire found gingivally at the top of the loop. Figure 5-47 shows that by increasing the gingival amount of wire (dimension G), the M/F ratio is increased and the load-deflection rate is reduced. One advantage of the T-loop design over a simple vertical loop is that the T-loop produces a much higher M/F ratio to control the root and a low load-deflection rate, thereby ensuring greater force constancy.[77,80,81]

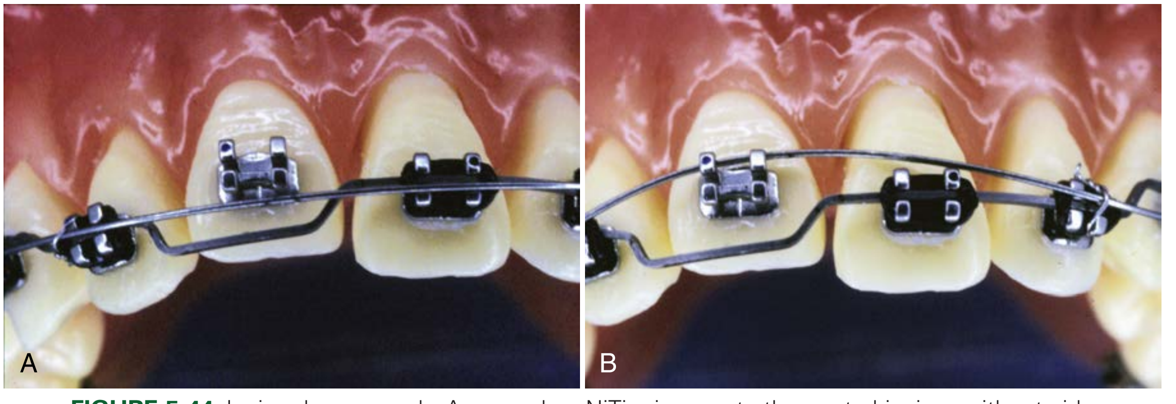

FIGURE 5-44 Incisor bypass arch. A secondary NiTi wire erupts the central incisor without side effects on the adjacent teeth. **A,** Activated. **B,** Passive.

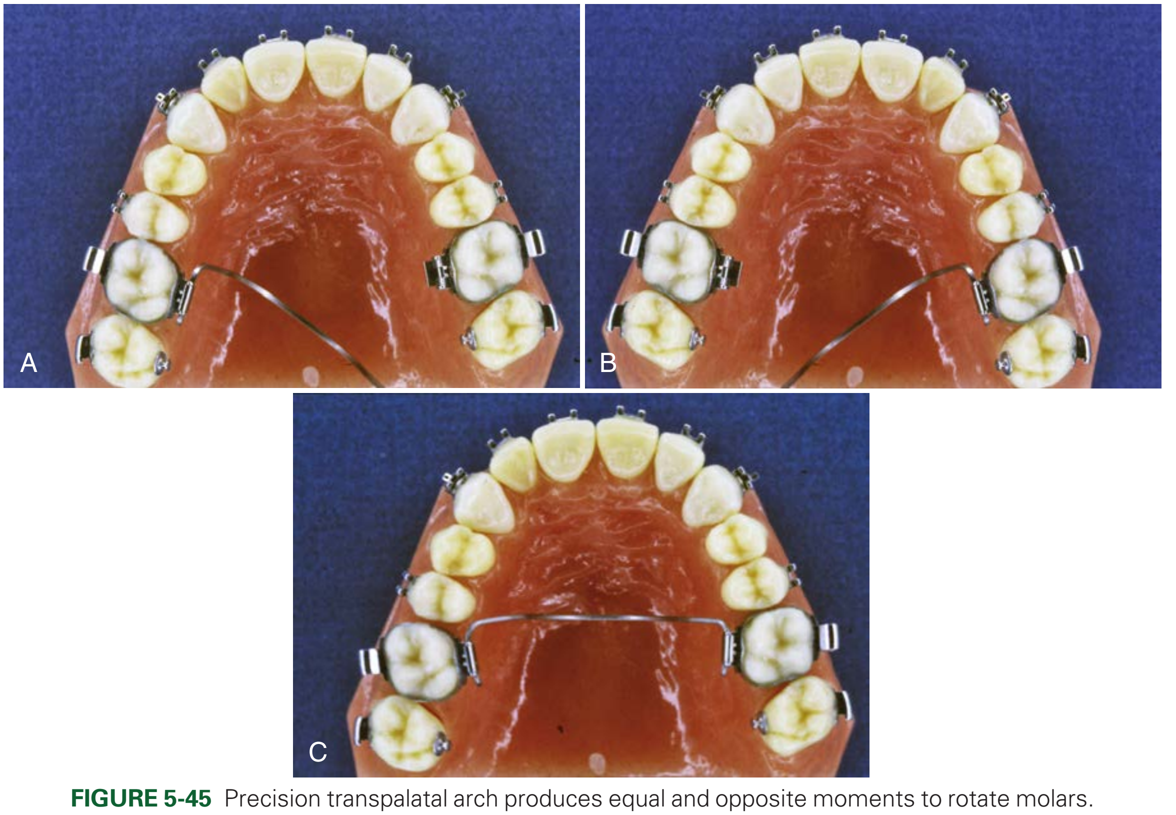

FIGURE 5-45 Precision transpalatal arch produces equal and opposite moments to rotate molars. If both arches are angled equally, no horizontal forces are produced (**A, B**). **C,** Transpalatal arch inserted showing rotated molars.

The moment produced by a retraction spring during activation is called the *activation moment*. The activation moment depends on the change in angle that the horizontal arms of the spring make with the bracket when a loop is pulled apart. Even if the design is improved by use of a configuration such as a T-loop, the M/F ratio may not be high enough to affect translation. To achieve a higher M/F ratio, an angulation or a gable-type bend must be put in the spring. The moment produced by gabling is known as the *residual moment*. Ideally, a retraction spring delivers a relatively constant M/F ratio. If the ratio changes each time the tooth moves, the tooth will not have a constant center of rotation. Two principles to remember in obtaining a constant M/F ratio are to (1) use the highest activation moment and the lowest residual moment that are possible and to (2) lower the force-deflection and moment-deflection rates.

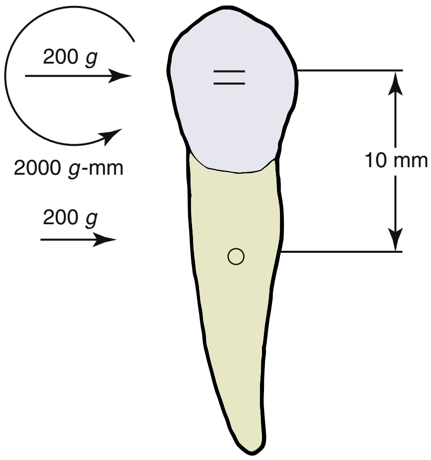

FIGURE 5-46 A force acting at the center of resistance (CR) of a tooth translates the tooth. A couple (moment) and a force (*white arrows*) acting at the bracket can produce the same effect. Note that the magnitude of the moment is equal to the force multiplied by the distance from the bracket to the center of resistance. (Redrawn from Burstone CJ, Koenig HA. *Am J Orthod*. 1976;70:1. With permission from the American Association of Orthodontists.)

An important factor in the use of a loop for space closure is the mesiodistal position of the loop. If the loop is placed midway between the attachments, equal and opposite activation moments are produced.[79] If the loop is positioned off-center to the distal, the posterior teeth receive a larger tip-back moment. In addition, intrusive forces are delivered anteriorly. This concept can be applied in anchorage cases when mesial movement of posterior teeth is not indicated. Conversely, placing a loop mesially off-center increases the moment to the anterior teeth and can be useful in bringing buccal segments forward.

Use of a T-loop for en masse space closure is shown in Figure 5-48. Both the anterior and posterior segments are steel; the active T-loop is TMA, which lowers the force-deflection rate and increases the range of activation. The loop (spring) is attached to auxiliary tubes on the first molar and canine. Centering the spring produces approximately equal translation of posterior and anterior segments during space closure. T-loops were used to affect differential space closure, to hold anchorage, and to correct deep overbite (Fig. 5-49). The upper loop was placed distally off-center. Note that the upper-anterior teeth have tipped somewhat lingually; this is to be expected because the moment to the incisors is sufficient to produce only tipping around their apices, not translation. A separate stage of en masse anterior root movement is required after space closure.

One of the problems with using sliding mechanics for canine retraction is the unpredictability of frictional forces. Much of the friction arises from the tendency of the wire to prevent tipping and rotation. In Figure 5-50, a T-loop is used to deliver force during canine retraction. The loop also produces moments that prevent tipping and rotation; hence, friction is reduced. Another approach to reducing friction with sliding mechanics is shown in Figure 5-51; flexible 0.016- × 0.022-inch TMA extensions with helices attached to canine and molar

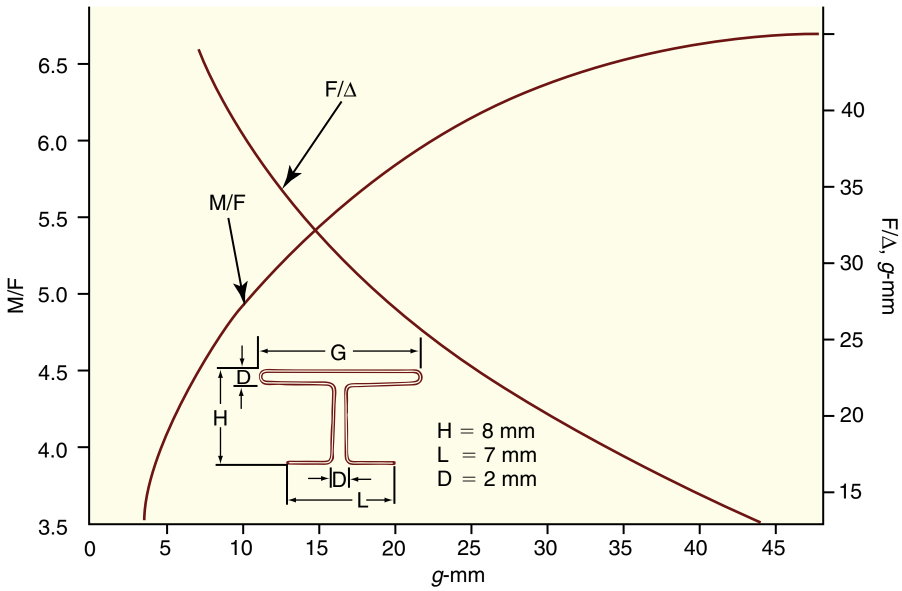

FIGURE 5-47 As the gingival horizontal length increases, the moment-to-force ratio increases and the F/D continues to decrease. (Redrawn from Burstone CJ, Koenig HA. *Am J Orthod*. 1976;70:1. With permission from the American Association of Orthodontists.)

auxiliary tubes place the force closer to the center of resistance of the canine. Unlike rigid "power" arms, the extensions have a relatively low force-deflection rate of 40 *g*/mm and a typical activation of 6 mm.

Fiber-Reinforced Composite Applications

The design of fixed orthodontic appliances historically has required materials with excellent engineering properties such as metals and ceramics. Polymers, although user friendly, are structurally weak and hence have limited use, mainly in removable appliances.

A new generation of materials that incorporates long fibers, such as glass or carbon, has been developed that possesses properties approaching those of metals. To optimize the mechanical properties, fibers are wetted and oriented, and the plastic matrix is added under controlled manufacturing conditions. Wires or strips that are impregnated by the matrix and are unpolymerized are called *pre-pregs.* These wires can be shaped passively to the shape of the arch and, when light-cured, harden to form a stiff orthodontic component.[82,83]

The application of a fiber-reinforced composite (FRC) is shown in Figure 5-52. The upper-left second molar has tipped forward into the first molar extraction space, and the treatment plan calls for some mesial molar movement to close the space and mesial root movement to correct the axial inclination. Traditionally, metal or ceramic brackets are placed on all the anterior teeth to afford sufficient anchorage. In this patient, a pre-preg composed of long fiberglass and Bis-GMA resin was formed to the shape of the upper arch and then light-cured to form a metal-like rigid, strong, and passive anchorage unit. Attachments were placed only on the second molar and on the FRC in the region of the first bicuspid. A simple wire segment connects the two attachments. The long interattachment span and the use of only a few brackets increase biomechanical efficiency and patient comfort. The correction of the upper-second molar axial inclination and space closure is shown in Figure 5-52, *B*. An additional FRC has been placed in the lower arch to facilitate correction of the terminal molar. Following major corrections with an FRC segment, some but not all brackets may be needed for finishing detail.

The development of FRC segments, or arches, offers a new dimension in appliance design. Anchorage is enhanced because play is eliminated between wire and the bracket. Because these wires accurately fit the teeth, the possibility of undisturbed teeth and a completely passive wire is now possible. In addition, the glass fibers are good for anterior aesthetics.

The Role of Friction

Tooth movement is determined by the total forces applied to the teeth. This includes not only forces from the appliance but also muscular forces that are produced during function. In addition, frictional forces can operate that can considerably alter the force system.

The mechanical principles and their application that govern friction are complicated and beyond the scope of this chapter. However, a discussion of some basic principles can be very useful for the clinician. The classic formulas below define a relationship between friction force (F_F), coefficient of friction (μ), and forces operating at 90 degrees to the archwire (i.e., normal forces [F_N]). M is a moment in loading by a couple and W is the bracket mesial–distal width (Fig. 5-53).

$$F_F = \mu \times F_N$$

$$F_F = 2\mu \cdot M/W$$

Thus, friction force is produced by many possible appliance activations: buccal, lingual, apical, and occlusal forces. Friction force is also produced by moments acting on the archwire by "tip"

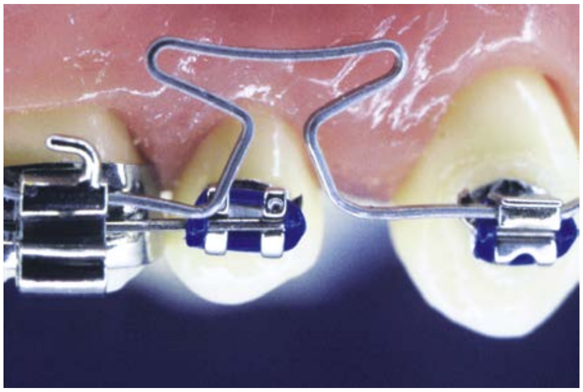

FIGURE 5-48 Centered T-loop is connected to auxiliary tubes on the canine and molar.

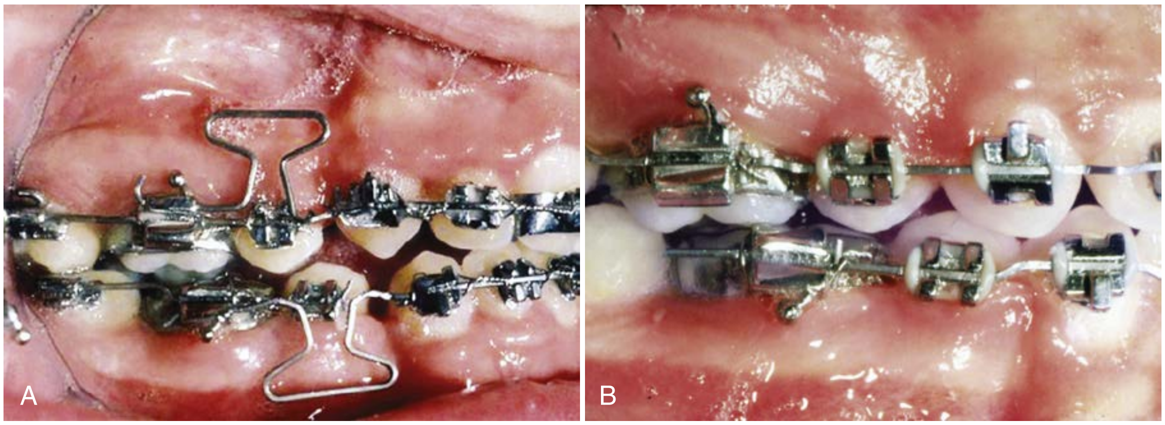

FIGURE 5-49 Differential space closure. Greater tip-back moment was achieved on the posterior teeth by putting the loop distally off center. **A,** After en masse anterior tipping. **B,** After en masse anterior root movement.

or "torque." The ligation mechanism produces normal forces adding to the friction force. The purpose of ligation is to keep the archwire from being displaced from the bracket. Any additional ligation force will add to the friction force and usually is not desired. The coefficient of friction (μ) is determined by such factors as the material, the material interface if more than one material is used, and lubricants. From an orthodontic perspective, the force system used is the main determinant of the friction force.

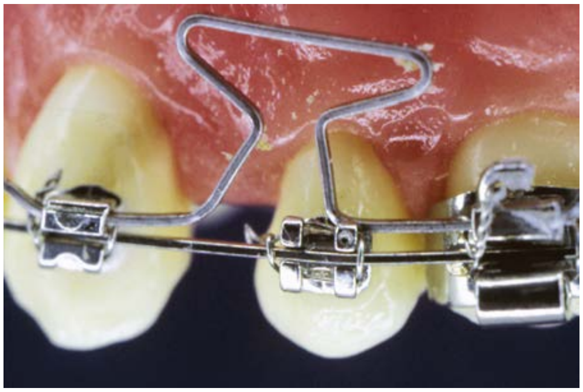

FIGURE 5-50 Canine retraction using sliding mechanics. T-loop moments minimize friction.

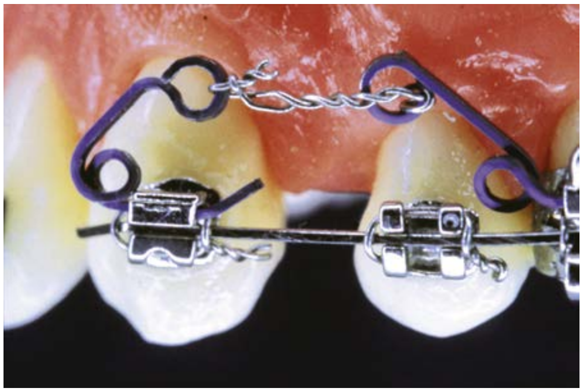

FIGURE 5-51 Canine retraction using sliding mechanics. Flexible extensions deliver more constant force, and the force is closer to the center of resistance of the canine.

Which bracket will produce the most friction force: a narrow or wide bracket? It depends on the stage of tooth movement. If there is initially play between the wire and the bracket, there is little friction—hence, a narrow bracket produces less friction until the wire engages the bracket. Once there is engagement with a single force (e.g., an occlusal force), bracket width does not make any difference if the force magnitude is the same. With torque and tip moments, for the same magnitude moment, the wider bracket produces less friction.

In special situations such as canine retraction, different stages of tooth movement can be identified during sliding mechanics. Initially, the canine will tip; later, the tooth will translate followed by root correction. Translation requires a larger moment with a distal force, and therefore, frictional forces are greater during the translational stage of retraction. Although there has been much discussion about the role of the bracket ligation method as the cause of friction, it should be recognized that most friction is produced by the forces required to correct the malocclusion. Particularly, moments produce large frictional forces since the bracket is far from the center of resistance at the root; hence, for translational or bodily movements, high moments are a necessity.[84]

Friction can be either good or bad depending on the application. With too much friction, force is lost and tooth movement can be reduced. On the other hand, commonly too much force is used and friction reduces the force to more acceptable biological levels. Friction during space closure can also be helpful in reducing tipping.

When heavier normal forces are applied to an archwire, wire abrasion and indenting can occur. Calculation of the friction force becomes more complicated, and the simple, classic formulas are not applicable. It has been demonstrated that vibration or cyclic loading can reduce friction associated with the ligation force.[85]

3D Biomechanics

Orthodontic treatment has always been in three dimensions; limitations in methodology and visualization have been responsible for two-dimensional thinking. Now, with widespread applications of 3D imaging, the necessity of 3D force analysis becomes imperative.

In three dimensions, the center of resistance becomes an axis of resistance. Unlike a center of mass, in three dimensions all axes in a restrained body may not intersect at a point. This can

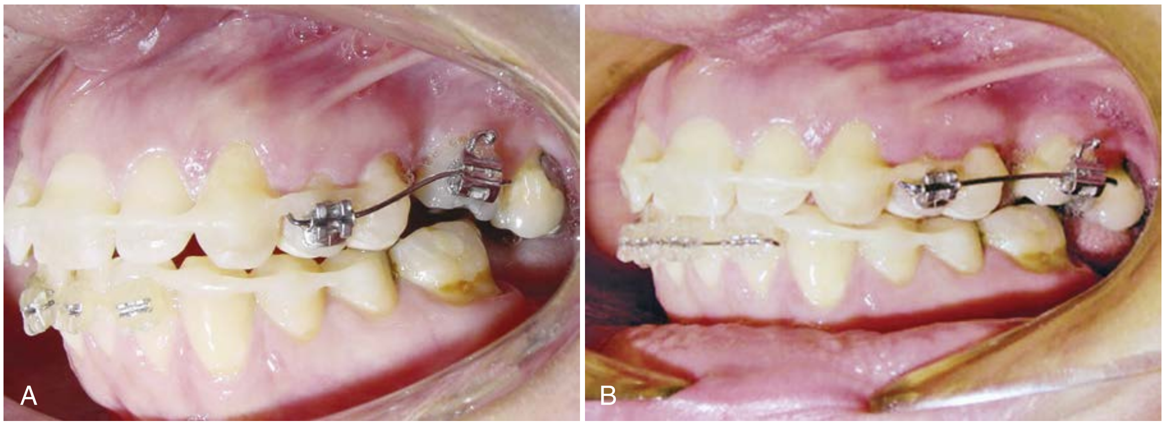

FIGURE 5-52 A fiber-reinforced composite wire (FRC) is used for anchorage instead of brackets to upright the upper-left second molar. The aesthetic FRC connects rigidly and passively the anterior teeth. **A,** Before. **B,** After. (Courtesy Philip Depasquale, Avon, CT.)

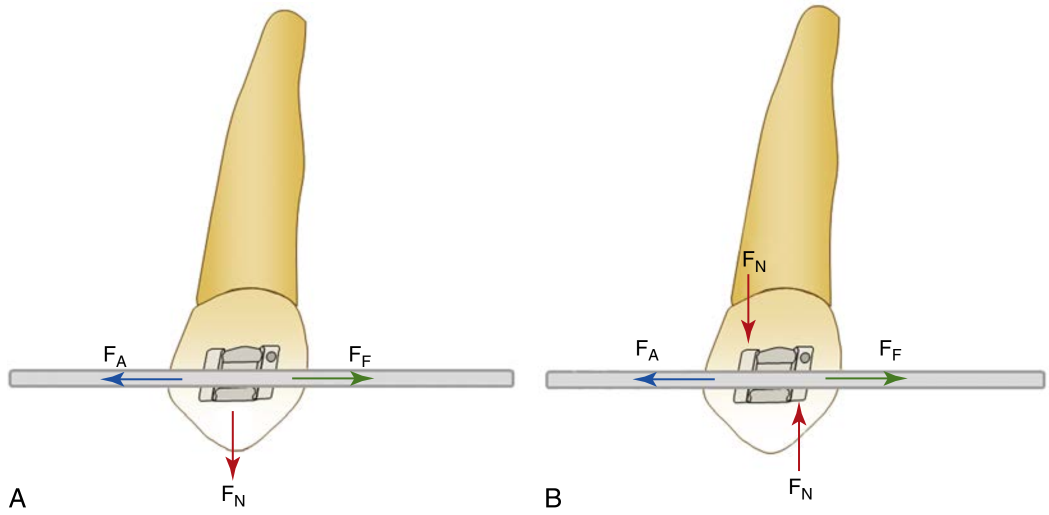

FIGURE 5-53 Normal forces (F_N) in respect to an archwire produce friction forces (F_F). F_A is the applied force. The force that the tooth feels is the applied force minus the friction force. **A,** F_N is a single occlusal force. **B,** A couple or pure moment is applied to the bracket of the canine. These normal forces also lead to friction.

occur if there is asymmetric root morphology or PDL constitutive behavior is asymmetric. Thus, the center of resistance concept becomes a useful fiction.[86]

Also, much variation can exist in generally finding a center of resistance. Therefore, the center of resistance can be considered instead of a point as a sphere. Most likely, in most clinical situations, the radius of a sphere encompassing all intersecting axes is relatively small; however, more research is need. The clinician can still visualize one plane at a time for convenience. It should be remembered that different projections are required in any study to properly localize all axes in three dimensions.

In this chapter, for purposes of simplicity, the discussion and diagrams have shown only one plane. The clinician, however, must think three dimensionally if major side effects are to be avoided.

SUMMARY

Design of an orthodontic appliance requires a thorough understanding of biological and physical variables. Design is an area in which the concepts of biology and physics can be wedded to form a true biomechanical discipline.

Although the author's purpose is not to attempt a cookbook approach to appliance design, there is merit in pointing out the steps that may go into the design of an orthodontic appliance:

1. The orthodontist, as a designer, must make certain assumptions about the nature of forces and tooth movement. Objectives relative to tooth movement must be biologically sound, recognizing not only the tissue changes around the tooth but also the generalized growth changes in the face. The biological objectives of treatment must come first because without them appliance design has no basis.
2. A basic configuration must be selected, depending on the limitations of space in the oral cavity. The configuration should be determined partly by patient hygiene and comfort. Most important, the configuration must be capable of delivering the required force system, should have a desirable maximal elastic load and load-deflection rate, and must deliver the needed M/F ratio. The members should be analyzed so that stress distribution at critical sections does not result in failure.
3. After the general configuration has been established, its dimensions can be determined. Length is established consistent with patient comfort and oral hygiene.
4. When the dimensions of a component are known, the type of material or alloy from which it is to be made can be chosen.[87]
5. Finally, the cross section of the wire is determined.

This is not to suggest that appliances can always be designed by following the same logical sequence. The many variables in appliance design are related and cannot be separated. Furthermore, this list of steps is not meant to suggest that all that is needed in designing an appliance is a group of engineering formulas. Background in the physical sciences can help in the design of appliances, but appliance development still requires a certain amount of intuition, as well as clinical and laboratory experimentation. Basic science, rather than trial and error, offers the greatest possibilities in the development of the orthodontic appliances of the future.

This chapter has discussed the scientific basis of biomechanics and clinical orthodontics. It includes concepts and terminology that are common to physics and engineering. If orthodontists can speak the same language as the physical scientists, they have a better chance to integrate biology and physics as a true science of orthodontic biomechanics is developed.

Clinically Relevant Aspects of Dental Materials Science in Orthodontics

Theodore Eliades and Losif Sifakakis

OUTLINE

The application of dental materials science in orthodontics coincided with the use of gold and steel wire alloys by Edward. Angle, although the father of the specialty might not have imagined the impact that materials and technological advancements would have in current orthodontic practice. In the United States, the emphasis on mechanics received extraordinary attention, possibly because of the unique educational system and the requirement for a previously earned degree prior to applying to dental school. This prerequisite allowed for the cultivation and growth of materials research because dental graduates entering orthodontic programs were equipped with a bachelor's level of formal training in natural or engineering sciences, thus bringing a new perspective to traditional and empirically taught concepts of mechanics.

The emphasis of this chapter will be on the actual differences that material properties may have on mechanotherapy rather than typically reporting various properties of metallic and polymeric materials. Moreover, a new section will briefly summarize the materials science of fixed retention, assessing the evidence from the mechanics and properties of wires and composites used for the fabrication of fixed retainers.[1]

IMPACT OF APPLIANCE PROPERTIES ON MECHANICS

Stainless Steel Brackets

The following paragraphs will examine these parameters for brackets and analyze their importance in defining the performance of metallic, polymeric, and ceramic appliances (Table 6-1). For a more formal treatise of the subject the reader is referred to Brantley and Eliades' orthodontic materials textbook, where the atomic arrangement, bonding, and mechanical properties are analyzed.[2]

Stiffness

Stiffness reveals the resistance of the appliance to deformation (within the elastic range). High stiffness (or high modulus of elasticity) implies high resistance to deformation and as such is suitable for the areas where no deflection is preferred. These include the slot walls and wings, which should not be compliant to allow for efficient transmission of the loads applied by an activated archwire to the tooth. The reader would appreciate the importance of stiffness by considering the train/railway analogy: railway alloys receive a special surface treatment to gain high stiffness so that they are not deformed during the course of movement,

TABLE 6-1 The Role of Mechanical Properties in Treatment

Property	Effect on Mechanotherapy/Performance
Modulus of elasticity (*E*)	Low E allows for deformation at low forces, facilitating ease in deboning (peel-off effect) because of plastic deformation of base. High E provides resistance to deformation during engagement of archwires (especially torque) of wings and slot
Hardness	Structural integrity against the applied loads during engagement of wire into the brackets slot
Roughness	Full seating of wire into the slot, shielding against high forces arising from the decreased contact points between wire and slot surfaces

Adapted from Eliades T, Pandis N, eds. Self-Ligation in Orthodontics. London: Wiley-Blackwell; 2009.

BOX 6-1 The Role of Stiffness in Different Bracket Components

Various bracket components require different stiffness variants. Wings and slot should be of high stiffness, whereas the base should be compliant for different reasons: wings must withstand the loads applied without being deformed, whereas the base must furnish easy peel-off effect.

and no obstacles are presented to impede rolling of the wheels. To this end, ceramic brackets show higher stiffness as a result of the arrangement of atoms and bonding inside their structure, and for this reason they present better performance when it comes to transmission of loads, whereas plastic brackets, apart from their lower stiffness, which in most cases makes them unsuitable for this task, show several other disadvantages.[2] Loading rate and ambient temperature changes substantially alter the stress–strain characteristics of polymers.[2] In addition, when cyclic loading involves increased strain rates, a thermal softening effect may be induced, leading to a reduction in the fatigue life.[5]

Although high stiffness is preferred for some components of the brackets, for others, such as the base, this is an undesirable feature. For bases, a compliant or low-stiffness alloy is preferred because this bracket component is not an active part of treatment. Box 6-1 summarizes the role of stiffness on desired bracket characteristics, and Figure 6-1 depicts the variable hardness of bracket components.[6]

Roughness

Roughness may differentiate the force because of the effective contact between the wire and bracket. At the microscopic level, this contact is not continuous but possesses a profile of opposing peaks arising from the variation of surfaces between the two materials coming in contact. Figure 6-2 illustrates the roughness of slot surfaces. The implication of roughness in friction during sliding mechanics has been overestimated, and several research and review articles have demonstrated that the rougher wires did not consistently show the highest friction.[7]

Base-Wing Joint

The puzzle of combining both features (a stiff wing and compliant base) was solved with the application of welding or soldering of two different alloys.[8,9] Alloy soldering is used to join the two bracket components. Initially, stainless steel

The difference in the size of pyramids corresponds to the different alloys used for bracket manufacturing.

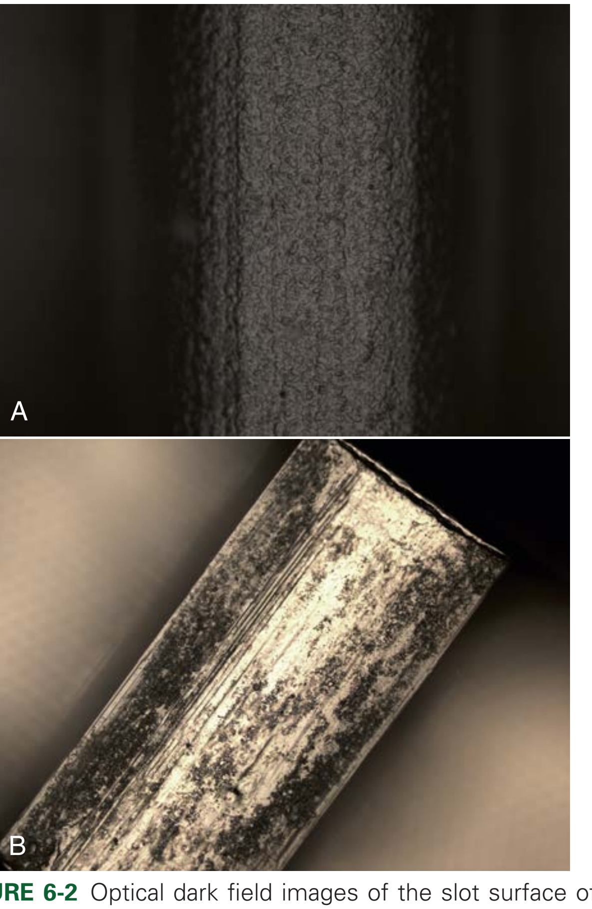

FIGURE 6-2 Optical dark field images of the slot surface of a ceramic (A) and stainless steel bracket (B) demonstrating the increased roughness of the surfaces (original magnification ×10).

BOX 6-2 Bracket-Wing Joints in Metallic Brackets

Base-wing joint is achieved with alloy (Ag, Ni, Au) soldering with potential problems with galvanic corrosion or ionic release, or laser welding with lack of soldering medium and absence of unfavorable effects. MIM brackets are one-piece appliances and show lack of galvanic corrosion, but have higher porosity and are made of one alloy type, which does satisfy the requirements for a stiffer wing component and compliant base.

brackets were brazed with silver (Ag)-based filler alloys, which are also the most frequently used brazing filler metals for stainless steel in industrial applications. However, orthodontic silver brazing alloys contain the cytotoxic element cadmium (Cd), which is added to lower the melting temperature and improve wetting.[10,11] Moreover, Ag-based brazing alloys introduce a galvanic couple with stainless steel alloys, inducing release of metallic ions with copper (Cu) and tin (Zn), the most easily leached out elements from Ag brazing alloys. Because brazing alloys that contain Cu and Zn are cytotoxic, galvanic corrosion, which is the main reason for the progressive dissolution of brazing filler metal,[12] may have both mechanical (detachment of the base-wing component) and biologic implications.[13-17]

To overcome this problem, several manufacturers have introduced gold-based brazing materials. However, this may lead to dissolution of stainless steel, which is less noble than the gold alloys, and this may be the explanation for the in vivo corrosion of bracket bases as well as for Ni leaching from stainless steel alloys.[18] Metal ion release[19] from brackets and orthodontic appliances in general is of great concern because of the adverse effects of allergic reactions or cytotoxicity.[20]

Brackets produced by MIM technology are actually single-piece appliances and thus supposedly free from the corrosion risk associated with the galvanic couple of brazing alloys with stainless steel. However, appliances manufactured with the MIM method have shown extended porosity.[8]

Last, laser welding has not been expanded, and a limited number of products are fabricated with this method. The main advantages of the method relate to the fact that although two alloys with different stiffnesses can be used, the absence of an intermediate phase and potential corrosion risk optimize the prospective performance of the final product. Box 6-2 summarizes the characteristics of base-wing joint.

Hardness

An increased hardness, as in the case with stiffness, is necessary to facilitate surface integrity and preclude binding of the wire onto the bracket slot walls. The latter may affect the force levels experienced by the tooth by increasing the friction variants, thus necessitating an increase in force to achieve tooth movement.[2,19] This is based on the significance of surface roughness on slot–archwire interfacial sliding during displacement of the bracket along the archwire.

The Vickers hardness number (VHN) of MIM-manufactured brackets has been found to vary between 154 and 287, which found much lower than the hardness (400 VHN) of wing components of conventional stainless steel. This difference may have significant effects on the wear phenomena encountered during the archwire activation into the bracket slot.[21] Stainless steel archwires demonstrate a hardness of 600 VHN while the hardness of NiTi archwires ranges from 300 to 430 VHN. The clinical significance of the hardness finding may pertain to the fact that low-hardness wing components may complicate the transfer of torque from an activated archwire to the bracket and may preclude full engagement of the wire to the slot wall and possible plastic deformation of the wing.[21-23]

BOX 6-3 The Overestimation of Actual Clinical Impact of Friction

In vitro assessment of friction includes many assumptions and oversimplifications such as horizontal pathway of wire into the slot; arbitrary movement rate; absence of aging of materials; lack of vibrational movements arising from mastication, which cancel out the frictional resistance; and measurement of an irrelevant component (force required to introduce sliding). Recent clinical trials testing brackets or wires with different fiction do not show difference in treatment duration.

Friction

Bracket–archwire friction has received wide attention during the past 15 years. A number of critical reviews have demonstrated the clinical irrelevance of the typical in vitro assessment of friction protocols presented in a large number of studies during the past decade.[24-29] Various factors related to the oversimplification of experimental configurations and an overwhelming number of assumptions in the experimental design have deprived ex vivo friction assessment from the clinical relevance and scientific soundness required to establish this issue as clinically vital. These briefly include the inappropriateness of the use of the terms *friction* and *sliding resistance* interchangeably, the clinically irrelevant choice of rate of wire sliding onto slot walls, lack of intraoral aging of materials, and study of variables, which possess little or no relevance with the actual clinical analogue.[29] A thorough analysis of the incoherence of the majority of friction research protocols is provided in the Brantley and Eliades orthodontics text.[3] Box 6-3 summarizes the factors that render conventional friction protocols methodologically incoherent and clinically irrelevant.

During the past 5 years, the results of a body of evidence on this issue derived from clinical trials suggest that the bracket–archwire free play may not be the most critical factor in altering tooth movement rate.[30-33] In general, the majority of clinical trials is not supportive of a faster tooth movement rate in "low-friction" brackets.[30-33]

The large clearance and presumed lower binding of a low-friction bracket–wire combination relative to a conventional one may be eliminated as archwires of larger cross sections are gradually inserted in the bracket slot. The clinician may empirically appreciate the free play with low-friction brackets, especially in cases of extreme tooth malalignment, where full engagement of a large-diameter NiTi wire to conventional brackets requires increased pressure. In this first stage, there is a definitive advantage of low-friction brackets relative to conventional appliances; this situation, however, changes dramatically as treatment progresses and wires of higher stiffness are engaged in the bracket. Completion of the correction of rotations and achievement of proper buccolingual crown inclination (torque), which are frequently required in the mandibular and maxillary incisors, respectively, necessitate the presence of a couple of forces. This assumes the formation of contacts of wire inside the bracket slot walls to generate force, and thus the major advantage of low-friction brackets, namely, the free play, is eliminated as tooth crowns gradually obtain their proper spatial orientation.[34]

Apart from the foregoing factors, in vitro studies dealing with this issue have shown that friction increases with increased roughness of the wire or bracket surfaces, although the opposite has also been suggested. Studies have indicated that beta-titanium and NiTi wires and ceramic brackets have shown increased friction due to their roughened surfaces arising from the manufacturing process. Nonetheless, Kusy and Whitley[28] have shown that although beta-Ti (titanium molybdenum alloy, or TMA) wires exhibited the highest coefficient of friction, the highest roughness was obtained from NiTi wires, with evidence of mass transfer from the beta-titanium wire to the stainless steel and polycrystalline alumina contact flats, attributed to the relatively low compressive yield strength of the beta-titanium wire alloy.

Moreover, frictional testing in most cases involves dry and relatively clean samples (i.e., wires and brackets), and therefore no biofilm or calcified regions are included.[35] The adsorption of these intraoral integuments might increase the surface roughness and resistance to shear forces. A prominent fluctuation of the curve of the frictional loss over the measured displacement of the bracket along the wire has been noted; this could be attributed to the complexes precipitated intraorally.

Material Properties and Torque

Proper buccolingual crown inclination is a key factor to achieving appropriate interincisal inclination and adjusting for minor discrepancy in arch length[36] and may concomitantly be critical in avoiding relapse of deep bite correction, especially in a typical Angle Class II, Division 2, case. A torque transfer of the activated archwire to a bracket assumes ideal materials, no torque loss due to slot design, accuracy of prescription with minimum deviation from actual and reported prescription values, and full expression of the prescribed value. Unfortunately, none of the foregoing assumptions is valid, and the reason is that we deal with real materials that possess various defects.[23]

Let us examine the sequence of events associated with the engagement of a rectangular wire into a bracket slot. First, the edges of the wire will have to be twisted to come in contact with the slot walls, to an extent determined by the size of the slot and the cross section of the wire. The rotation of the wire into the slot prior to contact with the bracket is expressed as *torque loss*, alternatively termed *free play*, *clearance*, or *slack*. The value of this loss has been found to show a difference between theoretic estimation and experimentally derived values, with higher loss occurring in measurements. The source of this discrepancy may be attributed to the rounded edges of the bracket and slot, as well as the tolerance in size; that is, the slot is slightly larger than described and the wire smaller than defined by the manufacturer. The magnitude of this slack is on the order of 10 degrees for a 0.016- × 0.022-inch archwire engaged into an 0.018-inch slot,[37] thereby eliminating the torque transferred to the a maxillary central incisor with a Roth prescription appliance, leading to undertorqued anteriors. As the wire is brought in contact with the slot walls, there is a tendency for the former to be pushed out of the slot because the stresses developed tend to displace it labially. Thus, a second factor—namely, the efficiency of ligating medium—comes into play. Elastomeric ligatures are a poor means to secure the wire in place because of the relaxation they present, which reaches high values within the first 24 hours.[38] For this reason, stainless steel ligatures are suggested to increase friction, which in this case is desirable, because otherwise there will be no adequate inclination change.

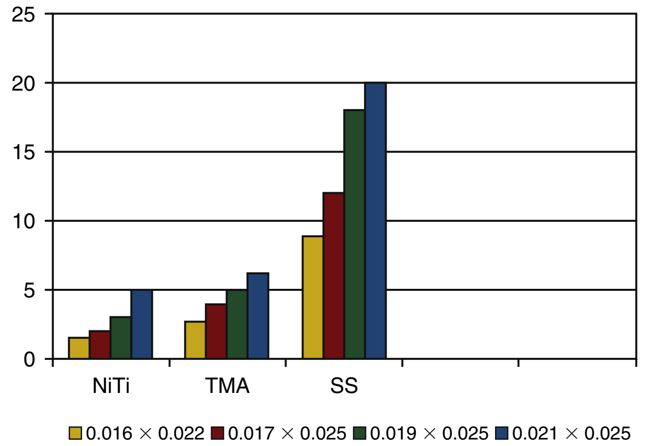

FIGURE 6-3 Graph depicting the relative torsional stiffness of wires of various cross sections and compositions demonstrating that increasing the size of the wire does not secure more effectiveness in torquing crowns. (Compiled from data presented by Kusy RP. On the use of nomograms to determine the elastic property ratios of orthodontic arch wires. *Am J Orthod.* 1983;83:374–381.)

Having eliminated the foregoing variables on slack, the next step is the application of stress of wire onto the slot wall surfaces. As the wire applies a force to the bracket, the wire or the bracket will experience a surface alteration, which will be determined by the difference in hardness. The harder material will leave an imprint in the softer material, and in most cases that is the stainless steel on NiTi and TMA wires and stainless steel wire in Ti or plastic brackets. Also, TMA wires will leave traces of material in ceramic brackets. The resultant wear will presumably take out some of the activation of the wire, further decreasing the potential for torquing the crown of the tooth.

When the residual activation finally outweighs all the above-mentioned obstacles, the torsional stiffness of the materials may modulate the torque expression.[39,40] Kusy[41] very effectively described this relationship with the construction of nomograms, where the relative stiffness in torsion of various sizes of archwires is provided in a scale. Figure 6-3 depicts the relative torsional stiffness of various alloys of different cross sections.

Thus, although a 0.017- × 0.025-inch NiTi archwire in a 0.018-inch slot will result in decreased play compared with a 0.016- × 0.022-inch archwire in the same slot, its torsional stiffness is much lower than the latter. This reveals that a larger cross section is not the critical factor in determining torque efficiency. The emphasis placed on the size of wire as an indication of its stiffness derives from the fallacy that a larger wire will always express the slot prescription more efficiently than one of a smaller cross section. This concept has its roots in the time when orthodontists were able to increase the stiffness of the wire only by incrementally increasing its size. With new alloys with different moduli, it is the combination of size and modulus that determines the stiffness of the wire, not the size alone.[42] Box 6-4 recapitulates the requirements for effective torque transmission with the straight wire technique.

BOX 6-4 Factors Affecting Efficient Torque Expression with the Straightwire Technique

Torquing with the Straightwire technique requires large cross-section stainless steel wires or NiTi wires with a pretorque of almost 40° of activation; stiff wings and wires; hard wing and wire surfaces; and an inelastic ligating medium, with minimum relaxation with time.

BOX 6-5 Clinical Factors with Titanium Brackets

The reduced hardness of titanium brackets imposes several unfavorable implications in sliding and torquing with harder alloys such as stainless steel wires, and thus their use should be limited to cases of proven allergic reaction to nickel.

Titanium Brackets

The introduction of Ti brackets was based on the biocompatibility and lack of allergenic elements, such as Ni, in these appliances. The results of the limited available evidence on Ti brackets indicated that there are substantial structural differences in composition, structure, and manufacturing processes among currently available Ti brackets. These have been found to be single-piece appliances or two separate parts joined together by laser welding, composed of Ti, with a Vickers hardness close to grade II commercially pure (cp) Ti or of a Ti alloy type (Ti-6Al-4V).[43]

These brackets present differences in hardness, which, in general, is much lower than the stainless steel and NiTi archwire alloys. This may induce increased wear rate during orthodontic treatment. It is well known that pure Ti and its alloys have poor wear resistance and require surface modification treatments before being used for biological applications. The use of Ti-6Al-4V alloy with a friction coefficient of 0.28 may have different frictional coefficients from the values available in literature because the latter have been calculated for the cp Ti friction coefficient of 0.34. Box 6-5 notes the clinical implications of reduced hardness of Ti brackets.

The clinical significance of the hardness findings may pertain to the fact that a low-hardness wing component may complicate the transfer of torque from an activated archwire to bracket. The low-hardness–induced wear may preclude a full engagement of the wire to the slot walls and possible plastic deformation of the wing. Thus, whereas Ti brackets may be a viable alternative in the rare cases of proven allergic reaction to Ni-containing products, their reduced hardness may be implicated in wire binding in the slot during mechanotherapy.

Ceramic Brackets

Ceramic brackets were introduced for superior aesthetics, but there are several issues that arose from their large-scale use. Most of the research efforts on this topic were focused on their fracture strength and deboning characteristics, following an unfavorable deboning pattern reported during the early 1990s.

The observation that ceramic brackets fracture frequently, usually at the wings and most often during deboning, is a universal, empirically derived knowledge for most readers. But why do these wires fracture clinically at rates much higher than the ones based on laboratory tests?

Brittleness and Fracture

We shall first provide substantiation for the brittleness of ceramics. These materials are composed of atoms bound together with such strong forces that their flexibility is notably impaired. As a result, the application of a force on ceramics leads only to a minimum elastic deformation with absence of permanent deformation. It follows that these materials maintain their dimensions and shape after fracture because no deformation has set in: this is why broken pieces of china can be glued together. In contrast to this effect, metals and polymers can absorb some of the energy provided during load application by altering their shape or dimensions, thus presenting ductile fracture. The bonding energy and their strong directional characteristics are what make these materials unable to deform. Also, the atomic packing factor in these materials is high, implying that a dense distribution of atoms in a three-dimensional array results in a high crystal density. Therefore, no plastic deformation of the wings is possible, and when the force exceeds a certain value, the wing fractures.

Nonetheless, the foregoing discussion fails to explain the observed higher rate of ceramic fractures clinically compared with that expected from laboratory studies, where ceramic brackets seem to pass the tests. Figure 6-4 illustrates a fractured ceramic bracket.

The mechanism underlying this effect was proposed by Sir Griffith in the early 1920s, when he provided substantiation to the noted deviation of the theoretical strength of ceramics from experimentally estimated strength.[5] Ceramic brackets, like most brittle ceramics, include manufacturing process–induced defects in the form of voids or microcracks, which are most visible in everyday utensils, when glassware subjected to many cycles of dishwashing is examined under bright light. Factors that predispose to crack growth and fracture include manufacturer-controlled and operator-dependent variables; the former relates to the design of the bracket with the presence of many sharp edges and corners enhancing this phenomenon acting as stress raisers, whereas the latter relates to the accidental contact with instruments or burs, which initiate crack growth and propagation.

Ceramics in Wet Environments

Apart from the foregoing discussion, the exposure of ceramics or brittle materials to wet environments may further contribute to the reduction in strength. Assuming a brittle material, the critical stress (σ_{crit}) to induce fracture in a material with crack of size c can be expressed as

$$\sigma_{crit} = (2E\gamma/\pi c)^{1/2}$$

where E is the modulus of elasticity and γ is the critical surface tension of the brittle ceramic.

When this material is exposed to a wet medium (i.e., water or saliva), the previous equation of the critical stress is altered because the critical surface tension (γ) of the material is the only variable that is altered; actually, it is reduced. Because γ is on the numerator, it follows that a reduction in γ will result in a lower value for the whole term, and thus the new critical stress would be decreased relative to one corresponding to the dry state. That means that when the ceramic brackets come into contact with water, their fracture strength is decreased.

Experimental work published in the field has verified this proposal, demonstrating that alumina (aluminum oxide) and zirconia (zirconium oxide) show decreased fracture toughness, faster

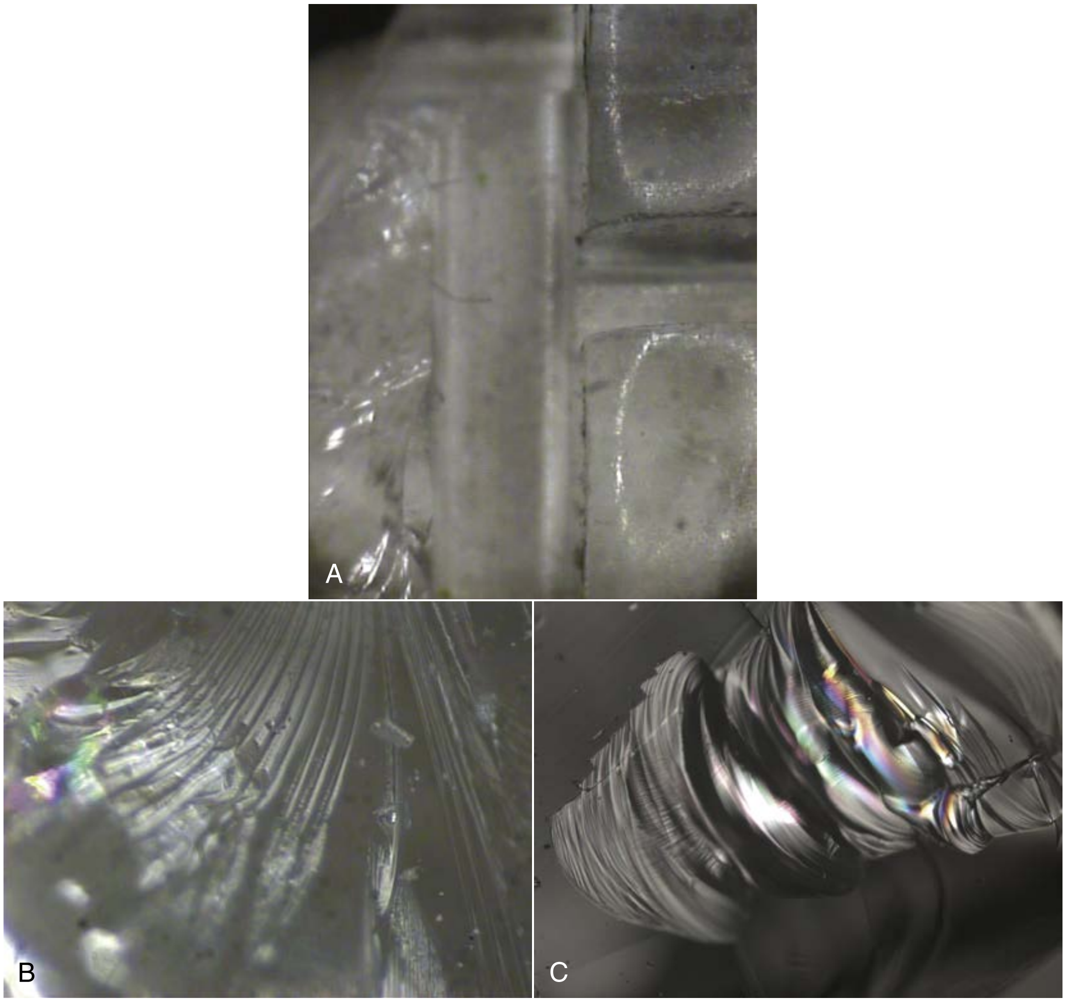

FIGURE 6-4 Optical light transmission image of a ceramic bracket showing a fractured wing (**A**). The radial pattern corresponds to the fracture plane (**B**). (**C**), Under a dark field mode, the dramatic surface effects in **B** are shown.

crack growth rate, and reduced bending strength when they are exposed to water, normal saline, or Ringer's solution.[4] The presence of electrolytes, enzymes, flora, and other factors may further increase the detrimental impact of aging on strength.

Effect of Grain Size

The different behavior of polycrystalline ceramic brackets compared with the single-crystal appliances to crack growth is attributed to the fact that the crack is impeded at the grains' boundaries of the former, where cracks propagate easier in the latter. It is interesting to note that the same reason for the superb aesthetics of single-crystal brackets arising from their high light transmittance, associated with a reduced light scattering due to the lack of grain boundaries, is also responsible for their reduced fracture toughness. Accordingly, the size of grains may also play a role in determining fracture properties of ceramics: the ones possessing small grain size tend to favor the initiation of cracking because the increased packing capacity of grain boundaries allows for the initiation of the crack in the periphery of force application.[5] On the contrary, large-grained ceramics show a higher resistance to crack initiation because the presence of crystals at the front of crack initiation does not favor crack formation. When the crack is initiated, there are fewer boundaries to inhibit its propagation and thus their fracture toughness is lower than that of their small-grain counterparts.

ARCHWIRES

Clinical Impact of NiTi Archwire Properties

The materials chapter in the 5th edition of this book clarified the concept of phase transformation of superelastic NiTi wires. In the current edition, this section will deal with the actual impact of these crystallographic changes on orthodontics. NiTi archwires have become an integral part of orthodontic treatment because their low load-to-deflection ratio provides a desirable force level and better control of force magnitude.[42] Their initial classification included three categories: superelastic, nonsuperelastic, and true shape memory. This classification was confusing with respect to the meaning of the terms, and as a result, an alternative, structure-based classification was proposed by Kusy as (1) martensitic stabilized, which shows a stable martensitic structure, and thus no shape memory or superelasticity is expressed; (2) martensitic active, also termed thermoactive, in which an increase in the temperature leads to the transformation of the martensitic back to the austenitic structure;

and (3) austenitic active, which demonstrates a pseudo-elastic behavior, where the martensitic structure transformation of these alloys is stress induced, resulting from the activation of the wire. The words *martensite* and *austenite* are named after two prominent metallurgists, Adolf Martens and Sir William Chandler Roberts-Austen, respectively.

The majority of studies investigating the mechanical properties and structural conformation of NiTi wires has used three main routes to elucidate certain aspects of the wire structure and performance.[44-48] The most commonly used method consists of deflection curves, or cantilever testing of segments of archwires under various loading patterns. A problem with this method may be that superelasticity is, by definition, a property referring to the crystallographic structural elements of the material, and depending on the mechanical test, the response of the wires to loading may differ. Also, it is possible that nominally identical curve patterns are derived from different crystallographic structures.

On the other hand, X-ray diffraction studies of archwires are limited by the inherently near-surface nature of this technique, which shows a 50-micron penetration depth, thus providing evidence for the surface layers of the material. Alternatively, differential scanning calorimetry (DSC), which in principle determines the enthalpy for structural transformations, can provide information about the bulk material.[48]

Apart from the limitations on the analytical tools used in relevant research, there is some skepticism over the fact that the actual clinical performance of these wires in the intraoral environment has not been studied to the same extent as their mechanical properties.[49] Studies assessing the rate of tooth movement during treatment using different archwire alloys showed no significant differences among superelastic, nonsuperelastic NiTi wires, and multistranded stainless steel wires.[50]

Superelastic and Nonsuperelastic NiTi in Crowding Alleviation

A recent, randomized, controlled clinical trial has reported no difference in the duration of alignment CuNiTi thermoactive archwires and NiTi wires.[34] This finding, which verified previous clinical research, was attributed to two potential factors: an alteration of transformation temperature ranges occurred in vivo, limiting the transformation of NiTi archwires, or the overall irrelevance of laboratory-derived mechanical behavior of wires to the loading conditions under clinical conditions.

The first hypothesis uses the effect of oral cavity conditions as a key variable affecting the clinical performance of wires. The effect of intraoral conditions on transformation of CuNiTi wires derives from a single study, which assessed the DSC parameters of intraorally exposed and as-received wires.[51] This investigation reported no difference between as-received and clinically retrieved wires in key variables related to phase transformation, except for a significant reduction in heating enthalpy associated with the martensite-to-austenite transition in the 27°C CuNiTi archwires. Therefore, the lack of difference between NiTi and CuNiTi specimens cannot be assigned to intraorally induced changes in the phase transformation pattern of the latter. The temperature sensitivity of superelastic NiTi wires indicates that variations in mouth temperature could cause a stress fluctuation in NiTi wires during orthodontic treatment.[45]

BOX 6-6 Effect of NiTi Structure on Clinical Parameters

The finding that no difference exists between CuNiTi and NiTi with respect to the duration of treatment implies that the loading pattern of wire inside the slot does not allow for expression of superelastic properties either because of aging or free play. It seems that crystallographic structure of materials possesses little importance in clinical outcome.

An alternative hypothesis pertains to the differences of loading conditions between the laboratory conditions and the oral cavity.[37] Such a pattern cannot be simulated in laboratory configurations and may differentiate the performance of the material. This effect, along with the unrealistic force variants at which plateau levels are reached in the stress–strain curve of NiTi wires, may preclude the expression of the full spectrum of properties of NiTi archwires. Box 6-6 summarizes the reason for absence of clinical effects from crystallographically different NiTi wires.

The foregoing considerations, coupled with the complexity of the oral environment, might explain the results of a study[50] on the effect of using archwires of different surfaces on the rate of space closure with sliding mechanics in vivo. Results from this investigation suggested that there was no difference with respect to the time required for space closure in vivo between conventional and ion-implanted beta-Ti wires.

PHOTOCURING AND ADHESIVES

Photocuring

Photocuring in orthodontic bonding has received wide acceptance because of the favorable characteristics of this technique, which include both material and handling advantages. Light-cured adhesives show decreased oxygen inhibition of polymerization, shorter polymerization reaction, and extended working time, which allows for extended handling in the positioning of bracket, thus being ideal for educational purposes.[52]

The development of various types of light sources for use in polymerization has resulted in a multiplicity of factors taking an active role in the polymerization kinetics of the polymeric material.

Light Intensity

When a light beam hits an orthodontic adhesive surface, the extent of light penetration into the relatively thin layer of material depends on the distance of the source from the material surface and the path that the incident beam will have to travel to reach the adhesive.[53]

Likewise, the literature shows a wide array of studies from the field of restorative dentistry dealing with the effect of material composition on the light penetration and degree of cure. In general, the translucency of the composite, which allows for the penetration of light away from the light source, increases with an increasing matching of the refractive indices of the matrix and fillers. Matrix includes the co-monomer system of bis-GMA/TEGDMA mixture, which is used to facilitate the combined favorable features of both monomers, along with several other organic constituents such as polymerization inhibitors, initiators, colorants, etc.[54,55] The choice of these specific monomers is due to the increased molecular weight of bis-GMA, which offers stability and a thicker consistency, and the short-chained

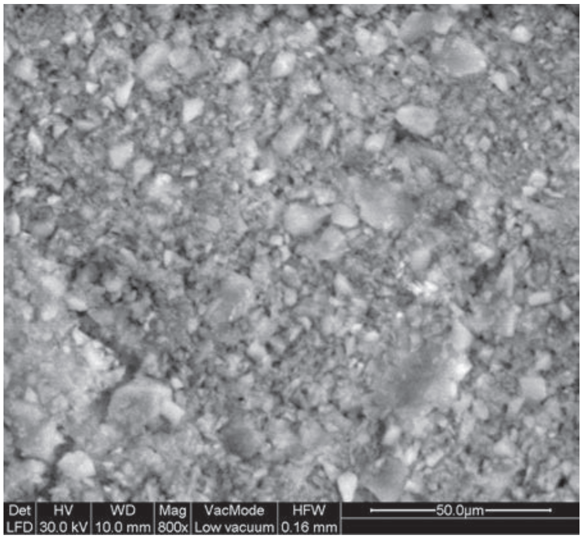

FIGURE 6-5 Secondary electron image of a ground light-cured orthodontic adhesive depicting the variability in filler size (original magnification ×800).

TEGDMA, which contributes to the larger degree of cure because of its decreased molecular weight and higher mobility. Varying the proportion of these constituents, as well as other materials such as amines, accelerators, inhibitors, and initiators, may slightly affect the refractive index of the matrix, which in methacrylate resins is about 1.5.[54]

Fillers, on the other hand, which are contained in the adhesive in a ratio of 60% to 70% per weight in the form of silica particles and barium glasses, possess an index of 1.55 at the wavelength of the photoinitiator.[56] Figure 6-5 depicts the variability in filler size of an adhesive.

The evidence available in the field of composite resins suggests that maximum light scattering occurs at particle size equivalent of the half of the wavelength of a photoinitiator of the polymerization, which for camphorquinone is 468 nm. Almost all the light-cured adhesives use camphorquinone as a photoinitiator of the polymerization. This molecule is contained in the resinous phase at a concentration of 0.2% to 1% of the matrix and shows a peak absorbance wavelength of 468 nm, which implies that increased light intensity in other frequencies may not be effective to excite the molecule.[54] This is an important factor that must be considered in the selection of lamps based on the peak intensity reported by the manufacturer; it is critical that this peak should correspond to the absorbance wavelength of the photoinitiator. Because of its yellowish tint and resultant undesirable matching in uncured versus cured materials, camphorquinone has been recently replaced in some composite resins by 1-phenyl-1,2-propanedione (PPD) with a peak absorbance in the area of 390 to 410 nm.[57]

Lamps

Light-cured orthodontic adhesives require a light-curing source with sufficient intensity and defined wavelength to initiate the polymerization reaction. Increased light intensity and curing time have been advocated for fast polymerization and high degree of cure.[58,59] Recently, various types of commercially available light-curing units have shown comparable bond strength values to those produced by conventional halogen lights at shorter irradiation times.[60] The wide array of new light-curing sources includes plasma arc, laser, and LED lights, which were integrated in the profession to facilitate short irradiation times.

Plasma lamps present very high intensity compared to halogen lights (1600 to 2100 mW/cm^2), an effective spectrum of 450 to 500 nm, and a significantly higher cost, which nevertheless is counterweighed by their increased life span of 5000 hours relative to 40 to 100 hours for halogen. Orthodontic bonding with these light sources can be achieved with only 6 seconds of irradiation for stainless steel brackets or 3 seconds for ceramic brackets.[61]

Laser lights show an intensity of 700 to 1000 mW/cm^2, with a basically monochromatic spectrum of variable wavelength (454, 458, 466, 472, 477, 488, and 497 nm) and are costly but have an almost infinite life span. Application of these light sources to orthodontic bonding has shown that 5 seconds of irradiation provided bond strength values comparable to those found for halogen.[62]

Light-emitting diode (LED) curing units yield a maximum intensity of 1100 mW/cm^2 at a spectrum of 420 to 600 nm, have a cost comparable to that of conventional halogen lights, and possess a nearly infinite life span, while offering handling advantages with a cordless photocuring option. The results of bond strength studies show contradictory evidence on the performance of these lights, with most investigations demonstrating comparable bond strength to halogen lights at the same irradiation duration and reduced strength when shorter time frames are applied.[59,63-65] Conventional bond strength protocols have not been proved to be clinically relevant,[66] and therefore, care should be exercised in extrapolating laboratory results to a clinical situation.

Biological Properties of Blue Light and Adhesives

Apart from standard cytotoxicity assays reported in the literature, the use of high-intensity curing lamps and polymeric molecules has given rise to the investigation of potentially unfavorable effects relevant to orthodontic treatment, which could be proved hazardous to the patients and treatment provider. These include the effect of blue light on mucosa, the action of ground adhesive particulates at deboning as aerosol, and the examination of the role of bis-GMA–based adhesive resins as endocrine disruptors.

Blue Light Effects

Although initially blue light was characterized as relatively harmless, more recent studies have shown that it affects several aspects of cell physiology. Particularly, it has been reported that it disturbs mitochondrial function, thus causing an oxidative stress leading to activation of the stress-responsive pathways.[67] The group of investigations cited earlier suggested that blue light induces effects on the DNA integrity, cellular mitosis, and mitochondrial status in various cell types through the generation of reactive oxygen species (ROS). Investigations in the field have used a variety of mouse and human, normal and transformed cell types, as well as a vast array of assays, which extended from assessment of cell vitality to markers of cell metabolism and oxidative status. This multiplicity of testing protocols has resulted in a variety of effects described.

The result of the sole investigation adopting the time exposures seen in an orthodontic routine bonding[67] has shown that blue light did not affect the viability of these cells, and no immediate effect on the regulation of proliferation was noted 24 hours after irradiation. One week after treatment, however,

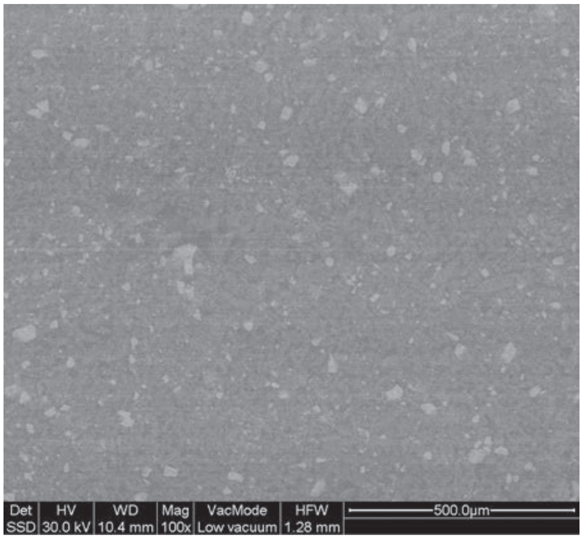

FIGURE 6-6 Backscattered electron image of the particulates of a chemically cured adhesive produced by grinding as occurred during deboning (original magnification ×100).

all types of irradiation induced a significant inhibition of cell proliferation compared with untreated cultures.

The source of this effect has been the subject of several investigations, which have reported that exposure to blue light leads to the generation of ROS, proposing that these are responsible for the adverse biological effects of blue light. However, in a study using a simulation of photocuring in orthodontics,[67] the use of a potent antioxidant agent did not annul the inhibitory effect of irradiation on cell proliferation.

In summary, there is evidence that the biological effects of blue light are confined to long-term effects and are not mediated by oxidation mechanism or DNA damage. The array of effects described suggests that high energy sources such as plasma lamps should be used with caution, especially when bonding mandibular tubes where a close contact between the tissue and the lamp tip occurs.

Grinding of Adhesives: Production of Aerosol and Estrogenic Action

A recent review on the subject has presented the potential action of orthodontic adhesives as endocrinologic disruptors and summarized the available evidence.[52] A substantial body of literature has demonstrated the cohort of phenomena accompanying the exposure of organisms to bisphenol-A (BPA).[68-71] Moreover, the effects of BPA on tissues follow a nonmonotonic curve pattern, which is characterized by intense reactivity at low levels and no response at very high ones, respectively.[71] The concept of "critical concentration," referring to the required amount of substance to induce effects, may not apply in the case of exposure to BPA.[71,72]

In orthodontics, the removal of the brackets and cleanup of the enamel surface that follow the completion of orthodontic treatment involve grinding of the adhesive layer with rotary instruments at low or high speed. The aerosol produced by this process contains polymer matrix and filler degradation by-products as well as particulates arising from the wear of bur. Figure 6-6 illustrates the morphologic condition of particulates produced after the use of rotary instruments on an adhesive. The potential hazardous nature of aerosol is twofold: first, it relates to the production and circulation of a dust with a sufficiently small aerodynamic diameter to reach the alveoli of the lungs.[73-75] Second, there is a potential hormone-disrupting action of these particles derived from the presence of a double benzoic ring in the bis-GMA monomer, which, under specific conditions, has been reported to lead to the formation and release of BPA.[76-78] Although bulk, intact orthodontic adhesive specimens have not demonstrated BPA release or estrogenic action,[79,80] the biological properties of particulates examined with a standard in vitro assay[81,82] have shown opposite effects.[78] Grinding, especially without water spray, increases the temperature locally, with unpredictable effects on the composition and formation of resin by-products, while, concurrently, this process dramatically increases the effective surface area of the material with host tissues, enhancing the reactivity of the material, with potentially altered outcome on the tissue–material interactions. In the broader biomedical literature, the difference between the biological properties of bulk materials and their particulates has been established for inert alloys such as Ti.[82] Box 6-7 notes the potentially estrogenic action of adhesive in a particulate form.

BOX 6-7 Estrogenic Action of Adhesives

Grinding of the adhesive at deboning results in a twofold hazardous sequla: generation of particles, which act as an aerosol with detrimental action on the respiratory system, and potential estrogenicity, owing to the incorporation of Bis-GMA monomer, which gives rise to bisphenol-A formulation with xeno-estrogenic properties. It is interesting to note that no release of bisphenol-A and no estrogenicity have been reported for chemically cured and light-cured adhesives when they are not ground.

Grinding of the adhesive introduces heat into the material, exposing the matrix to severe heat shock and mechanical aging. It has been long known that grinding and polishing increase the C—C bond conversion to C═C on the surfaces of resin composites mainly due to the heat produced. The chemical alterations induced in the abraded powder compounds possessing double benzoyl rings, including bis-GMA, are unknown. It may be hypothesized that this procedure may accelerate or induce formation of BPA, with endocrinologic disruption as an outcome.

This finding is of interest considering that receptors for estrogen have been identified in human gingival tissues, and thus this tissue can be a target organ for sex hormones.[83,84] It has been reported that the oral mucosa of premenopausal women was significantly more sensitive to sodium lauryl sulfate in toothpastes than that of postmenopausal women.[85] This might indicate a sex hormone influence on the oral epithelium reactivity to chemical challenge.

Because a given day in practice may include several appointments involving removal of bonded orthodontic appliances, the treatment provider, patients, and staff are exposed to substantial amounts of adhesive aerosol on an almost daily basis. Care should be taken to apply preventive measures such as mask and protective glasses, access to fresh air, and use of suction.

MATERIALS FOR FIXED RETAINERS

Fixed retention is used widely after orthodontic treatment in order to prevent the relapse of the malocclusion in cases with higher relapse tendency. Since their first use 40 years ago, various indications were suggested.[86,87] Unfortunately, definite

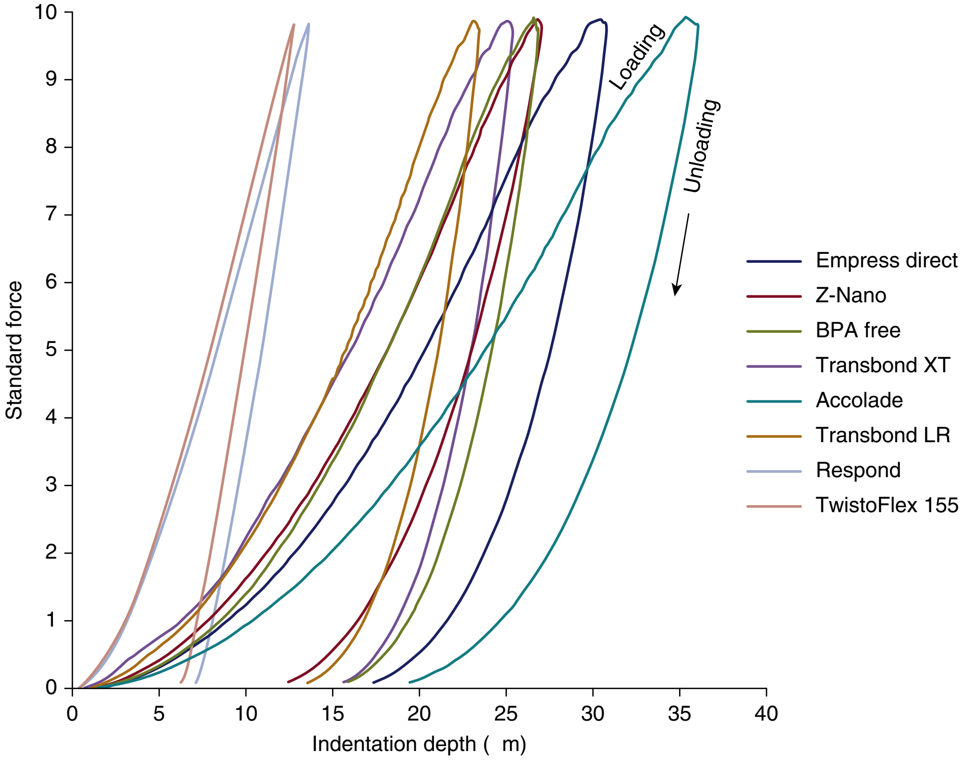

FIGURE 6-7 Force indentation depth loading–unloading curves for various materials used for fixed retainers alongside some dental restorative composites for purposes of comparison.

retention protocols are still unavailable, and the extent of their use is largely based on the experience or the beliefs of the orthodontist. Nowadays, stainless steel archwires are preferred, in the form of either a light round multistrand archwire bonded on all or only four anterior teeth or a heavy round solid wire bonded only on the canines (canine-and-canine). Several less common alternatives have been described in the recent orthodontic literature, regarding the design or the preferable material.[88]

Properties of Wires and Composite Resins Used for Fixed Retainers

It's rather difficult to make a safe assumption about the biomechanical performance of a fixed retainer, since it's influenced by a variety of factors, such as the physical and mechanical properties of the wire or the composite, the tooth dimensions, and the properties of the periodontal ligament. Moreover, the effect of aging on the properties of the retainer should not be underestimated.[7,89-91] Figure 6-7 illustrates the force indentation depth loading–unloading curves for some materials used for fixed retainers along with some dental restorative composites for comparison purposes.

Wires

Stiffness is a measure of resistance to deformation mainly in bending and is dependent on the modulus of elasticity. Stiffness in torsion of the retainer wire is important too since the main movement in the unexpected posttreatment changes observed long term after debonding[92,93] is the labiolingual rotation of the tooth (Fig. 6-8). Stiffness tells how much force will be applied for a certain deflection of the retainer wire and is the same for wires of the same alloy, regardless of their hardness. Size is the most potent variable for controlling stiffness of fixed retainers,[94] and for multistrand archwires the stiffness is influenced also by the composition and the

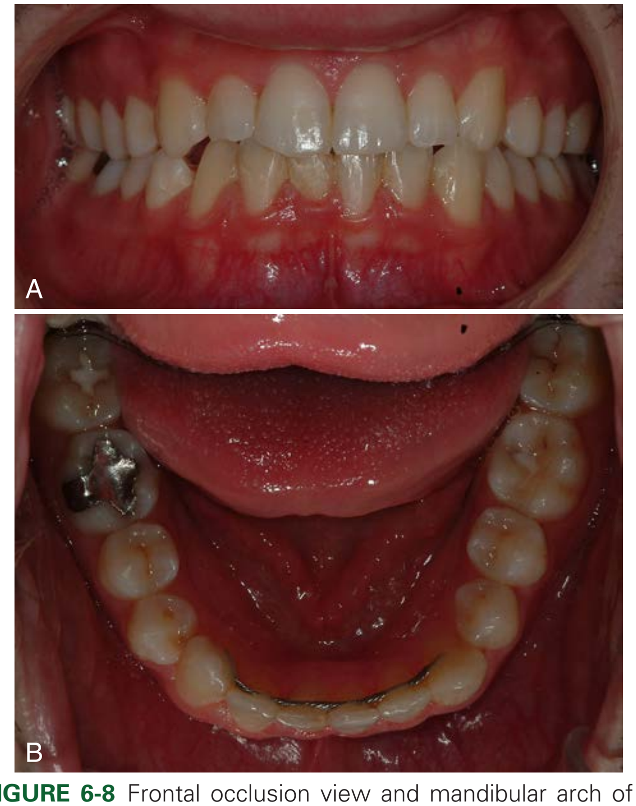

FIGURE 6-8 Frontal occlusion view and mandibular arch of a patient 5 years after deboning. Unexpected labiolingual rotation of both canines was observed in the direction of straightening/untwisting of the multistrand fixed retainer (7-strand 0.027-inch steel), which was still bonded on all anterior teeth. Deformation of the wire is clinically visible, at least between the left lateral incisor and canine.

number of the strands.[95] For a given length of a multistrand archwire, stiffness is reduced by increasing the length of the strands, in comparison with a solid archwire or a multistrand archwire with a lower pitch. However, the tight twisting of the strands increases the stiffness so finally the twisted archwires offer essentially the same stiffness as multiple straight strands but lower stiffness as a solid archwire.[96,97] The forces recorded in vitro on a canine or lateral incisor bonded on various types of lingual canine-to-canine fixed retainer wires might exceed 1 N and are large enough to produce unwanted tooth movement during retention.[98]

In conventional stainless steel wires, range decreases with increasing wire thickness, but in multistrand wires this property is not influenced to the same extent as in solid wires by the cross-section size and appears to be nearly constant for a particular wire configuration.[96] For a given overall wire diameter and helix angle, the ranges of multistranded wires were independent of wire configurations.[99] The increased length of the strands for a given length of an archwire increases its range, in comparison with a solid archwire or a multistrand archwire with a lower pitch.[96,97] The strength of round wires in bending and torsion is proportional to the cube of the wire diameter, but range is inversely related to the diameter. In bending, strength is inversely proportional to the length, but strength in torsion is not dependent on length.[94]

Heat treatment of stainless steel archwires increases the malleability of the wire while improving its properties by relieving the stresses retained from archwire formation into an arch, loops, or coils.[94,96,97] Heating of austenitic stainless steel wires above 650°C should not be done because loss of the wrought microstructure causes degradation of mechanical properties.[100] However, in these archwires, the desirable ease of formation becomes undesirable ease of deformation.[94,101] In the cases of unexpected post-treatment changes observed long term after deboning, a 3-strand 0.0195-inch, heat-treated stainless steel fixed retainer was still in place.[92,93] Clinical observations expand the incidence of these movements in several cases of 7-strand 0.027-inch steel canine-to-canine retainers, still bonded on all lower anterior teeth. This type of loading approximated the vertical incisor bite force during mastication, in a similar way as anterior biting. The results demonstrated residual forces and moments in all retainer types tested, of the highest magnitude in cases of the above-mentioned softer archwires. These findings suggest that the evaluated lower canine-to-canine fixed retainers may not be passive after short- or long-term use, especially these high formable/low yield strength retainers. Archwires with higher bending and torsional stiffness may be more suitable for the construction of fixed retainers.

Regarding the failure rates of the fixed retainers, the heavy canine-and-canine wire displayed a lower detachment rate in comparison with thinner, flexible spiral wire canine-to-canine retainers; however, the former type induced frequent relapse of incisors not bonded to the retainer.[102,103] Box 6-8 summarizes the main points regarding the archwires used for the construction of fixed retainers.

BOX 6-8 Wires Used for Fixed Retention

Most common types of fixed retainers are the light round multistrand steel archwire bonded on all anterior teeth and the heavy round solid steel wire bonded only on the canines. The latter displays lower detachment rate, but the former type induces frequent relapse of incisors not bonded to the retainer. In order to avoid the unexpected movements of teeth bonded on fixed retainers, archwires with higher bending and torsional stiffness may be more suitable for the construction of fixed retainers.

BOX 6-9 Adhesives Used for Fixed Retention

The adhesive resins indicated for lingual retainers should be hard and inelastic with high abrasion resistance and bond strength. An optimal degree of conversion and minimal polymerization shrinkage are extremely important in order to ensure minimal solubility and microleakage and decrease the levels of residual monomers.

SUMMARY

This chapter analyzed selective aspects of orthodontic materials with direct implications in mechanics, treatment duration and hazardous nature of materials, and applications to patient and care provider. In the last section, the advantages and disadvantages of the materials used for the construction of fixed retainers are discussed. Archwires with higher bending and torsional stiffness may be more suitable for the construction of fixed retainers. It is advisable to use adhesives with high hardness, especially designed for fixed retainers (Box 6-9).

The Role of Evidence in Orthodontics

David L. Turpin and Greg Huang

OUTLINE

INTRODUCTION

The field of orthodontics has the distinction of being the first recognized specialty in dentistry, and we should all be proud of our profession's history, which is older than 100 years. With our designation as a specialty, we also inherited some responsibilities—one being to lead in the acquisition, evaluation, and dissemination of scientific knowledge. We have accepted this challenge from the beginning, but the mechanisms by which we acquire, assess, and transfer knowledge have changed considerably over the past century. In this chapter, we describe the evolution to evidence-based orthodontics and why we should all utilize this approach in providing care to our patients.

Edward Angle, the father of modern orthodontics, was constantly trying to improve his craft, and certainly, he should be credited with the development of many important orthodontic ideas and principles, some of which we still utilize. His schools on both coasts of the United States have influenced orthodontists not only in North America but also in Europe, Asia, and Australia. His textbooks are still on the reading lists at many orthodontic programs. In the late nineteenth and early twentieth centuries, he was "the man," and as "the man," Dr. Angle exemplified the "Age of the Expert." Few dared to question Dr. Angle's approach to orthodontics, and when this happened, it sometimes led to bitter debates.

Upon Dr. Angle's death in 1930, no one stepped forward to continue his school of "orthodontia."[1] Instead, the responsibility for educating future orthodontists shifted to dental schools, and we entered the "Age of Education." Medicine and dentistry became professions associated with university settings, and standards were developed to insure educational uniformity nationwide. This model certainly has many advantages, and has become the accepted mechanism for training health care providers all over the world.

With the beginning of World War II, scientific innovation flourished. Entire countries underwent tremendous advances and development in response to challenging new conditions. Scientists developed new medications, surgical techniques, sources of energy, etc., and we entered the "Age of Science." The scientific method was embraced to answer our health care questions, and orthodontists were busy conducting studies to improve our understanding of diagnosis and treatment planning. There was much to be learned, and orthodontics was as productive as any field of dentistry. However, much of our research was conducted without rigorous guidelines, and upon reflection, suffered from various types of problems that accompany retrospective or observational studies.

As we entered the latter part of the twentieth century, a shift occurred in medicine. New methods were being proposed to conduct, analyze, and synthesize clinical research. Archie Cochrane and David Sackett, two physicians who both had formal training in epidemiology, were bothered greatly that medicine was often practiced with an unscientific approach. Through their efforts,[2,3] medicine was nudged toward the "Age of Evidence." They wanted physicians to recognize good evidence from bad evidence, and they felt there was value in synthesizing evidence from multiple studies. More important, they wished for this information to then be applied routinely in the clinical setting. This was the birth of evidence-based medicine.

The American Dental Association (ADA) became interested in evidence-based dentistry (EBD) during the late 1990s, and by 2000, the organization had defined EBD as "an approach to oral healthcare that requires the judicious integration of systematic assessments of clinically relevant scientific evidence, relating to the patient's oral and medical condition and history, with the dentist's clinical expertise and the patient's treatment needs and preferences."[4] This definition has served the dental profession well, and the ADA has continued to take a leadership role in promoting EBD. They have created a center for EBD with a vision to "Lead in the promotion of oral health by disseminating the best available scientific information and helping practitioners implement it into clinical practice."[4] The ADA has set up recurring meetings and educational programs to encourage dentists to become familiar with evidence-based principles, and they have also created the ADA Center for EBD, an online resource that is accessible to everyone. One of the features of the ADA Center for EBD is a listing of all of the systematic reviews, meta-analyses, and practice guidelines in the field of dentistry, sorted by various topics. The ADA also

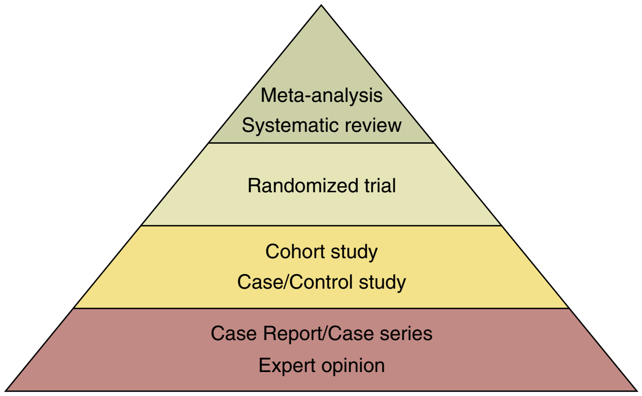

FIGURE 7-1 Hierarchy of evidence.

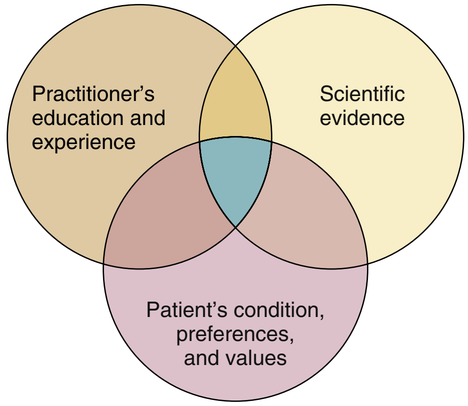

FIGURE 7-2 Evidence-based care is the intersection of three primary factors.

has established panels that summarize systematic reviews and meta-analyses, and translate them into critical summaries for dental professionals, as well as plain language summaries for patients.

In concert with the ADA's shift toward evidence-based practice, the Council on Dental Accreditation (CODA), which oversees the education of dentists and dental specialists in the United States, has also incorporated EBD into dental curricula. Currently, CODA lists "evidence-based care" as one of the "core principles" necessary in the dental educational environment.[5] Likewise, in the CODA standards for Graduate Programs, it is stated that, "Advanced specialty education programs must include instruction or learning experiences in evidence-based practice".[6] With early and intensive exposures to EBD being mandated during education programs, it hopefully will only be a matter of time before all dentists employ an evidence-based approach to practice.

Let's explore the elements of an evidence-based practice. The evidence, naturally, is one fundamental component. The Hierarchy of Evidence allows us to understand the different types of study designs, along with their relative strengths and weaknesses (Fig. 7-1). Thus, we are able to evaluate the merits of a specific publication. The top components of the Hierarchy of Evidence, the systematic review and meta-analysis, allow us to evaluate the strength of the body of literature that may exist for a specific clinical question. Another element of evidence-based care is a focus on patient values and preferences rather than a paternalistic model in which the practitioner dictates treatment. Finally, we must consider the role of the practitioner, who plays a critical role in the delivery of evidence-based care. It is the practitioner who must incorporate his or her own education and experience, as well as the scientific literature and the patient's preferences, in order to arrive at final recommendations for the patient (Fig. 7-2).

How different is our approach to scientific evidence? Just consider the changes that have occurred over the past 20 years. The Internet and digital media have become our routine mechanism for accessing evidence. PubMed, the ADA Evidence-based Dentistry Website, the Cochrane Collaboration, and the AAO Evidence-based Literature Website are only a few of the web-based resources that are available. Most of these sites have at least partial access for everyone, and while some information is targeted toward professionals, these sites often have information that is summarized in a fashion that is friendly to patients seeking guidance.

When reading an article, it is important to understand where it falls on the Hierarchy of Evidence, in order to understand the relative strength of the information. It is also important to judge a few critical parameters under which the study was conducted. Was there a systematic method to select patients? Was a control or comparison group utilized? Was blinding employed to avoid introducing bias? What was the source of funding? All these are simple, but extremely important, elements of evaluating research.

The development of guidelines for conducting systematic reviews has helped to standardize the process and has resulted in more valid and useful reviews. With more than 200 systematic reviews on orthodontic topics, it is often possible to update our knowledge on a particular topic with a 10- or 15-minute Internet search. This is a huge improvement over looking up references in Index Medicus, and then searching through heavy, bound issues of orthodontic journals in all corners of the library!

While much of the information mentioned above is familiar to our recently trained orthodontists, those of us graduating 15 or 20 years ago have witnessed a real revolution in producing, accessing, and utilizing orthodontic literature. Evidence-based methods are an enormous improvement in allowing us to obtain information in a quick and efficient manner.

Entire books have been devoted to evidence-based practice, and it is not our intent to undertake such an effort here. However, in the remainder of this chapter, we would like to briefly address some additional topics regarding an evidence-based practice:

- Comment on the Hierarchy of Evidence
- Review the basic elements of systematic reviews and meta-analyses
- Discuss the quality and quantity of evidence we need to make clinical recommendations
- Provide references to access evidence
- Discuss the future of evidence in orthodontics

THE HIERARCHY OF EVIDENCE

While our patients may not routinely demand that we cite the best evidence as we make our treatment recommendations, keep in mind that orthodontic evidence is abundantly available on the Internet. Therefore, if you are not incorporating the evidence into the fabric of your practice, you may be caught

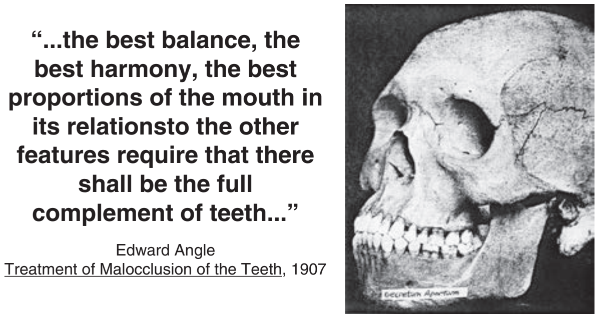

FIGURE 7-3 Old Glory—illustrating a full complement of teeth. (From Wahl N: Orthodontics in 3 millennia. Chapter 12: Two controversies: Early treatment and occlusion, *American Journal of Orthodontics and Dentofacial Orthopedics* 130(6): 799-804, 2006.)

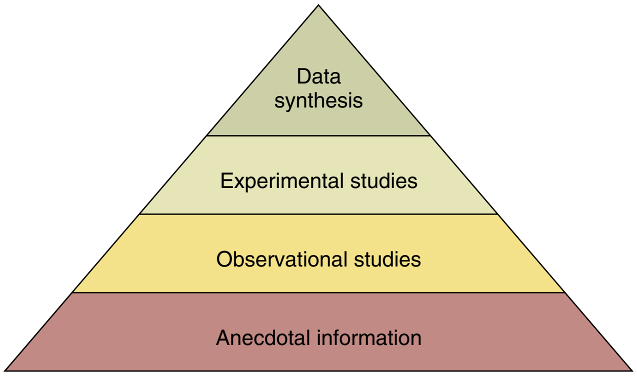

FIGURE 7-4 Anecdotal evidence is low on the evidence pyramid.

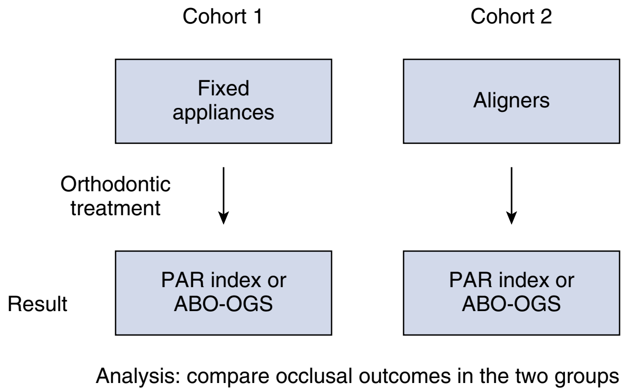

FIGURE 7-5 An example of a cohort study.

off guard, as patients and parents have become increasingly sophisticated about asking for the research that may or may not accompany various treatment options. Every orthodontist should be familiar with the study designs in the Hierarchy of Evidence, which is illustrated in Figure 7-1.

Some have recommended that the term *Hierarchy of Evidence* be replaced with the term *Levels of Evidence,* as the word *hierarchy* might imply a system that was too simplistic and rigid.[7,8] While the relative position of the study designs in the schema were minimally affected, the term *levels* allowed a little more latitude in evaluating the strength of an individual study. Higher level studies will generally provide stronger evidence, and a well-conducted systematic review, if available, would usually provide the best evidence-based information. Therefore, it makes sense to start any search by looking for a systematic review or meta-analysis on a topic. However, it would be unwise to believe that we can blindly apply a hierarchical system to our literature without some degree of judgment and thought. Sometimes, a well-conducted observational study can provide better evidence than a poorly conducted randomized trial. The point is, whether we use the word *Hierarchy* or *Levels* of Evidence, we can never stop thinking critically when we are assessing evidence.

Let's briefly review the Levels of Evidence. At the bottom is expert opinion. While this might have been highly regarded in the past, one person's view of an issue without any evidence is not very convincing today. There is simply too much possibility for bias.

The next type of evidence is the case report or the case series. As the name implies, these are simply one or a few cases illustrating a certain concept or type of treatment. Edward Angle based his non-extraction philosophy from several skulls, including "Old Glory," that all showed excellent occlusion and displayed a full complement of teeth (Fig. 7-3).[9] He extrapolated that the condition represented by the series of skulls could be applied to everyone. Obviously, the selection of cases is subject to bias, and they may or may not be very generalizable. Thus, this level of evidence is considered anecdotal (Fig. 7-4).

The next two study designs, case/control studies and cohort studies, could be labeled "observational studies" because investigators are simply observing the results of treatment rather than manipulating any treatment parameters. The case/control study is not a common design in orthodontics, so we will only say that it is utilized more in the medical field, especially when investigating diseases with rare outcomes. The type of study that is very common in orthodontics is the cohort study, in which two cohorts (or groups) undergo different treatments, and then their outcomes are compared (Fig. 7-5). Cohort studies are well suited to orthodontic research and can be conducted in a retrospective or prospective manner. In the retrospective flavor, one could go back in time and create cohorts that were treated with different techniques and compare their outcomes. The main advantage to this design is that all the treatment has been completed, and only the records need to be identified. However, one potential problem is that patients may have received different treatments for a reason, and perhaps the patients who make up the different cohorts are not very similar in their initial characteristics. Consider a comparison of occlusal outcomes in patients treated with fixed appliances versus aligners, in which the initial severity of the malocclusions may be quite different in the two groups if measures are not taken to match on this parameter.

Prospective cohort studies usually take more time to complete than retrospective cohort studies, as data are being gathered at some predetermined point in the future, usually when treatment is finished. However, there might be opportunities to standardize on some parameters of recruitment and treatment. This may help in creating cohorts that are more evenly matched on initial characteristics, and it also may allow better comparison of different treatments. For example, we might be interested in assessing how well unilateral crossbites are corrected in the mixed dentition using different techniques. If Practitioner A always uses a quad helix and Practitioner B always uses a Hyrax, then we could compare all the 8- to 11-year-old patients whom they treat with their respective techniques over a 1-year period,

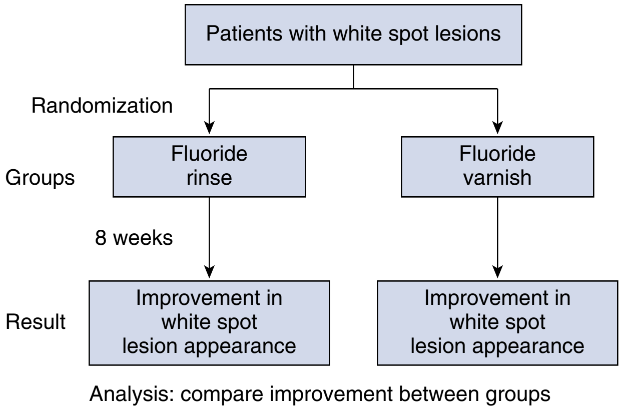

FIGURE 7-6 An example of a randomized trial.

and assess them initially, at the time of expander removal, and at 1 year after expander removal.

Finally, we move to the randomized trial, which is actually very similar to the design of a prospective cohort study (Fig. 7-6). However, there is one very important distinction: all subjects who are eligible for inclusion into the study are randomly assigned to one of the treatment arms. This step helps to ensure that the patients are distributed in an equitable manner into the various treatment groups. Given enough patients, this will help to create groups of patients in each arm of the trial that are as equal as possible in all characteristics, with the exception being the intervention. Randomized trials are considered an experimental design, rather than an observational design, due to the fact that investigators are prospectively manipulating the conditions under which patients will receive care.

Randomized trials should result in the least bias, and when possible, this design should be employed. However, they are expensive, time-consuming, and sometimes not possible to conduct due to ethical issues. We are not likely to find the resources to conduct randomized trials for all our orthodontic questions. However, we should consider conducting randomized trials, whenever possible, for our more important orthodontic questions.

SYSTEMATIC REVIEWS AND META-ANALYSES

At the top of the Levels of Evidence are two types of studies that are considered data synthesis. These are the systematic review and the meta-analysis. Actually, these designs are very similar, and both involve the systematic searching and evaluation of the body of literature that exists for a specific clinical question. The Cochrane Collaboration has published handbooks on conducting these reviews, which has improved their quality tremendously over the past decade.[10] The steps in conducting these studies are similar, but if the data identified during the systematic review are similar enough to allow pooling from several studies, then the data can be summarized using forest plots. This pooling of data is the key feature that distinguishes a systematic review from a meta-analysis. Some consider a systematic review as a qualitative evaluation of the evidence, while a meta-analysis is a quantitative assessment.

When planning a systematic review or meta-analysis, several elements are important to specify *a priori*. First, a very focused and precise question should be formulated. The PICO format is often suggested, with the letters indicating the Population, Intervention, Comparison or Control group, and the Outcome. An example of a PICO question might be, "Among adolescents with posterior crossbites (population), does tooth-borne expansion (intervention), compared with TAD-borne expansion (comparison group), result in comparable amounts of skeletal expansion as measured by CBCT (outcome)?" Second, the databases and references that will be searched should be described. For example, authors might state that they will search PubMed, Embase, and ClinicalTrials.gov. Third, inclusion and exclusion criteria for the studies should be specified, in order to fairly decide which studies will and won't be included. Some reviewers, such as those conducting Cochrane reviews, will limit their searches to randomized trials. If randomized trials are available, then it makes sense to limit reviews to these studies, as they should provide the best evidence. However, in the field of orthodontics, employing that criterion would result in no eligible studies for many topics, and therefore, most orthodontic systematic reviews and meta-analyses do include observational studies. Oftentimes, the conclusions of these reviews frustrate clinicians, as they report that, due to limitations in the quality of the current evidence, conclusions must be viewed with caution, and additional research is warranted.

HOW MUCH EVIDENCE DO WE NEED?

On that note, it is helpful to consider how much evidence we need to make robust clinical recommendations. After all, applying the results of research to the clinical setting is the ultimate goal of an evidence-based approach to practice. Is one cohort study enough, or do we need a couple of randomized trials, or is a systematic review of well-conducted randomized trials necessary? There is a famous article in the *British Medical Journal* that pokes fun at the shortcomings of evidence-based practice.[11] The authors conduct a systematic review of randomized trials on the use of parachutes to prevent death and trauma during free fall. Disappointingly, they find no randomized trial and conclude that "the effectiveness of parachutes has not been subjected to rigorous evaluation by using randomized controlled trials." Obviously, in this instance, it is not necessary or desirable to conduct a randomized trial. We know jumping out of a plane with no parachute is a very bad idea. However, the "interventions" in this experiment are at two extreme ends of the spectrum, as are the outcomes.

In our profession, a parallel question might be, "Does an expander correct a crossbite better than no expander?" The answer would be yes, without performing a randomized trial, because we know most crossbites do not self-correct. Of course, this is a much different question from the one we usually ask in orthodontics, as we often wish to determine which treatment or therapy might be most effective or efficient. Orthodontics has been referred to as the 6-mm specialty (the amount of correction from Class II to Class I molar), and with outcomes of this magnitude, more rigorous study designs must be employed. For example, if I asked, "What is the best and most stable way to perform rapid maxillary expansion," does our profession have a robust answer? Is tooth-borne better than tissue-borne, and is TAD-borne even better? What is the optimal age to perform expansion, and up to what age is acceptable? And what is the optimum regimen for activating a rapid palatal expander? To answer these questions, we would need well-conducted trials to assess the less dramatic differences that might exist among these orthodontic interventions.

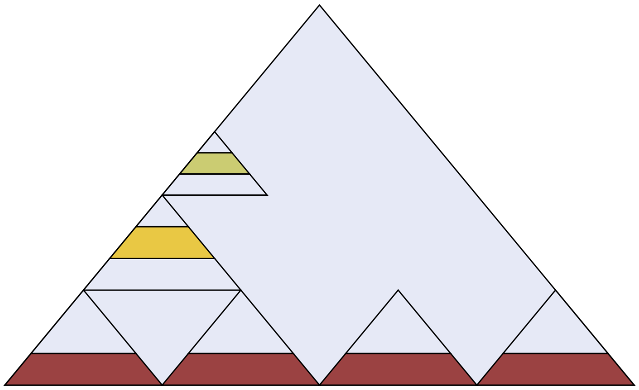

FIGURE 7-7 An illustration of the body of evidence on a particular topic, which consists of a few randomized trials, a few observational studies, and many anecdotal studies.

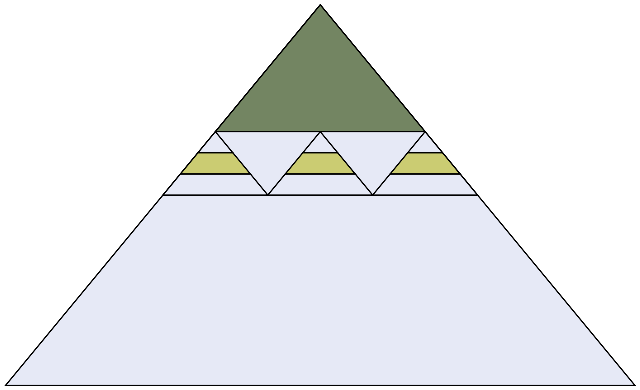

FIGURE 7-9 An illustration of the body of evidence included in a systematic review, which consists of only randomized trials.

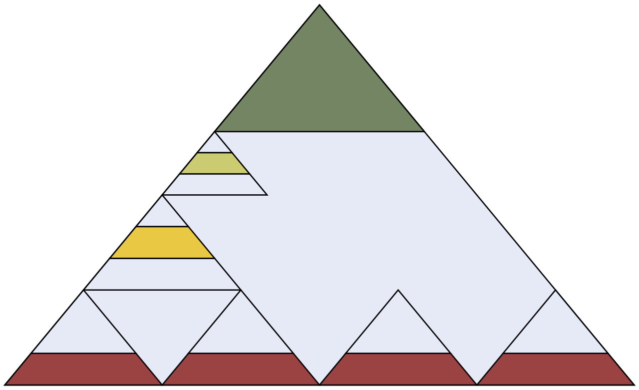

FIGURE 7-8 An illustration of the body of evidence included in a systematic review, which consists of a few randomized trials, a few observational studies, and many anecdotal studies.

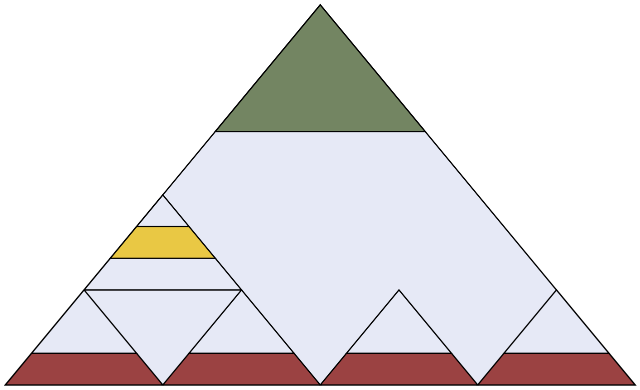

FIGURE 7-10 An illustration of the body of evidence included in a systematic review, which consists of a few observational studies and many anecdotal studies.

To help judge the strength of our evidence, many scales have been developed by various entities. The Centre for Evidence-based Medicine has a chart showing the levels of evidence,[12] and two additional scales are the Strength of Recommendation Taxonomy (SORT)[13] and the Grading of Recommendation Assessment, Development and Evaluation (GRADE).[14] However, these scales can be confusing, as they use phrases like "Level 2" evidence or "Code A" evidence or the "GRADE recommendation is strong." Adding to the confusion is the fact that the scales have been evolving and continue to do so.

At this time, we would like to introduce some simple diagrams that help to depict the level of evidence that exists on a topic. First, take a look at the levels of evidence (see Fig. 7-4), with the anecdotal evidence coded in red, the observational studies coded in yellow, the randomized trials coded in light green, and the systematic reviews and metaanalyses coded in dark green. If we searched on the expansion literature, we would find just a few randomized trials, some observational studies, and many case series. This could be depicted schematically as in Figure 7-7. We would also find several systematic reviews, based on the body of evidence I just mentioned. One of these systematic reviews could be depicted as in Figure 7-8, where the top green triangle represents the existence of a systematic review, and the lower triangles depicts the various types of studies found in this review in their relative proportions. As another example, what if we asked about the evidence comparing 2-phase to comprehensive Class II treatment? There is a Cochrane systematic review that addresses this topic that only includes randomized trials.[15] This would be represented in Figure 7-9—a systematic review including only randomized trials.

Now, back to our question: "What is the quality and quantity of evidence needed to make a robust clinical recommendation in orthodontics?" Well, to be fairly confident of an answer regarding different treatments or techniques, we probably need to have multiple well-conducted randomized trials that report consistent findings. For example, if there are three well-conducted randomized trials on 2-phase versus 1-phase Class II treatment, and they all indicate that patients will arrive at similar outcomes with both strategies, then we can be fairly confidant of this finding, especially if no randomized trials provide opposing evidence. Similarly, if investigators were to perform a systematic review on this topic, and identified well-conducted randomized trials that were all consistent in their findings, we would have pretty good confidence about the conclusions of the systematic review (see Fig. 7-9). On the other hand, if our only systematic review on this topic included many case series and perhaps a few cohort studies, this would not be considered strong evidence, as these types of studies have a high potential for bias (Fig. 7-10).

Consider another question: "Are remineralization agents effective in improving the appearance of white spot lesions that form during orthodontic treatment?" Using the best evidence available, a recent systematic review of seven randomized trials, the answer is: "There is a lack of reliable evidence to support the effectiveness of remineralizing agents for the treatment of post-orthodontic white spot lesions."[16] How convincing is this evidence? It is depicted by Figure 7-9, a systematic review that only includes randomized trials. This is relatively strong evidence that we do not have a reliable agent to address white spot lesions at this time.

As mentioned earlier, there are now more than 200 systematic reviews and meta-analyses on orthodontic topics. Because much of our literature consists of observational data, many systematic reviews and meta-analyses include these types of studies. This helps to explain why we are routinely cautioned when we read the conclusions of these reviews—they look like the diagram depicted in Figure 7-8. On the other hand, when we have multiple randomized trials that have similar findings, or when we have systematic reviews of randomized trials that have similar findings, we should really take note. This may be information that we can be relatively confident about. However, this brings up a very important issue—what we believe is best and true today may not be what we think is best and true tomorrow. Medicine has many examples of this, and in fact, some of our well-accepted guidelines about dietary cholesterol are expected to be reversed on the basis that the recommendations were based upon "insufficient evidence."[17]

WHERE TO FIND THE EVIDENCE

Where you search for information may influence the quality of advice you receive. For instance, one may look for information that is posted on the Web. Many Websites provide little oversight of the material they post, so information may or may not be accurate. On the other hand, there are other sites in which information is highly reviewed and/or refereed, and this information is updated as the knowledge base changes. The Cochrane Collaboration comes to mind as having a well-deserved reputation for maintaining the highest standards in summarizing evidence that is of the highest quality.[18] Likewise, journals come in all flavors, some not refereed at all, some "lightly" reviewed, and some highly refereed by experts in the field. Only a few orthodontic journals have a respected Impact Factor (IF), and this is usually due to a thorough peer-review process that strives to identify and publish only the most meritorious work. The quality of material published in most other venues can drop off quickly if a rigorous review process is not in place.

PubMed provides an opportunity to easily conduct searches of most current journals, even in fields other than orthodontics.[19] Once references are identified, university students or faculty members usually have access to many publications via their university affiliations. This privilege is available through the institutional subscription paid for by the university. Although open source for all published scientific journals is something appealing to scholars and some publishers, it is still not universally available. Someone still has to pay the cost of publishing scientific findings. Options include charging the authors for every page published, while others favor advertising. Banner advertising is the most common type, but in the future it may be common for publishers to electronically push groups of articles that have common interest to specific subscribers, with all paid for by commercial entities. As long as the advertisers do not select the articles, this convenience to readers is considered ethical. Many organizations already select and screen studies of the highest level in specific fields to provide to members of the organizations. They might be notified by e-mail every month or whenever another study is added to the collection. The American Dental Association (ADA)[20] and the American Association of Orthodontists (AAO)[21] provide this member service, as do the librarians of most universities and scholarly organizations.

Evidence-based clinical recommendations are developed through critical evaluation of the collective body of evidence on a particular topic to provide practical applications of scientific information that can assist orthodontists in clinical decision making. In addition to scientific journals, dental schools, and approved courses, sources of this information may be found in the following locations:

1. **PubMed**[19] - The National Library of Medicine's searchable database of more than 12 million indexed citations from more than 4600 medical, dental, health, and scientific journals.
2. **Cochrane Collaboration**[18] - An international nonprofit organization that develops evidence-based systematic reviews on health care interventions.
3. **ADA Center of Evidence-Based Dentistry**[20] - A resource for evidence-based dentistry that is periodically updated and accessible to dentists and the public. It provides a resource on evidence-based terms, houses guidelines, and catalogs systematic reviews for general dentistry, as well as specialty areas. It also provides critical summaries of some systematic reviews.
4. **Websites for various dental specialty organizations** - An example is the evidence-based Website that the AAO Library[21] maintains at its member Website.
5. **Textbooks** - There are several textbooks on evidence-based dentistry and two textbooks on evidence-based orthodontics.[22,23]
6. **Evidence-based Journals** - There are two evidence-based journals, the *Journal of Evidence-based Dental Practice* and *Evidence-based Dentistry*.[24,25]

THE FUTURE OF EVIDENCE-BASED ORTHODONTICS

Orthodontists have been asking "Why, What, and How" for more than a century. For example, "Why do some patients have such bad growth patterns, what is the best way to treat them, and how can we ensure that these corrections will be stable?" Or, "Why do some patients exhibit severe root resorption, what can we do to minimize it, and how can we predict who will be susceptible?" Although we have volumes of publications on orthodontic treatment, is seems that our research has often failed to produce sound, conclusive evidence for many important questions. Obviously, our traditional methods of research have not been adequate, and this is why our profession needs to employ an evidence-based approach toward education, research, and practice.

One exciting opportunity for our profession is the emergence of dental practice–based research networks. Borrowing from a medical model in which physicians conduct clinical research in their own practices, the National Institutes of Health has developed regional and national dental research networks over the past decade. The most recent endeavor in the United States,

FIGURE 7-11 The National Dental Practice-Based Research Network is funded until 2019. (National Dental Practice-Based Research Network (Website): http://www.nationaldentalpbrn.org. Accessed 09.28.15.)

the National Dental Practice-based Research Network, targets questions related to general dentistry (Fig. 7-11).[26] However, specialists are encouraged to join the network and to submit projects that would be of importance to their field. The American Association of Orthodontists (AAO) is aware of this opportunity and has encouraged orthodontists to submit important questions to this national network.

The advantages of this type of research are many. First, the research topics originate from clinicians and reflect the real-life questions that practitioners would like to have answered. Second, experienced researchers can assist with designing and implementing studies. This helps to ensure the validity of the findings. Third, the research is conducted in private offices, rather than in the sometimes artificial setting that can be associated with university research. Fourth, the network is able to allow simultaneous participation from the network practitioners. Therefore, the results will be much more informative regarding practice patterns and will also be more generalizable. Fifth, the pool of potential subjects is greatly expanded by utilizing a network or practitioners, which is particularly helpful if conditions or treatments may be relatively rare, like severe root resorption. Sixth, researchers will be able to work with network statisticians and epidemiologists in analyzing and interpreting the data. And finally, once the results of the investigation are obtained, the network provides the ideal vehicle for dissemination of information.

The current National Network in the United States was awarded more than $66 million by the National Institute of Dental and Craniofacial Research to conduct practice-based research in dentistry. Hopefully, by the time you are reading this chapter, our profession will have launched two or three studies in this setting, and perhaps you will even be a participant in one of the studies.

Another trend will be the accumulation of more and more systematic reviews and meta-analyses, which will continue to be conducted and revised with better methods and also based upon better evidence. These reviews will eventually cover almost every topic in orthodontics and will become the standard method for obtaining information. The American Board of Orthodontics modifies its reading list for the written exam every year, and based on recent trends, perhaps within a decade, most of the references on this list could be systematic reviews and meta-analyses. Having teams of experienced academicians search and summarize the literature makes sense. It is a tedious and methodical process and probably not a responsibility that the average busy practitioner would wish to shoulder. However, it is absolutely the responsibility of every clinician to be very familiar with the components of systematic reviews and meta-analyses. As methods to perform reviews continue to improve, we can feel more confident in the conclusions that are published. However, practitioners must never relinquish the skills to judge the quality of our literature. These skills will increasingly be the ones that apply to judging systematic reviews and meta-analyses.

Technology will also help us. We will be asking our smartphones and smartwatches to retrieve the evidence for a particular clinical question. Our patients will, too, and we may be pressed to stay as current as some of them. As the evidence becomes more available, perhaps it will help our profession to arrive at some consensus on the effectiveness and stability of various treatments, techniques, and procedures. In a nutshell, the future is promising, due to better evidence, better summaries of our evidence, and better access to our evidence.

CONCLUSIONS

In conclusion, we should all be grateful that evidence-based methods have become incorporated into the specialty of orthodontics over the past decade. They have helped us to assess the state of our literature and to recognize its deficiencies. Evidence-based methods have also challenged us to conduct more rigorous studies. After more than a century as a specialty, we still have many important questions to answer. Evidence-based methods will help us to investigate these questions and then allow us to translate this knowledge into providing the safest and most effective, efficient, predictable, and stable treatments to our patients. This is the reason we are all part of the orthodontic profession, and this is why evidence-based orthodontics is so important.

8 The Decision-Making Process in Orthodontics

Tung Nguyen and William Proffit

OUTLINE

Many of the ideas presented here originated with Dr. James L. Ackerman, and the diagnosis/treatment planning scheme reflects his development of these ideas during a distinguished career in academics and private practice. We thank him for his contributions to this work and to the orthodontics specialty.

This chapter is written primarily for residents in orthodontics and for current practitioners who want an update on the changes in diagnosis and treatment planning that have affected orthodontics in recent years. Because the purpose is to outline the basics of orthodontic assessment and treatment planning without going into detail about all aspects of the process, it should be used as a companion piece to Chapters 1, 6, and 7 in *Contemporary Orthodontics*.[1] It is also a natural introduction to Chapter 9, which is a detailed analysis of dentofacial appearance from an orthodontic point of view.

A competent orthodontist today must use broad background information in the life sciences and social sciences in assessing and planning treatment for patients, and a comprehensive evaluation is a necessity. The goal of this chapter is to review the many steps in the decision-making process in orthodontics while demonstrating how a comprehensive evaluation can be quickly and seamlessly telescoped into a practical guide for everyday practice.

BACKGROUND CONCEPTS

Before we begin the steps in evaluation of a patient and continue to treatment-planning principles, some important concepts underlying orthodontic diagnosis and treatment planning are important to discuss.

Quality of Life: The Modern Health Care Paradigm

Until fairly recently, the goal of health care was conceived as primarily the control of disease and infirmity. Orthodontists struggled for many years to fit "correction of malocclusion" within the confines of this narrow definition. Today, the concept of health is a state of complete physical, mental, and social well-being, and the goal of treatment now is to maintain and enhance the patient's quality of life.

For orthodontics, this has tipped the scales from greatest emphasis on dental occlusion, usually defined as the static relationship of the teeth when they are brought into occlusion, to far more weight placed on facial appearance and tooth display. It is simply a fact of life that appearance, particularly facial appearance, has a greater effect on how one is perceived in social interactions than performance. The evolutionary psychologist Geoffrey Miller said it well: "Our vast social-primate brains evolved to pursue one central social goal: to look good in the eyes of others."[2] People seek and value orthodontic treatment primarily as a way to overcome or minimize a social handicap that decreases their quality of life.

This does not mean that dental function is an unimportant component of quality of life. It does mean that malocclusion is an inadequate description of orthodontic problems and that ideal occlusion is not the primary goal of modern treatment. Should orthodontic treatment be restricted to only those with major deviations from normal occlusion? Not in a modern view. Nearly every specialty of medicine and dentistry now offers interventions that are enhancements of normal traits or conditions rather than correction of disease. Medical examples are cosmetic plastic surgery and medications like fluoxetine (Prozac) for patients who desire to feel "better than well."[3] In dentistry, tooth whitening, clinical crown lengthening, and porcelain veneers are examples of enhancement technologies designed to transform normal conditions to states beyond normal. This trend has had remarkable implications for orthodontic diagnosis and treatment planning, in the context of altered goals of treatment.

In an operational sense, the goals of modern orthodontic treatment are to:

- Improve smile and facial appearance with resultant improvement in an individual's social well-being and quality of life.
- Establish normal oral function and performance, allowing for an adequate range of physiologic adaptation.
- Obtain optimal proximal and occlusal contact of teeth (occlusion), defining optimal occlusion in the context of the preceding goals. It is apparent now that there is no one ideal occlusion that is optimal for every patient.
- Achieve stability of the dentition within the bounds of expected physiologic rebound.

Understanding Normal versus Ideal Occlusion

The concept of ideal dental occlusion is a surprisingly recent one and dates back only to Edward Angle, who for all practical purposes invented dental occlusion[4] (the term was not used to describe dental relationships previously) and popularized the terms *occlusion* and *malocclusion* in his development of a classification with four categories:

- Normal occlusion, defined from two characteristics:
  - alignment of the teeth within each arch along a "line of occlusion" through the central fossa of the maxillary teeth and along the cusp tips of the mandibular teeth (Fig. 8-1).
  - occlusion, with the mesiobuccal cusp of the maxillary first molar occluding with the central fossa of the lower first molar. With the teeth aligned along the line of occlusion, this would produce normal occlusion (Fig. 8-2).
- Class I malocclusion, with a normal molar relationship but teeth not aligned along the line of occlusion.

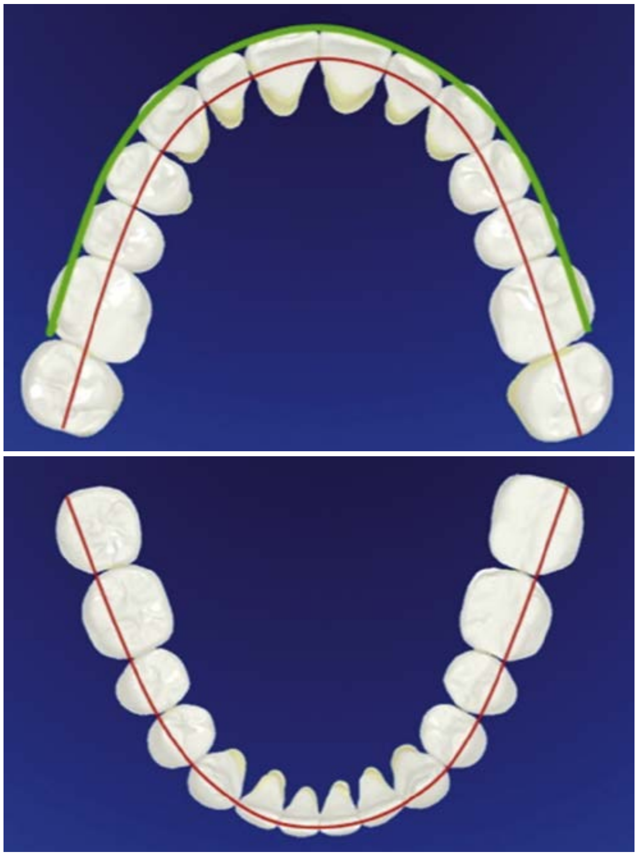

FIGURE 8-1 Bonwill and Angle proposed that if the buccal occlusal line of the mandibular teeth coincided with the central fossae line of the maxillary teeth, ideal occlusion would result. The only recent addition to this concept is that from an appearance point of view, the line corresponding to the line of occlusion that one sees when an individual smiles is the facial occlusal line (the esthetic line of the dentition), which is shown in green. The anterior segment of the esthetic line of the dentition is called the *smile arc*.

- Class II malocclusion, with the lower molar distally positioned relative to the upper molar.
- Class III malocclusion, with the lower molar positioned mesially relative to the upper molar.

The relationship of the teeth to the line of occlusion was not defined for Class II and III.

In the United States, even with a minor deviations from ideal being accepted as normal, two-thirds of the population have one of the forms of malocclusion.[5] Usually a typical trait in a population is considered normal and an atypical trait (in this case an ideal arrangement of the teeth) is considered abnormal. In the older model of health care where practitioners treated abnormal conditions or corrected deformities, how could orthodontists justify treating malocclusion if it was neither atypical nor a major abnormality? Even before the quality of life paradigm was widely accepted, they did it because patients wanted it, for reasons that we now understand more clearly.

The modern goals of orthodontic treatment make it clear that problems needing orthodontic treatment could arise in the absence of malocclusion. For example, ideal occlusion accompanied by dentoalveolar protrusion with excessive facial convexity and lip incompetence, in a patient whose chief concern is social problems

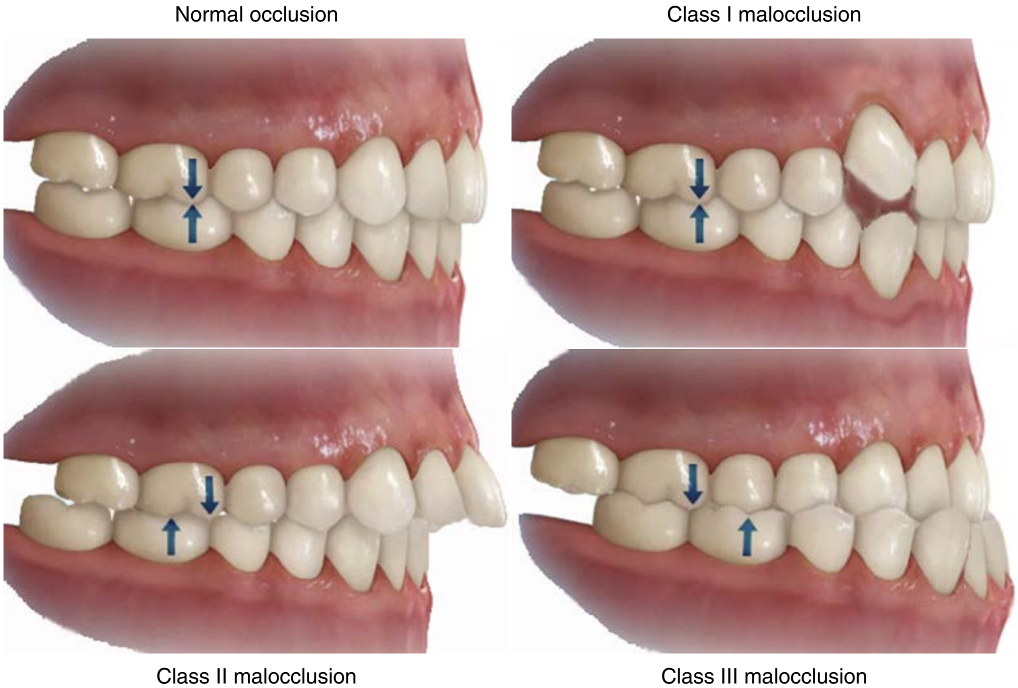

FIGURE 8-2 Angle suggested that in ideal occlusion, the mesiobuccal cusps of the maxillary first molars should rest in the buccal grooves of the mandibular first molars. He called the permanent first molars the keys to occlusion and designated this ideal molar relationship Class I. He observed that two variations of this molar relationship exist and he designated these Class II and Class III. Subsequently, the relationship of the canines also became part of the description of Class I, II, and III, probably as a result of Simon's influential but erroneous belief that the maxillary canines were the keys to occlusion. Nonetheless, the maxillary canines should ideally fit in the embrasures between the mandibular canines and first premolars.

related to appearance, is a definite indication for treatment (one that Angle refused to accept—if you did not like the way you looked with protrusive teeth in ideal occlusion, he questioned your perception). Nor are all malocclusions indications for treatment. Malocclusions are only indications for treatment if they create a problem for the patient (or potential problem for a child), in social interactions or functionally. Nonetheless, we are not suggesting completely abandoning the term *malocclusion* but rather restricting its use to contexts where its meaning cannot be misconstrued, and using *orthodontic problem* in the larger context of indications for treatment.

Are there disease/pathology considerations related to malocclusion, so that orthodontics is needed to treat or control them? Until fairly recently, it was thought that unstable occlusion promotes periodontal disease, because drift of teeth is associated with periodontal bone loss. This is a misinterpretation of cause and effect.[6] In fact, it is loss of periodontal attachment resulting from periodontal disease that causes teeth to drift, not vice versa. It was also believed that traumatic occlusion was a primary factor in causing periodontal problems; it is recognized now that occlusal trauma, if associated at all with a periodontal problem, is a secondary, not a primary, factor in its causation.

Another possible misinterpretation of the role of occlusion in oral health resulted from erroneous conclusions about the "high filling" effect. If a restoration is placed so that it creates a premature occlusal contact, the patient often develops tooth pain lasting days or even weeks. This finding supported the theory that faulty occlusion created microtrauma that caused pulpal hyperemia as well as periodontal lesions. In orthodontics today, composite is often added to the occlusal surfaces of the posterior teeth temporarily to serve as mini–bite planes without patients complaining of dental pain. It is likely that pulpal hyperemia associated with a high filling is primarily the result of caries removal during tooth preparation for restoration, with occlusal trauma being only a secondary or compounding factor in causing pain.

The same type of misinterpretation of causality has been responsible for erroneous conclusions regarding occlusion and temporomandibular pain/dysfunction (TMD).[7] It is now widely accepted that flawed occlusion is not a primary factor in causing TMD. In some individuals, occlusal prematurities can lead to the parafunctional habit of clenching or bruxing, thereby secondarily causing muscle spasm, fasciitis, or tendonitis that results in pain in the region of the TM joint. However, there is no evidence that malocclusion without premature contacts leads the TMD or that any specific occlusal scheme within the normal range of variation provides more efficient mastication.

Dental and Skeletal Compensations: Nature's Way of Camouflaging Discrepancies

Perhaps the most common misperception of beginning residents in orthodontics is that if theoretically ideal occlusion can be defined, there must be an ideal skeletal pattern (jaw relationship) as well. Nothing could be further from reality. When ideal occlusion exists, it is because there have been 3D compensatory linear and rotational adaptations in the relationship of the dentition to the underlying skeleton. These structural alterations can be as far removed from the dentition as the cranial base, the

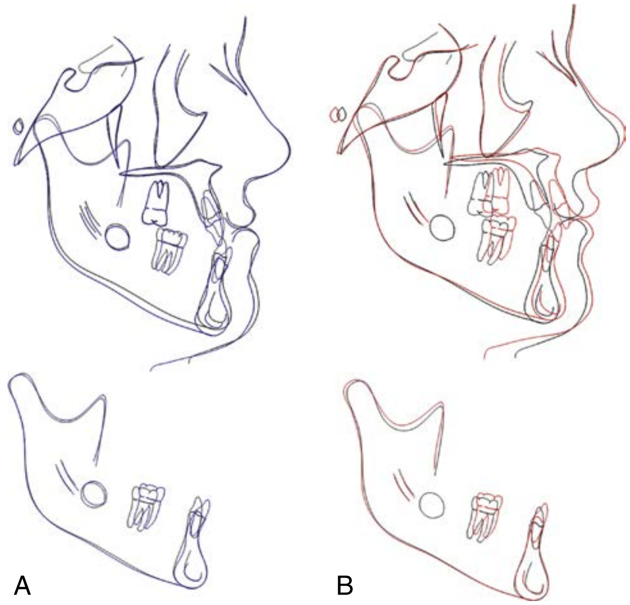

FIGURE 8-3 In preparation for orthognathic surgery, removal of dentoalveolar compensation for the skeletal deformity is often required to optimally position the jaw in a harmonious relationship. This figure of steps in treatment of a Class III problem due to maxillary deficiency shows (A) (black to blue) cranial base and mandibular superimpositions of pretreatment (black) to presurgery (blue), and (B) presurgery to posttreatment (red). Note the retraction of the maxillary incisors and proclination of mandibular incisors in preparation for surgery, so that an adequate amount of maxillary advancement for acceptable soft tissue relationships could be done without dental interferences.

nasomaxillary complex, and the condylar neck and ramus of the mandible. In addition, the corpus of the mandible and the maxillary and mandibular dentoalveolar structures are morphologic features that are remarkably adaptable.

Thus, dental compensations can effectively mask underlying anteroposterior skeletal discrepancies. The simplest demonstration of this is that in Class III skeletal patterns, where either the mandible is too far forward or the maxilla is too far back, the maxillary teeth almost always tip facially (procline), and the mandibular teeth tip lingually (retrocline). The same thing happens in reverse in Class II skeletal patterns, although often not as extensively. The extent to which the teeth are able to compensate determines whether the teeth will be in normal occlusion despite a jaw relationship that predisposes to malocclusion or whether a malocclusion less severe than the jaw discrepancy will develop. Much of orthodontic treatment is simply directed toward completing nature's insufficient compensation, but when the jaw discrepancy is so great that acceptable facial appearance and function can be obtained only by surgery, preparation for the surgical treatment often requires removal of dental compensation so the jaws can be properly positioned (Fig. 8-3 and Case Study 8-1).

Recognizing Orthodontic Problems

Data from the third U.S. National Health and Nutrition Examination Survey (NHANES-III) provide a clear picture of malocclusion in the U.S. population in the 1990s[8] and an important background for evaluating orthodontic treatment need.

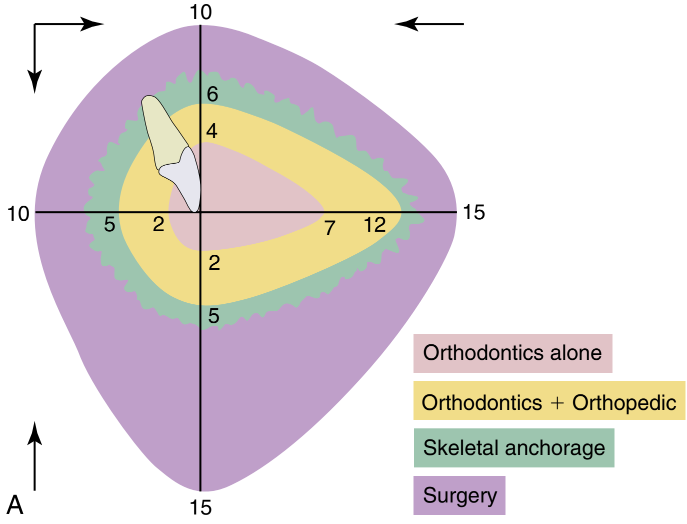
Incisor crowding occurs in the majority of all racial and ethnic groups, with only 22% of American adults having well-aligned lower incisors. Incisor irregularities are severe enough in 15% of the population to produce major effects on appearance, function, or both. About 20% of the population have major deviations from the ideal bite relationship (excess or inadequate overbite and overjet), and in 2% the deviations are severe enough to be disfiguring. Less than 10% of the population have posterior crossbites, more than a 6-mm overjet, or more than 6 mm of overbite. Discrepancies in molar relationship of more than 6 mm (i.e., Class II or Class III molars) occurred in 11% to 15% of the people surveyed, with differences between racial/ethnic groups.

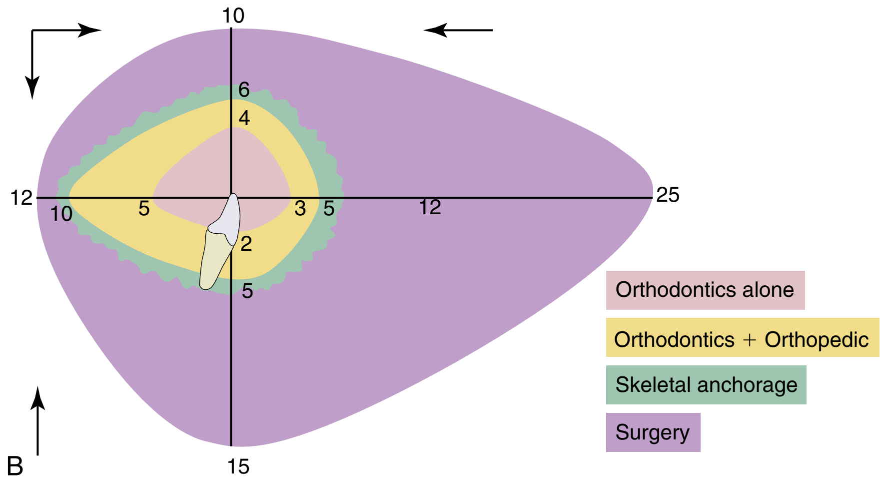
If one calculates from the NHANES data the percentage of individuals who fall into Angle's three malocclusion groups, by far the greatest number are Class I (50% to 55%). The next highest group is Class II (15%), and the smallest number is Class III (less than 1% for all other groups but 5% for those of Asian descent). Even with acceptance of minor irregularity and bite deviations, only 30% were scored as normal.

Dentofacial appearance and associated psychosocial issues, not just the way teeth fit together, play a major role in defining orthodontic treatment need. For this reason, determining treatment need just from an examination of dental casts or radiographs is difficult at best. The Index of Treatment Need (IOTN), developed in the United Kingdom,[9] places patients in one of five grades ranging from "no need for treatment" (grade 1) to "treatment required" (grade 5). IOTN has two components: dental health (based on deviations from ideal occlusion) and esthetic concerns (based on the way patients identify themselves relative to a graded set of photographs of malocclusions). As might be expected, a high correlation exists between scores on the two components of the index, which provides some confidence in using the dental health component alone as an indicator of treatment need. A consensus panel of orthodontists established the significance of various occlusal discrepancies, and IOTN grades seem to reflect clinical judgments better than previous methods.

Applying IOTN to the NHANES-III survey data indicates that 57% to 59% of each of the American racial and ethnic groups have at least some degree of orthodontic treatment need. Treatment is much more frequent in higher income groups, but 5% of the lowest income group and 10% to 15% of intermediate income groups report being treated. Although all states are now required to include orthodontic services as part of their Medicaid programs, which in itself is testimony to the importance of overcoming severe orthodontic problems, fewer than 1% of orthodontic patients have their treatment covered through social programs. Despite this, nearly 10% of the adolescents in the lowest income groups and 15% of those in modest income groups now report receiving orthodontic treatment. This shows that even families with modest resources often give orthodontics a high priority because of its role in improving social well-being and a person's social potential in life, as well as quality of life.

Why are orthodontic problems so prevalent? Tooth irregularities and jaw disproportions are developmental conditions resulting from a combination of genetic, epigenetic, and environmental factors. In most instances, malocclusion and dentofacial deformity are caused not by some pathologic process but by moderate distortions of normal development due to intrinsic and extrinsic factors. Occasionally a single specific cause is apparent; for example, an anterior open bite in the early transitional dentition may result from thumb sucking. A more dramatic example of a condition arising from extrinsic causes is mandibular asymmetry secondary to a subcondylar fracture of the jaw in childhood (Fig. 8-4). In some craniofacial syndromes,





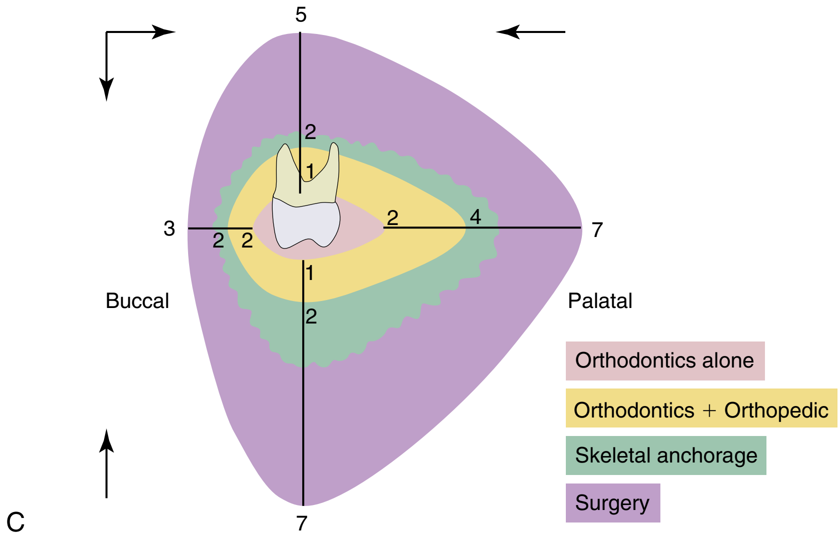


FIGURE 8-4 **A-C,** The anteroposterior, vertical, and transverse millimetric range of treatment possibilities in orthodontics can be expressed as an envelope of discrepancy. What is meant by treatment possibilities is the amount of tooth movement that can be accomplished by orthodontics alone, orthodontics plus dentofacial orthopedics with or without skeletal anchorage, or orthodontics plus orthognathic surgery. The different colored zones describe the range of potential tooth movement. The arrows designate the direction of the movement in the diagram. The pink zone represents the envelope for orthodontics alone, the yellow zone depicts orthodontics plus orthopedics, the green zone shows skeletal anchorage, and the blue zone any combination of the above with orthognathic surgery. The reason the green zone is shown in "fuzzy" fashion is that there is only sufficiently reliable data to make estimates at this point. The same limitation is the reason there is not a figure depicting the mandibular transverse envelope.

characteristic malocclusions develop from the influence of multiple genes. Most often, however, deviations from normal occlusion result from a complex interaction among many factors that influence growth and development, and it is impossible to describe a specific etiologic factor.

Fundamental to good taxonomy, the science of classification, is the concept that etiology should be included in any classification. The major weakness of all current classifications of malocclusion is that they totally ignore etiology. One of the most exciting aspects of current research to clarify the biological basis of orthodontics is the prospect that advances in genetics will allow differentiating patients within the classic Class I/II/III classification so the specific types of treatments can be related to their pattern of growth.

Limitations of Orthodontic Treatment

One of the most important concepts for a beginning orthodontic resident to grasp is the range of tooth movement that can be accomplished within the biological limits of the system. One way to describe the theoretical boundaries of the potential range of tooth movement is the envelope of discrepancy (Fig. 8-5).

The envelope can be thought of as an elastic 3D, asymmetric closed container. Orthodontics alone rearranges the contents of the container; growth modification treatment and surgery change the shape of the container. For any characteristic of malocclusion, four ranges of correction exist: (1) the amount that can be accomplished by orthodontic tooth movement alone; (2) a larger amount that can be accomplished by orthodontic tooth movement aided by absolute anchorage (bone anchors);

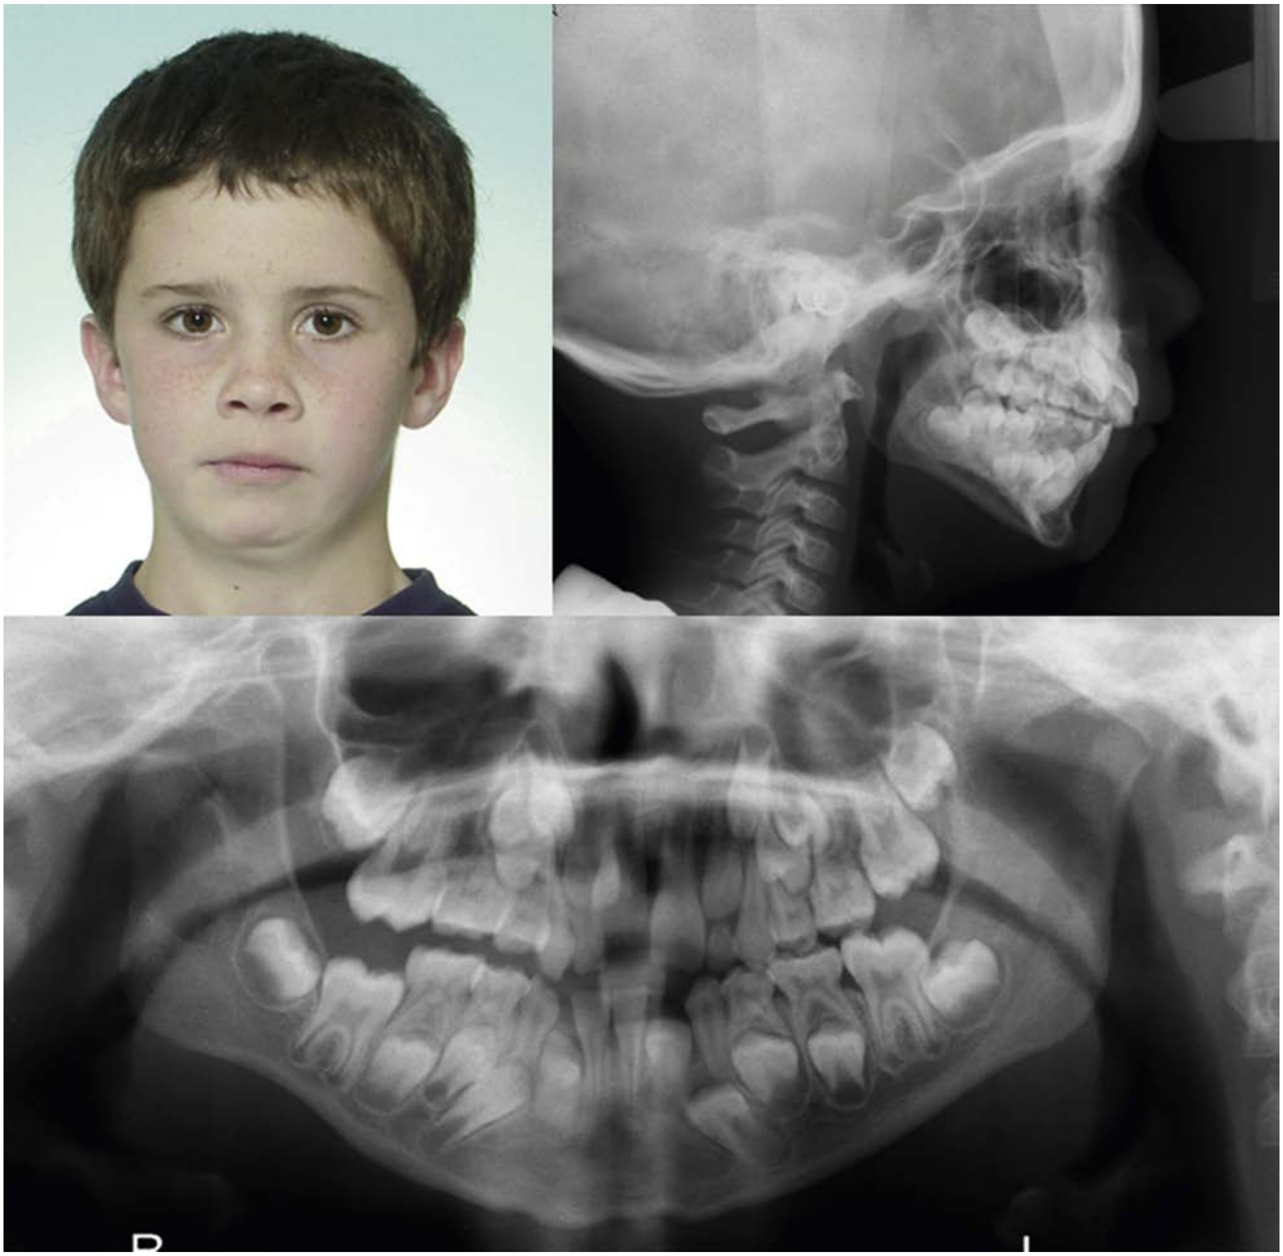

FIGURE 8-5 A patient with an untreated right condylar fracture. The asymmetry can be seen with the chin deviation to the right on the clinical photos, a shorter right condylar neck on the panoramic film, and two distinct lower mandibular border on the cephalometric film. Asymmetries should be diagnosed with a CBCT.

(3) an additional amount that can be achieved by functional or orthopedic treatment to modify growth; and (4) a still larger amount that requires surgery as part of the treatment plan. The magnitude of the potential changes shown in the diagram is a combination of good data for some dimensions and an educated guess for others.

Thus, if a patient presents with an overjet of 7 mm, attributable to forward position of the maxillary incisors, correction of the overjet by retracting the incisors is just within the range of orthodontic tooth movement. Maxillary premolar extractions would provide 7 to 8 mm of space, but 7-mm incisor retraction might require bone anchors to close the extraction space solely by retraction. Correction of greater overjet (which almost surely would have a component of mandibular deficiency as a cause) would require redirection of facial growth with dentofacial orthopedics, and if the mandibular deficiency were severe enough (greater than 10 to 12 mm), a combination of orthodontics and orthognathic surgery would be needed. The same reasoning applies to the transverse and vertical possibilities of orthodontic treatment. In general, orthodontic and growth modification treatment can create larger sagittal (anteroposterior) corrections than in the vertical or transverse planes of space.

The timing of treatment is a factor in the amount of change that can be produced. The amount of tooth movement that is possible is about the same in children as it is in adults. However, the growth modification range diminishes steadily as a child matures and disappears after the adolescent growth spurt, so some Class II and Class III conditions that could have been treated in a growing child with growth modification and tooth movement would require surgery if treated later on. Controlling excessive vertical growth in children is difficult, and TADs can be useful for this in older patients.

The envelope of discrepancy was developed from cephalometric data and thus uses tooth movement relative to the underlying jaw and jaw relationships relative to the cranial base. It is compatible, however, with the newer concept that soft tissue relationships are the key to both dentofacial appearance and treatment limitations.[10] For that reason, the orthodontist must plan treatment within the patient's limits of soft tissue adaptation and soft tissue contours. This requires greater emphasis on soft tissue function and dentofacial appearance during the clinical examination. Limitations in orthodontic treatment related to the soft tissues include (1) pressures exerted on the teeth by the lips, cheeks, and tongue; (2) limitations of the periodontal attachment; (3) neuromuscular influences on mandibular position; (4) the contours of the soft tissue facial mask; and (5) lip–tooth relationships and anterior tooth display during facial animation. The physiologic limits of orthodontic treatment (i.e., the ability of the soft tissue to adapt to changes in tooth and jaw positions) are related to the first three of these limitations and are often narrower that the anatomic limits of treatment shown in the envelope of discrepancy. For instance, in expansion of the lower arch (Fig. 8-6), the envelope is zero for expansion across the canines, broadening to about 4 mm in the molar region. With modern orthodontic appliances and bone anchors, it is quite possible to move the teeth beyond the point of acceptable adaptation, physiologically and esthetically. The esthetic soft tissue limitations relate to facial contours created by jaw and tooth position and to the display of the dentition, both of which must be kept in mind when the acceptability of tooth movement is being determined.

Edward Angle sought perfection in dental alignment and occlusion and thought that this natural condition would have been present if something had not interfered with normal development. The modern view is just the opposite: nature does not intend for the orthodontist to achieve perfection but rather contends with the orthodontist trying to achieve it. Treatment "failures" are generally the result of poor treatment response rather than inadequate treatment. Rather than designating orthodontic outcomes as successes and failures, it is more logical to categorize patients as responders and nonresponders to the treatment procedures. Similarly, since posttreatment relapse is determined by physiologic adaptation and any subsequent growth, postretention patients can be characterized as adapters and nonadapters to the changes that were made. Using this construct, the orthodontic treatment population can be represented by a bell-shaped curve, with the most favorable responders and adapters at one end and the most unfavorable at the other end. For the most part, patients who are presented at meetings as the dramatic successes and failures are merely the outliers on a normal distribution curve. Any individual's position on that curve will be determined, to a great extent, by soft tissue influences on the treatment process and outcome.

Limitations, of course, also relate to the hazards of orthodontic treatment. Known hazards include root resorption, decalcification, pulpal devitalization, fenestrations or dehiscences of alveolar cortical plates, and general alveolar bone loss. It must be kept in mind that some patients are more susceptible to these hazards than others, and advances in genetic analysis may clarify this.

Another major task for the orthodontist in treatment planning is to estimate the effectiveness and efficiency of possible treatment plans, so that the best combination of these important factors can be selected. This determination

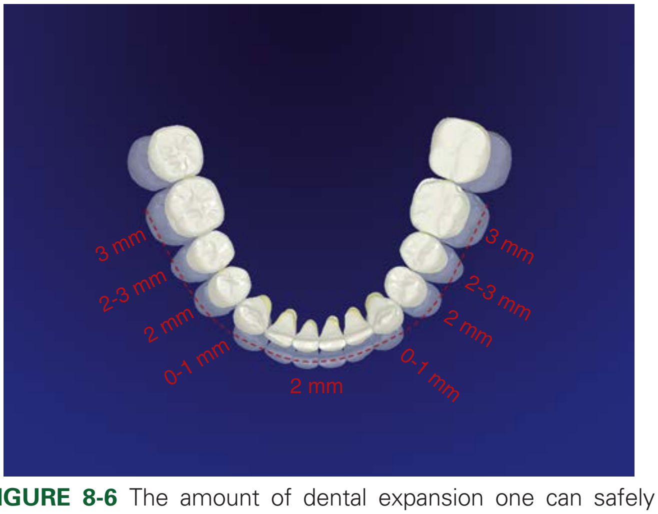

FIGURE 8-6 The amount of dental expansion one can safely achieve with orthodontics is related to three major factors: (1) stability, determined largely by the soft tissues; (2) appearance, particularly in regard to profile; and (3) the periodontium, particularly the labial cortical plate of bone and the amount of attached gingivae on the facial aspects of the tooth roots. These constraints make it infeasible to move the mandibular teeth facially more than 2 to 3 mm. To do otherwise would simply be an invitation for instability, unfavorable facial changes, and unfortunate periodontal sequelae. Of course, there are exceptions to every rule.

is the research goal of both careful retrospective studies of treatment outcomes and randomized prospective clinical trials when these are possible. For example, the now classic Class II clinical trials of recent years, which studied the response to early (preadolescent) versus later (adolescent) treatment, showed that despite some individuals responding well to early treatment, on average there was no significant difference in outcome between early two-stage and later one-stage treatment. Does that mean there should be no preadolescent Class II treatment? Of course not. It does mean that patients should be selected for preadolescent treatment for problems specific to that individual child. Relying on these types of data in planning treatment is what is meant by "evidence-based orthodontics."

PATIENT EVALUATION: THE DIAGNOSTIC PROCESS IN ORTHODONTICS

Overview of the Problem-Oriented Approach

Decision making in orthodontics requires the establishment of a prioritized problem list before considering treatment options. In this method, the prioritized problem list becomes the "diagnosis." Essential to the establishment of a complete problem list is the creation of an adequate database. The elements of the database are:

1. Questionnaire and interview data.
2. Clinical examination data including the systematic description of the patient's dentofacial traits (classification).
3. Data from diagnostic records (Fig. 8-7).

The problem list is derived from the database and is prioritized. Tentative solutions are then proposed for the individual problems. Favorable or unfavorable interactions among the tentative solutions are considered, and one or more alternative unified treatment plans are synthesized. The alternatives are presented to the patient, parent, or both, and with their input, an individualized treatment plan and mechanotherapy are established (Fig. 8-8).

The more systematically an orthodontist approaches the collection of adequate diagnostic data, and the more thoroughly he or she interprets these data in terms of expected treatment responses, the better the probabilities will be for successful correction. At the same time, it is necessary to keep in mind the inherent uncertainties in response to treatment so that there is no reluctance to adapt treatment to meet an unexpected turn of events.

Effective use of the problem-oriented approach in evaluation of orthodontic patients requires generation of an appropriate database prior to generating a problem list. In this context, appropriate simply means gathering the information needed for a specific patient. That can vary from a minimal amount when a modest problem in an adult merely requires enhancement, such as the ironing out of a few wrinkles in a smile, to a cone beam CT scan and/or TM joint magnetic resonance imaging (MRI) in a patient with a severe jaw discrepancy and impaired jaw function.

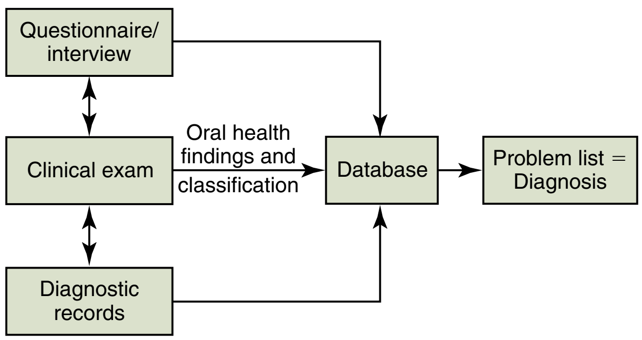

FIGURE 8-7 This flow chart shows the elements of the database and how a problem list is derived from the database. What has changed in recent years is that it is no longer considered necessary to have "complete" orthodontic records before systematically describing the patient's orthodontic condition. Today, the systematic description (i.e., classification) is accomplished during the clinical examination.

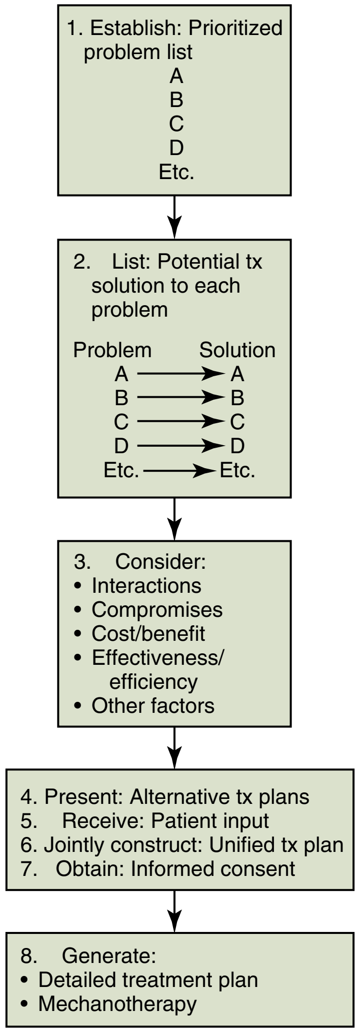

FIGURE 8-8 This flow chart outlines the eight steps that must be taken from the time a prioritized problem list is established to when a detailed treatment plan and mechanotherapy are generated. The essential components of the process are (1) being sufficiently careful to not overlook any aspect of the problem, (2) taking enough time to solicit patient–parent input, and (3) being certain that the patient–parent decision is an informed one. The number of visits required to accomplish these eight steps is determined by the complexity of the orthodontic condition and the orthodontist's practice management style.

Collection of Interview Data

First Contact

Data collection and development of the diagnostic database begin with the very first encounter with the patient or parent. This first contact is almost always by telephone, and important demographic information, including the e-mail address, should be obtained at this time. The patient's age, the source of the referral, the family dentist, and other patients and families whom the prospective patient knows are all clues regarding what the patient and family may already know of an orthodontist's practice. Obviously, if the call is to set up an appointment for the sibling of a patient already in the practice, there is usually instant rapport. If the prospective new patient is another patient's best friend in school, it is likely that she or he already has great awareness of the practice. Today, the majority of patients' parents have had orthodontics themselves, and it is generally easy to quickly integrate them into one's practice routine.

Just as it would be an error in taking for granted that the parent is an old hand at orthodontics, there is an equal danger of having the caller feel the receptionist is talking down to them. The ease or difficulty with which the receptionist can schedule the first appointment may indicate the types of demands this family may make and the cooperation that might be received in the future. All information should be entered directly into the office's computer system, including discrete notes regarding the receptionist's first impressions. When he or she takes the phone call, the receptionist should have a window opened on the computer screen that will serve as a checklist to guide in systematically collecting these data. Usually, the receptionist will be able to glean the motivation for treatment during the first call. This is the first step in building an orthodontic database.

At the end of the initial telephone call regarding scheduling a patient evaluation, the caller should be informed that if they would be kind enough to fill out a patient questionnaire and have it ready at the first visit, as it will greatly facilitate the initial appointment. The caller should have the option of downloading the questionnaire from the office website, having it e-mailed as an attachment, or having it mailed as a hard copy.

Interview at First Appointment

A well-designed patient information questionnaire allows the patient or parent to provide the medical and dental health history so that all positive findings prominently stand out. Then, a simple glance at the questionnaire alerts the clinician to the questions that require follow-up. A few major questions always must be asked. The first, of course, is when the patient last saw his or her physician. If it was within the past year and was for a regular checkup, this usually is a good sign.

Another important question is whether the patient has ever been hospitalized and, if so, for what reason. For prospective orthodontic patients, one usually includes a specific question as to whether the patient has had tonsillectomy, adenoidectomy, or both. This may be a clue that the patient had an earlier airway problem, which might have affected jaw and tongue posture. Sometimes the admission to the hospital was the result of trauma, and it is important to know whether the jaws, face, or teeth were involved. If the injury involved one or more teeth, a closer evaluation of the vitality of the teeth involved is clearly indicated, and the patient or parent should be made aware that orthodontic tooth movement can possibly exacerbate periapical symptoms. Because parents do not realize the relationship between overall health, dental health, and dentofacial development, persistence in pursuing these questions is important.

The next issue that must be considered is whether the patient is taking any medications. Occasionally parents are reluctant to inform the orthodontist in front of the child that seizures (epilepsy) has been a problem, but they will indicate that phenytoin (Dilantin) or some other anticonvulsant drug is being taken. This will not only influence the management of the child in regard to medical emergencies but also influence tooth movement if there is gingival hyperplasia. If a patient is taking medication typically prescribed for attention-deficit disorder, the issue of potential compliance with treatment should be explored further. If a patient has recently been prescribed isotretinoin (Accutane) for severe cystic acne, the orthodontist and patient should be aware that severe lip dryness with cracking is a common side effect of this medication and that becoming pregnant while taking Accutane is associated with a high risk of birth defects.[11] In adults being treated for arthritis or osteoporosis, high doses of prostaglandin inhibitors or resorption-inhibiting agents may impede orthodontic tooth movement. These examples should serve as a reminder that an orthodontist must know the contraindications of orthodontic treatment and be able to rule out that any of these factors are involved with any given patient.

Meeting the Patient and Eliciting the Chief Concern

Before the orthodontist meets the patient at the first appointment, the demographic and historical information should be reviewed, and photographs and a panoramic radiograph should be available. The advent of digital photography and radiography has markedly improved the ease and efficiency of obtaining these records immediately prior to the orthodontist meeting the patient.

Some practitioners prefer to have the parent present when he or she meets the patient; most find it advantageous to examine a child patient independently first and then invite the parent to the treatment area to receive the report. It is sometimes far easier to establish rapport with the patient if there is no parent present. "Helicopter" parents who insist on hovering over their children in every situation should be given the choice of being present if they wish. It is poor form for a staff member or orthodontist to say that the parent's presence or absence is an "office policy," because most people resent rigid adherence to some arbitrary rule.

At the first meeting, the orthodontist should not assume that appearance is the patient's major concern just because the teeth appear unattractive. Nor should the dentist focus on the functional implications of, for instance, a crossbite with a lateral shift, without appreciating the patient's concern about what seems to be a trivial space between the maxillary central incisors. As we have noted, for an individual with what appears to be reasonably normal function and appearance and appropriate psychosocial adaptation, the major reason for treatment may well be a desire to improve appearance "beyond normal." The greater orientation of modern family practice toward cosmetic dentistry increases the chance that a patient may be referred to an orthodontist for comprehensive treatment to improve dental and facial appearance.

From the outset, the orthodontist must determine whether the prospective patient is a suitable candidate for treatment, because there are notable exceptions to the validity of self-determination of the need for orthodontic intervention. An example is an adult patient with body dysmorphic disorder (BDD), which is a condition marked by excessive preoccupation with an imaginary or minor defect in a facial feature or localized part of the body.[12] These individuals almost always have unreasonable expectations as to how a change in one or more of their dentofacial features will alter their sense of social well-being and quality of life. They can be very persuasive, and they often goad health professionals into performing treatments against the professionals' better judgment. If BDD is suspected, the patient and the orthodontist are both well served by seeking a consultation with a mental health professional. Potential adult patients who might have a mild form of BDD may be more prevalent than currently suspected. The orthodontist also must be wary of parents (the "pageant mom") who push for early treatment with questionable benefit or adolescents who have unrealistic expectations about what orthodontic treatment might accomplish for them.

Perhaps the easiest and most direct way to find out how the patient feels about orthodontic treatment is to ask the simple question, "Do you think you will need braces?" Most children today think that braces are inevitable and thus usually answer affirmatively. Occasionally, the reaction is a shrug of the shoulders. Only rarely will a child say that although his (or her) parents think he should have braces, he does not want them. For the patient who responds with a shrug, the important follow-up question is, "If your parents and I think you will be helped by braces, will you go along with the recommendation?" Children or adolescents who do not appear to be motivated to have treatment rarely exercise good oral hygiene or elastic wear during treatment. From almost anyone's perspective, it is much more acceptable to have treatment that is done for you than to have treatment that is done to you. In this circumstance, there is merit in telling the parent that postponing treatment until the patient is either more mature or simply more motivated may be the best alternative.

For the individual who is convinced he or she will require orthodontics, an important question is whether any one feature is of greater concern than another. It is important to know this for two reasons. First, one of the most embarrassing mistakes an orthodontist can make is failing to address an issue that is of major concern to the patient. The orthodontist may or may not agree with the patient's assessment—that judgment comes later. At this stage, the objective is to find out what is important to the patient. Second, to allow for the most effective treatment planning, it is important to take into consideration what dentofacial trait or traits are most important to the patient or parent when prioritizing the problem list.

Clinical Evaluation

Facial Proportions and Appearance

Although the sequence of steps in completing the database can vary depending on the complexity of the case (see further discussion later), a comprehensive clinical examination usually follows immediately after the interview with the patient. The orthodontist should make some diagnostic determinations "from the doorway" regarding the patient's face, posture, and expression. One can often tell from the first moment whether the orthodontic problem will be largely a dental one or a difficult skeletal or facial problem.

The evaluation of facial appearance should be done with the patient's head in a natural head position (NHP) (i.e., standing or sitting up, looking at the horizon), not with the patient prone in a dental chair. To determine lip incompetence (more than 4-mm separation at rest), the frontal view should be assessed first in repose and then with the lips sealed, which would show evidence of lip strain to confirm incompetence. The patient is then observed during facial animation while speaking (when there should be 2-mm exposure of the teeth) and in a social (posed) smile (when there should be exposure of at least half the crown of the maxillary incisors but not more than 2 to 3 mm of gingiva). Greater exposure is expected in the spontaneous (gratification) smile. After all, it is ultimately anterior tooth display (the social smile zone) over which the orthodontist has the greatest control (see Chapter 9).

In assessing the face in its broadest context, one tries to rule out any genetic defects or partial expression of genetic defects. The distance separating the eyes can often give a clue to this kind of problem. In a number of genetic defects affecting the face and teeth, one frequently finds hypertelorism (eyes that are too far apart). Malformations of the ears may be associated with one of the brachial arch syndromes, which can affect the mandibular condyle.

Although orthodontists in private practice rarely treat patients with malformations other than cleft lip and/or palate, it is important to consider the possibility of other syndromes. A patient with severe mandibular retrognathia at age 15 years, for instance, may have had a Pierre Robin sequence and earlier in development may have had a more pronounced problem. Frequently, knowledge of this type does not markedly affect the treatment plan, but it does often temper the treatment goals based on therapeutic modifiability. Sometimes a surgical approach to treatment will be selected, based on the recognition that one is dealing with the result of a pathologic process rather than normal anatomic variation. For a more complete account of this subject, see Gorlin et al.[13]

After having assessed the overall head and face, the orthodontist then focuses on the lower face, which is most easily affected by tooth position. Lip prominence is evaluated relative to the nose and chin. A large nose and well-developed chin can easily mask what otherwise would be judged a protrusive dentition, and thereby keep it from being a problem. Similarly, the opposite situation of a small nose and weak chin can create a protrusion problem.

Although the facial photographs and lateral cephalogram that are obtained after the clinical examination are helpful in assessing certain aspects of facial appearance, some features must be examined chairside. Assessment of the dental midline as it relates to the midline of the face and the symmetry of the face are examples. Lip competence is another. Can the patient or does the patient keep his or her lips approximated when at rest, and is this done with ease or strain? Does the patient, when in repose or smiling, have a high upper lip line showing a wide band of gingiva? Chapped lips and inflamed gingiva in the maxillary anterior region are often indications of a patient who is a mouth breather or whose oral seal is inadequate because of extremely protrusive teeth.

Intraoral Examination

Health of hard and soft tissues. Once the visual and tactile examination of the face is complete, an evaluation should be made of the intraoral hard and soft tissues. This will immediately reveal the general oral health of the patient. Just as the orthodontist should view the overall health of the child broadly, he or she should also look at oral health from the broadest possible perspective. What has been the caries incidence? How faithful has the child been with home care, and, generally speaking, what is the oral health picture? Some orthodontists begin plaque control programs for children before initiating orthodontic treatment. In university clinics, patients are usually not accepted for treatment until they can demonstrate adequate home care. The experienced orthodontist knows that this is as fundamental to success in orthodontics as the appliance that is used.

Poor gingival health adversely affects tooth movement and may progress to a more significant periodontal problem. Most periodontal sequelae of orthodontic treatment are self-correcting once the orthodontic appliances are removed, but enamel decalcification resulting from poor hygiene can mar an otherwise beautiful orthodontic result. It has been suspected that systemic disorders such as allergies may be associated with root resorption, but when this hypothesis was tested, no statistically significant correlations were found.[14] It is believed that prolonged treatment can increase the risk of root resorption, devitalization, and obliteration of the pulp chambers, although at present little is known about the undoubted molecular genetic basis underlying these processes. Hazards of orthodontic treatment of this type can be minimized with careful diagnosis and treatment planning.

As part of visual and tactile examination of the dentition, it is important to count the teeth. It is particularly easy to overlook a missing lower incisor. A quick check should be made for mobility of primary or permanent teeth. In the mixed dentition, one should palpate for unerupted canines, since it often is not possible to ascertain from the radiographs whether these teeth are erupting labially or lingually. Ankylosed primary teeth usually appear submerged. Tapping these teeth with the handle of a dental instrument usually produces a somewhat higher "ring" than a normal tooth. Any other abnormalities of the hard tissues should be noted, such as enamel defects and internal or external root resorption.

Examination of the intraoral soft tissues for a prospective orthodontic patient begins with checking the buccal and labial mucosa, the tongue and sublingual areas for possible abnormalities. Significant oral pathology in children is a rare finding. However, the orthodontist should take particular note of unusual frenum attachments. Two points should be noted: (1) Is there a heavy frenum attachment in the area of a maxillary midline diastema? The diastema may or may not be caused by the frenum in such cases, and surgical removal of the frenum by itself is not effective in closing the diastema. Orthodontists often recommend frenum removal after closing the diastema and laser surgery now is often recommended; the extent to which this is helpful is not well documented and remains controversial.[15] (2) Is there gingival clefting or recession in the lower incisor region near a high frenum attachment? Such an attachment often causes periodontal problems, and surgical repositioning of a frenum of this type is indicated, perhaps in conjunction with a free gingival graft to prevent further recession.

Gingivitis is relatively common in children; it is generally due to poor oral hygiene, although it can be exacerbated by faulty tooth alignment such as a high labially positioned maxillary canine. Severe periodontal problems, however, are uncommon in children even in the presence of severe malocclusion, and discovery of bone loss should lead to suspicion of underlying systemic illness such as diabetes, hormonal imbalances, or blood dyscrasias. Occasionally, aggressive juvenile periodontitis (rapid bone loss around central incisors and first molars for no apparent cause) is observed in children referred for orthodontic treatment. Although periodontal treatment methods have improved and a recurrence of this problem is unlikely to recur after treatment,[16] the prognosis for involved teeth in this situation is questionable, and orthodontic treatment may be indicated to prepare the patient for ultimate prosthetic replacements.

Two other periodontal problems often are observed in patients who are candidates for orthodontic treatment. These are clefts of the gingiva around severely protrusive or badly rotated mandibular incisors and gingival hyperplasia and fibrosis in children on seizure medication such as Dilantin. Patients who have gingival clefts and poor oral physiotherapy will frequently require periodontal surgery to provide a wider zone of attached gingiva, while those on Dilantin or equivalent drugs may require gingivectomy or gingivoplasty while under orthodontic treatment. Both types of periodontal surgeries can be performed while orthodontic appliances are in place, but early consultation with the family dentist or periodontist is necessary before proceeding with an orthodontic treatment plan. New surgical techniques with lasers can deal effectively with removing excess gingiva such as an operculum distal to a permanent second molar or performing a soft tissue uncovering of an unerupted tooth.[17]

In adults and children, the orthodontist should use a periodontal probe during the gingival evaluation. In a child, it is important to probe the sites of aggressive juvenile periodontitis: the maxillary molars and mandibular incisors. In an adult, bleeding on gently sweeping the probe along the gingival margin is an indication of a periodontal condition that can simply be marginal gingivitis on the one hand or more serious periodontal disease with loss of attachment and alveolar bone loss at the other extreme. It is not necessary to chart pocket depths. The goal is to see whether chronic inflammation that leads to easy bleeding is present. The basic principle is that orthodontic tooth movement in the absence of inflammation is similar to the physiologic response related to tooth migration or drift. If the same tooth movement is attempted in the presence of inflammation, the process becomes pathologic and more like periodontal breakdown and disease. Therefore, in adult patients, it is necessary for either the general dentist or a periodontist to perform initial periodontal preparation before orthodontics to eliminate any inflammation.

Soft tissue function. The size of the tongue is often hard to assess, but an attempt should be made to evaluate its general dimensions at rest and when protruded. It is important to ask the patient to raise the tongue to the roof of the mouth with the mouth open. Inability to do this suggests ankyloglossia, and the patient may benefit from surgery to allow better tongue movement.

Speech evaluation properly belongs in the hands of trained speech specialists, but sometimes parents seek orthodontic treatment as a way to help their child with speech problems, and an orthodontist should be able to discuss errors in speech that could be related to malocclusion versus those that are not (Table 8-1). Correcting the orthodontic condition is unlikely to remedy even related speech errors without associated speech therapy. Orthodontic treatment will, of course, have no effect on other common speech errors of children, such as substituting one sound for another.

Jaw function. An important part of the clinical examination is to establish the path of closure of the mandible and to determine if the maximum intercuspal position (centric occlusion) corresponds with the retruded contact position (centric relation). If these positions do not correspond, one should note any premature contacts and convenience shifts that

TABLE 8-1 Speech Difficulties Related to Malocclusion

Speech Sound	Problem	Related Malocclusion
/s/, /z/ (sibilants)	Lisp	Anterior open bite, large gap between incisors
/t/, /d/ (lingua-alveolar stops)	Difficulty in production	Irregular incisors, especially lingual position of maxillary incisors
/f/, /v/ (labiodental fricatives)	Distortion	Skeletal Class III
th, sh, ch (linguodental fricatives [voiced or voiceless])	Distortion	Anterior open bite

might exist. It is normal to have a 2-mm forward shift from the most retruded position; it is not normal to have a lateral shift. The patterns of wear on the cusps and incisal edges of teeth often indicate parafunctional movements of the jaws. Grinding or clenching of the teeth can affect orthodontic treatment, particularly in regard to the vertical dimension.

During the clinical examination, the TM joints should be palpated, and any crepitus or pain in the joints should be noted. Even when severe occlusal disharmonies are present, children presenting for orthodontic treatment rarely have TMD problems. The orthodontist is more likely to encounter these problems during or after treatment in older adolescents or in adults whose tolerance of muscular imbalances is reduced. The tolerance of children for occlusal disharmonies does not mean that these are unimportant in orthodontic diagnosis. It is particularly important that occlusal shifts and slides are detected and corrected during the orthodontic treatment. For a complete evaluation of TM joint function, the reader should refer to texts on this subject.[18]

Diagnostic Records

What Records Are Needed?

The final goal of the clinical evaluation is to determine what diagnostic records are needed for this particular patient. As we have noted above, it is neither necessary nor desirable to order the same set of records for every patient. As a rule, facial and intraoral photographs and a panoramic radiograph are needed for every patient (and are ordered before the orthodontist sees the patient so they can be available during the clinical examination). For some patients who will not receive comprehensive orthodontic treatment, everything else is optional except photographs of any soft tissue lesions that were noted in the clinical exam. For those who will be treated comprehensively, dental casts and a lateral cephalometric radiograph are added routinely; for those with impacted teeth, a small field-of-view (FOV) cone beam CT image is recommended; for those with asymmetry, a frontal ceph and often a large FOV cone beam CT is needed; for those with suspected injury or pathology within the TM joint, MRI is indicated.

Virtual versus physical dental casts. Taking impressions and pouring up dental casts is rapidly being superseded by obtaining digital images directly from intraoral scans, and storage of dental casts now has been almost completely eliminated by scanning casts and analyzing the resulting virtual images. It doesn't matter whether virtual or physical casts are obtained—it does matter that 3D rather than 2D images of the occlusal surfaces are obtained (i.e., just photographs are not good enough).

An initial complaint regarding virtual models is the lack of "haptic" feel as the clinician articulates the models, but they have gained popularity because of their convenience. In practices where 75 to 100 or more patients are seen each day, the task of "pulling models" becomes onerous for the orthodontic staff. In a multioffice practice where patients are occasionally seen at more than one location, the innovation of using all digital records and cloud-based storage has been a real boon. Scanning methodology to obtain virtual models is discussed below in the technologic advances section.

Head orientation for cephalograms. In modern cephalometrics, it is important that the cephalograms are obtained with the head oriented in NHP rather than automatically using the ear rods to establish the sagittal orientation and the Frankfort plane to establish vertical orientation. NHP is the orientation of the head that one presents to the world. It is obtained by having the relaxed patient look at the horizon or, more practically in an enclosed X-ray room, into his or her own eyes in a mirror.

The more severe the facial anomaly, the more likely it is that unthinking use of a cephalostat will produce an image in a distorted head position. For most patients, the ears are bilaterally symmetrical, and a line between them represents the true transverse axis, so using ear rods does not put the head in an unnatural orientation, but it is important to evaluate this. If the ears are not symmetric, putting the ear rod only in the right ear (to establish the distance between the X-ray source and patient) and then establishing head position (using the mirror) can prevent distortion.

Similarly, for most patients, Frankfort plane is a good estimator of the true horizontal plane, but for a significant number of patients, the true horizontal deviates from Frankfort, and it can be difficult to orient the head with Frankfort level. It is much better to let the patient orient the head while looking into the mirror and then fix that position with the anterior bar of the cephalostat. This also can be done using only one ear rod if necessary.

Additional records. Technologic advances have significantly added to the possible additional records that could be obtained. They are considered in detail in the following section.

Technologic Advances in Diagnosis

New methods that have affected current orthodontic practice and have even greater potential for changing the way orthodontists will practice in the future include digital photography, videography, 3D photography, computer imaging, virtual dental models, cone beam computed tomography, stereolithographic models, custom milling of attachments, and robotic wire bending. Nonetheless, technologic innovations should not be confused with fundamental changes in orthodontic thinking. It is similar to when recorded music became digital. The tone of the music improved, but the tune remained the same. This can be the litmus test for a clinician considering the adoption of any new technology. Will it change the tune or simply the tone? Only time tell which technology will survive. The new technologies in orthodontics are summarized next.

Digital photography, videography, and 3D photography. The conversion of photography from an analog to a digital process has revolutionized imaging in all fields, with orthodontics very much the beneficiary of this stunning technologic advance. The ability of digital video to capture the dynamics of anterior tooth display during speech and smiling has not yet been fully embraced by orthodontists despite the potential value of viewing the rapid changes that occur during function. This appears to be a rational judgment because current studies do not indicate that digital video is significantly better than clinical photography in evaluating smile characteristics.[19]

3D facial photography had great promise for orthodontic applications when it was introduced in the early twenty-first century, but this technology also has yet to live up to its potential. Soft tissue asymmetries can be evaluated more precisely with 3D photography and imaging mirroring software, but the benefit to the patient is limited unless major surgical interventions are planned. Perhaps the best use of this technology lies with research. Initially it was touted as a noninvasive, radiation-free method for quantification of longitudinal soft tissue changes during growth; it is more often used now to evaluate posttreatment soft tissue outcomes, especially with surgical correction of cleft lip/palate and facial syndromes.[20] One must be cautious, however, when interpreting longitudinal data obtained from 3D photography studies because registration on stable soft tissue regions still presents a major challenge.

Another growing area of research utilizing this technology is 3D facial norms, initially developed by Coenraad Moorrees. Improvements in spherical harmonic algorithms and their availability through NIH-funded centers (Fasebase.org) will make 3D population norms and morphometrics a reality in the near future. If and how these data will be used for clinical orthodontics remains unknown. Medicine is currently facing the same dilemma with so called personalized/precision medicine versus guideline-based medicine.[21]

Computer imaging. The ability to morph images with special computer software and the creation of algorithms that can simulate the facial outcomes of tooth and jaw movement provide an excellent treatment planning and communication tool in orthodontics[22] (Case Study 8-2).

This can be particularly useful in helping patients understand alternative treatment possibilities. That is the key to true informed consent and is discussed in more detail in that section below.

Cone beam computed tomography. Cone beam computed tomography (CBCT) produces 3D volumetric images that can be reliably measured.[23] Among the advantages of CBCT imaging are true-scale images without magnification artifacts, the ability to correct errors in head positioning after image capture, and being able to see around extraneous structures that would otherwise obscure the desired view. Surface reconstruction of CBCT images has greatly enhanced treatment planning for impacted canines and asymmetric craniofacial growth (Fig. 8-9). The ability to rotate and visualize an impacted canine in any manner around the x-, y-, and z-axes gives the clinician the information needed to bring the tooth into occlusion while avoiding damage to adjacent teeth. The same approach can be applied to virtual surgery to correct jaw asymmetries. By merging digital models of the teeth with CBCT skeletal data, surgeons can better visualize precise surgical movements as well as the impact of these movements to the soft tissue.

This technology has opened new avenues of orthodontic research. New data are emerging from CBCT studies that give us a better understanding of how the TM joint, sutures of the midface, and airway are affected with orthodontic and orthopedic appliances. Yet, this technology is not without cost. The typical CBCT scan has 3 to 20 times the radiation dose of digital panoramic and cephalometric radiographs, and the stochastic effect of radiation on growing children is not fully understood. Practicing clinicians should adhere to the principles of ALARA (As Low As Reasonably Achievable), balancing between radiation risks and the benefits of having more information. While the risk-benefit ratio in diagnosis and treatment planning for impacted canines and jaw asymmetries is high enough to justify CBCT, it is questionable that CBCT scanning of patients without impacted teeth or major jaw discrepancies provides enough additional benefit to the patient to justify the increased radiation. Unfortunately, low-dose CBCT units to this point are not the answer to this problem, because often the decreased radiation comes at the expense of image quality.

Intraoral scanning. Plaster models of the teeth have been used to obtain 3D diagnostic records since the beginning of orthodontics. The advent of laser-scanned dental impressions and more recently intraoral scanning to produce a three-dimensional image of the teeth overcomes the problem of having to pour and trim plaster casts, while eliminating a major component of laboratory work and the need to store and retrieve the models for use when patients are seen. Now it is possible to view a virtual dentition on a computer screen by rotating the virtual models to allow the same type of 3D view as hand-held models. The accuracy of these virtual models for tooth setups in planning treatment is acceptable, but care must be taken to avoid inadvertent reduction in tooth width because of overlap in the digital images.[24]

Intraoral scanning is among the faster growing technologies in dentistry, and some foresee the end of impressions and casts. These scanners incorporate a variety of technologic modalities ranging from light-based to red or blue laser-based emitters combined with 3D stitching software to create a virtual model of the dentition and adjacent gingiva. However, the scan time and discomfort to patients is higher when compared to conventional impressions.[25] Scan times vary depending on the unit but typically range from 7 to 15 minutes, too long for patient comfort, although emerging technology will further decrease this. Much like the arms race between VHS and Betamax in the early 80s or Blu-ray versus HD-DVD in recent years, the better technology might not emerge as the winner, and only time will decide which technology gains mass acceptance in the orthodontic community.

Software for virtual dental models has emerged rapidly in recent years (Fig. 8-10). Semi-automated software can measure for arch length and Bolton discrepancies, and multiple virtual treatment setups can be performed with minimal effort. One of the biggest advantages of virtual models is fabrication efficiency when combined with other 3D commercial CAD-CAM products. Initially, records for Invisalign or Insignia CAD-CAM brackets were PVS impressions that were sent to the company's lab, digitized, and a virtual setup created for the clinician's approval. Intraoral scanning and cloud-based uploading has decreased the time for this process from weeks to days. Furthermore, 3D tooth movement software allows the clinician to change the virtual treatment setup in any manner without the need for communication with the laboratory technician.

In a somewhat humorous vein, it is interesting how deeply ingrained orthodontic traditions and rituals are, such as insisting on having simulated plaster bases on virtual orthodontic models. Edges and angles on conventional plaster models served two purposes: the back sides were trimmed to establish

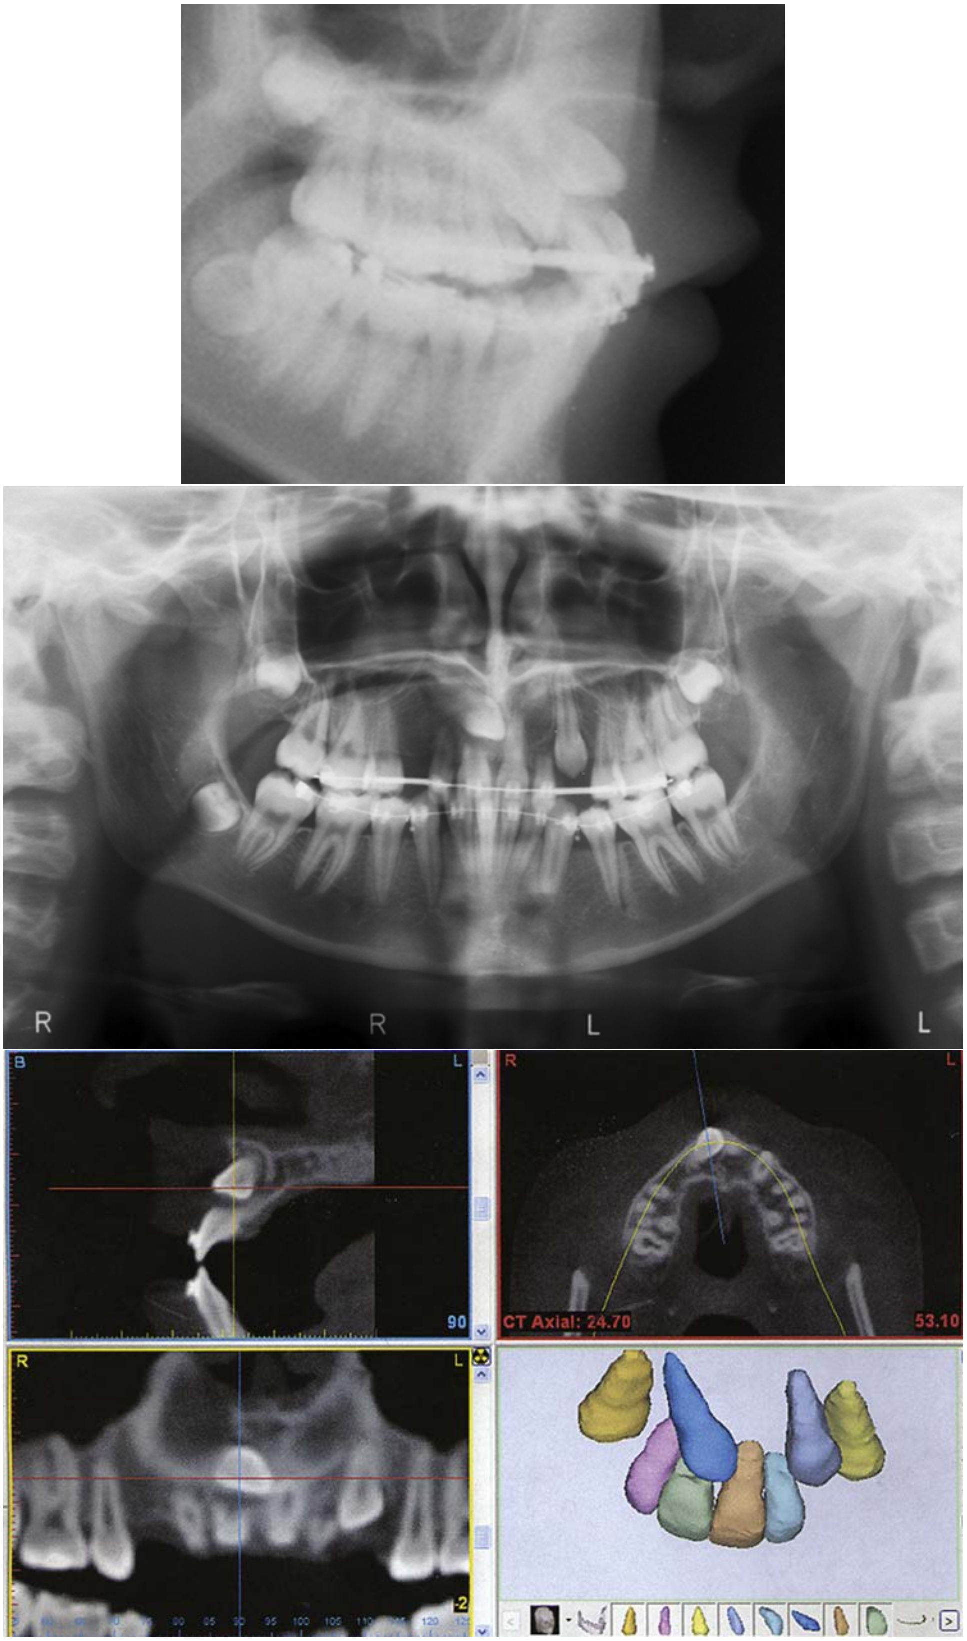

FIGURE 8-9 3D radiographic imaging with CBCT can be a valuable adjunct to panoramic radiography and periapical localizing films in assessing impacted canines. For this patient, although the position of the impacted canine and the significant resorption of the root of the central incisor can be seen clearly from the panoramic image and from the lateral cephalogram, the 3D images add important information as to the path the canine would have to be moved to avoid further damage to the root of the central incisor if it is to be saved, and whether it would be prudent to try to save the incisor or extract it. For difficult situations like this one, 3D imaging now is indicated.

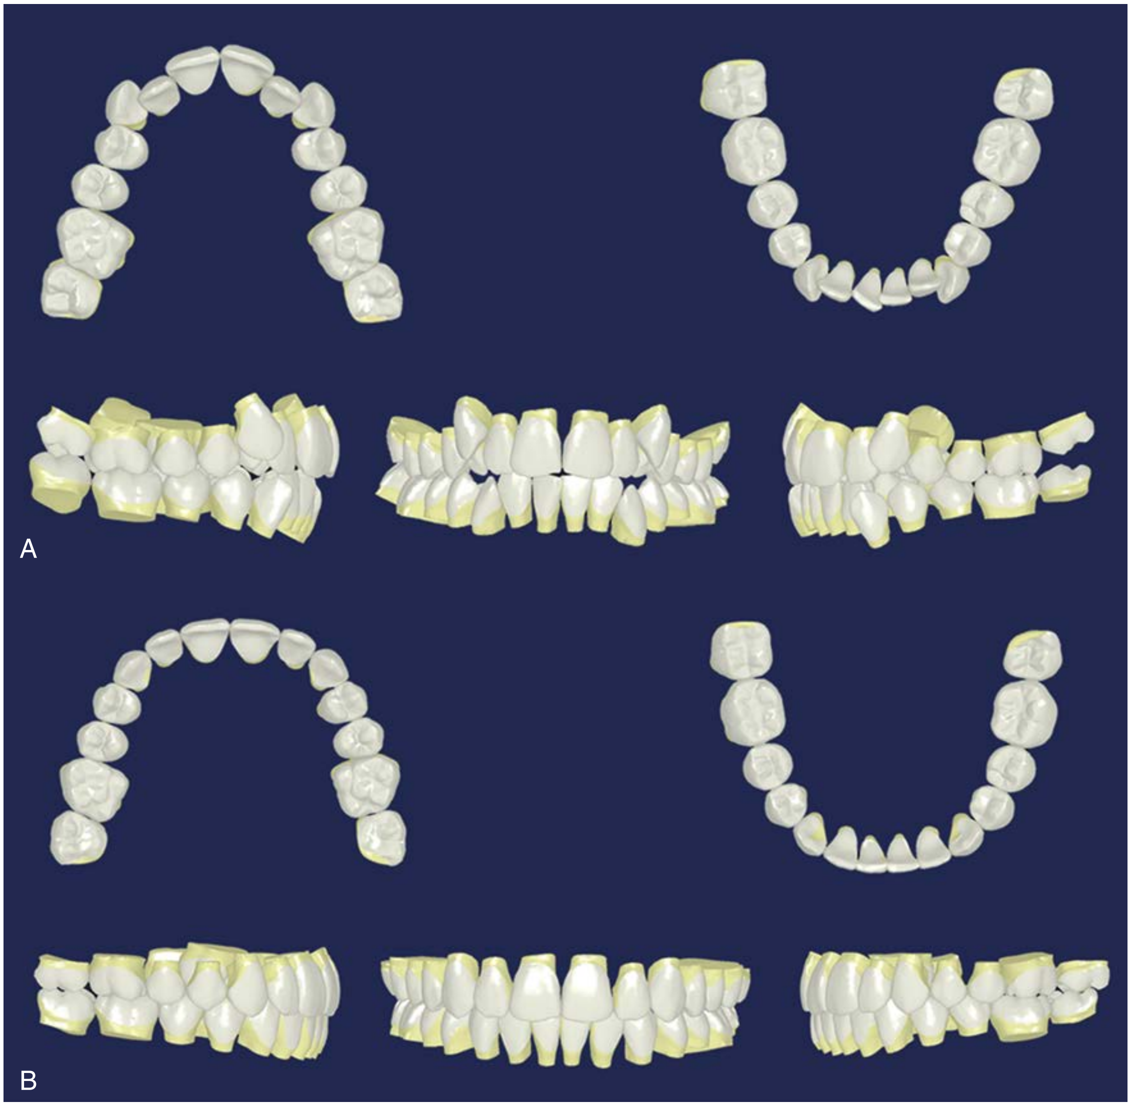

FIGURE 8-10 For complex orthodontic problems or borderline extraction cases, it is sometimes useful in diagnosis and treatment planning to look at 3D (virtual) setups. **A,** A virtual scan of the initial malocclusion and nonextraction digital setup (**B**) can be performed digitally by the clinician with 3D Imaging software or through commercial vendors.

the occlusal relationships, and the symmetric base made it more obvious if the dental arches were asymmetric. Today, the dental occlusion is documented within the software, but the bases are primarily decorative yet they remain.

By far the greatest limitation of plaster casts and virtual models is that although they are excellent facsimiles of the crowns of teeth, they give no clue about three important traits:

1. The inclinations of tooth roots in relationship to their alveolar housing. After all, the critical elements in the biology of tooth movement are the tooth roots in relationship to their surrounding bone.
2. The relationship of tooth crowns to the soft tissues of the tongue and lips. In the long run, it is this relationship that determines functional stability of the dentition.
3. The relative inclinations of tooth crowns in relation to the overall skeletal and soft tissue facial framework. In the end, dentofacial appearance is a critical factor in assessing orthodontic outcome.

Emerging technology from SureSmile and other companies is aimed at overcoming these limitations by merging CBCTs with intraoral scans. A successful system of this type will be a step toward defining the biological bony limits of tooth movement and give us quantifiable outcomes such as tip and torque. Like any new technology, this needs to be validated with scientific rigor—and the question of risk versus benefit remains when adding CBCT to the standard orthodontic records.

Analysis of Diagnostic Records

Analysis of the diagnostic records is the final step in assembling the diagnostic database. This is best discussed in the context of analyzing dental alignment and occlusion from the dental casts; evaluating jaw relationships and tooth–jaw relationships (i.e., how the maxillary teeth relate to the maxilla and the mandibular teeth relate to the mandible); and analyzing 3D images when indicated to obtain a more detailed picture of skeletal and dental relationships.

Cast Analysis

Analysis of the dental casts was the key diagnostic procedure in Edward Angle's era and was used to generate the appropriate Angle classification. From the beginning, that had to be supplemented with information as to the location and severity of dental crowding. In the mid-twentieth century, after cephalometric radiography turned from a research tool for investigation of facial growth into a clinical tool, skeletal and dental components of malocclusion were differentiated, and cast analysis was relegated to a secondary position.

It still is valuable, however, to evaluate the location and severity of dental crowding and to evaluate tooth-size relationships within the dental arches. Both of these now can be done more easily with virtual casts (digital images) than with physical ones. Quantification of crowding is a component, but certainly not the deciding one, of the decision to expand the dental arches or obtain additional space by extraction. Most patients do not have a tooth-size discrepancy, but it is critically important to know whether they do. In a modern orthodontic practice, the amount of crowding in each arch and the amount/location of tooth-size discrepancy should be measured and added to the database as discrete measurements.

Cephalometric Analysis

Development of clinical cephalometrics. It is not possible to establish the true nature of a malocclusion without information about the underlying skeletal relationships, and this cannot be gained from dental casts or photographs. Prior to cephalometrics, these relationships were evaluated (usually quite well) from the patient's soft tissue profile and general appearance. Cephalometric analysis in modern usage provides more detail about dental and skeletal relationships, but it still supplements rather than supplants a careful clinical evaluation of the patient. At best, the radiographic image (often referred to as a cephalogram) is merely a static 2D representation of the hard tissues involved in a complex 3D system.

The problem in using cephalograms to obtain clinically useful information is that the image contains far too much information. The initial solution was to use tracings of clearly defined structures as researchers had done and then use angles and distances between landmarks on the tracing to evaluate relationships between structures. A small set of these measurements then was chosen to compare a specific patient to "normal" individuals (those with ideal occlusion), so that the patient could be described relative to the Angle classifications and subclassifications.

With the proliferation of named analyses (just different sets of measurements) as time passed, analyses began to become ends in themselves instead of guides in making decisions about relationships. Since the typical cephalometric analysis chooses one or two specific measurements from the multitude of measurements that might be used to evaluate a single criterion, there is not and will not be any single analysis that is ideal for every patient. Instead, certain measurements will be useful in providing information about certain patients but not so useful for others.

An alternative way to compare an individual patient with normal controls is to compare the patient's tracing to a composite image based on a group of normal patients, i.e., with landmark positions and relationships created from an average of the group. Despite the difficulty of doing this manually, templates based on a normal reference group (from the Bolton growth study and later from other growth studies) were created. Doing the comparison of the reference and patient tracings is more intuitive than using measurements, because it does not require a digital-to-analog conversion of data—and the human brain is an analog computer, not a digital instrument. Template superimpositions, however, were never used for cephalometric analysis by most orthodontists.

With the replacement of X-ray films with digital X-ray images, manual tracing of films was replaced by landmark identification on a computer screen. Although good data do not exist, it is generally conceded that landmark identification on the digital images is not better than it was previously and probably not as good. It is much easier and faster, however, to have the computer make angular and linear measurements. The advent of digitized landmarks and multiple measurements has made it easy to assess a cephalogram using many different analyses—and to become confused by contradictory interpretations of the measurements among the varied analyses. For detailed information about cephalometric landmarks and the measurements incorporated into various analyses, the reader is referred to Chapter 6 in *Contemporary Orthodontics*[1] and textbooks that focus on cephalometrics.[26,27] One could, of course, superimpose a reference template on the image on the computer screen and just look at it, but that rarely is done.

Goals of modern cephalometric analysis. In this chapter, we wish to emphasize that it is the relationships between skeletal and dental units and not any particular set of measurements that should be evaluated for a given patient. This concept is most easily grasped in terms of block diagrams of the relationships in question (Fig. 8-11). There are five key units in understanding anteroposterior and vertical relationships: the cranial base, maxilla, maxillary dentition, mandibular dentition, and mandible. Although orthodontists are primarily concerned with the position of the teeth and the jaws, it must be kept in mind that there is no certainty that the cranial base will have escaped malformation in individuals who have deviations from ideal proportion elsewhere. It is safe to say that the greater the malocclusion severity, the greater is the chance that there will be deviations in the cranial base as well as in the jaws and the teeth.

Can a series of small deviations in relationships as evaluated cephalometrically add up to a big problem? Can a large deviation in one relationship be compensated by a series of small deviations in other relationships? The answer to both questions is yes. This concept of potential dental and skeletal counterpart compensations that take place during growth of the dentofacial complex is best illustrated by Enlow's classic diagram (Fig. 8-12).

Perhaps the modern approach to cephalometric analysis, developing the ability to evaluate the pattern of relationships that exist for individual patients, is best put into perspective in the context of what now is called "learning to see data." The characteristic of experts in many fields is their ability to quickly view a series of gauges, dials or images and pick out patterns in what initially is a confusing, almost chaotic overload of information. For an experienced orthodontist, a look at a cephalometric radiograph is enough to understand the pattern of dental and skeletal relationships without relying on a series of measurements. Psychologists call this perceptual learning. Recent work has demonstrated that having students (in this case, airplane pilots) repeatedly scan a set of instruments and receive immediate feedback as to what the pattern indicates greatly reduces the time to reach the expert level. Future instruction in

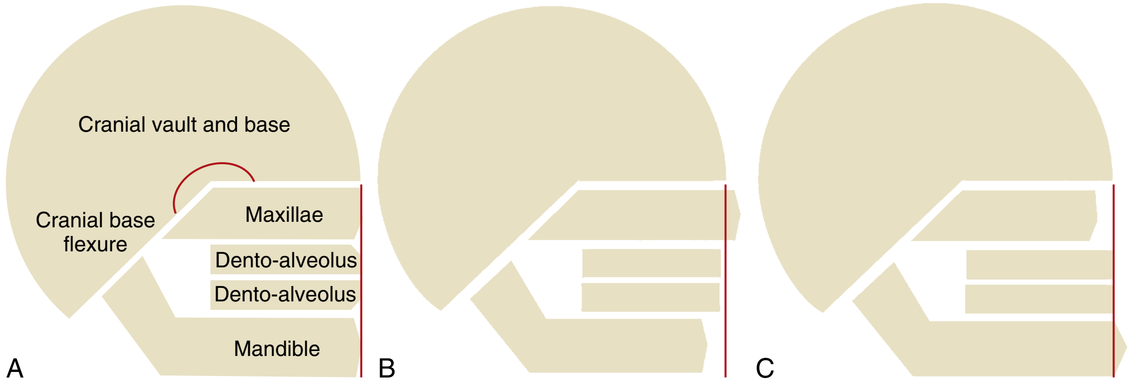

FIGURE 8-11 A, Schematic representation of normal jaw proportions and ideal dental relationships. B, Schematic depiction of a jaw disproportion characterized by maxillary excess and mandibular retrusion, yet ideal dental relationships. C, Schematic showing a jaw disproportion characterized by maxillary deficiency and mandibular excess. Again, in this illustration normal occlusion is due to dentoalveolar compensation.

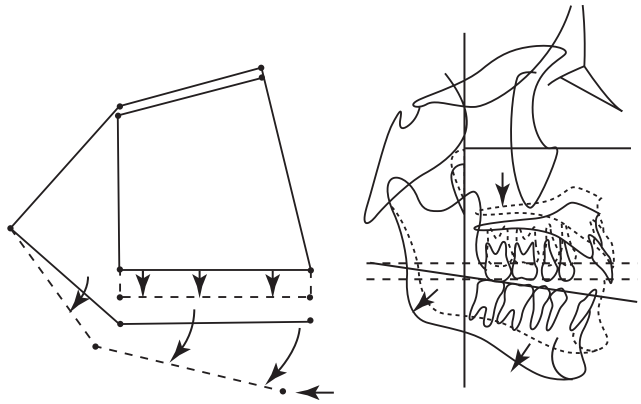

FIGURE 8-12 Enlow proposed that without dental and skeletal counterpart compensations for underlying jaw disproportions, malocclusion results. This example shows a hypothetical situation simulating exuberant vertical growth of the maxillae and dentoalveolus, which in turn caused the mandible to rotate backward causing a concomitant anteroposterior jaw discrepancy with no dental compensation, producing a Class II skeletal and dental open bite malocclusion. (From Enlow DH. *Essentials of Facial Growth*. 4th ed. Philadelphia: WB Saunders; 1996.)

cephalometric analysis undoubtedly will be based more strongly on this type of feedback. After all, perceiving patterns, not making measurements, is the diagnostic goal. Following is a brief description of the type of information regarding the anteroposterior and vertical dental and skeletal relationships that can be gleaned from a lateral cephalogram (mostly by just looking at it with a trained eye) and added to the database for a patient.

Evaluation of Class II malocclusion. In any patient, a Class II dental relationship may be due to any combination of four major factors: (1) maxillary skeletal excess, (2) maxillary dental excess, (3) mandibular skeletal deficiency, and (4) mandibular dental deficiency.

Maxillary skeletal excess can also be called midface protrusion, and the increased facial convexity that accompanies it is one of the easy ways to recognize it. Nasal prominence, heavy orbital and malar ridges, and increased convexity of the facial profile occur together in true midface protrusion. Unless there is a compensating malposition of the maxillary dentition, skeletal maxillary excess or midface protrusion will have a naturally accompanying maxillary dental protrusion as well. Once the relationship of the maxilla to the cranial base has been examined, it is necessary to examine additionally only the relationship of the maxillary dentition to the overlying maxilla.

Since Angle's concepts continue to color our view of the primary anatomic cause of Class II malocclusion, there has been a concentration of attention on mandibular deficiency. The dental occlusion would be the same whether the mandible were small in absolute terms, of reasonably normal size but positioned distally, or rotated so that its effective length was reduced. The latter situation represents an interaction between sagittal and vertical components. McNamara's method of cephalometric evaluation can be credited with making orthodontists aware of the fact that more Class II malocclusions result from mandibular deficiency than maxillary excess.[28] A patient can have Class I occlusion as the result of overclosure of the mandible with short lower face height and a dental deep bite. These individuals are said to have "masked" Class II skeletal patterns. Using Enlow's terminology, these people have had compensatory counterpart alterations in the sagittal and vertical relationships of the teeth and jaws, masking the true nature of the problem.

Mandibular dental deficiency is obvious from the dental casts where there are either small or missing teeth or both. It is possible for the dentition to be relatively deficient, however, in terms of being positioned distally on the mandible. In Class II malocclusion, this can occur simultaneously with protrusion of maxillary incisors as one often finds in inveterate thumb suckers.

Evaluation of Class III malocclusion. Measurements to provide recognition of maxillary skeletal deficiency or midface retrusion rarely are included in traditional cephalometric analyses, and if this is suspected, visual observations of the relationship of the maxilla to a true vertical line dropped from nasion can be helpful. A mandible that is rotated and overclosed can simulate mandibular skeletal excess. The interaction between the sagittal and vertical deviations makes it important to consider the effect of the vertical on sagittal relationships in Class III and Class II patients.

Vertical skeletal problems. The Angle classification focused cephalometric attention on the anteroposterior plane of space

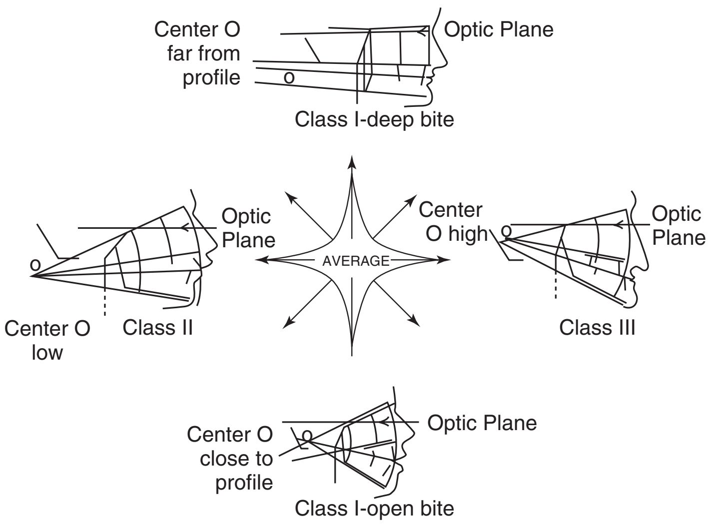

FIGURE 8-13 Sassouni's major contribution to cephalometric analysis was his observation that the relative parallelness or convergence of the horizontal planes of the face—i.e., the anterior cranial base, palatal plane, occlusal plane, and mandibular plane—are related to anterior and posterior face height and frequently reflects a tendency toward deep bite or open bite as seen in Sassouni's original diagram. The more parallel the planes, the greater the deep bite tendency. His "Center O" (outlined in yellow) is the approximation of where the planes converge posteriorly. The theory is that the further Center O is from the profile, the less convergent are the planes. This is seen most dramatically in the Class I deep bite and open bite representations. Note that the profiles in this schematic drawing coincide with those in Figure 8-18. (Modified from Sassouni V. The Class II syndrome: differential diagnosis and treatment. *Angle Orthod* 1970;40:334–341.)

and directed attention away from the vertical plane of space. Much work has been spent on correcting this disproportionate emphasis, but cephalometric standards for vertical relationships remain less well developed than anteroposterior standards. Four major vertical problems exist: (1) anterior open bite, (2) anterior deep bite, (3) posterior open bite, and (4) posterior collapsed bite with overclosure. As with the sagittal and transverse planes of space, skeletal and dental effects must be distinguished to make an accurate evaluation of the situation. Since bite depth is determined by the contact relationships of the teeth, the terms *skeletal open bite* or *skeletal deep bite,* in a sense, are inherent contradictions.

This leads to the first method for detection of vertical dysplasia—namely, measuring anterior face height. Both anterior and posterior skeletal vertical dimensions need to be examined, however, and analysis of the posterior vertical is not done easily. No outstanding method of establishing posterior vertical standards has yet emerged.

Another method for evaluating vertical proportions relies on the convergence or divergence of the mandibular, occlusal, and palatal planes, as suggested by Sassouni (Fig. 8-13).[29] If these three planes converge acutely and meet at a point close behind the face, posterior vertical dimensions are relatively smaller than anterior vertical ones. This produces a skeletal tendency toward anterior open bite, which is now routinely called *skeletal open bite.* It also implies a short ramus and an obtuse gonial angle, although these features do not necessarily have to be present. The open bite tendency is accentuated if the palatal plane is tipped up anteriorly and down posteriorly, a condition that is seen often enough to demonstrate that the skeletal problems leading to open bite are not exclusively in mandibular positioning.

Palatal, occlusal, and mandibular planes that run almost parallel to each other, on the other hand, lead to a skeletal predilection toward anterior deep bite. Individuals with this condition tend to have a longer ramus and a nearly perpendicular gonial angle. The Wits cephalometric analysis[30] recognizes that the relationship of the anteroposterior cant (pitch) of the occlusal plane in relationship to the maxillae and mandible offers a strong clue about the sagittal relationship of the jaws.

The interaction between sagittal and vertical factors is perhaps nowhere seen better than in the person who has a short ramus, steep and convergent mandibular plane angle, and a Class II malocclusion including elements of true as well as relative mandibular deficiency. The label is Class II malocclusion in such a patient, but the problem is frequently more a vertical than a horizontal one. Especially as such patients reach their adult years, even surgical correction can be very difficult and relapse tendencies can be great. The interaction between sagittal and vertical problems extends into an interaction between these factors and the structure of the cranial base.

Vertical dental problems. Dental vertical problems refer to too much or too little eruption of teeth in relation to their own supporting bone. A common example is excessive eruption of mandibular incisors, which is a usual concomitant of most Class II malocclusions. The lower incisors continue to erupt past the anteriorly positioned upper incisors and frequently contact the palate. If there are no skeletal vertical disproportions, this will be observed as a lengthening of the distance from the apex of the mandibular incisor roots to the lower border of the mandible.

Similarly, an open bite may be caused by insufficient incisors in either arch. This can be seen cephalometrically by a decrease in the distance from the incisor to the mandibular plane or palatal plane. Overall proportions must be taken into account in judging this, since excessive eruption of posterior teeth is also a factor in open bites. The relationship of the upper molar roots to the height of the palatal vault, which is easily observed cephalometrically, can be a great help in evaluation. The root apices of the upper molar in an adult should be at 2 to 3 mm below the height of the palatal vault. Distances in excess of this indicate excessive eruption; roots that are above the height of the palatal vault indicate a deficiency in eruption.

If anterior teeth meet and posterior teeth do not, there is by definition a posterior open bite, which is almost always related to failure of dentoalveolar development in one or both arches. In this situation, the orthodontist must rule out the possibility of primary failure of eruption (PFE).[31,32] PFE is characterized by a nonsyndromic eruption failure of secondary teeth in the absence of mechanical obstruction. The hallmark features of this condition are (1) infraocclusion of affected teeth, (2) increasing significant posterior open bite malocclusion accompanying normal vertical facial growth, and (3) inability to move affected teeth orthodontically. At the present time it has no orthodontic or surgical remedy—the unerupted teeth do not respond to orthodontic force, and repositioning them surgically rarely is practical.

If eruption of both anterior and posterior teeth is deficient, the result will be an overclosure of the mandible. This can be established by evaluating anterior facial proportions and confirmed from an excessive freeway space.

Classification: Organizing the Database

Angle Classification

Even though several treatises on orthodontics had already been written by the beginning of the twentieth century, these authors had no acceptable method for describing irregularities and abnormal relationships of the teeth and jaws. The Angle classification, described at the beginning of this chapter, was readily accepted by the dental profession, because it was simple and brought order out of what previously had been confusion regarding dental relationships.

It was recognized almost immediately, however, that there were deficiencies in the Angle system. In 1912, a report to the British Society for the Study of Orthodontics suggested that malocclusions be classified with regard to deviations in the transverse dimension, the sagittal dimension, and the vertical dimension.[33] Critics also pointed out that Angle's method disregarded, both in classification and in treatment planning, the relationship of the teeth to the face.[34] In the 1920s, Simon, in a technique he called *gnathostatics,* used a facebow transfer and mounting to relate the dental models to the rest of the face and cranium in all three planes of space.[35] Simon's facial reference line (the Frankfort plane) was more rational than Angle's skeletal reference, the key ridge (the lowest extent of the zygomaticomaxillary suture).

If it had not been for the introduction of cephalometrics in the 1930 and 1940s, gnathostatics probably would have made a more lasting impact on orthodontics. With the advent of the lateral cephalogram, many of the relationships that could be determined from gnathostatic casts could more easily be observed on a cephalometric radiograph. Arguably, radiographic cephalometrics, although an important milestone in the evolution of orthodontics, in many ways hindered viewing the teeth and jaws as a 3D issue.

As orthodontic treatment became more widespread and treatment possibilities other than arch expansion were considered, several other problems with the Angle classification emerged, all of which revolved around its narrow focus on the dentition and absence of a diagnosis that points logically to a treatment plan. This difficulty becomes apparent when it is recognized that malocclusions having the same Angle classification may, indeed, be only analogous (having only the same occlusal relationships) rather than homologous (having all characteristics in common). Despite the informal additions to Angle's system that most orthodontists use, there is a tendency to treat malocclusions of the same classification in a similar manner. Homologous malocclusions require similar treatment plans, whereas analogous malocclusions may require different treatment approaches. Some poor responses to treatment are undoubtedly related to this fault in diagnosis.

Figure 8-14 illustrates two nearly identical Angle Class II, Division 1 malocclusions in children of the same age. There are differences in skeletal proportions and in the relationships of the teeth to their respective jaws, both of which affect the profile, and the two cases should not be treated exactly the same. These are analogous malocclusions. For one, an effort has to be made to retract the maxillary teeth without further proclining the mandibular incisors. For the other, proclining the mandibular incisors might be justifiable, and interarch Class II mechanics could probably retract the maxillary teeth while proclining the mandibular teeth.

Since Angle and his followers did not recognize any need for the extraction of teeth, the Angle system does not take into account the possibility of arch-perimeter problems. The reintroduction of extraction into orthodontic therapy has made it necessary for orthodontists to add arch-perimeter analysis as an additional step in classification.

A final, but not inconsequential, difficulty with Angle's classification procedure is that it does not indicate the complexity and severity of the problem. In modern orthodontics, it is necessary to organize the database using a more complete system.

Systematic Description: Ackerman-Proffit Classification

Development of the classification scheme. To overcome the difficulties just discussed, we recommend using a classification scheme in which five or fewer characteristics of orthodontic problems and their interrelationships are assessed.[36,37] The scheme has three major components: (1) dentofacial appearance, (2) dental alignment/symmetry, and (3) spatial relationships of the teeth and jaws.

To fully describe the spatial relationships of the jaws and teeth and their relationship to the facial soft tissues is exactly analogous to what is necessary to describe the position of an airplane in space, which must be combined with rotation about three perpendicular axes (yaw, pitch, and roll) (Fig. 8-15). In engineering terminology, the object has 6 degrees of freedom. In orthodontics, introduction of the rotational axes into the description of orthodontic problems significantly improves the precision of the description and therefore facilitates development of the problem list (Fig. 8-16).

Our representation of the interaction of the five major characteristics of malocclusion, in which both the translational and rotational components are combined in a single Venn diagram, is shown in Figure 8-17. A Venn diagram offers a visual demonstration of interaction or overlap among parts of a complex structure. A collection or group in this system is defined as a set, and all elements contained in a set have some common property. Common to all dentitions is their effect on anterior tooth

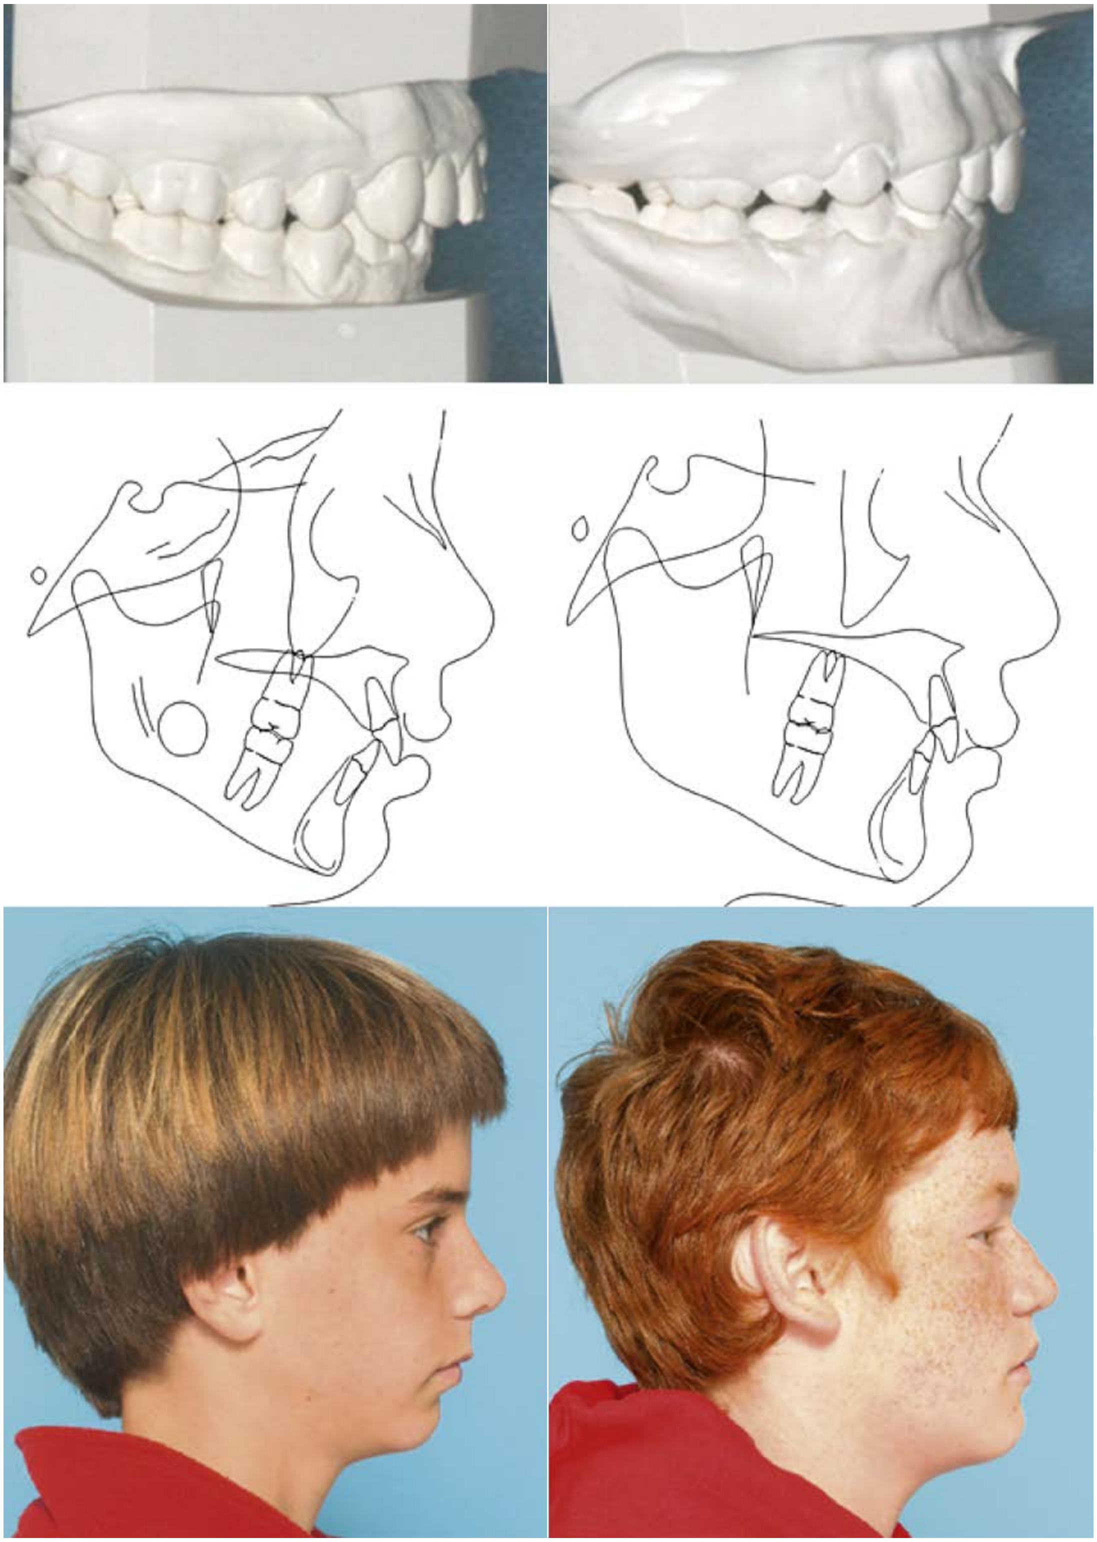

FIGURE 8-14 Shown here are two patients of nearly the same age who have similar orthodontic conditions when only the characteristics of their dental occlusion are taken into consideration. Their underlying skeletal patterns and resultant dental compensations (e.g., mandibular incisor inclinations) are quite different. These two analogous patients require quite different treatment plans.

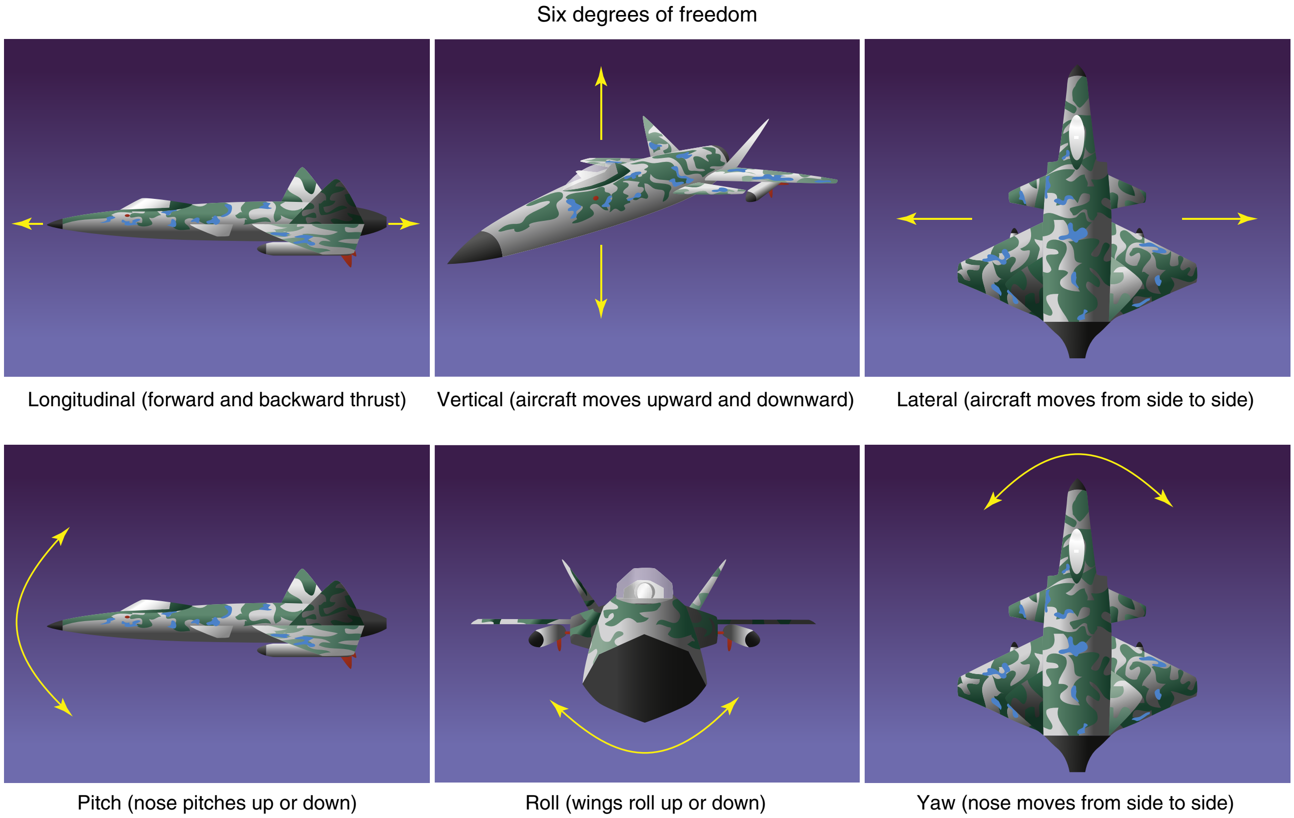

FIGURE 8-15 An airplane's ability to maneuver in space can be described as 6 degrees of freedom. An airplane's attitude, or orientation relative to the direction of travel, is analogous to the orientation of the dentition within the dentofacial complex. Pitch, roll, and yaw are descriptors that can be used for the esthetic line of the dentition. Pitch represents the occlusal plane in sagittal view, roll is analogous to the occlusal plane in frontal view, and yaw is a way of describing rotation of the dentition and jaws around a vertical axis. Yaw problems are manifested as midline deviations or facial asymmetries.

display and the soft tissue drape. We represent this as the framework or "universe" within which all other deviations from the theoretical ideal reside.

Also common to all dentitions is the degree of alignment, arch form, and symmetry of the teeth within the dental arches. For this reason, alignment, arch form, and symmetry are represented within the overall framework represented by the face and smile. Any deviation from the line of occlusion is described and included in this collection of possible discrepancies.

If the teeth are perfectly aligned in both arches, by definition ideal occlusion will occur when the mesiolingual cusps of the maxillary first molars rest in the central fossae of the mandibular first molars, provided the curves of Spee are harmonious and there is no tooth-size discrepancy. This, of course, is the original Angle concept.

Relationships of the teeth and jaws must be considered in all three planes of space, and deviations large enough to be orthodontic problems may occur in any or all of these planes. These are represented by the interacting sets within the alignment/symmetry set.

Application of systematic description. Although it helps to understand the logic of the system, it is understood best by viewing how it is used in organizing the database into the five characteristics of orthodontic problems. The evaluation is carried out in five steps corresponding to each of the five characteristics, or descriptors.

In this classification, a patient with ideal occlusion accompanied by excellent facial balance and a balanced smile requires no descriptors at all to characterize the situation, since no orthodontic problem exists. A patient with crowding/malalignment of the incisor teeth, but excellent balance of the face and smile and no other problems, requires only one descriptor: the location and severity of the resulting malalignment. If the patient has problems related to facial appearance and/or occlusal discrepancies, these descriptors would be added. The steps in organizing the database would be, in sequence:

Step 1: Evaluation of dentofacial appearance. This includes assessing anterior tooth display, as well as the relative convexity and concavity and divergence of the face in profile view and vertical proportions of the face. As discussed previously, faces can be categorized in profile view by their relative convexity and divergence (Fig. 8-18). In anterior view, the vertical characteristics of the face can be expressed by the proportion of facial width and height. In doing so, patients present along a spectrum from short and wide (brachyfacial) to long and narrow (dolichofacial). Average facial proportions are more or less of ovoid shape, and these faces are called *mesofacial.* Dolichofacial individuals often have anterior open bite dental and skeletal relationships, and

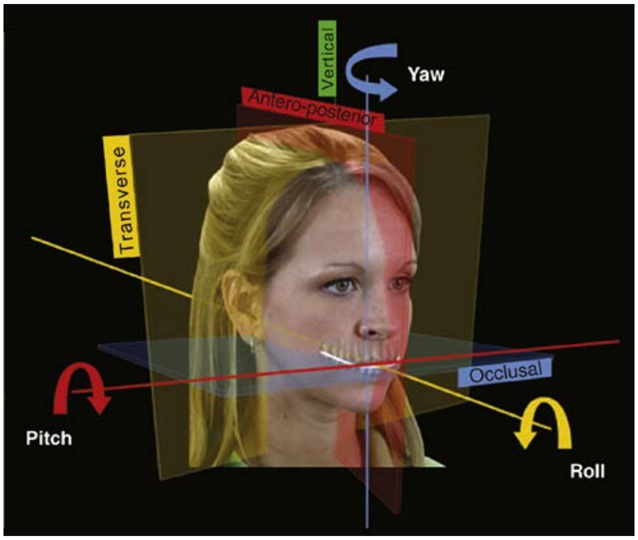

FIGURE 8-16 The face and dentition depicted with 6 degrees of freedom. The classic anatomic planes of the face are coronal, sagittal, and transverse. In the Ackerman-Proffit classification, the sagittal plane is referred to as anteroposterior, the coronal plane is designated vertical, and the transverse plane is the same as the occlusal plane and is used as a reference for the relative widths of the dental arches and any crossbite relationships that might exist. When the three discs representing the three planes of space are rotated they demonstrate pitch, roll, and yaw of the occlusal plane. When the vertical disc rotates it creates roll of the occlusal plane, when the sagittal disc rotates it creates pitch of the occlusal plane, and when the transverse plane rotates it simulates yaw. From Proffit, William R., Henry W. Fields, and David M. Sarver. *Contemporary Orthodontics*. St. Louis, MO: Elsevier/Mosby, 2013. Figure 6-66, p. 209.

brachfacial individuals often have dental and/skeletal anterior deep bite relationships. In most instances, the clinician simply classifies faces from a vertical standpoint as short, average, or long (Fig. 8-19). In terms of anterior tooth display, a smile is characterized by how well the teeth and gingival fit within the smile zone, which is defined by the lips. The lateral and sagittal cants of the occlusal plane and esthetic line of occlusion, as well as the rotation of the maxillae and mandible around a true vertical axis, are described using the terms *pitch, roll,* and *yaw*. These features can be assessed when evaluating anterior tooth display. A more detailed analysis of facial form and appearance is presented in Chapter 9 of this volume.

Step 2: Analysis of the dental alignment and intra-arch symmetry. Alignment is the key word in this group; among the possibilities are ideal, crowded (arch length deficiency), spaced, and mutilated. It is obviously important to count the teeth in order to ascertain which teeth are present or absent.

If the maxillary and mandibular dental midlines do not correspond, the fault should be determined by looking at the midline of the face to decide whether the maxillary or mandibular midline deviates or both are at fault, and whether the deviation is the result of an intra-arch alignment issue or whether it is a yaw problem in which either the maxilla or mandible has rotated slightly around an imaginary vertical axis.

Step 3: Lateral dimensions (transverse plane of space). The faciolingual relationships of the posterior teeth are noted and whether posterior crossbite is present. A judgment is also made as to whether the deviation from ideal proportions and occlusion is basically dentoalveolar, skeletal, or a combination of the two. Most patients have components of both, with one or the other predominating. If a bilateral palatal crossbite is the result of a narrow palatal vault, it would be called a skeletal problem; constriction of the maxillary dental arch alone with normal palatal width would be designated a dentoalveolar problem. Dental compensation for a narrow maxilla, with the teeth tipped facially, often is observed.

As a general rule, *maxillary* or *mandibular* is used to indicate where the problem is located. "Maxillary palatal crossbite" implies a narrow maxillary arch, while "mandibular buccal crossbite," describing the same dental relationship, indicates excess mandibular width as the cause.

The lateral cant of the occlusal plane (roll) is evaluated in relationship to both the intercommissure line and the interpupillary line (Fig. 8-20).

Step 4: Anteroposterior dimensions (sagittal plane of space). In this dimension, the Angle classification is useful, but the goal is to evaluate overjet/reverse overjet in terms of whether it is due to deviations in skeletal, dentoalveolar, or both relationships. In Class II or Class III patients, it is important to distinguish which jaw is affected and to also distinguish skeletal from dentoalveolar problems.

It is important to understand the terminology. For example, a Class II patient has a Class II malocclusion; a skeletal Class II could be due largely to mandibular deficiency (and that should be specified) but could have a dentoalveolar component (also to be specified); and a dental Class II would be due largely to displacement of the mandibular teeth forward on the mandible and/or displacement of the maxillary teeth distally on the maxilla. Class III would be described similarly.

It also is important to evaluate the sagittal cant of the occlusal plane (pitch). Doing this from a ceph is problematic unless it was taken in NHP.

Step 5: Vertical dimensions (vertical plane of space). Bite depth is used to describe the vertical relationships. Again, one must determine whether the problem is skeletal, dentoalveolar, or a combination, and the interaction of vertical and a-p relationships must be kept in mind.

A steep mandibular plane, 35 degrees or greater to the Frankfort plane, indicates an open bite tendency, which would be affected or even prevented by dental compensation in the form of excessive eruption of the incisors. A depression in the lower border of the mandible (antegonial notching) just anterior to the gonial angle indicates deficient vertical growth at the condyle and a degree of compensation by addition of bone in the muscle attachment area (Fig. 8-21). A palatal plane that tips down posteriorly also is an indicator of an open bite tendency, because this often leads to downward–backward rotation of the mandible.

Similarly, a relatively flat mandibular plane represents a deep bite tendency, which would be affected by the extent to which deficient incisor eruption provides compensation or excessive eruption makes the deep bite worse.

Summary of Diagnosis

By working from a comprehensive database, orthodontic diagnosis becomes the process of systematically synthesizing the manifold factors involved in a complex situation into a discrete list of problems, described in a way that indicates the anatomic source and severity of the problem and suggests a tentative solution. The information source is a combination of

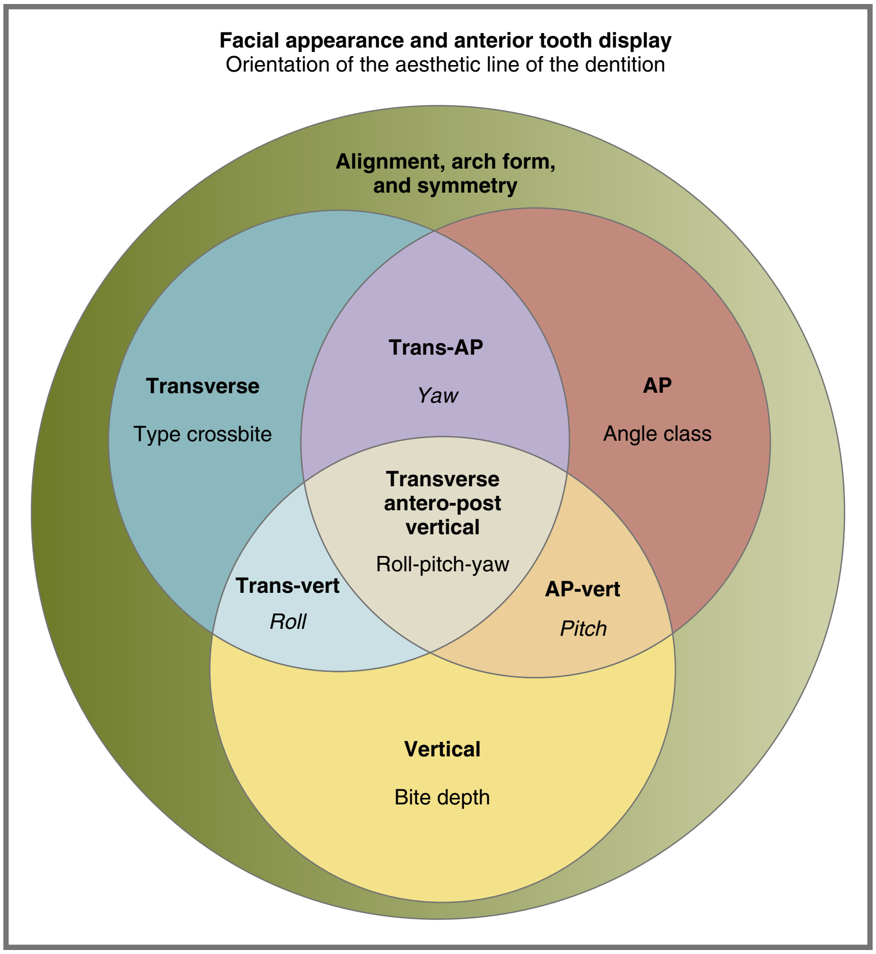

FIGURE 8-17 Ackerman-Proffit Orthogonal Analysis. When the disks representing the three planes of space are stacked as a Venn diagram, we see the interactions between the antero-posterior, transverse, and vertical dimensions. The three overlapping disks are shown atop a disk representing dental arch alignment, symmetry, and arch form, and all four disks are shown on a box representing the framework of facial appearance, anterior tooth display, and orientation of the esthetic line of the dentition. With this classification five or fewer characteristics can fully describe the dentofacial traits of any orthodontic condition.

the components of the database, and classification by the characteristics of dentofacial appearance, alignment of the teeth and occlusal/jaw relationships is used to organize it while being sure nothing important is overlooked. Classification can be accomplished clinically, without the aid of a cephalogram, simply by careful observation of the patient's occlusion and facial appearance. When the orthodontist trains himself or herself to make these judgments at the initial examination, and to substantiate the clinical original estimate from carefully looking at the cephalogram and making selected measurements if there are any doubts about relationships, diagnosis becomes a more natural process.

Proper diagnosis in clinical orthodontics is equivalent to a good hypothesis in basic research. A well-stated hypothesis is a question so well phrased that the path to an answer is inherent in the question. A well-stated orthodontic problem list automatically suggests alternative treatment plans. This analogy can be taken one step further. Orthodontic treatment is to diagnosis what the experiment is to a research hypothesis. The results tend to support or reject one's diagnosis or hypothesis.

TREATMENT PLANNING: THE PROBLEM-ORIENTED APPROACH

Prioritizing the Problem List

The problem list was generated using the interview to identify health problems and then identifying the orthodontic problems and their severity in the five steps in classification. The first step in planning treatment is to put the problems in priority order (see Fig. 8-8). This is a critically important step, because the same problem list prioritized differently will result in a different treatment plan. What are the important considerations in prioritization?

First, the patient's health problems are separated from the list of orthodontic problems, to be considered separately and dealt with before orthodontic treatment begins. This is not because they are more important but because health problems must be under control before active orthodontics begins. As we have noted, uncontrolled diabetes and active periodontal disease contraindicate orthodontic treatment because alveolar bone loss will be accelerated by tooth movement. This is not true when diabetes is under control and active periodontal

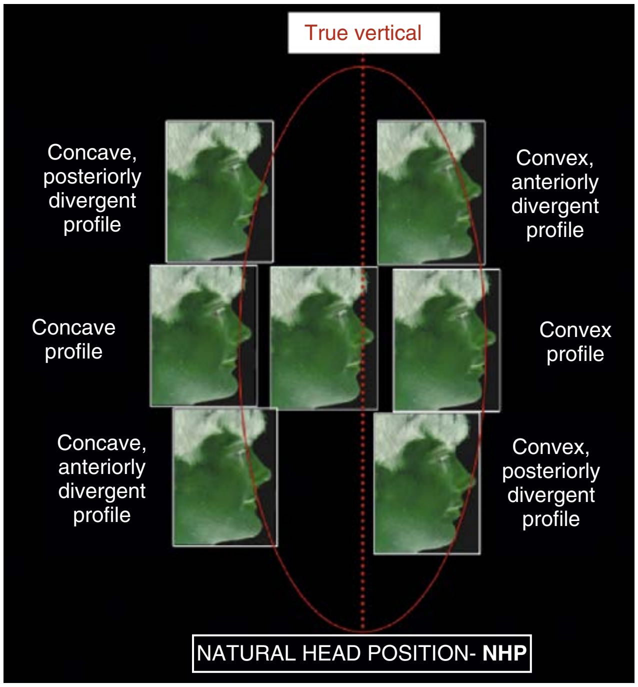

FIGURE 8-18 This illustration demonstrates that any facial pattern can be adequately described using the relative convexity or concavity of the facial profile and the relative anterior divergence or posterior divergence of the chin in relationship to the midface and upper face. Adding a description of face height, as well, nicely completes the picture (see Fig. 8-19).

disease has been eliminated. The same principle applies to other diseases—orthodontics usually is quite feasible when health problems have been brought under control but not when active disease is present.

Second, the orthodontic problems are prioritized, with the patient's chief concern in mind. This is a critically important step, because the same problem list prioritized differently will result in a different treatment plan. It is important to remember that from the patient's perspective, unless the chief concern was corrected during treatment, the treatment was not successful—even if it corrected what the doctor thought was the patient's most important problem.

That does not mean that the patient's chief concern is necessarily the first priority. There certainly is a role for patient education in the process of prioritizing the problem list—but agreement between the doctor and patient about the treatment priorities is the key to true informed consent (see further discussion below).

Then the treatment possibilities for the orthodontic problems are listed and evaluated, starting with the most important problem and continuing with each additional problem in priority order, taking into account the considerations in evaluation that are discussed immediately below.

There are two major advantages to this "individual problem–individual plan" approach before a final synthesis into a unified plan takes place. The first is that there is less chance of rejecting a treatment possibility too soon or never thinking of it at all. The second, which is even more important, is that this approach allows the orthodontist to keep the patient's various problems in perspective as to their priority in treatment. Since

FIGURE 8-19 Classically, the face width to face height ratio defines three basic types of faces. Today, the important observation rests with recognizing either an increased or decreased lower face height. This illustration shows computer-altered lower face heights ranging from short lower anterior face height to long lower face height. Long, narrow faces with increased lower face height usually have a tendency toward anterior open bite. Lower anterior face height is a reflection of the underlying skeletal pattern. Individuals with short lower face heights usually have relatively parallel horizontal facial planes—i.e., palatal plane, occlusal plane, and mandibular plane. Patients with long lower face heights have horizontal facial planes that tend to converge posteriorly (see Fig. 8-13).

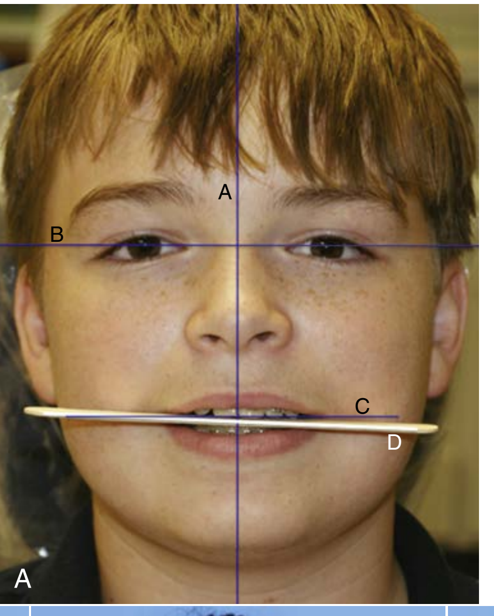

FIGURE 8-20 Determining the anteroposterior and lateral cants of the occlusal plane (pitch and roll) is important in diagnosis and treatment planning, particularly since we have the means today via skeletal anchorage to alter occlusal plane cants without having to resort to orthognathic surgery. There are two useful methods for ascertaining occlusal plane cants. One is a tongue depressor (**A**) and the other a Fox plane (**B**). Certainly the tongue depressor is more convenient because it is disposable, but for complex occlusal plane cants particularly in the posterior region there is still not a good substitute for the Fox plane. It is hoped that in the era of 3D imaging there will be new and more precise ways of measuring these types of cants and asymmetries.

compromises are invariably necessary in treatment planning, it is important that the most relevant issues are favored at the sacrifice of less significant factors. With our fetish about achieving theoretically ideal occlusion, we as orthodontists sometimes overlook the patient's "chief concern" because of our compulsion about how the teeth fit. We must satisfy not only ourselves but the patient as well.

Considerations in Evaluating Treatment Possibilities

To Extract or Not to Extract?

There are two major considerations in this important decision: the management of dental crowding or incisor protrusion (which, for incisor crowding, can be considered two aspects of the same thing) and the possibility of camouflage for skeletal problems.

Management of crowding or protrusion. If a patient presents with severe crowding or with procumbent maxillary and mandibular incisors, marked facial convexity, and severe lip protrusion, it should be obvious that removing premolars to alleviate crowding or allow retraction of the anterior teeth would be the best strategy for solving the problem. Unfortunately, most patients do not present such a clear-cut choice, and a debate about extraction versus expansion has raged in orthodontics for more than 100 years.[38] To better understand the grounds for

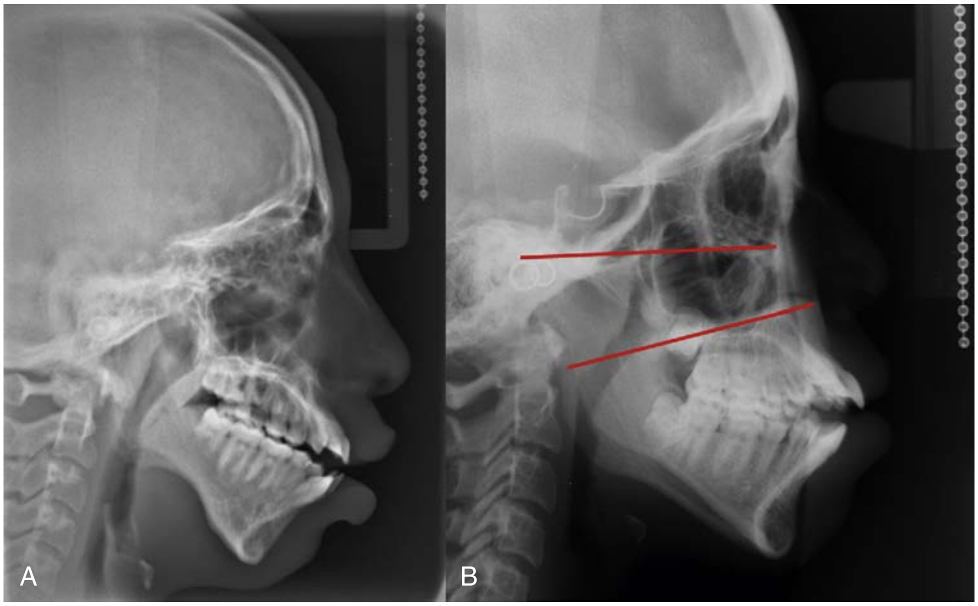

FIGURE 8-21 Cephalometric analysis is a useful tool in the diagnosis of open bite patterns. **A,** Steep mandibular plane (SN-GoGn) and antegonial notching result from deficient vertical growth at the condyle and compensatory bone apposition at the site of muscle attachment. **B,** Open bite can also result from a posteriorly tipped palatal plane in relation to Frankfort horizontal.

the debate, we must consider the pros and cons of dental arch expansion.

There are three reasons why an orthodontist cannot under usual circumstances significantly expand the dental arches. First, the tissues over the labial surfaces of the teeth cannot usually tolerate the teeth being moved into a more facial position. Bone tends to resorb vertically or, if the roots are moved out in advance of the rest of the teeth, fenestration or dehiscence of the labial cortical plate occurs. If a dehiscence is produced, the gingiva in later life may recede in that area.

The second reason is that the teeth will be unstable if they are moved labially or buccally "off their bony base"[39] and into positions where the soft tissue equilibrium can no longer be maintained. The intermolar and especially the intercanine widths for the most part have to be maintained close to their original dimensions during and after treatment, although it is not possible to predict arch stability on the basis of arch dimensions alone.[40] Depending on the initial incisor position, slight incisor advancement may be tolerated by their bony support and soft tissue constraints. Somewhat more lateral expansion in the molar area may be tolerated than in the premolar region (see Fig. 8-6).

Third, major dental arch expansion, particularly when the anterior teeth are moved facially, can have an adverse effect on facial appearance. It is simply not true that arch expansion always creates a more esthetic treatment outcome—an already convex face that has been made more convex as a result of orthodontic treatment does not become more attractive. By the same token, retracting the anterior teeth into an extraction space has the potential to have an adverse esthetic effect in a patient who already has a flat or concave profile. Thus, the general rule in regard to profile is "the principle of opposites." If a profile is convex, consider whether making it less convex would be enhance facial appearance, and if a profile is concave, consider whether making it less concave would be an enhancement.

This realization is what caused orthodontists to reject Angle's dogmatic proscription against tooth extractions.

Incisor repositioning for camouflage. Changing the positions of anterior teeth to compensate for an underlying skeletal disproportion is called "camouflaging the skeletal discrepancy." If a jaw discrepancy exists but is not too severe, camouflage allows correction of the dental relationships while maintaining an acceptable facial appearance. In minor skeletal disproportions, it almost always makes more sense to camouflage the discrepancy with tooth movement rather than correcting the jaw discrepancy with orthognathic surgery. On the other hand, if a major skeletal disproportion is accompanied by a significant facial imbalance, there is a limit to the amount that the situation can be effectively camouflaged with orthodontics alone. The limits of camouflage are not defined by the amount of tooth movement that is possible, but by the patient's acceptance of the resulting appearance.[41]

At the tentative treatment plan stage, a key decision is establishing a target for the anteroposterior position of the incisors after treatment. If the incisors do not provide enough lip support and this is a problem for the patient, they can and should be proclined, but it must be recognized that periodontal health becomes an important consideration and that permanent retention will be required. If the incisors are too protrusive, so that lip separation at rest is apparent, the retraction requirements can be defined as the degree to which they have to be retracted: minimum, moderate, and maximum retraction. This defines the amount of extraction space required for retraction of the anterior teeth. Sometimes it is necessary to define the retraction requirements for each arch separately, especially when the goal is camouflage.

Visual treatment objectives in the extraction decision. To a great extent the retraction requirements influence the decision regarding which teeth are to be extracted and whether skeletal anchorage might be required. In the past, a method of

FIGURE 8-22 The decision to attempt treating this borderline extraction patient with nonextraction treatment related to her already pleasing facial balance and her attractive smile. During the course of treatment, the patient and her parents became concerned about what they saw as unfavorable changes in her dentofacial appearance related to the tooth movement. The orthodontist was concerned about the potential that the teeth might be less stable due to having moved the teeth "off basal bone" and perhaps beyond the limits of soft tissue adaptation. The patient, parent, and orthodontist jointly agreed to have four first premolars removed.

representing treatment goals two-dimensionally (sagittally and vertically) was by simulating the proposed skeletal and dental changes on the cephalometric tracing and estimating the facial soft tissue changes likely to result. This approach produced a visualized treatment objective (VTO) that could be achieved through the planned mechanotherapy. This was particularly effective in planning treatment for nongrowing patients (adults) and for planning surgical treatment. It was and is more difficult to produce reasonable VTOs for growing patients because of the limitations in our ability to forecast growth.

If we accept appearance and stability as the valid criteria for extraction in orthodontics, how well can we determine a priori in a child what the face will look like later on in adulthood and what the new functional environment will be after treatment? In fact, one cannot always predict what the face and dentition would look like after extracting teeth. For that reason, in borderline extraction cases, it is wise to judge the patient's response to initial alignment of the teeth before making a decision to extract (Fig. 8-22). Such an initial decision, of course, should be discussed at the patient–parent conference. It is one way to remove all doubt about the need for extraction, and both adult patients and parents usually appreciate such an approach even if the final decision is to extract. In essence, a reasonably longer treatment time is traded for a more predictable outcome.

In orthodontics, we have tended to be extreme in our views regarding extractions. In the early twentieth century, Angle's influence made it a sin to extract in any case; by mid-century, nearly all irregularities became extraction cases; and at the turn of the twenty-first century, extraction percentages were back to about where they were 100 years previously.[42] A recent study of the 2000–2012 period showed that there seems to be an equilibrium now in extraction percentages in a university clinic where these decisions are made individually by a group of attending orthodontists, with less change in extraction rates than previously.[43] It is clear now that many patients can be treated satisfactorily with extraction or expansion by controlling the amount of retraction or proclination of the anterior teeth.

Therapeutic Modifiability

A second important consideration is therapeutic modifiability, which is best considered in the context of the ratio between benefit and cost/risk for both treatment problems and treatment procedures. Some problems are more difficult and expensive to treat than others, whatever the method to treat them. For example, severe anterior open bite is very difficult to correct while a patient is growing; in contrast, severe deep bite is much easier to modify. Some treatment procedures are more difficult and expensive, whatever the problem to which they would be applied. An excellent example is that single bone screws are easier and less expensive than bone plates because the orthodontist can place bone screws but would not want to reflect flaps as is necessary for bone plates.

The judgment when therapeutic modifiability is evaluated is whether there would be enough additional benefit from the more difficult and expensive choice to justify choosing it. You could be appropriately reluctant to begin treatment of anterior open bite while starting deep bite treatment at an earlier age; you could choose bone plates over orthognathic surgery for less severe anterior open bites while acknowledging the greater benefit from surgery in the more severe cases.

Interaction among potential solutions to problems. An additional consideration is the interaction among the problems and their potential solutions, since all of the factors eventually must be integrated into a unified treatment plan. It is quite possible that the solution to one problem would make another problem worse. For instance, if two of a patient's problems are maxillary constriction with bilateral maxillary palatal crossbite and excessive vertical height of the face accompanied by an anterior open bite, the potential solutions to these two problems would not be compatible. Maxillary expansion to correct the crossbite probably would increase vertical face height, which in turn would increase face height and exacerbate the anterior open bite. This interaction is well demonstrated in Case Study 8-2 (Fig. 8-24, *A–F*). Would you do maxillary expansion to correct the crossbite despite the effect on face height and open bite? Or accept the crossbite and focus on correcting the open bite? It is a far happier circumstance if correcting one problem also addresses another problem on the list, but it may be necessary to leave a less important problem uncorrected or partially corrected in order to correct a more important one.

Patient cooperation. A final consideration would be the patient cooperation needed during treatment. The more cooperation that is needed, the greater the chance that the patient's activity (or lack of it) will compromise the treatment.

Many orthodontists have the distinct impression that an increasing proportion of their practice today consists of children who are less compliant with treatment than patients in the past. This has led many practitioners to use "noncompliance" appliances whenever feasible. The two major types of noncompliance treatments are the Herbst appliance, which is nearly 100 years old, and skeletal bone anchors, a recent advance. Although both methods have considerable merit, their availability tends to drive treatment-planning decisions. The old expression "If one's only tool is a hammer, everything begins to look like a nail" is very apt in describing the impact of noncompliance treatment on the decision-making process in orthodontics. In a more perfect orthodontic world where patient compliance was not such an important factor, a broader choice of appliances would be considered—and for compliant patients, better results might be obtained.

Presenting the Tentative Treatment Plan, Finalizing It, and Obtaining Informed Consent

The Patient–Parent Conference

In the patient–parent conference that precedes the beginning of treatment, it should be emphasized that treatment plan to be discussed is a general strategy for treatment, based on the solution to problems requiring such things as tooth extractions or arch expansion, growth modification, control of tooth eruption or surgical orthodontics, and on explaining the patient's role in obtaining success in treatment.

As an example of the plan to be presented to the patient and parent, refer to the patient records shown in Case Study 8-2. The crowding, and the patient's concern about it, gives the alignment problem a high priority. Tentative treatment plans are immediately suggested by this listing of problems: extraction of a dental unit in all quadrants to solve the crowding or reducing the mesiodistal widths of maxillary teeth or an asymmetric extraction pattern to deal with the tooth-size discrepancy, with the parent or patient able to play a role in deciding which approach would be best.

Obviously, before an overall treatment plan can be written and a precise course of action outlined, all of the other problems and their tentative solutions and interactions must be considered. At the conference, there would be a similar discussion of possibilities for other problems, and a choice would be made there.

Informed Consent

The style of this conference reflects a major change in orthodontics that has resulted from reinterpretation of the legal doctrine of informed consent, which now emphasizes the ethical imperative of greater respect for patient autonomy in the decision-making process.[44] In the modern world, the orthodontist no longer makes decisions alone. He or she now does so jointly with the patient, parent, or both. Arguably this change in approach has had greater impact on orthodontic treatment planning than any technical innovations, even those as dramatic as current computer applications.

Informed consent sequence. Informed consent often is considered just the review of possible complications of treatment and a signature on that form. It is important to do that, but problems related to informed consent almost always involve a difference between what the doctor and patient understood about the goals of treatment and the expected outcome. The sequence for the parent–patient conference should be:

- "Johnny (or Mr. Jones), these are your orthodontic problems …."
- "I think the most important one of those is …. Do you agree?" (further discussion if needed)
- "Based on that, our plan for treatment is to …." (laid out in steps, with discussion about each problem and the possible ways to deal with it)
- "There are some possible potential problems that you should know about:
  - Your cooperation with treatment is important. You will need to ….
  - It is unlikely, but there are some complications you should know about:
    - decalcification
    - root resorption
  - (anything else pertinent to that specific patient)"
- "In summary, my staff and I look forward to working with you. Our goal is to help you with these problems to the best of our ability." (Note what that says about the ownership of the problems: they belong to the patient, not the doctor.)

Computer image predictions. At this conference, should patients and parents be shown computer image predictions of the effect on the profile of alternative treatment plans? There is no doubt that when the alternative plans are orthodontic camouflage versus orthognathic surgery, the predictions help patients to understand the proposed treatment in a way they rarely gain from just a verbal description. A clinical trial established that patients who were shown their predictions appreciated the doctor's openness in doing this and that those who saw the predictions were more satisfied with their treatment than those who did not see them. It appears, therefore, that there is considerable benefit in showing the predictions and minimal risk in doing so.[45]

Treatment response. In the past, the great variation in treatment response among patients was too often ignored, and as a result rigid treatment plans were often set and almost religiously adhered to during the course of treatment. It is now well understood that each time a patient presents during treatment, the treatment plan has to be reconsidered in light of the treatment response and/or some element of the original problem that might have been overlooked. That applies primarily but not exclusively to the mechanotherapy plan—sometimes the strategic plan also has to be modified during treatment. That should be done only after a discussion with the patient or parent.

The Final Step: The Treatment Plan Details (Mechanotherapy Plan)

As part of informed consent, the patient–parent has understood and accepted the treatment plan concept (strategy). Since the mechanotherapy plan is for the doctor's use in maintaining the sequence of treatment and specifying the planned treatment procedures, it can be written as sparely or elaborately as desired. Typically, it would specify how the steps in treatment presented to the patient were to be accomplished biomechanically. After all, the goal and the strategy should be similar for patients with the same problems, but there are many ways to accomplish the desired tooth movement, growth modification, or other types of treatments.

Applications of skeletal anchorage. One of the fundamental principles in orthodontics is anchorage control. Using temporary titanium screws or plates (TADs) to obtain desired tooth movement or growth modification, while limiting unwanted dental side effects, has become a routine part of clinical orthodontics. To some extent, this has extended the envelope of tooth movement, blurring the line between orthodontic camouflage and orthognathic surgery. Moderate open bites[46] and, to a limited extent, Class III skeletal malocclusion[47] can be treated successfully using skeletal anchorage; transverse problems such as posterior crossbites, however, have met disappointing results.[48] The clinician has to balance the decreased morbidity for the patient with skeletal anchorage against improved facial harmony with orthognathic surgery to assure that patient treatment objectives are met.

Perhaps the most common use for skeletal anchorage is as a substitute for extraoral anchorage devices to retract incisors in noncompliant patients. It is important to remember that these devices make it easier to move the teeth within the biological boundaries of the bone; it does not create new bone; therefore, overzealous retraction of incisors for severe Class II camouflage could result in root dehiscence and resorption. More generally, skeletal anchorage does not change the limitations in tooth movement discussed previously.

Stereolithographic models and printing. One of the remarkable benefits of 3D imaging in orthodontics, the use of stereolithographic models in planning treatment and fabricating appliances, was not appreciated until fairly recently. The concept of producing a stereolithographic model on which an orthodontic appliance could be constructed came as a surprise when it was announced by Align Technology 20 years ago, but broader use of this technology is developing rapidly. Stereolithographic models have been used in oral-maxillofacial surgery during the past decade as guides in modifying bone plates for rigid fixation in orthognathic surgery, placing dental implants, or placing TADs.[49] In the near future, 3D printing will be possible for most materials including titanium, stainless steel, or even bone. Will it replace traditional wire fabrication, and if so, how will this change the practice of orthodontics? That, of course, remains to be seen.

Custom milling of attachments and robotic wire bending. Application of computer-assisted design and manufacturing (CAD-CAM) to clinical practice in orthodontics has made great strides recently, with two general approaches. The first application is the creation of customized brackets for individual patients, which will allow the use of "straight wires" to attain closer and closer approximations to theoretically ideal occlusion (Insignia, Ormco Corp., Monrovia, CA), versus the alternative approach of using laser scans of the positions of the attachments on the teeth and then having the archwires bent by a robot (SureSmile, Orametrix, Houston, TX). Of course, it is possible to use these approaches in combination (Incognito, 3M Unitek, Minneapolis, MN). These techniques have considerable appeal, and it will be interesting to see which methodology prevails in the future.

Problems with increased commercialization. It is an increasing concern that the commercialization of orthodontics has begun to short-circuit certain aspects of diagnosis and treatment planning. It can be argued that the commercialization of orthodontics began with Angle's patenting of his various appliance systems in the early 1900s. Yet, it has only been in recent years that direct marketing to consumers by the pharmaceutical industry has influenced commercial companies in dentistry and orthodontics to do the same. The classic example has been Invisalign's advertising campaign to influence prospective orthodontic patients to seek treatment with this method. Unfortunately, other orthodontic suppliers are beginning to follow this malign example.

The impact, of course, is that patients may arrive with a treatment plan already in their minds. In this circumstance, the orthodontist needs to keep in mind that patient health considerations and the other aspects of a comprehensive evaluation are necessary. From this perspective, patient education is an important consideration in obtaining informed consent, even if a quick evaluation suggests that what the patient says he or she wants would be satisfactory mechanotherapy.

CASE STUDY 8-1

Patient History

Patient A.B. was a healthy and socially well-adjusted 12-year-old African American girl who presented for an orthodontic evaluation with a chief complaint of "crooked teeth" and an "underbite" (which was interpreted to represent her negative overjet). There is no history of caries or periodontal disease.

Initial Records

Photographs and a panoramic radiograph were obtained by the treatment coordinator before the clinical examination by the orthodontist (see Fig. 8-23, *A*). A brief review of the photographs and panoramic radiograph allowed the orthodontist to make the four major treatment-planning

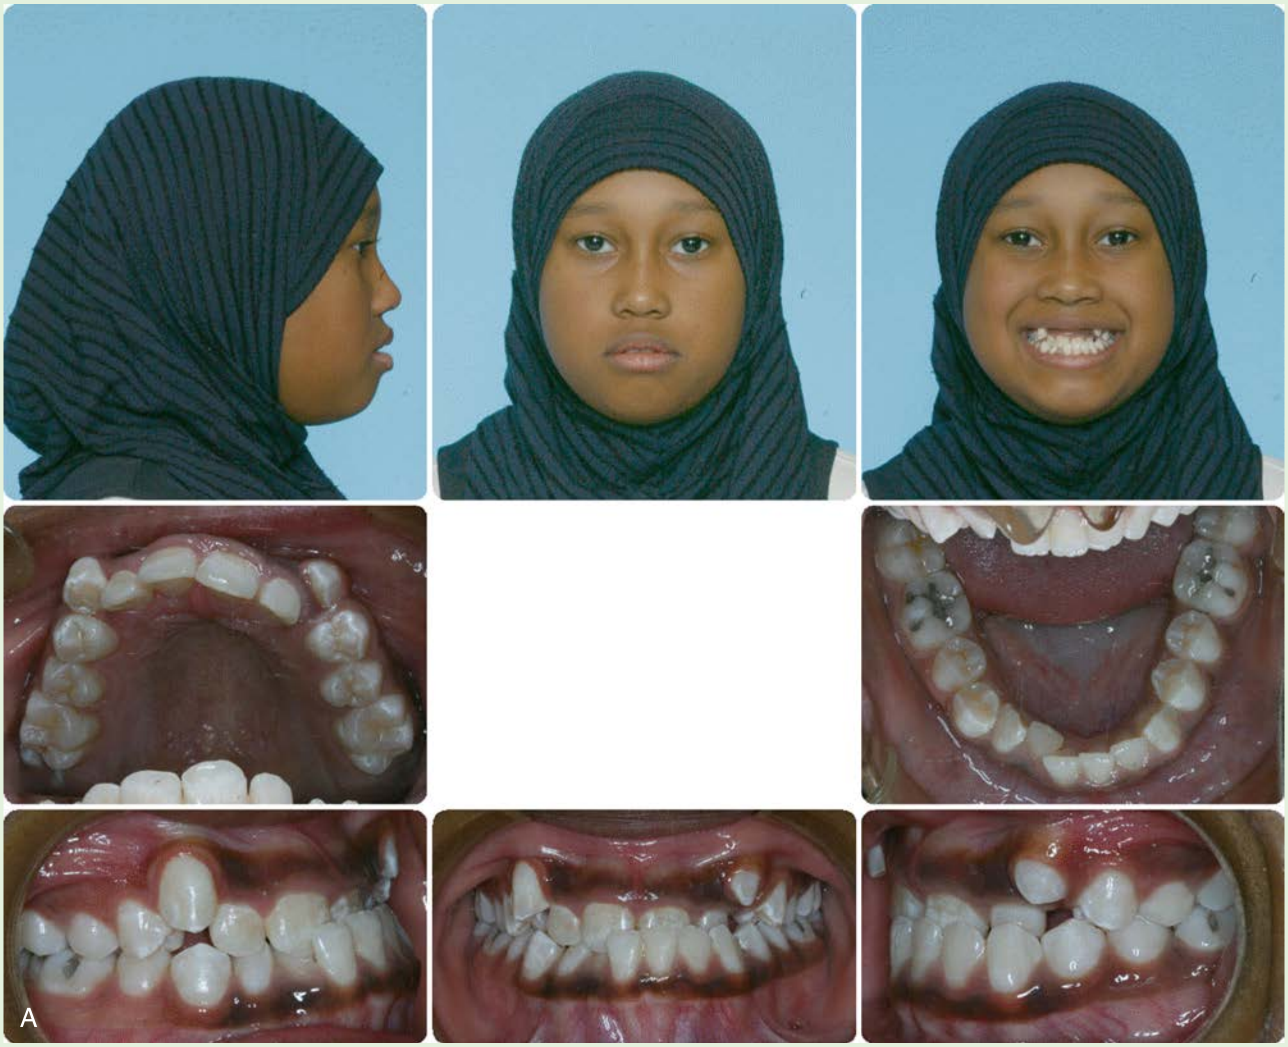

FIGURE 8-23 **A,** Patient A.B. Pretreatment photographs. **B,** Patient A.B. Pretreatment cone beam-computed tomography.

Continued

CASE STUDY 8-1—cont'd

CASE STUDY 8-1—cont'd

decisions in orthodontics, which in turn determine the number of visits required for a complete diagnosis and treatment plan:

1. Extraction versus nonextraction: A.B.'s crowding was sufficient to warrant maxillary premolar extractions, but this treatment option would worsen her overjet.
2. Surgical orthodontics versus nonsurgical treatment: A.B.'s facial appearance was acceptable, but her dental relationship put her at the borderline between orthodontic camouflage and orthognathic surgery.
3. Treat now versus treat later: A.B. is too old to attempt conventional protraction facemask orthopedic therapy. With the unpredictable nature of the Class III growth, possible treatment options include (1) limited Phase I treatment to extract the maxillary 1st premolar and align the incisor, (2) skeletal anchorage growth modification, or (3) wait until cessation of growth and treat with orthognathic surgery.
4. Conventional anchorage versus skeletal anchorage: this will largely depend on the treatment choice decided by the orthodontist and family.

Clinical Examination

The clinical examination revealed the following:

1. Dentofacial appearance
   a. Increase maxillary gingival display
   b. Increased mandibular incisor display
   c. Slightly convex profile resulting primarily from maxillary retrognathism
   d. Lip protrusion and increased interlabial gap
2. Alignment, arch form, and symmetry
   a. An 11-mm maxillary arch-perimeter deficiency, 2-mm mandibular arch-perimeter deficiency
   b. Elliptical maxillary and mandibular arch form with slight asymmetry of the mandibular anterior segment
3. Transverse relationships
   a. Maxillary midline deviation of 1 mm to the right
4. Anteroposterior relationships
   a. Class III skeletal with maxillary retrognathia
   b. Class III dental relationship with 2-mm overjet
   c. Maxillary and mandibular anterior dental compensation with retroclination of the maxillary incisors and retroinclination of mandibular incisors
   d. Anterior crossbite
5. Vertical relationships
   a. Anterior deep bite (50% overbite)

Prioritized Problem List

- Class III skeletal and dental, negative overjet and compensated incisors
- Crowding
- Slightly increased gingival display
- Anterior deep bite
- Slight midline deviation

Potential Solutions to the Individual Problems

- Class III—protract maxilla, restrain mandibular growth, LeFort advancement to position the maxilla anteriorly
- Crowding—extract maxillary premolar, distalize maxillary arch, procline maxillary incisors, procline mandibular incisors
- Increased gingival display—intrude maxillary incisors, impact the anterior maxilla with orthognathic surgery
- Anterior deep bite—intrude maxillary incisors, impact anterior maxilla with orthognathic surgery
- Midline deviation—elastics

Interactions and Risk/Benefit Considerations of Potential Solutions

- The interactions of the potential solutions to the prioritized problems show two clear options: skeletal anchorage orthopedics or orthognathic surgery.
- The risks of skeletal anchorage orthopedics include failure of bone anchors, lack of compliance with elastics, and sutural maturation/interdigitation that prevents skeletal change, while the risk of orthognathic surgery includes increased morbidity.
- The decision to extract in the maxillary makes the biomechanics of alignment easier for the orthodontist but complicates the anteroposterior goals unless adequate maxillary orthopedics can be obtained.

Mechanotherapy

Alternatives

- Fixed appliances with or without extractions if A.B. and her parent chose orthognathic surgery
- A combination of fixed appliances and bone anchor placement for orthopedic treatment
- A maxillary Hawley retainer and a bonded mandibular canine-to-canine fixed retainer

At this point in the process, the orthodontist turns over the following tasks to the treatment coordinator.

Patient–Parent Input

Given the two alternatives, the family expressed a preference for a nonextraction, skeletal anchorage orthopedics. A.B. and her family wanted treatment now due to a self-esteem issue associated with her malocclusion.

Informed Consent

A modification of the AAO informed consent booklet was used to outline the risk/benefit considerations of treatment, including retention considerations. The patient and parent were informed about the nature of Class III skeletal growth and the potential need for additional treatment including orthognathic surgery should she outgrow her correction. The estimate of treatment time and the cost of treatment were discussed.

Supplemental Records

A cone beam computed tomography (CBCT) scan and dental impressions were taken to confirm the findings from the clinical examination (see Fig. 8-23, *B*). The CBCT was taken to evaluate zygomatic bone thickness required for Class III skeletal anchorage orthopedics.

Detailed Treatment Plan

At a later date, the supplemental records were reviewed and the prioritized problem list, detailed treatment plan, and stepwise outline of the mechanotherapy were recorded and placed in a readily accessible part of the patient's file.

Posttreatment Evaluation

3D cranial base registration is shown in Figure 8-23, *D*. The initial CBCT is shown in green, while the posttreatment CBCT is overlain in ivory.

CASE STUDY 8-2

Patient History

Patient A.D., a healthy, 14-year-old Caucasian girl presented for an orthodontic evaluation with a chief complaint of "a space between my upper front teeth" and "the next tooth over is in toward the roof of my mouth" (which was interpreted to mean a palatally displaced lateral incisor). None of her parents or siblings had yet had orthodontic treatment, although they, A.D., and her brother had been evaluated by two other orthodontists.

Initial Records

Photographs and a panoramic radiograph were obtained by the treatment coordinator before the clinical examination by the orthodontist (see Fig. 8-24, *A* and *B*).

Triage

A brief review of the photographs and panoramic radiograph allowed the orthodontist to make the following critical preliminary judgments:

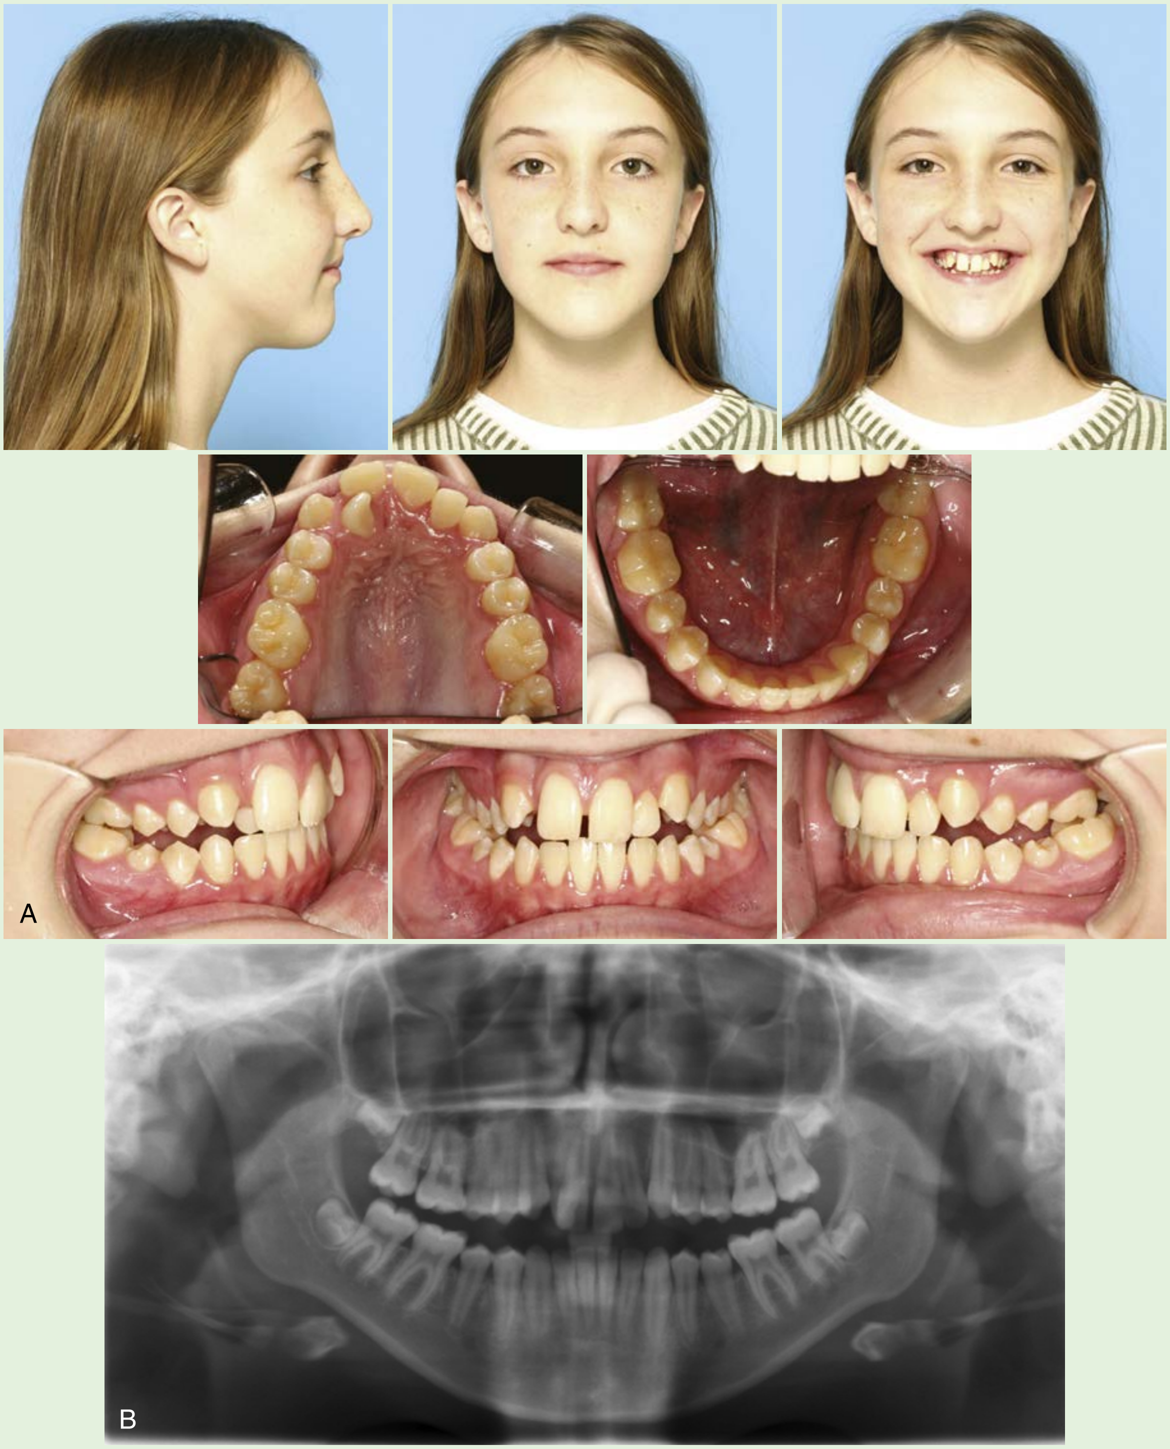

FIGURE 8-24 **A,** Patient A.D. Pretreatment photographs. **B,** Patient A.D. Pretreatment panoramic radiograph.

CASE STUDY 8-2—cont'd

Initial — Orthognathic surgery — Skeletal anchorage

FIGURE 8-24, cont'd **C,** Patient A.D. Pretreatment cephalogram. **D,** Patient A.D. Treatment predictions.

1. A.D.'s crowding, although the maxillary right lateral incisor was largely blocked out of the arch, was insufficient to warrant tooth extractions.
2. Several of the characteristics of A.D.'s orthodontic condition possibly required either orthognathic surgery or skeletal anchorage to completely resolve the problems.

Clinical Examination

The clinical examination revealed the following:

1. Dentofacial appearance
   a. Dolichofacial appearance with long lower face height
   b. Excessive posterior gingival show on smile
   c. Downward posterior cant (pitch) of the esthetic line of the dentition
   d. Mild dental cant (roll) of the anterior teeth slightly up on the patient's right side
   e. Maxillary midline shifted 2 mm to the right side
   f. Concave, straight profile with retrusive lips and thin upper lip vermilion
   g. Obtuse nasolabial angle
   h. Flat mentolabial fold
2. Alignment, symmetry, and arch form
   a. "V-shaped" maxillary arch and "U-shaped" mandibular arch
   b. A 4-mm maxillary arch-perimeter deficiency in the region of the blocked out maxillary right lateral incisor, although there is a 1-mm maxillary midline diastema
   c. Maxillary midline is shifted 2 mm to the patient's right.
   d. Tooth-size discrepancy due to the maxillary right lateral incisor
   e. Maxillary right permanent first molar is rotated mesially, contributing to the arch-perimeter deficiency affecting the maxillary right lateral incisor.
   f. Maxillary canines in slight labial ectopic position
3. Transverse relationships
   a. High constricted palatal vault
   b. A 7-mm maxillary transverse deficiency at the level of the first and second molars
   c. Bilateral maxillary palatal crossbite
4. Anteroposterior relationships
   a. Class II, with 4-mm overjet and palatal crossbite of the maxillary right lateral incisor

CASE STUDY 8-2—cont'd

5. Vertical relationships
   a. Lateral open bites in the canine and premolar regions on the right and left sides
   b. Anterior open bite tendency
   c. Only three points of occlusal contact—maxillary and mandibular second molars and the maxillary right lateral incisor

Prioritized Problem List

- Maxillary midline diastema
- Palatoversion of the maxillary right lateral incisor
- Unesthetic anterior tooth display
- Bilateral maxillary palatal crossbites
- Lateral open bites
- Anterior open bite tendency
- Increased lower face height

Potential Solutions to the Individual Problems

- Maxillary midline diastema—After maxillary expansion, redistribute maxillary anterior space to close the diastema.
- Palatal displacement of the maxillary right lateral incisor—After posterior expansion and redistribution of maxillary anterior spacing, level and align lateral incisor.
- Esthetic anterior tooth display—If possible, intrude maxillary posterior teeth and change orientation of the esthetic line of the dentition and level and align teeth.
- Bilateral maxillary palatal crossbites—Rapid palatal expansion (10 mm)
- Lateral open bites—Either extrusive forces on the maxillary canines and premolars or intrusive forces on the molars
- Anterior open bite tendency—Intrusion of maxillary molars and autorotation of the mandible or extrusion of mandibular incisors
- Increased lower face height—Intrude maxillary posterior teeth or consider a LeFort I osteotomy to superiorly reposition the maxillae and gain autorotation of the mandible.

Interactions and Risk/Benefit Considerations of Potential Solutions

- Expanding the maxillary arch has the potential for increasing face height, which is already long, particularly since the maxillary molars manifest buccal crown inclination.
- Maxillary expansion can increase the open bite tendency by tipping the maxillary molars, effectively bringing the palatal cusps inferiorly.
- The risk of maxillary expansion is that it might ultimately lead to instability of the maxillary dental arch.

Treatment Possibilities

Alternatives

1. Rapid palatal expansion to correct posterior crossbites and skeletal anchorage to control the vertical dimension, particularly posteriorly.
2. Surgical correction of the posterior crossbites and open bites using a LeFort I maxillary osteotomy.

Supplemental Records

A lateral cephalogram and dental impressions were taken for further study. Video imaging simulated the potential facial outcomes that might result from orthodontics plus surgery (see Fig. 8-24, *C*).

Patient–Parent Conference

All records were reviewed with the patient and parent. The family was told about the treatment alternatives and was shown bone anchors, a rapid palatal expansion appliance, and multibonded appliances, as well as simulations of orthognathic surgical technique and the potential changes that might be derived from surgery in this case.

Given the two treatment alternatives, the family expressed a strong preference for the less invasive treatment plan, despite the fact that a more optimal facial outcome might have resulted from orthognathic surgery (see Fig. 8-24, *D*).

Unified Treatment Plan

- Relieve crowding of the maxillary right lateral incisor with 10 mm of rapid palatal expansion and correct posterior crossbites.
- Intrude maxillary posterior teeth with the aid of skeletal anchorage.
- Improve appearance of anterior tooth display with multibonded appliances.

Informed Consent

A modification of the AAO informed consent booklet was used to outline the risk/benefit considerations of treatment, including retention considerations. The 2-year estimate of treatment time and the cost of treatment were discussed.

Detailed Treatment Plan and Mechanotherapy

After the conference, the prioritized problem list, detailed treatment plan, and stepwise outline of the mechanotherapy were recorded and placed in a readily accessible part of the patient's file. The plan was similar to one of the original treatment alternatives (i.e., rapid palatal expansion to correct posterior crossbites, skeletal anchorage to control the vertical dimension, particularly posteriorly and fixed appliances).

Posttreatment Evaluation

The outcome of treatment is shown in Figure 8-24, *E* and *F*.

Special Considerations in Diagnosis and Treatment Planning

David M. Sarver

OUTLINE

Orthodontic diagnosis and treatment planning are in a period of remarkable change, away from a previous focus on dental occlusion and hard tissue relationships and toward a greater emphasis on soft tissue adaptation and proportions.[1,2] This change has been driven by new technology and interpretation of cosmetic dental principles into the treatment planning process. Dentists themselves have become more aware of the developments in cosmetic dentistry and the benefits now available to their patients. Television and advertising spread consistent images of aesthetic faces and smiles worldwide. Parents and patients now notice and disapprove of the aesthetic liability of unattractive smiles and as a result, orthodontists know that treatment success must be judged by more than the dental occlusion. Chapter 8 of this book has cogently discussed the current philosophical changes in the approach to diagnosis and treatment planning, departing from the traditional model consisting of an initial visit followed by records and subsequent analysis and treatment plan presentation. Until the past decade, the emphasis in planning orthodontic treatment was based on photographs, model analysis, and cephalometric analysis. The contemporary approach involves a much more detailed clinical examination where many aspects of the treatment plan reveal themselves as a function of the systematic evaluation of the functional and aesthetic presentation of the patient. Because Chapter 8 also covered the functional aspects of orthodontic treatment, our intent in this chapter is to present the components of clinical assessment of the hard tissue and soft tissue that logically lead the clinician to the final treatment plan. In planning treatment, to visualize and establish the appearance of the teeth and face that is desired as a treatment outcome and to work backward ("retroengineer") to the hard tissue relationships that are needed to obtain these soft tissue proportions and lip–tooth relationships make much more sense. This approach is not completely contradictory to the records-based approach, where the hard tissues are analyzed (cephalometric head film and models) and the outward soft tissue is a secondary consideration but should be considered an expansion of how we diagnose and form the treatment plan. It is important that in many instances the clinical observations should override the cephalometric impression.

The purpose of this chapter is to explore in detail the new concepts that underlie clinical application of the soft tissue paradigm with the major emphasis on appearance and aesthetics. The next objective will be to illustrate how treatment approaches change when these concepts are applied. The focus is on the things that have not been emphasized in previous discussions of orthodontic diagnosis and treatment planning. The author recognizes that the reader will have a background in those fundamentals, because Chapter 8 covers that in exquisite detail.

PURPOSES AND GOALS OF ORTHODONTIC TREATMENT

Orthodontics and Quality of Life

In general, the goal of orthodontic treatment is to improve the patient's life by enhancing dental and jaw function and dentofacial aesthetics. From this perspective, the role of orthodontics is analogous to that of several other medical specialties, such as orthopedics and plastic surgery, in which the patient's problems often do not result from disease but rather from distortions of development. As the health care field has evolved from a disease-oriented focus to a wellness model,[3] orthodontics now is viewed more clearly as a health service dedicated to establishing emotional and physical wellness. Dental and facial distortions create a disability that can influence physical and mental health. Appropriate treatment can be important for the patient's well-being.

In diagnosis, whether in orthodontics or other areas of medicine or dentistry, practitioners must not concentrate so closely on their own specialized areas (and a medical or dental professional does not have to be a specialist to take a specialized point of view) when assessing patients' overall conditions that they overlook other significant problems. The problem-oriented approach to diagnosis and treatment planning has been advocated widely in medicine and dentistry as a way to overcome this tendency to concentrate on only one part of a patient's problem. The essence of the problem-oriented approach is the development of a comprehensive database of pertinent information that precludes the possibility of problems being overlooked. We suggest that the problem-oriented treatment-planning approach has grown further to include examination, documentation, and assessment of patient attributes that are normal or positive. The reason for this is the recognition that in orthodontic treatment we may often have an unwittingly negative impact on patient attributes that are good.[4-6] The most commonly cited example of this is the case in which correction of a Class II malocclusion secondary to mandibular deficiency is performed via maxillary first premolar extraction and reduction of overjet. This plan corrects the "problem" of the Class II malocclusion but at the expense of a normal or ideal midface. This leads us to an expanded concept of "problem-oriented treatment planning" to include a "protection strategy" (Fig. 9-1). In other words, identification of both the problems and the normal or ideal attributes of a patient are important as illustrated in the example in Figure 9-2. If the ideal attributes at the initial presentation are not recognized, then the treatment plan, which is focused solely on the problems, may lead to deleterious effects on the ideal attributes.

Chapter 8 gives the reader a basic understanding of the problem-oriented approach to orthodontic diagnosis and treatment planning and of dental cast and cephalometric analysis; therefore, the focus of this chapter is on soft tissue considerations that previously have not received as much consideration in orthodontic evaluation as they should have and on the integration of traditional orthodontic treatment procedures with other treatment (periodontal, restorative, surgical) that can improve the outcome for many patients.

Role of the Orthodontist in Total Facial Aesthetic Planning

One of the first major influences in changing orthodontic thinking and approach began when orthognathic surgery became a more refined and less traumatic procedure; it rapidly became a reasonable treatment option for orthodontists to incorporate into their differential diagnoses and treatment planning strategies. The facial changes created by improvement of skeletal malformations were truly remarkable, and the facial effect of orthognathic treatment moved to the forefront of orthognathic surgical goal setting.

The retreatment of orthodontically camouflaged cases and the recognition of the effect of orthodontics and growth modification on the face have changed the focus of "routine" orthodontic treatment. The goals of orthognathic treatment for the improvement of facial appearance may be attained readily by

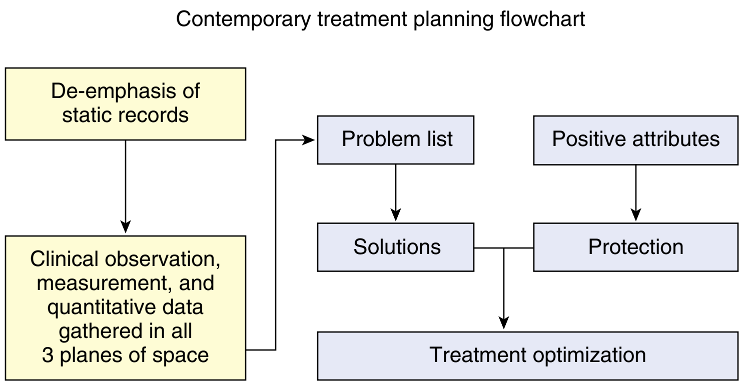

FIGURE 9-1 We suggest an expansion of problem-oriented treatment planning to include a "protection strategy" to avoid unwittingly negative impacts on a patient's positive attributes.

orthodontic methods in children, but the tools are different for different ages: orthognathic surgery in the adult for skeletal modification and growth modification in the adolescent.

The aesthetic and functional goals for growing patients should be the same as they are for adult patients. Growth modification techniques may allow the orthodontist to direct growth to achieve dramatic facial changes similar to those produced by surgery; these changes are an important part of patient motivation and satisfaction. Individualized treatment plans with differential functional and aesthetic options of

FIGURE 9-2 A classic example of problem-oriented treatment planning with the focus on hard tissues only is best illustrated by the Class II mandibular deficiency treated with premolar extraction rather than a contemporary growth modification approach. **A**, This 18-year-old female had undergone premolar extraction for retraction of her anterior teeth to correct her overjet, resulting in an obtuse nasolabial angle, an exaggeration of nasal projection, and inadequate lower facial projection. **B**, Seeking aesthetic improvement 4 years after her original orthodontic treatment, she underwent retreatment through orthodontic decompensation of her previous orthodontic treatment combined with a surgical bimaxillary advancement and rhinoplasty to an obvious aesthetic improvement. **C,** This adult patient in her 40s was prompted to seek treatment after the previous patient, her niece, had completed her treatment. Impressed with the outcome, she presented for correction of her aesthetic issues, and the same plan was recommended and completed. **D**, The final outcome for her was just as outstanding as that for her niece. What is the point here? The young adolescent was treated in the exact same manner her aunt had been fully treated three decades before, to the same unfortunate outcome.

FIGURE 9-3 This "selfie" illustrates the emphasis on frontal aesthetics and its importance in defining our aesthetic problem list. (Photo © istock.com.)

treatment should be planned and discussed with the parents of young patients. Adult patients may choose more aggressive approaches to treatment, whereas the parents of adolescent patients are more cautious. This occurs probably for two reasons: (1) the parents are making decisions on behalf of the child and tend to be more conservative, whereas the adult is making personal treatment decisions; and (2) some surgical decisions are not needed or indicated during adolescence.

Before cephalometric radiography, astute clinicians looked at the face and made general correlations with the way tooth movement might affect the esthetics of the face. Cephalometrics quantified dentoskeletal relations, established norms, and focused the profession on anatomic relations, including the skeletal pattern. Cephalometric diagnostic guidelines, however, pay only marginal attention to the soft tissue profile; although many analyses include soft tissue evaluation, it is usually limited to the profile. The emphasis on cephalometrics that developed in clinical orthodontic diagnosis and treatment planning departed from the original vision of its developers. Brodie[7] cautioned that cephalometrics was never intended as the sole decision maker in orthodontic treatment plans and that its main strength was in quantification of growth and research.

Interestingly, orthodontics is now coming full circle, looking carefully at dentofacial proportions before the cephalometric radiograph is even considered. Of even greater significance is the modern emphasis on the frontal evaluation and the effect of orthodontics and surgery on the frontal vertical relationships. The current popularity of "selfies" is instructive in that the subject's emphasis is the frontal face, generally on smile (Fig. 9-3). Rarely will you see a person taking a profile selfie on his or her phone camera.

The greater recognition of facial planning is only one leg of the contemporary diagnostic tripod. We recommend that aesthetic planning be approached with three major divisions in mind: macroaesthetics (the face), miniaesthetics (the smile), and microaesthetics (tooth and gingival shape and form). (To see case studies demonstrating this approach, please go to www.orthodontics-principles-techniques.com.) Contemporary records should reflect this approach and facilitate the complete three-dimensional evaluation of the patient's aesthetic presentation.

Records

Facial Photographs

For ideal photographic representation of the face, we recommend that the camera be positioned in the portrait position to maximize use of the photographic field. Orienting the camera in the landscape position captures much of the background that is unneeded and detracts from the image by diminishing the size of the face in the picture.

The following facial photographs are recommended as the expected routine for each patient:

1. Frontal: The patient assumes a natural head position and looks straight ahead into the camera. Four types of frontal photographs (Fig. 9-4) are useful:
   a. *Frontal at rest*. If lip incompetence is present, the lips should be in repose and the mandible in rest position.
   b. *Frontal view with the teeth in maximal intercuspation, with the lips closed, even if this strains the patient*. This photograph serves as clear documentation of lip strain and its aesthetic effect, and the lips-together picture is recommended in patients who have lip incompetence. If lips-apart posture is present, then an unstrained image is also recommended as an additional image. The reason for this image is to allow visualization of the philtrum–commissure height relationship, etiologic in the differential diagnosis of excessive gingival display on smile.
   c. *Frontal dynamic (smile)*. As described in more detail later in this chapter, the smile can vary with emotion. A patient who is smiling for a photograph tends not to elevate the lip as extensively as a laughing patient. The smiling picture demonstrates the amount of incisor show on smile (percentage of maxillary incisor display on smile) and any excessive gingival display. However, the still image of the smile can be variable. Think about it—we squeeze off a picture that is about a 1/125-second duration of a process that has a start and a finish (from the lips together through the smile animation back to the lips being together). Also, having a child relax during the photograph session can also be a challenge. Many times we can only obtain a forced smile at best. Because of this variability, we recommend the addition of digital video clips as part of the patient record.[6,7] This recommendation will be discussed in detail later in this section.
   d. *A close-up image of the posed smile*. This view now is recommended as a standard photograph for careful analysis of the smile relationships. The posed-smile photograph is discussed in greater detail later in the chapter.
2. *Oblique (three-quarter, 45-degree)*
   Patient in natural head position looking 45 degrees to the camera. Three views are useful (Fig. 9-5).
   a. *Oblique at rest*. This view is useful for examination of the midface and is particularly informative of midface deformities, including nasal deformity. Orthodontists should recognize that persons are not seen just on profile or frontally and that the three-quarter view is particularly valuable in assessing the way a patient's face is viewed by others. This view also reveals anatomic characteristics that are difficult to quantify but are important aesthetic factors, such as the chin–neck area, the prominence of the gonial angle, and the length and definition of the border of the mandible. The view also permits focus on lip fullness and vermilion display. For a patient with obvious

FIGURE 9-4 Recommended frontal images. **A,** Frontal at rest. If lip incompetence is present, the lips should be in repose and the mandible in rest position. **B,** Frontal view with the teeth in maximal intercuspation, with the lips closed, even if this strains the patient. This photograph serves as clear documentation of lip strain and its aesthetic effect, and the lips-together picture is recommended in patients who have lip incompetence. **C,** Frontal dynamic (smile). A patient who is smiling for a photograph tends not to elevate the lip as extensively as a laughing patient. The smiling picture demonstrates the amount of incisor show on smile (percentage of maxillary incisor display on smile), as well as any excessive gingival display. **D,** A close-up image of the posed smile. This is now recommended as a standard photograph for careful analysis of the smile relationships.

facial asymmetry, oblique views of both sides are recommended.

b. *Oblique on smile*. As mentioned in Chapter 8, there are diagnostic limitations of plaster casts, virtual models, and, as far as we are concerned, virtually all static records because they do not reflect the relationships of the teeth to the lips and surrounding soft tissue, especially in evaluation of the smile. Standard orthodontic records consist of the frontal smile, frontal rest, and profile. Often, in clinical practice, a parent will ask why the teeth appear flared, and they attempt to describe what they are seeing by holding their hands next to the child's face in angulated fashion to make sure the orthodontist sees it, too. This observation is often not discernible on the models or on the cephalogram but is readily observable on the patient. So the oblique view of the smile reveals characteristics of the smile not obtainable through those means, and it aids the visualization of both incisor flare and occlusal plane orientation. A particular point for observation is the anteroposterior cant of the occlusal plane. In the most desirable orientation, the maxillary occlusal plane is consonant with the curvature of the lower lip on smile (the smile arc, discussed in detail in the section on smile evaluation). Deviations from this orientation that should be noted as potential problems include a downward cant of the posterior maxilla, an upward cant of the anterior maxilla, or variations of both. In the initial examination and diagnostic phase of treatment, visualization of the occlusal plane in its relationship to the upper and the lower lip is important.

c. *Oblique close-up smile*. This allows a more precise evaluation of the lip relationships to the teeth and jaws than is possible using the full oblique view.

Figure 9-6 illustrates the close-up smiles on the oblique view of a child presenting for correction of an open bite and his mother.

3. *Profile* (Fig. 9-7): The profile photograph also should be taken in a natural head position. The most common method used for positioning the patient properly is to have the patient look in a mirror, orienting the head on the visual axis. The picture boundaries should emphasize the areas of information needed for documentation and diagnosis. The authors recommend that the inferior border of the image be slightly above the scapula, at the base of the neck. This position permits visualization of the contours of the chin and neck area. The superior border should be only slightly above the top of the head and the right border slightly ahead of the nasal tip.

The inclusion of more background simply adds unneeded information to the photograph. Some clinicians prefer that the left border stop just behind the ear, whereas others prefer a full head shot. Under any circumstance, the hair should be pulled behind the ear to permit visualization of the entire face.

Two profile images are useful (see Fig. 9-7):

a. *Profile at rest*. The lips should be relaxed. Lip strain is illustrated better in the frontal view, so a profile photograph with the lips strained in closure is unnecessary.

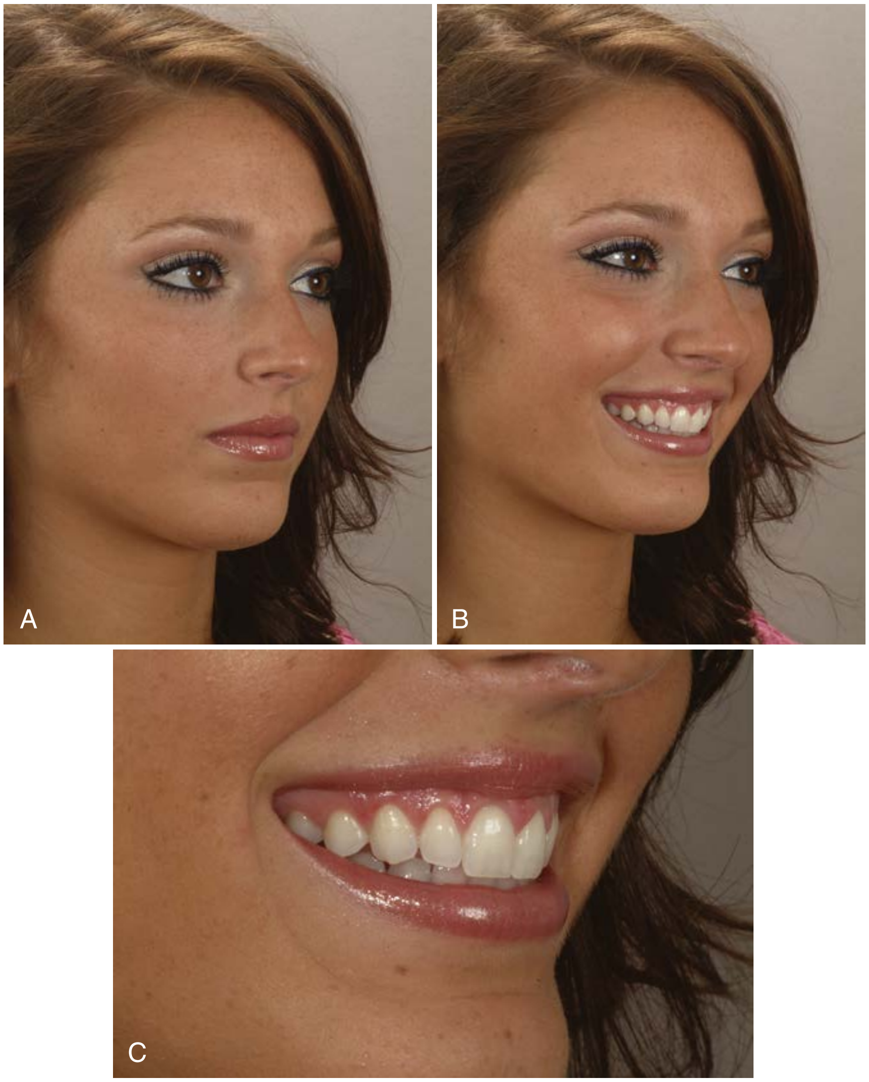

FIGURE 9-5 Oblique (three-quarter, 45-degree) views. Three views are useful. **A,** Oblique at rest. This view can be useful for examination of the midface and is particularly informative of midface deformities, including nasal deformity. This view also reveals anatomic characteristics that are difficult to quantify but are important aesthetic factors, such as the chin-neck area, the prominence of the gonial angle, and the length and definition of the border of the mandible. This view also permits focus on lip fullness and vermilion display. **B,** Oblique on smile. The oblique view of the smile reveals characteristics of the smile not obtainable on the frontal view and certainly not obtainable through any cephalometric analysis. **C,** Oblique close-up smile. This view allows a more precise evaluation of the lip relationships to the teeth and jaws than is possible using the full oblique view.

b. *Profile smile*. The profile-smile image allows one to see the angulation of the maxillary incisors, an important aesthetic factor that patients see clearly and orthodontists tend to miss because the inclination noted on cephalometric radiographs may not represent what one sees on direct examination.

4. *An optional submental view* (Fig. 9-8). Such a view may be taken to document mandibular asymmetry. In patients with asymmetries, submental views can be particularly revealing.

Digital Video Technology in Orthodontic Records

In standard photography, the image represents an approximate 1/125-second exposure of a patient's smile. In taking a picture for a smile, the subject is asked to smile and the picture is snapped. The problem in this process lies in the knowledge that the lips start the smile process at rest and animate over a very short time period. The image is taken somewhere in this dynamic process and may not represent the patient's consistent and repeatable smile. In practical terms, the image may be taken halfway into the smile or halfway to the end of the smile and may not represent the smile the patient uses consistently. Certainly almost all practicing clinicians have had the frustrating experience of looking at the patient's smile image during treatment planning and having the subject show a forced smile or one without the teeth showing (Fig. 9-9) (particularly 12-year-old boys!). The dynamic recording of smile and speech may be accomplished with digital videography. Digital video and computer technology currently enable the clinician to record anterior tooth display during speech and smiling at the equivalent

FIGURE 9-6 **A,** Close-up smile on oblique view represents a child presenting for correction of an open bite. **B,** The smile of his mother, who has an anteroposterior cant of the maxilla with the posterior maxilla clearly being inferiorly positioned and incomplete display of the anterior teeth. Note that the child has the same pattern.

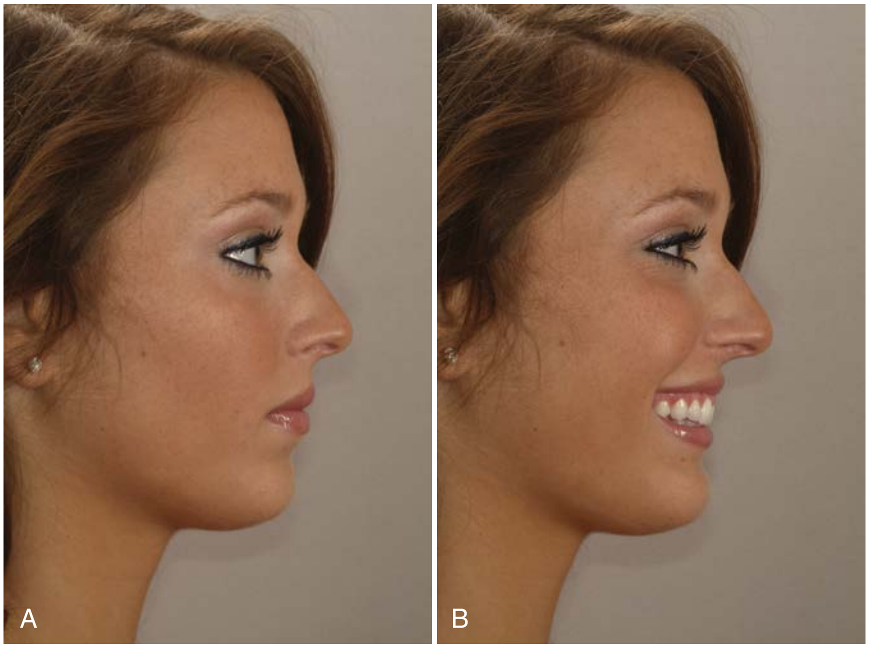

FIGURE 9-7 Two profile images are useful. **A,** Profile at rest with lips relaxed. **B,** Profile smile. This image provides a good view of maxillary incisor angulation and overjet in a way that patients see frequently, but clinicians often don't look at their patients' smiles in this orientation.

of 30 frames per second. With video clips of this type, one can review the video clip on a computer screen for repeated playback or set up a printout sequence that reflects the smile curve, which is a series of frames chosen to reflect the animation of the smile from start to finish (Fig. 9-10). This gives the clinician an opportunity to both visualize the smile from start to finish in dynamic viewing and see the individual frames in sequence to visualize the sustained smile—the smile with the most consistent lip incisor position during the smile.

FIGURE 9-8 An optional submental view may be taken to evaluate and document mandibular asymmetries further.

Intraoral Photographs

Standard intraoral photographic series consists of five views: right and left lateral, anterior, and upper and lower occlusal (Fig. 9-11). The occlusal photograph should be taken using a front surface mirror to permit a 90-degree view of the occlusal surface.

The orthodontist also can use specially designed mirrors that improve cheek retraction with the lateral views to obtain more direct views of buccal occlusion. To reflect buccal interdigitation accurately, as much cheek retraction as possible is needed, or one can use a mirror to gain a more perpendicular view. A 45-degree view from the front makes a Class II malocclusion appear to be Class I. Because occlusal relationships are captured more accurately on casts, mirror views of the lateral occlusion are usually not absolutely necessary.

The major purpose of the intraoral photographs is to enable the orthodontist to review the hard and soft tissue findings from the clinical examination during analysis of all the diagnostic data. What is surprising is how often one discovers something on the photographs that was overlooked at the time of oral examination. Another purpose of the intraoral photograph is to record hard and soft tissue conditions as they exist before treatment. Photographs that show white-spot lesions of the enamel, hyperplastic areas, and gingival clefts are essential to document that such preexisting conditions are not caused by any subsequent orthodontic treatment. The authors also recommend, in addition to the standard intraoral images, close-up images taken with a black background for microaesthetics (Fig. 9-12). This is a standard view for cosmetic dentistry and demonstrates tooth shape more clearly, as well as other aesthetic considerations such as color, zeniths, embrasures, connectors, etc.

FIGURE 9-9 The frustrating experience for the clinician is attempting to obtain a natural and repeatable smile. **A,** This patient obviously presents a forced and unnatural appearance. **B,** The same patient at the end of treatment with a more natural smile.

Cephalometric Radiographs

A lateral cephalometric radiograph is needed for diagnosis. Lateral cephalograms have two purposes: (1) they reveal details of skeletal and dental relationships that cannot be observed in other ways, and (2) they allow a precise evaluation of response to treatment. In many instances, an adequate orthodontic diagnosis can be made without a cephalometric radiograph; however, an accurate assessment of a patient's response to treatment is practically impossible without comparing cephalometric films before, during, and after treatment. For this reason, lateral cephalometric films are desirable but not always necessary. Many patients whose dental and skeletal relationships seem perfectly straightforward (e.g., Class I crowding problems) may not actually benefit from a cephalogram sufficiently to warrant the radiographic exposure involved. Treating skeletal malocclusions without cephalometric evaluation is a serious error.

The diagnostic value of lateral cephalometric films can be improved by taking the films with the patient in a natural head position rather than orienting the head to an anatomic plane as was done in the original cephalometric techniques.[2] Cephalometric head-holders fix the patient's head at three points: the external auditory canals bilaterally and the bridge of the nose or forehead. It is possible to obtain a natural head position cephalometric film, controlling both the source-to-subject and subject-to-film distances, without using a head holder at all.[5] Such films are made by having the patient orient the midline of the face (midsagittal plane) to the midsagittal plane of the head holder without actually attaching the head holder. For patients with growth deformities in which the ears are malpositioned, this may be the only feasible approach.

As a general guideline, differences between natural head position and Frankfort plane positioning are most likely to be encountered in patients with jaw discrepancies, so the further out the patient is on the deformity scale, the more important it is to use natural head position. In most patients, the difference between a natural head position film and an anatomically positioned one is in the vertical orientation of the head. The patient's head is positioned with the ear rods placed lightly into the ears, gently manipulated into a relaxed position as the patient looks into a mirror a few feet away or out a window at a distant horizon, and then fixed in the cephalostat. For greater diagnostic usefulness, the patient's lips should be relaxed rather than pulled into a strained closure when the cephalometric film is made. This step is particularly important when one contemplates a vertical repositioning of the teeth by orthodontic intrusion or extrusion or surgical repositioning of the segment. A number of the published soft tissue cephalometric analyses

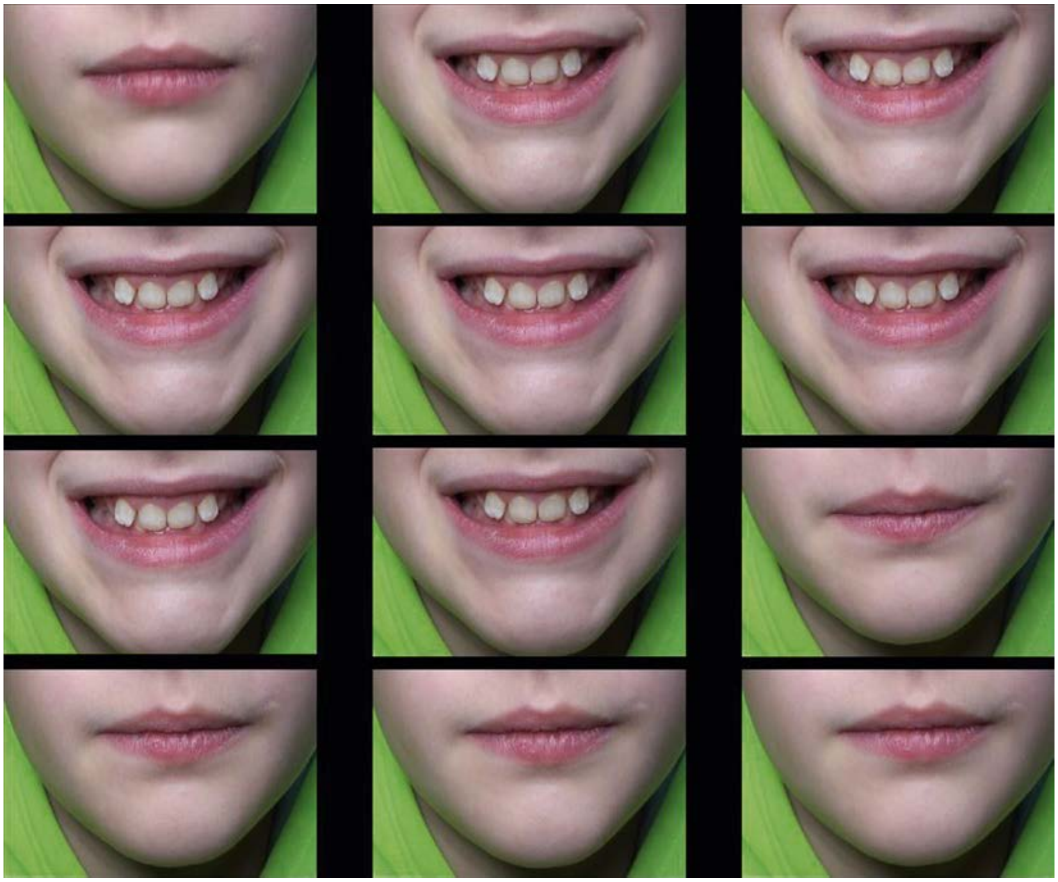

FIGURE 9-10 Digital video clips can be a useful adjunct in smile evaluation. Seeing the series of photographs allows the clinician to see the sustained smile, which we would accept as the posed smile. We currently use additional LED lighting rather than ambient light to give even lighting to eliminate an emphasis of shadowing and buccal corridors, which gives an unrealistic representation of hard and soft tissue relationships.

FIGURE 9-11 A, The right buccal dental photograph, mirror view. B, The left buccal dental photograph, mirror view. C, The frontal centered dental photograph, showing teeth and surrounding soft tissue and excluding retractors and lips. D, The maxillary occlusal dental photograph. E, The mandibular occlusal dental photograph.

have been derived from cephalograms with the subject's lips in closed position even if strained. These analyses neglect the vertical component and may present a distorted view of the anteroposterior lip position because of the lip strain factor.

The teeth should be held lightly together in centric (habitual) occlusion when the cephalogram is obtained. If a severe centric relation–centric occlusion discrepancy exists, obtaining a second film with the mandible retruded may be helpful. However, getting the patient into a true centric relation position in the cephalometric head holder can be difficult. For this reason, the centric relation film is of less diagnostic value than might be thought initially, and taking two lateral head films rarely is indicated.

Contemporary Applications of Cephalometry

The original purpose of cephalometrics was for research on growth patterns and the craniofacial complex, but cephalometric radiographs came to be recognized as valuable tools in evaluating dentofacial proportions and clarifying the anatomic basis for malocclusion. Malocclusion is a result of an interaction between jaw and tooth position and the position the teeth assume as they erupt, which is in turn affected by the jaw relationships. For this reason, two apparently similar malocclusions as evaluated from dental casts may turn out to be different when evaluated more completely, using cephalometric analysis to reveal differences in dentofacial proportions.

Still another use for cephalometrics is to predict changes that should occur in the future for a patient. The result is an architectural plan or blueprint of orthodontic treatment called a *visualized treatment objective* (VTO). The accuracy of the prediction is a combination of the accuracy of predicting the effect of treatment procedures and the accuracy of predicting future growth. Unfortunately, growth predictions and predictions of the effects of treatment on growth remain relatively inaccurate, so a VTO for a growing child often is only a rough estimate of the actual outcome. Nevertheless, preparation of the VTO can be helpful in planning treatment for patients of any age with complex problems. The VTO has matured from its cephalometric origins with pencil tracings to today's incorporation of digital imaging and an expanded vision from the profile only to frontal and dental functional and aesthetic treatment. (Fig. 9-13).

In contemporary patient analysis, the cephalogram is used as an initial diagnostic tool and in the integration of the VTO concept into image projection. The emphasis in this chapter is on the extension of this methodology in modern treatment planning. In modern orthodontics, cephalometric findings no longer are the major determinant of treatment goals.

Computer Imaging in Contemporary Treatment Planning

Patients are keenly interested in knowing what they will look like after treatment both for the face and the smile. Although profile line drawings based on manipulation of cephalometric tracings may provide a reasonable feedback system for the orthodontist, they have little cognitive value to the patient. Computerized cephalometric programs streamline the laborious manual measurement of dimensions and angular relationships on patient cephalograms and have made it much easier to create and use facial VTOs. Before the use of computers in the treatment planning process, the VTO concept required the clinician to use acetate templates of the teeth and jaws to predict what treatment was needed to attain aesthetic and functional goals. Computer imaging technology now allows clinicians to modify facial images to project treatment goals accurately and discuss them with patients. The computer image is much easier for the patient to comprehend than is just the soft tissue profile of a cephalometric tracing. Computer imaging is the next step in the natural progression of the application of technology to orthodontic treatment planning.

For this purpose, integrated profile image–cephalometric planning offers several advantages:

1. Profile visualization for better comprehension of the facial response to the dental and soft tissue manipulation involved in a particular treatment plan.
2. Quantification of the planned dental and osseous movements to reduce the guesswork regarding the facial response to the proposed orthodontic treatment plan.
3. Evaluation of various treatment plans before deciding on the final plan, essentially image "mock-ups" for visualizations.

This is the essence of the concept of image-directed diagnosis because it allows clinicians, at least in adult or surgical cases, to determine beforehand the facial result of proposed treatment.

A VTO is mandatory in the development of a surgical orthodontic treatment plan in which growth effects are not a problem (see Fig. 9-13). Many surgeons are leery of providing imaging projections preoperatively out of the fear that it represents an implied warranty or that a lawsuit may result if the result does not match closely. Studies indicate just the opposite,[8] that patients are more satisfied with their final outcome when their presurgical counseling included imaging than those who did not have imaging. In addition, in one study all patients indicated that they actually liked the final result better than the image projection.[9]

Computer imaging also is useful in counseling and communicating with patients because it allows presentation of treatment options that are often difficult to explain verbally. The counseling phase involves the use of facial- or dental-image modification without any quantitative aspect to the process. This modification is a graphic way of communicating concepts that are difficult to present verbally. For example, facial imaging, smile image modification, or a smile bank can be used to explain to patients how their teeth will look after treatment. A sample of smiles with aligned teeth can be used to demonstrate to patients the changes they may expect in their dental appearance. This process, which is facilitated greatly by the use of computer images, improves the chance of true informed consent.

After the patient decides to proceed with treatment, the clinician must consider ways to maximize the chance of actually producing the outcome the patient desires. The planning phase of computer imaging permits quantification of the treatment plan so that the clinician knows precisely what and how much to do. The principle of quantification and retroengineering as described in the surgical VTO section is also important in smile design. Calibration of a smile image and the ability to measure the amount of change needed to reach smile goals are recent developments (Fig. 9-14).

CLINICAL EXAMINATION OF FACIAL SYMMETRY AND PROPORTION: ITS SIGNIFICANCE IN TREATMENT PLANNING

The clinical examination requires direct measurement of a number of hard and soft tissue relationships, most of which cannot be documented in any form of imaging or models. After the clinical examination data are entered into a database program, the data become as easily retrieved and used as any other digital record.

Application of Database Programs to Clinical Information

The goal of orthodontic diagnosis, as stated previously, is to determine the patient's chief complaint and give it the highest priority in designing treatment. Identification of the patient's problems and specifying potential solutions have been the major focuses of diagnostic efforts.

In contemporary diagnosis, however, orthodontists now include the concept of *treatment optimization*. The term

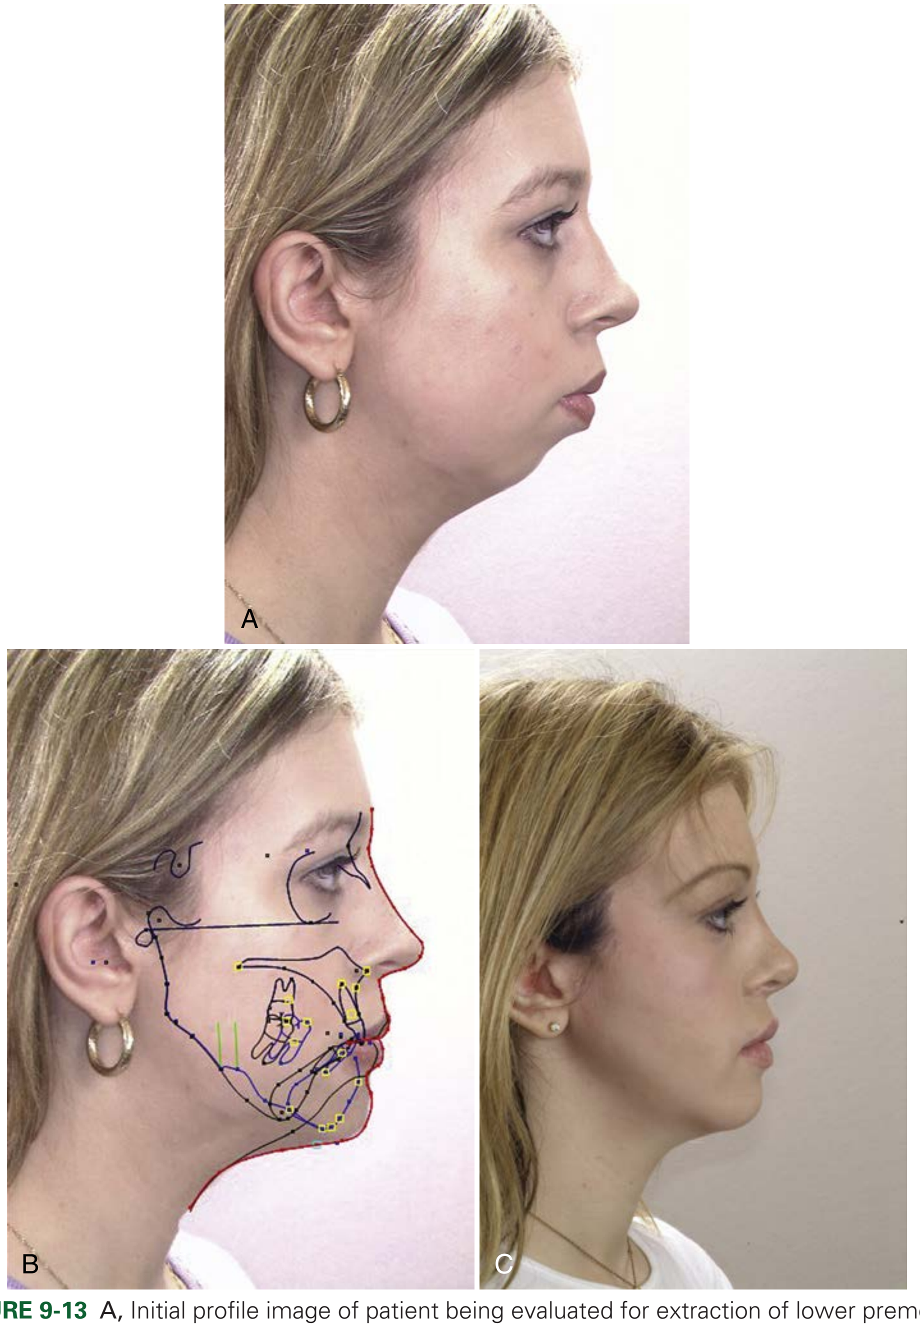

FIGURE 9-13 **A,** Initial profile image of patient being evaluated for extraction of lower premolars and advancement of the mandible and chin. **B,** Visualized treatment objective (VTO) of patient demonstrating the soft tissue outline anticipated with these orthodontic and surgical movements, and the amount of movement is retroengineered through a quantitative table reflecting the exact magnitude of movement. **C,** Final profile image reflects the outcome and its proximity to the VTO.

optimization has become familiar to most orthodontists through the increased use of computer technology. With computer hardware, it is wise periodically to "optimize the hard drive" on your computer to keep it running at its top performance level. What this does is scan the computer disc for damaged or corrupted files and eradicate them. The process also identifies good files and keeps them. Treatment plan optimization is similar. Optimization means that the orthodontist assesses the patient's problems and identifies ways to eliminate them and then identifies the patient's positive attributes and designs treatment to keep them. A familiar example in orthodontics is the correction of Class II malocclusion in a patient with mandibular deficiency and a normal upper face. Extraction of maxillary first premolars and retraction of the upper incisors solves the problem of the Class II malocclusion but ignores the positive attribute of a normal upper face, and the patient then has the normal upper lip retracted and flattened to fit the distorted lower jaw. The more appropriate treatment plan is advancement of the deficient mandible, correcting the Class II malocclusion and maintaining the normal upper face. In miniaesthetics, the smile arc is also an excellent example. If a consonant

FIGURE 9-14 **A,** This patient had an undersized maxillary right lateral incisor, which had been restored with bonding material and a congenitally missing maxillary left lateral incisor (replaced by a removable pontic). In preparation for final restoration, the gingival margins had been placed appropriately, and it was time to coordinate the transition from orthodontic care to restorative care. **B,** Her smile revealed incomplete maxillary incisor display and the placement of the gingival margins relative to the upper lip on smile and incisor heights. **C,** Utilizing the smile image and computer software, we were able to visually outline the treatment targets (the smile arc). Through software calibration of the image to the subject, we then were able to measure the distance of the existing incisal edges on smile to the smile target, thus aiding in the of the veneers to be fabricated in the laboratory. **D,** Utilizing computer software, the intraoral image was calibrated, the known measurements of incisor heights were noted (*in blue*), the projected target distances added to the incisal edges (*yellow*), and the final veneer sizes were calculated and noted in white. **E** and **F,** This coordination of care, and quantification of treatment goals, resulted in an outstanding outcome.

smile arc is not recognized at the beginning of treatment, studies indicate that one-third are flattened by orthodontic treatment.

The problem-oriented treatment-planning process is especially useful in this context because it demands a systematic and thorough approach to evaluation. The generation of the problem list then leads to the diagnosis, and treatment options for each problem lead to a logical treatment plan. In clinical practice, this methodical process may give way to expedience, and the clinician may fall back on techniques and treatment systems rather than individualized treatment plans carefully derived for each patient. The evolution of computer technology has facilitated this process so that the clinician can organize the information to be used in the decision-making process in a streamlined fashion without getting lost in the details.

Database programs work by setting up fields that represent sections of data entry. The data fields allow orthodontists to preload choices through the use of pop-up windows. The database program is designed to facilitate everyday functions in the problem-oriented diagnostic and treatment planning process:

1. *The information-gathering process is thorough but streamlined.* In the traditional examination, measurements are written down on a sheet of paper and then transcribed or dictated into a planning format. The database program facilitates this process by using the computer screen interface as the entry point (Fig. 9-15). Pop-up menus are used for entering data. As the computer cursor is placed on one of the data entry levels, a pop-up box with a number of choices appears, beginning with the most common choice at the top (most easily accessed for entry). As soon as a choice is identified and clicked with

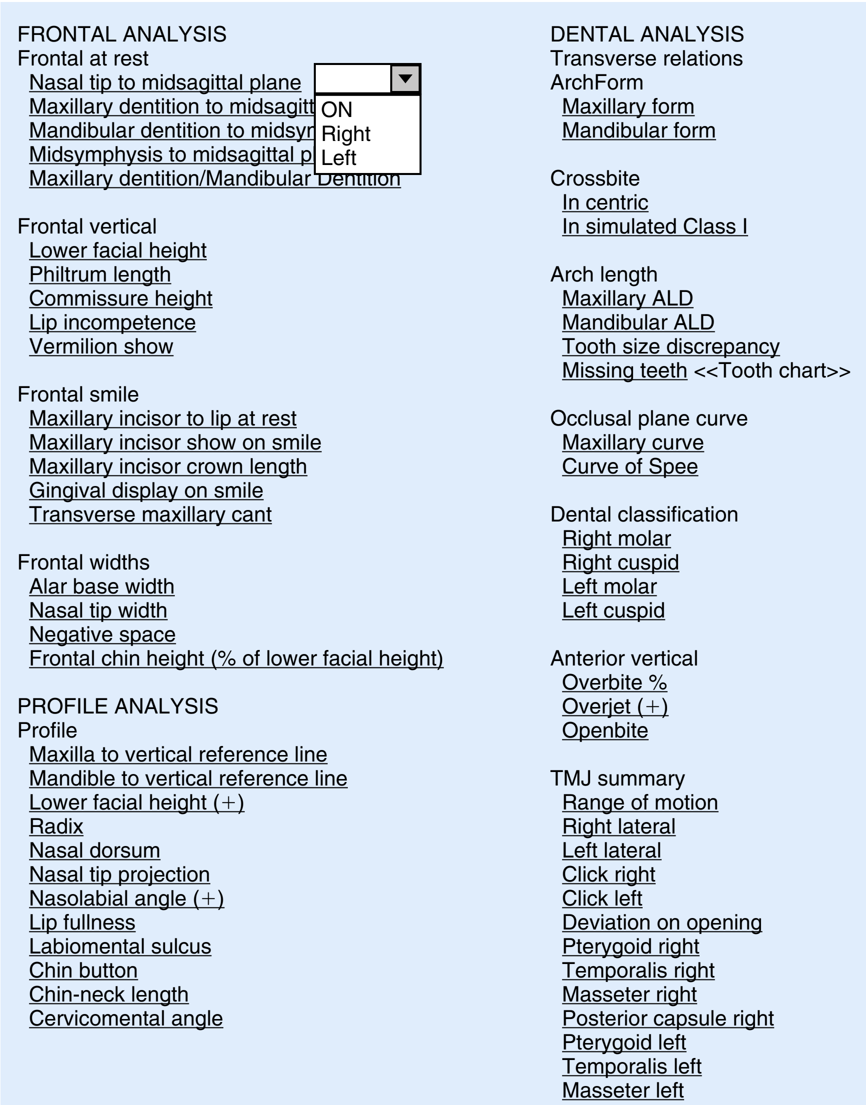

FIGURE 9-15 Database programs facilitate the data-gathering process by using the computer screen interface as the entry point. All components of the clinical examination are displayed on one screen, as in this screen shot, and as the clinician goes through the examination process and calls off each measurement, the data are entered through the use of pop-up menus. The pop-up menus allow data entry, and as each entry is made, the window closes and automatically opens the next for a smooth and rapid transition from one parameter to the next. This process facilitates a thorough examination and evaluation.

the mouse, the menu box closes and the next one is opened, complete with choices. In the clinical setting, this is usually the function of a staff auxiliary member, such as a treatment coordinator. For example, when the field "nasolabial angle," is clicked, a small window with the choices of "obtuse," "normal," and "acute" appears next to the nasolabial angle field, and the clinician can identify the choice by clicking it with a pointing device. After the selection is made, the program moves immediately to the next choice. This greatly streamlines the examination process and forces the clinician to measure each detail of the dentofacial analysis.

The first patient appraisal should be thorough and consistent, maximizing the chance that nothing of importance will be overlooked. Examiners should avoid situations in which they perform a cursory examination, jotting down notes regarding abnormalities they see and not really making note of any other descriptive data, normal or abnormal. Practitioners may assume that most diagnostic decisions can be made from the records they take of patients. Is that bad? Yes, it is, and for several reasons:

a. Static records cannot reflect the dynamic relationships that are important in the overall functional and aesthetic assessment of the patient. For example, the relationship of the upper incisor at rest and on smile to the upper lip is not reflected in radiographs or models and is evaluated poorly in photographs. As described previously in this chapter, dynamic (video) records help but still do not replace careful clinical observation.
b. The comprehensive facial and dental analysis process is streamlined and enhanced greatly by the database program.
c. The notation of normal observations is a powerful medicolegal aid. An unhappy patient may begin to "pick apart" the outcome, and the well-prepared practitioner should be able to document treatment changes with as many observations as possible.

Orthodontists currently enter this information into a computer in the examination room, but other options include the use of laptop and notebook computers. The use of personal digital assistants also is evolving. A handheld personal digital assistant permits even greater mobility, allowing data entry at chairside or any other location in the office or in auxiliary offices. Data may be entered with an electronic pen rather than a mouse and keyboard.

2. *The problem list is generated automatically through the use of predetermined parameters*. Each data entry is processed through the parameter field set by the clinician to test for its range of normality. For example, in the measurement of the maxillary midline to the midsagittal plane, the midline is coincident with the midsagittal plane or it is not. If the midline is not coincident, it is automatically a problem and is identified as such by the software and dropped into the problem list of the appropriate area (in this case, frontal facial examination). In more complex measurements, one may place ranges. For example, a mandibular plane measurement greater than 37 degrees is identified as a high mandibular plane angle; a measurement less than 32 degrees is identified as a low mandibular plane angle. Measurements may be changed by clinicians to fit their ranges because all doctors have their own parameters of what they consider problematic.
3. *Access to information is enhanced greatly in the traditional examination and treatment planning process.* After the clinical examination is finished, the observations then are transcribed into a more formal record system or left on the sheet to be retrieved from the chart when needed. This means that one of three things happens:
   a. If the information is left as is, it is not recalled easily during treatment because the information is not accessible. Also, the information is not transmitted easily to or shared with other doctors or with patients.
   b. The doctor writes the notes in a more organized fashion, which is time-consuming to complete.
   c. If the record is dictated, the doctor's time involvement is reduced significantly because dictation is much faster than handwriting. However, staff time then is needed to transcribe the dictation; therefore, elimination of dictation is desirable if possible.

Database programs require entry of information only one time, and this information can be retrieved and transported into any document, transported into spreadsheets for research purposes, or recalled for the clinician at any time on computer screens in the clinic, consultation area, or even at home.

EVALUATION OF FACIAL PROPORTIONS (MACROAESTHETICS)

Frontal Vertical Facial Relationships

Attractive faces tend to have common proportions and relationships that generally differ from normative values. Treatment planning in the past focused on linear and angular measurements, while the trend today is to recognize the interrelationships of proportions. The ideal face is divided vertically into equal thirds by horizontal lines adjacent to the hairline, the nasal base, and menton (Fig. 9-16). This figure also illustrates two other characteristics of the ideal lower third of the face: the upper lip makes up the upper third and the lower lip and chin comprise the lower two-thirds. What has become increasingly important is to recognize not just the vertical relations but also the relationship to the facial widths—the height-to-width ratio.

FIGURE 9-16 Frontal vertical thirds of the ideal female face with ideal symmetry. The vertical thirds should be roughly equal, with the lower third further subdivided into an upper third and lower two-thirds. In the adult, philtrum height should be equal roughly to commissure height.

Increased Face Height

The patient in Figure 9-17, *A* and *B*, is a good example of vertical maxillary excess (VME). In addition to the long upper third, this patient had a long lower face with excessive incisor at rest, excessive gingival display on smile, and interlabial gap—all of which are characteristics of VME. Surgical correction of the skeletal deformity was performed through superior repositioning of the maxilla, which also dramatically shortened the lower face (Fig. 9-17, *C*). The gummy smile also was improved with the procedure (Fig. 9-17, *D*), and an advancement genioplasty with vertical shortening contributed to the shortening of the lower facial third.

Does a patient with a long lower face always represent a VME problem? Of course not. Figure 9-18, *A*, presents an example of excessive vertical disproportionality of the lower facial height resulting from excessive chin height. Pretreatment facial analysis revealed an excessive lower facial height with normal upper facial thirds. An initial diagnosis of VME was considered, along with the possibility of surgical maxillary impaction. However, the patient had a normal smile line and a normal relationship between the resting upper lip and incisor, which is not associated with VME. The chin height from menton to the lower vermilion was significantly greater than the desired two-thirds of the total height of the lower facial third. This clinical assessment led to the conclusion that the vertical facial disproportionality resulted primarily from excessive chin height rather than VME. The treatment prescribed consisted of a wedge osteotomy and skeletal shortening of the chin to reduce the lower facial height (Fig. 9-18, *B*).

Decreased Face Height

Short lower facial height can result from vertical maxillary deficiency, mandibular deficiency with diminished mandibular body or ramus height, or a short chin height. Characteristics of vertical maxillary deficiency include (1) insufficient incisor

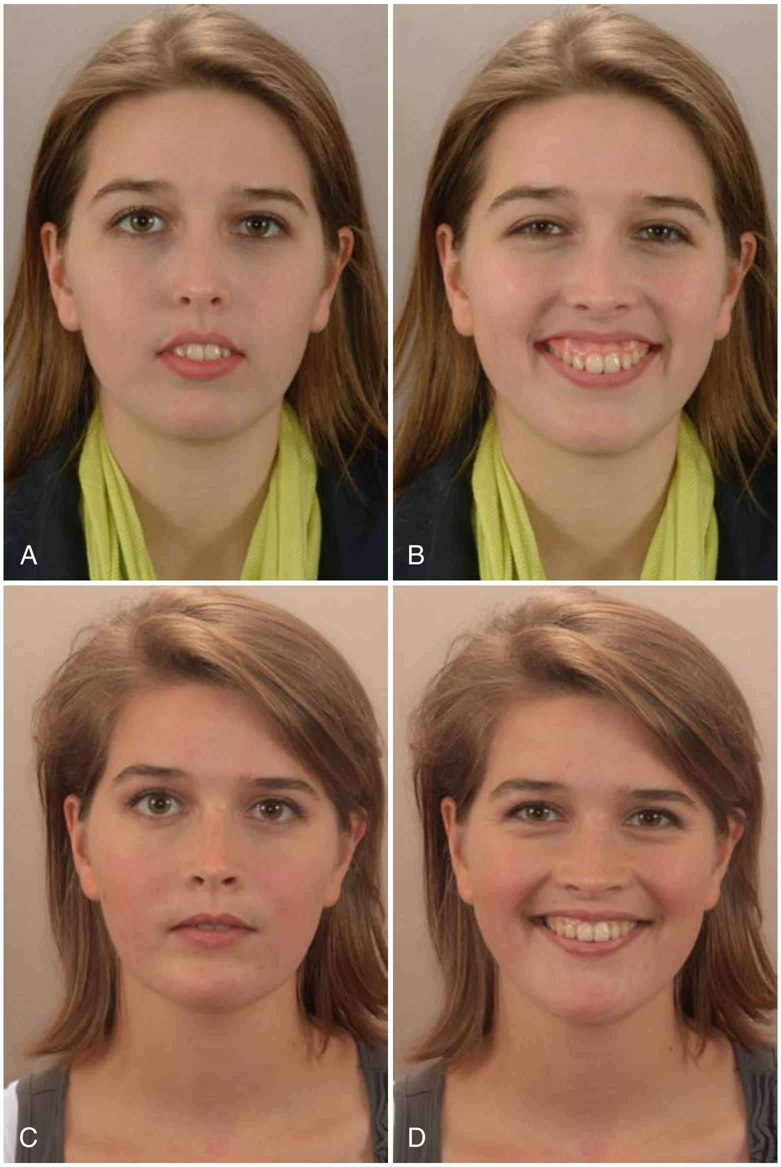

FIGURE 9-17 Pretreatment (A, B) and posttreatment (C, D) facial views of a patient with the characteristics of vertical maxillary excess: a long, lower facial height, excessive incisor display at rest, interlabial gap, and excessive gingival display on smile.

display at rest, (2) inadequate upper incisor display on smile, and (3) short lower facial height. Improvement in the adult often includes surgical maxillary downgraft. This surgical procedure lengthens the midface and rotates the chin down as the mandible hinges around the condylar axis.

The patient in Figure 9-19, *A* and *B*, presented with a disproportionately short lower facial third and mandibular deficiency. Clinically, he had diminished incisor display at rest, and on smile, characteristics of vertical maxillary deficiency. Dentally, he had a Class II malocclusion, a deep overbite, and 9 mm of overjet. Surgical correction was required, consisting of maxillary downgraft and mandibular advancement to correct his malocclusion, improve proportionality of his lower facial third, and increase incisor display at rest and on smile (Fig. 9-19, *C* and *D*).

Lower facial height increase in the adolescent may be improved through modification of growth, dental eruption, or both. Some examples of the ways this may be achieved, ranked in order of effectiveness, include the following:

1. *Functional growth modification appliances that increase lower facial height by promoting posterior dentoalveolar eruption.* Eruption occurs more rapidly in some patients than in others and is affected by the amount of freeway space, resting mandibular posture, and amount of wear. This type of treatment is most effective in younger patients in active phases of growth.
2. *Anterior bite plates incorporated into fixed appliances (such as a Nance-type appliance) or removable appliances.* Anterior bite plates hold the lower incisors against the acrylic while permitting the posterior teeth to erupt freely. The bite plate must be worn continually and also should be worn even after bite opening to maintain the increase in facial height and bite opening.
3. *Cervical headgear to encourage maxillary posterior eruption during growth modification.* Cervical headgear produces an extraoral force in a posterior and inferior direction below the center of resistance of the teeth and the maxilla, resulting in dentoskeletal extrusion and an increase in lower facial height.
4. *Eruptive wire mechanics designed to extrude the mandibular posterior segments.* A reverse curve of Spee commonly is placed in the lower archwire to open the bite through some lower incisor intrusion and a more substantial amount of posterior extrusion, resulting in an increase in the lower facial height (Fig. 9-20).

The analysis of the vertical thirds of the face is an initial barometer of the skeletal structures of the face and serves the clinician well by focusing on the face before the teeth, allowing observation of the gross proportionality of the face before the details are addressed.

Transverse Facial and Dental Proportions

The interrelationships of the widths of the components of the face are important in the overall proportionality of the face (Fig. 9-21). Few linear or angular "normative" measurements or values are available because the interrelationship of these component parts is what is most important. For example, a vertically long, oval face most often is correlated with narrow gonial angles and a narrow nose. A wide nose on a narrow face tends to appear most noticeable and incongruous with the facial type described.

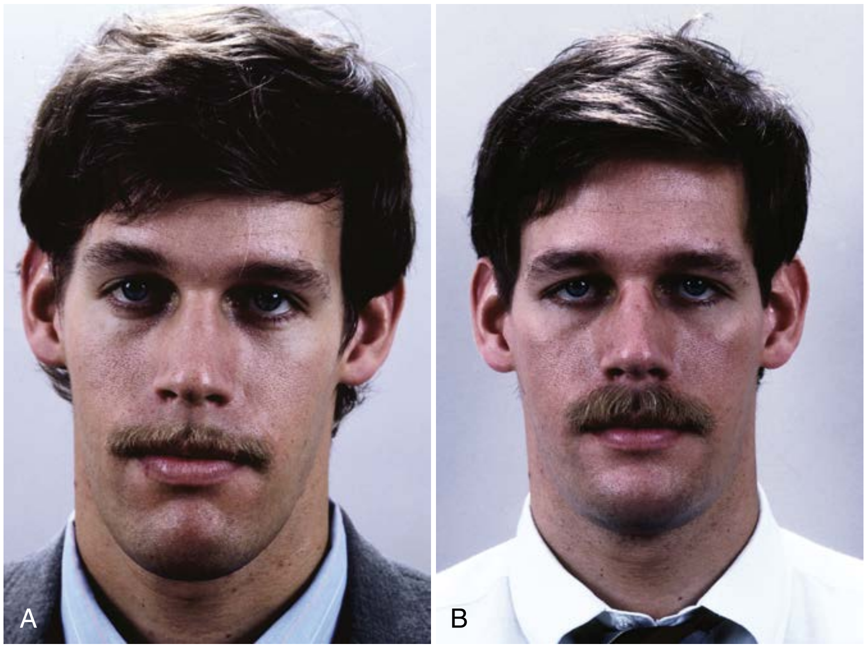

FIGURE 9-18 Before treatment (**A**), this patient had excessive lower facial height. The upper incisor-to-lip relationships were normal, which eliminated vertical maxillary excess as a potential cause of the long lower facial height. The chin height was 75% of the lower facial third, so more ideal facial proportions (**B**) were achieved with an inferior border osteotomy and removal of a wedge of bone above the chin to reduce chin height. (From Sarver DM. *Esthetic Orthodontics and Orthognathic Surgery*. St. Louis: Mosby; 1998.)

FIGURE 9-19 This adult patient presented with a short lower facial height, insufficient incisor display at rest and on smile, a deep bite, and a Class II malocclusion (**A** and **B**). A maxillary downgraft procedure was performed in addition to mandibular advancement surgery to achieve the desired increase in facial height (**C** and **D**).

Central Fifth of the Face

The central fifth of the face is delineated by the inner canthi of the eyes. The inner canthus of the eye is the inner corner of the eye containing the lacrimal duct. A vertical line from the inner canthus should be coincident with the ala of the base of the nose.

Medial Two-Fifths of the Face

A vertical line from the outer canthi of the eyes should be coincident with the gonial angles of the mandible. Disproportionality is a subtle clinical judgment, but procedures to augment or reduce the prominence of the lateral mandibular area are available to improve aesthetic problems here.

Outer Two-Fifths of the Face

The outer two-fifths of the face are measured from the base of the ear to the helix of the ear, which represents the width of the ears. Unless this abnormality is part of the chief complaint, prominent ears are often the most difficult abnormality to discuss with a patient because only in the most severe cases do laypersons recognize their effect on the face. Otoplastic surgical procedures are relatively atraumatic and can improve facial appearance dramatically. They may be recommended to and performed on adolescents and adults, but changing the hairstyle to conceal the ear may be a more practical solution.

FIGURE 9-20 The facial characteristics of this short face, deep bite patient direct the orthodontic mechanics for occlusal correction, facial improvement, and restoration of malformed teeth. **A,** Her frontal relationships were characterized by a short lower facial third and an overclosed facial appearance. **B,** On smile, she did not display all of her maxillary incisor due to mild vertical maxillary deficiency and tooth malformation. **C,** Her profile was characterized by moderate mandibular deficiency and an acute nasolabial angle. Her short lower facial height and overclosed appearance were also apparent on profile. **D,** After 24 months of treatment, her lower facial height was dramatically improved. **E,** The profile also reflected growth modification with improvement in mandibular projection and increase in lower facial height. Lower facial height increase was achieved with cervical headgear and posterior extrusive mandibular arch mechanics. **F,** After restoration of the malformed teeth, incisor display was dramatically improved.

FIGURE 9-21 Sagittal facial proportions: the rule of fifths. From the midsagittal plane, the ideal face is composed of equal fifths, all approximately equal to one-eye width. The commissure width should also be coincident with the medial limbus of the eyes, and the alar width should be coincident with the intercanthal distance.

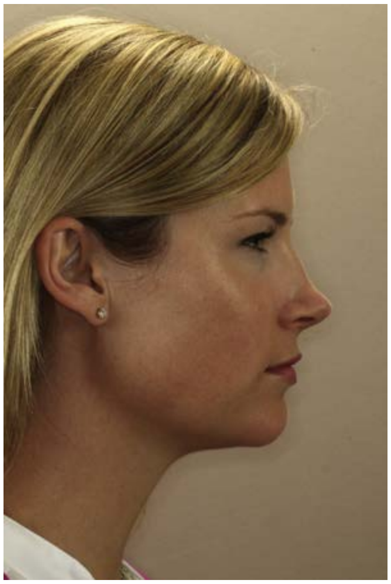

FIGURE 9-22 Profile of a patient with ideal nasal anatomy, illustrating the nasofrontal angle (*radix*), supratip break, double break of the nasal tip, and nasolabial angle.

Evaluation of Nasal Proportions

The nose dominates the middle portion of the face on profile (Fig. 9-22) but is an area that has not been emphasized in orthodontic training. A number of articles in the orthodontic literature have not received the attention from orthodontists they deserve (see the Suggested Readings at the end of the chapter). This is probably because many orthodontists are uncomfortable talking to patients about their noses and often soft tissue traits when the main focus of the patient and the orthodontist is the teeth.

Orthodontic treatment plans and mechanics can affect dramatically the way the nose fits the face. In addition, nasal growth in the adolescent can produce changes that diminish the aesthetic result as the patient matures. The orthodontist needs to understand nasal anatomy and the treatment of nasal deformities well enough to be comfortable with discussions of nasal morphology, recognition of aesthetic problems, and potential treatment.

Radix

On profile, the radix is the area orthodontists generally associate with soft tissue nasion. Radix projection is a discrete but important aspect of nasal aesthetics and is quantified in terms of the nasofrontal angle. Lack of radix projection can make an otherwise normal nose appear to have a dorsal hump.

Nasal Dorsum

One-third to one-half of the nasal dorsum is called the *bony dorsum* because it is formed by the confluence of the two nasal bones. The rest is called the *cartilaginous dorsum* or *septal dorsum* because it is composed of septal cartilage. The septal cartilage combines with the bony nasal septum to divide the nasal cavity into two chambers. On profile, the septal cartilage protrudes in front of the piriform aperture. Most nasal humps are formed by the dorsal border of the septal cartilage in combination with the nasal bones. The removal of an overprojected dorsal hump is one of the most common and familiar of rhinoplastic procedures.

Nasal Tip

The nasal tip is the most anterior point of the nose, and the supratip is just cephalic to the tip. The supratip break is the area just cephalic to the nasal tip where the lobule meets the dorsal portion of the nose. On the aesthetic nose, a slight depression is present on the supratip, which should be more pronounced in the female than in the male. The double break represents the angular formation of the nasal tip created by the distinct definition of the tip cartilages created by the supratip, tip, and infratip.

Columella

The columella is the portion of the nose between the base of the nose (subspinale) and the nasal tip. The columella comprises the cartilaginous nasal septum and membranous septum.

Nasolabial Angle

The nasolabial angle measures the inclination of the columella in relation to the upper lip. The angle should be in the range of 90 to 120 degrees.[1] The morphology of the nasolabial angle is a function of several anatomic features. Procumbency of the maxilla tends to produce an acute nasolabial angle, and maxillary retrusion tends to produce an obtuse nasolabial angle, but the angle is very much affected by nasal form itself.

Lip Projection

Although lip projection appears to be a fairly simple concept, it is a more complex issue in the comprehensive facial analysis in the contemporary hard and soft tissue approach to evaluation. Attempts have been made to quantify lip projection in the orthodontic literature by measurements such as the Rickett's E (aesthetic) line and Holdaway's line. These measurements are dentally oriented and are not facially comprehensive.

For example, it often is stated that in an ideal E-line relationship, the lower lip should be coincident with a line from the nasal tip to the anterior chin, and the upper lip should be about 1 mm behind it. If a patient has a long nose, the E-line describes the problem as dental or maxillomandibular retrusion rather than nasal overprojection.

Lip projection is a function of the following:

- *Lip thickness*: Lip thickness is affected directly by patient age, gender, and ethnicity.
- *Dental protrusion or retrusion*: Hard tissue support of the lips is a recognized determinant of lip position.
- *Maxillomandibular protrusion or retrusion*: Essentially affecting soft tissue support.

Excessive versus Inadequate Lip Projection

Lip projection is difficult to quantify because of its close interrelationship with other structures. Measurement of lip thickness is possible, and enough studies have been published in the literature to provide a sufficient database for this measurement. Lip thickness and its relation to other facial structures heavily influence the perception of lip projection. For example, in a patient with a deficient chin, the lower lip may appear full or procumbent. Advancement of the chin may result in better balance of the lower face and diminish the protrusive appearance of the lips.

The patient in Figure 9-23 is a good example of this interplay of anatomy. This young man was referred for correction of his mild Class II malocclusion. His parents thought that he had protrusive lips (see Fig. 9-23, *A*). His profile (see Fig. 9-23, *B*) confirms that relative to his chin and nose, the lips are more prominent than most orthodontists would consider ideal. A reasonable orthodontic plan would involve four-premolar extraction to create space for retraction of the anterior teeth and reduction of dental protrusion and lip fullness over approximately a 2-year period. A plastic surgeon or oral and maxillofacial surgeon might be inclined to define this patient's profile as chin deficient and recommend chin augmentation. We refer to this as "diagnosis by procedure"—that is, "What I do is what you need."

As the consultation proceeded, the maturational soft tissue changes were discussed (i.e., expected nasal growth and profile flattening). The consultation was visually facilitated through the use of digital image projections, and the parents elected to forego extractions in favor of 1 year of nonextraction treatment to be followed by an advancement genioplasty at the appropriate age (see Fig. 9-23, *C* to *F*).

Much emphasis is now given to nonextraction treatment, but in cases of dental protrusion and an excessively full profile, extraction treatment still has a significant role. The patient in Figure 9-24, *A* to *C*, presented with congenitally missing maxillary lateral incisors and a large maxillary diastema. Facially, she exhibited excessive lip fullness and protrusion. Rather than close the diastema to make space for placement of lateral incisor implants, the treatment plan was to extract the mandibular first premolars, close the space in the maxillary arch to treat her with cuspid substitution, and retract the lower incisors, resulting in protrusion reduction (Fig. 9-24, *D* to *F*).

Effects on the Labiomental Sulcus

The labiomental sulcus is defined simply as the fold of soft tissue between the lower lip and the chin; it may vary greatly in form and depth. The sulcus is affected by facial height, overjet, and chin projection.

Orthodontists commonly see the effect of decreased vertical dentoskeletal relations on the labiomental sulcus because many orthodontic patients have short faces and Class II malocclusions. An exaggerated but excellent analogy of the effect decreased vertical dimension has on chin position is the edentulous patient who has removed his dentures before closing his mouth. The vertical overclosure causes tremendous loss in the vertical dimension, resulting in soft tissue redundancy of the lips expressed as a deep labiomental sulcus.

The adolescent patient in Figure 9-25, *A* and *B*, started treatment with 6 mm of overjet and a 53% lower facial height. Orthodontic treatment included cervical headgear for its orthopedic effect on the lower face and Class II anteroposterior correction. With the downward vector of force application, the posterior maxilla and maxillary dentition are extruded, thus increasing the lower facial height. Eruptive lower archwire mechanics also were used with fixed appliances to extrude the mandibular posterior teeth and increase the lower facial height. The finished result Figure 9-25, *C* and *D*, reflects the longer, lower facial height and decrease in the depth of the labiomental fold achieved by growth and orthodontic and orthopedic treatment.

Chin Projection

Chin projection is determined by two factors: (1) the amount of anteroposterior bony projection of the anterior inferior border of the mandible and (2) the amount of soft tissue that overlays that bony projection. The combination of these two characteristics equals the total amount of chin projection.

NB-Pg is the cephalometric measurement most orthodontists refer to as "chin projection" and is quantified as the amount of bone projecting past the cephalometric NB line (a linear measurement in millimeters). Soft tissue thickness is also a variable in chin projection and has been studied extensively.[1]

Throat Form

Although throat form often is not considered in planning orthodontic treatment, it is an important aspect of facial aesthetics, and one must take into account the effect treatment has on it (Fig. 9-26). An obtuse cervicomental angle often reflects the following:

- *Chin deficiency*: Chin deficiency results in slackening of the submental and platysmal musculature, resulting in an obtuse angle.
- *Lower lip procumbency*: Lower lip procumbency results in lip projection, which simply increases the obtuseness of the lip–chin–throat angle.
- *Excessive submental fat*: Excessive submental fat contributes to the bulk of the neck, increasing the lip–chin–throat angle.
- *Retropositioned mandible*: A retropositioned mandible also results in slackening of the submental musculature and an obtuse angle.
- *Low hyoid bone position*: Low hyoid bone position contributes to the obtuseness of the lip–chin–throat angle through its mechanical location and the attachment of the submental musculature.

Miniaesthetics (Evaluation of the Smile)

Importance of the Smile in Orthodontics

The subject of the smile and facial animation as it relates to communication and expression of emotion should greatly interest orthodontists. Although the English language is replete with words such as *smirk, insipid smile, wry smile, sardonic*

FIGURE 9-23 Because lip prominence is evaluated relative to the chin and nose, orthodontic retraction of anterior teeth or advancement genioplasty may yield a similar result. This patient presented with protrusive lips (**A**), and the profile (**B**) reflected lip fullness with chin deficiency. The patient was offered the option of orthodontic treatment to retract the anterior teeth but chose advancement genioplasty with nonextraction orthodontic treatment. Frontal (**C**) and profile (**D**) relationships are shown after completion of orthodontic treatment. The frontal (**E**) and profile (**F**) changes are shown after advancement of the chin. This case illustrates the nature of differential treatment choices in aesthetic treatment selection.

FIGURE 9-24 **A** to **C**, This adolescent patient presented with missing maxillary lateral incisors, dental protrusion, and lip protrusion. **D** to **F**, Protrusion reduction with lower first premolar extractions improved the balance of the lips and chin.

FIGURE 9-25 A and B, This growing patient had a Class II malocclusion, deep labiomental sulcus caused by overjet, and diminished lower facial height resulting in lip redundancy. The recommended orthodontic treatment included cervical headgear and extrusive mechanics of the posterior teeth to reduce overjet while increasing lower facial height. C and D, The deep labiomental sulcus was improved through overjet reduction and increase in lower facial height.

smile, ironic smile, inscrutable smile, infectious smile, warm smile, and *enigmatic smile*, all of which conjure up specific images, these descriptions are entirely subjective. An attractive smile helps win elections, and a beautiful smile sells products for companies whose subliminal message in advertisement is "look better, feel younger." A well-treated orthodontic case in which plaster casts meet every criterion of the American Board of Orthodontics for successful treatment may not produce an aesthetic smile.

Interestingly, few objective criteria exist for assessing attributes of the smile, establishing lip–teeth relationship objectives of treatment, and measuring the outcomes of therapy. Without morphometric data for smile characteristics, orthodontists have no choice but to be entirely subjective in assessing smiles. Subjectivity can be reduced, however, by incorporating the measurements described below into the clinical examination.

Analysis of the Smile

The perception of dentofacial aesthetics by orthodontists and patients has differed considerably. A nonposed smile is involuntary (i.e., not obligatory) and is induced by joy or mirth. A smile is dynamic in the sense that it bursts forth but is not

FIGURE 9-26 **A**, This 19-year-old patient had mandibular and chin deficiency resulting in an obtuse chin–neck angle and full-throat form. **B**, On oblique view, she had poor definition of her jawline and mandibular angle. **C**, After surgical advancement of both jaws, combined with soft tissue submental liposuction, platysmal lift, and chin advancement, the throat form was greatly improved on profile. **D**, Her posttreatment oblique view demonstrates improvement in definition of her jawline and mandibular angle.

sustained. All the muscles of facial expression are recruited in the process, causing a pronounced deepening of the nasolabial folds and squinting of the eyes. A nonposed smile (Fig. 9-27, *A*) is natural in the sense that it expresses authentic human emotion. A posed smile (Fig. 9-27, *B*), by contrast, is voluntary and need not be elicited or accompanied by emotion. Such a smile can be a learned greeting, a signal of appeasement, or an attempt to indicate self-assurance.

A posed smile is static in the sense that it can be sustained. If the smile is typical for a particular individual, a posed smile is natural, but the smile also can be "forced" to mimic a nonposed smile. In the latter circumstance, the smile cannot be sustained and will seem to be strained and unnatural. In the Peck classification, a Stage II smile is a forced or strained posed smile resulting in maximal upper lip elevation. Thus, two types of posed smiles are possible: strained and unstrained. When a person is asked to pose for a photograph, the smile that is desired is a voluntary, unstrained, static, yet natural smile. Hulsey[9] and Rigsbee et al.[10] agree that reproducibility of the posed smile is good.

In a two-and-a-half-year period of observation during adolescence, the changes in smile characteristics in untreated patients and in patients undergoing orthodontic treatment were remarkably small. If the conventional thinking that lip–tooth relationships change over time is correct, these changes must occur gradually or much later in life. These changes are likely a part of aging, rather than part of growth and development.

FIGURE 9-27 A, The nonposed smile is natural in the sense that it expresses authentic human emotion. B, A posed smile is voluntary and is static in the sense that it can be sustained.

Diagnostic Smile Analysis: Measurement of Characteristics

Direct measurement permits the clinician to quantify the resting and dynamic tooth–lip relationships. Observation of the smile is a good start, but quantification of resting and dynamic tooth–lip relationships is critical to smile visualization so that the information gathered in the measurement of smile characteristics then can be translated into terms meaningful to the treatment plan. Systematic measurement of resting tooth–lip relationships and how the dynamics of the smile also interact with the maxillary teeth affect the appearance of the smile virtually lead the clinician to a quantified treatment plan.

The following frontal measurements at rest should be performed systematically:

- *Philtrum height* (Fig. 9-28, *A*). The philtrum height is measured in millimeters from subspinale (the base of the nose at the midline) to the most inferior portion of the upper lip on the vermilion tip beneath the philtral columns. The absolute linear measurement is not particularly important, but what is significant is its relationship to the upper incisor and the commissures of the mouth. The philtrum lengthens with maturation and aging and at a faster rate than the commissures.
- *Commissure height*. The commissure height (Fig. 9-28, *B*) is measured from a line constructed from the alar bases through the subspinale and then from the commissures perpendicular to this line. The difference between philtrum height and commissure height decreases from adolescence to adult life. In adults in whom philtrum height remains considerably shorter than commissure height, the effect is an unwitting frown, so that the individual tends to look angry all the time regardless of whether he or she is angry. This effect can be improved with surgical lengthening of the philtrum (Fig. 9-29).[11]
- *Interlabial gap*. The interlabial gap is the distance in millimeters between the upper and lower lips. An interlabial gap of greater than 4 mm is outside the normal range and is considered lip incompetence.
- *Amount of incisor display at rest* (Fig. 9-28, *C*). The amount of upper incisor display at rest is a critical aesthetic parameter because one of the inevitable characteristics of aging is diminished upper incisor display at rest and on smile. As patients get older, the amount of incisor at rest decreases with age, as does the amount of tooth display on smile. The clinician must be aware of this because the effect of diminishing incisor display results in hastening the aging process in terms of smile appearance. For this reason, in orthodontic treatment the choice to open a deep bite with upper incisor intrusion may correct the occlusion at the cost of making the patient look significantly older.

  Measurements on smile are as follows:
- *Amount of incisor display on smile* (Fig. 9-28, *D*). On smile, patients will show either their entire upper incisor or only a percentage of the incisor or gingival display. Therefore, the number of millimeters of crown display on smile is recorded, and this may include the entire crown or, in cases of incomplete incisor display on smile, the amount of incisor shown.
- *Crown height and width*. The vertical height of the maxillary central incisors in the adult is measured in millimeters and is normally between 9 and 12 mm, with an average of 10.6 mm in men and 9.6 mm in women. The age of the patient is a factor in crown height because of the rate of apical migration in the adolescent. The width is a critical part of smile display in that the proportion of the teeth to each other is an important factor in the smile. Most references specify the central incisors to have about an 8:10 width-to-height ratio.
- *Gingival display*. The aesthetically acceptable amount of gingival display on smile varies, but one must always remember the relationship between gingival display and the amount of incisor shown at rest. In broad terms, treating a patient less aggressively in reducing smile gumminess is better when considering that the aging process will result in a natural diminishment of this characteristic. A gummy smile is often more aesthetic than a smile with diminished tooth display.
- *Smile arc*. The smile arc is defined as the relationship of the curvature of the incisal edges of the maxillary incisors and canines to the curvature of the lower lip in the posed social smile. The ideal smile arc has the maxillary incisal edge curvature parallel to the curvature of the lower lip on smile, and the term *consonant* is used to describe this parallel relationship (Fig. 9-28, *E*). Nonconsonant or flat smile arc is characterized by the maxillary incisal curvature being flatter than the curvature of the lower lip on smile. The smile arc relationship is not as quantitatively measurable as the other attributes, so the smile arc is noted merely as consonant, flat, or reversed.

In treating the smile, the social smile in most cases represents a repeatable smile. An important note, however, is that a "maturation" of the social smile may occur in many patients, and the smile may not be consistent from time to time in specific patients.

FIGURE 9-28 **A,** Philtrum height is measured from the base of the nose to the most inferior portion of the upper lip. **B,** Commissure height is measured from the alar base to the outer commissure of the lips. **C,** Incisor display at rest is an important measurement because it reflects the "relative age" of the patient. **D,** Incisor display and gingival display are recorded within the framework of the smile. In cases of incomplete incisor display on smile, the amount of incisor displayed is measured. In this same patient, crown height is also recorded because the entire crown is visible on smile. **E,** The smile arc, defined as the relationship of the curvature of the incisal edges of the maxillary teeth to the curvature of the lower lip, is evaluated in the posed social smile.

The author has chosen the social smile as the representation from which to analyze the smile in four dimensions: frontal, oblique, sagittal, and time-specific.

Vertical Characteristics of the Smile

The vertical characteristics of the smile are categorized broadly into two main features: those pertaining to incisor display and those pertaining to gingival display. The patient shows the entire tooth or does not and shows the gingiva or does not. Inadequate incisor display can be a combination of vertical maxillary deficiency, limited lip mobility, and short clinical-crown height. If short clinical-crown height is the primary contributor to the inadequate tooth display, one must differentiate between a lack of tooth eruption (which may take care of itself as a child gets older), gingival encroachment (treated with crown lengthening), and short incisors secondary to attrition, treated by restorative dentistry with laminates or composite buildups (Fig. 9-30).

Another feature of vertical smile characteristics is the relationship between the gingival margins of the maxillary incisors and the upper lip. The gingival margins of the canines should be coincident with the upper lip, and the lateral incisors should be positioned slightly inferior to the adjacent teeth (Fig. 9-31). That the gingival margins should be coincident with the upper lip in the social smile is generally accepted.

FIGURE 9-29 **A,** While the short philtrum in the adolescent is often a normal maturational characteristic, in the adult it's an unaesthetic feature. **B**, Soft tissue surgical procedures may be utilized to increased philtrum height.

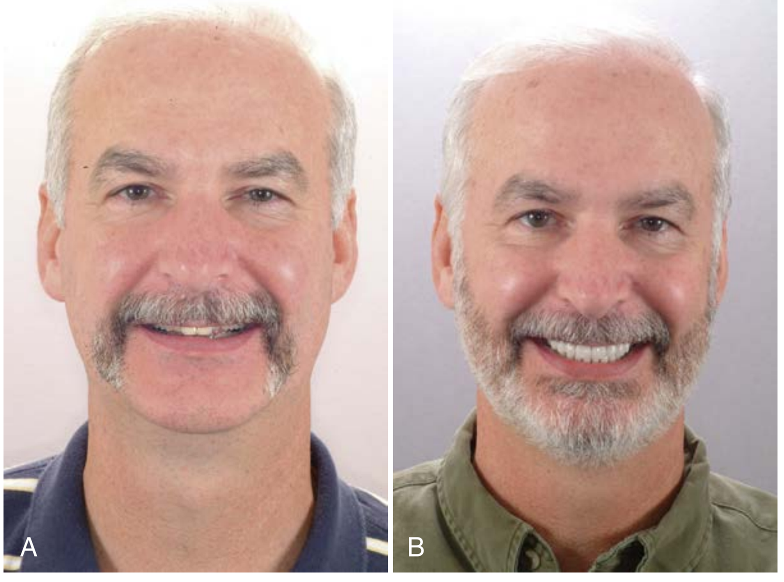

FIGURE 9-30 A flat smile arc can be caused by attrition of the maxillary incisors. **A,** This patient sought orthodontic consultation for smile improvement and was counseled that his problem was less of an orthodontic problem and more of a restorative problem. **B,** After laminate veneers were placed, incisal height and smile arc were restored.

However, this is very much a function of the age of the patient because children show more tooth at rest and gingival display on smile than do adults.

Transverse Characteristics of the Smile

Three important influences on the characteristics of the smile in the transverse plane of space are (1) buccal corridor width,[12] (2) arch form, and (3) transverse cant of the maxillary occlusal plane.

Buccal corridor width. This consideration was introduced into dentistry by the removable prosthodontics of the late 1950s. When setting denture teeth, prosthodontists sought to recreate a natural dental presentation transversely. A *molar-to-molar* smile was seen as fake and a tip-off to a poorly constructed denture. More recently, orthodontists have emphasized the diminished aesthetics of an excessively wide buccal corridor, often referred to as *negative space.* In orthodontics as in prosthodontics, the proportional relationship between the

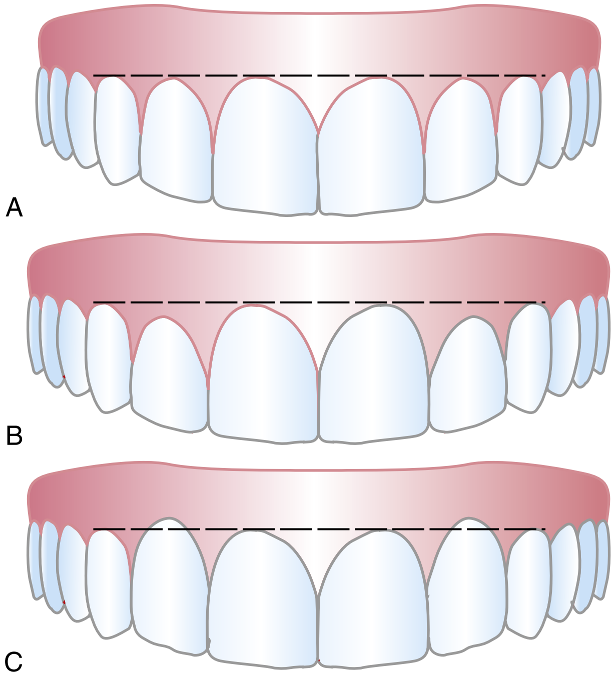

FIGURE 9-31 The gingival margins of the canines should be coincident with the upper lip, and the lateral incisors should be positioned slightly inferior to the adjacent teeth. **A,** Equal gingival height is acceptable. **B,** Ideal gingival height relationship. **C,** Least desirable gingival height relationship.

width of the dental arch and the width of the face must be kept in mind.

The buccal corridor is measured from the mesial line angle of the maxillary first premolars to the interior portion of the commissure of the lips. The corridor often is represented by a ratio of the intercommissure width divided by the distance from first premolar to first premolar.

Arch form. Arch form plays a pivotal role in the transverse dimension of the smile. In patients whose arch forms are narrow or collapsed, the smile also may appear narrow, which is less appealing aesthetically. An important consideration in widening a narrow arch form, particularly in the adult, is the axial inclination of the buccal segments. Patients in whom the posterior teeth are already flared laterally are not good candidates for dental expansion. Patients in whom the premolars and molars are upright have more capacity for transverse expansion in adolescence, but the characteristic is particularly important in the adult in whom sutural expansion is less likely.

Orthodontic expansion and widening of collapsed arch form can improve the appearance of the smile dramatically by decreasing the size of the buccal corridors and improving the transverse smile dimension (Fig. 9-32). The transverse smile dimension (and the buccal corridor width) is related to the lateral projection of the premolars and the molars into the buccal corridors. The wider the arch form in the premolar area, the greater is the amount of the buccal corridor that is filled.

Expansion of the arch form may fill out the transverse dimension of the smile, but two undesirable side effects may result, and one should take care to avoid them. First, excessive expansion obliterates the buccal corridor. Prosthodontists emphasize that this is unaesthetic. Second, when the anterior sweep of the maxillary arch is broadened (Fig. 9-33), the prominence of the incisors relative to the canines is likely to decrease. When these undesirable aspects of expansion are being considered, the clinician must make a judgment in concert with the patient as to what tradeoffs are acceptable in the pursuit of the ideal smile.

When the maxilla is retrusive, the wider portion of the dental arch is positioned more posteriorly relative to the anterior oral commissure. This creates the illusion of greater buccal corridor in the frontal dimension. The patient in Figure 9-34 had a Class III malocclusion caused primarily by maxillary deficiency, vertically (characterized by only 50% of maxillary incisor show on smile) and anteroposteriorly (as evidenced by the flatness of the profile). After orthodontic decompensation, the surgical plan was to advance the maxilla, rotating it clockwise to increase the amount of incisor display at rest and on smile. This occlusal plane rotation not only improves the incisal display but also increases midfacial projection and diminishes mandibular projection. The smile was enhanced greatly by the increased vertical anterior tooth display, but the transverse smile dimension also was improved greatly (see Fig. 9-34, *B*). How was the negative space on smile reduced when there was no maxillary expansion? As the maxilla came forward into the buccal corridor, the negative space was reduced by the wider portion of the maxilla coming forward into the static intercommissure width. Transverse smile dimension, therefore, is a function of arch width and anteroposterior position of the maxillary and mandibular arches.

Transverse cant. The last transverse characteristic of the smile is the transverse cant of the maxillary occlusal plane. A canted or asymmetric smile can be a result of (1) asymmetric vertical growth of the mandible resulting in a compensatory cant to the maxilla, (2) lip curtain asymmetry, or (3) differential gingival heights. A true transverse cant usually is related to asymmetric vertical growth of the mandible, resulting in a compensatory cant to the maxilla and, if present, may be an indication for orthognathic surgery. The appearance of a transverse cant, however, can result from differential eruption and placement of the anterior teeth or differential anterior crown heights requiring soft tissue modification, both of which should be considered in planning orthodontic treatment. Neither intraoral images nor mounted dental casts adequately reflect the relationship of the maxilla to the smile (Fig. 9-35). Only frontal smile visualization permits the orthodontist to visualize any tooth-related asymmetry transversely. The frontal smile photograph (see Fig. 9-35, *B*), not a frontal view of the teeth achieved with a lip retractor, is needed to record what is seen clinically. With good documentation of tooth–lip relationships, the orthodontist subsequently can make any appropriate adaptations in appliance placement or make a decision on the need for differential growth or dental eruption modification of the maxilla in the adolescent or surgical correction in the adult.

Smile asymmetry also may be due to asymmetric lip animation. A differential elevation of the upper lip during smile gives the illusion of a transverse cant to the maxilla. This characteristic emphasizes the importance of direct clinical examination of the smile because this soft tissue animation is documented poorly in static photographic images but is documented best in digital video clips. This can become an important informed consent issue if the patient is concerned about the asymmetry on animation because neither orthodontic tooth movement nor orthognathic surgery will affect it.

FIGURE 9-32 **A,** This adolescent patient has excessive buccal corridor width or negative space on smile. **B** and **C,** The intraoral views demonstrate the transverse deficiency of the maxilla. **D,** After orthodontic correction of the malocclusion, including orthodontic expansion, the transverse smile dimension is dramatically improved with projection of the teeth into the buccal corridor (**E**).

FIGURE 9-33 When the anterior sweep of the maxillary arch is broadened, the prominence of the incisors relative to the canines is likely to decrease, and flattening of the smile arc may occur. The clinician must make a judgment in concert with the patient as to what tradeoffs are acceptable in the pursuit of the best possible smile.

FIGURE 9-34 This patient exhibited a Class III malocclusion primarily caused by maxillary deficiency. **A,** Some aspects of vertical maxillary deficiency are present, including 50% of maxillary incisor display on smile. Her transverse smile dimension was characterized by excessive buccal corridors. **B,** Surgical maxillary advancement improved the buccal corridors on smile by bringing a wider portion of the maxilla forward into the buccal corridors, and bringing the maxilla down anteriorly resulted in increased incisor display.

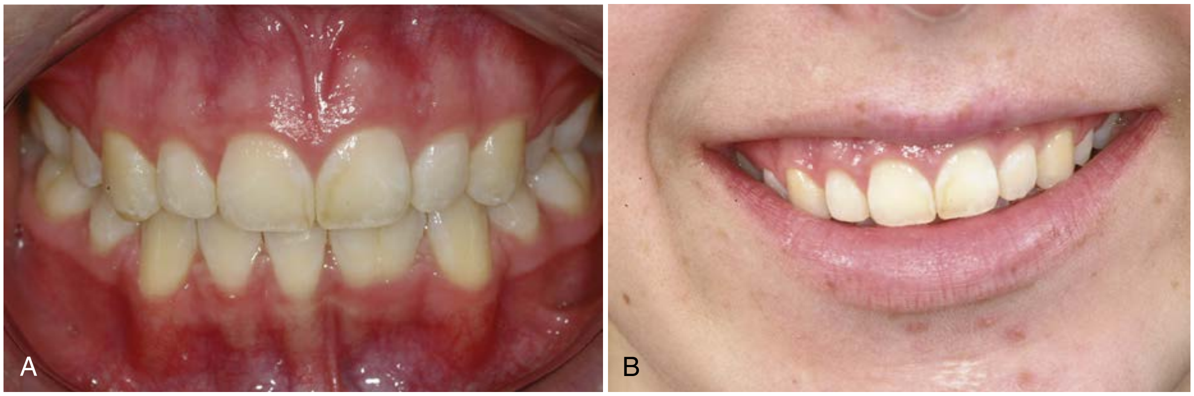

FIGURE 9-35 Neither intraoral images nor mounted casts adequately reflect the relationship of the incisors to the smile. In a close-up intraoral image (**A**), one sees an apparently well-treated occlusion, while a more distant smile view (**B**) reveals the same occlusal relationships with an obvious cant to the maxilla.

FIGURE 9-36 The close-up of the oblique smile, as in this patient in the last stages of preparation for orthognathic surgery to correct severe open bite, facilitates evaluation of the curvature of the molars (when visible), premolars, and anterior teeth in relation to the lower lip on smile. This also enhances closer evaluation of any anteroposterior cant to the palatal and occlusal planes.

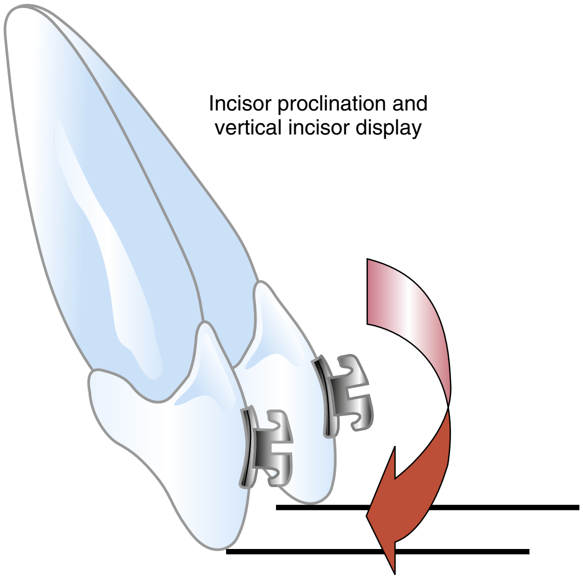

FIGURE 9-37 The amount of proclination of the maxillary incisors can affect how much they are displayed at rest and on smile. In general terms, flared maxillary incisors tend to reduce incisor display, and upright maxillary incisors tend to increase incisor display.

Oblique Characteristics of the Smile

The oblique view of the smile reveals characteristics not obtainable on the frontal view and certainly not obtainable through any cephalometric analysis. The contour of the maxillary occlusal plane from premolar to premolar should be consonant with the curvature of the lower lip on smile (a view of the smile arc, discussed previously). Deviations include a downward cant of the posterior maxilla, upward cant of the anterior maxilla, or variations of both. Figure 9-36 illustrates a patient in preparation for maxillary surgery to close an anterior open bite. Deciding how much the posterior maxilla should be impacted versus the anterior maxilla coming down depends on the amount of incisor display at rest and on smile and on the smile arc relationship, both of which are well visualized in the oblique view.

The amount of incisor proclination also can have dramatic effects on incisor display. In simple terms, flared maxillary incisors tend to reduce incisor display, and upright maxillary incisors tend to increase incisor display (Fig. 9-37). A good example is the patient in Figure 9-38. This patient had an anterior open bite caused primarily by extreme anterior proclination of the maxillary and mandibular incisors. The sagittal view of the smile shows the flare of the maxillary incisors, which resulted in diminished incisor show from the frontal view. The treatment plan involved interproximal reduction of the incisors to provide space for retraction and uprighting of the incisors. The incisors were retracted in such a way to allow the crowns to tip distally so that they also elongated toward the occlusal plane. This movement closed the anterior open bite, increased incisor display as the teeth, and decreased the unaesthetic flare of the incisors.

Dental Microaesthetics and Its Applications to the Smile

Gingival Shape and Contour

Important factors in finishing orthodontics cases for optimal smile aesthetics now include concepts that are important in cosmetic dentistry: gingival shape and contours, tooth proportionality, and crown heights.[13] Most orthodontists have reshaped incisal edges and tooth contours to refine the finish of treatment, but alteration of the gingival contours has been limited primarily to crown lengthening. Of the many concepts from cosmetic dentistry that are important to the microaesthetic smile appearance, two that are important for the final aesthetic outcome of orthodontic cases are gingival shape and gingival contour.[14]

According to the American Academy of Cosmetic Dentistry,[15] "the gingival shape of the mandibular incisors and the maxillary laterals should exhibit a symmetrical half-oval or

FIGURE 9-38 **A,** The frontal smile relationship demonstrates diminished incisor display on smile. **B,** On sagittal smile, the flare and proclination of the upper incisors are apparent. **C,** Before treatment, a mild anterior open bite was present, and the flare of the maxillary incisors contributes to the open bite and the incomplete incisor display on smile. After interproximal reduction and retraction and uprighting of the maxillary incisors, the amount of incisor display increased.

FIGURE 9-38, cont'd D, Interproximal incisor reshaping and retraction of incisors result in uprighting of the anterior teeth, reduced flare, and increase incisor display on smile. **E,** The saggital smile demonstrates how uprighting of the maxillary incisor improves the smile arc relationship as well. **F,** This uprighting also results in closure of the anterior open bite.

FIGURE 9-39 **A,** This 12-year-old, prior to treatment, had a nice smile with consonant smile arc but short incisal crown height, **B,** The close-up smile demonstrates the short crown height and slight gingival display on smile. **C,** Her initial intraoral image reflects the diminished crown height. In order to protect her already ideal smile arc, her brackets were place slightly closer to the gingival margin than standard protocol. **D,** Nearing completion of treatment, while the smile arc was ideal, the gingival hypertrophy secondary to oral hygiene issues (possibly exacerbated by the bracket proximity interfering with ideal oral hygiene technique) created periodontal pseudopocketing as well as unaesthetic gingival display and form. **E,** The finishing close-up smile demonstrates the incisal edge placement and the gingival irregularities. **F,** Upon bracket removal, hypertrophy of the papillae and marginal gingival tissues were noted, resulting in poor gingival shape and contour as well as diminished crown height. Upon reflection, in a more contemporary approach, we might have considered crown lengthening prior to bracket placement in order to avoid this unfortunate sequel of orthodontic appliance treatment. **G,** Often brackets are removed, hoping a visit to the hygienist and time would resolve the tissues back to their ideal condition. In our experience, this often does not happen since the tissue is fibrotic and is hard to clean. In today's world, parents are often beyond disappointed in the result. Either an immediate appointment with the periodontist is indicated, or as in this case, a diode laser is employed upon bracket removal to recover an improved condition.

FIGURE 9-39, cont'd **H,** The aesthetic benefit is immediate, as is the elimination of pseudopockets and inflamed, hypertrophic tissue. Healing is promoted because of the tissue sterilization characteristics of the laser procedure as well. **I,** One week later, the inflamed gingival tissues were resolved and a more aesthetic and healthy soft tissue resulted. **J,** The final frontal smile. **K,** The final close-up smile.

half-circular shape. The maxillary centrals and canines should exhibit a gingival shape that is more elliptical. Thus, the gingival zenith (the most apical point of the gingival tissue) is located distal to the longitudinal axis of the maxillary centrals and canines. The gingival zenith of the maxillary laterals and mandibular incisors should coincide with their longitudinal axis" (see Fig. 9-31).

Recontouring gingival shape and contour now can be accomplished readily, in the orthodontist's office if desired, with a diode laser.[3]

The patient in Figure 9-39, *A*, chose to pursue orthodontic treatment at age 12 for correction of some spacing and slight occlusal discrepancies. Her close-up smile assessment (Fig. 9-39, *B*) showed an ideal smile arc with complete incisor display but had slightly short crowns due to incomplete passive eruption and had slightly more gingival display than ideal. Her deep overbite was shown in her intraoral image (Fig. 9-39, *C*), as was the short height/width ratio of the anterior teeth with some enlargement to the interdental papillae. Assessing the progress of treatment after 9 months of full-fixed appliances (Fig. 9-39, *D* and *E*), we noted that the vertical incisor position had been protected as planned, but she had an excessively gummy smile. This aesthetic shortfall was secondary to the gingival inflammation unfortunately seen in many orthodontic cases. The intraoral image (Fig. 9-39, *F*) permits a more detailed microaesthetic evaluation. Gross gingival inflammation was apparent, but gingival height was disparate, the gingival papilla proportions were excessively large, and the zeniths individually varied. When faced with this situation, the frequent orthodontic action is to remove appliances and immediately refer for cleaning and prophylaxis, followed by observation for soft tissue resolution. This may occur over time, but often the tissues are fibrotic and do not recover as readily as we might wish, and a referral to the periodontist is indicated. While controlling hygiene treatment would have been the ideal approach, this is not always possible in spite of all the promises the patient or parents may give. The periodontal procedure is then met with resistance because of fear of pain, expense, and further delay of the desired aesthetic outcome. In this case, we probed the pocket depths for assessment of removal of the excessive gingival tissues and immediately upon removal of appliances performed simple gingivectomy with a diode laser (Fig. 9-39, *G*). This removed

FIGURE 9-40 A, This patient's smile line was asymmetric because of differential crown heights. B, Three weeks after soft tissue contouring and lengthening of the right central and lateral incisors, the smile was more symmetric and greatly improved.

the excess tissue, cauterizing and sterilizing the ablated wound margin (promoting healing), resulting rapidly in the final outcome (Fig. 9-39, *H* and *J*).

When finishing the anterior aesthetic relationship within the smile framework, the average location of the gingival margins should demonstrate a symmetric level of the margins of the central incisors and a lower location of the lateral incisors and gain a higher and ideally symmetric level on the canines. The patient in Figure 9-40, *A*, was treated to an excellent occlusal and a good aesthetic result. However, the smile line was asymmetric because of differential crown heights of the maxillary right central and lateral incisors, relative to the left side. Using the diode laser, the excess gingiva was excised on the right central and lateral. Three weeks later, the smile was more symmetric and greatly improved (Fig. 9-40, *B*).

Bracket Placement in Preparation for Changes in Gingival Shape

When a dentist is preparing teeth for laminates, it is not uncommon to reshape and idealize the gingival heights and contours with a soft tissue laser before final preparations are made and impressions are taken. In orthodontic treatment, because orthodontists usually are not able to make contour or shape adjustments, their recognition factors are low relative to these problems. Orthodontists must be able to visualize the crown in ideal proportion before bracket placement and in many cases shape and contour the gingiva prior to bracket placement.

The patient in Figure 9-41, *A*, has a disproportionate width-to-height ratio of the maxillary incisors. Most aesthetic dentists strive for a central incisor width-to-height proportion of 8:10, and this patient's incisors have the same width and height. This disproportion could be due to lack of incisor height (gingival encroachment or delayed or incomplete passive eruption requiring gingival reshaping) or incisors that are morphologically wider than ideal in terms of crown shape itself (requiring reshaping of the crown). Bracket placement in orthodontics has traditionally been directed by the relationship of the bracket slot to the incisal edge. Anterior teeth vary in crown height and incisal edge shape. The two most common current methods for placing brackets are to (1) relate the bracket position to the incisal edge or (2) position the bracket in the center of the clinical crown, whatever its dimensions. In this patient, positioning of the bracket a prescribed 4.5 mm from the incisal edge would place the bracket too close to the gingival margin, potentially causing gingival overgrowth and oral hygiene problems. Positioning of the bracket in the center of the clinical crown (Fig. 9-41, *B*) would cause unwanted maxillary incisor intrusion and a reduction in incisor display on smile. In this case, the decision was to improve tooth proportion through laser crown lengthening before bracket placement to maximize the chance of positioning the incisors in their ideal vertical position (Fig. 9-41, *C*).

Bracket positioning for optimal aesthetics. As orthodontists diagnostically move away from the procrustean approach to diagnosis and treatment planning (every patient gets fitted to the same cephalometric analysis, and all patients have their brackets placed the same distance from the incisal edge or cusp tip, according to a chart), concepts of bracket placement also are evolving. Rather than bracket placement being a function of the dental-centric preadjusted appliance demands, placement of the maxillary and mandibular anterior teeth should be directed by concerns such as the following:

1. How much maxillary incisor is displayed at rest (recall the data on incisor display at rest and the aging smile)?
2. How much maxillary incisor is displayed on smile (also a characteristic of the youthfulness of the smile)?
3. The relationship of the anterior teeth to the smile arc.
4. Crown height and width incisor proportionality.
5. Gingival height and contour characteristics.

What is the process to determine the desired bracket placement for each individual patient? As in the macroaesthetic and miniaesthetic treatment goal setting, a systematic approach to these microaesthetic considerations is needed. The authors recommended the following sequence of measurements to be made on the initial examination, recorded in the database program. To determine optimal bracket placement:

1. Determine the incisor display at rest (Fig. 9-42, *A*):
   a. Refer to the chart of incisor display related to age for a guideline as to appropriate incisor display at rest (Fig. 9-42, *B*)

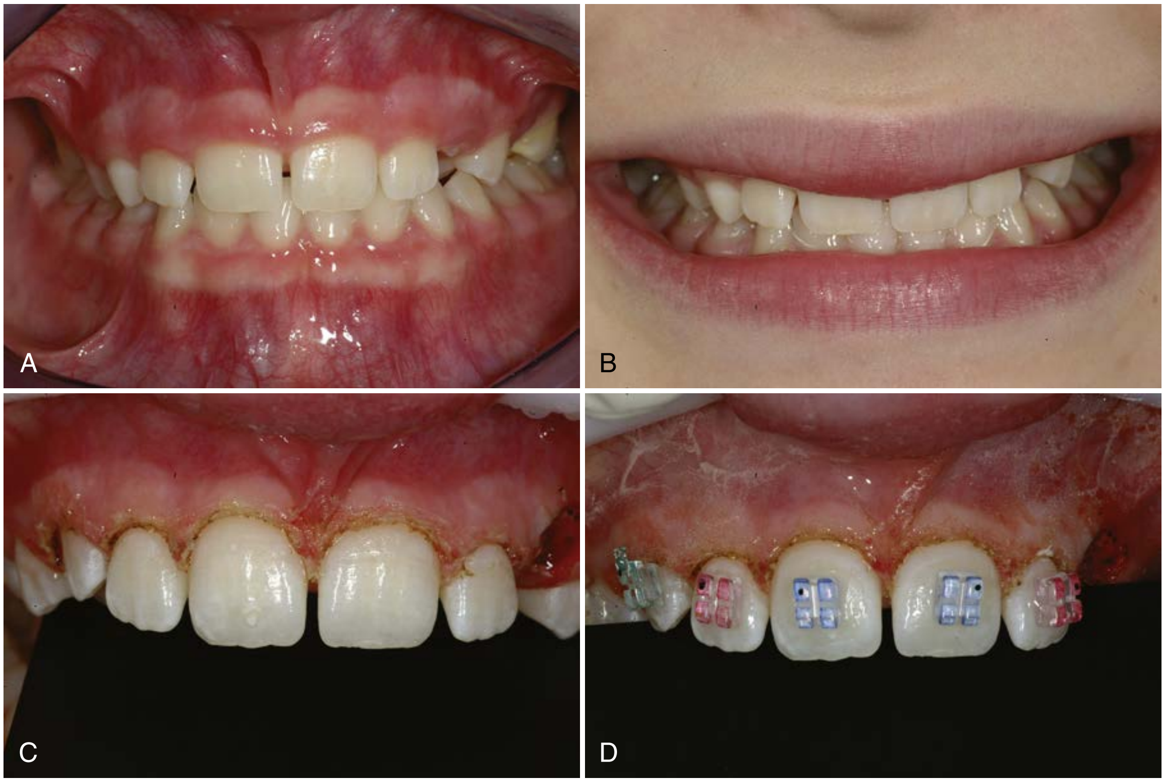

FIGURE 9-41 A, This patient has a disproportionality of the width and height of the maxillary incisors. The short crown heights were due to incomplete passive eruption. Positioning the brackets relative to the incisal edge would position them too close to the gingival margin, which would contribute to poor oral hygiene and result in gingival overgrowth. Positioning the brackets in the center of the clinical crown would cause unwanted incisor intrusion (B) in a patient where this was not desired. **C,** The decision was made to improve tooth proportion through laser crown lengthening before bracket placement to maximize the chance of positioning the incisors in their ideal vertical position. **D,** Immediately after bracket placement.

2. Determine how much maxillary incisor is displayed on smile in millimeters (Fig. 9-42, *C*).
3. Determine crown height and width of the incisors. This helps establish whether tooth shape discrepancies exist. If the tooth is too wide, tooth reduction may be desirable before bracket placement. If the incisor is short because of delayed passive eruption or gingival encroachment, crown lengthening may be indicated.
4. Note the number of millimeters of gingival display on smile if present.
5. Refer to chart of gingival display by age (Fig. 9-42, *D*).
6. Determine the smile arc–consonance relationship.
7. Measure gingival height relationships.
   a. Canine–lateral–centrals
   b. Canine–lateral–centrals to upper lip on repeatable social smile
8. Make final decisions and establish applications. For example, if incisor display at rest and on smile is inadequate, then do the following:
   a. Decide how much more tooth display is desired at rest or on smile and how far the incisal edge needs to go to reach the smile arc.
   b. Measure to the center of the clinical crown where most bracket systems require placement.
   c. Place the bracket more apically the distance the incisor is to be moved inferiorly.

The application of this approach to bracket placement is illustrated next.

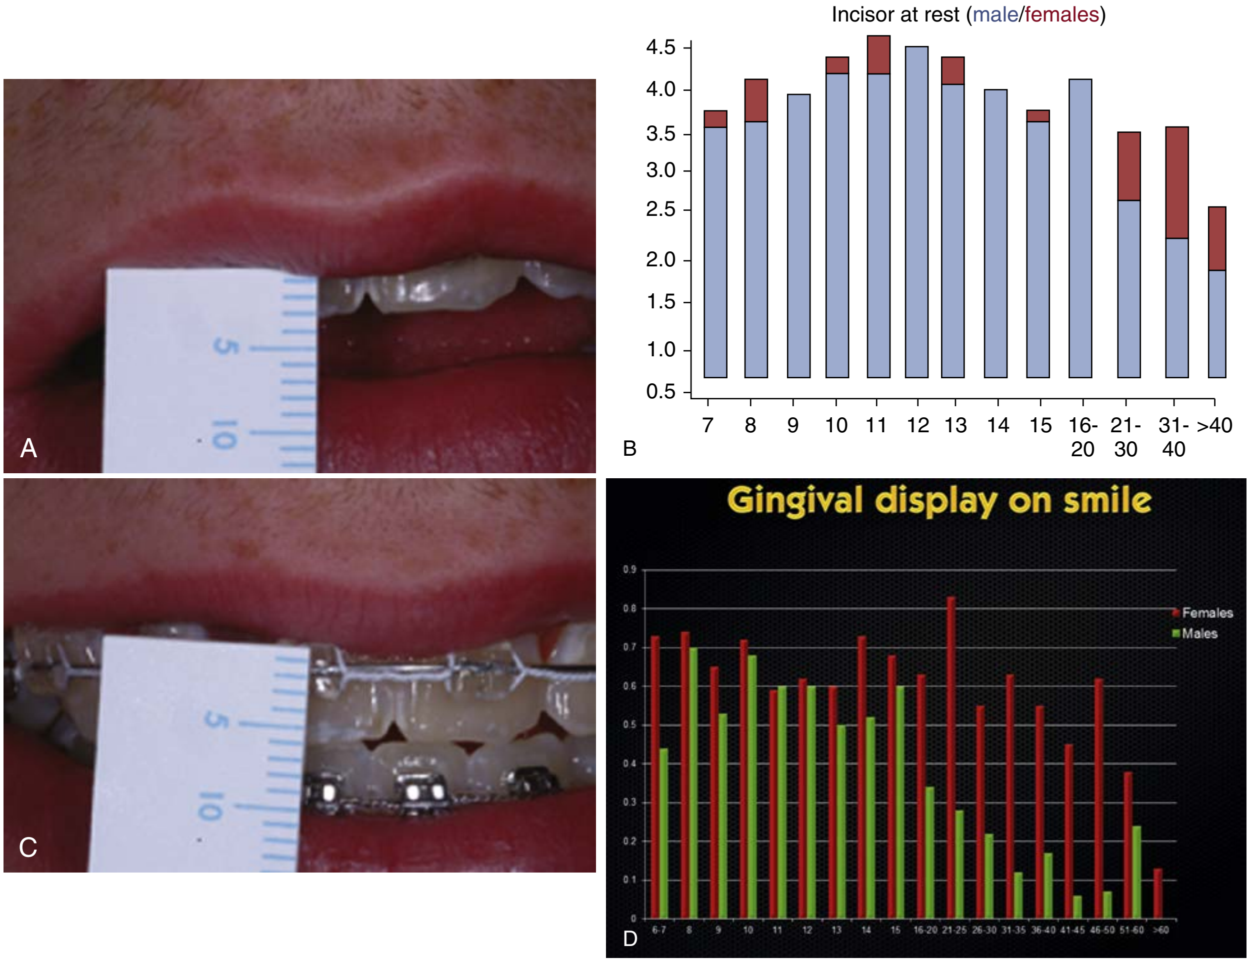

FIGURE 9-42 **A,** The first step in individualizing bracket placement is to determine how much the maxillary incisor shows at rest. The purpose of this measurement is to place the incisor in the best position for smile display and to anticipate the long-term effects of aging. **B,** Refer to the chart for appropriate amounts of incisor display for the patient in a particular age group who is to receive brackets. The clinician should consider that these data represent an untreated population, and if smile youthfulness is desired, then greater incisor display may be planned in certain cases. **C,** Next, the orthodontist asks the patient to smile (social smile) and makes a direct measurement of how much upper incisor shows on smile. **D,** The amount of gingival display is measured when present and is compared against the chart for gingival display and to the crown height measurement. If gingival display on smile is excessive, the clinician can determine whether it is caused by vertical maxillary excess or short crown height.

CASE STUDY 9-1 SMILE REFINEMENT: MINIAESTHETICS AND MICROAESTHETICS

It is critical in planning smile aesthetics that the orthodontist understand all the principles of mini- and microaesthetics. In presenting a case for smile refinement, we feel it would be beneficial to review some of the important points in this chapter, applied specifically to this case for clarity of teaching.

Miniaesthetics

In smile assessment, there are many characteristics attributable to what is considered the ideal smile. In cosmetic dentistry, there have been numerous publications and quantitative research on what makes the ideal smile. Applications of the principles they have developed along with our orthodontic concepts can be of real significance in treatment planning our cases to be exceptional, and not just normal, as Figure 9-43 offers guidelines on accepted parameters for the ideal smile. At the beginning of this chapter, we described the clinical examination we recommend for smile analysis, taking into account both the mechanism of the smile and the resting characteristics of incisor display. Important aspects of the many miniaesthetic analyses include:

1. The positioning of the upper lip during social smile—the final position of the upper lip during smile and how much gingival display there is can be quite variable, depending on the patient's age. The final position impacts not only how much gingival display there is but also how much incisor display there is on smile. In general terms, the older we get, the less incisor we show on smile, as well as less gingival display. This has clinical impact on us when we are judging whether the adolescent has a gummy smile that will improve with time or whether orthodontic treatment should be directed to increasing incisor display. In both the adolescent and the adult, opening a deep overbite with maxillary incisor intrusion in general is a procedure that has a negative effect on the maturation and aging of smile.
2. Gingival display on smile—as noted above, the amount of gingival display on smile varies with age, and the interaction of gingival display and orthodontic mechanics is linked directly.
3. The percentage of incisor display on smile—in general terms, males show less upper incisor on smile than do females, regardless of age. However, the trend is for both genders to show less incisor as time goes by, but with the male degrading more quickly than the female. In other words, male smiles age more quickly than do female smiles.
4. Buccal corridors—as described previously as a prosthodontics concept from the 1950s, buccal corridors were originally described in terms of denture construction. Translating prosthodontic concepts to today's aesthetic demands and a full dentition is not realistic. Currently, quite a bit of research is being carried out and published on how much buccal corridor show is the ideal amount. Leaving the patients to judge, the current trend is "the wider the better."
5. The smile arc—the smile arc has been described previously in this chapter as the relationship of the maxillary occlusal plane to the lower lip on smile. Ideally, we like for the curvature of both on frontal smile to be parallel, or consonant. However, we would like to emphasize that ideal smile arcs are not always achievable due to other factors such as inherited skeletal patterns, dental attrition, and many other factors. Therefore, we also emphasized that attainment of an ideal smile arc is a guideline, not a rule.

Microaesthetics

In cosmetic dentistry, tooth shape and proportions have been studied extensively. In addition to the height and width proportions of the teeth, the concepts of tooth contacts and connectors can be of real significance in treatment planning the appearance of the smile. Figure 9-44 is a graphic representation of the many attributes we have pieced together to constitute what is considered the ideal microaesthetic analysis.

1. Long axis—the inclination of the anterior teeth should be tipped slightly to the distal aspect.
2. Incisor height/width ratio—incisor height tends to be more variable than incisor width because of the variability of soft tissue biotypes and, in the adolescent, stages of active and passive eruption. The ideal ratio, however, should be 8:10 of width to height.
3. Contact—the contact between the teeth is, of course, where the teeth touch. However, it was described best by Morley and Eubank as, "the point which the teeth appear to touch and makes of the floss pop." The vertical positioning of the contact is important, because it affects the next two attributes.
4. Connector—the connector is "where the teeth appear to touch but does not grab the floss." The accepted ratios to central incisor height are for the connector to be 50% the length of the maxillary incisor height between centrals, 40% of the length of the central incisor between the central incisor and the lateral incisor, and between the lateral incisor and the canine, the percentage should be 30% of central incisor height.
5. Incisal embrasure—what patients sometimes mistake as a space problem is actually a large embrasure. The central incisor embrasure should be smallest, while the width of the embrasure should increase as it progresses away from the midline.
6. Papilla height—40% of the central incisor height is the accepted ideal but is somewhat variable among studies. If the papilla height does not reach the connector, then a gingival embrasure, or an unaesthetic "black triangle," results.
7. Gingival height—the accepted ideal for the most superior aspect of the gingival shape/margin is for the centrals and cuspids to be roughly the same length, with the lateral incisors being slightly shorter with the gingival margin positioned slightly more inferior than the canine and central.
8. Zenith—defined as the apex of the gingival shape and should be slightly distal to the long axis of the tooth on both the maxillary centrals and canines, but on the maxillary lateral it should be coincident.

The 15-year-old female in Figure 9-45 presented with what would be by anyone's standards considered a nice smile. However, her smile was problematic to her, so we undertook a thorough assessment as to what her needs might be in presenting a potential treatment plan. Many options existed, of course, from orthodontics to veneers, but at age 15, the orthodontic option was, without question, the most appropriate. Her occlusal relationships were quite good (Fig. 9-46), but, looking critically, the maxillary lateral incisors would benefit from some facial root torque. In her close-up smile image (Fig. 9-47), adhering to our quantitative clinical assessment, we observed a slightly flat smile arc, incomplete incisor display of the maxillary incisors, and disproportionate height/width ratio of the maxillary lateral incisors. Utilizing computer imaging, the smile targets were identified (Fig. 9-48, *A*) and quantified (Fig. 9-48, *B*) so that we can plan precise bracket positioning to extrude the maxillary incisors to the desired amount to increase incisor display and reach the smile arc target. A visual mockup of the gingivectomy was demonstrated so that the patient and the parents could visualize the periodontal procedure to address the gingival issue, and the extrusion of the incisors is also displayed (Fig. 9-49). The value of informed consent during this entire process is an important aspect of the incorporation of digital imaging into the consultation process when aesthetics is a very important element of the treatment.

The next step in treatment is, of course, to deliver the demonstrated treatment as accurately as possible. Custom bracket placement may be placed according to the orthodontist's design, as well as wire selection. Figure 9-50 represents a calibrated screen image in the planning template in which we have virtually extruded the maxillary incisors to the length we determined to be needed from our clinical exam. The existing dental relationships are in green, while the planned movement is in white. The grid represents 1-mm increments, so on the computer screen we can "grab" the tooth and drag it to the position that we want it to be in. Also, in this case, we can direct the amount of torque desired in the lateral incisors (Fig. 9-51). An indirect bracket setup is then created, and in this case, custom brackets were also produced to allow us to design in the desired torques needed on laterals on the initiation of treatment.

The final results (Fig. 9-52) were quite good, and the patient's parents were quite pleased. This case illustrates the coordination of the direct clinical biometric examination, visualization and quantification of treatment goals, and digitally designed fixed appliances to maximize the outcome.

David M. Sarver, DMD, MS

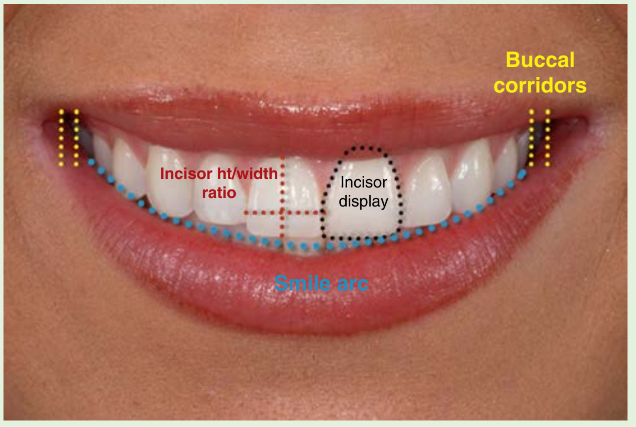

FIGURE 9-43 Here are some guidelines on accepted parameters for the ideal smile.

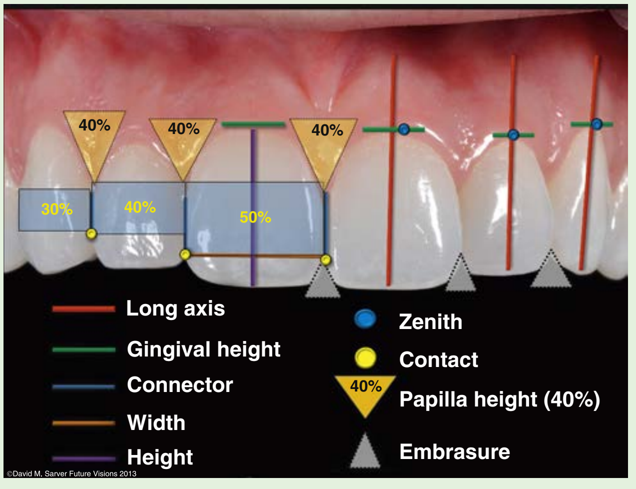

FIGURE 9-44 Ideal microaesthetic characteristics are graphically represented in this figure. This analysis is rather extensive, including orientation of the long axis of the anterior teeth, incisor height/width ratio, contacts, connectors, incisal embrasures, papilla heights, gingival heights, and zeniths.

FIGURE 9-45 This 15-year-old female presented with a very nice occlusion but was not completely happy with her smile. She was unsure as to what she did not like and sought a recommendation as to what might be improved.

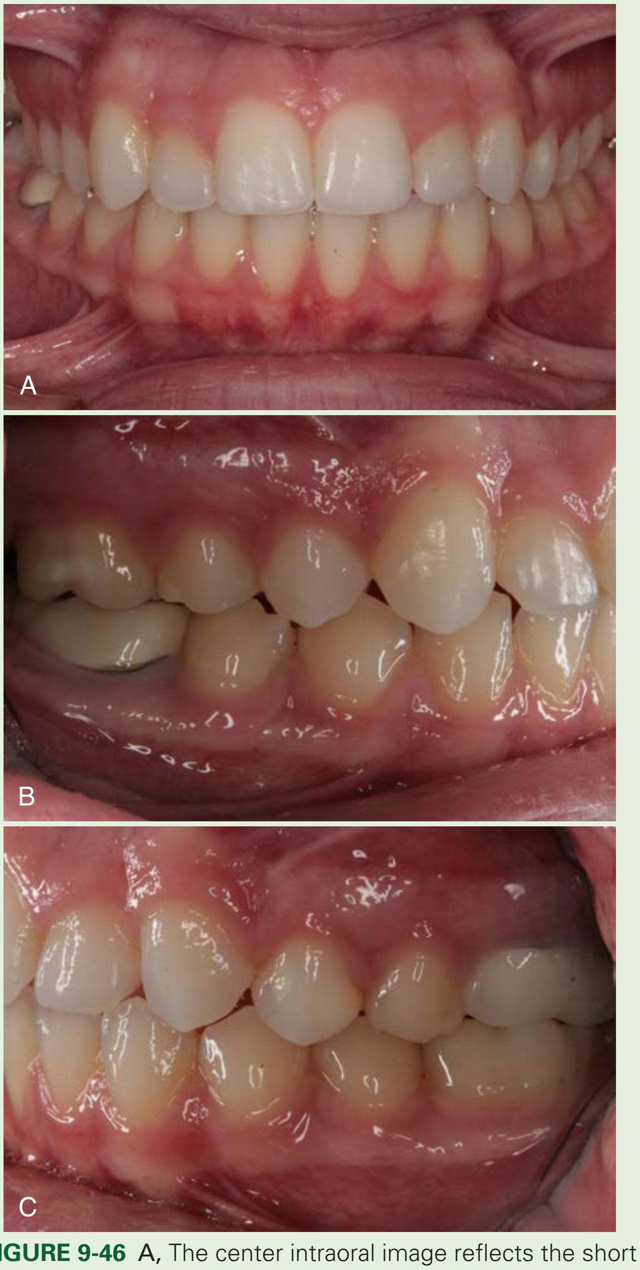

FIGURE 9-46 **A,** The center intraoral image reflects the short lateral incisors in comparison to maxillary central incisor proportion and palatal root displacement of the lateral incisors. **B,** The buccal occlusal on the right side was functionally quite good. **C,** The buccal occlusal on the left was also functionally quite good.

FIGURE 9-47 Her close-up smile reflected a flat smile arc, incomplete incisor display, and disproportionality of the height/width ratio of the maxillary incisors.

CASE STUDY 9-1 SMILE REFINEMENT: MINIAESTHETICS AND MICROAESTHETICS—cont'd

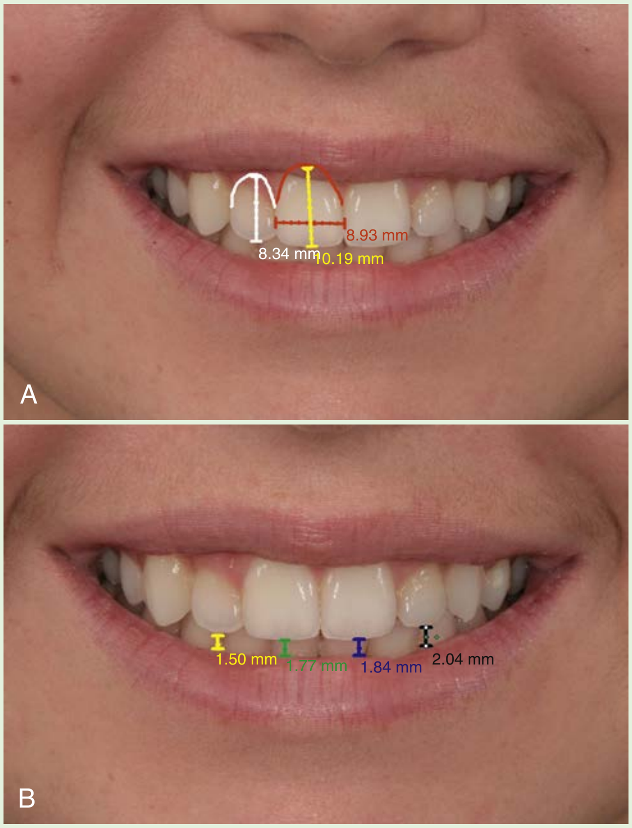

FIGURE 9-48 **A,** Utilizing computer imaging, we were able to graphically outline proposed improvements—for example, the ideal maxillary right lateral shape and form as outlined in white and its height also measured through a calibrated image. This calibration also allowed quantification of the height/width ratio of the maxillary right central and the distance from the incisal edge to the lower lip curvature representing the smile arc. **B,** In order to facilitate maxillary bracket placement, precise measurements were made from the incisal edge to the smile arc target, and this update was used in compensating the vertical position of our normal bracket placement. In other words, the center of the bracket was moved superiorly the same amount as the target indicated. This is particularly useful in this case, since the maxillary incisors have a slight transverse cant, and the left side needs to be extruded slightly more than the right.

FIGURE 9-49 In a final graphic illustration of our proposed treatment outcome for the patient and parents, simple cut-and-paste tools were used to simulate extrusion of the incisors to the smile line target and reshaping the gingival margin of the lateral incisors to simulate the potential result of gingivoplasty.

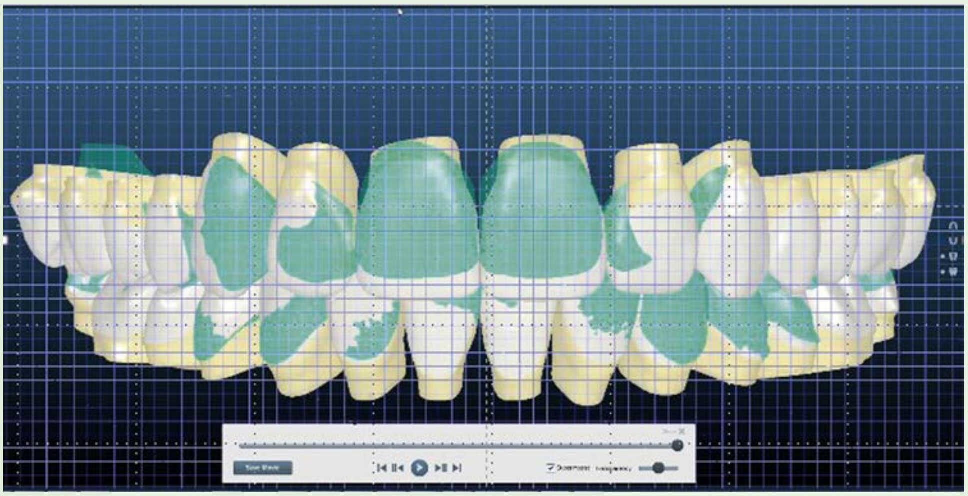

FIGURE 9-50 After intraoral scanning, a three-dimensional rendition of the patient's dentition was loaded for treatment planning. Utilizing tools available in software, we move the incisors downward the prescribed amount determined in the calibrated smile image.

Psychological Aspects of Diagnosis and Treatment

Leslie A. Will

OUTLINE

Orthodontists learn very early in their careers that moving teeth is only one aspect of taking care of their patients. Every patient is different, and every person comes with his or her unique pattern of responding to others, making decisions, and carrying out plans. Each patient's personal experience, family history, and cultural differences will naturally influence individual responses to orthodontic treatment strategies.

Communication between the orthodontist and the patient is extremely important in achieving treatment goals. In addition to encouraging cooperation and maximizing good treatment results and patient satisfaction, good communication is essential from a medicolegal standpoint. Instead of just giving the patient information, the orthodontist needs to be concerned with what the patient understands and expects from treatment.

Research has shown that patients do not always understand or remember what they have been told about their malocclusion or the orthodontic treatment. Mortensen, Kiyak, and Omnell[1] interviewed 29 pediatric patients aged 6 to 12 years and their parents 30 minutes after an informed-consent discussion. Both the children and their parents were asked about the reasons for treatment, risks, and responsibilities that were mentioned during the informed consent discussion. It was discovered that although an average of 4.7 risks were mentioned by the orthodontist during each discussion, on average the parents remembered 1.5 risks and the children remembered less than 1. Similarly, 2.3 reasons for treatment were mentioned by the orthodontist during the discussion, but the parents on average remembered 1.7 and the children remembered 1.1. Clearly, not all the desired information is being remembered by the patients or their parents.

PATIENT PERCEPTIONS

Psychological factors may influence a patient's perception of his or her malocclusion as well as the treatment plan. It is difficult to know or predict how a patient will view his or her individual situation. Fortunately, there are several research approaches that can give some insight as to how patients see malocclusion, and some generalities have been learned that may help orthodontists assess how their patients are likely to react.

One key method is to show the patient profiles. By altering one aspect of the profile in successive photographs or silhouettes and asking the patient to indicate which profile is most like theirs, it is possible to determine how accurately patients can perceive profiles.[2]

A version of this is the Perceptometrics technique that was developed by Giddon et al.,[3] in which computer alterations are made to photographic images, with the feature of interest "morphed" by the computer so that the feature is moved back and forth in one dimension at gradual, predetermined intervals. By clicking on the image, the range of photographs can be traversed, with each photograph being displayed the same amount of time. Patients can then indicate the beginning and end of the acceptable range of profiles by holding down the computer mouse, and they can also indicate which profile is most attractive. This tool enables clinicians to determine the range of what patients consider acceptable (Fig. 10-1).

Many studies have been done using a variety of methods exploring patient perceptions on many aspects of facial aesthetics. Kitay et al.[4] found that orthodontic patients are less tolerant of variations in their profiles than are nonorthodontic patients. To determine their range of acceptability, 16 patients and 14 nonorthodontic adult patients were asked to respond

FIGURE 10-1 Four frames from animation of horizontal chin distortion including both extremes and two intermediate frames (From *Am J Orthod Dentofacial Orthop*. 114(6):632, Fig. 1.)

to computer-animated distortions of profiles that distorted the lower third of their own faces using the Perceptometrics program. Both groups of subjects were equally accurate in identifying their own profiles. However, the orthodontic patients had a smaller zone of acceptability (ZA) in features in a control face, with a significant disparity between one feature in their own profile and the most pleasing position for that feature. This suggests that the orthodontic patients are motivated to seek treatment by specific features in their own face that they perceived as undesirable.

Using the Perceptometrics technique, Arpino et al.[5] compared the ZA of profiles selected by orthognathic surgery patients, their "significant others," orthodontists, and oral surgeons. Patients with both Class II and Class III jaw discrepancies evaluated their own photographs with four features altered horizontally (upper lip, lower lip, both lips together, and chin) and one feature, lower facial height, altered vertically. Although there was some variation, the magnitude of the ZA was smallest for the patient, followed by the surgeon, the significant other, and finally the orthodontist. Whereas the patient and the significant other groups differed in only two instances, the orthodontists and oral surgeons had significantly different ZAs for all but the Class II bimaxillary relationship. These results show that orthodontists are most tolerant of different profiles, while the patients themselves are least tolerant, perhaps reflecting the reality that orthodontic treatment compared with orthognathic surgery is a slower biological process with a wider range of acceptable outcomes.

Hier et al.[6] used the same technique to compare the preferences for lip position between orthodontic patients and untreated subjects of the same age. They found for both males and females that the untreated subjects preferred fuller lips than did orthodontically treated subjects, which is greater than Ricketts' ideal measurement of lip protrusion to the E-line, between the tip of the nose and soft tissue pogonion.

Miner et al.[7] compared the self-perception of pediatric patients with the perceptions of their mothers and their treating orthodontists. Using the Perceptometrics technique, the upper lip, lower lip, and chin were distorted as the images moved from retrusive to protrusive extremes in counterbalanced order. The patients, mothers, and clinicians were asked to indicate the ZA for each feature and the most accurate representation of the child's profile, as well as indicate the ZA for a neutral female face. Both patients and mothers were found to overestimate the protrusiveness of the child's actual mandible, and both groups preferred a more protrusive profile for both the child and the neutral face. In addition, the mothers had the smallest tolerance for change in the soft tissue profile. These studies are valuable for pointing out the inherent inaccuracies of patient's perceptions as well as the differing preferences of patients.

These techniques are also useful for exploring perceptions of different racial and ethnic groups. In a study by Mejia-Maidl et al.,[8] 30 Mexican Americans and 30 whites of varying age, sex, education, and acculturation indicate their perceptions of four profiles of individuals of Mexican descent. Using the Perceptometrics program, the authors found that in general, Mexican Americans preferred less protrusive lips than did the whites. In addition, there was a wider ZA or tolerance for male lip positions and female lower-lip positions among the whites than among the Mexican Americans of low acculturation. These observations were not true of highly acculturated Mexican Americans, who may have assimilated American cultural aesthetic preferences. Park et al.[9] compared the perceptions of Korean-American orthodontic patients with those of white orthodontists and Asian-American orthodontists. Statistically significant differences were found between the Korean-American patients and the white orthodontists for the acceptable and preferred positions of the female nose and the male chin, finding that the Korean Americans preferred a more protrusive nose for females and a more retrusive chin for males. McKoy-White et al.[10] compared the ZA for black females among black female patients, black orthodontists, and white orthodontists. The patients were also asked to correctly identify their most accurate pretreatment and posttreatment profile. It was found that the white orthodontists preferred flatter profiles than did the black women, who in turn preferred fuller profiles than the black orthodontists. Although the patients could correctly identify their own posttreatment profile, they all recalled a fuller pretreatment profile than they actually had.

These studies underscore the importance of racial and cultural influences on the esthetic perceptions and preferences of orthodontic patients. Such studies are also valuable for pointing out the inherent inaccuracies of patients' perceptions as well as the cephalometric bases of their facial preferences. Orthodontists need to be sensitive to differences between patients' and their own preferences in formulating treatment plans.

PATIENTS WITH PSYCHOLOGICAL DISORDERS

Different and unanticipated behaviors among patients often become challenging for the orthodontist. When does such behavior become a problem? When are some behaviors simply difficult, while others may be evidence of pathology? How do we recognize these difficulties and deal with them?

The preceding research explores the perception of psychologically healthy individuals. However, many orthodontic patients may have preexisting psychological disorders when they present for orthodontic treatment. Many patients who seek orthodontic treatment are functioning within society while being treated for a psychological disorder. Although these patients are usually controlled, it is important to recognize how these disorders may be manifested. In addition, orthodontists should be aware of side effects of medications that may have implications for oral health.

Common psychological conditions are delineated by the American Psychiatric Association in the *Diagnostic and Statistical Manual of Mental Disorders*, or *DSM- V*.[11] The most common conditions that orthodontists may encounter are attention-deficit/hyperactivity disorder (ADHD), obsessive-compulsive disorder (OCD), body dysmorphic disorder, bipolar disorder, panic disorder, and depression. In addition, there are some personality disorders and other psychological conditions, such as eating disorders, that may acutely affect adolescents.

Attention-Deficit/Hyperactivity Disorder

ADHD is a chronic disorder characterized by inattention, impulsivity, and hyperactivity. A survey carried out by the Child Trends of National Health Interview in 2013 reported that 8.8% of children ages 3 to 17 were diagnosed with ADHD, including 12% of boys[12] as well as more than 4% of the adult population.[13] Some diagnostic criteria, however, are nonspecific and the disorder may be overdiagnosed, with some signs of ADHD being observed in almost everyone sometime in their life. Nevertheless, the main criterion is that the behavior must cause impairment in the individual's life for a prolonged period of time.[11]

The precise etiology of ADHD is not known. Although it is considered to have a genetic basis in the majority of cases, it is most likely that a combination of genes, rather than a single gene, is responsible.[14] Approximately 20% of cases may be due to prenatal brain injury, such as hypoxia accompanying prematurity or tobacco smoke, or trauma. Food allergies and food additives are suspected as possible aggravating factors.

Medication is considered to be the most effective method of treating ADHD.[15] However, behavioral therapy for parents of children with ADHD may also be useful to assist parents in managing their children most effectively. A recent systematic review examined 403 primary studies that evaluated treatment outcomes of either pharmacologic, behavioral, or combination treatment.[16] The review concluded that combination treatment resulted in the highest proportion of improved outcomes, at 83%. A majority of outcomes improved regardless of treatment duration or age at initiation of treatment. However, it should be noted that longer follow-ups revealed less benefit from treatment, suggesting that some treatment outcomes may not persist to the same extent after several years.

Hyperactivity and the inability to focus can be problems during orthodontic treatment. Patients with ADHD may have trouble sitting still during procedures and may not be compliant in maintaining good hygiene, wearing elastics, or performing other tasks because of forgetfulness and inattentiveness. These patients can be best managed by giving short, clear instructions and giving written instructions or reminders to them or their parents, with follow-up questions to determine their comprehension and rewards for successful compliance. Dental prophylaxis may be needed more frequently to avoid decalcification and caries. To increase the likelihood of treatment success, it may be wise to avoid treatment plans that require a high degree of patient compliance. During treatment, it is often helpful to give the patient breaks during prolonged procedures.

Obsessive-Compulsive Disorder

OCD is characterized by intrusive thoughts and repetitive, compulsive behaviors.[11] The patient's behavior is intended to reduce the anxiety that accompanies the intrusive thoughts. This disorder affects 1% to 4% of the population and is often associated with eating disorders, autism, or anxiety disorders.[17]

Although OCD is also considered to be genetic in etiology,[18] specific genes causing OCD have not been identified, and the molecular basis of the disorder has not been determined. The clinical variability suggests that the etiology is heterogeneous, with the possibility of gene–gene and gene–environment interactions.[19]

Treatment of OCD can take one of two forms. For milder cases, cognitive-behavioral therapy (CBT) is usually used. During this form of treatment, the patient is exposed to a feared stimulus with increasing intensity and frequency so that the patient will learn to tolerate what had previously caused anxiety. In addition to CBT, more severe cases and adult patients usually require medication, such as selective serotonin reuptake inhibitors (SSRIs), including clomipramine (Anafranil), fluoxetine (Prozac), fluvoxamine (Luvox), paroxetine (Paxil), and sertraline (Zoloft).[18] One side effect of this class of psychopharmacologic agents is xerostomia, so orthodontists should be aware of this possibility and advise patients accordingly.

The greatest predictor of psychiatric problems in adulthood is a similar disorder in childhood. Obsessive-compulsive behaviors can be noticed in a dental setting.[20] Orthodontists are thus well positioned to detect possible problems and refer a patient for evaluation.

Body Dysmorphic Disorder

Body dysmorphic disorder (BDD) is characterized by an intensely negative emotional response to a minimal or nonexistent defect in the patient's appearance. The head and face are common foci for this preoccupation, so orthodontists may see patients who have excessive concerns about their dentofacial appearance.[21] Other characteristics of this disorder involve multiple consultations about their perceived defect, an obsessive concern with appearance, and emotional volatility. This preoccupation may lead to stress and related disorders and behaviors.[22] Patients are likely to become socially isolated since so much time and attention are devoted to this concern.[23]

Diagnosis can be difficult and misleading, without recognition that BDD involves more than obsessive thoughts. Underdiagnosis is also common, because many patients may not seek help. Approximately 1% of the population may suffer from BDD, which may coexist with other disorders, such as depression and OCD.[24,25]

BDD is also treated most successfully with SSRIs, although CBT can help.[26] Using photographic imaging of the patient's own face as a reality check may help with some patients (Giddon DB, personal communication). The cognitive aspect of therapy aims to restructure faulty beliefs that lead patients to focus on an imagined defect. The behavioral therapy works to reduce the social avoidance and repetitive behaviors. It is not known which mode of therapy is better or if a combination is best.[26]

If this disorder is not treated, most patients will seek dental, medical, or surgical treatment to "correct" their flaws, which usually fails.[23] Physical improvement, however, does not signify psychological improvement. Dissatisfied patients may become violent toward themselves or attempt suicide. Thus, orthodontists and other clinicians who are consulted are advised to be particularly wary of such patients, who can disrupt office routines, leading to great frustration for both clinicians and patients.

Even if patients do not have a diagnosis of BDD, they may have excessive concerns about minimal or nonexistent deformities or malocclusion. The orthodontist can screen out patients who may have excessive concerns that are impossible to satisfy by taking a careful history on every patient, particularly probing the extent and nature of aesthetic concerns. Since most patients with aesthetic concerns are not significantly disfigured, these deformities would probably be considered minimal. If patients show an inordinate focus on them, the orthodontist would be well advised to look further before starting treatment, or not begin treatment at all. Polo[27] has developed questions that can be used as starting points to identify patients who may have excessive concern over esthetic problems (Box 10-1).

BOX 10-1 Screening questionnaire for Body Dysmorphic Disorder in orthodontic patients.

- How does the patient rate the severity of the orthodontic concern or defect?
- How would the patient rate the amount of distress or worries produced by the orthodontic concern, defect, or "unattractive" appearance?
- Does this (minor or perceived) defect cause significant distress either socially or related to family/work activities?
- Why is orthodontic treatment sought?
- Have previous evaluations concerning the orthodontic "defect" been performed?
- Why are additional orthodontic evaluations sought?
- Are the expectations for this particular orthodontic procedure reasonable?
- Have requests for other cosmetic procedures ever been obtained?
- Have these other cosmetic procedures been performed? Are these frequent? How many? When?
- Is there a history of dissatisfaction with previous cosmetic procedures? Are these multiple?
- Does the patient report any history of psychiatric or psychological disturbances or any previous referrals for psychological/psychiatric evaluations?

(From Polo M: Body Dysmorphic Disorder: A Screening Guide for Orthodontist, Am J Orthod Dentofac Orthop 139(2):170-173, 2011 Fig. 2.)

With such patients, limits on therapeutic intervention must be set. Patients should be given realistic options with definite endpoints, including the option of no treatment. Concrete comparisons and predictions should be shown to reinforce reality and not lead to unrealistic expectations. Treatment options and the final treatment plan, along with possible obstacles to ideal results, should be put in writing. If ongoing, treatment should be stopped and/or the patient referred to other health professionals.

Bipolar Disorder

Bipolar disorder, formerly known as manic-depressive disorder, consists of two phases: depression and mania. These mood swings are so severe as to interfere with normal life. The lifetime prevalence of this disorder is 1.6%, although the course of the disorder varies. The peak time of onset is between 15 and 24 years, stabilizing in later years.[28]

Accompanying the mood swings can be a variety of other disorders. It is estimated that 50% of patients also abuse illegal substances. Between 25% and 50% attempt suicide, with 10% to 15% being successful.[28]

The pathogenesis of this illness consists of neurochemical abnormalities with an etiology that is at least partially genetic. If one parent is affected, there is a 25% risk that children will be affected, but if both parents are affected, the risk jumps to 50% to 75%. There is a 70% concordance in identical twins.[28]

Treatment for BD with mood stabilizers such as lithium, valproate, or carbamazepine is most important.[28] Drugs that calm agitation, such as chlorpromazine or olanzapine, may also be useful. Antidepressants are not usually prescribed because they may trigger mania.

Of concern in bipolar disorder is that for most patients, 5 to 10 years elapse between the beginning of symptoms and treatment.[28] This is probably due to the fact that for a certain period of time, the mood swings do not seem serious enough to warrant treatment, and people will often try to accommodate to their symptoms as long as possible before submitting to psychiatric care. During this time, however, these patients may be difficult to manage, with periods of depression and mania. For the orthodontist, bipolar disorder may be manifested with poor hygiene, a lack of compliance, and a general apathy toward treatment. In the patient under treatment, medications can produce xerostomia, with its deleterious effects on the dentition.[28]

Panic Disorder

Panic disorder (PD) is diagnosed when the patient experiences sudden, recurrent panic attacks consisting of heart palpitations, dizziness, difficulty breathing, chest pains, and sweating that are unrelated to any external event and are not due to any medical condition. It is estimated that 2% of males and 5% of females are affected in their young adult years, and the majority have concurrent depression. This condition can be extremely disabling because the patient often avoids certain situations in an effort to prevent recurrences, with the result that patients are socially and vocationally impaired.

A genetic susceptibility to PD combined with environmental stresses is likely, and the heritability is estimated to be 48%.[29] It has been hypothesized that there is a mutation in 13q, with an organic defect in the amygdala and hippocampus, that portion of the midbrain responsible for emotion and memory with input from the visual, auditory, and somatosensory systems.[30] In PD, the amygdala misinterprets sensations from the body, leading to the characteristic extreme reactions.

Treatment for PD consists of medication either by itself or in combination with CBT. Meta analysis has shown that a combination is most effective,[31] although SSRIs have many possible side effects that may affect the oral health of patients, including xerostomia, glossitis, gingivitis, stomatitis, dizziness, headache, and loss of the sense of taste.[32] Suicide has also been reported. In addition, interactions are also possible between SSRIs and erythromycin or codeine.

Depression

Depression is one of the most common psychiatric disorders, affecting an estimated 20% of the population at sometime in their lives.[33] The course of depression may vary widely; it may affect a patient once or recur; it can appear gradually or suddenly and can last a few months or a lifetime. Not only are patients with depression at higher risk for suicide, they also have a higher mortality rate from other causes such as accident, trauma, or homicide. Depression is the leading cause of disability in North America.

Depression can take many forms, but common symptoms, lasting for at least 2 weeks, are a pervasive low mood, a loss of interest in usual activities, significant (5%) weight gain or loss, change in sleep patterns, loss of energy, persistent fatigue, recurrent thoughts of death, and a diminished ability to enjoy life.[34] Adolescents are more apt to be irritable and act out when they are depressed, but patients generally report feeling empty and anxious, with fatigue and decreased energy. It is sometimes difficult to distinguish between “normal” or situational depression, which is a natural response to trauma or illness, and clinical depression, which may be related to underlying endogenous factors. One distinguishing characteristic of normal depression is that these patients still can communicate, make their own decisions, and participate in their own care. Patients with pathologic depression have symptoms that are out of proportion to the circumstances.

The cause of depression is linked to a lack of stimulation of the postsynaptic neurons in the brain. There is an increase in monoamine oxidase (MAO) A, an enzyme that decreases the concentration of serotonin and other monoamines that help maintain a positive mood. As with other psychological disorders, there is a genetic component, although it is poorly defined.[35]

Because orthodontic patients come regularly for appointments and usually interact with the orthodontist and office staff, orthodontists are in a good position to notice whether their adolescent patients exhibit such symptoms or signs of depression. Orthodontists should be particularly attentive to patients who have dropped out of their normal activities, changed their appearance, report insomnia, have abrupt deterioration in academic performance in conjunction with a lack of interest in their usual activities, or show signs of drug or alcohol abuse.

Treatment for depression, as with other disorders, consists of a variety of drugs and psychotherapy.[32,35] In addition to pharmacologic and psychological intervention, alternative therapies such as electroconvulsive therapy, hypnotherapy, meditation, and diet therapy have been suggested. Hospitalization may become necessary if suicide is a possibility. Drugs currently used for depression include SSRIs such as sertraline (Zoloft), fluoxetine (Prozac), citalopram (Celexa), and paroxetine (Paxil); MAO inhibitors; and dopamine reuptake inhibitors such as bupropion (Wellbutrin and Zyban). SSRIs have not been found to work significantly better than placebo for moderate depression but have been found to be effective for severe depression. MAO inhibitors are effective but can have interactions with decongestants or tyramine-rich foods such as cheese. Dopamine reuptake inhibitors are better than SSRIs for fatigue and insomnia.

Nondrug therapies for depression, such as CBT, are directed at helping the patient learn to cope with their symptoms and improve interpersonal communication. In supportive therapy, patients may also discuss their problems with others who can share strategies for coping with their illness. In family therapy, the entire family learns how to undo patterns of destructive behavior.[35]

Eating Disorders

Eating disorders, including anorexia nervosa or bulimia nervosa, affect up to 2% of adolescent and young adult females, although they can affect both sexes at many ages.[34] The fundamental defect lies in the distorted body image that leads patients to control their weight by extreme dieting or vomiting. Patients usually go to great lengths to hide their symptoms and behaviors, so that close family members often are unaware of their existence. Bulimia and anorexia can lead to severe metabolic disturbances and even death, and thus they require treatment.

Both anorexia and bulimia have oral manifestations. Bulimia may lead to dental erosions, which can be sometimes be noted as extruding amalgams, as well as dentinal hypersensitivity and salivary gland hypertrophy. Both conditions can be accompanied by cheilosis.

If orthodontic patients are suspected of having an eating disorder, these concerns should be addressed directly. Therapy for eating disorders consists of CBT, so that patients can develop realistic ideas about how much they should eat, what is good nutrition, and their own body image. SSRIs can also be used.

Personality Disorders

While depression, BDD, and OCD are classified by the *DSM-IV* as Axis I disorders and are predominantly related to mood, personality disorders are classified as Axis II disorders (i.e., disorders that involve maladaptive behaviors and patterns of thinking that lead to problems at home, school, and work). Personality disorders most frequently seen are the narcissistic personality, borderline personality disorder (BPD), and the antisocial personality disorder (APD). It is estimated that the prevalence of these personality disorders ranges from 4.4% to 13% in the United States.[36] Environmental influences such as prior abuse, poor family support, family disruption, and peer influences, as well as biological causes, are important risk factors for the development of such disorders.

Patients with narcissistic personalities believe that they are special and therefore entitled to special treatment. The typical narcissistic patient has a very brittle self-esteem and a strong need for approval, which are manifested as arrogance and demands for special attention. These patients are thus more intolerant of minor complications and are more likely to seek legal recourse when dissatisfied.

BPD has an estimated prevalence of 0.7% to 2.0%.[36] It is characterized by erratic moods, impulsivity, and poorly controlled anger. These behaviors can lead to unstable relationships and chronic interpersonal problems. One interesting feature is that patients with BPD often begin treatment with an extremely positive view of the orthodontist but, with treatment, quickly changes to hatred and anger in response to complications.

APD affects more males than females by a ratio of 4 or 5:1, with an overall prevalence of 2% to 3%.[36] Those affected by APD exhibit unacceptable behavior such as lying, theft, destructive behavior, and aggression to people and animals, accompanied by a lack of remorse.

Patients with any form of personality disorder can be difficult to manage in an orthodontic office, being disruptive and trying for clinicians. Such individuals may be hard to identify or label, even though they may not be compliant and may show some signs of depression or substance abuse and even attempted suicide. Staff members need to handle these patients with evenhandedness, not allowing them to disrupt the office procedures or abuse office personnel. Orthodontists should beware of excessively dependent or manipulative behaviors, which can cause conflict among staff members. If necessary, care can be discontinued and the patient dismissed.

"Difficult" Patients

As noted earlier, patients with no known psychopathology can still be difficult to manage, exhibiting a number of different behaviors that are disruptive, hostile, or otherwise difficult for the orthodontist to handle. According to Groves,[37] they can be categorized into four distinctive types:

- *Dependent clingers* have needs for reassurance from their caregiver that escalate. Patients are initially reasonable in their needs but become progressively more helpless, ultimately becoming totally dependent upon their doctors. These patients must be given appropriate limits with realistic expectations. Clear verbal and written instructions can be helpful in reinforcing the limits of patient access to the professional staff.
- *Entitled demanders* are also needy but manifest it as intimidation and attempts to induce guilt. They have a need to control the situation and often make threats, either overt or implied, in order to get what they want. Their aggressive behavior may be due to feelings of dependency and fear of abandonment. These patients are best dealt with by validating anger but redirecting the feelings of entitlement to realistic expectations of good care. Again, limits must be placed so that office procedures are not disrupted.
- *Manipulative help-rejecters* focus on their symptoms but are resigned toward failure. They seem satisfied with a lack of improvement. Clearly, these patients who are difficult to treat must be involved in all decisions and should have regular appointments. Because they must either agree to all treatment or choose not to proceed, the orthodontist does not have the responsibility for the success of the treatment.
- *Self-destructive deniers* take pleasure in defeating any attempts to help them. They do not seem to want to improve. These patients may be sufficiently depressed to consider not rendering or limiting treatment.

In general, all demanding and needy patients should have limits placed on their behavior at the time when treatment alternatives are discussed. Orthodontists should not promise too much in describing treatment plans and outcomes. They should describe how they would address the orthodontic needs, noting potential problems and obstacles to the treatment, and explain how progress might be evaluated. In fact, some variation of the Perceptometrics method might be helpful to present patients with an acceptable range of suggested treatment outcomes (Giddon DB, personal communication). This will minimize the possibility that patient expectations are too high. As Groves commented, "Difficult patients are typically those patients who raise 'difficult' feelings within the clinician."[37] Orthodontists must learn to address these difficult feelings and deal with them. The orthodontist should remain friendly, unemotional, and professional at all times. Emotional outbursts should be responded to with an acknowledgment of feelings but an expectation of appropriate behavior. Noncompliance must be countered with an appropriate alternative treatment plan. The clinician and staff must avoid being provoked and remain professional and emotionally neutral while maintaining a correct office atmosphere.

PATIENTS HAVING ORTHOGNATHIC SURGERY

Psychosocial aspects of orthognathic surgery patients, who receive orthodontic treatment combined with jaw surgery, deserve special consideration because their treatment often involves changes in appearance which may or may not be the motivation for treatment as well as the fact that surgery entails risks beyond those of orthodontics alone.

Psychological Status and Motivation

When considering the success of combined surgical-orthodontic treatment, there are several aspects to consider. First, what is the psychological and physical situation of the patients that brings them to the point of considering having jaw surgery? What motivates patients to consider this combined treatment? Is their decision a normal reaction to a debilitating dentofacial deformity, or do they have an abnormal perception that surgery will not correct?

Early studies into this area were prompted by reports in the plastic surgery literature which found that many patients seeking plastic surgery had significant psychiatric problems.[38-41] However, two studies examining the psychological profile of orthognathic patients found that these patients were psychologically normal.[42,43] Although earlier studies had shown that orthognathic patients typically did not suffer from depression or anxiety, Alanko et al., sought to determine whether orthognathic patients were psychologically different from patients who had not been referred for orthognathic treatment.[44] They identified 60 patients with a mean age of 17 and asked them to complete five questionnaires and a structured diary which elicited information regarding their quality of life, experiences with bullying, self-image, and self-esteem. Their results were compared with those from questionnaires completed by a matched group of patients who had not been referred for orthognathic treatment. Each participant was also asked to rate their own dental appearance on a visual analog scale. An objective assessment of each participant's occlusion was provided by an orthodontist using the same scale and study models. The authors determined that those patients who rated their dental aesthetics lower had lower orthognathic quality of life scores and poorer body image than the control subjects, while those who rated their dental esthetics higher only had poorer oral function. The authors concluded that many patients cope very well with their deformities, and that their perception of their dental appearance is a key influence in determining the patients' reaction to their deformity.

The issue of motivation was explored by Ryan et al.,[45] who prospectively interviewed 18 patients, 18 to 40 years old, before having orthognathic surgery. The interviews revealed that the deformity affected the patients in either practical or psychological ways, or in a combination. Practical effects included functional problems including difficulty eating, speaking, or issues such as lip entrapment or biting the cheeks, or structural problems such as asymmetries or overjet. Psychological problems included feeling helpless about their appearance, avoiding social situations, and not applying for jobs due to low self-esteem and fear of rejection. It was noted that those who had functional concerns only did not have low self-esteem. Although they had feelings of embarrassment, these were not related to problems of self-image. Patients coped with these problems in two ways: either avoiding confronting the problem (including social isolation), or continuing normal activities while modifying their behavior to minimize the impact of their condition. This type of behavior modification included altering their rest position to mask their true bite, and not posing for photos. Motivation for treatment has traditionally been classified as external or internal, but this study discussed the practical and psychological motivations that led from the impacts described above. Both factors resulted in the patients deciding that they wanted a change in their lives, whether that meant feeling more confident about themselves or being able to chew more effectively. The authors stressed that both external and internal motivations were present, but that many patients reported a combined external/internal motivation. Although this study did not identify a clear reason for the dissatisfaction of some patients toward their surgery, it very clearly demonstrates that the degree of impact deformities can have on a person's life is not necessarily proportional to the physical deformity, and that the problem as perceived by the patient may be quite different in type and degree than that observed by the clinician.

Quality of life is defined as individuals' perception of their position in life in the context of the culture and value system in which they live and in relation to their goals, expectations, standards, and concerns.[46] This concept that has been increasingly applied to assess how a peoples' physical problems influence their overall well-being; in this context, how dentofacial deformities affect a person's quality of life.

Lee et al.[47] studied patients with dentofacial deformity in order to determine and compare the effect of dentofacial deformity on the patients' quality of life. They asked 76 patients who were referred for orthognathic surgery to complete three different questionnaires that included a generic health-related questionnaire, a generic oral health–related questionnaire, and a condition-specific quality of life measure. Their responses were compared with those from a control group of patients who were referred for removal of asymptomatic third molars. Lee found that in the generic health-related questionnaire, there were no differences in any domain of general health, such as physical functioning, pain, mental health, vitality, and social functioning. However, they found significant differences in the overall oral health quality of life questionnaire in such areas of functional limitation, psychological discomfort, psychological disability, and handicap, with specific problems in areas such as being able to pronounce words properly, being self-conscious or embarrassed because of the mouth or teeth, and feeling that life in general was less satisfying because of problems with the teeth or mouth. Finally, the condition-specific quality of life inventory demonstrated significant differences in five areas, including reporting significantly more problems biting and chewing, and reporting significantly more often disliking seeing a side view of the face, having their photograph taken, or being seen on video. Clearly, these results indicate that patients with dentofacial deformities have a poorer quality of life in a variety of aspects.

De Avila et al.[46] also assessed 50 patients one year before undergoing orthognathic surgery to determine if they exhibited any signs of depression in greater frequency than a nonsurgical population. The patients were given modified QOL (quality of life) questionnaires as well as the Beck Depression Inventory. The adapted questionnaires included 36 questions that evaluated how the physical health influenced the patient's daily life, including emotional state, social activities, energy, and mood. The Beck Depression Inventory asked the patient to rate 21 questions as to how often something bothered the patient (never, occasionally, fairly, and often). The patient was then judged either to have some degree of depression or not depending on the total score. Using this method, 19 patients were judged to have some degree of depression. De Avila noted that the diagnosis of depression was positively correlated with a lack of energy ($p < 0.001$), less social activity ($p = 0.011$), and poorer mental health ($p = 0.008$).This study emphasizes the interrelationships between aspects of mental health and physical health and underlines the necessity of carefully screening patients for potential problems when considering orthognathic surgery.[46]

Yu et al. used QOL instruments to determine motivations for orthognathic surgery in Chinese patients.[48] Two hundred ten healthy patients completed a questionnaire that included self-esteem measures as well as oral health QOL items. Their responses were compared with those from 219 individuals who were not undergoing surgery. Both males and females listed improvement of their facial appearance as the #1 reason for having orthognathic surgery. Men listed occlusion second and self-confidence third, whereas women reversed the positions of these two motivations. Self-esteem was significantly lower in the patient group. The authors concluded that attention needs to be paid to social and cultural motivations of the patient.

Expectations

Regardless of patients' reasons for undergoing orthognathic treatment, patients' ultimate satisfaction with the outcome can often be related to what they expect to gain from the treatment. Ryan interviewed 18 adult patients and found two broad categories of expectations: those related to changes in physical features, and those related to the effect these changes would have on their lives.[49] The authors found that the patients fell into four categories that had been earlier delineated by Ritchie: metamorphosizers, pragmatists, shedders, and evolvers.[50] *Metamorphosizers* had expectations of both physical and psychological problems being fully corrected by the surgery. These patients would be more likely to be dissatisfied and may require more exploration of their expectations. *Pragmatists* expect a physical but not psychological change since they see the impact of the deformity as totally physical. However, these patients may have lower satisfaction because the physical changes may not happen to the extent expected, and there may be unforeseen emotional changes that trouble the patient. A third type of patient, *shedders*, expect little physical change but profound psychological change. These patients also require careful counseling to determine their true motivations and expectations. Finally, *evolvers* have very low expectations for both physical and psychological changes. This, too, poses some risk for dissatisfaction for several reasons: first, there may be more changes, both physical and emotional, than the patient was ready for. Furthermore, without positive expectations, patients may find the postoperative course difficult to manage.

In this study, the investigators made no distinction between realistic and unrealistic expectations, since this would require that judgments be made regarding the likelihood of changes occurring. However, clinicians need to probe in some detail as to what the expectations of the patients are and, in their judgment, whether the expectations are realistic. This will require that the clinician spend as much time as necessary with patients discussing their perceptions and motivations, and a willingness to listen objectively and openly.

Another method of examining expectations was used by Bullen et al.[51] They constructed an average patient profile that was then altered with incremental movements of the lips to create a 13-photo sequence showing gradual differences in lip position. Eighty-five patients who were either in active orthodontic treatment or considering orthodontic and/or orthognathic treatment were then given a photo of their own profile as well as a questionnaire that included the series of constructed profiles. First, the patients were asked how satisfied they were with their current profile. The patients were then asked to choose which of the 13 profiles in the constructed series most closely matched their own. The profile chosen was compared to the individual's profile to measure the difference between the patient's real and perceived profile. The authors found that while the younger patients (15 to 25 years) thought that their lips were more retrusive than they actually were, older patients (over 25 years of age) thought that their lips were significantly more protrusive than they actually were. The authors concluded that older patients, in whom soft tissue changes have continued throughout their adult life, may need additional efforts to make sure they have an accurate view of their facial profile, and thus have an accurate expectation of the outcomes of orthognathic surgery.

Satisfaction

The ultimate goal of orthognathic surgery is patient satisfaction. It might be said that even with a technically successful procedure, success has not been achieved without a satisfied patient. Thus, the factors determining patient satisfaction need to be determined so that, where possible, they can be ensured.

Kiyak et al. were among the first to comprehensively examine patient satisfaction with orthognathic surgery. They gave questionnaires to 74 consecutive orthognathic surgery patients at six time points, from before surgery to 24 months postoperatively. They found that at 1 month and 4 months postoperatively, those who experienced less pain and numbness than expected had a higher self-esteem and were overall more satisfied than those who had more pain and numbness than expected. However, although the levels of satisfaction and self-esteem rose after surgery from 1 to 2 days to 3 weeks to 4 months, the levels were uniformly lower at 9 months. The authors hypothesized that by 9 months, patients might see their results as permanent, so that any problems that remained would decrease their sense of satisfaction.[52] By 24 months, however, the various categories of self-esteem had rebounded, though not quite to preoperative levels, while patient satisfaction was at its highest level. The authors concluded that changes resulting from the orthognathic surgery may persist for at least 2 years and suggested that clinicians work with patients long term to make sure they have adapted well to the surgical outcome.[53]

In 2007, Findlay et al. evaluated the satisfaction of 61 orthognathic patients to determine whether the surgery had any influence on the patients' self-esteem.[54] Preoperatively, patients were given three questionnaires that assessed the patient's extraversion/introversion status, general health, and feelings toward their bodies. They were also asked questions surrounding their motives and expectations with regards to the surgery. At three time points postoperatively, the patients were given some or all of these questionnaires once again to examine changes. They found that 87% of the patients were satisfied with their result. Those who were not satisfied had neuroticism scores on the personality tests that were significantly higher. No associations between satisfaction and general health, sex, extroversion, or self-esteem were found. All dissatisfied patients reported experiencing more pain, swelling, numbness, and scarring than expected, in contrast to the large majority of the group at large. Forty two percent of all patients felt that they had received too little information 3 months after surgery, but gradually this decreased to 26% at 1 year.

Cunningham et al. conducted a similar study, querying 83 preoperative and 100 postoperative patients to determine self-esteem and level of postoperative satisfaction.[55] They found that 95% of patients were satisfied with their treatment at least 9 months after surgery. The reasons given for dissatisfaction were inadequate preparation for postoperative problems and one case of not having as great a change as expected. There was no significant difference in self-esteem between the pre- and postoperative groups. The authors concluded by recommending that preoperative patients be given advice and information regarding the postoperative course and potential problems both verbally and in writing to help prevent dissatisfaction that may persist.

Lee et al. tracked changes in quality of life in 36 patients preoperatively as well as 6 weeks and 6 months postoperatively.[56] A significant increase in quality of life was revealed immediately after surgery as well as long term (Fig. 10-2). Both general mental and physical scores improved after 6 weeks as well as specific improvements in facial aesthetics, psychological discomfort, and social functioning. As would be expected, there was an increase in functional limitation, which later decreased far beyond the preoperative level. Clearly, patients benefit in a variety of ways from orthognathic surgery.

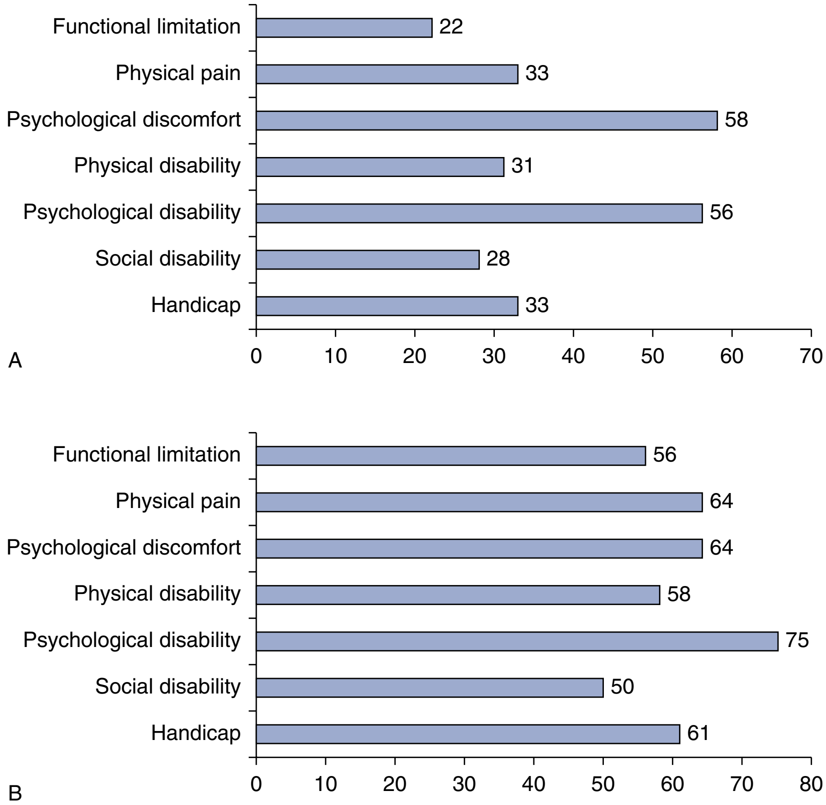

FIGURE 10-2 **A,** Percentage of subjects with decrease in OHIP-14 score at 6 weeks. **B,** Percentage of subjects with decrease in OHIP-14 score at 6 months. (From Lee S, McGrath C, Samman N: Impact of Orthognathic Surgery on Quality of Life, J Oral Maxillofac Surg 66(6):1194-1199, 2008.)

Phillips et al. more closely evaluated patients' postoperative course by asking 170 patients to complete a 20-item health-related QOL survey each postoperative day for 90 days.[57] One hundred seventy patients completed at least 30 days' of questionnaires and brought them to clinic visits at 1, 4-6, and 12 weeks. By the end of the first postoperative week, most patients had little postoperative sequelae such as bruising or food collection in the incision. Fewer than 7% reported any significant problems after 2 weeks. Pain and discomfort lasted 2 to 3 weeks after surgery for most patients, although 20% of patients still were taking pain medication after 1 month. The return to daily activities followed a similar pattern with 85% reporting no substantial problems with their daily life by the end of the first month. The problem that lasted the longest was oral function. Problems with chewing persisted significantly longer than problems with opening or eating. By 64 days postoperatively, 75% of patients reported no or slight problems with opening and eating, but the same level of recovery was not reported for chewing until day 70. The authors recommended that similar diaries be routinely completed by all patients as a way for clinicians to track the patient's recovery and quality of life.

Perhaps the ultimate indicator of treatment success is the long-term benefit experienced by patients. Motegi et al. evaluated 93 patients who had received bilateral sagittal split osteotomy for a Class II malocclusion preoperatively as well as 2 and 5 years postoperatively.[58] They evaluated health-related abilities, daily activities, and current symptoms. They found that after both 2 and 5 years, there was significant improvement in all areas. Although there was no control group employed, it was clear that for this group of patients, there was a long-term benefit to orthognathic surgery.

Lazaridou-Terzoudi et al.[59] also looked at long-term benefits as they surveyed 117 patients who had orthognathic surgery 10 to 14 years earlier to assess the patients' perceptions of problems with functioning, socializing, eating, sleeping, and other aspects of self-image and quality of life. The results were compared with two control groups: one group waiting for orthodontic treatment, and a group of comparably aged adults not seeking treatment. They found a linear improvement in all four subscales of function, health, interpersonal relations, and appearance from preoperative state through immediate postoperative state to the present. Compared with both control groups, the orthognathic surgery group reported current functioning in the four areas that was higher than either control group, but their reported level of functioning before surgery was lower than the nontreatment controls in all four areas, and lower than patients awaiting treatment with motivations in appearance and interpersonal relations (Fig. 10-3). The authors also looked at the patients' body image by having them rate their feelings toward different aspects of their physical appearance. In contrast to the improvement of quality of functioning reported in the earlier subscales, the orthognathic patients had lower overall facial body image than either control group, but similar assessments of total body image. In assessing the influence of age on the long-term results, the authors found that the youngest patients, who had undergone surgery in their teens, were significantly less likely to be satisfied with the overall result and the least satisfied with their current appearance. This is consistent with a report by Cunningham et al. that patients in their thirties are more satisfied with their appearance after surgery.[60] In summary, the authors concluded that the improvement in appearance that results

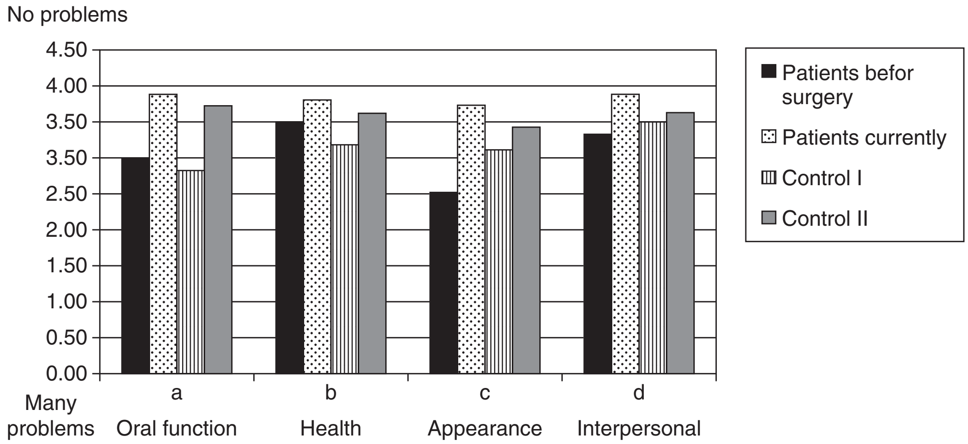

FIGURE 10-3 "Problems" for patients versus controls (^{a}F =16.78, P = .001; ^{b}F = 7.03, P = .001; ^{c}F =7.08, P =.001; dF = 4.25, P =.001, comparison of current status across groups). (From Lazaridou-Terzoudi T, Asuman Kiyak H, Moore R, et al.: Long-term Assessment of Psychologic Outcomes of Orthognathic Surgery, J Oral Maxillofac Surg 61(5):545-552, 2003.)

from orthognathic surgery is associated with improvement in psychosocial adjustment, and that patients should be offered appropriate treatment to address such handicaps.

Soh and Narayanan carried out a systematic review of 21 studies that assessed patient motivations, perceptions, or postoperative changes in QOL in an attempt to objectively evaluate all methods of appraising the quality of life of orthognathic patients.[61] Their conclusions can serve to summarize all the studies discussed here:

1. Orthognathic surgery does result in an improved quality of life. The biggest improvements are seen in the social/emotional and psychological areas.
2. The use of validated QOL questionnaires has significantly improved the ability of clinicians to evaluate details of the affect of surgery on patients.
3. Aesthetic concerns as well as occlusion are the main motivations for patients to undergo orthognathic surgery.
4. When patients are dissatisfied with the outcome of their surgery, most of these complaints are due to short-term surgical sequelae, which can take months to resolve. However, some patients have expectations that are not realistic, and these need to be detected before surgery to attempt to prevent dissatisfaction with outcome.

In conclusion, significant time needs to be taken to understand the patient's motivation for treatment and what they expect. Quality-of-life questionnaires and other instruments may be helpful in gathering information. All patients need to be given detailed information during consultations as well as in writing in order to obtain the best possible outcome and greatest patient satisfaction from surgery.

PATIENTS WITH CRANIOFACIAL DEFORMITIES

Psychological Issues

Orthodontists see patients with facial deformities or other disfigurement. Their orthodontic treatment may be a part of a coordinated surgical-orthodontic plan to address the deformity or may be isolated. Whatever the circumstances, these patients will be fundamentally different psychologically from patients who are not deformed. Pertschuk and Whitaker[62] compared a group of 43 patients with craniofacial anomalies between the ages of 6 and 13 with children matched for age, sex, intelligence, and family income to determine differences in psychological functioning before surgery. They studied levels of anxiety, self-concept, social experiences, intelligence, and personality characteristics and found that the craniofacial patients were more anxious and more introverted and had a poorer self-concept. Their parents reported teasing from peers about their facial appearance. Treatment was being sought out of a desire to improve appearance, but patients could not specify what they wanted to change. When these patients were evaluated 12 to 18 months after surgery, they demonstrated reduced levels of anxiety but more negative social interactions, possibly because their social skills had not developed as the patients grew. Pertschuk and Whitaker thus concluded that modest improvements in psychological adjustment were due to craniofacial surgery.

Pillemer and Cook[63] evaluated 25 patients aged 6 to 16 years at least 1 year after craniofacial surgery and found that these children still exhibited an inhibited personality style, low self-esteem, impaired peer relationships, and greater dependence on significant adults. They concluded that treatment per se does not solve psychological issues, suggesting that long-term follow-up and support from interdisciplinary teams may be of greater benefit.

Sarwer et al.[64] examined 24 adults born with a craniofacial anomaly in terms of their body image dissatisfaction, self-esteem, quality of life, and experiences of discrimination and compared them with an age- and gender-matched control group who were not disfigured. The adults with craniofacial disfigurement reported significantly greater dissatisfaction with their facial appearance, a significantly lower self-esteem, and a significantly lower quality of life than the control group. It is interesting to note that dissatisfaction with facial appearance was correlated with the degree of residual facial deformity. It should also be noted that these problems are by no means universal among adults with facial deformities.

These studies point out the psychological differences in patients whose self-image is intrinsically different. Clinicians should realize that these patients have a much different perspective on orthodontic treatment. Their expectations of treatment outcome may therefore also be quite different, and this should be explored when orthodontic treatment is discussed.

Patients with Clefts of the Lip and Palate

The most common facial deformity that orthodontists will see is cleft lip and palate. Considerable research has been done examining the psychological aspect of this congenital anomaly. Kapp-Simon[15] explored whether primary school-age children with clefts have negative self-concepts by using the Primary Self-Concept Inventory (PCSI) and compared the results from tests administered to 172 children without noncleft children. Kapp-Simon[15] found that the children with clefts had low self-concepts based on the following areas: social self, emotional state, and helpfulness. It is apparent that this group of children feels stigmatized by their cleft from a very early age and therefore can be expected to have a much different attitude toward orthodontic treatment from those without clefts.

More recently, Broder et al. assessed the quality of life of patients with clefts using the Child Oral Health Impact Profile scale.[65] This instrument is a 34-question inventory that has been validated for use with children and was given to patients aged 7 to 19 years at six craniofacial centers around the United States. It asks the degree to which the patient has difficulty with a variety of items in five general areas: oral symptoms, functional well-being, social-emotional well-being, school/environment, and self-esteem. It was found that those patients who needed surgery had a lower quality of life in all aspects except for self-esteem, which is consistent with earlier reports that the majority of patients with clefts do not “appear to experience major psychosocial problems.”[66] The authors also found that with increasing age, girls had a greater reduction in quality of life than boys. This was thought to be due to the greater importance that attractiveness has for girls during adolescence and underscores the importance of listening carefully to patients’ concerns during orthodontic visits.

Patients with Acquired Deformities

An important subset of patients with facial deformities includes those who were born without dentofacial deformity but acquired it after birth from trauma, tumor, or disease. Because these patients had normal faces or occlusions prior to the insult, they may have more psychological stress in adapting to their acquired dysmorphic appearance than those patients who have never known any other morphology. Patients who have congenital anomalies have had time to incorporate the defect into their body image,[67] but patients who suddenly lose their normal appearance have a much more difficult time coping with their deformity. Consequently, their expectations from treatment may be quite different from those patients who have never had a “normal” face. Because the responses to acquired or congenital deformities may differ, it is critical that the patient’s expectations and wishes be discussed in detail and that the orthodontist discusses realistically what can be achieved.

De Sousa reviewed, in some detail, the psychological issues that may arise with reconstructive oral and maxillofacial surgery.[68] In addition to craniofacial anomalies, mentioned above, facial trauma can create significant problems for patients, not only because of the adaptation required to abrupt changes in facial appearance, but also due to posttraumatic stress disorder. Between 20% and 30% of patients with facial injuries may experience intrusive and disturbing thoughts, reexperiencing the trauma, sleep disturbances, irritability, or depression related to the original injury. In addition, brain injury may have also occurred during the trauma. These patients may need management by a team of physicians including neurologists, neuropsychologists, and psychiatrists to help the patient cope with and recover from the past trauma. Patients with facial cancer also experience anxiety and depression, although levels were found to be lower than in patients with facial trauma. It has been found that a patient’s personality, coping ability, and social and family support are significantly related to how well a patient adjusts to their disease.[68] These patients also may need mental-health screening and care to recover psychologically.

SUMMARY

Every patient has individual perceptions, desires, needs, and related behavior, some of which are outside the usual experience of most orthodontists. It is hoped that the information provided in this chapter will help orthodontists to more effectively manage patients with abnormal or difficult perceptions and behaviors. Clear communication is critical when discussing orthodontic problems, proposed treatment, and treatment alternatives and expectations. In addition, the clinician must become completely familiar with the patient’s medical and psychosocial history, needs, questions, and perceptions. The patient must also be given clear guidelines for office procedures. In this way, many problems arising from abnormal psychological problems and behaviors can be minimized.

Orthodontic Diagnosis and Treatment Planning with Cone-Beam Computed Tomography Imaging

Lucia Cevidanes, Erika Benavides, John B. Ludlow, and Antonio Carlos de Oliveira Ruellas

OUTLINE

The interrelationships of the dentition, craniofacial skeleton, and soft tissues involve the three dimensions (3D). The increasing availability of cone-beam computed tomography (CBCT), over the past 10 years, now allows visualization of these relationships in 3D. Such 3D assessments are likely to promote improved orthodontic diagnosis, treatment planning, evaluation of growth and development, assessment of treatment progress and outcomes, and retention. It is very important that clinicians are prepared and familiar with the technology advances now available.

This chapter describes (1) strategies for assessment of radiation dose risk; (2) clinical applications and potential limitations of the use of CBCT in orthodontics, including suggested optimal imaging selection for each clinical application; and (3) image analyses and the use of 3D surface models and superimpositions.

STRATEGIES FOR ASSESSMENT OF RADIATION DOSE RISK

Because cancer is the principal long-term biological effect of exposure to x-rays, one of the greatest issues facing CBCT in orthodontics is justification of the increased dose of ionizing radiation administered to patients compared with standard two-dimensional (2D) imaging techniques.[1] This is especially important when considering the adolescent and pediatric populations that routinely receive orthodontic treatment in whom cellular growth and organ development is associated with increased radiosensitivity of tissues. In conjunction with a longer life expectancy in which cancer can develop, children may be two times to five times more sensitive to radiation carcinogenesis as mature adults.

The International Commission on Radiological Protection (ICRP) has recommended a calculation called the *effective dose* as the preferred method for comparing risks from different exposures to ionizing radiation.[2] Effective dose is a calculation that considers the most radiosensitive tissues and organs of the body and provides a fractional weighting reflecting the degree of sensitivity for each of those organs. Effective dose is reported in sieverts and for diagnostic imaging is more commonly expressed in millisieverts or microsieverts. Stochastic effects are associated with long-term, low-level (chronic) exposure to radiation, where "stochastic" refers to the likelihood that something will happen: increased levels of radiation exposure make these health effects more likely to occur but do not influence the type or severity of the effect.[3] Because estimation of the risk of the stochastic effects of genetic mutation and cancer formation has evolved with additional data reported from observations of a variety of exposed populations, the ICRP has changed the calculation of effective dose several times. The most recent change was in 2007[4] and is noteworthy because weights of several tissues located in and around the maxillofacial region were changed, and several other tissues within this region were added to the calculation.[5] Changes in tissue weights have resulted in a 10% increase in weight of tissues located in the maxillofacial area and a 28% increase in weight after adjusting for the distribution of tissues. Newly added tissues for effective dose calculation that are entirely within the maxillofacial area include the oral mucosa, salivary glands, and extrathoracic airways. A recent meta-analysis of effective dose estimation of dental CBCT examinations reported that adult effective doses for any protocol ranged from 46 to 1073 μSv for large fields of view (FOVs), 9 to 560 μSv for medium FOVs, and 5 to 652 μSv for small FOVs. Child effective doses from any protocol ranged from 13 to 769 μSv for large or medium FOVs and 7 to 521 μSv for small FOVs. Mean adult effective doses grouped by FOV size were 212 μSv (large), 177 μSv (medium), and 84 μSv (small). Mean child doses were 175 μSv (combined large and medium) and 103 μSv (small). Large differences were seen among different CBCT units. Additional low-dose and high-definition protocols available for many units extend the range of doses (Fig. 11-1).[3]

The ongoing challenge in the optimization of CBCT is to reduce radiation dose without dramatically decreasing imaging quality and diagnostic information. As an example, the contrast-to-noise ratio was reduced by approximately two thirds when Ludlow and Walker[2] compared QuickScan+ with standard exposure parameters. A potential means of reducing patient risk from CBCT examinations is to limit the area of exposure by using variable fields of view that are sized for the location of the anatomy of interest. However, voxel size is linked to field of view (FOV) in CBCT units, and smaller voxel sizes associated with smaller FOVs may actually increase dose because of increases in exposure that are needed to maintain adequate contrast-to-noise ratio. Another approach is to reduce exposure for diagnostic tasks that theoretically require lower contrast-to-noise ratios or lower signal modulation transfer functions. An example of this type of task might be checking angulation of roots. The combination of careful selection of exposure parameters and FOV may result in an optimal use of dose for specific diagnostic tasks in orthodontic practice.[2]

Factors That Influence Dose and Risk Estimation[1]

Biological Factors

Age has a significant impact on both individual dose and risk. Children are physically smaller, which places peripherally located brain and thyroid tissues closer to the dental area that is being imaged. Even if not directly exposed, these organs receive increased scatter radiation with increased proximity to the location of the scanned volume. Children are also at increased risk from any exposure to ionizing radiation owing to cellular growth and organ development, which increases the radiosensitivity of tissues. In conjunction with a longer life expectancy in which cancer can develop, children may be two times or more sensitive to radiation carcinogenesis than are mature adults.[6,7] Females are at risk for breast cancer and ovarian cancer, and males are at risk for prostate cancer. Because these organs are distant from the maxillofacial area, gender differences do not impact dose and risk estimation for maxillofacial imaging.

Technical Factors

Receptor Technology and Field of View. Two types of receptor technologies are used to acquire image data. Image intensifiers use a round receptor and produce a spherical FOV. Square or rectangular flat panel detectors are incorporated in many CBCT units, and these produce a cylindrical FOV. In general, the cylindrical field is more efficient at capturing the anatomy of the maxillofacial complex when the top of the field includes the temporomandibular joint (TMJ) areas. A cylindrical volume diameter, which captures both TMJ and chin anatomy, requires

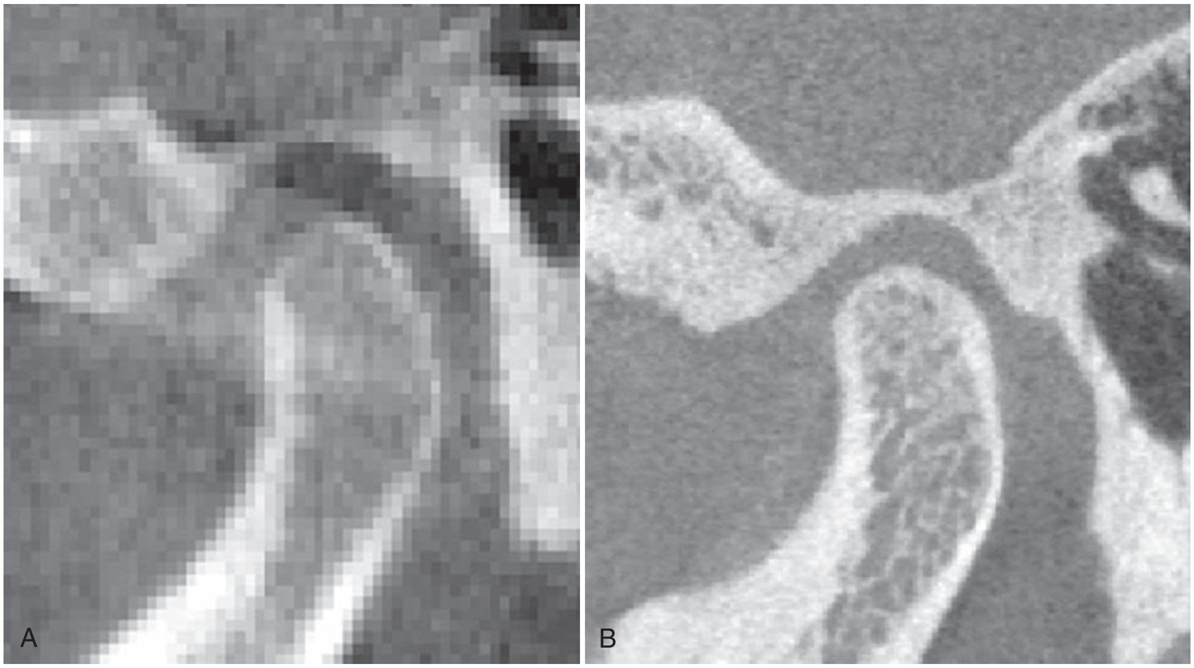

FIGURE 11-1 Images from cross sections of two scans acquired in different cone-beam computed tomography units. **A,** NewTom3D, large field of view. **B,** Accuitomo, small field of view.

a spherical volume diameter that is approximately 25% larger to cover the same anatomy.

mAs. X-ray tube current (mA) and exposure time (s) are directly proportional to dose when other factors remain constant. Some CBCT units produce continuous output of radiation during scanning, with equal scan time and exposure time. Most detectors are unable to record x-ray exposure during the period when the image detector integrates the x-ray energy absorbed in individual receptor pixels and transfers this signal to the computer. To eliminate this unnecessary patient exposure, many CBCT units use a pulsed x-ray source, in which x-ray emission is intermittently turned off during the image acquisition process.

kVp and Beam Filtration. Increasing filtration of the x-ray beam reduces patient exposure to lower energy x-ray photons that are more likely to contribute to patient dose without contributing to image formation.[8] Use of 0.4 mm of additional copper filtration in conjunction with increased kVp was demonstrated to reduce patient dose by an average of 43% with one unit.[9]

Resolution. Exposure must be increased as the voxel size is reduced to create higher resolution images and maintain an adequate signal-to-noise ratio. With some CBCT units, this choice is under operator control, but at other times, the unit dictates which exposure factors may be used with different resolutions.

CLINICAL APPLICATIONS AND POTENTIAL LIMITATIONS OF THE USE OF CONE-BEAM COMPUTED TOMOGRAPHY IN ORTHODONTICS

From a radiation-protection perspective, CBCT should be required when its indication overcomes the fact that conventional images may deliver lower doses to patients. 3D CBCT imaging in orthodontics and orthognathic surgery offers benefits and diagnostic information for the following complex conditions[10]:

Tooth Morphology and Relative Position within the Alveolar Bone

Small or medium FOV high-resolution images that include an arch quadrant or both upper and lower arches are needed to evaluate buccal and lingual plates of the alveolar bone, bone loss or formation, bone depth and height, presence or absence of unerupted teeth, tooth development, tooth morphology and position, amount of bone covering the tooth, and proximity or resorption of adjacent teeth. It is very important that both multiplanar images in the three planes of space and 3D rendered views with or without transparency be used for detailed assessments because isolated views could lead to misdiagnosis (Fig. 11-2). CBCT findings may lead to modifications in the treatment planning (e.g., avoid extraction, help decision of which tooth to extract, evaluate dilacerated roots or placement of bone plates and miniscrews), reduced treatment duration, and additional root resorption control and in the orthosurgical planning.[11–19] Before placing temporary anchorage device (TADs), CBCT is being used as a clinical tool to identify optimal position and to avoid damage to roots.[20] The use of surgical guides based on CBCT data has also been suggested.[21]

Temporomandibular Joint Health and Disease

Small or medium FOV high-resolution images that include one joint at separate right and left acquisitions yield the best quality of images for TMJ assessments (Fig. 11-3). The spectrum of the clinical and pathologic presentation of TMJ osteoarthritis ranges from structural and functional failure of the joint with disc displacement and degeneration (best diagnosed with magnetic resonance imaging [MRI]) to subchondral bone alterations and sclerosis (best diagnosed in multiplanar cross-sectional images from CBCT or CT scans), bone erosions

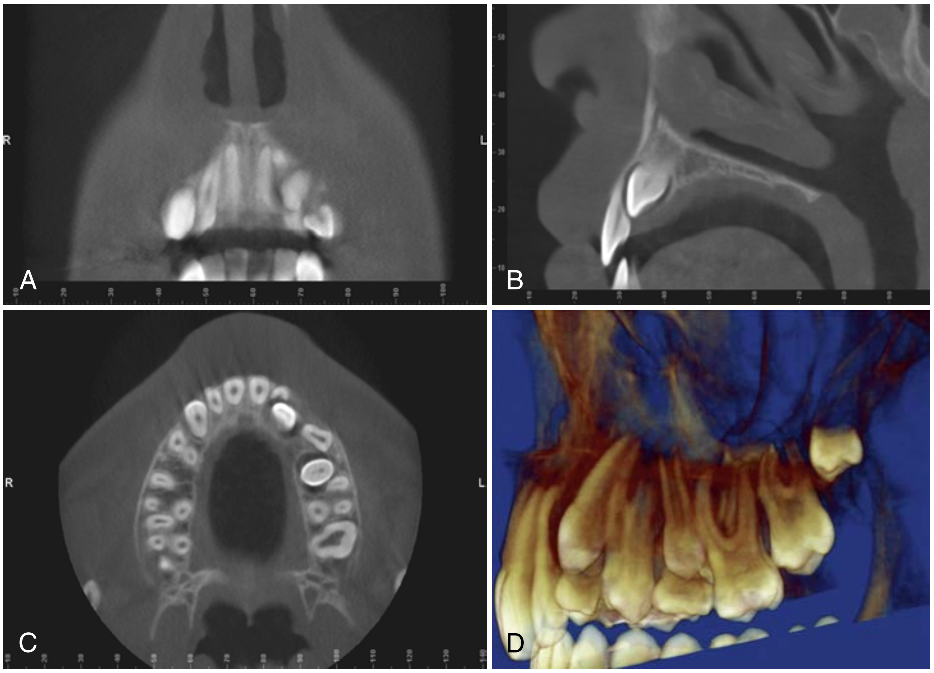

FIGURE 11-2 Multiplanar images in the three planes of space. B, Three-dimensional rendered view.

or overgrowth (osteophytes, best diagnosed complementing multiplanar cross-sectional images with assessment of the respective solid 3D surface models constructed from CBCT or CT scans), and loss of articular fibrocartilage and synovitis (best diagnosed with MRI). For detecting TMJ bony changes, panoramic radiography and MRI have only poor to marginal sensitivity.[22] For this reason, CBCT has recently replaced other imaging modalities as the modality of choice to study TMJ bony changes.[23–25] The Research Diagnostic Criteria for Temporomandibular Disorders (RDC/TMD)[26] was revised recently to include image analysis criteria for various imaging modalities.[22] The RDC/TMD validation project[27–29] concluded that revised clinical criteria alone, without recourse to imaging, are inadequate for valid diagnosis of TMD and had previously underestimated the prevalence of bony changes in the TMJ. TMJ pathologies that result in alterations in the size, form, quality, and spatial relationships of the osseous joint components lead to skeletal and dental discrepancies in the three planes of space.[30,31] In affected condyles, the perturbed growth or bone remodeling, resorption, and apposition can lead to progressive occlusal changes that are accompanied by compensations in the maxilla, "nonaffected" side of the mandible, tooth position, occlusion and articular fossa, and unpredictable orthodontic outcomes (Fig. 11-4).

The intriguing insights into TMJ health and disease provided by recent applications of 3D imaging CBCT[32] have revealed that the TMJ is prone to a myriad of pathologies that could be didactically divided as "degenerative pathologies" and "proliferative pathologies." Such pathologies can dramatically affect other craniofacial structures and be easily recognized, or the TMJ pathology can be challenging to diagnose even to experts when its progression is subtle and limited even though it is still clinically relevant. In any situation, longitudinal quantification of condylar changes has the potential to improve clinical decision making by identifying the most appropriate and beneficial therapy.

The TMJ is unique in relation to the other joints in the body. Adult joint bone surfaces, with the exception of the TMJ, are composed by hyaline cartilage. The TMJ has its articular bone surfaces covered by a thin layer of fibrocartilage that has a tremendous capacity for morphologic adaptation due to function. The threshold between functional physiologic stimulus with its positive biochemical effects on the TMJ and joint overloading that lead to degenerative changes is beyond current knowledge.[33–35] This threshold is influenced by a multitude of factors, including but not limited to the joint loading vectors and their magnitude,[36] and patient inherited or acquired (genetic and mostly epigenetic) factors, including hormonal and autoimmune imbalances. Current methods to detect pathologic conditions in a cross-sectional diagnostic assessment (bone scintigraphy and positron emission tomography [PET]) are highly sensitive; however, they do not have enough specificity because there are no standard normal values for baseline assessments. Longitudinal 3D quantification using CBCT offers a relatively low-cost, low-radiation technology compared with PET-CT and bone scintigraphy and can make a significant difference on treatment planning as an additional biomarker or risk factor tool.

The use of biomarkers to aid diagnosis in TMJ disorders is very promising, but it is not novel. Several biomarkers, including C-reactive protein and markers of inflammation, angiogenesis, and bone turnover (e.g., angiogenin, growth differentiation factor 15 , tissue inhibitors of metalloproteinases 1, chemokine ligand 16, matrix metalloproteinases 3 and 7, epithelial neutrophil activating peptide, plasminogen activator inhibitor-1, vascular endothelial cadherin, vascular endothelial growth factor, granulocyte macrophage colony-stimulating factor, transforming growth factor-β, interferon gamma, tumor necrosis factor-α, interleukin-1α, interleukin-632), have previously been identified in blood and in synovial fluid biopsies of patients with TMJ condylar bone resorption and related to the pathologic progress.[37–39] Such techniques, still currently restricted to academic environments and research centers, are certainly very promising and will complement CBCT 3D techniques that are already clinical tool protocols.

Airway Assessment

Airway morphology and changes over time after surgery, as well as growth and the airway relationship to obstructive sleep apnea, have been recently assessed in either medium or large FOV CBCT scans.[40–43] However, the boundaries of the nasopharynx superiorly with the maxillary and paranasal sinuses and the boundaries of the oropharynx with the oral cavity anteriorly and inferiorly with the larynx boundary are not consistent among subjects, which warrants very careful interpretation of volumetric and 3D assessments and multiplanar cross-sectional

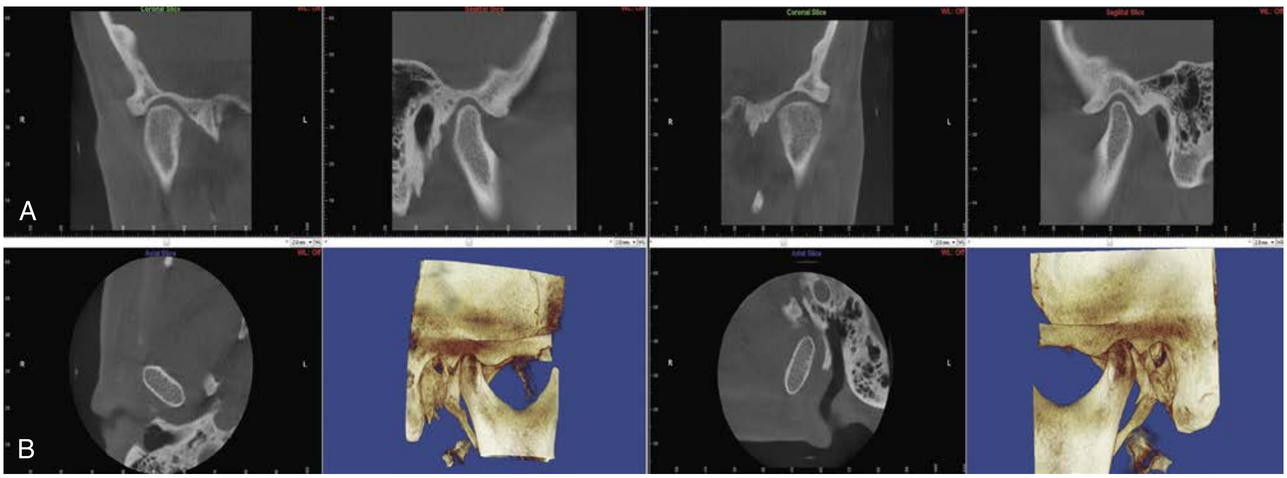

FIGURE 11-3 Right (**A**) and left (**B**) temporomandibular joint (TMJ) images acquired with a 6 × 6 field of view. The high-resolution images provide proper assessment of the TMJ bone anatomy.

slices of the airway. Additionally, image acquisitions and airway shape and volume vary markedly with functional stage of the dynamic process of breathing and head posture. If head posture is not correctly reproduced in longitudinal studies, differences in head posture will lead to variability in airway dimensions. Longitudinal assessments of mandibular setback have not shown consistent reduction of airway space nor have mandibular propulsion advancement devices shown enlargement of the airway space that might be helpful for obstructive breathing conditions (Fig. 11-5).

Dentofacial Deformities and Craniofacial Anomalies

Large FOV CBCT images offer the ability to analyze facial asymmetry and anteroposterior (AP), vertical, and transverse discrepancies associated with complex craniofacial problems. The virtual treatment simulations using 3D virtual or printed surface models constructed from CBCT or CT images can be used for treatment planning in orthopedic corrections and orthognathic surgery and for printing surgical splints after performing virtually simulated surgery. Computer-aided surgery (CAS) of the jaw is described in more detail in the Image Analysis section of this chapter, and its clinical application has increased because of the possibility to incorporate a high level of precision for accurately transferring virtual plans into the operating room. In complex cases, follow-up CBCT acquisitions for growth observation, treatment progress, and posttreatment observations may be helpful to assess the stability of the correction over time (Fig. 11-6).[44–47]

IMAGE ANALYSES AND THE USE OF THREE-DIMENSIONAL SURFACE MODELS AND SUPERIMPOSITIONS

Challenges to Advance Our Understanding of Growth and Treatment Responses

Even with the availability of 3D volumetric images, the clinical questions on the most appropriate quantitative approaches still remain a field for research. Before describing in detail the 3D image analysis procedures in this section of the chapter, we outline below three important challenges.

1. **Construction of 3D volumetric label maps (segmentation)**
   Although assessment of the multiplanar cross-sectional slices is limited to 2D evaluations of each slice and poses challenges toward standardization of which cross-section to analyze,[11] 3D representations of the craniofacial anatomy allow visual and quantitative assessments of the whole 3D anatomic surfaces reconstructed from CBCT scans (Fig. 11-7, *A* and *B*). A distinction must be made between virtual 3D renderings and 3D surface meshes or models that are generated from 3D volumetric label maps. The CBCT volumes can be visualized as projected images (renderings), without the construction of surface models, but these renderings can be used only for perspective visualizations and not for quantitative assessments because they are simply projected images, "ghostlike," and not solid surface meshes (Fig. 11-7, *C*). The 3D surface meshes or models provide additional diagnostic information on size, shape, and exact location of the bone abnormality (Fig. 11-7, *D* and *E*).[48] The process of constructing 3D volumetric label maps, known as *image segmentation*, by examining cross sections of a volumetric data set to outline the shape of structures, remains a challenge.[49–51] Even though image segmentation has been a field of active research for many decades, representation of fine anatomic details remains one of the most time-consuming steps in image processing. A major challenge with segmentation lies with the fact that hard and soft tissues from CBCT have no corresponding Hounsfield units. The same CBCT taken from the same individual may have different intensity levels for the bones depending on their position in the volume and relationship to adjacent anatomy. No standard segmentation method can be expected to work equally well for all tasks. Much commercial software incorporates intensity thresholding algorithms for their segmentation. Although this often works well for thick and dense bones such as the mandibular bone, it often fails for thin bone such as the condyles and labial surfaces of the teeth. The morphology and position of the condyles and maxilla are challenging for adequate segmentation and diagnosis. Therefore, precise segmentation and representation of these anatomic regions are very important.
2. **Image registration**
   For standardized baseline diagnosis or longitudinal assessments, the CBCT scans and their respective 3D surface models require registration in a common coordinate system using a choice of target region or areas of reference. The choice of reference for the registration can also be based on landmarks, surfaces, or voxel gray intensity. Different areas and sources of reference for registration lead to different interpretations of the results. The process of registration involves computing transformations, although the image analysis software can display or allow the user to see it or not. Transformation is a mathematical operation that applies a matrix to move the points of a 3D image or surface model (or both) in multiple planes and degrees of freedom in the 3D space. Longitudinal CBCT scans acquired at different time points can be registered by computing the differences of the head position relative to a stable anatomic structure of reference. The image registration computes the translational (AP, transverse, and vertical) and rotational displacements (pitch, roll, and yaw) in a procedure known as *rigid registration*.[52] The image registration can also compute differences in scale (size changes

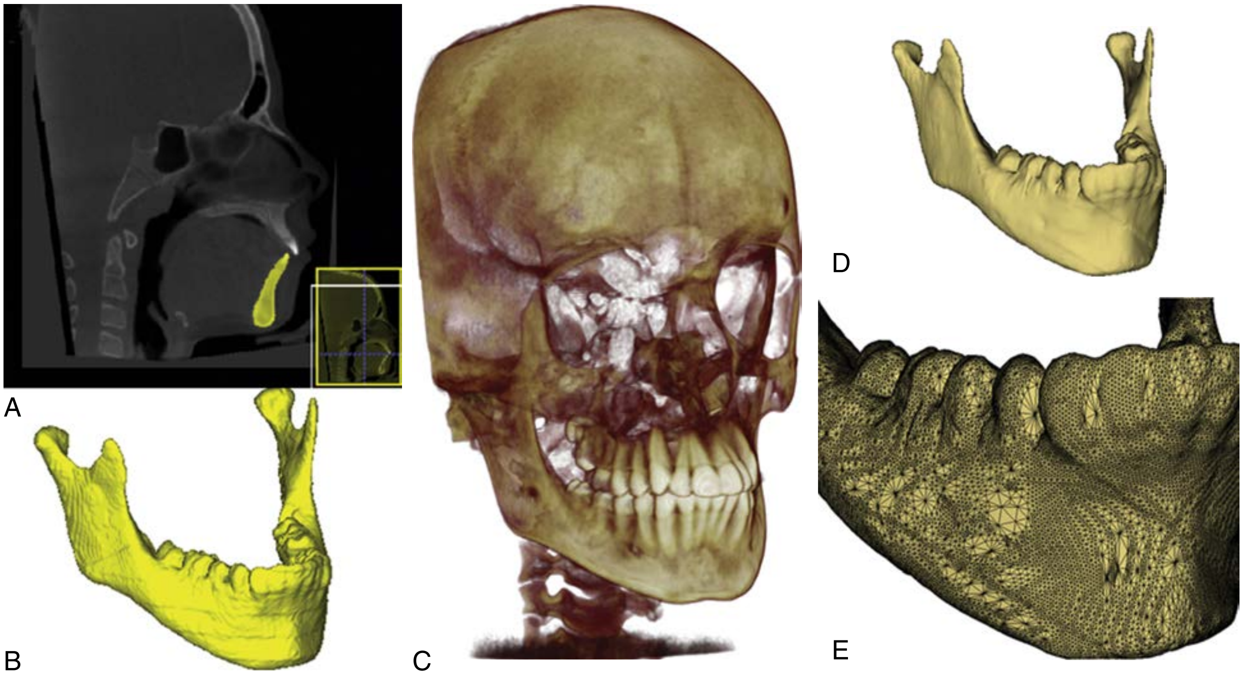

FIGURE 11-7 Image analysis procedures in the construction of three-dimensional (3D) virtual surface models. **A,** Scan acquired and 3D label map being constructed for the mandible. **B,** 3D label maps. **C,** Rendering image. **D,** 3D surface mesh models. **E,** 3D surface mesh models showing the surface mesh in detail.

with growth /or treatment) and shape in image analysis procedures known as *nonrigid registration*. The challenges of using nonrigid registration for clinical studies are that the 3D models are deformed.[53] To avoid distorting or morphing the images, nonrigid registration can be used to compute transformations considering scale and shape differences and then apply only the rigid movements (rotation and translation) to preserve the actual scale and shape features.[54,55]

3. **Quantitative measurements**
   Three-dimensional imaging can only advance our understanding of clinical questions if beyond visual assessments, it provides clinicians with improved quantification methods for diagnosis, treatment planning, and assessment of treatment outcomes in short and long terms. The facial changes can be quantified by obtaining measurements in cross-sectional slices of scans or in 3D surface models at two or more time points or between scans or surface models registered relative to a stable structure of reference such as cranial base (a validated voxel-based method to assess posttreatment changes in growing[55] and adult[56] patients). Linear and angular measurements based on landmarks can camouflage bone remodeling because subtraction between time points, for example, is used as a representation of growth and may lead to confusion about what is happening (analysis of rotations, treating shape separately from size, and registering angles on landmarks as vertices).[57] Since the original work of Moyers and Bookstein,[58] advanced morphometric (i.e., that measure morphology or form) methods using semi-landmarks,[59] matrices of interlandmark distances (EDMA),[60] curved distances, or tensor-based morphometry[61] have been proposed. However, these methods involve complex mathematical information that is not easily interpreted by clinicians. Current quantification methods of dental and skeletal displacements and bone remodeling of both the maxilla and the mandible include:
   a. **Volume**[52] changes do not capture shape changes as structural changes at specific locations are not sufficiently reflected in volume changes; volume assessment does not reveal the location and direction of proliferative or resorptive changes, which would be relevant for clinical results assessment.
   b. **3D linear surface distances in triangular meshes**
      i. Based on **observer-defined landmarks**[62]: Locating 3D landmarks on complex curving structures is not a trivial problem for representation of components of the craniofacial form.[63] As Bookstein[57] noted, there is a lack of literature about suitable operational definitions for the landmarks in the three planes of space (coronal, sagittal, and axial), which leads to errors and variability in landmark location. Gunz et al.[64] and Andresen et al.[65] proposed the use of semi-landmarks (i.e., landmarks plus vectors and tangent planes that define their location), but information from the whole curves and surfaces must also be included. The studies of Subsol et al.[66] and Andresen et al.[65] provided clear advances toward studies of curves or surfaces in 3D, referring to tens of thousands of 3D points to define geometry. For clinical assessments, the challenges remain (1) the awareness of limitations based on measurements derived from 3D landmarks and (2) the choice of landmark anatomic locations that describe and "represent" different components of maxillomandibular growth and response to treatment. Although 3D linear distances are a simplification of complex morphologic changes, they provide relevant clinical evaluation of changes in the space related to differences between time points.

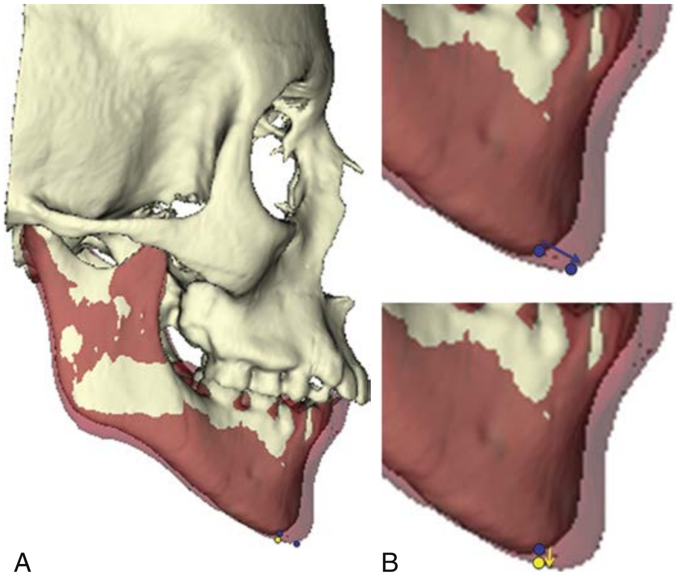

FIGURE 11-8 Mandibular overlay of surface mesh models from two time points (A and B) displaying the differences between measurements based on corresponding points (*blue arrow*) and closest point (*yellow arrow*).

ii. Based on thousands points in triangular meshes automatically defined in the surface models:

(a) **Closest point measurements** between the surfaces can display changes with color-coded maps as proposed by Gerig et al.[67] However, the closest point method measures the closest 3D linear distances between surfaces, not corresponding distances between anatomic points on two or more longitudinally obtained images (Fig. 11-8). For this reason, the closest point measurements fail to quantify rotational and large translational movements, and this method cannot be used for quantitative longitudinal assessments of growth or treatment changes, nor the physiologic adaptations, such as bone remodeling that follows surgery. This standard analysis is currently used by most commercial and academic software but does not map corresponding surfaces based in anatomic geometry and usually underestimates rotational and large translational movements. Closest point color maps measure surgical jaw displacement as the smallest separation between boundaries of the same structure, which may not be the correct anatomic corresponding boundaries on pre- and postsurgery anatomic structures.

(b) **Shape correspondence measurements**[68] were developed as part of the National Alliance of Medical Image Computing (NA-MIC, NIH Roadmap for Medical Research) and have been adapted for use with CBCTs of the craniofacial complex.[69,70] The correspondence between thousands of surfaces points is generated by computing point-based models using a parametric boundary description for the computing of shape analysis. The 3D virtual surface models are converted into a corresponding spherical harmonic description (SPHARM), which is then sampled into triangulated surfaces (spherical harmonics-point distributed models [SPHARM-PDM]). This work presents an improvement in outcome measurement as compared with closest point correspondence–based analysis (see Fig. 11-8). The challenges with SPHARM-PDM are that this shape analysis method is currently highly computational intensive, the surface parameterization can only be applied to closed surfaces, and complex anatomy may not be properly represented and require control of the quality of the point-to-point correspondence.

(c) Quantification of directional changes in each plane of the 3D space (**3D components**). 3D linear distances, based on observer-defined landmarks or automatically defined points, express different amounts of changes in the three axes of the space, and clinical questions require more precise information regarding the location and amounts of changes in each direction (*x*-, *y*-, and *z*-axes). In particular, clinicians plan their expected results of treatment based on anterior, posterior, inferior, superior, medial, or lateral movements and displacements. Quantification of directional changes in each plane of the 3D space (3D components) can be obtained by the distances between projections of the 3D landmarks and require a standardized common *x, y, z* coordinate system across time points and all patients in the Slicer software.

c. **3D angular measurements** can be represented as pitch, roll, and yaw and can be used to evaluate the rotation of the whole skull or only the mandible or maxilla. Evaluations using each of the three views (sagittal, coronal, and axial) allow these angles be measured by the intersection of two lines based on the coordinates of landmarks or by the intersection of two planes being each one from different time points. The challenge of angular assessments is that they also require consistency of a standardized common *x, y, z* coordinate system across time points of all patients.

Step-by-Step Three-Dimensional Image Analysis Procedures

A step-by-step description of image analysis procedures includes (1) image acquisition; (2) construction of 3D volumetric label maps; (3) image registration; (4) conversion to 3D surface models; (5) establishment of a common coordinate system; (6) visual analytics with graphic display of 3D morphologic variability or changes; and (7) quantification of location, directions, and magnitude of 3D morphologic variability or changes:

1. **Acquisition of 3D diagnostic records**

Diagnosis of maxillomandibular discrepancies is based on data coming from different sources: clinical examination, 3D photographs, CBCT, CT, MRI, and digital dental models. All different records need to be integrated in order to characterize the orthodontic diagnosis and formulate the treatment plan. CBCT, CT, and MRI are acquired as volumetric 3D images (saved in file formats such as DICOM, gipl, or nrrd) that can be used to visualize cross-sectional slices and renderings in various 3D viewer software. These volumetric images can be visualized as 3D projected images (3D renderings) or used to construct polygonal meshes or surfaces of specific anatomic structures of interest. To simplify the description of image analysis procedures, this chapter specifically describes 3D analysis of images acquired with CBCT because CBCT has been recently widely used in our field. The same image analysis procedures are applicable and can be generalized for images acquired with any 3D imaging modality.

2. **Construction of 3D volumetric files that label with color the anatomic structures of interest**
The CBCT scans (DICOM files) can be opened and visualized in any 3D image analysis software of choice. Examples are 3DMDvultus (3DMD, Atlanta, GA)[71]; Maxilim, Medicim (Mechelen, Belgium)[72]; Dolphin Imaging (Dolphin Imaging & Management Solutions, Chatsworth, CA)[73]; InVivo Dental (Anatomage, San Jose, CA)[74]; SimPlant OMS or Mimics (Materialise, Leuven, Belgium)[75]; and open source tools such as TurtleSeg,[76] ITK-SNAP,[77] and 3D Slicer.[78] In a procedure known as image segmentation, we identify and delineate the anatomic structures of interest in the CBCT scan to obtain a 3D representation of the hard and soft tissues (3D volumetric label map files). To best capture the facial anatomy, our method of choice for the segmentation procedures uses ITK-SNAP[79] software that has received continuous National Institutes of Health (NIH) support for further open source software development. ITK-SNAP was developed, based on the NIH Visualization Tool Kit (VTK) and Insight Tool Kit (ITK), as part of the NIH Roadmap Initiative for National Centers of Biomedical Computing. The automatic segmentation procedures in ITK-SNAP use active contour methods to compute feature images based on the CBCT image gray level intensity and boundaries. It is important to understand that ITK-SNAP is more versatile than other open and commercial software because it allows the adjustment of the parameters for automatic detection of intensities and boundaries as well as allows user interactive editing of contours. On a laptop computer equipped with 1 GB of RAM, the initial segmentation step typically takes about 15 minutes. Manual postprocessing of the segmentation usually takes longer, up to a couple of hours. (Separation of the upper and lower teeth can be particularly tedious.)
For longitudinal CBCT scans or scans of a group of patients, further image analysis procedures are required and described below as performed in Slicer open source software in steps (3) image registration, (4) conversion to 3D surface models, (5) establishment of a common coordinate system, (6) visual analytics, and (7) quantitative measurements as follows:

3. **Image registration**
Both commercial and open source tools now allow registration procedures based on landmarks, surface models, or voxel gray intensity for craniomaxillofacial registration (https://sites.google.com/a/umich.edu/dentistry-image-computing/).[79] The image registration procedures that our research group has found to provide the most reliable results consist of two steps:
    a. **Manual approximation of T1 and T2 scans:** If head position was not controlled and standardized during imaging acquisition, the T1 and T2 scans should be approximated by the observer reorienting one of the scans guided by the best fit of the outlines of a region of reference. The approximation can be visualized in each of the 3D multiplanar cross sections using open source software (Slicer CMF, http://www.slicer.org).[78,80] Videos tutorials are available at http:/www.youtube.com/user/DCBIA.[79]
    b. **Voxel-based registration for longitudinal assessments:** The major strength of the voxel-based registration method is that registration does not depend on how precisely the 3D volumetric label maps represent the anatomic truth or on the location of a limited number of landmarks. In fact, for voxel-based registration methods that use the 3D volumetric label maps as the input of the region of reference, these multiplanar label maps should be extended slightly (1–2 voxels) beyond the actual bone boundaries to provide the complex gray-level information needed for the automatic detection of the bone boundaries during the voxel-based registration. Importantly, the 3D volumetric label maps of the anatomic structures of reference for the registration are not the "clean" 3D surface models and are only used as references to mask anatomic structures that change with growth and treatment. The voxel-based registration methods actually compare voxel by voxel the gray-level values in two CBCT images to calculate the rotation and translation parameters between them. Because not all "voxel-based" registrations are similar in methodology and accuracy, because they can use different structures of reference, different numbers of iterations (e.g., the software can run for 1 minute and compute 100 attempts of best voxel match or run for 10 minutes and compute 1000 comparisons of best fit among thousands of voxels). After registration, the 3D volumetric label maps should be further edited for finer definition of the patient actual bony anatomic contours.

It is also important to understand that the clinical implications that can be derived from 3D registrations or superimpositions depend on the structures selected as reference for registration. Clinicians should become familiar and trained on the new technologies to avoid misunderstandings and incorrect interpretations of the 3D images. Registration on different regions of reference will lead to different interpretations of the results. We have developed a novel sequence of fully automated voxel-wise rigid registration at the cranial base (for overall facial assessments relative to cranial structures that complete their growth early in childhood)[55] and regionally (to assess maxillary and mandibular bone remodeling).[81,82] After these registration steps described earlier, the registered 3D volumetric label maps can then be saved as a 3D triangular or polygonal meshes (3D surface models) in, for example, .obj, .ply, .vtk, or .stl file formats. All image registration procedure conversions from 3D volumetric label maps to 3D surfaces models can be accomplished in Slicer CMF (http://www.slicer.org).[78–80] They were initially developed as part of the(NA-MIC, NIH Roadmap for Medical Research and have been widely used internationally.

4. **Conversion to 3D surface models**
After segmentation, for a single one-time point image, the 3D volumetric label map can be saved or converted as a 3D triangular/polygonal mesh (3D surface model), in .obj, .ply, .vtk, or .3ud file format (see Fig. 11-7). Then it can be visualized in different 3D viewer software programs.

5. **Establishment of a common coordinate system across subjects for group comparisons**
Establishment of a common coordinate system not based on a single line or plane is essential to allow group comparisons and consistent measurements across subjects. To achieve such a common coordinate system, all T1 surface models in

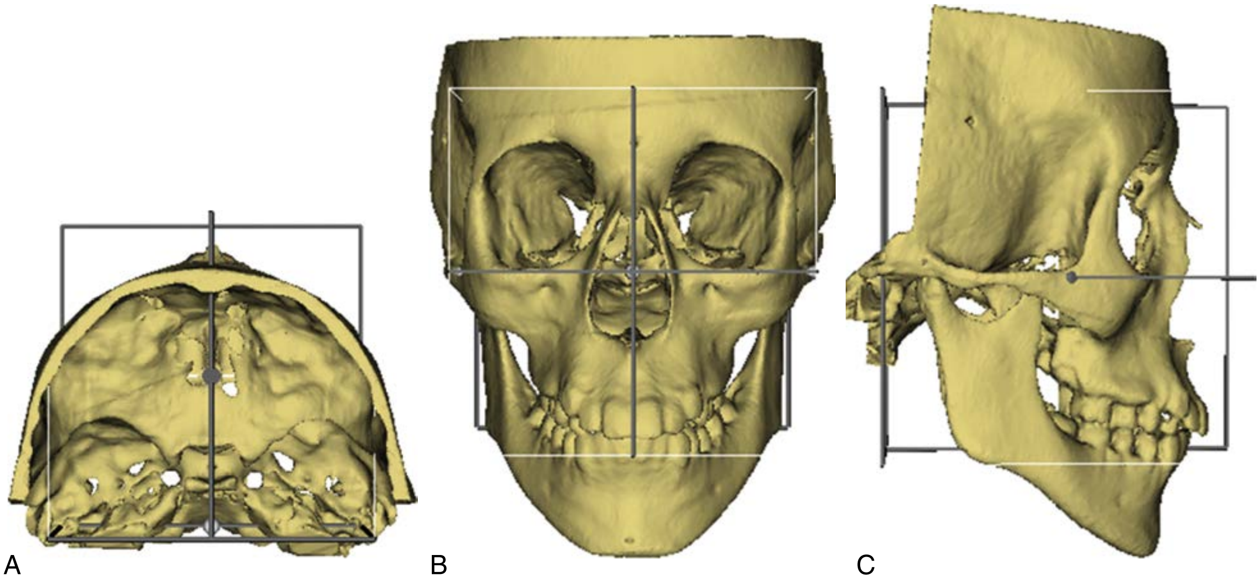

FIGURE 11-9 Head orientation procedure. **A**, Superior view. **B**, Frontal view. **C**, Lateral view.

a study sample can be oriented, for example, in the Slicer software (Fig. 11-9). The 3D orientation can be achieved by using intracranial reference planes defined by at least three landmarks or two landmarks and a plane[83]: Frankfurt horizontal, midsagittal, and transporionic planes. Slicer software displays a fixed 3D coordinate system that can be used as reference to orient the 3D models. Using axial, coronal, and sagittal views of the 3D models, the T1 model can be moved to orient the midsagittal plane vertically and coincident with the vertical (sagittal) plane of the 3D coordinate system. The Frankfurt horizontal plane can be oriented to match with the horizontal (axial) plane. The horizontal transporionic line can be oriented to be coincident with the intersection between the axial and coronal planes in both sides of the head. The matrix generated from this step can then be applied to the T2 registered surface model, obtaining the same head orientation. This same procedure can be repeated for all subjects in the sample with the goal of obtaining a common coordinate system for quantitative steps described in step 5 below. After registration, it is important for visualization and quantification purposes that all models be clipped (cropped) simultaneously with similar boundaries, which can be accomplished in Slicer software.

6. **Visual analytics with graphic display of 3D morphologic variability or changes over time**
   Registered surface models can be visualized using contrasting opaque or semi-transparent colors, and the surface distances between two time points can be graphically displayed with color-coded maps. The overlays provide visual qualitative assessment of the location and direction of changes or morphologic differences. The graphical display of color-coded or "heat" maps may contain information computed using closest or corresponding surface points, statistical significance *P* value maps of group and interaction comparisons, and vector maps and displayed within Slicer CMF (Fig. 11-10).
7. **Quantitative measurements**
   a. **Volume**[52] changes can be measured in the user's software of choice, such as Slicer, ITK-SNAP, Dolphin, or Invivo,

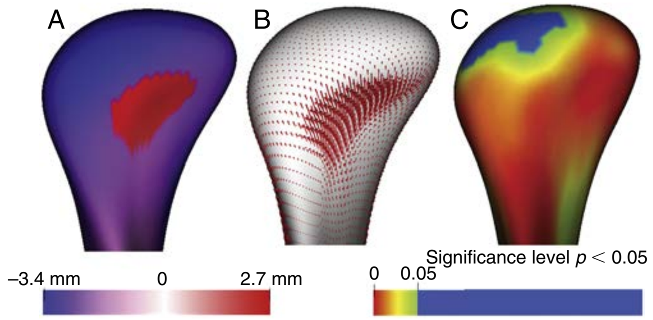

FIGURE 11-10 Assessment of surface distances between two time points displayed with color-coded maps: signed surface distances map (**A**), vector map (**B**), and *P* value map (**C**).

   to reflect the overall changes in size, such as for the airway, condyles, or bone graft.
   b. **3D linear surface distances in triangular meshes**
      i. Based on **observer-defined landmarks**[62]: 3D landmarks should be identified using all three views (axial, sagittal, and coronal), for example, in the Slicer software and use a reference surface model for consistency of landmark location. Different 3D surface mesh models can be loaded simultaneously, for example, in the Slicer software, and the landmark coordinates (*x*, *y*, and *z*) are generated and displayed for each landmark on T1 and the registered T2 surface models. Two kinds of quantitative assessments of the differences between landmarks can be performed:
         (a) At one time point (baseline or follow-up): The 3D linear distances correspond to the Euclidean distances between the user-defined landmarks for characterization of dimensions, for example, prior to treatment.
         (b) Differences between two time points (T1 and T2): The 3D linear distances in each plane of the space for displacements of the maxilla or mandible (or

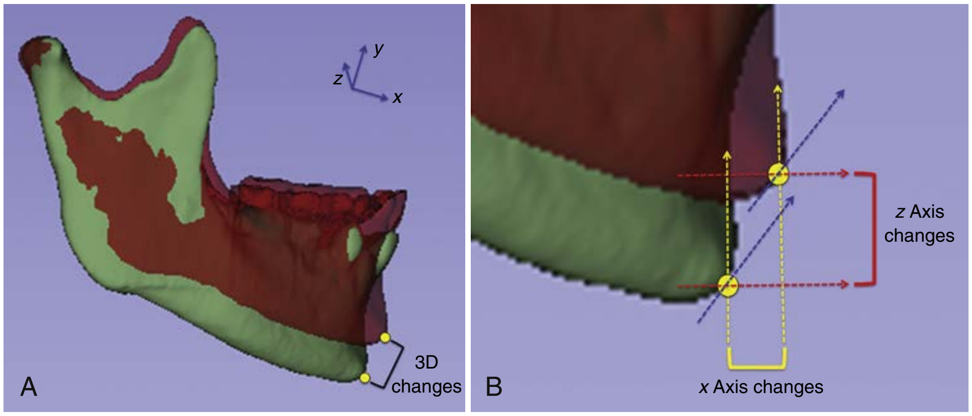

FIGURE 11-11 Representation of the three-dimensional (3D) differences and its components in the 3D space (*x* and *z* components) between two different time points (**A** and **B**) that were registered on the cranial base.

both) can be measured. The 3D measurements correspond to the Euclidean distances[84] between the T1 and T2 landmarks 9 (Fig. 11-11).

ii. Based on thousands of points in triangular meshes automatically defined in the surface models:

(a) 3D surface distances computed at the vertices of the triangular meshes can be computed as **closest points** between noncorrespondent surfaces meshes. The computation of the surface distances can be stored as color-coded 3D linear distances within .obj, .ply, or .vtk file formats in the user software of choice, such as Paraview (http://www.paraview.org)[85] or within Slicer (video tutorial, http://www.youtube.com/user/DCBIA).[79] Closest point 3D linear distances measure the closest distances between the vertices of the triangular meshes in two surfaces, not corresponding distances between anatomic points on two or more longitudinally obtained models (Figs. 11-12 to 11-14). Even though this standard analysis currently used by most commercial and academic software programs does not map corresponding surfaces based in anatomic geometry, if used in conjunction with semi-transparent overlays, the graphic display of the color-coded maps can help clinicians and researchers understand the complex overall surface changes. Localized measurements in closest point color-coded maps can be made from point to point or at any radius defined around the landmark.

(b) **Shape correspondence**, as computed using the SPHARM-PDM module[67] in the Slicer software, computes point-based surface models, in which all models have the same number of triangular meshes and vertices in corresponding (homologous) locations. Corresponding surface distances and vectors can then be calculated and graphically displayed in Slicer (see Figs. 11-12 and 11-14; video tutorial available at http://www.youtube.com/user/DCBIA).[79] Localized measurements in corresponding color-coded maps can be made at one point or at any radius defined around the landmark (Fig. 11-15).

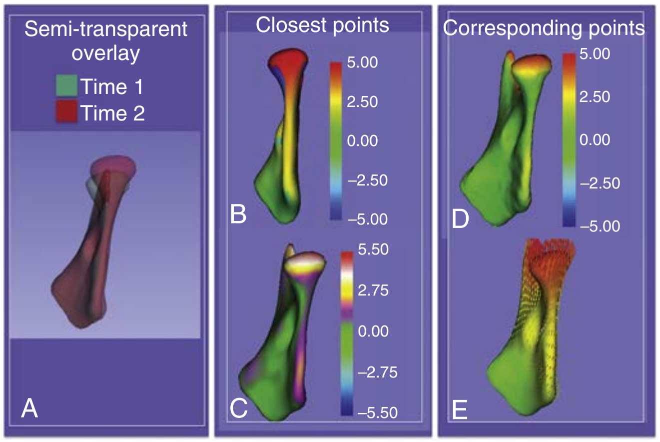

FIGURE 11-12 Posterior views of assessments between two time points. **A,** Semi-transparent overlay. **B** and **C,** Quantitative color-coded maps of the differences between closest distances of two time points represented by color-coded maps with five colors in *B* and seven colors in *C* to better define the regional measurements. **D,** Quantitative color-coded maps of the differences between corresponding points represented by color-coded maps. **E,** The vectors of the growth direction based on corresponding points.

(c) Quantification of directional changes in each plane of the 3D space (**3D components**)

The components in each plane of the space of the 3D linear distances can be measured based on observer-defined landmarks or automatically defined points. The distances between corresponding coordinates of corresponding landmarks can be quantified in the transversal (*x*-axis), AP (*y*-axis), and vertical (*z*-axis) direction using Slicer software (see Fig. 11-11).

c. **3D angular measurements:** 3D angular measurements between lines or planes defined in common 3D coordinate systems can be used to quantify pitch, roll, and yaw of the whole skull or only the mandible or maxilla. Evaluations using each of the three views (sagittal, coronal, and axial) allow these angles to be measured by the intersection of two lines based on the coordinates of landmarks or by the intersection of two planes being each from different time points.

Such angular measurements can be accomplished in Slicer for either characterization of facial morphology at any time point or for comparison of rotational changes between time points. Positive and negative values can be used to indicate rotations in different directions, such as clockwise or counterclockwise rotation. The choice of which landmarks or planes should be selected depends on which kind of evaluation researchers would perform to answer their aims. For example, mandibular rotations between two time points can be assessed in the following ways: pitch can be measured as the angle obtained by the intersection of the planes through the right and left condylion and pogonion in each time point or by the intersection of two lines through the pogonion and medium point between right and left condylion in the sagittal view; roll is calculated by the intersection of two lines through the right and left condylion in the coronal view; and yaw is calculated by the intersection of two lines through the right and left condylion in the axial view (Fig. 11-16).

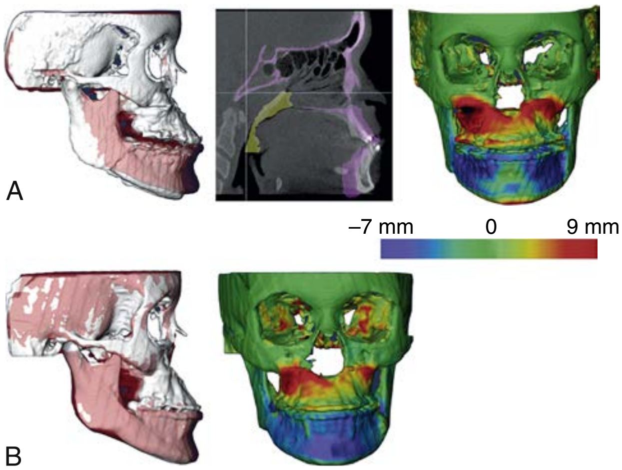

FIGURE 11-13 Assessment of postsurgical changes relative to the cranial base using overlays and closest point color coded maps. The overlays aid verification of whether the closest point color map properly represents the changes. Note that for the large mandibular setback with surgery, at splint removal the closest point color-coded map fails to quantify the changes in the chin. **A,** As shown in the lateral cross-sectional view, the closest point of the time 1 facial surface is close to the lingual surface of the time 2 and the closest point measurements are minimized. **B,** At 1 year after surgery, because the mandibular displacement is smaller, the color-code map better represents the changes.

TREATMENT PLANNING WITH COMPUTER-ASSISTED SURGERY

The methods for CAS systems in jaw surgery follow procedures from the image scanners to the operating room and have included commercially a number of systems, including Medical Modeling (3D Systems Healthcare, Littleton, CO)[86] and Maxilim (Medicim, Mechelen, Belgium).[72] The advantages of these systems are that they do not require time or computer expertise from the surgeon, and for a service fee, the commercial companies construct surface models from CBCTs and impressions or digital dental casts registered to the CBCT, perform the virtual surgery, and print surgical splints. The CAS steps include (1) data acquisition (collection of diagnostic data), (2) image segmentation, (3) quantitative measurements for diagnostic purposes (Fig. 11-17), (4) planning and simulation (preparation of the operative plan by using the virtual anatomy, simulation of the outcome with 3D printed surgical guides, grafts, or prosthetic repair), and (5) intraoperative guidance (assistance for intraoperative realization of the virtual plan). CAS steps 1 to 3 are described in detail in this chapter's section called Step-by-Step Image Analysis Procedures.

Surgical Planning and Simulation

After establishment of the diagnosis, the next step is to use the 3D representations of the anatomy to plan and simulate the surgical intervention. In orthognathic surgery, corrective interventions designate procedures that do not require an extrinsic graft, and reconstructive interventions are designated for situations in which a graft is used. In corrective procedures, it is important to determine the location of the surgical cuts, to plan the movements of the bony segments relative to one another, and to achieve the desired realignment intraoperatively. In reconstructive procedures, problems consist in determining the desired implant or graft shape. In the case of implants and prostheses, the problems are to select the proper device and shape it or to fabricate an individual device from a suitable biocompatible material. With a graft, the difficulties lie in choosing the harvesting site, shaping the graft, and placing the implant or graft in the appropriate location.[87]

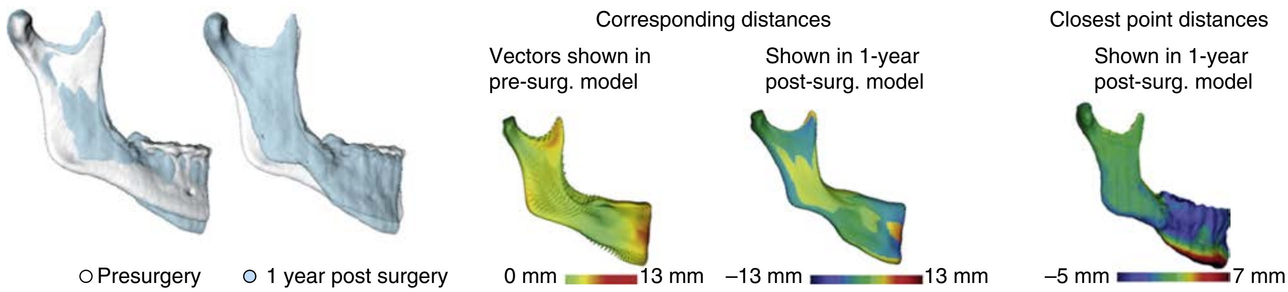

FIGURE 11-14 Comparison of mandibular postsurgical changes relative to the cranial base. Note that the qualitative pattern of changes shown in the semi-transparent overlays is more clearly quantified by the corresponding color-coded maps than the closest point maps.

Virtual osteotomies allow for the planning of cuts and position and size of fixation screws and plates, taking into account the intrinsically complex cranial anatomy; regions of thin (or absent) bone, such as the maxillary sinus anterior wall, create sudden discontinuities in the mesh, and inner structures (e.g., mandibular nerve canal) are often included in the surface model. After the virtual osteotomy, the virtual surgery with relocation of the bony segments can be performed with quantification of the planned surgical movements.[88,89] Relocation of the anatomic segments with six degrees of freedom is tracked for each of the bone fragments. This allows for the correction of the skeletal discrepancy for a given patient and simultaneous tracking of measurements of X, Y, and Z translation and rotation around each of these axes. The segment repositioning produced can be used as an initial suggestion to the surgeon; for discussions of the 3D orthodontic and surgical treatment goals for each patient; and for printing surgical splints if high-resolution scans of the dental structure are registered to the CT or CBCT and if the software tool presents an occlusion detection functionality to detect occlusal contacts, conflicts, and the precise occlusion in the virtual simulations.

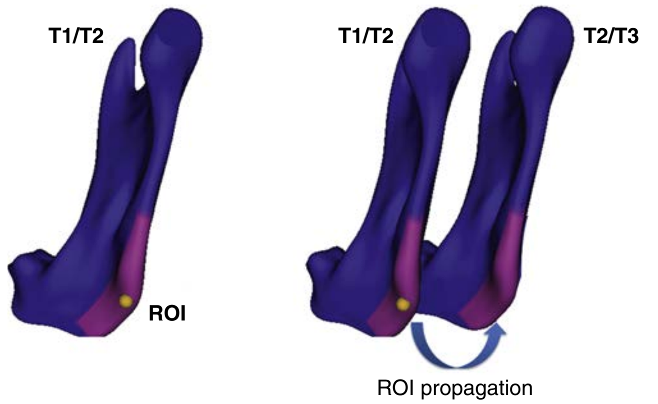

FIGURE 11-15 Corresponding surface distances can be calculated at the same region of interest (ROI) consistently by propagating the same ROI to different color maps. Selecting the ROI in the T1/T2 color map, slicer software allows to propagate the same ROI to the T2/T3 color map.

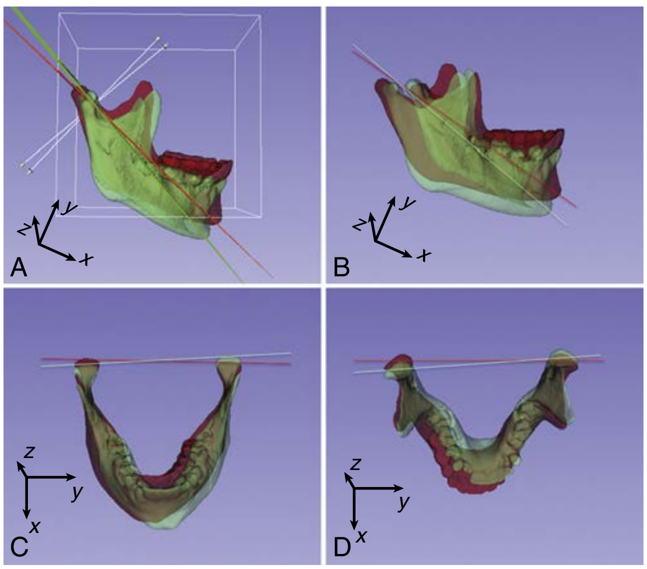

FIGURE 11-16 Representation of three-dimensional angular measurements. **A** and **B**, Pitch. **C**, Roll. **D**, Yaw.

Simulation of Soft Tissue Changes

Methods that attempt to predict facial soft tissue changes resulting from skeletal reshaping use approximation models because direct formulation and analytical resolution of the equations of continuum mechanics are not possible with such geometrical complexity. Different types of models have been proposed, including displacements of soft tissue voxels are estimated with the movements of neighboring hard tissue voxels[90]; bone displacement vectors are simply applied on the vertices of the soft tissue mesh[91]; and multilayer mass-spring models,[92] finite element models,[93,94] and mass tensor models[95] that assume biological properties of soft tissue response. In any case, thorough validation reports for all these methods are still lacking. Comparisons of the simulation with the postoperative facial surface have not yet been performed. Surgical planning functions generally do not fulfill the requirements enumerated earlier for preparation of quantitative facial tissue simulation for surgical planning. Other functionalities that have been incorporated into different software systems include simulation of muscular function,[96] distraction osteogenesis planning,[97] and four-dimensional surgery planning.[98]

Intraoperative Guidance: Surgical Navigation

In surgical procedures, achieving the desired bone segment realignment freehand is difficult. Also, segments must often be moved with very limited visibility, such as under the (swollen) skin. Approaches used currently in surgery rely largely on the

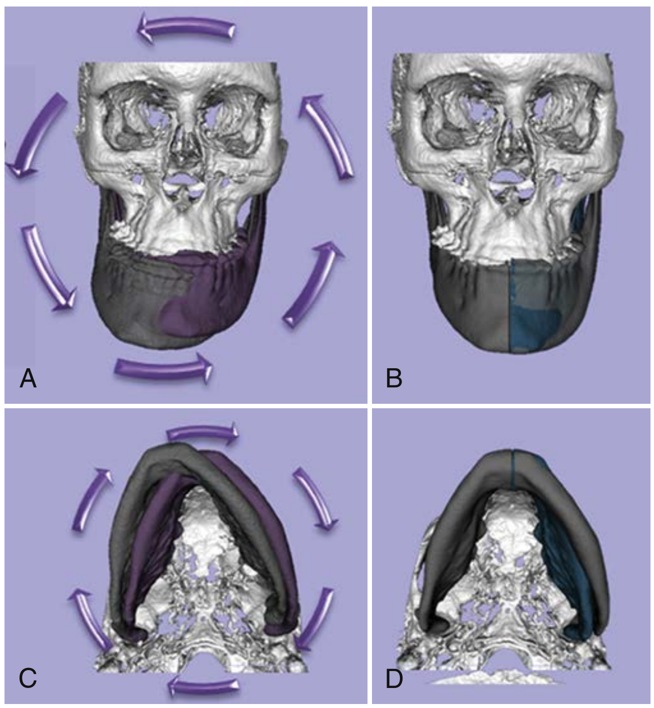

FIGURE 11-17 The use of mirroring techniques requires an initial simulation procedure step to first correct positional asymmetry (roll and yaw) followed by mirroring techniques to assess asymmetry in shape.

clinician's experience and intuition. In maxillary repositioning, for example, a combination of dental splints, compass, ruler, and intuition is used to determine the final position. It has been shown that in the vertical direction (in which the splint exerts no constraint), only limited control is achieved.[99] Although the surgical splint guides the position of the maxilla relative to the mandible, in two-jaw surgeries, the spatial position of the two jaws relative to the face is influenced by the splint precision and the transsurgical vertical assessment. As the splints are made over teeth and guide bone changes away from those teeth, small splint inaccuracies may reflect in significant bone position inaccuracies. The predictability of precise osteotomies in the wide variety of patient morphologies and consequent controlled fractures such as in the pterygoid plates, sagittal split osteotomies, or interdental cuts are still a concern. In reconstructive procedures, the problems of shaping and placing a graft or implant in the planned location also arise. Surgical navigation systems have been developed to help accurately transfer treatment plans to the operating room.

Tracking Technology

Different tracking technologies[100] for the tracking of the displacement of a mobilized fragment in the course of an osteotomy can be used with respective advantages and disadvantages:

1. In ultrasonography, an array of three ultrasound emitters is mounted on the object to be tracked, but the speed of sound value can vary with temperature changes and the calibration procedure is very delicate
2. In electromagnetic tracking, a homogeneous magnetic field is created by a generator coil. Ferromagnetic items such as implants, instruments, or the operation table can interfere strongly with these systems, distorting the measurements in an unpredictable way. Newer systems claim reduction of these effects and feature receivers the size of a needle head, possibly announcing a renewal of interest for electromagnetic tracking in surgical navigation (examples are the 3D guidance trackstar, Ascension, Burlington, VT; StealthStation AXIEM, Medtronic, Louisville, KY; and Aurora, Northern Digital Inc., Ontario, Canada)
3. Infrared (IR) optical tracking devices rely on pairs or triplets of charge-coupled devices that detect positions of IR markers. In these devices, a free line of sight is required between the cameras and markers (Fig. 11-18).

FINAL CONSIDERATIONS

The clinical use of CBCT imaging in orthodontics now has guidelines proposed by European and American associations,[10,101] and the hardware for image acquisition as well as software for image analysis have continued to develop and evolve dramatically in recent years. Careful image analysis requires combined multidisciplinary efforts among orthodontists, oral maxillofacial surgeons, radiologists, and image analysis experts to properly interpret the wealth of information now available for clinicians.

Upper Airway, Cranial Morphology, and Sleep Apnea

Juan Martin Palomo, Hakan El, Leena Palomo, and Kingman P. Strohl

OUTLINE

INTRODUCTION

Air is essential for human life. The path that air takes into the body and through to the lungs is called the *airway.* Since much of the upper airway (UA) is part of the craniofacial complex, the orthodontist can observe the airway and modulate it in case of potential obstructions. This places the orthodontist in a strategic position to intervene when airway complications exist or may develop. Since airway obstructions can have far-reaching effects, the importance of airway assessment has been part of orthodontic literature for over a century. Now, more than ever, with the emergence of state-of-the-art technologies and treatment options, the orthodontist has a responsibility and obligation to recognize respiratory problems.

AIRWAY COMPLICATIONS HAVE FAR-REACHING EFFECTS

When nasal obstruction occurs, the body is forced to breathe through the mouth; the ensuing effects have yet to be fully elucidated. Reportedly, when an individual switches to mouth breathing, the body adapts through extended head posture, anterior tongue position, and low mandibular position.[1] When the nasal obstruction is chronic in young children, these long-term adaptations can affect craniofacial growth. However, disagreement exists among investigators as to whether nasal obstruction is the cause of malocclusion or whether it is the result of the craniofacial pattern. Historically, the first mention of UA obstruction forcing individuals to be mouth breathers was made by Meyer in 1869.[2] He describes subjects who had to adapt to mouth breathing as clinically having a more nasal voice, an open mouth, and pouting lips.

In 1872, Tomes[3] described the *adenoid facies*, and the concept that facial form can be influenced by enlarged adenoids became accepted as a hypothesis. In 1907, Angle[4] included airway obstruction as an important etiologic factor in malocclusion. Tomes' view was supported by many leading orthodontists, including Todd and Broadbent in 1939,[5] and was later referred to as the "long face syndrome" in the orthodontic literature.[6] According to Moss' functional matrix theory,[7] nasal breathing allows the proper growth and development of the craniofacial complex interacting with other functions such as mastication and swallowing.[8] A narrow maxilla, hypotonia, and a small nose are also descriptions consistent with Moss' functional matrix theory, in which the lack of function (nasal breathing) creates a lack of area development.

A more complete analysis was later suggested by Linder-Aronson, who described in greater detail the craniofacial characteristics of the adenoid facies.[9] The adenoid facies craniofacial characteristics include open-mouth posture, hypotonia, narrow base in the area of the ala of the nose, proclined maxillary incisors, proclined lower lip, increased lower facial height, high mandibular angle, narrow maxilla, high palate, anterior tongue position, frequent mandibular retrognathia, and a vacant facial expression.[1,10,11] Despite still being a topic of controversy, recent articles reinforce the theories that nasal obstruction is the cause of craniofacial changes, as the body attempts to adapt to the abnormality.[12,13]

Meyer was also the first to report that improvements may almost immediately occur after the removal of the obstruction[2]; since then, through the years, several reports show craniofacial improvements after the nasal breathing is normalized at any age but with more dramatic improvements in younger patients.[14,15]

Another adaptation of mouth breathing is that the upper lip's muscular tonicity is lost. A short and flaccid upper lip may be unable to cover the anterior teeth, thereby displaying more maxillary anterior teeth when at rest. Additionally, gingival display is increased and the potential of a gummy smile appearance increases. As a result of lip incompetence, salivary flow to the area is decreased, resulting in reduced effects of salivary cleaning mechanisms. The incidence of caries is increased, and maxillary anterior teeth are most affected. The gingiva also repeatedly alternates from wet (with saliva from the tongue and lip) to dry (as the short incompetent lip returns to its open rest position). This repeated wet-dry cycle results in a histologically incomplete keratinization of the gingiva. Clinically, the gingiva has a red color, rolled gingival margins, and bulbous papilla.[16] Inflammation may occur alone or with hyperplasia. Mouth breathing, increased lip separation, and decreased upper lip coverage at rest have all been associated with higher levels of plaque and gingival inflammation.[17] As a result of long-term plaque accumulation and poor oral hygiene, a mouth breather's gingivitis can progress to pocket formation and bone loss.

Another consequence of mouth breathing is that air brought into the body through the nose is different from air brought in through the mouth. Only the nose is able to filter, warm, moisturize, and dehumidify air; furthermore, each nostril independently and synergistically functions.[18] Small amounts of nitric oxide are made by the nose and sinus mucous membranes. Nitric oxide is lethal to bacteria and viruses and is also known to increase oxygen absorption in the lungs from 10% to 25%. Breathing through the nose increases blood circulation and blood oxygen and carbon dioxide levels, slows the breathing rate, and improves overall lung volumes as a consequence to providing almost double the resistance than when breathing through the mouth.[19] The nasal resistance is crucial to maintain adequate elasticity of the lungs.[20] There are reports of hypoxemia (low levels of oxygen in the blood), hypercarbia (high levels of carbon dioxide in the blood), and hypoventilation after only 24 hours of nasal obstruction, forcing the individual to breathe through the mouth. Oxygenation changes are the foundation of systemic consequences of airway obstruction. Adults who habitually breathe through the mouth, attributable to nasal obstruction, are more likely to have sleep disorders and attention-deficit/hyperactivity disorder (ADHD).[21] Patients with obstructive sleep apnea (OSA) are noted to have high blood pressure as a result of overactivation of the sympathetic nervous system. Exaggerated negative intrathoracic pressure during obstructive apneas further increases left ventricular afterload, reduces cardiac output, and may promote the progression of heart failure. Intermittent hypoxia and postapneic reoxygenation cause vascular endothelial damage, which can progress to atherosclerosis and, consequently, to coronary artery disease and ischemic cardiomyopathy, although the mechanisms of progression have not yet been fully explained. Chronic OSA is also characterized by apnea, hypoxia, and increased sympathetic nervous activity and, when present in heart failure, is associated with increased risk of death. Since heart failure, atherosclerosis, and coronary artery disease remain major causes of mortality in the industrialized countries, the significance of investigating, diagnosis, and managing OSA has been emphasized to prevent its development and progression.[22]

ANATOMY AND GROWTH

Overview

The respiratory tract is the complete path that air takes through the nose or mouth, ending at the lungs. The respiratory tract can be divided into the upper respiratory tract and lower respiratory tract, also known as UA and lower airways (LA). The LA comprises the trachea, bronchi, and lungs. The UA, which is more relevant to orthodontics, includes the nasal cavity, the pharynx, and the larynx. However, no consensus exists among investigators as to which terminology to use when describing the anatomic limits of the UA.[23] According to *Gray's Anatomy* classification, the pharyngeal airway can be divided into the following three regions of interest, with one subdivision very relevant to orthodontics[24,25] (Fig. 12-1):

1. Nasopharynx: Is located between the nares and hard palate.
2. Oropharynx: Is located from the soft palate to the upper border of the epiglottis. The velopharynx or retropalatal oropharynx is located between the soft palate and the posterior pharyngeal wall and is found within the oropharynx.
3. Laryngopharynx or hypopharynx: Is located from the base of the tongue to the inferior border of the cricoid cartilage.

The UA forms the passage for movement of air from the nose to the lungs and also participates in other physiologic functions such as phonation and deglutition.[26] The properties of the UA are a compromise among these different functions, which variably require maintenance of patency (during breathing) or closure of the airway (as in swallowing).

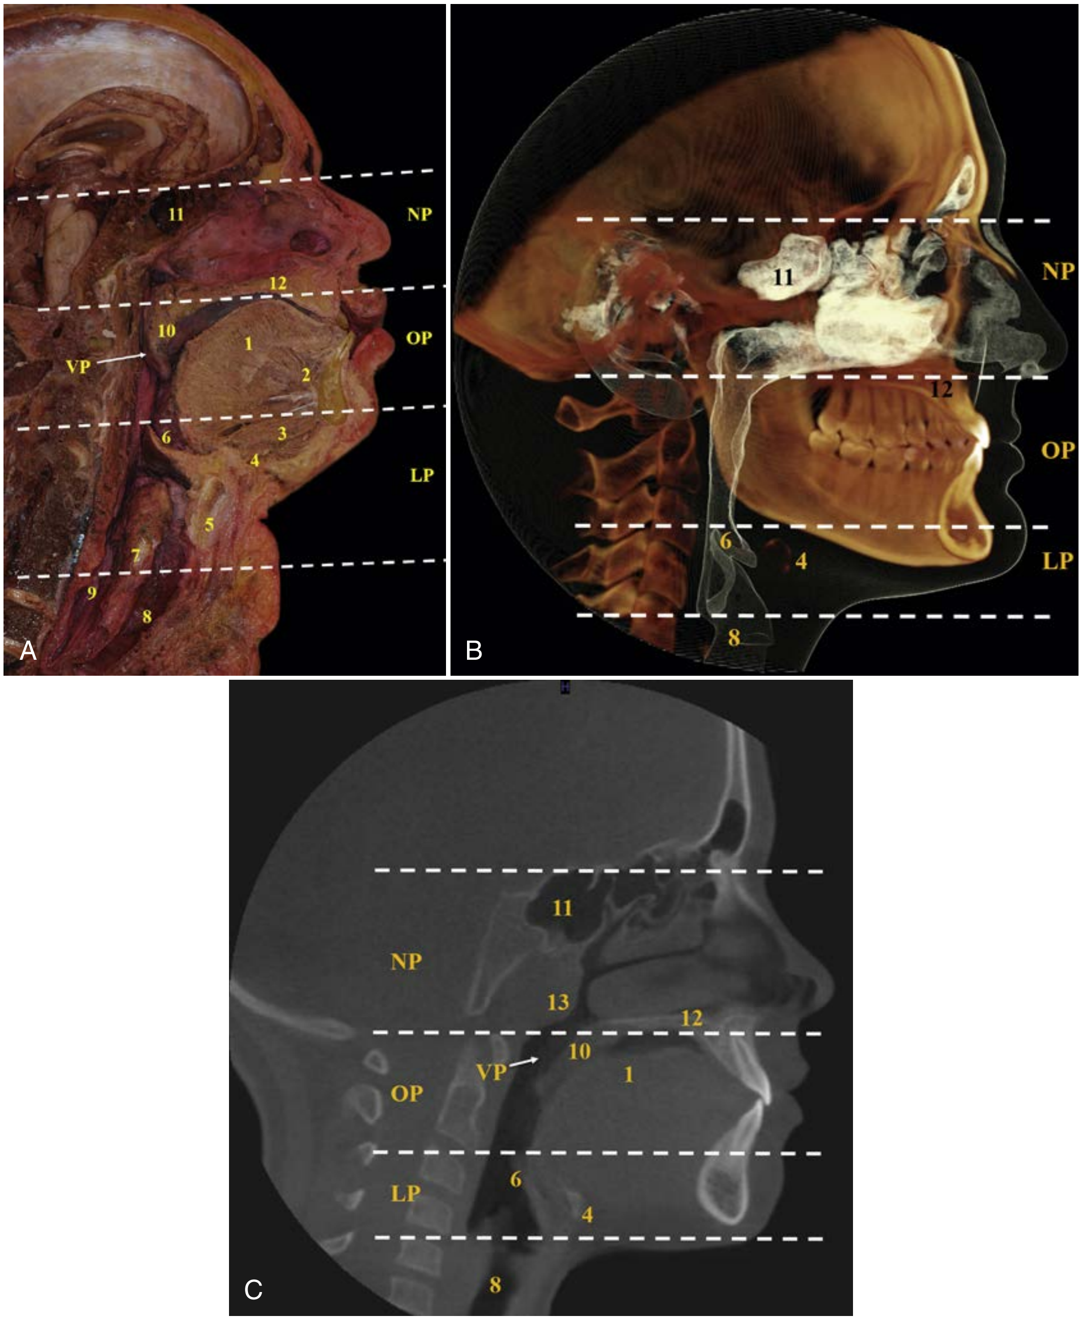

FIGURE 12-1 Anatomic midsagittal view shows human (adult) upper airway and surrounding structures. **A,** Cadaver. **B,** Cone-beam computed tomography (CBCT) volumetric view. **C,** CBCT sagittal slice. *NP,* Nasopharynx; *OP,* oropharynx; *VP,* velopharynx; *LP,* laryngopharynx; *1,* tongue; *2,* genioglossus muscle; *3,* geniohyoid muscle; *4,* hyoid bone; *5,* thyroid cartilage; *6,* epiglottis; *7,* posterior part of cricoid cartilage; *8,* trachea; *9,* esophagus; *10,* soft palate; *11,* sphenoid air-sinus; *12,* hard palate; *13,* pharyngeal tonsils (adenoids). (**A,** Courtesy of Dr. Michael Landers.)

The muscles surrounding the airway that actively constrict and dilate the UA lumen[27,28] can be classified into four groups:

1. Muscles regulating the position of the soft palate: ala nasi, tensor palatini, and levator palatine
2. Tongue: genioglossus, geniohyoid, hyoglossus, and styloglossus
3. Hyoid apparatus: hyoglossus, genioglossus, digastric, geniohyoid, and sternohyoid
4. Posterolateral pharyngeal walls: palatoglossus and pharyngeal constrictors

These groups of muscles interact in a complex fashion to determine the patency of the airway. Soft tissue structures form the walls of the UA and include the tonsils, soft palate, uvula, tongue, and lateral pharyngeal walls (Fig. 12-2).[29]

Taylor and colleagues[30] examined healthy children to elucidate the pattern of bony and soft tissue growth of the oropharynx. Lateral cephalograms of 32 untreated subjects belonging to the Bolton-Brush Growth Study were examined at 6, 9, 12, 15, and 18 years of age. Hard and soft tissue

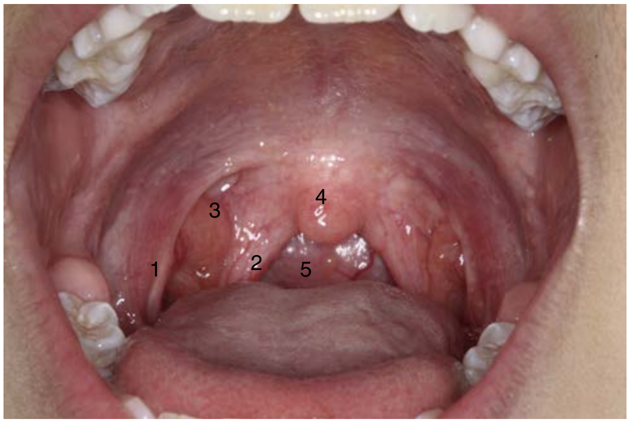

FIGURE 12-2 Intraoral picture of an 8-year-old child shows the palatoglossal fold (1), palatopharyngeal fold (2), palatine tonsils (3), uvula (4), and posterior pharyngeal wall (5).

tracings were compiled at different ages to generate tracing templates. Pharyngeal soft tissues exhibited two periods of accelerated change (ages 6 to 9 years and 12 to 15 years) and two periods of quiescence (ages 9 to 12 years and 15 to 18 years). Beginning at age 9 years, the soft palate increased in both length and thickness. The increase in airway size that occurs from ages 6 to 9 years is thought to occur because of the continued growth of the pharyngeal region, the surgical removal of adenoid tissue, and the natural involution of adenoid tissue, either alone or in combination with one another. These three mechanisms are suspected to play a role in the increase of the airway during the 12- to 15-year-old period. Moreover, inferior regions of the airway located below the tonsils and adenoids also demonstrated these periods of growth and quiescence.

The primary craniofacial bony structures that determine the airway size are the mandible[31] and the hyoid bone[32]; these presumably act by providing the anchoring structures to which muscles and soft tissue attach. In normal, non-obese individuals, the mean minimum cross-sectional area across multiple segments of the UA has been measured using several techniques: estimates vary from 320 mm^2 (acoustic reflection),[24] 59 mm^2 (fast computed tomography [CT] at functional residual capacity [FRC]),[33] 64 mm^2 (magnetic resonance imaging [MRI]),[29] 144 mm,[2,34] 188 mm,[2,35] and 138 mm^2 (conventional CT).[36] This wide range of sizes reflects the differences attributable to individual variability but also to differing locations of measurement, positional change (sitting or supine), and differences imposed by the choice of imaging modality (e.g., mouth open is required for acoustic reflection). The minimum caliber of the UA in the wake state is primarily in the velopharynx,[37] which makes it a site of interest as the potential location of collapse during sleep. The anterior wall of the oropharynx primarily comprises the soft palate, tongue, and lingual tonsils, and the posterior wall is bounded by a muscular wall made up of the superior, middle, and inferior constrictor muscles that lie in front of the cervical spine. The lateral pharyngeal walls are a complex structure made up of muscles (hypoglossus, styloglossus, stylohyoid, stylopharyngeus, palatoglossus, palatopharyngeus, and pharyngeal constrictors), lymphoid tissue, and pharyngeal mucosa. Such complexity of interactions among these different muscles makes the oropharynx an extremely difficult structure to evaluate.

Hyoid Bone Position and Morphologic Features

The hyoid bone is strategic because, as a bone, it is more readily seen in radiographs, as compared with muscles. The hyoid bone is the only bone in the head and neck region without a bony articulation. It freely lies suspended by the same muscles that are integrally related to the pharyngeal region of the airway. As such, the hyoid bone is a useful indicator of how the soft tissue is functioning. Its muscle attachments can be described as belonging either to the suprahyoid group or the infrahyoid group. Arising from the cartilages of the second and third branchial arches, the hyoid bone consists of a central body that posteriorly projects as a left and right greater horn. Attaching to the superior surface of the hyoid bone are the left and right lesser horns.[38] Papadopoulos and colleagues[39] used the hyoid bones from 76 cadavers to demonstrate their lack of symmetry. Among their sample, almost 50% of hyoid bones were found to be asymmetric in the transverse dimension. Nearly 60% of the hyoid bones examined displayed some differences in the extension of the greater horns.

A combination of linear and angular measurements shows that the hyoid bone descends and moves slightly anteriorly up to age 18 years. Anterior movement of the hyoid bone is believed to be related to the forward translation of the mandible that occurs during cephalocaudal skeletal growth. The descent of the hyoid bone may be explained by the growth of the cervical vertebrae. The combined anterior and downward displacement results from the hyoid bone being suspended between the cervical vertebrae and the mandible.[30]

The position of the hyoid bone is determined by the combined activity of the suprahyoid and infrahyoid muscle groups, with the UA dilator muscles being of great importance.

Behlfelt and associates in 1990[40] concluded that age was positively correlated with linear measurements of the sagittal and vertical posture of the hyoid bone. Enlarged tonsils can impinge on the UA, leading to a restricted passage and smaller airway volumes. They observed that children with enlarged tonsils had a more caudally positioned hyoid bone with respect to the mandibular plane (hyoid to mandibular plane [H-MP]). When comparing the sagittal position of the hyoid bone, either in relation to the cervical spine or to the gnathion, no significant differences were found between subjects in the control group and those with enlarged tonsils. Cohen and colleagues[41] found that during growth and development, the tongue increases in size and becomes larger with respect to the intermaxillary space, especially in males. This disproportionate increase in tongue mass relative to the oral cavity may lead to the tongue moving downward as the individual grows. This descent of the tongue may play a role in the inferior and anterior movements of the hyoid bone that occurs as one ages.

Similar to Taylor's group,[30] Nelson and colleagues[42] found that the H-MP distance increased over time, irrespective of whether the person was a snorer or not. Their study demonstrated that snorers have a greater H-MP distance during the prepubertal and pubertal period ($p < 0.10$). Similarly, adult snorers displayed a significantly larger H-MP distance ($p < 0.05$), compared with nonsnoring control subjects. Hyoid bone position can potentially be influenced by anatomic variables, neuromuscular control, and even deposition of fat in the neck region.

Sforza and colleagues[43] hypothesized that excessive submental fat deposition in obese patients could be responsible for inferiorly moving the hyoid bone further. Upon examining lateral cephalograms, Sforza and others[43] showed that differences in the position of the hyoid bone and measurements of the posterior airway space exist between control subjects and snorers. They proposed that the pharyngeal critical (Pcrit) pressure, which represents the airway pressure above which airflow can pass through the UA, is a measure of pharyngeal collapsibility. Upon examining male patients with OSA, significant correlations were found between Pcrit and the distance from the hyoid bone to the posterior pharyngeal wall ($r = 0.29$, $p = 0.03$) and the vertical position of the hyoid bone ($r = 0.32$, $p = 0.02$). A lower hyoid position was theorized to predispose a subject to pharyngeal collapse by influencing the Pcrit pressure, thus contributing to an anatomic deficit in patients with OSA.

Verin and colleagues (2002)[44] demonstrated that segmental UA resistance was correlated with the posterior airway space and the distance from the H-MP and the distance from the hyoid bone to the posterior pharyngeal wall (H-Ph) ($p < 0.05$). Patients with OSA displayed a greater UA resistance, which was linked to various anatomic variables, especially the position of the hyoid bone. A more downward and anterior position of the hyoid bone was demonstrated in subjects with OSA, compared with both snorers and normal subjects. The H-MP distances averaged 12 ± 5 mm in the control group, 18 ± 3 mm in the snorers group, and 24 ± 7 mm in OSA group, showing a statistical significance at all levels. The anterior position of the hyoid bone was not significantly different between the control group and the snorers group (35 ± 5 mm and 39 ± 6 mm, respectively), but both were significantly smaller than in the OSA group (46 ± 1 mm).[44]

Relationship of Different Skeletal Patterns to Airway Morphologic Structure

Since mandibular retrognathia and vertical excess are often associated with airway problems, the question remains whether different sagittal skeletal patterns have different airway sizes. It has been suggested through various three-dimensional (3D) studies that airway morphologic structure varies among patients with different craniofacial characteristics,[45-50] but conflicting findings are also available.[51,52] The primary consideration that arises from this discrepancy is that there is still no methodologic consensus on these studies. The differences in such studies when evaluating airway are patient position (supine or upright), consistency among subjects' ages, and the variability of two-dimensional (2D) and 3D landmarks used to define the UA. Although it has been shown that the airway volume and characteristics change with age, some studies include both adolescents and adults within the same group. Some studies use the Angle classification for stratification of groups, but this stratification could be too general. In a study by El and Palomo, groups were further stratified to Class II maxillary protrusion and mandibular retrusion and Class III maxillary retrusion and mandibular protrusion subgroups.[53] It was observed that subjects with Class II mandibular retrusion had the lowest airway values. When the mandible was in the opposite sagittal relationship—that is, the Class III mandibular protrusion group—the highest oropharyngeal volume, nasal airway volume, and minimum axial cross-sectional areas were seen. The nasal volume was lower in the Class II mandibular retrusion group, compared with Class I subjects, which was also previously found by Kim and colleagues.[47] Although still somewhat controversial, it makes sense that different sagittal positions of the jaws would influence the airway space, especially considering that approved treatment approaches include the movement of the mandible forward (with surgery or through oral appliances [OAs]), and bimaxillary advancement surgery for treatment of OSA (Fig. 12-3).

As for the orientation, subjects with a Class III skeletal pattern present a more vertical orientation of the airway in the sagittal plane, compared with Class I and Class II subjects, whereas a Class II skeletal pattern is associated with a more forward orientation of the airway.[48] Changes in the overall volume, area, or linear measurements of the sagittal airway are not of greatest significance; rather, detecting the location presenting with the minimum axial cross section (i.e., area of maximum constriction) is most critical. This area of maximum constriction is responsible for disturbance in breathing periods and is most susceptible to negative pressure. Furthermore, a correlation between the minimum axial area of the oropharynx and oxygen saturation and quantity has been presented, as well as apnea episodes.[54] Although some results concerning airway morphologic structure and different skeletal patterns are contradictory, most of the studies agree that minimum axial cross-sectional areas present a high positive correlation with the volume,[45,51,55] which means that as the minimal area increases, volume is expected to increase as well. This concept has also been realized by the software developers of the widely used segmentation programs, and most of the commercially available programs on the market today are capable of automatically finding the minimum axial cross-sectional area within the region of interest.

Although most studies have tendencies to relate the airway to skeletal tissue, Solow and Kreiborg presented a "soft tissue stretching hypothesis," proposing that a change in jaw posture caused by mouth breathing could lead to stretching of the lips, cheeks, and musculature, resulting in upright incisors and narrower dental arches, as observed in patients with a long-face and open bite growth pattern.[56] Patients with a vertical growth pattern have shown a narrower airway, both anteroposteriorly and coronally, when compared with patients showing more horizontal growth (Fig. 12-4).[46,48] Most vertical growers may also have a skeletal anteroposterior (AP) malocclusion (Class II or Class III), and often a strong tongue indentation can be noted at the anterior wall of the airway.[48] Joseph and colleagues evaluated the airway of hyperdivergent and normodivergent facial types and found smaller dimensions in the hyperdivergent group, attributing this finding to the retrusion of the maxilla and mandible and a low-set hyoid position, suggesting a compensatory mechanism.[57]

The relationship between the AP position of the jaws and the airway is not completely understood. Not everybody with a retruded mandible will have airway issues, but the airways of those with retruded jaws and/or hyperdivergent growth may need special attention.

AIRWAY MEASUREMENTS AND IMAGING

Overview

The objective measurement of airway patency is an important part of airway assessment. The measurement of nasal cavity geometry has proven to be a great challenge for researchers in modern rhinology. A number of techniques have been used to study the airway, including nasal pharyngoscopy, cephalometric

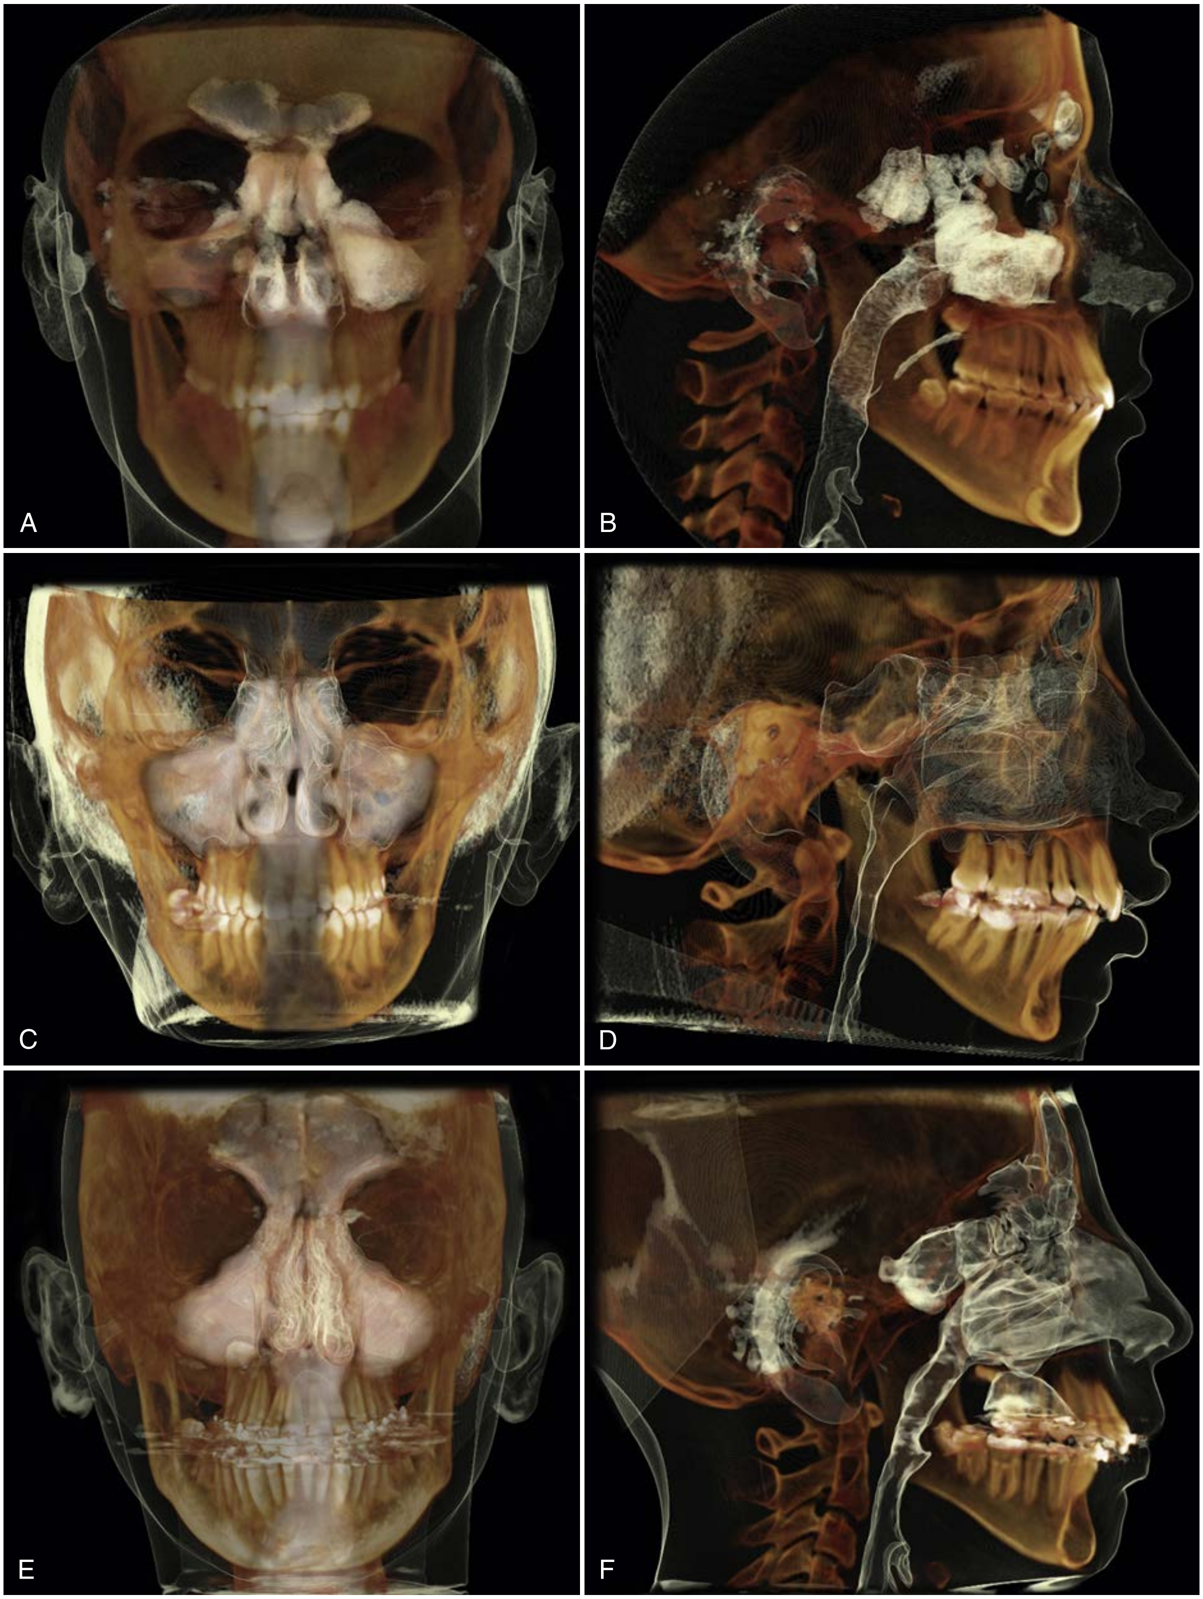

FIGURE 12-3 Airways from the sagittal and coronal views for different anteroposterior skeletal patterns are demonstrated. Class I (**A, B**), Class II with mandibular retrognathia (**C, D**), Class II with maxillary prognathia (**E, F**), Class III with maxillary retrognathia (**G, H**), and Class III with mandibular prognathia (**I, J**).

radiographs, fluoroscopy, conventional and electron-beam CT, acoustic reflection, and MRI.[58] Although MRI is considered to be very accurate in measuring the soft tissue lining, fat pad, and surrounding structures of the airway in three dimensions,[58] it is not as useful in orthodontics because of the use of metals, which interfere with this imaging modality. Patel and colleagues in 2006 reported that fixed metal orthodontic appliances can produce artifacts and obscure the area of the MRI.[59]

Probably the most common imaging modality found in an orthodontic office is the cephalogram, which provides a 2D radiographic view of the patient profile. Cephalograms have been found useful in identifying airway obstruction, adenoid hypertrophy, and very constricted airways.[60] However, the cephalogram is an image with incomplete information as it attempts to represent a 3D structure in 2D. Since many of the airway deficiencies and changes have been shown to occur in a mediolateral direction, the use of cephalograms for airway assessment is limited. (A classic cephalometric assessment of the airway is described later in this chapter.)

Some studies suggest that nasoendoscopy presently holds the position of gold standard diagnosis for UA obstruction.[60] However, nasoendoscopy has drawbacks as well; primarily, it allows little opportunity for objective measurement but relies, instead, on professional opinion, often causing low interobserver agreement.[61] Acoustic rhinometry (AR) or acoustic pharyngometry and cone-beam computed tomography (CBCT) are more widely used in otolaryngology and orthodontics, respectively. Current trends are transitioning to CBCT as it provides a 3D perspective and can be used to look precisely at hard tissue structures.

UA imaging techniques have also been used to visualize the airway lumen and to define the surrounding structures. In awake subjects, Schwab and colleagues[37] have shown that the normal UA has a longer lateral (coronal) than AP (sagittal) dimension using MRI techniques.

In addition, by using fast cardiovascular CT (cine CT), they also showed that airway size stays fairly constant during inspiration and reaches a minimum during end expiration, suggesting that muscular stabilization of the airway lumen during inspiration against the negative intraluminal pressure is more important than actual dilation, as had previously been believed. According to these authors, most respiratory-related changes (e.g., end-expiratory loss of diameter) are predominantly in the lateral dimension.[37]

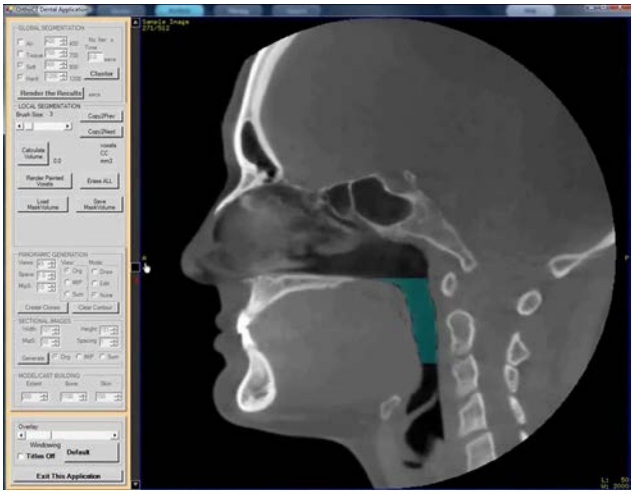
Cone-Beam Computed Tomography

CBCT is a medical imaging modality that has been applied in different fields of medicine (e.g., cardiac imaging, radiotherapy). CBCT is very popular in orthodontics and has brought 3D radiography to clinical orthodontics. The principle behind this technique is a cone-shaped x-ray bundle, with the x-ray source and detector (image intensifier or flat-panel detector) rotating around a point (or field) of interest of the patient. The conical shape of the beam distinguishes this technique from helical CT, which uses a fan-shaped beam. During a CBCT scan, the scanner (x-ray source and a rigidly coupled sensor) rotates, usually 360 degrees, around the head to obtain multiple images (ranging from approximately 150 to 599 unique radiographic views). These 2D images received by the detector are then compiled by the acquiring software into volumetric data, creating a 3D image (primary reconstruction). The scan time can range between 5 and 40 seconds, depending on the unit and settings used.

From its introduction, the use of CBCT has been criticized for its additional radiation exposure when compared with more traditional methods. The latest generation CBCT scanners are able to scan a patient with 180-degree rotation and with pulse technology, which uses radiation only when capturing the 2D images, resulting in approximately 2 seconds of total radiation time.[62] In addition, CBCT may now result in less radiation exposure to the patient than the usual combination of a panoramic radiograph and a lateral cephalogram. The combination of less radiation with equal or more diagnostic information may make CBCT more common in the near future.

Osorio and colleagues[63] suggested that CBCT has the potential to eventually emerge as a comprehensive and practical system to evaluate the airway and could become an excellent research and teaching tool for understanding the normal and abnormal airway. The axial plane, which is not visualized on a lateral cephalogram, is the most physiologically relevant plane because it is perpendicular to the airflow. The airway can be accurately assessed through segmentation. In medical imaging, segmentation is defined as the construction of 3D virtual surface models to match the volumetric data.[64] UA segmentation can be performed either manually or semiautomatically. In the manual approach, the user identifies the airway in each slice through the length of the airway (Video 12-1). The software then combines all slices to form a 3D volume. This method is time-consuming and almost impractical for clinical application. In contrast, semiautomatic segmentation of the airway is significantly faster.[65] In the semiautomatic approach, the computer automatically differentiates the air and the surrounding soft tissues by using the differences in density values (gray levels) of these structures. In some programs, the semiautomatic segmentation includes two user-guided interactive steps: (1) placement of initial seed regions in the axial, coronal, and sagittal slices, and (2) selection of an initial threshold (Videos 12-2 to 12-5). El and Palomo[65] showed that manual segmentation was more accurate than semiautomatic segmentation using different commercially available software; however, all of them showed high correlations, suggesting the existence of a systematic error in the derivation of the airway volume. Similar results were reported by Weissheimer and colleagues[66] using a more comprehensive list of software.

Proper analysis of the airway starts with the orientation of the 3D image, adjusting all three planes of space.[67] For a complete assessment of the airway, using a combination of 2D and 3D measurements is better. Calculating the volume is relatively easy and is probably the first measurement that comes to mind when studying the airway; however, the volume alone is not descriptive enough to describe all of the changes that may have occurred. An example to describe the shortcomings of using only the volume is to think of a birthday party air balloon. The same balloon, tied up with a fixed volume of air inside, can be deformed and have its shape changed without altering the air volume inside. When comparing air volumes, the result would suggest that no deformation took place (Fig. 12-5). Using anatomic limits when measuring the airway is very important to ensure that the same segmented volume is being compared among patients and groups. Unfortunately, no consensus has been reached at this point on which planes or landmarks to use as anatomic limits. The minimum axial area, also known as the *area of maximum constriction* (mm^2), is probably more useful



VIDEO 12-1 Manual segmentation of the airway. When performing a manual segmentation of the airway, the user identifies the airway in each slice through the length of the airway. This is a labor-intensive procedure that gives the operator total segmentation control.

than the airway volume. Figure 12-6 shows the most commonly used 2D and 3D measurements of the UA.

Acoustic Rhinometry

AR was introduced by Hilberg and associates in 1985[68] as an objective method for examining the nasal cavity (Fig. 12-7). This technique is based on the principle that a sound pulse propagating in the nasal cavity is reflected by local changes in acoustic impedance. AR is a simple, fast (approximately 30 seconds), and noninvasive technique that became widely accepted in a short period. Most previous investigations of living human subjects have demonstrated reasonably good agreement between the cross-sectional areas in the anterior part of the nasal cavity determined by AR and those determined by imaging techniques such as MRI and CT. However, this does not hold true for the posterior part of the nasal cavity and the epipharynx, in which AR significantly

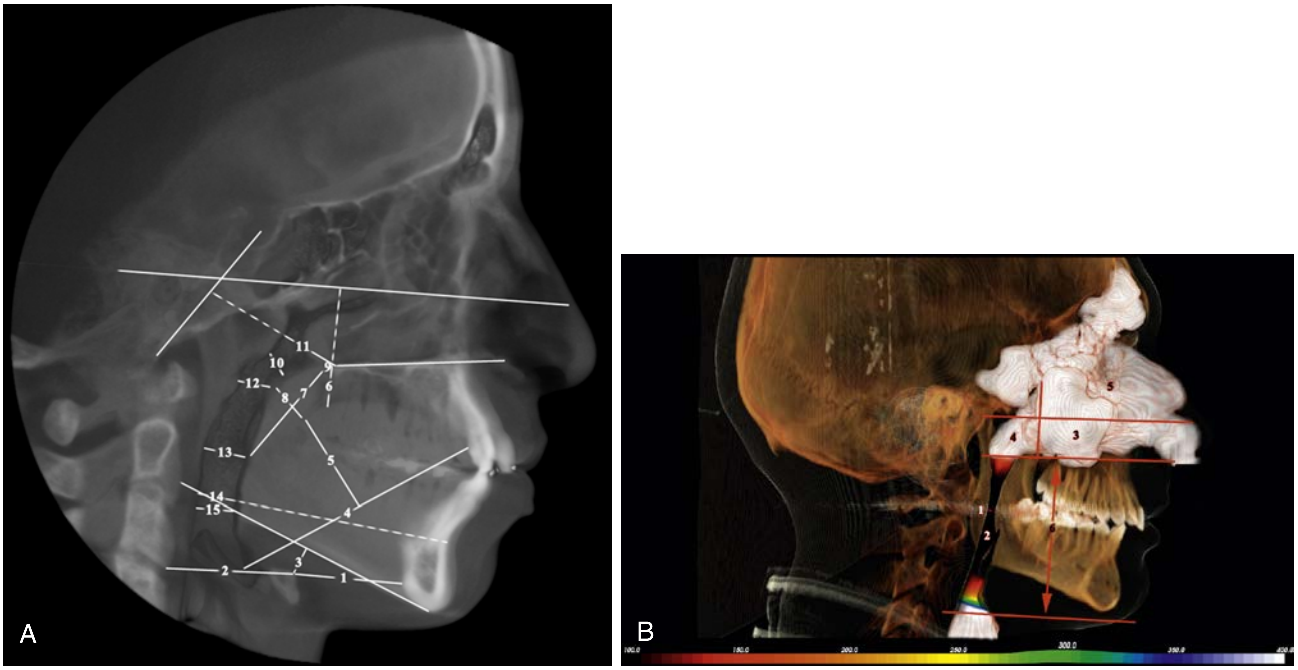

FIGURE 12-6 Common measurement made for airway analysis. **A,** Two-dimensional image: *(1)* line between the most posterior point of symphysis and the most superior and anterior points on the body of the hyoid bone; *(2)* line between the most anteroinferior part of the third cervical vertebra and the most superior and anterior points on the body of the hyoid bone; *(3)* perpendicular distance from the most superior and anterior points on the body of the hyoid bone to the mandibular plane; *(4)* tongue length: distance between the base of the epiglottis to the tip of the tongue; *(5)* tongue height: maximum height of the tongue along a perpendicular line of tongue length line to the tongue dorsum; *(6)* vertical distance between the dorsum of the tongue and posterior nasal spine (PNS) on a perpendicular line to the Frankfort horizontal (FH) plane; *(7)* soft palate length: distance between the PNS point and the tip of soft palate; *(8)* soft palate thickness: maximum thickness of the soft palate measured on a line perpendicular to the PNS and tip of soft palate line; *(9)* soft palate angle: angle that forms between the distance between PNS point and the tip of soft palate and the posterior nasal spine–anterior nasal spine (ANS-PNS) line; *(10)* shortest distance between soft palate and the adenoid tissue; *(11)* distance between AD2 point (intersection of the posterior nasopharyngeal wall and the PNS and the midpoint between the sella-basion [S-Ba] line) and PNS; *(12)* width of the most constricted airway space behind the soft palate along a parallel line to the Gonion-Point B [Go-B] line; *(13)* width of the airway along a parallel line to the Go-B line through the soft palate tip; *(14)* width of the airway space along the Go-B line; *(15)* posterior airway space: shortest distance between the radix of the tongue and the posterior wall of the pharynx. **B,** Three-dimensional image: *(1)* minimum axial cross-sectional area; *(2)* oropharynx volume: superior limit is defined by the ANS-PNS line, inferior limit is the line passing from the most anteroinferior part of the third cervical vertebrae and parallel to the ANS-PNS line; *(3)* nasal passage volume: inferior limit is defined by the ANS-PNS line, superior limit is the last axial slice before the nasal septum fuses with the posterior wall of the pharynx; *(4)* nasopharynx volume: located in the superior part of the ANS-PNS line and posterior of the line that passes from the PNS and is perpendicular to the ANS-PNS line until the most superior part of the nasopharynx; *(5)* nasal cavity: inferior limit is the ANS-PNS line, posterior limit is the line that is perpendicular to ANS-PNS line and passes through the PNS point; and *(6)* vertical oropharyngeal length: distance between the ANS-PNS line and the line passing from the most anteroinferior part of the third cervical vertebrae and parallel to the ANS-PNS line.

overestimates cross-sectional areas compared with MRI and CT scans. So far, few attempts have been made to validate AR by comparison with other methods, including nasal casting, fluid-displacement, and MRI. Kaise and colleagues[69] tested the AR method using small experimental animals, comparing the readings with impression material instilled postmortem into the nasal cavity of the animals and then measured through fluid displacement. The results deemed RA useful and reliable, estimating 73.7 ± 20.0% of the actual volume. Cakmak and colleagues[70] conducted a clinical study of 25 healthy adults that focused on the nasal valve region in particular, also reporting AR as a valuable method for measuring the passage area of the nasal valve. Numminen and associates[71] compared RA to high-resolution CT volumetry, considered one of the best imaging modalities available for evaluating the nasal cavity and paranasal sinus geometry, showing 1% error in segmented volumes when compared with actual volumes. Numminen concluded that AR is clinically useful and shows very good reliability in the anterior and middle parts of the nasal cavities but decreasing accuracy in the posterior part.

Pharyngometry

The acoustic reflection technique may also assess the pharyngeal cross-sectional area. This technique has been previously applied to study the pharynx, glottis, and trachea in humans in vivo. The technique has been validated against CT scans and experimental models.[72] Unlike the nose, the oropharyngeal airway is geometrically more complex and variable and includes mobile structures (soft palate and tongue); therefore establishing a standard operating protocol and an understanding of the possible sources of artifacts is of great importance in obtaining reliable results. Pharyngometry provides a noninvasive assessment of the dimensions, structure, and physiologic behavior of the UA from the oral cavity to the hypopharnyx while the patient breathes. Computer processing of the incident and reflected sound waves from the airways provide an area distance curve that represents the lumen from which minimal cross-sectional area and volume can be derived. This dynamic test measures the dimensions of the airway through the oral cavity and 25 cm down the pharynx. Marshall and associates[73] compared acoustic measurements of the pharyngeal and glottal areas in human volunteers during free breathing with MRI measurements of the same areas and showed no statistically significant differences between the measurements taken using either technique. Of equal importance is testing the repeatability of measurements obtained to ensure the validity of both the technique and the results. In 2004, Kamal[74] showed that measurements of the pharyngeal cross-sectional area in a different session on the same day did not significantly differ from those obtained in different days. Provided that a standard operating protocol is adopted and maintained, repeatability of acoustic reflection results can be achieved. Hatzakis and colleagues,[75] on the other hand, when examining 40 patients between the ages of 3 and 9 years before and after an adenoidectomy, suggested that pharyngometry was not reliable in assessing pharyngeal volumes in a pediatric population. They concluded that the results given by this method were not consistent with their clinical examination and hypothesis of what happened after the surgical procedure.

In 2007, Gelardi and colleagues[76] assessed variations of pharyngometric parameters in patients with sleep disorders and established a correlation between volumetric variations of oro-pharyngo-laryngeal spaces and the presence and severity of disease. A total of 110 patients, 70 with sleep disorders and 40 healthy subjects, had acoustic pharyngometry to evaluate the mouth and hypopharynx. A significant difference in parameters was observed between patients with sleep disorders and those in the control group, especially in patients with macroglossia. The authors concluded that although not a standardized test, acoustic pharyngometry was shown to be a useful method to assess OSA and in postoperative monitoring of UA surgery in patients with sleep disorders. When attempting to maintain good reliability and obtain accurate results, posture may play an important role in determining the pharyngeal area. Flexion of the neck and back, as well as raising the shoulders (which occurs near residual volume), may compress the pharynx and decrease its cross-sectional area.[77]

Pharyngometry is often marketed as a screening method to assess quickly a patient for potential sites of sleep-related UA obstruction and to better determine whether an OA or continuous positive airway pressure (CPAP) device may be appropriate for the patient. Proper sleep-related diagnosis is accomplished through polysomnography, which is discussed later in this chapter.

INFLUENCE OF ORTHODONTIC TREATMENT ON THE AIRWAY

Since orthodontists work around the UA and the changes made by orthodontic treatment are spatially related to the airway, several studies elucidate the relationship.

Treatment Including Extractions

Since the 1911 paper written by Calvin S. Case started the debate that came to be known as the “Great Extraction Debate,” extraction treatment is one of the most discussed subjects of orthodontics.[78] For today’s orthodontic practice, extraction treatment is a necessity for a not-to-be-underestimated number of patients. It is well documented in the literature that after four premolar extractions using maximum anchorage mechanics, a change in the soft tissue profile, retraction and uprighting of upper and lower incisors, and a slight change in the mandibular plane may be observed.[79-82] On the other hand, minimum anchorage mechanics may sometimes be desired for patients having good facial balance and moderate crowding, as well as when a counterclockwise rotation of the mandible is anticipated. In such cases, mesial molar movement is desired after the resolution of anterior crowding. Closure of extraction sites with mesial movement carries the molar to a narrower part of the arch, which could potentially have an effect on the tongue position.[83] Therefore investigating the effects of extraction treatment on the incisor, molar, and soft tissue position would be worthwhile, as this could potentially affect tongue position and may cause an alteration in the UA anatomy, especially the oropharynx.

Tongue position is considered to be an important factor for the UA since the root and posterior part of the tongue form the anterior wall of the oropharynx. Existing evidence suggests that extraction treatment with maximum anchorage mechanics may cause the tongue’s length and height to decrease slightly and move to a more retracted position against the soft palate.[83,84] This movement results in an adaptation and may lead to the narrowing of the UA. However, because one study was a 2D study[83] and the other lacked a control group,[84] reaching definitive judgments is difficult. Valiathan and colleagues assessed 40 subjects (20 with extractions and 20 age- and gender-matched controls without extractions) and reached a conclusion that extractions do not affect the oropharyngeal dimensions.[85] Stefanovic and associates who analyzed the pharyngeal airway of 62 subjects (31 subjects with extractions and 31 age-, gender-, and treatment duration–matched control subjects) also concluded that extraction of four premolars does not affect the pharyngeal airway volume or the minimum axial cross-sectional area.[86] The latter two studies were performed in university settings using different samples and subjects treated to the supervising faculty's personal treatment philosophy. Therefore interpreting the findings is also difficult because of the lack of data about the anchorage mechanics used. As previously discussed, a minimum axial cross-sectional area is important for the patency of the airway. It has been shown by Valiathan and colleagues that when the anterior teeth are retracted to a new position, predicting how the minimum axial cross-sectional area will respond to this movement and how respiratory function will be affected is impossible.[85]

Another possible explanation for UA reduction after incisor retraction is the movement of the hyoid bone in a posterior and inferior direction.[87] Wang and colleagues reported that this change in hyoid bone position was an adaptation that prevents an encroachment of the tongue into the pharyngeal airway. Shannon, in contrast, evaluated the 3D changes in the hyoid position in extraction and nonextraction subjects and concluded that the hyoid position had no significant change attributable to extractions.[88] Therefore the impact of backward and downward movement of the hyoid on UA dimensions remains controversial.[89]

On the other hand, mesial movement of the molars in to extraction spaces seems to enlarge the space behind the tongue, which is considered to play a vigorous role in improving UA dimensions.[83] Minimum anchorage and vertical control mechanics are also preferred in vertically growing patients to obtain a counterclockwise rotation of the mandible.[90] It has been reported that hyperdivergent patients with an obtuse mandibular plane angle have a narrower AP pharyngeal dimension, compared with normodivergent patients.[47,91,92] Therefore obtaining a counterclockwise rotation and a forward positioning of the mandible in such situations may contribute to enhanced dimensional changes in the UA.

To date, conclusive data on the effect of orthodontic extraction on the dimensional changes of the UA do not exist. Even if the oropharynx narrows, due to extractions, the assumption can be made that extractions may still be beneficial from the standpoint of addressing the malocclusion. To be more specific, whether extractions have an effect over the UA, actual functional assessment of breathing patterns must be evaluated in further studies, and higher quality trials are necessary to verify reliability.[89] Furthermore, no adverse effects of extraction treatment over the nasopharynx area have been reported to date.

Rapid Maxillary Expansion

Nasal resistance to airflow is an important factor in determining the nasal breathing pattern. Several methods such as intranasal and nasopharyngeal surgery have been recommended to increase airflow through the nose.[93] Rapid maxillary expansion (RME) is commonly used to correct maxillary constriction.[94,95] Because of the nature of the procedure, an increase in the nasal cavity width and posterior nasal airway is anticipated, not only attributable to the opening of the median palatal suture[96] but also to an increase in the sagittal and vertical dimensions.[97,98] As a result, an improvement in nasal respiration is expected, along with expansion in patients with a transverse arch discrepancy. Surgically assisted rapid palatal expansion (SARPE), on the other hand, is a frequently used surgical modality of RME preferred in skeletally mature individuals to overcome the resistance of the closed sutures.[99] Studies have documented nasal resistance reduction and intranasal capacity increase with both RME and SARPE treatments.[100,101] When speaking of the success for all treatment modalities, stability is a primary concern. The same holds true for the gain in nasal airway dimensions after RME treatment. In a systematic review by Baratieri and colleagues, changes after RME in growing children have been shown to improve the conditions for nasal breathing, and the results can be expected to be stable for at least 11 months after therapy.[96] El and Palomo reported a twofold increase in the nasal passage volume of patients who underwent RME treatment, compared with controls even at the end of approximately a 2-year treatment.[102]

Lateral and posteroanterior cephalometric records were used earlier for the evaluation of nasal airway. Although these methods proved to be useful in determining the contractions along the airway, they did not provide adequate information on measuring nasal resistance, airflow, minimum axial cross-sectional areas, or volumetric data. Rhinomanometry and AR have proven to be useful methods in providing an objective assessment of the air flow through the nose and to measure nasal cavity dimensions, respectively.[68,103] Furthermore, AR, CT, and MRI measurements show good correlation, especially for the anterior 6 cm of the nasal cavity area, which is most favorably affected by REM.[100] However, due to sound loss in the paranasal sinuses, the same probably does not hold true for the posterior nasal cavity and nasopharynx.[104]

As for the oropharynx area, using CBCT data in growing patients with a unilateral or bilateral posterior crossbite have demonstrated that oropharyngeal airway volume is significantly smaller, compared with patients without constriction.[105] After RME, the increase in intermolar width is a fact, especially in the maxillary arch, which may cause the tongue to reposition more anteriorly in the oral cavity.[106] Additionally, secondary to RME treatment, mandibular position also changes in various directions in patients with different malocclusions.[107] Therefore thinking that these outcomes may most likely cause dimensional changes for the oropharynx is not erroneous. However, the latest studies failed to confirm an enlargement or narrowing of the oropharyngeal volume, either in adults or in adolescents, despite the increase in intermolar width and mandibular positional changes.[102,105,108]

Functional Orthopedic Appliances

The position of the mandible, relative to the anterior cranial base and mandibular length, seems to have an impact over the oropharyngeal airway. Several studies have shown a significant but weak negative correlation between oropharyngeal dimensions and the skeletal configuration according to the A point–nasion–B point (ANB) angle.[45,49,50,109] In addition, mandibular corpus length and oropharyngeal airway volume, along with minimum axial area, have shown a positive correlation.[45,109] Thus thinking that functional appliances that advance the mandible could have a positive impact over the UA is logical, and an increase in the oropharyngeal airway dimensions has been previously reported.[110-112] When the mandible is protruded, a different posture of the tongue caused by increased genioglossus muscle activity and/or other soft tissue activity may play an important role over airway dimensions.[113] A study by Hänggi and associates, using activator-headgear therapy in patients with a mean age of 10.2 years, showed improved distance behind the tongue (velopharynx) by 2.5 mm on average, resulting in an increase of the oropharyngeal dimensions.[114] Children with large adenoids and tonsils can show growth impairment attributable to abnormal nocturnal growth hormone secretion, pointing out the importance of proper clinical examination by the orthodontist before any treatment. In such cases, adenotonsillectomy may be needed to obtain a significant increase in serum levels of growth hormone mediators and potentially to help bring the somatic growth to normal levels.[115,116]

Iwasaki and colleagues found that a frequently used fixed functional appliance, the Herbst appliance (American Orthodontics, Sheboygan, WI), enlarges the oropharyngeal and laryngopharyngeal airways of Class II subjects at the prepubertal growth spurt stage, compared with an age-, sex-, and Frankfort mandibular angle (FMA)-matched skeletal Class I subjects.[117] One of the most interesting findings in such studies is that the majority of the airway enlargement occurs in the mediolateral dimension—in other words, in the width of the airway.[118-120] This effect cannot be seen in a lateral cephalogram, and identifying it in a posteroanterior film is difficult because of the superimposing anatomic structures. On the other hand, when fixed functional appliances are used in the later stages of growth, when most dental changes take place, no significant posterior airway changes are usually seen after treatment is completed.[121]

Other extensively used orthopedic appliances are headgears, to inhibit the forward maxillary growth, and the face mask for maxillary protraction. Kirjavainen and Kirjavainen found that cervical headgear treatment increased the velopharyngeal airway space but did not significantly affect the rest of the oropharynx or hypopharynx.[122] Although headgear treatment is intended to restrict the forward growth of the maxilla, which may suggest a negative influence over the airway, they speculated that this restriction was only limited to the maxillary alveolar process. Headgear is extensively used by patients during sleep.

The literature shows that the protraction face mask with or without RME can produce favorable skeletal and dental changes for patients with maxillary retrusion. The use of a face mask at an early age, along with an RME appliance, is reported to help obtain greater stability and skeletal effects.[123] However, neither type of treatment protocol seems to create a significant change for the oropharyngeal or nasopharyngeal sagittal airway dimensions when compared with subjects with untreated Class III malocclusions.[124] The literature also emphasizes that sagittal airway dimensions induced by therapy or physiologic growth show great interindividual variability in Class III subjects.

Orthognathic Surgery

Recent advances in surgical techniques, 3D imaging techniques, and surgical simulation programs offer a new perspective on treatment planning where face, airway, and bite are linked.[125] Today, planning and obtaining sagittal maxillary and mandibular movements and/or rotations in three planes of space are possible. The most common surgical procedures can be roughly categorized as concerning the mandibular or maxillary region only and bimaxillary surgical procedures. When the UA is in question, an important aspect of orthognathic surgery is how the skeletal movements and changes will affect the position of the hyoid bone and the tongue. A consensus in the literature suggests that when mandibular setback osteotomy is performed, the hyoid bone tends to move to a more posterior and inferior position, and the tongue is carried to a more posterior position, regardless of whether using bilateral intraoral vertical ramus osteotomy or sagittal split ramus osteotomy.[126-128] As a result, narrowing in the width and depth of the hypopharyngeal and oropharyngeal areas has been reported. However, there seems to be an adaptation of the airway in the oropharyngeal and hypopharyngeal levels after surgery. However, 1-year follow-up shows that the airway is still narrower, compared with its preoperative dimensions.[127] On the contrary, mandibular advancement surgery results in an increase in the dimensions of the oropharyngeal airway.[129-131] Maxillary advancement, on the other hand, creates a significant increase in the nasopharyngeal and oropharyngeal airway dimensions. It has also been reported that hypopharyngeal airway may as well present an enlargement after maxillary advancement.[132] Therefore performing bimaxillary orthognathic surgery rather than only mandibular setback surgery would be advisable, even if the patient exhibits mandibular prognathia. Recent studies also confirm that maxillary advancement, combined with mandibular setback surgery, compensates for the narrowing of the UA, and, as a consequence, sleep quality and efficiency improve.[133-135] Probably the highest gain in the UA is obtained with maxillomandibular advancement surgery, which is a frequently used surgical modality in the treatment of patients with OSA.[136] Additionally, when maxillomandibular advancement surgery is performed in conjunction with genial tubercle advancement, which pulls the geniohyoid and genioglossus muscles forward, the gain in the UA is even better.[137,138]

Craniofacial anomalies involving the midface (Crouzon, Apert, and Pfeiffer syndromes), the ones primarily involving the mandible (Nager and Stickler syndromes and Pierre Robin sequence), and those affecting the midface along with the mandible (Treacher Collins syndrome and hemifacial microsomia) can lead to a decrease in the size of the oropharyngeal and nasopharyngeal airways. In these disorders, the reduced size of the mandible and its retruded position cause retrodisplacement of the tongue and concomitant reduction of the oropharyngeal airway, which may lead to UA obstruction. Distraction osteogenesis (DO) has become an accepted method of treatment for patients requiring reconstruction of a hypoplastic mandible and a severely retruded maxilla to increase airway dimensions.[139,140] DO is debated as a promising surgical technique and an alternative to tracheotomy for long-term management of the airway.[141-143]

Different types of distraction devices are used for the treatment of craniofacial anomalies. These are primarily classified as external and internal distraction devices, and they have been extensively used for the maxillary and mandibular regions according to the patients' needs. It has been shown on CT studies that especially the airway region above the uvula and posterior nasal spine level of young patients with severe midface retrusion significantly improve with LeFort III osteotomy and DO.[140] In addition, a slight difference seems to exist between internal and external distractors used for maxillary distraction in terms of airway enlargement. External distractors, although bulky and having a negative impact on a patient's psychosocial life, appear to provide more extended bone osteogenesis advancement when compared with internal devices.[144-146] Therefore a greater gain is obtained in the UA (Fig. 12-8).

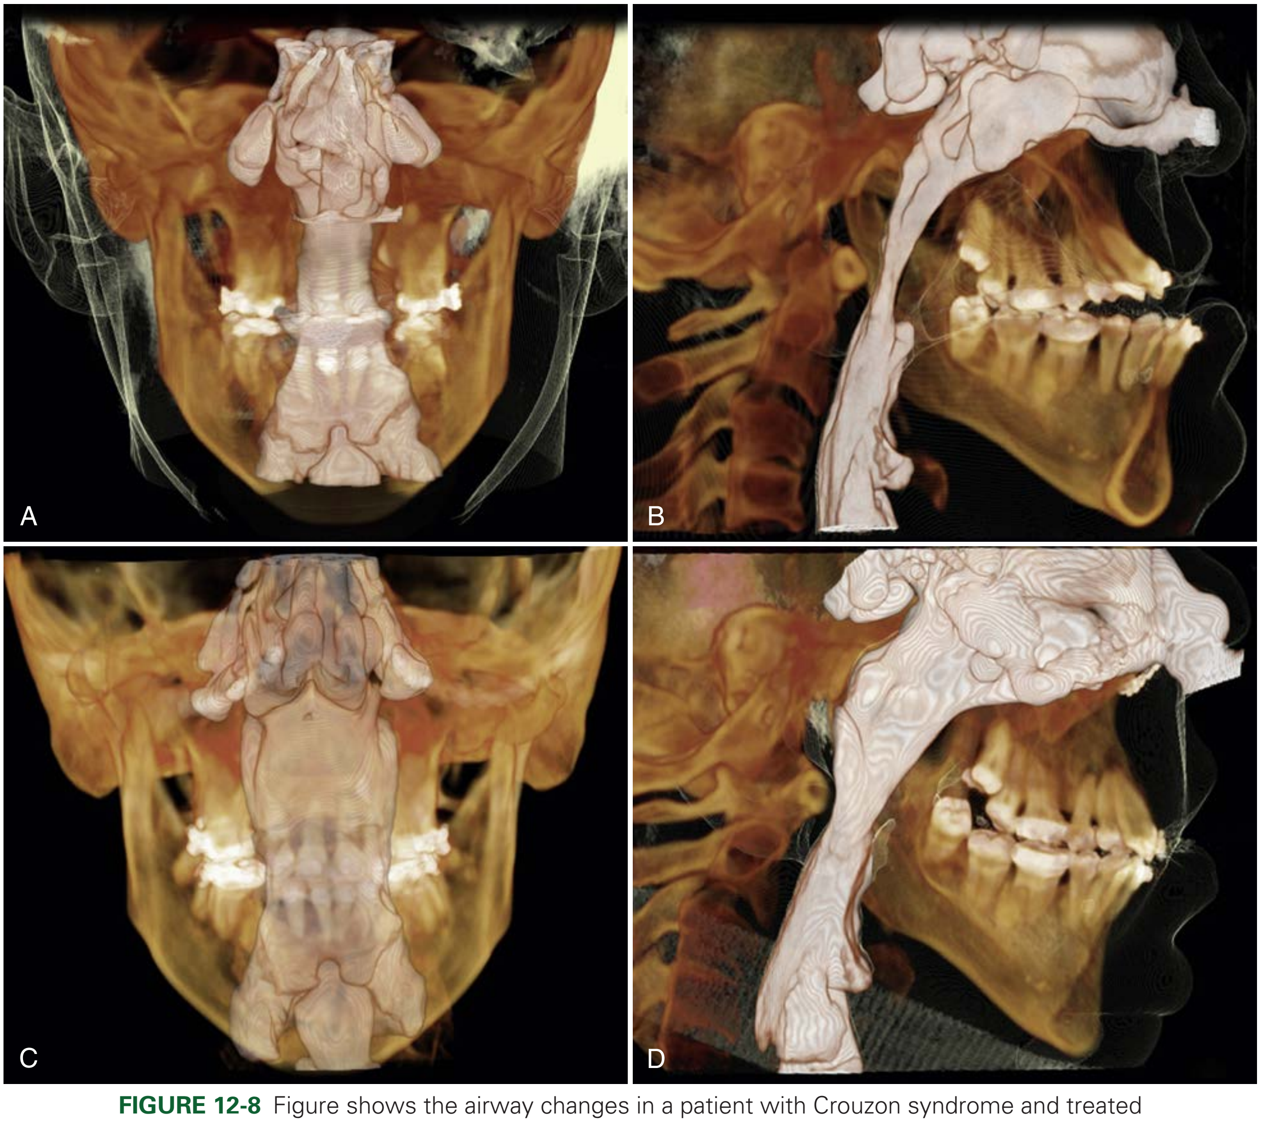

FIGURE 12-8 Figure shows the airway changes in a patient with Crouzon syndrome and treated with rigid external distractor (RED). **A** and **B** show frontal and lateral pre-treatment views, while **C** and **D** show the equivalent post treatment views. (Courtesy of Dr. Muge Aksu.)

Similarly, mandibular DO has been proposed as a useful method to resolve oropharynx airway obstruction.[147] This effect is primarily due to the displacement of the hyoid bone away from the posterior pharyngeal wall.[148] Furthermore, the small size of the mandible and its retruded position causes a corresponding retrodisplacement of the tongue, which also contributes to a reduction in the airway. Mandibular DO also creates a change in the position of the tongue and is believed to aid in increasing the airway (Fig. 12-9).[149]

Summary of Orthodontic Treatment Effects on the Airway

Studies show that certain orthodontic treatments may impact the UA, but there are limitations on this impact. Therefore some final recommendations in light of current literature can be as follows:

- Extraction treatment does not seem to affect the airway's size, but caution may be taken in patients who have respiratory problems or already constricted airways, possibly avoiding maximum anchorage approaches, if possible.
- RME may be able to help solve the nasal resistance to airflow if the problem originates from the anterior nasal cavity. Therefore in a possible relationship with an ear, nose, and throat (ENT) specialist, the clinician must be aware of the limitations of the procedure.
- Functional appliances are most useful in patients with a horizontal growth pattern of the mandible. If so, using fixed or removable appliances in a timely fashion may increase the dimensions of the airway. On the contrary, vertical-growing patients may not benefit from such a treatment since it is not the sagittal correction but rather a counterclockwise rotation that may increase the airway space.
- When planning surgical treatments, consideration should be given to avoiding large amounts of mandibular setback even if the patient's diagnostic records indicate mandibular prognathia. Bimaxillary surgeries are probably better choices for such patients.

Incorporating the morphologic airway into the orthodontic treatment plan is important. Orthodontics is not only about crooked teeth or jaw discrepancies. Airway patency is more important for patients than aligning teeth.

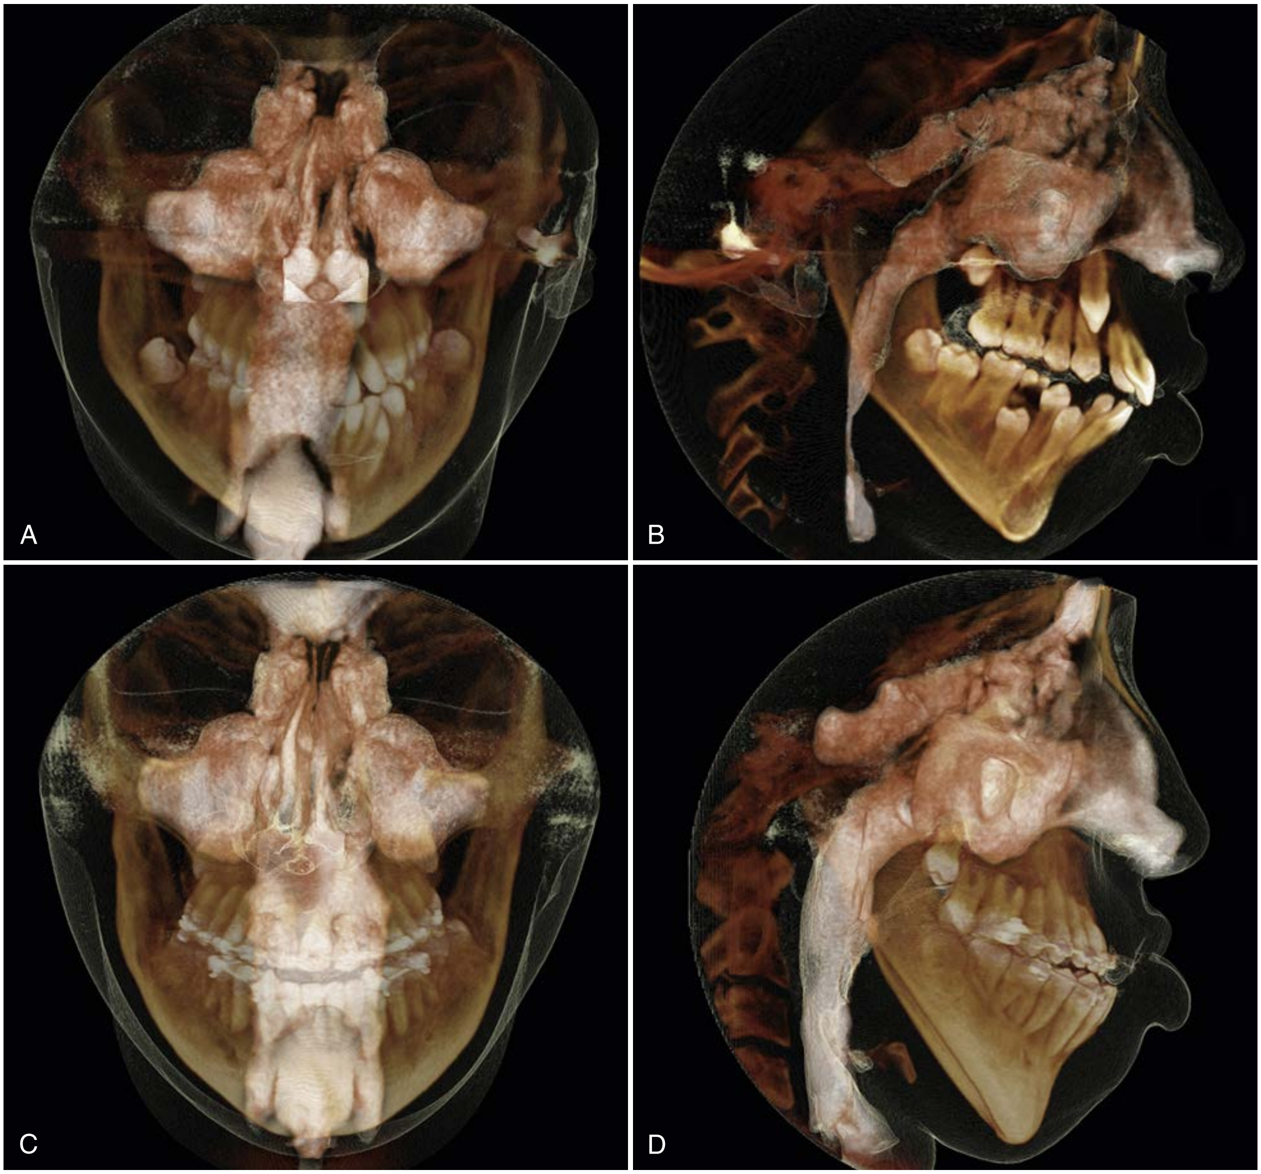

FIGURE 12-9 Figure showing the airway changes in a patient treated with mandibular distractor. A and B show frontal and lateral pre-treatment views, while C and D show the equivalent post mandibular distractor views.

SLEEP-DISORDERED BREATHING: AIRWAY DISORDERS AND MANAGEMENT

Sleep plays a vital role in good health and well-being throughout life. Getting enough quality sleep can help protect mental health, physical health, quality of life, and safety. Inadequate sleep contributes to heart disease, diabetes, depression, falls, accidents, impaired cognition, and a poor quality of life. In children and teenagers, sleep also supports growth and development.

OSA, which the orthodontist will most frequently encounter, is considered part of a group of disorders called *sleep-disordered breathing* (SDB). This class of disorders refers to abnormal respiratory patterning during sleep; but, ironically its presence or a suspicion of disease is made when the patient is awake. A finding of a narrow airway or a report of heavy snoring results only in a pre-test probability for any one of a number of respiratory pattern abnormalities, all which produce decreases in oxygen and increases in carbon dioxide levels, and arousals during sleep. Sleepiness by itself is not specific for SDB.

OSA is estimated to affect approximately 8% of men and 2% of women, averaging 5% of the general population, with many affected individuals going undiagnosed, considering themselves as healthy individuals.[150,151] The orthodontist who treats many patients a day probably encounters several people daily with OSA. Although the role of the orthodontist is not to diagnose SDB, an opportunity to screen for SDB exists. Proper diagnosis can only be done through polysomnography (PSG) or home testing with portable monitors, with PSG being the gold standard. It is important for the orthodontist to recognize the signs and symptoms of SDB and refer the patient to a sleep medicine physician for proper diagnosis. An otorhinolaryngologist (also known as ENT physician), may also be consulted in suspected cases of chronic nasal obstruction or adenotonsillar hypertrophy.[152]

Definitions and Testing Reports

Breathing abnormalities detected during sleep are classified as apnea, hypopnea, respiratory effort–related arousals, and hypoventilation. Apnea is the cessation, or near cessation, of airflow. It exists when airflow is less than 20% of baseline for at least 10 seconds in adults.[153] In children, the duration criteria are shorter. Apnea is most commonly detected using airflow sensors placed at the nose and mouth of the sleeping patient. Inspiratory airflow is typically used to identify an apnea, although both inspiratory and expiratory airflows are usually abnormal. Some laboratories use surrogate measures instead, such as inspiratory chest wall expansion. Three types of apneas may be observed during sleep:

- OSA occurs when airflow is absent or nearly absent but ventilatory effort persists. It is caused by complete, or nearly complete, UA obstruction.
- **Central apnea** occurs when both airflow and ventilatory effort are absent.
- Mixed **apnea** is mix of intervals during which no respiratory efforts occur (i.e., central apnea pattern) and intervals during which obstructed respiratory efforts occur.

The most common breathing abnormality scored in a sleep study is called *hypopnea*, which is an abnormal reduction of airflow to a degree that is insufficient to meet the criteria for an apnea. As further classified, obstructive hypopneas are due to partial UA obstruction, which can be heard as snoring. Central hypopneas are due to reduced inspiratory effort. Although the criteria for hypopnea vary among sleep laboratories, a common definition is ≥30% reduction of breathing movements or airflow for at least 10 seconds, with ≥3% or 4% oxyhemoglobin desaturation. Similarly to apnea, hypopnea is detected using airflow sensors or surrogate measures, such as chest wall expansion. Airflow is typically used to identify hypopnea, and both inspiratory and expiratory airflows are usually abnormal.

Another class of breathing abnormalities, respiratory effort–related arousals (RERAs), which are episodes during which breathing and oxygenation are maintained at the expense of a great increase in respiratory efforts, results from increased UA resistance. RERAs are terminated by an arousal, which is often characterized by a resuscitative snore or an abrupt change in respiratory measures with arousal and a change in breathing sounds. Patients with RERAs tend to have frequent microarou sals of 3 seconds or less during sleep.

Repetitive RERAs associated with daytime sleepiness was previously called UA resistance syndrome, a subtype of OSA. These patients may exhibit abnormal sleep and cardiorespiratory changes that are typical of OSA.

Sleep hypoventilation is expressed by a reduction in only the oxygen level or an increase in the carbon dioxide level without measurable changes in breathing patterns evident in the airflow monitor. Sleep hypoventilation is usually presumed when persistent oxyhemoglobin desaturation is detected without an alternative explanation.

Some reported measures from a sleep study are common to assess the severity of suspected sleep apnea, either an attended in-house study with sleep measures and cardiopulmonary monitoring or an unattended patient-based home monitor with no sleep measures.

- **Apnea-Hypopnea Index (AHI)**—The AHI is the total number of apneas and hypopneas per hour of sleep. The AHI is most commonly calculated per hour of total sleep and is the current defining measure of disease and disease risk.[154-156] However, an AHI is occasionally calculated per hour of non-REM sleep, per hour of REM sleep, or per hour of sleep in a certain position to provide insight into the sleep-stage dependency or sleep-position dependency. If AHI values are 4 or less, then the patient is within normal limits. OSA is mild when the AHI reflects 5 to 15 episodes per hour of sleep, moderate when the AHI reflects 15 to 29 episodes per hour of sleep, and severe when the AHI reflects 30 and higher episodes per hour of sleep.[157]
- **Respiratory Disturbance Index (RDI)**—The RDI is the total number of events (apneas, hypopneas, and RERAs) per hour of sleep. The RDI is generally larger than the AHI, because the RDI considers the frequency of RERAs, whereas the AHI does not.[153] OSA severity is defined as mild when the RDI reflects 5 to 15 episodes per hour of sleep, moderate when the RDI reflects 15 to 30 episodes per hour of sleep, and severe when the RDI reflects 30 or more episodes per hour of sleep.
- **Reporting oxygen saturation.** Oxygen desaturation is a consequence of SDB. The oxygen desaturation index (ODI) is the number of times that the oxygen saturation falls by more than 3% to 4% per hour of sleep. The percent of sleep time during which oxygen saturation is <90% quantifies the exposure to hypoxemia. This measure and mean oxygen saturation are associated with a risk for cardiovascular disorders and glucose intolerance.[158] Minimum levels (i.e., troughs) of oxygen saturation are important because severe hypoxemia is considered a risk for cardiac arrhythmias.[159]

If sleep is measured by a monitor, then the sleep stages and comments on whether the sleep stages are all present and in order will be reported. One measure of interrupted sleep is the arousal index, calculated as arousals per hour of sleep. The arousal index score is generally lower than the AHI or RDI score because approximately 20% of apneas or hypopneas are not accompanied by arousals. However, the arousal index score can be greater than the AHI or RDI score if arousals that occur are due to causes other than apneas or hypopneas. As examples, arousals can be caused by periodic limb movements, noise, and sleep state transitions.

There are limitations common to the definitions and indexes previously described, and each will differ according to the diagnostic study performed. Specifically, indexes determined by PSG define the number of events per hour of electroencephalographically documented sleep, whereas indexes determined by portable monitoring define the number of events per hour of recording time, subjectively estimated sleep time, or time in bed. In portable monitoring, the tendency is to overestimate the sleep time and thus underestimate the index.

Classifications of Sleep-Disordered Breathing

The syndromic classification of SDB results from a combination of testing results and symptom presentations.

Obstructive Sleep Apnea

OSA is defined as either[160]:

- More than 15 apneas, hypopneas, or RERAs per hour of sleep (i.e., an AHI or RDI >15 events per hour) in an asymptomatic patient, OR
- More than 5 apneas, hypopneas, or RERAs per hour of sleep (i.e., an AHI or RDI >5 events per hour) in a patient with symptoms (e.g., sleepiness, fatigue, inattention) or signs of disturbed sleep (e.g., snoring, restless sleep, respiratory pauses).

OSA syndrome applies only to the latter definition. In both situations, more than 75% of the apneas or hypopneas must have an obstructive pattern.

Upper Airway Resistance Syndrome

Individuals previously diagnosed with upper airway resistance syndrome (UARS) are now classified as having OSA by the most recent *International Classification of Sleep Disorders—Third Edition* (ICSD-3).[161] UARS refers to RERAs accompanied by symptoms or signs of disturbed sleep.

Central Sleep Apnea Syndrome

Central sleep apnea syndrome (CSAS) exists when symptoms or signs of disturbed sleep are accompanied by more than five central apneas plus hypopneas per hour of sleep and normocarbia during wakefulness.[162] The threshold frequency of events that warrants treatment beyond that required for the underlying disease is unknown. The UA has little or no involvement in CSAS. A special case of recurrent central apneas is called Cheyne-Stokes respiration and refers to a cyclic pattern of central apneas and crescendo-decrescendo tidal volumes. Cheyne-Stokes respiration is considered a type of CSA and is commonly associated with heart failure or stroke. UA obstruction does not play a major role in this syndrome.

Sleep Hypoventilation Syndromes

Patients with one of the hypoventilation syndromes generally have mild hypercarbia when awake, which worsens during sleep. The two hypoventilation syndromes are congenital central hypoventilation syndrome (CCHS) and obesity hypoventilation syndrome (OHS).

Epidemiologic Factors

The term *sleep apnea* encompasses a number of different clinical problems. In OSA, the most common form of sleep apnea, episodes of apnea occur during sleep as a result of airway obstruction at the level of the oropharynx and velopharynx (also called the *nasopharynx*). Several studies have shown that OSA is a common disorder that represents a significant public health problem.[163] A large prevalence study in state employees found that undiagnosed SDB "is prevalent and has a wide range of severity in middle aged women and men."[164] In this study, 9.1% of men and 4.0% of women had an apnea and/or a hypopnea index of 15 or more events per hour of sleep. Therefore in the United States alone, more than 3 million men and 1.5 million women meet at least one definition of OSA (apnea and/or hypopnea index of 5 or more plus a complaint of daytime sleepiness). In addition, clinicians are recognizing OSA in their patients with increasing frequency. In the United States, the annual number of patients diagnosed with sleep apnea between 1990 and 1998 increased from 108,000 to over 1.3 million—a 12-fold increase.[165]

Although the pathophysiologic factors do not really differ across ages or genders, subtle differences in the presentations and management of disease are emerging.

OSA in children is a special case for several reasons. The presenting symptoms are more likely to be behavioral problems during the day and below expected performance in school.[166] Sleepiness during the day is less common than hyperactivity, and a consideration of OSA is warranted in those with ADHD. Adenotonsillar hypertrophy by itself or in the presence of obesity, the prevalence of which is increasing, is a major cause for OSA in children. The scoring rules for diagnosis are different in children, with less emphasis on the number of apnea episodes or hypoxemia and more emphasis on the number of hypopneas, RERAs, and arousals from sleep.[167] Adenotonsillary surgery plays a greater role in children than in adults, although one suspects that as the individual ages, he or she might be at greater risk for SDB.

In young women and in women before menopause, OSA is accompanied with more complaints of fatigue and depression than with snoring or sleepiness, and a workup for hypothyroidism is more often negative.[168] The results of a PSG may be dominated by arousals, RERAs, and hypopneas.[153] The special case of pregnancy is also a time when a woman is more vulnerable to OSA because of edema, nasal congestion, progesterone and small lung volumes, resulting in increased oscillation from hyperventilation to apnea.[169]

Pathophysiologic Factors

The preponderance of evidence indicates that the pharynx is abnormal in size and/or is capable of collapsing or being collapsed in patients with OSA. This single tube, the pharynx, is obligated by nature to serve a number of functions that, at face value, seem to conflict. The pharynx must be collapsible because, as an organ for speech and deglutition, it must be able to change shape and close. However, as a conduit for airflow, it must also resist collapsing. The parsimonious solution to this design problem involves a group of muscles that can alter the shape of the pharynx when an individual swallows or speaks but will hold it open when he or she inhales.

With sleep, there is a reduced tonic input to the UA muscles, diminished reflexes that protect the pharynx from collapsing, reduced compensation for resistive loading, and an increased chemoreceptor set point during non–rapid eye movement (non-REM) sleep, which reveals a sensitive hypocapnia-induced apneic threshold. An abnormal pharynx can be kept open in wakefulness by an appropriate compensatory increase in dilator muscle activity,[170] but this compensation fails during sleep and the airway collapses. Partial collapse results in snoring, hypopneas, and, in some cases, prolonged obstructive hypoventilation. Complete closure results in an apnea.

The anatomic location of a UA obstruction may be anywhere from the nose to the glottis, with the most frequent site of primary obstruction being the velopharynx at the level of the soft palate and the oropharynx.[170] Isolated or a few apneas and hypopneas normally occur at sleep onset and in REM sleep; therefore when the events become recurrent, a disease process is recognized. Besides anatomic vulnerability, the physiologic causes for recurrent apneas during sleep are three-fold: ventilation transitions from waking to sleeping and back (for it is *sleep* apnea rather than *wake* apnea), a reduced UA activation in response to an apnea or hypopneas, and a high arousal threshold that awakens the patient with a ventilatory overshoot before a compensatory response occurs during sleep.[171] There is a history of relevant computational approaches for understanding recurrent obstructive and central apneas with models using mechanical properties (lungs, chest wall, and UA), fluid dynamics, circulation, and controller (brainstem) characteristics.[172,173]

Clinical Presentation

The most recognized manifestations of the OSA are stentorian snoring and severe sleepiness; however, both snoring and sleepiness may be denied or minimized by the patient or are less obvious than other symptoms, such as insomnia or fatigue or inattention. Sleepiness may develop fatigue very slowly over years or sleepiness may be considered normal, considering the prevalence of sleep deprivation.[160] The observations of someone who has seen the patient's sleep behavior and can report on daytime alertness can be helpful; however, if the patient does not consider the report as a problem, then the next step of diagnosis and the adherence to treatment are often viewed with skepticism. When obstructive events during sleep in a habitual snorer are witnessed, these events are a strong predictor of the presence of sleep apnea, but it does not predict its severity.[160] OSA increases with age and is twofold higher in men than in women up until the age of approximately 60 years, after which the opportunity for finding snoring, increased AHI, and OSA is equal.[168]

In adults, some other common reports include:

- Physically restless sleep and reports of insomnia
- Morning dry mouth or sore throat from mouth breathing upon recovery from apnea and/or hypopnea
- Morning confusion and headache from increases in carbon dioxide levels
- Personality changes (irritability and distracted demeanor) and judgment changes resulting from sleepiness
- Night sweats, secondary to increased work of breathing
- Erectile dysfunction, especially in the setting of hyperlipidemia

Physical Characteristics

The patient with OSA exhibits a greater prevalence of hypertension, obesity, a large neck, and a structurally abnormal or crowded UA.[174] The abnormal airway is the critical factor; consequently, OSA is not really an age- or gender-specific disease. The loci of obstruction in the UA are not easily assessed by the clinician while the patient is awake. The orthodontist can detect nasal obstruction, a low hanging soft palate and large uvula, enlarged tonsils and adenoids, and retrognathia or micrognathia. Nasopharyngeal tumors are rare but must be ruled out. Other disorders that can crowd or affect the pharynx include hypothyroidism, acromegaly, amyloidosis, neuromuscular disease, and vocal cord paralysis. Neck size is an important predictor of sleep apnea and, in some cases, is a better predictor than body mass index (BMI; the weight in kilograms divided by the square of the height in meters), presumably because additional tissue can influence the size or compliance of the UA.

Clinical Prediction of Significant Sleep-Disordered Breathing

Clinical features may not reliably predict sleep apnea in all patients suspected of having the disorder or being screened for sleep apnea. Some of the reasons are the nature of the definitions for significant OSA, meaning that the range of severity is from 5 events (1 event every 12 minutes) to 60 events or more. However, several models have been developed that can help the clinician decide which patients could be referred for more definitive testing.[160] The most useful models use the following clinical domains:

- Presence of hypertension (or hypertension treatment)
- BMI 30 or higher
- Neck circumference (or collar size) of >17 inches for men and >16 inches for women
- History of habitual snoring, snorts, observed apneas, and restless sleep
- Observed reports of nocturnal choking or gasping
- Reported or observed sleepiness, inattention, and nocturnal changes in energy

Although questionnaire scorings vary, these reports should be tallied, either as binary traits or in a graduated fashion. A patient with a low clinical score will have a low or very low posttest probability of having important sleep apnea and does not need further evaluation. A patient with a high probability of having clinically important sleep apnea requires further testing. Patients with a clinical score that is intermediate can be potential candidates, but further evaluation is needed. If the context is a screening questionnaire, then some discussion is needed to alert the patient to the cost and treatment implications of only a questionnaire result. If the quiz is conducted in the context of an already suspected sleep apnea (e.g., a referral for an OA), then the questionnaire is used to assess clinical severity.

Clinical severity profiles are being developed and range from severe (very high sleepiness and profiles for abnormal breathing during sleep) to mild (loud snoring without cardiovascular or behavioral indications for immediate treatment). Moderate severity may be initially managed by weight loss or the treatment of an anatomic problem, such as a nasal polyp or rhinitis, leaving the use of a CPAP device or an OA and surgery for consideration after appropriate diagnostic testing.

However, no clinical algorithm or test, including these, is a substitute for clinical judgment. For instance, as previously noted, daytime sleepiness is both ubiquitous and underrecognized in this relatively sleep-deprived society and is therefore not a statistically significant predictor of sleep apnea. Nevertheless, all patients with an otherwise unexplained complaint of excessive daytime sleepiness deserve further evaluation. A sleepy, stentorian snorer who has had witnessed apneas probably should be examined during sleep, regardless of the size of his or her neck.

Tests and Questionnaires

The presence or absence and predicting the severity of OSA must be determined before initiating any kind of treatment.[175] The gold standard of OSA diagnosis is clinical examination, daytime sleepiness, and overnight PSG.[176] Other clinical tools that are more time efficient and clinically feasible are available and include screening questionnaires, indexes, and cephalometric analyses. Nevertheless, no consensus has been reached on which of these scoring questionnaires or indexes are the most valid and reliable.[177] Dentists should play a role in the diagnosis of OSA, which begins with patient history, physical examination, and objective testing.[175,177] Different screening methods have been developed to diagnose OSA to avoid mistakenly diagnosing it as simply snoring.[176] Examples of some screening methods are the Berlin Questionnaire, the Epworth Sleepiness Scale (ESS), the Sleep Disorders Questionnaire (SDQ), the STOPBang Questionnaire, the Kushida Index, apnea prediction score,[178] and the Friedman classification that includes the modified Mallampati (MMP) score.

Friedman Classification

In 1999, Dr. Michael Friedman showed that the combination of many factors such as tonsil size, MMP score, and BMI plays an important role in clinically predicting OSA.[179]

The tonsil size can be graded from 0 to 4 (Fig. 12-10).[180] The MMP scoring system was developed in 1983; it was initially developed to help clinically predict the ease versus difficulty of laryngeal intubation[181] and was performed to minimize the risk of failed intubation that could have fatal consequences since intubation is the only mean of breathing for patients undergoing general anesthesia.[182] This scoring system is based on the direct visualization of the soft palate, uvula, faucial pillar, and hard palate and on the concept of examining the tongue size relative to the oral cavity. Because measuring the size of

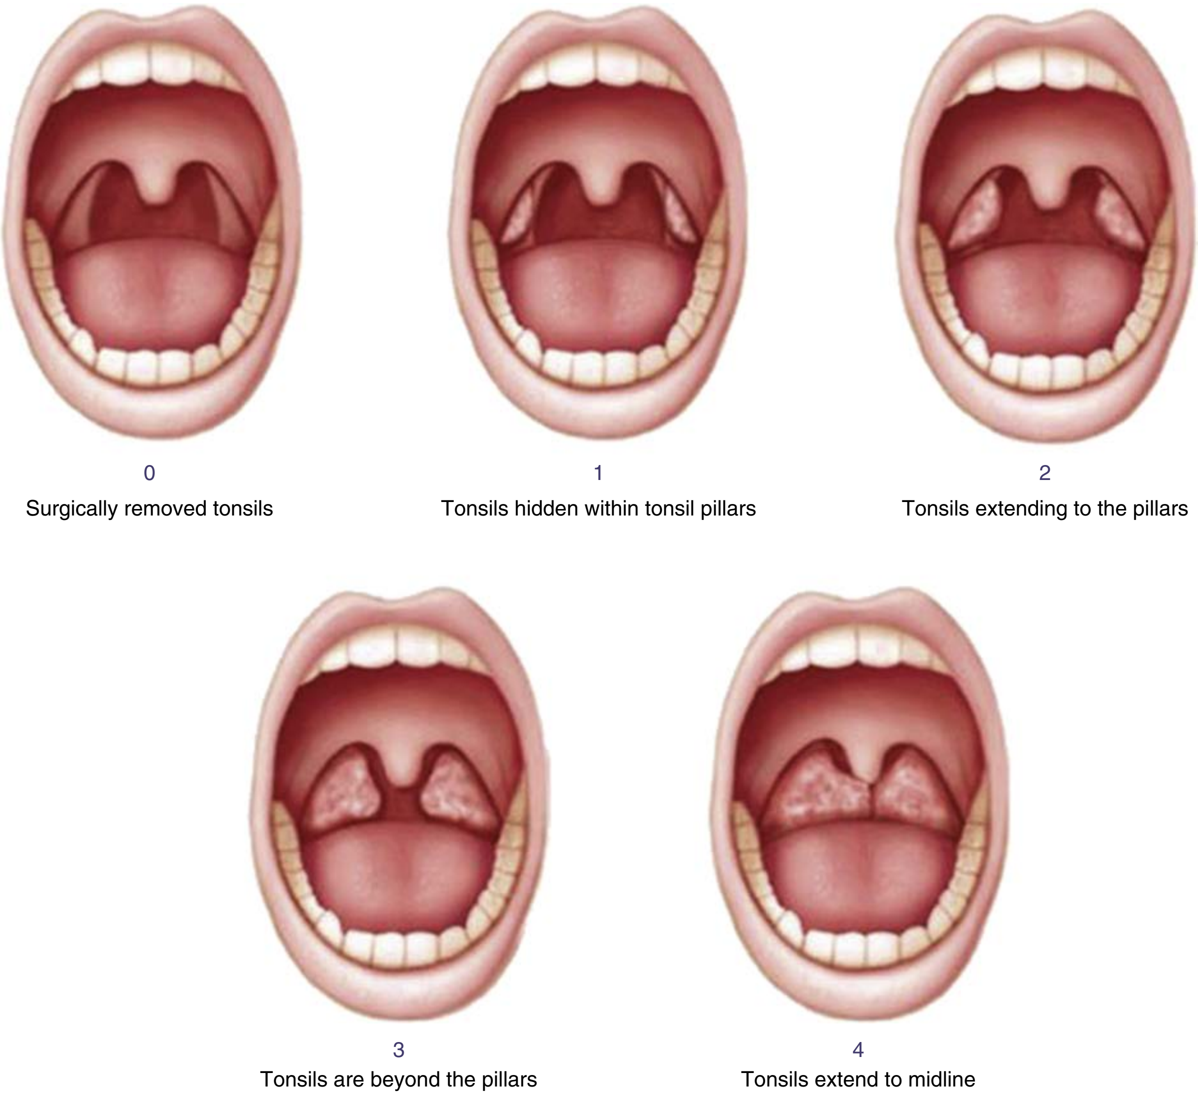

FIGURE 12-10 Tonsil classification. 0: surgically removed tonsils; 1: tonsils hidden within pillars; 2: tonsils extended to the pillars; 3: tonsils beyond the pillars; 4: tonsils extended to the midline.

the tongue relative to the oropharyngeal cavity is not possible, the MMP score is considered an indirect way of assessing the size of the base of the tongue.[182] The original classification was divided into three classes, Classes I, II, and III, that, respectively, coincide with the severity and difficulty of intubation. In 1987, Samsoon and Young suggested a modified Mallampati test (MMT), adding a fourth class (Fig. 12-11).[183] Although it was initially designed for predicting the difficulty of tracheal intubation, today, this clinical tool is used to assess patients with OSA and to detect those who have breathing problems attributable to UA obstruction.[184] A 2006 study reported the MMP score as an independent predictor of OSA, showing that, on average, for every point increase in the MMP score, the OSA increased by more than twofold and the AHI increased by more than five events per hour.[184]

As all different assessment scores and tools, the MMP score shows reliability in some tests for OSA and intubation prediction but was found inaccurate for postsurgical outcome assessments.[185]

It is important to note that the MMP score increases in certain conditions such as pregnancy; therefore it is important that clinicians not confuse high scores when they are caused by pathologic versus physiologic reasons.[186]

Mallampati Score Method

Three steps are followed to determine the MMP score:

Step 1. Patients are asked to take a seated or supine position. A study showed that the accuracy of predicting the intubation using the MMT was observed more in the sitting position; however, both positions are reliable.[187] If seated in an upright position, the head is in neutral position.

Step 2. Patients are asked to protrude their tongue as far forward as they can without emitting a sound. In the Friedman classification, the patient opens his or her mouth wide without protruding the tongue.[179]

Step 3. Through visual observation, a Class I to Class IV MMP score is determined.

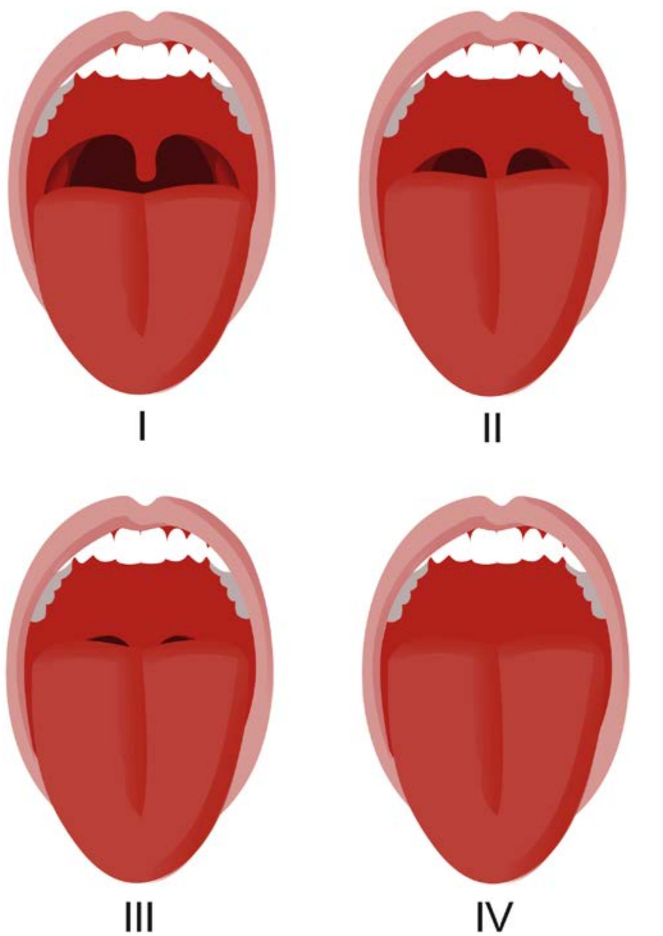

FIGURE 12-11 The modified Mallampati test (MMT) classifications. I: Soft palate, fauces, uvula, and pillars are visible. II: Soft palate, fauces, and uvula are visible. III: Soft palate and base of uvula are visible. IV: Soft palate is not visible.

Kushida Index

The Kushida index was developed in 1997 through a mathematical formula and is considered to have high levels of sensitivity and specificity.[188,189] It combines different measurements with BMI and neck circumference, creating a morphometric mathematical model to predict OSA. After the calculations are made, if the result is 70 or above, then it indicates a high risk of OSA. The Kushida index is calculated as follows:

$$\{P + (Mx - Mn) + 3 \times OJ\} + 3 \times [\mathrm{Max}\,(BMI - 25, 0)] \times (NC/BMI).$$

where *P*, palatal height; *Mx*, maxillary intermolar distance; *Mn*, mandibular intermolar distance; *OJ*, overjet; *BMI*, body mass index; and *NC*, neck circumference.

The first part of the formula reflects the contribution of the craniofacial dysmorphism to predict OSA through measurements from the oral cavity, whereas the second part reflects the contribution of obesity.

Berlin Questionnaire

The Berlin questionnaire was developed in 1996 at the Conference on Sleep in Primary Care that took place in Berlin, Germany. This 10-question questionnaire is considered to be a very accurate method of predicting OSA.[190] The complete method is explained in Table 12-1.

STOPBang Questionnaire

The STOPBang questionnaire was developed in 2008 based on the Berlin Questionnaire by anesthetist Chung Frances and sleep specialists in Canada to screen patients at high risk for OSA preoperatively. It was first identified as the STOP Questionnaire, which stands for yes or no questions on snoring (S), tiredness (T), observed events (O), and blood pressure (P). It was later modified to STOPBang, adding BMI (B), age (A), neck circumference (N), and gender (G) (Table 12-2). Such modification improved the questionnaire's sensitivity.[191] A 2014 study reports that the STOPBang Questionnaire has the highest sensitivity to diagnose the patient with moderate to severe OSA when compared with other screening tests such as the Berlin Questionnaire, the original STOP questionnaire, and the ESS. Their result showed that with AHI of ≥5 events per hour, AHI of ≥15 events per hour, and AHI ≥30 events per hour as cut-offs, the sensitivities of the STOPBang Questionnaire were 83.6%, 92.9%, and 100%, and the specificities were 56.4%, 43%, and 37%, respectively.[192]

Epworth Sleepiness Scale

The ESS was introduced by Dr. Murray Johns in 1991 and is a tool for assessing daytime sleepiness.[193] It assesses eight situations with a likelihood of falling asleep and assigns scores from 0 to 3, giving a total scale of 0 to 24. ESS was found to play a relatively small role in screening patients at high risk of OSA and cannot be used to predict or screen patients for OSA.[194]

Cephalometric Analysis

Although cephalometrics has an inherent limitation of being a 2D representation of a 3D structure, cephalometric analysis is still common in orthodontic offices. The sagittal and vertical position of different structures such as soft palate, tongue, airway, and hyoid position measurements could help detect an airway problem. In 1984, McNamara described his cephalometric technique,[195] which included assessment of the UA. He suggested taking two measurements, one for the upper pharynx and the other for the lower pharynx dimension. The upper pharynx dimension was described as the minimum distance between the upper soft palate and the nearest point of the posterior pharynx wall. This distance was determined to increase with age, with its norm established at 17.4 ± 3.4 mm. The lower pharynx dimension is the minimum distance between the posterior wall of the pharynx and a point seen in the cephalograms as the intersection between the posterior contour of the tongue with the lower border of the mandible. The lower pharynx dimension was not seen to change with age, and its norm was determined to be 11.3 ± 3.3 mm for females and 13.5 ± 4.3 mm for males (Fig. 12-12).[195] The anteroposterior and vertical positions of the hyoid bone can also be seen in the cephalograms, but a 3D modality such as the CBCT allows a far more comprehensive analysis, including axial and mediolateral assessments.

Sleep Disorders Questionnaire

The SDQ was developed from the sleep questionnaire and assessment of wakefulness in 1993 by retrieving the best questions, creating a multivariate scoring scale (Table 12-3). The four clinical diagnostic scales are sleep apnea (SA), narcolepsy (NAR), psychiatric sleep disorder (PSY), and periodic limb movement (PLM) disorder.[196] In a 2003 study, the 12 SA-SDQ questions proved to be valid and useful in screening OSA with a good degree of sensitivity and specificity.[197] It is important to

TABLE 12-1 Berlin Questionnaire

Ten multiple-choice questions, divided into three categories. Asterisk (*) marks answers that would give a positive score. A category becomes positive when two or more questions score positive. If no or one category is positive, then the patient is at low risk of obstructive sleep apnea (OSA). If two or more categories are positive, then the patient is at high risk of OSA.

Height (m) ________ **Weight (kg)** ________ **Age** ________ **Male/Female** ________

Please choose one response per question.

Category 1

1. Do you snore?
   a. Yes*
   b. No
   c. I do not know

If you snore, please answer 2-4.

2. Your snoring is:
   a. Slightly louder than breathing
   b. As loud as talking
   c. Louder than talking*
   d. Very loud and can be heard in adjacent rooms*

3. How often do you snore?
   a. Nearly every day*
   b. Three to four times a week*
   c. One to two times a week
   d. One to two times a month
   e. Never or nearly never

4. Has your snoring ever bothered other people?
   a. Yes*
   b. No
   c. I do not know

5. Has anyone noticed that you quit breathing during your sleep?
   a. Nearly every day*
   b. Three to four times a week*
   c. One to two times a week
   d. One to two times a month
   e. Never or nearly never

Category 2

6. How often do you feel tired or fatigued after you sleep?
   a. Nearly every day*
   b. Three to four times a week*
   c. One to two times a week
   d. One to two times a month
   e. Never or nearly never

7. During your waking time, do you feel tired, fatigued, or not up to par?
   a. Nearly every day*
   b. Three to four times a week*
   c. One to two times a week
   d. One to two times a month
   e. Never or nearly never

8. Have you ever nodded off or fallen asleep while driving a vehicle?
   a. Yes*
   b. No

If you answer No, please skip to 10.

9. How often does this occur?
   a. Nearly every day*
   b. Three to four times a week
   c. One to two times a week
   d. One to two times a month
   e. Never or nearly never

Category 3

10. Do you have high blood pressure?
   a. Yes*
   b. No
   c. I do not know

From Netzer NC, Stoohs RA, Netzer CM, Clark K, Strohl KP. Using the Berlin Questionnaire to identify patients at risk for the sleep apnea syndrome. Annals of internal medicine. 1999;131(7):485-91.

TABLE 12-2 STOPBang Questionnaire

The patient is at low risk of obstructive sleep apnea (OSA) if "Yes" is chosen fewer than three times and is at high risk of OSA if "Yes" is chosen three or more times.

Height (m) _______ **Weight (kg)** _______ **Age** _______ **Male/Female BMI** _______

Collar size of shirts: S, M, L, XL; or Neck Circumference (measured by staff): _______

Please answer the following questions:

1. Snoring
   Do you snore loudly (louder than talking or loud enough to be heard through closed doors)?
   a. Yes
   b. No
2. Tired
   Do you often feel tired, fatigued, or sleepy during the day?
   a. Yes
   b. No
3. Observed
   Has anyone observed you stop breathing during your sleep?
   a. Yes
   b. No
4. Pressure
   Do you have or are you being treated for high blood pressure?
   a. Yes
   b. No
5. Body Mass Index (BMI)
   Is your BMI more than 35 kg/m^2?
   a. Yes
   b. No
6. Age
   Are you 50 years of age or older?
   a. Yes
   b. No
7. Neck circumference
   (*male*) Is your shirt collar 17 inches (43 cm) or larger?
   (*female*) Is your shirt collar 16 inches (41 cm) or larger?
   a. Yes
   b. No
8. Gender
   Is your gender male?
   a. Yes
   b. No

note that the SDQ is not a diagnostic tool that can establish the presence or absence of OSA; rather, it is a screening tool that detects potential risk factors.

Diagnostic Testing of Obstructive Sleep Apnea

Diagnosis of OSA requires that the patient be examined during sleep,[174] and the gold standard is to diagnose through PSG.[175] PSG can be performed as an in-laboratory full-night or split-night test that includes the analysis of the following tests: electroencephalogram, electrooculogram, chin electromyogram, airflow analysis, oxygen saturation, respiratory effort, and electrocardiogram, sometimes replaced by heart rate. Body position and excessive movements are also observed during this test.

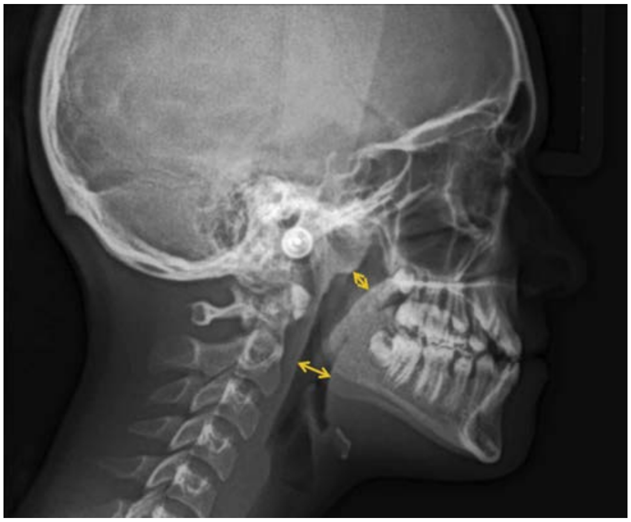

FIGURE 12-12 McNamara's airway analysis, showing upper and lower pharyngeal measurements (*arrows*).

The extent and location of the examination are the subjects of both clinical and cost-benefit concerns, but a full laboratory PSG is likely not necessary in most patients within whom the issue is merely the counting and classification of events for consideration of treatment of moderate to severe presentations of SDB and when no comorbidity, such as heart failure, chronic obstructive pulmonary disease (COPD), or other sleep behaviors exists that might require detection of sleep, arousals from sleep, and other measures for leg movements, seizures, or unusual behaviors (parasomnias). However, the proper diagnosis of OSA through PSG is recommended before any treatment is rendered to avoid potential life-threatening results.

Treatment Modalities

Conservative estimates suggest that 13% of men and 6% of women in the United States have clinically important OSA, and approximately 33% have moderate to severe disease.[198] Despite the transformative benefits of therapy with the CPAP device, many patients remain inadequately treated because they cannot or will not tolerate CPAP therapy. For these patients, other therapies can be considered.[199] Those most commonly considered include OAs[200] and surgery to the UA.[201,202] New forms of therapy include expiratory nasal valves, unilateral hypoglossal stimulation, and muscle exercises.[199,203] Bariatric surgery is indicated for eligible men and women and can reduce OSA to low levels in 85% of patients; the durability of this approach is under active consideration.[198]

Treatment Options

OSA should be approached as a chronic disease, requiring long-term, multidisciplinary management. The desired outcome of treatment includes the resolution of the clinical signs and symptoms, and the normalization of the AHI and oxyhemoglobin saturation.

TABLE 12-3 Sleep-Disorder Questionnaire Showing 34 Check Questions

Question are divided into four groups for scoring. Questions 1-12: Three or more checked boxes means symptoms of sleep apnea. Questions 13-19: Three or more checked boxes means symptoms of insomnia. Questions 20-27: Three or more checked boxes means symptoms of narcolepsy. Questions 28-34: Three or more checked boxes means symptoms of periodic limb movement disorder (uncontrollable leg or arm jerks during sleep) or restless leg syndrome.

Patient Name: ______________________ **Date:** __________

☐ 1.	I have been told that I snore.	☐ 18.	I wake up earlier in the morning than I would like to.
☐ 2.	I have been told that I stop breathing when I sleep.	☐ 19.	I lie awake for one-half hour or longer before I sleep.
☐ 3.	I have high blood pressure.	☐ 20.	When I am angry or surprised, I feel like my muscles go limp.
☐ 4.	My friends and family say that I am grumpy and irritable.	☐ 21.	I often feel like I am in a daze.
		☐ 22.	I have experienced vivid, dreamlike scenes.
☐ 5.	I have fallen asleep while driving.	☐ 23.	I have fallen asleep in social settings such as the movies or at a party.
☐ 6.	I have noticed my heart pounding or irregularly beating during the night.	☐ 24.	I have trouble at work because of sleepiness.
		☐ 25.	I have dreams soon after falling asleep or during naps.
☐ 7.	I get morning headaches.	☐ 26.	I have "sleep attacks" during the day, no matter how hard I try to stay awake.
☐ 8.	I suddenly wake, gasping for a breath.	☐ 27.	I have had episodes of feeling paralyzed during my sleep or on awakening.
☐ 9.	I am overweight.	☐ 28.	Other than when exercising, I still experience muscle tension in my legs.
☐ 10.	I seem to be losing my sex drive.	☐ 29.	I have noticed (or others have commented) that part of my body jerks during sleep.
☐ 11.	I often feel sleepy and struggle to remain alert.		
☐ 12.	I frequently wake with a dry mouth.	☐ 30.	I have been told I kick at night.
☐ 13.	I have difficulty falling asleep.	☐ 31.	When trying to go to sleep, I experience an aching or a crawling sensation in my legs.
☐ 14.	Thoughts race through my mind and prevent me from sleeping.		
		☐ 32.	I experience leg pain and cramps at night.
☐ 15.	I anticipate a problem with sleep several times a week.	☐ 33.	Sometimes I cannot keep my legs still at night. I just have to move them to feel comfortable.
☐ 16.	I wake up and cannot go back to sleep.		
☐ 17.	I worry about things and have trouble relaxing.	☐ 34.	Although I slept during the night, I feel sleepy during the day.

No treatment should be rendered without proper diagnosis through PSG.

According to the American Academy of Sleep Medicine, positive airway pressure (PAP) is the treatment of choice for mild, moderate, and severe OSA and should be offered as an option to all patients; however, depending on the severity of the OSA, the patient's anatomy, risks factors, and patient preferences, other options such as OAs and surgery may be adequate.[175]

Lifestyle and Behavioral Modification

According to the American Academy of Sleep Medicine, positive lifestyle modifications or behavioral treatments that can help in the treatment of OSA include the loss of weight to a BMI of 25 kg/m^2 or less, exercise, positional therapy during sleep, and avoidance of alcohol or sedatives before going to sleep.[175] Weight loss alone has not shown success in solving OSA; therefore it should always be accomplished in conjunction with other therapy.[204]

Sleeping in a supine position can affect the airway size and patency, helping the collapse of all structures. Positional therapy consists of a method that keeps the patient sleeping in a nonsupine position. Positional therapy will not always have a positive effect; consequently, PSG should be performed in both the supine and nonsupine positions before deciding if it will be a primary or secondary therapy for a patient. To prevent the patient from sleeping in a supine position, using objects such as tennis balls, pillows, or a backpack is recommended.[205]

Such behavioral changes can help achieve more positive outcomes and could be used as adjunctive therapy. For a patient diagnosed with OSA, however, using behavioral changes as the only treatment could be dangerous.

Positive Airway Pressure

PAP is the treatment of choice for all levels of OSA; it provides pneumatic splinting of the UA and shows positive outcomes in reducing the AHI.[206] PAP may be delivered as continuous (CPAP), bilevel (BPAP), or autotitrating (APAP) modes. The airway pressure can be applied through nasal, oral, or oronasal mask. PAP therapy is also indicated for improving sleepiness and quality of life and as an adjunctive therapy to lowering blood pressure in patients with OSA who also have hypertension. CPAP therapy is highly efficacious and currently the reference standard of treatment in preventing airway collapse. Early CPAP systems and masks were cumbersome and intrusive, but newer systems are light, less noisy, and easier to use. Nonetheless, many patients find the system difficult to tolerate.[207,208]

Oral Appliances

When the OSA is diagnosed as mild to moderate, OAs are considered a viable option.[175] Over the past decade, OAs have gained increasing acceptance as a viable treatment alternative to CPAP therapy for the treatment of OSA (Fig. 12-13). Patients often prefer OAs instead of a CPAP device because of their portability, ease of use, and comfort. OAs are also helpful with patients who snore or have UA resistance syndrome. Although they are currently indicated for mild to moderate OSA, there is increasing evidence of the potential role of OAs in patients with severe OSA who are intolerant or fail a trial of CPAP therapy

FIGURE 12-13 Patient with and without an oral appliance. The oral appliance positions the mandible forward and opens the mouth, increasing the vertical dimension. Intraoral frontal view without the appliance **(A)** and with the appliance **(B)**. Intraoral right side view without the appliance **(C)** and with the appliance **(D)**. (Courtesy of Dr. Aurelio A. Alonso.)

(Fig. 12-14 and Videos 12-6 and 12-7).[209-213] As a general rule, patients with severe OSA are not treated with OAs because of the concern that failed treatment or partial treatment may lead to respiratory failure. CPAP therapy has shown better results than OA therapy in bringing the AHI to <10 events per hour, but when Smith and Stradling substituted an OA for a CPAP device for a month, they reported that OA therapy produced a similar reduction in hypopneas from 29 to 4 events per hour.[214]

Better treatment responses have been found in younger patients,[215-217] patients with smaller neck circumferences,[210] women,[216] and supine-dependent patients with OSA.[216] A 10-year study found that the BMI does not play a role in long-term success of OAs.[218]

Cephalometric variables associated with better treatment responses have included a longer maxilla, shorter facial heights and soft palate, reduced overjet, and shorter distances between mandibular plane and hyoid bone. These variables are consistent with less severe OSA.[210,219,220]

Using an AHI of <5 events per hour as a measure of treatment success, approximately 35% to 40% of patients are successfully treated when using OA therapy. Another 25% showed at least a partial response.[209,210] Some individuals showed a worsening of OSA symptoms while on OA therapy; consequently, proper follow-up is important.[221,222] Overall, two-thirds of patients will experience improvement in OSA symptoms with OA therapy.[215,222]

A randomized cross-over study concluded that OA is effective in the treatment of patients with mild to moderate OSA with fewer side effects and greater patient satisfaction than nasal CPAP therapy.[223] Kyung and colleagues[118] indicated that OAs appear to enlarge the pharynx to a greater degree in the lateral plane than in the sagittal plane at the velopharynx. Such change would be visualized with 3D imaging and allow for proper follow-up.

The three general groups of OAs that are available include soft palate lift devices, tongue retention devices, and mandibular advancement splints (MAS).[224] A cross-over clinical trial comparing different OA designs[225] found MAS to be an effective alternative in treating patients with severe OSA, whereas tongue retention and soft palate lift devices did not achieve satisfactory results. MAS are the predominant type of OA used in clinical practice and have shown the best results. MAS effects include:

1. Enlargement of velopharyngeal airway caliber in the lateral dimension[226,227]
2. Increasing UA neuromuscular tone
3. Stimulation of UA dilator muscles[228,229]

MAS can be one piece (monobloc) or two pieces (bibloc) in design, custom-made or prefabricated, and titratable or nontitratable. Titratable appliances have shown greater reductions in obstructive events than nontitratable OAs, especially in patients with moderate to severe OSA.[217] The use of a dental implant–retained MAS[230] and mini-implants have been reported in edentulous and partially dentate patients.[231,232] Tongue-retaining and tongue-stabilizing devices, which protrude and hold the tongue forward by using suction, have also been suggested as a treatment alternative for edentulous patients.

Contraindications to the use of OA therapy include:

- Multiple comorbid conditions such as heart failure and respiratory failure, as well as when the possibility of central apnea and/or central hypoventilation exists
- Severe periodontal disease, when the risk for teeth mobility and loss is significant
- Severe temporomandibular disorder (TMD), in which the pain and dysfunction are aggravated with mandibular protrusion

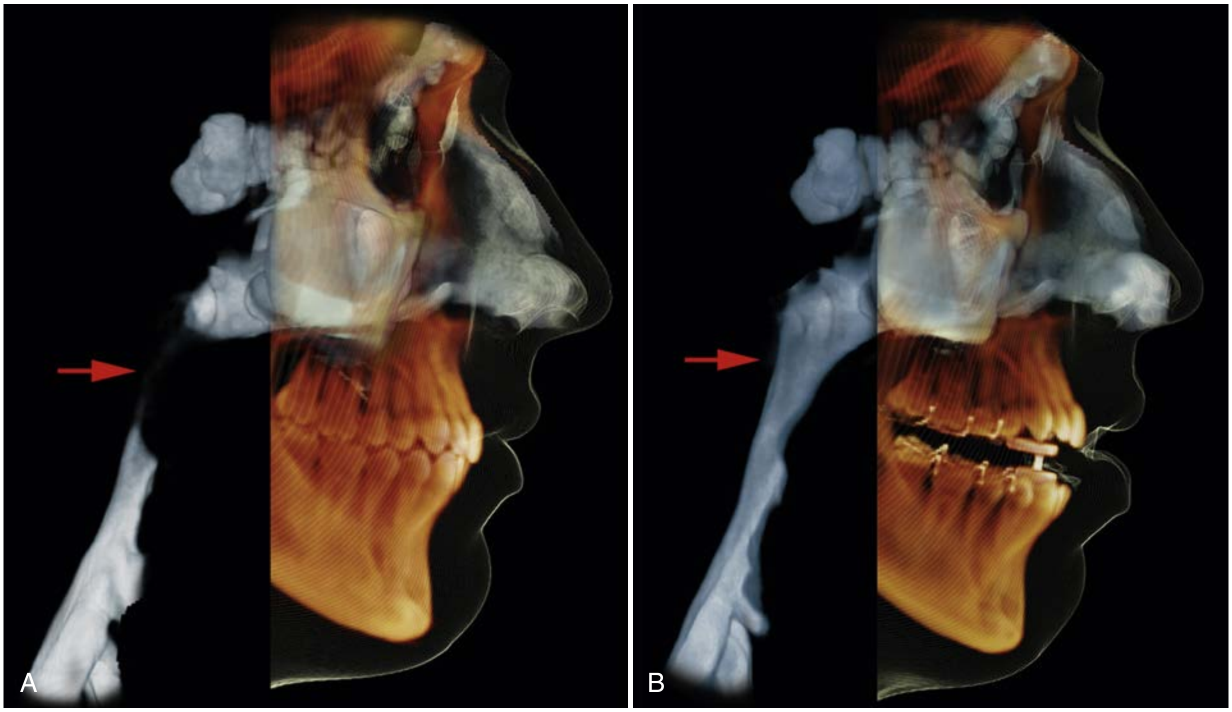

FIGURE 12-14 Three-dimensional images show the patient's airway without **(A)** and with **(B)** an oral appliance. With the appliance, the oropharyngeal airway volume went from 2128 mm^3 to 7797 mm^3. A most significant change occurred in the minimum axial area, which went from 1.1 mm^2 to 38.7 mm^2.

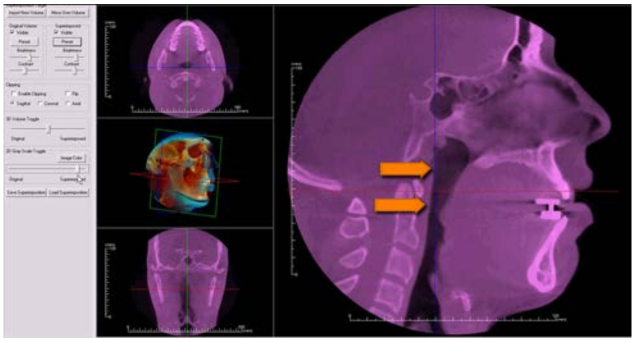
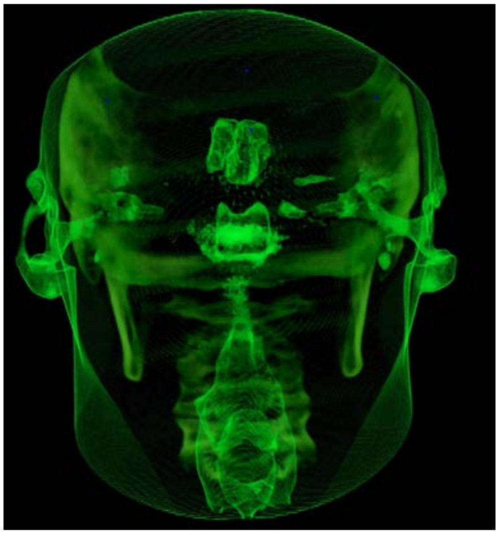


VIDEO 12-6 Superimposition of an OSA patient. Superimposition of an OSA patient with *(purple)* and without *(grey)* a mandibular advancement oral appliance, in all three planes of space. (From Anatomage Inc. San Jose, CA.)



VIDEO 12-7 Three dimensional superimposition of an OSA patient. 3D superimposition of an OSA patient with *(orange)* and without *(green)* a mandibular advancement oral appliance. Notice the medio-lateral change in the airway width, which would not be apparent in a lateral cephalogram.

- Severe gag reflex
- Poor coordination or dexterity as required for the placement and removal of OAs

Side effects of wearing an OA include excessive salivation, dry mouth, tooth discomfort, gingival irritation, masticatory muscle tenderness, and temporomandibular joint (TMJ) discomfort. With as few as 6 months of OA use, changes in facial height, as well as tooth and jaw positions, have been noted to occur.[233] Longer term 5-year studies reveal increases in facial height, occlusal changes, incisor inclination, and molar positional changes.[233-235]

Both the American Academy of Sleep Medicine and the American Academy of Dental Sleep Medicine released a joint resolution stating that the evaluation and management of patients with OSA should be overseen by a qualified physician trained in sleep medicine, which is defined as being licensed by a state to practice medicine and maintaining certification from the American Board of Sleep Medicine or a sponsoring sleep medicine board of the American Board of Medical Specialties. Similarly, OA therapy should be provided by a qualified dentist who completes additional education in dental sleep medicine and pursues objective verification of competency in OA therapy.[236]

Surgical Treatment

Although PAP treatment is the first line of treatment for moderate to severe OSA, successful long-term treatment is difficult to achieve.[208,237,238] Surgical procedures may be considered as a secondary option when the patient is intolerant of CPAP or OAs or when CPAP therapy is unable to eliminate OSA.[238] Surgery may also be considered as a secondary therapy in patients with mild to moderate OSA, when the patient is also intolerant of OAs, or when OA therapy provides unacceptable improvement of the clinical outcomes of OSA.[238,239] Surgery for OSA has been shown to improve important clinical outcomes including survival and quality of life.[208,238,239]

Surgical treatment of pediatric SDB with tonsillectomy and adenoidectomy is the recommended first-line treatment. In the pediatric population, resolution of OSA occurs in 82% of patients who are treated with tonsillectomy and adenoidectomy.[238,240]

Surgical treatment alternatives for OSA treatment include:

- **UA bypass procedure or tracheostomy:** This procedure creates an opening in the trachea to bypass the UA where obstruction is causing OSA. A tube or stoma is placed for ventilation.
- **Nasal procedures:** The objective of procedures such as septoplasty, functional rhinoplasty, inferior turbinate reduction, and nasal polypectomy[241-244] is to eliminate the obstruction that is preventing nasal breathing.
- **Tonsillectomy and/or adenoidectomy:** When OSA is properly diagnosed, as previously described in this chapter, such procedures can provide significant improvements in the treatment of OSA in children and young adults.
- **Uvulopalatopharyngoplasty:** The purpose of this procedure is to enlarge the velopharyngeal area, including trimming and reorienting the tonsillar pillars and excising both the uvula and the posterior part of the palate. Uvulopalatopharyngoplasty shows mixed results in the literature. This procedure can also be performed using a laser-assisted method, during which incisions are placed along both sides of the uvula, followed by laser ablation of the uvula rather than excision.
- **Radiofrequency ablation:** This technique consists of placing a temperature-controlled probe in the base of the tongue and/or soft palate with the objective of stiffening the area.[245] Soft palatal implanting of malleable plastic rods is also used with the same objective.
- **Orthognathic surgery:** Simultaneous advancement of both the maxilla and mandible has shown to provide significant enlargement of the velopharyngeal and overall oropharyngeal airway. Whenever possible, this procedure should be performed in conjunction with the orthodontist to achieve proper functional and aesthetic results.

Surgical procedures should be preceded by a thorough evaluation that includes an anatomic examination to identify possible surgical sites; an assessment of any medical, psychologic, or social comorbidities that might affect the surgical outcome; and a determination of the patient's desire for surgery. Tracheostomy as a bypass procedure can eliminate OSA but does not appropriately treat central hypoventilation syndromes.[175]

Maxillary and mandibular advancement can improve PSG parameters that are comparable with CPAP therapy in the majority of patients.

Bariatric surgery as an adjunctive surgery is an effective means to achieve major weight loss and is indicated in individuals with a BMI of ≥40 kg/m^2 or those with a BMI of ≥35 kg/m^2 with important comorbidities and in whom dietary attempts at weight control have been ineffective.[246]

Oropharyngeal Exercises

A less invasive option for the treatment of snoring and/or OSA includes exercises administered by an expert in myologic structure, arrangement, and action of orofacial muscles. As previously described, one of the reasons why OSA could occur in some patients is the larger size and hypotonicity of the oropharyngeal muscles. Oropharyngeal hypotonia may be linked to the pathogenesis of an individual and predispose him or her to OSA. To treat patients with OSA, the muscles responsible for blocking the UA need to be exercised to prevent airway collapse. The goal of the exercise is to strengthen the muscles located around the airway and to increase their tonicity, especially during sleep when muscles tend to relax. Oropharyngeal exercises can also improve stomatognathic function and reduce neuromuscular impairment.[247] The oropharyngeal muscles are the tongue, soft palate, neck muscles, and pharyngeal muscles. UA dilator muscles are very important to the maintenance of the pharyngeal opening and may contribute to the beginning of OSA.[248] In addition, if the neck muscles are flabby and weak, then they can exert pressure on the airway, which may lead to its collapse and obstruction of airway flow.

The oropharyngeal exercises target the soft palate, tongue, and facial muscle, as well as stomatognathic function. They are frequently performed during the day for few minutes in an isotonic (intermittent) and an isometric (continuous) way. Some examples of possible exercises include[248,249]:

1. **Soft palate:** An oral vowel is intermittently and continuously pronounced. The palatopharyngeus, palatoglossus, uvula, and tensor veli palatini and levator veli palatini muscles are recruited in this exercise. The intermittent exercise recruits the pharyngeal lateral wall as well. A blowing exercise is also performed, whether blowing a balloon or inhaling through the nose and exhaling through the mouth while keeping the lips together.
2. **Tongue:** Exercises that target the tongue include brushing the superior and lateral surfaces of the tongue while the

tongue is positioned in the floor of the mouth; placing the tip of the tongue against the front of the palate and sliding the tongue backward, which forces tongue sucking upward against the palate; pressing the entire tongue against the palate; and forcing the back of the tongue against the floor of the mouth while keeping the tip of the tongue in contact with the inferior incisive teeth.

3. **Facial:** The exercises of the facial musculature use facial imitations to recruit the orbicularis oris, buccinator, major zygomaticus, minor zygomaticus, levator labii superioris, levator anguli oris, lateral pterygoid, and medial pterygoid muscles.
   a. Muscle pressure of the orbicularis oris with the mouth closed
   b. Suction movements contracting only the buccinators (These exercises are performed with repetitions and holding position.)
   c. Recruitment of the buccinator muscle against the finger that is introduced in the oral cavity, pressing the buccinator muscle outward
   d. Alternating elevation of the mouth angle muscle
   e. Lateral jaw movements with alternating elevation of the mouth angle muscle
4. **Stomatognathic functions:**
   a. Breathing and speech: Forced nasal inspiration and oral expiration in conjunction with phonation of open vowels, while sitting; balloon inflation with prolonged nasal inspiration and then forced blowing
   b. Swallowing and chewing: Alternate bilateral chewing and deglutition, using the tongue in the palate, closed teeth, without perioral contraction, whenever feeding

A study performed in 2009[248] compared 15 control subjects with 15 matched experimental subjects, diagnosed with moderate OSA, and found statistically significant improvements after only 3 months of oropharyngeal exercises in snoring frequency, daytime sleepiness, sleep quality, and AHI levels, which reduced from 29.8 ± 12.7 to 17.4 ± 15.9 events per hour. The sample size was relatively small but shows promising results to this less invasive approach.

Other types of exercises, such as wind instrument playing and singing, have been studied in the literature and show mixed results.[250] A randomized trial with 25 subjects showed that 4 months of playing a particular wind instrument, the indigenous Australian didgeridoo, for approximately 25 minutes a day, 6 days a week, was associated with a significant reduction in snoring and daytime sleepiness. AHI reduced from a mean of 22 to 12 events per hour in the didgeridoo group, compared with a mean of 20 to 15 events per hour in the control group ($p < 0.05$).[251]

Playing the didgeridoo requires the use of circular breathing, a technique used to produce a continuous tone without break, accomplished by the use of the cheeks as a reservoir of air while breathing through the nose rather than the mouth. It has been suggested that practicing this wind instrument may train airway muscles, leading to less collapse of oropharyngeal muscles at night and resulting in its beneficial effect on OSA. Limitations of the study are a small sample size, and BMI <30. In contrast, a larger study that compared 369 orchestra wind instrument players with 736 orchestra non-wind instrument players found no significant differences between the groups. The study has some limitations, such as being an e-mail survey, lacking proper OSA diagnoses, and the presence of significantly higher BMI levels, as well as male players in the wind instrument group.[252] A more important limitation, which may welcome future studies, was the lack of sample power to stratify properly the different types of wind instruments. Special attention should be given to instruments requiring circular breathing, and this was not the objective of this particular study.

The oropharyngeal exercise option could use further studies and possibly develop into an adjunctive treatment option to the patient with OSA.

Upper Airway Electrical Neurostimulation

UA stimulation using a unilateral implantable neurostimulator for the hypoglossal nerve is a relatively novel and cutting-edge therapy for the treatment of patients with moderate to severe OSA who are intolerant to CPAP therapy. Patients with AHI >65 and/or BMI >32 are not good candidates for this therapy, attributable to a decreased likelihood of response to treatment. This therapy is also contraindicated when central and mixed apneas represent 25% or more of the AHI and when neurologic problems in the UA are due to a condition or previous procedures. The device is implanted in the chest and has a small generator, a breathing sensor lead, and a stimulation lead. The patient can turn on the therapy before bedtime and turn it off in the morning through a remote control (Fig. 12-15). When the device is activated, it senses the person's breathing patterns and delivers a mild stimulation to keep the airway open, acting in a similar fashion as a pacemaker. The hypoglossal nerve is accessed through a horizontal incision in the upper neck at the inferior border of the submandibular gland. The median time for surgical implantation has been reported as 140 minutes (65 to 360 minutes), with most patients spending the night at the hospital.[253] A clinical trial that included 126 patients showed a 68% decrease in AHI, from 29.3 events per hour to 9 events per hour, and a 70% ODI decrease, with an average reduction from 25.4 events per hour to 7.4 events per hour.[253]

Preventive Management

Morbidity is related to loss of alertness and cardiovascular complications. Patients with severe OSA, especially those with excessive sleepiness and neurocognitive impairments, have a two to seven times increased risk of having a motor vehicle accident.[254] Those at highest risk have had a fall-asleep car crash or near miss attributable to sleepiness or inattention. Therefore a health professional with expertise in the diagnosis and management of sleep apnea is expected to inform the patient of this potential risk and to suggest steps such as more sleep, timely diagnosis, and/or treatment, or avoidance of driving until the sleepiness is under better control.

Prospective studies suggest an increased risk of stroke, myocardial infarction, cardiovascular disease, and all-cause mortality.[155,156,255] Below 70 years of age, there is an increased risk for early death, although not necessarily during sleep. Other than for hypertension,[154] however, too few prospective studies have determined whether the treatment of OSA alone is sufficient to reduce risk.

IMPORTANCE OF A MULTIDISCIPLINARY APPROACH

The relationship of the UA and orthodontics is such that a teamwork approach is essential. From an orthodontist's screening to physician referral for diagnosis, monitoring throughout orthodontic treatment, airway outcomes and beyond, involvement and coordination among multiple clinicians bring forth specific responsibilities of various specialists to patient care. The concept of a *patient care team* was first introduced in 1968 by the National Institutes of Health (NIH) and has since been recognized by the World Health Organization, The Joint Commission, and the American College of Physician Executives, among others, as a means to improve patient and process outcomes, as well as patient satisfaction.[256]

The importance of this approach is demonstrated in the case of a 62-year-old male patient. A three-unit fixed bridge from #8 to #10 had been placed by a general dentist without incident, other than waxing and waning plaque accumulation around the abutment margins over 3 years before being diagnosed with OSA by a sleep medicine physician. Two years after being fitted with a CPAP device, #8 abutment began to show signs of gingival trauma at the site where the CPAP device contacted #8's facial surface. Since plaque accumulation remained in check, few changes were noticeable. As plaque accumulation waxed and waned around the #8 abutment, gingival trauma was visible as fenestration (Fig. 12-16). However, with habitual plaque accumulation and ensuing inflammation around the gingival margins, secondary trauma from the CPAP device progressed to attachment loss. Unchecked, the combination of trauma and inflammation progressed to pathologic migration of the abutment. The patient's aesthetic complaints to the orthodontist centered on "a change in my smile"; however, secondary trauma from the CPAP device resulted in attachment loss and eventual abscess (Fig. 12-17).

This case underscores the need for primary teamwork skills. Leadership is needed to coordinate between the sleep medicine physician, the dentist, and the orthodontist to ensure that the CPAP fit does not create trauma (Fig. 12-18). Since inflammation is transient, situational monitoring among the physician, dentist, and orthodontist is needed to identify plaque accumulation, gingival inflammation and trauma from the CPAP fit, and ensuing gingival changes. Communication among all specialists is needed for clear and accurate informational exchange. Four key skills—leadership, situational monitoring, mutual support, and communication—are needed among the physician, dentist, periodontist, and orthodontist.

FIGURE 12-16 **A,** Gingival trauma at the point where the CPAP device contacts lip-over-labial surface of #8 abutment. **B,** The CPAP device fits over the lip and the labial surface of teeth #8 and #9. The gingiva has developed a fenestration at the traumatized site. **C,** No clearance is found between the CPAP device and the underlying abutment #8, as evidenced by the inability for a mouth mirror to fit passively between the lip and the facial gingiva of #8. **D,** After switching to a CPAP device of different design and fit, there is ample clearance for the mouth mirror to fit between the lip and facial gingiva of #8. (Courtesy of Dr. Alan Robbins.)

FIGURE 12-17 Gingival trauma from CPAP contact points and pressure has remained for over 2 years. Attachment loss progression and evidence of purulent abscess are demonstrated. (Courtesy of Dr. Alan Robbins.)

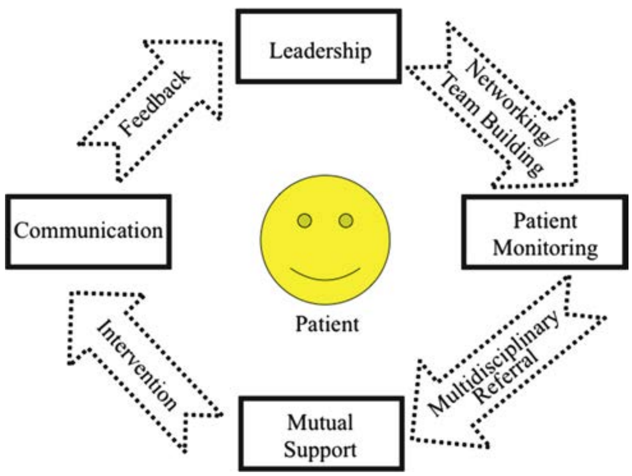

FIGURE 12-18 Teamwork flowchart.

SUMMARY AND CONCLUSIONS

The airway is an integral part of the craniofacial complex, often ignored during clinical examination and when determining the diagnosis and treatment options. Sleep disorders, most commonly OSA, affect a great portion of the adult population. Many patients go undiagnosed. In children, airway problems reportedly have detrimental effects on craniofacial growth and development. The orthodontist is strategically positioned to screen children and adults. The simple incorporation of a few questions and radiographic examination are probably sufficient to identify risks and to refer for proper diagnosis. Official diagnosis of a sleep problem through PSG is required before any treatment is rendered. Even if the orthodontist decides not to treat an airway problem, understanding the condition for the purpose of screening and referral is still an important responsibility of the orthodontist.

Acknowledgments

This chapter would not have been possible without the invaluable contributions provided by Dr. Noha Orabi, Dr. Ehab Ben Nasir, Dr. Ioannis Tsolakis, Dr. Adriano Farina, Dr. Athanasios Xofyllis, and Mrs. Cynthia McConnaughy.

Orthodontic Therapy and the Patient with Temporomandibular Disorder

Jeffrey P. Okeson

OUTLINE

INTRODUCTION

There are two main goals of orthodontic therapy. The first, and often the most important to the patient, is improving aesthetics. Although aesthetics may be the primary goal of the patient (and parent), it is certainly not the most important goal. The second goal, which is achieving sound masticatory function, is actually the most important treatment goal of orthodontic therapy. Developing a healthy, orthopedically stable masticatory system enables sound function, which is essential for the lifetime of the patient. No other dental specialist routinely alters the patient's occlusal condition as a part of the therapy. The orthodontist is in a unique position to either improve or worsen the occlusal condition while carrying out the aesthetic goals of the therapy. It therefore behooves the orthodontists to be knowledgeable of normal masticatory function and the goals that need to be achieved to maintain normal function. These goals should be met in all patients, both those with and without masticatory dysfunction.

This chapter will first discuss the principles of normal orthopedic stability in the masticatory system and define treatment goals that will help assure normal masticatory function. Next, concepts of how orthopedic instability may relate to temporomandibular disorders (TMDs) will be reviewed, and also when orthodontic therapy may influence TMD symptoms. A brief TMD history and examination will be presented so that important symptoms will be identified before orthodontic therapy is begun. Lastly, this chapter will provide some clinical considerations regarding the management of TMD symptoms that may arise during the orthodontic therapy.

THE CONCEPT OF ORTHOPEDIC STABILITY

For many years, the dental profession has debated the relationship between occlusion and TMDs. We have often concentrated on the precise contact pattern of the teeth and perhaps overlooked the more significant aspect of orthopedic stability. If occlusion is important to masticatory function, it must relate to how the occlusal contact pattern of the teeth relates to orthopedic stability of the entire masticatory system. In other words, the clinician needs to better understand sound orthopedic principles to more completely appreciate the importance of occlusion and its role on function or dysfunction of the masticatory system.

In establishing the criteria for the optimum, orthopedically stable joint position, the anatomic structures of the temporomandibular joint (TMJ) must be closely examined. The TMJ is made up of the condyle resting within the articular fossa with the articular disc interposed. The articular disc is composed of dense, fibrous connective tissue devoid of nerves and blood vessels.[1] This allows it to withstand heavy forces without damage or creating a painful stimulus. The purpose of the disc is to separate, protect, and stabilize the condyle in the mandibular fossa during functional movements. The articular disc, however, does not determine positional stability of the joint. As in any other joint, positional stability is determined by the muscles that pull across the joint and prevent separation of the articular surfaces. The directional forces of these muscles determine the optimum, orthopedically stable joint position. This is an orthopedic principle that is common to all mobile joints. It might be stated that every mobile joint has a *musculoskeletally stable (MS) position*, that being, the position stabilized by the activity of muscles that pull across it. The MS position is the most orthopedically stable position for the joint and can be identified by observing the directional forces applied by the stabilizing muscles.

The major muscles that stabilize the TMJs are the elevators. The direction of the force placed on the condyles by the temporalis muscles is predominantly in a superior. The temporalis muscles have some fibers that are oriented horizontally; however, because these fibers must transverse around the root of the zygomatic arch, the majority of fibers elevate the condyles in a straight superior direction (Fig. 13-1, *A*).[2] The masseter and medial pterygoid muscles provide forces in a superoanterior direction, which seats the condyles superiorly and anteriorly against the posterior slopes of the articular eminences (Fig. 13-1, *B*). These three muscle groups are primarily responsible

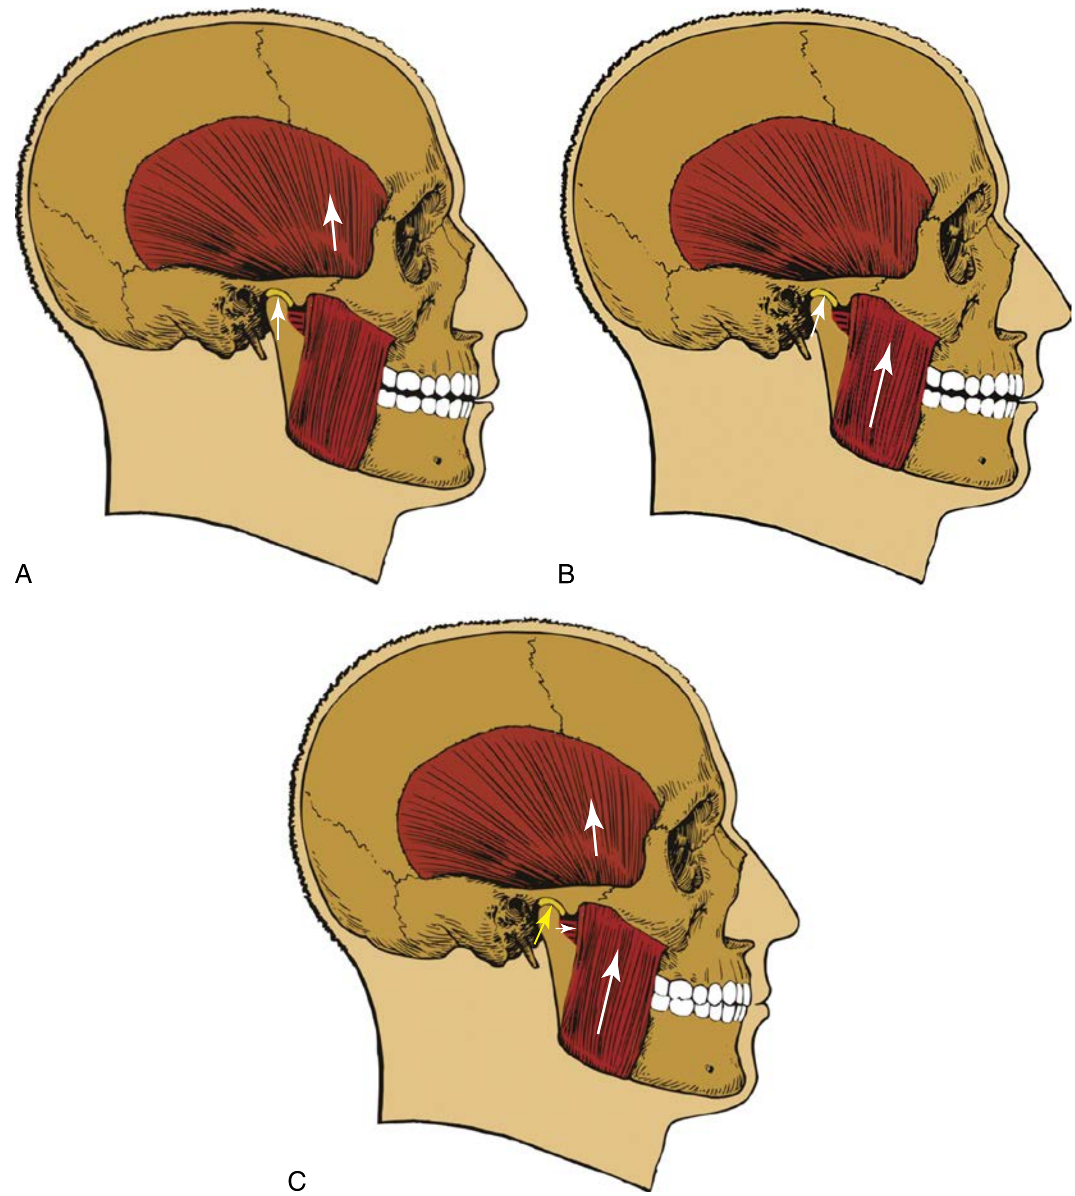

FIGURE 13-1 A, The directional forces applied to the condyles by the temporal muscles are to seat the condyles in a superior position in the fossae (*white arrow*). B, The directional forces applied to the condyles by the masseter and medial pterygoid muscles are to seat the condyles in a superior–anterior position in the fossae (*white arrow*). C, When these forces are combined with the lateral pterygoid muscle (note shown), the condyles are seated into their superoanterior position in the fossae against the posterior slopes of the articular eminences.

for joint position and stability; however, the lateral pterygoid muscles also contribute to joint stability by stabilizing the condyles against the posterior slopes of the articular eminences (Fig. 13-1, *C*).

In the postural position, without any influence from the occlusal condition, the condyles are stabilized by muscle tonus of the elevator and the inferior lateral-pterygoid muscles. The temporalis muscles position the condyles superiorly in the fossae. The masseter and medial pterygoid muscles position the condyles superoanteriorly. Tonus in the inferior lateral pterygoid muscles positions the condyles anteriorly against the posterior slopes of the articular eminences.

Therefore, the most orthopedically stable joint position as dictated by the muscles is described to be when the condyles are located in their most superoanterior position in the articular fossae, resting against the posterior slopes of the articular eminences. This description is not complete, however, until the positions of the articular discs are considered. Optimum joint relationship is achieved only when the articular discs are properly interposed between the condyles and the articular fossae. Therefore, the complete definition of the most orthopedically stable joint position is that position when the condyles are in their most superoanterior position in the articular fossae, resting against the posterior slopes of the articular eminences, with the articular discs properly interposed. This position is the *most MS position* of the mandible.

The most orthopedically stable position just described does not consider the stabilizing effects of the structures at the other end of the mandible, namely the teeth. The occlusal contact pattern of the teeth also influences stability of the masticatory system. It is important that when the condyles are in their most stable position in the fossae and the mouth is closed, the teeth occlude in their most stable relationship. The most stable occlusal position is the maximal intercuspation of the teeth. This type of occlusal relationship furnishes maximum stability for the mandible while minimizing the amount of force placed on each tooth during function.

In summary, the criteria for optimum orthopedic stability in the masticatory system would be to have even and simultaneous contact of all possible teeth when the mandibular condyles are in their most superoanterior position, resting against the posterior slopes of the articular eminences, with the discs properly interposed. In other words, the MS position of the condyles coincides with the maximum intercuspal position of the teeth.

One additional consideration in describing the occlusal condition is the fact that the mandible has the ability to move eccentrically, resulting in tooth contacts. These lateral excursions allow horizontal forces to be applied to the teeth, and horizontal forces are not generally well accepted by the dental supportive structures; yet the complexity of the joints requires that some teeth bear the burden of these less-tolerated forces. When all the teeth are examined, it becomes apparent that the anterior teeth are better candidates to accept these horizontal forces than posterior teeth because they are further from the force vectors, which results in less force to these teeth. Of all the anterior teeth, the canines are the best suited to accept the horizontal forces that occur during eccentric movements.[3-5] They have the longest and largest roots and therefore the best crown/root ratio.[6] They are also surrounded by dense, compact bone, which tolerates the forces better than does the medullary bone found around posterior teeth.[7]

The laterotrusive contacts need to provide adequate guidance to immediately disocclude the teeth on the opposite side of the arch (mediotrusive or nonworking side). When the mandible moves forward into protrusive contact, the anterior teeth should also provide adequate contact or guidance to disarticulate the posterior teeth.

The following is a summary of the conditions that provide optimum orthopedic stability in the masticatory system. This represents the orthodontic treatment goals for all patients.

1. When the mouth closes, the condyles should be in their most superoanterior position (MS), resting on the posterior slopes of the articular eminences with the discs properly interposed. In this position, there should be even and simultaneous contact of all posterior teeth. The anterior teeth may also contact, but more lightly than the posterior teeth.
2. When the mandible moves into laterotrusive positions, there should be adequate tooth-guided contacts on the laterotrusive (working) side to immediately disocclude the mediotrusive (nonworking) side. The canines (canine guidance) provide the most desirable guidance.
3. When the mandible moves into a protrusive position, there should be adequate tooth-guided contacts on the anterior teeth to immediately disocclude all posterior teeth.
4. When the patient sits upright (in the alert feeding position)[8] and is asked to bring the posterior teeth into contact, the posterior tooth contacts should be heavier than anterior tooth contacts.

FINDING THE MUSCULOSKELETAL STABLE POSITION

Now that the orthopedic treatment goals for all orthodontic therapy have been described, the next question that needs to be asked is, "How can I locate the MS position of the condyles in the fossae?" In order for these treatment goals to be useful, the clinician must be able to repeatedly and reliably locate this treatment position. An easy and effective method of locating the MS position is the bilateral manual-manipulation technique.[9,10] This technique begins with the patient lying back and the chin pointed upward (Fig. 13-2, *A*). Lifting the chin upward places the head in an easier position to locate the condyles near the MS position. The dentist sits behind the patient and places the four fingers of each hand on the lower border of the mandible at the angle. The small finger should be behind the angle with the remaining fingers on the inferior border of the mandible. It is important that the fingers be located on the bone and not in the soft tissues of the neck (Fig. 13-2, *B*). Next, both thumbs are placed over the symphysis of the chin so they touch each other between the patient's lower lip and chin (Fig. 13-2, *C*). When the hands are in this position, the mandible is guided by upward force placed on its lower border and angle with the fingers while at the same time the thumbs press downward and backward on the chin. The overall force on the mandible is directed so the condyles will be seated in their most superoanterior position braced against the posterior slopes of the eminences (Fig. 13-2, *D*). Firm but gentle force is needed to guide the mandible so as not to elicit any protective reflexes.

Locating the MS position begins with the anterior teeth no more than 10 mm apart to ensure that the temporomandibular ligaments have not forced translation of the condyles. The mandible is positioned with a gentle arcing until it freely rotates around the MS position. This arcing consists of short movements of 2 to 4 mm. Once the mandible is rotating around the musculoskeletally stable position, force is firmly applied by the fingers to seat the condyles in their most superoanterior position.

In this superoanterior position, the condyle–disc complexes are in proper relation to accept forces. When such a relationship exists, guiding the mandible to this position should not produce pain. If pain is elicited, it is possible that some type of intracapsular disorder exists. When a pain condition exists, an accurate mandibular position will not likely be found. Therefore, the reason for this pain needs to be investigated and managed before any orthodontic therapy is begun.

Another method of finding the MS position is by using the muscles themselves to seat the condyles. This can be accomplished with a leaf gauge (Fig. 13-3, *A* and *B*).[10,11] The concept behind a leaf gauge is that when only the anterior teeth occlude (disengaging the posterior teeth), the directional force provided by the elevator muscles (temporalis, masseter, medial pterygoid) seats the condyles in a superoanterior position within the fossae. The anterior stop provided by the leaf gauge acts as a fulcrum, allowing the condyles to be pivoted to the MS position in the fossae. A leaf gauge must be used carefully, however, so the condyle will not be deflected away from the stable joint position. If the leaf gauge is too rigid, it may provide a posterior slope, deflecting the mandible posteriorly as the elevator muscles contract. Another error may result if the patient attempts to bite on the leaf

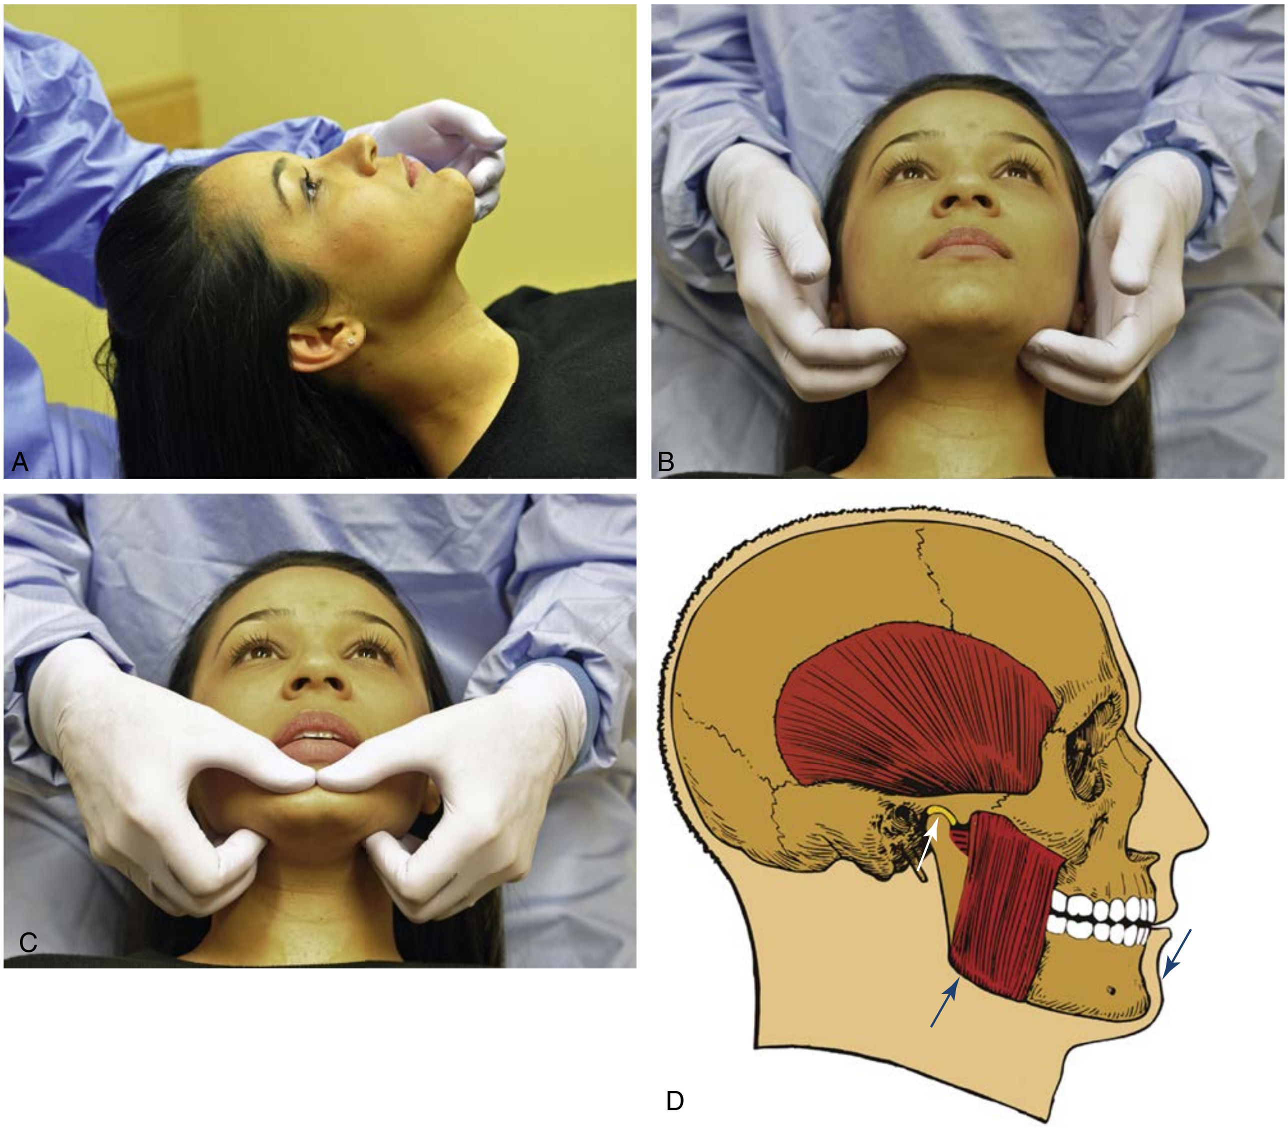

FIGURE 13-2 A, Successfully guiding the mandible into the musculoskeletally-stable position begins with having the patient recline and directing the chin upward. B, The four fingers of each hand are placed along the lower border of the mandible. The small finger should be behind the angle, with the remaining fingers on the inferior border of the mandible. An important point is to place the fingers on the bone and not in the soft tissues of the neck. C, The thumbs meet over the symphysis of the chin. D, Downward force is applied to the chin (*blue arrow*) while superior force is applied to the angle of the mandible (*blue arrow*). The overall affect is to set the condyle superoanterior in the fossae (*white arrow*).

gauge in a slightly forward position, as if to bite off a sandwich. This will lead to protruding the mandible from the MS position.

For effective use of the leaf gauge, the patient must attempt to close down on the posterior teeth with mild force. Enough leaves are placed between the anterior teeth to separate the posterior teeth slightly. The patient is instructed to close by trying to use only the temporalis muscles, avoiding any heavy masseter contraction. At first this is a difficult request; however, by having the patient place two fingers over these muscles, the examiner can demonstrate how they feel when contracting. The patient will quickly learn to contract the temporalis muscles predominantly, which will minimize protrusive forces. Once this has been mastered, the leaves are removed one by one until the teeth become closer, and therefore so that the occlusal relationship can be evaluated in the MS position.

Before beginning any orthodontic therapy, the orthodontist should feel confident that the MS position has been located. Nothing is worse than completing the orthodontic therapy only to learn that the patient was habitually posturing the jaw in a forward position, and that a duel bite has been developed. This condition does not occur often, but being suspicious that it can will help assure that it does not. If the operator feels unsure in locating the stable mandibular position, orthodontic therapy should be delayed until certainty is established.

Still another condition that should raise suspicion is the presence of a unilateral cross-bite. Patients with a unilateral cross-bite often shift the mandible to one side during final tooth contact.

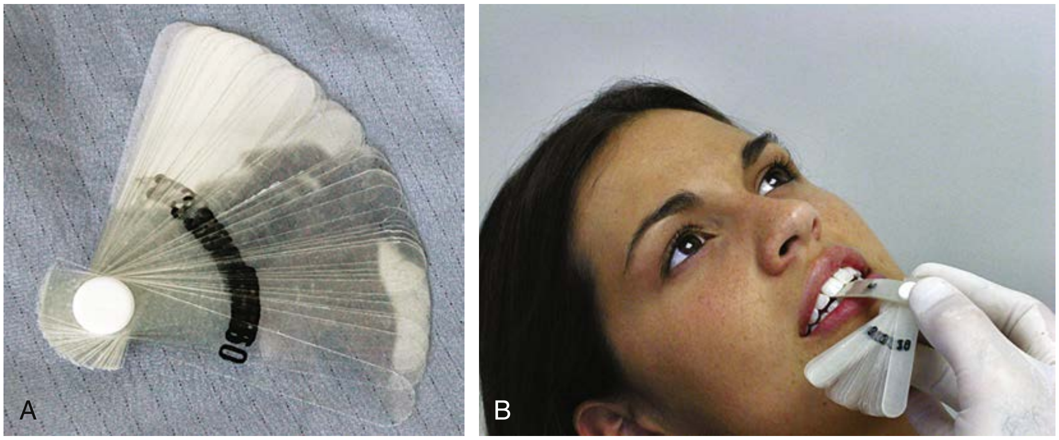

FIGURE 13-3 A, A leaf gauge. B, A leaf gauge may be used to assist in locating the musculoskeletally stable position. The patient is asked to close, and enough leaves are placed between the anterior teeth to separate the posterior teeth slightly. As the patient is asked to close on the posterior teeth, the condyles will be seated to their musculoskeletally stable position. Care should be taken to ensure that the patient does not protrude the mandible while closing and that the leaf gauge doses not exert a retruding force on the condyles. Once the position has been located, the leaves are removed one at a time so that the initial contact in the musculoskeletally stable position can be identified.

This shifting may prevent a condyle from being maintained in a stable position in the fossa. The orthodontist should observe the patient, while the mouth is being closed, for any deviations or deflections as the teeth reach intercuspation. In cases when the shift is great, tomography may be useful in identifying the position of the condyle in the fossa. However, it should be noted that tomograms have limited use in identifying condylar position unless gross positioning abnormalities exist. The reason for this is because tomography, as with any radiograph, only images subarticular bone and not the soft tissues, which are the true articular surfaces of the joint. Since these tissues can vary in thickness, the condylar position may not appear to be seated, when in reality it is in a MS position. Transcranial and panoramic radiographs are even less reliable for identifying the condylar position in the fossa.

As previously stated, being suspicious that a condyle may not be fully seated is the beginning of developing a successful treatment plan. If the operator has any doubt regarding the location of the MS position, a stabilization appliance should be fabricated until a stable and reproducible condylar position is found.

Once the MS position has been reliably located, the relationship of the maxillary and mandibular teeth is observed in this mandibular position. Since the orthodontic treatment goal is to develop the maximum intercuspal position of the teeth in this mandibular position, the orthodontist needs to develop the correct orthodontic strategies that will accomplish this goal. In some instances, the orthodontist may find it useful to mount the patient's casts on an articulator to better visualize the occlusal relationship. This may be especially helpful when a significant intra-arch discrepancy exists. This author does not believe it is necessary to mount every orthodontic case on an articulator. In most growing patients, the orthodontic therapy will likely be completed before final maturation of the condyle/fossae relationship. It is important that the orthodontist always be aware of the MS position of the condyles, and finalize the occlusion in relationship to this position. However, final precision of the position is likely accomplished by the physiology of form and function as the young adult matures. In other words, the orthodontist needs to provide an occlusal condition that is within the physiologic tolerance or adaptability of the patient. In a growing patient, it would be reasonable to assume that this is within a millimeter or two of the MS position of the joint. Once the orthodontic therapy is finalized, the patient's individual loading during function will normally assist in stabilizing the masticatory system. The only point in question is, "How adaptable are the patient's masticatory structures?" Of course this is unknown, and therefore the orthodontist needs to always strive toward developing the occlusal position as close to the MS position as possible. In difficult cases, the articulator may be useful in achieving this goal. However, it should always be remembered that an articulator is merely a tool that may assist in achieving your goal, not a magical instrument that will assure success.

In adult patients, it more important to precisely develop the orthopedically stable position since growth is less likely and adaptability may be less. The articulator may be of greater assistance in these cases, but once again, articulators are not always needed. The clinician needs to assess the dental relationship and then determine if an articulator will assist in accomplishing the treatment goals. Remember that the articulator is only as accurate as the operator who takes the records and mounts the casts.

EVALUATING THE PATIENT FOR TEMPOROMANDIBULAR DISORDERS

Since TMD symptoms are common, it is recommended that every orthodontic patient be screened for these problems, regardless of the apparent need or lack of need for treatment. Since orthodontic therapy will likely influence the patient's occlusal condition, it is important to identify any dysfunction in the masticatory system before therapy is ever begun. Knowing the functional condition of the masticatory system in advance helps prepare the patient and the orthodontist to what can be expected after the therapy has been completed. This

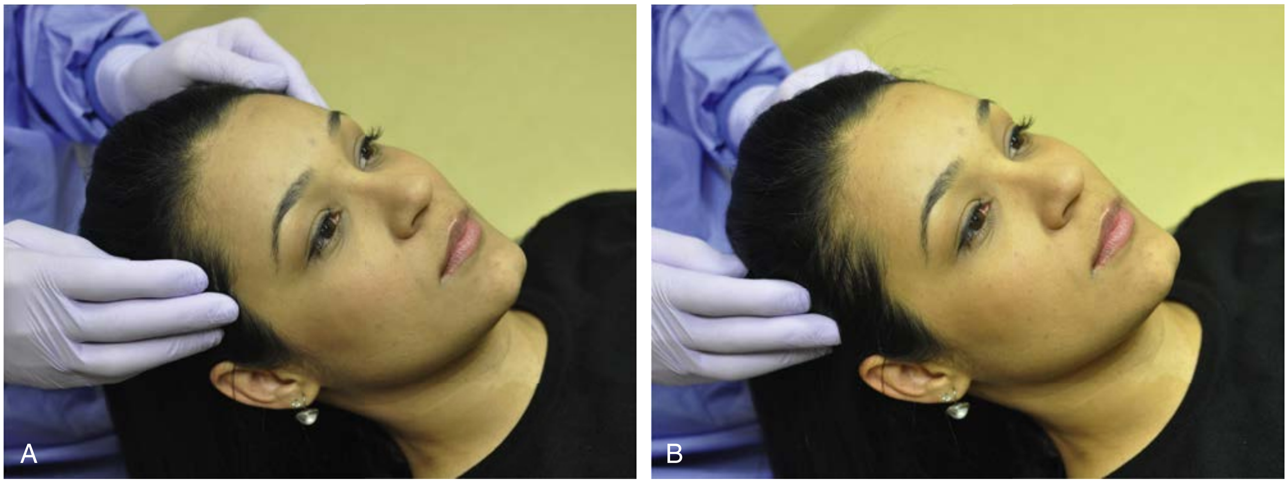

FIGURE 13-4 A, Palpation of the anterior portion of the temporalis muscle. B, Palpation of the posterior portion of the temporalis muscle.

information also helps develop the most appropriate treatment plan that will minimize dysfunction in future years. Nothing is more disheartening to the orthodontist than to be in the middle of orthodontic therapy and have the patient report that a preexisting TMD symptom was a result of the orthodontic therapy. It greatly behooves the orthodontist to be aware of all conditions in the masticatory system *before* any therapy is begun.

A TMD Screen History

The purpose of the screening history and examination is to identify any TMD signs and symptoms of which the patient may or may not be aware (i.e., headaches, ear pain). The screening history consists of several questions that will help alert the orthodontist to any TM disorder symptoms. These can be asked personally by the clinician or may be included in the general health and dental questionnaire that the patient completes prior to developing the treatment plan. The following questions can be used to identify functional disturbances.[12]

1. Do you have difficulty and/or pain opening your mouth, for instance, when yawning?
2. Does your jaw get "stuck, locked, or go out"?
3. Do you have difficulty and/or pain when chewing, talking, or using your jaws?
4. Are you aware of noises in the jaw joints?
5. Do your jaws regularly feel stiff, tight, or tired?
6. Do you have pain in or about the ears, temples, or cheeks?
7. Do you have frequent headaches, neck aches, or toothaches?
8. Have you had a recent injury to your head, neck, or jaw?
9. Have you been aware of any recent changes in your bite?
10. Have you previously been treated for any unexplained facial pain or a jaw joint problem?

If a patient reports positively to any of these questions, the clinician should request additional information to clarify the condition.

A TMD Screen Examination

A screening examination should accompany the screening history.[12] This should be relatively brief and is an attempt to identify any variation from normal anatomy and function. It begins with an inspection of the facial symmetry. Any variation from the general bilateral symmetry should raise suspicion and indicate the need for further examination. The screening examination should include the palpation of facial muscle, and the TMJs as well as observations of jaw movement. The occlusal condition should also be evaluated with respect to the orthopedically stable position of the joint.

Muscle Palpation

Several important muscles of the masticatory system are palpated for pain or tenderness during the screening examination. The temporalis (Fig. 13-4, *A* and *B*) and masseter muscles (Fig. 13-5, *A* and *B*) are palpated bilaterally. Palpation of the muscle is accomplished mainly by the palmar surface of the middle finger, with the index finger and forefinger testing the adjacent areas. Soft but firm pressure is applied to the designated muscles, the fingers compressing the adjacent tissues in a small circular motion. A single firm thrust of 1 or 2 seconds duration is usually better than several light thrusts. During palpation, the patient is asked whether it hurts or is just uncomfortable.

For the muscle examination to be most helpful, the degree of discomfort is ascertained and recorded. This is often a difficult task. Pain is subjective and is perceived and expressed quite differently from patient to patient. Yet the degree of discomfort in the structure can be important to recognizing the patient's pain problem as well as an excellent method of evaluating treatment effects. An attempt is made, therefore, not only to identify the affected muscles, but also to classify the degree of pain in each. When a muscle is palpated, the patient's response is placed in one of four categories.[13,14] A zero (0) is recorded when the muscle is palpated and there is no pain or tenderness reported by the patient. A number 1 is recorded if the patient responds that the palpation is uncomfortable (tenderness or soreness). A number 2 is recorded if the patient experiences definite discomfort or pain. A number 3 is recorded if the patient shows evasive action, eye tearing, or verbalizes a desire not to have the area palpated again. The pain or tenderness of each muscle is recorded on an examination form, which will assist diagnosis and later be used in the evaluation and assessment of progress.

Temporomandibular Joint Palpation

The TMJs are examined for any signs or symptoms associated with pain and dysfunction. Pain or tenderness of the TMJs is determined by digital palpation of the joints when the mandible is both stationary and during dynamic movement. The

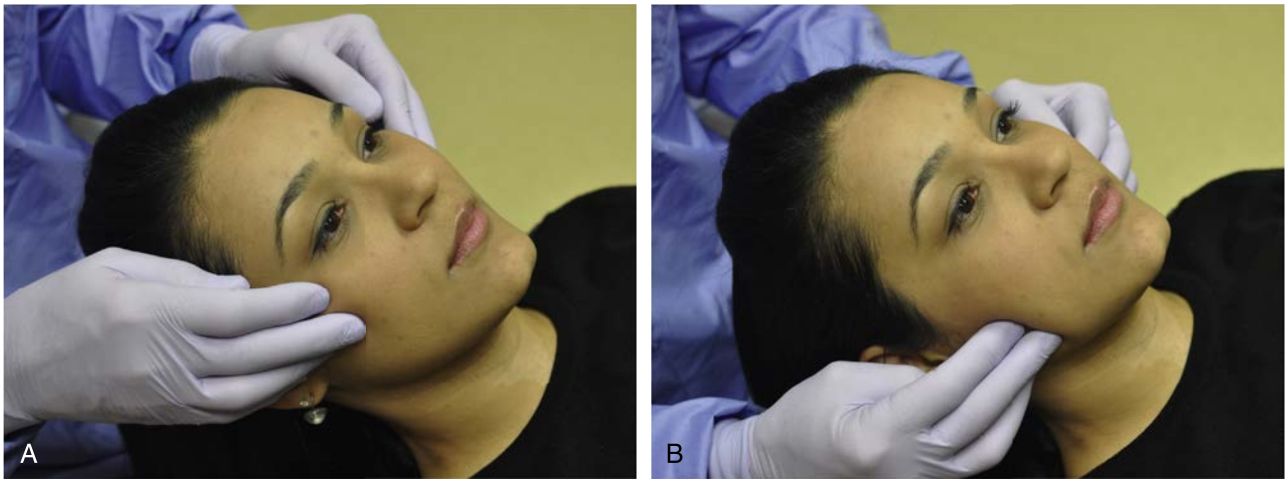

FIGURE 13-5 **A,** Palpation of the masseter muscle at the superior attachment to the zygomatic arch. **B,** Palpation of the masseter muscle at its attachment of the lower border of the mandible.

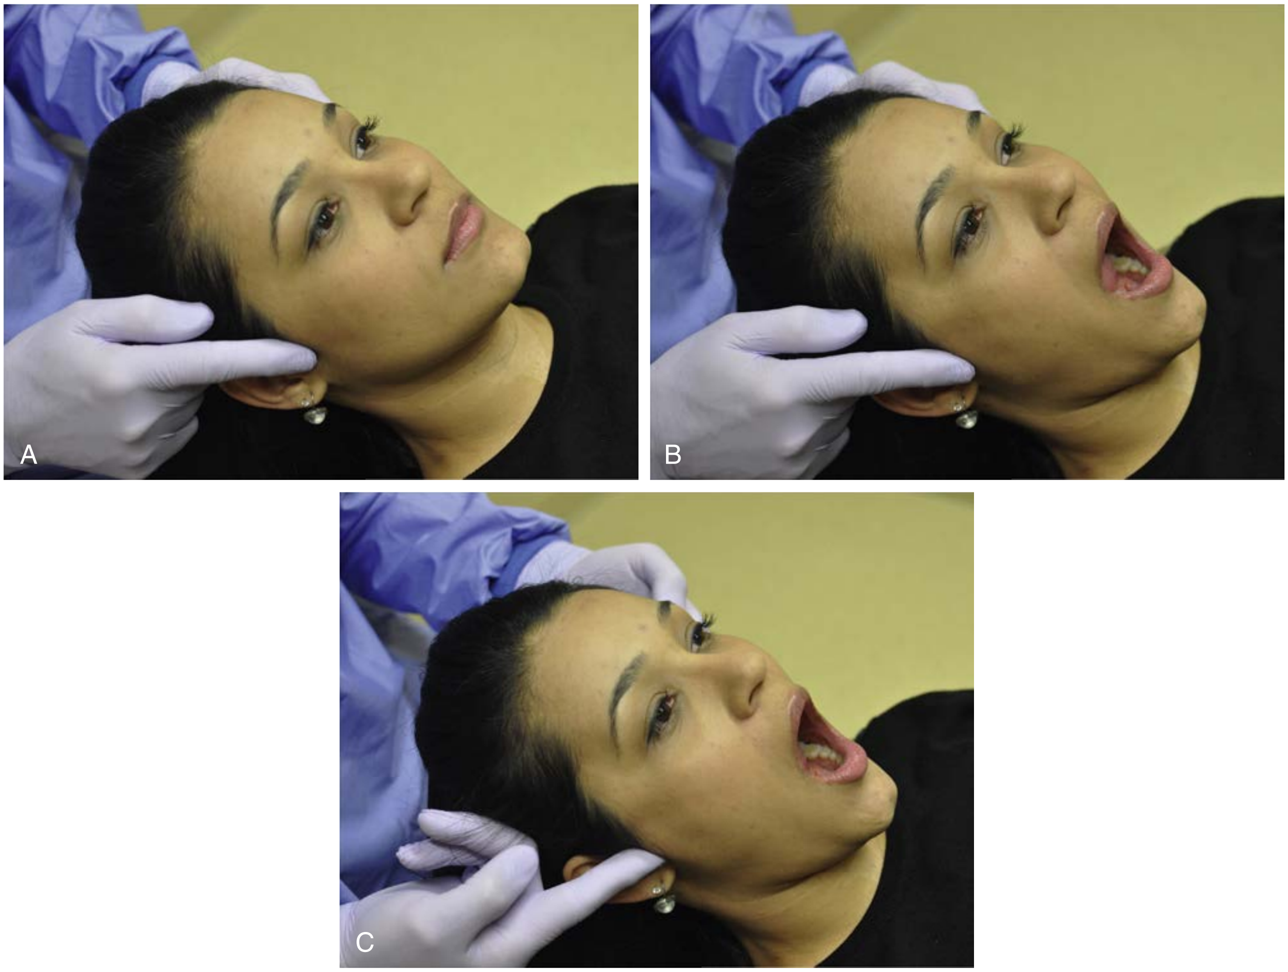

FIGURE 13-6 **A,** Palpation of the temporomandibular joint in the closed-mouth position. **B,** Palpation of the temporomandibular joint in the opened-mouth position. **C,** Palpation of temporomandibular joint with the mouth fully open. The finger is moved behind the condyle to palpate the posterior aspect of the joint.

fingertips are placed over the lateral aspects of both joint areas simultaneously (Fig. 13-6, *A*). If uncertainty exists regarding the proper position of the fingers, the patient is asked to open and close a few times. The fingertips should feel the lateral poles of the condyles passing downward and forward across the articular eminences. Once the position of the fingers over the joints has been verified, the patient relaxes and medial force is applied to the joint areas. The patient is asked to report any symptoms and they are recorded with the same numerical code that is used for the muscles. Once the symptoms are

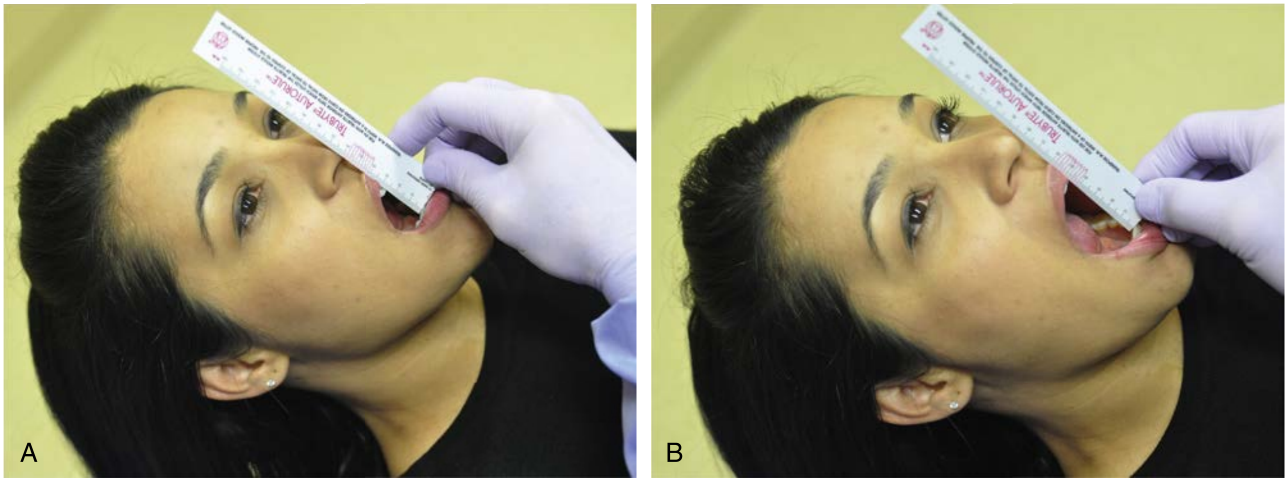

FIGURE 13-7 Measuring mouth opening. **A,** The patient is asked to open the mouth until pain is first felt. The interincisal distance is measured, which is called the maximum comfortable opening. **B,** The patient is then ask to open as wide as possible, even if this is painful. This measurement is called the maximum mouth opening.

recorded in a static position, the patient opens and closes, and any symptoms associated with this movement are recorded (Fig. 13-6, *B*). As the patient opens maximally, the fingers should be rotated slightly posteriorly to apply force to the posterior aspect of the condyle (Fig. 13-6, *C*). Posterior capsulitis and retrodiscitis are clinically evaluated in this manner.

Joint sounds are recorded as either clicks or crepitation. A click is a single sound of short duration. If it is relatively loud, it is sometimes referred to as a pop. Crepitation is a multiple, gravel-like sound described as "grating" and "complicated." Crepitation is most commonly associated with osteoarthritic changes of the articular surfaces of the joint.[15-18]

Joint sounds can be perceived by placing the fingertips over the lateral surfaces of the joint and having the patient open and close. Often they may be felt by the fingertips. A more careful examination can be performed by placing a stethoscope over the joint area. Not only should the character of any joint sounds be recorded (clicking or crepitation), but also the degree of mouth opening associated with the sound. Of equal importance is whether the sound occurs during opening or closing or can be heard during both these movements.

It is not wise to examine the joint for sounds by placing the fingers in the patient's ears. It has been demonstrated that this technique can actually produce joint sounds that are not present during normal function of the joint.[19] It is thought that this technique forces the ear canal cartilage against the posterior aspect of the joint; either this tissue produces sounds or this force displaces the disc, which produces the additional sounds.

Range of Mandibular Movement

A screening examination should also include evaluation of the patient's range of mandibular movement. The normal range[20-22] of mouth opening when measured interincisally is between 53 and 58 mm. Even a 6-year-old child can normally open a maximum 40 mm or more.[23,24] The patient is asked to open slowly until pain is first felt (Fig. 13-7, *A*). At that point, the distance between the incisal edges of the maxillary and mandibular anterior teeth is measured. This is the maximum comfortable opening. The patient is next asked to open the mouth maximally. This is recorded as the maximum opening (Fig. 13-7, *B*). In the absence of pain, the maximum comfortable opening and maximum opening are the same.

A restricted mouth-opening is considered to be any distance less than 40 mm. Only 1.2% of young adults[23] open less than 40 mm. Less than 40 mm of mouth opening, therefore, seems to represent a reasonable point to designate restriction; however, one should always consider the patient's age and body size.

The patient is next instructed to move his mandible laterally. A lateral movement less than 8 mm is recorded as a restricted movement (Fig. 13-8). Protrusive movement is also evaluated in a similar manner.

FIGURE 13-8 Measuring the distance of lateral eccentric movement using a millimeter ruler.

Occlusal Evaluation

The occlusal examination[12] begins with an observation of the occlusal contacts when the condyles are in their optimum orthopedic position (MS position). As already described, this position is located by using a bilateral manual manipulation technique. In this position the mandible can be purely rotated, opened, and closed approximately 20 mm interincisally while the condyles remain in their MS position. Once the MS position is located, the mandible is brought into tooth contact and the occlusal relationship of the teeth in this joint position is evaluated. Once tooth contact is achieved, the patient is asked to hold the mandible on the first occlusal contact and the relationship of the maxillary and mandibular teeth is noted. Then the patient is requested to apply force to the teeth, and any shifting of the mandible is observed. If the occlusion is not stable in the MS position, a shifting will occur that carries the condyles away from their orthopedically stable positions to the more stable maximum-intercuspal position. This shifting represents a lack of orthopedic stability.

It is important to observe the horizontal and vertical components of the slide. Some slides occur in a straight, anterosuperior direction into intercuspal position. Others have a lateral component. It has been reported[25,26] that slides that deflect the mandible to the left or right are more commonly associated with dysfunction than are slides that create a straight, anterovertical movement. The distance of the slide is also important in that slides greater than 3 to 4 mm have been associated with increased incidence of TMD symptoms. Conversely, slides of 1 to 2 mm or less, which are very common, do not seem to be related to TMD symptoms. If the patient is asked to apply force to the teeth and no shift occurs, the intercuspal position is said to be coincident with MS position.

If the screening history and examination reveal positive findings, a more thorough history and examination for TM disorders is completed. A thorough TMD examination can be found in other sources.[12]

The clinical significance of joint sounds. Joint sounds most commonly occur as a result of disc displacements.[10] When the disc is displaced during mouth opening, an abnormal translatory movement can occur between the condyle and the disc, causing a clicking sound. Although disc displacements are considered abnormal, they are certainly not uncommon. The published prevalence of disc displacement in asymptomatic children and young adults is approximately 30%.[27] Recent studies suggest that a majority of adolescent preorthodontic patients, regardless of gender, present with some disc displacement.[28,29] The question that needs to be asked is, "Does the click represent pathology?" Often clicks occur in the absence of any pain or signs of progression. In a very interesting study by Magnusson et al.,[30] joint sounds were recorded in a 15-year-old population and then again in the same population at age 20. Of the 35 subjects who had sounds at age 15, 16 (or 46%) no longer had them at age 20. None of these subjects was provided any treatment. It was also interesting to note in this study that of the 38 15-year-olds who did not have joint sounds, 19 (or 50%) did have joint sounds at age 20. These data suggest that a 15-year-old with TMJ sounds has a 46% chance the sound will resolve without treatment by the age of 20. The study also suggests, however, that if a 15-year-old does not have TMJ sounds, there is a 50% chance he or she will acquire a sound by age 20. The authors concluded that joint sounds come and go and are often unrelated to major masticatory symptoms. Ten- and twenty-year follow-up examinations of this same population continue to reveal the lack of a significant relationship between joint sounds and pain or dysfunction.[31,32]

In a similar study, Kononen et al.[33] observed 128 young adults longitudinally over 9 years at ages 14, 15, 18, and 23 years. They reported that although clicking did increase significantly with age from 11% to 34%, there was no predictable pattern, and only 2% of subjects showed consistent findings during the periods of evaluation. They found no relationship between clicking and the progression to locking.

A significant long-term study by de Leeuw et al.[34] found that 30 years after nonsurgical management of intracapsular disorders, joint sounds persisted in 54% of the patients. Although these findings reveal that joint sounds remain in many patients, it is important to note that none of these patients was experiencing any discomfort or even dysfunction from their joint condition. This study, like the others referenced here, suggest that joint sounds are often not associated with pain or even major TM joint dysfunction. This research group[35,36] also found that long-term osseous changes in the condyle were commonly associated with disc dislocation without reduction and not so commonly associated with disc dislocation with reduction. Yet even in the patients with significant alterations in condylar morphology (osteoarthrosis), little pain and dysfunction were noted.

Studies such as these suggest that joint sounds are not always progressive and therefore may not need to be treated. Several studies[33,37-41] report that progression of intracapsular disorders as determined by joint sounds only occurs in 7% to 9% of the patients with sounds. One study suggests, however, that if the disc derangement disorder results in significant catching or locking, the chances that the disorder will progress is much greater.[42]

The long-term studies certainly suggest that joint sounds are not necessarily a significant problem for most patients. However the majority of these studies have evaluated adult populations. What about a young adult who will be undergoing significant occlusal changes with orthodontic treatment? This may pose a different question for the orthodontist. Certainly the orthodontist who is trying to achieve orthopedic stability in the masticatory structures needs to be able to assess the status of the TMJs prior to treatment.

Animal studies demonstrate if a disc displacement is surgically induced, histologic changes are observed in the condylar cartilage.[43] In this study, the investigators also noted that the condylar cartilage on the contralateral control side was also affected, though to a lesser degree. In studies conducted by Legrell et al., surgically induced unilateral disc displacement without reduction in animal models resulted in developmental facial asymmetry. Animals subjected to bilateral disc displacement developed Angle Class II relationship.[44] These results demonstrate that alterations in the disc position can influence three-dimensional growth patterns of the condyle. Similarly, experimentally induced disc displacements without reduction in growing animals have been shown to actually hinder mandibular growth relative to controls. The negative effects were greater on anterior and superior growth of the mandible while posterior growth was relatively unaffected.[45] According to A. Björk, bone apposition on the posterior aspect of the condyle causes clockwise rotation of the mandible, resulting in a receded chin and an open bite, which would be an unfavorable situation for orthodontic treatment.[46]

Although these experimental studies suggest that disc displacements can lead to condylar changes, the question remains, on a clinical level, how often this occurs in the young adult. This question is very important but very difficult to determine. The musculoskeletal system is very adaptive, especially in this young population. It is very likely that the individual with a disc displacement will adapt to this change and show very little clinical consequence. However, this may not be true for every patient. Therefore it is very important for the orthodontist to evaluate the health of the TMJs prior to any treatment. As a general rule, individuals who are having a problem with adaption have greater degree of pain and dysfunction. Therefore, if the history and examination reveal any pain or significant dysfunction, more investigation is indicated.

If the examination determines the presence of pain or significant dysfunction, additional information may be needed. Images such as cone beam CT or MRIs may be able to provide more information. Cone beam CT three-dimensionally visualizes morphologic alterations in bony structures, degenerative changes, and to some degree the position of the condylar within the fossa.[47] MRIs can identify disc displacement and its degree, location, and direction. MRIs can also detect certain disc conditions such as hypertrophy, and T2-weighted images visualize joint effusion. These data may be useful in understanding the health of these tissues. The interpretation of diagnostic images will be described later in detail through a clinical case.

For patients who exhibit TMD symptoms, abnormality in images, unstable jaw position, and/or facial asymmetry, the orthodontist should consider resolving the TMD symptoms and stabilizing the joint position before any orthodontic therapy is begun. A stabilization appliance may be useful in reducing the TMD symptoms. With this appliance, the causal relationship between the patient's occlusion and TMD symptoms can be better appreciated (as will be discussed later in this chapter). Improvement in soft and hard tissues of the TMJs can also be expected during the occlusal appliance therapy, providing a repeatable and stable jaw position. With a stabilized joint, the orthodontist can develop a treatment plan that will provide optimum occlusal contacts in this position (orthopedic stability).

DEVELOPING THE ORTHODONTIC/TMD TREATMENT PLAN

All potential orthodontic patients should be evaluated for both their aesthetic needs as well as for their functional needs. Once the history and examination data are collected, this information is used to develop a treatment plan that will appropriately meet the overall needs of the patient. When considering the possibilities, the patient can have only aesthetic needs, only TMD needs, or both aesthetic and TMD needs. The type of needs determines the treatment sequence. When the patient has only aesthetic needs, the clinician need only consider the best therapy to fulfill the orthodontic goals. Included with these goals, of course, is not only the best mechanics to move teeth, but also the goals of achieving orthopedic stability, which have already been presented in this chapter.

When a patient presents with only TMD symptoms the clinician should not assume that orthodontic therapy would be a part of the treatment plan. Orthodontic therapy is only indicated for TMD patients when it has been determined that orthopedic instability is present and this instability is contributing to the TM disorder. The mere presence of orthopedic instability is not enough evidence to be certain that it is contributing to the TM disorder. Many individuals have orthopedic instability without any functional complaints or complications. Therefore, when TMD symptoms are present, the clinician should first attempt to determine if the orthopedic instability is contributing to the TM disorder. The best way to identify this relationship is by first providing orthopedic stability reversibly with an occlusal appliance. If the occlusal appliance adequately provides the desirable stability but does not reduce the TMD symptoms it can be assumed that orthopedic stability is not related to the symptoms and orthodontic therapy should not be considered for this patient. It is important to remember that orthodontic therapy can only affect TMD symptoms by changing the occlusal contact pattern of the teeth and the resulting function of the masticatory system (improved orthopedic stability).

If an occlusal appliance successfully reduces the TMD symptoms, the clinician often assumes that the occlusion and its relationship to orthopedic instability are etiologic factors in the TM disorder. Although this may be true, it makes an assumption that the only manner in which an occlusal appliance affects TMD symptoms is by altering the patient's occlusion. This is a very naive assumption. In fact there are several factors that may explain how occlusal appliances reduce symptoms associated with TM disorders. Consider the following factors:

1. *Alteration of the occlusal condition*: All occlusal appliances temporarily alter the existing occlusal condition. A change, especially toward a more stable and optimum condition, generally decreases protective muscle co-contraction, leading to a reduction of symptoms.
2. *Alteration of the condylar position*: Most appliances alter condylar position to either a more MS or a more structurally compatible and functional position. This effect on the joint stability can be responsible for a decrease in symptoms.
3. *Increase in the vertical dimension*: All interocclusal appliances increase the patient's vertical dimension while they are being worn. This effect is universal regardless of treatment goals. It has been demonstrated that increases in vertical dimension can temporarily decrease muscle activity[48-50] and symptoms.[51-53]
4. *Cognitive awareness*: Patients who wear occlusal appliances become more aware of their functional and parafunctional behavior. The appliance acts as a constant reminder to alter activities that may affect the disorder. As cognitive awareness is increased, factors that contribute to the disorder are decreased. The result is a decrease in symptoms.[54-56]
5. *Placebo effect*: As with any treatment, a placebo effect can result.[57,58] Studies[59-62] suggest that up to 40% of the patients suffering from certain TM disorders respond favorably to such treatment. A positive placebo effect may result from the competent and reassuring manner in which the doctor approaches the patient and provides the therapy. This favorable doctor–patient relationship, accompanied by an explanation of the problem and reassurance that the appliance will be effective, often leads to a decrease in the negative emotional state of the patient, which may be the significant factor responsible for the placebo effect.
6. *Increased peripheral input to the CNS*: Evidence suggests that nocturnal muscle hyperactivity appears to have its source at the central nervous system level.[63-65] Any change at the peripheral input level seems to have an inhibitory effect on this CNS activity.[63,66] When an occlusal appliance is placed between the teeth, it provides a change in peripheral input and thus decreases CNS-induced bruxism. The appliance does not cure bruxism; it only inhibits the bruxing tendency while it is being worn. Studies[67-69] show that even with long-term use of an appliance, bruxism seems to return.
7. *Regression to the mean*: Regression to the mean is a statistical term that addresses the common fluctuation of symptoms associated with chronic pain conditions.[70] If one follows the musculoskeletal symptoms of a particular patient, it will be observed that the intensity of pain will usually vary on a daily

bases. Some days will be quite painful, while other days are more tolerable. If the patient is asked to rate the intensity of his pain each day on a visual analog scale, with 0 being no pain and 10 the worst possible pain, the patient may report an average day to be 3. This would represent his mean pain score. However, some days the pain may reach a 7 or 8 but then often with time the pain returns back to its mean level of 3. Patients most commonly report to the dental office when the pain intensity is great since that is often the factor that motivates them to seek treatment. When the clinician provides therapy (such as an occlusal appliance) and the symptoms reduce back to the average level of 3, one must question if the reduction of symptoms was actually the therapeutic effect of the treatment or did the patient's symptoms merely "regressed to the mean." This factor can be very confusing to the clinician and may lead to misdirection of future treatment. Uncontrolled short-term studies that report success of various therapies need to be questioned regarding their actual effect. Is it actually the therapeutic effect of the modality or was it regression to the mean? The importance of well-controlled, blinded studies becomes obvious when attempting to answer this question.[58]

When a patient's symptoms are reduced by occlusal appliance therapy, each of these seven factors must be considered as responsible for the success. All permanent (irreversible) treatment should be delayed until significant evidence exists to determine which factor(s) was important in reducing the symptoms. This can be accomplished by first allowing the patient to wear the appliance for 1 to 2 months to assure that the symptoms have been adequately controlled. It should be noted that the appliance may not need to be worn 24 hours a day.[71] Many patients do very well with only part-time use, most commonly at night. The amount of time needed is dependent upon the type of TMD that is being treated.[72] Once the patient is comfortable for several weeks, perhaps months, the patient should be asked to reduce the use of the appliance. In many instances, the patient can discontinue use of the appliance and not experience a return of symptoms. When this occurs, factors that relate to dental etiology, such as the occlusal condition, condylar position, or vertical dimension, are not likely the causes of the TMD. When this occurs, the patient should be encouraged to wear the appliance occasionally as needed to manage any return in symptoms secondary to bruxism or emotional stress. These patients do not need orthodontic therapy.

If reducing the use of the occlusal appliance reestablishes the original symptoms, then factors such as the occlusal condition, condylar position, or vertical dimension may need to be considered as potential etiologic factors. But which factor is the likely cause? This question needs to be answered before any therapy begins. If the clinician is suspicious that the vertical dimension is the etiology of the TMD symptoms, then an attempt should be made to verify this assumption. The appliance should be gradually thinned while maintaining the same occlusal contacts and condylar position. The significance of the vertical dimension is confirmed if the symptoms return as the appliance is thinned. However, if the symptoms do not return as the appliance reaches the original vertical dimension, the clinician should be more suspicious that the factors responsible for the reduction of symptoms are either the occlusal condition or the condylar position. It is now important to realize that these two remaining factors are accessed together by evaluating the patient's orthopedic stability. The patient's mandible should be bilaterally manipulated to the MS position and the occlusal contact pattern assessed. At this time, the clinician will now be able to observe the orthopedic instability and have some reasonable clinical certainty that this condition is contributing to the TMD symptoms. Since the clinical evidence now suggests that a change in the occlusal condition would likely reduce the TMD symptoms, the clinician should accurately mount the patient's study casts on an articulator and determine the most appropriate method of achieving the goals of orthopedic stability (i.e., orthodontic therapy).

By way of summary, although occlusal appliances may have some diagnostic value, conclusions regarding the rationale for their success must not be hastily made. Before any orthodontic treatment plan for TMD is begun, ample evidence must exist that the treatment will be of benefit to the patient. In reality, only a select group of TMD patients benefit from orthodontic therapy.

The last situation to be discussed is the patient with TMD who also has aesthetic needs. When patients have both needs, the clinician's first efforts should be directed toward resolving the TMD symptoms. The clinician may decide to use an occlusal appliance to help reduce the symptoms. When an appliance is used, it will not only help reduce symptoms but also assist in locating the MS position of the joint. Once the symptoms are reduced, the orthodontic treatment plan is developed with respect to the MS position of the joints, and therapy can begin.

MANAGING TMD SYMPTOMS THAT ARISE DURING ORTHODONTIC THERAPY

Occasionally a patient will present with TMD symptoms while actively undergoing orthodontic therapy. This may pose a challenge to the orthodontist. These symptoms may demand immediate attention, yet traditional TMD therapy would be difficult and likely delay the orthodontic treatment plan. Therefore, the orthodontist needs to have some treatment strategies that will help reduce the patient's symptoms while orthodontic therapy continues.

The first important consideration with a patient who develops new TMD symptoms is to review the orthodontic progress toward achieving orthopedic stability in the masticatory system. This is especially important if the TMD symptoms are related to intracapsular concerns such as joint clicking. The orthodontist should locate the MS position of the condyles using a bilateral manual manipulation technique and determine if the orthodontic therapy is moving toward developing a favorable intercuspal position in this stable joint position. If it is determined that this goal is not being achieved, the orthodontic treatment plan should be redirected in a manner to better accomplish this goal.

Once it is determined that the direction of treatment is correct, but not yet achieved because orthodontic therapy has not been finalized, the patient's specific symptoms can be addressed. The response to symptoms should be appropriate for the type and intensity of the patient's complaints. Although the management of muscle pain disorders is often different than intracapsular disorders, some general treatment strategies can be used to manage both. Much of this management is conservative and easily applied to the patient.

One of the most important things the orthodontist can do for the patient is to provide education. The patient needs to know that TMD symptoms are common and benign. They do not shorten one's life. The nature course of most TMD is to experience fluctuations of symptoms, often resolving with little to no significant treatment. Therefore, informing the patient of these can be very therapeutic. Since emotional stress can be an etiologic factor of TMD, often worrying about the problem makes the situation even worse.

Education is also important for it can be used to actively bring the patient into the treatment that can help them the most. Some simple behavioral interventions can be most helpful. For example, advising the patient to reduce jaw use to within painless limits goes a long way in symptom reduction. The patient should be instructed to eat softer foods, smaller bites and slower chewing. Don't let it hurt. Increased pain can maintain the pain cycle, which may prolong the pain experience.[73] Sometimes patients chew gum, bite on pencils, or bite their fingernails. These activities can further enhance muscle pain. The patient needs to be informed that it is common to put the teeth together even at times when we are unaware. Bruxing and/or clenching the teeth are good examples of such activity. Making the patient aware of these activities (cognitive awareness) is the beginning of therapy. Once the patient is aware, the patient should be instructed that at any time he catches himself with the teeth in contact and he is not chewing or swallowing, he should immediately puff a little air between the lips and teeth, let the jaw relax, and then allow the lips to seal. This will place the mandible in the postural position, disengaging the tooth. This position minimizes muscle activity and joint loading. Although this technique seems too simple to work, it has been demonstrated to be very effective in reducing TMD symptoms.[74] The concept of "lips together and teeth apart" is powerful in reducing most acute TMD pains.

If the acute TMD symptoms are associated with pain, the clinician may wish to suggest that a mild analgesic be used for 5 to 7 days to reduce the pain. As previously mentioned, pain can reinforce the condition beginning cyclic muscle pain.[73] Mild analgesics can be used to break this cycle. An NSAID such as ibuprofen can be very useful. It should not be take only as needed because it will not effectively break the pain cycle. Therefore, the patient should be instructed to take 400 to 600 mg of ibuprofen three times a day with meals for 5 to 6 days. Most individuals can tolerate this medication without problems, but if there is a history of gastrointestinal upset, other options should be used.

Another very conservative therapy for muscle pain is moist heat. A moist, hot towel can be placed over the painful muscle(s) for 15 to 20 minutes and repeated several times a day as needed. This therapy can be very helpful in reducing acute muscle pain.

Still another option that may be considered relates to sleep quality. If the patient reports poor sleep quality and is waking up with increased pain, one may be suspicious of sleep-related bruxism. When this occurs, a mild muscle relaxant such as cyclobenzaprine, 5 to 10 mg before sleep, may be helpful. This may only be needed for 5 to 7 days.[73]

For many acute TMD symptoms, these simple therapeutic interventions will be adequate to resolve the condition. There is no need to alter the orthodontic treatment. The patient should be reassessed in 7 to 10 days to make sure that the symptoms have been resolved. Once the symptoms have resolved, continue with the orthodontic therapy with the goals of establishing orthopedic stability and an acceptable esthetic.

If in 10 days the symptoms have not adequately resolved, additional steps may be needed. Continue to reinforce the important behavioral aspects of resting the masticatory systems but also consider other factors that may help reduce muscle activity. If the patient is wearing interarch elastics, they should be temporally discontinued. Some patients have a tendency to play with these elastics, which further activates the muscles. Also it may be time to consider temporary methods of disengaging the teeth during sleep. Making a stabilization appliance may be difficult with all the orthodontic brackets and wires so on a short term base one can consider a more generic soft appliance.[75,76] These appliances do not require individual fabrication, making them easy to use with orthodontic brackets and wires. Although these types of appliances have not been shown to be as effective as more traditional, hard-stabilization appliances, they can certainly be used for a brief period of time to hopefully reduce acute TMD symptoms.

The patient should again be reevaluated in 1 to 2 weeks for symptom reduction. If the TMD symptoms have resolved, proceed with the orthodontic treatment plan. If the symptoms have still not resolved, a more significant TMD is present and therefore a more traditional approach to management may be needed. At that time, the orthodontist may need to discontinue the active orthodontic therapy by removing the arch wire and fabricate a more traditional stabilization appliance. The stabilization appliance should provide even contact of all teeth on flat surfaces when the condyles are in the MS position (orthopedic stability). Eccentric guidance is provided by the canines. This appliance may be a little more difficult to fabricate with the orthodontic brackets in place, but certainly not impossible. The brackets can be blocked out with wax on the model, allowing a good fit. In many patients, this appliance may not need to be worn for very long.

Another appliance that may be considered is the anterior bite plane.[77] This appliance provides only anterior tooth contact and can be useful in reducing symptoms. Since the posterior teeth do not occlude, it may be easier to fabricate and adjust. As soon as the symptoms have resolved, the appliance can be removed and active orthodontic therapy can be resumed.

At that time, the orthodontist needs to consider all the etiologic factors that may be contributing to the TMD, such as emotional stress, trauma, deep sources of pain, and uncontrolled parafunctional activity. The patient should receive a complete history and examination for TMD and be managed appropriately.[12] Orthodontic therapy should not be reinitiated until the TMD symptoms have been properly managed.

In those instances when the TMD symptom is clicking and the orthodontic therapy is effectively moving toward establishing orthopedic stability, the clinician needs to be aware that this symptom is relatively common in the young adult and does not always lead to significant consequence. In fact, one study[30] that observed untreated subjects at the age of 15 years and then again at age 20 found that clicking is very common in this age group, and that clicking can come and go unrelated to any major clinical symptoms. Therefore, if the patient reports the onset of a joint sound unrelated to pain and the occlusal condition is being developed in harmony with the stable joint position, patient education regarding the problem may be all that is needed.

On occasion, the clicking joint is associated with significant pain or joint dysfunction, such as catching or locking. When this occurs, active orthodontic therapy should be discontinued and therapy should begin for the specific disorder that has been diagnosed. This might include appliance therapy and/or active physical therapy to the involved joint. The precise treatment for the intracapsular disorder is outside the goals of this chapter, and therefore other texts[78,79] should be pursued for a complete description of therapy.

SUMMARY

The goal of the orthodontist is to develop an esthetic smile and a functional masticatory system. Although initially esthetics is often considered the most important goal, function eventually becomes far more important in the overall success of treatment. Therefore, the orthodontist must always consider how the orthodontic therapy will affect function. To maximize sound orthopedic function, the occlusal condition must be finalized in harmony with the MS position of the TMJs. Accomplishing this goal will maximize the success of masticatory function in future years.

The Orthodontist's Role in a Cleft Palate–Craniofacial Team

Katherine W.L. Vig and Ana M. Mercado

OUTLINE

Historically, children who were born with facial clefting in addition to other manifested craniofacial anomalies underwent a succession of evaluations and hospitalizations by their independent caregivers. This individualized delivery of care, although considered in the best interests of the patients, resulted in additional hospital admissions and multiple instances of general anesthetic administration. The American Cleft Palate–Craniofacial Association (ACPA) was established in 1943 to foster a team approach and to serve as an advocate for patients with clefts of the lip and/or palate and their families. The association defined the role of the orthodontist on a cleft palate team and recognized a team approach as the most appropriate method to manage the care of patients with orofacial clefts. In 1972, craniofacial teams became established as an extension of the cleft palate team. This development was in response to clinical geneticists and dysmorphologists becoming increasingly aware that orofacial clefts were part of a phenotypic spectrum of craniofacial anomalies.[1]

Currently in the United States, care for individuals with craniofacial anomalies, including orofacial clefts, is delivered in a variety of collaborative models: hospital-based teams, university-based teams, or in independent clinics where multidisciplinary evaluations and treatment are coordinated. The ACPA has published the document "Standards for Cleft Palate and Craniofacial Teams," which describes the essential quality characteristics for team composition and functioning (http://www.acpa-cpf.org/team_care/standards/). The ACPA Commission on Approval of Teams reviews and identifies those cleft palate–craniofacial teams that meet the specified standards. The Cleft Palate Foundation maintains a list of approved cleft palate–craniofacial teams in the United States and around the world (http://www.cleftline.org/parents-individuals/team-care/) and provides information about their services to patients and families.

The team approach to comprehensive care requires the orthodontist to work collaboratively to determine the appropriate timing and sequencing of treatment in the context of the patient's other health care needs. This interactive, evidence-based, and patient-centered care provides the basis for a rational approach to diagnosis and treatment planning. Just as multiple methods and alternative treatment interventions are available, so also the team approach to management advocates that patients and their parents be aware of the choices through a risk-cost-benefit appraisal. This appraisal allows patients to make informed decisions and to understand the consequences of the different options available, especially in light of emerging technologies and treatment modalities for which long-term outcomes are not available. The document "Parameters for Evaluation and Treatment of Patients with Cleft Lip/Palate or other Craniofacial Anomalies"[2] was the product of a consensus conference in 1992 to develop guidelines and practices in the care of patients with craniofacial anomalies. The parameters, revised in 2009,[3] also serve as guidelines for the patient-oriented clinical management of those patients with craniofacial anomalies.

The purpose of this chapter is to consider a rational team approach to the orthodontic management of the patient with cleft lip and/or palate.[4,5] Orthodontic interventions should be confined to discrete stages in skeletodental development of the craniofacial complex and should not be considered as a continuum of treatment from birth to adulthood.

DIAGNOSTIC CONSIDERATIONS

Clefts of the lip and palate occur in approximately 1:700 live births in the United States and are the fourth most common craniofacial birth defect. The incidence varies in different races, and prevalence of cleft type varies by gender. The estimated cost of treatment is about $108,000 for this craniofacial birth defect compared with other birth defects. The high total cost of cleft lip/palate is a reflection of its incidence and also relates to the associated morbidity and mortality.[6]

Cleft lip and/or palate may be diagnosed by prenatal ultrasound, which has become more common because refinements of this diagnostic tool provide images by which congenital and developmental anomalies may be detected more clearly. The ability to make the diagnosis in utero gives the parents the opportunity to be prepared for the birth of their infant with a facial anomaly and to understand the surgical procedures available for repair of the facial cleft. Prenatal counseling provides parents with both a level of awareness and realistic expectations at the time of the delivery. If the diagnosis of a craniofacial anomaly has not been identified prenatally, parents may experience an overwhelming disappointment and sense of guilt when the obstetrician or neonatologist informs them of their baby's birth defect. However, the distinction between a syndromic/nonsyndromic facial cleft and its recurrence risk is the domain of the geneticist, dysmorphologist, or syndromologist, who provides this information to the parents and later to the patient at the appropriate time in his or her maturation.[7]

Prenatal Diagnosis of Cleft Lip/Palate

Ultrasonography is a noninvasive diagnostic tool widely used as a routine component of prenatal care. Ultrasonography serves to confirm fetal viability, determine gestational age, establish the number of fetuses and their growth, check placental location, and examine fetal anatomy to detect any malformations.[8]

Ultrasound Technique and Limitations

Christ and Meininger[9] reported that optimal imaging of the fetal face is not reliable with transabdominal ultrasound until gestational week 15. The position of the face and the disproportionate size of the transducer and fetus make it more difficult to show the anatomy of the fetal nose and lips before that point of gestation. Robinson and coworkers[10] reported that the detection rate for fetal cleft lip is improved when transabdominal sonography is performed at or after 20 weeks of gestation. At that time the lips become more developed and prominent as the fetus grows, allowing for better imaging as long as there is an amniotic fluid interface and no obstructions. Transvaginal sonography, although not routinely used, has been reported to allow earlier visualization of the face and better image resolution, yielding high specificity and sensitivity of prenatal cleft lip detection.[11]

Babcock and McGahan[12] described a systematic approach that allows for fast and thorough sonographic evaluation of the midface structures. Starting with the coronal plane, the soft tissues of the fetal nares and upper lip are examined for continuity (Fig. 14-1, *A*). Once a cleft is detected in the coronal view, anatomic assessment continues in the axial plane, evaluating the superficial skin margin of the upper lip, the underlying orbicularis oris muscle, and tooth-bearing alveolar ridge (Fig. 14-1, *B*). An isolated cleft lip is diagnosed if discontinuity exists in the upper lip with no evidence of disruption in the underlying alveolar ridge. Cleft lip and palate is diagnosed if a cleft is identified in the lip and disruption of the alveolar ridge, whether unilateral or bilateral, is present. Bilateral clefts of lip and palate are well visualized in the sagittal plane because protrusion of the premaxillary segment is evident.[12,13] Isolated clefts of the hard palate are viewed best in the axial plane (Fig. 14-1, *C*).[14] Acoustic shadowing from facial bones, which obscure the palatal structures, makes isolated clefts of the hard palate particularly difficult to visualize and diagnose prenatally.[12] Movement of the tongue above the level of the hard palate may suggest the presence of a secondary palate cleft.[15,16] Color Doppler ultrasonography has been used to visualize abnormal flow of amniotic fluid from the mouth to the nasal cavity, a finding that may suggest the presence of a palatal cleft.[17] Factors that may limit the sensitivity of diagnosing an orofacial cleft during ultrasound screening include an unfavorable position of the fetus, hand or umbilical cord overlying the face, maternal obesity, presence of a multiple gestation, oligohydramnios (reduced amniotic fluid), prior abdominal surgery, and the presence of additional fetal abnormalities.[10,18]

Advantages of Prenatal Cleft Diagnosis

There are several potential advantages for informing parents of a prenatal diagnosis of facial clefting[18]:

1. Psychological preparation of parents and caregivers to allow for realistic expectations at the time of delivery.
2. Education of parents on the management of the cleft: presurgical neonatal orthopedics, plastic surgery for lip and palate closure, and alveolar bone grafting.
3. Preparation for neonatal care and feeding.
4. Opportunity to investigate for other structural or chromosomal abnormalities.
5. Possibility for fetal surgery.

An additional advantage of prenatal diagnosis of cleft lip and palate is the ability of the plastic surgeon to prepare a customized plan of management for surgical repair of the cleft once the sonologist characterizes the specific type of cleft and describes the extent of the anomaly. With this information, the plastic surgeon may wish to educate the parents about the severity of the deformity, the need for any adjunctive intervention before surgery, and the predicted outcome of repair.[16]

Disadvantages of Prenatal Cleft Diagnosis

Parents and professionals report an emotional disturbance and high maternal anxiety after prenatal diagnosis of cleft lip/palate is disclosed.[19,20] However, parents of affected children strongly favor being informed and involved in prenatal testing and counseling decisions and view this preparation as valuable despite acknowledging the increased anxiety and dysfunction during pregnancy.[21] As the sensitivity of ultrasound screening in the detection of facial clefts increases, the potential exists for an increased number of families choosing to terminate the pregnancy even in the absence of other malformations.[18] Factors such as perceived burden, expectation of recurrence, religious and cultural beliefs, professional advice, and gestational age at diagnosis are considered influential in the family's decision to terminate pregnancy.[20,21]

THE TEAM APPROACH

The timing and sequencing of orthodontic treatment are not carried out in isolation from other members of the team but

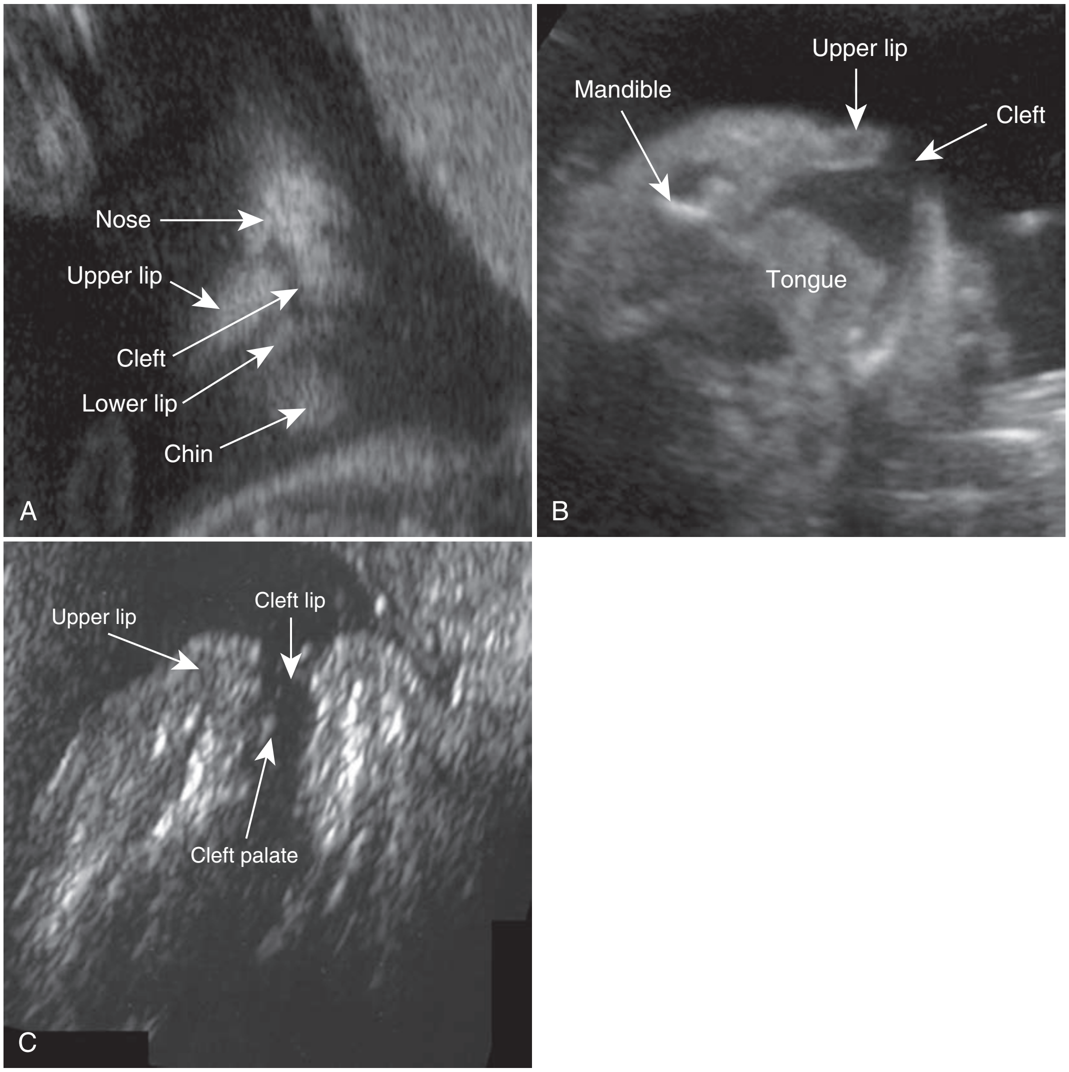

FIGURE 14-1 Transabdominal ultrasonography images of the midface of a fetus with unilateral cleft lip at 21 weeks of gestational age. **A,** Two-dimensional, coronal view: the defect in the upper lip extends into the nostril. **B,** Two-dimensional, axial view at the tongue level: discontinuity in the upper-lip skin and muscle is observed. **C,** Axial view. Discontinuity of the upper lip, alveolar ridge, and hard palate can be visualized.

as a result of collaborative decisions made in a coordinated, patient-centered manner sensitive to the patient's and family's needs (Fig. 14-2). Several texts provide specific details of treatment intervention, but the overall care of affected infants should rely on interdisciplinary team decisions rather than a series of independent, critical events by individual specialists on a team.[22]

The orthodontist serving on a cleft palate team should consider additional priorities other than malocclusion. The timing and sequencing of treatment should be sensitive to other interventions by specialists on the team to provide the affected individual with a patient-centered interdisciplinary approach that follows critical pathways.[23,24] These critical pathways have been well defined in a document on critical elements of care for children with special health problems developed by the Washington State Department of Health in 1997.[25] These guidelines were developed through a consensus process including primary and tertiary care providers, family members, and representatives from a health insurance plan.

ROLE OF THE ORTHODONTIST

Timing and sequencing of orthodontic care may be divided into four distinct developmental periods. These periods are defined by age and dental development and should be considered as time frames in which to accomplish specific objectives. Such sequencing avoids the common tendency to allow an early phase of treatment intervention to extend through infancy, childhood, adolescence, and into adulthood. With the understanding that children born with cleft lip and/or palate should be treated by an interdisciplinary team approach, the following four time periods in the child's development provide a framework for discussing and recommending defined objectives.

Neonate and Infant (Birth to 2 Years of Age)

Presurgical orthodontics or neonatal maxillary orthopedics is initiated during the first or second week following birth unless complications arise from other congenital anomalies or medical problems.[26-28] This treatment may be carried out by the

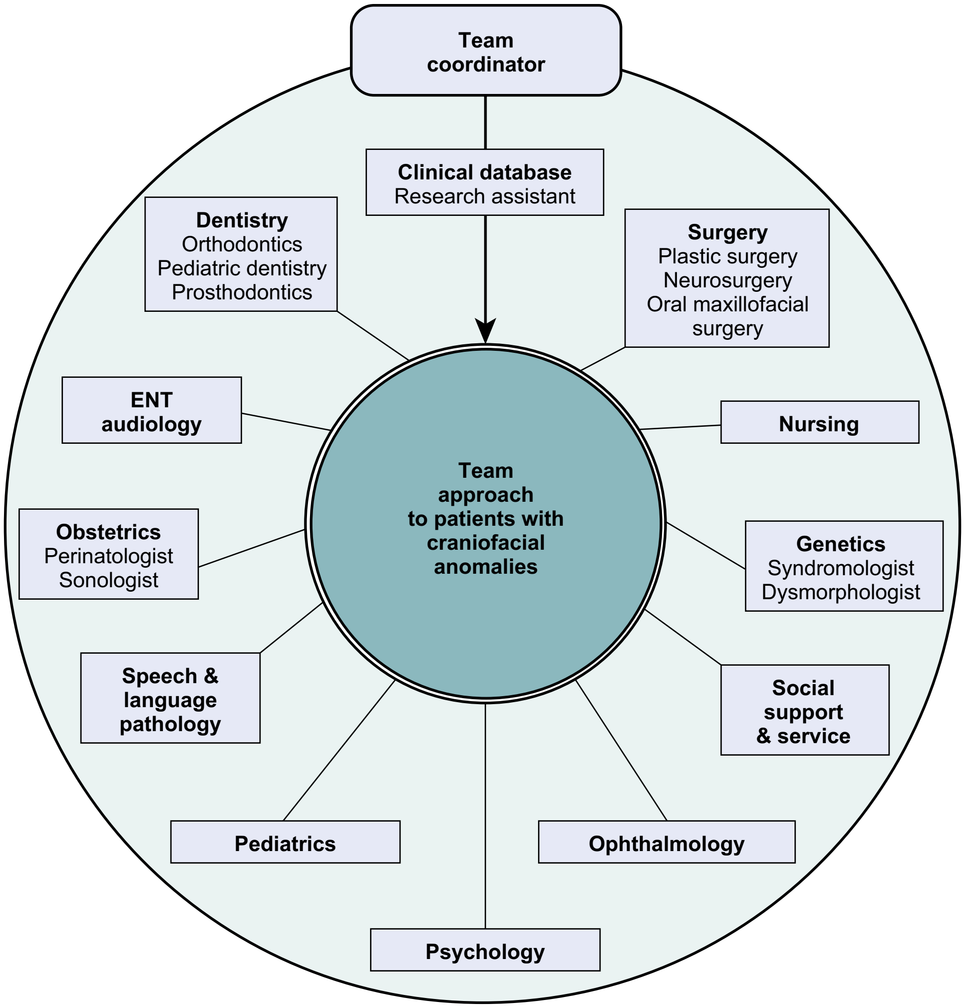

FIGURE 14-2 Members in the team approach to patients with craniofacial anomalies. (Reprinted from Vig KWL, Mercado AM. Contemporary management of craniofacial anomalies: Will past experiences influence and predict the future? In: McNamara JA Jr, ed. *The 40th Moyers Symposium: Looking Forward … Looking Back*. Ann Arbor: Department of Orthodontics and Pediatric Dentistry and Center for Human Growth and Development, The University of Michigan; 2014. Monograph 50, Craniofacial Growth Series.)

orthodontist, the pediatric dentist, or the prosthodontist. The popularity of this early intervention was well accepted in the 1960 and 1970s to eliminate the need for subsequent orthodontic treatment after the segments were aligned. Later reports suggested that although the initial results of lip repair were easier to attain with cosmetic improvement, the procedure seemed to accrue no long-term benefit on the growth of the midface and dentoalveolus. Growth of the nasomaxillary complex and the occlusal results in the primary and mixed dentition appeared clinically similar to those cases without this early treatment intervention. Additionally, the literature also reported that primary bone grafting and associated presurgical maxillary orthopedics further confounded the cause-and-effect relationship.[29] Early or primary bone grafting associated with maxillary orthopedics at the time of primary lip repair may have compromised the long-term follow-up of treated patients. Results suggested that neonatal maxillary orthopedics produced little effect on the developing malocclusions if assessed when the child was 10 years old, especially if treatment had included primary bone grafting to stabilize and prevent maxillary collapse in the infant.[30-32]

Because no long-term benefit was to be gained from these interventions when used indiscriminately on every affected infant, the use of neonatal orthopedics before definitive primary surgical lip repair became an ongoing controversy between clinicians.[30,33] Several institutions continue to advocate early bone grafting and report substantial benefits.[28,34] The perspective of contemporary wisdom is that when provided as an adjunctive procedure to primary definitive lip repair, neonatal maxillary orthopedics does have presurgical benefits. Therefore, the popularity of neonatal maxillary orthopedics has returned, albeit with different objectives than to eliminate future need of orthodontic treatment for the child. A considerable literature has developed on this procedure, and the enthusiasm of many clinicians in this field attests to the variety and complexity of the appliances.[24,35-38] The feature that all these appliances, whether fixed or removable, have in common is the ability to adjust the position of the cleft segments into a more ideal relationship before definitive surgical repair of the lip.

In the 1990s, there was renewed enthusiasm for neonatal maxillary orthopedics with the introduction of Naso-Alveolar

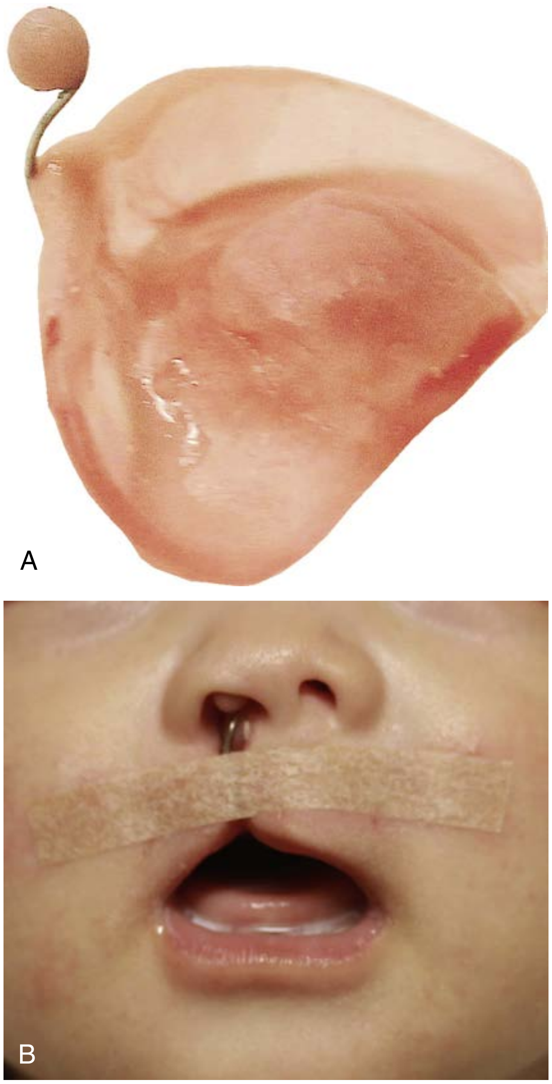

FIGURE 14-3 Presurgical nasoalveolar molding. **A,** Custom intraoral plate to mold the alveolar segments. From the labial vestibular flange, there is a wire extension with acrylic at the tip that serves as a nasal stent to mold the nasal alar cartilage. **B,** Molding plate in place in a neonate with unilateral cleft lip and palate. Lip taping is applied to approximate the lip segments.

Molding (NAM). This technique consists of an intraoral molding plate, nasal stents, and extraoral taping.[35,36] The alveolar ridges are molded to reduce the size of the cleft to approximately 1 to 2 mm of each other. Concomitantly, the use of nasal stents and taping lengthens the columella and realigns of the lower lateral alar cartilages (Figs. 14-3, *A* and *B,* and 14-4, *A* to *D*). The goal is to prepare the infant for a one-stage primary lip–nose repair in combination with a gingivoperiosteoplasty surgery to close the alveolar defect. It is advocated that the reorientation and molding of cartilages that is achieved with NAM may eliminate or reduce future surgical procedures for the nose. Longitudinal follow-up from infancy into adolescence is necessary to evaluate the long-term effect of presurgical maxillary orthopedics within the context of overall nasomaxillary growth.

European investigators have created the Dutchcleft, which is the Dutch Inter-center prospective two-arm randomized clinical trial (RCT).[39] Dutchcleft was designed to study the outcome of neonatal maxillary orthopedics in subjects with unilateral cleft lip and palate (UCLP). In this trial the infant presurgical orthopedics technique consisted of passive intraoral plates adjusted every 3 weeks to mold the alveolar segments. The control group received no intraoral plates. Prahl and coworkers[40] found no significant difference between the randomized plate versus control group of infants up to 2 years of age on feeding, nutritional status, or somatic growth. Konst and coworkers[41] assessed speech development at age 2.5 years and found a significant improvement in children treated with intraoral plates compared to children who did not receive plates, with acceptable cost-effectiveness of the intervention in regards to speech development. Bongaarts and coworkers[42] reported that infant orthopedics had no significant effect in maxillary arch dimensions at ages 4 and 6 when compared to similar-aged children who had not been treated with infant orthopedics. Similarly, there was no significant effect of infant orthopedics on dental arch relationships at ages four and six including overjet, overbite, and sagittal occlusion.[43] Only minor group differences were revealed at age 6 by cephalometric analyses of soft tissue, skeletal, and dental structures.[44] In regards to facial appearance, group differences in facial appearance observed at age 4 were no longer observed at age 6.[45] The Dutchcleft investigators alerted that clinicians who promote different methods of infant orthopedics including NAM should evaluate the long-term effects of these interventions under the rigorous methodology of an RCT.[44] In 2011, Uzel and Alparslan[46] published a systematic review of the long-term effects of presurgical infant orthopedics. They analyzed eight RCTs and four controlled clinical trials (CCTs), with follow-up periods of up to 6 years. The systematic review did not show a positive effect of infant orthopedics on the treatment outcomes evaluated until the age of 6 years, including motherhood satisfaction, feeding, speech, facial growth, maxillary arch dimension, occlusion, and nasolabial appearance.[46]

The benefits from early presurgical orthopedic appliances need to be weighed against the increased burden of care because of the number of clinic visits necessary to adjust the appliance during the first year of life.[31,36] Neonatal maxillary orthopedics continues to be practiced in a number of centers in the United States and Europe, although contemporary opinion generally does not consider that the evidence supports the intervention as an essential or desirable routine procedure for all infants born with a facial cleft. Nonetheless, the molding of the segments achieved by these appliances does make definitive lip repair easier for the surgeon, especially for patients with a severely protruding premaxilla caused by a bilateral cleft lip.[24]

The results in aligning the cleft segments with appliances have been considered similar to those produced by surgical lip adhesion. Surgical lip adhesion is a partial lip repair procedure often reserved for wide, complete clefts to convert these into incomplete clefts.[47,48] Narrowing a wide cleft and aligning the alveolar segments under the compression forces of the partially repaired lip is advocated. When the alignment of the segments has been achieved following lip adhesion, then definitive lip repair with muscle continuity is performed. This early surgical repair of the lip by an adhesion technique has much to commend it because the parents are not required to remove or adjust appliances, the cosmetic appearance is

FIGURE 14-4 Neonate with complete unilateral left cleft lip and palate. **A,** Defect before any orthopedic or surgical intervention. The left lower alar cartilage is depressed. The nasal tip is displaced and the columella is deviated over the cleft. **B,** Intraoral view of palate before orthopedics or surgery. The columella is located more medially. **D,** Intraoral view of palate after nasoalveolar molding. Note close approximation of the alveolar segments.

improved with a minor initial surgical procedure, and postoperative care by the parents is minimal. The most serious problem with this approach is the potential of wound dehiscence and the need for an additional surgery.[29] Currently, lip adhesion is not typically performed, and contemporary primary surgical lip repair restores continuity of the mucosa, skin, and circumoral musculature in the infant's cleft lip with a single procedure.

Definitive lip repair usually is achieved by the time the infant is 3 to 6 months old, and repair of the palate typically is delayed until 12 months to 2 years of age. Palatal repair is another controversial issue, and many methods are available for repairing just the soft palate or the hard and soft palate simultaneously. The rationale for the timing of the palatal repair is related to the developing speech and language skills of the child, which typically evolve around the first year of age. This rationale is usually in conflict with the effect of early surgical repair and the constraints of scar tissue on the growth and development of the nasomaxillary complex. Early repair of the palate and the resulting scar tissue may have an effect on the growth and development of the maxilla, which is reflected in the occlusion as a crossbite of anterior and posterior teeth. The severity of the malocclusion has been associated with certain surgical methods of palate repair, and evidence from unrepaired clefts in children and adolescents indicates that crossbites in the dentition rarely develop in the absence of surgical repair and resulting scar tissue.

Primary Dentition Stage (2 to 6 Years of Age)

At 2 to 3 years of age, the establishment of the primary dentition permits classification of the type of developing malocclusion. This determination may be part of the diagnostic regimen in which the contribution of the skeletal and dental components may be identified.

The facial soft tissues may mask the underlying skeletal deficiency of the midface in young children (Fig. 14-5, *A* to *C*). Growth of the intermaxillary space in three dimensions results in a redistribution of the facial soft tissues as the chubby face of infancy takes on the more mature and defined facial proportions of the child. These facial characteristics start to unmask the underlying skeletal discrepancy more accurately than in the younger child. The dentition often reflects the skeletal relationship, especially if the dentoalveolar component (axial inclination of the teeth) has not compensated for any skeletal discrepancies. Dental compensation for maxillary skeletal deficiency may result in retroclination

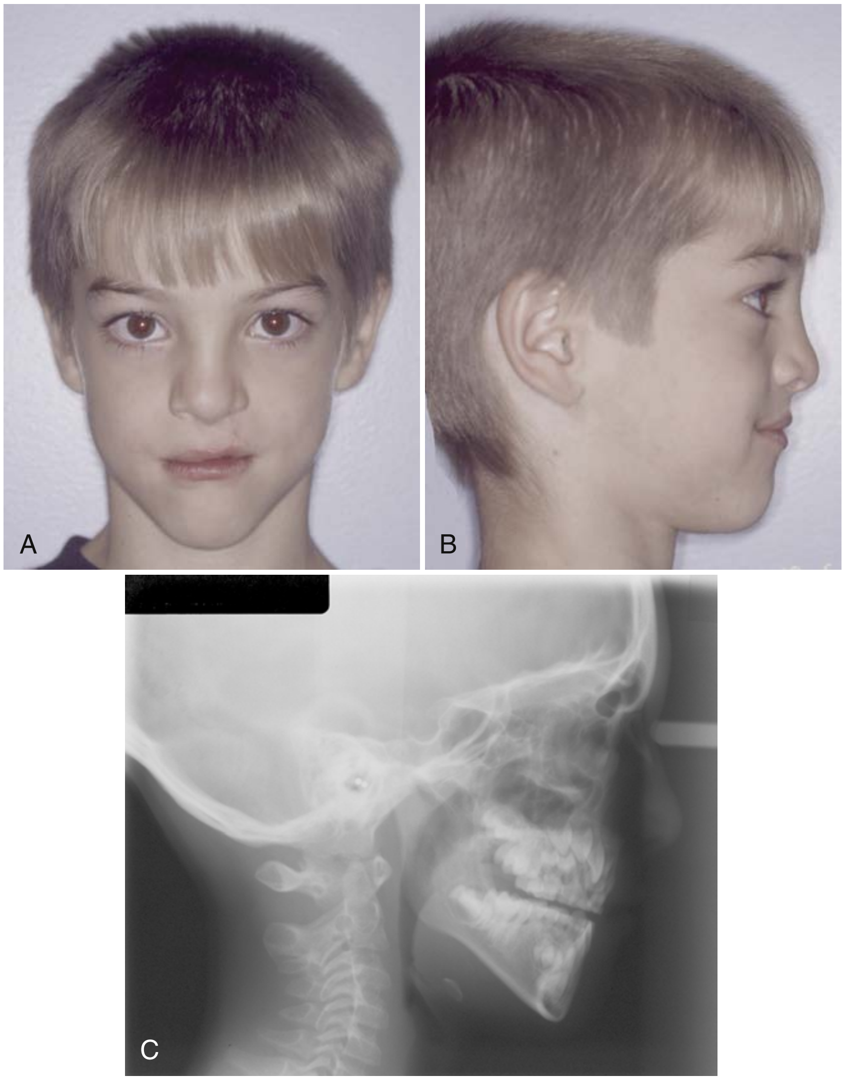

FIGURE 14-5 **A,** Frontal view of a 7-year-old boy with repaired unilateral left cleft lip and palate. **B,** Profile view showing mild bimaxillary retrusion. **C,** Lateral skull radiograph in early mixed dentition.

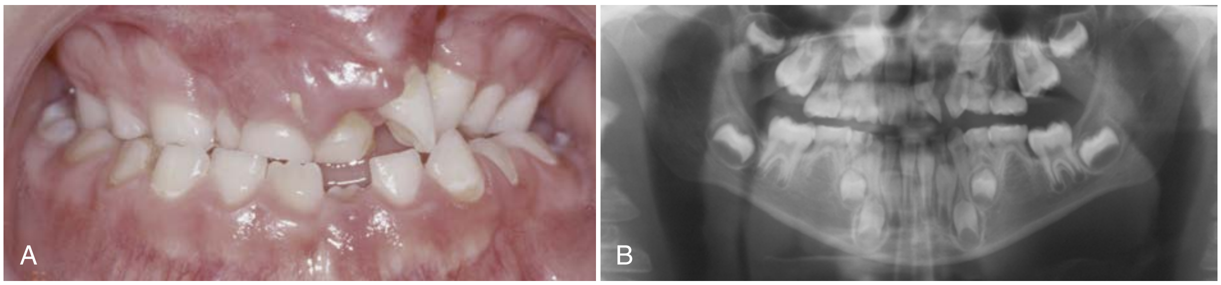

FIGURE 14-6 **A,** Intraoral view in occlusion of the same child as in Figure 14-5. of mandibular incisors with proclination of the maxillary incisors to mask the anteroposterior discrepancy, although in children with repaired orofacial clefts, the scar tissue following lip repair may constrain the maxillary incisor axial inclination (Fig. 14-6, *A* and *B*).

Because the primary incisors tend to be more upright than their successors, an anterior crossbite may be unilateral or bilateral with or without a functional shift of the mandible. This shift occurs when the child closes the teeth together. To eliminate mandibular shifts, orthodontic treatment may be

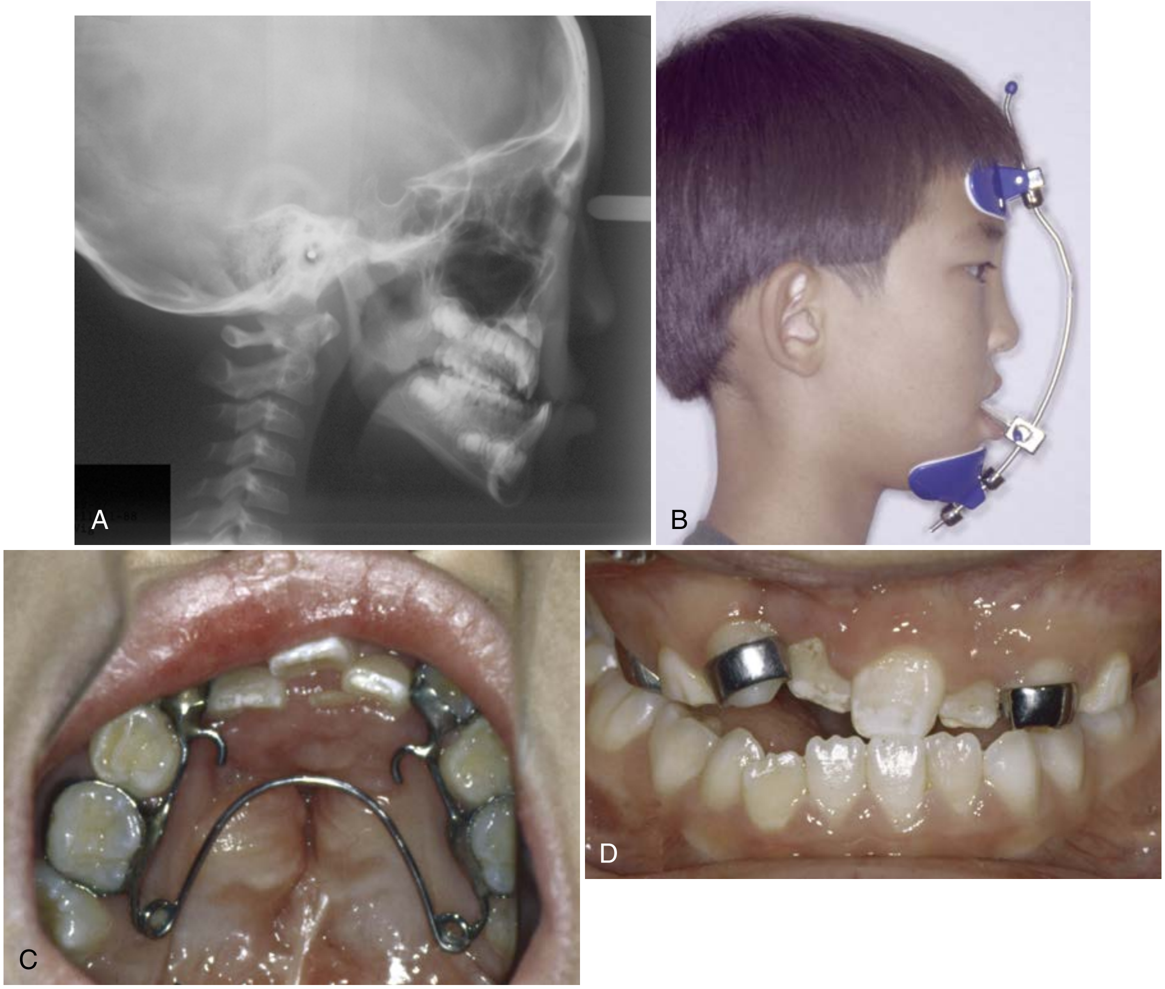

FIGURE 14-7 Eight-year-old boy with repaired unilateral right complete cleft lip and palate with sagittal and transverse maxillary deficiency. **A,** Lateral skull radiograph. Note the 7-mm reverse overjet. **B,** Protraction face mask with elastics attached to palatal hooks on expander. **C,** Palatal expander with bands cemented on the maxillary second primary molars and canines with palatal hooks to attach the protraction face mask. **D,** Lateral and anterior crossbites improving with palatal expansion and maxillary and dental protraction. (D, Adapted from Lidral AC, Vig KWL. The role of the orthodontist in the management of patients with cleft lip and/or palate. In: Wyszynski D, ed. *Cleft Lip and Palate: From Origin to Treatment.* New York: Oxford University Press; 2002.)

indicated to remove the interfering contact by tooth movement. This process may involve the maxillary incisors if an anterior crossbite exists or expansion of the posterior segments to eliminate a posterior crossbite (Fig. 14-7, *A* to *D*). If the dental crossbite relationship is a continuing problem once the dentition is established, it may be a reflection of the underlying skeletal discrepancy for which growth modification and redirection may be indicated with a protraction face mask (see Fig. 14-7, *B*). Some skeletal change occurred in Figure 14-8, *C*, with proclination of the maxillary incisors and forward movement of A point. However, with further growth the compensated incisal relationship may deteriorate. In cases of bilateral cleft lip and palate, severe constriction of maxillary posterior segments often is associated with bilateral crossbite and protrusion/extrusion of the premaxillary segment (Fig. 14-9).

The orthodontist should consider many factors in determining when to initiate orthodontic treatment during the primary dentition stage. These factors include the ability of the child to cooperate, the severity of the malocclusion, timing of secondary bone grafts, and the need for future orthodontic treatment in the early mixed or permanent dentitions. Contemporary opinion recognizes a need for orthodontic treatment in the early mixed and permanent dentitions. However, no strong evidence supports a benefit from routinely treating dental malocclusions in the primary dentition, suggesting that orthodontic treatment may be best delayed until it can be combined with other treatment goals and thus shorten the overall duration of treatment.

Severe skeletal discrepancies in the primary dentition are a more complex problem. Modification or redirection of growth has been advocated, and the use of functional or orthopedic appliances, including the forward protraction face mask, has been reported to have some success.[49,50] More commonly, the "apparent correction" is achieved by a transient change in the position of the teeth only, so that with subsequent growth,

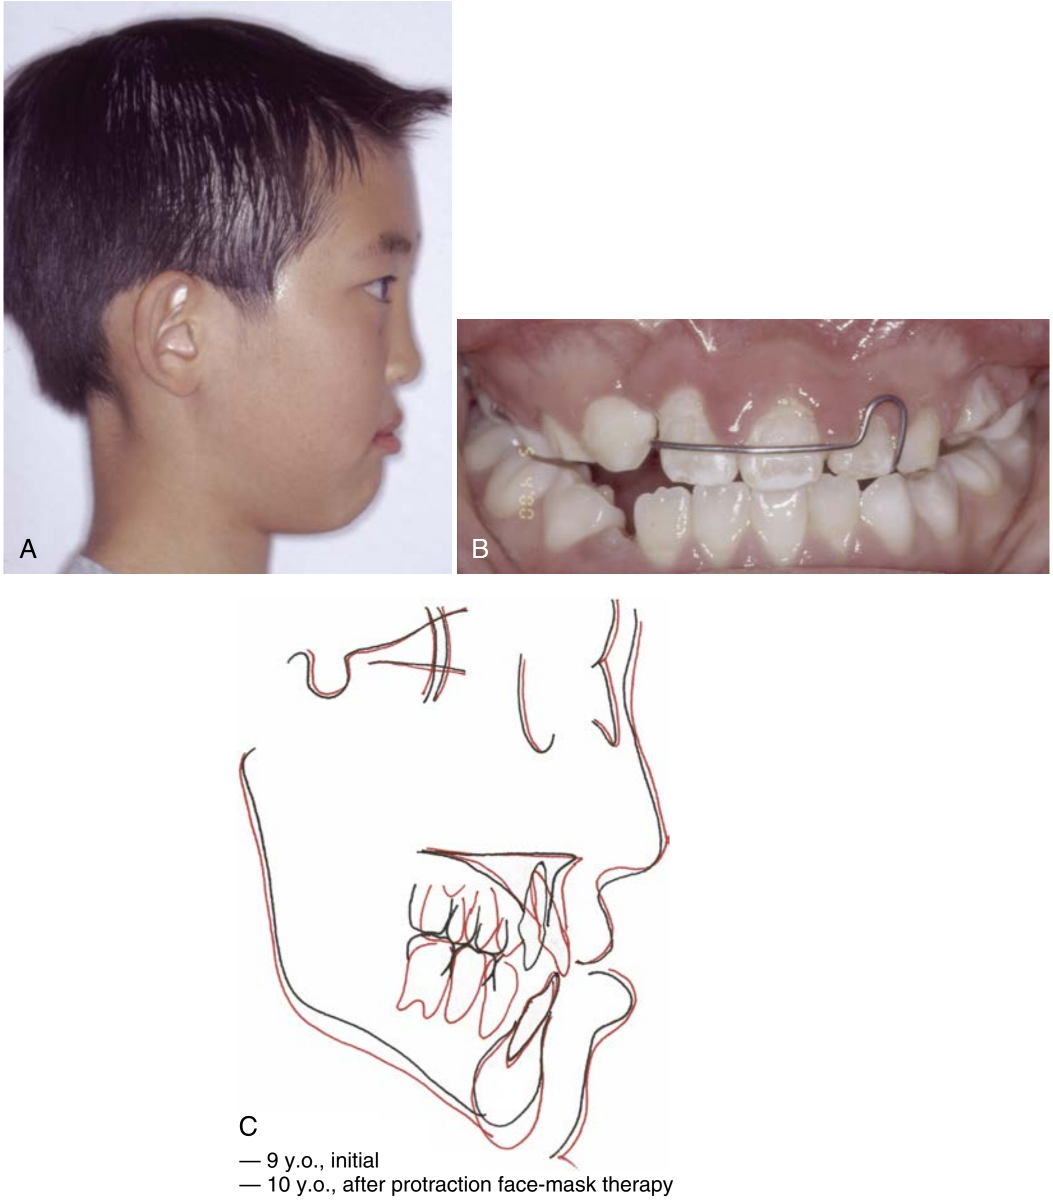

FIGURE 14-8 **A,** Facial profile after 9 months of protraction face-mask therapy and palatal expansion (same patient as in Fig. 14-7). **B,** Intraoral view with correction of anterior and posterior crossbites; maxillary retainer is in place. **C,** Superimposition of initial and postprotraction lateral cephalogram tracings showing correction of reverse overjet and mild maxillary advancement.

the skeletal discrepancy once again is reflected in the reestablishment of the malocclusion. Early treatment procedures, in common with neonatal maxillary orthopedics, require a long-term follow-up period to evaluate the outcome of treatment when the child reaches adolescence (see Fig. 14-8). Excessive changes attributable to therapeutic growth modification now are considered to be the exception rather than a predictable outcome of this early intervention.[51,52] One must carefully consider the severity of the skeletal discrepancy to determine the likelihood of successful growth modification and subsequent long-term results compared with conventional orthognathic surgery at a later stage. A more conservative option may be to provide a combined orthodontic/orthognathic surgery treatment plan than to promote long-term growth modification strategies that ultimately may not be successful.

Mixed Dentition Stage (7 to 12 Years of Age)

The transition to the mixed dentition starts at 6 to 7 years of age with the eruption of the first permanent molars and incisors. Further growth of the craniofacial complex often accentuates a previously mild skeletal discrepancy (Fig. 14-10). As the permanent teeth erupt, children are undergoing a period of psychosocial transition when friendships become more intimate and there is increased independence from parents.[53] In a

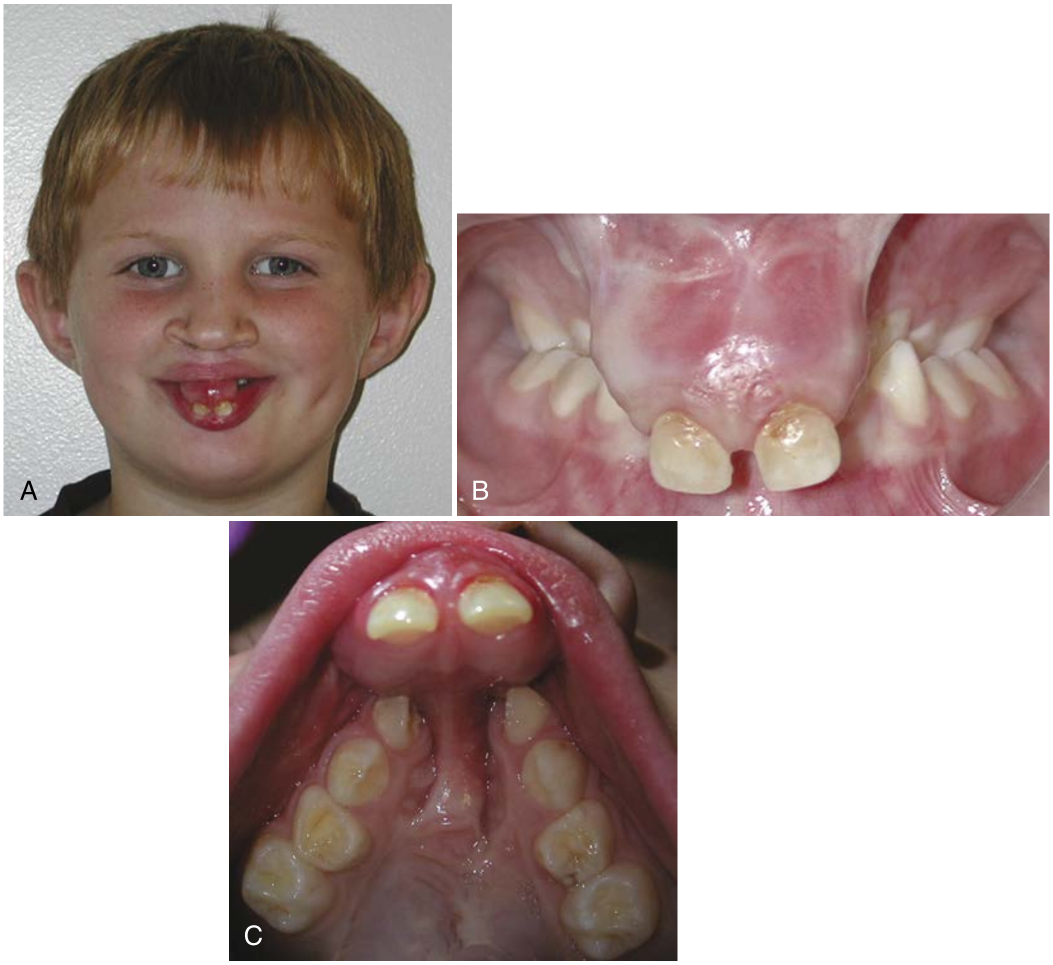

FIGURE 14-9 A, Five-year-old boy with repaired bilateral complete cleft lip and palate. Note the severe extrusion of premaxillary segment. B, Frontal intraoral view showing premaxillary segment out of the plane of occlusion. C, Maxillary occlusal view showing severe constriction of posterior segments and extrusion of premaxillary segment.

study by Ward and coworkers,[54] it was found that the presence of an orofacial cleft decreases the Oral Health-Related Quality of Life (OHRQoL) in children and adolescents. The dissatisfaction with appearance experienced by preadolescents with craniofacial anomalies is related to social withdrawal, social anxiety, and self-consciousness.[55] It is important for the health professionals on the team to be cognizant and empathetic of the psychosocial challenges that children and adolescents with craniofacial anomalies experience. Such challenges may influence the youngsters' participation in treatment decisions and their adherence to treatment protocols.

As the permanent incisors erupt adjacent to the cleft site, they typically are rotated, misplaced, malformed, or hypoplastic. In addition, incisors may be supernumerary, absent, or peg shaped. These characteristics are considered the result of early disruption of the dental lamina at the cleft site reflected in the developing tooth germs (Figs. 14-11 and 14-12). Constriction of the maxilla with a characteristic V-shaped arch form contributes to the posterior crossbite relationships usually seen in the mixed dentition. Tooth-borne maxillary expansion appliances such as a rapid palatal expander, a W-arch, or a Quad-helix can be anchored on the permanent first molars and extended anteriorly to improve arch form while correcting the crossbite (Fig. 14-13). By adding hooks bilaterally to these appliances, a protraction face mask may be used during expansion to treat a mild to moderate skeletal midface deficiency. The correction of an anterior crossbite results from dentoalveolar proclination of incisors with usually a slight and transient skeletal advancement. By incorporating miniplates and miniscrews, the intraoral appliances become bone-borne allowing the orthopedic force from the protraction face mask to be transmitted to the maxilla rather than to the teeth. Such an approach was developed by DeClerck and coworkers[56] and Baek and coworkers,[57] placing miniplates on the zygomatic buttress as anchorage for skeletal maxillary protraction and placing miniscrews in the anterior mandible and in the posterior maxilla to allow the use of intraoral Class III elastics. Both approaches have resulted in favorable short-term orthopedic changes in maxilla while minimizing common side effects such as proclination of the incisors, molar extrusion, bite opening, or clockwise rotation of the mandibular plane.

Because deficiency of tissue is an inevitable consequence of facial clefting, not only are the teeth missing, but the supporting alveolar bone at the cleft site is also compromised. In the past, rehabilitation of the maxillary dentition depended on the expertise of the prosthodontist to replace the missing teeth and

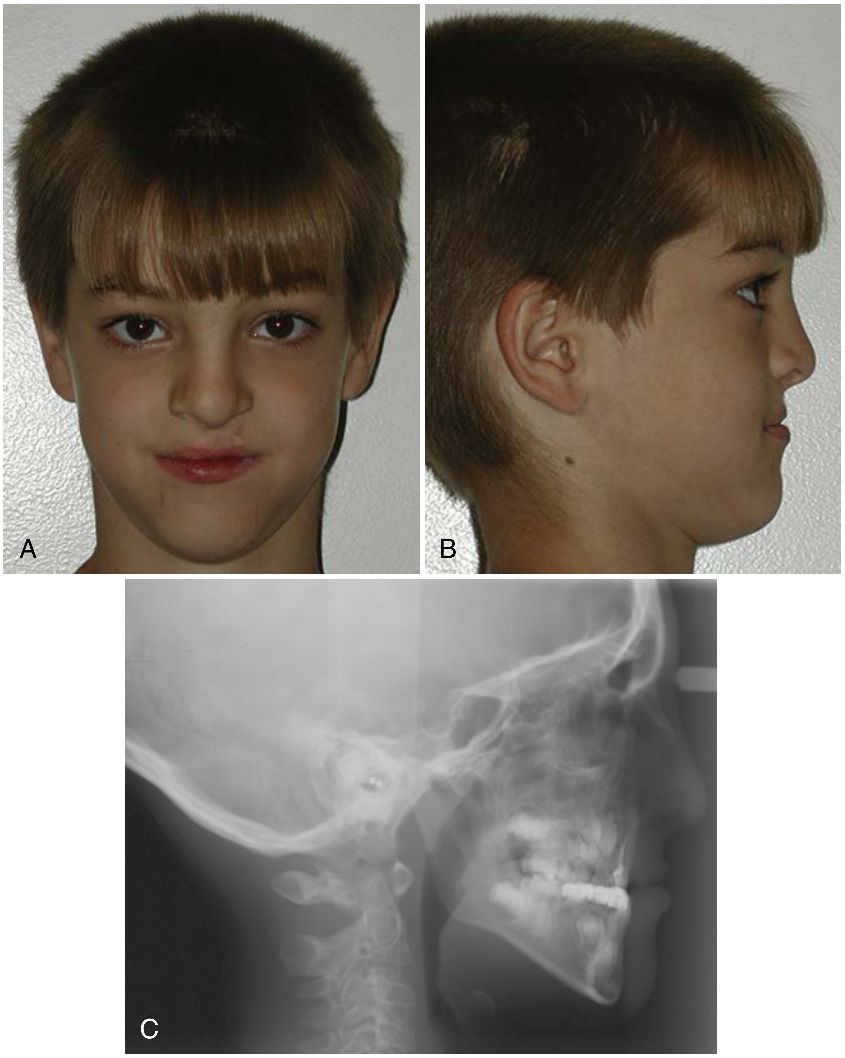

FIGURE 14-10 **A,** Same patient as in Figures 14-5 and 14-6 shown at 9 years of age. **B,** Profile view showing mild midfacial deficiency. **C,** Lateral skull radiograph in mixed dentition with anterior crossbite.

alveolus in the cleft defect with an overdenture. The challenge to restore the missing tissue at the cleft site was resolved with the advent of secondary alveolar bone grafting in the 1970s.[58-60] This bone grafting procedure provided the orthodontist with one of the most important milestones in managing the cleft site: restoration of an uninterrupted, continuous alveolar ridge that allows for eruption of teeth into the graft and orthodontic movement of teeth into the cleft site (Fig. 14-14). Additionally, placement of osseointegrated implants is now possible with prosthetic replacement of missing teeth. The elimination of the residual cleft provided a major advance in the contemporary management of the cleft maxilla and is an example of the outcome of a coordinated and problem-oriented approach to developing new strategies in treatment protocols.[58,61,62]

Primary Alveolar Bone Grafting

Primary bone grafting is performed in the infant cleft site before eruption of the primary incisors, usually at the time of primary surgical lip repair. In the United States, primary alveolar bone grafting was discontinued following a 5-year posttreatment outcome study in 1972 by Jolleys and Robertson,[30] who reported that patients with complete clefts of the lip and palate who had received primary bone grafting had limitation of maxillary growth compared to a control group of patients with clefts but no primary bone grafting. In Eurocleft, the study of treatment outcomes among five European cleft palate centers, it was found that the only center performing primary alveolar bone grafting obtained the worst dentoalveolar relationships suggesting growth impairment of the maxilla.[63] Similarly, poor dentoalveolar outcomes in a center using primary bone grafting were reported by the Americleft intercenter study in North America.[64] Postponing bone grafting surgery until more maxillary growth has occurred is preferred among most cleft palate centers.[65]

Secondary Alveolar Bone Grafting

By definition secondary or delayed alveolar bone grafting is performed after primary lip repair.[59,60] The age at which the bone graft is placed defines whether it is early secondary bone grafting (2 to 5 years), intermediate or secondary bone grafting (6 to 15 years), or late secondary bone grafting (adolescence to adulthood).

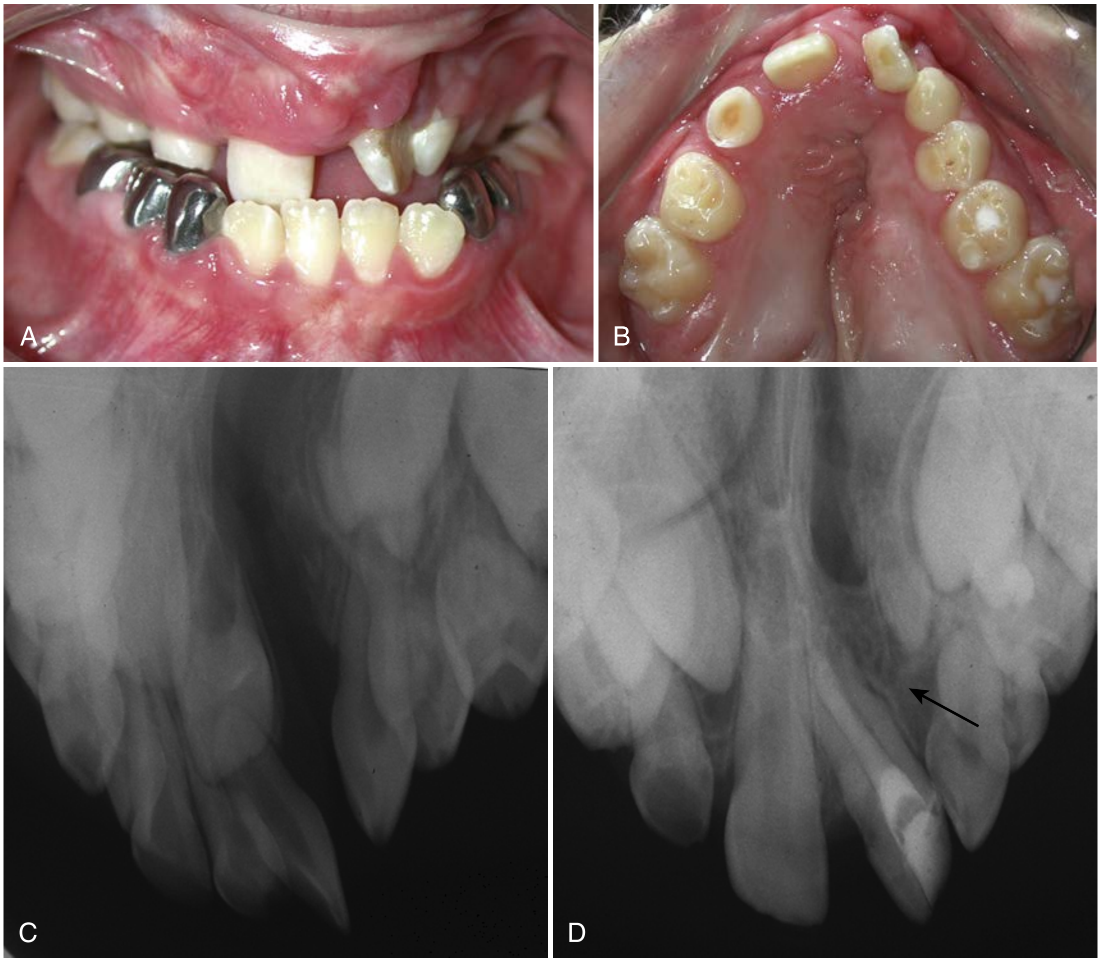

FIGURE 14-11 **A,** Same patient as in Figure 14-10. Intraoral view showing bilateral posterior and anterior crossbites. Note severely rotated maxillary central next to the cleft. **B,** Maxillary occlusal view showing V-shaped arch form with palatal scarring. **C,** Occlusal radiograph showing the bony defect at the cleft site before alveolar bone grafting. **D,** Occlusal radiograph showing successful alveolar bone grafting (the *arrow* points to cancellous bone at the cleft site). Note decayed and endodontally treated maxillary left-central incisor. A developing maxillary left-lateral incisor is now evident at the grafted cleft site.

Intermediate or secondary alveolar bone grafting (6 to 15 years of age). The success of this intervention requires collaborative treatment planning between the orthodontist, surgeon, and other team members.[66-69] Secondary alveolar bone grafting offers five main benefits:

1. Provision of bone support for unerupted teeth and those teeth adjacent to the cleft. If a bone graft is placed before eruption of teeth adjacent to the cleft, it will improve the periodontal support of those teeth. If a bone graft is placed after eruption of the canine, the bone will not improve the crestal height of support and will resorb quickly to its original level.
2. Closure of oronasal fistulae. By using a three-layered closure technique, with the graft sandwiched between the two soft tissue planes, an increased success rate of fistula closure has been reported.
3. Support and elevation of the alar base on the cleft side. This benefit helps to achieve nasal and lip symmetry and provides a stable platform on which the nasal structures are supported. If this procedure is performed alone or is combined with alar cartilage revisions, improved esthetic changes occur.
4. Construction of a continuous arch form and alveolar ridge. This benefits the orthodontist for moving teeth bodily and for uprighting roots into the cleft site. A continuous arch form also benefits the surgeon and prosthodontist by enabling a more esthetic and hygienic prosthesis in preparation for implants to be placed when teeth are missing.
5. Achieve stabilization and some repositioning of the premaxilla in those patients with a bilateral cleft. Controversies concerning alveolar bone grafting require a rational and evidence-based approach for resolution. These controversies relate to the timing of the alveolar bone graft, the sequencing of orthodontic treatment to correct a transverse discrepancy with palatal expansion, and the sites and types of bone for the graft.[70-72]

Timing. The timing of surgery depends more on dental development than on chronologic age. Ideally, the permanent canine root should be half to two thirds formed at the time the

FIGURE 14-12 **A,** Same patient as in Figures 14-5, 14-6, 14-10, and 14-11 shown at 11 years of age undergoing phase I orthodontic treatment (maxillary arch only). **B,** Profile view showing more marked midfacial deficiency. **C,** Intraoral view showing limited bonding of orthodontic appliances in maxillary arch, correction of anterior and posterior crossbites, and alignment of incisors. **D,** Maxillary occlusal view shows palatal expander in place and improved arch form. **E,** Right buccal view showing proclined maxillary incisors, retroclined mandibular incisors, and Class III molar relationship. **F,** Panoramic radiograph showing alignment and uprighting of the endodontically treated maxillary left-central incisor adjacent to the cleft site.

graft is placed (see Fig. 14-14). Permanent canine root formation generally occurs between the ages of 8 and 11 years. Rarely is the graft placed before this time, although occasionally the graft may be placed at an earlier age to improve the prognosis of a lateral incisor. Once teeth have erupted into the cleft site, their periodontal support will not improve with a bone graft. Instead, the height of the crest of alveolar bone resorbs to its original level. For this reason, performing the graft before the eruption of the permanent canine is recommended. If the lateral incisor is on the distal side of the cleft, the graft should be placed earlier. Results from primary bone grafting indicate an adverse effect on maxillary development but, because maxillary growth is almost completed by 10 years of age, performing secondary alveolar bone grafting at this age should have minimal, if any, effect on subsequent facial growth and development.

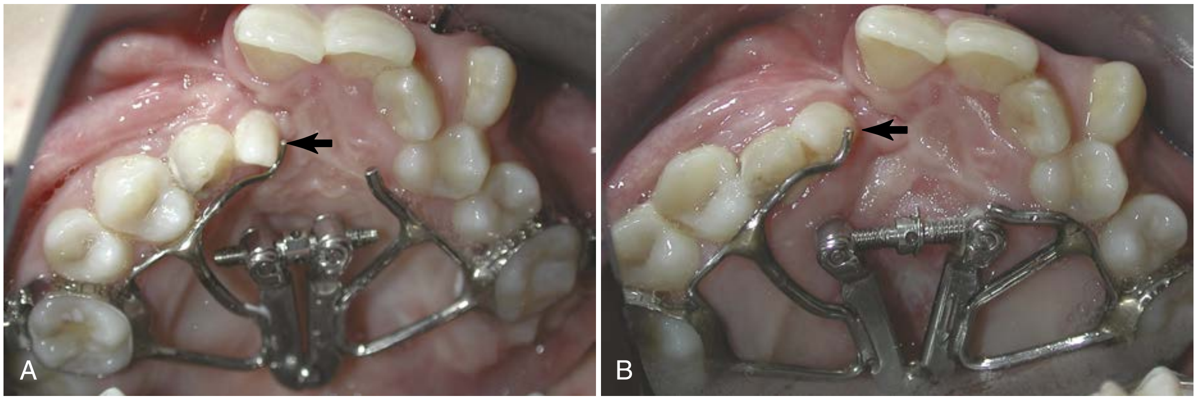

FIGURE 14-13 A, Maxillary occlusal view of 12-year-old patient with repaired, unilateral, right-cleft alveolus. Palatal Spider appliance (*Leone S.P.A. Orthodontic Products, Oxnard, California*) cemented in place. Adjustments of the screw system produce differential expansion in the premolar and canine regions while pivoting around a posterior hinge next to the molars. *Arrow* points to right lateral incisor. Note improved position of right segment (*arrow* points to lateral incisor) in relation to maxillary central incisor, with minimal expansion at the molar region.

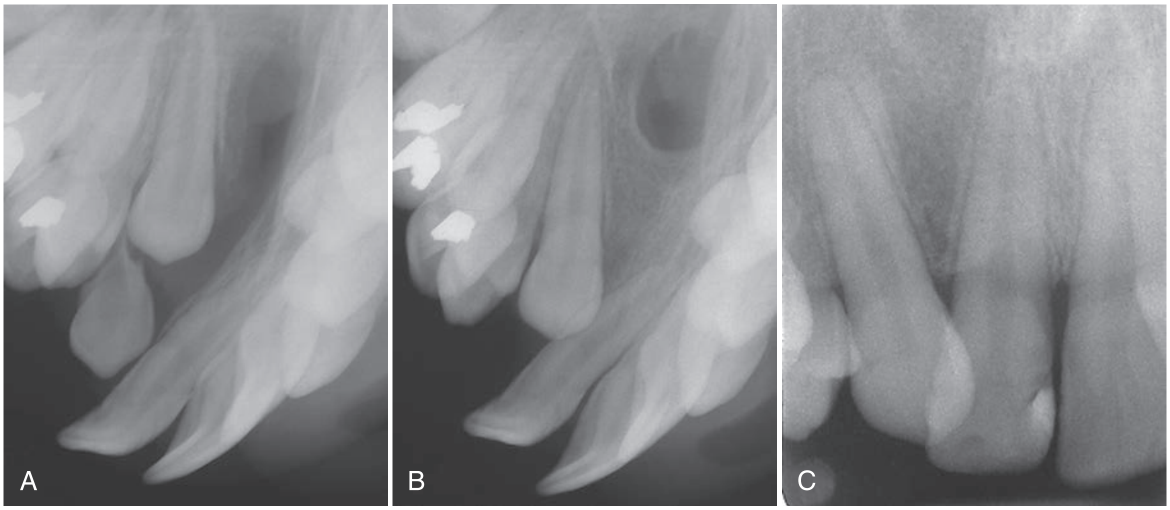

FIGURE 14-14 A, Occlusal radiograph of bone defect at the cleft site before alveolar bone grafting. Lateral incisor is missing and canine has more than two-thirds of its root developed (close to eruption). Note the thin layer of alveolar bone on the central incisor directly adjacent to the cleft. B, Occlusal radiograph taken 7 months after alveolar bone grafting. Note excellent fill of cleft defect with cancellous bone. Canine is erupting through the grafted bone. C, Periapical radiograph taken 4 years after alveolar bone grafting. Note excellent alveolar crest levels adjacent to central incisors and canine.

Sequencing. Secondary bone grafting has been divided into early (2 to 5 years of age), intermediate (6 to 15 years of age), and late (16 years to adult). Since Bergland and coworkers[66] published the results from the Oslo study in which 378 consecutive patients had undergone alveolar bone grafting, contemporary opinion supports the intermediate period as the most appropriate time for grafting. Bone grafting in the intermediate period has the greatest benefits and least risk for interfering with midfacial and skeletodental growth and development. The sequencing of procedures surrounding alveolar bone grafting requires interdisciplinary communication and cooperation resulting in better and more predictable patient care. The general or pediatric dentist ensures that any decayed teeth, especially those adjacent to the cleft, are restored before the grafting procedure. Patient and parents are instructed on good oral hygiene practices to maintain at home. In addition, orthodontic treatment may be required presurgically to reposition maxillary teeth that are in traumatic occlusion or to expand a severely constricted maxilla, thus providing the surgeon better accessibility to the cleft defect. In bilateral cleft lip and palate cases, a vertically extruded premaxilla can be repositioned upward with the use of a labial intrusion archwire, moving the incisors en masse with the bone in vertical alignment with the posterior segments prior to bone grafting (Fig. 14-15). Alternatively, a miniscrew can be placed directly in the premaxilla to stabilize, intrude, or align an edentulous and mobile premaxilla prior to alveolar

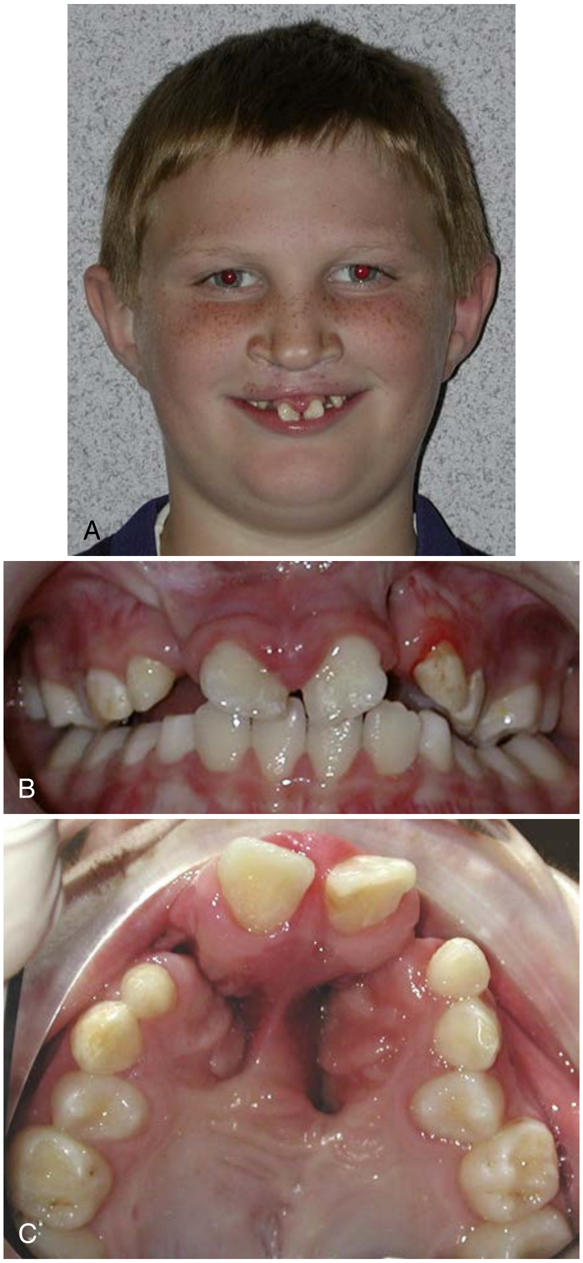

FIGURE 14-15 A, Same patient as in Figure 14-9 shown at 11 years of age after maxillary expansion and orthodontic repositioning of premaxilla. B, Frontal intraoral view showing premaxillary segment in better vertical alignment with the rest of the arch. C, Maxillary occlusal view showing improved arch form. There are persistent palatal fistulas, which are adequately obturated by a Hawley retainer (not shown).

bone grafting.[73] Any erupted teeth adjacent to the cleft that have poor periodontal or endodontic prognosis should be extracted at least 2 months in advance to allow healing of mucosal tissues before surgery.

Surgical technique. The grafting procedure uses tissue lining the cleft defect to construct a nasal floor and close the nasal side of the oral-nasal fistula. The cleft lining is elevated in a subperiosteal plane that leaves bare the osseous margins of the cleft. Cancellous bone taken from the ilium, cranium, or mandibular symphysis is then packed into the cleft defect. Cancellous bone is preferred over cortical bone because it revascularizes more rapidly and is less likely to become infected.[72] Once the cleft defect is packed with bone and the margins are overpacked, soft tissue coverage of the graft is required. The surgeon determines the choice of the donor site from which the bone is harvested. Traditionally, the iliac crest, ribs, and tibia have been used because of their abundant supply of cancellous bone. The morbidity of harvesting bone from these sites results in most patients being hospitalized postsurgically because of complications associated with the donor site more so than with the oronasal recipient site. The cranium has become an alternative site from which to harvest cancellous bone because of the lack of associated discomfort and the amount of hospitalization time involved. However, the operating risks are higher and the abundance of cancellous bone is less than from the iliac crest. The mandibular symphysis is another donor site but should be recommended only when the permanent mandibular canines have been located so as to minimize the chances of injuring these developing teeth.

Orthodontic considerations associated with secondary bone grafting. Orthodontic concerns regarding secondary bone grafting relate to the transverse dimension, incisor alignment, and eruption of the maxillary canines.

The transverse dimension. Orthodontic expansion of the posterior segments (see Fig. 14-7, *C*) preoperatively may improve the occlusion but also widen an existing fistula. The expansion provides better access at surgery for incision and elevation of flaps with closure of the palatal and vestibular oronasal fistulae following the cancellous alveolar bone graft. Expansion also improves the buccolingual orientation of the collapsed posterior segment with the anterior segment, restoring arch symmetry (see Fig. 14-15, *B*). Retention of the corrected crossbite with orthodontic appliances postsurgically may be indicated because the bone graft is unlikely to stabilize the expansion.

Incisor alignment. Alignment of incisors adjacent to the cleft, which typically are rotated, displaced, or tipped, is limited by the available bone into which the roots of the teeth may be moved. If appliances have been placed presurgically, individual orthodontic tooth movements should be delayed until 2 to 6 months following placement of the bone graft. The early movement of the roots into the grafted bone appears clinically to consolidate the alveolar bone and improve the crestal alveolar height. The orthodontist should confirm with the surgeon on the timing of tooth movement into the grafted cleft site. When there are severely rotated incisors near an edentulous space, such as a maxillary central next to a grafted alveolar cleft, the long interbracket span limits the control on force application to effect the derotation. Proff and coworkers[74] reported that placing a miniscrew directly on a well-consolidated graft is an effective method of anchorage to help straighten adjacent teeth.

Eruption of the maxillary canine. Following surgery, the maxillary canine erupts through the grafted bone (see Fig. 14-14, *C*). With orthodontic movement of teeth, sufficient space is created in the arch to allow the canines to erupt successfully. Removal of unerupted supernumerary teeth usually is performed at the time that the bone graft is placed to create an unobstructed path of eruption for the canine. Often the canine will erupt rapidly following the bone graft. If the lateral incisors are malformed or absent, especially in patients with bilateral clefts, the canine is encouraged to erupt adjacent

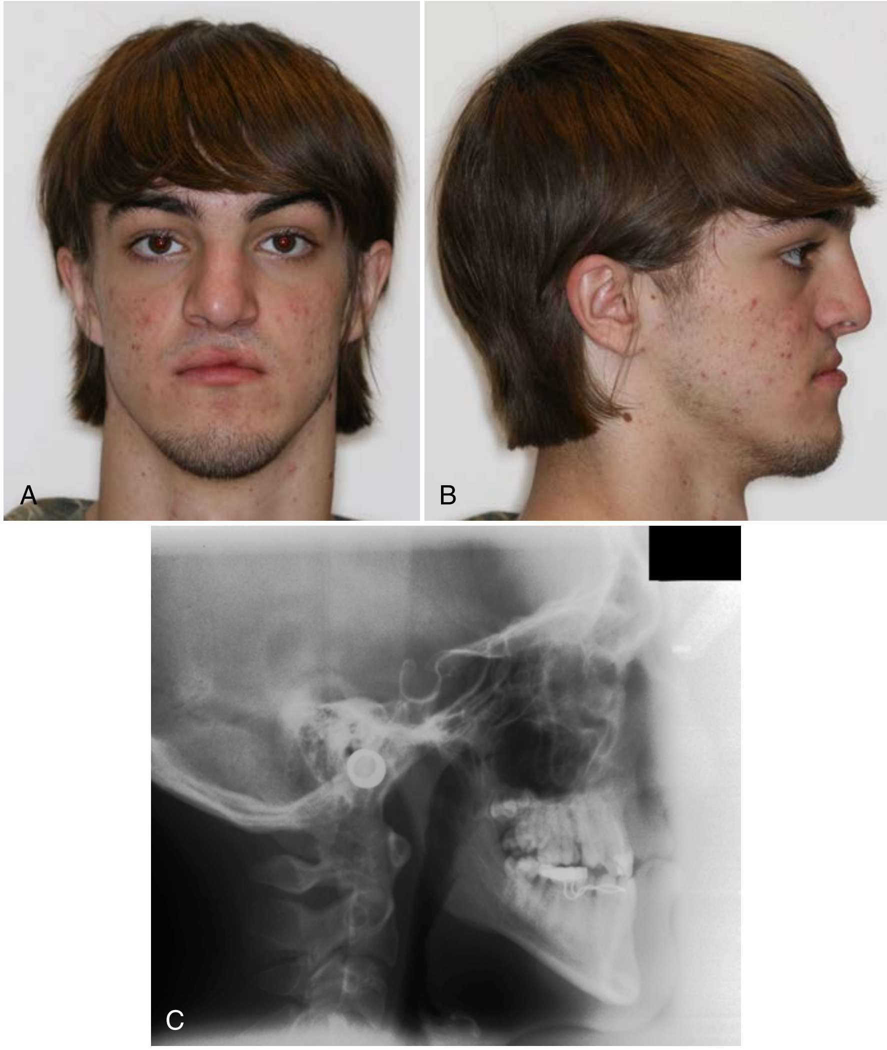

FIGURE 14-16 **A,** Frontal view of same patient as in Figures 14-5, 14-6, and 14-10 to 14-12, hereby shown at age 16. He is interested in combined orthodontic-surgical treatment and future dental implants. **B,** Profile view showing bimaxillary retrusion, especially in the maxilla, concave profile, malar deficiency, and increased lower facial height. **C,** Lateral skull radiograph. Note bimaxillary retrusion, high mandibular-plane angle, and upright incisors in anterior crossbite. (Reprinted from Mercado AM, Vig KWL. Orthodontic principles in the management of orofacial clefts. In: Losee J, Kirschner RE, eds. *Comprehensive Cleft Care*. 6th ed. London: CRC Press Taylor & Francis Group, Inc.; 2015.)

to the central incisors. Closing the edentulous space is an advantage, thus avoiding the need for a prosthetic replacement of the absent lateral incisors. However, "canine substitution" needs to be considered in the context of the occlusion, crown morphology, and the need for orthognathic surgery.

Permanent Dentition Stage

With the eruption of the canines and premolars, the permanent dentition is established. During this time, the adolescent growth spurt and onset of puberty occur. The skeletal discrepancy becomes accentuated and facial appearance and occlusal relationships deteriorate (Figs. 14-16 and 14-17). These changes occur at a time when individuals are most self-conscious about their body image and facial appearance. Facial scars already detract from the cosmetic appearance, and derogatory comments by peers may have a profound psychological effect. Ward and coworkers[54] found that children with clefts reported lower social-emotional well-being compared with noncleft children. This effect was greater in adolescents 15 to 18 years of age than in younger children, pointing to the challenges that adolescents with clefts encounter with peer interactions. During adolescence, involution of the adenoidal lymphoid tissue occurs, often with impairment of speech from the resulting hypernasality. With a decline in cosmetic appearance and speech communication, many patients have a special need for early intervention by the surgeons, orthodontists, speech therapists, and psychologists.

Growth Considerations

Patients with unilateral complete clefts of the lip and palate typically become more maxillary deficient and mandibular prognathic in their appearance, because of sagittal maxillary

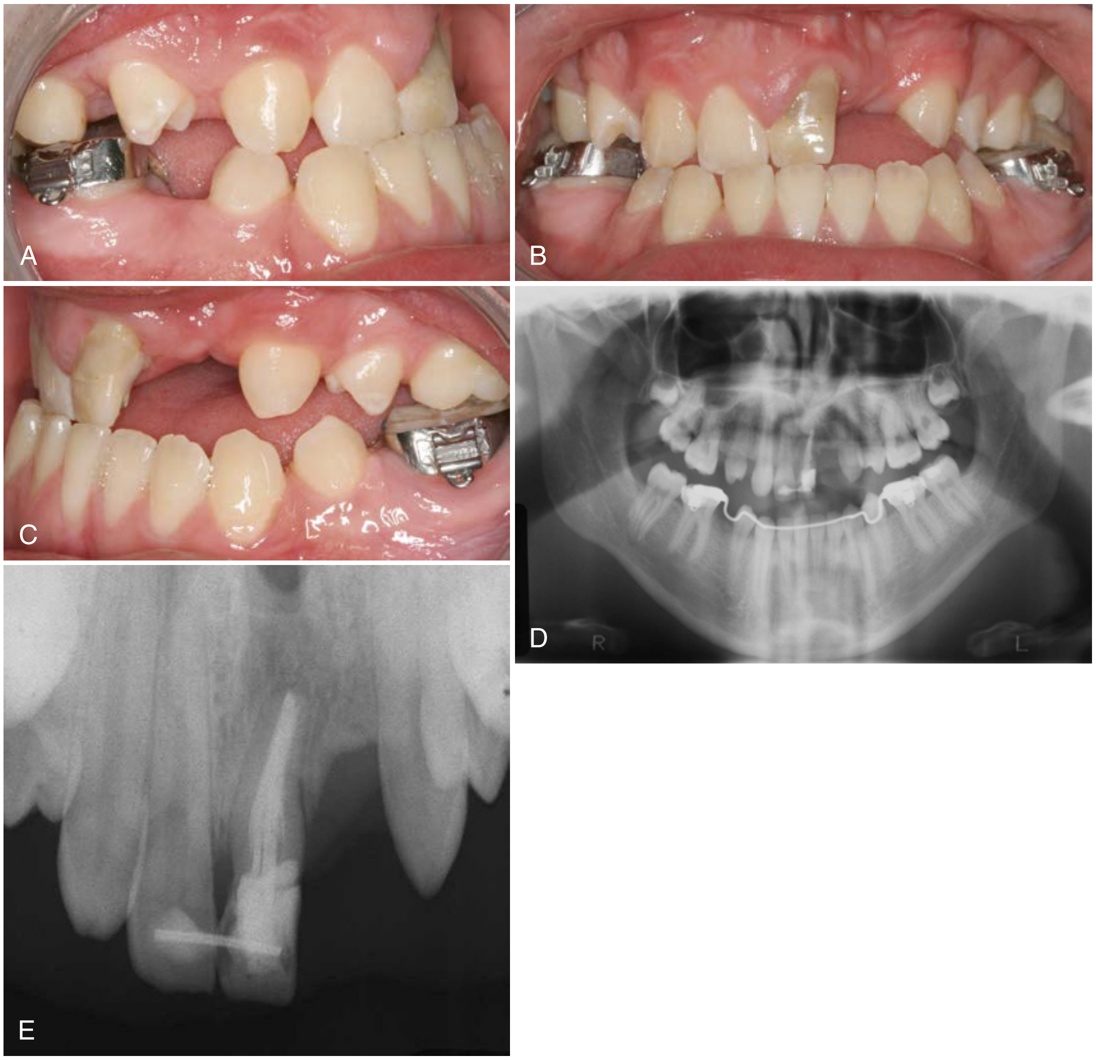

FIGURE 14-17 A to C, Intraoral views of same patient illustrated in Figures 14-5, 14-6, 14-10 to 14-12, and 14-16, shown at age 16. Note right Class III molar and left Class I molar, anterior crossbite with retroclined incisors, signs of gingival recession of #9, and labial aspect of lower incisors. Tooth #9 is discolored due to previous endodontic involvement. Maxillary midline is deviated to the right. Lower lingual holding arch in place. D, Panoramic radiograph showing congenitally missing teeth #4, 7, 13, 20, and 29. Tooth #10 was removed previously due to malformation and lack of root development. Evidence of endodontic treatment and large composite restoration on tooth #9. E, Occlusal radiograph showing adequate alveolar bon-fill at cleft site but lacking in vertical height, especially on distal aspect of #9. Prognosis of #9 is poor. (Reprinted from Mercado AM, Vig KWL. Orthodontic principles in the management of orofacial clefts. In: Losee J, Kirschner RE, eds. *Comprehensive Cleft Care*. 6th ed. London: CRC Press Taylor & Francis Group, Inc.; 2015.)

deficiency. Vertical maxillary deficiency may result in overclosure of the mandible to achieve occlusion of the teeth, thus accentuating the Class III tendency. Clinical evaluation of the extent of overclosure contributing to the Class III relationship by measuring the interocclusal clearance at the premolar region with the patient in resting posture is important. The Class III dental relationship in the sagittal plane may accentuate discrepancies in the transverse plane and are often manifested as posterior crossbites. To evaluate the occlusion, study models are necessary to assess the relationship of the maxillary to mandibular dentition in all three dimensions.

The pattern of facial growth results from the interaction of genetic and environmental factors. Continued growth in early adulthood may enhance or detract from treatment results that have been obtained during childhood and adolescence (Fig. 14-18). These dynamic properties of the face make the management of facial growth challenging and rewarding.[49,50] A patient whose treatment in the permanent dentition allowed camouflage of the skeletal discrepancy is illustrated in Figures 14-19 and 14-20.

Skeletal-Facial Considerations

Examination of facial balance and proportions is critical in determining a treatment plan that combines surgery and orthodontics. This clinical evaluation should be carried out with the patient standing so that one can consider the overall

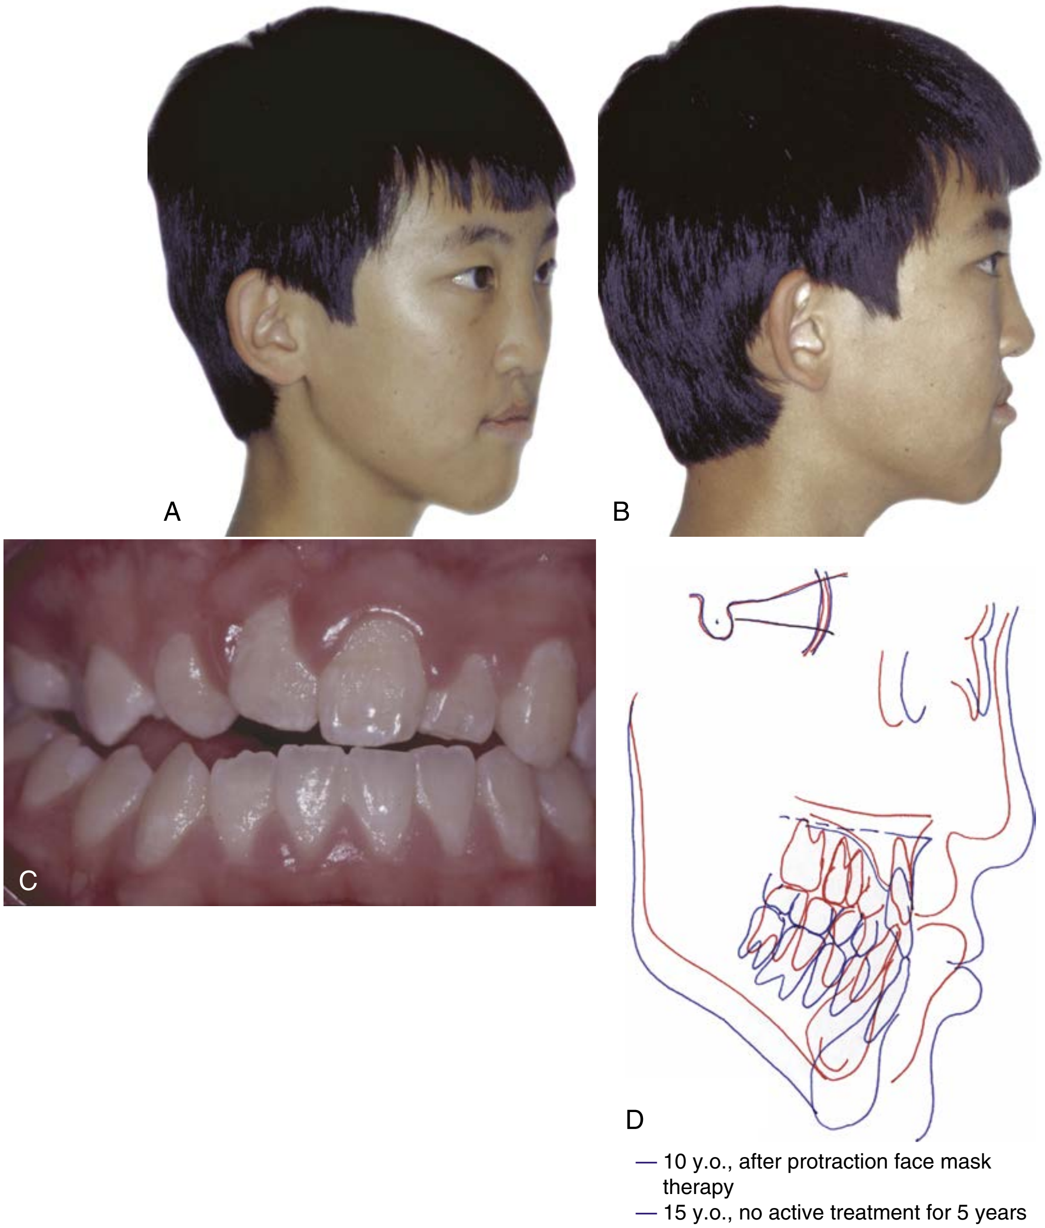

FIGURE 14-18 A, Same patient as in Figures 14-7 and 14-8 shown at 15 years of age. No active orthodontic treatment had been delivered for 5 years after completion of protraction face-mask therapy. B, Profile view shows a straight to slightly concave profile with long, lower facial height. C, Intraoral view shows anterior edge-to-edge relationship, mild incisor rotations, and constricted maxillary-posterior segments. D, Superimposition of lateral cephalogram tracings from immediately after protraction and 5 years after protraction (no active treatment), showing skeletal growth in a predominantly vertical downward pattern.

stature. Full-face and profile assessment provides a database incorporating all three dimensions, and this information should be documented with the patient in resting position and also in occlusion. Cephalometric analysis and prediction tracings provide further information for deciding whether a patient can be treated by orthodontics alone or by orthodontics and an orthognathic surgical procedure. If the skeletal discrepancy is mild and aesthetic concerns are minimal, dental compensation by orthodontic treatment alone may be recommended. A change in axial inclination of the teeth may camouflage the skeletal relationship adequately (see Figs. 14-19 and 14-20). However, one should be cautious because the individual may outgrow the dental correction so that ultimately orthognathic surgery is indicated. The presurgical phase of orthodontic treatment requires decompensation of the dentition so that the maxillary and mandibular teeth are placed in their correct relationship to the underlying skeletal bases. If orthodontic therapy has achieved the ideal relationship of the teeth to the maxillary and mandibular skeletal bases, surgical movements will result in the dentition and the maxilla and mandible being optimally related. With conventional orthognathic surgery techniques for patients with severe

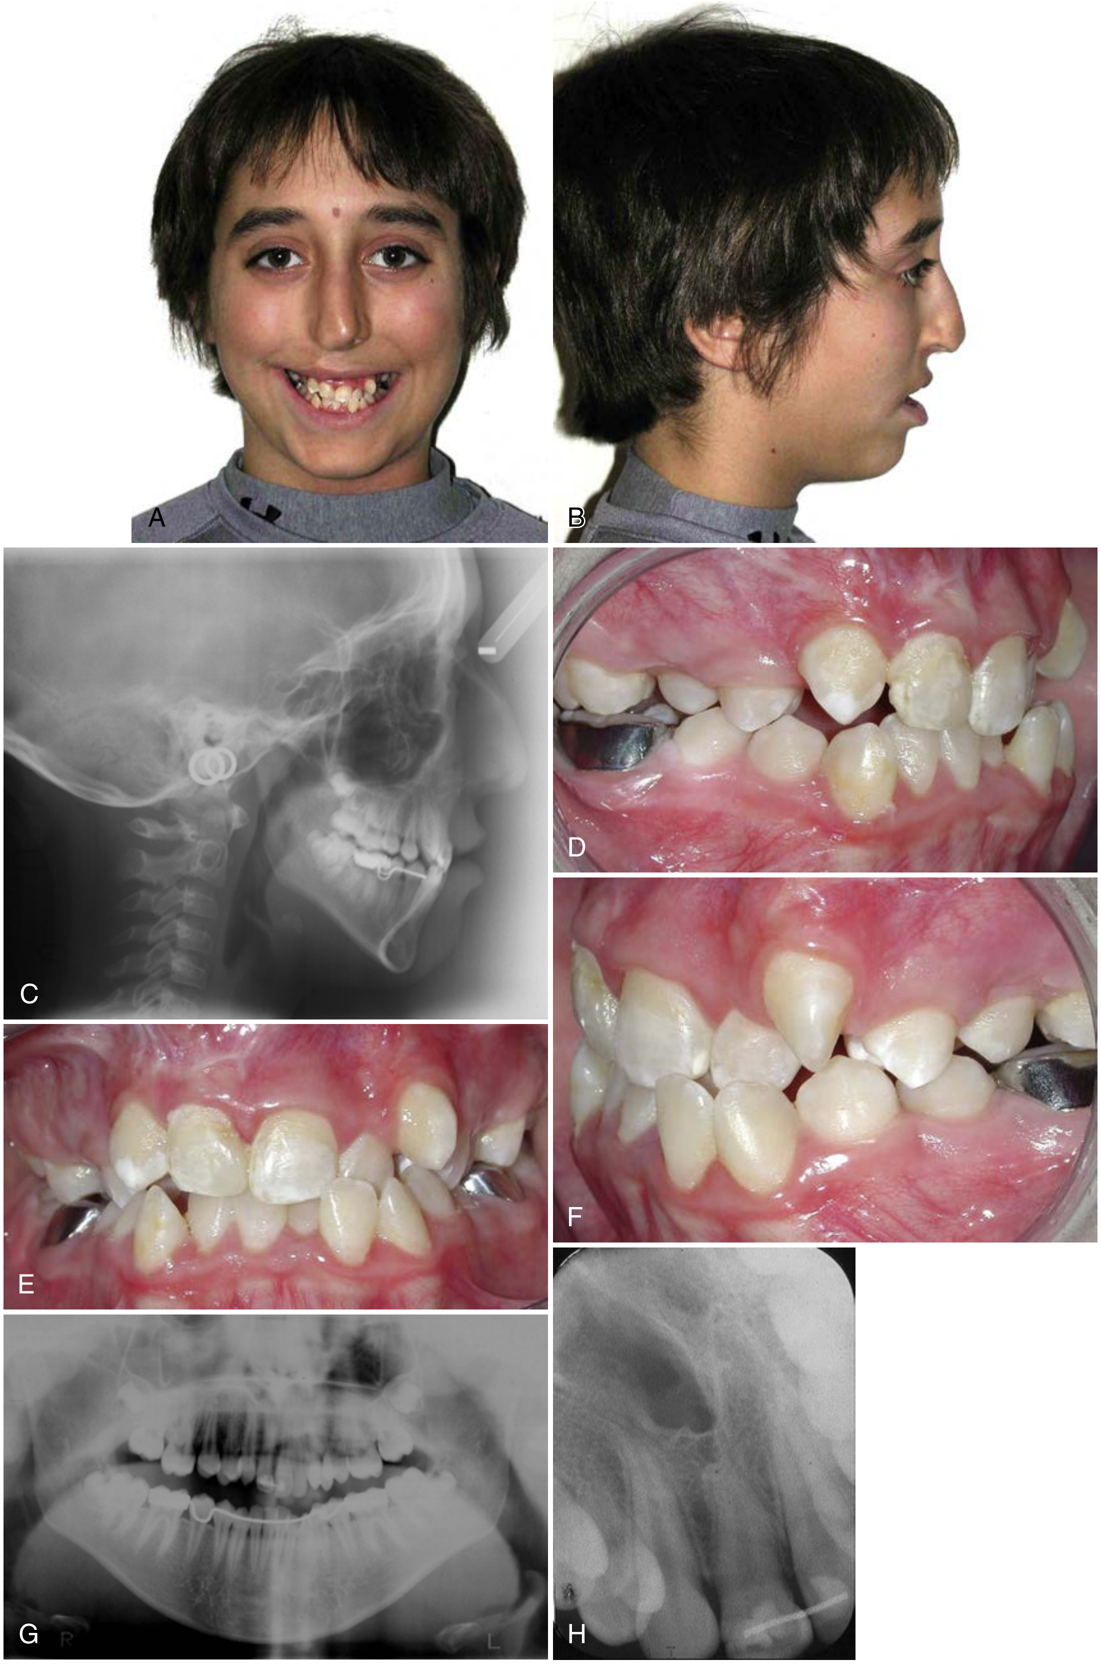

FIGURE 14-19 **A,** Frontal view of a 13-year-old boy with repaired, complete, and unilateral right cleft lip and palate. He is interested in orthodontic treatment without orthognathic surgery. **B,** Profile view showing bimaxillary retrusion, mildly convex profile and lip incompetence. **C,** Lateral skull radiograph. Tooth #9 was extracted due to increased bone loss and mobility. Gingival grafting was done on labial aspect of lower incisor region prior to incisor proclination. (Reprinted from Mercado AM, Vig KWL. Orthodontic principles in the management of orofacial clefts. In: Losee J, Kirschner RE, eds. *Comprehensive Cleft Care*. 6th ed. London: CRC Press Taylor & Francis Group, Inc.; 2015.)

maxillary hypoplasia, surgeons would advance the maxilla as much as possible in the presence of the scar tissue from the lip and palate repairs (Figs. 14-21 to 14-23). The remaining skeletal discrepancy would be corrected with a mandibular setback. Essentially, this was a surgical camouflage of the inability to correct the underlying maxillary hypoplasia predictably. Additionally, the velopharyngeal mechanism may be compromised by maxillary advancement, especially if a pharyngeal flap has been already performed to improve speech.

Orthognathic Surgery

Treatment planning. The timing and sequencing of treatment require close collaboration of the team. The decision to delay surgical orthodontic treatment until growth is stabilized may be sound but not always in the patient's best interest, especially when psychosocial development is affected. In some instances, skeletal surgery may be indicated before growth is completed, knowing that another procedure may be necessary if the patient outgrows the correction. As a general

FIGURE 14-22 **A,** Frontal view of same patient illustrated in Figures 14-5, 14-6, 14-10 to 14-12, 14-16, 14-17, and 14-21; shown at 20 years following orthognathic surgery. He underwent an 8-mm LeFort I advancement. **B,** Profile view shows a more balanced facial profile. **C,** Lateral skull radiograph showing improved maxillary position and rigid fixation. Endosseous implants have been placed for #7, 20, 29. Miniscrews have been placed to hold a bone graft augmenting the bone level in edentulous region of #9 and 10. (Reprinted from Mercado AM, Vig KWL. Orthodontic principles in the management of orofacial clefts. In: Losee J, Kirschner RE, eds. *Comprehensive Cleft Care*. 6th ed. London: CRC Press Taylor & Francis Group, Inc.; 2015.)

rule, skeletal surgery, orthodontic intervention, and final prosthetic rehabilitation should be completed before final soft tissue nose and lip revisions or rhinoplasty are instituted. The outcome of soft tissue surgical revisions, combined with osteotomies for the mobilization of the maxilla and mandible, is often unpredictable until the skeletal discrepancy has been corrected.

Role of the Orthodontist

A coordinated approach to the presurgical phase of orthodontic treatment is indicated. Twelve to 18 months of presurgical orthodontics are usually necessary to align the teeth, correct any compensations in axial inclination of teeth and any dental midline discrepancy, coordinate arches, and localize space for prosthetic replacement of the teeth (see Fig. 14-21). The provision of space for surgical cuts between the crown and the roots of adjacent teeth is also an important part of the presurgical preparations. Ideally, the patient is referred to the surgeon for a presurgical consultation, and the surgical movements are performed on mounted dental casts. Close communication between the surgeon and the orthodontist should identify any occlusal discrepancies that may prevent coordination of arches. The placement of full-size edgewise arch wires, with lugs, provides a means of intermaxillary fixation at the time rigid internal fixation is performed. After surgery is completed, the postsurgical phase of orthodontics details the occlusion, which should be completed within 4 to 6 months (see Figs. 14-22 and 14-23).

Distraction Osteogenesis

With the advent of distraction osteogenesis, correction of severe maxillary hypoplasia solely by advancing the maxilla

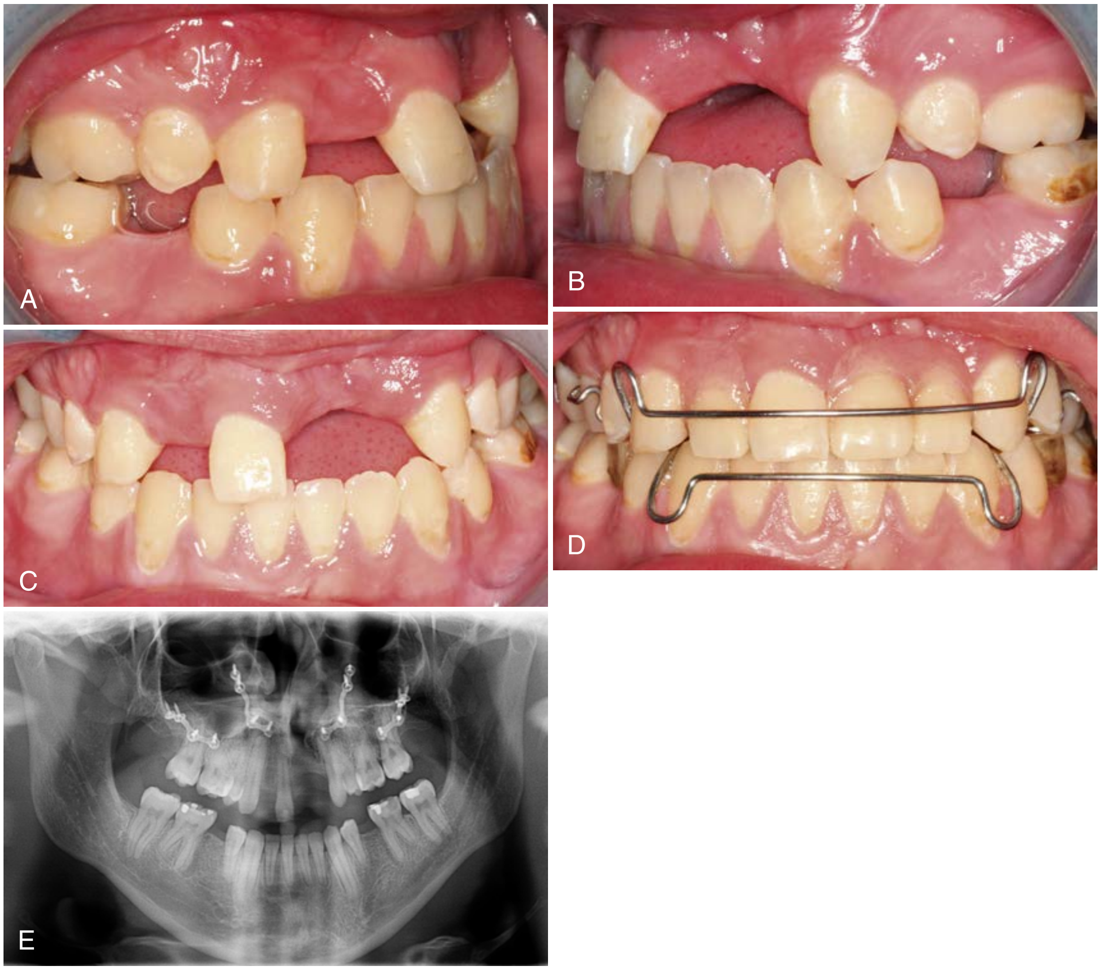

FIGURE 14-23 A to C, Intraoral views of same patient illustrated in Figures 14-5, 14-6, 14-10 to 14-12, 14-16, 14-17, 14-21, and 14-22, shown at age 20 following orthognathic surgery. Note bilateral Class II molar and Class I canine relationships, adequate overbite, and overjet. D, Intraoral view with Hawley retainers in place. The maxillary retainer has pontics for temporary replacement of #7, 9, and 10. E, Panoramic radiograph taken upon debonding, before implant placement. (Reprinted from Mercado AM, Vig KWL. Orthodontic principles in the management of orofacial clefts. In: Losee J, Kirschner RE, eds. *Comprehensive Cleft Care*. 6th ed. London: CRC Press Taylor & Francis Group, Inc.; 2015)

may be possible.[75-77] Such correction would be accomplished by expansion of the scar tissue at the same time distraction osteogenesis is performed. Briefly, rigid external distraction (RED) involves cementation of an intraoral tooth-borne splint in the maxilla with hooks extending extraorally for traction. The appliance is usually fabricated and delivered by the orthodontist. This tooth-borne method of attachment to the maxilla may place the teeth at risk of periodontal damage. Bone-borne methods of attachment reduce such risk and include miniscrews placed bilaterally in the alveolar ridges to guide the skeletal movements[73] or preadapted miniplates fixated to the anterior surface of the maxilla beside the piriform aperture for traction[78] (Figs. 14-24 to 14-26). A complete LeFort I osteotomy is performed, and a RED device is placed intraoperatively. The vector of the anterior force can be adjusted for each patient during the course of distraction, which is done at home by patients turning the activation screw at a rate of 1 mm per day. Following advancement, the RED device is maintained for 2 to 3 weeks for bone consolidation. This is followed by a retention period during which the patient wears a protraction face mask. Internal distractors, which typically are bone-borne, have also been used in patients with cleft maxillas.[79] The distractor rod penetrates into the oral cavity, thus activation of the system is possible via an intraoral approach. After the desired advancement is achieved, the turning arms are removed and the submucosal components stay in place. This method has the added benefit of allowing for long consolidation periods (3 months).

The benefit of distraction osteogenesis in a hypoplastic maxilla with scar tissue and a compromised blood supply lies in a more gentle skeletal advancement with corticotomy cuts without downfracture of the maxilla. The orthodontist may monitor for hypernasal speech that could occur with advancement of the maxilla. Because the nasomaxillary complex is advanced slowly, at a millimeter per day, speech may be evaluated at intervals as the advancement proceeds and adaptation of the velopharyngeal mechanism occurs. Again, the treatment benefits need to be weighed against the burden of care

FIGURE 14-24 21-year-old male with repaired cleft lip and palate on the right side undergoing comprehensive orthodontic treatment. **A** to **C,** Facial images showing lack of support for upper lip, excessive lower-incisor display, and concave profile due to severe maxillary retrognathia. Patient is interested in orthognathic surgery for maxillary advancement. **D** to **F,** Facial images after 13-mm maxillary advancement using a RED device and bone-anchored plates. Note improved upper lip support, improved smile aesthetics, and more balanced profile.

and considered in the context of the scientific evidence of the probability of achieving quantifiable outcomes of success and failure.[80,81]

In craniofacial anomalies presenting with severe mandibular retrognathia, such as Pierre Robin sequence or Goldenhar syndrome, mandibular advancement is needed to improve a compromised airway. When distraction osteogenesis is done to advance the mandible, there is often an unfavorable side effect in the vertical dimension manifested as an anterior open bite. Miniscrews can be placed bilaterally on the alveolar ridges of maxilla and/or mandible to serve as attachments for intermaxillary elastics during protraction, therefore preventing the development of an open bite (Fig. 14-27).[73]

MANAGEMENT OF THE MISSING LATERAL INCISOR SPACE

Patients with clefts often have an edentulous ridge in the cleft region, either due to congenital agenesis or previous extraction of teeth. In such cases, the most common options for management of the edentulous area include space closure, fixed versus removable prosthesis, and osseointegrated implants.

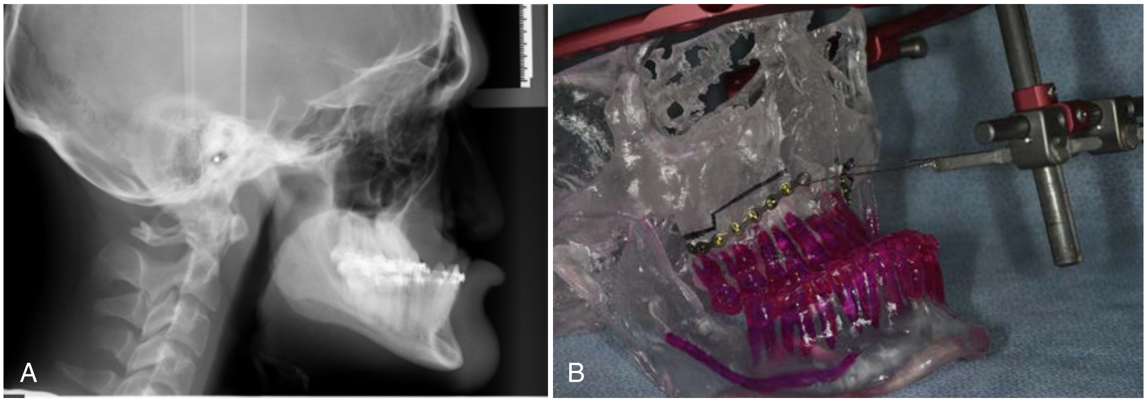

FIGURE 14-25 Same patient illustrated in Figure 14-24. **A,** Cephalometric radiogram before distraction. SNA angle = 62 degrees (severe maxillary retrusion); SNB angle = 81 degrees (normal mandibular position); ANB angle = −19 degrees (severe maxilla-mandibular discrepancy). **B,** To avoid excessive dental movement often associated with tooth borne anchorage, 2-mm plates are adapted along the osteotomy and anchored to the maxilla with a minimum of six screws on each side. Wires extending from the anterior hole of the plate exit via percutaneous punctures adjacent to the ala bilaterally. This allows for skeletal anchorage and a more controlled vector of distraction. In this figure, the plates are shown adapted to a stereolithic model for illustrative purposes. Adaptation is easily accomplished during surgery and a model is not generally required. The wire extensions connect to the adjustable screw system in the vertical bar of the RED.

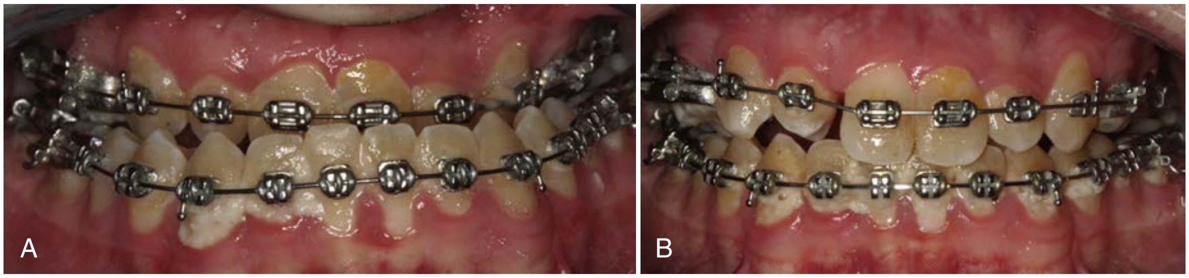

FIGURE 14-26 Same patient illustrated in Figures 14-24 and 14-25. **A,** Frontal intraoral view prior to distraction. Overjet is −10 mm. Overbite is nearly 50%. **B,** Frontal intraoral view after distraction. Overjet is 2 mm. Positive overbite has been maintained.

FIGURE 14-27 Intraoral view of an 8-year-old child with Goldenhar syndrome who underwent mandibular advancement with distraction osteogenesis to improve his airway. Anterior open bite is evident. Miniscrews were inserted in anterior maxilla and composite resin was applied on the miniscrew heads for increased retention of elastics and for patient comfort. Miniscrews could not be placed in anterior mandible due to close proximity of roots. A lower labial arch with hooks was cemented. Patient was instructed to wear intermaxillary elastics between the miniscrews and the hooks, to help close the bite.

The need for prosthetic replacement of the missing lateral incisor can be avoided by allowing mesial eruption of the canine, moving the posterior teeth anteriorly with orthodontics, and cosmetic "reshaping" of the canine (see Fig. 14-20, *E*). If the space is preserved, the options to consider for the replacement of missing teeth at the cleft are fixed versus removable prosthesis. Fixed prostheses are a feasible option for patients with a single tooth missing in the cleft area, patients with failed or nonexistent alveolar bone grafts who need stabilization of the maxillary segments, and patients whose teeth adjacent to the cleft are decayed or malformed. Removable prostheses are a better option for replacing multiple teeth, restoring long edentulous spans, simultaneous obturation of residual palatal fistulas, improvement of lip support by using acrylic flanges, and for transitional replacement of teeth in young patients prior to definitive prosthetic rehabilitation. The orthodontist should work in consultation with the prosthodontist to determine the optimal space distribution between teeth that will allow an unrestricted path of insertion for the prosthesis, and will ultimately result in a functional occlusion with harmonious aesthetics.

Endosseous implants can be used effectively to restore the edentulous cleft area, most commonly when there is a single

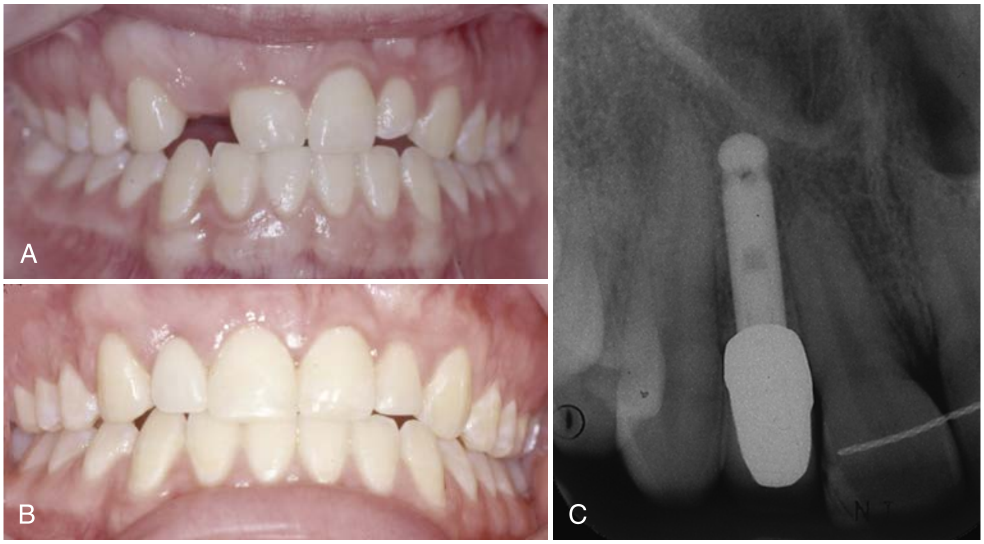

FIGURE 14-28 Sixteen-year-old patient with bilateral cleft lip and unilateral cleft palate on the right alveolus. **A,** Intraoral view after alveolar grafting and orthodontic treatment, showing edentulous ridge in area of missing #7. Tooth #10 is malformed. Note uneven gingival margins. **B,** Intraoral view after implant and crown for replacement of #7 and cosmetic bonding of #8 and 10. Gingivoplasty was done to achieve gingival symmetry and adequate soft tissue contours. **C,** Periapical radiograph showing osseointegration of implant fixture in the former site of the cleft alveolus. Endosteal fixtures of smaller diameters are now available with ideal indication for narrow interdental spaces typical such as cleft sites.

missing tooth, healthy adjacent teeth, and an adequate volume of alveolar bone (Fig. 14-28).[82-84] This requires careful planning with the oral surgeon and the prosthodontist prior to orthodontic distribution of the adequate spaces between the teeth. The orthodontist must ensure that roots of teeth adjacent to the edentulous area are upright and parallel, which will allow the surgeon to insert the endosteal fixture without risk of damaging adjacent roots. For the young adolescent patient who completes orthodontic treatment, it is recommended to postpone implant placement until the patient has completed both sagittal and vertical growth.[85,86] In such cases, a Hawley retainer with pontic teeth can be used to maintain the alignment and arch form (see Fig. 14-23, *C* and *D*). In the postadolescent period, the orthodontist should assess facial growth by superimposing cephalometric radiographs taken 6 months apart and looking for longitudinal changes in the sagittal and vertical dimensions. When serial superimpositions show no significant dimensional changes, then completion of facial growth has been attained. During the growth monitoring period, the edentulous grafted area may show radiographic evidence of resorption over several years in adolescents whose lateral incisor space is preserved for future implant placement. The greater the interval between secondary bone graft and implant placement, the more likely that the residual graft will need to be augmented with a new bone graft.[83] Kearns and coworkers[83] recommend that patients who receive secondary bone grafts in the mixed dentition should be regrafted between 15 and 17 years of age, followed by implant placement within 4 months thereafter.

SUMMARY

The orthodontist's role in the cleft palate team requires close collaboration with the other team members. The rationale of timing and sequencing of orthodontic treatment have been discussed in four periods of development: (1) neonatal or infant maxillary orthopedics, (2) orthodontic considerations in the primary dentition, (3) mixed dentition to include presurgical considerations before an alveolar bone graft is placed, and (4) final treatment in the permanent dentition with orthodontics only or combined with orthognathic surgery. The latter period combines an orthodontic and surgical approach to the correction of dental and skeletal components of malocclusion and facilitation of any necessary prosthodontic treatment. Speech considerations and the communicative skills of the patient with a cleft are important aspects in planning orthognathic surgery for these patients. Subsequent nose and lip revisions for cosmetic improvement also must not be underestimated in the enhancement of the final, soft-tissue, facial aesthetic result following correction of the skeletal and dental discrepancies. Provided that the team members plan the timing and sequencing of appropriate treatment modalities in a closely coordinated, problem-oriented approach, patients with clefts should have optimal functional and aesthetic results. Outcome measures for reporting the results of surgical interventions require the choice of valid and reliable measures to be identified and implemented.[80,81] The ultimate outcome for team-based care is to have a fully rehabilitated patient who is satisfied with the treatment outcomes in terms of speech, occlusion, facial and dental aesthetics, and function. The patient should continue to receive conventional dental and medical routine evaluations similar to any adult to maintain optimal oral health.

Acknowledgements

We thank Dr. Philip Samuels (perinatologist) and Ms. Pamela Foy (sonographer) at The Ohio State University Department of

Obstetrics and Gynecology for their permission to publish Figure 14-1. We are indebted to Dr. Supakit Peanchitlertkajorn for permission to publish Figures 14-3 and 14-4 (neonatal orthopedics). Our gratitude goes to Dr. Peter Larsen for permission to publish Figures 14-24, 14-25, and 14-26 and to Dr. Lawrence Wright, orthodontist who treated the patient in those figures. We thank the past and present members of the Cleft Palate–Craniofacial Team at Nationwide Children's Hospital in Columbus, Ohio, and of The Ohio State University College of Dentistry for their collaboration in the treatment of the cases illustrated in this chapter.

Patient Management and Motivation for the Child and Adolescent Patient

Patrick Turley and Patricia Turley

OUTLINE

BEHAVIOR GUIDANCE

Behavior guidance skills are an important aspect of providing quality and efficient treatment for the child or adolescent patient. Patients seek our services for the treatment of dental diseases or malocclusions, but performing these services often requires modifying the child's behavior.

The American Academy of Pediatric Dentistry (AAPD) first published guidelines on behavior guidance in 1989,[1] with the most recent revision occurring in 2011.[2] Some of what is discussed in this chapter is based on that document. Behavior guidance is described as "a continuum of interaction involving the dentist, dental team, patient, and the parent directed toward communication and education. Its goal is to ease fear and anxiety while promoting an understanding of the need for good oral health and the process by which that is achieved."

In addition to allowing the orthodontist to perform quality treatment safely and efficiently, behavior guidance allows the doctor and staff to teach appropriate coping mechanisms; guide the child to be cooperative, relaxed, and self-confident in the dental setting; extinguish inappropriate behavior; and establish communication. Finally, behavior guidance allows the clinician to develop and nurture the relationships between the patient and doctor, which ultimately builds trust and allays fear and anxiety.

Pain Management

Pain management is essential for proper behavior guidance. Children respond differently to painful stimuli; hence, the orthodontist must be vigilant in listening to the patient and observing signs of pain such as facial expression, crying, complaining, and body movement.[3–7] Pain perception is strongly related to psychological characteristics. Dental anxiety has been shown to be higher in patients who were high pain responders, and they experienced more pain than low pain responders.[8] Inadequate pain management not only makes the delivery of treatment more difficult; it also makes future treatment more complicated. A painful past medical or dental experience is a common cause of fear and behavior problems in the dental environment.[9,10]

First Impressions

Setting the stage for optimum behavior can begin even before the patient presents to the office. Having a customized website introduces the parent and child to the practice and can begin to allay fears of the unexpected. The initial telephone call is extremely important in establishing rapport with the parent. These calls should be scripted, and every staff member who answers the phone should be trained to obtain all essential information while beginning to establish a trusting relationship. Many orthodontists have treatment coordinators (TCs) who are responsible for conducting most of these new patient calls.

When the child and parent present to the office for a first appointment, the receptionist should be trained to greet them in such a manner that they feel welcomed and special. Some practices have a bulletin board where the day's new patients' names are displayed. A tour of the office gives the patient the chance to view the areas where they will be treated, as well as areas of the practice where they can play and have fun while waiting for their appointments. The child needs to be assured that this first appointment will be an easy one.

Ultimately, it is the orthodontist who is responsible for delivering dental care and managing the associated patient behavior. The doctor must have good communication skills and be caring, supportive, and empathetic. In addition to being a clinician, the orthodontist is a teacher who must explain the dental health problems that the patient has and the procedures needed to resolve those problems. The doctor must guide the parent and child's behavior to achieve optimal care. The communication skills of the orthodontist are a large factor in patient satisfaction.[11,12] Some doctor behaviors are associated with low patient satisfaction; such behaviors include rushing through appointments, not taking the time to explain procedures, not allowing the parent in the treatment room, and being impatient.[13] On the other hand, studies have shown behaviors that are effective in managing uncooperative patients include directing, empathizing, persuading, giving the patient the feeling of control, and operant conditioning.[14–17]

Many factors affect the child's behavior in the dental environment. These factors include the child's age and cognitive level,[18–22] temperament and personality,[23–27] fear and anxiety levels,[18,24,28] the parent's dental anxiety,[29–31] reaction to strangers,[32] and previous dental experience.[18,20,29] Chapter 3 reviews psychological aspects also to be considered.

A parent who had negative dental experiences either as a child or adult may affect his or her child's behavior. In these situations, procedures focused on reducing parental anxiety are important. Although most children behave well when the parent is chairside, the presence of a parent can sometimes impede the communication between the child and dentist. Parenting style may also correlate with child behavior.[33] Children with authoritative parents exhibit more positive behavior and less caries than children with authoritarian or permissive parents. Children attending day care or school also exhibit better behavior than children who do not.[34]

DIFFERENCES IN BEHAVIOR MANAGEMENT BETWEEN PEDIATRIC DENTISTRY AND ORTHODONTICS

In pediatric dentistry, the focus on behavior management (BM) is the successful completion of in-office treatment procedures usually related to restorative dentistry. In very young children, BM techniques may be needed to perform simple intraoral examinations or the prophylaxis of teeth. In older children, BM techniques are necessary to allow restorative dentistry to be accomplished with such procedures as local anesthetic injection, rubber dam and clamp placement, use of a handpiece to remove decay, or the extraction of teeth. In children with a high caries rate, modifying the behavior of the child and the parent regarding oral hygiene practices and diet is also very important.

Behavior management in orthodontics has a different focus. Although some procedures may cause discomfort or pain, such as placing separators, fitting bands on partially erupted molars, or taking impressions on a patient prone to gagging, the focus in orthodontics is on modifying behavior outside the office. All patients must perform certain tasks in the course of their orthodontic treatment. A patient who best complies with assigned tasks is more apt to complete treatment on time with the desired result with and the absence of complications such as white spot lesions and decalcification.

The initial orthodontic examination should be a positive experience, with the orthodontist obtaining as much information as possible about the child's dental condition. Examination and treatment discussions should be done in a private setting so the parent feels free to openly discuss his or her children's needs. Many orthodontic practices have a new patient examination room and a TC who assists the doctor with examinations and case presentations. Based on examination findings, a treatment plan is discussed with the parent to address the problems identified. After the doctor leaves the room, the TC reviews with the parent and child the doctor's findings and treatment recommendations, finally asking if they have any unanswered questions. The TC should listen to the parent's response to make sure there is no misunderstanding. After the treatment discussion is complete, the TC then discusses financial arrangements. Patient education applications are available for iPads and personal computers to help parents visualize such things as malocclusion and treatment.

Communication Guidance

Implementing the procedures on the treatment plan will require optimal patient compliance. The AAPD recommends the following behavior guidance techniques: communication guidance, tell–show–do, voice control, nonverbal communications, positive reinforcement, and distraction.[2] All of these techniques become integrated into the daily routine of a well-functioning practice.

Especially for patients without much experience in the dental setting or for those who might have had a prior negative experience, "tell–show–do" is extremely important. The doctor should explain the exact steps of the appointment using age-appropriate wording. The doctor should show the patient all instruments, materials, and lights to be used during the procedure and match the size of the instruments to the size of the mouth. When treatment starts, the doctor should work quickly with constant positive reinforcement for younger patients such as "I am so proud of you" or "You are such a big boy/girl." Be patient; if the child becomes antsy, stop for a few seconds until the patient composes themselves and then resume treatment. You must be assured the patient is not in pain. If the patient states that something hurts, believe them and use additional pain control measures.

Although certain orthodontic problems can be identified early, such as a crossbite or Class II or III malocclusion, orthodontics is elective and should be postponed until the child is old enough to cooperate. The best guide for acceptable level of cooperation is to schedule beginning orthodontic records. A child who can accomplish impressions, radiographs, and photographs is mature enough to handle band fitting and impressions for an appliance. A child who is deemed too young to initiate orthodontic treatment should be recalled at 6-month intervals until the child is ready to start.

Tell–show–do is commonly used in orthodontics and involves verbal explanation of the procedure appropriate to the level of the patient and demonstration of the procedure in a nonthreatening environment. For example, the procedure of fitting bands on molars to fabricate an expansion appliance could be demonstrated as being like fitting a ring on a finger. We may have to try on a few before we find the correct size. Sometimes when attempting to fit bands on partially erupted permanent molars, the procedure becomes too painful. It is often best to switch to the second primary molar rather than have this first appointment be a negative one. After bands are fitted, the patient is praised for their cooperation, and a brief tell–show–do is done for the impression. After the impression, praise is offered again for the successful completion of the appointment.

Impressions can be difficult for some patients. They feel the alginate is going to go down their throat, or they feel like they can't breathe, causing a gag reflex and sometimes vomiting. For these patients, the successful completion of an impression can be a game changer for their future happiness in the dental environment. Skinner's[35,36] method of successive approximations can be effective in this situation. It involves first reinforcing a behavior only vaguely similar to the one desired. Then you move on to behaviors that come a little closer to what you want. For patients who are extremely anxious, we may start by taking an impression of their fingers so they can sense what the alginate feels like and what the final product will be. Next try in a lower impression tray, smaller than the ideal but easy to insert; you may even have the patient self try in the tray themselves. If things go well, try in a tray correct for the child's arch, and if that is successful, attempt a lower impression. Not all impressions require extensive vestibular rolls. The orthodontist and staff need to know when to modify their procedures to make it more comfortable for the child. One scoop of alginate (not three) is sufficient to obtain all the teeth in the lower arch while minimizing the gag reflex. Flavors can be mixed into the alginate for anxious patients. Allow the child to select the flavor they want and have them smell the flavor they have chosen. Knowing ahead of time that the patient is a "gagger" obviously helps, but the child may not have had an impression before. Patients who are gaggers should not be seen right after a heavy breakfast or lunch. The lower impression should be taken first; it is easier to tolerate than the upper, and it lets the patient know that they can accomplish this procedure. The technique of distraction works well in these situations. While the tray is being inserted, talk to the patient about a subject other than the impression. If televisions are in view, have the patient focus on the movie and even talk about the scene they are watching. Counting from 1 to 10 gives the patient notice that the procedure will soon be over. Have the patient touch the alginate with their fingers to feel it turn into rubber. Seconds before removing the tray, tell the patient that it is going to come out now, and They will hear a "woosh" sound as the suction is broken. The tray is removed, and the staff, doctor, and parent cheer for the patient as if they just scored the winning goal in a soccer game.

PATIENT AT-HOME RESPONSIBILITIES

Successful orthodontic treatment requires the patient to perform certain procedures away from the office. Various factors influence the child's ability to comply with these tasks. Although the age and gender of the patient do not seem to influence compliance, academic performance is positively correlated.[37] Patients receiving above-average grades at school are also above-average compliers in the orthodontic setting. To obtain compliance with these procedures, the parent and patient must be educated on the importance of the task to the child's treatment, as well as how to perform the task. The method of presenting educational and motivational material is important. Studies have shown that the key to obtaining excellent patient compliance is spending time with patients and having good communication skills.[38,39] For communication to be effective, it must be remembered and understood.[40] Information written at the level of a 12-year-old child has been shown to be most effective.[41] The format of the written information also is important. Headings that stand out, short sentences, and use of the active rather than passive tense are recommended.[42–44] Technical jargon should be avoided.[45]

To help the patient and parent better understand the information being presented to them, we present it in multiple ways. Whenever possible, instruction is provided in oral, written, and visual forms. Supplementing verbal information with written and visual material has a positive effect on information recall, motivation for treatment, compliance, and treatment satisfaction.[39,46–48]

Oral Hygiene and Diet

Optimal oral hygiene requires professional instructions, adequate tools, and patient motivation, which are crucial factors to obtain compliance.[49] The day orthodontic appliances are placed, the patient and parent are given extensive instruction on home care and diet. We show a video that discusses the importance of plaque removal with brushing and flossing. Adjunctive aids such as electric toothbrushes, water picks, topical fluoride, floss threaders, and so on also are discussed. Using the home care kit we provide for each patient, the assistant then demonstrates proper brushing and flossing. Last, written instructions with photographs can also be given as reference. Diet is discussed with the focus on foods that can cause damage to the appliances or foods that can cause damage to the teeth. The avoidance of juices and soda with high acidity is stressed.

At subsequent appointments, oral hygiene instruction (OHI) needs to be a priority in treatment. Research has shown that repeated OHI and motivation significantly improved oral hygiene over patients who receive OHI only at the beginning of treatment.[50,51] Patients who received multiple motivational techniques, including plaque disclosure, demonstration of a horizontal brushing method, video of plaque bacteria, and the viewing of their own plaque under a phase contrast microscope, showed the greatest improvement in gingival health over a 6-month period.[52]

Oral hygiene should be graded and recorded at the beginning of each appointment. The dental staff needs to be trained on what exactly to say to the patient who presents with poor oral hygiene. Instruction should be given in a manner that is not embarrassing. Our responsibility is "to inform, not scorn."[53] Consider first pointing out areas where the patient is brushing well (if there any) and then ask the patient if he can see areas that need improvement. After giving additional OHI, tell the patient that you are confident he can improve his hygiene by the next appointment. Some practices have a reward system for patients who have excellent oral hygiene or no broken appliances at each appointment. Although one study found some improvement in oral hygiene scores, rewards did not improve appointment attendance or appliance wear and maintenance.[37]

New technology brings new ways to motivate patients. Apps and online programs are available that teach oral hygiene and braces care to children and teenage patients. Rather than lecturing patients when they are in the office, these apps engage patients the way they want to be engaged. Patients can also use these apps to send the office pictures if they have a problem such as a broken wire or bracket.[54] Sending motivational text messages to patients regarding their at-home responsibilities may improve compliance. Research showed that at-risk patients who were sent weekly text messages significantly increased their toothbrushing frequency.[55] Instituting a system for sending motivational text messages could lead to better dietary choices, improved oral hygiene behaviors, and better compliance in wearing appliances and elastics.

Nothing slows the progress of treatment and wreaks havoc on the schedule like loose brackets or bands. Although a small percentage may be attributable to contamination that occurs during the bonding appointment, the majority are caused by patients eating foods they have been asked to avoid or habits such as pencil chewing or even bruxism. For repeat offenders, we stress the estimated completion date (ECD) may not be met and that treatment may be extended and compromised. These discussions should be done in a nonthreatening manner with the parent present.

REMOVABLE ORTHODONTIC APPLIANCES

Many types of removable orthodontic appliances are commonly used in everyday orthodontic practice. Treatment success, however, is based on the patient wearing the appliance as instructed. Optimal compliance includes both wear time (number of hours per day) and wear behavior. Wear behavior is related to whether the appliance was worn every day or whether there were days when the appliance was not worn. Studies have shown that a majority of patients may not wear their appliance as instructed[56]; hence, patient motivation is the highest of priorities when using removable appliances.

For every appliance that we use, we have a written handout that describes the appliance, its purpose, how to wear and care for it, what to expect in regard to discomfort, and what problems may occur along the way. This handout is given to the patient and parent to read before they leave the office, after which any questions they have are addressed. Basic information also can be given at the initial examination or consultation before the start of treatment. Numerous companies have videos that are designed to illustrate and educate the patient and parent in this regard.

EXTRAORAL APPLIANCES

Compliance with extraoral appliances is extremely important for the successful correction of various skeletal-type malocclusions. These appliances must be comfortable and easy to wear. Extraoral appliances can be especially problematic because they are visible and may embarrass the patient.

To obtain acceptable compliance, the orthodontist needs to go to great lengths in devising ways to motivate the patient. An example of the way we motivate patients to wear extraoral appliances involves the use of a face mask or reverse headgear for the correction of the Class III malocclusion. We have previously described using a face mask that is custom made to a plaster mold of the patient's face and attached to an intraoral cemented expansion appliance with elastics.[57] Because we request the child to wear the headgear to school the first 6 weeks, we spend considerable time in educating the parent and child on the importance of compliance. From age 5 to 7 years, children will do whatever the teacher, doctor, or parent requests, of them. It is winning over the parent that is the most difficult. The following methods are important in obtaining the compliance requested. Thorough explanation of the structural etiology of the malocclusion is important, stressing that patients who become adults with this type of malocclusion may require surgery of the jaws in order to correct it. We describe the mode of action of the appliances to be used, keeping an open mind on full-time wear until the appliances are finally delivered. We advise the parent to meet with the teacher to discuss the child's wearing the headgear to school. Plan for the teacher, parent, or TC to perform a tell–show–do to the class. Using a cartoon-type drawing of the face mask, have each member of the class design a face mask with his or her favorite colors, stickers, and so on. Be excited at the delivery appointment when the custom appliance is first shown and delivered. Make sure the appliance fits well and is comfortable. Provide thorough instructions on how and when to wear the appliance and how to store it safely when it is not being worn. Have the child fill out a time card, recording the hours of wear each day. Measure overjet at each appointment, and inform the patient and parent as to the improvement in that measurement, providing praise and encouragement. As the overjet improves, reduce the hours per day as promised. This rewards the patient for his cooperation and sends a message to the parent and child that treatment is progressing as planned.

HEADGEAR FOR CLASS II CORRECTION

Cervical traction headgear is one of the appliances used for Class II correction. The use of this appliance, however, has decreased over the past several decades, in favor of removable functional appliances purposed to stimulate mandibular growth and more recently by fixed-functional or distalizing appliances that require less patient cooperation.[58] Rather than abandoning headgear completely, we accept the fact that a certain percentage of patients will not comply and a certain percentage will.[59] Why totally discard the appliance because of the patients who won't wear it? We have found that patients generally fall into three groups. Group 1 wears the appliance as instructed and reports it as being easy to wear and tolerate. Group 2 wears the appliance but doesn't like it and struggles to get the required hours. Group 3 patients don't like it, can't sleep with it, won't wear it, and parents choose not to force the issue and request other options. Having an open discussion with both the patient and parent at the treatment planning stage can help identify whether or not the patient is a good candidate for cervical headgear. After establishing cervical headgear as the treatment of choice and the child agreeing to wear it, there are certain things that can increase compliance. The appliance should be comfortable and easy to insert and remove. The inner bow should insert easily into the buccal tubes such that it can be inserted and removed with the slightest of finger pressure. Adjustments to rotate molars should wait until the appliance is comfortable to wear and the patient has shown compliance. The innerbow–outerbow connection should be positioned comfortably 3 to 5 mm in front of the upper incisors at the level of the lip embrasure. Adjust the outer bow close to the face to make it easier to sleep in. Provide neck straps that are comfortable and available in assorted colors. Keep forces low at the beginning. Have the patient record her hours and days of wear, and provide praise or rewards for good compliance. Measure overjet and molar relation at each appointment and provide praise as the measures improve. Some patients may not show improvement in overjet and molar relation even though they are wearing the headgear. Don't let them become discouraged. Measurable improvement may take more time for some patients.

REMOVABLE INTRAORAL APPLIANCES

The removable Hawley appliance is a commonly used appliance that can incorporate springs for individual tooth movement, an anterior bite plate to aid Class I or Class II deep bite correction, activation of the labial bow to retract anterior teeth and close spaces, and even expansion incorporating a jackscrew. Because these appliances are most commonly lost away from home, especially when taken out to eat, we have some patients wear them only at home and most learn to eat with them in their mouths. The Hawley appliance can be made in special colors or designs, and each is delivered along with a case for storage when the appliance is not being worn. The appliance should be brushed along with toothbrushing and especially before placing it in its case, where plaque can dry on the appliance, making it "grungy." Dogs (and cats!) love to chew on these appliances even when they're inside the case; hence, patients are instructed to "beware of dogs." The appliance is easy to wear, and hence compliance is generally good.

A study examining wear time using a temperature-sensitive microsensor found that patients wore a removable appliance only 7.6 hours per day even though 15 to 16 hours per day was prescribed.[60] Research has shown that to improve compliance, wear time must be measured.[61] Newly developed temperature-sensitive microsensors, incorporated into removable appliances by polymerization, can provide data that can be discussed with patients at their appointments.[62–64] Wear time documentation is reported to be well received by patients[65] and has a positive effect on adherence.[66] Wear time measurement is especially important when treatment does not progress satisfactorily. Rather than engaging in a contentious discussion, which can strain the doctor–patient relationship, objective data can be used to discuss patient behavior and possible alternate therapies.

Removable appliances should be delivered in a passive state to allow the appliance to settle or seat into the dental arch and allow the patient to adjust to having something in the mouth. After the appliance has seated and the patient has adjusted to it, the appliance can then be adjusted by tightening the retention clasps and then the active components. The patient should be instructed that some tooth soreness is to be expected and should subside after a few days. Tissue impingement should be reported to the orthodontist so that comfort adjustments can be made.

In the 1980s, the "British invasion" occurred in US orthodontics. No, it wasn't the Beatles, and it was more a "European invasion" that found removable functional appliances now being advocated for Class II malocclusions (See Chapters 16 and 35). As American orthodontists became experienced with these appliances and long-term data began to be published, the effects on mandibular length were less than expected, although they were excellent appliances in correcting the Class II malocclusion. The major problem with them (i.e., the bionator, activator, Frankel appliance), however, was patient compliance. They are bulky appliances; difficult to wear; need to be removed for eating and cleaning; and similar to the cervical headgear, were not worn well by a significant portion of the patients for which they were prescribed. Because of concerns for compliance, these appliances have fallen out of favor in the United States in favor of fixed functional appliances such as the Herbst, MARA, or various spring-loaded modules.[58] See Chapter 16 and 35 for a thorough discussion of these appliances.

An increasing number of adolescents are requesting treatment with clear removable aligners. The appropriateness of such treatment depends on the type and severity of the malocclusion; the experience of the orthodontist; and, of course, the anticipated cooperation of the patient. Although these patients appear committed and are enthusiastic about this treatment choice over traditional braces, adolescents are still adolescents, and enthusiasm can wane. A patient who doesn't wear the trays as instructed, misses an appointment for additional trays, or loses a set of trays can derail the progress of treatment, frustrating the doctor and parents while increasing costs and treatment time. Proper oral hygiene procedures are important, and the avoidance of soda and fruit juices while wearing the trays is stressed. Cases of decalcification with clear aligner therapy have been reported.[67]

ORTHODONTIC APPOINTMENTS

Keeping regular appointments is integral to the success of orthodontic treatment. Missed appointments can lengthen treatment and increase the chances of root resorption, white spot lesions, and periodontal problems.[68–70] Researchers have investigated factors affecting children's adherence to regular dental appointments.[71] Studies have shown a significant correlation with the parents' level of education,[72–80] economic status,[78,79,81–83] and marital status.[73] A missed appointment is usually followed by a telephone call from the office and a message to reschedule. If the family does not respond to the telephone contact, then letters can be sent with increasing seriousness. The last letter is sent registered and informs the family that the orthodontist is discontinuing treatment because of lack of cooperation. What could have been done earlier in treatment to avoid ending up in this situation? There are many situations that can interfere with maintaining orthodontic appointments. A family with multiple children attending multiple schools and participating in different school activities makes scheduling orthodontic appointments difficult. Crises also can upset the routine of life and the routine of keeping orthodontic appointments. Death, divorce, or the diagnosis of a family member with cancer or other serious illness may take precedence over keeping orthodontic appointments, but they shouldn't. Just as children will continue to attend school, and after-school activities, they need to keep their orthodontic appointments. Keeping regular appointments needs to be stressed both in the written material presented to the family as well as in verbal discussions at the beginning of treatment.

Modifying behavior is best done by rewarding behavior that we want repeated. This should be kept in mind when calling patients who have missed their appointment. "Mrs. Jones, this is Cari calling from Dr. Turley's office. Jeremy missed his appointment yesterday, and we were a little concerned because he is one of our patients who is always on time."[53]

Getting child patients to accept some responsibility for keeping their appointments also can improve compliance. Patients assume a lot of responsibility for getting to their after-school activities, such as sports teams and music lessons. Children know when their next practices are scheduled and are commonly involved in arranging transportation. Orthodontic appointments, however, are generally left up to the parent, with some being less than responsible in making it a top priority. When a pattern of missed appointments appears, our staff communicates with the parent, but we also discuss it with the child, especially if they are in high school and responsible for other outside school activities. We first discuss how the child's pattern of missed appointments is going to extend the treatment time, meaning he probably won't be getting his braces off when they expected. We'll ask him, "Does your mother need to remind you when volleyball practice is? No, of course not. In fact, you're the one who's reminding your parent that you need to be at practice at a certain day and time. Well, you need to start thinking of your orthodontic appointments the same way. If you want your braces off as soon as possible with the best results, when you leave today and make your next appointment, write that date and time in your own phone calendar and remind your parent as the date is approaching that you need to be at that appointment to keep your treatment progressing as scheduled." This adult-type conversation is appreciated by the parent and often changes a noncompliant family into a cooperative one. The doctor's communication skills have been shown to have a positive influence in families adhering to dental appointments.[71] On the other hand, an unpleasant dental visit, dissatisfaction with previous appointments, uncertainty about dental treatment and its import, children's aversion to dental visits, and dental care–related anxiety can have negative effects regarding parents' adherence to keeping dental appointments.[72,77,79–80,83–85]

INTRAORAL ELASTICS

Intraoral elastics are an integral part of treating many orthodontic patients. If possible, the patient should know early in treatment that wearing elastics will be an important part of achieving an ideal result. Patients report pain, laziness, forgetfulness, and embarrassment as reasons for not wearing elastics (or headgear).[86] When elastic wear is scheduled, sufficient time needs to be given to instruct the patient how to place and remove the elastics and how often to wear them. An information sheet showing the position of the elastics is given to the patient. This information sheet should describe when and where to wear the elastics, where to keep elastics at home, how to carry spare elastics when not at home, and how to manage problems with elastics.[87] Researchers found that elastic wear was related to three subcategories of factors: remembering to wear or change elastics; physically having elastics available; and a series of barriers that impeded wearing or changing elastics, such as eating, pain or discomfort, difficulty in placement, and social concerns. Cues from parents or caregivers can help remind forgetful patients. Elastic force can be light at the beginning or delayed until the soreness of the recent archwire adjustment diminishes; then heavier elastics can be initiated. When placing elastics, start with the most posterior tooth and pull forward and engage the most anterior tooth. Multiple packs of elastics should be given so there is never an excuse to not wear them. A pack can be carried in the school backpack, another in the bathroom at home, at one's desk, in the car, or in any other familiar place. Elastic placement should be diagrammed on each pack. In the case of triangular elastics, different colored bracket ties can be used on the teeth to receive the elastics. Colored elastics may motivate some patients. Most patients do well wearing the elastics to bed and after breakfast, but many forget to replace them after lunch.

If elastic wear is found to be inadequate, we recommend they be worn while eating, replacing them when they break. Make patients aware of the goal you're trying to achieve (i.e., how much overjet or midline correction). Measure overjet and occlusal relationships at each appointment, and give praise for positive changes. If progress is ignored at the next appointment, the patient will lose motivation. Patients may telephone the office stating that they have forgotten where to attach the elastics or that they have lost them. Elastics should be diagrammed and the size and force recorded on the treatment card so the front desk staff can correctly assist the patient. "I lost them 4 weeks ago" is not an acceptable excuse for not wearing elastics. Packs of elastics can be mailed to the patient, saving them a trip to the office. Some patients get confused and reverse elastics (e.g., wear a Class III direction rather than Class II). At the end of every appointment, have the patient place her elastics so the doctor can make sure they are being worn correctly. Apprise each patient of the ECD of the treatment. Patients who are not compliant may need to have the ECD extended. Seeing the doctor cross out the ECD and write in a later date or a question mark can be effective in getting the patient's attention. Motivated patients can often accomplish more in 8 weeks than they did the previous 8 months.

REMOVABLE RETAINERS

It is important for patients to have realistic expectations about retention. No retainers hold the teeth 100%, even bonded retainers. Patients can expect to see or feel changes equal in magnitude to their last adjustment appointment. All teeth move when the braces come off. Our hope is that they will move but not become "crooked." See Chapter 33 for further discussion.

We offer three types of retainers at the end of treatment: bonded lingual retainers, clear aligners, and Hawley retainers. The pros and cons of each are discussed at the last adjustment appointment, and impressions are taken that day if a bonded retainer is chosen. Similar to any other removable appliance, a significant percentage of patients will not follow the prescribed regimen for wear and will experience posttreatment tooth movement. Because these patients are now older adolescents or adults, they are often beyond the stage of motivation.[88] Before scheduling the removal of braces, have the patient tell you truthfully if he can adhere to wearing removable retainers. If there is any doubt, a bonded retainer, especially in the lower arch, should be used, with a clear upper aligner for home wear. Hawleys are used for the most compliant patients. I tell patients that one patient per year fails to wear his retainers properly and needs to have braces placed back on to restraighten the teeth (usually the lowers), stating, "I don't want you to be that patient!" We offer a second set of removable retainers at 50% discount if made at the time of debanding. Most patients take advantage of this offer. Some adult patients prone to relapse may benefit from "belt and suspenders," a bonded retainer with a removable retainer to fit over it for insurance. As with other adjunctive appliances, verbal instruction is given in addition to a written handout.

We use a form that both the patient and parent sign indicating the doctor's preference and choice of retainers. The form reinforces the pros and cons of each type, as well as our policy of a 50% discount for a second set. In the past, we would occasionally have a patient not wear or lose her retainers, with relapse occurring and the need for additional treatment. An upset parent would state that she was not adequately informed or given the choice of a bonded retainer. We even had a parent who demanded a new free retainer because she was unhappy with the color chosen by the child without consulting the parent. These issues have not occurred since we initiated the use of this signed form.

Certain catchphrases can help remind and motivate patients to wear their retainers as prescribed. Nighttime wear can be described as “pajamas for your teeth.” When you get ready for bed, you put on your pajamas, and you put on your retainers. We describe retainers as an “insurance policy” for your teeth—an insurance policy you’ve already paid for! As long as you continue to wear retainers at some interval, you can be reasonably assured of continuing to have straight teeth. Many patients are concerned that they will have to wear retainers every night for the rest of their lives. Although this may be true for a small number of patients, most will be able to reduce their wear over the years. Every night will decrease to every other night, to once a week, and to twice a month as time passes.

SUMMARY

1. The key to obtaining excellent patient compliance is spending time with patients and having good communication skills.
2. For communication to be effective, it must be both understood and remembered.
3. Proper parent and patient education leads to increased compliance.
4. Good verbal, visual, and written explanations are necessary.
5. All staff members should be trained so the messages are clear and consistent.
6. Systems to identify less than optimal behavior and methods to modify behavior and obtain compliance should be developed and continually updated.

Optimizing Orthodontics and Dentofacial Orthopedics: Treatment Timing and Mixed Dentition Therapy

James A. McNamara, Laurie McNamara McClatchey, and Lee W. Graber

OUTLINE

This chapter describes the integration of various orthodontic and orthopedic protocols that can be used to treat the myriad of dentoskeletal problems seen routinely in orthodontic practice. Some malocclusions respond well when orthodontic treatment is begun in the mixed dentition; other conditions are treated optimally at the time of the circumpubertal growth spurt or even later. The nature of the problem, as revealed by the process of proper differential diagnosis and treatment planning, determines whether intervention is best begun early (as in the early mixed dentition) or late (late mixed or permanent dentition).

If a late treatment is initiated, a single phase of comprehensive orthodontic therapy usually is involved, the duration of which typically spans anywhere from 12 to 30 months. If treatment begins in the early mixed dentition, however, in most instances, a two-phase treatment protocol is anticipated, with a second phase of fixed orthodontic appliances required in the vast majority of such patients.

The goal of such early treatment is to correct existing or developing skeletal, dentoalveolar, and muscular imbalances to improve the orofacial environment before the eruption of the permanent dentition is complete. By initiating orthodontic and orthopedic treatment at a younger age, the overall need for complex orthodontic treatment involving permanent tooth extraction and orthognathic surgery presumably is reduced.

THE TIMING OF TREATMENT INTERVENTION

A topic of much conversation and debate among orthodontists and even the lay public has been orthodontic treatment timing, with articles concerning this subject appearing not only in refereed orthodontic journals but also occasionally in such publications as *The New York Times*, *The Wall Street Journal*, and *US News and World Report*. These articles reflect one of the dilemmas facing the practicing orthodontist—whether to intervene before the eruption of the permanent dentition is complete.

One can argue that in many patients, it is best to allow for the eruption of all permanent teeth (except for third molars) before initiating orthodontic treatment. By having all teeth erupted fully, treatment often is provided in a relatively straightforward manner within a predictable period of time (12 to 30 months). When dealing with a postpubescent patient in whom most growth has terminated, the clinician usually does not have to contend with unwanted changes associated with aberrant growth patterns. In fact, in some types of malocclusions, as, for example, in a Class III malocclusion characterized by significant mandibular prognathism, definitive orthodontic and surgical treatment is best deferred until the end of the active growth period.

Although deferring treatment of orthodontic problems to the adolescent age period is viewed as an advantage by some clinicians, others view it as a significant disadvantage. Many clinicians seek to intervene in the mixed dentition so as to eliminate or modify skeletal, muscular, and dentoalveolar abnormalities before the eruption of the permanent dentition occurs. On the surface, this concept seems reasonable because it appears more logical to prevent an abnormality from occurring than to wait until it has become developed fully. Not all clinicians, however, use early treatment protocols. The decision concerning whether to intervene before the eruption of the permanent dentition can be viewed on the basis of a number of interactive factors.

Modification of Craniofacial Growth

The name of the *American Journal of Orthodontics* was changed by then editor-in-chief T.M. Graber to the *American Journal of Orthodontics and Dentofacial Orthopedics* in 1985. Ten years later, the orthodontic specialty changed its name from *Orthodontics* to *Orthodontics and Dentofacial Orthopedics*. Both of these changes in designation are a reflection of the importance now given to the orthopedic aspect of orthodontics. Despite this change in emphasis, however, the role of dentofacial orthopedics remains controversial.

During the past 45+ years, there has been much discussion among orthodontists and craniofacial biologists regarding the extent and location of therapeutically induced neuromuscular and skeletal adaptations throughout the craniofacial complex. Most would agree that the downward and forward growth of the maxillary complex of the growing individual can be influenced by such therapeutic techniques as extraoral traction and activator therapy. The ability to widen the transverse dimension of the maxilla through rapid maxillary expansion (RME) no longer is considered particularly controversial, although the long-term stability of this form of treatment only recently has been evaluated thoroughly.

The question of whether the mandible can be increased in length in comparison with untreated controls also has been addressed in numerous experimental and clinical studies (for a review of the literature in this area, see Chapter 15 in McNamara and Brudon[1]). Although controversial, the bulk of scientific evidence indicates that, in growing individuals, mandibular growth can be enhanced over the short term. A recent study of functional jaw orthopedics (FJO) by Freeman and coworkers[2] that considered the long-term effect of the function regulator (FR-2) of Fränkel showed that in late adolescence, the average increase in mandibular growth in the treatment group was 3 mm in comparison with matched untreated Class II subjects. Investigations of other functional appliance systems by our group have led to similar findings of 3 to 5 mm over the long term in comparison with untreated matched control participants.[3-6] Other long-term studies, however, have shown residual mandibular length increases of only 1 to 2 mm.[7,8]

In contrast, there is limited evidence that the growth of the mandible can be diminished substantially[9] either through the use of a chin cup or through orthopedic facial mask (FM) therapy, although a redirection of mandibular growth in a more vertical direction has been observed using a number of orthopedic techniques.[10]

Patient Cooperation

The ability to motivate a patient to comply is an essential ingredient of successful orthodontic therapy, whether initiated in the mixed or permanent dentition. One of the great fears of many orthodontists is that by beginning treatment in the mixed dentition, patient and parental cooperation will wane before fixed appliance therapy has been completed to the clinician's satisfaction. The goals and objectives of treatment must be established clearly in order to prevent unnecessary, prolonged treatment that may "burn out" the patient in the future.

In our opinion, the most significant problem regarding cooperation, particularly in a mixed dentition patient, is in the mind of the orthodontist or the parent rather than in that of the young patient. Every effort must be made to incorporate the patient and parents in treatment decisions and to stress the importance of appliance wear according to the specific needs of the patient. Indeed, motivating parents to provide the home support necessary for treatments that require strict compliance often is the greatest challenge to the clinician, as parents look for quick solutions to complex treatment challenges. Regimens requiring maximal patient cooperation should be used only after it has been determined that this type of appliance is the optimal approach for a given skeletal and neuromuscular imbalance. The treatment time should be estimated reasonably and should be known to the patient and parents at the beginning of the treatment period. Chapter 15 discusses this further.

A critical point in patient cooperation is related to the transition to high school, with the start of ninth grade often coinciding with a decrease in patient motivation. Thus, it is desirable to complete either phase II treatment or a comprehensive single-phase treatment before this time. It has been our experience that most patients who begin phase I orthodontic or orthopedic treatment in the second or third grade finish phase II before high school, although there is substantial individual variation. Scheduling of orthodontic appointments also is much easier during middle school or junior high school years than later.

Practice Management

It is obvious that when patients begin treatment in the mixed dentition, the time from the onset of treatment to the completion of the final fixed appliance phase will extend well beyond the duration of a typical orthodontic protocol initiated in the permanent dentition. When many of the currently used early treatment protocols were being developed in the late 1970s and early 1980s, there were many instances of prolonged treatments that not only had a negative effect on patient and parental enthusiasm but also became a nightmare from a practice management perspective. Thus, more efficient and effective early treatment protocols have evolved. These protocols have a defined duration as well as a reasonably predictable outcome.

In general terms, an initial phase of treatment is provided that is approximately 1 year in duration followed by intermittent observation during the transition from the mixed to the permanent dentition. The naturally occurring increases in arch space are incorporated into the overall treatment plan by anchoring the permanent first molars in position as the second deciduous molars are lost, usually by placing a transpalatal arch (TPA) in the maxilla and, in about one-third of patients, a lingual arch in the mandible. After all of the permanent teeth have erupted fully into occlusion (except for, perhaps, the erupting second and developing third molars), fixed appliances then are used to align and fine detail the occlusion. Treatment typically is not begun until the eruption of the second molars has taken place or is anticipated within a 6- to 9-month period.

From a practice management perspective, separate charges are levied for the initial phase of early treatment and for the final comprehensive phase of treatment. In our practices, no charges are levied for appointments during the "interim" period when the eruption of the permanent dentition is monitored two or three times a year. These visits are important to monitor any space-holding appliances and are extremely valuable to ensure proper timing for full fixed appliance treatment, a point that must be repeated for parents by staff making recall appointments. We stress to patients and parents that we have two separate stages of "active" treatment so as to mitigate the perception of "being in braces forever."

THE CERVICAL VERTEBRAL MATURATION METHOD

Before we begin a detailed description of the protocols that can be used to treat various malocclusion types, a discussion of the skeletal maturational level of the patient is in order. In some instances, it is desirable to treat the patient at the time when the patient is growing rapidly, as during the circumpubertal growth period, when FJO has been shown to be particularly effective. In other circumstances, we would like to know if a patient has reached his or her growth potential, as in planning corrective jaw surgery or the placement of endosseous implants, so that substantial further growth is not anticipated or desired. We also would like to know if a patient is early in the growth process and would respond skeletally rather than dentally to forces placed against the circumaxillary sutural system (e.g., RME, Facial mask (FM) therapy).

One of the most inaccurate ways of determining a patient's maturational level is to use chronologic age as an indicator. It is well known that in a classroom of 12-year-old children, there may be as much as a 7-year spread developmentally among the children, with girls maturing faster than boys on average by at least 1 year. On the other hand, orthodontists in general have relied on the stage of dental eruption and development[11,12] as a starting point. This scheme of using tooth eruption as an indicator certainly is more accurate than using chronologic age; however, other biological indicators can be used as well.

Biological indicators of skeletal maturity refer mainly to somatic changes at puberty, thus emphasizing the known interactions between the development of craniofacial structures and the modifications in other body regions. Individual skeletal maturity can be assessed by means of several biological indicators, including increase in body height,[13,14] skeletal maturation of the hand and wrist,[15] menarche or voice changes,[16] and changes in the morphology of the cervical vertebrae.[17-19]

Of the skeletal indicators available routinely to the orthodontic practitioner that do not require the taking of additional records (e.g., hand–wrist film), the cervical vertebral maturation (CVM) method has proved clinically useful for us for more than 15 years. This method has been available since the early 1970s when it was developed by Don Lamparski as part of his master of science thesis at the University of Pittsburgh.[17] The CVM method remained relatively unused for the next 25 years, with few references made to it in the literature. The CVM method was reintroduced by our group first in 2000,[20] with an updated and simplified version presented in 2005.[21] The following is a brief summary of the most current CVM method.

There are six stages of cervical maturation in all, as shown diagrammatically in Figure 16-1. For the purpose of this evaluation using the lateral head film, only the bodies of the second, third, and fourth cervical vertebrae (C2, C3, and C4) are considered. Two morphologic characteristics are monitored, the first of which is the presence or absence of a notch or indentation on the inferior border of each of the three vertebral bodies. The second feature is the shape of the third and fourth cervical bodies, which change from trapezoid to rectangular horizontal to square to rectangular vertical (see Fig. 16-1).

The first three stages are differentiated from one another by the presence or absence of the notch. In the first cervical stage (CS-1), the inferior borders of vertebral bodies C2 to C4 are flat (or sometimes slightly convex; Fig. 16-2). From a practical standpoint, the notch must be at least 1 mm in depth at the center of the notching. The third and fourth cervical bodies are trapezoidal in morphology, assuming the shape of a typical wedge of cheese (Fig. 16-3), with the posterior border of the vertebral body taller than the anterior border and the superior surface sloping forward and downward. This stage occurs from approximately the time of the eruption of the deciduous dentition until about 2 years before the peak in skeletal growth. Our research[22] has shown that the ideal age to intervene with FM therapy combined with RME is at CS-1. Maximum skeletal adaptations occur in the midfacial region during this stage as the sutures are more open, in the

FIGURE 16-1 Schematic representation of the six stages of cervical vertebral maturation, according to the protocol described by Baccetti and coworkers. The second, third, and fourth cervical bodies are shown. Note the increase in notching and the changes in the shape of the third and fourth cervical bodies with maturation. (From Baccetti T, Franchi L, McNamara JA Jr. The cervical vertebral maturation (CVM) method for the assessment of optimal treatment timing in dentofacial orthopedics. *Semin Orthod* 2005;11:119–129.)

younger patient. Less skeletal and greater dentoalveolar adaptations are noted when RME combined with FM therapy is used during later stages (e.g., CS-3, CS-4).

The second cervical stage (CS-2) is characterized by a notch present along the inferior border of the second cervical vertebra (odontoid process). The lower borders of the third and fourth vertebral bodies remain flat (Fig. 16-4). Usually both C3 and C4 retain a trapezoidal shape, again the wedge of cheese appearance. CS-2 can be considered the "get-ready" stage because the peak interval of mandibular growth should begin within 1 year after this stage is evident.

FIGURE 16-2 The first CVM stage (CS-1). Note that the inferior borders of the three cervical bodies are not indented but are flat or slightly convex.

The third cervical stage (CS-3) is characterized by notching of the inferior borders of C2 and C3. C4 remains flat (Fig. 16-5). At least one of C3 and C4 bodies still retains a trapezoidal shape while the other can assume a more rectangular horizontal shape. At this stage, the maximum craniofacial growth velocity is anticipated. It must be remembered that the difference between stages is gradual, not abrupt, so that saying that someone is a "late CS-3" or an "early CS-4" is appropriate, depending on the transitional morphology of the third and fourth vertebrae.

In the fourth cervical stage (CS-4), all three bodies have notches along their inferior bodies, the more important factor being the shape of C3 and C4 (Fig. 16-6). At this stage, both vertebral bodies have a rectangular horizontal rather than a trapezoidal shape. It is easiest to remember this stage as the "bar of soap" stage because the bodies of both C3 and C4 assume this well-known shape (Fig. 16-7). During this stage, continued craniofacial growth can be anticipated but at a lesser rate than is seen at CS-3. Placing an endosseous implant to replace a missing maxillary lateral incisor would be inappropriate at this stage of maturation because of anticipated growth in the future.

The fifth cervical stage (CS-5) can be differentiated from CS-4 on the basis of the shapes of C3 and C4, with these bodies becoming square in shape (Fig. 16-8). All three cervical bodies have notches, so the presence of notching no longer is important in the differential diagnosis. We have found it easy to remember this stage as the "marshmallow" stage, in that the bodies now resemble the soft white puffy confection seen so commonly at summer campfires (Fig. 16-9). When this stage is reached, most substantial craniofacial growth has been achieved. The patient can be evaluated for corrective jaw surgery or the placement of endosseous implants in the aesthetic region. It should be noted that even though CVM staging is useful here, the gold standard for determining the continuation or cessation of significant

FIGURE 16-3 C-3 and C-4 usually have a trapezoidal shape and appear similar to a "wedge of cheese," as shown here.

FIGURE 16-4 The second CVM stage (CS-2). A notch is present in the inferior border of the odontoid process (C2). The vertebral bodies of C3 and C4 are in the shape of a wedge or trapezoid.

FIGURE 16-5 The third CVM stage (CS-3). Distinct notches are present on the inferior border of C2 and C3. At least one or both of the third and fourth cervical bodies still have a trapezoidal shape.

FIGURE 16-6 The fourth CVM stage (CS-4). Notches are present in all vertebrae. The bodies of C3 and C4 are rectangular and horizontal in shape.

FIGURE 16-7 The vertebral bodies of C3 and C4 at CS-4 resemble the shape of an ordinary bar of soap, as shown here.

FIGURE 16-8 The fifth CVM stage (CS-5). The bodies of C3 and C4 now are square in shape, with the posterior height the same as the width.

FIGURE 16-10 The sixth CVM stage (CS-6). The bodies of C3 and C4 now are rectangular vertical in shape (i.e., greater posterior height than width).

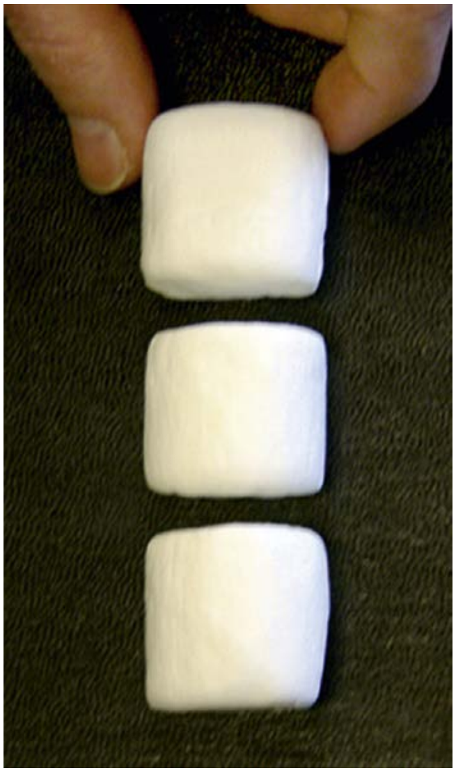

FIGURE 16-9 C3 and C4 at CS-5 resemble the shape of a stack of marshmallows, as imaged here.

craniofacial growth is the evaluation of two lateral head films taken at least 6 months apart.

It has been our experience that the most difficult stage to determine is the sixth cervical stage (CS-6). At CS-6, at least one of the third and fourth cervical bodies has assumed a rectangular vertical morphology (Fig. 16-10). In addition, the cortical bone appears better delineated in CS-6 than at CS-5.

Estimating patient maturational level by staging the second through fourth cervical vertebral bodies as seen in the lateral head film gives the clinician one additional piece of information that can be used to reach an appropriate diagnosis and treatment. CVM staging should be used in concert with a thorough evaluation of the hard and soft tissue during the treatment planning process as well as other maturational indicators and the family history. As with any subjective clinical evaluation, the precision of the CVM method improves with experience.

WHEN TO INTERVENE

The timing of orthodontic intervention is of critical importance, and the initiation of our treatment protocols varies according to the type of malocclusion being treated. For example, tooth-size/arch-size discrepancy problems typically are treated when the patient is 8 or 9 years of age. Normally, this treatment is initiated after the lower four incisors and the upper central incisors have erupted. In many instances, there is insufficient space to allow for the unimpeded eruption of the upper lateral incisors. Depending on the size of the permanent teeth, space maintenance, serial extraction, orthopedic expansion, or a combination of these protocols is used.

In the instance of a Class III malocclusion, the onset of treatment usually is earlier than for a Class I patient. An optimal time for the beginning of an early Class III treatment regimen (e.g., orthopedic FM combined with a bonded acrylic splint expander to which have been attached FM hooks) is coincident with the loss of the upper deciduous incisors and the eruption of the upper permanent central incisors (the maxillary permanent first molars should be erupted as well). Reduction of a Class III pattern in which the patient is shifting into anterior crossbite and there is a family history of Class III may start in the primary dentition. This earlier intervention in Class III patients obviously will result in a longer period of time between the start of the initial phase of treatment and the end of the fixed appliance phase after the permanent dentition has erupted.

The timing of treatment of Class II malocclusions differs substantially from that described previously for Class I and Class III malocclusions. In contrast to our positive recommendations concerning early intervention in Class III malocclusions and in many tooth-size/arch-size discrepancy problems, we typically recommend a delay until the circumpubertal growth period (i.e., cervical stage CS-3) before using FJO in patients with Class II malocclusions characterized in part by mandibular skeletal retrusion. Both clinical and experimental studies have shown that there is a greater mandibular growth response with functional appliances when treatment is initiated during the circumpubertal growth period.[23-26] Ideally, functional appliance therapy (e.g., Herbst, twin block, mandibular anterior repositioning appliance [MARA], bionator, FR-2 of Fränkel) will be followed directly by a phase of fixed appliance therapy to align the permanent dentition. In reality, besides the routine use of Class II intermaxillary elastics, we use two Class II correction appliances primarily, both in the early permanent dentition. These two appliances are the stainless steel crown Herbst appliance and the Pendex appliance. Still used are the MARA and modifications of the Pendex, including temporary anchorage device (TAD) secured appliances for patients with maxillary dental protrusion.

In patients who present with severe neuromuscular and skeletal problems that lead to what we have termed “socially debilitating” malocclusions, the initiation of treatment earlier in the mixed dentition sometimes is indicated. From a physiologic standpoint, it may be better to delay treatment until the circumpubertal growth period so that a maximum response to FJO can be achieved. However, earlier intervention may be necessitated because of psychological issues related to the underlying severity of the malocclusion. Fortunately, such “socially debilitating” malocclusions are not observed frequently.

In Class II patients who present with maxillary prognathism, the timing of treatment does not appear to be crucial. Extraoral traction can be used in either the mixed or permanent dentition to treat this type of skeletal imbalance satisfactorily.[27,28]

It also should be noted that in many patients with Class II malocclusions identified in the 7 to 9-year-old age range, treatment is initiated at that time to handle intraarch problems (e.g., crowding, spacing, flaring); interarch discrepancies are addressed later. In other words, the same protocols (e.g., orthopedic expansion, extractions) that can be used for Class I patients may be initiated in Class II patients with arch length discrepancies. The attempt to correct mandibular deficiency, however, is best delayed until near the circumpubertal growth period in patients with mild to moderate Class II sagittal problems.

TREATMENT OF TOOTH-SIZE/ARCH-SIZE DISCREPANCY PROBLEMS

The most common type of malocclusion noted in the mixed dentition usually is described as *crowding*. These patients are referred by the family dentist or by the patient’s parents because of obvious dentoalveolar protrusion or lack of sufficient space for permanent tooth eruption. Most commonly, this type of patient presents with a Class I molar relationship or a tendency toward either a Class II or Class III malocclusion.

In the permanent dentition, discrepancies between tooth size and arch size usually are handled by one of three treatment modalities: extraction, interproximal reduction, or arch expansion. Comparable treatment protocols in the mixed dentition are serial extraction and orthopedic expansion, with interproximal reduction usually being reserved for permanent dentition patients only. Additional methods of treating discrepancy problems in the mixed dentition that are not available for use in permanent dentition patients include techniques of space management (e.g., maintenance of leeway space).

Space Maintenance during the Transition of the Dentition

An integral part of any mixed dentition protocol is monitoring the transition from the mixed to the permanent dentition. Significant differences exist between the sizes of the second deciduous molars and the succeeding second premolars.[29] On average, 2.5 mm per side of arch space can be gained in the mandibular arch, and about 2 mm per side can be gained in the maxillary arch. There is wide variation in tooth size among patients, however, and thus each patient must be evaluated with radiographs to determine the relative size of the second deciduous molars and their successors. Simply maintaining available arch space during the transition of the dentition may be sufficient to resolve minor to moderate tooth-size/arch-size discrepancies,[30] particularly if judicious interproximal reduction is used after the permanent dentition has erupted.

Two types of arches are used as holding appliances in the late transition of the dentition: the transpalatal arch (TPA) and the mandibular lingual arch. These arches routinely are cemented in place before the loss of the second deciduous molars.

Transpalatal Arch

The TPA,[1] as the name implies, extends from one maxillary first molar along the contour of the palate to the molar on the opposite side (Fig. 16-11). Although both fixed and removable types of TPAs are available, we routinely use the soldered TPA that is made from 0.036-inch stainless steel wire and that is soldered to the molar bands at their mesiolingual line angles and has an omega-shaped adjustment loop at the midpalatal height of contour.

The major function of the TPA in the mixed dentition is to prevent the mesial migration and mesial rotation of the maxillary first molars during the transition from the second deciduous molars to the second premolars. If desired, this appliance also is capable of producing desired molar rotations and changes in root torque[1] by sequential unilateral activation of the appliance. The TPA also can be used for stabilization of molar position. The TPA is often left in place until the final comprehensive phase of orthodontic therapy is completed. Interestingly, the TPA does not function well as an anchorage appliance in extraction cases.[31]

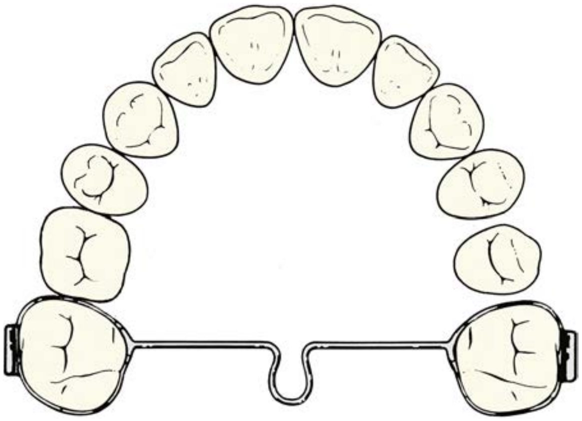

FIGURE 16-11 Transpalatal arch. This arch can be used as both an active appliance and a stabilization appliance during the transition of the dentition. Note the potential net increase in available space after the transition from the second deciduous molar to the second premolar. (Adapted from McNamara JA Jr, Brudon WL. *Orthodontics and Dentofacial Orthopedics*. Ann Arbor, MI: Needham Press; 2001.)

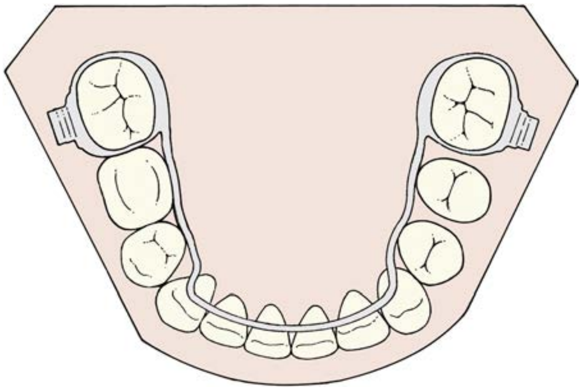

FIGURE 16-12 Lower lingual arch. Note the maintenance of arch space after the loss of the second deciduous molar and the eruption of the second premolar on the left side. Adjustment loops can be placed in the arch in the second premolar region, if desired. (Adapted from McNamara JA Jr, Brudon WL. *Orthodontics and dentofacial orthopedics*. Ann Arbor, MI: Needham Press; 2001.)

Lingual Arch

The lingual arch, usually used in the mandible as part of our early treatment protocol, has a similar function to the TPA in the maxilla, which is as a molar anchorage appliance. The lingual arch, also made of 0.036-inch stainless steel, extends along the lingual contour of the mandibular dentition from the first molar on one side to the first molar on the other (Fig. 16-12). Optional adjustment loops (not shown) can be placed in the lingual arch in the region of the second deciduous molars, providing added ability to adjust arch vertical and horizontal position.

The lower lingual arch is used less frequently (30% of our early treatment patients) than is the TPA (90+% of patients) because many patients undergo early orthodontic treatment who do not require the maintenance of arch space in the lower second premolar region. Thus, the lower lingual arch is indicated only in patients in whom maximum molar anchorage is to be maintained. In contrast to the TPA, the lingual arch usually is removed after the eruption of the second premolars is completed and the proper positioning of these teeth has been achieved.

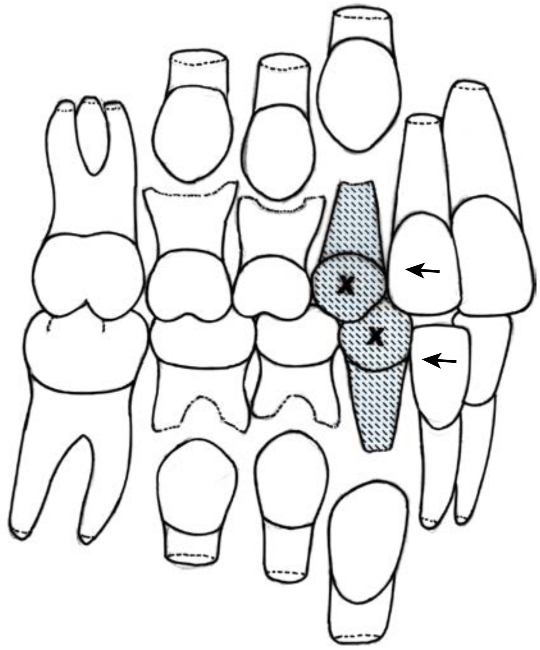

FIGURE 16-13 Serial extraction protocol. The removal of the upper and lower deciduous canines (x) allows for an improvement in the alignment of the upper and lower incisors.

Not only is the lingual arch used in Class I individuals in whom arch space is to be stabilized but also in the treatment of patients with Class III malocclusions. In this instance, molar position is maintained to prevent the forward movement of the molars (thus aggravating the Class III molar relationship) and facilitating the more posterior eruption and potential distal movement of the mandibular premolars.

SERIAL EXTRACTION

Another protocol that is used less frequently in the management of tooth-size/arch-size discrepancies is *serial extraction*. This treatment technique involves the sequential removal of deciduous teeth to facilitate the unimpeded eruption of the permanent teeth. Such a procedure often, but not always, results in the extraction of four premolar teeth. The sequence of serial extraction has been clarified in a series of articles by Dewel[32,33] as well as in several book chapters (See Chapter 34).[34,35]

The typical serial extraction protocol is initiated about the time of the appearance of the permanent lateral incisors, which erupt in rotated positions or initially are prevented from eruption by the deciduous canines. In the most commonly used protocol, the first teeth to be removed are the deciduous canines (Fig. 16-13). The removal of these teeth allows for the eruption, posterior movement, and spontaneous improvement in the alignment of the permanent lateral incisors.

In about 6 to 12 months, the removal of the four deciduous first molars is undertaken (Fig. 16-14). Ideally, the root development of the four first premolars is ahead of that of the permanent canines, so that the first premolars will erupt before the canines. At this stage, if the canines are erupting close to the same time as the first premolars, some clinicians prefer to extract the first premolars at the same time that the

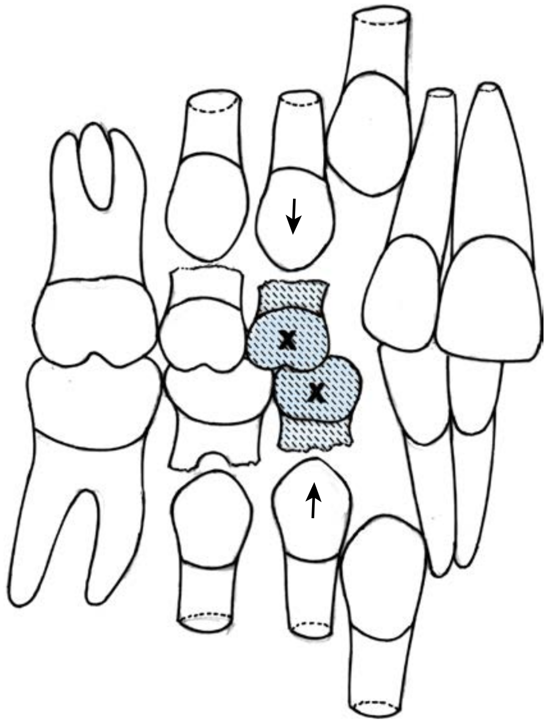

FIGURE 16-14 Serial extraction protocol (continued). The removal of the deciduous first molars encourages the eruption of the first premolars. Some clinicians choose to remove the first premolars at the same time to allow the lower canines to migrate posteriorly before emergence. (From McNamara JA Jr, Brudon WL. *Orthodontics and dentofacial orthopedics*. Ann Arbor, MI: Needham Press; 2001.)

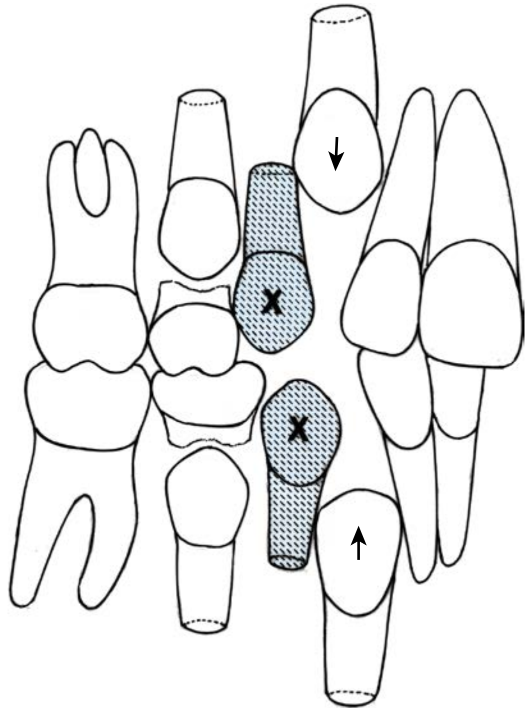

FIGURE 16-15 Serial extraction protocol (continued). The removal of the first premolars encourages the eruption and posterior movement of the permanent canines. (From McNamara JA Jr, Brudon WL. *Orthodontics and dentofacial orthopedics*. Ann Arbor, MI: Needham Press; 2001.)

first deciduous molars are removed, under the assumption that changes that are even more favorable are obtained when the first premolars are removed before they emerge. Before emergence, the permanent canines can move within the jaws toward the space where the first premolar crowns were located.

The next step in the usual protocol is the extraction of the first premolars (Fig. 16-15) after these teeth have been allowed to erupt. It is common to observe that the adjacent canine and potentially second premolars erupt toward the extraction sites, as is shown in Figure 16-16. The lower incisors often upright as well, sometimes too much so. As soon as the second molars near emergence, fixed appliances are used to align and detail the dentition and occlusion (Fig. 16-17).

Graber[34] states that serial extraction may be indicated when it is determined "with a fair degree of certainty that there will not be enough space in the jaws to accommodate all the permanent teeth in their proper alignment." Whereas Proffit and coworkers[36] cite a predicted tooth-size/arch-size discrepancy of 10 mm or greater as an indication for serial extraction, Ringenberg[37] mentions a discrepancy of 7 mm or more. In many serial extraction patients, a TPA is used to maintain maxillary molar position as the transition to the permanent dentition occurs.

From our perspective, the primary factor to be evaluated when making a treatment decision concerning serial extraction is large tooth size. In instances in which tooth sizes are abnormally large (e.g., maxillary central incisor width >10.0 mm),[29] the initiation of serial extraction protocols may be appropriate. Another factor that must be considered is the anteroposterior positioning of the lower incisors relative to the adjacent

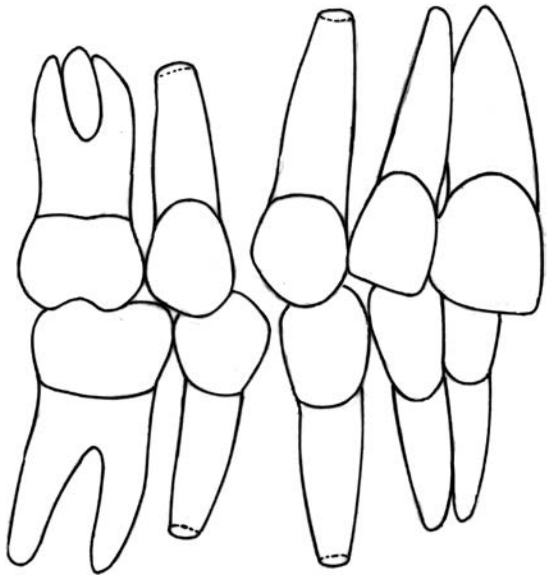

FIGURE 16-16 Serial extraction protocol (continued). The remaining teeth tend to tip toward the extraction sites. The lower incisors often tip lingually as well. (From McNamara JA Jr, Brudon WL. *Orthodontics and dentofacial orthopedics*. Ann Arbor, MI: Needham Press; 2001.)

skeletal elements as well as to the soft tissue, especially the lip musculature.

Serial extraction patients with tooth crowding with extreme bialveolar retrusion and flat facial profiles obviously are not

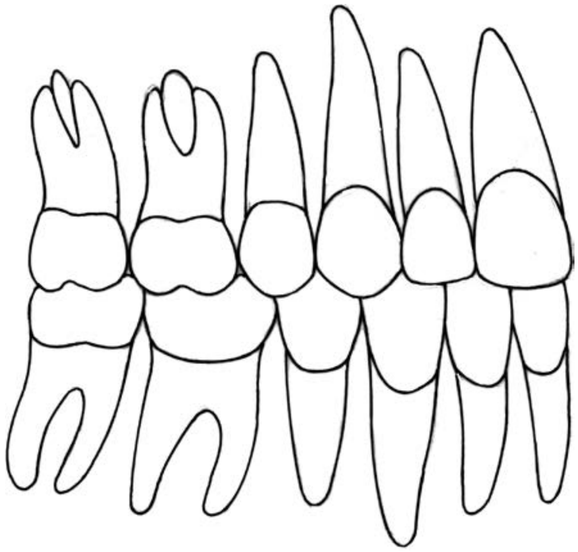

FIGURE 16-17 Serial extraction protocol (continued). After the lower second premolars near emergence, fixed appliances are used to align the teeth and level the occlusal plane. (From McNamara JA Jr, Brudon WL. *Orthodontics and dentofacial orthopedics*. Ann Arbor, MI: Needham Press; 2001.)

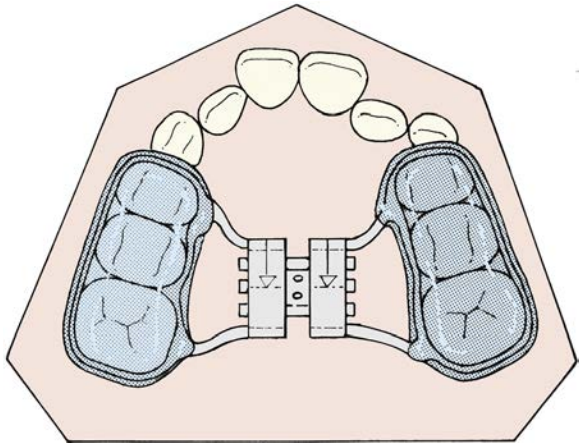

FIGURE 16-18 An acrylic splint RME appliance that is bonded to the maxillary primary molars and the permanent first molars. The occlusal coverage of acrylic produces a posterior bite block effect on the vertical dimension. (Adapted from McNamara JA Jr, Brudon WL. *Orthodontics and dentofacial orthopedics*. Ann Arbor, MI: Needham Press; 2001.)

recommended because of potential unfavorable facial contour changes. In fact, mild residual crowding of the lower incisors is more preferable to creating a "dished-in" facial appearance. Similarly, a serial extraction protocol in patients with bialveolar protrusion also is not indicated because maximum retraction of the incisors is desirable and is not usually attainable with serial extraction. Maximum anchorage mechanics using fixed appliance therapy potentially combined with extraoral traction[38] or temporary anchorage devices[39] are treatments of choice.

Serial extraction may be combined with RME in certain patients with significant arch-length discrepancy problems who also present with a narrow tapered maxilla and negative space in the corners of the mouth during smiling. The use of RME is particularly appropriate in patients with broad facial contours. The arches can be expanded first to broaden the smile, and then after reevaluation, serial extraction procedures may be initiated subsequently to reduce or eliminate emerging tooth–arch imbalances.

It is well known that serial extraction is not a panacea in all patients who present with dental crowding in the mixed dentition.[37] Great care must be taken to avoid lingual tipping of the lower incisors as well as unfavorable changes in the sagittal position of the upper and lower dentitions. In addition, the initiation of serial extraction procedures may result in unwanted spacing in the dental arches. When used appropriately as based on a solid diagnosis, however, a protocol of sequentially extracting the deciduous dentition has proven to be an efficient, cost-effective, and satisfactory treatment for tooth-size/arch-size discrepancy problems (see Chapter 34 for in-depth discussion).

ARCH EXPANSION

Types of Expansion

It is well known that expansion of the dental arches can be produced by a variety of orthodontic treatments, including those that incorporate fixed appliances. The types of expansions produced can be divided arbitrarily into three categories.

Orthodontic Expansion

Orthodontic expansion, produced by conventional fixed appliances as well as by various removable expansion plate and finger spring appliances, usually results in lateral movements of the buccal segments that primarily are dentoalveolar in nature. There is a tendency toward a lateral tipping of the crowns of the involved teeth and a resultant relative lingual tipping of the roots. The resistance of the cheek musculature and other soft tissue remains, providing forces that may lead to a relapse or rebound of the achieved orthodontic expansion.[40,41]

Passive Expansion

When the forces of the buccal and labial musculature are shielded from the occlusion, as with the FR-2 appliance of Fränkel,[42] a widening of the dental arches often occurs. This *passive* expansion is not a result of the application of extrinsic biomechanical forces but rather by intrinsic forces such as those produced by the tongue. Brieden and coworkers,[43] in an implant study conducted in patients treated with the FR-2 appliance of Fränkel, have demonstrated that bone deposition occurs primarily along the lateral aspect of the alveolus rather than at the midpalatal suture. A related type of spontaneous arch expansion also has been observed after lip-bumper therapy.[44]

Orthopedic Expansion

Rapid maxillary expansion appliances (Fig. 16-18) are the best examples of true *orthopedic* expansion, in that changes are produced primarily in the underlying skeletal structures rather than by the movement of teeth through alveolar bone.[45-47] RME not only separates the midpalatal suture but also affects the circumzygomatic and circumaxillary sutural systems.[48] After the palate has been widened, new bone is deposited in the area of expansion so that the integrity of the midpalatal suture usually is reestablished within 3 to 6 months.

Rationale for Early Orthopedic Expansion

The cornerstone of the early orthopedic expansion protocol used in the treatment of patients with arch-length discrepancy problems is the actual RME itself. The use of RME is based in part on our previous studies of the development of the dental arches in untreated individuals, both in the permanent dentition and the mixed dentition.[1,29,49]

Permanent Dentition

When arches are crowded, what is the cause? Howe and coworkers[49] carried out an investigation in which the dental casts of patients with severe crowding were compared with the dental casts of untreated individuals who were classified as having ideal or near-ideal occlusions. No statistically significant differences in tooth size were noted between the uncrowded and crowded populations, regardless of whether aggregate tooth size or the sizes of individual teeth were considered. In contrast, there were statistically significant differences in arch width and arch perimeter.

Maxillary intermolar width was of particular importance as an easily measured clinical indicator. In noncrowded male patients, the average distance between the upper first permanent molars, measured at the point of the intersection of the lingual groove at the gingival margin, was about 37 mm, a value that can be compared with a similar measure in the crowded males of 31 mm. Similar but slightly smaller measures and differences were noted in the female sample.[49] Howe and coworkers concluded that a transpalatal width of 35 to 39 mm suggests a bony base of adequate size to accommodate a permanent dentition of average size (of course, a larger aggregate tooth size requires a larger bony base and vice versa).

Mixed Dentition

Because Howe and coworkers'[49] study was conducted using data from individuals in the permanent dentition, it did not address the issue of the normal development of the dental arches. This question was considered in a second study[50] that examined the nature of normal changes in maxillary and mandibular transpalatal width from the early mixed dentition to the permanent dentition. Longitudinal changes in an untreated population from 7 to 15 years of age were evaluated. The average increase in transpalatal width between the upper first molars was about 2.5 mm.[49,50]

One of the conclusions that can be drawn from the studies cited earlier concerning dental arch development is that by providing some mechanism of widening the bony bases and increasing arch width and perimeter, more space can be obtained for the alignment of the permanent dentition. Of course, the dental arches cannot be expanded *ad libitum* because of the physiologic limits of the associated hard and soft tissues. It seems reasonable, however, to consider increasing arch size at a young age so that skeletal, dentoalveolar, and muscular adaptations can occur before the eruption of the permanent dentition.

Orthopedic Expansion Protocols

Our appliance of choice for use in patients with mixed dentition is the bonded acrylic splint expander (see Fig. 16-18). This appliance, which incorporates a Hyrax-type screw into a framework made of wire and acrylic, is used to separate the halves of the maxilla. It is widely recognized that maxillary expansion is achieved easily in a growing individual, particularly in individuals with mixed dentition.[51,52] The acrylic-splint type of appliance that is made from 3-mm-thick, heat-formed Biocryl has the additional advantage of acting as a bite block because of the thickness of the acrylic that covers the occlusal surfaces of the posterior dentition. The posterior bite block effect of the bonded acrylic splint expander prevents the extrusion of the posterior teeth,[53] a movement often associated with banded RME appliances,[54] thus permitting the use of this type of expander in some patients with steep mandibular planes. It also unlocks the occlusion, immediately aiding resolution of a functional jaw shift into crossbite.

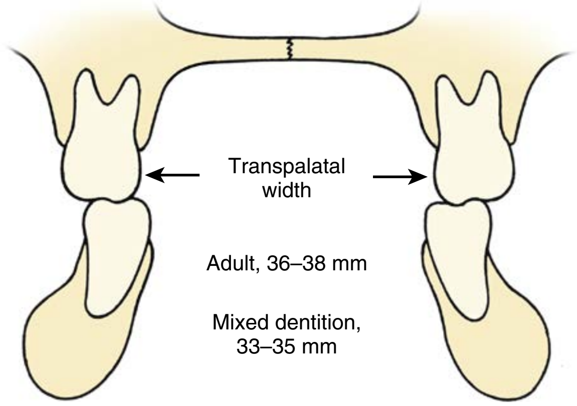

FIGURE 16-19 Frontal cross-sectional view of transpalatal dimensions through the molar region. Ideal transpalatal widths of the adult patient and the mixed dentition patient are shown. (Adapted from McNamara JA Jr, Brudon WL. *Orthodontics and dentofacial orthopedics*. Ann Arbor, MI: Needham Press; 2001.)

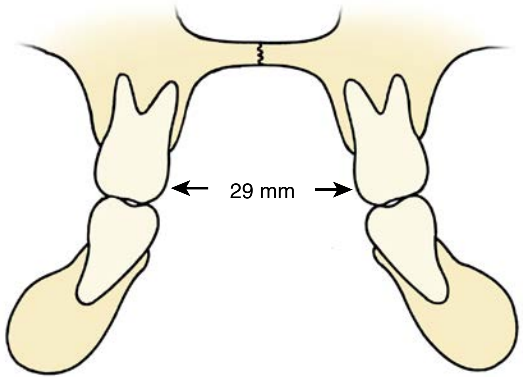

FIGURE 16-20 Frontal cross-sectional view of a patient with a constricted maxilla, as indicated by the intermolar width of 29 mm. (Adapted from McNamara JA Jr, Brudon WL. *Orthodontics and dentofacial orthopedics*. Ann Arbor, MI: Needham Press; 2001.)

Maxillary Adaptations

The treatment protocol that involves the use of a bonded expander is illustrated by the following example. The morphology of a patient in the mixed dentition with an idealized (e.g., 34 to 35 mm) transpalatal width (Fig. 16-19) can be compared with a patient with a narrow (e.g., 29 mm) transpalatal width (Fig. 16-20). A goal of the orthopedic treatment initiated in the mixed dentition is to reduce the need for extractions in the permanent dentition through the elimination of arch-length discrepancies as well as the elimination of bony base imbalances. In instances of restricted transverse dimensions, a bonded RME appliance is placed. The screw of the expander is activated one-quarter turn (90 degrees, 0.20 to 0.25 mm) per day until the lingual cusps of the upper posterior teeth approximate the buccal cusps of the lower posterior teeth (Fig. 16-21). In contrast to Haas,[47] who recommends full opening of the expansion screw to 10.5 to 11.0 mm (an action that can produce a buccal crossbite), we advocate only as much expansion as is feasible while still maintaining contact between the upper and lower posterior teeth.

After the active phase of expansion is completed, the appliance is left in place for an additional 5 months to allow for a reorganization of the midpalatal suture as well as other sutural systems affected by the expansion and to maximize the effect of the posterior bite block. At the end of the treatment time, the RME appliance is removed, and the patient is given a removable palatal plate to sustain the achieved result (Fig. 16-22).

The active expansion of the two halves of the maxilla produces a midline diastema between the two upper central incisors. During the period after the active expansion of the appliance, a mesial tipping of the maxillary central and lateral incisors usually is observed. Such spontaneous tooth movement is typical after RME, and this movement often is interpreted as being evidence of "relapse" by the patient or the parents. The clinician should advise the family about the probability of such spontaneous tooth migration. At 3 or 4 months after the initiation of RME treatment, brackets often are placed on the upper incisors to close the midline diastema and align the anterior teeth (Fig. 16-23). In limited instances, a utility arch is used to retract, intrude, or protract the upper incisors, depending on the needs of the individual patient.

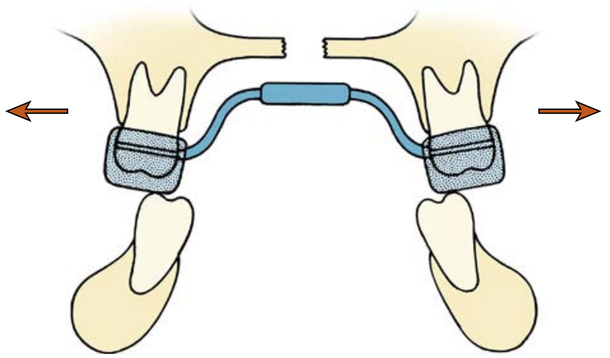

FIGURE 16-21 The effect of the bonded acrylic splint rapid maxillary expansion appliance. Note that the lingual cusps of the upper posterior teeth approximate the buccal cusps of the lower posterior teeth. (Adapted from McNamara JA Jr, Brudon WL. *Orthodontics and dentofacial orthopedics*. Ann Arbor, MI: Needham Press; 2001.)

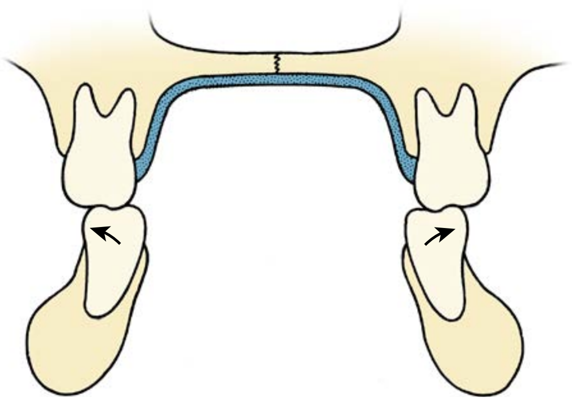

FIGURE 16-22 The same patient during the post–rapid maxillary expansion period. A removable palatal plate has been added to stabilize the intraarch relationship. Note the slight spontaneous uprighting of the posterior mandibular dentition. (Adapted from McNamara JA Jr, Brudon WL. *Orthodontics and dentofacial orthopedics*. Ann Arbor, MI: Needham Press; 2001.)

Mandibular Adaptations

In patients whose lower arch exhibits moderate crowding of the anterior teeth or in whom the posterior teeth are tipped lingually, two types of appliances can be used before RME: the removable Schwarz appliance and the lip bumper. The use of these "decompensating" (i.e., expanding, uprighting) appliances began as a result of our initial experiences using the bonded RME appliances alone. We were able to produce the expected changes in maxillary transverse dimensions with the bonded expander readily, but we made no attempt to widen the lower dental arch actively. After evaluating RME in mixed dentition patients over a 5-year period, we discovered that in some patients, a spontaneous uprighting and "decrowding" of the lower teeth occurred, yet in others, there was no change in the position and alignment of the lower teeth.

Because one of the cardinal rules of orthodontics was that one never should expand the lower arch, we were reluctant to do so. However, because expansion or uprighting was observed in the lower arch on a sporadic basis using RME and because arch expansion was produced routinely by the FR-2 appliance of Fränkel,[42,55-57] we decided to attempt orthodontic expansion or uprighting of the lower dental arch using either the removable Schwarz appliance or the lip bumper before orthopedic expansion of the maxilla. We assumed that expansion of the lower arch would not be stable unless the expansion was followed by maxillary orthopedic expansion.

Mandibular Dental Uprighting and Expansion Appliances

The Schwarz Appliance

The Schwarz appliance is a horseshoe-shaped removable appliance that fits along the lingual border of the mandibular dentition (Fig. 16-24). The inferior border of the appliance extends below the gingival margin and contacts the lingual gingival tissue. A midline expansion screw is incorporated into the acrylic, and ball clasps lie in the interproximal spaces between the deciduous and permanent molars.

The lower Schwarz appliance is indicated in patients with mild to moderate crowding in the lower anterior region and

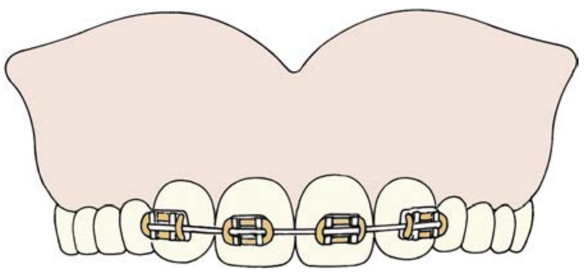

FIGURE 16-23 The placement of brackets on the upper anterior teeth to achieve incisal alignment with mesial movement of incisors providing added space for the permanent canines. (Adapted from McNamara JA Jr, Brudon WL. *Orthodontics and dentofacial orthopedics*. Ann Arbor, MI: Needham Press; 2001.)

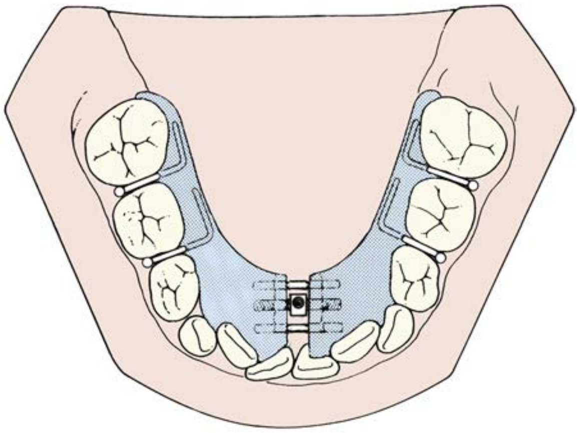

FIGURE 16-24 The removable lower Schwarz appliance that is used for mandibular dental decompensation. This appliance produces an orthodontic tipping (uprighting) of the lower posterior teeth and may create additional arch space anteriorly. (Adapted from McNamara JA Jr, Brudon WL. *Orthodontics and dentofacial orthopedics*. Ann Arbor, MI: Needham Press; 2001.)

especially in instances in which there is significant lingual tipping of the posterior dentition. The appliance is activated once per week, producing 0.20 to 0.25 mm of expansion in the midline of the appliance. Usually the appliance is expanded for 4 to 5 months, depending on the degree of incisal crowding, producing about 4 to 5 mm of arch length anteriorly.

Clinicians frequently have experienced difficulty understanding the reasoning underlying the use of the Schwarz appliance before RME. The following example illustrates the logic for this treatment decision. Figure 16-25, *A*, is a schematic of a bilateral posterior crossbite, a condition that clinically is recognized easily and for which RME is a generally accepted treatment regimen. In this example, the mandibular bony base and dental arch are of normal width, and there is normal posterior dental angulation, whereas the maxilla is constricted.

The example shown in Figure 16-25, *B*, is from a patient who has maxillary constriction but in whom also there has been mandibular dentoalveolar "compensation" (i.e., the positions of the lower teeth have been influenced by the size and shape of the narrow maxilla). No obvious crossbite is present. Even

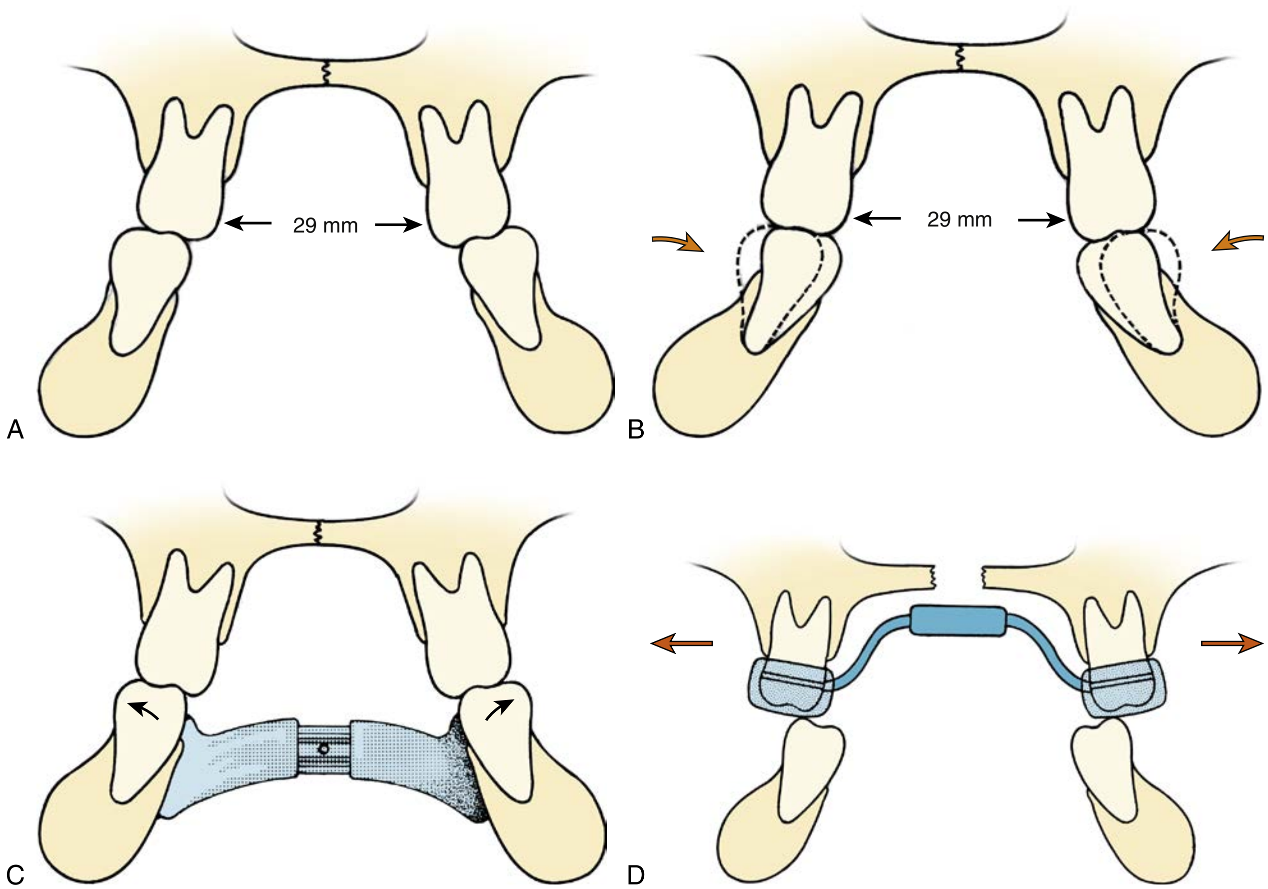

FIGURE 16-25 Frontal cross-sectional views. **A,** Patient with a constricted maxilla, properly uprighted lower posterior dentition, and a bilateral crossbite. **B,** Patient with a similar transpalatal width and with the body of the mandible in the same position as in A. Note the lower posterior teeth are more lingually inclined, camouflaging the maxillary constriction. The uprighting of the lower posterior teeth (i.e., mandibular dental "decompensation") is indicated before rapid maxillary expansion (RME). **C,** The removable lower Schwarz expansion appliance uprights the lower molars, orthodontically producing a tendency toward a posterior crossbite. **D,** RME after mandibular dental decompensation. The upper lingual cusps approximate the lower buccal cusps at the end of expansion. (Adapted from McNamara JA Jr, Brudon WL. *Orthodontics and dentofacial orthopedics*. Ann Arbor, MI: Needham Press; 2001.)

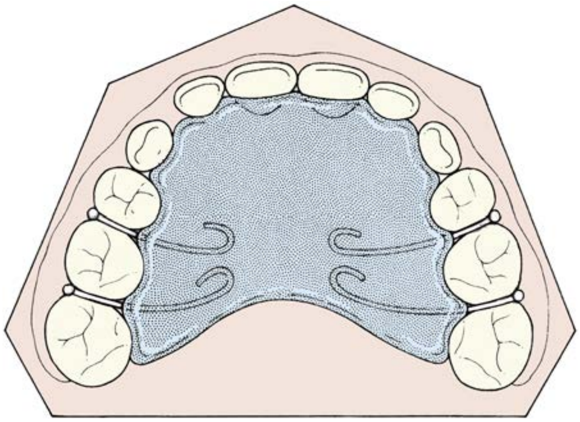

FIGURE 16-26 Maxillary stabilization plate. This appliance usually is worn on a near full-time basis for at least 1 year after rapid maxillary expansion removal. The acrylic of the plate also may serve as a guide plane for erupting canines and premolars. A labial bow, clasps, or both may be added. (Adapted from McNamara JA Jr, Brudon WL. *Orthodontics and dentofacial orthopedics*. Ann Arbor, MI: Needham Press; 2001.)

though maxillary width is the same as in Figure 16-25, *A*, the lower posterior teeth have erupted in a more lingual inclination. The palate appears narrow (in this example, a transpalatal width of 29 mm), and the arches are tapered in form. Mild to moderate lower incisor crowding also is present (not shown). In such a patient, mandibular dental "decompensation" using a removable lower Schwarz appliance often is undertaken. The width and form of the mandibular dental arch are made more ideal before the time that RME is attempted. By decompensating the mandibular dental arch, greater arch expansion of the maxilla can be achieved than when RME is used alone.[58,59]

Simply stated, the purpose of the Schwarz appliance is to produce *orthodontic tipping* of the lower posterior teeth, uprighting these teeth into a more normal inclination (Fig. 16-25, *C*). This movement is unstable if no further treatment is provided to the patient. A tendency toward a posterior crossbite is produced that is similar in many respects to the posterior crossbite shown in Figure 16-25, *A*.

Usually the Schwarz appliance is left in place until the maxillary orthopedic expansion phase is completed (Fig. 16-25, *D*). As described earlier, the maxilla is expanded using a bonded acrylic splint appliance until the upper lingual cusps barely touch the lower buccal cusps. After a 5-month period of RME stabilization, which allows adequate time for the midpalatal suture and the adjacent sutural systems to reorganize and reossify, both appliances are removed, and the patient is given a simple maxillary maintenance plate (Fig. 16-26), with no retention provided in the mandible. In instances of severe anterior malalignment in either arch, fixed appliances may be placed on the incisors to align these teeth, and interim lingual arch retention may be used.

Lip Bumper

The lip bumper (Fig. 16-27) is a removable appliance that also can be used for mandibular dental decompensation.[44,60] The lip bumper is particularly useful in patients who have very tight or tense buccal and labial musculature. The lip bumper lies away from the dentition at the gingival margin of the lower central incisors and shields the teeth from the forces of the adjacent

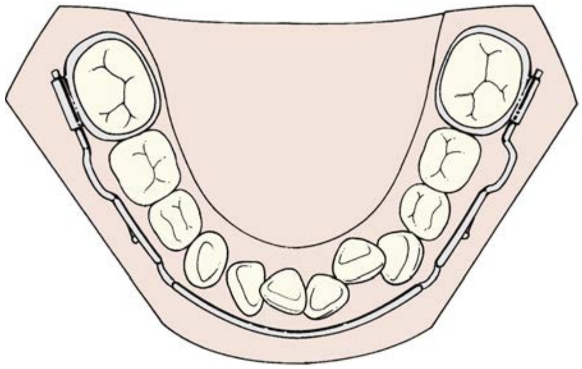

FIGURE 16-27 Occlusal view of a mandibular lip bumper that inserts into buccal tubes on the lower first permanent molar bands. (Adapted from McNamara JA Jr, Brudon WL. *Orthodontics and dentofacial orthopedics*. Ann Arbor, MI: Needham Press; 2001.)

soft tissue. The appliance usually is worn on a full-time basis and may be ligated in place. This appliance not only increases arch length through passive lateral and anterior expansion but also serves to upright the lower molars distally, adding to the available arch-length increase. Patients with lip bumper therapy must be monitored to avoid impacting the erupting second molars.

From a neuromuscular perspective, the lip bumper theoretically creates a more desirable treatment effect than does the Schwarz appliance. (The Schwarz appliance simply produces orthodontic tipping of the teeth through direct force application to the dentition and alveolus.) On the other hand, the lip bumper shields the soft tissue from the dentition, allowing for spontaneous arch expansion as is seen with the Fränkel and other soft tissue shielding appliances. We tend to favor the use of the Schwarz appliance over the lip bumper, however, in most instances because of the predictability of the treatment outcome and the ease of clinical management. Only in patients with very constricted (tense) soft tissue is the lip bumper the appliance of choice.

SPONTANEOUS IMPROVEMENT OF SAGITTAL MALOCCLUSIONS

The major focus of this section of the chapter thus far has been the resolution of intraarch tooth-size/arch-size discrepancy problems. Interestingly, there is another phenomenon that has been a serendipitous finding—"spontaneous" improvement of mild Class II and Class III malocclusions after RME.

Class II Patients

There are many patients in the mixed dentition who not only have intraarch problems but also have a Class II malocclusion or a strong tendency toward a Class II malocclusion. Generally, these patients do not have severe skeletal imbalances but rather may be characterized clinically as having either slight mandibular skeletal retrusion or an orthognathic facial profile with minimal neuromuscular imbalances.

According to the routine protocol described previously, these patients undergo RME with or without prior mandibular dental decompensation. At the time of expander removal, these patients will have a buccal crossbite tendency, with only the lingual cusps of the upper posterior teeth contacting the buccal cusps of the lower posterior teeth (Fig. 16-28, *A*). A maxillary

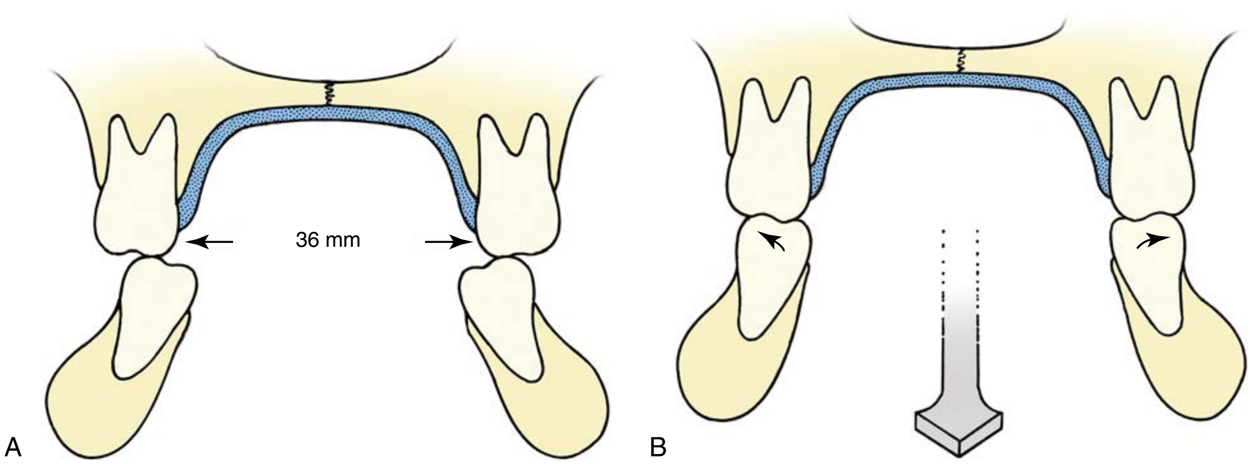

FIGURE 16-28 Frontal cross-sectional view of patient during the post–rapid maxillary expansion period. **A,** The maxilla has been expanded so that the intermaxillary width is 36 mm, as measured between the upper first permanent molars. Note the tendency toward a buccal crossbite bilaterally. **B,** During the postexpansion period, note that the lower dentition has uprighted slightly, and there has been a forward, sagittal movement of the mandible as the patient seeks to find a more stable position in which to occlude. (Adapted from McNamara JA Jr, Brudon WL. *Orthodontics and dentofacial orthopedics*. Ann Arbor, MI: Needham Press; 2001.)

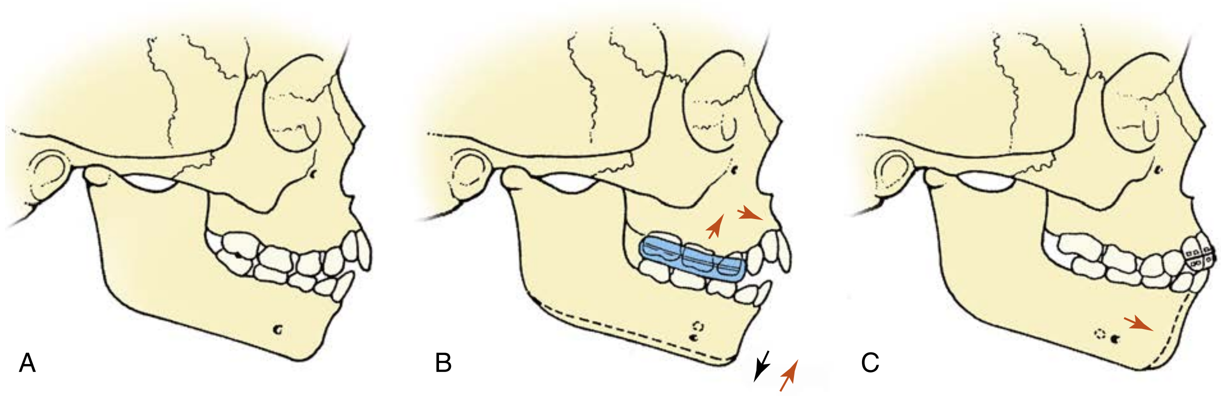

FIGURE 16-29 Sequence of events leading to a spontaneous improvement in the sagittal malocclusion. **A,** Pretreatment. The patient has excessive overjet and an end-to-end molar relationship. **B,** The placement of the appliance immediately creates a downward rotation of the position of the mandible due to the posterior occlusal acrylic. During treatment, an intrusive (and slightly protrusive) force is produced on the skeletal and dental structures of the maxilla. **C,** During the postexpansion period, the upper dental arch has been widened. The lower jaw often is postured forward to achieve a more stable occlusal relationship—a forward functional occlusion. In this illustration, brackets have been placed on the upper anterior teeth to facilitate incisal alignment.

maintenance plate typically is used to stabilize this relationship. Several appointments later, some interesting observations are noted: the tendency toward a buccal crossbite has disappeared (Fig. 16-28, *B*), and the patient now has a significant improvement in molar relationship, sometimes the establishment of a solid Class I sagittal occlusal relationship.

The orthodontist traditionally has viewed a Class II malocclusion as primarily a sagittal and vertical problem. Our experience with the post-RME correction of the Class II problem indicates that many Class II malocclusions also have a strong transverse component. The overexpansion of the maxilla, which subsequently is stabilized through the use of a removable palatal plate, disrupts the occlusion. It appears that the patient becomes more comfortable by positioning his or her lower jaw slightly forward, thus eliminating the tendency toward a buccal crossbite and at the same time improving the overall sagittal occlusal relationship. In many respects, the teeth themselves act as an endogenous functional appliance, encouraging a change in mandibular posture and, ultimately, a change in the maxillomandibular occlusal relationship.

The correction of a Class II tendency patient is illustrated in Figure 16-29. Figure 16-29, *A*, shows the sagittal view of the skeletal and dentoalveolar structures of a Class II tendency patient who has excessive overjet and a narrow maxilla. The placement of a bonded maxillary expansion appliance immediately causes an increase in the vertical dimension of the face

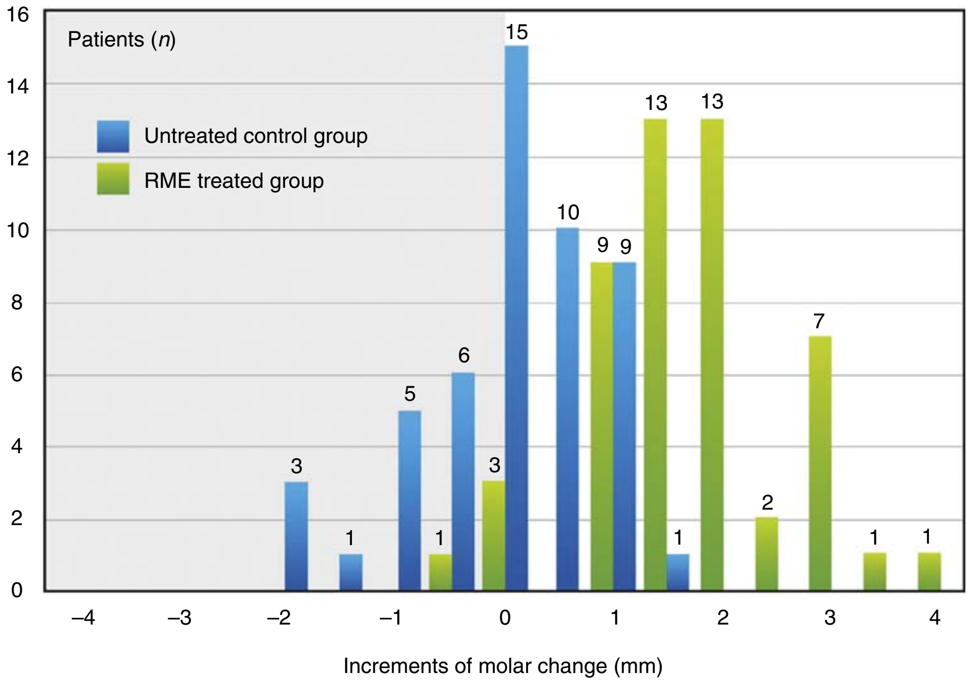

FIGURE 16-30 Prospective clinical study of spontaneous improvement in Class II molar relationship after expansion in the early mixed dentition. Both the treated and control groups had 50 patients or participants. The interval between the two lateral cephalometric films analyzed was 4 years. There was virtually no change in the control subjects, but 92% improved toward Class I in the treated group, nearly 50% by 2 mm or more. *RME,* Rapid maxillary expansion. (From Guest SS, McNamara JA Jr, Baccetti T, Franchi L. Improving Class II malocclusion as a side-effect of rapid maxillary expansion: a prospective clinical study. *Am J Orthod Dentofacial Orthop* 2010;138:582–591.)

because of the posterior occlusal coverage. This change is beneficial in most patients, in that the temporary increase in the vertical dimension prevents extrusion of the posterior teeth during the expansion process.[53] This treatment also may result in an upward and slightly forward displacement (Fig. 16-29, *B*) of the maxilla. (This phenomenon will be discussed subsequently in the discussion of the spontaneous improvement of Class III malocclusion.) During the post-RME period, during which a removable palatal plate is worn (Fig. 16-29, *C*), the mandible is postured forward by the patient because of the overexpansion of the maxilla. Thus, the spontaneous improvement of patients with a tendency toward a Class II malocclusion does not occur during the active expansion period but rather during the time that the maintenance plate is being worn.

Because of the perceived importance of this issue, we have conducted two prospective clinical trials investigating this phenomenon. Guest and coworkers[61] contrasted the treatment results of 50 Class II or end-to-end patients treated with a bonded expander to 50 matched untreated control participants (Fig. 16-30). The analysis of serial cephalometric films taken 4 years apart indicated that the bonded RME had its greatest effects at the occlusal level, specifically producing highly significant improvement of Class II molar relationship and a decrease in overjet. The Class II molar relationship remained virtually unchanged in the control group, but the RME group showed an improved molar relationship of more than 1 mm in more than 90% of the expansion patients and more than 2 mm in almost 50% (see Fig. 16-30). The second study[61] on a larger group of patients (500 RME patients from the McNamara private practice; 188 control participants) revealed similar results.

Thus, this improvement in Class II relations occurs with such frequency that it can be included as part of the overall treatment plan. If the resulting occlusion remains Class II at the time of phase II treatment, then definitive Class II corrective procedures can be initiated.

Class III Patients

The use of a bonded RME appliance also can lead to a spontaneous occlusal improvement in a patient with a tendency toward a Class III malocclusion. At first glance, this phenomenon seems paradoxical, given the previous discussion concerning the spontaneous improvement of Class II tendency problems. The mechanism of Class III correction, however, is distinctly different from that described previously.

An examination of Figure 16-29, *B*, provides some explanation for this phenomenon. The placement of an acrylic splint expander that opens the bite vertically 3 mm not only provides an intrusive force against the maxilla,[53] presumably because of the stretch of the masticatory musculature, but also may produce a slight forward repositioning of the maxilla. A slight forward movement of the maxilla after RME has been documented in both clinical[62] and experimental[63] studies. In addition, the placement of a bonded expander with acrylic coverage of the occlusion helps eliminate a tendency toward a pseudo–Class III malocclusion.

As with the Class II tendency patients described previously, patients in whom a borderline Class III malocclusion exists usually have a reasonably balanced facial pattern, often with only a slight tendency toward maxillary skeletal retrusion. Obviously, in patients in whom Class III malocclusion persists after expansion, more aggressive types of therapies are indicated, as will be discussed later.

When contrasting the spontaneous improvement of both Class II and Class III tendency patients, it must be emphasized that any spontaneous improvement of a Class III malocclusion usually occurs (if it does occur) during the *active* phase of treatment (within the first 30 or 40 days). The spontaneous correction of Class II malocclusion usually is noted during the *retention* phase, after the bonded expander has been removed and the maintenance plate has been worn for 6 to 12 months. When planning the treatment for a Class III tendency patient, FM hooks may be attached to the expansion appliance to facilitate the use of an FM if that treatment is deemed necessary from the original plan or at a later time.

THE TREATMENT OF CLASS II MALOCCLUSION

A number of treatments are available for correcting Class II malocclusions, including a variety of extraoral traction appliances, arch expansion appliances, extraction procedures, and FJO appliances. Each treatment approach, however, differs in its effect on the skeletal structures of the craniofacial region, sometimes accelerating or limiting the growth of the various craniofacial structures involved. As noted at the beginning of this chapter, timing of treatment usually is most effective during the circumpubertal growth period, the late mixed to permanent dentition.

Components of Class II Malocclusion

Numerous studies have considered the components of Class II malocclusions, with most focusing on patients in the adolescent or adult age range.[64-66] These studies have shown that the term *Class II malocclusion* is not a single diagnostic entity but rather can result from numerous combinations of skeletal and dentoalveolar components.

McNamara[67] has shown that in mixed dentition Class II subjects before treatment, mandibular skeletal retrusion was the most common single characteristic of his large Class II sample ($n = 277$). Substantial variation also was noted in the vertical development of the face, with one-third to half of the sample having increased vertical facial dimensions. The anteroposterior position of the maxilla on average was neutral, with far more instances of maxillary skeletal retrusion than maxillary skeletal protrusion being observed. When measures independent of mandibular position were used for evaluation, the upper incisors of the Class II sample were on average in a normal anteroposterior position, with more instances of maxillary dentoalveolar retrusion than maxillary dentoalveolar protrusion being observed.[67] The lower incisors usually were well positioned anteroposteriorly, but instances of mandibular dental retrusion and protrusion also were noted.

Available Class II Treatment Strategies

After the skeletal and dentoalveolar components of an individual Class II malocclusion are identified, using data gathered from the clinical examination and a radiographic evaluation as well as from study models, the appropriate treatment regimen can be selected. This discussion focuses on the treatment of problems of Class II malocclusion that are primarily skeletally related, with specific emphasis on *maxillary distalization* and *mandibular enhancement* mechanics, two of the most commonly used treatment approaches.

Maxillary Distalization

In patients with a forward positioning of the maxillary dentition relative to the bony base of the maxilla, either extraction protocols (i.e., ultimately removing the upper first premolars) or dentoalveolar distalizing mechanics (e.g., Pendulum/Pendex appliance,[68-70] Distal Jet,[71,72] TAD-secured distalizers) can be used.

Extraoral Traction

Historically, the most common treatment for true maxillary skeletal protrusion has been extraoral traction. Extraoral traction appliances can be divided arbitrarily into two types: facebows and headgears. Whereas facebows attach to tubes on the maxillary first molar bands, a headgear attaches directly to the archwire or to auxiliaries connected to the archwire.

The cervical (low-pull) *facebow* (Fig. 16-31, *A*) is used most frequently in patients with normal or decreased vertical facial dimensions. The inner bow of the facebow is anchored to tubes that are placed on the buccal surface of bands that are attached to the upper first molars. The outer bow is connected to a safety release elastic strap that extends to the cervical region and is anchored against the dorsal aspect of the neck. Usually the outer bow of the facebow lies above the plane of occlusion (e.g., 15 to 20 degrees) so that the force is directed through the center of resistance to prevent distal tipping of the molars during treatment. Numerous clinical studies[28,73,74] have shown that the forward movement of the maxilla can be inhibited through the use of this type of appliance. Cervical traction also can increase the vertical dimension through the extrusion of posterior teeth.

The direction of extraoral force can be altered, depending on the placement of the attached anchoring units. For example, an occipital (high-pull) facebow (Fig. 16-31, *B*) is used in individuals in whom increases in vertical dimension are to be minimized or avoided. The facebow is anchored to an occipital anchoring unit (headcap) to produce a more vertically directed force. As a growth guidance appliance, a high-pull facebow can decrease the vertical development of the maxilla, thereby allowing for autorotation of the mandible and maximizing the horizontal expression of mandibular growth. A facebow also can be anchored simultaneously to a cervical neckstrap and an occipital headcap, a combination often termed a *straight-pull* or *combination facebow* headgear.

The forces produced by extraoral traction also can be attached anteriorly to the archwire through the use of a J-hook *headgear*. Flared upper incisors can be retracted using either a straight-pull (Fig. 16-32, *A*) or a high-pull headgear (Fig. 16-32, *B*) combined with J hooks that are attached to the archwire anteriorly or by using a closing arch supported by headgear. A headgear with J hooks also is used to potentiate archwire mechanics by helping control forces incorporated into the archwire (e.g., torque, intrusion).

The use of the Interlandi-type headgear (Fig. 16-33) provides an additional treatment option with a variable direction of force. J hooks can be applied to the maxillary teeth in a variety of force vectors to retract and intrude the upper incisors (Fig. 16-33, *A*). A similar type of retraction-stabilization of the

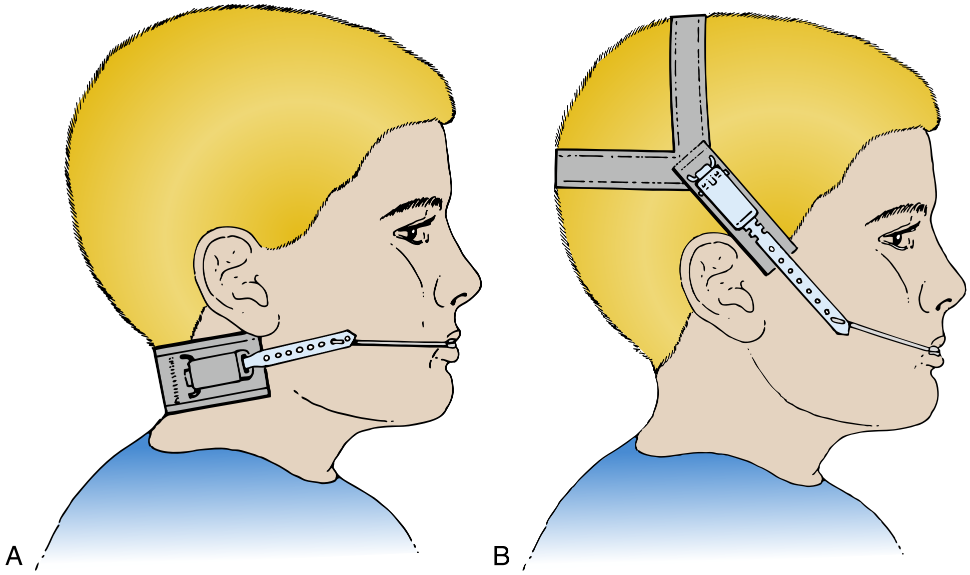

FIGURE 16-31 Extraoral traction. **A,** Low-pull (cervical) facebow with safety connector. **B,** High-pull (occipital) facebow with safety connector. (Adapted from McNamara JA Jr, Brudon WL. *Orthodontics and dentofacial orthopedics*. Ann Arbor, MI: Needham Press; 2001.)

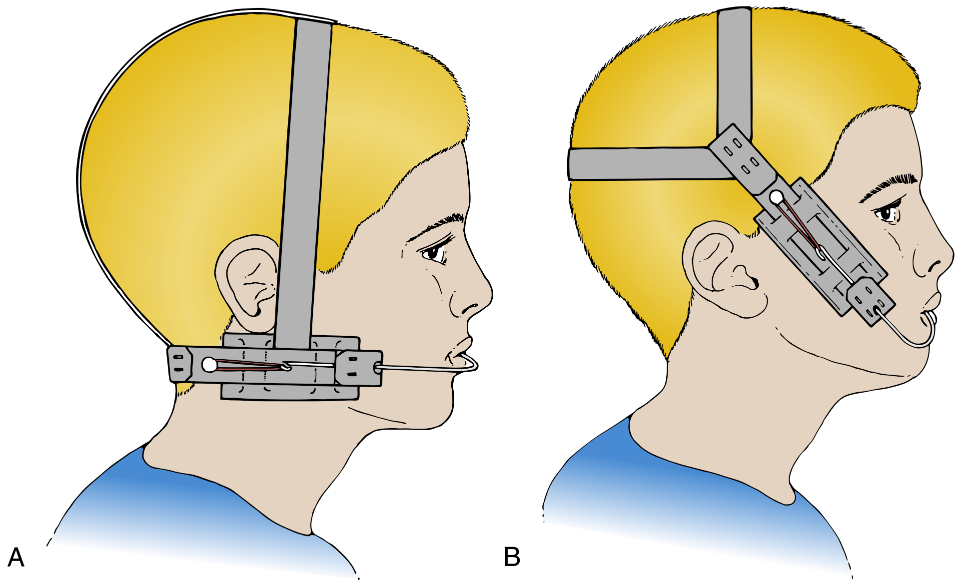

FIGURE 16-32 Headgear. **A,** Straight-pull headgear with J hooks. **B,** High-pull headgear with J hooks. (Adapted from McNamara JA Jr, Brudon WL. *Orthodontics and dentofacial orthopedics*. Ann Arbor, MI: Needham Press; 2001.)

mandibular dental arch also can be achieved. In addition, it is possible to attach to a high-pull headgear to the upper arch and a straight-pull headgear to the lower arch simultaneously (Fig. 16-33, *B*).

Virtually all of the extraoral traction appliances described earlier restrict the normal downward and forward movement of the maxilla and also may help retract the maxillary and mandibular dentitions to differing degrees depending on a nonextraction or premolar extraction plan—and patient cooperation. These types of appliances are indicated in instances of maxillary skeletal protrusion, maxillary dentolaveolar protrusion, and mandibular dentoalveolar protrusion. The direction of force (i.e., low pull, straight pull, high pull) is determined in part by the pretreatment vertical dimensions of the patient and treatment goals.

Maxillary Molar Distalization

The use of distalization mechanics to correct Class II malocclusions is a common treatment modality. A survey by Sinclair[75] found that all responding orthodontists reported use of molar distalization. However, nearly all indicated that patient cooperation was the most significant problem encountered in distalizing maxillary molars. Most traditional approaches to molar distalization, including extraoral traction, Wilson distalizing arches, removable spring appliances, and intermaxillary elastics with sliding jigs, require considerable patient compliance

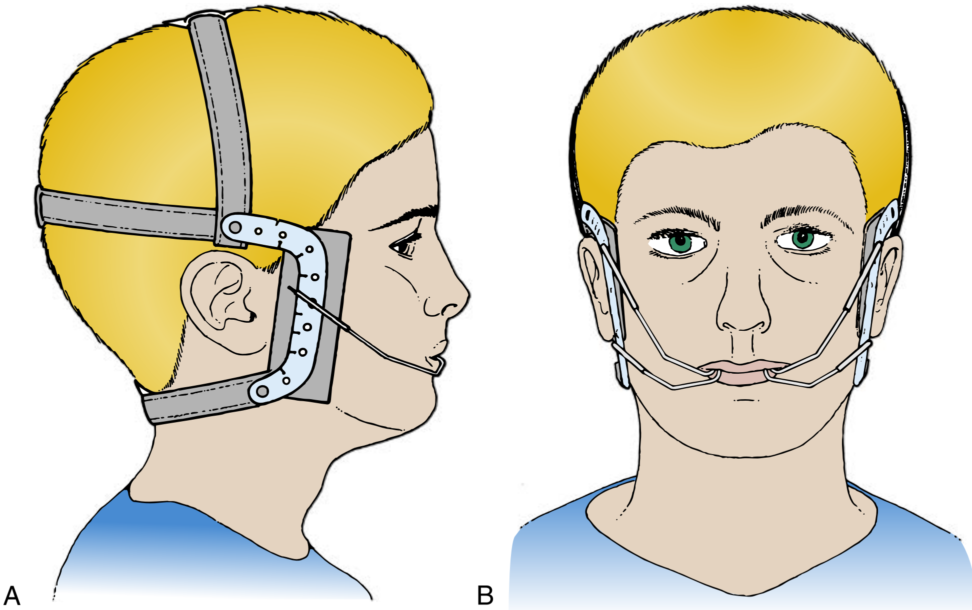

FIGURE 16-33 Interlandi-type headgear. **A,** Single pull to the maxillary dentition. **B,** Attachment of the J hooks to both the maxillary and mandibular dental arches. (Adapted from McNamara JA Jr, Brudon WL. *Orthodontics and dentofacial orthopedics*. Ann Arbor, MI: Needham Press; 2001.)

to be successful. More recently, problems of predicting patient behavior have led many clinicians to devise appliances that minimize reliance on the patient and that are under the control of the clinician. Relying on the patient's willingness to wear an appliance consistently may result in increased treatment time, a change of treatment plans, or both with related uncertainty in attaining treatment goals.

Pendulum and Pendex Appliances

A popular method of molar distalization that requires no direct patient cooperation is the Pendulum appliance system. In 1992, Hilgers[76] described the development of two hybrid appliances, the Pendulum and Pendex.

The *Pendulum appliance* (Fig. 16-34) consists of a large acrylic Nance button that covers the middle part of the palate. The acrylic pad is connected to the dentition by means of occlusal rests that extend from the lateral aspect of the pad and are bonded to the occlusal surfaces of the upper first and second premolars. Posteriorly directed springs, made of 0.032-inch titanium molybdenum alloy (TMA) wire, extend from the distal aspect of the palatal acrylic to form a helical loop near the midline, then extending laterally to insert into lingual sheaths on bands cemented on the upper first molars.

When in a passive state, the springs extend posteriorly, paralleling the midpalatal raphe. When activated and inserted into the lingual sheaths, they produce a distalizing force against the upper first molars that moves the molars distally and medially. Hilgers[76] estimates that these springs deliver approximately 230 g per side to the maxillary molars. The springs also may have adjustment loops that can be manipulated to increase molar expansion, molar rotation, or distal root tip.[77,78]

The design of the *Pendex appliance* (Fig. 16-35) is essentially the same as the Pendulum, except for the addition of a palatal expansion screw in the midline (hence the name "Pendex"). In most instances, we use the Pendex design because of the

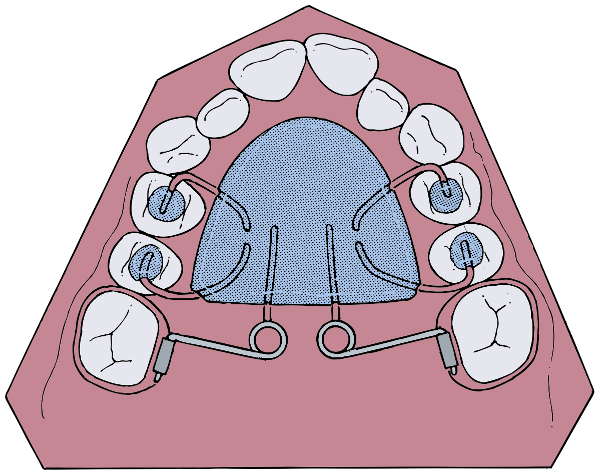

FIGURE 16-34 The Pendulum appliance of Hilgers that has been bonded in place after cementing the molar bands. The distalizing springs are activated after the occlusal rests have been bonded to the premolars by placing the ends of the springs into the lingual sheaths on the upper first molars.

tendency toward transverse maxillary constriction in patients with Class II malocclusion as well as the trend toward the lingual movement of molars as they are distalized with this type of appliance.

The so-called T-Rex configuration of the Pendex is our design of choice. This design features two wires that extend from the palatal acrylic and are soldered to the lingual aspect of the upper first molars. These wires provide additional stability to the Pendex appliance during the expansion phase of treatment (Fig. 16-36). They are removed when the molar distalization phase is initiated after adequate expansion has been achieved (Fig. 16-37). After molar distalization is complete, the occlusal rests can be removed from the maxillary second

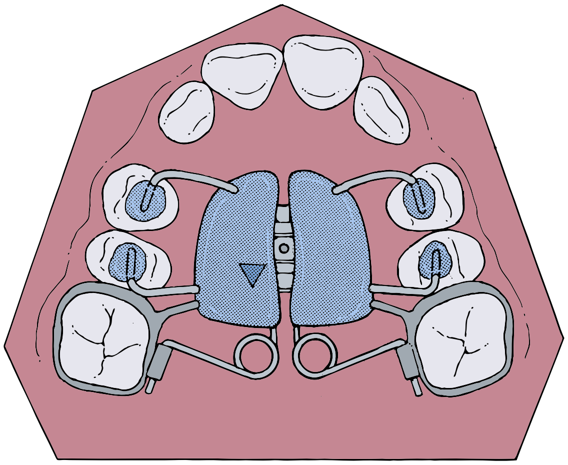

FIGURE 16-35 The "T-Rex" design of the Pendex appliance of Hilgers. Locking wires connect the bands on the upper first molars to the acrylic button. These connecting wires are removed after the desired expansion has been achieved, partially counteracting the medial action of the distalizing molar springs.

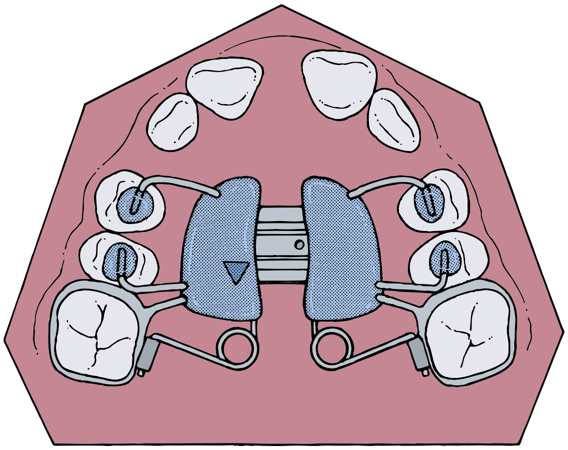

FIGURE 16-36 The "T-Rex" design of the Pendex appliance after expansion. The locking wires still connect the molar bands to the acrylic Nance button.

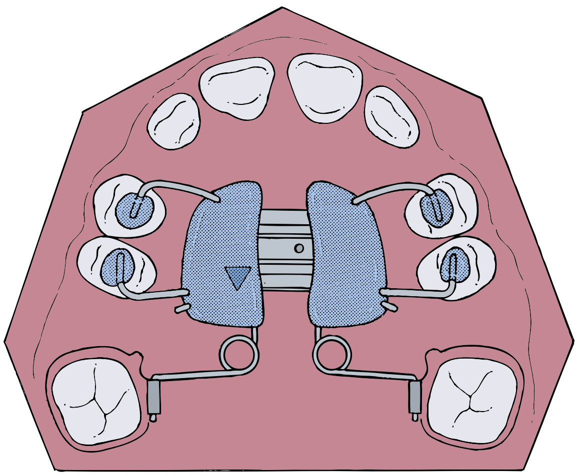

FIGURE 16-37 Full activation of the Pendex appliance. The upper first molars now are in an overcorrected ("super Class I") relationship with the lower first molars.

premolars, allowing for distal migration as a result of the pull of the transseptal fibers (Fig. 16-38).

After appliance removal, a Nance holding arch with a palatal button (Fig. 16-39) is delivered to the patient within the next 24 hours. The Nance holding arch is left in place until proper distalization of the premolars and canines is achieved. Final distalization of the premolars and canines is accomplished by placing brackets on these teeth and using elastomeric chain sequentially to move these teeth distally one at a time per side (i.e., moving "beads on a string"). Anterior space closure can be achieved by way of a retraction utility arch or an anterior closing loop arch. Typically, space closure also is supported by Class II elastics. For further details concerning the clinical management of the appliance, the reader is referred to the McNamara and Brudon text.[1]

Mandibular Enhancement: Functional Jaw Orthopedics

The previous section described several approaches aimed at correcting a Class II molar relationship by moving the maxilla

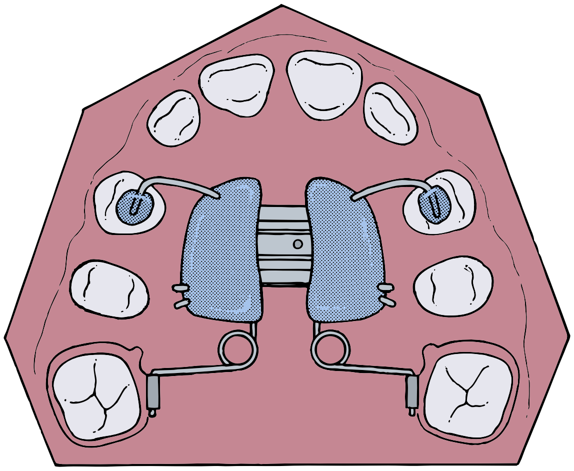

FIGURE 16-38 The spontaneous movement of the upper second premolars distally due to the pull of the transseptal fibers after the occlusal rests on the maxillary second premolars are removed.

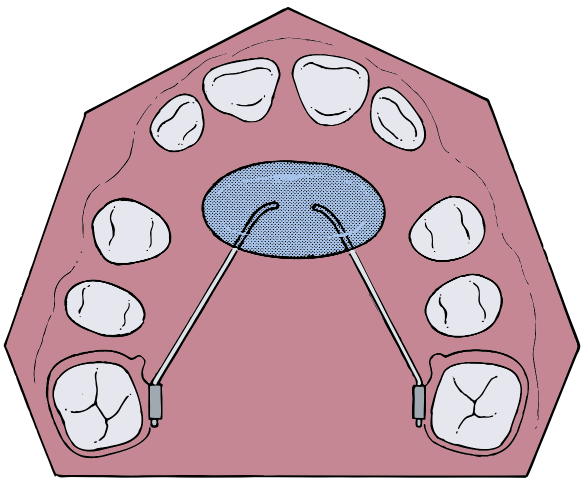

FIGURE 16-39 Placement of a Nance holding arch after molar distalization. The button should be contoured to engage both the anterior slope and superior "flat" portion of the palate.

and/or the maxillary posterior teeth distally. A second type of treatment modality aimed at correcting a Class II malocclusion focuses its mechanics on influencing the mandibular dentition and the growth of the mandible. This type of treatment is referred to as *functional jaw orthopedics*, with the intent of treating occlusal problems associated, at least in part, with mandibular skeletal retrusion.

The concept of FJO or advancement of the mandible is not new to dentistry. In 1880, Kingsley[79] wrote of "jumping the bite" and forward posturing the mandible. Yet given its long history, such appliances were used rarely in the United States until the mid-1970s. Over the past 40 years, there has been a gradual evolution of the way in which FJO is used in a contemporary orthodontic practice, especially concerning appliance selection, the timing of intervention, and the need for preorthopedic orthodontic treatment.

Like in most aspects of orthodontics, there are many ways to achieve a similar outcome. This is true of FJO appliances, with their differences in both material and design. The orthodontic literature describes a variety of appliance designs, including the activator,[80] the bionator,[5,81] the function regulator (FR-2) appliance of Fränkel,[42] the Herbst appliance,[1,82] the MARA appliance,[83] and the twin block appliance.[84] Although these appliances may appear very different at first glance, they all work to achieve a Class I occlusion by posturing the mandible forward during a time of growth (see Chapter 35).

It is not the purpose of this chapter section to debate whether FJO appliances do or do not enhance mandibular growth, a topic of great controversy during the past 35 years. The question of whether the mandible can be increased in length in comparison with untreated controls has been addressed in numerous experimental studies, and many clinical studies of various appliances have been conducted as well (see McNamara and Brudon[1] for a discussion of these issues). As mentioned earlier, the bulk of scientific evidence indicates that, in growing individuals, mandibular growth can be enhanced over the short term. For example, one of the more rigorous studies of FJO that analyzed patients treated by Rolf Fränkel showed that the residual increase in mandibular length was on average 3 mm,[85] not 5 to 8 mm (an amount that would be equivalent to a surgical mandibular advancement). The long-term effect on mandibular length remains open to question.

The major question remaining is whether or not the extra growth and development throughout the dentofacial region have clinical relevance. It is our belief that the skeletal adaptations, combined with dentoalveolar changes, can lead to a significant correction of a Class II malocclusion using a variety of FJO treatment modalities. Whereas these questions regarding the existence of extra growth as a result of FJO can be studied and debated further, the clinical effectiveness of the use of these appliances is less debatable. Experience has shown us that by posturing the lower jaw forward into a Class I or an end-on Class III relationship during a time of maximum mandibular growth, the lower jaw grows forward into its postured position without dragging the upper teeth with it. With proper appliance selection, treatment timing, and patient compliance, one may achieve a major orthodontic goal of obtaining a Class I molar and canine relationship and often improved maxillary–mandibular balance.

Appliance Selection

All FJO appliances have one aspect in common: they induce a forward mandibular posturing as part of the overall treatment effect. Presumably, this alteration in the postural activity of the muscles of the craniofacial complex ultimately leads to changes in both skeletal and dental relationships.[78]

Herbst Appliance

An appliance that has proved excellent in the treatment of Class II malocclusions in the permanent dentition is the Herbst appliance (Fig. 16-40), a fixed or removable functional appliance depending on the anchoring system used. The original bite-jumping mechanism was developed by Herbst,[86] and the banded design of the appliance was reintroduced in the late 1970s by Pancherz[82] and refined later by Rogers.[87] Designs that incorporate stainless steel crowns as anchoring mechanisms have been advocated by Dischinger,[88] Smith,[89] and Mayes.[90]

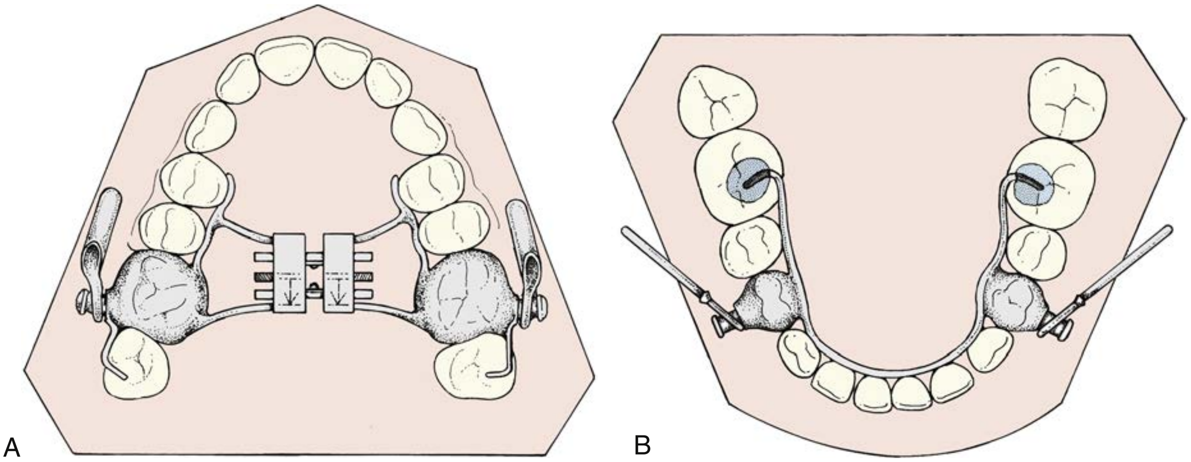

FIGURE 16-41 The stainless steel crown Herbst appliance. **A,** Maxillary portion. Stainless steel crowns are placed on the upper first molars, and a rapid maxillary expansion screw typically is placed in the midpalatal region. **B,** Mandibular portion. Stainless steel crowns are placed on the lower first premolars. A lower lingual wire made from 0.036-inch stainless steel extends from first molar to first molar. Occlusal rests are bonded to the lower first molars bilaterally. There are a variety of designs commercially available, with the clinician cautioned to match desired anteroposterior and vertical effects with treatment goals.

FIGURE 16-42 The banded Herbst provides ease and accuracy of fit, minimal increase in bite opening, and ease of removal. The advancing arm is telescoping (providing for a smaller appliance profile), and the anterior attachments of the lower member allow for increased lateral range of mandibular function. The lingual wire is 0.051 inch, and rests are placed either on the first or second premolars. The "bands" are either occlusal-removed crowns or heavier material bands with reinforcing wires on the occlusal. Archwire tubes are incorporated to control intraarch mechanics.

We have used many types of fixed Herbst appliances over the years, with the current preferred version incorporating stainless steel crowns on the maxillary first molars (Fig. 16-41) and mandibular first premolars (see Fig. 16-41). Our routine prescription also includes an RME screw with lingual wires extending anteriorly to the premolars. A removable acrylic splint design Herbst appliance[91,92] also has been used successfully in our practice for several decades (see Fig. 16-40). The banded Herbst design as described by Rogers[87] (Fig. 16-42) has a number of features that prove helpful. In particular, there is no interference with the occlusion, it is easier to fit precisely, and removal of the appliance is easier.

Clinical studies of the fixed and removable designs of the appliance indicate that both skeletal and dentoalveolar adaptations are produced.[70,93,94] Generally speaking, about 50% of the treatment effect is due to tooth movement, primarily the backward and upward movement of the posterior maxillary dentition. The primarily skeletal treatment effect produced is a short-term increase in mandibular growth (i.e., 2.0 to 2.5 mm greater than normal values).[70,93-95]

There is no question that a Class I molar relationship can be achieved in most growing Class II patients after Herbst appliance treatment. It has been our experience, however, that a Herbst appliance is not the appliance of choice in mixed dentition patients. After having followed patients originally treated in the mixed dentition for several years after Herbst therapy was completed but before the placement of fixed appliances was initiated, we have noted a significant tendency toward a relapse to the original malocclusion. This finding also has been noted by Pancherz,[96] among others.

This observation concerning Herbst patients treated in the mixed dentition may be due, in part, to the lack of direct effect on the orofacial musculature produced by the Herbst appliance (in contrast to the FR-2 appliance) and also may be related to the shape of the deciduous teeth. The posterior deciduous teeth tend to be relatively flat or are lost and thus do not provide the same type of occlusal interdigitation as occurs in the permanent dentition.

Our lack of success using the Herbst appliance in the mixed dentition does not eliminate this appliance from consideration. As mentioned earlier, we initiate regimens in the early mixed dentition to address intraarch space discrepancy problems and postpone functional appliance treatment until after all deciduous teeth are lost and the succeeding teeth are erupted. This delayed intervention is particularly useful in patients who have excessive vertical facial development and steep mandibular plane angles. We have found that by intervening in the early permanent dentition using the Herbst appliance, satisfactory skeletal and dental adaptations have been noted overall. This appliance is used most effectively in patients who do not have profound neuromuscular imbalances.

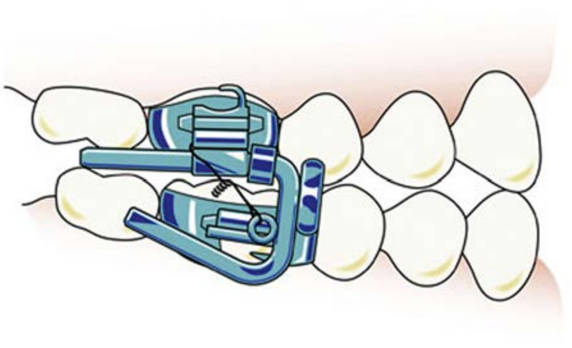

FIGURE 16-43 Mandibular anterior repositioning appliance (MARA). The arm soldered to the lower stainless steel crown guides the lower jaw anteriorly as it articulates with the maxillary arm during closure.

Mandibular Anterior Repositioning Appliance

Another appliance that has gained in popularity for correction of Class II malocclusions is the mandibular anterior repositioning appliance, or MARA.[83] The MARA is a fixed tooth-borne appliance that is fabricated on stainless steel crowns commonly placed over the maxillary and mandibular first permanent molars (Fig. 16-43). It has been used throughout the mixed and early permanent dentition stages, with similar indications as the Herbst appliance described earlier. The MARA acts by prohibiting the patient from closing in a natural, Class II relationship. Upon mandibular closure, the MARA's extension arms interfere, making it so that the mandible must be postured forward in order for full occlusal contact to occur.

The MARA appliance produces treatment effects that generally are similar to those of the Herbst, except for a few differences. Whereas maxillary molar intrusion is a characteristic feature of Herbst use,[93,97] this finding has not been reported with the MARA. Although it has been demonstrated that the MARA and Herbst appliances both produce significant change with respect to controls in the horizontal position of the mandibular incisors, the MARA has been shown to produce less flaring of the lower incisors.[83]

The anteroposterior treatment effect of the MARA is achieved through both skeletal and dental changes. Studies on skeletal changes indicate that the MARA produces increases in mandibular length but exerts negligible skeletal effects on the maxilla. In contrast, dental changes seen are due mainly to the distalization of the maxillary molar, which is said to be about 75% of the total dental correction.[83] Mesial movement of the mandibular molar accounts for approximately 25% of the total dental correction.

Because of the MARA's design, possible undesirable dental movements should be considered. In the sagittal plane, distal rotation of upper molars or mesial rotation (or both) of the lower molars may be observed. These movements may be controlled by incorporation of additional support into the design of the MARA (e.g., a TPA, a fixed expander, and/or a lower lingual holding arch). Because of crowns on both maxillary and mandibular first molars, there is often a transient intrusion of the molars on crown removal that self-corrects quickly. Overall, the appliance works well in correcting Class II problems. The biggest drawback to using the MARA, however, is appliance breakage and initial patient perception of bulk, which can be perceived as a significant problem. To mitigate this issue on patients with small mouths and tight cheeks, one can leave off the second premolar brackets so that the MARA arms may be constructed more closely to the dental arch. Small shields can also be placed to help keep tight cheeks away from the MARA arms.

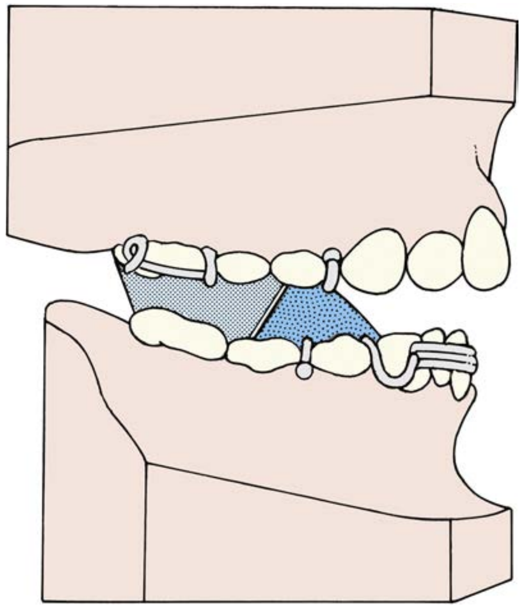

FIGURE 16-44 Sagittal view of the twin block appliance. A labial bow to which clear acrylic has been added increases the anterior retention of the lower appliance, especially during the period of the transitional dentition. The angled interface between maxillary and mandibular appliances guides the mandible into a forward functional position.

The Twin Block Appliance

Our choice of functional appliance selection for mixed dentition patients has changed during the past decade because of our increased clinical experience with the twin block appliance. This appliance, developed more than 30 years ago by Clark,[84] is composed of maxillary and mandibular removable acrylic components that fit tightly against the teeth, alveolus, and adjacent supporting structures (Fig. 16-44). Interproximal clasps are used bilaterally to anchor the maxillary appliance to the first permanent molars and premolars.

The maxillary occlusal view of the twin block appliance is shown in Figure 16-45. We have modified the design of the twin block appliance slightly by adding a second midline screw in the midsagittal region of the appliance. Our experience has shown that in patients in whom significant expansion is desired during twin block treatment, the appliance becomes unstable and too flexible if only one midline screw is used. Each screw is activated once per week (≈0.2 mm) until adequate expansion is attained. Clasps are used to secure the appliance to the first molars.

In the lower arch, Clark[84] has recommended the use of a series of ball clasps that lie in the interproximal areas between the canines and lower incisors. We have modified this design (Fig. 16-46) by placing a labial bow anterior to the lower incisors that has labial acrylic similar to that of a lower spring retainer.[1] In contrast to the spring retainer laboratory setup, however, the positions of the lower incisors are not altered in the work model before appliance construction.

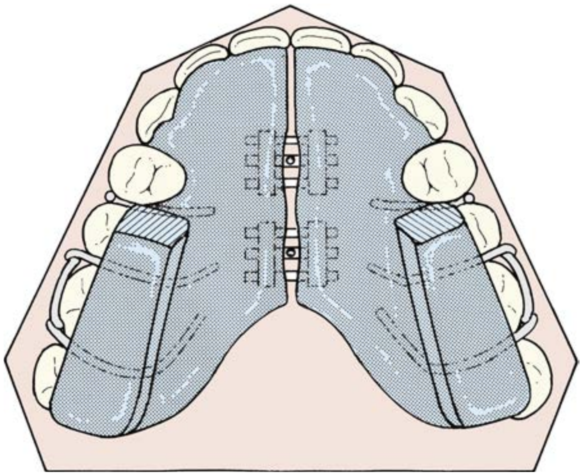

FIGURE 16-45 Maxillary occlusal view of the twin block appliance. Two expansion screws are placed in the midline. Delta clasps are used to secure the appliance to the molars posteriorly, and ball clasps are used to anchor the appliance in the premolar and deciduous molar region.

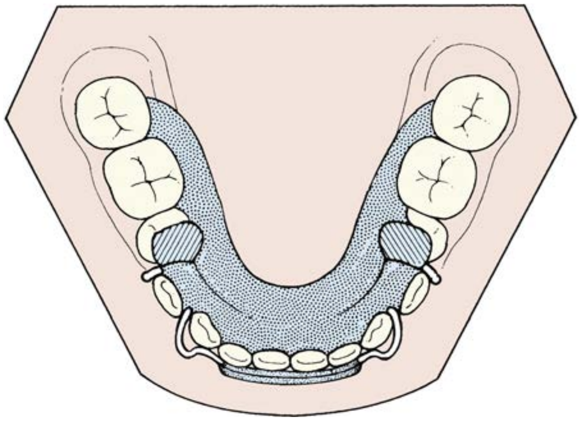

FIGURE 16-46 Mandibular occlusal view of the twin block appliance. Preferred modified design in which the lower lingual acrylic extends posteriorly into the permanent molar region. The lower labial bow with clear acrylic covering extends anteriorly to cover the labial surfaces of the lower anterior teeth. The bite blocks terminate 2 to 3 mm in front of the lower first molar.

The twin block appliance has been shown to produce increases in mandibular length as well as variations in lower anterior facial height.[1,84] The posterior bite blocks of the twin block appliance can be trimmed to facilitate the eruption of the lower posterior teeth in patients with a deep bite and an accentuated curve of Spee. The blocks also can be left untouched to prevent the eruption of the posterior teeth in patients with a tendency toward an anterior open bite, increased lower vertical facial height, or both.

One of the primary reasons why the twin block appliance is indicated in the treatment of Class II malocclusion is a reasonably high level of patient compliance. Because the twin block is composed of two parts, speaking typically is not a problem. The duration of treatment usually is 9 to 12 months followed by nighttime wear of the appliance or by the use of a stabilization plate to allow for the eruption of the canines and premolars into occlusion. Phase II treatment with fixed appliances usually is begun after the transition to the permanent dentition is complete.

Treatment Timing for Class II Malocclusion

As mentioned earlier, one of the major changes that has occurred during the past 35 years has been an alteration in the timing of treatment using functional appliances. An early study by our group[24] indicated that, when comparing two cohorts of patients who were treated with the FR-2 appliance of Fränkel, those patients who began treatment at an average of 11.5 years showed a greater mandibular growth response than did patients beginning treatment at approximately 8.5 years of age. The reason for this increased growth response may be related to the synergistic interaction between a change in function, produced by the functional appliance, and growth hormone and related substances that are in greater quantity during the circumpubertal growth period.

A follow-up study by Franchi and Baccetti[98] that considered CVM stages (CS-1 and CS-2 vs. CS-3 and CS-4) of the same populations also showed substantially more mandibular growth in patients receiving FJO treatment during the circumpubertal growth period than earlier when the treated samples were compared with matched control participants. The interaction between altered function and growth hormone also has been demonstrated in the experimental studies of Petrovic and coworkers,[23] among others. (See Chapter 1 for more detailed description of the growth-related factors.)

In general, the onset of FJO therapy in a mild to moderate Class II patient typically is delayed until the middle or end of the mixed dentition. It is our intention to schedule FJO treatment so that this treatment will be followed immediately by a comprehensive phase of fixed appliance therapy. In patients with a significant overjet and mandibular skeletal retrusion, treatment with the cantilever-type Herbst appliance or twin block appliance may be initiated in the early mixed dentition as a single appliance or as part of a more comprehensive protocol that includes RME before the eruption of the permanent dentition. In instances of significant neuromuscular imbalances, however, the FR-2 appliance is the appliance of choice.

Additional Comments Regarding Class II Treatment

There is no one ideal method of treating all Class II malocclusions. After a thorough clinical examination, a precise analysis of both the radiographic images and the dental casts should be undertaken to identify the components of the malocclusion that make an individual patient unique. After a thorough diagnosis has been established, the clinician can select the appropriate treatment regimen from a wide variety of available treatment modalities.

In recent years, our use of FJO appliances has decreased in frequency compared with 10 to 15 years ago. This change is in response to our experiences using RME during the mixed dentition to improve the underlying transverse discrepancy, observing spontaneous improvement of some Class II problems. Additionally, we have focused on providing our patients with noncompliance-based treatment options. It has been our experience that patient cooperation with removable orthopedic appliances has become more difficult to secure as children's activities remove them from the home and parents provide less appliance wear monitoring. Because true maxillary skeletal protrusion patients are observed relatively infrequently[67] and noncompliance treatments have become available, extraoral traction is a minimally used treatment option within our patient population.

TREATMENT OF CLASS III MALOCCLUSION

One of the most difficult types of malocclusions to treat is a Class III malocclusion. The occurrence of an end-to-end incisor relationship or a frank anterior crossbite is identified easily by both the family practitioner and the parent as an abnormal occlusal relationship. Thus, it is common for Class III patients to be referred for early treatment. The outcome of various early treatment protocols may or may not be successful, however, depending on the severity of the problem, the familial malocclusion and respiratory histories of the patient, and the age at which treatment is initiated.

Components of Class III Malocclusion

Various authors have estimated that 3% to 5% of the population demonstrates a Class III malocclusion. Government survey data from the National Health and Nutrition Examination Survey (NHANES) also show that the prevalence of extreme reverse overjet (Class III) is three times higher in Asians than in blacks or whites and twice as great in Hispanics (Mexican Americans).[99] Class III patients comprise about 5% of the typical orthodontic patient load in the United States.[100] This type of malocclusion is far more prevalent in other regions of the world, particularly in Pacific Rim countries. Thus, the treatment of Class III problems comprises a significant portion of orthodontic and orthopedic treatment with excellent clinical reports primarily from Japan, Taiwan, and Korea.

Class III malocclusion does not encompass a single diagnostic entity. Rather, it can be due to maxillary skeletal retrusion, mandibular skeletal protrusion, or a combination of the two.[101,102] As with all malocclusions that are considered by the Angle classification system, Class III malocclusions include a variety of skeletal and dental components that may vary from our concept of normal or ideal in all three dimensions.

Available Class III Treatment Strategies

Before discussing early treatment strategies, it is important to review briefly the usual approach to the correction of Class III malocclusions in an adolescent or adult patient. When a patient first is diagnosed as having a Class III malocclusion in the permanent dentition, treatment options are limited, particularly if there is a strong skeletal component to the Class III occlusal relationship. Such treatment usually includes comprehensive orthodontic therapy combined with extractions, orthognathic surgery, or both.

The orthognathic surgical procedure is designed to address the imbalance of the skeletal component (e.g., sagittal split osteotomy or vertical ramus osteotomy to posteriorly reposition the mandible in instances of mandibular prognathism, LeFort I advancement in instances of maxillary skeletal retrusion; procedures in both jaws may be used in instances of severe maxillomandibular skeletal imbalances). In other words, the surgical procedure is designed to correct whatever skeletal imbalances are present. In patients in whom significant skeletal growth is anticipated, the surgical procedure is deferred until the end of the active growth period. Such patients, however, still face potentially adverse psychosocial problems during childhood and the teen years that have been shown to be associated with this type of malocclusion.[103]

The treatment of Class III malocclusion in the primary and mixed dentition can be approached from a slightly different conceptual viewpoint. It is possible to select a treatment protocol that is intended to address the skeletal imbalance in a Class III mixed dentition patient. For example, Fränkel[42,104] recommends the function regulator (FR-3) appliance in patients whose malocclusion is characterized primarily by maxillary skeletal retrusion. On the other hand, the orthopedic chin cup[9] has been used in patients whose malocclusions are characterized primarily by mandibular prognathism, a procedure that has its greatest effect when used in primary and early mixed dentition patients.

The orthopedic FM that has been popularized by Delaire[105] and refined by Petit[106] is the appliance most widely used in the United States today. Each of these treatments has been shown to produce favorable effects in Class III patients, but the long-term outcomes have been variable. Also, there are substantial differences with regard to the speed of correction and in the regions of the craniofacial complex that are affected.

Appliance Selection

A basic axiom of orthodontic treatment is that the treatment approach should be designed to address the specific nature of the skeletal or dentoalveolar imbalance (or both). This axiom is illustrated by the selection of the specific surgical procedure or procedures used in the correction of a Class III malocclusion in an adolescent or adult patient. In patients with a Class II malocclusion, it also is demonstrated by the selective use of extraoral traction in the correction of maxillary prognathism and of FJO in the correction of mandibular retrusion. A seeming exception to this rule may be the interceptive treatment of the developing Class III malocclusion.

The Orthopedic Facial Mask

Of the three mixed dentition treatment strategies discussed earlier, the orthopedic FM (Fig. 16-47) has the widest application and produces the most dramatic results in the shortest period of time. Thus, the orthopedic FM is our customary appliance of choice for most Class III patients seen in the early mixed dentition or late deciduous dentition. The use of this single regimen in most early Class III patients seems arbitrary and paradoxical at first glance, given the various combinations of skeletal and dental components of Class III malocclusions in mixed dentition patients.[101,107] Because intervention using an orthopedic FM is undertaken at such an early age, however, the treatment effects produced by the FM ultimately are incorporated into the future craniofacial growth of the patient that occurs over a long period of time. Importantly, the appliance system affects virtually all areas contributing to a Class III malocclusion (e.g., maxillary skeletal retrusion, maxillary dentoalveolar retrusion, mandibular prognathism, decreased lower anterior facial height) by manipulating force vectors, and thus this treatment protocol can be applied effectively to most developing Class III patients regardless of the specific etiology of the malocclusion.

The orthopedic FM system has three basic components: the FM, a bonded maxillary splint, and elastics. The FM (see Fig. 16-47) is an extraoral device that has been modified by Petit[106] and now is available in various forms commercially. It can also be custom designed as discussed in Chapter 15. In essence, the FM is composed of a forehead pad and a chin pad that are connected by a heavy steel support rod. To this support rod is

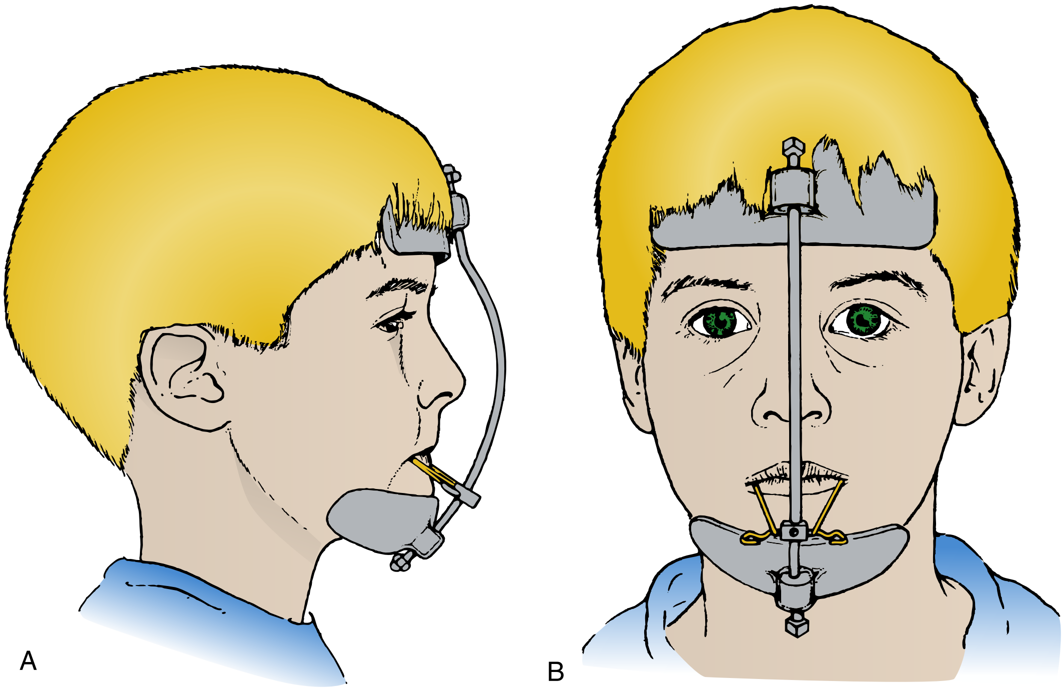

FIGURE 16-47 The orthopedic facial mask of Petit. **A,** Lateral view. **B,** Frontal view. This appliance, best used in patients in the early mixed dentition, is worn on a full-time basis for about 6 months, after which it can be worn on a night-time basis as a retention appliance. The elastics are connected to a bonded maxillary splint (see Fig. 16-18), to which have been attached hooks in the upper first deciduous molar region. The angle of elastic pull from the horizontal affects the amount of vertical versus horizontal movement. In overclosed patients, the downward angle is greater, but in patients with excessive vertical height, the pull is more parallel to the Frankfort horizontal plane. The most common is 15 to 20 degrees downward from the Frankfort horizontal plane.

connected a crossbow to which are attached rubber bands to produce a forward and downward elastic traction on the maxilla. The position of the pads and crossbow can be adjusted simply by loosening and tightening set screws within each part of the appliance.

Although Petit[106] has recommended a number of different intraoral devices, both fixed and removable, to which the elastics can be anchored, it is our strong preference to use a bonded maxillary expansion appliance that is similar in design to that discussed previously in the treatment of arch-length discrepancy problems. The major modification in the splint design is the addition of FM hooks in the region of the maxillary deciduous first molar (Fig. 16-48).

Even though the orthopedic FM has been available for more than 100 years, surprisingly few studies have dealt with the treatment effects produced by the FM. Until recently,[108-112] most published studies dealing with FM therapy have been anecdotal in nature.[113-115] It appears that the FM, especially when combined with a rigid maxillary anchorage unit (e.g., a bonded acrylic splint expander) that unlocks the occlusion, can produce one or more of the following treatment effects:

1. Correction of a discrepancy between centric occlusion and centric relation, a shift in occlusal relationship that is immediate and is associated with pseudo–Class III patients
2. Maxillary skeletal protraction, with 1 to 2 mm of forward movement of the maxilla often (but not always) observed
3. Forward movement of the maxillary dentition

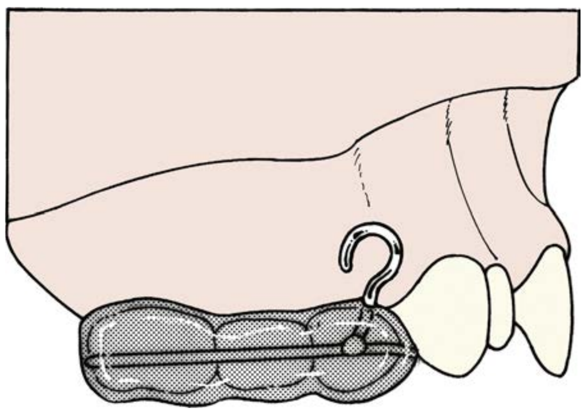

FIGURE 16-48 The bonded maxillary acrylic splint (lateral view). The hooks for the elastics usually are placed adjacent to the upper first deciduous molars. (Adapted from McNamara JA Jr, Brudon WL. *Orthodontics and dentofacial orthopedics*. Ann Arbor, MI: Needham Press; 2001.)

4. Lingual tipping of the lower incisors, particularly in patients with a preexisting anterior crossbite and labial incisor flare
5. Redirection of mandibular growth in a downward and backward direction, resulting in an increase in lower anterior facial height[112,116]

After the decision has been made to use an orthopedic FM, the first step of the appliance therapy is the fabrication and bonding of the maxillary expander/splint (see McNamara and Brudon[1] concerning the technical details). The expander/splint is activated 0.25 mm once per day at bedtime until the desired increase in maxillary width has been achieved. In patients in whom no increase in transverse dimension is desired, the appliance still is activated for 8 to 10 days to disrupt the maxillary sutural system and to promote maxillary protraction.[1]

After the patient has become accustomed to wearing the maxillary splint, FM treatment is initiated. A sequence of elastics of increasing force (200, 350, 600 g per side) is used during the break-in period until a heavy orthopedic force is delivered to the maxillary complex. Ideally, the FM is worn on a full-time basis (≈20 hours per day) for 4 to 6 months, and then it can be worn on a nighttime basis only for an additional period of time. It usually is unwise to have the splint remain bonded in place for longer than 9 to 12 months because of the potential risk of leakage and subsequent decalcification of the underlying dentition.

The ideal stage of dental development during which to begin FM therapy is at the eruption of the permanent maxillary central incisors. Usually, the lower incisors already have erupted into occlusion. Achieving a positive horizontal and vertical overlap of the incisors during treatment is essential in providing an environment that will help maintain the achieved anteroposterior correction of the original Class III malocclusion. In patients with mild to moderate Class III problems, a positive overjet of 4 to 5 mm is achieved before the time that the FM is discontinued. It is anticipated that there will be some regression of the overjet relationship during the early posttreatment period. Every effort should be made, however, to maintain a positive overbite and overjet relationship throughout the retention period.

After the FM and the RME appliance have been removed, the patient can be retained using a number of appliances, including a simple maintenance plate (see Fig. 16-26), an FR-3 appliance of Fränkel, or a chin cup (or a combination of these). Because the FM usually is used in the early mixed dentition, a substantial amount of time may elapse before the final phase of fixed appliance treatment can be initiated. In some instances, multiple stages of orthopedic intervention may be required; thus, these patients must be monitored until all major facial growth is completed. It is very important to discuss with parents the potential need for long-term orthopedic or orthodontic management for Class III patients, especially those starting treatment in the primary or early mixed dentition. Additionally, the potential for future orthognathic surgery, if growth or treatment response proves adverse, should be reviewed.

The FR-3 Appliance of Fränkel

An intraoral appliance that has been used quite effectively in the treatment of Class III malocclusions in the mixed dentition is the function regulator FR-3 appliance of Fränkel.[42,104,117] Of all the Fränkel appliances, the FR-3 appliance (Fig. 16-49) perhaps is the easiest to manage clinically because there is no substantial postural change produced in the maxillomandibular relationship. As with all of Fränkel's appliances, the base of operation of the FR-3 appliance is the maxillary and mandibular vestibules. The appliance is designed to restrict the forces of the associated soft tissue on the maxillary complex, transmitting these forces through the appliance to the mandible.

A major advantage in using the FR-3 appliance of Fränkel is that it is relatively inconspicuous, especially compared with

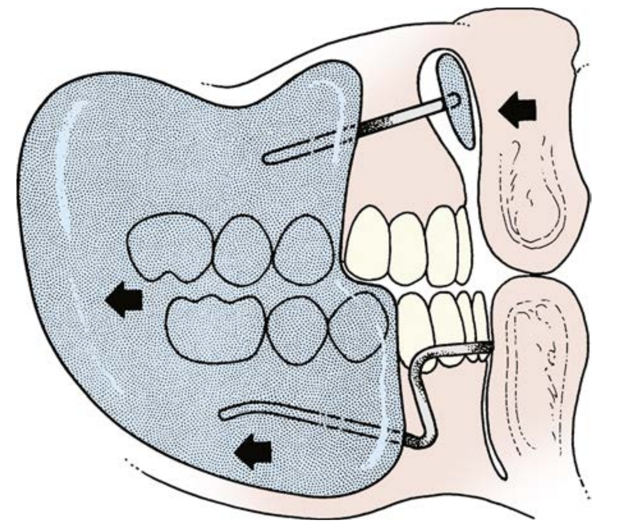

FIGURE 16-49 The FR-3 appliance of Fränkel. The vestibular shields and the upper labial pads shield the maxillary alveolus from the forces of the surrounding soft tissue. These forces are transmitted through the appliance to the mandible, providing a soft tissue generated distalizing force. (Adapted from McNamara JA Jr, Brudon WL. *Orthodontics and dentofacial orthopedics*. Ann Arbor, MI: Needham Press; 2001.)

the orthopedic FM or chin cup. The FR-3 is worn intraorally, and often wearing the appliance actually improves the appearance of the patient by filling out the upper lip region in individuals with substantial maxillary skeletal retrusion. It also helps to reduce forward mandibular posture and overclosure. This appliance is worn easily by the patient. Interestingly, the treatment effects produced by the FR-3 appliance have been shown to be similar to those produced by the orthopedic FM.[42,118]

A major difference between the FR-3 appliance and the orthopedic FM is the duration of treatment. In a routine Class III patient, the orthopedic FM may produce a correction of the malocclusion within the first 6 months after initiating treatment. Normally, 12 to 24 months is necessary to produce a similar response with the FR-3 appliance. It is obvious, however, that the FR-3 appliance has much more of an effect on the associated soft tissue, particularly on any existing hyperactivity in the muscles associated with the maxilla, than does the FM. This appliance was designed by Fränkel, based on the principles of Roux,[119] in that the primary action of the appliance is on the associated soft tissue, hopefully leading to a reprogramming of the central nervous system and a retraining of the craniofacial musculature.

When used as the primary appliance, the FR-3 is worn for about 20 hours per day, with the patients removing the appliance only during such activities as eating and playing contact sports. If the appliance is worn as a retainer after either full-time FR-3 therapy or FM therapy, it usually is worn only during the nighttime hours.

The Orthopedic Chin Cup

The oldest of the orthopedic approaches to the treatment of Class III malocclusion is the chin cup. The effects of this appliance have been investigated thoroughly,[9,120-123] with much of the research conducted on Asian populations because of the higher incidents of Class III malocclusion in these groups.

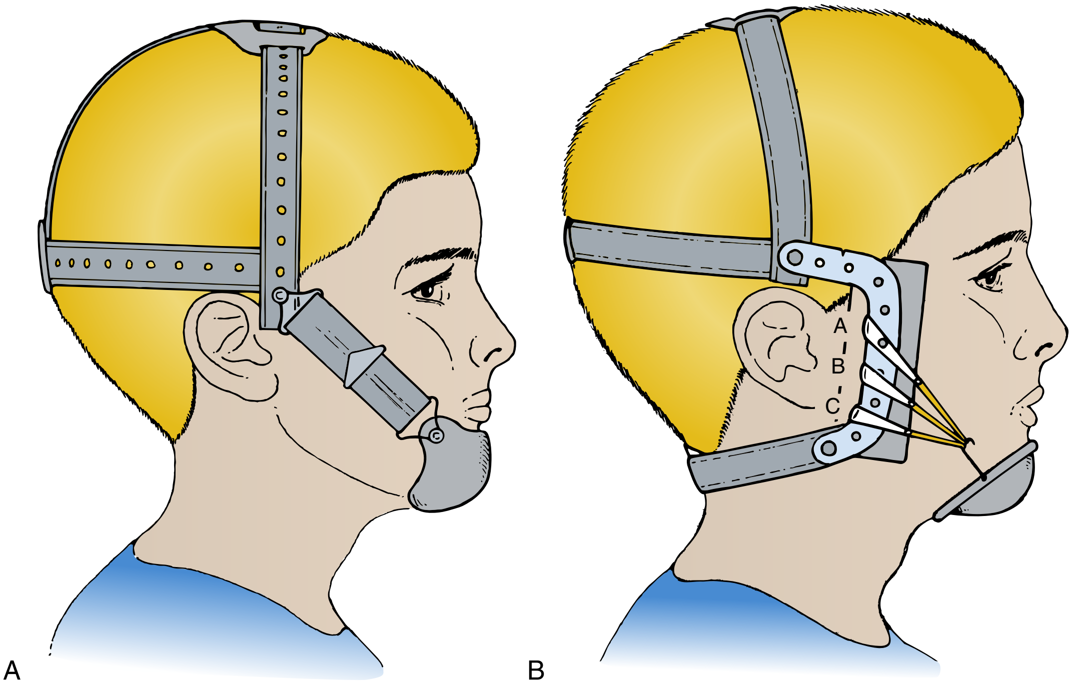

FIGURE 16-50 The occipital-pull chin cup. **A,** Soft elastic appliance with a soft chin cup. The direction of force is determined by the position of the head cap. Patients can use cloth baby diaper material cut in squares inside the cup to provide more comfort. **B,** Hickam-type headgear. Used as anchorage for a hard chin cup. The direction of pull can be adjusted according to the placement of the elastics (A–C). (Adapted from McNamara JA Jr, Brudon WL. *Orthodontics and dentofacial orthopedics*. Ann Arbor, MI: Needham Press; 2001.)

Although a wide variety of chin cup designs are available commercially, in general, these appliances can be divided into two types. The *occipital-pull chin cup* is used in instances of mandibular prognathism, and the *vertical-pull chin cup* (VPCC) is used in patients with steep mandibular plane angles and excessive lower anterior facial height.

The occipital-pull chin cup (Fig. 16-50, *A*) frequently is used in the treatment of Class III malocclusions. This type of chin cup is indicated for use in patients with mild to moderate mandibular prognathism. Success is greatest in patients in the primary and mixed dentition who can bring their incisors close to an edge-to-edge position when in centric relation. This treatment is useful particularly in patients who begin treatment with a short lower anterior facial height because this type of treatment can lead to an increase vertical facial height. If the pull of the chin cup is directed below the condyle, the force of the appliance may lead to a downward and backward rotation of the mandible. If no opening of the mandibular plane angle is desired, the force should be directed through the condyle to help restrict and redirect mandibular growth. The use of a Hickham-type headcap combined with a hard chin cup (Fig. 16-50, *B*) allows for variable vectors of force to be produced on the lower jaw.
