If no increase in lower anterior facial height is desired, the VPCC can be used (Fig. 16-51, *A*). Pearson[124,125] has reported that the use of a VPCC can result in a decrease in the mandibular plane angle and the gonial angle and an increase in posterior facial height in comparison with the growth of untreated individuals. This type of extraoral traction can be used not only in individuals who have a Class III malocclusion but also for patients in whom an increase in the anterior vertical dimension is not desired. A study by Schulz and coworkers[126] that compared the VPCC combined with the bonded acrylic splint expander with the bonded expander used alone in high-angle patients indicated that a modest improvement can be obtained in the mandibular plane angle and in lower anterior facial height with the use of the VPCC. They noted, however, that the effect of the vertical orthopedic treatment was observed only during early phase I therapy, not during comprehensive fixed appliance treatment.

It is difficult to create a true vertical pull on the mandible because of the problems encountered in anchoring the appliance cranially. One of the easiest of the vertically directed chin cups to manipulate clinically is shown in Figure 16-51, *A*. A padded band extends coronally and is secured to the posterior part of the head by a cloth strap. A spring mechanism is activated by pulling the tab inferiorly and attaching the tab to a hook on the hard chin cup.

Another type of chin cup that produces a vertical direction of force is shown in Figure 16-51, *B*. This appliance incorporates a cloth headcap that curves around the crown of the head and is secured posteriorly with two horizontal straps. A throat strap also secures the appliances to the head of the patient. This particular design is useful in patients in whom anchorage in the cranial region is difficult to achieve. Either of these designs may be modified further with the construction of a custom chin cup that may be fabricated from acrylic. If customized, the attachment hook may be placed more to the posterior of the cup, closer to the throat angle, providing a more effective vertical direction of pull.

One of the substantive concerns regarding chin cup therapy is whether the growth of the mandible can be retarded through

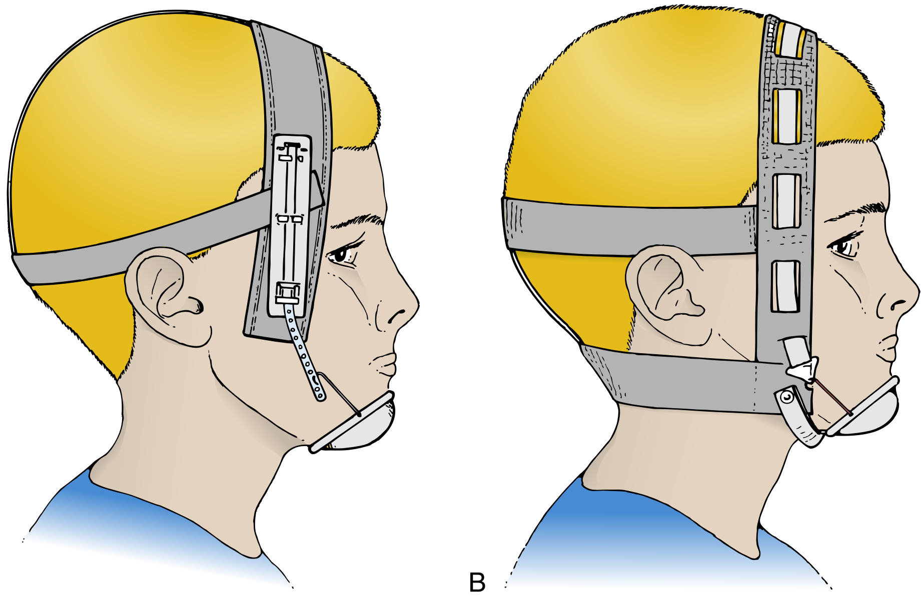

FIGURE 16-51 The vertical-pull chin cup. **A,** Unitek design. A spring force design is used to create a vertical direction of pull. **B,** Summit Orthodontics design. A cloth head cap curves around the crown of the head and is secured posteriorly with two horizontal straps. The force is produced by the stretch of the elastic material. In both of these examples, a hard chin cup is shown. (Adapted from McNamara JA Jr, Brudon WL. *Orthodontics and dentofacial orthopedics*. Ann Arbor, MI: Needham Press; 2001.)

wearing a chin cup. Sakamoto[127] and Wendell and coworkers[128] have noted decreases in mandibular growth during treatment. Wendell and associates, when examining a group of Class III patients treated in the mixed dentition, noted that the mandibular length increases in the treated group were only about two-thirds of those observed in the control group of mixed dentition individuals who received no treatment. Mitani and Fukazawa,[129] however, noted no differences in mandibular length in Class III individuals who began treatment during the adolescent growth period in comparison with control values. In addition, in a recent study of long-term adaptation to the chin cup, Sugawara and Mitani[123] noted that such treatment seldom alters the inherited prognathic characteristics of skeletal Class III profiles over the long term. Changes in the vertical direction of mandibular growth, however, have been noted. L.W. Graber[10] reported that, in a sample of young Class III patients with mandibular prognathism, the predominantly horizontal mandibular growth pattern was redirected more vertically, with changes noted in both the maxilla and mandible. The orthopedic chin cup usually produces an increase in lower anterior facial height while correcting the anteroposterior malrelationship.

It has been our observation that the chin cup works best when used in the primary and early mixed dentition and when the adverse mandibular growth has been mild to moderate in nature. The earlier the problem is addressed, the more successful treatment appears to be. Multiple "stages" of active chin cup home wear are often required to be successful in the case of moderate prognathism. Thus even the "corrected" patients need to be monitored at 4- to 6-month intervals until major growth has ceased. This need for follow-up treatment is to be expected for any orthopedic treatment that is redirecting excessive jaw growth or a severely deficient jaw growth pattern because of the genetic basis for growth and development. As noted earlier, parents must be apprised from the start of treatment that growth guidance may be needed in multiple stages and that the patient must be monitored throughout the growing years.

Bone-Anchored Maxillary Protraction. The most recent addition to the armamentarium of Class III treatment is the bone-anchored maxillary protraction (BAMP) therapy of De Clerck et al.[130] This approach involves the surgical placement of bone plates in the infrazygomatic region of the maxilla and the canine region of the mandible. Class III elastics that are attached to these surgical plates allow the forces produced to be transmitted to the bony bases (Fig. 16-52). De Clerck and coworkers[130-132] have shown dramatic results in young adolescent patients when Class III elastics (150-250 g) are worn full time, in that the force of the elastics is applied directly to the bones rather than on the teeth. Treatment changes are seen in the maxilla as well as the mandible, including remodeling in the temporomandibular joint. Interestingly, the effects of the BAMP therapy closely mimic findings from Class III nonhuman primate studies completed in our laboratory in the 1970s.

There are several limitations to this procedure, including patient age; De Clerck recommends using this approach in patients at least 10 to 11 years of age. The quality of bone is insufficient in younger patients to anchor the bone plates, especially in the maxilla. In addition, the lower permanent canines should be erupted before the lower bone plates are secured mesial to the canines.

Although this technique has an added surgical procedure (and related cost), there are biomechanical and patient management advantages in the technique that reduce the potential adverse effects of other treatment protocols. In addition, the appliance can be worn 22 to 23 hours per day without social liability to the patient. The timing of treatment is critical, balancing dental eruption and bone density maturation with the need to control the adverse Class III growth. Use of this technique at a later stage of growth, though, allows for decreased

FIGURE 16-52 Cone beam computed tomography scan of patient with Bollard plates placed surgically in the infrazygomatic region of the maxilla and the canine region of the mandible. Class III elastics (150–250 mg) are worn bilaterally full time for about 1 year depending on the severity and patient response. (Courtesy of Hugo De Clerck and Lucia Cevidanes.)

time for adverse catch-up Class III growth when treatment is completed.

Additional Comments Regarding Class III Treatment

As discussed previously, the appearance of Class III malocclusion is relatively easy to identify in young patients, yet the treatment of this occlusal problem is fraught with many difficulties. Fortunately, the level of patient cooperation in primary and young mixed dentition patients generally is excellent, and thus satisfactory compliance usually is achieved.

Of the four treatment modalities considered in this section, the orthopedic FM combined with a bonded maxillary splint seems most applicable in growing Class III patients. This type of appliance produces treatment effects in both skeletal and dentoalveolar aspects of the craniofacial complex. Given a young patient, the resolution of the underlying Class III relationship occurs relatively quickly (4 to 6 months), and then the mask can be worn for an additional period as a retainer at night before the bonded maxillary splint is removed.

The FR-3 appliance of Fränkel can be used either as a primary interceptive appliance or as a retainer. This treatment regimen makes the most biologic sense because the primary focus of this therapy is on the soft tissue, particularly the musculature, which in part may have been the etiology of the Class III relationships. The FR-3 appliance is less intrusive to the everyday life of the patient but may take two or three times as much treatment time to achieve correction of the malocclusion. The FR-3 appliance also can be used as a retention appliance after orthopedic FM or chin cup therapy.

Because mandibular growth exceeds maxillary growth during adolescence, early Class III correction may be lost during the teenage years. Indeed, orthopedic appliances may be required during the typical retention stage of treatment, particularly in males, in whom mandibular growth often continues well after fixed orthodontic appliances are removed. It cannot be overly stressed that at the onset of any interceptive treatment the patient and parents should be advised of the possibility of multiple stages of orthopedic intervention as well as the potential need for surgical correction. The wise clinician never makes guarantees regarding the treatment of Class III malocclusion because the outcome of any individual Class III patients is very difficult to estimate. We agree with T.M. Graber,[133] Sakamoto,[127] and Sugawara and coworkers,[9] who advocate the treatment of Class III malocclusion as early as is practical. Primary dentition chin cup treatment may be started to intercede in a developing Class III with subsequent maxillary protraction as the patient matures.

SUMMARY

An attempt has been made in this chapter to synthesize a coherent approach to orthodontic and orthopedic treatment, making available to the orthodontist a variety of early and late treatment protocols. Virtually all orthodontists are well versed in the management of adolescent and adult patients. Many orthodontists, however, are uncomfortable (and perhaps a bit skeptical, given the controversy) about mixed dentition treatment.

Although this latter topic has been addressed in many of the orthodontic texts since the beginning of the past century, mixed dentition treatment generally has been considered as secondary or peripheral to full banded or bonded appliance therapy in the adolescent or adult patient. By taking advantage of many of the newer technologies available, especially the bonded acrylic splint expander, the Herbst appliance, and the Pendex appliance, we have attempted to provide the reader with a conceptual framework on which the selection and timing of various treatment modalities can be based.

A few concluding comments should be made on the basis of our own clinical experiences. Some of these comments are obvious; some are not.

The timing of orthodontic and orthopedic treatment protocols varies with the underlying nature of the malocclusion. Some problems respond well to early intervention, others to late treatment. The selection of specific protocols and when to use them should be based on evidence derived from rigorous prospective and retrospective clinical studies.

Implicit in initiating early treatment is that the overall treatment time of the patients will be extended from the normal 12 to 24 months generally needed for comprehensive treatment of an adolescent patient. Initiating treatment in a patient with mixed dentition, however, does not imply that treatment will be provided continuously from the time of eruption of the permanent incisors until the time that the permanent second molars are aligned with fixed appliances. We have tried to structure our treatment protocols so that typically a concentrated period of early treatment is initiated, generally in the early mixed dentition. There are a defined beginning and ending of the treatment that are known to the patient and to the parents before the protocol is started.

Intermittent observation of the patient during the transition of the dentition is a prime component of early treatment. We generally prefer to see our patients every 4 to 6 months after the first phase of treatment is completed. The appliances used during this time are simple, usually consisting of only a removable palatal plate typically without a labial wire that is worn full time for at least 1 year. Monitoring the patient on an intermittent basis allows the clinician to take advantage of the transition of the dentition, particularly in the second deciduous molar regions. It also allows observation of an adverse growth spurt and the opportunity to intercede as needed.

Passive holding arches (i.e., TPA, lingual arch) should be placed before the loss of the second deciduous molars in most early treatment patients. Not only will the leeway space be maintained (i.e., on average 5 mm in the mandible, 4 mm in the maxilla), but also maxillary molar rotation and uprighting can be achieved at the same time.

Almost all patients undergoing early treatment will require a final phase of fixed appliances. Usually the treatment time is reduced to 12 to 18 months because the majority of patients undergoing comprehensive therapy will be treated as nonextraction patients with Class I or near Class I molar relationships. Parents must be informed at the start and reminded at the end of mixed dentition treatment that a second stage of orthodontic treatment will be required after permanent teeth erupt.

Initiating early treatment does not imply that all patients treated in the mixed dentition will avoid the extraction of permanent teeth. It has been our experience that even in patients in whom orthopedic expansion protocols are initiated, the extraction of permanent teeth (usually premolars) is necessary in about 10% of these patients. In some instances, orthopedic expansion of the maxilla is initiated to broaden the smile in patients with severe maxillary constriction, and subsequently permanent teeth are extracted as part of the overall treatment protocol.

We have emphasized the importance of treatment timing in Class II malocclusion. In most Class II patients seen in the mixed dentition, we often start early treatment by managing the transverse dimension, with definitive Class II treatment rendered (if necessary) at the time of the circumpubertal growth period (the "spontaneous improvement" in Class II malocclusion is a frequently occurring phenomenon). Only in instances of a socially disabling malocclusion will definitive Class II intervention be undertaken by us in the early mixed dentition.

Early treatment will not eliminate the need for corrective jaw (orthognathic) surgery in all patients with severe skeletal and neuromuscular imbalances. FJO or maxillary distalization can be used to minimize substantially the sagittal maxillomandibular imbalance, but it may be impossible to eliminate this imbalance entirely without compromising the facial aesthetics of the individual. In these instances, orthognathic surgery in combination with fixed appliances is the treatment of choice. The need for orthognathic surgery also is obvious in patients with a Class III malocclusion characterized by significant skeletal imbalances, especially in those with a family history of significant Class III malocclusion. There may well be, however, an important psychological benefit for both child and parent in reducing a malocclusion and providing an "interim" aesthetic smile, knowing that orthognathic surgery for skeletal balance may or will be required after growth has been completed.

Patient compliance usually is excellent in patients treated in the mixed dentition, particularly if the appliance that is selected requires no or minimal patient cooperation other than that usually associated with a routine orthodontic treatment (e.g., good oral hygiene, diet control, and wearing of retainers). By initiating treatment in the mixed dentition, many of the skeletal and dentoalveolar problems associated with malocclusion often are eliminated or reduced substantially, thus lessening the need for prolonged fixed appliance therapy in the adolescent years.

In conclusion, we have attempted to provide an overview of various early and late treatment protocols that may be appropriate for certain orthodontic patients within a given practice. As with all such technologies, each of these protocols should be evaluated with healthy skepticism and should be initiated slowly until the parameters of success and failure are clearly established. The protocols outlined in this chapter have been used routinely by us for four decades and have proved to be satisfactory if approached within a framework of common sense and with a thorough understanding of comprehensive orthodontic biomechanics. Routine fixed appliance therapy is characterized by a series of "individual specific midcourse corrections," and our type of treatment is no different. Observation and diagnosis that will influence treatment are never static.

Finally, it must be stressed that early intervention is not always necessary or appropriate. In some instances, early treatment does not change appreciably the environment of dentofacial development and permanent tooth eruption. In such instances, early treatment may serve only to increase treatment time and cost and may result in a lack of patient cooperation in later years. If every effort is made, however, to time the treatment appropriately so as to maximize the treatment benefit in the shortest period of time and if the implemented treatment protocol has a reasonably predictable duration and outcome, orthodontic and orthopedic intervention can be provided successfully.

ACKNOWLEDGMENTS

The authors recognize the enormous contributions of Dr. Lorenzo Franchi and the late Dr. Tiziano Baccetti (1966–2011) of the University of Florence, whose collaborative work has been cited throughout this chapter. Their insights have influenced our approach to treatment timing through a series of evidence-based clinical studies that have been published jointly with us since the mid-1990s.

The authors thank our long-time friend and collaborator, the late William L. Brudon (1921–2009), associate professor emeritus in the School of Art and the Department of Medical and Biological Illustration in the School of Medicine at the University of Michigan, for producing almost all of the line drawings used in this chapter. The colorizing of the line drawings was provided by Chris Jung.

Contemporary Straight Wire Biomechanics

Antonino G. Secchi and Jorge Ayala Puente

OUTLINE

It is not only the appliance system you have, but how you use it."

The straight wire appliance (SWA) was developed and introduced by Lawrence Andrews in 1970[1] with the idea of having an orthodontic fixed appliance that would enable the orthodontist to achieve the "six keys" of normal occlusion[2] in the vast majority of cases in an efficient and reliable fashion.

Even though the SWA is 40 years old and has become the most common appliance concept over the past three decades, a review of some of the original concepts on which the SWA was designed and the evolution it has gone through are fundamental to better understand the beauty of this appliance and the treatment mechanics, which we then discuss.

STRAIGHT WIRE APPLIANCE DESIGN AND VALUES

There are a few features that need to be present in an appliance to be considered a true SWA.[3] First, each bracket has to be tooth specific and have built-in torque, tip, in/out, and (for the molars) proper offset. Second, the torque has to be built in the base of the bracket, not in the face, and the tip in the face of the slot. These prerequisites are very important in order to achieve proper alignment of the center of the slot, the center of the base, and the reference point (middle of the clinical crown occlusogingivally along the facial long axis of the crown) for all teeth at the completion of treatment. This is the only way that the desired built-in features can be properly transferred from the bracket to the tooth. Third, the base of the bracket must be contoured mesiodistally and occlusogingivally. This has been referred to as a "compound contour" base, and it allows the bracket to firmly adapt to the convexities of the labial surface of each tooth, helping the orthodontist to achieve an optimal bracket placement.

Although Andrews thought his appliance could be used to treat a large variety of cases, he introduced a series of additional brackets with different degrees of overcorrection to account for undesired tooth movement that would occur specifically when sliding teeth in extraction cases. For example, if a maxillary canine had to be moved distally, because Andrews uses round stainless steel wires to slide teeth through, the canine most likely would tip and rotate distally. Therefore, he introduced more mesial tip and rotation to the canine bracket. Andrews then came out with a line of overcorrected brackets, which he first called *extraction brackets*[3] and then *translation brackets*.[4] Andrews' complete bracket system (standard and translation brackets) was less popular than expected, partly because of the large bracket inventory needed to satisfy his treatment mechanics. However, in the mid-1970s, Ronald H. Roth took the Andrews SWA and combined some of the standard bracket prescription values with some of the overcorrected values found in the translation bracket prescription to create the "Roth setup."[5] The Roth setup became the most popular SWA prescription in the world. Roth realized that because the size of the brackets at that time caused bracket interferences, it was virtually impossible to place each tooth in its final ideal position. Also, he observed that when appliances were removed, teeth would rebound and settle. Therefore, he slightly overcorrected some of the original Andrews values to allow teeth to properly settle in the ideal final position after removal of the appliances. After the Roth prescription, a great number of clinicians came out with small variations to either the Andrews prescription or the Roth prescription. Most of these changes were done for a commercial purpose, to compensate for unknown errors in bracket position, or to suit a particular orthodontist's type of mechanics.

Today, there are a large number of preadjusted appliances wrongly called SWA only because they have built-in torque, tip, and in/out. However, if they are not manufactured with the features specified earlier, the appliance will not transfer the built-in information correctly to the teeth. Therefore, selecting the proper appliance is paramount when using an SWA.

STRAIGHT WIRE APPLIANCE AND SELF-LIGATION

Both of the authors of this chapter use a self-ligating bracket (SLB) system, and, consequently, some of the concepts on mechanics that will be reviewed later take advantage of such appliance systems. Therefore, even though self-ligation is the subject of Chapter 17 in this book and thus is extensively reviewed, it is important to point out a few aspects of this type of appliance that will allow the reader to better understand the information provided in this chapter.

Self-ligating brackets have been classified as "active" or "passive" depending on the behavior of the gate or clip on the archwire. Active SLBs have a clip with a spring effect that exerts pressure on the archwire, pushing it onto the base of the bracket's slot. This pressure is based on the archwire size and/or bracket and archwire configuration (Fig. 17-1). On the other hand, passive SLBs have a gate that passively opens and closes without exerting pressure on the archwire. Passive SLBs also have been described as tubes.[6] Today it is known that active SLBs have some important advantages over passive SLBs. In active SLBs, as stated earlier, one can manage the amount of activity that the clip will have by the size of the archwire. For instance, at the beginning of treatment when less resistance to sliding is desirable and usually the archwire of choice is a small, round thermal-activated wire, both active and passive brackets have shown equal behavior.[7] As treatment progresses, an increased resistance to sliding is desired to achieve proper torque expression. At this stage of treatment, passive SLBs have demonstrated poor behavior compared with active SLBs.[8,9] It is important to remember that the active clip is a very important feature of active SLBs, and therefore the quality of it will determine to some extent how good is the bracket. Substantial differences have been shown in clip performance when some SLBs' clips lose an important percentage of force during treatment. Also, it is important to note that not every active available SLB is a true SWA. The SLB must have all the other features mentioned earlier to be a true SWA.

Optimal Bracket Placement

Assuming we have the right appliance, the next most important factor when working with an SWA is bracket position. This is where the orthodontist's dexterity is of great value. As with techniques that require bending the wire, the quality and precision of each bend will determine to some extent the quality of the final result, as the precision of bracket placement will do it when using an SWA. When using an SWA, you "start finishing" your case the day you place the brackets. This is why an important percentage of problems that orthodontists experience toward the end of active treatment—such as marginal ridge discrepancies, difficulty correcting rotations, lack of root parallelism, and, ultimately, less than ideal tooth position—are caused by incorrect bracket placement. As Andrews described 40 years ago, the brackets should be placed at the FA point. The FA point is the middle of the clinical crown occlusogingivally and mesiodistally, following the long axis of the crown, for each tooth in the mouth (Fig. 17-2).

Because all the brackets are working at the same time through the wire, one misplaced bracket will automatically affect the adjacent brackets. If more than one bracket is misplaced, the problem will increase and become more noticeable as the wire sequence progresses. This issue, if not corrected, can prevent the orthodontist from finishing the case in an optimal and efficient way.

Because we have a limited space in this chapter, we will not describe the specific bracket position for each individual tooth but rather focus on the teeth that usually cause more problems for clinicians. It is important to emphasize the following concepts:

- Andrews demonstrated that trained clinicians are able to place brackets consistently at the FA point without any aids but their own eyes.
- The use of any gauge as an aid to position the brackets is not necessary; in fact, to use any predetermined height from the incisal edge to locate the brackets, as some orthodontists advocate, is wrong and negates the use of the FA point, which is one of the fundamentals of the proper management of the SWA. However, you have to take into account shorter crowns caused by excessive gingival tissue, worn teeth, or fractured teeth that eventually will be restored, so in some of these situations, the brackets will look more incisally or gingivally than they should be.
- To fully level and express the torque, tip, and in/out of each bracket, the slot of the bracket has to be filled, which requires 0.021- × 0.025-inch stainless steel wire. It is important to know that a 0.019- × 0.025-inch stainless steel wire has about 10.5 degrees of play on a 0.022-inch bracket slot.[10] However, this is not the case when using active SLBs, as explained later in the chapter.

FIGURE 17-1 The design features that make a self-ligating bracket active. **A,** Notice the difference in the depth of the occlusal wall of the slot compared with the gingival wall. **B,** This particular active self-ligating bracket (In-Ovation R) wire is smaller than 0.019 inch; the clip is not active. **C,** A wire larger than 0.019 inch pushes out the clip and therefore activates it.

Although the FA point and long axis of clinical crowns are key to bracket position, a few specific considerations facilitate bracket placement on certain teeth, such as the upper and lower canines, upper and lower first molars, and sometimes upper lateral incisors and premolars.

- **Canines:** The long axis of the upper and lower canines, which is also the most convex part of the labial surface, is located more mesial than the true mesiodistal center of the tooth; therefore, the FA point looks a little bit more mesial than the dead center of the tooth. If you err and place the bracket on the center of the crown mesiodistally, the canine will rotate mesially.
- **Molars:** The landmark that Andrews used as the long axis of the clinical crown for the molar is the buccal groove. The FA point then lies along the buccal groove, midway occlusogingivally (see Fig. 17-2). It is important to realize that the center of the tube mesiodistally should be in agreement with the FA point. As some manufacturers have reduced the mesiodistal length of tubes, orthodontists have started positioning tubes too far mesial, resulting in distal overrotation of the molars.
- **Upper lateral incisor:** After the third molars, the upper lateral incisors are the teeth with problems involving size and shape. This makes it difficult to determine the long axis of the crown from the buccal. It is wise to use a mirror to look at the lingual surface of the incisor and then extend the long axis of the clinical crown from the lingual to the buccal.
- **Premolars:** Usually premolars, specifically second premolars, represent a challenge at the time of bonding because of a lack of direct vision. In these cases, it is advisable to look with a mirror from the occlusal and the buccal to locate the FA point and the long axis of the clinical crown.

Both authors believe that indirect bonding can be of great help to better position the brackets, specifically on premolars and molars, decreasing the need for “fine tuning” rebonding toward the end of treatment.

Treatment Mechanics

For didactic purposes, treatment mechanics usually has been divided in different stages, from three to seven depending on authors’ preference. Simplicity is of paramount importance when teaching; therefore, all the mechanics to be accomplished in our orthodontic treatments with the SWA can be divided into three stages: stage 1, leveling and alignment; stage 2, working stage; and stage 3, finishing stage.

During each of these stages, there are specific movements of teeth that will occur and specific goals that have to be achieved before continuing to the next stage of treatment. It is important to emphasize that both the treatment outcome and its efficiency will be greatly improved if the orthodontist follows these stages. The following stages of treatment mechanics, with their respective wire sequence, have been tailored for active SLBs, although they can be applied to any SWA.

Stage 1: Leveling and Aligning

Leveling and aligning is a complex process in which all the crowns are moving at the same time and in different directions. As the teeth level and align, reciprocal forces between them develop, which can be of great help to guide the movements to our advantage. Then, when possible, all teeth should be engaged from the beginning to obtain maximum efficiency of tooth movement. Usually at this stage, round small-diameter thermal-activated wires, such as a 0.014 inch for severe crowding or a 0.018 inch for moderate to minimum crowding, are preferred. In cases that required retraction of the incisors, it is recommended to cinch the wire back of the second molar tube or to place crimpable stops to avoid undesirable movement of the wire, causing discomfort to the patient. These round wires can be in place for as long as 8 to 12 weeks before proceeding to the next wire, which usually is a 0.020- × 0.020-inch thermal-activated wire. This wire is a low-deflection thermal-activated wire that works very well as a transitional wire from stage 1 to stage 2. The 0.020- × 0.020-inch wire corrects most of the rotations left by the previously used round wires and provides more stiffness to start leveling the curve of

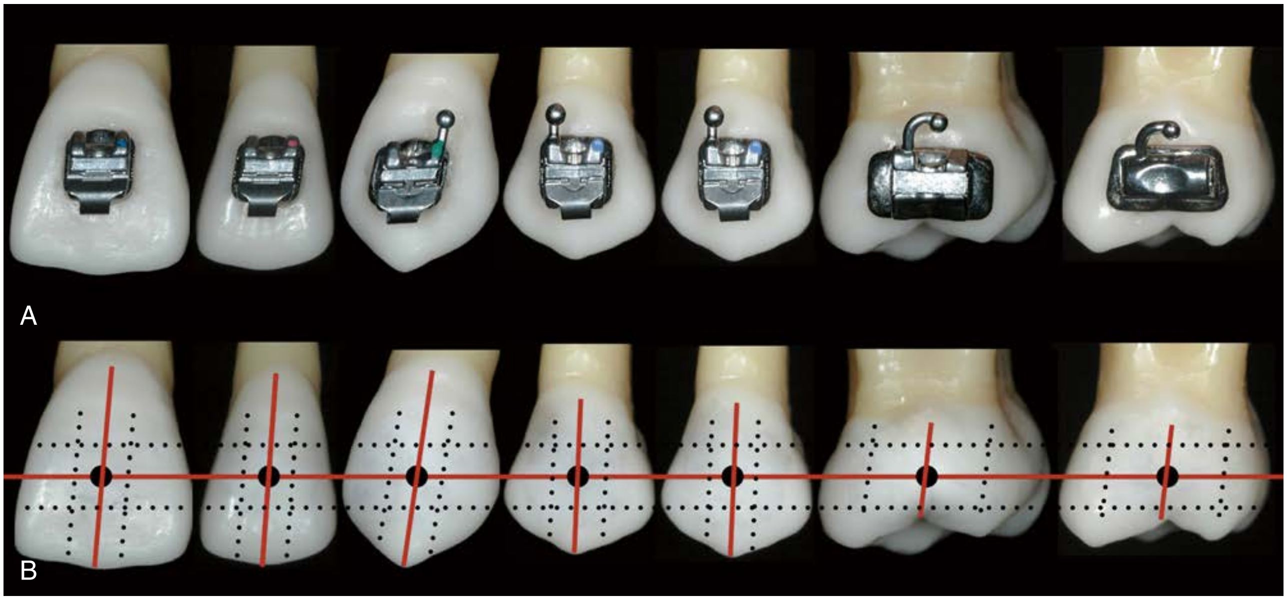

FIGURE 17-2 **A,** All the brackets aligned along the references described by Andrews, such as the FA point and the long axis of the clinical crowns. In **B,** the long axis of the clinical crown for the molars is the buccal groove.

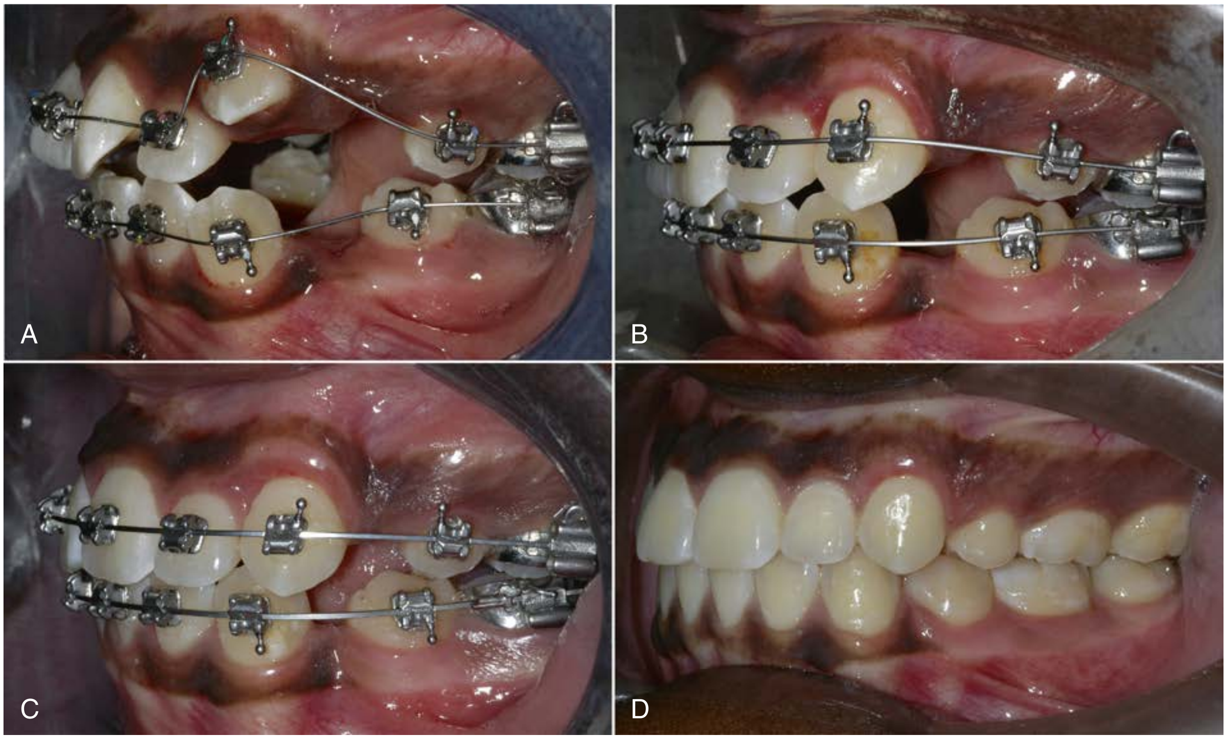

FIGURE 17-3 As the initial alignment occurs, molars upright, and the maxillary and mandibular planes of occlusion become more parallel, helping to retract the incisors and improve the overbite. The wire sequence is very important to control tip, torque, and rotations. Small, round Sentalloy wires such as 0.014 **(A)** and 0.018 **(B)** inch are excellent to control initial alignment; upright incisors, premolars, and molars; and correct major rotations. Bioforce wires such as 0.020- × 0.020-inch **(C)** are ideal to finish with the leveling and aligning stage. This wire finishes correcting the rotations still present after the round wires. It also expresses more crown tipping and starts providing a small amount of torque because its dimension mildly activates the springing clip of the bracket. **D,** Finished case.

Spee and therefore flatten the occlusal plane. It is important to notice that even if you could start treatment with a rectangular or square thermal-activated low-deflection wire, with the assumption of saving time and providing torque from the beginning of treatment, this is absolutely not recommended because it may cause loss of posterior anchorage. This happens for two main reasons: first, the only teeth with positive labial crown torque are the maxillary central and lateral incisors, and second, the mesial crown tip of the maxillary and mandibular canines is rather large. Therefore, if we start treatment resolving the crowding with a rectangular or square wire, we are providing labial crown torque to the maxillary incisors and mesial crown tip to canines, which will increase our anchorage in the front part of the arch, facilitating the loss of anchorage in the posterior part of the arch. This is critical in cases in which the treatment plan calls for maximum retraction of the maxillary or mandibular incisors (or both). In these particular cases, the use of a 0.020-inch thermal-activated wire can be better indicated than the 0.020- × 0.020-inch wire and thus will not provide torque and the tip effect on the canines will be minimal. This allows the molar and premolars to level, align, and upright, which will produce a "lasso" effect on the incisors that will upright and sometimes even retract them (Fig. 17-3).

The 0.020- × 0.020-inch wire will make the clip of the SLB active and thus start delivering torque; nonetheless, its strength is not sufficient to compromise the anchorage that has already been created with the round wires. Usually, after 8 to 10 weeks with the 0.020- × 0.020-inch wire, the stage 1 of leveling and aligning is finished, and in the authors' opinion, it is the first time to evaluate bracket placement and debond or rebond as necessary. Then we are ready to start stage 2, the working stage.

The following are the movements we should expect and goals we should accomplish when leveling and aligning, before starting stage 2:

- Teeth move individually.
- It is mainly crown movement.
- Molars and Premolar (PM) derotate and upright distally.
- Incisors are upright and sometimes even retract.
- Start building posterior anchorage.
- Before proceeding to stage 2, check bracket position (gross errors) and debond or rebond as indicated.

The following are the most common wires and sequence used at stage 1 of treatment:

- Mainly round, small-diameter, superelastic wires (ideal thermal activated)
- Square or rectangular superelastic wires to correct remaining rotations and level the occlusal plane (Tables 17-1 and 17-2)

Stage 2: Working Stage

This stage of treatment is the one on which we will spend more time. At this stage, the maxillary and mandibular arches are coordinated, proper overbite and overjet are achieved, Class II

TABLE 17-1 Types of Wires, Size, and Sequence Suggested for Stage 1 of Treatment Mechanics in Cases with Moderate to Severe Crowding

	SEVERE TO MODERATE CROWDING	
STM1 Type	**Size (inches)**	**Sequence**
Niti thermal activated	0.014	0.014
	0.018	
Niti thermal activated	0.018 × 0.018	0.018
	0.020 × 0.020	
	0.019 × 0.025	0.020 × 0.020

STM, Stage of Treatment Mechanics.

TABLE 17-2 Types of Wires, Size, and Sequence Suggested for Stage 1 of Treatment Mechanics, in Cases with Mild Crowding

	MILD CROWDING	
STM1 Type	**Size (inches)**	**Sequence**
Niti thermal activated	0.014	0.018
	0.018	
Niti thermal activated	0.018 × 0.018	0.020 × 0.020
	0.020 × 0.020	
	0.019 × 0.025	

STM, Stage of Treatment Mechanics.

or Class III are corrected, maxillary and mandibular midlines are aligned, extraction spaces are closed, and maxillary and mandibular occlusal planes are paralleled. Although most of these corrections happen simultaneously, we will describe them separately for didactic reasons so key points can be emphasized.

Arch Coordination. The maxillary and mandibular archwires must be coordinated in order to obtain a stable occlusal intercuspation and proper overjet. In an ideal intercuspation of a Class I, one-tooth to two-teeth occlusal scheme, the palatal cusps of the maxillary molars should intercuspate with the fossae and marginal ridges of mandibular molars, the buccal cusp of the mandibular premolars should intercuspate with the marginal ridges of the maxillary premolars, and the mandibular canines and incisors should intercuspate with marginal ridges of the maxillary canines and incisors. If this occlusal scheme occurs, it will then provide an overjet of 2 to 3 mm all around the arch from second molar to second molar. Then the maxillary archwire must be 2 to 3 mm wider than the mandibular archwire. The archwire coordination is done with the stainless steel wire. Even if they come preformed, the clinician should not rely on it and check them before insertion.

Another important aspect of arch coordination is the effect that it has on the vertical dimension and the sagittal dimension. Arch coordination is a transverse issue. The maxillary teeth should be upright and centered in the alveolar/basal bone and coordinated with the mandibular teeth, which should also be upright and centered in the alveolar/basal bone to obtain a proper intercuspation. Often, this is not the case, and we find maxillary molars buccally inclined, also referred as an *accentuated curve of Wilson*, which can produce contacts between the palatal cusp of maxillary molars and the inclines or even the cusps tip of the mandibular molars. This decreases the overbite and sometimes produces even an open bite (vertical problem), which in turn can produce a downward and backward movement of the mandible (sagittal problem). This phenomenon is due to the lack of palatal crown torque of the maxillary molars. Depending on the amount of palatal crown torque needed for the maxillary molars to level the curve of Wilson, we suggest three solutions:

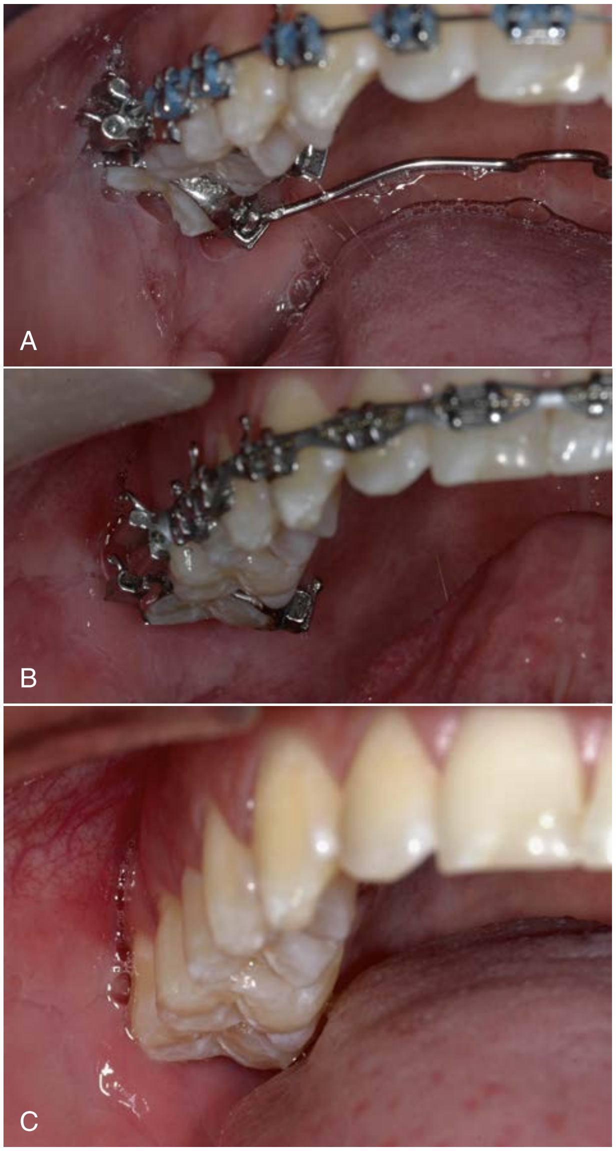

FIGURE 17-4 Asequence of a maxillary second molar severely tipped to the buccal corrected with a transpalatal bar. **A,** Initial. **B,** After correction is done. **C,** Finished case.

1. For minor problems with torque, we can wait until the finishing stage when a larger size wire (0.021- × 0.025-inch stainless steel) can be used to fill the slot and deliver more torque to the molars.
2. For moderate problems with torque, we can add palatal crown torque to the working wire.
3. For severe problems with torque, the use of a transpalatal bar (TPB) is suggested. A TPB can be used to easily place and deliver palatal crown torque to maxillary molars (Fig. 17-4).

Overbite and Overjet Correction. An optimal overbite–overjet relationship does not have to be a certain predetermined number of millimeters. More important is the functional relationship

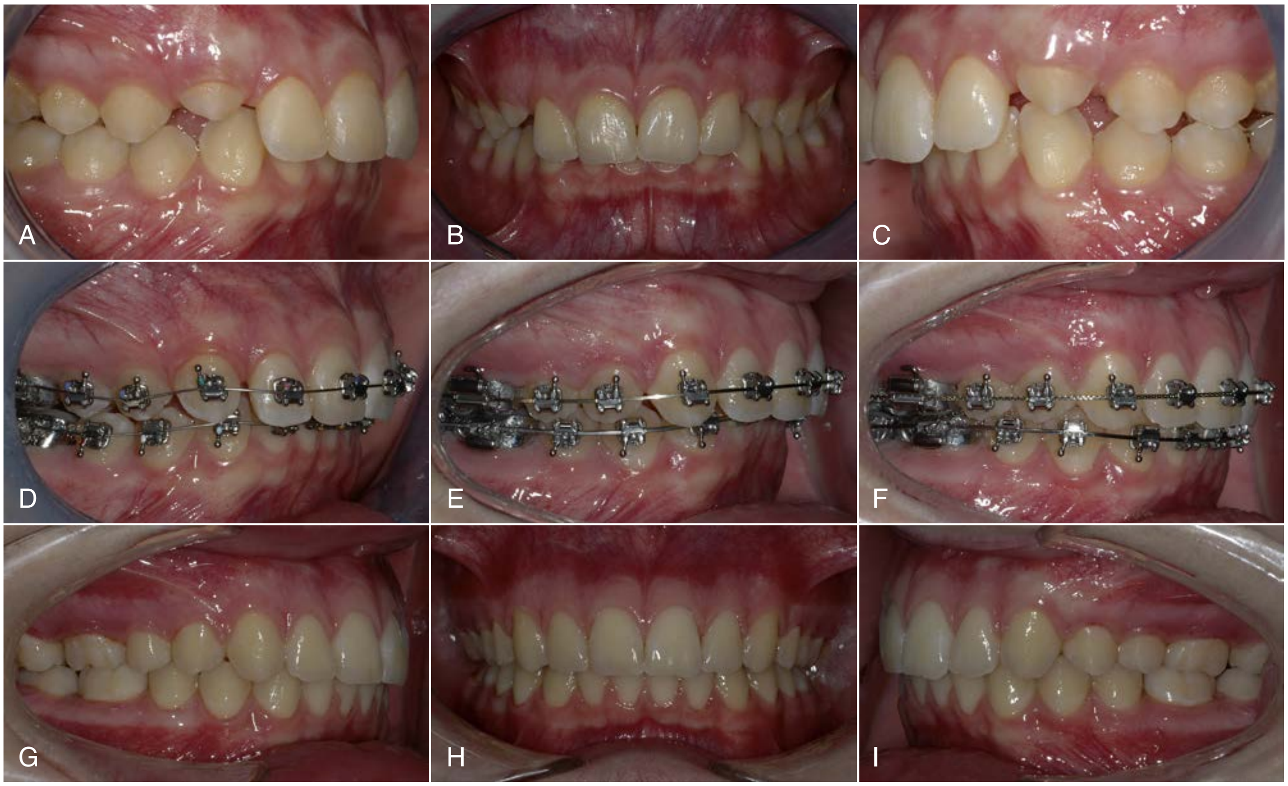

FIGURE 17-5 A deep bite case in which the occlusal plane was flattened with the use of a reverse curve of Spee on a 0.019- × 0.025-inch stainless steel wire. **A–C,** Initial intraoral views. **D,** Initial wire to level and align. **E,** A 0.019- × 0.025-inch stainless steel wire with reverse curve of Spee before correction. **F,** A 0.019- × 0.025-inch stainless steel wire with reverse curve of Spee after correction. **G–I,** Final intraoral views.

they have. This means that the overbite–overjet should be compatible with a mutually protected occlusal scheme and thus allows for a proper anterior guidance in protrusion and lateral excursive movements. Although, as already discussed, the number of millimeters is less important than the function, we find that an optimal overbite is usually around 4 mm and an optimal overjet is 2 to 3 mm. When diagnosing and treatment planning overbite–overjet problems, it is important to take the following key points into consideration: arch space management, position of the mandible in centric relation, and relationship of the upper and lower incisors with the lips. Arch space management is important to understand because the SWA tends to flatten the curve of Spee, which requires space in the arch. If not enough space is available or created, the incisors will procline, increasing the arch perimeter. This incisor proclination will also decrease the overbite and may help, if it only occurs in the lower arch, to decrease the overjet. Flattening the maxillary and mandibular occlusal planes proclining the incisors can be of help in deep bite cases (Fig. 17-5). When the incisors are not allowed to procline, space in the arch must be created. This is specifically important to avoid periodontal problems in cases with thin bone surrounding the incisor area. Advanced diagnostic imaging tools, such as cone-beam computed tomography (CBCT), could be of great help to precisely identify the condition of the bone in this area. Up to 4 to 6 mm can be created with interproximal reduction of teeth, usually done on the incisors and less often the canines and premolars. If more than 6 mm of space is required, extraction of premolars could be indicated.

Another important factor to consider when evaluating overbite–overjet problems is the position of the mandible. Often, differences between a maximum intercuspation (MIC) and centric relation (CR) can produce significant differences in the overbite–overjet relationship. This can be clearly seen in Figure 17-6, in which what looks like a normal overbite–overjet relationship in MIC is an anterior open bite in CR. In this case, as the mandible rotates close in CR, a primary contact found at the second molar keeps the bite open in the anterior, decreasing the overbite and preventing the mandible to achieve a more stable occlusal scheme.

Last, but by no means the least important, is the sagittal and vertical relationship of the maxillary and mandibular incisors with the lips. In an open bite case, should we intrude the molars or extrude the incisors? In a deep bite case, should we intrude the maxillary incisors, the lower, or both? These basic but very important questions can be answered through an understanding of the optimal relationship of the incisors with the lips. According to contemporary a esthetic trends and taking into account the aging process, for adolescents and young adults, the maxillary incisors should have, at rest, an exposure of about 4 mm beyond the most inferior point of the upper lip known as the *upper stomion*. As explained earlier, an optimal functional overbite should be about 4 mm. Now, if we put together the last two concepts, the incisal edge of the lower incisors should be at the same level with the most inferior point of the upper lip. Therefore, any vertical change of the incisors will affect not only the function through changes of the anterior guidance but also the aesthetics through the amount of tooth exposure. These

FIGURE 17-6 An example of a case with a clinically significant discrepancy between a maximum intercuspation (MIC) and centric relation (CR). This case was treated with the aid of mini-implants to control the vertical position of the maxillary first and second molars. **A, B,** Initial intraoral views in MIC. **C, D,** Initial intraoral views in CR. **E, F,** Intraoral view before molar intrusion. **G, H,** Intraoral view after molars have been intruded and open bite closed. **I, J,** Intraoral view with the final wire. **K, L,** Intraoral view after appliances have been removed. **M–O,** Occlusal intraoral views of the maxillary arch before treatment, during treatment with mini-implant, and after treatment.

anterior functional and aesthetic references, explained by Ayala as the "upper stomion concept" (Fig. 17-7), will help the clinician to determine the best strategies to correct overbite–overjet problems and will be of special importance for planning cases involving orthognathic surgery.

Closing Extraction Spaces. Usually after leveling and aligning, the extraction spaces left are smaller than at the beginning of treatment because some of the space has been taken to unravel the initial crowding and to upright the maxillary and mandibular incisors, as described earlier in this chapter. Also, the maxillary and mandibular occlusal planes should be flat or almost flat, and the six anterior teeth should be consolidated into one unit. Then, to efficiently close the remaining spaces, achieving the desired functional and aesthetic goals, we need to determine the anchorage requirement. This will allow us to know which teeth should be moved more mesially or distally

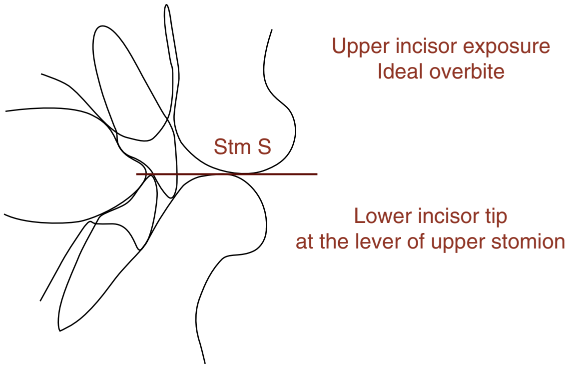

FIGURE 17-7 Diagram of anterior functional and a esthetic references, the "upper stomion concept." *Stm S,* Stage of Treatment Mechanics.

and therefore to choose the appropriate mechanics. We believe that one of the easiest ways to determine the anchorage requirement is to perform a visual treatment objective (VTO). The VTO is a cephalometric exercise in which we modify the patient's cephalometric tracing to achieve the desired end-of-treatment result, and then, by superimposing both tracings, we can visualize the movements that need to occur to obtain that result. The VTO is not a formula or equation that will determine or impose a specific type of treatment but rather an exercise in which we take into account our experience gathered from other similar cases, an estimation of the growth the patient will have during treatment, the patient's biotype and soft tissue characteristic, and so on to more accurately plan treatment in our cases and have a visual representation of it. Thus, after the VTO has been performed, the anchorage requirement can be minimum, medium, or maximum. Before describing each one of these anchorage situations, it is important to indicate the wires and auxiliaries used at this stage. In our mechanics, we use either a double keyhole loop (DKH) or a straight wire with hooks and Niti thermal-activated coils. Both of these types of wires are stainless steel and can be either 0.019- × 0.025-inch or 0.021- × 0.025-inch, depending on the anchorage situation. The Niti thermal-activated coils can be light (100 g), medium (150 g), or heavy (200 g). Also, when the anchorage situation calls for it, we use TPBs and temporary anchorage devices (TADs).

Double Keyhole Loop Activation. The DKH archwire can be activated in two different ways. It can be pulled from the distal of the first or second molar, so as to open the loops 1 mm, and then cinched back to keep the loops open. As the loops close, the teeth come together, closing the space. A different activation method is to open the loops 1 mm and then use a stainless steel ligature to ligate the distal loop to the hook of the first or second molar tube, with sufficient tension to keep the loops open. As the loops tend to close, the ligature will exert force on the molar tube, and the teeth will come together. In either way of activation, changes in wire size and place of activation will determine the type of anchorage obtained.

Niti Thermal-Activated Coil Activation. Niti thermal-activated coils come in three different strengths: 100 g (blue dot), 150 g (yellow dot), and 200 g (red dot). It is the authors' preference to use the 150-g Niti thermal-activated coil. These coils deliver the same force independent of the amount of activation. In our mechanics, we usually crimp a surgical type of hook distal of the canine from which a Niti thermal-activated coil is engaged all the way to the hook of either the first or second molar. If a surgical hook is not available, the Niti thermal-activated coil can be engaged to the hook of the canine's bracket. This situation requires the six front teeth to be tied together with either an elastomeric chain or a stainless steel ligature so they act as a unit.

Minimum Anchorage. On a minimum anchorage situation, molars will be moved mesially to close the remaining extraction spaces. We use a 0.021- × 0.025-inch wire. This wire will express the buccal crown torque of the maxillary incisors and the mesial tip of the canines. In the mandible, this wire will express the mesial tip of the canine. This situation increases the anchorage in the anterior part of the mouth because it would be more difficult to retract or even tip back the anterior teeth while moving the molars forward. It also has been recommended to reduce the size of the wire in the posterior part, specifically the edges, to decrease the anchorage of the posterior teeth. The activation of the DKH or the Niti thermal-activated coils must be done from the first molars. Then, after the first molar has been moved forward as desired, the second molar can be activated and moved forward, too. Often, though, this is not required because the second molars will travel forward as we move the first molars, and then the space remaining between the first and second molars will be very small and easily closed with an elastomeric chain.

Medium Anchorage. This is the most common anchorage situation encountered in our cases. Medium anchorage means that the remaining spaces should be closed reciprocally. For this situation, we use a 0.019- × 0.025-inch wire. The activation of the DKH or Niti thermal-activated coils is done, most of the time, from the first molar. However, it can also be done from the second molars depending on how the case is progressing. The bone and attachment apparatus are not the same for every patient, and therefore, the response to the closing mechanics could differ among cases. Then a clinical examination of the overbite–overjet, canine and molar relationship, and facial aesthetics should be done at each visit to evaluate any changes in activation that may be required. This should not take any extra time because the activation of a DKH or Niti thermal-activated coil is a rather easy procedure.

Maximum Anchorage. In a maximum anchorage situation, most of the remaining space left after leveling and aligning is closed because of distal movement of the anterior teeth. We use a 0.019- × 0.025-inch wire. The DKH or Niti thermal-activated coil is activated from the second molars. Although not frequently required, auxiliaries to enhance posterior anchorage such as TPB, TADs, or extraoral force (headgear) can be used as needed.

Intermaxillary Elastics. *Discretion* is a good word to describe the use of intermaxillary elastics. We use them and like them, but it is important to understand how they are used to avoid problems. We do not use intermaxillary elastics in the following situations:

- Round wires
- Initial leveling and aligning, low-deflection wires
- To a terminal tooth, last tooth in the arch
- In the anterior part of the mouth to close open bites
- In the posterior part of the mouth to correct crossbites
- For an extended period of time

We use intermaxillary elastics in the following situations:

- At the working and finishing stages
- On square or rectangular stainless steel wires
- On the buccal side of the mouth, short Class II or III, or triangular verticals

The three types of intermaxillary elastics we commonly use are 3/16-inch 4 oz, 6 oz, and 8 oz elastics as well as 1/8-inch 4 oz, 6 oz, and 8 oz. Short means, in a Class II, for instance, from the maxillary canine to the mandibular second premolar in a nonextraction case and to the first mandibular molar in an extraction case.

The following are the movements we should expect and goals we should accomplish at the working stage before starting stage 3:

- Movement of group of teeth in all planes of the space: sagittal, vertical, and transverse
- Overjet–overbite correction
- Class II and III correction
- Close all remaining extraction spaces, aligning maxillary and mandibular midlines
- Finish leveling the occlusal plane
- Arch coordination

The following are the most common wires and sequence used at stage 2 of treatment:

- In nonextraction cases, a 0.019- × 0.025-inch stainless steel wire. Reverse curve of Spee can be manually added to the wire if needed
- In extraction cases, either a 0.019- × 0.025-inch or a 0.021- × 0.025-inch stainless steel wire depending on the anchorage requirement, as previously explained (Tables 17-3 and 17-4)

Stage 3: Finishing Stage

At this stage, to place each tooth on its ideal position and flatten the occlusal plane, full bracket expression is desired; thus, a larger wire such as a 0.021- × 0.025-inch or a 0.022- × 0.028-inch stainless steel may be required. In our experience using an active SLB with the clip pushing and sitting the wire onto the slot, often optimal bracket expression is achieved after a 0.019- × 0.025-inch stainless steel wire has been in place for a few months. This is especially true in nonextraction cases with an average curve of Spee. However, in some cases, the size and stiffness of a 0.021- × 0.025-inch or 0.022- × 0.028-inch stainless steel are indicated, such as in cases with a deep curve of Spee, extraction cases that have required an important amount of tooth movement, and cases that required significant labial crown torque of maxillary incisors such as Class III camouflage cases and Class II, Division 2 cases. When the maxillary and mandibular occlusal planes are parallel and all the bracket slots are aligned, bracket position should be carefully checked for minor correction of tooth position, and therefore the second time of debond or rebond should be done. It is also suggested, at this point in treatment, to mount the models in an articulator to better visualize the intercuspation of the posterior teeth, which is very difficult to do clinically. The last wire we use is a stainless steel multibraided 0.021- × 0.025-inch archwire. Although this wire is large enough to fill the slot of the bracket and then maintain the tip, torque, and offset of each tooth, its resilience permits both minor bracket repositioning and "end of treatment" optimal intercuspation. It is important to notice that at this point in treatment, all the appliance interferences should be removed using a finishing carbide burr on a high-speed handpiece. With a thin articular paper, all contacts must be checked. Only tooth–tooth contacts should be allowed. All bracket, tube, or band contacts must be removed to allow proper settling. Vertical triangular 3/16-inch elastics, either 6 oz or 8 oz, are used to achieve proper intercuspation. These vertical elastics should not be used with the braided wire for more than 6 weeks to avoid rolling premolars and molars lingually, which can be detected not from the buccal but rather from the lingual, where premolars and/or molars will not be contacting. Finally, before removing the appliance, a complete assessment of the occlusal end-of-treatment goals should be performed. We strive to finish our cases with a static occlusal scheme compatible with the six keys of optimal occlusion described by Andrews[1] and a dynamic mutually protected occlusal scheme in centric relation described by Roth[11] (Table 17-5).

TABLE 17-3 Types of Wires, Size, and Sequence Suggested for Stage 2 of Treatment Mechanics in Nonextraction Cases

FUTURE DIRECTIONS

Although alternative SWA prescriptions for the maxillary anterior teeth such as "high torque" as well as "low torque" have been in existence for many years, it has not been until recently that SWA systems with variable prescriptions and/or a fully customized prescription have gained some traction. The SWA was developed based on measurements taken from the facial surface of each tooth of 120 individuals with an optimal occlusion who never had orthodontic treatment. It is generally known that tooth anatomy varies among individuals, and therefore, there are variations in the form such as degree of convexity, inclination, length, and width of the facial surface of each tooth. These variations could result in different degrees of optimal torque, tip, offset, and in/out needed for each tooth of each individual. The idea is clear, and it does certainly make sense to individualize the bracket prescription for each patient.[12] Some manufactures have already attempted to customize the bracket prescription based on individual needs, but as of now, it is not practical for the clinician, and it is expensive; therefore, this technology has not increased in popularity at all. However, we think that because of recent advances in digital technology such as low-radiation CBCTs, faster intraoral scanners, and three-dimensional printing, individualized prescriptions will soon be an interesting option to consider for orthodontists.

Another important reason that favors the use of an individualized prescription is the different amount of bone surrounding teeth that we find among our patients. The increased use of CBCTs over the past decade has helped us to better understand the anatomic limitations of tooth movement. Recent studies[13] have shown that a significant percentage of our patients have dehiscence and fenestrations before orthodontic treatment, so special biomechanical considerations need to be taken if buccal tooth movement such as protrusion and arch expansion are required. Also, in cases of canines and molars that are too close to the buccal cortical bone, adjustment of the buccal–lingual inclination (torque) should be done to prevent root damage as well as periodontal problems (dehiscence and fenestrations) that could lead to gingival recession.

CASE STUDY 17-1

A 20-year-old woman presented with an anterior open bite and a unilateral posterior crossbite (Fig. 17-8). The open bite was closed by leveling, aligning, and flattening the maxillary and mandibular occlusal planes. Triangular vertical elastics were used only on the buccal segment at the working and finishing stages. A transpalatal bar attached to the maxillary first molars was used to help with arch coordination and correct the unilateral posterior crossbite. An active self-ligating straight wire appliance (In-Ovation R and C, Dentsply/GAC) was used. Active treatment was for 15 months.

Dr. Antonino G. Secchi

CASE STUDY 17-2

An 11-year-old boy presented with Class II-2 deep bite, crowding, and severe retroinclination of maxillary incisors. After initial leveling and aligning with a 0.014 and 0.020 Niti wires, the Class II was treated with a high-pull headgear (Fig. 17-9). The mandibular plane was flattened with a 0.019- × 0.025-inch stainless steel wire. Proper buccal crown torque was obtained with a 0.021- × 0.025-inch stainless steel wire and final interdigitation with a 0.021- × 0.025-inch stainless steel braided wire and 1/8-inch heavy elastics. During the final stage, mounted models and bracket rebonding were done. A Roth 0.022 straight wire appliance (True Roth, A Company, Sorrento Valley, San Diego, CA) was used. Active treatment was for 28 months.

Dr. Jorge P. Ayala

CASE STUDY 17-3

A 12-year-old girl presented with a deep bite, Class II canines, crowding, and severe retroclination of maxillary incisors (Fig. 17-10). After initial leveling and aligning, the mandibular occlusal plane was flattened using a 0.019- × 0.025-inch stainless steel wire with reverse curve of Spee. Short Class II elastics were used at the working stage. Proper buccal crown torque to the maxillary incisors was achieved with a 0.021- × 0.025-inch stainless steel wire. An active self-ligating straight wire appliance (In-Ovation R) was used. Active treatment was for 25 months.

Dr. Antonino G. Secchi

FIGURE 17-10 **A–D,** Facial photographs before treatment. **E–G,** Intraoral photographs before treatment. **H–J,** 0.014-inch Sentalloy initial wires only in the maxillary arch. CASE STUDY 17-4

An 18-year-old male, Class I dental with crowding came to our clinic to continue a treatment started in another country (Fig. 17-11). During the initial alignment with cinched-back 0.014-inch Sentalloy wires, the extraction spaces were reduced and the incisors passively retracted. The second wire was a 0.018- × 0.025-inch NeoSentalloy in the mandibular arch and a 0.020-inch Sentalloy in the maxillary arch. Spaces were closed with minimum anchorage using a 0.019- × 0.025-inch Double Key Loops (DKL) reduced in the posterior segment. Finishing was obtained with a 0.021- × 0.025-inch stainless steel wire followed by a 0.021- × 0.025-inch stainless steel braided wire and triangular 1/8-inch heavy elastics. During the final stage, mounted models and bracket rebonding were done. The case was treated with a 0.022 straight wire appliance (Mini-twin Dentsply/GAC). Active treatment was for 24 months.

Dr. Jorge P. Ayala

SUMMARY

The advantages of the SWA are unquestionable. At 40 years after its introduction to our specialty, it remains the most popular orthodontic appliance used in the world. But today, at the beginning of the 21st century, the challenge is to integrate the SWA with recent changes in bracket design such as self-ligation and technologically advanced low-deflection thermal-activated archwires to provide orthodontists with a state-of-the-art appliance system that can deliver, through a practical, efficient, and reliable biomechanical system, excellent results for a wide range of dentofacial problems. The objective of this chapter is to delineate some of the basic principles of the SWA, emphasize the importance of optimal bracket placement, and provide readers with the framework of a simple, but complete, biomechanics tailored for active SLBs.

Nonextraction Treatment

Robert L. Vanarsdall, Jr., and Raffaele Spena

OUTLINE

The decision of whether or not to extract permanent teeth in planning the treatment of an orthodontic case is a crucial moment for the clinician, especially when facing a borderline case. The education, experience, and skill of the clinician on one side and the requests or the limitations imposed by the patient on the other side may greatly influence the final solution and, eventually, the outcome.

Clinical research has so far failed to demonstrate that nonextraction treatment is better than extraction treatment (or vice versa). No difference in influencing the final dental and facial aesthetic result, no difference as far as the final functional result, and no difference in final stability have been established because of the great variability and unpredictability from patient to patient. Dogmas have been proposed, but most have proved to be inadequate.

The nonextraction approach proposed by Norman Cetlin has long been used by several clinicians with excellent clinical results. In the past few years, some modifications have been proposed in order to overcome the problems related to the headgear appliance and the distalizing plate, trying to reduce the level of patient compliance required.

New procedures and techniques have been adopted to improve control of the dental anchorage and movement, including mini-implants to ensure skeletal anchorage for both dental and orthopedic modifications, alveolar corticotomy to facilitate dental movement, active self-ligating brackets with new prescriptions associated to thermal NiTi wires trying to increase control of tooth movement in Class I, II, and III mechanics and reduce the level of applied force and friction produced.

This chapter is divided into two parts. In the first part, the original nonextraction approach is described. In the second part, modifications and implementations of the technique with the adoption of new appliances and protocols are presented.

THE ORIGINAL CETLIN APPROACH

In its original version, the Cetlin nonextraction approach was divided into two phases: (1) an initial space-gaining phase and (2) a final space-utilization phase. Sagittal and transverse corrections and major tooth movements were accomplished in the first phase, and full bracketing and final detailing were achieved in the second phase.

The objectives of the first, or space-gaining, phase were to increase space and change the original malocclusion into a "super Class I" malocclusion with ample spaces in both the upper and lower arches. Molar rotation, inclination, and crossbite were corrected, and the curve of Spee was leveled. In the second, or space-utilization, phase, Andrews' six keys to normal occlusion[1] were obtained, with some modifications as described. Overbite, overjet, and all dental malpositions were corrected. Spaces were closed, and a good anchorage was established during the entire treatment period. The final objective was a mutually protected occlusion with canine and incisal guidance.

This approach is most suitable for treating Class I and II malocclusions with upper and lower crowding. The best patients are those who are growing and who are in the late mixed dentition stage (i.e., right before the exfoliation of second deciduous molars). This stage offers several advantages:

- The leeway or "E" space is still available.
- Facial growth is at its peak.
- Because good cooperation is an essential factor, more can be obtained before the patient becomes socially and academically active.

With proper timing, treatment could be completed in 18 to 30 months, depending on how rapidly teeth erupt and skeletal changes occur. It should be noted that the procedures presented in this system are viable and acceptable for both children and adults. A lesser and slower response generally is expected in adults, but the final result can be equally satisfactory.

Gaining space in the upper and lower arch is the key phase of any nonextraction treatment because crowding is very often found. The objectives of this initial part are (1) correction of molar inclination, rotation, and crossbite; (2) overcorrection of molar relationship; and (3) generalized spacing in both the upper and lower arch.

Space may be gained in the arch in several modalities. If we exclude surgical modalities (e.g., distraction osteogenesis, surgical assisted maxillary expansion) that have specific and limited indications, there are 10 ways to create space in an arch:

1. Distolateral rotation of mesially rotated and constricted upper molars (found in most of Class I and II malocclusions with crowding)
2. Distalization of upper molars (in both Class I and II malocclusions)
3. Distal and buccal uprighting of lower molars (as leveling of the curve of Spee occurs)
4. Distal rotation of ovoid premolars
5. Maintenance of the leeway space
6. Modification of the arch width (orthopedic/orthodontic transverse increase in the maxilla; orthodontic transverse increase in the mandible)
7. Modification of the arch form (an initial constricted, tapered arch form needs to be changed in the same way a rotated tooth needs to be corrected)
8. Selective stripping on trapezoid teeth or teeth with interproximal fillings or teeth with abnormal anatomy. In these cases, the Bolton ratio must be carefully evaluated.
9. Incisor repositioning (depending on periodontal, aesthetic, skeletal, and dental features of the patient)
10. Extraction of teeth (the last option)

Phase Sequences

The most commonly used treatment sequence in the space-gaining phase was as follows:

- Upper arch
- Crossbite correction, as well as rotation, distalization, and torque of upper molars with one or more palatal bars (PBs)
- Molar distalization
- Creation of a super Class I molar relationship
- Molar anchorage to allow spontaneous distal drift of premolars and canines
- Lower arch
- Insertion of a lip bumper on the first or second lower molars
- Achievement of an upright and rotated position of lower molars
- Constant reactivation of lip bumper to permit spontaneous lateral dentoalveolar growth and leveling of curve of Spee
- Use of Class III elastics from overcorrected upper molars to canine hooks on lip bumper to enhance uprighting force on lower molars

The most commonly used treatment sequence in the space-utilization phase was as follows:

- Upper arch
- Creation of a posterior anchorage unit
- Leveling and alignment of the upper arch
- Closure of residual spaces
- Detailing of the arch and occlusion
- Lower arch
- Correction of rotations and dental malpositions
- Complete leveling of curve of Spee
- Closure of residual spaces
- Detailing of the arch and occlusion

PHASE I: SPACE-GAINING PHASE

Upper Arch

Space was gained in the upper arch through the use of three appliances: the PB, the headgear, and the removable distalizing plate. The PB helped to correct maxillary constriction, rotation, distalization, and torque of both first and second upper molars; it also controlled them vertically. The extraoral forces (cervical or occipital, depending on the skeletal pattern) were used to control the roots and the vertical dimension of the upper molars.[2] The removable Cetlin plate, with two distalizing springs against the first molars, tipped the crowns distally while maintaining a good control of anterior anchorage. The combined actions of extraoral force and the plate created a two-force system that allowed bodily distal movement of the upper molars.

Space was gained in the sagittal dimension as well as in the transverse dimension. The premolars and canines followed the molars in a more distal and lateral position. The entire upper arch widened and spontaneously changed its form. The overjet often decreased because the upper front teeth tipped lingually in a better position and/or the mandible, released from a constricted upper arch, repositioned and grew forward.

Palatal Bar

Cetlin and TenHoeve[3] have modified the Goshgarian's anchorage appliance to make it a removable tooth-moving appliance. The PB is made of a 0.036-inch stainless steel (spring temper) wire, doubled back at the ends to be inserted in a 0.036- × 0.072-inch horizontal lingual sheath (Fig. 18-1, *A*). The PB incorporates a small "U-shaped" Coffin loop (Fig. 18-2), which is positioned generally toward the mesial for two reasons: (1) to make the PB more comfortable and (2) to improve vertical upper molar control because of forces exerted by the tongue during speech and swallowing anterior to the center of resistance (CR) of molars, an effect on upper molars only when the PB is distant from the palate and low in the oral cavity.

Clinical Use of the Palatal Bar. The PB is used on both first and second permanent molars. Second molars should be banded and moved with the PB as soon as possible to facilitate distal movement of the first molars.

Forces applied with a PB must be light and in one direction. For example, rotation and torque should not be attempted at the same time. Overactivation leads to soreness, mobility, destruction of the lamina dura, and periodontal breakdown and does not produce results more quickly. Reactivation is required approximately every 6 weeks. Terminals must always be checked to ensure that they are passive to their tubes before additional force is added.

Palatal bars must be tied. This can be done with an elastic or chain from the hook of the sheath to the curved end of the bar. Ligatures prevent the PB from being dislodged or, worse, swallowed.

Palatal bars can be used for the following purposes:

- Distalization
- Rotation
- Expansion or constriction

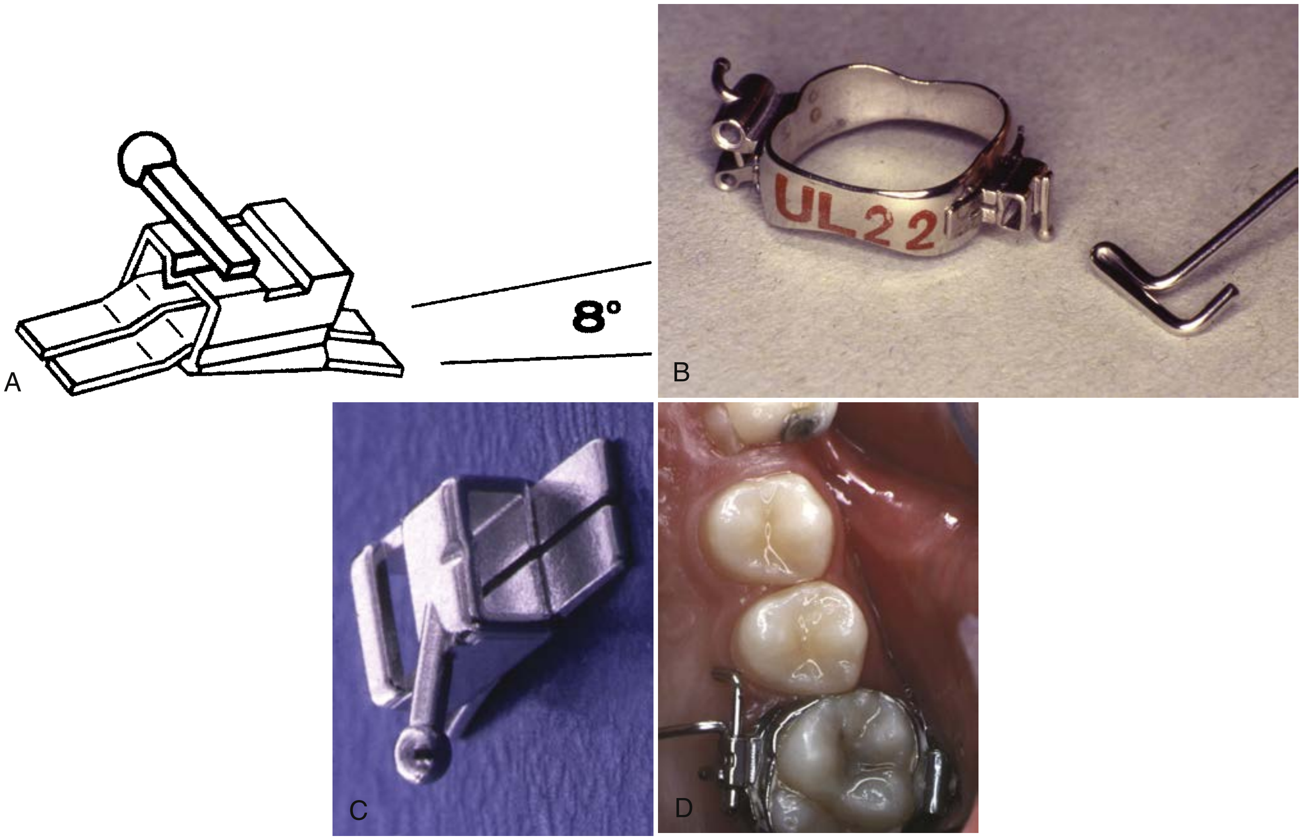

FIGURE 18-1 A, A lingual sheath holds the palatal bar (8-degree medial offset). B, The lingual sheath is welded to the maxillary first molar band; a gingival hook is used. C, A close-up distal view of the lingual sheath. D, A maxillary left molar with a palatal bar held in place with an elastic attached to gingival hooks.

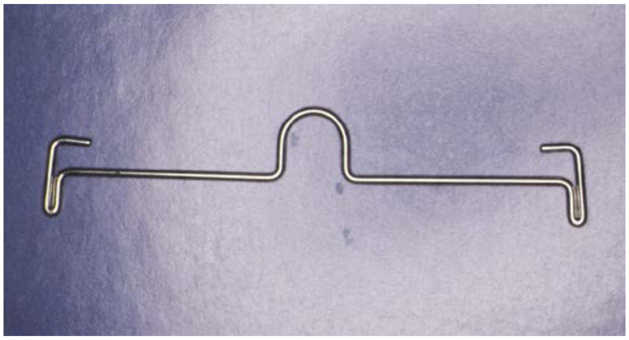

FIGURE 18-2 A transpalatal bar with a U-loop positioned generally toward the mesial.

- Vertical control
- Torque
- Anchorage increase

Distalization. Distalization is the only unilateral activation of the PB. It can be used in two clinical situations: (1) when, in a malocclusion, there is a Class II molar relationship on one side and the other side is normal or (2) when both upper molars must be distalized and the patient does not want to wear headgear.

In the first situation, rotation on the Class I side is offset with a headgear with an inner bow that has a toe-out on this side or an edgewise wire extended at least to the controlateral premolar (Figs. 18-3 to 18-8).

Rotation. L.F. Andrews[1] (see Chapter 14) has observed that molar relationships in untreated normal patients are defined by three contacts between the upper molars and lower molars: (1) the mesiobuccal cusp of upper first molars occludes with the mesiobuccal groove of lower first molars, (2) the distal marginal ridge of upper first molars contacts the mesial marginal ridge of lower second molars, and (3) the palatal cusp of upper first molars occludes with the central fossa of lower first molars. Most Class I and Class II malocclusions present mesiolingually rotated and constricted upper molars. When the upper first molars are rotated, several problems may occur:

1. The relationship between the upper first molars and the lower molars on the buccal side is different from that on the palatal side. Molar relationships always look worse in the buccal view. If the palatal cusps still seat in the central fossa, the faulty molar relationship is easier to correct; however, if occlusion occurs mesial to the central fossa, the Class II molar relationship is more difficult to solve.
2. The upper first molar distal surface faces buccally, and second molars tend to erupt laterally.
3. If the upper molars are banded, archwires or headgears may be difficult to insert.

An upper first molar measures approximately 10 mm from mesial to distal. From its mesiobuccal corner to its distopalatal corner, it measures 13 mm. For this reason, distal rotation of upper molars may gain as much as 3 mm of space per side. Furthermore, several false Class II relationships (i.e., those in which

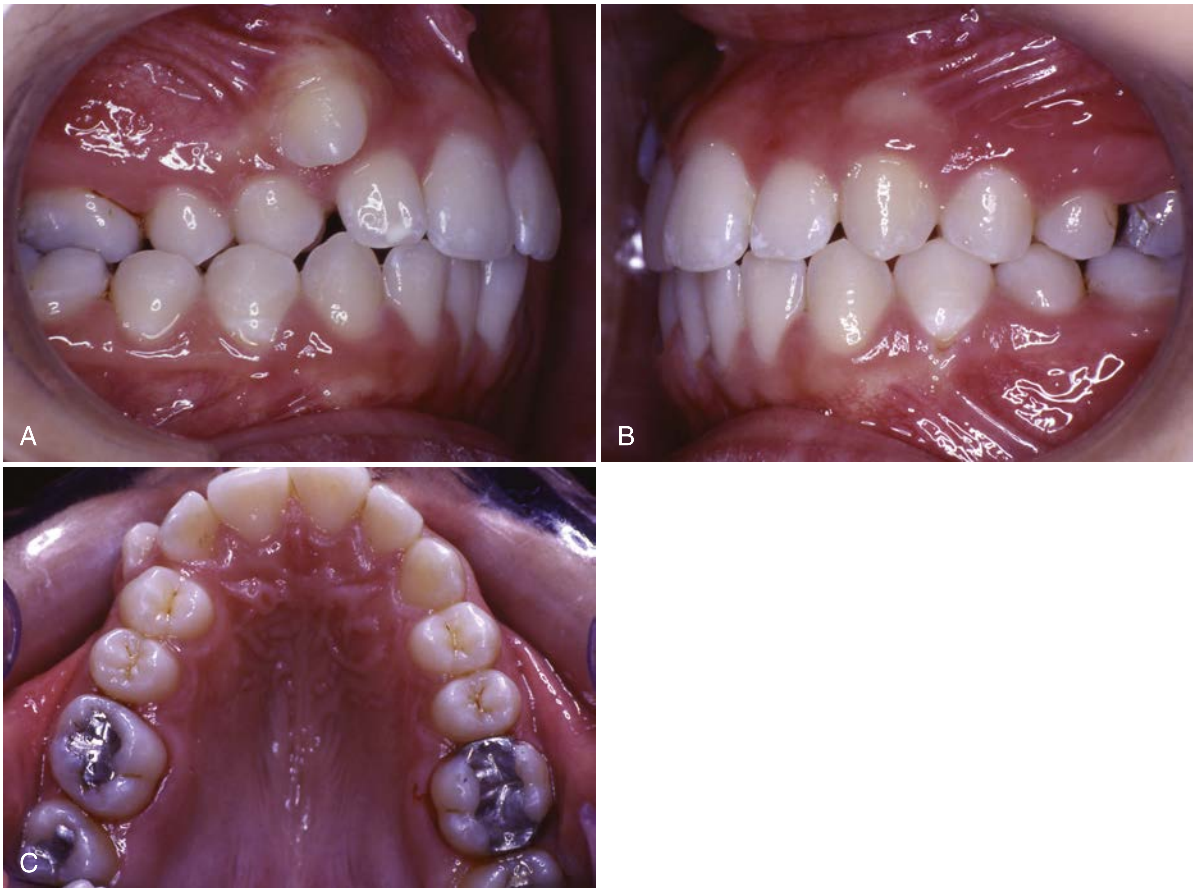

FIGURE 18-3 A–C, A malocclusion with Class II molar relationship on the right side and Class I molar relationship on the left side. A unilateral crossbite is present on the right side.

the palatal cusp of the upper molar sits in the central fossa of the lower molars) may be resolved simply by rotating the upper molars distally.

Upper second molars are usually triangular. Rotating these molars helps gaining additional space in the upper arch and facilitates distalization of the first molar. They therefore should be banded and moved as soon as possible. If needed, an extraoral force should be added on the first molars as soon as it can be easily inserted.

As a final objective, whereas the upper first molars occupy a wider part of the arch, the upper second molars are more lingually placed. For this reason, the activation of the PB on the first molars is different from the activation on the second molars. The premolars usually follow molars laterally in a distal direction because of the transseptal fibers. It should take 3 to 4 months to rotate the upper molars completely.

Expansion or Constriction. The PB can solve transverse problems such as crossbite and lateral overjet. These corrections should be made before rotating or distalizing the molars. Activation should be in the range of 1.0 to 1.5 mm of expansion or constriction per side and per activation until the problem has been corrected. If bodily movement is required, buccal-root torque (when expanding) or lingual-root torque (when constricting) must be added.

To correct a unilateral crossbite, a vertical elastic (to maintain occlusion on the normal side) and a cross elastic (to increase lateral movement of the abnormal side) are added to the expanded PB (Fig. 18-9). Premolars usually follow upper molars in the lateral movement, thus spontaneously correcting their position. In young patients, expansion with a PB may cause the palatal suture to open.

Vertical Control: Intrusion. Vertical control of upper molars is a peculiar aspect of this nonextraction mechanics. Most nonextraction approaches deal nicely with molar distalization but afford little or no vertical and transverse control. Control is needed in almost any case, but it is mandatory if nonextraction treatment is to be used in cases with a dental or skeletal open bite tendency.

The PB, alone or with a high-pull headgear, can be used to take advantage of the intrusive force exerted by the tongue during chewing, swallowing, and speech. The PB is kept low in the oral cavity, 4 or 5 mm away from the palatal vault. To increase the surface on which the tongue will be acting, two extra loops (Fig. 18-10) or an acrylic button can be added to the Coffin loop; this makes the PB more comfortable and effective.

By controlling molar eruption, or even more by intruding the molars, the orthodontist can correct or prevent vertical problems, obtain an upward and forward rotation of the mandible, and correct sagittal problems. In mixed dentition, the effect can be enhanced by grinding the occlusal of the primary molars (Fig. 18-11) as the upper permanent molars are kept away from the occlusion.

In a study conducted at the University of Ferrara, 13 male and 12 female patients, with an average age of 7.3 years (range, 6.7 to 8.5 years), with an anterior open bite due to various causes (i.e., thumb sucking, oral breathing, tongue thrust, and so on)

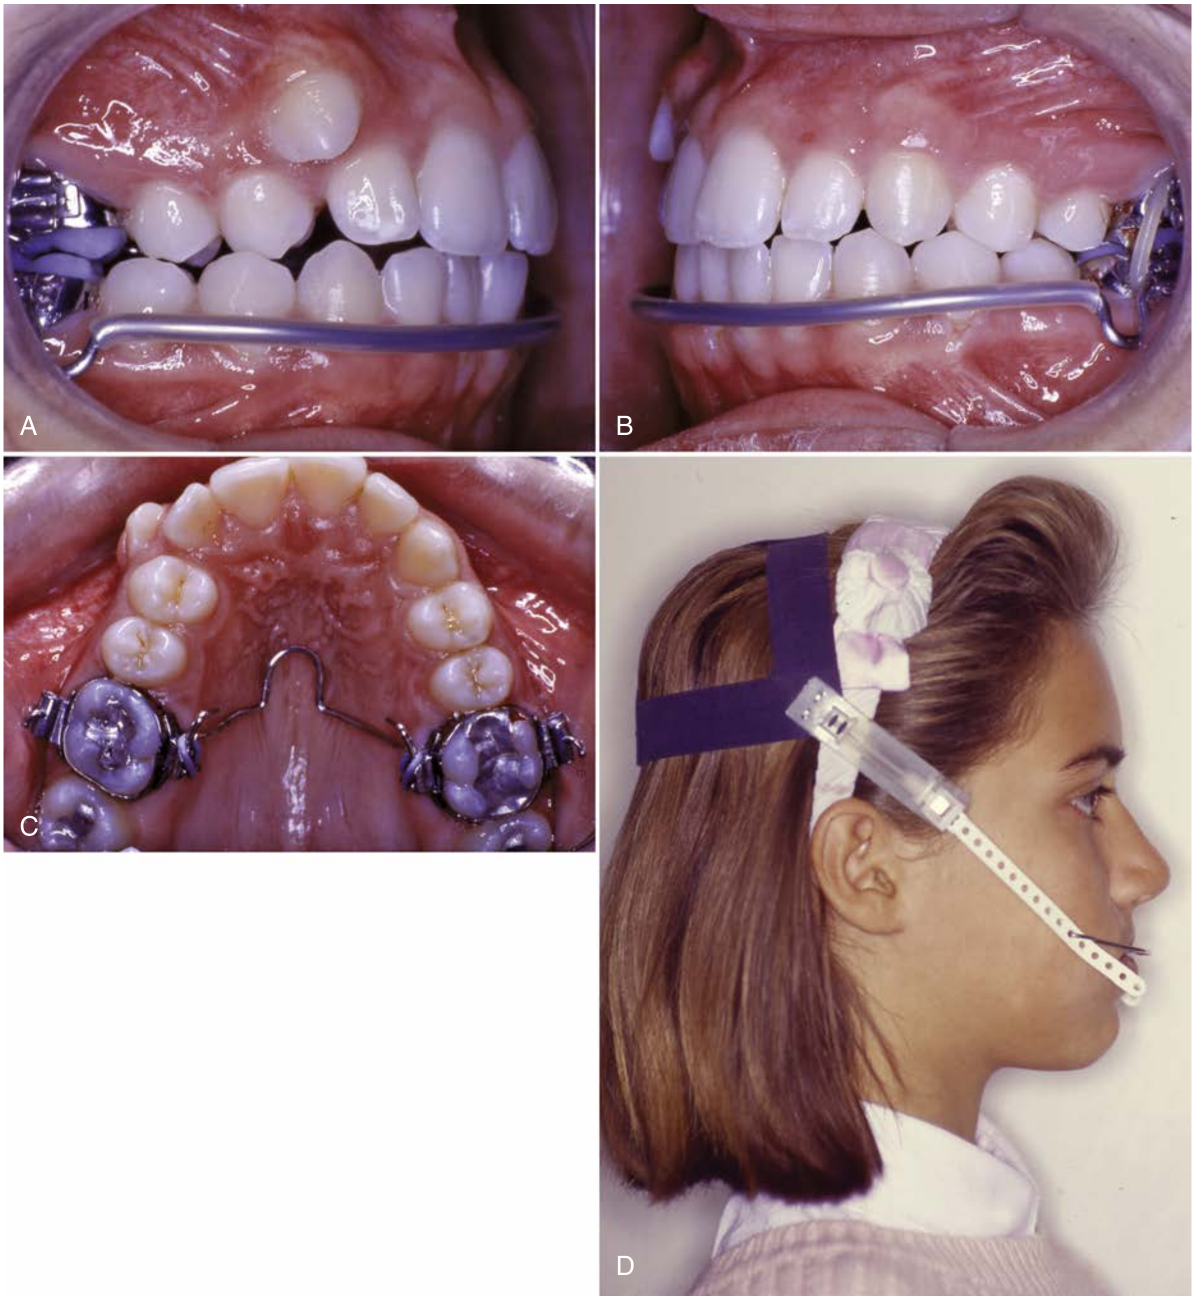

FIGURE 18-4 **A–D,** An expanded palatal bar with distal force on the right side is inserted. The lateral force is offset on the left side with a vertical elastic, and the rotational force is offset on the left side with the extraoral force.

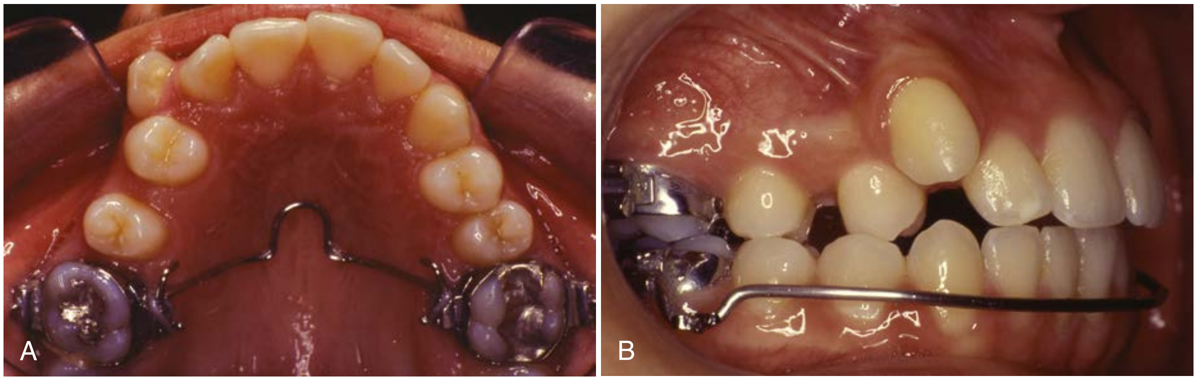

FIGURE 18-5 **A,** After a few activations, the upper right molar has been distalized and moved laterally to correct the Class II relationship and the crossbite. **B,** In the second situation, the palatal bar is activated first on one side and then on the other to obtain as much distalization as possible without the use of headgear or distalizing plate (see Figs. 18-7 to 18-9).

and a skeletal divergence were treated with a low PB, a high-pull headgear and progressive grinding of the primary molars to reestablish an occlusal contact between the upper and lower first molars. Treatment was carried out until the anterior open bite was closed (Figs. 18-12 and 18-13).

At this time, treatment was discontinued, and patients were reevaluated. Pretreatment and posttreatment cephalometric mean values revealed a reduction of both sagittal and vertical skeletal problems. Functional improvements were observed in all subjects. Space was gained in both the upper and lower arches in all cases. Changes during the interceptive treatment helped in a subsequent definitive phase II treatment to finish the cases without extracting teeth (Tables 18-1 and 18-2).

Torque. Several mechanics tend to extrude or to make more prominent molar palatal cusps (i.e., high-pull headgear, expansion, intrusion arches). Other mechanisms tend to extrude buccal cusps (i.e., cervical headgear, constriction). The PB allows an excellent control of upper molar torque. Buccal root torque is more often required because it helps keep palatal cusps high and away from occlusal interference (Fig. 18-14). This third order bend tends to extrude the upper molars. If control of the extrusive component is needed, the PB should be kept low and/or a high-pull headgear could be added to the upper molars.

Anchorage. After space has been created, control of the upper molars is crucial. In this biomechanical sequence, three-dimensional control is achieved with the BP alone or with the use of extraoral forces.

Extraoral Force

In this nonextraction approach, extraoral forces were used during most of the treatment. During the space-gaining phase, headgear was applied with the PBs and eventually with the removable plate to distalize upper molars in a bodily fashion. During the second phase, when the spaces were used to finish up the case, extraoral forces helped to maintain posterior anchorage. The two types of extraoral forces were:

1. The occipital force (high-pull headgear) used in all those cases where molar vertical control was important (i.e., malocclusions with dental open bite tendencies, hyperdivergent skeletal patterns, and biomechanical systems that tended to extrude upper molars). When used with the Cetlin plate, the high-pull headgear allowed a backward and upward bodily movement of the molars (Fig. 18-15, *A* and *B*).
2. The cervical force (low-pull headgear) used in cases involving a dental deep bite and a skeletal hypodivergent pattern or, generally, when vertical control of the upper molars was not crucial. When this appliance was combined to the removable plate, the molars were moved bodily backward and downward (Fig. 18-16, *A* and *B*). Forces of occlusion might limit the amount of extrusion, and favorable condylar growth could compensate for molar extrusion.

Clinical Management of Headgear

Extraoral forces were applied to upper first permanent molars as soon as the molars had been rotated with PBs, when facebows could be easily inserted into molar tubes. When headgear was used together with a PB, the inner bows had to be passive to molar tubes. When the headgear was used alone, the inner bows of the high-pull device should have been slightly constricted, but those of the low-pull device should have been expanded to prevent the upper molars from rolling out or in.

Facebows had to lie on lower lip. In this way, when traction units were applied, the facebow lay right at the level of labial rim and was comfortable for the patient (Fig. 18-17). If the facebow had two canine hooks on its inner bows, a light elastic (L10) could be applied to fit on the labial screen of the Cetlin plate to increase anterior anchorage.

Extraoral forces had to be about 150*g* per side to exert orthodontic and not orthopedic effects. The devices had to be worn at least 12 to 14 hours a day, and at each appointment, the headgear had to be checked to ensure that it was applying the desired force system. The facebow had to be kept a safe distance from the upper front teeth and the screen of the plate. For the patient's safety, the neck pad and the occipital cap had to have breakaway traction units.

The Class II relationship was corrected by moving the maxillary teeth distally until the patient closed in a super-, or over-corrected, Class I occlusion and mandibular forward growth had occurred. The maxillary molars were distalized initially, and the premolars and anterior teeth were treated later. Distalization was accomplished by the combination of (1) headgear and a PB or (2) headgear and the Cetlin Distalizing Plate.

Distalization was accompanied by rotation or overrotation of the molars, which significantly improved intercuspation (this technique is described in the following section).

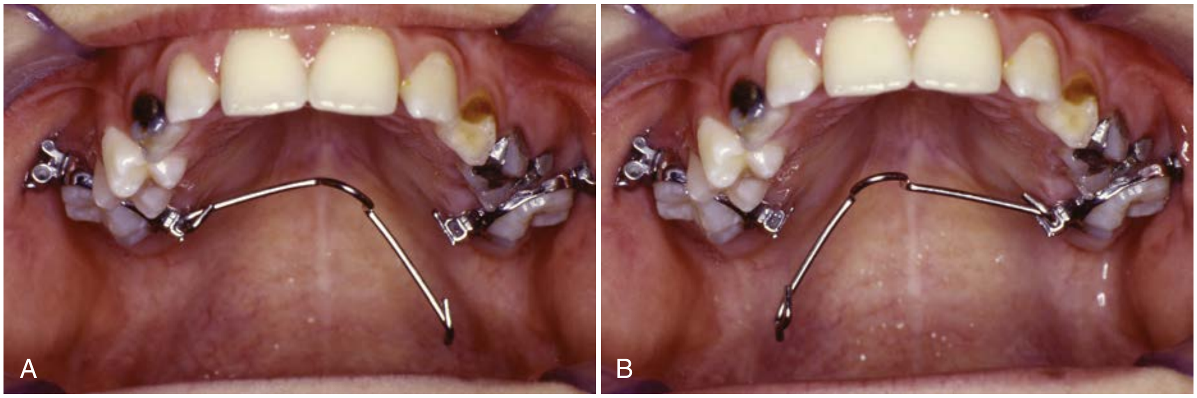

FIGURE 18-14 **A,** To achieve palatal root torque, both terminals are twisted so that when inserted into the right molar, the left (or opposite) terminal stands low to its sheath. **B,** When the transpalatal bar is inserted into the opposite side, it stands low to the right side.

The Removable Distalizing Plate

The removable distalizing plate was used to continue distalization of the upper molars when a "super Class I" relationship could not be obtained using only PBs and headgear. This plate was designed (Fig. 18-18) to apply a gentle, constant force of approximately 30*g* to the upper first permanent molars with minimal reaction on the upper front teeth. However, its forces might tend to incline molar crowns distally and extrude the molars. For this reason, it always had to be used in conjunction with an extraoral force to control molar roots, ensure vertical control, and thus obtain the desired distal bodily movement of the molars.

Clinical Management of the Distalizing Plate

The distalizing plate had to be worn 24 hours a day except for meals and hygiene. It always had to be used with the extraoral force to control molar roots and obtain a distal bodily movement. The springs had to be very lightly activated. An activation of 2.0 to 2.5 mm per side gave approximately 30*g* of distal force either bilaterally or adjusted on alternate sides, as it was done with the PB. Greater activation only increased the chance of molar tipping and loss of anterior anchorage, resulting in worsening of the overjet. Excessive spring force could dislodge the plate or cause it to fit loosely, exerting little distalizing force. The arm of the spring had never to

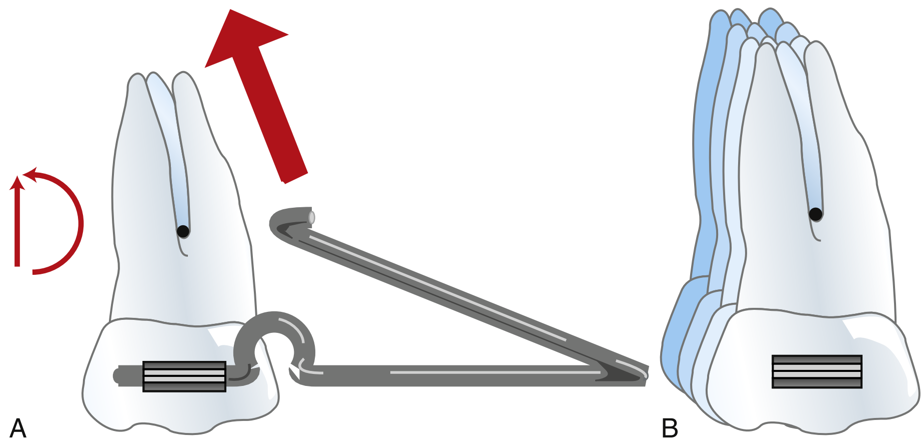

FIGURE 18-15 **A,** When the high pull is applied to upper first molars by means of a facebow with the outer bow the same length as the inner bow, the point of force application and the line of force lie above the center of resistance of the upper molar. **B,** When used with the Cetlin plate, the high-pull headgear allows a backward and upward bodily movement of the molars.

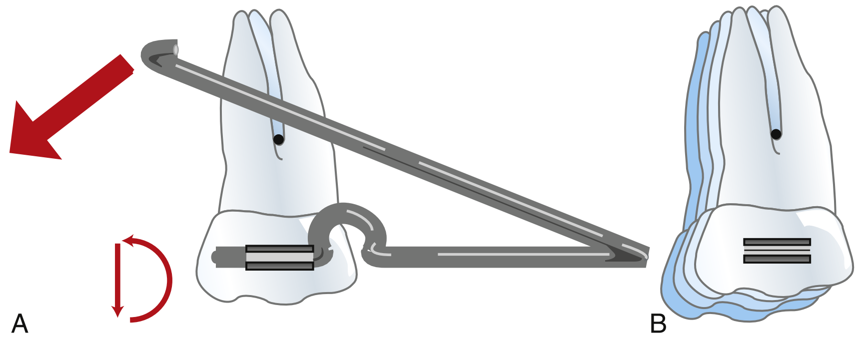

FIGURE 18-16 **A,** In cervical gear traction force the point of force application and the line of force lie above the center of resistance of the upper molar. **B,** When this appliance is combined to a removable plate, the molars are moved bodily backward and downward.

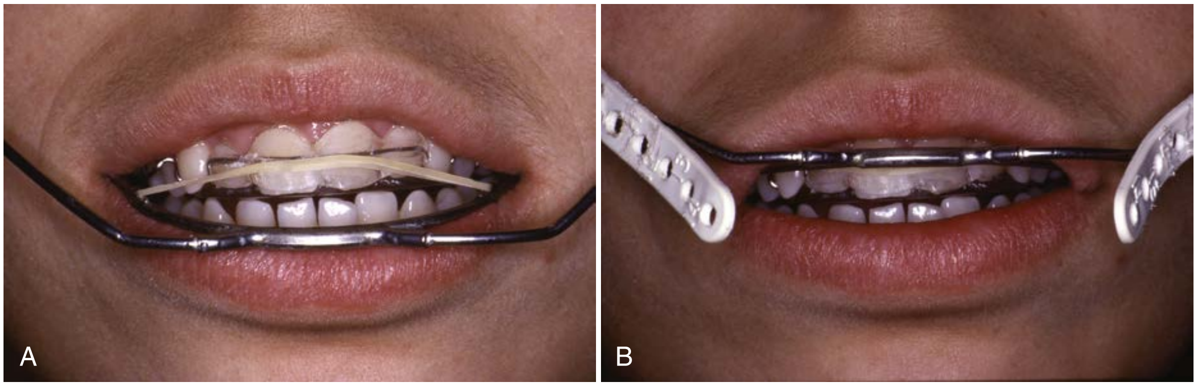

FIGURE 18-17 **A,** Facebow adjusted to lie on the lower lip. An elastic extends from the inner headgear bow to the labial aspect of the removable appliance to increase anterior anchorage. **B,** When traction is applied, the facebow goes to the level of the labial rim, which is more comfortable for the patient.

be bent buccally around the molars because this prevented spontaneous lateral movement of the molars. The anterior bite plane had to articulate with as many lower front teeth as possible and provide a small disclusion of posterior teeth (Fig. 18-19, *A* and *B*). It was not to be included in open-bite or hyperdivergent cases.

The acrylic of the plate had never to limit the distal movement of the molars and second premolars. After the first permanent molars had been brought to a super Class I relationship, the Adams clasps were removed, and the acrylic palatal to the canines and first premolars was trimmed to allow spontaneous distal movement of these teeth through the action of the transeptal fibers, with no strain on the anchorage. The patient had to continue to wear the plate with springs that were passive against the molars. Retention was provided by the labial shield, which was relined with cold-cure acrylic (Fig. 18-19, D).

FIGURE 18-18 The removable distalizing plate: anterior biteplate, molar distalizing springs, Adams clasps for the first premolars or deciduous molars, and labial screen, which covers the incisors.

To increase sagittal control of the upper front teeth, a groove was cut into the labial shield to engage a light anterior elastic attached to the inner bow of the headgear.

Lower Arch

Space gaining in the lower arch was accomplished with the lip bumper.

The objectives of the first phase of Cetlin's nonextraction approach in the lower arch were accomplishing rotation and upright positioning of the lower molars, leveling of the curve of Spee, encouraging lateral growth of the arch, and creating space to align all the teeth.[3]

Lip Bumper

The lip bumper is a fixed functional orthodontic appliance. It works by altering the equilibrium between cheeks, lips, and

FIGURE 18-19 A–E, Class II malocclusion with the upper canine blocked out of the arch. Distalization of the upper molars with a palatal bar, followed by the Cetlin distalizing plate and a cervical headgear. After having distalized the molars, the plate is left in place to prevent the upper molars from moving forward. A palatal bar is reinserted to allow spontaneous drift of all the teeth anterior to the distalized molars.

tongue and by transmitting forces from perioral muscles to the molars where it is applied (Fig. 18-20, *A–C*). The lip bumper has been used for various purposes:

- Molar anchorage[4]
- Therapy of habits[5,6]
- Space gaining in the lower arch.[7,8] The differences in results, which were published in the orthodontic literature,[9,10] probably are related to the fact that several types of lip bumpers are available, and they can be used in various ways.[11–13] Cetlin and TenHoeve[3] have described a lip bumper that is easy to use and very effective. All three purposes listed previously can be obtained with it. If used for an appropriate length of time, this lip bumper can help gain an incredible amount of space in the lower arch while maintaining good control of the molars and incisors (Fig. 18-20, *D* and *E*).

Characteristics of the Lip Bumper. The lip bumper was essentially composed of a 0.045-inch stainless steel wire that runs in the lower vestibule from molar to molar between teeth and lip and cheeks inserted in 0.045-inch molar tubes with 4-degree mesial offset to facilitate insertion.

Cetlin[3] has described two different lip bumpers. One type, which has been used since the early days of his practice, is custom made for each patient. It has two loops at the molar level that allow modifications of the appliance during therapy. The second type is preformed and available in different sizes (Fig. 18-21). It has four loops, two at the molar level and two at the canine level. The two additional loops give a better shielding effect in the canine region and allow the use of Class III elastics in more severe cases.

Fitting the Lip Bumper. The lip bumper must keep cheeks and lip away from the lower dentoalveolar area, and this shielding effect must be verified at each appointment. The lip bumper should not exert any expansion or contraction on the molars. It must be easy for both the clinician and the patient to insert and remove. As the arches anterior to the molars respond to the reshaping and widening of the lip bumper, they take on a wider natural arch form.

Guidelines are given next for obtaining an optimal adaptation of the appliance:

1. **Transverse position:** The wire must be 2.0 mm from the lower canines and 3.0 to 4.0 mm from the premolars. Protection of the canine area is crucial, and the four-looped bumper definitely is more effective.
2. **Sagittal position:** The lip bumper should not be more than 1.0 to 2.0 mm away from the labial surface of the lower incisors. The position offers good support of the lower lip for the anterior seal without rendering the appliance uncomfortable.
3. **Vertical position:** In the lateral segments, the wire must be positioned generally at the middle third of premolar and canine crowns. In the severest cases, in which good vertical control is necessary, the bumper can be adapted to rest deeper in the vestibule. The cheeks override the bumper

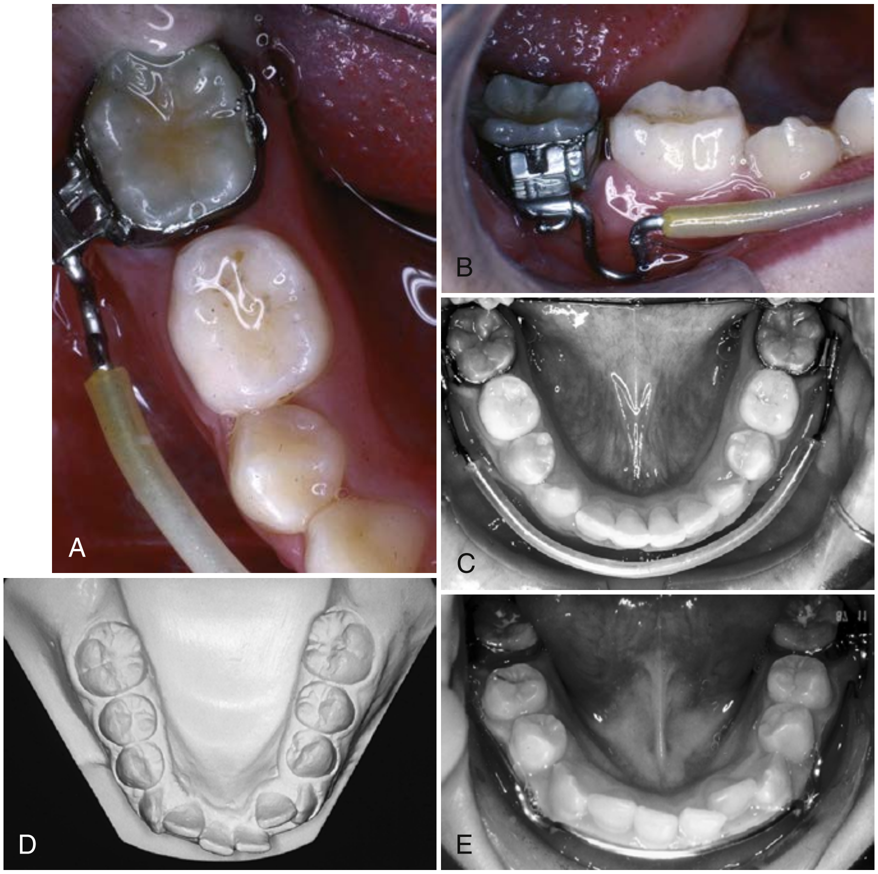

FIGURE 18-20 **A,** Occlusal view of lower right molar and lip bumper. **B,** Buccal view of lower right molar with lip bumper in place. **C,** Occlusal view of lip bumper placement in the mandibular arch. **D,** The mandibular arch before treatment. **E,** The same lower arch after 11 months of lip bumper wear. Note the space gained from dentoalveolar widening and reduction of incisor crowding.

during function, producing an intrusive force on the lower molars. In the anterior region, depending on the overbite, the bumper can be positioned at three different levels with respect to the incisor crowns.

- **Incisal edge:** This position usually is used during the initial phase of treatment. It helps to upright mesially inclined molars because the lower lip tends to lift the anterior part of the bumper, creating a long lever effect on the molars.
- **Middle third:** This is the position to use when a shielding effect on the incisors is desired. The lower lip is kept away from the teeth, altering the equilibrium in favor of the tongue. The incisors slowly translate labially.
- **Gingival level:** This level is used when the orthodontist does not want to alter the equilibrium between centripetal and centrifugal forces. Because the incisors are still under the lower lip action, they maintain their position. The lip bumper must be kept very close to the incisors.

Activating the Lip Bumper. After space has been obtained in the lower arch and bonding of the lower arch has been planned in a few appointments, the bumper can be activated to correct the rotation of the lower molars. A slight lingual bend is placed in one terminal (or both, if necessary), adding approximately 1.0 mm of expansion to counteract the lower molar tendency to tip lingually.

In a few circumstances, the appliance can be expanded if the lower molars are lingually inclined. The activation should not exceed 1.0 to 1.5 mm per side.

Clinical Management of the Lip Bumper. The appliance must be worn 24 hours a day and should be removed only for meals and hygiene. Although patient adaptation may not be optimal during the first month, the appliance should be worn as much as possible during that time. The two-looped bumper has the shrink tubing that gradually discolors as the patient wears the device. If cooperation is still a problem after a few months, the appliance can be tied to molar hooks with an elastic chain.

If the appliance has been well fitted, a red line can be seen on the inside of the cheeks and the lower lip where the wire runs. If the lip bumper is too distant from the teeth, ulcers may appear. In such cases, the appliance is removed for a day or two, lesions heal, and treatment is restarted with an appliance that runs closer to the teeth. At each appointment, the bumper is checked to ensure that it is still passive on the molars and that it maintains the desired distance from the teeth. This prevents undesirable mechanical expansive forces on the molars. At the end of the space-gaining phase, use of the bumper is discontinued. If it is needed for anchorage problems, it is readapted so that it does not contact brackets, while not being too procumbent.

FIGURE 18-21 Preformed lip bumper with four loops: two adjustment loops mesial to each molar and two in the canine area. The additional loops provide a better shielding effect in the canine area and can be used for Class III elastics in more severe cases. The custom-made bumper (shown in Fig. 18-20, *C*) has only two loops (mesial to each molar).

Class III Mechanics

If the upper arch has been overcorrected and the upper molars are in super Class I relationship but space is still needed in the lower arch, the lip bumper's action can be enhanced by the use of light (2–3 oz per side) Class III elastics that are driven from the upper first molars to the bumper's hooks at the canine level. Anchorage on the upper molar can be controlled with a PB, an extraoral force, or both. If lower second molars are present, it is better to bond them and put a sectional between the first and second molars; otherwise, a discrepancy may result between marginal ridges.

PHASE II: SPACE-UTILIZATION PHASE

Intrusion and retraction of the upper incisors concluded the nonextraction mechanics of Cetlin's approach. Depending on the inclination of the upper front teeth, the appropriate system was used to correct overjet and overbite without risking loss of molar anchorage and achieved buccal correction.

EVOLUTION OF THE TECHNIQUE

The Cetlin mechanics, as it has been just described, had some limitations because good cooperation of the patient for most of the treatment was required, and the use of removable appliances has some inherent inefficiency. Problems have been encountered mainly with the use of (1) the distalizing plate that needed full-time wear to obtain a bodily distalization of the upper permanent molars as well as a continuous disclusion between the two arches to achieve mandibular growth, leveling of the lower curve of Spee, and lateral dentoalveolar growth in both the upper and lower molar and premolar area and (2) the headgear that, even if it has always been considered the home appliance to be worn afternoon and night as much as possible, has often been a difficult-to-accept appliance.

Modifications have become necessary to overcome these problems of compliance. Clinical research has been carried out in four major directions:

1. Reduction of patient's compliance
2. Increase of the anterior anchorage
3. Reduction of molar resistance to distalizing force
4. Improvement of the archwire–bracket interaction

Reduction of Patient's Compliance

In the early 1990s, several distalizing intraoral appliances were described in the literature. Among them, the Pendulum Appliance presented by Dr. Hilgers seemed to fit perfectly in the Cetlin mechanics. It has replaced the Cetlin Distalizing Plate and, partly, the headgear.

The original Cetlin mechanics has not been dramatically changed. The use of the PB as the initial appliance in the upper arch has been kept for several reasons:

1. Correction of the first permanent molar position (rotation, torque, and so on) is more easily achieved by the use of a PB and no anterior anchorage is required.
2. Starting molar movement with a PB and then applying distalizing forces with a pendulum may give better anchorage control and make the pendulum more effective.

The pendulum as described by Hilgers has been slightly modified to better satisfy the therapeutic needs. The original appliance is anchored on all four premolars. In this way, the second premolars are not free to move distally and laterally together with the first permanent molars as with the Cetlin Distalizing Plate. For this reason, anterior anchorage has been limited to the first premolars. The applied force to distalize molars has been notably reduced to the level of the force produced by the Cetlin Distalizing Plate. An uprighting and expansion force has been added as described by Byloff et al. In this way, molars are distalized in a more bodily fashion, and the second premolars are free to move distolaterally together with the first molars thanks to the transseptal fibers as in the original Cetlin mechanics (Fig. 18-22).

The sequence of treatment has gradually changed in the following way:

- Crossbite correction, as well as rotation, distalization, and torque of upper molars with one or more PBs
- Molar distalization with the modified pendulum appliance
- Creation of a super Class I molar relationship

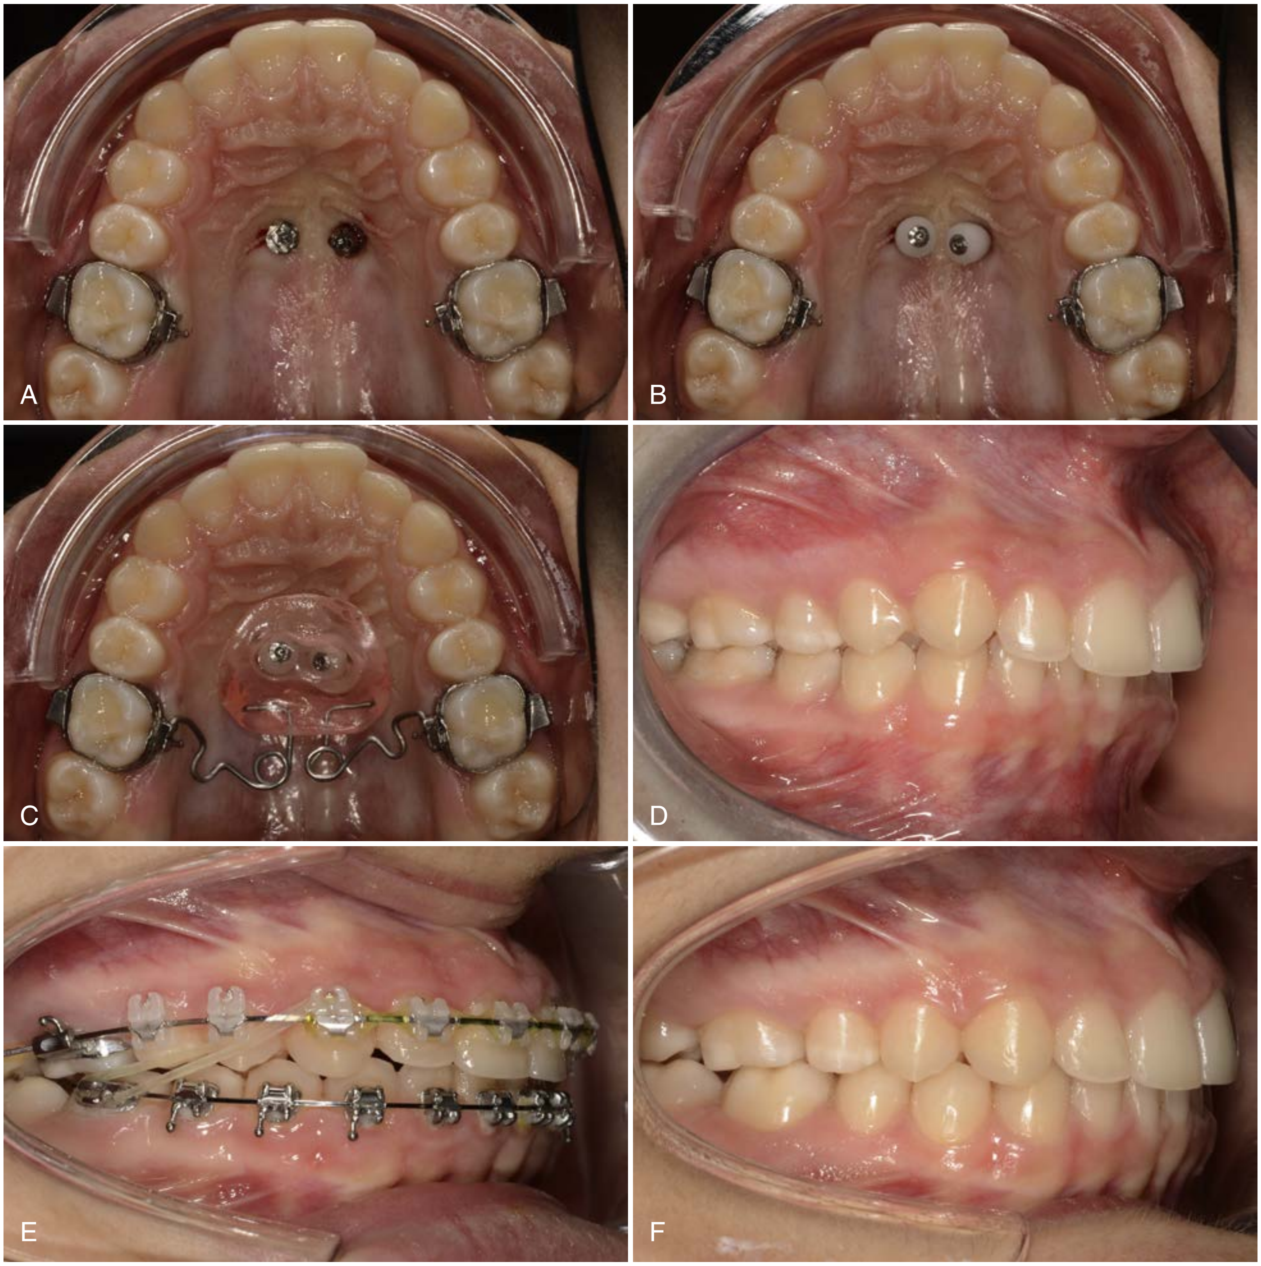

FIGURE 18-22 Pendulum with skeletal anchorage. A case in which molars were distalized with this type of appliance. **A–C,** Occlusal view of the Nance button screwed on the temporary anchorage devices, allowing easy insertion and removal for reactivation. **D–F,** Sagittal view of initial, progress, and final treatment.

- Molar anchorage and control with a PB with a "biscuit-like acrylic button" (Fig. 18-23) to upright and intrude molars and to allow spontaneous distal drift of premolars and canines

Several other similar appliances and procedures to distalize upper molars can be found in the current literature. They could be easily and effectively integrated in the Cetlin's nonextraction treatment of both growing and nongrowing patients.

Increase of Anterior Anchorage

The latest version of the Pendulum appliance is with two miniscrews placed in the palate in the first premolar region. The Nance button supporting the distalizing springs embeds two silicon caps that fit perfectly on the heads of the miniscrews. The Pendulum is placed and fixed onto the miniscrews with two small screws. In this way, it can be easily removed for spring reactivations. Skeletal anchorage helps with excellent control of the anterior teeth, allows spontaneous distal drift of all the premolars and canines, and allows earlier bonding of teeth for final positioning (Fig. 18-24).

Reduction of Molar Resistance to Distalizing Forces

Corticotomy has long been used in orthodontic treatment to accelerate dental movement and improve its efficacy and to reduce the appearance of undesired phenomena such as root resorption, loss of vitality, and relapse of the corrections carried out. In 2001, Wilcko et al.[14] published a case report in which corticotomy was used in conjunction with resorbable alloplastic grafts of demineralized freeze-dried bone to increase the amount of alveolar bone, regenerate the bone in the zone of dehiscence and fenestration, and avoid gingival recession resulting from expansion of the arches. These authors found that the fast orthodontic tooth movement was not due to repositioning of single tooth-bone units, as believed by Kole and Suya,[15] but to a cascade of physiologic events (area of transitory secondary osteoporosis and greatly reduced bone density) described by Frost as regional accelerated phenomena (RAP).

The surgical-orthodontic protocol, subsequently patented as Periodontally Accelerated Osteogenic Orthodontics (PAOO), claims as effects (1) accelerated tooth movement with reduction of the total treatment time, (2) osteogenic modifications with transportation of the bony matrix and final improvement of hard and soft tissue support of the teeth treated orthodontically, and (3) increase of the short- and long-term stability of the orthodontic treatment.

A large number of studies and case reports have been produced trying to give scientific evidence to these claims. As of today, six aspects seem to be important for effective and realistic use of alveolar corticotomy in an orthodontic treatment.

1. **Corticotomy has limited effect in time.** It seems that we can rely on a maximum 4 to 6 months of accelerated bone metabolism after decortication. For this reason, tooth movement may be accelerated only for a limited part of the therapy. Different aspects must be taken into account when we try to evaluate orthodontic treatment time.[16-19] A randomized clinical trial in which similar patients are treated with or

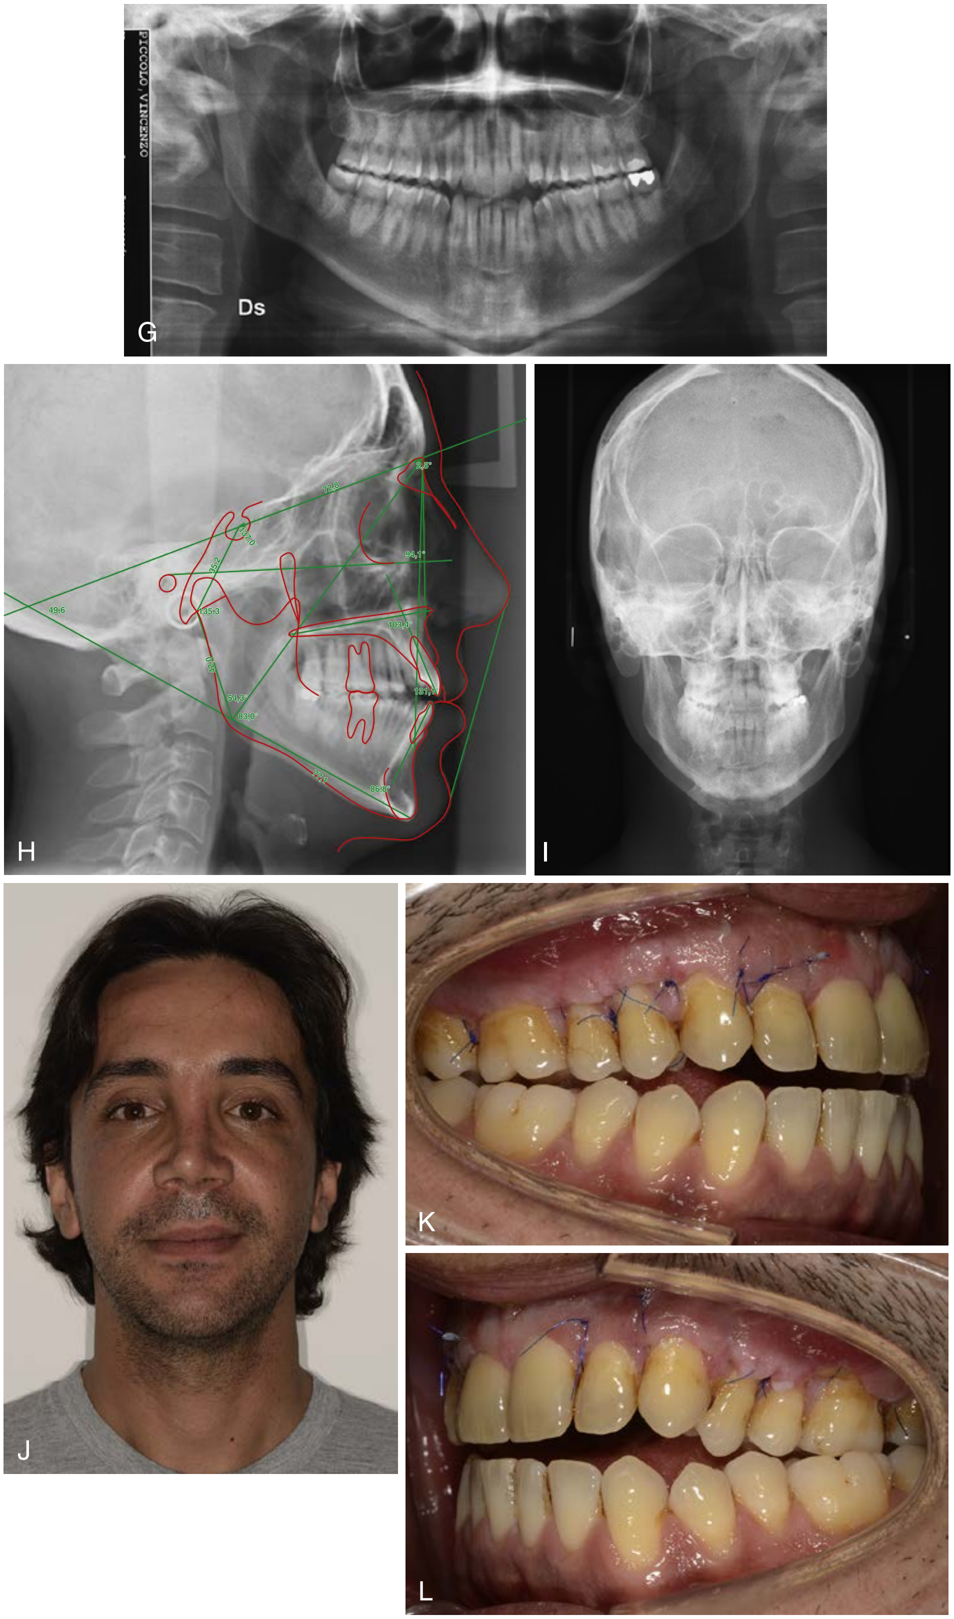

FIGURE 18-24, cont'd

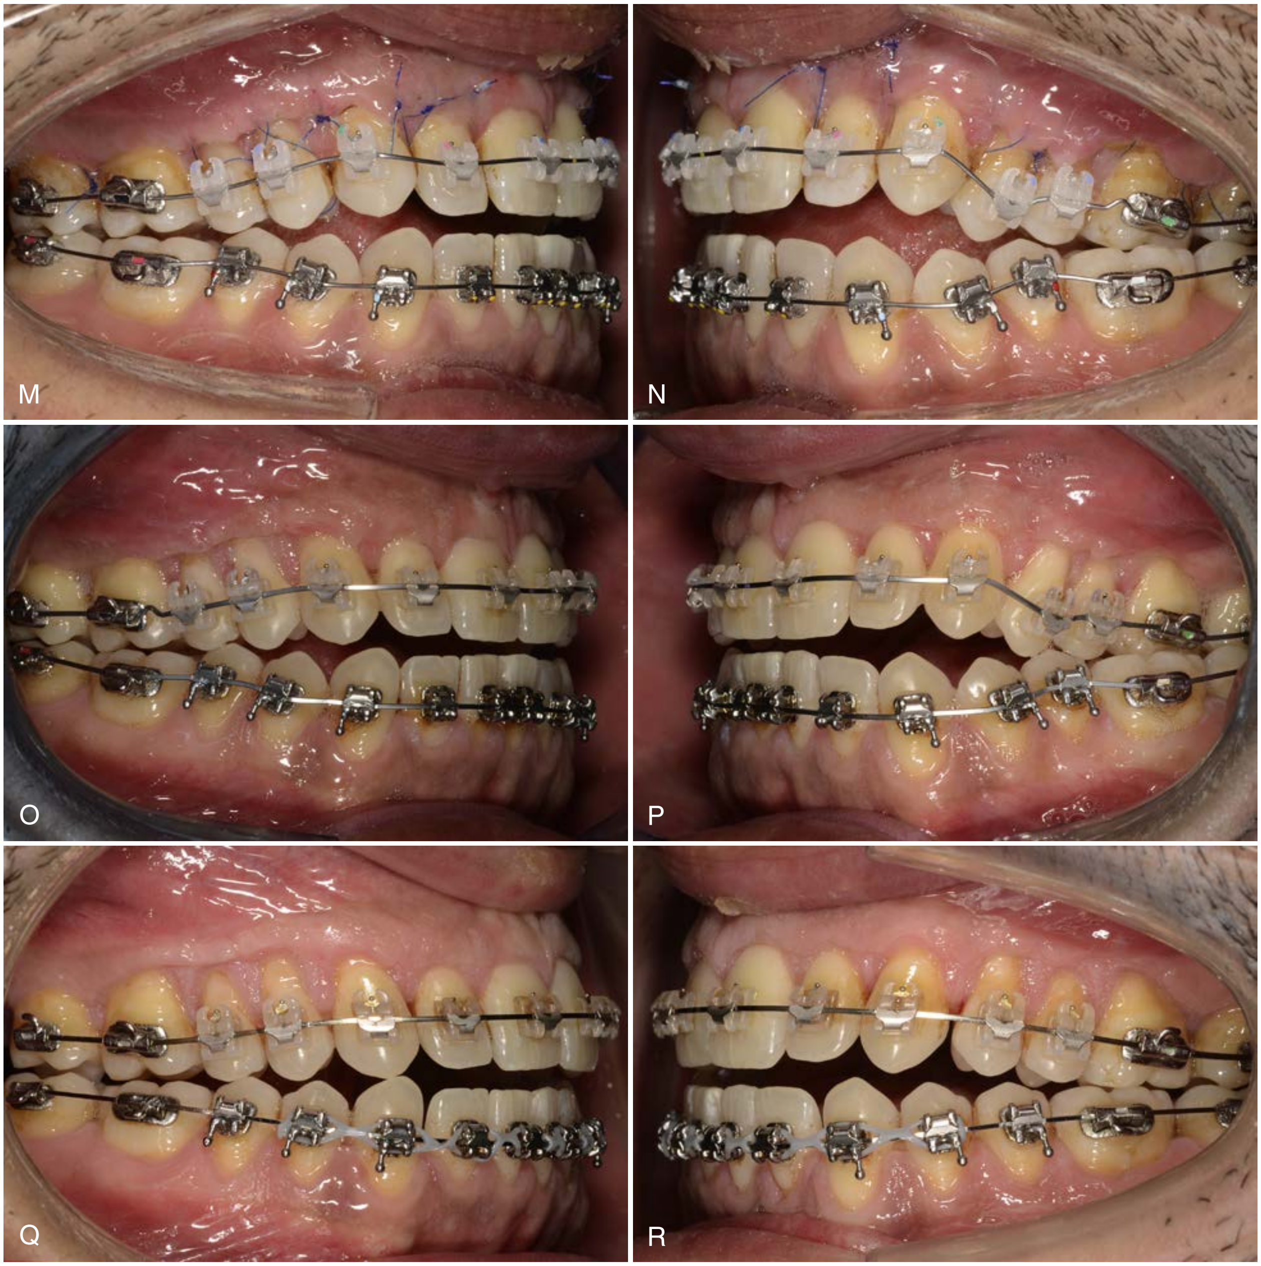

FIGURE 18-24, cont'd

without corticotomy using the same appliance and finished with the same quality of treatment result would be the only way to give the final word on this matter, but it has not been done yet.

2. **Corticotomy has limited effect in space.** It seems that the changes in bone metabolism caused by decortication are well correlated to the amount of the insult (the greater the insult, the greater the reaction), but they are restricted to the decorticated area.[20] This aspect is very important from an orthodontic point of view because it may affect the clinical and biomechanical effects of corticotomy on Orthodontic Tooth Movement (OTM): when moving multirooted teeth and when bodily translating a tooth, the outcome may not be as expected. This may be a limitation for surgeries that do not extend the surgical insult around the entire radicular area (both buccal and lingual) of the teeth to move.
3. **Corticotomy facilitates tooth movement.** Clinical research has been focused almost entirely on acceleration of tooth movement. It is the idea of the authors that corticotomies are mainly able to facilitate biomechanically complex orthodontic movements. Spena et al.,[21,22] in two studies made on a total of 12 adult patients with Class II malocclusions treated with distalization of the upper molars, showed how upper molars could be bodily distalized with simple buccal

mechanics and no anterior anchorage. Corticotomy was performed only on the teeth to move, thus reducing their resistance to distal forces and the anterior anchorage needs. Periodontally Facilitated Orthodontics (PFO) is preferred to PAOO to describe the advantages of alveolar corticotomies.

4. **Corticotomy needs proper surgical management.** Open flap surgery is preferred in most cases. The design of the flap should provide clear access to the area of decortication and a tension-free flap closure to provide optimal coverage of the decorticated area, the grafted material, and allow final soft tissue healing. Decortication of the alveolar bone is preferably performed with calibrated piezo blades and possibly extended around the entire root area of the teeth to move. Interproximal vertical cuts from 2 mm below the alveolar crest to 1 to 2 mm beyond the root apices are associated to horizontal cuts in the supra-apical area. The depth of the cuts is approximately 2 to 3 mm, just slightly extended into the medullary bone. Grafting is not always needed and may include hard tissue, soft tissue, or both. Thin gingival biotype, gingival recessions, dehiscences, fenestrations, and tooth movements that may cause periodontal problems are just some of the clinical situations that call for grafting with corticotomy.
5. **Corticotomy needs proper orthodontic management.** Orthodontic treatment associated with alveolar corticotomy may be carried out with any fixed or removable appliances. It is our choice to combine PFO procedures with fixed active self-ligating appliances (Inovation) with the new prescription of the Complete Clinical Orthodontics (CCO) System. The management and wire changes are similar to any orthodontic case. No initial heavy force is necessary. There is no rule as far as timing of the bonding: in some cases, appliances are placed at the suture removal, but in other cases (e.g., when distalizing upper molars or repositioning impacted teeth), they are placed several months before corticotomy. The enhanced tooth movement deriving from the RAP reaction is obtained when needed. The major difference is that after the periodontal surgery, the visits are every 2 weeks instead of the usual 6 to 8 weeks. During the RAP reaction, teeth will move faster and more easily, and what we usually see happen in 6 to 8 weeks will happen in less time. The idea is to get as much as possible from these metabolic changes after alveolar surgery, knowing that at some point, tooth movement will go back to a normal pace. PFO may be easily associated to skeletal anchorage devices. Whereas temporary anchorage devices are used to increase anchorage, corticotomies are to used reduce anchorage.
6. **Corticotomy has to have precise indications.** Corticotomy is not for every patient. Alveolar decortication should not be combined to orthodontic treatments with the only objective of accelerating OTM and reducing treatment time. Corticotomies should be used to facilitate biomechanically complex orthodontic movements, reducing their risks of periodontal and root damage and future instability.

Improvement of Appliance Efficiency

In the previous nonextraction sequence, after maxillary molars had been distalized, a generally long period followed to wait for spontaneous drift of premolars and canines. No apparent active treatment was carried out. Bonding of the arch was contraindicated because friction of brackets and archwires and ligatures would have jeopardized the spontaneous movement of teeth in an improved position and would have caused anchorage loss. If indicated, only intrusion of the maxillary incisors was initiated to remove the last obstacle to mandibular repositioning and growth.

The new self-ligating brackets combined with the light small wires seem to overcome these problems and allow bonding of the arches earlier without compromising spontaneous changes. At present, the self-ligating brackets are the best way to standardize force application, wire seating, friction deriving from the "fourth wall," and everyday clinical maneuvers when changing wires.

The new prescriptions for the active self-ligating brackets (Inovation) incorporated into the CCO System of Dr. Secchi, together with an efficient sequence of initial round thermal NiTi archwires, followed by square and rectangular thermal NiTi to complete correction of rotations, start expressing torque, and allow easy insertion of the stiff working archwires as the 0.019- × 0.025-inch and 0.021- × 0.025-inch stainless steel, allow better three-dimensional control of both anterior and posterior teeth during the treatment and finalization of nonextraction cases.

Two cases in which alveolar corticotomy with proper nonextraction treatment has been combined are shown in Figures18-23 and 18-24.

CONCLUSIONS

Nonextraction treatment mechanics as described by Cetlin has been proved to be a successful way of treating Class I and II malocclusions with crowding. The original mechanics needed to be updated to overcome problems related to patient cooperation and to take advantage of the new appliances and methods. Clinical research will continue to improve the efficacy of this unique therapeutic approach.

Standard Edgewise: Tweed-Merrifield Philosophy, Diagnosis, Treatment Planning, and Force Systems

James L. Vaden, Herbert A. Klontz, and Jack G. Dale

Nothing worthwhile ever departs.

OUTLINE

HISTORICAL PERSPECTIVE

An obsession for order motivated Edward Hartley Angle (Fig. 19-1) to create, in 1888, the Angle system. This system ultimately resulted in the introduction of the edgewise multibanded appliance 5 years before Angle's death, which has been the progenitor of all modern appliances.

THE ANGLE SYSTEM

Edward Angle, after graduation from dental school in 1878 and before his introduction of the Angle system in 1888, experienced many technical problems and frustrations in patient treatment that motivated and inspired him to develop a standard appliance.[1,2] He believed that an orthodontic appliance must have five properties:

1. **Simplicity:** It must push, pull, and rotate teeth.
2. **Stability:** It must be fixed to the teeth.
3. **Efficiency:** It must be based on Newton's third law and anchorage.
4. **Delicacy:** It must be accepted by the tissues, and it must not cause inflammation and soreness.
5. **Inconspicuousness:** It must be aesthetically acceptable.

Angle designed a standard appliance composed of a specific number of basic components (Fig. 19-2). He had these

FIGURE 19-1 Edward H. Angle.

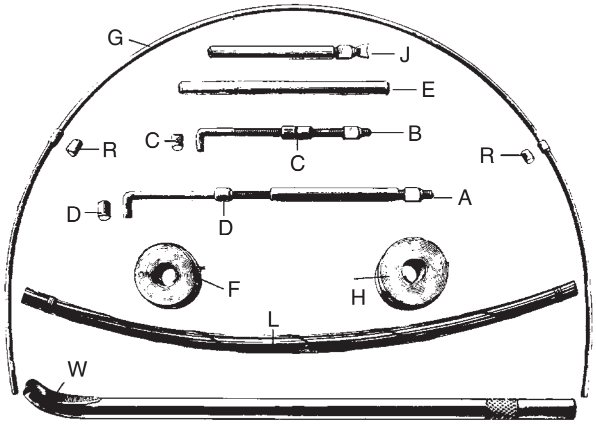

FIGURE 19-2 The basic components of Angle's standard appliance, illustrating traction screws (A, B), attachment tubes (C, D), jackscrews (E, J), lever wires (L), band material (F, H), archwire (G), wrench (W), and archwire lock (R). (From Angle EH: *Treatment of Malocclusion of the Teeth*. Philadelphia: SS White; 1907.)

components mass produced so that they could be assembled into a simple, stable, efficient, delicate, and inconspicuous treatment device, without difficulty, in less time and with minimal pain and discomfort to the patient. This universal application enabled practitioners to treat more patients at a higher level of excellence and at less cost than they had done previously. In effect, it was the beginning of a relationship among manufacturers, suppliers, and orthodontists; it was the Angle system.

THE EDGEWISE APPLIANCE

Two years before he died, with knowledge born from experience and gained from his other appliance inventions, Angle set out to devise an appliance that would not only overcome past difficulties but also would have a greater chance than did its predecessors of treating to "ideals." He changed the form of the brackets by locating the slot in the center and placing it in a horizontal plane instead of a vertical plane. The archwire was held in position first by a brass ligature and later by a delicate stainless steel ligature. The new edgewise bracket consisted of a rectangular box with three walls within the bracket, 0.022 × 0.028 inch in dimension. The bracket slot opened horizontally (Fig. 19-3). This new design provided more accuracy and thus a more efficient torquing mechanism.

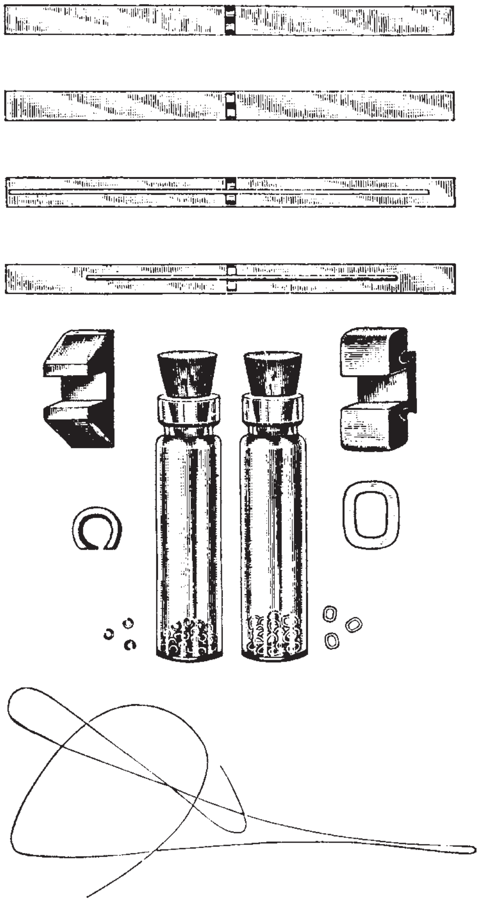

FIGURE 19-3 Original edgewise brackets.

Because Angle introduced the edgewise bracket only 2 years before he died, he had little time to teach its manipulation, develop it further, and improve its use—and he knew it.

CHARLES H. TWEED

When Charles H. Tweed graduated from an improvised Angle course given by George Hahn in 1928, he was 33 years old, and Angle was 73 (Fig. 19-4). Angle was bitterly disappointed by the reception that had been accorded the edgewise appliance. He was infuriated and bitter about the modifications that were being made by several of his graduates (e.g., Spencer Adkinson). To him, it was obvious that something had to be done if the edgewise appliance was to survive intact.

Angle decided that an article describing the appliance must be published in *Dental Cosmos*. He asked Tweed to help him with the article because Tweed had just finished the Angle "course" and because he admired and respected Tweed's ability.

FIGURE 19-4 Charles H. Tweed.

For 7 weeks, they worked together and in the process became close friends. During this time, Angle advised Tweed that he could never master the edgewise appliance unless he limited his practice solely to its use. And so with the completion of the article for *Dental Cosmos*, Charles Tweed returned to Arizona and established in Phoenix what was probably the first pure edgewise specialty practice in the United States.

For the next 2 years, the two men worked together closely. Tweed treatment planned and treated his patients, and Angle acted as his advisor. Angle was pleased with Tweed's treatment and was instrumental in getting Tweed on several programs. During these 2 years, in a series of more than 100 letters that are now housed in the Tweed Memorial Center Library, Angle urged his young disciple to carry out two vital requests: (1) to dedicate his life to the development of the edgewise appliance and (2) to make every effort to establish orthodontics as a specialty within the dental profession.

Tweed followed Angle's advice. First, he instigated the passing of the first orthodontic specialty law in the United States. He did this by canvassing patients, persuading dentists, influencing and arousing politicians, speaking at meetings, having petitions signed, and even taking patients before the legislature. In short, it was a one-man blitz. His untiring and relentless efforts were successful, and in 1929, the Arizona legislature passed the first law limiting the practice of orthodontics to specialists. Tweed received Certificate No. 1 in Arizona and became the first certified specialist in orthodontics in the United States.

In 1932, Tweed published his first article in the *Angle Orthodontist*. It was titled "Reports of Cases Treated with Edgewise Arch Mechanism."[3] Tweed held to Angle's firm conviction that one must never extract teeth. This conviction lasted for 4 years.

The facial aesthetics Tweed began to observe in his patients was discouraging to him, so discouraging in fact that he almost gave up orthodontic practice. He knew he had the appliance, and he knew he had the ability, but his results were aesthetically unsatisfactory and unstable. He devoted the next 4 years of his life to the study of his successes and failures. During this 4-year period, he made a most important observation: upright mandibular incisors frequently were related to both posttreatment facial balance and stability of the treated dentition. To position mandibular incisors upright, he concluded that one must, in many instances, extract teeth and prepare anchorage. He selected his failures, extracted four first premolar teeth, and retreated the patients. He did this without charging a fee.

In 1936, Tweed delivered a paper on the extraction of teeth for orthodontic malocclusion correction to the membership of the Angle Society and subsequently published it.[4,5] "Mother" Angle, the editor of the *Angle Orthodontist* and a member of the Angle Society, refused to attend the lecture. George Hahn, the man who went out of his way to create the opportunity for Tweed to take the Angle course, criticized him severely. Angle disciples considered Charles Tweed to be a traitor to the greatest man orthodontics had ever known. Tweed was crushed by the response, but he returned home determined to continue his research.

He worked even harder than before. By 1940, he had produced case reports, with four sets of records, of 100 consecutively treated patients who were first treated with nonextraction and later with extraction. He managed to get himself on the program of the next meeting of the Angle Society in Chicago, where he would present a paper and display his case reports.

Dr. Robert Strang, one of Angle's students in the early years, described the event this way:[6]

> *I noted that Dr. Charles Tweed was scheduled to be on the program of the meeting in Chicago. I planned to be there with the objective of lacing into him for violating Dr. Angle's sacred principle of non-extraction in treatment.*
>
> *Previous to reading his paper, Dr. Tweed had placed on tables before and after casts and photographs of one hundred consecutively treated patients. The results in all of these one hundred patients were magnificent and beyond criticism.*
>
> *Dr. Tweed read his well-written and illustrated paper. He explained his objective of keeping the teeth over basal bone, which made it necessary to extract teeth in many patients; however, it did produce stable results. Then he sat down. There was no applause. The room filled with shouted demands from the floor. For at least an hour, Charlie got the worst tongue-lashing that you can possibly imagine and not one word of praise for the beautiful results of treatment. Here was a student of Dr. Angle's violating the most fixed and rigid rule in his instruction—never extract teeth.*
>
> *During all this vicious attack, my mind took a complete turnover. I could visualize nothing but that marvelous exhibit of treated cases. Not one individual in the room had complimented the essayist. They were all ripping him to pieces for extracting teeth. Finally, I obtained the floor and complimented and defended him to the best of my ability. When I sat down, I, too, took a tongue-lashing that compared very favorably with the one Charlie had just received. Subsequently, I took his course, and practiced, taught and published his techniques in my textbook.*

Tweed's many contributions to the specialty established a benchmark in orthodontic thought and treatment. Most notable among his many contributions were the following:

1. He emphasized four objectives of orthodontic treatment: aesthetics, health, function, and stability, with emphasis and concern for balance and harmony of the lower face.

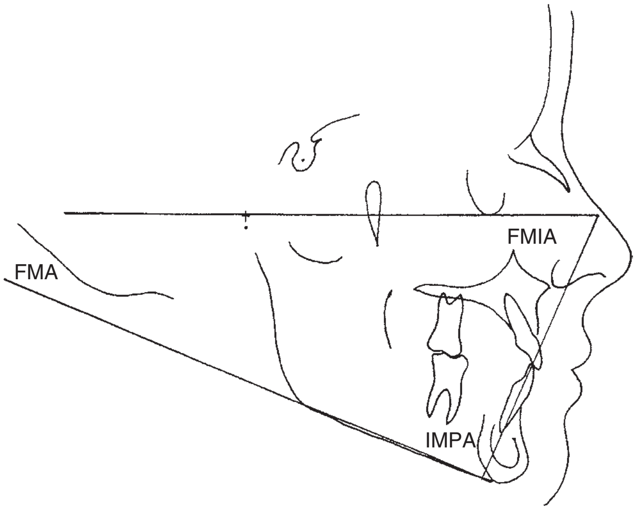

FIGURE 19-5 Tweed's diagnostic facial triangle. *FMA,* Frankfort mandibular plane angle; *FMIA,* Frankfort mandibular incisor axis angle; *IMPA,* lower incisor mandibular plane angle.

FIGURE 19-6 Levern Merrifield.

2. He developed the concept of positioning teeth over basal bone with emphasis on the mandibular incisors.[7]
3. He made the extraction of teeth for orthodontic correction acceptable and popularized the extraction of the first premolars.[8]
4. He enhanced the clinical application of cephalometrics.
5. He developed the diagnostic facial triangle[9] in order to make cephalometrics a diagnostic tool and a guide in treatment and in the evaluation of treatment results (Fig. 19-5).
6. He developed a concept of orderly treatment procedures and introduced anchorage preparation as a major step in treatment.[10]
7. He developed a fundamentally sound and consistent pre-orthodontic guidance program that popularized serial extraction of primary and, later, permanent teeth.

In addition to his many clinical contributions to the specialty, Tweed gave guidance, inspiration, and leadership to more orthodontists in the world than anyone else of his time. Because of Charles Tweed's skill and determination, the edgewise appliance became universally popular, and the practice of clinical orthodontics became a health service requested by the public.

Angle gave orthodontics the edgewise bracket, but Tweed gave the specialty the appliance. Tweed was considered the premier edgewise orthodontist of his day. Many who admired his results wished to learn his techniques. The orthodontic world journeyed to Tucson, Arizona, to take Tweed's course and learn his method of treatment with the edgewise appliance. The Tweed philosophy was born.

LEVERN MERRIFIELD

In 1960, Tweed selected one of his most outstanding students, Levern Merrifield, from Ponca City, Oklahoma, to continue his work on the edgewise appliance (Fig. 19-6). Tweed asked Merrifield to join him and be the codirector of his course. Merrifield took Tweed's course in 1953 and became a member of Tweed's staff in 1955. He became the course director at the time of Tweed's death in 1970. Merrifield devoted the remaining 45 years of his life to the study of orthodontic diagnosis and the use of the edgewise appliance. Merrifield's contributions have been disseminated and popularized. They include the following:

Diagnostic Concepts

1. The fundamental concept of dimensions of the dentition[11]
2. Dimensions of the lower face[12]
3. Total space analysis[13]
4. Guidelines for space management decisions to achieve the following:
   a. Facilitate maximum orthodontic correction of a malocclusion.
   b. Define areas of skeletal, facial, and dental disharmony.[14]

Treatment Concepts

1. Directional force control during treatment[15]
2. Sequential tooth movement
3. Sequential mandibular anchorage preparation[16]
4. The organization of treatment into four orderly steps that have specific objectives

   Merrifield's innovations in diagnosis and treatment planning and his experience with the edgewise appliance have augmented Tweed's contributions and concepts to give modern orthodontists a more accurate, reliable, precise, efficient, and practical protocol of diagnosis, treatment planning, and treatment. Adherence to this protocol allows the clinician to do the following:
   a. Define objectives for the face, the dentition, and the skeletal pattern.
   b. Properly diagnose the malocclusion and treatment plan the malocclusion correction.
   c. Use the edgewise appliance to reach predetermined objectives efficiently.

DIMENSIONS OF THE DENTITION

The clinical practice of orthodontics has always been based on the various dimensions of the dentition: height, width, and length (vertical, transverse, and sagittal). These dimensions allow the teeth to be moved in six directions: mesially, distally, facially, lingually, intrusively, and extrusively. All of these movements, which are accomplished routinely with orthodontic appliances, are limited and restricted by the physical environment of bone, muscle, and soft tissue, all of which exert an influence on the teeth and jaws.

Since the beginning of the orthodontic specialty, an effort has been made to determine the extreme limits of this environment. Each engineering change in appliance fabrication appears to bring about a new challenge to the physical limitations of the dentition's environment. Dimensions of the dentition includes four basic premises, *provided that the musculature is normal:*

Premise 1: An anterior limit exists. The teeth must not be placed forward, off basal bone. If the teeth are too far forward, all the objectives of treatment are compromised.

Premise 2: A posterior limit exists. Teeth can be positioned and/or impacted into the area behind the mandibular first molar in the mandibular arch, even as they can be moved too far forward off basal bone.

Premise 3: A lateral limit exists. If the teeth are moved buccally into the masseter and buccinator muscles, relapse is likely to result over the long term.

Premise 4: A vertical limit exists. Vertical expansion is disastrous to facial balance and harmony in the sagittal plane, except in deep-bite cases.

In summary, orthodontists must recognize the limitations of the dental environment and design treatment to conform to these dimensions when normal muscle balance exists.

DIFFERENTIAL DIAGNOSIS

Merrifield, in his effort to establish a sound diagnostic basis for directional force treatment with multibanded mechanotherapy, introduced diagnostic analyses that allow clinicians to determine (1) whether and when extractions are necessary and (2) if extractions are indicated, which teeth should be removed. His work enables the clinician to arrive at a differential diagnosis[17,18] instead of treating all extraction problems by the removal of four first premolars, as did Dr. Tweed. Merrifield's diagnostic philosophy can be outlined as follows:

1. Recognize and treat within the dimensions of the dentition. This means nonexpansion of malocclusions when normal muscular balance exists.
2. Recognize the dimensions of the lower face and treat for maximum facial harmony and balance.
3. Recognize and understand the skeletal pattern. Diagnose and treat in harmony with normal growth and developmental patterns, and optimize the less than normal pattern. After the major areas of disharmony are identified, all necessary and practical means should be expended to correct the problem.

Facial Disharmony

A study of the face and its balance or lack of balance must be the first concern during a differential diagnosis. The clinician must have an intuitive concept of a balanced face. Essentially, three factors influence facial balance or lack thereof: (1) the positions of the teeth, (2) the skeletal pattern, and (3) the soft tissue thickness.

Facial balance is influenced by protrusion and crowding of the teeth. Protruded teeth cause facial imbalance. The lips are supported by the maxillary incisor teeth. The upper lip rests on the upper two thirds of the labial surface of the maxillary incisors, and the lower lip is supported by the lower one third of the

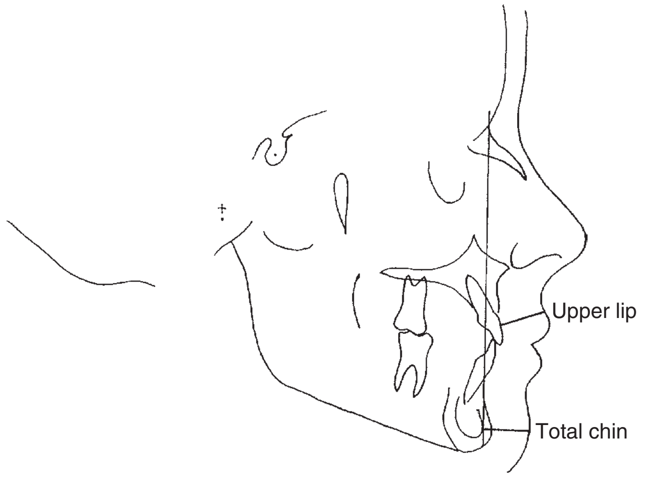

FIGURE 19-7 Upper lip equals total chin. Upper lip thickness should equal total chin thickness in a balanced face.

labial surface of the maxillary incisors; thus, lip protrusion is a reflection of the degree of maxillary incisor protrusion. Maxillary incisor position is related directly, of course, to the position of the mandibular incisors.

Facial disharmonies can often be the result of abnormal skeletal relationships. The clinician must understand the skeletal pattern and have the ability to compensate for abnormal skeletal relationships by changing the positions of the teeth.[19] The Frankfort mandibular plane angle (FMA) is a skeletal angular value that is crucial in differential diagnosis. Dental compensation for a patient with a high FMA requires additional uprighting of mandibular incisors. Lower facial balance for the patient with a high FMA can be improved dramatically by using this knowledge.

Conversely, dental compensation for a patient with a low FMA requires less mandibular incisor uprighting. Decisions regarding tooth position objectives must be made after a thorough study of the skeletal pattern.

Facial disharmonies that are not the result of skeletal or dental distortion are generally the result of poor soft tissue distribution.[20,21] Poor soft tissue distribution needs to be identified during differential diagnosis so that dental compensations can be planned. The millimetric measurements of total chin thickness and upper lip thickness are essential components in any study of facial balance. Upper lip thickness is measured from the greatest curvature of the labial surface of the maxillary central incisor to the vermilion border of the upper lip (Fig. 19-7). Total chin thickness is measured horizontally from the NB (Nasion-pt B) line extended to soft tissue pogonion. Total chin thickness should equal upper lip thickness. If total chin thickness is less than upper lip thickness, the anterior teeth must be positioned more upright to facilitate a more balanced facial profile because lip retraction follows tooth retraction.

Careful consideration of the positions of the teeth, the skeletal pattern, and the soft tissue overlay will give crucial information about the face and enable the clinician to determine whether dental compensations will improve facial balance. Before initiating tooth movement, the clinician must clearly understand its impact on the overlying soft tissue.[22]

The profile line and its relationship to facial structures and to the Frankfort plane can be used to give the orthodontic practitioner an idea of lip procumbency. If the profile line lies outside

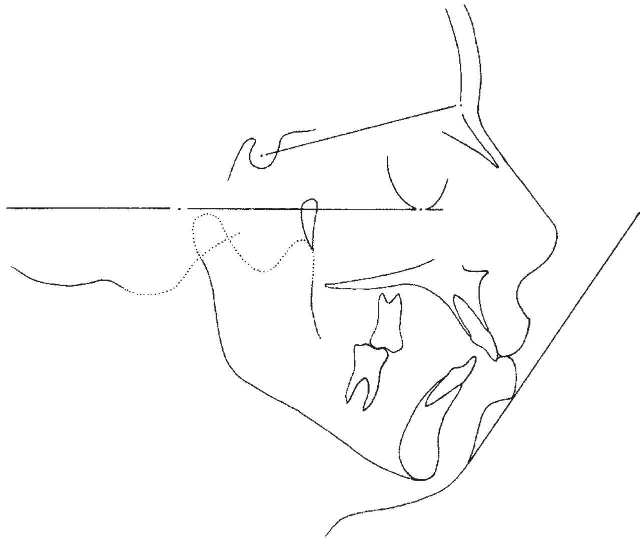

FIGURE 19-8 Profile line drawn on a protrusive face.

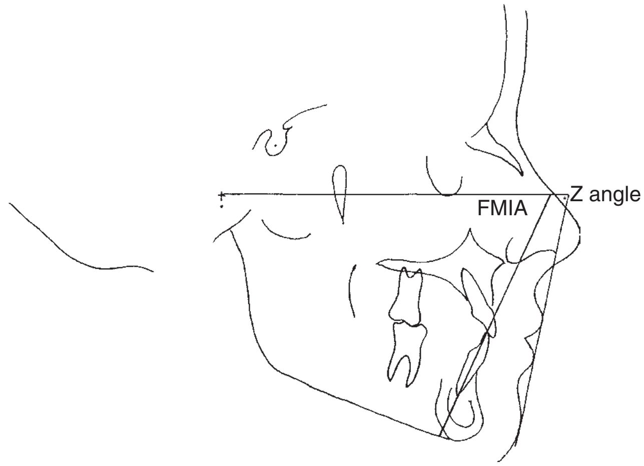

FIGURE 19-10 The Z angle and Frankfort mandibular incisor axis angle (FMIA). Tweed used the FMIA as an indicator of facial balance. Merrifield's Z angle quantifies balance of the lower face.

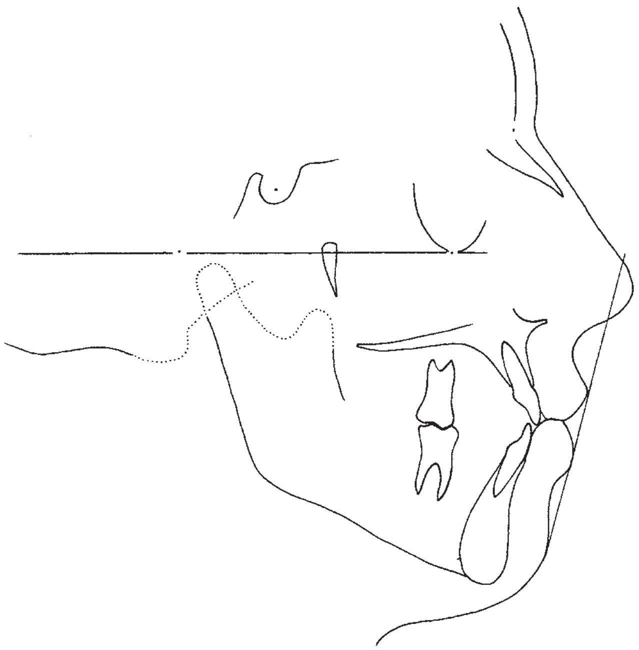

FIGURE 19-9 Profile line drawn on a facial profile that exhibits balance and harmony.

the nose, a protrusion exists (Fig. 19-8). When facial balance is present, the ideal relationship of profile line is to be tangent to the chin and the vermilion border of both lips, and it should lie in the anterior one third of the nose (Fig. 19-9). For centuries, the premise has been that this type of relationship of the profile line to the lips, chin, and nose reflects a pleasing and balanced appearance.

Similarly, on frontal view, the face should be balanced. The vermilion border of the lower lip should bisect the distance between the bottom of the chin and the ala of the nose. The vermilion border of the upper lip also should bisect the distance from the vermilion border of the lower lip to the ala of the nose. These relationships are universally accepted orthodontic standards for facial balance and harmony.

Several cephalometric angles quantify facial balance. Two that have been found to be useful are the Z angle and the Frankfort mandibular incisor axis angle (FMIA) (Fig. 19-10).

Z Angle

The chin/lip soft tissue profile line relationship to the Frankfort horizontal plane quantifies facial balance (see Fig. 19-10). The normal range is 70 to 80 degrees.[12] The ideal value is 75 to 78 degrees, depending on age and gender. This angle was developed to define facial aesthetics further and is an adjunct to the FMIA. The Z angle is more indicative of the soft tissue profile than the FMIA and is responsive to maxillary incisor position. Maxillary incisor retraction of 4 mm allows 4 mm of lower lip retraction and about 3 mm of upper lip response. Horizontal mandibular repositioning also affects this value. Vertical facial height increase, either anterior or posterior, can influence the Z angle.

The Z angle quantifies the combined abnormalities in the values of the FMA, FMIA, and soft tissue thickness because all have a direct bearing on facial balance. The Z angle gives immediate guidance relative to anterior tooth repositioning. If the patient has a normal FMA of 25 degrees, a normal FMIA of 68 degrees, and good soft tissue overlay distribution, the Z angle value should be about 78 degrees.

Frankfort Mandibular Incisor Angle

Tweed established a standard of 68 degrees for individuals with an FMA of 22 to 28 degrees. The standard should be 65 degrees if the FMA is 30 degrees or more, and the FMIA will increase if the FMA is lower. Tweed believed that this value was significant in establishing balance and harmony of the lower face (see Fig. 19-10).

The records of one patient shown in Fig. 19-11 graphically illustrate the facial aesthetics "issue" in orthodontics. The pretreatment facial photographs (Fig. 19-11) confirm an acceptable face. The casts (Fig. 19-12) reflect mild crowding and a very moderate Class II occlusion. The pretreatment cephalometric tracing (Fig. 19-13) shows skeletal and dental values that are "almost" normal.

The patient was treated for 18 months without regard for facial aesthetics (Fig. 19-14). The progress cephalometric

tracing (Fig. 19-15) illustrates mandibular incisor flaring and loss of vertical dimension control. Compare the pretreatment photos with the "progress" photographs (Fig. 19-16). Note the respective profile lines.

The patient's treatment plan was altered. Premolars were removed. The posttreatment facial photographs (Fig. 19-17) show a balanced face. The posttreatment casts (Fig. 19-18) illustrate a well-interdigitated occlusion. The posttreatment cephalometric tracing (Fig. 19-19) confirms mandibular incisors that are now in a proper position over basal bone. The pretreatment, "progress," and posttreatment facial photographs (Fig. 19-20) illustrate the Tweed-Merrifield concept of treatment planning for maximum balance and harmony of the lower face.

Cranial Disharmony

An analytic assessment of the skeletal pattern is an integral part of any diagnosis. A careful cranial analysis must include an understanding of the following information, which can be gleaned from a cephalogram (Figs. 19-21 and 19-22).

Skeletal Analysis Values

Frankfort Mandibular Plane Angle. The FMA is probably the most significant value for skeletal analysis because it defines the direction of lower facial growth in the horizontal and vertical dimensions. The standard or normal range of 22 to 28 degrees for this value reflects a skeletal pattern with normal growth direction. An FMA greater than the normal range indicates excessive vertical growth direction, and an FMA less than the normal range indicates deficient vertical growth.

Incisor Mandibular Plane Angle. The incisor mandibular plane angle (IMPA) defines the axial inclination of the mandibular incisors in relation to the mandibular plane. The IMPA is a good guide to use in maintaining or positioning these teeth in their relationship to basal bone. The standard of 88 degrees indicates an upright mandibular incisor position that with a normal FMA will ensure optimal balance and harmony of the lower face. If the FMA is above normal, the orthodontist must dentally compensate with more uprighting of the mandibular incisors. If the FMA is below the normal range, compensation can be made by leaving the mandibular incisors in their pretreatment position or, in rare instances, by positioning them more to the labial. Labial inclination of the mandibular incisors is generally limited to their original inclination if the patient has normal muscular balance.

Sella-Nasion-Subspinale Angle (SNA). The sella-nasion-subspinale (SNA) angle indicates the relative horizontal position of the maxilla to cranial base. The range at the termination of growth is 80 to 84 degrees for a white population sample.

Sella-Nasion-Supramentale Angle. The sella-nasion-supramentale (SNB) angle expresses the horizontal relationship of the mandible to the cranial base. A range of 78 to 82 degrees indicates a normal horizontal mandibular position. If the value is less than 74 degrees and a large maxillomandibular discrepancy exists, orthognathic surgery should be considered as an adjunct to orthodontic treatment. The same concern should be accorded to a value of more than 84 degrees.

Subspinale-Nasion-Supramentale Angle. The normal range for the subspinale-nasion-supramentale (ANB) angle is 1 to 5 degrees. This value expresses a very "treatable" horizontal

FIGURE 19-16 Pretreatment photographs with the "progress" photographs.

FIGURE 19-17 Posttreatment facial photographs.

relationship of the maxilla to the mandible. Class II malocclusions become proportionally more difficult with higher ANB angles. A patient with an ANB greater than 10 degrees will usually require surgery as an adjunct to proper treatment. The negative ANB angle is even more indicative of facial disproportion in the horizontal dimension. An ANB angle of −3 degrees or more, when the mandible is in its centric relation, indicates a possibility for the need of surgical assistance in Class III malocclusion correction.

Subspinale (Pt. A) perpendicular to occlusal plane; supramentale (pt. B) perpendicular to occlusal plane. Orthodontic treatment becomes more difficult when the AO-BO is outside the normal range of 0 to 4 mm. The AO-BO changes in direct proportion to the occlusal plane angle.

ANB	2	AFH	74 mm
AO-BO	–1 mm	Index	0.63

FIGURE 19-19 Posttreatment cephalometric tracing. See Figure 19-13 for abbreviations.

Occlusal Plane. The occlusal plane angle expresses a dentoskeletal relationship of the occlusal plane to the Frankfort horizontal plane. A range of 8 to 12 degrees is normal, with variations of about 2 degrees between males and females. The angle for females averages about 9 degrees and for males about 11 degrees. Values greater or less than the normal range indicate more difficulty in treatment. During most orthodontic malocclusion corrections, the original value should be maintained or decreased. An increase in the occlusal plane angle during treatment indicates a loss of vertical control. An increase is usually unstable because the occlusal plane is determined by muscular balance, primarily the muscles of mastication. The occlusal plane angle frequently returns to its pretreatment value when it is increased. The result is a detrimental relapse of the "corrected" interdental relationship.

Posterior Facial Height. Posterior facial height (PFH) is a linear millimetric measurement of ramus height from articulare to the mandibular plane tangent to the posterior border of the ramus. The value is related to facial form, vertically and horizontally. The relationship of PFH to anterior facial height determines the FMA and lower facial proportion. In a growing child with a Class II malocclusion, ramal growth change and its relationship to anterior facial height in proportion and in volume are crucial.

Anterior Facial Height. Anterior facial height (AFH) is a linear millimetric measurement of the vertical distance between the palatal plane and menton. The line is drawn perpendicular to the palatal plane. A value of about 65 mm for a 12-year-old individual indicates a normal anterior facial height. This vertical value must be monitored carefully if it is 5 mm more or less than normal. During Class II malocclusion correction, limiting an increase in AFH is essential and can be accomplished by controlling maxillary and mandibular molar extrusion in conjunction with an anterior "high-pull" force on the maxilla.

Facial Height Index. André Horn[23] studied the relationship of AFH to PFH. After developing the facial height index, he found that normal PFH is 69% of AFH. The normal range of PFH to AFH is 0.65 to 0.75. If the value is less than or greater than this range, the malocclusion is more complex, and the orthodontist will encounter more difficulty in correction. An index of 0.80 is severe and indicates a "low FMA" malocclusion caused by too much posterior ramal growth or too little anterior growth. As the index approaches 0.60, the skeletal pattern demonstrates too little posterior height or too much anterior height.

Facial Height Change Ratio. Radziminski,[24] Gebeck and Merrifield,[25,26] Issacson,[27] Pearson,[28,29] and Schudy[30] have described the important relationship between vertical dimension control and successful treatment of Class II malocclusions. After an evaluation of successfully and unsuccessfully treated Class II malocclusions, Merrifield and Gebeck[26,31,32] concluded that successfully treated patients exhibited favorable mandibular changes. These changes occurred in part because AFH was controlled while PFH increased. Unsuccessful treatment results were more likely to occur in patients in whom an increase was observed in AFH but not in PFH.

Craniofacial Analysis

For a period of about 15 years, until his untimely death in June 1993, Jim Gramling of Jonesboro, Arkansas, was the research director for the Charles H. Tweed Foundation. During those years, Gramling compiled a large sample of successfully and unsuccessfully treated Class II malocclusions.[33,34]

FIGURE 19-20 Pretreatment, "progress," and posttreatment facial photographs.

ANB, Subspinale-nasion-supramentale angle; *FMA,* Frankfort mandibular plane angle; *FMIA,* Frankfort mandibular incisor axis angle; *SNB,* sella-nasion-supramentale angle.

From the background of evidence gathered from these studies, Gramling formulated a probability index[35] for three specific purposes:

1. To augment diagnostic procedures
2. To guide treatment procedures
3. To predict possible treatment success or failure

Gramling statistically established a difficulty factor and assigned a specific number of points to each variable (Table 19-1).

In 1989, Gramling studied a different sample of 40 successful and 40 unsuccessful Class II malocclusion corrections.[36] After this study, he changed the "successful" FMA range of 18 to 35 degrees to 22 to 28 degrees (Table 19-2).

Using information from the previously described clinical research, the craniofacial analysis (Table 19-3), an integral component of the differential diagnostic analysis system, was developed. Each of the six cephalometric values used has been determined to have significant merit. In determining the difficulty of correction, the areas were weighted, taking into consideration the necessary diagnostic decisions and the complexity and importance of treatment management.

The FMA, the AFH/PFH ratio, and the occlusal plane to Frankfort angle are significant when used as a group. These values make up the vertical component of the craniofacial analysis. The vertical skeletal pattern can be a problem of excessive AFH in the presence of a decreased PFH, or conversely, a problem of excessive PFH and a decreased AFH. If facial height, anterior or posterior, is out of proper proportion, correction of the

malocclusion is more difficult, and one must take great care with treatment procedures so that the vertical disharmonies do not significantly worsen.

The horizontal skeletal component of the craniofacial analysis is composed of the SNB and the ANB. A high ANB caused by a low SNB makes the horizontal skeletal disharmony much more difficult to manage than if the high ANB is caused by an excessive SNA. The low SNB requires a treatment compromise or, if a more ideal result is desired, orthognathic surgery.

The previously described Z angle value is the only nonskeletal measurement in the craniofacial analysis. The Z angle was included because it is a facial reflector of craniofacial imbalance.

Dental Disharmony

Total Dentition Space Analysis

Along with a consideration of the face and the skeletal pattern, the orthodontist must consider the dentition (Table 19-4). Total space analysis as described by Merrifield[13] is divided into three parts: anterior, midarch, and posterior. This division is made for two reasons: (1) simplicity in identifying the area of space deficit or space surplus and (2) accuracy in differential diagnosis.

Anterior Space Analysis

Anterior space analysis includes the measurement in millimeters of the space available in the mandibular arch from canine to canine and a measurement of the mesiodistal dimension of each of the six anterior teeth. The difference is referred to as a surplus or deficit. Tweed's cephalometric discrepancy is used to further analyze this area. The cephalometric discrepancy is defined as the amount of space required to upright the mandibular incisors for optimum facial balance. This value is added to the anterior space measurement.

The sum of the anterior tooth arch surplus or deficit and the cephalometric discrepancy is referred to as the anterior discrepancy. Each of the values in the anterior discrepancy calculation has been given a difficulty factor so that an anterior space analysis difficulty value can be calculated.

TABLE 19-4 Total Space Analysis

Area	Value	Difficulty Factor	Difficulty
Anterior

Occlusal disharmony (Class II or Class III)	—	2	—
Posterior			
Tooth arch discrepancy	—		
Expected increase (–)	—		
Total	—	0.5	—
Space analysis total	—	Space analysis difficulty total	—

Midarch Space Analysis

The midarch area includes the mandibular first molars and the first and second premolars. The midarch is an important area of the dentition. Careful analysis of this area may show mesially inclined first molars, rotations, spaces, a deep curve of Spee, crossbites, missing teeth, habit abnormality, blocked-out teeth, tooth size discrepancies, and occlusal disharmonies. Careful measurement of the space from the distal of the canine to the distal of the first molar should be recorded as available midarch space. An equally accurate measurement of the mesiodistal width of the first premolar, the second premolar, and the first molar must also be recorded. To this value is added the space required to level the curve of Spee.[37] From these measurements, the orthodontist can determine the space deficit or surplus in this area.

Occlusal disharmony, a Class II or III buccal segment relationship, although not a part of the actual midarch space analysis, must be measured because an occlusal disharmony adds a great deal to the difficulty of correction of any malocclusion and requires careful treatment strategy and space management.

Occlusal disharmony is best measured by articulating the casts and by using the maxillary first premolar cusp and its relationship to the mandibular first premolar–second premolar embrasure as a reference. Measure mesially or distally from the maxillary first premolar buccal cusp to the embrasure between the mandibular first and second premolars. This measurement is made on both sides and is then averaged to determine the occlusal disharmony. The difficulty factor for occlusal disharmony is 2, so the averaged disharmony is doubled and added to the midarch difficulty because it has to be corrected by moving teeth that are in the midarch area of the dentition.

Posterior Space Analysis

The posterior dentition area is of great importance. The dentition has a posterior limit. Regardless of age, this posterior limit appears to be the anterior border of the ramus. The required space in the posterior space analysis is the mesiodistal width of the second molars and the third molars in the mandibular arch. The available space is more difficult to ascertain in an immature patient. It is a linear measurement in millimeters of the space distal to the mandibular first molars. The measurement is made from the distal of the mandibular first molar to the anterior border of the ramus along the occlusal plane. The posterior limit is recognized as being 2 to 3 mm distal to the anterior border of the ramus because of the lingual shelf that exists to accommodate the mandibular molars. However, teeth on the lingual shelf are not generally in good functional occlusion.

An estimate of posterior arch length increase based on age and gender is added to this value. Certain unpredictable variables must be considered in estimating the increase in posterior available space. These variables are the following:

1. Rate of mesioocclusal migration of the mandibular first molar
2. Rate of resorption of the anterior border of the ramus
3. Time of cessation of molar migration
4. Time of cessation of ramus resorption
5. Gender
6. Age

A review of the literature[38-40] reveals that the consensus from researchers suggests that 3 mm of increase per year occurs in the posterior dentition area until age 14 years for girls and age 16 years for boys. This is an increase of 1.5 mm per year on each side of the arch after the complete eruption of the first molars. In a mature patient (girls beyond 15 years and boys beyond 16 years), a measurement from the distal of the first molar to the anterior border of the ramus at the occlusal plane is a valuable determination of the space available in the posterior area. This measurement is important in diagnosis and treatment because it gives the clinician the ability to know whether a surplus or deficit of space exists in this area.

To create a posterior discrepancy while making adjustments in either the midarch or anterior area is not prudent. Equally imprudent is to not use a posterior space surplus to help alleviate midarch and anterior deficits. The most easily recognizable symptom of a posterior space deficit in a young patient is the late eruption of the second molars. If space is not available for these teeth by the age of their normal eruption, it should be obvious that a posterior space problem exists. The posterior space analysis surplus or deficit has been given a low difficulty factor of 0.5 because a posterior space deficit can be easily resolved with third molar removal.

Differential Diagnostic Analysis System

The two diagnostic tools that have been described, the craniofacial analysis and the total dentition space analysis, used together, make up the differential diagnostic analysis system (Table 19-5). Use of this diagnostic methodology will significantly improve the clinician's ability to diagnose, plan, and execute treatment. The sum of the craniofacial difficulty and the total dentition space analysis difficulty is called the *total difficulty*. This value gives the clinician a quantitative method of evaluating the difficulty of correction for each malocclusion. The analysis identifies the specific areas of major disharmony (i.e., facial, skeletal, and dental) and gives guidance for treatment strategy.

Other factors such as habit evaluation, joint health, muscle balance, dental or skeletal malrelationships, and other cephalometric values must be duly noted, evaluated by the orthodontist, and factored into any diagnosis. The orthodontist must also evaluate the patient's motivation and desire for correction of the malocclusion. The range of values for the total difficulty that have been found to be most appropriate when malocclusion correction difficulty is studied are as follows: mild, 0 to 60; moderate, 60 to 120; and severe, more than 120.

TWEED-MERRIFIELD EDGEWISE APPLIANCE

Brackets and Tubes

An appliance is an instrument used to achieve orthodontic goals. As Angle stressed, an appliance must have certain characteristics: simplicity, efficiency, and comfort. An appliance must also be hygienic and aesthetic and, above all, have a wide range of versatility. The neutral 0.022 slot edgewise appliance consists of posterior bands and anterior mesh pads with single, double-width 0.022 brackets on the six anterior teeth; intermediate single-width brackets on premolar bands; twin brackets on first molar bands; and heavy edgewise 0.022 tubes with mesial hooks on second molar bands (Fig. 19-23).

All bands have lingual cleats attached. Lingual cleats increase versatility and are especially necessary to correct and control rotations. Each of the brackets and tubes is placed at a right angle to the long axis of the tooth. The brackets are positioned precisely in relation to the incisal edges of the incisor teeth and the cusps of the remaining teeth. No tip, torque, or variations in thickness are present in the bracket. A slot size of 0.022 allows the clinician to use a multiplicity of archwire dimensions.

Archwires

Resilient edgewise archwire is used with the Tweed-Merrifield 0.022-inch edgewise appliance. The dimensions (in inches) of the wire commonly used are 0.017×0.022, 0.018×0.025, 0.019×0.025, 0.020×0.025, and 0.0215×0.028. These wire dimensions give a great range of versatility with the 0.022×0.028 bracket slot and allow the sequential application of forces as needed for various treatment objectives. The objective is to enhance tooth movement and control with the proper edgewise archwire at the appropriate time.

First-, Second-, and Third-Order Bends and Their Interaction

Knowledge of the action, interaction, and reaction of teeth to bends in the archwire is crucial to the use of any orthodontic appliance. Such knowledge is fundamental and dramatically affects clinical results.

First-Order Bends

The action and reaction of first-order bends affect expansion or contraction. These actions are monitored easily and are routinely used to move individual teeth. The interaction of the bends can affect the third-order position of the teeth if expansion forces are used.

FIGURE 19-23 Tweed-Merrifield edgewise appliance. The appliance is composed of neutral 0.022-inch edgewise slots with double-width brackets on the six anterior teeth, intermediate single-width brackets on the premolar bands, twin brackets on the first molars, and 0.022-inch tubes with mesial hooks on the second molars.

Second-Order Bends

Second-order bends in the posterior segment of the mandibular archwire are antagonistic to the teeth in the anterior segment. Without excellent directional control and a careful application of these second-order forces in a sequential manner, vertical control of the anterior teeth will be lost.

Second-order bends in the posterior segment of the mandibular archwire also negatively affect the third-order position of the mandibular anterior teeth. Therefore, the mandibular anterior teeth generally require lingual crown torque in the archwire because posterior second-order tipping bends apply labial crown torque force to the incisors. This fact must be given careful consideration in archwire fabrication and force application.

In the maxillary arch, second-order bends (an exaggerated curve of Spee) in the posterior segments are generally desirable or complementary to the teeth in the anterior segment. The reaction to the tipping forces intrudes the maxillary incisors and gives a lingual root torque effect to these teeth. This is generally positive or complementary to treatment objectives.

Third-Order Bends

Third-order bend reaction in the mandibular archwire is complementary to all the teeth if properly placed. The objective is to have some degree of lingual crown torque on all the mandibular teeth. The posterior and anterior segments work together in action, reaction, and interaction. The ideal third-order bends (lingual crown torque) in the mandibular archwire are as follows: incisors, 7 degrees; canines and first premolars, 12 degrees; and second premolars and molars, 20 degrees.

Conversely, third-order bends in the maxillary archwire are antagonistic. The anterior segment needs no torque (0 degrees), or it needs lingual root torque, and the posterior segment needs lingual crown torque: canines and first premolars (7 degrees) and second premolars and molars (12 degrees). Application of active third-order force simultaneously in segments with opposite third-order requirements is not wise. In the maxillary arch, applying active third-order bends sequentially and in only one direction at any given time is prudent.

Auxiliaries

The auxiliaries routinely used with the Tweed-Merrifield edgewise force system are elastics and directionally oriented headgear, primarily the high-pull J-hook headgear. Patient compliance with auxiliaries is imperative.

Variations of the Appliance

Many variations of the edgewise appliance have been introduced in the past 30 years. Most notable of the variations is the "straight wire" appliance (SWA) introduced in 1972 by Larry Andrews.[41] The SWA incorporates first-, second-, and third-order bends into the bracket. The theory behind this approach is that these bends will not have to be placed in the archwire. Another variation in the standard appliance is a decrease in slot size from 0.022 to 0.018 inch and even to 0.016 inch. Various orthodontic suppliers market numerous variations of the SWA with different tips and torques to suit the individual operator's desires. Other modifications have been extensively described by Burstone,[42] Lindquist,[43] and Roth.[44]

TREATMENT WITH THE TWEED-MERRIFIELD EDGEWISE APPLIANCE

Any treatment protocol must complement a diagnostic philosophy. Using Tweed's treatment concepts as a foundation, Merrifield developed force systems that simplify the use of the edgewise appliance. For example, Tweed used 12 sets of archwires during the treatment of each patient. Today, with the modern edgewise appliance, only three to five sets of archwires are used. Merrifield's sequential directional force technology[45-47] is simple, straightforward, and fundamentally sound. From the era of Tweed and into the era of Merrifield, the key to quality treatment with the edgewise appliance continues to be directionally controlled precision archwire manipulation. Essentially, five concepts compose the treatment philosophy: (1) sequential appliance placement; (2) sequential or individual tooth movement (or both); (3) sequential mandibular anchorage preparation; (4) directional forces, including control of the vertical dimension to enhance a favorable mandible to maxilla spatial change; and (5) proper timing of treatment.

Sequential Appliance Placement

The application of the appliance to the patient is important. In a first premolar extraction patient, the second molars and the second premolars are banded. Initially, the first molars are left unbanded. The central incisors, lateral incisors, and canines are bonded. Anterior teeth that are malaligned are not ligated to the archwire or are ligated passively. This method of sequential appliance placement is less traumatic to the patient and is easier and less time consuming for the orthodontist. The method allows much greater efficiency in the action of the archwire during the first months of treatment because it gives the posterior segment of the archwire much longer interbracket length. This length creates a power storage that accomplishes second molar movement more rapidly. Sequential appliance placement also gives the orthodontist the opportunity to insert a wire of larger dimension that is less subject to occlusal or bracket engagement distortion.

After the banded and bracketed teeth respond to the forces of the archwire and auxiliaries, the first molars are banded. The maxillary first molars are banded after one appointment. The mandibular first molars are banded after the second appointment.

Sequential Tooth Movement

Tooth movement is sequential. It is not the en masse movement that was introduced by Tweed. Individual teeth are moved rapidly and with precision because they are moved singly or in small units.

Sequential Mandibular Anchorage Preparation

Tweed attempted, with varying degrees of success, to prepare mandibular anchorage with Class III elastics. All the compensation bends were placed in the archwire at one time. Sequelae of this force system were often labially flared and intruded mandibular incisors. Sequential mandibular anchorage preparation, developed by Merrifield, is a system that allows mandibular anchorage to be prepared quickly and easily by tipping only two teeth at a time to their anchorage prepared position. This system uses high-pull headgear and anterior vertical elastics rather than Class III elastics for support. Unlike the en masse anchorage of the Tweed era, movement is controlled, sequential, and precise.

Directional Force

The hallmark of modern Tweed-Merrifield edgewise treatment is the use of directional force systems to move the teeth. Directional forces can be defined as controlled forces that place the teeth in the most harmonious relationship with their environment.

To use a force system that controls the mandibular posterior teeth and the maxillary anterior teeth is crucial. The resultant vector of all forces should be upward and forward to enhance the opportunity for a favorable skeletal change, particularly during dentoalveolar protrusion Class II malocclusion correction (Fig. 19-24). An upward and forward force system requires that the mandibular incisor be upright over basal bone so that the maxillary incisor can be moved properly (Fig. 19-25). For the upward and forward force system to be a reality, vertical control is crucial. To control the vertical dimension, the clinician must control the mandibular plane, palatal plane, and occlusal plane. If point B drops down and back, the face becomes lengthened, the mandibular incisor is tipped forward off basal bone, and the maxillary incisor drops down and back instead of being moved to a proper functional and aesthetic position (Fig. 19-26). The unfortunate result of point B dropping down and back is a patient with a lengthened face, a gummy smile, incompetent lips, and a more recessive chin.

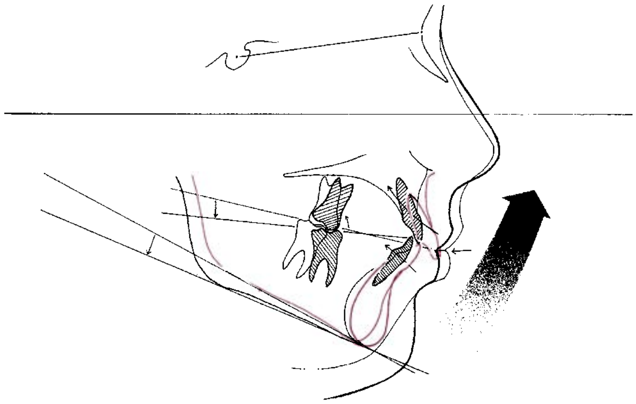

FIGURE 19-24 Upward and forward force system.

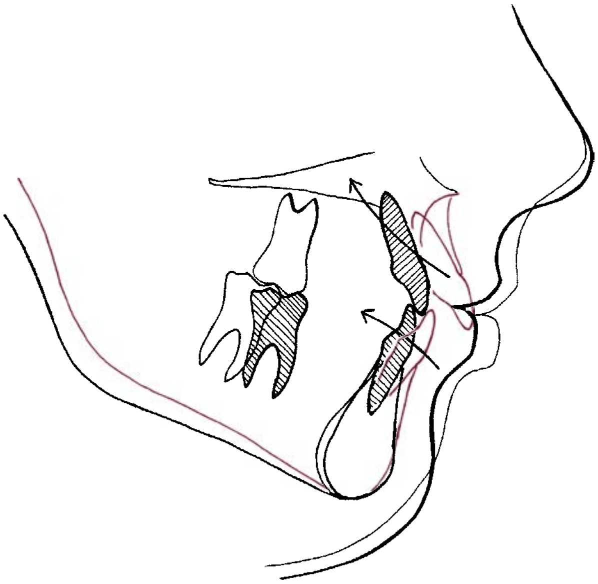

FIGURE 19-25 Upright mandibular incisor and maxillary incisor moved up and back.

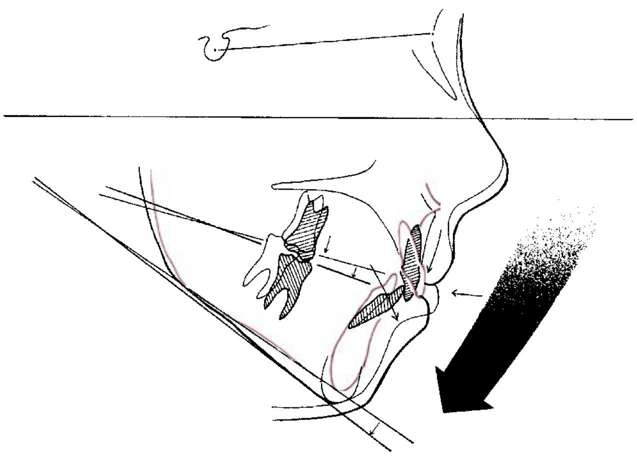

FIGURE 19-26 Downward and backward force system.

Timing of Treatment

The timing of treatment is an integral part of the philosophy. Treatment should be initiated at the time when treatment objectives can be accomplished most readily. This may mean interceptive treatment in the mixed dentition, selected extractions in the mixed dentition, or waiting for permanent second molar eruption before initiating active treatment. Diagnostic discretion is the determinant.

STEPS OF TREATMENT

Tweed-Merrifield edgewise directional force treatment can be organized into four distinct steps: denture preparation, denture correction, denture completion, and denture recovery. During each step of treatment, certain objectives must be attained.

Denture Preparation

Denture preparation prepares the malocclusion for correction. Objectives include the following:

1. Leveling
2. Individual tooth movement and rotation correction
3. Retraction of maxillary and mandibular canines

The denture preparation step of treatment takes about 6 months. One mandibular archwire and one maxillary archwire are used to complete this step.

The teeth of the original malocclusion are sequentially banded and bonded (Fig. 19-27). After the placement of the appliance, an 0.018- × 0.025-inch resilient mandibular archwire and a 0.017- × 0.022-inch resilient maxillary archwire are inserted. The omega loop stops are flush against the second molar tubes in each arch. The mandibular second molar receives an effective distal tip that will upright its mesial inclination. In the maxillary arch, a 20-degree tip is placed in the wire distal to the omega loop stop to maintain the distal inclination of the second molar. The objective in each respective arch is to maintain the maxillary molar in its distally tipped position and to begin to distally tip the mandibular second molar enough to level it into the arch.

A second premolar offset bend is placed mesial to the second premolar bracket in each archwire. The purpose of this bend is to prevent the canines from expanding labially as they are retracted with the headgear. The third-order bends in each

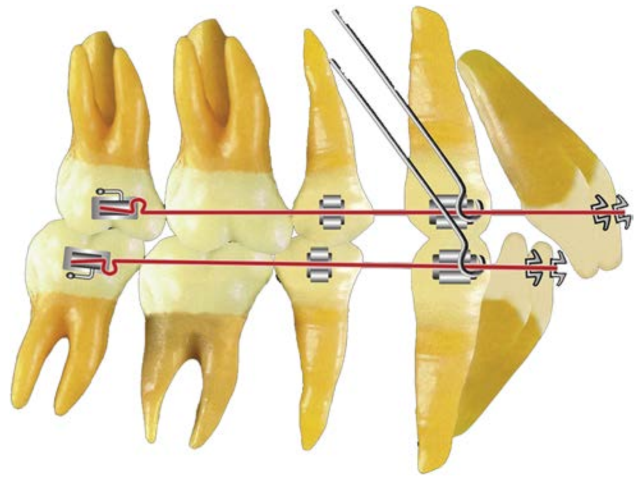

FIGURE 19-27 Denture preparation: Initial archwires consist of a 0.017- × 0.022-inch resilient maxillary archwire and a 0.018- × 0.025-inch resilient mandibular archwire.

archwire are ideal. High-pull J-hook headgear is used to retract maxillary and mandibular canines. After the first month of treatment, the maxillary first molars are banded, and after the second month of treatment, the mandibular first molars are banded. As the canines retract and the arches are leveled, the lateral incisors are ligated, and power chain force to aid canine retraction can be used (Fig. 19-28).

One must remember that at each visit during denture preparation, the archwires are removed; carefully coordinated; checked for proper first-, second-, and third-order bends; and religated. Canine retraction is continued with power chain and headgear force. At the end of the denture preparation stage of treatment, the dentition should be level, the canines should be retracted, all rotations should be corrected, and the mandibular second molars should be level (Fig. 19-29).

Denture Correction

The second step of treatment is called denture correction. During denture correction, the spaces are closed with maxillary and mandibular closing loop archwires. Vertical support to the maxillary arch is achieved with J-hook headgear attached to hooks soldered to the maxillary archwire between the maxillary central and lateral incisors. Vertical support of the mandibular anterior teeth is accomplished with anterior vertical elastics. The mandibular archwire is a 0.019- × 0.025-inch working archwire with 7.0-mm vertical loops distal to the lateral incisor brackets. The 0.020- × 0.025-inch maxillary archwire has 7.5-mm vertical loops distal to the lateral incisor brackets. In both arches, the omega loop stops are immediately distal to the brackets of the first molars (Fig. 19-30). The maxillary archwire is coordinated with the mandibular archwire. The archwires are activated each month until all space is closed. At the end of space closure (Fig. 19-31), the curve of occlusion in the maxillary arch should have been maintained, and the mandibular

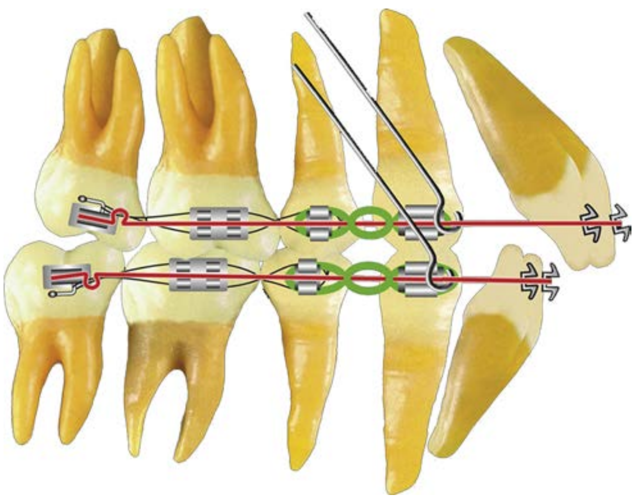

FIGURE 19-28 Denture preparation: The canines are retracted with a J-hook headgear during denture preparation.

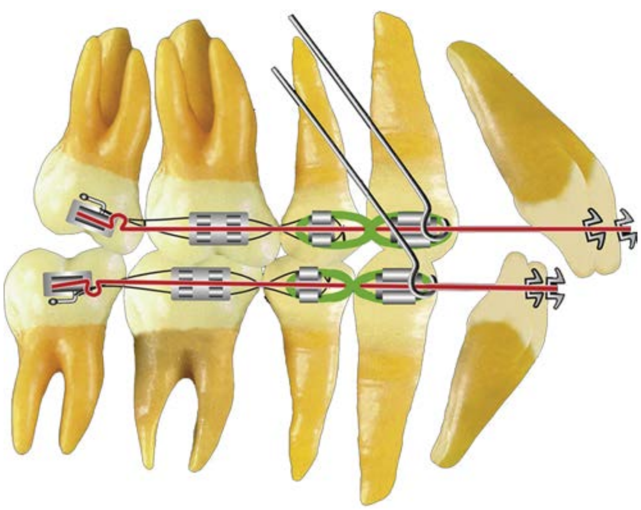

FIGURE 19-29 Denture preparation: At the end of denture preparation the arches are level, rotations are corrected, and the canines are retracted.

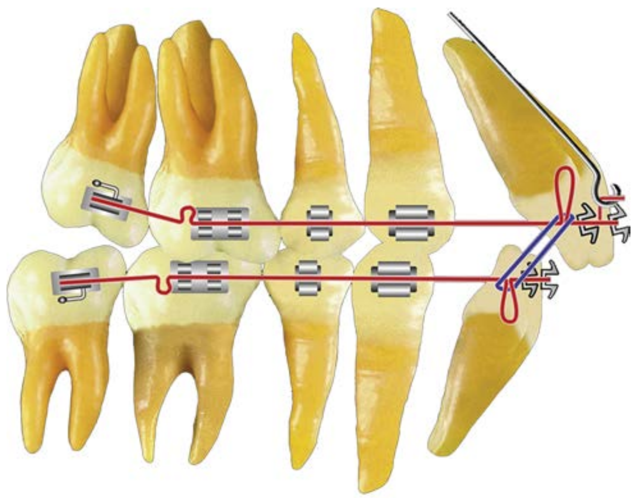

FIGURE 19-30 Denture correction: Maxillary and mandibular closing loops are used to close the space mesial to the distalized canines.

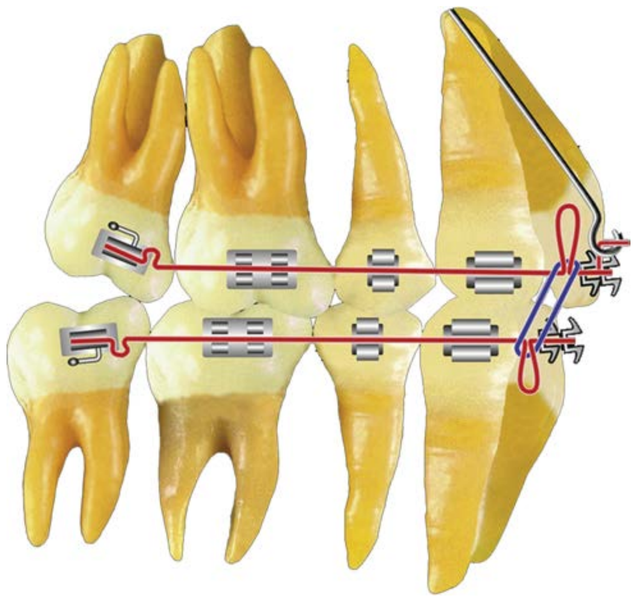

FIGURE 19-31 Space closure. The arches are level, and all spaces are totally closed.

arch should be completely level. The dentition is now ready for mandibular anchorage preparation. This step positions teeth in the mandibular midarch and posterior areas into axial inclinations that will allow final coordination with the maxillary teeth for normal functional occlusion.

Sequential Mandibular Anchorage Preparation

Sequential mandibular anchorage preparation is based on the concept of sequential tooth movement. The archwire produces an active force on only two teeth while remaining passive to the other teeth in the arch. Therefore, the remaining teeth act as stabilizing or anchorage units as two teeth are tipped. The method is referred to as the "10-2" (10 teeth vs. 2 teeth) anchorage system, and it allows a quickly controlled response without serious adverse reaction. The anchorage preparation system is supported by anterior vertical elastics attached to spurs that are soldered distal and gingival to the mandibular lateral incisors. The elastics are hooked to the closing loops of the maxillary archwire. They are supported by a high-pull headgear that is attached to hooks soldered to the maxillary archwire.

After closing the mandibular space, the mandibular arch must be level. At this time, the first step of sequential mandibular anchorage preparation, second molar anchorage, is initiated. Another 0.019- × 0.025-inch archwire with the omega loop stops bent flush against the second molar tubes is fabricated. First- and third-order bends are ideal. Gingival spurs for anterior vertical elastics are soldered distal to the lateral incisors.

To tip the mandibular second molars to an anchorage prepared position, a 15-degree tip is placed distal to the omega loop stop. The second molar is tipped to an anchorage prepared position. It should have a distal inclination of 10 degrees to 15 degrees, which can be verified with a readout (Fig. 19-32, *A*).[48]

After the second molar has been tipped, the first molar is tipped to its anchorage prepared position by placing a 10-degree distal tip 1 mm mesial to the first molar bracket. When this first molar tip is placed in the archwire, a compensating bend that maintains the 15-degree second molar inclination must be placed mesial to the omega loop stop (Fig. 19-32, *B*).

The archwire is now passive to the second molar and crosses the twin brackets of the first molar at a 10-degree bias. The second molars are now part of the 10 stabilizing units, and the first molars are the two teeth that receive the action of the directional forces and the archwire. After 1 month, the archwire is removed, and a readout should show a 5- to 8-degree distal inclination of the first molars. The second molars should continue to read out at 15 degrees.

The denture correction step of treatment should now be complete for the Class I malocclusion. The objectives of the denture correction step are (1) complete space closure in both arches, (2) sequential anchorage preparation in the mandibular arch, (3) an enhanced curve of occlusion in the maxillary arch, and (4) a Class I intercuspation of the canines and premolars. The mesiobuccal cusp of the maxillary first molar should fit into the mesiobuccal groove of the mandibular first molar. The distal cusps of these teeth should be discluded, as should the second molars.

Class II Force System

For patients with an "end-on" Class II dental relationship of the buccal segments at the conclusion of space closure, a new force system must be used to complete the denture correction stage of treatment. A careful study of the cusp relationships will determine the force system required. Making a final diagnostic decision for Class II correction is usually based on (1) the ANB relationship, (2) a maxillary posterior space analysis, and (3) patient cooperation. The following guidelines are used:

1. If the maxillary third molars are missing or if the ANB is 5 degrees or less and the patient is cooperative, the system to be described will accomplish the best result. If the third molars are present and are approaching eruption, they should be removed to facilitate distal movement of the maxillary teeth.
2. If a cooperative patient has (a) a mild Class II dental relationship, (b) a normal vertical skeletal pattern (FMA of ≤28

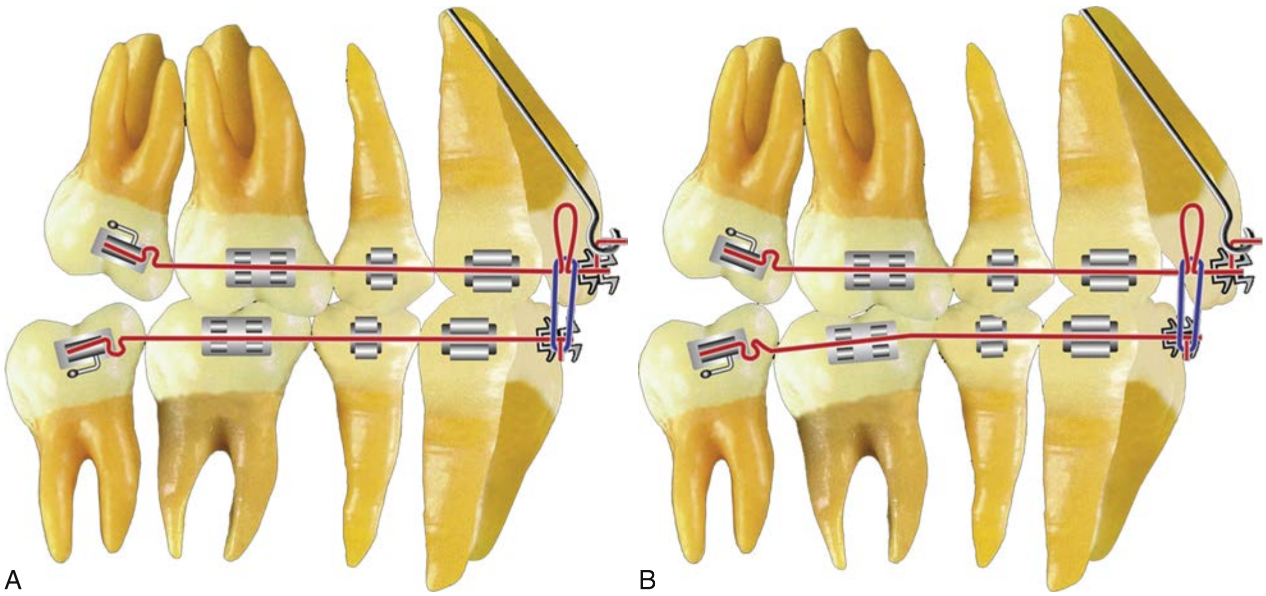

FIGURE 19-32 Mandibular anchorage preparation. **A**, 10-2-7. The second molar is tipped to its anchorage prepared position. **B**, 10-2-6. The first molar is tipped to its anchorage prepared position.

degrees), (c) an ANB of 5 to 8 degrees, and (d) normally erupting maxillary third molars, the extraction of maxillary second molars is most advantageous. The force system to be described is used to distalize the maxillary dentition into the second molar extraction space.

3. If (a) the ANB is approaching 10 degrees, (b) maxillary third molars are present, (c) there is a full step Class II molar occlusion, or (d) the patient's motivation is questionable, the first molars may be considered for removal after the maxillary and mandibular first premolar has been closed. Surgical correction may also be considered. Facial balance and harmony "projections" after correction with either molar extraction or orthognathic surgery should be considered carefully before making either decision.

The Class II force system cannot be used unless compliance requirements are strictly followed by the patient. If one attempts to use the Class II force system without cooperation, the maxillary anterior teeth will be pushed forward off basal bone.

Orthodontic Correction of the Class II Dental Relationship

At the end of sequential mandibular anchorage preparation, a mandibular 0.0215- × 0.028-inch stabilizing archwire is fabricated. Ideal first-, second-, and third-order bends are incorporated into the archwire. The omega loop stop must be 0.5 mm short of the molar tubes, and the wire must be passive to all the brackets. Gingival spurs are soldered distal to the mandibular lateral incisors. The wire is seated and ligated, and the terminal molar is cinched tightly to the loop stop.

A 0.020- × 0.025-inch maxillary archwire with 7.5-mm closed helical bulbous loops bent flush against the second molar tubes is fabricated. The helix is wound to the lingual during fabrication. This archwire has ideal first- and second-order bends. The molar segment has 7 degrees of progressive lingual crown torque. A gingival spur is attached to the archwire immediately distal to the maxillary second premolar bracket. Gingival high-pull headgear hooks are soldered distal to the central incisors. Class II "lay on" hooks with a gingival extension for anterior vertical elastics are soldered distal to the lateral incisors. Before archwire insertion, the closed helical bulbous loops are opened 1 mm on each side. The anterior segment of the archwire will be 1 mm labial to the maxillary incisor brackets. The archwire is ligated in place. Class II elastics are worn from the hooks on the mandibular second molar tubes to the Class II hooks on the maxillary archwire. Anterior vertical elastics are worn from the spurs on the mandibular archwire to the gingival extension hooks on the maxillary archwire. The high-pull headgear is worn on the maxillary headgear hooks (Fig. 19-33, *A*).

This force system is used to sequentially move the maxillary second molars distally. At each appointment, the mandibular archwire is removed and checked, and the helical bulbous loops are activated 1 mm. The activation of the maxillary archwire is repeated until the second molars have a Class I dental relationship (Fig. 19-33, *B*). When the Class I relationship of the second molars has been established, a closed coil spring is "wound" distal to the second premolar spur and compressed between the spur and the first molar bracket when the maxillary archwire is inserted. (The coil spring length should be 1.5 times the space between the second premolar and the first molar brackets.) An elastic chain is stretched from the second molar to the distal bracket of the first molar. The spring and the elastic chain create a distal force on the maxillary first molar. Additionally, a Class II elastic is worn continuously from the mandibular second molar hook to the Class II hook on the maxillary archwire. An anterior vertical elastic is worn 12 hours each day (Fig. 19-34). The high-pull headgear is worn 14 hours per day on the spurs soldered to the maxillary archwire. This is an efficient force system for first molar distalization (Fig. 19-35).

After the first molars have been moved distally into an overcorrected Class I dental relationship, the spur that was attached distal to the second premolar bracket is removed. The coil spring is moved mesially so that it is compressed between the lay-on hook and the canine bracket. Subsequently, the maxillary second premolars and the maxillary canines are moved distally with elastic chain and headgear force (Fig. 19-36). Four months

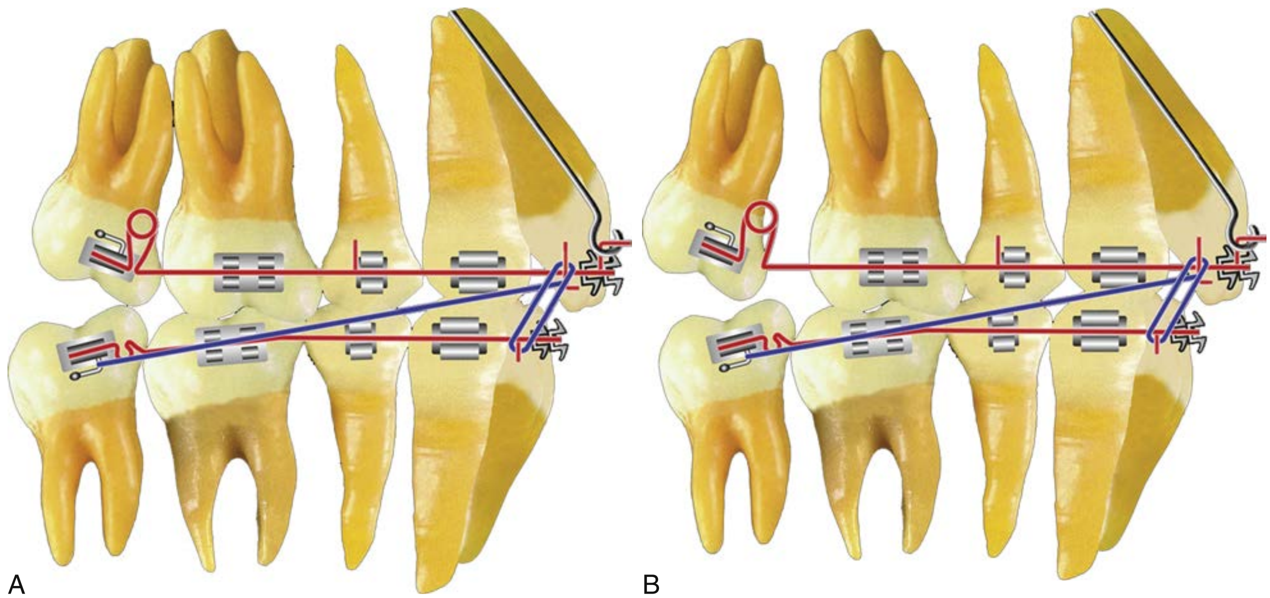

FIGURE 19-33 Denture correction: Class II force system. Maxillary second molar distalization. **A,** Step 1. A helical bulbous loop is placed against the maxillary second molar. **B,** Step 2. The helical bulbous loop pushes the maxillary molar distally to a Class I relationship.

of treatment with monthly reactivation should position the posterior teeth and the maxillary canine in an overtreated Class I relationship. This system will not strain the mandibular arch if the anterior vertical elastics are worn and if sufficient space is available in the maxillary posterior denture area.

After overcorrection of the Class II dental relationship, a 0.020- × 0.025-inch maxillary archwire with 7.5-mm closing loops distal to the lateral incisors is fabricated. This archwire has ideal first-, second-, and third-order bends. Gingival headgear hooks are soldered distal to the central incisors (Fig. 19-37). The closing loops are opened 1 mm per visit by cinching the omega loop stops to the molar tube. Class II elastics, anterior vertical elastics, and the maxillary high-pull headgear are used. After all the maxillary space is closed, the denture correction step of treatment has been completed. The dentition is ready for the next step of treatment—denture completion.

Denture Completion

The third step of treatment is identified as denture completion. Ideal first-, second-, and third-order bends are placed in finishing mandibular and maxillary 0.0215- × 0.028-inch resilient archwires. The mandibular archwire duplicates the previously used mandibular stabilizing archwire. The maxillary archwire has artistic bends and hooks for the high-pull headgear, anterior vertical elastics, and Class II elastics. Supplemental hooks for vertical elastics are soldered as needed (Fig. 19-38).

The forces used during denture completion are based on a careful study of the arrangement of each tooth in each arch. The orthodontist must also study the relationship of one arch to the other and the relationship of the arches to their environment. The orthodontist makes necessary first-, second-, and third-order adjustments in each archwire as needed. A progress cephalogram and tracing

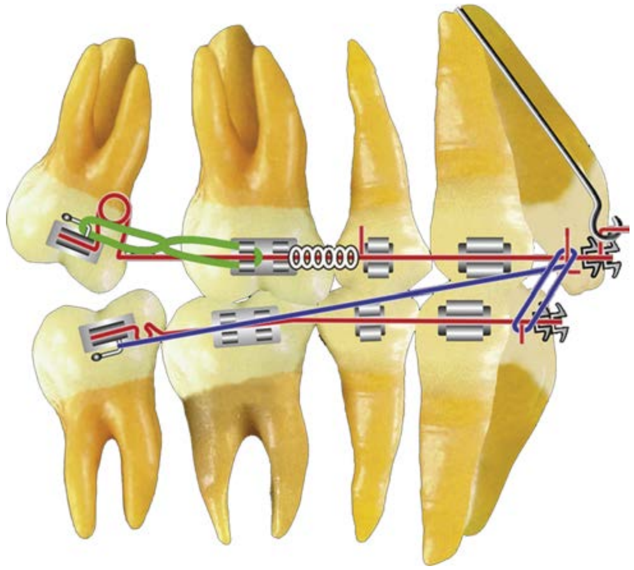

FIGURE 19-34 Denture correction: Class II force system. A coil spring is trapped mesial to the first molar.

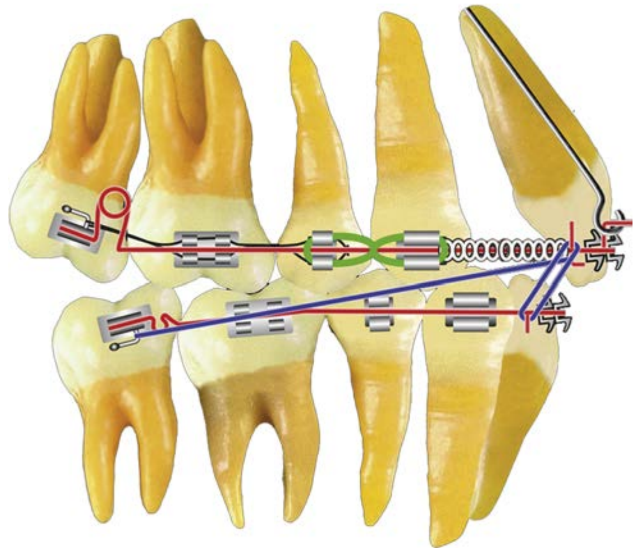

FIGURE 19-36 Denture correction: Class II force system. Maxillary second premolar and maxillary canine distalization. After molar distalization the premolars and canines are distalized.

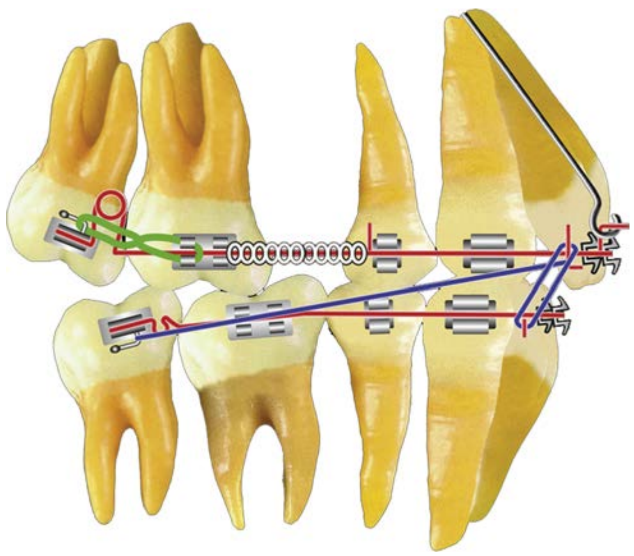

FIGURE 19-35 Denture correction: Class II force system. Maxillary first molar distalization.

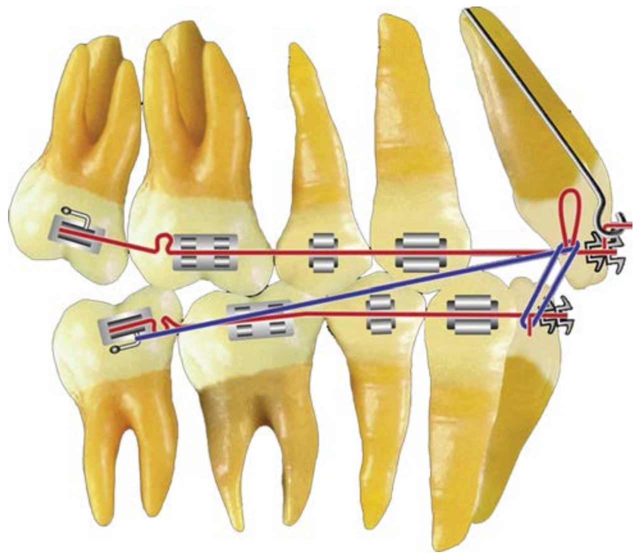

FIGURE 19-37 Denture correction: Class II force system. Maxillary anterior space closure. A 0.020- × 0.025-inch maxillary closing loop archwire is used to close the maxillary anterior space.

can be evaluated to determine the final mandibular incisor position and any minor control of the palatal, occlusal, and mandibular planes that may be needed. Study of the cephalogram may also reveal to the clinician the requirement for lingual root torque in the maxillary incisors. Visual clinical observations permit evaluation of the lip line, the maxillary incisor relationship, and the amount of cusp seating and artistic positioning of the incisors that is necessary.

Denture completion can be considered as minitreatment of the malocclusion. During this treatment step, the orthodontist uses the forces that are necessary until the original malocclusion is overcorrected.

Denture Recovery

An ideal occlusion will be present only after all treatment mechanics are discontinued and uninhibited function and other environmental influences active in the posttreatment period stabilize and finalize the position of the total dentition. When all appliances are removed and the retainers are placed, a most crucial "recovery" phase occurs. During this recovery period, the forces involved are those of the surrounding environment, primarily the muscles and the periodontium. If mechanical corrective procedures barely achieve normal relationships of the teeth, relapse is inevitable. Any change is likely to be away from ideal occlusion toward malocclusion. Recovery, based on a concept of overcorrection, is predicated on clinical experience and research.

The posttreatment occlusion, which is carefully planned, sometimes referred to as Tweed occlusion but properly identified as transitional occlusion (Fig. 19-39), is characterized by disclusion of the second molars. The mesiolingual cusp of the maxillary first molar is seated into the central fossa of the mandibular first molar with the mesial inclined plane of the mesial cusp of the maxillary first molar contacting the distal inclined plane of the mesial cusp of the mandibular first molar. This arrangement allows the muscles of mastication to effect the greatest force on the "primary chewing table" in the midarch area. The slightly intruded distally inclined maxillary and mandibular second molars now can "reerupt" to a healthy functional occlusion without trauma or premature contact. Because of overtreatment of Class I and Class II deep-bite patients, the anterior teeth are positioned in an end-to-end relationship with no overbite or overjet. This relationship, however, is transitory and will adjust rapidly to an ideal overjet and overbite relationship (Fig. 19-40).

The correction of two malocclusions will be illustrated. These patients were treated with the Tweed-Merrifield edgewise appliance. The reason for showing the records of these patients is to illustrate that all treatment objectives can be routinely attained in the treatment of different types of malocclusions if the force

FIGURE 19-39 Transitional occlusion: The occlusion must be overtreated. The anterior teeth should be edge to edge. The canines, second premolars, and first molars should have a solid Class I dental relationship. The second molars should be tipped out of occlusion.

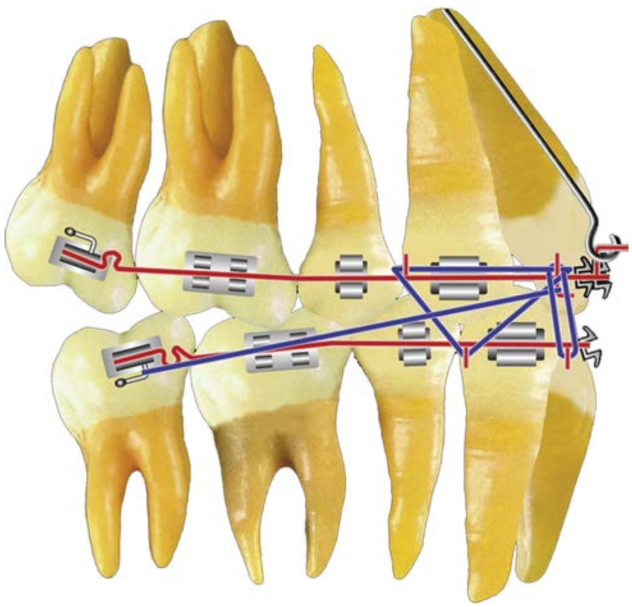

FIGURE 19-38 Denture completion: Maxillary and mandibular stabilizing archwires, along with the proper elastics and headgear force, are used to complete the orthodontic treatment.

FIGURE 19-40 Final occlusion is characterized by the teeth settling into their most efficient, healthy, and stable positions.

system that has been presented is used. The diagnosis of the first malocclusion is described in detail to illustrate the use of the craniofacial analysis and the total dentition space analysis for making the differential diagnosis from which the treatment plan is formulated. This first malocclusion was a protruded Class II, division I subdivision malocclusion with facial imbalance. The force system used to correct the malocclusion was the Class II force system previously described in this chapter.

SUMMARY

The standard edgewise appliance has endured the test of time. Angle was determined to use it to correct malocclusions while preserving the "full complement of teeth." Angle collaborated with Charles H. Tweed, who, after countless failures, introduced the extraction of four first premolars and anchorage preparation to produce facial balance. The use of the appliance evolved with Levern Merrifield over many more years. He introduced the following: (1) differential diagnosis, which led to the removal of the teeth that would best produce balance, harmony, and facial proportion within the cranial–facial complex; (2) directional force technology; and (3) sequential archwire manipulation. The edgewise appliance is a precise instrument for the routine correction of major malocclusions. Although the Tweed-Merrifield edgewise appliance is the direct descendent of the appliance invented in 1928 by Edward H. Angle, it is used with a totally different philosophy of treatment. A consistent effort is being continuously directed toward its further sophistication. The edgewise appliance has stood the test of time and will be used in the future by many more generations of orthodontists.

Acknowledgment

The images that illustrate the force systems that are described in this chapter were created by Sergio Cardiel Rios, Morelia, Michoacan, Mexico.

CASE REPORTS: MALOCCLUSION CORRECTION WITH THE EDGEWISE APPLIANCE

Patient 1: NY

This 12-year-old boy shows a malocclusion with facial, dental, and craniofacial disharmony.

Profile and full face photographs (Fig. 19-41) illustrate the protrusion and the facial imbalance. The casts (Fig. 19-42) exhibit an Angle Class II end-to-end occlusion on the right, a deep impinging overbite, and flared and protrusive maxillary and mandibular incisors. The pretreatment cephalogram and its tracing (Fig. 19-43) illustrate an ANB of 7 degrees and an AO-BO

FIGURE 19-41 Pretreatment facial photographs.

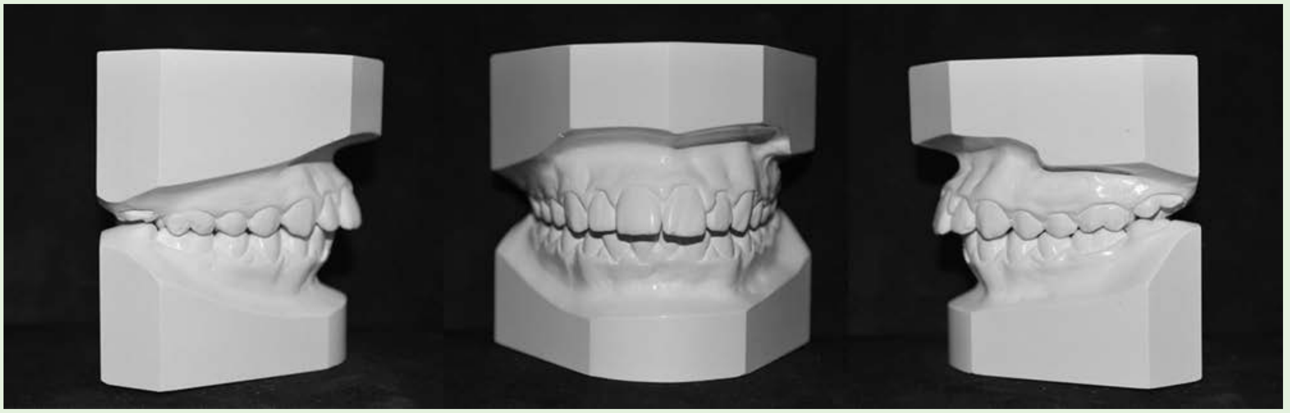

FIGURE 19-42 Pretreatment casts.

of 14 mm, both of which are indicators of the severity of the malocclusion. The FMIA of 58 degrees and the Z angle of 63 degrees reflect the protrusive face. Mandibular incisors are flared. The differential diagnostic analysis system was used to give some objectivity to the patient's skeletal, dental, and facial problems. The craniofacial analysis shows a craniofacial difficulty total of 71.0. The SNB is lower than normal. The ANB is larger than normal. The facial protrusion needs to be corrected. The total dentition space analysis reflects the protrusion in the anterior dentition area with a cephalometric correction discrepancy factor of 9.6, a curve of Spee of 2.5 mm, and a 5-mm Class II occlusal issue. The total anterior discrepancy difficulty was 14.1 mm, the midarch and the occlusal disharmony discrepancy was 12.5 mm, and the posterior discrepancy was 9 mm. The space analysis difficulty was 35.6 mm. Total dentition difficulty was 106.6 (Fig. 19-44).

CASE REPORTS: MALOCCLUSION CORRECTION WITH THE EDGEWISE APPLIANCE—cont'd

Because of facial and dental protrusion and the immediate need to upright the mandibular incisors, maxillary and mandibular first premolars were extracted. The patient was banded and bonded according to the protocol that has been described. The force system that has been described was used. The patient's malocclusion correction was completed with 22 months of active appliance therapy. The patient's posttreatment facial photographs (Fig. 19-45), when compared with the pretreatment photographs, exhibit a significant and positive change in facial balance. The protrusion no longer exists, and the patient has a pleasing profile. The posttreatment casts (Fig. 19-46) exhibit control of the dentition and creation of an ideal Angle Class I dental relationship on the right side. Some distal tipping of the mandibular molars should be noted. These teeth have been tipped out of occlusion because of the anchorage preparation that enhanced vertical control during the Class II elastic wear. Arch form has been maintained. The posttreatment cephalogram and tracing (Fig. 19-47) illustrate changes in many of the cephalometric values. FMIA increased from 56 degrees to 69 degrees. IMPA decreased from 96 degrees to 84 degrees. The Z angle increased from 63 degrees to 78 degrees. These values are clear indications that the goals for facial balance and harmony were met. Superimposition tracings (Fig. 19-48) illustrate the control of the maxillary and mandibular molars, uprighting of the mandibular incisors, and the upward and backward movement of the maxillary incisors. The direction of the spatial change of the mandible in relation to the maxilla was downward and forward. This downward and forward change contributed greatly to the improved facial balance and harmony. The smiling photographs of the patient (Fig. 19-49) confirm intrusion of the incisors and a considerably better smile with less gingival display.

Patient 2: CL

A patient whose treatment plan requires the extraction of maxillary first premolars and mandibular second premolars generally has the following characteristics: (1) Balance and harmony of the lower face (Fig. 19-50) is within reasonable limits, or there is only a mild facial imbalance. In other words, these patients do not generally exhibit a great degree of unbalance of the lower face. (2) The dentition (Fig. 19-51) is most often a Class II dental relationship and mild mandibular and/or maxillary anterior crowding. Many of these patients have a protrusion of the maxillary anterior teeth. (3) The cephalometric examination of the skeletal pattern most often reveals a moderate mandibular plane angle, mandibular incisors that are "reasonably upright" over basal bone, and a discrepancy in the

FIGURE 19-51 Pretreatment casts.

anteroposterior relationship of the mandible to the maxilla. In our example, patient CL has an ANB of 7 degrees, an FMIA of 61 degrees, and an IMPA of 97 degrees (Fig. 19-52). These are values that one would expect for patients who "fit" into this facial, skeletal, and dental pattern.

When making the differential diagnosis, it is important to understand the relationship of the mandible to the maxilla and the relationship of the teeth to the face. In this particular example, the FMIA, Tweed's "facial angle," must be increased if the patient is to have improved balance and harmony in the lower face. Patient CL was treated with the extraction of the maxillary first premolars and the mandibular second premolars. The mandibular incisors were uprighted, the posterior occlusion was corrected by mesial movement of the mandibular posterior teeth, and crowding was ameliorated.

The mesialization of the mandibular first molar is accomplished with a variation of the mandibular archwires used during denture preparation (Fig. 19-53, *A–D*). This system is based on control of the mandibular anterior and posterior teeth as the second premolar extraction space is closed. As the mandibular first molar is protracted, the second molar drifts mesially. When all mandibular space is closed, the second molar is banded, mandibular anchorage is prepared, and treatment is finished with the archwire sequences that have been previously described.

The posttreatment facial photographs (Fig. 19-54) illustrate improvement in balance and harmony of the lower face. The chin is not as recessive. There is a nice curl in the maxillary lip and less eversion of the lower lip. The pretreatment–posttreatment casts (Fig. 19-55) confirm correction of the posterior occlusion and crowding amelioration. The posttreatment cephalogram and cephalometric tracing (Fig. 19-56) confirm mild uprighting of the mandibular incisors, an increase in FMIA from 61 degrees to 66 degrees, maintenance of the mandibular plane angle, and reduction of the ANB from 7 degrees to 3 degrees because of retraction of point A. The superimpositions (Fig. 19-57) confirm a nice spatial change of the mandible in its relationship to the maxilla, vertical control of the molars, mild uprighting of the mandibular incisors, and intrusion and retraction of the maxillary incisors.

The correction of two distinctly different types of malocclusions has been illustrated. Both of these malocclusions were recently treated. The intent of showing NY's records is to illustrate the fact that all treatment objectives can be routinely obtained in the treatment of a difficult malocclusion if the force system that has been presented is used. The treatment planning of NY's malocclusion is described in detail to illustrate the use of the craniofacial analysis and the total dentition space analysis. This malocclusion was an Angles Class II, division I, subdivision, with facial imbalance. The Class II force system, which has been described in this chapter, was used on the patient's right side after all premolar extraction spaces had been closed. Because this patient was recently treated, his casts reflect the transitional occlusion that will settle into the final occlusion.

The second case report is presented to illustrate the carefully planned correction of a malocclusion that was treatment planned for the extraction of the maxillary first and mandibular second premolars. The treatment goal was to improve the mild facial imbalance and to correct the dental disharmony. The Tweed-Merrifield force system that was used to protract the mandibular first molars was described and illustrated.

Biomechanical Considerations with Temporary Anchorage Devices

Jong Suk Lee, Jung Kook Kim, and Young-Chel Park

OUTLINE

CHARACTERISTICS AND CLINICAL SIGNIFICANCE OF TEMPORARY ANCHORAGE DEVICES

Mechanics using temporary anchorage devices (TADs) follow general biomechanical principles; however, several characteristic features are specific to TAD mechanics when compared with conventional mechanics. These features not only simplify treatment with conventional techniques and increase efficiency, but they also make treatment of seemingly impossible cases with challenging anchorage preparation feasible. A good understanding of TAD mechanics with the proper biomechanical treatment principles can minimize side effects while maximizing the efficiency of TAD mechanics.

Characteristics of Temporary Anchorage Device Mechanics

Characteristics of TAD mechanics can be divided into three categories: mechanics using rigid anchorage, intrusive mechanics, and high-efficiency mechanics.

Rigid Anchorage

When the TAD achieves bony support via a stable osseous interface, immobile rigid anchorage to the orthodontic load can be supplied within physiologic thresholds.[1,2] This means that the use of a TAD can easily secure rigid anchorage without any additional preparation of the dentition while relieving the limitations of anchorage found with conventional orthodontic mechanotherapy.

Intrusive Mechanics

Conventional mechanics essentially consist of characteristics of extrusive mechanics.[3] Conversely, the TAD is generally located apical to the brackets, and, in this location, TAD mechanics are advantageous in achieving intrusive mechanics (Fig. 20-1).[4–6]

High-Efficiency Mechanics

TAD mechanics generally use a single force without moments, which is very efficient for tooth movement[6] (see Fig. 20-1). The line of action, point of application, and direction of

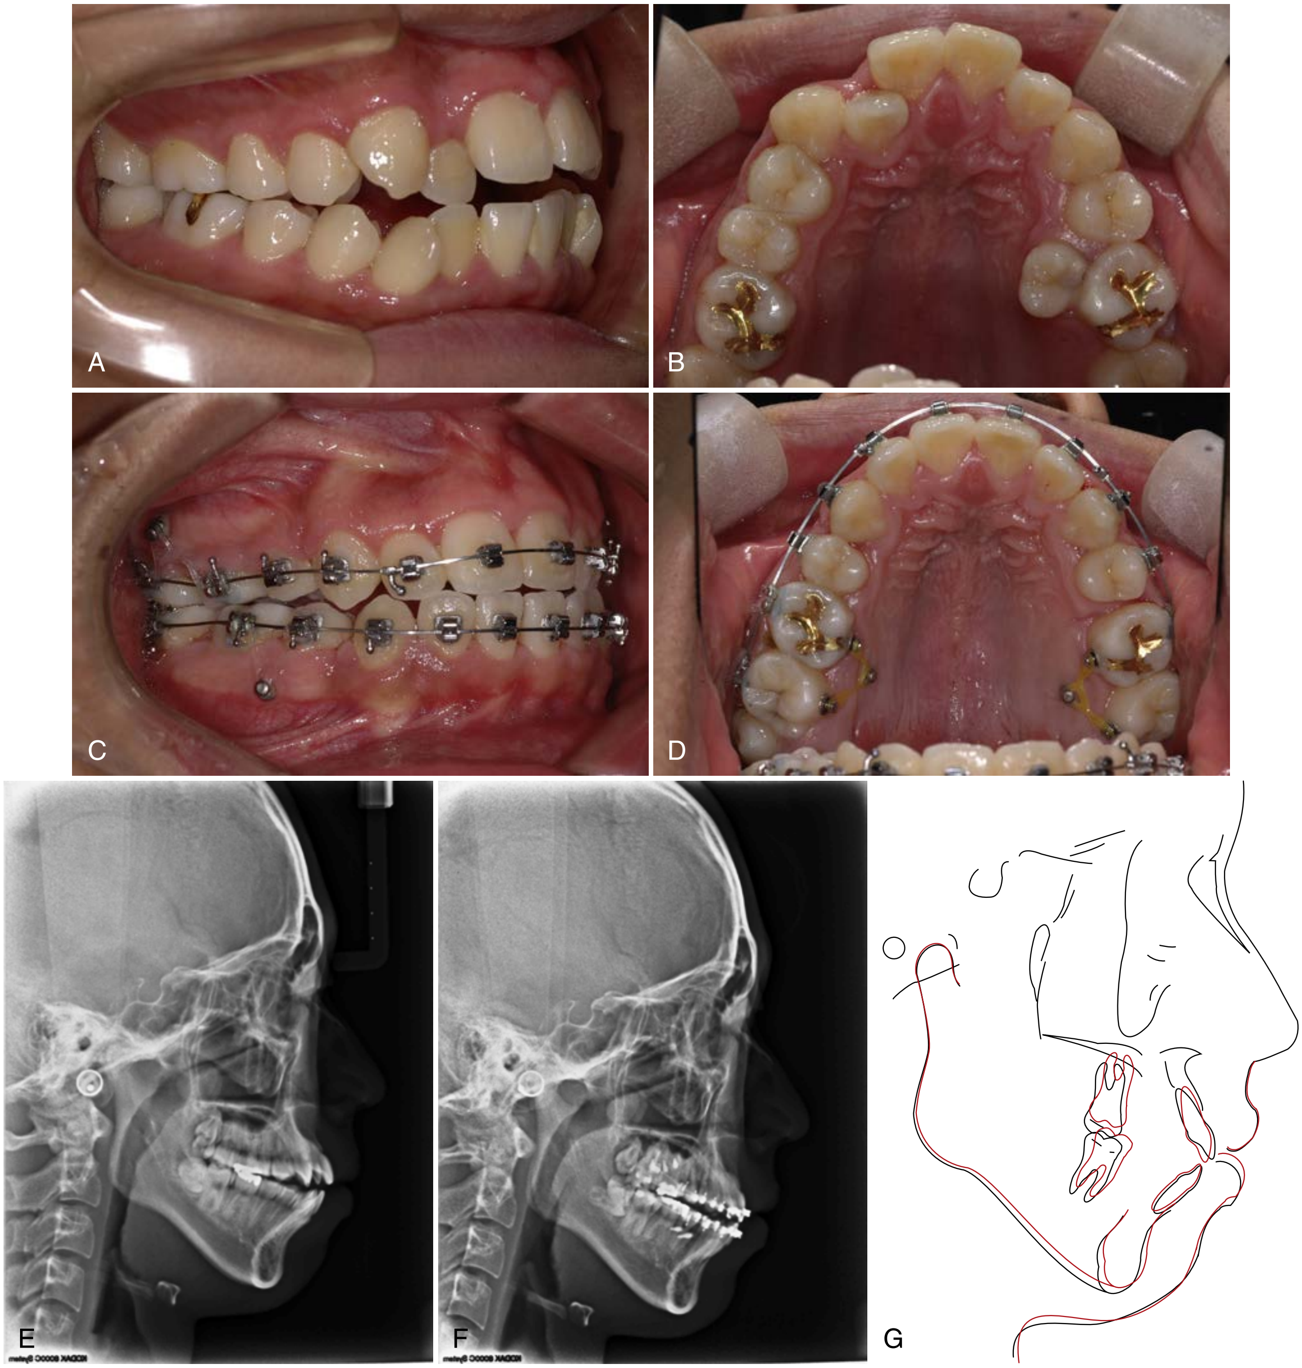

FIGURE 20-1 Buccal and palatal temporary anchorage devices (TADs) were placed, and two single continuous forces without moments were applied for efficient molar intrusion. FIGURE 20-2 The mesially angulated second molar was uprighted and protracted to the first molar position with a temporary anchorage device (TAD) and bonding of sectional orthodontic attachments. The third molar was guided to erupt into the second molar position. **A,** Intraoral view before treatment. **B,** A single TAD was placed between the canine and the premolar and splinted to the first premolar. The first and second premolars and the second molar were bonded and common tied to prevent distal uprighting of the second molar. **C,** The second molar was uprighted and mesially protracted to the first molar position by root movement. **D,** The third molar was guided into the second molar position. **E,** Panoramic radiograph before treatment visualizes the residual roots of the first molar (*black arrow*). **F,** Panoramic radiograph after treatment.

force can be designed for efficient tooth movement by controlling the location of TAD placement.

Clinical Significance of Temporary Anchorage Device Mechanics

The characteristics of TAD mechanics contribute to the following four features of clinical treatment (Case Studies 20-1 through 20-4).

Easy and Simple Anchorage Preparation

Orthodontic anchorage can be easily prepared using TADs, regardless of the condition of the dentition. Treatment mechanics can also become simpler than conventional mechanics. For example, designing mechanics for asymmetric tooth movement is comparatively convenient because the teeth are not providing the anchorage.[7–10] Furthermore, adjunctive treatment of tooth loss or impacted teeth can be addressed with the use of TADs and sectional orthodontic attachments (Figs. 20-2 and 20-3).

Increased Treatment Efficiency

As a result of the rigid anchorage supplied by the TAD, orthodontic treatment can be more easily and efficiently conducted.[11–21] Moreover, mechanotherapy can be designed using a treatment objective–centered approach, as opposed to a mechanics-centered approach, which frees orthodontic mechanotherapy from the biomechanical limitations of anchorage.

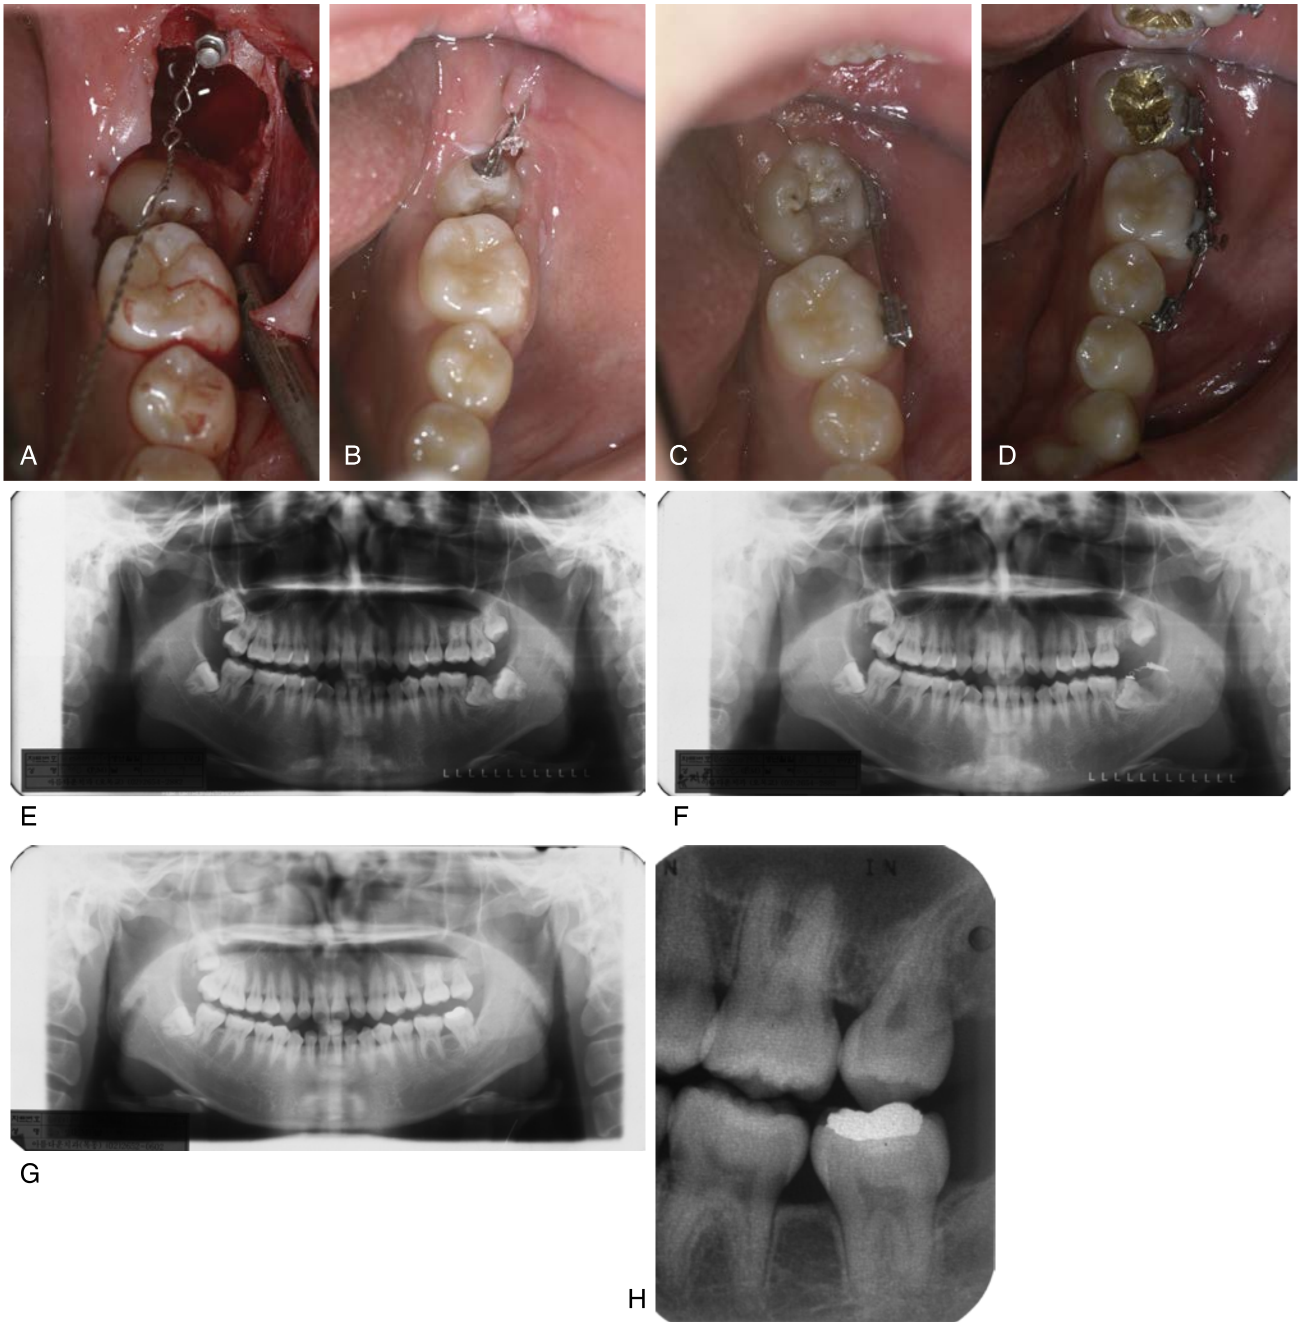

FIGURE 20-3 A 22-year-old female patient had an impacted second molar blocked by the third molar. When the third molar was extracted, a temporary anchorage device (TAD) was simultaneously placed in the retromolar area. The maxillary second molar was extracted as a result of supereruption, and guided eruption of the third molar into the second molar position was planned. The mandibular second molar was guided to erupt to the proper position, and a tube was bonded on the second molar to level and align. The alveolar bone level of this second molar was in good condition. **A,** Intraoral view shows the extraction of the third molar and TAD placement. **B,** Intraoral view at the start of molar uprighting. **C,** Attachments were bonded on the first and second molars for leveling. **D,** Intraoral view after molar uprighting. **E,** Panoramic radiograph before treatment. **F,** Panoramic radiograph while the molar was uprighted with the TAD. **G,** Panoramic radiograph at the completion of treatment. **H,** Bitewing radiograph shows a healthy bone level between the molars.

Molar distalization becomes simpler and more predictable, even in adult patients, and can be a very useful option for the treatment of cases with moderate crowding or for camouflage treatment of anteroposterior skeletal discrepancies.[22–30] Furthermore, all of the anterior and posterior teeth can be moved at the same time using rigid anchorage (Fig. 20-4).

Expansion of the Range of Orthodontic Mechanotherapy

TAD mechanics can expand the range of orthodontic mechanotherapy. One of the most significant changes is the potential for intrusion of the posterior teeth.[6,8–10,31–46] By intrusion of the entire dentition or intrusion of the posterior teeth, nonsurgical orthodontic mechanotherapy can change the occlusal plane and the position of the chin point, similar to that seen

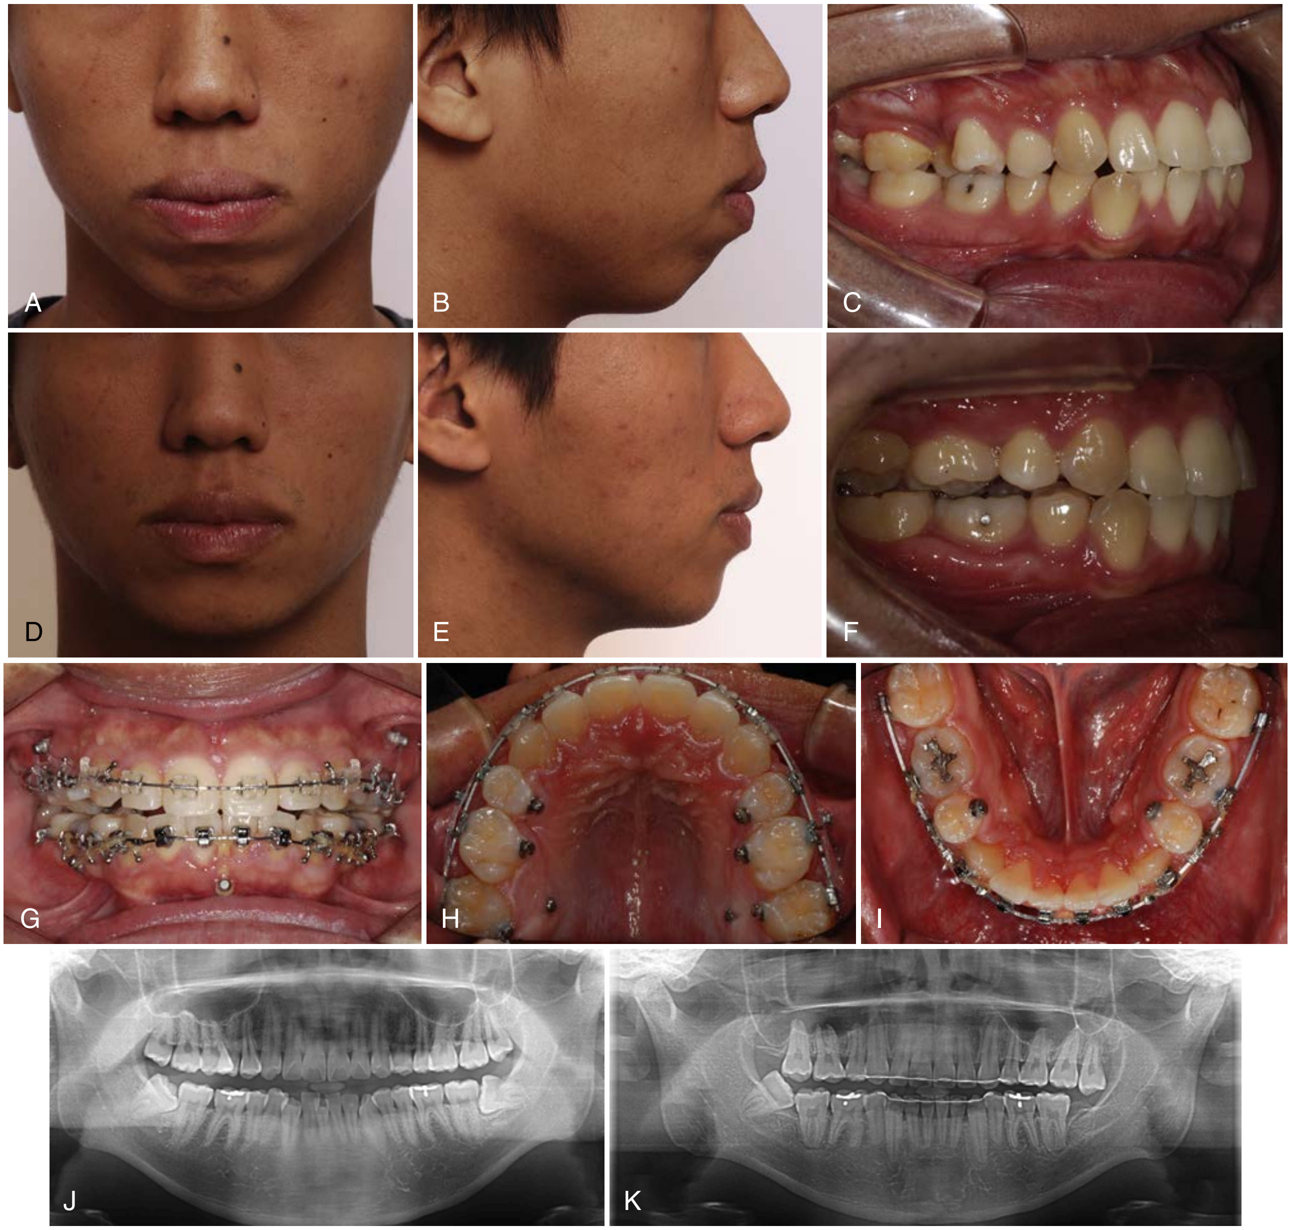

FIGURE 20-4 A 22-year-old male patient's chief complaint is protrusive lips and a retrusive chin. After premolar extractions, anteroposterior and vertical disharmonies were improved by anterior retraction and molar intrusion. The chin position was also altered through molar intrusion and subsequent autorotation of the mandible. The duration of active treatment was 31 months. **A,** Frontal facial view before treatment. **B,** Lateral facial view before treatment. **C,** Intraoral view before treatment. **D,** Frontal facial view at the completion of treatment. **E,** Lateral facial view at the completion of treatment. **F,** Intraoral view at the completion of active treatment. Overcorrection of molar intrusion was performed. **G–I,** Intraoral views during active treatment. **J,** Panoramic radiograph before treatment. **K,** Panoramic radiograph at the completion of treatment.

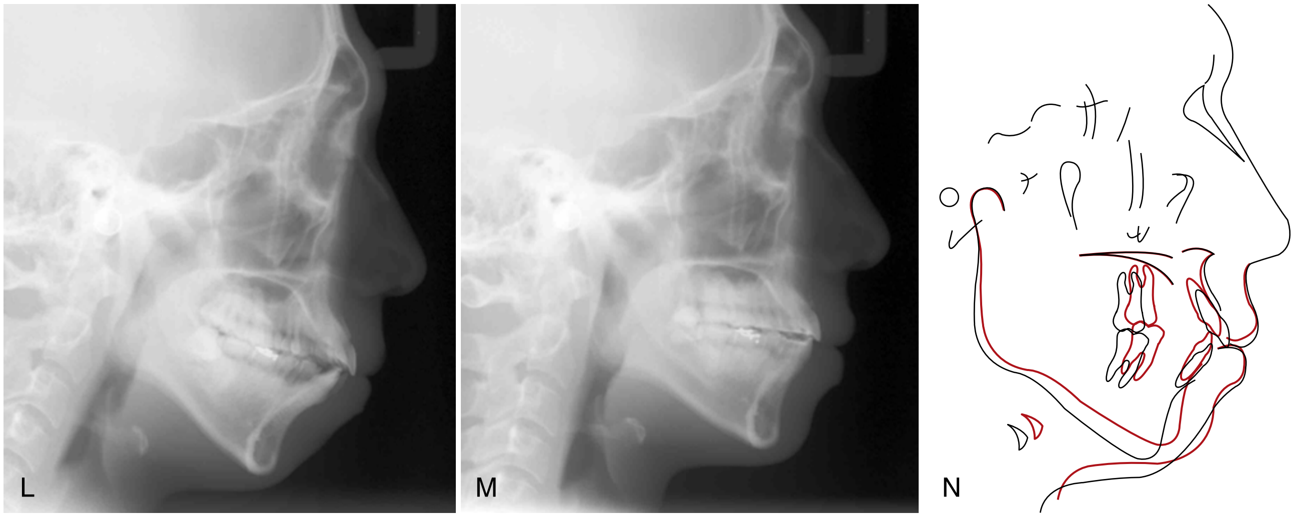

FIGURE 20-4, cont'd L, Cephalometric radiograph before treatment. M, Cephalometric radiograph at the completion of treatment. N, Superimposition of pretreatment and posttreatment cephalometric radiographs.

by surgical repositioning of the maxilla (see Fig. 20-4).* The stability of molar intrusion with TADs is clinically acceptable if proper treatment protocols are followed.[6,32,38,39]

Shifting from a Mechanics-Centered Approach

Although anchorage preparation has become easier and simpler with TADs and the range of orthodontic therapy has broadened, with this has come the need to consider several additional factors for treatment. To put it more simply, deciding between extraction and nonextraction treatment has been the key with conventional mechanics in the past. However, further considerations, such as whether to intrude teeth, have become necessary with TAD mechanics. Furthermore, with the shift from two-dimensional tooth movements to three-dimensional tooth movements, the sheer amount of information that the orthodontist must process has tremendously increased. The *mechanics* portion of biomechanics has been the primary limiting factor in anchorage control in conventional treatment, whereas the *bio* portion has become the primary limiting factor in treatment using TAD mechanics.

The importance of establishing a diagnosis and treatment plan based on an understanding and reflection of the physiologic functions of the stomatognathic system, including the temporomandibular joint (TMJ) and masticatory muscles, is growing ever more important.[47,48] For greater amounts of tooth movement, a thorough understanding of the biologic side effects, such as root resorption or attachment loss, has gained importance as well.[49–52] Extra precautions need to be taken with regard to understanding and considering the functional aspects of more extensive tooth movements to prevent and manage biologic problems properly. Placing the TAD in the exact desired position with minimal side effects and maximum stability requires as much skill of the clinician as precise bracket positioning.[53,54] Accurate placement, referral of TAD placement, and all related patient communications are also issues that the clinician needs to weigh before treatment.

* References 6, 21, 31–34, 36, 38–40, 42–46.

Considerations for Temporary Anchorage Device Mechanics

TAD mechanics are useful in solving mechanical problems, but they have restrictions when addressing the biological limitations encountered with mechanotherapy.

Temporary Anchorage Device Stability

TAD mechanics is entirely based on the stability of the TAD. The success rate of TADs is greater than 80%, which is clinically acceptable.[55–64] Loosening of a TAD is not clinically uncommon.[65] The more favorable alternative when loosening occurs is to modify the location of TAD placement. However, if the location of the TAD cannot be compromised, a 3- to 6-month waiting period is essential for cortical bone formation before replacing the TAD in the same location.[66–68] In cases of repeated failure, an alteration of the treatment plan may be required. The patient should be thoroughly informed in detail about such changes to the treatment plan before treatment with the TAD is initiated.

Temporary Anchorage Device Positioning

Selecting a TAD position is extremely important to the design of TAD mechanics. In some instances, TADs cannot be placed in the desired position because of limitations of the anatomic structures and accessibility.[69–74] Considering the fact that substantial individual variations exist among patients, the clinician must perform single measurements in specific anatomic sites for TAD placement to prevent potential damage to anatomic structures, to minimize the risk of failure, and to obtain the most favorable clinical results.[69,71,74] Cone-beam computed tomography (CBCT) imaging is very useful in helping achieve these goals.[64]

Moreover, TADs placement in interradicular areas may restrict tooth movement of adjacent teeth because of the lack

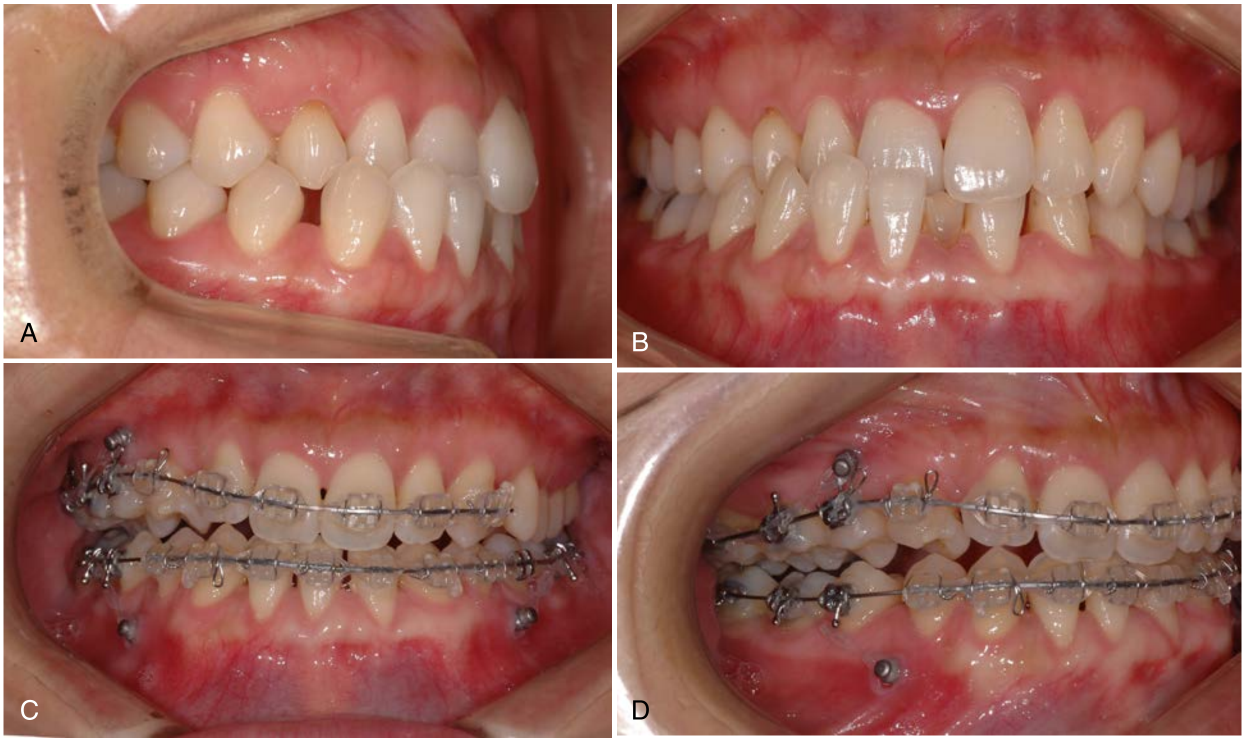

FIGURE 20-5 Orthodontic force was applied to protract the molar unilaterally from the temporary anchorage devices (TAD) to close the space of the upper right deciduous canine. However, an open bite developed as a result of mesial tipping of the molar, as well as the intrusive force vector in the premolar area. Using lever-arm mechanics, intermaxillary elastics can prevent such side effects and can solve similar problems. **A, B,** Intraoral views before treatment. **C, D,** Intraoral views during treatment. Occlusal canting developed.

of space between the roots.[70–74] The mechanics design can compensate for such restrictions.[75,76]

Load-Bearing Capacity of the Temporary Anchorage Device

The orthodontic load-bearing capacity is closely related to the size and biocompatibility (i.e., bonding strength at the implant-bone interface) of the TAD.[77–79] According to a finite-element model (FEM) analysis study, a miniscrew-type TAD made of titanium alloy can withstand approximately 200 to 400 g of orthodontic force, depending on the bone condition and diameter of the TAD.[6] However, splinting two TADs or placing extra TADs can allow for heavier forces to be applied.[80,81] The use of wider and longer TADs may also be helpful.[6,82–84]

Biomechanical Considerations

The TAD itself can provide favorable orthodontic anchorage but cannot offer an ideal force system for all types of tooth movements. Rigid anchorage is only one of the contributing factors to ideal treatment. However, rigid anchorage alone does not guarantee successful tooth movement; anchorage loss and unwanted side effects can result, even with TAD mechanics. For example, the intrusive force vector of TAD mechanics can produce unforeseen side effects with conventional mechanics (Figs. 20-5 and 20-6). These consequences are very difficult to correct. Therefore removing or controlling unwanted force vectors from the TAD is necessary in all three dimensions of space.

Biological Considerations

TAD mechanics move teeth using the same principles as conventional mechanotherapy and must be used with consideration paid to its biological limitations. Tooth movement should take place within the periodontal complex,[85–89] as with all mechanotherapy.

The ability of TADs to address vertical discrepancies nonsurgically has resulted in the need for greater precautions for biological considerations. For example, molar intrusion using TADs can affect treatment progress and maintenance of a decrease in the overall vertical dimension. When protracting molars into spaces left by missing or extracted teeth, especially in the mandible, more attention to the periodontal management of the molars being protracted, including attachment loss, is necessary.[90,91] Although TADs have resolved many of the problems concerning the *mechanics* portion of biomechanics, the importance of managing problems related to the *bio* aspect have become greater.

Although research and clinical trials have been reported,[92–108] a clear protocol of the orthopedic effects to the basal bone using TAD mechanics is not yet established. Further studies are needed to clarify the orthopedic effects of TAD mechanics. With regard to transverse orthopedic expansion, several studies examining the expansion of the lateral envelope of movement of the posterior teeth have been conducted,* but no definite conclusions have been established.

* References 94, 99, 100, 103–106, 108.

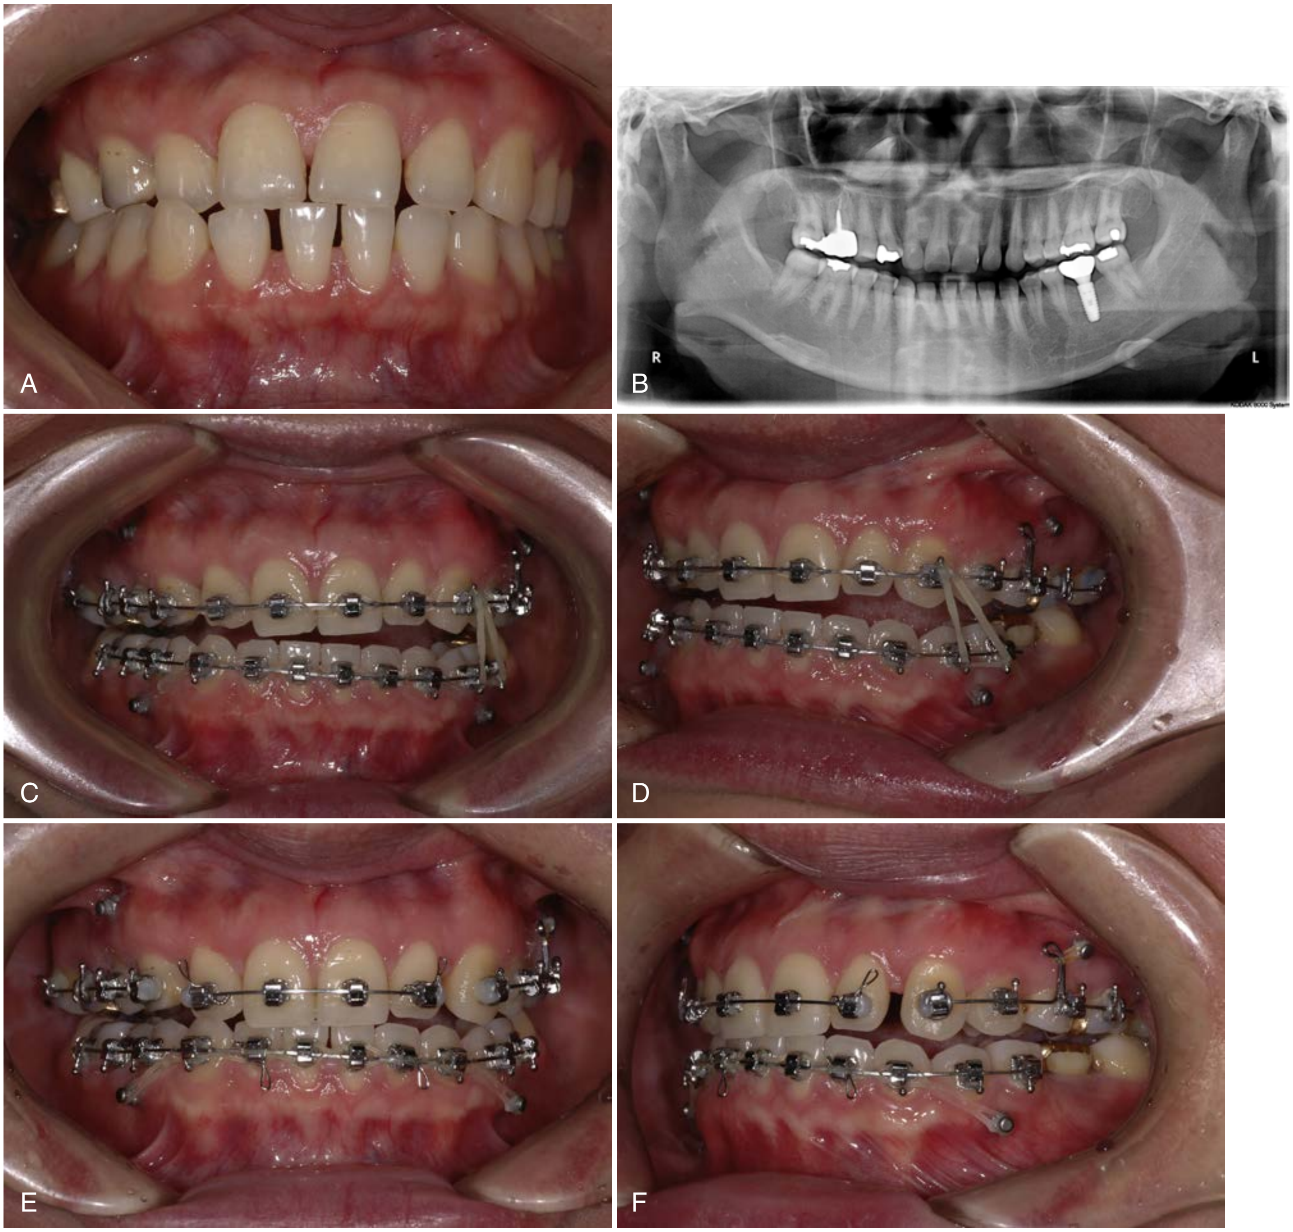

FIGURE 20-6 Bilateral, symmetric retraction, and intrusive forces were applied, but occlusal canting developed as a result of the different anchorage values on either side—that is, more intrusion developed in the left anterior area because the left first molar prosthodontic implant was not included in the full bonding. Using intermaxillary elastics, canting was improved. Conventional extrusive mechanics are useful to compensate for the disadvantages of the intrusive components of temporary anchorage device (TAD) mechanics. **A,** Intraoral views before treatment. **B,** Panoramic radiograph before treatment. **C, D,** Intraoral views during treatment. Occlusal canting developed. **E, F,** Intraoral views during the canting correction.

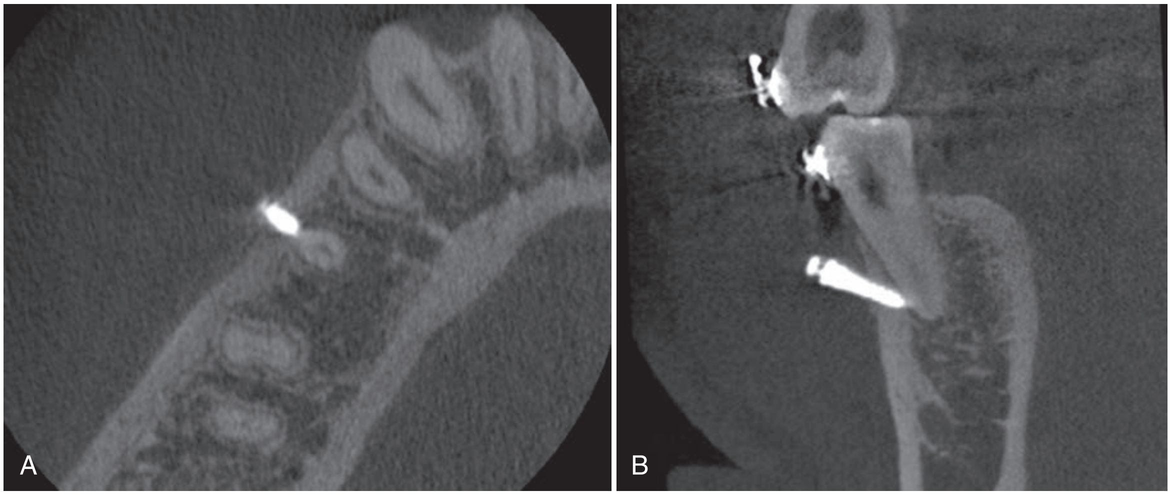

FIGURE 20-7 The most important thing to remember in root injury prevention is that root injuries can and do occur. If even a hint of doubt is present, then the entire procedure should be double and triple checked. During the insertion process, if the temporary anchorage device (TAD) makes contact with the root, then the patient will likely experience an abrupt pain. If the patient suddenly reports pain, then the insertion procedure should be stopped and the location of the implant reconfirmed. **A,** The best way to check the location is with three-dimensional cone-beam computed tomography (CBCT) imaging. Complaints of pain from patients should not be regarded lightly, as they have the potential for becoming sources of legal conflicts in the future. **B,** Contact of the TAD tip with the apex of the root was confirmed, and the location of TAD placement was modified on the basis of the examination results of three-dimensional CBCT imaging.

Side Effects Related to Temporary Anchorage Device Mechanics and Their Management

Unexpected iatrogenic side effects such as root injuries and penetration into the nasal cavity or maxillary sinus may occur during the surgical placement of the TAD.[109–111] Root injuries are reversible in many cases[112–120]; however, a crack to a root or root fracture is considered irreversible.[6,121,122] Remembering that root injuries are always possible is of the utmost importance in preventing iatrogenic injury. In addition, if an injury is suspected, then the clinician should halt the procedure and carefully double check the entire placement process (Fig. 20-7). Adherence to proper surgical protocols can prevent iatrogenic injuries to anatomic structures.[6,123]

Root injuries that occur near the apex may not require any particular treatment (Fig. 20-8). Furthermore, root injury without attachment loss can be managed to some extent with endodontic treatment or apical surgery (Fig. 20-9).[124–128] If the maxillary sinus is healthy, then simple penetration to the sinus under proper aseptic principles does not pose a significant problem (Fig. 20-10).[110]

TAD mechanics can expand the envelope of discrepancies of tooth movement but may also contribute some negative aspects.[50,51,87] Side effects that are not common to conventional mechanics, which are related to intrusive mechanics, can develop. Additionally, TAD mechanics may worsen the conventional side effects of orthodontic treatment. Root resorption and periodontal problems, in particular, may occur as a result of large amounts of tooth movement using rigid anchorage. Side effects resulting from misdiagnosis and overtreatment should also be avoided.

TAD mechanics can increase the expectation level of patients and may cause further dissatisfaction in a subjective patient. For satisfactory and successful treatment, the operator should engage in thorough communications with the patient regarding the effectiveness and limitations of the TAD.

CLINICAL AND BIOMECHANICAL APPLICATIONS OF TEMPORARY ANCHORAGE DEVICES

General Principles in Biomechanical Application of Temporary Anchorage Device Mechanics

Establishment of an Individualized and Optimal Treatment Plan

An individualized treatment plan should be determined by collecting an adequate database of information with regard to the patient and by interviewing the patient and any persons concerned.[129] Cost-benefit analyses should also be considered when deciding treatment options.

Selection of a Temporary Anchorage Device System and Insertion Site

Various TAD systems are available on the dental market,[130,131] as well as numerous reported clinical applications. A specific TAD system and insertion site should be selected according to the individual treatment plan.

FIGURE 20-8 Root injuries in the vicinity of the apex can be addressed by ensuring that the affected tooth is not subject to secondary trauma, which can be accomplished with occlusal adjustments. If properly handled, then root injury near the apex will not cause any particular problems, even without the aid of root canal treatment. **A,** During temporary anchorage device (TAD) insertion, a distinct breaking sound was heard. Confirmation with three-dimensional cone-beam computed tomography (CBCT) imaging revealed that the TAD had been placed in the mesial root of the first molar. **B–D,** Antibiotics were prescribed for 5 days after the removal of the TAD. At the 1-week check-up appointment, no additional treatment, such as root canal, was administered because no symptoms were present. After occlusal adjustment and a 3-month observation period, orthodontic treatment was continued. **E–G,** After the completion of treatment, the patient was monitored for 2 years. The affected tooth remained vital, and no particular pathologic signs developed.

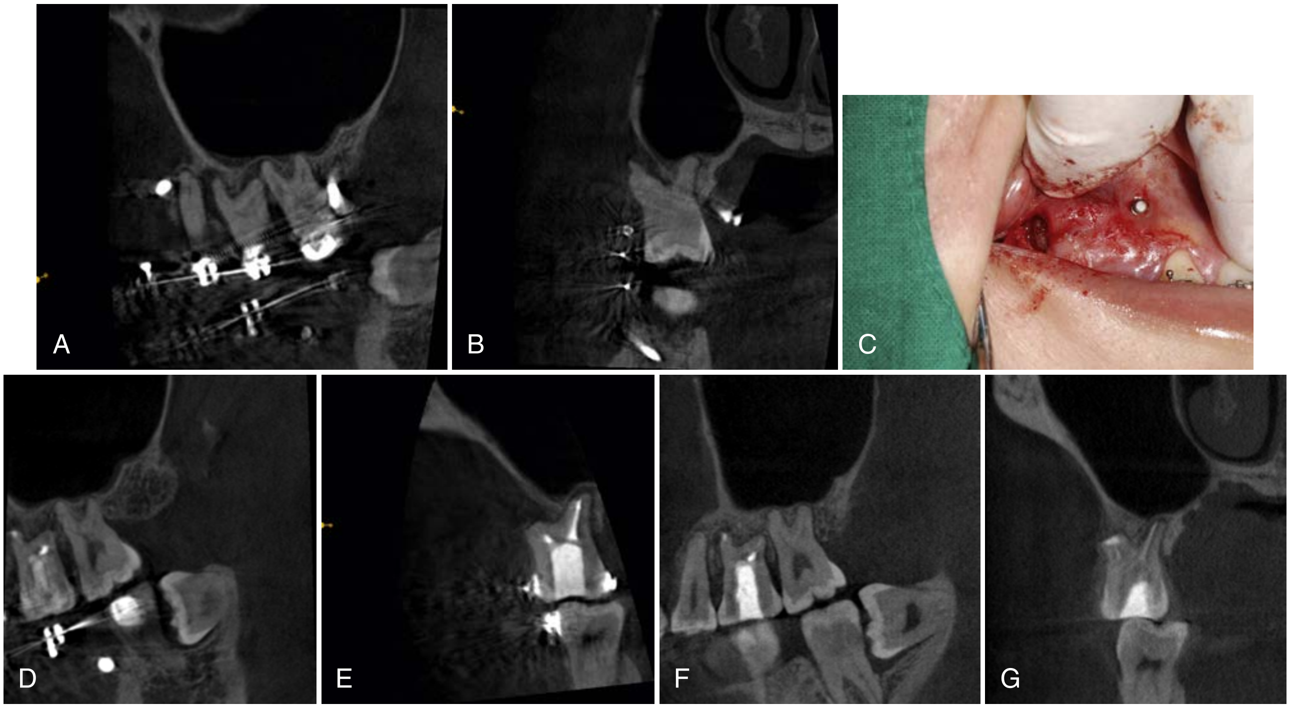

FIGURE 20-9 Injuries to the root or adjacent periodontal tissues can be efficiently managed using root canal treatment or apicoectomy procedures, depending on the extent of damage and location. **A, B,** An examination was performed with three-dimensional cone-beam computed tomography (CBCT) imaging when continuous pus discharge was observed after temporary anchorage device (TAD) removal. Root injury and consequent surrounding bone loss were observed; furcation involvement was also noted. **C,** When the operative field for apical surgery was secured, a hole was observed in the distal root, presumably attributable to the TAD. **D, E,** Three-dimensional CBCT image 1 month after root resection. Preventing secondary trauma with occlusal adjustment is very important for favorable healing. **F, G,** Normal lamina dura was observed in radiographs 12 months after the root resection was performed. No abnormal signs or symptoms were present.

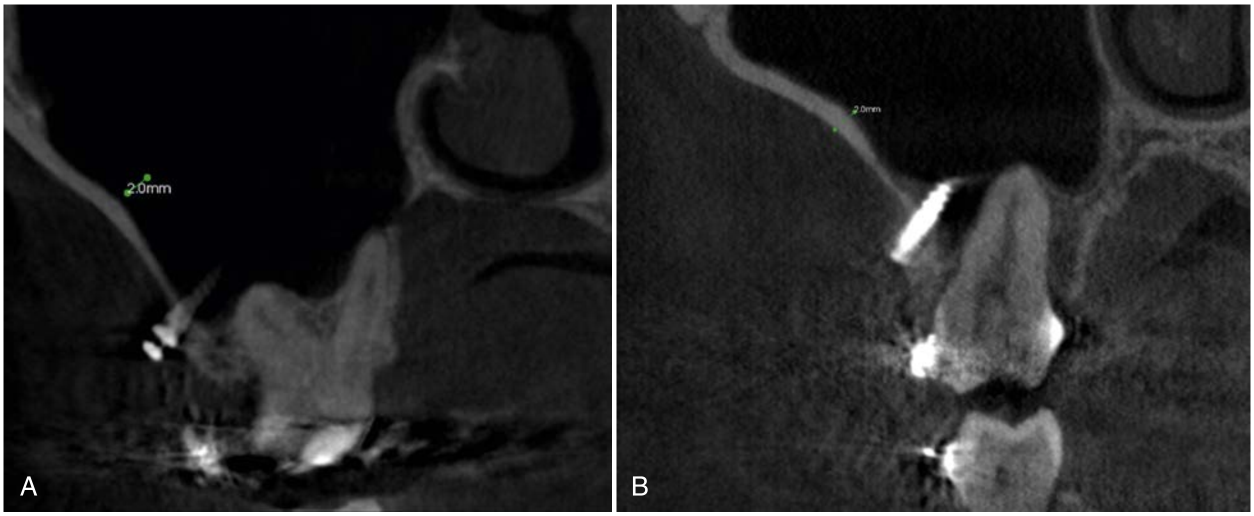

FIGURE 20-10 Even temporary anchorage devices (TADs) placed in thin bone can provide orthodontic anchorage that can withstand approximately 150 g of orthodontic force. **A,** No feeling of resistance was detected while placing the TAD; therefore a radiographic examination with three-dimensional cone-beam computed tomography (CBCT) was performed. A computed tomography (CT) image, taken just after placement, shows that the thickness of the supporting cortical bone is 0.7 mm, which is comparatively thin. The image also shows that the TAD has penetrated the maxillary sinus. **B,** A CT image taken 14 months after TAD placement and application of orthodontic force shows no particular signs of inflammation of the maxillary sinus. No new bone formation was observed. Approximately 150 g of orthodontic force was applied using a nickel-titanium (NiTi) coil spring, and no mobility or movement of the TAD was observed.

Anatomic factors. Proper cortical bone thickness is a key factor in gaining sufficient primary stability (mechanical stabilization from cortical bone immediately after implantation), and thus adequate cortical bone is required for early stability and favorable healing.[132–134] However, even if the TAD is placed in thinner cortical bone, a certain amount of primary stability can be obtained, and this stability is capable of withstanding approximately 150 g of orthodontic force (see Fig. 20-10).[64,135] Sufficient support from cortical bone is important in gaining stability; however, primary stability itself does not entirely account for the success of the TAD, although it is an important contributing factor. The management of forces attributable to function or parafunction, which are significantly stronger and more continuous than orthodontic forces, is also important.

Edentulous areas may have low bone quality, sometimes attributable to atrophy. In these areas, bone probing is necessary after anesthesia to check the quality of cortical bone.

Although not always necessary for TAD maintenance,[56,61,136] attached gingiva is more favorable, compared with the oral mucosa. However, stability may be compromised if the TAD is irritated by the oral mucosa and can lead to unfavorable conditions.

TAD placement in areas where significant stress is applied should be avoided when possible. For example, stability of a TAD near the mandibular first molar can be compromised[55,60] as a result of masticatory stress. Good accessibility during surgical placement is advantageous in achieving primary stability. The risk of irreversible injury to important anatomic structures should be minimized. Furthermore, the TAD, itself, should not be an obstacle for planned tooth movements.

Biomechanical factors. The TAD should be placed in a biomechanically suitable position for planned tooth movements. Moreover, the TAD position must be predominantly favorable for the primary target tooth.

Clinical factor. Pain and discomfort during or after surgical placement of TADs are clinically acceptable.[137–140] Furthermore, the TAD should be placed in areas that result in minimal discomfort for the patient during treatment.

Treatment Strategy

First, to achieve treatment objectives efficiently, a strategy should be planned (Fig. 20-11) according to the TAD type to compensate for any respective disadvantages. The priority of tooth movement should be decided before instituting a plan to move the target tooth. In other words, the teeth to be moved and the establishment of an anchorage unit at each stage of treatment should be identified before movement begins.

Mechanotherapy Design

To obtain the desired tooth movement according to the treatment strategy, mechanics with an optimized orthodontic force system should be designed (Fig. 20-12). During this process, two things need to be considered: (1) how to produce tooth movement and (2) how to control this movement.

With regard to producing tooth movement, the operator needs to determine what kind of orthodontic force system will be used. The force system of the mechanics at the start of treatment and any changes to this force system that come about when the tooth is moving are important and are related to mechanical efficiency and to the speed of tooth movement. This determination is especially imperative in difficult types of tooth movements.

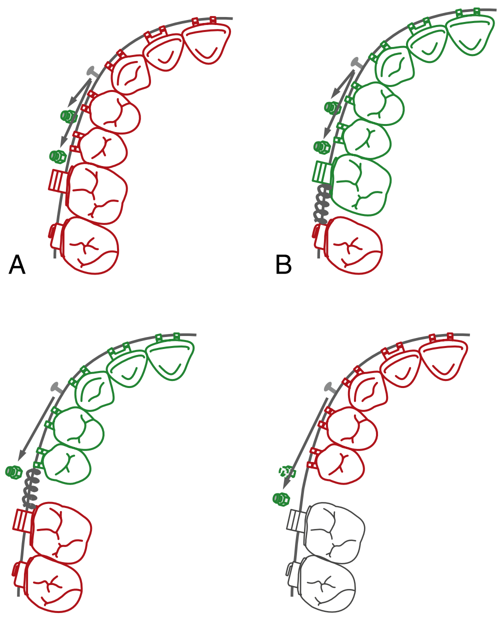

FIGURE 20-11 There are two methods for molar distalization: the entire dentition can be distalized (**A**) or the second molars can be distally moved first with the rest of the dentition following (**B, C**). When the entire dentition is distalized, temporary anchorage devices (TADs) alone provide anchorage for movement of all the teeth. On the other hand, when only the molars are distally moved first, the rest of the dentition and the TADs both provide anchorage. Treatment mechanics may be simpler and the treatment time shorter when distalizing the entire dentition at once. However, treatment predictability also lessens as more teeth are involved. Conversely, when separately distalizing the molars, tooth movement is more predictable because of the increased anchorage and the movement of fewer teeth. Furthermore, distalization of more than one-half a cusp width can be gained when a second TAD is placed after the first segment has been distalized with the first TAD (**C**). This method aids in overcoming the restricted interradicular space found between the first and second molars. (*Green* indicates an anchorage unit; *red* indicates the unit to be moved.)

The operator should also decide how to control the teeth three-dimensionally during treatment. Unwanted movements can occur as treatment progresses, even in an ideally designed force system. For successful application of TAD mechanics, proper monitoring and three-dimensional adjustments should be made on tooth movement (Case Study 20-1). There are several different ways to make such modifications: the use of a single force with or without an additional TAD, the use of brackets and wires, and the combination of both.[6]

More specifically, three types of mechanics can be used (Fig. 20-13): force-driven mechanics, which use a single force; shape-driven mechanics, which use the shapes of the archwires engaged in the brackets; and a combination of the former two types of mechanics.[141]

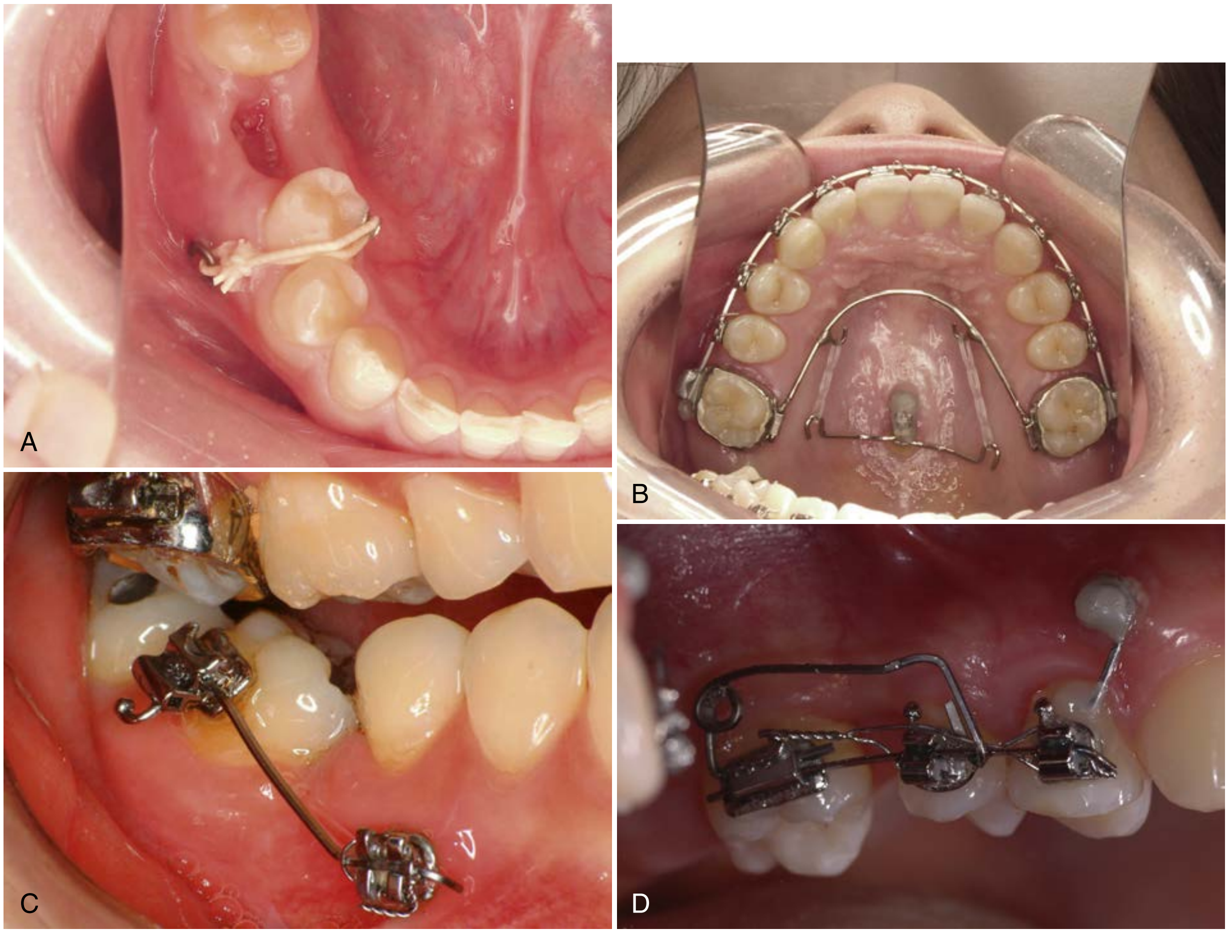

FIGURE 20-12 Diverse methods using temporary anchorage devices (TADs). **A,** *Direct application of a single force.* When using a single force, precise calibration is possible. Moreover, the whole force system does not significantly change even as the tooth is moved. To control the tooth movement, the line of action should be adjusted. **B,** *Indirect application of a single force.* Using attachments on TADs, the line of action can be controlled. **C,** *Direct application of a force and moment.* If wires can be engaged to TADs, TADs can produce not only a force but also a moment. When the wire attached to the TAD is engaged into the bracket slot on the opposite side, it becomes a statically indeterminate force system, and this force system cannot be precisely predicted. When the tooth is moved, the total force system will be altered as well. Additionally, complex use of a TAD can negatively affect its stability. **D,** *Indirect application of a force and moment.* The combination of a TAD and tooth can be considered a total anchor unit. It can provide three-dimensional anchorage, but little movement of the anchorage unit occurs. When using this unit for an indirect application, the operator has to consider that the tooth, which has a periodontal ligament (PDL), can be moved, but the stable TAD with an osseous interface cannot be moved. This means that if the TAD is splinted with a wire of higher stiffness to a tooth receiving heavier occlusal forces, a detrimental effect to the stability of the TAD will occur.

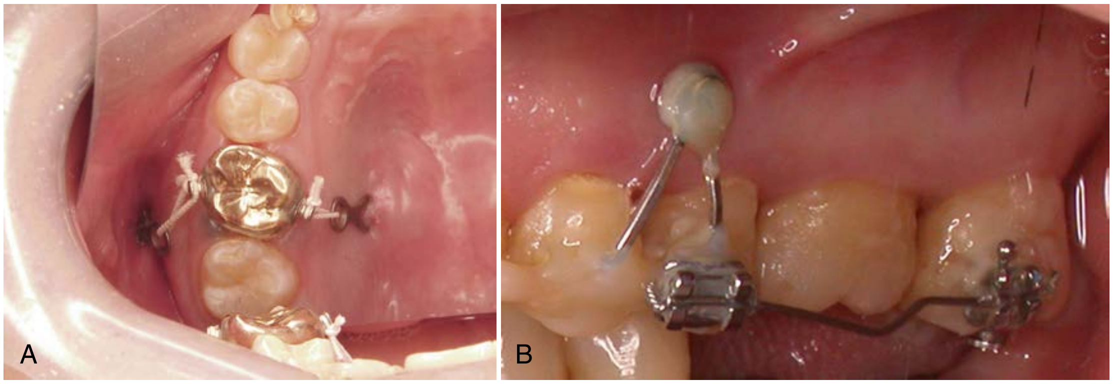

FIGURE 20-13 Molar intrusion can be achieved by force-driven mechanics **(A)** or shape-driven mechanics **(B)**. **A,** Force-driven mechanics use only single forces without moments. **B,** Shape-driven mechanics use continuous archwires, which are engaged into the brackets. As a consequence, forces and moments are produced but cannot be calculated chairside.

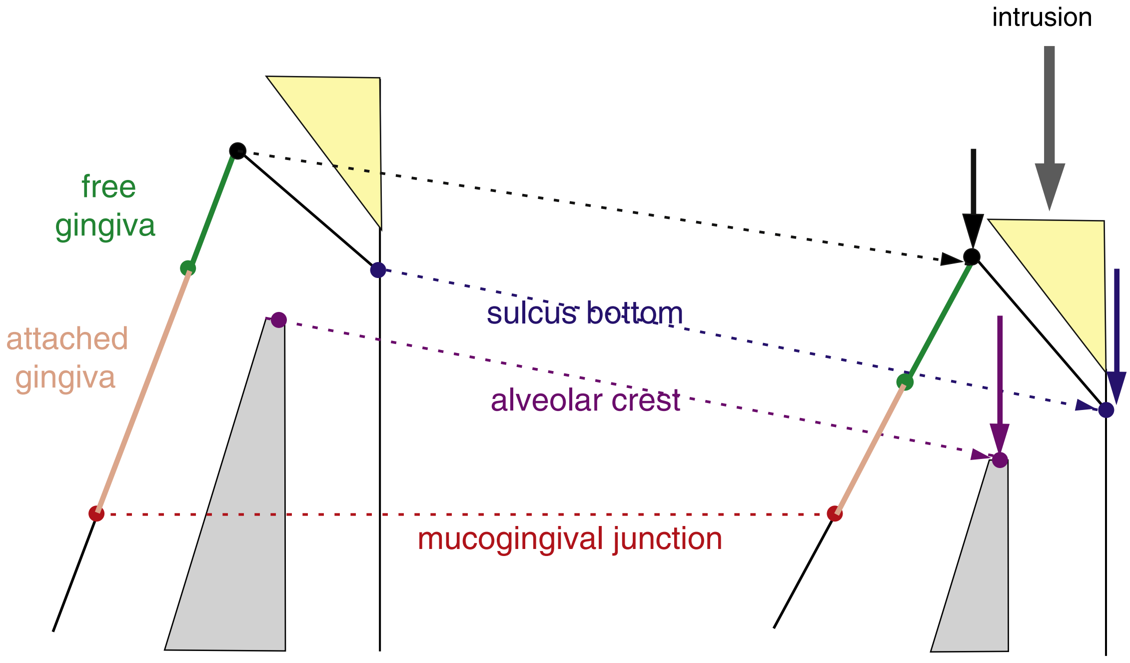

FIGURE 20-14 Local effects of molar intrusion. As the molars are intruded, the alveolar bone crest and free gingival margin will eventually move together if proper oral hygiene control is maintained. However, the mucogingival junction does not change; therefore the width of the attached gingiva decreases.

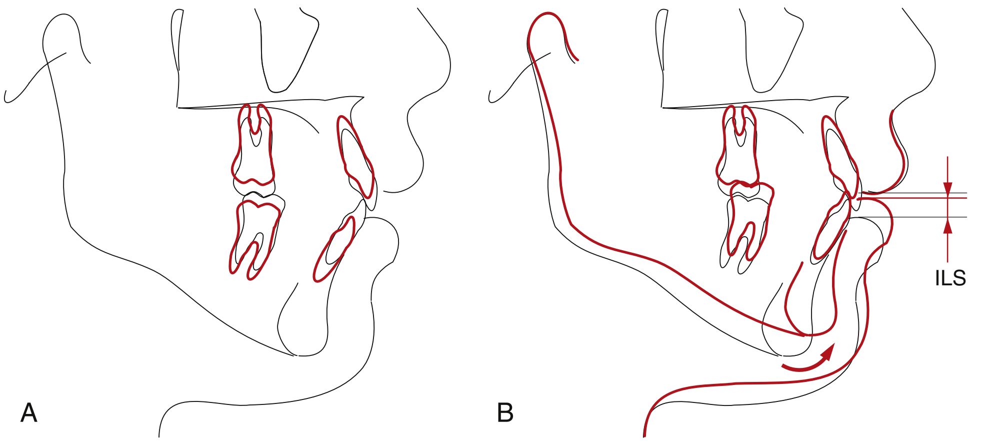

FIGURE 20-15 General effects of molar intrusion. After molar intrusion (**A**), the mandible rotates around the horizontal condylar axis to align itself to maintain interocclusal rest space. Consequently, the chin moves upward and forward, and the interlabial space (ILS) at rest decreases (**B**).

Force-driven mechanics have a statistically determinate force system, whereas shape-driven mechanics have a statistically indeterminate force system. From the standpoint of efficiency, force-driven mechanics are more advantageous because the force system can be precisely designed and does not significantly change, even with tooth movement.

The force system of shape-driven mechanics cannot be precisely designed, and it significantly changes with tooth movement because it is a statistically indeterminate force system. Therefore shape-driven mechanics are not efficient in cases with difficult types of tooth movements, such as molar intrusion. However, shape-driven mechanics are more effective in detailed and clinical adjustments of tooth positions. The combination of both types of mechanics takes advantage of the strengths that are exhibited by each.

Molar Intrusion

Decision Making

When considering the effects of molar intrusion* (Figs. 20-14 and 20-15) and deciding whether a molar should be intruded, three major factors should be evaluated.

Local factors. The intermaxillary occlusal relationship should be considered. The condition of the alveolar bone and attached gingiva should also be evaluated.

* References 6, 31–46, 129, 142–157.

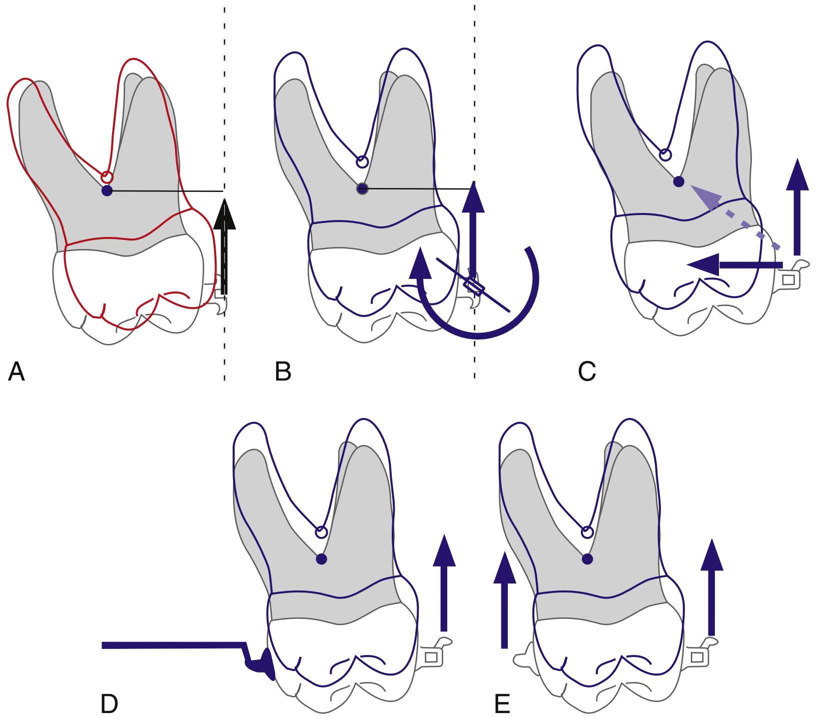

FIGURE 20-16 Posterior torque and arch form control during molar intrusion. Posterior torque and arch form (buccolingual positioning) control are related. **A,** Buccal intrusive forces away from the center of resistance cause buccal tipping and arch expansion. **B,** Lingual crown torque can be used to offset the tendency of buccal tipping for bodily movement. However, the precise amount of moment (palatal crown torque) needed is difficult to calculate. Theoretically, even if palatal crown torque is precisely applied, slight tooth movements can generate changes to the force system, rendering it biomechanically inefficient. To apply lingual crown torque, the archwire can be torqued or brackets with sufficient lingual crown torque can be used. **C,** In the case of using buccal intrusive forces, a constriction force can be applied to reduce the tendency for buccal tipping. The degree of constriction force should be similar to that of the intrusion force, but this force system is difficult to control precisely. **D,** An active or passive transpalatal archwire (TPA) or lingual archwire (LA) is effective for controlling torque and arch form. However, these appliances may be uncomfortable for patients while lowering the rate of tooth movement as well. **E,** Labial and lingual combined intrusion forces are most effective for torque control. This system can also control the arch form.

General factors. In addition to occlusal relationships, facial and smile aesthetics should be assessed. To reduce lower facial height, the upper and lower dentition should be controlled at the same time. If only one arch is intruded, then unwanted extrusion of the posterior teeth occurs in the opposing arch.[6,38,39,44]

Factors for stability. Stability of molar intrusion and anterior facial height reduction can be achieved by orthodontic overcorrection.[6,44,146] Anterior open bites can be corrected through surgery as well; however, surgical correction does not always guarantee stability.[158,159] For retention of an anterior open bite correction, functional improvement of the musculature after treatment is essential.* Tongue thrust during swallowing should be especially controlled for increased stability.[6,160,162,163]

Management of problems related to TMJ function and the masticatory muscles is also important for stability.[47,48] The mandible can rotate posteroinferiorly in the presence of a temporomandibular disorder (TMD), night teeth clenching, or bruxism, and, as a result, open bites can relapse.

Biomechanics

Mechanical efficiency. Molar intrusion is one of the most difficult tooth movements to achieve. Therefore mechanical efficiency is very important in the design of molar intrusion mechanics; that is, force-driven mechanics should be included in the mechanical design, considering its efficiency and predictability (Fig. 20-16). Approximately 80 to 100 g of intrusive force per molar can achieve 0.3 to 0.4 mm of intrusion per month.[31,35,36] Orthodontically induced root resorption is not clinically significant after the application of such intrusive forces, and no clinically critical side

* References 6, 38, 39, 44, 47, 48, 160–164.

FIGURE 20-17 Biomechanical efficiency of posterior intrusion. As seen with anterior intrusion, the use of a single force (e.g., force-driven mechanics) for posterior intrusion is effective and efficient, as opposed to the use of simply the brackets and wires. Intrusion can also be more quickly achieved with a single force. A single force, however, is not effective for controlling arch form, tooth axis, inclination of the occlusal plane, and detailed adjustments. A continuous arch, which is a statically determinate force system, is advantageous for controlling the arch form, tooth axis, and individual tooth positions yet disadvantageous from the viewpoint of efficiency. If a combination of the two force systems is used, then the disadvantages of each system are mutually compensated. For maxillary molar intrusion, force-driven mechanics (e.g., single force) were used to increase efficiency on the palatal side, and shape-driven mechanics (archwire with compensating curve) were used on the labial side to make detailed adjustments. **A, B,** Intraoral views before treatment. **C, D,** Intraoral views after 3 months of molar intrusion with buccal and palatal temporary anchorage devices (TADs) and a continuous archwire.

effects, such as attachment loss, are expected if trauma from occlusion (TFO) is adjusted and if the clinical situation is carefully monitored.

Three-dimensional control. Mechanics for posterior intrusion should be designed to achieve three-dimensional control of the molar, and the molar must be monitored in all dimensions during movement (Figs. 20-17 through 20-19; see also Fig. 20-16).[6] More specifically, rotations, tipping, torque, mesiodistal positioning, and inferosuperior positioning of the tooth all need to be controlled. Arch form, inclination of the occlusal plane, and the frontal occlusal plane should also be evaluated.

As previously mentioned, three-dimensional control can be managed in three ways: the use of a single force from the TAD, the use of brackets and archwires, and a combination of both of these methods (see Fig. 20-19). The use of a single force generated from a TAD in an appropriate position (i.e., force-driven mechanics) is more effective for gross control.

Treatment Mechanics

Maxillary molar intrusion. Palatal root control is important for upper molar intrusion because the center of resistance of the maxillary molar is located on the palatal side.[165] A palatal intrusion force is very effective for palatal root control and for an increase in biomechanical efficiency. However, palatal intrusive forces have a tendency to constrict the arch form and should be taken into consideration before applying these forces.

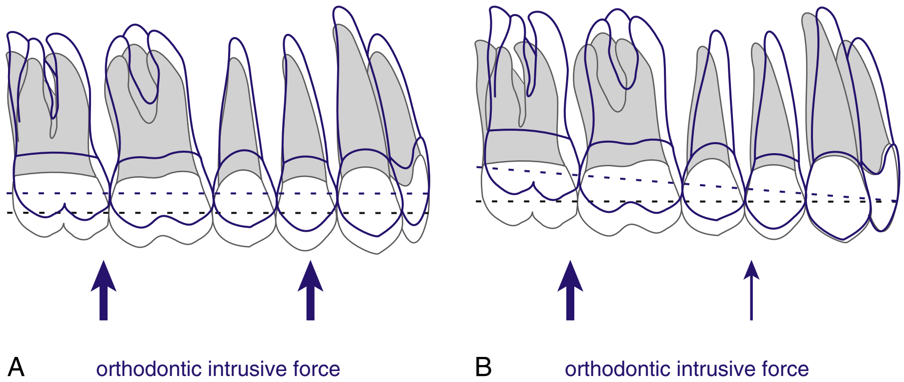

FIGURE 20-18 Control from a lateral view. Clinically, control of the inclination of the occlusal plane is one of the most important considerations in posterior intrusion, and, more specifically, the intrusion of the maxillary second molar is key. Occlusal plane inclination is related to molar axis control. **A,** To maintain the inclination of the occlusal plane, the premolars and anterior teeth should also be intruded approximately the same amount as the molars. This is especially indicated in the correction of a gummy smile or long face. **B**, The second molars should be intruded more than the premolars if the occlusal plane is to be steepened, especially in the correction of open bites. A steepening of the occlusal plane is difficult to achieve. Note the change in the inclination of the posterior occlusal plane and the changes in the axes of the individual posterior teeth, which suggests that axis control is related to occlusal plane control. Furthermore, the individual posterior teeth should be tipped back to aid in a steepening of the occlusal plane.

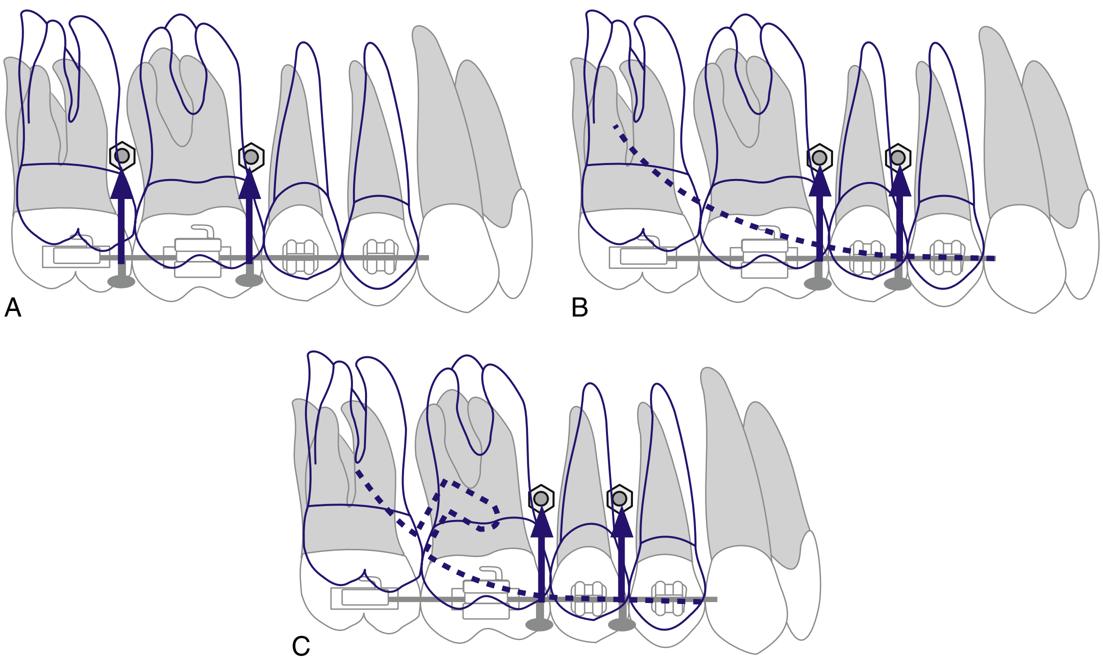

FIGURE 20-19 Second-order control. A single force generated from the temporary anchorage device (TAD) near the second molar is effective for intrusion of the second molar **(A)**. TADs may not always be ideally positioned, but the mechanical design can compensate for such limitations in placement. For example, tip back bends and/or step down bends **(B)** or L-loops **(C)** can be used to increase efficiency.

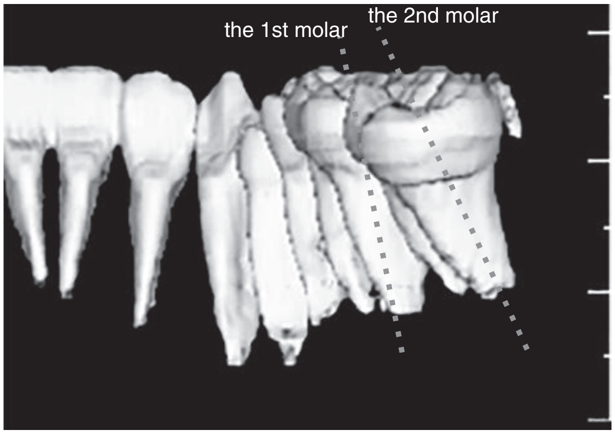

FIGURE 20-20 Root inclination of the mandibular molar. From a lingual view, three-dimensional computed tomography (CT) reconstruction view shows that the lingual inclination of the roots of the posterior teeth increases from the premolars to molars. The mandibular second molar is tipped more lingually than the mandibular first molar.

Mandibular molar intrusion. Mandibular molar intrusion is different from maxillary molar intrusion; biologically, the mandible comprises harder and denser bone, contributing to a slower bone turnover rate. Clinically, the success rate of a miniscrew-type TAD placed between the mandibular molars may be lower than a TAD positioned between the maxillary molars[55,60] because of masticatory stresses. The mandibular lingual area is especially difficult for TAD insertion because of low accessibility attributable to the tongue.

However, lingual intrusive forces are less of a necessity in mandibular molar intrusion than in maxillary molar intrusion because buccal intrusive forces in the mandible produce less buccal tipping, which is due to the fact that more lingual inclination exists in the mandibular molars, compared with the maxillary molars (Fig. 20-20). Considering these obstacles, control of the second molars should be a priority from the very beginning.

Yet when unilateral mandibular molar intrusion or posterior intrusion in conjunction with arch constriction is required, lingual miniscrew-type TADs prove to be very useful (Fig. 20-21). When the mandibular second molar is distally tipped, the interradicular space between the first and second molars is very limited, necessitating special precautions when placing TADs in this area. Additionally, because of low accessibility and thick lingual cortical bone, the risk for TAD fracture in the posterior lingual area is high.

Molar Distalization

Decision Making

- Required space: If more than 3 mm of space per side is required to achieve the treatment objectives, then premolar extraction may be preferable from the standpoint of treatment efficiency.
- Hard tissue conditions: There must be enough space for distalization. Second or third molar extraction should be considered before distalization to secure adequate space (Fig. 20-22).
- Soft tissue conditions: A clinically acceptable amount of attached gingiva must be present after distalization, especially on the distobuccal aspect of the molar.

Biomechanics

Mechanical efficiency. Distalization forces need to be efficiently applied to the molar as opposed to the other teeth. The distalization forces can be applied en masse or singly to each tooth.

In the maxilla, TADs placed on the palatal side can directly apply distalization forces to the molar. Moreover, these TADs can also control the mesiodistal axis of the molar through manipulation of the line of action (Figs. 20-23 through 20-25).

Although adjacent teeth may limit mesiodistal tooth movement, buccal interradicular miniscrew-type TADs are very useful in molar distalization because of the ease of placement and simple application during treatment (Figs. 20-26 through 20-28). With a properly positioned TAD, 3 mm of distal movement per side can be achieved, after which the initial TAD can be removed and a new TAD placed to gain further distalization.

Three-dimensional control. As with molar intrusion, three-dimensional control of the molar is important in molar distalization when using TAD mechanics (Figs. 20-29 through 20-34). Thus the mechanics should be designed to manage the three-dimensional position of the molar. Once again, three methods will achieve this control: the use of a single force from the TAD, the use of brackets and archwires, and a combination of both systems.

Notably, in molar distalization, special attention to vertical control is needed because distalization can inadvertently cause an increase in the overall vertical dimension.

En masse distalization. All of the anterior and posterior teeth can be distalized at the same time using rigid anchorage. The same principles are applied for full dentition distalization as for single tooth movement. Considerations for mechanical efficiency and three-dimensional control are necessary as well. With regard to three-dimensional control, the center of resistance of the total dentition can be estimated.[166] Theoretically, if the force is applied through the center of resistance of the whole dentition, then translation of the entire dentition will be achieved. Clinically, however, the tendency for the teeth to move individually as opposed to entirely is great (Fig. 20-35). Furthermore, if the dentition moves as a whole body and does not allow for tipping of individual teeth, then movement will be very slow. Even in en masse distalization, the key factor is molar control. If the molars are three-dimensionally well controlled, then moving the remaining teeth is comparatively easy. En masse movement is indicated when intrusion is needed in addition to distalization.

Molar Protraction

Decision Making

TADs can provide stable anchorage for molar protraction.[167–170] However, molar protraction toward an edentulous area can be more affected by biologic conditions than by biomechanics.[90,91,171,172]

When the first molar or second premolar is missing, protraction in the maxilla is somewhat predictable. However, in the mandible, various individual differences exist. According to research conducted by Roberts and colleagues,[169] the rate of molar traction can be as low as 0.2 mm per month. Extra caution should also be taken when moving teeth into edentulous areas in the mandible because severe periodontal attachment loss can be induced during protraction, depending on the condition of the alveolar bone.[90,91,172]

FIGURE 20-21 A 25-year-old female patient reported chief complaints of protrusion, an anterior open bite, long face, and missing molars. Vertical disharmony was improved by anterior and posterior intrusion, as was the chin position attributable to molar intrusion and subsequent autorotation of the mandible. A–C, Intraoral view before treatment. D–F, Intraoral view after intrusion. Lingual temporary anchorage devices (TADs) between the mandibular molars were used to control the mandibular molars vertically and anteroposteriorly.

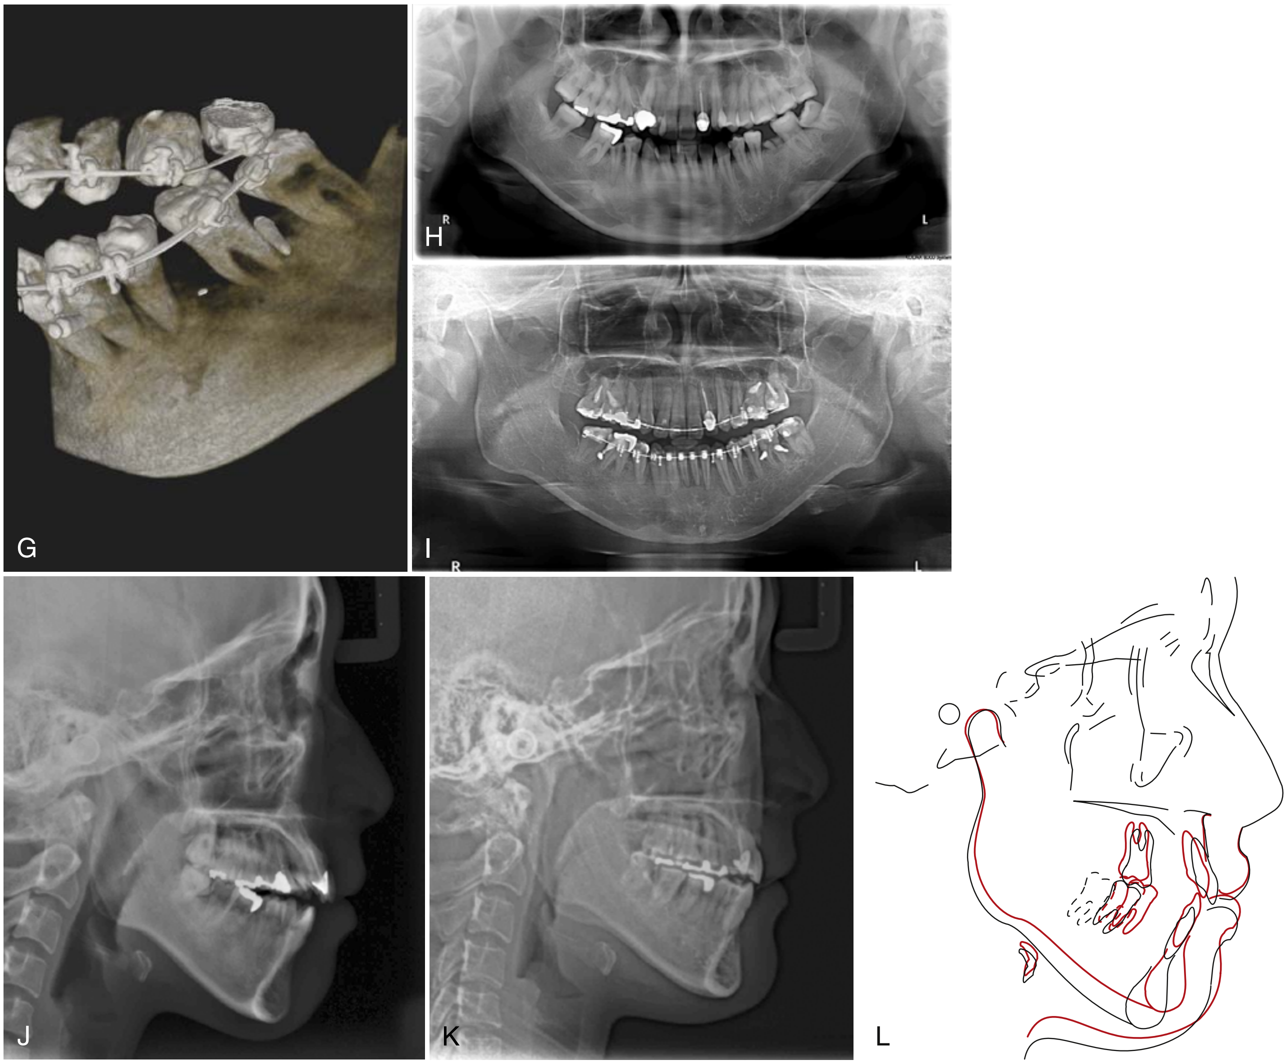

FIGURE 20-21, cont'd G, A three-dimensional cone-beam computed tomography (CBCT) image shows buccal and lingual TAD placement. Anterior buccal TADs were used to protract the posterior teeth, and lingual TADs between the molars were used to increase the efficiency of molar intrusion and to control the arch form. H, Panoramic radiograph before treatment. I, Panoramic radiograph at the completion of treatment. J, Cephalometric radiograph before treatment. K, Cephalometric radiograph at the completion of treatment. L, Superimposition of pretreatment and posttreatment cephalomatric radiographs. The solid line refers to the mandibular right first molar, and the dotted line indicates the mandibular left second molar.

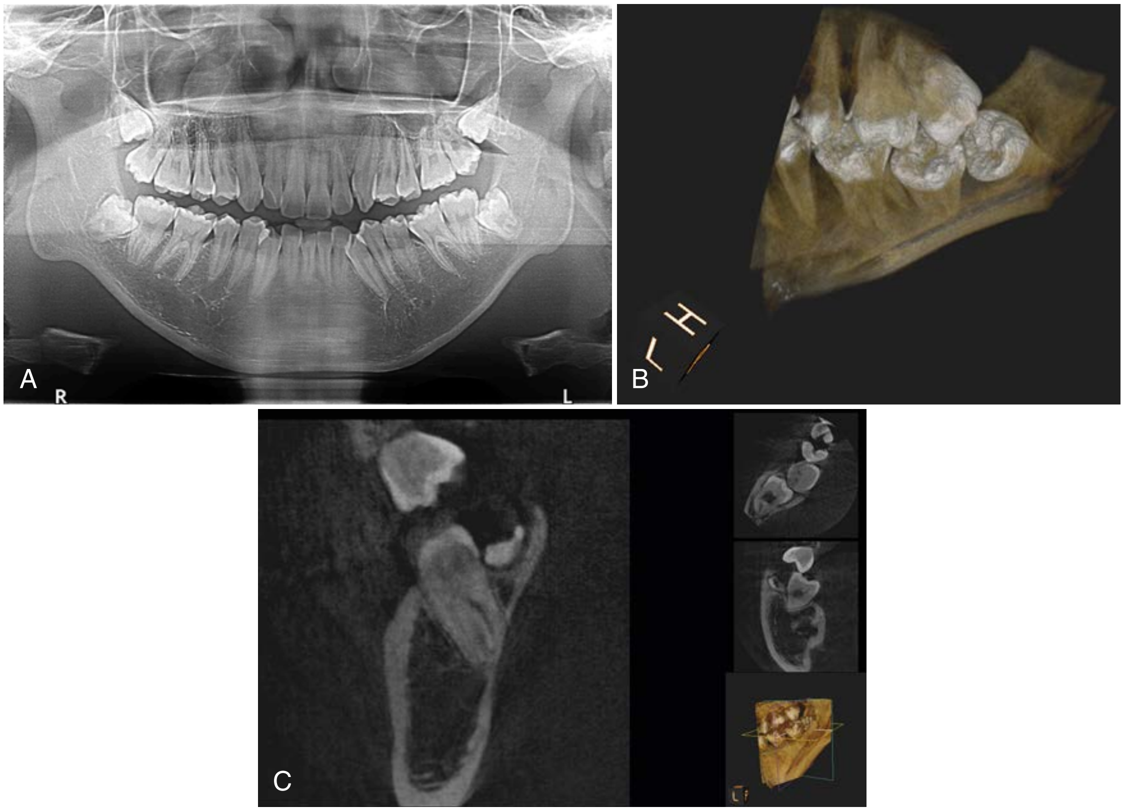

FIGURE 20-22 Even when the mandibular third molars are extracted, sufficient space to distalize the second molars cannot always be secured because of the three-dimensional morphologic structure of the mandible, which can cause the third molars to be located buccal to the mandibular second molars. **A,** Securing a moderate amount of space in the mandible was necessary to treat this 25-year-old male patient. The panoramic radiograph reveals an impacted right mandibular third molar. **B,** The three-dimensional view from the upper inner side shows the root tip of the mandibular second molar touching the inferior border of the mandible. **C,** A sagittal view at the level of the root tip of the mandibular second molar also shows contact between the root tip of the mandibular second molar and cortical bone. There is no space for distalization of the second molar.

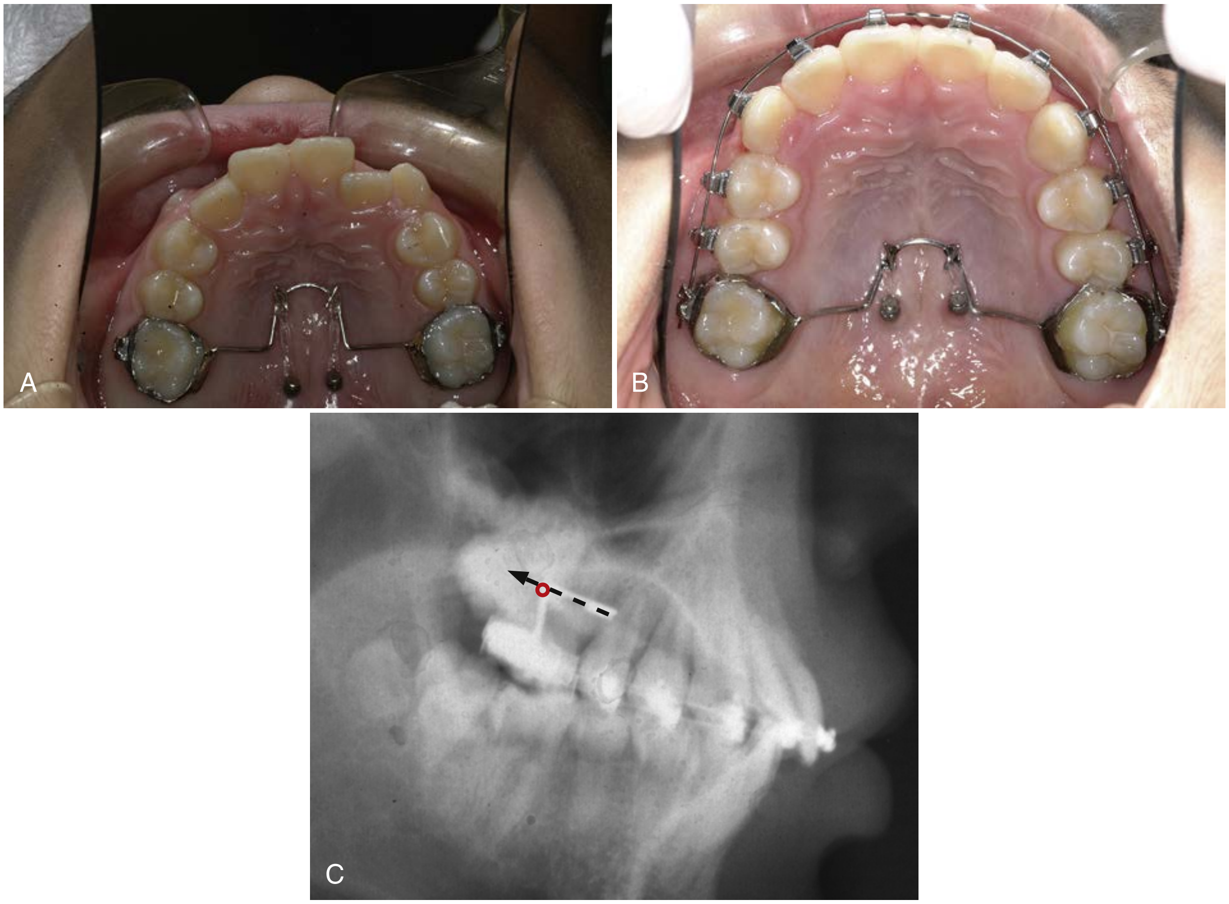

FIGURE 20-23 With a shallow palatal vault, mechanics, which consist of temporary anchorage devices (TADs) in the midpalatal suture area and a transpalatal arch, are simple and effective. With this anatomic structure, distalization forces from TADs travel through the center of resistance of the molar, which results in distalization by bodily movement. In this clinical case, the patient was in the middle of a growing period. Thus parasagittal TADs were placed, as opposed to midsagittal TADs, because palatal suture growth was not completed. **A,** Intraoral view before treatment. **B,** Intraoral view during treatment. **C,** Cephalometric radiograph during molar distalization. Distalization force (*black arrow*) travels through the center of resistance of the molar (*red circle*).

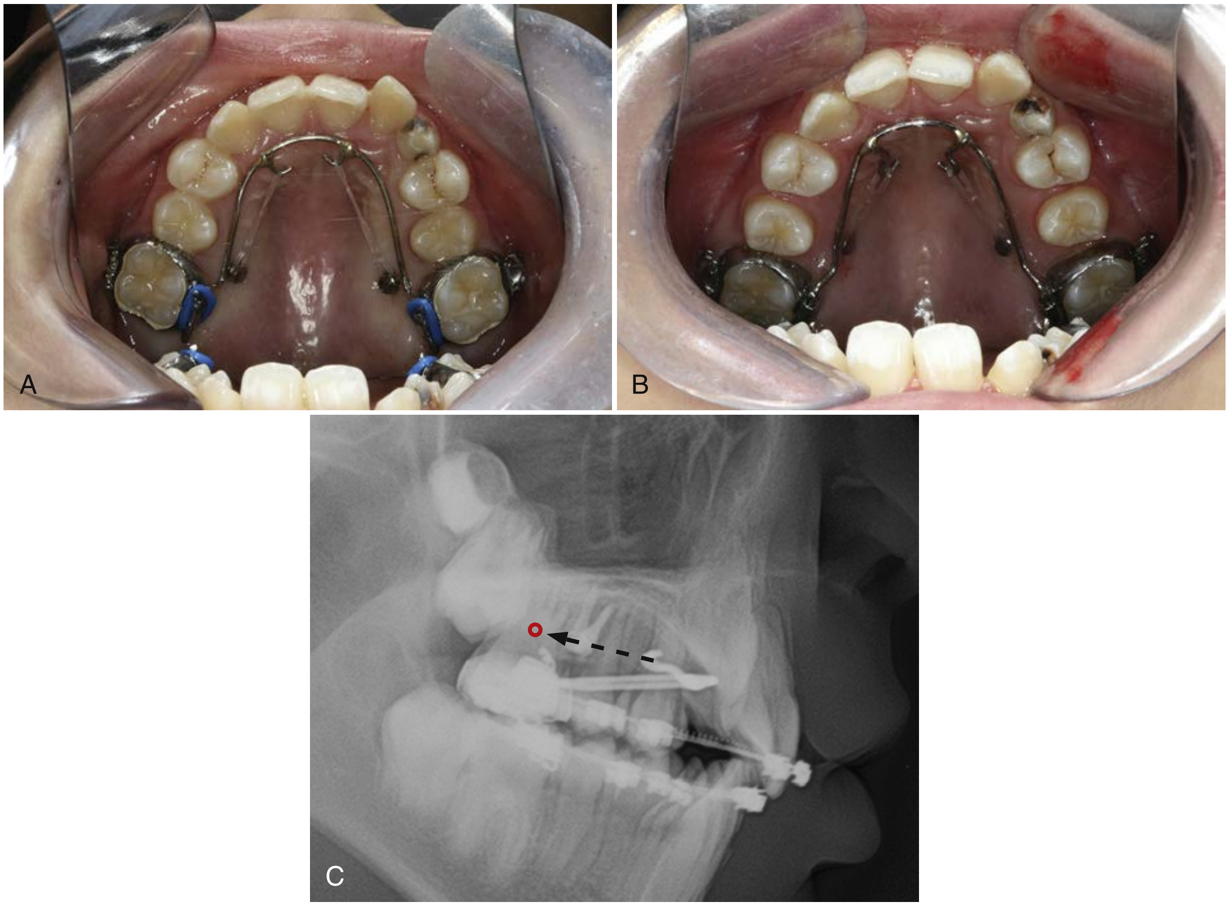

FIGURE 20-24 By modulating the line of action, distalization by bodily movement can be produced. With deep palatal vaults, temporary anchorage devices (TADs) in the palatal interdental area and a transpalatal arch can produce distalization forces that travel through the center of resistance of the molars. **A,** Intraoral view before molar distalization. **B,** Intraoral view after 5 months of molar distalization. **C,** Cephalometric radiograph before during molar distalization. Distalization force (*black arrow*) travels through the center of resistance of the molar (*red circle*). When compared with the case in Figure 20-23, the line of action moves occlusally, attributable to TAD positioning.

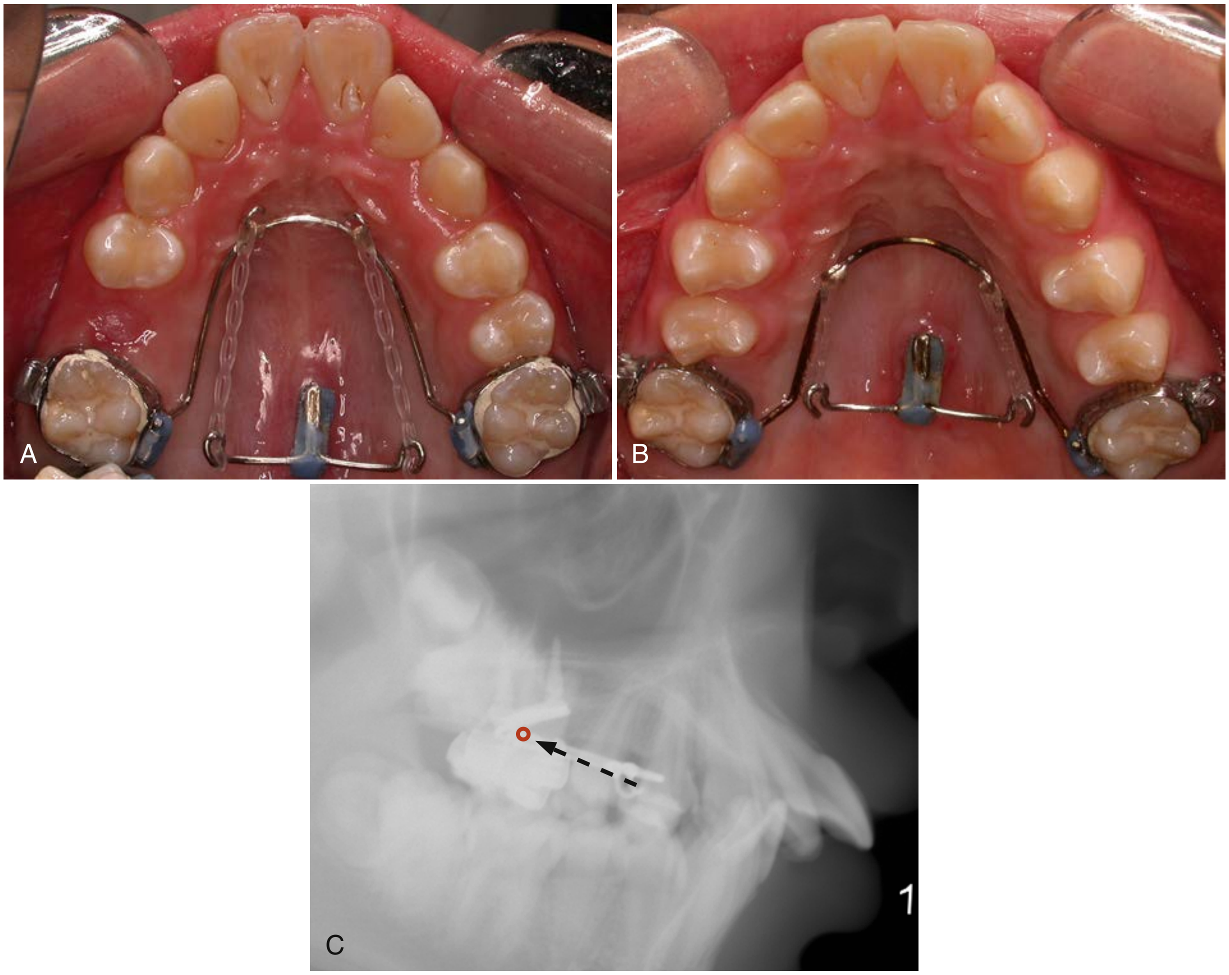

FIGURE 20-25 With deep palatal vaults, temporary anchorage devices (TADs) in the midpalatal suture area with attachments can modulate the line of action to produce distalization forces (**C,** *black arrow*) that travel through the center of resistance of the molars (**C,** *red circle*). If the distalization force is directly coming from the midpalatal TADs, as in this clinical case, then the line of action passes more apically (**C,** *black arrow*) than the center of resistance of the molar. **A,** Intraoral view before distalization. **B,** Intraoral view during molar distalization. **C,** Cephalometric radiograph taken during molar distalization.

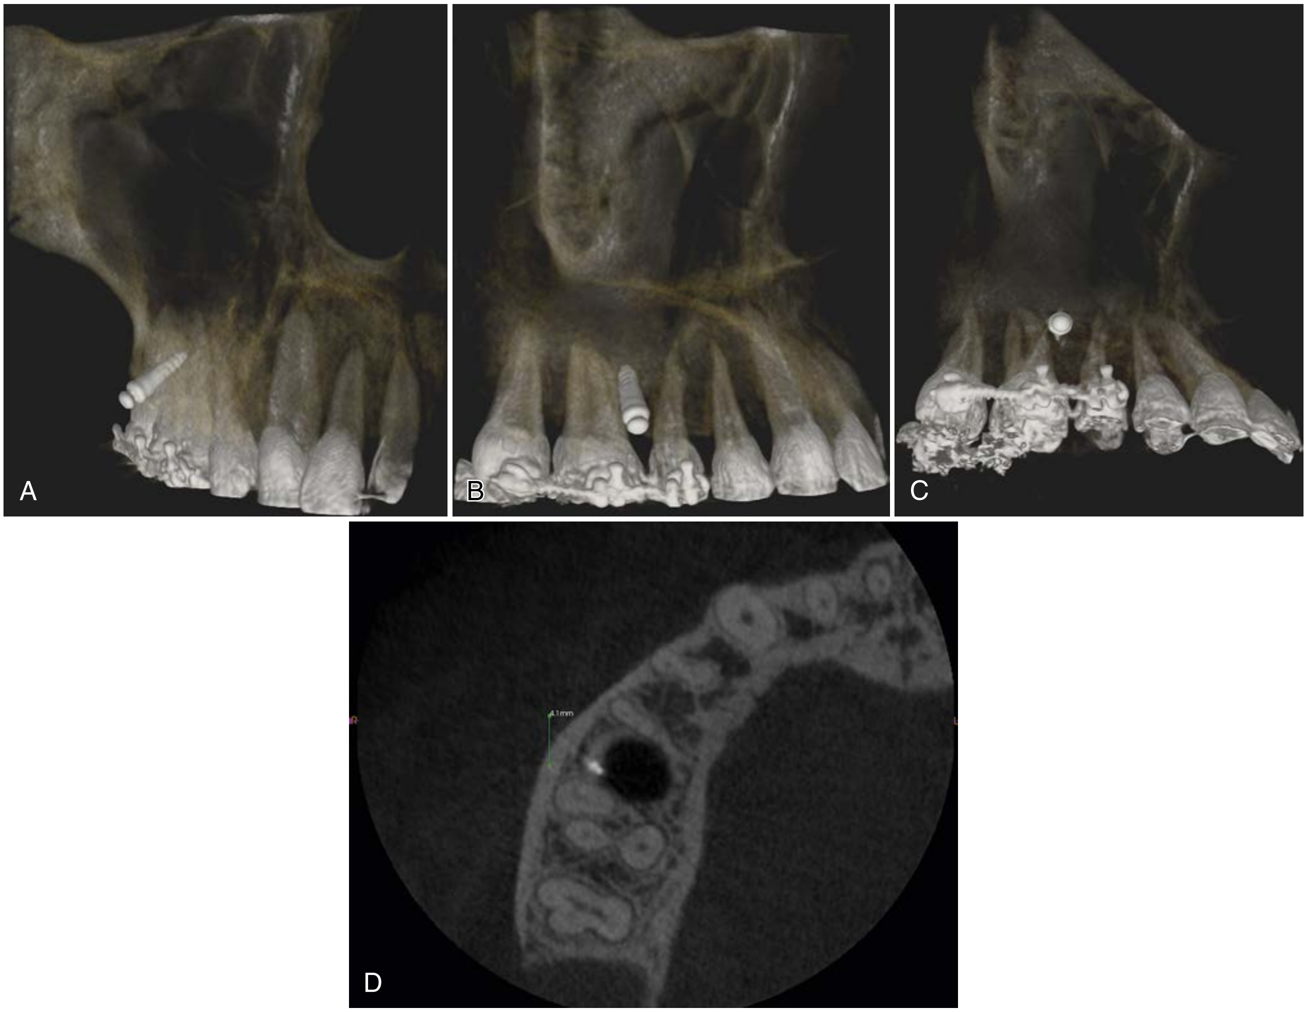

FIGURE 20-26 Buccal alveolar bone can provide enough space for a half-cusp width of distalization if the temporary anchorage device (TAD) is properly placed. However, narrow interradicular widths cannot provide enough space for mesiodistal movement. Angular placement of the TAD to the occlusal plane can take advantage of a wider buccal space. **A,** A three-dimensional view from the right side. The TAD was placed at an angle near the first molar for distalization. **B,** A three-dimensional view from the occlusal plane. **C,** A three-dimensional frontal oblique view. **D,** An axial view at the level of the tip of the TAD shows that the second premolar can move distally at least 4.0 mm.

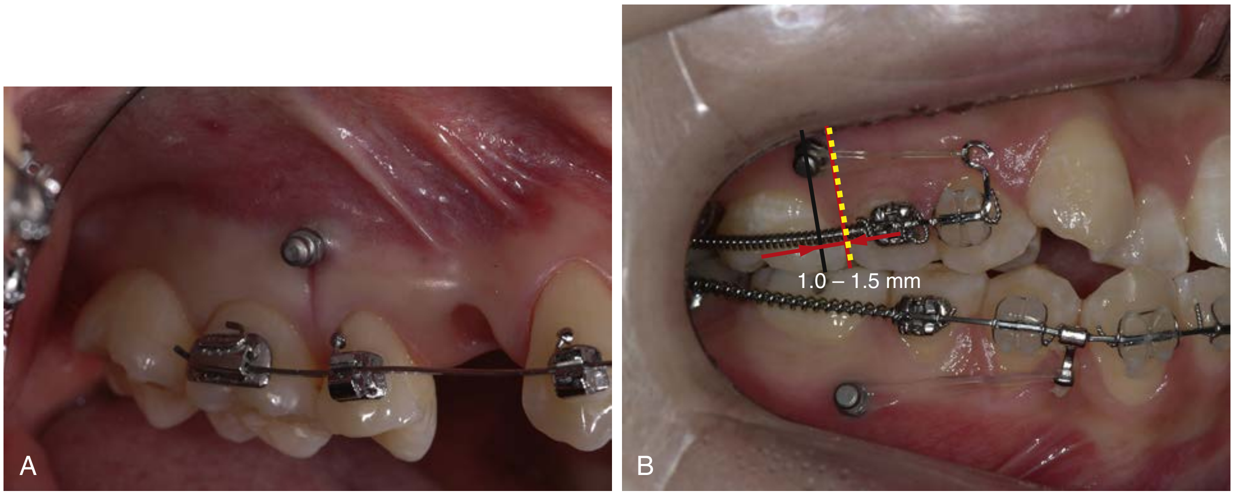

FIGURE 20-27 Off-center distal placement of the temporary anchorage device (TAD) is important in molar distalization. However, the protocol for the prevention of root injury should be followed to minimize the possibility of root injury. Normal insertion site in the buccal alveolus: **A,** The orthodontic TAD is usually placed on the midline between the adjacent teeth where it intersects with the mucogingival junction (MGJ). **B,** The TAD is placed 1.0 to 1.5 mm distal from the midline (*yellow dotted line*) because molar distalization is planned.

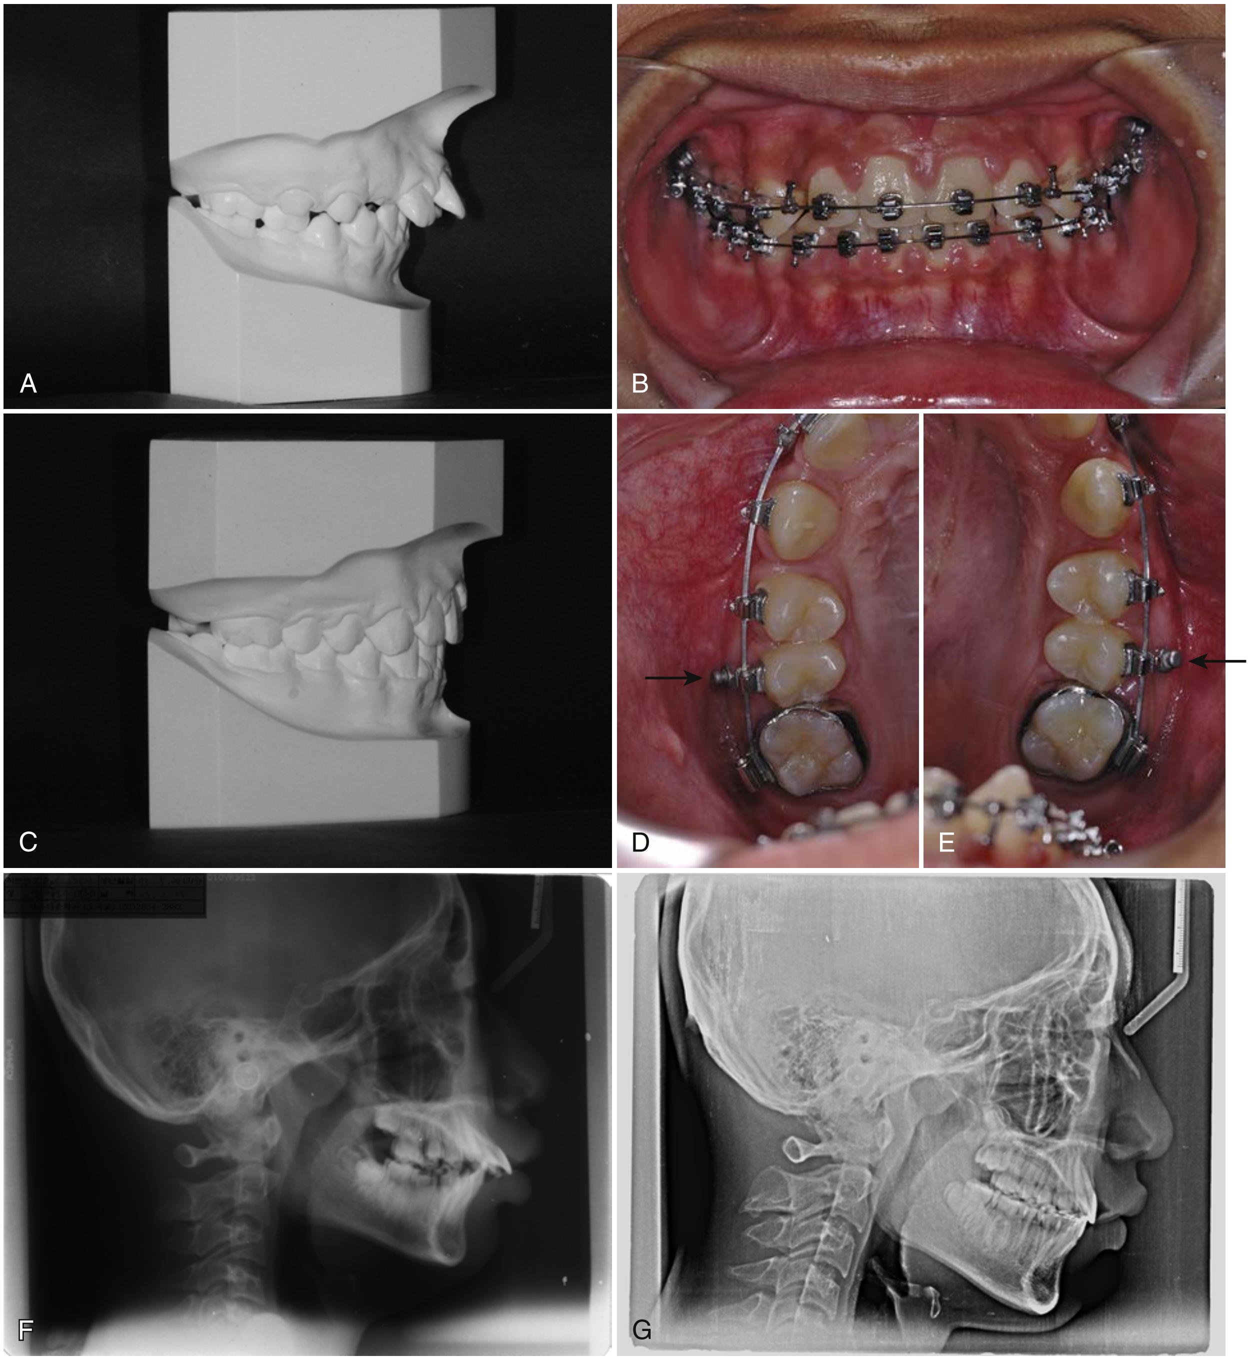

FIGURE 20-28 The patient was a 12-year-old boy whose chief complaint was protrusion. Severe overjet and a Class II canine and molar relationship were corrected by molar distalization using temporary anchorage devices (TADs) placed in the buccal interdental areas. Initial positions of the TADs at the beginning of treatment were close to the first molars. After distalization, the TADs appeared to be on the same line as the roots of the second premolars (**D, E**). If placed with proper angulation to make use of the buccal space and placed more distally rather than in the middle of the interproximal space, then buccal TADs are useful in molar distalization. **A,** View of occlusal relationship before treatment. **B,** Intraoral view during molar distalization. **C,** View of occlusal relationship at the completion of active treatment. **D, E,** Intraoral view during treatment. Buccal TADs are in line with the second premolars (*black arrows*). **F,** Cephalometric radiograph before treatment. **G,** Cephalometric radiograph at the completion of active treatment.

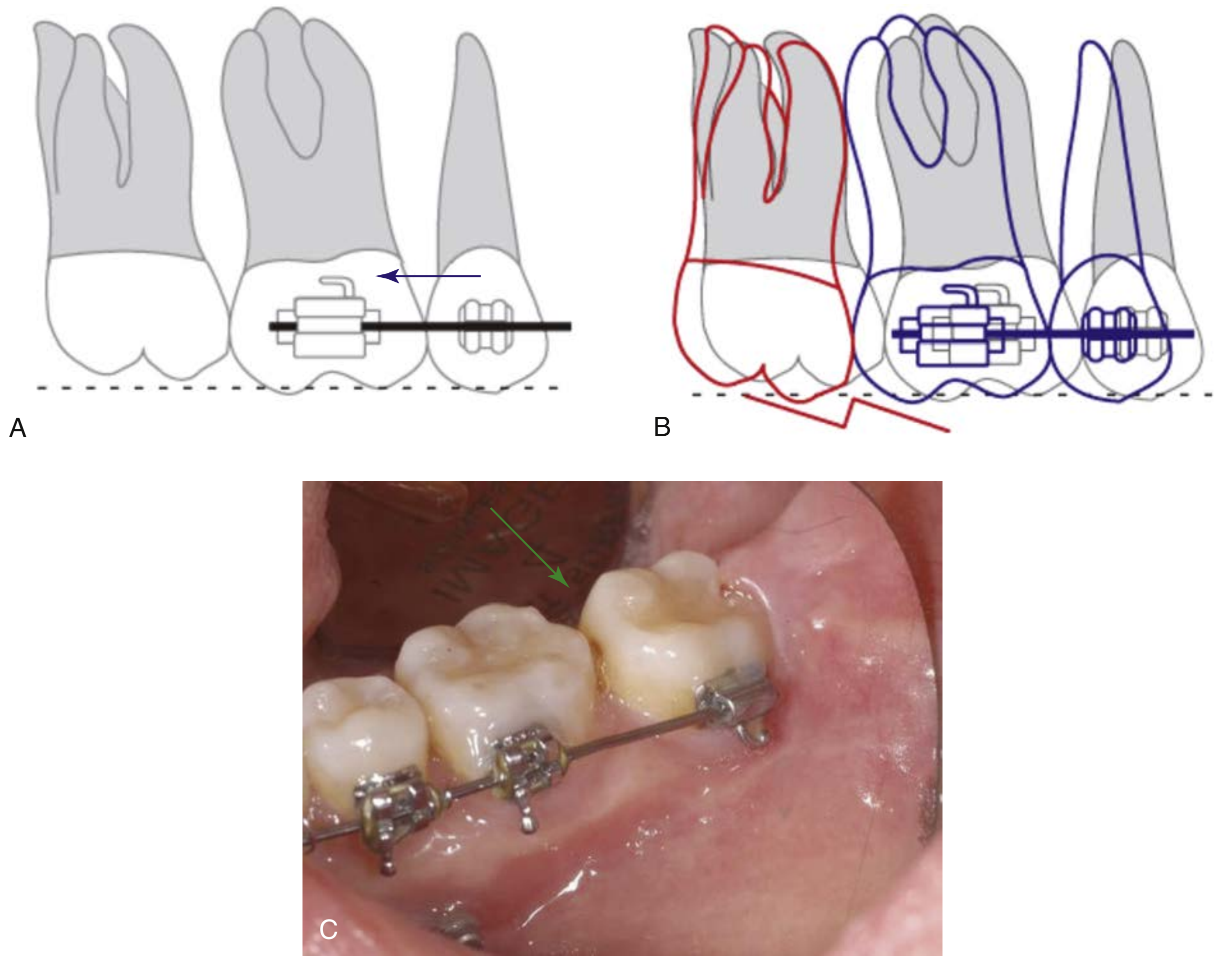

FIGURE 20-29 Mesiodistal axis control. **A, B,** If the second molar is not included, then it may tip back as a result of the distal movement of the first molar; marginal ridge discrepancies can result. The second molar should be simultaneously controlled whenever possible during molar distalization to prevent any vertical discrepancies. **C,** Even with the strap-up including the second molar, bodily distalization of the second molar is not easy to attain because tipping can easily occur. A clinical sign of tipping is the elevation of the second molar mesial marginal ridge (*green arrow*). To prevent distal tipping while distalizing, the use of wires of adequate stiffness is also a practical consideration.

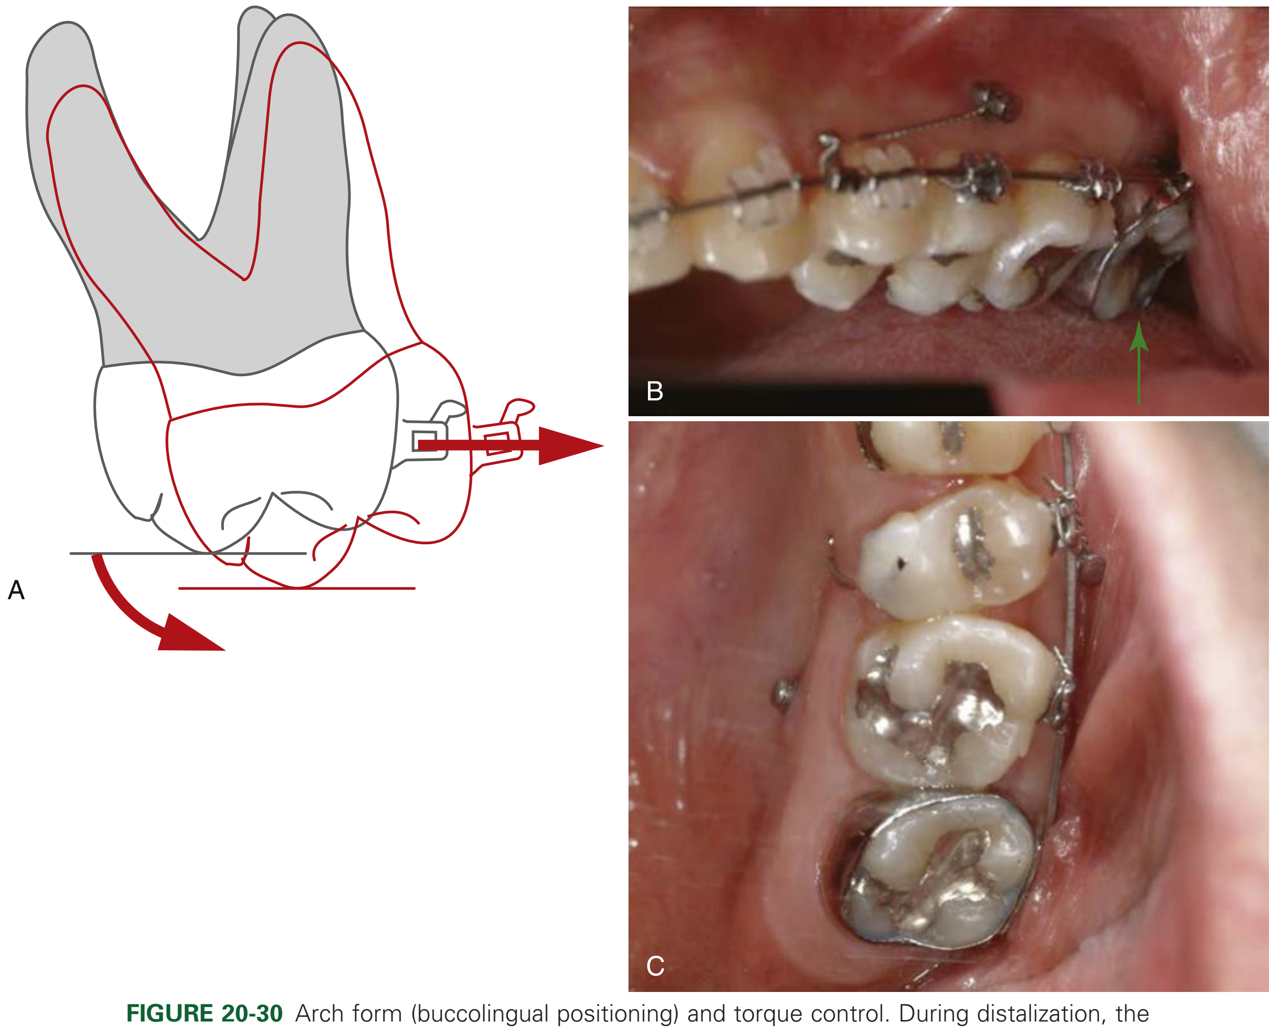

FIGURE 20-30 Arch form (buccolingual positioning) and torque control. During distalization, the maxillary second molar can easily tip buccally, whereas the mandibular second molar can easily tip lingually, attributable to the respective buccolingual inclinations of these molars. In addition, posterior torque control and arch form (buccolingual positioning) control are related. If the second molar is tipped to the buccal, then the palatal cusps inferiorly fall and the torque of the second molar worsens. A slight toe-in bend may aid in controlling the buccolingual positioning of the second molar and, as a result, may also be useful in controlling torque. **A,** Schematic illustration of arch form changes and the relationship between buccolingual position and torque. **B, C,** An intraoral view after molar distalization. The second molar torque worsened because of buccal tipping (*green arrow*).

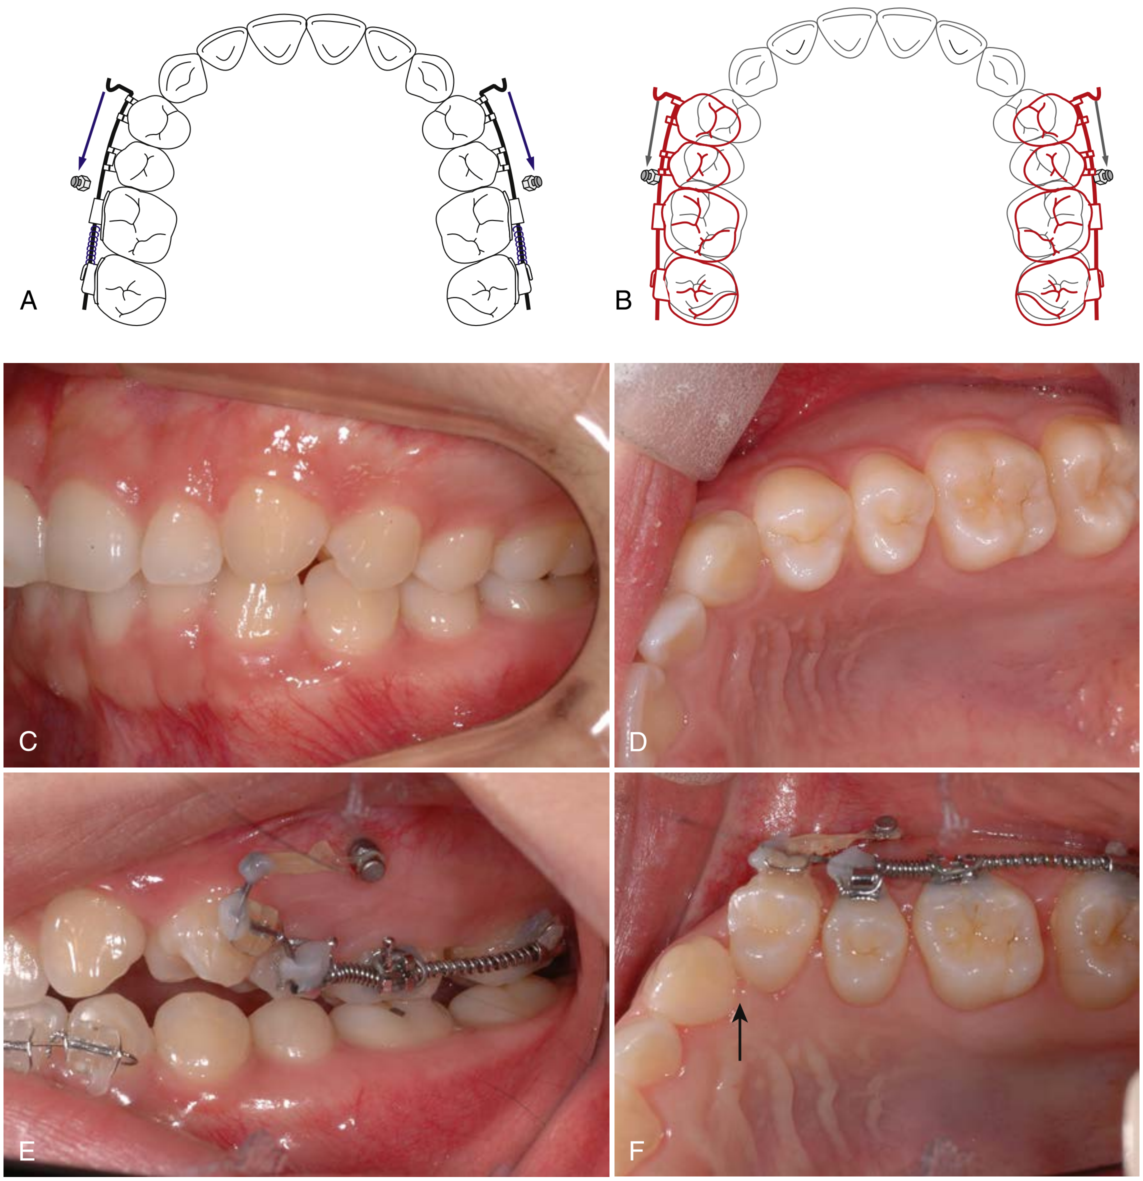

FIGURE 20-31 Arch form control. Sectional mechanics without cross-arch splinting are not adequate for arch form control because of the tendency for mesial outrotation of the posterior segment. A, B, Schematic illustrations demonstrate the rotation of the buccal segment by distalizing forces. C, D, Intraoral views before molar distalization. E, F, Intraoral views during molar distalization demonstrate the mesial outrotation (*black arrow*).

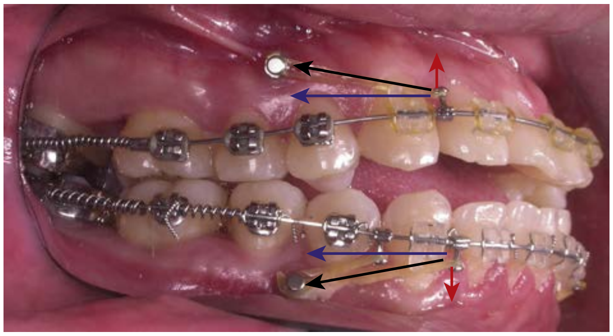

FIGURE 20-32 Vertical control: Distalization forces may have intrusive force vectors because of geometric positions of the temporary anchorage devices (TADs). Intrusive force vectors, in turn, can cause unwanted intrusion, such as anterior bite opening or occlusal plane canting, both of which are difficult to correct once developed. Therefore such intrusive force vectors should be controlled. The use of lever arms is one way to eliminate intrusive force vectors effectively (*black arrows*, retraction force; *purple arrows*, distalizing force vector; *red arrows*, intrusive force vector).

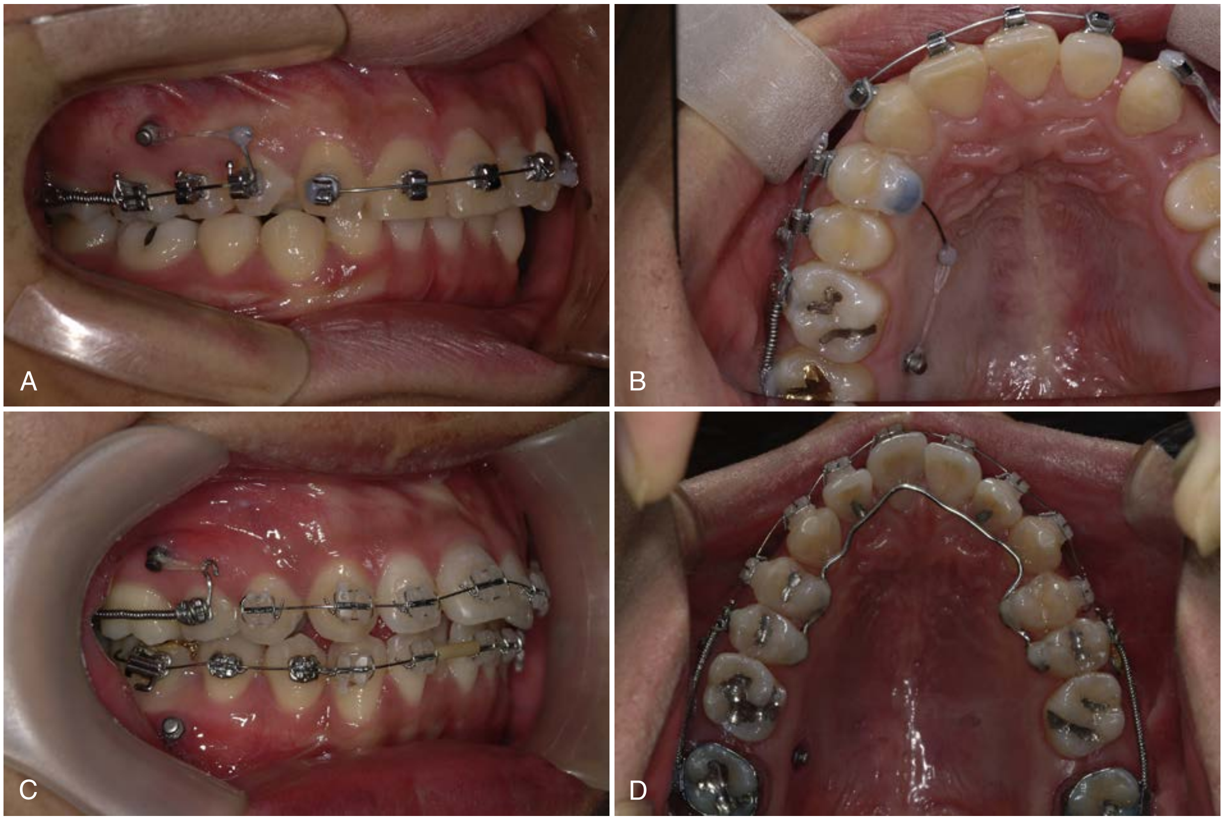

FIGURE 20-33 Arch form and vertical control. **A, B,** Lever arms are used for vertical control. Simultaneously applying buccal and palatal distalizing forces is also effective for arch form control and is useful for asymmetric distalization. Lever arms are used for vertical control **(C)**, and cross-arch splinting is used for arch form control **(D)**.

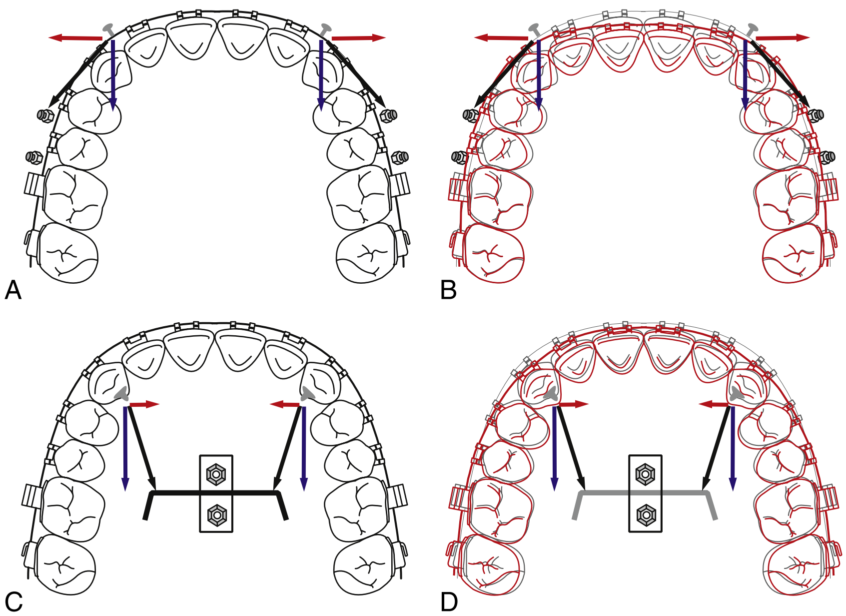

FIGURE 20-34 According to the geometric positions of temporary anchorage devices (TADs), distalizing forces have a horizontal force vector. In addition to distal movement, buccolingual tipping is more likely to occur than distal movement because the sum of the circumcemental area of the molar roots is greater than the sum of the anterior teeth. These horizontal force vectors can lead to arch expansion **(A, B)** or constriction **(C, D)**.

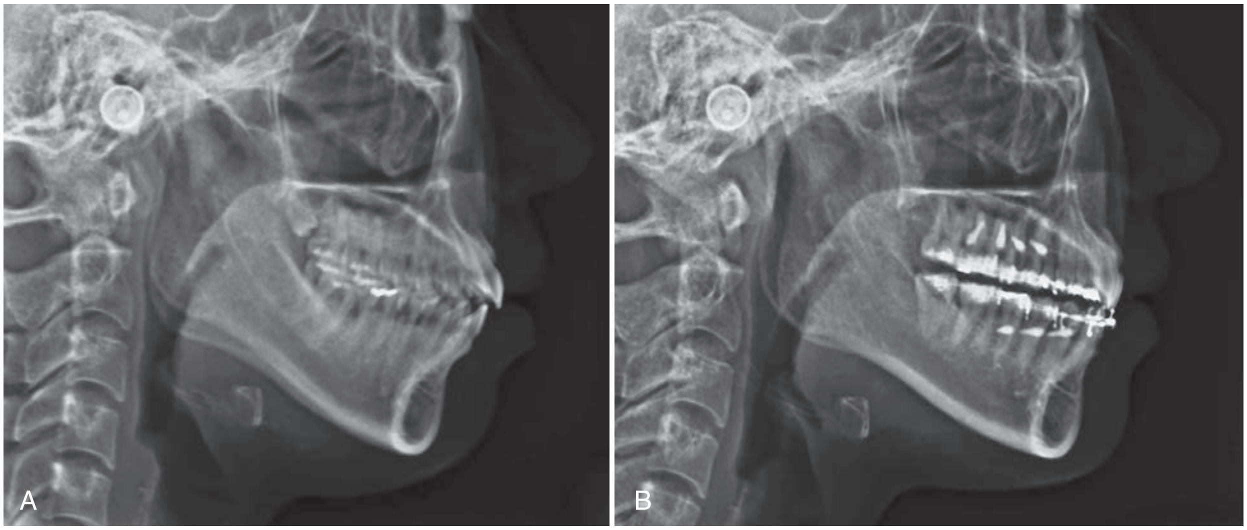

FIGURE 20-35 The entire dentition was distalized to correct protrusion. Although twin brackets were used, distal tip back of the individual teeth was observed. **A,** Cephalometric radiograph before treatment. **B,** Cephalometric radiograph after molar distalization.

Therefore, to prevent loss of attachment, the following precautions should be considered when protraction into an edentulous area is planned, especially in the mandible. Evaluating the periodontal condition is necessary in the area where protraction is planned. Vertical and transverse bone quantity influences the periodontal prognosis. Low alveolar bone levels and narrow alveolar bone result in a greater chance of attachment loss. An inadequate amount of attached gingiva has a greater chance of attachment loss as well. The patient's chronologic and dental ages should be also considered as growing children and patients with incomplete third molar development have a lower chance of attachment loss. The number of roots and the shape of the roots of the tooth to be protracted, in addition to the thickness of the surrounding cortical bone, influence the level of difficulty of the case.

Biomechanics

Mechanically, three-dimensional control is also important for successful protraction (Fig. 20-36 through Fig. 20-38).

Biologically, additional considerations may be necessary during mandibular second molar protraction after extracting the first molar.[173] Removal of a tooth results in both horizontal and vertical changes to the dimensions of the hard and soft tissues. Considering the slow speed of tooth movement observed during molar protraction, hemisection and then sequential extraction of the first molar, in conjunction with second molar protraction, should be considered (Fig. 20-39).[174]

Anterior Retraction in Extraction Treatment

A unique feature of TAD mechanics in premolar extraction cases is the ability to adjust the anteroposterior position of the anterior teeth and molars. Moreover, TAD mechanics can simultaneously address vertical disharmony anterior retraction (see Fig. 20-4).*

Decision Making

First of all, the amount of anterior retraction and the type of tooth movement that will be used to retract the anterior teeth must be determined. If the anterior teeth are excessively retracted, then smile aesthetics can, in fact, be negatively affected. Adequate alveolar space is also necessary for bodily retraction of the roots of the anterior teeth. Verification of the amount of alveolar bone is necessary during the treatment planning process. When a large amount of retraction is planned, the risk for root resorption and periodontal attachment loss is higher[50,51,87]; therefore risk management is important. In addition, precaution is greatly needed to avoid overretraction and overintrusion of the anterior teeth when using rigid anchorage.

Biomechanics

Biomechanically speaking, no significant difference exists between conventional mechanics and TAD mechanics with regard to anterior retraction. The general principles in extraction treatment with conventional edgewise techniques are also important in extraction treatment with mini-implants. A proper force system should be designed, and monitoring this system is especially important, as it is with conventional mechanics.

The TAD can supply rigid anchorage for maximum anterior retraction and anterior torque adjustment. Moreover, TADs are generally placed apically, making it advantageous to control the line of action for canine axis and torque control during retraction (Fig. 20-40).

To achieve successful anterior retraction, canine axis control and anterior torque control are imperative, even with TAD mechanics. Canine lingual tipping, which is loss of canine torque, should be closely followed in cases with large amounts of anterior retraction (Fig. 20-41).

When the retraction force is directly generated and only from the TAD, further considerations are needed (Fig. 20-42 and Fig. 20-43).[15,20,21,175–177] For example, canine control becomes more critical. Additionally, the intrusive force vector of TAD mechanics is available for vertical control of the anterior teeth; however, when left improperly monitored, side effects such as occlusal plane canting can occur.

One should remember that the TAD itself is not controlling the canine axis and anterior torque.

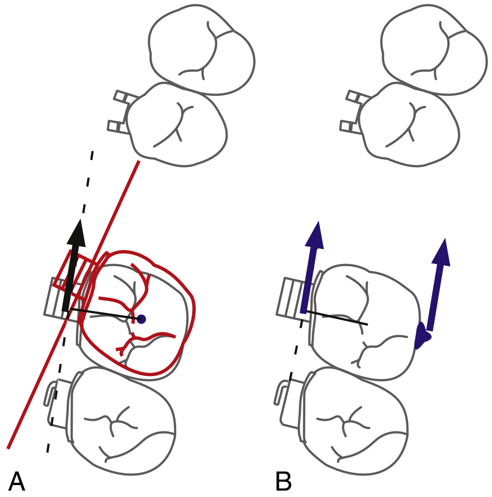

FIGURE 20-36 Rotation control: **A,** Buccal protraction forces (*black arrow*) produce a moment of mesial inrotation (red line). **B,** Combination of buccal and lingual protraction forces (*blue arrow*) is a simple and effective way to offset this mesial inrotation tendency.

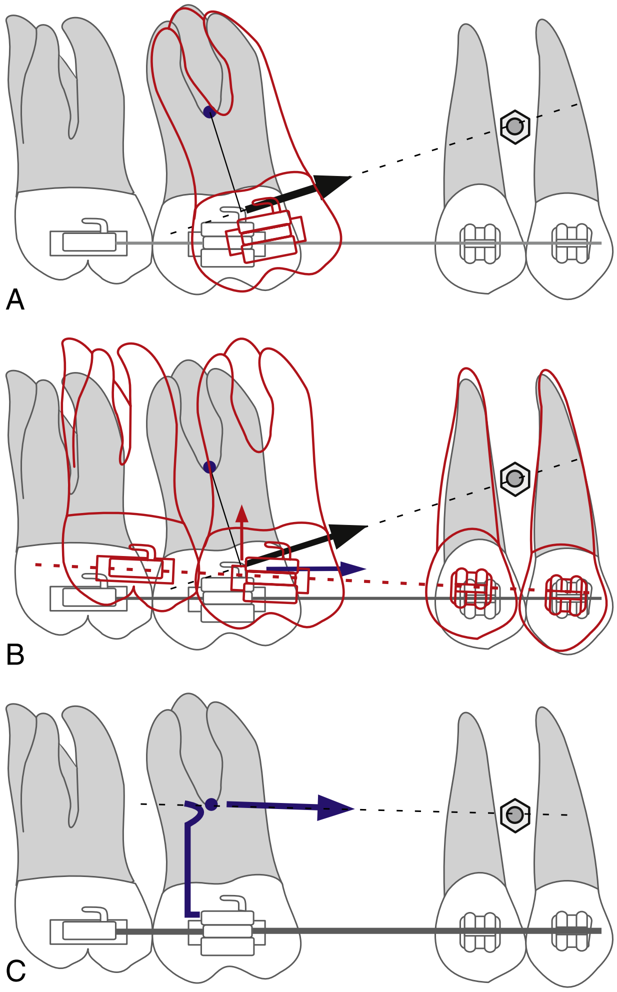

FIGURE 20-37 Molar axis and vertical control from a lateral view. **A,** Protraction forces (*black arrow*) away from the center of resistance (black dot) cause an inclination for mesial tipping. **B,** Generally, temporary anchorage devices (TADs) are apically placed, and as a result, protraction forces (*black arrow*) have intrusive force vectors (*red arrow*). If intrusion occurs on only one side, then occlusal canting can develop, which is very difficult to correct. **C,** A lever arm (blue wire) engaged in an auxiliary tube on the first molar is effective in vertical control.

FIGURE 20-38 The patient was an 18-year-old girl, whose problem was the severely mutilated upper first molar. Because of prolonged inflammation, little alveolar bone was left in the upper first molar area. Using temporary anchorage devices (TADs), the second molar was protracted after extraction of the first molar, and the third molar erupted to its proper position. The periodontal tissue of the protracted second molar was in good condition. Indirect application is also effective in vertical control, and this same application can also provide stable anchorage in cases of unilateral molar protraction. **A, B,** Intraoral views at the start of treatment. **C, D,** Intraoral views at the completion of treatment.

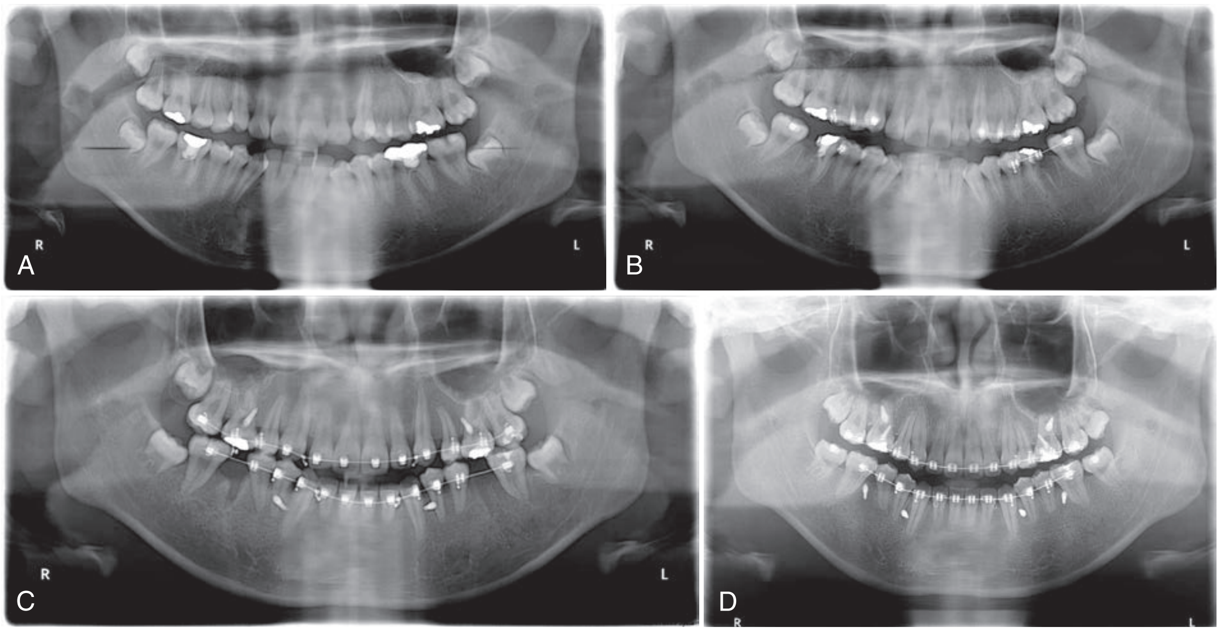

FIGURE 20-39 For the orthodontic treatment of this 18-year-old female patient, extraction of the premolars was needed. However, the treatment plan was established to include extraction of the mandibular first molars instead, as they were compromised with multiple pulpotomy procedures and mesial protraction of the third molars. When a first molar is extracted, a large amount of space is left behind, requiring prolonged treatment time to close. Considering alveolar bone loss after extraction, consecutive extractions after hemisection of the first molar were decided upon to minimize the risk of delayed tooth movement attributable to narrowing of the alveolar ridge. **A,** Panoramic radiograph before treatment. **B,** Panoramic radiograph after hemisection and extraction of the distal portion of the first molar. **C,** Panoramic radiograph after extraction of the mesial portion of the first molar. **D,** Panoramic radiograph after space closure.

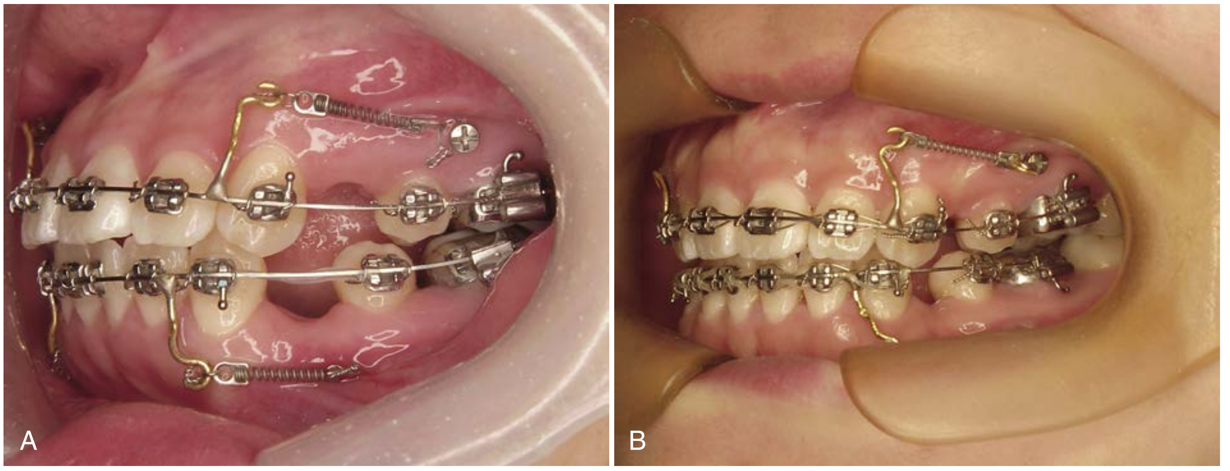

FIGURE 20-40 The line of action can be apically moved by using long lever arms for anterior torque control during retraction. **A**, Intraoral view at the start of anterior retraction. **B**, Intraoral view during anterior retraction.

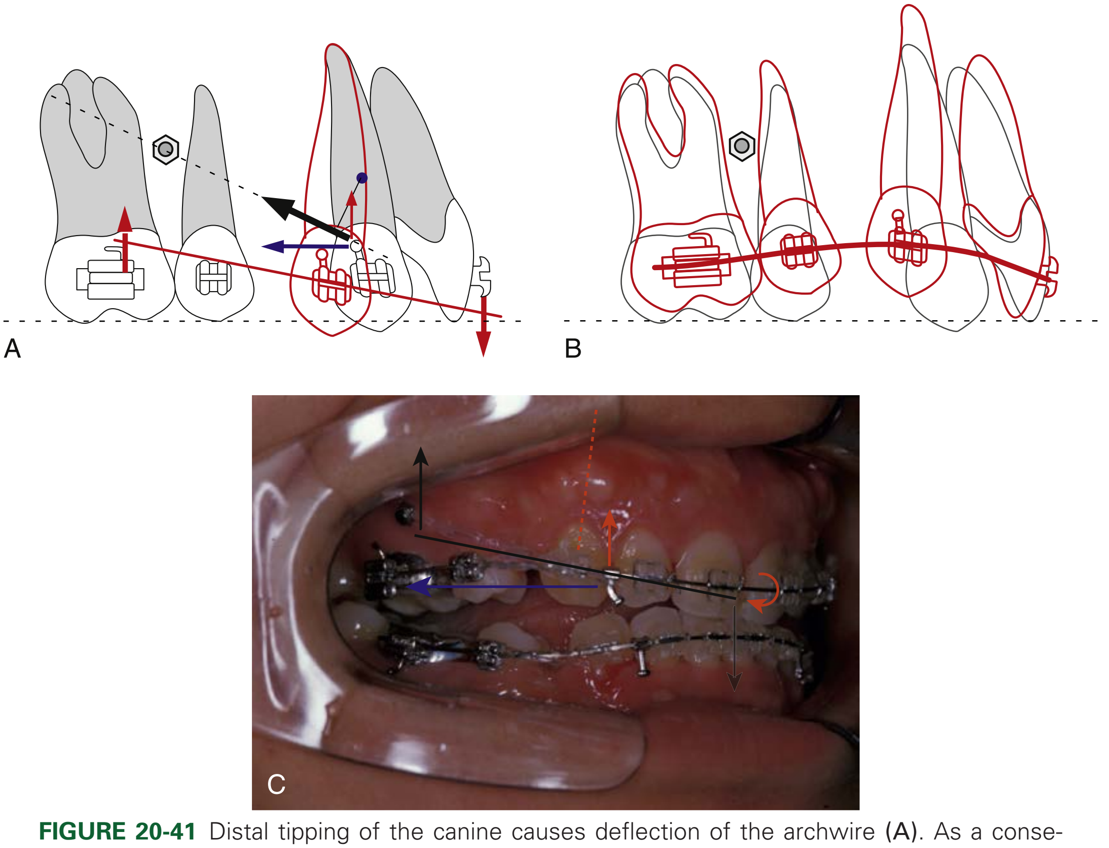

FIGURE 20-41 Distal tipping of the canine causes deflection of the archwire **(A)**. As a consequence, an extrusive force develops in the anterior teeth and anterior torque worsens. Moreover, as a result of the deflection (twisting) of the archwire, lingual crown torque is produced in the anterior teeth, which induces loss of anterior torque. The posterior segments are intruded because of deflection of the primary archwire, which is caused by distal tipping of the canine and the intrusive force vector from the retraction force **(B, C)**.

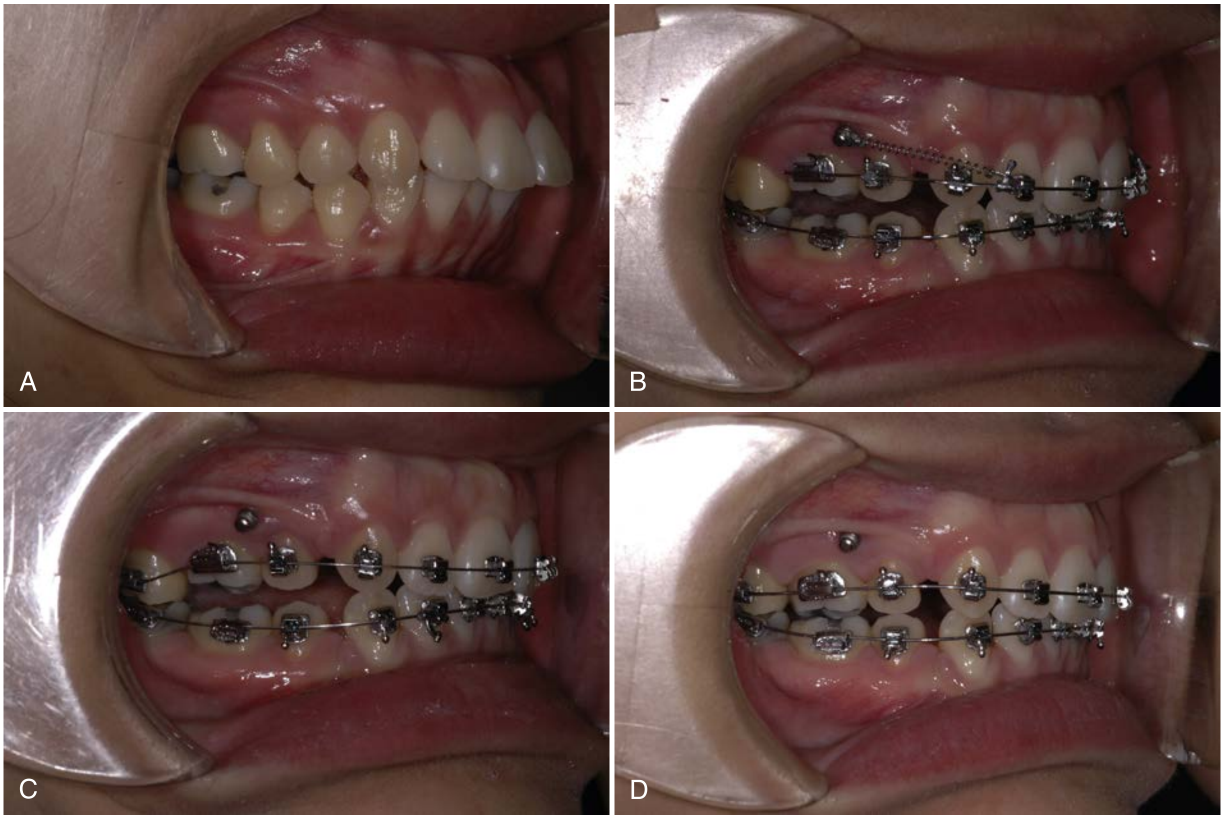

FIGURE 20-42 Canine axis control and control of the intrusive force vector are important in preventing posterior bite opening. A posterior bite opening was corrected by canine axis control and wire engagement into the second molar. **A,** Intraoral view before treatment. **B,** Intraoral view during anterior retraction, demonstrating a posterior bite opening. **C,** An attachment was bonded to the second molar. A leveling archwire was placed, and the retraction force was removed. **D,** Intraoral view during anterior retraction, demonstrating an improvement in the posterior bite.

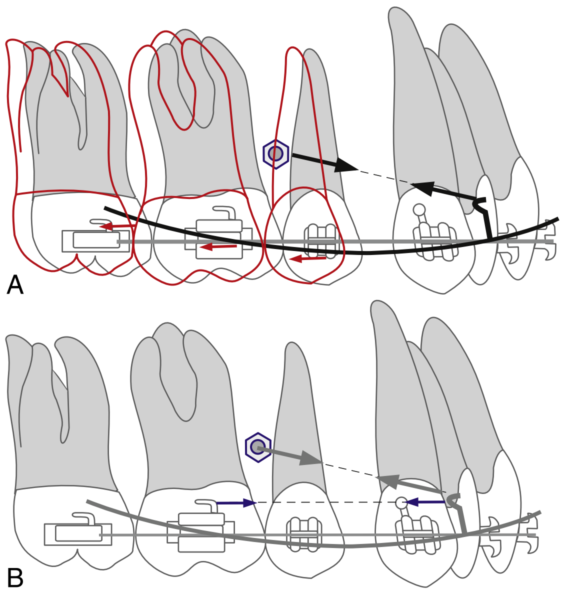

FIGURE 20-43 When a temporary anchorage device (TAD) is used for anterior retraction, particularly with a curved main archwire, the retraction force can be delivered to the posterior teeth by friction of the archwire. As a consequence, the posterior teeth can be distalized **(A)**. This distal movement of the posterior teeth can be monitored by checking the intermaxillary occlusal relationship. Application of a light force to the molar is useful in maintaining molar position **(B)**.

CASE STUDY 20-1 Treatment of Congenitally Missing Teeth: Molar Protraction Using Asymmetric Mechanics

Jung Kook Kim

The patient is a 20-year-old woman whose chief complaints are mobile primary molars, anterior crowding, and minor protrusion. Prosthodontic treatment after extraction of the primary molars is an option, but the patient desires a conservative approach and also wishes to address the anterior crowding. Therefore protraction of the maxillary left and mandibular right molars with temporary anchorage devices (TADs) is planned to close the spaces left by the congenitally missing premolars and to relieve the anterior crowding. The presence of the mandibular right third molar allows for proper occlusion with the maxillary right second molar after protraction of the mandibular right second molar.

For satisfactory treatment results and facial aesthetics, overretraction of the anterior teeth has to be prevented, and each molar needs to be anteroposteriorly controlled using asymmetric mechanics.

In an effort to protract the molars while controlling their anteroposterior positions, continuous arch mechanics and lever arm mechanics are used (Fig. 20-44, *C* and *D*). The mechanics consist of 0.022-inch slot SPEED brackets (SPEED System Orthodontics, Ontario, Canada), buccal Orlus TADs (1.8 mm in diameter and 7.0 mm in length in the maxilla, 1.6 mm in diameter and 7.0 mm in length in the mandible) (Masel Orthodontics, Bristol, PA) and 0.017- × 0.022-inch SPEED stainless-steel wires. An average compensating curve (reverse curve of Spee) is placed in the wires to prevent mesial angulation of the molars during protraction. Furthermore, constriction bends are used to prevent arch widening.

Lever arms are placed on the molars to apply protraction forces near the center of resistance to prevent mesial tilting and unwanted intrusive forces that could lead to occlusal canting.

The second molars are included during full bonding, first to aid order rotation control of the first molars and then to maintain arch form.

The design of the mechanics is important, but the three-dimensional monitoring of the factors that contribute to the design is more critical. For example, if first-order rotation and arch form control are insufficient, then the mandibular second molar will buccally tilt and the buccal overjet will be shallow or a crossbite may develop. If a shallow overjet or crossbite results after the protraction force is reduced and the arch form is adjusted, then components that control first-order rotation and arch form, such as lingual attachments and lingual force vectors, can be added to the design of the mechanics.

Active treatment to achieve the desired results is completed after 24 months. Radiographic examination shows that all of the molars are vertically and anteroposteriorly well controlled (Fig. 20-44, *M–R*). Furthermore, although pneumatization of the maxillary sinuses is present, it does not present an obstacle in the protraction of the maxillary left molars.

Fixed retainers extending from first premolar to first premolar are used in the maxilla and mandible. In addition, a maxillary circumferential retainer is worn at night.

The results are well maintained 1 year after treatment.

CASE STUDY 20-2 Nonsurgical Correction of Anterior Open Bite and Vertical Excess: Retraction and Intrusion of the Maxillary and Mandibular Dentitions

Jong Suk Lee

The patient is a 28-year-old woman whose chief complaints are lip incompetence and an anterior open bite. She exhibits the typical features of a long-faced patient: a long lower third of the face, lip incompetence, extreme mentalis strain upon lip closure, and a recessive chin. Cephalometric analysis confirms vertical excess with a flat occlusal plane. Surgical correction is an option, but the patient desires a nonsurgical approach. Therefore intrusion of the maxillary and mandibular dentitions with temporary anchorage devices (TADs) is planned to correct the anterior open bite and vertical excess and to improve the facial aesthetics.

First of all, the posterior segments are vertically controlled to establish an anterior occlusion for functional rehabilitation. For this purpose, the maxillary posterior teeth are intruded, but no orthodontic forces are applied to the maxillary anterior teeth at this time. Buccal and palatal Orlus TADs (1.8 mm in diameter and 8.0 mm in length) (Masel Orthodontics, Bristol, PA) are used to control the maxillary molars three dimensionally during intrusion. The mandibular teeth are vertically controlled with Orlus TADs (1.8 mm in diameter and 8.0 mm in length) to prevent extrusion (Fig. 20-45, *B* and *C*).

After an anterior occlusion is established, the anterior and posterior segments are vertically intruded further to improve the disharmony between the soft and hard tissues caused by vertical excess.

In an effort to distalize and intrude the entire dentition, continuous arch mechanics are used. The mechanics consist of continuous arch mechanics with 0.017- × 0.025-inch titanium molybdenum alloy (TMA) wires (Ormco Corporation, Orange, CA) with tip back bends to intrude the molars and to control occlusal plane inclination in addition to the TADs. In the maxilla, palatal TADs are used to increase treatment efficiency and to control arch form and occlusal plane inclination. In the mandible, a constriction bend is applied to control arch form.

The duration of active treatment is 16 months. The entire dentition is distalized and intruded. The cephalometric superimposition shows that the chin point has moved upward and forward (Fig. 20-45, *P*). The anterior facial height is decreased by 6 mm, and the mandible is rotated counterclockwise 4.3 degrees.

Fixed retainers extending from first premolar to first premolar are used in the maxilla and mandible. Functional rehabilitation, such as tongue function, is achieved, and instruction about the importance of controlling habits for temporomandibular joint (TMJ) health is thoroughly reviewed with the patient.

A maxillary circumferential retainer with tongue cribs is also worn at night to control tongue posture.

At the 3-year posttreatment follow-up, the results are well maintained.

CASE STUDY 20-3 Nonsurgical Correction of Vertical Excess: Retraction and Intrusion of Maxillary and Mandibular Dentition

Jong Suk Lee

The patient is a 28-year-old woman whose chief complaint is protrusion of the lips, even after orthodontic treatment with three premolar extractions. She exhibits an acceptable occlusion and a nice posed smile but has the typical features of a long-faced patient: long lower third of the face, lip incompetence, extreme mentalis strain upon lip closure, and a recessive chin. Cephalometric analysis confirms anterior vertical excess with a flat occlusal plane. Surgical correction may have been an option, but the patient desires a nonsurgical approach. Therefore maxillary and mandibular molar intrusion and distalization with orthodontic mini-implants are planned to correct the protrusion and vertical excess and to improve the facial aesthetics.

In an effort to distalize and intrude the entire dentition, continuous arch mechanics are used. To provide the proper space for the lower dentition, lower third molars are extracted. The mechanics consisted of buccal Orlus temporary anchorage devices (TADs) (1.8 mm in diameter and 7.0 mm in length in the maxilla, 1.6 mm in diameter and 7.0 mm in length in the mandible) (Masel Orthodontics, Bristol, PA) and 0.017- × 0.025-inch titanium molybdenum alloy (TMA) wire (Ormco Corporation, Orange, CA) with a tip back bend to intrude the molars and control occlusal plane inclination. A constriction bend is also applied to control arch form (Fig. 20-46, *G-I*). Palatal or lingual TADs are not used.

Active treatment to the desired position is completed after 20 months. The entire dentition is distalized and intruded with only the use of buccal

FIGURE 20-46 **A–C,** Facial views before treatment. **D–F,** Intraoral views before treatment.

CASE STUDY 20-3 Nonsurgical Correction of Vertical Excess: Retraction and Intrusion of Maxillary and Mandibular Dentition—cont'd

TADs. The cephalometric superimposition shows that the upper and lower anteriors are retracted and that the chin point has moved upward and forward (Fig. 20-46, *W*).

Fixed retainers extending from first premolar to first premolar are used in the maxilla and mandible. A maxillary circumferential retainer is also worn at night.

At 18 months' posttreatment follow-up, the results are well maintained (Fig. 20-46, *P–R*).

CASE STUDY 20-4 Correction of Occlusal Cant and Midline: Maxillary Molar Intrusion with Mandibular Molar Extrusion

Young-Chel Park

The patient is a 22-year-old man whose chief complaint is "my orthodontic treatment was finished 2 months ago, but my chin has slanted to one side after treatment."

His presentation includes temporomandibular joint (TMJ) symptoms of intermittent pain and clicking on the left TMJ, and the upper left first premolar has been extracted. Clinically, the patient's maxillary dentition is canted downward on the right side. The patient also exhibits upper and lower midline deviations of approximately 2 mm to the left from the facial midline at maximum intercuspation (Fig. 20-47, *F*). A significant lateral shift is noted from centric relation to maximum intercuspation, and the lower dental midline coincides with the facial midline in centric relation (Fig. 20-47, *I*). Facial examination reveals that the chin deviates to the left with canted lips at maximum intercuspation, but this deviation is alleviated once the mandible is in the centric relation position.

Radiographic examination confirms that the mandibular asymmetry is due to a significant lateral shift from centric relation to maximum intercuspation. The upper right first molar is 3.3 mm lower than the upper left first molar (Fig. 20-47, *K*).

There are two possible options to correct such canting. The first is surgical correction of the maxilla, and the second is nonsurgical correction using temporary anchorage devices (TADs) to intrude the maxillary molars. The patient opts for the nonsurgical treatment plan.

The treatment plan calls for intrusion and distalization of the upper right molars to correct maxillary canting, as well as the midline deviation to guide the mandible to the centric relation position.

Five TADs, 1.8 mm in diameter and 7.0 mm in length, are placed in the buccal and palatal areas (Fig. 20-47, *M-P*).

After 10 months of treatment, the upper right molars are intruded and distalized. The canting of the occlusal plane is improved, and the mandible is also guided into centric relation (Fig. 20-47, *Q* and *R*).

After 12 months of treatment, one Orlus TAD, 1.6 mm in diameter and 7.0 mm in length (Masel Orthodontics, Bristol, PA), is placed on the right buccal slope of the mandible. Then an extrusion spring, made of 0.016- × 0.022-inch titanium molybdenum alloy (TMA) wire (Ormco Corporation, Orange, CA), is positioned to extrude the lower right posterior teeth. The spring is connected and bonded to the TADs and is then applied to the bracket bases to produce an extrusive force (Fig. 20-47, *S* and *T*).

At 18 months after the start of treatment, the appliances are removed and fixed retainers are used (Fig. 20-48, *A–F*). Additionally, an active retainer using TADs in the maxillary arch is worn at night (Fig. 20-48, *H–J*).

The occlusal and mandibular planes have rotated 6.2 degrees and 7.5 degrees, respectively.

Menton, therefore, has moved 6.4 mm to the right, and the facial asymmetry has improved (Fig. 20-48, *G*).

At a follow-up examination 27 months after the end of treatment, the results are well maintained (Fig. 20-48, *K–M*).

Adult Interdisciplinary Therapy: Diagnosis and Treatment

Robert L. Vanarsdall, Jr., and David R. Musich

OUTLINE

CURRENT STATUS OF ADULT INTERDISCIPLINARY THERAPY

In the past several years a major reorientation of orthodontic thinking has occurred regarding adult patients. The following list cites several reasons for the increased interest by orthodontists in adults as patients, as well as several reasons for increased interest shown by adults in orthodontic treatment.

In 1971, Lindegaard et al.[1] stated that three main factors determine which problems (including adult interdisciplinary conditions) could be treated from both a medical and an orthodontic point of view:

1. A disease or an abnormality must be present.
2. The need for treatment should be determined by the clinical gravity of the disorder, the available resources for orthodontic care, the prognosis for successful treatment, and the priority for orthodontic care based on personal and professional judgment.
3. The patient must have a strong desire for treatment.

In this context, the past 40 years have seen a major change in orthodontic practices. Changed lifestyles and patient awareness have led to a continued increased demand for adult orthodontic treatment, and multidisciplinary (more appropriately called interdisciplinary) dental therapy has allowed better management of the more complicated and unique requirements of the adult patient population. Much of the improved technology and its application have greatly improved the quality of care and treatment prognosis for our adult patients.[2]

Department chairs of several teaching institutions participating in a round table discussion concerning the future of orthodontics[3] made significant statements regarding adult orthodontic therapy. At this conference 40 years ago (1976), Reidel and Dougherty most accurately predicted the status of adult orthodontic treatment today. Reidel was supportive regarding the future of adult therapy, adding that clinicians should not forget adjunctive orthodontic services provided by periodontists and restorative dentists. Dougherty claimed that "orthodontics is total discipline and it makes no difference whether the patient is young or old."[3] Demographics of the American population further dictate that orthodontists provide services sought by "aging baby boomers."

The Population Reference Bureau, a nonprofit demographic study group in Washington, D.C., has predicted that by 2025, Americans older than 65 years of age will outnumber teenagers by more than 2:1. According to the U.S. Census Bureau, by

2030, the median age is expected to be 41 years. By 2050, it is likely that as many as one in four Americans will be older than 65 years. Many demographers consider these projections to be very conservative; by some estimates, the median age will eventually reach 50 years (Fig. 21-1). Thus, the demographic considerations demonstrated here and illustrated in Figure 21-2

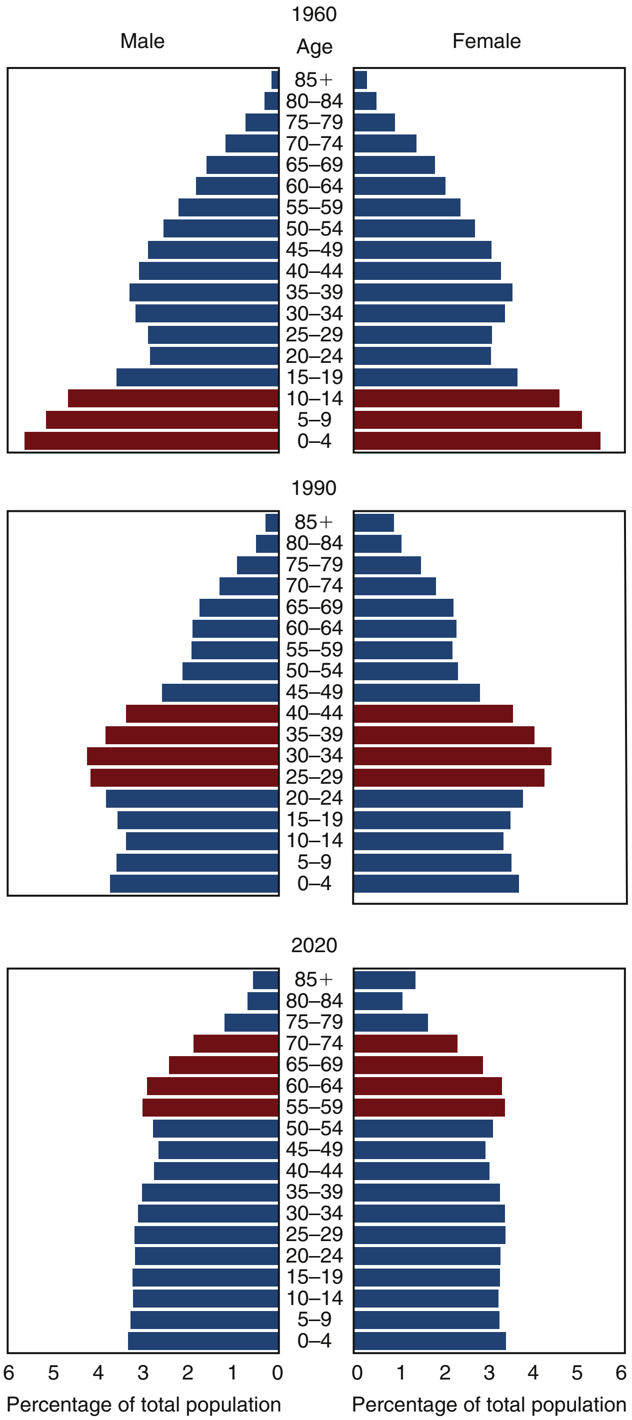

FIGURE 21-1 Percent of U.S. population by age and sex: 1960, 1990, and projections for 2020. Note the graphic illustration of the aging of the U.S. population. The implications for providing optimal interdisciplinary dental therapy to provide the best quality of life for our aging population are quite clear. (Source: U.S. Bureau of the Census.)

emphasize the importance of orthodontists developing the skills necessary to manage the increasing number of interdisciplinary adult orthodontic patients.

In addition to recent improvements in treatment techniques and changes in treatment philosophies, important statistical reasons explain why orthodontists have become more involved in the management of adult patients (see Fig. 21-2).[4] Practices that grew reported a higher percentage of adult patients than those that did not grow. The treatment of adults was rated significantly higher as a practice-building method by growing practices than by declining practices. As the volume (percentage) of adult patients increased in orthodontic practices, the skills required of orthodontists changed. Musich's 1986 paper demonstrated the scope of treatment planning considerations[5] (Fig. 21-3). Of the almost 1400 consecutively examined adults in Musich's study, about 70% to 75% of the sample required multidisciplinary management to attain optimal treatment outcomes.

When treating adults, the orthodontist needs to be prepared to do the following:

1. Determine which cases require orthognathic surgical management and which ones require incisor reangulation to camouflage the skeletal base discrepancy
2. Diagnose different stages of periodontal disease and the associated risk factors
3. Diagnose temporomandibular joint (TMJ) dysfunction (TMD) before, during, or after tooth movement
4. Work cooperatively with a team of other specialists to give the patient the best outcome. It is to be noted that the orthodontist must frequently take a leadership role in both the diagnosis and the treatment planning of adult interdisciplinary therapy (AIT) patients.

GOALS OF ADULT INTERDISCIPLINARY THERAPY

Ideal Orthodontic Treatment Goals and the Adult Patient

In 1972, Andrews described the six keys to normal occlusion, and this description of orthodontic treatment objectives is still the standard by which orthodontic treatment results are measured. More recently, the American Board of Orthodontics (AJODO) sought to quantify further optimal treatment (November 1998, AJODO).[6]

However, adult patients have many preexisting conditions that are not seen in the adolescent population, including tooth loss, severe skeletal dysplasias, periodontal disease, and various forms of TMD. Frequently, the preexisting conditions that are present in an adult patient interfere with the achievement of orthodontists' general idealized goals. In such adult cases, an attempt to achieve ideal tooth positions that are feasible only in dentitions with a Class I skeletal relationship may be considered overtreatment. This is not to say that the orthodontic therapy provided is any less precise; rather, it suggests a need to customize orthodontic treatment for the individual patient so that the achievement of any one goal (perhaps facial aesthetics) does not undermine a less obvious but equally important functional need.

Problem-oriented synthesis of the dental needs of each case will help determine specific treatment objectives that must be established before the orthodontic treatment plan can be determined. Beginning treatment without knowing the specific goals for the individual patient or with unrealistic goals can lead to treatment failure.

In addition to goal clarification, adult patients desire treatment efficiency, convenience in appointment times, and good communication with other health care providers. Both the examination and consultation should allow for two-way communication so the orthodontist and the patient understand the treatment process. Unlike the typical adolescent, an adult may exhibit rapid (within 2 to 3 months) periodontal breakdown and bone loss. Therefore, adult therapy requires the establishment of goals and efficient mechanotherapy so that completion occurs as expeditiously as possible. It is necessary to inform adult patients of the need to keep all of their appointments and to optimize their compliance with periodontal maintenance.

Individualized Adult Interdisciplinary Orthodontic Treatment Objectives

The generally applied orthodontic treatment goals of (1) favorable dentofacial aesthetics, (2) effective stomatognathic system function, (3) short- and long-term stability, and (4) a static and dynamic Class I occlusion often may not be realistic or necessary for all adult patients. Treatment in which general goals are not achieved is not necessarily a compromised result; rather, the mechanotherapy should satisfy the objective of providing the minimal dental manipulation appropriate for the individual patient. Many Class I occlusal goals can be considered overtreatment for patients who also require restorative dentistry, prosthetics, plastic surgery, and other multidisciplinary dentofacial corrections. Box 21-1 contains a list of additional goals particularly useful for adult problems requiring tooth replacement but not requiring surgical skeletal correction.

Additional Adult Treatment Objectives

1. **Parallelism of abutment teeth.** The abutment teeth must be placed parallel with the other teeth to permit insertion of multiple unit replacements and allow for restorations that involve both the anterior and posterior teeth. A restoration will have a better prognosis if the abutment teeth are parallel before tooth preparation[7] because that position does not require excess cutting or devitalization during abutment preparation and allows for a better periodontal response. For full-arch splints, the posterior teeth should be reasonably parallel to anterior abutments. Parallel abutments allow for better restorative retention and help prevent cement washout and caries (Fig. 21-4).
2. **Most favorable distribution of teeth.** The teeth should be distributed evenly for replacement of fixed and removable prostheses in the individual arches (Fig. 21-5). In addition, they should be positioned so that occlusion of natural teeth can be established bilaterally between arches.[8]
3. **Redistribution of occlusal and incisal forces.** Cases with significant bone loss (60%–70%) require that occlusal forces be directed vertically along or on the long axis of the roots to maintain the occlusal vertical dimension (Fig. 21-6). When the posterior teeth are missing, the anterior teeth can be positioned to allow for more axially directed transfer of force and can then be reshaped to function as posterior teeth (supporting the vertical dimension).[8]
4. **Adequate embrasure space and proper root position.** This allows for better periodontal health, especially when the placement of restorations is necessary (Fig. 21-7). The anatomic relation of the roots is important in the pathogenesis of periodontal disease,[9] interproximal cleaning, and placement of restorative materials.[10]
5. **Acceptable occlusal plane and potential for incisal guidance at satisfactory vertical relationship.** To establish the acceptable occlusal plane for a mutilated dentition exhibiting bite collapse, the Hawley bite place (Fig. 21-8) is inserted with the platform of the anterior plane adjusted at a right angle to the long axis of the lower incisors.[11] This allows a centric relation at an acceptable vertical relationship. Even with extended incisolingual platforms in Class II patterns, patients can usually speak well. However, if the vertical dimension is excessive, they will whistle involuntarily and complain of muscle fatigue in the morning, or the acrylic will develop etched lines or wear streaks. When properly adjusted at the correct vertical height, the bite plane will allow simultaneous bilateral neuromuscular activity. It is important that no contact occurs between the posterior teeth during excursive movements and no interferences occur between anterior teeth while the bite plane is in place. Such interferences will prevent the patient from demonstrating simultaneous bilateral neuromuscular activity and correct location of centric relation.

The curve of Spee should be mild to flat bilaterally. This is difficult to achieve if supraerupted molars are present. However, the most extruded posterior segment will be the ruling factor in determining the potential for an orthodontic solution at an acceptable vertical. Adult molars with amalgam restorations and normal pulpal recession and mixed constrictions

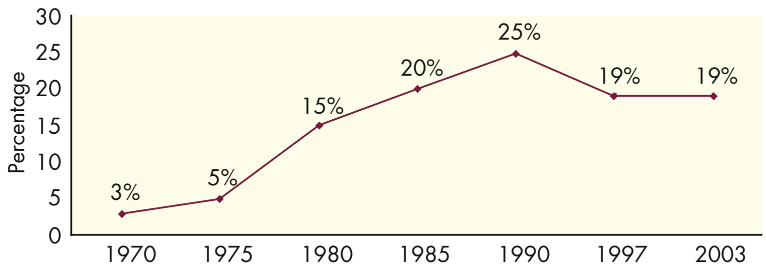

FIGURE 21-2 This graph illustrates an 800% increase of adult patients in the United States receiving orthodontic treatment from 1970 to 2003. The median percentage of patients identified as adults in orthodontic practices seems to have leveled off or even decreased as a percentage of the total number of patients in braces. The actual number of adults in orthodontic therapy probably has increased and has the potential to increase even more as more sophisticated and aesthetic methods of providing care are used. (From Keim RG, Gottleib EL, Nelson AH, et al: 2003 JCO orthodontic practice study. 1. Trends, *J Clin Orthod* 2003;37:545–553.)

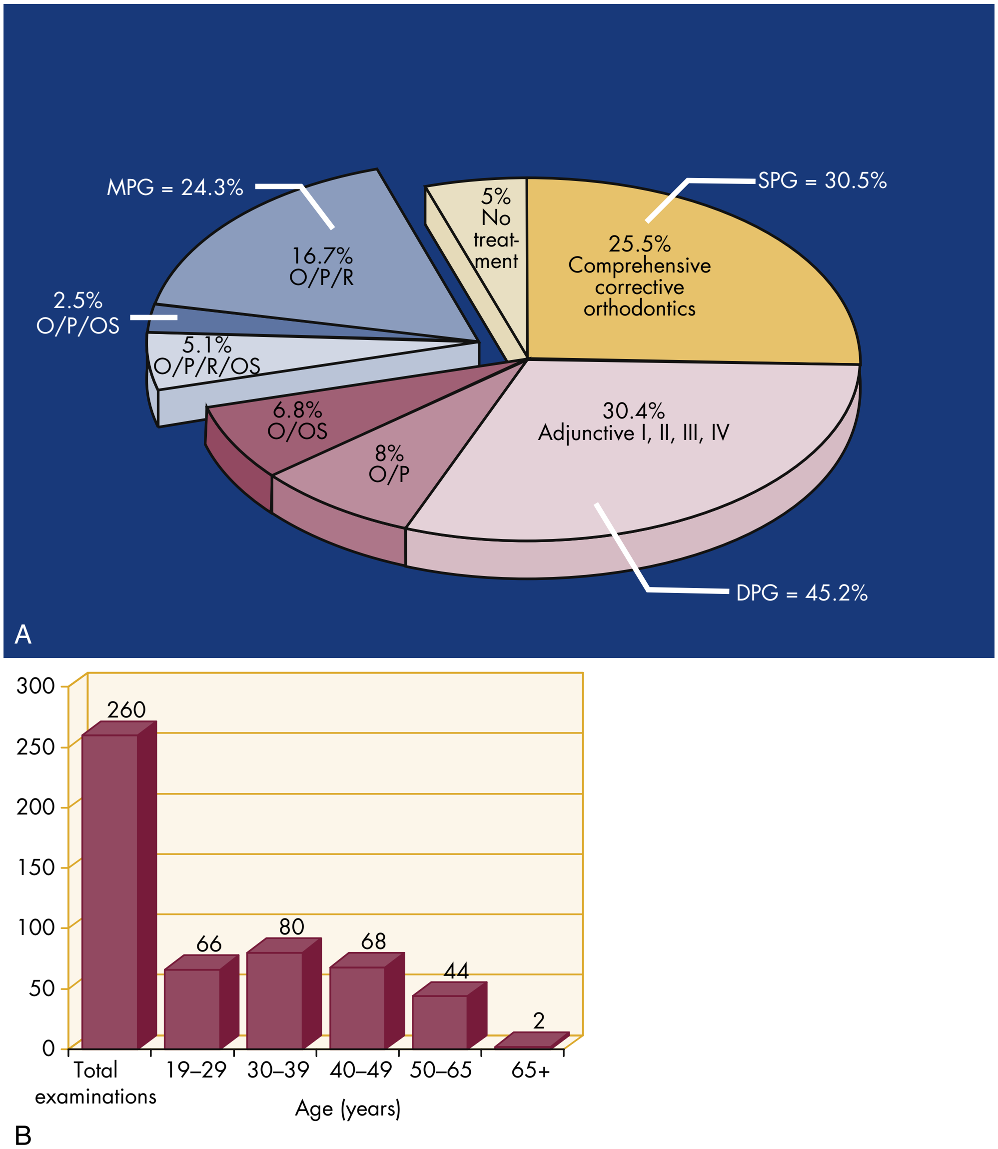

FIGURE 21-3 **A,** A summary diagram of findings from Musich's study[5] of 1370 consecutively examined adults: 30.5%, solo provider group (SPG)—25.5% required conventional corrective orthodontics; 45.2%, dual provider group (DPG)—within this group two primary providers were required to complete the treatment (orthodontist/restorative dentist [O/R], 30.4%; orthodontist/periodontist [O/P], 8.0%; orthodontist/oral surgeon [O/OS], 6.8%); and 24.3%, multiple provider group (MPG). Note that 5% required no orthodontic treatment and 65% required dual or multiple provider therapy. **B,** Graph showing number of adults examined by author according to age. Note that 90% of adults were examined between the ages of 19 and 49 years of age.

Adult Patients Redefined: 19 to 80 Years

Age (yr)	Abbreviated Social Factors
19–29	Many still in transition to adult level of independence
30–39	Pressure, pregnancy (70% of adults seeking orthodontic care are women), stress, money, temporomandibular joint
40–49	Time for self (before it is too late)
50–65	Use of insurance, prepare for retirement, other health issues ("stay younger longer")
66–80	Preserve and restore, major role of interdisciplinary therapy, including implants

Graph based on a recommended division of adult patients by decade of life, which may factor into treatment decisions.

often can be occlusally reduced 2 to 4 mm and still allow for placement of restorations without the need for devitalization. With the aid of heavy musculature, molars may be intruded 1 to 2 mm in treatment. The unilateral orthodontic treatment of an accentuated occlusal plane should be avoided; one side cannot be left extruded. For the extruded posterior segments, temporary anchorage devices (TADs) are available to help level the occlusal plane and to provide proper dental relationships for the restorative phase of therapy (see Chapter 20).

1. **Adequate occlusal landmark relationships.** As previously described for adult patients, the transverse dimension is the most difficult to correct and maintain orthodontically, the sagittal next, and the vertical least. However, when teeth are to be restored, they must be positioned to achieve acceptable buccolingual landmarks. Posterior teeth in crossbite that are not corrected through a surgical procedure should be positioned so that the maxillary buccal cusps contact the lower central fossae with the crossover for incisal guidance in the premolar area or the canine positions. Figure 21-9 illustrates the achievement of favorable occlusal landmark relationships in a patient who has a true skeletal imbalance both in the transverse plane and the sagittal plane without incorporation of surgical procedures. The sagittal correction occurred through incisor reangulation, and the transverse

BOX 21-1 Additional Orthodontic Treatment Goals in Adult Treatment

Parallelism of abutment teeth
Most favorable distribution of teeth
Redistribution of occlusal and incisal forces
Adequate embrasure space and proper tooth position
Acceptable occlusal plane and potential for incisal guidance at satisfactory vertical dimension
Adequate occlusal landmark relationships
Better lip competency and support
Improved crown-to-root ratio
Improvement or self-correction of mucogingival and osseous defects
Improved self-maintenance of periodontal health
Aesthetic and functional improvement
Best outcome with least risk (using minimally invasive approach)

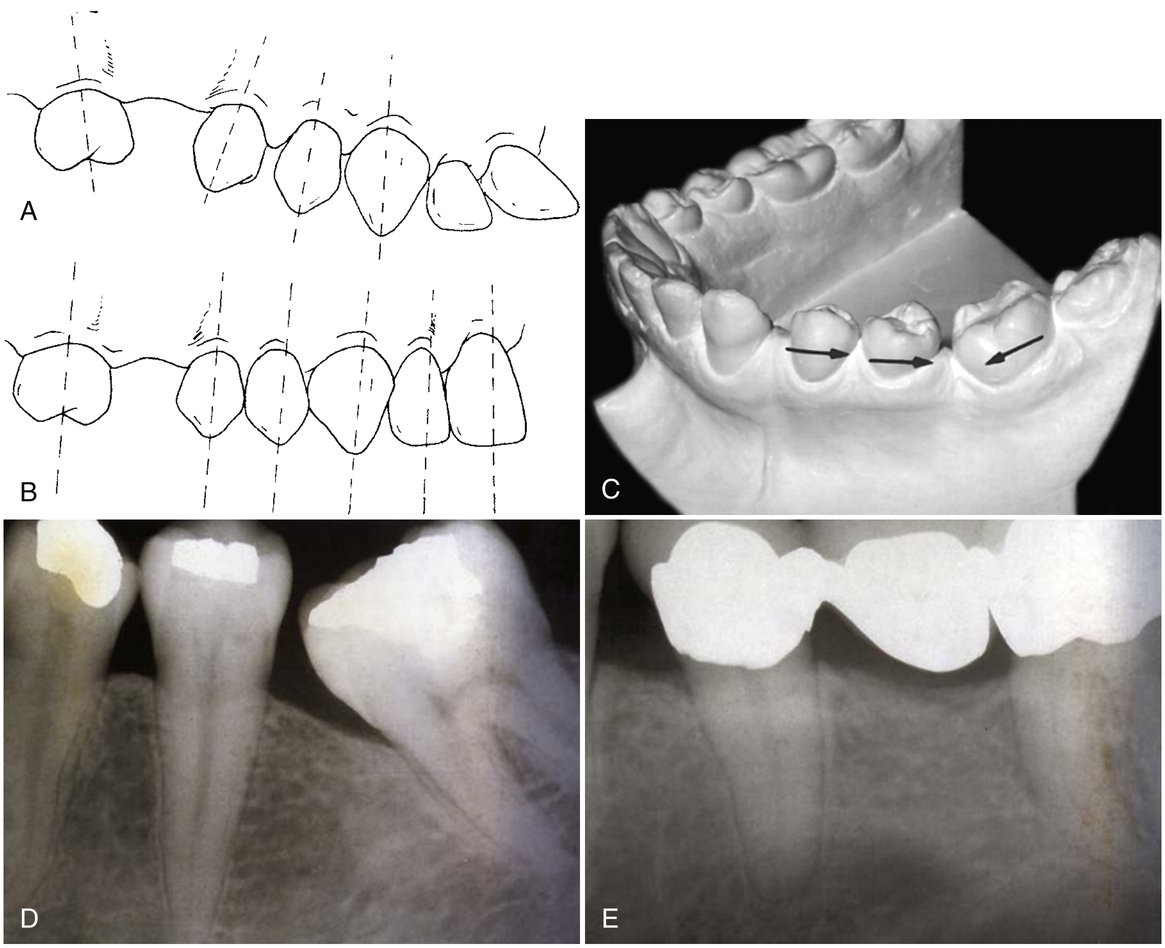

FIGURE 21-4 Clinical example of adult treatment objective 1: parallelism of abutment teeth. **A,** Drifting and flaring of the maxillary teeth caused by mutilation, periodontal disease, and occlusal and muscular forces. **B,** Orthodontic preparation. This should produce parallelism of the anterior and posterior segments before restorative dentistry that involves full arch stabilization. **C,** Lower model of collapsed arch with missing no. 19. **D,** Radiograph of tilted molar. **E,** Molar uprighted and restoration placed with roots parallel. Orthodontic reangulation of teeth adjacent to missing teeth is an important goal to facilitate long-term periodontal health and the aesthetics of the replacement tooth in posterior and anterior portions of the mouth.

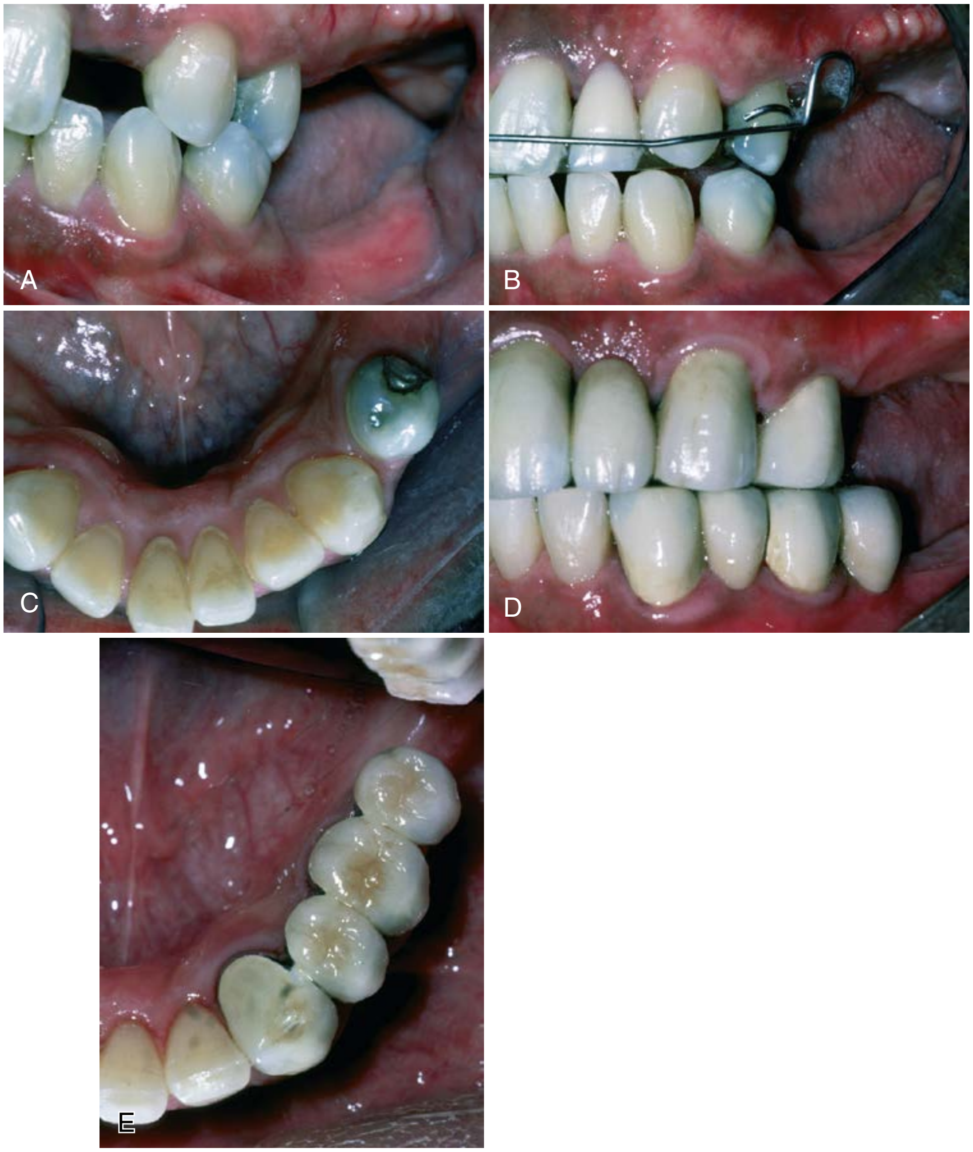

FIGURE 21-5 Clinical example of adult treatment objective 2: most favorable distribution of teeth. **A,** First premolars, the only teeth present in the left maxillary and mandibular quadrants of a 56-year-old man. **B,** A combination of fixed and removable appliances was used to move the mandibular first premolar one pontic space distally in the left quadrant. **C,** Preoperative. Note the lower left first premolar adjacent to the canine. **D,** Final restoration. Distal movement of the first premolar abutment created a pontic space between the canine and the distal premolar abutment. **E,** Better distribution of abutments allowed for this lower left four-unit restoration, preventing the need for a distal extension partial denture or implants.

was restored in a "functional" crossbite described earlier, resulting in a stable outcome.

2. **Better lip competency and support.** Many adults have long upper lips that preclude significant maxillary retraction. In cases requiring anterior restorations, retraction is recommended to achieve lip competency while maintaining lip support. The restoration then can be shaped to provide incisal guidance on the canines or by 1- or 2-mm palatal extension of the incisors. Incisors extended more than 1 or 2 mm palatally cause constant palatal soft tissue irritation. In some Class II, division 1 cases (when orthognathic surgery is rejected), the lower incisors can be advanced into a more procumbent position than the usual orthodontic norm to establish incisal guidance. With the aid of bilateral posterior flared positions (incisor mandibular plane angle [IMPA] of 105–120 degrees). In some Class III patients as well, the maxillary incisors can be kept in stable relation (even though more flared than normal) with posterior restorations. Inadequate support may create a change of anteroposterior and vertical position of the upper lip and increase wrinkling. This often makes the face seem prematurely aged and is a major aesthetic concern of adults, especially women, who are usually anxious about changes of the upper lip (Fig. 21-10).
3. **Improved crown-to-root ratio.** In adult patients who have lost bone on individual teeth, the length of the clinical crown

FIGURE 21-6 Clinical example of adult treatment objective 3: redistribution of occlusal and incisal forces. **A,** No natural tooth stops in a 45-year-old woman. The initial tooth contact in centric relation was between the mandibular first premolar and the maxillary second premolar. **B,** Anteriorly, the mandible fits within the maxillary arch. **C,** No tooth contact on the left side. **D,** Soft tissue indentations indicate the location of lower incisor contact with the palate. **E,** Severe maxillary protrusion. A Hawley bite plane was used to locate centric relation at the acceptable vertical. **F,** After maxillary and mandibular alignment, a splint was placed before maxillary segmental osteotomy. The osteotomy positioned the maxillary canines axially to contact the lower dentition bilaterally. **G,** After surgery, occlusal platforms placed on the maxillary canines support the vertical dimension. **H,** Three years post treatment. **I,** Lower anteriors bonded with composite resin as a form of retention. **J,** Pretreatment. **K,** Three years post treatment. **L,** Pretreatment cephalogram. Acceptable vertical dimension. **M,** One year post treatment.

can be reduced with the high-speed handpiece; as the tooth is erupted orthodontically (the same amount of bone will remain on the clinical root), the ratio of crown to root will be improved (Fig. 21-11).[12]

4. **Improvement or correction of mucogingival and osseous defects.** Proper repositioning of prominent teeth in the arch will improve gingival topography (Fig. 21-12). In adolescents, the brackets are placed to level marginal ridges and

FIGURE 21-7 Clinical example of adult treatment objective 4: adequate embrasure space and proper root position. **A–E,** Pretreatment intraoral photographs showing compromised embrasures and altered root position of lower second molars preventing proper restorations. **F–J,** Posttreatment intraoral photographs showing corrected crown and root position. Note no. 7 rotation correction and lower anterior spacing correction. **K,** Pretreatment radiographs. Note rotated no. 7 and no. 10 and tilted nos. 18 and 31. **L,** Long-term panoramic radiograph. Note the continued stability of nos. 18, 19, 30, and 31 and the previously rotated no. 7 at 7 years after orthodontic treatment. **M,** Long-term cephalogram. Note the continued stability of the posterior occlusion 7 years after orthodontic treatment.

FIGURE 21-8 Clinical example of adult treatment objective 5: acceptable occlusal plane and potential for incisal guidance at satisfactory vertical dimension. **A,** No occlusal stops bilaterally in a 61-year-old patient. The lower right premolar had only soft tissue attachment. **B,** Lower canines tipped lingually and mobile. **C,** Preoperative. **D,** Upper and lower removable appliances were placed to support the vertical height and move each lower canine labially over its basal support. **E,** After the lower canines were positioned axially, the restorative dentist (Dan Casullo, Philadelphia) placed a provisional restoration. A platform then was added to the upper appliance (to determine the satisfactory vertical), and the maxillary incisors were aligned. **F,** Seven years postoperative. **G,** Final restoration. **H,** Twenty-year follow-up of patient with advanced attachment loss.

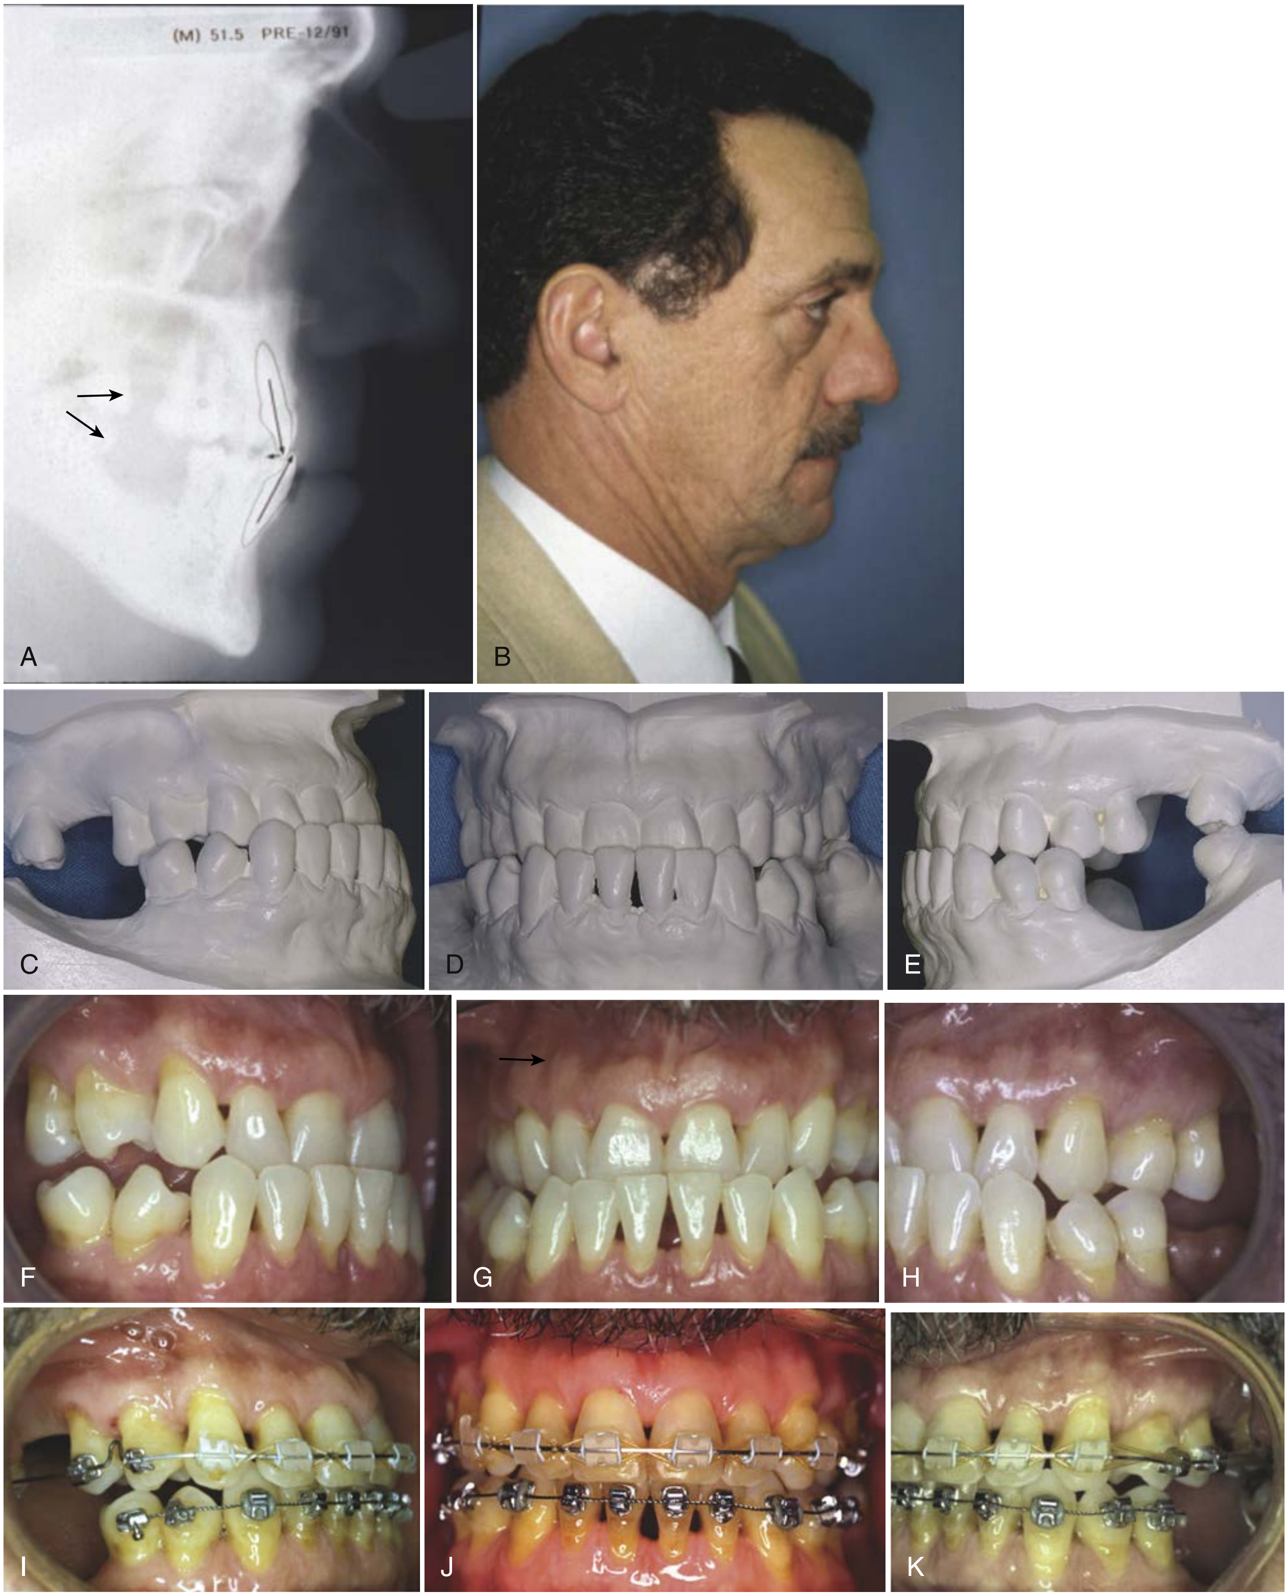

FIGURE 21-9 A-B, Pre-treatment cephalometric radiograph and profile picture showing Class III with anterior crossbite of a 51:6 male. C-E, Pre-treatment study models of the patient for whom jaw surgery was the only option recommended by several surgeons and other orthodontists. F-H, Pre-treatment intra-oral photographs of same patient, showing evidence of mild functional shift. Arrow at the abundant attached gingival tissue in maxillary anterior, indicating adequate tissue available for incisor re-angulation and camouflage therapy for this patient. I-K, Intra-oral photographs illustrating favorable response to initial stages of therapy.

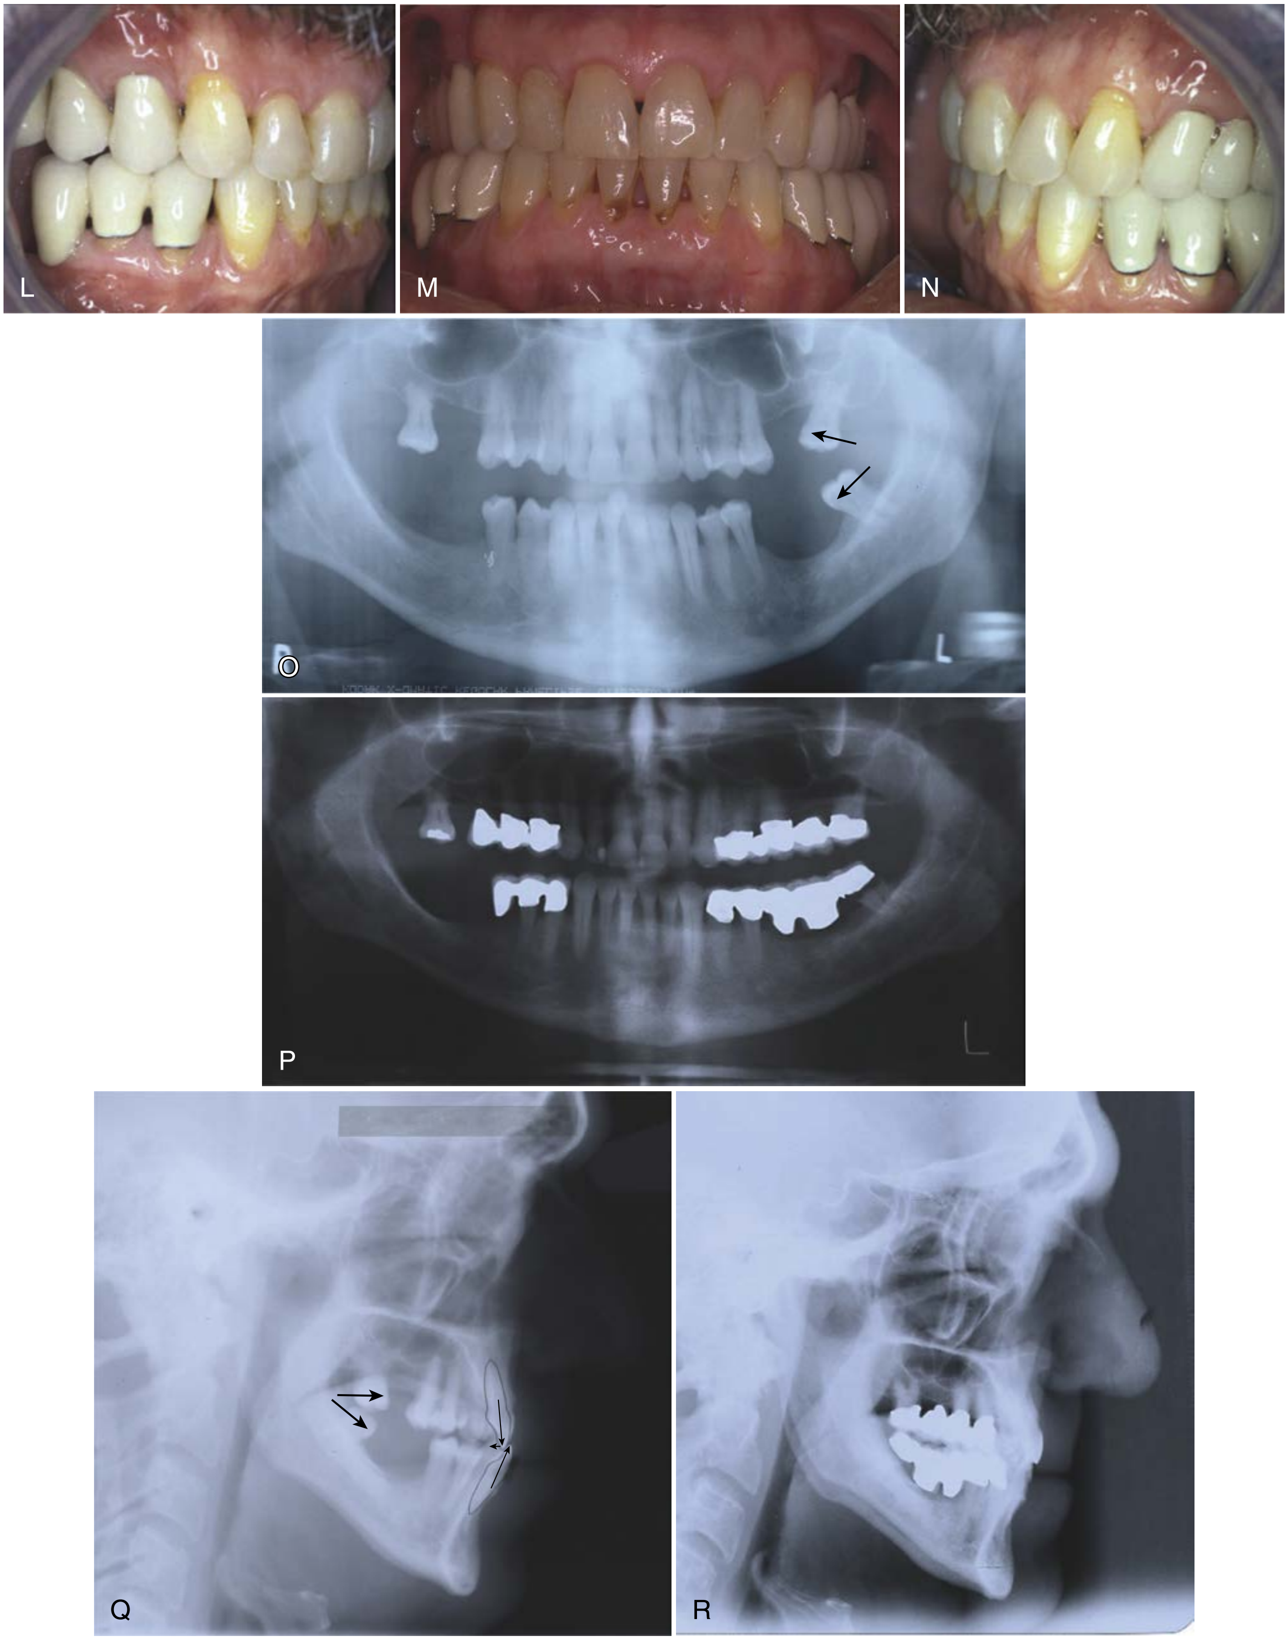

FIGURE 21-9, cont'd L-N, Intra-oral photographs with posterior restoration complete. Posterior segments left in cross-bite. O, Pre-treatment panoramic radiograph showing loss of several posterior teeth and bone loss. P, Post-orthodontic and restorative radiograph showing restoration of posterior occlusion. Q, Pre-treatment cephalometric radiograph showing Class III with anterior crossbite and loss of posterior vertical support due to extensive tooth loss. Class III relationship has a mild skeletal component and a moderate dental component with a functional shift that increases the severity of the Class III appearance. R, Post-treatment cephalometric radiograph with corrected anterior relationship and restored posterior occlusion.

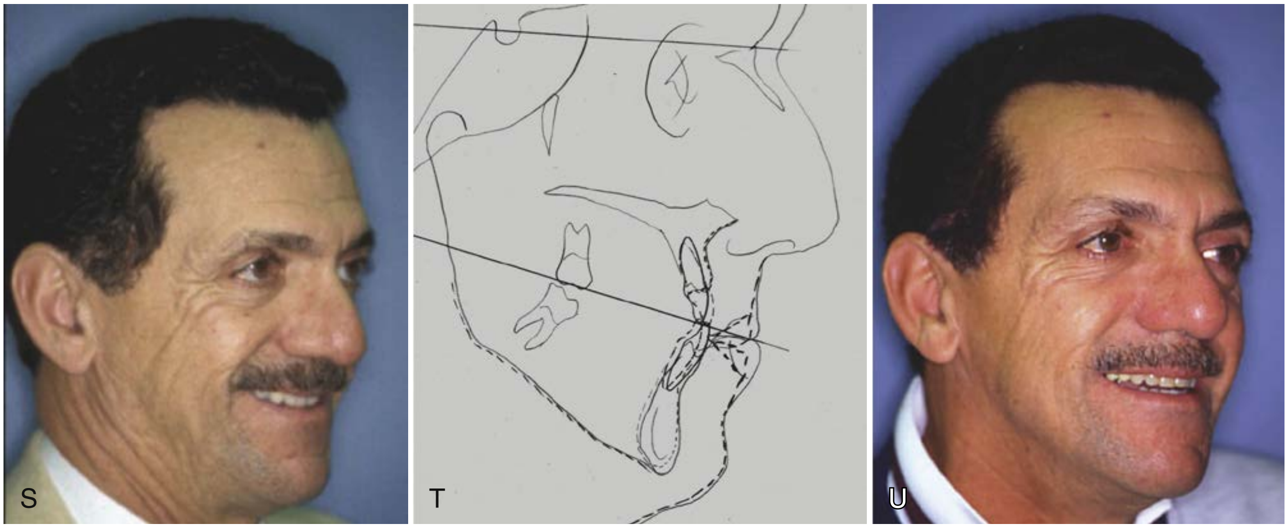

FIGURE 21-9, cont'd **S,** Pre-treatment of 51:6 year old male with long-standing Class III malocclusion. Several specialist had recommended jaw surgery to resolve this problem. Jaw surgery would have been "over-treatment" for this patient. **T,** Pre and Post treatment cephalometric supra-impositions improved facial balance due to camouflage therapy and the elimination of the functional shift. **U,** Post-treatment of patient with very favorable achievement of Objective #6 (Adequate Occlusal Landmark Relationships) through non-surgical management of his Class III malocclusion.

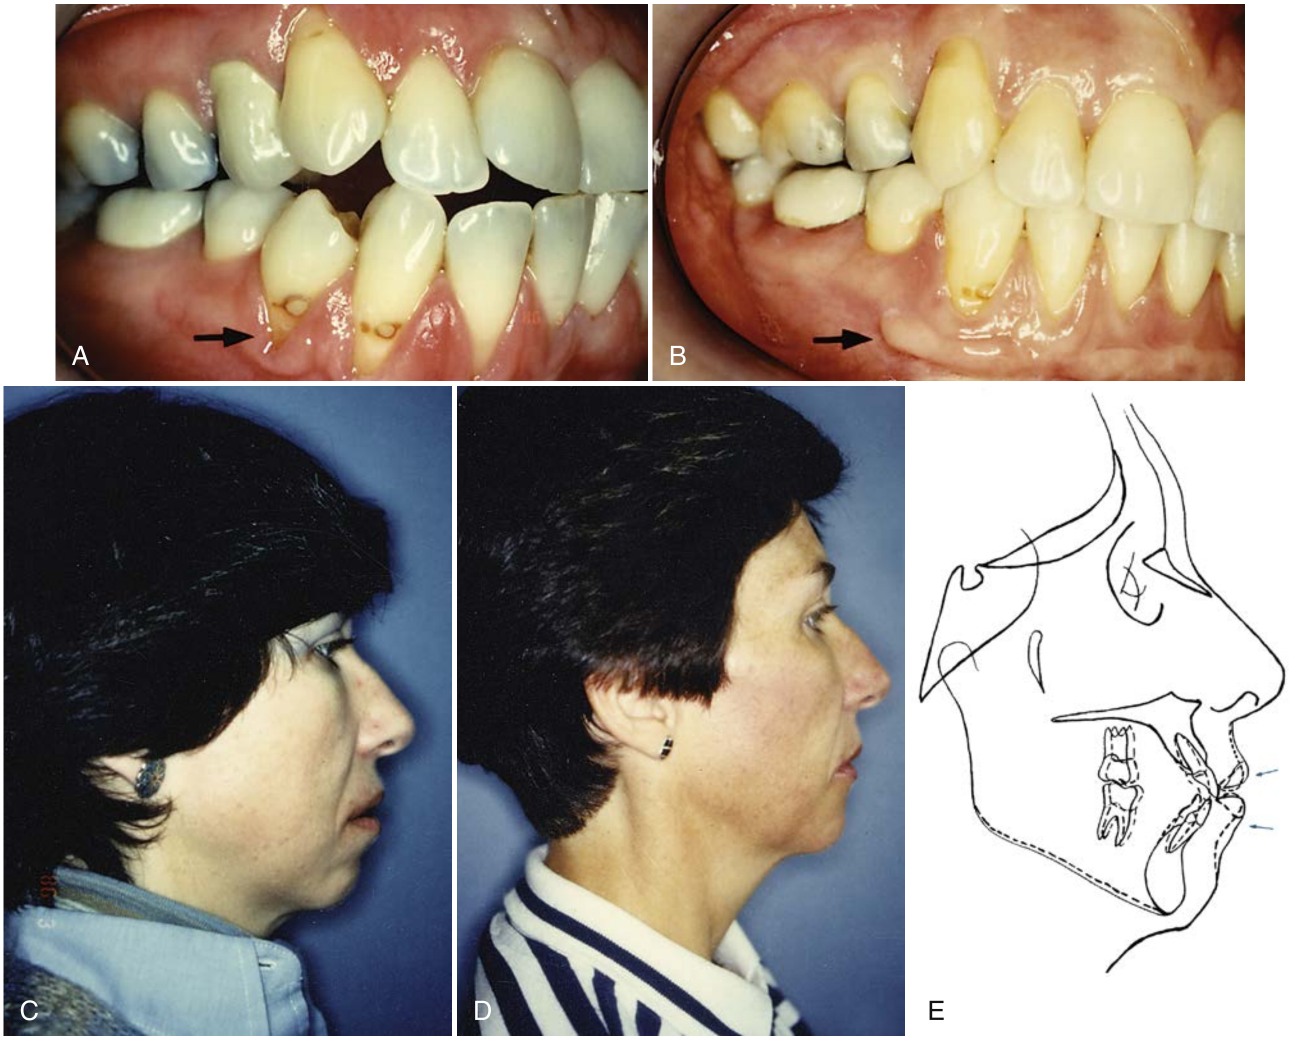

FIGURE 21-10 Clinical example of additional adult orthodontic treatment objective 7: better lip competency and support. **A,** Pretreatment right occlusion illustrating open bite, protrusive upper and lower incisors with crowding and gingival recession (*arrow*). **B,** Posttreatment right occlusion illustrating correction of preexisting malocclusion and incisor retraction with extraction of nos. 5,12, 21, and 28 and correction of gingival recession (*arrow*). **C,** Pretreatment profile showing lip incompetence caused by dentoalveolar protrusion. **D,** Posttreatment profile showing improved lip competence and relaxed mentalis. **E,** Cephalometric superimposition showing corrected incisor protrusion and subsequent lip position improvement (*arrows*).

FIGURE 21-11 Clinical example of adult treatment objective 8: improved crown-to-root ratio. **A,** Before correction of an incisor crossbite. Note the normal gingival position on the labially displaced lower left lateral incisor in a 14-year-old patient. After lower incisor alignment the gingival margins were confluent. **B,** Narrow zone of attached gingiva in a 61-year-old patient. As the lower incisors were retracted and allowed to erupt, more gingiva was created incisogingivally. **C,** Woman with large osseous defect on the mesial of the lower left premolar. Note the significant probing depth. **D,** Preoperative radiograph of intrabony defect. **E,** Before orthodontic movement, guided tissue regeneration was used to create new attachment, and then eruption was used to eliminate any remaining osseous defect. Note nonresorbable membrane that was placed over the defect, which was allowed to heal, and was removed 8 weeks later. **F,** The tooth was extruded to resolve the intrabony defect. **G,** Buccal view of the preoperative intrabony defect. **H,** Buccal view of the new bone after the tooth was extruded and prepared for a restoration. **I,** Lingual view of the preoperative intrabony defect. **J,** Lingual view of the new bone after regeneration and tooth movement. **K,** Provisional restoration. The osseous defect has been corrected and the crown-to-root ratio has been improved. **L,** Radiographic appearance of the premolar. (C–J, Courtesy of Eric Saacks, Bondi Junction, Australia.)

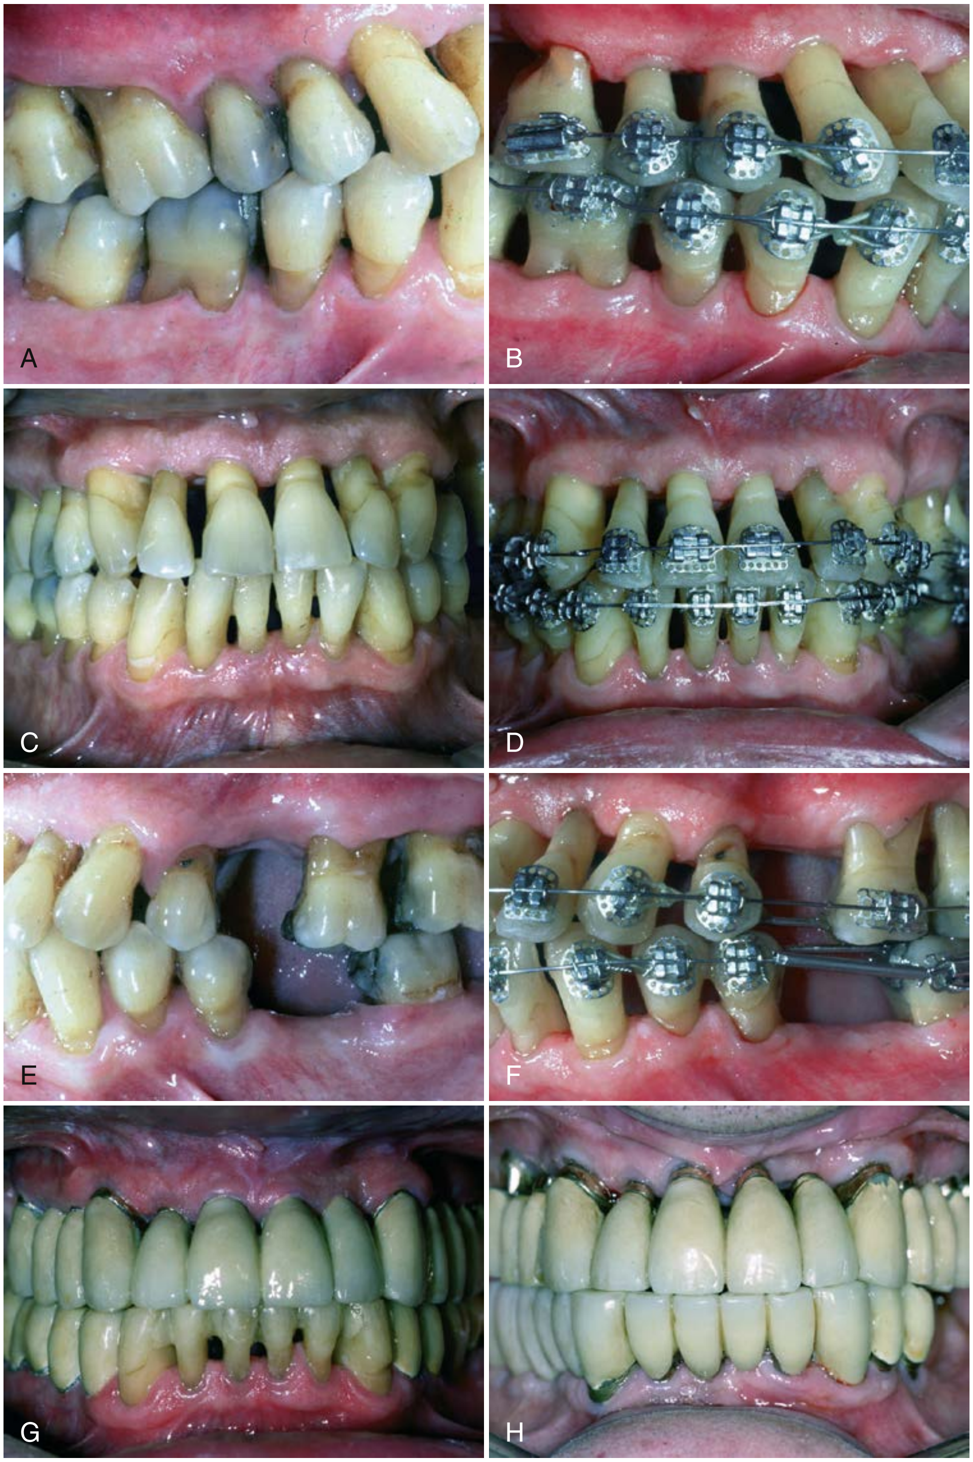

FIGURE 21-12 Clinical example of adult treatment objective 9: improvement or correction of the mucogingival and osseous defects; and adult treatment objective 10: better self-maintenance of periodontal health. **A, C, E,** Gingival form after control of inflammation and occlusal therapy with a bite plane in a 58-year-old man. In patients with posterior bite collapse, the posterior teeth are disarticulated with a Hawley bite plane appliance during scaling and root planing. **B, D, F,** Ahexial positioning of the teeth. Note the changes in gingival form. (The topography improved as the bite collapse was corrected and the teeth were properly positioned.) In addition, controlling gingival inflammation is easier after better tooth position has been established. **G,** Two years post treatment. **H,** Twenty-two-year follow-up. The patient has maintained his natural teeth.

cusp tips. In adults, the goal should be to level the crestal bone between adjacent cementoenamel junctions. It has been demonstrated that the need for osseous and mucogingival surgery may be diminished by favorable changes of the osseous and soft tissue topography during tooth movement. Therefore, attachments should be placed on individual teeth to allow the leveling of the attachment apparatus. This creates more physiologic osseous architecture with the potential to correct certain osseous defects.[13] During leveling stages, any teeth that have erupted above the occlusal plane should be grossly reduced occlusally. Also, continuous adjustment should be done to prevent the patient from contacting individual posterior teeth prematurely and causing occlusal trauma.

5. **Better self-maintenance of periodontal health.** The location of the gingival margin is determined by the axial inclination and alignment of the tooth. Clinically, it appears that improved self-maintenance of periodontal health occurs with proper tooth position.[14–16] This can be seen in adult patients as a result of correction of bite collapse and accelerated mesial drift (see Fig. 21-12).

Patients who need weekly periodontal maintenance during the initial leveling phases of therapy may require less frequent scaling and root planning as periodontal status improves. Poor tooth position and improper tooth preparation before irreversible restorative dentistry are causative factors that may contribute to periodontal disease. For better periodontal health on an individual pattern basis, teeth should be positioned properly over their basal bone support. In the nonsurgical management of skeletal Class III and Class II malocclusions, a delicate balance exists between periodontally desirable tooth positions and achievement of other nonsurgical treatment objectives.

1. **Aesthetic and functional improvement.** As stated previously, a plan should provide acceptable dentofacial aesthetics and allow for improved muscle function, normal speech, and masticatory improvements. This is possible when a therapeutic occlusion is provided that enables the anterior teeth to function as disarticulators and the posterior teeth to support the vertical dimension (Fig. 21-13).[11]
2. **Best outcome with least risk (using minimally invasive approach).** As technology increases therapeutic options, it is more incumbent on treatment providers to assess the advantages and disadvantages of each treatment option available. For example, certain borderline extraction situations can benefit from judicious therapeutic diagnosis that allows the providers and the patient to achieve a result equal to the outcome if extraction therapy was part of the treatment plan (Fig. 21-14).

DIAGNOSIS OF ADULT ORTHODONTIC CONDITIONS

Adult patients present numerous and demanding problems requiring both more specialized data pertinent to the patient's dental and orthodontic problem and a highly skilled mechanism to interpret it. The problem-oriented medical record (POMR) of Weed[17] takes the following into account:

1. Tremendous growth in medical knowledge
2. Resulting increase in specialization
3. Fragmentation of knowledge that has followed this increase
4. Consequential impossibility of relying on memory for adequate patient care

The needs that prompted development of the POMR have also influenced dentistry, particularly adult orthodontics. Figure 21-15 is a synthesized description of the steps necessary to include all variables into the adult patient's treatment planning process. The format and mechanism used for interpreting problems into orthodontic dental records are important steps in improving the practitioner's understanding of the adult patient and in providing treatment measures that can optimize the overall treatment result. Problem-oriented dental records significantly aid in making the appropriate diagnosis because they require that a problem list be developed to manage each problem.[16,17] This is an important improvement over the morphologically oriented diagnostic method that dates from the introduction of Angle's original classification of malocclusion.

A coordinated, logical approach is crucial to successful adult treatment. The following diagnostic steps are recommended.

Skeletal Differential Diagnosis

The correct skeletal differential diagnosis is the key responsibility of the orthodontic member of the interdisciplinary team. Although the lateral cephalogram has been relied on for the skeletal diagnosis in the anteroposterior and vertical planes, the frontal or posteroanterior (PA) cephalogram (Fig. 21-16) has not been routinely used by orthodontists to make an appropriate three-dimensional (3D) diagnosis. Recent advances in 3D radiographic imaging make the skeletal assessment in all planes of space more efficient and predictable. These 3D images allow the clinician to make both a thorough diagnosis and to use improved imaging for patient education. (See Chapter 11 of this textbook for examples of diagnosis enhanced by 3D imaging.) It should be noted that in a recent study of adult patients who sought orthodontic retreatment, it was reported that about 20% of retreatment adults have a maxillomandibular skeletal discrepancy of 6 mm or greater in the transverse dimension that requires jaw surgery (usually surgically assisted rapid palatal expansion [SARPE]) to achieve an optimal treatment outcome[5] (see Fig. 21-16).

Diagnoses in the anteroposterior and vertical planes are typically completed using a variety of cephalometric analyses,[19–25] and newer computerized software programs allow cephalograms to be digitized and analyzed, allowing an abundant amount of numeric information about the patient's skeletal jaw relations. Frequently, the analyses generate confusing and, at times, conflicting information regarding differential diagnosis of the patient's conditions.

In 1979, Jacobson presented the use of a simplified approach to aid in the diagnosis of skeletal disproportions that might be evident on a patient's lateral cephalogram.[26] This excellent report demonstrated the value of using normative, composite templates to aid in diagnosis and treatment planning. Since that time, two of America's most respected department chairs made statements that validated the use of templates to aid in differential diagnosis. In 1987, Lysle Johnston made the following straightforward statement:

> *Many clinicians stop tracing cephalograms at about the time their practices start to get busy. Ideally, a descriptive analysis should consist only of those measurements that are needed to illuminate the clinically significant idiosyncrasies of the patient at hand. Template analysis may seem an ideal solution.*[27]

Proffit pointed out in his 1991 textbook on surgical orthodontics that "the template may appear to be somewhat less scientific than a table of cephalometric measurements with

FIGURE 21-13 Clinical example of additional adult orthodontic treatment objective 11: aesthetic and functional improvement. **A–C,** Pretreatment intraoral photographs showing diminished occlusal function because of significant anterior open bite and posterior crossbite. At initial examination, patient had severe temporomandibular joint and myofascial pain because she was forced to "fulcrum" with second molar occlusion. **D–F,** Posttreatment intraoral photographs showing correction of malocclusion through a treatment sequence that included (*1*) splint therapy to improve comfort, (*2*) gingival grafting of lower anterior to protect from further recession, (*3*) orthodontic decompensation and alignment to prepare for jaw surgery, (*4*) orthognathic surgery with maxillary posterior impaction and mandibular auto rotation with mandibular setback, (*5*) completion of orthodontic treatment, and (*6*) stabilization with ongoing nightguard therapy. **G,** Pretreatment profile photograph. **H,** Posttreatment profile photograph illustrating favorable aesthetic improvement that accompanied functional improvement. **I,** Cephalometric superimposition showing overall dental, basal bone, and soft tissue changes that accompanied the interdisciplinary treatment plan. Note that temporomandibular joint and myofascial pain and headaches diminished as functional malocclusal relationships of the masticatory system were corrected.

standard deviations, but the template is a *visual analog* of a table and is just as valid." Proffit also states:

> *What a template does is place the emphasis on the analysis itself; that is, deciding what the distortions are, rather than on an intermediate measurement step that too often becomes an end in itself rather than just a means to an end.*[28]

For the past 30 years, one of the authors of this chapter has used a variation of the Jacobson template method of

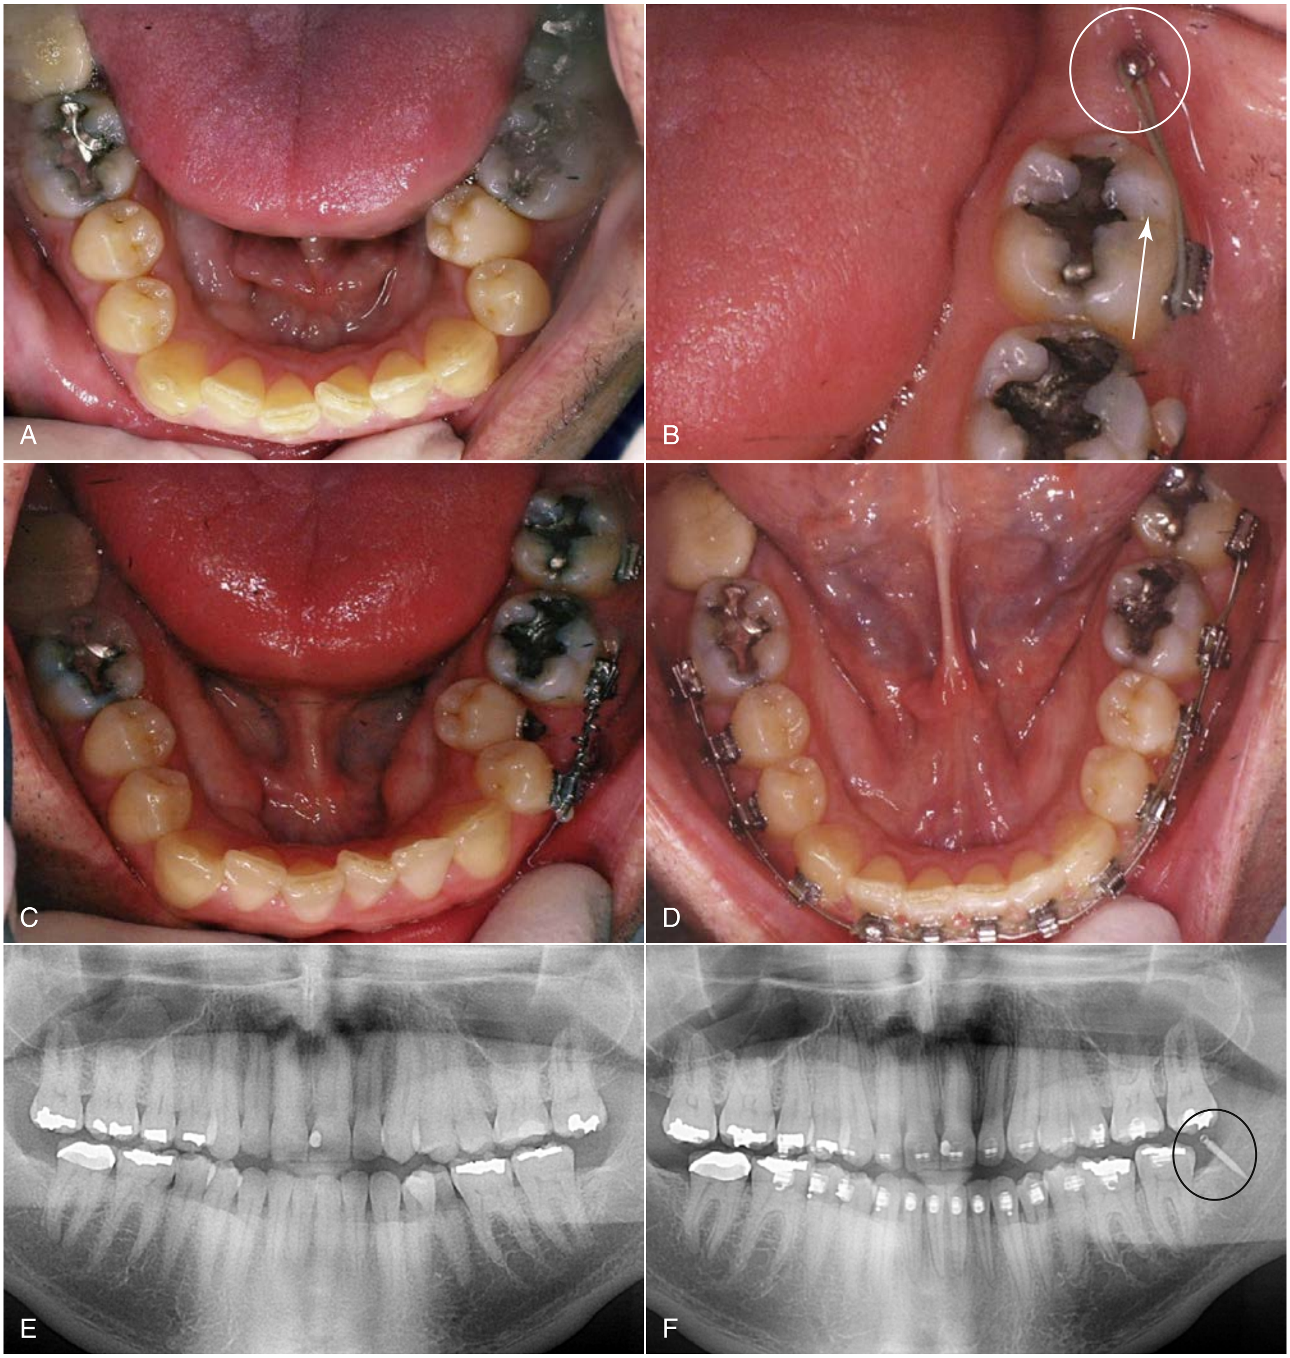

FIGURE 21-14 A, Intraoral occlusal photographic view of mandibular arch showing mild anterior crowding and collapse of the arch in the area of no. 20. One could assume that this arch collapse was a result of early loss of "k" without appropriate space maintenance and subsequent mesial drift of the posterior teeth in that area, disturbing the eruption path of no. 20. **B,** Close-up occlusal view of that area illustrating a minimally invasive approach using temporary anchorage devices (TADs) to allow posterior movement (reversal of arch collapse) of Nos. 19 and 18 to allow uprighting of #20 and improved axially positioning for better long-term periodontal health in that area (*white circle* at TAD and *white arrow* showing direction of movement). **C,** Lower occlusal view after 4 months of appliance activation. A small amount of room is becoming available for future movement of #20. **D,** Lower occlusal view after 12 months of appliance activation. Mechanotherapy included incorporation of TAD for distal anchorage and open coil spring at area of no. 20, and light enamel contouring created adequate space for no. 20 and preserved a healthy, natural dentition. **E,** Pretreatment panoramic radiograph illustrating the root proximity in the area of the collapse arch at no. 20. **F,** Progress radiograph illustrating TAD (*circle*) with favorable molar repositioning caused by mechanotherapy described in **D**.

superimposition; its use has been described as *template-guided diagnosis and treatment planning* (see Figs. 21-21 to 21-26). The method described in Chapter 23 of the current text incorporates the following concepts:

1. Standardized templates from the Bolton study provide a composite tracing of proportionate soft and hard tissue that can be of diagnostic value when compared with the patient's cephalometric tracing (for adults, the 18-year-old standard is used).
2. This superimposition technique acknowledges that the size of the patient's nose is a key factor in actual visualized, profile perceptions (e.g., a patient with a large nose and a moderate mandibular deficiency may appear to have a severe mandibular deficiency when viewed in profile because of nasal dominance).
3. The template method described and illustrated thoroughly in Chapter 23 is very "staff and patient friendly" because it allows rapid visualization of the skeletal discrepancy, which helps patients understand why surgical intervention may be needed in a variety of situations.
4. This method is called *template-guided diagnosis and treatment planning* because it provides an excellent orientation for the clinician to make decisions that will help guide the planning of both the skeletal and dental corrections "in the direction of balanced hard and soft tissue facial proportions" (Fig. 21-17).

Periodontal Differential Diagnosis

Periodontally involved or compromised patients who have experienced shifting migration, extrusion, or flaring or lost teeth can benefit from orthodontics designed to correct local causative factors, predisposing malpositions, and certain bony and periodontal pockets.[29,30] Clinical evidence in periodontics shows overwhelmingly that changing local environmental factors can improve periodontal health and reduce the frequency of long-term periodontal maintenance. Orthodontics is one of the most dramatic means available to modify local factors and site specificity of the disease process.

Patients who have already been affected by periodontal disease and have lost significant tooth support are at risk for recurrent episodes of active disease; this group is especially susceptible because of their past history. In the United States, 80% of older adults have experienced some degree of periodontitis, and 95% of older adults have moderate to severe periodontal disease. Movement of teeth for periodontally susceptible or previously compromised patients in the presence of inflammation can result in increased loss of attachment, irreversible crestal bone loss, or both. Fortunately, research and clinical studies have shown that dentitions with a history of periodontitis or teeth with reduced attachment height can be moved without significant loss of attachment.[31] Identification of the susceptible sites or areas and control of the inflammatory lesion are crucial to

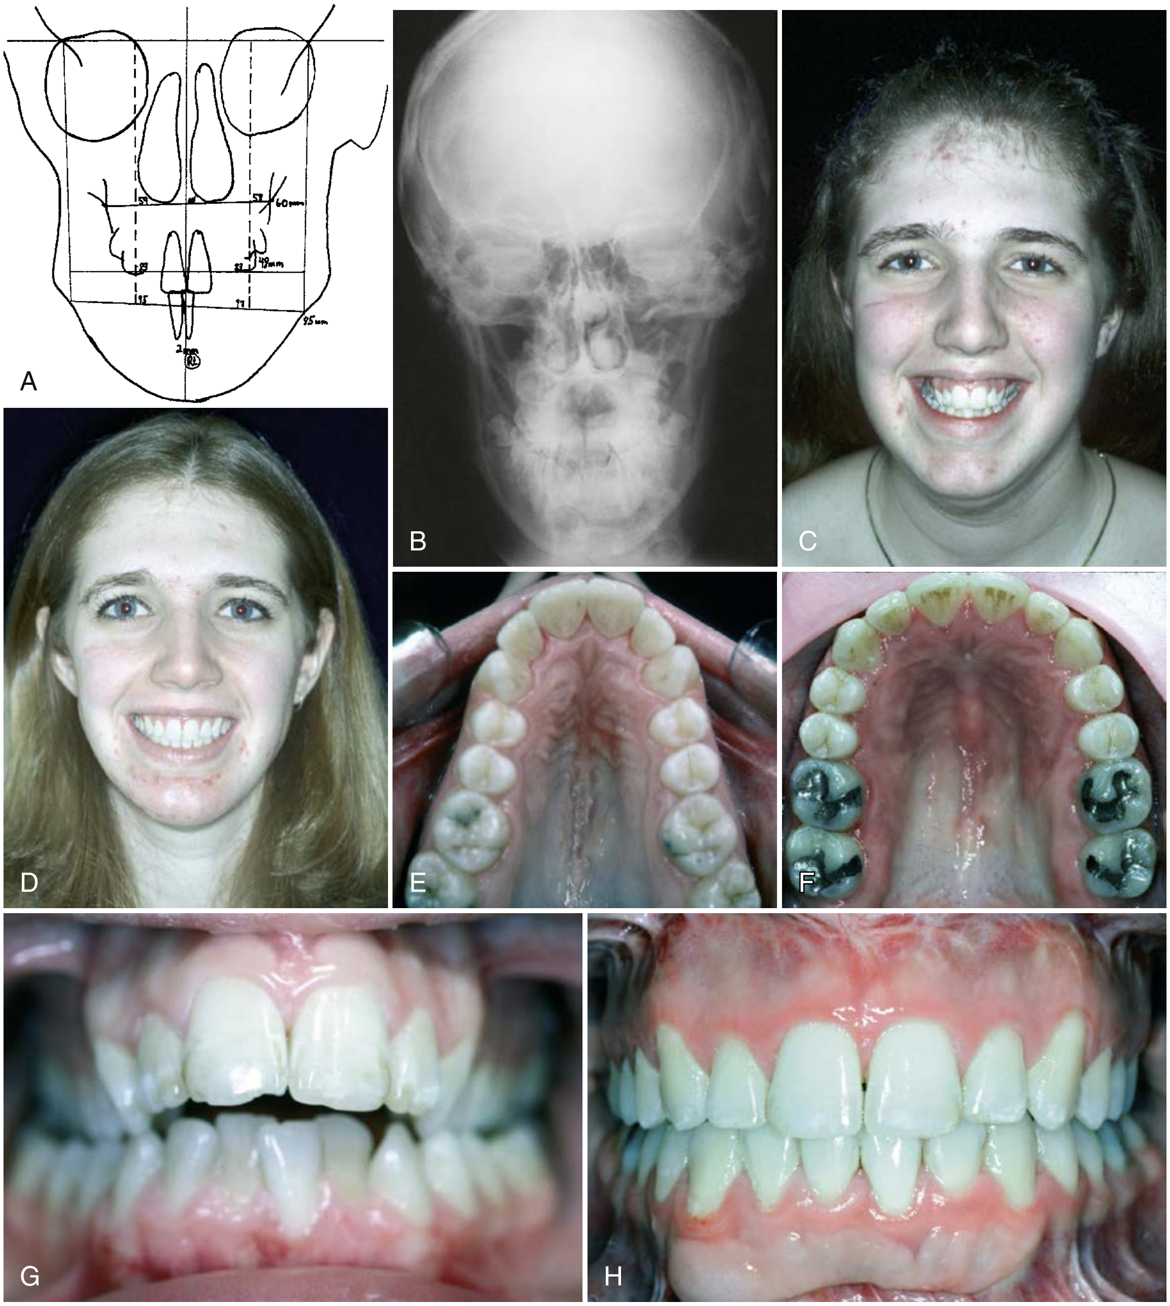

FIGURE 21-16 **A,** Rocky Mountain transverse analysis indicates a mandibular width (AG to AG) of 85 mm and a maxillary width (MX to MX) of 60 mm. The maxillomandibular difference is 25 mm, and the normal for this patient is 18 mm. Therefore, the expected/actual difference is 7 mm. Surgically assisted rapid palatal expansion may be considered a form of osteodistraction and has been found to be stable if large amounts (>7 mm) of expansion are required. **B,** Pretreatment posteroanterior cephalogram. **C–H,** Class II, Division 1, 14-year-old white female patient (skeletal age, 17 years), with an A point–nasion–B point angle of 7 degrees, a high mandibular plane, a severe transverse skeletal discrepancy with a differential index of 7.6 mm because of a wide mandible and a narrow maxilla, bilateral posterior crossbites, and 10-mm overjet. **C,** Note the large negative space at the corners of the mouth on the pretreatment photograph. **D,** Note the increased buccal tooth visibility and elimination of the negative space after a surgically assisted rapid maxillary expansion to correct the transverse dimension and achieve a natural or broader arch form. **E,** Pretreatment maxillary arch. **F,** Posttreatment natural or broader arch form. **G,** Pretreatment anterior view. **H,** Post treatment. A second-stage surgery consisted of Le Fort 1 osteotomy with 5 mm of maxillary impaction allowing for mandibular autorotation and a 7-mm advancement genioplasty for profile improvement. Surgically assisted maxillary expansion has been shown to be more stable than two or more segments of Le Fort 1 osteotomy with expansion. The treatment strategy addressed the type and magnitude of the transverse skeletal deficiency, vertical maxillary excess, growth status, dentofacial aesthetics, stability factors, and periodontal health.

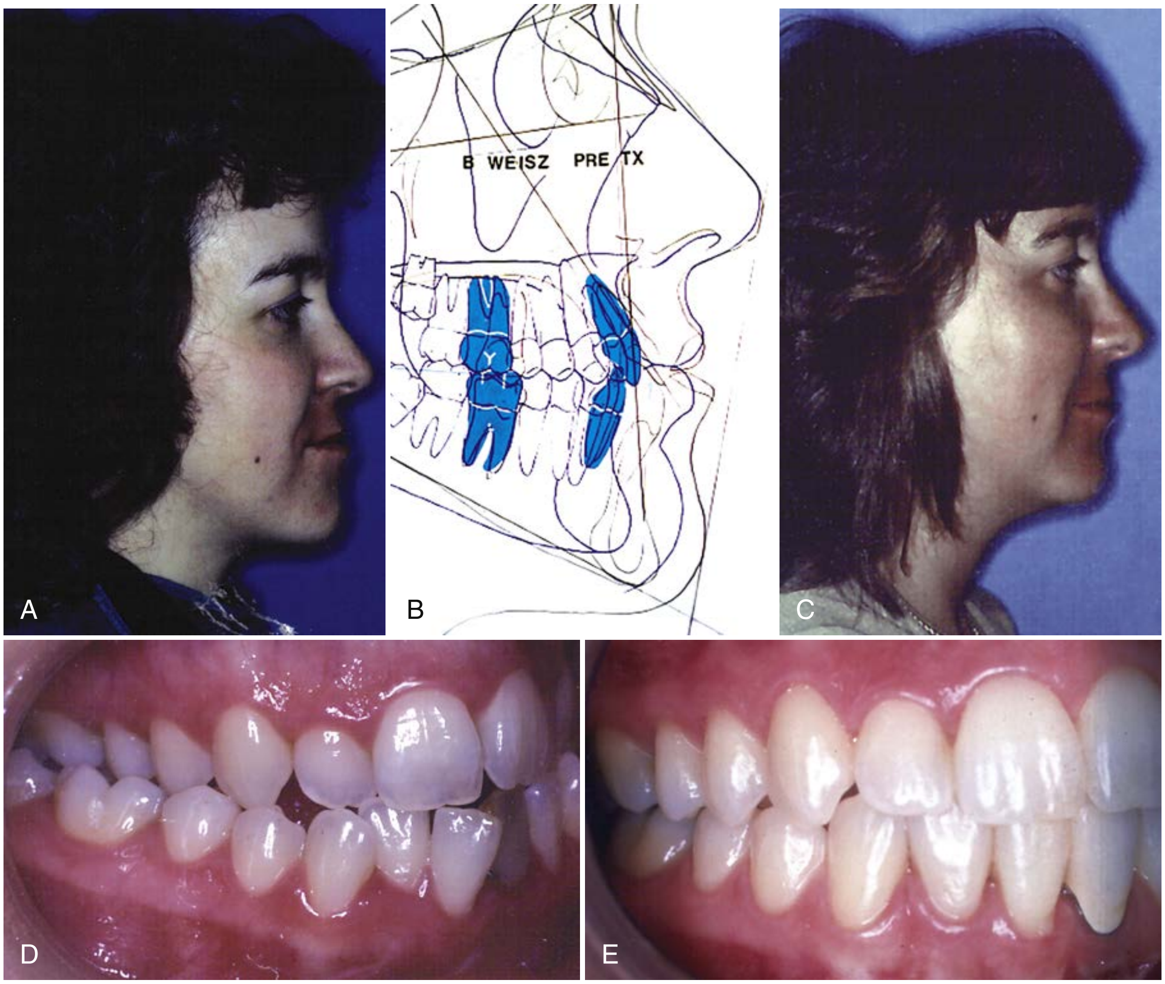

FIGURE 21-17 Differential diagnosis of Class III problem using Bolton template technique to guide the diagnosis and treatment plan. **A,** Pretreatment profile of a Class III patient before orthodontic/surgical treatment. **B,** Bolton template (*blue*) superimposed on the patient tracing: nasal tip with the nasal tip and forehead parallel. **C,** Profile after orthodontics and surgery. **D,** Right occlusion before orthodontic decompensation and surgery. **E,** Right occlusion after orthodontic decompensation and surgery.

successful therapy. All patients, however, will have some degree of inflammation, and it is important to ensure that periodontitis remains stable or quiescent throughout orthodontic treatment.

To manage the periodontal issues in adult treatment effectively, the orthodontist must make an accurate assessment of the patient's potential for bone loss or gingival recession during orthodontic tooth movement. A common problem occurs when the orthodontist assumes that the general dentist will provide skilled inflammation control for a patient with incipient periodontal disease. After months of tooth movement and clenching or grinding instigated by movement interferences, dental radiographs may reveal significant bone loss. Consequently, regaining control of periodontal inflammation is harder than controlling it from the beginning. The orthodontist needs to monitor every adult case closely and collaborate with the periodontal specialist to properly treat adult patients. The orthodontist must bear in mind that periodontal disease continues to be a large percentage of dental malpractice claims. The basis for the litigation appears to originate from a number of sources:

- Poor case selection
- Poor office procedure in insisting that prospective patients be periodontally stable
- Patient reluctance for or refusal of periodontal checkups
- Dentists' acquiescence in the patient's neglectful behavior
- Ill-defined protocol between orthodontist and general dentist (or periodontist)[32]

Therefore, appropriate management of several factors is needed to prevent negative periodontal sequelae during orthodontic treatment:

1. Awareness and vigilance of the orthodontist and the staff must be heightened.
2. Awareness and vigilance of the patient must be frequently reinforced.
3. Awareness of risk factors related to periodontal breakdown must be understood by and reviewed with the patient (see Chapters 22 and 30).
   - General factors
   - Family history of premature tooth loss (indication of immune system deficiency in resistance to chronic bacterial infection associated with periodontal disease)
   - General health status and evidence of chronic diseases (e.g., diabetes)
   - Nutritional status
   - Current stress factors
   - Periodontal biotype[33]
   - Life stage of women[34]

- Local factors
- Tooth alignment (e.g., marginal ridge, cementoenamel junction relationship)
- Plaque indices
- Occlusal loading
- Crown-to-root ratio
- Grinding, clenching habits (parafunctional activity)
- Restorative status

One of the most overlooked considerations in the management of adult patients is the impact of patient susceptibility to periodontal disease coupled with the preexisting habit of smoking. Until 2003, many orthodontists' health history did not include a question on the adult medical history form asking if the patient used tobacco products and a follow-up question about the frequency of use. In 1996, the American Academy of Periodontists published a position paper titled "Tobacco Use and the Periodontal Patient."[35] In this well-researched paper, the American Academy of Periodontists reference 97 published papers that verify the following:

> *Clinical and epidemiological studies support the concept that tobacco use is an important variable affecting the prevalence and progression of periodontal diseases, such as adult periodontitis, refractory periodontitis, and ANUG [acute necrotizing ulcerative gingivitis]. Several studies have demonstrated that the severity of periodontal disease appears to be related to the duration of the tobacco use, smoking status, and amount of daily tobacco intake.*[35]

If there is no health history question regarding tobacco use and no follow-up in which the patient is informed of the risk of accelerated bone loss and a poor prognosis for long-term health and function, both the patient and the providers could have an undesirable outcome—the patient could because a large investment in his or her dental treatment has high probability of failure, and the providers could because they could be named in legal action for lack of diagnosis and lack of informed consent. The added risk of orthodontic appliances reducing oral hygiene capacity and the "jiggling trauma" of changing tooth positions in a mature neuromuscular environment could lead to rapid periodontal breakdown and blame placed on the orthodontist for "moving the teeth too fast," which hypothetically may lead to expensive restorative procedures and an angry patient.

Temporomandibular Joint Differential Diagnosis

Because the signs and symptoms of TMD often increase in frequency and severity during adult treatment, it is imperative that orthodontists be familiar with their diagnostic and treatment parameters (see Chapter 7). A study by Howard shows that the majority of 3428 TMD patients were between the ages of 15 and 45 years (mean age, 32.9 years).[36] However, it is important to note that "craniomandibular disorders are self-limiting, or they fluctuate over time as suggested by declining incidence with age."[37] Unfortunately, knowledge regarding the natural history or course of TMD is limited.[38,39]

In a prevalence study, Schiffman and Friction found that the group of patients whom they treated for TMD problems were divided into several types:[40]

Muscle disorders	23%
Joint disorders	19%
Muscle–joint combinations	27%
Normal	31%

It is important to note that prevalence data frequently overstate the clinical significance of the problem because many patients have mild signs that may be transitory and are better left untreated. The orthodontist treating adults would be wise to have a separate TMD questionnaire to supplement other health history information as part of the initial evaluation process. The goals of such a questionnaire would be to answer the following questions:

1. What type of TMD does the patient have? Muscle, joint, combination, psychosomatic? Where is most of the problem located?
2. Is there pain? What is the degree of pain? What is the frequency of pain? Is the pain chronic or acute? "Chronic pain syndromes are defined as persistent pain that lasts more than 6 months with significant associated behavioral and psychosocial factors."[41]
3. Has there been previous treatment for this problem? What treatment? How long? How effective? Any medication?
4. What is the patient's understanding of his or her condition? Does he or she need a program designed to educate?
5. Is there an occlusal factor that may be exacerbating the problem? Are there occlusal habits that are known or apparent?

The differential diagnosis may not be established until there are more assessments, records, and imaging. However, the orthodontist must have a clear perspective of diagnostic possibilities. An excellent discussion of TMDs is summarized in Chapter 13.

> *Each of these five factors [symptoms, conditions of the dentition, systemic health, aesthetics, and finances] needs to be considered before an appropriate occlusal treatment plan can be developed. It is important to realize that the priority of the factors may be different for the patient and for the therapist. When symptoms are not severe, finances and aesthetics will often be more important concerns of the patient. At the same time, however, the dentist may believe that the condition of the dentition is more important. In any case, the patient's concerns must always remain foremost in the development of a successful treatment plan.*[42]

Although there is no established cookbook for 100% reliability in the management of temporomandibular disorders, Dr. Okeson has presented a series of diagnostic algorithms of appropriate steps in the management of a variety of TMDs.[42]

In summary, an orthodontist treating adults plays a key role in diagnosing a skeletal problem that may require surgery, a periodontal condition that may worsen as a result of tooth movement, and a TMD that requires its own differential diagnosis and plan. Diagnostic steps described previously provide an overview to lead the orthodontist and the team of dental providers to a comprehensive treatment plan that has the highest probability of achieving the desired goals of treatment (Fig. 21-18).

CLINICAL MANAGEMENT OF THE INTERDISCIPLINARY ADULT THERAPY PATIENT

Before the initiation of treatment for the IAT patient, there are several skills that are required beyond those commonly used in the orthodontic treatment of child and adolescent patients. Although not every adult patient requires each of the considerations listed next, treatment will progress more easily if the concepts in the section are understood and the orthodontist

FIGURE 21-18 **A–C,** Pretreatment intraoral photographs illustrating previous temporomandibular joint surgery, condyle remodeling, and anterior open bite. **D–F,** Posttreatment intraoral photographs illustrating improved function and bite closure using orthodontics to prepare for surgery, orthognathic surgery, and long-term splint therapy. **G, H,** Pretreatment facial photographs. **I, J,** Posttreatment facial photographs show minimal facial change because of patient's desire to proceed with single-jaw surgery instead of double-jaw surgery. **K, L,** Pretreatment panoramic radiograph and cephalogram. **M, N,** Posttreatment panoramic radiograph and cephalogram. Note that surgery resolved open bite with Le Fort surgery only. Mandibular advancement surgery would have been ideal for profile change but was not used to prioritize reduced risk to fragile and remodeled condyles. *SNB,* Sella-nasion-supramentale angle.

is already skilled at providing the necessary strategy at the appropriate time.

Biomechanical Considerations

Control of Occlusion

There are three crucial ways to control occlusal forces during appliance therapy: disarticulation or disclusion of teeth moved, selective grinding with a high-speed drill, and modification of mechanotherapy for a periodontally susceptible or compromised individual.

Disarticulation. The Hawley bite plane is used for disarticulation (and for diagnosis of TMD patients), to establish centric relation at the acceptable vertical dimension, and as necessary throughout orthodontic treatment to prevent excessive tooth mobility. During the leveling stages, the bite plane is used (in conjunction with posterior sectional archwires) to allow teeth to move free of occlusal forces. The appliance is worn at all times except while the patient is eating or sleeping. A significant biomechanical advantage of disarticulation (or disclusion) in an adult is that it allows mesially inclined tooth crowns to tip distally to an upright position with only slight mesial movement of their root apices, thereby creating space in the mandible distal to the canines for alignment of crowded lower anterior teeth. If the posterior teeth are not disarticulated, occlusal forces may cause the buccal segment roots to move mesially so that no space is gained distal to the canines during uprighting. Note also that uprighting of posterior teeth, free of occlusal forces, requires much less time and reduces the hazard of mesial root movement and root resorption. The use of disarticulation appliances is particularly important when treating patients who have bone loss or short facial height with strong masseter activity or patients with evidence of posterior bite collapse requiring molar uprighting (Fig. 21-19).

Selective Grinding. The typical adult malocclusion is characterized by posterior teeth that have moved and tipped mesially (accentuated mesial drift) and bite collapse. There is less wear on the mesial marginal ridges than on the distal marginal ridges of mesially inclined posterior teeth. After these teeth start to upright, the mesial marginal ridges need to be reshaped so that the occlusal table will be perpendicular to the long axis of the tooth. Many teeth need to be extruded to correct osseous defects and level the crestal bone but must not be allowed to remain in premature contact after eruption has occurred.

Therefore, at each appointment, the bite plane is removed, and selective grinding is done as necessary to ensure simultaneous bilateral contact with the posterior teeth when in centric relation. After a malocclusion involving mesially inclined posterior teeth has been uprighted, the posterior segments will not be stable unless selective grinding is used to reshape the occlusal surfaces along with any required operative and restorative dentistry to ensure simultaneous bilateral contact along the long axis when in centric relations. The objectives of selective grinding then are to allow leveling of the attachment to crestal bone and leveling of the marginal ridges to achieve simultaneous bilateral occlusion.

Modification of Mechanotherapy. With traditional multibonded techniques in non–periodontally involved patients, both arches are usually bonded, and full continuous archwires are placed. In adult patients (for reasons stated previously), the authors delay appliance placement on both the maxillary and mandibular anterior segments. This approach is well accepted by adults, who invariably prefer no brackets on the anterior teeth during the initial 9 to 12 months that it takes for posterior segments to be axially aligned and for transverse correction to be made. The objective is to set up the posterior occlusion before placing appliances on the anterior segments—these are moved last. After posterior teeth are aligned and axially positioned, the bite plane is removed, and the upper and lower anterior teeth are bonded. Space closure is begun and anterior alignment is completed. In Class II patients in whom upper premolars may need to be extracted, the extractions can be delayed, and then maxillary canines can be immediately retracted into the extraction site, minimizing the time for maxillary space closure. It is more difficult to traumatize posterior segments by parafunctional habits after the teeth have been axially positioned. However, if significant bruxism and clenching during stressful periods cause increased mobility, an immediate impression should be taken for a bite plane. The patient should be given a bite plane for disarticulation and referred for inflammatory control (scaling and root planning) as well. After mobility patterns have been reduced, mechanotherapy can be continued.

Removable Appliances. Within the removable appliance group are appliances designed for both diagnostic purposes and tooth movement. The diagnostic appliances are generally bite planes and splints. The acrylic splints are acrylic and wire bite planes with several features that are helpful, depending on the patient's problem. Some of the ways in which these appliances prove useful follow:

- For neuromuscular deprogramming[25,41–43]
- As therapeutic adjuncts to reduce joint inflammation, pain, and parafunction[7,15,44–46]
- As intermediaries during corrective orthodontic therapy to avoid transitory occlusal trauma or treatment-induced TMJ symptoms[22,47–50]

Removable appliances thus serve the patient as a crutch during specific treatment stages. Some patients whose problems cannot be therapeutically resolved without surgery instead will choose to wear a bite plane splint permanently to help maintain a symptom-free joint. Although tooth-movement appliances are in a separate group, on some occasions the appliance can be diagnostic initially and then therapeutic after the diagnostic phase has been completed.

The authors use the following appliances for adults:

- The sagittal appliance for distalizing buccal segments or individual teeth, thereby reducing the need for extraoral anchorage (headgear). This type of appliance with a spring-loaded jackscrew is particularly useful for patients who have had maxillary mesial buccal segment drift and thus require distal movement to create or to regain space. Frequently, a bite plane is used with this appliance to open the bite and allow more rapid distal tooth movement without occlusal or intercuspal interference.
- The slow palatal expander (Schwartz plate) for mild dental transverse discrepancy cases. This appliance has the potential for the addition of an anterior or posterior bite plane to minimize the resistance of occlusal or intercuspal interference during the occlusal correction. Also, bite planes on a palatal expander can deprogram an existing mandibular functional shift. However, skeletal transverse problems in adults resist treatment with this type of appliance and usually require surgical intervention for a stable correction. The most reliable and stable procedure for correction of maxillary skeletal transverse problems is the SARPE procedure.[51]

- The phase I appliances (placed before full appliances) used for reducing the length of time the patient must wear fixed appliances, for testing patient acceptance of the treatment plan, and for initiating tipping movements that may be more efficiently handled by a removable appliance. Orthodontists using phase I removable appliances appreciate the rapid tooth movement initiated by them. In addition, the use of this type of appliance frequently provides early insight into the patient's degree of motivation that would otherwise be unattainable without a much longer treatment commitment.
- Bite plane therapy is used in periodontally susceptible or already compromised bite collapse cases (and for diagnostic aspects in the treatment of TMD patients) and for disarticulation to find the centric relationship at the acceptable vertical dimension. During this phase of treatment, an evaluation can be made of the patient's response to the removal of adverse local factors, helping the clinician determine not only the prognosis but also the best therapy for the patient.[48,52]

Preorthodontic inflammation and occlusal control can be managed by a general dentist or the periodontist, but an orthodontist should monitor this phase and evaluate patient response over time before initiating the orthodontic phase of treatment. In addition, obviously, all caries control should have been completed, overhanging margins corrected, overbulked contacts reduced, irregular marginal ridges reshaped, and endodontic procedures completed.

Fixed Appliances. Accurate predictable interarch and intraarch tooth positioning in most adults requires the use of fixed orthodontic appliances. With continued advancement in bracket design featuring prescribed torque and other angulations, orthodontists now have the capability of more precise tooth movement with shorter periods of therapy.[53] Advancements in boding techniques, new compositions, and types of fixed

FIGURE 21-19 **A–C,** Pretreatment intraoral photographs showing Class II malocclusion with a 9-mm overjet. This patient was initially treatment planned for mandibular advancement jaw surgery before a second opinion with the recommended nonsurgical correction illustrated. **D–F,** Posttreatment intraoral photographs with occlusal correction through reversal of posterior bite collapse through early extraction of no. 30. **G,** Periapical radiograph showing collapsed area from loss of no. 30 about age of 10 years because of "deep caries." This resulted in no. 31 migrating mesially and nos. 29, 28, and 27 erupting distally and worsening the Class II posterior relationship.

Lower incisors were moved forward as part of the posterior bite collapse reversal as room was created for missing no. 30 restoration.

appliances have become available, thereby adding to the orthodontist's armamentarium of mechanotherapy options. Pretorqued and preangulated stainless steel labially affixed appliances are described elsewhere in this text and are generally regarded as the most predictable appliances for accomplishing desired tooth movements in all three planes of space. However, plastic brackets, porcelain brackets, mini-brackets such as the Hanson SPEED appliance, self-ligating brackets (see Chapter 24), and lingual or invisible appliances (see Chapters 25 and 26) have additional appeal to adult patients because of their more cosmetic appearance.

Although plastic and porcelain brackets have cosmetic advantages, they also present significant mechanical disadvantages for certain types of tooth positioning problems. From an analysis of the patient's records, the orthodontist must determine whether the problem is treatable (i.e., treatment goals achievable) within the limitations imposed by the use of cosmetic appliance choices. Recent advances have been made regarding the effectiveness of a progressive series of plastic aligners made from simulated movements on computer-generated models. (See Chapter 26 for a thorough review of aligner therapy and its application for adult patients.) These removable aligners using computer-simulated movements to guide the progressive application of desired forces can be effectively used in a variety of adult treatment situations. The initial choice of appliances can be altered during treatment, but it is wise nonetheless to provide for an alternative treatment plan (and appliances if needed) that will accomplish the treatment goals efficiently and predictably, especially when treating adults whose expectations of treatment may be extremely high.

Use of Temporary Anchorage Devices. Miniscrew implants for orthodontic anchorage have become a useful clinical tool that can simplify orthodontic treatment. Tooth movement that has been considered beyond ordinary mechanotherapy (e.g., asymmetric extractions, bimaxillary protrusions, molar intrusions, distalization, mesialization) can be achieved with minimal patient cooperation with the use of miniscrews (see Chapter 20).

Orthognathic surgery may not be needed in certain open bite and bimaxillary protrusion cases. Patients may be presented with an option other than orthognathic surgery. Chapter 20 in this textbook has excellent clinical examples of the effectiveness of TADs in the management of complex dentoalveolar and borderline surgical skeletal conditions.

Occlusal Control. Occlusal control during the leveling phase of treatment in advanced cases can be accomplished with the aid of the Hawley bite plane and posterior sectional arches (see Fig. 21-8). To prevent excessive forces from bruxism and clenching, it may also be necessary to insert bite planes during stressful periods throughout the course of orthodontic care.[45] Fortunately, after the posterior segments have been axially positioned and the transverse correction made, it is more difficult for the patient to traumatize posterior segments by parafunctional habits.

Periodontal Accelerated Osteogenic Orthodontics. The periodontally accelerated osteogenic orthodontic (PAOO) technique has been suggested to enhance orthodontic treatment by acceleration of treatment, better stability, and improvement of the periodontium.[54] Drs. Blasi and Pavlin illustrate several examples of the effective use of minimally invasive approaches to accelerate tooth movement. It has been observed that the duration of appliance wear can be particularly important to adult orthodontic patients (see Chapter 31).

Periodontal Management During the Orthodontic Tooth Movement

Patients who have already been affected by periodontal disease and have lost significant tooth support are at risk for recurrent episodes of active disease; this group is especially susceptible because of their past history. In the United States, 80% of adults have experienced some degree of periodontitis, and 95% of older adults have moderate to severe periodontal disease.[55] Movement of teeth for periodontally susceptible or previously compromised patients in the presence of inflammation can result in increased loss of attachment, irreversible crestal bone loss, or both. Fortunately, research and clinical studies have shown that dentitions with a history of periodontitis or teeth with reduced attachment height can be moved without significant loss of attachment.[56] Identification of the susceptible sites or areas and control of the inflammatory lesion are crucial to successful therapy. All patients, however, will have some degree of inflammation, and it is important to ensure that periodontitis remains stable or quiescent throughout orthodontic treatment. Additional important considerations on the periodontal–orthodontic interface are described by Drs. Vanarsdall, Blasi, and Secchi in Chapter 22 of this textbook.

Significance of Tooth Mobility

Many experimental studies have demonstrated that traumatic lesions in the presence of a healthy periodontium do not initiate loss of attachment or periodontitis. Investigations using beagles[57] and monkeys[58] have improved our understanding of the relationship between inflammation and occlusal trauma.

Studies in the beagle by Svanberg have shown that trauma from occlusion that had created increased tooth mobility can also cause increased vascularity, increased vascular permeability, and increased osteoclastic activity during a traumatic phase lasting approximately 60 days.[59,60] After a stable, permanent hypermobility was established, vascularity and osteoclastic activity returned to normal. These findings led Svanberg to suggest that only through measurements taken at intervals can one determine the existence of progressively increasing mobility that may be diagnosed as trauma from occlusion. Jiggling occlusal forces have been found to aggravate active periodontitis, accelerate loss of connective tissue attachment, and possibly diminish gain in reattachment after periodontal treatment.[61,62] A study evaluating the association between trauma from occlusion and severity of periodontitis concluded that teeth with increased mobility have greater pocket depths and less bone support than teeth without these findings.[63] A University of Pennsylvania study evaluated initial alignment and level of teeth and also determined the effect of probing depths on healthy teeth.[32] The results indicated that test teeth in this study did not show significant change (i.e., the increase in the plaque or sulcular bleeding indices between the initial appointment and the appointment at which maximal tooth mobility was recorded) to ensure that any increase in probing depth could not be caused by increased periodontal inflammation. Eleven patients served as their own controls. The test teeth that became mobile demonstrated an increase in probing depth by an average of 1.09 ± 0.53 mm between the initial appointment and the appointment at which the maximal tooth mobility value was recorded. Therefore, it was concluded that during orthodontic alignment and leveling, teeth with significant increase in mobility will also have an increase in probing depth and that severely rotated teeth will have a greater increase in mobility.

The findings of this preliminary study indicate that increased tooth mobility has a detrimental effect on the periodontium and that increased probing depth indicates an increased periodontal risk such as an increase in the patient's susceptibility to periodontal disease. Therefore, subgingival microbiota should be removed during periods of increased mobility, and appropriate steps should be taken to prevent further tooth mobility in patients who have already demonstrated periodontal susceptibility.

Periodontal Preparation of Adults before Orthodontic Therapy

Successful adult orthodontic treatment for many patients will depend on the periodontal preparation before treatment and the maintenance of periodontal health throughout all phases of mechanotherapy. Gingival inflammation must be eliminated by acceptable oral hygiene measures and removal of accretions on the teeth (usually by scaling and root planning). The occlusion also must be controlled during periods of stress and severe bruxism throughout orthodontic treatment so that occlusal trauma[49,64] and excessive tooth mobility will be prevented.[65] The Hawley bite plane is used for disarticulation as necessary throughout treatment (see Fig. 21-8).

Smoking Cessation. Oral health providers can have a significant impact on patient tobacco cessation. Established tobacco intervention protocols, such as those advocated by the National Cancer Institute, can be easily applied in the clinical setting. Providers should apply the 6 As:

1. Ask—Systematically identify all tobacco users at every visit.
2. Advise—Strongly urge tobacco users to quit. Advice should be clear, direct, and personalized for each patient.
3. Assess—Determine willingness to make a quit attempt.
4. Assist—Aid the patient in quitting. Tell the patient to remove tobacco products from his or her environment and to avoid situational cues, such as alcohol consumption or socializing with active smokers, that may facilitate unplanned relapse.
5. Arrange—Schedule follow-up contact. Follow-up contact should occur soon after the quit date, preferably during the first week. A second follow-up contact is recommended within the first month. Schedule further follow-up contacts as indicated.
6. Actions during follow-up—Congratulate success (if tobacco reuse has occurred, review circumstances and elicit recommitment to total abstinence). Remind the patient that a lapse can be used as a learning experience. Identify problems already encountered, and anticipate challenges in the immediate future. Assess pharmacotherapy use and problems. Consider use or referral to more intensive treatment.[54,66–72]

Gingival Tissue. The orthodontist should make a clinical distinction between thin, delicate gingival tissue and normal or thickened tissue that is in the labiolingual plane.[73,74] The thin, friable tissue is more prone to undergo recession during orthodontics than normal or thick tissue (see Chapter 22).

In addition, if a minimal zone of attached gingival exists, particularly on abutment teeth, it is prudent to place free gingival grafts to help control inflammation before orthodontic treatment begins. It is important to note that the orthodontist controls the timing of referral for grafting procedures. The prognosis for successful gingival grafts and prevention of bone loss is better if these are done before any recession has taken place.

Osseous Surgery. As a rule, orthodontics should logically precede definitive osseous surgery. The optimal approach is as follows: (1) complete the orthodontic therapy, (2) establish a stable occlusion, and (3) wait a minimum of 6 months before requesting the periodontist to intervene for definitive periodontal procedures.

Inflammation Control. Several visits with a periodontist or hygienist will not suffice to prepare a periodontally compromised adult properly for orthodontic correction. Meticulous root surface preparation and curettage are required. In patients with significant bone loss, furcation involvement, and severe pocket depths, it may be necessary for the periodontist to perform open-flap procedures[75] for removal of diseased gingival tissue and proper root surface preparation before orthodontic therapy. Better visualization and access may allow deeper pocket areas and tortuous root configurations to be root planed properly. Before open-flap debridement in cases with advanced periodontal disease, control of adverse occlusal factors using the Hawley bite plane is essential.

Gingival bleeding provides the most reliable index for determining the presence of clinically significant gingivitis,[76] and before placement of appliances, no significant gingival bleeding should occur on gentle probing.

Healthy tissue does not bleed when a thin Michigan probe is gently inserted into the sulcus. To keep the patient free of inflammation during treatment, root planning and curettage should be scheduled as frequently as necessary to prevent significant bleeding. Also, to assess disease activity, the tendency to bleed should be evaluated at each appointment. If this inflammation control is not rigidly adhered to, irreversible bone loss will inevitably result in the periodontally susceptible patient.

Behavioral Management Orthodontist and Staff Preparation for Adult Interdisciplinary Patient Management

Adult patients present an ongoing challenge before, during, and after the prescribed treatment. To meet this challenge and improve the quality of care for each patient, orthodontists treating adults should integrate several steps in the areas of behavioral and clinical management into their professional activities.[77]

1. **Advanced continuing education courses**

Because a larger percentage of adult patients (1) have conditions that require interdisciplinary therapy and (2) require treatment in areas of the emerging knowledge, it is helpful to seek continuing education that provides an opportunity to update the orthodontic clinician's knowledge and skills in the specialty areas of periodontics, orthognathic surgery, TMD management, and restorative dentistry. In addition, opportunities exist to play an efficient role in the delivery of care.

2. **Refined consultation techniques**

Methods of consultation or case presentation vary from orthodontist to orthodontist.[78,79] When reviewing records with adults, particularly patients who require interdisciplinary dental therapy (60%–70%), it is valuable to use a consultation format designed to inform and educate. For patients with tooth size discrepancies, borderline or atypical extraction problems, restorative uncertainties, or some unique surgical situations, using a diagnostic setup on mounted models is usually informative and sometimes quite revealing to both the orthodontist and the patient.

For cephalometric analysis of a patient with a skeletal disharmony, the Broadbent-Bolton transparencies or the Jacobson templates are helpful. They have proved to be graphic tools that enable the orthodontist to translate cephalometric data into a visually understandable reference for the patient who is considering orthodontics and orthognathic surgery (see Figs. 21-21 and 21-27).

Also, the chart enables orthodontic/orthognathic patients to consider anticipated changes resulting from combined therapy in a more informed way. A patient with skeletal disharmony, particularly one with a borderline skeletal-dental problem, requires a clearer explanation regarding therapeutic alternatives than do many other patients.[80,81]

Educating and informing the patient about the presence and significance of moderate or advanced periodontal disease can be a delicate process if the referring dentist has not discussed this with the patient.[82–84]

Frequently, the orthodontist's hygienist may have made the patient aware of the existence of this problem at the initial examination. The orthodontist will then be in a better position to refer the patient to a periodontist for needed therapy. A recent publication provides excellent schematics that help to educate patients.[85]

Other innovative consultation devices (i.e., a before and after photographic bulletin board, videotaped interviews with similarly treated adults) can greatly enhance the patient's knowledge and confidence. Grateful patients who have successfully undergone complex treatment will often provide a reassuring person-to-person consultation with a prospective patient regarding their own experiences with a proposed treatment modality. This is a frequently used educational procedure for patients who are considering orthognathic surgery. A patient who has already received the projected care is uniquely qualified to fill any knowledge voids, especially in areas of family care and inconvenience, work interference, rate of recovery, and pain and discomfort. Finally, adult patients who are about to undergo multidisciplinary therapy seem to appreciate dual or multi-specialist consultation so that all questions and information exchanges can be addressed on one occasion, thereby increasing patient trust regarding a shared level of agreement and permitting unanimous approval and understanding of upcoming treatment.[37] Dual or multi-specialist consultations also aid in organizing the timing and sequencing of steps needed to complete the planned therapy.

3. **Appliance modifications for adult treatment to reduce concern about appearance**[6,74,86]

Numerous appliances are available to provide for tooth movement within a biologically sound range. Two basic appliances, removable and fixed, are widely used. Within the categories are a multitude of choices, and it is logical that each orthodontist will use the one that is both comfortable for the patient and reliable in accomplishing the desired treatment goals.[87]

Key elements of diagnosis and patient preparation have been discussed in this chapter thus far. Incorporation of the skeletal diagnosis, periodontal assessment, and TMJ management lead to the treatment plan and to patient education. After these steps have been taken, the adult interdisciplinary team and the patient should be ready to identify the specific sequence of steps that need to be taken to create a balanced occlusion, with healthy supporting tissue, harmonious facial proportions, and restorations to repair damaged or lost teeth.

SEQUENCE OF ADULT INTERDISCIPLINARY THERAPY

As has been discussed, the diagnostic considerations are more complex for the AIT patient, and the treatment planning decisions vary greatly between adults and their adolescent counterparts. Many points discussed in the previous two sections may seem self-evident to the practicing orthodontist, but although they may be self-evident, it must be emphasized that it is the orthodontist who is frequently placed in the position of treatment plan director. For example, decisions regarding extraction or nonextraction and surgery to correct or tooth movement to camouflage skeletal problems are key orthodontic responsibilities. Along with these decisions, the orthodontist, as treatment plan director, must establish the sequence of implementing the treatment plan—who does what when and how the orthodontist communicates the sequence and the rationale of the sequence to the patient and to the other providers for their input and modification. The written sequence then becomes the blueprint for the restoration of the skeletally and dentally imbalanced, diseased, mutilated, or worn stomathognathic system.

An important advantage of categorizing patients into provider groups is in the area of patient education, particularly as it relates to sequence of treatment. After the diagnostic process, the practitioners involved must be precise in outlining the steps of treatment and the rationale for these steps to their patients. Patients under dual provider and multiple provider care must also be educated to the plateaus of treatment progress and how these relate to their well-being.[5]

1. Active disease
2. Disease arrested
3. Disease controlled
4. Contributing structural malrelationships corrected
5. Periodontal defects corrected
6. Restorative and reconstructive dentistry completed
7. Optimal oral health maintained

Failure to adequately educate patients in this area will result in high rates of noncompliance and potential litigious action. Informed consent is essential.

Evaluation of the Skeletal Component of the Malocclusion

One of the first questions that must be asked to determine the sequence of AIT is, "Does the skeletal problem require surgical intervention to create a stable correction?" Patients with skeletal imbalances who plan to undergo orthognathic procedures require our utmost attention and care (see Chapter 23). Although they have the potential to receive the greatest benefits from combined therapy, they also are exposed to the greatest risk. Each step in this outline (see Box 23-2) is essential for consistent success and quality outcomes. Note: Step 16 in the sequence, posttreatment (6–12 months) records, is often skipped. However, it is crucial for refinement and improvement of future team efforts. This step can become an important in-house approach to the team's continuing education protocol.

Interdisciplinary adult patients require treatment sequencing information, as outlined below, so that standardized communication of the treatment plan is available to the patient and all providers.

The key elements are as follows (see Fig. 21-15):

- Orthodontic diagnosis
- List of dental problems

- Sequence of treatment to manage problems
- Rating of severity
- Rating of prognosis with treatment (include a discussion of limiting factors)
- Addressing patient concerns

Periodontal Preparation

Does the periodontal problem require intervention to create a stable correction? One of the most frequently overlooked aspects of orthodontic treatment for adults is the patient's level of periodontal health before the placement of fixed orthodontic appliances. Frequently, the orthodontist is responsible for determining the level of periodontal health so that thorough measures can be undertaken to stop the advancement of periodontal destruction during tooth movement.

For the orthodontist, the periodontal health of adult patients may be classified in one of three categories: incipient periodontal disease, moderate periodontal disease, or advanced periodontal disease. Each level of periodontal disease requires different therapy with consistent monitoring throughout fixed mechanotherapy to ensure the disease is arrested and inflammation is controlled.[76,88] Careful compliance with these steps will help ensure no loss of the supporting alveolar bone during orthodontic treatment.

Although various types of procedures have been recommended to control periodontal disease, it should be remembered that conservative approaches are effective in the treatment of cooperative patients with periodontal disease, and no orthodontic appliances should be applied to patients who are undergoing periodontal treatment. Adult orthodontic patients generally have 12 to 30 months of fixed appliance therapy, and these appliances interfere with convenient oral physiotherapy with the additional potential negative effects of iatrogenic transitional occlusal trauma induced during certain states of orthodontic tooth movement.

Before beginning tooth movement, inflammation should be reduced by root planning and curettage. As pointed out in Chapter 22, it may be necessary to perform open-flap curettage for direct visualization. All members of the interdisciplinary dental team must accept responsibility for adequate oral physiotherapy and mechanical maintenance of gingival health in deep pocket areas. This is achieved by root planning, tooth polishing, and curettage throughout tooth movement as frequently as necessary to keep the periodontium free of significant inflammation. Bleeding on gentle instrumentation or problem is the most reliable clinical indication of inflammation. If, during curettage, blood pools in the gingival margin surrounding a tooth, too much inflammation will be present to perform tooth movement for a periodontally susceptible patient. The frequency of visits during tooth movement will be determined not by orthodontic adjustments but by the necessity to control soft tissue inflammation during appliance therapy. This could become a biweekly basis in the 60- to 70-year-old patient. A periodontally susceptible patient should never be placed on an automatic 2- to 3-month recall program for removal of subgingival microbiota, as has been suggested in the literature.[89] Periodontally susceptible patients who are undergoing orthodontic treatment may have very rapid repopulation of the gingival bacteria and require appointment-to-appointment monitoring.

Periodontally involved or compromised patients who have experienced shifting migration, extrusion, flaring, or lost teeth can benefit from orthodontics designed to correct local causative factors, predisposing malpositions, and certain bony and periodontal pockets.[29] Clinical evidence in periodontics shows overwhelmingly that changing local environmental factors can improve periodontal health and reduce the frequency of long-term periodontal maintenance. Orthodontics is one of the most dramatic means available to modify local factors and site specificity of the disease process.

DENTOALVEOLAR COLLAPSE: ORTHODONTIC AND RESTORATIVE CONSIDERATIONS IN THE ADULT INTERDISCIPLINARY PATIENT

Because alveolar and basal bone are fundamental to successful oral health, it is not surprising that any new findings regarding bone healing and bone remodeling would be important to dental specialists. This interest becomes particularly true with an increased number of aging patients who seek oral rehabilitation (Fig. 21-20). The recent study by Osterberg and Carlsson[90] found that as fixed partial denture technology improved, so also did patients' desire for implant restoration as part of oral rehabilitation. Before the reported success and acceptance of the Branemark system of dental implants in the 1980s, oral rehabilitation was a very complicated process incorporating the principles of perioprosthetics that were well documented by Morton Amsterdam in 1974.[11]

In 1974, when very sophisticated perioprosthetics were required to provide fixed restorations to avoid removable dentures, dentists were reminded of the role that orthodontics can play in optimizing the restorative outcome. "It should be noted that when an orthodontic malocclusion also exists in the presence of disease, more frequently than not, it will be necessary to correct or modify those functional aspects of the malocclusion which may be acting as contributing factors to the disease process."[11]

However, current treatment planning strategies for patients with missing teeth and secondary dentoalveolar collapse (DAC) frequently neglect to incorporate important occlusal improvements and orthodontic biomechanical components of orthodontics to the treatment plan. Bone remodeling advantages made possible by tooth movement are often bypassed. For example, in Misch's recently published 1088-page textbook on implant dentistry, there are only two pages that discuss the value of orthodontics in cases of DAC, and these pages discuss orthodontics only as an aid for implant site development (accelerated eruption before extraction and implant replacement).[91]

Many dental providers encourage expedited treatment plans for patients with missing teeth, and as a result, key orthodontic considerations have been undervalued and therefore generate minimal attention to those providing expertise on implants and their restoration. The key considerations that are often overlooked in oral rehabilitation procedures are:

1. **Updated understanding of principles of bone physiology (originally Wolff's law), particularly as it relates to the alveolar bone:**

"There are no mathematical optimization rules for bone architecture; there is just a biological regulatory process, producing a structure adapted to mechanical demands by the nature of its characteristics, adequate for evolutionary endurance."[92] In this regard, Atwood documented the degree of bone

FIGURE 21-20 **A,** A youthful appearance has a well-defined mandibular line and good definition between the face and neck. **B,** An aged face has a less-defined mandibular line and lack of definition between the face and neck. **C,** Pretreatment profile photograph of a Class II mandibular deficiency patient treated with camouflage. The patient declineda mandibular advancement procedure that was recommended. **D,** Ten-year postorthodontic camouflage occlusal correction. Note the degree of facial aging, related to the mandibular deficiency, that occurred in the 10-year follow-up period. (**A** and **B** from Koury ME, Epker BN. The aged face: the facial manifestations of aging. *Int J Adult Orthod Orthognath Surg* 1991;6(2):81–95.)

loss that can occur, over time with tooth loss in the anterior segment of the mandible (Fig. 21-22).

2. **Epigenetic components of alveolar development and maintenance (functional matrix hypothesis [FMH] of Moss)**

"More precisely, the FMH claims that epigenetic, extraskeletal factors and processes are the prior, proximate, extrinsic, and primary cause of all adaptive, secondary responses of skeletal tissues and organs. It follows that the responses of the skeletal unit (bone and cartilage) cells and tissues are not directly regulated by informational content of the intrinsic skeletal cell genome per se. Rather, this additional, extrinsic, epigenetic information is created by functional matrix operations."

3. **Tooth movement–induced alveolar remodeling**[12,93] According to the equilibrium theory of tooth position of Weinstein with new concepts of orthodontic tooth movement must be taken into consideration over time:

Conclusion 1. Forces exerted on the crown of the tooth by the surrounding soft tissue may be sufficient to cause tooth movement in the same manner as that produced by orthodontic appliances.

Conclusion 3: Differential forces, even when they are of small magnitude, if applied over a considerable period of time can cause important changes in tooth position (DAC).[94]

Masella and Meister's work coupled with Weinstein et al.'s work in 1963 brings us to a clearer understanding of the orthodontist's role as bioengineer:

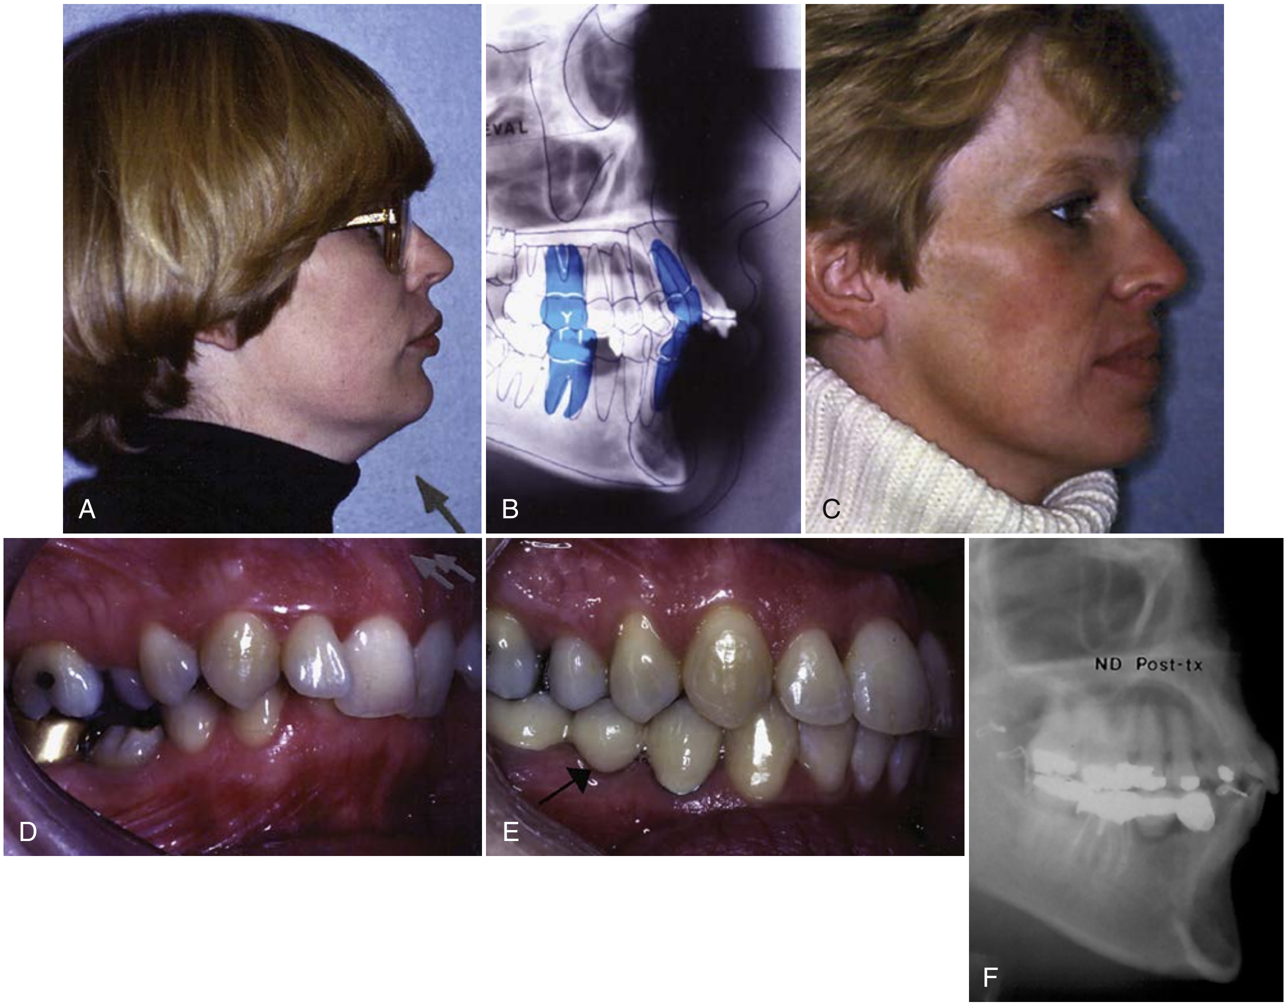

FIGURE 21-21 **A,** Profile photograph taken after preliminary leveling (same as cephalogram in **B**). Evidence of maxillary dentoalveolar protrusion and mandibular deficiency is apparent. Two different treatment plans make sense: the one chosen will depend on what goals are prioritized. The *arrow* illustrates "youthful" throat–chin soft tissue contour. **B,** Cephalogram after 4 months of incisor reangulation (decompensation) to allow reassessment of treatment plan using Bolton template to guide decision regarding extraction of the upper first premolars and camouflage of moderate mandibular deficiency or "slow aging" of the lower third of the face by correction of mandibular deficiency with mandibular advancement. **C,** Profile photograph taken after orthodontic treatment and mandibular advancement surgery. Although a camouflage treatment plan would have worked, the patient indicated the importance of chin position improvement. The Bolton template superimposition guided the treatment plan and indicated that mandibular advancement would be appropriate based on landmark comparison to the proportionate facial guidelines of the superimposed template. **D,** Pretreatment right occlusion illustrating anterior crowding; retroinclined maxillary incisors; deep bite; retained deciduous right mandibular second molar; and a Class II, Division 2 malocclusion. **E,** Posttreatment comparing right occlusion with **D.** The patient desired to position her chin more forward to avoid the potential "aging effects of chin deficiency," which the patient observed as her mother aged. **F,** The patient chose a conventional bridge to replace the missing lower right second premolar shown with an *arrow* in **E.**

Adaptive biochemical response to applied orthodontic force is a highly sophisticated process. Many layers of networked reactions occur in and around periodontal ligament and alveolar bone cells that change mechanical force into molecular events (signal transduction) and orthodontic tooth movement (OTM). Osteoblasts and osteoclasts are sensitive environment-to-genome-to-environment communicators, capable of restoring system homeostasis disturbed by orthodontic mechanics. Five micro-environments are altered by orthodontic force: extracellular matrix, cell membrane, cytoskeleton, nuclear protein matrix, and genome. Gene activation (or suppression) is the point at which input becomes output, and further changes occur in all 5 environments. Hundreds of genes and thousands of proteins participate in OTM.[95]

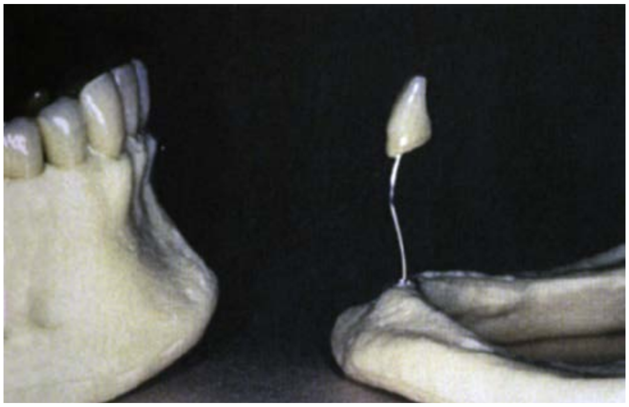

FIGURE 21-22 Alveolar bone requires the function of the dentition to avoid progressive atrophy. This vivid photograph illustrates how much alveolar bone can be lost over time when there is no dentition and no function. Preserving the dentition and the alveolar process are key responsibilities of general dentists and orthodontists.

Because dentists frequently refer patients with missing teeth to the orthodontist for treatment planning, the orthodontist becomes the "gatekeeper" in the following:

1. Determining whether the collapse will be reversed or camouflaged (see Fig. 21-23 and Boxes 21-2 and 21-3)
2. Setting up the spacing for tooth or root replacement
3. Aiding in the provision of temporary tooth replacement

Application of Principles

Understanding the physiologic principles of alveolar bone remodeling and the role that tooth movement can play in guiding bone preservation and regeneration can alter the choices made when patients proceed through the treatment planning process. Prevention of alveolar collapse (AC) through alveolar bone preservation and reversal of AC through alveolar bone regeneration apply to patients in the deciduous dentition, mixed dentition, and adult dentition. Often the orthodontist is the key person in the treatment plan for patients with missing teeth and should consider the implications of AC when developing the treatment plan.

FIGURE 21-23 In patients with congenitally missing teeth, orthodontists frequently have to decide whether the "collapse" into the area of congenital absence should be reversed and stabilized with implants or camouflaged with substitution of adjacent teeth. **A–C,** Pretreatment intraoral photographs of a 14-year-old young woman who has congenital absence of nos. 7 and 10.

FIGURE 21-23, cont'd D–F, Posttreatment intraoral photographs of a 16.5-year-old young woman from A to C in whom the decision was made to "reverse" the anterior arch collapse and to move the canines into their correct anatomic and functional positions. G, Pretreatment smile showing unaesthetic spacing in the areas of the missing lateral incisors. H, Posttreatment smile illustrating dental, occlusal, and alveolar stabilization after implant replacement with crowns for teeth nos. 7 and 10. Favorable aesthetic balance was achieved with the decision to reverse the dentoalveolar collapse. I, Posttreatment panoramic radiograph illustrating properly positioned implants allowing long-term health and function.

BOX 21-2 Characteristics of Dentoalveolar Collapse

- Missing tooth or teeth
- Migration of adjacent teeth into area of missing tooth or teeth
- Migration of adjacent teeth is in horizontal, transverse, or vertical plane.
- Time impacts degree of tooth migration.
- Alveolar changes (atrophy) related to the missing teeth are progressive until new equilibrium positions are achieved with accompanying bone loading.

BOX 21-3 Etiology of Dentoalveolar Collapse

Collapse secondary to:

- Early loss of deciduous teeth (especially c's and e's—this may not be addressed until adult treatment)
- Delayed exfoliation of deciduous molars
- Ankylosis of deciduous molars
- Missing first molars
- Missing second premolars
- Missing upper anteriors (congenital absence or trauma)
- Missing lower anteriors (congenital absence or trauma)
- Unilateral or bilateral cleft repair
- Cancer and bone resections

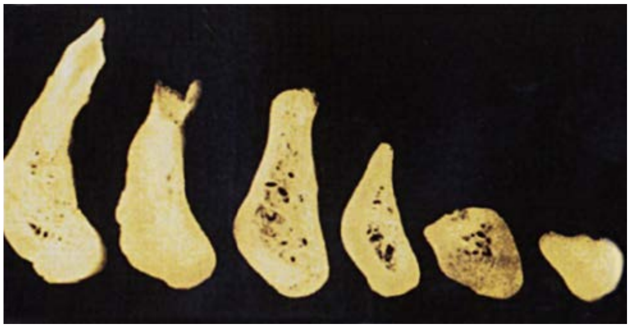

FIGURE 21-24 Atwood's work illustrates the significant alveolar atrophy that accompanies the absence of teeth and roots in the anterior portion of the mandible. This documentation should be a constant reminder of the responsibility of all members of the dental profession to preserve the natural dentition or replace teeth that are lost with implants as soon as is possible.

The following cases illustrate the application of the principles of alveolar preservation and collapse reversal for varying age groups. Figures 21-24 through 21-26 demonstrate how components of DAC impact the many aspects of the malocclusion and frequently require a treatment plan to include implants and restoration to stabilize DAC reversal.

Conclusion for Adult Interdisciplinary Therapy Patients with Missing Teeth and Dentoalveolar Collapse

Patients with a diagnosis of AC due to tooth loss or congenital absence should be notified of the etiology of this aspect of their malocclusion and guided to the most predictable methods of successful oral rehabilitation. Dental teams will benefit from bringing each specialty's unique perspective into treatment planning for patients who present with characteristics of DAC. Most DAC cases require:

1. Etiologic recognition
2. Early collapse reversal through orthodontic measures
3. Alveolar bone stabilization through implant placement when facial growth is complete
4. Followed shortly thereafter with occlusal stabilization through restoration

Although this seems to be a simple concept to understand and to apply, the range of situations that are part of the AC "umbrella" of conditions has, to this point, been undocumented in the orthodontic literature. As recent as 1996, a survey published in the *Journal of Clinical Orthodontics* presented their findings related to three conditions that frequently occur when there is AC:

1. "When questioned about their preferred approach to manage patients with congenitally missing maxillary laterals, nearly 80% of orthodontists preferred substitution of canines for the missing laterals."[72] Current studies indicate a 2.2% incidence of missing lateral incisors.[96]
2. When questioned about their preference for congenitally missing lower second premolars, the majority chose forward movement of molars.[72] Current studies indicate a 3.4% incidence of second premolar agenesis with lack of a single premolar being most frequent; absence of three premolars occurs least frequently.[96]
3. Again, for the condition of congenital absence of a lower incisor, the majority of surveyed orthodontists preferred to accept the occlusal discrepancy and deep bite to space opening.[72]

Implant reliability and interdisciplinary interaction have improved the awareness of the orthodontists to the implant option when teeth are missing. In assessing the cases illustrated in the Applications of Principles section (see Figs. 21-24 through 21-26), the concept of AC is better understood as an etiologic factor complicating the severity of many features of a malocclusion. It is the authors' opinion that as the short- and long-term impacts of DAC on the occlusion and the alveolar bone become better understood, dentistry will be better able to provide optimal care by achieving the goals of occlusal stability, dental and facial aesthetics, and bone preservation.

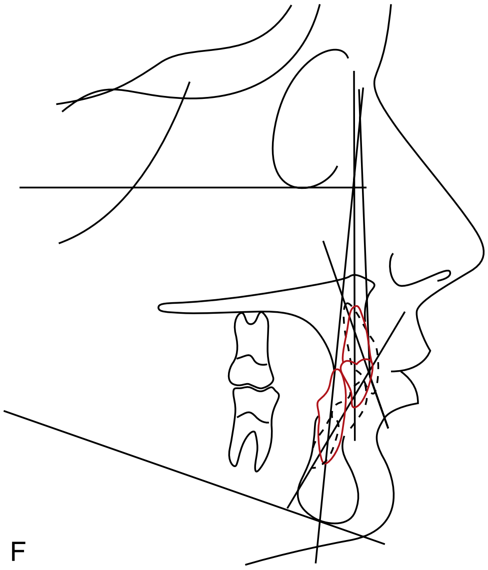
The issues related to sequencing treatment for patients with skeletal problems, susceptibility to periodontal disease, TMDs, and DAC with restorative requirements add to the list of intraprovider planning requirements. Clearly, improved technology, patient education, and interdisciplinary teamwork allow dental providers to achieve outstanding outcomes and achieve treatment goals of function, aesthetics, stability, and health through the use of reliable methods that thereby reestablish longevity to the "mutilated" stomatognathic system.

Evaluation before Debonding or Debanding

The orthodontist should consider the following before debonding or debanding:

1. **Root parallelism:** The orthodontist must verify this by panoramic, periapical radiographs or a cone-beam scan (for select situations.) This assessment can be done during progress records about three-fourths of the way through treatment.
2. **Coincidence of centric relation and habitual occlusion:** This can be done through clinical assessment with the aid of deprogramming appliances.

FIGURE 21-25 **A,** Pretreatment photograph of the anterior dentition of a young adult who had congenital absence of nos. 13, 20, and 29. The missing posterior teeth and the subsequent extraction of deciduous "K and T" resulted in progressive dentoalveolar collapse of the posterior and anterior portion of her dentition. **B,** Posttreatment of the anterior dentition after 2 years of orthodontic treatment to reverse the posterior and anterior collapse and open the space for the missing lower second premolars. Current dental therapy would use implants to replace the missing premolars; 20 years ago, the collapse reversal was stabilized with bridges on the right and left posterior. **C,** Pretreatment panoramic radiograph showing the missing premolars—nos. 13, 20, and 29. Overeruption of the upper and lower incisors can be seen as well. **D,** Pretreatment ¾ posed smile photograph illustration of the retroinclination of the incisors secondary to the progressive dentoalveolar collapse and overeruption. **E,** Posttreatment ¾ posed smile photograph illustrating improved aesthetics of reangled incisors as the arch collapse was reversed and the interincisal angle improved.



F

FIGURE 21-25, cont'd F, Cephalometric superimposition illustrating the improved interincisal angle. The pretreatment interincisal angle was 176 degrees, and the posttreatment interincisal angle was 137 degrees.

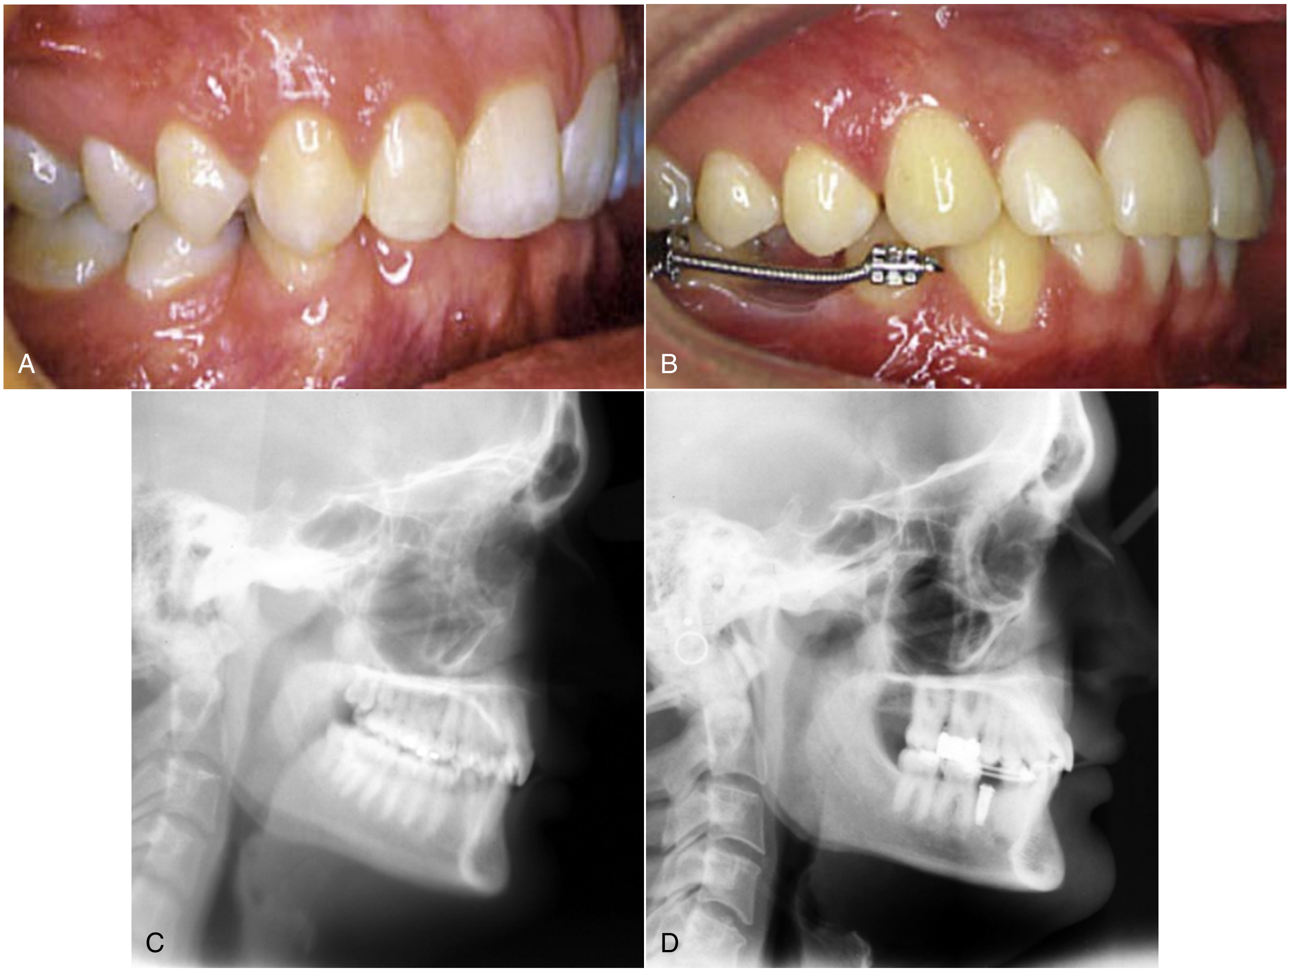


FIGURE 21-26 A, Pretreatment side view of right posterior occlusion showing a Class II canine relationship but with a Class I molar relationship. The upper incisors are very upright, and the bite is very deep with apparent lack of the second premolar. B, Postorthodontic side view of the right posterior occlusion after orthodontics to reverse the dentoalveolar collapse, reangle the incisors, "open the bite," and prepare for posterior restoration to stabilize anterior and posterior occlusion. C, Pretreatment view of lateral cephalogram illustrating the "collapsed" dentoalveolar relationship with very upright incisors with minimal vertical "stops." D, Postorthodontic interincisal relationship corrected with a normal interincisal angle, which will provide long-term vertical stability in the area of the incisors.

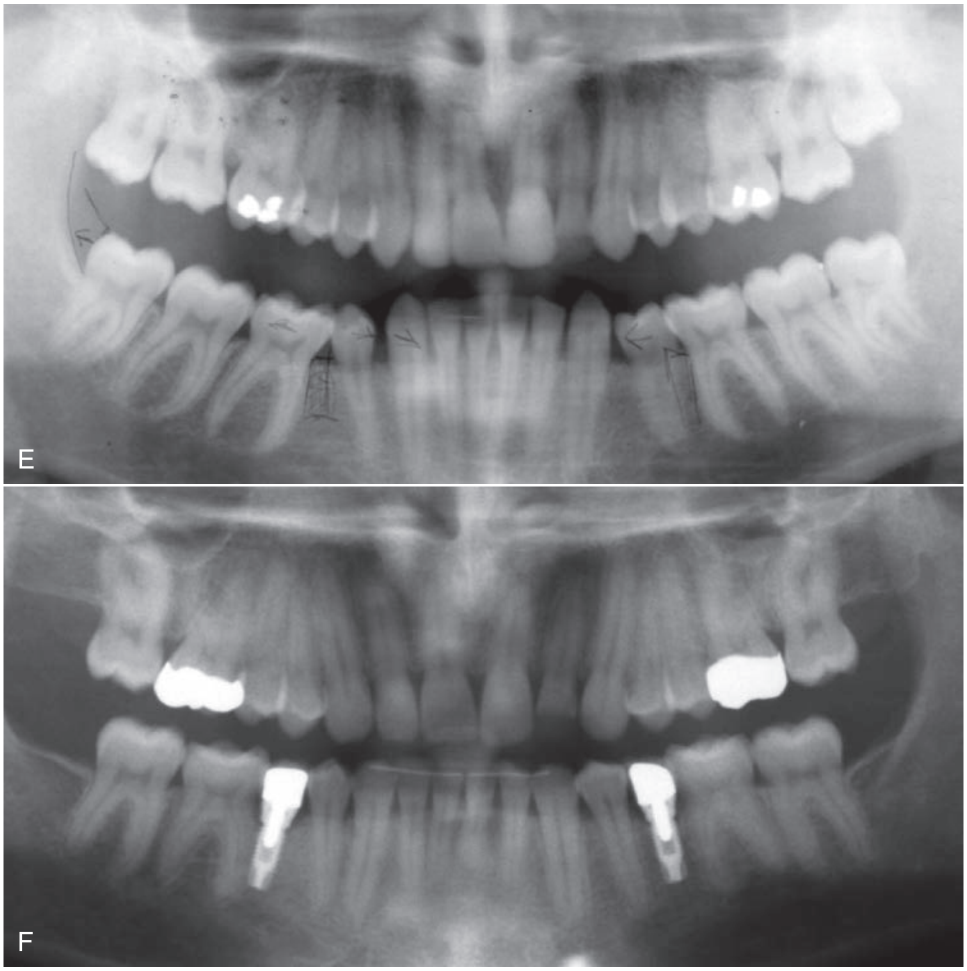

FIGURE 21-26, cont'd E, Pretreatment panoramic radiograph showing the congenital absence of the lower second premolars. The third molars are present, and some of the third molars are only partially erupted. The third molars require removal to allow collapse reversal and occlusal correction with space reopening in areas of nos. 20 and 29. This will also allow proper replacement of the missing second premolars. F, Posttreatment panoramic radiograph showing the space opened at nos. 20 and 29 with implants placed to preserve the alveolar housing and crowns placed to preserve the corrected occlusion.

3. **Incisal guidance:** The orthodontist should evaluate this clinically, in some cases, with mounted study models.
4. **Joint symptoms:** These should be assessed clinically and appropriate treatment or referral provided as needed.
5. **Excursive movements:** The orthodontist examines these clinically and augments examination in some cases with mounted models.
6. **Patient input:** The orthodontist should encourage patients to discuss existing dentofacial aesthetics before appliance removal. Many patients point out concerns that may be correctable with minor modifications in mechanotherapy.
7. **Reaffirmation of restorative commitment:** The orthodontist should review this commitment with the patient and discuss it with the restorative dentist and the periodontist. The timing of the restorative procedures and the coordination of restorative treatment with the orthodontic retention schedule are very important.
8. **Reevaluation of periodontal considerations:** The orthodontist reevaluates clinically with radiographs; the orthodontist should also check for mobility and fremitus, perform probing, and make a careful gingival tissue assessment.
9. **Reevaluation of anterior and posterior tooth size discrepancies:** The orthodontist informs the patient and the general dentist of additional measures that may be necessary to resolve tooth size discrepancies without adversely altering the posterior occlusal relationships or incisal guidance (i.e., acid-etched add-on technique).
10. **Anticipated retention problems:** The orthodontist should make plans and provisions and should enter them on the patient's chart if retention problems are anticipated so that problem-solving steps can be recalled easily in the future as indicated.
11. **Reassessment of the characteristics of the original malocclusion:** This is helpful to determine the specific anatomic retention needs of the case (i.e., skeletal or dental deep bite situations, open bite, or overcorrection of rotations) (see Fig. 21-27).

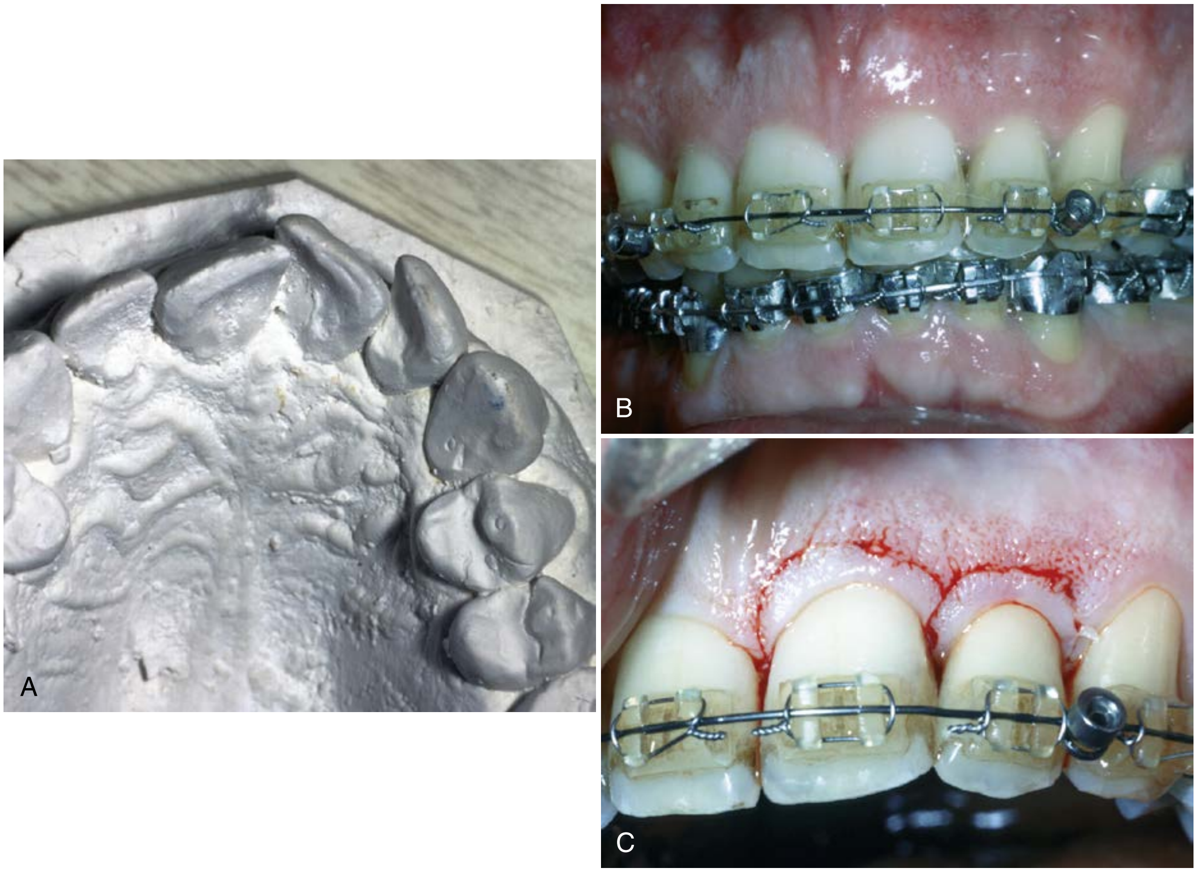

FIGURE 21-27 A, Before maxillary left central and lateral incisor rotations. B, Incisors correctly aligned. C, Before appliance removal; a circumferential fiberotomy was performed to enhance posttreatment stability.

Coordination of Debonding or Debanding with Other Treatment Providers

The orthodontist should also consider the following to coordinate debonding and debanding with other treatment providers:

1. **Posttreatment radiographs**
2. **Periodontal reevaluation and treatment**
3. **Restorative treatment and retention considerations:** Frequently, this may include the use of stabilizing sectional appliances that can be removed by the restorative dentist before placement of restorations. Removable appliances may be used for temporary tooth replacements when the patient is missing anterior teeth and there is an aesthetic concern.
4. **Duration of the retention period:** The retention period will vary according to the case type, overall restorative treatment plan, orthodontic result, and various causative factors (which again must be customized to the individual patient). Generally, the retention period for adults is longer. The weaning period from removable retainers also takes place over a longer time. To enhance the overall stability of treatment, selective grinding for centric and anterior disclusion during excursive movements is essential. In the case of significant (≥2.5 mm) centric relation to centric occlusion discrepancy, occlusal adjustment is required. A Hawley appliance with an anterior bite plane helps eliminate muscle dysfunction and facilitates selective grinding to achieve a stable centric relation position.

STABILITY AND RETENTION INDIVIDUALIZED FOR THE INTERDISCIPLINARY ADULT THERAPY PATIENT

Treating a Class I relationship in teenage patients in which the skeletal bases are normal is usually satisfactory and often quite stable. Unfortunately, these are not the clinical circumstances presented by most adult patients. Frequently, adults have skeletal Class II problems that are more appropriately treated with extraction in the upper arch only; the outcome is finished with a Class II molar relationship that usually requires occlusal adjustment by selective grinding that may or may not be done. A tooth size discrepancy is created by removing maxillary first premolars only, and this approach has been shown to be less stable than extraction in both arches. Also, the effects of the periodontium in creating instability in posttreatment orthodontic cases are well documented.[2] Picton and Moss have shown that the effects of transseptal fibers on the teeth with a constant and mesial migration of the dentition throughout life could cause incisor irregularities and crowding[97] (see Fig. 21-27). Horowitz and Hixon stated in their 1969 article that “the significant point is that orthodontic therapy may temporarily alter the course of continuous physiological changes and possibly for a time can even reverse them. However, following mechanotherapy and a period of retention restraint, the developmental maturation process resumes.”[97]

In addition, there has been the apical base school through the history of orthodontics (discussed in Chapter 22). Holdaway cautioned that facial harmony could be achieved as long as the apical base did not exceed a range permitting compensating dental adjustments.[98] Apical base discrepancies are important limiting factors in adult treatment unless orthognathic procedures are accepted by the patient so that these discrepancies can be corrected rather than camouflaged. (See Fig. 21-9 for an example of a camouflaged Class III apical base patient and Fig. 21-1 for an effectively camouflaged Class II apical base discrepancy.)

Figure 21-28 illustrates a high mandibular plane angle Class II adult male patient who has multiple characteristics related to his malocclusion, including crowding of upper and lower arch, overjet, open bite, and mild lip incompetence with an accompanying mandibular apical base deficiency. After a review of different treatment options, this man decided to pursue an interdisciplinary treatment plan that would address both the skeletal and dental concerns identified. Through the use of presurgical orthodontics and maxilla-mandibular surgery with an occlusal plane change, this patient's treatment achieved an optimal outcome with high probability of long-term stability.

Figure 21-29 demonstrates the skeletal limitations of orthodontic treatment, particularly in adult patients. The sagittal limitations, without treating the skeletal discrepancy through surgical procedures, with a normal vertical relationship would be approximately a Class II subspinale-nasion-supramentale (ANB) angle of 7 or 8 degrees (this would exclude bimaxillary protrusion; see Fig. 21-1), and in the Class III skeletal problems, an ANB of –3 degrees or WITS of less than 8 mm usually requires restorative procedures or orthognathic surgery to achieve compensated anterior tooth stability. (See Fig. 21-9 for a good Class III example of this point.) With patterns that involve vertical open bite, excessive face height, and associated muscle problems, it is common with the use of vertical elastics to encounter more root-blunting resorption. Clinicians are well aware of the problems of Class II elastics in high-angle cases, tending to tip the occlusal plane, moving the lower dentition forward, and creating periodontal problems that result in discrepancies in centric relation and habitual occlusion. Patients with open bites who do not accept an orthognathic solution can now be treated with the use of TADs that have been illustrated in Chapter 20. These devices allow the intrusion of posterior teeth, mandibular autorotation and bite closure without the adverse side effects associated with the extrusion of the incisors and the need for Class II elastics.

The familiar long face problem exhibits excessive eruption of maxillary teeth, maxillary transverse constrictions, excessive overjet, anterior open bite, and associated mouth breathing. The patient shown in Figure 21-30, with a long face and a gingival smile, who elected to go through orthodontic treatment first, could only have been improved to look as he does on the right through the use of the Le Fort osteotomy technique.

In adult treatment, common pitfalls leading to instability are as follows:

1. Tendency to extract premolars in borderline cases and extracting in the lower arch as well, when the mandibular dentition is more distally placed
2. With vertical excess problems of lip incompetency, extracting upper premolars only
3. Attempting to close excessive extraction spaces when the problem should be treatment planned for alignment of the teeth and using prosthetic replacements to replace teeth rather than attempting space closure.

A significant report was made by Casko and Shepherd[99] in *The Angle Orthodontist* in 1984; the authors evaluated 79 untreated adults with ideal Class I dental occlusions. None of the patients subjectively was thought to have poor or unacceptable profiles. Casko and Shepherd discovered that the cephalometric values for the skeletal discrepancies in this group were far beyond mean figures often used as treatment goals. Figure 21-31 illustrates the envelope of discrepancy in the sagittal and vertical dimensions and can be used as a guide when treatment planning adult patients. As well, cases must be evaluated in the transverse dimension for transverse skeletal discrepancy, also seen in Figure 21-31; this can best be done at the present time with the use of the PA radiograph. A significant skeletal discrepancy in a transverse dimension diagnosed by looking only at the dentition and attempting to use archwires to laterally expand the teeth on a constricted maxillary apical base frequently creates buccal gingival recession as one of the side effects of camouflaging patients with transverse dysplasias. Clinicians must develop an envelope of discrepancy concept for the transverse dimension, as well as for the sagittal and vertical dimension (see Fig. 21-31). In transverse skeletal problems in adults, treatment options are to leave the patient in crossbite, use restorative dentistry to change the contour of the posterior teeth to achieve a more normal dental buccolingual landmark relationship, or correct the skeletal pattern by surgically assisted palatal expansion. Camouflaging the transverse skeletal deficiency by only moving the teeth may cause periodontal problems, mainly buccal gingival recession and instability of the occlusal scheme. The effective surgical procedure to use was reported in August 1976.[100]

In the transverse dimension, the clinician may elect to camouflage the skeletal discrepancy by tipping the teeth and creating occlusal instability and periodontal problems; if a surgical procedure is used, the expansion appliance should have acrylic that covers the palate. With an effective surgical procedure, tissue-borne appliances do not create excessive pressure on the palatal mucosa and will not create vascular ischemia by pressure against the palatal tissue. Tooth-borne appliances alone, however, tend to allow for more dental tipping than is seen with appliances that have acrylic on the palate. Therefore, Hyrax-type appliances are not recommended. The case in Figure 21-32 illustrates significant dental tipping that occurred as a result of using that appliance. A more effective appliance is the Haas-type appliance. The surgical procedure involves raising the mucoperiosteal tissue in the buccal vestibule bilaterally in the maxilla; a horizontal osteotomy is made through the lateral wall of the maxilla 4 to 5 mm, superior to the posterior teeth. In addition, to facilitate the separation of the maxilla, an osteotome is used between the central incisors to separate the palate. Usually the procedure is a day surgery procedure and does not require the patient to stay overnight in the hospital.

For Class II orthodontic patients, extraction in the maxillary arch only is necessary to effectively camouflage skeletal deformities, vertical growth patterns, and bimaxillary protrusions. Figures 21-1, 21-9, and 21-29, *A* and *B,* show examples of limitations that exist in adult treatment when orthognathic procedures are not accepted by the patient or when there is no insurance coverage. Another example of limiting factors in Class II camouflage patients is the need to graft the lower anterior to allow more lower incisor proclination to achieve incisor guidance. In the case shown in Figure 21-29, *A* and *B,* the patient also demanded that all appliances be removed before complete space closure; a

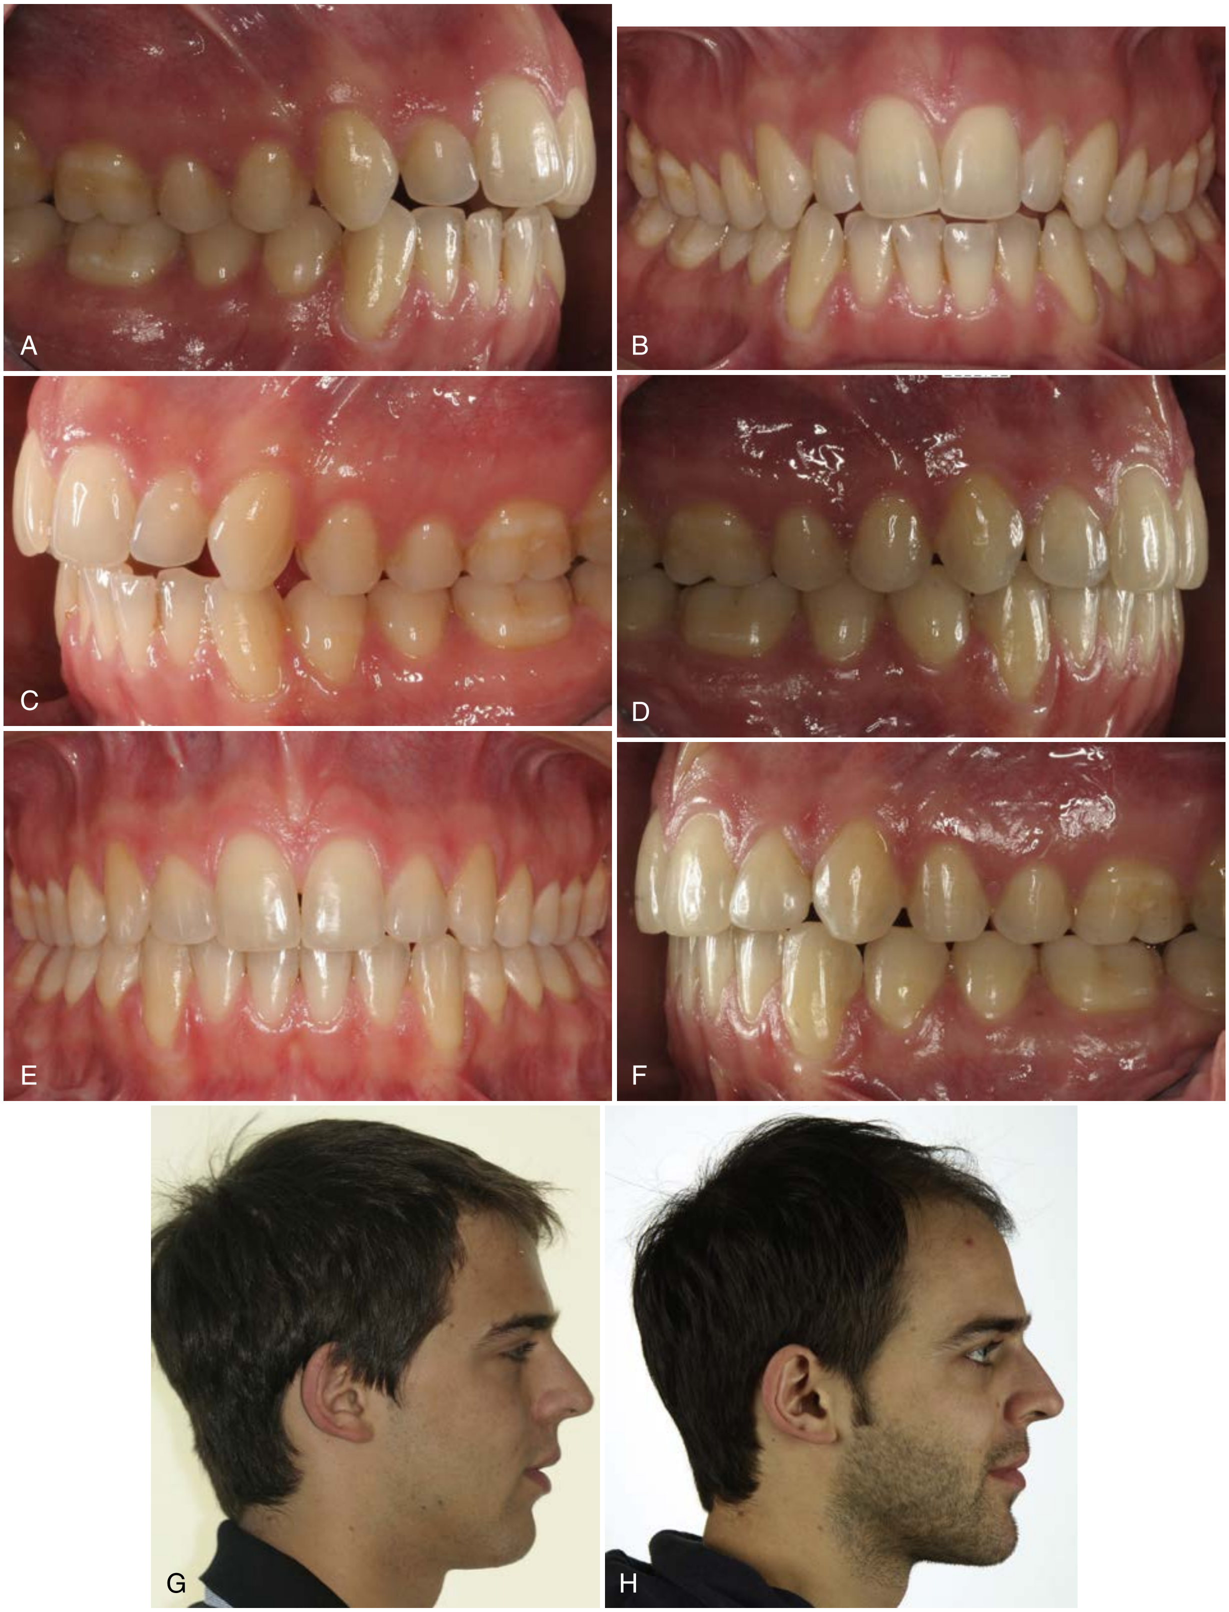

FIGURE 21-28 A–C, Pretreatment intraoral photographs. D–F, Posttreatment intraoral photographs. G, Pretreatment profile. H, Posttreatment profile showing improved facial balance and elimination of the appearance of mandibular deficiency.

Surgery by Prof. Mirco Raffaini, Italy.)

retainer was bonded to the lower, canine to canine. The lower right molar had a large amalgam filling and was crowned so that mesiodistal contact (arch integrity) was maintained through the second molar (Fig. 21-33). An operative restoration was placed on the patient's left side, and "immediate" removable retainers were inserted. An impression was taken for the upper arch with instructions for the laboratory to carve off all the brackets, and at the time the case was debonded, the retainer was placed immediately because of the muscle problem (tongue thrust). The patient was given two retainers for the maxillary arch. One was worn during the day (a regular removable retainer) for an indefinite period of time until it could be left out during the day. The termination of daytime wear was indicated when the patient felt no pressure on the teeth at the insertion of the night crib appliance. The day appliance may be required for as long as 1 year, but the night crib is used indefinitely. The crib appliance at night prevents the tongue from being placed between the anterior teeth, which would allow for eruption of molars and a return of the open bite. The tongue appliance that is given to all patients with a forward-resting tongue posture problem is illustrated in Figure 21-34.

Patients who exhibit a tongue placement habit can also be recognized by their forward tongue placement during speech. Retention requires special consideration for posttreatment stability, as indicated in Figure 21-33.

The forward-resting tongue posture problem is significant, particularly for an adult patient who has maintained the habit of placing his or her tongue between the anterior segment beyond the adolescent years. In an article published in *The Angle Orthodontist* in 1989, Denison, Kokich, and Shapiro[101] divided the sample population into three groups based on the degree of pretreatment overbite in the open bite subsample; results show clearly that the three subsamples tested responded differently during the posttreatment interval. Among the subsample, 42.9% showed a significant increase in facial height, eruption of maxillary molars, and decrease in overbite; 26.6%

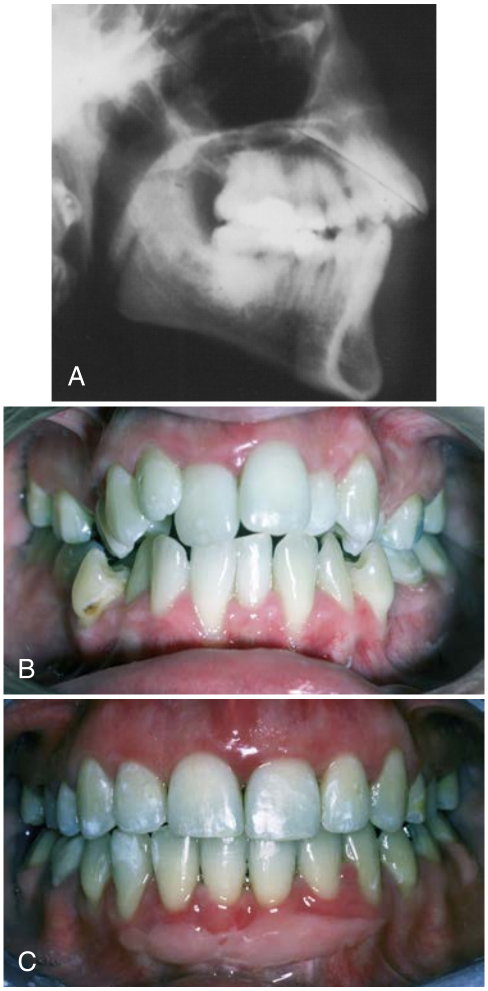

FIGURE 21-29 **A,** Pretreatment cephalometric film reveals an anterior open bite and overjet. **B,** Pretreatment alignment. **C,** Posttreatment alignment.

of the open bite sample and 16.7% of the overlap subsamples showed a significant increase in facial height, significant eruption of posterior teeth, and no change in overbite. The incisal contact sample had no significant posttreatment changes.

Among the possible reasons for posttreatment instability and one of the factors not taken into consideration in retention with this study population was the unconscious forward placement of the tongue, and a crib at night only could have prevented the open bite relapse. Open bite that recurred in 42.9% of subjects with pretreatment open bite could have been reduced with the use of a tongue crib retainer at night. As stated earlier, patients commonly place their tongues between the anterior segments, allowing vertical eruption to occur at the molars and resulting in recurrence of the dental open bite.

For skeletal Class II patients, it may be necessary to advance the lower incisors (compensation is placed in the mandibular dentition and not in the maxillary incisors) and place tooth material bilaterally in the posterior segments of the mandible, as seen in Figure 21-35, where two restorations were placed in the mandible. In Class III cases, orthodontists may compensate the maxillary incisors for the Class III skeletal pattern by adding tooth material in the maxillary posterior segments bilaterally to maintain a more procumbent maxillary incisor without allowing the upper incisors to be placed into permanent trauma or fremitus because of the Class III skeletal pattern.

Figure 21-36 exhibits a Class III case in which the maxillary centrals are moved to the midline: two bridges were placed in the maxillary posterior segments, allowing the anterior teeth to be stable without putting permanent trauma on the upper anterior teeth. To remove the appliance and merely insert an upper and lower removable retainer would not ensure stability. Placing two retainers without reshaping old restorations that have been carved up in the preorthodontic occlusion would not achieve stability. When tooth size discrepancies exist or when teeth are taken out, it may be necessary to reshape remaining teeth with bonding material. It is much easier to establish intimate occlusion and stability for a patient who does not have

FIGURE 21-30 **A,** Long-faced patient who initially refused surgery and after 1.5 years of orthodontics requested to be reevaluated for a maxillary impaction. **B,** Appearance after orthognathic surgery. Note the excellent lip competency.

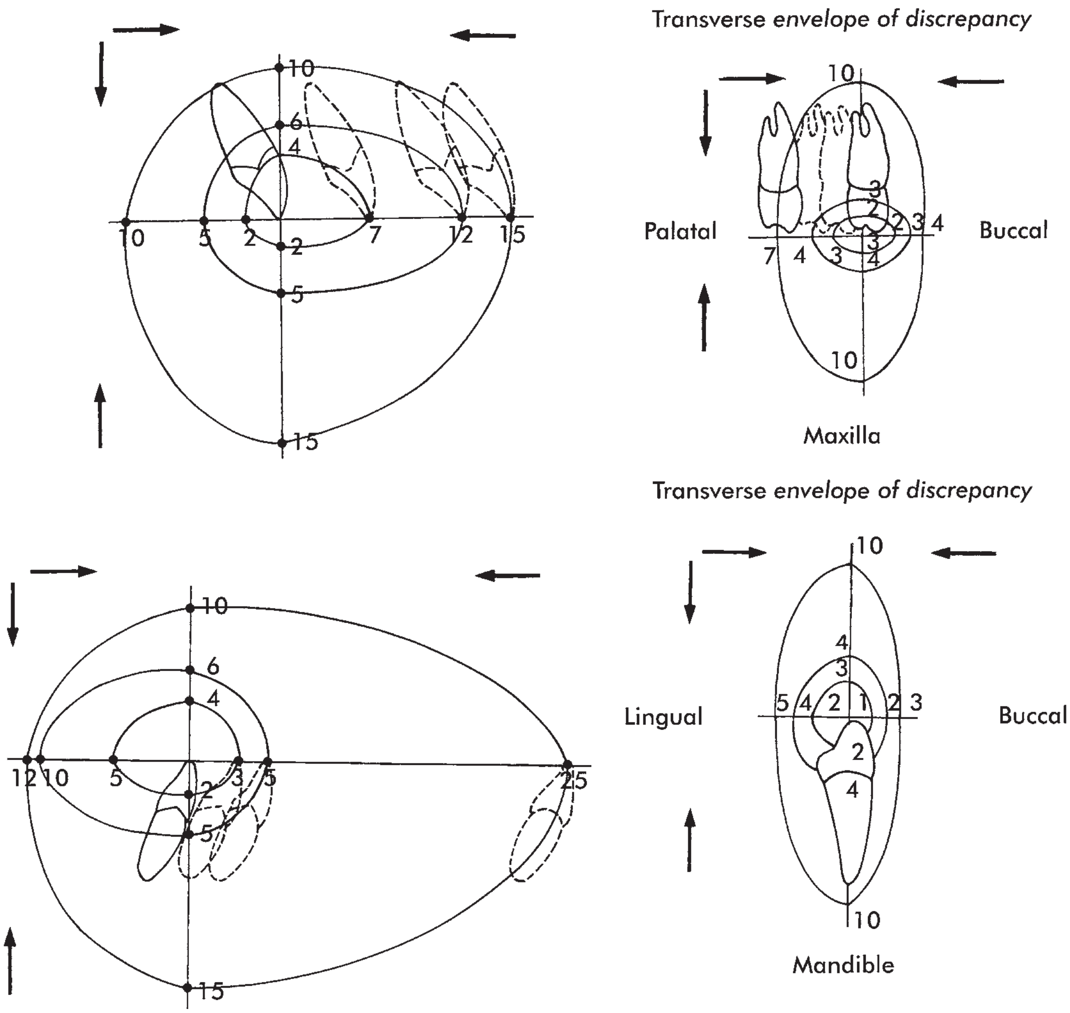

FIGURE 21-31 The envelope of discrepancy for the maxillary and mandibular arches in three planes of space. The ideal position of the upper and lower incisor in the anteroposterior (AP) and vertical planes is shown in the center of the incisor diagrams. The millimeters of change required to retract a protruding incisor, move forward a posteriorly positioned incisor, or extrude or intrude an incorrectly vertically positioned incisor are shown along the horizontal and vertical axes, respectively. The limits of orthodontic tooth movement alone are represented by the inner envelope, possible changes in incisor position from combined orthopedic and orthodontic treatment in growing individuals are shown by the middle envelope, and the limits of change with combined orthodontic and surgical treatment are shown by the outer envelope. The inner envelope for the upper arch suggests that maxillary incisors can be brought back a maximum of 7 mm by orthodontic tooth movement alone to correct protrusion but can be moved forward only 2 mm. The limit for retraction is established by the lingual cortical plate and is observed in the short term; the limit for forward movement is established by the lip and is observed in long-term stability or relapse. Upper incisors can be extruded 4 mm and depressed 2 mm, with the limits being observed in long-term stability rather than as limits on initial tooth movement. The envelopes of discrepancy for the transverse dimension in the premolar areas are much smaller than those for incisors in the AP plane. The transverse dimension can be crucial to long-term stability, periodontal health, and frontal dentofacial aesthetics. The orthodontic and surgical envelopes can be viewed separately for the upper and lower arches, but the growth modification envelope is the same for both: 5 mm of growth modification in the AP plane to correct Class II malocclusion is the maximum that should be anticipated, whether occlusion is achieved by acceleration of mandibular growth or restriction of maxillary growth. The outer envelope suggests that 10 mm is the limit for surgical maxillary advancement or downward movement, although the maxilla can be retracted or moved up as much as 15 mm; the mandible can be surgically set back 25 mm but can be advanced only 12 mm. These numbers are merely guidelines and may underestimate or overestimate the possibilities for any given patient; however, they help place the potential of the three major treatment modalities in perspective.

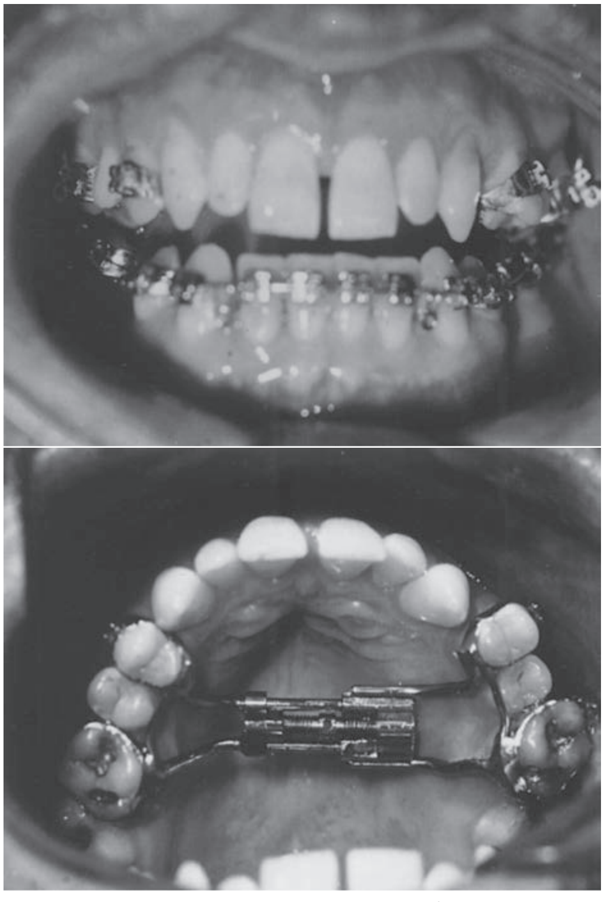

FIGURE 21-32 Frontal and occlusal view of severe dental tipping with the Hyrox-type palatal expander.

old fillings and restorations. Patients with old crowns that were carved to a previous malocclusion or large restorations and amalgams that need to be reshaped also require occlusal adjustment by selective grinding to create a definitive occlusion that coordinates maximal intercuspation and central relation.

Adaptations that occur with aging have been well described by Behrents.[102] The adult orthodontic patient will need to have indefinite retention in the mandibular anteriors. The Sillman collection at the University of Pennsylvania features long-term records of Class I individuals (who received minimal or no treatment) who had well-aligned incisors at age 13 years but had crowding at 22 years of age, together with normal dentitional compensation of aging. Prerestorative space or pontic areas that are created in treatment require indefinite retention, and the forward tongue position, particularly in adults, requires a crib to be worn at night for an indefinite time.

Three important situations demand indefinite retention:

1. Patients who have generalized spacing, in which the arches are large and the tooth structure is not sufficient to close all the space
2. In circumstances of lip competency, the objective should be to transfer the space to the posterior segments and add tooth material in the posterior areas to achieve arch integrity. With adult patients, the object is to keep the restorative dentistry in the posterior segments and have natural tooth material in the anterior.
3. With tooth size discrepancies in the anterior area, it may be necessary to correct the tooth material problem where the tooth size discrepancy exists. If the discrepancy is in the anterior teeth, bonding and reshaping of the anterior group are mandatory; if the discrepancy is in the posterior teeth, the solution lies in treating the posterior midline and advancing the canine and premolar teeth mesially, shifting the space to the posterior segments.

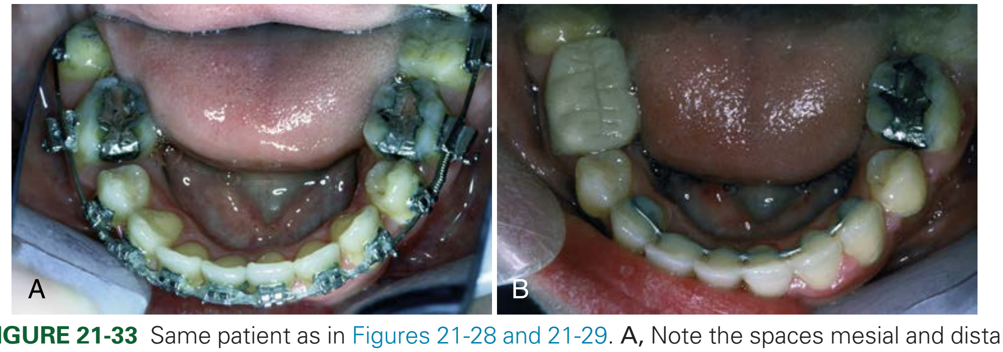

FIGURE 21-33 Same patient as in Figures 21-28 and 21-29. A, Note the spaces mesial and distal to the lower right molar when the patient demanded that appliances be removed. B, The large mandibular molar provisional was placed at the time appliances were removed.

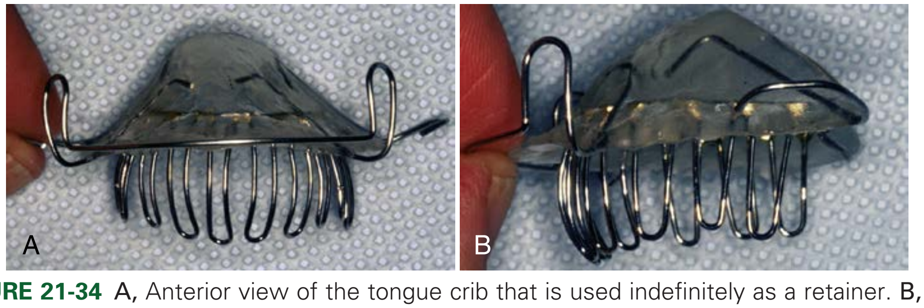

FIGURE 21-34 A, Anterior view of the tongue crib that is used indefinitely as a retainer. B, The appliance has a labial bow with ring clasps, and the crib extends back to the second molar area to the lingual mucogingival junction of the mandible when the patient is in maximal intercuspation.

FIGURE 21-35 **A,** Left lateral view of a 59-year-old Class II adult. **B,** Lower incisors, canines, and first premolars were advanced to obtain a Class I dental relationship and incisal guidance. **C,** Mandibular arch after pontic space was created in lower left quadrant between the premolars and before a pontic space had been created between the mandibular right premolars. **D,** Postrestorative occlusal view with the bridges having been placed bilaterally, allowing the more procumbent incisors to remain stable. **E,** The compensated mandibular incisors remain stable 20 years after treatment.

Again, it is recommended that the orthodontist refer to the basic concepts of retention clarified in Chapter 33. Those concepts and research findings can guide clinicians in further integrating a retention approach that is optimal for each patient.

Communicating with Team Members

Preorthodontic inflammation and occlusal control can be managed by the general dentist or the periodontist, but the orthodontist should monitor this phase and evaluate patient response over time before initiating the orthodontic phase of treatment. In addition, obviously, all caries control should have been completed, overhanging margins corrected, overbulked contacts reduced, irregular marginal ridges reshaped, and endodontic procedures completed. Consequently, adult interdisciplinary dental therapy requires treatment sequencing information so that standardized communication of the treatment plan is available to the patient and all providers.

RISK MANAGEMENT AND THE ADULT INTERDISCIPLINARY THERAPY PATIENT

According to recent statistics from the American Association of Orthodontists Council on Insurance, adult patients account for 50% of malpractice claims. Because adult patients account for fewer than 20% of the orthodontic patients, it would seem that each time orthodontists treat an adult versus a child, they are

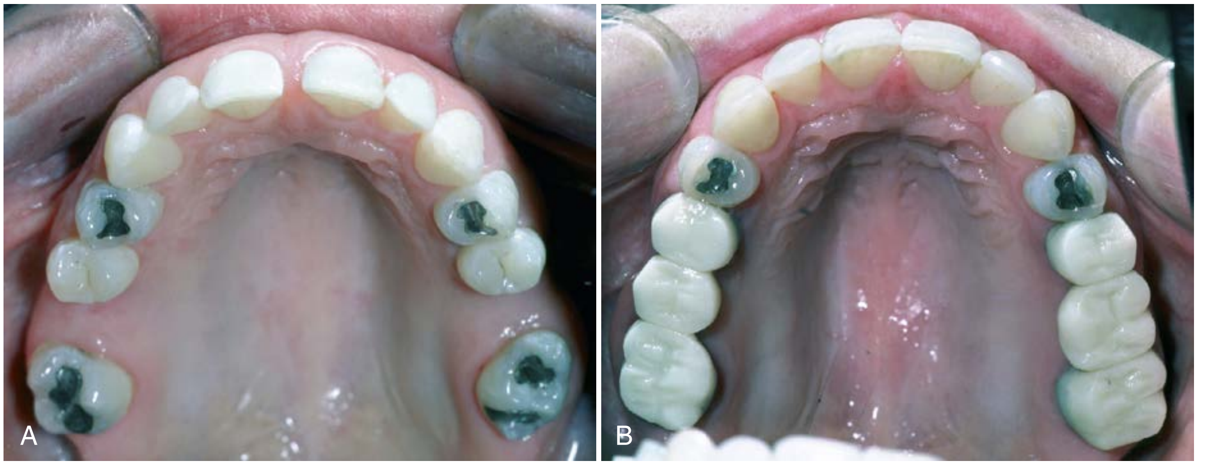

FIGURE 21-36 **A,** Occlusal view of the maxillary arch in a Class III patient who is missing posterior teeth bilaterally. If a Class III patient has an A point–nasion–B point greater than –3 degrees, space can be created bilaterally in the maxillary posterior areas, and bonding material can be added mesiodistally to achieve arch integrity and maintain more procumbent maxillary incisor stability without occlusal trauma. **B,** The incisors are advanced and centered on the midline, and restorations have been placed bilaterally in posterior areas.

four times more likely to be named in some form of malpractice claim. Is the increased risk simply because the cases are more complicated? Is the increase in risk because adult patient expectations are so much higher than those of the adolescent patient or parent of the adolescent? Or is the problem simply a lack of communication, as several articles have suggested?[78,83]

Because almost 80% of adult patients require interdisciplinary treatment planning and treatment execution, the role of communication among providers and with the patient cannot be emphasized enough. In Roblee's text, there is an important discussion of the role of communication:[57]

Extensive communication between team members is crucial to the success of Interdisciplinary Therapy . . . lack of communication or improper communication between team members is frequently the most common source of breakdown of therapy and of the team. The various team members must have a common purpose with the same objectives, as well as common knowledge that allows them to communicate intelligently and effectively with one another.[57]

If an orthodontic clinician plans on emphasizing more availability of adult treatment to their community, they would be wise to form an interdisciplinary study group of key members of an interdisciplinary team (IDT)—periodontist, oral and maxillofacial surgeon, restorative dentist, endodontist, psychologist, physical therapist, and other professionals who might be appropriate for team interaction.[57]

As the outline of this AIT chapter indicates, the IDT members should clarify their own concepts and the dental team's concept of:

- Goals of treatment
- Diagnosis of AIT problems
- Sequence of treating various conditions
- Stabilization and retention

In addition, the team's approach to communicating the plan of treatment to each of the providers and to the patient needs to be very clear. Many offices that function as part of an IDT have assigned staff as treatment coordinators to assist in the communication process because IDT patients frequently require occasional updates so they are kept appraised of treatment progress.

The authors suggest that a *disciplined* approach to patient communication be part of the treatment protocol for each patient. Four key conferences should be considered fundamental to adult interdisciplinary patient management, and with each of these conferences, it is advisable to have a written report to summarize what was said for future reference if needed.

1. **Treatment conference report** (Fig. 21-37): The report shown is a summary of the treatment plan that was discussed and presented to the patient. It should include the diagnosis, a problem list, a plan of treatment in sequential order (including proposed future consultations), a list of providers for each procedure, a statement of the prognosis, a list of potential treatment limitations, and a statement of patient concerns. This report is frequently generated by the orthodontist member of the team in collaboration with other key team members.
2. **Progress report** (Fig. 21-38): After about 12 to 14 months of orthodontic treatment, photographs and a panoramic radiograph (periapical radiographs, cephalogram, and study models are elective) should be taken and a progress report generated. This is used to evaluate tooth response, periodontal health, root positioning for restorative considerations, and potential treatment idiosyncrasies. Time should then be scheduled to provide an opportunity to sit quietly with the adult patient (other providers if indicated) to advise him or her of the progress of treatment, time remaining in treatment, and any problems or changes in the treatment plan that now needs to be considered. These few minutes of the orthodontist's time are greatly appreciated by the adult interdisciplinary patient and his or her restorative dentist. In addition, the time taken for a **formal progress update** may provide the patient and the referring dentist with the necessary positive reinforcement that is needed to reduce the stress of a long, complicated, and expensive treatment plan.
3. **Stabilization or retention report** (Fig. 21-39): After removal of fixed appliances, a retention conference is scheduled, and

a written report is generated so that the adult patient can review the treatment and the treatment outcome. This is an important opportunity to discuss any treatment limitations (e.g., skeletal imbalances, missed appointments, compliance issues) and any negative sequelae (e.g., root resorption, gingival recession or bone loss). On a positive note, the authors have found that giving the adult patient a copy of before-and-after photographs is a well-appreciated good-will gesture. The photographs also illustrate to the patient the positive changes that have occurred with treatment. Also, this provides the orthodontist with a good opportunity to reorient the patient to the additional periodontal and restorative procedures that are needed. Any patient concerns should be noted and appropriately managed during the retention phase of treatment. (See Figs. 21-33 and 21-34 with special attention to the graphs of the patient's emotional "highs and lows" during their interdisciplinary treatment.)

4. **Treatment completion** (Fig. 21-40): Approximately 12 to 18 months after the removal of appliances, a final evaluation of the patient and the stability of the correction should be done. Again, any problems or additional treatment steps can be discussed. This is a good time for a formal review of future retention requirements that need to be considered. It is helpful to advise them of your office's availability for further retainer maintenance and what type of fees would be charged for new retainers, office visits, and bonded retainer maintenance.

Progress Note

To: Dr. ______________________ Date: ______________________

Re: ______________________ Age: ______________________

Your patient was seen in our office today for an appointment/mini-conference to discuss: (❑ **Parent Present)**

❑ **Progress panoramic radiograph (see enclosed x-ray) findings:**
- ❑ Decay or Pathology ______________________
- ❑ Shape of Condyles and Symmetry ______________________
- ❑ Root Resorption ______________________
- ❑ Root Alignment/CEJ ______________________
- ❑ Third molars ______________________

(We typically make recommendations regarding third molar status during the retention phase)

❑ **Growth response to treatment:**

RETENTION/STABILIZATION CONFERENCE REPORT

TO:____________________ DATE:______________________

RE:____________________

Fixed orthodontic appliances were removed on_________________; and_________________has been referred back to you with the following observations and recommendations:

I. RETENTION PHASE:

Estimated Retention Time:______________________________

Appliances Prescribed:

Maxillary:______________________________

Mandibular:______________________________

Frequency of Retention Recall:______________________________

II. FUTURE TREATMENT CONSIDERATIONS:

Your patient,______________, has been advised to make an appointment with you to be evaluated for the following:

- ☐ Routine post-orthodontic examination and caries check:____________________
- ☐ Cleaning/fluoride:____________________
- ☐ Radiographic survey (as you see fit):____________________
- ☐ Periodontal Evaluation:____________________
- ☐ Restorative Treatment:____________________
- ☐ Equilibration Needed:____________________
- ☐ Future Extractions:____________________
- ☒ Other: JAW GROWTH- for girls who are 15 and younger and boys who are 21 and younger, studies have shown that 5-8% of persons in this age group experience "late stage growth changes" that may affect the bite.

III. TREATMENT APPRAISAL:

Description of original problem and treatment objectives:______________________________

Limitations imposed by complexity of orthodontic problem:______________________________

Limitations imposed by patient cooperation:______________________________

Overall assessment and comments:______________________________

If there are any questions regarding this report, please call me, at your earliest convenience.

Doctor

FIGURE 21-39 Retention and stabilization conference report used after adult interdisciplinary dental therapy to review treatment plan and future periodontal and restorative needs. Many times interdisciplinary treatment patients forget the sequence of who is doing what next. This is a great time to show orthodontic outcome and reinforce future treatment steps.

SUMMARY

This chapter has described the diagnosis, planning, sequencing, and stabilizing involved in the interdisciplinary management of complicated adult patient care. Advances in technology have provided IDTs with new methods of reliably managing the restoration of the stomatognathic system. In a high percentage of adult patients, interdisciplinary interaction among providers is critical. Therefore, a disciplined communication approach (provided to each patient) is required for each AIT patient. The more thorough the communication among providers and with the patient, the more likely it is that an optimal outcome will be achieved.

Orthodontic Completion Summary

To Dr: ______________________ Date of Report: ______________________

Re: ______________________ Appliance Removal Date: ______________________

Retention Phase: ____________ to ____________

Now that your braces have been removed and the supervised retention phase of treatment is completed, we want to release you from our care back to the long term care of your general dentist. As far as your orthodontic correction is concerned, your teeth have shown good stability while we have observed you during the retention period. Due to the dynamic nature of your mouth (i.e. speech, chewing, breathing, swallowing, and the possibility of clenching and grinding habits) your teeth will most likely continue to shift a little as times goes by. This is nature's way of allowing your teeth to achieve your mouth's "position of equilibrium".

OUR RECOMMENDATIONS:

The following recommendations require your attention:

- ❑ *A decision about your third molars* (wisdom teeth) will have to be made in the future. Your general dentist will monitor their development and advise you if extraction is appropriate. Comments: ____________
- ❑ *Bonded Retainers* need to be checked by your dentist periodically - if loose, they need to be rebonded. We can do this or your dentist can do this. However, if the retainer is not rebonded, decay may occur. NOTE: If a bonded retainer is removed, expect some minor shifting due to "adult stage" lower incisor crowding.
- ❑ *Removable Retainers* - it's a good idea to wear them periodically to be sure that your teeth have stabilized.
- ❑ *Jaw Growth* - for girls who are 15 and younger and boys who are 21 and younger, studies have shown that 5-8% of persons in this age group experience "late stage growth changes" that may affect the bite. If you feel this happening, please call us so we can determine if an additional phase of treatment is needed.

ADDITIONAL TREATMENT:

Charges for future treatment that you may request are:

- ❑ *Office Visit:*
  $40.00 - $80.00.
- ❑ *Diagnostic Records:*
  Fees at prevailing office rates.
- ❑ *Orthodontic Re-treatment:*
  The fee for this is variable depending on the problem and the underlying etiology of the need for additional treatment.
- ❑ *Therapy for Temporomandibular Joint (TMJ) Problems:*
  Many patients who grew up with malocclusions also have a weakened ligament apparatus controlling TMJ function. Many factors like stress, trauma, clenching, grinding, and gum chewing can cause the jaw joint to make noise or become painful. The fee for any additional treatment in this area will be based on the severity of the problem and the amount of treatment which is needed to resolve the problem.

Thank you for taking the time to review this material. We will miss seeing you, but we hope that you will continue to make healthy choices and, thereby, maintain your optimal health in the future.

Patient/Responsible Party Doctor

FIGURE 21-40 Completion conference report used 12 to 18 months after appliance removal for the orthodontist to complete the communication process with the patient and providers and to bring closure to the treatment retention phase. Without "formal closure," the patient may drop in any time for ongoing treatment that may not be part of the initial orthodontic treatment plan.

Acknowledgments

The authors express the deepest appreciation to the restorative dentists, periodontists, and oral and maxillofacial surgeons and their staff members who make interdisciplinary therapy for our patients possible and successful. Special appreciation goes to our staff, whose diligence and professionalism have helped each patient through the intricacies of interdisciplinary dentofacial therapy. Also, special thanks to Elizabeth Barrett, Beth McFarland, and Melissa Carstens for their time and assistance with the preparation of this chapter; without their outstanding professional input, this chapter would not have been possible.

Periodontal–Orthodontic Interrelationships

Robert L. Vanarsdall, Jr., Ignacio Blasi, Jr., and Antonino G. Secchi

OUTLINE

As orthodontists enter the 21st century, the adoption of evidence-based health care[1] and the invention of new preventive strategies are primary goals. Recent studies have provided compelling evidence of the importance of these two objectives.

Orthodontics is the most conservative and predictable treatment to improve many of the local etiologic factors that contribute to periodontal diseases and periodontal breakdown.

For example, statistically significant periodontal differences have been demonstrated in patients with crossbite, excessive overjet, and crowding compared with members of a control group.[2] Another investigation has shown that alveolar bone height in 19-year-old men was reduced in regions of severe malocclusion (8 mm of overjet) compared with the corresponding regions in healthy men who had near ideal occlusion.[3] A recent study evaluated the relationship between the irregularity of teeth and the incidence of periodontal disease; the results indicated that overlapping of incisors is related directly to gingivitis and that this relationship could not be explained simply by an effect on oral hygiene.[4] In a similar investigation involving 15 adults, subgingival bacterial samples were taken from anterior crowded and uncrowded teeth, and control samples were taken interproximally between two aligned teeth on the contralateral side within the same sextant.[5] Statistically, the pathologic levels of bacterial cells were significantly higher in the anterior crowded dentition than in the anterior well-aligned dentition. Furthermore, as crowding increased, the number of subgingival microorganisms increased at a predictable rate. This report offers strong evidence that orthodontics can promote periodontal health and even can prevent periodontal disease. Previous reports tended to conclude that malalignment of teeth could contribute to the establishment of periodontal disease only when poor oral hygiene was a factor.[6] Periodontal inflammatory response is considered to be a reaction to the local microbial biofilm. However, the biofilm may not be the determinant of the progression of the disease to periodontitis.[7] The concept of periodontitis occurs when the periodontal tissues provide an ecologic environment for opportunistic bacteria to exist and flourish.[8]

The short- and long-term successful outcomes of orthodontic treatment are influenced by the patient's periodontal status before, during, and after active orthodontic therapy. The long-term prognosis of the natural dentition depends to a significant extent on optimal responses and systemic resistance and on the patient's predisposition to the different clinical forms of

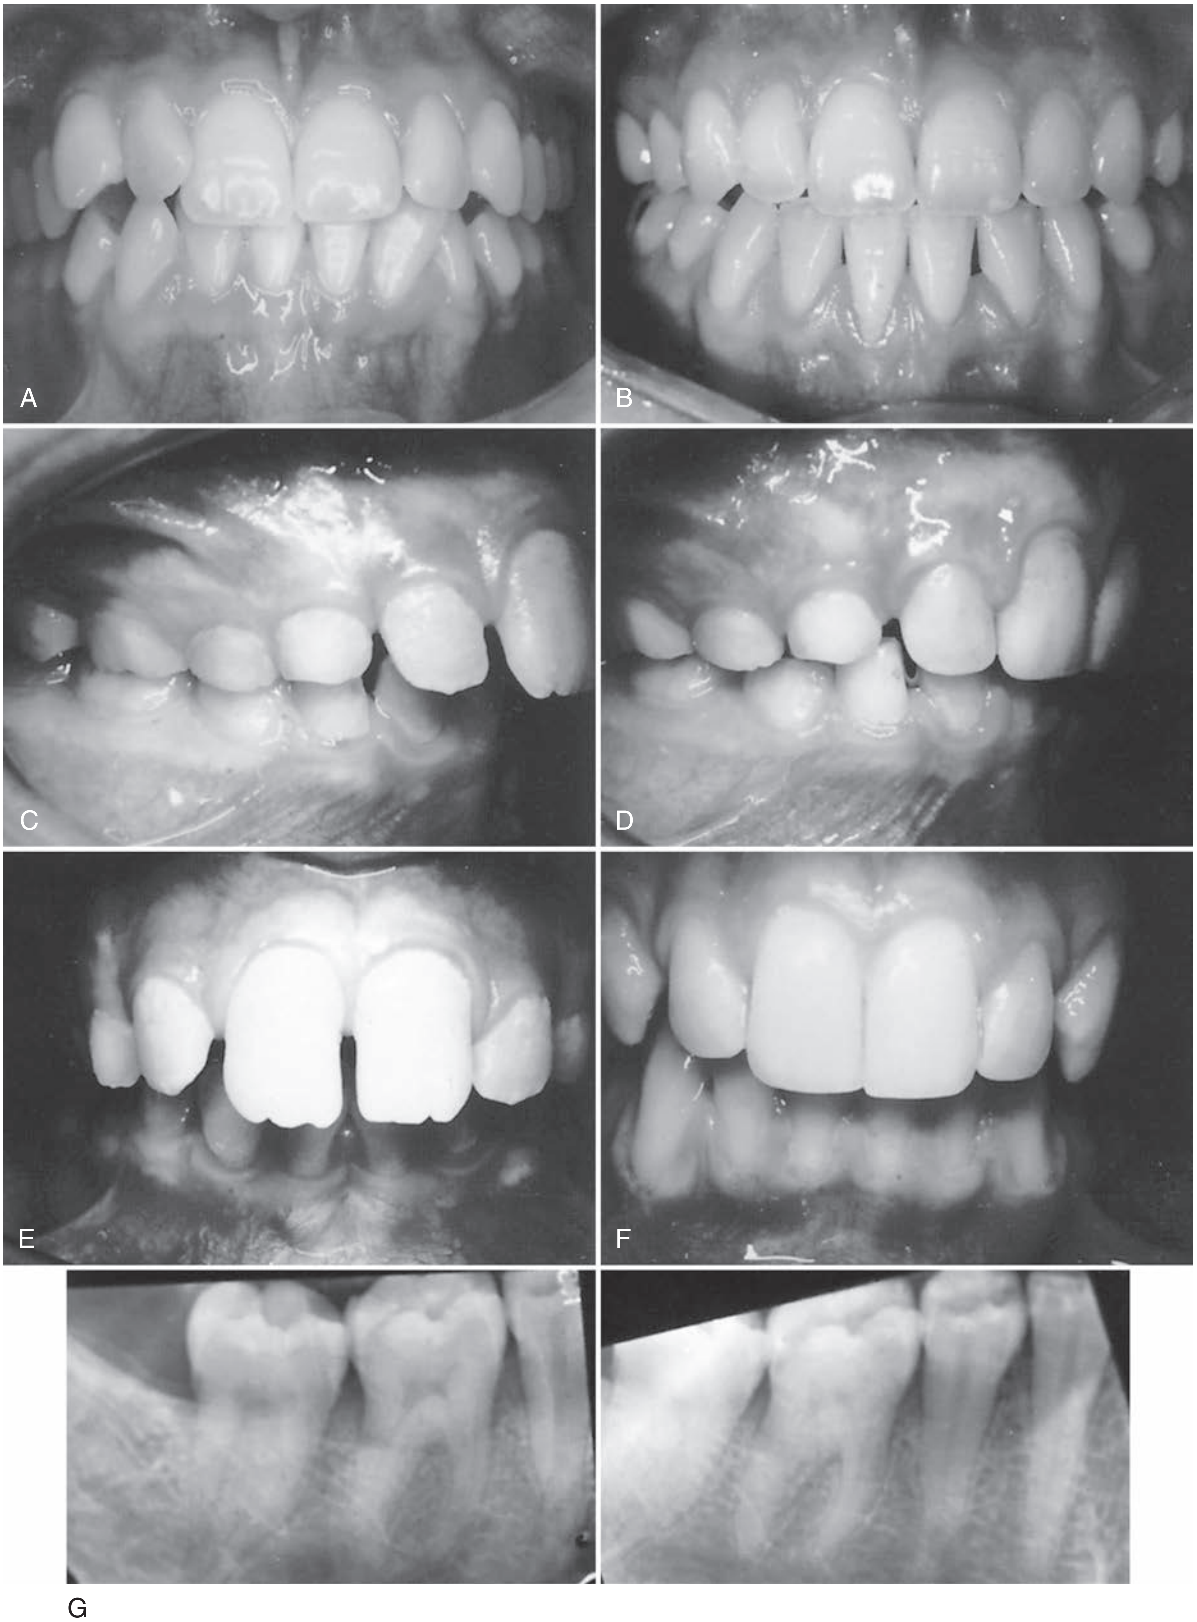

FIGURE 22-1 **A,** A 12-year-old girl before orthodontic treatment. **B,** After removal of the appliances. Note the gingival recession, labial root exposure, and interproximal space under contacts in the mandibular incisor area. **C,** Highly susceptible 9-year-old boy with thin, friable tissue before phase I therapy involving a headgear. **D,** Note the good cooperation, resulting in distalization of the maxillary dentition. **E,** Anterior view before placement of orthodontic appliances. **F,** Anterior view at the end of phase I shows excessive exposure of the anatomic crowns and beginning root exposure on all lower anterior teeth. **G,** Periapical radiographs of a woman's teeth taken before placement of orthodontic appliances.

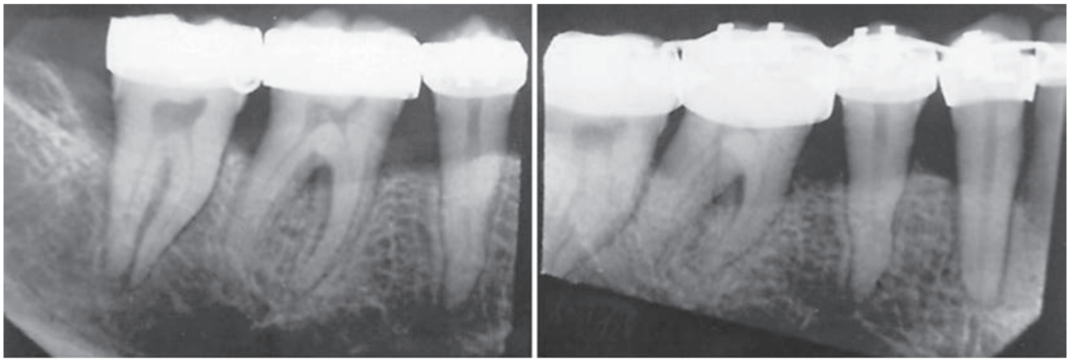

H

FIGURE 22-1, cont'd H, Several months later, progress films are taken because of excessive tooth mobility. Note the radiographic evidence of accelerated bone loss.

periodontal diseases. Periodontal pathogenesis is a multifactorial process, and the orthodontist must recognize the clinical forms of inflammatory periodontal diseases. At the 1989 World Workshop in Clinical Periodontics, a classification system was established for the various types of periodontal infections (microbial combinations) even though these disorders still may be difficult to distinguish by their clinical features.[9] The need for a revised classification system for periodontal diseases was emphasized during the 1996 World Workshop in Periodontics.[10] In 1999, the International Workshop for a Classification of Periodontal Diseases and Conditions agreed on a new classification.[11] Classification systems should always be considered "a work in progress." The systems should be adapted as more is known about the basic characteristics of the diseases and conditions.[12]

No matter how talented the orthodontist, a magnificent orthodontic correction can be destroyed by failure to recognize periodontal susceptibility (Fig. 22-1). Therefore, identifying periodontally susceptible patients is critical for the outcome of treatment.

TYPES OF INFLAMMATORY DISEASES

Gingivitis: The Reversible Lesion

The accumulation of microorganisms around teeth can cause gingival redness, bleeding, and edema; changes in gingival morphology; reduced tissue adaptation to the teeth; an increase in the flow of gingival crevicular fluid; and other clinical signs of inflammation.[13,14] Obviously, mechanical removal of plaque can reduce chronic gingivitis, but many orthodontic patients may not be motivated to remove the plaque; therefore, plaque removal must be done by the referring dental office or through other professional services such as scaling and thorough tooth cleaning during orthodontic treatment. Patients whose compliance is poor with a manual toothbrush may be more willing to use an electric device (e.g., Interplak [Conair, Stamford, CT], Rota-dent [Professional Dental Technologies, Batesville, AR], Oral-B plaque remover [Boston, MA]) that can improve oral hygiene.[15]

The removal of supragingival bacteria has been shown to have an inhibiting effect on the formation of subgingival plaque. One of the more effective antiplaque, antigingivitis agents is chlorhexidine digluconate; however, the orthodontist must monitor the side effects of reversible staining, tissue response, and taste alterations. Exaggerated gingival overgrowth and response to plaque have been reported with hormonal changes in pregnancy, with puberty, during the menstrual cycle, and in response to steroid therapy and birth control medications.[16]

Gingivitis (without attachment loss) has been classified as having initial, early, and established stages.[17] The initial lesion develops 1 to 2 days after plaque is allowed to remain on the teeth. The established lesion develops weeks later, when inflammation has advanced to proliferation of epithelium into the connective tissue. Only the established lesion can be observed as clinical gingivitis. The important point is that alveolar bone loss has not yet occurred, and one can hope that the lesion can be prevented from spreading into the supporting tissues. Therefore, determining the appropriate plaque control interval for the patient is crucial to prevent destructive alveolar bone loss. Pseudo-pockets or gingival overgrowth or enlargement of the gingival margin and papilla, whether they are drug induced (e.g., phenytoin or cyclosporine) or primarily plaque related, are exacerbated by poor oral hygiene. Constant professional reinforcement is necessary.

Periodontitis: The Irreversible or Destructive Lesion

Although gingival inflammation may be a prerequisite, the actual mechanisms responsible for conversion of gingivitis to periodontitis are still being debated.[18] All forms of periodontitis are marked by loss of connective tissue attachment and usually gingival inflammation.

Chronic periodontitis is the most common form of periodontitis. One of every two American adults aged 30 years and older has periodontal disease, according to recent findings from the Centers for Disease Control and Prevention. Around 47.2%, or 64.7 million American adults, have mild, moderate, or severe periodontitis, the more advanced form of periodontal disease. In adults 65 years of age and older, prevalence rates increase to 70.1%.[19] The organisms most often reported that have been associated with adult periodontitis are the ones associated with the red complex, which include *Porphyromonas gingivalis*, *Tannerella forsythensis*, and *Treponema denticola*. These bacteria are usually found together in periodontal pockets, suggesting that they may cause destruction of the periodontal tissue in a cooperative manner.[20]

Chronic periodontitis results in inflammation within the supporting tissues of the teeth, progressive attachment, and bone loss. It is characterized by the formation of pockets or recession of the gingiva (or both). It is prevalent in adults but can also occur in children and adolescents. Conventionally, this form of periodontitis has been characterized as a slowly progressive disease. However, data indicate that some patients may experience short periods of rapid progression.[11] Good plaque control as well as removal of bacteria and calculus deposits from the subgingival environment by mechanical instrumentation constitutes an effective approach to reduce signs of inflammation in most cases of chronic periodontitis.

Aggressive periodontitis, by definition, causes rapid destruction of the periodontal attachment apparatus and the supporting alveolar bone. It can present in a localized or generalized form. It occurs in patients who are otherwise clinically healthy (Fig. 22-2). The primary features to diagnose the disease include a history of familial aggregation with rapid attachment loss and bone destruction. Secondary features include elevated proportions of *Aggregatibacter actinomycetemcomitans* and, in some far East populations, *Porphyromonas gingivalis*; phagocyte abnormalities; hyper-responsive macrophage phenotype, including elevated production of prostaglandin E2 (PGE2) and interleukin-1β (IL-1β) in response to bacterial endotoxins; and progression of attachment loss and bone loss may be self-arresting. There is compelling evidence that adjunctive antibiotic treatment frequently results in a more favorable clinical response than mechanical therapy alone. Indeed, several authors have reported success in the treatment of aggressive periodontitis using antibiotics as adjuncts to standard therapy.[11,21,22]

Periodontitis also can be associated with **systemic diseases** such as familial and cyclic neutropenia, Down syndrome, Papillon-Lefèvre syndrome, hypophosphatasia, and leukemias.[11,23]

Necrotizing periodontal diseases is an infection characterized by necrosis of gingival tissues, periodontal ligament (PDL), and alveolar bone. The major consistent symptoms noted are pain and bleeding, but low-grade fever and halitosis (bad breath) may also be noted. These lesions are most commonly observed in individuals with systemic conditions such as HIV infection, malnutrition, and immunosuppression. Treatment can be successful if begun early and if there is no predisposing systemic illness. Acute-phase emergency treatment may include pain relief, debridement of necrotic gum tissue, antiseptic mouth rinses, thorough regular dental cleaning and flossing, oral antibiotics if it is severe or there are signs of systemic infection, and antifungal agents for immunosuppressed patients treated with antibiotics. Also, it is important to treat any predisposing illness or trigger (e.g., smoking). Finally, surgical correction should be done of any remaining defects such as craters with gingivectomy and gingivoplasty. It is essential to maintain good dental hygiene and good health to reduce the risk of recurrence. However, where there is a predisposing condition such as AIDS, recurrence or relapse is common.[24,25]

The 1989 classification did not include a section on periodontal abscesses and a connection between periodontitis and endodontic lesions, nor a section on developmental or acquired deformities and conditions. This was remedied by the addition of these lesions the International Workshop for a Classification of Periodontal Diseases and Conditions held in 1999.[26]

In general, one should recognize that children can develop severe forms of periodontitis, but the prevalence of destruction is much less than in adults. Severe bone loss in a child or adolescent also may be an early sign of systemic disease and may indicate the need for medical evaluation.

As is described in this chapter, orthodontic patients may be at greater risk of attachment loss after teeth have become mobile because of tooth movement (see Fig. 22-1, *G* and *H*). The orthodontist must recognize and control clinical signs of inflammation and tooth mobility during treatment to prevent extensive bone loss. Identification of occlusal trauma should be done clinically by identifying fremitus and increased tooth mobility and radiologically by the widened PDL and bone loss.[27,28] The signs of occlusal trauma are reversible. The trauma must be eliminated and teeth protected from the adverse effects of plaque-induced inflammation to allow healing of the attachment apparatus.[29] Periodic monitoring of the periodontal status with probing, microbiologic assessment by immunologic assays, DNA probes, and culturing, as well as clinical findings are useful in determining scaling intervals and detecting potential sites of increased risk of attachment loss. These methods may be used to assess the end point of the effectiveness of scaling and root planing before orthodontic treatment to ensure that no putative pathogens remain. Genetic studies offer potential benefit in identifying high-risk individuals,[30] such as those with neutrophil chemotactic abnormalities who are family members of patients with aggressive periodontitis; such individuals are 10 times more likely to develop periodontal disease than most family members.

HIGH-RISK FACTORS

The orthodontist must assess each patient for periodontal factors that may place the patient at higher risk of developing periodontal disease during orthodontic therapy.

A significant dental history could include unsuccessful orthodontic treatment at an earlier age. A patient with a history of previous periodontitis[31] obviously is more susceptible to the disease. Although predicting which sites may progress from gingival inflammation to periodontitis is difficult, those who have had the disease previously are more vulnerable to further bone loss. In fact, in individuals who have had previous bone loss, gingivitis may be a greater threat for further bone loss.[32] No one should begin orthodontic treatment if active destructive sites are present, and a person who has had periodontal disease before should be monitored more closely to prevent new bursts of active sites that may result in rapid bone loss. A small percentage of adolescents (10%) and a much larger group of susceptible adults (50%) must be treated differently. Other risk factors include gingival bleeding from probing; tooth mobility; and thin, friable gingival tissue. This chapter discusses each of these factors. In addition, tobacco use and diabetes mellitus have proved to be risk factors for a higher prevalence of periodontal disease.[33–35]

The orthodontist should record a list of periodontal risk factors for any patient who seeks orthodontic treatment. Risk factors are important, for example, in identifying patients who will need a special management approach with individualized periodontal recall intervals. The orthodontist must control for risk factors before beginning orthodontic treatment so that periodontal problems are less likely to develop. Stress, diabetes mellitus, tobacco smoking, osteoporosis, and genetic predisposition are examples of disease modifiers.[36] Genetic testing could be used as part of risk assessment for the development of future disease, and the patient can be informed of the greater risk of developing disease.[30,37]

FIGURE 22-2 A 14-year-old patient seeking orthodontic treatment. Upon clinical and radiographic examination, the patient was diagnosed with localized aggressive periodontitis and referred for phase I periodontal treatment. **A, B,** Intraoral photographs before treatment. **C,** Note probing depth of 11 mm on the affected area. **D,** Periapical film showing an angular bone defect. The patient was treated with scaling and root planing and adjunctive antibiotic therapy as phase I. Then extrusion during orthodontic treatment was completed. **E, F,** Probing depth of 3 mm after treatment and periapical film showing healing of the angular crest defect. **G, H,** Final intraoral pictures after orthodontic treatment. (Case treated by Drs. Blasi and Bockow.)

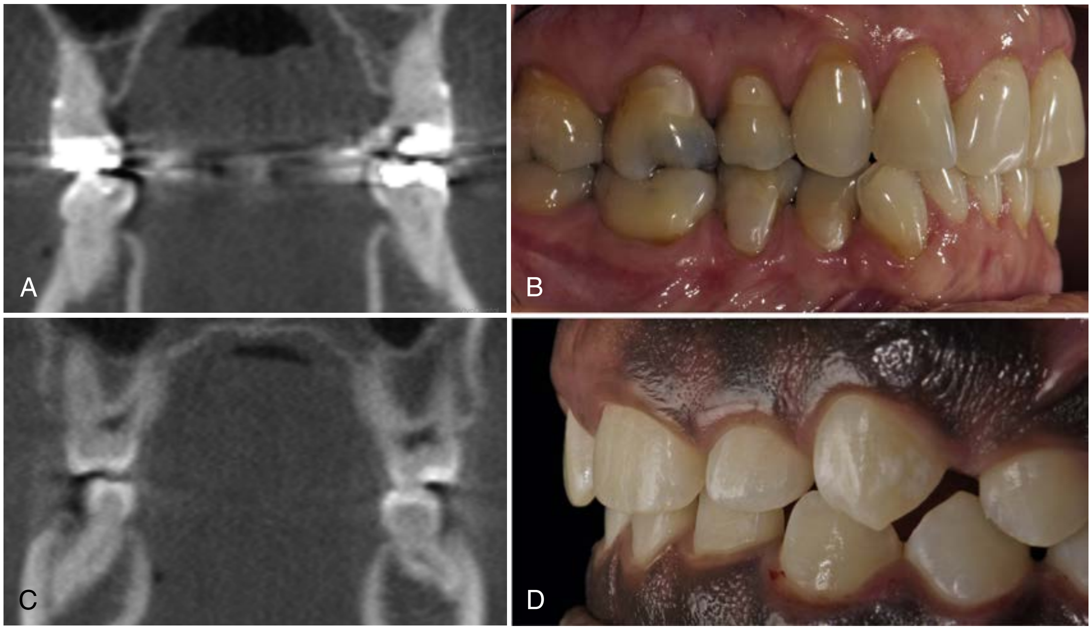

FIGURE 22-3 A, Coronal cone-beam computed tomography cut of a treated patient with a thin hard tissue biotype; note the minimum width of the cortical plate. B, The gingival of the same patient presents with an average soft tissue biotype. C, The thick bone tissue biotype correlates to the thick soft tissue biotype (D); the patient presents with altered passive eruption (APE).

The clinician must identify susceptible patients and develop strategies to prevent loss of attachment and gingival recession.

Gingival Recession

Gingival recession is not uncommon in young adults and could be related to past orthodontic treatment.[38] A recent study by Remeka et al.[39] concluded that the prevalence of gingival recessions steadily increases after orthodontic treatment. They observed that there was a continuous increase in gingival recessions after orthodontic treatment with full fix appliances from 7% at end of treatment to 20% at 2 years after treatment and to 38% at 5 years after treatment. The same group concluded that orthodontic treatment and the retention phase may be risk factors for the development of labial gingival recessions.[40]

Orthodontic movement of teeth should be carefully made within the alveolar housing. A failure to a correct diagnosis could make orthodontics an etiologic factor to gingival recession.

Biotype

The periodontal tissue and its clinical appearance may differ from subject to subject.[41] The tissue thickness on the faciopalatal dimension has been described as a biotype.[42–48] The identification of the hard and soft tissue biotype is important in clinical practice since differences in gingival and osseous architecture have been shown to exhibit a significant impact on maintaining the integrity of the periodontal tissues during treatment (Fig. 22-3).

Subjects with thick-flat biotype have wider and voluminous gingiva and slightly scalloped or flat gingival margin with short and wide teeth; the contact areas between the teeth are large and more apically located, and the interdental papillae are short. On the other hand, a person with a thin-scalloped biotype has a narrow zone of gingiva, highly scalloped gingival margin, long and slender teeth with tapered crown form, and interdental contact areas that are located incisally.[49,50] In the presence of inflammation, a flat periodontium results in pocket depth; a scalloped periodontium results in gingival recession.[41]

Gingival biotype can be evaluated by direct visual assessment only,[50,51] recognizing the washboard effect, visual assessment with visual periodontal probe through the tissue,[52] and direct measurement with gingiva perforation.[53–55]

Although the hard tissue and bone biotype could be evaluated with cone-beam computed tomography (CBCT) (see Fig. 22-3, *A* and *C*), not yet with 100% accuracy,[56,57] the only diagnostic method to accurately determine the hard tissue biotype is direct visualization with an open flap. On the other hand, bone sounding of each individual tooth remains the gold standard in the evaluation of alveolar crest position.

The periodontal biotype is partially related to the dimensions of alveolar process, the shape of the teeth and tooth eruption, rotations, inclinations or other malpositions.[58–60]

Even though subjects with a thin-scalloped gingival biotype are more likely to have thin, hard tissue architecture, variations occur among individuals.[58] Patients with thin or thick gingival tissue might present with thin or thick bone tissue (see Fig. 22-3).

The biotype of the soft and hard tissue may play a critical role in the outcome of treatment.[61] A thin-scalloped biotype has a higher prevalence of gingival recession.[41,62,63] Therefore, an accurate diagnosis and special attention should be given to hard and soft tissue biotype when treatment planning and before proceeding with orthodontic treatment to achieve predictable outcomes.

Transverse Dimension

A risk marker is a characteristic that identifies a patient who is likely to have periodontal disease. In this regard, the transverse

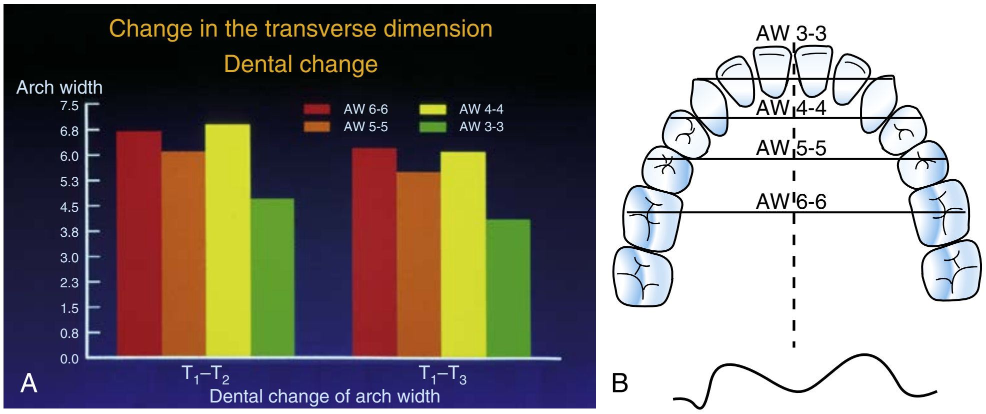

FIGURE 22-4 **A,** A histogram of maxillary dental change, with rapid palatal expansion from T_1 (before expansion) to T_2 (completion of expansion). skeletal pattern may be the most crucial evaluation in gauging the potential for facial gingival recession.

In a study on patients from two private orthodontic practices conducted at the University of Pennsylvania, 55 patients (ages 8–13 years at the time of treatment with a Haas expander) were recalled 8 to 10 years after rapid palatal expander (10–10.5 mm over 3 weeks) and compared with 30 control patients (matched for age) from the same practices who were evaluated for stability and clinical crown height after edgewise nonexpansion.[64] The patients were assessed from models, Kodachrome slides, and posteroanterior (PA) cephalograms made before and at the end of orthodontic treatment; they were recalled 10 years later for examination and new records. The study indicated that of the expanded cases, although the results were stable (Fig. 22-4), 11 (20%) showed unusual facial gingival recession on one or more teeth compared with only 6% gingival recession in the nonexpanded control patients (Fig. 22-5). Skeletally, 9 of the 11 patients who had undergone expansion and experienced facial gingival recession had maxillary transverse deficiency and mandibular transverse excess, and the other 2 patients had excessively large mandibles (Fig. 22-6). Therefore, in an adolescent patient with a small maxilla and a large mandible, a potential exists to move teeth beyond the envelope of the alveolar process, predisposing the patient to gingival recession. The envelope of discrepancy for the transverse dimension is much more crucial from a stability and periodontal standpoint (see Chapter 21).

Another study[65] evaluated posttreatment gingival recession in three groups of individuals. At 7 to 10 years after nonextraction treatment, 75 patients treated with RPE therapy (group 1), 22 patients (from the same practice) treated with standard edgewise therapy only (group 2), and an untreated control group (mean age, 17.2 years; group 3) were evaluated for cemental exposure, and PA cephalograms were evaluated to determine whether a transverse skeletal discrepancy existed between the maxilla and mandible for all subjects. The graph (see Fig. 22-6, *H*) shows transverse discrepancy (width of the mandible minus width of the maxilla) larger than the normal value (Rocky Mountain normal for age) expressed as a negative number. Twenty percent of all three groups experienced gingival recession. Individuals in each group who exhibited a negative

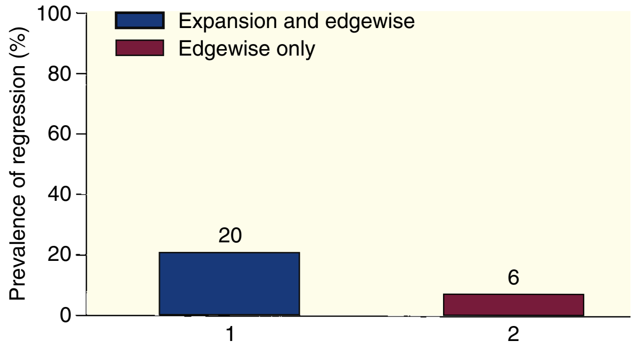

FIGURE 22-5 About 20% (11 of 55) of the expanded cases showed gingival recession compared with only 6% in the edgewise-only treatment group. The hypothesis that recession is distributed evenly across expanded and edgewise groups was rejected ($p = 0.0025$).

skeletal differential greater than 5 mm (from the norm value) experienced gingival recession. The individuals with a normal transverse skeletal differential in all three groups did not experience recession. Therefore, the transverse skeletal severity is a critical risk marker for identifying patients susceptible to gingival recession and periodontal disease. This is important diagnostic information that can result in a treatment plan that may improve future periodontal health for patients in whom the transverse skeletal differential can be corrected.

Untreated susceptible adults with significant transverse skeletal discrepancy show advanced stages of destructive periodontal disease. Hundreds of adult orthodontic retreatment patients have achieved excellent stability from surgically assisted RPE to correct transverse skeletal discrepancy. Growth in the transverse dimension slows severely by 15 years of age and has been reported to be essentially complete.[66,67] Therefore, early orthodontic treatment in the deciduous or early mixed dentition is ideal for correcting transverse skeletal abnormalities orthopedically when growth is significantly active and palatal separation is most effective. It is important to identify the patient's skeletal age to determine whether

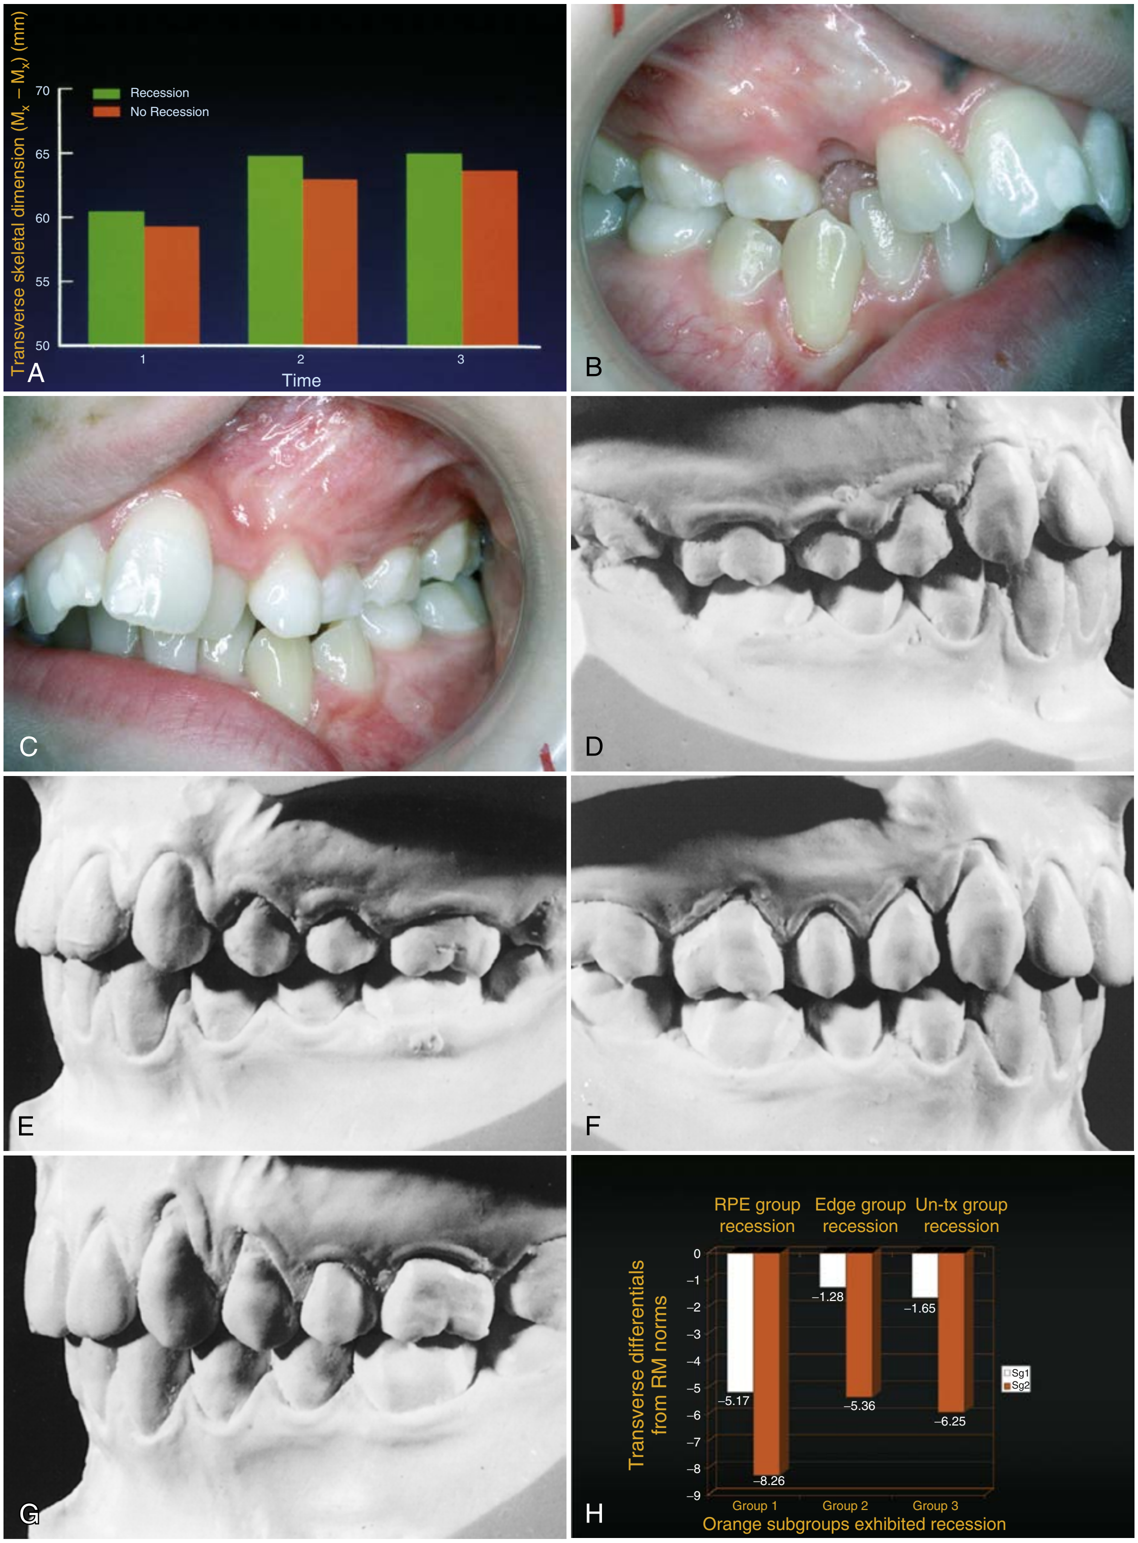

FIGURE 22-6 **A,** From the histogram, note that all 55 of the expanded patients at T_1 had a maxillary (Mx–Mx) transpalatal dimension of about 60 mm (deficient) and were expanded at the bony base 4 to 5 mm at T_2 and at T_3 (final period). The basal skeletal increase remained stable and increased with time only 0.33 mm. Little difference was seen in the maxillary skeletal dimension between the patients who showed recession (11 [*dark screen*]) and the patients who did not (44 [*lighter screen*]). The relationship between the maxillary and mandibular widths was a crucial factor in the evaluation, and this proportional evaluation identified the 11 individuals with problems. **B, C,** Buccal views of a 9.4-year-old girl (Class I, Division 1 condition) with a 9-mm narrow maxilla and an excessively wide mandible in the transverse dimension. Observe that there are no crossbites. **D, E,** Models made when appliance was removed. **F, G,** Models made 10.8 years after completion of treatment. Note the gingival recession in the maxillary buccal segments observed years after the appliances had been removed. **H,** This graph represents the mean differentials (difference between Ricketts Mx–Mx and Ag–Ag measurements in width) for Rocky Mountain norm values in the rapid palatal expansion group 1, orthodontic-only group 2, and control group 3. *White bars* represent the norm-recession individuals, mean differential, and *orange bars* indicate the mean value found for individuals with gingival recession. *Orange* subgroups exhibited recession. All groups were found to have individuals with gingival recession, but recession occurred in those with severe transverse skeletal discrepancy greater than 5 mm.

FIGURE 22-7 **A,** A 12-year-old girl before rapid maxillary expansion. **B,** After completion of active expansion. Note the midline diastema and tissue level on the left first premolar. **C,** Note the tissue level on the maxillary left first premolar before expansion. **D,** Several weeks after expansion. or not orthopedic expansion would be effective on correcting the skeletal maxillary base. Expansion of buccal segments with fixed appliances has limitations and tends to be unstable, regressing toward pretreatment widths.[68]

Orthopedic expansion of the palate has been studied with the use of implants. This study confirmed 50% dental movement and 50% skeletal movement in young children. In adolescents, however, only 35% of the movement was skeletal, and 65% was dental.[69] Therefore, as the young patient grows older, dental tipping becomes greater, which puts the teeth at higher risk of gingival recession (Fig. 22-7, *A* and *B*). Lindhe[70] has stated that "[when] during orthodontic treatment a tooth is moved through the envelope of the alveolar process . . . at sites with thin and inflamed gingiva [there is] a risk that gingival recession may occur." The labial plate of bone in the maxilla is thin on the facial surfaces of the teeth (Fig. 22-8, *A*). The buccal plate in the mandible is thin in the coronal thirds from the first molar area, moving anteriorly, and is considerably thinner in the premolar/incisor areas (Fig. 22-8, *A* and *C*).

Garib et al.[71] compared the periodontal effects of RPE with tooth-tissue-borne (Haas-type expander) and tooth-borne (Hyrax) using computed tomography. They observed that both expanders reduced the bone buccal plate thickness of the maxillary posterior teeth and induced bone dehiscences on the anchorage teeth buccal aspect (Fig. 22-9). The tooth-borne (Hyrax) expander produced more reduction of first premolar buccal alveolar crest level than did the tooth-tissue-borne expander. Dental expansion and alveolar bending predispose to recession and dental instability if treated beyond the limits of the envelope of discrepancy. Therefore, proper diagnosis and proper selection of the type of appliance should be made.

Bone-Anchored Rapid Palatal Expansion

Temporary anchorage devices (TADs) have raised orthodontics to a completly different level of excellence, expanding the treatment limits, even in apparently impossible cases.

In our 2012 study[72] on patients treated, by one operator alone, with a bone-anchored expander (TAD type), 11 patients (11.3–17 years) were evaluated after expansion and compared with a group of 24 patients[73] (7.8–12.8 years) treated with a bonded tooth-tissue-borne expander (bonded type) from a different practice. The hand–wrist radiograph was used to establish treatment response of the needed correction. The patients were assessed from CBCT data taken before and right after the expansion was completed (Fig. 22-10).

A *t*-test was conducted and found that there were statistically significant differences, with a $p < 0.05$ between the mean of maxillary basal bone change at the first molars of both groups. Furthermore, the percent of the mean screw expansion associated with the width of the palatal expansion at the first molar was calculated. The mean value of the basal expansion with the bonded RPE was 40.65%, and the mean value of the expansion with the TAD RPE was 65.04%. It can be concluded that the large difference in the magnitude of this difference in the efficiency of the expansion was due to the direct effects of the expansion on the palate itself and not the surrounding molars

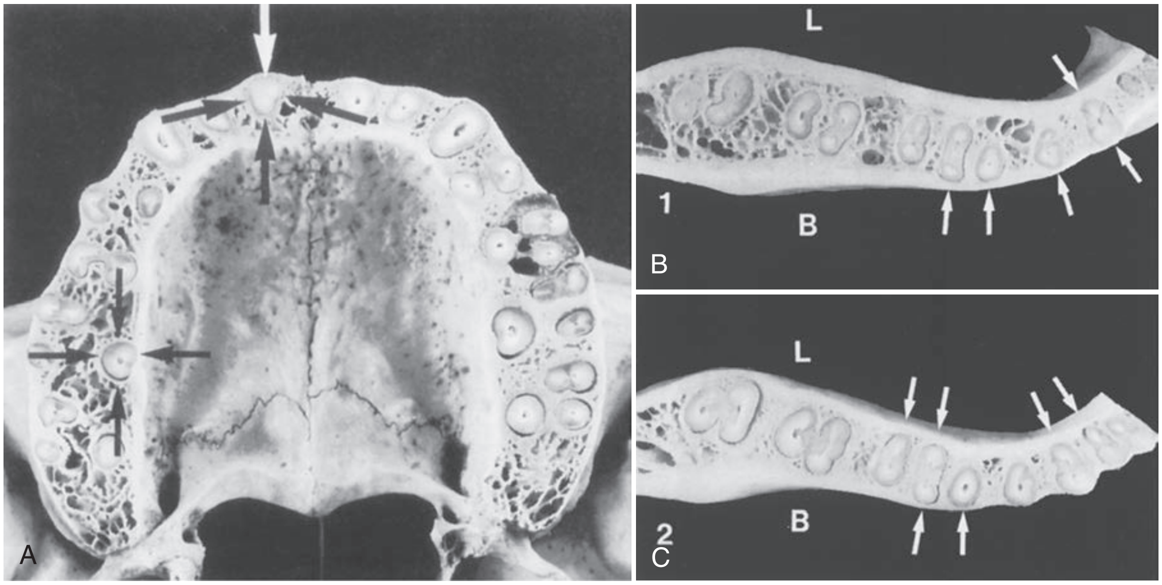

FIGURE 22-8 **A,** Cross-section through the maxillary alveolar process at the midroot level of the teeth, showing the extreme thinness of the buccal bone in the maxillary arch. **B,** and **C,** Cross-section through the mandibular alveolar process at the coronal and apical thirds of the roots. FIGURE 22-9 Patient treated beyond the limits of the envelope of discrepancy. Note the dehiscence created by a tooth-born (Hyrax) rapid palatal expander. **A,** Pretreatment computed tomography (CT) scan of the right first premolar. **B,** Post-RPE CT. (From Garib DG, Henriques JF, Janson G, et al. Periodontal effects of rapid maxillary expansion with tooth-tissue-borne and tooth-borne expanders: a computed tomography evaluation. *Am J Orthod Dentofacial Orthop* 2006;129(6):749–758.)

of the maxillary arch where the bonded tooth-tissue-borne RPE device ordinarily engages (Fig. 22-11).

This interpretation is also strongly supported by the substantial intermolar tipping angle effect of the bonded TX, which resulted in a mean 11.7 standard deviation (SD) ± 3.05-degree difference over the course of TX and the near absence of any mean effect 0.2 SD ± 3.47-degree difference in the case of the TAD TX group. In this case, a *t*-test of the differences between the two groups demonstrated a highly significant difference at $p < 0.00001$ (Fig. 22-12).

Comparing the bone-anchored to the bonded tooth-tissue-borne expander treatment, expansion efficacy demonstrated in both significant skeletal changes. However, the bone-anchored devices achieved (25%) significantly more skeletal change (Mx–Mx) without dental compensation than did the bonded tooth-tissue-borne device. More maxillary expansion was noted with the bone-anchored versus the bonded tooth-tissue-borne expander, and a highly statistically significant difference in the molar tipping.

With all the emphasis on evidence-based orthodontics, Lagravère et al.[74] reported in a CBCT randomized clinical trial (patients were 14.05–14.54 years old) that bone-anchored maxillary expanders and traditional (Hyrax) rapid maxillary expanders showed similar results. The tooth-borne group exhibited more first premolar expansion than the bone-anchored appliance, and both exhibited significant increase in

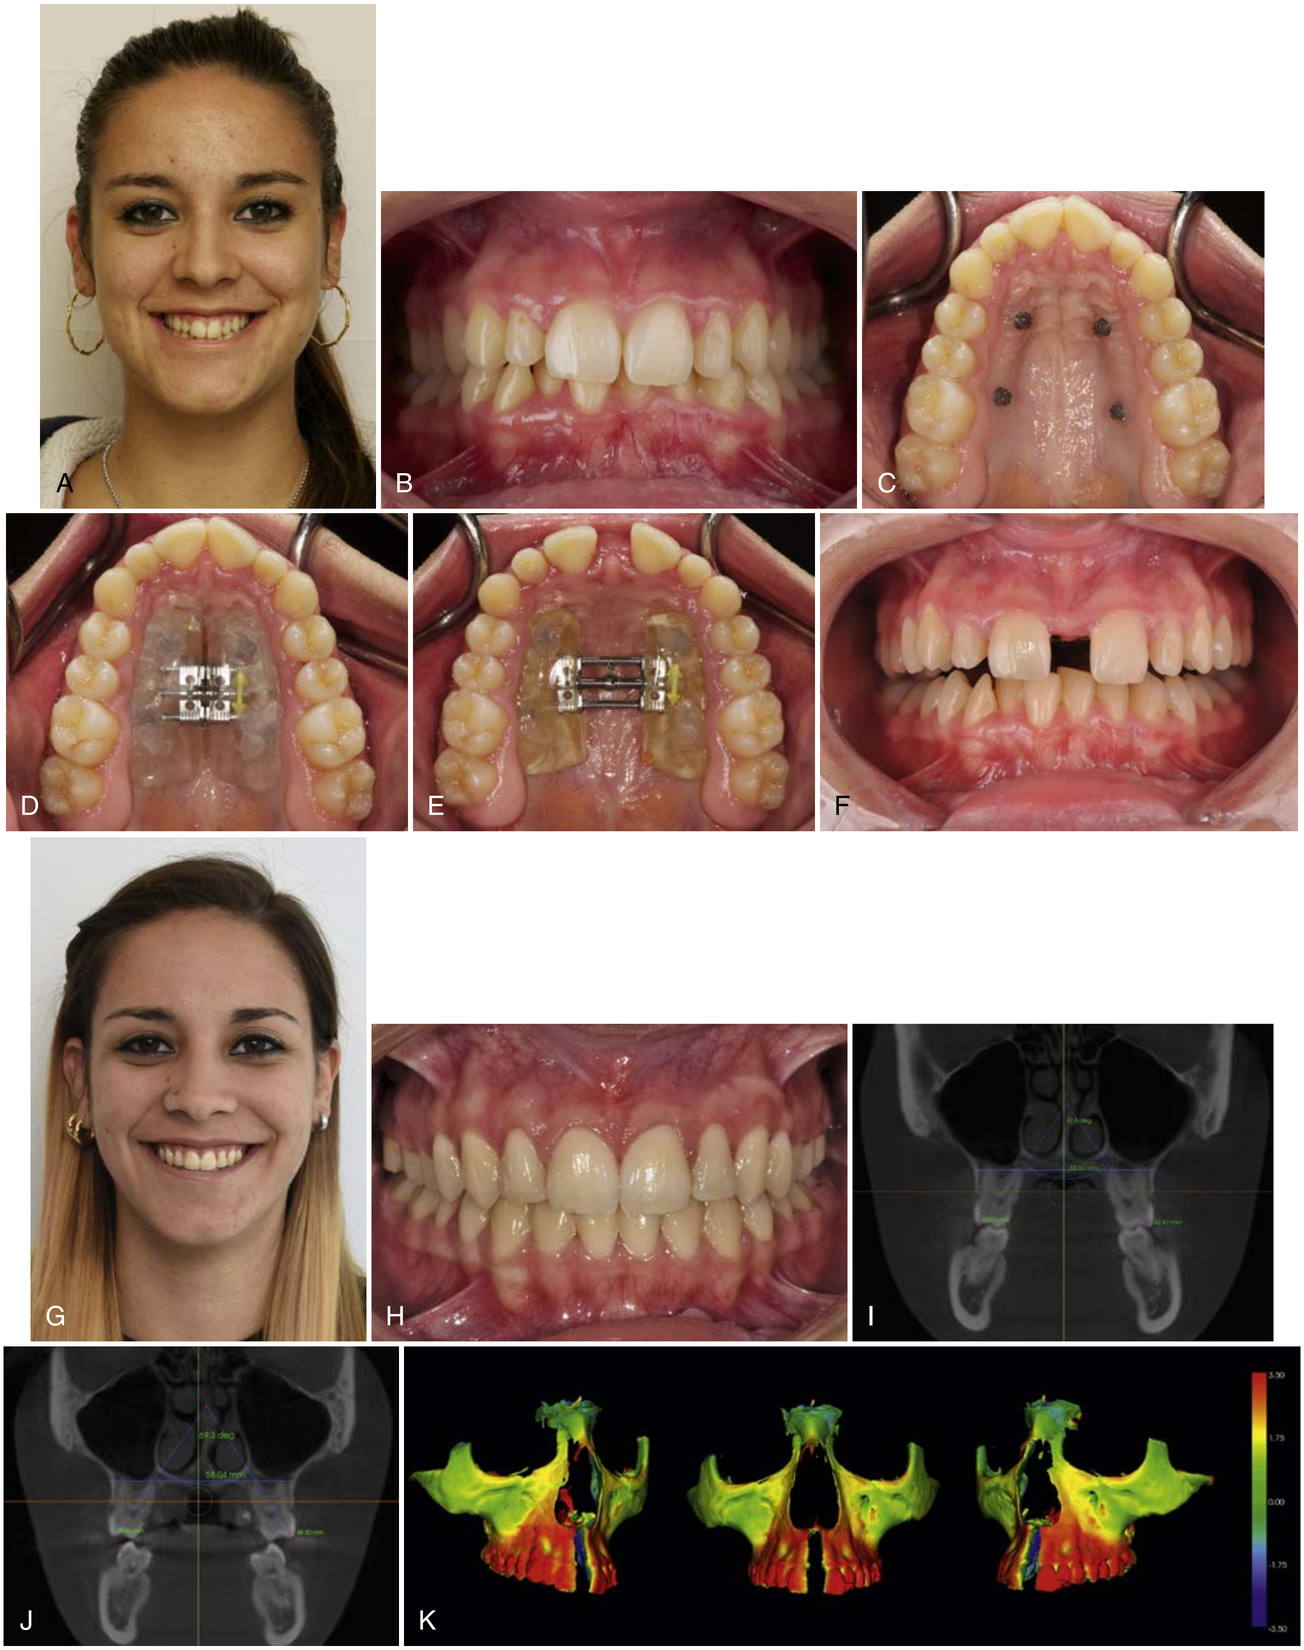

FIGURE 22-10 A, B, A 16-year-old girl before rapid maxillary expansion with a bone-anchored expander. Note the posterior negative spaces. C, Four temporary anchorage devices (TADs) were inserted between the canine and first premolar and between the second premolar and first molar. D, Rapid palatal expander (RPE) cemented 1 week after TAD insertion. E, F, After completion of active expansion. Note the midline diastema and minimum dental tipping. G, H, Final treatment outcome 18 months of treatment duration. Peg laterals were restored, and diastema was closed to the patient's facial midline. Note that the posterior negative spaces were eliminated. I, J, Coronal cone-beam computed tomography cuts at the level of the first molar. Note the molar inclination compensating for the narrow maxilla. The comparison of before (I) RPE and after (J) RPE exhibits 5.68 mm of skeletal expansion achieved at the Mx level of the maxilla and a negative (−1.2 degrees) dental tipping caused by a purely skeletal expansion. K, Treatment evaluation in three dimensions after RPE. Note the skeletal change on the color-mapping superimposition.

crown inclinations. They found that dental expansion was greater than skeletal expansion. However, they only evaluated dental objectives and focused on the dental correction of posterior crossbites. There were no skeletal objectives and/or evaluation of the skeletal transverse dimension changes at the basal bone level. In addition, they used only two TADs for their appliance design, while it has been reported that the use of four TADs on the palatal slopes makes a better force distribution.[75]

Our findings have been substantiated by Lin et al.[76] They evaluated and compared the effects of a tooth-borne expander (Hyrax; $n = 13$; age $= 17.4 \pm 3.4$ years) and a bone-borne expander ($n = 15$; age $= 18.1 \pm 4.4$ years). The bone-borne expander group produced more skeletal expansion except in the first premolar area that exhibited alveolar tipping. The Hyrax group had more buccal tipping of the dentition and alveolar process, except in the area of the second molar, and significant adverse buccal dehiscences at the first premolar level. The authors concluded that the bone-borne expanders produced greater orthopedic changes and fewer dentoalveolar tipping than the Hyrax expander.

Skeletal anchorage should permit orthopedic change without the adverse dental changes by applying force directly to the maxillary bone.[77a] It has been reported that the skeletal-anchored RPE produced less molar tipping than the tooth-tissue-borne RPE.[72,76]

The skeletal anchorage could be reserved for moderate to severe skeletal discrepancies, skeletally mature individuals, periodontally involved cases, or patients with missing teeth.

The palatal skeletal change that is predictably possible remains unknown, and future research is needed. Even though there is also a need to determine the skeletal age barriers of the bone-anchored RPE, it is clear that the envelope of discrepancy has been increased to include older patients (Fig. 22-13).

The keys to diagnosis and treatment of the transverse dimension are skeletal age that determines the response to

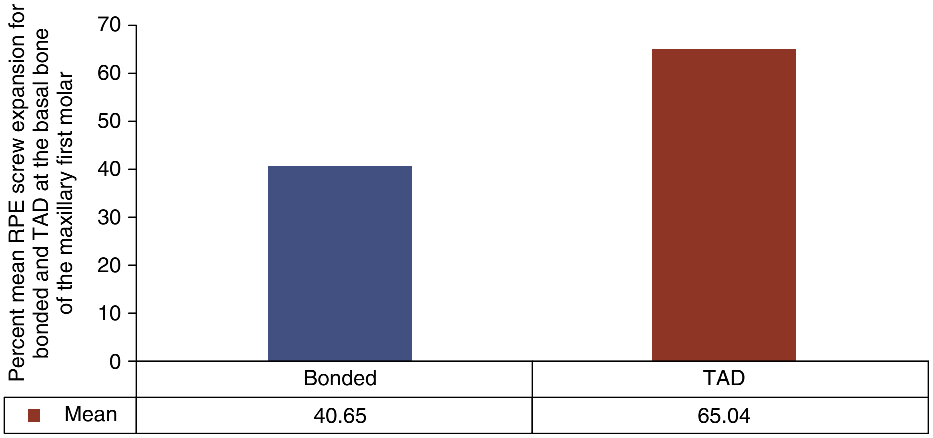

FIGURE 22-11 Histogram showing percentage of the basal bone expansion of the mean jack-screw opening at the levels of the first permanent molars. The mean value of the basal expansion with the bonded rapid palatal expander (RPE) was 40.65%, and the mean value of the expansion with the bone-anchored RPE was 65.04%.

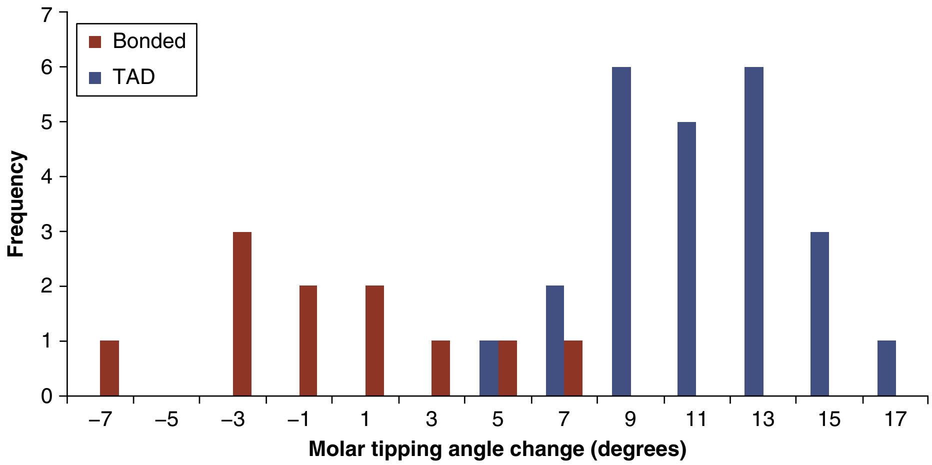

FIGURE 22-12 Comparison of the bonded tooth-tissue-born rapid palatal expander (RPE) and bone-anchored RPE intermolar tipping angle change. A *t*-test of the differences between the two groups exhibited a highly significant difference ($p < 0.00001$). *TAD,* Temporary anchorage device.

treatment, the severity of the discrepancy of the skeletal pattern (the quantitative difference between the maxillary and mandibular basal bone and not the dental relationship), and the selection of the appliance (Haas, 20% basal change; bonded RPE, 41% basal change; TAD RPE, 65% basal change) (Fig. 22-14).

Facial movement of the teeth into thin tissues has been tested in monkeys. Extensive bodily movement of incisors in a labial direction through the alveolar bone (Fig. 22-15) resulted in small apical displacement of the gingival margin, which appeared to be thinned by the tooth movement, and reduction of the alveolar bone height.[77] Therefore, less tooth movement and greater orthopedic change in the transverse dimension could be obtained by a bone-anchored RPE or surgical adjunct, which has not been shown to create the adverse gingival changes seen with orthopedic expansion in severe or skeletal transverse maxillary deficiency problems. The decision to use a surgical adjunct is based on comparison of the maxillomandibular proportions with individual normal variations. The transverse skeletal discrepancy is corrected (1) to prevent periodontal problems; (2) to achieve greater dental and skeletal stability (Fig. 22-16, *A–C*); and (3) to improve dentofacial aesthetics by eliminating or improving lateral negative space, which accompanies maxillary transverse deficiency (Fig. 22-16, *D–G*).

EARLY TREATMENT

A transverse correction may have more periodontal significance than an AP correction. In addition to changing skeletal characteristics, studies have shown that posterior airway space increased (Fig. 22-17), and there has been a considerable decrease in obstructive sleep apnea after expansion procedures of the maxilla as well.[78,79]

Rapid maxillary expansion is the orthopedic treatment used to correct the skeletal transverse problem in children.[80] Proper orthopedic treatment with skeletal landmarks as goals to correct the skeletal transverse dimension does not required overcorrection. The mandible can be adjusted using a mandibular lip bumper appliance in conjunction with a maxillary RPE.[81] Through the interaction of the tongue and lip bumper, spontaneous decrowding of the lower incisors occurs as space is gained by growth and widening. The lip bumper allows for dentoalveolar widening and reshaping, which are induced without direct attachments to the teeth except contact at the molar tubes. For most practitioners, diagnosis of the transverse dimension is

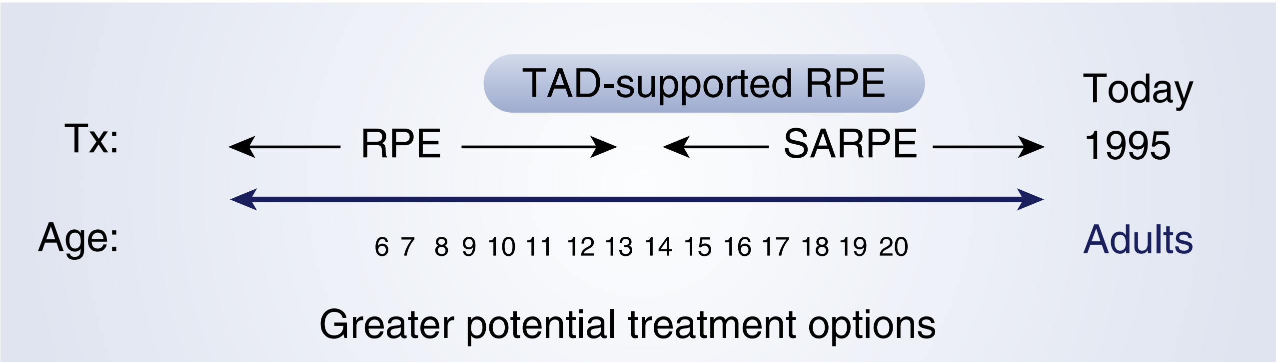

FIGURE 22-13 Treatment envelope of the transverse skeletal dimension. Today, although there is a need to determine the skeletal age limits of the bone-anchored rapid palatal expander, the envelope of discrepancy has been increased to treat older patients without surgically assisted rapid palatal expansion (SARPE).

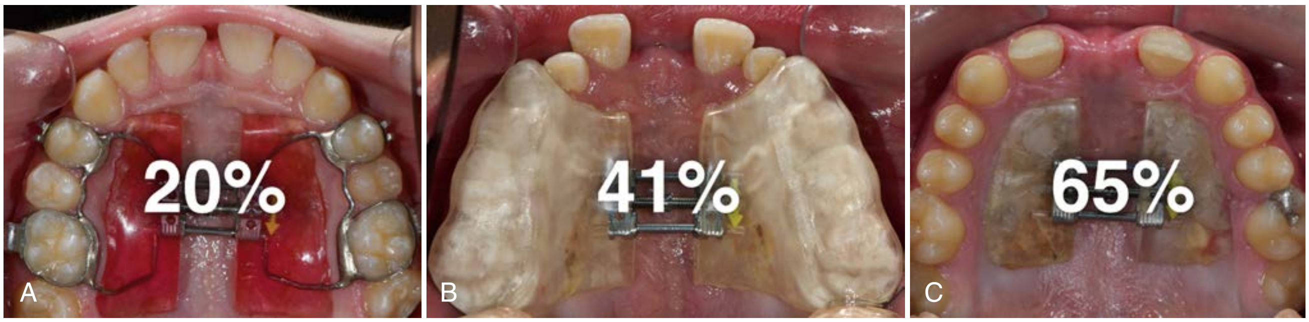

FIGURE 22-14 Selection of appliance is important depending on the skeletal correction needed (transverse skeletal discrepancy between the mandible and maxilla) and the skeletal age. **A,** Haas, 20% basal change. **B,** Bonded rapid palatal expander (RPE), 41% basal change. **C,** bone-anchored RPE, 65% basal change of the mean jackscrew opening at the levels of the first permanent molars.

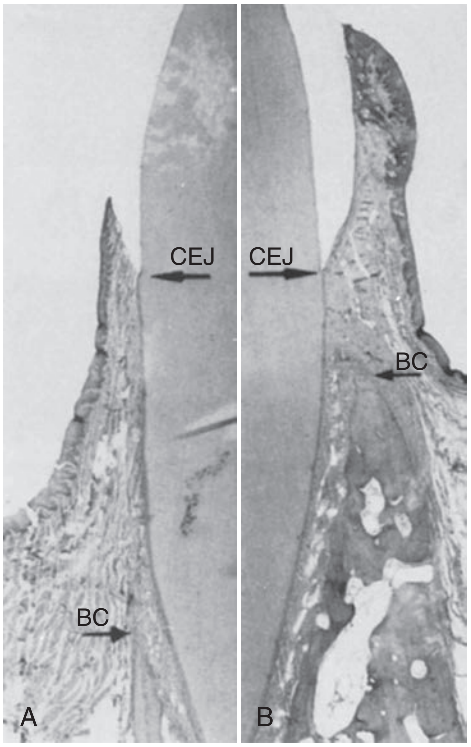

FIGURE 22-15 Histologic specimens demonstrating reduced alveolar bone height at an incisor that has been bodily moved in a labial direction (**A**) and normal alveolar bone height at an unmoved control tooth (**B**). Note that the connective tissue attachment has been maintained; however, the free gingival tissue on the labially displaced incisor (**A**) has been reduced in height. *BC,* Bone crest; *CEJ,* cement-enamel junction. based on the clinical appearance of the teeth without properly assessing the skeletal width of both the maxilla and the mandible. It has been established that no tooth in the mandible correlates with the skeletal width, and only the maxillary first molar correlates with the skeletal width of the maxilla.[82] Furthermore, clinical and visual evaluation of the maxillary width are not diagnositic.[83] Compensatory buccal or lingual inclination of the maxillary or mandibular teeth (or both) usually masks the underlying transverse skeletal discrepancy. Therefore, the presence of crowding, crossbite, or constricted arches does not necessarily indicate a transverse skeletal problem or the severity of the discrepancy.

Established skeletal landmarks should be used to diagnose the skeletal width of the maxilla and mandible. In the past, we have emphasized the used of the PA cephalogram to diagnose the skeletal width or determine the severity of the problem. Figure 22-18 illustrates the landmarks and norms developed by Rickkets in 1969.[84] The severity of the transverse discrepancy, age, and the appliance are the most important factors in determining appropriate treatment and prognosis. To achieve optimal skeletal correction, the Haas, bonded occlusal, or bone pin expanders that use palatal contour for anchorage and produce orthopedic response, minimizing adverse dental tipping, are recommended. As the patient matures, the skeletal expansion obtained can be less than one-third of the expansion produced at the level of the jackscrew. A post-expansion PA cephalogram or CBCT view is useful to evaluate the amount of skeletal correction achieved.

TISSUE RESPONSE TO CERTAIN TYPES OF TOOTH MOVEMENTS

Age-related changes occur in the skeleton and alveolar bone, and adults show a greater lag, or delayed response, to mechanical force, than that seen in younger patients.[85] However, teeth move equally well in adults and children, and no evidence indicates that they move more slowly in adults. In a healthy periodontium, regardless of the direction in which a tooth is moved, the bone around the tooth remodels without damage to the supporting tissues. The bone should follow the tooth in changes of position; this principle is used to create favorable alveolar changes in patients with periodontal defects. Significant evidence shows that drawing mesially inclined molars upright reduces pocket depth and improves altered bony morphology[60,86] (Fig. 22-19). The bone on the mesial erupts as the molar tips distally. Every dentist has seen teeth erupt, and as a tooth moves occlusally, the healthy alveolar process moves with it (Fig. 22-20, *A*). With chronic inflammation, as a tooth erupts, the alveolar bone is lost, and the tooth appears to extrude from the periodontal tissues (Fig. 22-20, *B*). When molars are uprighted, the connective tissue attachment on the mesial aspect of the molar to the crestal bone creates tension and allows for remodeling of the bone (see Fig. 22-19, *C* and *D*).

Clinically, ranges of force exist that are biologically acceptable to the periodontium. One should remember that because tooth movement is primarily a phenomenon induced by the PDL, identical forces do not put the same stress on the supporting tissues of different teeth. The root length and configuration, the quantity of bone support, the point of force application, and the center of rotation come into play to determine stress areas in the PDL. To prevent tissue damage, one must consider areas of maximal stress that might occur in the PDL. The risk of bone loss is higher if inflamed connective tissue is located apical to crestal alveolar bone,[87] and certain types of force may aggravate the progression of inflammatory periodontal disease.[88] Periodontal disease in a PDL under stress has been shown in rats (between M1 and M2), where infectious inflammatory infiltration spreads from the epithelial aspect into the transseptal ligament (Fig. 22-21, *A*). These animals showed complete destruction of the transseptal ligament within 28 days.[89]

To prevent aggravated loss of attachment or tissue damage, therefore, determining maximal stress areas, which can occur crestally or in the PDL, is crucial. Although most tooth movement involves combinations of movements, clinicians tend to view movement more simply in terms of extrusion (eruption), intrusion, tipping, translation, and torque.

Extrusion (Eruption)

Extrusion, or eruption, of a tooth or several teeth, along with reduction of the clinical crown height, has been reported to reduce infrabony defects and decrease pocket depth.[90,91] Single-tooth eruption should be distinguished from overbite correction and control of the vertical dimension during routine orthodontic correction. Extrusion of an individual tooth is used specifically for correction of isolated periodontal osseous lesions. Studies have shown that eruption in the presence of gingival inflammation

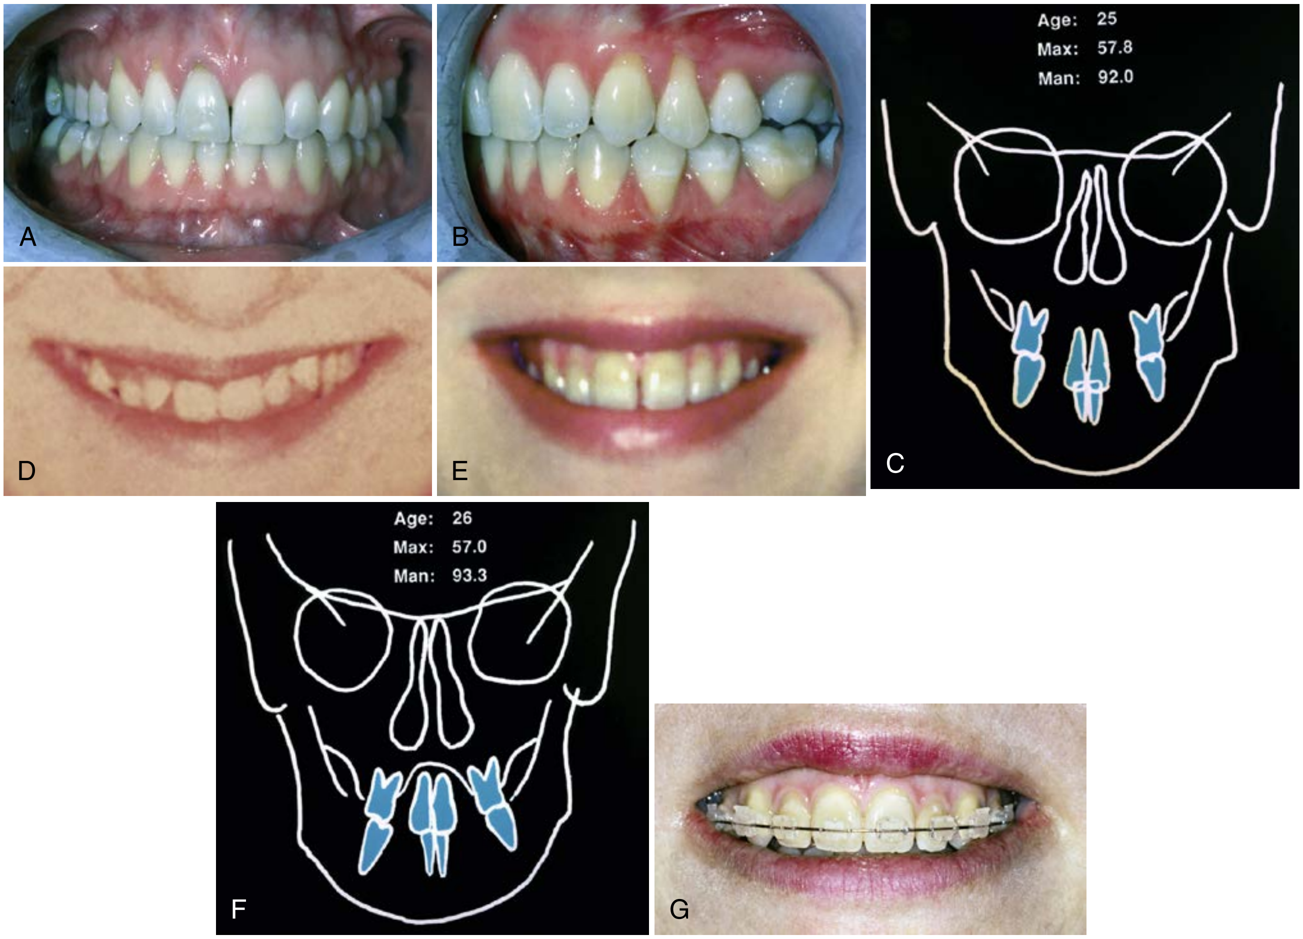

FIGURE 22-16 A case in which orthodontic treatment was done and the transverse skeletal discrepancy was camouflaged. **A,** Posttreatment right lateral view. The case is unstable and has significant gingival recession in buccal segments and poor dental aesthetics with negative space between the cheeks and the buccal segments. **B,** Gingival recession on the maxillary and mandibular premolars. **C,** The skeletal pattern is normal in the sagittal and vertical dimensions. On the posteroanterior (PA) cephalometric tracing, note the maxillary and mandibular widths. The Mx-to-Mx maxillary distance (57.8 mm) and the AG-to-AG mandibular distance (92.0) can be evaluated from the PA cephalometric radiograph. **D,** A 15-year-old patient with a severe Class III condition and normal transverse skeletal dimension; with a full smile, there is no negative space. **E,** Note the large negative spaces in the corners of the buccal segments of a 26-year-old woman with transverse maxillary deficiency and mandibular excess. **F,** Posteroanterior cephalometric tracing. Note the maxillary and mandibular widths. **G,** Negative space is eliminated by surgically assisted rapid palatal expansion performed to correct the transverse skeletal dysplasia. Excess gingiva was removed with the gingival retention procedure at appliance removal.

reduces bleeding on probing, decreases pocket depth, and even causes the formation of new bone at the alveolar crest as teeth erupt, with no occlusal factor present and while controls remain unchanged.[92] Eruption or uprighting of molars without scaling and root planing in human patients has been shown to reduce the number of pathogenic bacteria.[93] During clinical treatment, however, inflammation always should be controlled to ensure that the supracrestal connective tissue remains healthy and that the crestal alveolar bone height remains at its original level.

In the double-blind molar uprighting study done at the University of Pennsylvania,[93] bacterial samples were taken from the mesial pockets of molars to be uprighted (experimental tooth) and from the contralateral mesially inclined molar that served as the control in each subject. Indirect immunofluorescence was used to identify *Bacteroides forsythus, B. gingivalis, B. intermedius,* and *Actinobacillus actinomycetemcomitans*. During the study, no scaling, root planing, or subgingival inflammatory control was used. This study revealed that in all experimental sites that showed these microorganisms at the time of bonding, the number had diminished significantly by the end of treatment. However, Hawley bite planes were worn by all patients to disarticulate the molars during molar uprighting. In a similar study of 10 patients over a 12-week period, in which the effects of molar uprighting on the microflora of human adults were assessed using DNA probes, the number of *Bacteroides* pathogens was found to decrease at the experimental site with uprighting.[94]

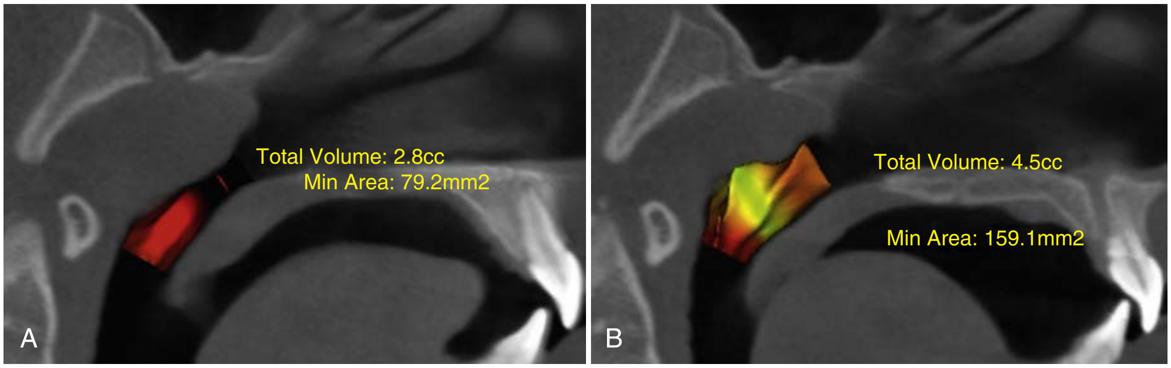

FIGURE 22-17 The skeletal transverse correction increases the posterior airway space. Furthermore, it could decrease the severity of the symptoms of sleep breathing disorders in patients. This patient's cone-beam computed tomography scan demonstrates the changes on the posterior airway space in a three-dimensional volumetric measurement. **A,** A 9-year-old patient before expansion with a bonded rapid palatal expander (RPE) showing a minimum area of constriction of 79.2 mm^2 and a volume of 2.8 cc of the posterior airway space. **B,** After RPE, note the changes on the minimum area of constriction (159.1 mm^2) as well as the volume (4.5 cc) of the airway posterior space.

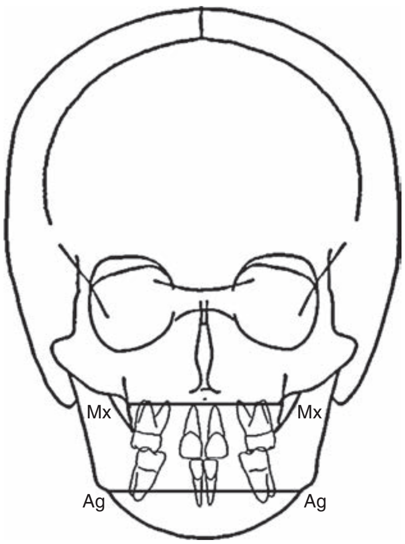

FIGURE 22-18 Posteroanterior cephalogram tracing with skeletal landmarks used to evaluate the transverse dimension, the width of maxilla and mandible. The maxillare (Mx), or J point, is located at the depth of concavity of the lateral maxillae contours, where the maxilla intersects the zygomatic buttress. *Mx–Mx,* distance between left and right Mx (mm) that represents the skeletal width of the maxilla. Antegonion (Ag), or antegonial notch of mandible is defined as the innermost height of the contour along the curved outline of the inferior mandibular border, low and medial to gonial angle. *Ag-Ag,* distance between left and right Ag (mm); represents skeletal width of the mandible.

Eruption of a tooth is the least hazardous type of movement to solve osseous morphologic defects on individual teeth created by periodontal disease or tooth fractures (Fig. 22-22). Forced eruption has been used to enhance soft and hard tissue dimensions.[95] Extrusion of anterior segments in skeletal openbite patterns with muscular problems has shown shortening of the roots. If teeth have normal bone support or if bone loss has been horizontal (the alveolar crests and the cement-enamel junctions [CEJs] are level), then movement should involve intrusion or extrusion as necessary to correct the orthodontic deformity.

Intrusion

Conflicting evidence has been reported regarding the benefits of intrusion of individual teeth. One study has reported that intrusion of individual teeth did not result in the development of pockets.[96] This same investigator had reported earlier that intrusion in monkeys induced increased new attachment levels after flap operations to excise pocket epithelium and place an experimental notch on the root.[97] In periodontal research, dogs and monkeys are well known to show new attachment during normal healing after surgical flap procedures without tooth movement (Fig. 22-23), and this has been described.[98] Others have observed that intrusion may result in root resorption, pulpal disturbances, and incomplete root formation in younger individuals.[99] Clinicians have cautioned that intrusion of anterior teeth during leveling of the occlusal plane to correct overbite can deepen infrabony defects (Fig. 22-24) on individual teeth.[100] These conflicting reports indicate that intrusion can be a more hazardous type of movement; because the force is concentrated at the apex, root resorption has been a well-known sequela, and light forces have been recommended (see Chapters 3 and 4).

Intrusion has been reported to alter CEJ and angular crest relationships and to create only epithelial attachment roots; therefore, a periodontally susceptible patient is at greater risk of future periodontal breakdown (see Fig. 22-24, *B* and *C*). Tooth movement, when properly executed, improves periodontal conditions and is beneficial to periodontal health (Fig. 22-25). Whenever intrusion forces are applied, the mucogingival junction remains unchanged, but there can be a reduced amount of attached gingiva (Fig. 22-26). Extrusion is much more predictable than intrusion in accomplishing this purpose. Whenever the treatment objective is new connective tissue attachment or periodontal regeneration to restore lost supporting periodontal tissues, guided tissue regeneration (e.g., barrier membranes) is the predictable way to manipulate cells that lead to new attachment. Guided tissue regeneration procedures always should

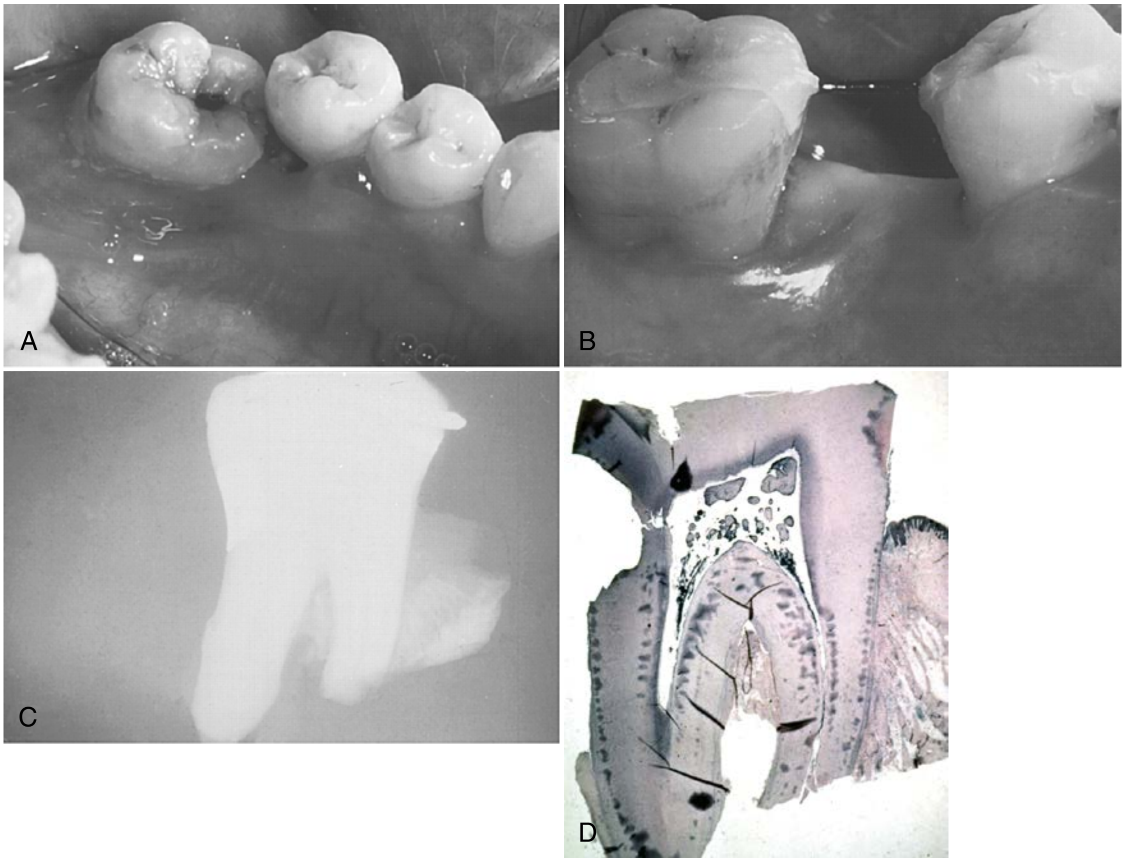

FIGURE 22-19 **A,** Mesially inclined molar before being uprighted. **B,** Reduction of mesial soft tissue pocket depth. The extrusive component of uprighting the molar allows for eversion of the pocket epithelium. **C,** Radiograph of a human clinical case after a tooth has been uprighted. **D,** Histologic slide of the tooth. Note the new bony spicules on the mesial where the alveolar crest has remodeled from the tension of the connective tissue attachment. No reattachment or increase in new attachment is evident. precede orthodontic tooth movement and should be part of the initial therapy before active orthodontic treatment is begun.

Tipping

When a single force is applied to the crown of the tooth, the tooth can rotate around its center of resistance (for an incisor, about the midpoint of the root), and compression (pressure) is increased at the crest and at the root apex. In this case, half of the PDL has the potential to receive high pressure from essentially light force.

Experiments in beagles demonstrated that with tipping and intruding movements, forces were capable of causing conversion of a gingival lesion to a lesion associated with attachment loss.[101] In tipping movements, the force should be light and the area should be kept clean to prevent the formation of angular bony defects.

Bodily Movement into a Defect

Movement into infrabony defects has been suggested to result in healing and regeneration of the attachment apparatus.[102] In addition, periodontists have believed that if a wide osseous defect is adjacent to a tooth and the tooth were moved to narrow the defect, better healing potential may be possible. Unfortunately, it has been shown that if infrabony defects are created in the lower incisor area of rhesus monkeys (undergoing good plaque control) and the tooth then is moved into and through the original defect, a long epithelial attachment to the roots is created, with no new attachment apparent.[103] The results, however, indicated that even though movement into infrabony periodontal defects did not result in regeneration of attachment, no further loss of connective tissue attachment occurred.

The most recent study performed in four beagles found that angular bony defects were created, and plaque was allowed to accumulate. Teeth were translated into inflamed, infrabony pockets, and additional attachment loss occurred on the teeth moved into the infrabony pockets.[104] Therefore, the conclusion was that bodily tooth movement may increase the rate of destruction of the connective tissue attachment of teeth with inflamed, infrabony pockets.

At the University of Pennsylvania, teeth have been moved into defects, with the patients' contralateral side serving as the control (Fig. 22-27). Radiographs revealed that loss of attachment occurred when a tooth was moved into a defect in an edentulous area (see Fig. 22-27, *D* and *E*). The tooth can move away from a defect and, with sufficient eruption, a bony defect can be reduced or eliminated; this usually is the treatment of choice to improve osseous architecture.

A new connective tissue attachment has formed and extends coronally from the apical border of the notch prepared at the surgically created bone crest to the apical termination of the apical junctional epithelium (aJE). (Courtesy of J Lindhe, Göteborg, Sweden.)

A study involving closure of edentulous spaces in the mandible was done on a group of patients ranging in age from 11 to 17 years, and the results were compared with those from a group of patients aged 23 to 46 years.[105] The results indicated that the older adults had more loss of crestal bone and greater root resorption than the younger patients.

MUCOGINGIVAL CONSIDERATIONS

During tooth movement, the periodontal tissues should maintain a stable relationship around the cervical area of the tooth. An adequate amount of attached gingiva is necessary for gingival health and to allow appliances (functional or orthopedic) to deliver orthodontic treatment without causing bone loss and gingival recession. Clinical experience and animal studies clearly have established that more pronounced, clinically recognizable inflammation occurs in regions with a lack of attached gingiva (Fig. 22-28, *A*) than in areas with a wider zone of attached gingiva (Fig. 22-28, *B*). Histologically, the teeth lacking gingiva were thinner in the buccolingual dimension than were those with a wide zone of attached gingiva; however, investigators reported that inflammatory cell infiltrate and its apical extrusion (degree of inflammation) were similar.[106,107] Two studies have indicated that as teeth are moved labially and tension is created on the marginal tissue, the thickness of the gingival tissue on the pressure side becomes important.[108] With labial bodily movement, incisors showed apical displacement of the gingival margin, but no loss of connective tissue attachment was apparent where there were no signs of inflammation. Where inflammation was present, loss of connective tissue attachment occurred.[60] Therefore, if the tooth movement is expected to result in a reduction of soft tissue thickness and an alveolar bone dehiscence may have occurred in the presence of inflammation, gingival recession is a risk. Obviously, all orthodontic cases involve gingival inflammation, and bodily facial movement can predispose the patient to gingival recession; a gingival graft can be used to prevent this.

Soft tissue graft used for gingival augmentation is performed before recession occurs. It is considered to be less traumatic and highly predictable, and it prevents recession during orthodontics. However, many periodontists still believe that with younger patients, a wait-and-see attitude is acceptable because so many predictable ways of correcting recession have become available. Root exposure is most likely to be progressive in a younger patient because labial bone loss may be impossible to correct; it is essential to prevent labial bone loss. For this reason, clinical judgment and animal studies support the need to create a thicker gingiva that can withstand the inflammatory insult better during tooth movement.

Thin, delicate tissue is far more prone to exhibit recession during orthodontics than is normal or thick tissue. If a minimal zone of attached gingiva or thin tissue exists (Fig. 22-29), particularly on abutment teeth, a soft tissue graft that enhances the type of tissue around the tooth helps control inflammation; this should be done before orthodontic movement is begun. The orthodontist also should evaluate differences in alveolar housing. That a thin, soft tissue is associated with a thin labiolingual osseous support is not necessarily true. All combinations are seen, such as thick, soft tissue with a thin labial plate of bone. To change the labial osseous thickness (especially the thin type) that is characteristic of the individual patient is difficult; however, to improve the soft tissue with a soft tissue graft is not difficult or traumatic. Obviously, the decision concerning prophylactic periodontal procedures must be made with consideration, among other things, for growth and development, tooth position, type and direction of anticipated tooth movement, oral physiotherapy, integrity of the mucogingival junction, tissue type, inflammation, muscle pull, frenum attachment, mucogingival and osseous defects, anticipated tissue changes, and profile considerations (Box 22-1).

Critical evaluation of the periodontium before orthodontic treatment begins can prevent, minimize, or at least avoid aggravation of an existing periodontal condition. Other areas that frequently involve conflicting periodontal management are frenum considerations, gingival hyperplasia, mouth breathing, and ectopically positioned teeth.

Mandibular Midline Frenum

When a frenum is associated with a mucogingival problem, it most often relates to an inadequate zone of attached gingiva. For this reason, the use of frenectomy to correct mucogingival problems is considered obsolete. The high frenum insertion contributes to movement of the marginal gingiva where the keratinized tissue has been lost or detached or where mechanical trauma exists. This problem is most prevalent in the lower anterior area.

Maxillary Midline Frenum

In the past, frenectomy has been recommended in the maxillary midline for young children on the grounds that the midline diastema is caused by the maxillary labial frenum. Many believe

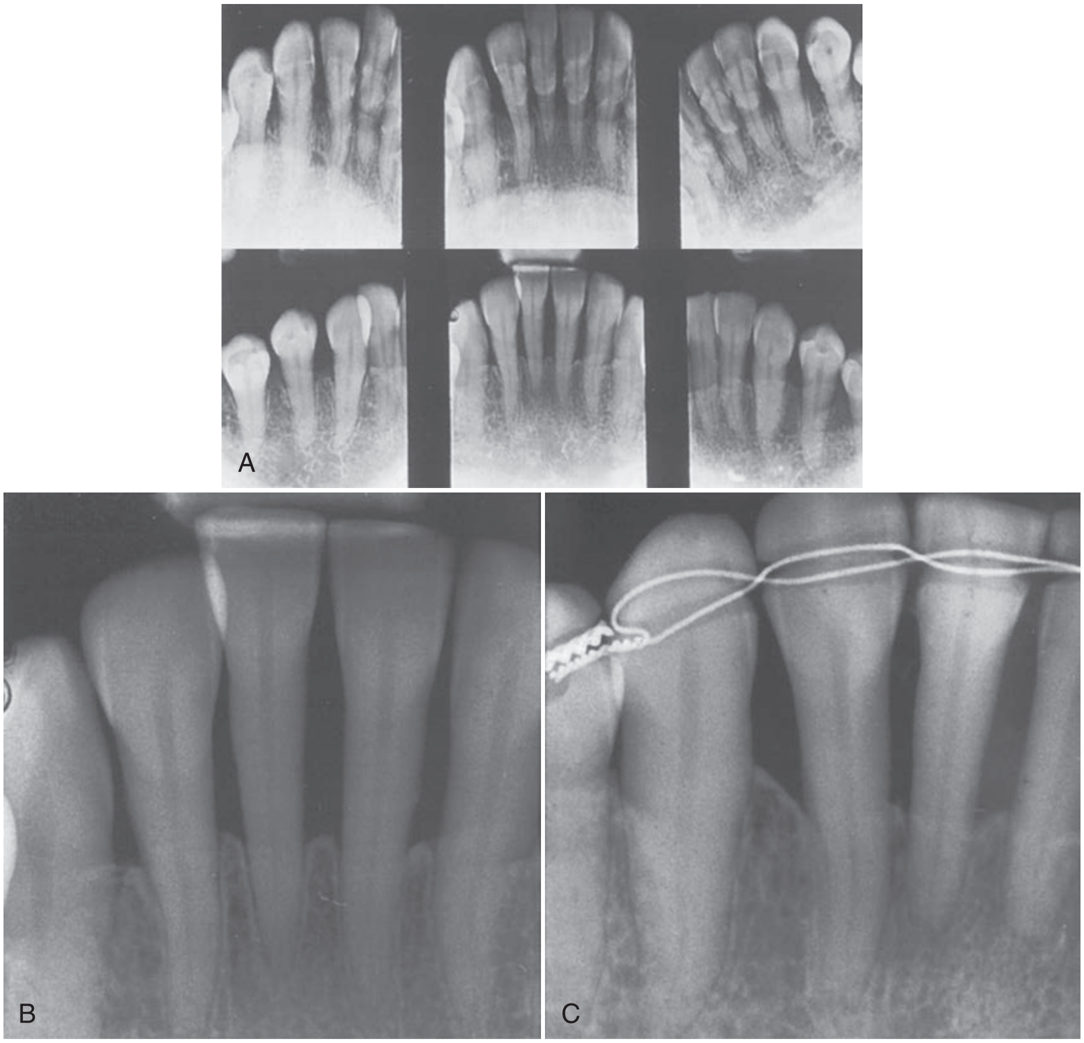

FIGURE 22-24 A, Radiographs of lower anterior teeth showing loss of bone before scaling. Lower radiographs were taken after scaling. Note that bone loss is horizontal (level alveolar crests) between the canine and incisor groups. The ideal way to reduce the overbite would have been to reduce the crowns with a high-speed bur and improve the crown-to-root ratio, keeping the bone level between adjacent teeth. Instead, the teeth were banded according to the incisal edge and were intruded. B, Preorthodontic periapical radiograph of lower anterior teeth before intrusion. Note the level alveolar crest between the canine and the lateral incisors. C, Periapical radiograph of lower anterior area after intrusion. Note that the cement-enamel junction is no longer level between the canine and the lateral incisors; however, a large angular crest has been created between those two incisors. An angular crest has been described as a predilected site for periodontal breakdown. (From Marks MH, Corn H, eds. *Atlas of Adult Orthodontics*. Philadelphia: Lea & Febiger; 1989.)

that this frenum prevents mesial migration of the maxillary central incisors and that it should be removed before orthodontic therapy is begun. Others have suggested that removal of the frenum allows the space to be closed more easily orthodontically. However, the practitioner must remember that a physiologic space normally is present between the maxillary central incisors until eruption of the canines in the adolescent dentition. In addition, a frenectomy may cause scar tissue that could prevent orthodontic space closure. With large diastemas (6–8 mm) in the early transitional dentition, a frenectomy usually is recommended to facilitate space closure, regain space at the midline, and prevent ectopic eruption of the lateral incisors or canines. These interceptive early treatment problems require complete orthodontic supervision, usually additional mechanotherapy, and several stages of treatment.

A U- or V-shaped radiographic appearance of the interproximal bone between the maxillary central incisors is a diagnostic key to the persistent midline diastema (Fig. 22-30). This radiograph of the mature midline suture with firm teeth before orthodontic treatment indicates that relapse will follow even excellent orthodontic treatment (i.e., no occlusal discrepancies, muscular habits, or problems; no tooth-size discrepancies; and ideal axial inclinations, overbite, and overjet). The patient should be informed before orthodontic treatment of the need for indefinite retention with bonding of the central incisors after treatment to prevent return of the maxillary midline diastema.

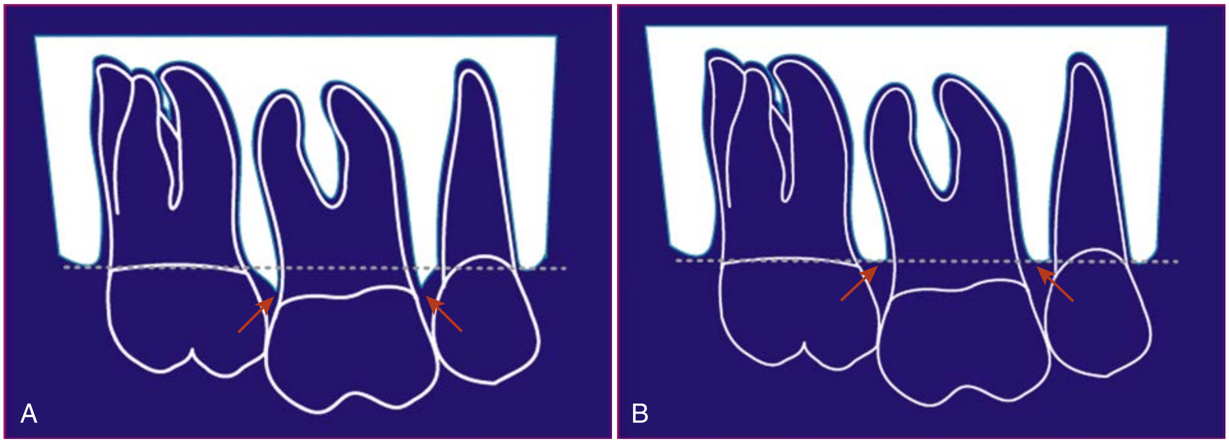

FIGURE 22-25 It is important to carefully evaluate the periodontal condition of the tooth to be intruded. **A,** Diagram of a healthy periodontium. The bone followed the tooth during extrusion. Intrusion mechanics are indicated, as the crestal bone will level after orthodontic movement. **B,** This diagram shows a periodontally compromised situation in which the bone has not followed the tooth during extrusion. If intrusion forces are applied, an angular crest defect may be created. Therefore, intrusion is not indicated in this situation.

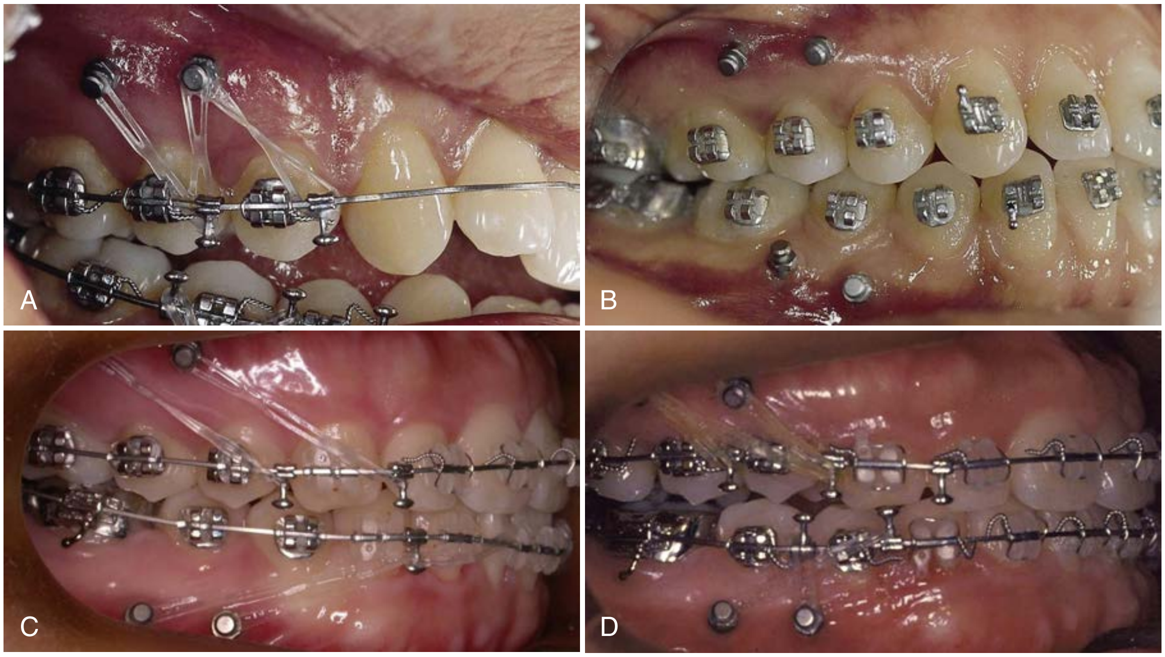

FIGURE 22-26 Intraoral images of two patients with healthy gingival tissues that underwent posterior intrusion. **A, C,** Before intrusion. **B, D,** After intrusion is completed. Note that the mucogingival junction remains unchanged, but there is a reduced amount of attached gingiva.

Generally, surgical removal of a maxillary labial frenum should be delayed until after orthodontic treatment unless the tissue prevents space closure or becomes painful and traumatized (Fig. 22-31). Removal may be indicated after treatment to change irreversible hyperplastic tissue to normal gingival form and to enhance posttreatment stability. This is particularly helpful on incisors during phase I of early treatment problems.

Gingival Hyperplasia

Mild gingival changes associated with orthodontic appliances seem to be transitory, and the periodontal tissues sustain little permanent damage.[109] Gingival hyperplasia usually resolves itself or responds to plaque removal, curettage, or both. If the gingival tissue or enlargement interferes with tooth movement, however, it must be removed surgically. Otherwise, waiting until the appliances are removed to correct surgically abnormal gingival form[110] and using the procedure to enhance posttreatment stability are preferable.

Gingival Retention and Aesthetic Considerations

Often tissue shows an exaggerated response to local factors, and gingival reflection with internal bevel incision (gingivectomy) can be done to promote stability and achieve optimal aesthetics and gingival topography (see Chapter 21). In

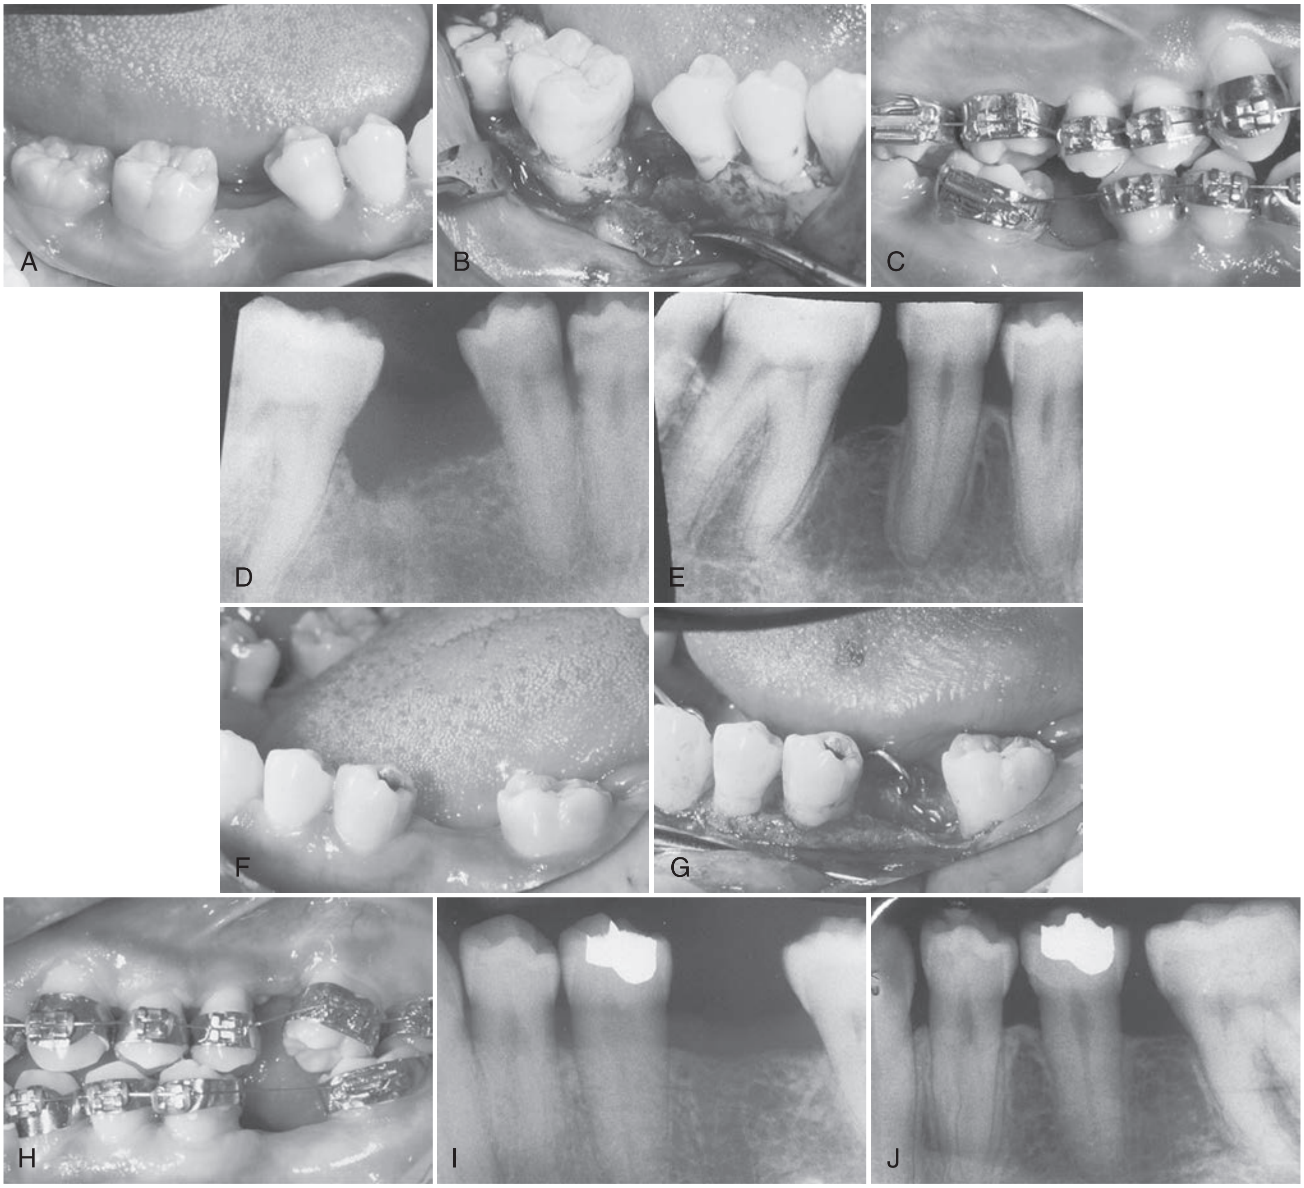

FIGURE 22-27 **A,** A 37-year-old man with bilaterally missing mandibular first molars. Note the evidence of bone loss on the mesial of the second molar during space closure. **F,** Lower left preorthodontic view of the side without a vertical defect in the ridge. **G,** Tissue reflected in the lower left (control side). Note that no defect is seen in the osseous ridge mesial to the second molar. **H,** Appliance placement on the left side to begin space closure. **I,** Periapical radiograph of the lower left side before space closure. Note the mesial attachment on the second molar. **J,** Periapical radiograph after space closure. No radiographic evidence of bone loss appears on the mesial of the second molar on the control side.

adults with altered passive eruption (APE), the gingival tissue fails to recede, and the patient thinks that the teeth are short (see Figures 22-3, *D,* 22-30, and 22-32). Many such patients have thick buccal alveolar bone that must be thinned by minor osteoplasty; if necessary, the clinician should establish a normal 1.5-mm relationship between the osseous crest and the CEJ. This prevents the return of the tissue incisally on the anatomic crown during healing. The operator should not do internal bevel gingivectomy and gingival reflection procedures on the labial aspect of anterior teeth that have thin gingival tissue. Also, the clinician should reflect tissue on bell-shaped anterior teeth only on the lingual or palatal aspect. The interdental tissue in these two instances may not heal back to the level of the contact points, creating an unaesthetic result. Spaces below the contact points are disturbing to the patient.

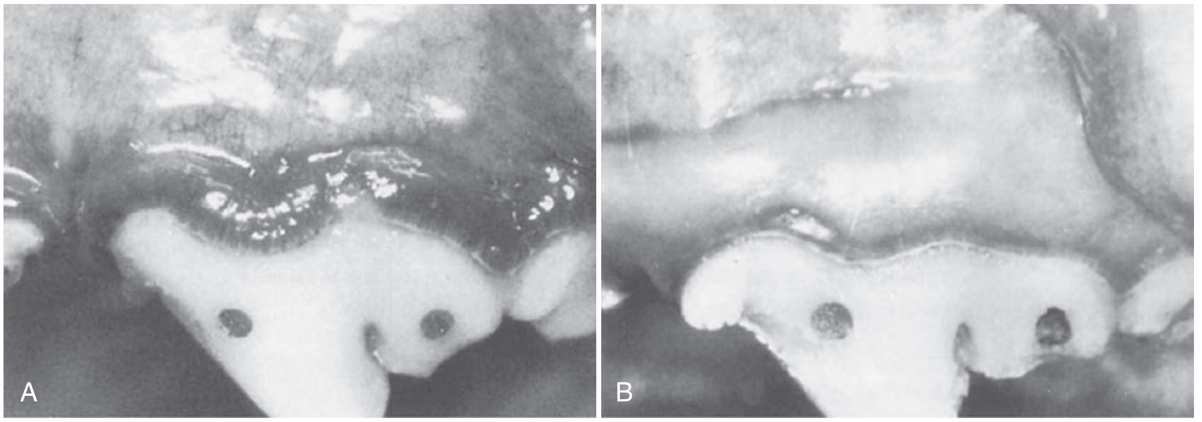

FIGURE 22-28 Teeth in a dog after 40 days of plaque accumulation. The clinical signs of inflammation are more pronounced at the site with the narrow band of gingiva (**A**) than at the site with a wide zone of attached gingiva (**B**). The vascular system is believed to have been more readily visible in its thinner units that lack gingiva. (From Lindhe J. *Textbook of Clinical Periodontology*. Copenhagen: Munksgaard; 1989.)

FIGURE 22-29 **A,** Inadequate attached gingiva on the lower central incisors of an 8-year-old girl. The signs of inflammation are pronounced, especially on the left central side; a free graft should be placed before early treatment protocols are begun. **B,** Donor tissue from the palate in place. **C,** Postoperative result before treatment was begun.

BOX 22-1 Diagnostic Considerations in Case Selection for Grafting before Orthodontic Treatment

- Growth and development
- Tooth position
- Oral physiotherapy
- Types of hard and soft tissues
- Inflammation
- Integrity of the mucogingival junction
- Mucogingival and osseous defects
- Type and direction of anticipated tooth movement
- Tissue changes associated with tooth movement
- Profile considerations
- Mechanotherapy to be used
- Patient cooperation

Fiberotomy

Fiberotomy[111,112] should be done after any preorthodontically rotated teeth have been corrected, especially maxillary and mandibular anterior teeth (e.g., maxillary lateral incisors with Class II, division 2 problems). The procedure should be done before debonding after mild overcorrection (3–5 degrees). The overcorrection is removed 1 week after the surgical procedure and before impressions for retainers are taken (Fig. 22-33). Internal bevel gingivectomy or labiolingual flap reflections with interproximal sutures (see Chapter 21) enhance alignment and reduce labiolingual and vertical dental relapse. These procedures should be done before fixed appliances are removed.

Mouth Breathing

A significant problem in orthodontic patients is the added periodontal insult of mouth breathing. The drying effect on the exposed tissue in susceptible patients is associated with enlarged, erythematous labial gingivae, particularly in the maxillary and mandibular anterior regions. With a short upper lip, a demarcation line usually can be seen where the lip contacts the labial tissue (Fig. 22-34). Mouth breathers usually have dry, cracked lips as well. Although orthodontic retraction of anterior segments may help provide a better lip seal, extraoral appliances and lip bumpers exacerbate the problem and even may cause mouth breathing in a normal patient. A patient who shows symptoms of an inability to breathe properly (tongue posture; enlarged adenoid tissue; narrow, high palatal vault; allergies) should be referred for evaluation for nasal obstruction and adenoid tissue. Although the plaque index is not significantly higher in mouth breathers, an increase in the gingival index has been reported.[113] This increased inflammation should be

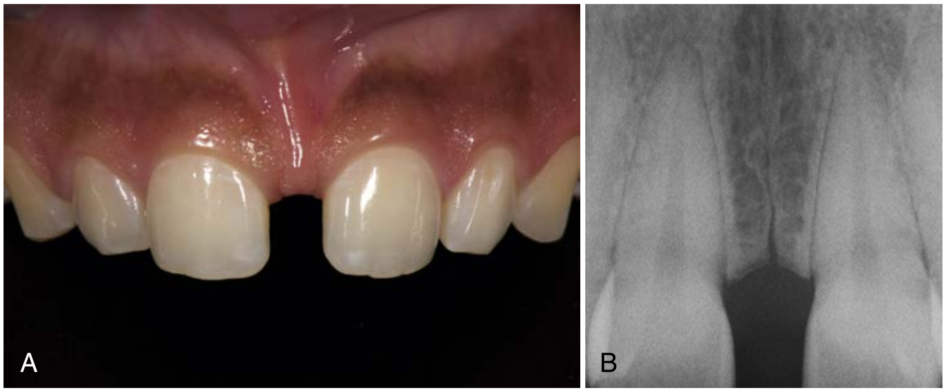

FIGURE 22-30 **A,** Clinical appearance of a persistent midline diastema in a 22-year-old woman. **B,** Radiographic appearance of midline interdental bone before orthodontic treatment, showing a V-shaped suture, which is the diagnostic key to potential relapse.

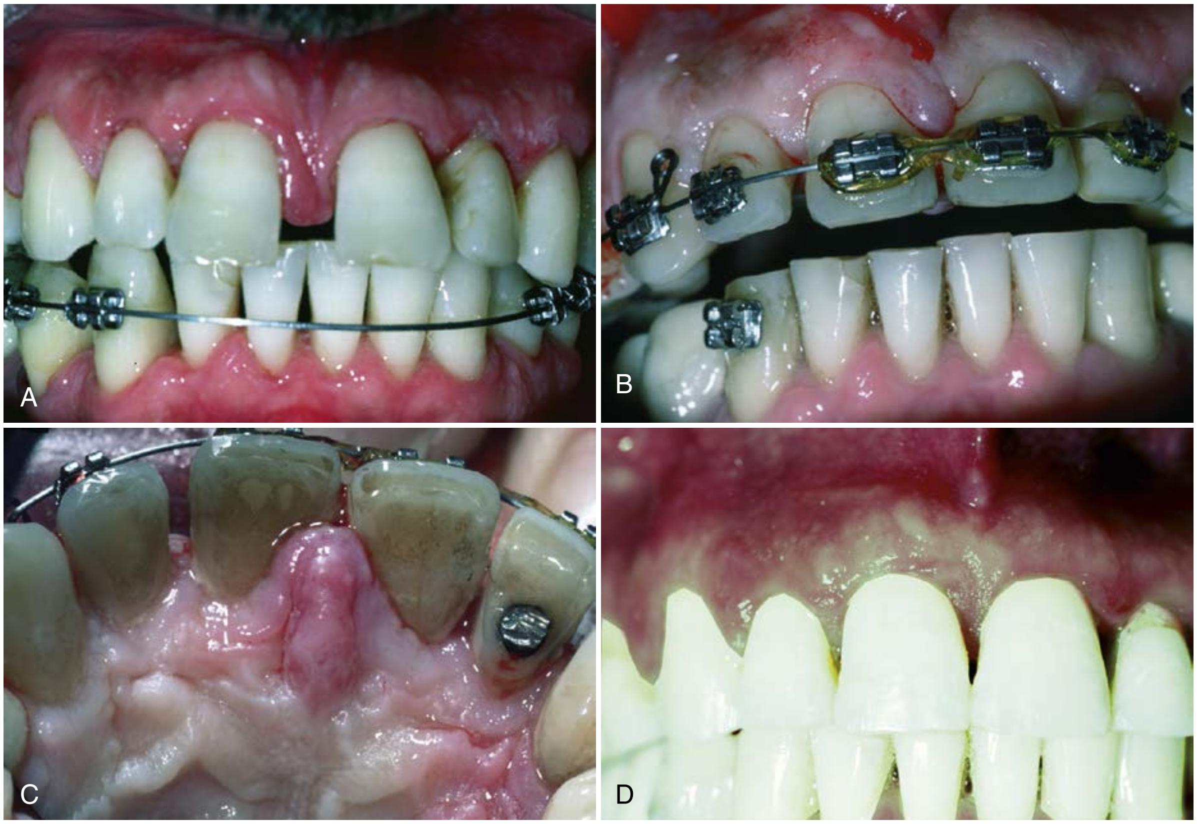

FIGURE 22-31 **A,** Preorthodontic diastema of a 40-year-old man with significant periodontal disease and loss of posterior support. **B, C,** During closure of the midline diastema, the soft tissue became enlarged and sore and prevented complete space closure. A frenectomy was performed to remove the frenum, which allowed completion of tooth movement. **D,** Midline area after completion of tooth movement and reestablishment of posterior support.

reduced to a minimum before fixed appliances are placed, and this usually is accomplished by scaling and curettage.

CONSIDERATIONS WITH ECTOPICALLY POSITIONED AND UNERUPTED TEETH

Many orthodontic patients have teeth that have not penetrated the oral mucosa or that will not erupt. Certain teeth demonstrate eruption that has been delayed significantly beyond the time when normal dental eruption for a particular patient should have occurred. Clinical orthodontists who have treated cases involving unerupted teeth have faced the problems of devitalization, reexposure or reuncovering of a tooth, ankylosis, external root resorption, and injury to adjacent teeth when an unerupted tooth has been surgically uncovered from the wrong side of the alveolar ridge. The marginal bone loss, gingival recession, and sensitivity problems that occur after the roots have been exposed are

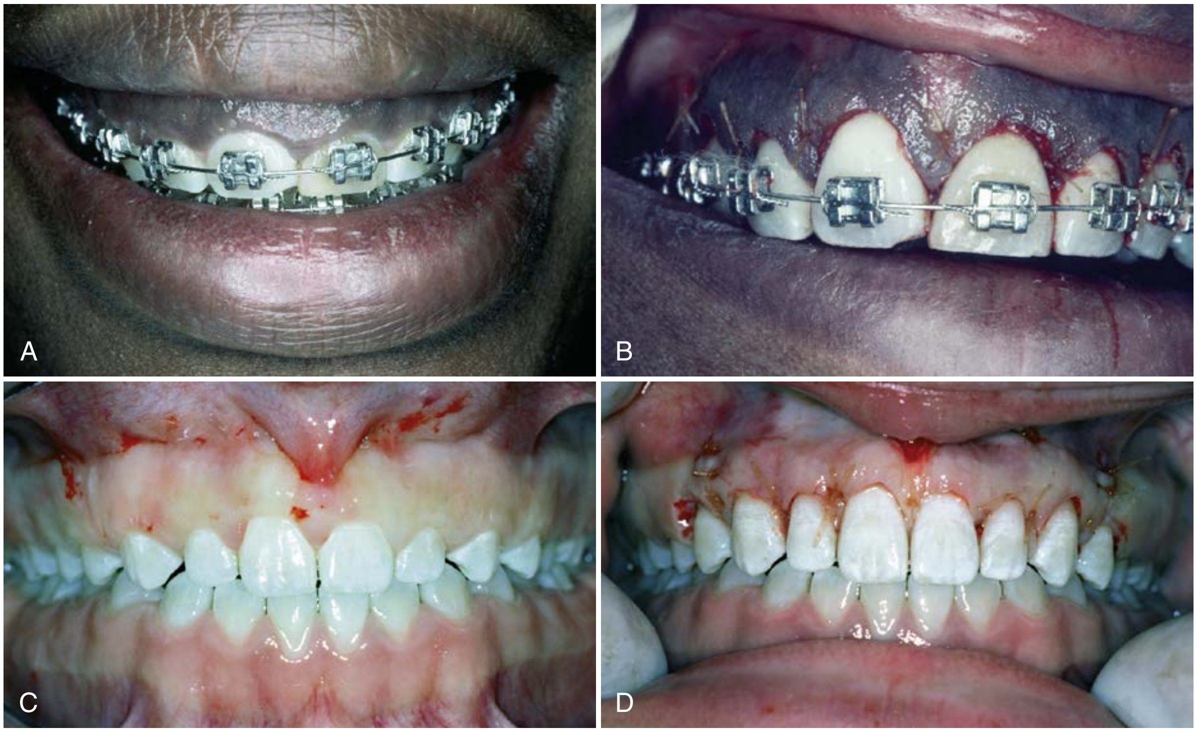

FIGURE 22-32 **A,** A 37-year-old woman who complained of short teeth. The woman has a normal vertical dimension and upper lip length. **B,** Note the normal-sized anatomic crowns at the time an internal bevel gingivectomy was performed for aesthetics and stability. **C,** A 14-year-old girl with short clinical crowns. **D,** After gingival tissue removal.

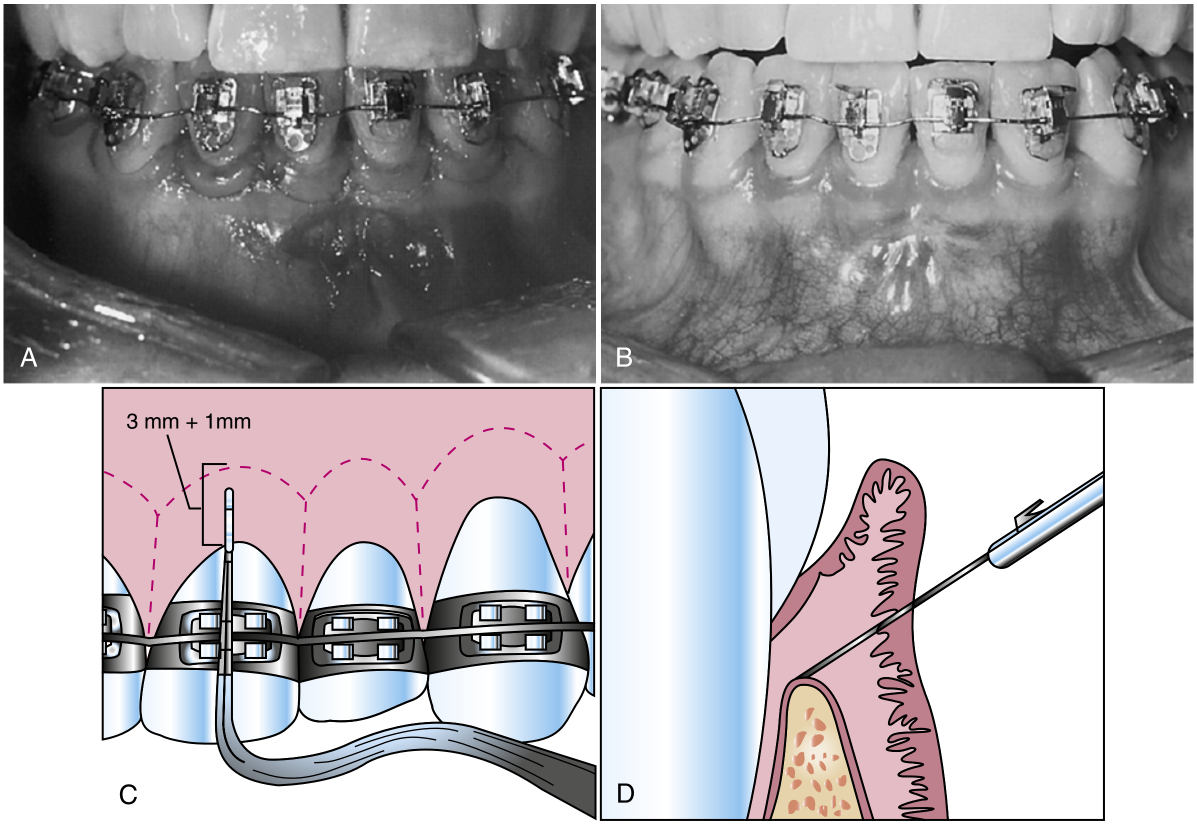

FIGURE 22-33 **A,** Mild overcorrections have been done for the mandibular incisors. Sounding-type incisions are made through the incisal papilla to bone and are angled toward the tooth. The interproximal incisions are joined labially in an attempt to sound out the osseous crest. Incisions are made on the lingual aspects as well. In this case, a mandibular frenum was released so that the tissue would not be retracted on the labial aspect of the central incisors. **B,** Two weeks after surgery; overcorrections will be removed. **C,** Representation of probing to establish bleeding points. **D,** Diagram of sounding incision made at a 45-degree angle to the long axis of the tooth. FIGURE 22-34 Exaggerated response to mouth breathing. Note the lip line over the central incisors, where the lip covers the labial gingiva. Enlarged gingival tissue harbors dentobacterial plaque, and the deeper pseudo-pocket acts as a reservoir for retention of subgingival plaque.

complications that invariably result in prolonged treatment time, aesthetic deformities, and in many cases, loss of teeth (Fig. 22-35, *A–E*). Most of these problems (i.e., reexposure, gingival recession, and bone loss) can be prevented. Proper management of the periodontal tissues is crucial in preventing loss of attachment. For example, one should not use electrosurgery or lasers to uncover teeth. These techniques have attracted considerable attention recently, but they should be used strictly to remove the overlying tissue; excision of the surrounding tissue on the unerupted tooth leaves inadequate keratinized tissue.

Vermette et al.[114] found no difference in periodontal attachment levels between control teeth and teeth uncovered by an apically repositioned flap or a closed surgical technique. However, they reported that teeth uncovered by apically repositioned grafts had more gingival scarring, were less aesthetic, and experienced intrusive relapse more often than did a group of teeth subject to closed eruption or flap replacement. These findings were not in agreement with the study by Kim et al.[115] on labially apically repositioned flaps, in which it was concluded that ectopically positioned maxillary canines treated by apically positioned flap techniques had satisfactory results for periodontal, radiographic, aesthetic, and endodontic outcomes compared with orthodontically moved control teeth. Periodontally, the control teeth had normal values, and there were no significant differences in plaque index, gingival index, pocket depth, width of attached gingiva, and clinical crown length between the treated teeth and control teeth. Aesthetically, there were no differences in recession, scarring, and texture of gingiva. Radiographically, control teeth had normal crestal and bone support values. Furthermore, reflecting a surgical flap, bonding an attachment with a gold chain, and suturing the flap over the crown always prolongs the treatment time, requires additional surgical procedures, diminishes control of tooth movement, and may cause adverse periodontal responses (Fig. 22-35, *F* and *G*). Localization and the exact position of the tooth must be known before the tooth is uncovered surgically. Palpation, evaluation of the teeth in the arch, CBCT, panoramic radiographs, periapical views, and occlusal or cephalometric evidence can be helpful.

Labial impactions should not be uncovered unless keratinized tissue is placed on the tooth. It should not have a free gingival graft placed on it; free gingival grafts do not survive on enamel.

Surgical Technique

The preferred surgical procedure is primarily an apically or laterally positioned pedicle graft[116] (Fig. 22-36). The maxillary incisors can be done nicely from an orthodontic standpoint. When uncovering a tooth, the orthodontist should create a space in the arch before uncovering the tooth if the tooth is on the labial aspect of the arch. The edentulous space created in the arch provides a tissue area to act as a donor site so that an adequate zone of attached gingiva can be taken for the partial thickness of the apically or laterally positioned graft. If space is unavailable between the teeth in the arch, the clinician may place a free graft at the mucogingival junction and convert it into a pedicle graft to be placed on the unerupted tooth. Whenever the tissue for a particular patient is so thin that it cannot be dissected away as a partial-thickness graft, one can place a free graft at the mucogingival junction. Grafts should be partial thickness; the orthodontist should express this preference to the periodontist or oral surgeon because full-thickness grafts are thick and unaesthetic.

Large dental follicles often occur, especially on maxillary canines in 9- or 10-year-old children, before the teeth have erupted from the palate. When these enlarged dental follicles are resorbing hard tooth structure in the arch (i.e., the roots of teeth), they must be uncovered (Fig. 22-37). Even though the follicles may not have more than 50% root formation at that point, the clinician should uncover the canine and place a bonded attachment. The orthodontist should move the canine into contact with the palatal mucosa, take off the attachment, and allow the root to continue to develop on the canine. If the canine is not uncovered and brought into contact with the oral cavity, the enlarged follicle usually continues to resorb the roots of the incisor teeth. If the palatal tissue is allowed to recover, it begins to resorb the tooth structure again.

The question often arises whether a tooth will erupt into the arch. The real key is the incisal edge; if the incisal edge is headed away from the occlusal plane or if the tooth is upside down, it will not erupt into the oral cavity. If a tooth is erupting slowly or if it is holding up treatment time, it should be surgically uncovered and orthodontically positioned into the arch. The most difficult canine is the canine that erupts between the roots of a premolar, particularly a maxillary first premolar with a bifurcated root (Fig. 22-38). The orthodontist should evaluate the periapical radiograph closely for this type of premolar root form. When the canine erupts and lodges between the roots of a bifurcated first premolar, it is difficult to uncover without getting into the apices of the premolar. This is true whether the canine is uncovered from the palatal or labial side of the arch. In this situation, the premolar would have to be extracted to salvage the maxillary canine (see Fig. 22-38, *E* and *F*). Labial impactions are much less difficult to manage if a soft tissue grafting procedure is used (Fig. 22-39).

Maxillary Palatal Impactions

With maxillary palatally positioned canines, which occur three times more often than labially malposed canines, the problem is different. Because the palate is all masticatory mucosa, a graft is not placed on the teeth. To uncover these teeth, the orthodontist reflects the palatal tissue, places a window, and replaces the tissue over the palate (Fig. 22-40). A periodontal dressing is

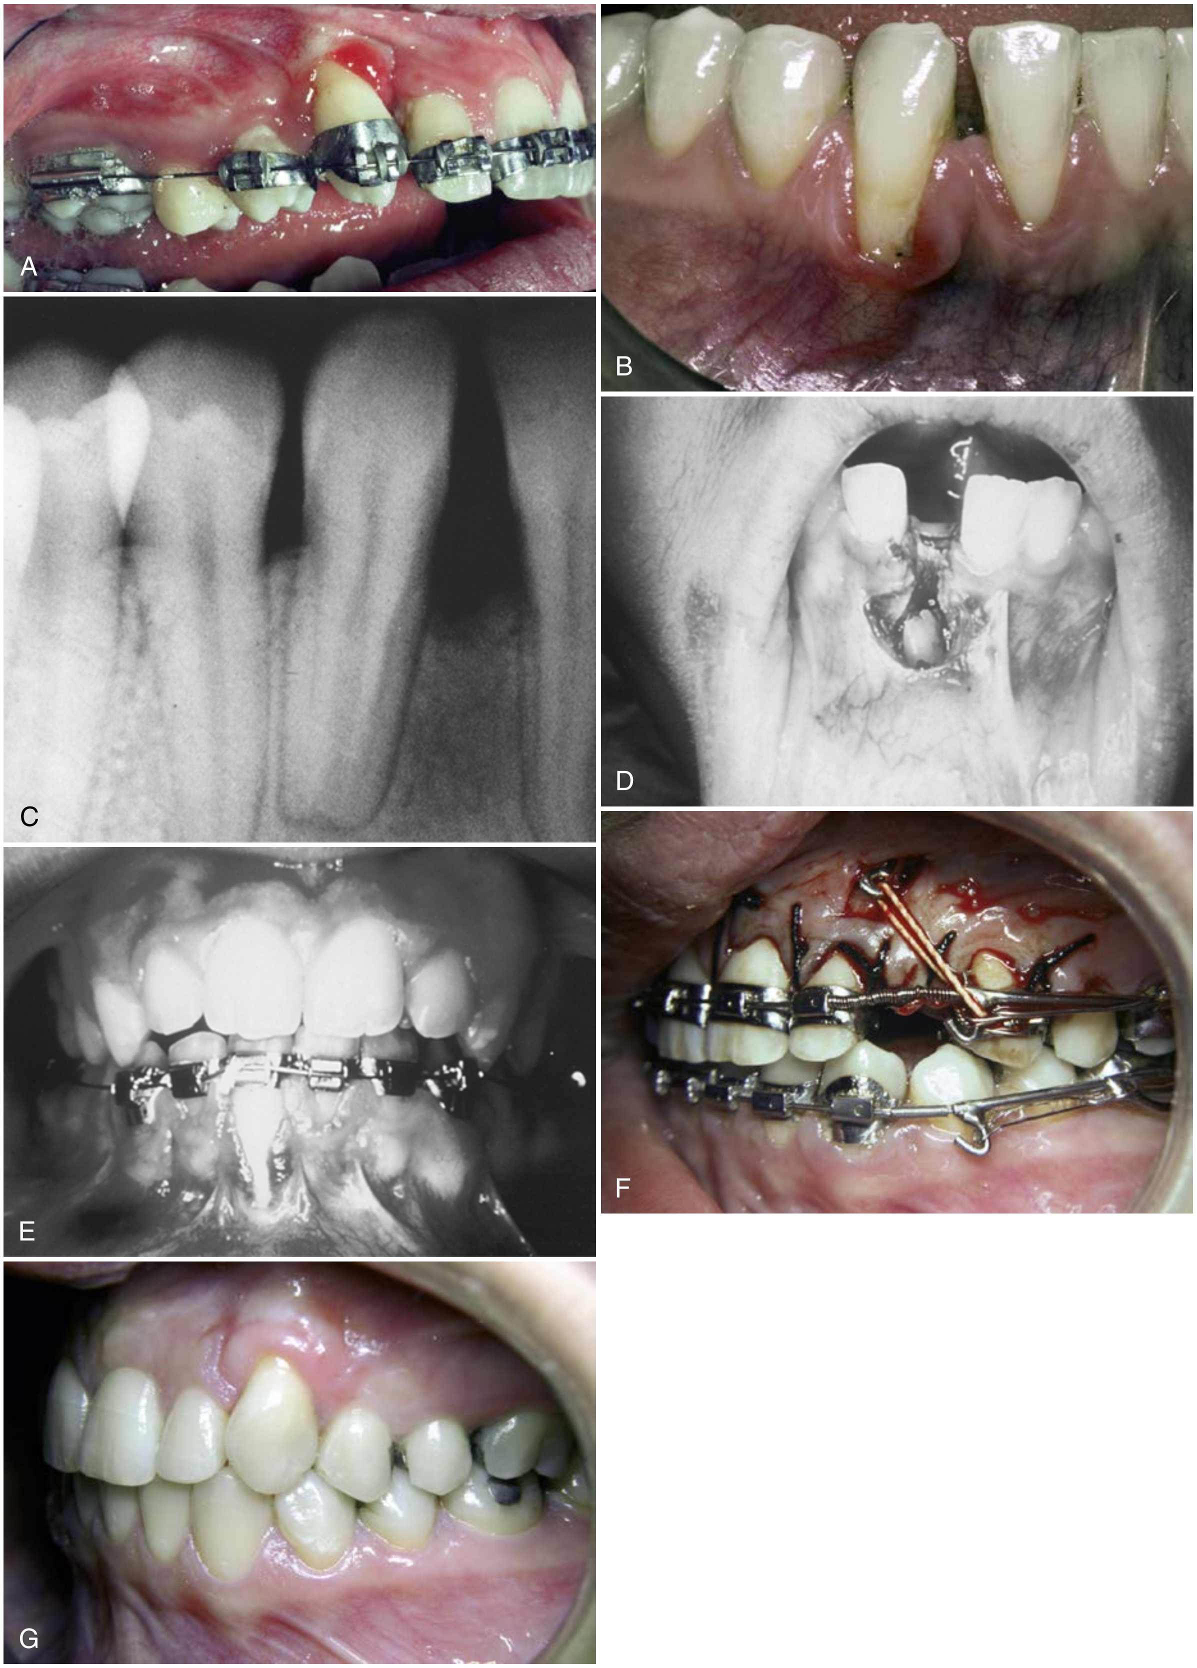

FIGURE 22-35 **A,** A typical aesthetic and recession problem on a maxillary canine that was surgically uncovered without keratinized tissue being placed on the tooth. **B,** Clinical appearance of a previously unerupted and surgically uncovered mandibular canine. Note the absence of attached gingiva and the gingival recession; the tooth is an aesthetic concern to the patient. **C,** A periapical radiograph reveals marginal bone loss of one-third of the alveolar support and root blunting. These complications could have been prevented. **D,** Surgical uncovering involved extraction of the primary tooth and removal of all overlying soft and hard tissue. The surgery did not provide for attached gingiva over the labial of the tooth. **E,** An undesirable response, with recession and loss of attachment as the tooth is guided into the arch. **F,** The maxillary canine was uncovered, an attachment was placed, and the flap was sutured back into place. An elastic was used, with the objective of guiding the tooth into the zone of keratinized tissue. **G,** When a tooth is covered over with soft tissue, it is difficult to guide into the zone of keratinized tissue. Note the root exposure and recession after the tooth has been positioned in the arch with a flap replacement procedure.

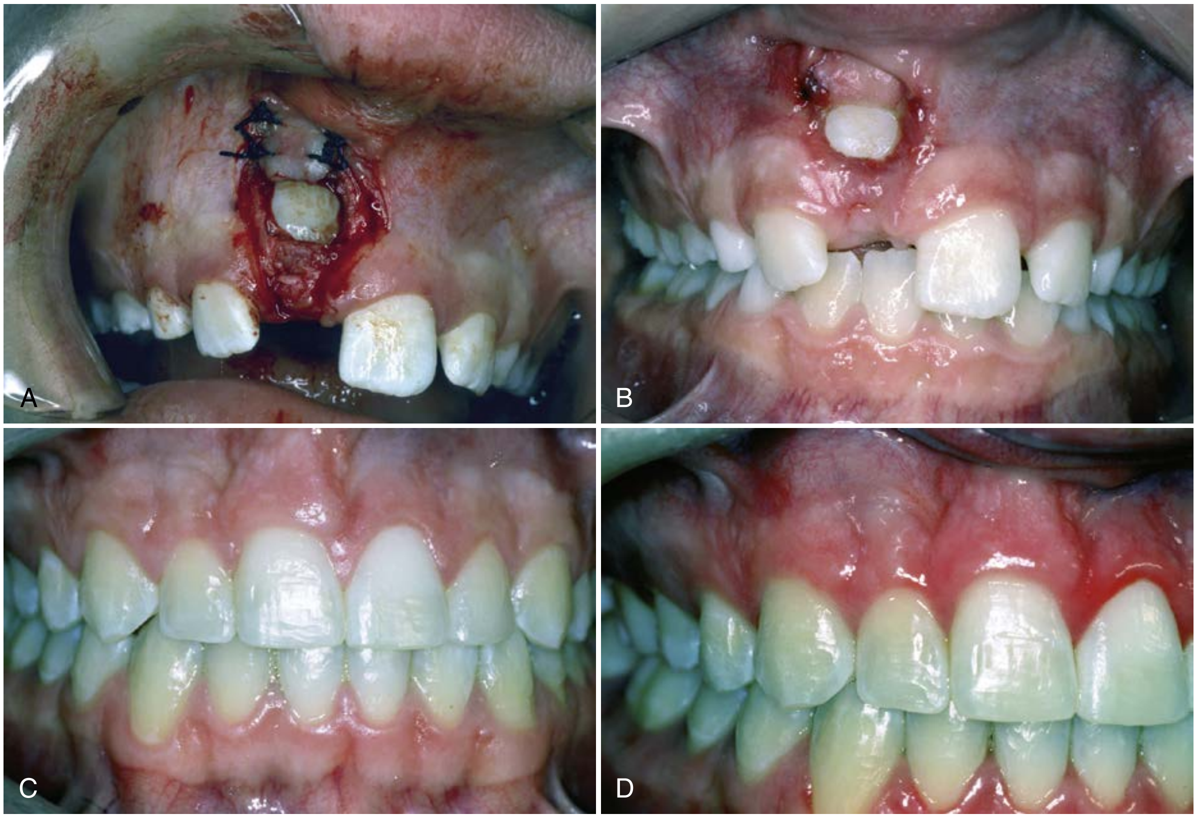

FIGURE 22-36 **A,** A right central incisor was uncovered surgically, and an apically positioned partial-thickness pedicle graft was placed on the cervical area of the anatomic crown. **B,** Several months later. Note that normal eruption has occurred without the use of an appliance. **C,** From the anterior view several years after orthodontic treatment, the gingiva has the same appearance on both central incisors. Detecting that the tooth was grafted is impossible, and normal periodontal support is present. **D,** Right lateral view of the incisor 10 years after surgery.

kept in place for 7 to 10 days, and then the orthodontist places a bonded attachment and begins tooth movement. It is important to postpone the bonded attachment, to allow the periodontal tissues (hemidesmosomal attachment) to heal around the CEJ and protect it from the acid etch during bonding, which might damage the PDL cells of the tooth side and induce ankylosis.

A major orthodontic principle that applies to palatal canines is the importance of using a sufficiently large base arch (at least an 0.018-inch or a rectangular stainless steel base arch). The base arch must be large enough to prevent deflection of teeth in the maxillary arch into the opposing occlusion each time the patient closes the mouth. Devitalization of lateral incisors often occurs when a flexible, multistranded base arch or a light nitinol base arch is used; when the palatally impacted tooth is activated over a long period, it deflects teeth (particularly maxillary lateral incisors) into the opposing occlusion. Lateral incisors also can be devitalized by occlusal trauma. In adults, the primary teeth are left in place until the palatally displaced tooth has been moved close to the arch; the primary tooth then is taken out. After removing the primary tooth, the orthodontist places an acrylic pontic on the archwire for aesthetics.

The orthodontist must evaluate palatally impacted teeth constantly for bleeding around the crown and active bleeding around the tooth; ideally, this is done with a curette. If excess bleeding is noted, the orthodontist should refer the patient back to the general dental office or to the periodontal office for periodic scaling and curettage to remove bacteria from the subgingival area. Bacterial buildup occurs because of the depth of the palatal tissue around unerupted teeth. Otherwise, a small chance exists of loss of attachment on a palatally impacted tooth. At each visit, the orthodontist should check any tooth that has been uncovered surgically for excessive mobility. In many instances, the dental follicle can grow aggressively around the erupting tooth that has been uncovered and can displace or detach the graft from the crown on labial impactions. The follicle also can cause bone loss around the entire tooth as the tooth is moved into the arch.

If excessive mobility is observed, the orthodontist must refer the patient to the periodontist to find out whether bone is following the erupting tooth. An x-ray examination should be done to determine whether osteoid tissue is present and to ensure that the periodontal attachment is following the tooth as it is guided into the arch. To aid eruption of a deeply positioned palatal impaction, a 0.012- or 0.014-inch stainless steel wire should be twisted until taut directly across the palate from the canine or premolar area to the premolar area on the opposite side of the arch. The authors do not recommend the use of auxiliary springs because these springs tend to overextrude the canine. The orthodontist uses an explorer to tighten the wire with a Spanish windlass technique and then places the attachment on the palatally positioned tooth and ties a power thread from a tooth to the wire that goes across the palate. The force

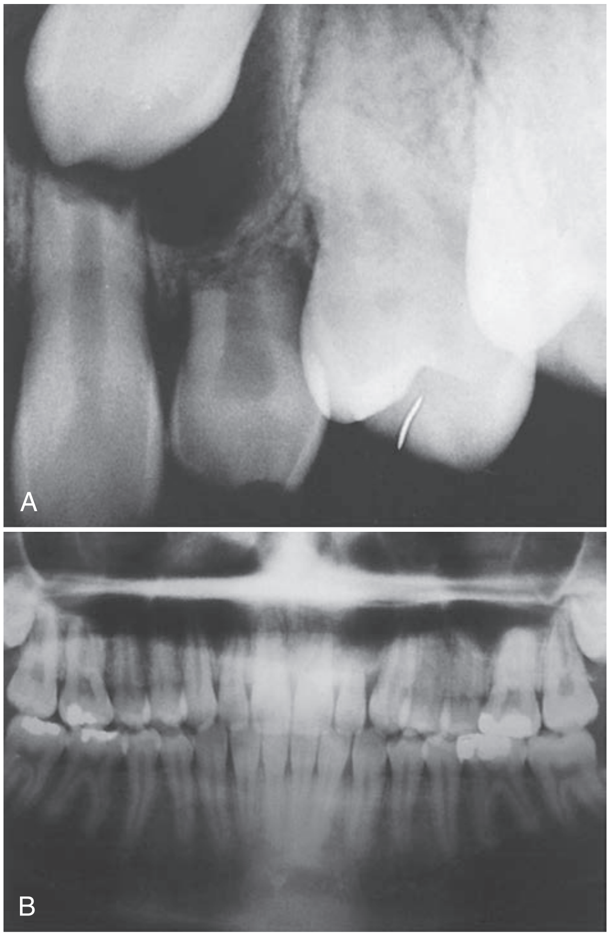

FIGURE 22-37 A, Periapical radiograph shows more than 50% resorption of the root of a lateral incisor. The crown of the canine had to be uncovered surgically and kept in contact with the oral cavity. B, Panoramic radiograph shows no further resorption of the lateral root in the finished case.

is directed so as to erupt the tooth into the palate out of the palatal soft tissues (Fig. 22-41). The orthodontist then rotates the tooth and moves it directly into the arch. If palatal tissue recovers the tooth and the tooth erupts through the palatal tissue into the arch, treatment time is prolonged by many months. Therefore, the tooth should be erupted within 7 to 10 days after the surgical procedure and should be erupted down out of the thick tissue and brought to the level of the palatal contour. At this point, the orthodontist can determine whether the tooth is backward and needs to be rotated; rotational movement should be initiated immediately (even in the center of the palate) as the tooth is moved toward its proper position in the arch.

Second Premolar and Second Molar Impactions

After the canines, the second premolar is the tooth that most often requires surgical uncovering. As with mandibular premolars, apically repositioned grafts are necessary. If the tooth is located on the lingual, the graft is placed on the lingual only. If the tooth is in the center of the arch (an occlusal radiograph is needed to locate these teeth before they are uncovered), an apically positioned graft on the facial and on the lingual is required (Fig. 22-42). Ideally, the orthodontist should give the surgeon as much assistance as possible in determining the location of teeth, as well as any special information about the surgical uncovering. With the mandibular molars, one also must do a buccal and a lingual graft when these teeth are located in the middle of the ridge. The osseous surgery must allow the graft to be placed onto the enamel on the buccal and lingual aspects of the anatomic crown.

Incisor Impactions

Less often, a mandibular incisor (or several mandibular incisors) may need to be uncovered. With mandibular incisors, a labial and a lingual graft must be done, and these grafts must be extended beyond the line angle of each crown (Fig. 22-43). If the grafts are not placed beyond the line angle of the unerupted tooth, a mucogingival defect may be created on the line angle, whether it is on the lingual or the facial aspect, even when teeth are in the center of the ridge.

As persons get older, the teeth tend to become ankylosed, particularly as an individual reaches the 30s and 40s; radiographs can reveal this complication. A radiograph of a tooth that appears to fade into the bone indicates ankylosis (Fig. 22-44). Teeth with this radiographic appearance should be considered hopeless, and no attempt should be made to bring them into the oral cavity. All unerupted teeth cannot be salvaged, and the prognosis may be poor. Certain impacted teeth, even the canines, should be extracted. However, the number of successfully treated unerupted teeth can be increased by proper management of the tissues attached to these teeth. Protecting the marginal integrity of the attachment apparatus and preventing an apical shift of the dentogingival junction result in fewer aesthetic deformities and a more favorable long-term prognosis; these goals can be accomplished most effectively by using a pedicle graft, as has been described.

Ankylosis and External Root Resorption

In addition to surgical procedures and orthodontic management of unerupted teeth, impacted teeth present other, more perplexing problems.[117] Most clinicians have been confronted with ankylosis of deciduous and permanent molars in the primary and transitional dentition. Some permanent teeth that have been exposed to the oral cavity are ankylosed. The most common cause of ankylosis generally is believed to be trauma to a tooth. External root resorption commonly is associated with tooth replantation. Many reports have discussed the possible causative factors associated with ankylosis.[118–121]

All too often a clinical orthodontist has ordered extraction of teeth with the expectation of bringing an unerupted tooth into the arch. The oral surgeon exposes the unerupted tooth, and later the orthodontist finds that the tooth will not move. After repeated attempts at luxation, with ankylosis returning, the surgeon removes the tooth. The statement "One in the mouth is worth two in the gums" may seem to apply.

A high incidence of tooth ankylosis and external root resorption reportedly has been associated with impacted teeth that have been uncovered and ligated with dead soft stainless steel at the CEJ area[122,123] (Fig. 22-45). This procedure,[124] first reported in 1942, was extensively used before bonding.[125,126] Use of the wire loop has been called the "simplest and most often used means of attachment . . . of an unerupted tooth."[127]

However, to tighten a wire placed in the cervical third of an impacted tooth and not impinge on the normal CEJ–alveolar bone relationship requires an extreme amount of surgical

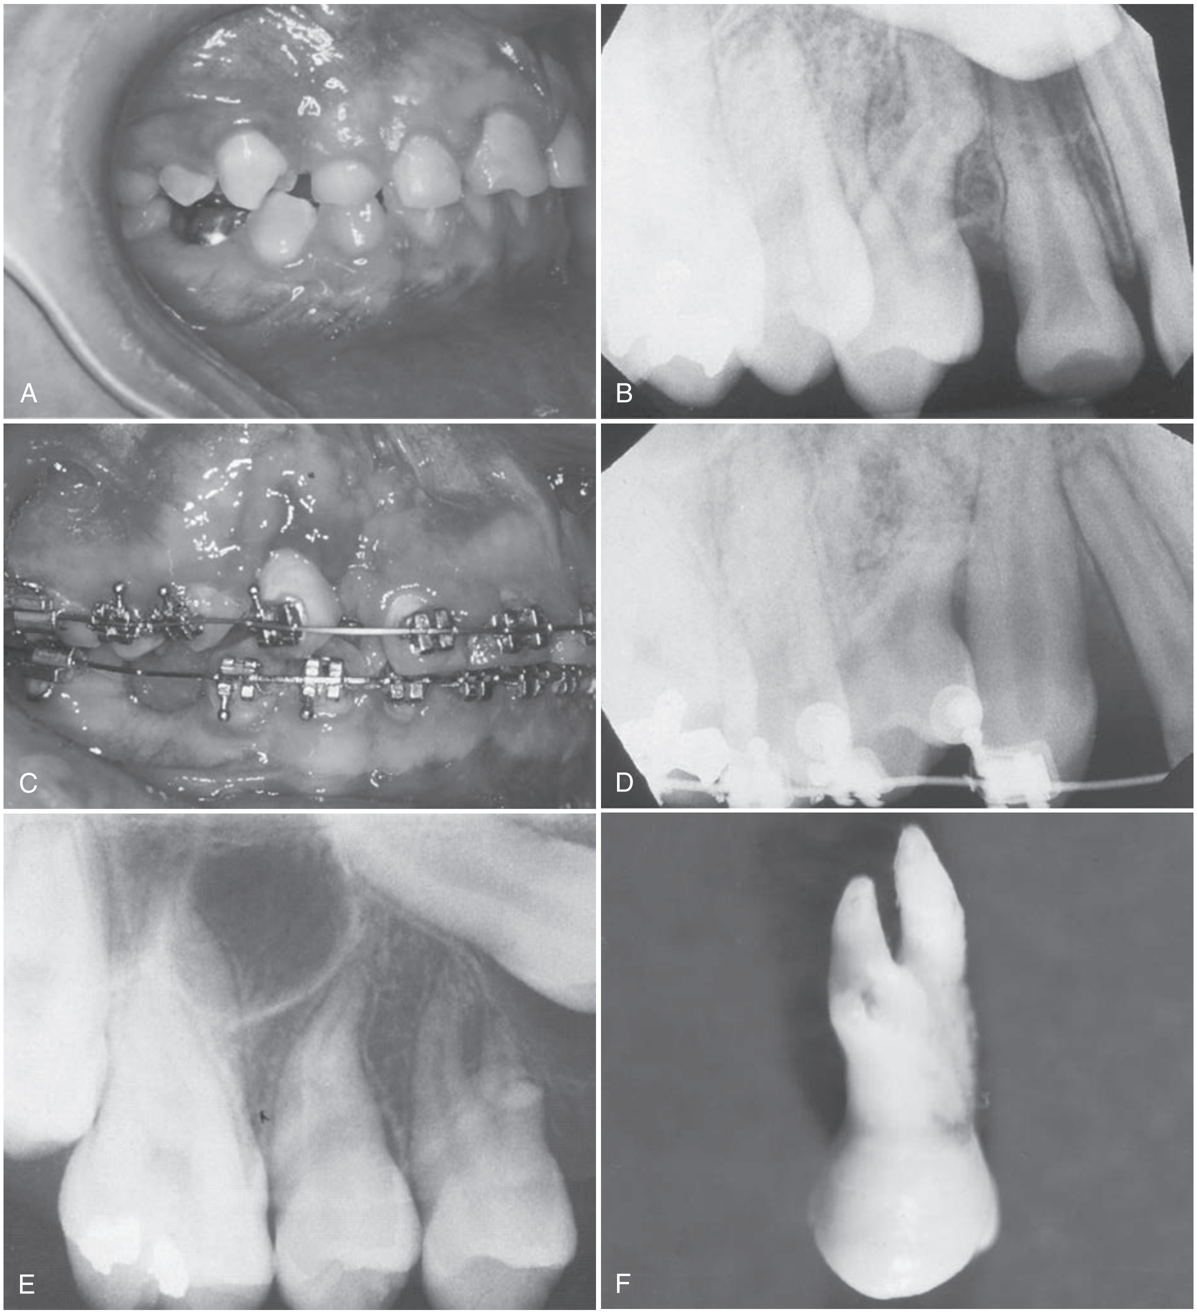

FIGURE 22-38 **A,** Right clinical view of a primary canine still in position before appliances were placed. **B,** On this preoperative periapical radiograph, note the bifurcated first premolar root with the maxillary right canine lodged between the roots. **C,** Several years later, the tooth has been guided anteriorly from the labial into the arch. This is an adolescent boy whose oral hygiene, despite constant reinforcement, remained inadequate; note the significant gingival hyperplasia. **D,** Progress periapical film indicates possible loss of attachment, although the probing depth is minimal. **E,** A young girl with an unerupted maxillary right canine. A pretreatment periapical radiograph shows a bifurcated first premolar. This root form can complicate and prolong treatment. **F,** The premolar was extracted.

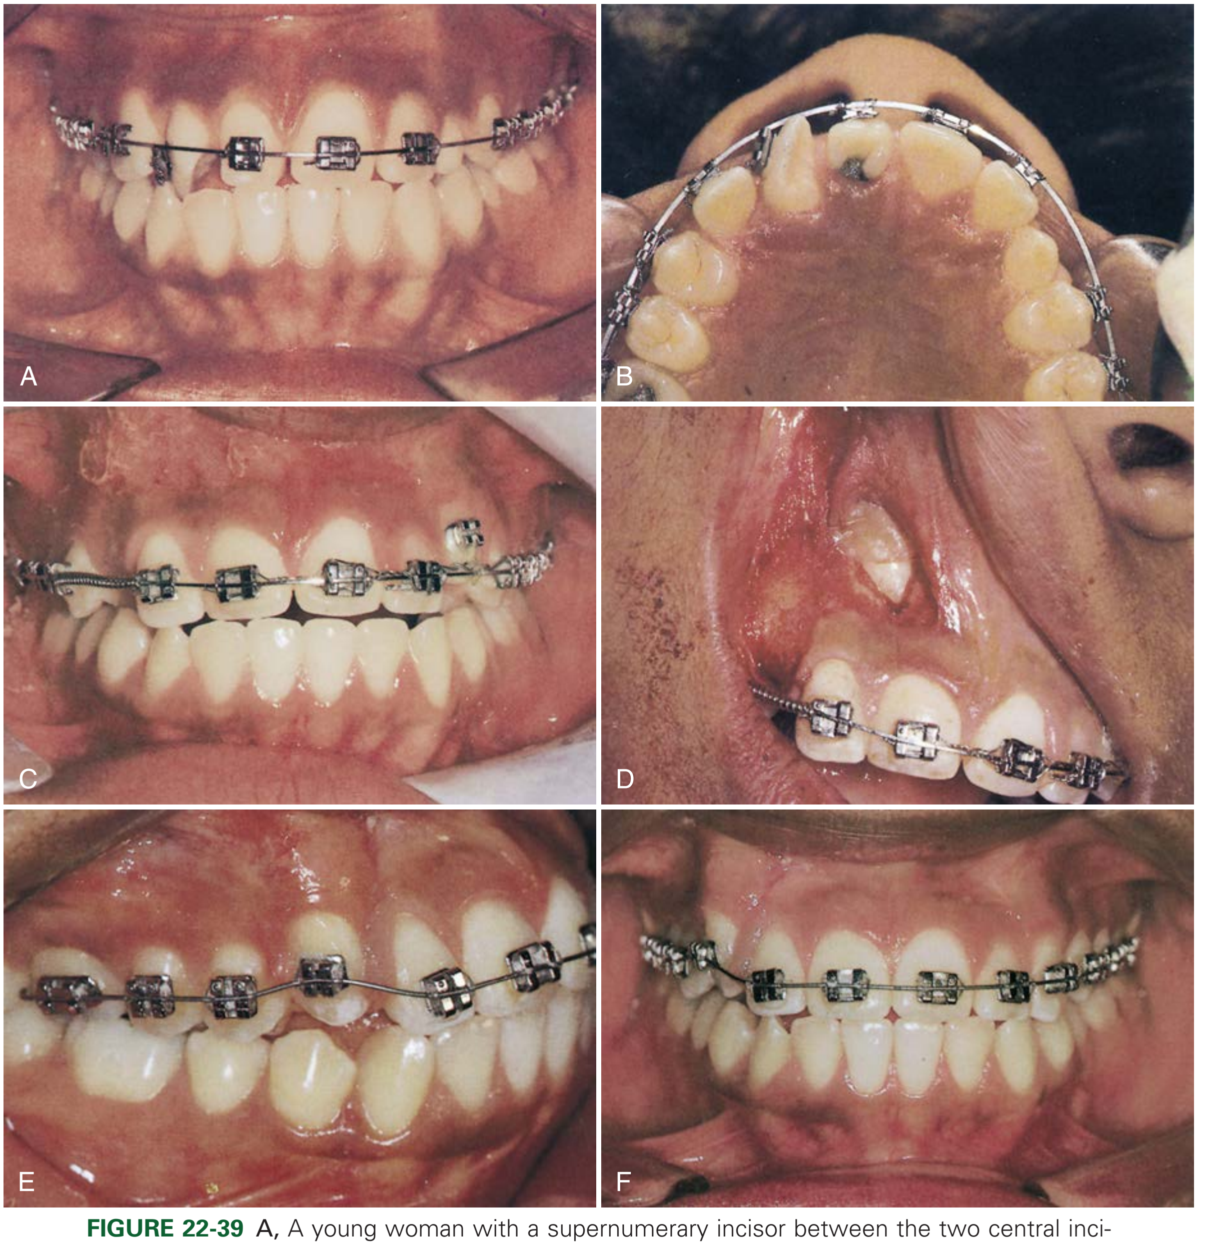

FIGURE 22-39 **A,** A young woman with a supernumerary incisor between the two central incisors. **B,** Palatal view of the supernumerary incisor to the right of the midline. **C,** The supernumerary tooth was removed, and the right central and lateral incisors were positioned properly. **D,** The maxillary right canine was uncovered surgically, and a pedicle graft was placed on the labial. **E,** Note the tissue health as the tooth is moved into position. **F,** Anterior view of the maxillary right canine.

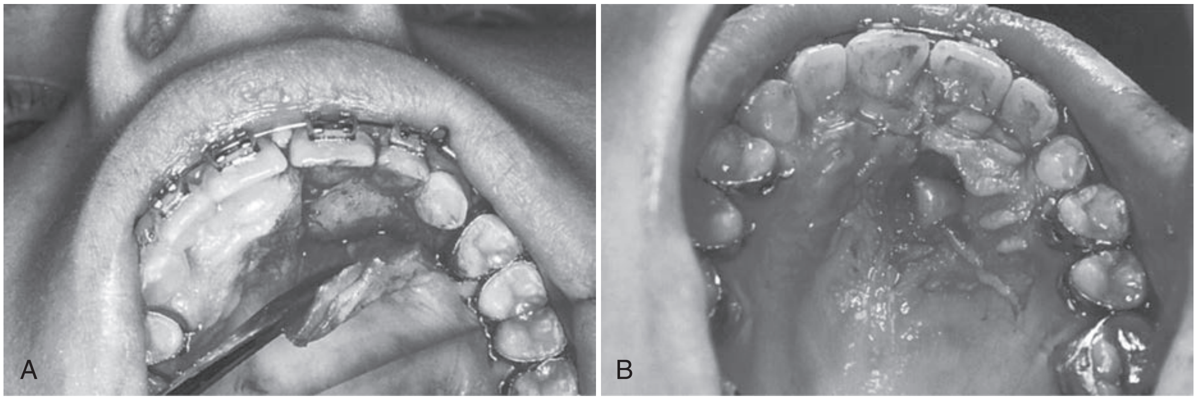

FIGURE 22-40 **A,** An ectopically positioned palatal canine rarely can be palpated. The palatal soft tissue must be reflected, and osseous surgery is required to enter the follicular space. Inadequate exposure not only prolongs treatment but also may result in injury to the tooth because of the inadequate field of vision. **B,** The palatal tissue is put back in position, and a soft tissue window is created in the orientation of the long axis of the anatomic crown.

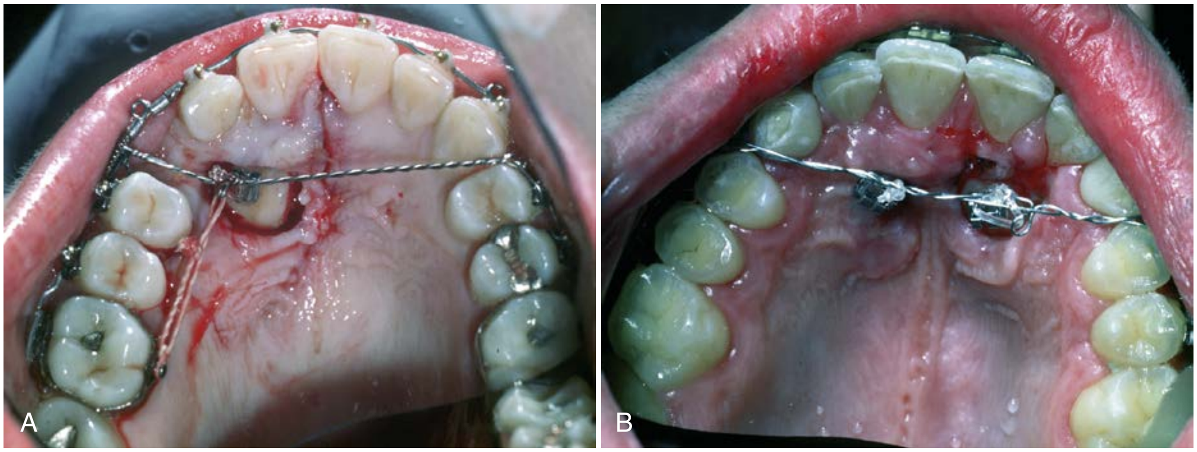

FIGURE 22-41 **A,** A 0.014-inch dead soft stainless steel wire is placed across the palate, with thread used to erupt the canine distally toward the tongue. **B,** A 0.012-inch stainless steel wire is used to tie elastomeric thread to each canine to erupt both teeth to the level of the palatal vault. They then can be guided toward the arch.

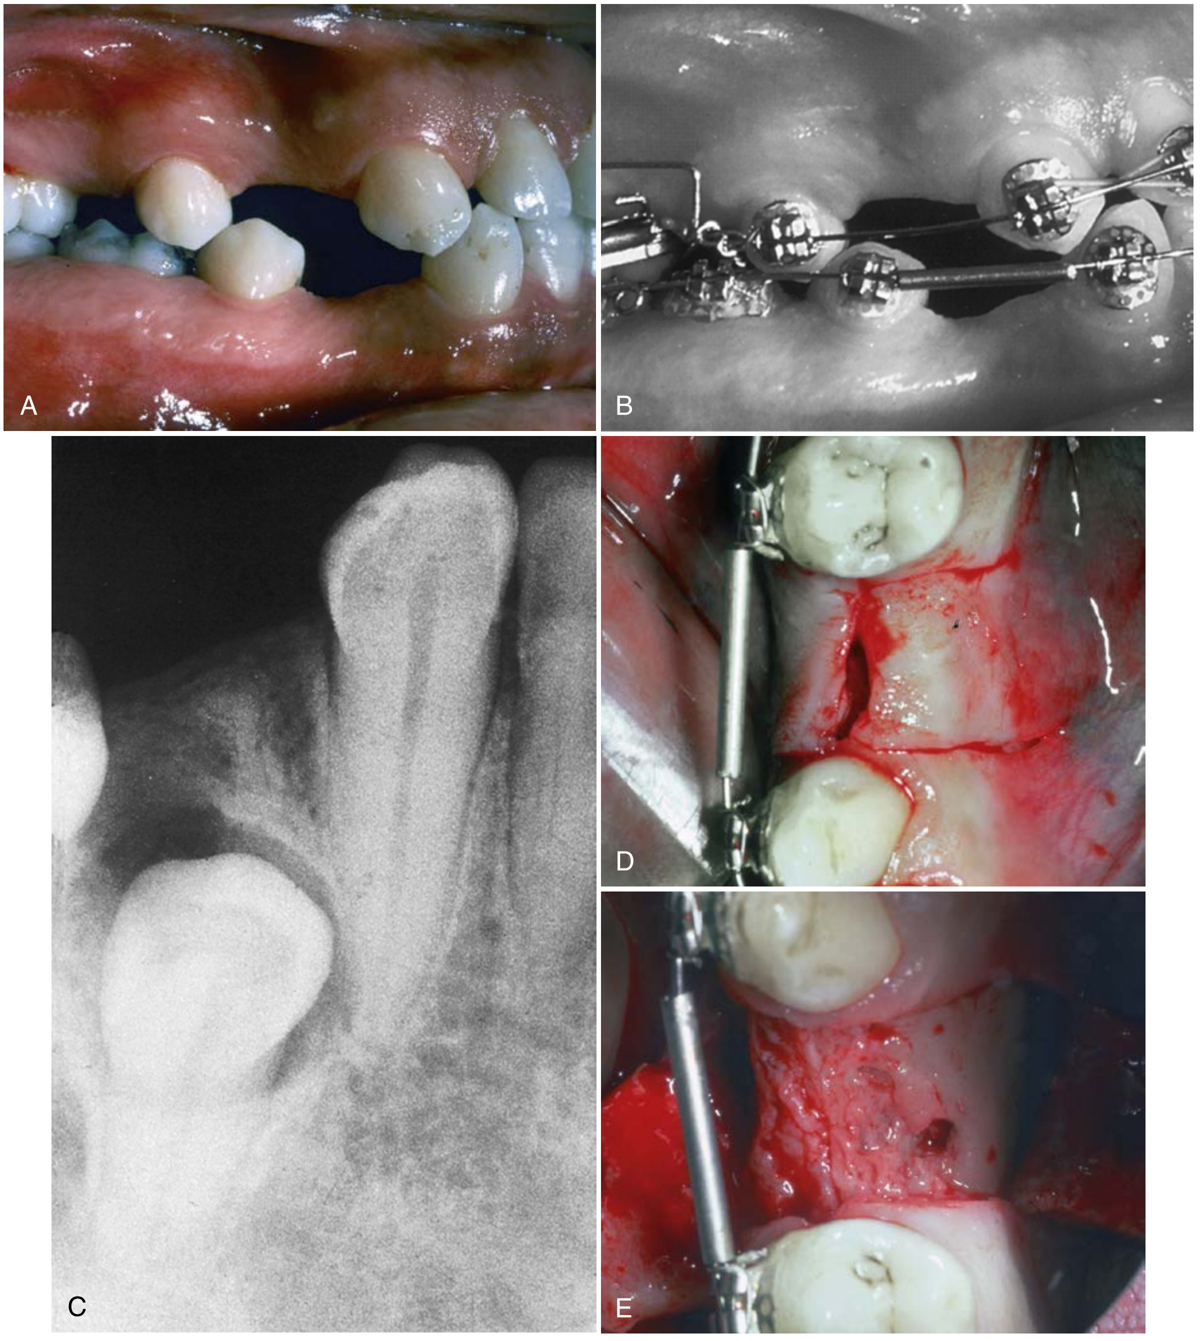

FIGURE 22-42 **A,** A 37-year-old woman who needs alignment in the maxillary right posterior segment before restorative dentistry. The lower right first premolar is impacted and ankylosed. The patient was advised to have the tooth extracted, but she elected to have orthodontic treatment. **B,** Appliances were placed to align the maxillary arch and allow immediate activation of orthodontic force on the lower premolar after it had been luxated. **C,** Preoperative radiograph of the ankylosed first premolar before it was uncovered. **D,** Initial releasing incisions made to mobilize a pedicle graft for the lingual and the facial of the unerupted premolar. **E,** With the tissue reflected, one can see that the premolar is covered completely by bone.

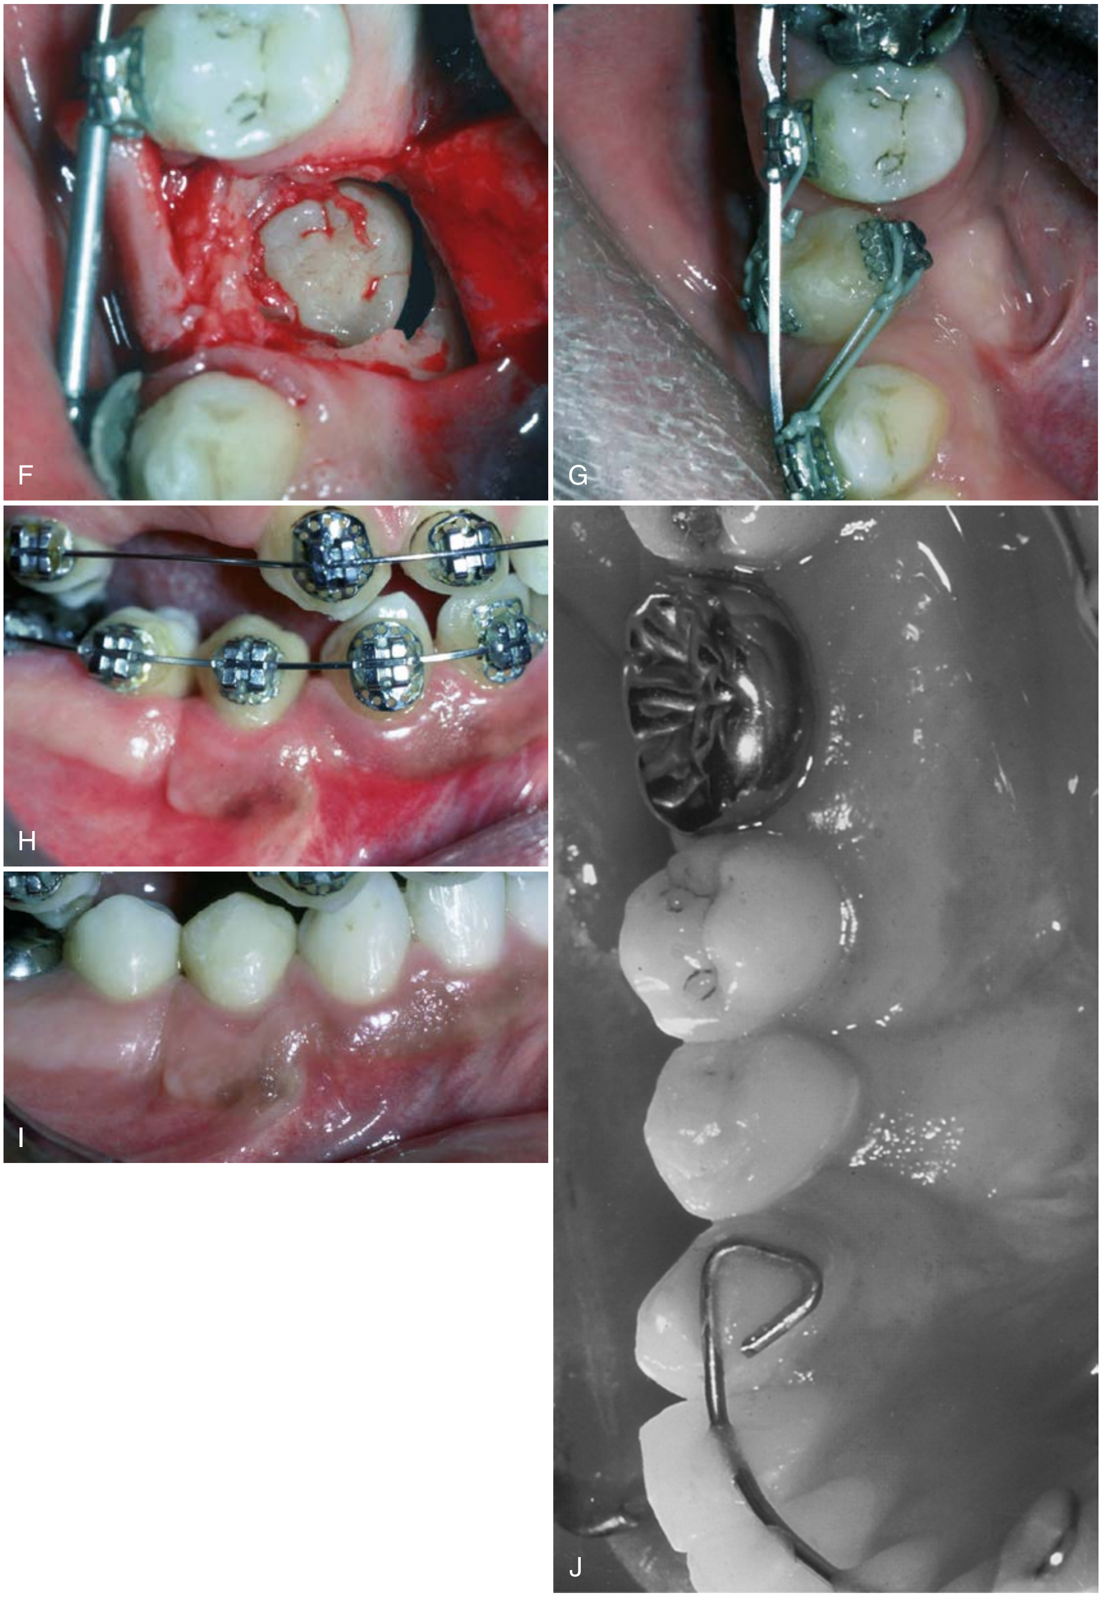

FIGURE 22-42, cont'd **F,** Osseous surgery is performed to uncover the tooth, which is located toward the lingual. The tooth is luxated carefully (moved occlusogingivally) until the area of fusion has been broken. A bonded attachment is placed (bonding should be done only on an ankylosed tooth at the time of surgery), and power thread must be activated within 24 hours and reactivated every 10 days, or the tooth will reankylose. **G,** Two points of attachment are needed to rotate the premolar effectively. **H,** Note that as the tooth moves toward the occlusal plane, the facial gingiva moves with it. **I,** One year after the tooth was positioned in the arch, it had not reankylosed. **J,** On the lingual aspect, note that more gingiva was created as the tooth was erupted. When the tissue attaches to the bone and the tooth (as eruption occurs), more gingiva is created. (From Hösl E, Zachrisson BU, Baldauf A, eds. *Orthodontics and Periodontics*. Chicago: Quintessence; 1985.)

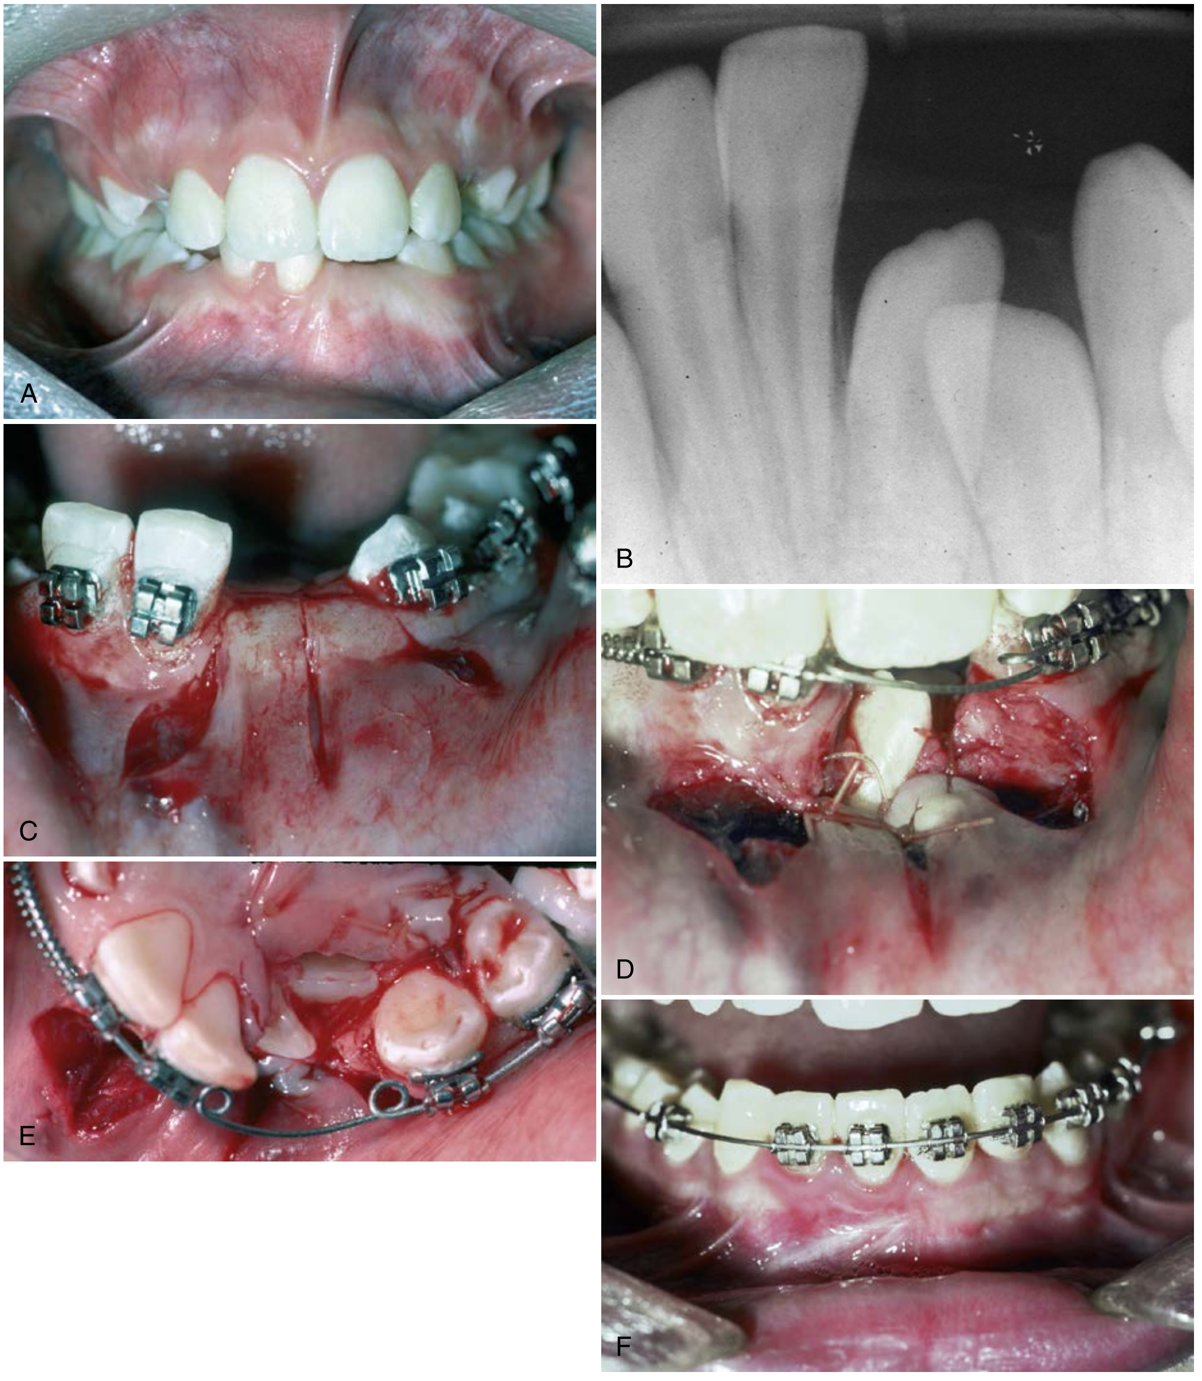

FIGURE 22-43 **A,** An 11-year-old girl in whom the mandibular left central and lateral incisors would not erupt. **B,** Preoperative radiograph of the unerupted mandibular incisors. **C,** Initial incisions made to establish individual pedicle grafts for each incisor on the labial and lingual aspects of the two teeth. **D,** The mandibular arch was bonded and archwire was placed before the surgical procedure. Individual apically positioned pedicle grafts were placed on the labial surface of each incisor. **E,** Occlusal view showing the apically positioned pedicle grafts that were placed on the lingual aspect of each mandibular incisor. The margins of the grafts were placed on the enamel coronal to the cementoenamel junction area. **F,** Note that the incisors with grafts attached to the enamel on the left central and lateral incisors show normal gingival contour. (From Schatz JP, Joho J, eds. *Minor Surgery and Orthodontics.* Chicago: Quintessence; 1992.)

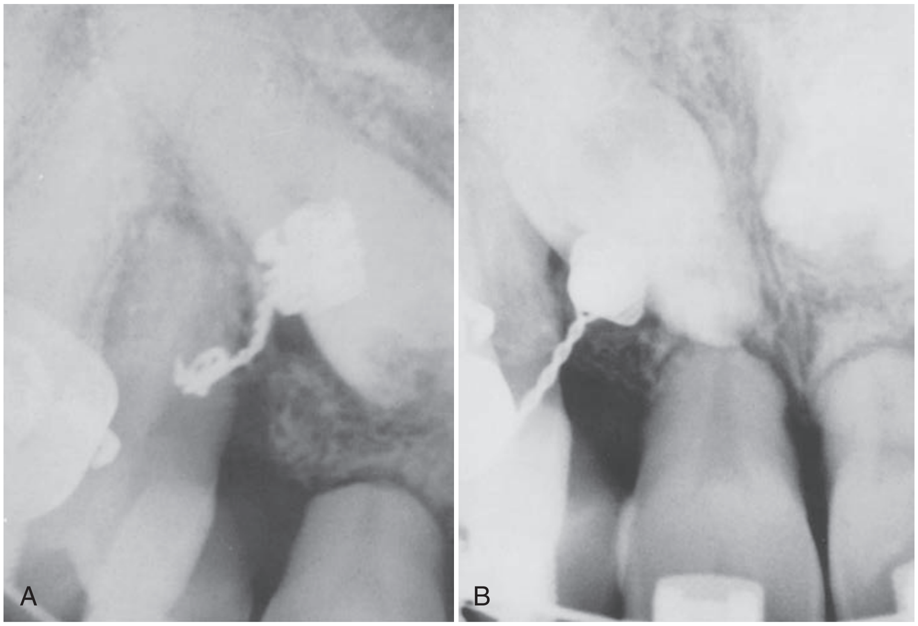

FIGURE 22-44 **A,** Periapical radiograph of a 50-year-old woman; the root is not well defined, and a periodontal ligament space is not evident on the unerupted canine teeth. The pulp also appears to be obliterated. **B,** Both canine crowns seem to fade or blend into the bone. Note the resorption areas on the anatomic crowns of both canines and the bonded incisors. The canines are ankylosed and cannot be moved into the arch.

finesse. This form of attachment can cause permanent loss of crestal bone at the time the tooth is ligated. In addition, the wire may damage the tooth and act as an irritant on the tooth side of the PDL space; this could result in injury or create an environment (in a susceptible patient) prone to ankylosis (see Fig. 22-45, *C–I*). Recent studies in periodontal wound healing have clarified the biologic response that allows replacement resorption and ankylosis. The wire can damage the cells on the tooth side of the PDL and prevent apical downgrowth of epithelium. The epithelium can protect the root against resorption and ankylosis. Granulation tissue derived from the bone against the root is known to induce resorption and ankylosis. Ankylosis, however, always occurs at the crestal area where the wire is positioned. One hypothesis is that the circumferential destruction of the PDL extending from the cementum to the bone may be a necessary prerequisite for ankylosis.[5] Several researchers have suggested that ankylosis can occur because of the repopulation of the PDL from the adjacent bone marrow.[128,129]

The mechanism of injury and ankylosis are becoming better understood;[130] however, patients with this problem predictably show one common denominator: all demonstrate rapid healing clinically. In periodontics, supracrestal external root resorption has been reported to occur when fresh hip marrow with cancellous bone was used as osseous autograft material. The wire loop also may allow inflammation to be established in the area of resorption. The replacement resorption may be arrested by removal of the bone, or the tooth may become extensively resorbed at the crestal area.

Similar to the lasso wire technique, the gold chain (close technique) has a high incidence of tooth ankylosis, in addition to pain in every activation (the soft tissue grows in between the chain), prolonged treatment time, additional surgical procedures, multiple debondings, lack of visibility to change direction of pull, and persistence of the inflammatory dental follicle, which may all cause periodontal damage (Fig. 22-46).[131]

Usually, when teeth that show external root resorption are exposed (if one assumes that ankylosis has been allowed to exist for a short period), only a small area (12 mm) is involved. The bone can be removed with a chisel, and the tooth can be orthodontically positioned into the arch, with continuous force being placed the same day the tooth is uncovered surgically and is freed up (Fig. 22-47). If the force is allowed to dissipate for any length of time, the tooth may become reankylosed. After the tooth has been freed from the bone by osseous surgery or luxation (so that the tooth has a vertical component to the mobility), the force must be reactivated every 10 days.

Many teeth that are ankylosed do not have crestal external root resorption or crestal ankylosis that can be seen on tissue reflection, thus allowing the ankylosed spot to be removed surgically. These teeth can be freed merely by luxation, and an immediate continuous force can be used to position the tooth orthodontically into the arch. Multirooted molars or canines with dilacerated roots have a poorer prognosis for movement after luxation than normally shaped, single-rooted teeth. Because of crestal replacement or resorption (or ankylosis), tooth extraction may be prevented by osseous surgery to remove the bone attached to the tooth followed by orthodontic movement into the arch and reestablishment of the normal anatomic crown for the tooth using restorative dentistry.

One should understand that all ectopically positioned or ankylosed teeth cannot be treated successfully. However, a higher percentage of success can be achieved with unerupted teeth by attending to normal development, supporting tissue, atraumatic surgery, bonded attachments, control of gingival inflammation, and use of minimal orthodontic forces.

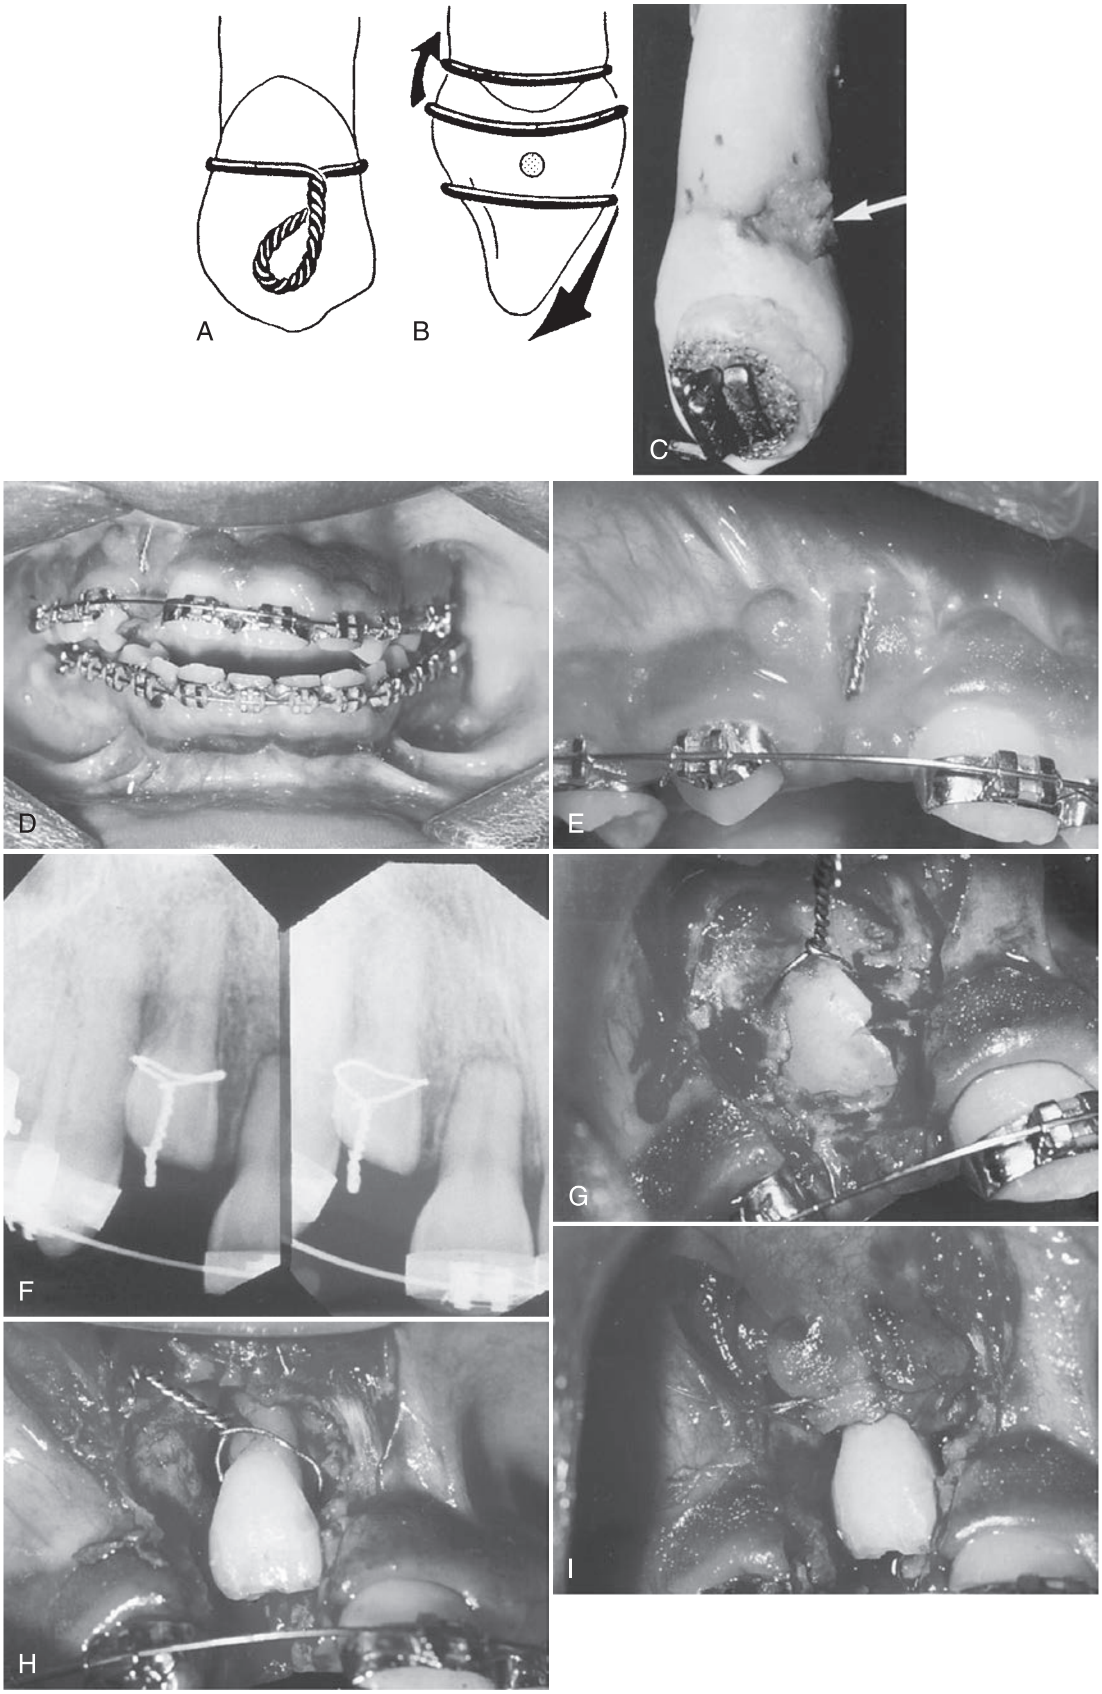

FIGURE 22-45 **A,** Diagrammatically, the ligature tied in the area of the cementoenamel junction (if it were to stay above the contact area) will move incisally and come off the tooth. **B,** If the tooth is ligated below the contact area, the ligature will tend to move apically and impinge on the cement-enamel (CEJ) area, damaging the root surface. **C,** An extracted canine that was uncovered surgically and ligated with a wire loop. The bone invading the root had spread from the CEJ area into the root and the anatomic crown. **D,** In the case of this 16-year-old girl, the lateral incisor was uncovered, and a wire looped attachment was placed by the surgeon; ankylosis occurred. The ankylosed lateral incisor caused an open bite by intruding the maxillary arch as wire changes continued. **E,** Wire that penetrated the alveolar mucosa was tied to the base arch by elastomeric thread. **F,** Note the radiographic appearance of bone invading the root apical to the wire loop. **G,** On reflection of the soft tissue, note the bone over the wire loop and invading the tooth. **H,** Osseous surgery was performed to create a sound tooth structure, and all bone attached to the root was removed. **I,** A pedicle graft was placed on the tooth, which was salvaged.

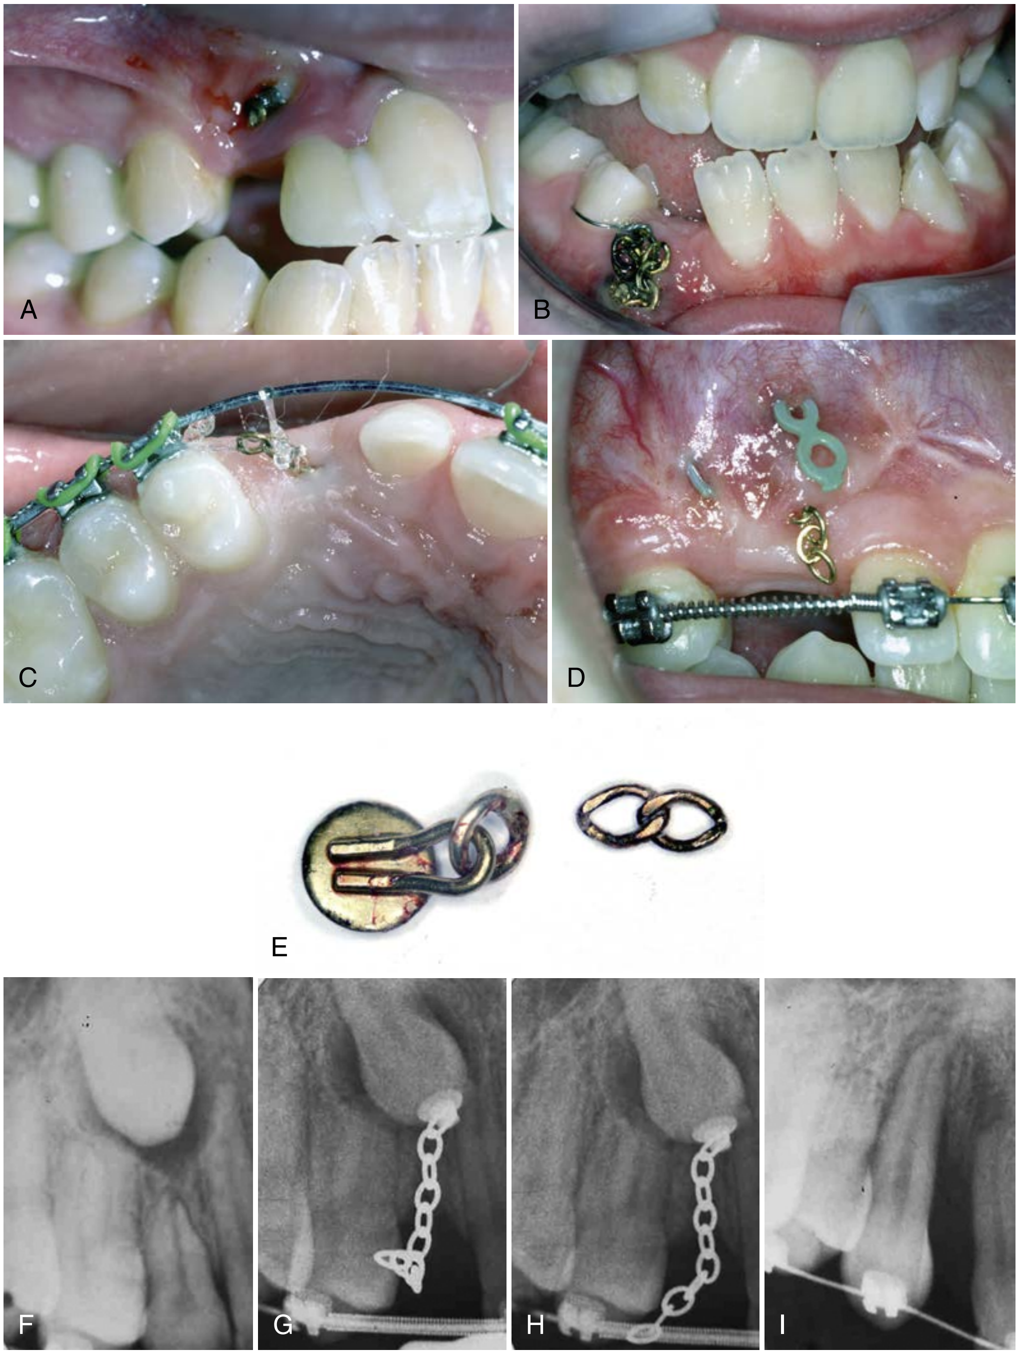

FIGURE 22-46 The gold chain and closed eruption has been a misleading technique for many clinicians. **A–E,** Problem cases with no arch preparation and arch distortion caused by forces applied (**A, B**), diminished control over the direction of pull (**C**), additional surgical interventions (**D**), and multiple debondings (**E**). Prolonged treatment time and the persistence of the inflammatory follicle are additional problems of this technique that may cause periodontal damage. **F,** Initial periapical film of an impacted cuspid with an existent follicle that (**G, H**) was exposed with a closed technique and a gold chain. **I,** One year and 3 months later, the cuspid was brought into the arch. Note the damage on the adjacent tooth and the severe bone loss.

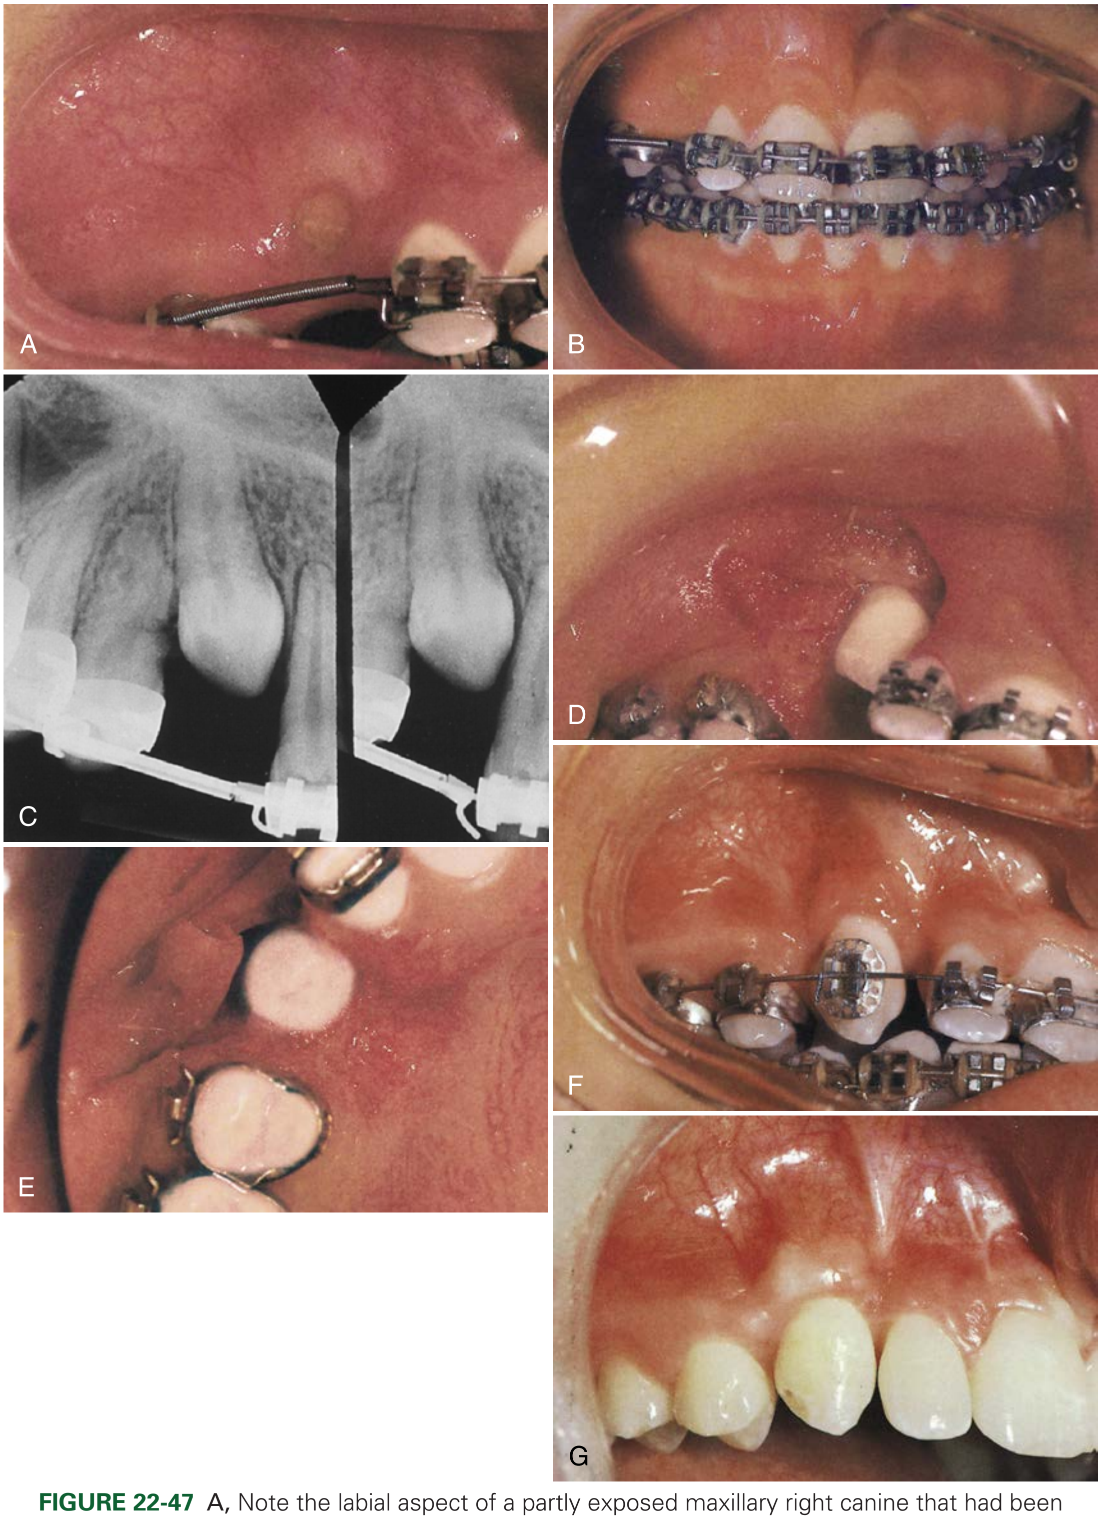

FIGURE 22-47 **A,** Note the labial aspect of a partly exposed maxillary right canine that had been uncovered on three previous occasions. **B,** Anterior view after the arch had been intruded and leveled again. **C,** Periapical radiograph made when the tooth was uncovered. **D,** An apically positioned graft was placed on the labial. **E,** A small area of spot ankylosis was found and removed on the palatal aspect, and the tooth was moved into the arch. **F,** The tooth has been in the arch for 2 months after the surgical procedure. **G,** Appliances were removed, and the tooth was stable.

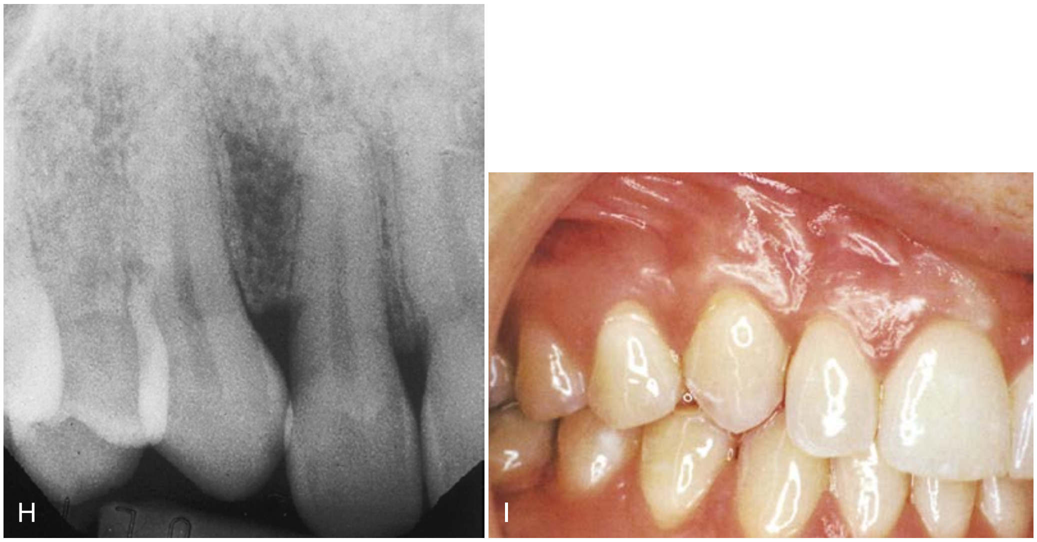

FIGURE 22-47, cont'd H, Periapical radiograph made 18 years later. I, Eighteen-year follow-up finds excellent function of the tooth.

ALVEOLAR DECORTICATION AND AUGMENTATION GRAFTING

The thickness of the alveolar bone delineates the limits of the tooth movement. Exceeding these boundaries may produce adverse consequences for the periodontal tissues. Moreover, bone resorption occurs in the direction of tooth movement, so the reduced volume of the cortical bone, sometimes with minimal thickness and sometimes nonexistent, is a risk factor for loss of attachment.[132] Reducing the cortical alveolar bone may increase the incidence of dehiscences and fenestrations, which are the most common alveolar defects. An alveolar dehiscence represents the lack of facial or lingual cortical plates, which exposes the root surface; an alveolar fenestration is a circumscribed defect of the cortical plate that exposes the underlying root surface without affecting the marginal bone.[133–135] In general, whereas fenestrations are commonly observed in the maxilla (maxillary first molar), dehiscences are more predominant in the mandibular arch (mandibular canine).[133,134,136] In the mandible, the bone becomes thinner in the anterior region.[137] Huynh-Ba et al.[138] evaluated socket bone wall dimensions of extracted teeth and reported that only a minority (6.5%) of the maxillary teeth, including incisors, canine, and premolars, had a buccal bone wall width of 2 mm or more. For the anterior sites (canine to canine), the mean width of the buccal bony wall was 0.8 mm. For the posterior (premolar) sites, it was 1.1 mm.

Clinically, gingival recession is always accompanied by alveolar bone dehiscences.[139] The incidence of dehiscence is positively correlated with thin alveolar bone.[140] The direction of movement, the frequency and magnitude of orthodontic forces, and the volume and anatomic integrity of periodontal tissues also influence the occurrence of dehiscence and fenestration during orthodontic treatment.[141]

Dental arch expansion and incisor buccal-lingual movement are the most critical orthodontic movements.[142] Based on the amount of orthodontic movement and the initial morphology of the alveolar bone, orthodontics may result in alveolar defects.

Therefore, an alveolar bone morphology determination[143] and the need for the surgical procedure are keys to avoid these complications. Alveolar decortication in combination with bone grafting would be indicated to resolve existing dehiscences or fenestration and possible combination with orthodontic treatment. If excessive labiolingual movement is needed, grafting material should be considered.

Background

The alveolar decortication–assisted orthodontic treatment is an established and efficient technique that has been extensively studied in the past decade. It is defined as a surgical procedure that helps orthodontic tooth movement by stimulation of bone metabolism caused by controlled surgical damage. It is done to induce a state of increased tissue turnover and a transient osteopenia, which are followed by a faster rate of orthodontic tooth movement.

The application of corticotomy surgery to correct malocclusion was first described in 1892 by L.C. Bryan.[144] But it was Heinrich Köle[145] in 1959 who reintroduced alveolar corticotomy to resolve malocclusion. He combined interdental alveolar corticotomy surgery with a through-and-through osteotomy apical to the teeth. In 1975, Duker[146] found in a study on beagle dogs treated with vertical corticotomies and horizontal osteotomies that approximately 4 mm of movement occurred in an 8- to 20-day period on the maxillary incisor area with minimal changes in the marginal mucosa. Suya[147] also believed that the tooth movement occurred by movement of the independent bony blocks created during the surgery. In 2001, Wilcko et al.[148] described alveolar decortication with augmentation grafting combined with orthodontic treatment to accelerate tooth movement and to provide increased alveolar volume. They speculated that the dynamics of physiologic tooth movement in patients who underwent decortication might be due to a demineralization–remineralization process rather than bony block movement. They suggested that this process would manifest as a part of "the regional acceleratory phenomenon" (RAP).

Alveolar Bone Biological Response (Regional Acceleratory Phenomenon)

The orthopedist Herald Frost documented that surgical wounding of osseous tissue results in a restructuring activity adjacent to the site where the surgery was performed. He named this cascade of physiologic healing events "the regional acceleratory phenomenon."[149,150]

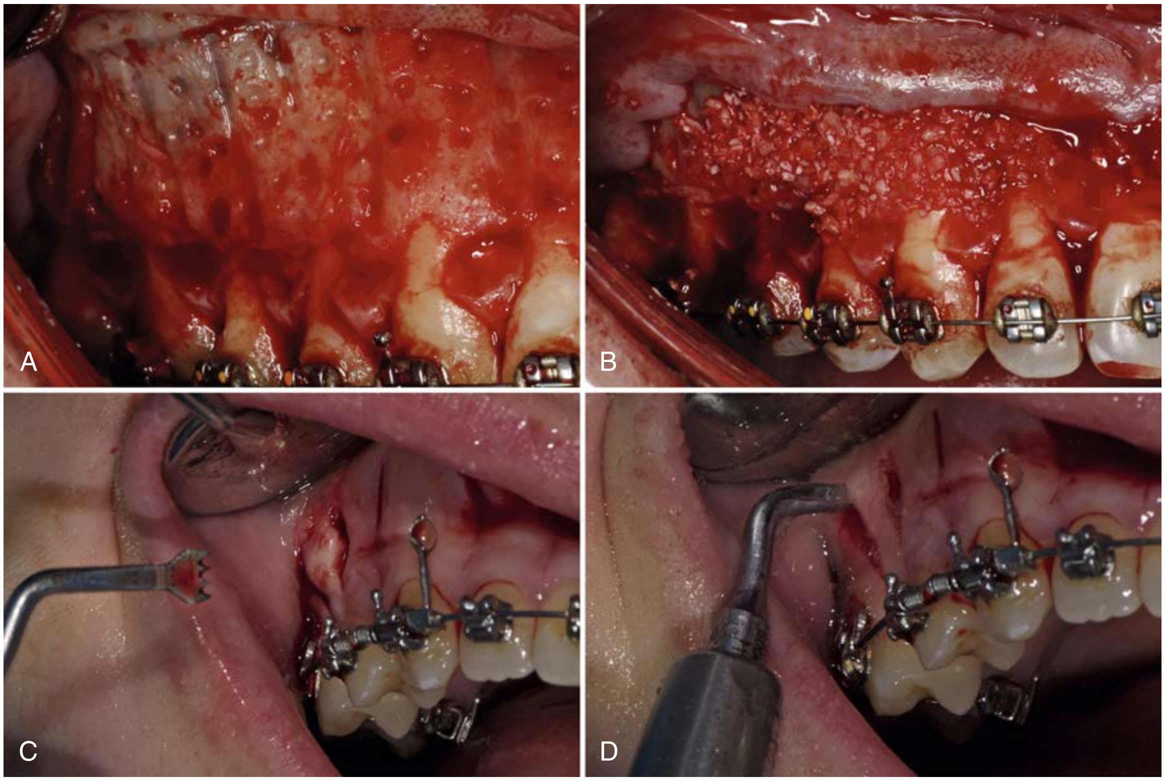

FIGURE 22-48 A, Surgical technique. Note the surgical damage to the cortical plate to induce the regional acceleratory phenomenon. B, Particulate bone grafting. C, D, A modified flapless technique, with vertical incisions and piezoincision. (Case treated by Drs. Blasi and Dhyllon.)

RAP is a local response of tissues to noxious stimuli by which the rate of remodeling in the region of a bone defect exceeds the ordinary tissue activity to potentiate tissue healing and local tissue defense reactions.[151] This response differs in duration, size, and intensity with the extent of the stimulus. The duration of RAP depends on the type of tissue and usually consists around 4 months in human bone. This phenomenon produces bone healing to occur 10 to 50 times faster than regular bone turnover.[152]

The healing phases of RAP have been studied in rat tibias. After a burr hole defect, there is an initial phase of maximally stimulated bone formation followed by a phase of predominant resorption. The first osteogenic phase consists of woven bone formation. It takes place in the periosteal area and then covers the medullary bone, attaining its maximal thickness on day 7. This cortical bridge of woven bone provides mechanical stability of bone subsequently injury. From day 7, whereas most of the medullary bone undergoes resorption, the woven bone in the cortical area begins to be replaced to lamellar bone. It was also found that restoration of a bone defect leads to a systemic acceleratory phenomenon (SAP) of osteogenesis caused by systemic release of humoral factors.[152] In human long bones, after surgical injury, RAP initiates within a few days, usually peaks at 1 to 2 months, and may take from 6 to 24 months to subside completely.[150] RAP causes osteopenia in healthy tissues, but the volume of bone matrix remains constant.[149,152,153] It is hypothesized that small perforations of the buccal cortical plate of the maxilla would lead to the expression of inflammatory cytokines. These inflammatory cytokines have been related with the acceleration of bone remodeling process and therefore the rate of tooth movement.[154] Studies of knockout mice deficient for tumor necrosis factor–alpha receptors revealed reduced tooth movement in response to orthodontic forces.[155] Previous reports have shown that anti-inflammatory medication can decrease the rate of tooth movement.[156] Orthodontic force application alone triggers mild RAP activity. But when tooth movement is combined with selective decortication, RAP is maximized.

Surgical Technique

Decortication

The goal of decortication is to initiate RAP response. It is performed around the teeth planned for movement, with bone cuts made using a round bur or piezoelectric knife.[157] Bone is injured with a surgical bur, taking into account the areas where the cortical bone is thick rather than satisfying any particular preconceived pattern. Typically, it is done between the root prominences where a vertical groove is placed. The groove extends 2 to 3 mm below the crest of the bone to a point 2 mm beyond the apices of the roots. Then vertical corticotomies are connected with the circular-shaped corticotomy (Fig. 22-48).

Particulate Grafting

The combination of corticotomy with an alveolar graft was introduced by Wilcko et al.[148,158] and is referred to as accelerated osteogenic orthodontics (AOO) or periodontally accelerated osteogenic orthodontics (PAOO).[159–161] Wilcko et al. asserted that bone grafting of the labial and lingual cortical bones would increase the range of possible tooth movements, enhance alveolar bone volume, provide a more structurally stable periodontium, and gain stability of orthodontic treatment.[162] It is surmised that the stability found in the mandibular anterior segment may be due to increased cortical bone thickness.[163] Furthermore, there is the assumption that after performing a flap surgery and the decortications, there is a substantial tissue memory loss.[164]

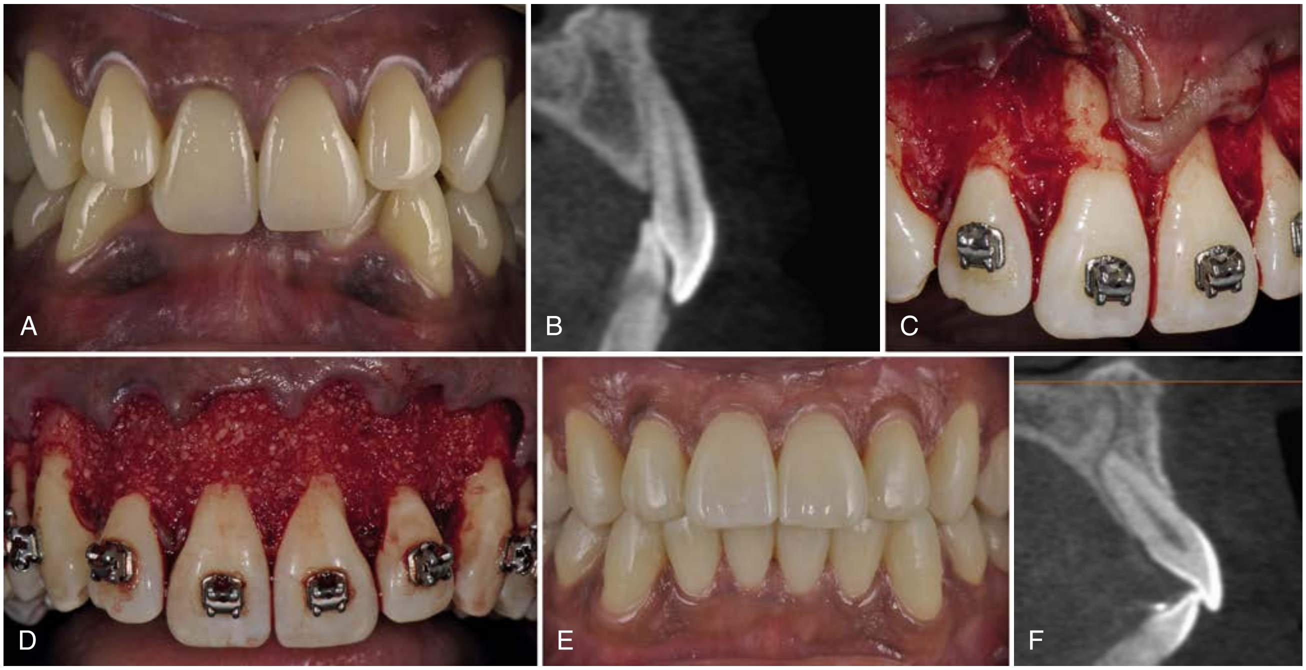

FIGURE 22-49 **A,** A 25-year-old man with a deep bite, retroclined upper incisors, and average biotype. **B,** Cone-beam computed tomography (CBCT) sagittal cut demonstrating inclination of upper incisor and dehiscence. The patient was diagnosed and treatment planned by the orthodontist; referred to a periodontist for decortication to initiate the regional acceleratory phenomenon and achieve a predictable correction with decrease of anchorage; and to perform bone grafting augmentation to modify the alveolar bone width and cover the dehiscence. **C,** Open flap view of the area of interest. Note the lack of buccal plate with full exposure of the root demonstrating a true positive finding on the CBCT. **D,** Labial augmentation bone grafting on the anterior segment. **E,** Finished case with reduced risk of loss of attachment. **F,** Posttreatment CBCT sagittal cut of the upper incisor. Note the presence of bone on the facial aspect of the incisor. (Case treated by Drs. Blasi, Boucher, and Evans.)

In a study with five beagle dogs by Choi et al.,[165] new bone formation was found at the buccal surface in an augmented corticotomy site. Another study by Araujo et al.[166] using five beagle dogs demonstrated that it was possible to move a tooth into an area of an alveolar ridge that 3 months previously had been augmented with a biomaterial. It was also demonstrated that 12 months after grafting, Bio-OssA particles were not present in the area of tension site where the tooth movement was but were present in small amounts in a zone where the pressure side was. No objective data exist comparing one grafting material with another in terms of superiority. The most commonly used materials are deproteinized bovine bone, autogenous bone, decalcified freeze-dried bone allograft, or a combination of these (see Fig. 22-48, *B*).[159] Use of platelet-rich plasma or calcium sulfate increases the stability of the graft material.[159] Antibiotics can be mixed with bone graft. Wilcko et al.[148,158,167,168] recommended the use of a mix of demineralized freeze-dried bone and bovine bone wetted with a clindamycin phosphate solution. Alveolar augmentation with demineralized freeze-dried bone allograft (DFDBA)/xenograft (bovine bone) or alloplastic graft (bioactive glass) was described by Wilcko et al.[148] to cover any fenestrations and dehiscences and increase bony support for teeth with corticotomy-assisted orthodontic tooth movement. The author noticed that particles of xenograft were not fully incorporated at 15 months of reentry; however, these particles were simply wiped off with a piece of gauze, revealing a layer of bone with a marbleized appearance. Additionally, the fenestration buccal of the root of the first premolar was covered.[148] Later, in two cases reports, it was noticed that the dehiscence areas were completely filled in with bone shown in histology of bone biopsy.[160] Furthermore, a recent study reported that augmented corticotomy using nonautogenous grafts facilitated tooth movement without fenestrations and accelerated new bone formation.[169]

There are case reports that describe predictability of combination with ridge augmentation procedures, facilitating force eruption procedures and in combination with soft tissue procedures for the treatment of gingival recessions.[170] Some authors report less invasive techniques with the use of a tunneling technique with piezoincision (see Fig. 22-48, *C*).

Patient Management

Activation of appliances should be done every 2 weeks.

The technique allows the clinician to change the patient biotype (described earlier in this chapter) of the patient. Alveolar decortication and augmentation grafting might be indicated in thin-scalloped biotypes, especially if teeth might be moved past the anatomic boundaries or basal bone.

Treatment Indications and Limitations

Unfortunately, there is a misunderstanding of the benefits of this procedure because of the emphasis placed on speed of movement rather than **enhancing the periodontium** and expanding limits of the treatment (Fig. 22-49). Shortening the treatment plan should not be an indication; rather, it

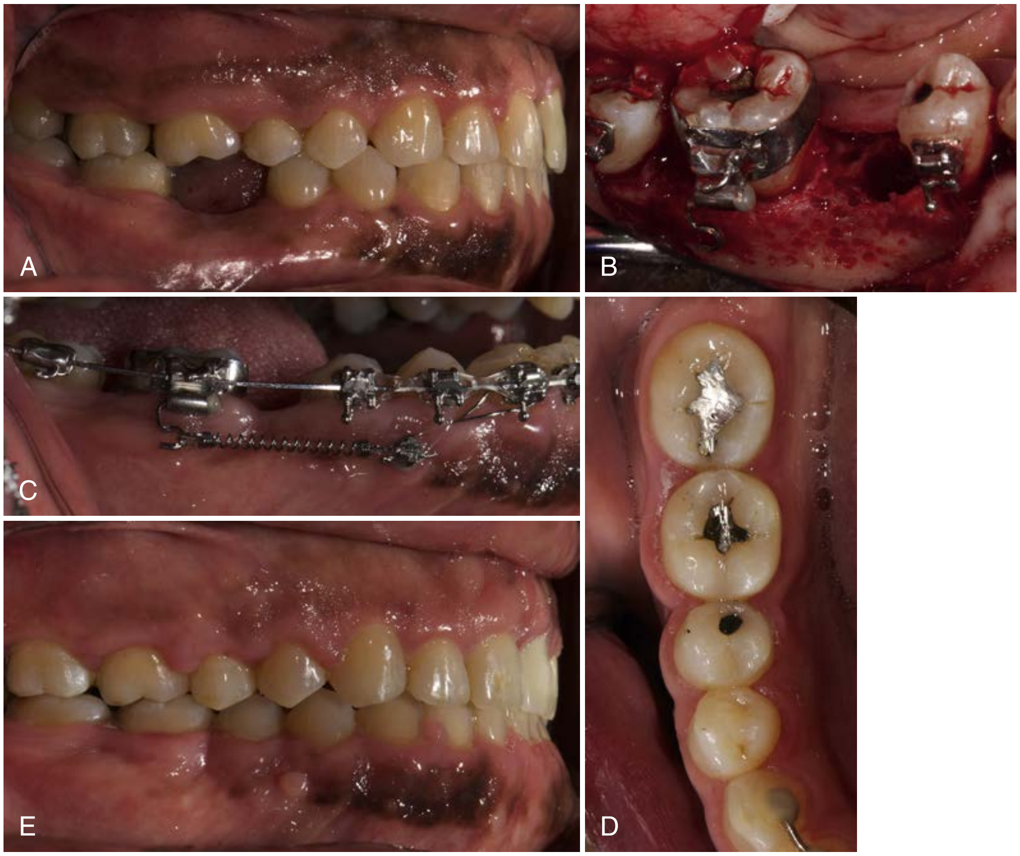

FIGURE 22-50 **A,** A 56-year-old woman before orthodontic treatment. The patient had a history of dental extraction. Upon radiologic evaluation, there was noted a radicular rest left on the molar extraction site, and it was decided to perform decortication at the time of the surgical extraction. **B,** Decortication of cortical plate to facilitate closure of the 11-mm edentulous space. **C,** Activation of force applied with a closed coil. A temporary anchorage device was used for maximum protraction. A passive stainless steel ligature was tied to the cuspid to maintain the position of the anterior segment. **D, E,** Finished case with full protraction of second and third molars into first and second molar position. Note that the Class I dental relationship was maintained. (Case treated by Drs. Blasi and Tanna.)

should be seen as a beneficial side effect (see Chapter 31). It is critical to make a differential diagnosis between the severity of the skeletal and dental components for proper case selection.

It has been reported that the major resistance to the forces acting in orthodontic treatment comes from the cortical bone.[171] Therefore, alveolar decortication allows reducing anchorage, decreasing the resistance of the cortical bone, and achieving difficult tooth movements, movements that were considered to be impossible to achieve in the past.

The envelope of discrepancy for the maxillary and mandibular arches in three planes of space, described in Chapter 21, indicates the limits of tooth movement. Orthodontic treatment is limited by the scope of the alveolar bone, and additional surgical procedures are needed if the limits have to be surpassed. Therefore, an alveolar decortication and augmentation grafting surgical approach increases the alveolar bone volume and expands the anatomic alveolar limits on which teeth can be moved. The quantified limits have to be yet determined. It is important to remember that this approach only changes the alveolar bone, not the basal structures. It does not substitute for or equal the benefits of an orthopedic expansion and changes on the maxillary basal bone described in this chapter. The decortication procedures combined with orthodontic treatment could be indicated for mild transverse discrepancies (only for changes of arch form). The camouflage treatment of skeletal discrepancies in three planes of space could be expanded with PAOO. However, for severe skeletal discrepancies, orthognathic surgery remains the best or a combination of both (orthognathic surgery and PAOO).[172]

PAOO is indicated to resolve anterior crowding, close extraction or edentulous space (Fig. 22-50), change the shape of the alveolus (expansion, asymmetric or mutilated cases), forward movement of lower anterior teeth, intrusion, correction of open bites, unilateral case types, decrease or change anchorage (see Chapter 18 for change of anchorage), and correct dehiscence and fenestrations. The advantages of this procedure are that it enhances the periodontum, increases stability, increases the scope of alveolar change, leads to less root resorption, reduces treatment time, and reduces the risk of periodontal breakdown. Its potential disadvantages include that it is a surgical procedure (invasive and aggressive, surgical complications (discomfort, loss of bone, and so on), increased treatment cost, and inconvenience (appointments every 2 weeks).

Alveolar decortication and augmentation grafting is a legitimate modality that provides enhanced treatment outcomes and accelerated leveling and alignment with reduced risk of loss of attachment.

SUMMARY

No attempt has been made in this chapter to provide a complete discussion of orthodontic and periodontal interrelationships. The intent has been to highlight frequent problem areas. Gingival retention procedures, management of adult patients, and correction of periodontal problems are discussed in Chapter 21. Research information and documented periodontal problems—gathered from clinical observation, clinical trials, animal research, and retrospective analysis—are sufficient to allow the formulation of clinical guidelines for the achievement of orthodontic objectives in problem cases; the ultimate objective is that the patient will be better off for having received treatment. Periodontal problems have not been eliminated for all patients, but significant progress has been made toward prevention of many adverse responses.

About 10% of adolescents, as well as patients with special problems and adult patients, remain periodontal challenges for the future. For orthodontists, the prerequisite for providing effective treatment is a periodontal knowledge base sufficient to prevent periodontal injury.

Orthodontic Aspects of Orthognathic Surgery

David R. Musich and Peter Chemello

OUTLINE

BACKGROUND

The intrinsic genetic factors and extrinsic epigenetic factors affecting facial development are extremely complex, often leading to dental and skeletal imbalances that require interdisciplinary treatment plans to achieve a functional balance. The functional matrix hypothesis of Moss describes the many complex elements of facial development that must integrate to create the final form and function of the stomatognathic system.[1–3]

The development of the greatest amount of a patient's stomatognathic system occurs during the first 14 to 18 years of life, and its development occurs in the transverse, vertical, and sagittal dimensions.[4] When there are growth imbalances in the early stages of facial growth and development, the orthodontist takes the lead, makes a differential diagnosis and treatment planning decision, and decides on an appropriate treatment plan; however, as the patient nears the end of his or her growth cycle and when there is evidence that the skeletal imbalance exceeds orthodontic or orthopedic capacity for correction, patient education and referral for surgical assessment become the next steps in the management of the patient's imbalanced masticatory system. This chapter focuses on current concepts of the teamwork necessary to diagnose and to treatment plan complex skeletal malocclusions.

Goals

Orthodontists and oral and maxillofacial surgeons must individualize the goals of treatment for each adult patient through an interview process that takes place as part of the history and clinical examination and is continued when the records are reviewed in the treatment planning conference. Although achieving functional balance of the intricate stomatognathic system is generally the primary goal of therapy, aesthetic improvement is a natural component of balancing the bones and dentition that make up the chewing system. When treating patients with complex imbalances, we strive to achieve **f**unctional balance using **r**eliable methods that achieve **r**ealistic, a**e**sthetic outcomes that are **e**conomically feasible. In addition, the orthodontist's or surgeon's teamwork also strives to provide a **s**table, **s**atisfactory relationship that enhances the overall orofacial **h**ealth of the patient. The acronym FRESH (Box 23-1) has been useful as a guide to describe the major goals of orthodontic–orthognathic treatment to patients considering this option.[5–8]

Although treatment goals among orthodontists and surgeons are generally consistent, many differences exist in the specific meanings of terms such as *stability*, *facial balance*, *aesthetics*, and even *function*.[34] For example, does the term *stability* always

BOX 23-1 Orthodontic–Orthognathic Treatment Objectives Summarized by the Acronym FRESH

Function—The fundamental goal of improving occlusal relationship is paramount; it is desirable to establish optimal gnathologic parameters for the stomatognathic system (incisal guidance, canine rise, balanced, bilateral posterior occlusal support) and temporomandibular joint (TMJ) health and TMJ stability without symptoms.[9,10]

Reliable—Use of methods of treatment that have been scientifically verified to be highly successful in achieving correction of skeletal imbalances and that are of lower risks than other available procedures for the improvement of a given condition.[11–13] Recent examples of techniques that have proven their reliability are (1) rigid fixation approaches[14] (2) jaw surgery to resolve sleep apnea,[15,16] and (3) use of microscrews as anchorage to improve the range of nonsurgical treatment.[17]

Realistic—The plan of treatment has a high probability of correcting the patient's chief concern and offers the best option to achieve an outcome with a high probability of meeting both the patient's and doctors' expectations.[18–21]

Aesthetics—Issues of aesthetics relate to both dental and facial appearance; facial aesthetics requires assessment of both the profile and frontal view to achieve soft tissue balance as well optimal symmetry. The facial balance should be present both statically and dynamically in speech and during facial expression, especially when the patient is smiling. The role of the "aging process of the face" should also be integrated into the treatment planning process, especially when considering camouflage options.[8,22–24]

Economic—The cost of the proposed treatment does require consideration because most patients have a budget for their medical and dental needs. With limited insurance for orthodontic care and reducing coverage for orthognathic surgical procedures, financial considerations frequently interfere with the optimal combined orthognathic–orthodontic treatment plan.[25]

Stability—A key part of the treatment outcome is ending with jaw and tooth positions that are reasonably stable. There are several variables that require consideration to achieve a stable outcome and there are many adult orthodontic problems that require fixed retention to achieve stability, especially of the lower and upper incisors,[26,27] (also see Chapter 27).

Satisfaction—Achieving both patient and provider satisfaction is important. This usually occurs when there is open discussion, before treatment, about the goals that both the doctor and patient are striving to achieve in this individual situation. This includes a frank discussion from the doctor about the "down side" or "limits" of the accepted plan. This is particularly true in cases that have a skeletal diagnosis and are being considered for camouflage therapy when skeletal correction is more ideal. The role of visualized treatment objectives and computerized predictions can assist the patient and the providers.[17,28,29]

Health—Includes periodontally healthy tissues, Temporomandibular Joint (TMJ) health, comfort and function, and emotional health. With complicated interdisciplinary treatments, it is important that the Interdisciplinary Dentofacial Teams (IDT) teams work well together and are clear on the combined goals of therapy to provide optimal outcomes in these challenging cases. Treatment plans must always strive to preserve the healthy aspects of the case while improving aspects that are diseased or nonfunctional.[30–33]

mean "without continual retention"? Is long-term mechanical retention to create stability acceptable, as suggested by Zachrisson and Buyukilmaz (see Chapter 27)? Who is the judge of aesthetics: the orthodontist, the surgeon, the spouse or significant other, the parent, or the patient? Each of these important persons may differently judge the aesthetics of the profile, the smile, the tooth angulation, and the chin (see Chapters 9 and 10). In additional recent studies, Montini et al. found variation in perception of aesthetic improvement of profiles: "Data was gathered to see if Class II, mandibular deficient patients who had surgery had a more pleasing profile based on assessment by lay persons, orthodontists, and surgeons. Statistical results showed esthetic improvement was perceived for 13/14 silhouetted pairs of profiles. In some cases there were differences in perceived changes as judged by the different judges."[35]

In addition to this problem of a lack of uniform definition or understanding of the terms used for accepted treatment objectives, the clinician often must prioritize those objectives with the patient. For example, a patient may have a moderate chewing problem and incipient myofascial imbalance caused by a lack of incisal function and a mild skeletal open bite (mandibular deficiency with maxillary protrusion) (Fig. 23-1). The ideal treatment plan is orthodontic treatment and jaw surgery to achieve stability, function, and facial balance; a secondary plan may be the extraction of upper first premolars to close the bite. The functional goal is prioritized, but stability (extraction space rebound), vertical excess, and facial balance (change in the nasolabial angle) are compromised (deprioritized). Therefore, two prerequisites for achieving treatment goals and a successful outcome are:

1. A clear understanding of the patient's chief concerns and *the patient's* treatment goals, documented, clarified, and illustrated through simulation and diagnostic setup
2. A clear explanation by the orthodontist of the treatment goals that can be achieved

This is especially true for patients with skeletal jaw malrelationships.[18] In Chapter 8 of this text, Proffit and Nguyen properly describe the process that most clearly allows clarification of goals (see Figs. 8-7 and 8-8). The team, led by the orthodontist and the oral surgeon, carefully develops a problem list, which is reviewed with the patient; this provides an opportunity to discuss the treatment options for achieving the desired outcomes. The orthodontist informs the patient and family, and then all must agree on a plan that they believe will provide the best possible outcome with the least exposure to risk. The plan of action cannot be finalized until the other members of the provider team have contributed to the treatment plan and sequence. Careful integration of each team member's perspective helps to prevent last-minute surprises—for example, Which jaw is having the surgery? How much movement is needed? and Is two-jaw surgery recommended instead of one-jaw surgery? Such unexpected changes can undermine the outcome and the patient's trust.

Current treatment planning approaches include significant patient participation requiring more of the practitioner's time and, at a humanistic level, more emphasis on educating the patient and less emphasis on arbitrary directives—for example, "Go to the surgeon for jaw surgery." From a risk management perspective, the steps in Proffit's problem-oriented approach (see Figs. 8-7 and 8-8), if well documented, create a record that can assist the clinician if the patient subsequently initiates legal action. Machen[36] clarified that risk management is an important consideration when the orthodontist embarks on treatment using an alternative plan. As described here, the orthodontist started treatment with the plan of mandibular advancement for the Class II patient. During treatment, the patient decided against the recommended jaw surgery and proceeded to have camouflage therapy with the upper first premolars extracted. During protrusion reduction and extraction space closure, the patient developed temporomandibular joint (TMJ) symptoms and eventually sued the orthodontist.

FIGURE 23-1 **A–C,** Pretreatment intraoral photographs showing Class II malocclusion (10.5-mm overjet). **D–F,** Long-term postorthodontic intraoral photographs 12 years after treatment completion showing good stability of orthodontic correction. **G,** Pretreatment facial smile photograph. **H,** Cephalometric superimposition of pretreatment tracing and posttreatment tracing showing successful Class II camouflage treatment. **I,** Long-term postorthodontic facial smile photograph 12 years after treatment completion. **J,** Pretreatment lateral cephalogram radiograph. **K,** Bolton template–guided diagnosis showing maxillary skeletal and incisor protrusion and mandibular deficiency. Moderate skeletal imbalances in which both jaws contribute to dental protrusion are generally good candidates for camouflage treatment. **L,** Long-term postorthodontic lateral cephalogram radiograph 12 years after treatment completion.

In evaluating this case, several factors appear to have been deemed important by the jury in determining that the practitioner fulfilled his obligations to the patient. First, the practitioner performed a complete evaluation and suggested a course of treatment designed to correct the patient's problem. Second, an alternative plan was made available that was clearly identified as a compromise. Third, the potential risks and complications associated with the alternative treatment were presented to, discussed with, and acknowledged by the patient. And, finally, a paper trail existed confirming each of the above-mentioned steps.

Following the steps referenced in Figures 8-7 and 8-8 may seem time consuming, but doing so will prove invaluable because the technologic capabilities now available for changing the form and function of the stomatognathic system are profound and require judicious care in their use (Fig. 23-2). With orthognathic surgical insurance coverage unavailable in many situations, clarification of the treatment plan options with an explanation of the risks and benefits is more critical than ever.

NEED VERSUS DEMAND

Stomatognathic system imbalances are generally not life threatening, thus placing their need for treatment into a category of "elective." However, because imbalances in the stomatognathic system can have a major negative impact on one's masticatory function, muscle comfort, dental health, facial aesthetics, and self-esteem, proper treatment is important to each individual patient.

A recently published study from Finland found that there was a significant oral health impact among patients with severe malocclusions. Those with severe malocclusions perceived a significant oral impact "fairly often" or "very often," which was seven times higher than found among adult Finns in the National Health 2000 survey.[37] In addition, through a series of psychological tests, Frejman et al. found that adult patients with severe Class II or Class III skeletal imbalances had lower self-esteem

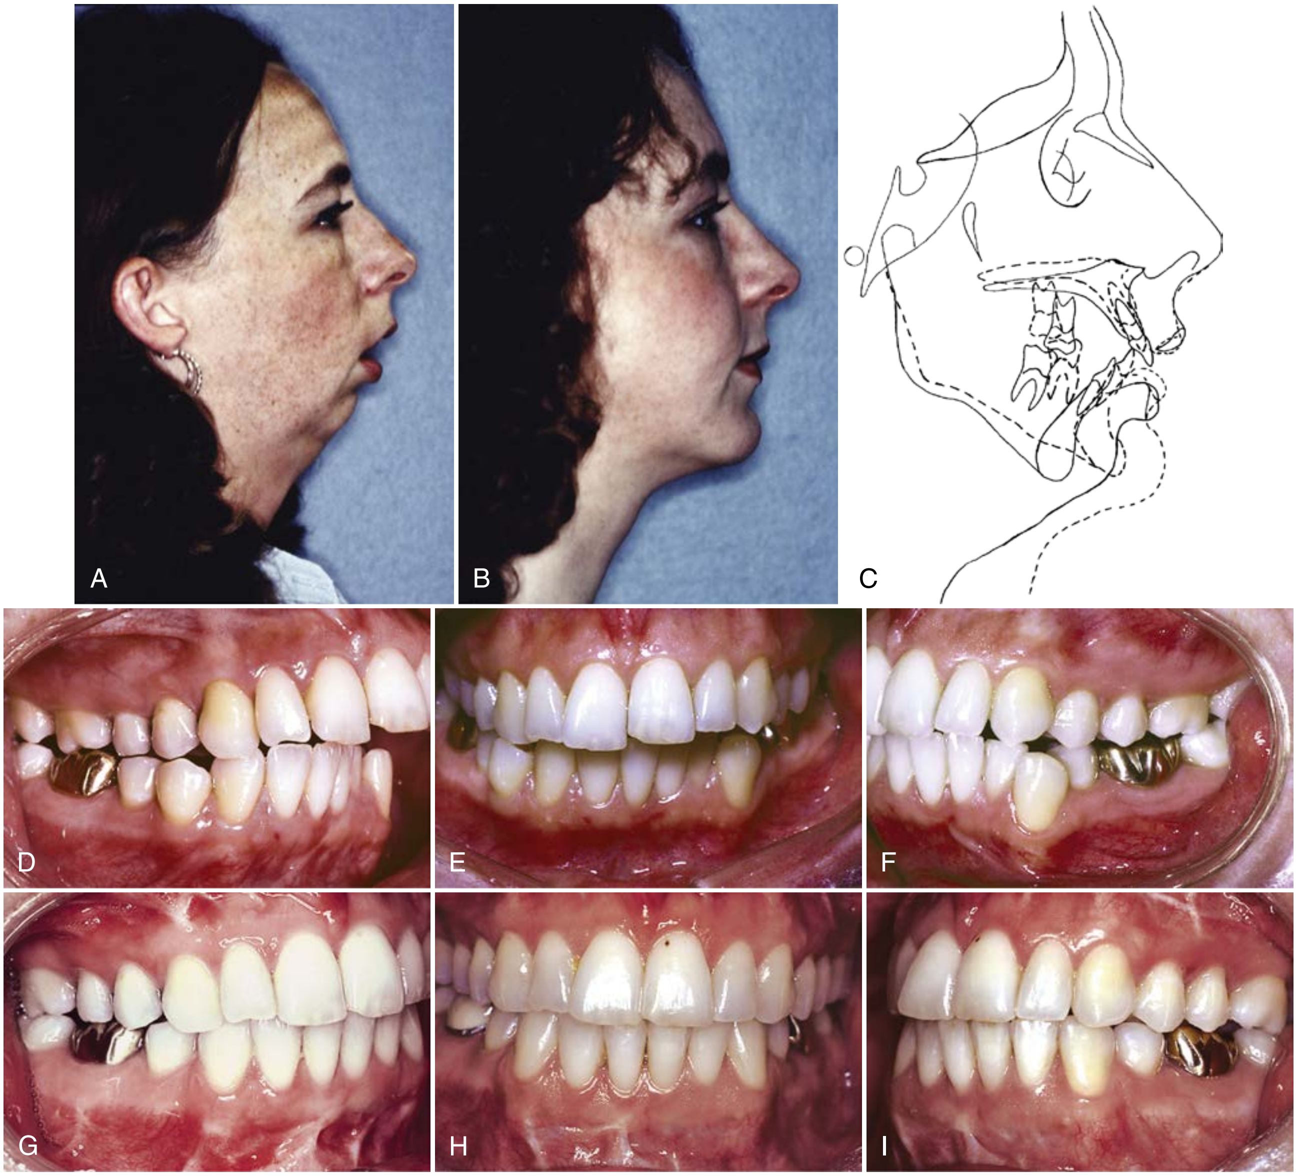

FIGURE 23-2 **A,** Presurgical profile photograph showing severe mandibular and chin deficiency. **B,** Postsurgical profile photograph showing correction of mandibular and chin deficiency. **C,** Superimposition of lateral cephalogram tracing (*solid lines* represent pretreatment appearance; *dashed lines* represent posttreatment appearance). **D–F,** Presurgical intraoral photographs showing severe malocclusion. **G–I,** Posttreatment intraoral photographs showing occlusal correction through orthodontics and jaw surgery.

compared with adults without the skeletal imbalances.[38] It is probable that the lower self-esteem is a motivating factor for patients to seek out a solution to their skeletal imbalance through orthognathic surgery. Johnston et al. assessed self-perception in 162 patients who required orthodontics and orthognathic surgery and compared their findings with a control group without skeletal imbalances.[39] With questionnaires that used a visual analog scale, they found that the Class II and Class III patients seeking orthognathic surgery were significantly more unhappy with their dental and facial appearance.

Because orthodontic–orthognathic treatments of skeletal dysplasias are in most cases elective procedures, further discussion of need and demand considerations is warranted. Proffit and White[40] helped to clarify this discussion with the following statement: "The indication for surgical-orthodontic treatment is that a skeletal or dentoalveolar deformity is so severe that the magnitude of the problem lies outside the envelope of possible correction by orthodontics alone." An arbitrary "envelope of discrepancy" (see Fig. 8-4) was developed to illustrate the concept of limitations of various treatment modalities.[40] To further develop this concept, Squire et al.[41] identified the following nonsurgical limits of certain malocclusion types. They found that the following were not considered treatable by the 28 orthodontists surveyed[41]:

1. Positive overjet greater than 8 mm
2. Negative overjet of –4 mm or more
3. Maxillary transverse discrepancy greater than 3 mm

Orthodontic Retreatment and Skeletal Malocclusions

The main problem with many orthodontic patients who required retreatment appeared to be significant differential growth that led to Class II open bites, maxillomandibular transverse discrepancies with posterior crossbites, or Class III type occlusal problems[42] (Box 23-2). As specialists, orthodontists know that these are difficult growth patterns to manage. Although many of these malocclusions can be corrected with orthopedics and good compliance, many cannot. Therefore, the orthodontist is obliged to diagnose in all three planes of space, to discuss therapeutic modifiability of skeletal imbalances openly, and to present the possibility of a surgical phase if compliance or the growth response is inadequate to achieve an optimal occlusal result with acceptable facial balance.[43] In many of these cases, cephalometric reassessment of therapeutic response is important.

It becomes critical in these cases to communicate more clearly about treatment progress, treatment outcome, and the risks of instability. To refine communication systems so that trained administrative and clinical staff can step into the "treatment coordinator" role at any patient appointment to discuss the various stages of treatment with the patient or parent is advantageous. The communication system should provide a standardized office protocol for the conference and report process with patients and parents and the family dentist, pediatric dentist, or periodontist. Within the recommended communication process are four conference reports that are recommended

BOX 23-2 Sequence of Treatment for Patients with Significant Dentofacial Imbalances

1. Multiple provider team selection
   - Orthodontist
   - Periodontist
   - Restorative dentist
   - Oral surgeon
   - Psychologist
2. Goal clarification for team members
   - Functional occlusion
   - Reliable methods
   - Stability
   - Health
   - Aesthetics
3. Clinical awareness of dentofacial deformity
   - Self, general dentist, friend
4. General assessment of patient
   - A good candidate?
   - Periodontal status
5. Evaluation of preliminary records by the dental team
   - Splint therapy for diagnosis of temporomandibular dysfunction, if needed
6. Completion of diagnostic records
   - May include lifestyle assessment by clinical psychologist
   - May require more sophisticated temporomandibular joint studies
7. Multidisciplinary review of dentofacial problem based on patient records
8. Explanation to patient of available treatment options
   - Optimal treatment plan
   - Alternatives
9. Consultation with the patient and significant other by dental team providers
   - Risk-to-benefit ratio
   - Fees and insurance coverage
   - Treatment time
   - Other concerns
10. Patient acceptance of treatment plan
11. Comprehensive orthodontic treatment (usually for 8–18 months before surgery)
    - Orthodontic movement to decompensate tooth positions
    - Coordination of arches in anticipation of surgical repositioning
    - Alignment of teeth and correction of rotations
12. Presurgical reevaluation records
    - Complete records
    - Prediction tracing (detailed movements planned)
    - Model surgery (reviewed by orthodontist and surgeon)
    - Determination of specific fixation needs
    - Patient–spouse review with orthodontist and surgeon
    - Reevaluation by psychologist
13. Orthognathic surgery
    - Simplest procedure or procedures to achieve professional goals and satisfy the patient's needs
14. Postsurgical period
    - Early: 2 to 3 weeks of fixation
    - Late: 3 to 8 weeks of fixation
    - Reevaluation of surgical procedure
    - Meeting between patient and psychologist for update and support
15. Evaluation of surgical stability
    - Orthodontic finishing, occlusal adjustments, and retention procedures
    - Optimal continuation of contact with psychologist
16. Posttreatment records
    - 1 year posttreatment
    - Reevaluation with dental team, especially oral surgeon and psychologist
17. Treatment experience (used in management of future cases)
    - Positive reinforcement
    - Problem solving
    - Reevaluation of degree of success in achieving goals
    - Treatment evaluations by patient and all providers

FIGURE 23-3 **A–C,** Patient at age 9 years, 11 months. Intraoral photographs before any orthodontic treatment. **D–F,** Patient at age 13 years, 1 month. Intraoral photographs after phase I expansion with Class III intraoral traction. **G–I,** Patient at age 14 years, 11 months. Intraoral photographs illustrating bite change secondary to adolescent growth spurt showing greater Class III jaw imbalance with increasing asymmetry to right. **J–L,** Patient at age 17 years, 4 months. Intraoral photographs after orthodontic arch preparation and maxillomandibular jaw surgery to resolve the maxillary deficiency and mandibular excess with asymmetry.

and serve as "milestones" in the treatment and communication process:

1. **Treatment planning conference report:** to finalize the treatment planning process and document treatment goals
2. **Progress conference report:** sent to family dentist with panoramic radiographs and any other appropriate growth evaluation records
3. **Stabilization or retention conference report:** to discuss treatment successes and treatment shortcomings and to highlight patients at high risk for needed additional treatment
4. **Treatment completion conference report:** to review treatment results and prepare patient for postretention requirements

This formal, predictable conference system provides information that patients, parents, and dentists appreciate. More important, the conference system is a mechanism that minimizes miscommunication, particularly in complicated cases that without proper documentation could lead to adverse legal action. This communication system is particularly relevant in skeletal imbalance cases in which the orthodontic plan may be "heroic" and only achievable with excellent growth response and excellent cooperation. This process also "conditions" the patient and parent to the possible need for retreatment or more advanced treatment, including braces and jaw surgery.[44]

The patient in Figure 23-3 illustrates a patient for whom orthodontic and orthopedic therapy was initially attempted, but her mandibular growth excess exceeded the capacity to orthopedically modify the maxilla's growth to create a balanced

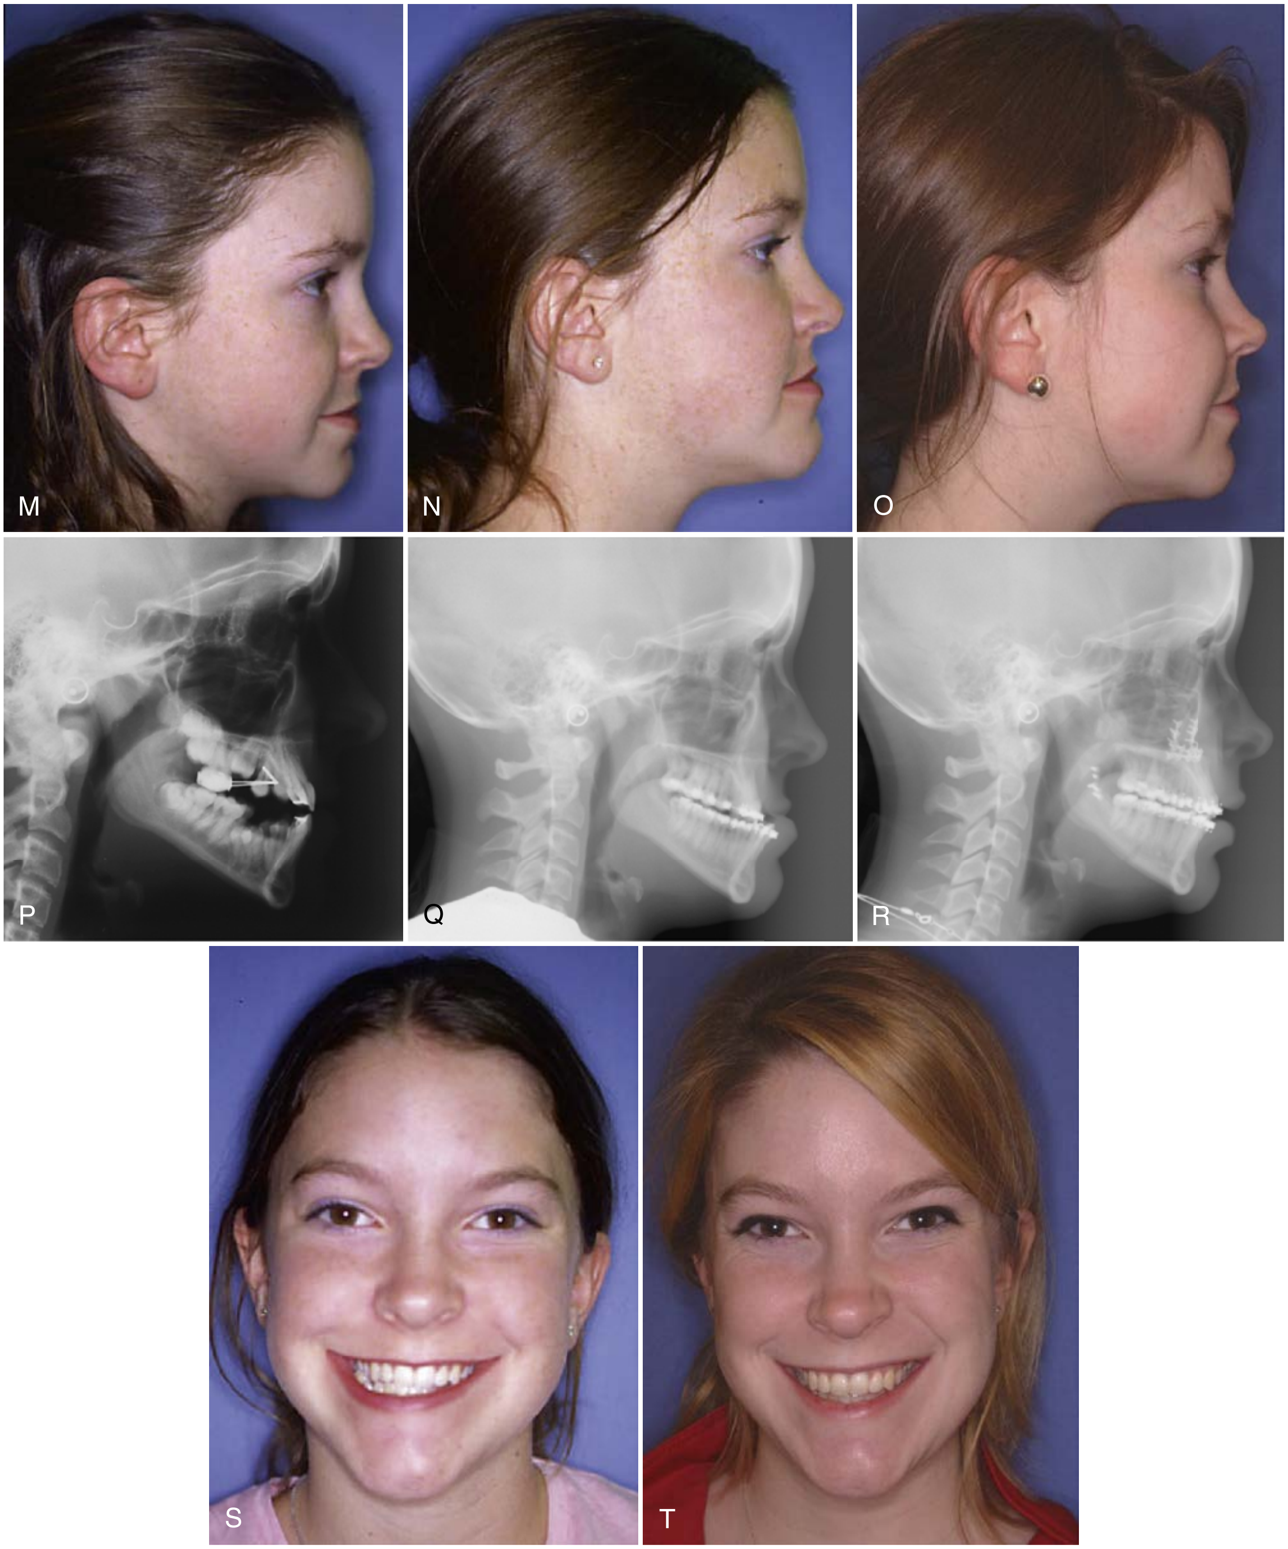

FIGURE 23-3, cont'd M and P, Profile facial view, lateral view of cephalogram at age 9 years, 1 month, respectively. N and Q, Profile view, lateral view of cephalogram at age 16 years, 1 month, respectively. O and R, Profile view, lateral view of cephalogram at age 17 years, 4 months, respectively. S, Frontal facial smile photograph at age 14 years, 8 months, before initiating presurgical orthodontic treatment. T, Frontal facial smile photograph at age 17 years, 4 months, after orthodontics and maxillomandibular surgery. (Surgery by Dr. Peter Chemello, Arlington Heights, IL.)

occlusion. The preferred treatment was then to wait for growth cessation and provide a surgical solution. The number of patients needing and demanding orthodontic–orthognathic correction is increasing with population increases and awareness (Tables 23-1 to 23-3). The following list identifies the categories of patients for whom orthodontists and oral and maxillofacial surgeons will continue to provide advanced management through the refined techniques of orthodontics and orthopedics and, in many cases, orthognathic surgery:

- Genetic growth imbalances beyond the orthodontic–orthopedic range of correction (see Tables 23-1 to 23-3)
- Facial trauma causing growth alterations
- Orthodontic retreatment problems that grew outside the range of conventional orthodontic correction
- Patients with sleep apnea disorders that require orthognathic procedures to completely resolve

TABLE 23-1 Estimated Prevalence of Mandibular Deficiency Severe Enough to Indicate Surgery

	Percentage	Number
Prevalence of skeletal Class II malocclusion	10*	22.5
At appropriate age for surgical treatment	68	4,625,000
Severe enough to warrant surgery	5	731,250
Mandibular advancement	70	510,000
Maxillary setback	10	67,500
Both	20	145,000
New patients added to population yearly†	0.5	21,250

*Assuming a U.S. population of 325 million.
†Assuming 4.25 million live births per year.

TABLE 23-2 Estimated Prevalence of Class III Problems Severe Enough to Indicate Surgery

	Percentage	Number
Prevalence of skeletal Class III malocclusion	0.6*	1.35 million
At appropriate age for surgical treatment	65	877,500
Severe enough to warrant surgery	33	290,000
Mandibular setback	45	130,000
Maxillary advancement	35	101,000
Both	20	58,000
New patients added to population yearly†	0.2	8500

*Assuming a U.S. population of 325 million.
†Assuming 4.25 million live births per year.

TABLE 23-3 Estimated Prevalence of Long-Face Problems Severe Enough to Indicate Surgery

	Percentage	Number
Prevalence of severe anterior open bite	0.6*	1.35 million
At appropriate age for surgical treatment	65	877,500
Severe enough to warrant surgery (superior repositioning of the maxilla)	25	220,000
New patients added to the population yearly†	0.2	6375

*Assuming a U.S. population of 325 million.
†Assuming 4.25 million live births per year.

TECHNOLOGIC ADVANCES IN ORTHOGNATHIC SURGERY

Advances in medical management and surgical techniques have improved the predictability of favorable outcomes and improved functional and aesthetic results for patients undergoing orthognathic surgery. This section presents a brief discussion of medical advances that includes anesthetic technique and edema, nausea, and infection control. Surgical advances are discussed and include surgical procedures and treatments as well as fixation techniques.

Medical Advances

Hypotensive anesthesia has been well documented to decrease blood loss during orthognathic surgery.[45] The technique is sufficiently flexible that a variety of medications can be used to achieve the desired effect. The determination of which medications are used is based on the patient's medical history and the anesthesiologist for the case.[46] Hypotensive anesthesia allows the surgeon to perform complicated orthognathic procedures in highly vascular areas with minimal blood loss.[47,48] This technique has reduced the need for blood transfusion, and the lower blood loss has been shown to be a significant factor for a decreased length of stay in the hospital.[49]

Edema control is essential to allow a quick return to normal function. Measures for controlling edema include (1) minimizing surgical trauma, (2) shortening operating time, (3) maintaining careful hemostasis, and (4) ensuring pharmacologic control of the inflammation process. Pharmacologic control is achieved primarily through the use of corticosteroids. Although corticosteroids can affect leukocyte function adversely, short-term use shows minimal negative effect. Commonly used corticosteroids include methylprednisolone and Decadron.

Nausea is the most common postoperative complication after orthognathic surgery and general anesthesia.[49] Nausea can lead to an increase in hospital stay as well as medical issues such as dehydration. Nausea can also lead to poor patient satisfaction. Silva et al.[50] found that the following factors are associated with an increased risk of postoperative nausea and vomiting:

1. Female gender
2. Young patients (15–25 years old)
3. Nonsmoking status
4. Presence of predisposing factors (prior history of nausea or vomiting or motion sickness, vertigo, migraine headaches)
5. Use of volatile general anesthetics
6. Maxillary surgery
7. Postoperative pain level in the postanesthesia care unit
8. Use of postoperative analgesic opioid drugs

Infection is an uncommon occurrence after orthognathic procedures.[51] The incidence of infection is decreased with antibiotic use preoperatively and postoperatively.[52] However, when infection does develop, it usually is a local inflammation that responds well to incision and drainage and systemic antibiotics. Prophylactic antibiotics are still used; commonly 1 million units of penicillin are administered intravenously just before surgery and again every 6 hours for 2 days after surgery. Cefazolin (Kefzol), clindamycin, and amoxicillin–clavulanate can be used as alternatives to penicillin G.

Surgical Advances

Oral and maxillofacial surgeons have studied the effects of a variety of surgical techniques over the past 20 years. The following criteria generally are considered in determining which technique best serves the patient's needs:

- Safety of the technique
- Reduced morbidity (neurologic and vascular)
- Stability of the procedure
- Enhanced rate of healing
- Reduced surgical time under anesthesia

Figures 23-3 to 23-13 are schematic illustrations correlated with treated patients for some of the more common and considered conventional surgical procedures currently

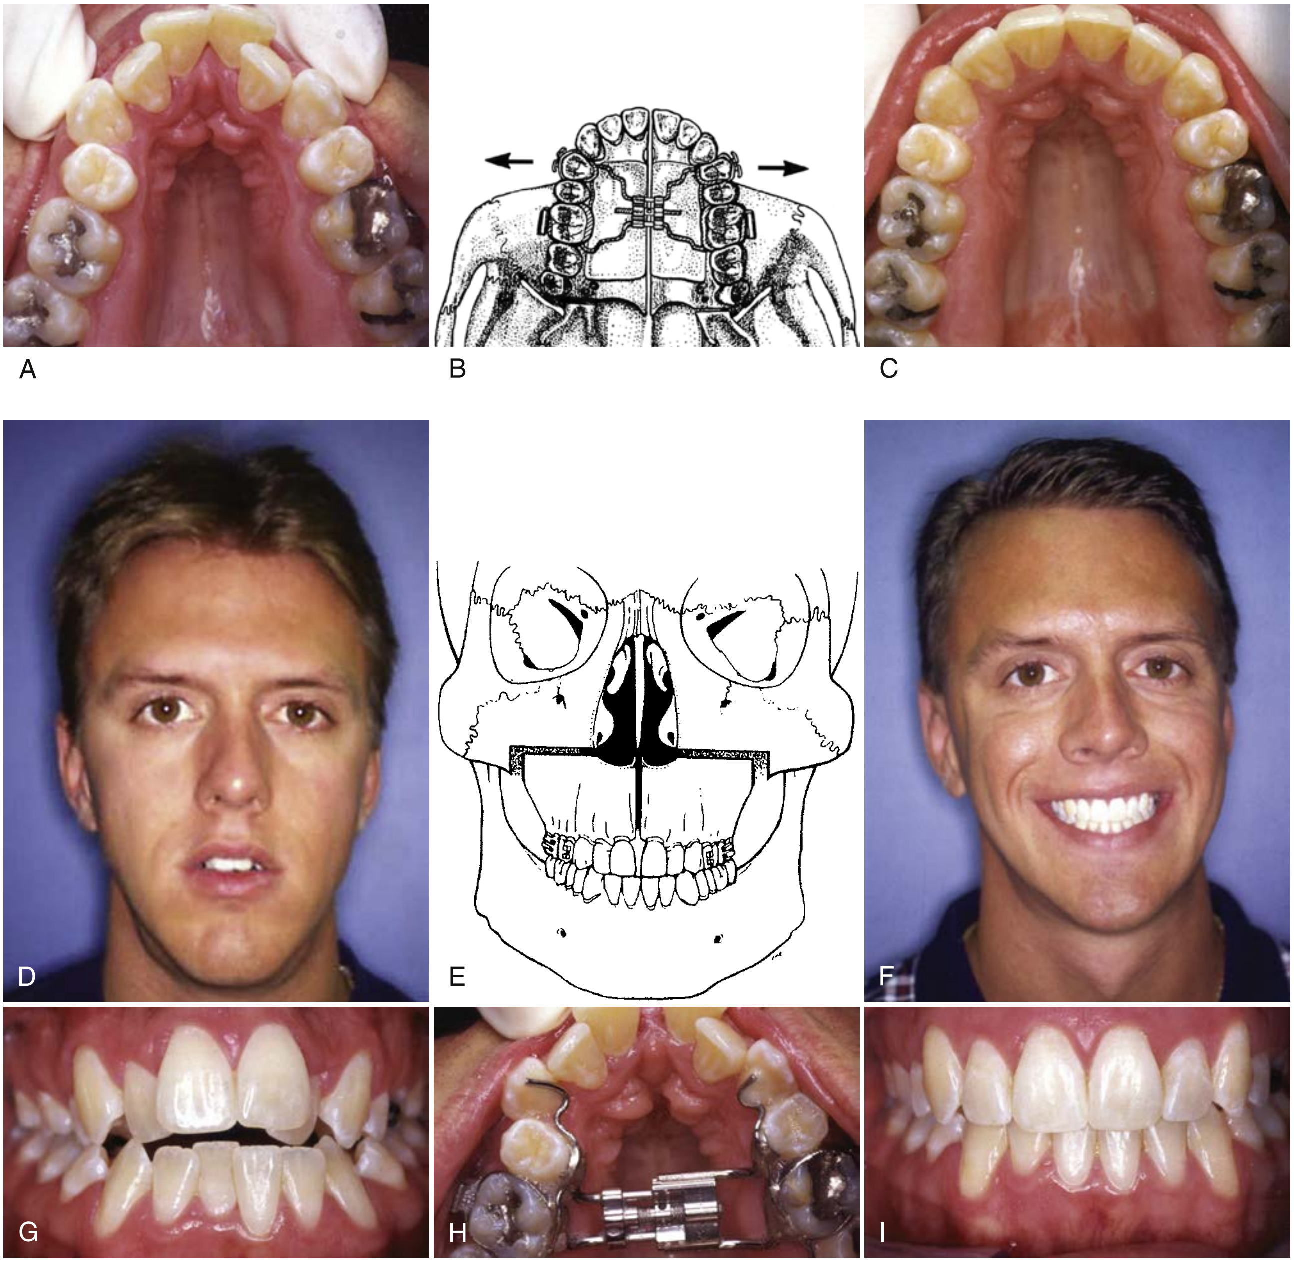
(Surgery by L. Lagrottia, Schaumburg, IL.)

used to correct skeletal malocclusions. Wolford changed a key approach when he presented the benefits of occlusal plane changes in orthognathic surgery.[53] Since that time, orthognathic procedures with occlusal plane change components have become more common and have received more attention because of their benefits in treatment planning. This technique of occlusal plane change allows the surgeons to address both the functional and aesthetic concerns of a patient.[54] For example, classic orthognathic surgery would not move the occlusal plane in a counterclockwise direction to minimize the chance of postsurgical relapse. However, in long-term studies, it has been shown that occlusal plane changes in the counterclockwise direction are indeed stable.[55,56] The use of this technique allows for optimal function as well as profile enhancement with desirable lower third of face and chin repositioning. One of the more recent surgical technique modifications used by surgeons using the occlusal change approach to manage skeletal corrections is the design of the mandibular sagittal split (Fig. 23-14). Incorporating proper orthodontic preparation with the surgical technique of occlusal plane change creates outstanding functional and esthetic results as illustrated in the patients treated by the surgical-orthodontic teams in northern Italy (Figs. 23-15 and 23-16).

Occlusal plane changes are stable in patients with normal TMJ function. However, it has been shown that patients with articular disc displacement who underwent counterclockwise movements exhibit more of a tendency to relapse in both the occlusal plane change area and horizontally at B point and menton.[57]



Treatment Milestones for Patients Requiring Surgically Assisted Rapid Palatal Expansion

Diagosis	Evaluation (1–4 Months)	Initial Treatment Steps (3 Months)	Orthodontic Correction (18–38 Months)	Stabilize (12–18 Months)
With appropriate orthodontic study models and radiographs	By orthodontist and surgeon • Discuss procedure • Discuss risks and benefits • Evaluate insurance issues • Timing of procedures • Dental decompensation of lower arch • Preventive care of general dentist	1. Place expander (1 week before surgery)—Orthodontist 2. Outpatient surgery—oral surgeon 3. At 5 days, initialize widening—oral surgeon 4. Check in 1 week—orthodontist 5. At approximately 14 days, place upper braces (RPE remains for 4–8 months)—orthodontist	1. Level and align arches 2. Correct crowding and spacing 3. If needed, second-phase jaw surgery for bite correction 4. Complete orthodontics	Orthodontist • Bonded maxillary or mandibular retainers (or both) • Removable maxillary retainer Reevaluate for restorative needs with general dentist

FIGURE 23-13 **A, D,** and **G,** Maxillary transverse deficiency before treatment. **B, E,** and **H,** Schematic of surgical procedure: surgically assisted rapid maxillary expansion; a secondary surgical procedure (Le Fort osteotomy) was used to close the anterior open bite (shown in Figure 23-7, *B*). **C, F,** and **I,** Orthodontic–surgical outcome: results after combination therapy. **J,** Milestones involved in a typical surgically assisted rapid palatal expansion treatment plan include the diagnosis using orthodontic study records, evaluation by the orthodontist and surgeon, initial treatment steps involving rapid palatal expansion (RPE) surgery, orthodontic correction with full-bonded orthodontics, and stabilization with bonded or removable retainers (or both types of retainers). (Surgery by M. Stohle, Glenview, IL.)

Another important surgical technique modification that has been presented in the literature recently is called *surgically facilitated orthodontic therapy* (SFOT).[58] This new technique, involving single- or multiple-tooth osteotomies combined with the principles of distraction osteogenesis, facilitates rapid changes in the alveolar position of the dentition (Fig. 23-17). The SFOT concept builds on the corticotomy technique that allows rapid tooth movement because of the bone demineralization caused by the regional acceleratory phenomenon. The technique can be considered for borderline surgical cases instead of orthognathic procedures, especially when a restorative component is required. It has the advantage of increasing the adult alveolar bone volume in both the anteroposterior (AP) and transverse directions. For a properly selected case, the economic advantage may be of great value with declining insurance coverage for certain orthognathic procedures. Case selection and outcomes can be seen in the treatments presented by Roblee et al.[58] Complications associated with the technique have been minor and uncommon but include gingival recession, devitalized teeth, and ankylosis of teeth.[59]

Coscia et al. studied corticotomy plus bone grafting to aid presurgical decompensation of lower incisors for 14 skeletal Class III patients.[60] They found that that the corticotomy plus bone grafting procedures allowed patients in their study to experience shorter decompensation time, to proceed more with less risk of typical periodontal complications, and to complete decompensation with or without significant labial bone loss using cone-beam computed tomography (CBCT) comparisons.

Skeletal Fixation

Immobilization of bone fracture sites is a necessity for proper healing of the bone. The acceptance of the technologic advances in orthognathic surgery by patients and the orthodontic profession has been influenced greatly by recent changes in fixation techniques. For many years, interdental fixation with arch bars was the method of choice for orthognathic surgery patients. As presurgical orthodontic treatment became state of the art in the late 1960s, arch bars were replaced by interdental fixation with modified orthodontic appliances and by surgical archwires with soldered hooks. Because of the limitations imposed by periodontally compromised teeth, short-rooted teeth, mutilated dentition, and double-jaw procedures, more stable forms of fixation using the skeletal bases were required.

Skeletal fixation used suspension wires from stable bone such as the infraorbital rim, the zygomatic arch, or the anterior nasal spine to the mobilized maxilla. The fixation period would last for at least 6 weeks. Postsurgical depression was common, and the patient's interaction with the outside world was severely hampered. Weight loss, loss of appetite, TMJ pain, and facial muscle pain also became common concerns. Rigid fixation was introduced in 1980 in the oral and maxillofacial surgery literature. This technique helped eliminate one of the major hurdles for many patients considering jaw surgery, jaw immobilization. This advantage allows (1) a normal ability to communicate, (2) a more normal diet, (3) less time away from work, (4) less sense of being handicapped or of feeling stigmatized, and (5) better oral hygiene during healing. Rigid fixation techniques use malleable plates, which are contoured to fit over a bony osteotomy and are fixated using screws. These fixated plates hold the maxilla or mandible in the new position while healing.

Studies have shown that rigid fixation has acceptable but variable relapse rates depending on the procedure.[61–67] Factors that affect stability in the mandible include magnitude

FIGURE 23-14 **A–C,** Intraoral photographs before any orthodontic treatment; note the degree of anterior open bite and arch constriction. **D–F,** Intraoral photographs after orthodontic treatment and orthognathic surgery.

Continued

of movement; proper seating of condyles, soft tissue, and muscles; the mandibular plane angle (a low angle has greater vertical relapse; a high angle has greater horizontal relapse); remaining growth; preoperative age; and hyperdivergent facial pattern.[68,69] Maxillary inferior positioning surgery is one of the more unstable orthognathic procedures.[70] Issues with rigid fixation include relapse, condylar resorption, and infection of plates or screws. Condylar position devices have been tried at length to help minimize relapse potential. Many different devices and techniques are available, but Gerressen et al.[71] found that their use did not lead to an increase in skeletal stability compared with the manual technique of seating the condyles in the fossa. The benefits of rigid fixation include the previously mentioned patient issues as well as less pain as a result of less micromovement at the osteotomy site afforded by rigid versus nonrigid fixation. There have been concerns that rigid fixation may increase the risk of temporomandibular disorders, but a study by Nemeth et al.[72] showed no difference in the incidence of these disorders whether rigid or wire fixation was used.

Along with the advances that have developed with three-dimensional (3D) imaging, surgeons now have the capacity to use computer-aided design and computer-aided manufacturing (CAD/CAM) splints as they virtually treatment plan their

orthognathic cases and in their fixation splint design. The accuracy of this technique was tested by Zinser et al.[73] In their 2013 prospective, observational study, three techniques were assessed for 30 patients who underwent bimaxillary osteotomy:

- Approach A (8 patients): virtual treatment planning with surgical planning transfer using CAD/CAM splints
- Approach B (10 patients): approach using a surgical waferless navigation system
- Approach C (12 patients): classic approach using a semi-adjustable articulator and acrylic intermaxillary occlusal splints

This study determined that the highest precision for the virtual treatment occurred when the CAD/CAM splints were used. In addition, Zinser et al.[73] found that the CAD/CAM splint group was the only approach that maintained the condyles in their central position in the temporomandibular fossa.

Some surgeons continue to use previously successful skeletal fixation in orthognathic surgery. Use of the rigid fixation technique will continue to be less than 100% until more long-term data are reported that clarify any possible latent negative effects for mandibular surgery. Examples of several fixation techniques are shown in the postsurgical cephalograms in Figure 23-18. The patient's choice obviously favors rigid fixation methods for all types of jaw surgeries as long as stability and safety are not sacrificed. During the past several years, the most common material being used for rigid fixation has been titanium screws and plates. Some patients require removal of the titanium plates

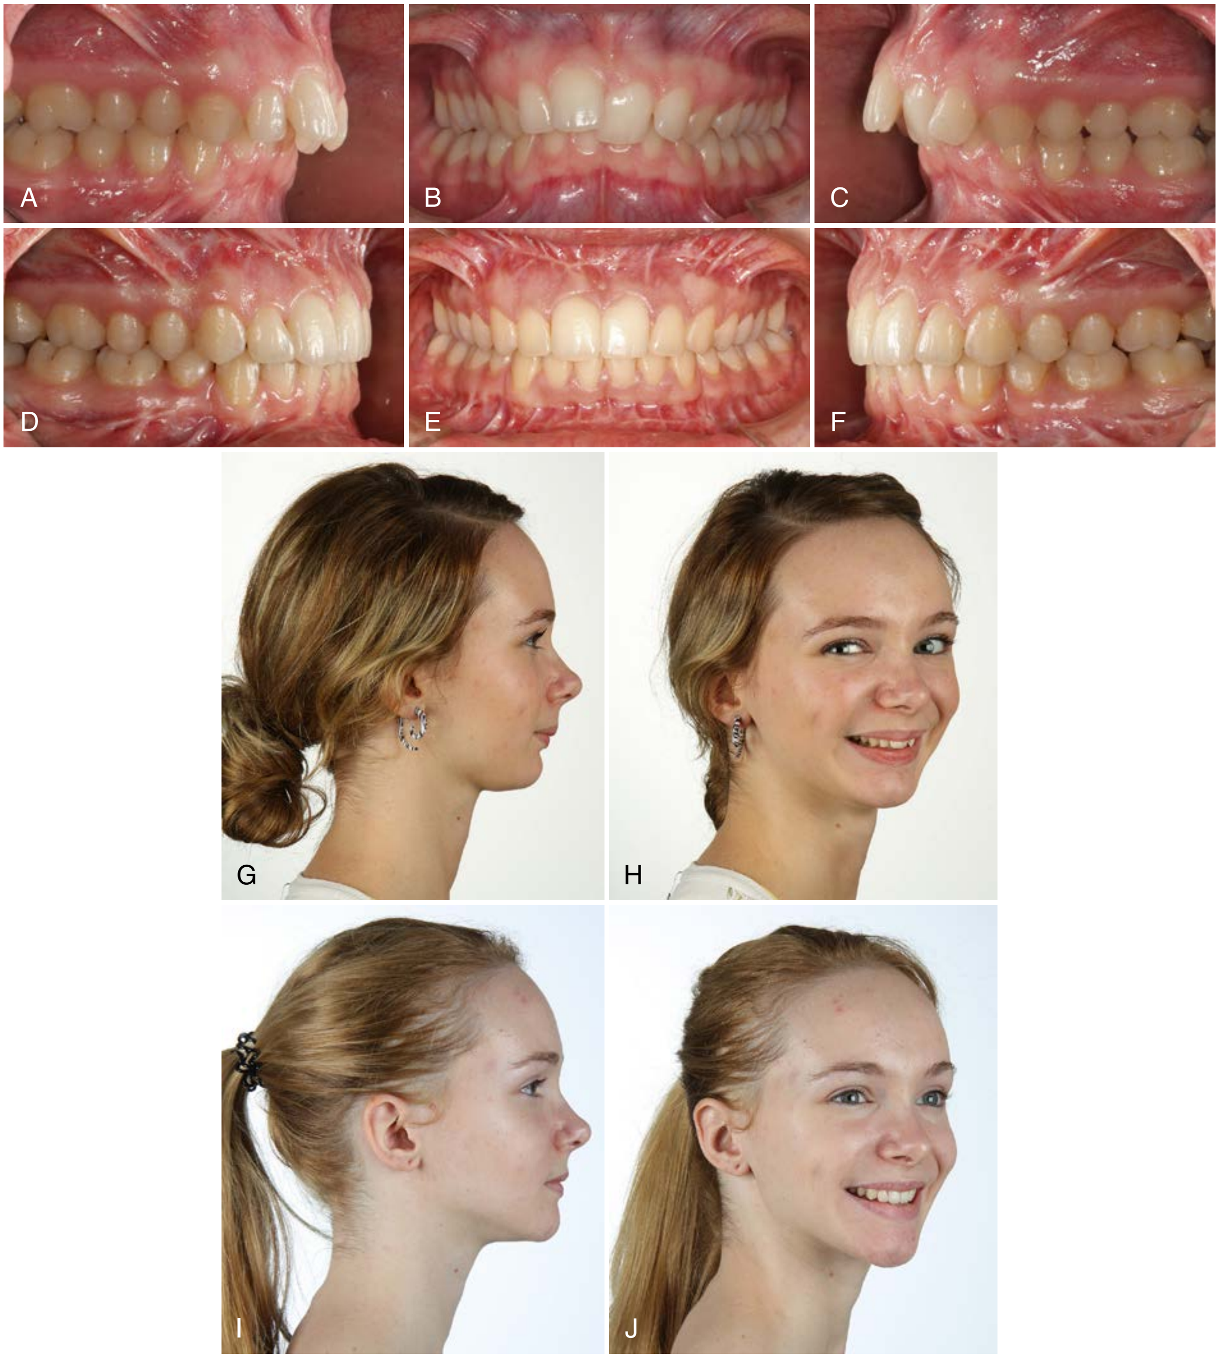

FIGURE 23-16 **A-C,** Intraoral photographs before orthodontic treatment; note degree of overbite. **D-F,** Intraoral photographs after orthodontic treatment and orthognathic surgery. Note the favorable vertical changes as a result of treatment. The removal of lower 1st premolars was necessary to decompensate the lower incisors and to optimize the degree of mandibular advancement for the best facial balance. (Orthodontic treatment by Drs. Ute Moser and Lorenz Moser from Italy and surgery by Dr. Mirco Raffiani from Italy) **G-H,** Pre-treatment facial photographs **I-J,** Post-treatment facial photographs

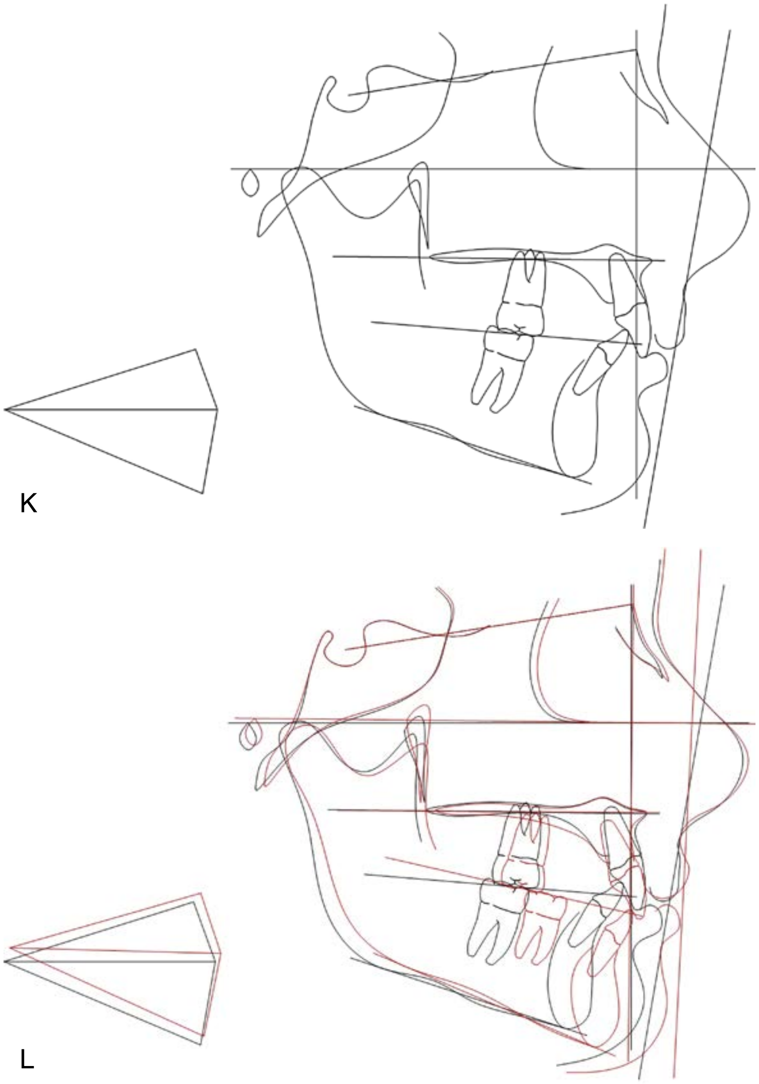

FIGURE 23-16, cont'd K, Pre-treatment cephalometric tracing L, Pre & Post-treatment cephalometric superimposition on SN; black tracing is pre-treatment and red tracing is post-treatment. Note the positive impact of the occlusal plane change to enhance the facial balance.

because of "cold" sensation, loosening, and even infection. In 2010, Ahn et al.[74] conducted a retrospective study comparing titanium plates and resorbable fixation plates in a group of 272 orthognathic patients. Although the authors believed the success rate was 98%, both groups did have complications: 8.6% for the titanium group and 18.3% for the resorbable plate group. Some of the complications revolved around relapse of the resorbable plate group who started with open bites.

The rate at which chewing capacity, range of motion, and functional comfort return is affected greatly by the type of surgery, the type of fixation, and the quality of postoperative management. Studies have shown that functional improvement occurs faster if physical therapy is added to the postsurgical regimen.[75] Figure 23-19 presents the basic flowchart for jaw rehabilitation used by the surgical team at the University of North Carolina School of Dental and Hospital Medicine.[76]

Figures 23-4 to 23-13 are schematic illustrations of some of the more common surgical procedures currently used to correct skeletal malocclusions. Figure 23-14 illustrates the positive effect of including the "occlusal plane change" technique to the orthognathic procedure. With occlusal plane change as part of the double-jaw procedure, the open bite can be closed and corrected.

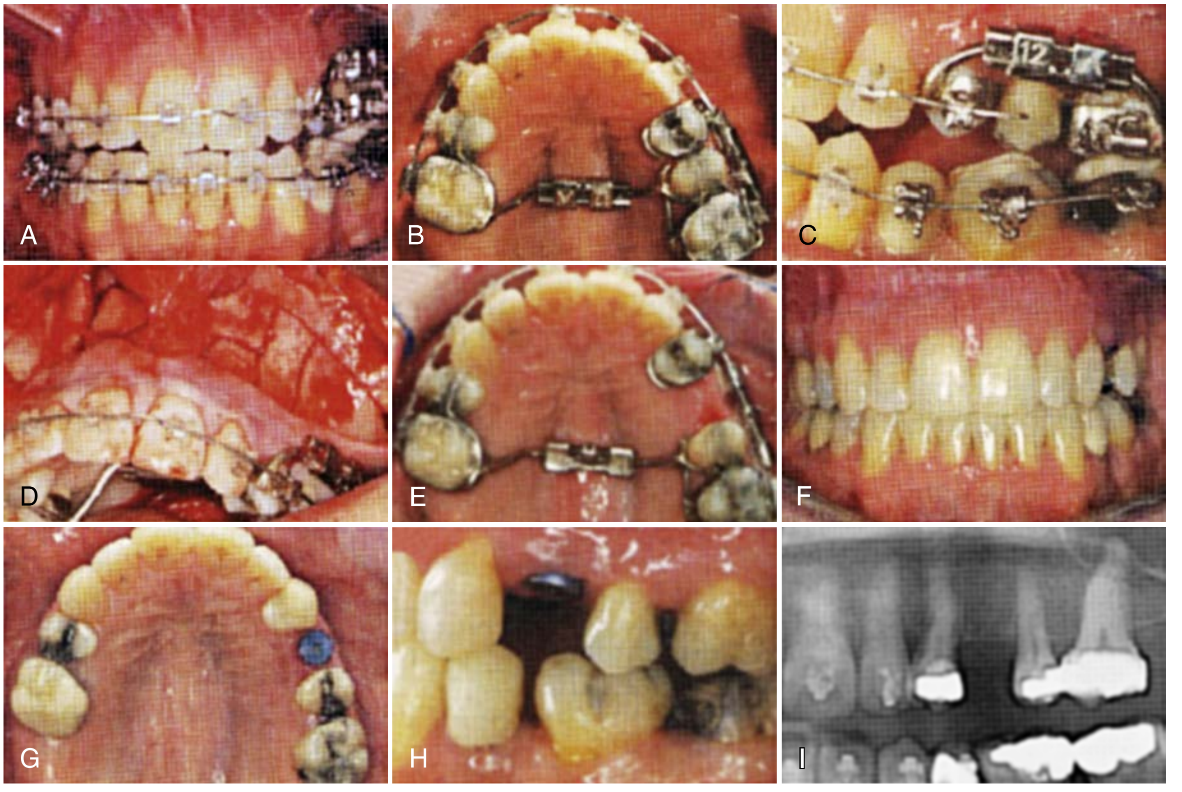

FIGURE 23-17 **A–C,** An osteotomy in surgically facilitated orthodontic treatment (SFOT) consists of cuts through both the cortical and medullary bone and typically indicates the creation of one or more dento-osseous segments. Shown here is a 50-year-old woman concerned about her appearance and bite. A jackscrew appliance was placed after 6 months of orthodontic alignment. **D–F,** The patient was missing no. 11 and had anteroposterior and transverse maxillary deficiencies with anterior and left posterior crossbites. The bite was opened with glass ionomer cement. Single-tooth osteotomies were performed on nos. 6 to 12, and multiple osteotomies were completed on nos. 3 to 4, 7 to 10, and 13 to 14. **G,** Corticotomies were also performed on nos. 7 to 10 segment. **H,** Jackscrews were activated 0.5 mm/day after a 5-day latency period. Note the pure translation of segments without tipping. Result 8 months after surgery. **I,** Tooth no. 12 was converted to a canine, and an implant was placed in regenerate bone. Note the amount of alveoloskeletal correction and increase in volume of maxillary arch.

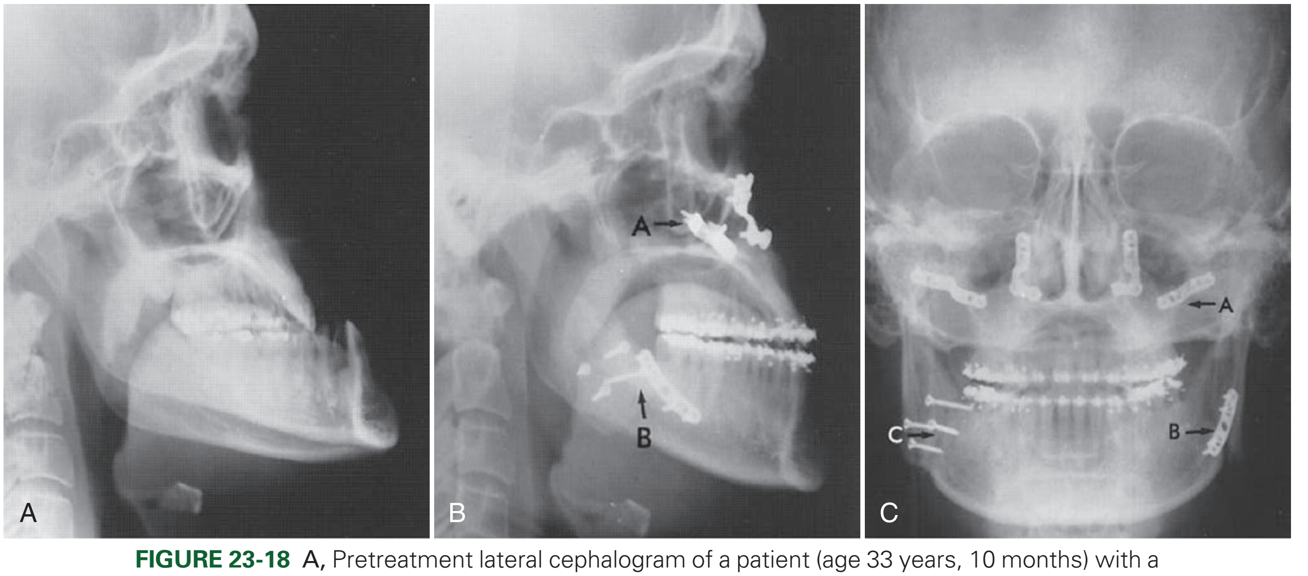

FIGURE 23-18 **A,** Pretreatment lateral cephalogram of a patient (age 33 years, 10 months) with a severe maxillary deficiency and mandibular excess. **B,** Postsurgical lateral cephalogram showing advancement of the maxilla and mandibular setback. *Arrow A*: Rigid fixation plates stabilizing the maxillary Le Fort advancement; *arrow B*: rigid fixation screws and plate stabilizing the sagittal split mandibular setback. **C,** Postsurgical frontal cephalogram. *Arrow A*: Maxillary fixation plates; *arrow B*: mandibular fixation screws; *arrow C*: mandibular fixation plate. This patient delayed surgery for 9 years to avoid 8 weeks of intermaxillary fixation and the downtime from work. Five days after his double-jaw surgery, he returned to work. Stabilization was with rigid fixation devices only.

PATIENT TREATMENT

See Box 23-3.

Diagnostic Considerations

Cone-beam computed tomography has become increasingly available and gives a 3D view of the patient's facial structure.[77–85] Information gained is used for treatment planning and gaining a better preoperative understanding of a jaw deformity in all three planes of space. Cephalometric analyses are being developed to bring information to the operating room (Fig. 23-20).[81] Surgical splints can be prefabricated based on data from the CT scan after the maxilla or mandible (or both) has been virtually moved.[82,84] Stereolithographic models based on scans can help increase intraoperative accuracy.[83] These models are extremely useful in fully uncovering a patient's deformity so that proper planning will occur to produce an optimal result (Figs. 23-21 and 23-22). In addition, these stereolithographic models are very useful for patient education regarding the needed surgical procedures to solve the skeletal aspect of the malocclusion.

For most patients, orthodontic treatment decisions have a significant elective component. Although the patient is examined for any pathologic conditions and medical problems, the orthodontist generally focuses on diagnostic considerations of the structural imbalances (Table 23-4). Three fundamental factors in the diagnostic process are (1) the standardization of high-quality records, (2) consistency of record analysis, and (3) clarity and integration of diagnostic thought by the members of the orthognathic team.

Franchi et al.[86] indicated that cephalometric "floating norms" be considered in understanding the diagnosis of skeletal imbalances: "The use of cephalometric floating norms may be helpful for diagnosis and treatment planning in orthognathic surgery and dentofacial orthopedics." Cephalometric analyses using a template method (Jacobson)[87] are graphically able to qualify (demonstrate which jaw is not in balance) and quantify (demonstrate the degree to which each jaw's dental and skeletal components contribute to the imbalance).

Superimposition of the Broadbent/Bolton template, similar in concept to the Jacobson approach, has proved to be a simple,

BOX 23-3 Characteristics of Adult Patients Seeking Orthodontic Retreatment

A. Distribution of orthodontic conditions identified in study of 100 patients seeking retreatment (most serious problem prioritized in tabulations)
   1. Skeletal problems (42%): Class II, open bites, Class III, and transverse maxillary deficiency
   2. Lower incisor (25%): unacceptable alignment
   3. Upper incisors (21%): unacceptable alignment
      - Central incisor problems
      - Lateral incisor problems
   4. Other (12%): temporomandibular joint, trauma, and periodontal issues

B. Distribution of skeletal problems identified in study of 100 patients seeking retreatment
   - Class II, high angle: 20
   - Class II, medium angle: 3
   - Class III, several types: 15
   - Class I, high angle: 3
   - Class I, maxillary transverse deficiency: 1

C. Case characteristics of skeletal patients from retreatment study
   - Age (range): 15 to 59 years
   - Age (mean): 30.12 years
   - Number of males: 13 (31%)
   - Number of females: 29 (69%)

D. Acceptance rate of skeletal cases identified in retreatment study
   - Accept braces and surgical plan: 29 of 42 (69%)
   - Accept orthodontics only; leave bite uncorrected: 4 of 42 (10%)
   - Did not accept additional treatment: 9 of 42 (21%)

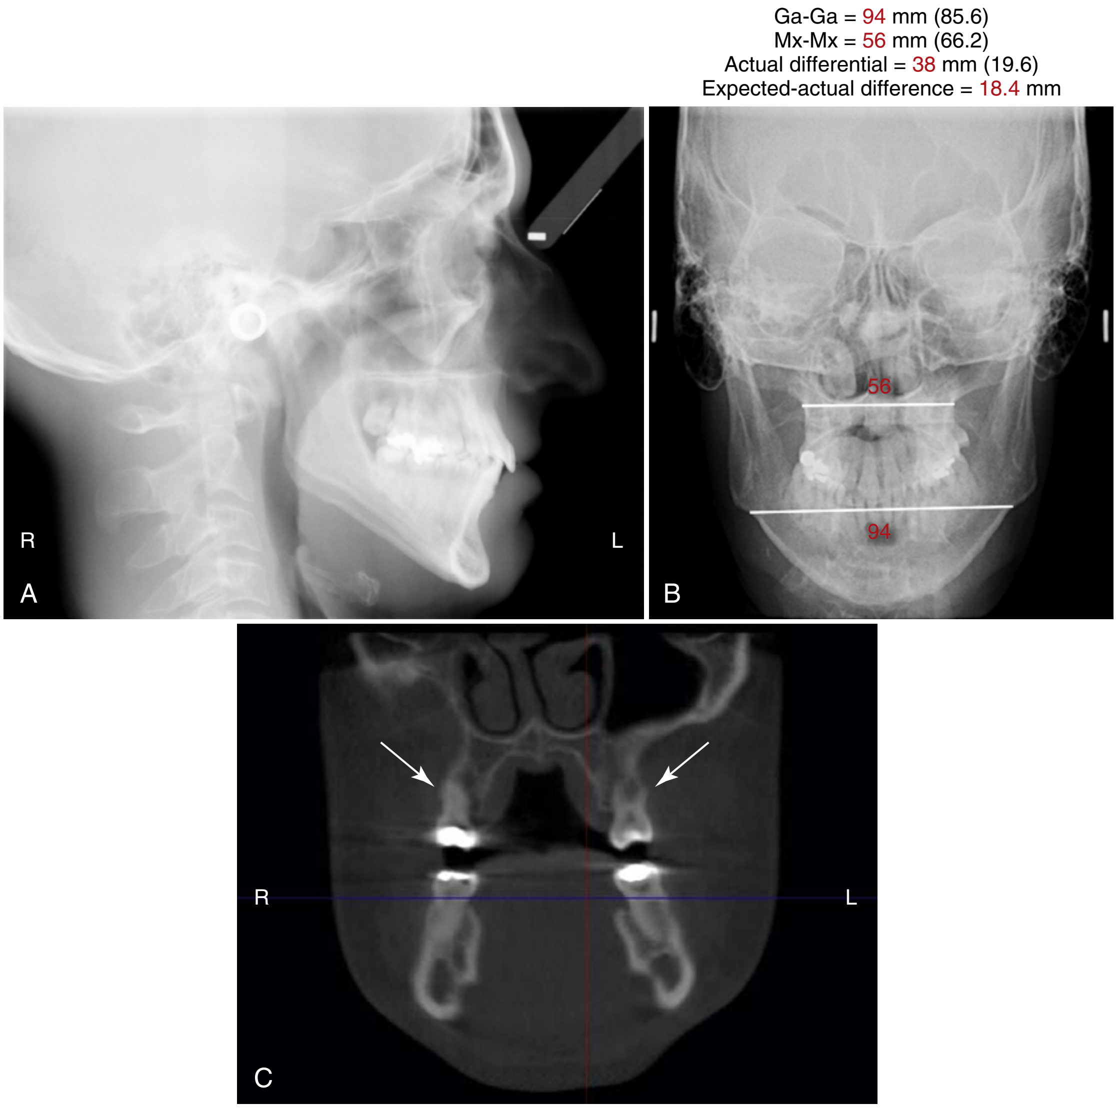

FIGURE 23-20 A, Lateral cephalogram illustrates antero-posterior dento-skeletal diagnostic landmarks. B, Postero-anterior (Frontal) cephalogram illustrates the transverse diagnostic landmarks. C, Postero-anterior (Frontal) Cone Beam image provides additional diagnostic information to manage width discrepancies of the maxilla and mandible.

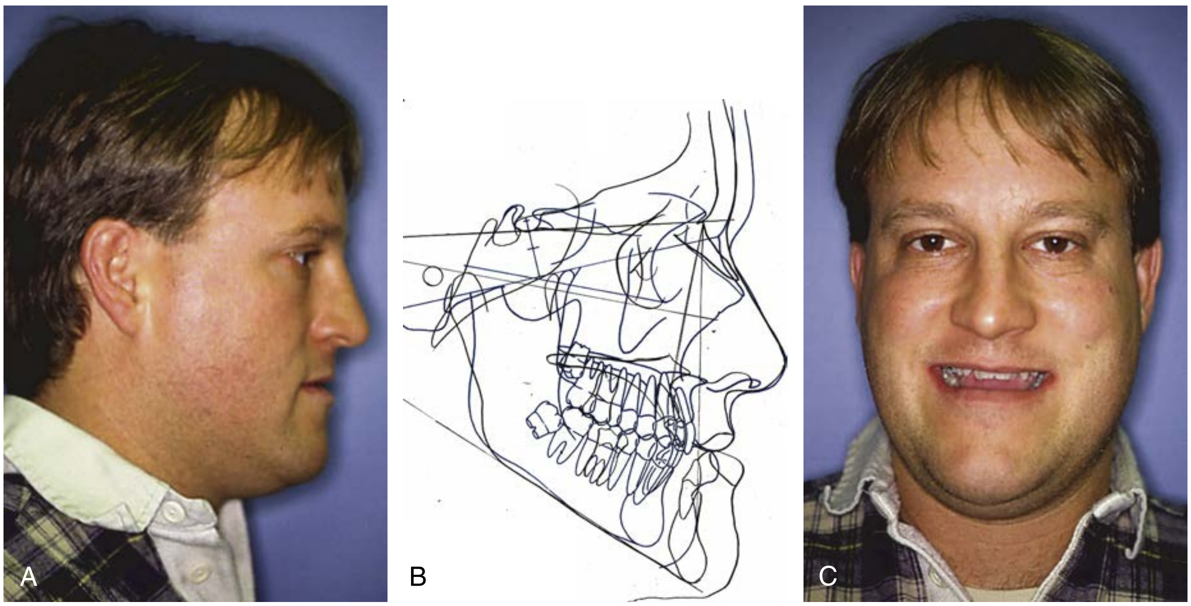

FIGURE 23-22 A, Pretreatment profile photograph. B, Patient tracing with Bolton template used to guide direction and amount of skeletal and dental changes needed for correction. C, Pretreatment facial photograph.

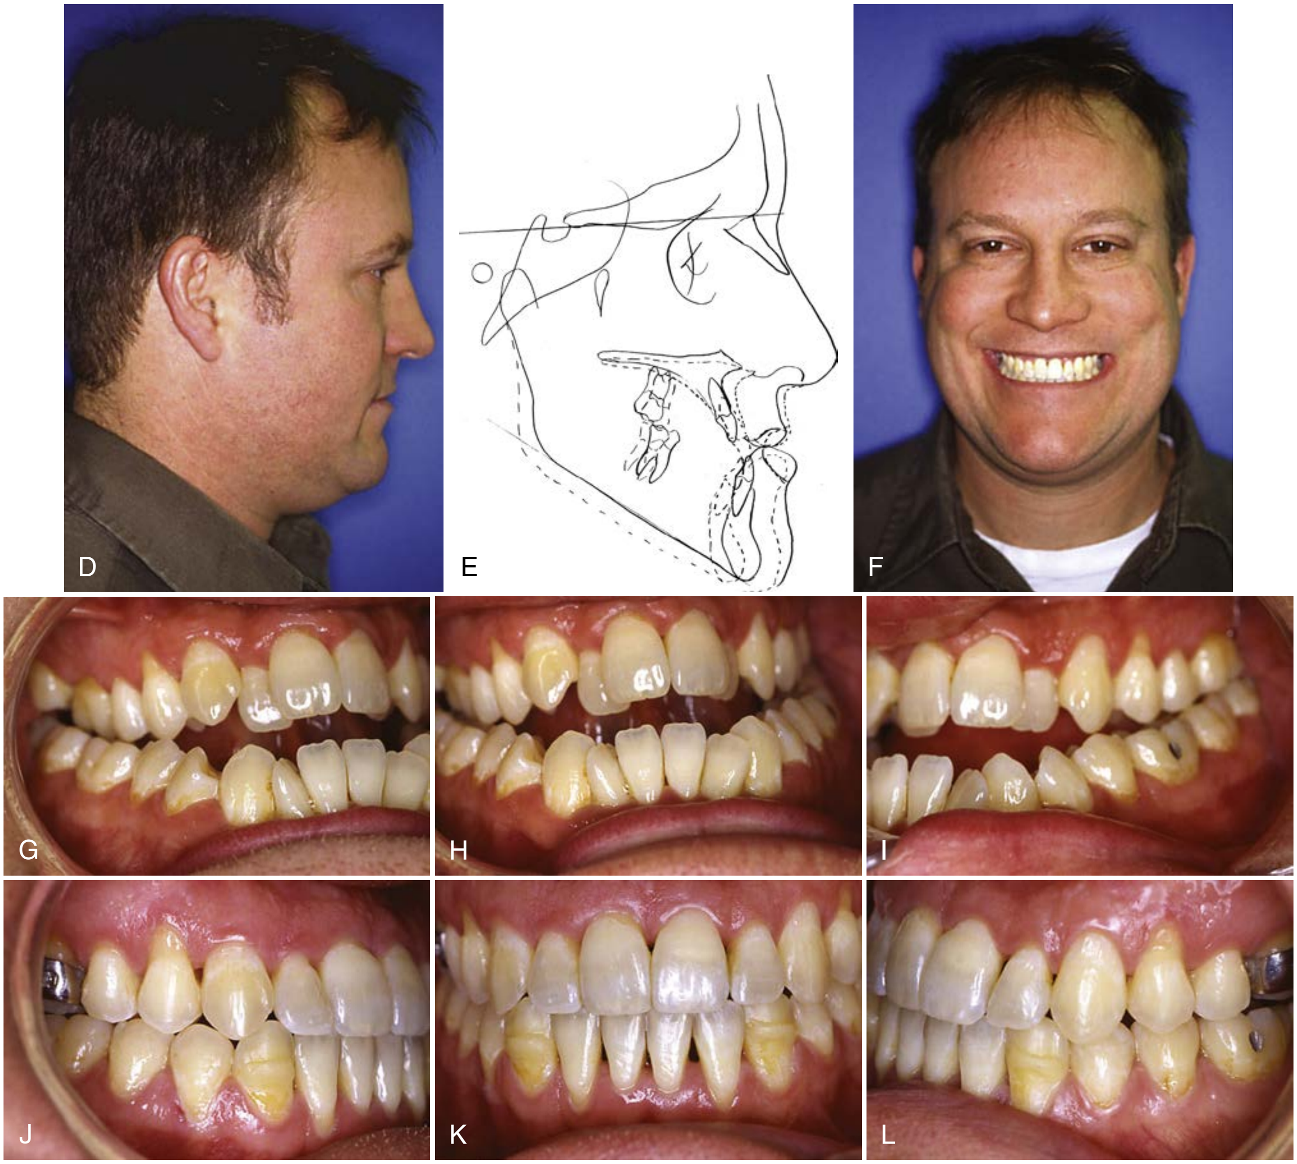

FIGURE 23-22, cont'd **D,** Posttreatment profile photograph. **E,** Superimposition of lateral cephalogram tracing (*solid lines* represent pretreatment appearance; *dashed lines* represent posttreatment appearance). **F,** Posttreatment facial photograph. **G–I,** Pretreatment intraoral photographs showing severe skeletal Class III malocclusion, crowding, anterior and posterior crossbites, and anterior open bite. **J–L,** Posttreatment intraoral photographs showing Class III correction after (*1*) phase I distraction surgery to resolve maxillary transverse deficiency and to reduce anteroposterior (AP) maxillary deficiency, (*2*) orthodontic treatment for about 22 months to decompensate dental malpositions, and (*3*) phase II jaw surgery to advance maxilla to complete the AP correction and to set mandible back and correct mandibular asymmetry and excess.

quick, and reliable tool that could be used in consultation with the treating oral surgeon and with patients to demonstrate the direction and approximate amount of surgery needed to correct the skeletal disharmony (Figs. 23-23 to 23-29). Proffit has discussed the use of template analysis in the surgical textbook he wrote with White.[40] Proffit pointed out that the template may appear to be less scientific than a table of cephalometric measurements with standard deviations, but he also noted that "the template is a visual analog of a table and is just as valid." Proffit also explains, "What the template does is place the emphasis on the analysis itself; that is, deciding what the distortions are, rather than on an intermediate measurement step that too often becomes an end in itself rather than just a means to an end."

The authors have found that the template approach to cephalometric analysis allows an assessment of skeletal landmarks compared with age-matched norms. Use of nasal superimposition fully integrates the nose into cephalometric assessment and allows the clinician to assess soft tissue compensation for skeletal imbalance. The authors have found this approach to

TABLE 23-4 Medical Problems Significant for Surgical-Orthodontic Treatment*

Condition	Significance	Comments
Diabetes mellitus	Susceptible to periodontal breakdown during orthodontic treatment; decreased resistance to infection; poor wound healing	Maintenance of excellent control is necessary.
Hyperthyroidism	Increased metabolic rate; tendency to osteoporosis	Infection may create crisis; psychological instability is possible.
Adrenal insufficiency	Decreased stress tolerance; delayed healing	Knowledge of steroid dosage is important.
Pregnancy	Major hormonal changes; increased susceptibility to periodontal breakdown	Defer surgical treatment; limited orthodontic treatment is acceptable, but careful periodontal monitoring is required.
Rheumatic heart disease, other heart disease	Susceptible to endocarditis	Antibiotic coverage is required for invasive procedures (in orthodontics, for banding but not for bonding or routine adjustments).
Bleeding disorders (e.g., hemophilia, von Willebrand disease, and thrombocytopenia)	Susceptible to bleeding	Replace missing clotting factors before surgery (in orthodontics, bonded attachments instead of bands and avoidance of aspirin and related drugs for pain control).[106]
Sickle cell anemia	Susceptible to sickle cell crisis and bone loss	Patients are not good candidates for general anesthesia; therefore, they usually are not considered for orthognathic surgery.
Allergy-immune problems	Excessive reaction to drugs and other antigens	In rare cases, nickel content in stainless steel orthodontic appliances causes problem.
Rheumatoid arthritis	Episodic involvement of multiple joints and possible destruction of temporomandibular joint (TMJ)	Manipulation of TMJ tends to exacerbate problem; avoid functional appliances, Class II elastics, and mandibular advancement.
Osteoarthritis	Progressive involvement of multiple joints, possibly including TMJ, with increasing age	Orthodontics or orthognathic surgery has little effect for better or worse on involved TMJ.
Behavioral disorders	Depends on degree of control; patients often taking potent medications	Drug effects may slow orthodontic tooth movement; bizarre reactions to surgery are possible.

*In all instances, surgical-orthodontic treatment should be undertaken only after these and related conditions are under medical control.

Adapted from Proffit WR, White RP. *Surgical-Orthodontic Treatment*. St. Louis: Mosby; 1990.

be excellent for diagnosis and treatment planning for skeletal dysplasias. In its application, it should be considered *template-guided diagnosis and treatment planning* and is illustrated in Figures 23-23 to 23-29.

In addition to diagnosing the AP and vertical skeletal components of the patient's disharmony, it is also essential to make an accurate diagnosis of the contributing transverse skeletal component. Until 3D diagnostic parameters are clearly established (see Chapter 11), the analysis of frontal radiographs continues to be an effective approach to identify true transverse skeletal discrepancies that may require surgical management (Fig. 23-30).

Diagnosing Class II Mandibular Deficiency and Class III Mandibular Excess

The authors use the expanded version of the Angle classification system to create a more accurate perspective to diagnostic descriptions (Class II mandibular deficiency—low Mandibular Plane (MPl) angle as illustrated in Figure 23-23, or Class III mandibular excess—high angle as illustrated in Fig. 23-28). These descriptions are then integrated with the diagnostic steps of quantification and a rating of severity to illustrate diagnostic and treatment differences of the basic types of problems that arise with mandibular deficiency and mandibular excess (see Figs. 23-23 to 23-28). In each of these figures, note that the Bolton template superimposition is used to show the skeletal deviations from the template ideal. The process of differential diagnosis of the structural problem, then, includes the following steps:

1. **Classification:** The condition is assigned to a category of Class I, II, or III. (Angle's traditional system of classification still is important and can help with codification for insurance purposes.)
2. **Qualification:** The problem location is determined (i.e., Is the problem in the upper jaw only? The lower jaw only? Is it all skeletal, or part skeletal and part dental?).
3. **Quantification**: The extent to which each jaw contributes to the problem is determined by percentage or in millimeters.
   - Severity: A scale of 0 to 10 provides a rating of the severity of AP, transverse, and vertical problems, as well as of tooth alignment, dental pathologic conditions, TMJ status, psychosocial factors, and the patient's degree of motivation. Although each problem could be rated individually, the concept of using one number to rate the whole constellation of problems helps the patient understand, in a relative way, the severity of the current condition. Whereas a rating of 0 means that conditions are ideal or that no problems exist, a rating of 10 indicates a severe dentoskeletal imbalance with possible pathologic sequelae. This number also can be used to project the prognosis for the outcome of the various treatment options under consideration.
4. **Prediction of the prognosis:** (This may vary depending on the treatment plan chosen.) Again using the visual analog scale (0–10), it is helpful to predict the improvement of the patient's condition based on the treatment plan. For example, a patient with a transverse problem who accepts surgical expansion may improve from severity of 7 of 10 to 1 of 10 with surgery but only improve to a 5 of 10 without surgery.

Treatment Planning Options

With the safety of jaw surgery techniques improving as a result of modifications in surgical approaches and with anesthetic procedures becoming more sophisticated, orthognathic surgery offers the orthodontist and the patient a range of treatment planning options. When a patient has a problem in which

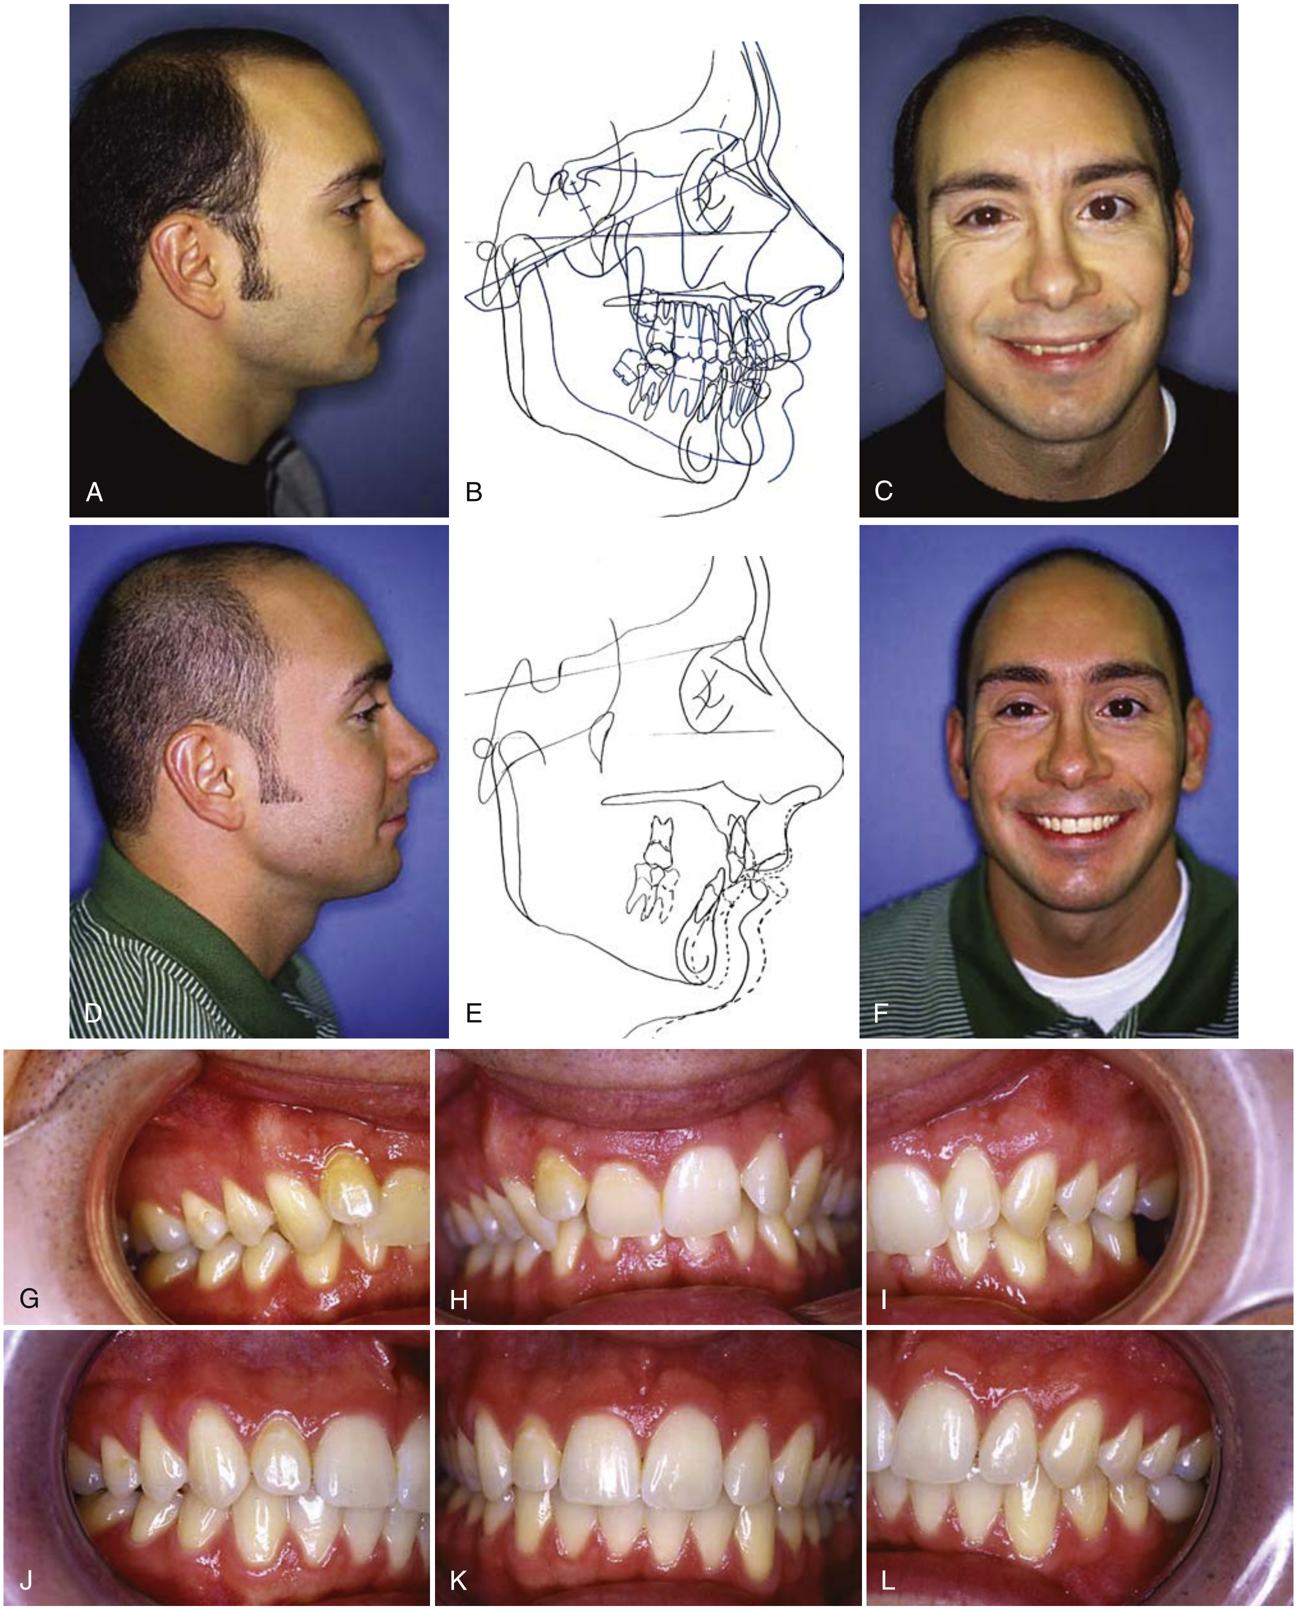

FIGURE 23-23 Patient: TH; age 27 years, 10 months; male. Classification: Class II, Division 2, deep bite, and bite collapse on left. Qualification: Mandibular anteroposterior deficiency and vertical deficiency. Quantification: 100% mandibular skeletal deficiency; mandibular vertical deficiency; moderate horizontal excess in chin area camouflages the skeletal deficiency of the mandible. Severity: 8 of 10, with 10 being most severe and 0 being perfect. Prognosis: 1 of 10 with comprehensive orthodontics and jaw surgery. **A,** Pretreatment profile photograph. **B,** Bolton template–guided diagnosis and treatment plan. **C,** Pretreatment facial photograph. **D,** Posttreatment profile photograph. **E,** Cephalometric superimposition. **F,** Posttreatment smile photograph. **G–I,** Intraoral pretreatment photographs showing Class II malocclusion. **J–L,** Intraoral posttreatment photographs showing optimal correction with replacement of missing no. 19.

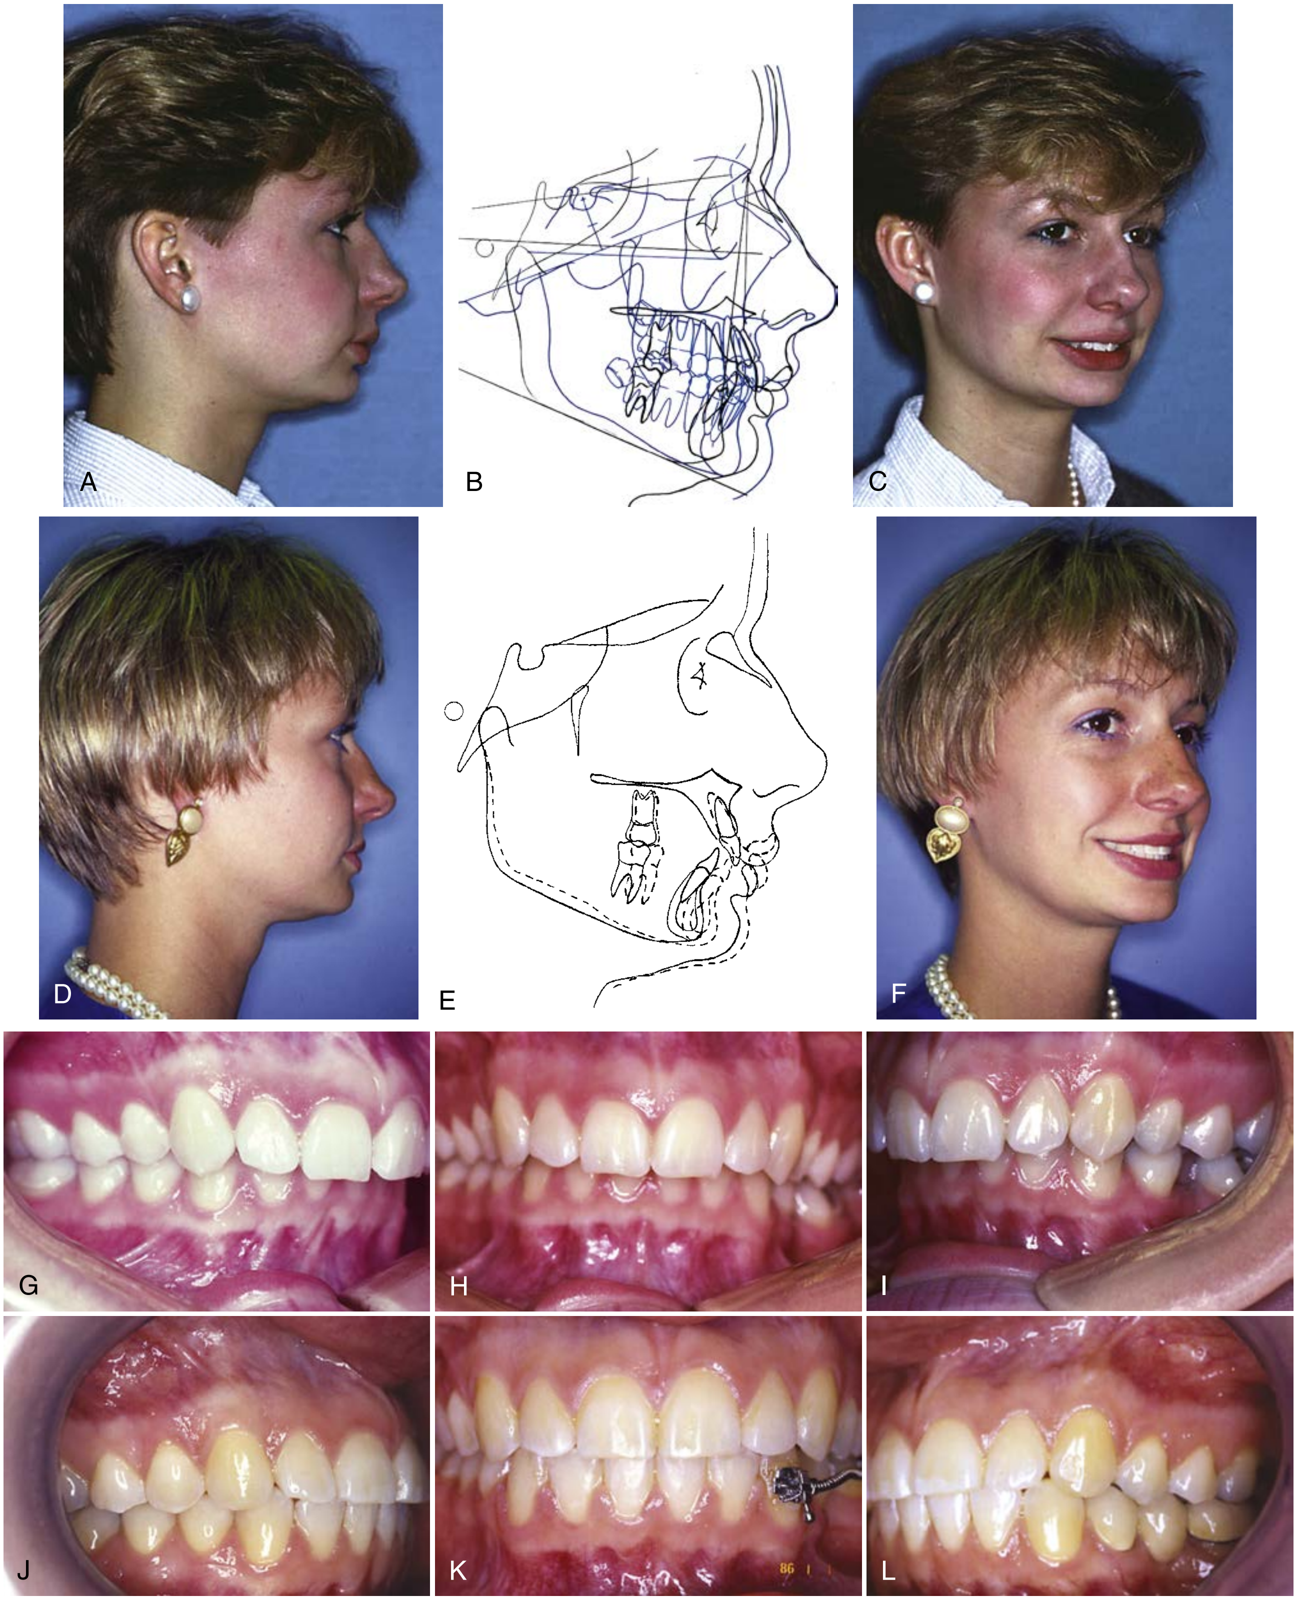

FIGURE 23-24 Patient: JT; age 17 years, 11 months; female. Classification: Class II, Division 1. Qualification: Mandibular deficiency type II. Quantification: 100% mandibular deficiency with normal maxillary skeletal and dental position as seen through template analysis (14C). Severity: 7 of 10. Prognosis: 0.5 of 10 with comprehensive orthodontics and jaw surgery. **A,** Pretreatment profile photograph showing evidence of mandibular deficiency. **B,** Bolton template–guided diagnosis and treatment plan used template superimposition that shows good maxilla position and horizontal and vertical mandibular deficiency. **C,** Pretreatment facial photograph. **D,** Posttreatment profile photograph showing change as a result of orthodontic treatment and mandibular advancement. **E,** Cephalometric superimposition showing corrected mandibular deficiency. **F,** Posttreatment smile photograph. **G–I,** Intraoral pretreatment photographs showing Class II malocclusion, bite collapse, and deep bite. **J–L,** Intraoral posttreatment photographs showing correction with bridge in **L** replacing no. 19.

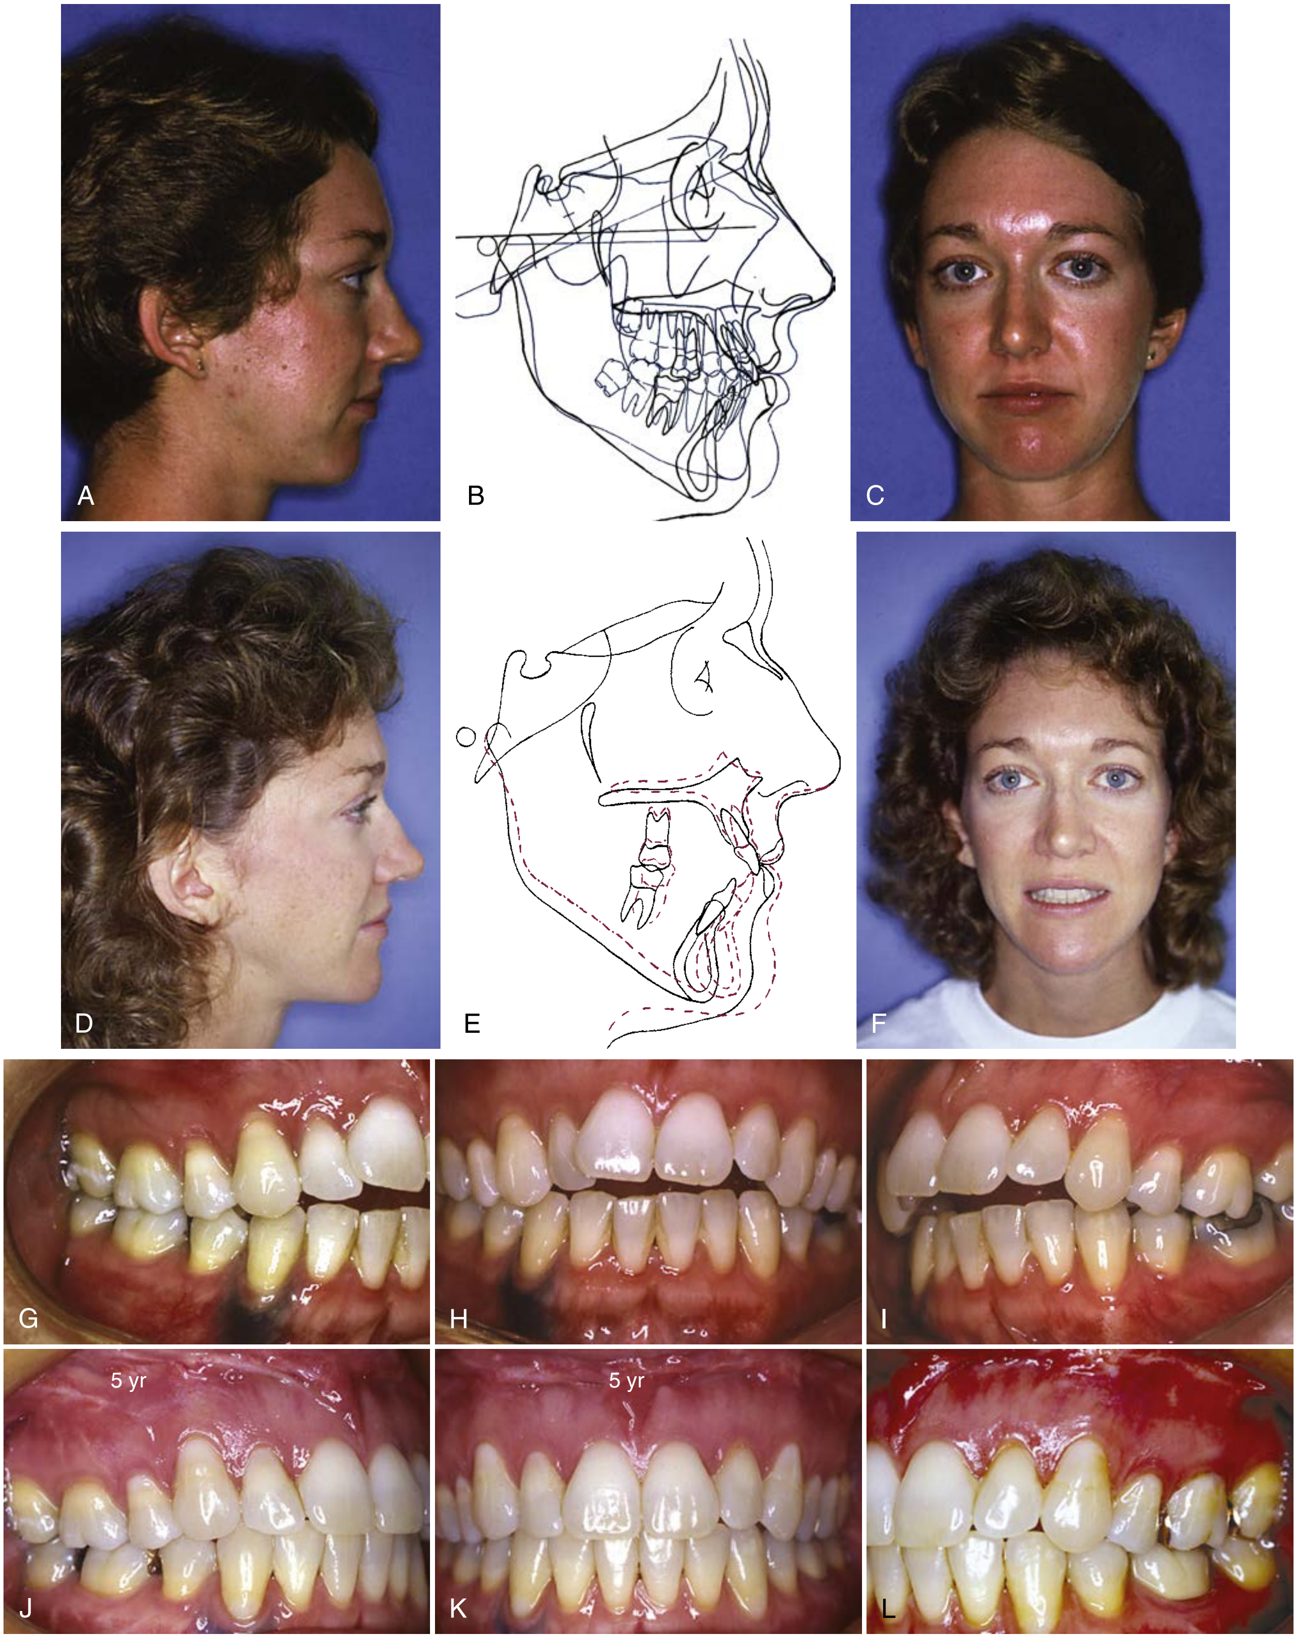

FIGURE 23-25 Patient: LG; age 26 years, 4 months; female. Classification: Class II, Division 1. Qualification: Mandibular deficiency type III with open bite. Quantification: Maxillary posterior vertical excess in 100% mandibular deficiency. Severity: 8 of 10 (patient also has temporomandibular joint pain and disk displacement with reduction). Prognosis: Temporomandibular (reevaluate) occlusal function, 1 of 10; favorable prognosis with comprehensive orthodontic treatment and jaw surgery. **A,** Pretreatment profile photograph. **B,** Bolton template–guided diagnosis and treatment plan. **C,** Pretreatment facial photograph. **D,** Posttreatment profile photograph. **E,** Cephalometric superimposition. **F,** Posttreatment smile photograph. **G–I,** Intraoral pretreatment photographs showing malocclusion. **J–L,** Intraoral posttreatment photographs showing optimal correction.

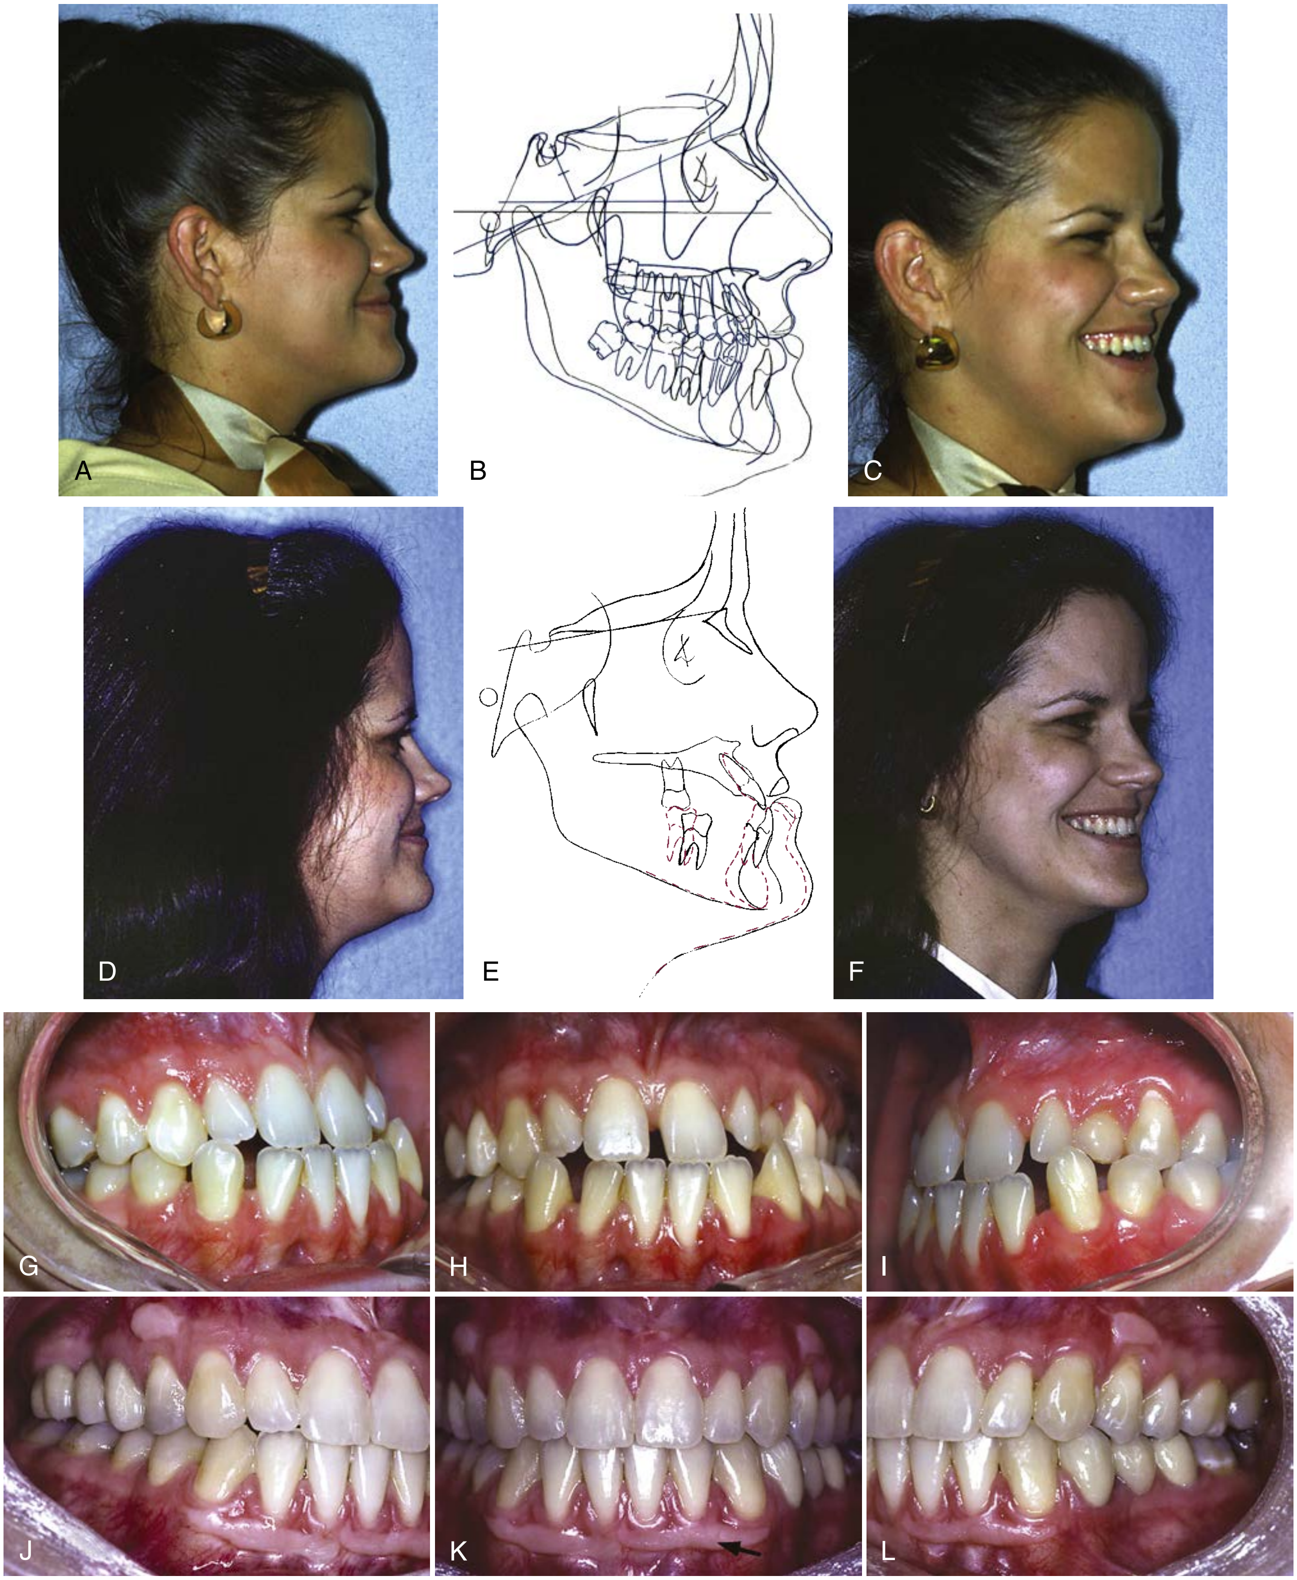

FIGURE 23-26 Patient: PM; age 24 years, 3 months; female. Classification: Class III mandibular excess type I (low mandibular plane angle). Qualification: Mandibular skeletal excess with significant maxillary dentoalveolar compensation and relative protrusion. Quantification: 100% mandibular excess. Severity: 8.5 of 10; severe skeletal problem; impaction of no. 11, dental spacing, and mucogingival deficiency. Prognosis: 2 of 10; prognosis is estimated at 2 because of the impacted canine and other dental problems that require management; the patient has a good attitude for handling complicating factors in treatment. **A,** Pretreatment profile photograph. **B,** Bolton template–guided diagnosis and treatment plan. **C,** Pretreatment facial photograph. **D,** Posttreatment profile photograph. **E,** Cephalometric superimposition. **F,** Posttreatment smile photograph. **G–I,** Intraoral pretreatment photographs showing malocclusion. **J–L,** Intraoral posttreatment photographs showing optimal correction. Note an extra premolar was added between no. 20 and no. 21 to aid in dental decompensation and to stabilize excess lower spacing.

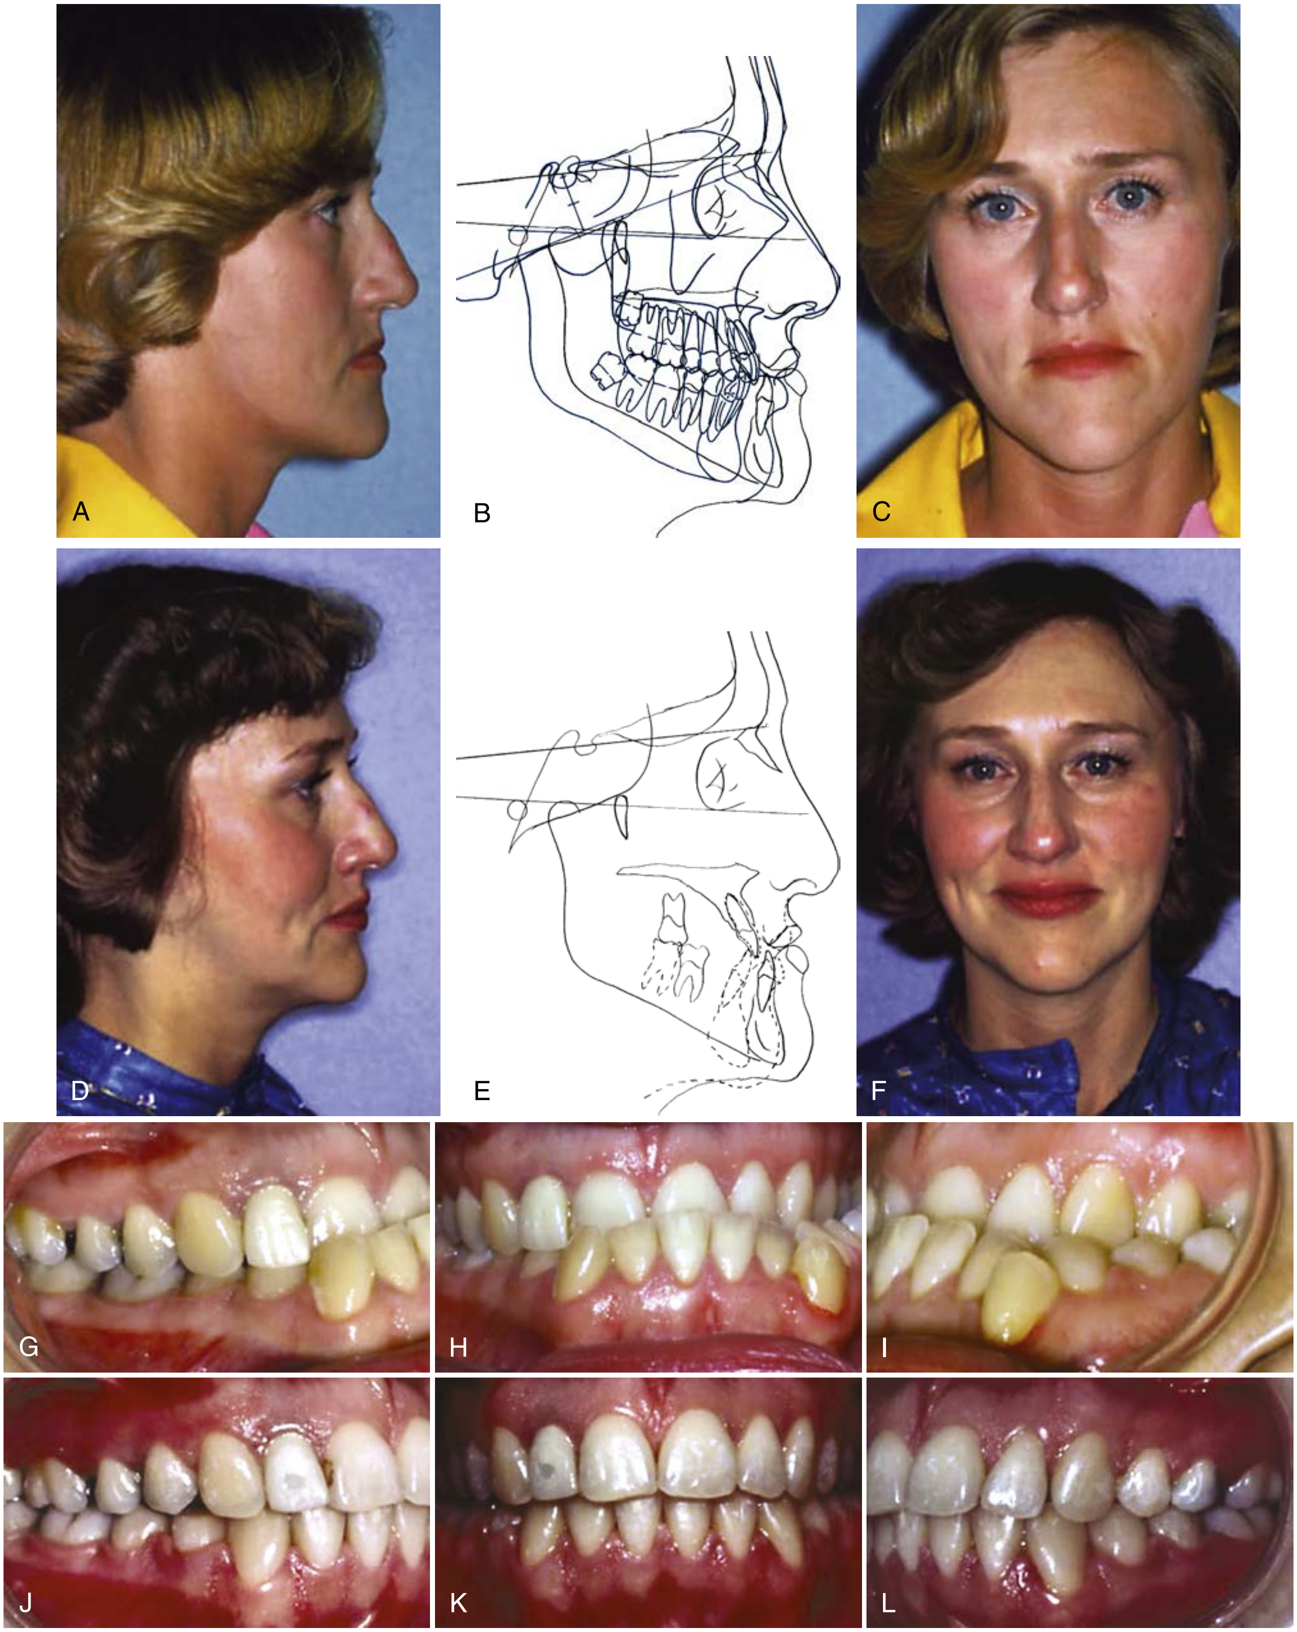

FIGURE 23-27 Patient: EF; age 30 years, 8 months; female. Classification: Class III skeletal condition. Qualification: Mandibular excess type II (moderate mandibular plane angle). Quantification: 100% mandibular excess. Severity: 7 of 10 skeletal severity and long-standing dental compensation of the lower incisors. Prognosis: 2 of 10; the prognosis is good with full orthodontic treatment and jaw surgery (chin excess and nasal form may require cosmetic procedure for ideal outcome). **A,** Pretreatment profile photograph. **B,** Bolton template–guided diagnosis and treatment plan. **C,** Pretreatment facial photograph. **D,** Posttreatment profile photograph. **E,** Cephalometric superimposition. **F,** Posttreatment smile photograph. **G–I,** Intraoral pretreatment photographs showing malocclusion. **J–L,** Intraoral posttreatment photographs showing optimal correction.

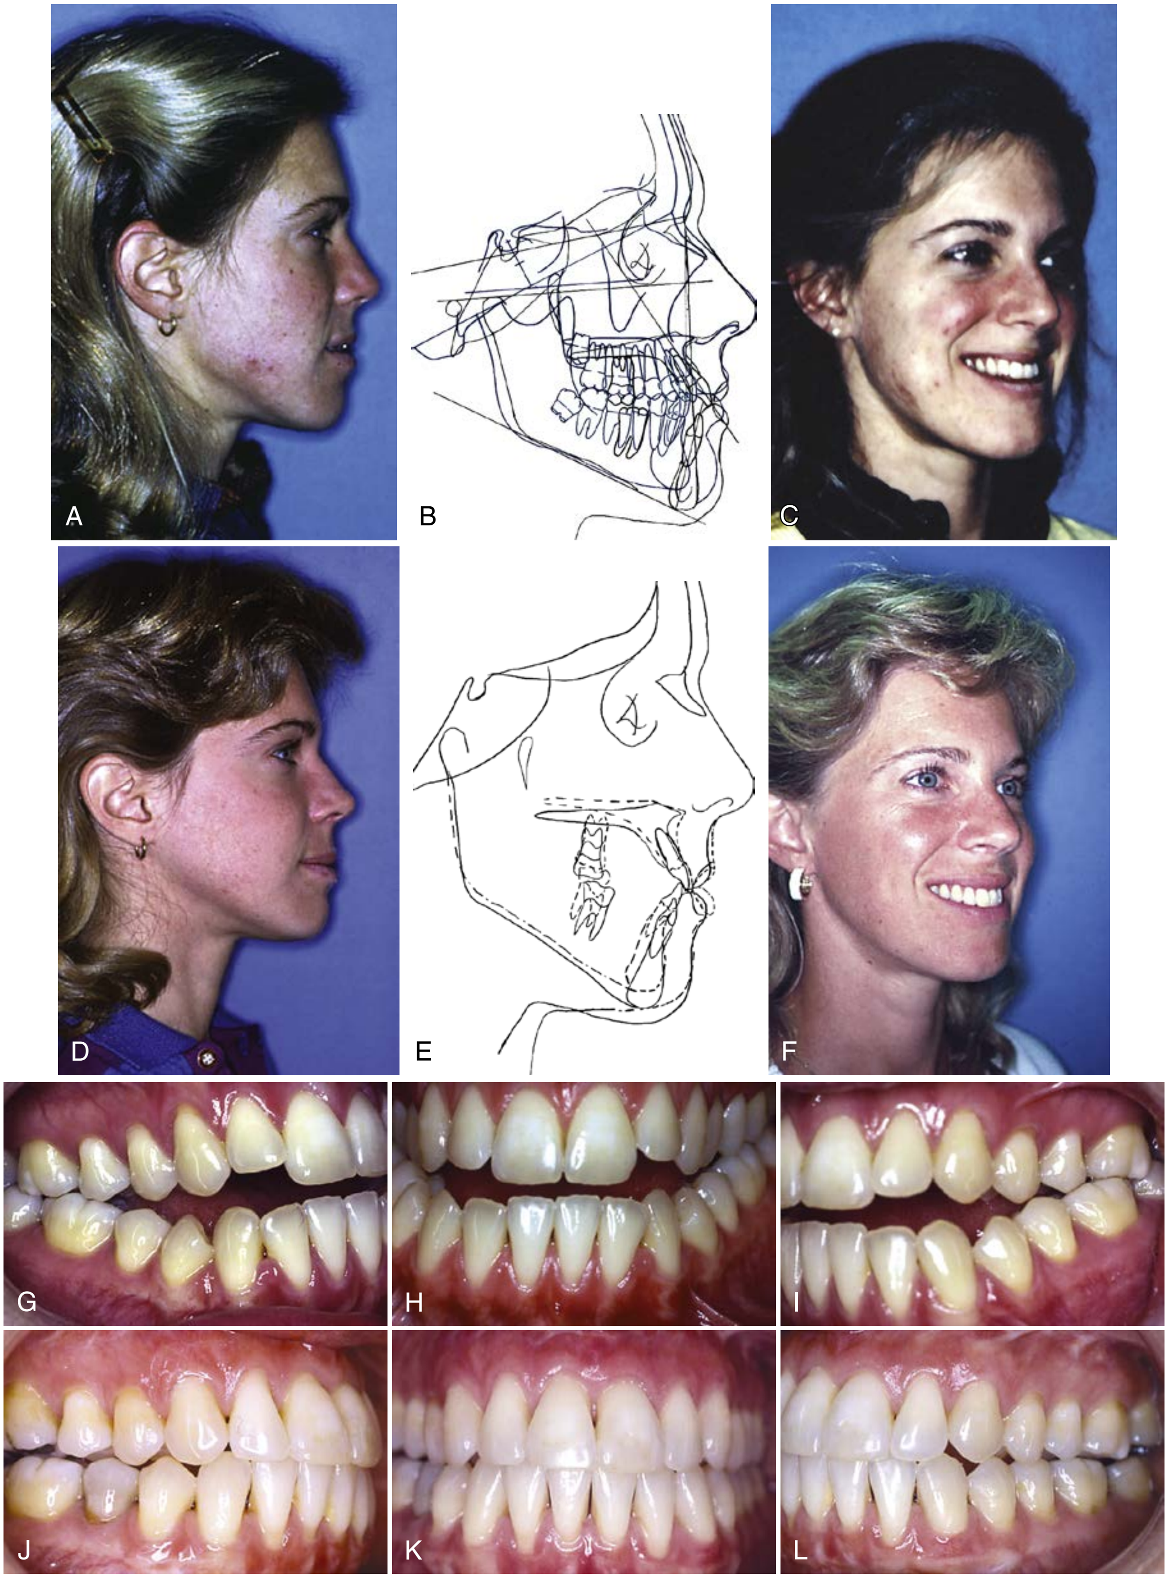

FIGURE 23-28 Patient: AL; age 25 years, 6 months, female. Classification: Class III skeletal condition with mild alignment problems and no incisor occlusion. Qualification: Mandibular excess with a high mandibular plane angle. Quantification: Mandibular horizontal excess with maxillary posterior vertical excess and an anterior open bite+. Severity: 8.5 of 10; the condition is a multifaceted problem complicated by muscle and joint pain and severe gingival deficiency in the lower anterior and upper posterior areas. Prognosis: 2 of 10; significant improvement can be achieved with successful interdisciplinary therapy using proper temporomandibular dysfunction management, orthodontic and surgical treatment, and periodontal grafting procedures. This patient was highly motivated and complied with the provider team's interdisciplinary treatment recommendations. Her condition responded well to the therapy, as can be seen in the posttreatment photographs. **A,** Pretreatment profile photograph. **B,** Bolton template–guided diagnosis and treatment plan. **C,** Pretreatment facial photograph. **D,** Posttreatment profile photograph. **E,** Cephalometric superimposition. **F,** Posttreatment smile photograph. **G–I,** Intraoral pretreatment photographs showing malocclusion. **J–L,** Intraoral posttreatment photographs showing optimal correction.

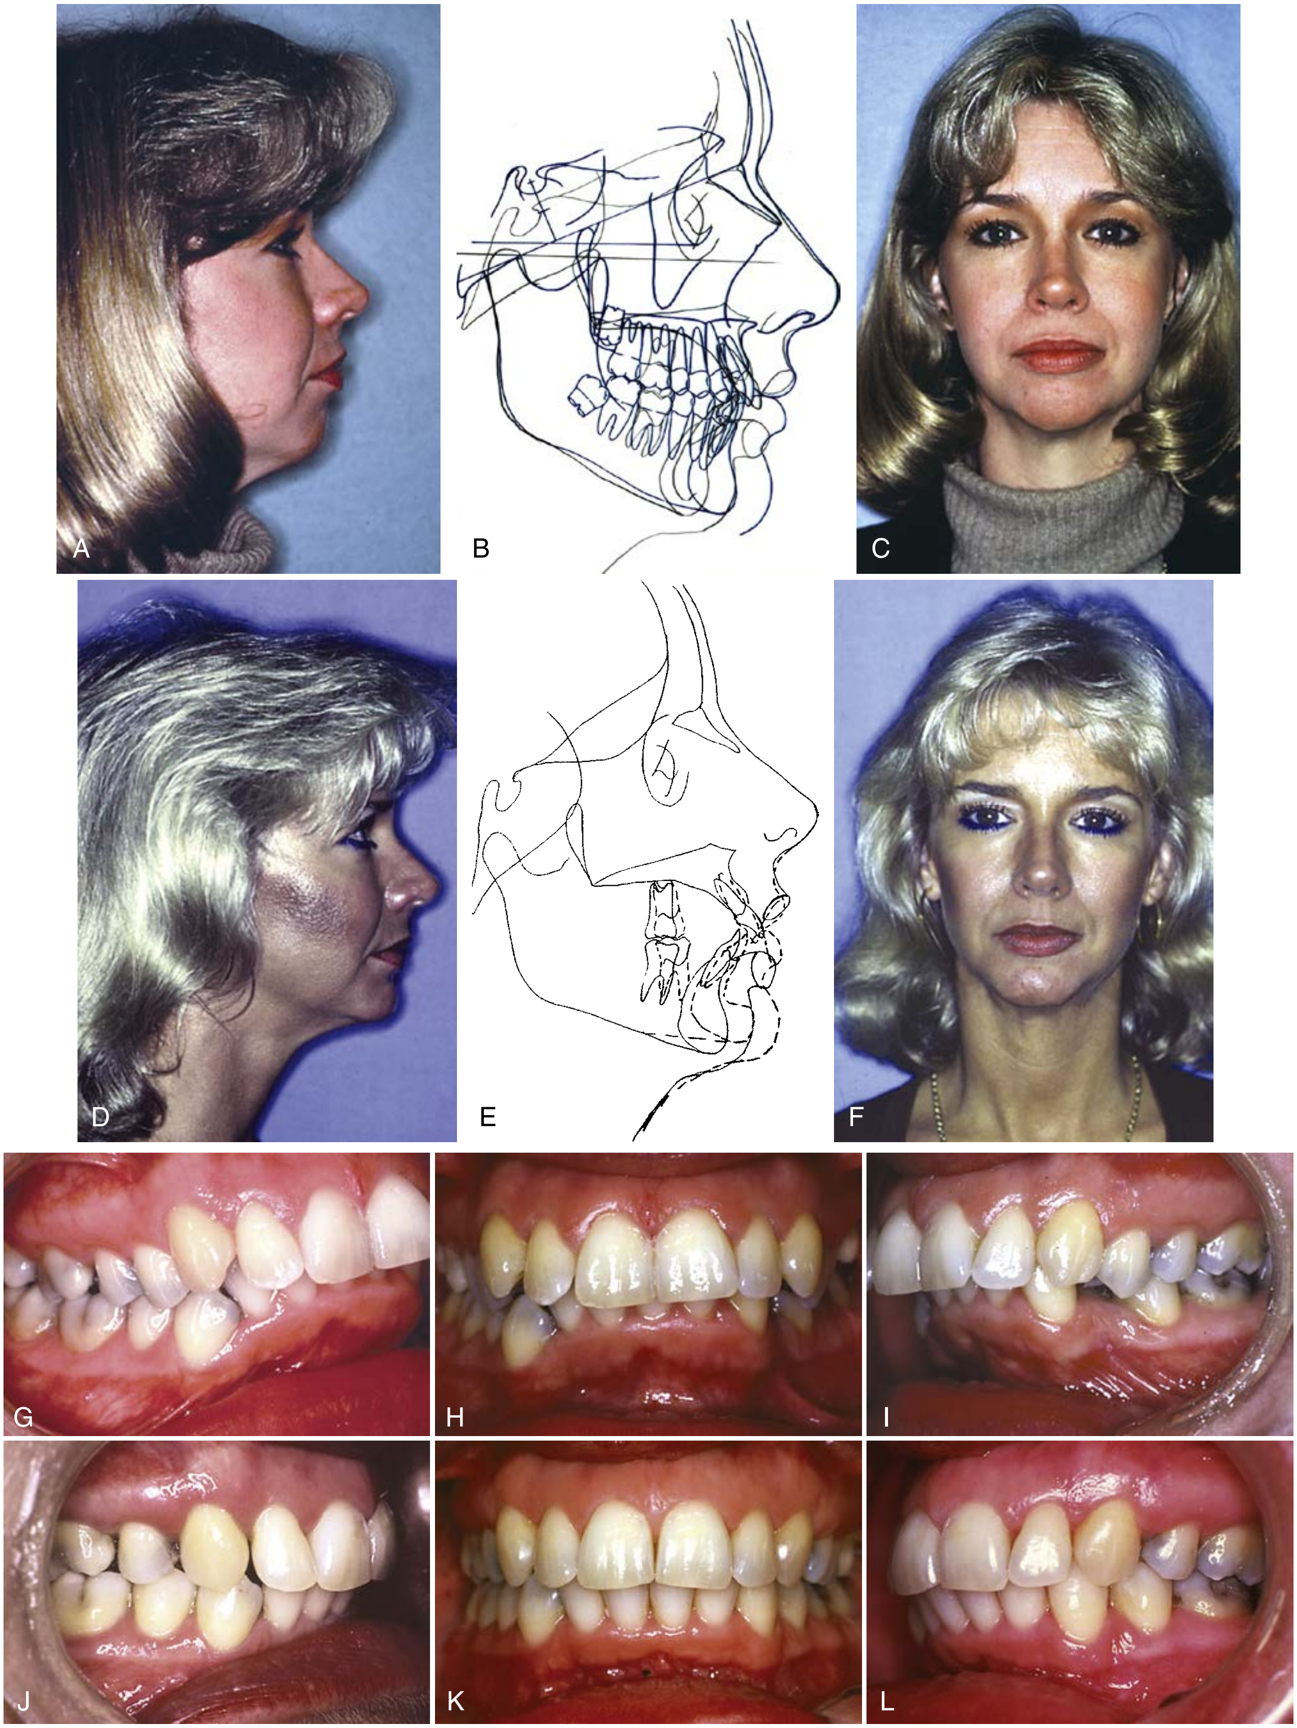

FIGURE 23-29 **A,** Pretreatment profile photograph. Note protrusive lip and minimal throat and chin definition. **B,** Patient tracing with Bolton template indicates maxillary dentoalveolar protrusion and mandibular deficiency with chin deficiency. **C,** Pretreatment facial photograph. **D,** Posttreatment profile photograph showing improved throat and chin definition because of soft tissue "stretch" from successful chin implant. **E,** Superimposition of lateral cephalogram tracing showing dental retraction of upper incisors (camouflage skeletal Class II) and improved hard and soft tissue in chin area. **F,** Posttreatment facial photograph. **G–I,** Pretreatment intraoral photographs. **J–L,** Posttreatment intraoral photographs.

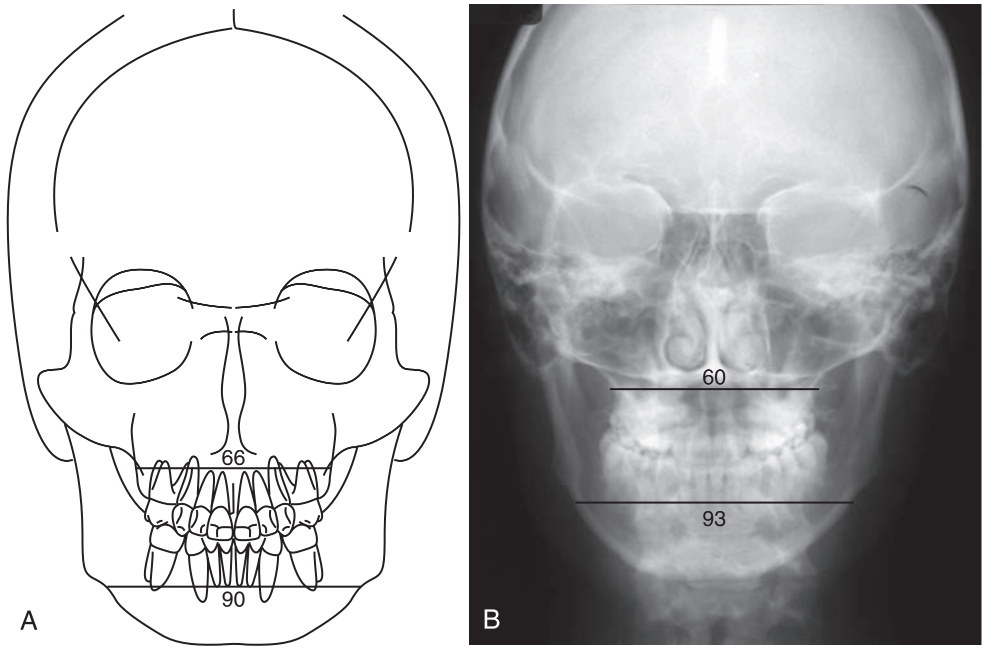

FIGURE 23-30 A, Composite frontal tracing of Bolton standard for adults. The normal maxillary width is 66 mm, and the mandibular width is 90 mm, as measured from 18 adults from 5000 who were determined to be the standard (normal) with a maxillomandibular differential of 24 mm. B, Frontal cephalogram of a woman who required orthodontic retreatment because of inadequate correction of maxillary–skeletal transverse deficiency. This patient had a maxillomandibular differential of 9 mm and required surgical expansion in conjunction with her orthodontic therapy.

both the maxilla and mandible are major components of the problem, both jaws may require surgery. If the patient accepts the optimal treatment plan and when the result achieved matches the patient's, orthodontist's, and maxillofacial surgeon's expectations, optimal outcomes result (see Figs. 23-8, 23-11, and 23-12).

Treatment planning options for cases with *skeletal (basal bone discrepancy) components* affecting the malocclusion include:

- Mild skeletal factors: Comprehensive orthodontics is generally effective.
- Moderate skeletal factors (with growth): comprehensive orthodontics + orthopedics + camouflage with the need to periodically reevaluate the response while growth proceeds[88]
- Moderate skeletal factors (without growth): comprehensive orthodontics + camouflage + skeletal anchorage to amplify the camouflage effort[89]
- Moderate to severe skeletal factors: comprehensive orthodontics + one-jaw surgery
- Severe skeletal imbalance: comprehensive orthodontics + one- or two-jaw surgery; considerations for two-stage orthognathics if transverse discrepancy is also severe
- Moderate skeletal (without growth) and moderate to severe skeletal factors with dentoalveolar components: may be candidates for SFOT, as discussed previously in this chapter and presented by Roblee et al.[58] It is to be noted that a recent systematic review of the literature on the topic of corticotomy assisted tooth by Hoogeveen et al.[90] revealed:
  - There is need for more well-designed studies on this topic because only 18 of 510 articles met the criteria for inclusion in the systematic review.
  - Corticotomy-facilitated orthodontics temporarily enhanced the rate of tooth movement.
  - There were minimal complications.

Indications for Camouflage Treatment

To illustrate the treatment planning process further, one should be able to answer this question: What makes a borderline orthodontic–surgical case into a successful camouflage treatment? Craniofacial characteristics make up only part of several important considerations in determining the effectiveness of camouflage treatment (see Figs. 23-1 and 23-31 and Box 23-4).

Other important considerations include the following:

1. Moderate basal bone discrepancy as determined by conventional cephalometric standards
2. Double-jaw involvement in the discrepancy; that is, 50% of the skeletal problem is due to maxillary AP excess, and the remaining 50% of the AP problem is related to mandibular deficiency (preferably with some chin contour). This allows the appearance of a more balanced soft tissue profile in the presence of a large AP discrepancy, thereby allowing more latitude for dental compensations.[91] One effective mechanism to assess this discrepancy quantitatively is by comparison of the patient's cephalogram with the Bolton template using nasal superimposition and Frankfurt horizontal (FH) parallel to the patient's FH (see Fig. 23-1).
3. Adequate alveolar bone and gingival tissue for incisor reangulation: Sometimes gingival grafting procedures are indicated to allow for the compensatory movements, and this is usually acceptable to achieve proper incisor guidance.
4. Patient acceptance of the possibility of long-term lingual arch bonded to mandibular anterior teeth

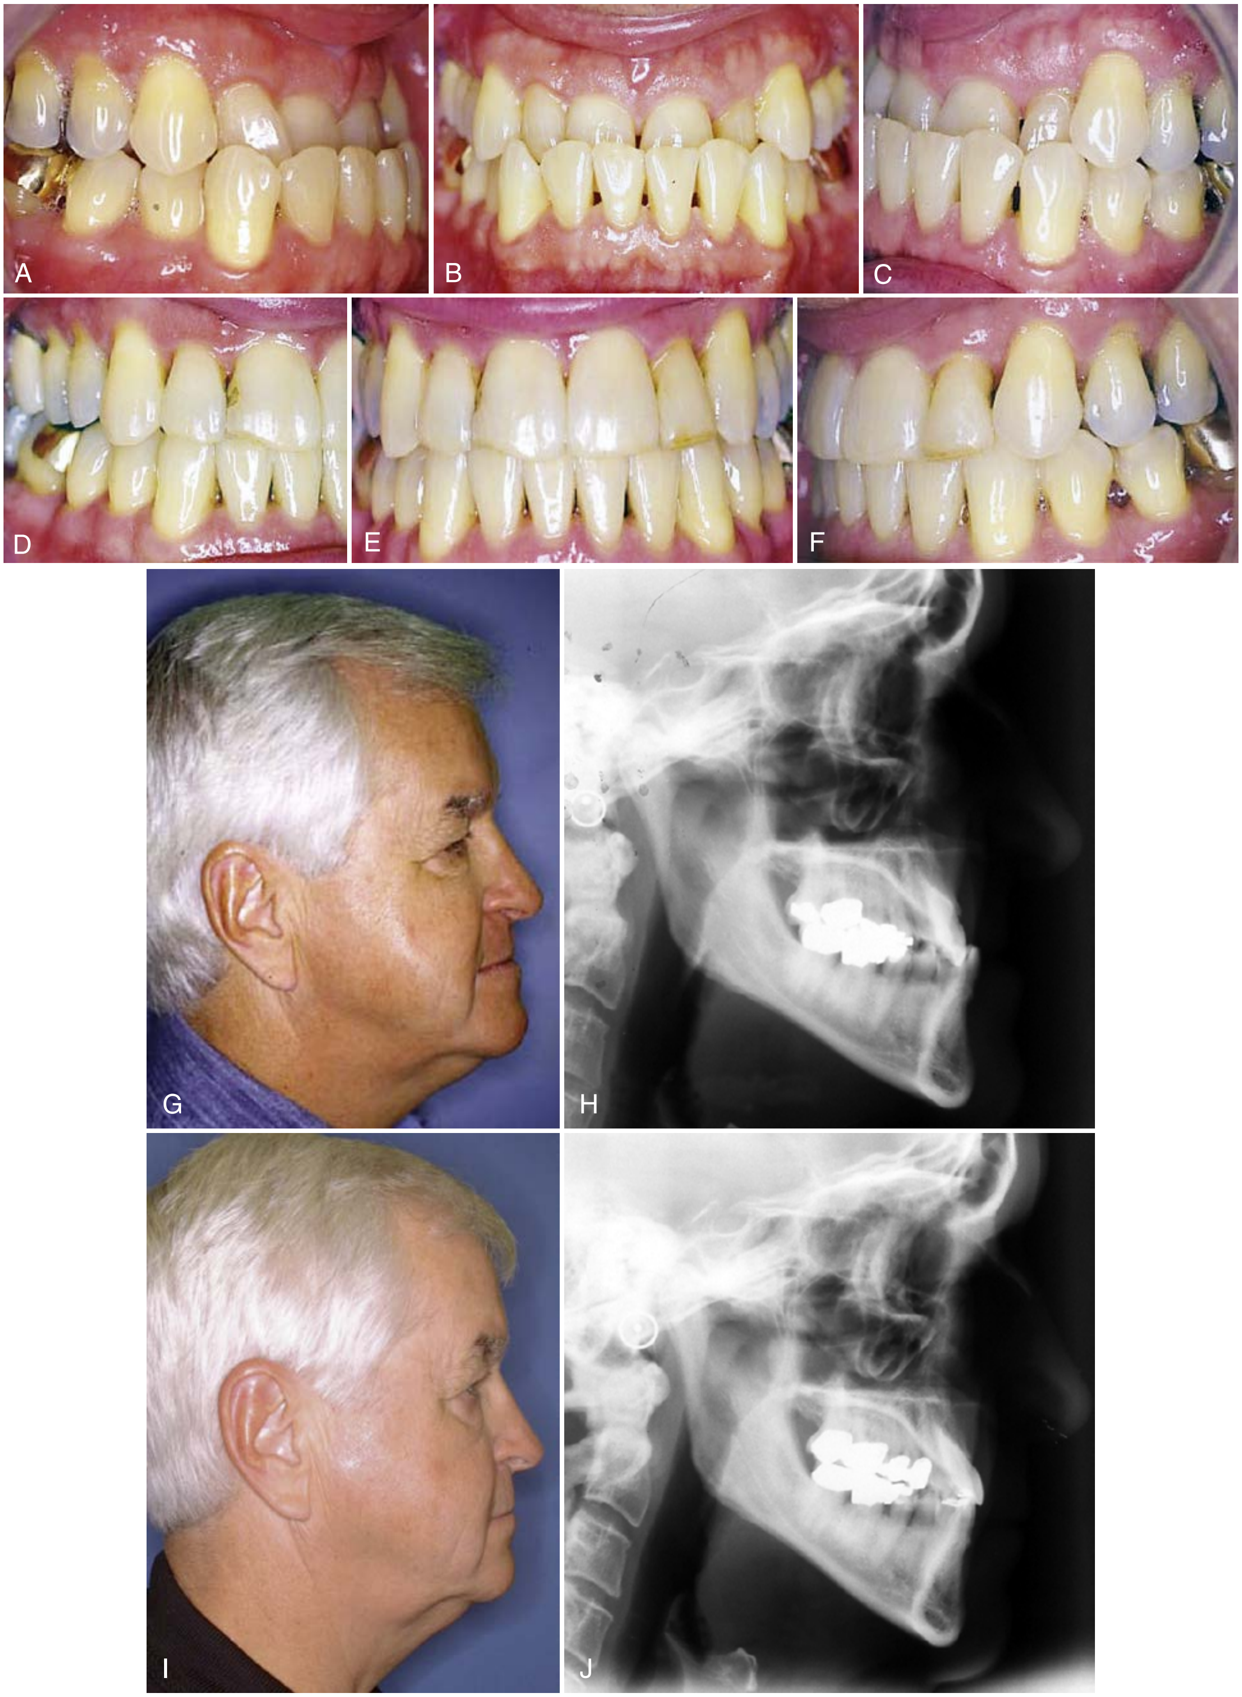

FIGURE 23-31 **A–C,** Intraoral photographs before any orthodontic treatment. Note the degree of anterior crossbite in this 62-year-old man. This functional imbalance is now causing tooth fracture and accelerated wear. **D–F,** Intraoral photographs after orthodontic treatment. Principles of therapeutic diagnosis were applied to determine if nonsurgical, or camouflage, treatment could be incorporated to solve this long-standing bite problem. Although a significant skeletal imbalance was present, the skeletal Class III problem was made worse because of incisal prematurity that forced the patient to shift his mandible forward 4 mm. **G** and **H,** Pretreatment profile photograph and pretreatment lateral cephalogram, respectively. **I** and **J,** Posttreatment profile photograph and posttreatment lateral cephalogram, respectively.

BOX 23-4 Camouflage Checklist for Class II Patients

- Skeletal malrelationship with Wits differential +4 mm or greater
- Bolton template superimposition (as described in this chapter)
- With almost equal portions of the Wits differential being contributed by maxillary basal (measured by "A" point) excess and mandibular deficiency (measured by "B" point) compared to the template. When the skeletal differential is present because of each jaw playing a part, as it relates to the nose, camouflage can more easily occur without having deleterious effects on soft tissue aesthetics. In other words, after upper premolar extractions, facial balance continues to be proportionate.
- If the cephalogram shows a Wits differential of +7, for example, and the template shows that the differential is all because of mandibular deficiency, camouflage therapy may help reduce the overjet, but it will result in overretraction of the upper incisors, require a great deal of incisal root torque (possible root resorption), and accelerate the aging of the face.
- Moderate upper incisor crowding and minimal lower incisor crowding also helps to justify camouflage because correcting the anterior alignment limits the degree of retraction and there is less impact on negative soft tissue changes of the upper lip.
- Patient acceptance of the possibility of long-term bonded lingual arch to lower anteriors
- If slightly more of the mandibular deficiency (Class II) is in the mandible, then to preserve upper lip support, the lower incisors may have to be compensated (proclined) more. In such cases, the amount of attached gingival of the lower anterior segment needs to be assessed. If the tissue is thin or deficient, gingival grafting may be needed to avoid gingival recession during proclination. In addition, the long-term stability of the lower anterior segment may require a lifetime bonded lower lingual arch.
- Another consideration is the aesthetic balance of the chin. Is there enough chin to create facial balance? Will proclination of the lower incisors reduce the effective chin to an undesirable aesthetic position? Should advancement genioplasty be considered and discussed with the patient? How much less risk does the advancement genioplasty carry than a mandibular advancement in this case?
- Stability of the outcome should also be included in the considerations of which treatment plan would serve the patient the best. With the above considerations, nongrowing Class II, Division 1 patients with maxillary dentoalveolar protrusion, moderate maxillary crowding, and minimal mandibular deficiency are good candidates for successful camouflage therapy with upper premolar extractions.

In the successful planning for camouflage treatment, the foregoing factors determined by template-guided diagnosis and evaluation help to define the orthodontist's treatment planning limits without surgical intervention and give the patient an opportunity to consider available treatment alternatives.

Contraindications to Camouflage Treatment

When treatment planning moderate skeletal imbalances, one should be aware, however, that not all borderline cases can accommodate camouflage treatment planning. In general, camouflage therapy is contraindicated when single-jaw imbalances are severe; that is, a patient demonstrates, on clinical evaluation and cephalometric measurement confirmation, that the total skeletal Class II malocclusion is secondary to mandibular deficiency (see Figs. 23-2 and 23-23 to 23-25). Although an incisal relationship may be achieved with camouflage treatment, the resulting profile would be imbalanced; the upper incisors would be excessively retroinclined and the lower incisors excessively proclined to achieve incisal contact. The skeletal Class II case in which there are both maxillary and mandibular deficiencies (relative to nasal superimposition) is another case type for which camouflage treatment planning should be avoided. This case type is seldom presented in the literature unless it is referenced to sleep apnea in which both maxillary and mandibular surgery is medically indicated.[15,69]

Upper and Lower Jaw Skeletal–Dental Problem

The orthodontist should consider the following three steps in addressing a skeletal–dental problem of the upper and lower jaws:

1. Discuss treatment options: conventional and expanded options, including skeletal anchorage[92] to enhance dentoalveolar changes as well as SFOT.[58]
2. Analyze anticipated outcomes.
3. Consider the tradeoffs that may result from non-orthognathic surgery management.

Therapeutic Diagnosis of Borderline Cases

Because of the range of treatment plan options, the concept of therapeutic diagnosis is even more important today than when it was first introduced. Ackerman and Proffit clarify this diagnostic approach in the following quotation:

> *Therapeutic diagnosis is not a substitute for established procedures, nor should it become a cover for fuzzy thinking and diagnosis. Where uncertainty exists despite a careful diagnostic evaluation, there is danger in formulating a rigid treatment plan. Systematic evaluation of the initial response to orthodontic treatment can help a great deal in making the difficult diagnostic and treatment planning decisions, especially as concerns the basic question of extraction or nonextraction. Borderline cases in which the treatment response should be considered before one decides to extract are more common than many diagnostic systems indicate. It is strength, not weakness, to recognize true uncertainty.*[93]

The process calls for the use of therapeutic aids indicated in Table 23-5. Borderline surgical–nonsurgical cases often require initial therapy followed by appropriate new records and reevaluation to allow a thorough review of treatment compromises if the surgical approach is not undertaken. A case may be a definite surgical case but borderline in terms of the number of osteotomies. Achieving a practical, safe objective rather than a hypothetical ideal is important. In essence, borderline surgical cases have moderate skeletal malrelationships that affect both jaws equally; an example is Class II maxillary protrusion and mandibular deficiency (see Fig. 23-29). In such cases, dental camouflage rather than surgical correction may be considered appropriate. Another example of a borderline case is a situation in which a surgical plan has been selected and a decision must be made between two-jaw and one-jaw surgery. For example, a Class III mandibular excess and vertical maxillary excess with a moderate mandibular asymmetry may achieve the best result with double-jaw surgery. An alternative procedure with one-jaw surgery would leave the vertical excess uncorrected. Sometimes the added risks of a double-jaw procedure, in relation to the minor gains anticipated, make a single osteotomy the procedure of choice. Occasionally, a patient will present with a situation that appears to require two-stage surgery (stage I for the skeletal transverse discrepancy and stage II for the AP and

TABLE 23-5 Therapeutic Aids

Appliance	Used to Assess	Duration
Bite splint	Neuromuscular habits and deprogramming muscles of mastication	1–6 months; reevaluate new cephalogram and mounted study models
Superior repositioning splint High-pull headgear orthopedic effect limited to growing patient	1. Degree of patient cooperation 2. Orthopedic response of Class II with vertical maxillary growth	6–12 months (possibility of continuation)
DeLaire face mask	1. Orthopedic response in Class III with mild to moderate maxillary deficiency 2. Maxillary horizontal growth acceleration	6–12 months (possibility of continuation)
Chin cup	1. Orthopedic response in Class III with mild mandibular excess 2. Restraint or redirection of mandibular growth, primarily in early years 3. Reprogramming of jaw muscles with pseudoskeletal Class III problems	6–24 months
Fixed appliances to level and align (also test compliance with cervical or high-pull headgear)	1. Combination maxillary protrusion and mandibular deficiency (Class II, Division 2 type) 2. Upper lip contour and option between upper premolar extraction and mandibular advancement	6 months

vertical problem). The patient illustrated in Figure 23-32 was treatment planned as a two-stage surgical patient, but after the surgically assisted rapid palatal expansion (SARPE) procedure, her open bite continued to improve to the point that we agreed to camouflage the Class II open bite with conventional orthodontic treatment.

Key Considerations of the Integrated Treatment Plan

After both the orthodontist and the surgeon have determined that a patient is ready for surgery, the surgeon will create a surgical prediction tracing or surgical treatment objective (STO) and model surgery.[53] There are now many computer programs that allow the surgeon to digitize a cephalometric radiograph and create a prediction tracing. These programs allow movements in any direction by entering the amount of movement at a given cephalometric point. Rustemeyer et al.[94] evaluated the accuracy of two-dimensional predictive software with the actual outcomes for 54 patients who underwent bilateral sagittal split ramus osteotomy (BSSRO) with or without a Le Fort procedure. Their findings indicated that there is some variance between the predicted outcome and the actual result, but they thought that the software was relatively accurate. Another method is to trace a cephalometric radiograph and create tracings on acetate paper to predict the surgical movement. The benefit of this method is that it provides a visual road map that can be used during the surgery as a guide to the desired result. A sample case is provided with the steps involved in creating the STO (see Fig. 23-14).

Step-by-step instructions are presented in Box 23-5. Using the patient's cephalometric tracing and simulating the surgical movements, this method shows the skeletal movement anticipated by moving the skeletal structures to normal positions. The magnitude of movement is shown at the reference lines both in the AP and vertical directions. The soft tissue is drawn and is variable, but most studies indicate that the AP movement of the upper lip is 50% of the skeletal movement.[54]

The image from 3D capture software shows no significant difference between the lateral cephalometric images when superimposed[78] (see Chapter 11).

A common occurrence in daily practice for orthodontists is to guide their patients toward a surgical treatment plan or away from a surgical treatment plan. This guidance depends on the orthodontist's training, personal experiences, professional experiences, and diagnostic data along with a clear awareness of the variable goals of treatment based on individual patient treatment requirements. In addition, the surgical or nonsurgical treatment planning decision often is made with the patient's own process of gathering detailed treatment information; a careful determination of the patient's own goals for comprehensive treatment; and, in many cases, on the availability of insurance coverage to assist in the fees for surgical aspects of treatment. As a result of this multilayered decision-making process, the orthodontist must define goals with the patient and establish a plan that may include several well-thought-out options and not just present a plan to the patient.

Borderline orthodontic cases provide orthodontists with excellent examples of the benefits of setting mutually defined treatment goals. The strategy for treating borderline orthodontic cases with camouflage therapy is to create dentoalveolar changes that will compensate for a skeletal base imbalance. Although clinical orthodontists commonly use this approach in treatment planning, there is a limit to how much dentoalveolar change can compensate for an imbalanced skeletal structure. To discuss the limits of camouflage properly, one must define the goals of treatment clearly. Because orthodontic treatment is elective, the orthodontist and the patient must visualize the goals of treatment in the same way. The orthodontist, for example, may have a clear concept of goals for treatment as taught during the orthodontic graduate program. However, orthodontic providers must individualize the treatment goals for each adult surgical patient through a detailed interview process that starts at the initial examination appointment and continues through the review of the diagnostic records at the treatment planning conference with the patient.

The treatment planning process for patients with malocclusions plays a pivotal role in guiding the patient to a treatment that will satisfy his or her short-term concerns and long-term functional requirements and establish reasonable stability. Although the three steps listed previously seem simple, in several specific treatment planning modalities, orthodontists must strive to gain expertise to achieve maximal effectiveness. With each of these modalities, the orthodontist should be able to answer the following pertinent questions:

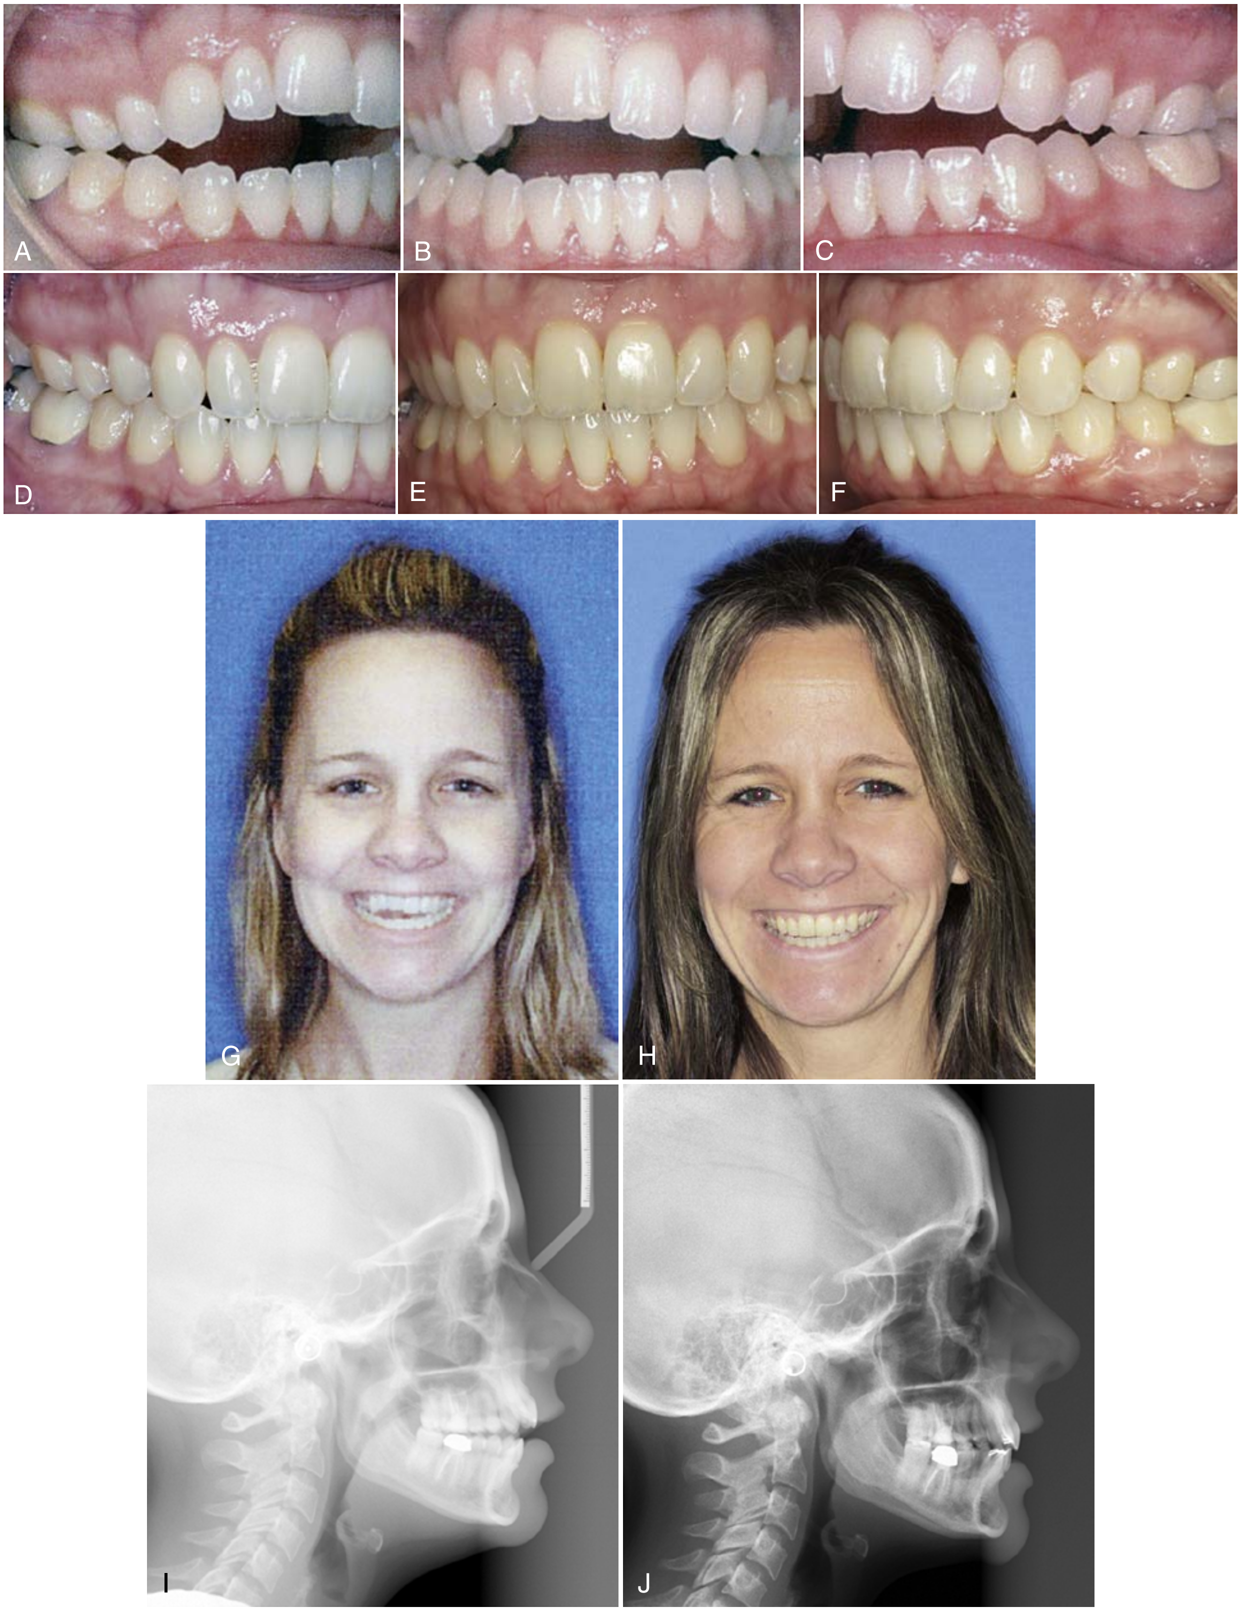

FIGURE 23-32 **A–C,** Intraoral photographs before any orthodontic treatment; note the degree of anterior open bite and arch constriction with posterior crossbite. Incisor position is consistent with an ankylosed no. 8. Previous trauma to the area of nos. 8 and 9 was ruled out, and the results of percussion test for ankylosis of nos. 8 and 9 were negative. **D–F,** Intraoral photographs after orthodontic treatment and orthognathic surgery. This patient was originally treatment planned for two-stage surgery. She responded sufficiently well to stage I surgery of surgically assisted rapid palatal expansion procedure and orthodontic movement that the patient, the surgeon, and the orthodontist agreed to complete treatment without the second-stage Le Fort procedure that was anticipated. **G** and **H,** Frontal facial photographs showing pretreatment smile and posttreatment smile, respectively. **I** and **J,** Lateral cephalograms illustrating pretreatment and posttreatment smile, respectively. Initially, incisor position showed that the incisor could be erupted to allow more incisal display. Long-term stability and soft tissue (tongue) adaptation is being monitored. Long-term tongue crib may be indicated. (Surgery by Dr. Peter Chemello, Arlington Heights, IL.)

BOX 23-5 Orthognathic–Orthodontic Treatment Milestones for the Typical Orthognathic Surgical Patient

Evaluation (2–3 mo)
- Orthodontic records
- Diagnosis and treatment plan
- Surgical consultation

Presurgical Orthodontics (6–18 mo)
- Presurgical alignment
- Presurgical records
- Presurgical reconsult with surgeon

Surgical Treatment
- Orthodontic placement of surgical wires or hooks
- Surgical correction
- Postsurgical records and reevaluation

Postsurgical Orthodontics (6–12 mo)
- Postsurgical tooth alignment to finalize bite correction
- To complete arch coordination

Retention and Observation (12–18 mo)
- Observe tooth “settling”
- Monitor retainers
- Bite adjustment as needed

1. **Clarification and individualization of treatment plan for patients with skeletal malocclusion**
   - Is it imperative that every patient be guided to a treatment plan exemplifying a textbook ideal result?
   - When will a “practical,” nonsurgical result suffice?
   - Whose concept of facial aesthetics and balance takes precedence: that of the patient, the orthodontist, the surgeon, the parent(s), or the significant other?
   - Is it acceptable to achieve stability with mechanical approaches (e.g., lifetime bonded retainers, lifetime removable retainers, or both)?
2. **Differential diagnosis**
   - What is a borderline surgical case? What are the risks if a patient with a severe skeletal problem does not accept surgery?
   - At what point does a stomatognathic system skeletal imbalance change from a nonsurgical problem to a surgical problem?
   - Is the surgical–nonsurgical decision made by the patient, the orthodontist, the surgeon, or the insurance company?
3. **Extractions**
   - Will extraction of teeth be effective for orthodontically camouflaging the malocclusion?
   - Is extraction of premolars needed to decompensate a condition before surgery?
   - Is extraction of premolars being planned for alignment purposes only?
   - Should molar or premolar extraction be planned to maximize autorotation of the mandible?
   - What happens when several of these extraction considerations are applicable to one patient?
   - Should the extraction decision be made even though the final treatment plan has not been defined?
4. **Is there a clear cephalometric measure of an “acceptable compromise”?**[40]
   - Can patients with a +5 degree or greater A point–nasion–B point (ANB) difference or a −3 degree ANB difference have an acceptable result without surgery? If so, under what conditions?
   - Should the concept of acceptable compromise be redefined with the understanding of new surgical capabilities?
5. **Visualized treatment objectives**
   - Can cephalometric predictions be achieved routinely?
   - Do patients have an overly optimistic perception of the outcome?[17,32]
   - Will computerized 3D predictions be an integral part of visual treatment objectives in the future (see Chapter 8)?[8,88]
   - Is computerized imaging a treatment planning tool, a marketing tool, or both?[78,95]
   - Are a patient’s presurgical expectations a predictor of postsurgical satisfaction?
6. **Patient expectations**[8,22,29,96–98]
   - What percentage of surgical-orthodontic patients eventually indicate that they are satisfied with the treatment outcome?
   - Are immediate postsurgical patients prone to be less satisfied than expected? If so, why?
   - Will the planned procedures affect facial aging?

Treatment Timing

The orthodontist generally is the key person in deciding the appropriate time to initiate treatment plans that fall into one of the following categories:

1. Orthodontic only
2. Orthopedic and orthodontic (growth modification)
3. Orthodontic and surgical
4. Independent arch alignment with nighttime splint therapy to provide interim occlusal “balance”

General concepts that are accepted for specific treatment problems are reviewed in this section. The principles presented must be applied to each individual patient.

Treatment Timing for Maxillary Deficiency Patients

Deficiency of the maxilla with AP and transverse components is managed best in the mixed dentition stage. The orthopedic effect is predictable, and the early treatment staging enhances the environment for future harmonious growth. The early permanent dentition stage is not too late to plan treatment for many patients with maxillary deficiency, but the stability of the results may be less than if the patient were treated earlier (see Chapter 16).

Treatment Timing for Mandibular Excess Patients

Patients with a family history of moderate to severe mandibular excess and who demonstrate growth patterns coincident with mandibular growth imbalance are treated best when growth is complete, as verified by wrist films and head-plate superimposition (Fig. 23-33).[99]

An important note is that some patients have mild mandibular excess, mild maxillary deficiency, and a functional forward shift of the mandible (Fig. 23-34). The combination of these factors creates the clinical appearance of a severe Class III mandibular excess pattern. Accurate recording of mandibular position, early orthopedics, and some compensatory camouflage (compensate upper incisor labially and lower incisor lingually)

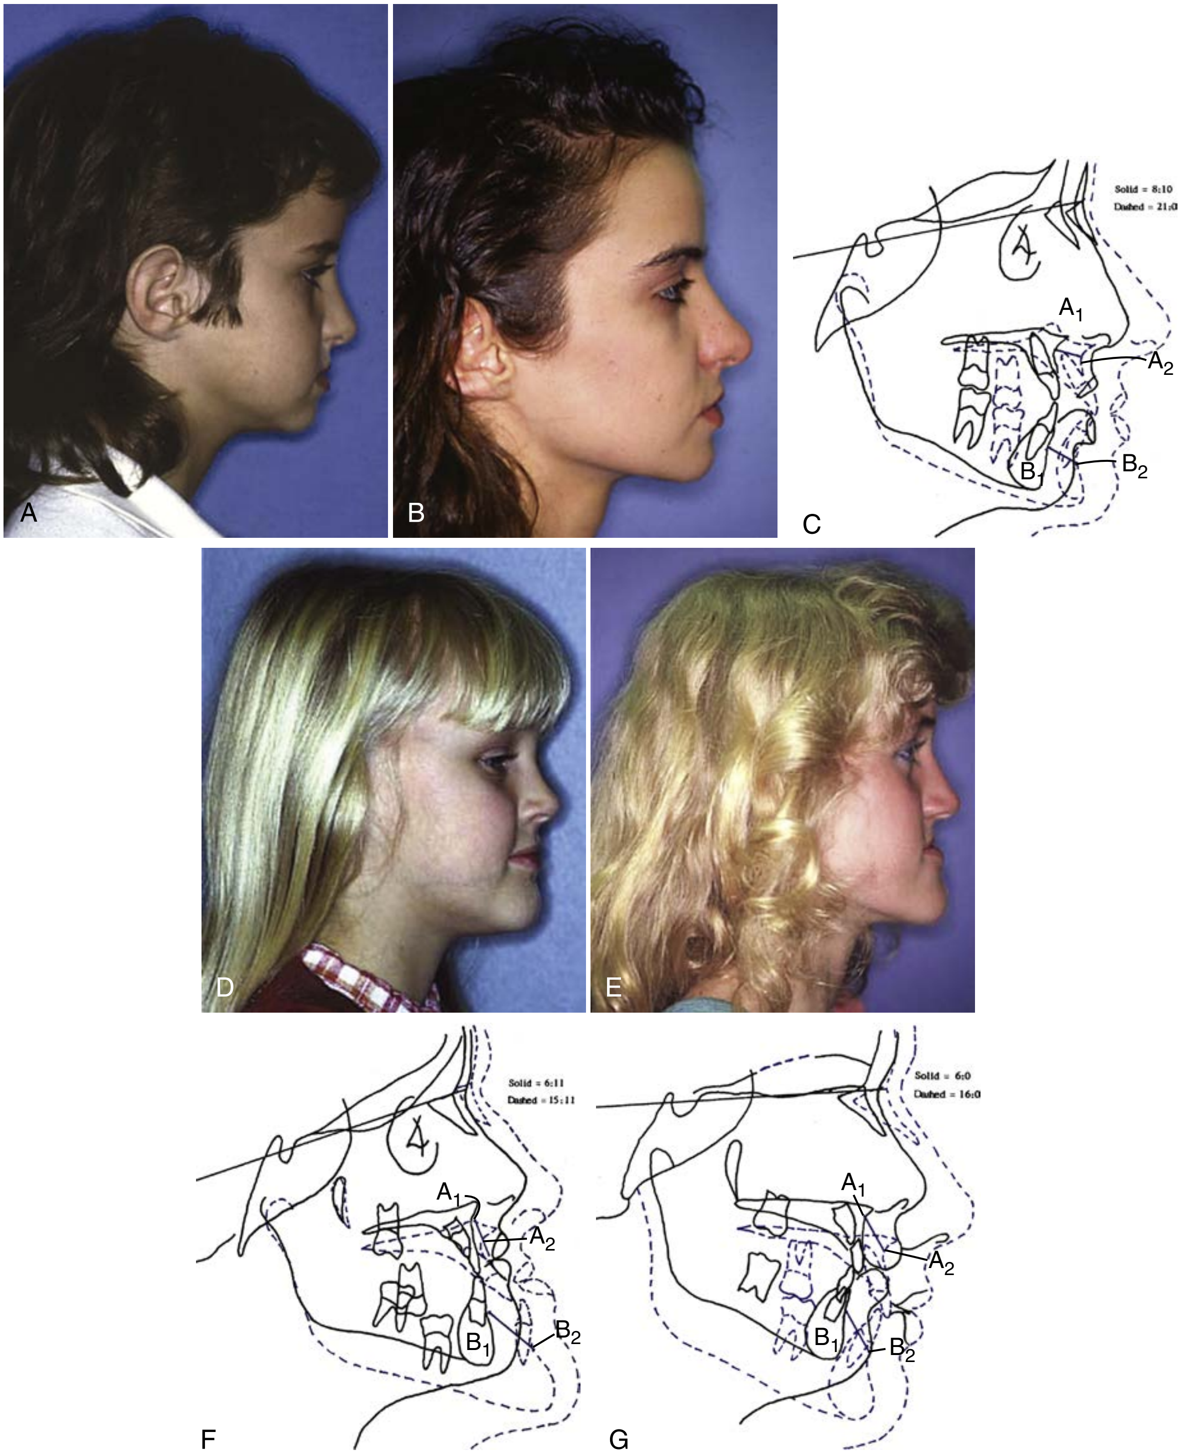

FIGURE 23-33 **A,** Pretreatment profile photograph of an 8-year-old patient who had full Class III malocclusion with anterior crossbite. She was treated with two-stage Class III orthopedics and orthodontics. **B,** Profile of same patient at age 21 years. Acceptable facial balance was achieved without surgical intervention. **C,** Cephalometric superimposition. Note favorable response because of early correction and favorable maxillary (*A1–A2*) and mandibular (*B1–B2*) growth vectors. **D,** Pretreatment profile photograph of 7-year-old girl who had a developing Class III problem. She was treated with Class III orthopedics. **E,** Profile at age 16 years showing unfavorable pattern of maxillary and mandibular growth. **F,** Cephalometric superimposition. Note the unfavorable response with orthopedic attempt at early correction and unfavorable maxillary (*A1–A2*) and mandibular (*B1–B2*) growth vectors. **G,** Cephalometric superimposition of Bolton template for the 6- to 16-year-old standard, illustrating maxillary and mandibular growth vectors for maxilla and mandible in patients with optimal occlusions and having proportionate facial growth.

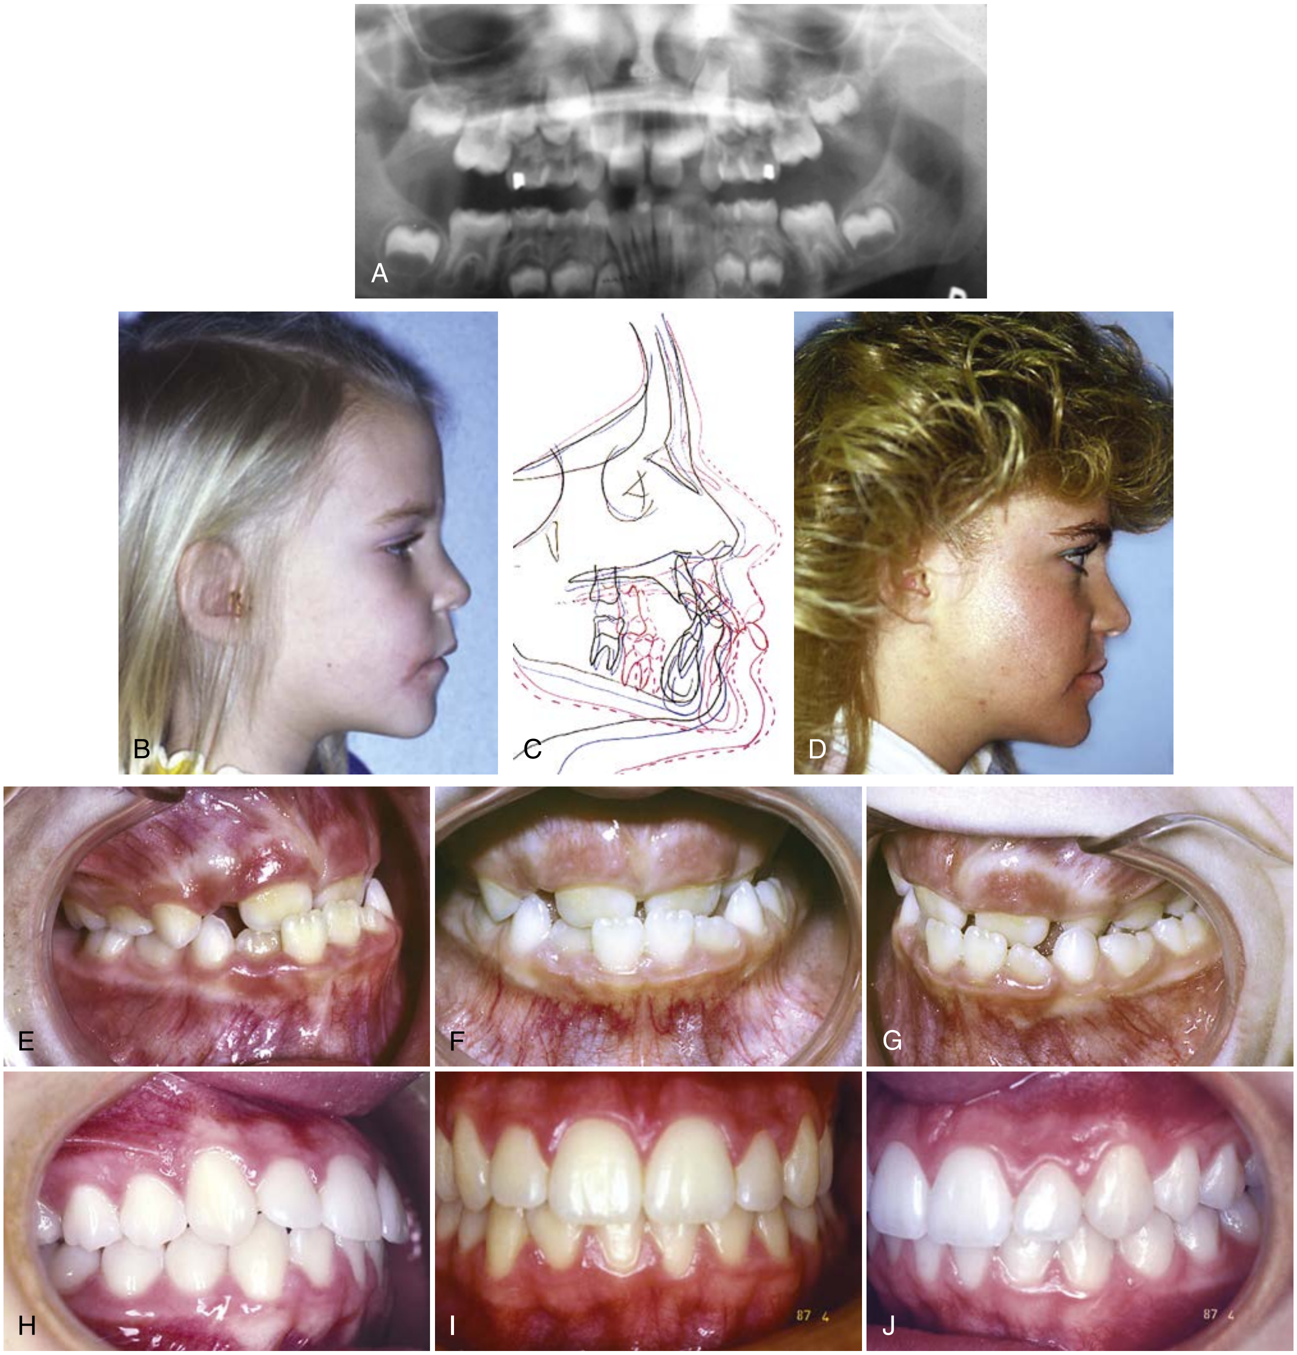

FIGURE 23-34 **A,** Pretreatment panoramic radiograph showing severe maxillary crowding. **B,** Pretreatment facial photograph at 6 years of age. **C,** Cephalometric tracing illustrating skeletal relationship at 6 years old (*solid black*), 8.5 years old (*solid blue*), 16 years old (*solid red*), and 18 years old (*dashed red*). **D,** Facial photograph taken 3 years after treatment during the retention period. **E–G,** Pretreatment intraoral photographs of a 6-year-old girl with the appearance of a significant Class III problem. A functional shift of the mandible to the left and forward has occurred, which makes the problem look worse than it is. **H–J,** Posttreatment photographs illustrating corrected Class III malocclusion. This borderline Class III surgical problem was able to be treated nonsurgically because of early intervention.

BOX 23-6 Phase I Orthodontic Milestones for Patients with Skeletal Components to Their Malocclusion (Ages 4–12 Years)

Evaluation (1–3 mo)
- Orthodontic records
- Diagnosis and treatment plan

Appliances in Place (12–18 mo)
- Growth and treatment response monitored (patient cooperation is essential)
- Remind parents and patients of the importance of compliance

Observation (6–12 mo)
- If favorable progress, go to stabilization program
- Evaluate growth treatment response vectors (GTRV)

Periodic Recall (18–24 mo)
- Continue growth guidance and monitor dental development
- Reevaluate GTRV

Phase II
- Evaluate for new problems
- Full braces to complete bite correction
- Additional orthopedics possible
- If poor response—wait and plan orthognathics

may allow satisfactory nonsurgical management. This type of patient benefits from therapeutic diagnosis and periodic reevaluation of growth. One must take care not to overtreat these patients orthodontically through camouflage if the mandibular excess growth continues, however. Orthodontic overtreatment can lead to an unstable result, traumatic incisor occlusion, incisor mobility, and gingival recession (Box 23-6, Phase I, Orthodontic Milestones).

Assessment of the growth treatment response vector (GTRV) (see Fig. 23-33) is an important tool to be used by an orthodontist when trying to determine if a Class III mandibular excess and Class III maxillary deficiency patient is growing outside the range of nonsurgical correction.[100,101]

Treatment Timing for Mandibular Deficiency Patients

The degree of mandibular deficiency (mild, moderate, or severe) and the type of the deficiency (type I [low angle], type II [medium angle], or type III [high angle]) are factors in deciding the timing of treatment.

Most orthodontists attempt conservative (nonsurgical) measures in the 14- to 16-year-old age group to limit maxillary horizontal growth and enhance mandibular growth. The mandibular growth rate slows earlier in girls than in boys. Therefore, for girls who have severe cases of pure mandibular deficiency or mandibular deficiency with asymmetry, surgery can be recommended along with orthodontic treatment in this age group.[102,103]

In boys, there is evidence of protracted mandibular growth until age 21 to 23 years. Although a mandibular deficiency will not self-correct, the maxillomandibular growth differential can be used with directional force orthopedics to improve significantly many low and medium mandibular plane angles to the point that surgery is not necessary.

With moderate or severe type III mandibular deficiency, boys and girls usually require orthodontics and surgery to achieve facial balance, stability, and good function. The timing of surgical intervention in these cases ultimately depends on (1) growth factors, (2) emotional maturity, (3) self-image considerations, (4) school and work plans, (5) insurance factors, and (6) the patient's and family's perception of relative need.[17,96,104]

Considerations in the Management of Facial Asymmetry

One of the more challenging treatment planning decisions that orthodontists face is the management of facial asymmetry. Key questions must be addressed early in the analysis of the case:

1. **Is the developing asymmetry a result of trauma?** A careful history must be taken. An excellent discussion of acute care of a condylar fracture can be found in Proffit and White's textbook.[40]
2. **Is the asymmetry affecting the maxilla and the mandible?** Is it getting worse with time? Panoral radiographs and serial posteroanterior cephalograms, as well as a submental vertex radiograph, are needed to aid in this assessment.
3. **Would functional appliance therapy be effective in this case?** Some authors have shown good improvement using a functional appliance approach (see Chapter 14). Severe cases of hemifacial microsomia, however, may require orthopedic treatment to prepare for staged surgery to correct the growth imbalance.
4. **What is the appropriate timing for surgical intervention?** Early consultation with a surgeon familiar with the range of considerations in asymmetry cases is desirable. Periodic functional and emotional assessment also is desirable in preparing the patient for the corrective steps. Orthopedic measures can be taken, but orthodontists need to avoid patient burnout and disappointment if further surgery will be needed, especially in cases of moderate and severe asymmetry (see Fig. 23-12). A recent case report (2009) illustrates the effective use of miniscrew anchorage to intrude the overerupted maxillary molars in a case of mandibular asymmetry. The use of bone screw anchorage to level the compensatory cant of the maxillary molars allowed the patient to be treated with just mandibular surgery.[105]

In patients who have condylar hypertrophy, a scintigraphy analysis (isotope uptake) can help to determine the appropriate timing based on hot spot analysis. Waiting until the hypertrophy burns itself out is the most judicious way to proceed in these cases.

It is important to remember that facial asymmetries can have skeletal manifestations that need to be understood in treatment planning. In an asymmetric face, the body of the mandible may be vertically larger than the opposite side. Although the dentition can be leveled via orthognathic surgery, there still may be a residual facial asymmetry because of a size discrepancy in the mandible. The patient needs to be aware of this discrepancy so that decisions can be made to address the problem. Unilateral disc displacement without reduction (UDDN) may display altered craniofacial morphology and needs to be assessed, especially in growing patients.[106]

SEQUENCE OF TREATMENT FOR ORTHOGNATHIC PATIENTS

Although many believe that the sequence of treatment starts with the interview and examination of patients with skeletal jaw imbalance, the most important steps take place long before the surgeon or orthodontist meets the patient. The feedback loop sequence described in Box 23-2 has 17 significant steps that provide the patient and doctors with an excellent means of achieving the desired treatment outcome.

Importance of the Sequence

In the sequence of treatment for patients with major dentofacial imbalances (see Box 23-2), steps 1, 2, and 17 are most often underemphasized. Because of this deficiency in private practice, these steps of the treatment sequence are reviewed to emphasize the reasons for their importance.

Step 1: Multiple Provider Team Selection (Interdisciplinary Therapy)

The dentist will refer patients with skeletal malocclusion to an orthodontist if the dentist is confident that the patients will receive appropriate state-of-the-art care. The orthodontist must select surgeons who are experienced and well trained in the spectrum of orthognathic procedures. A periodontist, psychologist, and physical therapist may become key team members in selected cases. An additional consideration is the desirability to continue to educate the orthodontic staff who will be on the "front line" of questions from potential orthognathic patients. It might even be advisable to invite an oral surgeon to an orthodontist's office to discuss critical communication aspects of patient care for surgical cases.[107]

Step 2: Goal Clarification

The members of the provider team should share similar concepts of treatment goals. Functional occlusal goals, stability of outcome, and dental and facial aesthetic goals can mean different things to different professionals. Periodic group meetings oriented to individual case analysis offer an opportunity for team members to discuss their concepts of the treatment goals that apply to the individual patient (see Box 23-1). For example, Arnett and Gunson discuss how their *systematic* approach to assess and treatment plan orthognathic cases facilitates the orthodontic preparation for surgery. Their article emphasizes the importance of manipulation of the occlusal plane to achieve the most desirable result.[108]

Steps 3 Through 16

Steps 3 through 16 are self-explanatory and commonly performed by provider groups. By following the general concepts stated in each step, the orthodontist automatically spends time with the patient and can address most of the patient's pre- and postsurgical concerns.

The orthodontist can explain the sequence of treatment to the patient and the general dentist through the use of a treatment conference report.

Orthodontists and their staffs must be reminded constantly, through appropriate chart designation, of patients who have orthognathic treatment plans. These patients often are subject to increased anxiety and have extra questions that need to be addressed to maintain their confidence and trust. At the presurgical consultation (step 12), the orthodontist and the surgeon must listen to the patient and determine the patient's physical, dental, and emotional readiness for surgery.[17,28,29,96]

The surgeon should present a clear review of the surgical procedure and the risks of surgery. The surgeon and the orthodontist must remember that most orthognathic patients have much to learn about their options, the recommended procedures, and the incumbent risks. The current trend to have a "one-step consultation" for orthodontic patients generally does not apply to orthognathic patients. One must respect the individual patient's "learning curve" requirements and be supportive by providing needed information and patience.

Several authors have done numerous studies assessing patients' responses to current ortho-surgical treatment modalities.[17,28,29,96,98] A thorough review of their work is necessary to help orthodontists and their staff members appreciate the range of feelings that orthognathic patients report before and after surgical procedures. Table 23-6 describes the psychological considerations during the various treatment steps for a patient who is having jaw surgery.

Step 17: Treatment Experience

Step 17 is seldom incorporated in the routine policy sequence of private orthodontic and surgical practices. To gain the most from this step, all team members should review postsurgical records and discuss the positive and negative aspects of the overall treatment plan, the sequence of treatment, and provider interaction. Each completed case provides an opportunity for providers to consider feedback from one another and the patient. This step is the most effective continuing education program in which a practitioner can participate. Having each orthognathic patient complete a posttreatment questionnaire also provides additional feedback and is an integral part of practice maturation.

APPLIED CONCEPTS FOR SPECIFIC TYPES OF CASES

Certain concepts that have been discussed in this chapter are integrated and applied to case types previously introduced in the differential diagnosis section. A summary of the concepts that are fundamental to consistent excellence in the management of skeletal disharmonies is as follows:

- *Treatment goals*: These are defined and agreed on in principle by the providers (see Box 23-1).
- *Technique advancements*: These are used to enhance the safety of all orthognathic procedures.[26,52,55,100,101]
- *Current capacity to alter dentofacial structures:* Because the potential degree of change is so great, the responsibility of the surgeon and the orthodontist in planning treatment also is great. Psychosocial and emotional balance may be at risk.[96,109]
- *Differential diagnosis process*: The differential diagnosis process generates a problem list and treatment planning options. The so-called textbook ideal result should be considered and discussed with all patients; however, not all patients have the resources for state-of-the-art treatment.
- *Treatment planning*: Treatment planning therefore creates alternatives. The good, better, best approach to patient education yields understanding and trust.
- *Borderline cases*: Borderline cases (e.g., Class II with moderate lower jaw deficiency) can benefit from therapeutic diagnosis with initial leveling and alignment. Facial balance then can be assessed with the mandible postured forward. Computer and video imaging also can be used to teach patients about their options and potential outcomes.[79,110]
- *Standardized sequencing*: Following the 17 steps presented in Box 23-2 ensures a well-educated patient and a well-prepared treatment team.

TABLE 23-6 Psychological Considerations in Clinical Interaction

Treatment Stage	Steps in Psychological Management
Initial assessment	Explore motives for treatment and expectations from treatment in detail. Why treatment? Why now instead of last or next year?
	Consider using an auxiliary with a warm personality to do at least part of the interview. Patients often are intimidated by the doctor and may not reveal their true concerns.
	Be careful not to create unrealistic expectations: it is better not to discuss the specifics of treatment procedures before the diagnostic workup has been completed, but a broad outline including the possibility of surgery should be presented.
Orthodontic consultation	The spouse, a family member, or a close friend should attend if at all possible, but be careful about invasion of patient's privacy.
	Begin with a discussion of the patient's problems; be sure the doctor and patient agree as to what is most important; then describe how the problems might be solved, beginning with the most important problem and presenting the alternatives.
	Encourage—indeed, insist on—an early appointment with the surgeon if surgical treatment may be needed.
Surgical consultation	Review patient's records with same general approach as the orthodontist, emphasizing the problems and their possible solutions.
	Discuss the functional and aesthetic benefits of surgery in that order. To tell patients they will have functional benefits and aesthetic changes is better than the reverse. Functional changes nearly always are appreciated; aesthetic changes may not be.
	Provide more detail about the surgical experience, to the extent the patient has questions, but keep the discussion relatively general. Many details can wait until just before surgery. (Some patients may want a complete discussion.)
	Consider using patient education materials at this stage, such as booklets, videocassettes, and videodiscs.
	Offer to help with insurance preauthorization.
Presurgical treatment	Evaluate the patient's personality characteristics and psychological stability in more detail. Focus on neuroticism, degree of external locus of control, introversion in males, mood states (particularly depression and current major life events), and tendency for patient to be a vigilant coper.
Immediate surgery	Review the planned surgery in detail, but take the patient's psychological profile into account. Patients who expect the worst are more likely to experience it.
	Discuss with family members and close friends the importance of their psychological and emotional support postoperatively. Be sure significant others are prepared for changes in the patient's facial appearance so that they do not express shock or dismay.
Immediate postoperative period	Expect a period of mood swings and negative emotions, which usually peak at about 2 weeks. Reassure the patient, family, and friends that these emotions are normal and will soon disappear.
	A visit from the orthodontist and perhaps flowers or a care package of easy-to-eat foods keep the patient from feeling forgotten.
Postoperative orthodontics	Negative emotions and mood swings are more likely to be seen by the orthodontist in patients who return for finishing orthodontics. Reassurance and psychological support may be needed.
	Remember that a decrease in satisfaction and facial body image occurs if active treatment takes more than 6 months postoperatively. If treatment has not been completed by this time, progress should be reviewed with the patient, and an anticipated completion date should be discussed.

From Kiyak HA, Bell R. Psychosocial considerations in surgery and orthodontics. In: Proffit WR, White RP, eds. *Surgical Orthodontic Treatment*. St. Louis:, Mosby; 1990.

An important part of orthognathic treatment planning involves surgical prediction. Hard tissue changes are easy to predict; however, soft tissue changes are less predictable (see Chapter 11). In Table 23-7, a variety of general guidelines are used to predict soft tissue changes in the lateral cephalometric view. However, with current surgical treatments, the most difficult soft tissue predictions to make are those that deal with changes in the frontal view. The patients in Figures 23-23 and 23-25 illustrate the outcome of treatment using the concepts described in this chapter.

The patient in Figure 23-23 has a classic skeletal Class II mandibular deficiency type I, low mandibular plane angle, condition (see template assessment in Fig. 23-23, *B*). The patient in Figure 23-25 has a classic skeletal Class II mandibular deficiency type III, high mandibular plane angle (see template assessment in Fig. 23-25, *B*).

Figures 23-27 and 23-29 illustrate the treatment outcomes of three types of Class III skeletal mandibular excesses. The patient in Figure 23-27 represents a classic patient whose skeletal problem can be described as Class III mandibular excess type II (see the template superimposition in Fig. 23-27, *B*). Complete surgical correction of the mandibular excess depended on lower incisor decompensation from pretreatment incisor to mandibular plane angle of 77 degrees to presurgical angulation of 89 degrees.

The patient in Figure 23-28 demonstrates a classic example of mandibular excess type III (high mandibular plane with open bite). Generally, patients with high mandibular plane angles and open bites require a maxillary Le Fort procedure with impaction and a mandibular procedure. Maxillary and mandibular procedures were performed on this patient. The patient in Figure 23-35 illustrates a well-treated patient who was not fully satisfied with her treatment (see Fig. 23-35, *F*). Notice the improved response (see Fig. 23-36, *K*) to treatment, using more current techniques of rigid fixation, in the patient who had a similar complicated skeletal problem (Fig. 23-36).

OPTIMIZING STABILITY

Of the treatment goals discussed in the chapter introduction, orthodontists and surgeons are alike in their quest to recommend and perform procedures that give their patients lasting stability.[111–113] The stability of orthognathic procedures has been one of the most studied aspects of the techniques in use.[26,42,114–118] Stability is a key goal of orthodontic treatment and orthognathic treatment; lack of stability is considered a complication, particularly as it relates to the surgical aspect of the correction. To discuss the general concept of stability, one must consider several factors necessary to achieve stability (see Chapter 33).

TABLE 23-7 Soft Tissue Changes Related to Specific Surgical Movements

Treatment	Soft Tissue Change	Notes
Anteroposterior movement of incisors: maxillary or mandibular, forward or back, surgical or orthodontic	60%–70% of incisor movement Minimal unless jaw rotates	1–5
Vertical movement of incisors	Soft tissue: chin 1:1 with bone; lower lip 60%–70% with incisor	6
Mandibular advancement	Nose: slight elevation of tip	7, 8
Maxillary advancement	Base of upper lip: 20% of point A Upper lip: 60% of incisor protraction, shortens 1 to 2 mm	
Mandibular setback	Chin: 1:1 Lip: 60%	5
Maxillary setback	Nose: no effect Base of upper lip: 20% of point A Upper lip: 60% of incisor Advancement of lower lip: variable; may move back	3
Mandibular setback plus maxillary advancement	Changes similar to a combination of the two procedures separately	
Maxillary superior repositioning	Nose: usually no effect Upper lip: shortens 1 to 2 mm Lower lip: rotates 1:1 with mandible	7
Mandibular advancement plus maxillary superior repositioning	Chin: 1:1 Lower lip: 70% of incisor Upper lip: shortens 1–2 mm 80% of any incisor advancement Nose: slight elevation of tip	
Mandibular inferior border repositioning	Soft tissue forward: 60%–70% bone Chin: Up—1:1 with bone Back—50% bone Laterally—60% bone Down—?	

1. Little difference occurred with surgery or orthodontics.
2. If both upper and lower incisors are retracted (bimaxillary protrusion), lip movement stops when lips come into contact.
3. Lip shortens 1 to 2 mm with vestibular incision (more if surgical technique is poor).
4. Lip rotates with mandible 1:1.
5. If face height increases, lip may uncurl and lengthen.
6. If lip uncurls, it will go forward less.
7. Nose change is usually temporary.
8. Less soft tissue change occurs after cleft lip repair.

Data from Jensen AC, Sinclair PM, Wolford IM. Soft tissue changes associated with double-jaw surgery, *Am J Orthod Dentofac Orthop* 1992;101(3):266.

Orthodontic Considerations

1. Differential diagnosis[119]
2. Growth factors and the timing of the referral[12,120]
3. TMJ stability when planning the treatment[121]
   - Centric relation–habitual occlusion discrepancies[10,122]
   - Asymmetric growers
4. Dental stability
   - Crown-to-root ratio is important (periodontal health must be maintained).
   - Temporary crowns can be a source of instability during intradental fixation.
5. Presurgical orthodontic preparation to reduce dental compensations

Stability

- Orthodontic considerations
- Dental stability
- Presurgical orthodontic treatment to eliminate dental compensations
- Surgical considerations

Surgical Considerations

1. Treatment plan correlated with diagnosis
   - Surgery on which jaw
   - Single- or double-jaw procedures, especially for open bite and Class III situations[113]: Al-Delayme et al. assessed two Class III groups to compare the stability of two surgical procedures. One group exhibited mandibular setback only and the other with double-jaw surgery (maxillary advancement and mandibular setback). The authors found that patients who had double-jaw surgery were much more stable; the mandible-only group had about 44% relapse, and the lower incisors compensated by retroinclining 4 degrees to compensate for the mandibular AP relapse.
2. Design of osteotomy
   - Maintenance of blood supply and achievement of surgical objectives[44,47,123]
3. Type of fixation
   - Dental, skeletal, rigid, semirigid, or combination
4. Muscles of mastication and blood supply
   - In a sagittal split of the mandible, one is advised not to strip the pterygomasseteric attachment to avoid ischemia, delayed healing, and unusual nerve complications.
5. Type of mandibular rotation
   - Downward, backward movement is considered more stable than upward, forward movement.
   - Recent research has verified that occlusal plane change surgery and counterclockwise mandibular rotation can be very stable.[55]
6. The stability decreases as the magnitude of surgical correction increases, especially in the following:
   - Maxillary vertical deficiencies
   - Mandibular horizontal deficiencies

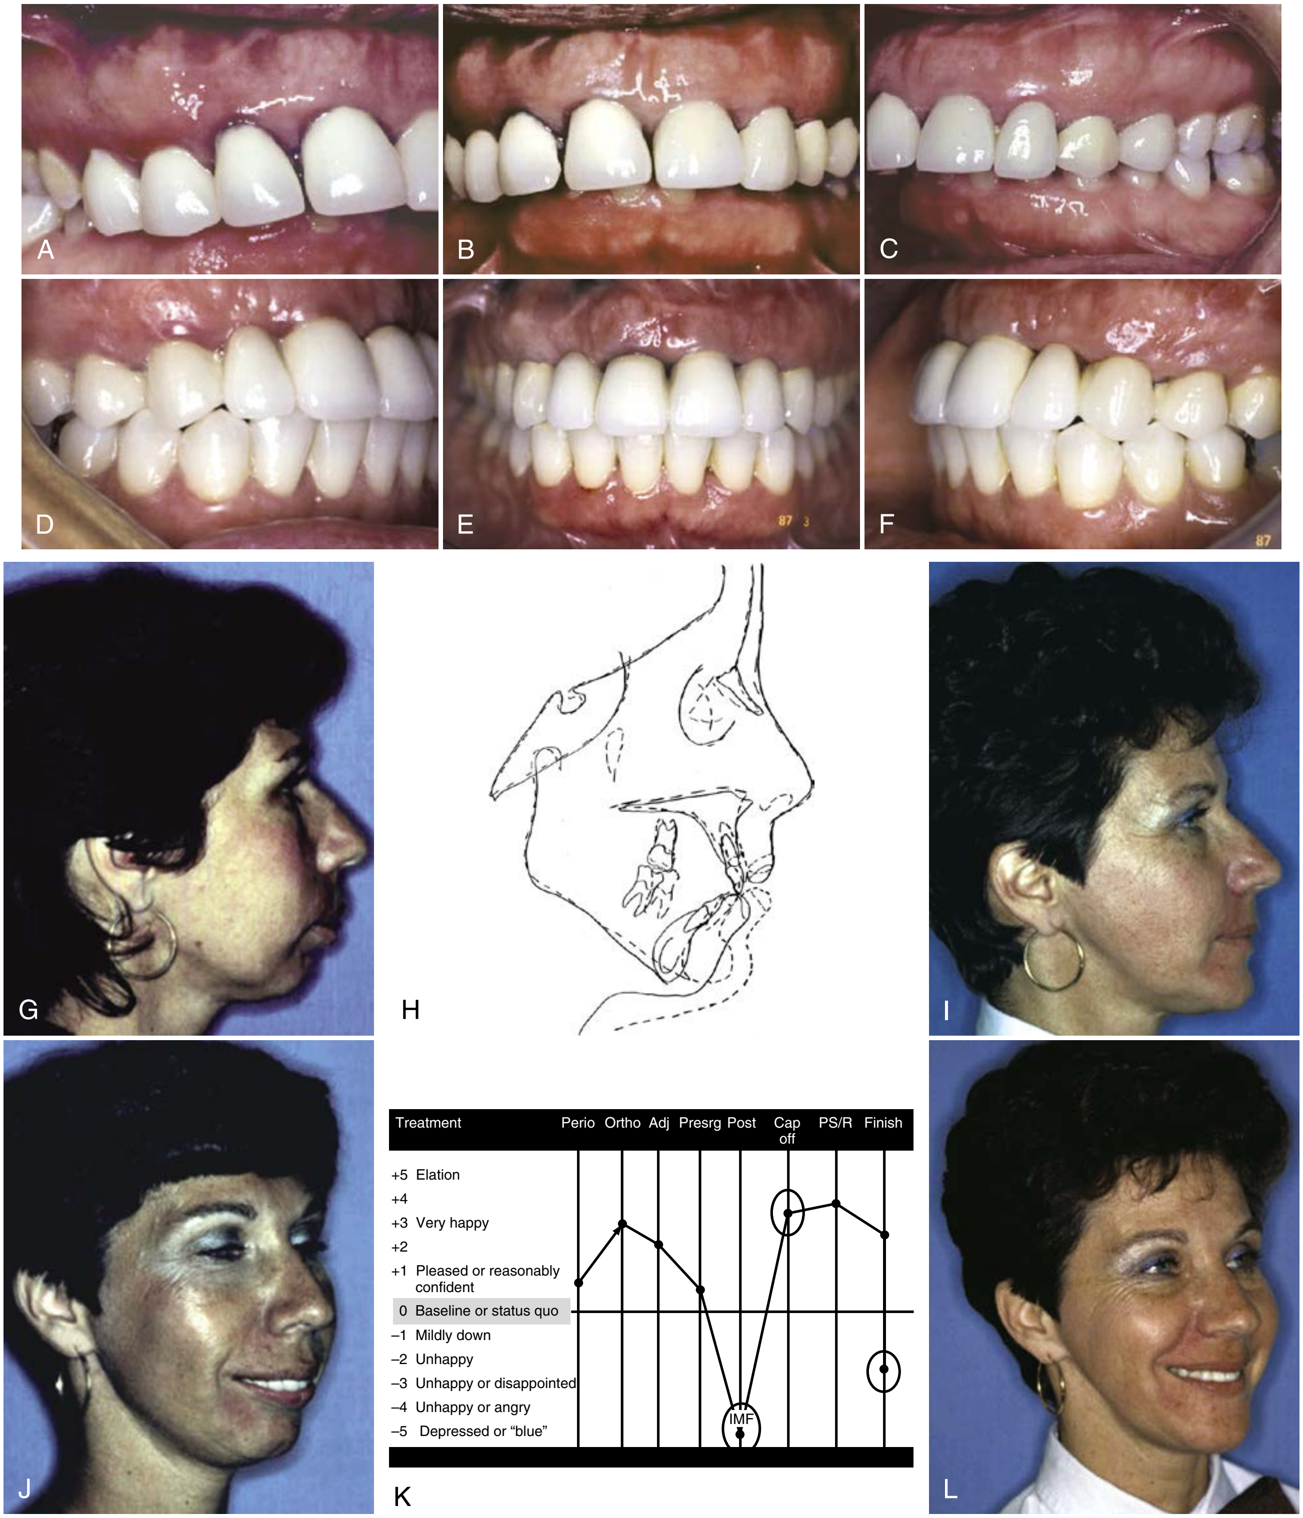

FIGURE 23-35 **A–C,** Pretreatment intraoral photographs. **D–F,** Posttreatment photographs. **G,** Pretreatment profile. **H,** Cephalometric superimposition; *solid line* indicates pretreatment contours, and *dashed line* indicates results after treatment. Treatment included the following: Le Fort osteotomy with 5 mm of impaction and movement of A point 2 mm distally Mandibular autorotation and advancement; B point came forward 13 mm Vertical reduction and advancement genioplasty; pogonion came forward 16 mm **I,** Posttreatment profile. **J,** Pretreatment three-quarter view, smiling. **K,** Graph showing the patient's attitude changes during the program of state-of-the-art comprehensive dentistry. Her posttreatment negative feelings were related to residual temporomandibular joint discomfort and to the belief that she had not been informed fully about-some of the downsides of the multidisciplinary treatment. *Adj,* adjustments; *Ortho,* orthodontics; *Perio,* periodontics; *Post,* post-surgery; *Presrg,* pre-surgical; *PS/R,* post surgical restorative. **L,** Posttreatment three-quarter view, smiling. FIGURE 23-37 **A,** Right posterior occlusion in a woman (age 35 years, 10 months) after two orthodontic treatments and two separate orthognathic procedures. **B,** Lateral posterior occlusion after two orthodontic treatments and two separate orthognathic procedures. **C,** Lateral cephalogram after two separate orthodontic and surgical treatments. Note the lack of incisal contact. The patient stated that the "open bite is progressively getting worse." **D,** The right condyle shows degenerative changes, and the left condyle shows degenerative changes similar to those described by Arnett and Tamborello. (From Proffit WR, Phillips C, Turvey TA. Stability after mandibular setback: mandible-only versus 2 jaw surgery. *J Oral Maxillofac Surg* 2012;70(7):e408–e414.)

7. Stability of the condylar position
   Stable condylar position applies to presurgical assessment, surgical control of the proximal segment, and the patient's postsurgical adaptation to the new neuromuscular and functional environment. In the early postsurgical stage of recovery, patients are frequently concerned about the lack of mobility of the mandible. In 2014, Ueki et al.[122] assessed the border movements of the mandible following Class III surgical correction. Their sample consisted of 73 patients; 41 underwent a sagittal split ramus osteotomy (SSRO), and 32 had SSRO and a Le Fort I osteotomy. For 52 of the patients, mandibular movements were measured with the Myotronics measurement system before and then 6 months after surgery. For 21 of the patients, the measurements were delayed for 18 months. Based on the findings of this paper, patients who had mandibular setback with or without a Le Fort I procedure did have hypomobility at the 6-month measurement stage. However, those evaluated after 18 months demonstrated that the measured border movements returned to pretreatment levels.

   A second important consideration related to surgical orthodontic outcomes is the long-term stability of the patient's condyle. Gunson et al.[57] have described the condition of idiopathic female condylar resorption, which may be responsible for late condylar changes (e.g., cheerleader's syndrome, avascular necrosis, or condylosis). These findings led the authors to hypothesize that some women are prone to condylar resorption that occurs after increased joint load and may be related to oral contraceptive pill use, which is well tolerated by most women (Fig. 23-37).[124]
8. Neuromuscular adaptation
   The surgical procedures that change the skeletal structures also change long-standing neuromuscular patterns of the stomatognathic system; achieving a balance or an equilibrium of the skeletal structures, dental structures, and muscles is the ultimate biologic challenge for the orthognathic team. Although the procedures performed today are based scientifically on a variety of working hypotheses, the relapse problems that still occur are reminders that some of the treatment provided may have empirical components.

Planning treatment for orthognathic cases can aid the stability of the treatment outcome through the following:

1. Proper *differential diagnosis* of patients who would most benefit from combined therapy: The classic example is the Class III grower. The orthodontist must determine through differential diagnostic studies and growth forecasting whether the patient has a mandibular excess condition. In borderline situations, an early phase of treatment can test, through therapeutic diagnosis, for skeletal modifiability and functional shifts. In other cases, surgery clearly is needed. However, the orthodontist still

may resolve the maxillary transverse deficiency and the anterior alignment during phase I while anticipating the second phase of braces at ages 16 to 23 years and surgery when facial growth is complete. The orthodontist plays a major role in guiding these cases to completion. For example, heroic orthodontic efforts to treat skeletal Class II problems nonsurgically for a protracted period in camouflage therapy may overcompensate the teeth and interfere with the ultimate need to provide corrective surgery later.[125] "The efficacy data of 34 Class II subjects who underwent surgical-orthodontic treatment with mandibular advancement and rigid fixation demonstrated that presurgical orthodontic treatment often does not fully decompensate the incisors, which limits the surgical outcome."[118]

This is also true of moderate to severe mandibular deficiency, high mandibular plane angle (downward and backward) growth patterns. Early introduction of the concept of combined therapy (orthodontics and surgery) conditions parents to the necessity of surgical correction and begins the psychological preparation of the patient. One must take care to use terminology that does not frighten or stigmatize young patients. The authors recommend conducting preliminary surgical consultations with the parents only for patients younger than age 16 years. This allows the parents to assimilate the surgical information and make the final decision as to the desirability of including the adolescent in the surgical discussion at the current time.

2. *Growth factors and the timing of the referral*: Orthodontists know that posttreatment growth is a destabilizing factor in orthodontic treatment results. In a study by the author, 42 of 100 adult patients (42%) who required retreatment did so because of growth changes that moderately or severely altered the original orthodontic correction.[44]

   If the differential growth is minimal, the occlusal change can be handled by 4 to 8 months of orthodontic retreatment. However, if growth undermines an orthodontic correction, the patient may not easily accept retreatment by means of surgery.

   To avoid growth-induced complications, one should consider the following guidelines:

   a. For moderate and severe Class III mandibular excess patients, surgery should be delayed until standardized cephalograms demonstrate completion of mandibular growth. In boys and young men, this could be as late as 22 to 24 years of age.
   b. For patients with asymmetry and unilateral hypertrophy, surgery should be delayed until bone scans demonstrate cessation of growth activity of the hypertrophic condyle.[126]
   c. In selected patients with excessive vertical growth (Class I and Class II), the maxillary Le Fort procedure can be considered before growth is complete when psychosocial factors dictate.[96] The effect of this procedure on the future growth of the nasal cartilage is not understood fully. However, a risk exists that premature double-jaw surgery for mandibular deficiency, high mandibular plane angle type III patients will be unstable if the mandible persists in a downward and backward growth mode and reopens the bite.[127]
   d. For patients with maxillary transverse deficiency, orthopedic expansion may be effective for most girls up to 14 years of age and for many boys up to 16 years of age. Successful orthopedic expansions have been reported in both genders at older ages, especially with surgical assistance. The predictability of nonsurgical orthopedic success declines as the patient's age increases.[28,29,116]
   e. Psychosocial needs may supersede growth factors when the patient has a severe growth imbalance. Self-esteem considerations during adolescence deserve concern, and two-stage sequential surgery may be desirable for patients whose psychological and social development is affected by their jaw growth imbalance[128–130] (see Fig. 23-12).
   f. The timing of the referral to the maxillofacial surgeon and the initial patient education process are important responsibilities of the orthodontist. The orthodontist should try to determine the patient's level of awareness about the growth imbalance. If a patient is unaware that the condition may require surgical adjuncts, the education process may take longer and require more than one consultation with the orthodontist to create sufficient understanding to pursue the consultation.

3. *TMJ stability*: The orthodontic literature emphasizes the importance of planning treatment based on a reproducible condylar–fossa relationship.[131,132]

   This concept is all the more true when diagnosing and planning treatment for orthognathic patients. The orthodontist's skill in diagnosing and documenting functional shift problems in the occlusion is important. Without such skill, a mandibular functional shift may make a case look better than it is, causing a treatment plan to fail because of under-treatment. Or at the other extreme, it may make a case look worse than it is (e.g., Class III skeletal problem amplified by a functional shift) because of functional forward shift, causing treatment plan failure by overtreatment (i.e., insisting on surgery when the case can be managed with conventional treatment only) (see Fig. 23-31).

   The time to diagnose mandibular shifts is before treatment is initiated and is accomplished through the use of superior repositioning deprogramming splints, leaf gauge condylar seating, or careful manipulation of the mandible.[10] If such discrepancies are not detected before appliance placement but show up during treatment, the clinician has an obligation to document and inform the patient of the diagnostic data arising during treatment and advise the patient of any recommended change in the plan. The patient then must decide whether to pursue or reject the surgical plan. Undetected functional shifts in maxillary vertical excess and mandibular deficiency cases can lead to a treatment plan that calls for Le Fort impaction only. The operating room, with the patient under general anesthesia, is not the place for the surgeon to revise the treatment plan from a one-jaw procedure to a double-jaw procedure. Clarification and documentation of centric relation mandibular position should be done before the treatment plan is finalized.[13,26,133] Other TMJ stability concerns are addressed in the Risks section of this chapter.

4. *Dental unit stability*: One aspect of dental instability may be an unfavorable crown-to-root ratio, which occurs after bone loss from periodontal disease or as a result of short roots, whether genetic or acquired (Fig. 23-38). The orthodontist should be able to detect tooth mobility problems and advise the surgeon of the need for skeletal rather than interdental fixation.

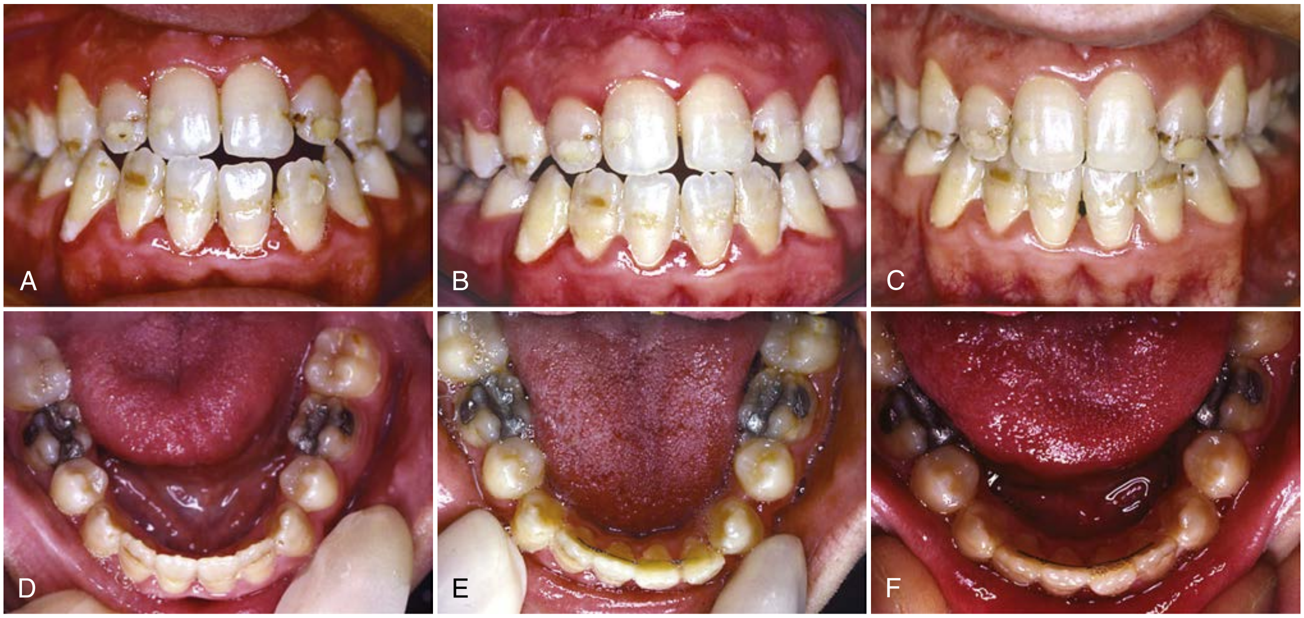

FIGURE 23-38 **A,** Anterior occlusion after braces and maxillary and mandibular surgery on a 14.5-year-old Class III patient. **B,** Anterior occlusion after 1.5 years of retention. Note lower incisor displacement. **C,** Anterior occlusion after phase II orthodontics; the patient refused additional jaw surgery. **D,** Lower incisors after braces and maxillary and mandibular surgery on a 14.5-year-old patient. **E,** Lower incisor displacement after 1.5 years of retention with bonded retainer. Note the tongue size. **F,** Lower incisors after phase II orthodontics and tongue reduction.

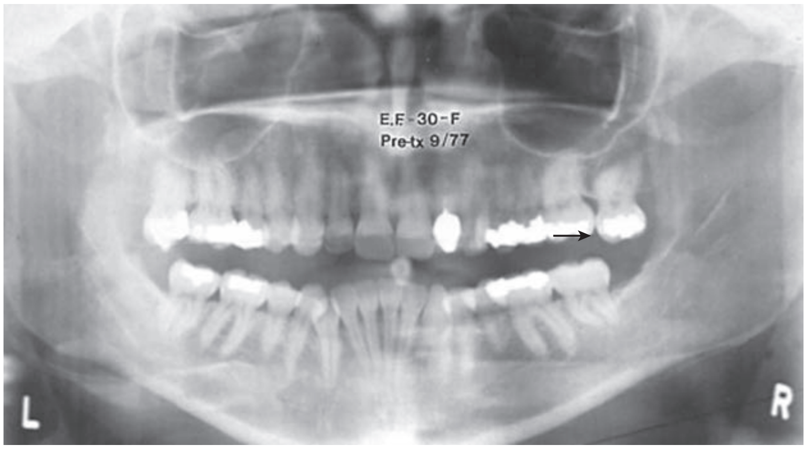

FIGURE 23-39 Pretreatment panoral radiograph showing several problems arising from mandibular excess (this patient's condition was shown in Figure 23-25). Note the supererupted right second molar (*arrow*).

Another form of dental instability features temporary crowns cemented as part of a periorestorative program. Brackets break easily from these crowns, and the crowns dislodge easily from the teeth. For these reasons, interdental fixation in a patient with temporary crowns is not advisable.

5. *Presurgical orthodontic preparation*: Arch leveling should be inclusive of second molars. In mandibular excess cases, the upper second molar frequently is supraerupted (Fig. 23-39), and in mandibular deficiency cases, the lower second molar may be supraerupted. These distal teeth, if not level vertically, can interfere with proper occlusal seating at the time of surgery, creating condylar distraction and instability. In addition, the lower incisors may be supraerupted in a skeletal Class II or III problem and require leveling with intrusion to prepare for the surgical phase. Certain surgical treatment plans may call for segmental intrusion, and the arch may require segmental leveling to satisfy the stability and aesthetic requirements of the case. Continuous archwires may cause instability through unwanted incisor extrusion (in an open bite case), causing less skeletal correction of the open bite and dental relapse.
6. *Considerations of pre- and postsurgical airway function* (see Chapter 12)
With current knowledge regarding obstructive sleep apnea, both the orthodontist and surgeon must assess the patient's presurgical sleep tendencies. If the patient has characteristics

of obstructive sleep apnea, surgical procedures that have a narrowing effect on the airway (e.g., mandibular setback for Class III patients) should also include maxillary advancement to aid in the correction of the Class III skeletal imbalance.[134,135] Aydemir and colleagues confirmed that the type of surgery on Class III patients can impact the airway. They assessed 48 patients with Class III malocclusions. Maxillary advancements were performed on 9 subjects, 7 subjects had mandibular setbacks, and 32 subjects had double-jaw procedures.[136] They found that the superior pharyngeal space and inferior pharyngeal space decreased after mandibular setback.
In the bimaxillary and maxillary advancement group, the palatopharyngeal space was significantly increased.

Additional prospective research on airway issues related to Class III jaw surgery has been reported by Uesugi et al.[135] In their study, 40 mandibular prognathic subjects were treated with orthodontics and orthognathic surgery: 22 patients had single-jaw mandibular setback surgical procedures; the other group of 18 had a double-jaw procedure with mandibular setback and a Le Fort I maxillary advancement surgical procedure. This was a CBCT study that included 16 control participants with normal occlusions and who had CBCT on two separate days for comparison. This study assessed pre- and postsurgical apnea-hypopnea index (AHI), morphologic differences in airway anatomy, and pharyngeal airway volume. Although Uesugi and colleagues found that there was a decrease in pharyngeal volume for patients having mandibular setback surgery, *they did not find an increase in AHI.* This well-done study and findings of are useful for assessing and planning orthognathic surgery for Class III patients.

As treatments are planned, the eight key responsibilities of the surgeon to maximize the stability of the orthognathic outcome (presented earlier in this section of the chapter) require periodic review with the surgeon.

RISKS OF ORTHODONTIC–ORTHOGNATHIC SURGERY

The risks to which patients are exposed during routine orthodontic therapy are minimal compared with the complications that may occur during orthognathic procedures. Practicing orthodontists must understand all the differential diagnostic considerations of the patient with skeletal imbalances and should also be well aware of the risk factors associated with the orthognathic procedures recommended. As the range of corrective procedures has widened, the reported negative sequelae have increased.

In the previous section of this chapter, the undesirable risk factors of instability were discussed. This section focuses on a variety of other complications that have been associated with orthognathic procedures (i.e., risk management). Complications are not common in orthognathic surgery, but they do occur. Several studies have shown complication rates.[49,50,76,137] Box 23-7 summarizes the complications recorded in the studies referenced.

There is a broad range of complications related to orthognathics that can be divided into the following categories: A, physical well-being; B, stomatognathic function; C, emotional well-being; and D, oral health sequelae.

BOX 23-7 Common Complications in Orthodontic–Orthognathic Surgery

Most Common Complications with Maxillary Surgery[21]

- Nausea or vomiting—40.08%
- Infection rate (acute or chronic)—7.4%
- Anatomic complications including deviated nasal septum—2.65%, nonunion at osteotomy gap—1.0%
- Extensive bleeding requiring blood transfusion—11%
- Ischemic complications causing aseptic necrosis of the alveolus—0.2%, gingival recession—0.8%
- Insufficient fixation—0.5% (most common in patients with clefts, craniofacial dysplasias, or vascular anomalies)

Most Common Complications with Mandibular Surgery

- Neurosensory deficit, mild—32%
- Disturbing—3%
- Infection rate—7.4%

A. Physical well-being
 1. Excessive blood loss[76,137,138]
 2. Neurologic injury (anesthesia, paresthesia)[138]
  a. Hypoesthesia (decreased sensation)
  b. Hyperpathia (increased sensation)
  c. Dysesthesia (altered sensation that is painful)
 3. Allergic reaction to anesthetic, antibiotic, or anti-inflammatory drugs
 4. Postoperative infections[76,139]
  a. Surgical site
  b. Skeletal fixation wires
  c. Rigid fixation plates[140]
  Current infection prevention techniques are discussed by Spaey and colleagues.[52] In addition, orthodontists can aid surgeons in reducing the potential iatrogenic incidence of nidi of infection by using soldered or slide-on surgical hooks, well-secured brackets, and stainless steel ligatures (not A-lastics because their force decays rapidly, and they are not radiopaque; if A-lastic ligatures inadvertently fall into the surgical site, they are difficult to locate and remove). Figure 23-40 shows the postsurgical migration of a molar bracket that broke off the left first molar during surgery. Fortunately, no infection developed.
 5. Bone fractures (Fig. 23-41)
  Reports exist in the literature of unfavorable surgical splits of the mandible, including buccal plate fracture associated with impacted third molar teeth that were extracted at the time of the mandibular osteotomy. When sagittal split procedures are planned for mandibular deficiency or mandibular excess, it is prudent to remove third molars 6 to 12 months before the osteotomy to avoid the risk of unfavorable fractures. When unfavorable splits occur, the stability of the procedure is jeopardized, and the likelihood of neuropathies and facial deformities is greater. If an unfavorable split occurs, the surgeon must decide whether to proceed with the surgery or repair the fracture and redo the surgery at a later time.
 6. Delayed healing and nonhealing
  Delayed healing and nonhealing occur most often when unexpected microtrauma or macrotrauma occurs in the surgical and postsurgical periods. Intraoperative complications such as those discussed previously and including unfavorable splits in the sagittal split or unfavorable

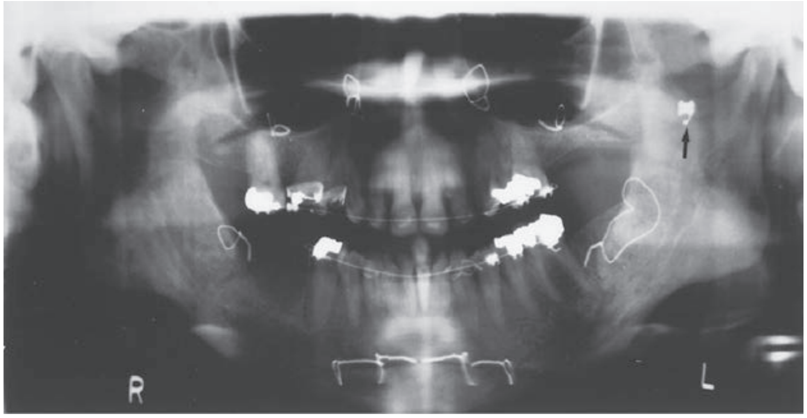

FIGURE 23-40 Postsurgical panoral radiograph showing molar bracket (*arrow*) that broke off during surgery. The bracket has migrated to the coronoid notch.

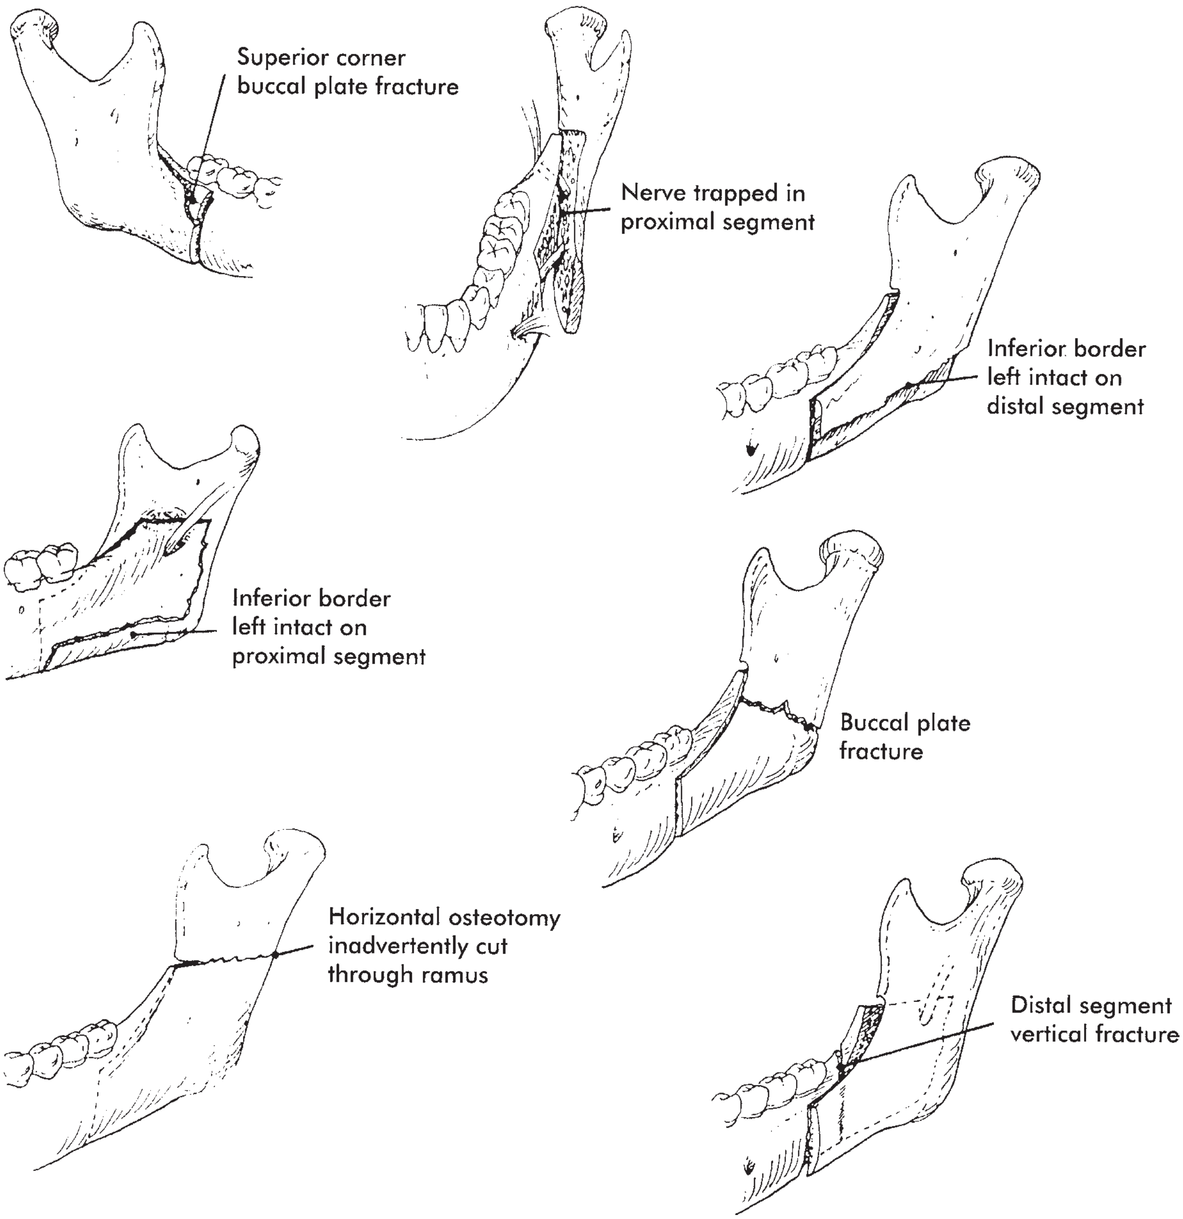

FIGURE 23-41 Common types of unfavorable splits. (From Sinn DP, Ghali GE. Management of intraoperative complications in orthognathic surgery. *Oral Maxillofac Clin North Am* 1990;2(4):872.)

downfracture in the Le Fort osteotomy can result in incomplete bone healing. An inaccurate preoperative medical assessment (see Table 23-5) or postoperative surgical traumatic occlusion also can result in poor bone healing and fibrous unions.

7. Secondary surgery
   A small percentage of orthognathic patients must return to the operating room for secondary surgery because of unexpected surgical outcomes. Some return before release from the hospital after the first surgery; others return months or years later (Fig. 23-42). The most common reasons for secondary surgery include the following:
   - Early relapse
   - Posthealing relapse
   - Unfavorable split
   - Patient dissatisfaction with the aesthetic result (in the early years of the Le Fort procedure, the maxilla was impacted beyond an aesthetic smile line in some patients)

   Overimpaction of the maxilla can occur for several reasons:
   - Removal of an excessive amount of bone from the lateral walls
   - Presence of thin, concave maxillary bone that may collapse on loading
   - Use of overly tight interosseous suspension wires that tend to pull the maxilla superiorly
   - Excessive masticatory function that overrides the stability of the bony interfaces
   - Lack of bony contact
   - Inappropriate treatment planning

   Correction of overimpaction cannot be achieved short of surgically repositioning the maxilla inferiorly and returning the dentoalveolar portion to its original position. This would require interpositional bone grafting and rigid internal fixation and possibly concomitant mandibular surgery.[138]
8. Sinus complications
   Several authors who have studied postsurgical patients have found that a higher percentage than expected reported sinus problems after Le Fort procedures.[141,142] Other authors have indicated that postsurgical sinus disease is no greater than that in the general population.[138] Postsurgically, the maxillary sinus function may have been altered such that it interferes with proper drainage, causing sinus-type headaches, or sinuses may congest more frequently, causing interference with nasal breathing. Although this complication may seem relatively minor, it can have an adverse effect on the quality of life of patients who must deal with chronic sinus flare-ups.

B. Stomatognathic system function
1. Decreased efficiency and discomfort during chewing
   Two common causes of postsurgical occlusal inefficiency are the following:
   - Posterior open bites caused by overseating of condyles during mandibular surgery
   - Excessive superior positioning of the posterior maxilla, especially when posterior vertical stops are inadequate in the area of the osteotomy
2. Temporomandibular dysfunction, discomfort, and pain
   In some cases, orthognathic surgery is justified because it has the potential to reduce temporomandibular dysfunction symptoms. Karabouta and Martis[143] reported that temporomandibular dysfunction symptoms declined from 40% to 11% of the sample. However, 4% of previously asymptomatic patients developed temporomandibular dysfunction symptoms after surgery. In another study Kerstens et al.[144] and Kim et al.[145] found a 66% reduction in temporomandibular dysfunction symptoms; they also found that 11.5% of preoperatively asymptomatic patients experienced symptoms after surgery. Many of these patients may have had latent temporomandibular dysfunction problems that were activated by the altered joint loading after jaw surgery. Management requires a team effort and appropriate care, depending on the nature of the problem. In a recent systematic review of 1776 articles, Lindenmeyer et al.[146] found 23 articles seeking to establish a therapeutic role of orthognathic surgery in relation to TMD issues. After assessing the data in these articles, the authors were unable to establish a positive or negative role of the orthognathic procedures causing or "curing" TMD issues.
3. Limitation in range of motion
   A program of physical therapy is prescribed for most orthognathic patients shortly after the release of fixation. If mandibular hypomobility is present after jaw surgery, it could have an intracapsular or extracapsular cause. Intracapsular problems are characterized by a sharp pain localized in the TMJs. Extracapsular problems are characterized by less intense, dull pain that is generalized and diffuse and may or may not be aggravated by mandibular surgery; often the pain is alleviated by biting.

   A prospective study of 55 orthognathic patients by Aragon et al.[147] found that the maximal incisal opening (MIO) decreased in most of these patients after surgery. The percentage of MIO decrease depended on the surgery performed

Procedure	**Percentage of Maximal Incisal Opening Reduction**
Sagittal split osteotomy (SSO)	29% (mean)
Vertical subcondylar osteotomy (VSO)	10% (mean)
Le Fort I	2% (mean)
Le Fort I and SSO	28% (mean)
Le Fort I and VSO	9% (mean)

C. Emotional well-being
1. Adaptation to facial appearance change
   In the authors' experience, negative emotional responses seldom occur with single-jaw mandibular advancement or mandibular setback procedures because these procedures mainly affect the patient's profile, and therefore the patient does not observe these changes readily. Changes that occur with single-jaw Le Fort procedures or Le Fort procedures with mandibular advancement or setback alter the frontal facial appearance immediately, and the patient must adapt to the new look.[5] Although it has been determined that appearance change is not the primary motivating factor to pursue orthognathic surgery, it remains a key factor in the choice to pursue jaw surgery. After evaluating a retrospective questionnaire of 500 patients who underwent orthognathic surgery, Proothi et al.[148] determined that the primary motivating factor for patients to pursue jaw surgery was "bite improvement." Additional motivating factors in their study were appearance, pain, smile, and speech.

FIGURE 23-42 **A–C,** Intraoral photographs during evaluation for exposure to third orthodontic and surgical treatment plan. Instability resulted from previous treatment, which included orthodontics and four premolar extractions followed by double-jaw surgery. Instability of the initial surgical result and temporomandibular joint pain created a need for a second surgical procedure with the same orthodontist and surgeon. **D–F,** Intraoral photographs after orthodontic preparation and third surgical treatment with a new orthodontist and surgeon. Because of previous dental instability, permanent, fixed retention was incorporated in her treatment. **G** and **H,** Profile photograph before and after surgery, respectively. **I–K,** Lateral cephalograms: initial, presurgical (after decompensation), and postsurgical, respectively. Vertical chin reduction and advancement were considered, but the patient declined this procedure.

Esperao et al.[149] recently assessed the broader topic of quality of life issues in three groups of patients who were in different stages of surgical-orthodontic treatment: 20 patients who were in consultation phase of surgical-orthodontic treatment, 70 patients who were in presurgical orthodontic treatment, and 27 patients who had completed presurgical and orthognathic treatment but were still in postsurgical orthodontic treatment. The 14 questions from the Oral Health Impact Profile (OHIP) were used to compare the oral health impact profile of the three different groups. The authors found that those in the consultation phase and those in the presurgical phase were 6.48 and 3.14 times, respectively, more likely to experience a negative impact of their oral condition compared with patients in the postsurgical phase.

2. Self-esteem changes caused by unexpected facial changes[17,28,29,32,96,97,148,149]
   In Jacobson's study.[150] most patients (80%) said that orthodontic-orthognathic treatment influenced their lives positively, and 4% said that treatment had a negative influence on social activities. The remaining 16% were neutral about the impact of surgery on their lives. In their study of 55 patients, Kiyak et al.[28] found that at the 9-month postoperative interval, the patients' self-esteem had declined significantly from an early postsurgical period. The orthodontist and staff who follow these patients after surgery must be aware of the potential for emotional highs and lows during the postsurgical period. Having a psychologist available who is aware of the needs of orthognathic patients and who is able to intercept significant patient emotional problems is imperative.
3. Lack of preparation for changes in interpersonal relationships
   As the surgical technology has improved to allow more stable, functional results, so too has the capacity to alter a person's appearance and identity. Most orthognathic patients are women between the ages of 20 and 40 years. Many are married and have husbands and young children. When this person returns home from the hospital after a Le Fort osteotomy and genioplasty, she is swollen and black and blue (bruised), and she may be in fixation with limited speech and eating capacities. If the immediate family members in the support group are not prepared fully for her to return looking so different, significant stress and disruption of normal family functions will result. As one patient in the study by Kiyak et al.[28] commented, "I would not recommend this surgery to anyone without counseling."

   Patients who have had the surgery have many good ideas about ways to enhance the recovery process. Another patient in the study said the following:

Much more time is needed to prepare the patient with facts and information. I was unprepared for the bleeding and earaches, leaving the hospital so soon—less than 24 hours after surgery. I lost more weight than expected and really suffered psychologically and felt little support during the fixation period. Maybe the patients could be invited to form a mutual support group.[28]

Bhamrah et al.[151] assessed 1912 randomly selected Internet posts from an online orthognathic discussion forum to determine effectiveness of this mechanism as a support resource and information resource. The study used five major themes as topics for study:

a. Reasons for undergoing orthognathic treatment
b. Pre- and postsurgical treatment stages, including orthodontics
c. Surgery including postsurgical complications and difficulties
d. Expected and actual end-of-treatment changes
e. Seeking and sharing information

Bhamrah et al. found that Internet forums can be used to provide curious patients with additional information about orthognathic treatment, and the forums can be a source of support and emotional encouragement. The authors' findings provide practical insights into the mindsets of their patients going through the preparation and process of pursuing orthognathic surgery.

In a 2011 study, Oland et al.[152] provided orthognathic teams with additional insights into posttreatment patient satisfaction of surgical orthodontic patients. From the 118 patients who were studied via a pre- and posttreatment questionnaire that assessed pretreatment motivation and posttreatment satisfaction, it seemed that the degree of posttreatment satisfaction was correlated to pretreatment motivation:

Those who were motivated by oral functional motives before treatment had lower post-treatment satisfaction than those who were motivated by a change in appearance. Additionally, the more fulfilled a patient's motive for appearance change, the greater were the measurable improvements in self-concept and social interaction.[152]

4. Depression
   Postsurgical depression has received little attention in the orthognathic literature and only recently has been discussed as a legitimate complication of jaw surgery.[153] Generally, dentists are not trained properly to handle depression medically, even if it is likely to be a transitory state of mind for orthognathic patients. However, the orthodontic members of the health care team have the duty to recognize the symptoms of depression, discuss them with the patient and family, refer the patient when necessary, and interact with the psychologist to aid in the patient's recovery. In addition, the orthodontist should try to be aware of other stressful events in the patient's life that may add to the anxiety level during the 2 to 3 years these patients are followed.

   Although the current literature discusses the postsurgical sequelae of depression, the authors' experience is that patients with rigid fixation show rapid psychological rebound and fewer signs of depression than patients 5 to 10 years ago whose jaw surgery required intermaxillary fixation for 6 to 10 weeks.

D. Oral health complications and sequelae

1. Bone loss[150]
   Although this complication is not reported frequently, the exacerbation of existing periodontitis is a potentially serious problem. Patients with mild, moderate, or advanced periodontal disease require strict supervision and management by a specialist before orthognathic procedures. Patients with moderate or advanced periodontal disease are at high risk for further periodontal breakdown after orthognathic surgery because of ensuing dietary changes, interference with oral hygiene (depending on the mode of fixation), and transitory occlusal trauma.

2. Gingival deficiency with recession
   During the treatment planning stage, orthodontists need to consider the degree of decompensation of the lower incisors as they prepare the patient for jaw surgery. Frequently, in Class III patients, for example, lower incisor decompensation requires gingival grafting before tooth movement to avoid gingival recession (see Figs. 23-26 and 23-28).
3. Pulpal changes
   The osteotomies that are performed, particularly Le Fort I procedures and segmentals, often approximate root apices. Occasionally, after an osteotomy, the affected tooth starts to change color and lose its vitality, and eventually it requires a root canal. The likelihood of loss of vitality is minimal, but it does occur. Careful preparation by the orthodontist and planning by the surgeon should eliminate this annoying complication.
4. Tooth loss
   Tooth loss is an uncommon sequela, but it does warrant brief discussion. A cohort study published in 2012 by Williams et al.[154] assessed complications after SARPE. This retrospective study evaluated 120 patients who had a SARPE procedure at the Kaiser Permanente Oakland Medical Center. The average age of the patients was 29 years, and the sample was half male and half female. Although most orthodontists and surgeons consider the SARPE procedure to have minimal complications, this study determined that 41 of the 120 patients assessed had at least one complication. Most of the complications were minor and were resolved with local measures. There were, however, 15% who required additional unanticipated treatment. The most common problem was symmetric or inadequate expansion. This occurred in 13% of the sample. The most common dental or periodontal problem involved the maxillary central incisor. There were reports of discoloration, gingival recession, and periodontal bone loss that occurred in 15% of the patients in this study. The authors also reported "catastrophic" midline bony defects with the loss of both central incisors. These data are important informed consent information for both the surgeon and the orthodontist.

   Tooth loss may also occur because of inadequate apical root space (4 mm is the desired amount of separation between apices). Proper preparation of the area to be segmented reduces the probability of tooth loss sequelae.

Although this discussion of complications associated with orthognathic surgery is far from complete, it should give the orthodontist an awareness of some of the more common postsurgical sequelae that must be managed in cooperation with the oral surgeon for the overall well-being of the patient. Orthodontists who refer patients for orthognathic surgery should review the informed consent policy of the surgeon's office so that the orthodontist and staff can help their patients understand any aspects that are unclear. The routine surgical practice in the United States is to review potential negative sequelae with the patient before surgery. This is part of the informed consent procedures and is appreciated greatly by patients.[18]

SUMMARY

This chapter began with a discussion of treatment goals and the technologic advances that have helped orthodontic-surgical teams enhance the lives of many patients who were born with facial skeletal disharmonies. The chapter intentionally concluded with a discussion of complications. New surgical technology has broadened the scope of orthodontists' treatment capability and at the same time has expanded their responsibilities. In his very informative book *Second Opinions*, Jerome Groopman[155] provides a valuable insight from his medical experience to orthodontists and surgeons. He states:

> *In a predictable world, clinical decision making would be a well-defined, scientific exercise with set methods for diagnosis and treatment. The unfortunate truth is that this is not possible. People adapt differently, physically and emotionally, to each illness (condition) and react in varying ways to a given therapy. This means that diagnosis and treatment cannot be strictly bound by generic recipes, but must be made individual, to be consistent with the particular clinical and psychological characteristics of the person.*

As the orthodontic specialty and the surgical specialty continue to study factors that reduce risk and enhance success, the surgeon and the orthodontist have the responsibility to integrate many important variables to provide optimal patient care.

Acknowledgments
With great appreciation to my staff and the oral and maxillofacial surgeons who have made these dramatic changes possible for our patients. Also, tremendous appreciation to Elizabeth Barrett, Beth McFarland, and Melissa Carstens for their time and assistance in editing the text and organizing the figures for this chapter.

Self-Ligating Bracket Biomechanics

Nigel Harradine

OUTLINE

THE HISTORICAL CONTEXT OF SELF-LIGATION

In the context of the current popularity of self-ligation, the continuing lack of consensus about its clinical benefits, and the plethora of types of self-ligating brackets, it is helpful to review the origins and motivations for development of this form of ligation. The vast majority of fixed orthodontic appliances have stored tooth-moving forces in archwires that are deformed within their elastic limit. For this force to be transmitted to a tooth, wires need a form of connection to the bracket. This connection has for many years been referred to as *ligation* because the early forms of connections were most frequently a type of ligature, for example, silk ligatures. The more recent forms of connections between bracket and archwire have all retained this title of ligation. *Elastomeric ligatures* and *self-ligating brackets* are firmly established orthodontic terms.

Stainless Steel Ligatures

When stainless steel became available, it was universally adopted as the method of ligation. Stainless steel ligatures have several beneficial inherent qualities. They are cheap, robust, and essentially free from deformation and degradation, and to an extent, they can be applied tightly or loosely to the archwire. They also permit ligation of the archwire at a distance from the bracket. This distant ligation is particularly useful if the appliance tends to use high forces from the archwires because this high force prevents sensible full archwire engagement with significantly irregular teeth. Despite these good qualities and their widespread use over many decades, wire ligatures have substantial drawbacks, and the most immediately apparent of these is the length of time required to place and remove the ligatures. One typical study[1] found that an additional 11 minutes was required to remove and replace two archwires if wire ligatures were used rather than elastomeric ligatures. Additional potential hazards include those arising from puncture wounds from the ligature ends and trauma to the patients' mucosa if the ligature end becomes displaced.

Elastomeric Ligatures

Elastomeric ligatures became available in the late 1960s and rapidly became the most common means of ligation, almost entirely because of the greatly reduced time required to place and remove them compared with steel wire ligatures. It was also easier to learn the skills required to place these ligatures, so new clinicians and staff greatly preferred elastomerics. Intermaxillary elastics had been employed since the late 19th century, pioneered by well-known orthodontists such as Calvin S. Case and H.A. Baker. Initially, these elastic bands were made from natural rubber, but production of elastomeric chains and ligatures followed the ability to produce synthetic elastics from polyester or polyether urethanes. The ease of use and speed of placement of elastomeric ligatures did, however, lead to other definite disadvantages being generally overlooked although readily apparent. Elastomerics frequently fail to fully engage an archwire when full engagement is intended. Twin brackets with the ability to "figure of 8" the elastomerics are a significant help in this respect but at the cost of greatly increased friction, which is discussed later in this chapter. A paper by Khambay et al.[2] quantified the potential seating forces with wire and elastic ligatures and clearly showed the much higher archwire seating forces available with tight wire ligatures. A second and well-documented drawback with elastomerics is the substantial degradation of their mechanical properties in the oral environment. A comprehensive literature review of elastomeric chains[3] gave a good account of the relevant data, and a more recent article[4] discusses the underlying reasons and clinical significance of this loss of mechanical properties. Typically, elastomeric chains and ligatures suffer more than 50% degradation in force in the first 24 hours[5] when tested under in vitro experimental environments. The higher temperature in the mouth, enzymatic activity, and lipid absorption by polyurethanes are all cited as in vivo sources of force relaxation. This leads to the well-known potential for elastomeric ligatures to fail to achieve or to maintain full archwire engagement in the bracket slot.

Figure 24-1 shows the familiar loss of rotational control of canines during space closure. Twin brackets with the ability to "figure of 8" the elastomerics are a significant help in this respect but certainly not a complete answer. A further factor of potential clinical importance is the variability in mechanical properties of elastomerics. This is well described by Lam et al.,[6] who reported substantial variation in the range and tensile strength of elastomerics from different manufacturers and for different colors of elastomeric from the same manufacturer. Last, there is a large body of literature to demonstrate the much higher friction between bracket and archwire with elastomeric ligation compared with wire ligatures. Interestingly, this had been proposed as a factor of clinical significance more than 30 years ago[7] but was largely disregarded until more recently. The potential importance of friction and its relation to forms of ligation are discussed in more detail later in this chapter. The great popularity of elastomeric ligation in the past 40 years was achieved despite these substantial deficiencies in relation to wire ligatures. Speed and ease of use were the overriding assets of elastomerics, and it is no surprise that the strongest motivation behind the early efforts to produce a satisfactory self-ligating bracket was a desire to have all the benefits of wire ligation but in addition have a system that is quick and easy to use.

Begg Pins

In the 1950s, Raymond Begg, a former pupil of Edward Angle, developed his light-wire technique using Angle's ribbon arch brackets with round wire archwires.[8] A key feature of the technique was the use of brass pins as the method of ligation. These pins constituted the fourth (gingival) wall of the bracket slot and formed a rigid metal wall analogous in some ways to that of a molar tube or a self-ligating bracket. The pins were designed with shoulders to keep from binding the archwire in the early alignment stages and without shoulders as "hook pins" to hold the archwire in a more precise vertical position when thicker wires and auxiliaries were added later in the treatment. This author used many such pins, being trained simultaneously in Begg and edgewise mechanics during his initial specialist training. Begg pins had none of the disadvantages of elastomeric rings and were probably more rapid to place and remove than wire ligatures. These pins cannot be assessed in complete isolation from the rest of the Begg technique, but in relation to self-ligation, it is well worth noting the reputation that the Begg technique acquired for rapid early alignment and the effectiveness of lighter forces when there was no friction to be overcome from tight engagement with elastomerics. As a footnote in orthodontic history, it should be recalled that self-ligating Begg brackets were produced in the 1970s and were used by this author on a number of cases. They had an inbuilt pin that was rotated into position over the archwire with the intention being to further simplify and speed the process of ligation. Interestingly, when the Tip-Edge appliance was developed to be a successor to the Begg technique, it abandoned the metal, low-friction form of ligation that Begg pins represented and reverted to elastomerics.

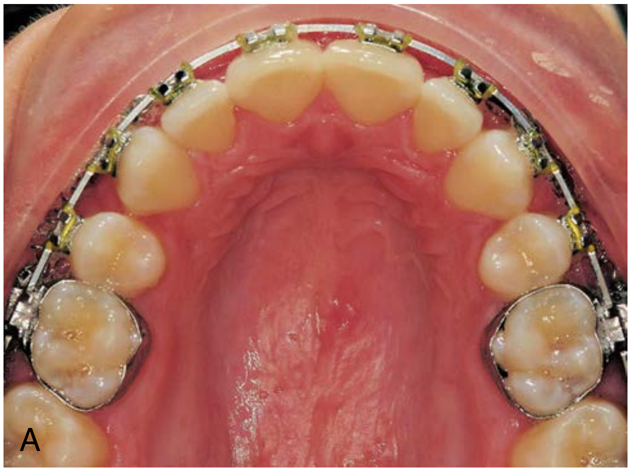

FIGURE 24-1 **A,** Loss of archwire control on upper canines with elastomeric ligation. **B,** Loss of elastomeric ligature causing loss of control of lower canine.

Self-Ligation

Self-ligating brackets by definition do not require an elastic or wire ligature but have an inbuilt mechanism that can be opened and closed to secure the archwire. In the overwhelming majority of designs, this mechanism is some form of metal labial face to the bracket slot, which is opened and closed with an instrument or fingertip. Brackets of this type have existed for a surprisingly long time in orthodontics, the Russell Lock edgewise attachment being described by Stolzenberg[9] in 1935. This was by modern standards a very primitive mechanism consisting of a labial grub screw to retain the archwire. Since that time, many designs have become commercially available. Self-ligating orthodontic brackets have a relatively long history, but their development should be viewed against the background of an almost universal use of elastomeric ligatures despite the known advantages of wire ligatures and—in a different context—of brass Begg pins. Elastomeric ligation gives unreliable archwire control, high friction, and perhaps an added oral hygiene challenge. Wire ligation is better in every respect but is very slow and highly inconsistent in its force application,[10] and the wire ends can cause trauma to patient and operator. Orthodontists accommodated these shortcomings for several decades. Self-ligation has always offered the potential for very substantial improvements in relation to all of these drawbacks, but for many years remained the choice of a small minority of clinicians. The 21st century has seen a dramatic acceleration of bracket development, with at least 32 new bracket types becoming available. An overview of the status of self-ligation earlier in the current century[11] summarizes the situation at that time. The early part of this century also saw a proliferation of the advocated advantages of self-ligation and, more recently, a much greater research effort to gather the necessary related evidence. Before examining these claims and the associated evidence, it is helpful to look at the reasons why it took so long for self-ligation to attract this degree of attention.

FACTORS THAT HINDERED THE ADOPTION OF SELF-LIGATION

A contributory historical factor in this respect has been the significant imperfections in bracket design and performance. These imperfections have varied with different bracket designs. The author of this chapter has used 15 different types of self-ligating brackets and is therefore in a position to speak from some experience as well as from first principles. An ideal method of ligation should deliver ligation that is rapid and secure and provides low resistance to tooth movement relative to the archwire. Specific requirements for a self-ligating bracket are that:

- It is very easy to open and close with low forces applied to the teeth during these procedures and with all archwire sizes and materials.
- It never opens inadvertently, allowing loss of tooth control.
- It has a ligating mechanism that never jams or breaks or distorts or changes in its performance through the treatment period.
- It has a positively held open clip or slide position, so that the clip or slide does not obstruct the view of the bracket slot or the actual placement of the archwire.
- It is tolerant of a reasonable excess of composite material without obstructing the clip or slide mechanism.
- It is not significantly affected by buildup of calculus.

FIGURE 24-2 Edgelok bracket. An early passive self-ligating bracket.

- It permits easy attachment and removal of all the usual auxiliary components of an appliance such as elastomeric chain, under-tie ligatures, and laceback ligatures without interfering with the self-ligating clip or slide.
- It permits easy placement and removal of hooks and posts and possibly other auxiliaries on the brackets. With the security of self-ligation, the use of elastics or other traction directly to a bracket is much more frequently appropriate than with conventional ligation.
- It has a suitably narrow mesiodistal dimension to take advantage of the secure archwire engagement and permit large interbracket spans and hence lower force levels and a longer range of action.
- It has the performance expected of all orthodontic brackets in terms of bond strength, accuracy of slot dimensions, and smoothness of contour.

Many brackets have been less than satisfactory in several of these requirements, and this can be illustrated with a few better known examples.

- Edgelok brackets[12] (Ormco Corporation, Orange, CA) (Fig. 24-2) were the first self-ligating bracket to be produced in significant quantities. Disadvantages included inadequate rotational control, bulkiness, and some inconvenience with opening and closing the slide, and they were never widely adopted.
- The well-known Speed brackets[13] (Fig. 24-3) have remained in successful production since 1980. This testifies to the inherent soundness of many of the original design features. However, early Speed brackets (Fig. 24-4) were handicapped by clips that could too easily be displaced or distorted. These drawbacks have since been successfully addressed by improvements in the bracket body and in the clip itself, but combined with the inherent unfamiliarity for clinicians of a bracket with no tie wings, these aspects probably hindered the wider popularity of Speed in previous years.

FIGURE 24-3 Speed bracket with clip-restraining slot, labial clip-opening aperture, and slot preadjustment.

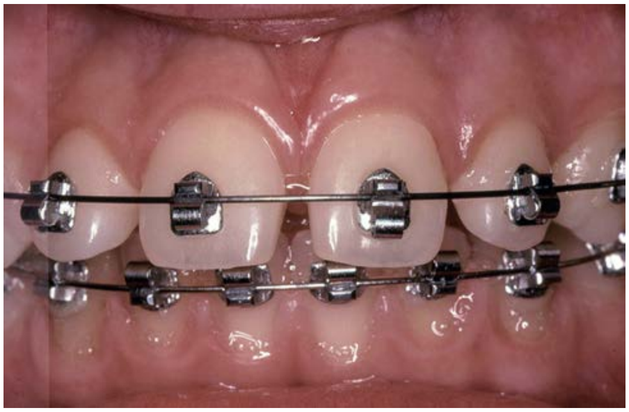

FIGURE 24-4 A case treated with early Speed brackets in 1982. There is no restraining slot preventing clip displacement and no straight-wire preadjustment in the bracket.

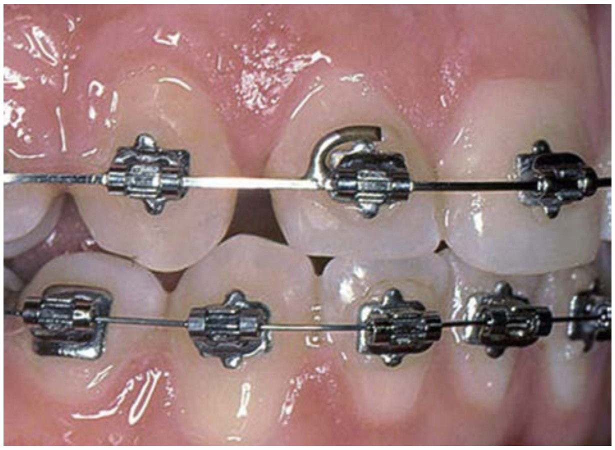

FIGURE 24-5 Activa brackets in 1990, illustrating the undesirable bracket width that reduces interbracket span, the concavity of the rotating clip, the lack of tie wings, and the unorthodox bonding base.

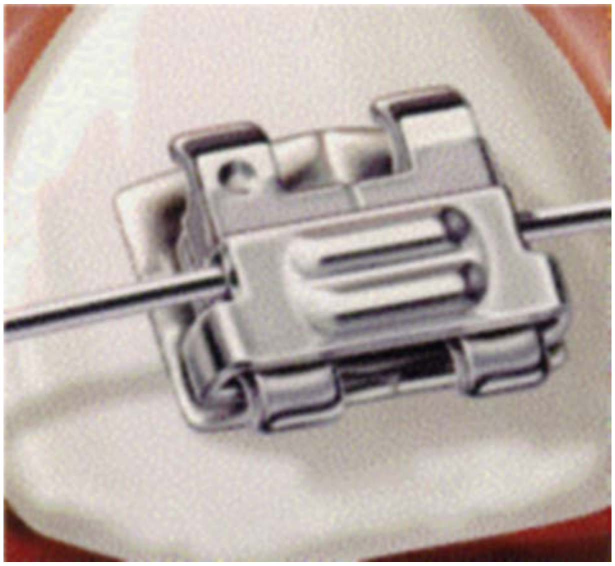

FIGURE 24-6 Damon SL bracket 1996, showing the wraparound slide which was prone to fracture and loss.

- Activa brackets[14] (Fig. 24-5) ("A" Company, San Diego, CA) had a rotating slide that therefore gave a concave inner radius to the labial surface of the slot. This curvature increased the effective slot depth with small diameter wires, diminishing labiolingual alignment with such wires. The slide was retained on the mesial and distal ends of the slot, and this made for a wider than average bracket, which reduced the interbracket span with the consequent disadvantages, and the slide was not robust. The absence of tie wings was an additional nuisance when placing the elastomeric chain, and the unfamiliar shape of the early bonding base made bracket positioning more difficult. Finally, a combination of the design features substantially reduced bond strength. Despite these substantial drawbacks, cases could be successfully treated that demonstrated the now-familiar potential advantages of self-ligation, but the deficiencies of the design ensured that they were only adopted by a minority of enthusiasts.
- Damon SL brackets[15,16] (Fig. 24-6) ("A" Company) became available in the mid-1990s and had a slide that wrapped around the labial face of the bracket.

These brackets were a definite step forward but suffered two significant problems—the slides sometimes opened inadvertently because of the play of the slide around the exterior of the bracket, and they were prone to breakage because of work hardening on the angles of the slide during manufacture. One study[17] quantified these problems. In 25 consecutive cases in treatment for more than 1 year, 31 slides broke, and 11 inadvertently opened between visits. This is compared with 15 broken and lost elastomeric ligatures in 25 consecutively treated cases with conventional brackets, so the difference in ligation fragility was not enormous, but when a clinician has paid extra

FIGURE 24-7 Damon 2 bracket released in 2000, showing the more protected and more rigid slide that was produced by metal injection molding as was the bracket body.

for a novel bracket design and the main design feature is not highly robust and is susceptible to inexpert handling from inexperienced operators, it has a significant negative effect on widespread adoption of that bracket. Nevertheless, these brackets generated a substantial increase in the appreciation of the potential of self-ligation.

- Damon 2 brackets (Fig. 24-7) (Ormco Corporation, Orange, CA) were introduced to address the imperfections of Damon SL.

  They retained the same vertical slide action and U-shaped spring to control opening and closing but placed the slide within the shelter of the tie wings. Combined with the introduction of metal injection molding manufacture, which permits closer tolerances, these developments almost completely eliminated inadvertent slide opening or slide breakage and led to a further acceleration in the use of self-ligation. However, the brackets were not immediately and consistently easy to open, and this aspect of functionality is very important to new users. Also, it was possible for the slide to be in a half-open position, hindering archwire removal or placement.
- Damon 3 brackets (Fig. 24-8) (Ormco Corporation) had a different location and action of the retaining spring, and this produced a very easy and secure mechanism for opening and closing.
- In addition, Damon 3 brackets were semiaesthetic. However, early Damon 3 production brackets had three very significant problems: a high rate of bond failure, separation of the metal from the reinforced resin components, and fractured resin tie wings. These three problems all received fairly rapid investigation and improvement but illustrate that it continues to be a significant challenge for manufacturers to extrapolate from the experience with prototype brackets in the hands of skilled enthusiasts to subsequent full-scale production and the use by relative novices. The subsequently launched all-metal Damon D3 MX bracket (Fig. 24-9) and more recent Damon Q bracket (Fig. 24-10) have clearly benefited from previous manufacturing difficulties and from further clinical experience and expertise. As with other brackets such as Speed and In-Ovation (GAC International, Bohemia, NY), these later Damon brackets also feature a slot for drop-in hooks, which was mentioned above in the list of ideal requirements.

FIGURE 24-8 Damon 3 semiaesthetic bracket showing the improved slide mechanism and the junction of metal and resin components, which was initially prone to separation.

FIGURE 24-9 Damon MX brackets showing the vertical auxiliary slot that permits placement and removal of drop-in hooks in this bracket and in the Damon Q. Drop-in hooks are very useful for placement of early intermaxillary elastics.

In-Ovation (Fig. 24-11) became available in 2002 and has more recently been called In-Ovation R and is very similar to the Speed bracket in conception and design but of a twin configuration with tie wings. Both of these additional features probably contributed to a greater acceptability of these brackets to new users. In 2002, smaller brackets for the anterior teeth became technically possible and available as In-Ovation R (Reduced, referring to the reduced bracket width), and this narrower width was certainly desirable in terms of greater interbracket span. Several self-ligating brackets have become smaller with development. This has been enabled by advances in manufacturing technology but is also driven by an appreciation that the

FIGURE 24-10 Damon Q bracket showing the additional horizontal slot for auxiliary archwires, a feature of several self-ligating brackets, including In-Ovation, Quick, and Speed.

secure ligation provided by a self-ligating bracket requires less bracket width to give good rotational control, within reason. In-Ovation is certainly a successful design, but some relatively minor disadvantages in relation to the list of ideal requirements can be experienced with the several examples of this type of bracket that use a spring clip that moves vertically behind the archwire slot. Some such brackets are a bit difficult to open, and this is more common in the lower arch, where the gingival end of the spring clip is difficult to visualize. Excess composite at the gingival aspect of brackets in the lower arch can be difficult to see and may also hinder opening. Similarly, lacebacks, under ties, and elastomerics placed behind the archwire are competing for space with the bracket clip. Both Speed and In-Ovation R as well as the similar and the more recent Quick brackets (Fig. 24-12) (Forestadent Bernhard Foerster GmbH, Pforzheim, Germany) have aimed to address some aspects of this potential difficulty by providing a labial hole or notch in the clip in which a probe or similar instrument can be inserted to open the clip.

The need to acquire the expertise of opening an unfamiliar bracket can dishearten new users of self-ligating brackets, and these more recent refinements of the method of opening are a definite advance in this respect. These refinements are also typical of the incremental improvement of self-ligating brackets that can take place without being appreciated by clinicians who have experienced difficulties with earlier production examples and consequently discontinued their use.

- SmartClip (3M, St. Paul, MN). This bracket (Fig. 24-13) is distinctive in retaining the wire through two C-shaped spring clips on either side of the bracket slot. The pressure required to insert or remove an archwire is therefore not applied directly to a clip or slide but to the archwire, which in turn applies the force to deflect the clips and thus permits archwire insertion or removal. This mechanism therefore has to cope with providing easy insertion and removal through the jaws of the clips but must also prevent inadvertent loss of ligation for both small, flexible archwires and large, stiff archwires.

FIGURE 24-11 An early In-Ovation bracket showing the tie wings that distinguished this bracket from Speed brackets.

FIGURE 24-12 Forestadent Quick bracket showing the design features shared by many active self-ligating brackets.

FIGURE 24-13 3M Unitek SmartClip bracket showing the distinctive external spring clips with their jaws through which archwires of all sizes and stiffness must ideally pass very easily and comfortably during archwire changes but never between patient visits.

This is an inherent conflict in requirements and one that is difficult to balance satisfactorily. Other spring clips, such as on the Speed and System R brackets with their vertical action, have a rigid bracket component to assist the spring in resisting a loss of ligation and are opened and closed vertically and independently of forces from the archwire. It became apparent with wider clinical use that the force required for insertion and removal of thick stainless steel wires from SmartClip brackets was uncomfortably high. More recent modifications have been aimed at addressing this difficulty by lowering the effective stiffness of the spring clips.

These examples all illustrate the difficulties that have been experienced by manufacturers aiming to meet the requirements of an ideal ligation system. The resulting imperfections in bracket design undoubtedly slowed the adoption of self-ligation systems by clinicians in previous years. Current self-ligation designs have benefited greatly from previous clinical experience and from advances in the available production techniques such as metal-injection molding, laser forming, and computer-aided design and computer-aided manufacturing technology. Although there remain current self-ligating brackets that do not succeed to a sufficient degree in meeting the listed characteristics of an ideal bracket, there are several that perform very well. Technical shortcomings in bracket design and functionality are no longer a reason to avoid self-ligation.

Psychological Factors and Adoption of Self-Ligation

Psychological factors are possibly of equal importance in their influence on the adoption of new technology or new ideas. Most of us have as part of our mindset an innate conservatism and a desire to stay mentally and technically within our comfort zone. We learn a skill that minimizes the deficiencies of our equipment, and then we stick with it because we are comfortable. The more skilled we become in a technique (e.g., bending complex archwires), the more unimpressed by and resistant to a new development (e.g., the straight-wire appliance), which reduces the need for this skill or demands different skills. We also make treatment plans that consciously or otherwise reflect the strengths and weaknesses of our current armamentarium. For example, an anchorage-demanding technique inherently leads to more extractions and more anchorage reinforcement as part of our plans. A second and related factor that previously hindered the rate of adoption of self-ligation has been a lack of widespread appreciation—and indeed of optimal scientific investigation—of what low-friction, secure archwire engagement and light forces can achieve in combination. This chapter examines the evidence for these potential benefits.

A further factor currently—and understandably—influencing the adoption of self-ligation has been the lack of support from clinical trials of some of the more enthusiastic claims made by originators of self-ligating brackets. This sequence of possibly optimistic claims followed by a lack of research support and consequent rejection by some of any and all merits in an appliance or technique is a common feature in most clinical disciplines. In orthodontics, another example is the reaction to functional appliances in the light of the lack of evidence of significant growth modification effect, disregarding the very useful dentoalveolar effects. Finally, the generally higher price of self-ligating brackets has acted as a deterrent despite evidence of reduced chairside time, which would offset some or all of the additional cost. It is perhaps important for clinicians to bear such factors in mind when forming their own reaction to any innovation.

AESTHETIC SELF-LIGATING BRACKETS

There have been several approaches to production of a more aesthetic self-ligating bracket. First, there are lingual self-ligating brackets. There are at least three lingual self-ligating brackets currently available. Forestadent (Bernhard Foerster GmbH, Pforzheim, Germany) has its lingual system, sometimes referred to as the Philippe bracket.[18] The ligation mechanism involves deforming two retaining wings with a Weingart plier to close and a spatula to open. This mechanism requires considerable care not to damage the enamel if an instrument slips. Also, the wings can be hard to open, which can cause detachment of the bracket. Adenta (Adenta GmbH, Gliching, Germany) produces the Evolution bracket, which is essentially a lingual version of the Time bracket produced by the same company; the same applies to In-Ovation L from GAC. Incognito appliances (LingualCare, Dallas, TX) have more recently added an accessory self-retaining slot on their incisor brackets. Ligation is inherently more difficult with lingual appliances, so an easy form of self-ligation clip or slide that can deliver the advantages of security and low friction are equally or even more valuable in the situation when the interbracket spans are inherently smaller. Combining a successful self-ligation mechanism with the particular lingual demands of low-profile, easy archwire insertion, inbuilt bite ramps on some teeth, and narrow bracket width is a demanding task. Further development is needed on this side of the teeth.

On the labial surface, Oyster (Gestenco, Gothenburg, Sweden) and OPAL Ultradent, South Jordan, UT 84095) and Damon3 (partially) were resin brackets. These had the disadvantages of all-resin polymer brackets and were not successful. Ceramic brackets with metal clips Clarity SL (3M Unitek) and In-Ovation C (GAC) have been more successful, and recently, completely ceramic brackets (Damon Clear and Damon Clear2 (Ormco) have taken aesthetic self-ligating brackets to what is probably an entirely satisfactory level of aesthetics and mechanical performance. It is still possible that the optimal combination of self-ligation and aesthetics will come from a breakthrough in the technology for coating metal brackets.

PROPOSED CORE ADVANTAGES OF SELF-LIGATING BRACKETS

When considering the sometimes confusing advantages that have been proposed for self-ligation, it is helpful to divide these into the proposed core advantages and, in a second category, the various proposed consequent advantages that may possibly derive from this core. In the past 2 decades, a consensus has emerged on the potential core advantages, which can be summarized as:

- Faster archwire removal and ligation
- More certain full archwire engagement
- Less or no chairside assistance for ligation
- Low friction between bracket and archwire

Speed of Archwire Insertion and Removal

The principal motive when developing the earlier self-ligating brackets was to speed the process of ligation. A paper by Maijer and Smith[19] demonstrated a fourfold reduction in ligation time with Speed brackets compared with wire ligation of conventional brackets. Shivapuja and Berger[1] have shown similar results but also that the advantages compared with elastomeric ligation are less dramatic (≈1 minute per set of archwires). Voudouris[20] also reported a fourfold reduction in archwire removal or ligation time with prototype Interactwin brackets. A study by Harradine[17] found statistically significant but clinically much more modest savings in ligation or religation time with Damon SL, an average of 24 seconds per archwire removal and replacement. It should, however, be remembered that archwire "ligation" using self-ligating brackets does not require a chairside assistant to speed the process because self-ligating brackets require no passing of elastomeric or wire ligatures to the operator during ligation.

Turnbull and Birnie[21] investigated the difference in time taken to open and close brackets for different archwire groups with Orthos and Damon 2 brackets. The authors found time savings slightly greater than those of Harradine, with Damon SL brackets being 1 second per bracket for opening brackets and 2 seconds per bracket for closing brackets. It was twice as quick to close Damon 2 brackets as to ligate conventional Orthos brackets. For both bracket systems, the time taken to ligate and unligate archwires decreased with increasing archwire size and correspondingly better tooth alignment. The Damon 2 bracket was not the easiest of self-ligating brackets to open and close, and it is very probable that the more recent bracket types from that manufacturer would show much greater savings in time for archwire changes. The increased speed of archwire changes may not seem immediately compelling, but with brackets being ever-easier to open and close, a time saving of 1 to 2 minutes per archwire change is probably clinically significant. In looking at such studies, it should be remembered that archwire changes with self-ligating brackets were being done by a single-handed operator and were compared with four-handed changing of elastomeric ligatures. It is perhaps significant that there have been no more recent studies of this aspect of bracket performance; this probably reflects the current general acceptance that the evidence that self-ligation is more rapid is sufficiently strong.

Secure Archwire Engagement

Figure 24-1 illustrates the loss of full archwire engagement, which is commonly seen with elastomeric ligation. An inbuilt metal face to the bracket slot has the potential to ensure full archwire engagement. In the past, several self-ligating designs did not sufficiently fulfill that potential, but many self-ligating brackets now provide reliably secure ligation. A study by Mezomo[22] was one of many to show that the speed of tooth movement was no greater with self-ligation, but it also found that rotational control of the canine being retracted was better on the canines with a self-ligating bracket. A further consideration arises from the thoughtful study by Pandis et al.[23] that reveals that it cannot be taken for granted with at least one bracket type with an active flexible clip and that the designed mechanical properties of some self-ligation mechanisms will be sustained throughout treatment.

Friction and Self-Ligation

This is a well-researched area but one that remains open to misunderstanding. Very low friction was clearly demonstrated and quantified in many studies in the early 1990s for both Activa and Speed brackets and indeed Edgelok. More recent representative studies include one by Kapur et al.[24] that found that with nickel-titanium (NiTi) wires, the friction per bracket was 41 *g* with conventional ligation and 15 *g* with Damon brackets; with stainless steel wires, these values were 61 *g* and only 3.6 *g*, respectively. Thomas et al.[25] confirmed extremely low friction with Damon brackets compared with both conventional preadjusted and Tip-Edge brackets, but Time brackets with their active clip produced lesser but still substantial reductions in friction with larger diameter wires. Pizzoni et al.[26] similarly reported that the passive Damon brackets showed lower friction than Speed brackets, which in turn had less friction than conventional brackets. Earlier work that had concluded that each elastomeric placed in an "O" configuration produces an average of 50 *g* of frictional force per tooth was supported by Khambay et al.[2] using a method that gave zero friction for Damon 2 brackets and found mean frictional forces ranging between 43 and 98 *g* (0.43 and 0.98 cN) for various elastomeric–archwire combinations. All of these laboratory studies investigated the situation with essentially passive archwires in well-aligned brackets, so although this was a sensible starting point for investigating friction and does indeed accurately quantify the friction, it is a very imperfect and incomplete model of an actual clinical situation.

Friction with Active Archwires: Thick, Stiff Wires

When archwires are active, the total resistance to sliding (RS) is composed of FR (frictional resistance) + binding (BI) + (potentially) notching (NO). Several studies in the 1990s concluded that if the wires were active, the RS [It was defined above] with self-ligating brackets was not statistically significantly less than with conventionally ligated brackets. More recent studies are more sophisticated in terms of modeling the clinical situation and more perceptive in their assessment and interpretation of the clinical significance. In the investigation of RS on thick, rigid archwires, four excellent papers by Thorstenson and Kusy remain the best yardstick. Thorstenson and Kusy[27] examined the effects of varying active tip (angulation) of a 0.018- × 0.025-inch stainless steel wire on the RS. They found that angulation beyond the angle at which the archwire first contacts the diagonally opposite corners of the bracket slot—at which point, binding begins—causes a similar rate of rise in RS for self-ligating (Damon SL) and conventional brackets. The greater the angle of tip, the smaller the percentage of total RS was attributable to friction (FR) because the friction remained constant while the binding linearly increased. So although at all degrees of tip, the Damon brackets produced less RS, for these authors, the key to correct interpretation of their study was the calculation, when clinically advisable forces were applied, of the realistic limiting angle of tipping at which the forces in that stiff wire would upright the tooth as part of a tip-and-upright walking of the bracket along the archwire. For Thorstenson and Kusy, that realistic angle of tip was calculated to be 6 degrees with a 0.018- × 0.025-inch stainless steel wire, at which angle the reduction in RS was from 140 to 80 *g*— that is, 60 *g* per tooth— and this value is very probably of clinical significance. At much higher experimental angles, the increase in binding "drowned out" this 60-*g* difference. In their words, "at low angles, the binding contribution to RS is small. As the angle increases, binding overwhelms friction and the overall effects of the ligation type and method decrease." It is important to note that the percentage contribution of friction to RS is very low with self-ligating brackets precisely because the friction is low. However, the difference in RS compared with conventional ligation remains at 60 *g* according to this research.

The second paper[28] compared different self-ligating brackets for RS with active angulations. It quantifies a little more closely the lower RS with passive self-ligation and points out that low resistance to tooth movement can lead to unanticipated movement as is discussed later in this chapter. The third and fourth papers[29,30] examined the same factors with wires of different sizes and in the dry state and in conventionally ligated brackets with novel design features aimed at reducing RS. The increase in friction when larger wires deflect the clips in active self-ligating brackets is quantified, and the scanning electron micrographs of the different brackets show very clearly the relationship between small and large wires and active clips and passive slides. More recently, Pliska et al.[31] also assessed tipping moments in relation to RS in thick (0.019- × 0.025-inch) wires with self-ligating and conventional brackets. They too found that with "low" forces of 200 *g*, there was a 40-*g* reduction in RS per bracket with self-ligating brackets but that this difference was lost as the applied forces increased to 400 *g*. These investigations are consistent in indicating that although binding provides the majority of RS (and indeed is essential for the force of the wire to be transmitted), the greatly reduced friction with self-ligation contributes a reduction of 40 to 60 *g* per tooth, and at appropriately low levels of force application, this is likely to represent a clinically significant reduction.

Friction with Active Archwires: Thin, Flexible Wires

The relationship between friction and RS has also been extensively researched in thin, flexible wires. Matarese et al. (2008)[32] is an early but sound study of RS in self-ligating brackets with such wires. Using the simple setup of a variably offset bracket (Damon 2 in this instance) and a straight section of wire, this study showed a substantial reduction in RS compared with conventional elastomeric ligation. More recently, Heo and Baek (2011)[33] found similar reductions in RS with self-ligation using a greatly more sophisticated laboratory apparatus that incorporated teeth of realistic anatomic size and shape, periodontal ligaments of a material of similar mechanical properties, and a full dental arch. The differences varied with different aligning wires and brackets, but when modeling a 3-mm vertical displacement of a canine, the RS ranged from 2700 to 3800 cN with conventional ligation and 390 to 850 cN with self-ligation. These differences seem to be of potentially greater clinical significance than those found in thick, stiff archwires.

Baccetti (2009)[34] perceptively researched the important corollary to this difference in RS. He clearly demonstrated that the increased RS with conventional ligation is accompanied by a corresponding reduction of force available to align the displaced tooth. This effect was such that at a 4-mm displacement of a bracket, no residual aligning force remained on the displaced tooth. Of course, Newton's laws tell us that the total force in the system is the same with both types of brackets, but the distribution of force is markedly different if the teeth are significantly irregular, and it can be inferred that the pattern of tooth movement would be correspondingly different. In fact, this observation had been made 8 years earlier by Thorstenson and Kusy[27] in relation to thick archwires. "The self-ligating bracket allows more of the applied force to be used for sliding than does the conventional bracket." Other workers, including Franchi et al. (2009)[35] investigating buccally displaced teeth and Petersen et al. (2009)[36] investigating lingually displaced teeth, have demonstrated the same marked and unfavorable alteration in force distribution with different patterns of tooth irregularity with conventionally ligated brackets.

The group at the University of Alberta has carried out an even more sophisticated experimental modeling of forces and moments[37] (Fig. 24-14). This has shown a similar markedly different force and moment distribution when comparing self-ligating and conventionally ligated brackets for a vertically displaced canine. With conventional ligation, the reciprocal forces on either side of the high canine were not only much more widely spread around the arch but also had a much larger labial/buccal component. These results fit with the conventional clinical wisdom that advises against full engagement of markedly displaced teeth on the grounds that the very irregular teeth may not move much but that previously well-aligned

FIGURE 24-14 The Orthodontic Simulator (OSIM) developed at the University of Alberta. Multiaxis force and moment transducers are attached to all 14 teeth. Micrometer screws permit quantified and incremental movement in the vertical and horizontal planes and simultaneous recording of forces and moments in all three planes. (By kind permission of Dr. Hisham Badawi.)

teeth may move adversely, for example, producing labial flaring of the anteriors in this instance. Figure 24-15 shows a clinical example of self-ligation in the high canine scenario that was researched in the paper by Fok et al.[37] It shows the effective movement of the canine with no detectable adverse tooth movement from reciprocal forces that would be anticipated with conventional ligation and that was indicated by the striking results of the research by the Alberta group.[37] All of these investigations have demonstrated that engaging significantly displaced teeth in self-ligating brackets gives greater desirable force on the displaced teeth and less unwanted reciprocal forces on the other teeth.

Such work strongly supports the view that even though ligation is only one source of the RS, self-ligation can reduce this resistance to a clinically significant extent and that this has consequences on force distribution. A systematic review of this question by Ehsani et al.[38] concluded that the case is proven for lower RS with self-ligation with round wires but not for the larger rectangular wires or with active archwires where more evidence is still required. An interesting facet of the study selection for this review is that two of the seminal papers by Thorstenson and Kusy referred to earlier were not mentioned. The conclusions of that review may have been overtaken by some of the more recent research summarized here. The most appropriate response to these research findings in terms of their clinical application is discussed later in this chapter.

Friction in Vivo: Occlusal and Masticatory Forces

A further potentially confounding factor has been investigated in studies by Braun et al.[39] and O'Reilly et al.,[40] who found that various vibrations and displacements of a test jig (to mimic intraoral masticatory forces) can substantially reduce the frictional component of RS with conventional ligation. This is a valid line of inquiry and an interesting finding, but the question then arises as to how accurately these laboratory studies mimic intraoral masticatory "jiggling" forces. An impressive study by Iwasaki et al.[41] used an intraoral device to produce a combination of tipping and ligation forces and measured the effect of chewing gum on the resulting RS. They concluded, "These results refute the hypothesis that masticatory forces consistently and predictably decrease friction." It could also be proposed that any beneficial effects of masticatory forces might apply equally to conventional and to self-ligation and therefore maintain the RS differential between these types of brackets. Clinically—and rather ironically—the low friction with self-ligating brackets seems very evident from the need to place a stop on all archwires to prevent the much greater tendency for the archwire to slide through the brackets and traumatize the mucosa distally. Measurement of the variables that influence in vivo friction will remain a challenge, but progress is being made. Although there is still ample scope for more and better studies of this potentially complex field, current evidence supports the view

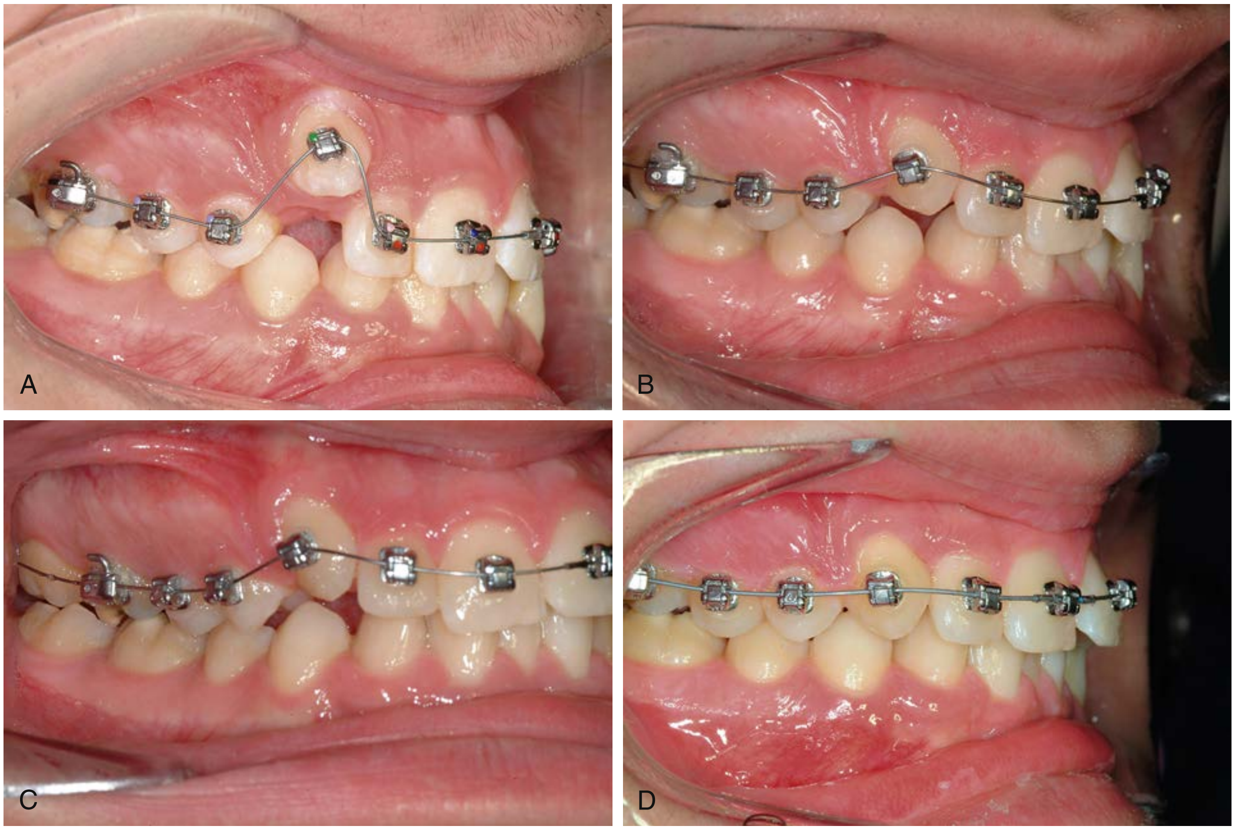

FIGURE 24-15 Full ligation of a markedly irregular canine tooth with self-ligating brackets results in the movements that laboratory research predicts. **A,** A fully engaged 0.014-inch nickel–titanium (NT) wire. **B, C,** The next visit. **D,** Engagement of a 0.014- × 0.025-inch NT at the following visit. Low friction (and hence lower resistance to sliding) ensures that sufficient extrusive force remains to align the canine while the reciprocal force causes very little incisor extrusion and the excess wire escapes distally with no detectable incisor proclination.

that RS in vivo is lowered to a clinically very significant extent with self-ligation, especially with passive self-ligation.

Secure Ligation and Low Friction as a Combination of Properties

Other bracket types—most notably, Begg brackets—have low friction by virtue of an extremely loose fit between a round archwire and a very narrow bracket, but this is at the cost of making full control of tooth position correspondingly more difficult. Some brackets with an edgewise slot have incorporated shoulders to distance the elastomeric from the archwire and thus reduce friction, but this type of design also produces reduced friction at the expense of reduced control because the shoulders that hold the ligature away from the archwire increase the slot depth and reduce the tension in the elastomeric. This reduces the control of rotations or of labiolingual tooth position. Elastomeric rings cannot provide and sustain sufficient force to maintain the archwire fully in the slot without also pressing actively on the archwire to an extent that increases friction. Comparison with a molar tube is helpful in this context because such an attachment is in essence a passive self-ligating bracket with the slide permanently closed. If a convertible molar tube is converted to a bracket by removal of the slot cap or straps, an elastomeric or even a wire ligature can prove very ineffective at preventing rotation of the tooth if it is moved along the wire or used as a source of intermaxillary traction. These ligation methods simultaneously increase friction while attempting to retain full archwire engagement. The challenge of simultaneously combining low friction and good control was very nicely illustrated in an article by Matasa[42] and is reproduced here with his kind permission (Fig. 24-16).

Matasa investigated "low-friction" conventional brackets. He showed that all steps to reduce friction in the design of such brackets that involved distancing the elastomeric from the archwire produced a consequent reduction of tooth control. The investigation into three such "low-friction" bracket types by Thorstenson and Kusy[30] also found no evidence that bumps in the floor of the archwire slots reduced RS. With tie-wing brackets and conventional ligation, a reduction in friction is usually at the cost of deterioration in control. The combination of very low-friction and very secure full archwire engagement in an edgewise-type slot is currently only possible with self-ligating brackets (or with molar tubes) and is likely to be the source of the most beneficial effects of such brackets. This combination enables a tooth to be slid along an archwire with lower and more predictable net forces and yet under good control with almost none of the undesirable rotation of the tooth resulting from a deformable or degradable mode of ligation such as an elastomeric.

The Clinical Significance of Low Friction

Friction between the archwire and bracket must be overcome for the majority of tooth movements to occur. Such movements include vertical leveling, buccolingual alignment, rotation, correction of angulation, opening of space, and any space closure with sliding mechanics. All of these tooth movements involve movement of the bracket relative to the archwire. Frictional forces arising from the method of ligation are one source of the resistance to this relative movement, and although its relative contribution to RS decreases with increasing archwire activation, the research summarized earlier indicates that a clinically significant difference remains with both thick and thin archwires. Correspondingly higher forces must therefore be applied to overcome this resistance, and this has two related potential effects that would be expected to inhibit or change tooth movement. First, the net effective force is much harder to assess and is more likely to be undesirably higher than levels best suited to create the optimal histologic response. Second, the binding forces are correspondingly higher both between bracket and wire and also at the contacts between irregular adjacent teeth. These binding forces also inhibit the required relative movement between bracket and wire. Only a few tooth movements such as space closure with closing loops placed in the space, expansion of a well-aligned arch, and torque (inclination) changes are not potentially influenced by a low-friction method of ligation. One situation in which the combination of low friction and secure full engagement would theoretically be expected to be particularly useful is in the alignment of very irregular teeth and especially the resolution of severe rotations when the capacity of the wire to slide through the brackets of the rotated and adjacent teeth significantly facilitates derotation. This relationship between friction and derotation has been classically described and quantified by Koenig and Burstone[43] in which the potential adverse forces from friction were shown to be very large. Low friction should theoretically therefore permit more rapid alignment while the secure bracket engagement with self-ligation permits full engagement with severely displaced teeth and full control while the brackets move relative to the archwire.

Figure 24-17 shows the ability of self-ligation to fully engage and maintain engagement and control of an archwire in a very rotated tooth, while the low friction enables release of binding as the archwire slides through all the brackets in the arch. Modern

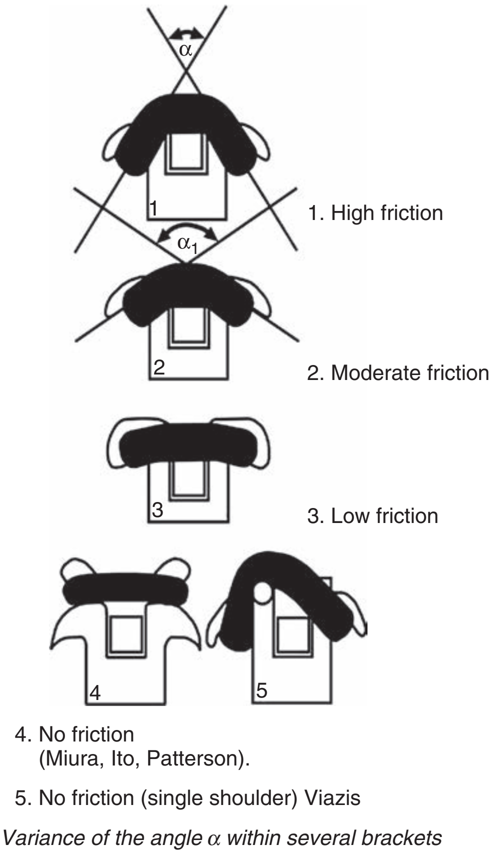

FIGURE 24-16 Illustration showing the trade-off between low friction and good archwire control with conventional ligation. (From Matasa CG: Brackets' shape influences friction, Orthod Materials Insider 13: 2-5, 2001)

FIGURE 24-17 A–C, Three consecutive visits illustrating the effectiveness of rotational alignment that results from the combination of low friction and good archwire engagement with self-ligation.

low-modulus wires with their high elastic limit would be expected to substantially enhance our ability to harness these benefits.

ACTIVE CLIPS AND PASSIVE SLIDES

The choice of design is an issue that has attracted assertive debate.[44] It is therefore worth a fairly detailed consideration.

Speed, In-Ovation, and Forestadent Quick brackets are examples of a number of brackets that have a spring clip, which encroaches on the slot from the labial aspect, potentially generating an additional force on the tooth. With some of the force being stored in the deflection of the spring clip, these brackets are referred to as active clips. In contrast, passive brackets have a slide that closes to create a rigid labial surface to the slot with no intention or ability to invade the slot and store force by deflection of a metal clip. Damon, SmartClip, Lancer Pacific Praxis Glide, Class One/Ortho Organisers Carrière LX, American Orthodontics Vision LP, Ortho Technology Lotus, and OrthoClassic Axis are examples of passive systems. Some literature has occasionally contained statements to the effect that the term “passive” is inappropriate because there must be force between the bracket and the wire for teeth to move. This is an unhelpful and possible disingenuous interpretation of the word passive when used in this context, and the term “passive” is entirely comprehensible when defined as above, meaning a bracket analogous to a molar tube.

An active clip can store some of the applied force in the clip as well as in the wire. The intended benefit is that in general terms, a given wire will have its range of labiolingual and possibly torqueing action extended and produce more alignment than would a passive slide with the same wire. This needs more detailed consideration. It is perhaps helpful to think of the situation with three different wire sizes.

Thin Aligning Wires Smaller Than 0.018 Inch in Diameter

The potentially active clip will be passive and irrelevant unless the tooth (or part of the tooth if it is rotated) is sufficiently lingually placed in relation to a neighboring tooth that the wire touches the clip. In this situation, a higher total force is usually applied to the tooth compared with a passive slide. Even if there is no significant clip deflection, there is still a force on the wire that would not exist with a passive clip because the active clip effectively reduces the slot depth from 0.028 inch to approximately 0.018 inch, either immediately—if the clip is not deflected—or as the wire goes passive if it is deflected. For teeth that were initially placed lingual to their neighbors, the active clip can bring the tooth more labially (up to a maximum of $0.028 - 0.018 = 0.010$ inch) with a given wire. These figures are slightly complicated by the fact that the active clip does not reduce the slot depth to the same extent over the whole height of the slot; all active clips impinge into the slot more at the gingival end than at the occlusal. This is well visualized in the illustrations in Thorstenson and Kusy.[28] This asymmetry would make a difference with small-diameter wires depending on the relative vertical positions of neighboring teeth. The effect of having an active clip at this early stage of treatment can be thought of as having a potentially shallower bracket slot. This will frequently produce higher forces and correspondingly higher friction with a given wire but a potential maximum extra 0.010 inch of labial movement of some teeth for a given small-diameter wire. This figure is approximate for the reasons given earlier.

Wires Larger Than 0.018 Inch in Diameter

The active clip will place a continuous lingually directed force on the wire even when the wire itself has gone passive. On teeth that are in whole or in part lingual to a neighboring tooth, the active clip will again bring the tooth (or part of the tooth if rotated) to a fractionally more labial position than would have been the case with a passive slide. The maximum difference will be the difference between the labiolingual dimension of the wire and 0.028 inch. For a typical 0.016- × 0.022-inch intermediate wire, this would give a maximum difference of 0.006 inch. 0.016- × 0.025-inch or 0.014- × 0.025-inch NiTi wires are recommended as the intermediate aligning wire for passive brackets, and this wire reduces this potential difference to a clinically insignificant 0.003 inch. Lingually placed teeth would have a higher initial force with an active clip and wires of this intermediate size. With an active clip, an active lingually directed friction force will remain on the wire even when it is passive.

Thick Rectangular Wires

An active clip will probably make a labiolingual difference in tooth position of 0.003 inch or less, which is clinically very small. The suggestion that continued lingually directed force on the wire from an active clip (or from a conventional ligature) will cause additional torque from an undersized wire is interesting and is addressed later in this chapter. In relation to active clips or passive slides, a representative study is by Major et al.,[45] who demonstrated that the lingually directed force from an active clip does not contribute to torqueing capacity by reducing the “slop” or “play” angle at which sufficient force is generated to influence third-order tooth position.

Aging of Spring Clips

Finally, there are the important questions of robustness, security of ligation and ease of use. Is a clip, which is designed to flex, more prone to breakage or permanent deformation or to inadvertent opening or closing? This question has not yet been investigated sufficiently, but one pertinent piece of work has been conducted by Pandis et al.,[46] who retrieved spring clips from Speed and In-Ovation R brackets after treatment and compared the stiffness and range of action of these spring clips with those of unused spring clips. The two types of brackets had spring clips of very different initial stiffness and differed in their performance during treatment. The Speed clips changed insignificantly in their performance, but the In-Ovation clips lost an average of 50% of their stiffness during the treatment. This change in properties is sufficient that it may well have biomechanical consequences of clinical significance.

Active or Passive: Conclusion

Alignment

It is probable that with an active clip, initial alignment is more complete for a wire of given size to an extent that is potentially clinically useful. With modern low-modulus wires, it is possible to sequentially insert thicker wires into a bracket with a passive slide and arrive at the largest desired archwire size after a similar number of visits.

Friction

Overall, an active clip will generate higher archwire forces and higher resistance to tooth movement. The increased clearance between a given wire and a passive slide will generate lower forces and may facilitate dissipation of the adverse binding forces and the ability of teeth to push each other aside as they align. This may also lead to qualitative differences in the direction and amount of tooth movement, or the differences in friction may be too small to have a clinical effect. The evidence is insufficient on this question.

Robustness and Ease of Use

These are factors of almost overriding importance compared with the active versus passive issue per se. In any specific bracket, these factors are frequently related to the type of clip or slide, whether active or passive.

SELF-LIGATION AND TREATMENT EFFICIENCY

In the light of substantial experimental evidence that self-ligation reduces RS and alters the ratio of favorable to unfavorable forces, an important area of study has focused on whether these differences can be shown to translate into more efficient or more effective treatment. Principally, these have focused on speed of treatment, number of patient visits, and final occlusal irregularity as assessed by the PAR score. The hypothesis is that lower RS enables more effective relative movement between archwire and bracket at lower levels of applied force and hence more rapid tooth movement, and the reliable and full bracket engagement prevents the waste of time regaining tooth control. Some published retrospective case control studies[17,47] have indeed found greater treatment efficiency, but another study[48] did find a reduction in patient visits but no reduction in treatment duration. In contrast, the more recent randomized controlled trials (RCTs)[49–57] have almost all failed to show any such effect, although one[57] did find an average reduction of 50 minutes in chairside time with self-ligation. This contrast requires some scrutiny.

Possible Reasons for Some Retrospective Studies Finding an Efficiency Advantage for Self-Ligation

In the retrospective studies that did find an efficiency advantage for self-ligation:

- The groups may not have been adequately matched for type and complexity.
- Some other factor may have been confounding the comparison with an RCT in which only the bracket is different (e.g., a different policy on extractions, archwire sequence, or appointment interval with the different brackets).
- The case mix may have been unusual (e.g., more complex cases than average).

With regard to matching of cases, in one of these studies,[17] great care was taken to match the patients in terms of age, type of malocclusion, extraction pattern, and initial PAR score. Regarding case mix, this may well be a factor because it is probable that any actual advantages of self-ligation would be more pronounced in certain cases. The cases in one paper[17] were substantially more complex than average, reflecting the particular tertiary referral setting of that study.

A significant potential confounding factor would be a concurrent change of practice as well as change of bracket. A clear potential instance would be a change to prescribing fewer extractions when also adopting self-ligating brackets. This was not the case in one of these papers,[17] but this does raise an interesting point about experimental design. Assuming for a moment that self-ligation, through a reduced RS, facilitates the alignment of adjacent crowded teeth, it can be argued that it is only sensible to take advantage of a lessening of one of the several reasons for extraction and to change the pattern and extent of extractions. Similar reasoning can be applied to choice and use of archwires. If particular wires or treatment intervals are more suitable with self-ligation (which in certain circumstances, they are), is it sound scientific investigation to insist on keeping these the same for both bracket types? Although cases should surely be well matched, there is a tenable argument that aspects of treatment mechanics should play to the perceived strengths of each type of bracket. However, the problem with varying more than just the bracket between the groups studied is, of course, that it is hard to attribute any differences that are found to a specific factor. This dilemma is discussed further in the next section.

Possible Reasons for Randomized Controlled Trials Finding No Efficiency Advantage for Self-Ligation

Similar considerations apply to the design RCTs, which have almost all failed to find a difference in treatment efficiency.

- As discussed earlier, factors such as case mix, appointment interval, archwire sequence, and biomechanics may not have been optimized for the self-ligating brackets but have been chosen to be identical regardless of bracket type and may in fact be more suited to treatment with conventional ligation.
- When a difference in treatment for the two groups was permitted,[57] the self-ligating group was treated with 12-week intervals throughout and the conventional group with 6-week intervals. This was certainly defendable in that, at the time of planning the study, the manufacturers' written advice was indeed for 12-week intervals with their self-ligating brackets. It is now self-evident that this was a misguided extrapolation of a sensible proposal, namely, that because research has indicated that more full engagement of early aligning wires in substantially irregular arches is more appropriate with self-ligation, it follows that a longer first appointment interval is sensible in that situation. It is not logical to extrapolate from that to propose that a much longer appointment interval should be used in all cases and throughout treatment. The result in this study was that although the self-ligation cases required an average of 50 minutes less chairside time, the treatments took slightly longer than for the conventionally ligated group. It is surprising that the difference in treatment length was not larger. These are findings of interest but are not testing the central question about treatment efficiency when the current best assessment of the optimal use of self-ligation is used.
- RCTs of novel orthodontic appliance systems are susceptible to the involvement of clinicians who are unfamiliar with one of the appliances. This may be a factor in some of these studies.
- The study on closure of extraction spaces[54] primarily involved the archwire sliding only through molar tubes, which therefore applied equally in both groups. There have been several such studies that are clearly not suited to testing the demonstrated biomechanical differences of self-ligation.
- The NiTi dilemma refers to the fact that it is almost universally accepted that NiTi wires are superior for tooth alignment compared with their stainless steel predecessors. However, none of the studies that investigated that hypothesis ever demonstrated its truth. Similarly, none of the relevant studies ever demonstrated that straight-wire appliances were superior to plain edgewise, but the former are overwhelmingly preferred for reasons that are regarded by clinicians as being self-evident and in no need of the highest order of scientific proof.

A Suggested Treatment Protocol for Future Randomized Controlled Trials

With regard to the choice of patients, archwires, appointment intervals, extraction patterns, extent of bracket engagement, and timing of such biomechanics as intermaxillary elastics, a suggestion would be to insist on these being the same for each group in an RCT, but the protocol chosen should be that which the evidence suggests is most appropriate to take advantage of self-ligation rather than that which has evolved over many decades to best suit conventional ligation.

Conclusions

Although there has been much good research, the question of treatment efficiency remains incompletely resolved. The current evidence strongly suggests that there is not a substantial, blanket enhancement of treatment efficiency that is generally applicable in all cases and situations, however the brackets are used. Perhaps there is no efficiency advantage. The laboratory research does, however, suggest that if investigators and funding persist (and they did not with NiTi wires or the straight-wire appliance) and the best design of study is chosen as outlined earlier, then it may be shown that in some malocclusions treated with particular brackets and wires and treatment intervals, self-ligation is more efficient. It would be surprising if those fairly frequent cases in which conventional ligation allows a loss of tooth control (such as in Fig. 24-1) do not take longer or more chairside time to treat. Currently, the only clearly substantiated gain in efficiency results from faster ligation and the lack of need for assistance with ligation. A summary of opposing slants on the current evidence can be found in the two point–counterpoint articles[58,59] commissioned by the *American Journal of Orthodontics and Dentofacial Orthopedics* to take those opposing stances.

SELF-LIGATION AND PATIENT COMFORT

The hypothesis that self-ligation may be less painful is based on the assumption that forces on the teeth will be lower. This is not necessarily the case, being particularly sensitive to the clinician's choice of archwire. There have been a number of studies investigating the hypothesis that self-ligation produces less patient discomfort than conventional brackets and ligation, and their findings have varied.[60,61] However, a systematic review[62] concluded that the evidence to date did not support a reduced level of pain with self-ligation. A very interesting paper by Yamaguchi et al.[63] examined the question not by self-reported discomfort levels but via an objective marker of the inflammation and associated pain resulting from orthodontic forces. They measured levels of the neuropeptidase substance P in gingival crevicular fluid. They found that treatment with Damon brackets significantly lowered the levels of this marker of pain and inflammation compared with conventional ligation at 24 hours after archwire placement. Force levels are discussed later in this chapter.

SELF-LIGATION AND EFFECTIVENESS OF TORQUE CONTROL

The hypothesis has been advanced that torque control is more difficult with self-ligating brackets and perhaps particularly with passive brackets. This proposal is based on the belief that the labiolingual forces between the base of the bracket and a ligature system are a significant additional source of force couple, adding to the couple between the upper and lower bracket walls that exists with all brackets. Several good studies have been carried out to assess the contribution of ligation force to torque effectiveness. Major et al.[64] and Brauchli et al.[65] found that the additional force from the active clips of Speed and In-Ovation brackets did not provide any effective additional torque force. Sifakakis (2014)[66] found that elastomeric ligatures also added no clinically effective force even immediately after placement, and this finding was reinforced by Al Fakir et al. (2014).[67] The situation with wire ligatures is a little more nuanced. Al Fakir found that if "tight" wire ligatures were added to conventional or Damon Q brackets when no active torque was present and then the brackets twisted to create torque, then the "slop" or play before torque forces became effective was reduced from 15 degrees to 9 degrees, indicating some added torque control from tight wire ligatures. However, if wire ligatures were added to brackets already producing active torque, then the torque "slop" or play was not reduced. These are helpful findings. Elastomeric ligatures add nothing to torque delivery, and tight wire ligatures add a little under some circumstances.

FURTHER CURRENT HYPOTHESES ABOUT SELF-LIGATION

The core advantages of faster ligation, better archwire control, and lower RS can and should continue to benefit from scientific study on points of detail, but they can at this stage be safely regarded as sufficiently proven. The further hypotheses concerning more efficient treatment, more comfortable treatment, and healthier treatment are all receiving appropriate investigation but remain unproven hypotheses. There remains a third category of proposed advantages that can be described as proposed qualitative differences in tooth alignment. Many clinicians who use self-ligating brackets believe that when combined with light round wires, they facilitate the alignment of crowded teeth. However, some clinicians have additionally proposed that the teeth align in a qualitatively different manner, producing less incisor proclination and more lateral expansion than conventional ligation. In this respect, the following qualitative differences have been proposed with self-ligation:

- Less incisor proclination for alignment of a given amount of crowding
- Wider arches, which may be more aesthetic
- Wider arches that have better preserved bone levels and consequent periodontal health than those resulting from more rapid and forceful expansion
- Wider arches that may be more stable
- Less need for extractions
- Easier Class 2 correction through a "lip bumper" effect

These proposals are far from established. Many of them have been set out and illustrated with case examples and medical computed tomography scans.[68] A well-known case example (Fig. 24-18), which helps to illustrate several of these proposals, is reproduced by kind permission of Dr. Dwight Damon. In this Class 2, Division 2 malocclusion, the very crowded arches have been aligned without extractions. The expectation would be that this would result in very pronounced incisor proclination. In fact, the incisors moved labially less than 3 mm, but the posterior arch expansion was much greater than might have been anticipated (Fig. 24-19).

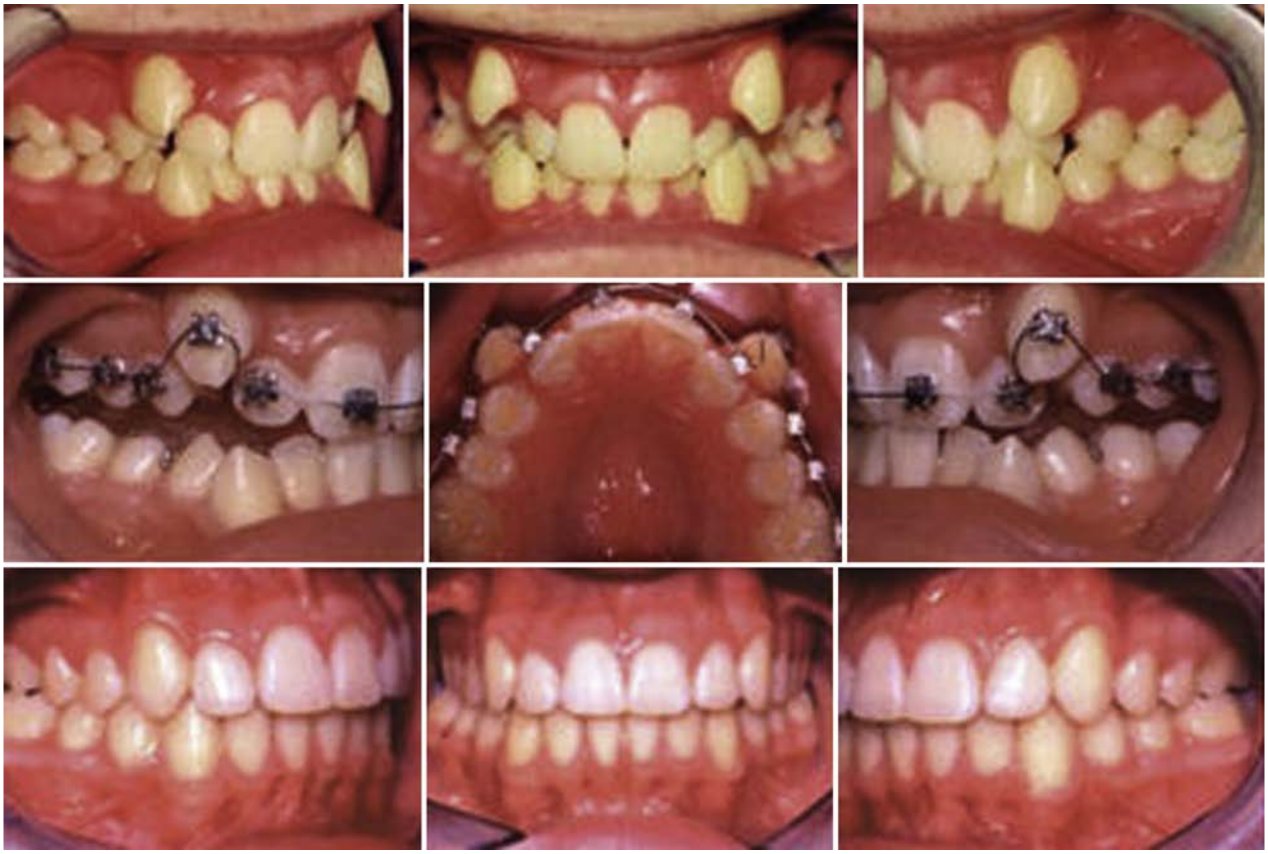

FIGURE 24-18 Class 2, Division 2 malocclusion treated with Damon 2 passive self-ligating brackets and without extractions. The buccally placed canines and palatally inclined premolars and molars at the start of treatment are evident. (By kind permission of Dr. Damon.)

This pattern of tooth movement has been attributed by some clinicians to a qualitatively different interaction of forces. In particular, it is suggested that the applied forces are so low that the lips can compete with orthodontic forces and restrain labial movement of the teeth, sometimes referred to as “the lip bumper effect.” Additionally, it has been proposed that the tongue position may alter in response to this expansion and possibly assist in the tooth movement or in its subsequent stability. The author of this chapter suggests that the expansion in this case example may well be entirely explicable by the balance of forces between the teeth and particularly the lateral forces arising from the buccally placed canines and acting on palatally inclined premolars, but the ratio of proclination to expansion still remains surprisingly low in the light of experience with conventional ligation. The relationship between expansion and proclination is discussed further later, but first it is helpful to look at two consecutive visits in a case reproduced by kind permission of Dr. David Birnie (Fig. 24-20).

It can be seen in Figure 24-20 that the incisors have extravagantly (although temporarily in this instance) proclined. A major factor must surely be the high RS produced by the figure-of-8 elastomeric ligatures on the premolars that has prevented the excess wire sliding distally as the canines moved buccally. The extensive evidence reviewed above concerning friction and self-ligation indicates that self-ligation does not necessarily result in lower forces but can generate a higher percentage of desirable force and a lower percentage of unwanted forces, and this difference may potentially alter the resulting tooth positions. In the case in Figure 24-20, the unwanted force is the high and persistent proclining force on the incisors that has arisen because of the friction from the elastomeric premolar ligatures. This is in marked contrast to the behavior of the upper incisors in Figure 24-15, where full engagement of a markedly displaced canine has resulted in good alignment with no detectable incisor proclination. Similarly, Figure 24-21 shows alignment in a Class 3 case who subsequently at an older age underwent the planned orthognathic surgery.

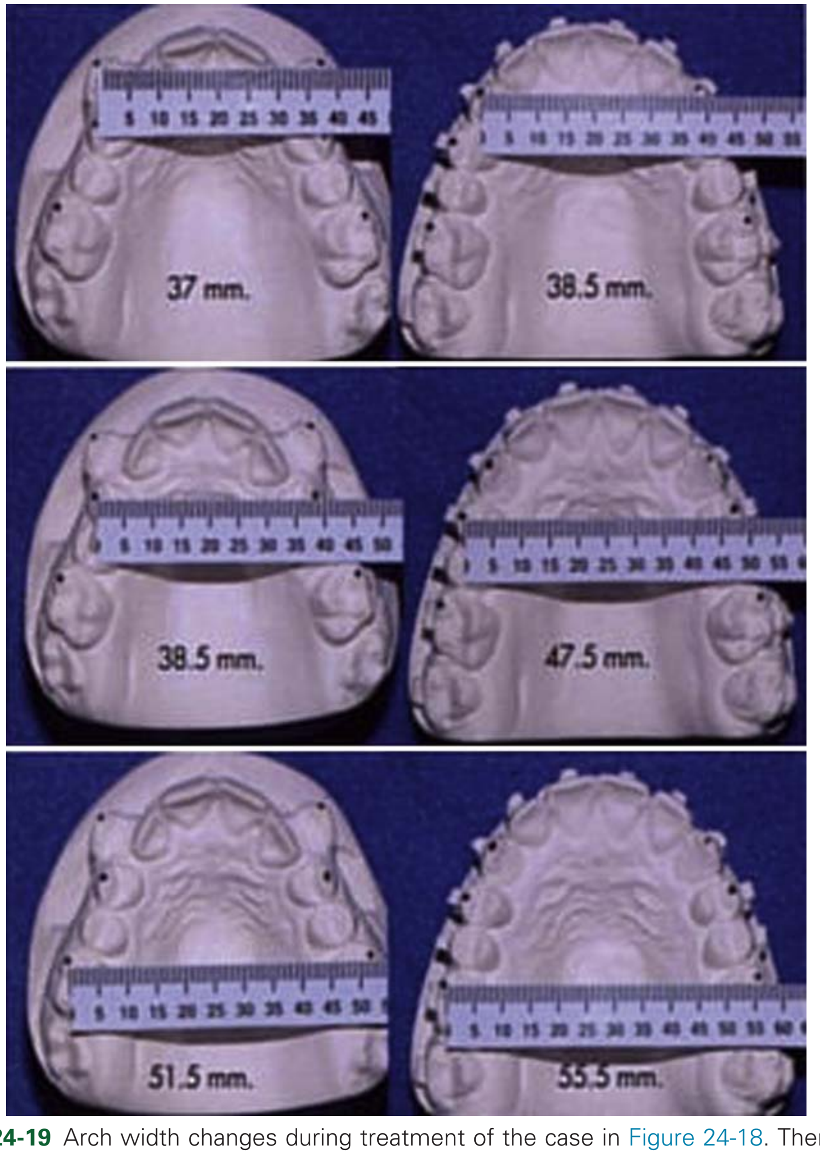

FIGURE 24-19 Arch width changes during treatment of the case in Figure 24-18. There is minimal expansion of the canines but substantial uprighting and expansion of the premolars and molars. This should be distinguished from expansion of posterior teeth, which are already at an upright buccopalatal inclination.

FIGURE 24-20 Proclination of upper incisors between consecutive appointments associated with figure-of-8 elastomeric ligation on all teeth except the palatal canines. 0.014-inch archwire.

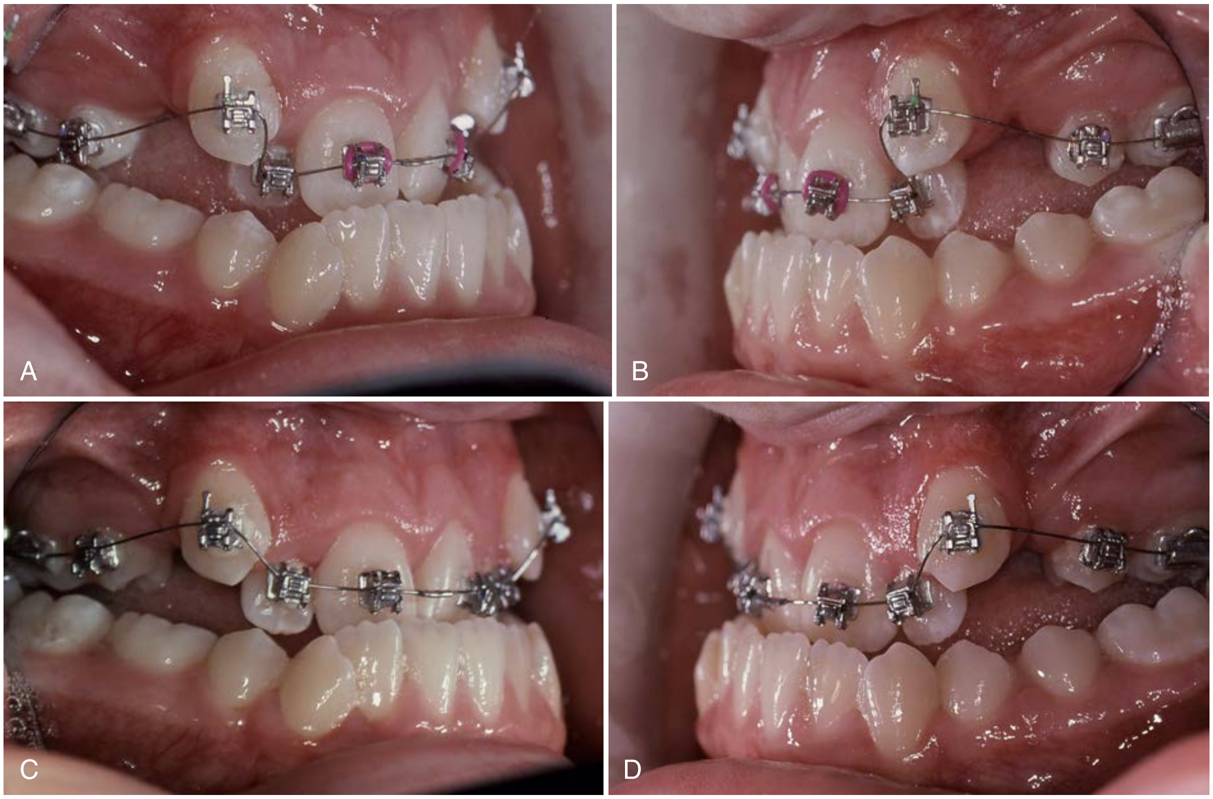

FIGURE 24-21 Three consecutive visits at 8-week intervals. First visit (**A**, **B**) Damon 2 passive brackets with initial 0.012-inch wires were left unchanged at the second visit (**C**, **D**) and replaced by 0.014- × 0.025-inch wires at the third visit (**E**, **F**). The lack of significant central incisor intrusion or proclination is evident. The elastomeric ligatures on some teeth were for decoration at the patient's request and were deliberately placed on teeth anterior to the crowding where no sliding of the archwire relative to the bracket was required. (The author no longer receives requests for this decoration!)

FIGURE 24-21, cont'd

The intention in aligning the upper arch was to do so without significantly proclining the upper incisors and hence compensating for the Class 3 skeletal pattern. The untreated lower incisors act as a reference to demonstrate that there has indeed been very little upper incisor proclination. The initial proclining forces on the incisors must have been very significant and indeed all the higher for the full engagement that self-ligation has enabled and maintained on the lateral incisors. It is suggested that the ability of the wire to release from the binding in the canine and the premolar as soon as tooth movement begins has enabled the alignment to occur with the wire sliding distally rather than by incisor proclination. The hypothesis of a qualitative difference in the pattern of tooth movement would seem to have enough credibility to justify further investigation, although the proposal that the differences arise from interaction with the soft tissues seems less likely and has very little research support.

FORCE LEVELS WITH SELF-LIGATION AND CONVENTIONAL LIGATION

Self-ligation has been described as a "low-force technique." The potential for measurement and comparison of these forces and moments has been potentially advanced to a very substantial degree by the development such systems as used by Heo and Baek and Fok et al., which can model a large range of situations mentioned earlier in the section discussing friction. What clearly emerges from these investigations is that the use of self-ligation does not inherently reduce forces. Indeed, the forces placed on displaced teeth (with any given wire) are higher than would be the case with conventional ligation because less force is dissipated through increased RS on the adjacent teeth. Rather, these studies show that that the distribution of forces is favorably changed and that lighter forces will (if the clinician applies them) be more effective because less force is dissipated. For example, the higher percentage of desirable force that can result from self-ligation is neatly and simply shown in the excellent study by Baccetti et al.[34] The study shows that with conventional ligation, a tooth displaced 3 mm vertically from the line of the arch with a 0.012-inch wire has only 50 *g* of net aligning force available compared with more than 90 *g* with the several types of self-ligating brackets that were tested. With 4.5 mm of displacement, there is zero remaining force available for alignment of the displaced tooth with conventional brackets, but more than 80 *g* remains with self-ligating brackets despite the binding at each corner of the brackets.

DOES SELF-LIGATION REDUCE THE NEED FOR EXTRACTIONS?

In many minds, self-ligation has become associated with an emphasis on nonextraction. A scrutiny of this claim benefits from some dissection of the indications for extraction, which can be categorized as follows:

- Space for alignment of crowded teeth
- Profile improvement
- Interarch relationship
- Correction of overjet
- Correction of overbite

Crowding

The combination of low friction and good archwire control that self-ligation provides would theoretically be expected to facilitate the alignment of crowded arches without extractions, if that is desired. This biomechanical reason for extraction should therefore be correspondingly reduced. It should, however, be recalled that despite the strong evidence for lower friction and good control, studies to date have not confirmed a generic increase in speed of alignment. This may be because the cases in such studies have not a sample with substantial crowding treated nonextraction. The case study of patient AG treated by Dr. David Birnie demonstrates that severe crowding can be accommodated without extraction if that is the desired goal in a specific instance.

CASE STUDY 24-1 A SEVERELY CROWDED LOWER ARCH TREATED WITHOUT EXTRACTION

Patient AG presented at age 14 years, 0 months with moderate upper arch crowding and severe lower arch crowding. His facial appearance was prepubescent; he did not seem to have entered his pubertal growth spurt, and it was thought that significant nasal tip and chin growth would occur during his teenage years. He had a left unilateral crossbite. The lower right central incisor had a long clinical crown (Fig. 24-22). When looking at the severe lower arch crowding, it should be noted that he still retained lower deciduous second molars and that the first premolars were in a Class 1 relationship. All permanent teeth were present on the dental pantomogram except for the upper third molars. His oral hygiene was good but still capable of improvement. Treatment was initiated with light 0.014-inch wires and lightly activated coil spring with the most ectopic instanding teeth being lightly engaged from an early stage to act as a restraint on overall incisor proclination.

Figure 24-23 shows treatment progress after 7 months of treatment. Alignment has almost been achieved in the upper arch, but there is still insufficient space for the lower left lateral incisor. The lower deciduous molars are still present. No crossbite correction has yet taken place; note that the right second molars, which are just visible, are not in crossbite. Figure 24-24 shows the situation 15 months into treatment. Alignment within the arches has been achieved, but crossbite correction has not yet taken place. Figure 24-25 was taken 25 months into treatment. The second molars were bonded 16 months into treatment, and crossbite correction then occurred spontaneously without the need for auxiliary appliances or cross elastics. After stainless steel archwires were placed, the upper archwire was expanded and the lower contracted to ensure maximal correction. Figure 24-26 shows the posttreatment cephalometric radiograph and the superimpositions. There has been no significant change in the skeletal pattern. The lower incisors have proclined by 10 degrees with approximately 3 mm of labial movement, and the upper incisors are at their pretreatment position and inclination. Despite the lack of upper incisor retraction, the nasolabial angle has become more obtuse, and the upper lip is substantially farther from the E line, reflecting the substantial nasal growth. The arch widths show increases in varying amounts. The 10-mm increase in the lower intercanine width reflects the inevitable increase if all such crowded incisors are to be accommodated. The increase in the lower intercanine width would have had to be substantial even had premolars been extracted and the canines moved distally as well as buccally. The upper arch expansion additionally reflects the correction of the posterior crossbites. Figure 24-27 was taken 3 years after the end of active treatment. The clinical crown heights of the lower incisors have equalized and continue to show no recession. In addition to the fixed retainers, the patient wears vacuum-formed retainers at night. Despite the significant arch expansion, there is no undesirable buccal inclination of the upper incisor crowns.

CASE STUDY 24-1 A SEVERELY CROWDED LOWER ARCH TREATED WITHOUT EXTRACTION—cont'd

This case illustrates the ability of passive self-ligation with light wires and gentle activation to accommodate extremely crowded teeth without extractions and perhaps with less incisor proclination that might have been anticipated. The periodontium appears to be remaining healthy. With regard to stability, almost all clinicians would place a fixed lower lingual retainer in this situation however the teeth had been aligned. A clinician with different treatment planning priorities may equally have chosen to accommodate the crowded teeth and correct the overjet by means of extractions. This would have had different consequences for the width and prominence of the dentition within the adult face. The proposal is that without the biomechanical properties of self-ligating brackets, a nonextraction treatment plan would have been much less practicable and therefore not an available option.

Profile

If research confirms that self-ligation can align teeth with less incisor proclination and relatively more lateral expansion, then this would reduce the need for extractions to prevent or correct a profile that is too full. At present, this remains an interesting and plausible hypothesis.

CASE STUDY 24-2 INTERARCH RELATIONSHIP

Self-ligation in itself does not, in the opinion of this author, reduce the potential role for extractions to reduce an overjet. It may, however, help prevent the creation of an unwanted overjet as illustrated through the cases in Figures 24-20 and 24-21. With regard to establishing a positive overbite, it is equally possible that a reduction in incisor proclination for a given amount of tooth alignment may reduce the need for extractions to maintain a positive overbite, but there will always be cases in which any such effect will be insufficient to eliminate the need for extractions. Such a case is illustrated in Case MG (Figs. 24-28 to 24-32) in which self-ligation probably facilitated the alignment of very crowded teeth but in which extractions were still included in order to help achieve the incisor relationship.

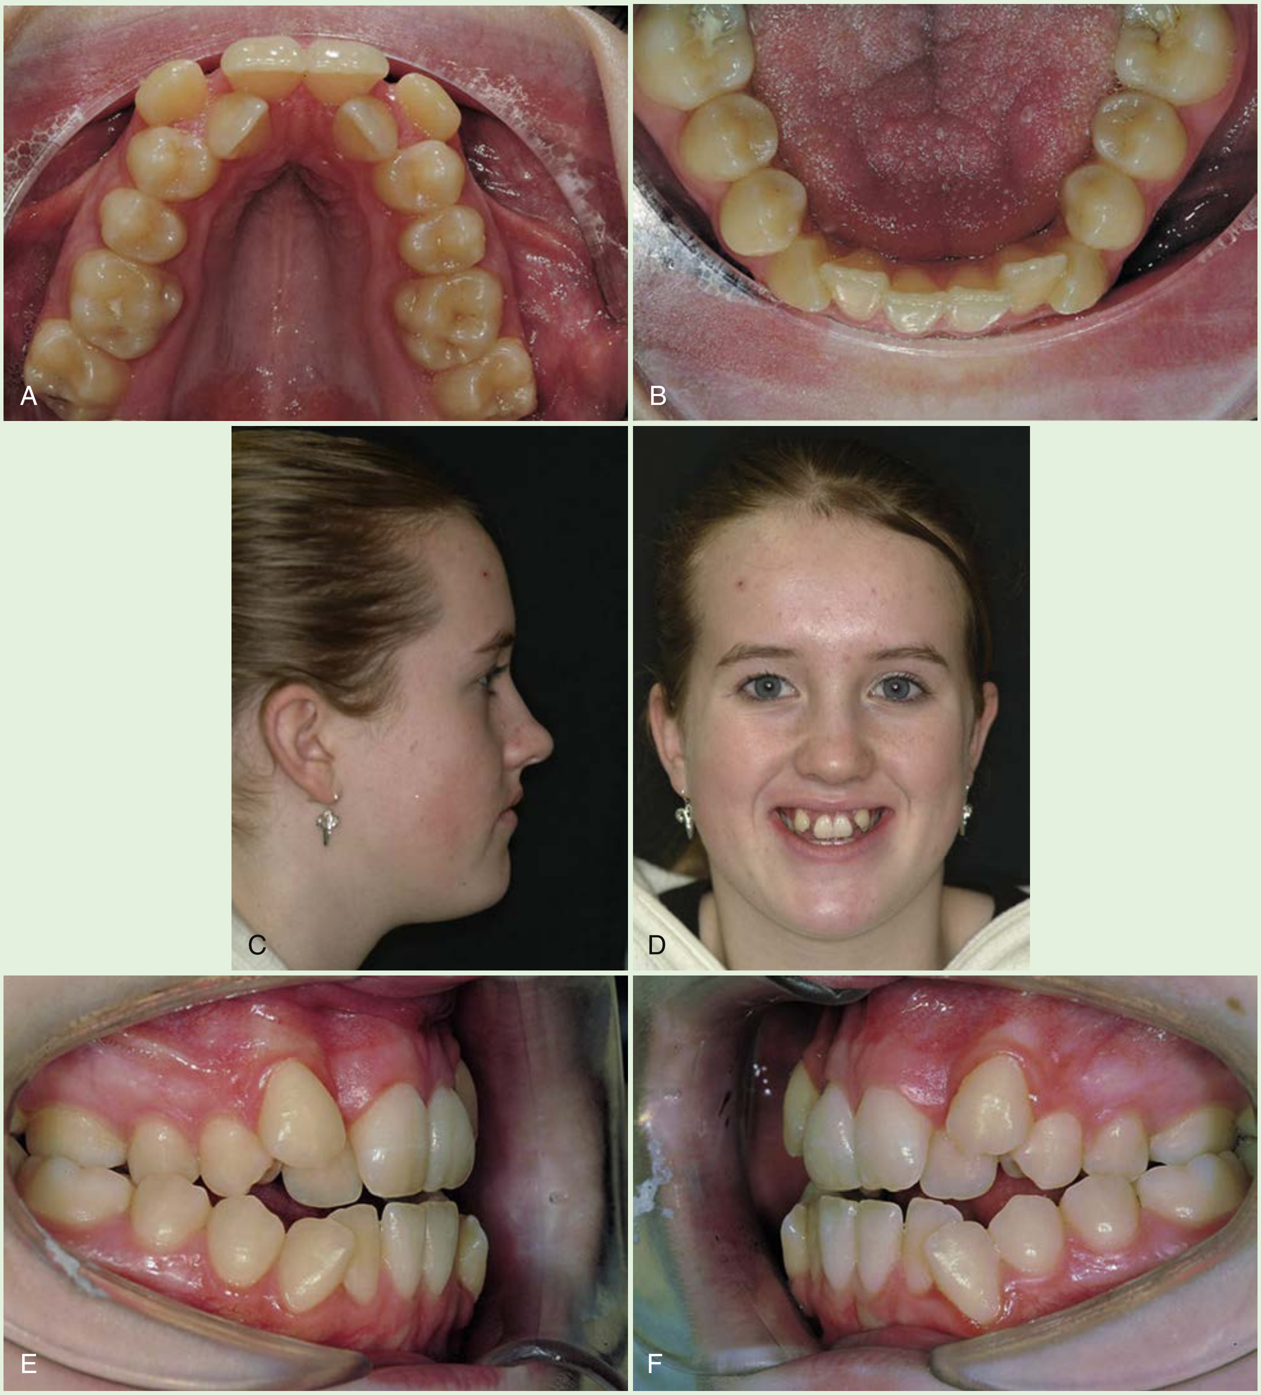

FIGURE 24-28 **A–F,** Pretreatment records of case MG. The crowding could have been resolved nonextraction (see case AG), but the Class 3 incisor relationship and in particular the lack of overbite strongly influenced the decision to extract.

PRACTICAL CONSEQUENCES FOR CLINICAL TECHNIQUE

Choice of Self-Ligating Bracket

A bracket type should be chosen that most closely meets the list of desirable properties for an ideal self-ligating bracket, listed earlier in the section on factors that may have hindered the adoption of self-ligation. Although a large number of designs are available, some come much closer to fully meeting this list than others. Particular value should be placed on a bracket that is very easy and comfortable to open and close and yet can reliably engage and retain archwires of the full range of diameter and stiffness. A good view of the degree of engagement of the wire in the slot before and during attempted slide or clip closure is a big advantage in preventing excessive and ineffective forces being placed on the teeth during attempted archwire insertion. One significant and recommended feature is the presence of an auxiliary slot permitting elastics to be placed directly to a bracket even with a light aligning wire. This aspect of biomechanics is discussed below.

Practical Tips in Light of the Evidence

In view of the currently established properties of self-ligation as evidenced by the investigations discussed earlier, it seems logical to recommend the following differences in clinical technique in comparison with conventional ligation.

- Because archwire changes are faster and easier,[19–21] take advantage of this to more routinely remove, check, and replace archwires. This can be useful in checking the remaining activation and any deformation of aligning wires and can facilitate oral hygiene instruction during the appointment.
- In view of the much lower friction and hence RS,[27,38] be rigorous in placing stops or hooks on the archwire to prevent distal wire pokes. Archwires with preloaded crimpable stops or presoldered hooks are the most efficient method, but stops can be purchased separately. An upper arch will require two such stops because of the larger anterior interbracket spans and the need to place stops anterior to any crowding to permit distal movement of an aligning wire unhindered by the stop(s).

- Because the low friction means higher net forces on displaced teeth[34] aligning wires must be of smaller diameter or higher transformation temperature to ensure sufficiently low aligning force. In a 0.022-inch slot, initial wires should rarely be larger than 0.014 inch and frequently smaller than that. An important second advantage of thin initial wires is that the greater space between archwire and bracket facilitates the relative movement between bracket and archwire and hence between adjacent teeth that is necessary for teeth to align, especially if space is not made available by extraction.
- In view of the research into force levels and distribution (e.g., Baccetti[34] and Fok[37]), it is sensible and advantageous to engage more displaced teeth at the start of treatment rather than partial and progressive engagement as has traditionally been advocated. As with all such features, this change can be extrapolated too far. Even self-ligating brackets can behave like conventional ligation if the wire deflections to engage the displaced tooth are too severe.
- When planning extractions, the easier alignment of irregular teeth with self-ligation without extraction spaces should be one of the factors in the decision. This may appropriately lead to more therapeutic diagnosis in relation to extractions. If after arch alignment, extractions are judged to be necessary, little time will have been lost because of the properties of self-ligation during alignment. If extractions prove not to be necessary, then this irreversible step will have been avoided.
- After teeth are aligned, there is then no advantage in scheduling appointments less frequently than with conventional ligation. This only prolongs treatment.
- Especially with passive ligation, it is important that intermediate aligning archwires have a buccolingual dimension that is as large as the subsequent stainless steel archwire. The full and secure archwire engagement has the corollary that incomplete archwire engagement cannot inadvertently occur and persist as it can with conventional ligation. So a 0.014- × 0.025-inch wire is significantly preferable to a 0.016- × 0.022-inch as an intermediate wire, ensuring easier progression to full engagement of a stiffer wire with a 0.025-inch buccolingual dimension.
- "Begg mechanics with straight-wire control": In view of the secure archwire engagement, it is possible to be much less wary of applying light traction directly to a tooth rather than to a hook on the archwire. Such a tooth will experience very little loss of rotational control. Light (2-oz) elastics can confidently be placed on 0.014-inch archwires. The greater effectiveness of light forces will increase the chances of a favorable tooth movement while the lighter applied force, the better force distribution, and the guaranteed secure archwire engagement reduce the traditionally anticipated adverse side effects of such biomechanics. This represents a change from a very sequential form of biomechanics in which all the hard work awaits the arrival of "working archwires" to a more simultaneous approach, which is analogous to that previously used with Begg brackets. Begg brackets were another low-friction bracket that greatly enhanced the effectiveness of light forces but with much less tooth control. Figures 24-33 and 24-34 show this approach in action.
- Disclusion via anterior bite ramps or posterior additions of glass ionomer are potentially more beneficial with self-ligation because lighter forces are being expected to achieve tooth movement, and the scope for occlusal interference is correspondingly greater.
- Anticipate greater benefit from the combination of low friction and good control in cases in which individual teeth require sliding along the archwire. This is a particular feature of the treatment of hypodontia cases.

SUMMARY

Self-ligating brackets are a highly active area of technical development, thought-provoking clinical practice, and research. They have been commercially available for almost 30 years but only in the past decade has their use spread beyond a minority of enthusiasts. This proliferation of types of self-ligating brackets and the large increase in their clinical use have been sparked partly by very significant advances in bracket design and manufacture. Brackets are now available that are very reliable and very easy to use. Of equal importance has been a rapid growth in the evidence for and appreciation of the combined advantages of secure full ligation, lower RS, and speed of archwire ligation and removal. The shortcomings of the previously dominant elastomeric ligation have come to be generally appreciated, and orthodontists who are understandably more skeptical about some of the claims made for self-ligation are nevertheless using these brackets and enjoying the speed of archwire changes, the cleanliness of appliances that lack elastomerics, the effectiveness of light archwires with low friction, and the security of ligation and resulting tooth control. However, beyond these core advantages, much remains to be securely supported by research. In particular, the evidence to date has failed to support the hypothesis of faster treatment, with only reduced chairside time being a demonstrated efficiency. Equally, hypotheses that torquing or finishing performance is deficient with self-ligation also lack supporting evidence.

The question of a greatly reduced need for extractions is of real interest and is stimulated by some impressive case presentations but currently lacks hard data. First principles concerning low friction and good archwire control support the clinical impression that the need for extractions purely to provide space for arch alignment may therefore be reduced. An encouraging trend is the recent development and use of much more sophisticated force measurement systems and more realistic simulations of in vivo effects. An important conclusion from such research is the concept that self-ligation does not automatically reduce forces applied to teeth but does enable much lighter applied forces to be effective at moving teeth by substantially altering the ratio between desirably light tooth-moving forces and the unwanted reciprocal forces. At the least, self-ligation is now established as a neat, rapid, and very reliable form of ligation. It does not of necessity change a clinician's treatment goals or mechanics, but it can fairly be said to facilitate a wider choice in these respects. The next few years will resolve many of the questions discussed in this chapter, but it is beyond doubt that the questions are stimulating and of very significant consequence for the care of our patients.

Lingual Appliance Treatment

Dirk Wiechmann and Dan Grauer

OUTLINE

INTRODUCTION

Appearance during orthodontic treatment with labial appliances has been related to social discomfort and lack of confidence in public.[1] Despite numerous efforts by experienced clinicians and continuous improvements, a lingual technique using conventional appliances has not been fully established.[2–9] Several completely customized and semicustomized lingual appliances and appliance systems are currently available; these include Harmony (American Orthodontics, Sheboygan, WI), Incognito (3M-Unitek, Monrovia, CA), Suresmile lingual (Orametrix, Richardson, TX), and WIN (DW Lingual Systems GmbH, Bad Essen, Germany). The Suresmile system differs in that instead of a custom lingual bracket, it uses a standard lingual bracket chosen by the clinician but custom-designed and computer-fabricated archwire(s).

In this chapter, the use of completely customized brackets and archwires is described and illustrated as used in the WIN System. Completely customized lingual appliances (custom-designed and manufactured brackets for each tooth and individually formulated archwires) have allowed clinicians to integrate the lingual technique successfully into their everyday practice.[10–14] These appliances have become the most widely used lingual appliances since their introduction in 2004 (Fig. 25-1). Although lingual appliances are the most aesthetic alternative for correcting malocclusions, other far more important reasons for using completely customized lingual appliances have emerged when compared with alternative treatments.

Customized Treatment Goals and Lingual Appliances

Use of a Target Setup Model System

The highly variable morphology of lingual surfaces of teeth and the need to reduce the profile of the lingual braces, increasing patients' comfort, require full customization of the lingual appliances. For each patient, a treatment goal is defined with the help of a target setup.[11,13] Establishing a target setup has both diagnostic and therapeutic advantages. Diagnostic advantages include the assessment of the desired treatment goals before initiation of treatment, which improves communication with the dental team and the patient;[15] the possibility of evaluating more than one treatment goal in complex cases; and a more accurate estimation of treatment time. The main treatment advantage is the fabrication of accurate appliances based on the target setup; these appliances are designed to move the teeth that need to be moved and remain passively on the teeth that should stay stationary,[16] as opposed to average preadjusted appliances that would produce unwanted tooth movements in some teeth because of anatomic variations. This can be explained by the fact that intraindividual variation in tooth morphology is greater than variation in preadjusted appliances' prescription.[17]

Accurate Realization of Individual Treatment Goals

The test of any appliance system is how accurately the clinician can achieve treatment goals. For each custom lingual appliance patient, a setup is fabricated according to the specific individual treatment plan goals. A customized prescription in six degrees of freedom is applied to each tooth, and the individual dental arch shape is formed. Attainment of treatment goals can be evaluated by comparing the orthodontic outcome with the target setup fabricated at the beginning of treatment. Several studies reported on the accuracy of completely customized lingual appliances. Pauls[18] compared setup and final models for 25 lingual appliance patients. They superimposed models from both time points and compared the position of the bracket in the setup model with the position of the bracket in the final model. The discrepancies in position between brackets were translated into three rotation and three translation parameters. The author concluded that the setup objectives were achieved in the finished cases.

Grauer and Proffit[19] compared setup and final models for 94 consecutive patients. Models were compared based on a surface-to-surface registration. The discrepancies between the

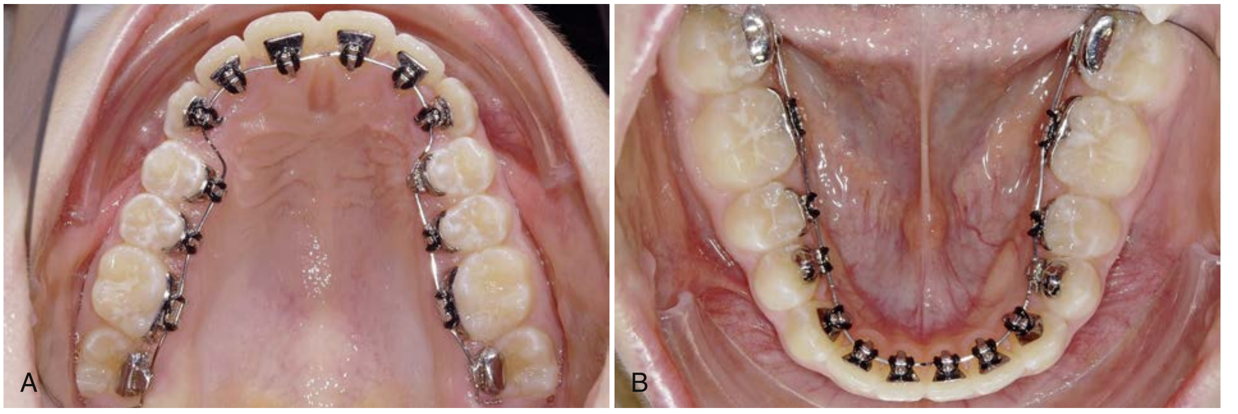

FIGURE 25-1 A, B, Completely customized lingual appliance. Note the occlusal coverage on the second molars and lower second premolars. Superelastic NiTi wires were inserted; these wires were designed and manufactured to achieve the desired individual arch form.

position of the teeth in the setup and outcome model were translated into rotation and translation parameters. Discrepancies in translation (mesiodistal, labiolingual, and vertical) and in rotational parameters (inclination, angulation, and axial rotation) between the setup and outcome were small for all teeth (generally <1 mm and 4 degrees) except for the second molars, where some larger discrepancies were observed. They concluded that fully customized lingual orthodontic appliances were accurate in achieving the goals planned at the initial setup.

A third study compared the desired intercanine distance at the target setup with the attained intercanine distance after treatment. The authors reported a mean deviation of less than 0.5 mm between the initial setup and finished treatment. This result was expected given that after teeth are aligned with no spaces among them, the change in arch form between canines has little influence on the arch perimeter.[20] Wiechmann et al.[21] assessed the inclination of the lower incisors after orthodontic treatment with completely customized lingual appliances combined with the Herbst appliance. There was no statistical difference ($p > 0.05$) between planned incisor inclinations of the target setup and achieved incisor inclinations on the day of debonding. The overall mean difference was 2.2 degrees ± 1.0 degree. It is important to note that when Herbst appliances are used, a wire that completely fills the bracket slot is used; hence, the full prescription of the appliance gets expressed.

Reduced Risk of Decalcification

White spot lesions (WSLs) associated with fixed orthodontic appliances are a common adverse effect of labial fixed orthodontic treatment; these are not distinct types of carious lesions but are the result of enamel demineralization as a stage of the carious process occurring around orthodontic fixed appliances.[22] The prevalence of WSLs occurring during orthodontic treatment is reported to range from 13% to 75%.[23–26] In a randomized clinical trial, it was shown that the incidence of WSLs is five times smaller when customized orthodontic appliances are used as opposed to conventional labial fixed appliances. Moreover, the severity of the lesions occurring during orthodontic treatment was 10 times smaller on the lingual side as opposed to the labial side.[27] In a recent study, the incidence of WSLs during orthodontic treatment with completely customized lingual appliances was determined and

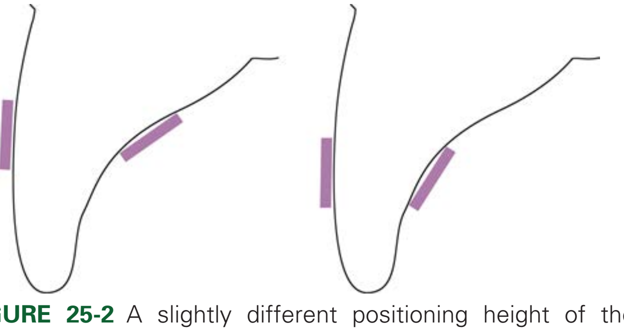

FIGURE 25-2 A slightly different positioning height of the bracket has only a small impact on torque (2 degrees) with a labial appliance. On the lingual aspect, the same height difference results in a major torque difference (22 degrees).

compared with the published incidence of WSLs when labial appliances are used. The authors concluded that the incidence of WSLs in maxillary front teeth was six times smaller when customized lingual appliances were used in terms of subjects and 12 times smaller in terms of teeth.[28] Based on this evidence, completely customized lingual appliances are classified as low risk for WSL (see Chapter 30).[22]

MAIN DIFFERENCES BETWEEN LABIAL AND LINGUAL TECHNIQUES

Anatomic Variations of the Lingual Tooth Surfaces

The labial and lingual differences in tooth morphology are substantial. Morphologic variability of the lingual surfaces of teeth results in a wide range of individual variation compared with the labial surface. For instance, the labial surface of an upper central incisor always follows a similar pattern, but its lingual surface shows marked morphologic variations among individuals. Therefore, designing the treatment appliance based on mean values, as with labial techniques, is impossible. Moreover, even a small height (vertical) deviation in the position of the brackets results in a marked effect on the third-order prescription (Fig. 25-2). Therefore, the application of the intended torque values can only be routinely achieved with an approach combining completely customized bracket bases with indirect bonding protocols. Without an understanding of the different requirements in bracket placement between lingual and labial

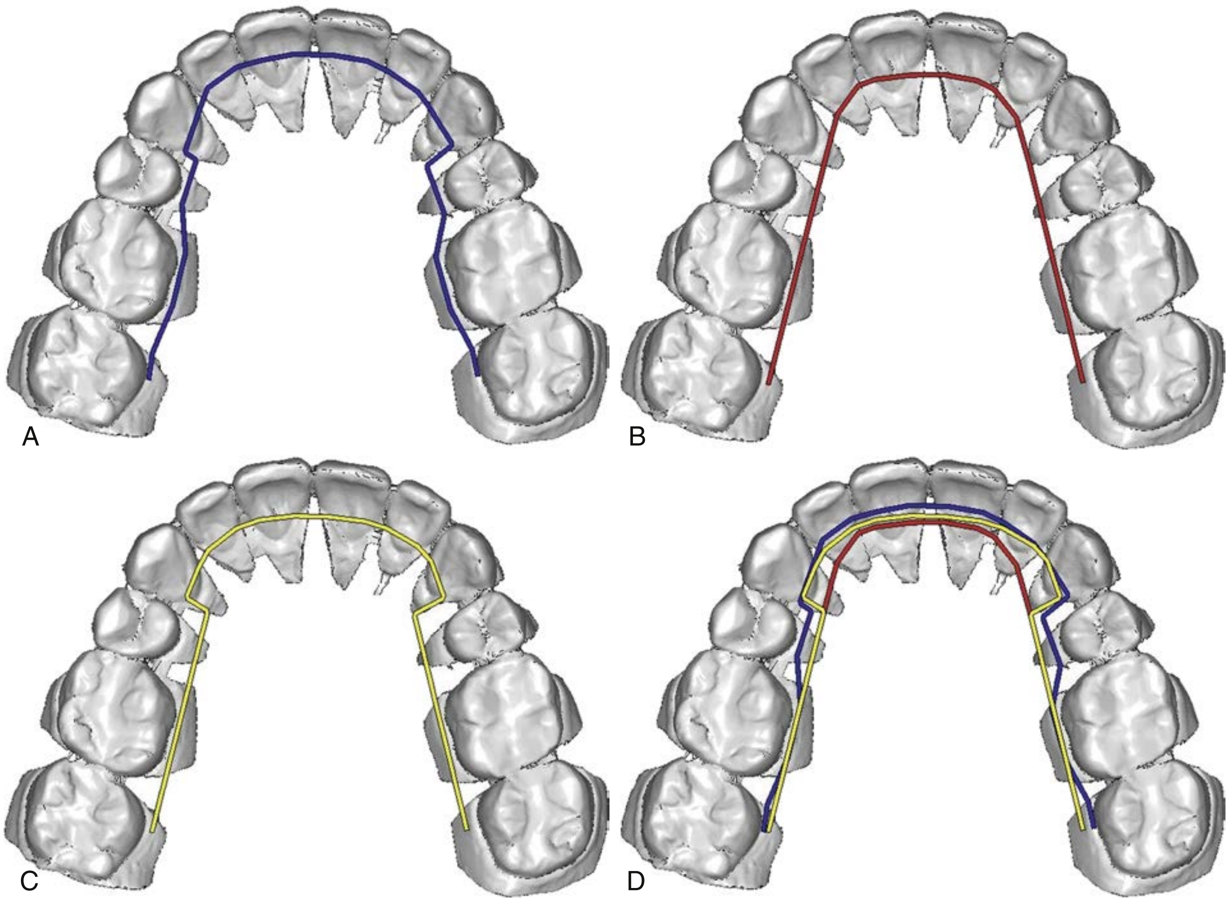

FIGURE 25-3 **A,** Different tooth thicknesses are compensated by first-order archwire bends. **B,** The archwire is straight. Compensation of the different tooth thicknesses must be accomplished by thicker brackets; therefore, additional composite is required under the brackets in the laboratory process, or the bracket bases themselves have to be thicker. **C,** Mushroom arch form. Two first-order bends are placed between the canines and first premolars. **D,** Superposition of the three types of archwires. In the anterior segment, major differences can be noticed. The archwire, which is completely individual in the first order (*blue*), allows for the flattest appliance. The straight archwire (*red*) produces by far the biggest restriction for the tongue.

appliances, just reproducing the approach of conventional labial techniques led to disillusionment with lingual appliances in the 1980s, especially in the United States.

First-Order Compensations

While looking at an ideal dental arch from the occlusal view, the labial surfaces of the teeth can be found along a regular arch line. On the lingual side, the teeth exhibit a pattern where surfaces are irregular. To develop an efficient lingual appliance, these differences in thickness occurring among teeth have to be compensated for with a laboratory process. There are three main strategies to compensate for these differences (Fig. 25-3):

1. **Compensation with first-order customized archwires that level out the tooth thickness differences** (see Fig. 25-3, *A*). The customization of the brackets only incorporates the customized programming of the second-order and third-order dimensions, which allows for a comparatively flat profile.[10,11,13]
2. **Compensation by adjusting the bracket base thickness.** In this strategy, brackets are set up not only with second-order and third-order programming but also with first-order programming.[8] This results in a considerable increase in appliance thickness, which may lead to patient discomfort. Because the brackets incorporate the three-dimensional programming in its entirety, "straight wires" may be used (see Fig. 25-3, *B*). Although the use of straight wire appliances has been established in labial techniques, it results in considerable disadvantages in the lingual technique for both the patient and the orthodontist because of the markedly thicker brackets. Hohoff et al.[29] and Stamm et al.[30] reported that thicker appliances cause more patient discomfort and more problems during speaking and eating. Tongue irritation is also observed more frequently when brackets encroach on tongue space. The interbracket distance becomes even shorter because of the increased bracket thickness. This not only makes inserting the archwires more challenging but also makes complete bonding of all brackets impossible at the start of treatment, even in moderate cases of crowding, because of the brackets' size. When thicker brackets are used, the distance between the center of resistance of the tooth and the point of force application increases, making it more challenging to correct

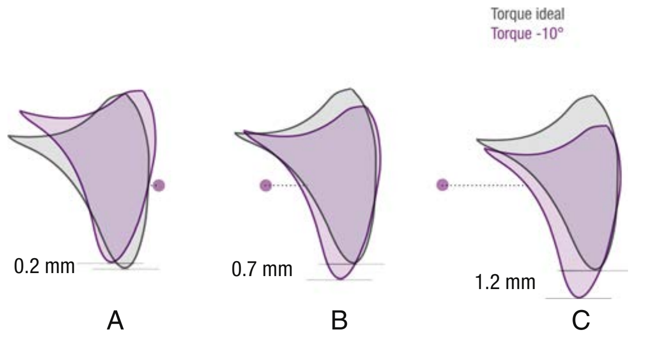

FIGURE 25-4 Effect of incorrect torque (−10 degrees) on the vertical position of the incisor edge of an upper central incisor. **A,** With a labial appliance, only 0.2 mm of vertical discrepancy can be noticed. **B,** The same incorrect torque creates an increased vertical discrepancy (0.7 mm) even if a very flat lingual appliance is used. **C,** Thicker lingual appliances (e.g., lingual straight wire appliances) are not only much more uncomfortable for the patient; they are also much more prone to third-order problems.

torque problems in the third dimension (Fig. 25-4). The larger and thicker the bracket, the higher the rate of bracket loss because there is more chance of biting and debonding a thicker bracket.

3. **Compensation by partial first-order bend of the archwires.** In this case, only the difference in thickness between the canine and the first premolar is compensated with a first-order bend of the archwire. The archwire is straight from canine to canine and from first premolar to second molar. The shape of this archwire setup reminds one of a mushroom, which is why the lingual technique was also called the "mushroom technique" by its pioneers[4] (see Fig. 25-3, *C*).

Torque Control

One major difference between labial and lingual appliances with regard to treatment mechanics is the importance of accurate torque control and its consequences on vertical tooth position. Incorrect torque control results in a completely different effect in a labial bracket versus a lingual bracket as illustrated in Figure 25-4. Two upper central incisors are depicted, one of which exhibits an ideal position; the other one displays a torque problem of −10 degrees. When a labial appliance is used, the effect of 10 degrees of torque discrepancy will be unnoticed by the patient, and only a very detail-oriented orthodontist could recognize the problem (see Fig. 25-4, *A*). When a lingual appliance is used, an incorrect torque of −10 degrees directly causes a visible malposition in the vertical plane, and the tooth appears extruded (see Fig. 25-4, *B*). This is even more severe as the distance between the tooth surface and the archwire increases, which is the standard situation when using a lingual straight wire approach with thicker brackets; vertical discrepancies are easily detected by the patient (see Fig. 25-4, *C*).

In state-of-the-art lingual orthodontic appliances, torque control is achieved by the exact fit of a rectangular archwire into the bracket slot. To ensure perfect third-order control, either full engagement of the slot by the archwires or smaller archwires with overcorrections are needed. Acceptable torque control in the course of the lingual treatment can be realized only if archwires and slots are precisely manufactured with only minimal tolerances.[31] The main cause for marked torque play in labial appliances, in particular in the "passive self-ligating systems," is their design with considerably oversized bracket slots.[32] Oversize of more than 15% on average of the nominal size may occur in these labial appliances. As an example, the slot in a 0.022-inch bracket system may have a real slot size of 0.025 inch. Nonetheless, reproducible, good outcomes can be obtained with these types of labial systems. The clinician must recognize that there are differences between the need for precise bracket–wire interfaces between the labial and lingual techniques, with lingual appliances demanding a higher focus on precision and potentially added torque to provide proper control. Consequently, the requirements for lingual appliances continue to be different even during routine orthodontic tooth movements such as anterior tooth retraction.

Exposure of Bonding Area

Most orthodontic patients are children and adolescents. Within this age group, the bonding area of the lingual surface can be reduced, especially in teeth that have just erupted. This is true, particularly for the upper and lower second molars and the lower premolars. Bonding conventional lingual appliances is therefore difficult or impossible in this age group. This is one of the main reasons why in the past, lingual treatment has been provided only to adults. The number of adults requesting orthodontic treatment has always been relatively low, so conventional lingual appliances were only appropriate for a limited group of patients. The use of the completely customized lingual appliances, in which bonding pads can be individually designed, and in cases of a reduced lingual bonding area, partially extended over the occlusal surface, now opens up a new target group that includes both children and adolescents (see Fig. 25-9, *H* and *I*).

Innovation in Completely Customized Lingual Appliances

In recent years, the lingual WIN System has increased its popularity among the customized lingual appliances around the world. Besides exact implementation of the planned treatment, the focus of this appliance is on simplification of clinical handling to the user's benefit. Users can rely exclusively on inserting traditional ligatures as are common in fixed labial appliances. Additionally, treatment duration is shorter on average compared with other customized lingual appliances because of very low rates of bracket loss[33] and a more efficient leveling and aligning stage. Because manufacturing expense is substantially lower than with other custom lingual bracket systems, lingual treatment has become affordable for a larger share of patients.

Efficient Leveling and Aligning with Lingual Appliances

The leveling and aligning stage presents important differences between common labial and lingual approaches. Labial appliances allow bonding of all brackets from the start of treatment in most cases. This is not often the case for lingual systems, where in the mandibular arch braces have to be bonded in a multistage process depending on the inserted system. Because of both the repeated performance of bracket bonding sessions and the more complex task this represents for the preparatory step of gaining space for the respective

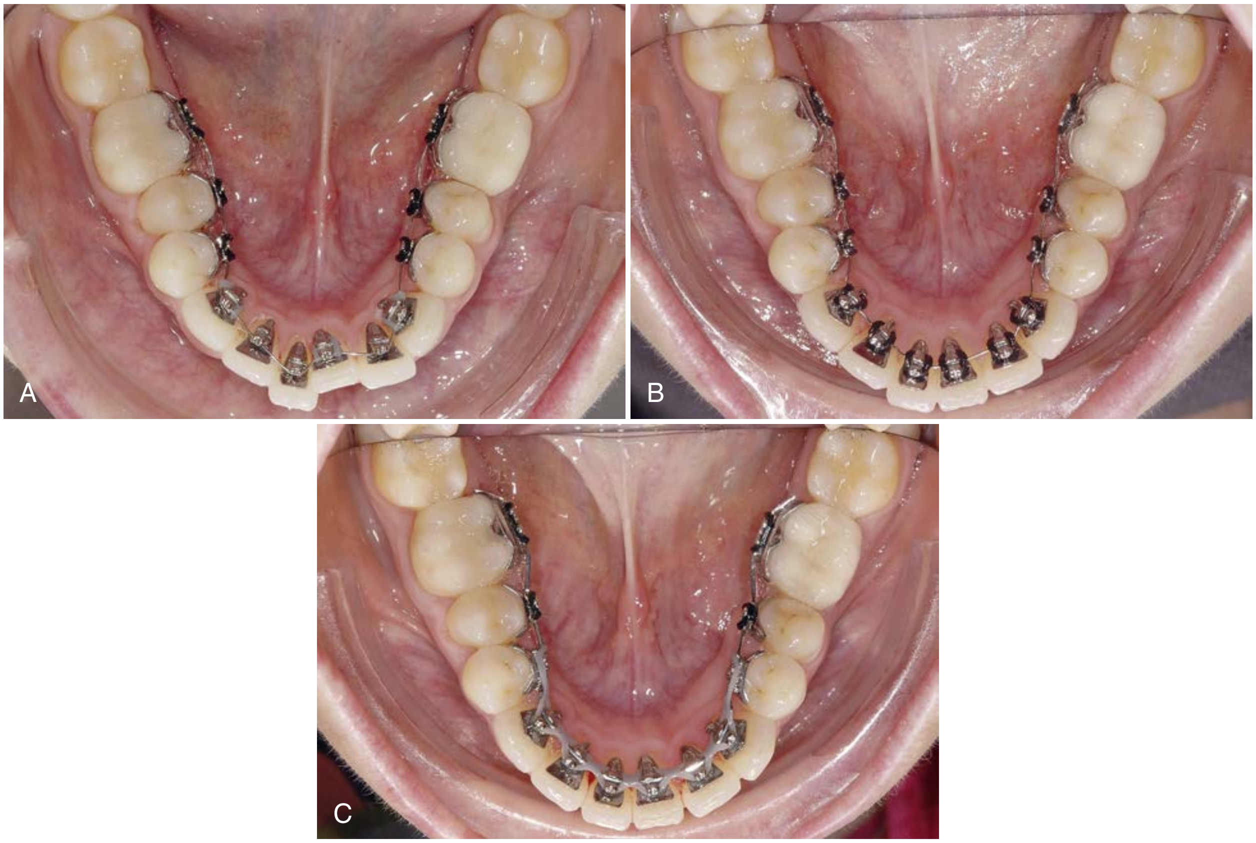

FIGURE 25-5 Aligning type 1. **A,** The first archwire, a 0.012-inch round SE-NiTi wire, is placed behind the incisal wings of the anterior teeth. **B,** Eight weeks later, the same archwire is placed into the normal slot with simple elastics. **C,** Nine weeks later, aligning is completed with a 0.016- × 0.022-inch SE-NiTi wire.

individual teeth and attachments, this multistage bonding process is associated with a considerable additional investment in treatment time. Three types of aligning are used in lingual orthodontics, depending on characteristics of the presenting malocclusion.

Aligning Type 1

Aligning type 1 is used when all brackets can be bonded from the start of treatment (Fig. 25-5). In cases of significant crowding, however, it is recommended not to insert the archwire into the bracket slot but rather one level higher, in the area of the wings. This enables initially longer archwire lengths in the interbracket area and resultant posterior tooth uprighting and anterior tooth proclination. At a later stage, the archwire can then be inserted into the slot proper using standard elastic ligatures.

Aligning Type 2

Aligning type 2 is indicated when there are brackets that cannot be bonded because of insufficient surface exposed (Fig. 25-6). In these cases, there is enough surface exposed to bond a smaller attachment constructed with a bonding pad and a flexible winglet. The thin NiTi archwire is set behind the winglet right at the start of treatment. As soon as space has been gained, the lingual bracket can be bonded in a subsequent bonding session. After all brackets are bonded, the clinical process described under Aligning Type 1 is carried out.

Aligning Type 3

Aligning type 3 is defined by a clinical situation when the dental surface is not exposed at all, typically when the tooth is impacted or deviated out of arch form (Fig. 25-7). In these cases, the insertion of thin NiTi archwires activated by stops is recommended. When the space has been opened and bonding can occur at this tooth, the respective treatment steps described under Aligning Type 1 or 2 are applied.

SUMMARY

Completely customized lingual appliances and techniques have revolutionized lingual orthodontics in recent years. In addition to the aesthetic advantages of these appliances, reduced risk of decalcification, superior third-order control, and accurate achievement of the treatment goals along with the possibility to treat children and adolescents have led to a better acceptance of lingual appliances in routine orthodontic practice. Indeed, the number of patients treated with lingual or combined lingual and labial appliances continues to rise worldwide. However, within the triad of orthodontist, patient, and appliance, which is of such great importance in any orthodontic therapy, even an ideal appliance alone will still not offer any guarantee of a successful treatment outcome. Rather, the know-how and continued attention to the details of diagnosis, treatment planning, and ongoing execution of biomechanics by the orthodontist finally and always determine the results.

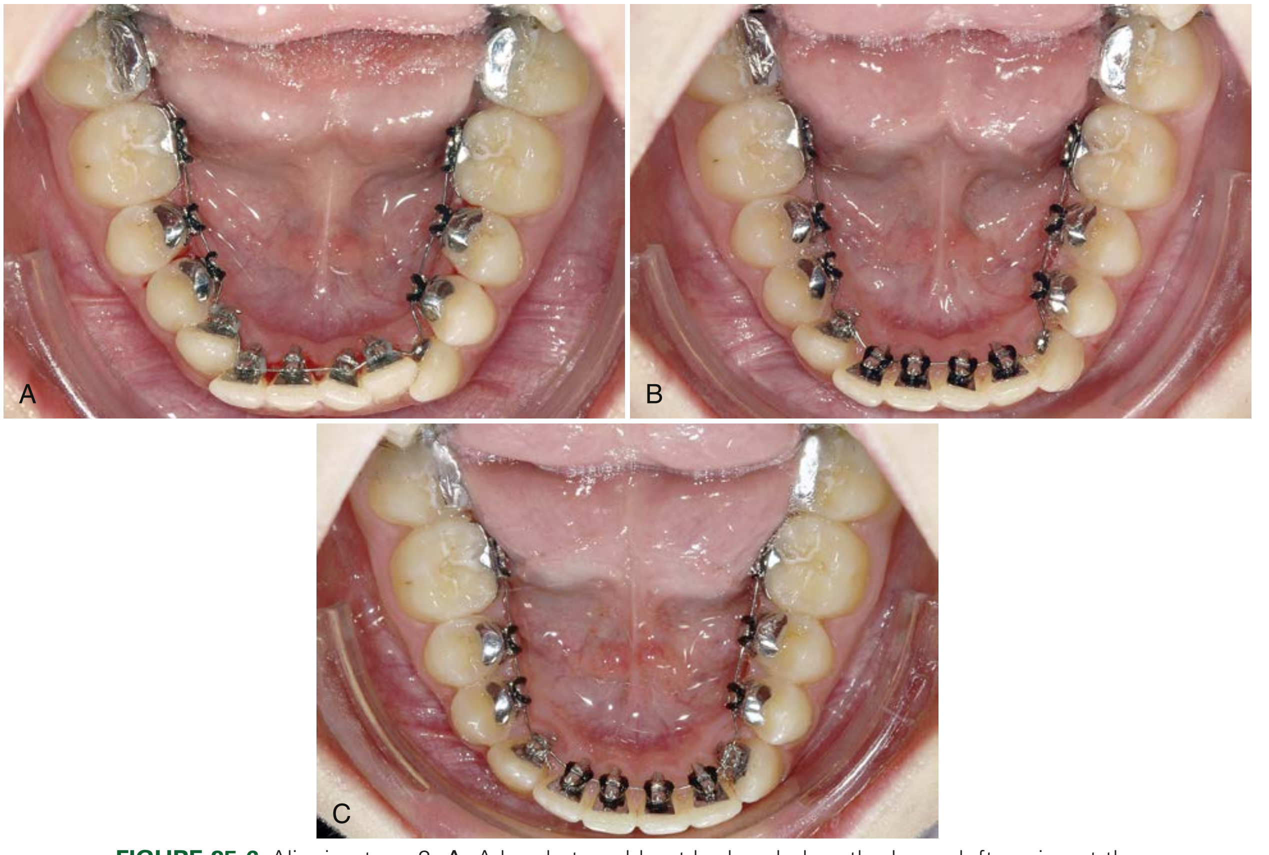

FIGURE 25-6 Aligning type 2. **A,** A bracket could not be bonded on the lower left canine at the initial stage. Therefore, a two dimensional control winglet is used for initial alignment of the tooth. Because of the amount of crowding, the archwire is placed behind the incisal wings. **B,** Twelve weeks later, the same archwire is placed into the normal slot. A lasso elastic is used to derotate the lower left canine. **C,** One month later, a bracket could be bonded. The archwire used is still the initial 0.012-inch superelastic NiTi wire.

FIGURE 25-7 Aligning type 3. **A, B,** A 0.012-inch round superelastic NiTi wire with two stops mesial of the first premolars is used for creating space. In the area of the blocked out lower right lateral incisor the archwire is compressed. **C,** Two months later, a winglet can be bonded to the lower lateral incisor. The two stops were removed, and now the archwire is placed behind the incisal wings. **D,** Three months later, a bracket can be bonded. Note: Only one wire was used.

CASE STUDY 25-1 LINGUAL TREATMENT OF ADULT PATIENTS

Completely customized lingual treatment of a man with previous asymmetric extraction. Treatment goals were incorporated into a diagnostic and therapeutic setup on which the appliances were fabricated. An indirect bonding procedure was used, and wires were designed and optimized to the desired dental arch form and needed mechanics. These included leveling and alignment, asymmetric space closure, Class II mechanics, correction of upper midline position, torque control, and finishing and detailing.

FIGURE 25-8 A–I, A 27-year-old patient with severe upper midline deviation to the left. The patient previously underwent orthodontic treatment with asymmetric extraction in the upper arch during adolescence. The right side presented a full Class II canine relationship. The lower midline was slightly shifted to the right. Relapse of the lower crowding occurred despite an original bonded mandibular retainer.

CASE STUDY 25-1 LINGUAL TREATMENT OF ADULT PATIENTS—cont'd

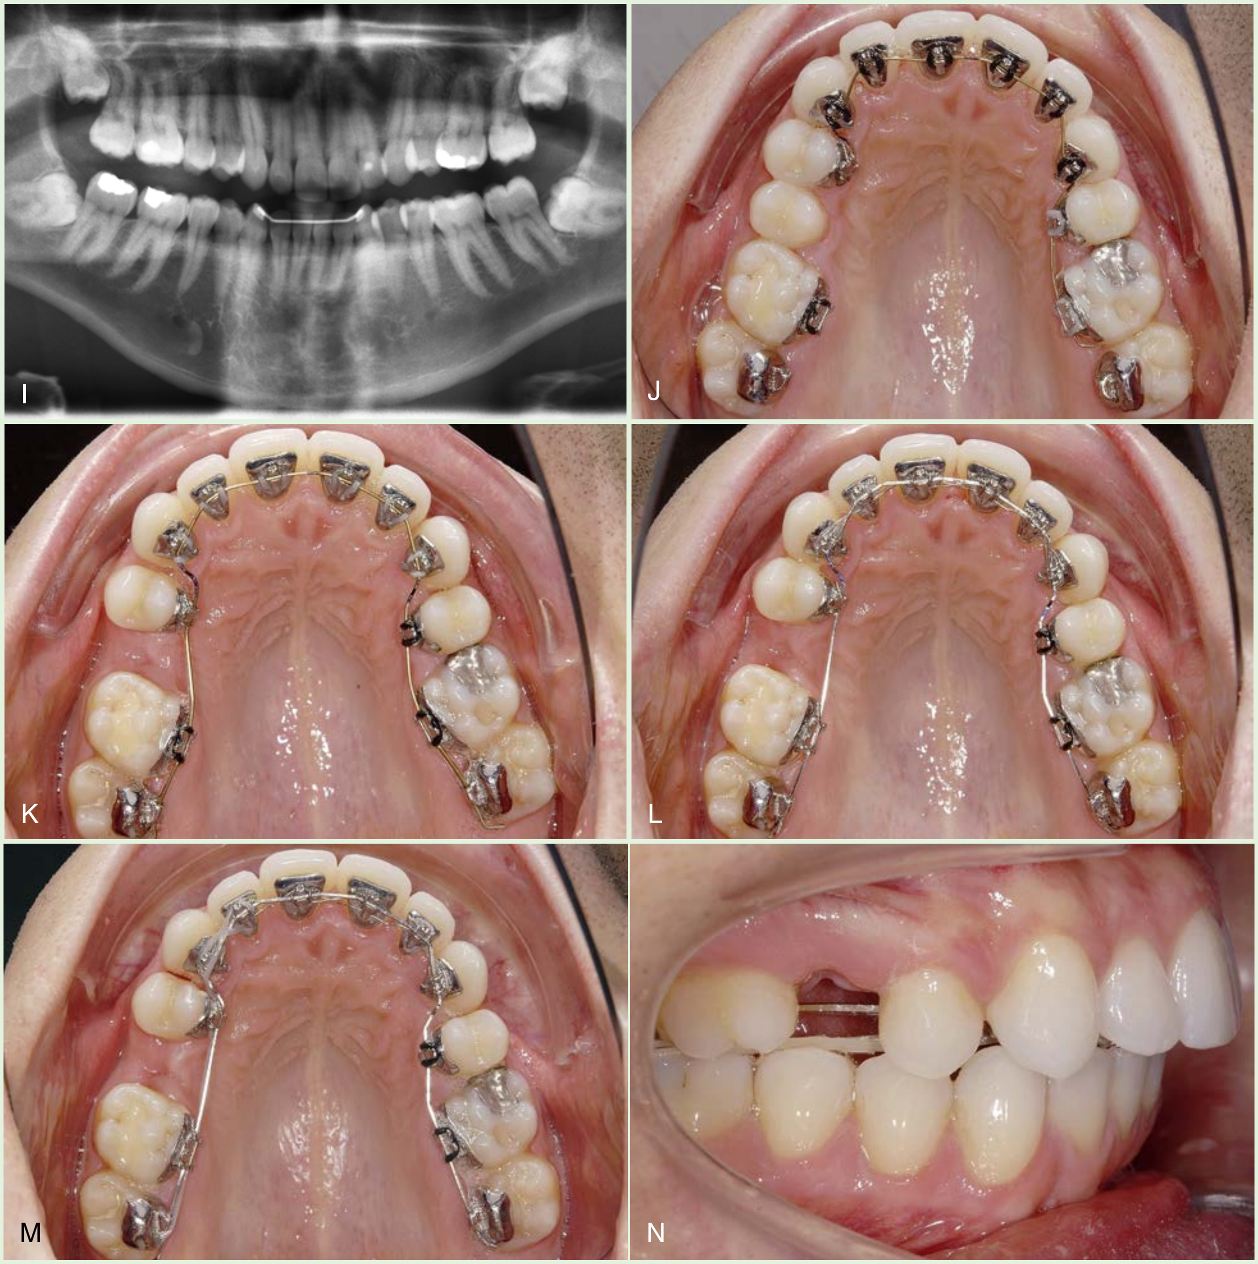

FIGURE 25-8, cont'd **J,** Immediately after upper arch bonding, a 0.012-inch round NiTi wire was placed for initial alignment. Indirect bonding protocol requires that the extractions are performed after bracket placement. **K,** A 0.016- × 0.022-inch NiTi wire was used for further alignment. The archwire was straight on its right side. **L,** A 0.016- × 0.024-inch stainless steel archwire was inserted for space closure and midline correction. Before the archwire insertion, a metal ligature was placed to attach the upper incisors and canines. The wire was ligated with metal ligatures. Note the different archwire shape on the right side (straight) and on the left side (individual). **M,** At the next appointment, the upper right canine was retied with a new steel ligature to improve tip control in the vertical slot during retraction. A power chain for space closure was attached to the lateral incisor for simultaneous wear of Class II elastics. **N,** The patient was able to attach Class II elastics on the hook of the canine.

CASE STUDY 25-1 LINGUAL TREATMENT OF ADULT PATIENTS—cont'd

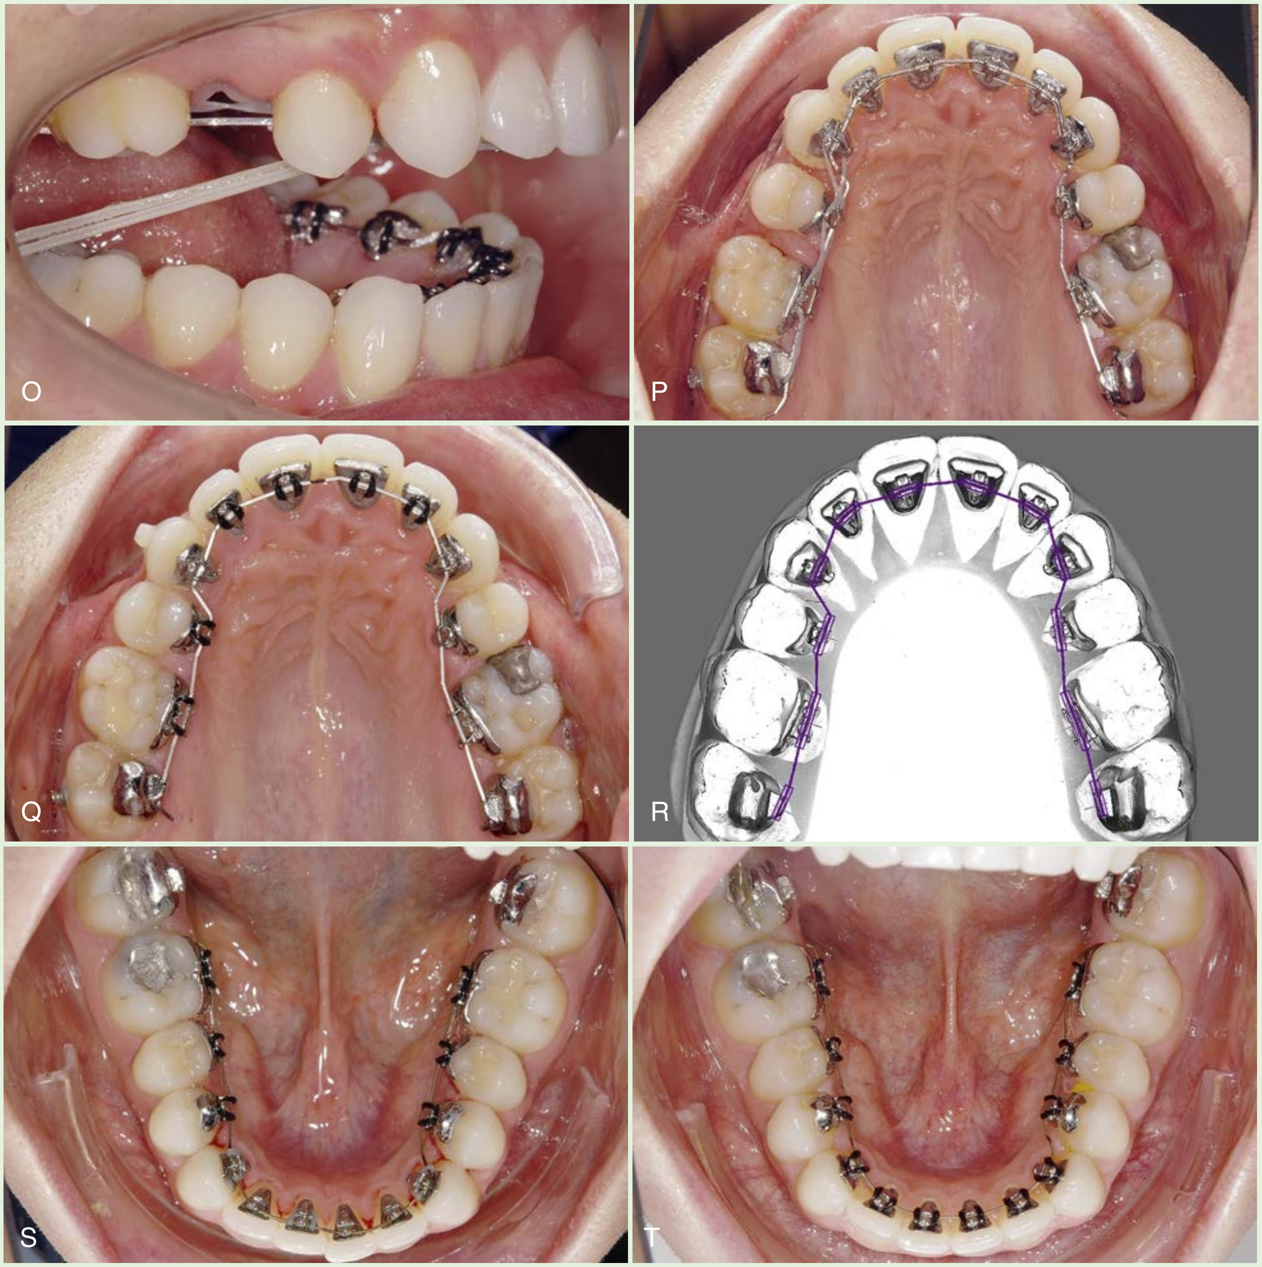

FIGURE 25-8, cont'd N, O, The remaining space had to be closed mainly by distalizing the anterior teeth to a Class I canine relationship. Class II elastics were worn full time to support space closure with power chains. P, The elastic extended from the upper canine hook to a labially bonded button on the lower second molar. At the final stage of space closure, double-cable mechanics with one power chain lingual and a companion clear chain buccal were used for residual space closure. The transparent labial power chain was attached to the archwire between the lateral incisor and the canine and connected to a labial button on the upper second molar. Q, After space closure, a 0.018- × 0.018-inch beta-titanium archwire was inserted for first-order detailing on the right side. To improve tip control, the upper right canine was ligated with a metal ligature. A vertical bend back prevented space from reopening. R, The final result and the treatment plan as represented by the virtual archwire are compared in the occlusal view. S, T, A 0.012-inch round NiTi wire was used for initial mandibular arch aligning. The wire was placed behind the wings of the brackets initially, and later the wire was ligated in to the slot.

CASE STUDY 25-1 LINGUAL TREATMENT OF ADULT PATIENTS—cont'd

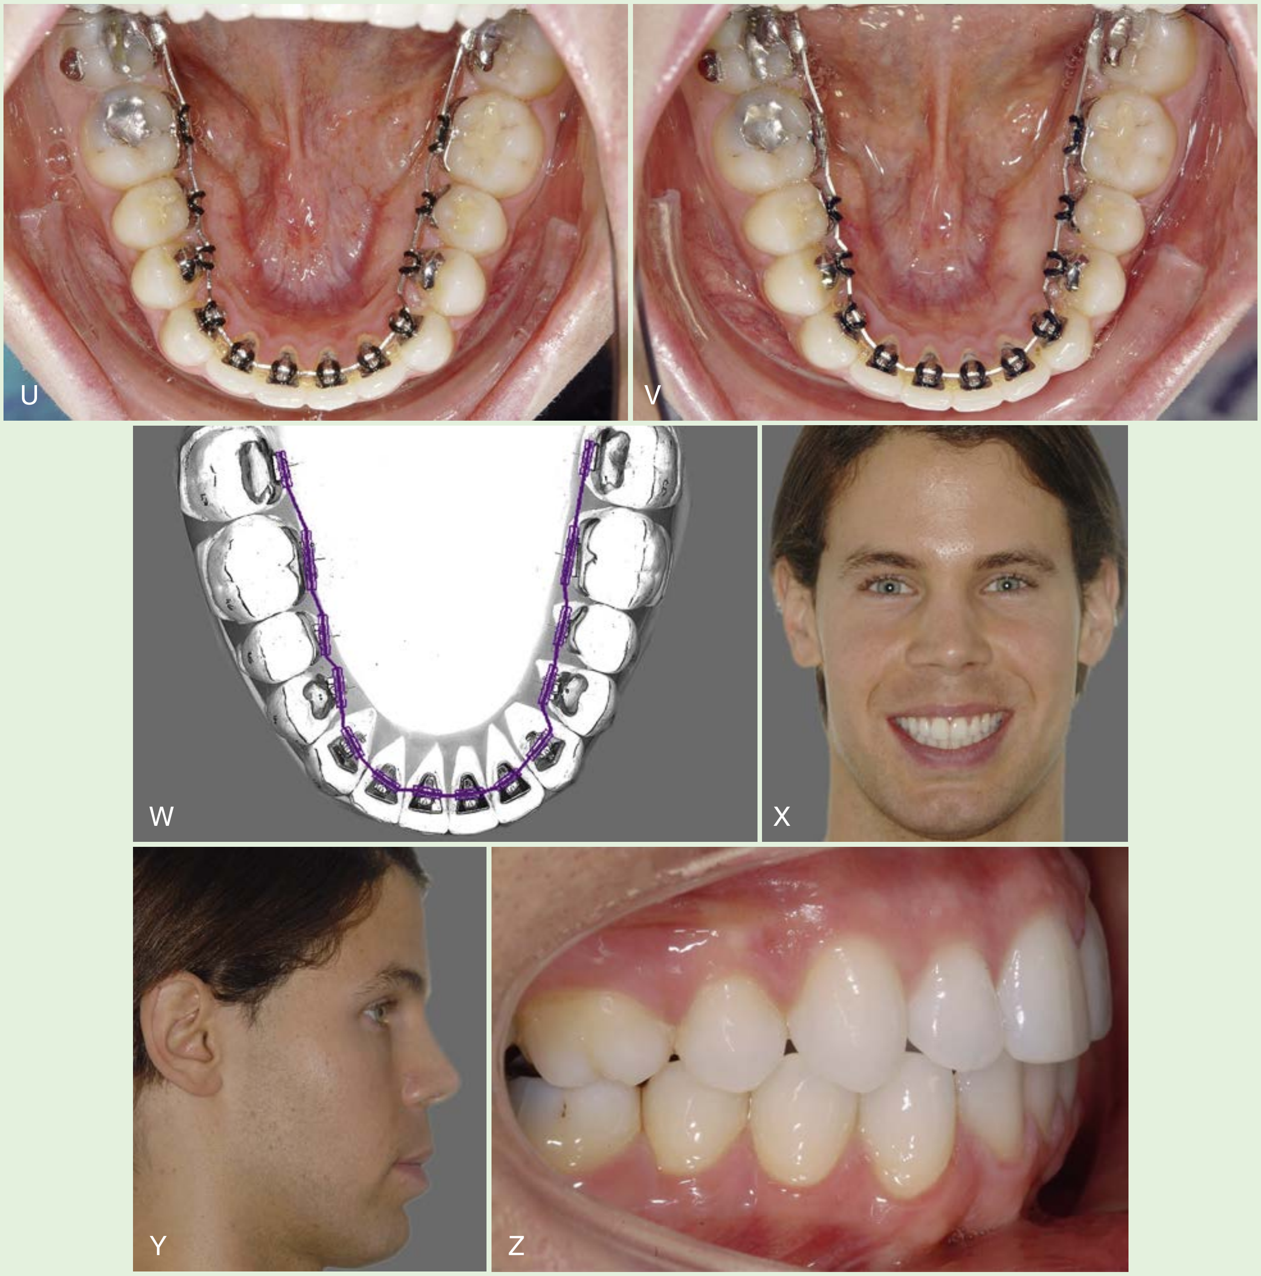

FIGURE 25-8, cont'd **U,** After the insertion of a 0.016-inch × 0.022-inch NiTi wire, a 0.016- × 0.024-inch stainless steel archwire was placed for intermaxillary elastic wear. **V,** Final torque control was achieved with a 0.018- × 0.018-inch beta-titanium archwire. Note that no over-ties were used. **W,** The final result and the treatment plan as represented by the virtual mandibular archwire are compared in the occlusal view.

CASE STUDY 25-1 LINGUAL TREATMENT OF ADULT PATIENTS—cont'd

FIGURE 25-8, cont'd AA–FF, The patient after 26 months of treatment. The upper midline deviation was corrected. Despite vertical insertion of the archwire in the frontal area, any unwanted tipping of the incisors was prevented. A Class I canine relationship was achieved on both sides. Upper and lower fixed retainers were bonded for retention.

CASE STUDY 25-2 LINGUAL TREATMENT OF CHILDREN AND ADOLESCENTS: NONEXTRACTION CASE WITH USE OF CLASS II ELASTICS

Completely customized lingual treatment of a female teenager with full dental Class II division 2. Treatment involved customization and fabrication of appliances through an individualized setup, use of half-occlusal coverage molar attachments for bite opening and debonding prevention, an extra-torque upper archwire for torque expression, Class II mechanics, and finishing and detailing.

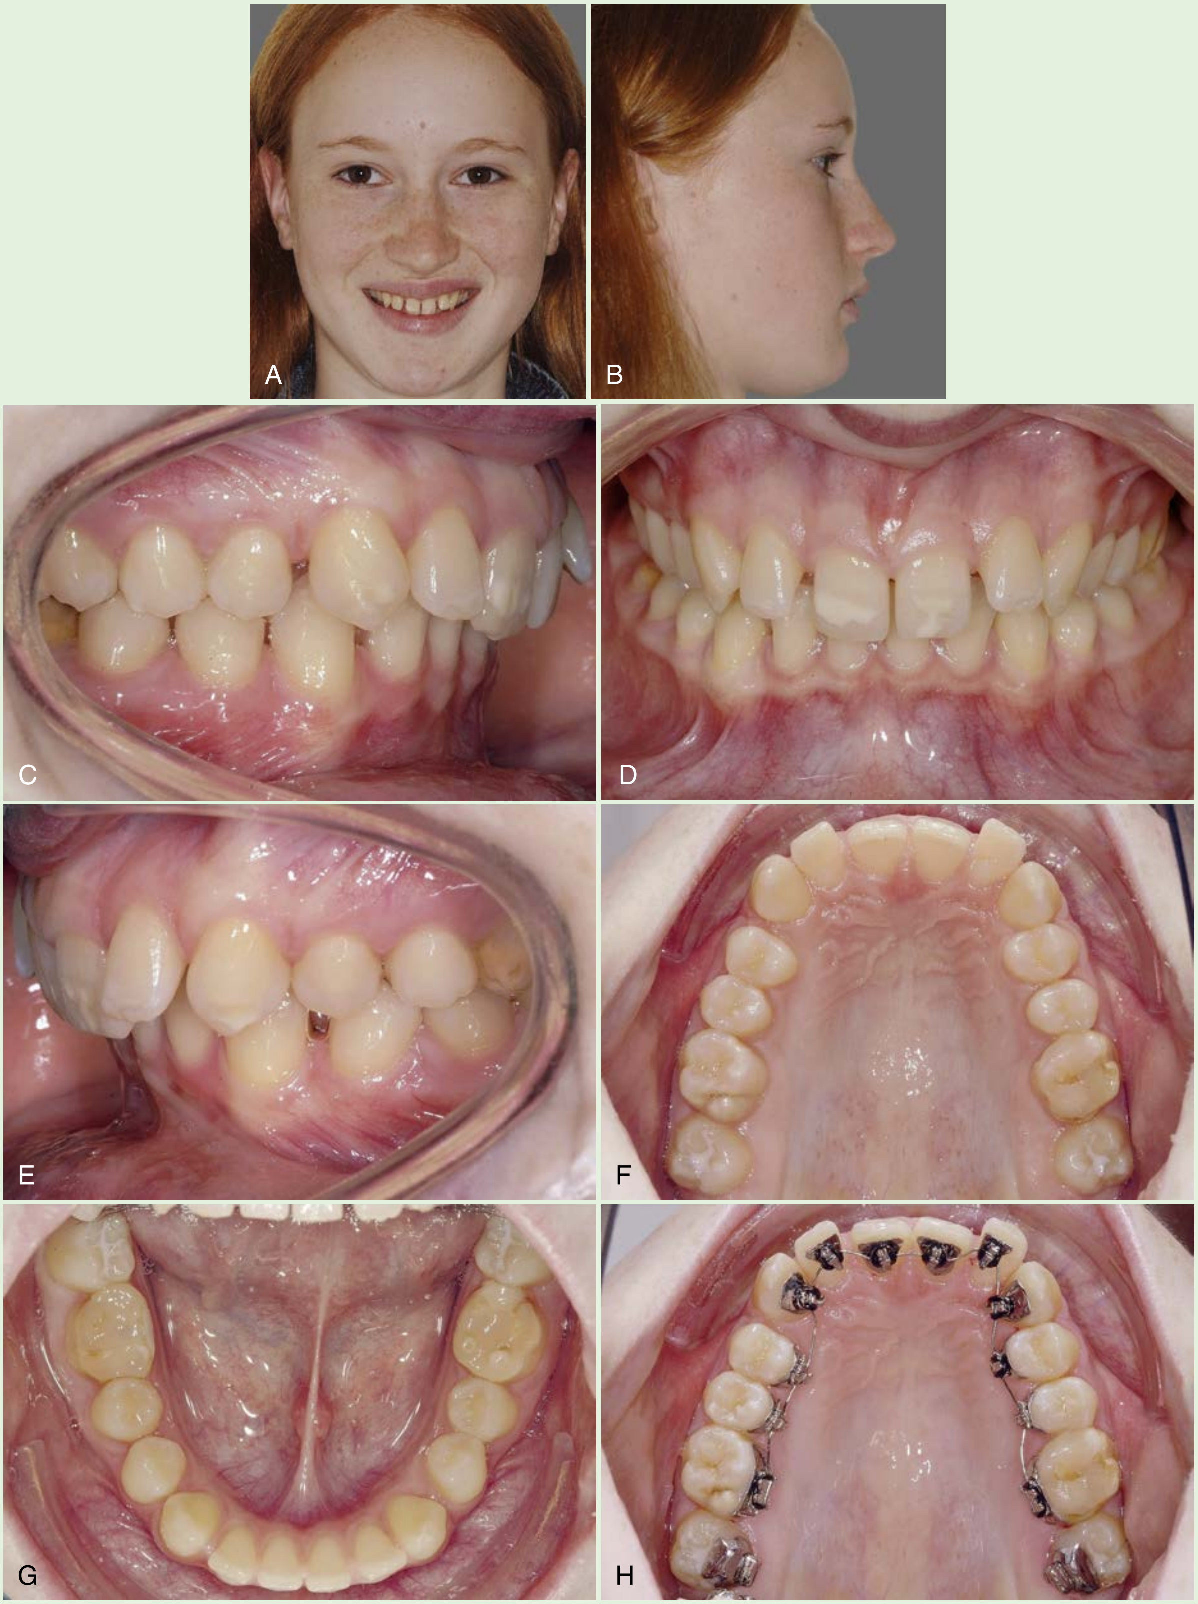

FIGURE 25-9 A–G, A 14-year-old patient with a bilateral full Class II malocclusion and retroclined upper incisors. All first molars had an enamel defect that was restored with composite. Both the upper central incisors and upper canines showed negative torque.

CASE STUDY 25-2 LINGUAL TREATMENT OF CHILDREN AND ADOLESCENTS: NONEXTRACTION CASE WITH USE OF CLASS II ELASTICS—cont'd

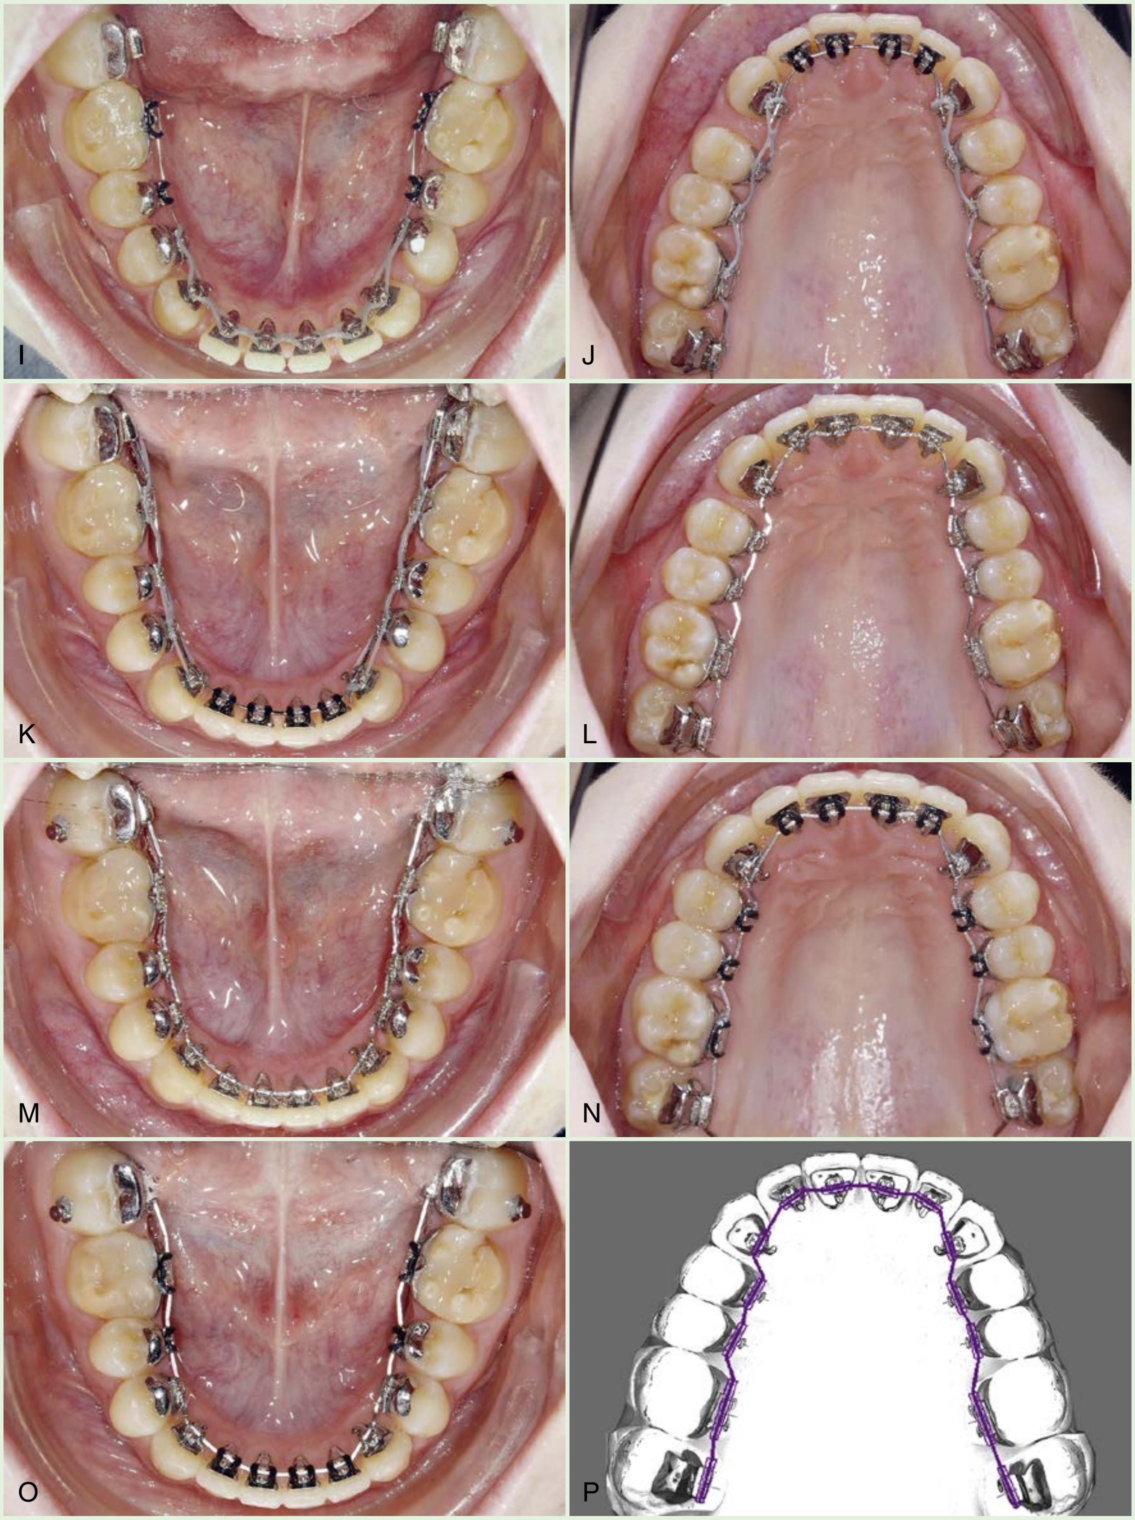

FIGURE 25-9, cont'd **H, I,** All brackets were bonded in the first appointment. 0.012-inch round NiTi archwires were placed in both arches. To prevent further space opening during leveling, a prestretched power chain was used in the lower arch. Partial extension of the bracket bases on the occlusal surfaces of all second molars helped to prevent bracket debonding and opened the bite. **J, K,** 0.016- × 0.022-inch NiTi archwires were placed in both arches for further leveling and aligning. No over-ties were used. **L, M,** 0.016- x 0.024-inch stainless steel archwires were placed in both arches. The upper archwire had extra torque of 13 degrees in the anterior region from canine to canine. Buttons were bonded on the labial surface of the lower second molars for Class II elastic wear. **N, O,** After achievement of slight overcorrection of the Class II relationship, 0.018- × 0.018-inch beta-titanium archwires were placed in both arches. To prevent space reopening, the wires were vertically bent back distal to the second molars in both arches.

CASE STUDY 25-2 LINGUAL TREATMENT OF CHILDREN AND ADOLESCENTS: NONEXTRACTION CASE WITH USE OF CLASS II ELASTICS—cont'd

FIGURE 25-9, cont'd **P, Q,** The final result and the treatment plan are compared by way of overlying the virtual wire on the treated model in the occlusal view. Total treatment time was 19 months. **R, S,** Upper and lower bonded retainers were placed for retention. The patient was asked to wear a night activator to stabilize the anteroposterior correction. **T–V,** At the end of leveling and aligning, the torque in the upper front teeth was too negative and prevented achieving a Class I relationship. The torque of the upper canines was also a major obstacle for the lower canines to move forward.

Continued

CASE STUDY 25-2 LINGUAL TREATMENT OF CHILDREN AND ADOLESCENTS: NONEXTRACTION CASE WITH USE OF CLASS II ELASTICS—cont'd

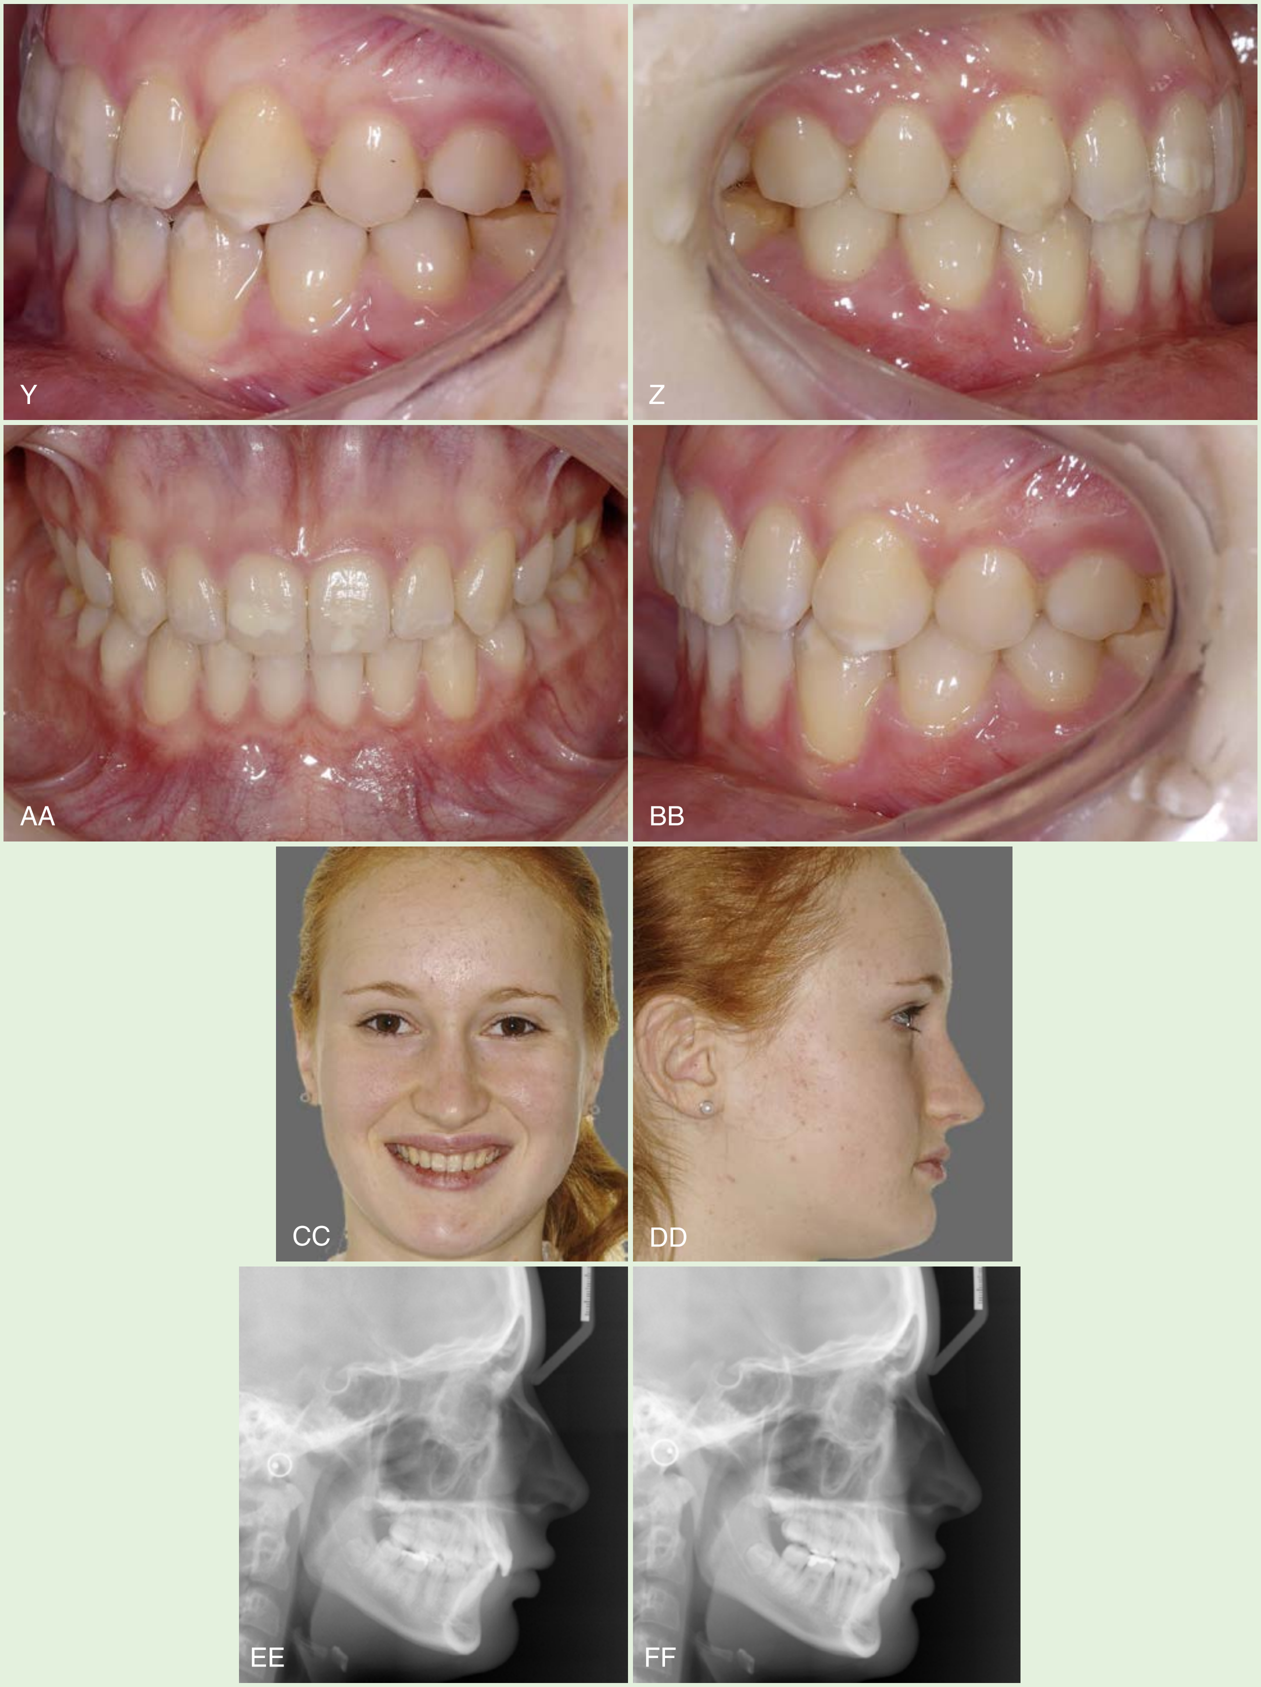

FIGURE 25-9, cont'd W—Y, Torque was corrected with the upper 0.016- × 0.024-inch stainless steel archwire mainly because of the extra torque built into the anterior area of the wire. Continued attention to torque management is critical to anterior retraction in lingual appliances because of the lingual bracket placement relative to the center of tooth rotation. The patient had to wear Class II elastics full time. Z–DD, Final results after 19 months of lingual treatment.

CASE STUDY 25-2 LINGUAL TREATMENT OF CHILDREN AND ADOLESCENTS: NONEXTRACTION CASE WITH USE OF CLASS II ELASTICS—cont'd

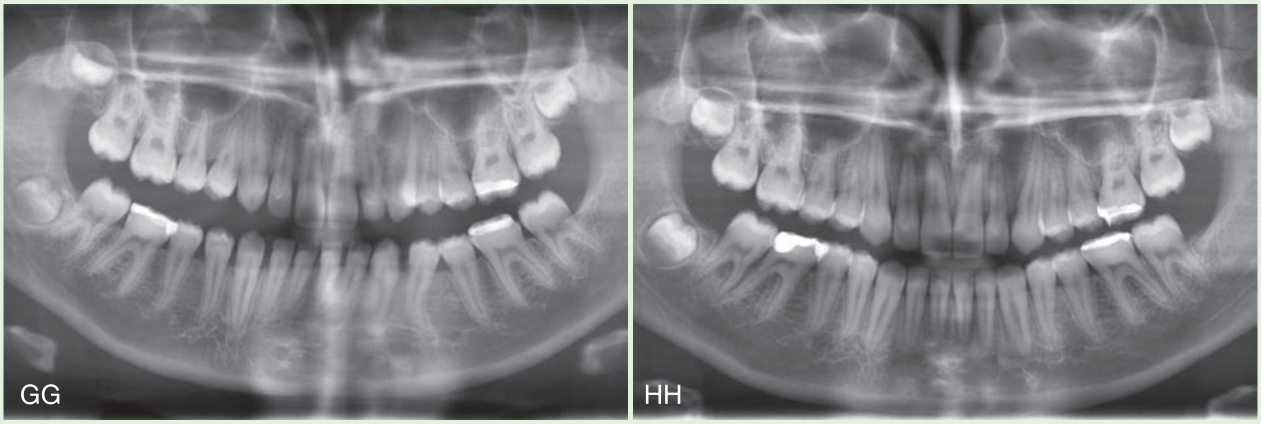

FIGURE 25-9, cont'd **EE, FF,** The lateral headfilm shows excellent torque control in both arches. Lower incisor proclination was prevented. **GG, HH,** The panoramic radiograph shows good tip control.

Clear Aligner Treatment

David E. Paquette, Clark Colville, and Timothy Wheeler

OUTLINE

BRIEF HISTORY OF CLEAR ALIGNER TREATMENT

Invisalign is an orthodontic technique that uses a series of computer-generated custom plastic aligners to guide the teeth gradually into proper alignment. Although the use of clear aligner treatment is not new, it is a growing part of the orthodontic market, and, as a result, many new products have become available. The concept on which treatment with clear aligners is based has been around since the 1940s. In 1945, H. D. Kesling[1] suggested that a series of tooth positioners be used to produce the types of movements that are needed for orthodontic treatment. Some years later, Nahoum[2] described a method to change tooth contours using thermoformed plastic. In 1971, Pontiz[3] introduced a thermoformed plastic appliance called the "invisible retainer" made on a master model that repositioned teeth with base-plate wax. He claimed that this appliance could produce limited tooth movement. McNamara and others[4] also described using invisible retainers to achieve minor tooth movement. Sheridan and colleagues[5] later developed a technique involving interproximal tooth reduction and progressive alignment using clear Essix appliances, and those techniques were further developed by Hilliard and Sheridan[6] with a series of special thermoforming pliers designed to enhance specific movements. Although these techniques based on Kesling's proposal of using removable appliances have been used to some degree in the past, the laboratory construction has always been tedious and has previously limited the widespread adoption of removable aligner techniques.

Clear aligners can be categorized into four basic categories as presented in Tables 26-1 to 26-4. Table 26-1 lists what are commonly known as positioners or guides along with their manufacturers, common use, and the material of which they are made. This category includes the original Allesee Orthodontic Appliances (AOA) positioner described by Kesling.[1] The second category (see Table 26-2) consists of those thermoformed appliances, sometimes known as Essix Retainers (Raintree Essix, DENTSPLY International, York, PA) and removable appliances referred to as spring aligners. The Essix appliance can be fabricated in the orthodontist's office or sent to a commercial laboratory, and it uses the techniques of Sheridan and Hilliard to move teeth. Table 26-3 lists those aligners that are fabricated from models that have had teeth cut out and manually moved to the correct position. If done in a series of models, an aligner can be fabricated from each model. These appliances can be used for minor movement of upper and lower anterior teeth and usually consist of three to five aligners. The last category, aligners fabricated from digitally manipulated models (see Table 26-4), is the largest growing area in aligner treatment. This growth is most likely attributable to the ability of these aligners to be used to treat malocclusions ranging from minor to complex, including both posterior and anterior teeth. Using digital technology to control tooth movement, intricate and precise tooth movements can be staged for each sequential aligner. However, tooth movement with aligners is as variable as it is with fixed appliances and can be dependent on individual variables (e.g., periodontal status, age, medication), as well as aligner variables (e.g., attachments, plastic). In this category, and the focus of this chapter, is Invisalign (Align Technology, Inc., Santa Clara, CA).

As a technique, Invisalign has now been commercially available to orthodontists since 1998. Invisalign treatment has a terminology that differs from traditional fixed appliances. A *midcourse correction* involves a temporary pause in treatment while a new scan is taken or impressions are made; treatment is then continued once new aligners are fabricated. The reasons for this midcourse correction can be many and include the following: lack of patient compliance; midtreatment restorative that rendered the current set of aligners unusable as a result of tooth morphologic structure; lack of one or more teeth tracking with aligners as planned, making the fit of the aligners unacceptable;

TABLE 26-1 Aligners Currently Available: Positioner and Guides

Product Name	Manufacturer	Description	Use	Material
Orthodontics Positioner	TP Orthodontics, Inc.	Custom stone setup done to finish	Remove braces 3–6 months earlier	Soft rubber or Crystal-Flex
Orthodontic Positioner	AOA	Custom setup on articulator	Minor tooth movement	Polyurethane
Nite-Guide; Occlus-o-Guide; Ortho-T; Preformed Positioner	Ortho-Tain	Premade guides for ages 5 years to adult	Arch formation and guided eruption; minor tooth movement	Polyurethane
Myobrace i-3, i-2, Myobrace	MRC	Premade guides for ages 2 years to adult; soft trainer and hard Myobrace Inner hard core and outer soft	Myofunctional development Use Frankel principles	Soft: silicone Hard: polyurethane

TABLE 26-3 Aligners Currently Available: Teeth Manually Reset

Product Name	Manufacturer	Description	Use	Material
Clear Image Aligners	Specialty Appliances	Up to 4 aligners/arch initially	Minor movement of U/L anterior teeth	No information
Red White Blue Simpli[5]	Ormoc AOA	Up to 3 aligners/arch Up to 5 aligners/arch; uses assist attachments	Minor movement of U/L anterior teeth; Move teeth up to 2.5 mm/tooth	No information
Triple Play	Ortho Organizers	Up to 3 aligners/arch	Minor movement of U/L anterior teeth	No information
MTM Clear Aligner	DENTSPLY International	No attachments; available as in-office and lab-created versions	Minor movement of U/L anterior teeth	Raintree Essix ACE: Copolyester-proprietary
Originator Clear Aligner System	TP Orthodontics	Available in 0.020-, 0.030-, 0.040-inch thickness	Minor to moderate U/L anterior crowding or spacing	
EZ-Align	Dynaflex	Up to 5 aligners	Minor movement of U/L anterior teeth	Dynaflex: Copolyester
Dual Laminate	TruTrain			Copolyester-PETG (hard/soft laminate)
Smart Moves	Great Lakes	Up to 3 setups/impression; 2 aligners/setup (1 hard aligner with soft center, 1 hard aligner) Individual tooth movement up to 1.0 mm/setup	Minor movement of U/L anterior teeth	Invisacryl: Copolyester proprietary
Graham Orthodontic Aligner	Graham Tool Co.		Anterior: 1–3-mm crowding; 1–2-mm spacing	Polyester-PETG (.040 inch)

AOA, Allesee Orthodontic Appliances; *MTM,* Minor Tooth Movement; *NiTi,* nickel titanium; *PETG,* polyethylene terephthalate glycol; *U/L,* upper and lower.

or a change in the treatment plan. Many orthodontists consider midcourse correction to be similar in concept to repositioning brackets partway through treatment with fixed appliances. Another term unique to aligner treatment is *refinement.* Refinement is similar to midcourse correction in that it generally involves pausing treatment and taking new impressions and ordering a new series of aligners. The only difference is that refinement takes place near the end of treatment when one or more teeth are apparently not positioned exactly as desired. This malposition could be attributable to small amounts of permanent distortion of the aligners, resulting in actual tooth positions that do not match the virtual treatment plan, or it could be because insufficient attention was paid to the details during the virtual setup phase. In any event, to achieve the desired results, another series of aligners is required. Refinement can be considered similar to artistic detail bends with fixed appliances. The final term unique to aligner treatment is *attachment*. Attachments are small composite additions to the tooth surface that

TABLE 26-4 **Aligners Currently Available: Teeth Digitally Reset**

Product Name	Manufacturer	Description	Use	Material
Invisalign Full, Invisalign Teen, Invisalign Assist, Invisalign Express 10, Invisalign Express 5	Align Technology, Inc.	Number of aligners dependent on treatment; simultaneous tooth movement of all teeth; SmartForce features (attachments, torque, bite opening)	Range from minor anterior tooth movement to complex treatment of all teeth	SmartTrack: Multilayer polyurethane and copolyester proprietary material (released in 2013)
Insignia: Clearguide Express	Ormco AOA	Up to 10 aligners/arch Move tooth up to 2.5 mm/tooth (0.25 mm/aligner) Monitor movement with "Heat N Bite"	Alignment of U/L anterior teeth	No information
Vivid Aligners	ODL	Sets of 3–5 aligners ; move tooth up to 0.5 mm/tooth		Zendura: rigid polyurethane
ClearCorrect	ClearCorrect	Aligners created in phases; models included to fabricate replacement aligners	Range from minor anterior tooth movement to treatment of all teeth	Zendura: rigid polyurethane
Minor Alignment Correction	Digi3DWorks	Return model with teeth moved for aligner to be made in office; will make aligner if desired	Alignment of U/L anterior teeth	Raintree Essix ACE: Copolyester proprietary
Clarus Clear Aligners	Clarus (Egypt)	Use attachments, buttons, and elastics Standard aligner: 4 aligners/mo, each worn for 1 wk, movement 0.5–0.7 mm/mo Smart aligner: 2 aligners/mo, each worn for 2 wks, movement 1.0 mm/mo	Range from minor anterior tooth movement to treatment of all teeth	Standard clear aligner material unknown; Smart clear aligner material unknown
AIRAligner	Nivol (Italy)	AIR One (one arch treatment); AIR Light (treatment of both arches <22 aligners); AIR Complete of (treatment both arches >22 aligners)	Move all teeth	No information
TwinAlignerSystem	Orthocaps (Germany)	Two aligners: hardCAPS for day wear, softCAPS for night wear	Move all teeth	hardCAPS, softCAPS: no information
In-LineClear Aligners	In-Line Orthodontic UK Ltd.	Twin layer laminate aligner; moves teeth up to 0.6 mm/aligner; aligner wear for 4–6 wks; IPR performed for anterior crowding	Minor to moderate U/L anterior crowding or spacing	No information
Clear aligners	NimroDENTAL Orthodontic Solutions (UK)	Few aligners	Minor U/L anterior crowding	No information

enhance areas of undercut either for retention or to facilitate specific movements. (Attachment design and placement are also discussed in greater detail later in this chapter.)

SCANNING AND DIGITIZATION

The unique combination of computerized virtual treatment planning and the first of its kind use of stereolithographic rapid prototyping technology for mass custom manufacturing gave Invisalign a commanding leadership role in aligner therapy. Over the course of the first decade of custom manufactured aligner treatment, the treating physician was required to obtain highly accurate impressions that were then sent to the manufacturing entity where the impressions were converted into digital data using industrial three-dimensional radiography.

The advent of intraoral scanners has made the process of digitization simpler and has eliminated the need for a third party to convert an impression into a virtual model. An instant virtual model from an intraoral scanner, in combination with multiple software platforms, now allows the orthodontist to manipulate teeth with or without the assistance of a technician. That, along with a three-dimensional printer, allows the orthodontist to make aligners easily in his or her office once the cost of the three components (scanner, software, and three-dimensional printer) becomes more affordable.

Let's look at intraoral scanners as the first step in the process. Every current scanner has a hand-held wand containing a camera that is connected to a computer for data collection and manipulation. The wand may project either laser or white light onto the tooth surface where it is reflected back to the camera, after which hundreds of thousands of measurements per inch are performed to recreate the three-dimensional representation of the teeth.

All intraoral scanning technologies using a wand have had to deal with cross-arch distortion as the information is stitched together to form a full arch image. Cross-arch distortion has not been as much of an issue in restorative dentistry because full-arch restorations are rare. In orthodontics, cross-arch distortion will result in orthodontic appliances that simply do not properly fit. Fortunately, the scanner manufacturers have managed to correct such distortions. The technology engineered into the wand, which captures the surface data, determines the measurement speed, resolution, and accuracy of the scanner. Four types of imaging technologies are currently used: (1) triangulation, (2) parallel confocal imaging, (3) accordion fringe interferometry, and (4) three-dimensional in-motion video. In addition, intraoral ultrasound scanning, although not yet commercially available, is currently in development and should soon be released. Let's review each imaging technology in order.

CEREC (**C**hairside **E**conomical **R**estoration of **E**sthetic **C**eramics or **CE**ramic **REC**onstruction) (Sirona USA, Charlotte, NC) was the first in-office intraoral scanner introduced to dentistry in the early 1980s. It was originally developed to scan a crown preparation and then to send the data to a milling machine to create single crowns in the office without the need for impressions. CEREC works using triangulation. This technique measures the angles and distances from known points (laser source and sensor) with projected laser light. This technology requires a thin coating of opaque powder to be applied to the target tissue. The CEREC system determines the angle of reflection and the distance from the laser source to the object's surface as light reflects off the object.

Parallel confocal imaging (iTero, Align Technology, Inc., Santa Clara, CA) projects laser light through a pinhole to the target. The sensor is placed at the imaging plane where it is in focus (confocal). A small opening in front of the sensor blocks any light from above or below. Only the focused light reflecting off the target tissue will reach the sensor for processing. This type of system creates thousands of tomographic slices and stitches them together to form the three-dimensional picture.

Two sources of light are used with accordion fringe interferometry (AFI) to project three patterns of light, called "fringe patterns," onto the teeth and tissue (True Definition Scanner, 3M ESPE, St. Paul, MN). Based on the shape of the object, the fringe pattern distorts and takes on a new pattern. Surface data points of the fringe curvature are recorded by a high-definition video camera that is offset from the projector by approximately 30 degrees. Because the differences among the three precision optical measurements determine the distance measurement, the differential measurement is unaffected by changes in tooth colors and materials.

Three-dimensional, in-motion video (Lythos Digital Impression Systems, Ormco Corporation, Orange, CA) uses three tiny high-definition video cameras at the lens to capture three precise views of the target. A sensor behind the cameras converts the light energy into electrical signals, which allows the distances between two data points to be calculated simultaneously from two perspectives to create the three-dimensional data. The data points are captured in a video sequence and modeled in real time. Although powdering may be required to capture surface data points, only a light dusting is needed, compared with the thicker coating needed for triangulation. The ClearView SCAN (S-Ray Incorporated, Reno, NV), uses high-definition ultrasound imaging to capture both the tooth and the bone and soft tissue in three dimensions. Early prototypes suggest that these scans will use a disposable mouthpiece to scan the entire arch at once and will be significantly faster and more accurate than light-based scans.

The second part of the process is integrating the software that provides the ability for the technician or orthodontist to manipulate teeth in preparation for manufacturing aligners. The software must accomplish two things. First, it must fill any voids in the scan itself to produce a workable model; second, it must allow for tooth segregation and three-dimensional manipulation to produce the intended final setup. Furthermore, the amount of movement per aligner or stage must be determined by either the orthodontist with a three-dimensional digital orthodontic system (Orchestrate Orthodontic Technologies, Rialto, CA) or be programmed into the software in the form of a proprietary algorithm (Invisalign). If the aligners are manufactured by a vendor, then the orthodontist simply orders them once the setup is complete, and the rest is taken care of by the vendor of his or her choice.

If the orthodontist should decide that he or she wants to manufacture his or her own aligners, then a three-dimensional printer is required to produce the models on which the aligners will be formed. At the time of this writing, the three-dimensional printers with adequate resolution for fabricating aligners are still too expensive for the average orthodontist ($40,000 to $50,000). However, similar to most technologic advancements, the cost for these printers continues to decrease; it is not unreasonable that, in the very near future, in-office three-dimensional printing will be routine. Having said that, reviewing the four types of three-dimensional printers currently available is appropriate.

All three-dimensional printers build the object (for orthodontics a model of the teeth) in layers. The height of the model and the thickness of each layer determine how long it takes to print. Objects may be printed out of a variety of substances, depending on the printer and the intended use of the object. In **stereolithography**, liquid resin is held in a build tray and cured layer by layer with an ultraviolet laser light that "draws" a cross-section or outline of each layer in a bottom-up sequence until the model is submerged in the resin bath by the thickness of the build layer for each pass of the laser. Align Technology uses **stereolithography (SLA) models** to manufacture Invisalign. **Fused deposit modeling (FDM)** lays down layers of material heated just beyond its melting point, and the material immediately hardens as each layer is applied. The material in FDM printing is generally held on a replaceable spool. **Digital light processing (DLP)** is based on a chip technology developed by Texas Instruments and is commonly used in home theater projectors. With DLP printers, the process is similar to SLA modeling; however, an entire layer is cured at once, resulting in faster build times and a smoother surface finish. **PolyJet photopolymerization (PPP) printers** are similar to inkjet printers, but PPP printers work in three dimensions rather than two. In PPP printers, the material is sprayed out of nozzles and immediately cured with ultraviolet light. With some models, the build layers can be quite thin, resulting in minimal surface stratification. Similar to all technology, three-dimensional printers require routine maintenance for proper operation, as well as the selection of proper materials, the cost of which varies among both the manufacturer and the type of printer.

It would be remiss not to mention four-dimensional printing, the brainchild of Dr. Skylar Tibbits at Massachusetts Institute of Technology (MIT). Four-dimensional printing involves using three-dimensional printing and special geometric properties along with material characteristics to print objects that can change their configuration based on outside influences, such as motion or pressure. Imagine an aligner that creates its own dimple by increasing the pressure in a specific place on the tooth if the tooth failed to respond as anticipated. This feature is only one aspect of four-dimensional printing that may assist orthodontists in improving efficiency and outcomes with aligner treatment.

DIAGNOSIS AND TREATMENT PLANNING FOR CLEAR ALIGNER TREATMENT

Diagnosis and treatment planning are the cornerstones for successful outcomes in orthodontic treatment. As described by Proffit in *Contemporary Orthodontics*,[7] the clinical examination, health history, and evaluation of quality diagnostic records lead to the development of a prioritized problem list. This problem list is further synthesized to produce realistic treatment objectives to correct the individual problems. The individual treatment objectives are then sequentially prioritized to form the optimal treatment plan. Specific mechanotherapy or force systems are then selected to achieve the treatment goals. The choice of one particular appliance or force system over another is a personal preference and infers that often more than one specific treatment plan is capable of producing the desired results.

As reported by Owens and colleagues[8] in 2006, the American Board of Orthodontics (ABO) developed the Case Management Form (CMF), which provides an objective tool to establish definitive treatment goals for the three major areas in the orthodontic treatment plan—skeletal analysis, dental analysis, and facial analysis. Based on the analysis of pretreatment records, the candidate records definitive therapeutic treatment goals for each of the three areas in three planes of space—vertical, sagittal, and transverse. The CMF defines the treatment goals for each of the tissues that can be altered during the orthodontic treatment. Treatment modalities (mechanotherapy or force systems) have the potential to affect each of the tissues. Some forms of mechanotherapy are specifically targeted to correct skeletal structures, such as a Hyrax appliance for the transverse correction of a narrow maxilla and a Herbst appliance designed to affect both the skeletal and the dental components in the patient with a deficient mandible. Clear aligner therapy provides a specifically controlled force system that primarily affects the maxillary and mandibular dentition in all three planes of space. Growing patients wearing aligners have the potential to have a small effect on the maxilla and the mandible, whereas in adults, the effect will be negligible.

Treatment planning, when considering clear aligner treatment using Invisalign-branded clear aligners, combines the process introduced by Proffit, Owens, and others. First, the determination should be made that clear aligner treatment is the appropriate force system, based on the treatment goals derived from the prioritized treatment objectives. More to the point, clear aligners are tooth-moving appliances that have very minimal impact on skeletal structures. Therefore clear aligners would not be the appropriate force system for transverse skeletal problems or for severe sagittal problems attributable to poorly aligned skeletal structures. Clear aligners are well suited and appropriate when the treatment goals can be achieved by tooth movement in all three planes of space. Examples are numerous and include all sagittal Angle molar classifications, with mild to moderate corrections in the transverse and vertical planes. Understanding the capabilities and limitations of moving teeth with clear aligners is essential to determining when their use is appropriate. The second part of treatment planning begins when the prescription form is submitted to Align Technology. The Invisalign prescription walks through a list of treatment objectives, and the orthodontist indicates how the treatment objectives should be achieved in the virtual setup. Having specific goals for the amount and direction of desired tooth movement in all three planes of space helps the orthodontist guide the technician to provide the initial setup that reflects the desired treatment result.

CLINCHECK—AN OVERVIEW

The virtual setup for Invisalign-branded clear aligner treatment is viewed by the orthodontist in a software program called ClinCheck. ClinCheck is not *the* treatment plan; rather, it is the three-dimensional interpretation of the treatment plan by the technician from the prescription form submitted online. The goal of the virtual setup, when modified and completed by the orthodontist, is to make the individual tooth movements shown in the ClinCheck depict the actual individual tooth movements required to correct the malocclusion. Strict attention to each crown and to the root movement in all three planes of space is required. A common misconception is that the technician providing the initial setup has diagnosed the patient's malocclusion and has sent back a ClinCheck treatment plan that is ready for approval. The technician is neither qualified nor responsible for delivering a treatment plan for the patient. The technician's responsibility is to provide a virtual set-up that (a) follows the instructions on the prescription form and (b) delivers tooth movements that fall within the predetermined defaults of Invisalign's Treat software. Although technicians receive training in basic occlusion principles and are well versed in orthodontic terminology, they do not have benefit of orthodontic training that incorporates biological principles of tooth movement, including concepts such as anchorage, reciprocal forces, and biomechanics. The technician uses a very robust proprietary software called Treat, and the orthodontist's interface with that program is a scaled-down version called ClinCheck. Treat software, although robust, is not a substitute for the didactic training received by an orthodontist in a postgraduate residency program.

Once the orthodontist has completed the virtual setup, the true power of the Treat program is exhibited by the application of SmartForce enhancements. SmartForce features are patented engineered solutions designed to create precise biomechanical forces on selected teeth or groups of teeth. Research and development of the SmartForce features, combined with the proprietary plastic, are unique to Invisalign. (SmartForce features are listed in Table 26-5.) These enhancements generally consist of customized computer-designed attachments added to the tooth surface or pressure areas applied to the tooth surface created by altering the digital model before fabricating the aligner. These features are discussed in further detail when discussing the biomechanics of tooth movement. Noting that SmartForce features are specific only to Invisalign-branded clear aligners is impor tant. The treating orthodontist will enhance the predictability of treatment outcomes by gaining a thorough understanding of all the SmartForce features and the defaults that cause them to be applied to the virtual setup.

ClinCheck is also a proprietary software program unique to Invisalign-branded clear aligners. The treating orthodontist uses ClinCheck software to review the initial setup provided by the technician and to make modifications to the virtual setup until the desired tooth movements are displayed, at which time

the treatment is approved and the aligners are manufactured. ClinCheck Pro (v4.1) is the most recent version of the software. ClinCheck Pro allows the orthodontist to control individual tooth movements in all three planes of space. In addition, arch shape can be changed by expanding or narrowing the posterior segments. All changes made by the orthodontist appear in real time with immediate adjustments automatically performed to adjacent teeth and arch form. All communications between the orthodontist and the technician are displayed on the right of the ClinCheck homepage and are listed in chronological order from the newest to the oldest, enabling all previous communications to be reviewed at any time (Fig. 26-1). ClinCheck Pro, with its ability to control tooth and arch movement, is a paradigm shift in the way orthodontists now achieve the desired virtual setup. Before the release of ClinCheck Pro (v3.1) in 2014, written communication with the technician was required to make modifications to the virtual treatment plan and often presented a barrier to getting the exact setup desired by the orthodontist. Another problem with previous versions was the inability to see the values for each tooth movement. The orthodontist had limited tools to assess the amount of tooth movement—a superimposition tool and a millimeter grid. Although these tools were helpful, they were inadequate to evaluate small changes in all three planes of space. The process of requesting changes and waiting to see the results was time consuming and often required multiple modifications before the treatment was accepted. With the introduction of ClinCheck Pro (v3.1) and subsequent updates in ClinCheck Pro (v4.1), the value of tooth movement measured to within hundredths of a millimeter are displayed on the bottom of the screen (Fig. 26-2). Orthodontists can now couple the proposed tooth movements in their treatment plans to the virtual setup and verify that all tooth movements are accurate in all three planes of space. The orthodontist's control of tooth movement not only increases the accuracy of the final positioning of the teeth, but it also saves considerable time by requiring fewer modifications.

BIOMECHANICS OF ALIGNER TREATMENT

Control of root position and anchorage is often the greatest challenge faced by any orthodontist. The question then becomes: Is treatment with Invisalign a practical alternative to fixed appliances? Several authors have examined the outcomes of Invisalign treatments. Patel and colleagues[9] found significant improvement in the peer assessment rating (PAR) index in patients treated with Invisalign. Vincent[10] found improvements in the ABO objective grading system (OGS) with tooth alignment but not in posterior occlusal contacts. Djeu and colleagues[11] compared Invisalign with fixed appliances and found the ABO OGS scores were improved more for the fixed appliance group than for the aligner group, whereas Brown and others[12] reported that, overall, Invisalign was found to be more effective than fixed appliances at producing the outcome defined by the OGS. In a systematic review in 2005, Lagravere and Flores-Mir[13] found the literature lacking and concluded that "Clinicians will have to rely on their Invisalign clinical experience, the opinions of experts and the limited published evidence when using Invisalign appliances." After the following section on biomechanics and Invisalign, the authors of this text hope the reader will be better equipped to make sound clinical decisions and have a greater understanding of the strengths and weaknesses of aligners.

One question to keep in mind during this entire discussion of biomechanics is the following: If teeth were capable of cognition, would they know what was applying the force? In 1999, Sims[14] predicted the future of orthodontics would include the abolition of bracket systems. In his 1986 textbook *Contemporary Orthodontics*,[15] Proffit stated that "adult patients traditionally have been somewhat reluctant to wear obvious fixed appliances and frequently indicate their preference for a removable appliance." He also described the characteristics required of an orthodontic appliance system. "No matter what the type of orthodontic appliance, it must meet certain basic design criteria: it (1) should not interfere with function; (2) should cause no harm to the oral tissues or interfere with the maintenance of good oral hygiene; (3) should be as light and inconspicuous as possible, yet sufficiently strong to withstand masticatory forces and a reasonable amount of abuse; (4) must be firmly retained in position; (5) must be capable of exerting an appropriately controlled force in the correct direction and delivering this force

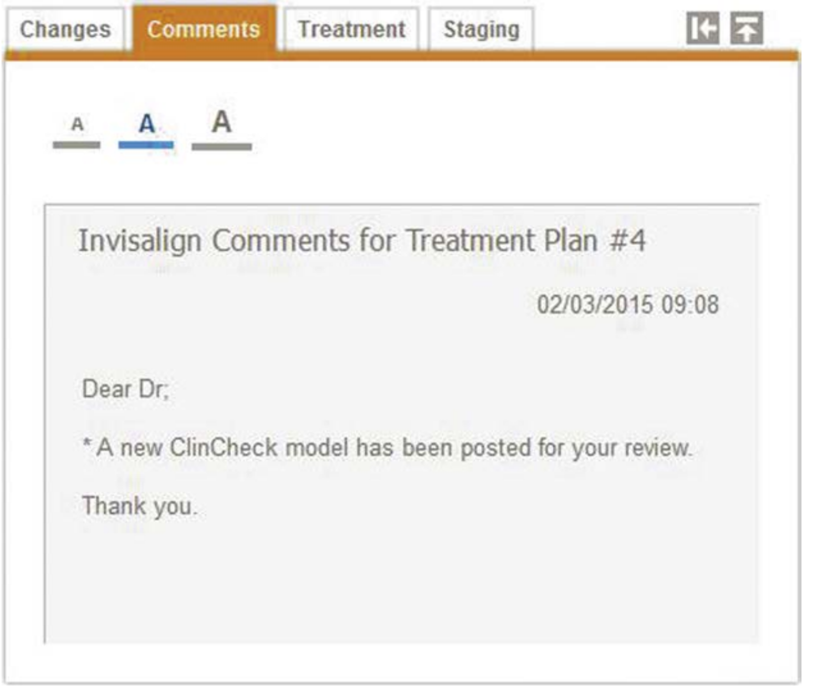

FIGURE 26-1 ClinCheck comments. (Courtesy of Align Technology, Inc.)

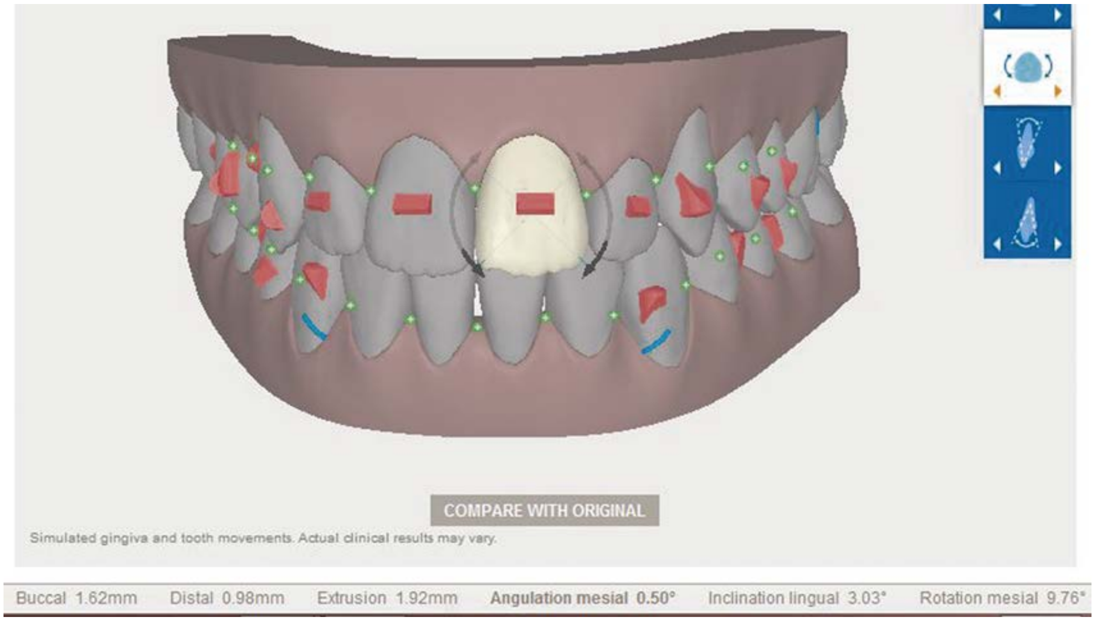

FIGURE 26-2 ClinCheck values of tooth movement. (Courtesy of Align Technology, Inc.)

for as long as possible between adjustment visits; and (6) should allow control of anchorage so that tooth movements other than those intended are minimized." On the surface, it would appear that Invisalign satisfies all of these criteria.

According to Proffit,[15] "removable appliances by their very nature produce simple tipping movements of teeth, making control of tooth position extremely difficult" and "as a practical matter, it can be difficult to maintain removable appliances in place against the displacing effects" of the forces required to produce controlled root movement. He concluded that the usual solution to this problem was to use fixed appliances. When describing the experiences with Invisalign at the University of the Pacific, Dugoni[16] wrote in 2002, "We then went on to patients in whom the mandibular incisors would have to be extracted to determine whether we could close those spaces in a parallel manner. This involved changes not only in the material but also in the technique. Ultimately, we were able to move the teeth bodily. Experimentation has continued with extraction cases to determine whether we could bodily move canines into first premolar positions after extractions." His conclusion was that "the use of the Aligners is far more complicated than most people believe. It takes a knowledgeable clinician with considerable experience to use the appliance to its maximum. What that maximum is, I do not know."

To determine what the maximum might be with Invisalign in its current rendition of aligner materials, we must first examine the biomechanics of tooth movement with Invisalign.

Simple versus Difficult Movements

To examine the biomechanics of tooth movement with aligners, how aligners move teeth will first be described. With a typical fixed appliance, the wire is engaged in a bracket with the adhesive retaining the bracket on the tooth. The active archwire is elastically deformed and moves the tooth to a determined position as it returns to its original shape. With an aligner, the plastic encapsulates the tooth and, in doing so, must provide both retention and activation to move the teeth. In general, the natural undercuts of the teeth provide the retention and the active component to move teeth by the elastic deformation of the aligner, which is important for two reasons. First, the aligner elastic deformation cannot be as great as to overcome the retention forces; and second, certain directions allow the aligner a greater inherent ability to undergo elastic deformation. For instance, a faciolingual movement is fairly predictable because the entire body of the aligner can be elastically distorted; it then returns to its original shape, carrying the tooth with it. The total desired movement is then subdivided in such a way that the aligners remain within this range of elastic deformation, and a sequence of aligners is made to accomplish the entire desired movement. The number of aligners or stages, then, is based on the distance the tooth must be moved. In contrast, a vertical movement would require the aligner to stretch essentially within the matrix of the plastic and, at the same time, maintain retention of the tooth it is attempting to move. Because the ability for such elasticity within the plastic itself is very limited, these movements must be divided into very small increments and are considered difficult. Given this understanding of the basic nature of how aligners move teeth, it is not surprising that multiple movements are considered unpredictable with aligners. Some of these difficult movements include controlling torque, root parallelism, rotations, and extrusions. These issues are discussed within the context of traditional orthodontic biomechanics, specifically how aligners deal with forces and moments. The purpose of this chapter is not to provide a detailed review of orthodontic biomechanics; rather, its purpose is to discuss how aligners relate to these concepts.

The material composition of the aligner is important in delivering the desired properties to the aligner. Aligners are comprised of polyurethane, polyester, or some combination or modification of such (see Tables 26-1 through 26-4). Ideally, aligner plastic should be the appropriate stiffness to deliver a constant force. To accomplish this, the stress relaxation of the material needs to be low to ensure that the delivered force is constant. The material should be of high enough formability to enable it to conform precisely to teeth and to any attachments that may exist. Aligner plastic should be highly elastic; when it is stretched, it will return to the shape similar to an archwire should when activated. Last, the material should be highly aesthetic and comfortable for the patient to wear. Previous studies[17] have shown that aligners have less impact on the quality of life and less pain than orthodontic treatment with traditional braces. Research is currently being conducted in the area of aligner thermoplastics to examine the impact of aligner thickness[18] and the other force delivery properties of aligners.[19-22] It should be noted that the basis of current discussion using Invisalign is the proprietary plastic used to make the aligners known as SmartTrack (Align Technology, Inc.), a biocompatible multilayer thermoplastic polymer comprised of polyurethane and a copolyester, which was released in early 2013. A recent study[23] showed that the SmartTrack material achieved a significantly higher amount of prescribed tooth movement than the previous Align Technology's Exceed-30 aligner material that was used before 2013. Over the course of the past 20 years, the levels of force thought to be required to perform different movements has steadily decreased (see Table 26-1).

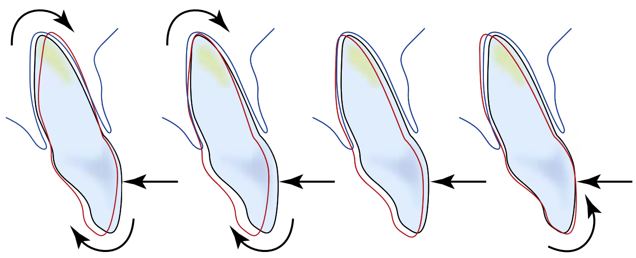

FIGURE 26-3 Effect of moment-to-force (M/F) ratios.

Continuing with that trend, recent studies have suggested that given time, even forces as low as 18*g* are sufficient to produce bodily movement.[24] Because the force delivered with an aligner made from Exceed 30 is initially 200*g* and decays to essentially a constant level of 40*g* within approximately 48 hours, delivering adequate forces to the teeth to create desired movements should pose no problem. Controlling those forces then becomes the issue.

How the force is delivered and the reaction of the tooth to that force are functions of multiple factors. These include the center of rotation, the center of resistance, and the point at which the force is applied.

The goal is to control root position during movement to achieve the desired end results with the minimum amount of complexity. Controlling the moment-to-force ratio can do this. Classic orthodontic biomechanics has described the effects of changing the moment-to-force ratio as illustrated in Figure 26-3.[25]

In traditional orthodontic biomechanics, the discussions are typically centered on fixed attachments in the form of brackets with forces applied by wires, with a small moment arm and relatively high forces required to meet moment-to-force ratios.

To better understand the dynamics of root control with aligners, the biomechanics of tooth movement with aligners are examined, and a comparison that, with an understanding of movement with fixed appliances, is made. Specifically, the design and placement of attachments and auxiliaries to accomplish controlled two-point force application are examined. In all of these discussions, it is important to understand that for effective tooth movement to take place, even in simple situations, aligners must be worn 22 hours a day, essentially the same as for fixed appliances.

One of the problems that is seen when attempting incisor root movements with aligners is that the intended movement and the actual movement are sometimes different. The reason for this difference is exactly what Proffit described as happening with removable appliances in general—not enough retention is

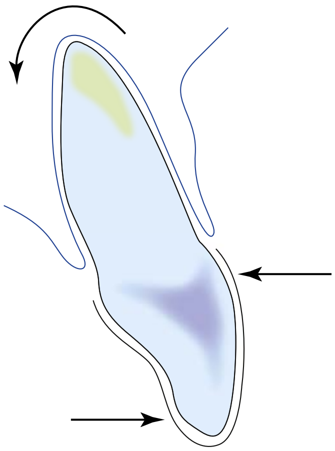

FIGURE 26-4 Theoretical moment-to-force ratio to achieve lingual root movement with an aligner.

present to offset the force needed to generate the movement. The results are demonstrated in Figures 26-4 and 26-5, *A* and *B*.

STAGING OF TOOTH MOVEMENT IN CLINCHECK

An important aspect of controlling tooth movement with aligners is staging. *Staging* is the sequence in which and the speed at which teeth are moved with aligners. Figure 26-6 represents a classic staging diagram. As in the collision table,

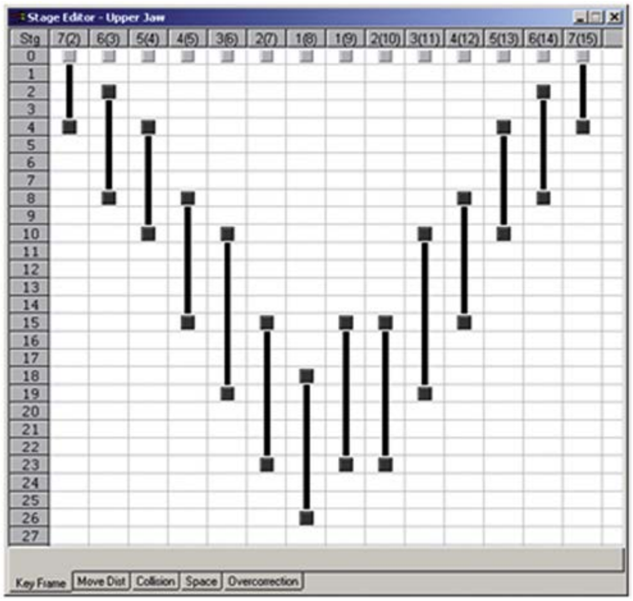

FIGURE 26-6 Segmented staging diagram.

the numbers across the top represent different teeth, and the vertical axis represents an aligner number. The difference is that the staging diagram is available to the orthodontist in ClinCheck. The vertical black bars in the diagram indicate the timing and rate of tooth movement. Each aligner number then represents one stage. The staging diagram has one shortcoming; that is, the rate of tooth movement is not illustrated. In other words, the staging diagram simply informs the orthodontist of whether the tooth is being moved. The orthodontist must then interpolate the rate of movement by estimating the total distance and dividing by the number of aligners, assuming equal rates of movement occur throughout the entire distance moved. In addition, the orthodontist has no way of knowing whether the movement represents linear movement or rotational movement. He or she only knows that the tooth is moving. The original default staging plans involved segmented tooth movements (see Fig. 26-6). The thought process was based on the classic notion of anchorage in which one group of teeth is held stationary while a smaller group of teeth is moved. Difficult movements were often left to the end of treatment and resulted in prolonging treatment time by adding multiple additional stages. To reduce excessive numbers of additional stages, some difficult movements were accelerated beyond a reasonable rate of movement. It sometimes became a self-fulfilling prophecy that difficult movements were unsuccessful with aligners. In addition, teeth that were supposedly held in place as an anchorage unit moved in the same manner that anchorage units move with fixed appliances.

An alternative to segmented staging that more closely mimics fixed appliance treatment is *simultaneous staging*. First suggested by Foy in 2004[26] and then refined by David Paquette (Staging Strategies, Effectiveness and Efficiency with Invisalign Treatment, 2005 Invisalign Summit, Las Vegas, NV) and then, after several years, the simultaneous movement concept was adopted by Align Technology in 2007 (Fig. 26-7). This standard simultaneous staging pattern is also referred to as *X staging pattern*. The basis for simultaneous movement is that all of the teeth within each arch are moved together from the initial stage through the final stage.

FIGURE 26-10 Simultaneous staging diagram rotational movement.

The tooth that moves the most dictates the overall number of stages, based on the maximum allowable tooth velocity. Simultaneously moving the other teeth from the first to the last stage reduces the velocity for all the other movements and increases their predictability without increasing the overall number of aligners. A detailed examination of a series of screen captures from the Treat software provides the actual measures of intended velocities of tooth movement (Figs. 26-8 to 26-12). In Figure 26-8, all of the anterior teeth are moving at maximum velocity, 0.25 mm per stage. This velocity was established as the default for the maximum amount of tooth movement allowed per aligner in the first iteration of the Treat software and has not been changed up to the current version of the Treat software. This rate of linear velocity of movement per aligner has not been scientifically proven to be the correct amount of tooth movement in all three planes that can be achieved for each aligner change over time, but this rate of movement has, none- theless, persisted because empiric evidence suggests that it works on a large percentage of tooth movements.

In Figure 26-9, the upper left lateral was determined to be the rate-limiting tooth. When these movements were started from the beginning of treatment along with all of the other teeth, the result was a decrease from 16 stages to 12 stages, and all of the teeth except the rate-limiting tooth actually moved more slowly at each stage than previously.

There are times when the linear velocity is not the rate limiting determinant; rather, the rotational velocity of tooth movement determines the minimum number of aligners for a given treatment sequence (see Figs. 26-9 and 26-10). In Figure 26-10, the linear movements were under the maximum velocity, resulting in the rotational velocity to be greater than desirable. To increase the predictability of treatment, rotational velocity will be limited to proceed at less than two degrees per stage (see Fig. 26-11). Two degrees is currently the standard default in the Treat software. When the rotational velocity is reduced to an acceptable limit, the number of stages once again increases to 19 stages.

The side effect of reducing the rotational velocity is to reduce further the linear velocity at the same time. The reduction of the velocity of linear movement of the upper left lateral from 0.24 mm per stage to 0.15 mm per stage is noted (see Figs. 26-8 to 26-12), and although the number of stages may increase slightly, the predictability of treatment outcomes is greatly improved.

Alternative staging patterns also exist that are associated with certain types of treatments and are briefly described. Distalization of the maxillary dentition, starting with the molars, followed by the bicuspids, and ending with the retraction of the anterior teeth, is a type of staging known as *V staging pattern* and typically applies only to the upper arch. Although this pattern makes a great three-dimensional visualization of correcting a Class II Angle molar relationship to a Class I molar Angle relationship, the reality is that teeth that appear to be anchoring the arch are still subject to the forces applied by the aligner material. As previously mentioned, teeth that show no movement in a ClinCheck are still subject to forces that make any changes in the arch perimeter. Moving molars from a Class II relationship to a Class I relationship and then holding the teeth motionless, simulating maximum anchorage while the rest of the arch moves distally to a Class I relationship, is not something that will translate to the clinical setting. The other negative aspect of this staging pattern is the significant increase in overall treatment time.

The opposite of V staging pattern, in which the anterior teeth move anteriorly, followed by posterior teeth moving anteriorly, is known as *A staging pattern*. This pattern could be used in either arch to open previously closed extraction spaces or to attempt to mesialize an entire arch in a segmental fashion. Again, this pattern will significantly lengthen the treatment time, as compared with X staging pattern staging, and has limited clinical applications.

FIGURE 26-12 Segmented staging diagram reduced rate of linear movement.

M staging pattern is solely used for bicuspid extraction treatment. In this staging pattern, movement starts by first closing the extraction spaces, followed by the alignment of anterior teeth, and finishing with molar movement. This three-dimensional simulation attempts to mimic maximum anchorage of the molars by showing no movement as the remainder of the arch changes. Again, this simulation does not clinically and exactly translate as shown in the three-dimensional simulation because forces are being applied to the molars as the arch perimeter changes with each successive aligner. In response to the need to create a solution for the extraction treatment, which specifically addresses molar anchorage and root parallelism, G6, the latest SmartForce feature has been introduced. G6 combines SmartForce optimized attachments along with a specific staging pattern that is similar to the M staging pattern. To date, clinical results have not been evaluated to determine the clinical efficacy of G6 SmartForce enhancements.

Although significant clinical testing has gone into the development of staging patterns, understanding that the orthodontist can always request custom staging is important when he or she feels it is necessary to improve treatment outcomes. Ultimately, the orthodontist controls all aspects of the Invisalign treatment, including how much movement per aligner is desired. Although not recommended by Align Technology, some orthodontists greatly reduce the amount of linear movement per stage by increasing the number of active stage aligners using simultaneous tooth movement or X pattern staging for complex movements. Increasing the number of active stages with simultaneous tooth movement effectively reduces the amount of tooth movement per stage for all teeth in the arch. If the number of active stages were doubled, then the movement of the rate-determining tooth would decrease to nearly 0.12 mm per stage, and all of the other teeth in the arch would be significantly less than 0.12 mm linear movement per aligner. Reducing tooth movement per aligner then allows an accelerated changing schedule because of less elastic deformation of the aligner material. Many orthodontists who increase the number of active stage aligners deliver fresh aligners on a weekly basis to have the aligners provide a more consistent force, with less force diminution between aligner changes. Although twice as many aligners are the result, the total treatment time remains the same.

ATTACHMENT DESIGN IN THE INVISALIGN SYSTEM

One solution to aligner displacement is the proper design and placement of attachments. Attachments can be used for the retention of the aligner, as well as to enhance or facilitate specific tooth movements. Figure 26-13 illustrates the evolution of attachments used to help eliminate this problem. The goal is to provide a ledge for the aligner to grip that is perpendicular to the direction of displacement and of sufficient size to provide enough surface area to offset the force delivered. Another simple rule of thumb is to place the attachment far enough away from the gingival margin that the aligner will not spread or stretch and slip off the attachment. This concept is important because the aligners tend to relax over time; that is, they exert less force. The clinically observed side effect is that the gingival third tends to become less retentive, which is in contrast to the findings of Jones and colleagues,[27] based on laboratory results with in-office–fabricated aligners whose properties were not affected by the oral environment.

Movements that are termed difficult require a more sophisticated approach to attachment design than was used in the past. Recognizing the limitation of aligners and empirically designed attachments to accomplish certain tooth movements, engineers at Align Technology initiated efforts to design a better aligner and attachment system. Align Technology thus developed the Virtual Invisalign Laboratory, which is a sophisticated series of software tools that enable the evaluation of the expected clinical response to various attachment designs and placements. The approach, based on the principles of biomechanics, has three parts: virtual modeling, in vitro testing, and clinical evaluation of the resulting designs. Using this approach, the probability of achieving the movement displayed in the three-dimensional ClinCheck treatment is greatly enhanced.

Virtual modeling is first used to test a myriad of possible solutions and then to identify those that produce the desired force system. These models may include changes in attachment shape, as well as variations in the geometry of the aligner itself (Fig. 26-14, *A–C*). After considering possible designs, the models are then fabricated, and the force systems are measured using laboratory equipment specifically designed to measure force systems from aligner and attachment combinations. Successful designs are then moved into clinical testing.

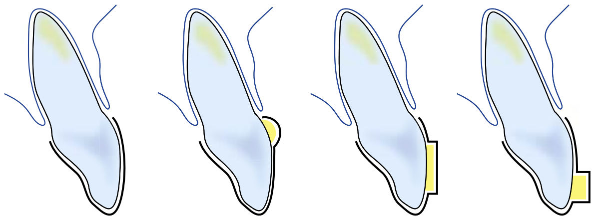

FIGURE 26-13 Evolution of attachments.

At the time of this printing, a significant number of *optimized* attachments have been developed and introduced to provide specific force systems for challenging tooth movements. These optimized attachments allow the proprietary aligner material (SmartTrack) to produce the required force, which creates the moment required to move the tooth as shown in the ClinCheck. The term *SmartForce* has been patented by Align Technology to describe the computer-generated attachment designs that are generated by Align Technology's Treat software. Each optimized attachment is now custom designed for a specific movement on a specific tooth for an individual patient. The optimized attachments are automatically generated by the Treat software. The orthodontist is responsible for moving each individual tooth to the desired position using ClinCheck Pro. The tooth movements prescribed by the orthodontist are measured in all three planes of space; when a default in any one direction is exceeded, the Treat software will place the SmartForce attachment on the tooth at the correct location to create the required force system to cause the tooth to move as depicted in the ClinCheck. Each SmartForce attachment feature has a default that must be exceeded to place the optimized attachment, and the technician cannot override the software to have these specific attachment designs placed on the teeth. As a result, it is incumbent for the orthodontist to understand each SmartForce feature and what movement is required to have the optimized attachment placed.

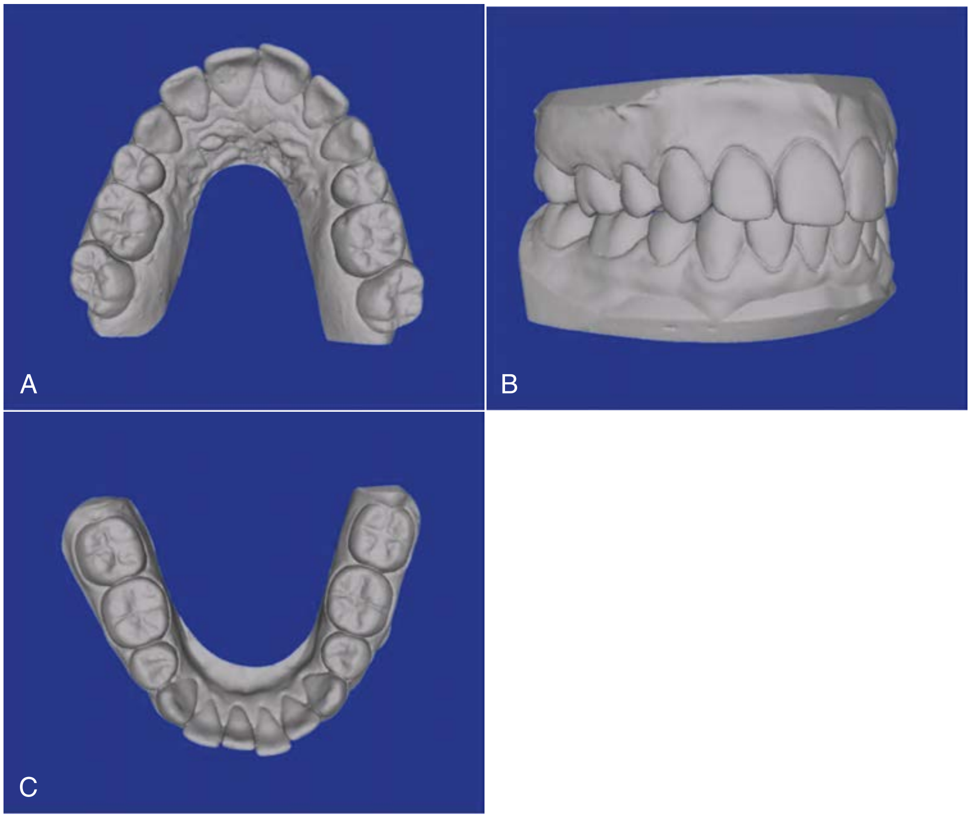

FIGURE 26-14 A–C, Virtual models generated from computer tomographic (CT) scans of polyvinyl siloxane (PVS) impressions.

One internal design feature from Align Technology allows computer-designed attachments to provide specific directions of force application upon inserting the first aligner. The initial force application applied to optimized attachments is generated by preactivating the aligner-attachment interface (see Fig. 26-14). Preactivation is achieved by using an attachment template for attachment placement, which will alter only the optimized attachments that are slightly offset from the position of the attachment in the subsequent aligner that will be placed. This offset positions the active surface of the attachment to engage fully the aligner material, thus eliminating a lag period of one to two aligners before achieving the full force system required to move the tooth as shown in the ClinCheck. In addition to preactivation, one additional feature has been designed to allow tooth movement using optimized attachments. Some optimized attachments will have excess space opposite the active surface to allow the tooth to move unimpeded in the correct direction. Although, clinically, this may give the appearance that the attachment is not fully seated in the aligner, this excess space is intentional by design.

As the number of optimized attachments has increased, it has become apparent that the ability to move teeth effectively with clear aligners is a function of the material, the velocity of tooth movement, and the ability to produce the correct force system by using computer-designed attachments and, last but not least, patient compliance.

Another group of attachments are available to be placed by the orthodontist when modifying a virtual treatment plan. These attachments, referred to as manually placed or physician-prescribed attachments, are those previously referred to in the section on ClinCheck. After turning the three-dimensional controls ON and selecting ATTACH & CUTS from the vertical dropdown list, the choice of attachments is visible. The design of these attachments was completely empiric and has evolved since the initial inception of the attachments. The first of the manually placed attachments was the ellipsoid attachment. This attachment is widely considered the least effective attachment because of its small size and lack of a defined active surface. All other attachments are variations of the initial rectangular attachment design. This design was the primary attachment for any tooth movement that was considered moderate or difficult, without deference to the actual forces and moments generated by its placement. The patient has difficulty inserting and removing the aligners, which is an inherent problem with rectangular attachments. If the attachment and the aligner are not completely coupled, then the result is an unwanted force system and unpredictable tooth movements (Figs. 26-15 and 26-16).

To facilitate greater ease of insertion and removal, as well as to eliminate the all-or-none situation, the beveled attachment was developed by rotating a portion of the rectangular attachment virtually into the tooth surface[28] (Figs. 26-17 and 26-18).

The beveled attachment can be used in multiple orientations by simply rotating the attachment in a different manner. The latest version of ClinCheck Pro (v4.1) allows the orthodontist to not only place and remove the manual attachments but also to orient the manually placed attachments by rotating, raising, or altering the bevel. Although the available attachments to be placed manually show a different orientation (e.g., vertical and horizontal), the ability for the orthodontist to alter the attachment location, orientation, and height makes all these choices duplicitous. Essentially, only two choices—ellipsoid or rectangular—are now available. The orthodontist can now make one rectangular attachment be any type of rectangular attachment he

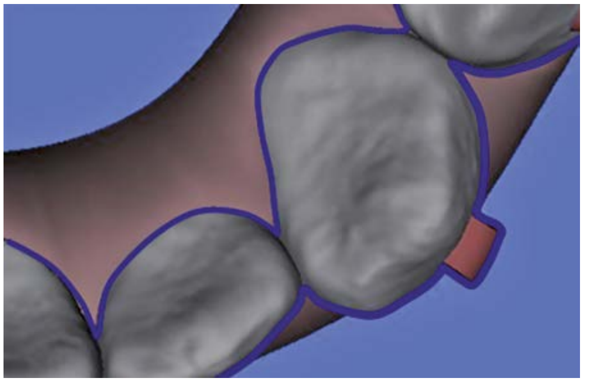

FIGURE 26-15 Aligner and rectangular attachment properly coupled.

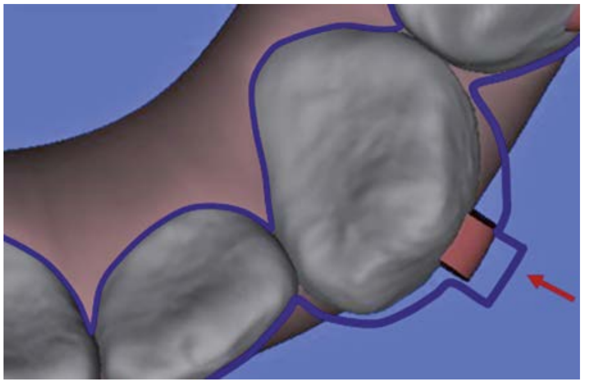

FIGURE 26-16 Aligner and rectangular attachment improperly coupled.

FIGURE 26-17 Beveled attachment.

FIGURE 26-18 Clinical appearance of the beveled attachment.

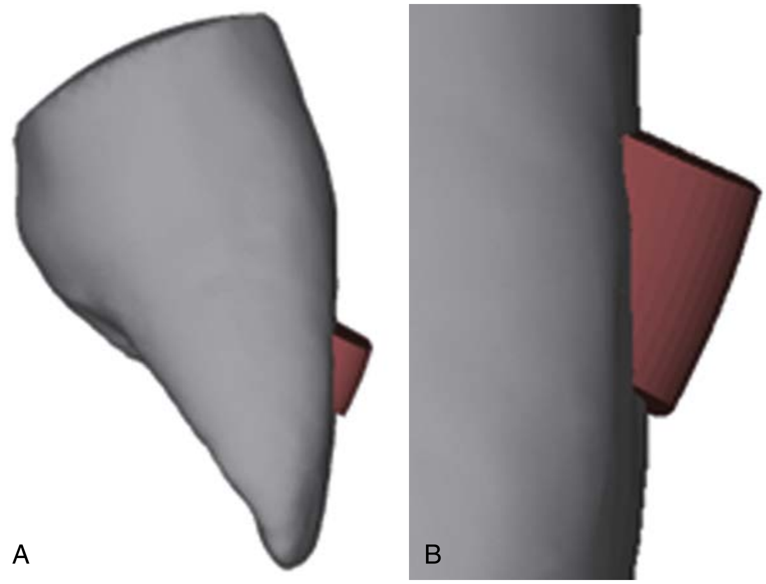

FIGURE 26-20 A, Occlusally beveled attachment. B, Occlusally beveled attachment close-up.

or she prefers—horizontal or vertical, bevel incisal or gingival. In addition, once the rectangular attachment is placed on the tooth, the length of the attachment can be selected by right clicking on the attachment, which will activate a pop-up list to select a 3-mm, 4-mm, or 5-mm attachment or to remove the attachment. In this way, attachments can be sized according to the orthodontist's preferences and can be used in any location that will enhance retention or movement. Theories suggest that rotating the bevel in specific directions will enhance specific movements.[29] Ongoing research will determine the effectiveness of such orientations. (Examples are given in Figs. 26-19 and 26-20.)

POWER RIDGES AND PRESSURE AREAS IN THE INVISALIGN SYSTEM

A net force of 40*g* (base level force of an aligner after 48 hours) intended to move the tooth lingually would require a moment of 320 to 400*g*/mm (moment-to-force [M/F] ratio 8 to 10) for bodily movement or greater than 400*g*/mm (force-to-moment [F/M] ratio less than 10) for lingual root movement (Figs. 26-21 and 26-22). Improper attachment design or placement allows the delivery of only 280*g*/mm moment in conjunction with 40*g* force, resulting in controlled lingual crown tipping (Fig. 26-23). Although the forces may be in opposite directions, the aligner provides the same level of force on both sides of the teeth. In the absence of spaces to close, just as with fixed appliances, some outside force system such as interarch elastics must be present to provide a net distalizing force on the maxillary anterior teeth to produce lingual root movement.

An alternative to attachments that help facilitate torque control is the SmartForce feature known as a *power ridge*. Similar to optimized attachments, power ridges are engineered corrugations placed at specific locations to enhance the undercut near the labial gingival margin of teeth undergoing torquing movements. The power ridges function in two ways: (1) to stiffen the gingival third of the aligner to make it more resilient; and (2) to

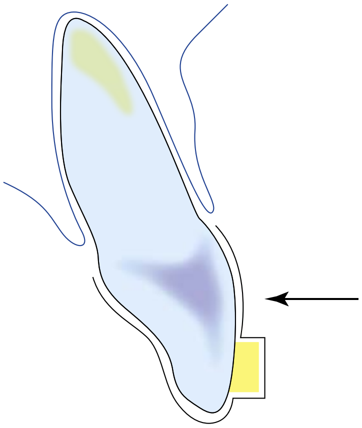

FIGURE 26-21 Force applied by aligner on facial surface.

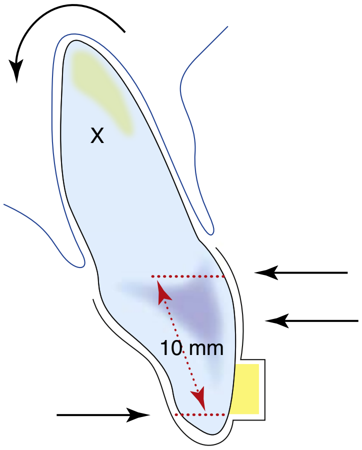

FIGURE 26-22 Force-to-moment diagram with attachment in incisal third of tooth.

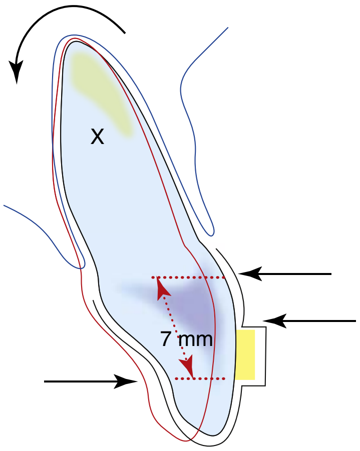

FIGURE 26-23 Force-to-moment diagram with attachment in middle third of tooth.

provide additional force as close to the gingival margin as possible to increase the effective moment arm of the aligner. The obvious advantage to power ridges is that attachments need not be placed or removed, and they are more aesthetically acceptable to the patient (Fig. 26-24). However, power ridges also have two disadvantages. First, they cannot be combined with any other attachment or SmartForce feature. For the force system to work

FIGURE 26-24 Power ridges.

as designed, the two points where the aligner places pressure on the tooth should be separated by as large a distance as possible, without interference from any other force system. In effect, the gingival protrusion in the aligner has a dual purpose. Not only does it create a force near the gingival margin, but it also lifts the aligner away from the facial surface of the tooth until the aligner re-engages the tooth on the lingual surface of the incisal edge of the tooth. The second problem with power ridges is that they can create irritation of the buccal tissues attributable to the protrusion of the margin of the aligner. Although generally acceptable to most patients, some will find this irritation very uncomfortable, more often on the lower arch than on the upper.

Power ridges were the first of a group of SmartForce features that are currently used to create force systems that clear aligners alone cannot achieve. These pressure areas may take the form of a power ridge, pressure point, or pressure area, and each may be a stand-alone feature or may work in conjunction with optimized attachments. Lingual root torque is achieved by the creation of power ridges as previously described. The multiplane attachment for the upper lateral incisors is an example of a pressure point on the lingual surface combined with an optimized attachment on the facial surface. Root control attachments on the upper and lower bicuspids will also use this combination of pressure points and optimized attachments to produce the required moment to correct root alignment on these teeth. The latest additions to this family of SmartForce features are pressure areas on the lingual surface of maxillary and mandibular centrals and laterals and the lower cuspids to direct intrusive forces more closely down the long axis of the tooth when any of these teeth are intruding more than 0.5 mm. Similar to optimized attachments, these pressure areas are all added by the Treat software when the amount and direction of movement extend beyond and surpass the default that triggers their placement. The orthodontist can control whether these features appear or disappear by moving the teeth above or below the threshold required by the software.

ROOT CONTROL IN THE INVISALIGN SYSTEM

Another aspect of biomechanics, especially pertinent to extraction treatment, is to control tipping to achieve root parallelism. When a force is applied in an attempt to move a canine distally, the tooth will rotate around the center of resistance. A sufficient moment is required to oppose the tipping movement. This area is more problematic because in a typical mesiodistal movement as in an extraction scenario, the aligner contacts the tooth on a surface that is parallel to the direction of force. The result is that little, if any, moment arm is created without the use of substantial attachments (Figs. 26-25 through 26-29).

An idea dating back to the late 1800s[30] was to place an attachment on the gingival aspect of a bracket extending toward the center of resistance in an attempt to decrease the amount of tipping when teeth are moved in a mesiodistal direction along

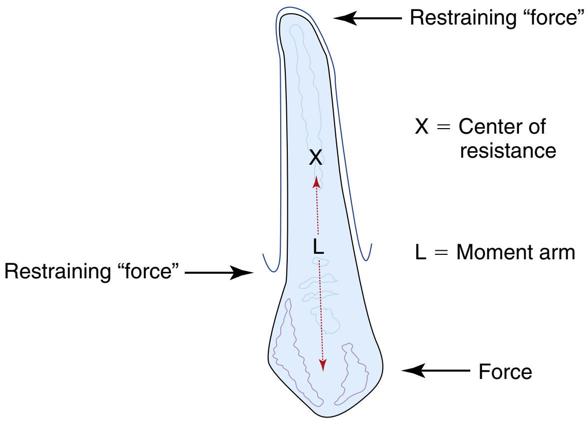

FIGURE 26-25 Force application against mesial of upper canine.

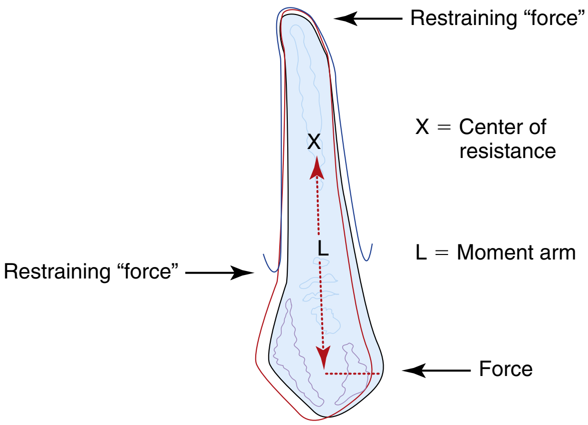

FIGURE 26-26 Effect of force application against mesial of upper canine.

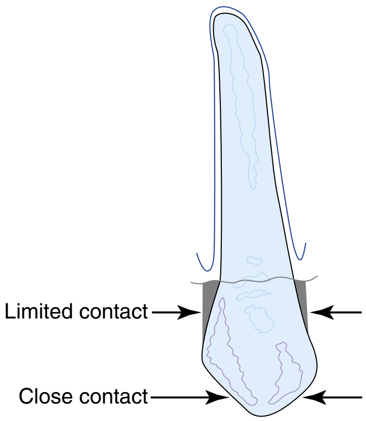

FIGURE 26-27 Diagram of aligner contact with upper canine.

the arch. These gingival extensions are often described as power arms. Power arms have been added to the force system with Invisalign in an attempt to alter the force-moment system (Figs. 26-30 and 26-31). In theory, the addition of a power arm auxiliary accomplishes two things. First, it moves the application of force closer to the center of resistance. Second, it creates a secondary moment attributable to pressure against the distal of the aligner. Unfortunately, the clinical application is not as beneficial as with fixed appliances because molar root control is more difficult than canine root control.

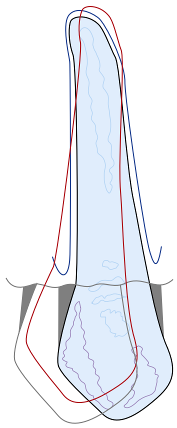

FIGURE 26-28 Displacement of aligner when force is applied against mesial of upper canine.

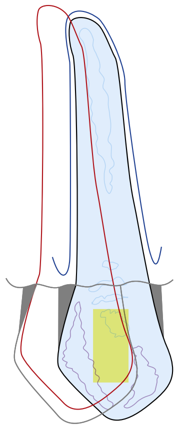

FIGURE 26-29 Controlled movement of upper canine with vertical attachment.

FIGURE 26-30 Handmade power arms in combination with aligners.

Align Technology has introduced engineered solutions in an attempt to mitigate the dumping in extraction cases and to help align the mesiodistal position of the roots of bicuspids, cuspids, and lateral and central incisors. The previous section notes that these root control enhancements are SmartForce features, consisting of pairs of optimized attachments or one optimized attachment and a corresponding pressure area. Short clinical crowns on the maxillary and mandibular bicuspids will dictate the use of the attachment and pressure area design. Maxillary central incisors, maxillary cuspids, and mandibular cuspids use only the paired attachments where two facial attachments will create the couple designed to tip the roots. The upper lateral

FIGURE 26-31 Manufactured power arms in combination with aligners.

FIGURE 26-35 Mesial tipping of maxillary molars after premolar extraction.

FIGURE 26-36 Mesial tipping of maxillary molars after premolar extraction.

incisor multiplane feature uses an optimized attachment on the facial surface and a pressure area on the lingual surface.

The root positions of lower incisors have been successfully maintained during single incisor extraction treatment without the use of engineered root control features (Figs. 26-32 and 26-33), and cases of successful premolar extraction treatment using Invisalign have been reported.[31-33] Unfortunately, canines often remain upright during retraction into premolar spaces, whereas the clinical crowns of molars, especially maxillary molars, tend to tip mesially, which is frequently referred to as "dumping" (Figs. 26-34 to 26-36). Dumping occurs when the molars are being used as anchorage for anterior retraction. As the arch perimeter is reduced, closing extraction spaces, pressure is applied to the molar crowns in a mesial direction. This pressure is probably caused by the undesirable crown-to-root ratio combined with the large root surface area over which forces are distributed. G6, the latest release of SmartForce features, has antitipping attachments and pressure areas built into the molars to limit dumping of the clinical crowns in extraction cases. At this printing, no clinical cases have been reported that demonstrate the effectiveness of these latest root control features. To date, only the lower incisors are left without some form of engineered root control attachment design.

ROTATION CORRECTION IN THE INVISALIGN SYSTEM

Correcting rotations with aligners can be problematic for two primary reasons. First, aligners produce tooth movement by the plastic being slightly distorted and then elastically rebounding back to the predetermined shape, carrying the tooth with it. In the case of rotations, the aligner material is incapable of being distorted in a manner that can produce significant rotational movement. An analogous comparison would be attempting to rotate a tooth with a large steel archwire. Some suggest that beveled attachments with the bevel turned 90 degrees (i.e., mesiodistal; Fig. 26-37) would provide a surface that allows the aligner to rotate teeth. Even with a properly designed attachment, the second problem with rotations is that the tooth root is not a cylinder. Because of dilacerations and root surface variations, the computer software cannot adequately estimate

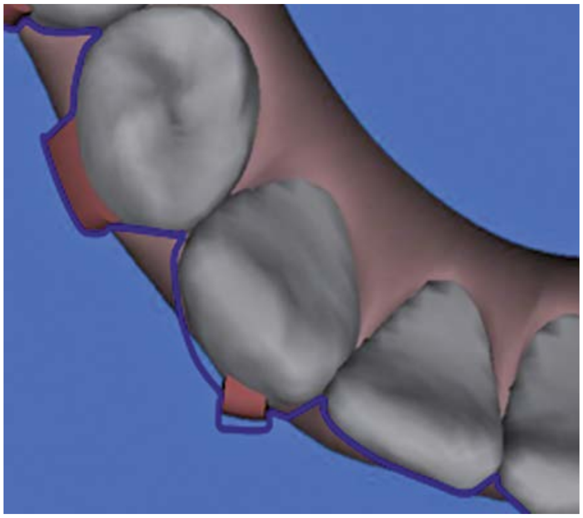

FIGURE 26-37 Rotation beveled attachment.

FIGURE 26-38 Rotational auxiliaries.

FIGURE 26-39 Rotational auxiliaries.

the true rotational long axis. In many cases, what is thought of as rotation of the tooth crown turns out to be bodily movement of the root surface; thus estimating the proper rate of tooth movement becomes impossible. When this happens in fixed appliances, it simply takes longer for the tooth to rotate; when it happens with aligners, the challenge is to keep the aligner fitting over the tooth. The result is the lack of desired movement; in addition, the aligner

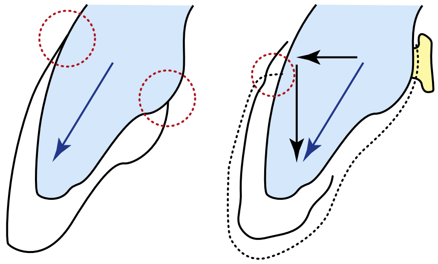

FIGURE 26-40 Extrusion auxiliary. Diagram of extrusion mechanics with button and trimmed aligner.

is now contacting different tooth surfaces than was intended. The result is either no movement or undesirable tooth movements. Before the addition of SmartForce attachments, many of which are specifically designed to correct rotated teeth, using auxiliaries before, during, or after aligner treatment was needed to accomplish the rotational correction (Figs. 26-38 and 26-39). With the advent of the newer optimized attachments, the predictability of rotational movements has significantly improved. Optimized attachments are now available for all bicuspids and cuspids. The default for the bicuspids and cuspids is rotation correction greater than 5 degrees in either direction. Molars and incisors do not have engineered rotation attachments to date. (Note that the upper lateral incisor attachment is not a rotation correction attachment; rather, it is designed for extrusion in combination with root or crown tip.)

EXTRUSION CORRECTION IN THE INVISALIGN SYSTEM

Extrusions were once thought to present problems with aligners. The reason for this assumption is similar to that of rotations. In the same way that the aligner itself is incapable of elastic deformation in the direction needed for effective rotational movement, the aligner cannot stretch within the plastic itself; consequently, an elastic deformation in the direction needed for extrusion is not possible. One method previously used to overcome this problem was to use the gingival beveled attachment to provide a longer surface area that can be elastically deformed and provide an extrusive force on the tooth. This model obviously had merit because Align Technology subsequently released an engineered solution to assist extrusion of maxillary and mandibular incisors and cuspids. The optimized attachments that assist extrusion are very similar to horizontal beveled attachments, beveled toward the gingival margin. The default that causes the attachment to be added to the virtual plan is extrusion of more than 0.50 mm down the long axis of the tooth. Relative extrusion, in which the crown of each incisor lingually reclines, may not trigger the placement of optimized extrusion attachments, even though the extrusion may be quite obvious. An additional SmartForce feature improves the tracking of anterior teeth extrusion when all four upper incisors are individually extruding more than 0.50 mm. This additional feature alters the digital model to create a pressure area at the bases of the optimized attachment on the upper lateral incisors. This pressure area produces a higher force on the optimized attachment to keep the teeth fully engaged in the aligner. The addition of optimized attachments for extrusion and pressure areas on the upper lateral incisors has made Invisalign the preferred appliance for treatment of mild to moderate anterior open bite treatment.

In particularly challenging situations, a button bonded to the tooth, together with an elastic, will assist with the extrusion (Figs. 26-40 to 26-42). This method is infrequently used after the introduction of optimized attachments and can also be a very useful technique to finish treatment when only minor extrusion of a single tooth is required.

AUXILIARIES AND THE INVISALIGN SYSTEM

Other auxiliaries can be used to facilitate specific movements. Class II and Class III elastics are frequently needed, just as they are with fixed appliances. One can directly attach the elastics either to the aligner or to the buttons bonded to the teeth. If the elastics are directly attached to the aligner, then attachments are generally required to prevent displacement of the aligner. Engineers at Align Technology have developed an elastic hook with the proprietary name "precision hooks and button cut-outs" that are manufactured into the aligner. The orthodontist can place either of these options when modifying the ClinCheck using the ATTACH & CUTS interface.

Miniscrews can also be effectively used with aligners in the same manner as with fixed appliances, either initially planned as part of the treatment or to help with movements that are not progressing as desired. Miniscrews can be used with aligners alone or in combination with other auxiliaries to simplify the movements the aligners are required to accomplish. The two most common uses of miniscrews with aligners are for vertical and sagittal movements. One such example is the extrusion of an upper canine. Figures 26-43 to 26-45 demonstrate placing a miniscrew in the lower arch and then running a rubber band from a clear button near the gingival on the upper canine to the miniscrew as the aligner guides the tooth into the correct position.

Another vertical movement that is easily enhanced with miniscrews is the intrusion of molars that have supererupted into an edentulous space. Figures 26-46 to 26-48 illustrate

FIGURE 26-41 Extrusion auxiliary. Clinical photograph of extrusion mechanics with lingual button and trimmed aligner.

FIGURE 26-42 Extrusion auxiliary. Clinical photograph of extrusion mechanics with facial button and trimmed aligner.

FIGURE 26-43 High canine.

FIGURE 26-44 Canine with miniscrew placed.

FIGURE 26-45 Final with canine extruded.

FIGURE 26-46 Supererupted molar.

placing a miniscrew on the buccal and lingual aspects of an upper molar. The patient then wears an elastic from one mini screw over the top of the aligner to the other miniscrew. Many of these patients need to undergo significant restorative treatment, and wearing aligners during the orthodontic setup is often preferred by the patient to wearing fixed appliances.

Miniscrews can expedite Class II correction. The first example involves placing a Carriere Distalizer appliance (Henry Schein Orthodontics, Carlsbad, CA) in the upper arch along with a miniscrew in the lower arch in the molar or retromolar area. A Class II elastic is then worn 24 hours a day; generally, a Class I molar and canine correction can be expected in approximately 12 to 16 weeks. Once the sagittal molar and cuspid correction has been accomplished, then arch alignment and finishing can be accomplished with Invisalign (Figs. 26-49 to 26-52).

FIGURE 26-47 Supererupted molar with miniscrews and aligners.

Another application of miniscrews with aligners is correcting an arch asymmetry by enhancing the distalization of one side. This correction can be accomplished by placing a miniscrew in the retromolar area, bonding buttons on the facial and lingual aspects of the upper first or second molar, and then connecting an elastic chain from the buttons to the miniscrew. If the intended movement is planned into the aligner treatment, then the mini screw provides the anchorage and allows simultaneous movement in the ClinCheck to reduce treatment time (Figs. 26-53 to 26-55).

The previous images demonstrate a few examples of using miniscrews along with aligners to accomplish otherwise difficult movements. There are obviously multiple other applications of miniscrews with aligners.

INVISALIGN TEEN

Invisalign Teen (Align Technology, Inc., Santa Clara, CA) is not so much a different appliance as it is a specific feature set. Originally, Invisalign was anticipated for use with adults and approved by the U.S. Food and Drug Administration (FDA) for those individuals with a fully erupted permanent dentition. It soon became apparent, however, that being able to treat the late mixed dentition with aligners provided certain benefits as well. The shortcomings to overcome were anticipating tooth eruption of one or more permanent teeth, being able to monitor patient compliance to discuss the progress (or lack thereof) with parents, proper control of torque without the need for attachments when crowns were not yet fully exposed, and, finally, avoiding practice management issues over lost aligners. Eruption tabs are used to prevent supereruption of unerupted second molars (Fig. 26-56). Tooth forms of approximate anticipated crown size are used to both create and hold room

and to guide eruption of actively erupting second premolars and canines, planning for refinement aligners with proper fit once the teeth are adequately erupted to capture properly the crowns in the impression. Wear indicators are placed on the facial surfaces of the first molars (Fig. 26-57). Two different types of chemical indicators are available that turn from dark blue to clear as the aligners are worn. These indicators are designed so that creative teenagers cannot realistically figure out a method to have both indicators change without actually wearing the aligners. All SmartForce enhancements, including optimized attachments, pressure points, and pressure areas that are previously discussed were developed for the Invisalign Teen product and are a routine part of the feature set. The practice management part is actually quite easy. Align Technology charges a premium and provides free replacements for lost aligners. In reality, the patient prepays for the privilege of having them replaced if lost. Many adults can benefit from the features in Invisalign Teen, and it is perfectly acceptable to order the Invisalign Teen product for an adult to access any of the unique product features.

Understanding when and where to anticipate the use of aligners in combination with other techniques or auxiliaries is critical to both getting satisfactory results and satisfying patients. Several variables combine to produce either acceptable desired results or unacceptable undesired tooth movements. A review of these results with reference to specific movements follows. The first and most important variable is duration of wear. Aligners are not retainers and must be consistently worn for approximately 22 hours of a 24-hour period, essentially acting similar to fixed appliances. If not consistently worn, then results are extremely unpredictable. Patients who do not comply with wearing aligners for the daily required duration generally have less than desirable results.

The next most important variables are clinical crown length and shape. The longer the clinical crown and the greater the natural undercuts to facilitate aligner retention, the more likely that the desired movement will take place, because there is a greater amount of surface area for the aligner to contact. Patients with very short clinical crowns are not good candidates to attempt some movements with Invisalign such as root alignment with premolar extraction treatment. Single lower central incisor extraction tends to be successful because of the length of the clinical crowns of the lower incisors relative to the forces applied.

Closing anterior spaces, especially with protrusive incisors that require some intrusion, is extremely predictable and requires no attachments. Closing minor anterior open bites is predictable because one secondary effect of aligner wear is the vertical control of dentoalveolar eruption of the posterior teeth. In growing patients this is particularly poignant. Because aligners tend to limit posterior tooth eruption, when opening a deep bite, special consideration should be given to the virtual setup. If the curve of Spee is deep, then intruding lower second molars and lower incisors (using the aligner as if it were a reverse curve of Spee archwire) leaves only a small amount of extrusion of the premolars and first molars. Along with the reverse curve of Spee effect, heavy posterior occlusal contacts can be virtually created to compensate for the side effect of molars and bicuspids not being able to extrude easily. (Note that leveling the curve of Spee has now been made significantly easier with the addition of the virtual bite plane being added to the lingual aspect of the upper incisors. This addition was part of the G5 release in 2014 to address deep bite treatment). Opening the bite is accomplished by creating virtual collisions between the upper and lower molars when modifying the ClinCheck.

As previously discussed, some rotations are somewhat unpredictable as well. Often the decision is not whether to treat a patient with Invisalign but rather to predetermine whether adjunctive treatment may be required to gain the best end results for the patient and/or decrease overall treatment time. There are instances in which a short period of fixed appliances is of benefit to treat severe rotations, to align divergent roots, or to close significant spaces. This brief period of fixed appliances will be followed by comprehensive treatment with aligners. The benefit to this approach is the decrease in overall treatment time, as well as better results for difficult malocclusions. Success depends on patient demands and expectations, as well as the orthodontist's comfort with combining the two treatment modalities. No hard and fast rules have been written; each appliance may be used to do what it does best and tailor treatment to use whichever appliance meets the patient's personal needs and is the most efficient and effective in treating the orthodontic list of problems at hand.

PERIODONTAL CONSIDERATIONS

A growing body of evidence suggests that orthodontic treatment with aligners has less detrimental periodontal impact than that of fixed appliances. Miethke and Vogt[33] and Miethke and Brauner[34] compared the periodontal health of patients who underwent treatment with aligners with that of patients who underwent treatment with both labial fixed appliances and with lingual fixed appliances and found that the periodontal risk was no greater than with labial appliances and was lower than that of lingual fixed appliances. Boyd[35,36] found that periodontal health could actually improve during the course of treatment with Invisalign. He attributed this improvement to the patients' ability to remove the appliances and spend more time brushing and flossing their teeth and the aligner's ability to maintain an invisible appearance to the appliances.

SUMMARY

Successful treatment of many malocclusions with proper tip, torque, arch form, and aesthetic crown inclination is possible to achieve with clear aligners. Align Technology provides the most advanced clear aligner technology in the marketplace to date. Invisalign-branded clear aligners, using the proprietary plastic material and innovative SmartForce enhancements, provide predictable high-quality outcomes in the hands of a competently trained orthodontist. The appliance is neither intuitive to use nor easy to master. ClinCheck, although a great tool, requires considerable skill to manipulate the teeth to the desired positions. Besides the obvious aesthetic improvement over fixed appliances, periodontal health benefits may also be associated with Invisalign treatment. Understanding both the process of aligner manufacturing along with the biomechanics of tooth movement with aligners and applying that knowledge to treatment planning and clinical execution should enable the clinician to design a treatment plan with aligners alone or in combination with fixed appliances to make both simple and complex treatments predictable and routine.

CASE STUDY 26-1 CLASS I MODERATE CROWDING

A 39-year-old woman exhibited a typical orthodontic relapse, having been treated as a teenager and then failing to wear retainers. She exhibited significant lower crowding and dark triangles between upper incisors. Figure 26-58, *A–H*, shows her initial presentation. Figure 26-59, *A–H*, shows her final results. Figure 26-60, *A*, shows her final ClinCheck. Figure 26-60, *B*, shows her ClinCheck with staging, and Figure 26-61, *A–J*, shows the patient 2 years after treatment. To reduce dark triangles and control crown angulations, interproximal reduction (IPR) was prescribed and attachments were appropriately placed. Her treatment took 11 months, 9 upper aligners, 21 lower aligners, and 9 total appointments, including examination, impressions, and retainer delivery.

Bonding in Orthodontics

Björn U. Zachrisson, Serdar Usumez, and Tamer Büyükyilmaz

OUTLINE

INTRODUCTION

The introduction of bonding to orthodontics has had a dramatic effect on the profession. The many advantages of bonded brackets over cemented bands include the aesthetic improvement, the elimination of band seating, and the need for tooth separation, as well as the elimination of the thickness of the band material, which affected the arch length. Improved oral hygiene through easier access to the interproximal dental areas helps reduce the risk of enamel decalcification. Accessibility to the interproximal area also allows for earlier detection of caries at these sites and their restoration, improved access to interproximal contacts for mesiodistal contouring, and the elimination of the need for posttreatment space closure. The ability to bond partially erupted and malaligned teeth enables earlier force application during treatment, which was not previously possible with banded attachments.[1–3] Direct bonding of orthodontic attachments also increased the acceptability of orthodontic appliances by the public and popularized orthodontic treatment, thus increasing the number of new enrollments each year. Advances in direct bonding also induced the emergence of some new techniques such as lingual orthodontics, which would have made no sense when used with circumferential bands.

Today, as the profession is approaching over 50 years of successful, reliable orthodontic bonding, a recent survey indicates that the decline of banding against bonding is noteworthy, and maxillary first molars are routinely banded by only less than one third of U.S. orthodontists. Presently, the median bond failure rate for practitioners in the United States is approximately 5% for labial and 4% for lingual appliances.[4,5] This finding is in accordance with the dramatic decrease of use of all types of headgears in the past 6 years.[5]

Achieving a low bond failure rate should be a high-priority goal, since replacing loose brackets is disturbing, time consuming, and costly. Consequently, an endless search is on for higher bond strengths, better adhesives, simpler procedures, and materials that will bond in the presence of saliva. However, most bond failures are a consequence of inconsistencies in the bonding technique and are not related to bonding resins, inadequate bond strengths, or the quality of the brackets being used.[6] Newer resin systems and alternative methods to bond to enamel may be giving the false impression that an orthodontist does not need to be as careful with the bonding procedures as before.

The basis for the adhesion of brackets to enamel has been enamel etching with phosphoric acid, as first proposed by Buonocore[7] in 1955. In the early 1970s, a considerable number of preliminary reports were published on different commercially available direct and indirect bonding systems. The first detailed posttreatment evaluation of direct bonding over a full period of orthodontic treatment in a large sample of patients was published in 1977.[1] Since then, product development in terms of adhesive resins, brackets, and technical details has occurred at a rapid rate. In fact, the progress has made it difficult for the practicing orthodontist to remain properly oriented.

The purpose of this chapter is to update current available information on bonding to natural and artificial teeth. A special emphasis is given to those techniques and materials that are demonstrated to be trending in recent studies.[4,5]

To help organize the contents, the chapter is divided into four parts:

1. Materials and devices used in orthodontic bonding
2. Bracket bonding
3. Debonding
4. Bonded retainers

MATERIALS AND DEVICES USED IN ORTHODONTIC BONDING

Brackets

The two most common types of orthodontic attachments are stainless steel and ceramic brackets, which constitute 91% (80% metal plus 11% ceramic) of all brackets used.[5]

FIGURE 27-1 Ceramic brackets provide an aesthetic way of attaching to tooth surfaces, making orthodontic treatment more acceptable, particularly for some patients.

Ceramic Brackets

Ceramic brackets have become an important although sometimes troublesome part of today's orthodontic practice. Ceramic orthodontic brackets are machined from monocrystalline or polycrystalline aluminum oxide. Theoretically, such brackets should combine the aesthetics of plastic and the reliability of metal brackets.

Ceramic brackets bond to enamel by two different mechanisms: (1) mechanical retention via indentations and undercuts in the base, and (2) chemical bonding by means of a silane-coupling agent. With mechanical retention, the stress of debonding is generally at the adhesive–bracket interface, whereas the chemical bonding may produce excessive bond strengths, with the stress at debonding shifted toward the enamel–adhesive interface (see Debonding). Chemically cured and light-cured adhesives are useful for ceramic brackets (Fig. 27-1).

Metal Brackets

Metal brackets depend on mechanical retention for bonding, and a mesh structure is the most common method of providing this[4] (Fig. 27-2, *A* and *D*). However, many bracket-based designs such as standard mesh base (Ultraminitrim, Dentaurum GmbH & Co., Ispringen, Germany); supermesh base (Microarch-GAC, Dentsply GAC, Islandia, NY), integral base (Dyna-Lock, 3M Unitek, Monrovia, CA); MicroLoc GAC (Dentsply GAC, Islandia, NY), microetched base (Miniature Twin, 3M Unitek, Monrovia, CA); and laser-structured base (Discovery brackets, Dentaurum GmbH & Co., Ispringen, Germany)[8–10] are available for clinical use.

Mesh pad is the system most commonly used for retention. The improvement of these variables has been the goal of many research projects.[11–16] A new type of laser-structured base retention was found to produce double the bond strength produced by foil mesh without compromising debonding characteristics.[17]

Adhesives

Composite Resins

Modern dental composite restorations can be considered to have originated in Bowen's classic work on the development of

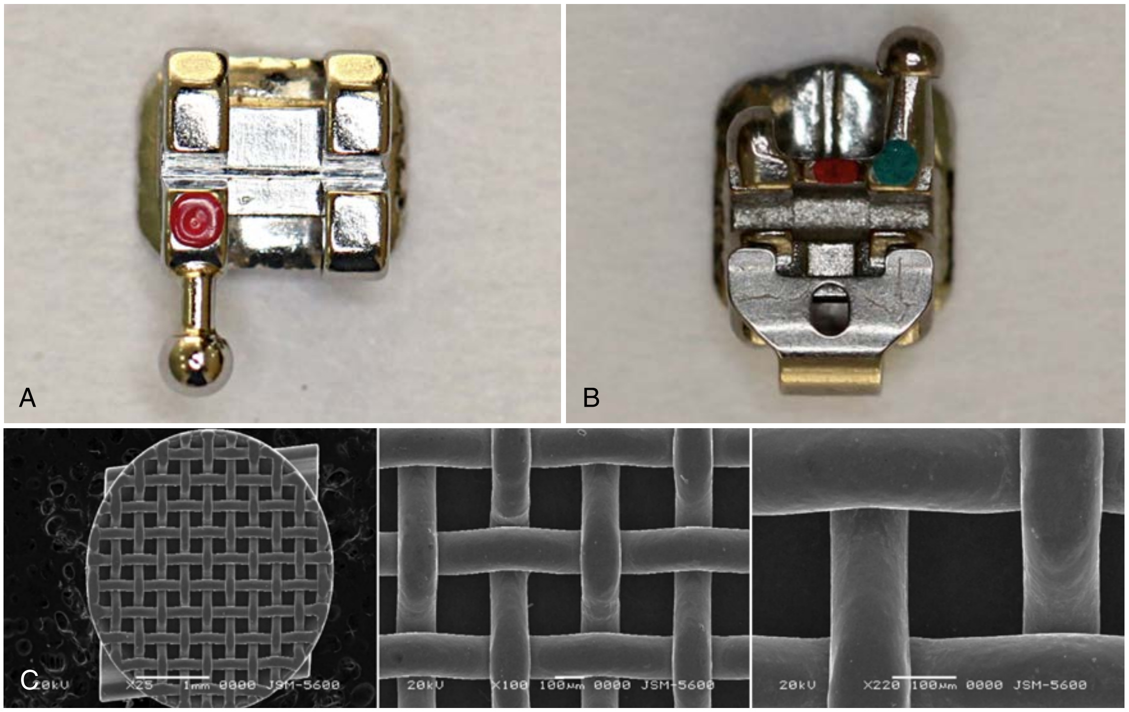

FIGURE 27-2 **A,** Metallic twin bracket sample (Mini Master Series, American Orthodontics, Sheboygan, WI). **B,** Metallic twin bracket sample with self-ligating clip (Empower Series, American Orthodontics, Sheboygan, WI). **C,** Bracket bases present a retentive base for holding the cured resin. Mesh pad is the system most commonly used for retention. Scanning electron microscopy (SEM) views of a standard mesh base bracket demonstrate undercut formations required for mechanical retention. (Ultraminitrim, Dentaurum GmbH & Co., Ispringen, Germany). (**A** and **B,** Courtesy Dr. Sabri Ilhan Ramoglu, Istanbul, Turkey. **C,** From Usumez S, Erverdi N. Adhesives and bonding in orthodontics. In: Nanda R, Kapila S, eds. *Current Therapy in Orthodontics*. 1st ed. St. Louis: Mosby; 2009:45–67.)

the monomer 2,2-bis-4(2-hydroxy-3-methacryloyloxypropoxy) phenylpropane.[18] The essential chemistry of the synthesis of this substance is the reaction of glycidyl methacrylate with bisphenol A to create a molecule informally known as bisphenol A–glycidyl methacrylate (bisGMA). The original aim of the synthetic studies of Bowen that led to the development of this monomer was to combine the advantages of the acrylic systems with those of epoxy systems based on bisphenol A but without the disadvantages. A fundamental difference is that cured acrylic resins form only linear polymers, whereas newer formulations may also be polymerized by cross-linking into a three-dimensional network. This cross-linking contributes to greater strength, lower water absorption, and less polymerization shrinkage.[19] The bisGMA is the basis of most of the contemporary composite resin systems clinically used today.[20,21]

Polymerization of composite resins can be initiated chemically or by light exposure.

No-mix adhesives. No-mix adhesives set when one paste under light pressure is brought together with a primer fluid on the etched enamel and bracket backing or when another paste on the tooth is to be bonded. No-mix adhesives are now routinely used by only 5% of the orthodontists in the United States, which indicates a dramatic decline, compared with a 2008 survey.[4,5]

Light-polymerized adhesives. The introduction of light-cure adhesives not only removed a step in the bonding procedure, but it also allowed practitioners the freedom to choose when to initiate the adhesive curing cycle after bracket placement. Light-curing resin composites were introduced to the market in the 1970s. In light-cure adhesives, the curing process begins when a photoinitiator is activated. Most dental photoinitiator systems use camphoroquinone as the diketone absorber, with the absorption maximum in the blue region of the visible light spectrum at a wavelength of 470 nanometers (nm).[22,23] The light-cured adhesives are routinely used today by more than 80% of orthodontists and are dominating the market[5] (Fig. 27-3).

These resins offer the advantage of extended, although not indefinite, working time. This advantage, in turn, provides the opportunity for assistants to place the brackets, with the orthodontist following up with any final positioning. Light-cured adhesives are particularly useful in situations during which a quick set is required, such as when rebonding one loose bracket or when placing an attachment on an impacted tooth after surgical uncovering, when the risk of blood contamination is present. Light-cured adhesives are also advantageous when extended working time is desirable, which is usually the case when difficult premolar bracket positions need to be checked and rechecked with a mouth mirror before the bracket positioning is considered optimal (Fig. 27-4).

Primers. Much confusion and uncertainty surround the use of sealants and primers in orthodontic bonding. Recent findings demonstrate that bonding with or without a primer (unfilled resin) before bracket placement is equally clinically successful as far as bracket failure rate is concerned.[24,25]

FIGURE 27-3 Current light polymerized adhesives are available in either syringe or capsule form and are best used with their respective primer (Transbond XT, 3M Unitek, Monrovia, CA).

FIGURE 27-4 Bracket position on difficult teeth may be checked with a mouth mirror.

Why, then, should a sealant be of any value in bracket bonding? If nothing else, a sealant permits a relaxation of moisture control because controlling moisture is no longer critical after resin coating. Sealants also provide cover for enamel in areas of adhesive voids, which is probably especially valuable with indirect bonding. The caries protection of sealant around the bracket base is more uncertain, and further studies are needed on the clinical merits of fluoride-containing sealants.

Moisture-Insensitive Primers. In an attempt to reduce the bond failure rates under moisture contamination, hydrophilic primers that can bond in wet fields (Transbond MIP, 3M Unitek, Monrovia, CA; Assure or Assure Plus, Reliance Orthodontic Products, Itasca, IL) have been introduced as a potential solution. Laboratory studies have demonstrated that water and saliva contamination of enamel during the bonding procedure lowers bond strength values of composite resins.[26,27] Although bond strengths were significantly lower under wet conditions than in dry conditions, the hydrophilic primers may be suitable in difficult moisture-control situations.[27,28] This may be the case in some instances of second molar bonding and when the risk for blood contamination is present on half-erupted teeth and on impacted canines. For optimal results, the moisture-insensitive primers should be used with their respective adhesive resins.

The hydrophilic resin sealants or primers polymerize in the presence of a slight amount of water, but they will not overcome routine saliva contamination. When bonding to enamel, the resin sealant or resin primer must be placed onto the prepared enamel before the pellicle (biofilm) formation from the saliva, which is not particularly difficult but is crucial to a successful enamel bond.[6]

Self-Etching Primers. Despite being demonstrated to provide only modest time saving (8 minutes for full mouth bonding),[29] the use of self-etch primers has steadily increased because of their great simplicity. A recent survey among U.S. orthodontists demonstrated that the routine use of a self-etching primer (SEP) is approximately 40%, which indicates a 10% increase in the past 6 years.[5] Combining conditioning and priming into one step may improve cost-effectiveness for clinicians and patients, provided the clinical bond failure rates are not significantly increased.

The unique characteristic of these bonding systems is that they combine the conditioning and priming agents into a single acidic primer solution for simultaneous use on both enamel and dentin; therefore separate acid etching of the enamel and subsequent rinsing with water and air spray is not required (Fig. 27-5). The active ingredient of the SEPs is a methacrylate phosphoric acid ester that dissolves calcium from hydroxyapatite. Rather than being rinsed away, the removed calcium forms a complex and is incorporated into the network when the primer polymerizes. Etching and monomer penetration to the exposed enamel rods are simultaneous, and the depth of etch and primer penetration is identical.

Three mechanisms act to stop the etching process. First, the acid groups attached to the monomer are neutralized by forming a complex with calcium from hydroxyapatite. Second, as the solvent is driven from the primer during the airburst step, the viscosity rises, slowing the transport of acid groups to the enamel interface. Finally, as the primer is light cured and the primer monomers are polymerized, transport of the acid groups to the interface is stopped.[30] Scanning electron microscopy (SEM) examination of the impression of SEP-treated enamel shows different surface characteristics from acid-etched enamel. Instead of the well-known distinct honeycombed structure with microtag and macrotag formation (Fig. 27-6, *A–F*), an irregular but smooth hybrid layer, 3 to 4 microns thick, and irregular tag formation with no apparent indentations of enamel prism or core material (Fig. 27-7, *A–C*) are found. The minimal etch obtained with the SEPs indicates that the majority of the bond may be more of a chemical bond with the calcium in the enamel than the mechanical bond achieved with a conventional phosphoric acid etch.[6]

The use of the new SEPs for orthodontic purposes has been extensively evaluated, and clinical bond strengths using SEPs may appear to be lower than those with conventional etching and priming.[31,32] Another recent systematic review and meta-analysis concludes that only weak insignificant evidence suggests higher odds of failure with an SEP than an acid etch over 12 months in orthodontic patients.[29] On the other hand, information on the effect of SEP application on enamel resistance against demineralization is controversial. Previous studies[33] show that the SEP provides no resistance to enamel demineralization and results in twice as many white spot lesions (WSLs), especially in patients with poor oral hygiene.[34] Recent studies, however, show that the enamel samples that are conditioned with the fluoride-releasing SEP (Transbond Plus, 3M Unitek, Monrovia, CA) display better remineralization.[35]

When deciding which SEP to use, each clinician must weigh bond failure rates and reduced resistance to demineralization against the time saved in bonding and debonding.

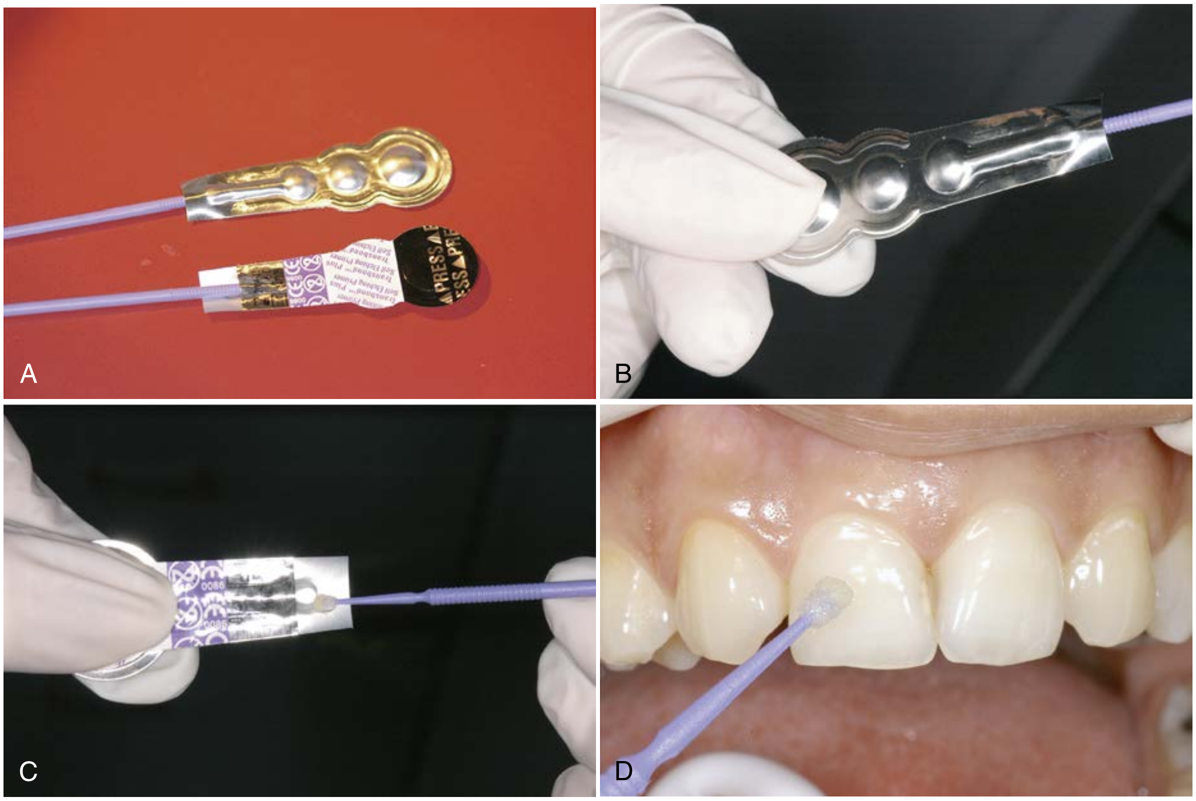

FIGURE 27-5 Application of a self-etching primer (Transbond Plus, 3M Unitek, Monrovia, CA) on enamel surface of maxillary incisor (see text for explanation).

Cytotoxicity of orthodontic resins. Regardless of the polymerization method, in vitro studies have shown that the polymerization reaction that produces the cross-linked polymer matrix from the dimethacrylate resin monomer is never complete, and approximately 15% to 50% of the methacrylic groups remain unreacted (32.4% and 44.5% for Transbond LR [3M Unitek, Monrovia, CA] and Lightcure LR [Reliance Orthodontic Products, Itasca, IL] orthodontic adhesives, respectively).[36–39] As a result of the efforts of the industry, the percentage of unbound monomers has decreased in the past 10 years, but the problem is still not eradicated. The quantity of residual monomers is less than one-tenth of the remaining methacrylic groups, which have been evaluated as no more than 1.5% to 5%, which is enough to contribute to major cytotoxic effects.[36,40]

Monomers identified in orthodontic composites (Transbond XT, Transbond LR [3M Unitek, Monrovia, CA]; Reliance Light Bond, Reliance FlowTain [Reliance Orthodontic Products, Itasca, IL] GC Fuji Ortho LC [GC America, Alsip, IL]) by liquid chromatography include bisGMA, triethylene glycol dimethacrylate (TEGDMA), urethane dimethacrylate (UDMA), and 2-hydroxylethyl methacrylate (HEMA) in the 0- to 99.8-μm range.[41] Resins and resin-modified glass ionomer cement (RM-GIC) also release ions such as fluoride, strontium, and aluminum.[36] These unbound free monomers seem to be directly responsible for the cytotoxicity of resin composites on pulp and gingival cells, and they are probably also implicated in the allergic potential of the material.[39] Recent in vivo research[42] shows morphologic signs of cytotoxicity of buccal cells after 6 months of fixed orthodontic treatment with different light-cured composites, with no genotoxic effects; and cell culture studies[43] suggest some adverse effects on cell viability with various current orthodontic adhesives. However, studies assessing orthodontic adhesives with a protocol that mimics the orthodontic bonding process are those of Eliades and colleagues,[44,45] which report no release of bisphenol-A or estrogenic effect. Another current systematic review[46] was unable to draw definitive conclusions as a result of a variety of setups and the different units allied to the diversity of reporting in different studies. For now, the conclusion can be reached that no controversy exists in the orthodontic community regarding the safety of the most commonly used materials. However, some simple and basic precautions may help fight the adverse effects of these materials for the patient population. First of all, the amount of composite resin used should be kept to a minimum, and any excess resin (flash) around the orthodontic attachments should be removed before the resin is polymerized. Minimizing the use of adhesive material may be of high importance when bonding fixed orthodontic retainers since these are left in the oral environment for a long time and are exposed to the cavity, unlike resin beneath the bracket base.[10] Degree of cure-conversion (DC) is another important factor, and current research emphasizes matching composites and light-curing units with one another to achieve satisfactory maximal biocompatibility and DC.[43] In addition, the speed of monomer release is at its maximum in the first 10 to 60 minutes.[41] Having a patient wash his or her mouth immediately after the bonding session and/or having him or her spit into a disposable cup for the first 30 minutes might be advisable as it is used after topical fluoride applications.[10]

(In **B** the prism centers have been preferentially removed, whereas in **C** the loss of prism peripheries demonstrates the head-and-tail arrangement of the prisms.) **D–F,** Transverse section of an etched porous enamel surface showing two distinct zones, the qualitative porous zone (QPZ) and the quantitative porous zone. In the latter, an even row of resin tags (*T*) may penetrate.

Glass Ionomer Cements

Glass ionomer cements were introduced in 1972, primarily as luting agents and as a direct restorative material, with unique properties for chemically bonding to enamel, dentin, and stainless steel and being able to release fluoride ions for caries protection. The second-generation water-hardening cements contain the same acids in freeze-dried form or in an alternative powdered copolymer of acrylic and maleic acids. Glass ionomer cements were modified to produce dual-cure or hybrid cements[19] ([Fig. 27-8], e.g., GC Fuji Ortho LC, GC America, Alsip, IL).

Glass ionomer and light-cured glass ionomer cements are the material of choice for cementing bands[5]; they are stronger than zinc phosphate and polycarboxylate cements, with improved adhesion to enamel and metal and less demineralization[47] at the end of treatment.

Glass ionomers are used by only 7% of the clinicians for direct bonding of brackets. For bonding of brackets and buccal tubes with resin-modified glass ionomer cements, few reports over a substantial time have been made with regard to clinical performance concerning the bond strength and incidence of demineralization. The pretreatment with polyacrylic acid facilitates a chemical bond between the glass ionomer and the enamel and thus should be performed before bracket bonding with the glass ionomer. When bond strength is the primary criterion for selecting an adhesive, composite resins are recommended.[48] Limiting the use of the glass ionomer with at-risk orthodontic patients is advisable to provide preventive actions and potentially remineralize early (subclinical) enamel demineralization.[47]

Light Sources

The variety of light sources available includes conventional and fast halogen lights, argon lasers, plasma arc lights, and light-emitting diodes (LEDs). A current systematic review and metaanalysis of randomized controlled trials and clinical controlled trials directly compare conventional halogen lights, LEDs, or plasma arc systems involving patients with full arch, fixed, or bonded orthodontic appliances (not banded) with follow-up periods of a minimum of 6 months. This systematic review suggests that no evidence supports the use of one light-cure type over another, based on the risk of attachment failure.[49] On the other hand, recent research demonstrates that LEDs today dominate not only the orthodontic but also the

whole dental field.[5] Therefore only this group is discussed in detail in this chapter.

Light-Emitting Diodes

A solid-state LED technology for the polymerization of light-activated dental materials was proposed by Mills and colleagues.[50] LEDs use junctions of doped semiconductors to generate light instead of the hot filaments used in halogen bulbs.[51] They have a lifetime of over 20,000 hours and undergo little degradation of output over this time.[52] LEDs do not require filters to produce blue light, are resistant to shock and vibration, and take little power to operate.[50] Earlier LED designs provided unsatisfactory results with metal brackets, possibly attributable to their low power output.[53] Current LEDs, however, manage to combine high power output (from 1000 to 3200 mW/cm^2) with a very narrow wavelength range around 465 nm, which very nicely matches the absorption peak of camphoroquinone (Fig. 27-9).[10]

BONDING

Bonding of brackets and other orthodontic attachments is one of the most important stages of the whole treatment process. The simplicity of bonding can be misleading. The technique undoubtedly can be misused, not only by an inexperienced clinician but also by more experienced orthodontists who do not perform procedures with care.[19] Minor errors in this stage will be dramatically reflected in the active treatment phase in forms of improper alignment of teeth, premature failure of attachments, which will require time-consuming and costly replacements, and increased susceptibility to the formation of demineralization around the attachment. Success in bonding requires an understanding of and adherence to the accepted principles of orthodontic and preventive dentistry, which are cleaning the adhesive surfaces, providing good wetting, providing intimate

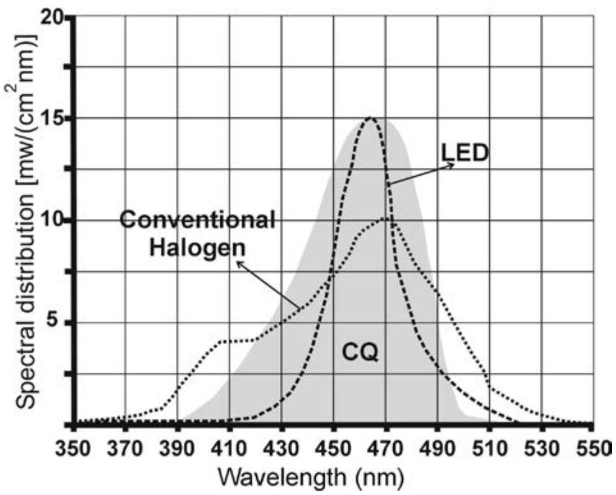

FIGURE 27-9 The spectral distribution and wavelength graphic demonstrates that the peak of light-emitting diode (LED) light sources better coincides with the absorption peak of camphoroquinone, which means that a photon emitted by an LED source is more likely to activate a camphoroquinone (CQ) molecule. (From Usumez S, Erverdi N. Adhesives and bonding in orthodontics. In: Nanda R, Kapila S, eds. *Current Therapy in Orthodontics*. 1st ed. St. Louis: Mosby; 2009:45–67.)

adaptation, and making use of maximum bond strength and adequate curing (polymerization).[10]

Bonding to Enamel

Premedication

Direct or indirect bonding of orthodontic attachments is a pain-free procedure, whereas initial activation of the orthodontic attachments may cause significant discomfort to the patient, particularly after a few hours. Recent research reveals that patients premedicated with 550 mg naproxen sodium 1 hour before archwire placement have significantly lower levels of pain at 2 hours, 6 hours, and nighttime after adjustment than patients taking a placebo.[54] Analgesic premedication may be considered for selected patients before proceeding to the bonding stage.[10]

The steps of direct or indirect bracket bonding on facial or lingual surfaces of teeth are as follows:

- Cleaning
- Enamel conditioning
- Sealing and priming
- Bonding

Cleaning

An ideal bonding surface should be free of any debris, and cleaning of the teeth with pumice will remove plaque and the organic pellicle that normally covers all teeth.[55] Care must exercised to avoid traumatizing the gingival margin and initiating bleeding on teeth that are not fully erupted.[19]

The need for conventional pumice polishing before acid etching has been questioned[56,57] since neither bond strength nor enamel surface etch pattern is altered by pumicing clean enamel.[58] However, pumice prophylaxis does not appear to affect the bonding procedure adversely, and cleaning the tooth may be advisable to removing plaque and debris that otherwise might remain trapped at the enamel–resin interface, particularly when bonding posterior teeth that are sometimes out

FIGURE 27-10 The Dri-Angle (Patterson Dental, St. Paul, MN) is an improvement on the cotton roll in the parotid area. The Dri-Angle covers the parotid or Stensen duct to restrict the flow of saliva. (Courtesy of Dental Health Products, Inc.)

of reach of efficient brushing activity.[59] On the other hand, it should be noted that pumicing before the use of an SEP is crucial (see related section).[59,60]

Enamel Conditioning

Moisture control. Salivary control and maintenance of a dry working field are essential after rinsing and drying. Many devices on the market accomplish this:

- Lip expanders and cheek retractors
- Saliva ejectors
- Tongue guards with bite blocks
- Salivary duct obstructors
- Gadgets that combine several of these devices
- Cotton or gauze rolls

These products are being continually improved, and the clinician must decide which devices work best. For simultaneous molar-to-molar bonding in both arches, a technique using lip expanders (Dri-Angles, Patterson Dental, St. Paul, MN) to restrict the flow of saliva from the parotid duct (Fig. 27-10) and saliva ejectors both work well.[19]

Present research indicates that antisialagogue agents do not present a statistically significant effect on the observed bond failure rates and generally are not needed for most patients.[61]

Enamel pretreatment

Conventional Acid Etching. Isolation of the operative field is followed by etching of the enamel surface. An untouched enamel surface is hydrophobic, and wetting is limited, which makes bonding to an intimate enamel surface a challenging procedure. An enamel pretreatment or surface conditioning is necessary to make successful bonds. This pretreatment is usually accomplished by etching the surface using various acids. The most commonly used etchant is 37% orthophosphoric acid for 15 to 30 seconds.[4,5]

At the end of the etching phase, the etchant is rinsed off the teeth with abundant water spray. A high-speed evacuator is strongly recommended for increased efficiency in collecting the etchant-water rinse and to reduce moisture contamination on the teeth and Dri-Angles (Patterson Dental, St. Paul, MN). Salivary contamination of the etched surface should best be avoided. (If contamination occurs, then rinsing with the water spray or re-etching for a few seconds is recommended; the patient must not rinse.) Since blood contamination has been shown to decrease the shear bond strength (SBS), teeth that are contaminated with blood should be rerinsed and dried.[62–64] Applying a protective liquid polish (BisCover, Bisco, Inc., Schaumburg, IL) to the etched surface before any contamination occurs has been shown to prevent the untoward effects of blood contamination.[62] This product may be beneficial in difficult bonding areas such as partially erupted or impacted teeth.

Next, the teeth are thoroughly dried with a moisture and oil-free air source to obtain the well-known dull, frosty appearance (see Fig. 27-6, *A*). Teeth that do not appear dull and frosty white should be re-etched.

This procedure probably reflects the general use of acid etching in orthodontics. Although considerable discussion of several aspects of enamel pretreatment remains, most of the debate concerning acid etching appears to be of limited clinical significance, because, apparently, good bond strength significantly depends more on both avoiding moisture contamination and achieving undisturbed setting of the bonding adhesive than on variations in the etching procedures.[19]

Some areas of debate and some short answers are provided:

Should the etching cover the entire facial enamel or only a small portion outside the bracket pad? Although laboratory research indicates increased susceptibility for WSLs by surplus orthodontic etching exceeding the bracket base area,[65] clinical experience over more than 25 years indicates that etching the entire facial enamel with solution is harmless—at least when a fluoride mouth rinse is regularly used.

Are gels preferable to solutions? Despite the fact that the liquid form is suggested for scientific studies, no apparent difference exists in the degree of surface irregularity after etching with an acid solution compared with etching with an acid gel.[66] Gels provide better control for restricting the etched area but may require a more thorough rinsing afterward.

What is the optimal etching time? Is it different for young and old teeth? Studies[66–70] and clinical experience indicate that 15 to 30 seconds is probably adequate for etching most young permanent teeth. However, important individual variation exists in enamel solubility among patients, between teeth, and within the same tooth. One benefit of conventional acid etching is that it tends to neutralize the differences among individuals and between teeth. Thus phosphoric acid etching of sufficient time can compensate for those individuals whose enamel is more resistant to acid.

Can recently bleached teeth be safely bonded? Today, bleaching is an increasing trend, and current information is conflicting, with some research[71] indicating no adverse effect, whereas other studies indicate that bleaching with 35% hydrogen peroxide significantly reduces bracket adhesion when bonded 24 hours after bleaching. However, no significant adverse effect of bleaching seems to occur after 7 days.[72] Therefore postponing the bonding procedure approximately 1 to 4 weeks for recently bleached teeth may be a good practice.

What is the preferred procedure for deciduous teeth? A recommended procedure for conditioning deciduous teeth is to sandblast with 50 microns of aluminum oxide for 3 seconds to remove some outermost aprismatic enamel and then etch for 30 seconds with phosphoric acid gel. The failure rate with this procedure for the authors of this text is less than 5%.[19]

Is prolonged etching necessary when teeth are pretreated with fluoride? Clinical and laboratory experience[66,67] indicates that extra etching time is not necessary when teeth have been pretreated with fluoride. When in doubt, the enamel should be checked for the uniformly dull and frosty white appearance after etching; if the desired appearance is confirmed, then surface retention is adequate for bonding. On the other hand, recent research shows that an adhesion promoter (Shofu, Inc., Kyoto, Japan) can recover the bond strength reduced by the long-term repeated topical applications of fluoride to the pre-fluoridation level.[73]

Is etching permissible on teeth with internal white spots, or is it more likely that the etchant will open up underlying demineralized areas? Caution should be exercised when etching over acquired and developmental demineralizations. The procedure is best avoided. If avoidance is impossible, then a short etching time, the application of a sealant or primer, and the use of direct bonding with extra attention to not having areas of adhesive deficiency are important. The presence of voids, together with poor hygiene, can lead to metal corrosion[74] and indelible staining of underlying developmental white spots.[75]

How much enamel is removed by etching, and how deep are the histologic alterations? Are they reversible? Is etching harmful? A routine etching removes from 3 to 10 microns of surface enamel.[75–78] Another 25 microns reveal subtle histologic alterations,[79–81] creating the necessary mechanical interlocks (see Fig. 27-1). Deeper localized dissolutions generally cause penetration to a depth of approximately 100 microns or more.[79,81,82] Although laboratory studies indicate that the enamel alterations are largely (although not completely) reversible,[81,83] the overall effect of applying an etchant to healthy enamel is not detrimental. This point is augmented by the fact that normal enamel is from 1000 to 2000 microns thick,[82,84] except where it tapers toward the cervical margin. Abrasive wear of facial enamel is normal and proceeds at a rate of up to 2 mm per year, and facial surfaces are self-cleaning and not prone to caries.[2]

What are other alternatives to etching with phosphoric acid (e.g., polyacrylic acid, maleic acid, SEPs)? The use of polyacrylic acid with residual sulfate is reported[74] to provide retention areas in enamel similar to those after phosphoric acid etching with less risk of enamel damage at debonding. However, other researchers have found much weaker bonds.[85–88] Research shows that 10% maleic acid, which is believed to decrease mineral loss alone, may produce similar bond strengths to 37% phosphoric acid.[89–93] However, the use of these milder acids has never been popularized.

Laser Etching. Laser treatment of dental enamel causes thermally induced changes within the enamel to a depth of 10 to 20 μm, depending on the type of laser and the energy applied to the enamel surface, in effect, etching takes place through a process of continuous vaporization and microexplosions due to vaporization of water trapped within the hydroxyapatite matrix (Fig. 27-11, *A–H*).[10] The degree of surface roughening is dependent on the system used and the wavelength of the laser.[94,95] The previous research demonstrated that achieved SBS diverge.[94,96,97] However, more recent findings with improved power and irradiation settings demonstrate more consistent enamel surface alterations and SBS values without any thermal damage.[98,99]

FIGURE 27-11 **A–F,** Lasers can be used to reshape the gingiva and to etch the enamel effectively with specific power settings (Gold Handpiece, Biolase Technology, Inc., Irvine, CA). **G,** With some new handpieces, the size and shape of the area to be etched can well be controlled (X-Runner handpiece, Fotona Technology, Ljubljana, Slovenia; San Clemente, CA). **H,** Laser irradiation causes thermal-induced changes within the enamel to a depth of 10 to 20 μm, depending on the type of laser and the energy applied to the enamel surface. The results regarding achieved shear bond strength diverge; in general, lasers are unable to produce a standard and reliable etching pattern at the moment. (**A–G,** Courtesy of Drs. Aslihan Usumez and Sertac Aksakalli, Istanbul, Turkey. **H,** From Usumez S, Erverdi N. Adhesives and bonding in orthodontics. In: Nanda R, Kapila S, eds. *Current Therapy in Orthodontics*. 1st ed. St. Louis: Mosby; 2009;45–67.)

The surface produced by laser etching is also claimed to be acid resistant as a result of the modified calcium-to-phosphorus (Ca/P) ratio, a reduced carbonate-to-phosphate ratio, and the formation of more stable and less acid-soluble compounds, thus reducing susceptibility to acid attack and caries.[100,101] Despite that it was shown[102] that subablative erbium:yttrium aluminium garnet (Er:YAG) laser irradiation before acid etching with a topical application of fluoride varnish increases the microhardness of enamel without reducing the SBS, current research[103] indicates that laser treatment of enamel does not significantly affect the mean percentage weights of elements. Therefore taking advantage of laser-induced caries resistance through an altered Ca/P ratio seems questionable in dental practice.

Sealing and Priming

After the teeth are completely dry and frosty white, a thin layer of bonding agent (sealant, primer) may be painted over the etched enamel surface. The coating may be thinned by a gentle air burst for 1 to 2 seconds (Fig. 27-12, *A* and *B*). A thick layer may cause drifting before curing is initiated and may interfere with the precise adaptation of the bracket base. Bracket placement should be immediately started after all of the etched surfaces are coated. Separate curing of the bonding agent is not necessary when light-cured products are used. The layer may be precured in hard-to-reach areas where moisture contamination is likely. Reapplication of the sealed layer is not required when saliva contamination occurs, but the area should be air dried before bracket placement.

Bonding

Immediately after all teeth to be bonded have been painted with a sealant or primer, the operator should proceed with the actual bonding of the attachments. At present, the majority of clinicians routinely bond brackets with the direct rather than the indirect technique. According to a 2014 survey in the United States, approximately 90% of orthodontists routinely use direct bonding. Indirect bracket bonding is routinely used labially by approximately 18% of orthodontists, which indicates an increase in its use.[5] Only 15% of the specialists in the United States are routinely using the chemically cured one- or two-paste adhesives (this was 50% in 2008), whereas 80% of those who have adopted the light-initiated bonding resins prefer the no-mix versions.[4,5]

Many different adhesives exist for direct bonding, and new ones continually appear. However, the basic bonding technique is only slightly modified for varying materials, according to each manufacturer's instructions. The easiest method of bonding is to add a slight excess of adhesive to the backing of the attachment (Fig. 27-13) and then place the attachment on the tooth surface in its correct position.

When bonding attachments one at a time with a light-cured adhesive, the operator can work in a relaxed manner and obtain optimal bond strength for each bracket. Hurrying is not necessary; plenty of time is available for placing the bracket in its

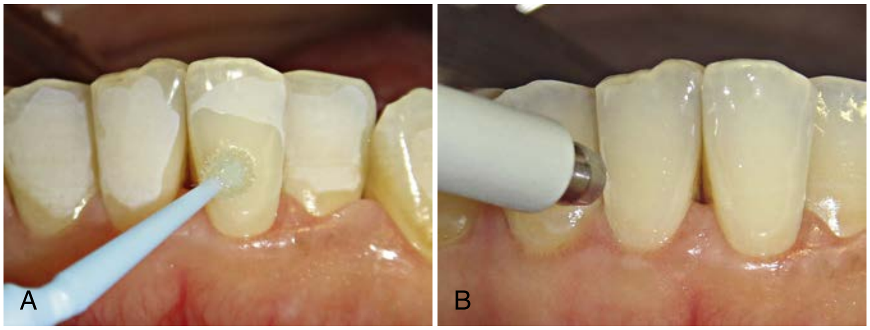

FIGURE 27-12 **A,** A thin layer of bonding agent (primer) is painted over the entire etched surface. **B,** The coating may be thinned by a light burst of air to avoid drifting of the attachment before curing and to improve its adaptation. (Courtesy of Dr. Sabri Ilhan Ramoglu, Istanbul, Turkey.)

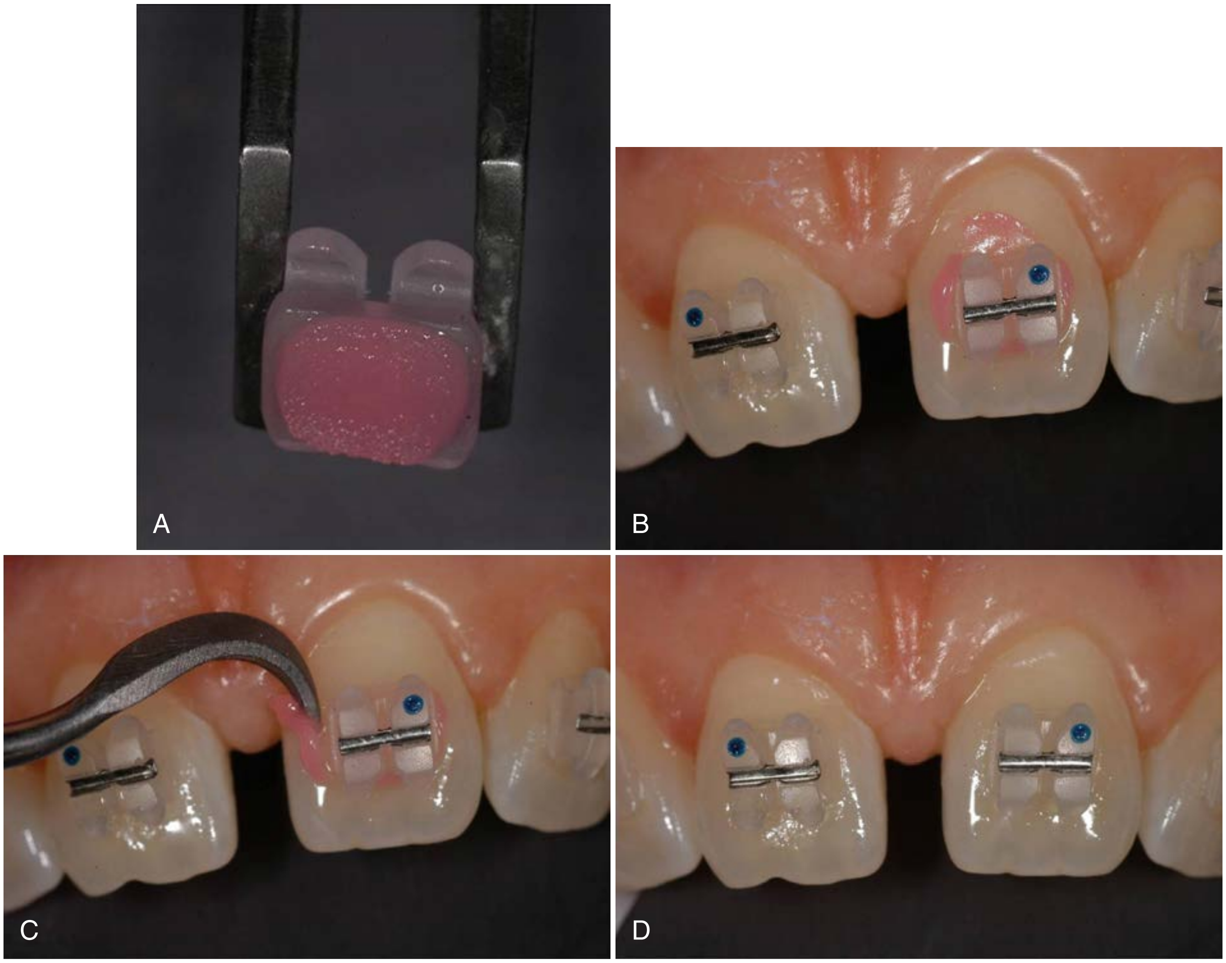

FIGURE 27-13 Direct bracket bonding with light-cured color-change adhesive resin. **A,** Adhesive resin on contact surface of bracket. **B,** Bracket transferred to tooth surface and oriented with placement scaler. **C,** Excess adhesive (*pink color*) is removed with the scaler before light activation. **D,** No color of adhesive resin after curing.

correct position, checking it, and, if necessary, repositioning it before light curing.

The recommended bracket bonding procedure[1,104] (with any adhesive) consists of the following steps[10]:

1. Transfer
2. Positioning
3. Fitting
4. Removal of excess
5. Curing

Transfer. The clinician grips the bracket with reverse action tweezers and then applies the mixed adhesive to the back of the bonding base. The clinician immediately places the bracket on the tooth, close to its correct position (see Fig. 27-13, *B*).

Positioning. The mandibular molar and premolar bracket wings must be kept out of occlusion, or the brackets may easily come loose. Therefore before positioning the brackets, the operator should do the following:

1. The patient is asked to bite with his or her teeth together; the operator should then evaluate the tooth area available for bonding.
2. The mandibular posterior brackets are bonded out-of-occlusion, which may necessitate adjusting bends in the archwires.

Later, the clinician uses a placement scaler to position the brackets mesiodistally and incisogingivally and to angulate them accurately, relative to the long axis of the teeth. Proper vertical positioning may be enhanced by different measuring devices or height guides.[105] A mouth mirror will aid in horizontal positioning, particularly on rotated premolars (see Fig. 27-4). Because of human limitations in the direct placement of brackets on both anterior and posterior teeth, using archwire bends or bracket repositioning to compensate for the inherent inaccuracies in bracket positions is still necessary.[105] Placing the brackets too far gingivally is important to avoid, unless dictated by the opposing teeth, which is sometimes the case in the lower arch. This leads to incomplete expression of the torque value built into the bracket and improper hygiene conditions. The brackets may come into contact with the gingival margin particularly after intrusive tooth movement as the gingival margin and the mucogingival junction moved in the same direction as the teeth by only 79% and 62%, respectively. A statistically significant decrease of the clinical crown length was also observed after intrusion.[106] The bite should be raised with occlusal stops from proper composite material when necessary (see Occlusal Buildup of Posterior Teeth).

Fitting. Next, the clinician turns the scaler and, with one-point contact with the bracket, firmly pushes toward the tooth surface.[107] The tight fit results in good bond strength, little material to remove on debonding, optimal adhesive penetration into bracket backing, and reduced slide when excess material peripherally extrudes. The clinician should remove the scaler after the bracket is in the correct position and should make no attempts to hold the bracket in place with the instrument. Even slight movement may disturb the setting of the adhesive. A totally undisturbed setting is essential for achieving adequate bond strength.[104]

Removal of excess. A slight bit of excess adhesive is essential to minimize the possibility of voids and to ensure that the adhesive will be buttered into the bracket backing when the bracket is being fitted. The excess is particularly helpful on teeth with abnormal morphologic structures. Excess adhesive will not be worn away by tooth brushing and other mechanical forces; it must be removed (especially along the gingival margin) with the scaler before the adhesive has set (see Fig. 27-13, *C*) or with burs after setting (Fig. 27-14).

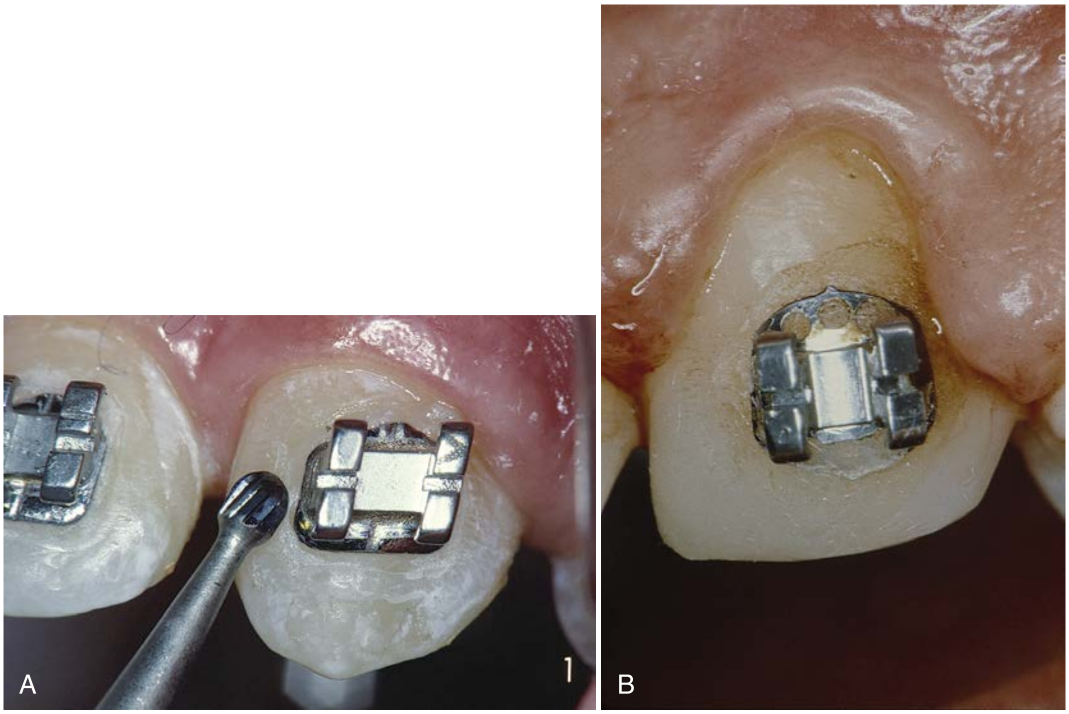

FIGURE 27-14 **A,** Use of a large (No. 7006) oval tungsten carbide bur for the removal of set adhesive around the bracket base. **B,** Relationship between excess adhesive and gingival inflammation. Note the hyperplastic gingival changes on the distal aspect, where excess adhesive is close to the gingival margin. Less reaction occurs on the mesial aspects, where adhesive is farther from the gingiva.

Removing the excess adhesive to prevent or minimize gingival irritation and plaque buildup around the periphery of the bonding base is most important (see Figs. 27-13 and 27-14). The removal of excess adhesive reduces periodontal damage and the possibility of decalcification. Clinically significant gingival hyperplasia and inflammation rapidly occur when excess adhesive comes close to the gingiva and is not properly removed.[1,104] In addition, the removal of excess adhesive can improve aesthetics, not only by providing a neat and clean appearance but also by eliminating exposed adhesive that might become discolored in the oral environment.

Some manufacturers add a coloring agent to assist in the visualization of the excess adhesive (APC II/Plus, 3M Unitek, Monrovia, CA) (see Fig. 27-14, *B* and *C*), although recent research revealed that this method does not reduce the amount of excessive adhesive around orthodontic brackets.[108] Another recent advance in this aspect is the introduction of a flash-free product (APC Flash-Free, 3M Unitek, Monrovia, CA) (Fig. 27-15). In this product, a new transparent APC adhesive formulation is contained within a form-fitting fiber mat on the base of the bracket. The manufacturer claims that when the flash-free adhesive coated bracket is placed on the tooth, the adhesive spreads out and conforms to the tooth surface, making uniform and consistent contact with no flash to clean. A recent study shows that the new flash-free adhesive performs just as well as the conventional adhesive with regard to bond quality and adhesive remnant cleanup; of the two products, clinicians preferred the flash-free adhesive over the conventional adhesive.[109] The clinical experience of the authors of this text, on the other hand, suggests that these appliances are best avoided when bonding to microdontic teeth or teeth with gross irregularities, as these brackets lack that small bit of excess adhesive that is essential to minimize the possibility of voids when a misfit between the bracket base and the enamel surface topography occurs.

When the procedure just described has been repeated for every bracket to be bonded, the clinician carefully checks the position of each bracket (see Fig. 27-4). Any attachment that is not in good position should be immediately removed with pliers and rebonded. After inserting a leveling archwire, the clinician instructs the patient how to brush properly around the brackets and archwires and gives a program of daily fluoride mouth rinses (0.05% sodium fluoride [NaF]) to follow.[110]

Curing. Once the bracket is secured in the desired position, the adhesive layer is cured with the light source. The correct setting should be preset before the curing. Today's light sources present different curing modes, including soft start modes to decrease polymerization contraction. On the other hand, polymerization contraction is irrelevant to the orthodontic setting where the bracket or the orthodontic attachment is actually free floating. Therefore presetting the light-curing unit to the maximum available setting or to the boost mode is advisable. Recent studies demonstrate no significant differences between the SBS values of brackets with curing distances of 0 to 4 mm.[111] The light is best initiated after being placed at the correct position and angulation as close to the bracket base as possible (Fig. 27-16). Divergent photon release will be avoided and curing efficiency increased if the light guide is brought into contact with the bracket after an initial cure of 1 to 2 seconds. Locating the guide tip before starting the light gun is crucial; with recent light sources, as little as even 2 or 3 seconds spent to position the guide tip correctly after shooting may well correspond to almost 40% of the total suggested curing time. Many manufacturers advise curing metal brackets from mesial and distal, direct bond molar tubes from mesial and distal or occlusal, and ceramic brackets through the bracket. Most current light sources can cure adhesives in approximately 10 or 5 seconds per metallic and ceramic brackets, respectively. A new plasma-emulating LED (VALO Ortho, Ultradent Products, Inc., South Jordon, UT) was demonstrated to cure resin under brackets in as few as 3 seconds,[43] which is also confirmed by the authors' clinical experience (Fig. 27-17). One clinical concern with this light source is the high heat reported by the patients at the gingiva, which is well tolerated when the patients are informed in advance. In the authors' recent laboratory studies, one of which was conducted under simulated blood circulation, the temperature increase in the pulp chamber was confirmed at 1.74° C, which is significantly lower than those resulting from longer exposures at lower power settings.[112,113] However, not every resin is compatible with every light source, and each combination should be individually assessed to achieve optimal results.[53,114,115]

FIGURE 27-16 The light guide is placed as close to the bracket base as possible and started to get the most benefit from the light energy. Physically touching the light guide to the bracket after 1 to 2 seconds is best to reduce divergent photon release.

Bonding to Artificial Tooth Surfaces

The number of adult patients being referred to orthodontic offices is steadily increasing,[5] and many adult patients have crown and bridge restorations fabricated from porcelain and precious metals in addition to amalgam restorations of molars. Banding becomes difficult, if not impossible, on the abutment teeth of fixed bridges. Recent advances in materials and techniques indicate, however, that effective bonding of orthodontic attachments to nonenamel surfaces now may be possible.[116,117] Particularly, the MicroEtcher (Danville Materials, Inc., San Ramon, CA) (Fig. 27-18), which uses 50-micron white or 90-micron tan aluminum oxide particles at approximately 7 kg/cm^2 pressure, has been advantageous for bonding to different artificial tooth surfaces. This tool is also useful for tasks such as rebonding loose brackets, increasing the retentive area inside molar bands,[13] creating micromechanical retention for bonded retainers, and bonding to deciduous teeth.

FIGURE 27-17 New high-intensity light-emitting diode (LED) curing lights are able to save the clinician chair time by reducing the curing time of orthodontics attachments to as few as seconds per tooth. (Courtesy of Ultradent Products, Inc., South Jordon, UT.)

Bonding to Porcelain

Most dental ceramic and metal ceramic crowns, bridges, and veneers are presently made from different feldspathic porcelains containing 10% to 20% aluminum oxide. However, such restorations can also be made from high-aluminous porcelains and glass ceramics.[118]

Several studies have reported that sandblasting porcelain alone is not suitable, but the addition of silane treatment may produce in vitro bond strengths that should be clinically successful[119]; however, these claims have not been verified by the authors' experiences, attributable to unacceptably high failure rates.

A more common and successful alternative to create an optimal retentive surface is the concept of etching the porcelain surface. The most commonly used porcelain etchant is 9.6% hydrofluoric acid in gel form. Although etching times vary anywhere from 1 to 2 minutes, this porcelain etchant has been reported to yield satisfactory results, and the gold standard seems to be 2 minutes, followed by silane application.[119–121] In the authors' hands, the addition of silane after hydrofluoric acid treatment did not significantly influence the bond strengths (failure rates of 8.2% versus 8.6%) (Figs. 27-19 and 27-20).

Hydrofluoric acid is strong and requires separately bonding to other teeth, careful isolation of the working area, cautious removal of the gel with a cotton roll, rinsing with high-volume suction, and immediate drying and bonding (see Fig. 27-19). The etchant creates microporosities on the porcelain surface that

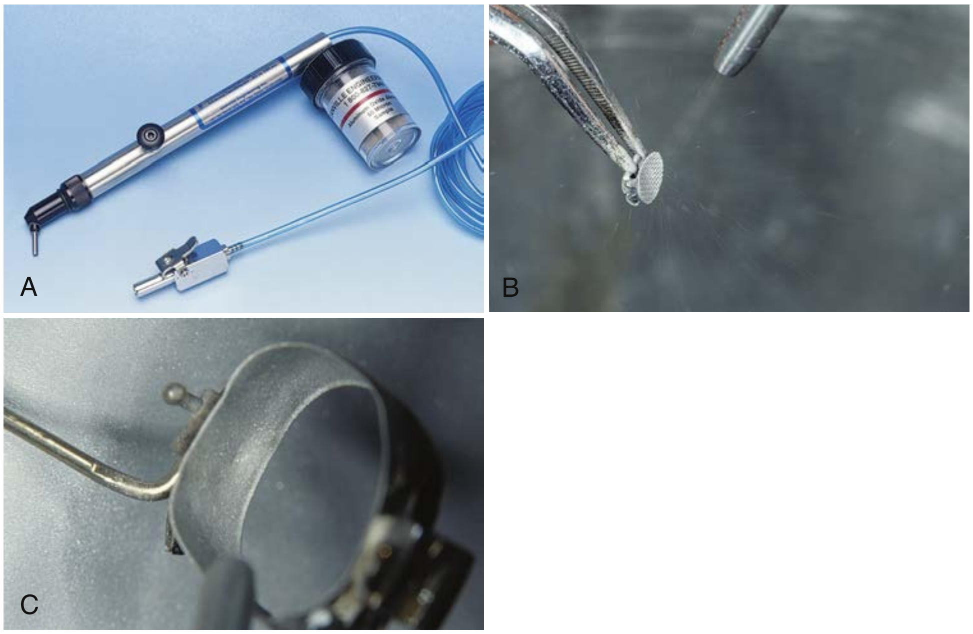

FIGURE 27-18 The MicroEtcher II (Danville Materials, Inc., San Ramon, CA) is an intraoral sandblaster approved by the U.S. Food and Drug Administration that is most useful for preparing microretentive surfaces in metals and other dental materials, whenever needed. **A,** The appliance consists of a container for the aluminum oxide powder, a pushbutton for fingertip control, and a movable nozzle where the abrasive particles are delivered. The MicroEtcher II is also useful for removing old composite resin and improving the retentive surface of loose brackets before rebonding (**B**) and the inside of the stainless steel molar bands (**C**).

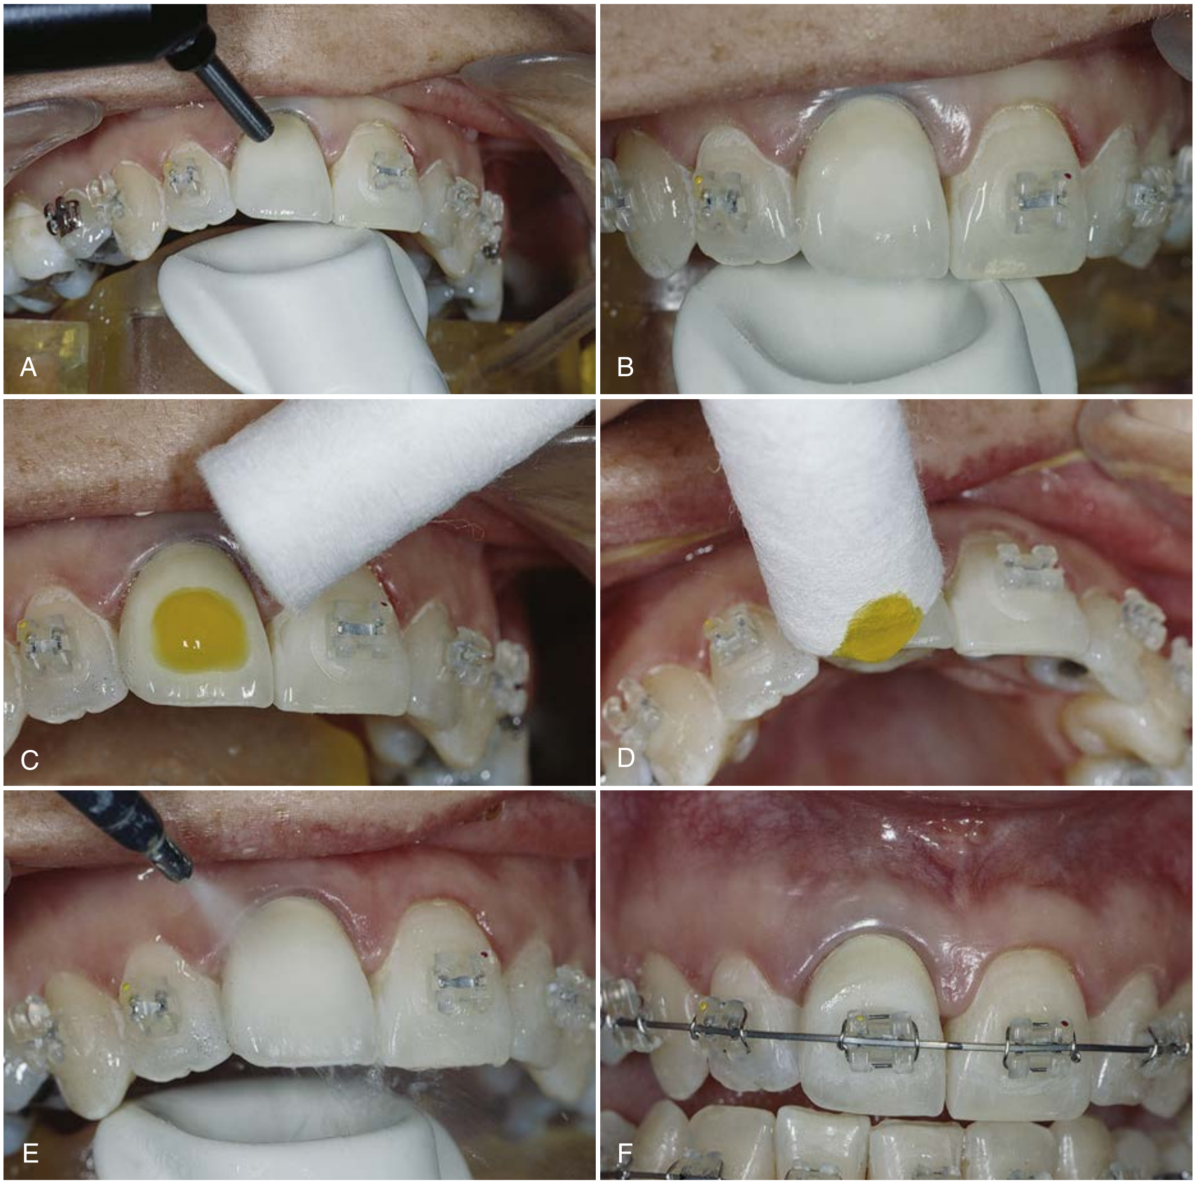

FIGURE 27-19 Technique for bracket bonding to porcelain surfaces includes reliable soft tissue retraction and separately bonding of the crown from other teeth. An area slightly larger than the bracket base is deglazed (**A, B**) before the hydrofluoric acid etching gel is applied for 2 minutes (**C**). The gel is removed with a cotton roll (**D**), and the teeth are rinsed with water and air spray under high-volume suction (**E**). **F,** Final result.

achieve a mechanical interlock with the composite resin.[122,123] The etched porcelain will have a frosted appearance similar to that of etched enamel.

Because of the caustic effects of hydrofluoric acid, several alternatives, including acidulated phosphate fluoride gel, or irradiation of ceramic surface with carbon dioxide or Er:YAG lasers were proposed all with similar or better results, compared with hydrofluoric acid.[124–127] However, none of these was popularized, attributable to either longer chair time or an unjustified amount of required investment.

For optimal bonding of orthodontic brackets and retainer wires to porcelain surfaces, the following technique is recommended (see Fig. 27-19):

1. Adequately isolate the working field, and bond the actual crown separately from the other teeth.
2. Use a barrier gel such as Kool-Dam (Pulpdent Corporation, Watertown, MA) (see Fig. 27-20) on mandibular teeth and whenever a risk exists that the hydrofluoric acid etching gel may flow into contact with the gingiva or soft tissues.
3. Deglaze an area slightly larger than the bracket base by sandblasting with 50 microns of aluminum oxide for 3 seconds.
4. Etch the porcelain with 9.6% hydrofluoric acid gel for 2 minutes.
5. Carefully remove the gel with a cotton roll, and then rinse using high-volume suction.
6. Immediately dry with air, and bond the bracket. Using a silane is optional.

Hydrofluoric acid will not be effective for bonding to high-alumina porcelains and glass ceramics, and new technique improvements are needed for successful orthodontic bonding

FIGURE 27-20 **A, B,** When hydrofluoric acid gel is used close to the gingival margin, particularly in the mandible, a light-cured blockout resin, such as Kool-Dam (Pulpdent Corporation, Watertown, MA) must be used to protect the soft tissues from the acid. **C,** A lower molar bracket must be positioned out of occlusion with the opposing teeth to avoid bracket loosening. If this is not possible, then the tie-wing in contact with the upper molar (usually the distal wing) should be ground with a green stone.

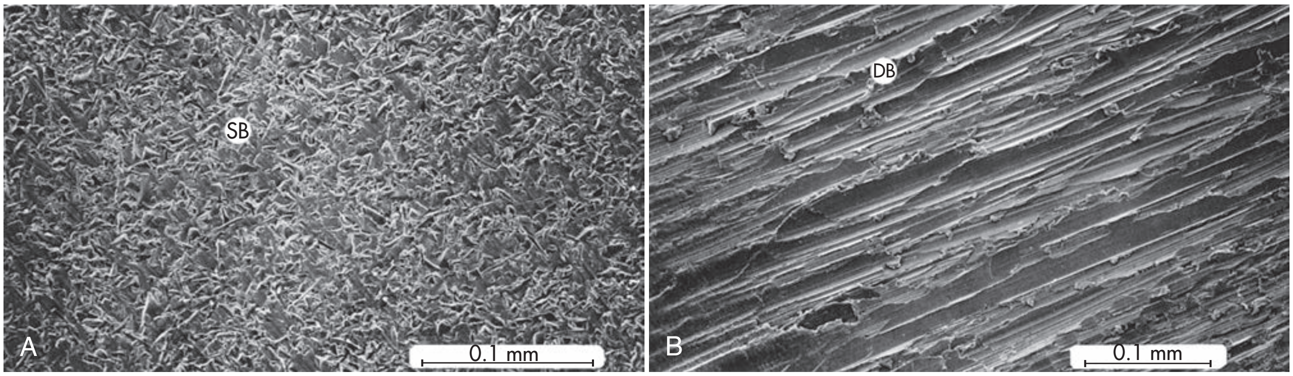

FIGURE 27-21 Scanning electron photomicrograph of a sandblasted (**A**) and diamond bur-roughened (**B**) metal surface. The use of the MicroEtcher (Danville Materials, Inc., San Ramon, CA) for approximately 3 seconds (*SB*) provides excellent micromechanical retention, whereas periodic ridges and grooves produced by medium-grit diamond bur (*DB*) have few undercuts for mechanical retention. *Bar*, 0.1 mm.

to such teeth. A newly introduced alternative technique to the use of hydrofluoric acid gel may be silica coating,[127–129] but further clinical trials are needed to obtain experience with the silica-coating technique.

Bonding to Amalgam

Improved techniques for bonding to amalgam restorations may involve (1) modification of the metal surface (sandblasting, diamond bur roughening) (Figs. 27-21 and 27-22), (2) the use of intermediate resins that improve bond strengths (e.g., ALL-BOND 2 [Bisco, Inc., Schaumburg, IL], Enhance and Metal Primer [Reliance Orthodontic Products, Itasca, IL]), and (3) new adhesive resins that chemically bond to nonprecious and precious metals (e.g., 4-methacryloxyethyl trimellitate anhydride [4-META] resins and 10-methacryloyloxi-decyl-dihydrogen-phosphate [10-MDP] bisGMA resins).[130,131]

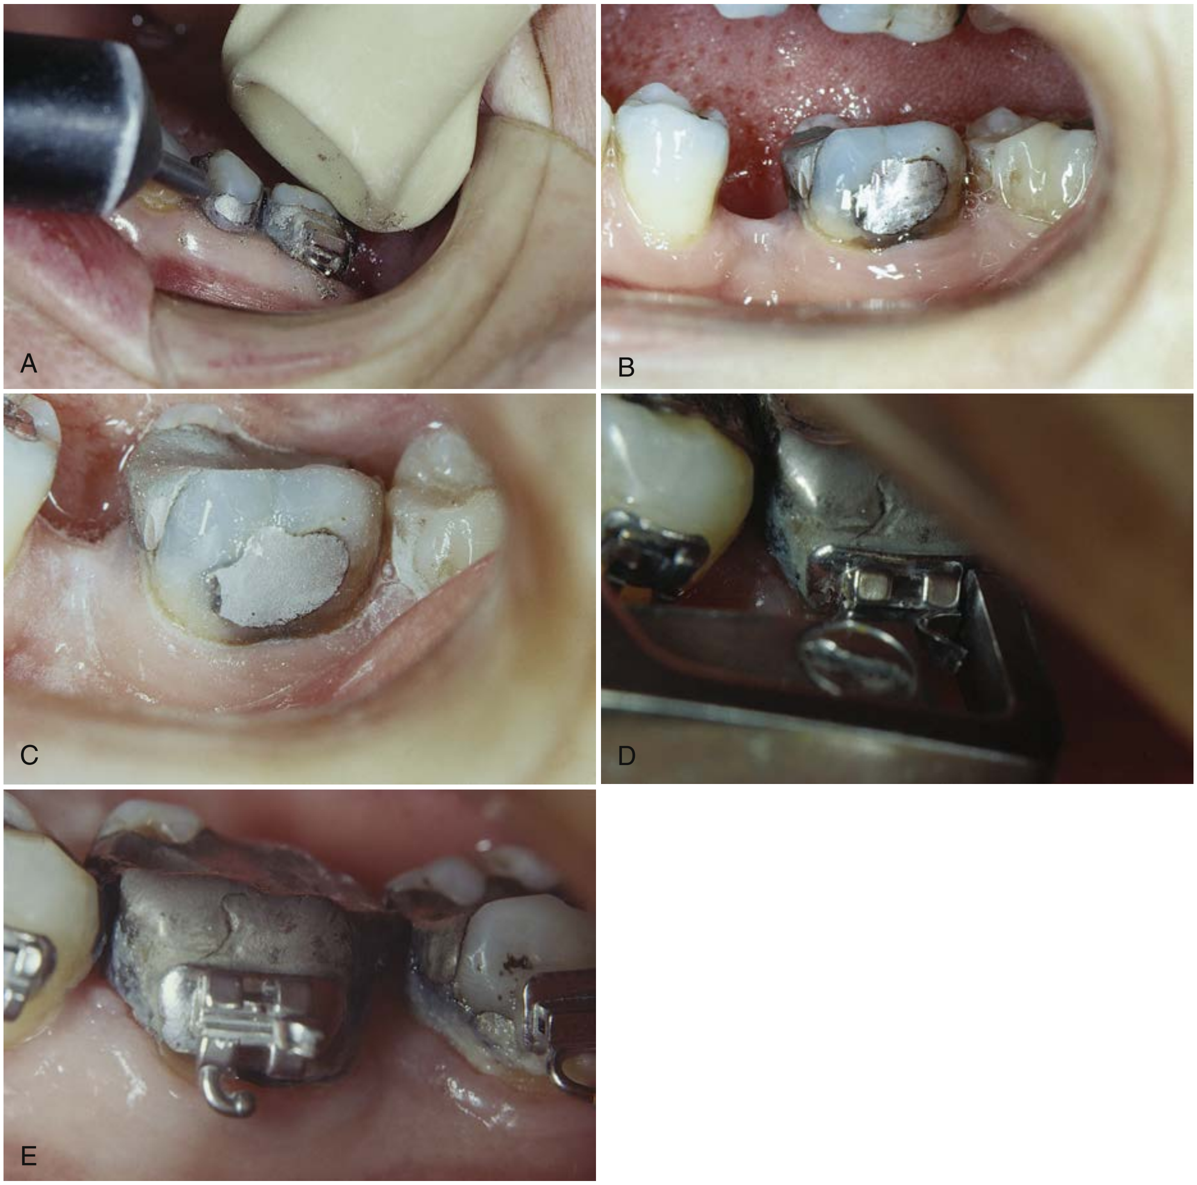

FIGURE 27-22 **A,** During air abrasion, high-velocity evacuation is necessary. **B, C,** Intraoral sandblasting of amalgam restorations produces frosted appearance, indicating increased micromechanical retention. **D, E,** Convertible cap removal on the attachment bonded to amalgam only on the mandibular first molar, indicating strength of bond.

Similar to bonding to porcelain, apparently a positive correlation does not exist between laboratory and clinical findings when it comes to orthodontic bonding to amalgam fillings. In vitro bonds to amalgam are significantly weaker than for similar brackets bonded to enamel of extracted human teeth.[130–132] However, the clinical performance with different techniques is satisfactory. In the first amalgam study in the authors' laboratory,[130] mean tensile bond strength to sandblasted amalgam tabs ranged from 3.4 to 6.4 megapascal (MPa), in contrast to control bonds to human enamel of 13.2 MPa. The strongest bonds to amalgam were obtained with a 4-META adhesive (Superbond C&B, Sun Medical Co., Ltd., Kyoto, Japan), but an intermediate resin (All-BOND 2, Bisco, Inc., Schaumburg, IL) and the Concise Enamel Bond (3M Dental Products, St. Paul, MN) were comparable with those of Superbond C&B.

A follow-up in vitro study with different intermediate primers on the three primary types of dental amalgams (spherical, lathe cut, admixed) showed better results for two 4-META primers (Metal Primer [Reliance Orthodontic Products, Itasca, IL], Amalgambond Plus [Parkell Co., Farmingdale, NY]) than for All-BOND 2.[132] Clinical observations have confirmed these results.

The following procedures are recommended for bonding to amalgam.

Small amalgam filling with surrounding sound enamel.

1. Sandblast the amalgam alloy with 50 microns of aluminum oxide for 3 seconds (see Fig. 27-22, *A-C*).
2. Condition the surrounding enamel with 37% phosphoric acid for 15 seconds.
3. Apply sealant, and bond with composite resin. Ensure the bonded attachment is not in occlusion with antagonists.

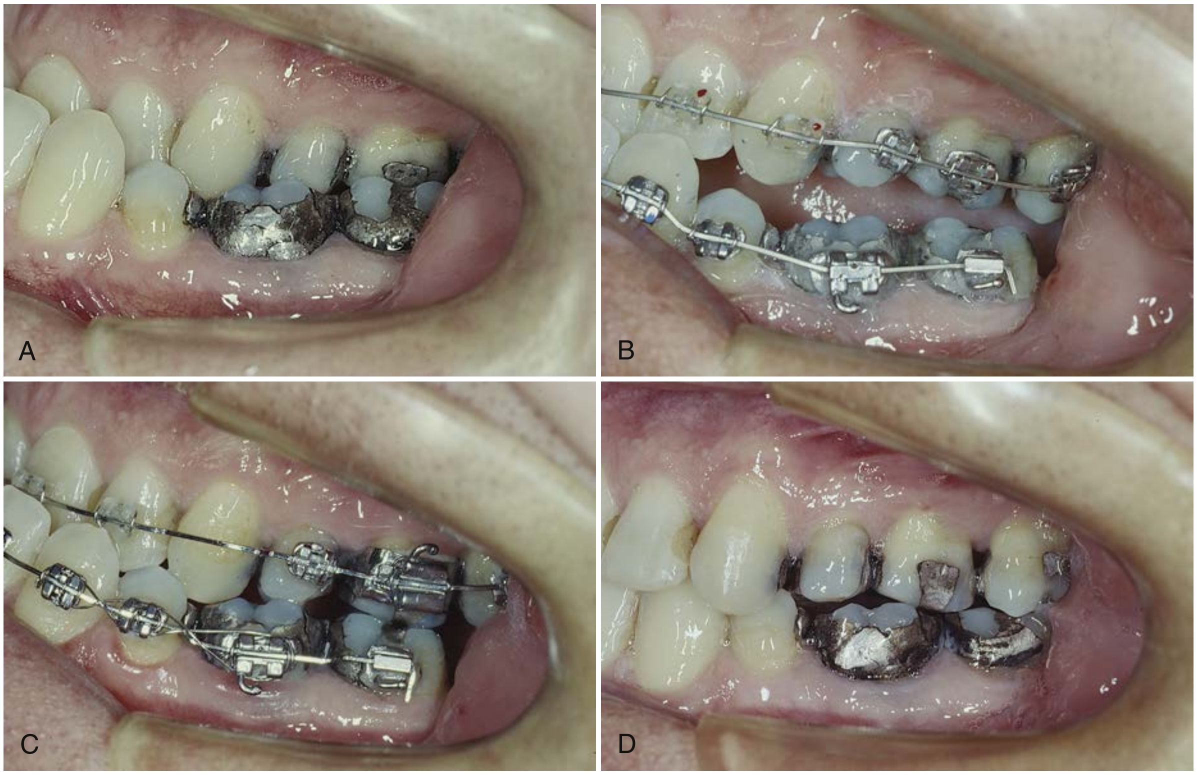

FIGURE 27-23 Orthodontic attachments bonded to large amalgam restorations on maxillary first and mandibular first and second molars in an adult Class III patient before (**A**), during (**B**, **C**), and after treatment (**D**). The superplastic (**B**) and rectangular stainless steel archwires (**C**) were bent over at the distal of the second molar during treatment without coming loose.

Large amalgam restoration or amalgam only.

1. Sandblast the amalgam filling with 50 microns of aluminum oxide for 3 seconds (Fig. 27-23; see also Fig. 27-22, *A–C*).
2. Apply a uniform coat of Reliance Metal Primer (Reliance Orthodontic Products, Itasca, IL), and wait for 30 seconds (or use another comparable primer according to the manufacturer's instruction).
3. Apply sealant, and bond with composite resin. Ensure the bonded attachment is not in occlusion with antagonists.

Of course, amalgam surfaces can be easily repolished with rubber cups and points after debonding.

Bonding to Gold

In contrast to bonding to porcelain and amalgam, excellent bonding to gold crowns is not yet available to orthodontic clinicians. This unavailability is surprising in light of the high bond strengths, which generally have been reported in different laboratory studies of gold alloys.[133] Different new technologies, including sandblasting, electrolytic tin-plating, or plating with gallium-tin solution (Adlloy), the use of several different types of intermediate primers, and new adhesives that chemically bond to precious metals (Superbond C&B [Sun Medical Co., Ltd., Kyoto, Japan] and Panavia Ex and Panavia 21 [Kuraray America, Inc., New York, NY])[117] have been reported to improve bonding to gold in laboratory settings. However, the high in vitro bond strengths to gold alloys have not been confirmed by satisfactory clinical results when bonding to gold crowns.

In the authors' experience, even a combination of intraoral sandblasting, coupled with the use of All-BOND 2 (Bisco, Inc., Schaumburg, IL) or 4-META primers and followed by bracket bonding with composite resin or special metal-bonding adhesives, may not optimally withstand the occlusal forces in clinical practice. Clinical studies are hampered by the fact that bracket bonding to gold restorations or retainer bonding to lingual metal-ceramic crowns (Fig. 27-24, *B*) is not frequently occurring in daily practice. A distinct difference between natural enamel or ceramic restorations and metal restorations is that curing light cannot travel through alloy or metal, and the amount of free radicals produced and the degree of conversion seem to be significantly less when bonding on the metal surface than on the enamel surface. Recently, it was demonstrated that primer precuring at the bracket base is required for secure bracket bonding on gold alloy surfaces using LED-curing units.[134] Further evaluation of this phenomenon is required for bonding to various gold alloys and large amalgam restorations.

Bonding to Composite Restoratives

The bond strength obtained with the addition of new composite to mature composite is substantially less than the cohesive strength of the material. However, brackets bonded to a fresh, roughened surface of old composite restorations after thorough air drying appear to be clinically successful in most instances.[135] The use of an intermediate primer is probably advantageous as well.

Indirect Bonding

Several techniques for indirect bonding are available. In some, the brackets are glued with a temporary material to the teeth on the patient's models, transferred to the mouth with a tray into which

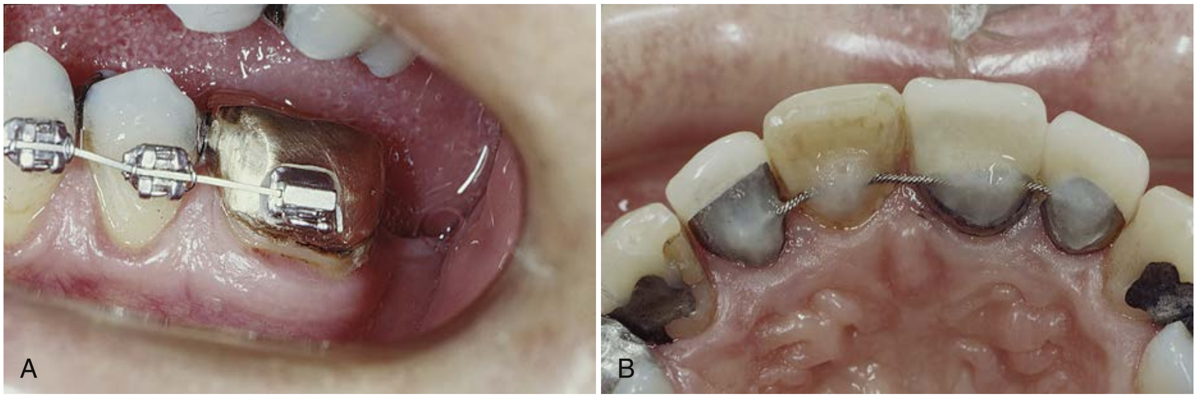

FIGURE 27-24 Bonding to tooth surfaces of gold alloy includes bracket bonding to molar crowns (**A**) and retainer wire bonding to the lingual of metal-ceramic crowns (right and left lateral incisors and right central incisor in **B**). If unfilled, then 4-methacryloxyethyl trimellitate anhydride (4-META) resin is used for retainer bonding; it may be covered with more abrasion-resistant composite resin. (From Büyükyilmaz T, Zachrisson YØ, Zachrisson BU. Improving orthodontic bonding to gold alloy. *Am J Orthod Dentofacial Orthop* 1995;108:510–518. Used with permission from the American Association of Orthodontics.)

the brackets become incorporated, and then simultaneously bonded with a bisGMA resin. However, most current indirect bonding techniques are based on a modification introduced by Thomas,[136] which attaches the brackets with composite resin to form a custom base (Fig. 27-25). A transfer tray of silicone putty or thermoplastic material is used, and the custom bracket bases are then bonded to the teeth with a chemically cured sealant.

Many advocates believe that reduced chair time and the delegation of the procedure make indirect bonding cost effective.[137] The claimed primary advantages of indirect compared with direct bonding are that the brackets can be more accurately positioned in the laboratory, and the clinical chair time is decreased. In fact, Hodge and co-workers[138] investigated the cost effectiveness in a hospital dental clinic and found a significant cost savings when using indirect bonding versus direct bonding in that setting, but clinical and laboratory studies fail to support this advantage in labial cases with a small gain in the accuracy of the height of the bracket.[138–140] Recent clinical and laboratory research also indicates similar adhesive quality and bracket survival rate with those of direct bonding.[141–143]

However, the indirect bonding is technique sensitive, and the chairside procedure is more crucial, at least for inexperienced clinicians; removal of excess adhesive can be more difficult and more time consuming with some techniques; the risk for adhesive deficiencies under the brackets is greater; the risk for adhesive leakage to interproximal gingival areas can disturb oral hygiene procedures; and the failure rates with some methods seem to be slightly higher.[144,145] Yet, indirect bonding deserves attention, as the trend to use this method among orthodontists in the United States is increasing (18% in 2014 compared with 13% in 2008).[4,5] In addition, in lingual orthodontics, the indirect technique is also a prerequisite for good bracket alignment because direct visualization has evident difficulties.

Numerous products and methods that are specifically designed for indirect bonding procedures are available. Different types of custom base composites may be light cured, chemically cured, or thermally cured.[135,145,146] One system (from Reliance Orthodontic Products, Itasca, IL) recommends the use of a thermally cured base composite (Therma-Cure), Enhance adhesion booster, and a chemically cured sealant (Custom I.Q.). Another system (from 3M Unitek, Monrovia, CA) recommends the use of light-cured base composite (Transbond XT) and chemically cured sealant (Sondhi Rapid-Set) in the clinic (Fig. 27-26).

Clinical Procedure

As previously mentioned, several indirect bonding techniques have proved reliable in clinical practice (see Figs. 27-25 and 27-26). The techniques differ in the way the brackets are attached temporarily to the model, the type of transfer tray used (e.g., full-arch, sectioned full-arch, single tooth, double-tray system), the sealant or resin used, whether segmented or full bonding is used, and the way the transfer tray is removed so as not to exert excessive force on a still-maturing bond.

Indirect Bonding with Composite Custom Bracket Base

Most current techniques use composite resin custom bracket bases (light cured, thermally cured, or chemically cured) and a chemically cured sealant as the clinical bonding resin. The following procedure may be useful (see Fig. 27-26)[19]:

1. Take an impression, and pour a stone (not plaster) model.
2. Select brackets for each tooth.
3. Isolate the stone model with a separating medium.
4. Attach the brackets to the teeth on the model with light-cured or thermally cured composite resin, or use adhesive precoated brackets.
5. Check all measurements and alignments. Reposition if needed.
6. Make a transfer tray for the brackets. The material can be putty silicone, thermoplastics, or similar.
7. After removing the transfer trays, gently sandblast the adhesive bases with a microetching unit, taking care not to abrade the resin base.
8. Apply acetone to the bases to dissolve the remaining separating medium.
9. Prepare the patient's teeth for a direct application.
10. Apply Sondhi Rapid-Set (3M Unitek, Monrovia, CA) resin A to the tooth surfaces and resin B to the bracket bases. If Custom I.Q. (Reliance Orthodontic Products, Itasca, IL) is used, then apply resin B to the teeth and resin A to the bases. Alternatively, apply a thin coat of the mixture of part A and part B adhesive to

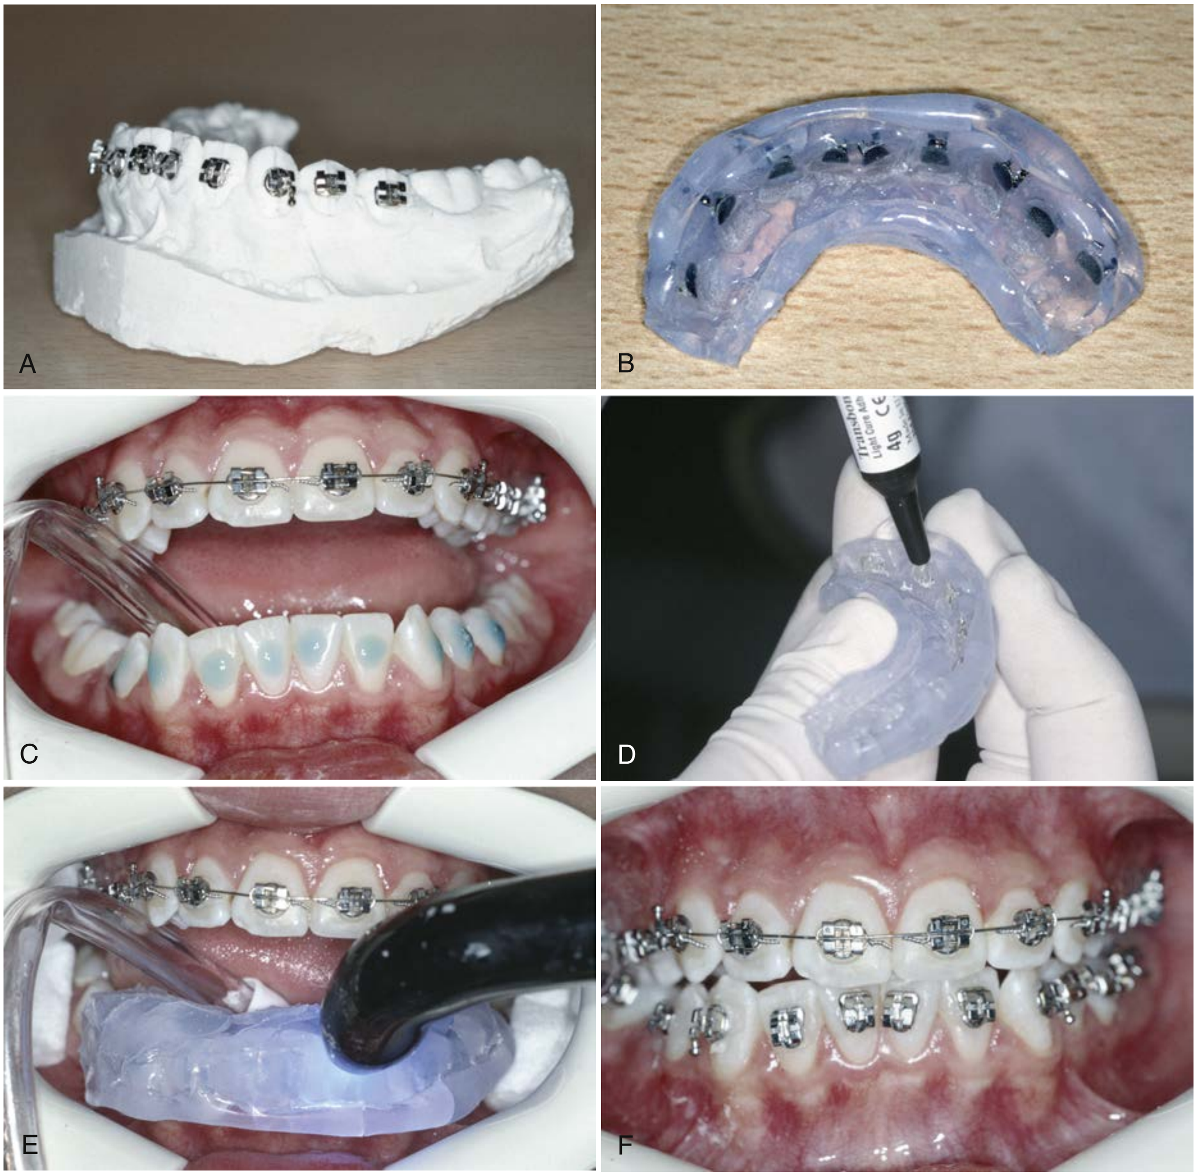

FIGURE 27-25 Indirect bonding using a Memosil 2 clear transfer tray (Heraeus Kulzer, Armonk, NY) and a light cure adhesive.

each custom resin base in the indirect bonding tray and to the tooth surface if using Transbond IDB Pre-Mix Chemical Cure Adhesive (3M Unitek, Monrovia, CA) (Fig. 27-27).

11. Seat the tray on the prepared arch, and apply equal pressure to the occlusal, labial, and buccal surfaces with the fingers. Hold for a minimum of 30 seconds, and allow for 2 minutes or more of curing time before removing the tray.
12. Remove excess flash of resin from the gingival and contact areas of the teeth with a scaler or contra-angle handpiece and tungsten carbide bur.

Rebonding

Bonded brackets that become loose during treatment, consuming significant chair time, are poor publicity for the office and are a nuisance to the orthodontist. The best way to avoid loose brackets is to adhere strictly to the rules for good bonding previously mentioned. Using a quick technique for rebonding loose brackets is also important.

The loose metal bracket removed from the archwire should first be inspected for any possible deformation of the slot that may have occurred during breakage. A bracket that seems to be deformed should be replaced with a new one. Any adhesive remaining on the tooth surface is removed with a tungsten carbide bur. The adhesive remaining on the loose bracket is best treated by sandblasting[147] (see Fig. 27-18) until all visible bonding material is removed from the base. The tooth is then etched with phosphoric acid gel for 15 seconds. On inspection, the enamel surface may not be uniformly frosty because some areas may still retain resin. The phosphoric acid will re-etch any exposed enamel and remove the pellicle on any exposed resin. After priming, the bracket is rebonded. The neighboring brackets are first religated, and then the rebonded bracket is ligated. The bond strength for sandblasted rebonded brackets is comparable to the success rate for new brackets,[147,148] but it should be noted that the brackets' SBS decreased as the size of the aluminum oxide particle used for sandblasting increased and as recycling was repeated.[149]

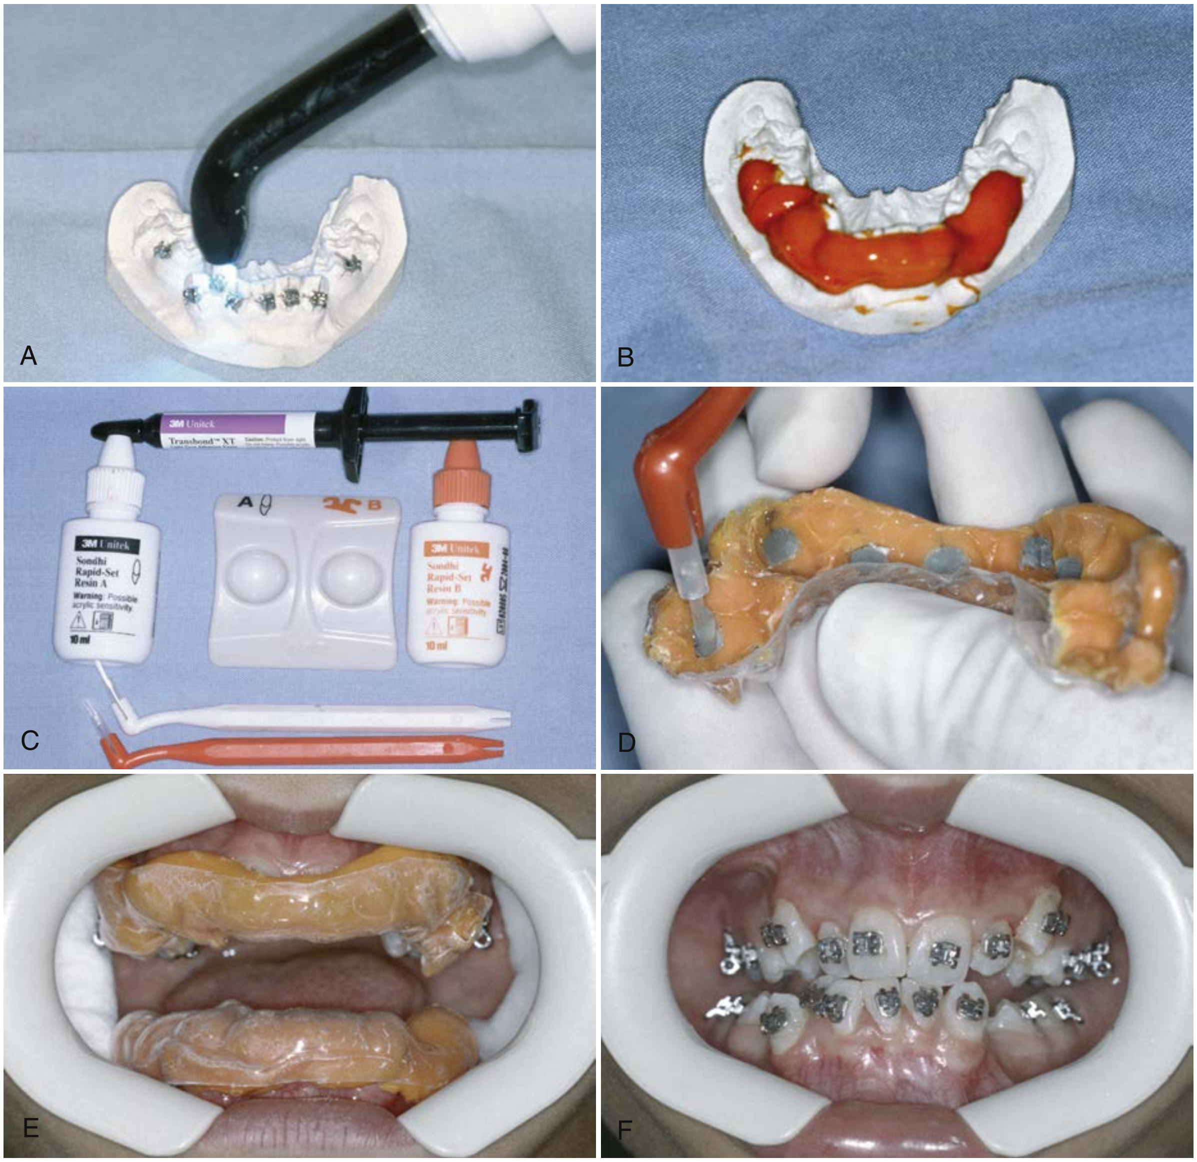

FIGURE 27-26 Indirect bonding using light-cured base composite (Transbond XT, 3M Unitek, Monrovia, CA) and chemically cured sealant (Sondhi Rapid Set, 3M Unitek, Monrovia, CA). (See text for details.)

FIGURE 27-27 Transbond IDB (3M Unitek, Monrovia, CA) is a premix chemical cure indirect bonding adhesive that can be used with custom-base adhesives. (Courtesy of 3M, © 2016 3M. All rights reserved.)

Reconditioning ceramic orthodontic brackets with an erbium, chromium:yttrium scandium gallium garnet (Er,Cr:YSGG) laser was found to be effective,[150] but a loose ceramic bracket should best be replaced with a new, intact bracket for optimal bond strength.

Conclusion

Bonding of brackets has changed the practice of orthodontics and has become a routine clinical procedure in a remarkably short time.[5]

In most routine situations, banding maxillary first molars provides a stronger attachment, and the availability of lingual sheaths (e.g., for transpalatal bars, elastics, and headgear) may give some interproximal caries protection. Finally, the procedure described for bonding mandibular second and third molars has proved to be successful in clinical use over many years. This success is particularly true in adolescents, whose teeth are erupting during the course of treatment. The

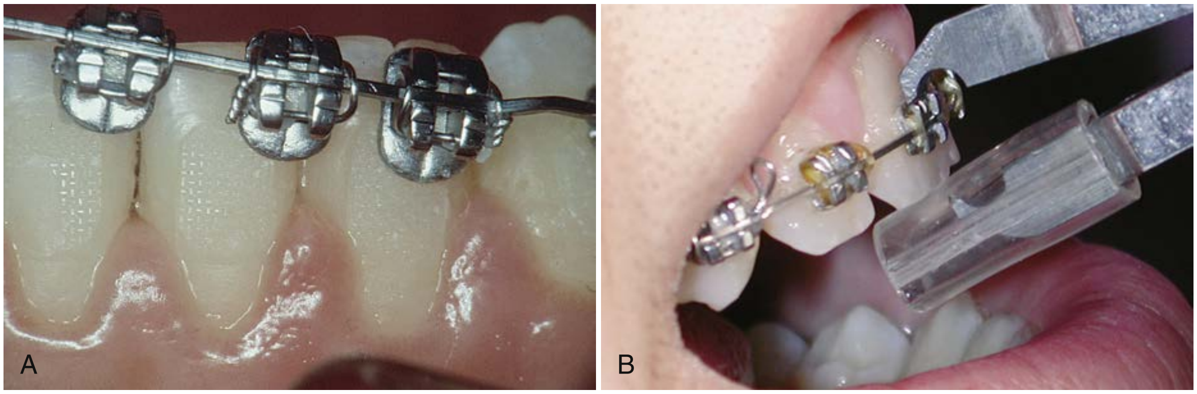

FIGURE 27-28 Bracket removal with pliers. Still ligated in place, the brackets are gripped, one by one, with 095 Orthopli Bracket-Removing Pliers (G&H Orthodontics, Inc., Franklin, IN) and lifted outward at a 45-degree angle. The indention in the pliers fits into the gingival tie-wings for a secure grip. This technique is quick and gentle and leaves the brackets intact and fit for recycling, if so desired. **A,** The bond breaks in the adhesive-bracket interface, and the pattern of the mesh backing is visible on the adhesive remaining on the teeth. **B,** The same technique is used for maxillary steel brackets.

mandibular second molar is better suited for bonding than for banding because gingival emergence of the buccal surface precedes emergence of the distal surface.

Modifications of technical devices, sealants and adhesives, attachments, and procedures are continuing. Careful study of the available information by the orthodontist will be mandatory in keeping up with the progress. However, cautious interpretation of in vitro studies is recommended because the in vivo results do not always reflect and verify the laboratory findings.[19] Long-term follow-up studies are needed in several areas such as bonding to amalgam, as well as for porcelain and gold, during a full period of routine orthodontic treatment in larger samples.[110]

Drawing valid clinical conclusions from laboratory bond strength studies is not possible for at least three different reasons: (1) a continually increasing tensile or shear load applied to bonded brackets in the laboratory is not representative for the force applications that occur clinically; (2) the type of debonding force in machines is not the same as the force applied in clinical debonding; and (3) the complex oral environment with variations in temperature, stresses, humidity, acidity, and plaque is not reproducible in the laboratory.[151]

The striking difference between the clinical and laboratory experiences with respect to bond strengths to porcelain, amalgam, and gold is challenging. The results from laboratory studies should be used only to indicate which products and materials seem most valuable to include in supplementary clinical evaluation. Clinical success is the final test.[116]

DEBONDING

Unlike other restorative practices in dentistry, the adhesive system set up in the beginning of the orthodontic treatment is removed and the brackets are removed after the completion of the therapy. The objectives of debonding are to remove the attachment and all the adhesive resin from the tooth and to restore the surface as closely as possible to its pretreatment condition without inducing iatrogenic damage. To obtain these objectives, a correct technique is fundamentally important. Debonding may be unnecessarily time consuming and damaging to the enamel if carelessly performed or performed with an improper technique.

Because several aspects of debonding are controversial, debonding is discussed in detail as follows:

- Clinical procedure
- Enamel tearouts and cracks (fracture lines)
- Removal of residual adhesive
- Amount of enamel lost in debonding
- Operator safety during debonding
- Prevention and reversal of decalcifications

Clinical Procedure

Although several methods have been recommended in the literature for bracket removal and adhesive cleanup, and some differences of opinion still exist, the techniques described have proved successful in the authors' experiences. Their rationales are mentioned throughout the ensuing discussion.

The clinical debonding procedure may be divided into two stages: (1) bracket removal and (2) removal of residual adhesive.

Removal of Steel Brackets

Whether metal or ceramic, the brackets should be individually removed to avoid force transfer from tooth to tooth, which may increase the risk of enamel crack formation.

Several different procedures are available for debracketing with pliers. An original method was to place the tips of a twin-beaked pliers against the mesial and distal edges of the bonding base and cut the brackets off between the tooth and the base. Several pliers are available for this purpose. A gentler technique is to squeeze the bracket wings mesiodistally and then lift the bracket off with a peel force. This technique is particularly useful on brittle, mobile, or endodontically treated teeth.

The recommended technique, in which brackets are not deformed, is illustrated in Figure 27-28. This technique uses a peeling-type force, which is most effective in breaking the adhesive bond. A peel force, as in peeling an orange, creates peripheral stress concentrations that cause bonded metal brackets to fail at low force values.[152] The break is likely to occur in the adhesive–bracket interface, thus leaving adhesive remnants on the enamel. Attempts to remove the bracket by shearing it off (as is done in removing bands) can be traumatic to the patient and potentially damaging to the enamel.

Removal of Ceramic Brackets

With the introduction of ceramic brackets, a new concern over enamel fracture and loss from debonding has arisen because debonding ceramic brackets is more liable to enamel fracture formation since they more strongly adhere to the enamel surface and will not flex when squeezed with debonding pliers.[153,154] Because of differences in bracket chemistry and bonding mechanisms, various ceramic brackets behave differently on debonding. The risk is lower with ceramic brackets using mechanical retention than those using chemical retention.[153,155–157] More recent ceramic brackets have a mechanical lock base and a vertical slot that will collapse the bracket by squeezing. Debonding collapsible ceramic brackets with the archwire in place and ligated (Fig. 27-29) to hold together the debonded bracket parts is recommended.

Mesiodistally cutting off the brackets with gradual pressure from the tips of twin-beaked pliers oriented close to the bracket–adhesive interface is not recommended because doing so may introduce horizontal enamel cracks.[19] Low-speed grinding of ceramic brackets with no water coolant may cause permanent damage or necrosis of dental pulps. Therefore water cooling of the grinding sites is necessary.

Lasers also have the potential to be less traumatic and less risky for enamel damage. This procedure first appeared to facilitate the removal of porcelain laminate veneers, which are bonded using a very strong resin cement. Öztoprak and colleagues demonstrated that with a new scanning method, the Er:YAG laser is effective for reducing SBS of ceramic brackets from high values to levels for safe removal from the teeth in 9 seconds per bracket.[158] Additionally, in a recent study, Mundethu and co-workers[159] reported that clear brackets can be debonded with a single pulse when irradiated with the Er:YAG laser operating at 600 mJ, 800-µs pulse, 1.3-mm fiber tip. With this method, 19 out of 20 brackets successfully debonded with a single pulse.[159] In this method, laser energy is transferred through the ceramic and absorbed at the composite layer where microexplosions occur, resulting in the detachment of the bracket without any thermal damage to the tooth[159,160] (Fig. 27-30, *A* and *B*).

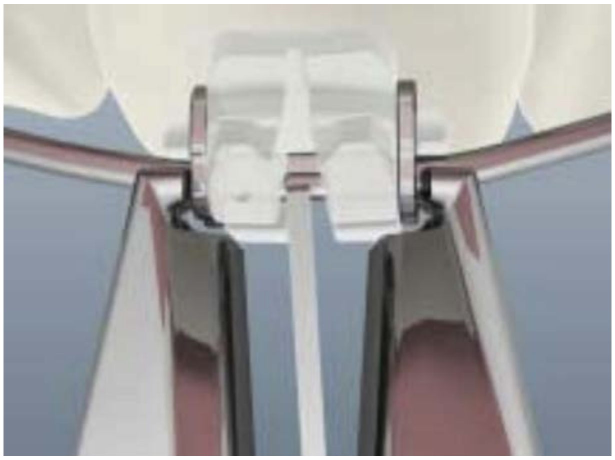

FIGURE 27-29 Debonding of collapsible ceramic brackets can be accomplished by using either Howe or Weingart pliers or respective debonding instrument of the company. Debonding collapsible ceramic brackets with the archwire in place and ligated is recommended. Whatever method is used, providing eye protection for the patient and operator to avoid scattering ceramic pieces is a good practice.

Enamel Tearouts and Cracks (Fracture Lines)

Localized enamel tearouts have been reported to occur associated with bonding and debonding metal and ceramic brackets. Ceramic brackets using chemical retention cause enamel damage more often than those using mechanical retention. A recent study demonstrated enamel tearouts in 26% of debonded polycrystalline brackets and in less than 1% of monocrystalline brackets with an average volume loss of 144 and 36 cubic micrometers (mm^3), respectively.[161] This damage probably occurs because the location of the bond breakage is at the enamel–adhesive interface rather than at the adhesive–bracket interface.

The prevalence and location of cracks among debonded, debanded, and orthodontically untreated teeth demonstrate no significant difference, and the most notable cracks (i.e., those invisible under normal office illumination) are on the maxillary central incisors and canines.[162] However, the sharp sound sometimes heard on the removal of bonded orthodontic brackets with pliers is possibly associated with the creation of enamel cracks. With ceramic brackets, the risk for creating enamel cracks is greater than for metal brackets. The lack of ductility may generate stress in the adhesive–enamel interface that may produce enamel cracks at debonding.

The clinical implications are (1) to use brackets that have mechanical retention and debonding instruments and techniques that primarily leave all or the majority of composite on the tooth (see Fig. 27-28, *A*) and (2) to avoid scraping away adhesive remnants with hand instruments.

Another important clinical implication may be the need for a pretreatment examination of cracks, notifying the patient and the parents if pronounced cracks are present (Fig. 27-31). The reason for this examination is that patients may be overly inspective after appliance removal and may detect cracks that were present before treatment of which they were unaware. They may question the orthodontist about the cause of the cracks. Without a pretreatment diagnosis and documentation (most cracks are not visible on routine intraoral slides), proving that such cracks are indeed unrelated to the orthodontic treatment is almost impossible.[19]

Removal of Residual Adhesive

Debonding of brackets usually leaves a residual adhesive volume of 0.6 to 2.48 mm^3 on the enamel surface.[163,164] Complete removal of all remaining adhesive is not easily achieved because of the color similarity between present adhesives and enamel. Spontaneous abrasive wear of present bonding resins is limited and should not be expected, and these remnants are also likely to become unaesthetically discolored with time.

The preferred method for the removal of excess adhesive is to use a suitable dome-tapered tungsten carbide bur (No. 1171 or No. 1172) in a contra-angle handpiece (Fig. 27-32). Clinical experience and laboratory studies[165] indicate that approximately 30,000 rpm is the optimum for rapid adhesive removal without enamel damage. Light painting movements of the bur should be used so as not to cause deep scratches on the enamel. Water cooling should not be used when the last remnants are removed because water lessens the contrast with enamel. Speeds higher than 30,000 rpm using fine fluted tungsten carbide burs may be

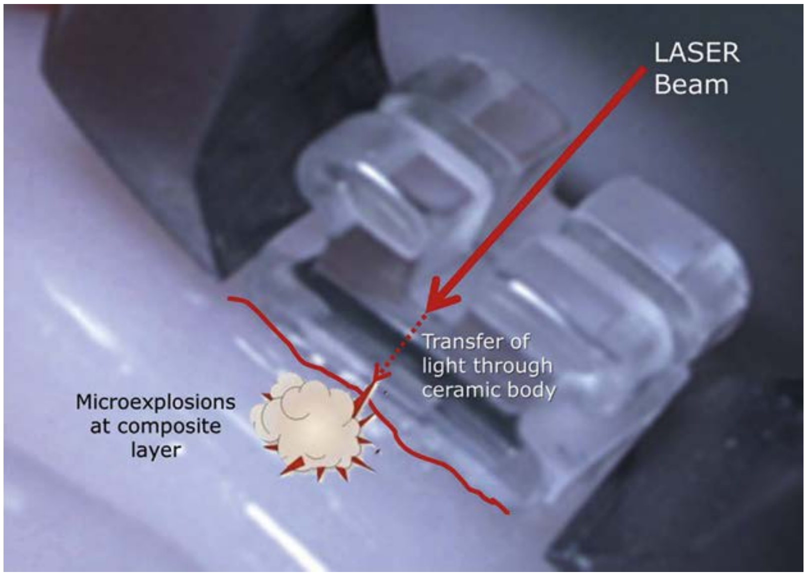

FIGURE 27-30 The laser tip is brought into contact with the ceramic bracket and initiated for laser-aided debonding. Laser energy is transferred through the ceramic and absorbed at the composite layer where microexplosions occur, resulting in the detachment of the bracket without any thermal damage to the tooth.

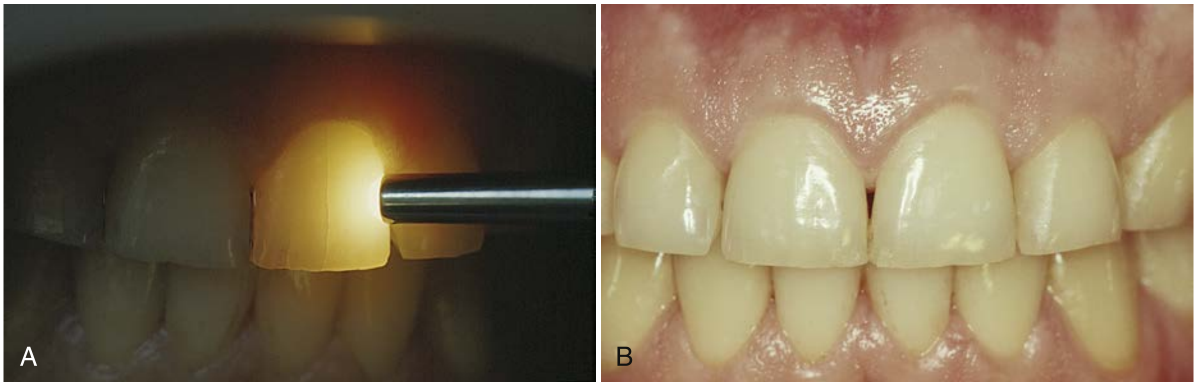

FIGURE 27-31 Enamel cracks generally are not visible on intraoral photographs. Several cracks are clearly seen on the left central incisor with fiberoptic transillumination (**A**) and are undetectable by routine photography (**B**). Note the vertical orientation of the cracks.

FIGURE 27-32 Adhesive remaining after debracketing may be removed with a tungsten carbide bur at approximately 30,000 rpm.

useful for bulk removal but are not indicated closer to the enamel because of the risk of marring the surface. Even ultrafine high-speed diamonds produce considerable surface scratches. Slower speeds (10,000 rpm and less) are ineffective, and the increased jiggling vibration of the bur may be uncomfortable to the patient.

Zachrisson and Årtun[165] compared different instruments commonly used in debonding procedures and ranked their degrees of surface marring on young permanent teeth. According to the results of this study, plain cut and spiral fluted tungsten carbide burs operated at approximately 25,000 rpm were the only instruments that provided the satisfactory surface appearance (Fig. 27-33); however, none of the instruments tested left the virgin tooth surface with its perikymata intact. The clinical implication of the study is that tungsten carbide burs produced the finest scratch pattern with the least enamel loss and are superior in their ability to reach difficult areas (Fig. 27-34). Recent research shows, however, that the use of carbide burs alone removes a substantial layer of enamel and roughens its surface and thus should be followed by multistep Sof-Lex disks and pumice slurry, which is

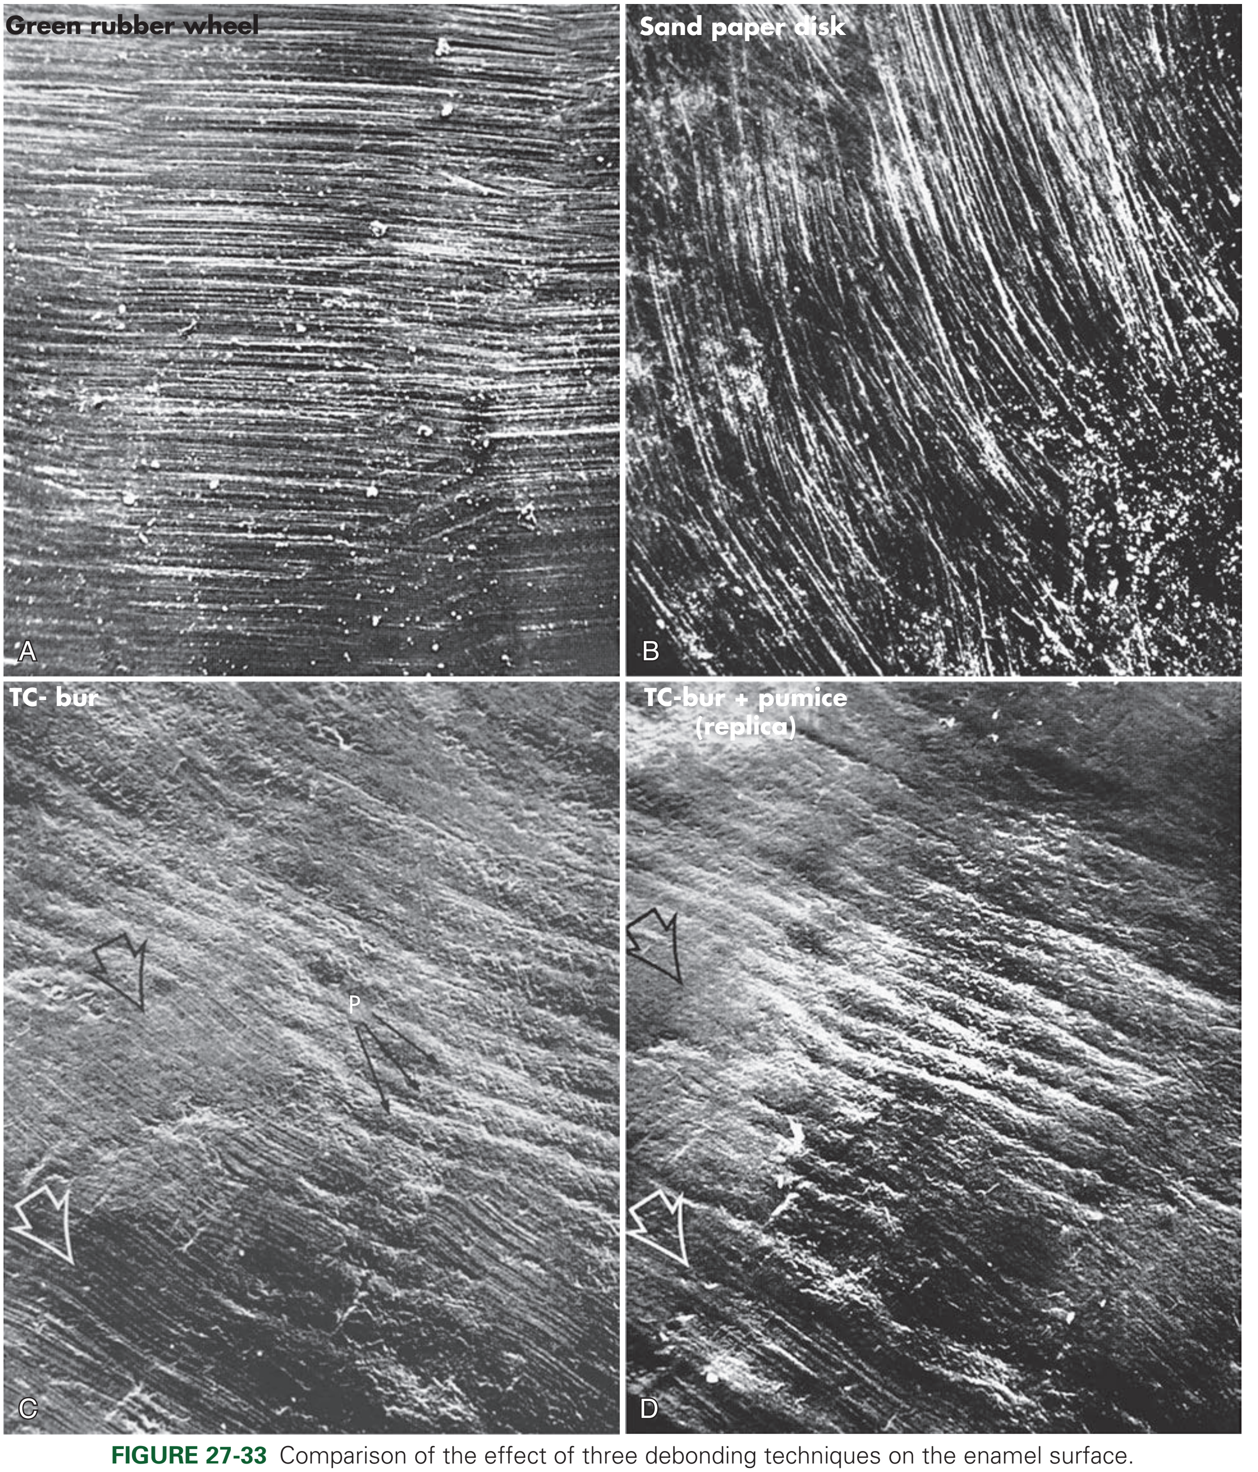

FIGURE 27-33 Comparison of the effect of three debonding techniques on the enamel surface. **A–C,** Scanning electron micrographs (×50) after adhesive removal without subsequent polishing. Note that the scratches are similar in appearance in **A** and **B**, but only sight faceting is visualized in **C** with fine scratches (*open arrows*) intermingled with the perikymata ridges (*P*). **D,** Same area as in **C** in replica after pumicing. The surface is smoother (*arrows*).

reported as a reliable method of polishing.[166] Using a carbide bur may also be followed by Astropol finish (F), polish (P), and high-gloss polisher (HP), as this combination is reported to provide a significantly lower enamel surface alteration with comparable composite remnants.[164]

Despite all efforts, a negligible amount of resin ranging from 0.11 to 0.22 mm^3 is left on the tooth surface, and the use of polishing systems with good composite polishing properties may leave a lustrous surface and therefore more composite remnants as they become invisible.[164]

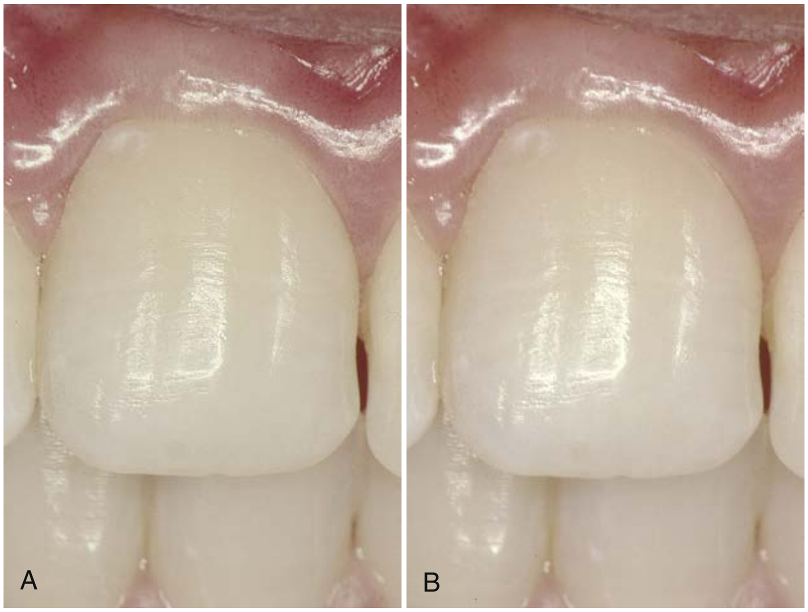

FIGURE 27-34 **A,** After debonding with a tungsten carbide bur at low speed. Gentleness of technique is reflected by the evident perikymata-like pattern on debonded teeth (**B**).

FIGURE 27-35 STAINBUSTER burs (Pearson Dental Supply Co., Sylmar, CA) gently remove cement, stains, and colored coatings from the surface of the enamel without abrading tooth enamel or ceramic. The burs are made up of the fiber sections with abrasive power, which cover the entire working surface and split up into small fragments as they act on a hard surface.

Some patients complain about color change of their teeth during and after orthodontic treatment. A recent study confirms this and states that both the orthodontic adhesive systems and the burs used to remove their residuals on tooth surfaces are responsible for this effect.[167] The authors suggest using STAINBUSTER burs (Pearson Dental Supply Co., Sylmar, CA) to remove the adhesive remnants close to the enamel surface[167] (Fig. 27-35).

Any recontouring considered necessary should be completed at this stage before proceeding to polishing. When all of the adhesive has been removed, the tooth surface is best polished with pumice (or a commercial prophylaxis paste) in a routine manner, which greatly improves the aesthetics of the teeth and the appreciation of the treatment results by the patient.

Amount of Enamel Lost in Debonding

Residual adhesive could be removed with minimal damage to the enamel by the careful use of a tungsten carbide bur, followed by finishing procedures,[168] but adequate clean-up without enamel loss is difficult to achieve.[164] Several factors, including the instruments used for prophylaxis and debonding and the type of adhesive resin used, dictates the amount of enamel actually removed, but the final surface topography is not influenced by different clean-up methods.[164]

Adequate removal of filled resin generally requires rotary instrumentation as described, and the reported amount of enamel loss is between 4.1 and 30 microns, which is approximately 0.05 mm^3 in volume.[161,164] In a clinical perspective, the enamel loss encountered with routine bonding and debonding procedures, exclusive of deep enamel fractures or gouges resulting from an injudicious use of hand instrument or burs, is not significant in terms of total thickness of enamel. The surfaces usually bonded have a thickness of 1500 to 2000 microns. The claim that removal of the outermost layer of enamel, which is particularly caries resistant and fluoride rich, may also be harmful is not in accordance with recent views on tooth surface dynamics and with clinical experience over many years. The facial tooth surfaces are left smooth and self-cleansing after debonding. Caries has been demonstrated not to develop in such sites even if the entire enamel layer is removed. Similarly, no histologic or clinical evidence of adverse effects was experienced after significant recontouring of canines that had been ground to resemble lateral incisors when approximately one half of the enamel thickness was removed as long as the surfaces were left smooth and sufficient water cooling was used.[84]

Operator Safety during Debonding

Another important but often ignored issue is the inhalation of aerosols produced during the removal of fixed orthodontic appliances. Recent research showed that aerosol particulates produced during enamel cleanup might be inhaled, irrespective of handpiece speed or the presence or absence of a water

FIGURE 27-36 Extreme degree of enamel demineralization after orthodontic treatment in a caries-prone patient **A**,. White spot lesions can occur on multiple teeth. **B**, The contour of the bonded brackets is visible on several teeth.

coolant. This aerosol may contain calcium, phosphorus, silica, aluminum, iron and lanthanum.[169] Blood, hepatitis B surface antigen (HBsAg), and hepatitis B virus–DNA were also detected in excess fluid samples of the two hepatitis B carriers.[170] Although the particles are most likely to be deposited in the conducting airways and terminal bronchi, some might be deposited in the terminal alveoli of the lungs and cleared only after weeks or months.[169]

Results of these reported studies indicate that orthodontists are exposed to high levels of aerosol generation and contamination during the debonding procedure, and preprocedural chlorhexidine gluconate mouth rinse appears to be ineffective in decreasing the exposure to infectious agents. Barrier equipment should be used to prevent aerosol contamination.[169,171]

Prevention and Reversal of Decalcification

White spots or areas of demineralization are carious lesions of varying extent. One prospective study[172] found that 50% of individuals undergoing fixed appliance treatment had nondevelopmental white spot lesions (WSLs), compared with 25% of a control group of patients. Another study[173] found that, even 5 years after treatment, orthodontic patients had a significantly higher incidence of WSLs than a control group of patients who had not had orthodontic treatment.

According to a recent survey, 37% of orthodontists reported that they had removed brackets because of patients' poor oral hygiene, and 69% of general dentists reported that they had treated WSLs during the previous year.[174] The presence of severe WSLs at the end of treatment decreases the value of efforts spent and disturbs the patient and the family. In addition, more than one-third of general dentists indicated that severe WSLs after orthodontic treatment could have a negative effect on a patient's perception of the treating orthodontist, thereby jeopardizing the referral base.[174] This obvious degree of iatrogenic damage suggests the need for preventive programs using fluoride associated with fixed appliance orthodontic treatment[19,175] (Fig. 27-36).

Daily rinsing with dilute (0.05%) sodium fluoride solution throughout the periods of treatment and retention, plus regular use of a fluoride dentifrice, is recommended as a routine procedure for all orthodontic patients.[110] Although effective, the weak fluoride mouth rinse has a few risks, and most patients can manage to use it easily for 1 to 2 years. Parents should also be adequately informed about the outcomes of failure to brush properly, and the definite responsibility also must be given to the patient to avoid decalcifications during treatment. In addition, painting a fluoride varnish[176] or other effective anticaries agents[177] over caries-susceptible sites at each visit may be useful in patients with hygiene problems.

Professional means of fluoride application have included fluoride-releasing bonding agents, fluoridated elastomeric ligature ties, fluoride varnish, and 10% casein phosphopeptide-amorphous calcium phosphate (GC Tooth Mousse, GC Corporation, Tokyo, Japan)[178–186] (Fig. 27-37). The professional application of 1% chlorhexidine collagen gel is also suggested to control *Streptococcus mutans* levels in an orthodontic patient with a high risk of caries.[187] The use of a polymeric tooth coating on the tooth surface around the brackets showed almost no demineralization-inhibiting effect.[188]

Visible white spots that develop during orthodontic therapy should not be treated with concentrated fluoride agents immediately after debonding because this procedure will arrest the lesions and prevent complete repair.[19] At present, a period of 2 to 3 months of good oral hygiene but without fluoride supplementation associated with the debonding session is recommended. This procedure should reduce the clinical visibility of the WSLs. High fluoride concentrations may tend to precipitate calcium phosphate onto the enamel surface and block the surface pores, which limit remineralization to the superficial part of the lesion, and the optical appearance of the WSL is not reduced.

Microabrasion

When the remineralizing capacity of the oral fluids is exhausted and WSLs are established (Fig. 27-38; see also Fig. 27-36), microabrasion is the optimal way to remove superficial enamel opacities. By the use of this technique, enamel stains can be eliminated with minimal enamel loss.[189]

Because microabrasion is comparably more invasive in nature, delayed application was thought to be beneficial, considering the spontaneous improvements of the lesion via saliva-based remineralization and spontaneous surface abrasion after debonding.[174,190]

Clinical procedure: A custom-made abrasive gel is prepared with 18% hydrochloric acid, fine powdered pumice, and glycerin. The active mixture is applied as follows[191]:

1. The gingiva is isolated using blockout resin or rubber dam. Dental floss may be useful to prevent soft tissue contact and injury from the acid.

FIGURE 27-37 MI Paste Plus (GC America Inc, Alsip, IL, USA) is a water-based, sugar-free crème containing Recaldent casein phosphopeptide–amorphous calcium phosphate (CPPACPF) and fluoride. When CPP-ACPF is applied to the tooth surfaces, it binds to biofilms, plaque, bacteria, hydroxyapatite, and surrounding soft tissue, localizing bioavailable calcium , phosphate and fluoride. (Courtesy of GC America Inc, Alsip, IL, USA)

FIGURE 27-38 White spot lesions before (**A**) and after (**B**) microabrasion. (See text for details.)

2. The abrasive gel is applied using an electric toothbrush for 3 to 5 minutes. The original toothbrush tip is modified by cutting the peripheral bristles to create a smaller brush tip to fit better on tooth surfaces.
3. Rinse for 1 minute.

To prevent enamel pitting, the acid should not be left on the tooth for an extended time. For best results and depending on the severity of the lesions, the procedure can be repeated monthly two to three times, which gradually makes the stains disappear. The microabrasion technique is effective in removing WSLs and streaks and brown-yellow enamel discolorations and considerably reduces the white opaque appearance of WSLs; however, this outcome is not resistant to discoloration.[191] In cases of more extensive mineral loss, however, grinding with diamond burs under water cooling or composite restorations is inevitable.

Resin Infiltration

More recently, a minimally invasive treatment approach was introduced, during which the WSL is infiltrated using a low-viscosity resin (ICON resin infiltrant, DMG, Hamburg, Germany) (Fig. 27-39). In this technique, the outer surface is transformed into a more permeable layer with the help of hydrochloric acid etching, and the porous structure beneath is infiltrated using a TEGDMA-based resin. It is noteworthy that this resin has a light refraction index similar to sound enamel, which improves the appearance of the lesion and reinforces the weakened enamel prism structure.[192–194]

The resin infiltration method was reported to produce satisfactory results, compared with remineralization using fluoride or amorphous calcium phosphate derivatives,[195–198] and is more resistant to discoloration, compared with microabrasion and in vitro fluoride treatments.[191]

FIGURE 27-39 Resin infiltration provides a minimally invasive treatment approach to transform the outer surface of affected teeth into a more permeable layer with the help of hydrochloric acid (HCl) etching, and infiltrating the porous structure beneath it using a triethylene glycol dimethacrylate (TEGMA)-based, low-viscosity resin. (Courtesy of DMG, Hamburg, Germany.)

Clinical procedure (Fig. 27-40):
1. Prophy teeth; rinse and dry.
2. Etch WSL with an Icon-Etch syringe (DMG America, Englewood, NJ), extending approximately 2 mm around the edges of the lesion for 2 minutes.
3. Rinse for 30 seconds, and completely dry with oil-free air.
4. Apply Icon-Dry (99% ethanol) (DMG America, Englewood, NJ) to the dried surface, and leave undisturbed for 30 seconds. Dry completely with air.
5. Apply ICON resin infiltrant (DMG, Hamburg, Germany) with a vestibular tip, and remove the direct overhead light source to avoid premature curing of the infiltrant. Leave undisturbed for 3 minutes. Maintain a moist surface by continuing to add infiltrant periodically during this time to ensure an adequate supply of resin to the lesion.
6. Remove any excess material, and light cure for 40 seconds.
7. Repeat the infiltration process with a new vestibular tip. Leave undisturbed for 1 minute, remove excess again, and light cure an additional 40 seconds.
8. Polish the teeth.

At this point, identifying lesions that are candidates for caries infiltration is critical; they contain the necessary porosities for infiltration. Lesions that occur from demineralization are the only suitable candidates for this procedure. Lesions from fluorosis, hypocalcification, hypoplasia, erosion, developmental anomalies, or trauma leading to enamel defects are not appropriate for caries infiltration.

BONDED RETAINERS

Permanent maintenance of the achieved result after successful treatment of malocclusion is undoubtedly a great, if not the greatest, problem for orthodontic clinicians, especially for adult patients.

A recent survey[5] indicates a dramatic increase in the tendency among U.S. orthodontists toward permanent retention and reports that fixed lingual retainers comprise approximately 85% of retention regimes followed. Bonded retainers have advantages such as:
1. Completely invisible from the front
2. Reduced need for long-term patient cooperation
3. Long-term (up to 10 years) and even permanent retention, whereas conventional retainers do not provide the same degree of stability

Bonded Fixed Retainer Materials

Early bonded fixed retainers were made with plain round or rectangular orthodontic wires,[199–203] but in 1977, Zachrisson proposed the potential advantage of the use of multistrand wire for their construction (see Multistranded Wire Retainers).[204] Novel materials proposed for lingual retainer fabrication include fiber-reinforced composite (everStick ORTHO, StickTech Ltd., Turku, Finland) and Ribbond polyethylene ribbon (Ribbond Inc., Seattle, WA). Prefabricated lengths of multistrand wire for bonded fixed retainers are also available on the market (Fig. 27-41, *A–D*).

Bonded Fixed Retainer Adhesives

Different composite resins have been advocated for bonding retainer wires.[205] Unlike the adhesive under a bracket, the lingual retainer resins remain exposed to the oral cavity and therefore require some specific physical properties. Several specific lingual retainer adhesives may offer ease of application, optimal handling, improved patient comfort, and minimal abrasive wear (Fig. 27-42, *A* and *B*). Recent findings[114] indicate that light-activated composites may have these properties. The amount of total light energy delivered to the composite resin determines hardness, wear resistance, water absorption, residual monomer, and biocompatibility.[37,206] These highly filled, light-cured resin pastes are also said to be a better choice when longevity and durability are required.[19,37] A recent randomized trial indicates no evidence that the use of either chemical or light-cured composite is associated with a difference in failure rate or failure mode of bonded lingual retainers.[207]

Flowable resin composites have been made with a variety of formulas and viscosities for different uses.[208–213] Recently, using flowable composites, which were originally created for restorative dentistry by increasing the resin content of traditional microfilled composites, have been suggested for bonding lingual retainers.[214–216] These composites are claimed to be advantageous because no mixing is required, needle tips on the application syringes allow direct and precise composite placement, the composite is not sticky and flows toward the bulk of the material rather than away from it, no trimming and polishing are required, and chair time is reduced.[214] A recent study of the authors of this text demonstrated that flowable composites provide SBS and wire pull-out values comparable with a standard orthodontic resin and can be used as an alternative for direct bonding of lingual retainers.[217] However, higher microleakage scores at the wire-adhesive interface and unclear wear resistance make the use of flowable resin composites questionable.[218] These resins are best avoided in lingual retainer bonding until long-term clinical studies prove their dependability.

Periodontal Health with Bonded Fixed Retainers

Another issue with the use of bonded fixed retainers is the periodontal health. The gingival reaction depends on careful removal of excess adhesive at the time of retainer bonding by the clinician and on proper oral hygiene of the patients. Daily flossing in each interdental space is recommended with the use of a dental floss threader or Superfloss gingival to the wire.

Clinical data are conflicting; some research studies indicate no significant difference in plaque and calculous accumulation between round and spiral retainer wires,[219,220] whereas others report more plaque accumulation on the distal surfaces of the

lower anterior teeth in patients with multistranded wire (MSW) retainers, compared with patients with round wire retainers.[221]

Many patients apparently have difficulties keeping the retainer area really clean, despite patient instruction in hygiene. Accumulations of supragingival calculus and stain are often noted along and beneath the retaining wire, whereas decalcification and caries are only exceptionally observed.[205,222] However, the presence of even large amounts of calculus around mandibular retainers is not alarming in young, healthy patients with no periodontal pockets according to a study, which compared the effect of toothbrushing after professional prophylaxis in patients with large amounts of calculus (removal requiring an average of 1 hour per patient) with the effect of toothbrushing as the sole hygiene method. The authors found no significant benefit of the calculus removal, which supports the hypothesis that it is not the calculus but the plaque that forms on it that has pathogenic potential.[223]

Recent research[221,224] demonstrates that the retainers are quite compatible with periodontal health even at long term, whereas other studies[225] question the appropriateness of lingual fixed retainers as a standard retention plan for all patients, regardless of their attitude to dental hygiene. Advanced periodontal cases probably need permanent retention (Fig. 27-43), but the effects of calculous accumulations on retainers in adults with existing periodontal problems are also unknown at present. Consequently, the selection of retention protocol and fixed retainer type may be based on case-specific parameters such as dental and gingival anatomy and oral hygiene status. In any case, the patient should be given detailed hygiene instruction for healthy preservation of the fixed lingual retainer.[10]

In the following section, two different retainer types are described.

1. Canine-to-canine lingual retainer bar (made of 0.030- to 0.032-inch plain round wire, bonded to the lower canines only)
2. Multistranded wire retainers (made of 0.0215-inch five-stranded wire, bonded to all teeth in a segment)

Canine-to-Canine Lingual Retainer Bar

In differential retention philosophy, the purpose of a bonded 3-3 retainer bar is to (1) prevent incisor recrowding, (2) hold the achieved lower incisor position in space, and (3) keep the rotation center in the incisor area when a mandibular anterior growth rotation tendency is present.

FIGURE 27-42 Specific lingual retainer adhesives may offer ease of application, optimal handling, improved patient comfort, and minimal abrasive wear over time. ((Top Image) Courtesy of 3M, © 2016 3M. All rights reserved; (Lower set of images) Courtesy Reliance Orthodontic Products, Inc.)

The standard appliance is bonded to the lingual surfaces of the canine teeth. The bar, which originally was constructed from plain blue Elgiloy wire with a loop at each terminal end for added retention[205] (Fig. 27-44, *A*), was replaced by a similar-diameter multistrand wire (Fig. 27-44, *B*). For some patients, this wire proved not solid enough and distorted, and the wire was difficult to bend to optimal fit. These drawbacks are eliminated in the third-generation design (Fig. 27-44, *C* and *D*), in which the bar is made from round 0.032-inch stainless steel or 0.030-inch gold-coated wire[204] and sandblasted on the ends for improved micromechanical retention. Bonding is performed with a chemically cured or light-cured composite resin because such adhesives provide the strongest bonds and show comparatively little abrasion over extended periods.[176]

In selected cases when the lower first premolars at the start of treatment are labially blocked out, severely rotated, or tipped, an extension of the 3-3 bar to include the first premolars (43-34 retainer) is useful. This extension is simply done by adding and bonding a small piece of thin wire between the premolar and canine (Figs. 27-45 and 27-46). The 43-34 design also may be used if, after orthodontic leveling of the six anterior mandibular teeth, the orthodontist desires to prevent their re-erupting above the functional occlusal plane.

Some companies supply preformed lingual 3-3 retainers with bonding pads, but these may be more difficult to fit and tightly bond. At the same time, obtaining maximal contact on the lingual surfaces of all four incisors may also be more difficult.

FIGURE 27-43 Adult female patient with advanced hard and soft periodontal tissue destruction and pathologic migration of the maxillary anterior teeth before (A–E), during (F), and after (G–J) orthodontic treatment. The improved dental result is retained by means of six-unit bonded lingual retainers in both dental arches (H, I). Some interdental gingival recession was unavoidable in the maxillary anterior region, but it does not clinically show much (J). The radiographs after treatment show no progression of periodontal tissue destruction, compared with the initial films (C).

FIGURE 27-43, cont'd

Bonding the 3-3 Retainer Bar

The following clinical recommendations (Fig. 27-47) represent basic principles that have been clinically tested over many years. Although taking shortcuts may seem possible, doing so is strongly discouraged; strict adherence to a meticulous technique has been found to be the key to long-term success.

1. While the orthodontic appliances remain in place, take a snap impression of the patient's teeth and pour a working model of hard stone.
2. Using the working model as a guide, bend a plain round stainless steel or gold-coated wire of 0.030- to 0.032-inch diameter with a fine, straight three-jaw or similar pliers

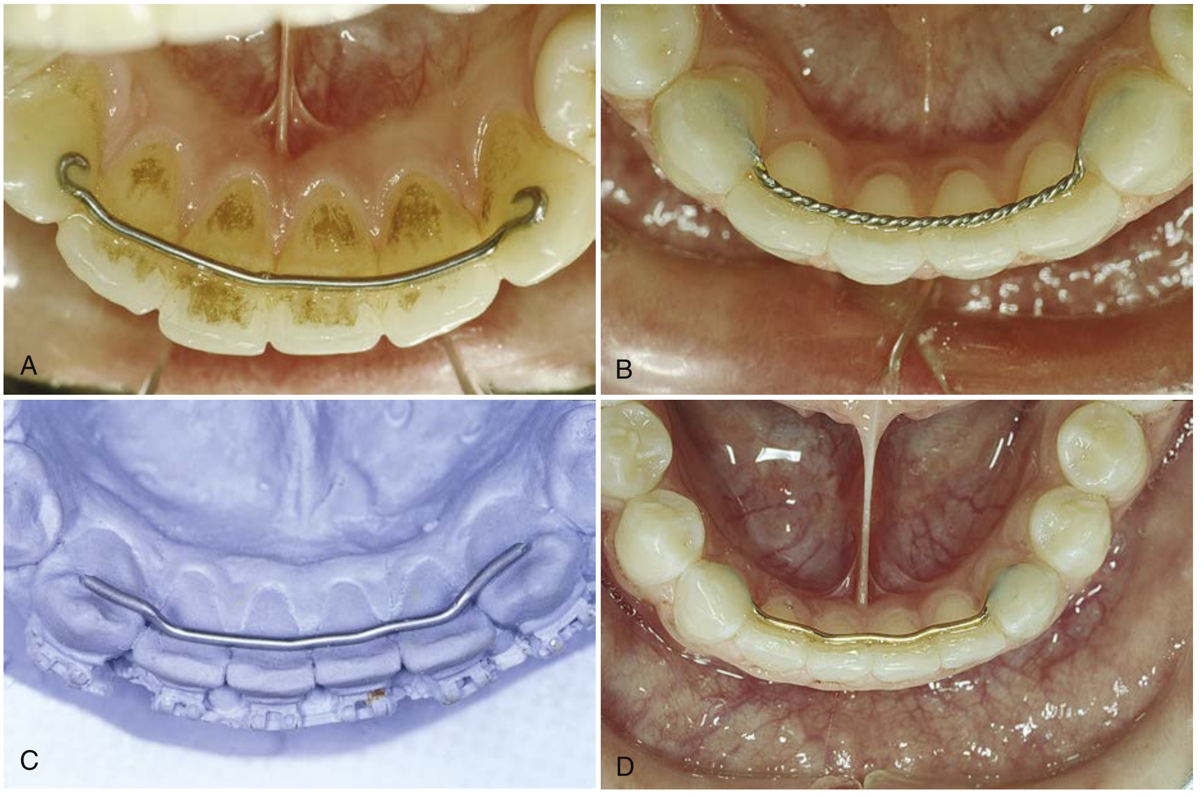

FIGURE 27-44 **A,** First-generation bonded mandibular lingual 3-3 retainer. **B,** Second-generation 3-3 retainer. **C, D,** Third-generation 3-3 retainer in stainless steel and gold-coated bar, respectively.

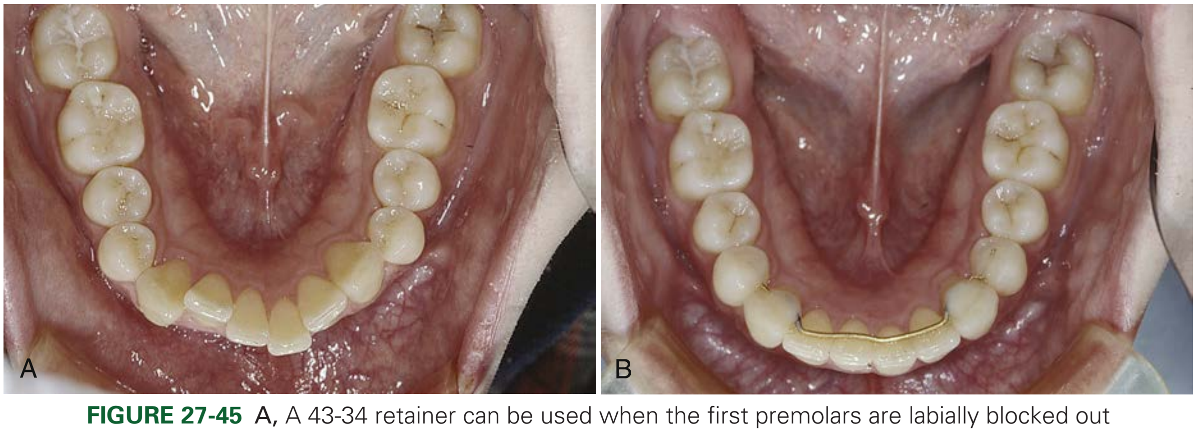

FIGURE 27-45 **A,** A 43-34 retainer can be used when the first premolars are labially blocked out or mesially tipped before treatment. **B,** The 0.030-inch 3-3 retainer bar is extended by means of a thin (0.0215-inch coaxial) gold-coated wire between the canine and the first premolar.

so that the wire precisely contacts the lingual surface of all mandibular incisors (see Fig. 27-47, *A*).

3. Sandblast the ends with 50 microns of aluminum oxide powder for approximately 5 seconds from different directions, using the MicroEtcher (Danville Materials, Inc., San Ramon, CA) (see Fig. 27-47, *B*) in a dust cabinet.
4. Clean the lingual surfaces of both canines with a tungsten carbide bur (No. 7006) or a large, round diamond bur.
5. Check the position of the wire in the mouth. When optimal, fix with three or four steel ligatures around the bracket wings of the incisors (see Fig. 27-47, *C* and *D*).
6. With the retainer wire in place, etch the lingual surfaces of the canines with colored phosphoric acid gel (see Fig. 27-47, *E*) for 30 seconds. Completely rinse and dry. Use a high-speed vacuum evacuator. Sealant is not needed on lingual surfaces, partly because of the reduced risk of decalcification. This fast and efficient procedure reduces the risk of moisture contamination.
7. Apply a thin coat of moisture-insensitive primer (Transbond MIP, 3M Unitek, Monrovia, CA) on the sandblasted ends of the retainer wire and on the etched enamel. This primer will reduce the risk of moisture contamination.
8. Apply the Transbond LR (3M Unitek, Monrovia, CA) adhesive to the right and left canines. Shape the resin bulk with fine brush strokes from the gingival margin to the incisal edge. A small amount of Transbond MIP on the

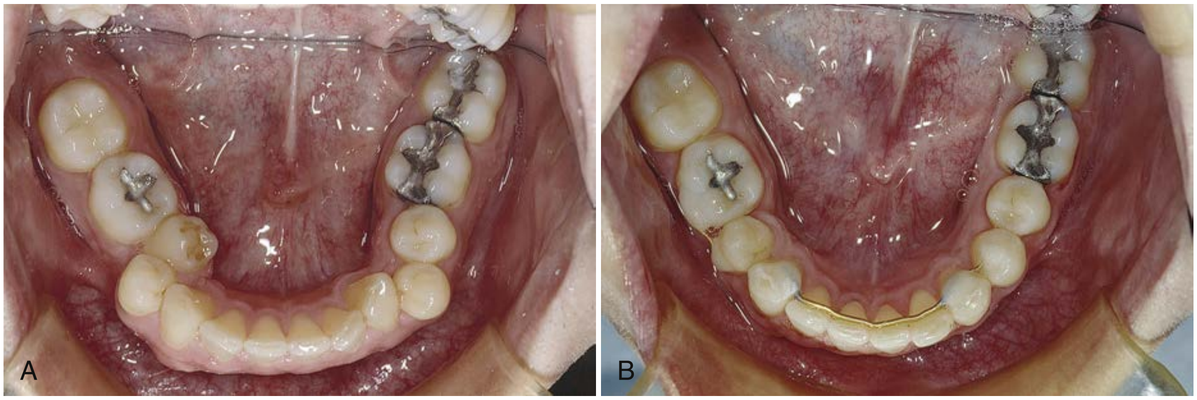

FIGURE 27-46 A, Adult patient with pretreatment blocked-out right second and left first premolar treated with the extraction of the second premolar on the right side. B, Final result is retained by means of a short labial gold-coated retainer in the closed extraction site and a 3-34 retainer.

brush tip will dilute the composite resin and make it flowable, creating a smooth, gentle contour in an incisogingival direction. It takes some experience to find the right consistency. If too much primer is added, then the adhesive will drift away from where it is placed and may interdentally flow and contact the gingiva. Optionally, the adhesive may be transferred from a mixing pad. The adhesive on the mixing pad should have a light-impermeable cover.

9. Light cure the composite resin according to instructions for light source used (e.g., 5 seconds for LED curing).
10. Cut the ligature wires. Trim (whenever necessary) along the gingival margin, and contour the bulk with an oval tungsten carbide bur (No. 7408; see Fig. 27-47, *I*) until it has a smooth contour in an incisogingival direction. Use a smaller bur (No. 2) interdentally.
11. Instruct the patient in proper oral hygiene and in the use of dental floss or Superfloss (Oral-B, South Boston, MA) beneath the retainer wire and along the mesial contact areas of both canines (Fig. 27-48). Instruct the patient to floss once daily to prevent the accumulation of calculus and plaque.

Failure Analysis and Long-Term Experience with the 3-3 Retainer Bar

Lingually bonded 3-3 retainers can provide excellent results[204,205,219,222,226] (see Fig. 27-44) if meticulous construction and bonding techniques are followed, along with some modifications of the original design.

Experience with bonded 3-3 retainer bars over 15 to 20 or more years is generally excellent, provided a careful bonding technique is used.[204,205,222] Particularly, the third-generation 3-3 retainer is a fine mandibular retainer.[226] Not only is the retainer solid, easy to place, and hygienic, but it also appears to be safer than mandibular retainers in which all six anterior teeth are bonded, which is equally important. A patient immediately notices whether a retainer comes loose when it is bonded only to the canines. The patient can then call for a rebonding appointment or remove the retainer, if necessary. For several years, a mandibular bar bonded only to the canines has been the authors' preferred retention method in adolescent and many adult patients.

Initial failures with first-generation bonded lingual 3-3 retainers were classified into two types. Type I failure related to the separation at the tooth-adhesive interface and occurred with the highest frequency. Type I failure most commonly resulted from moisture contamination or movement of the lingual bar during the initial polymerization of the composite. Type II failure occurred at the adhesive-retainer wire interface and resulted from inadequate bulk of adhesive for sufficient strength (or abrasive wear of the adhesive). An important note is that with adequate technique, one can avoid both types of failures. In other words, a clinician who experiences discouraging failure rates should reevaluate and improve the technique of making bonded lingual retainers.

The senior author's long-term (up to 12 years) experience with third-generation gold-coated 3-3 retainer bars[227] indicates the failure rates are considerably lower than those reported by others,[228] which is probably explained by the authors' careful bonding procedures (see Fig. 27-47).

Because the retainers are invisible, a problem may exist in deciding when to remove them. Extended retention periods (up to 10 years or longer) are now recommended by most clinicians. The long retention periods are favorable in many patients while waiting for the patient's third molars to erupt; long retention counters the effects of postpubertal growth activity and maxillomandibular adjustments, which may continue well into the second decade and longer. As an alternative, the bonded retainer may be replaced after several years with a removable one for long-term or permanent nighttime wear.[4, 5, 204, 224, 229, 230]

Multistranded Wire Retainers

Occasional cases of slight relapse anteriorly may occur when using retainers bonded only to the canines.[203] For this reason, a MSW retainer bonded to all anterior teeth may be indicated for adult patients with considerable pretreatment crowding.

Since the authors' early experiences in the mid-1970s with direct splinting of contacts between the incisors without wires were unsuccessful (they rapidly broke up into segments of one or two teeth because of their rigidity),[229] clinical experiments were begun with bonded flexible wires that allowed some physiologic movement of the individual teeth.[204] Such mobility was proven to be fundamental for the success of retainers bonded to several teeth in a segment.

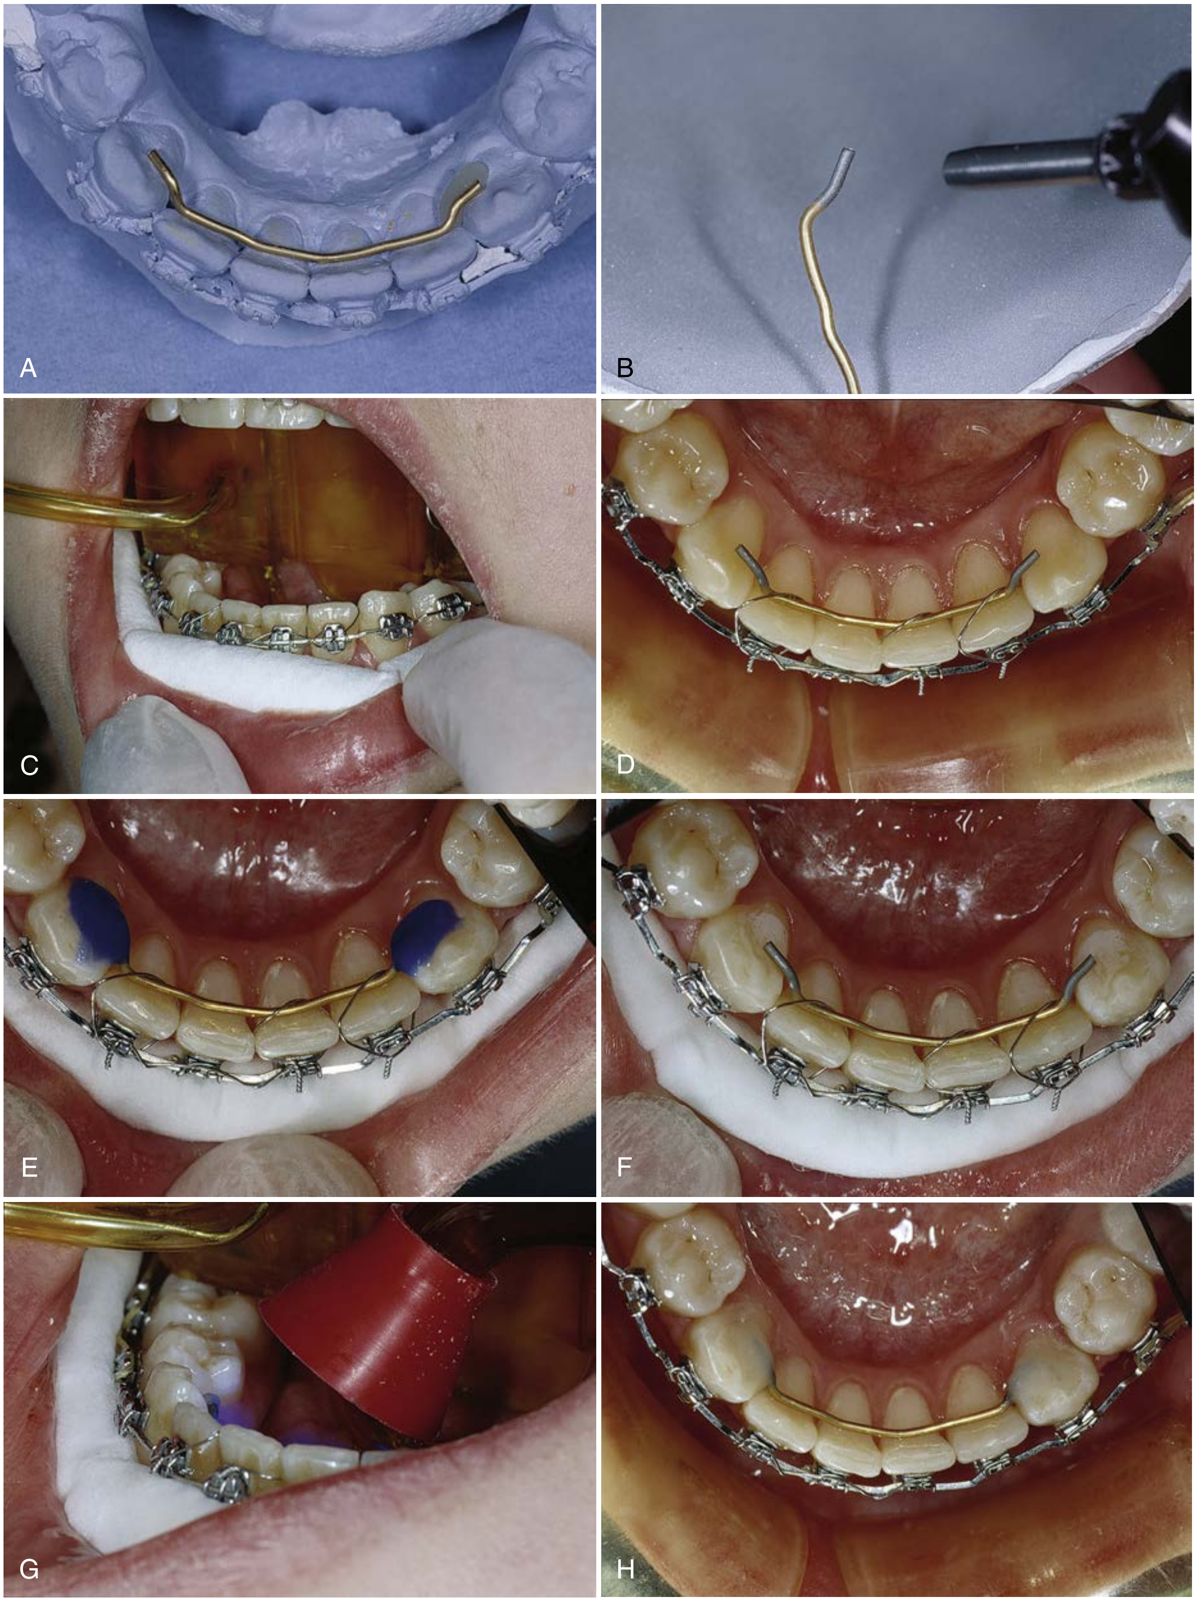

FIGURE 27-47 Making the bonded 3-3 retainer bar. **A,** Careful adaptation of retainer wire on stone model using fine three-jaw pliers. **B,** Sandblasting terminal ends of retainer bar. **C,** Lingual saliva ejector with high bite block (3M Unitek, Monrovia, CA) secures and optimally dries working field with no interfacing appliances. **D,** The 0.030-inch gold-coated wire is positioned by means of three steel ligatures. **E,** Ultratech 35% phosphoric acid gel for acid etching. **F,** Treated area clearly indicated. **G,** Initial tacking with small amount of flowable light-cured composite resin. **H,** Bulk of adhesive added to tacked retainer. **I,** Trimming adhesive with No. 7408 tungsten carbide bur. **J,** Final appearance.

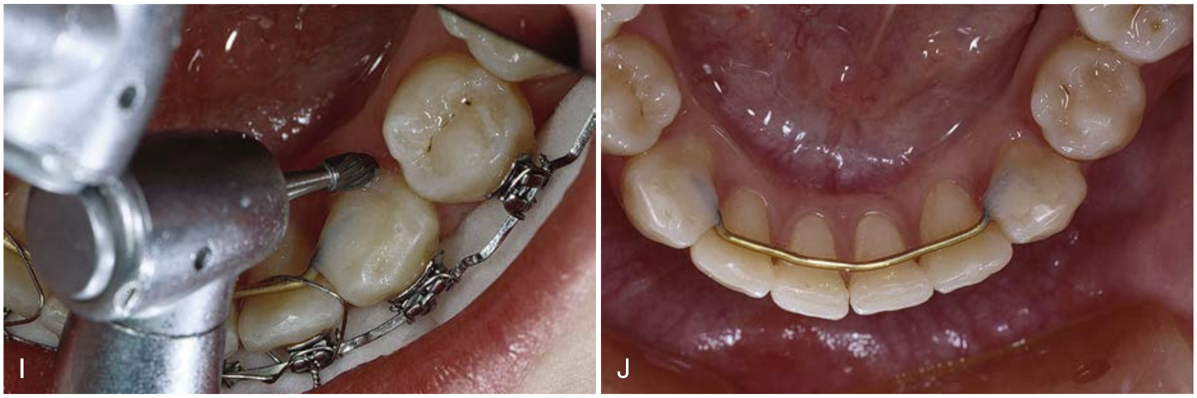

FIGURE 27-47, cont'd

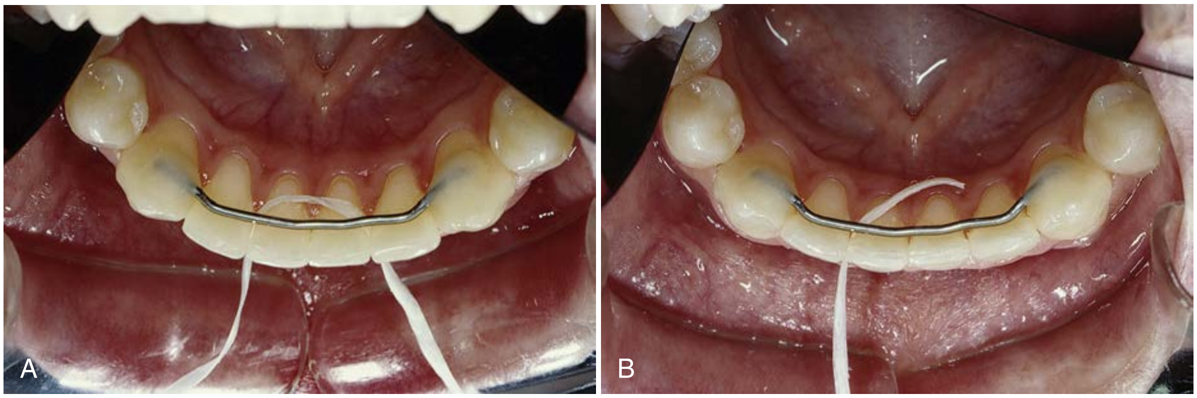

FIGURE 27-48 Interdental cleaning under a bonded 3-3 retainer. **A,** If a floss threader is not available, then a loop is formed over two incisors and moved under the retainer bar. **B,** When one end of the floss is pulled in, the other will snap free and can be grabbed with the fingers. Patients are instructed to move the floss over the interproximal surfaces once daily.

At least two indications or suggestions are helpful for using bonded MSW retainers (Fig. 27-49):

1. Prevention of space reopening
   a. Median diastemas
   b. Spaced anterior teeth
   c. Adult periodontal conditions with the potential for postorthodontic tooth migration
   d. Accidental loss of maxillary incisors requiring the closure and retention of large anterior spaces
   e. Mandibular incisor extractions
2. Holding of individual teeth
   a. Severely rotated maxillary incisors
   b. Palatally impacted canines

In these and other situations, the bonded spiral wire retainer can be used alone or with a removable retainer.

Bonding Multistranded Wire Retainer

Direct bonding of Multistranded wire retainer. The following clinical direct-bonding procedure is advocated for bonding with chemically cured or light-cured composite resin, respectively (Figs. 27-50 to 27-52):

1. Toward the end of orthodontic treatment, take a snap impression and pour a working model in stone.
2. Using fine, three-pronged wire-bending pliers and marking pen, closely and passively adapt the 0.0215-inch Penta-One steel wire (Masel Orthodontics, Carlsbad, CA) or gold-coated wire (Gold'n Braces, Inc., Palm Harbor, FL) to the crucial areas of the lingual surface of the teeth to be bonded. Cut the wire to the required length.
3. Check the retainer wire in the mouth for a good fit in an entirely passive state, and adjust, if necessary.
4. Clean the surfaces to be bonded with a tungsten carbide or diamond bur, and etch for 30 seconds with phosphoric acid gel (see Figs. 27-50 and 27-51).
5. Use a four-handed approach (or similar) for the initial tacking. Hold the wire by hand in the optimal position while tacking it to one incisor with a small amount of Transbond LR (3M Unitek, Monrovia, CA) (see Figs. 27-51, *E* and *F*, and 27-52, *B*). Check the wire for passive tension after tacking. If the wire is passive, then add more adhesive and light cure the remaining teeth; if it is not, then remove the wire and start over again.
6. Contour the bulk of adhesive with the brush dipped into the primer. Optionally, transfer the adhesive from a mixing pad, which should have a light-impermeable cover. Importantly, the adhesive must cover a large labiolingual area over the wire for strength and wear resistance. Trim with burs when necessary.
7. Instruct the patient in proper oral hygiene and in the use of dental floss and in each interdental area with a floss threader or Superfloss (Oral-B, South Boston, MA).

Indirect bonding of Multistranded wire retainer. The fixed lingual retainer also can be fabricated with an indirect technique

FIGURE 27-49 Four different clinical situations in which a lingual multistranded wire retainer is used for improved retention. The cases represent significant midline diastema of maxillary central incisors (**A, B**), bilaterally missing maxillary lateral incisors (**C, D**), one lower incisor extraction in Class III plus open-bite tendency case (**E, F**), and two palatally impacted maxillary canines (**G, H**). In **D,** the six-unit retainer is bonded in the occlusal fossa of the first premolars, whereas in **H,** a short labial retainer is bilaterally used to stabilize the mesially rotated and palatally displaced canines and the distally rotated first premolars.

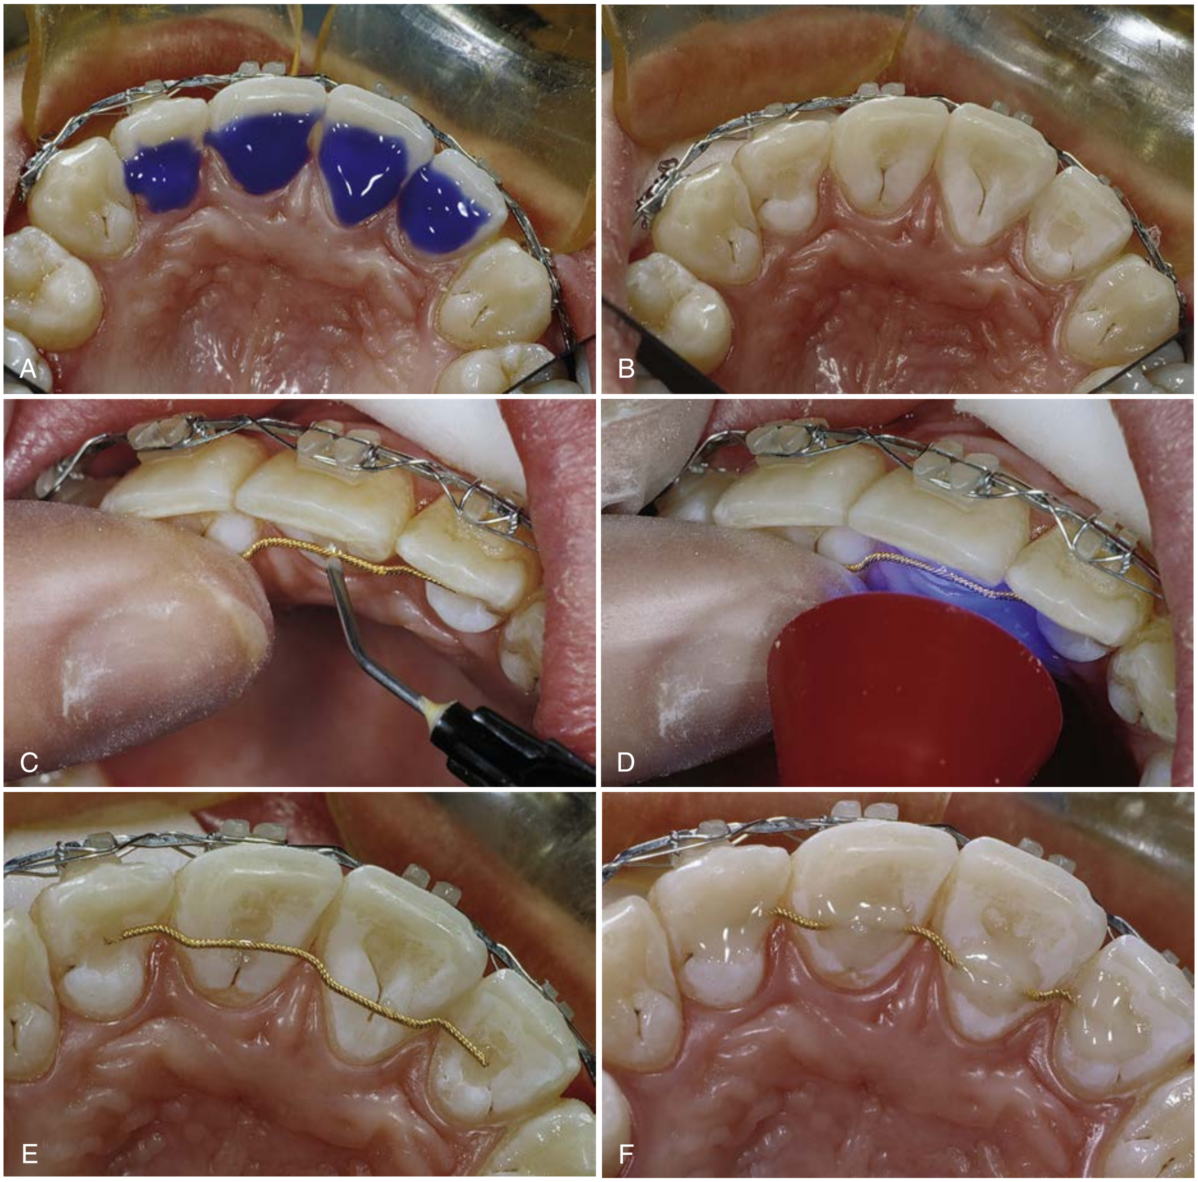

FIGURE 27-50 Fabrication of four-unit multistranded wire retainer with chemically cured composite resin. A gold-coated Penta-One wire is carefully adapted on a model with fine three-jaw pliers to fit the lingual contours of the incisors passively. **A, B,** Acid etching of the lingual surfaces of the upper incisors is demonstrated. **C, D,** The initial tacking to one incisor is made with flowable light-cured resin, with the wire held in the optimal position by a finger. This initial tacking to one tooth allows direct checking of position and fit of the retainer wire and is the key to avoid unwanted tooth movement as a side effect during the retention period. When correct and passive, the remaining teeth are tacked next with a small amount of light-cured flowable resin (**E**) before the bulk of adhesive is added in a gingival-occlusal movement (**F**). A thin mix of composite resin is then added with an explorer to fill in the bond mesially and distally on each tooth. Trimming is made with tungsten carbide burs (**G–I**). The No. 7006 is ideal incisal to the wire to avoid occlusal interference, whereas the contour gingival to the wire is made with the No. 7408 bur. **J,** Final result.

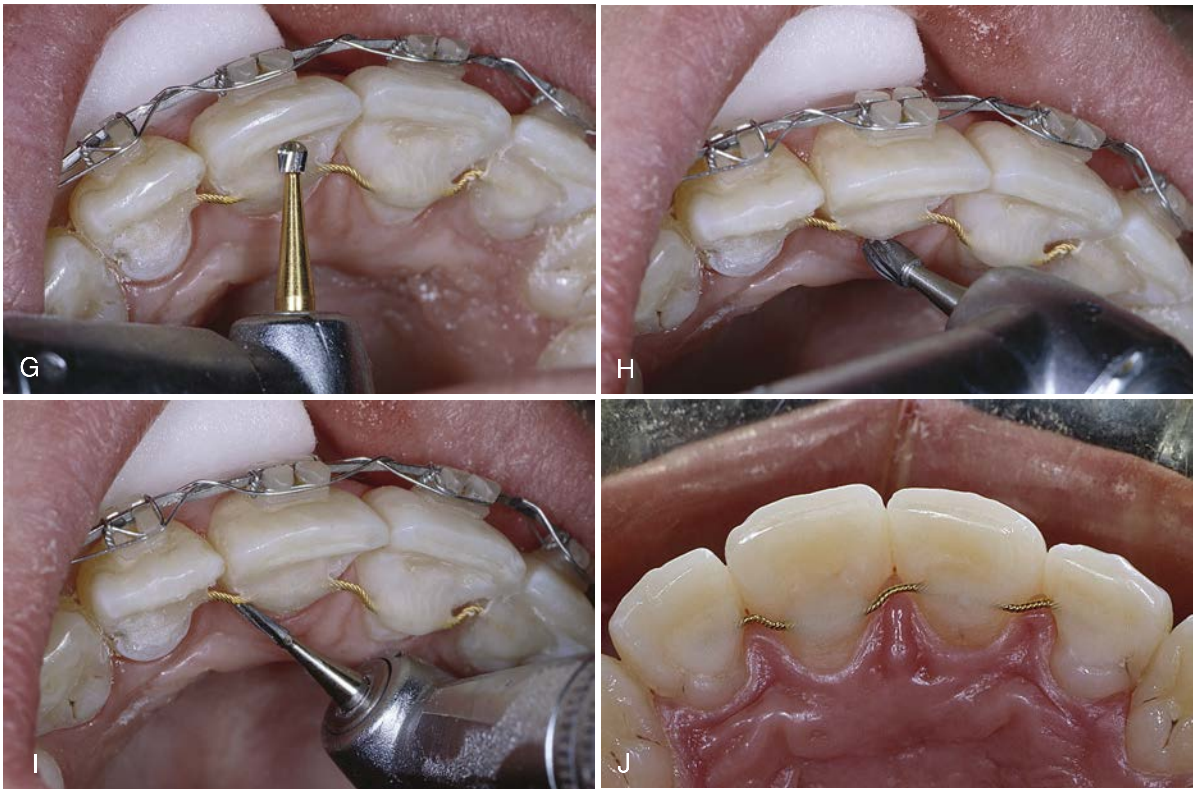

FIGURE 27-50, cont'd

as described elsewhere.[231] A practical approach for lingual retainers is to use indirect bonding with a 2-mm-thick polyethylene thermoplastic transfer tray and Transbond LR and Sondhi Rapid Set (3M Unitek, Monrovia, CA) as adhesive resins.[231] A recent randomized clinical trial indicates that indirect bonding is faster and shows a comparable failure rate.[232]

Failure Analysis and Repair

Experiments in the late 1970s and early 1980s used different sizes (0.015- to 0.020-inch diameter) and types of multistranded wires.[204] Early findings included the following:

1. The incidence of wire breakage appears to decrease with increasing wire diameter.
2. An unacceptable incidence of bond failures occurs when the wires are bonded to the lingual surfaces of premolars.[1,204]

The mandibular 3-3 bar and 321-123 retainer show similar success rates.[227] Dahl and Zachrisson reported in 1991 that for the five-stranded Penta-One wire (Masel Orthodontics, Bristol, PA), failure rates for loosening were 8% in the maxilla and 6% in the mandible; the failure rates for wire fracture were 3% in the maxilla and were nonexistent in the mandible.[233] Other authors, on the other hand, have reported failure rates of 37% to 46% over 2 to 3 years, which included any type of failure and may have exaggerated the overall failure rate.[207,234]

The discrepancies between the authors' experience and that of other studies probably can be explained by fewer occlusal interferences (with less contact with opposing teeth to allow for more wear) and by technical factors, such as adequate buccolingual width of composite over the wire, smooth contouring of the adhesive, completely undisturbed setting of the adhesive in every case, and careful adaptation of the wire to the lingual contours of the teeth. The reduction of wire breakage compared with earlier results is related to the increased flexibility of five smaller wires occupying the same diameter as the three larger wires in previous retainers. Because a common mode of failure with bonded MSW retainers is abrasion of composite and subsequent loosening of bonds between wire and composite,[220] one is advised to avoid occlusal contact or to add a thick layer of adhesive over the wire. Even in the absence of tooth contact, such as in the mandible, mechanical forces (e.g., tongue activity, tooth brushing) may cause notable abrasion over the years.

Because the failure rates significantly increase when the canines (and first premolars) are included in a maxillary MSW retainer, using a four-unit design, combined with a removable plate (Figs. 27-53 and 27-54) rather than a six-unit bonded retainer (Figs. 27-55 and 27-56), can be a safer alternative for routine retention in children and adults.[234]

The most common problem after wire fracture or the loosening of the bonding site(s) in MSW retainers is unwanted movement of one or more teeth. At this stage, the teeth are not firmly seated in their sockets and therefore can be generally forced back into position using techniques such as heavy pull with one or two steel ligatures (Fig. 27-57, *A* and *B*).

When the repair is made, a temporary contact splint using composite resin or a temporary bonded labial wire has proved to be of considerable value. The latter normally provides better stability and allows a good working area with undisturbed setting of the repair adhesive (Fig. 27-57, *C* and *D*). After the repair, the temporary labial wire (or contact splint) is removed with tungsten carbide burs.

Long-Term Experience with the Multistranded Wire Retainer

MSWs are invisible and can be placed out of occlusion in most instances. If not, then hiding the wire under a slight groove

FIGURE 27-51 Instruments (**A**) and method (**B–G**) for fabrication of six-unit lingual multistranded wire retainer with light-cured composite resin. After a 0.0215-inch stainless steel or gold-coated Penta-One wire is adapted for optimal fit on the lingual surfaces of all teeth (**B**), the teeth are acid etched with phosphoric acid gel (**C**). Composite resin is added to one incisor (**D, E**) and light cured. After checking that the wire is passive and has a good fit to the remaining teeth, composite resin is added, shaped with the aid of liquid resin and fine brush (**F**), and light cured (**G**). **H,** Final result.

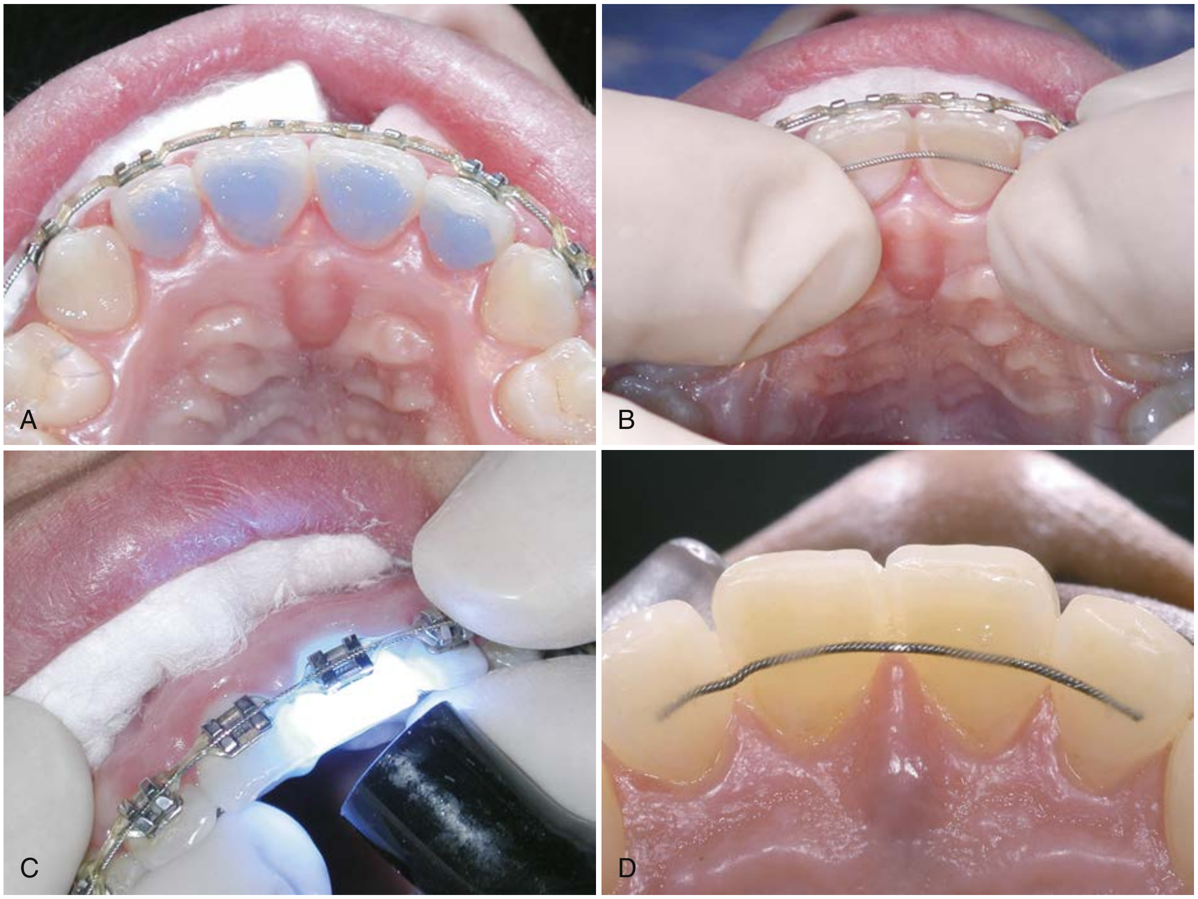

FIGURE 27-52 Fabrication of four-unit multistranded wire retainer with light-cured composite resin. **A,** Etching with phosphoric acid. **B,** Finger-holding of wire while tacking one incisor. **C,** Light curing the remaining teeth. **D,** Final result. (See text for details.)

in the enamel is a possibility and can be used alone or with removable retainers, and therefore the patient acceptance of the MSW retainer is excellent.[204,228,233] In addition, adults especially appreciate that the stability of the treatment result does not depend on their cooperation, which is the case when removable retainers are continuously worn or are worn at night.

MSW retainers allow safe retention of treatment results when proper retention is difficult or even impossible with traditional removable appliances. Recent research indicates the alignment of the mandibular anterior teeth is stable in 90.5% of patients at the 5-year follow-up, whereas in 9.5%, a mean increase of 0.81 mm in the irregularity index was observed.[235] MSW retainers are also better at maintaining incisor alignment than a round retainer bar.[221] The favorable long-term success can be attributed to the allowance of slight movement of all bonded teeth and segments of teeth with the MSW. Side effects in the form of undesirable movement of bonded teeth, on the other hand, may occur if the wire is too thin (three-stranded 0.015- to 0.0195-inch wires) or not entirely passive while bonding.[233,236]

When patients with previous multiple spacing of anterior teeth were in the retention phase of treatment, small spaces (1 to 2 mm) often opened distal to the terminal ends of the retainer wire after approximately 6 months. Because these spaces apparently did not open further, the conclusion was that they illustrated a settled occlusion with the MSW retainer in place in a new state of physiologic equilibrium.[205,228,233] Depending on the occlusion and the patient's dental awareness, such spaces could be filled with mesiodistally extended fillings or crowns or could be allowed to remain.

The 3-3 bar is a safe retainer, and this design may be recommended for most children. For adults and adolescent patients with pretreatment spacings and similar malocclusions, the bonding of all six anterior teeth may be preferable.

At present, little is known about the length of time that the bonded MSW retainer should be left in place. The type of original malocclusion and the patient's age and ability to keep the retainer clean may be decisive factors. As long as the retainer is intact, the treatment result is maintained; and as long as the patient performs adequate plaque control, no real reason exists to remove the retainer.

In selected cases, retainers may be used for permanent stabilization.[204,222] Further follow-up research is needed for semipermanent and permanent use of bonded retainers. As discussed for the 3-3 retainers, using the bonded lingual retainer for a prolonged retention period and then replacing it with a removable retainer for nighttime wear on a more permanent basis may be practical in some cases.

Direct-Bonded Labial Retainers

Clinical experimentation with short labial retainers was started in the late 1980s to try to improve the long-term results in

FIGURE 27-53 Recommended version of the removable plate to be used with a four-unit bonded lingual retainer. The rectangular (0.019- × 0.026-inch) labial wire of this plate distally extends to the lateral incisors and has a soldered extension wire to prevent flaring of the canines. A holding clasp of 0.8-mm round wire is distal to the second molars.

some specific retention situations.[228] The following were typical problems:

1. Inability to prevent some space reopening in closed extraction sites in adults
2. Tendency for some lingual relapse of previously palatal-impacted canines
3. Space reopening when molars and premolars had been mesially moved in cases with excess space

Common to these situations was that some support in the premolar area for 1 to 2 years appears advantageous to improve stability. The background for labially bonding retainer wires was based on unsatisfactory results when the orthodontist bonded wires to the lingual surface of premolars. The alternative—occlusally bonding the wire in the premolars—presents other problems. In most instances, antagonistic contact cannot be avoided unless a groove is prepared, which is probably not acceptable in routine situations. It was decided therefore to bond short retainer wires labially to examine success rates and patient reactions.

Technical Procedure

In principle, the fabrication of labial retainers is similar to the technique used for direct bonding of lingual retainers.

1. A straight piece of 0.0215-inch Penta-One wire (gold-coated or stainless steel) (Masel Orthodontics, Bristol, PA) is cut to the desired length.
2. After etching, the retainer wire is tacked on the teeth.
3. After the adhesive sets, a bulk of adhesive is added.
4. Contour trimming of excess is performed with tungsten carbide burs (No. 7408 and No. 7006), and interdental trimming is performed with small round burs (No. 1 or No. 2). Care is taken to avoid contact between composite and gingival margin at the bonding sites, as well as contact between the interdental papillae and the retainer wire.

Long-Term Results

The first follow-up study of direct-bonded labial retainers as reported by Axelsson and Zachrisson[228] demonstrated excellent results for short segments (two teeth) regarding bond success rate and, surprisingly, for patient acceptance. A gold-coated labial wire (Fig. 27-58) is understandably more acceptable than a steel wire, even if some of the plating may wear off over time. The failure rates for retainers of two teeth were approximately 4% over an average period of 2 years. The retainers were placed over closed extraction sites in adults (Fig. 27-59) or for added retention of previously palatally impacted canines (see Fig. 27-49, *H*).

When longer retainers (three to four teeth) were labially placed in the mandible, however, the bond failures increased significantly.[228]

OTHER APPLICATIONS OF BONDING

Bonding a Large Acrylic Appliance

Various acrylic appliances are used in clinical practice usually to expand the maxilla. Many of these appliances cover the upper buccal segment and require a certain amount of retention during their active phase. Usually the permanent dentition phase is uncomplicated with more than enough anatomic undercuts to hold the appliance in position. However, retaining such appliances in the deciduous or mixed dentition periods requires a dependable approach.

FIGURE 27-54 Recommended routine retention for adolescent patients. Young girl with unilateral crossbite (**A–C**) after orthodontic treatment involving four premolar extractions (**D, E**). **F,** After treatment. Retainers include an upper four unit multistranded wire retainer (**G**), a lower 3-3 bar (**H**), and a removable plate.

FIGURE 27-55 **A–C,** Combination of six-unit bonded lingual retainer and simplified Crozat appliance for retention in an adult female patient with an anteriorly constricted maxillary dental arch and rotated and blocked out lateral incisors and canines. **E,** The Crozat appliance is optimal for long-term retention of crossbites in adults. If the appliance is not worn for some time and slight transverse relapse occurs, then its flexibility allows for recovery (similar to a spring retainer), in contrast to what is possible with a conventional removable plate. Note improvement of smile fullness (**F**) compared with the start (**A**).

FIGURE 27-56 **A, C,** Recommended version of removable plate to be used with a six-unit bonded lingual retainer. The labial wire of this plate extends distal to the bonded retainer to avoid the risk of retainer wire fracture. The acrylic of the plate can be ground away from the teeth involved in the bonded retainer (**B, D**).

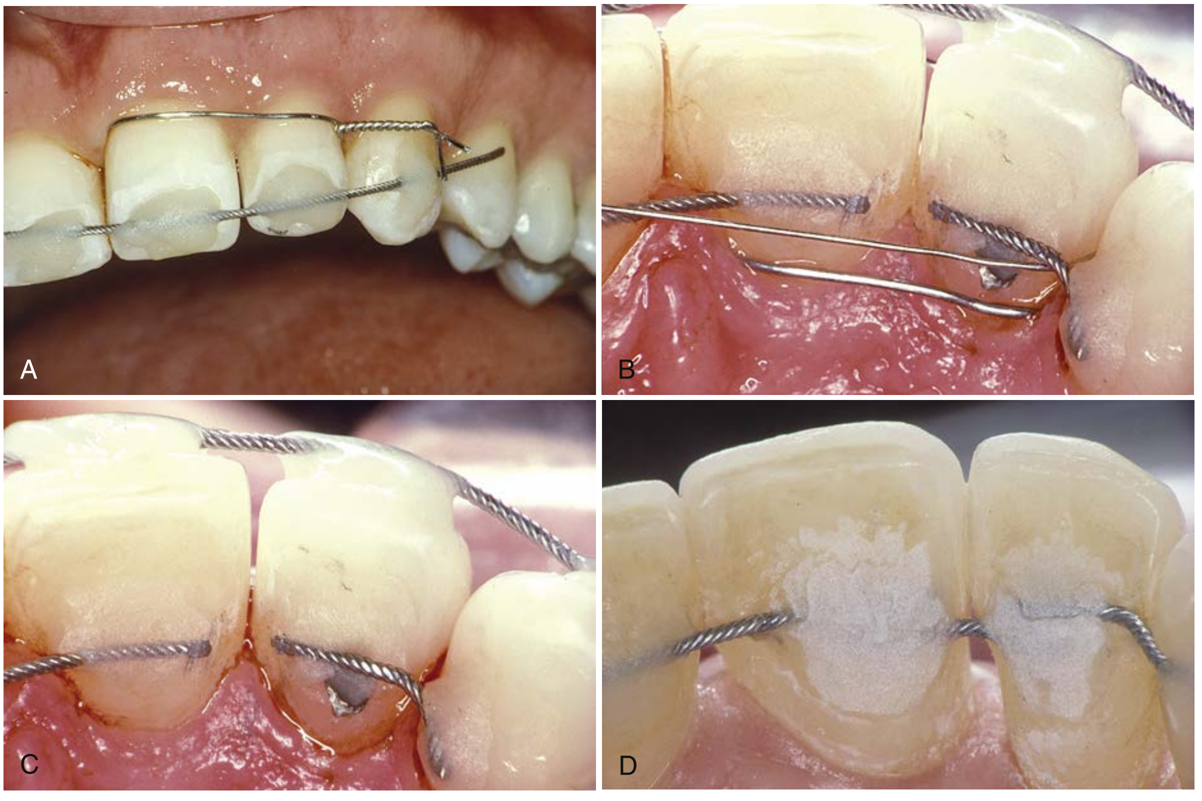

FIGURE 27-57 Repair of broken retainer (fatigue fracture of wire between left central and lateral incisor), using labial temporary wire for stabilization during rebonding. When the loose teeth have been pulled together with steel ligatures (**A, B**) to close a small space, the temporary wire is labially bonded with adhesive after a 5-second etch. After setting, the steel ligatures can be removed to provide a nice working field (**C**) where the repair wire can be bonded with no disturbed setting gingival to the main retainer wire (**D**).

FIGURE 27-58 Slight space reopening distally to short labial retainer in an adult woman requiring upper first premolar extraction. **A, B,** Gold-coated labial retainers. **C,** The reopening evidently reflects a tooth size discrepancy that can be addressed when remaking the amalgam fillings. **D,** The labial wire is inconspicuous on smiling.

Technical Procedures

Permanent Dentition

1. Clean the teeth to be bonded with pumice slurry. Wash thoroughly and air dry.
2. Cement the appliance with polycarboxylate cement. Have the patient bite down on a cotton roll or gauze. Remove the excess cement after approximately 30 to 60 seconds while still in the plastic phase.
3. Alternatively, if a certain amount of moisture cannot be avoided, use a hybrid glass ionomer cement (Multi-Cure Glass Ionomer Cement, 3M Unitek, Monrovia, CA). This cement works best on a moist surface; however, glass ionomers do not tolerate additional water or saliva introduced during the curing process. Cure for 10 seconds per tooth. Cement will also be chemically cured after 5 minutes.

Deciduous or Mixed Dentition

1. Clean the teeth to be bonded with pumice slurry. Thoroughly wash and air dry.
2. To improve the adhesion between the adhesive and the appliance, apply a uniform coat of plastic appliance conditioner (Reliance Plastic Appliance Conditioner, Reliance Orthodontic Products, Itasca, IL) or methacrylate monomer to the inner side of the acrylic appliance.
3. Acid etch the buccal and lingual tooth surfaces and the distal surface of the last molar. Occlusal surfaces should not be etched to facilitate clean-up at debonding. Thoroughly rinse and dry.
4. Apply a thin coat of adhesion booster (Assure, Reliance Orthodontic Products, Itasca, IL) to the etched deciduous enamel, and lightly air dry.
5. Load the appliance with light-cured band adhesive (Ultra Band-Lok, Reliance Orthodontic Products, Itasca, IL). When using colored band adhesives, turning off or dimming the overhead light is important, as these lights (particularly current LEDs) may cause premature curing of the resin.
6. Place the appliance into the mouth, and clean up the flash before light curing for 30 seconds per tooth with a conventional

FIGURE 27-59 **A–C,** Young adult female patient with typical Class II, Division 2 malocclusion before treatment. The maxillary first molar was extracted as part of treatment (**C**). The second molar and first premolar were held together with a short gold-coated labial retainer. The maxillary third molar is erupting. **D–F,** Note the improved maxillary canine occlusion and incisor torque.

halogen. Curing can be faster with new-generation light sources (Fig. 27-60).

Occlusal Buildup of Posterior Teeth

Occlusal buildup of posterior teeth is often necessary when bonding to the lower teeth in patients with deep bites or with severely malposed teeth or when a tooth or group of teeth in the crossbite is brought into the arch, which is easily achieved by composite occlusal buildups. Using colored light-cured band adhesives (Ultra Band-Lok, Reliance Orthodontic Products, Itasca, IL) is a good practice for easy detection and to remove the remnants completely.

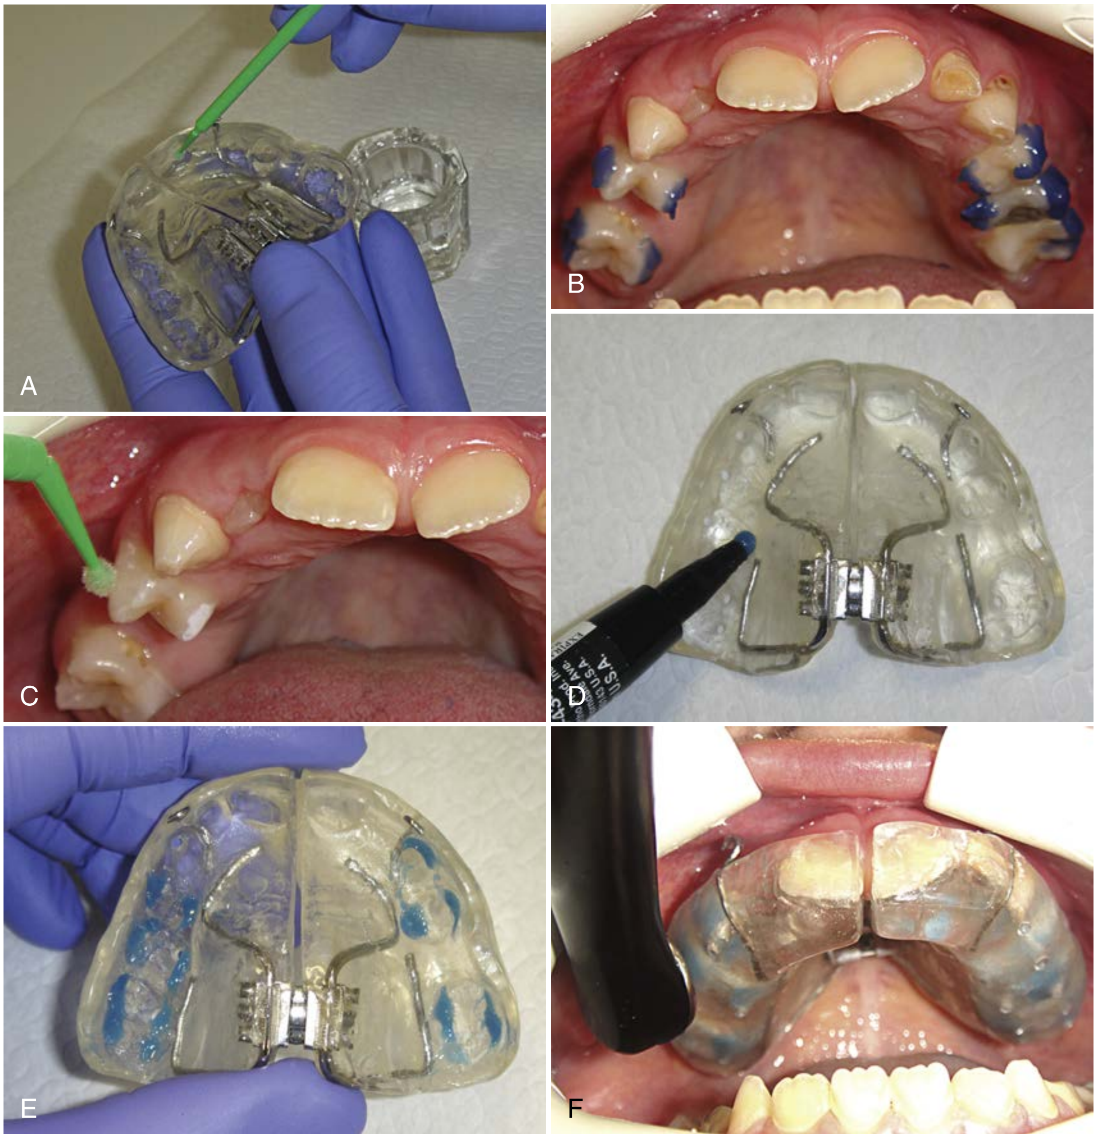

FIGURE 27-60 Various appliances may need to be bonded to teeth in the deciduous or mixed dentition period to provide better retention. All surfaces to be bonded should be cleaned with pumice slurry, thoroughly washed, and air dried. **A,** A uniform coat of Reliance Plastic Appliance Conditioner (Reliance Orthodontic Products, Itasca, IL) or methacrylate monomer is applied to the inner side of the acrylic appliance to improve adhesion between the adhesive and the appliance. **B,** The surfaces to be bonded are acid etched and thoroughly rinsed and dried. Etching the occlusal surfaces is avoided to facilitate clean-up during the debonding session. **C,** A thin coat of adhesion booster is applied to the etched enamel surfaces. **D,** The appliance is loaded with a light-cured band adhesive. **E,** An ungenerous amount of adhesive is loaded; the excess adhesive will move on to the occlusal surfaces and will complicate cleaning. **F,** The appliance is firmly placed into the mouth, and any flash is cleaned before light curing for 30 seconds per tooth with a conventional halogen. Curing can be faster with new-generation light sources. (Courtesy of Dr. Sabri Ilhan Ramoglu, Istanbul, Turkey)

Technical Procedure

1. Clean the occlusal surface to be bonded with pumice slurry. Thoroughly wash and air dry.
2. Acid etch the occlusal surface for 15 seconds, and avoid etching the deep occlusal groves for easy removal at the debonding session.
3. Apply colored band adhesive, and shape and adjust the resin bulk to the required height with fine brush strokes. As with appliance bonding, turning off or dimming the overhead light is important, as these lights (particularly current LEDs) may cause premature curing of the resin. Light cure for 30 seconds with a conventional halogen. Curing can be faster with new-generation light sources (Fig. 27-61).

Occasionally, some add-on may be required at the following appointments if the tooth with buildup gets intruded. The bulk can be easily removed by careful force application with a Weingart plier after treatment, and any remaining adhesive can be removed with a scaler.

FIGURE 27-61 **A,** The bite needs to be temporarily raised to bring the upper right lateral incisor into the arch. Temporary occlusal composite build-ups will be used for this purpose. **B,** The occlusal surface to be bonded is first cleaned with pumice slurry and thoroughly washed and air dried. **C,** The occlusal surface is acid etched for 15 seconds, avoiding etching the deep occlusal groves for easy removal during the debonding session. **D,** Note the frosty white appearance of the cusp tips and unconditioned occlusal grooves. **E,** Colored band adhesive is applied, and the resin bulk is shaped and adjusted to the required height with fine brush strokes and light cured. **F,** The raise of the bite can be seen. Note that an even occlusal contact should be provided on the contralateral side as well. (Courtesy of Dr. Sabri Ilhan Ramoglu, Istanbul, Turkey)

CONCLUSION

Today, adhesive resins, direct bonding, and light curing units are a very important part of the modern orthodontist's armamentarium. Our distinguished profession would not have been popularized without the application of direct bonding and advances in the material science.

Similar to any other material, composite resins and bonding have their particular benefits and drawbacks. Beyond a doubt, modern orthodontists need to have a thorough knowledge and comprehension of the materials available so that they can choose the best product available for their particular needs and to make the best use of them.

Management of Impactions

Adrian Becker and Stella Chaushu

OUTLINE

TEETH NORMALLY ERUPT! (CAUSES)

The most important and basic attribute of each tooth in the dentition is that it erupts into the oral environment. In the absence of eruption of a tooth in its due time, it must be assumed that something is wrong. Therefore the key to success in resolving noneruption or tooth impaction is to find the cause and eliminate it. Possible reasons may be listed under the following headings:

1. **Primary displacement of the tooth bud:** Displacement occasionally occurs with canines, but other teeth are not immune. The tooth develops in an ectopic location (Fig. 28-1); although it may have normal eruptive potential, its eruptive movements may not bring it in an appropriate direction, and thus the tooth may not emerge into the oral cavity. Aside from impaction, primary displacement is sometimes associated with tooth transposition. Treatment: The tooth is surgically exposed, followed by biomechanical redirection or extraction.

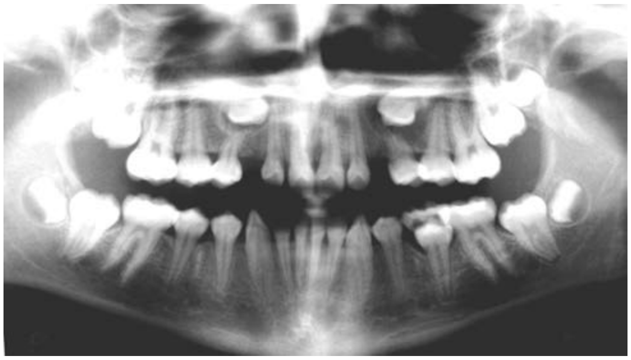

FIGURE 28-1 Maxillary bilateral impacted canines are transposed with the first premolars on this panoramic view. Shortening of the tooth length is due to the projection of the x-ray beams almost along their long axes. The apices of both canines are palatal and their crowns labial, in this case of primary displacement of the tooth buds.

2. Space inadequacy: Inadequate space includes crowding and space loss in the dental arch, such as the drifting that occurs after the early extraction of deciduous teeth. Teeth possess the intrinsic potential for eruption but, under these conditions, are prevented from erupting. Treatment: Space is re-created by moving neighboring teeth or by remedial extraction of other teeth.
3. Local obstruction anomaly: Examples of obstruction-related anomalies are supernumerary teeth,[1] odontomes (Fig. 28-2), dentigerous cysts, and gingival fibrosis. Teeth possess the intrinsic potential for eruption but, under these conditions, are obstructed. Treatment: The causative entity is eliminated, with or without the provision of extrusive orthodontic mechanics.[2]
4. Trauma: Early trauma to the deciduous anterior dentition may sometimes be transmitted to the developing permanent teeth, particularly the central incisors. Trauma may result in damage to the unerupted tooth, usually by causing attenuation or arrest of the development of the root. The result can be a short or dilacerate root and failure of the tooth to erupt (Fig. 28-3, *A*, *B*). Treatment: If long-term prognosis is poor, the tooth is surgically exposed, followed by orthodontic redirection with the intention of bringing the tooth into the arch, with its accompanying alveolar bone to provide a healthy base for a subsequent implant. In an extraction case, consideration should be given to extracting this tooth rather than extracting a normal healthy premolar.

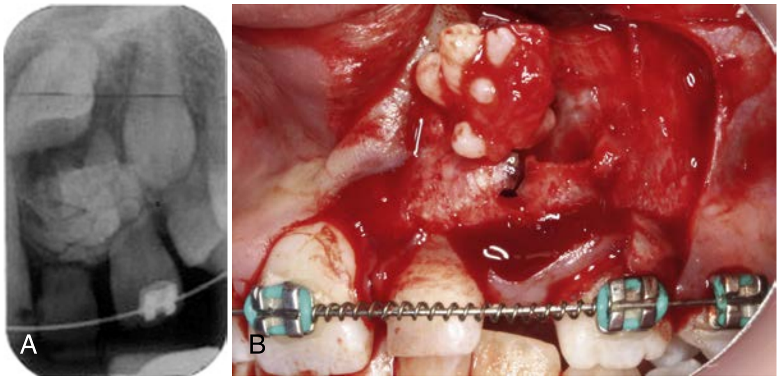

FIGURE 28-2 A, B, A composite odontoma is revealed in a periapical radiograph and at the time of surgical exposure before extraction of the odontoma.

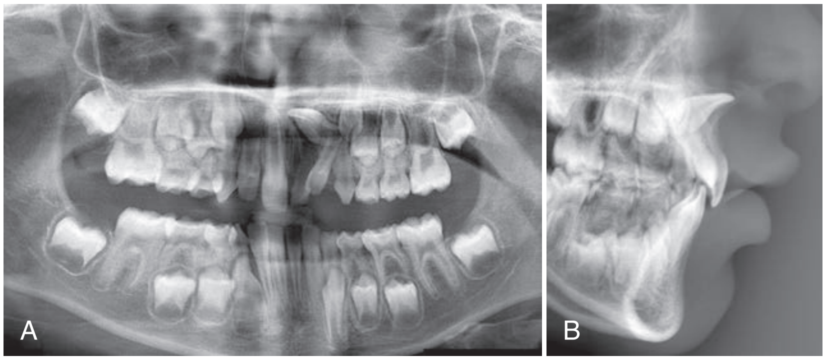

FIGURE 28-3 A, B, A severely dilacerated maxillary central incisor is revealed in the panoramic and lateral cephalometric views. The incisal edge is located within the anterior nasal spine.

5. Local pathologic cause of periodontic origin: For normal eruption, a tooth must have a periodontal ligament that is intact around the entire root surface. When a break of its integrity occurs, as in ankylosis, the tooth is in direct contact with the alveolar bone and will not erupt further. Invasive cervical root resorption (ICRR) (Fig. 28-4), on the other hand, is caused by infiltration of clastic cells through gaps in the cementum layer. There is loss of periodontal ligament (PDL) integrity and bony deposition in the depth of the ICRR lesion, adjacent to the resorption front.[3] Treatment: Therapeutic luxation followed by immediate traction may overcome an ankylosis. ICRR can be treated by surgically exposing the lesion and obliterating the resorption crater with filling material, provided it is not too extensive.
6. General conditions: With a primary failure of eruption (PFE),[4–6] cleidocranial dysplasia (CCD)[7] (Fig. 28-5) and hypoplastic amelogenesis imperfecta,[8] the teeth have little or no intrinsic potential for eruption. Treatment: Attempts to erupt the teeth in PFE and, in some cases with amelogenesis imperfecta, will usually fail, due to defective intrinsic factors that are not well understood. After the surgical elimination of over-retained deciduous teeth and multiple supernumerary teeth in CCD, the application of efficient extrusive mechanics will readily bring about a positive eruptive response on the part of the teeth.[9]

IS THERE AN IMPACTION? (DIAGNOSIS)

At the age of 7 years, one expects to see erupted maxillary central incisors in the mouth. Similarly, at the ages of 11 and 12 years, the maxillary canines should have appeared. These determinations are made using a correlation of the chronologic age with the eruption age of the patient. However, this method is not reliable because great variability exists in the ages at which teeth erupt, most often attributable to local factors. A more reliable assessment method is to use a key that is linked to dental development—the dental age of the patient.[10,11] Teeth normally erupt when two-thirds to three-quarters of their estimated final root length has developed. In many cases, several teeth may erupt before their time because of pathologic conditions and early extraction of their deciduous

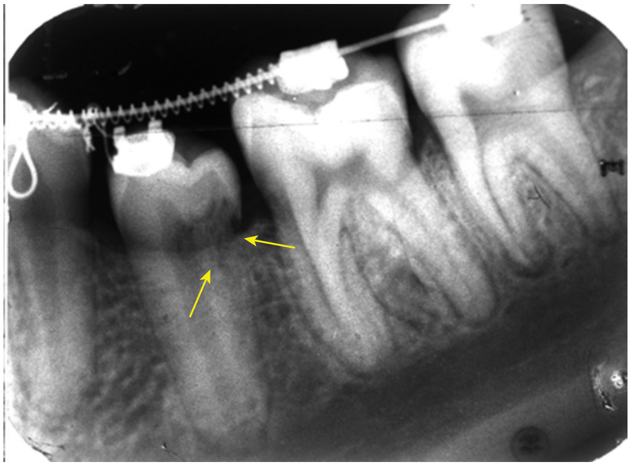

FIGURE 28-4 An invasive cervical root resorption (ICRR) lesion (*arrows*) is affecting the second premolar, which resisted active eruptive traction.

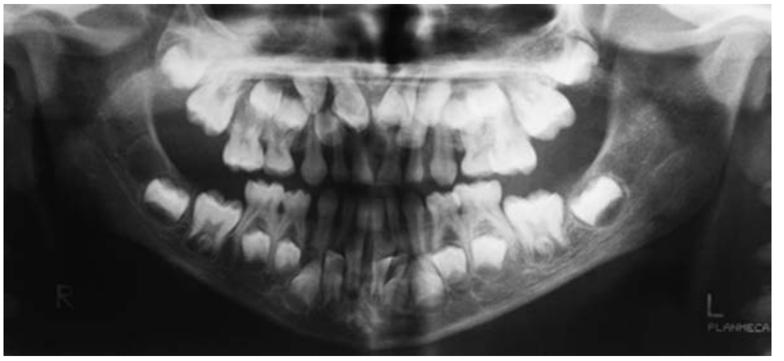

FIGURE 28-5 The dentition of an 11-year-old boy with cleidocranial dysplasia is depicted in this panoramic view. Note the very late dental development and the presence of several supernumerary teeth.

predecessors. Similarly, many instances of delayed eruption occur because of late shedding of the deciduous teeth. Diagnosis is made using radiographs, which may show unerupted teeth with advanced root development in excess of three-quarters of the final root length. For the most part and after the extraction of over-retained deciduous teeth, these teeth may still be expected to erupt normally, even if a little late. In contrast, an impacted tooth has been defined as "a permanent tooth whose root is developed in excess of this length and whose spontaneous eruption is not expected in a reasonable time"[11] (Fig. 28-6).

FIGURE 28-6 Horizontally impacted second permanent molars are revealed with almost completed root development.

WHICH TEETH ARE THE MOST LIKELY TO BE AFFECTED? (PREVALENCE)

Third molars are by far the most common teeth to be impacted, usually attributable to their location in relation to the length of the dental arch. Because of this tooth size–arch length discrepancy, conservative alignment of these teeth is not frequently advised, since no arch length into which they may be uprighted exists. On the other hand, when second premolars are absent, consideration of treatment aimed at mesially drawing first and second molars to provide space for the resolution of an otherwise impacted third molar often may be justified (Fig. 28-7, *A–C*).

Although less common, the maxillary canine is a far more important tooth to treat than its 1% to 2% impaction prevalence in most populations would suggest.[12–15] This is attributable to its position at the front of the mouth, its relative importance vis-à-vis the occlusion, and the patient's appearance.

Impacted maxillary central incisors[1,16–18] are the most disfiguring among all impacted teeth; fortunately, the frequency of their occurrence in the general population is very low. Prevalence figures from population studies are often inflated by the fact that affected individuals are far more likely to seek treatment and thus be included in an investigative sample of patients in dental hospitals, which unjustly purports to be a random sample.

WHERE IS THE TOOTH? (POSITIONAL DIAGNOSIS)

If the tooth has more than three-quarters of its expected root length and its eruption is not expected in a reasonable period, then the tooth needs assistance in resolving the impaction and, from the previous definition, the initiation of treatment is already late.

Before orthodontic treatment of the impacted tooth can be planned, accurately diagnosing its three-dimensional location in the jaw and its relation to the adjacent teeth and other anatomic structures is essential. The gathering of important relevant positional information is best achieved in four distinct diagnostic stages in the present context.

a. *Clinical examination.* When the patient attends a first visit, he or she generally comes without any diagnostic records. The intraoral examination should be conducted as with any orthodontic case, with an emphasis on searching for clues to the existence and location of unerupted teeth, based on certain features seen in the crown form and orientation of other teeth and other anatomic clues.[19] Thus the presence of a distally or labial flared lateral incisor, or a palpable bulge in the tissues overlying the palate, may indicate the location of an aberrant canine. Mobility or lack of mobility of deciduous molars at a certain age or early shedding of a deciduous canine may be very significant in this context.
b. *Plain-film radiography.* Perhaps the most popular film used by orthodontists in the earlier stages of diagnosis is the panoramic radiograph. It provides a good overall depiction of the dentition, much of the surrounding anatomy, and an occasional pathologic finding (Fig. 28-8). It offers a good two-dimensional indication of the presence and orientation of unerupted teeth but, by itself, lacks the facility to provide adequate buccolingual information[20,21] without the addition of supplemental films from other radiographic views, such as periapical, occlusal, lateral skull, and posteroanterior skull.

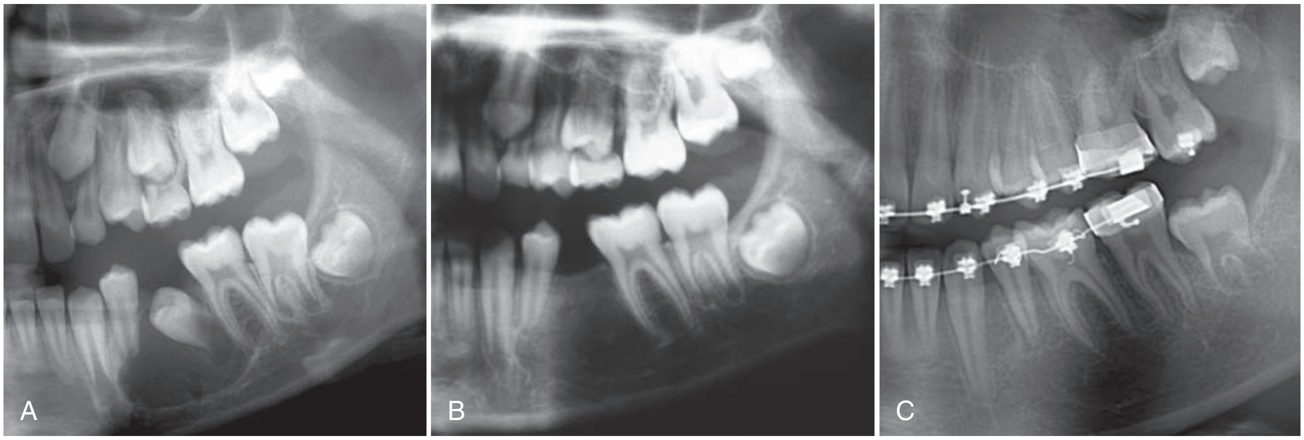

FIGURE 28-7 **A,** The right side of a panoramic radiograph shows a radicular cyst, which was enucleated with the second premolar tooth. **B,** The same view is shown after full healing and alveolar bone regeneration had occurred. **C,** The same view is shown during the final stages of orthodontic treatment, which is directed at mesially moving first and second permanent molars into the space to free the former impacted third molar to erupt normally.

FIGURE 28-8 A panoramic view prescribed to locate the position of the impacted maxillary canine reveals the chance finding of a radicular cyst associated with a nonvital second deciduous molar and an unerupted second premolar.

c. *Three-dimensional imaging.* Cone-beam computed tomography (CBCT) was introduced to dentistry, in general, and to orthodontics, in particular, at the turn of the 21st century; with CBCT came a quantum leap in the ability of the practitioner to see and easily understand the location and orientation of the tooth within the maxillofacial complex, because of its three-dimensional imaging.[22–24] When the reconstruction of the raw data has been properly prepared, it is difficult to understand how an orthodontist or a surgeon can possibly arrive at a mistaken positional diagnosis (Fig. 28-9, *A–E*).

Unerupted teeth cannot be evaluated for color, surface mottling, and enamel blemishes until they are surgically exposed. Assessment of tooth shape and size, crown, and root anomaly before exposure can be revealed only with the use of radiographs and/or CBCT imaging.[25] With the advent of these advanced radiographic imaging aids, the practitioner is responsible for rigorously scouring these diagnostic records for information regarding the existence of pathologic lesions, such as root resorption in teeth adjacent to an impacted tooth, which will undermine the long-term prognosis. Diagnosing conditions such as ankylosis and invasive cervical root resorption[26] (see Fig. 28-4) is significantly more difficult, because these conditions are insidious, asymptomatic, and not easily identified until they are quite extensive. Their presence will cause total resistance to any attempt to move the affected tooth.

By carefully appraising the wealth of information that will have been gathered, the orthodontist will be in a position to assess whether helping this tooth become an integral part of the envisaged orthodontic occlusal scheme for the specific patient is viable and whether the therapeutic cost of achieving this is justified.

ASSESSMENT OF THE OVERALL MALOCCLUSION (TREATMENT PLANNING)

In regard to the impacted tooth, four possible lines of treatment are available:

1. **Prevention and interception.** The literature is replete with studies investigating the efficacy of various measures intended to prevent, intercept, and/or mitigate the severity of impacted maxillary canine teeth, although little has been written in relation to other teeth. The measures have included the prophylactic extraction of the deciduous canines,[27–29] the deciduous canines and deciduous first molars,[30,31] space maintenance with a transpalatal arch,[32,33] molar distalization,[27,34] and maxillary expansion[32–34]; all of these measures have been successful to a limited degree, provided the diagnosis has been made early.
2. **Substitution.** Whether it is because of its surgical inaccessibility, its extreme displacement, its unacceptable shape or size, the presence of a pathologic finding, an unacceptable management problem in the child, or another legitimate reason for not attempting resolution, the simplest line of treatment is extraction. In this instance, substitution of the tooth by moving an adjacent tooth into its place, prosthodontic substitution with the use of an implant, or autotransplantation of another tooth will be considered. This treatment option is outside the scope of this chapter(see Chapter 20).
3. **Remedial extraction as part of an overall treatment plan.** If the overall treatment plan calls for the extraction of teeth because of crowding of the dentition or for another reason, then

consideration needs to be given to whether the impacted tooth should be one of the teeth of choice, together with other teeth in the remaining three quadrants of the arch. Again, the decision depends on factors such as the ability to disguise another tooth to simulate the missing tooth, particularly if a canine or incisor is the tooth of concern, and whether the appearance and longevity of the overall outcome would thus be improved. This treatment option is beyond the scope of this chapter.

4. **Resolution.** Resolving the impaction of the affected tooth and bringing it into its place in the dental arch—the orthodontic-surgical modality—is the most desirable result in the majority of cases that are seen. Resolving the impaction is predicated on the condition that the outcome conforms to the rigorous standards of health, function, and appearance of the tooth itself and of the dentition as a whole.

The remainder of the discussion in this chapter will be devoted to "resolution"— the orthodontic-surgical modality and how it may best be honed to produce the finest clinical outcomes in accordance with these standards.

With the decision to include the impacted tooth as an integral unit in the dentition, the overall malocclusion must be assessed in the manner described in earlier chapters of this text, regarding the orthodontic evaluation of every other case. In the fully erupted dentition, the initial task of the active orthodontic appliance therapy is to align and level the teeth in a single stage.

In the context of this chapter, leveling and aligning all erupted teeth will be completed and space will be prepared for the later alignment of the impacted tooth. A heavy passive archwire is then placed in the brackets of the aligned teeth with the express purposes of holding this alignment and of amalgamating the teeth into a compound anchor unit. The biomechanic appliance therapy for the resolution of the displacement of an impacted tooth will derive anchorage from this solid base.[35] Supplemental anchorage, in the form of intermaxillary elastics, soldered palatal arches, extraoral headgears, and temporary anchorage devices (TADs), should be considered in the initial treatment planning, if and when needed.

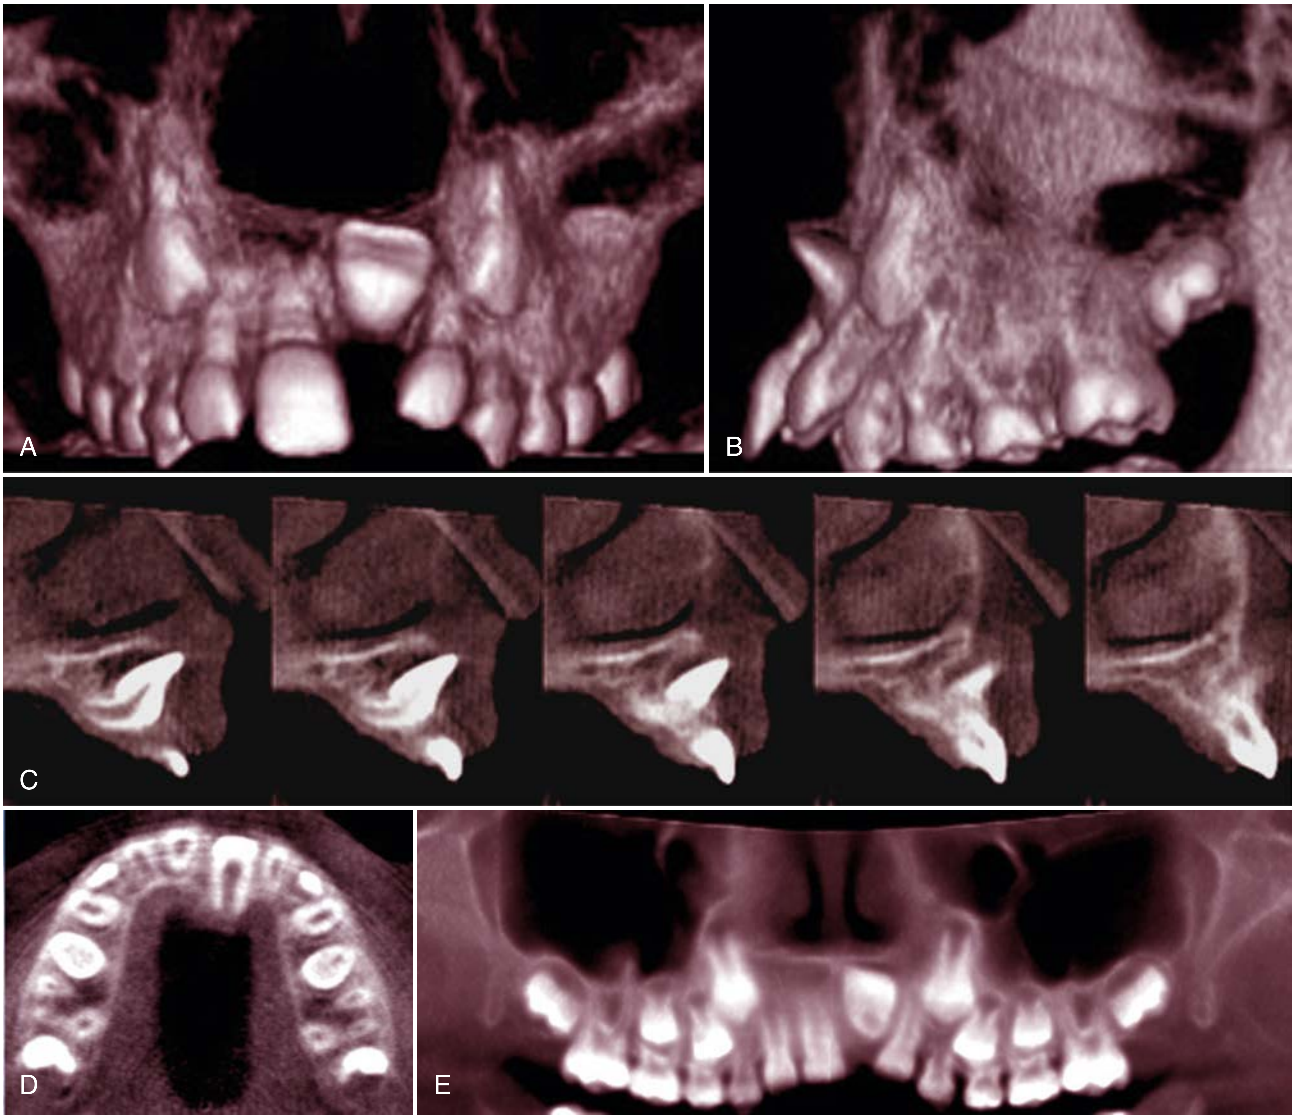

FIGURE 28-9 A–E, Cone-beam computed tomography (CBCT) images show classic dilaceration of the maxillary left central incisor on anterior and lateral three-dimensional views, cross-sectional cuts, an axial cut, and a panoramic view.

Occasional important exceptions to the treatment protocol are outlined here, specifically relating to the timing of the surgical exposure. Thus when the impacted canine is associated with resorption of the root of an adjacent (usually incisor) tooth, this resorption may be very aggressive and, in the absence of timely interceptive measures, can result in loss of the affected tooth. In these cases, the first step should be distancing the canine from the incisor, an intervention that has been proved to arrest the resorptive process.[36]

RESOLVING THE IMPACTION

In the absence of a pathologic condition, having diagnosed the location and orientation of the tooth in the three planes of space and having related its proximity to the locations of the adjacent teeth and other structures, the orthodontist should be able to plan an orthodontic strategy that will provide a path through potential obstructions and bring about the eruption of the tooth in the dental arch.

Many impacted teeth may be moved from their ectopic developmental position directly into their designated place in the line of the arch, in a simple tipping movement, without interference from the roots of adjacent teeth. For others, traction may need to be initiated in one direction to avoid an obstacle, and, once clear, the force may be redirected to bring the teeth into their place. Perhaps the most common example of when an indirect approach is needed is in relation to many palatally impacted maxillary canines. A typical scenario has the root apex of the canine high and in the line of the arch, with its apex-to-crown long axis deflected in a downward, forward, and palatally inclined vector. The crown is impacted on the palatal side, between the roots of the central and lateral incisors. The incisors may be in good positions, but the root of the lateral incisor, with its crown-to-apex orientation, lies in the canine's direct path to its intended location in the dental arch.

The panoramic radiographic presentation of this scenario is two-dimensional; because of this, defining the buccolingual orientation of the lateral incisor is impossible. The root of this incisor gives the misleading impression of being upright and parallel to that of the central incisors in the buccolingual plane, which will often encourage the orthodontist to plan a simple swing of the canine crown in an attempt to tip the tooth directly toward the labial archwire, not recognizing the obstacle in its path. Movement of the canine will be arrested by the clash with the lateral incisor root and the attempt will fail.[37-41] To avoid failure from this source, the canine should be vertically drawn downward toward the tongue, thereby erupting into the palatal area, inferior to the incisor root. From there, it may be tipped in a beeline to the archwire, in the normal manner.[37,38]

SURGICAL EXPOSURE

Surgical intervention in association with the presence of impacted teeth is needed for two primary purposes:

1. To eliminate a physical obstacle that restricts the normal eruption path of the tooth
   a. Resistant overlying soft tissue
   b. Supernumerary tooth
   c. Odontoma
2. To expose the tooth to provide access for the orthodontist to exercise control over its eruption
   a. To maintain the patency of the exposure and to supervise the tooth's natural autonomous eruption before an attachment is bonded to it for mechanical alignment[40]
   b. To permit attachment bonding and extrusive traction[37,38]
   c. To re-expose a tooth that has become reburied in the healing tissues

SURGICAL OPTIONS

Two basic approaches are used to expose impacted teeth. In the *open eruption exposure technique,* bone and soft tissues are removed around the crown, and it remains open to the oral environment at the end of the procedure (Fig. 28-10, *A*, *B*). The cut tissues are prevented from rehealing over the tooth by a broad elimination of the tissues down to the cement-enamel junction (CEJ) with or without the placement of a surgical pack,[39,41] which is left in place for 2 to 3 weeks or longer to permit healing to occur around it, while preventing the tissues from recovering the tooth. An attachment may be placed on the tooth and traction applied at the time of surgery or at a subsequent visit to the orthodontist after healing has occurred and the pack is removed (see Fig. 28-10, *B*).

Exposure must be immediately made in the mucosa overlying the unerupted tooth, and traction will bring the tooth into the oral environment through the tissues at this point. If the

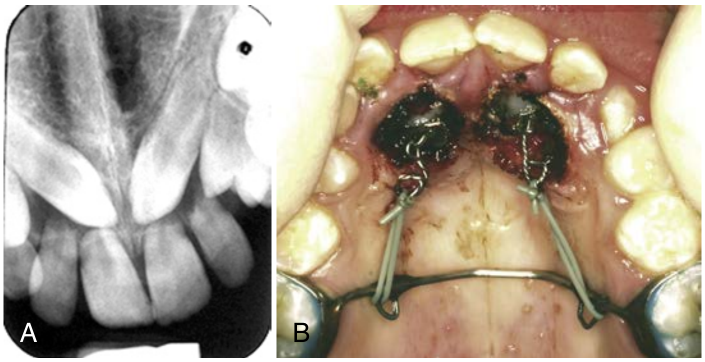

FIGURE 28-10 **A,** A periapical view reveals two impacted maxillary canines close to the midline that have caused the virtual disappearance of the roots of the four incisors. **B,** The same patient as shown in **A** is depicted after individual bilateral open surgical procedures with attachments are bonded to the palatal surfaces of the two canines and traction is immediately applied.

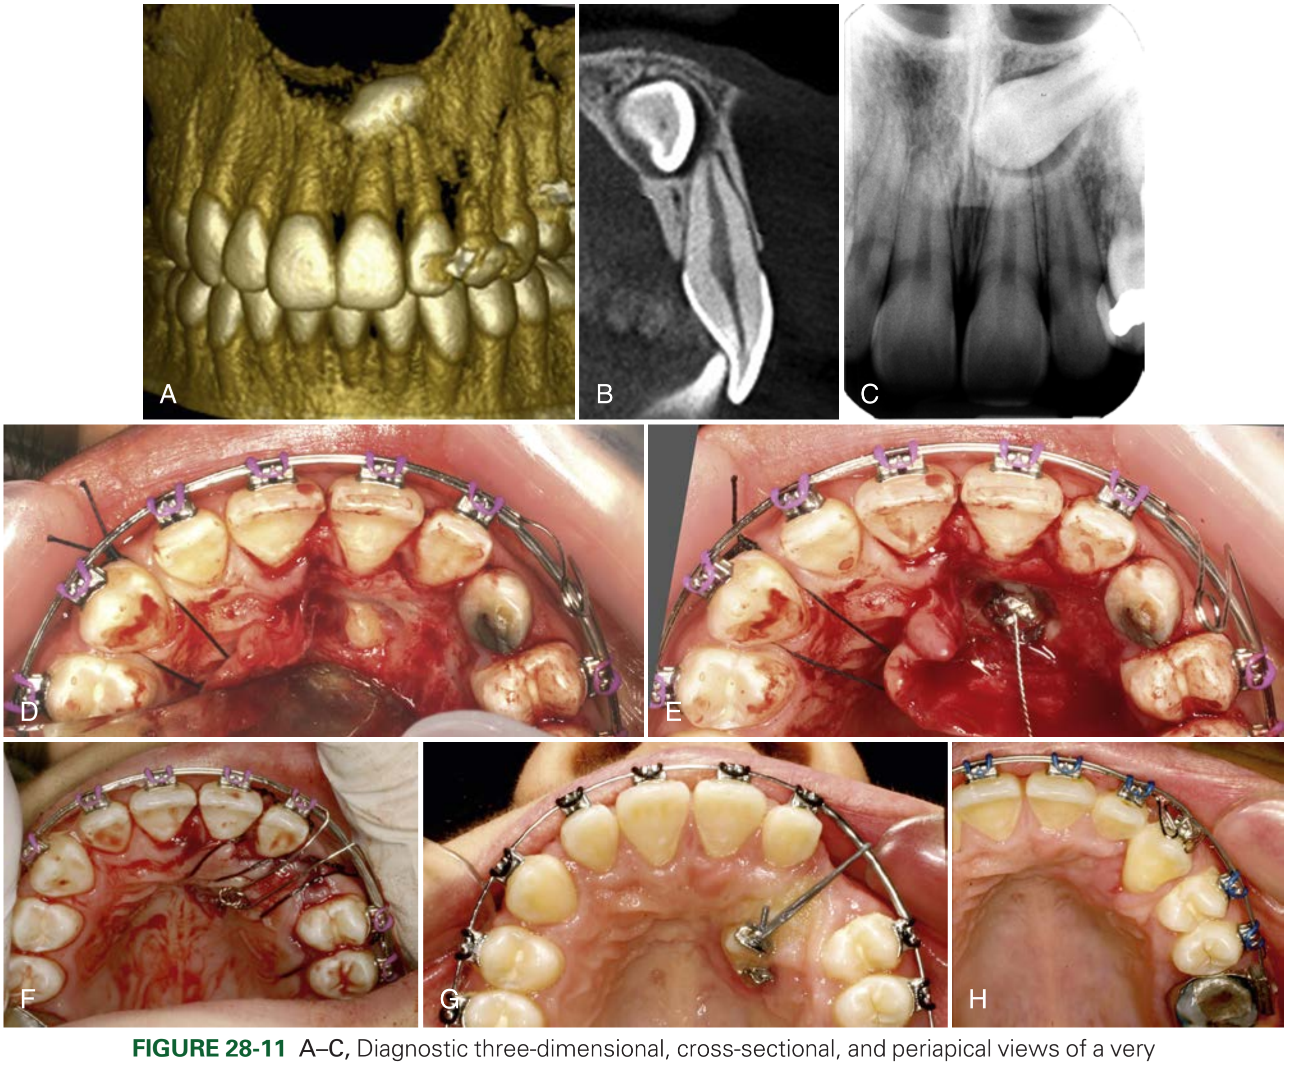

FIGURE 28-11 A–C, Diagnostic three-dimensional, cross-sectional, and periapical views of a very difficult palatal canine. D–F, With a very high canine, a closed surgical exposure has many advantages. Note the minimal exposure, attachment bonding, and fully replaced flap, with an auxiliary ballista-type spring already providing traction before the patient leaves the surgical unit. G, H, The canine is first erupted away from the incisor roots and into the midpalate before laterally moving into its place in the arch.

overlying tissues are comprised of nonkeratinized oral mucosa, as seen in impacted teeth that are exposed on the labial side, then the finally erupted tooth will be invested with oral mucosa, which is friable and easily damaged.

To avoid this undesirable sequel, a modification of the open exposure technique is recommended,[42] during which the tooth is exposed using a partial thickness apically repositioned flap of keratinized attached gingiva from the crest of the ridge or from the gingival crevice of the simultaneously extracted deciduous predecessor. In this way, the repositioned flap will come down together with the erupting tooth to provide it with a labial attachment of keratinized epithelium.[42]

In the *closed eruption exposure technique,* a wide surgical flap including attached gingiva is reflected, and the thin bone overlying the tooth is peeled away to reveal the follicle beneath. The follicle is minimally opened to permit a small area of the crown to be exposed. A more radical excision of bony or soft tissues is not needed, and surgery in the area of the CEJ is both superfluous and potentially damaging. The bonding area should be as small as possible and governed by the ability of the surgeon to maintain hemostasis while the orthodontist bonds the attachment with a twisted steel ligature or gold chain leading to the exterior.[43] The entire surgical flap is then resutured to its former place, leaving the steel ligature or gold chain as the means by which orthodontic traction may be applied to the impacted tooth[44,45] (Fig. 28-11, *A–H*, and 28-12, *A–E*), with the intention of erupting it through the attached gingiva, thereby simulating normal eruption.

Most studies have shown the superiority of the closed procedure with regard to the periodontal outcomes, especially for labially positioned canines and incisors,[44–53] although recent investigations do not support this view.[46,54] An open surgical procedure increases the risk for causing the loss of attached gingiva and long unaesthetic clinical crowns. Moreover, a closed procedure is also related to a shorter recovery time with less postoperative pain, especially for palatally displaced canines.[55–57]

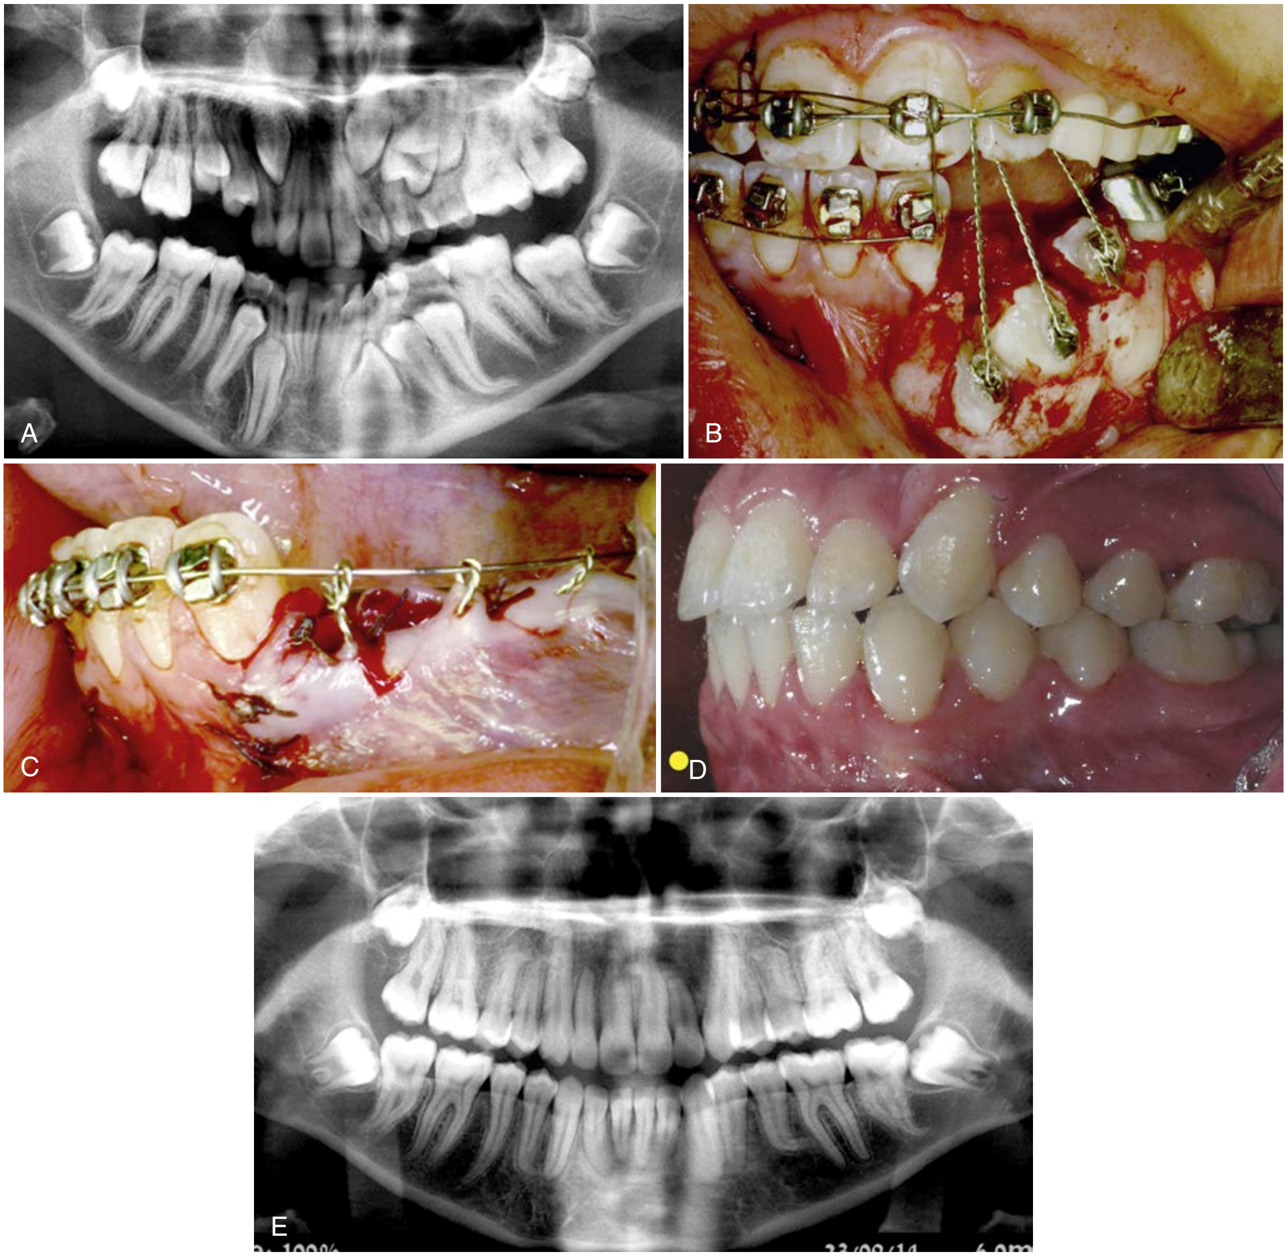

FIGURE 28-12 A–E, A young adult is suffering from nonsyndromic multiple impacted teeth. All four canine and premolar areas were treated with closed eruption exposures in a single surgical session under general anesthesia. Only the left mandibular quadrant is shown here.

ATTACHMENTS

By placing a sophisticated prescription bracket on a tooth, the operator acquires the capability to move a tooth in all directions, right and left, up and down, intruding and extruding, and it can also perform tipping, rotation, and torquing movements. However, these attributes presuppose its placement at a predetermined height on the midbuccal aspect of the crown of the tooth—the sole location for which the exquisite engineering specifications of the prescription bracket were designed. When placed elsewhere, it offers no advantage over a simple eyelet (see Fig. 28-10, *B*) and has many drawbacks.[11] At surgery, achieving the ideal placement of an attachment is not often possible because access to the midbuccal site is restricted by the adjacent incisor root or because considerably more bone and soft tissue would need to be removed to get there, as opposed to exposing the most superficially located bonding site.

The physical dimensions, shape, and protrusion of the angular corners of a precision orthodontic bracket will traumatize the gingival tissues through which it passes from its initial subgingival location, even following an open exposure procedure, during which a degree of rehealing of the tissues over the tooth and the consequent soft tissue impingement always occur.

Even assuming the presence of ideal conditions, to efficiently do more than extrude and tip a tooth that is not engaged in an archwire is not possible (see Fig. 28-11, *E–G*). Extrusion and tipping movements can be more readily achieved with a simple eyelet. This attachment is of more modest and rounded dimensions, more easily placeable in tight circumstances, much kinder to the tissues, and easier to ligate. For all these reasons, an eyelet should be used during or shortly after surgical exposure (see Fig. 28-12) and substituted only by a regular bracket when the tooth reaches the archwire.[46–48]

Ideally, the attachment is bonded in the surgical unit when the exposure has been performed. In preparation for its bonding, a soft stainless steel ligature of 0.014-inch gauge is threaded though the eyelet and tightly twisted to be fashioned into a hook or loop for traction. A pre-made chain/attachment may also be used.

TRACTION MECHANISMS, THEIR RANGE AND DIRECTIONAL POTENTIAL

Direct traction to the intended location of the tooth in the dental arch is the simplest and most frequently used mechanism and is most suitable when the tooth is displaced but has a direct and unobstructed path to that site. Elastic thread is directly tied between the attachment on the affected tooth and the heavy archwire that will have been placed at the end of the alignment and leveling stage. In this way, the tooth is moved in the desired direction and all the other teeth that are ligated into the archwire act as a composite anchor, while the rigidity of the archwire resists bowing adjacent to the ligated area. A common alternative in these cases is to use a nickel-titanium archwire, fully tied in to the brackets of all the teeth including the impacted tooth. However, this should only be used when the impacted tooth is very mildly displaced. Because of the flexibility of the wire, the brunt of the reactive force is borne by the two teeth that are adjacent to the impacted tooth, and these will move toward the impaction. Thus in the case of a palatal canine, these adjacent teeth would quickly move into a crossbite relation with their antagonists, and a flattening of the arch form would result.

Displaced canines that are more mesially or more palatally displaced are also considerably higher than the occlusal plane and thus must be brought occlusally before or at the same time as they are moved to their places; otherwise, they will become buried in the vertical alveolar process.

In the scenario discussed earlier, in which the root of a lateral incisor blocks the direct path for a palatal canine, evasive action must be taken. This is best performed by first drawing the tooth down from its initial location and erupting it in the palatal area to circumvent the incisor root. From there, a direct and unimpeded path to the archwire will be acquired.

To achieve this, a ballista-type auxiliary spring may be used, which has two versions. In addition to the heavy stabilizing arch, a second full arch of 0.016-inch steel wire incorporating a vertical loop with a terminal helix is tied into all the brackets piggyback style[38] (see Fig. 28-11, *F*). Alternatively, a unilateral sectional rectangular cross-section wire may be used, which is slotted into an auxiliary molar tube. The sectional wire mesially extends with a 90-degree vertically downward bend that is adjacent to the prepared space in the arch.[58] A small helix is incorporated into the end of this wire. In both cases, the auxiliary wire is tied into its place, with the vertical portion passively hanging down (see Fig. 28-11, *D, E*). This step is best performed while the surgeon is waiting for the local anesthetic injections to take effect and before the surgical procedure has begun.

After bonding of the eyelet attachment in a closed eruption procedure, the surgical flap is fully replaced and resutured with the twisted 0.014-inch steel ligature puncturing it at a point immediately overlying the recovered tooth. The vertical loop of the auxiliary ballista-type auxiliary spring is palatally turned upward and ensnared into the steel ligature that will be bent into a hook around it. The vertical loop is drawn up under finger pressure to lie against the palatal mucosa (see Fig. 28-11, *F*). The round wire loop or mesial portion of the rectangular auxiliary thus applies a measurable extrusive force on the tooth with a long range of action. In an open procedure, the attachment may be bonded several days or weeks later, but preferably, bonding is done at the time of surgery by following the same protocol.

FAILURE—PATIENT-DEPENDENT FACTORS

Intrinsic patient factors can contribute to the failure in the resolution of an impacted tooth. These include an abnormal morphologic structure of the crown of a tooth or an inappropriate configuration of its roots. Abnormalities of the tooth itself, such as ankylosis or ICRR,[26] will cause the tooth to resist all attempts at its movement. With advancing age, the dental follicle surrounding the crown of an impacted tooth may break down, bringing about direct contact with the alveolar bone. This, in the long term, may lead to a replacement resorption of the crown enamel and no response to orthodontic traction (Fig. 28-13).

Resorption of the root of an adjacent tooth has been found to occur in two-thirds of the patients with impacted canines,[23] and female patients with normally sized lateral incisors are more susceptible.[59] Although resorption of the root is very minor in its extent in most cases, it is progressive and may threaten the longevity of the affected tooth (see Fig. 28-10, *A*). As a general rule, distancing the canine from the immediate area will bring about a cessation of the resorption.[36] In these cases, the sequence of treatment should be changed to moving the canine away from the resorbing area in question, even before space has been made.

Needless to add, patient compliance in relation to the attendance for treatment, oral hygiene, and a preparedness to cooperate in the placement of prescribed supplementary aids, such as headgears and rubber bands, are important factors, and the absence of patient compliance will undermine the chances of success.

FAILURE—ORTHODONTIST-DEPENDENT FACTORS

Regardless of a potentially favorable location of the impacted tooth, insufficient space in the arch will cause the treatment to flounder; an appreciation of the fact that the space created must extend all the way up to the apical area of the neighboring teeth

FIGURE 28-13 Periapical view of the anterior maxilla of a 65-year-old female patient shows the indistinct presence of two impacted canines. Most of the follicles have disappeared, and the margins are blurry, attributable to replacement resorption of the enamel and dentin of the crown.

is essential. Occasionally, the palatal root of a premolar may be inadequately uprighted after space opening or it may possess a mesial curvature, causing it to obstruct the path of eruption of a palatal canine (Fig. 28-14).

It has been reported elsewhere that "Diagnosis of the location of the tooth and its immediate relationship with the roots of the adjacent teeth is generally treated with cavalier and often negligent simplicity, even though modern technology has provided the tools to achieve this with great accuracy in all 3 dimensions."[35] With an inaccurate positional diagnosis, it follows that traction will be applied in the wrong direction. It follows, too, that without the benefits of CBCT imaging and its proven superior diagnostic capabilities, the diagnosis of root resorption of adjacent teeth will be frequently missed.

Inefficient traction mechanisms can lead to failure, such as frequently tying elastic thread over a short distance. Elasticity of stretched elastic thread fatigues very rapidly, the knot does not hold well, and the aberrant tooth fails to move. The rebound effect of a deflected overlay nickel-titanium wire depends, for its efficiency, on being able to slide freely in adjacent brackets, which is not often easy to guarantee. Simple custom-made deimpaction springs need to be designed to deliver low-force values over a broad range of movement. These springs can be made to fit the particular circumstance at hand, and this surely is the *forte* of the experienced orthodontist.

In the more extreme cases of ectopy and in situations where significant root movement is needed, a lack of appreciation of the considerable anchorage requirements of the case and the need to exploit all available means of enhancing them will inevitably lead to inefficient mechanotherapy and unnecessarily longer treatment, if not abject failure.[35]

FAILURE—SURGEON-DEPENDENT FACTORS

For the surgeon, the orientation of the long axis of an impacted tooth is immaterial. The surgeon needs only to know where the crown of the tooth lies, and this positional information can usually be provided by plain periapical and panoramic views alone. Nevertheless, the CBCT records should be made available to

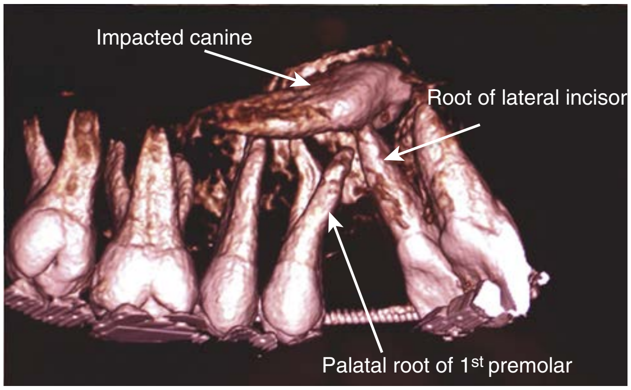

FIGURE 28-14 The three-dimensional cone-beam computed tomography (CBCT) lingual view reveals the left side of the maxilla in a patient with a horizontally impacted canine high above the roots of the adjacent teeth. Although space has been created at the occlusal level, note the mesial curvature of the palatal root of the premolar. The distance between the premolar and lateral incisor roots does not permit the passage of the canine.

the surgeon to prevent a *rummaging* exposure, in which insufficient positional information is available and the surgical field is opened up too widely with excessive amounts of bone removed in the quest for the buried tooth. This excessive removal may cause injury to the impacted tooth itself, to an adjacent tooth, and to the soft tissues. Mistaken positional diagnosis also has serious consequences in the medicolegal context. In the more extreme cases, law reports are replete with cases in which exposure of a labially impacted tooth has been attempted from the palatal side. Other frequent mistakes include radical elimination of tissue beyond the CEJ, exposing the root surface and damaging the cementum layer, which potentially raises the likelihood that ankylosis or invasive root resorption will occur.

In many cases and knowing that surgery will be necessary, the patient is incorrectly referred first to the surgeon, who is tempted to expose the impacted tooth without further discussion. Surgery without prior strategic orthodontic planning in these cases might occasionally be helpful; for the most part, however, it will have been a futile exercise if directional traction is needed in the resolution of the impaction and eventual alignment of the tooth.

Many orthodontists are happy for the surgeon to bond an attachment to the tooth at the time of surgery, but it should be remembered that, for the surgeon, attachment bonding is not a routine procedure; the chances of failure—and therefore a repeated surgical procedure—are higher. The surgeon is not familiar with the alternative directions of traction and will not know where to place the attachment or where to trail the gold chain or steel ligature from the attachment to the exterior. Many surgical procedures are sadly repeated, during which the attachment is already in place but simply redirecting these connectors is necessary.

The interrelations between the orthodontist and surgeon regarding the treatment of impacted teeth are particularly prone to mistakes and misunderstandings in surgical decisions. Each of these could sound the death knell to a treatment plan that may have appeared *a priori* to have been straightforward, with a potentially good prognosis.

Accordingly, the conclusion to be drawn from this is that the orthodontist has a major interest in being present at the surgeon's side during the exposure procedure. In addition to bonding the attachment while the surgeon maintains ideal hemostasis and dry conditions for acid-etch bonding, the orthodontist often needs a specific type of exposure—open or closed, a specific direction of traction, and the enormous benefit of immediate application of the traction mechanism. Short of the orthodontist attending the surgery, a mutual understanding of the orthodontic requirements and excellent communication are needed before and after the surgical procedures are completed. The surgeon may see the patient once more on a follow-up visit to remove sutures. However, the orthodontist will regularly see the patient over a long period to align the affected tooth as an integral part of the overall orthodontic treatment and in what is generally a demanding biomechanical venture. The fact that the most critical part of the procedure is well accomplished will simplify and streamline the treatment and offer an optimal prognosis.

Management of Dental Luxation and Avulsion Injuries in the Permanent Dentition

Patrick Turley

OUTLINE

Trauma to the dentoalveolar region is a common occurrence in children, and estimates suggest that 25% of all children will suffer dental trauma during their developmental years, with more than 60% of these reported to be luxation-type injuries.[1–3] Because of this high frequency, dentists and dental specialists who treat children should be familiar with the principles of managing dental trauma. The management of traumatic injuries has not traditionally been an area of practice for the orthodontist; consequently, he or she is often not well equipped to handle the injury. The frequency of orthodontic appointments, however, results in the orthodontist developing a close relationship with the patient and family, and since the injury often damages the orthodontic appliance, the orthodontist is often contacted first. The purpose of this chapter is to familiarize the orthodontist with the management of dental luxation and avulsion injuries, which by their nature (malposition) and treatment requirements (orthodontic splinting or alignment) can fall within the purview of the practicing orthodontist.

TISSUE RESPONSE TO TRAUMA

The proper management of luxation and avulsion injuries requires an understanding of the immediate and short-term response to the involved tissues: the periodontal ligament (PDL), pulp, and alveolar bone.

ROOT RESORPTION

Trauma to the tooth often results in damage to the PDL. Trauma to the PDL, not necessarily the pulp, usually results in teeth unable to survive a traumatic injury. The amount of damage depends on the severity and type of injury and may include tearing, severing, or compression of the ligament. Root resorption is the common response to PDL injury; generally, the three types are surface, inflammatory, and replacement resorption.[4] *Surface resorption* is the least invasive, although it may involve both cementum and dentin; it is self-limiting and shows spontaneous repair. Surface resorption radiographically appears as small excavations on the root surface adjacent to a PDL space of normal width. *Inflammatory resorption* results from infected necrotic pulp tissue, which then affects the traumatized PDL.[5] This type can quickly destroy root structure, and without endodontic treatment, the loss of the tooth usually occurs within 2 to 10 months. Characterized by bowl-shaped excavations in the root surface with an adjacent radiolucency in the bone, inflammatory resorption can be radiographically seen as early as 3 to 4 weeks after an avulsion injury. *Replacement resorption* usually follows severe injuries in which the PDL has been removed or severely damaged.[6] Ankylosis accompanies replacement resorption, and the slow process of continuous replacement of root structure by bone results in the eventual loss of the tooth over a period of years. Radiographically, the root surface is highly irregular, with the normal lamina dura absent and the tooth structure obviously diminishing. Progressive root resorption (inflammatory and replacement resorption) occurs most frequently after intrusion or avulsion injuries.[1] Removing the pulp tissue and placing calcium hydroxide in the canal is the treatment for inflammatory resorption.[1,7,8] The same treatment regimen is also used for replacement resorption, although this type of resorption is more difficult to control.[7,9]

PULPAL RESPONSE

Pulp Necrosis

Pulp response and survival depend on the type (severity) of the injury and the stage of root end development.[10] The diameter of the apical foramen is the most important factor in pulp survival.[11,12] Teeth with open apices show a higher survival rate, especially with the less severe injuries such as concussion, luxation, lateral displacement, and extrusion. Pulps of intruded and avulsed teeth with closed root apices rarely survive. To prevent the necrotic pulp from potentiating the process of progressive root resorption, endodontic treatment with calcium hydroxide is recommended within a few weeks after the injury.[1,9,13] Later, when no signs of root resorption are evident, calcium hydroxide is replaced with traditional endodontic therapy. In the case of a nonvital pulp with incomplete root formation, root-end induction procedures must be accomplished first.[14]

Pulp Canal Obliteration

In a significant number of cases (15% to 22%), the pulp may undergo a slow process of obliteration. Calcification usually starts coronally and may completely obliterate the pulp chamber.[11,15,16] Pulp canal obliteration more frequently occurs in teeth with open apices that have experienced a severe luxation injury and seems to be a sequel to revascularization and/or innervation of a damaged pulp. Since only a minority of these teeth will develop future pupal necrosis, endodontic treatment is not usually recommended.[16,17] However, because of the difficulty of performing endodontic treatment after pupal obliteration has occurred, some endodontists recommend prophylactic treatment, once root formation is complete and pupal obliteration is beginning to be apparent.

Internal resorption is an infrequent finding (2% to 4%) with luxated permanent teeth.[18]

ALVEOLAR FRACTURE

Luxation injuries are often associated with a fracture of alveolar bone. Fracture lines may be located at any level from the marginal bone to the root apex. In addition to regular periapical views, radiographs with varying horizontal angles, an occlusal view and/or a panoramic radiograph, or focused cone-beam computed tomography (CBCT) can be helpful in determining the course and position of the fracture lines.[19] In these cases, both the tooth and the attached alveolus need to be reduced and stabilized. The type of stabilization required depends on the stability of the segment after repositioning. Large, mobile segments may require more stable fixation for a period of 4 weeks, and smaller segments that reposition well may be treated with lighter stabilization for a shorter period. Clinical examination may reveal granulation tissue in the gingival crevice or the secretion of pus from the pocket.[1] Loss of marginal bone frequently occurs with intrusion injuries and other injuries associated with alveolar fracture.[16]

MANAGEMENT OF TRAUMA AND IMMEDIATE SEQUELAE

With an understanding of the common tissue response that follows a traumatic injury, the practitioner can better manage the different injuries that may occur. The management of traumatic injuries to be discussed is based on Guidelines published by the International Association of Dental Traumatology (IADT).[19] Luxation injuries are classified as concussion, subluxation, extrusive luxation, lateral luxation, and intrusive luxation. Avulsion is classified separately. The most noted change over the past 30 years in the treatment of these injuries has been the change to short-term and flexible, rather than rigid, splints to stabilize luxated, avulsed, and root-fractured teeth.[20–22] An extension of these methods has been the use of techniques to orthodontically rather than manually reposition teeth.

The PDL is anatomically classified as a fibrous joint. Similar to other joints in the body, rigid and long-term stabilization can result in hard tissue healing or ankylosis.[23] The routine use of physical therapy after an orthopedic joint surgery is because functional stimuli depress osteogenesis but enhance fibrous tissue healing.[24] Hence luxation and avulsion injuries are best stabilized by flexible means for only 7 to 10 days.[9,25,26] If the displaced teeth can be readily repositioned by hand, then the wire may be directly bonded to the teeth. If some further repositioning is required, then orthodontic brackets can be placed to include stable teeth mesial and distal to the injured teeth. In the early mixed dentition with only central incisors erupted, primary canines and/or primary molars may be bonded. A light braided or nickel-titanium alloy wire is then ligated in place.

Concussion and Subluxation

Concussion is an injury to the tooth and supporting structures without abnormal loosening or displacement, but it is tender to the touch or to tapping. The frequency of pulp necrosis and canal obliteration is low (2%), with necrosis occurring in teeth with completed root formation.[10] Subluxation is a similar injury except for the presence of increased mobility. Slight bleeding from the gingival crevice may be seen, which indicates damage to the periodontal tissues. Usually no immediate treatment is required unless severe mobility and/or multiple tooth injuries exist. In this situation, a flexible splint for patient comfort can be placed for up to 2 weeks. To relieve occlusal interferences, glass ionomer cement can be applied to the occlusal surface of the molars to open the bite temporarily. A soft diet for 2 weeks is recommended. The frequency of pulp necrosis and pulp canal obliteration ranges from 26% to 47%, always occurring in teeth with completed root formation.[10] Progressive root resorption is very infrequent (4%).[16]

Lateral Displacement

Lateral displacement occurs when the tooth is displaced in a direction other than axially. Because of the lateral support of adjacent teeth, this direction is often labial or palatal and is accompanied by comminution or fracture of the alveolar socket.[1] If the tooth is labially displaced, then it should be repositioned along with any attached alveolar bone. Lacerated gingiva should be adapted to the neck of the tooth and sutured. Light wire orthodontic stabilization is recommended for 4 weeks. When the crown is palatally displaced, the root apex is often displaced through the vestibular labial plate, locking it in this position.[19] Repositioning requires labial digital pressure over the apical area and on the lingual side of the crown to unlock the apex. Forceps may be needed to disengage the tooth from its bony lock. The tooth is gently repositioned into its original location. This procedure may require infraorbital regional block anesthesia on the appropriate side of the maxilla. When treatment for lateral displacement is delayed (>24 hours), the tooth is often consolidated in the new position, making reduction difficult or even contraindicated. In these situations, orthodontic appliances can be used to reposition the tooth gradually (Fig. 29-1). Periodontal and pulpal status should be radiographically monitored. Completed root formation is the major factor associated with the development of pulp necrosis.[10,11] Pulp survival is 93% with incomplete root formation, as opposed to 23% with complete root formation.[10] Progressive root resorption is uncommon with this injury.

Extrusive Luxation

An extrusion injury is characterized by a partial displacement of the tooth out of the alveolar socket. The tooth appears elongated and is excessively mobile. Treatment involves gently repositioning the tooth and stabilizing it with a light orthodontic wire for 2 weeks.

FIGURE 29-1 A, B, Lateral luxation in an 8-year-old girl is seen the day after the accident. C, Radiograph shows incomplete root formation of traumatized central incisors. D, A removable orthodontic appliance was used to open the bite and procline the incisors. E, Tooth position is improving 4 months after the trauma. F, Tooth position is visualized 7 months after the trauma. G, Root formation is continuing and pulp chamber shows narrowing 8 months after the injury. H, Radiograph 2 years after the trauma shows pulp canal obliteration.

Similar to lateral displacement, if the injury is treated many hours after the injury, then orthodontic brackets and a light archwire can be used to intrude the tooth. Pulp survival rates are 90% if the tooth has a wide open apex; in cases with completed root formation, pulp survival is less than 50%.[10] Progressive root resorption is significantly lower (7%) than with avulsion or intrusion injuries.[6,16] Pulp canal obliteration occurs in 24% of cases and is more frequent in teeth with incomplete root formation. The patient should be endodontically evaluated. If several signs and symptoms suggest a necrotic pulp, then endodontic treatment is indicated.

Intrusive Luxation

The least common displacement injury in the permanent dentition is intrusive luxation, a displacement of the tooth into the alveolar bone. These injuries are associated with a comminution or fracture of the alveolar bone. Pupal necrosis, progressive root resorption, and marginal bone loss are common sequelae to severe intrusion.[10,15,16] IADT guidelines recommend allowing *mild* intrusions to erupt without intervention.[19] If no movement occurs after 2 to 4 weeks, reposition orthodontically (or surgically) before ankylosis develops. If the tooth is intruded more than 7 mm, surgical or orthodontic repositioning is recommended. Manual/surgical repositioning has been shown to increase the frequency of complications; hence we prefer orthodontic extrusion.[10,16] In addition, our research has shown ankylosis may develop as early as 7 to 10 days following the injury; hence we prefer to initiate orthodontics within the first week following the injury for anything but a very mild intrusive injury.[27] A tooth that is tightly wedged into the bone with no mobility will not move under normal orthodontic forces and may predispose to ankylosis. These teeth should be luxated to produce some mobility before orthodontic activation (Fig. 29-2).[28] Severely displaced teeth embedded deep into bone may also need to be partially repositioned to allow the placement of orthodontic appliances and access for endodontic treatment. Because pulp survival with closed root apices is uncommon, pulp extirpation and calcium hydroxide fill are indicated within 14 days of the injury.[13,19] Teeth with immature root formation also should be observed for pathologic abnormalities since most (60%) of these pulps will not survive.[10]

Avulsion

The avulsion injury is seen in 0.5% to 3% of all dental injuries and is characterized by a complete displacement of the tooth out of the alveolar socket.[1,2] This injury is accompanied by comminution or fracture of the alveolar socket. Critical factors to the long-term survival of these teeth are the physiologic status of the PDL cells,[19] extraoral period,[6,8,29] stage of root development,[4,30] storage medium,[31,32] and method of stabilization.[23–26,33] Approximately 90% of the teeth reimplanted within 30 minutes showed no root resorption.[4] The best storage medium is in the patient's mouth; hence, parents or guardians should be instructed over the telephone how to reposition the tooth back into the socket. If the tooth cannot be repositioned, then it can be placed in the vestibule or under the child's tongue. If this is not possible, the tooth should be transported in a proper storage medium. Hanks balanced salt solution (HBSS), a tissue culture medium, is commercially available to dentists (www.Save-A-Tooth.com) and has been shown to improve the viability of remaining PDL cells.[34] Milk may be as good a storage medium as any of the commercially prepared solutions for up to 6 hours.[31] The tooth should not be stored in water.

The type of treatment for an avulsed tooth ultimately depends on two factors: (1) the maturity of the root (open or closed apex) and (2) the viability of the PDL cells.[19] The condition of the cells depends on the storage medium and the time out of the mouth. The clinician should classify the tooth into one of three groups before instituting treatment.

1. PDL cells are most likely viable as a result of immediate or short-term reposition.
2. PDL cells may be viable but compromised as a result of dry time approximately 60 minutes or less and kept in a storage medium.
3. PDL cells are nonviable as a result of oral dry time longer than 60 minutes.

TREATMENT OF AVULSED PERMANENT TEETH WITH CLOSED APEX

A tooth with a closed apex that arrives at the office having been replanted after a short time has an excellent chance of survival. The orthodontist should clinically and radiographically verify the position of the tooth. After cleaning the area with water spray, saline, or chlorhexidine, a flexible splint is applied and worn for up to 2 weeks. Endodontic treatment should begin 7 to 10 days after replantation but before removing the splint.

The tooth that arrives at the office in a physiologic storage medium or after a dry time of less than 60 minutes should be replanted by the orthodontist. The root surface and apical foramen are cleaned with saline, and the tooth is soaked in saline while preparing to replant. A local anesthesia is administered, and the socket is irrigated with saline. The alveolar socket is examined, and any fractured or displaced socket wall is repositioned. The tooth is slowly replanted with slight digital pressure, and the normal position of the tooth is clinically and radiographically verified. A flexible splint is applied, and endodontic treatment should begin 7 to 10 days after the replantation but before removing the splint.

If the closed apex tooth has dry time longer than 60 minutes, then the PDL cells are necrotic; hence, the eventual outcome is ankylosis and root resorption and the eventual loss of the tooth. Before replantation, the orthodontist should carefully remove attached nonviable soft tissue with gauze. Endodontic treatment can be performed before or after replantation. Replantation is performed as previously described, and a flexible splint is applied and worn for 4 weeks. To slow down osseous replacement of the tooth, some have suggested treating the root surface with 2% sodium fluoride for 20 minutes before replantation.

TREATMENT OF AVULSED PERMANENT TEETH WITH OPEN APEX

Teeth immediately replanted with open apices are treated as previously described but are not endodontically treated since the pulp may revascularize. If that does not occur, then endodontic treatment will be indicated.

Teeth with open apices in a proper storage medium or with a dry time less than 60 minutes should be replanted as previously described. Before replantation, the topical application of antibiotics (minocycline or doxycycline) has been shown to enhance the chances for revascularization, 1 mg per 20 mL of saline for a 5-minute soak.[35,36] The pulp space may revascularize; however, infection-related root resorption is very rapid in immature teeth. Therefore close endodontic monitoring is recommended.

Teeth with open apices and a dry time longer than 60 minutes have a poor long-term prognosis. They should be managed similarly to teeth with closed apices.

FIGURE 29-2 A, Severe intrusive luxation is revealed in a 23-year-old man. The tooth has no mobility. B, Radiograph of intruded tooth shows that no lamina dura is visible, which is attributable to tearing and crushing of periodontal ligament. C, Tooth is luxated and slightly extruded to provide a periodontal ligament space, some mobility, and access for orthodontic attachments and endodontic intervention with calcium hydroxide. D, Orthodontic brackets and light arch wire are placed the same day. E, Alignment of tooth is visualized 10 weeks after the trauma. F, Radiograph reveals alignment of the tooth 10 weeks after the trauma. Calcium hydroxide root canal was accomplished 2 weeks after the injury. No progressive root resorption or periapical pathologic condition is noted. G, Image reveals alignment after treatment. H, Radiograph 9 months after the trauma shows definitive root canal treatment. Tooth #9 subsequently became nonvital and was treated.

Tetanus prophylaxis should be administered if the child's immunization status is compromised or if the tooth or wound is dirty. Antibiotic coverage also should be prescribed in the first week—penicillin V or amoxicillin in an appropriate dose for age and weight. Avulsion injuries with closed apices rarely show pupal revascularization. As a result, with an extended extraoral period or a closed apex, the pulp should be extirpated after waiting 7 to 10 days and before splint removal. Calcium hydroxide should be placed in the canal to help prevent root resorption.[37] After 1 month, calcium hydroxide is replaced by a definitive root canal filling. Placing calcium hydroxide too soon, such as immediately after reimplantation, will promote inflammation that can lead to PDL damage.[38] Lengheden and colleagues[39,40] have suggested that long-term calcium hydroxide root canal fill may also have deleterious effects.

PREVENTION

Numerous studies have documented the increased incidence of traumatic dental injuries with Class II malocclusions.[41–43] Preventive measures should therefore include early correction of cases with significant overjet and lip incompetence. Evidence suggests that providing early orthodontic treatment for children with prominent upper front teeth is more effective in reducing the incidence of incisal trauma than providing one course of treatment when the child is in early adolescence.[44] Athletic mouth guards should be used for contact sports and can be fabricated to accommodate fixed orthodontic appliances, tooth movement, and exfoliation-eruption processes in the mixed dentition.[45–47] Stock mouth guards, available at sporting good stores, must be held in place with constant occlusal pressure, because of their poor fit. Boil-and-bite guards may provide a better fit, but some evidence suggests that neither type reduces the incidence of trauma and may actually give the athlete a false sense of security. Custom-fitted vacuum-formed mouth guards, or pressure laminating, which provides the best fit and shape stability, is the mouth guard of choice and can be fabricated in the office with proper equipment or by numerous commercial laboratories.

Traumatic injuries should always be managed with the cause of the injury in mind. Estimates suggest that 1 out of 10 children are physically abused, of whom 75% are reported to have injuries of the head and neck area.[48] Numerous studies note the low reporting frequency of dentists,[49–53] and preliminary data suggest orthodontists rarely report abuse.[54] Trauma prevention requires orthodontists to be knowledgeable of the signs of abuse and the obligation and methods for reporting. Avulsed or discolored teeth, bruises on the cheek or around the neck, burns in the shape of hot objects, and bite marks are often associated with child abuse. Children displaying psychosomatic complaints and seductive behavior or those with unusual knowledge of sexual behavior may have suffered sexual abuse. A strong correlation exists between dental neglect and physical neglect. Mandates in all 50 states require that dental professionals be aware of and report instances of child abuse and neglect to the proper state child protection authorities. State laws also protect the dental professional from civil retribution.[55,56]

Iatrogenic Effects of Orthodontic Treatment

Philip Edward Benson, Norah Lisa Flannigan, Glenn Sameshima, and M. Ali Darendeliler

OUTLINE

PREVENTION AND MANAGEMENT OF DEMINERALIZED WHITE LESIONS*

Despite many advances in orthodontic techniques, the occurrence of demineralized white lesions (DWLs) during treatment remains a serious side effect, particularly when using fixed appliances (Fig. 30-1). Early enamel demineralization clinically exhibits as *white spot lesions*, defined by Fejerskov and colleagues as "the first sign of a caries lesion on enamel that can be detected with the naked eye."[1] The *milky white* appearance is caused by an increased scattering of light that is attributable to the loss of crystal structure and is exaggerated when the enamel is dried.[2]

The risk of demineralization is greatest during fixed orthodontic treatment as a result of plaque collection and retention around the irregular surfaces of the attachments.[3] These stagnation areas also limit the self-cleansing mechanism of salivary flow,[4] resulting in the accumulation of cariogenic bacterial species.[5] After 14 days of completely undisturbed plaque, changes in the enamel are visible with air drying. After 3 to 4 weeks, the outermost surface exhibits further porosity, and clinical changes can be seen without air drying.[1] The rate of progression of mineral loss around fixed orthodontic appliances can be faster than the traditional caries process, with demineralization being clinically apparent within 6 months of starting treatment.[6]

Prevalence of Demineralized White Lesions

The reported proportion of patients with DWLs after fixed orthodontic treatment widely varies in the literature between 2% and 96%.[7–9] This variation can be attributed to differences in the standardization of clinical examinations, as well as the use of various detection tools, with different sensitivities and specificities in diagnosing demineralization.[10] Al Maaitah and colleagues[11] described

* Philip Edward Benson and Norah Lisa Flannigan.

FIGURE 30-1 The typical appearance of demineralized white lesions is revealed on the day a fixed appliance is removed.

a prevalence of 71.7% DWLs in 230 participants after orthodontic treatment. This finding was determined using a technique called *quantitative light-induced fluorescence* (QLF) (Inspektor Research Systems, Bussum, Netherlands), which has a high sensitivity for detecting DWLs. Julien and colleagues reported an incidence of 23.4% DWLs in 885 participants using digital photography.[12]

Some differences can be found in the literature about which teeth are most commonly affected with DWLs during orthodontic treatment. Several studies conclude that maxillary incisors are particularly susceptible,[7,13] whereas other studies found that canines and molars are more frequently affected.[3] Evidence suggests that patients with DWLs, particularly on the anterior teeth, and their parents, perceive the aesthetics to be poorer after treatment.[14] Ogaard has shown that a difference in prevalence of DWLs between those who have and those who have not had orthodontic treatment is still present 5 years after the appliances have been removed.[9]

Detection and Measurement of Demineralized White Lesions

Transverse Microradiography

The generally accepted gold standard method of measuring demineralization and remineralization is transverse microradiography (TMR). This technique is destructive, requiring cuts to be made to the enamel or dentine and microsamples to be removed for analysis. The basis of TMR is the measurement of x-ray absorption by a tooth section, compared with absorption by a simultaneously exposed standard.[15] In this technique, planoparallel sections (approximating 80 μm for enamel) are cut from the sample to be investigated. The sections, which are cut perpendicular to the anatomic tooth surface, are placed on high-resolution photographic film, along with an aluminum calibration stepwedge and irradiated with monochromatic x-ray beams.[16] Absorption of the x-ray beams by the tooth sample and stepwedge is directly reflected in the optical density of the developed film (microradiograph).

Analysis of the mineral content and distribution is calculated by means of Angmar's formula[17] from the optical density of the tooth sample and stepwedge images. Densitometry-based systems and, more recently, image analysis systems comprising a charge-coupled device (CCD) video camera and dedicated software are used for the evaluation of microradiographic optical densities and for the generation of mineral content profiles.[18] From the analysis, three primary parameters are obtained: mineral loss (ΔZ units Vol%.μm), lesion depth (Ld) (μm units), and lesion width (Lw) (μm units). ΔZ is the integrated difference between the microradiograph of the sample with mineral loss and that of the sound sample, whereas Ld and Lw values are determined from mineral distribution (Fig. 30-2).[16]

A major disadvantage of the TMR process is that either the tooth must be removed from the mouth and destroyed or a small enamel sample attached to the appliance (in situ method, Fig. 30-3) must be removed. If the tooth to be examined has to be extracted as part of an orthodontic treatment plan, then only the first few weeks of orthodontic treatment can be studied. Alternatively, an in situ enamel sample might not be truly representative of the environment around a bracket.[19]

This limitation of TMR, as well as the need for early detection of DWLs to prevent irreversible damage to the enamel, has made optical methods of demineralization analysis increasingly popular. Available optical methods include QLF, which allows the detection of demineralization before the lesions are clinically visible to a trained examiner (subclinical).[20]

Quantitative Light-Induced Fluorescence

QLF is a nondestructive diagnostic technique that uses visible light for the early detection of demineralization in enamel (Fig. 30-4). The principle behind the technique is that enamel will undergo autofluorescence under certain conditions. Demineralized enamel will fluoresce less, and this loss of fluorescence can be detected, quantified, and longitudinally monitored using QLF (Fig. 30-5). The teeth under investigation are illuminated from a lamp with a peak intensity of 370 nanometers (nm). A yellow high-pass filter (520 nm) is placed in front of a CCD microcamera, which captures the tooth image.[21] A live image of the tooth is displayed on a personal computer (PC) screen and can be stored for analysis.[22,23] The analysis software detects the darker area of the image and fluorescence radiance of sound enamel at the lesion site via a reconstruction algorithm.[21] QLF has been validated against TMR in permanent teeth and has shown excellent agreement.[24]

Quantitative Light-Induced Fluorescence–Digital

The quantitative light-induced fluorescence–digital (QLF-D) Biluminator (Inspektor Research Systems, Bussum, Netherlands) is a novel device based on QLF technology (Fig. 30-6). It takes two successive images, a white light (WL) image, which is a conventional digital photograph, and a QLF image. As the two images are almost simultaneously taken, it ensures consistency with regard to magnification and allows for comparisons between the images. Using this system, demineralization can be readily identified and assessed (Fig. 30-7). Plaque is barely visible in a WL image; however, with the change in the filter system, the emitted red fluorescence makes plaque visible (Fig. 30-8). The current cost of the complete QLF-D system is approximately 9000 British pounds (14,000 U.S. dollars). Clinicians have implemented the use of QLF-D onto the orthodontic clinic for routine plaque screening and also for monitoring initial subclinical lesions. Early detection allows the clinician to apply preventive measures before DWLs are clinically visible and avoid the development of unsightly lesions during the course of the orthodontic treatment.

Prevention of Demineralized White Lesions

In 1999, Featherstone proposed a model to explain the caries process called The Caries Balance concept (Fig. 30-9).[25] The model has been amended several times, but, essentially, it consists of three factors that lead to the loss of enamel, or demineralization: (1) fermentable carbohydrate, (2) acidogenic

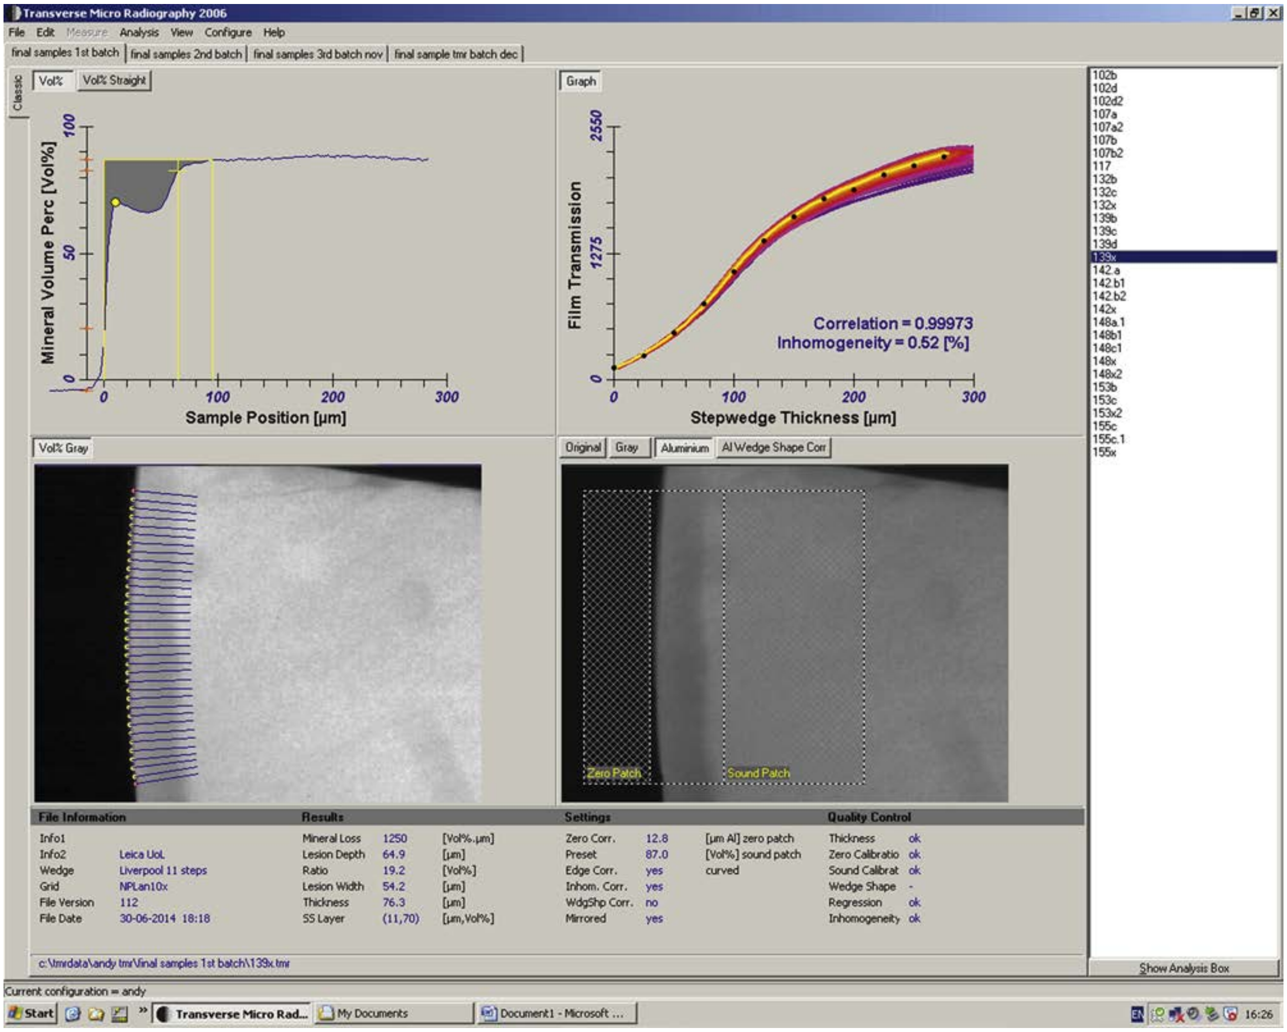

FIGURE 30-2 Output from dedicated transverse microradiography (TMR) software (Inspektor Research Systems, Bussum, Netherlands) illustrates subsurface mineral loss. (Courtesy of Inspektor Research Systems, Bussum, Netherlands.)

FIGURE 30-3 This example of an in situ enamel sample is used with a fixed appliance. (Reproduced with permission from Doherty UB, Benson PE, Higham SM. Fluoride-releasing elastomeric ligatures assessed with the in situ caries model. *Eur J Orthod* 2002;24:371–378.)

bacteria, and (3) reduced salivary flow; and three factors that lead to the uptake of mineral into enamel, or remineralization: (1) fluoride, (2) antimicrobial agents, and (3) salivary flow.[26] The Caries Balance model can be used to develop ways of preventing DWLs in orthodontic patients through:

- Preventing the loss of mineral from enamel (demineralization)
- Promoting the uptake of mineral into enamel (remineralization)

Preventing the Loss of Mineral from Enamel (Demineralization)

There are three ways of preventing demineralization:

1. Reducing the amount of acidogenic plaque through mechanical and/or chemical methods
2. Reducing the frequent consumption of sugar (diet advice)
3. Sealing the enamel

Reducing the amount of acidogenic plaque. Studies have suggested that inadequate oral hygiene before the placement of appliances is one of the most predictable risk factors for the development of DWLs during orthodontic treatment[11,27,28]; therefore clinicians must be satisfied that patients exhibit an acceptable level of oral health before placing any appliances.

FIGURE 30-4 Quantitative light-induced fluorescence (QLF) (Inspektor Research Systems, Bussum, Netherlands) hardware and camera handpiece (*inset*). (Courtesy of Inspektor Research Systems, Bussum, Netherlands.)

Reducing the levels of acidogenic plaque can be achieved through mechanical and/or chemical methods.

Mechanical. Plaque removal may be improved either through the use of more effective devices or by helping patients more efficiently use their devices (toothbrushing advice). Evidence suggests that electric toothbrushes are better than manual toothbrushes for removing plaque in people with[29,30] and without orthodontic appliances.[31] Little evidence supports the effectiveness of interdental cleaning, such as flossing, in orthodontic[32] or nonorthodontic populations.[33]

Some evidence suggests that intensive motivation techniques[34,35] or the use of reminders, such as weekly text messages to parents,[36] improve gingival health in the short term; however, more long-term studies over the full length of orthodontic treatment are required.[37] In addition, it has yet to be shown that all the effort put into encouraging patients to clean their appliances leads to a lower incidence of DWLs, but new lesions might be less severe.[38]

Chemical. Regular use of a chlorhexidine mouth rinse[39,40] or toothpaste[41] can reduce plaque and gingivitis in young people undergoing orthodontic treatment without the adverse effect of increased tooth staining. Concentrated chlorhexidine varnish can also reduce the numbers of *Streptococcus mutans* for up to 4 weeks in the mouths of young people with high initial levels wearing a fixed appliance.[42] Little evidence suggests that this reduction in the number or change in the type of bacteria in plaque leads to fewer new DWLs in orthodontic patients. One study found that the addition of chlorhexidine to a fluoride varnish regularly applied through orthodontic treatment did not provide additional protection from DWLs[43]; another study showed that the use of a triclosan/copolymer toothpaste in a nonorthodontic population leads to a small reduction in caries.[44] No reliable evidence suggests that adding an antimicrobial agent to a bonding material will prevent demineralization.[45]

Reducing the frequent consumption of sugar (diet advice). In addition to lowering the number of acidogenic bacteria,

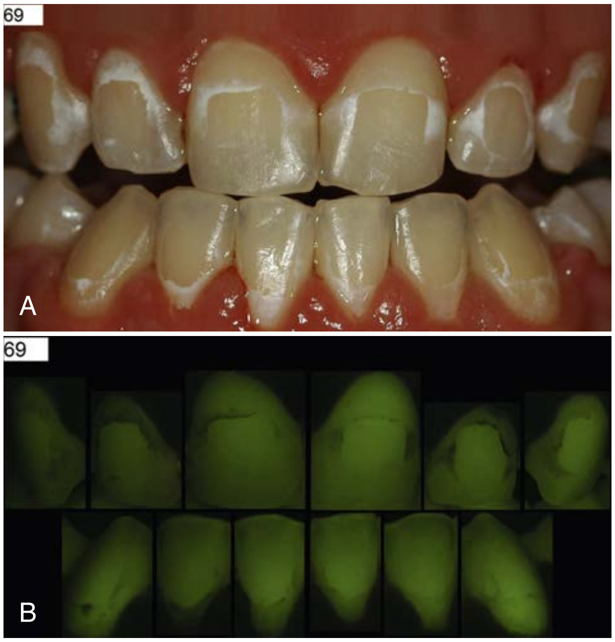

FIGURE 30-5 Two images illustrate the clinical photograph with demineralized white lesions on the day of debonding **(A)** and the corresponding quantitative light-induced fluorescence (QLF) image **(B)**.

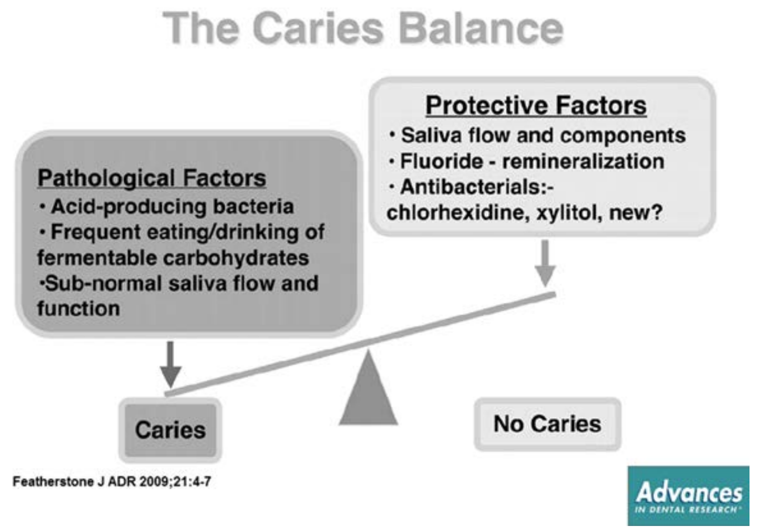

FIGURE 30-9 The Caries Balance model proposed by Featherstone. (Reproduced with permission from Featherstone JD. Remineralization, the natural caries repair process—the need for new approaches. *Adv Dent Res* 2009;21:4–7.)

another important way of reducing demineralization is to decrease the intake of fermentable carbohydrates used by the bacteria to produce acid, which dissolves the mineral. A few studies examined the effect of diet advice on orthodontic patients. One qualitative study found that a significant proportion of participants in the early stages of fixed appliance treatment said that they had heeded the advice of their orthodontist by reducing the frequency and amount of sugar they consumed[46]; however, little evidence in the wider literature suggests that professional advice changes the diet over the long term and is effective at reducing the level of caries.[47]

Patient and parental education and regular review of oral hygiene are important; however, additional measures to prevent demineralization are also necessary.

Sealing the enamel. Another proposed method of preventing mineral loss is to place a resin sealant over most of the labial enamel surface, when brackets are bonded to the tooth. The initial results with this technique were disappointing, possibly attributable to a loss of the sealant.[48,49] More recent studies have found a reduction in DWLs when the enamel surrounding the brackets is sealed with resin.[50–52] One study found a small reduction in the incidence but not in the severity of DWLs.[53] There does not seem to be any advantage in using a sealant containing fluoride, compared with one without fluoride.[54]

Promoting the Uptake of Mineral into Enamel (Remineralization)

Preventing the loss of mineral from the teeth of patients undergoing orthodontic treatment is desirable, but another approach is to change the balance within the mouth toward remineralization of the enamel. Remineralization is the natural repair of a carious lesion through the processes of inorganic chemistry,[26] and it has been extensively studied in the laboratory, as well as in the human mouth, and can be promoted in a number of ways.

Increasing the availability of fluoride in the mouth. Frequent exposure of dental enamel to fluoride has been known to reduce the incidence and severity of caries for years; however, only relatively recently has it been recognized that the primary mechanism of achieving this reduction, once the teeth have erupted, is through the promotion of remineralization. Laboratory studies have shown that remineralization is enhanced in the presence of fluoride, and the process actually makes enamel more resistant to further demineralization.[26] Ensuring that fluoride is available in the mouth can be achieved in a number of ways.

Toothpaste. Toothpaste is probably the most common regular source of fluoride for most orthodontic patients. Although little evidence suggests that toothpaste, containing a standard concentration of fluoride, prevents enamel caries in orthodontic patients, there is sufficient evidence in a general population[55]; therefore every orthodontic patient should be encouraged to use toothpaste with a fluoride concentration of at least 1000 parts per million (ppm), twice a day.[56] Some evidence suggests that toothpaste containing a higher concentration of fluoride (5000 ppm) is more effective at preventing DWLs in orthodontic patients than toothpaste with the conventional level of fluoride (1450 ppm).[57]

Mouth Rinses. Many orthodontists recommend the regular use of a fluoride mouth rinse to their patients to reduce the incidence of DWLs, even though very little reliable evidence suggests that fluoride mouth rinses are effective.[58] One study found that an amine fluoride–stannous fluoride toothpaste and mouth rinse combination was marginally more effective than a sodium fluoride toothpaste and mouth rinse combination at preventing DWLs in orthodontic patients.[59] Although little evidence supports the theory that the regular use of a fluoride mouth rinse is effective in orthodontic patients, a reasonable amount of reliable evidence in the nonorthodontic population suggests that it provides additional protection from caries to children over and above other sources of fluoride.[60] Orthodontic patients should therefore be encouraged to use a regular, daily fluoride mouth rinse (230 to 250 ppm) throughout the fixed appliance treatment. Unfortunately, only a minority of orthodontic patients will follow these instructions.[61]

Varnish. One good quality clinical trial has shown that regular professional applications of a varnish containing a high

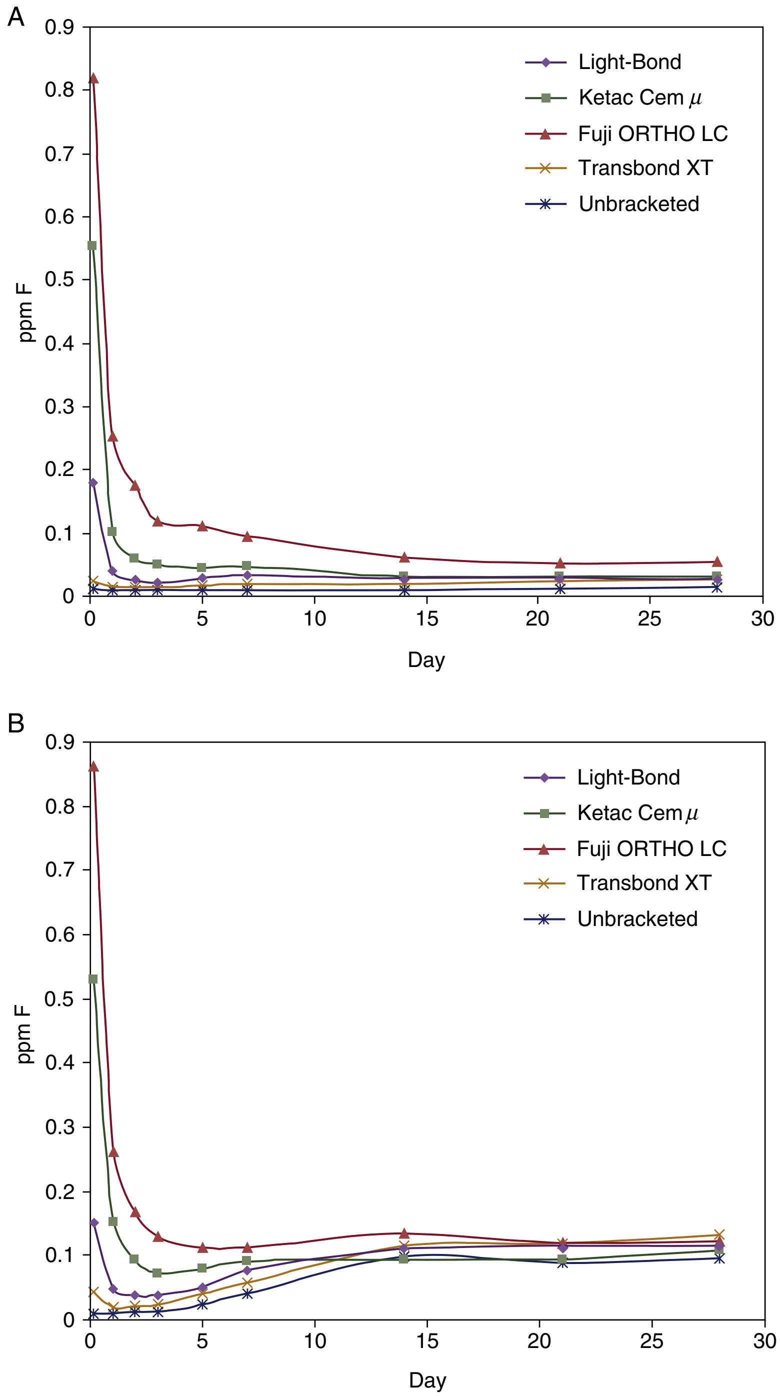

FIGURE 30-10 **A,** Graph demonstrates typical fluoride release profiles from materials in the laboratory with rapid loss within days, followed by very low but sustained fluoride release thereafter. **B,** Graph demonstrates that immersion in a fluoride mouth rinse leads to some increased release of fluoride. (Reproduced with permission from Chin MY, Sandham A, Rumachik EN, et al. Fluoride release and cariostatic potential of orthodontic adhesives with and without daily fluoride rinsing, *Am J Orthod Dentofacial Orthop* 2009;136:547–553.)

level of fluoride (7700 ppm wet; approximately 30,000 ppm dry) at each orthodontic adjustment visit reduces the incidence of DWLs, compared with a placebo varnish (absolute risk reduction 18%, number needed to treat 5.5).[62] Although this study is only one of its kind, regular applications of a fluoride-containing varnish may be considered a potentially effective approach, particularly in patients whose oral hygiene worsens during treatment.

Bonding Materials. Adding fluoride to the material that bonds the attachment to the tooth would seem to be an ideal means of delivering fluoride where it is needed. Unfortunately, fluoride released from these materials might not be sustained; they tend to show high levels of fluoride release initially, before the concentration quite dramatically drops (Fig. 30-10).[63] Some fluoride materials, such as glass ionomer cement, have the capacity to recharge, that is, to absorb fluoride from their

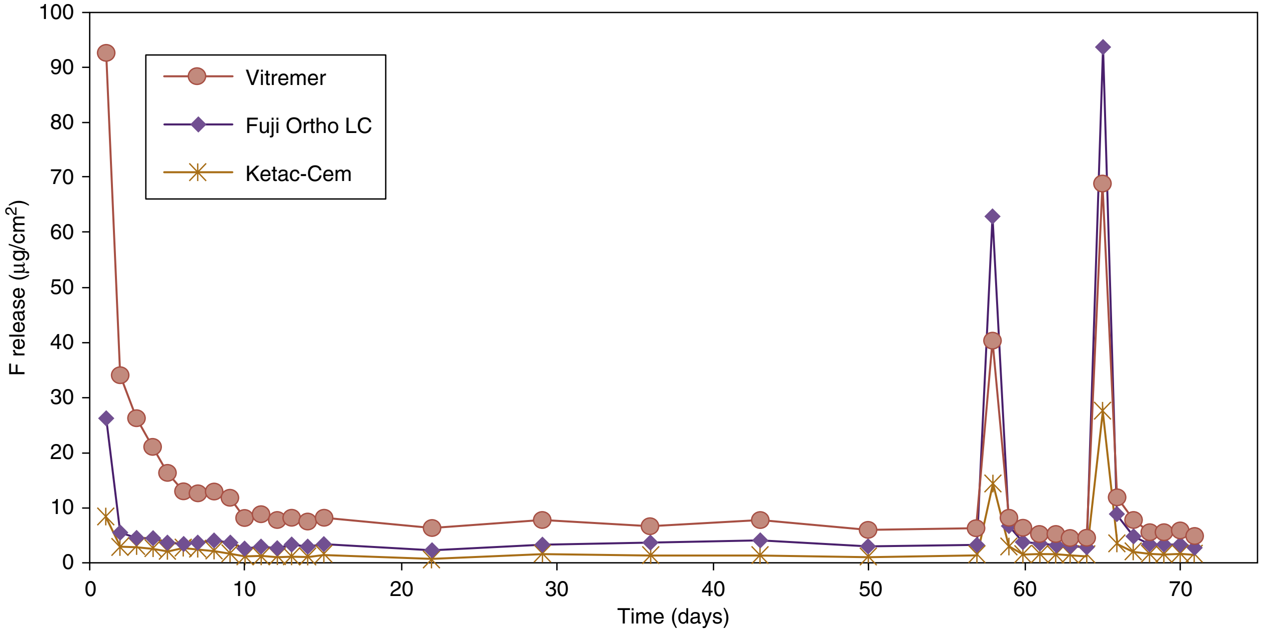

FIGURE 30-11 Graph shows the recharge of fluoride-containing materials when placed in 1.23% sodium fluoride gel for 4 minutes to simulate topical fluoride application. (Reproduced with permission from Lin YC, Lai YL, Chen WT, et al. Kinetics of fluoride release from and reuptake by orthodontic cements. *Am J Orthod Dentofacial Orthop* 2008;133:427–434.)

surroundings, as well as release it (Fig. 30-11)[64]; however, it is not entirely clear whether the fluoride released will be at a sufficient level over an adequate time (full length of orthodontic treatment) to prevent DWLs. The results of adding fluoride to composite materials have generally been disappointing.[65–68] Conventional glass ionomer cements showed promise in preventing DWLs,[69,70] but they are significantly weaker than composite materials, and the proportion of bond failures is high.[71] Newer resin-modified glass ionomer cements are stronger, but little reliable clinical evidence suggests that their use for bonding brackets prevents DWLs over the full course of treatment. Compomer, which is a hybrid between conventional resin-based and glass ionomer cement showed some initial promise,[72] but little research has been undertaken with the material since.

Elastics. In addition to placing fluoride in the orthodontic bonding material, adding fluoride to the elastomeric ligatures or elastic chain placed over the brackets would also seem logical. Fluoride would then be delivered to where it is most needed, and elastics are regularly changed, leading to a fresh boost of fluoride levels. Initial results with elastomeric ligatures were promising[73,74]; however, incorporating fluoride into the elastic changed the physical properties of the elastics, which rapidly deteriorated in the mouth (Fig. 30-12); consequently, finding any fluoridated elastomeric ligatures or elastic chain on the market today is very difficult.

Slow-Release Devices. Two primary types of devices are designed to provide slow and sustained release of fluoride in the mouth—copolymer membrane and glass beads.[75] One study reported the use of a copolymer membrane device,[76] and one reported the use of glass beads,[77] both in orthodontic patients (Fig. 30-13). Both reports may be considered at high risk of bias. Limited evidence proposes that slow-release devices are effective in the general population[78]; however, these devices could potentially provide sustained release of fluoride, and further research into their use for orthodontic patients might prove fruitful.

FIGURE 30-12 The fluoridated elastomeric ligature on the upper right lateral incisor has considerably deteriorated, compared with the conventional ligatures after 6 weeks in the mouth. The fluoridated ligature on the upper right central incisor has been lost. (Reproduced with permission from Benson PE, Douglas CW, Martin MV. Fluoridated elastomers: effect on the microbiology of plaque. *Am J Orthod Dentofacial Orthop* 2004;126:325–330.)

Diet. Limited evidence submits that fluoride in the diet or added to foods, such as milk or salt, is effective at preventing DWLs in orthodontic patients or in the general population.[79,80]

Unfortunately, at the present time, insufficient reliable evidence exists that recommends the most effective method of delivering fluoride to the orthodontic patient to prevent demineralization.[58] Hopefully, this lack of reliable evidence will be remedied in the future through the results of properly

FIGURE 30-13 Fluoride-containing glass bead on an orthodontic archwire. (Photograph supplied by Professor Jack Toumba and reproduced with permission. From Benson PE. Prevention of demineralization during orthodontic treatment with fluoride-containing materials or casein phosphopeptide–amorphous calcium phosphate. In: Huang GJ, Richmond S, Vig KWL, eds. *Evidence-Based Orthodontics*. Oxford: Wiley-Blackwell; 2011:149–165.)

designed clinical trials carried out over the full course of orthodontic treatment.[81] The current view of some cariologists is that supplemental topical fluoride alone might not be sufficient to prevent dental caries completely and that other ways need to be explored.[26]

Increasing the availability of calcium and phosphate. Ample evidence states that fluoride promotes the remineralization of enamel; however, this process also requires the presence of calcium and phosphate ions. Fluorapatite (chemical formula $Ca_{10}[PO_4]_6F_2$) contains three times more phosphate and five times more calcium than fluoride ions; therefore a relative deficiency of calcium and phosphate may delay or stop remineralization altogether.[82] To remedy this, a number of compounds containing calcium and phosphate have been proposed, the most thoroughly investigated being casein phosphopeptide–amorphous calcium phosphate (CPP-ACP).

Casein Phosphopeptide–Amorphous Calcium Phosphate. CPP-ACP has been considered an anticariogenic agent for over 20 years.[82,83] Previous clinical use of calcium and phosphate ions to enhance remineralization had not been a success because of the low solubility of calcium and phosphates, especially in the presence of fluoride ions.[83] CPP-ACP is a substance based on a group of peptides, casein phosphopeptides (CPPs), which have been shown to stabilize calcium and phosphate as nanoclusters of ions, in a metastable solution, known as amorphous calcium phosphate (ACP).[84] The CPP-ACP nanocomplexes can be used to intraorally deliver high concentrations of bioavailable calcium and phosphate ions to prevent demineralization and to allow a greater potential for remineralization.[85] CPP-ACP has been shown to aid more rapid remineralization of enamel subsurface lesions and can stabilize 100 times more calcium phosphate than neutral pH solutions.[86] It inhibits caries activity in a dose-response manner.[84,87] In addition, the incorporation of CPP into salivary pellicles reduces the adherence of cariogenic streptococcal species.[88] Anticariogenic activity has also been attributed to the ability of CCP to localize ACP at the tooth surface and, as such, leads to increased calcium phosphate levels in plaque.[86]

Reynolds and colleagues[84] showed that the use of a 3% CPP-ACP mouthwash increased the calcium content of plaque. This increase led to the idea that CPP-ACP would act as a reservoir in plaque for buffering free calcium and phosphate ion activities, maintaining a supersaturated state with respect to enamel. CPP-ACP has been shown to reduce caries activity in human in situ studies,[83,84,89–91] although the results of some trials suggest that the addition of CPP-ACP does not confer any additional benefits to that of fluoride toothpaste.[92,93]

A few studies have examined the effectiveness of CPP-ACP for the prevention of DWLs in orthodontic patients. Robertson and colleagues[94] compared nightly tray applications of a cream containing CPP-ACP and 900 ppm fluoride-containing cream with a placebo cream applied after brushing with toothpaste. They found that participants using the CPP-ACP and fluoride-containing cream after toothbrushing had fewer lesions forming and more lesions regressing (54% reduction in demineralization), compared with those using the placebo product; however, because of limitations in the study methodology, including this study in the latest Cochrane systematic review[58] was not possible.

A laboratory study examined the effect of incorporating CPP-ACP into a glass ionomer cement[95]; however, no clinical trials of this product have been undertaken.

Increase salivary flow or increase the pH of saliva

Chewing Gum. The use of sugar-free chewing gum has been suggested as a way of controlling caries in the general population.[96] Chewing gum stimulates the flow of saliva, increases its bicarbonate content and, consequently, increases the alkalinity of saliva, and has been shown to reduce both the amount of plaque in orthodontic patients.[97] Chewing mastic gum reduces the number of cariogenic bacteria in patients wearing fixed appliances[98]; however, adding chlorhexidine to gum did not significantly decrease plaque levels further, compared with gum without chlorhexidine.[97]

The addition of CCP-ACP into chewing gum has been shown to increase the amount of remineralization in nonorthodontic patients,[99] and a large randomized, controlled caries clinical trial found that CPP-ACP containing sugar-free chewing gum significantly slowed the progression of caries and enhanced the regression of caries, compared with the control subjects with sugar-free gum.[100] However, this finding has yet to be tested in patients wearing orthodontic appliances.

Treatment of Demineralized White Lesions

The aim of all orthodontists, with the help of their patients and parents, should be to attempt to prevent DWLs from appearing during orthodontic treatment; however, unfortunately, DWLs are still a common sight when the appliance is removed. It has been shown that regression of early DWLs can occur in the presence of saliva, without the additional use of fluoride or other remineralizing agents, once appliances have been removed,[101] but overall regression can be slow and limited.[3] Arends and Christoffersen have shown that even if remineralization of lesions does occur, the white marks may permanently remain.[102] As with the prevention of DWLs, a paucity of evidence suggests the best method of managing DWLs once the appliance is removed.[103]

Fluoride

As previously stated, ample evidence from numerous laboratory studies proposes that fluoride promotes remineralization; however, limited evidence is available regarding the concentration and frequency of fluoride that is most effective at reducing the visibility and the need for restorative treatment in patients with DWLs after their orthodontic appliance has been removed.

Du and colleagues[104] showed a greater reduction in readings, using a handheld laser caries detection aid (DIAGNOdent), when fluoride varnish was applied to DWLs post orthodontic treatment, as compared with a saline placebo; however, how the DIAGNOdent readings relate to the actual appearance of DWLs is not clear. Concern has been expressed about applying a high concentration of fluoride to a DWL, which might lead to hypermineralization of the surface and the persistence of a visible subsurface white lesion.[9,105]

Willmot undertook a double-blind, parallel groups, randomized controlled trial comparing a low fluoride (50 ppm) mouth rinse and toothpaste combination and a nonfluoride mouth rinse and toothpaste combination.[106] He found that, over 6 months, an average reduction of 57% in the size of the DWLs was reported, but no difference between the two groups was recorded. Baeshen and colleagues[107] found a significant reduction in both DIAGNOdent readings and the International Caries Detection and Assessment System scores when patients, with a minimum of four DWLs after orthodontic treatment, were asked to chew sticks (Miswaks) containing fluoride up to five times daily. There was also a reduction in the DWLs in patients who were given nonfluoridated sticks, but the reduction was not as large.

Casein Phosphopeptide–Amorphous Calcium Phosphate

In theory, the use of CPP-ACP in addition to fluoride should enhance the remineralization process, as CPP-ACP interacts with fluoride ions to produce nanoclusters of calcium, phosphate, and fluoride.[83] This CPP-ACP and fluoride complex thereby delivers fluoride, not only to the surface of the lesion but also to the subsurface, promoting remineralization. This complex also provides a source of soluble calcium, phosphate, and fluoride that is more resistant to pH changes. Reynolds and colleagues found that a mouth rinse with 2% CPP-ACP and 450 ppm fluoride significantly increased supragingival plaque fluoride content.[83] They also found that toothpaste containing 2% CPP-ACP and 1100 ppm fluoride was 2.6 times more effective than toothpaste with only 1100 ppm fluoride in remineralization of enamel subsurface lesions in situ.

The evidence for the effectiveness of CPP-ACP applications on the reduction of DWLs once orthodontic appliances have been removed is equivocal. Two studies found a positive effect of using a CPP-ACP containing cream, in addition to fluoride,[108,109] and three studies found a limited effect[110–112]; therefore further work in this area is required before a definitive answer is found.

Resin Infiltration

A new method of caries infiltration for early DWLs that has been suggested[113] involves etching the area with a 15% hydrochloric (HCl) acid gel and drying it with ethanol before placing a low-viscosity light-cured resin. Although the short-term results in patients with postorthodontic DWLs are promising,[114,115] no long-term data concerning staining or discoloration of the resin are available. Remineralization with calcium and phosphate must remain the ideal method of managing postorthodontic DWLs.

The development of unsightly white and/or brown demineralized lesions on the teeth during fixed orthodontic treatment remains a significant problem. Various approaches of preventing and treating DWLs during and after orthodontic treatment are available. Identifying the most effective and efficient of these approaches is the current challenge.

ROOT RESORPTION†

ETIOLOGIC FACTORS

The etiologic causes and origins of root resorption as a result of orthodontic forces are multifactorial and presently not clearly understood. Paradoxically, root resorption is common, but clinically significant root resorption is rare. Resorption of the root can occur any time an injury occurs, causing inflammation to the periodontal ligament (PDL) and/or to the pulp. Classification of root resorption is generally divided into internal resorption and external resorption. There are two types of internal resorption: (1) internal inflammatory resorption and (2) internal replacement resorption. These occur secondary to an insult to the dental pulp and are not related to orthodontic tooth movement. External resorption is classified into four categories: (1) surface resorption, (2) external inflammatory root resorption, (3) replacement resorption, and (4) ankylosis. Surface resorption is the physiologic process of resorption and repair that the root sustains during normal physiologic activity (e.g., mastication). External inflammatory root resorption includes any resorption mediated by the inflammatory process and includes resorption caused by orthodontic tooth movement and trauma, among others. This type of resorption can occur anywhere on the root resurface where there is periodontal attachment. Of particular interest to the orthodontist is the occurrence of external apical root resorption.

In normal orthodontic tooth movement, external root resorption is a naturally occurring side effect of the physiologic process of resorption and deposition as the bone remodels to accommodate the moving tooth caused by a cascading series of events initiated by pressure and tension in the PDL. On the pressure side of the root, as clastic cells are recruited during the initial inflammatory process, cementoclasts remove cementum, which is normal and has been shown to occur without exception. Along the side of the root, the cementum is repaired as soon as the force expression diminishes and cementoblasts replace the cementoclasts. This ongoing resorption-repair process along the sides of the root generally occurs without consequence to the health and longevity of the tooth. Lighter forces have been shown to produce fewer craters on the root surface than have heavier forces.[116] For reasons that are not completely understood, the resorption–repair process is different at the apex. Once resorption starts at or near the apex, it does not always repair. The role of exposed dentin or the possible involvement of the pulp through the apices may be a factor. The apex, itself, is complex with multiple foramina and complicated surface anatomy. The composition of cementum is variable near the apex. Stresses on the neurovascular bundle exiting the pulp may be involved. Distinguishing between the two forms (location) of external root resorption is important; what may be true in the former may not necessarily be so for the latter. To differentiate the unique type of resorption that takes place at the root apex, the term *external apical root resorption* (EARR) is the most appropriate appellation.

† Glenn Sameshima and M. Ali Darendeliler.

The complex nature of EARR probably precludes the identification of all patients at high risk as there will inevitably be cases of unknown causes, likely attributable to random events in the physiologic functioning of the individual. However, an individual's genetic predisposition is generally accepted as the primary cause of EARR. Figure 30-14 illustrates the percentage of EARR by cause, based on current research. The percentage attributed to biomechanical factors has become smaller as more studies have emerged. Studies of families with severe root resorption have established a firm genetic component implicating the interleukin gene family (see Chapter 2 for details).[117–119] In a twin study evaluating root resorption after full orthodontic treatment, an overall hereditary estimate of 0.34 was obtained.[120] Several candidate genes have been proposed, with the most likely scenario being that more than one gene will be implicated, and secondary or tertiary control of gene expression is undoubtedly involved as well. What genetic predisposition means to the clinician is that if a patient had significant EARR at the end of orthodontic treatment, then the risk for EARR is greater than usual when treating siblings. In addition, if a parent had severe EARR, then the orthodontist must more carefully look at the children and perhaps even the grandchildren of the patient as higher risk as well.

In summary, the physiologic cause is understood, but why it occurs more readily in some patients and not others is not known. Similar to most disease states with complex symptomatologic characteristics but little morbidity and mortality, EARR is epigenetic in origin with layered causes that will remain elusive for a considerable time to come.

RISK FACTORS

How does the clinician prevent EARR from occurring? Radiographically detectable root resorption is common. In the literature, the vast majority of teeth undergoing orthodontic tooth movement have been shown to have measurable EARR.[121,122] The crucial question, then, is how can *severe* root resorption be prevented? The orthodontic literature is replete with EARR investigations. The following paragraphs summarize the findings to give the clinician some insight into the risk factors.

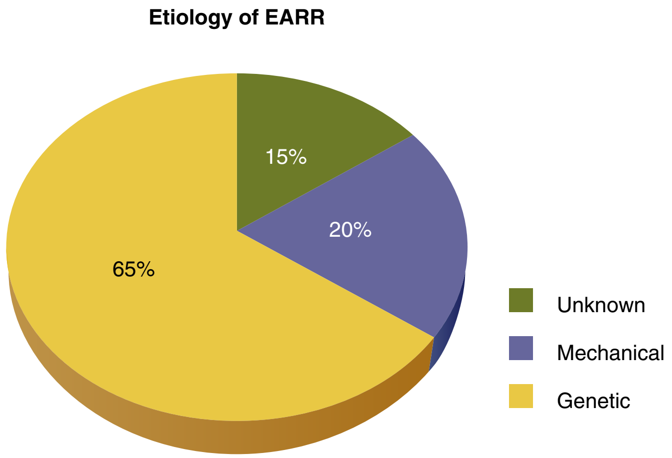

FIGURE 30-14 Etiology of external apical root resorption (EARR). The percent explained by genetics has significantly increased in the past decade, whereas the percent explained by treatment factors has proportionally decreased. (Adapted from Dr. James Hartsfield.)

Diagnostic Factors

Retrospective studies with large sample sizes have shown that the maxillary incisors have the greatest amount of root resorption of all teeth,[122–129] and lateral incisors are more resorbed than central incisors. The reported mean (average) amounts for all cases were approximately 1.2 to 1.6 mm.[122] Maxillary and mandibular canines follow in mean amounts of EARR with the rest of the dentition having less, but the clinician will see isolated teeth, particularly mandibular first bicuspids, with significant EARR.[122] Molars rarely resorb, but if they do, it is usually the mesial root(s). No studies explain why maxillary lateral incisors have more EARR, but several factors have been given serious consideration. Brin and others have shown that lateral incisors often have undetected EARR caused by erupting canines.[130,131] (The canine guidance theory of eruption proposed by Ericson and Kurol in 1988 supports these findings.[132]) Maxillary lateral incisors have the highest frequency of dilacerations of any tooth and also have a high frequency of microdont, peg shape, barrel shape, and being congenitally missing. Because of the variation in crown shape and size, the orthodontist must often adjust the position and torque of a maxillary lateral incisor more than any other tooth. Finally, maxillary incisors may have a composition of cementum that is different from the other teeth, and they are developmentally distinct early in origin as a unit. Interestingly, no difference in EARR among small or peg or barrel laterals has been found, compared with a normal antimere.[133]

Tooth Anatomy

Short teeth are at no higher risk than normal length teeth. Teeth with an odd root shape are probably at higher risk as shown by clinical and finite element models[122,134] (Figs. 30-15 and 30-16). Studies have shown that dilacerated roots, pointed roots, and pipette-shaped roots may have a higher risk for EARR.[122] The dilacerated portion of the root is often resorbed during active tooth movement. Using the two-dimensional representations that are routinely used (conventional radiographs) makes assessing the shape difficult. Although shape as a nominal variable in two dimensions is reproducible, recent three-dimensional studies have shown that dilacerations can occur perpendicular to the plane of the periapical, rendering the shape invisible in two-dimensional studies.[135] Figure 30-17 clearly demonstrates this with a root tip dilacerated completely in the palatal direction. Decalcified teeth and teeth with a high crown-to-root ratio are not at higher risk. Teeth with a history of trauma may be at risk, but teeth with prior resorption are not.[136,137] One study found that teeth with longer roots had greater EARR.[122]

Demographic Factors

For years, it was thought that women and teenagers were at greater risk, but the majority of studies show no difference in sex or age; most of the studies that did find a difference showed those of increasing age and men may be at higher risk.[122–129,138–142] Clinical experience and the known role genetics plays in the occurrence of EARR have led some to suspect ethnicity; one study found Hispanic patients to have more EARR than Caucasians or Asians.[122] In addition, some

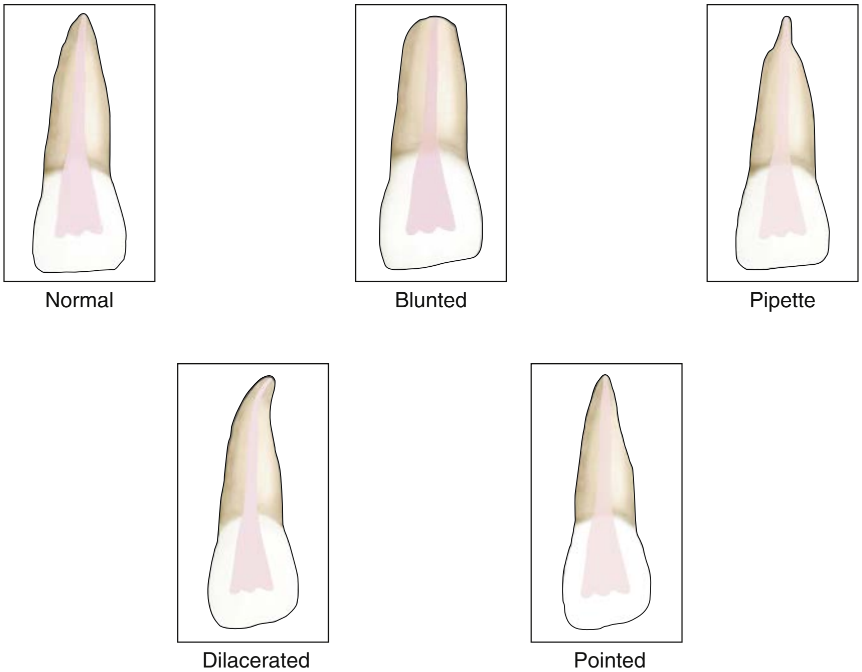

FIGURE 30-15 Classification of root shape. The five most commonly seen root shapes are visualized on periapical x-ray images. The pipette shape is almost unique to maxillary central incisors. Maxillary lateral incisors have, by far, the highest frequency of dilacerations. It is acknowledged that these classifications are fairly general and that all roots have an irregular surface and contour.

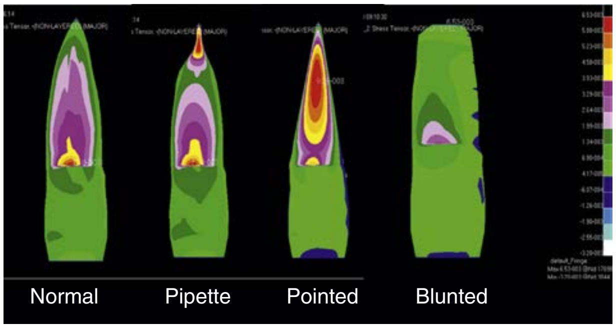

FIGURE 30-16 Finite element analysis of three root shapes. This figure shows the principal von Mises stresses from a pure linear tipping movement (areas of maximum stress on the root surface) of a static model of a maxillary central incisor. In the normal-shaped root, the stresses are concentrated at the cement–enamel junction at the alveolar crest. Blunted root shapes show a similar pattern. However, in the pipette-shaped and pointed-shaped roots, the stresses occur at the apical end and apical third, respectively, mirroring the increased external apical root resorption (EARR) clinically observed in these shapes.

evidence suggests that a significant variation exists among offices, even when many confounding variables are considered in the study.[122]

Malocclusion Factors

No evidence associates Angle classifications of malocclusion, cephalometric measurements, or the amount of crowding that may warrant extraction treatment with EARR.[122–129,138–142] The amount of apical displacement has been shown to be a primary factor causing EARR.[143–145] This, as well as a hypofunctioning PDL, makes anterior open bite cases more prone to EARR.[145]

Root Canal Treatment. Teeth that have been successfully treated endodontically were thought to be resistant to EARR; Sameshima and Sinclair found no EARR in any root-filled teeth in their study of 1000 patients,[122] as did two other studies.[147,148] Castro found no difference in EARR in posterior teeth between root-filled and vital teeth, but the amount of EARR in both groups was less than measurement error.[149] A systematic review[150] found no difference between root-filled and vital teeth but was very limited in validity and scope and included one study with a sample size of 16 and another using panoramic films for analysis. The latter is the only paper that found EARR in root-filled teeth.[139] Teeth with immature apices do not resorb, although the roots may not achieve full length if orthodontically moved[151,152] (Fig. 30-18).

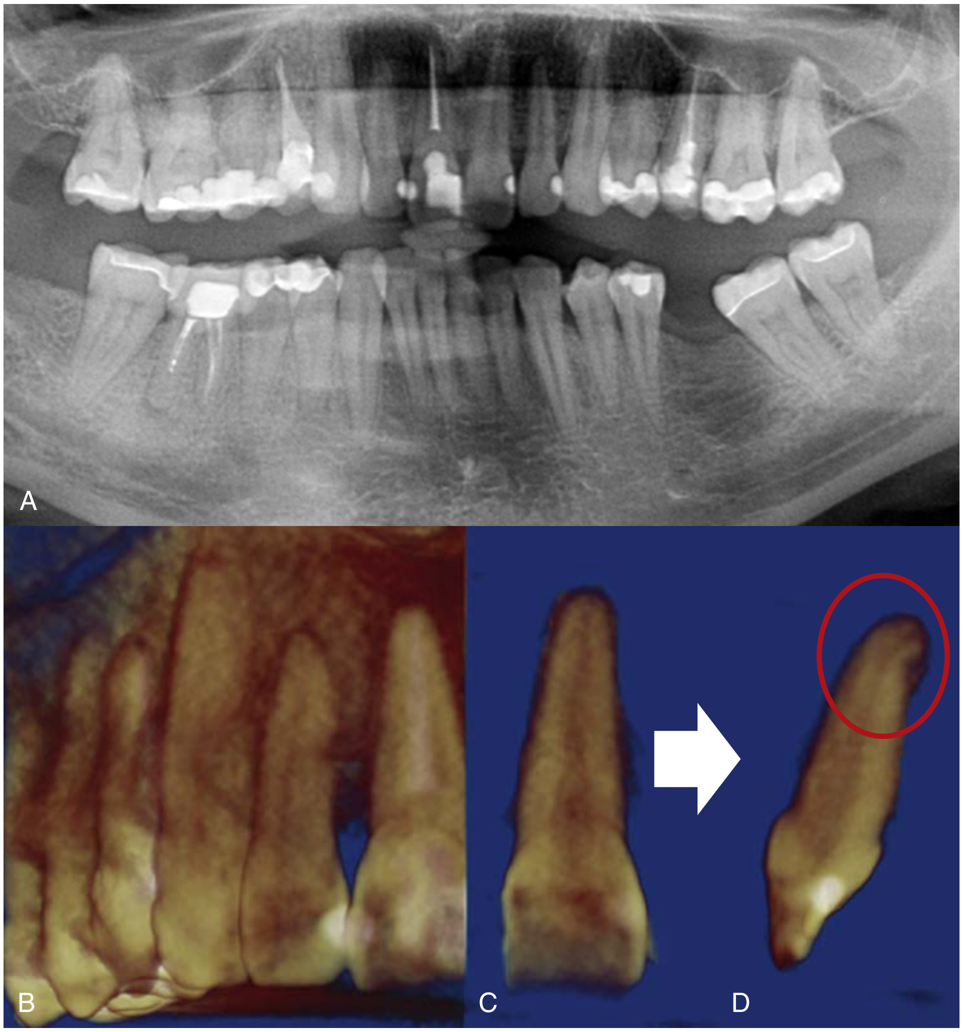

FIGURE 30-17 External apical root resorption (EARR) in 3D images. **A.** Initial PAN shows abnormal root shape for all four maxillary incisors. **B.** CBCT generated image processed with Dolphin 3D **C.** Segmented left central incisor (see arrow on PAN) from frontal and mesial views shows a palatal dilaceration that would not be visible on any conventional radiograph.

Patient Medical History and Habits

Primarily based on case reports, a few medical conditions, such as Turner syndrome, familial dysostosis (also known as familial expansile osteolysis),[153] and possibly any patient with severe and/or uncontrolled endocrine problems, are known to place patients at higher risk for EARR. Asthma has long been suspected of being a risk factor for EARR. The link with inflammation provides a sound theoretical basis, and three studies have found increased risk in patients with asthma.[154–156] Patients with allergies were found not to have higher prevalence in one study,[157] but they did have significantly higher risk factors for EARR in another study[154] with a proposed mechanism reported in an animal study by Murata.[158] Habits such as tongue thrusting, nail biting, or bruxing as independent risk factors for EARR have received much speculation but are supported by no clear evidence. Additionally, the clinician must be aware that documented cases of idiopathic root resorption (with no history of orthodontia) exist, sometimes involving multiple teeth and severe enough that teeth are eventually lost.[159–162]

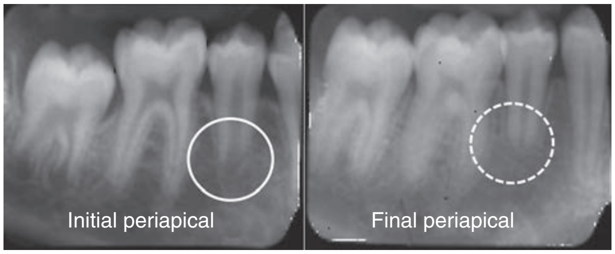

FIGURE 30-18 Movement of teeth with immature apices: initial periapical radiograph (*left*) and final periapical radiograph of mandibular bicuspids (*right*). Note no shortening of the root occurred, but, based on other teeth in the same state of development, the tooth did not achieve its predicted final length. Generally, however, immature root apices do not resorb.

Treatment Factors

Mechanical Factors

Treatment philosophy, bracket type and slot size, archwire composition or sequence, and use of headgear, among others, have not been found to be significant risk factors.[142,163,164] In particular, the claim that moving teeth with self-ligating brackets cause less EARR has been proven to be false.[165] Among clinicians, a nagging suspicion remains that inconsistent use of elastics by the patient can be a contributing factor, especially if carried out over a long period, although evidence is fleeting.

Recent case reports show that clear aligner treatment that applies enough force to move the roots the same amount as fixed appliances do will cause similar EARR.[166–168] Limited evidence supports the fact that orthodontic patients treated with periodontally accelerated osteogenic orthodontics do not have an increased risk for EARR.[169,170]

Magnitude of Applied Force

Both animal and human studies have provided strong evidence that force magnitude is directly proportional to the severity of root resorption.[116,171–174] Given the choice between heavy and light forces applied at the bracket–archwire interface, the clinical choice is light forces, although the distinction between light versus heavy forces in clinical practice is not a simple one to make. Indeed, although considerable evidence suggests that light forces cause less resorption along the root surface, there is no evidence that light forces directly translate to resorption, which occurs at the root apex.

Intermittent versus Continuous Force

A pause in tooth movement allows the resorbed cementum to heal. It follows that most of the studies comparing intermittent with continuous forces found that the latter is associated with greater resorption.[175–178] However, the amount of movement using intermittent forces is less than the amount produced by continuous forces.

Early Treatment

Brin and Bollen found that the spontaneous unraveling of incisor crowding often observed with serial extraction during early treatment does not prevent EARR in patients treated with late extractions, when the patients are treated in phase II.[179] If an advantage to early treatment exists, relative to EARR, it is that immature apices are not as susceptible (see above).

Expansion

An observational study using CBCT shows that rapid maxillary expansion (RME) or other similar fixed devices may increase the risk of EARR. Significant volume lost, linear surface area changes, and thinning and/or shortening of maxillary first molar and premolar roots were common findings with the use of tooth-borne RME therapy.[180,181] When slow and rapid expansion therapies were compared, no difference in the amount of EARR was found.

Extractions

The extraction of teeth has been found to increase risk.[182,183] The risk is the same whether the first bicuspid, second bicuspids, or upper bicuspids only are extracted.[122] For upper bicuspids only, it is a covariant with horizontal apical displacement and overjet correction.[122]

Prolonged Treatment Time

In theory, treatment that takes longer than usual has the potential for wearing down the system, for lack of a better description. There are likely limits to the amount of remodeling cycles the root apex can withstand. The model of EARR proposed by Al Qasami supports this theory.[118] The majority of studies that have measured an association between treatment duration and EARR have found a positive one.[122–129] The longer the active treatment time, the greater the amount of EARR,[182,183] which may also be related to root (apical) displacement (see the next paragraph). This theory would also partially explain why round-tripping of teeth produces more EARR, and jiggling in inconsistent wear of finishing elastics is thought to increase risk. Recently, the effects of 4 weeks of jiggling movement were studied; the conclusion was that short-term buccopalatal light and heavy jiggling movements do not increase the amount of EARR.[184] However, vertical jiggling movements, in comparison with buccopalatal jiggling movements, were shown to increase the instances of EARR.[185]

Apical Root Displacement

Most studies have found the distance the apex is displaced is a significant risk factor, but not all studies agree. Until recently, accurately measuring the actual displacement of the tooth has been difficult; serial cephalometric tracings superimposed on the maxilla were used to measure horizontal and vertical displacement of the apex quantitatively (Fig. 30-19). One of the many limitations of this method of measurement is the uncertainty in knowing which central incisor is traced on each film. Imminent studies with three-dimensional superimposition may provide more accurate answers and will show true displacement in all three planes of space. Moving the apex of maxillary central incisors against the cortical bone was shown in one study using cephalometric films to increase EARR, but it has been difficult to replicate the study,[127] and ongoing studies with stereolithography (STL) files may provide more solid evidence. Anecdotally, when practitioners used to rotate and torque the maxillary first molars (mesial buccal root) against the cortical bone for anchorage, EARR of the mesiobuccal root was often observed.

The fact that apical displacement is a risk factor to consider is also evident in the heroic distances that a tooth can now be moved using skeletal temporary anchorage devices (TADs). The orthodontist must take frequent progress films whenever moving teeth a long distance to correct overjet or camouflage malocclusion by using TADs to avoid extractions[186] (Fig. 30-20). Pure or absolute intrusion of teeth is now possible using TADs. Figure 30-21, *A*, *B*, demonstrate cases where absolute intrusion of molars with TADs resulted in EARR. The clinician will find that the risk of EARR significantly increases when absolute intrusion is performed.

Although no supporting evidence exists, a strong suspicion suggests that maxillary teeth in LeFort I osteotomies have a higher incidence of severe root resorption. Patients with controlled periodontal disease have no higher risk for EARR and periodontal bone loss, but attachment loss of 1 mm is considered as serious as 3 mm of EARR.[187] EARR results in a large crown-to-root ratio; but unless the tooth will support a load-bearing prosthesis, the longevity of the tooth is not affected. Figure 30-22, *A*, *B*, illustrates two typical cases of EARR of all four maxillary incisors found in a study of consecutively treated cases from a private practice.

A list of risk factors for EARR is shown in Box 30-1.

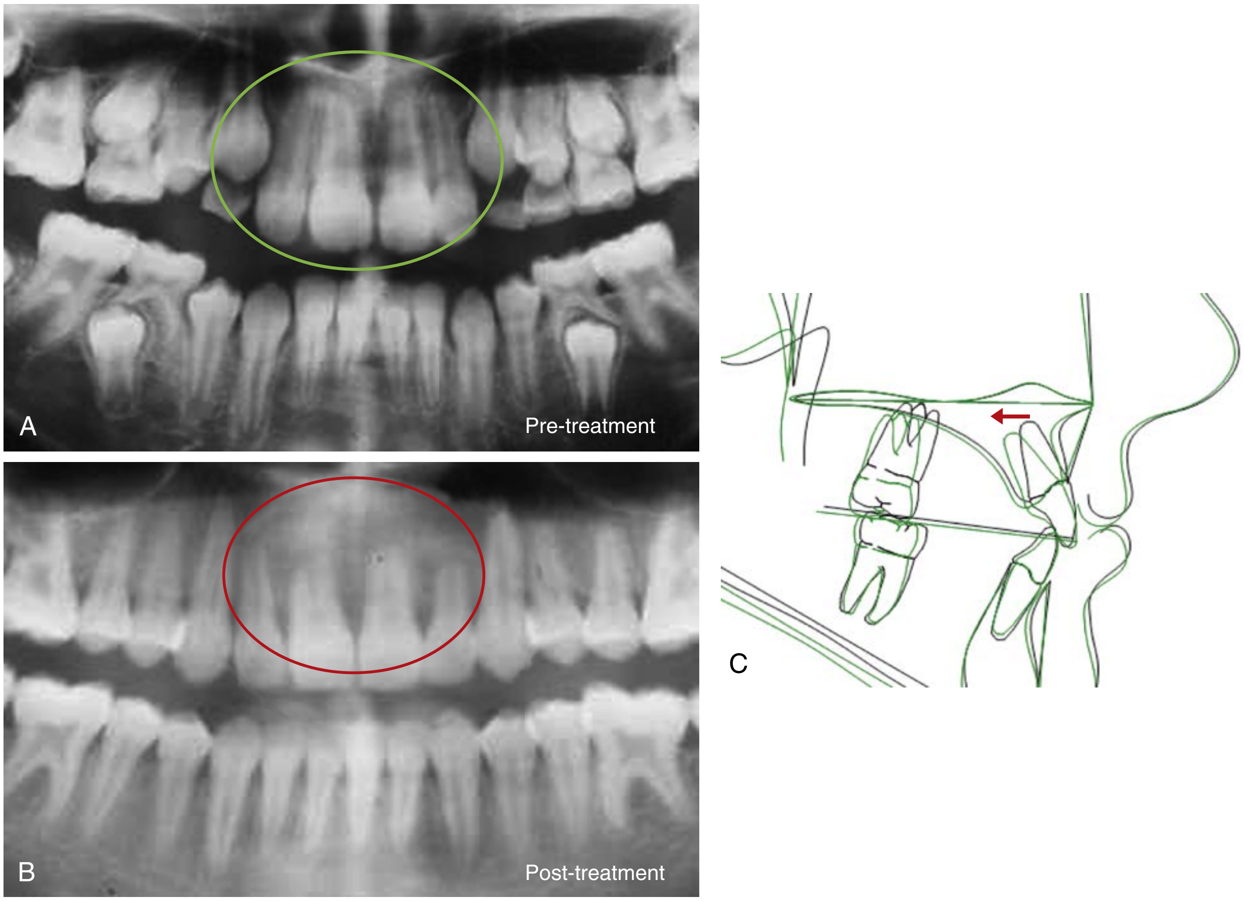

FIGURE 30-19 External apical root resorption (EARR) and horizontal root displacement. **A,** Pre-treatment. **B,** Post treatment showing significant EARR in all maxillary incisors (circled). **C,** Cephalometric superimposition shows amount of apical displacement (arrow).

BOX 30-1 Summary of Risk Factors

1. Siblings with external apical root resorption (EARR) from orthodontic treatment
2. Positive medical history for known conditions
3. Dilacerated, pipette, or pointed root shape
4. Long apical displacement
5. Long treatment time
6. Extractions
7. Open bite and deep bite
8. Excess overjet
9. Hispanic ethnicity

MANAGEMENT

Clinical management of EARR is summarized in Box 30-2.

Imaging

An initial periapical radiograph or limited-field CBCT is essential in adult patients to examine properly and with clarity the root morphologic structure and the location of the roots. Periapical radiographs have been shown to be superior to panoramic images for detecting EARR.[188] Apical displacement in all three planes of spaces often exceeds what can be observed in two-dimensional radiographs of the same area of the head. Limited-field CBCT with accurate software can now make details of the root apex and apical resorption quite visible.[189–191]

BOX 30-2 Clinical Management

1. Produce good pretreatment images.
2. If risk factors present, then document a special entry in the informed consent.
3. If risk factors present, take periapical radiographs at 6 and 12 months or when apical displacement has started.
4. During treatment:
   a. If external apical root resorption (EARR) is greater than 2 mm, then stop treatment for 4 months.
   b. If EARR is greater than 4 mm or more than one-third of the root, then stop active tooth movement and consider terminating treatment.
5. If severe EARR occurs on more than two adjacent teeth, the treatment must be terminated.
6. EARR stops when appliances are removed.
7. Patient and referring dentist must be kept informed at all time points.
8. If short roots are present at the beginning of treatment:
   a. Delay applying appliances on the affected tooth as long as possible.
   b. Avoid torque and apical displacement.
   c. Take more frequent periapical radiographs.

History

A careful history is essential. If a patient is at high risk, especially for families, then specific documentation of this level of risk must be included in the informed consent for treatment.

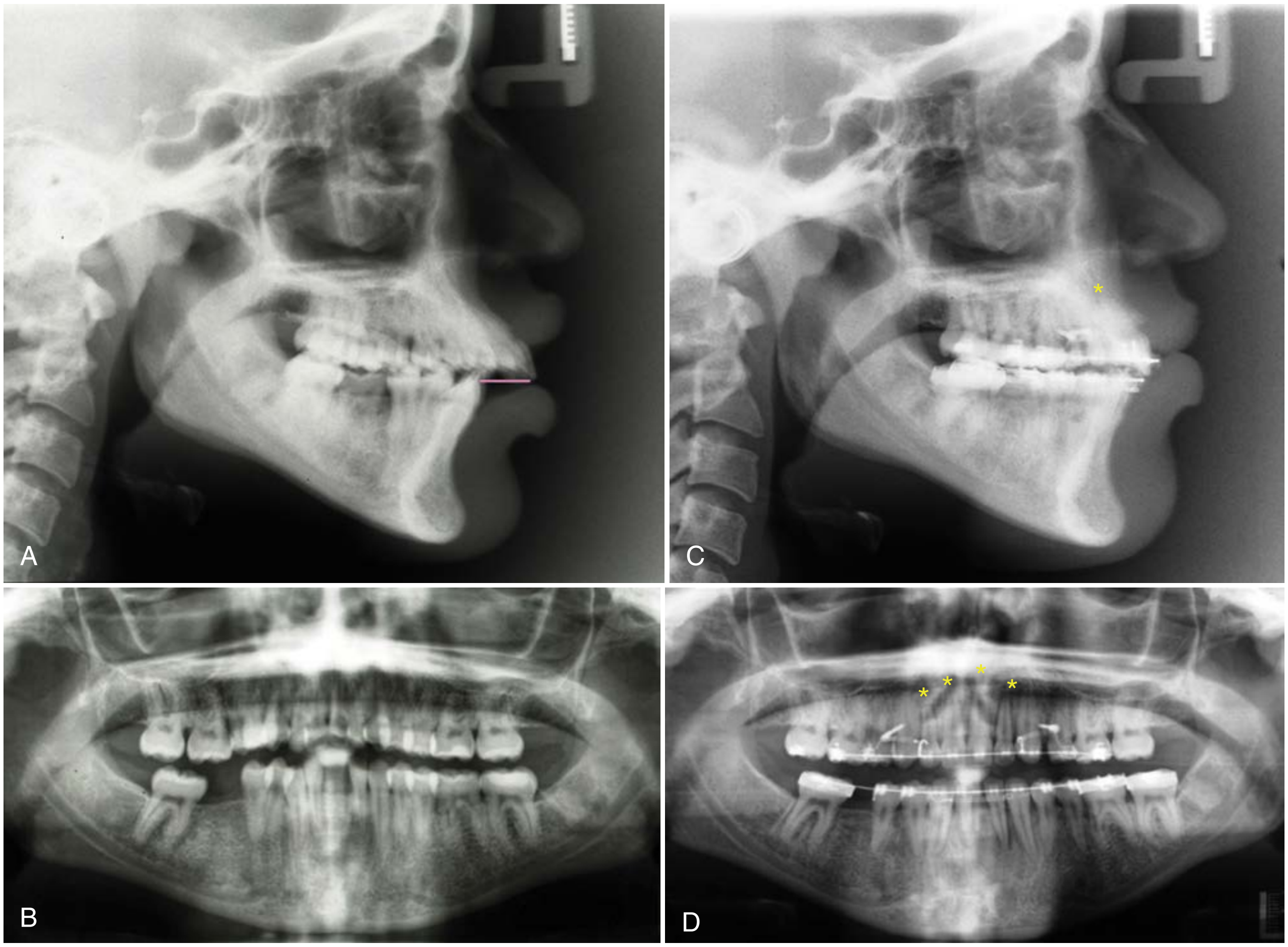

FIGURE 30-20 Extreme horizontal retraction of maxillary arch with temporary anchorage devices (TADs). Pre- (**A,B**) and progress (**C,D**) PAN and cephalometric radiographs. External apical root resorption (EARR) of approximately 25% was found on all four maxillary incisors after the apices were retracted over 5 mm over a 30-month period. Patient had no other risk factors. Case illustrates the distances possible and the caution needed with absolute skeletal anchorage.

Progress Review

Documenting the progress for all cases is a good practice, but documentation is particularly important if risk factors for EARR (and other potential issues such as periodontal problems) are present at the beginning of treatment. A commonly practiced time to take progress records seems to be 1 year into treatment. However, if a patient starts with short roots (approaching a crown-to-root ratio of one), then periapical radiographs should be taken sooner and more frequently. This need must be explained to the patient during the informed consent process before appliances are placed.

What to Do If Root Resorption Is Detected at Progress

The decision to continue active tooth movement is dependent on planned further movement of the tooth in question and the amount of resorption visible on the radiograph. It must be noted that there are no consensus standards on what constitutes severe EARR. A survey found that general dentists were of the opinion that 35% root shortening should terminate orthodontic treatment; orthodontists did not agree.[192] Generally for a normal length and nonperiodontally involved tooth, if the amount of resorption is greater than 2 mm, then the best course of action is to stop active treatment immediately and wait for 4 months. Ideally, the tooth should not be in hyperfunction and no force applied, which usually means placing a passive archwire to hold the teeth exactly where they are. After this resting period, treatment can continue (Fig. 30-23). No increased risk for the EARR has shown to resume, but overtorquing the tooth is unwise, and the orthodontist may have to compromise the amount of detailing as well. If the amount of EARR is 4 mm or more in a patient who has been in treatment for a long time and the apex has already been moved a significant distance (1 mm or more), then the orthodontist will have to decide whether to terminate treatment (deband the case) or modify the plan to finish without moving the affected teeth (Fig. 30-24). In both situations, the patient and his or her dentist must be informed of the change in plan.

When Does External Apical Root Resorption Start?

It has been hypothesized that EARR will start to occur when the root apex is displaced—in any direction. Artun found that teeth

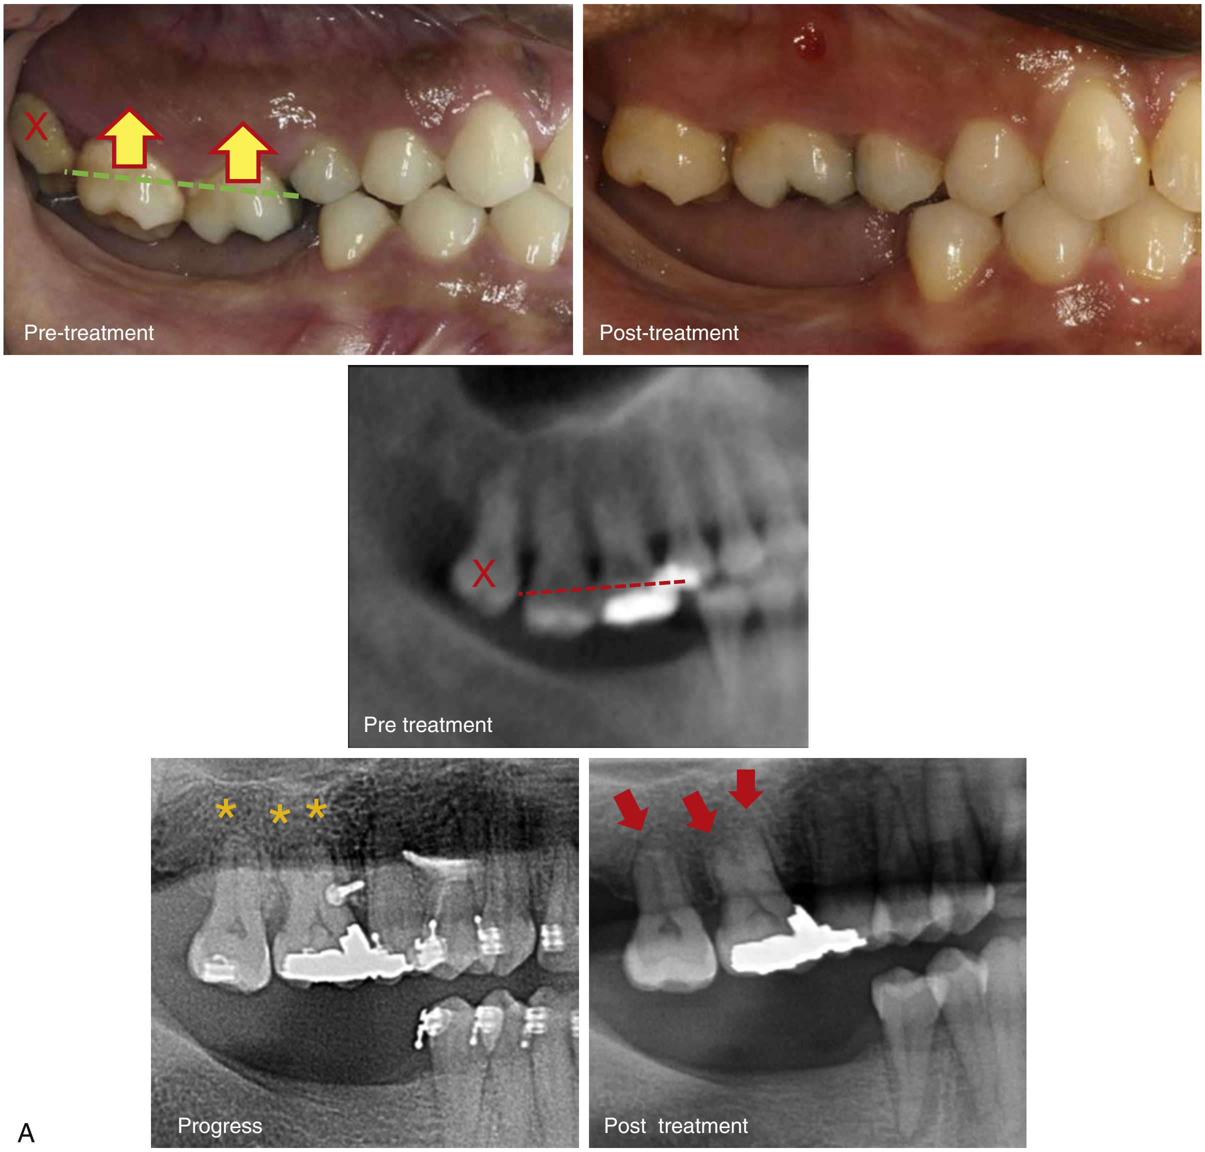

FIGURE 30-21 Absolute intrusion with temporary anchorage devices (TADs) for overerupted, unopposed maxillary molars is demonstrated. TADs were placed buccal and lingual to intrude the maxillary right second and first molars approximately 4 mm (*yellows arrows*). External apical root resorption (EARR) in the intruded molars was 1-2 mm at progress (asterisks) and 2-3 mm (*red arrows*) at completion of treatment.

with EARR at 6 months after fixed appliance placement were the most likely to have severe EARR by the end of treatment.[193]

When Does External Apical Root Resorption Stop?

It has been clinically observed that as soon as active forces are removed from the tooth, EARR stops. Studies have shown the reparative process (cementoblast activity) is completed within a few weeks. Generally, removable appliances do not cause EARR, and retainers with springs will not cause further resorption; however, tooth positioners may produce enough force to continue EARR (no evidence in the literature confirms either way).

What Happens to Teeth with Short Roots Long Term?

Teeth with congenitally extremely short roots do not spontaneously fall out unless periodontal disease remains untreated. The current faith in the permanency and longevity (forever) of implants in the dental world has become a call for the extraction of any compromised teeth (including teeth with EARR) and replacement with implants (Fig. 30-25). Case reports and long-term cohort studies have shown that no relationship exists between teeth with short roots and morbidity (loss of the tooth). Remington in 1989 recalled 100 patients with EARR after 14 years—no teeth had been compromised.[194] In 2002, Savage and Kokich presented long-term follow-up studies of three patients with severe EARR; the authors emphasized the need for a comprehensive, interdisciplinary approach to maintain the health of the afflicted teeth.[195] Lateral incisors with severe root resorption (not apical) from erupting canines can still be orthodontically moved; and even with a 20% increase in the crown-to-root

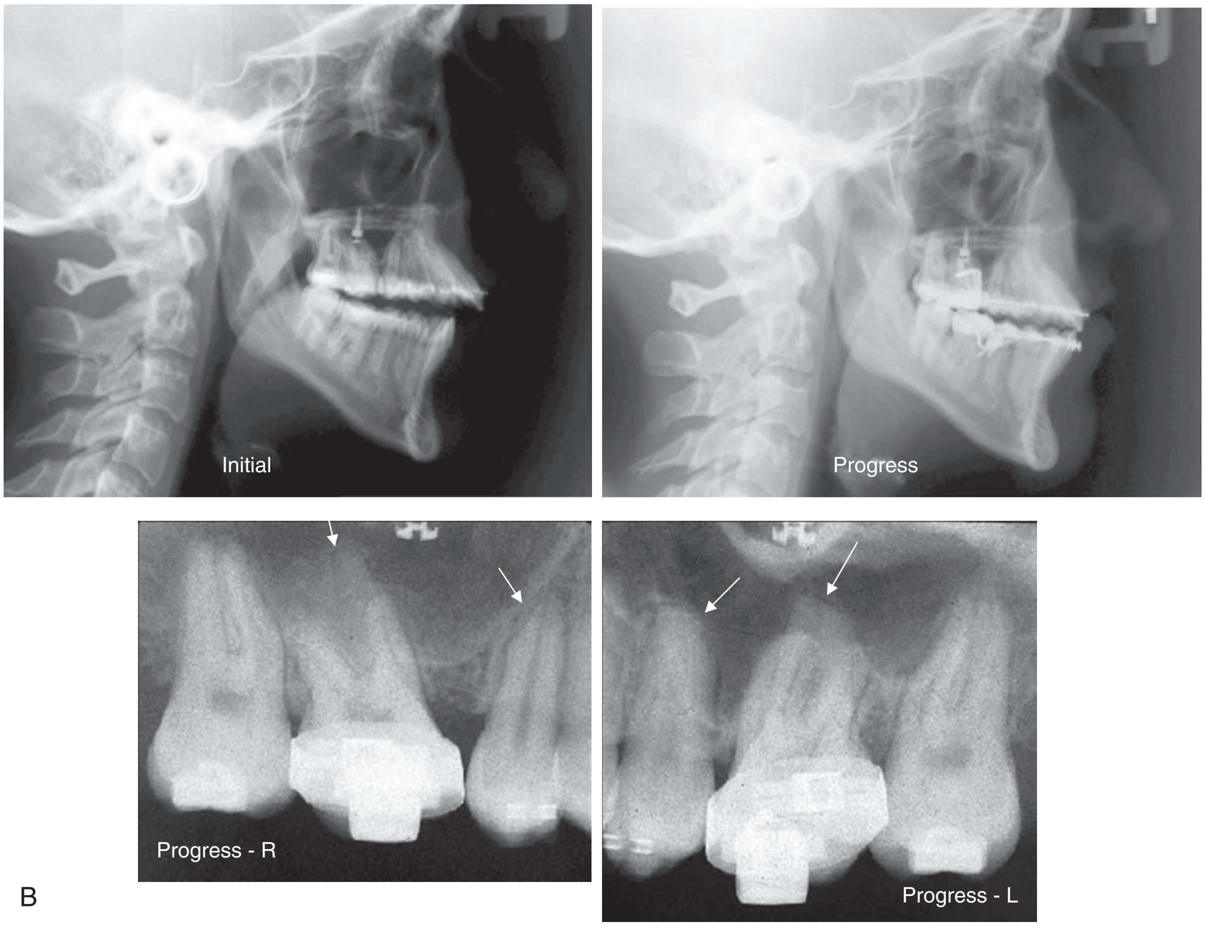

FIGURE 30-21, cont'd B, Molar intrusion to close anterior bite is demonstrated. EARR was detected on the bicuspids and first molars with possible impaction of apices with floor of maxillary sinus. Buccal segments intruded absolutely 2 to 4 mm. No EARR was found on anterior teeth. Case debanded soon after these in-progress periapical images were taken.

ratio, they are stable long term.[196] Jonsson and colleagues evaluated mobility in patients recalled 25 years later and found increased tooth mobility if the root length was less than 9 mm.[197] A single case of severe EARR of all four maxillary incisors treated with fixed appliances was stable 25 years later.[198] However, a prospective study following patients with and without short roots long term has not yet been published.

Finally, the orthodontist must also be aware of an uncommon form of root resorption called *invasive cervical root resorption* (ICRR). Heathersay[199] and others[200] describe ICRR as starting with an inflammatory process that penetrates the cementum from the PDL (thus it is external in origin) apical to the epithelial attachment. The lesion then resorbs the dentin and enamel, generally leaving the dentin surrounding the pulp intact but causing a hollowing of the tooth. The lesion is not visible early unless a radiograph happens to have the correct angulation of the lesion in cross section. Usually the first sign of ICRR is when the clinician notices a pink-appearing crown near the cement-enamel junction (CEJ). This pink hue is due to the granulation tissue filling in the resorbed dentin and enamel under the resorbed part of the crown. The tooth remains vital and asymptomatic. Unfortunately, by the time the patient or dentist notices the problem, enough destruction has occurred that heroic measures must be taken, with extraction often the outcome. The orthodontist must be aware of this; although no direct cause has been proven, orthodontic treatment has been identified as one of the most commonly associated factors with ICRR. Heathersay's classic paper identified eleven potential predisposing factors. Orthodontics was the most common sole factor (47 patients with 62 affected teeth).[199] Trauma was the second most frequent sole factor (31 patients with 39 affected teeth).[199] Other associated factors were bleaching, restorations, and combinations of factors; 33 cases were not associated with any predisposing factors.[199]

Are There Any Methods to Detect Root Resorption before It is Visible on Radiographs?

Many possibilities exists, but, practically speaking, the choices are limited. Methods to detect root resorption are available, but the ability to find markers has been promising and no practical methods have been developed for clinical use. Gingival crevicular fluid (GCF) is an intriguing possibility. Mah and Prasad compared levels of dentin phosphoproteins in the GCF among three groups.[201] They found significantly higher levels in resorbing primary teeth and teeth undergoing active

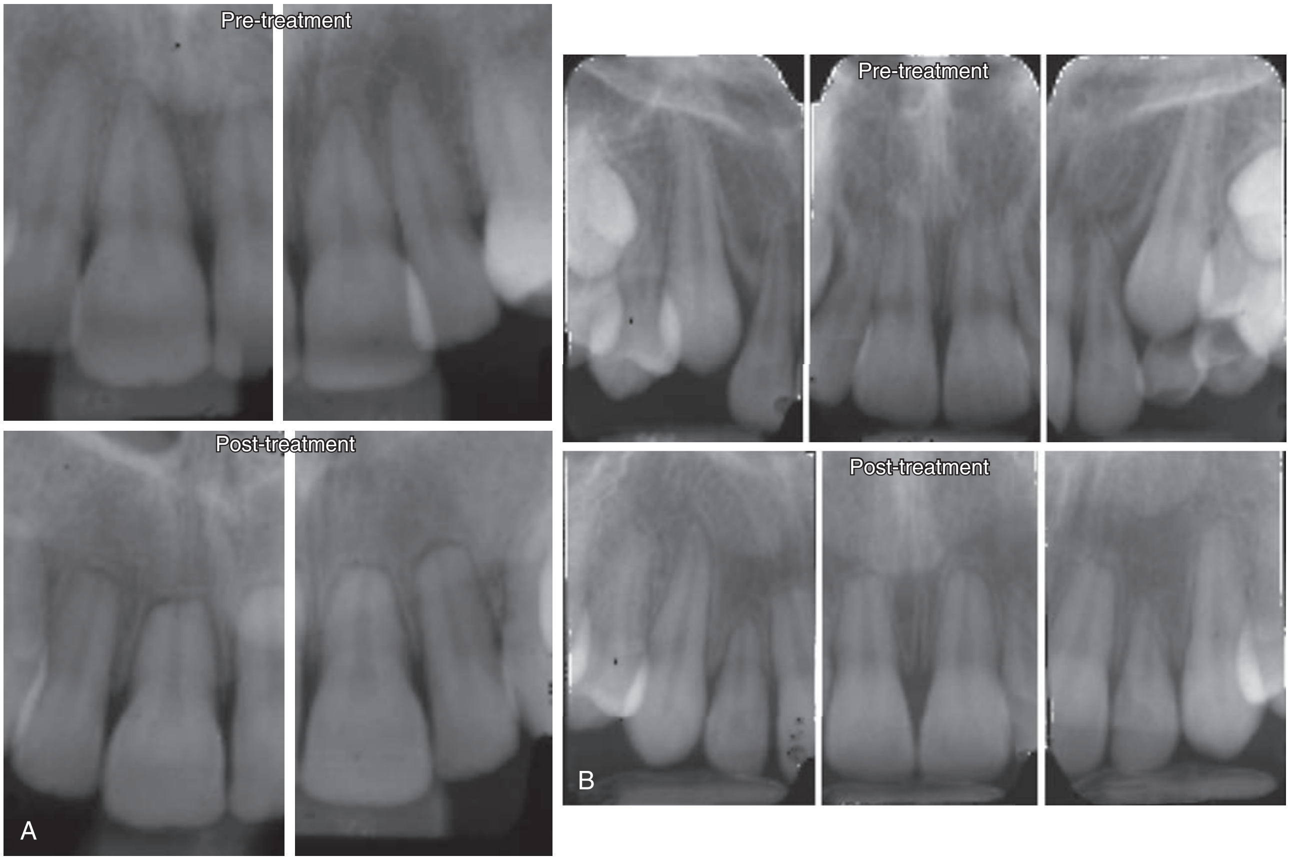

FIGURE 30-22 **A,** An extraction case shows severe root resorption of all four maxillary incisors. Pretreatment risk factors include an older sibling with moderate external apical root resorption (EARR). Female Caucasian, 12 years of age. 4-mm overjet. Normal overbite. Class II, Division 1. Extraction of four bicuspids. Pointed and dilacerated root shapes. Duration of treatment was 33 months. Root apex horizontally displaced 3.5 mm. **B,** A nonextraction case shows severe root resorption of all four maxillary incisors. Female Caucasian, 12 years of age. Negative health history for risk factors. Maxillary left lateral may have preexisting root damage from erupting canine. Nonextraction, deep bite with mild crowding. Extended treatment time. Root apex horizontally displaced 1.5 mm and vertically displaced 2.0 mm.

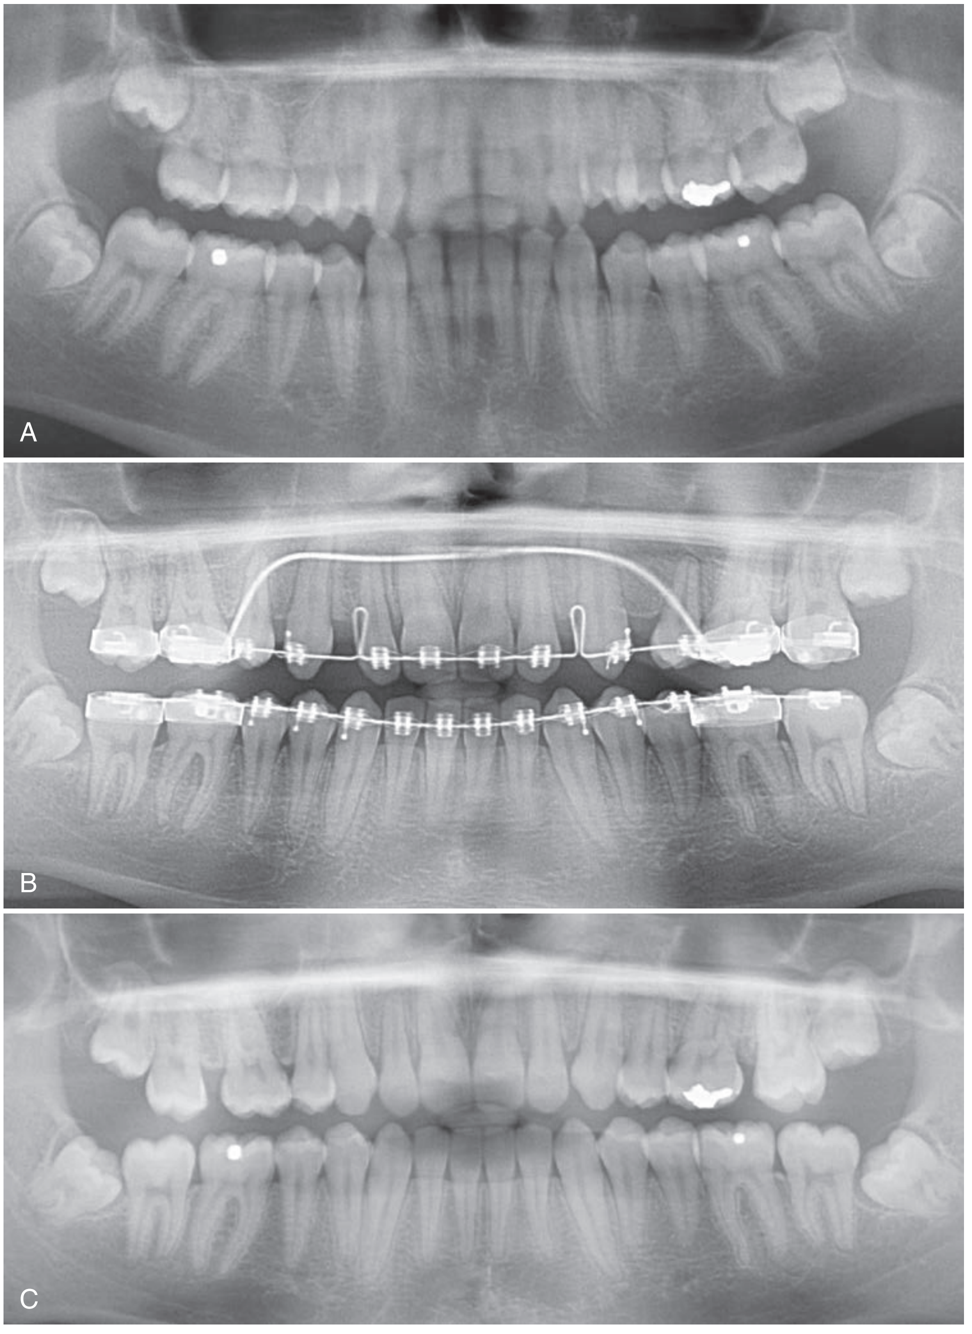

FIGURE 30-23 Management of external apical root resorption (EARR) at progress. When root resorption is found during treatment, the recommended course of action is to stop treatment temporarily. **A**, Initial panoramic x-ray image. **B,** Progress during retraction of incisors; note EARR on all four teeth. **C**, Final panoramic x-ray image. No further EARR is observed. Treatment was stopped for 6 months after EARR was found at progress.

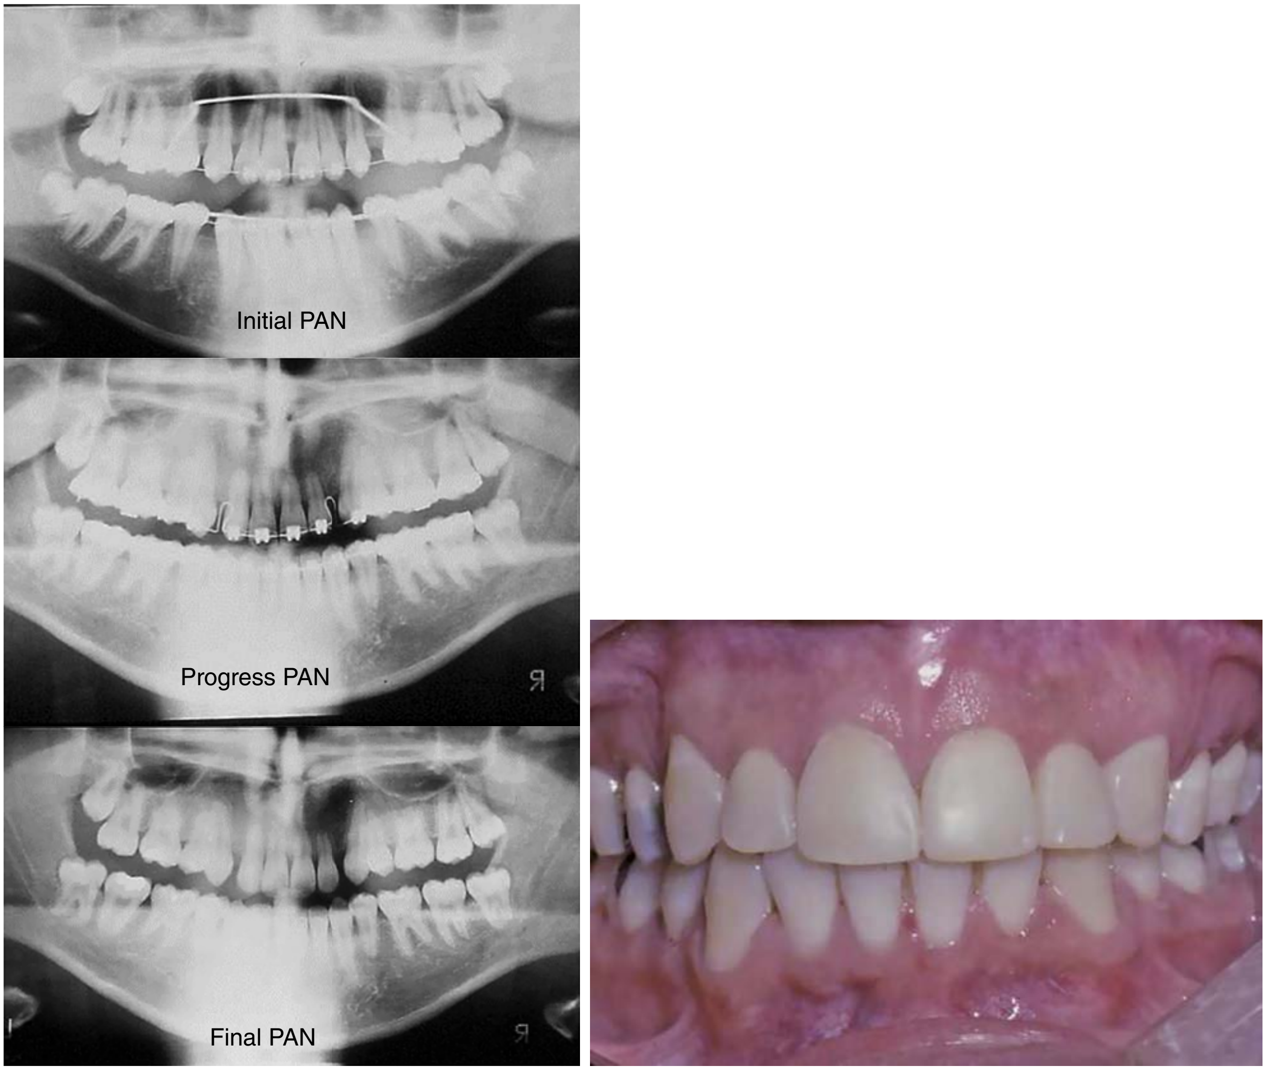

FIGURE 30-24 Management of severe external apical root resorption (EARR) after long treatment time. Initial (*left top*). After 3 years of treatment (*left center*) Final PAN (*left bottom*) and final photos (*right*)–(note restorations). By mutual agreement between the orthodontist and the patient, treatment was terminated; the patient did not want to stop treatment for 4 months then continue.

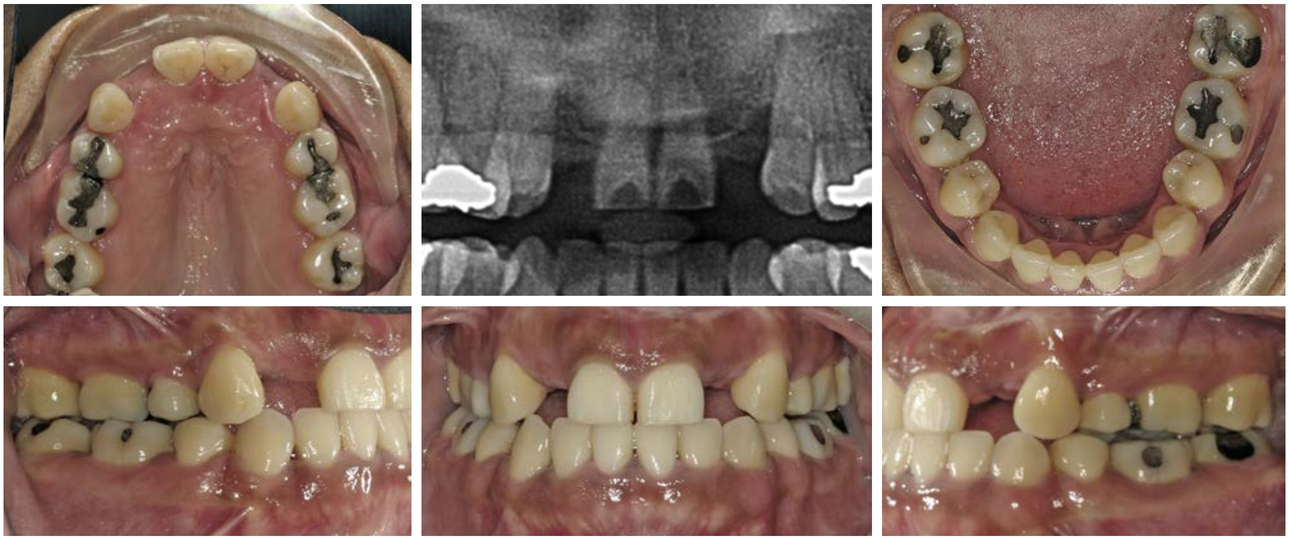

FIGURE 30-25 External apical root resorption (EARR) and implants visualized on posttreatment panoramic x-ray and intraoral images. Patient was seen by a prosthodontist who recommended extraction of the central incisors because "their prognosis was poor." Approximately one third of the root had been lost in 2 years of orthodontic treatment with fixed appliances. No mobility or periodontal problems were present. The patient eventually sought second and third opinions, and a restorative dentist replaced the missing maxillary lateral incisors without incident.

orthodontic tooth movement. Similar findings were reported by Balducci and colleagues.[202] George and Evans examined GCF levels of dentin phosphoproteins and other markers and found differences between teeth in patients with root resorption and a control group with no forces.[203]

There are genes (see previous discussion in this chapter and in Chapter 2) that identify patients at greater risk for EARR, but genetic material can only be obtained from blood or buccal swabs. However, a new method for detecting markers in saliva has been developed at the University of California, Los Angeles (UCLA). If reliable markers for either risk factors or active EARR can be established, then the technology exists to detect them in saliva, which is easier to collect.[204] An interesting study by Ramos showed that levels of a specific immunoglobulin are elevated during pretreatment in patients who subsequently had severe root resorption; someday, this could be another way to test for risk if elevated levels of a specific immunoglobulin can be detected in saliva.[205]

EARR is paradoxical; it occurs in nearly every tooth but is a benign side effect. Severe EARR is rare but can be destructive and affect more than one tooth. The primary risk factors supported by the literature and clinical observation are presented (see Box 30-1). Proper management of EARR should include an assessment of risk factors, taking quality images, and following established procedures if severe EARR is detected during treatment (see Box 30-2). Finally, it must be emphasized that the mere fact of a short root is not cause for the extraction of the tooth and replacement with an implant.

Minimally and Noninvasive Approaches to Accelerate Tooth Movement

Ignacio Blasi, Jr., and Dubravko Pavlin

OUTLINE

MICRO-OSTEOPERFORATIONS*

Introduction

Prolonged treatment time in orthodontics is an undesirable side effect for both the patient and the clinician. Usually, between 2 and 3 years of treatment are required for a case to be properly completed,[1,2] which depends on a variety of factors including the biological response of each individual to orthodontic forces, the complexity of the case, skeletal discrepancies, the amount of dental camouflage of skeletal problems, treatment mechanics, and patient compliance. Regardless of the length of required treatment, it is important to emphasize that a clinician should provide to the patient the best treatment outcome possible. For example, in a case with an excessive overjet and lack of anterior guidance, coupling of the anterior segments should not be compromised because of a prolonged treatment time.

The first of the two fundamental principles in minimizing the length of orthodontic treatment is a proper diagnosis and an individualized treatment plan that includes clear treatment objectives to correct a malocclusion and to provide optimal occlusion without trespassing on the anatomic boundaries and compromising aesthetics, while avoiding any harm to the adjacent tissues. The second principle is an understanding of orthodontic biomechanics, which allows the clinician to develop a sound mechanical plan and to select appropriate appliances to achieve the treatment goals specific for each patient.

In addition to these two basic principles, several approaches have been proposed to accelerate orthodontic tooth movement. These include self-ligating brackets,[3–5] robotic prefabricated wires (e.g., SureSmile, OraMetrix, Inc., Richardson, TX),[6,7] indirect bonding technique,[8–10] low-level laser therapy (e.g., OrthoPulse, Biolux Research Ltd., Vancouver, BC, Canada),[11–15] electrical currents stimulation,[16–19] pulsed electromagnetic fields,[20] piezoelectricity,[21] injections of pharmacologic agents such as prostaglandins,[22–25] Relaxin[26–29] and platelet-rich plasma (PRP),[30] decortication and related techniques (see Chapter 22),[31,32] as well as distraction osteogenesis,[33–35] corticision,[36,37] osteoperforations (e.g., Propel, Propel Orthodontics, Ossining, NY),[38] and low-level mechanical vibration (e.g., AcceleDent, OrthoAccel Technologies, Inc., Bellaire, TX).[39–41] However, limited clinical and scientific evidence can be found for the effectiveness of most of these techniques.[42,43]

Performing micro-osteoperforations is a minimally invasive technique used to accelerate the rate of tooth movement by stimulating the patient's own biologic response as an attempt to shorten treatment time. It can be also used to facilitate and accomplish certain difficult and challenging tooth movements in a more predictable manner. The concept is similar to other surgical techniques, such as alveolar decortication and variations, damaging or traumatizing the cortical alveolar bone to cause a localized inflammatory response and thereby increase the regular bone turnover (the regional accelerated phenomenon[44,45] [RAP]) and increase the rate of tooth movement.

Biological Mechanism

Orthodontic tooth movement occurs in the presence of a mechanical stimulus sequenced by remodeling of the alveolar bone and the periodontal ligament (PDL). Orthodontic tooth movement consists of three phases: (1) initial phase, (2) lag phase, and (3) postlag phase.[46]

The initial phase consists of an immediate and rapid movement and occurs within 24 to 48 hours after the initial application of force to the tooth. The rate of movement is largely attributed to the displacement of the tooth in the PDL space, causing its compression and undermining bone resorption on the pressure side. Bone resorption occurs through osteoclastic activity by creating bone lacunae that will later be filled in by osteoblast cells.

The lag phase lasts 20 to 30 days and displays relatively little to no tooth movement. This phase is marked by PDL hyalinization in the region of compression where the blood supply is cut off. No subsequent tooth movement occurs until the cells complete the removal of all of the necrotic tissues. Once the PDL regenerates,

*Ignacio Blasi Jr.

tooth movement continues. The postlag phase follows the lag phase, during which the rate of movement increases.[47,48]

When tooth movement occurs, the fibers on the tension side are stretched and resist further movement. Light continuous tension causes elongation of fiber bundles and subsequent bone formation mediated by osteoblasts. Osteoblasts are differentiated from the local precursor cells, called *mesenchymal stem cells*. Mature osteoblasts form the osteoids, and the mineralization processes follow.[49] In addition, endothelial nitric oxide synthase (eNOS) and enzyme profiles indicate bone formation in the tension area.[50]

Different cytokines and hormones are involved in the biological mechanism of tooth movement. Tumor necrosis factor–alpha (TNF-α), interleukin-1 beta (IL-1β), interleukin-6 (IL-6), prostaglandin E2 (PGE2), and other inflammatory cytokines can facilitate osteoclastic bone resorption processes[51,52] through activation of the nuclear factor kappa B (RANK) and the nuclear factor kappa B ligand (RANKL). In addition, osteoblastic cells regulate osteoclastic differentiation by synthesizing RANKL.[52,53]

Different cytokiness such as TNF-α levels are increased at the gingival sulcus with orthodontic tooth movement.[54,55] To assess the impact of tooth movement, studies blocking these factors have been conducted and have demonstrated less tooth movement when compared with the control group.[56–59] In an animal study, mechanical forces were applied to tumor necrosis factor receptor (TNFR)-deficient mice to investigate the role of TNF signaling in orthodontic tooth movement. The experiment demonstrated that tooth movement was delayed 6 days after the application of the appliance in TNFR-deficient mice compared with wild-type mice. Therefore these results revealed certain roles of TNF in orthodontic movement, and the assumption that increasing the levels of these factors can accelerate tooth movement is a reasonable conclusion.[60]

In a study in which micro-osteoperforations were performed in combination with orthodontic tooth movement in a rat model, the expression of different inflammatory markers was observed to increase. It was hypothesized that these markers, caused by the micro-osteoperforations, led to increased osteoclast activity and to increased speed of tooth movement (Fig. 31-1, *A*).[61]

Cytokines such as IL-1, IL-6, IL-8, and TNF-α have been proven to be linked with bone remodeling during orthodontic movement.[52] Alikhani and colleagues[38] demonstrated that some chemokines (CCL-2, CCL-3, CCL-5, and IL-8) and cytokines (IL-1, TNF-α, and IL-6) had increased levels during orthodontic tooth movement and that osteoperforations significantly increased the expression of these factors. Their study suggested that the higher presence of these cytokines is related with more osteoclast activity and therefore increased tooth movement (Fig. 31-1, *B*).

Techniques and Indications

The key to success when performing micro-osteoperforations depends first of a proper diagnosis and case selection and second of an appropriate application of the technique.

Micro-osteoperforations and decortication with bone grafting (see Chapter 22) employ the same biological and physiologic principles to accelerate tooth movement. Although both techniques accelerate the rate of tooth movement, they can be used for different treatment objectives. The objective for the first technique is the velocity of the tooth movement or achieving a complex movement; for the second technique, a periodontal benefit could be the principal objective and the acceleration of tooth movement a beneficial side effect. Therefore a careful periodontal evaluation should first be completed in each case.

Micro-osteoperforations involve a less invasive approach than corticotomy. The perforations are performed through the gingival tissues, penetrating the cortical plate (Fig. 31-2). There is no need to raise a mucogingival flap, create any incisions or perform a tissue punch to access the cortical bone. The osteoperforations are performed with a bone screw, which is self-drilling and self-tapping, and no pilot hole is necessary. The Propel device (Propel Orthodontics, Ossining, NY) is a good example. The first-generation Propel device was a single-use, sterile, disposable manual perforator similar in size to a small handheld screwdriver. It had a light-emitting diode (LED) depth stop indicator that illuminated once the desired perforation depth was achieved. The second-generation Propel device has a heavier, balanced metal handle and disposable screw tips with marks to indicate the depth of the perforation. The third-generation consists of a disposable screw tip, an automatic electric torque driver and a contra-angle.

The technique is performed by the orthodontist, requires no surgical instrumentation, and can be performed in a standard dental setting using a traditional aseptic protocol.

Techniques

Knowing and evaluating the anatomy surrounding the tissues of the site to be treated are important; the mandibular nerve and the maxillary sinuses should be located. Palpating and exploring the area for root proximity to ensure safety while performing the perforations are essential. A current panoramic or a cone-beam computed tomography (CBCT) x-ray image might be helpful tool a to verify the patient's anatomy and root location. The oral cavity should be aseptic to diminish the bacterial count on the site to be treated.

Either local infiltrative or topical anesthetic could be used to anesthetize the area. If topical anesthetic is chosen, then the compounded formulas are the best to be used.[62] Profound gel (Steven's Pharmacy, Costa Mesa, CA) is a mixture of 10% prilocaine, 10% lidocaine, and 4% tetracaine. The ingredients in the Baddest Topical in Town (BTT 12.5) (Woodland Hills Pharmacy, Woodland Hills, CA) are 12.5% lidocaine, 12.5% tetacaine, 3% prilocaine, and 3% phenylephrine gel. Before applying the topical anesthesia, the gingiva should be thoroughly dried with gauze to remove the saliva and salivary proteins that can act as a barrier to the medications within the compounded formula. The topical anesthetic should be in contact with the gingiva for at least 4 minutes or until the tissue gets a corrugated look. Local infiltration may be used to numb the patient in a more predictable manner and is definitely the choice for palatal perforations. The area should be tested to ensure numbness.

The osteoperforations should penetrate through the cortical plate into the cancellous bone to ensure trauma to the alveolar bone and to achieve an inflammatory response greater than orthodontic forces alone. The depths of the perforations are dependent upon the soft tissue and bone thickness. A transgingival perforation with a periodontal probe is recommended to determine the soft tissue thickness. Katranji and colleagues[63] reported that the buccal plate of the dentate maxilla and mandible ranged from 1.6 to 2.2 mm in thickness. The average cortical thickness in the maxilla is 2.23 mm in the molar, 1.62 mm in the premolar, and 1.59 mm in the anterior regions. In the mandible, the cortical thickness is 1.98 mm in the molar, 1.20 mm in the premolar, and 0.99 mm in the anterior regions. They found that the thinnest area is in the lower anterior region and the thickest area in the upper posterior region.[63] Although the cortical thicknesses may vary among individuals, the soft tissue

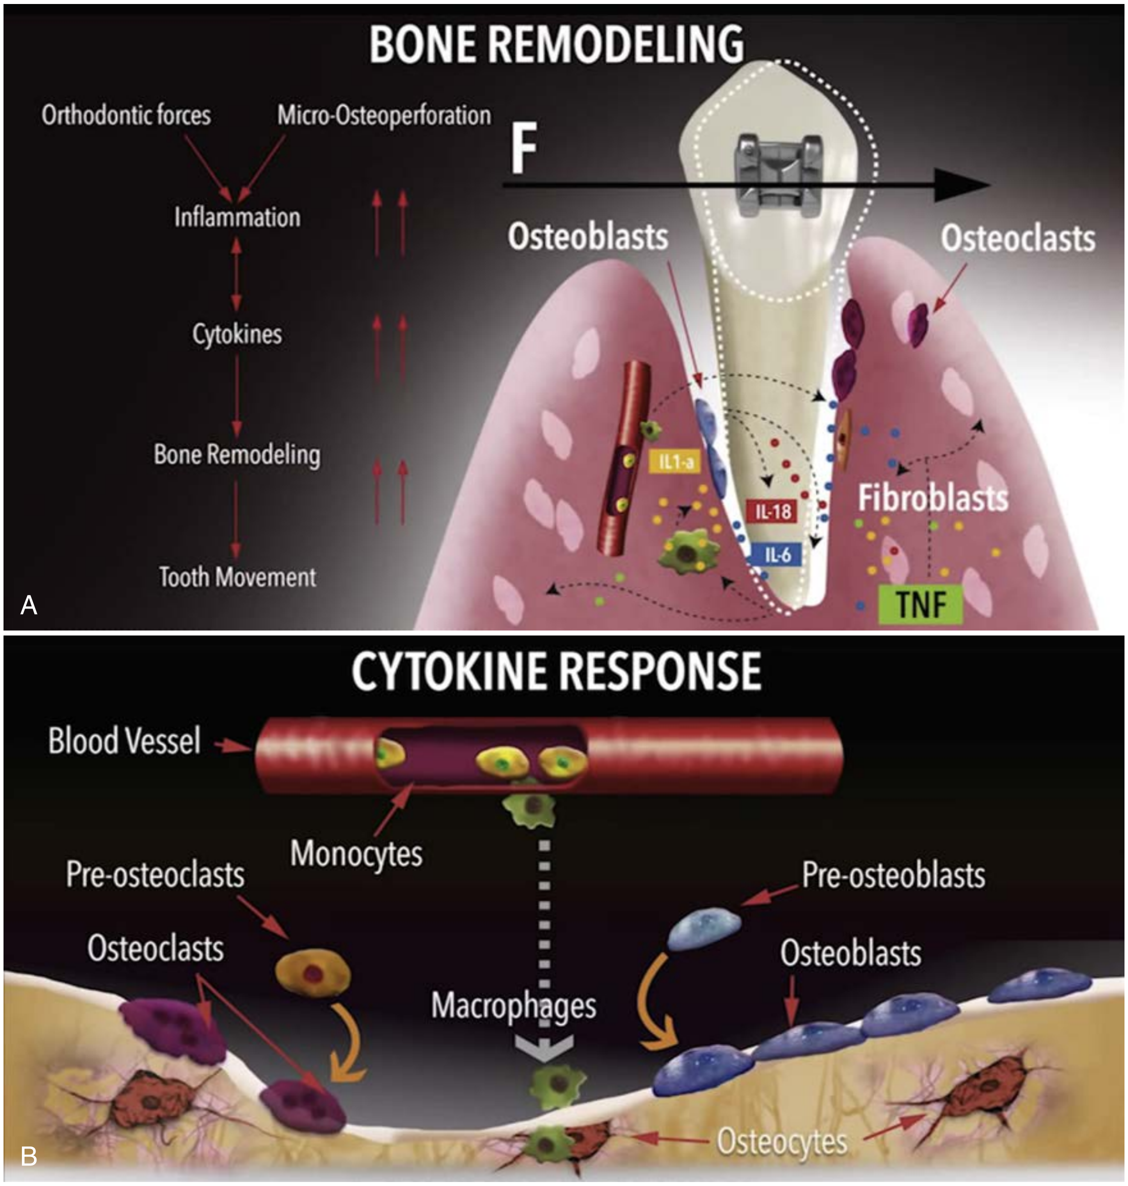

FIGURE 31-1 **A,** Cascade of events occurs with the initiation of tooth movement. (From Propel Orthodontics, Ossining, NY.)

thickness should be assessed and accounted for when calculating the depth of the perforations. For example, if osteoperforations are to be performed in the premolar area with a soft tissue thickness of 3 mm, then the selected length of the screw should be no less than 5 mm. In addition, the clinician may feel less resistance once the cortical plate is penetrated.

Once the depth is calculated, the perforations can be performed through the gingiva in the selected area. The perforations can be made either on the attached keratinized tissue or on the free gingival mucosa.

Ideally, three micro-osteoperforations in each interdental space of the area selected should be buccally and/or lingually performed. However, the practitioner may perform as many osteoperforations as desired. The perforations can be made in a linear or triangular distribution (Fig. 31-3). In the areas where performing three or more perforations is anatomically not possible as a result of root proximity, one or two may be sufficient. A patient could receive either a single micro-osteoperforation application or repeated multiple applications at different times to maximize the benefits of the biological stimulation. Studies have reported that an aggressive technique triggers higher osteoclastic activity and/or lower alveolar bone density, which in turn accelerates orthodontic tooth movement.[30] Therefore one can assume that a series of osteoperforations performed at periodic intervals will maintain a high level of inflammation. Further research is still needed to determine the exact number of perforations and frequency that is adequate to achieve the desired biological response.

Minor bleeding may occur after performing the procedure, especially in the alveolar mucosa. In general, minor discomfort is reported. However, some patients may experience some level of pain around the treatment site. If any discomfort is present, then it should be treated with acetaminophen (Tylenol). Nonsteroidal anti-inflammatory drugs (NSAIDs), such as ibuprofen (Advil), should be completely avoided. NSAIDs may diminish the effect created by the inflammation to accelerate the tooth movement.

Alikhani and colleagues[38] evaluated the effect of micro-osteoperforations on the rate of tooth movement. In this randomized, single-blinded clinical trial, the rate of canine retraction with and without perforations was studied. This trial also evaluated the stimulation of inflammatory markers and the discomfort of the patients during treatment. The sample of 20 patients (ages ranging between 19.5 and 33.1 years) was divided in two groups. The control group consisted of three men and seven women, and the experimental group consisted of five men and five women. Both groups had similar malocclusions (Class II, Division II) and were treated with maxillary first premolar extractions. The retraction mechanics of the maxillary canines consisted of nickel-titanium closing-coil springs activated from a temporary anchorage device (TAD) to a power arm on the canine bracket close to the center of resistance of the tooth. Its activation was delayed 6 months to minimize any inflammatory effect from the extraction procedure. The canines were checked for any occlusal interference that could affect the movement. The experimental group received three micro-osteoperforations distal to the canine on one side only, whereas the control group did not receive any perforations. The rate of canine retraction, measured at 28 days after activation, was a statistically significant (2.3-fold) increase in the experimental side when compared with the control side. Gingival crevicular fluid samples were collected from the canines to evaluate for inflammatory markers. The protein analysis was performed in different time points—before retraction and 24 hours, 7 days, and 28 days after activation. Increases in the levels of cytokines and chemokines analyzed 24 hours in both groups were significant, compared with their baseline values (before retraction). The differences between the two groups were also significantly different, with the experimental group higher than the control group. At day 28, only interluekin-1 was still significantly elevated in the control group and in the experimental group. The difference between the two groups was not statistically significant. Although the patients in this study reported local tolerable discomfort at the experimental site, it did not require additional medication.

FIGURE 31-2 This diagram illustrates the micro-osteoperforation into the alveolar bone. The insertion is performed flapless through the gingiva to reach the alveolar bone. (From Propel Orthodontic, Ossining, NY.)

Indications

Orthodontic tooth movement depends on a multitude of factors, including skeletal pattern of the patient, musculature, occlusal forces, anatomic characteristics of the jaws, and mechanical orthodontic forces.

One important factor is the alveolar bone shape and its density. Lekholm described a classification system of bone and divided it in four categories: type 1 to type 4 (from dense cortical bone to low-density trabecular bone).[64] The mandible generally has denser corticated bone than the maxillae, and in both arches, the thickness of the cortical plate decreases and trabecular space porosity increases moving posteriorly. As the bone density is reduced, the rate of tooth movement increases. For this reason, maxillary molars present a lower degree of

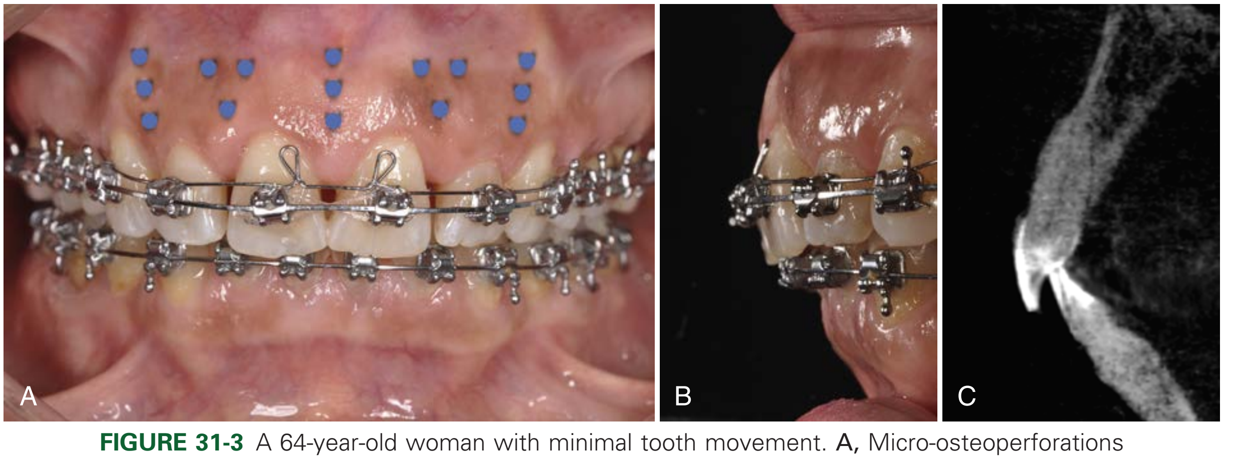

FIGURE 31-3 A 64-year-old woman with minimal tooth movement. **A,** Micro-osteoperforations can be performed in a linear or triangular shape distribution, depending on anatomic limitations. **B,** Note the vertically angulated upper incisors and the torquing auxiliary to upright the root over the alveolar bone. **C,** Cone-beam computed tomography (CBCT) sagittal cut at the level of the upper central incisors shows minimal buccal plate present. Note the root position of the incisor against the cortical plate that may have had an impact on decreasing the rate of tooth movement. In this case, micro-osteoperforations can be buccally performed between the interdental spaces in combination with palatal perforations to accelerate the bone turnover.

anchorage when compared with mandibular molars. A remark supporting this concept is the observation of higher tooth movement in children when compared with adults.[65] Therefore the micro-osteoperforation technique may help surpass these physiologic and anatomic barriers.

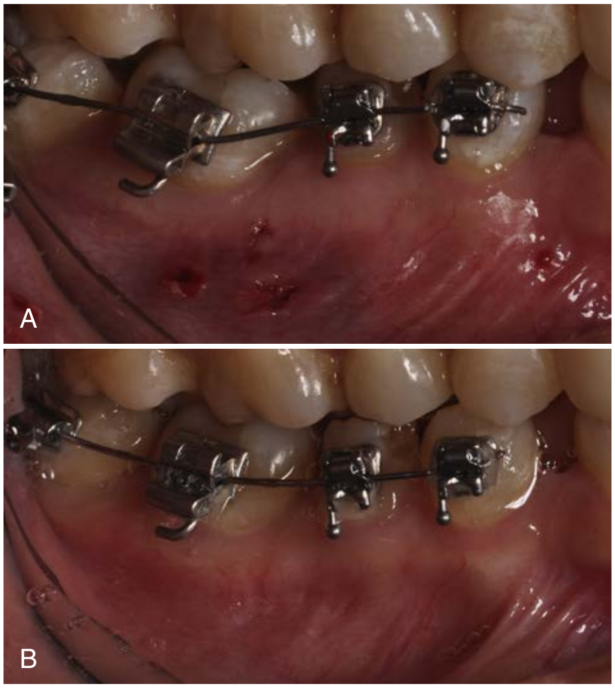

FIGURE 31-4 A, Three micro-osteoperforations were performed between the second premolar and the mesially inclined first molar in the leveling initial phase of treatment. B, The molar was uprighted after one visit. Note healing of the soft tissues.

Orthodontic tooth movement may be problematic when the alveolar width between the buccal and lingual cortical plates is not appropriate to accommodate the complete anatomic dimension of the roots. Consequently, tooth movement through the cortical plate may be reduced and buccal and/or lingual bone dehiscences and/or fenestrations might develop.[66] Therefore a proper periodontal evaluation is crucial (see Chapter 22). Bone augmentation procedures designed to increase the alveolar width in combination with orthodontic treatment are suggested to prevent these undesirable consequences.[67]

Micro-osteoperforations do not change the basal bone and/or alveolar bone. They do not expand the limits of the envelope of discrepancy for the maxillary and mandibular arches; tooth movement is still limited by anatomic alveolar boundaries. Primary indications are to (1) accelerate the rate of tooth movement to shorten the treatment time, (2) facilitate the tooth movement for challenging movements, and (3) modify anchorage.

The technique is contraindicated in systemically compromised patients (American Society of Anesthesiology (ASA) Class III), patients requiring chronic NSAID or steroid prescriptions, and patients in treatment with bisphosphonates. The technique is minimally invasive; however, potential disadvantages include damage to surrounding tissues, root perforation, and potential patient discomfort.

Micro-osteoperforations can be used in many different situations, depending on what is needed for each individual case. The clinician might decide to use this approach in simple cases where crowding and rotations are difficult movements to correct or simply to shorten the treatment time. It could be used during the initial stages of treatment for faster leveling and alignment (Fig. 31-4), during the working stages of space closure (Fig. 31-5), for single or multiple intrusions or extrusions (e.g., to correct a deep bite by intrusion of the lower incisors or to correct an open bite by intrusion of the posterior segments), for protraction (Fig. 31-6) of the dentition to be achieved in

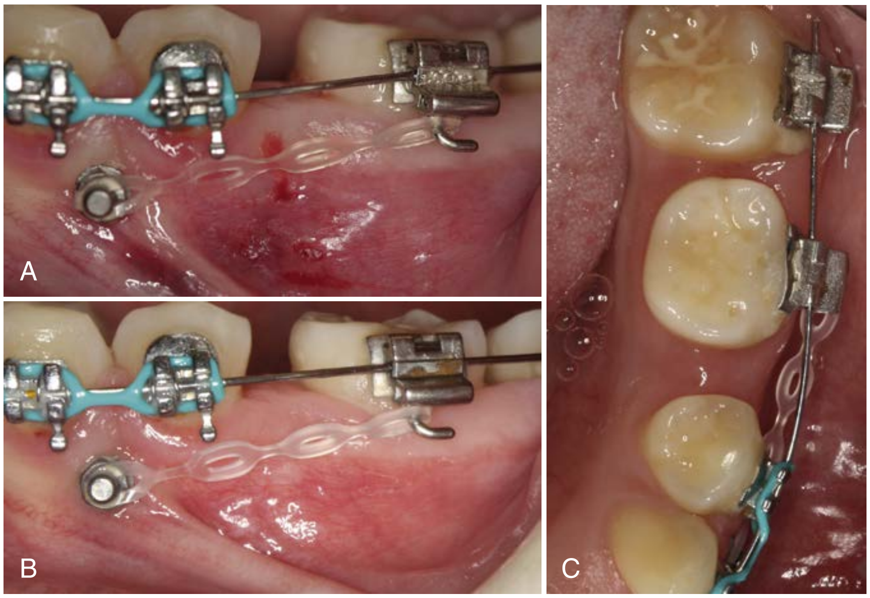

FIGURE 31-5 A, Micro-osteoperforations were performed in a lineal distribution on the open space to accelerate the rate of tooth movement. B, C, Two weeks after the procedure, the tissue is healing within normal limits, and forward movement is being achieved. The beneficial effects of the osteoperforations are accelerating the tooth movement and minimal root resorption of this temporary tooth.

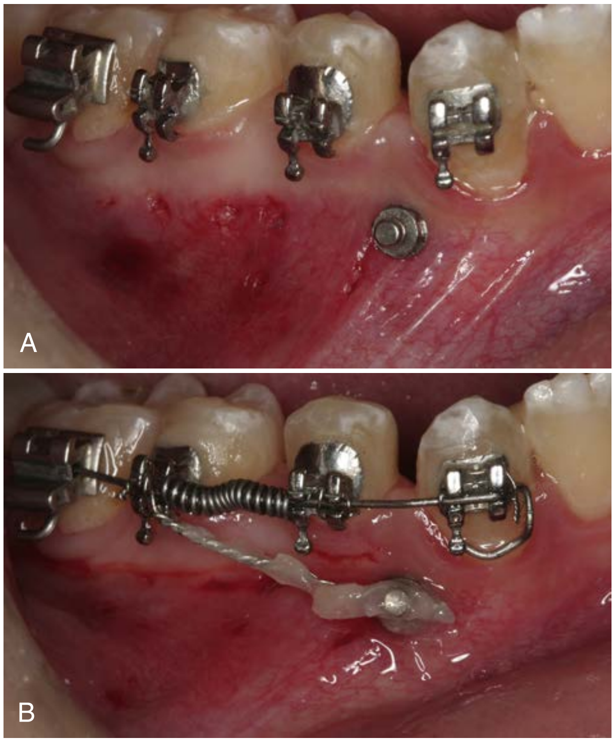

FIGURE 31-6 A, B, Six micro-osteoperforations are made in a triangular shape for protraction on the mandibular segment for faster tooth movement.

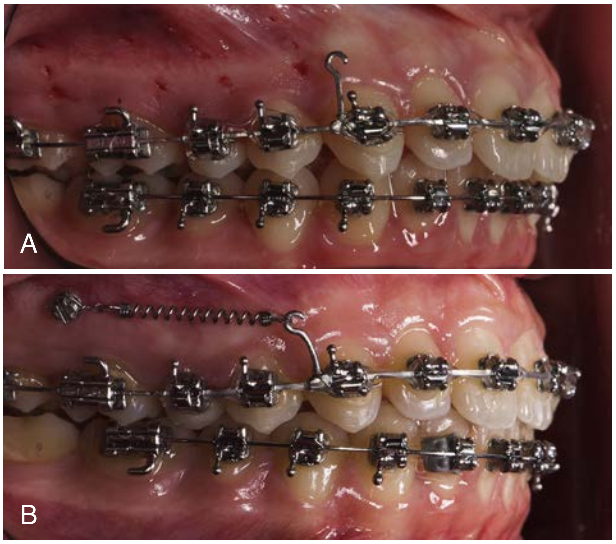

FIGURE 31-7 A 16-year-old female adolescent with unilateral Class II malocclusion and upper midline discrepancy. **A,** Micro-osteoperforations were performed in each interdental space on the posterior segment to maximize the inflammation effects for the challenging movement. **B,** Progress 4.5 months later, with two sessions of osteoperforations. The use of a temporary anchorage device and extraction of the 3rd molar also facilitated the distalization in a more predictable manner.

a more predictable way, and/or for distalization (Fig. 31-7) or mesialization of a single tooth or a whole segment (e.g., a Class II [see Fig. 31-7] or Class III correction). Micro-osteoperforations could be used for any limited treatment or adjunct orthodontics such as molar uprighting. It can be hypothesized that it could diminish the amount of external tooth resorption as a result of the decrease in orthodontic treatment time.[68,69]

In cases where this procedure may facilitate a specific challenging movement, the practitioner should prepare the teeth to get the maximum benefit from the biologic response of the osteoperforations.

In summary, the micro-osteoperforation technique is a clinical approach that can be performed to generally accelerate tooth movement or to achieve a particular movement that is needed in a particular area. Frequent repeated applications (approximately every 4 to 6 weeks until the desired movement is completed) should decrease the treatment time by maintaining a high level of the inflammatory markers that stimulates the osteoblast and osteoclast activity.

Although finishing a case is subjective, there are standards that must be met in every case. Treatment time is an important consideration in orthodontics, but quality should not be compromised for speed.

LOW-LEVEL MECHANICAL VIBRATIONS†

Introduction

A plethora of evidence from orthopedic research suggests that low-level mechanical oscillatory signals (vibrations) have a positive effect on bone metabolism, increasing the rate of remodeling in long bones during adaptation to mechanical loading.[70] This type of mechanical stimulation is currently used as a nonpharmacologic intervention in the prevention of osteoporosis.[71] Results from multiple clinical trials demonstrate that the application of low-magnitude, high-frequency mechanical stimulation causes in an increase in bone density and a decrease in bone loss in postmenopausal women.[72] In addition to clinical trials, animal studies have provided evidence from the cranial suture model[73,74] and long bone periosteum,[75] suggesting that dynamic loading can substantially improve bone formation. Results from a study using a rodent model showed that dynamic vibrational loading increased the rate of orthodontic tooth movement, with no negative side effects on the periodontium and surrounding tissues of the alveolar bone.[76] Loading with a pulsating force for 1.5 hours per day over 3 weeks resulted in approximately 1.3 to 1.4 times greater tooth movement than loading with a static force. However, until recently, clinical evidence concerning the effect of vibratory loading on orthodontic tooth movement was lacking, which prompted several clinical studies discussed in this section.

Clinical Studies

Based on an increasing body of evidence that low-level mechanical cyclic loading results in an anabolic effect on bone metabolism and stimulates remodeling in long bones, vertebrae, and cranial sutures, and that orthodontic tooth movement in rodents is also stimulated by this type of loading, a clinical trial was conducted at the Department of Orthodontics in San Antonio, Texas, to test the effect of vibrations on tooth movement in patients undergoing orthodontic treatment.[77] The objective of this study was to test the hypothesis that low-level mechanical vibration, as an adjunct to standard orthodontic

treatment, has a stimulatory effect on the rate of tooth movement in orthodontic patients treated for 20 minutes per day by the AcceleDent device (OrthoAccel Technologies, Inc., Bellaire, TX), which delivers a vibrational force of 0.25 newton (N) (25 grams) with a frequency of 30 Hertz (Hz) (Fig. 31-8). This study was preceded by a pilot study[78] and followed by two other clinical studies addressing similar topics, which are discussed later in this chapter.

The San Antonio study conducted at the Department of Orthodontics was a prospective, randomized, controlled, double-blind, parallel group clinical trial (described in detail elsewhere)[77]; a brief summary of its protocol and results is provided. The study fully adheres to the CONSORT guidelines and CONSORT 2010 checklist[79] for conducting and reporting randomized clinical trials (RCTs). The power analysis required a minimum sample size of 32, but the final total sample was increased to 45 subjects. Subjects were randomly assigned to a vibration group (n=23, vibration applied using the AcceleDent device) or to a control group (n=22, using a device in which vibration was internally disabled). A third-party vendor provided a computer-generated randomization schedule. One subject inclusion criterion was that the treatment plan required the extraction of the upper bicuspids. All subjects were treated by orthodontic residents under the supervision of one of the principal investigators. In both groups, a routine set of initial orthodontic records, including study models, photographs, and radiographs, were obtained. All subjects were bonded with a 0.022- × 0.028-inch prescription edgewise MBT Appliance System with twin brackets (3M Unitek, St. Paul, MN). Compliance with the device was assessed using a logbook with a daily record form, requiring the subjects to enter the times of initiation and cessation of device use. In both groups, the use of AcceleDent was prescribed for 20 minutes per day from the start of the treatment.

After the initial alignment, a mini-implant TAD (Tomas [temporary orthodontic micro anchorage system] anchorage pin, Dentaurum GmbH & Co., Ispringen, Germany), 1.6 mm in diameter and 9 mm in length, was inserted into the interdental bone between the roots of the maxillary second premolar and the first molar and immediately loaded using a nickel-titanium closing-coil spring stretched between the mini-implant and the hook on the canine bracket to provide a force of approximately 180 grams (Fig. 31-9). To determine the amount of canine movement, the distance between the canine and the TAD was measured before each closing-coil spring activation using a digital caliper placed parallel to the occlusal plane.

The analysis of the intent-to-treat (ITT) sample (n=45) reported that the rate of tooth movement in the treatment group (1.16 mm/month) was higher than in the control group (0.79 mm/month).[77] The rate of movement of the retracting cuspids in the per protocol (PP) sample (the patients in which treatment was finished according to the protocol n=39) was also faster when vibration was applied. Interpretation of the results is more meaningful by focusing on the ITT sample, since after enrollment and randomization, some subjects (6) were withdrawn from the group for various reasons (pregnancy, small extraction space after alignment, loose TADs), which could result in a bias in the remaining PP group.

The secondary outcome of this RCT was to determine the effect of AcceleDent-induced vibration on the rate of initial alignment of lower anterior teeth. This analysis was conducted by measuring the change in the arch perimeter before and after alignment on the plaster models of the lower arch. Because the arch perimeter measurement is not suitable in nonextraction cases, only the patients with extractions were analyzed, which reduced the sample size. Despite that limitation, initial findings indicate that the rate of alignment was increased by approximately 51% in the subjects exposed to vibration.

Results from other outcomes of this RCT were related to patients' safety, comfort, and ease of use of the AcceleDent device. The most significant safety outcome was to determine whether the low-level vibration increases the risk of external apical root resorption (EARR) during orthodontic treatment. Both cementum and bone are the mineralized tissues of the periodontium that can undergo resorption when exposed to a compressive stress during mechanical loading by orthodontic forces.[80,81] The anabolic effect on bone produced by vibratory (cyclic) loading reflects the increased rates of bone resorption and bone formation, thus raising the concern that tooth cementum could be subject to a higher level of resorption when exposed to concomitant stresses from orthodontic forces and vibrations. The root

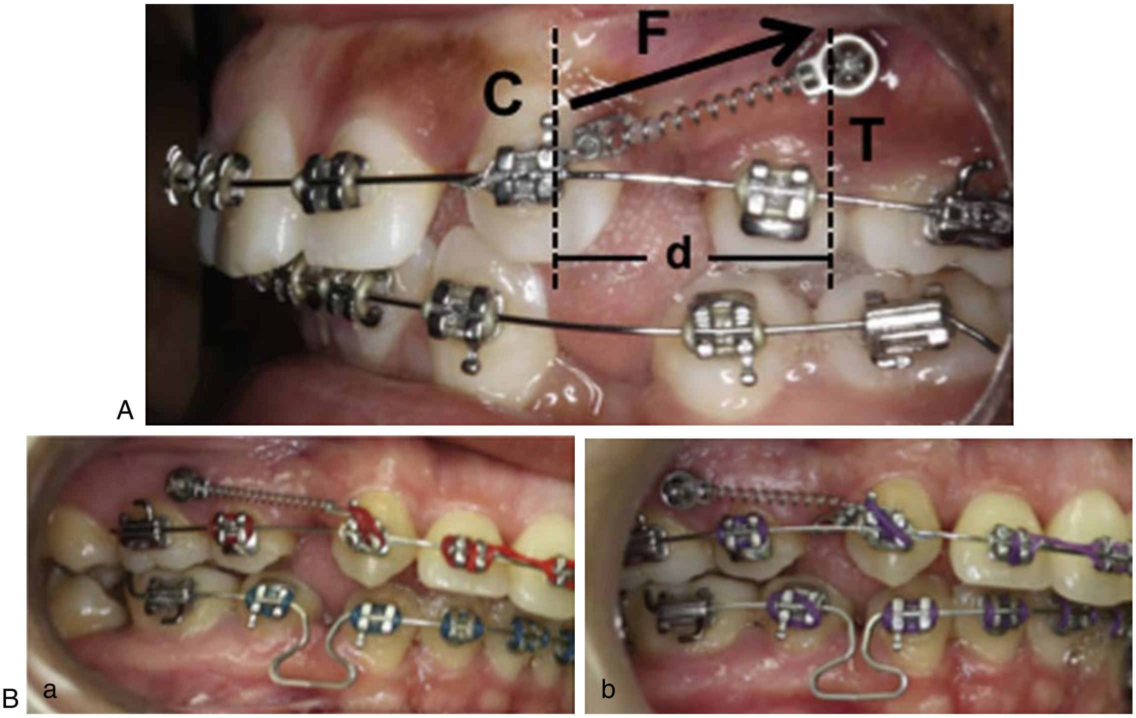

FIGURE 31-9 **A,** Orthodontic appliance for separate canine retraction. *C,* Canine being retracted; *T,* temporary anchorage device (TAD) (Tomas [temporary orthodontic micro-anchorage system] anchorage pin, Dentaurum, GmbH & Co., Ispringen, Germany), 1.6 mm in diameter and 9 mm in length was inserted between the maxillary second premolar and the first molar, under local anesthetic, and immediately loaded; *F,* retraction force of 180 *g* of force, measured by Dontrix gauge (American Orthodontics, Sheboygan, WI) was applied by a nickel-titanium closing-coil spring activated between the TAD and the canine bracket; *d,* distance measured parallel to the occlusal plane using a digital caliper before each closing-coil spring activation or reactivation. An average value from two measurements was entered at each visit; visits were approximately 4 weeks apart. The spring was truncated as needed and re-tied to deliver 180 *g* of force. **B,** Representative example of retraction mechanics for space closure. **a,** The activated closing-coil spring is in place at the beginning of space closure. **b,** One month later, the space opened mesial to the canine.

length analysis was conducted using panoramic radiographs from the subjects participating in the RCT, which were taken in the same laboratory before the start of treatment, at the end of space closure, and at the end of treatment in both the vibration and control groups. Total tooth length was measured using the digital ruler in the Medicor Imaging Picture Archive Communication System (MiPACS, Medicor Imaging, Charlotte, NC). Included were all the teeth from first molar to first molar, except for the first bicuspids because of the variability of root shape. The canines appeared to move predominantly by translation, based on the direction of the reversal lines in alveolar bone adjacent to the root, which represent the areas of the onset of the new bone formation on the tension side of the periodontium. The initial analysis of total tooth length showed no significant difference in this parameter between the AcceleDent device and the sham group at either the end of space closure or the end of treatment, indicating that mechanical vibration as an adjunct to orthodontic loading did not increase the risk of EARR in orthodontic patients.

Several outcomes of this RCT related to the patients' comfort and ease of using the AcceleDent device. The subjects were assessed at each study visit using a visual analog scale (VAS) to evaluate the following parameters: discomfort, hygiene, drooling, schedule disruption, reliability, ease of use, noise, cleanliness and maintenance, and overall satisfaction with the device. The VAS was based on a 100-point scale, and the scores from the control and AcceleDent groups were compared. The initial assessments are showing very similar VAS scores for both groups, indicating that the patients are very satisfied with treatment and the device is easy to use without disruption of their daily activities.

In addition to the RCT focusing on cuspid retraction discussed previously, the increased interest in accelerated tooth movement has resulted in several recent studies that focused on the effect of supplemental vibratory loading during the initial alignment/leveling stage of treatment. Miles and colleagues conducted a randomized trial with 66 patients, using the Tooth Masseuse device[82]. They found no effect on the rate of reduction of irregularity during anterior alignment. They also did not find any difference in alleviation of pain.

Three other studies have been published on the AcceleDent device. The most recent, by Woodhouse and colleagues, was a three-armed randomized trial, comparing AcceleDent with fixed appliances, sham AcceleDent with fixed appliances, and

A

FIGURE 31-10 Invisalign case, courtesy of Dr. Sam Daher. Number of aligners: 52; refinement aligners: 7; total: 59 aligners. Normal treatment time: 59 × 2 weeks = 118 weeks (2 years and 3 months). Treated with AcceleDent: aligners changed as follows: 7 days for initial 52 aligners and every 5 days for the 7 refinement aligners. Total treatment time (actual) was 1 year, 1 month. A: Initial, B: Progress, C: Final.

fixed appliances only[83]. The authors reported no difference in the time to reach initial or final tooth alignment among the three groups. Bowman in a retrospective study, reported a faster rate of alignment in an AcceleDent group, but also stated that the difference was not statistically different[84]. Bowman did report a significantly faster rate of leveling in the AcceleDent group. In addition, Kau and colleagues reported on a group of 14 patients (case series) all treated with fixed appliances and the AcceleDent device. Although there was no comparison group, the authors reported that the rate of tooth movement seen in their study was 2-3 times faster than conventional tooth movement (estimated to be about 1 mm per month)[78] .

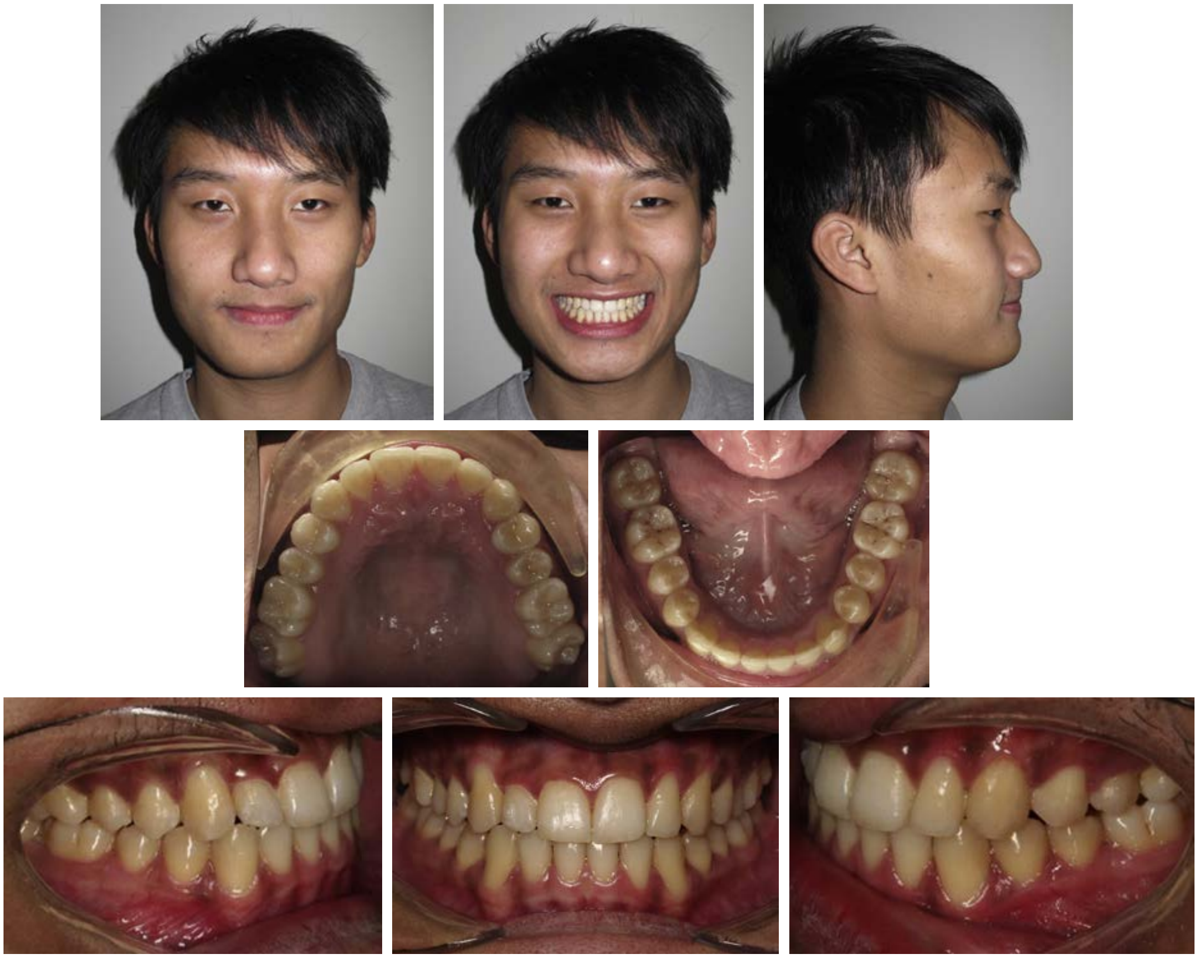
Vibration and Treatment with Clear Aligners

The use of the AcceleDent device as an adjunct to treatment with Invisalign is becoming increasingly popular among the clinicians in the United States and in other parts of the world. Although no clinical studies have been published on this subject, numerous personal reports of practitioners indicate that the treatment time can be cut by 50% or more when the AcceleDent device is used during treatment with Invisalign. The proponents of this approach report that the time for wearing each aligner can be cut down from the prescribed 2 weeks to 1 week or less when vibration is applied. Studies are needed to determine the mechanics underlying such a sharp decrease in treatment time. The fact that the tight contact of the aligner with the entire tooth surface allows a more efficient transmission of vibration to the root and surrounding bone is a logical speculation. Figure 31-10 shows a representative patient with Invisalign aligner trays whose treatment time was reduced by more than 50% with the adjunctive use of the AcceleDent device.

Biological Mechanism of Bone Response to Vibration

The biological mechanism underlying the anabolic effect of cyclic loading on bone metabolism is not fully understood. Several signaling pathways have been implied in the response of bone cells to mechanical loading,[85,86] and further studies are needed to determine which of these pathways is activated by low-level vibrations. Since oscillatory forces, even at the extremely low levels used in this study, are readily transmitted beyond the bone surface and into the deep compartments of bone, the speculation that the initial response occurs in the cells embedded in bone matrix, such as osteocytes, is reasonable.

B



C

FIGURE 31-10, cont'd

Our group and others have previously identified osteocytes as the early mechanoresponsive cells in the alveolar bone during orthodontic tooth movement.[87] As early as 6 hours after the onset of mechanical loading, a surge in the expression of genes for osteocalcin and dentin matrix protein was detected in the alveolar osteocytes. These mechanically induced signaling pathways could be triggered by fluid shear stress in osteocyte lacunae and canaliculi or by piezoelectric potentials induced by bone bending, all of which can occur during vibrations. In addition, bone microfractures, at the level similar to or lower than those exerted by physical activity, may be a contributing factor in the early response to oscillatory loading. Further studies showed that these early mechanoresponsive events in osteocytes are followed by increased differentiation of osteoblasts[88] and stimulation of bone characteristic genes (alkaline phosphatase, type I collagen) in these cells after 24 hours and up to 5 days.[89–90] Because similar signaling and gene regulatory events are most likely involved in response to orthodontic loading of bone with and without vibrations, one of the key questions to be addressed in future studies is whether cyclic loading superimposed on the force systems from an orthodontic appliance produces a faster and quantitatively higher levels of the same types of early anabolic signals or if completely different pathways of signaling and genetic responses are initiated that result in stimulation of bone remodeling and faster tooth movement.

Biodigital Orthodontics: Integrating Technology with Diagnosis, Treatment Planning, and Targeted Therapeutics

Rohit ChamanLal Sachdeva

OUTLINE

INTRODUCTION

The integration of digital technologies in diagnosis, treatment planning, appliance design, construction, and manipulation is changing the manner in which orthodontics is provided to patients. New opportunities for improved treatment, coupled with shorter and more comfortable patient experiences, are now available with these new paradigms. This chapter describes the practice of diagnostically driven, robotic-assisted (DDRA) orthodontics using as the technology example SureSmile technology: a total patient management system (OraMetrix, Inc., Richardson, TX). The foundation of DDRA orthodontics lies in a patient-centered, professional-based care model. The goal of DDRA orthodontics is to improve treatment outcomes continuously by providing targeted personalized care and minimizing variation in all aspects of care delivery and error proofing. Patient care is managed by applying sound principles grounded in conventional orthodontic biomechanics, using SureSmile's integrated digital technology platform and applying unique diagnostic, care planning, and therapeutic strategies developed, in large degree, by the author of this chapter. These strategies are enabled by capabilities that include three-dimensional (3D) imaging, a decision support system, robotic-assisted archwire bending,[1–7] and 3D printing with stereolithography (STL).

CURRENT CRAFT-BASED CARE MODEL

The current practice of orthodontic care may be characterized as *reactive*.[1] It has historically been appliance driven and error prone. Error is seeded early in the treatment as a result of a relatively cursory diagnosis and a limited treatment plan. The therapeutic strategy with the straight archwire approach to treatment relies on the intelligence built into the bracket prescription and its placement. In reality, great variation exists in the prescription of the brackets because of inaccurate manufacturing practices. Furthermore, both direct and indirect bonding bracket placement procedures are fraught with errors driven by perception, lack of reliable global and local reference coordinates (because of differences in tooth morphologic structure), and technique sensitivity. These sources of variations add to the error trap.[2]

Initially, treatment begins with the objective of removing "noise" in the malocclusion through alignment and leveling through a replacement approach—for example, the use of a series of archwires that are progressively changed until a working wire is established. Transition to this archwire generally marks the beginning of the finishing stage of treatment. The choice of archwires and archform by a clinician is commonly based on feel, clinical judgment, philosophic bent, or historical holdover. This approach to treatment adds another layer of complexity to patient care that consists of variation and error.

Generally, finishing begins approximately 1 year into the care cycle. In reality, this is often the error correction phase of treatment, which is managed very inefficiently through reactive processes. The doctor is challenged in managing issues arising from inadequate diagnosis and care planning, vagaries in appliance prescription, and misapplication and mismanagement of therapeutic appliances, all at a time when patient compliance to treatment is at its lowest ebb (Fig. 32-1, *A*, *B*).

This means that for all extant purposes, the patient is essentially placed into a doctor-devised orthodontic "intensive care unit" style of treatment in which the doctor applies every conceivable therapeutic strategy at his or her disposal to *rescue* the patient. This treatment can include bracket repositioning and/or archwire modification through manual bending,* reinforcement of greater patient compliance to wear elastics, or even reconsideration of treatment objectives.

This cycle of reactive therapeutics is driven by the fact that the clinician lacks the tools to validate the robustness of his or her decisions and has little assurance that the bracket repositions or the archwire bends are correct. As a result, the clinician awaits the patient's next visit to assess treatment response to verify the soundness of his or her decisions and the interventions made during the previous visit.

Unfortunately, the time dependency of this response adds another layer of complexity. A judgment has to be made as to when the next patient visit should be scheduled. Typically, at this point, the clinician resorts to following the patient at shorter intervals. The irony of this approach to managing care is that it triggers overuse of therapeutic interventions and invariably disrupts practice scheduling, jaundices the patient's care experience, and negatively affects the patient's lifestyle.

In summary, the current care model in managing orthodontic patients is *craft-based* and *doctor-centric* and is therapeutically driven by personal knowledge that is immune to clinical benchmarking. Customization is handcrafted, which increases the risk of vulnerability to both variation and error in care. Such treatment practices add to high internal costs, increase the care cycle, and place the patient at risk.

PATIENT-CENTERED AND PROFESSIONAL-BASED MODEL OF CARE

Professional-based care is diagnostically driven, proactively managed, and evidence based. The doctor is systems minded and manages care through streamlined processes and the use of appropriate technologies to minimize variation; its goal is to deliver error-proof care. The doctor promotes a generative practice environment with continuous quality improvement initiatives. Finally, the professional caregiver is mindful of waste and seeks to lower internal costs and shorten the care cycle (Fig. 32-2, *A–D*).

INTEGRATED DIGITAL TECHNOLOGY PLATFORM: SURESMILE AND THE ORAMETRIX DIGITAL LABORATORY

Technology

To demonstrate a global integration of technology to assist in patient care, the SureSmile system (OraMetrix, Inc., Richardson, TX) has been selected and will remain the focus of this chapter. There are other systems and some to come that also use some of the concepts articulated herein, but at the date of this publication, SureSmile provides the most comprehensive approach for clinicians, using a wide variety of labial, lingual, and aligner appliances. SureSmile is an integrated series of digital technologies, services, and product solutions that enables the orthodontist to practice a patient-centered, professional-based care model. The hardware technology includes a 3D image acquisition device (Fig. 32-3, *A*) and/or the use of 3D cone-beam computed tomography (CBCT) scans. SureSmile's software solution provides a comprehensive set of utilities that help the practice manage the patient in both the physical and virtual world. The software provides such tools as (1) image management; (2) patient tracking; (3) workflow automation; (4) decision support; (5) prescriptive archwire design and fabrication, indirect bonding trays, and aligner design; (6) outcome evaluation; and (7) patient reports. These tools allow the clinician to diagnose, communicate, plan care, and design prescriptive customized orthodontic archwires, custom removable tooth aligners, and indirect bonding trays (Fig. 32-3, *B*).

Care in the digital environment with SureSmile is entirely managed in a workflow process–driven environment. The orthodontist's care plan is used to create a target setup that, in turn, provides input parameters to drive a six-axis, archwire-bending robot remotely situated from the practice (Fig. 32-3, *E*). Materials such as copper-nickel-titanium (CuNiTi), beta titanium (titanium molybdenum alloy [TMA]), Elgiloy (Rocky Mountain Orthodontics, Denver, CO), and Azurloy (Ormco, Glendora, CA), comprising a range of cross sections (0.16- to 0.19-inch × 0.25-inch) and shapes (round, square, and rectangular), are bent by the robot to accomplish tooth movement prescribed by the orthodontist, with an angular and linear accuracy of 1 degree and 0.1 mm, respectively. Archwires can be for both labial and lingual techniques and for passive fixed retainers. Such versatility offers unlimited control to the doctor to achieve his or her treatment objectives. Furthermore, archwire design is not limited by bracket choice, and brackets can be placed on the labial or lingual aspects, depending on the therapeutic choice. The clinician is free to use any bracket system or prescription. In addition, the clinician can design aligners with SureSmile software and obtain staged models from OraMetrix to fabricate aligners in his or her office. If the doctor prefers, he or she can obtain STL files of their SureSmile patients and have the staged models printed by their preferred laboratory. Last, customized indirect bonding trays can be designed with SureSmile software with the indirect trays printed by OraMetrix.

* OraMetrix has introduced indirect bonding trays to reduce the error of the method. The results of clinical testing suggest that 3D printed trays enable bracket placement with the precision of 3 degrees and .2mm for horizontal and vertical position on labial tooth surfaces.

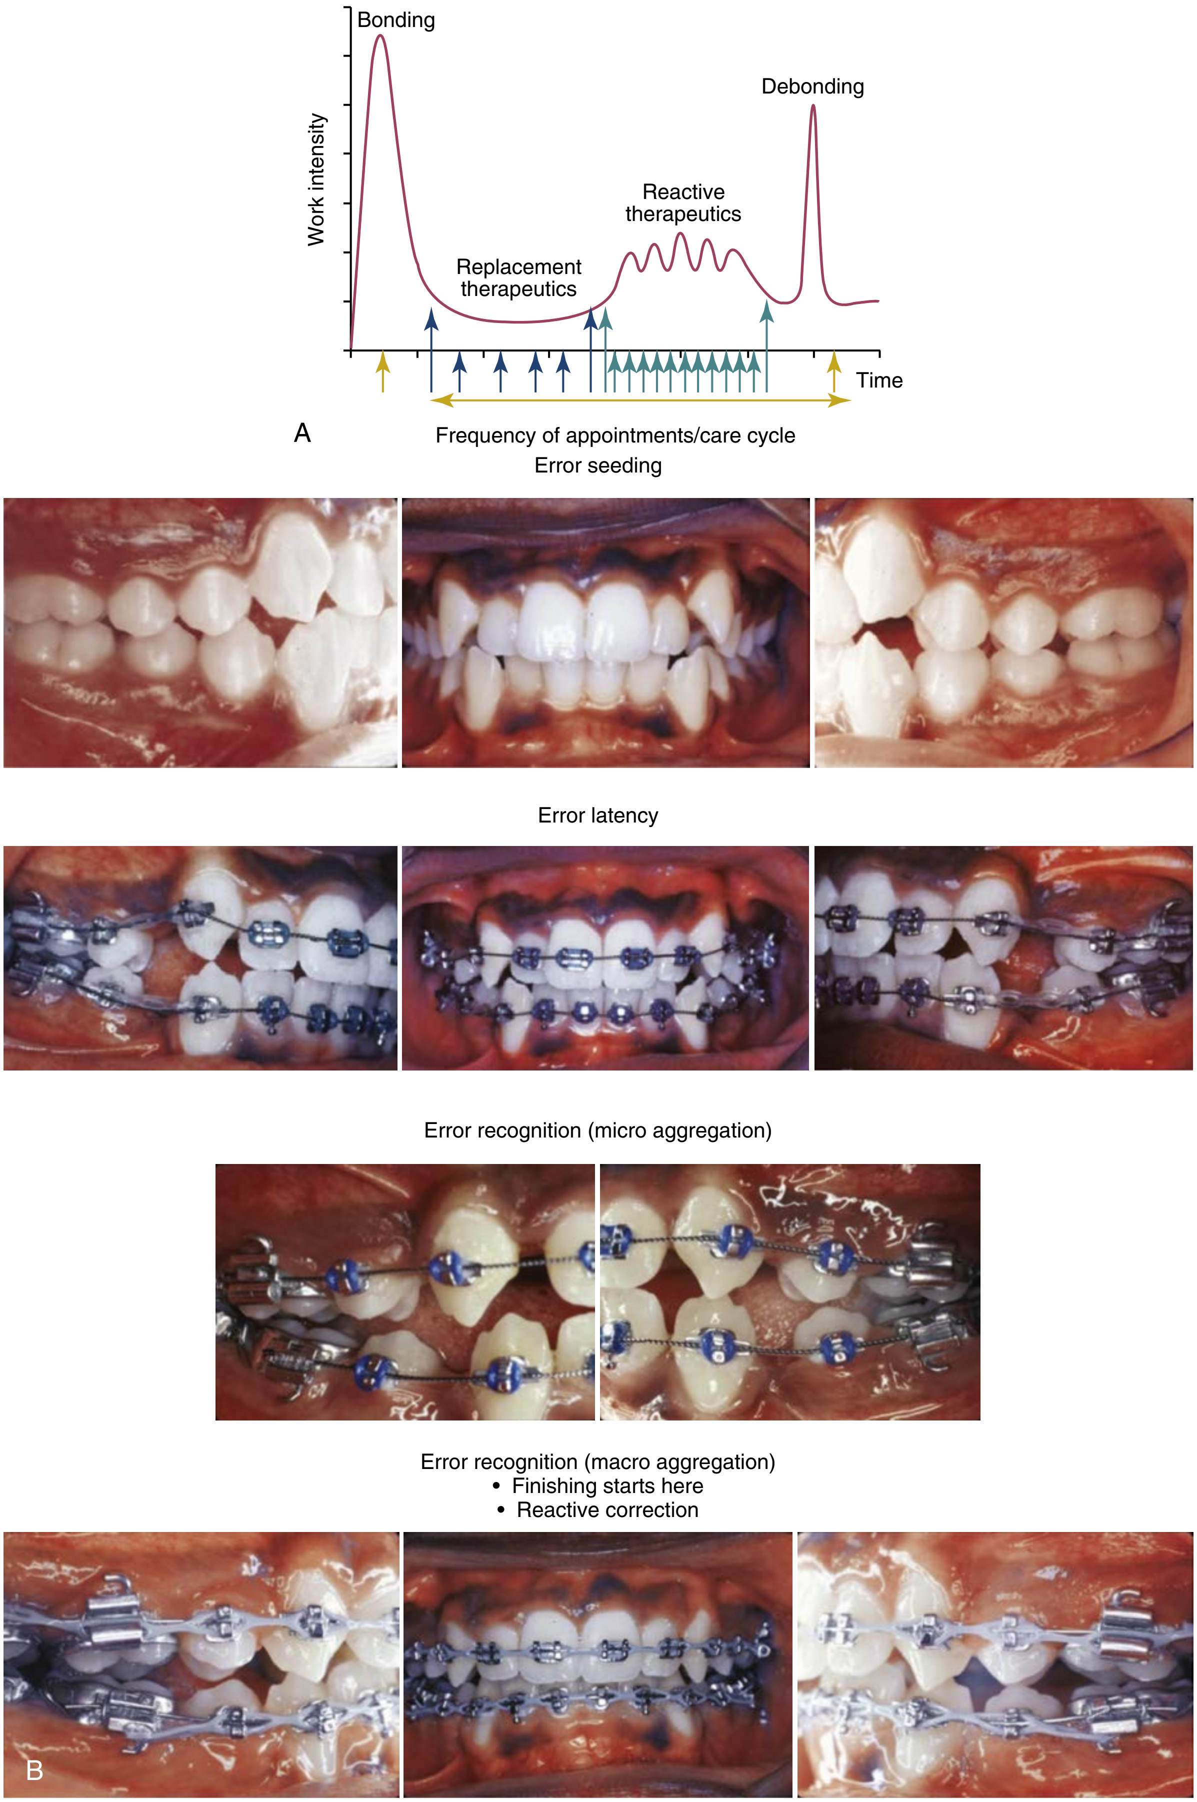

FIGURE 32-1 **A,** Craft-based care model in orthodontics. This stage begins with Replacement therapeutics followed by Reactive therapeutics, which is characterized by high work intensity and appointment density to correct for error. **B,** Finishing stage in orthodontics generally represents the error correction phase of treatment and commonly follows a blunt end path of error (i.e., errors are accumulated over time during the course of treatment).

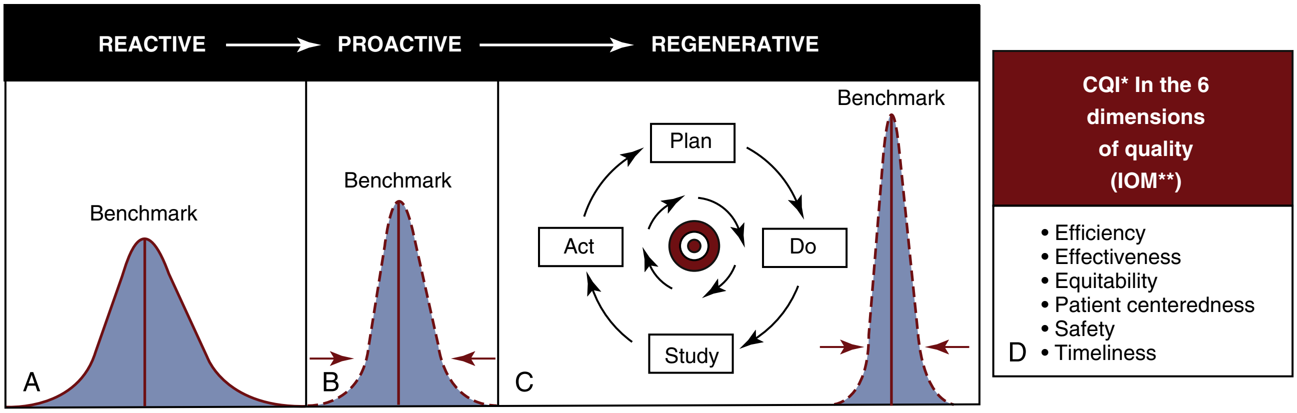

FIGURE 32-2 Practice models. **A,** Characterized by extreme variation. **B,** Characterized by active processes to reduce variation and error. **C, D,** Characterized by proactive management with continuous quality improvement (CQI) initiatives with the goal of continuously improving the six dimensions of quality recommended by the Institute of Medicine (IOM).

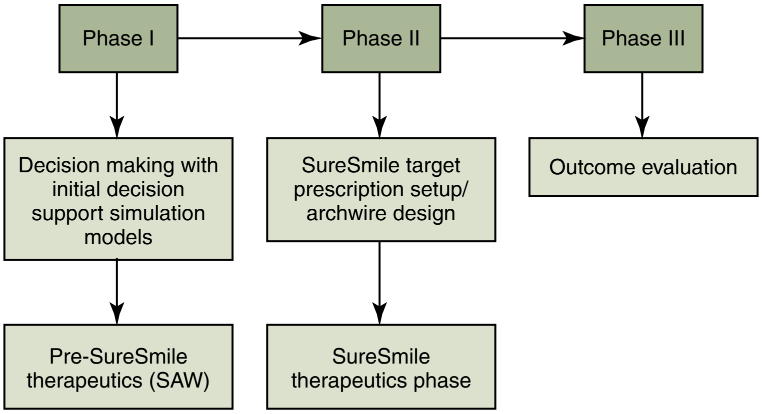

FIGURE 32-4 SureSmile workflow schema. Phase I is characterized by diagnosis, decision making, and managing the patient with straight archwire (SAW) therapy. This is followed by Phase II during which the custom setup and archwire are designed. The patient is managed with SureSmile-targeted personalized archwires. Finally, in Phase III the treatment results are evaluated.

OraMetrix Digital Laboratory and Manufacturing

The SureSmile laboratory is remote to the practice and provides the practice with digital office services. These include (1) modeling all of the 3D images (e.g., the initial pretreatment *diagnostic* models, therapeutic models, and posttreatment final models) and (2) creating the targeted setup based on the orthodontist's prescription. Bidirectional transfer of data between the practice and OraMetrix occurs using a high-speed Internet connection. The customized archwires, indirect bonding trays, and staged models for aligners are manufactured at the SureSmile production facilities and shipped to the practices on demand (Fig. 32-3, *C*, *D*).

SURESMILE IN CLINICAL PRACTICE

This section provides the reader with an overview of the digital integration and process in a technologically advanced practice, described herein using SureSmile. (The discussion in this chapter is limited to the use of SureSmile software tools in the management of patients with the added use of robotically constructed, individually prescribed archwires. Other technologies are commercially available that may also integrate computer-assisted treatment planning and appliance fabrication using some of the principles discussed herein.) SureSmile protocol can be conveniently divided into three distinct phases as shown in Figure 32-4.

Pre-SureSmile Therapeutic Phase: The Digital Diagnostic Model

The integration with the digital diagnosis and treatment planning starts with the consultation appointment and collation of a patient's diagnostic records. These include the patient's chief complaint and medical, dental, and orthodontic history. Records such as extraoral and intraoral photographs and cephalometric and panoramic or CBCT radiographs and models are taken to supplement the clinical findings (Fig. 32-5, *A–C*).

The orthodontist can create a digital diagnostic simulation (DDS) model to use for decision support during care planning. The DDS model can be created by scanning the rough pour of a patient's plaster model with the OraScanner. In addition, a direct in vivo CBCT scan of the patient can be processed to create the DDS model or a physical model scanned with CBCT. Digital models from other vendors in the STL format can also be used and converted into SureSmile DDS models.

The scan of the models is electronically sent to the digital laboratory for modeling. The laboratory sets the global orientation (position of the maxilla in space) and bite registration of the model and separates each tooth into an individual object to allow simulations of individual teeth (Fig. 32-6; see also Fig. 32-5).

The DDS model represents a virtual model of the patient's malocclusion with movable teeth (Fig. 32-7, *B*). The models can be used for 3D visualization and measurement; for example, the physician can perform a Bolton analysis and a dynamic arch length discrepancy by affecting the boundary conditions and also measure the American Board of Orthodontics (ABO) Discrepancy Index. All of these functions are automatically performed with the software (Fig. 32-7, *A–D*).

Decision support with 3D simulation allows the doctor to validate his or her mental model of the patient's treatment plan. The clincian can rapidly simulate multiple treatment scenarios to establish proactive treatment strategies and achieve efficient and effective orthodontic treatment (Fig. 32-7, *E–H*). The DDS model serves as an excellent interactive visual communication tool to discuss the patient's needs and treatment plan. Furthermore, consults can be given in a virtual environment with all stakeholders remotely located by using third-party Web-based collaborative tools such as GoToMeeting (www.gotomeeting.com).

The DDS model may also be used for planning strategic bracket placement (especially important in lingual treatment). Once the initial plan is complete, therapy for labial appliances begins with a conventional straight archwire. There are a number of reasons for this. It fits well within the practice workflow, and some initial alignment of the teeth allows for easier insertion of the customized SureSmile archwires later, minimizing the risk of tooth-wire and/or tooth-bracket collisions and in regions of severe crowding between the bends in the archwire and brackets. The use of additional therapeutic strategies such as constraint management and concurrent mechanics to help achieve more effective and efficient alignment and leveling with

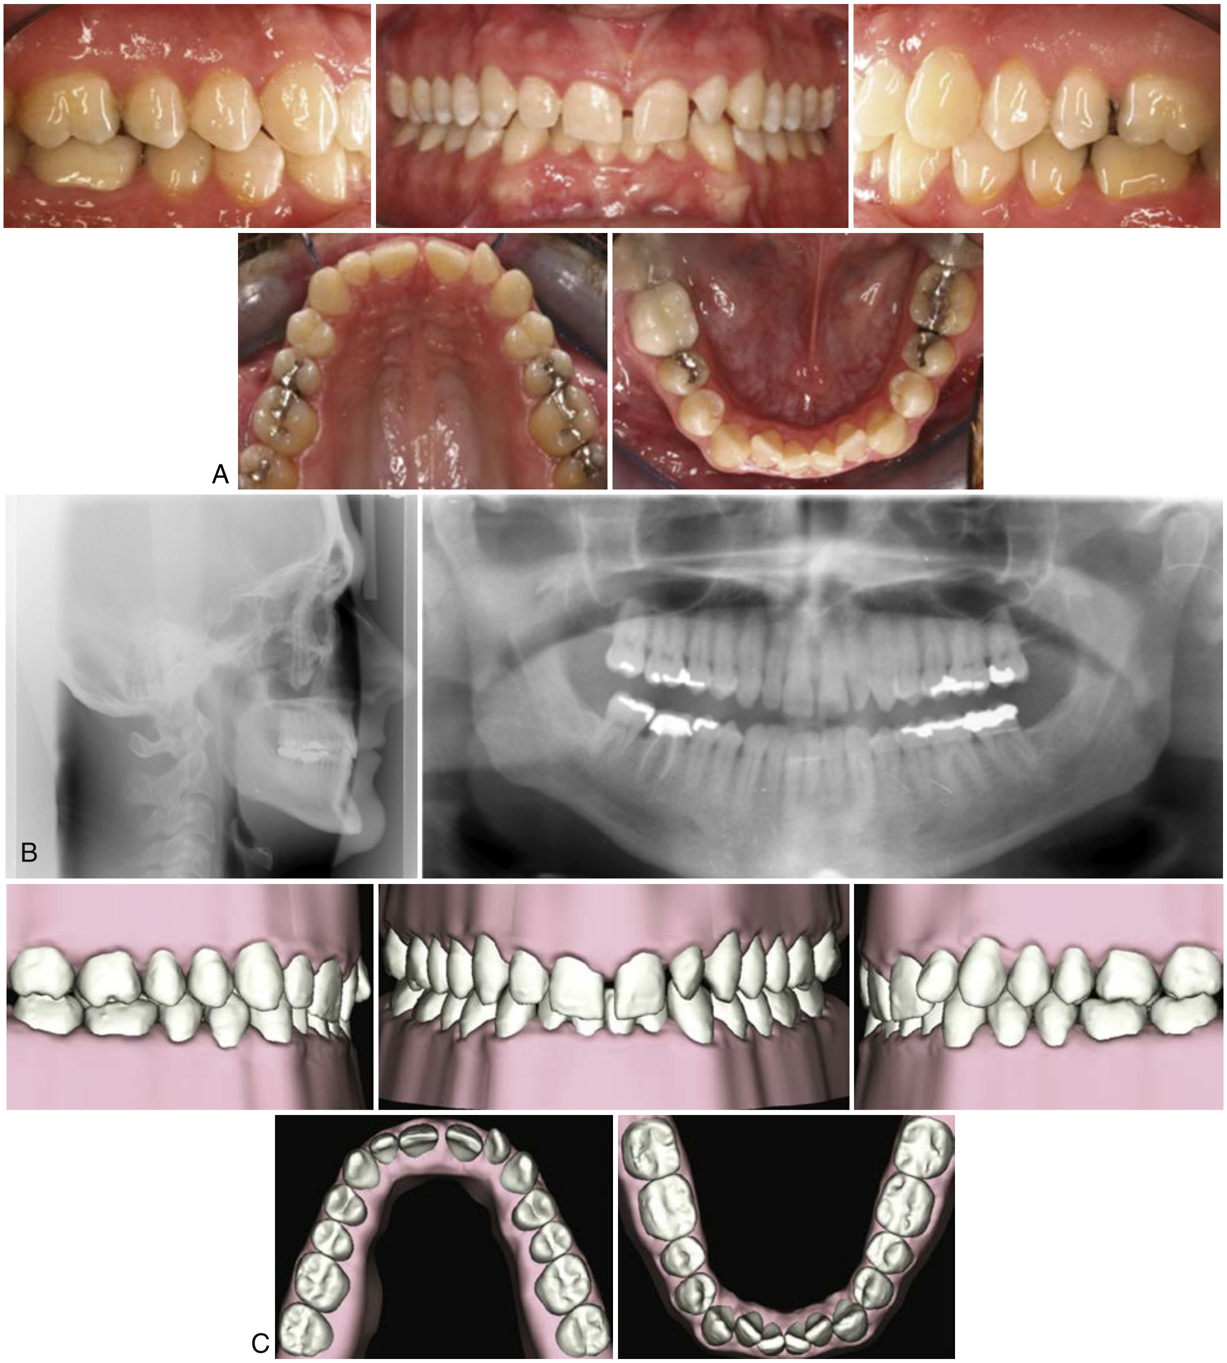

FIGURE 32-5 A, B, Initial SureSmile patient electronic record consists of a standard collage of the patient's two-dimensional images. C, Three-dimensional digital diagnostic simulation (DDS) model.

earlier torque control is also recommended to optimize treatment efficiency (Fig. 32-8, *A-E*). These approaches are discussed in detail later in this chapter. Generally speaking, for most types of malocclusions, the pre-SureSmile therapeutics phase does not exceed 6 months. However, with appropriate patient selection, an experienced clinician can start treatment with SureSmile-customized archwire from the start of treatment or very soon thereafter, which requires following the fast-track clinical pathway (Fig. 32-9).

SureSmile Therapeutic Phase

The SureSmile therapeutic phase is immediately triggered after initial alignment and leveling have been achieved, and the intra-arch form has been partially established. In a normal premolar extraction case, approximately 4 mm of extraction space should be closed before using SureSmile. Sagittal corrections can be performed either before or concomitantly to using SureSmile.

An in vivo scan is taken of the patient to capture the current 3D positions of the dentition and the brackets. This scan is called the *therapeutic scan* (see Fig. 32-8, *B*). The SureSmile intraoral scanning device (OraScanner or other OraMetrix-accepted scanner) or CBCT may be used to capture the therapeutic scan. The choice of using either of the technologies is determined by the doctor's preferences and abilities and the patient's needs.

The OraScanner uses structured white light to capture the image of the dentition and therefore poses no radiation risk to the patient. Image capture with an OraScanner is not sensitive to patient motion. An OraScanner does not capture root position but displays gingival tissue and has a higher resolution range of 30 to 50 microns (see Fig. 32-8, *C*). At this publication date, the iTero Element Scanner (Align Technologies, Santa Clara, CA) and TRIOS (3Shape) may also be used in lieu of the OraScanner.

Image acquisition with CBCT takes less than 10 seconds at a voxel size of 0.2 mm and is extremely sensitive to patient motion. Furthermore, although the root's position can be captured, the gingival tissue cannot be visualized at this point.

Once captured, the therapeutic scan is sent to the laboratory for postacquisition processing. The laboratory technician sets the global position and bite registration of the model, based on the submitted photographs and radiographs. The teeth are separated to create individual objects. The captured bracket image on the therapeutic scan is matched against 3D-bracket templates of the doctor-prescribed bracket, and the brackets are precisely registered on individual teeth in space with an accuracy of 10 microns (see Fig. 32-8, *D*). The therapeutic model is then electronically shipped to the practice (see Fig. 32-8, *E*). The orthodontist then orders an individualized setup prescription.

The clinician can use the therapeutic scan to evaluate treatment progress by best-fit registration on the diagnostic model

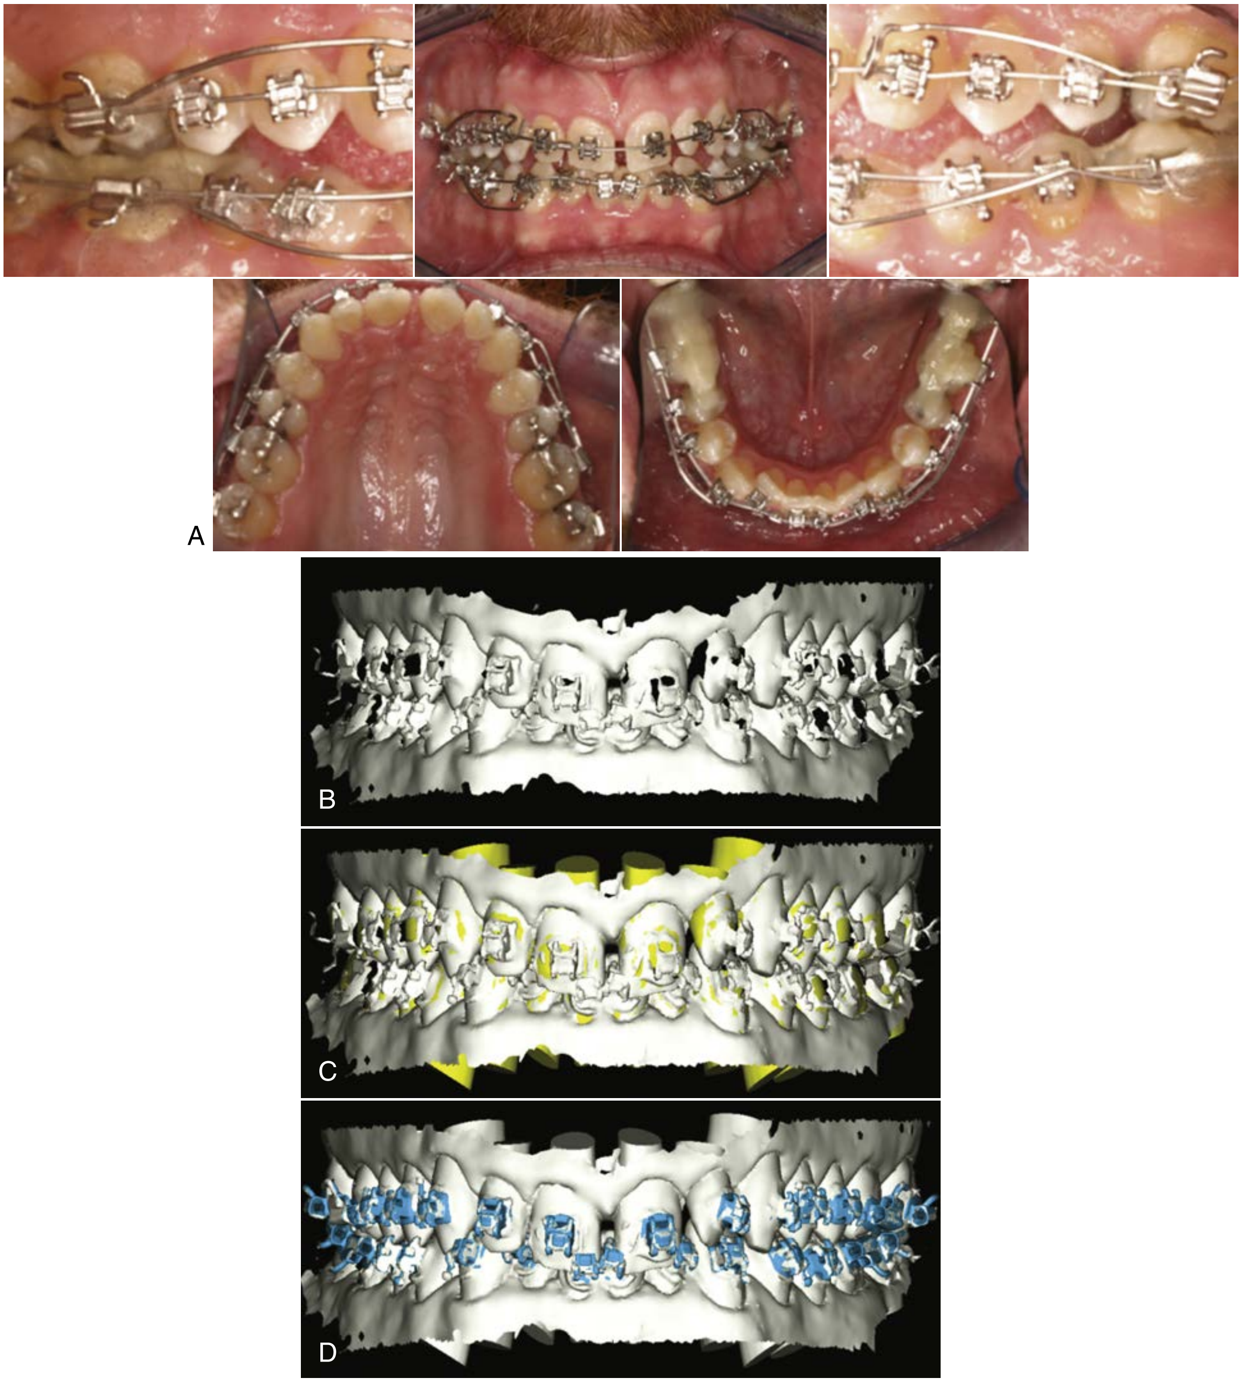

FIGURE 32-8 Intraoral images and corresponding therapeutic model. **A,** Initial pre-SureSmile therapeutics 17- × 25-inch copper-nickel-titanium (CuNiTi), 17- × 25-inch titanium molybdenum alloy (TMA) tip back springs helps arch leveling and posterior bite turbos to prevent interarch tooth collisions. **B,** Therapeutic raw scan data are demonstrated. **C,** Raw scan with tooth template is used for void filling. **D,** Bracket registration is visualized on a raw scan.

FIGURE 32-9 **A–D,** Full expression archwires (100%). In this patient, a full expression 17- × 25-inch copper-nickel-titanium (CuNiTi) archwire was used from the beginning (9/24/02) to the end of treatment (8/15/03). This is an example of a fast-track clinical pathway.

FIGURE 32-9, cont'd

and assess how the straight archwire has worked. The therapeutic model is used to establish the setup prescription (Fig. 32-10). A number of approaches are used to provide this prescription; these include clinician notes, a 3D simulation, and/or filling a prescription form. The choice is driven by the doctor's preference and consideration of the most effective way for the orthodontist to communicate with the laboratory technologists regarding the particular needs of the patient and the goals for treatment. A combination of approaches is usually used.

The prescription for the setup model is driven by considering six boundary conditions. The first letters of each of these boundary conditions form a memory mnemonic MACROS: (1) location of the **M**idline, (2) **A**rchform type, (3) **C**lass of occlusion, (4) choice of **R**eference teeth (i.e., the tooth positions that the clinician wishes to maintain), (5) **O**cclusal plane (commonly the aesthetic), and (6) **S**pecial instructions, which may include instructions such as the need for preferential spacing for restorative purposes and amount of interproximal reduction (IPR) permitted, among others. Additionally, the doctor can set elastic boundaries to allow a range of tooth movements based upon a professional assessment of the biologic constraints (see Fig. 32-10).

The setup prescription is electronically submitted to the laboratory, and the completed digital prescriptive setup is then returned to the practice. The clinician uses an editable checklist to evaluate the setup, complemented with a grading and measuring system (the doctor may choose to use the ABO objective grading system [OBG] and/or other systems). This detailed review of the setup model is critical to the success step in the management of the patient since the setup design directly affects the archwire prescription and represents the treatment goal (visualizing the end to develop the means!). The clinician can make or request the laboratory technologist to make changes in the setup (Fig. 32-11, *A-D*), but the overall treatment plan and plan of treatment are determined as a result of the orthodontist's specific patient prescription.

Tooth displacement with respect to the treatment setup and the working design of the prescriptive archwire(s) is also evaluated (Fig. 32-12, *A-B*).

Once the prescriptive setup is accepted, the orthodontist focuses on the archwire design. This phase includes design modifications such as setting limits of archwire expression and staging archwires, adding expansion or curve of Spee, overcorrection or limiting archwire bracket play by adding additional

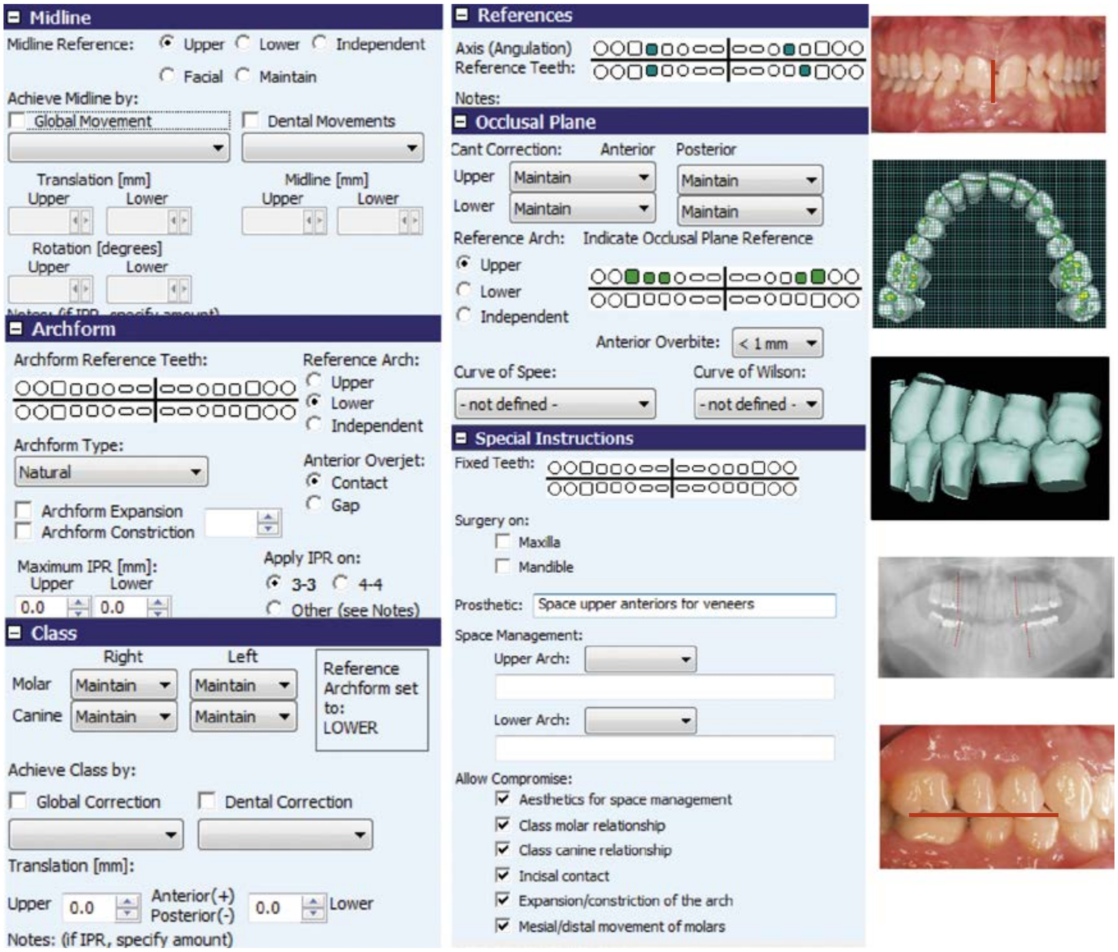

FIGURE 32-10 Electronic prescription form. The doctor fills in the form using a workflow-driven checklist using MACROS (Midline, Archform, Class, Reference teeth, Occlusal Plane, and Special Instructions) and can also set elastic boundary preferences (i.e., range of acceptable treatment limits).

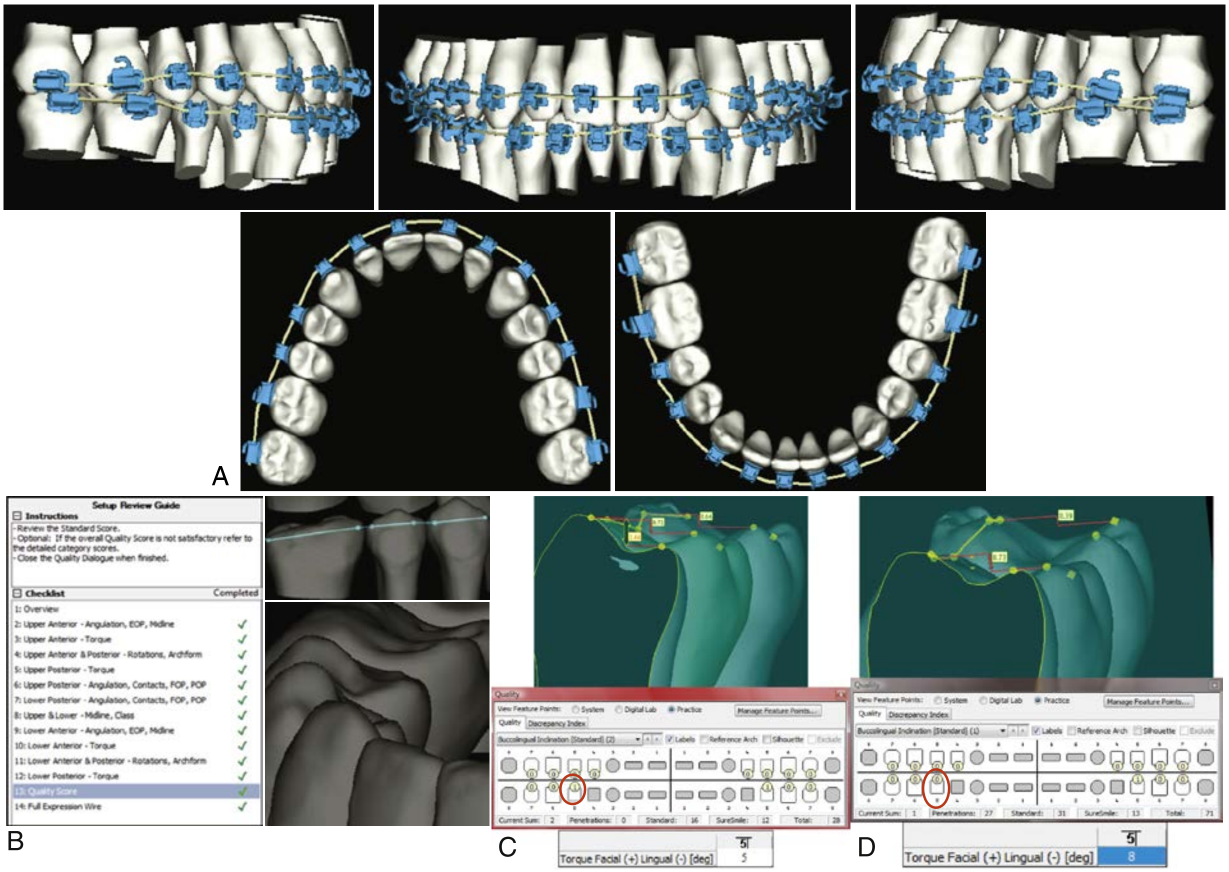

FIGURE 32-11 **A,** Target setup, based upon the doctor's prescription. **B,** Practice-based checklist. **C, D,** Measuring and grading tools to evaluate the setup. Modifications can be made at practice site.

torque in the archwire, and choosing archwire material and cross section.

This capability offers the clinician a wealth of therapeutic strategies to control tooth movement. (How these are used is discussed later in this chapter in greater detail.) Optimal archwire installation strategies can be simulated to minimize any archwire bend-bracket collisions on insertion or during tooth movement. Modifications of archwire design in terms of location of wire bends can be also made to minimize this occurrence (Fig. 32-13).

After the submission of the archwire prescription, archwires are fabricated in the OraMetrix laboratory, and the practice is sent the prescribed customized archwires. Before shipping, all archwires are scanned with a special laser scanner to measure the accuracy and precision of the archwire bends. Archwires are measured to an accuracy of 20 microns. This procedure is one of many steps instituted by the manufacturing facility to minimize errors in production through quality assurance and control.

Figure 32-14 shows a summary of Phase II practice—laboratory activity and customary timelines for product delivery. The customized wires are generally inserted within 6 weeks of taking the therapeutic scan. Instructions for inserting the archwires are provided, and the archwires are laser marked to minimize placement error. Patients are commonly seen 8 weeks after custom-designed wire insertion (Fig. 32-15).

At this visit, the doctor and the staff use a guided checklist to evaluate the progress of care. Using a checklist helps prevent any oversights during the evaluation process. By the 16th week, if the target occlusion has not yet been reached, the doctor may use a second level of support checklist and a guided therapeutic archwire modification schema to manage corrections. Archwire modifications may be accomplished at the chairside with the *virtual plier*.

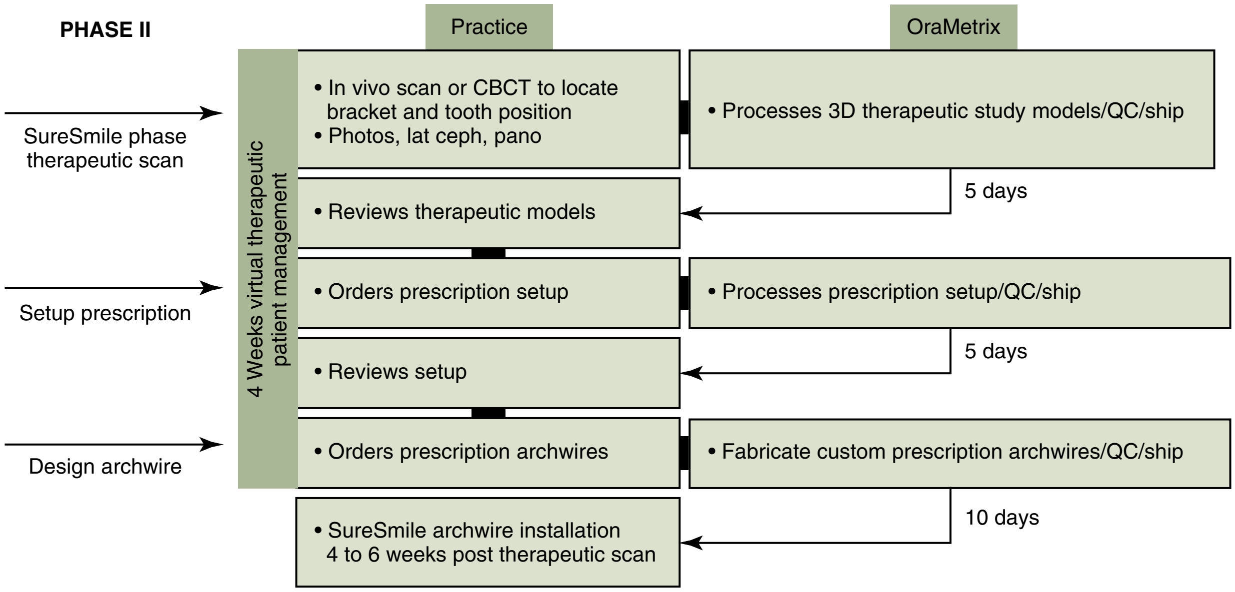

FIGURE 32-14 Phase II SureSmile work tasks at the practice and laboratory with work delivery times.

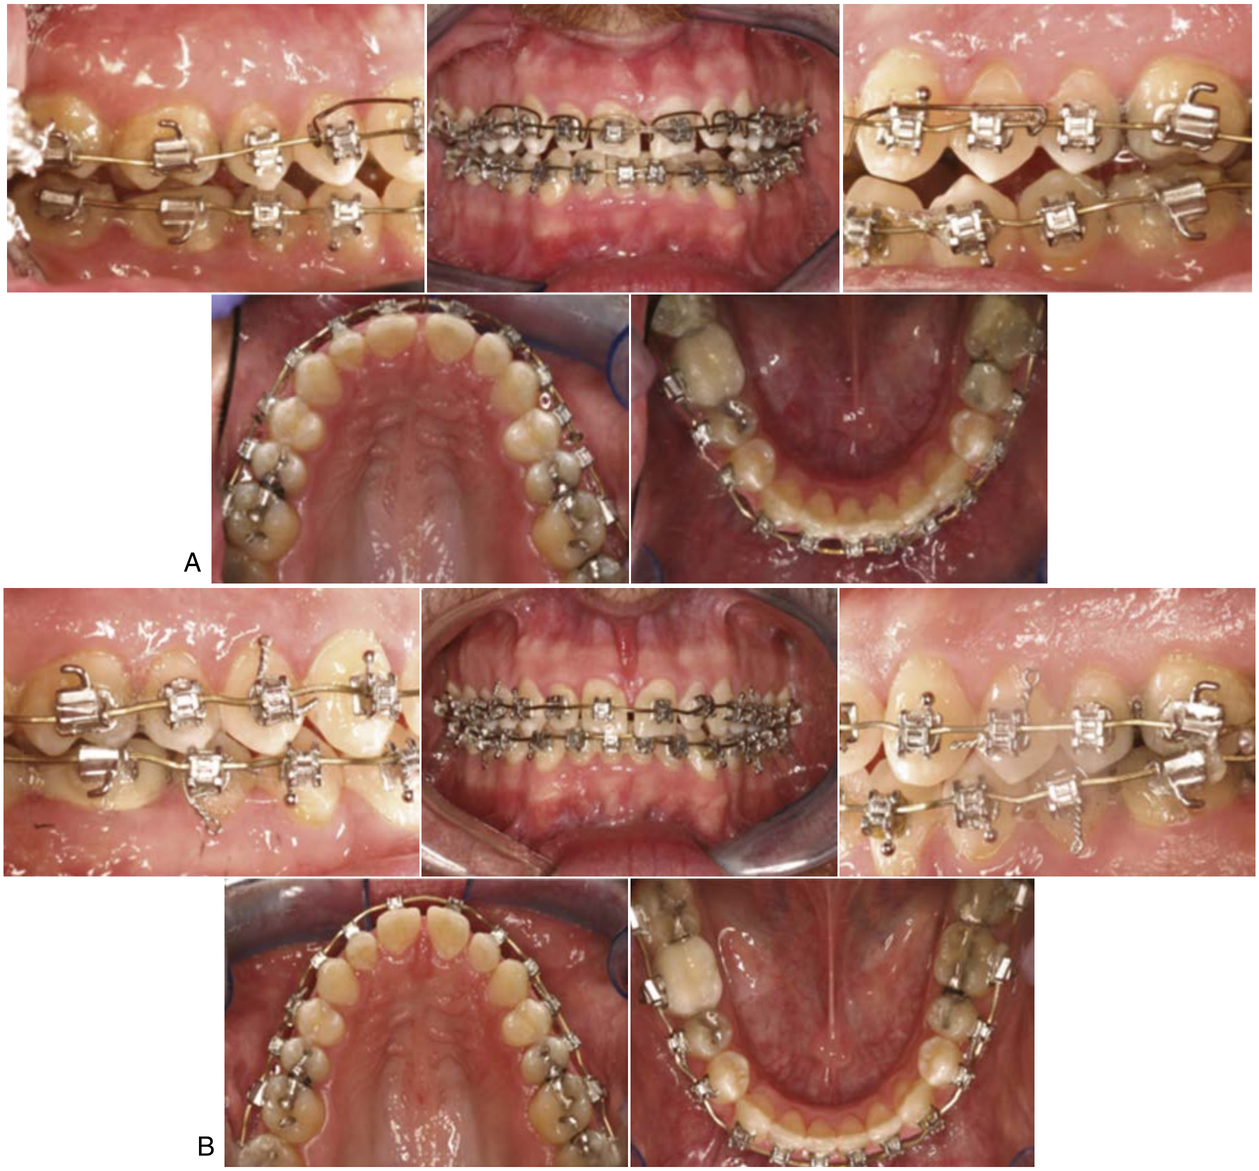

FIGURE 32-15 **A,** Insertion of 19- × 25-inch SureSmile archwire. **B,** Eight weeks after insertion.

There is great assurance in using the robot-assisted modified archwires since bends in areas requiring no modifications are maintained. Keeping tooth position unchanged is extremely difficult, if not impossible, to do with conventional archwires since their repeated removal, modification, and insertion deform the archwire and may lead to overworking a hand-bent archwire and to breakage. Replicating the geometry of the broken archwire is frustrating and usually cannot be accomplished with accuracy. In addition, if needed, the clinician may order a backup pair of bendable prescriptive archwires made from TMA or Azurloy (Ormco, Glendora, CA) in advance and make minor modifications at the chairside.

Generally speaking, most treatment with SureSmile prescription archwires is completed within 6 months after the placement of the SureSmile wires. Clinical judgment and the image of the target setup with the final position of the brackets on are used to gauge whether the prescriptive archwire has worked out and the treatment goals are achieved.

The final bracket position on the target setup is used to evaluate whether the archwire has worked out to completion (Fig. 32-16). The value of this verification step cannot be underestimated; in many busy practices, the treatment goals are generally forgotten and patient care continues, often with little progress achieved over time—a phenomenon the author of this chapter terms "orthodontic flagellation," which is costly to both the patient and the practice. A visual reference definitively provides an effective "stopping rule" for care. Furthermore, patients commonly forget the goals of treatment. When a visual treatment plan is designed with the patient's participation in advance and shared during treatment, the patient is aware of the end goal and is more accepting of the outcome. Furthermore, the plan is always visually accessible on a computer to show a patient if the need arises in response to special patient and/or parent questions. This approach is unlike the conventional practice where two different versions exist—one in the doctor's mind and the other in the patient's mind. A visual treatment objective provides a set point for motivating patients and parents.

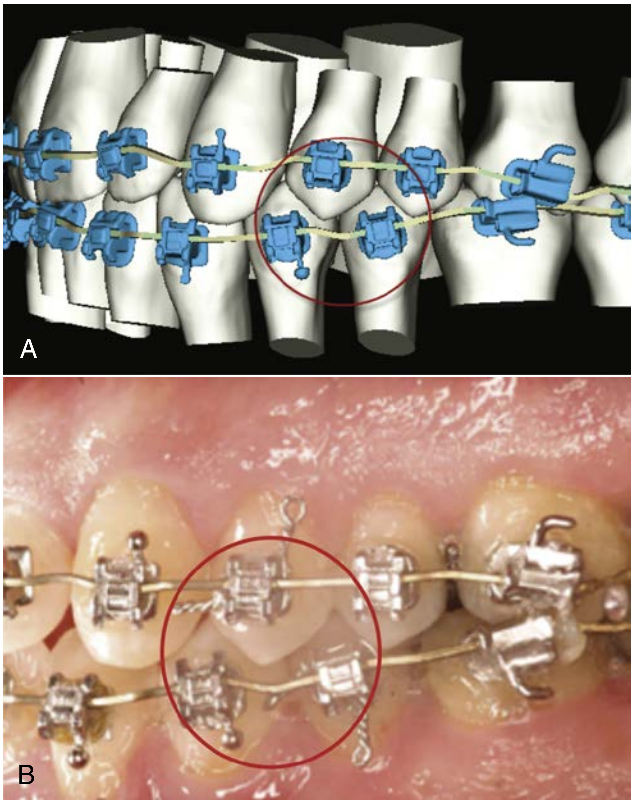

FIGURE 32-16 Final bracket position (*red circles*) on the target setup (A) is matched against the clinical situation (B) to assess whether the archwire has worked out.

Outcome Evaluation Phase

This final model can be evaluated by 3D inspection or by using the automatic grading system and by a comparative analysis using the best fit registration method against the diagnostic, therapeutic, or target setup (Figs. 32-17 and 32-18). Furthermore, to better analyze the patient's response to treatment and the physician's ability to achieve his or her treatment objectives, the models can be selectively superimposed by best fit registration to the diagnostic, therapeutic, or setup models.

PROACTIVE DECISION MAKING

A number of approaches may be used in planning the care for a patient using the DDS model and/or the Dental Technology Services (DTS) model. For an accomplished clinician, these simulations do not take longer than 10 minutes to accomplish. Effectively using these proactive simulation tools is a skill and can be learned only through deliberate practice. Practitioners new to digital tool sets should schedule extra time for simulation and other tasks as they build these skills. When the knowledge gained from these simulations is appropriately incorporated and sequenced in the management of a patient, not only do they add to the efficiencies in care and better outcomes, but they also increase patient safety by alerting the orthodontist to potential hazards.

Principle of Smart Orthodontics

The objective of simulations is to plan care with three objectives. The treatment plan should (1) be achievable, (2) require minimal tooth displacement, and (3) realistically reflect the ability of the therapeutic appliance under consideration. An example of using this approach in the correction of a functional shift accompanied with a posterior crossbite in the second molar area is shown in Figures 32-19 through 32-22.

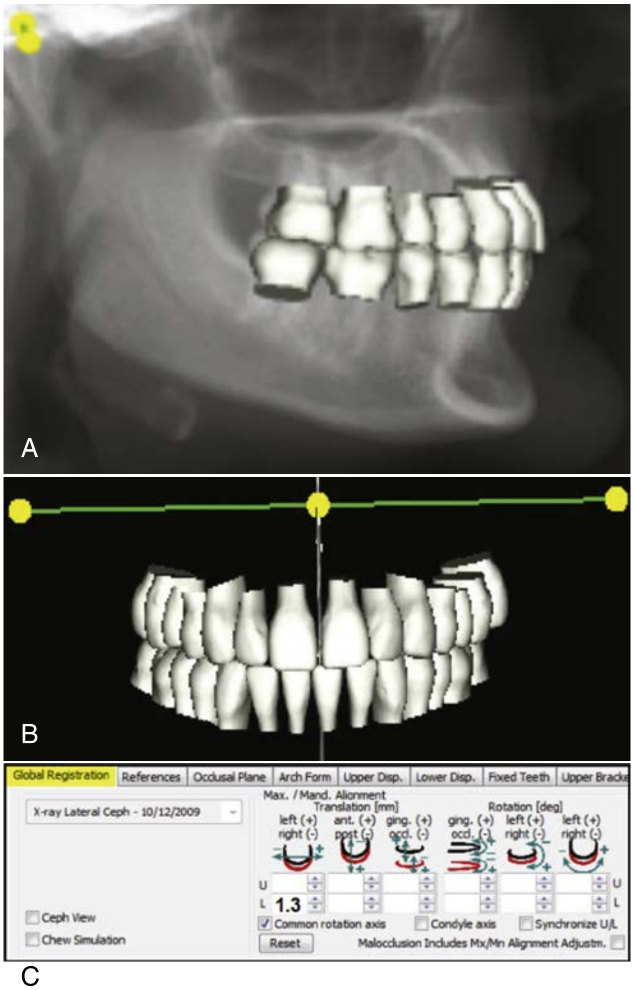

FIGURE 32-20 Smart tooth movement. **A, B,** Center of rotation simulates a mandibular shift. **C,** Input for simulation of mandibular shift.

Principle of Risk Analysis

The author of this chapter uses this simulation to visualize whether the plan may result in the violation of anatomic constraints (Fig. 32-23). In addition, since the gingival tissue is designed to move in a one-to-one ratio with tooth movement, the effect that tooth movement has on gingival architecture can be seen and plans can be made in advance for it (Fig. 32-24). The patient can also be proactively informed about the potential risks associated with treatment.

Principle of Constraint Recognition and Management

This simulation enables the orthodontist to better understand where the teeth will collide during alignment and plan for strategic and proactive IPR (Fig. 32-25). He or she can also see whether bracket interferences will occur and how these interferences could affect tooth movement.

Principle of Anticipatory Orthodontics

The orthodontist can develop chronologic milestone-driven, best-estimate prediction simulations that may be shared with both patients and staff. Patients find them very useful in tracking their care progress. They become active collaborators in care, and their personal motivation to adhere to the treatment regimen substantially increases. The simulations also allow the staff members to better understand treatment objectives, and the images provide them a template to assess orthodontic vital signs at each visit. The simulations also provide an excellent visual communication tool for both the clinician and staff to discuss the patient's progress in treatment at the chairside (Fig. 32-26). This collaborative care is another hallmark of a patient-centered practice. After years of performing such predictive simulations and comparing them with the actual tooth movement, patterns in tooth movement can be recognized that may be incorporated in the simulations to achieve more realistic expectations.

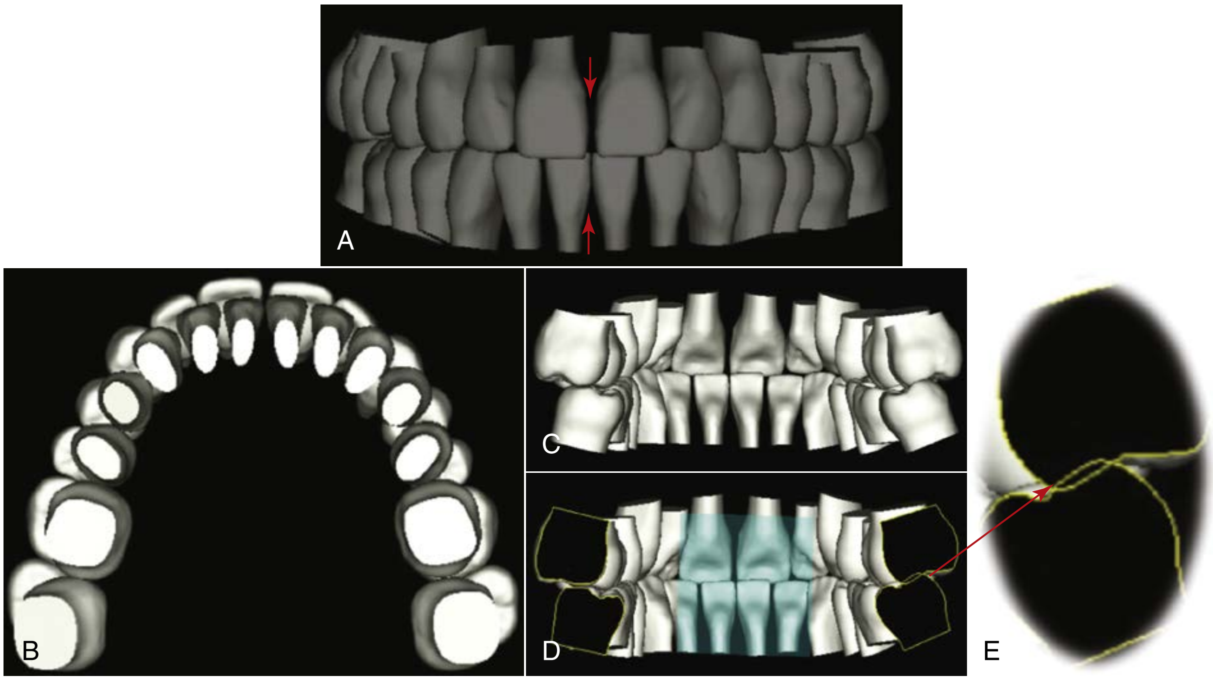

FIGURE 32-21 **A–D,** Mandible is shifted to the patient's left. The simulation of a mandibular shift corrects the midline but does not completely resolve the crossbite in the left molar region; crossbite also appears in the right molar region. **E,** Interference (*arrow*) appears on the inclined planes as in the upper right molar area as the mandibular shift is corrected.

PRINCIPLES OF TARGETED THERAPEUTICS

Achieving effective treatment outcomes in an efficient manner requires a proactive therapeutic strategy driven by a diagnosis in all of the therapeutic phases of treatment. A full-expression archwire based on the targeted setup is only one of the many therapeutic solutions that can be designed with digital analytic and treatment planning techniques and fabricated with the robot to achieve predictable and controlled tooth movement. The versatility of designing diagnostic-driven and condition-based appliances for managing a dynamic biologic system is where the true strength of robotic-assisted orthodontics resides. The following text describes the concept of the adaptive prescription, which provides the foundation of the design principles in managing patient care with robot-assisted orthodontics.

Adaptive Prescription

The straight archwire concept of treatment is designed on the principle of a deterministic system. The operating paradigm is that a bracket with an ideal prescription ideally placed on a tooth will lead to an ideal response. This strategy, at best, is naive and needs to be challenged. A bracket cannot be ideally placed most of the time. Anatomic constraints attributable to severely rotated teeth, partially erupted teeth, and variation in tooth morphologic structure are some clinical examples that limit their ideal placement.

Furthermore, only a slight alteration in bracket position, such as to avoid interferences, can substantially affect the expression of a bracket prescription, forcing the clinician to practice reactive orthodontics. The altered expression of the bracket as a result of repositioning can only be corrected by archwire bending (Fig. 32-27).

Even with fully erupted teeth and the use of indirect bonding techniques, ideal bracket placement remains difficult for some because of the lack of reliability in seating the transfer trays.[8,9]

In addition, indirect bonding does not overcome the impact of inconsistencies in tooth morphologic structure; it simply provides an efficient way to improve precision and place brackets en masse at the chairside. Another problem with the straight arch appliance brackets resides with the bracket prescription. Straight wire prescriptions are standard and do not reflect the individual patient's unique needs. Furthermore, the bracket slot dimensions often demonstrate poor manufacturing tolerances and diminish precise control.[10,11] It might be argued that customized brackets may solve this issue, but this is not necessarily true.[12,13] The slots in customized brackets are milled just as

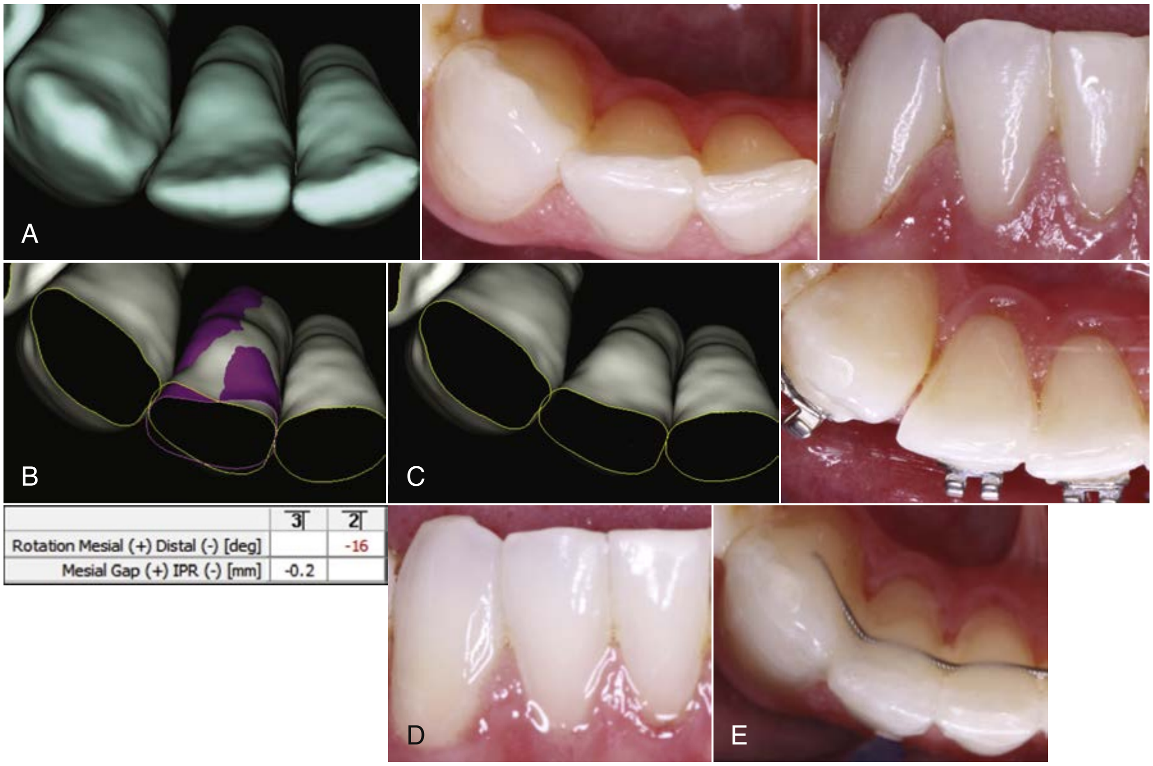

FIGURE 32-25 Constraint detection and management. **A,** Mesial outrotation of lower left lateral incisor is simulated. **B, C,** When the tooth is rotated 16 degrees (assuming no movement of the canine), then collision will occur on the distal surface of the lateral and mesial surfaces of the canine. The overlap automatically demonstrates the magnitude of the collision. The author of this text uses this as a guide to show how much interproximal reduction (IPR) is performed. **D, E,** Final photographs.

for the off-the-shelf brackets and therefore are subject to the same issues of poor manufacturing tolerances. Again, the conflict between vertical bracket placement and tooth morphologic structure cannot be reconciled by customized brackets. Any change in torque values exhibits itself not only in relative vertical discrepancies but also in buccolingual dimensions, setting up a vicious error-generating cycle.

Most important, however, is that orthodontic care occurs in an environment that reflects a complex adaptive system. John Holland has defined the complex adaptive system as, "A dynamic network of many agents acting in parallel, constantly acting/reacting to other agents." The overall behavior of the system is a result of a huge number of decisions made every moment with multiple variables affecting treatment response (Fig. 32-28). Many clinical instances, such as poor patient compliance, unplanned anchorage loss, and spurious tooth movement, force the doctor to reassess his or her treatment objectives in midtreatment. In such situations, deterministic-designed appliance systems fail to account for the altered therapeutic requirements to manage the new care objectives. They do not provide the clinician the flexibility to override the prescription built into the appliance, short of rebooting or resorting to craft-based reactive therapy. Robotic-assisted archwire bending driven by therapeutic diagnosis provides the doctor unprecedented control to modify the targeted prescription at will and to adaptively manage the dynamic clinical situation. Building constriction or expansion or selectively staging the expression in a static prescription offered by a bracket remains almost impossible without resorting to archwire shaping or bending.

Conventional straight archwire therapy and indirect bonding with or without customized prescriptive brackets are limited in their capacity to provide efficient control in the management of orthodontic patients. An adaptive prescription built into the archwire with robotic-assisted orthodontics provides a more realistic approach to manage orthodontic care, which is a manifestation of a complex adaptive system.

Principle of Image-Guided Smart Bracket Placement and Archform Selection

By using 3D-modeling simulation tools, the author of this chapter tries to understand the impact of tooth morphologic structure on bracket-archwire interaction and also uses the tool to determine where the brackets should be placed to achieve the treatment goals, minimize collisions, and avoid the risk of bracket failure. Additionally, the simulations are used to develop a visual guide to better position the brackets at chairside (Figs. 32-29 and 32-30) or in an indirect bonded setup. With the simulation tools, plans for the selection or modification of the straight archwire form, which will be initially used in the pre-SureSmile phase of treatment, are made.

Principle of Minimal Archwire Replacement

In the pre-SureSmile therapeutic phase, superelastic nitinol archwires are commonly used, and the goal is to minimize archwire changes through the appropriate selection of material, archwire cross section, and transformation temperature (Fig. 32-31). If tooth geometry leads to inconsistent force systems, segmental

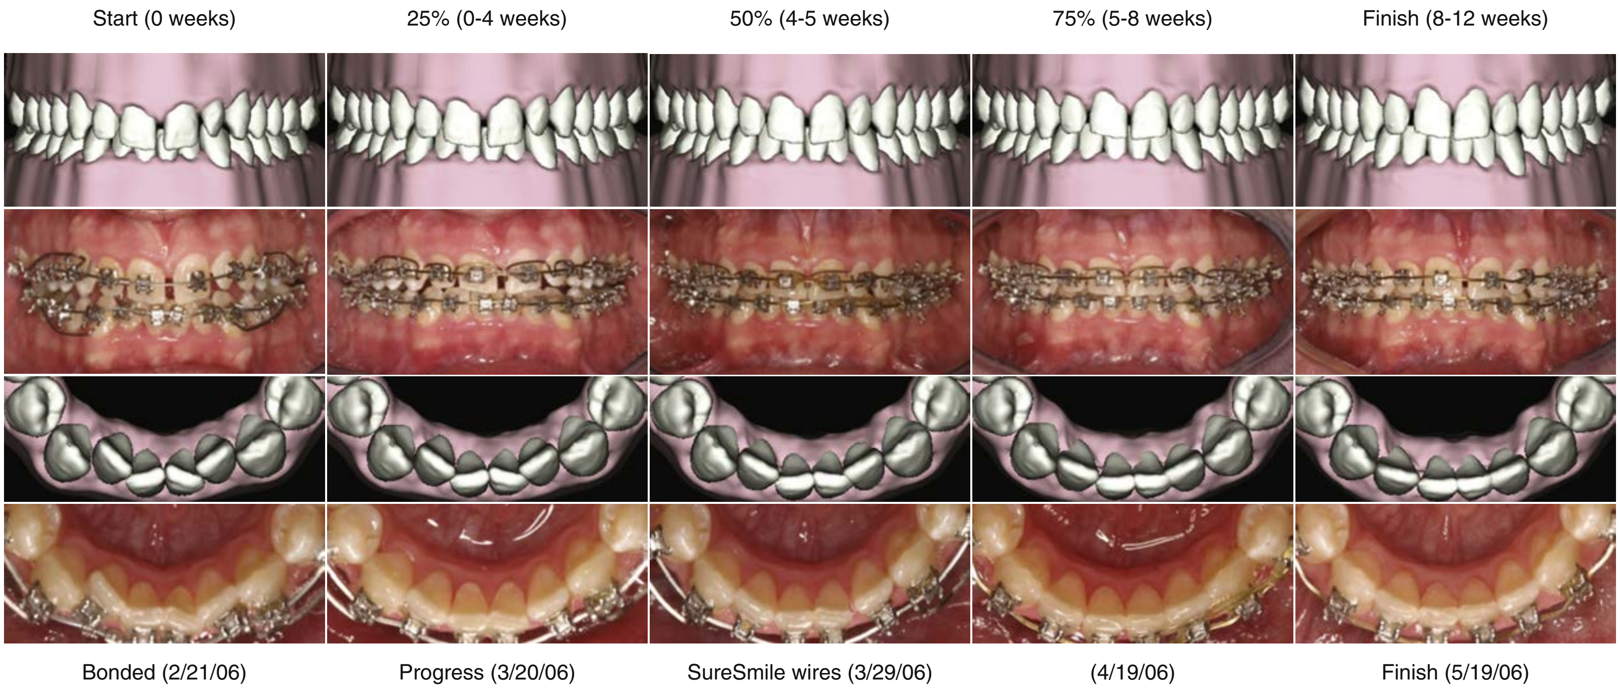

FIGURE 32-26 Anticipatory orthodontics. Progress milestones have been established with simulations.

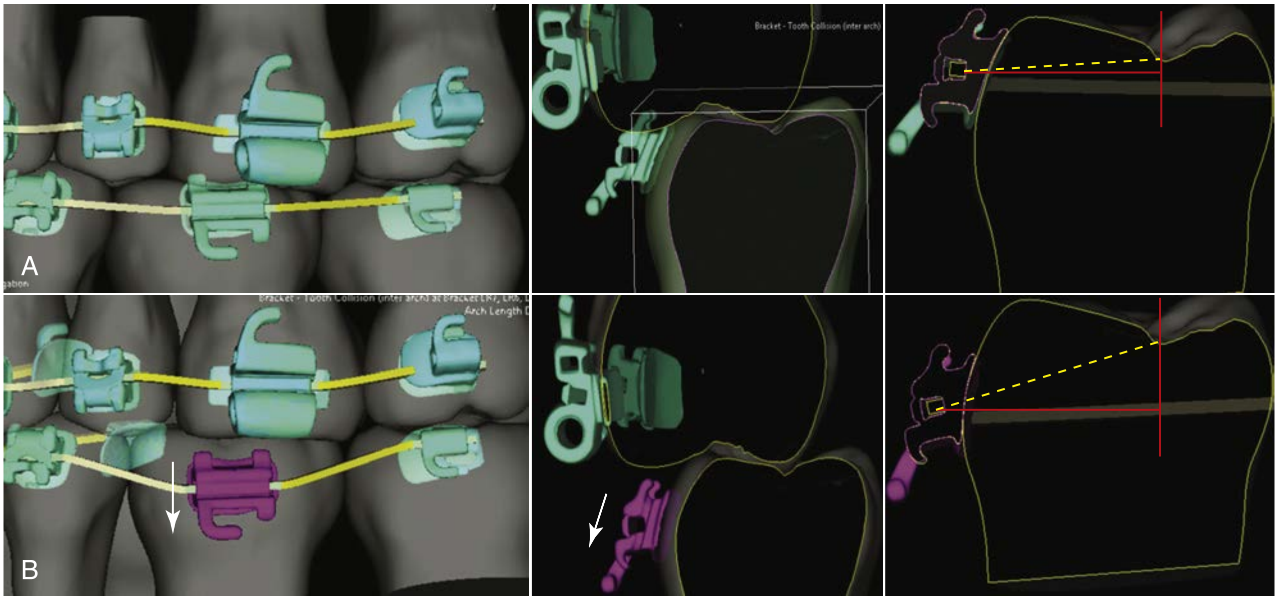

FIGURE 32-27 Reactive orthodontics are driven by bracket position. This example demonstrates the effect of vertical bracket repositioning on torque. **A,** Clipping plane view shows that the occlusal wings of the lower first molar are colliding with the upper first molar. Note the torque of the bracket. **B,** The bracket is gingivally repositioned to avoid collision. Note the effect this has on torque expression. Many times, adjustments are made in bracket placement without compensating for these effects, which then leads to reactive therapeutics with the archwire bending to manage the resulting spurious tooth movement.

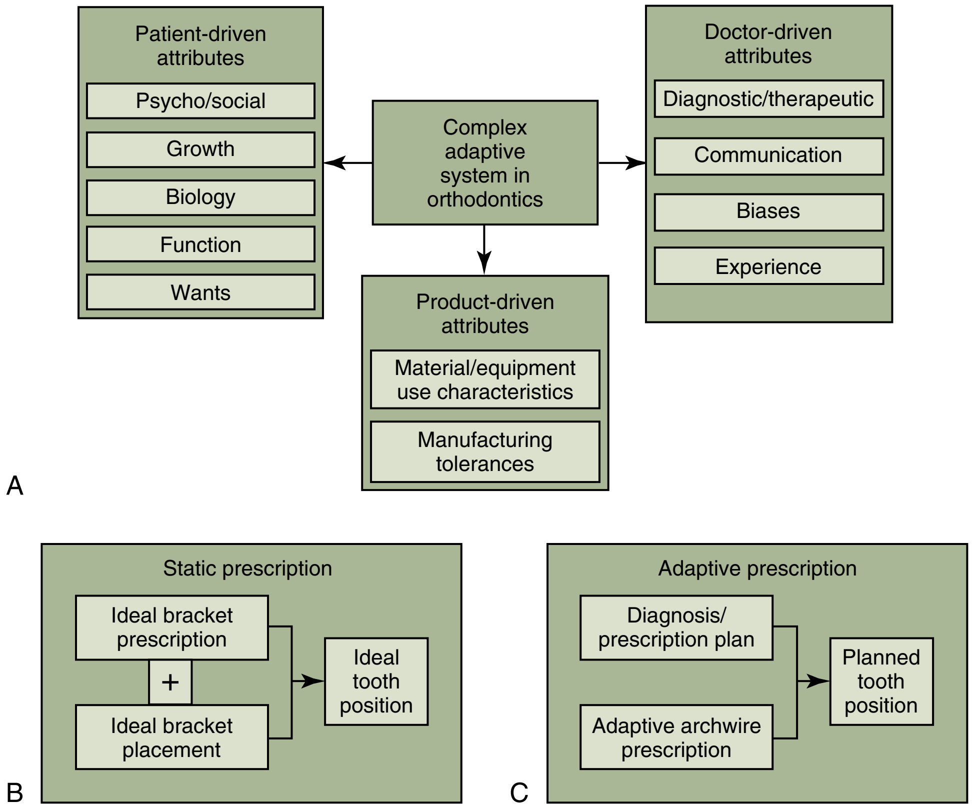

FIGURE 32-28 **A,** Factors affecting treatment response. **B,** Assumptions in appliance-driven mechanotherapy. **C,** Adaptive prescription therapy best serves in the management of the complex adaptive system such as in orthodontic care.

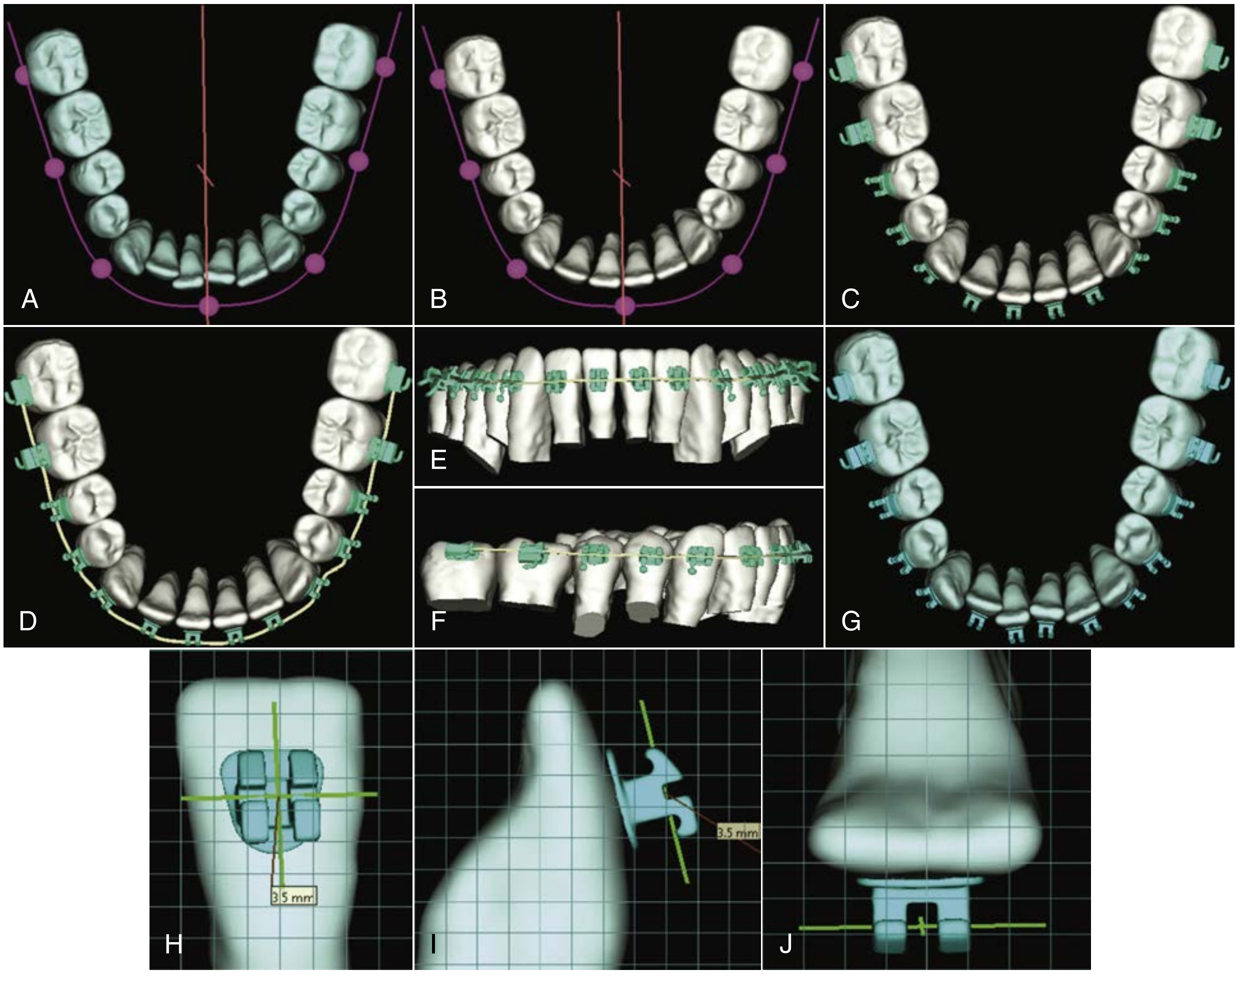

FIGURE 32-29 Smart bracket placement. **A,** Initial model with selected treatment arch form. **B,** Simulation of tooth alignment and leveling. **C,** Automatic bracket placement achieves the desired result. **D–F,** Despite optimization of bracket placement, archwire bends will be required to achieve desired result. **G–J,** Coordinate transfer used to place brackets on original model. The bracket position on each tooth can be visualized and measured to guide placement.

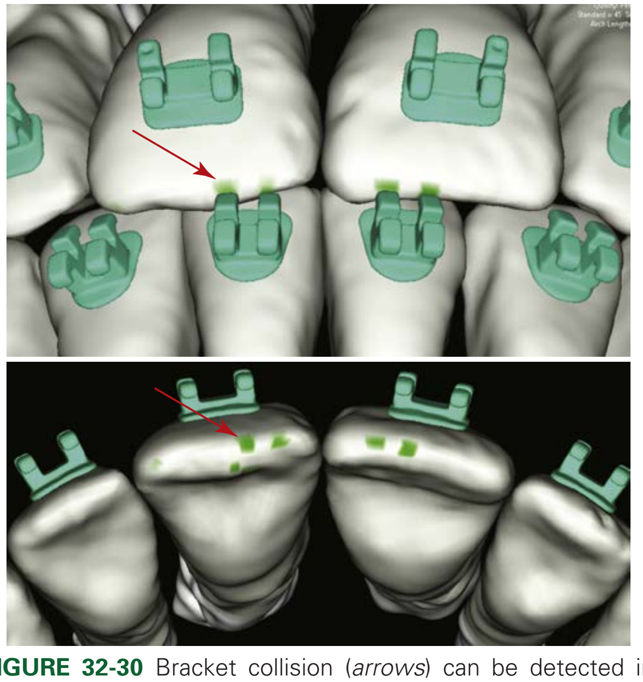

FIGURE 32-30 Bracket collision (*arrows*) can be detected in advance of placement and avoided.

mechanics may be used to achieve the desired control. The principle of concurrent mechanics (discussed later in this chapter) also minimizes replacement therapy.

Principle of Constraint Management

As mentioned earlier, if warranted by treatment objectives, IPR may be performed to minimize any potential collisions between the teeth, which allows for quicker alignment and leveling. Interferences between opposing teeth can prevent their movement through collision. The clinician may also bond bite blocks early in the treatment to disclude the arches and to prevent collisions from occurring (Fig. 32-32).

Principle of Concurrent Mechanics

Auxiliary appliances, such as torquing springs, tip-back springs, and elastics, may be used from the start of treatment when required. Complementary force systems may be generated to gain better control of tooth movement and to achieve multiple treatment goals, such as alignment leveling and space closure in parallel (Figs. 32-33 and 32-34).

FIGURE 32-31 Minimal replacement alignment achieved in 4 months with initial 0.19- × 0.25-inch copper-nickel-titanium (CuNiTi) A_F 40° C archwire that was fully engaged.

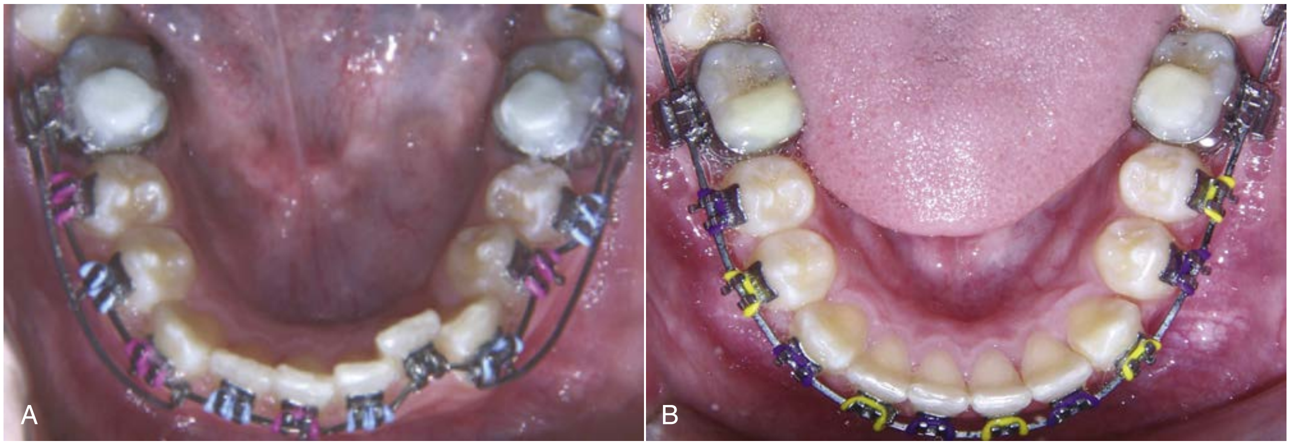

FIGURE 32-32 **A**, **B**, Posterior bite blocks are bonded to prevent interarch collisions.

Principle of Additive or Subtractive Bending, Preferential Staging, and Shaping

The expression of the digitally designed and robotically constructed archwire can be very effectively influenced to provide unprecedented control of tooth movement by either adding or subtracting bends at any point in the archwire or as a whole to achieve different levels of archwire expression.

A full-expression, 100%-active archwire can be designed for use from the start of treatment (see Fig. 32-9). The expression may also be incrementally staged to control the amount of tooth displacement, especially in situations during which the patient has a low threshold to pain, is not compliant, or is on an extended vacation (Fig. 32-35).

An added dimension of control can be achieved by limiting bends to any one plane of space. For example, control can be achieved by removing all bends except for the first order or creating a straight segment to achieve sliding mechanics during space closure (Fig. 32-36). A curve of Spee, reverse curve, expansion, and constriction can all be designed into the archwire to build additive forces or subtract the reactive forces observed when using elastics.

FIGURE 32-33 A–D, Concurrent mechanics; ART (Art Root Torquing) (Atlanta Orthodontics, Atlanta, GA). Torquing springs are being used at the onset of treatment with 17- × 25-inch copper-nickel-titanium (CuNiTi) 35° C archwire to correct edge-to-edge bite. The bite is anteriorly opened with posterior bite blocks to minimize anterior interference during correction.

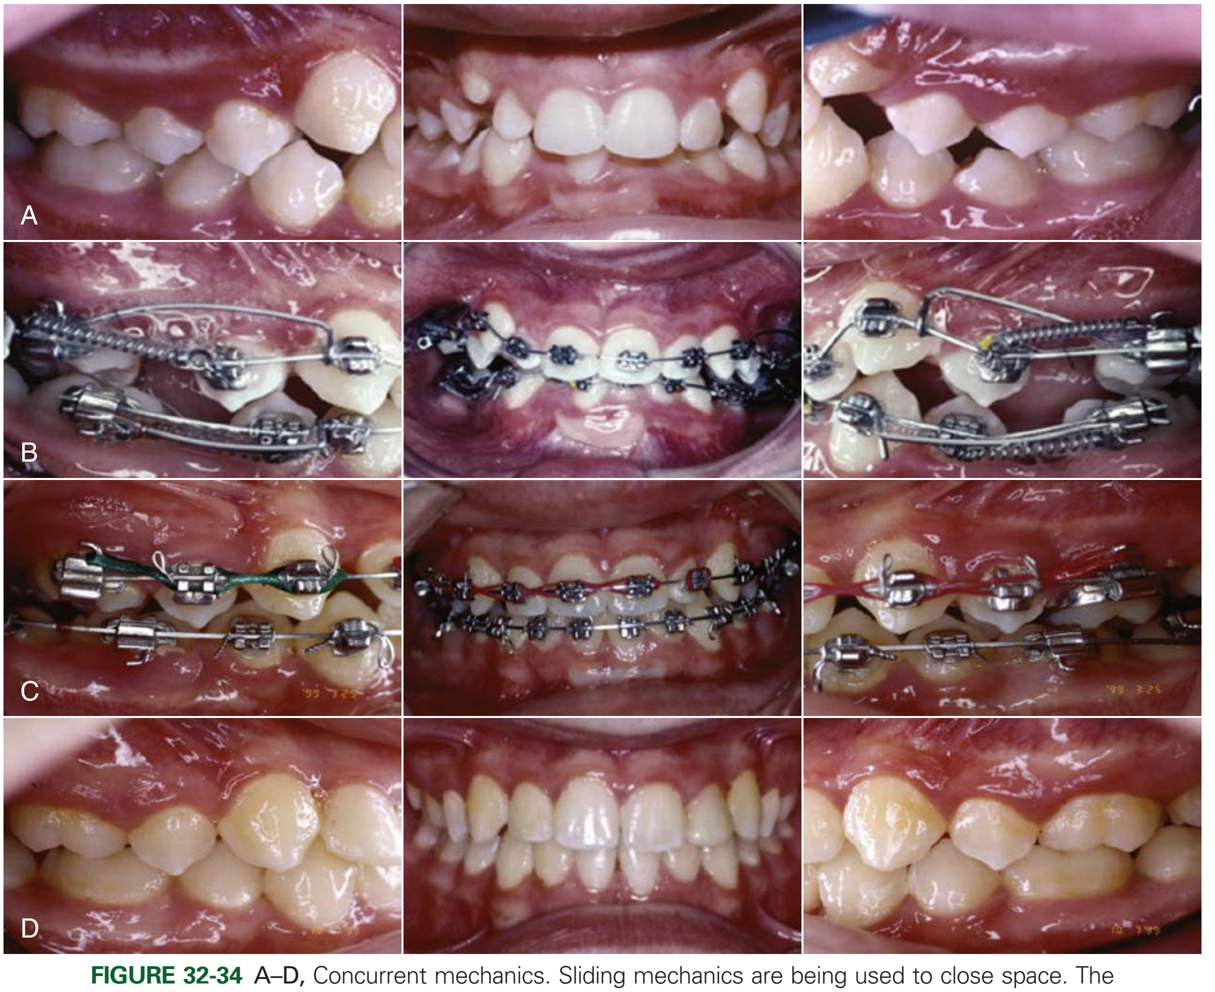

FIGURE 32-34 A–D, Concurrent mechanics. Sliding mechanics are being used to close space. The initial wire is a 0.17- × 0.25-inch copper-nickel-titanium (CuNiTi) A_F 35° C. Tip-back springs, fabricated from 0.17- × 0.25-inch titanium molybdenum alloy (TMA), were used to aid in leveling and minimizing the tip forward of the buccal segments and distal crown tipping of the canines during space closure.

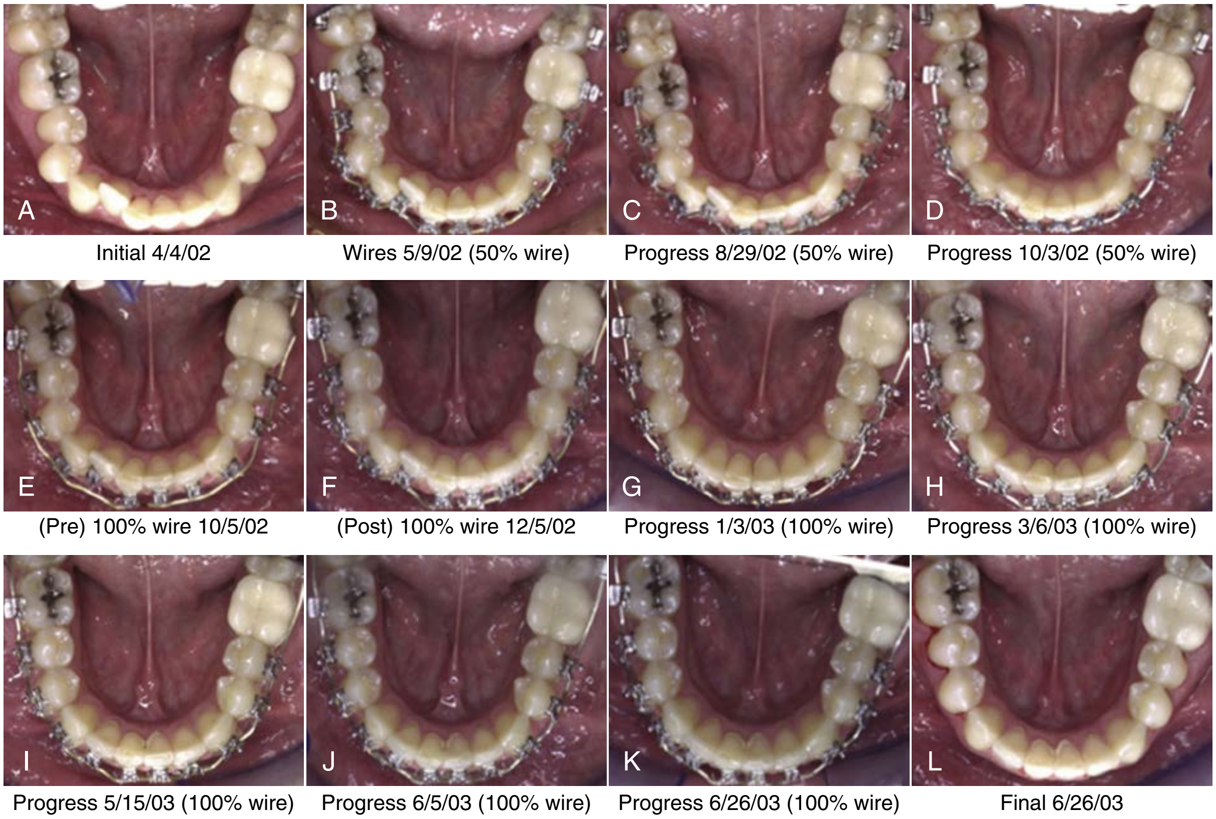

FIGURE 32-35 Progressive SureSmile expression archwire. **A,** Initial. **B,** SureSmile archwire with 50% expression inserted. **C, D,** Progress with 50% SureSmile expression archwire. **E,** SureSmile archwire with 100% expression inserted. **F–K,** Progress with SureSmile 100% expression archwire. **L,** Finish.

FIGURE 32-36 SureSmile archwire designed to enable sliding mechanics. **A,** Initial photograph and panoramic radiograph. **B,** Initial half of the space has been closed on straight archwire. **C,** Two types of SureSmile archwires are available. The first archwire is designed for space closure. It is straight distal to the canines and has full anterior expression. The second archwire will be used after the space is closed. It is the final archwire. **D,** Progress with SureSmile wires. **E,** Space is closed on the SureSmile wire.

Principles of Consistent Force Systems and Reactive Force Management

The unmanaged use of straight archwires will create inconsistent force systems in many situations, leading to spurious tooth movement (Fig. 32-37). Designing passive and reactive elements can prevent this movement. Furthermore, hybrid archwires can be designed with both active and passive elements to better distribute the reactive forces and target the active forces (Fig. 32-38). Passive archwires can be designed to minimize the side effects of Class II mechanics (Fig. 32-39).

Principle of Complementary Force System

Many times, toward the end of treatment, mild to moderate Class II or Class III correction remains unachievable, despite long-term elastic wear. The most common reason for this is that bracket archwire coupling may impose reactive force constraints and fight the Class II or Class III elastic forces. This eventuality may be designed for in bracket placement but becomes a daunting task; it requires precision bracket placement in all three planes of space. This kind of complex placement is difficult to accomplish clinically. Instead, when using a digital tool set, such situations can be anticipated on the target setup, and the virtually designed archwire can be made to complement the force system generated by the Class II or Class III elastics, springs, or functional appliances (Fig. 32-40).

Principle of Optimization of Archwire and Material Selection

The availability of different archwire materials, sizes, and shapes increases the doctor's need to be judicious when selecting archwires and to guide his or her decisions based on material characteristics, the patient's condition, the desired treatment objectives, and whether elastics are being used. High load–deflection rate materials such as Elgiloy (Rocky Mountain Orthodontics, Denver, CO) offer greater control of reactive segments, whereas superelastic archwires provide long-acting sustained forces that are beneficial for active movements over the long term.

The capability of being able to bend nitinol wire and retain its superelastic characteristics with robotic-assisted archwire bending offers the orthodontist a number of distinct advantages: (1) the ability to establish torque control very early in treatment extends its use and minimizes the number of wire replacements needed; (2) biologically friendly forces can be applied through the entire range of care; and (3) torque control

FIGURE 32-37 Passive SureSmile bypass wire controls inconsistent force systems. **A,** A common side effect of extruding canines with a continuous archwire is the intrusion of the anteriors, which creates an anterior open bite (*arrows*). **B,** The therapeutic strategy to minimize this side effect is to design a passive bypass archwire and piggyback an active archwire to extrude the cuspids. The bypass archwire helps stabilize the reactive segment and minimize side effects.

FIGURE 32-38 A–F, Hybrid SureSmile archwire design. A combination of passive and partially progressive bends is used to expand the lower left buccal segment. A continuous archwire would have had the tendency to expand both sides by creating a passive archwire from the lower left canine to the second molar on the right. A relatively rigid reactive segment is established that better distributes the reactive forces. In addition, by designing progressive expansion active bends 50%, followed by 100% on the left buccal segment, the displacement of the teeth is better titrated, minimizing the potential of spurious movement.

FIGURE 32-38, cont'd

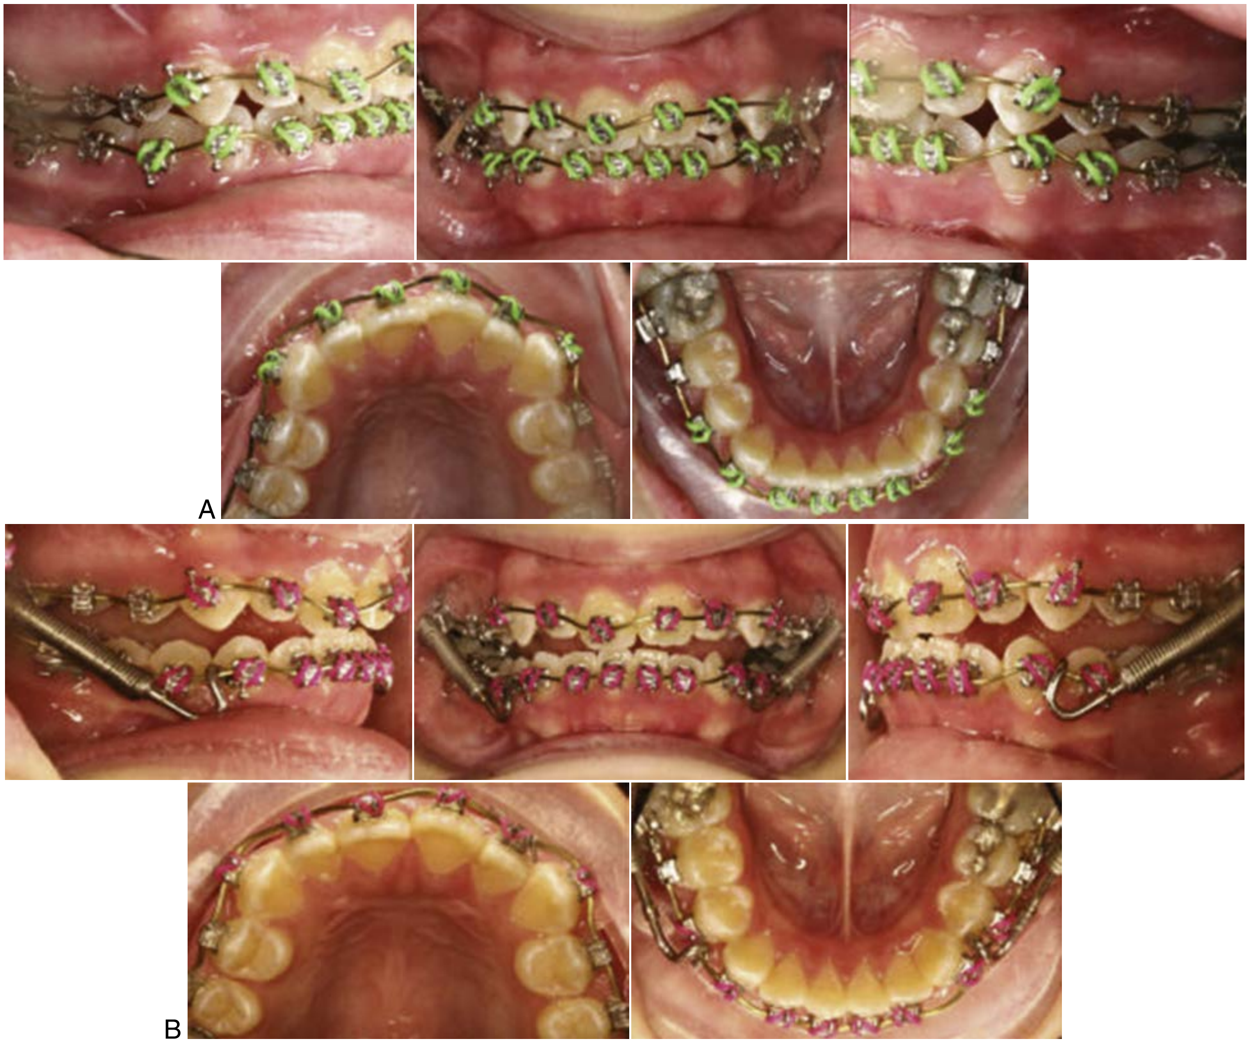

FIGURE 32-39 A, B, Class II correction with Forsus Fatigue Resistant Device (3M Unitek, St. Paul, MN). SureSmile spring/passive 19- × 25-inch copper-nickel-titanium (CuNiTi) A_F 35° C archwires are used for anchorage in the upper and lower dentition.

does not require the use of a near full-size archwire but can be accomplished by accommodating for bracket play in the region of interest. Such a situation can occur when substantial anterior crowding demands the anterior use of a smaller cross-section archwire, whereas posteriorly, a single tooth such as the second molar requires torque.

EFFICACY AND EFFECTIVENESS

A number of studies have been designed to understand the efficiency and effectiveness of using robotic-assisted orthodontics. Saxe and colleagues[14] studied 62 patients treated with advanced digital technology with a similar control sample and showed that the mean total months for treatment using the SureSmile process was 14.7 months versus 20 months for conventional methods ($p < 0.001$). The ABO OGS grades were 14% lower (better) than conventional treatment. A recent study by Alford and colleagues[15] also reported that treatment time with SureSmile was reduced by approximately 30%, compared with conventional treatment, and that the cast/radiographic evaluation (CRE) scores were 11% better.

To this point, over 12,000 patient records have been analyzed to understand the effectiveness of SureSmile. The results clearly demonstrate that technology-driven diagnosis and treatment favorably influence treatment time across the spectrum of practices and types of malocclusions. The median treatment time for SureSmile patients with Class I is 15 months (conventional method, 24 months); Class II, 13 months (conventional method, 23 months); and Class III, 16 months (conventional method, 25 months).[16] Recent research conducted by Patel and colleagues[17] at the University of Oklahoma demonstrated no statistical differences in root resorption between robotic-assisted technology and conventional treatment. Future studies need to be conducted to understand further both the efficiency and the effectiveness of this technology in the management of orthodontic patient care.

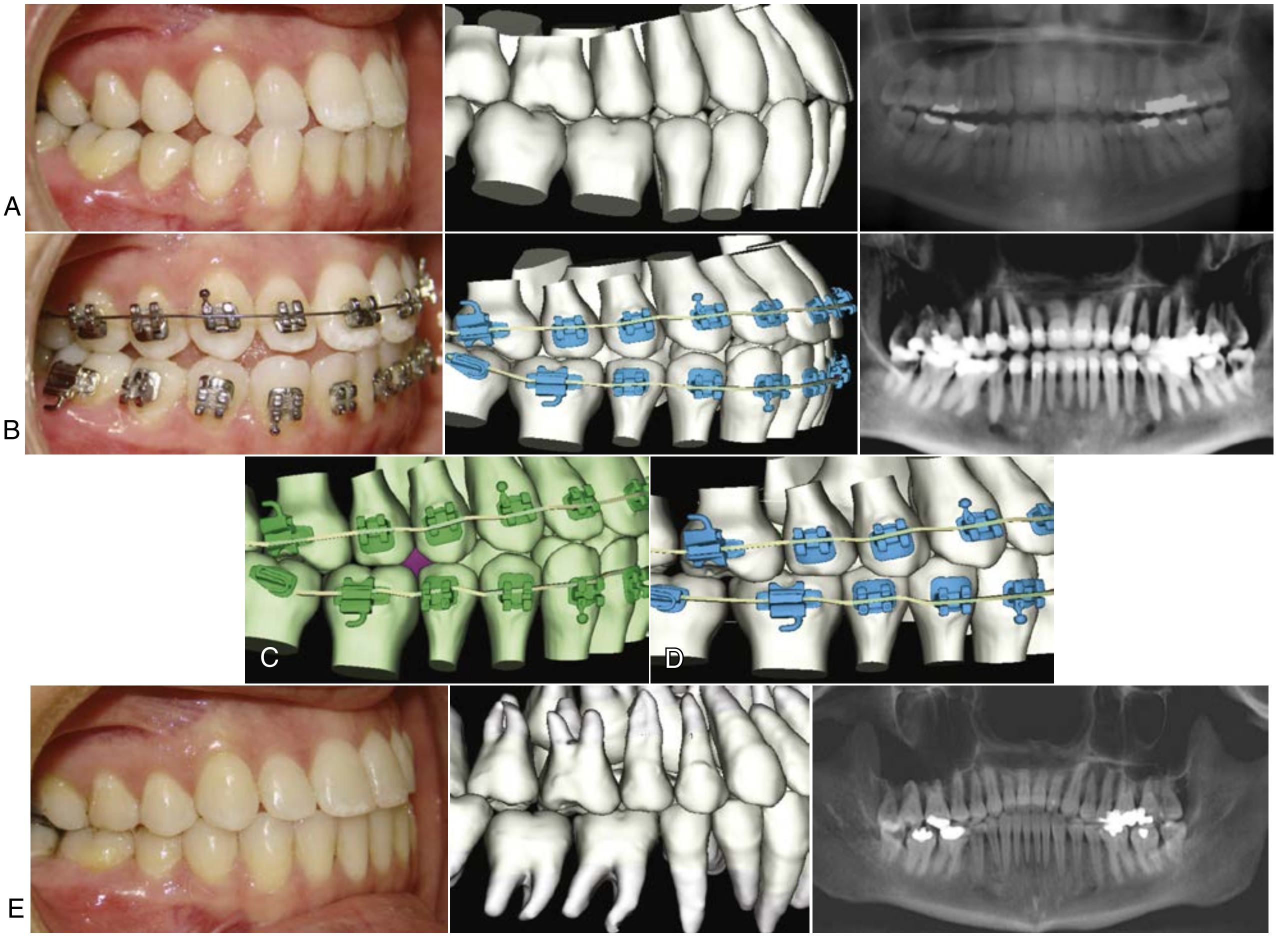

FIGURE 32-40 Complementary force system. **A,** The patient has a Class III occlusion on the right buccal segment. **B,** Before the SureSmile therapeutic phase, the Class III correction remains unresolved, although the patient has been cooperative and has been wearing Class III elastics for 6 months. **C, D,** In the target setup, the dentition in the buccal segment is subtly set to correct the Class III in the lower bicuspid canine area. The archwire bracket geometry reflects this. **E,** The patient continued the elastic wear with the SureSmile archwire. Correction in occlusion is achieved as planned in the setup by building dentoalveolar compensations.

SUMMARY

Our profession is at the threshold of reinventing itself. We have the ability to transform our orthodontic care environment in which quality thrives by using enabling technology and applying the science of process management to evolve from a craft-based to a patient-centered and professional-based care model.

We have the unique opportunity to adapt and customize care to specific patient needs, to streamline our clinical protocols by embracing evidence-based care and evidence farming, to establish new benchmarks in care, and to embrace system-minded thinking.

Some may perceive these advances as a step toward the loss of personal autonomy and craft. Some may also fear that the new integrated digital tools and processes widen the distance between orthodontists and their patients, causing a loss of the human connection that most of us prize. Both of these fears are misplaced. Technology and processes, when viewed as enabling, provide unprecedented control for the doctor and staff members to deliver better patient-centered care.

We must view each practice as a *practice of one* and hold ourselves accountable to giving the best in care for each patient. We must subscribe to the practice of providing the right treatment for the right patient at the right time and to avoid, at every cost, the lure of market-driven orthodontics.

Acknowledgments

I would like to express my sincere thanks to Drs. Takao Kubota, Jun Uechi, Richard Ingraham, Edward Lin, Ralph Mueller, and Mark Feinberg for kindly providing some of their patient records for this publication. I cannot thank my mentors enough, Drs. Charles Burstone, Michael Marcotte, Larry White, and Carl Gugino, for unselfishly sharing their knowledge of orthodontics with me. I am eternally indebted to my former residents and patients for giving me the privilege to learn from them. To my friends and colleagues, Drs. Mark Knoefel, John Lohse, Takao Kubota, Doug Haberstock, Blair Adams, Geoff Hall, Michael Stosich, Sam Wong, Antonella Maselli, Raffaele Schiavoni, Con Vanco, Todd Hickman, Michael Mahafee, and in addition, Karen Moawad: not only has your presence in my life professionally enriched me, but, more important, you have allowed me to see beyond the "to-do list" and enjoy the present.

CASE STUDY 32-1

Patient Histories

Diagnostically driven, robotic-assisted orthodontics provides a very effective tool to achieve targeted therapeutics with predictable and controlled tooth movement at any point during the care cycle. Furthermore, any type of malocclusion can be treated with this approach, independent of the bracket type used. The following patient histories demonstrate the wide applicability of this approach. The shorter care cycles are a result of proactive planning, process control, and targeted therapeutics. Teeth are not moved faster, but they are moved smarter (Figs. 32-41 to 32-46).

Stability, Retention, and Relapse

Donald R. Joondeph, Greg Huang, and Robert Little

OUTLINE

A working definition of retention in relation to orthodontics might be stated as follows: the holding of teeth in optimal aesthetic and functional positions.

The requirements for retention are often decided at the time of diagnosis and treatment planning. The correct problem list or diagnosis, a logical treatment plan, and the timing of treatment must be directed toward achieving favorable aesthetics, ideal function, and, as much as possible, the permanent maintenance of these goals. Incorrect diagnosis or treatment, on the other hand, can complicate the requirements for retention. For instance, gross expansion of the dental arches, severe changes in arch form, incomplete resolution of anteroposterior malrelationships, and incomplete correction of dental rotations may require additional retentive measures.

HISTORY OF RETENTION

For many years, clinicians did not agree about the need for retention. Hellman[1] said, "We are in almost complete ignorance of the specific factors causing relapses." Different schools of thought have existed over time, and present-day concepts generally combine several of the following historic concepts regarding retention.

Occlusal School

Kingsley[2] stated, "The occlusion of the teeth is the most potent factor in determining the stability in a new position." Many early investigators[3–18] agreed that proper occlusion was of primary importance in retention.

Apical Base School

In the middle 1920s, a second school of thought formed secondary to the writings of Axel Lundstrom,[19] who suggested that the apical base was one of the most important factors in the correction of malocclusion and the maintenance of a corrected occlusion. McCauley[20] also suggested that intercanine width and intermolar widths should be maintained as originally presented to minimize retention problems. Strang and

Thompson[21] further confirmed and substantiated this concept. Finally, Nance[22] also noted that, "arch length may be permanently increased only to a limited extent."

Mandibular Incisor School

Grieve[23] and Tweed[24,25] suggested that the mandibular incisors must be placed and kept upright over basal bone to maximize their stability.

Musculature School

Rogers[26] introduced a consideration of the necessity of establishing proper muscular balance. Others corroborated his thoughts. Over time, orthodontists have come to realize that retention is not separate from active orthodontic treatment; rather, retention is part of treatment itself and must be included in treatment planning. Stability has become a primary objective in orthodontic treatment; without it, ideal function, optimal aesthetics, or both may be lost.[27] Care must exercised to establish a proper occlusion within the bounds of normal muscle balance and with careful regard given to the apical base, as well as to the relationship of the maxillary and mandibular bases to one another.

RETENTION THEORIES PROPOSED IN THE LITERATURE

The orthodontic literature describes many theories regarding retention. Some are presented here, along with supporting literature.

Theory 1: Teeth That Have Been Moved Tend to Return to Their Former Position[27-29]

Investigators do not agree on the reason for this tendency. Suggested influences include morphogenetic pattern of musculature,[30] apical base,[31–33] transseptal fibers,[34] and bone morphology. Regardless of the reason, most clinicians agree that teeth should be held in their corrected positions for some time after changes are made in their position. Only a limited number of individuals have suggested that retention is routinely not necessary.[12,35]

Theory 2: Elimination of the Cause of the Malocclusion Will Prevent Recurrence[22]

Until more is known about the causative factors that are related to particular types of malocclusions, little can be done regarding their elimination. When obvious habits such as thumb or finger sucking or lip biting contribute to a malocclusion, recognizing them as etiologic factors is significantly easier. To improve retention prognosis, however, identifying and preventing, as much as possible, the causative factors that contribute to the malocclusion are important.

One of the more insidious habits that operate against successful retention is tongue posture and function, which results in anterior and, occasionally, lateral open bites. The mere fact that the patient has been directed along a course of tongue or speech therapy and is able to meet all the exercise requirements of the therapist on conscious command does not guarantee correction of this subconscious behavior pattern.[36] In fact, several investigators have suggested that open bite malocclusion may be attributable to mouth breathing, resulting from nasopharynx obstruction that could result from anatomic blockage, allergic disease,[28] or adenoid hyperplasia.[37] Mouth breathing may also be habitual, which then necessitates a compensatory low anterior tongue posture and rotated mandibular position for the individual to be able to breathe. Dentofacial changes associated with this functional alteration appear to become more severe with age[28] and are a challenge to diagnose accurately and to treat and retain successfully. This retention issue has been discussed by Lopez-Gavito and colleagues,[31] who conducted a long-term evaluation of patients with initial open bite malocclusions. Despite attempts to control posterior maxillary vertical changes during active treatment and retention, the authors of this study found that 35% of the patients with an initial open bite had an open bite of 3 mm or more 10 years out of retention.

Theory 3: Malocclusion Should Be Overcorrected

A common practice of many orthodontists is to overcorrect a Class II malocclusion into an edge-to-edge incisor relationship. One must be aware, however, that an overcorrection such as this could be the result of muscle *memory*, rather than the achievement of a true skeletal or dental correction. The use of prolonged Class II elastics, for instance, may produce a forward postural displacement of the mandible, which is difficult to detect until elastics have been discontinued long enough to allow normal mandibular posture to return, emphasizing the need to check patients in the centric relation position.

Overcorrection of a deep overbite is an accepted procedure by many clinicians. Satisfactory maintenance of overbite correction depends on the establishment of satisfactory correction, or overcorrection, during active treatment, as well as retention appliances, such as an anterior bite plate, designed to prevent vertical relapse.

One of the more common types of relapses is the tendency for a previously rotated tooth to attempt movement toward its former position. Overrotation is not often practical, and, furthermore, little evidence exists that indicates its effectiveness in preventing a return to the initial position. Preventing the anterior teeth from erupting rotated in the first place is often possible by providing space for unimpeded eruption through the use of orthodontic expansion appliances or by early removal of primary teeth. As Reitan has stated, "The principle is that if the tooth had never been rotated initially, it would have less tendency to re-rotate at a later time."[38] Additionally, increased stability of corrected rotations through minor surgical procedures has also been suggested by Allen,[39] Boese,[40] Brain,[41] and finally, Edwards,[42] who recommended transseptal fiberotomy.

Theory 4: Proper Occlusion Is an Important Factor in Holding Teeth in Their Corrected Positions

Fidler and colleagues[43] studied the long-term stability of well-finished Class II cases a mean of 14 years after the discontinuation of all retention appliances. The authors concluded that successful achievement of a good occlusion after active orthodontic treatment was very stable in the long term. In contrast, Norwick[44] evaluated the long-term stability of cases in which the final orthodontic result was judged to be unsatisfactory. Norwick found a statistically significant relapse in overjet and posterior dental relationships a mean of 14 years 8 months out of retention. When compared with successfully treated patients, the unsuccessful sample exhibited changes in overjet and posterior dental relationships that appear to be the result of inadequate occlusal correction at the end of active treatment.

Theory 5: Bone and Adjacent Tissues Must Be Allowed to Reorganize around Newly Positioned Teeth

In general, the orthodontist should use some type of fixed or removable retention appliance to maintain the achieved correction. Historic evidence shows that the alveolar bone and periodontal ligament around the teeth that have been moved are altered, and it takes considerable time before complete reorganization can occur. Some authors advocate fixed wire retainers (1) as *permanent* retention, whereas others suggest that retainers should have no *positive fixation* to allow for the natural functioning of teeth.[37,45] Oppenhein[46] argued that repair of tissues around the teeth more rapidly occurs if no fixed retention appliance is used.

Whether stability increases with prolonged retention is also difficult to determine as documentation and a control of variables, such as cooperation, length of retention time, growth, and appliance design, make reaching valid conclusions difficult.

Present-day orthodontic concepts consider tooth position to result from a state of equilibrium between the muscular environment and the influence of the transseptal and periodontal fibers surrounding the teeth.[47]

Theory 6: If the Lower Incisors Are Placed over Basal Bone, They Are More Likely to Remain in Good Alignment

According to this theory, direct attention should be paid to the proper angulation and placement of the mandibular incisors.[23,24,48–51] The difficulty in evaluating this theory is determining whether incisors have been placed upright over basal bone. The term *upright* may be defined as perpendicular to the mandibular plane, plus or minus five degrees, or some other specified angulation, to the occlusal or Frankfort horizontal planes. Specifying exactly where basal bone begins or ends with a satisfactory method of quantification is also difficult.[33,52–54]

In growing patients, the mandibular anterior segment may exhibit a physiologic migration or eruption pattern in relation to the mandibular body in a posterior direction that is apart from the intended orthodontic tooth movement.[55–58] If the mandibular anterior teeth are lingually moved during orthodontic treatment, then one can hypothesize that this movement may be in harmony with the normal eruption of these teeth and that retentive care may be minimized.[59]

Theory 7: Corrections Carried out during Periods of Growth Are Less Likely to Relapse

Orthodontic treatment therefore should be instituted, if possible, when the patient is young and actively growing. Little direct evidence exists to substantiate this theory, but it is plausible. If orthodontists are in any way able to influence the growth and development of the maxilla or mandible, then certainly one may logically presume that this growth can be influenced only while the patient is growing.[60–63] In 1924, Matthew Federspiel[64] said, “I am free to confess that we find it almost impossible to treat a true type of disto-occlusion without extraction after the developmental period and keep it in position.” When treatment depends on inhibition or an alteration of the growth direction, as anticipated with headgear or functional appliances, both fixed and removable treatment must be sufficiently initiated early to utilize active growth.

Early diagnosis and treatment planning appear to afford several advantages with regard to long-term stability. The institution of early intervention can prevent progressive, irreversible tissue or bony changes,[65] maximize the use of growth and development with concomitant tooth eruption, allow interception of the malocclusion before excessive dental and morphologic compensations occur (which may become more difficult to resolve) and allow correction of skeletal malrelationships while sutures are morphologically immature and more amenable to alteration.

Theory 8: Arch Form, Particularly the Mandibular Arch, Cannot Be Permanently Altered with Appliance Therapy

Treatment should be directed toward maintaining the arch form presented by the malocclusion as much as possible.[21] Nance[22] reported that attempts to alter the mandibular arch form were met with failure and recommended maintenance of the mandibular arch form as a treatment objective. In 1944, McCauley[20] stated, “Since these two mandibular dimensions, molar width and canine width, are of such an uncompromising nature, one might establish them as fixed quantities and build the arches around them.” Strang[21] reiterated in 1946, “I am firmly convinced that the axiom of the mandibular canine width may be stated as follows: The width as measured across from one canine to the other in the mandibular denture is an accurate index to the muscular balance inherent to the individual and dictates the limits of the denture expansion in this area of treatment.”

OTHER FACTORS RELATED TO RETENTION

Tooth-Size Discrepancies

A discrepancy in tooth size is an often-overlooked problem in retention. Ballard[66] reported that 90% of the casts of the 500 patients he examined had tooth-size discrepancies. When maxillary teeth are too large in relation to mandibular anterior teeth, the maxillary teeth must be in one of the following positions to compensate: (1) deeper overbite, (2) greater overjet, (3) combination of deeper overbite and excess overjet, (4) crowded maxillary anterior segment, or (5) tendency toward Class III posterior occlusion.

If the mandibular anterior teeth are too large in relation to the maxillary anterior teeth, then compensations may include (1) end-to-end incisor relationship, (2) space in the maxillary anterior segment, which may be closed through restoration, (3) incomplete resolution of mandibular anterior crowding, or (4) treatment of the maxillary posterior teeth to a mesial position, relative to the mandibular buccal segments.

Estimating and evaluating these compensations is possible by fabricating a diagnostic setup or by using a mathematical formula to determine the degree and location of a tooth-size discrepancy between the maxillary and mandibular arches.[67] Three-dimensional imaging allows a very precise means of direct tooth-size measurement and resultant planning for inherent discrepancies.

Interproximal Reduction

Measurements from dental study models or digital images can determine tooth-size ratios and the degree and location of a tooth-size discrepancy. When anterior tooth-size discrepancies exceed 2.5 mm, a trial setup is usually indicated to evaluate the anticipated final occlusion. If the teeth can only be satisfactorily occluded with interproximal reduction (IPR) in the setup, then the clinician should include IPR of these same teeth in the mouth.

IPR can usually be accomplished with more control and ease during the finishing stages of therapy. Approximately 2.5 mm of enamel can be removed from the maxillary or mandibular six anterior teeth (0.25 mm from each surface). To determine the surface best reduced, the size and shape of the teeth are considered in an attempt to correct any intraarch asymmetries and to minimize gingival interproximal *black triangles*. Enamel thickness should also be considered through the use of accurate periapical radiographs. Removing excessive enamel from the contact point to the extent that the crown width becomes narrower than the cervical dimension should be avoided, since doing so will prevent closing of the spaces in a normal contact relationship, and incisor root proximity could occur.

Growth Factors and Posttreatment Change

Growth can be an aid in the correction of many types of orthodontic problems, but it may also contribute to changes in treated orthodontic cases. For instance, although orthodontists take advantage of growth when treating patients through growth modification appliances such as headgear[68] or fixed or removable functional appliances, alterations of the postorthodontic occlusion can occur, not through tooth change but through disparate maxillary and mandibular growth. Progressive asymmetric growth after treatment may also be demonstrated with concomitant occlusal changes, despite successfully maintaining the teeth in their posttreatment positions.

With the possible exception of those who have an open-bite malocclusion, patients who have a Frankfort mandibular angle (FMA) within the normal range can generally be expected to show a reduction in this angle with continued growth. If, during orthodontic treatment, the FMA increases, then it may be expected to return to its former relationship, or less, if the patient continues to grow. If no further growth takes place, then the return to the original FMA will likely not occur. If, however, further growth occurs and the maxillary and mandibular teeth are retained in a position of minimal overbite, then the subsequent increase in posterior facial height and a leveling of the FMA may occur without an accompanying increase or relapse in the deep overbite.

Increases in the angulation of the occlusal plane to facial planes during orthodontic treatment are undesirable; the general tendency is for these angles to reverse or decrease after therapy. Class II mechanics, for instance, can rotate the occlusal plane in a clockwise direction by extruding mandibular buccal segments, proclining and intruding lower incisors and extruding and uprighting the maxillary incisors. If no further growth is forthcoming after the occlusal plane has been rotated in this manner, then the subsequent recovery change of the occlusal plane angle may mean the return of the original Class II buccal relationship also with a return of excess overjet as the dental changes reverse.[69]

The implications of mandibular growth and latent mandibular growth in the true Class III malocclusion are very well known, and, accordingly, orthodontists do not usually attempt to perform definitive treatment until all growth has ceased.

Removable functional appliances may play an important role during retention to assist in maintaining the correction of skeletal components. These types of removable appliances can be worn during sleep to minimize changes in the maxillomandibular relationship that may take place, secondary to unharmonious growth. Functional appliances may also be an effective way to encourage differential eruption and tooth movement in compensation for skeletal changes resulting from posttreatment growth.

Third Molars

Third molars are often implicated as causing crowding of the mandibular anterior teeth in the late teens and early 20s. Some authors have attributed the presence of third molars to long-term mandibular dental instability,[70–73] but others have published data suggesting that third molars play little, if any, role in long-term mandibular arch changes.[74–77]

Additionally, two systematic reviews address this issue. In the earlier review by Mettes,[78] one randomized trial[79] was identified for inclusion in the review that indicated third molars did not have an impact on lower incisor crowding over a 5-year period. In the more recent review by Zawawi,[80] 12 studies were identified for inclusion, although only 3 were prospective trials. The authors of this review indicated that most of the included studies had a high risk of bias, and they reported that most of the studies did not indicate a relationship between third molars and lower incisor crowding. However, they also stressed that the quality of the evidence on this topic prevented them from drawing any definitive conclusions.

Implicating third molars as a cause of crowding is tempting. Some postulate that mesial drift plus third-molar eruption may be cofactors that cause the onset of incisor crowding. However, many patients who have had third molars removed experience incisor crowding that progressively worsens.[74] Similarly, many individuals who are congenitally missing third molars will develop incisor crowding over time.[74]

Duration of Retention

Does prolonged retention provide greater stability? A prior study indicates no consensus has been reached on how long to use retention appliances.[81] Also, to date, no satisfactory comparisons have been made of patients with comparable malocclusions similarly treated but having different retention protocols and durations. Most clinicians would consider "longer is better" but recognize individual differences among patients. Long-term maturational changes are often confused with *relapse* and, no matter what the label, may be attenuated with semipermanent retainer wear. As a clinician, determining exactly how long (hours, days, months, years) to use retainers after active treatment and with what frequency is difficult. To complicate the issue, accurately assessing the actual time of retainer wear by the patient is often difficult. In the absence of conclusive evidence on the appropriate duration of orthodontic retention, the concept of semipermanent retention may be the safest bet for a patient, as long as retainers continue to be monitored on a regular basis by the orthodontist and/or general practitioner.

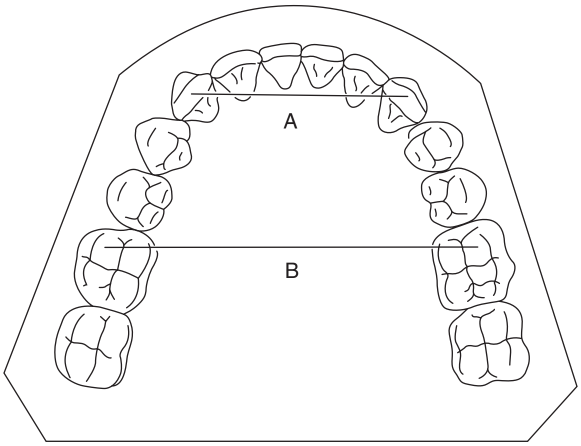
Occlusal Adjustment

Treatment objectives should include the basic principles of gnathology such as canine disclusion and incisal guidance whenever possible. Stability may be improved with occlusal adjustment, concomitant with or after orthodontic treatment, that includes the removal of interferences in centric relation, as well as cross-tooth and cross-arch deflective interferences not eliminated during orthodontic finishing. Attempts to achieve final functional balance immediately after the appliances are removed may not be desirable. The dental changes or settling that naturally occurs after appliance removal should be taken into consideration before undertaking extensive equilibration procedures. Indeed, any occlusal adjustment in the first 6 months after appliance removal should be solely performed to eliminate gross interferences. Restorations can be recontoured, cusps and incisal edges adjusted, and teeth aesthetically recontoured where excessive wear or lack of function has produced undesirable dental morphologic outcomes. Long-term considerations include periodic observation of posttreatment changes with possible detailed occlusal adjustment, as needed, to achieve desirable and functionally beneficial results.

UW POSTRETENTION REGISTRY: LESSONS LEARNED

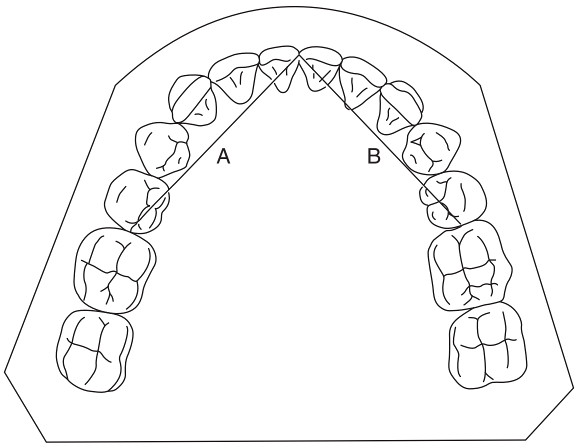
The idea for the postretention registry at the University of Washington (UW) should be credited to Dr. Richard Riedel (Fig. 33-1), former chairman of the Department of Orthodontics. As the story goes, Dr. Riedel wished to determine how his

FIGURE 33-1 Dr. Richard Riedel, founder of the postretention registry at the University of Washington, Seattle.



A = intercanine width
B = intermolar width

FIGURE 33-2 Arch width dimensions.



A + B = arch length

FIGURE 33-3 Arch length measurements.

American Board of Orthodontics cases held up many years after treatment. Upon collecting these records, he learned so much that he decided to increase the target population to all of his former patients. Later, Dr. Little joined Dr. Riedel in this effort, and they expanded the search to include cases from the graduate clinic, faculty practice, alumni, and other interested orthodontists. The result of this collaboration is a collection of approximately 900 cases that have follow-up records at least 10 years after the end of retention, that is, 10 years after all retainers have been removed or discontinued. This sample was not randomly collected nor was it consecutively chosen. Thus the potential for some selection bias is present. If these data could be collected again, then more emphasis would be given to the parameters for sample selection. However, Dr. Riedel tried to include all subjects who were willing to undergo the collection of long-term records, regardless of their long-term outcome. If there is bias, then it might be toward over-representation of patients who exhibited relapse; those who were stable may have had less reason to return to their orthodontists long-term. Nevertheless, the size of the sample is impressive, and given the known limitations of the observational data, this registry has certainly assisted orthodontists in understanding the changes that occur in alignment and arch dimensions many years after treatment.

As stated by Edward Angle[82] himself, "The period of retention of teeth, after they have been moved into normal occlusion, is one of the most important in treatment, and so complicated and persistent are the delicate forces that tend to derangement of the established occlusion as to necessitate the most thoughtful consideration of the problems involved, and a degree of skill in overcoming them which much experience alone can develop, even among those with talent for the work." That statement was written over 100 years ago, and the orthodontic professionals are still challenged by these same forces. As mentioned earlier, many theories have been proposed regarding retention and stability, such as occlusion, muscle balance, incisor proportions, the apical base width, and the placement of incisors over basal bone. Although all of these theories are interesting, the reality is that, today, orthodontists are still debating how to prevent teeth from moving after treatment. What lessons can be learned about relapse emerge from the orthodontic postretention UW registry?

1. **Postretention changes are unpredictable.** Upon meeting a new patient, how often have we wished for a "crystal ball" to predict influences such as growth, treatment response, and cooperation? Having this knowledge in advance would certainly allow us to customize our treatment. The same could be said for retention—if only we knew in advance whose teeth would have a high-relapse potential and whose teeth would stay in their corrected positions. This knowledge would certainly allow us to tailor the types of retainers we prescribe, as well as the wear regimen. However, as helpful as these predictors could be, the hundreds of cases in the registry seem to indicate that postretention changes are unpredictable. Based upon intercanine and intermolar distances (Fig. 33-2), as well as arch length (Fig. 33-3) and the Irregularity Index scores (Fig. 33-4), predicting the long-term outcome based on the initial or end-of-treatment condition was difficult[83] (Fig. 33-5). Therefore long-term retention seems to be the only predictable way to ensure a stable result. Even extraction cases, in which incisors are placed over basal bone, displayed only acceptable alignment in approximately one third of the treated cases after 10 years,[83] and by 20 years, this rate was down to 10%.[84] Although many

cases relapsed toward the original pattern, this movement was not always the case; we were sometimes surprised by teeth moving opposite of the original positions.

Of course, problems with long-term retention can occur using fixed retainers. Oral hygiene can be difficult, and the possibility for caries under or around the lingual retainers certainly exists. Most orthodontists believe periodically checking these retainers is their obligation to ensure that they do not become loose. When they do loosen, relapse can sometimes occur alarmingly quickly, perhaps faster than the patient can make an appointment to have the retainer repaired. On rare occasions, twisted wires can remain bonded to the teeth but, through the relaxation or distortion of the wire, express torque can cause roots or crowns to move considerable distances.

Given these limitations, bonded lower retainers are still a more reliable choice for long-term retention than removable retainers, which are notorious for being lost, thrown away, broken, and inadequately used. A study published in 2010 reported that 40% of orthodontists are routinely prescribing lower fixed retention, whereas 28% prescribe Hawley retainers (DDS Lab, Tampa, FL) and 18% recommend clear thermoplastic retainers.[85] In the maxillary arch, Hawley retainers were prescribed by

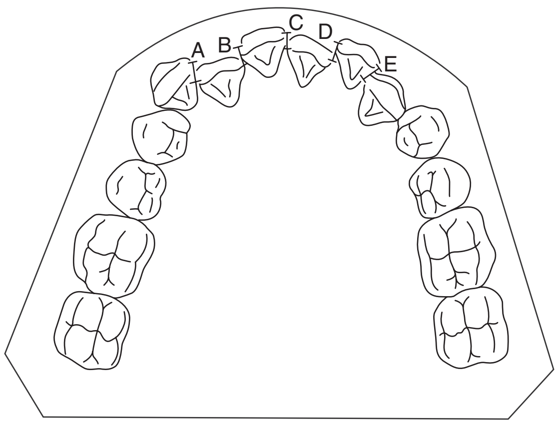


FIGURE 33-4 Calculation of the Irregular Index score.

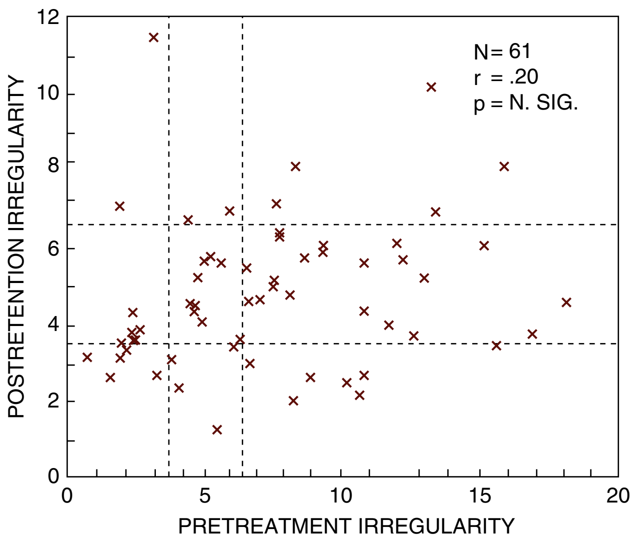

FIGURE 33-5 Relationship between pretreatment irregularity and postretention irregularity.

58% of the practitioners, and clear thermoplastic retainers were recommended by 30%.

2. Arch length and width constrict over time, especially intercanine width. Trends were noted in the postretention cases, and a particularly strong one was constriction in arch dimensions, especially intercanine width (Fig. 33-6). This trend may be related to the popular notion in dentistry known as the *mesial drift*, in which posterior teeth have a tendency to mesially migrate over time. Since the basal bone houses the roots and the lips and tongue provide a corridor for the crowns to exist in a state of equilibrium, mesial drift would eventually result in the crowding of the front teeth, especially the lower incisors. Thus to the extent possible, attempting to maintain or decrease intercanine width seems prudent. In patients with mandibular incisor crowding, aligning the incisors will always result in an increase in intercanine width and/or protrusion unless IPR or incisor extraction is performed. Even extraction of premolars cannot prevent an increase in intercanine width unless the above conditions are met, as the canines are moving into a wider area of the arch to allow alignment of incisors (see Fig. 33-6). Thus, in reality, alignment without an increase in intercanine distance is a difficult task to accomplish, and we must be prepared to deal with the arch constriction that almost inevitably follows.[83] Further complicating our understanding, not all cases show intercanine constriction after retention, a few actually show expansion.

Using the UW sample, investigators assessed the stability of cases undergoing lower incisor extraction. Interestingly, these cases seemed to exhibit better incisor irregularity scores long-term, compared with other types of extraction and nonextraction samples.[86] One might argue that incisor irregularity scores should be lower with incisor extraction cases, since they have fewer contacts to count. However, the investigators controlled for this factor by calculating an average of the incisor irregularity scores; the lower scores were still significant. As previously mentioned, incisor extraction is one of the few treatment modalities we have that can actually allow a reduction in intercanine width, and perhaps this reduction plays a role in the improved stability.

In recent decades, arch expansion using various techniques has become a popular method to address crowding. In particular, claims have been made that treatment with self-ligating brackets allows bone development and, subsequently, better stability. However, little scientific evidence indicates that these claims are true. Although the long-term cases in the UW retention registry were not treated with self-ligating brackets, their results indicate that patients undergoing arch development may be among the most unstable cases encountered.[87] Whether the arch development was in the transverse and/or in the anterior dimension, these patients' arches tended to relapse significantly when retention was discontinued.

3. Rotations usually relapse toward initial positions. If teeth relapse, then predicting that they will relapse toward their original positions seems logical. One philosophy of treatment to counteract this relapse potential is called 11/10 orthodontics,[88] in which teeth are overcorrected by approximately 10% in rotations or labial and/or lingual movement. The idea is that when the tooth relapses, the 1/10 overcorrection will be lost, leaving the tooth in the correct position. Unfortunately, predicting the amount and direction of relapse has proven to be difficult. Although some teeth, perhaps the majority, relapse toward their original position, approximately 20% of teeth unexpectedly relapse away from their original position,[89] making it very difficult to decide whether overcorrection will be harmful or detrimental (Fig. 33-7). Some have advocated a supracrestal fiberotomy to assist with preventing relapse, and some research suggests that this surgical technique can be effective.[37,42] For teeth that have undergone a fiberotomy, there is no guarantee that rotational relapse will not occur. The primary point is that the degree of rotational relapse is lessened but not fully eliminated after fiberotomy. Additionally, the cost and thought of undergoing surgery can be unpopular, especially if stability is not guaranteed.

To prevent relapse of lower incisors, lingual bonded retainers are very common. The two styles that are commonly used are either bonded only to the canines or bonded to each anterior tooth. Although not bonding to incisors that were normally positioned at the pretreatment phase has advantages for oral

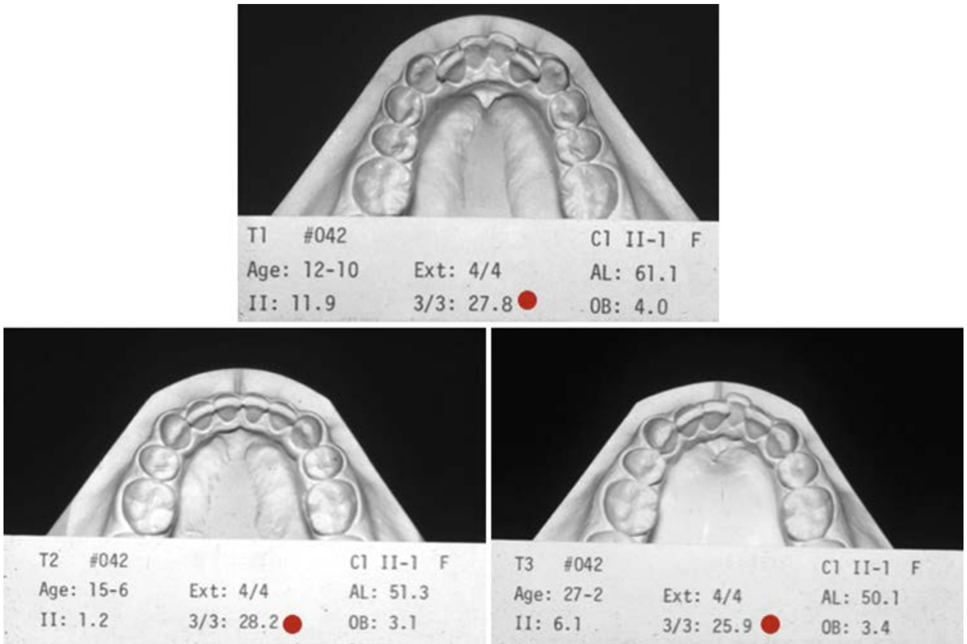

FIGURE 33-6 Photographs of constriction of mandibular intercanine dimension, from ages 12 years 10 months, 15 years 6 months, and 27 years 2 months.

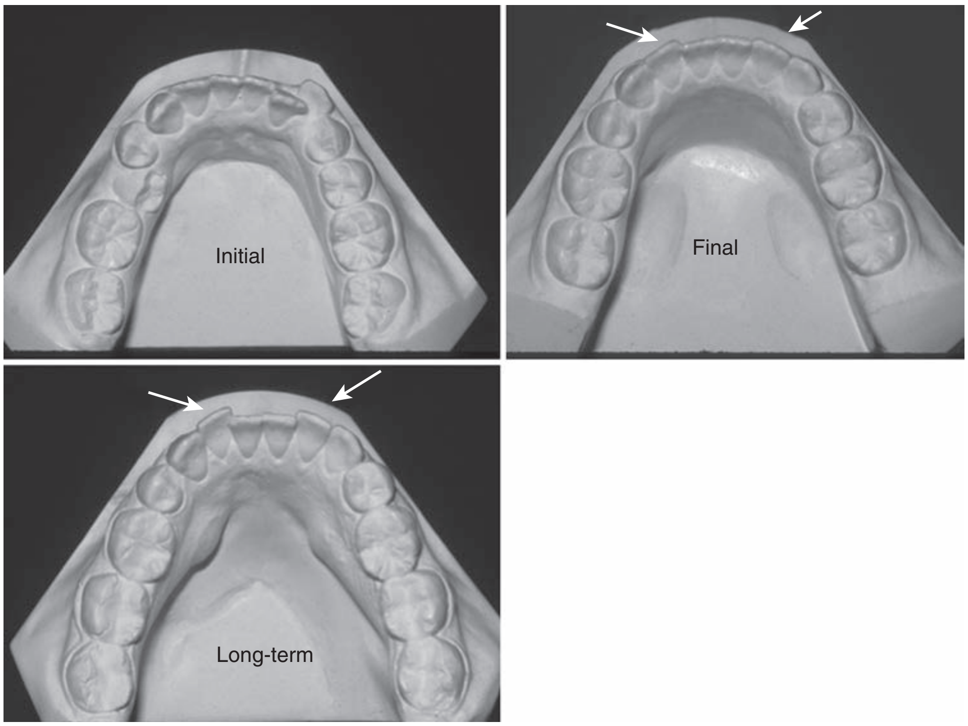

FIGURE 33-7 Photographs of 11/10 orthodontics, as the potential for rotations to move away from the pretreatment condition.

hygiene, any incisors that are not bonded can sometimes move labially or lingually or rotate, even though lip pressure should generally prevent this movement from happening (Fig. 33-8). Retainers bonded to each anterior tooth will prevent posttreatment movement, but hygiene can be more difficult, and more bonds are there to possibly fail.

4. Some cases will display more favorable results. A group of patients that seem to fare better than most are the ones who have adequate or excess arch length at pretreatment (Fig. 33-9). It seems intuitive that those with more than enough space are less likely to crowd in the long term. These patients probably have large jaws, small teeth, or a combination of the two, and either factor provides a considerable advantage for the maintenance of long-term alignment. Additionally, patients with adequate or excess arch length have the benefit of maintaining or decreasing their intercanine width during orthodontic treatment, similar to the incisor extraction cohort. One long-term study demonstrated that these patients rarely showed more than mild crowding.[90]

5. Early treatment may not improve long-term stability. One may ask whether the management of crowding at a younger age is associated with better long-term stability.

FIGURE 33-8 Photograph of an incisor moving away from a retainer only bonded to the canines. (Brackets were placed immediately before taking this photograph.)

Three approaches might be taken. The first strategy is early expansion or arch enlargement. There are some who advocate early expansion to address arch length issues.[91] However, early expansion is not immune from relapse. In fact, patients undergoing mixed dentition enlargement of the lower arch showed the poorest postretention results in our sample, with only 10% having acceptable long-term results.[87]

A second strategy is serial extraction. Unfortunately, this technique does not appear to have a better long-term outcome than premolar extraction in the permanent dentition.[92] Perhaps the reason for this is that patients are candidates for serial extraction because they have insufficient arch length at an early age and are destined for recrowding after treatment and retention, just as are most patients with crowded full dentition.

Orthodontists have hypothesized that those serial extraction cases who demonstrate self-improvement of alignment during the observation period and before full treatment will likely be more stable after retention. Unfortunately, this theory has not proven to be true. Those who favorably react during the observation period may or may not significantly relapse after retention, just as those who do not fare well during the observation period may or may not do well after retention. Serial extraction outcomes seem to be unpredictable in influencing alignment in the long term.

A third approach is utilizing the leeway space. Hayes Nance advocated this strategy, and, in fact, some evidence suggests that utilizing the leeway space may result in superior long-term outcomes.[93] Probably, however, patients who are candidates for preserving leeway space are not as crowded as those who undergo serial extraction; thus the initial crowding should be considered when assessing the long-term outcomes of patients undergoing serial extraction versus the utilization of the leeway space. If the leeway space is equal or greater than anterior crowding, then this strategy appears to give good results. If the leeway space is insufficient to permit anterior alignment without expansion, then this strategy will likely fail to improve retention.

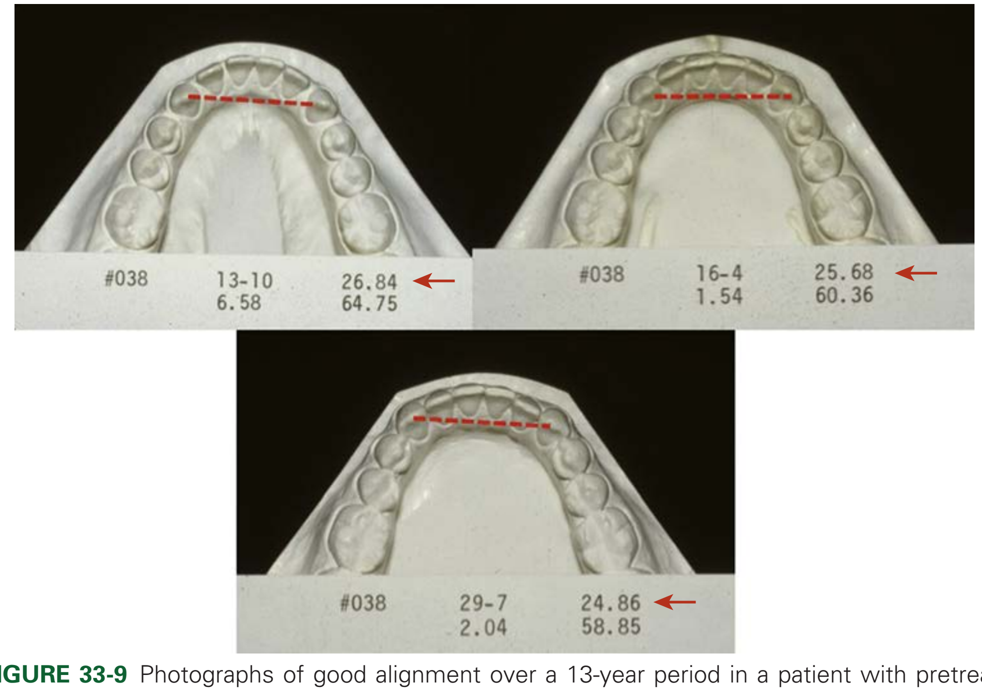

FIGURE 33-9 Photographs of good alignment over a 13-year period in a patient with pretreatment spacing (*red dotted lines*).

6. Early postretention stability is usually a mirage. Many of our patients with fixed retainers displayed a period of relative stability after the removal of retainers. However, this stability proved to be short lived; after a few years, more and more crowding occurred. One might wonder when the relapse ceases. Following cases from 10 and 20 years after retention, apparently, there is no end point. The rate of relapse seems to slow in these cases, but slow, undesirable alignment changes continued to happen.[84] Some patients seemed to have a period of accelerated tooth movement immediately after the fixed retainers were removed. For patients with a strong relapse tendency, many years of fixed retainers may not be enough. Unfortunately, once a bonded retainer is placed, the only way to test stability is by removing the retainer. A graduated lessening of retainer use, which can be done with removable retainers, is not an option.

7. Life-long retention is the best insurance policy. If there is a common theme to our long-term findings, then it is that life-long retention is the best insurance policy that can be provided to a patient. Of course, it is probably not realistic to expect patients to wear their retainers forever. Removable retainers can be lost, worn out, and forgotten, and fixed retainers eventually become loose. Perhaps one strategy is to enlist patients to become partners in the retention process. After all, they will quickly learn if their teeth have a tendency to move or shift, especially if they are using removable retainers. Retention visits should provide an opportunity to discuss retainer use and any observed relapse in a candid and cooperative fashion and to transfer ownership of posttreatment changes to the patient. Fixed retainers usually limit changes in the lower arch; however, when removable retainers are used, patients must be told that they should use their retainers as much as needed to maintain tooth position. Letting patients know that they are in charge and that you will provide assistance can be helpful. Then, when posttreatment movements do occur (and they will for most patients), offering retreatment options and letting patients decide how they would like to proceed are both significantly easier.

8. Extraction of third molars is not necessarily helpful to prevent crowding. One of the most common retention questions that orthodontists hear is whether third molars will cause crowding when they erupt, ruining the results of orthodontic treatment. Third molars often appear during the time that lower incisor relapse occurs, and ascribing the crowding to the eruption of the third molars is only natural. However, the best evidence to date, which comes from two systematic reviews,[78,80] indicates that third molars do not seem to play a large role in lower anterior crowding. In fact, even those with third molars removed or congenitally absent develop lower anterior crowding in the late teenage years and in the early 20s.[74] Coincidently, the typical age of third molar eruption seems to happen when active relapse begins to occur, even for those who have congenitally absent third molars. Nevertheless, this urban myth has proven extremely difficult to dispel, even among general dentists, oral surgeons, and orthodontists.

9. Here is some good news—maxillary teeth fare better. There are some positive findings from the UW retention registry. It appears that relapse occurs for the upper incisors to a lesser degree, and, in addition, the upper incisors do not necessarily mirror the alignment changes observed in the lower arch.[94]

10. Treat to excellence. Quality matters! There were also some interesting findings concerning finishing cases to the highest standards. A study investigating changes in patients with varying degrees of excellent to poor final results showed that an overall regression to the mean long term occurred; that is, cases with excellent finishes tended to deteriorate, whereas cases with poor finishes tended to show some long-term improvement in the scores from the American Board of Orthodontics objective grading system (ABO-OGS).[95] Although this finding might seem counterintuitive, the fact that patients with the best ABO-OGS scores have little room to improve should be given consideration. On the other hand, patients with poor ABO-OGS scores tended to improve in several areas, including marginal ridges, buccolingual inclination, and occlusal contacts. However, one additional important finding was that the cases with the best finishes had the best long-term ABO-OGS scores, indicating that high-quality treatment does, in fact, provide long-term benefits, compared with that of lesser quality treatment.

Feeling a little discouraged after reading the findings of the UW postretention registry is natural. Many of our patients did not hold up well in lower anterior alignment 10 or 20 years after discontinuing retainer wear. Certainly, after all the effort of straightening teeth and correcting occlusions, it would be ideal if teeth would remain in stable positions. However, we are reminded that our bodies undergo changes during our entire lifetimes; perhaps the concept that a perfect occlusion will be stable is unrealistic. In fact, some have proposed using the term *physiologic maturation* or *normal aging* rather than relapse to describe the changes that occur after treatment.

Of course, we should strive for excellence, as the study by Nett and Huang[95] indicates that better occlusions will, on average, exhibit better alignment in the long term. However, above all else, perhaps we need to have candid and honest discussions with our patients before initiating treatment to ensure that they will understand the importance of retainers. Patients should also understand that, despite the best efforts of orthodontists, teeth will and do move, change, and shift over time in somewhat unpredictable ways. Additionally, we also should acknowledge that our understanding of retention is less than perfect. In fact, a Cochrane systematic review published in 2006 concludes that, "There are insufficient research data on which to base our clinical practice on retention at present."[96]

CLINICAL APPLICATIONS OF RETENTION

Retention planning will divided into three categories, depending on the type and extent of retention treatment instituted: (1) limited retention, (2) moderate retention in terms of time and appliance wearing, and (3) permanent or semipermanent retention.

I. Limited retention required.
   A. Corrected crossbites
      1. Anterior: when adequate overbite has been established
      2. Posterior: when axial inclinations of posterior teeth remain reasonable after corrective procedures have been completed. An exception is posterior crossbites treated with either orthopedic or surgical expansion of the mid- palatal suture. In these cases, overcorrection and long-term retention are desirable.
   B. Dentitions that have been treated by serial extraction. The percentage of complete satisfaction secondary to extraction and autonomous eruption alone is typically rather low and depends on the degree of perfection desired by the patient and orthodontist. When extraction of the mandibular second premolars is possible or when they are congenitally absent, the resultant occlusions often are more satisfactory than those in first premolar serial extraction cases.[97]

C. High canine extraction cases.
D. Cases calling for extraction of one or more teeth such as subdivision types of malocclusions, or when the posterior teeth are in Class II relationship and the anterior teeth are treated to a Class I canine position. Occasionally, lingual bonded retainers can be used to prevent extraction spaces from opening.
E. Corrections that have been achieved by retardation of maxillary growth after the patient is through growing.
F. Dentitions in which the maxillary and mandibular teeth have been separated to allow for eruption of teeth previously blocked out. Typical examples are partially impacted mandibular second premolars and maxillary canines.

II. Moderate retention required.
A. Class I nonextraction cases, characterized by protrusion and spacing of maxillary incisors. These cases require retention until normal lip and tongue function has been achieved.
B. Class I or Class II extraction cases probably require that the teeth be held in contact, particularly in the maxillary arch, until lip and tongue function can achieve a satisfactory balance, as in the nonextraction group. Especially true in extraction cases is that the maxillary incisors can be retracted so far as to be unrestrained by lip pressure and to impinge on the space occupied by the tongue before treatment. Use of a maxillary removable retainer until normal functional adaptation has occurred generally is desirable. The time of application of this type of retention can be reduced as the patient adapts to new tooth positions, proceeding from full-time wearing of appliances to nighttime wear only, then perhaps every other night, once or twice a week, and finally wearing retainers at night as needed when they feel tight on insertion. Corrections of adult dentitions probably require longer retentive procedures. A predetermined time schedule for removing retentive appliances probably is undesirable in these cases, and the time of retention depends directly on the patient ‘s compliance and reactions during retention. Tongue and myofunc- tional therapy may be advantageous in this group of corrected cases.
C. Corrected deep overbites in Class I or Class II malocclusions usually require retention in a vertical plane.[98–100]
   1. If anterior teeth were depressed to achieve overbite correction, a bite plate on a maxillary retainer is desirable. To be effective in retaining overbite correction, the bite plate should be worn continuously for perhaps the first several months, including while the patient is eating. In deep overbite cases, overcorrection is usually desirable and occlusal adjustment to an ideal functional relationship is a consideration.
   2. If overbite correction was achieved as a result of clockwise mandibular rotation, vertical dimension should be held at least until growth of mandibular ramal height catches up and neuromuscular balance can adapt.

   A measure of bite opening can be assessed in the degree of change between the mandibular plane and a cranial base plane, such as the Frankfort or sella-nasion. Positive changes of the mandibular plane angle suggest continued retention until growth compensates or until the orthodontist determines that growth is complete. This seems to suggest that correction of deep overbites is desirable before the completion of facial growth. The work of Matthews in this field concludes that beneficial results may be achieved by beginning overbite correction as early as the primary or mixed dentition.

   Severe occlusal plane tipping also may require extended retention protocols and possibly additional maxillary restraint as well. Examination of cephalometric films taken at about 6-month intervals will reveal whether adaptive growth changes have taken place.[101]
D. Early correction of rotated teeth[33,38] to their normal positions.
   1. Perhaps before root formation has been completed
   2. In the mandibular incisor area, a fixed lingual or removable type of appliance with a labial bow is probably best. In this area the occlusal splint-type or Hawley spring retainer may be useful (Fig. 33-10). More recently, gingi- vectomy procedures have offered hope for increased stability of corrected rotations. Early correction of rotations, transeptal fiberotomy and long-term fixed retention may prove to be the most satisfactory.[39–42,46]
E. Cases involving ectopic eruption of teeth or the presence of supernumerary teeth require varying retention times, usually prolonged, and occasionally a fixed or permanent retentive device, such as bonded lingual retainers.
   1. Supernumerary teeth may be encountered in the maxillary anterior area and, on removal of these teeth, the maxillary incisors often erupt slowly and incompletely. When the latter have been brought to a normal level through orthodontic therapy, bonded lingual wires are desirable because these teeth seemingly have a tendency to reintrude when released. Palatally impacted canines, once brought into arch alignment, also may benefit from fixed lingual retention wires bonded to adjacent teeth to prevent reintrusion and palatal relapse (Fig. 33-11).
   2. Excessive spacing between maxillary incisors requires prolonged retention after space closure.
F. The corrected Class II, Division 2 malocclusion generally requires extended retention to allow for the adaptation of musculature. These cases, because they are

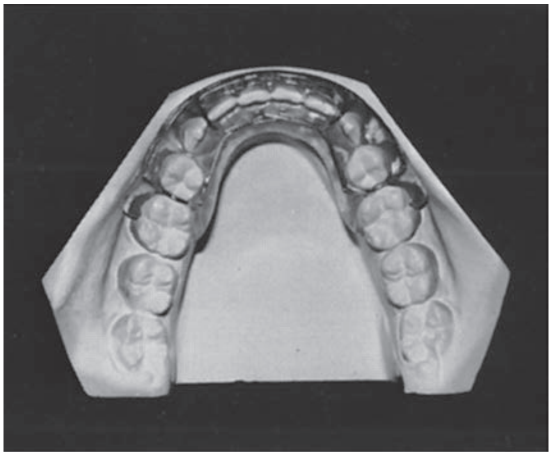

FIGURE 33-10 Mandibular splint retainer. Wire position can be altered to avoid passing through an extraction site or coming in contact with the maxillary dentition.

FIGURE 33-11 Lingual bonded retainers designed to prevent relapse of canines that were initially palatally impacted. A removable retainer is made to fit over and/or around the sectional wires to retain tooth position in other planes of space.

FIGURE 33-12 Lingual bonded 0.014-inch stainless steel wire is applied to hold midline diastema from relapsing. Care should be taken to keep retainer out of occlusion with mandibular incisors.

typically treated without extractions, generally undergo some increase in mandibular intercanine width and present with malalignment of maxillary incisors, which needs to be maintained during retention.

III. Permanent or semipermanent retention required.
  A. Cases in which expansion has been the choice of treatment, particularly in the mandibular arch, may require permanent or semipermanent retention to maintain normal contact alignment. In many instances, patients have aesthetically desirable dentofacial relationships, and extraction of permanent teeth would create aesthetically undesirable results. The orthodontist may be faced with a choice between stability and aesthetics, and often the patient's aesthetic requirements take precedence.
  B. Cases of considerable or generalized spacing may require permanent retention after space closure has been completed.
  C. Instances of severe rotation, particularly in adults, or severe labiolingual malposition may require permanent retention, as provided by lingual bonded retainers.
  D. Spacing between maxillary central incisors in otherwise normal occlusions sometimes requires permanent retention, particularly in adult dentitions (Fig. 33-12).

RETENTION APPLIANCES

The Hawley retainer[9] (DDS Lab, Tampa, FL) is one of the most frequently used retentive appliances available to the clinical orthodontist. The palatal or lingual portion is usually constructed of acrylic and may completely cover the palatal mucosa or can be constructed in a horseshoe shape contacting the lingual surfaces of the teeth and only a limited amount of palatal mucosa. A labial bow of round stainless steel 0.020- to 0.036-inch wire is usually constructed to contact the labial surfaces of

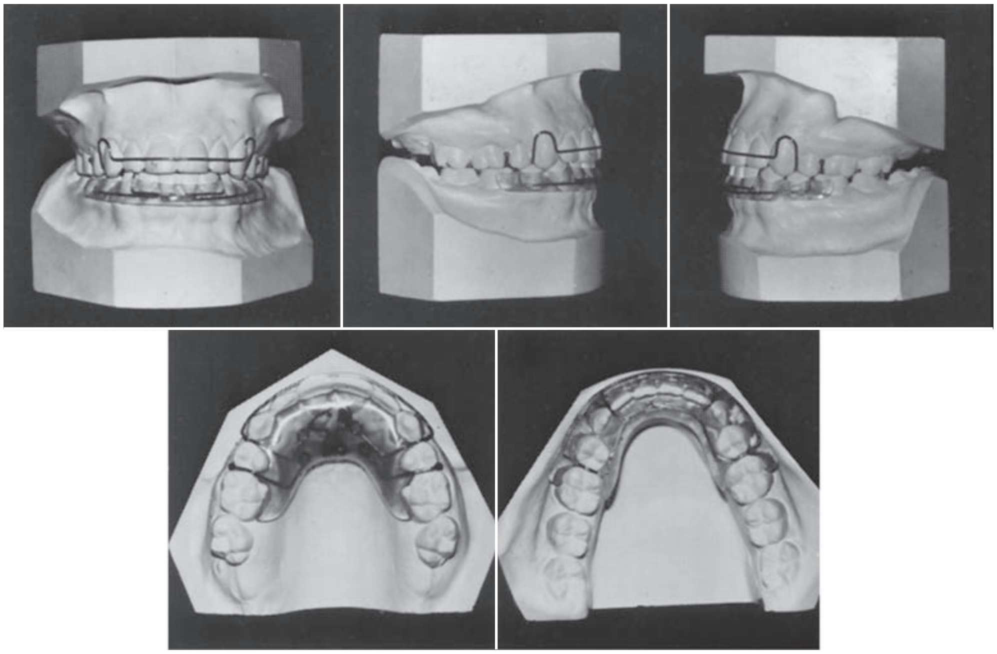

FIGURE 33-13 Typical Hawley and splint retainers. The models should be articulated in occlusion to ensure that the patient is not prematurely contacting on retainer wires or acrylic unless an anterior bite plate is desired. The maxillary labial bow may also cross the occlusion at the canine-lateral incisor embrasure with distal clasping of the canine to avoid a wire in the extraction site that might inadvertently aid reopening of the contact.

four or six maxillary anterior teeth (Fig. 33-13). Constructing the wire to cross incisally through the contact area between the canine and the lateral incisor may minimize occlusal interference in the area of the mandibular canine. If such construction is used, then inclusion of a restraint on the labial aspect of the canines is desirable to prevent their extrusion or labial drift.

The clinician may wish to alter the type and position of retention clasps to avoid traumatic occlusal interferences and to assist in eruption guidance or minor tooth movements, such as erupting second molars (Fig. 33-14). Additionally, the labial bow and retention clasps should not pass through extraction sites, if possible, because that may encourage the tendency for the space to reopen, especially in adult patients.

Circumferential maxillary retainers provide excellent retention with the added benefits of eliminating potential occlusal interferences and aiding in holding the space closed (Fig. 33-15). The clinician may place *keeper* wires between the lateral incisors and canines or flow acrylic on the wire facial to the maxillary anterior teeth to enhance the stability of the labial wire. The clinician also can efficiently adjust labial bow tension if recurved loops are included. Palatal acrylic should be distally extended to retain second molar position, which is particularly important in patients who have undergone changes in transverse dimension during active treatment, such as maxillary surgical or orthopedic sutural expansion.

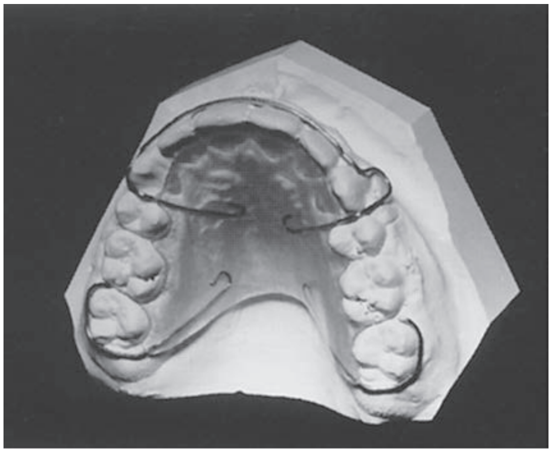

FIGURE 33-14 Maxillary Hawley retainer with C clasps is applied to guide second molar eruption.

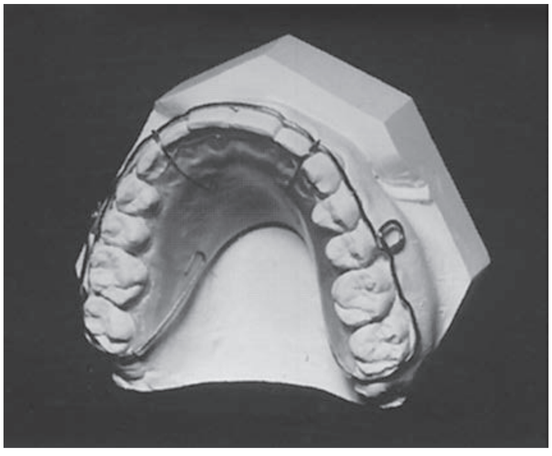

FIGURE 33-15 Maxillary circumferential retainer. Palatal acrylic can be reduced to minimize effects on speech and swallowing patterns. Closing loops allow adjustment of tension.

Pontics may be included in the retainer design to enhance aesthetics and to retain the edentulous area(s) during the transition from fixed appliances to prosthetic replacement of missing teeth (Fig. 33-16). Lingual bonded segmental wires are used to prevent the teeth from drifting into the edentulous areas, and a *flipper* with pontic(s), which is made to fit over the bonded wires, is worn during the day for aesthetics (Fig. 33-17). After the placement of the implants, the retainer can be relieved in the gingival area to allow maintenance of dental aesthetics while avoiding tissue impingement during the osseointegration stage. The clinician may adjust the retainer after completing the prosthetic phase simply by removing the pontic and recontouring the palatal acrylic to fit the final restoration.

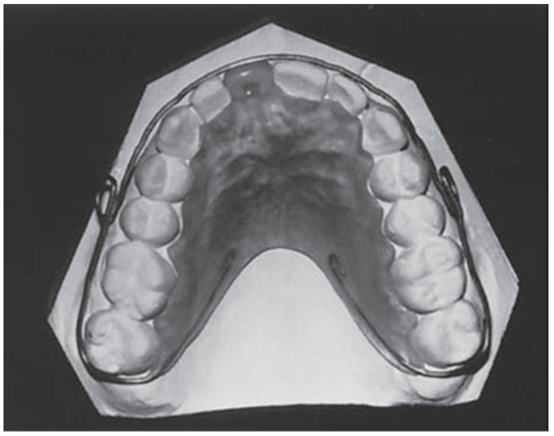

FIGURE 33-16 Maxillary circumferential retainer with pontic is applied to replace missing right central incisor.

FIGURE 33-17 A, Maxillary flipper with pontic to replace right lateral incisor is worn during the day for aesthetics. The flipper is made to fit over and/or around sectional wires bonded on the lingual side to prevent teeth from drifting into edentulous areas. B, Flipper is in place for aesthetic replacement of the maxillary right lateral incisor. Note the use of pink acrylic gingivally to blend into oral mucosa.

A clear removable retainer with pontic(s) held in place within the plastic is also typically made to be worn at night or for use in emergency situations if the regular retainer is lost or broken. The clear retainer is stronger and acts as a night guard to prevent breakage of the pontic from grinding or clenching teeth during sleep (Fig. 33-18).

Clear retainers are commonly used and have the benefits of excellent aesthetics, broad tooth contact to hold alignment, and function as a night guard for those patients who exhibit mild to moderate parafunction such as clenching or grinding teeth while sleeping (Fig. 33-19). These clear retainers are best adjusted or ground into occlusion to ensure even contact throughout the arches in centric relation occlusion.

The clinician also may alter the size of a retainer to accommodate special needs. A mandibular spring retainer, for instance, may include only six or eight anterior teeth to eliminate the difficulty of seating such an appliance over buccal segment undercuts, which are fairly common in adult patients with long clinical crown heights or undercuts created by excess lingual crown torque or restorations (Fig. 33-20).

The clinician may also use fixed retention appliances to retain potential areas of relapse more securely and to reduce the dependency on patient compliance (Fig. 33-21). The development of bonding materials has facilitated the fabrication of segmental retainers that splint two or more teeth together to maintain intraarch tooth position. The wires used for such retainers should be flexible (0.0175-inch twisted or 0.014- to 0.016-inch stainless steel) to allow physiologic tooth movement. Bonded retainers may also be effectively used to hold extraction spaces closed if relapse is anticipated (Fig. 33-22). Canine-to-canine bonded retainers can also be distally extended to include premolars if the premolars were initially ectopic or if holding the extraction spaces closed is the intent, as in adult extraction cases (Fig. 33-23). The clinician can also fabricate removable retainers

FIGURE 33-18 Clear retainer with the maxillary right lateral incisor pontic used during appliance therapy transferred and included in the retainer.

FIGURE 33-19 Example of clear maxillary overlay retainer.

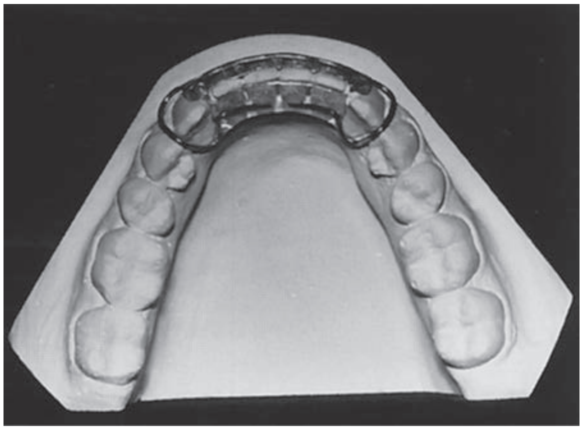

FIGURE 33-20 Mandibular spring retainer modified to maintain only anterior tooth position.

FIGURE 33-21 **A,** Mandibular bonded retainer. A braided wire is bonded to each tooth but allows physiologic tooth movement. **B,** A maxillary bonded retainer may also be placed to prevent relapse of initial spacing or irregularity. This retainer must be positioned and contoured to prevent premature mandibular incisor or canine contact.

FIGURE 33-22 Sectional wire bonded on the lingual to hold an extraction site closed.

FIGURE 33-23 Mandibular bonded retainers can be designed to extend distally to include premolars if premolars were initially ectopic or to hold extraction sites closed.

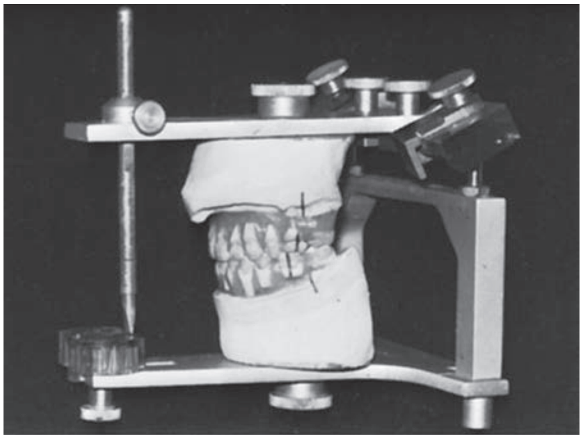

FIGURE 33-24 Diagnostic setup completed on an adjustable articulator after a facebow transfer. Fabrication of the positioner on this type of instrument allows the patient to bite into the positioner without altering condylar position.

to fit over bonded retainers to minimize potential relapse in the other planes of space and to maintain interarch relationships.

Studies[102,103] conclude that fixed bonded retainers are as dentally and periodontally healthy as wearing removable retainers if they are maintained with proper oral hygiene techniques. The clinician can consider, however, eventually removing fixed retention and fabricating removable retainers to be used as needed to minimize the impact of long-term relapse and maturation changes.

POSITIONER IN RETENTION PLANNING

The positioner appears to be particularly beneficial in reestablishing normal tissue tone and firmness where gingival hyperplasia has occurred during treatment. The advantages of a positioner are that it is clean and unlikely to be broken, tends to stimulate tissue tone, and constantly works toward maintaining or improving tooth position. The disadvantages are its limited time of wear, because the patient can neither eat nor talk with the positioner in place, and the possibility that it may keep teeth loose by producing intermittent forces contrary to natural muscle balance. The positioner is probably contraindicated in patients who have a tendency for nasal airway obstruction and are mouth breathers because of the difficulty of breathing with a positioner in place.

If a positioner is to be used on what has been a deep overbite malocclusion, then construction of a maxillary retainer with a bite plane to be used when the patient is unable to wear the positioner is a beneficial adjunct. Construction and placement of a positioner that fits over a fixed appliance, such as a lingual bonded retainer, are also considerations.

Positioner setups and fabrication should be done on an adjustable articulator after a facebow transfer (Fig. 33-24) to allow the patient to function into the positioner without altering condyle-fossa relationships.

DURATION OF RETENTION

As noted from the literature, various authors suggest retention protocols that range from no retention whatsoever[35,83] to permanent retention. Most clinicians will institute some form of mandibular retention until completion of growth is evident. The indefinite use of retainers should also be strongly considered, as needed, to ensure the maintenance of tooth relationships in the long term. The clinician should discuss retention procedures with patients before starting orthodontic treatment to impress upon them the importance of the retentive phase that follows active treatment. Retention may be described as a 12-month *healing phase*, during which the newly made movements of teeth are stabilized, and a *maintenance phase*, to guard against the maturational changes in tooth position that occur over time. The latter phase is, of course, long term.

RECOVERY AFTER RELAPSE

If, despite the utmost care in treatment and retention, relapse or further postorthodontic maturational change occurs, then the following suggestions may be useful:

1. Retreatment may take the form of rebanding or rebonding some or all teeth. Admittedly, this measure is extreme, but it may be necessary to accomplish the desired correction.

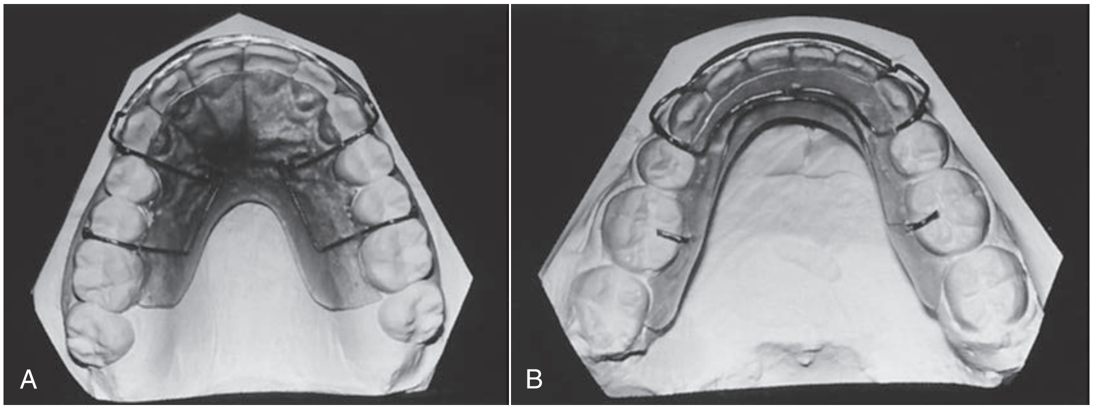

FIGURE 33-25 Maxillary (**A**) and mandibular (**B**) spring retainers. Incisors have been realigned in the working model.

Permanent and long-term retention is likely preferable after retreatment. In any case, discovering and eliminating the factors that appear contributory to the relapse should be attempted.
2. The mandibular lingual arch admirably serves to realign teeth in instances of mandibular collapse or crowding. Light pressure against the mandibular anterior teeth may be used to realign them. In this situation, a removable lingual arch that facilitates adjustment and recontouring is an advantage.
3. Springs and clasps can be added to removable retainers to assist in repositioning and controlling labiolingual deviations.
4. Spring retainers using facial and lingual acrylic for added leverage or clear aligners may be used for realignment. Teeth are sectioned and aligned as in a diagnostic setup or aligned on a computer simulation and the active retainer or aligner(s) is(are) fabricated to the realigned relationship (Fig. 33-25). The same spring retainer(s) used for alignment can be used to maintain the achieved correction. Interproximal stripping is sometimes beneficial as determined by the diagnostic wax-up or computer simulation.
5. A headgear or functional appliance may be used against the maxillary arch during growth to provide maintenance or recorrection in instances of relapse toward a Class II relationship.
6. Habit training in the form of myofunctional therapy may be beneficial when abnormal habit patterns have contributed to orthodontic relapse. Removable appliances are also helpful as tongue restraints and trainers.
7. Occlusal adjustment and interproximal tooth size reduction may be a consideration to achieve an optimal aesthetic and functional result. Interproximal reduction (IPR) or stripping in the crown width may reduce the tendency for further relapse.
8. In certain cases, the clinician may even suggest that the patient accept minimal relapse rather than continue with prolonged retreatment and retention.

SUMMARY

Retention is not a separate problem but is and will continue to be a problem to be considered during the initial and ongoing diagnosis and treatment planning for patients. As Oppenheim[46] so aptly stated, "Retention is one of the most difficult problems in orthodontia; in fact, it is the problem."

Interceptive Guidance of Occlusion with Emphasis on Diagnosis

Jack G. Dale and Hali C. Dale*

OUTLINE

"This "Classic Chapter in Orthodontics" is taken from our fifth edition of Orthodontics: Current Principles and Techniques published by Elsevier in 2012. It is presented as then written. The chapter contains perspectives and information that remain valuable to orthodontic residents and clinicians."

As we learn more about growth and its potentials, more about the influences of function on the developing denture, and more about the normal mediodistal position of the denture in its relation to basal jawbones and head structures, we will acquire a better understanding of when and how to intervene in the guidance of growth processes so that Nature may better approximate her growth plan for the individual patient. In other words, knowledge will gradually replace harsh mechanics, and in the not-too-distant future the vast majority of orthodontic treatment will be carried out during the mixed-dentition period of growth and development and before the difficult age of adolescence.

—Charles H. Tweed

The term *serial extraction* was first introduced by Kjellgren[1,2] in 1929. Special knowledge is required to carry out this procedure successfully. Unfortunately, Kjellgren's phrase resulted in the indiscriminate removal of teeth by individuals who have not appreciated the requisite knowledge. A common misconception is that the procedure is easy because it implies simply the removal of teeth serially.

Hotz,[3] however, referred to the procedure as *guidance of eruption*. This is a better title than Kjellgren's because it implies that knowledge of growth and development is necessary to direct the teeth as they erupt into occlusion. The term *guidance of occlusion* is even more appropriate because clinicians are interested in the final destination of eruption: the occlusion. One must have a thorough understanding of growth and development with all its ramifications and must be aware of occlusion of the dentition, with its relationship to the craniofacial structures and function. This chapter discusses the serial extraction of the primary teeth to guide the eruption of the permanent teeth into

*An article in memoriam of author Jack G. Dale can be found at the following link: http://www.sciencedirect.com/science/article/pii/S0889540616001827 a favorable occlusion to intercept, in part, the occurrence of a major malocclusion.

When the practitioner is contemplating the correction of an orthodontic problem, the most crucial decision to make is whether teeth should be extracted. Even more demanding is adding the morphogenetic pattern and the dimensions of time, complicating that with the growth and development of the dentition and the craniofacial complex and carrying out the procedure serially.[2]

Serial extraction is not easy, as so many mistakenly believe. Serial extraction should never be initiated without a comprehensive diagnosis. Teeth may be extracted with the greatest of ease during a so-called serial extraction procedure. However, if the basic principles of diagnosis are ignored, the result will be failure and disappointment. Serial extraction will be injurious not only to the patient but also to the reputation of the practitioner and ultimately to the profession. Legal concerns regarding risk management include promiscuous extraction.[4]

Unfortunately, since Bunon[5] introduced serial extraction to the profession 268 years ago, it has been grossly misunderstood. Lack of understanding and knowledge has produced disastrous results, including a deterioration of the dentition and facial balance. Serial extraction has been criticized and maligned unfairly by individuals who have never used the procedure in practice or acquired the necessary knowledge to perform it well.

If serial extraction is based on a thorough diagnosis and carried out carefully and properly on a select group of patients, the procedure can be an excellent and valuable treatment. Serial extraction can reduce appliance treatment time, the cost of treatment, discomfort to the patient, potential iatrogenic sequelae, and time lost by the patient and the parents.

To intercept a malocclusion as early as possible and to reduce or, in rare instances, avoid fixed appliance mechanotherapy at the sensitive teenage period is logical. Why allow an unfavorable dental, skeletal, or soft tissue relationship to exist for a number of years if it can be corrected, or significantly improved, early with a minimum of appliance treatment time?

Before attempting the treatment of an orthodontic patient using guidance of occlusion, the practitioner must be prepared to meet the challenge of diagnosis. Without question, the secret of success in orthodontic treatment is a thorough understanding of mixed dentition diagnosis. The orthodontist can have the most comprehensive and sophisticated treatment plan at work in the patient's mouth; however, if the plan is implemented in the wrong patient, treatment will fail. This chapter discusses guidance of occlusion with a special emphasis on diagnosis based treatment planning.

Charles Tweed, whose words are quoted at the beginning of this chapter, was a man who devoted more than 40 years of his life to the treatment of the permanent dentition and the development of precision edgewise mechanotherapy, sometimes referred to as "harsh mechanics." However, during the last 13 years of his life, he was vitally interested in treatment during the mixed dentition period, including preorthodontic guidance, guidance of occlusion, and serial extraction.

Tweed and many others found that serial extraction, especially in Class I tooth size–jaw size discrepancy malocclusions, improves the alignment of the teeth when they emerge into the oral cavity. As a result, it creates a better environment "so that Nature may better approximate her growth plan." Tweed also discovered that the interception of dentofacial deformities using "growth and its potentials" and biologic principles rather than "harsh mechanics" was an exhilarating and rewarding experience.

FIGURE 34-1 Class II, Division 2, malocclusion with an impacted permanent maxillary right canine. During a misguided serial extraction program, one mandibular incisor and the maxillary right first premolar were extracted.

FIGURE 34-2 A 13-year-old girl who did not have the benefit of serial extraction and early treatment.

Early consideration of the corrective measures necessary to remedy any type of malocclusion should be a prime concern of the practitioner. Whatever method is chosen, treatment time should be at a minimum.[6]

Patient requests for more technique sensitive lingual, esthetic labial and/or aligner appliances can make serial extraction even more important. There are increasing concerns of tissue damage and the iatrogenic potential of our armamentaria and materia technica (see Chapter 30).[4] The best way to hide appliances is to not use them or at least to diminish their use. By using the benefits of serial extraction in Class I malocclusions, orthodontists can concentrate more fully on the time-consuming and technically demanding Class II and III malocclusions; thus, these orthodontists increase their usefulness to their profession and to society.

Serial extraction often has been criticized as being a bad procedure, and it certainly can be more harmful than beneficial if not done properly (Fig. 34-1). The two girls in Figures 34-2 and 34-3 are 13 years of age, just at the beginning of adolescence. The girl in Figure 34-2 has a severe Class I tooth size–jaw size discrepancy. Her treatment required the extraction of four premolar teeth and 30 months of mechanotherapy beginning at 13 years. The retention period was prolonged because the teeth had been allowed to remain in a crowded irregular relationship for several years. The girl in Figure 34-3 had a similar malocclusion, but

FIGURE 34-3 A 13-year-old girl who had the benefit of serial extraction and early treatment.

her treatment was completed by 13 years. Serial extraction was begun at 8 years, and the multibonded appliance was inserted at 12 years. The retention period was minimal. Thus, two girls with similar malocclusions were treated differently. Whereas one was just beginning 30 months of treatment at 13 years, the other already was finished and had a more stable result.

The recommended routine office procedure performed before serial extraction requires a complete orthodontic evaluation, including a comprehensive patient history and a thorough clinical and diagnostic record evaluation followed by an appropriate parent or guardian consultation (see Chapters 8-11 and 16).

DIAGNOSTIC RECORDS

A complete set of diagnostic records is acquired to develop the diagnosis, including panoral radiographs and cephalometric radiographs (or cone-beam computed tomography [CBCT]), oriented facial photographs, study models, and intraoral photographs of the dentition. The objective of taking quality records is to secure clinical accuracy for the purpose of establishing a sound diagnosis and being able to communicate the therapeutic needs to the parent and patient as well as general or pediatric dentist.[7]

Intraoral, Panoral, or Cone-Beam Computed Tomography Images

Dental radiographs must be taken for the following reasons:

1. Protection of the patient and documentation for the orthodontist
2. Detection of congenital absences of teeth
3. Detection of supernumerary teeth
4. Evaluation of the dental health of the permanent teeth (detection of pathologic conditions in the early stages)
5. Assessment of trauma to the teeth after an injury
6. Detection of evidence of a true hereditary tooth size–jaw size discrepancy such as the resorptive pattern on the mesial of the roots of the primary canines
7. Determination of dental age of the patient by assessing the length of the roots of permanent unerupted teeth and the amount of resorption of primary teeth, as in dental age analysis
8. Calculation of the total space analysis (see Figs. 34-46 to 34-56)
9. Detection of root resorption before, and by means of comparison, during and after treatment (Fig. 34-4)
10. Evaluation of third molars before, during, and after treatment

FIGURE 34-4 Root resorption of the maxillary central incisors by impacted canines. (From Dale JG. Trauma: its influence on orthodontic treatment planning. *Dent Clin North Am* 1982;26:565.)

11. Posttreatment radiographic evaluation allows for appraisal and documentation of the dental health after orthodontic treatment.

Cephalometric Radiographs

Cephalometric radiographs are used for the following:

1. Evaluation of craniofaciodental relationships before treatment
2. Assessment of the soft tissue matrix
3. Classification of facial patterns (as in the proportional facial analysis) (see Figs. 34-8 to 34-17)
4. Calculation of tooth size–jaw size discrepancies (as in the total space analysis)
5. Determination of mandibular position
6. Prediction of growth and development
7. As a basis for monitoring of skeletodental relationships during treatment
8. Detection of pathologic conditions before and after treatment
9. Assessment of trauma after facial injuries
10. These radiographs and their pretreatment and posttreatment evaluation allow for long-term improvement in treatment planning.

Facial Photographs

Figures 34-5 and 34-6 illustrate the requirements of the American Board of Orthodontics for oriented facial and intraoral photographs.[8] Facial patterns play an important role in diagnosis and treatment planning, especially in serial extraction. From a practical standpoint, the photographs allow the orthodontist to better identify the patient. The prime objective of diagnosis and treatment in relation to the face should be the creation of harmony and balance: a favorable, proportionate relationship between the teeth, skeletal pattern, and soft tissue matrix, including the profile. Similar

Requirements:
Lateral view:
- Ears displayed
- Full face displayed in natural head position
- Left eyelash slightly visible

Frontal views:
- Teeth in occlusion
- Eyes are open and looking into camera
- Ears exposed
- Lips relaxed and in contact
- No distracting eyewear or jewelry
- Cropped to reveal facial symmetry and balance
- Inter-pupillary line bisecting the frame revealing top of shoulders and neck
- Use the same format for the smiling and nonsmiling photographs

FIGURE 34-5 American Board of Orthodontics requirements for facial photographs. (From American Board of Orthodontics. *Specific Instructions for Candidates*. St. Louis: 2016. www.americanboardortho.com/orthodontic-professionals/about-board-certification/clinical-examination/case-record-preparation/photograph-requirements.)

to cephalometric radiographs, facial patterns are invaluable for the following:
1. Evaluation and documentation of craniofacial (and dental) relationships and proportions before treatment
2. Assessment of soft tissue profile and muscle balance
3. Proportional facial analysis and evaluation of symmetry
4. Total space analysis in tandem with occlusal curve analysis
5. Monitoring of treatment progress
6. These photographs and their pretreatment and posttreatment evaluation allow for long-term improvement in treatment planning.

Study Models

Study models provide a three-dimensional record of the dentition and are essential for many reasons.[8] Although CBCT radiographic imaging and occlusal scanning and other imaging technologies may eventually allow us to replace this record, models are used for the following:
1. To calculate total space analysis
2. To assess and document the dental anatomy
3. To assess and document the intercuspation
4. To assess and document arch form
5. To assess and document the curve of occlusion (occlusal curve analysis)
6. To evaluate functional occlusion, potentially with the aid of articulators
7. As a basis from which to measure progress during treatment
8. To detect abnormalities (e.g., localized enlargements and distortion of arch form)
9. These records and their pretreatment and posttreatment evaluation allow for long-term improvement in treatment planning.

Intraoral Photographs

Figure 34-6 illustrates the requirements of the American Board of Orthodontics for intraoral photographs.[8]

Intraoral photographs are valuable to evaluate and document the immediate soft and hard tissue relationships surrounding the teeth. They present a time-stamped record of the visual characteristics of the gingiva as well as the enamel before placement of any appliances. Intraoral photographs add the dimension of color to the records, which aids in assessing and recording the health or disease of the teeth and soft tissue structures.[4]

Regarding serial extraction, photographs allow the clinician to record the steps in the technique, frequently without making study models. This is important for self-evaluation and discussion with patients and parents as well as our general and pediatric dental colleagues. A picture is truly worth a thousand words,

- Mid-palatal raphe centered
- Frame the entire arch with minimal amount of soft tissue displayed

- Fill the frame with the entire mandibular arch at least through the first molars
- Labial surface of the central incisors parallel to the bottom of the frame
- Midline centered in the frame

- Anteriorly include the contralateral central incisor
- Posteriorly include at least the first molars
- Occlusal plane should be parallel to the frame

- Occlusal plane should be horizontal and should bisect the photograph
- There should be equal display of the posterior dentition

- Use the same format as for the right lateral intra-oral photograph

FIGURE 34-6 American Board of Orthodontics requirements for intraoral photographs. (From American Board of Orthodontics. *Specific Instructions for Candidates*. St. Louis: 2016. www.americanboardortho.com/orthodontic-professionals/about-board-certification/clinical-examination/case-record-preparation/photograph-requirements.)

and with the ability to share digital images, we are better able to communicate and consult on important treatment decisions. The ability of a lay parent or guardian to see problems that have been identified, visualize changes, and share with family throughout treatment is a great benefit as well.

DIAGNOSIS

To differentiate, categorize, and treat specifically, successfully, and routinely requires an understanding of the fundamental principles of diagnosis. Several analyses related to the face and teeth are discussed in this section. These examples of the procedures should be followed if treatment is to be successful and serial extraction effective.

The Face

The infant face is not simply a miniature of the adult face (Fig. 34-7). The linkage of the terms *growth* and *development* indicates that the enlargement of the face involves more than progressive increases in size. Growth is a differential process in which some parts enlarge more or less than others and in a multitude of directions. Growth is a gradual maturational process taking many years and requiring a succession of changes in regional proportions and relationships of various parts. Many localized alterations occur that are associated with a continuous process of soft and hard tissue remodeling. An understanding of the mechanisms of growth and development of the face is essential to the practice of dentistry (see Chapter 1). To achieve this understanding, one must have some knowledge of faces.

Normal growth is unbalanced and therefore progressive, and, noticeably, alterations in facial form and pattern take place. Differential growth processes not only produce a wide range of topographic facial variations but also constitute the developmental basis for malocclusions and congenital facial abnormalities. To control and use the complex processes of growth in clinical procedures, an understanding of various concepts is essential for dentists.

Proportional Facial Analysis

The proportional facial analysis is basically a classification of facial patterns based on the Steiner analysis,[9] the Merrifield and Tweed cephalometric analyses,[10,11] and especially the counterpart analysis of Enlow and Hans.[12] Proportional facial analysis includes an evaluation of the following relationships (Fig. 34-8, *A*):

- Anterior cranial base (1, 2)
- Posterior cranial base (2, 3)
- Cranial base angle (1, 2, 3)
- Ramus of the mandible (3, 4)
- Corpus of the mandible (4, 5)
- Gonial angle (3, 4, 5)
- Nasomaxillary complex (6, 7, 8, 9)
- Maxillary dentition (10, 11)
- Mandibular dentition (12, 13)

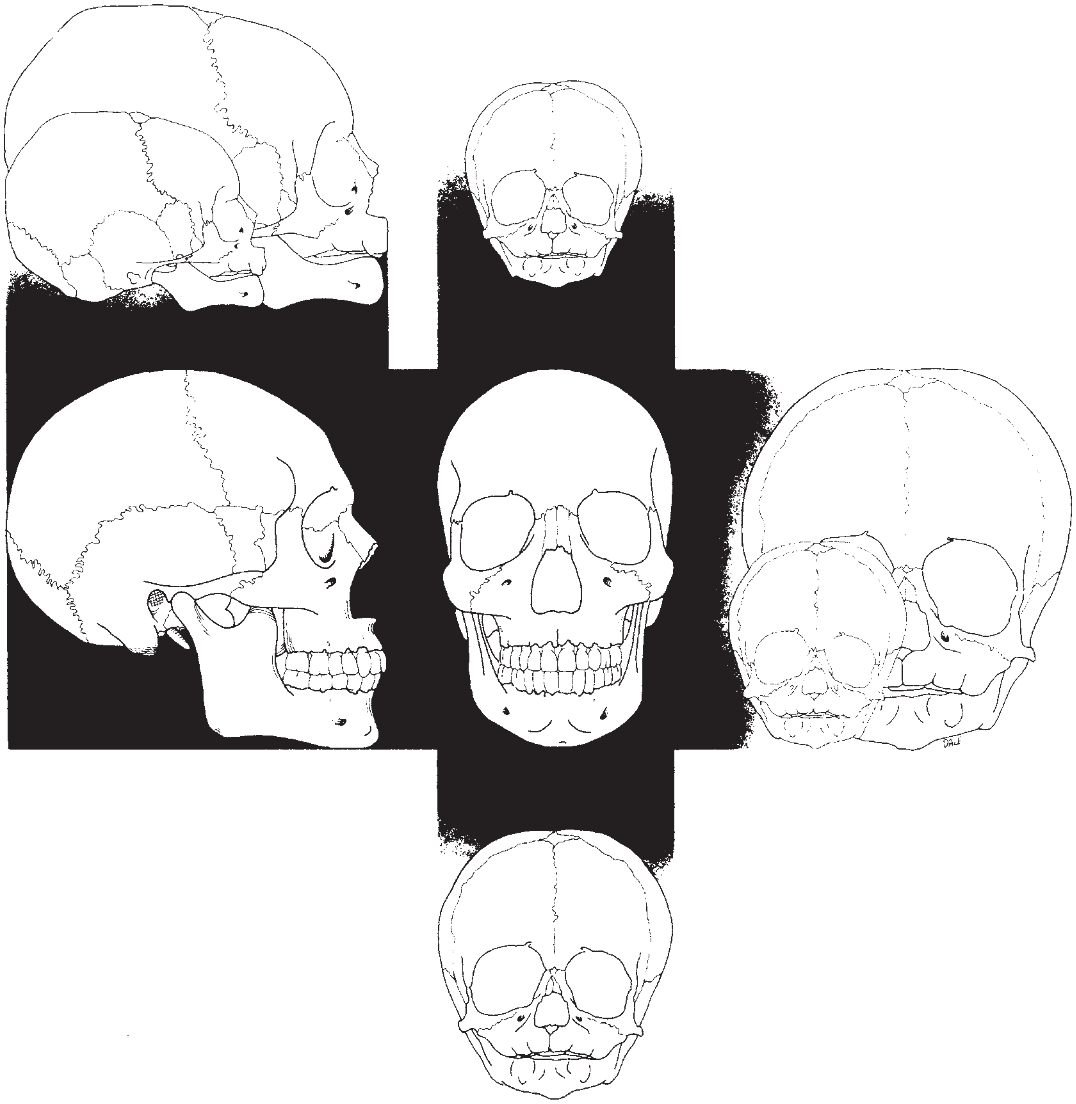

FIGURE 34-7 Changes in facial proportions throughout growth and development from infancy to maturity. To show the regional differences in height, depth, and breadth, the newborn skull has been enlarged to the same size as the adult skull. (From Enlow DH, Dale JG. Childhood facial growth and development. In: Ten Cate AR, ed. *Oral Histology: Development, Structure, and Function*. 5th ed. St. Louis: Mosby; 1998.)

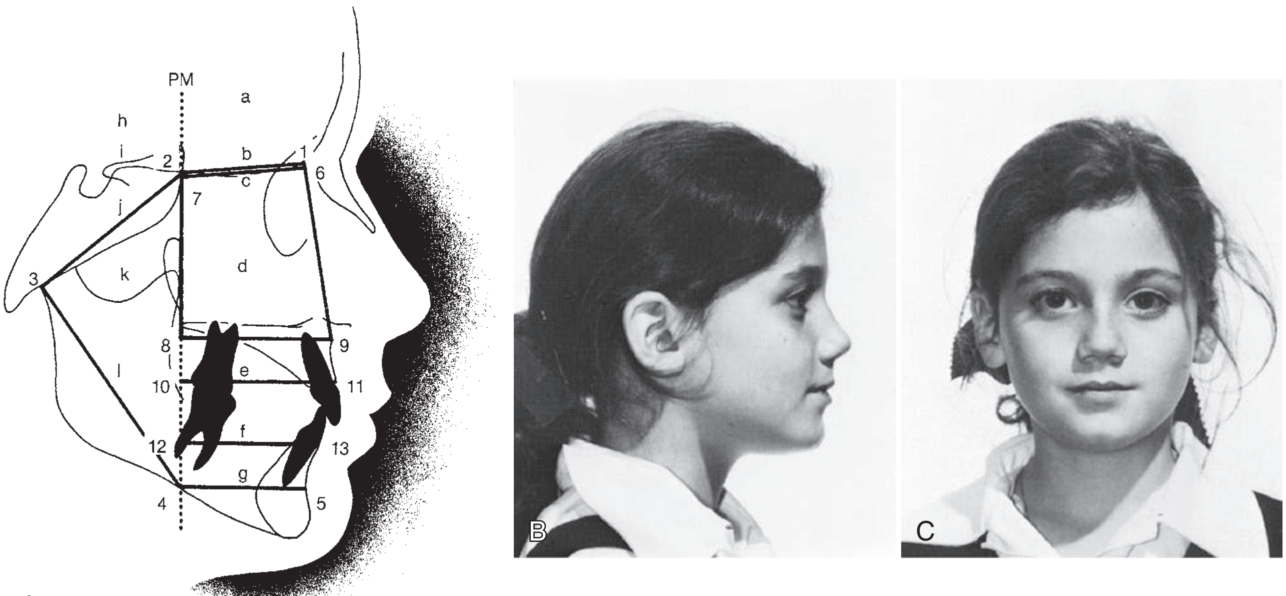

A

FIGURE 34-8 Standard or orthognathic facial pattern. **A,** The basic units associated with the proportional facial analysis. **B** and **C,** The patient.

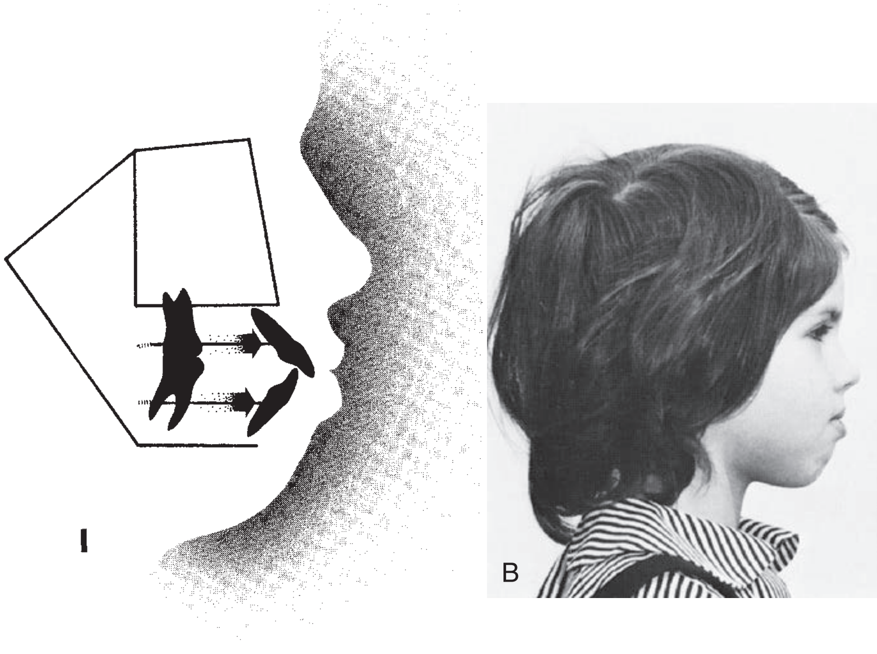

FIGURE 34-9 **A,** Class I maxillary and mandibular alveolodental protrusion. **B,** Typical patient profile.

The posterior maxillary (PM) plane is possibly the most significant plane in the craniofacial complex. The plane delineates, naturally, the various anatomic counterparts and is a developmental interface between the series of counterparts in front of and behind it. The PM plane thus retains a number of basic relationships throughout the growth process.

The Standard

The standard or orthognathic face, as in Figure 34-8, *B* and *C*, exhibits a harmonious relationship between the facial structures and the cranium, between the maxilla and the mandible, between the maxilla and the maxillary dentition, between the mandible and the mandibular dentition, between the maxillary dentition and the mandibular dentition, and between the soft tissue profile and the underlying hard tissue structures ("the mesiodistal position of the denture in its relation to the basal jawbones and head structures").[13]

Alveolodental Protrusion

Class I: Maxillary & Mandibular Alveolodental Protrusion. The maxillary and the mandibular dentitions are forward, and the teeth are in a Class I relationship (Fig. 34-9). This facial pattern in general responds well to extraction and, when caution is exercised, to serial extraction.[14,15]

Class II: Maxillary Alveolodental Protrusion. The maxillary dentition is forward, and the teeth are in a Class II relationship, but everything else is favorable (Fig. 34-10). Routinely, this malocclusion can be treated by the extraction of two maxillary first premolars and by serial extraction in the maxilla only.

Class III. In the interest of brevity and relevance, the Class III category of this analysis is not included in the discussion. Class III malocclusions are not suitable for serial extraction procedures. Mixed dentition Class III treatment is a complicated undertaking, is often extensive and prolonged, and may have to be repeated (see Chapter 16).

Alveolodental Retrusion

Class I: Maxillary & Mandibular Alveolodental Retrusion. The maxillary and mandibular dentitions are back, and the teeth are in a Class I relationship (Fig. 34-11). The orthodontist must be particularly careful in treating this type of facial pattern. If possible, treatment should be done without the extraction of teeth. This appearance can be seen in individuals who have had no orthodontic treatment and in patients who have had treatment with extractions and without. A dished-in face cannot always be avoided, regardless of the treatment.

Class II: Mandibular Alveolodental Retrusion. The mandibular dentition is back, and the teeth are in a Class II relationship (Fig. 34-12). Again, the practitioner must be careful about extracting teeth in this type of facial pattern.

Prognathism

Class I: Maxillary & Mandibular Prognathism. In maxillary and mandibular prognathism, both jaws are forward, and the teeth are in a Class I relationship (Fig. 34-13). Often this is a most aesthetic facial pattern. Many motion picture stars exhibit this type of profile. If the teeth are severely crowded, serial extraction should be performed. However, because of the increase in the size of the jaws, extractions are not always indicated.

Class II: Maxillary Prognathism. In maxillary prognathism, the maxilla is forward, and the teeth are in a Class II relationship (Fig. 34-14). This relationship may be because the maxilla itself is forward or may result from a long anterior cranial base. Also, the cranial base angle may be flat, creating a downward and forward position of the nasomaxillary complex. This in turn may rotate the mandible down and back. These are difficult Class II malocclusions to treat and certainly demand more than serial extraction. The malocclusions are complicated skeletal discrepancies that may require not only comprehensive mechanotherapy but also surgical intervention. Midface protrusions, as they are called sometimes, are difficult profiles to correct satisfactorily by orthodontic treatment alone. The nose, at the end of treatment, often is prominent.

Retrognathism

Class I: Maxillary & Mandibular Retrognathism. In Class I malocclusions exhibiting maxillary and mandibular retrognathism, the maxilla and mandible are back in relation to the other craniofacial structures (Fig. 34-15). It is difficult to produce a favorable profile in these patients because of the lack of horizontal growth and the recessive nature of their profiles. Every effort should be made to encourage a forward development of the jaws. However, this is difficult because the dentition is in a Class I relationship. Over a long time, such a profile can become more recessive and, if serial extraction is being done, the orthodontist could be saddled with the blame. It is important to explain to the parents during the case presentation that the patient appears to have an unfavorable growth pattern that may get worse regardless of treatment.

Class II: Mandibular Retrognathism. In Class II malocclusions exhibiting mandibular retrognathism, the mandible is back. The corpus of the mandible may be small (Fig. 34-16), or the ramus may be narrow. The gonial angle may be proportionately acute. Excessive vertical development may be evident in the nasomaxillary complex (Figs. 34-16 and 34-17), which in turn rotates the mandible down and back, producing a retrognathic mandible and a tendency to open bite. If this is the cause of the retrognathic mandible, the treatment of preference may be surgery or, if less extreme, use of temporary anchorage devices (TADs) to intrude posterior dental segments to allow the forward rotation of the mandible. Regardless, a patient with this facial pattern is not a good candidate for serial extraction. McNamara and Brudon[16] found the most common characteristic of Class II malocclusions to be a retrognathic mandible, with excessive vertical development.

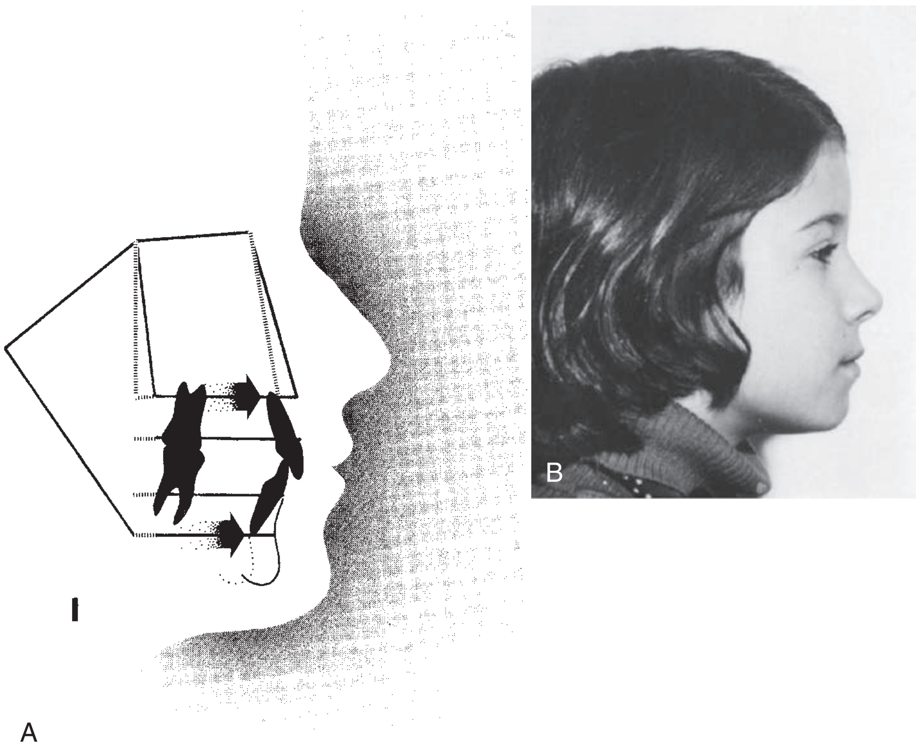

FIGURE 34-13 A, Class I maxillary and mandibular prognathism. B, Typical patient profile.

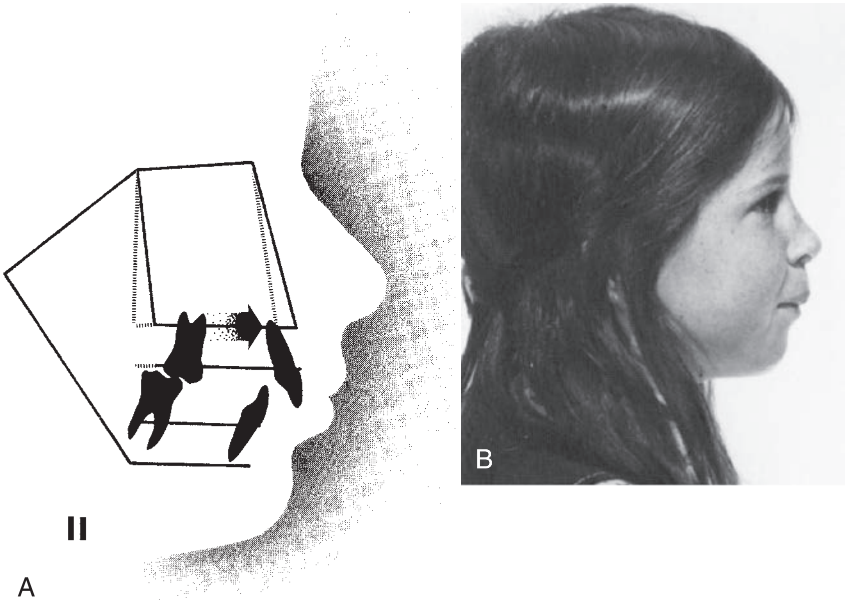

FIGURE 34-14 **A,** Class II maxillary prognathism. **B,** Typical patient profile.

According to the proportional facial analysis, a Class I malocclusion could be associated with a facial pattern characterized by a maxillary and mandibular alveolodental protrusion, maxillary and mandibular alveolodental retrusion, maxillary and mandibular prognathism, maxillary and mandibular retrognathism (even orthognathism), or a combination of these features.

What is evident from this analysis is that to treat all Class I malocclusions in the same manner would not be using sound clinical judgment. Class I malocclusions with excessive vertical development of the nasomaxillary area might be treated better by posterior segment impaction with TADS or combined orthodontics and orthognathic surgery or alternate tooth extraction protocols rather than by serial extraction followed by removal of the four first premolars.

Similarly, a Class II malocclusion could be a result of maxillary alveolodental protrusion; mandibular alveolodental retrusion; a prognathic maxilla caused by a forward nasomaxillary complex, long anterior cranial base, or flat cranial base angle; a retrognathic mandible caused by a short corpus, narrow ramus, acute gonial angle, and excessive vertical development of the nasomaxillary complex; or a combination of these features.

What is even more evident is that one should give serious thought before using serial extraction in Class II malocclusions. Serial extraction aids in the correction of tooth size–jaw size discrepancies but not necessarily in the correction of a Class II relationship. Therefore, the orthodontist must be prepared to place appliances for an extended time. The diagnosis is particularly important because growth guidance appliances and/or permanent teeth other than the four first premolars may be extracted in the treatment of these malocclusions, which is referred to later in the discussion of total space analysis.

The proportional facial analysis describes clearly the multifactorial basis for malocclusion and also explains the way compensation may occur to prevent or minimize a discrepancy. A patient's facial pattern may include a Class I profile with harmony and balance that results from a small cranial base angle (which is a Class III characteristic) and a short corpus (which is a Class II characteristic). Because the maxilla and the mandible tend toward retrognathism, the profile that results is in balance.

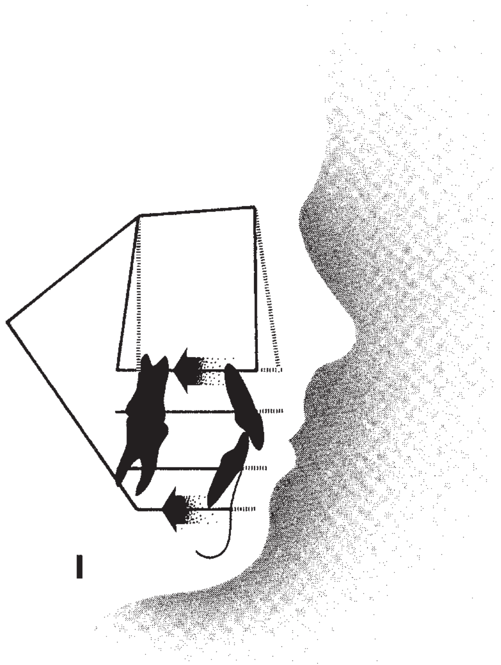

FIGURE 34-15 Class I maxillary and mandibular retrognathism.

Similarly, a combination of factors could result in a more severe malocclusion. A patient might have a Class I malocclusion as a result of excessive vertical development (a Class II characteristic) and a large gonial angle (a Class III characteristic). However, in this instance, the two factors do not balance one another but combine to make the malocclusion more severe. This Class I dentition would not be a good candidate for premolar extraction or serial extraction.

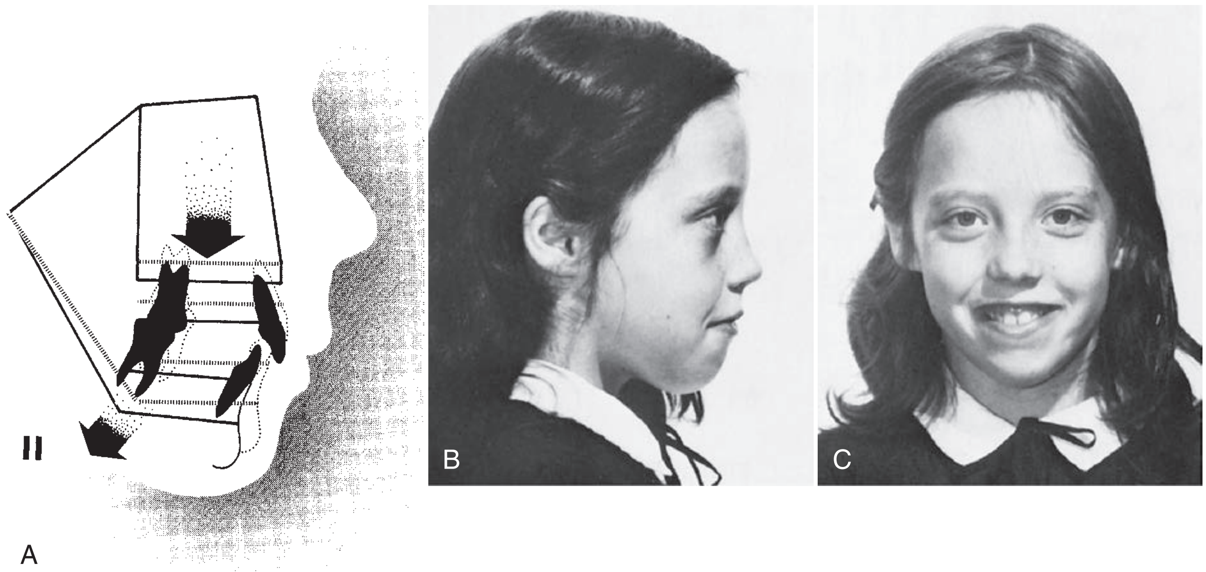

FIGURE 34-16 A, Class II mandibular retrognathism with increased vertical facial height. B and C, Typical patient profile and frontal view. Patients with excessive vertical development reveal substantial gingival tissue when smiling albeit philtrum height is within norm.

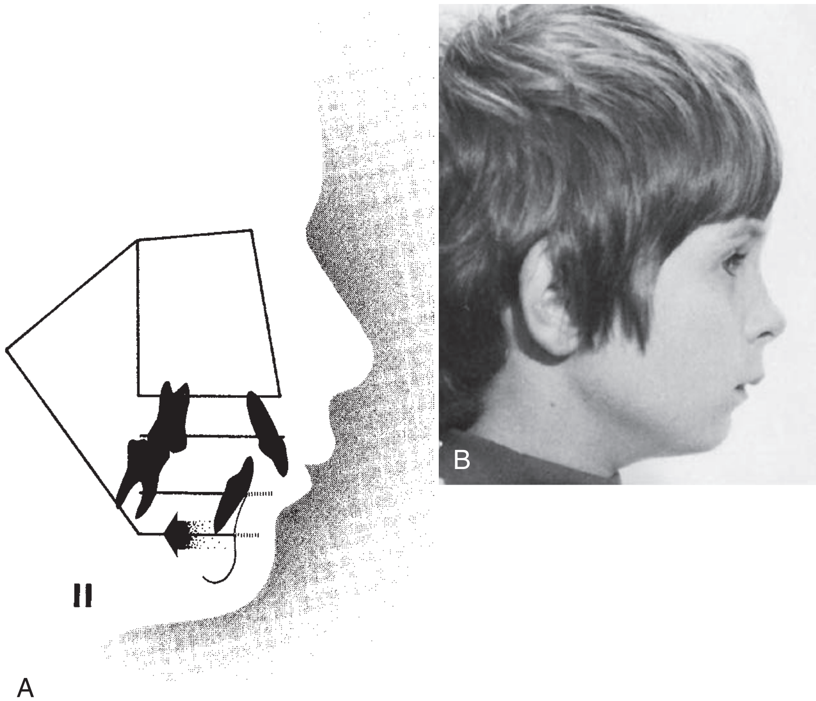

FIGURE 34-17 A, Class II mandibular retrognathism. B, Typical patient profile.

High Angle (Hyperdivergent). The hyperdivergent facial pattern includes a steep mandibular plane and usually is associated with a prognathic maxilla; a retrognathic mandible; a maxillary & mandibular alveolodental protrusion; an open bite relationship of the incisor teeth; an incompetent lip relationship; a long, sloping forehead with a heavy glabella and supraorbital rims; a nose that is long and thin; and a flattened recessive chin exhibiting muscle tension (Fig. 34-18).

Cephalometrically, the mandibular plane to S-N angle is greater than 32 degrees in the Steiner analysis. The Frankfurt mandibular plane angle (FMA) is greater than 25 degrees in the Tweed analysis. Additional features include dolichocephalic head form, leptoprosopic facial form, large gonial angle, short ramus, small coronoid process, antegonial notching, long anterior face height, short posterior face height, long lower face height relative to upper face height, large cranial base angle (which is responsible for a downward and forward position of the nasomaxillary complex), and a downward and backward position of the mandible. This pattern in turn contributes to a steep occlusal plane (OP) and frequently to an exaggerated curve of occlusion. The following are characteristic: microgenia, narrow and long symphysis, high and narrow palate, tooth size–jaw size discrepancy caused by large teeth, impacted third molars, small interincisal angle, overerupted incisors despite an open bite tendency, convex soft tissue profile, weak temporal muscles, restricted pharyngeal space with the tongue forward, mouth breathing, narrow nasal apertures, vertical mandibular growth, and ectomorphic body type with slow skeletal development and poor posture. The extraction of teeth is routinely part of the orthodontic treatment plan in these facial patterns. Extraction is necessary to relieve crowding, assist in the correction of the open bite tendency, and position the mandibular incisors upright. If not too severe, serial extraction may be permissible.

Low Angle (Hypodivergent). The low-angle facial pattern routinely exhibits a low MPA accompanied by a favorable horizontal skeletal relationship or an orthognathic facial pattern, maxillary and mandibular alveolodental retrusion, deep overbite relationship of the incisor teeth, prominent chin, straight or dished-in soft tissue profile, and a shorter nose (Fig. 34-19).

Cephalometrically the mandibular plane to S-N is less than 32 degrees in the Steiner analysis. The FMA is less than 25 degrees in the Tweed analysis. Additional features include a broad brachycephalic head form, a euryprosopic facial form, wide-set eyes, prominent cheekbones, a bulbous forehead, less prominent glabella and supraorbital ridges, a small gonial angle, a broad and long ramus, large coronoid processes, and no antegonial notching on the lower border of the mandible. The anterior face height equals the posterior face height. Compared with the upper face height, the lower face height is small. A small cranial base angle is responsible for an upward and backward position of the nasomaxillary complex and an upward and forward position of the mandible. Macrogenia

FIGURE 34-18 High-angle facial pattern. Facial planes are divergent. Chin profile projection is weak.

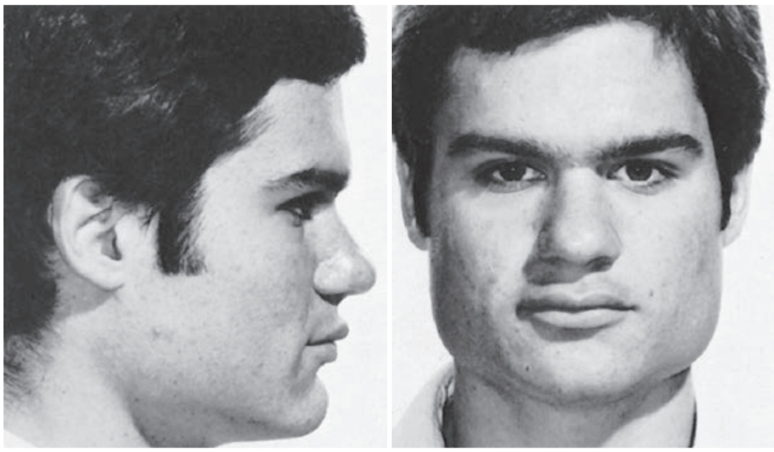

FIGURE 34-19 Low-angle facial pattern. Facial planes are convergent. Chin profile projection is strong.

is common. The palatal vault is flat with a wide dental arch and potentially small teeth. The mandibular incisors may be crowded as a result of a deep overbite, or spaced dentition may result. More abrasion of teeth occurs along with early formation and eruption of teeth; thin lips; deep mentalis sulcus; heavy masseter muscles, with vertical pull; strong temporal muscles; and large pharyngeal space, with a posterior tongue position. Less tongue thrusting occurs when swallowing with low-angle facial patterns. The nasal apertures are large. The mandibular growth is horizontal. The body is endomorphic with advanced skeletal age and upright posture. These patients have less need for extraction; indeed, every effort is made to avoid the extraction of teeth. Arch length can be gained by correcting the deep overbite and positioning the mandibular teeth upright. Serial extraction, in most instances, is contraindicated.

The Teeth

According to the Burlington Orthodontic Research Project,[17] 34% of 3-year-old children enjoy a normal occlusion. By the time they reach 12 years of age, only 11% have a normal intercuspation—a reduction of 23%. Local environmental factors are largely responsible. For example, crowded dentition results from a loss of arch length caused by the premature loss of primary teeth.

Serial extraction is an interceptive procedure designed to assist in the correction of hereditary tooth size–jaw size discrepancies. Because the malocclusions of 66% of 3-year-old children are hereditary (with a significant number of tooth size–jaw size discrepancies), serial extraction is an invaluable adjunct to interceptive treatment. This is especially true in the case of Class I malocclusions and to a lesser extent in the Class II malocclusions.

Class I malocclusions are ideal for serial extraction because the dentition is basically in a favorable relationship and successful treatment is possible with a minimum of mechanotherapy.[18,19] The ideal conditions for serial extraction are (1) a true, relatively severe hereditary tooth size–jaw size discrepancy; (2) a mesial step mixed dentition developing into a Class I permanent relationship; (3) a minimal overjet relationship of the incisor teeth; (4) minimal overbite; and (5) a facial pattern that is orthognathic or with a slight alveolodental protrusion.

Clinical Analysis

Hereditary Crowding. The signs of a true hereditary tooth size–jaw size discrepancy may be outlined as follows:

1. Maxillary and mandibular alveolodental protrusion without interproximal spacing
2. Crowded mandibular incisor teeth
3. A midline displacement of the permanent mandibular incisors, resulting in the premature exfoliation of the primary canine on the crowded side (Fig. 34-20)
4. A midline displacement of the permanent mandibular incisors with the lateral incisors on the crowded side blocked out, usually lingually (Fig. 34-21) but occasionally labially
5. A crescent area of external resorption on the mesial aspect of the roots of the primary canines caused by crowded permanent lateral incisors
6. Bilateral primary mandibular canine exfoliation, resulting in an upright positioning of the permanent mandibular incisors; this in turn increases overjet (Fig. 34-22) and/or the overbite as lower incisors retract
7. A splaying out of the permanent maxillary or mandibular incisor teeth caused by the crowded position of the unerupted canines (Fig. 34-23)
8. Gingival recession on the labial surface of the prominent mandibular incisor
9. A prominent bulging in the maxilla or mandible caused by the crowding of the canines in the unerupted position
10. A discrepancy in the size of the primary and permanent teeth, reducing the leeway space
11. Ectopic eruption of the permanent maxillary first molars, resulting in the premature exfoliation of the primary second molars, which indicates a lack of development in the tuberosity area (see Fig. 34-36)

FIGURE 34-20 Premature exfoliation of one primary mandibular canine with a resulting midline discrepancy.

FIGURE 34-22 Bilateral exfoliation of primary mandibular canines resulting in an increase in overjet, with uprighting of lower incisors.

FIGURE 34-23 Splayed maxillary lateral incisors. This is often coupled with mesial eruption of the permanent maxillary cuspids with potential for damage to the lateral incisor roots if appliances are placed.

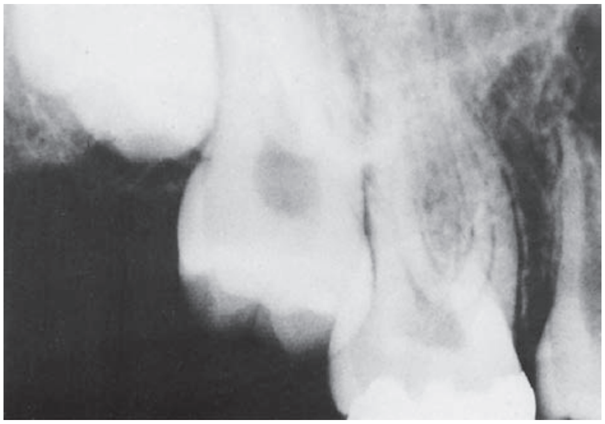

FIGURE 34-24 Palisading of the maxillary molars. The clinician should monitor for impaction of the second molars with potential need for early third molar removal.

12. A vertical palisading of the permanent maxillary first, second, and third molars in the tuberosity area, again indicating a lack of jaw development (Fig. 34-24)
13. Impaction of the permanent mandibular second molars in the absence of treatment

True hereditary tooth size–jaw size discrepancies must be differentiated from crowded dentitions resulting from factors that are more environmental in nature. True hereditary crowding likely will be treated with the aid of extractions and, if discovered early, with serial extraction. However, crowding resulting from environmental factors may be treated without extractions.

Environmental Crowding. Environmental crowding may result under the following conditions:

1. Trauma that affects surrounding hard and soft tissues
2. Iatrogenic malocclusion caused by ill-conceived space management
3. Discrepancy in the size of individual teeth (Fig. 34-25)
4. Discrepancy between mandibular tooth size and maxillary tooth size
5. Aberration in the shape of teeth (i.e., extra cusps)
6. Aberration in the eruptive pattern of the permanent teeth (Fig. 34-26)

FIGURE 34-25 Discrepancy in the size of individual teeth.

FIGURE 34-26 Maxillary canine erupted in the premolar position. This may be related to a transposed canine and ectopic premolar or an absent premolar.

FIGURE 34-27 Rotated maxillary premolar consuming more space than it would in its normal position.

7. Transposition of teeth (see Fig. 34-38)
8. Uneven resorption of primary teeth
9. Rotation of premolar teeth causing loss of space for erupting canines (Fig. 34-27)
10. Ankylosis of primary teeth, most often in first and second primary molars, with adjacent tooth tipping
11. Reduction of arch length caused by interproximal caries in the primary teeth (see Fig. 34-33)

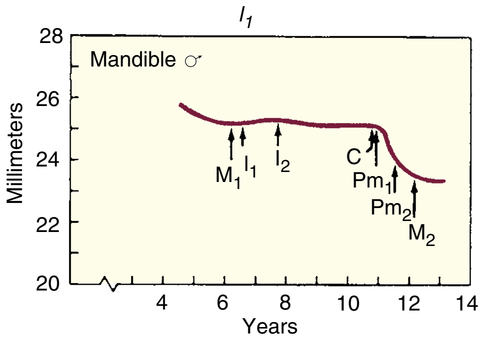

FIGURE 34-28 Reduction in arch length as a result of the moving forward of posterior teeth. *M*$_1$, first molar; *I*$_1$, central incisor: *I*$_2$, lateral incisor; *C*, canine; *Pm*$_1$, first premolar; *Pm*$_2$, second premolar; *M*$_2$, second molar. (From Moorrees CF, Reed RB. Changes in dental arch dimension expressed on the basis of tooth eruption as a measure of biologic age. *J Dent Res* 1965;44:129.)

12. Premature loss of primary teeth resulting in a reduction of arch length from subsequent drifting of permanent teeth (see Figs. 34-34 to 34-37, *A*)
13. Altered emergence sequence (see Fig. 34-43)
14. Exfoliation sequence of primary teeth (see Fig. 34-37, *A*)
15. Prolonged retention of primary teeth

Because serial extraction is performed during the mixed dentition period, careful examination of the transformation from the primary to the permanent dentition is of utmost importance. A thorough understanding of the eruption sequence and range of timing in tooth eruption is critical. One of the most important daily aspects in mixed dentition patient evaluation is the observation of the tooth eruption pattern and follow-up on alterations in the patient's sequence of eruption. Although there are many permutations on "normal," intercepting individual, specific developing problems results in reduced needs for mechanotherapy.

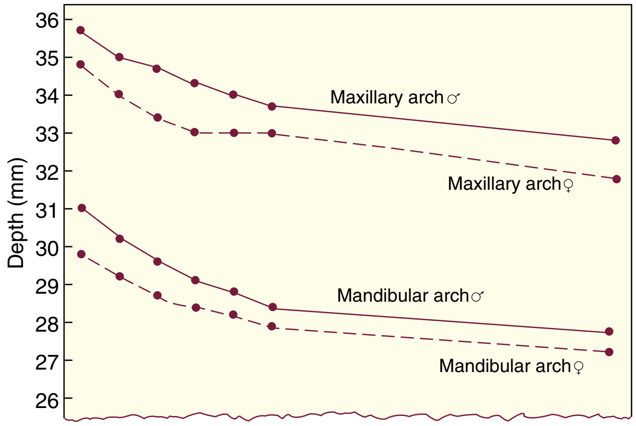

FIGURE 34-29 Reduction in arch depth. (From DeKock WH. Dental arch depth and width studies longitudinally from 12 years of age to adulthood. *Am J Orthod* 1972;62:56.)

Dental Development in the Mixed Dentition

At present, overwhelming scientific evidence indicates that the posterior teeth move forward throughout life. This tends to reduce arch length. Moorrees[20] has established that arch length decreases 2 to 3 mm between 10 and 14 years, when the primary molars are being replaced by the permanent premolars (Fig. 34-28). He also has demonstrated that the arch circumference is reduced about 3.5 mm in the mandible of boys and 4.5 mm in girls during the mixed dentition period.

DeKock[21] measured a 10% decrease in arch length for males and 9% for females over a period of 10 years beyond the period of the mixed dentition, from 12 years to 26 years (Fig. 34-29). Brodie[22] has observed that in newborn infants, the tongue tends to fill the oral cavity and often encroaches on the alveolar ridge area. As a consequence of the more rapid anterior growth of the jaws in the postnatal period, the tongue lags behind and comes to occupy a more posterior position in the oral cavity. This is consistent with the upright positioning of the incisors that occurs in many adolescents as noted by Enlow,[23] Bjork[24] (Fig. 34-30), Tweed,[11] and others.

These findings suggest that as facial growth continues in an anterior direction into adulthood, it thrusts the mandible into the facial musculature, which produces a posterior force vector on the crowns of the incisors. Thus, arch length decreases from the anterior and posterior sides. To repeat, serial extraction is

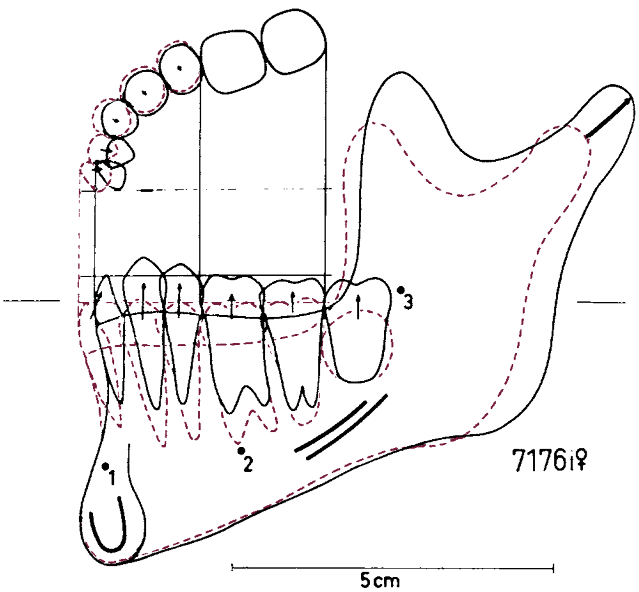

FIGURE 34-30 Upright positioning of incisors with forward growth. (From Bjork A. Variations in the growth pattern of the human mandible: longitudinal radiographic study by the implant method. *J Dent Res* 1963;42:400.)

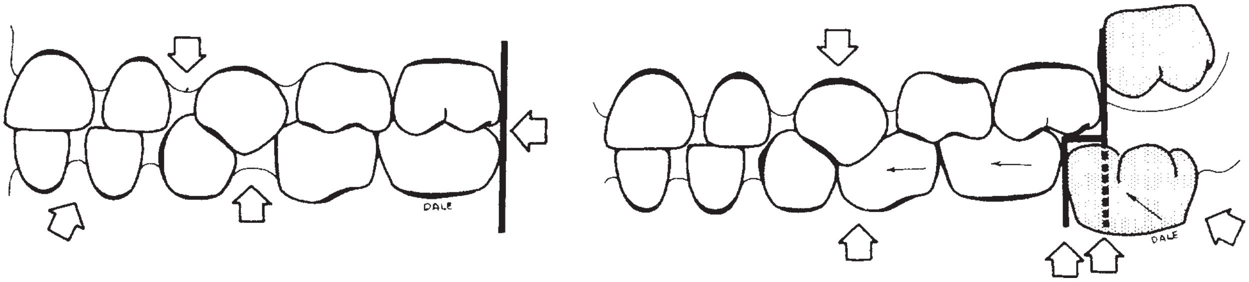

FIGURE 34-31 Early mesial shift. Note the use of normal developmental spaces in the mixed dentition to bias the occlusal development for a mesial shift of the mandibular teeth versus the maxillary teeth. (Adapted from Baume LJ. Physiological tooth migration and its significance for the development of occlusion. II. The biogenesis of the accessional dentition. *J Dent Res* 1950;29:331.)

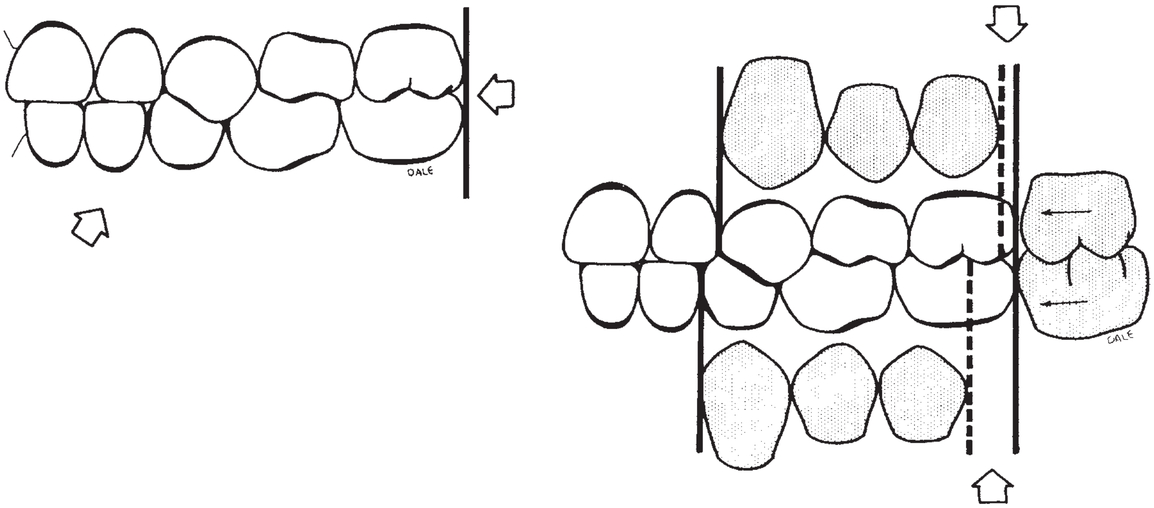

FIGURE 34-32 Late mesial shift. This pattern is seen when there is minimal developmental spacing in the primary and early mixed dentition. (Adapted from Baume LJ. Physiological tooth migration and its significance for the development of occlusion. II. The biogenesis of the accessional dentition. *J Dent Res* 1950;29:331.)

based on the fact that arch length does not increase. If crowding is evident at 8 years, it will not improve with further growth and development.

First Molars. Several situations can exist for the permanent first molars. In patients with a spaced primary dentition and a straight terminal plane relationship of the primary molars, the permanent mandibular first molars emerge at about 6 years, move the primary molars mesially, close the space distal to the primary canines, convert the straight terminal plane to a mesial step relationship, reduce arch length in the mandibular dentition, and allow the permanent maxillary molars to emerge into a Class I relationship. This has been referred to as the *early mesial shift* (Fig. 34-31).

In patients with a closed primary dentition and a straight terminal plane, the permanent maxillary and mandibular first molars emerge into a cusp-to-cusp relationship simply because no spaces exist. At about 11 years, the primary mandibular second molars are exfoliated, and the permanent mandibular first molars migrate mesially into the excess leeway space provided by the differences in mesiodistal dimensions of the primary second molars and the permanent second premolar teeth. Again, this reduces arch length, converts the straight terminal plane to a mesial step, and provides for a Class I relationship of the permanent first molars. This shift has been referred to as the *late mesial shift* (Figs. 34-28 and 34-32). If the permanent maxillary first molars emerge before the mandibular molars, just the reverse of the early mesial shift—an abnormal Class II relationship—will occur, and a reduction in the maxillary arch length will result.

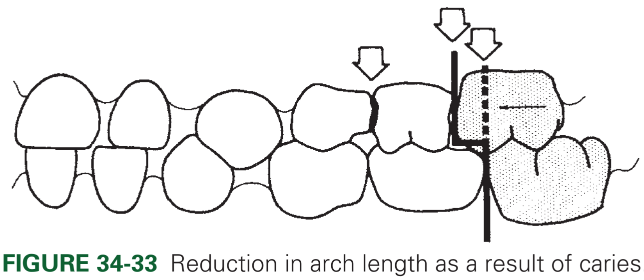

FIGURE 34-33 Reduction in arch length as a result of caries.

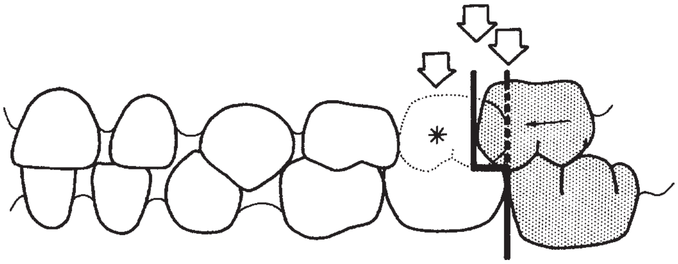
If extensive interproximal caries is allowed to develop in the maxilla, a similar situation will occur: a reduction of arch length causing crowding (Fig. 34-33). If the caries is so extensive that extraction of the primary maxillary second



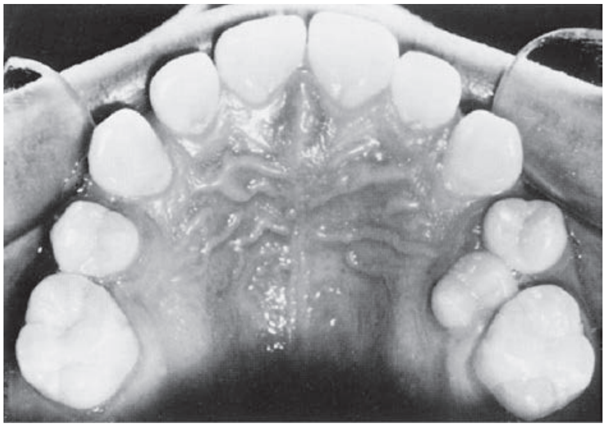


FIGURE 34-34 Reduction in arch length as a result of premature loss of primary maxillary second molars.

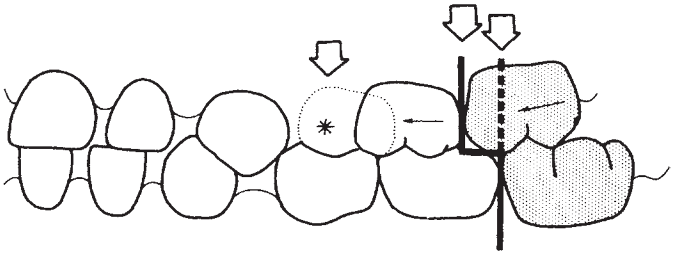

FIGURE 34-35 Reduction in arch length as a result of premature loss of the primary maxillary first molars.

molars is necessary, again, crowding will result (Fig. 34-34). Similarly, and this is contrary to popular belief, premature loss of the primary maxillary first molars will cause crowding (Fig. 34-35).

Ectopic eruption of the permanent maxillary first molars, resulting in premature exfoliation of the primary second molars and loss of arch length, indicates a lack of development of the tuberosity. This results in not only crowding but also a Class II molar relationship (Fig. 34-36).

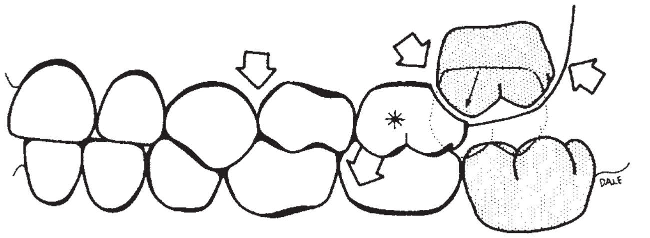

FIGURE 34-36 Reduction in arch length as a result of ectopic eruption of the permanent maxillary first molars.

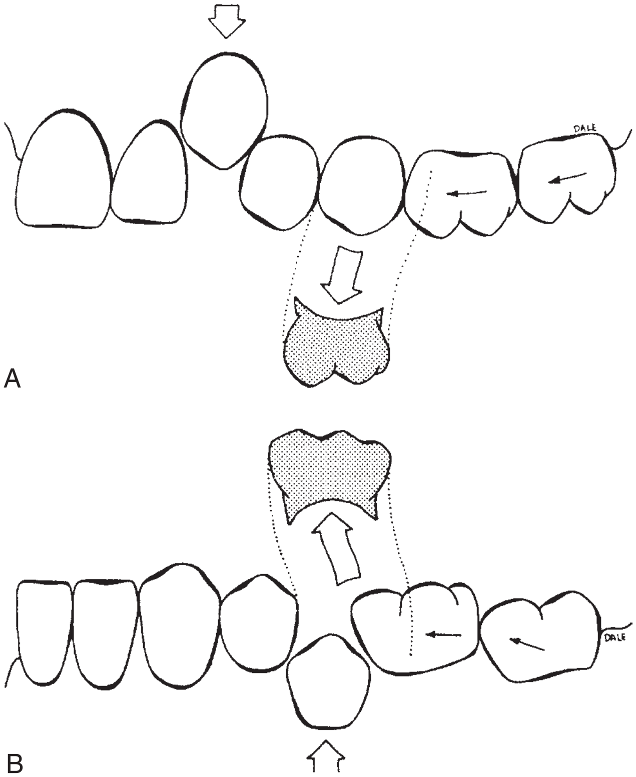
If the exfoliation sequence of the primary second molars is reversed and the maxillary molar is lost before the mandibular, a Class II relationship of the permanent first molars will result. Again, arch length will be reduced, and crowding will occur in the maxilla (Fig. 34-37, *A*).

However, if the primary mandibular second molar is lost far too early, the mandibular arch length will be reduced to such an extent that the normal leeway will be exceeded and crowding will occur (Fig. 34-37, *B*).

The normal leeway, according to Lo and Moyers,[25] is 2.6 mm (1.3 mm on each side) in the maxilla and 6.2 mm (3.1 mm on each side) in the mandible. However, this leeway varies considerably and should be measured on each patient. It is possible for a discrepancy to exist between the size of the primary teeth and the size of the permanent teeth to such an extent that no positive leeway is available. A negative leeway may exist. According to Horowitz and Hixon,[26] correlations in size between a single primary tooth and its successor range from $r = 0.2$ to $r = 0.6$. This means that anywhere from 4% to 36% of the successors are favorably correlated in size to the primary teeth. In other words, if the primary tooth is small, its successor will be small. According to Arita and Iwagaki,[27] Hixon and Oldfather,[28] Lewis and Lehman,[29] Moorrees and Chadha,[30] and Jensen et al.,[31] the size correlation between all the primary teeth and their successors is approximately $r = 0.5$. Therefore, 25% of the time, a positive relationship exists. That is not too favorable for optimal occlusion.

Incisors. Several situations can exist also for the incisors. Ideally, the primary spacing of the spaced primary dentition will be sufficient, together with other factors, to allow for the accommodation and favorable alignment of the succedaneous permanent incisors (Fig. 34-38).

In primary dentitions in which there is no interdental spacing, the permanent mandibular lateral incisors emerge, and the primary mandibular canines are moved laterally. Thus, a space is created that enables the permanent maxillary lateral incisors to emerge into a favorable alignment. This is referred to as *secondary spacing* and was first described by Baume (Fig. 34-39).[32] Secondary spacing also occurs when the permanent mandibular central incisors are emerging.



A

B

FIGURE 34-37 A, Reduction in arch length as a result of premature exfoliation of the primary maxillary second molar. B, Reduction in arch length as a result of premature loss of the primary maxillary or mandibular second molar.

Both of these observations have been substantiated by the findings of Moorrees[20] that show an increase in intercanine width during the period of incisor emergence (Fig. 34-40). Moorrees also has demonstrated an increase in arch circumference in the maxilla of boys of 1.5 mm and of girls of 0.5 mm during this period of development.[33]

If the primary canines are reduced in size or extracted when this natural phenomenon is occurring, an increase in intercanine distance and secondary spacing may not occur. Thus, borderline discrepancies may be converted from a nonextraction treatment to extraction.

Research conducted by Moorrees and Chadha[34] has revealed an increase in the crowding of maxillary and mandibular incisors when they are emerging into the oral cavity. However, 2 mm of crowding in the incisor segment in the mandible of boys will recover to no crowding by 8 years on the average. Girls recover to about 1 mm of crowding. The maxillary dentitions of boys and girls do not exhibit the same tendency to crowding. However, during the eruption of the incisors, 2 to 3 mm of spacing is reduced to 0 (Fig. 34-41). This is a significant finding because it tells the clinician not to be alarmed with a slight amount of crowding in the early stages of emergence of the permanent incisors. The reduction in size, or extraction, of the primary canines should be deferred. In fact, the patient may not require extraction at all.

Intercanine distance increases more in the maxilla and in closed dentitions, which lack primary tooth interdental spaces. A true hereditary tooth size–jaw size discrepancy is characterized by permanent mandibular lateral incisors and a premature exfoliation of the primary canines (Fig. 34-42).

Mayne[35] described a concept he termed *incisor liability*. In his discussion, he outlined the way in which incisor liability could be used clinically to determine anterior crowding. He described the following principal variables:

1. The four permanent maxillary incisor teeth are, on the average, 7.6 mm larger than the primary incisors.[36] The four permanent mandibular incisors are 6.0 mm larger. This size differential is the incisor liability. The liability varies greatly from individual to individual, and for this reason, the patient's own tooth measurements should be used in the analysis. A favorable incisor liability exists when the spacing of the

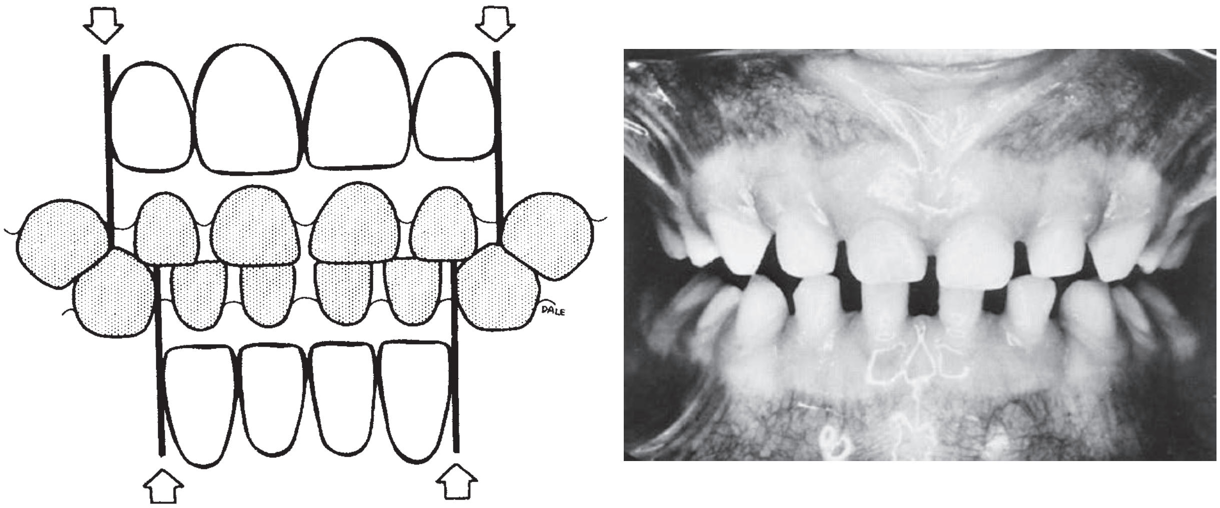


FIGURE 34-38 Primary spacing. Allows larger incisors to erupt with reduced chance of crowding.

primary anterior teeth is sufficient to allow for the eruption of the permanent incisors without any crowding (see Fig. 34-38).
2. A more precarious incisor liability situation exists when no primary spacing is present in a closed primary dentition. Then the individual must rely on the development of secondary spacing to create sufficient space for the permanent incisors to emerge without crowding (see Fig. 34-39).
3. An impossible situation exists when the incisor liability is of such magnitude that growth and development will never be able to meet the space demands required by the permanent incisors. Such patients are doomed to severe crowding and irregularity from the outset (see Fig. 34-42).
4. In the primary dentition, the interdental spacing may range between 0 and 10 mm in the maxilla, with an average of 4 mm, and between 0 and 6 mm in the mandible, with a range of 3 mm.
5. During the period of permanent incisor eruption, notable amounts of intercanine arch width development occur in the maxillary and mandibular dentition. In the mandible, the increase occurs between 6 and 9 years for boys and between 6 and 8 years for girls. In the maxilla, it increases longer, to 16 years in boys and 12 years in girls (see Fig. 34-40).
6. After 10 years of age, little intercanine arch width change is expected in the mandible of boys or girls. The average increase in the mandibular dentition of boys and girls is about 3 mm; in the maxilla, it is about 4.5 mm (see Fig. 34-40).
7. The permanent incisor teeth erupt slightly labial to the arch position of the primary incisors and for a time at least are more procumbent.[35]

Incisor crowding may be assessed by using the variables just described. First, a favorable situation, described previously,

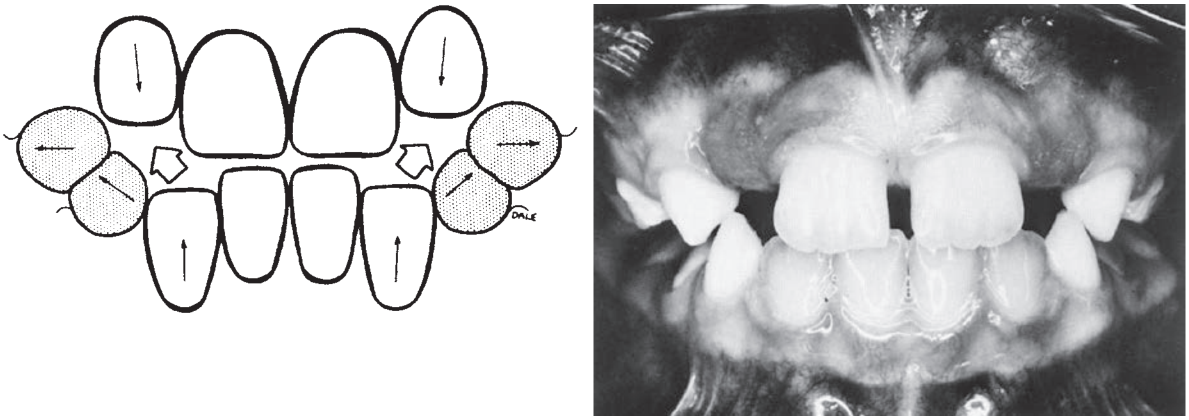

FIGURE 34-39 Secondary spacing occurring when the permanent mandibular lateral incisors are emerging.

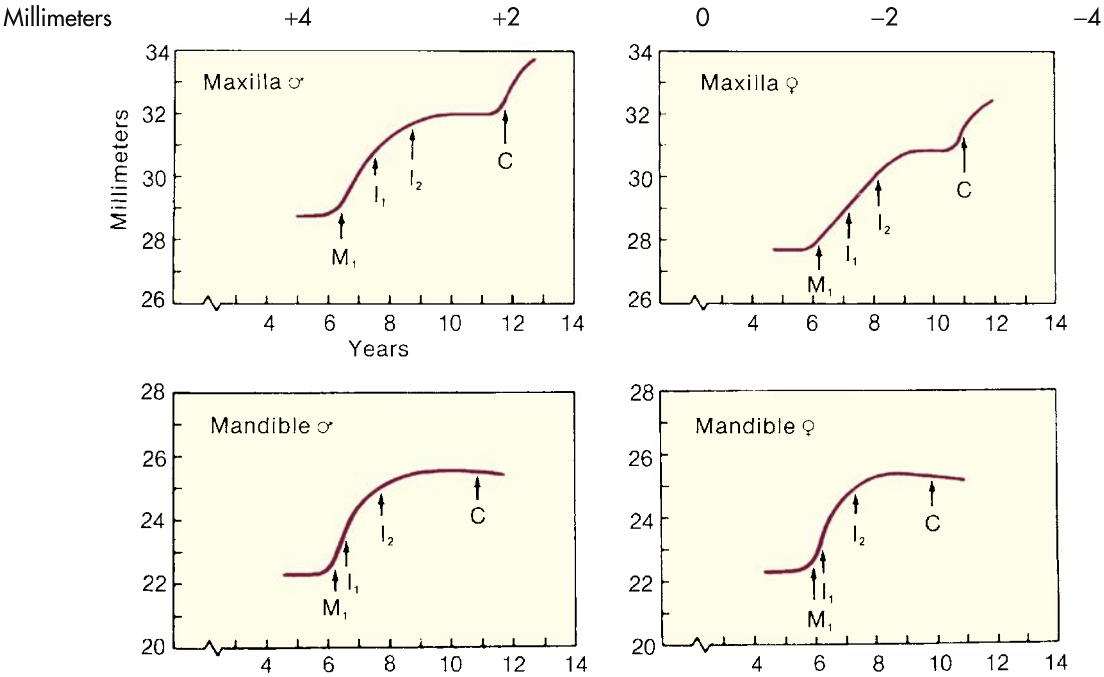

FIGURE 34-40 Average intercanine distance. *M1*, First molar; *I1*, central incisor; *I2*, lateral incisor; *C*, canine. (From Moorrees CF, Reed RB. Changes in dental arch dimension expressed on the basis of tooth eruption as a measure of biologic age. *J Dent Res* 1965;44:129.)

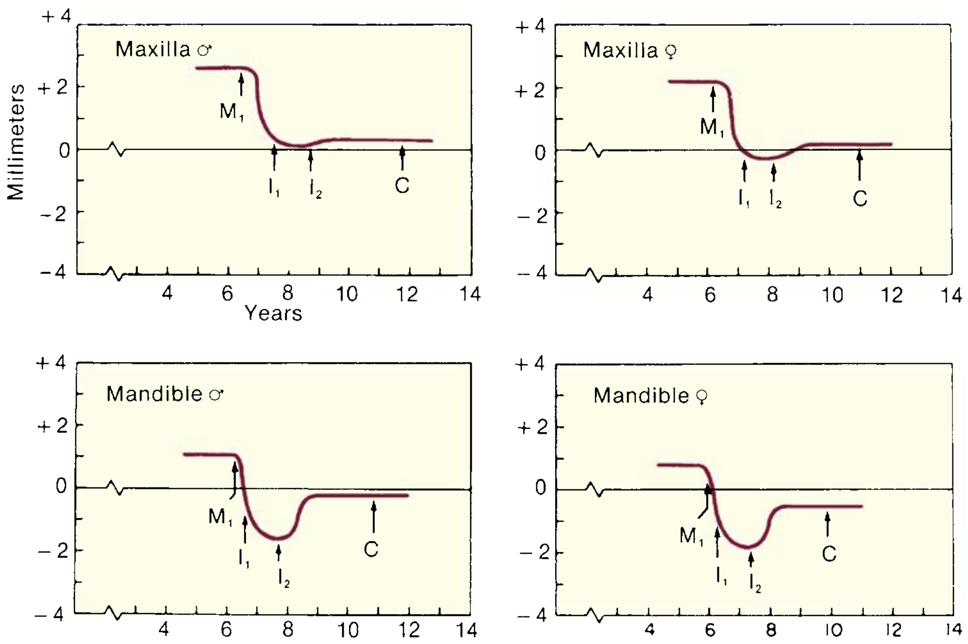

FIGURE 34-41 Available space in the incisor segment. (From Moorrees CF, Chadha IM. Available space for the incisors during dental development: a growth study based on physiological age. *Angle Orthod* 1963;33:44.)

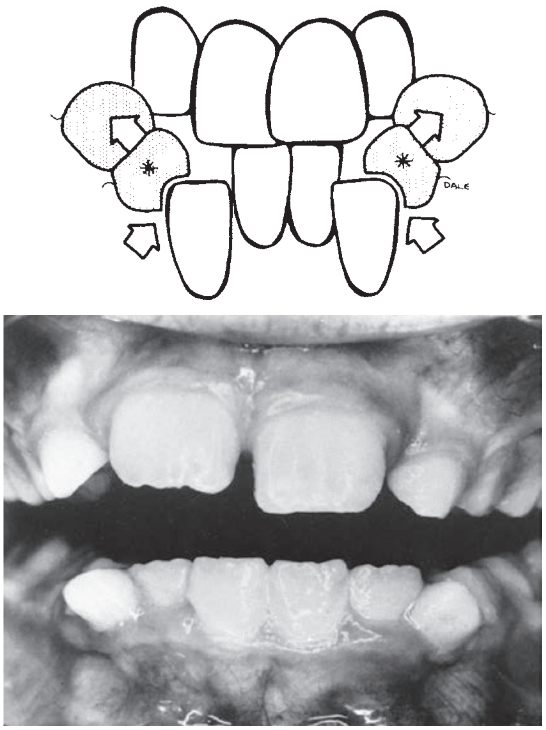

FIGURE 34-42 Lingual eruption of the permanent mandibular lateral incisors as a symptom of crowding and its effect on secondary spacing. Asterisks in drawing demonstrate inadequate arch length for erupting canines.

exists when sufficient primary spacing is present in the spaced primary dentition to allow for the eruption of the permanent incisors without crowding (Table 34-1; see also Fig. 34-38).

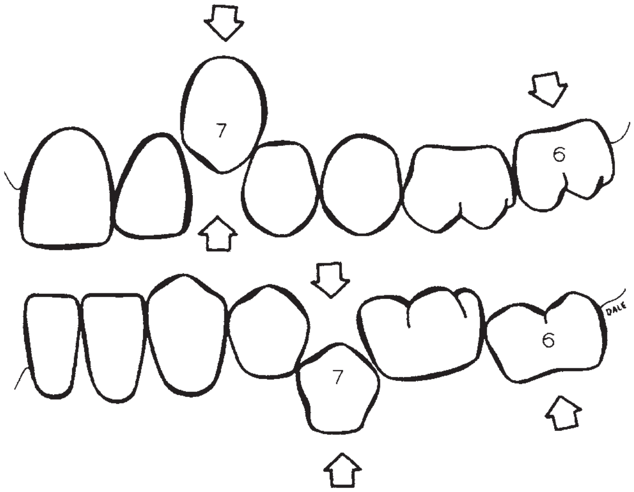
Second, a precarious situation exists with a primary dentition with no anterior developmental spaces. A substantial increase in intercanine width is necessary to provide secondary

TABLE 34-1 Incisor Liability

Situation	Maxilla (mm)	Mandible (mm)
Favorable: Primary Spacing		
Incisor liability	−6.2	−4.3
Interdental spacing	+4.0	+3.0
Incisor position	+2.2	+1.3
—	6.2	4.3
Amount of crowding	—	—
Precarious: Secondary Spacing		
Incisor liability	−9.2	−7.3
Interdental spacing	+4.0	+3.0
Intercanine arch width	+3.0	+3.0
Incisor position	+2.2	+1.3
—	9.2	7.3
Amount of crowding	—	—
Impossible: Crowding Exceeds Compensations		
Incisor	−14.2	−12.3
Interdental spacing	+4.0	+3.0
Intercanine arch width	+3.0	+3.0
Incisor position	+2.2	+1.3
—	9.2	7.3
Amount of crowding	5.0	5.0

spacing so that the permanent incisors erupt without appreciable crowding (see Fig. 34-39 and Table 34-1). In these patients, the practitioner avoids interproximal reduction or extraction of primary canines.

Finally, an impossible situation exists with a true hereditary tooth size–jaw size discrepancy and an incisor liability that cannot be compensated by interdental spacing, an increase in intercanine arch width, or labial positioning of the permanent incisors (see Fig. 34-42 and Table 34-1). Serial extraction can be beneficial for these individuals.



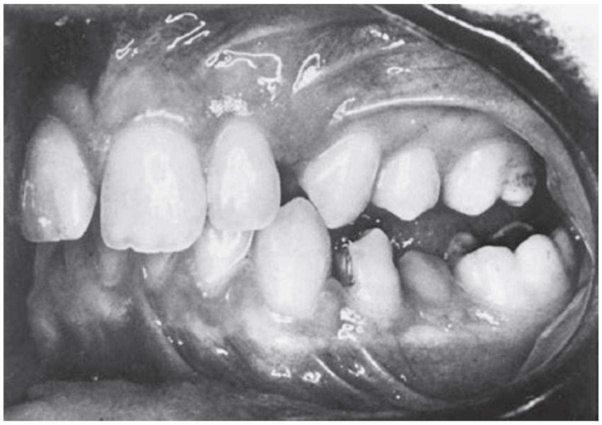


FIGURE 34-43 Unfavorable emergence sequence. The permanent second molars are emerging early, blocking the space for maxillary canines and mandibular second premolars.

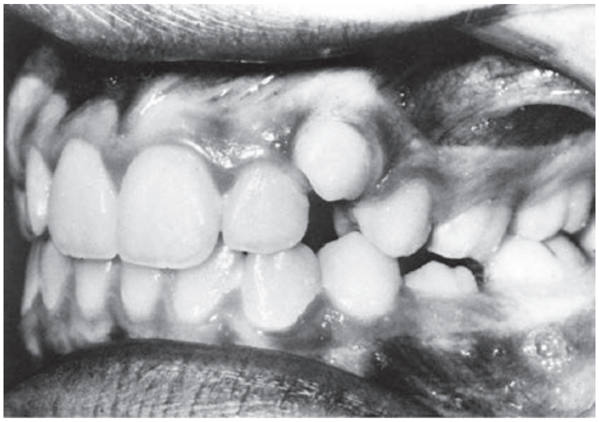

FIGURE 34-44 Prolonged retention of the primary maxillary second molar causing crowding of the permanent canine.

Canines, Premolars, and Second Molars. The most frequently occurring sequence of eruption in the maxilla is as follows: permanent first molar, central incisor, lateral incisor, first premolar, second premolar, canine, second molar. The most frequently occurring sequence in the mandible is permanent first molar, central incisor, lateral incisor, canine, first premolar, second premolar, second molar. According to Lo and Moyers,[25] this combination produces the highest incidence of favorable occlusion. More girls than boys have a favorable combination.

FIGURE 34-45 Prolonged retention of the mandibular second deciduous molar, causing crowding of the first premolar.

An unfavorable sequence can produce crowding. For instance, if the second molars erupt early, they may affect the canines in the maxilla and the second premolars in the mandible (Fig. 34-43). Maxillary second molars erupt ahead of mandibular molars in 89.11% of Class II patients, but in only 56.5% do maxillary first molars erupt ahead of their mandibular counterparts.[25] Therefore, second molars are more important than first molars in the development of a Class II relationship.

Early exfoliation of primary teeth can disrupt the alignment of the dentition, reducing arch length in the maxilla (see Figs. 34-34, 34-35, and 34-37) and mandible (see Fig. 34-37, *B*).

Prolonged retention of primary teeth can cause crowding of the permanent teeth in the maxilla (Fig. 34-44) or mandible (Fig. 34-45).

Clinically, the primary second molars appear to resist mesial migration to some extent. Rarely does the orthodontist observe primary mandibular second molars tipped mesially after the premature loss of primary first molars. However, the permanent mandibular first molars are observed to have an exaggerated mesial inclination after the premature loss of the primary second molars. The relative position of the unerupted premolars is crucial in this situation. When the primary mandibular second molars are lost prematurely, the permanent second premolars are often deep in the alveolar bone. This may encourage the permanent first molar to tip forward. When the primary mandibular first molar is lost prematurely, the permanent first premolar (which is scheduled to emerge before the second premolar) is not so deeply embedded in bone. Therefore, the tendency for tipping of the primary second molar is not as great. The unerupted first premolar tends to support the primary second molar.

Contrary to popular belief, arch length can be reduced, and space can be lost after premature exfoliation or extraction of the primary first molar (see Fig. 34-35). This is especially true in the mandible, where the formation of a knife-edge ridge of alveolar bone obstructs and retards the emergence of the underlying first premolar.

The premature loss of primary molars immediately leads one to consider space maintenance. However, the use of space maintainers depends on a thorough diagnosis and may be modified with subsequent treatment planning. If the patient has a normal dentition or the treatment plan does not include the extraction of permanent teeth, a space maintainer may be placed. Indeed, in the borderline situation, maintenance of the "E" space may be all that is indicated to maintain a nonextraction treatment approach (See also Chapter 16).

In the maxilla, about 90% of the time, the first premolar emerges ahead of the canine. This is favorable for serial extraction and maintenance of the overbite because the maxillary incisors are not held forward. About 10% of the time, the sequence is unfavorable for serial extraction and the overbite.

In the mandible, about 80% of the time, the canine emerges ahead of the first premolar.[25] This eruption sequence decreases overbite because it maintains the mandibular incisors in a forward position.[37] However, the sequence is not favorable for serial extraction. About 20% of the time, the sequence is favorable for serial extraction but not for maintenance of the overbite; that is, the first premolars are ahead of the canines.

Serial extraction is beneficial to prevent resorption of the roots of the maxillary lateral incisors by impacted canines. When the primary canine is extracted in serial extraction, the space between the lateral incisor and the primary first molar is reduced substantially. However, when the primary first molar is extracted at the proper time, the first premolar erupts, allowing the unerupted permanent canine to move away from the root of the lateral incisor. On extraction of the first premolar, the canine then erupts into place without difficulty and without danger to the lateral incisor. Certain conditions exist, which will be discussed later, under which primary first molars are extracted before the primary canines to allow the premolars to erupt. This extraction may even be done, in the presence of concern, in nonextraction malocclusions. To their knowledge, the authors have not had a lateral incisor root resorbed by an impacted canine in 33 years of practice using serial extraction procedures.

Total Space Analysis

The mixed dentition analyses historically were dentally oriented. Unfortunately, even today, tooth size–jaw size discrepancies diagnosed in the mixed dentition period still are evaluated by dental-oriented analyses. These analyses will be referred to as conventional methods. Their aim is to evaluate, as accurately as possible, future crowding in the permanent dentition using a prediction of the mesiodistal width of the permanent mandibular canines and premolars. The value obtained is added to the already known measurement of the permanent mandibular incisors. This represents space required. The space required is subtracted from the arch circumference of space available. If the result is significantly negative, future crowding can be predicted.

Tweed,[38] studying the relationship between the mandibular incisors and the mandibular plane, found that if the teeth are not in a stable relationship with the basal bone after treatment, the result may relapse. In view of this, the dental-oriented mixed dentition analysis alone is not adequate. A facial-oriented analysis, incorporating the relations of the incisor teeth to the basal bone, is preferable. This analysis will be described as the Tweed method.

Furthermore, the various mixed dentition analyses demonstrate the discrepancy only and do not indicate the exact area where the discrepancy occurs. In many instances, the problem is confined to one specific area. Because one can direct treatment specifically to one area, knowledge of the area affected is desirable. The total space analysis provides this precise information.[39]

Garcia-Hernandez and Dale[40] completed a study of 60 Class I mixed dentition patients in the authors' practice. One objective was to compare the conventional method, the Tweed method, and the total space analysis method in the diagnosis of tooth size–jaw size discrepancies before serial extraction. Sixty individuals (30 boys and 30 girls) with a mean chronologic age of 8 years, 4 months (range, 7 years 7, months to 11 years, 3 months) were selected from the records of the practice.

Conventional Method

The "conventional" calculations were done as follows. For space required, the four mandibular incisors were measured at their greatest mesiodistal crown diameter by means of a sliding Boley gauge with pointed beaks. All measurements were made with the gauge parallel to the incisal edges of the teeth, and all readings were to the nearest 0.1 mm (Fig. 34-46). The values for unerupted canines and premolars were obtained by measuring their greatest mesiodistal crown diameter or their images on the periapical radiograph (Fig. 34-47).

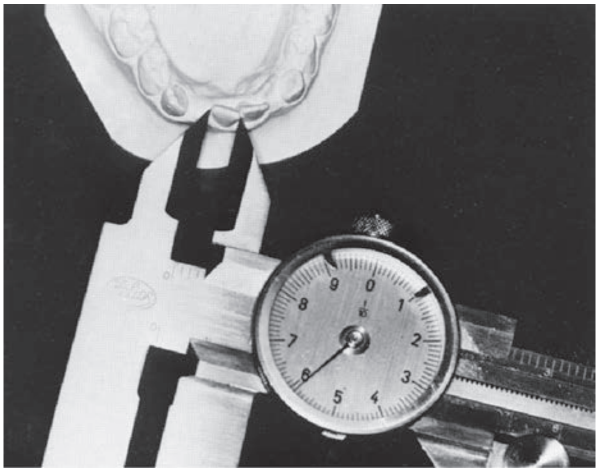

FIGURE 34-46 Measurement of space required on study models with a Boley gauge. Digital models allow this to be done efficiently with a variety of space analyses and size discrepancy evaluations.

FIGURE 34-47 Measurement of space required on the periapical radiograph with a Boley gauge.

To reduce the radiographic enlargement, the formula recommended by Huckaba[41] was used in all radiographic measurements:

$$X = (y)\left(x^1\right)/\left(y^1\right)$$

where X is the estimated size of the permanent tooth, x^1 is the radiographic size of the permanent teeth, y is the size of the primary mandibular second molar on the cast (Fig. 34-48), and y^1 is the radiographic size of the primary molar.

The values obtained for the mandibular incisors on the cast and those for the canines and premolars on the radiograph were added to provide the space required.

The space available was obtained by extending a brass wire from the mesiobuccal of the first permanent molar on one side to the mesiobuccal of the molar on the opposite side, passing through the buccal cusps and incisal edges of the remaining teeth (Fig. 34-49). The wire was straightened carefully and measured with a pointed Boley gauge to the nearest 0.1 mm.

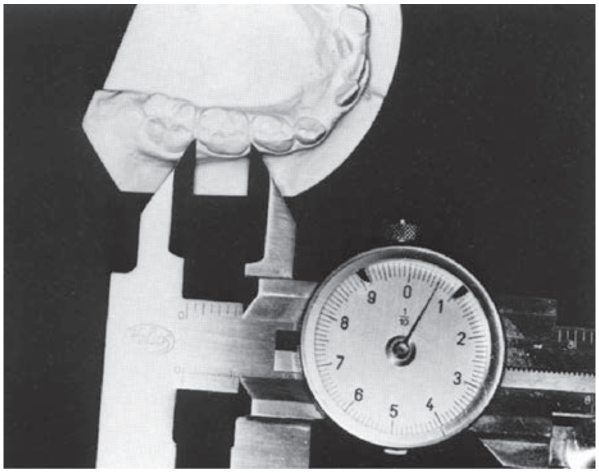

FIGURE 34-48 Measurement of the primary second molar on the study model with a Boley gauge to aid in assessing a radiographic enlargement.

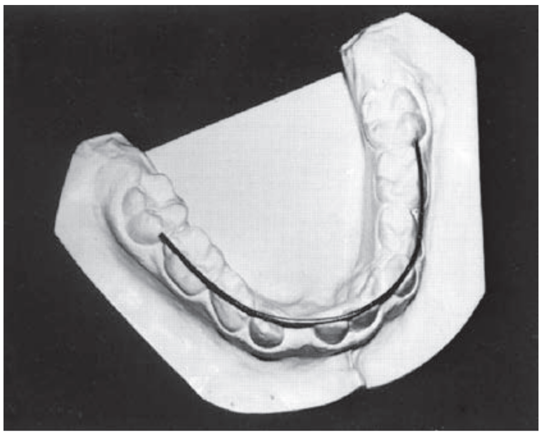

FIGURE 34-49 Measurement of space available on the study model with a brass ligature wire. Digital model analysis makes this manual measurement step unnecessary.

The difference in the values obtained for space required and space available was the amount of the discrepancy.

Tweed Method

The values for space required and space available were obtained as required for the conventional method (see Figs. 34-46 to 34-49). An assessment of the relations between the axial inclination of the mandibular incisors and the basal bone was made on a tracing of the lateral cephalogram. The amount of alveolodental protrusion or retrusion was assessed and incorporated into the mixed dentition analysis (Fig. 34-50).

Tweed Foundation research has established the following relationships:

- When the FMA is between 21 and 29 degrees, the Frankfort mandibular incisor axis angle (FMIA) should be 68 degrees.
- When the FMA is 30 degrees or greater, the FMIA should be 65 degrees.
- When the FMA is 20 degrees or less, the incisor mandibular plane angle (IMPA) should not exceed 92 degrees.

If for a specific FMA (30 degrees) the FMIA (49 degrees) did not correspond, an objective line was traced to form the required FMIA (65 degrees). Then the distance between this objective line and the line that passed through the actual axial inclination of the mandibular incisors was measured on the OP with pointed calipers to the nearest 0.1 mm (6 mm). This figure was multiplied by 2 to include right and left sides (12 mm). The total was the cephalometric correction, which then was added to the difference between space required in space available to yield the total discrepancy (see Fig. 34-50).

Total Space Analysis

This method was divided into three areas—anterior, middle, and posterior—and the resulting values for each area were added together to yield the final deficit.

Anterior Area. For the anterior area, the calculation of the difference between space required and space available was done as before. However, the space required included, in addition to tooth measurement and cephalometric correction, soft tissue modification.

Tooth Measurement. Measurements of mandibular incisor widths on the cast were added to the values obtained from the radiographic measurements of the canines. Both measurements were made according to a previously described technique (see Figs. 34-46 to 34-48).

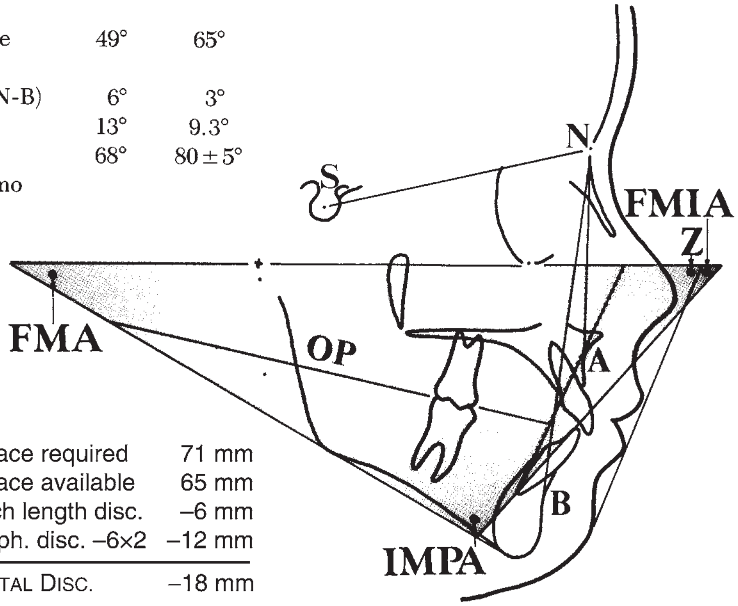
Cephalometric Correction. The cephalometric correction was calculated as for the Tweed method. However, instead of measurements being made of the distance (in millimeters) on the OP between the objective line and the line indicating the true axial inclination of the mandibular incisors, the actual FMIA (in degrees) was subtracted from the proposed angle, and the difference (in degrees) was multiplied by a constant (0.8) to give the difference in millimeters (Fig. 34-51).

Soft Tissue Modification. Whereas the Tweed method added the anterior skeletal dental (hard tissue cephalometrics) relationships to the dental-oriented mixed dentition analysis, this method also adds a consideration of the soft tissue profile. Thus, the teeth, jaws, and soft tissue are involved in the assessment.

The soft tissue modification was derived by measuring the Z angle of Merrifield[10,39] and adding the cephalometric correction (in degrees) to it. If the corrected Z angle was greater than 80 degrees, the mandibular incisor inclination was modified

		Objective
Frankfort–mandibular angle (FMA)	30°	30°
Incisor–mandibular plane angle (IMPA)	101°	85°
Frankfort–mandibular incisor angle (FMIA)	49°	65°
A point–nasion–B point angle (A-N-B)	6°	3°
Occlusal plane (OP)	13°	9.3°
Z angle	68°	80 ± 5°

Chronologic age, 7 yr 6 mo
Dental age, 6 yr 6 mo



1.	Space required	71 mm
2.	Space available	65 mm
3.	Arch length disc.	–6 mm
4.	Ceph. disc. –6×2	–12 mm
	TOTAL DISC.	–18 mm

FIGURE 34-50 Tweed method. Cephalometric (ceph.) correction to factor dental protrusion into space analysis. In this patient, according to Tweed goals, the lower incisal edge is 6 mm ahead of where it should be. If the incisor is to be uprighted to the Tweed goal, 6 mm per side of space (12 mm total) are required.

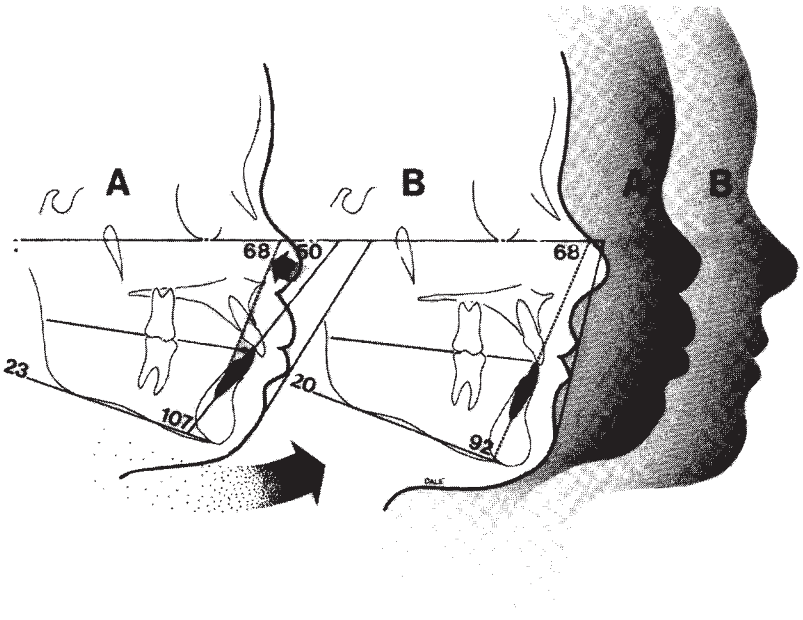


FIGURE 34-51 Total space analysis. Anterior arch cephalometric correction. For patient ML, using FMIA actual minus goal provides an 18 degree difference. Multiplied by .8 would indicate 14.4 mm of needed arch length to achieve the Tweed goal for lower incisor angulation.

as necessary (up to an IMPA of about 92 degrees). If the corrected angle was less than 75 degrees, additional upright positioning of the mandibular incisors was necessary. Upper lip thickness was measured from the vermilion border of the lip to the greatest curvature of the labial surface of the central incisor. Total chin thickness was measured from the soft tissue chin to the N-B line.

If lip thickness was greater than chin thickness, the difference (in millimeters) was determined, multiplied by 2, and added to the space required. If it was less than or equal to chin thickness, no soft tissue modification was necessary.

Figure 34-52 portrays patient M.L., described in Figure 34-51, who had a typical Class I malocclusion with an alveolodental protrusion and an incompetent lip relationship (see

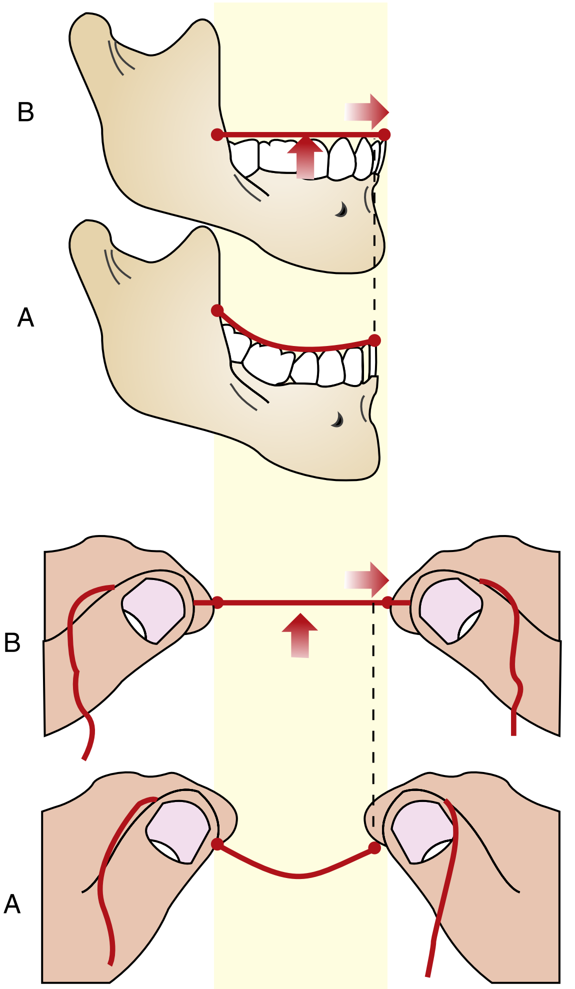

FIGURE 34-54 Total space analysis. **A**, curve of occlusion; **B**, leveled curve of occlusion increasing length.

Fig. 34-52, *A*). Note the improvement in muscle balance and facial harmony after serial extraction and active treatment (see Fig. 34-52, *B*).

The space available was obtained by placing a brass wire from the mesiobuccal of the primary first mandibular molar to the mesiobuccal of the opposite molar (Fig. 34-53). The wire then was straightened and measured with a pointed caliper to the nearest 0.1 mm. This value was subtracted from the total space required to yield the deficit.

Middle Area. For the middle area, calculations were made of the difference between space required and space available. In this instance, however, the mandibular curve of occlusion was considered.

Tooth Measurement. The crown widths of the permanent mandibular first molars were measured at their greatest mesiodistal diameter on the cast. These values were added to the measurements of the premolars obtained from the radiographs (see Figs. 34-46 to 34-48).

Curve of Occlusion. The following describes the procedures for the calculations for the curve of occlusion.

The space required to level the mandibular curve of occlusion was determined (Fig. 34-54). A flat object was placed on the occlusal surfaces of the mandibular teeth, contacting the permanent first molars and the incisors. The deepest point between this flat surface and the occlusal surfaces of the primary molars was measured on both sides. The curve of occlusion formula was applied, and the space required for leveling was determined. This was added to the tooth measurements to complete the space required. The curve of occlusion formula used the greatest depth of each side:

$$(\text{Right side depth} + \text{Left side depth})/2 + 0.5 \text{ mm}$$

The space available was determined by placing two brass wires from the mesiobuccal of the primary first molars to the distobuccal of the permanent first molars (Fig. 34-55). These were measured as before, added together, and subtracted from the space required.

Posterior Area. For the posterior area, the space required and space available were determined (including that presently available and that predicted). The space required consisted of the sum of the mesiodistal widths of the two second and third molars, which were unerupted in these patients (Fig. 34-56). Because they were unerupted, radiographic enlargements had to be calculated. However, the formula used for the conventional method was modified. In this instance, the permanent mandibular first molars were substituted for the

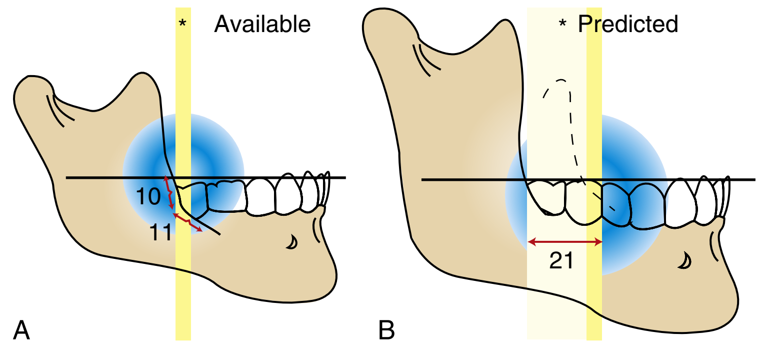

FIGURE 34-56 Total space analysis. Measurement of the (**A**) available and (**B**) predicted space in the posterior area.

primary second molars. A second complication was that often the third molars were not visible on the radiographs. In this case, Wheeler's measurements were used, and the calculation was as follows:

$$X = y - x^1/y^1$$

where X is the estimated value of the permanent mandibular third molar in the individual patient, x^1 is Wheeler's values for third molars, y is the actual size of permanent mandibular first molar on the cast, and y^1 is Wheeler's value for first molars.

The space available consisted of the space presently available plus the estimated increase or prediction. The estimated increase was 3 mm per year (1.5 mm for each side) until 14 years in girls and 16 years in boys. Therefore, the age of the patient was subtracted by 14 or 16. The result was multiplied by 3 to obtain the estimated increase for the individual patient. The space presently available was obtained by measuring the distance on the OP between a perpendicular line drawn from the OP tangent to the distal surface of the permanent first molar to the anterior border of the ramus on the lateral cephalometric tracing (see Fig. 34-56). After the presently available space and the predicted space were totaled to give the space available, the space required was subtracted.

Discussion. Because the total space analysis involves the permanent molars, it was not possible to compare its results with those of the other two procedures. However, when the results of the conventional method are compared with those of the Tweed method, the differences become highly significant.

The assessment of axial inclination of the mandibular anterior teeth with respect to the basal bone must be included in the analysis of mixed dentition malocclusion so that there will be harmony in the facial profile and stability in the dentition. The cephalometric correction in the Tweed method accounts for 9.8% of the space required, a considerable amount.

Table 34-2 illustrates the differences between the conventional method and the Tweed method in one of the subjects of the investigation. Comparison of the techniques makes it evident that completely different treatment plans will result.

Patient M.L. (see Figs. 34-51 and 34-52) exemplifies an ideal serial extraction situation: a Class I mixed dentition malocclusion with an anterior discrepancy in the form of an alveolodental protrusion and a posterior discrepancy with a medium angle facial pattern. The first premolars were extracted to correct the anterior discrepancy, and the third molars were extracted to correct the posterior discrepancy.

TABLE 34-2 Mixed-Dentition Analysis: Comparison of the Conventional and Tweed Methods in a Sample Patient

Sample Patient	Conventional Method (mm)	Tweed Method (mm)
Space required	−69.3	−69.3
Space available	+69.1	+69.1
Discrepancy	−0.2	−0.2
Cephalometric Correction	—	−8.0
Total discrepancy	−0.2	−8.2
Difference between two methods	—	−8.0

Patient M.R. (see Figs. 34-85 and 34-87) also is a good example of a favorable serial extraction situation: a Class I mixed dentition malocclusion with an anterior discrepancy in the form of a moderate alveolodental protrusion and a posterior discrepancy with a high-angle facial pattern. The same teeth were extracted as in patient M.L. for different reasons. The anterior discrepancy is more related to the alveolodental protrusion in patient M.L. than in patient M.R. The posterior discrepancy is more related to the high-angle facial pattern in patient M.R. than in patient M.L. Thus, each individual is treated differently depending on the results of the various diagnostic procedures, including total space analysis. Total analysis may thus result in extraction of varied teeth or nonextraction, with mechanotherapy varying to match the correction of individual discrepancies from a balanced dentofacial form.

Timing of Guided Primary Tooth Removal

Three factors may be applied by the clinician in deciding the optimal time for the removal of teeth in the guidance of occlusion:

1. The effect of extraction of the primary tooth on the eruption of its permanent successor
2. The amount of root formation at the time of emergence
3. The length of time for the attainment of various stages of root development

Serial extraction, if carried out too early in the primary dentition, can delay the eruption of permanent successors. In the case of early extraction of the primary molar, Fanning[42] reported an initial spurt in eruption of the premolar. This leveled off and the tooth then remained stationary, erupting later than its antimere with a normally shedding primary precursor.

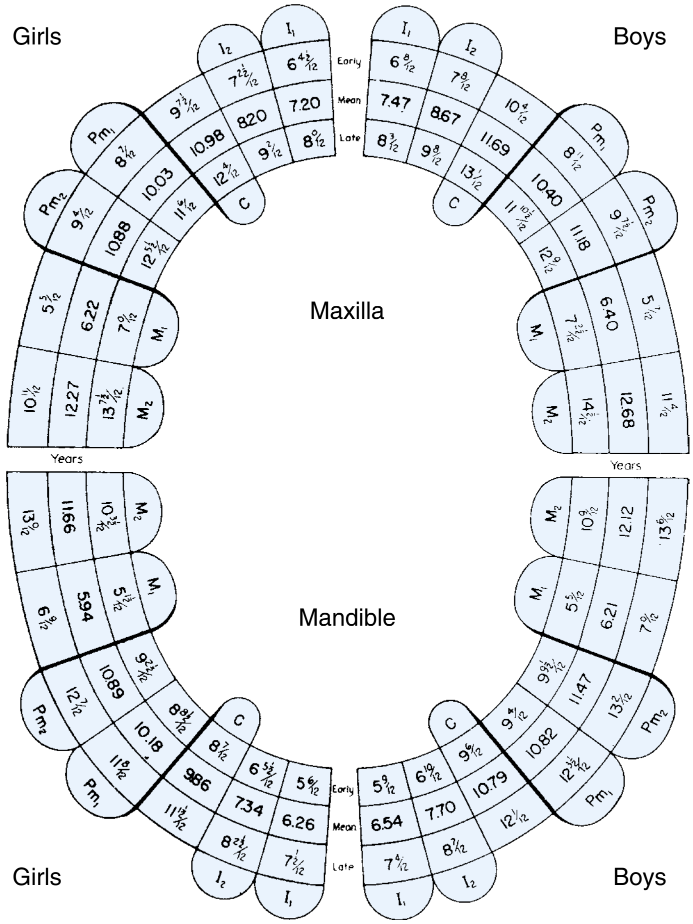

FIGURE 34-57 Assessment of dental age by means of tooth emergence (±1 standard deviation). This is a classic study taken from records of 93,000 children and demonstrates individual tooth variability and sex-linked timing of eruption. (From Hurme VO. Ranges in normalcy in eruption of permanent teeth. *J Dent Child* 1949;16:11.)

If serial extraction is initiated with the extraction of the primary canines, the length of the roots of the premolars is not an important consideration. If, however, the orthodontist is contemplating initiating serial extraction by removing the primary first molars, the length of the root of the premolar is an important consideration and guide for the commencement of the procedure.[43]

The relative eruptive rates of the permanent canines and first premolars influence the decision about which primary teeth should be extracted. If, for example, during an examination of the radiographs, the orthodontist observes the permanent mandibular first premolar crown ahead of the permanent canine crown, the premolar with less than one half its root formed, and the mandibular incisors crowded, the primary canine should be extracted to relieve the crowding. The primary first molar should be left until the first premolar has attained one half its root length. If, on examining the radiographs, the orthodontist observes the premolar crown even with the canine crown, the premolar with one half its root formed, and an alveolodental protrusion, the primary first molar should be extracted to encourage the emergence of its successor.

Dental age, assessed particularly by root length, is an essential requirement in the decision of a serial extraction program and in the initiation of interceptive and definitive fixed appliance treatment. A knowledge of root development, relative eruptive rates, and the emergence of permanent teeth (Fig. 34-57), together with root resorption of the primary teeth and the factors that influence these processes, is mandatory in the timing of serial extraction.

TREATMENT

The authors adhere to the principles and objectives of the Tweed philosophy. Clinically, Tweed advocated maximal facial harmony and balance. To achieve this goal, he recognized that mandibular incisor teeth must be placed upright over basal bone. The primary objective in treatment is to obtain maximal health, aesthetics, function, and stability. Specifically, it is excellence in tooth alignment, arch form, and axial inclination of the teeth, with optimal occlusal intercuspation of the maxillary and mandibular dentitions.

Objectives of treatment include the following:

1. Decrease in the FMA, indicating a favorable rotation of the mandible.
2. Decrease in the IMPA, indicating the reduction of the alveolodental protrusion.
3. Increase in the FMIA, also indicating an upright positioning of the mandibular incisor teeth.
4. Decrease in the OP angle throughout treatment, indicating that one is not extruding the posterior teeth or dumping the anterior teeth forward.

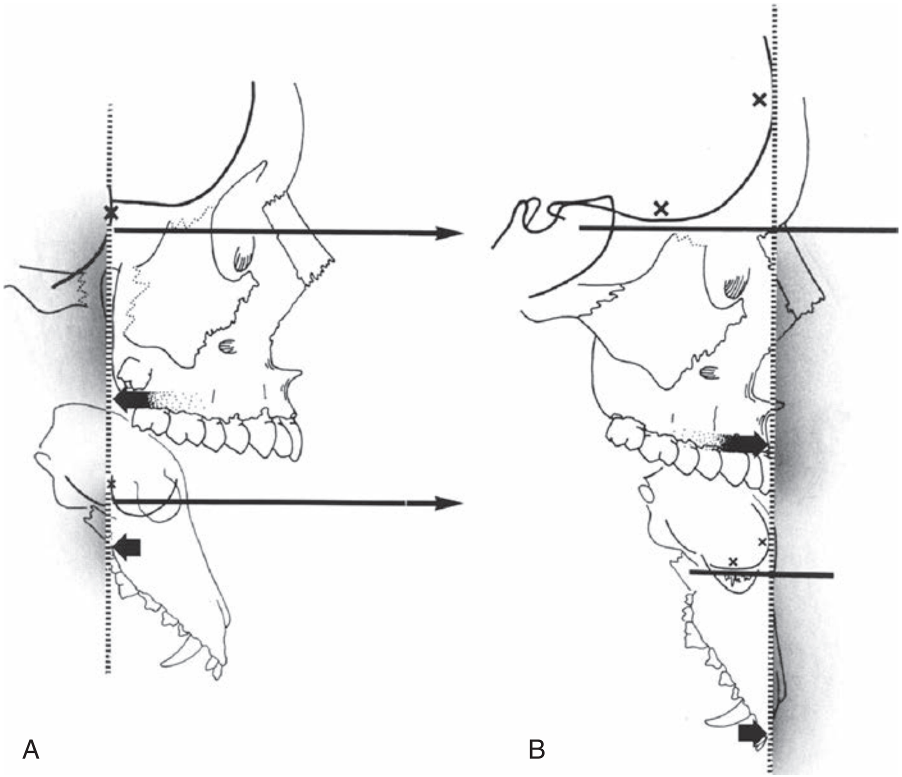

FIGURE 34-58 **A,** Posterior limits of the nasomaxillary area: a line perpendicular to the line of sight passing through the junction of the anterior and middle cranial fossae. **B,** Anterior limit of the nasomaxillary complex: a line extending from the internal surface of the frontal bone and running perpendicular to the ethmoid. (Adapted from Enlow DH, Hans MG. *Essentials of Facial Growth*. 2nd ed, Ann Arbor, MI: Needham Press; 2008.)

5. Decrease in the ANB (A point–nasion–B point) angle, indicating a correction of the skeletal discrepancy.
6. Increase in Merrifield's Z angle, indicating improvement in facial harmony and balance.
7. No lateral, anterior, or posterior expansion of the dentition. This is substantiated by the scientific investigations of Enlow,[23] who describes specifically the boundaries of the nasomaxillary complex (Fig. 34-58).

Many orthodontists have found from bitter experience that they cannot extend arch length posteriorly, anteriorly, or laterally unless the position of the teeth results from environmental factors such as premature loss of the primary teeth. Most of the problems during treatment and retention have been associated with creating space and maintaining alignment where teeth have not been extracted.[44] Teeth that have not been placed in the correct position relative to the skeletal pattern and soft tissue matrix are more likely to change after fixed appliances have been removed. The ideal conditions for stability are achieved when teeth are placed in a harmonious relationship early. Long-term use of mandibular fixed retainers may be needed to reduce age-related maturational changes in the lower anterior segment. These should be maintained in patients for a prolonged time to preserve the incisor alignment when the mandible grows horizontally (see Chapters 1 and 33).

Serial extraction allows teeth to become aligned when they emerge into the oral cavity rather than to remain in a crowded unfavorable condition for several years. In the case of alveolodental protrusion, the procedure allows the mandibular incisors to be positioned upright lingually into a position of balance. This alone will reduce mechanotherapy by 6 months and contribute to the stability of the treatment result. In many of these patients, the need for retention is minimal. However, the orthodontist must remember that under ideal serial extraction conditions, the orthodontist is not dealing with severe skeletal discrepancies or severe overjet and overbite problems. The need for long-term retention is greater when skeletal discrepancies have complicated the orthodontic treatment.

One may ask, "If the roots of the permanent incisor teeth complete their formation in a more favorable position, is their stability enhanced?" It seems logical that if a tooth completes its formation in a site where it will remain when treatment is completed, it will be more stable. Conversely, if a tooth is left in a crowded, tipped, and rotated position for several years and then moved to a new position relatively rapidly, it will be less stable for a time and will require a longer retention period.

One also may ask, "Does the initiation of serial extraction with the removal of primary teeth always mean that the permanent teeth will be removed?" After it has been initiated, serial extraction more often than not will culminate in the extraction of four premolar teeth because arch length, which is deficient to begin with, is reduced even more. Despite a thorough diagnosis, the treatment plan occasionally needs to be changed to nonextraction treatment. *The practitioner should always be prepared to treat without extraction if it appears that this can be done successfully with stability.* At the beginning of treatment, the parents should be informed that extractions may be necessary to produce a successful and stable treatment result. Later, they will be relieved and happy if extractions are not necessary.

An important objective in using the serial extraction technique is to make treatment easier and mechanotherapy less complicated, less expensive, and shorter (especially during the teenage years). Treatment can be divided into four categories:

1. A period of interceptive guidance, extending about 5 years from age 7.5 to 12.5 years. This consists entirely of the guidance of occlusion, including serial extraction or space maintenance (or both) and is the most ideal service that can be provided. Unfortunately, production of excellent occlusion with serial extraction, or space maintenance alone (or both) is possible in only a few patients. When guidance without further appliances is accomplished, it is most rewarding and satisfying because the results are achieved without mechanotherapy.
2. An initial period of interceptive guidance, extending about 4 years from age 7.5 to 11.5 years, plus a second period of fixed appliance treatment extending about 1 year from 11.5 to 12.5 years). Class I and specific types of dental Class II malocclusions fall into this category.
3. An initial period of interceptive treatment, extending about 1 year from 8.5 to 9.5 years, plus a period of interceptive guidance extending about 2 years from 9.5 to 11.5 years and a second period of mechanotherapy extending about 1.5 years from 11.5 to 13 years. Class II malocclusions fall primarily into this category.
4. A period of fixed appliance treatment, extending for 1.5 to 3 years from age 11.5 to 14.5 years. Serial extraction is not involved in this treatment. Wherever possible, the orthodontist should try to avoid extensive treatment in the teenage period because of potential adverse sociopsychological concerns that influence patient cooperation.

Of course, these are general classifications. They may vary considerably depending on the individual patient, the malocclusion, and the dental age.

CLASS I TREATMENT

Serial extraction has been classically characterized by the removal of the primary canines, primary first molars, and permanent first premolars. With scientific investigation and clinical experience, serial extraction has become increasingly sophisticated and precise. Results will be more rewarding if the orthodontist does not cling to a particular sequence but varies it according to the diagnosis and therapeutic goals. The sequence that the orthodontist believes is indicated for each patient should be selected.[45]

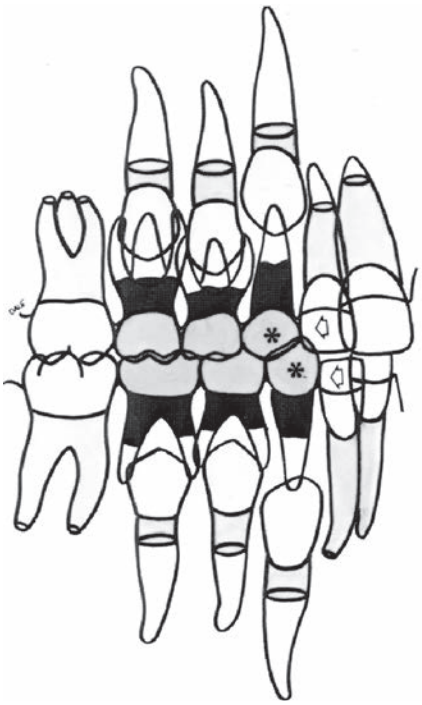
Treatment Procedures: Interceptive Guidance, Active Treatment

Serial Extraction in Class I Treatment

Group A: Anterior Discrepancy—Crowding. This is a typical serial extraction problem: severe crowding, a developing Class I malocclusion, a favorable overjet–overbite relation of the incisor teeth, and an ideal orthognathic facial pattern (Fig. 34-59). Examination of the radiographs often reveals a crescent pattern of resorption on the mesial of the primary canine roots (see Fig. 34-6). This is an indication of a true hereditary tooth size–jaw size discrepancy. Radiographic evaluation indicates that the first premolars are emerging favorably, ahead of the permanent canines. None of the unerupted permanent teeth have reached one half root length. Because of this, the primary first molars would not be extracted. The primary canines should be extracted to relieve the incisor crowding.

Step 1: Extraction of the primary canines

Step 2: Extraction of the primary first molars. The incisor crowding has improved, the overbite has increased, and the extraction site is reduced in size (Fig. 34-60). The radiographs reveal that the first premolars have reached one half root length. Now is the time to extract the pri-



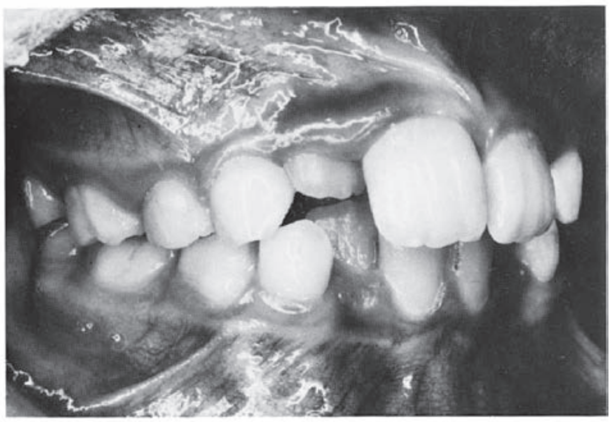


FIGURE 34-59

mary first molars to encourage the eruption of the first premolar teeth.

Step 3: Extraction of the first premolars. These teeth are emerging into the oral cavity (Fig. 34-61). Because the permanent canines have developed beyond one half root length, indicating that they are prepared to accelerate their eruption, the orthodontist extracts the premolars.

Step 4: Fixed appliance treatment. This is the typical result of serial extraction, a relatively deep overbite with a distoaxial inclination of the canines, a mesioaxial inclination of the second premolars, a Class I molar relationship, an improved alignment of the incisors, and residual spaces at the extraction sites (Fig. 34-62).

Step 5: Retention. When mechanotherapy is completed, an ideal occlusion should be observed, with minimal overjet–overbite relationship of the anterior teeth, parallel canine and premolar roots, ideal arch form, and no spaces (Fig. 34-63). In addition, the dentition should be aligned in harmony with the craniofacial skeleton and soft tissue matrix.

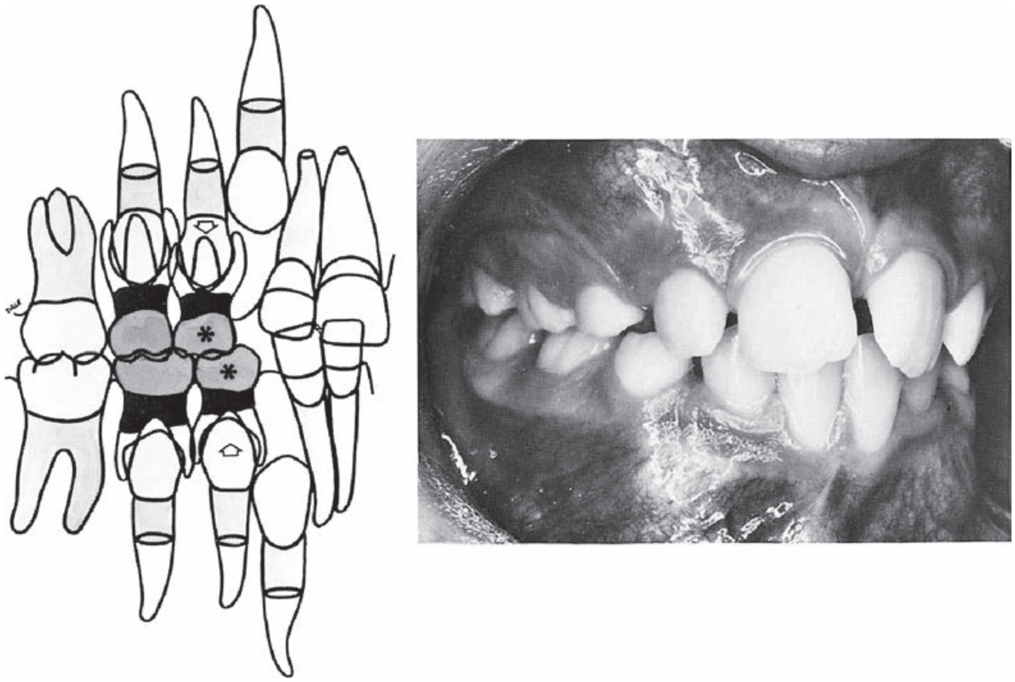

FIGURE 34-60

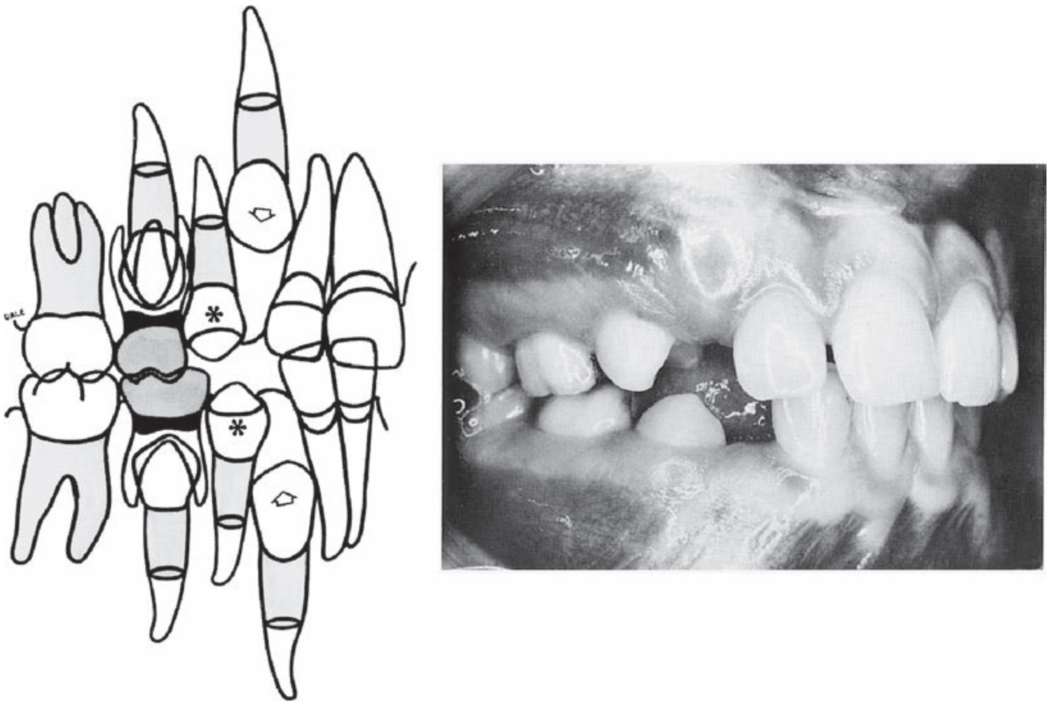

FIGURE 34-61

Step 6: Post retention. Again, an ideal occlusion with stability should be evident (Fig. 34-64). Initiating the serial extraction procedure with elimination of the primary mandibular canines tends to deepen the overbite. The primary first molars should be extracted when the underlying first premolars have reached one half their root length. If this is done, risk of collapse will be minimal. If the mandibular incisors are crowded, the primary canines should be extracted first, in preference to the primary first molars. The orthodontist rarely will be satisfied with the improved alignment of the incisors when the primary molars are extracted first. Again, the decision is based on the relative position and length of the roots of the first premolars and canines. Figure 34-64 illustrates the occlusion 18 years after treatment.

Group B: Anterior Discrepancy—Alveolodental Protrusion. A minor irregularity of the incisor teeth exists. Instead of crowding, the patient has an alveolodental protrusion (Fig. 34-65). The crowns of the first premolars and canines are at the same level. However, the canines are beyond one

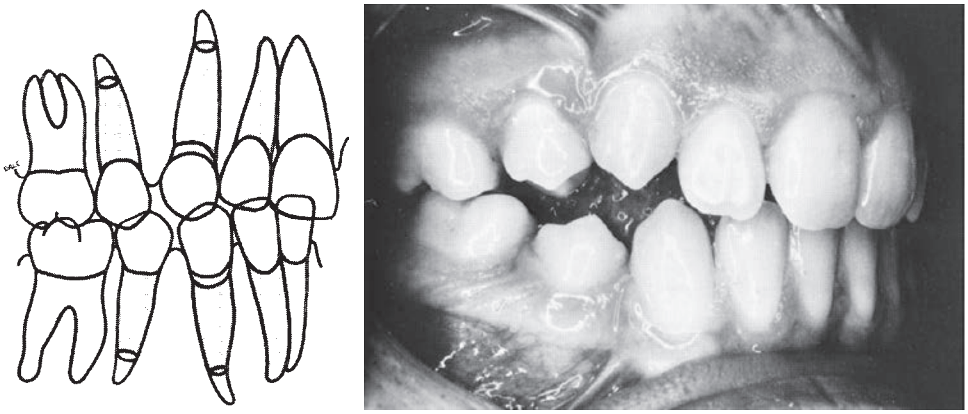

FIGURE 34-62

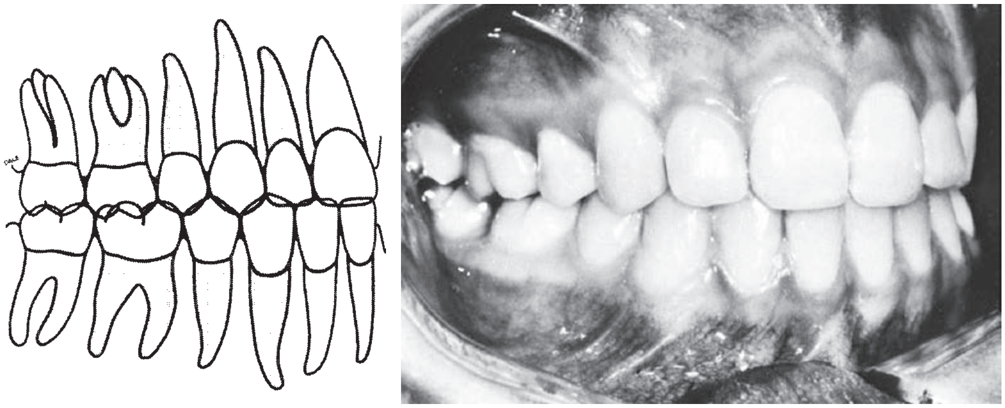

FIGURE 34-63

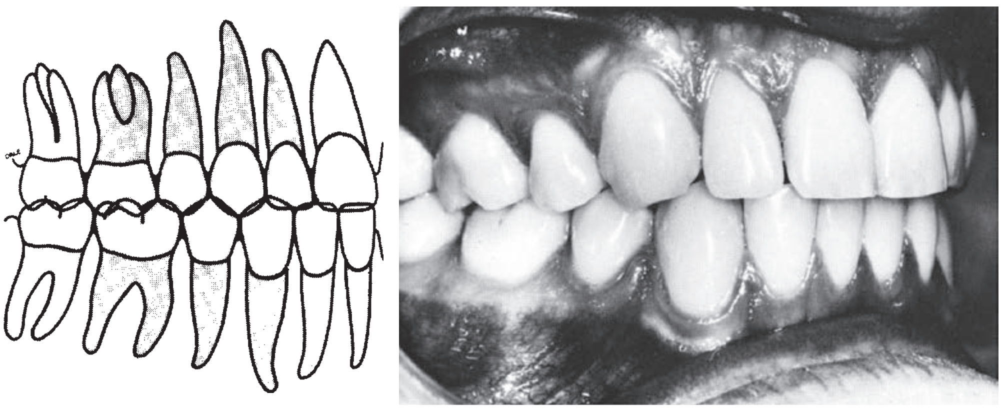

FIGURE 34-64

half root length and are erupting faster than the premolars. Because the first premolars have one half their root length developed, the primary first molars should be extracted to accelerate eruption of the first premolars. This will ensure that the premolars emerge into the oral cavity ahead of the canines. Timing is most important to prevent the formation of a knife-edge ridge.

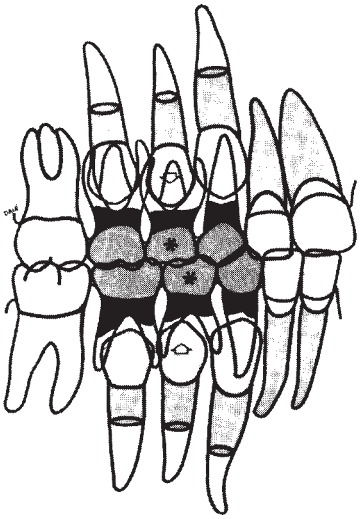

FIGURE 34-65

Step 1: Extraction of the primary first molars

Step 2: Extraction of the primary canines and first premolars. When the first premolars have emerged sufficiently, they are extracted along with whatever primary canines remain (Fig. 34-66). No effort is made to prevent lingual tipping of the incisor teeth because the objective is to reduce the alveolodental protrusion.

Step 3: Fixed appliance treatment. Note how beautifully the dentition is aligning itself (Fig. 34-67). Little mechanical treatment will be required.

Step 4: Retention. Retention in the mandible is less crucial because minimal irregularity was present before treatment (Fig. 34-68).

Group C: Middle Discrepancy—Impacted Canines. The tooth size–jaw size discrepancy is severe, causing premature exfoliation of the primary canines (Fig. 34-69). Note the splaying of the incisors because of crowding in the apical area. Often parents interpret this spacing as evidence for nonextraction treatment. The orthodontist must explain that this is a sign of severe crowding. The radiograph will reveal that the first premolars are ahead of the canines in eruption and have attained one half their

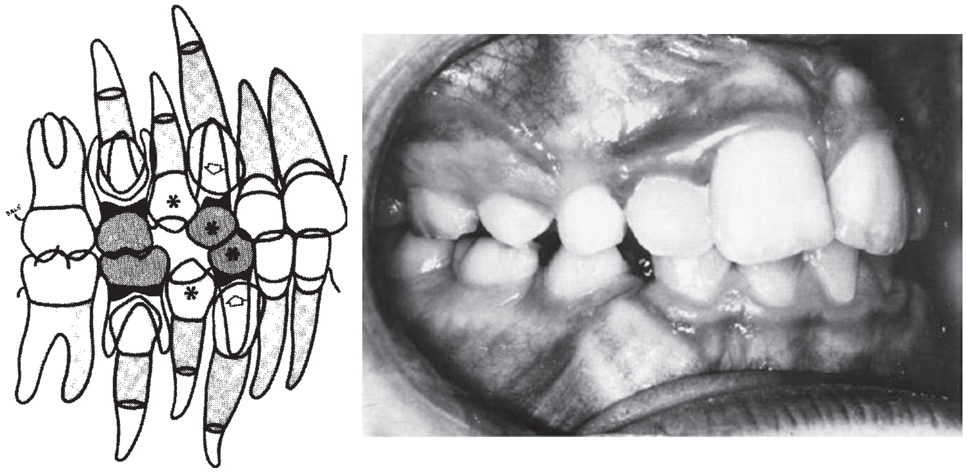

FIGURE 34-66

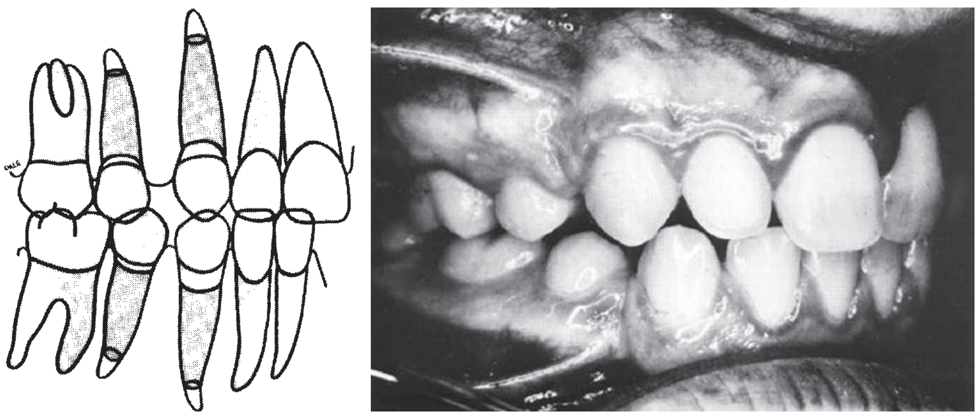

FIGURE 34-67

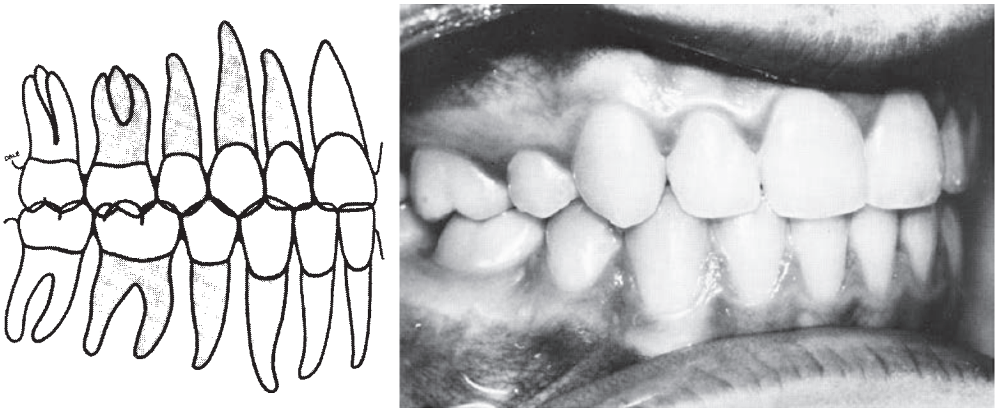

FIGURE 34-68

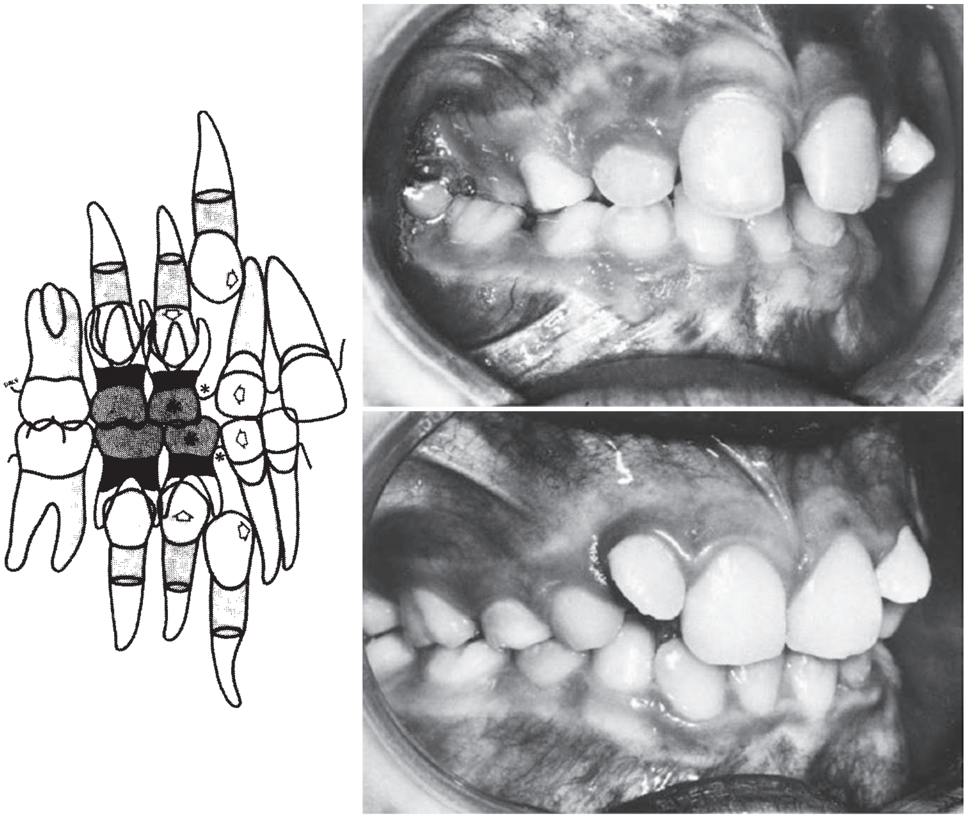

FIGURE 34-69

root length. Treatment begins with the extraction of the primary first molars (remember, here primary canines have been lost).

The impacted permanent maxillary canines may cause severe splaying of the maxillary incisors to such an extent that the lateral incisors do not contact the primary canines (see Fig. 34-69, *bottom right*). In this situation, extracting the primary canines first does little good. Better advice is to extract the primary first molars to encourage the first premolars to emerge as early as possible. The canines then will have space to migrate away from the apices of the incisors and begin their eruption into the oral cavity. In this instance, the practitioner should be concerned more with correcting canine crowding than with incisor irregularity. Every effort should be made to avoid correcting the incisors with fixed appliances for fear of causing the incisor roots to resorb as lateral incisor roots move distally.

Step 1: Extraction of the primary first molars

Step 2: Extraction of the first premolars. For reasons explained in group A, step 3, the first premolars are now due for extraction (Fig. 34-70).

Step 3: Fixed appliance treatment. Note the typical result of serial extraction (Fig. 34-71).

Step 4: Retention. Again, note the desired result of mechanotherapy (Fig. 34-72).

Group D: Enucleation in the Mandible. If it is evident that the canines will emerge into the oral cavity ahead of the first premolars, the primary first molars can be extracted and the first

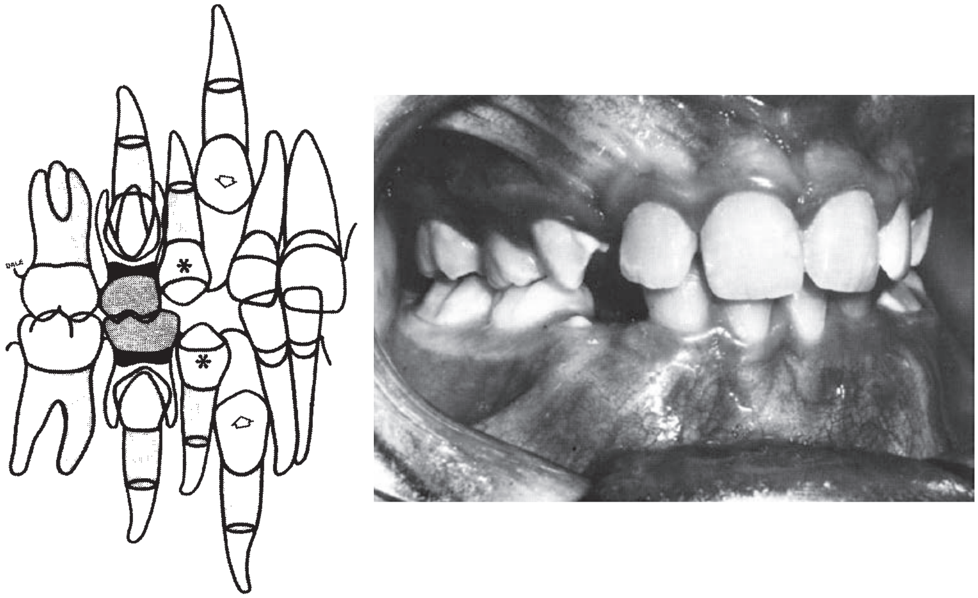

FIGURE 34-70

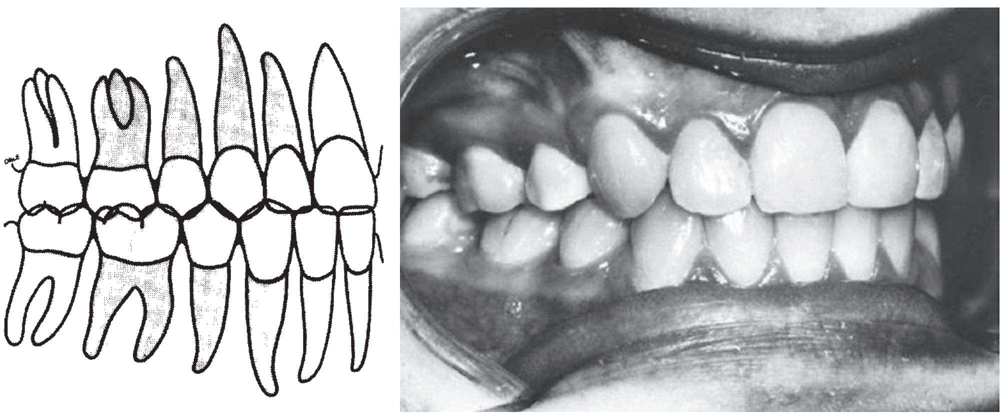

FIGURE 34-72

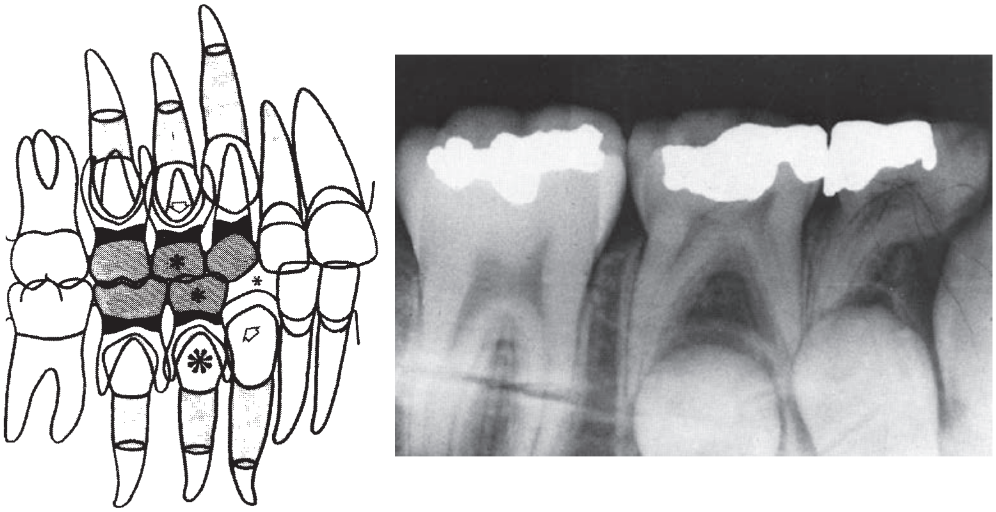

FIGURE 34-73

premolars may be enucleated (Fig. 34-73). This will encourage distal migration of the canines as they erupt.

Step 1: Extraction of the primary first molars and enucleation of the mandibular first premolars
Step 2: Extraction of the primary maxillary canines and maxillary first premolars. In the maxilla, the first premolars usually emerge before the canines (Fig. 34-74). Therefore, enucleation is less likely to be indicated. At this point, the mandibular canines can be observed emerging favorably into the oral cavity.
Step 3: Mechanotherapy (Fig. 34-75). The patient is now ready for the fixed appliance multibracket appliance treatment.
Step 4: Retention

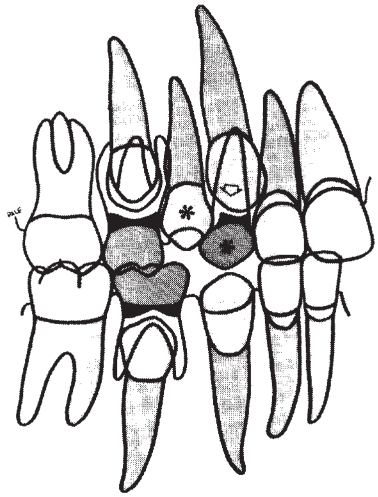

FIGURE 34-74

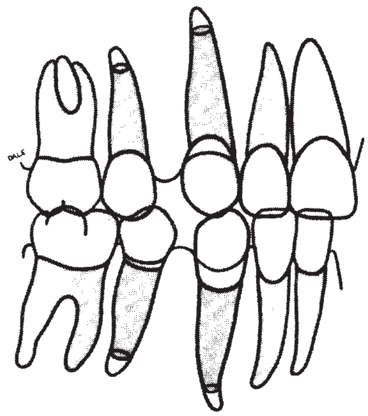

FIGURE 34-75

Group E: Enucleation in the Maxilla and Mandible. On occasion, the canines in the maxilla and mandible erupt before the first premolars (Fig. 34-76). If this is the case, the orthodontist might elect to extract the primary canines and first molars and enucleate the first premolars. This is acceptable if absolutely no opportunity exists to place fixed appliances at the completion of serial extraction. Otherwise, an alternative to enucleation is almost always preferable (see group F).

Step 1: Extraction of primary canines and primary first molars and enucleation of the first premolars
Step 2: Mechanotherapy (Fig. 34-77). The patient is now ready for the appliance treatment.
Step 3: Retention

Group F: Alternative to Enucleation. When the permanent canines are erupting ahead of the first premolars, enucleation of the premolars should be avoided if an opportunity exists to place fixed appliances at the completion of serial extraction (Fig. 34-78). When the first premolars have attained one half their root length, the primary first molars should be extracted.

Step 1: Extraction of the primary first molars
Step 2: Extraction of the primary maxillary canines, maxillary first premolars, and primary mandibular second molars. About 6 to 9 months later, when the emerging mandibular first premolar appears to be obstructed by the mesial contour of the primary second molar, the orthodontist should extract the offending tooth (Fig. 34-79). However, this sequence is usually not necessary in the maxillary dentition.
Step 3: Extraction of the mandibular first premolars. When these teeth emerge sufficiently, they are extracted (Fig. 34-80).

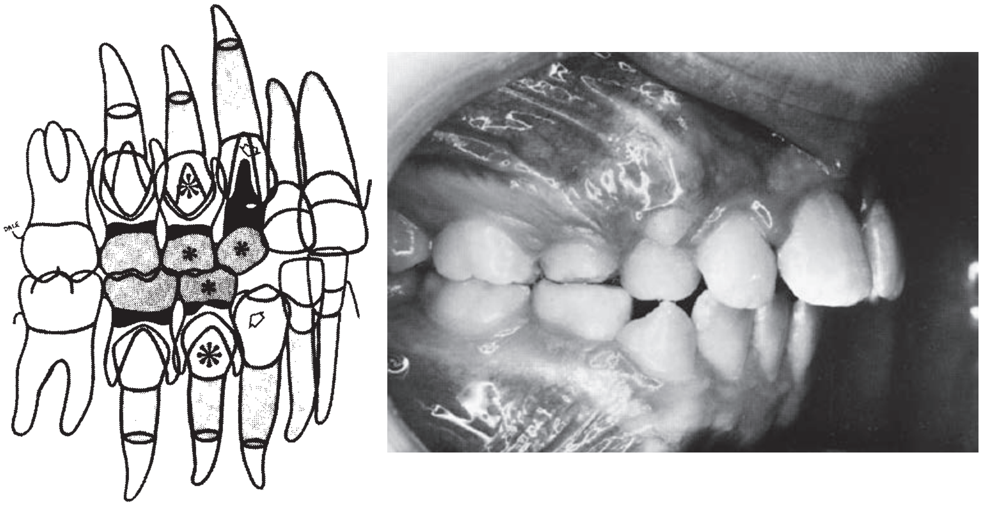

FIGURE 34-76

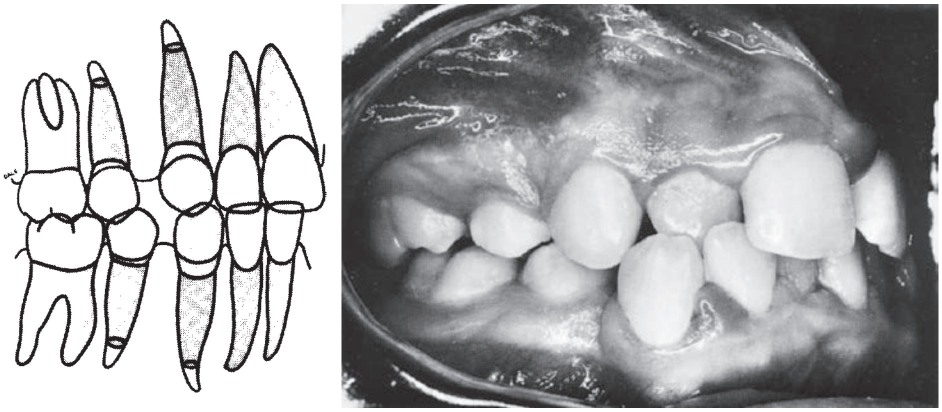

FIGURE 34-77

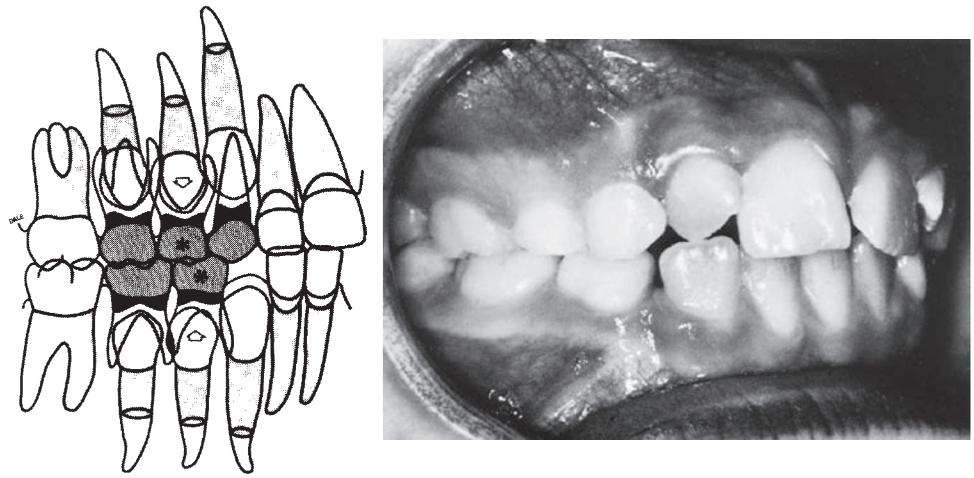

FIGURE 34-78

Step 4: Mechanotherapy. With this particular sequence, the least desirable extraction result is achieved (Fig. 34-81). However, extraction does not prolong the fixed appliance treatment significantly.

Step 5: Retention

Group G: Interproximal Reduction. Rarely should the mesial surfaces of the primary canines be reduced. These rare occurrences include when the practitioner does not intend to extract the permanent teeth and where a localized interference results in rotation of the lateral incisor.

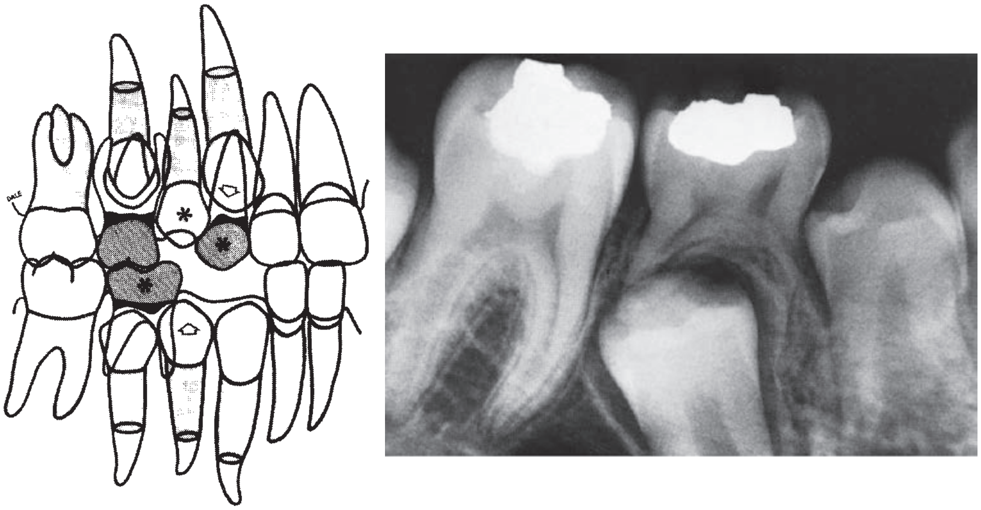

FIGURE 34-79

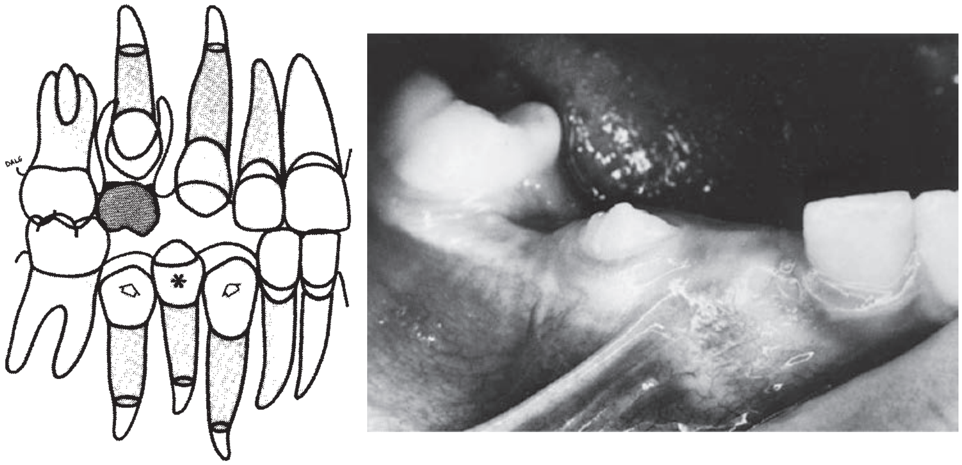

FIGURE 34-80

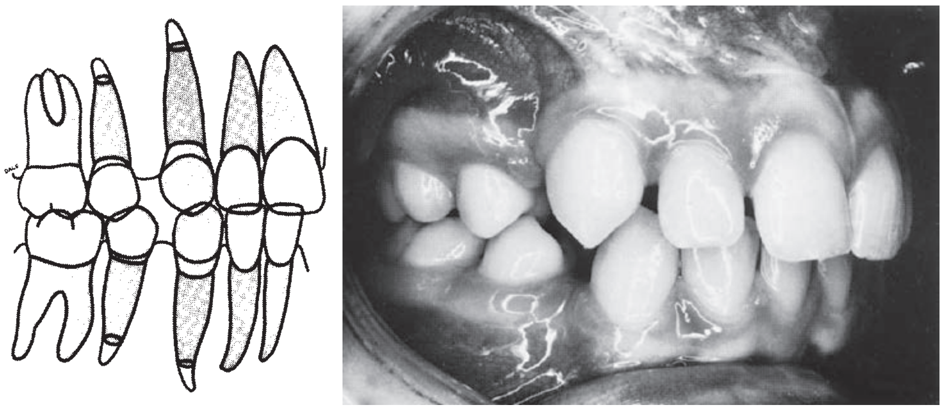

FIGURE 34-81

Occasionally, in nonextraction malocclusions, the primary second molars will be retained for an unusually long time. Because these teeth are wider mesiodistally than the underlying second premolars, they force the first premolars into a forward position in the dental arch and thus influence the permanent canines (Fig. 34-82, *A*). The long retention of these primary second molars also may interfere with the eruption of the first premolars after the permanent canines have emerged (Fig. 34-82, *B*). In each instance, the mesial surface of the primary second molars should be reduced by the amount of the leeway space. This usually results in a favorable alignment of the permanent teeth (Fig. 34-83).

The orthodontist may find it necessary at times to reduce the distal surfaces of the primary second molars (Fig. 34-84)

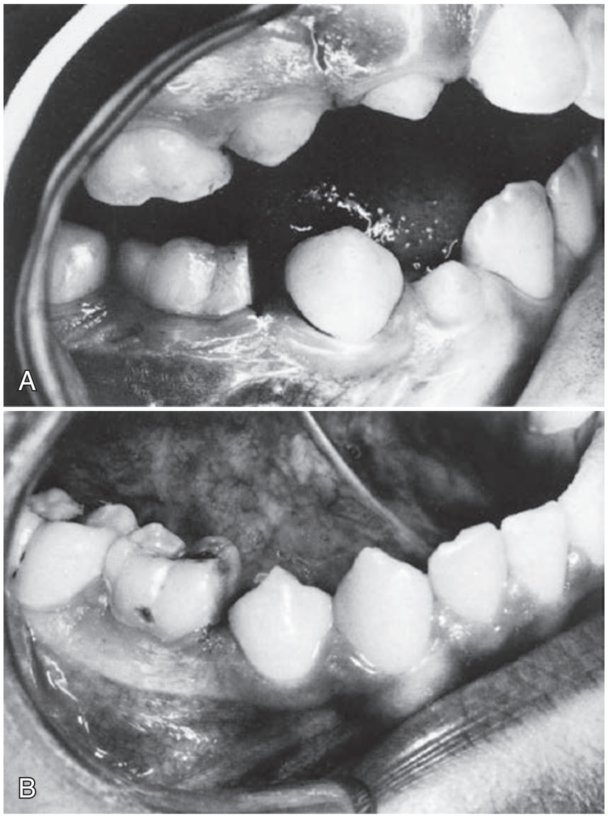

FIGURE 34-82 Interproximal reduction of the primary second molar to allow for emergence of the permanent canine (**A**) and the first premolar (**B**).

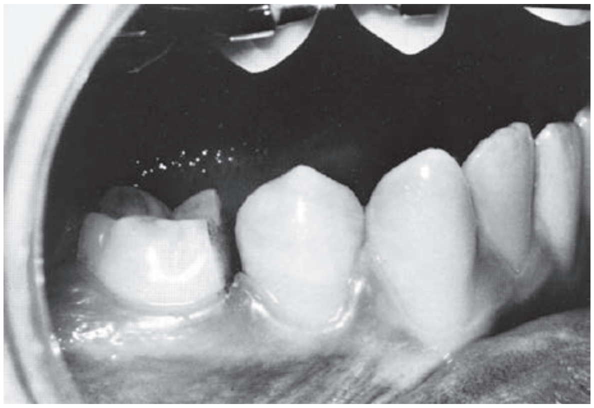

FIGURE 34-83 Favorable alignment after reduction of the primary second molar.

to ensure conversion of a straight terminal plane into a mesial step in preparation for a Class I relationship of the permanent first molars. This is accomplished when the primary maxillary second molars are exfoliated before those in the mandible and when space is present to allow the molars to move mesially. Ideally, the mandibular molars should be lost first. (For more detailed discussion of interproximal reduction of primary teeth, read the articles by Hotz,[3] Northway,[46,47] and Valencia et al.[48]).

Group H: Congenital Absence. Of utmost importance in patients with congenital absence of some teeth is to proceed with the conventional orthodontic diagnosis and treatment planning as if the teeth were present. Then treatment may proceed to cope

FIGURE 34-84 Reduction of the distal surface of the primary second molar to convert a straight terminal plane into a mesial step.

with the missing tooth or teeth. Whether the teeth are missing as a result of injury, disease, or developmental aberration matters little. Which teeth are missing and what is left to work with are the important factors in total correction of the malocclusion.

Maxillary Incisors. The maxillary lateral incisors are frequently missing or malformed. The percentage varies depending on the study consulted but in most practices is about 5% of the patients treated.

If a maxillary lateral incisor is congenitally absent, the dentition should be allowed to emerge completely before fixed appliance treatment begins. The orthodontist and primary care dentist should examine the crown of the canine carefully after emergence before deciding to place it in the lateral incisor position or its usual position.[49] The orthodontist should not rely on radiographs to evaluate the shape of unerupted teeth. Placing implant or fixed bridge restorations rather than using canines as lateral incisors may be needed if the size discrepancy exceeds the ability to restore the cuspid to appear as a lateral incisor. When canines are used as laterals, the orthodontist needs to be aware of arch size discrepancies between the arches and the potential to develop interproximal spaces during the retention period; in many instances, aesthetic considerations are the final deciding factor on whether or not to proceed with cuspid substitution.[50–52]

Mandibular Incisors. The patient in Figure 34-85 was treated by extraction of the mandibular central incisors. Such extraction disturbs arch length balance. Patients who have severe recession and malposition of the central incisors can be treated by routine serial extraction. The extraction of mandibular incisors, especially during development, definitely is not recommended; it complicates the total treatment plan and necessitates a compromise result. Every effort should be made to maintain the mandibular incisors, especially in unilateral situations.

Sometimes the orthodontist is faced with a single missing lower incisor. To repeat, every effort should be made to maintain the mandibular incisors, especially in the unilateral situation and during development. If one of the mandibular incisors is missing, it may be advisable to avoid extracting a premolar in that quadrant and use the canine as an incisor. If it is an extraction case, the molars on the affected side will be in a Class I relationship; if it is not, they will be in a Class III relationship.

PREMOLARS

Figure 34-26 illustrates a patient who had two maxillary first premolars missing. The clinical appearance that resulted was

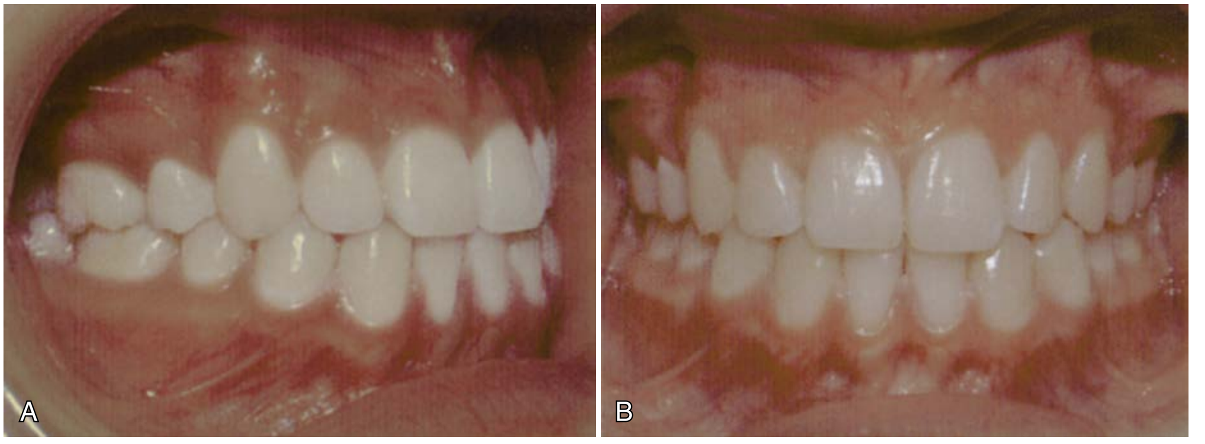

FIGURE 34-85 A and B, Alignment of the mandibular dentition after treatment in a patient with congenital absence of two incisors. The first premolars were extracted in the maxilla.

unusual. The canines erupted into the premolar locations, and the primary canines were retained. The treatment plan was altered to include extraction of the primary canines and movement of the permanent canines forward into their proper position with a resultant.

Class II Molar Relationship. Mandibular second premolars frequently are missing. Depending on the basic orthodontic diagnosis, treatment may involve moving the molars forward or replacing the missing teeth with implants or bridges. Treatment for Class II malocclusions that involved extractions may include moving the maxillary protruding incisors into the space provided by the extraction of the maxillary first premolars. Correction for a Class II molar relationship may involve moving the mandibular molars forward into the second premolar area, where the teeth are congenitally absent.

Mandibular second premolars constantly present difficulties in orthodontic treatment. They often are missing or erupting in the wrong direction and often are badly shaped with the potential for a size difference from the left to right side. The use of TADs to bring lower molars mesially without taxing anterior anchorage allows for space closure without adverse lingual tipping of the lower incisor teeth.

When one mandibular second premolar is congenitally missing, the clinician should proceed with serial extraction as normally done, extracting all four primary canines or primary first molars, depending on the development. When the four first premolars have emerged, three of them are extracted. In a quadrant where the second premolar is missing, the primary second molar is extracted. The first premolar then is moved into the second premolar site. This allows space for the canine to emerge. Occasionally, the primary second molar must be extracted earlier to allow the first premolar to emerge into a more distal position.

Garn and Lewis[53] have shown that in a congenital absence patient, more often than not, the treatment will not require extraction. In other words, congenital absence of teeth is related to small teeth; thus, serial extraction is not indicated.

If the diagnosis indicates the extraction of four second premolars or if the four teeth are congenitally missing, serial extraction is not indicated. Second premolar extractions are prescribed for a borderline tooth size–jaw size discrepancy in which the incisors are upright over basal bone. With extraction of the second premolars, the minimal crowding in the anterior area is corrected by using a fraction of the extraction space and without producing an alveolodental retrusion. It is difficult to encourage the emergence of second premolars ahead of the first premolars by extraction of the primary second molars early. Second premolars are notoriously slow in their eruption. Furthermore, if the primary second molars are extracted early, the permanent first molars may move mesially too rapidly. Second premolars are extracted when they have emerged partially into the oral cavity.

Often the question is asked about creating a dished-in face as the ultimate result of serial extraction when the four first premolar teeth are extracted. All orthodontists should be concerned about creating dished-in faces. *That is why serial extraction should be done only on a specific group of patients and only after a comprehensive diagnosis.* Because of this concern, the clinician should monitor the position of the mandibular incisors constantly. These should be allowed to tip lingually to the desired position and then held.

Some patients have a dished-in profile whether treated by extraction or nonextraction or left untreated. They exhibit a maxillary and mandibular alveolodental retrusion, a low MPA, a deep overbite of the incisor teeth, a short anterior facial height, a prominent chin, a prominent nose, and a tense perioral musculature. If a severe tooth size–jaw size discrepancy is superimposed, extraction may be called for to produce a stable result. Deferring consideration of extraction until all the permanent teeth have emerged is usually advisable with this facial pattern rather than performing serial extraction. If the orthodontist performs serial extraction, the orthodontist must use extreme caution and use holding appliances.[42,54,55]

A word of caution is necessary at this point regarding holding appliances, the labial upright positioning of permanent mandibular incisors, and the distal movement of permanent mandibular first molars by the use of fixed appliances including lip bumpers. Even the use of a lower fixed lingual arch can result in the impaction of the erupting mandibular second molars, another reason for continued monitoring during tooth eruption.

Typical Patient for Class I Serial Extraction

A typical Class I malocclusion with an anterior discrepancy manifested by an alveolodental protrusion and a posterior discrepancy manifested by a high-angle configuration is illustrated by patient M.R. (Figs. 34-86 and 34-87). The dentition when

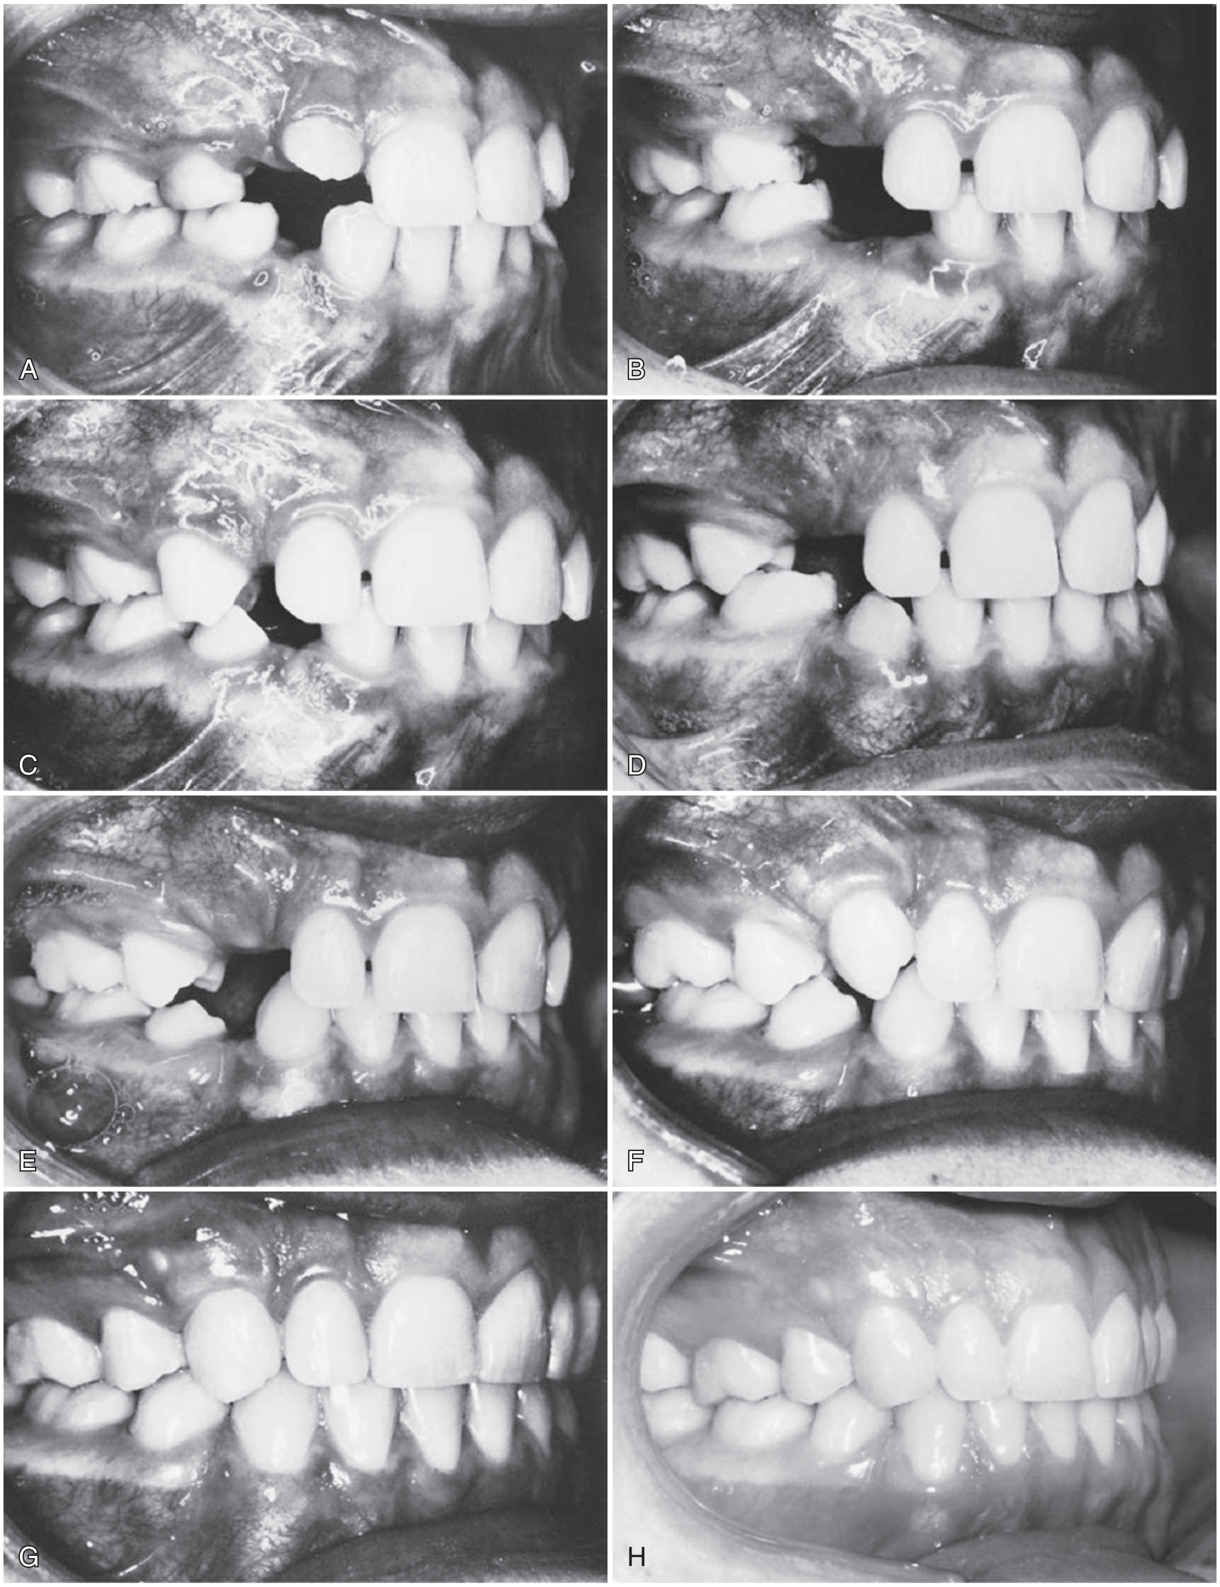

FIGURE 34-86 Patient M.R. **A,** At initial examination. The primary canines have been extracted. **B,** After extraction of primary first molars. **C,** Before extraction of the first premolars. **D,** Emergence of the permanent mandibular canines. **E,** Emergence of the second premolars. **F,** Before fixed appliance treatment. **G,** After fixed appliance treatment. **H,** Fifteen years after treatment. **I,** Response during interceptive guidance. **J,** Considerably less response during edgewise treatment. **K,** Response as indicated by the five cephalometric tracings (*1–5*) that were taken in each step in the treatment: *1*, before treatment; *2,* after extraction of the primary canines; *3,* after extraction of the primary first molars; *4,* after extraction of the first premolars; and *5,* after fixed appliance treatment.

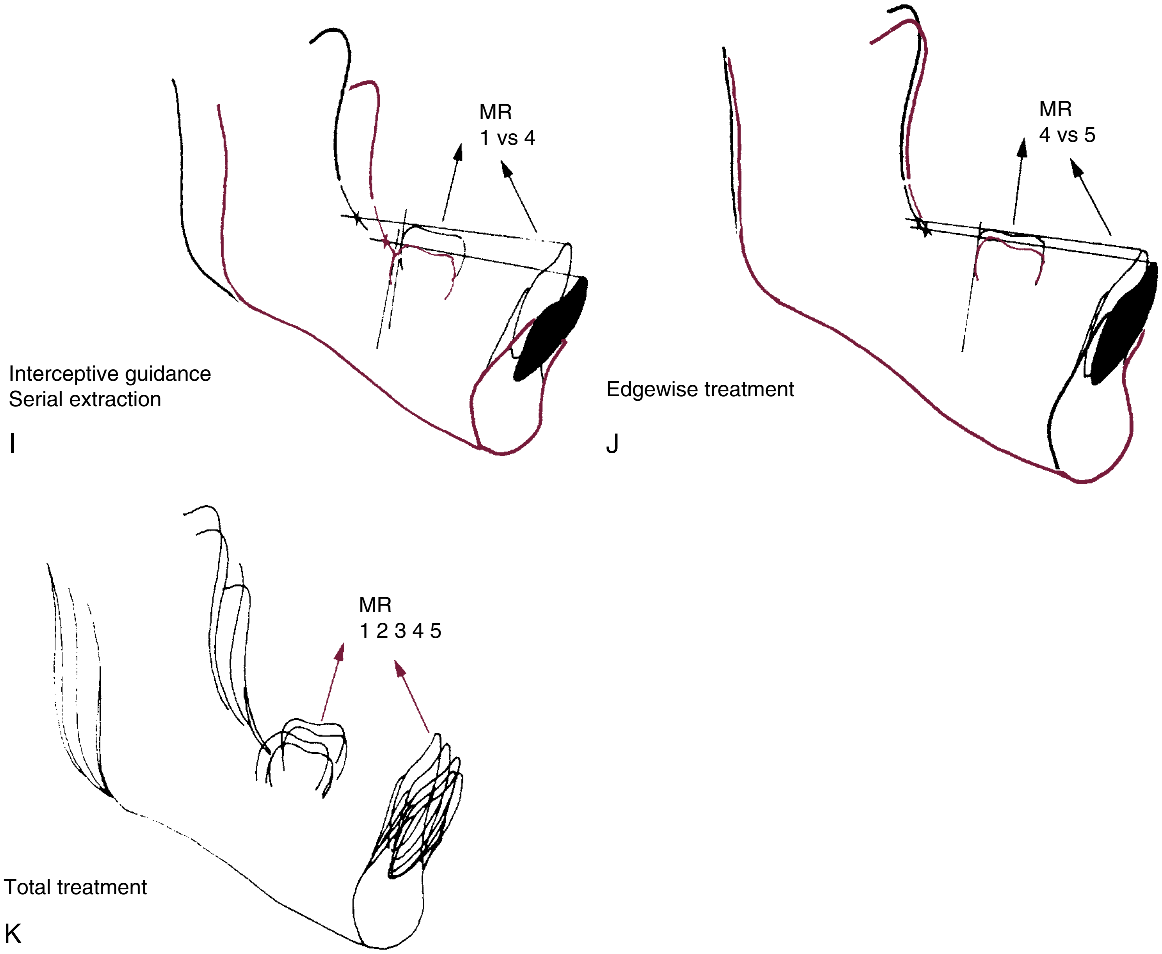

FIGURE 34-86—CONT'D

the patient came for examination and consultation is presented in Figure 34-86, *A*. The primary canines already had been extracted. In such patients, the clinician extracts the primary first molars to encourage the emergence of the first premolars so that they can be extracted as early as possible. This corrects the alveolodental protrusion by upright positioning of the incisor teeth.

With a relatively straight alignment of the incisor teeth, one does not need to extract the primary canines early. In Figure 34-86, *B*, the primary first molars have been extracted. Note the early eruption of the maxillary first premolar. A large restoration and a periapical infection of the primary molars possibly were factors in this situation. The orthodontist should wait until the other premolars have emerged into the oral cavity before advising extraction of these teeth (see Fig. 34-86, *B*). Note that in Figure 34-86, *C*, the four premolars have been extracted, and the incisor teeth are beginning to become upright over basal bone. In Figure 34-86, *D*, the permanent mandibular canines are beginning to emerge into the oral cavity. Note that the maxillary right primary second molar has been lost early. The premolar has emerged, and the first molar has drifted somewhat mesially. In Figure 34-86, *E*, all the primary second molars have now been lost, and the second premolars are emerging. Note the further upright positioning of the incisor teeth. With the emergence of the permanent maxillary canines and second molars, this patient is now ready for fixed appliance treatment (see Fig. 34-86, *F*). Figure 34-86, *G*, illustrates the end result, and *H*, the occlusion 15 years after retention. Cephalometric radiographs were taken of patient M.R. at the following times:

1. Before treatment
2. After extraction of the primary canines
3. After extraction of the primary first molars
4. After extraction of the permanent first premolars
5. After edgewise treatment

The response to serial extraction during interceptive guidance—superimpositions of cephalometric tracings numbers 1 and 4 (see Fig. 34-86, *I*)—is significantly greater than the response during the edgewise treatment—superimposition of cephalometric tracings 4 and 5 (see Fig. 34-86, *J*).

Figure 34-86, *K*, illustrates the response during the total treatment: interceptive guidance and edgewise appliance. The mandibular incisors gradually move upright, reducing the alveolar dental protrusion; the mandibular molars move upward and forward, accounting for an upward and forward rotation of the mandible.

Figure 34-87 presents the facial appearance before and after serial extraction and fixed appliance treatment. Note that this patient before treatment has a moderate high-angle facial pattern and alveolodental protrusion. After treatment the facial configuration exhibits harmony and balance. The smile has improved after serial extraction and again after multibanded treatment. Balance and harmony persist 15 years after treatment.

FIGURE 34-87 Facial appearance of patient M.R. Before (**A** and **B**) and after (**C** and **D**) serial extraction. **E** and **F,** After the fixed appliance treatment. **G** and **H,** Fifteen years after treatment. Cephalometric analysis of M.R. **I,** Before serial extraction. **J,** After serial extraction. **K,** After fixed appliance treatment. *ANB,* A point–nasion–B point; *FMIA*, Frankfort mandibular incisor axis angle; *IMPA*, incisor mandibular plane angle; *OP*, occlusal plane; *SNA*, sella-nasion-subspinale; *SNB*, sella-nasion-supramentale; *Z*, Z angle. The angle between the Frankfort Plane and Z Line (a line tangent to the chin and the vermilion border of both lips).

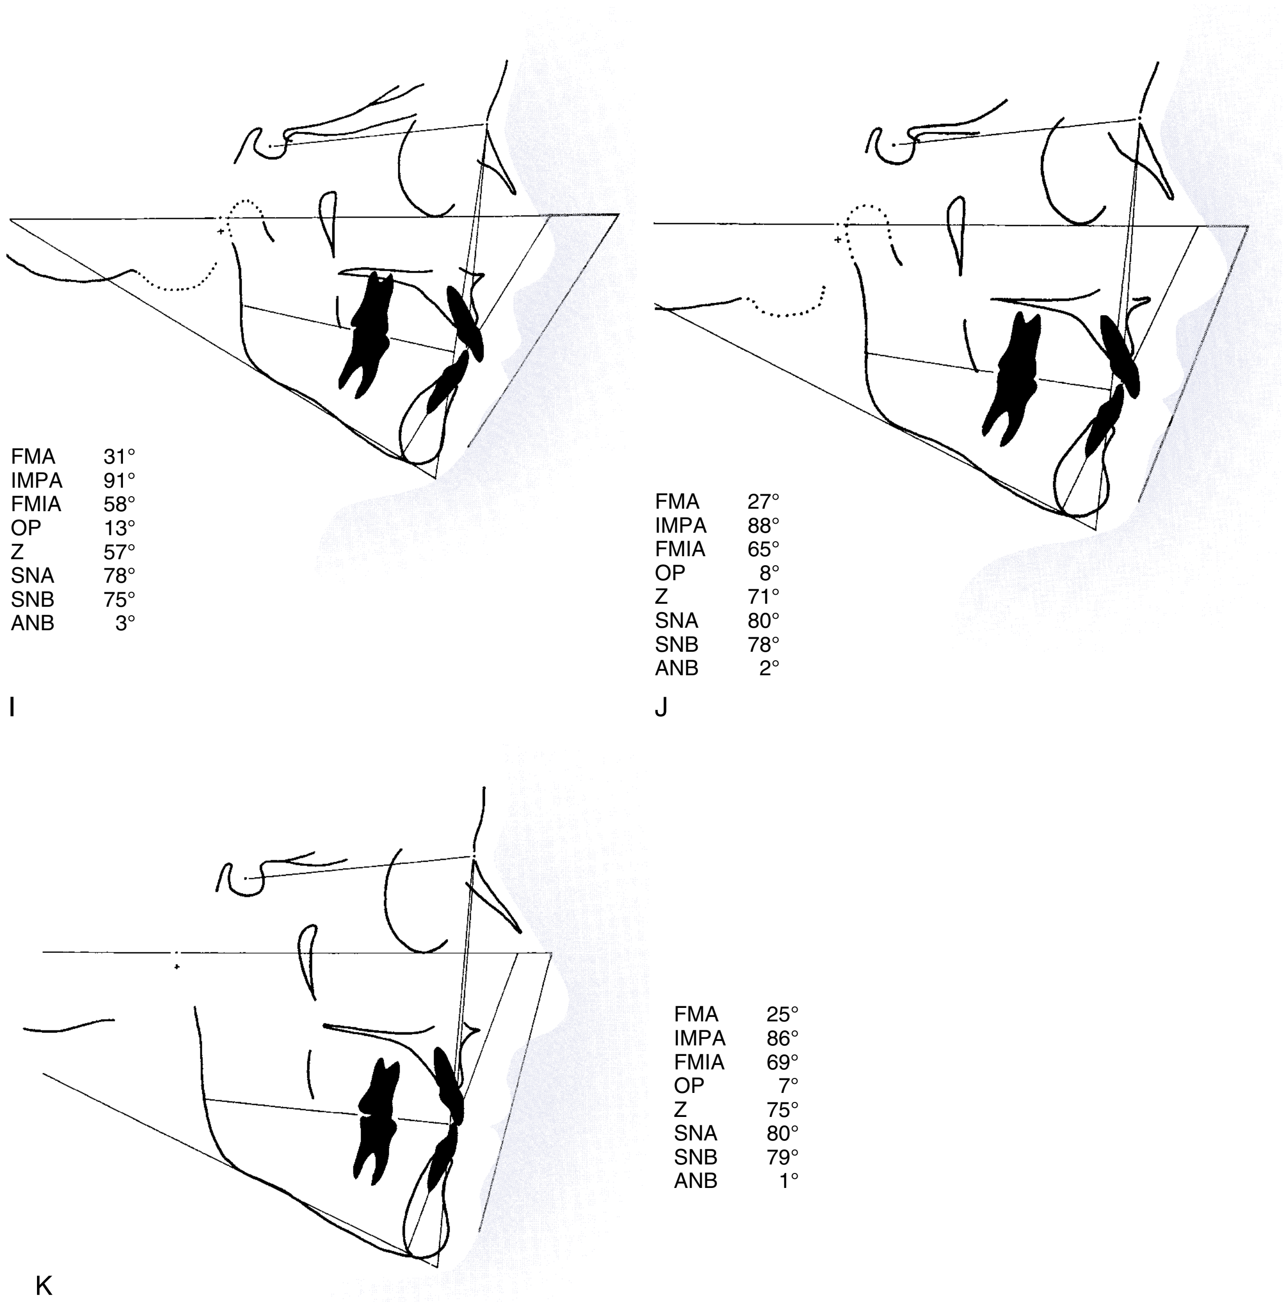

FIGURE 34-87—CONT'D

Before treatment, the cephalometric analysis of patient M.R. showed an FMA of 31 degrees. This represents a high-angle face. Throughout the course of serial extraction, the FMA was reduced to 27 degrees and throughout the course of fixed appliance treatment to 25 degrees. The 6-degree reduction indicated a favorable upward and forward rotation of the mandible. The patient's IMPA before treatment was 91 degrees, suggesting a moderate alveolodental protrusion for a high-angle facial pattern. During serial extraction, the mandibular incisors were positioned upright to 88 degrees and during active treatment to 86 degrees. This reduction of 5 degrees in the IMPA resulted in a slightly more balanced and harmonious soft tissue profile. The overall increase in the FMIA of 11 degrees (from 58 to 69 degrees) reflected a reduction in the FMA and the IMPA and a favorable rotation of the mandible and correction of the alveolodental protrusion. The reduction of the OP angle from 13 to 8 degrees during serial extraction indicated a mesial migration of the posterior teeth and an upright positioning of the mandibular incisor teeth, both favorable responses in the treatment of this particular facial pattern. The reduction of the OP angle from 8 to 7 degrees during active treatment indicated good control. The overall increase in the Z angle of 18 degrees (from 57 to 75 degrees) reflected a favorable rotation of the mandible and correction of the alveolodental protrusion. The maxilla grew slightly during the serial extraction period from 78 to 80 degrees and remained relatively constant during active treatment. Mandibular growth and rotation accounted for

3 degrees during the serial extraction period and for 1 more degree during the active period of treatment. Throughout total treatment, the ANB was reduced from 3 degrees to 1 degree, indicating a modest improvement in the jaw relationship (see Fig. 34-87, *I–K*).

Important in patient M.R.'s case was that the tooth size–jaw size discrepancy not be corrected by extension of the teeth posteriorly, anteriorly, laterally, or vertically. If this had been done in such a high-angle facial pattern, the molar extrusion would have resulted in an unfavorable downward and backward rotation of the mandible. With extrusion of the molars and the dumping forward of the incisors, the OP would have been tipped unfavorably and the alveolodental protrusion worsened. With the mandibular rotation and the tipped OP, the maxillary incisor would have been rabbited downward and backward, revealing more gingival tissue. Concomitant effects include impaction of the posterior molars and expanded dental arches. Furthermore, the mandibular incisors would have been tipped off basal bone, creating an unstable situation that required prolonged retention. The harmony and balance of the facial profile could have been worsened considerably.[56]

The total space analysis indicated an anterior and posterior space discrepancy. The anterior discrepancy was corrected by serial extraction and extraction of the permanent first premolars. The posterior discrepancy was corrected by extraction of the permanent third molars.

KEY MEASUREMENTS FOR DIAGNOSIS AND CASE EVALUATION

The Tweed Foundation has conducted several studies on the difference between successful and unsuccessful treatment.[57–63] They have indicated six measurements that are crucial in the evaluation of this difference: FMA, ANB, Z angle, OP, sella-nasion-supramentale (SNB), and the ratio of the posterior face height–to–anterior face height ratio (PFH/AFH) (Box 34-1). We have designed a "wiggle" to illustrate successful treatment (Fig. 34-88). Patient M.R.'s six measurements before serial extraction (see Fig. 34-88, *A*) were to the left of the wiggle, in the retrognathic, high-angle vertical growth area: FMA = 31, ANB = 3, Z angle = 57, OP = 13, SNB = 75, and PFH/AFH = 0.65.

After serial extraction (see Fig. 34-88, *B*), all six measurements were within the normal range: FMA = 27, ANB = 2, Z

BOX 34-1 Six Crucial Measurements for Treatment Success

FMA (Frankfurt mandibular plane angle) Indicates mandibular response. In most patients, successful treatment is associated with a favorable counterclockwise rotation indicated by a reduction of FMA.

ANB (A point–nasion–B point) angle Indicates the correction of a skeletal discrepancy. Successful treatment is associated with a reduction in ANB in most instances.

Z angle Indicates the alveolar dental and soft tissue profile response. With successful treatment, improvement in the soft tissue balance and harmony and reduction in the alveolar dental protrusion occur. This is associated with an increase in the Z angle.

OP (occlusal plane) Indicates the control of treatment. If the mandibular molars are prevented from extruding and the mandibular incisors are not "dumped" forward, the occlusal plane does not tip forward. If anchorage is prepared and the incisors are positioned upright, the OP decreases. Successful treatment is associated with a flattening of the OP.

SNB (sella-nasion-supramentale) angle Indicates the mandibular response. In most patients, if the treatment is successful, the SNB angle will increase.

PFH/AFH (posterior facial height/anterior facial height) Indicates the mandibular response. In successful treatment the PFH increases relatively more than the AFH; therefore, the ratio increases.

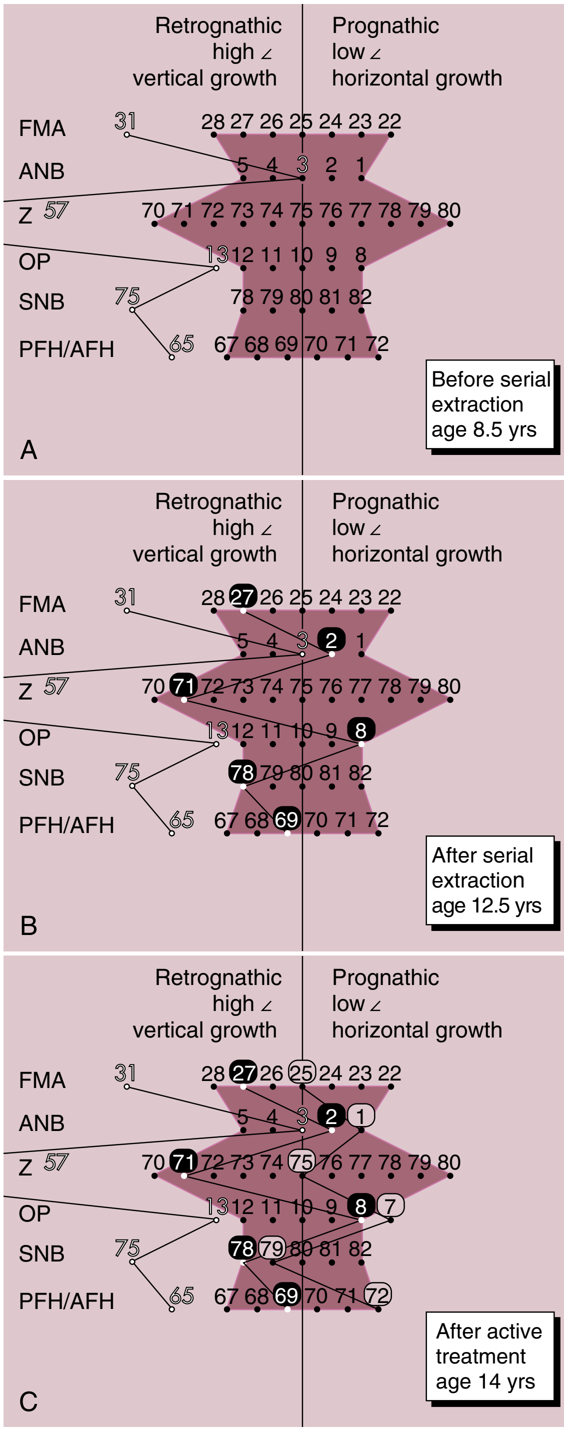

FIGURE 34-88 **A,** The graphic "wiggle" for patient M.R. before serial extraction. **B,** The wiggle for patient M.R. after serial extraction. **C,** The combined graphic wiggle for patient M.R. Note the improved measurements after both serial extraction and fixed appliances. *ANB,* A point–nasion–B point; *FMA,* Frankfurt mandibular plane angle; *OP,* occlusal plane; *PFH/ANH,* posterior face height–to–anterior face height ratio; *SNB,* sella-nasion-supramentale; *Z,* Z angle.

angle = 71, OP = 8, SNB = 78, and PFH/AFH = 0.69. Clinically, this is a highly successful response, especially without mechanotherapy.

After edgewise treatment (see Fig. 34-88, *C*), the measurements increased slightly but remained within the normal range, except for one reading, the OP, which was overcorrected slightly.

> *When facial deformity has been corrected and mental anguish eliminated, a dull and unhappy facial expression becomes bright and happy. What greater reward could any orthodontist want or expect?*
>
> **—Charles H. Tweed**

The earlier this beneficial result occurs, the better.

ACKNOWLEDGMENT

The concepts behind guided extraction and orthodontic treatment have been developed over a period of time and are reflected herein to be most current. Over the years, there have been a number of "champions" of the technique who worked hard to teach the concepts involved. Dr. Warren R. Mayne, one of the original champions, worked with Dr. Tom Graber and contributed the guided extraction chapter in the first and second editions of this text. Both the authors and the editors recognize his initial contributions. We are all happy to see the concepts underlying guided extraction still relevant for today's clinician.

Functional Appliances

*Thomas M. Graber**

OUTLINE

This "Classic Chapter in Orthodontics" is taken from our fourth edition of Orthodontics: Current Principles and Techniques published by Elsevier in 2005. It is presented as then written. The chapter contains perspectives and information that remain valuable to orthodontic residents and clinicians.

The stomatognathic system consists of the teeth, the periodontal membranes, alveolar and basal bone, the temporomandibular joints (TMJ), and the motivating and draping neuromusculature. This is a living, viable, and remarkably adaptive system, particularly during the period of growth and development of the craniofacial complex. Bone may be one of the hardest tissues in the human body, but it is also one of the most responsive to environmental stimuli. For example, persons have known for many centuries that the membranous bone cranial structures can be deformed by binding an infant's skull, as was done by the Inca Indians.[1] Pathologic manifestations can result in bizarre craniofacial asymmetries and deformities that involve cranial and mandibular structures. Practitioners can learn much about the normal condition from pathologic conditions.

Orthopedic surgeons have corrected skeletal endochondral deformities for many years, primarily in growing individuals. However, influencing endochondral bone is known to be a greater challenge. The chapters in this book by Thilander, Hatch, and Sun (Chapter 3) and Roberts and Huja (Chapter 4) describe the *raison d'être* for this tissue reaction, and the reader should become familiar with the minutiae to better understand important factors such as the way appliances work, the best time to use them, and their limitations. An orthodontic practitioner cannot help but be excited by the prospect of using the patient's own functional forces to achieve orthopedic and orthodontic correction of dentofacial abnormalities. Indeed, previous overconcentration on the mechanical aspects of orthodontics has been a barrier to the full realization of the magnitude of influence that is possible. Orthodontics is not only the appliance, but it is about which appliances, why, when, and for how long.

ORIGIN

Theories on bone plasticity may be traced to Wolff[2] and Roux,[3] who believed that form and function were intimately related. Changes in functional stress produced changes in internal bone architecture and external shape. Recent research has supported Roux's concept of functional "shaking of the bone," and the anabolic stimulus applied to achieve the optimal morphogenetic pattern.[4–6]

Early in the twentieth century, Pierre Robin of France introduced the plastic monobloc as a passive positioning device. This device was used in neonates with micromandibular development to prevent glossoptosis, which is literally a blocking of the airway by the tongue.[7] This congenital abnormality of development has been called Pierre Robin syndrome and is usually associated with cleft palate. The Robin appliance was modified from bite-jumping vulcanite maxillary anterior guide planes designed by Norman Kingsley.[8] However, the Kingsley guide plane was attached to teeth, whereas Robin had to use his monobloc as a removable device because newborns have no teeth.

ANDRESEN ACTIVATOR

Viggo Andresen of Norway also was familiar with the writings of American authors Norman Kingsley[8] and Calvin Case.[9] Their use of bite-jumping appliances was common among other orthodontists at the end of the nineteenth century. Even Angle originally resorted to and recommended such appliances for patients with mandibular retrusion.[10] Also on Andresen's bookshelf was a favorite of his, the orthodontic textbook of Benno Lischer,[11] published in 1912. Lischer presented graphic illustrations of the effect of abnormal perioral muscle function on the teeth and investing tissues. One conclusion to be drawn from Lischer's theory is that if compensatory and adaptive lip and tongue function could exacerbate excessive overjet in types of Class II malocclusions and if abnormal swallowing and prolonged finger-sucking habits could create anterior open bite and narrow maxillary arches, then could not the same muscles be used to correct these and other problems? This theory was particularly true of patients with Class II, Division 1 conditions who had protruding maxillary teeth and retrusive lower dentition, a combination that created excessive overjet and evoked compensatory, adaptive function. Why not use these same deforming muscles to reverse the procedure? Holding the mandible forward long enough could reverse the deleterious effects of a trapped lower lip, lack of normal lip contact, and abnormal respiration, characteristics associated with malocclusion and illustrated as early as 1861 by artist George Catlin (cited in Angle[12].)

Actually, Andresen was not thinking of "guiding growth" at that time but only of eliminating the adverse effects of abnormal function. This working hypothesis was tested on his own daughter, who was wearing fixed orthodontic appliances and who was going away to camp over the summer. Andresen removed the fixed appliances and placed a modified Hawley-type retainer on the maxillary arch. However, he added a lingual horseshoe flange that guided the mandible 3 to 4 mm forward when the teeth were brought into maximal closure allowed by the interposed acrylic guide plane[13–16] (Fig. 35-1), which was done to prevent any relapse over the 3-month vacation period. On his daughter's return, Andresen was surprised to see that nighttime wearing of the appliance not only eliminated the abnormal neuromuscular compensations, but it also produced a complete sagittal correction and significantly improved the facial profile. The result was stable. When trying this system on numerous other growing patients who were going away for the summer and then on patients undergoing routine care throughout the year, Andresen observed significant sagittal basal bone and neuromuscular improvement that he had not been able to achieve with devices such as conventional fixed appliances and intermaxillary elastics.[14]

The sagittal changes that Andresen observed occurred because the appliance increased the activity of the protractor and elevator muscles, with concomitant relaxation and stretching of the retractors. The elimination of the abnormal perioral muscle function by mandibular protraction prevented the deforming and restrictive action of the trapped lower lip and the hyperactivity of the mentalis and submandibular muscle groups (Figs. 35-2 and 35-3). Compensatory mandibular opening caused by concomitant mouth breathing also could be eliminated. The change in muscle pattern would thus produce not only a new and more favorable pattern but also a change in bony structures as the muscles adapted to the new functional stresses (Fig. 35-4).[6,17–63]

The intermittent forces produced by the loose appliance were thought to create favorable changes in tooth position, even though the appliance was worn only at night. Later, it was postulated that

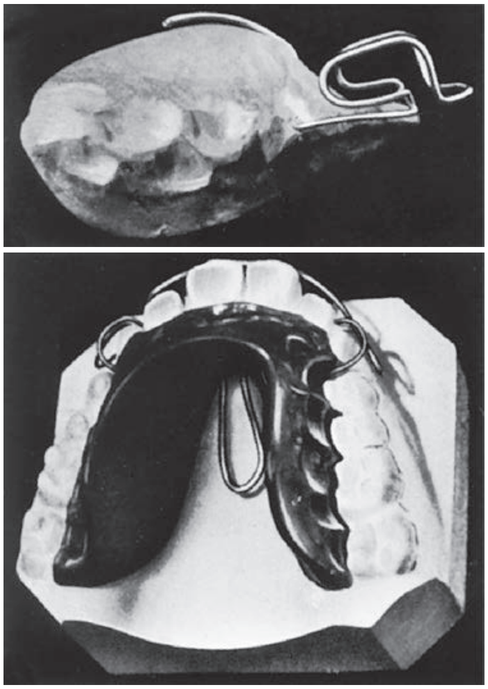

FIGURE 35-1 Andresen-Häupl activator. This device has no tooth-moving parts. The appliance was made to treat Class II, Division 1 malocclusions. Instead of palatal coverage, a heavy Coffin spring has been used to ensure stability and yet allow tongue contact with the mucosa. The loops in the canine region stand away from the teeth, allowing maxillary intercanine development. These loops are the forerunners of the Balters Bionator screening loops, which extend to the distal aspect of the deciduous second molar, and also of the Fränkel buccal shields, which are also meant to hold off cheek pressure. (From Andresen V, Häupl K. *Funktionskieferorthopädie: die Grundlagen des "Norwegischen Systems."* 2nd ed. Leipzig, Germany: H Meusser; 1936.

the appliance had an added benefit; it was thought to serve as a night guard, preventing the potentially deleterious effects of nocturnal parafunctional activity, actually stimulating normal muscle activity and enhancing the metabolic pump activity of the retrodiskal pad. This repetitive pump activity increased blood flow into the highly vascular posterior attachment on guided mandibular protraction and forced out the catabolic by-products on mandibular retraction.[64,65] The obvious benefits of a protracted, unloaded condyle were hypothesized to be enhancement of condylar growth increments and a more favorable upward and backward condylar growth direction.[4] Fundamental tissue research by Bierbaek and colleagues,[66] Braun and associates,[67] Buschang and Santos-Pinto,[24] Chen and others,[68] Decrue and Wieslander,[69] Droel and Isaacson,[70] Du and colleagues,[27] El-Bialy and associates,[71] Garattini and others,[72] Graber,[65] Ikai and colleagues,[32] Kantomaa and Pirttiniemi,[34] McNamara and associates,[43] Pancherz,[47] Paulsen,[49,50,73] Pirttiniemi and others,[51] Popowich and colleagues,[74] Rabie and associates,[75] Ruf and Pancherz,[53] Vardimon and others,[76] Voudouris and colleagues,[77–79] Ward and associates,[80] Watted and others,[61] Woodside and colleagues,[81] and Xiong and associates[82] stresses the changing position of the glenoid fossa during growth and the potential for influencing it, even as the Incas changed growth eons ago.

As with Robin's monobloc, Andresen's first appliances were passive, having no intrinsic force systems. Only when the patient bit into the appliance would the extrinsic force be in

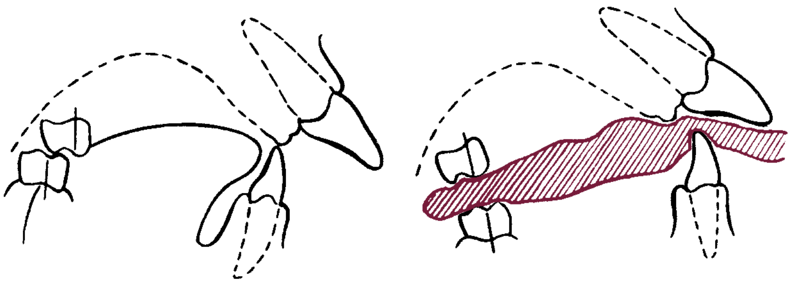

FIGURE 35-2 Construction bite. Correcting the buccal segment relationships from Class II to Class I is accomplished through mandibular advancement of approximately 6 mm. Note that the overjet is still excessive because of labially malposed maxillary incisors, which can be corrected after the buccal segment relationship has been normalized. An interocclusal clearance of 3 to 4 mm allows the mandible to come forward sufficiently to correct the buccal segment intercuspation. (Redrawn from Andresen V, Häupl K. *Funktionskieferorthopädie: die Grundlagen des "Norwegischen Systems."* 2nd ed. Leipzig, Germany: H Meusser; 1936.)

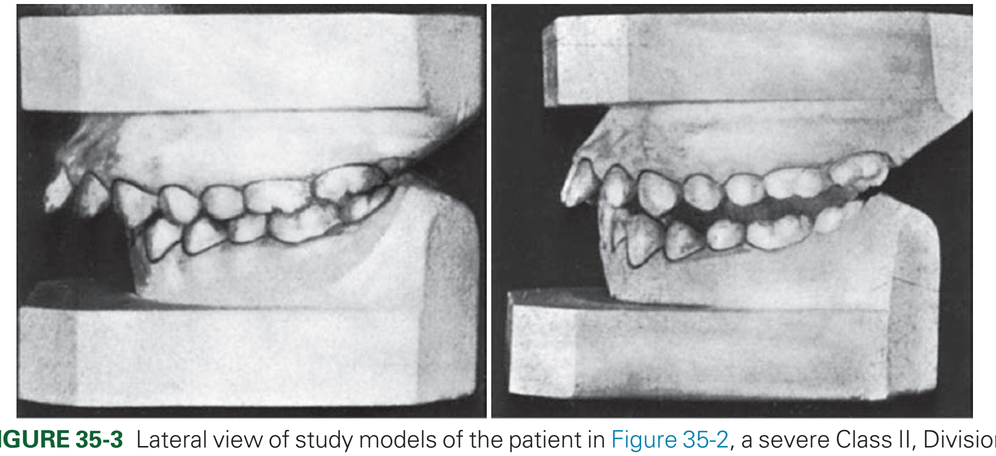

FIGURE 35-3 Lateral view of study models of the patient in Figure 35-2, a severe Class II, Division 1 malocclusion. The lingual inclination of the lower incisors is a favorable condition for functional therapy, as is the deeper-than-normal overbite. effect. The growth increments were hypothesized to be greater at night, a belief that later was validated by Hotz,[83] Igarishi and colleagues,[84] Korkhaus,[85] and Petrovic and associates.[86]

The original name Andresen used for this type of treatment was *biomechanical orthodontics*. Only later, after teaming up with Karl Häupl and doing further work on the concepts and technique refinements, was the name changed to *functional jaw orthopedics*, which was more descriptive.[10,15] The concepts were broadened to include the potential for altering skeletal relationships, depending on the amount and direction of jaw growth. The forward posturing of the mandible, as determined by the carefully manipulated construction bite, was reasoned to produce beneficial sagittal skeletal change by harnessing the growth potential. This was a contradiction of early bite-jumping procedures, which were deemed strictly positional changes of the mandibular condyle in the fossa; hence, the functional orthopedic connotation. The treatment became known as the Norwegian system to much of the orthodontic world, although Andresen was a Dane and Häupl was a German (both taught at the dental school in Oslo, Norway).[87]

BITE-OPENING CONTROVERSY

Although the concept of sagittal construction bite advancement was generally accepted by clinicians in Europe (it varied from 3 to 6 mm, depending on the severity of the anteroposterior dysplasia and the resultant abnormal buccal segment interdigitation), the theory pertaining to the amount of vertical opening and its effect on the muscles produced considerable controversy. Selmer-Olsen,[8] who became professor of orthodontics at the University of Oslo after World War II, believed that the muscles could not actually be stimulated during sleep; nature had designed them to rest at night, and swallowing occurred only four to eight times an hour. He interpreted the activator action as stretching of the muscles, fascial sheets, and ligaments when the mandible was opened beyond the postural resting position (i.e., viscoelastic response). In truth, the activator was a foreign body, and the tooth-moving force produced did not result from the kinetic energy of muscle function but from the potential energy of stretched tissues. Woodside and colleagues[81,88] called this the viscoelastic properties of the tissues. Current debate on the precise nature of the activator effect still reflects the divergence of opinion.[89] According to Lysle Johnston,[90] condylar unloading is a factor. Research by Graber[4,64] indicates that enhanced metabolic activity, accomplished through the stretched and enlarged TMJ retrodiskal pad during protraction, is a too-long-overlooked consideration.

Andresen and Häupl's interpretation presupposed freedom for the mandible to assume the physiologic rest position. Slagsvold,[91] later professor of orthodontics at Oslo, reported that his own observations did not completely substantiate this premise. Nevertheless, he concurred that forward posturing should not exceed the rest position vertical opening of 2 to 4 mm. Too wide an opening made compliance more difficult and could produce a depressing force on the posterior teeth—hardly desirable in deep-bite, Class II malocclusions. Grude[92] and Fränkel[93] strongly support this construction bite limit. Fränkel recommended incremental small advancements of 2 to 3 mm for his appliances rather than "the great leap forward" of 5 to 7 mm. Reactivation of optimal tissue response, as well as enhanced patient compliance, are factors. Petrovic and colleagues,[86] Komposch and Hockenjos,[35] and McNamara and associates[42] provide laboratory verification of this fact.

The philosophy of Harvold[94] and Woodside[88] has been to exceed the freeway space limits, if for no other reason than to keep the appliance in place at night during sleep so as to maintain a corrective stimulus. As for the cognitive interpretations of Selmer-Olsen, subsequent research by Ahlgren,[17] Herren,[95] Komposch and Hockenjos,[35] Sander,[54] Schmuth,[96] and Watted and colleagues[61] corroborated the finding that the activator does not *activate* muscles during sleep (Fig. 35-5).

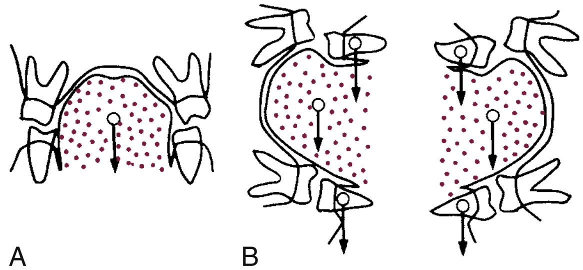

FIGURE 35-5 Various forces act on the upper and lower arches. In this case, the influence of gravity is different when the head is erect (A) than during sleep when the head is turned to one side or another (B). In the latter case, the activator tends to prevent the normal change or adaptation to varying postural and gravitational forces that elicits a positive reaction from the orofacial muscles, particularly the protracting and retracting muscles. Because the patient swallows only four to eight times an hour during sleep, this positive reaction is more likely responsible for any changes effected by the appliance. (From Herren P. The activator's mode of action. *Am J Orthod* 1959;45:512–527. With permission from the American Association of Orthodontists.)

Head Posture during Sleep

Another variable is the many changes of head posture that occur during sleep, altering the magnitude and direction of force.[91] At any particular moment, the mandibular rest position depends on the head and body posture; therefore the restriction of muscle movement required to create the desired mandibular position change without the activator in place constantly varies, involving different muscle groups and creating different force vectors on the activator (see Fig. 35-5). The plane of sleep (light or deep), the intraoral air pressure, the dream cycle, and the state of mind are additional conditioning factors, all uncontrolled by the clinician. Only the mandibular position (and the potential effect on the glenoid fossa), as held by the appliance, is controllable. However, the splinting or guiding effect on the mandible is such that it can help influence the net effect of the variable forces. If the activator is properly designed and worn as prescribed, then the result of all the controlled and uncontrolled forces is usually designed to enhance adaptation to the position created by the appliance (Figs. 35-6 and 35-7).[6,56]

Herren[95] has tried to assess the magnitude of the resultant forces acting on the mandible and the interaction between them. The weight of the mandible, tongue, and appliance is constant, averaging approximately 250 g. Muscle tonus and tensions vary, depending on factors such as the degree of stretching, the control from the central nervous system, the relation with the bed or pillow, and whether the head is prone or supine. If the patient is dorsally recumbent while sleeping and the head is upright, then the muscle forces must balance the weight of the lower jaw, associated soft tissue structures, and appliance. The multiple forces are different in prone, supine, and rotated combinations. The forces created are basically intermittent, however, even though some of the teeth or groups of teeth may be subject to pressure for a protracted period. The loose appliance is responsible for some of the intermittent action. Removal of the appliance during the day also produces a net intermittent action, calling up a new muscle engram to establish the neuromuscular engram consistent with diurnal postural changes and activities.*

The functional mechanism of the activator. *SSO Schweiz Monatsschr Zahnheilkd* 1953;63:829–879.)

Working Hypotheses

For conventional nighttime wear of the classic activator, two working hypotheses have been proposed for the effect on the teeth themselves:

1. The original Andresen-Häupl rationale attributed tooth movement to a loose-fitting, functionally generated mobility that provided intermittent forces created by the elevator and protractor muscles and by the elements of the buccinator mechanism. These forces jolted or shook the teeth, pushing the appliance back into position on the maxillary teeth when it dropped away. This hypothesis was supported by the Roux concepts. A prerequisite was that the bite opening should not exceed the normal interocclusal clearance or freeway space. This approach also enhanced the metabolic pumplike action of the TMJ retrodiskal pad, stimulating anabolic and catabolic exchange.[4,64,72]
2. The second hypothesis denies that enhanced functional activity is induced at night by the bite-opening activator and implies that the activator at rest moves the teeth and creates the desired changes. Current long-range case analysis of treated individuals shows some support for this thesis.[20,21,100] The interocclusal mass of acrylic exceeds the physiologic resting position. The appliance thus is squeezed between the jaws most of the time, splinting them in the desired sagittal relationship and preventing postural changes that would normally occur without the activator in place. The resulting intermittent forces vary from time to time in frequency and magnitude, but the net result is the distribution of functional forces to the activator, which transmits them to the teeth and alveolar bone, enhancing the adaptive process. The forces produce a strain in the tissues (i.e., viscoelastic stretch) and essentially act as mechanical phenomena[20,22,81,88,100] (Fig. 35-8).

Normal respiration is optimized with forward mandibular posturing, particularly in young patients with excessive epipharyngeal tissue. This appliance thus prevents the development of open bite problems, overeruption of posterior teeth, steeper mandibular plane inclination, and compensatory tongue posture changes that might be deleterious. This hypothesis has been validated by subsequent studies by Woodside and colleagues.[†]

Sagittal Change

The forward posturing of the mandible, produced by the construction bite, creates the desired sagittal change (Fig. 35-9). This aspect depends on the desired growth guidance and adaptive processes for the skeletal and dental modifications. Occasionally, a functional retrusion is eliminated, particularly in deep bite malocclusions, which has long gone unrecognized because only the apparent condylar position in the glenoid fossa was used as a criterion and the more retruded fossa in Class II problems was not.[66,70] Controversy still surrounds the interpretations, despite extensive research by Cevidanes and colleagues,[106] Graber and associates,[10] McDougall and McNamara,[39] McNamara and colleagues,[40,42] Pancherz,[46–48,107,108] Petrovic and associates,[86] Ruf and Pancherz,[54] Voudouris and colleagues,[78,79] and others.[*] These studies clearly indicate an enhancement of growth while the functional appliance is worn—that is, more condylar growth increments and a change in the direction of growth to a more upward and backward vector. Stutzmann's research demonstrates an actual change in the internal condylar structure, with a more posterior directional orientation of the trabeculae.[86] Some evidence also exists of minor retardation of maxillary sagittal growth.[10] Vertical growth, of course, can be controlled by the interocclusal acrylic mass, preventing or allowing eruption of posterior teeth. As previously mentioned (and a factor that has been too long neglected), the change in growth direction in the fossa, as well as modification of the fossa, have both been demonstrated by Decrue and Wieslander,[69] Droel and Isaacson,[70] Ikai and colleagues,[32] McNamara and associates,[43]

FIGURE 35-8 **A,** When the patient is upright, muscle tension, muscle tonus, and atmospheric pressure balance the weight of the mandible, the associated tissues, and the activator. **B,** If the patient reclines during sleep while wearing the activator, then gravity, muscle tension, and tonus act in the same direction. However, during sleep, the lips drop open, mouth breathing ensues, and function is minimal.

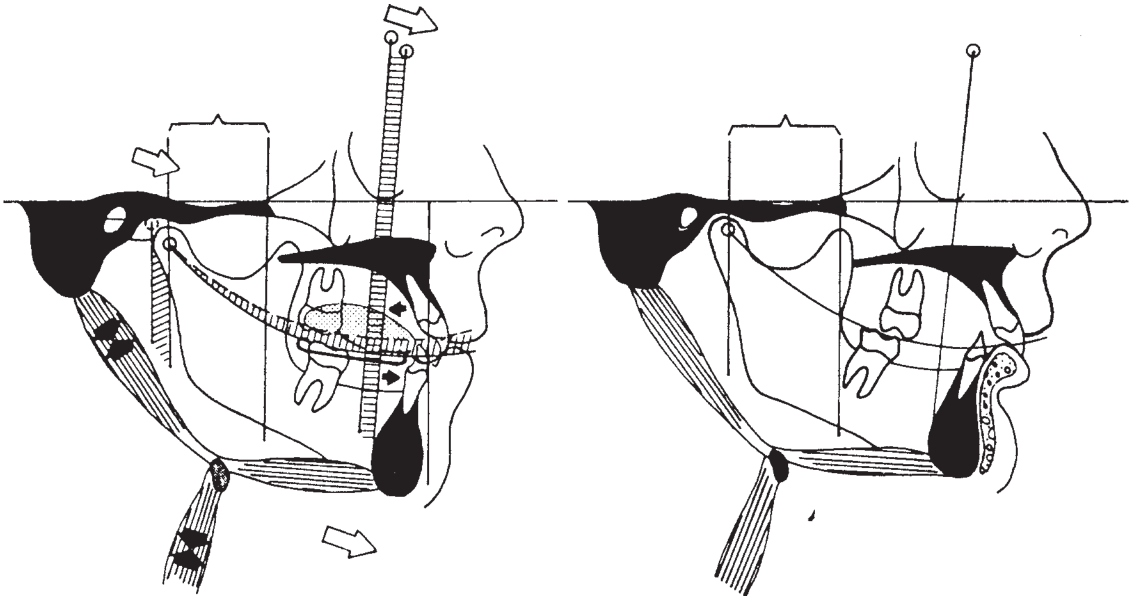

FIGURE 35-9 Modified cephalometric tracings illustrate the immediate effect of placing a functional appliance that postures the mandible forward (*arrows*). The condyle is brought forward and downward on the eminence, which removes the usual functional stresses. The retractor muscles are activated, exerting some force against the maxillary arch. Reduced masseter activity is evident. (Redrawn from Fanghänel J, et al. Changing muscle activity with functional appliances. *Eur J Orthod* 1998;20:468.)

Pancherz,[47] Paulsen,[49] Ruf and Pancherz,[53] Woodside and colleagues,[81] and others.[†]

Unfortunately, definitive incremental changes are hard to measure because of the limitations of two-dimensional radiographic superimpositions. However, Buschang and Santos-Pinto[24] have shown significant change in the position of the temporomandibular fossa with respect to the anterior cranial base. This component of sagittal change might be the most significant. Such change must occur during the growth period. Therefore sagittal change is a combination of incremental increases in condylar growth, a more favorable direction of condylar growth, repositioning and adaptation of the fossa and articular eminence, and some degree of withholding of the maxillary dentoalveolar area by the appliance, depending on factors such as the structural design, duration of wear, and possible use of an extraoral appliance.[119]

[†] References 9, 27, 34, 61, 64, 66, 72, 80, 100, 118.

Melanson and Van Dyken,[117] as well as Johnston,[90] believe that mere unloading of the condyle by forward posturing can be a significant factor. This belief is based on the seminal study conducted some years ago by Melanson and Van Dyken at the University of Michigan, in which unloading the condyles in primates actually stimulated condylar growth. The results can vary, as shown by Graber[120] in an analysis of 58 patients treated with the Fränkel functional regulator. When the enhanced metabolic action is coupled with neuromuscular and appliance stimulation, significant improvement can be attained during a period of active dentofacial growth that is not possible with conventional fixed mechanotherapy alone.[65]

The same analysis can be applied to the Herbst fixed functional appliance, as reintroduced and modified by Pancherz* (see also Graber[64,121]). (For an excellent discussion of this appliance and its modified versions, see Chapter 16 of *Dentofacial Orthopedics with Functional Appliances*, 2nd ed., by Graber and associates,[122] as well as a discussion later in this chapter.) Conversely, in early clinical reports based on minimal material and experience in the appliances, Creekmore and Elkund,[123] Gianelly and colleagues,[112] and Ricketts[124] noted little enhancement of mandibular length. However, long-term studies by Ruf and Pancherz[53,54] showed an additional 1 to 2 mm of growth over the normal mandibular growth pattern for Herbst cases. If left alone, the mandibular length for most Class II, Division 1 malocclusions is deficient. Furthermore, in addition to some enhanced condylar proliferation, the direction of growth changes to a more upward and backward vector for the condyle. Finally, significant glenoid fossa adaptation and positional change occurs, as previously noted.† Elimination of neuromuscular perversions that accentuate the overjet could be a significant factor in the ultimate status. This is too often ignored by "one phase, get in–get out" philosophies. The net effect is that these patients attain the achievable optimum of pattern, assuming that treatment is timed to coincide with the period that has the greatest growth and developmental potential for sagittal correction. Although such appliances can be used in a patient who is past the maximal growth period, more dentoalveolar response and more likelihood of proclination exist in the lower incisors.[22,57,95,126–129] The correct comparisons of treated functional cases are made not with a normal sample but with comparable untreated patients of the same age, pattern, gender, category of malocclusion, and degree of mandibular underdevelopment at the time of initiation of treatment.

Vertical Opening Variations

A number of modifications of the original Andresen appliance has been introduced. Many of the modifications are based on constructions of different vertical opening requirements and different amounts of forward posturing. The question of whether to posture the mandible in "one great leap forward" or in sequential steps has also given rise to different designs. Petrovic and colleagues[86] show clear evidence of greater response with periodic, sequential advancement procedures. Whether the appliance is to be worn only at night or full time is another factor in the design, as is the decision regarding whether the appliances are to be anchored to the maxilla (as with the Fränkel functional regulator and the Bionator) or kept loose with minimal wire appurtenances.[93]

* References 46–48, 53, 54, 107, 108.

† References 24, 32, 34, 43, 47, 49, 51, 54, 61, 64, 66, 70, 72, 80, 81, 120, 125.

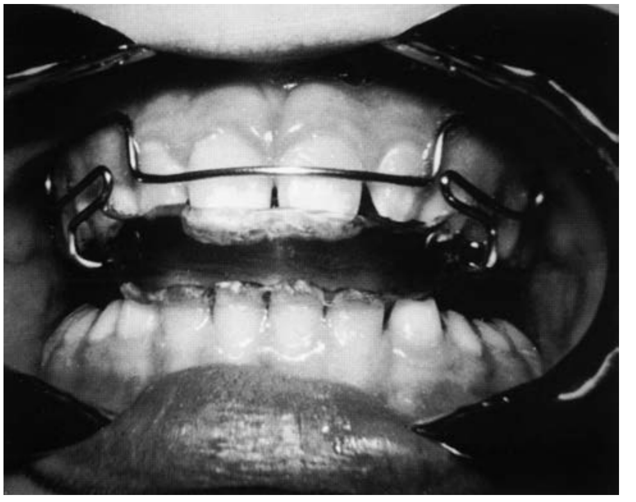

FIGURE 35-10 A number of activator models (e.g., Woodside, Herren, Harvold) require a larger vertical opening, which exceeds the freeway space at postural rest position and elicits the viscoelastic or stretch properties of the associated tissues. This illustration shows an 8-mm opening between the first molars. The lower incisors are capped to provide more stability and to offset the tendency of these teeth to procline.

The current use of skeletal design functional appliances mostly follows the original small opening, incremental sagittal advancement concept, and encourages daytime wear. The frequency of deglutition is increased, and phasic muscle activity is enhanced. Thilander and Filipsson[59] conducted electromyographic studies on daytime wear and found an insignificant increase in muscle forces when no active function occurred. During mandibular activity, however, increased force was exerted, especially by the retracting muscles. Increased deglutitional activity also was associated with the enhanced salivary flow. Sander[55] and Schmuth[96] have also studied the role of functional appliances. Their research indicates that patients with large protrusive construction bites tend to disclude the appliances during the day and at night, reducing the desired effect and jiggling selective teeth.[55] As with normal subjects, however, a broad range of individual activity exists from patient to patient.

Although openings as large as 12 to 14 mm have been successfully treated by clinicians such as Eschler,[130] Schwarz,[131] Woodside and colleagues,[81] and Herren[95] (Fig. 35-10), two factors favor the reduced opening and incremental sagittal correction.

Patient acceptance and compliance are significant factors for all removable activators. Daytime use mitigates against bulky functional appliances that interfere with speech, swallowing, eating, and other activities. The wider opening appliances have a smaller sagittal correction. They have the advantage of depressing the posterior segments if an occlusal cover is used, which allows the mandible to move upward and forward if the patient has an open bite tendency and reduced interocclusal clearance. This result is desirable in open bite problems but not in deep bite malocclusions. Histologic evidence also supports periodic incremental advancement because of the periodically enhanced condylar and fossa response with each adjustment.*

FIGURE 35-11 **A, B,** Class II, Division 1 malocclusion in an 11-year-old boy with a retained infantile swallowing habit. Initial success with the modified Bionator appliance was limited because of the lack of significant growth and patient cooperation. **C, D,** The patient became motivated after 2 years of intermittent wear, and the results seen were achieved. Pubertal growth acceleration obviously helped. (**A** and **B,** Courtesy Erich Fleischer.)

With a single 6- to 7-mm advancement, the condylar and fossa growth stimulus is shorter in duration, daytime wear becomes more difficult, and adverse labial proclination of mandibular incisors may be greater.[10,29,93] Again, for a fuller discussion of these differences and for design prescriptions for specific malocclusion characteristics, see *Dentofacial Orthopedics with Functional Appliances*, 2nd ed., by Graber and associates[10] or *Removable Orthodontic Appliances* by Graber and Neumann.[135]

MECHANISMS OF CLASS II CORRECTION WITH FUNCTIONAL ORTHOPEDICS

The efficacy of functional appliances no longer needs to be proved, unless one is ignoring many thousands of case reports. Dramatic facial and skeletal changes seldom seen with conventional fixed appliances are not only possible but fairly routine (Figs. 35-11 to 35-14). However, the

precise reasons that these changes occur are more obscure and vary from patient to patient, as orthopedic surgeons have observed with their growth guidance procedures in long bones. Unfortunately, the overly simplistic attribution of the change to condylar growth has clouded the picture and is similar to looking at the road as a horse with blinders does. Orthodontic practitioners are dealing with a cybernetic process.[10] The morphogenetic pattern, growth timing and direction of component parts, neuromuscular patterns, functional displacement, dentoalveolar compensation, fossa displacement and remodeling, type of appliance, and patient compliance are the most important variables but not the only ones.[136] Factors such as tissue response and rate of fibroblast turnover are discussed in the superb chapters by Thilander, Hatch, and Sun (see Chapter 3) and Roberts and Huja (see Chapter 4), all recognized as outstanding authorities. No longer can orthodontists simply estimate the amount of condylar change needed to provide the correction. The change is a multifactorial reaction that is too diverse to determine by measuring only one component.

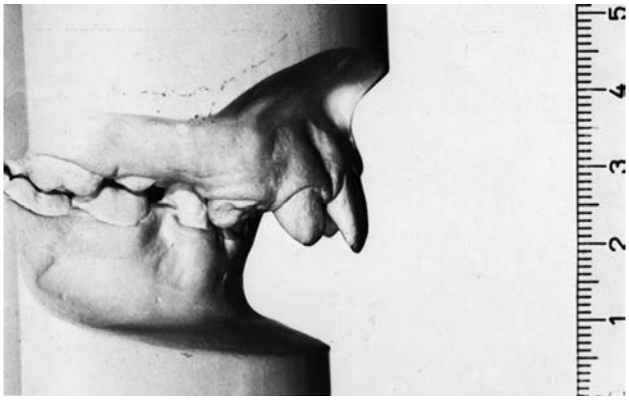

FIGURE 35-13 Initial study model depicts a boy, 9 years and 7 months old, who has a severe Class II, Division 1 malocclusion. (Courtesy Erich Fleischer.)

As research continues, the fact that nighttime wearing of appliances largely serves as a transient posturing splint is becoming increasingly clear. Telemetric studies, notably those of Sander,[55] show that function is not enhanced by wearing appliances only during sleep. Nevertheless, the forward posturing of the condyle does enhance metabolic action in the TMJ, as shown by Ward and colleagues.[80] Increased anabolic and catabolic exchange, not merely forward positioning, may account for enhanced growth of the condyle and posterior fossa wall proliferation.[4,32,65]

Class II Correction: A Likely Scenario

The amount of sagittal correction is 6 to 7 mm. The following anticipated growth and adaptational increments (assuming a favorable direction) are typical:

1. Condylar growth amount during treatment: 1 to 3 mm—The mandible outgrows the maxilla by 1 to 5 mm, with higher increments predominantly occurring in males.
2. Fossa displacement, growth, and adaptation—Recent research shows this growth to be 3 to 5 mm, with a dominant vertical vector[24] and a positive correlation with the pubertal growth spurt.*
3. Functional retrusion (see Fig. 35-52): This retrusion does not always occur in Class II malocclusions and can vary from 0.5 to 1.5 mm. Isberg and Isaacson,[139] as well as Kantomaa and Pirttiniemi,[34] show strikingly reduced TMJ metabolism in primates with functionally retruded condyles. Research conducted by Graber,[65] as well as that of McNamara[41] and Boman and Blume (see Graber[118]), confirms these observations. The controversy results from not knowing the technique for a correct determination (see Fig. 35-52).[118]
4. More favorable growth direction shown by trabecular orientation: Trabecular orientation changes and can account for between 0.5 and 1.5 mm.
5. Withholding of downward and forward maxillary growth[117]: Maxillary growth accounts for between 1 and 1.5 mm of the change.
6. Differential upward and forward eruption of lower buccal segments: Accounts for between 1.5 and 2.5 mm of Class II correction, depending on the depth of overbite.
7. Headgear effect[61,137]: Is between 0.0 and 0.5 mm

* References 24, 53, 54, 81, 88, 137, 138.

Obviously, no reliable method exists for predicting the contribution of each component for the individual patient. Not all functional assessments and physiologic phenomena are reducible to two-dimensional cephalometric tracings with angles and figures or to articulators. Orthodontic practitioners are as precise in their efforts as the best orthopedic surgeons, who would not think of using a cephalometric analysis and an articulator for any joint they treat. The seven components previously listed provide a potential for the needed sagittal change. However, skeletal malocclusions are three dimensional. Weinstein once said, "We are a generation of profiles!" This statement was based on the orthodontic preoccupation with only the lateral cephalogram and an unwillingness to use anteroposterior views to determine equally important transverse characteristics.[26,140] Today's three-dimensional diagnostic procedures provide more accurate information. Early functional appliances incorporated expansion screws or jackscrews to cope with the narrow maxillary arch of most Class II, Division 1 malocclusions (the third dimension), particularly when the narrowed maxillary arch is caused by abnormal perioral muscle function. Whether by slow or rapid palatal expansion or by fixed or removable appliances, modern orthodontics recognizes the need to produce a three-dimensional correction. In no way is this an excuse to expand teeth off basal bone, however. Axel Lundström's epic paper[116] on the apical base in 1923 is still valid. Some recognition of the need for a three-dimensional therapeutic attack on the problem must be incorporated in the functional appliance, or transverse correction can be done before the placement of functional appliances. Nature provides the answer to questions about the amount of expansion that can be achieved when perverted perioral muscle activity is eliminated. In many cases, wearing a functional appliance is likely to eliminate abnormal and deforming neuromuscular activity without active expansion adjustments. Too much rapid palatal expansion is being done without checking the inclination of the buccal segment teeth in their relation to basal structures before and after treatment. Herein lies a major precipitator of posttreatment relapse.

Bionator

The bulkiness of the activator and its limitation to nighttime wear have deterred clinicians interested in achieving a mixed dentition correction of sagittal discrepancies and eliminating their attendant neuromuscular perversions. The Bionator, as developed by Balters,[141] is the prototype of a less bulky appliance (Fig. 35-15). Its lower portion is narrow, and its upper portion has only the labial wire and the buccal screening wire extension, plus a stabilizing cross-palatal bar that actually can be adjusted for bilateral expansion, if needed. The palate is free for proprioceptive contact by the tongue. The appliance may be worn all the time except for meals, which is critical for maximum response.

According to Balters,[141] the equilibrium between the tongue and the circumoral buccinator mechanism is responsible for the shape of the arches and intercuspation. This hypothesis supports the early form and function concepts of van der Klaauw as cited by Graber[118] and the later functional matrix hypothesis of Moss.[142] The purpose of the Bionator is to establish good muscle coordination and to eliminate potentially deforming growth restrictions, while unloading the condyle through a protrusive mandibular position. The upper and lower incisors are usually in contact during wear. Balters attributed a major role to normal or abnormal tongue function and posture in deglutitional

maturation; Ballard[19] later elaborated on this. Research has shown that the tongue exerts three to four times as much force on the dentition as the circumoral muscles. If the morphogenetic pattern, resting force and viscoelastic properties, tissue rigidity, atmospheric pressure, and intercuspation are included, then obviously the dentition and its surrounding structures are in a multisystem balance.[64,88]

The standard Bionator (Fig. 35-16) consists of a lower horseshoe-shaped acrylic lingual flange that extends from the distal of the last erupted molar around to the corresponding point on the other side. For the upper arch, the appliance has only posterior acrylic lingual extensions that cover the molar and premolar regions. The upper and lower parts are interocclusally joined in the correct construction bite (protrusive) relationship. The anterior portion is kept free so as not to interfere with tongue posture and function. No acrylic capping of the lower incisors is done, although some clinicians choose this variance to attempt to control proclination of the lower incisors.

The function and posture of the cheeks and lips are guided by two wire configurations: the palatal bar and the labial bow with buccal extensions (Fig. 35-17). The palatal bar, which is made of 1.2-mm hard stainless steel, lies 1 mm away from the palatal mucosa and runs distally to a line drawn between the distal surfaces of the maxillary first molars. The palatal bar has a Coffin spring–like configuration. The bar stabilizes and also anteriorly orients the tongue to contact the palate. The labial and buccal bow is comprised of 0.9-mm stainless steel (Fig. 35-18) and does not actually contact the incisors or gingival tissue. The position of the wire produces a negative pressure, with the wire supporting lip closure. If necessary, the wire can be adjusted during the course of treatment, after the arch has been widened, to close the spaces and to retract the maxillary incisors. Selective eruption can be achieved during treatment by trimming the acrylic.

Of all the functional appliances, the Bionator and the Clark twin block (see Chapter 16) are the most popular. They are less subject to distortion than the efficient Bimler appliance,[21]

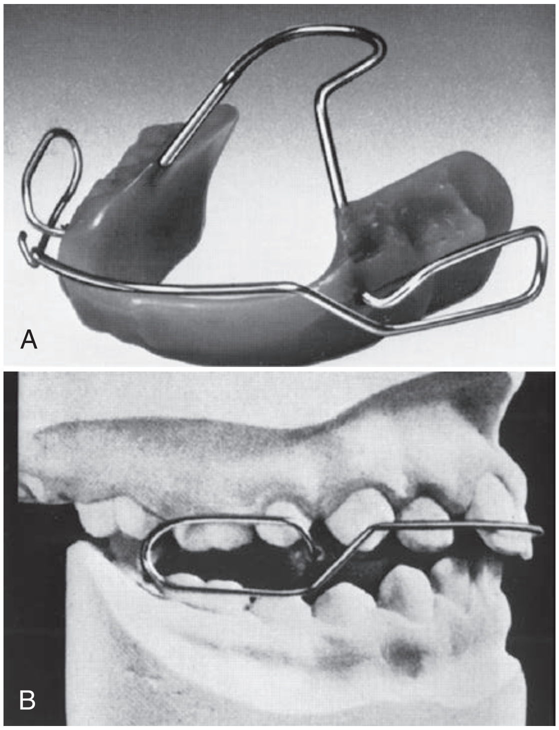

FIGURE 35-15 Bionator modified from Balters' original design. **A,** Note the use of a heavy transpalatal Coffin spring instead of acrylic construction. The large gauge labial and buccal wire is not a tooth-moving appurtenance but a screening wire. To enhance eruption, the acrylic can be removed in the interdental area. **B,** The construction bite is usually taken in an end-to-end incisal relationship, allowing enough room for passage of interocclusal wires. The appliance is an effective adjunct in many temporomandibular dysfunction problems.

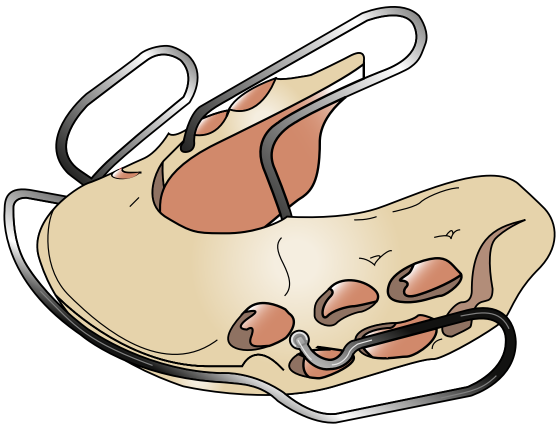

FIGURE 35-16 Basic Bionator appliance. Open palate enhances tongue proprioception and discourages abnormal growth. Heavy buccal and labial wires serve to screen off muscle forces.

which has more wire framework that can be distorted. The successful use of the Bionator in TMJ disturbances has been well documented[10] (see Figs. 35-11 to 35-14). For a fuller discussion of the Bionator philosophy and appliance variations for Class II, Class III, and open bite malocclusions, see Chapter 11 in *Dentofacial Orthopedics with Functional Appliances*, 2nd ed., by Graber and associates.[10]

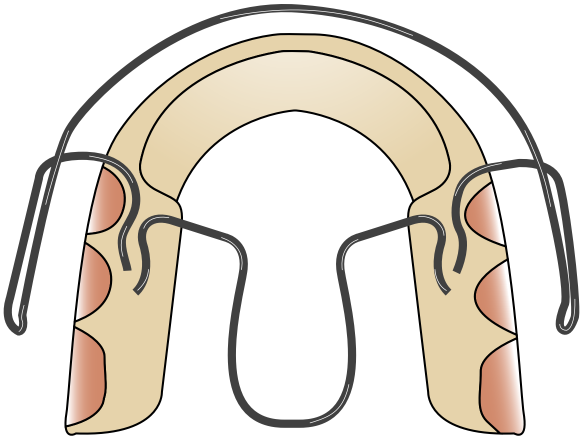

FIGURE 35-17 Palatal Coffin wire of 1.2-mm hard stainless steel is placed slightly away from the palatal tissue but did not interfere with proprioceptive tongue contact.

CONSTRUCTION BITE

Probably the most important aspect of fabrication is the assessment of optimal horizontal and vertical displacement before construction of the appliance. As previously noted, no cookbook exists for determining the relationships. Much depends on the specific appliance being used, the case selection, the dentofacial morphologic form and structure, the probable growth pattern and projected increments and direction, and the need for other therapeutic assists (e.g., fixed appliances, extraoral force, extractions).

The Bionator, originally developed by Balters,[10,141] is one of the most commonly used removable functional appliances today because of its simplicity, sturdiness, ease of construction, ability to be modified, patient acceptance, and use in temporomandibular disorders (TMDs); therefore this section is devoted to a discussion of the construction bite for that type of appliance[†] (Fig. 35-19). The technique can be adapted to other designs. A complete diagnostic discipline is essential before selecting a functional appliance for a patient.[134] As Rakosi and colleagues[52,148] emphasize, completing a three-dimensional cephalometric radiographic study and functional analysis for the mixed dentition, use of a functional appliance is no less important than it is for a full, fixed mechanotherapy problem. Facial pattern is important; growth amounts and growth direction are equally important (i.e., growth forecasting, such as developed by the late Dr. Ricketts,[124] and computerized digital projection to ensure that the patient is aware of the problem and the projected result [see Chapters 8,9 and 11]). Only if the patient satisfies the demanding functional appliance criteria and only if patient compliance is likely to be good should such an appliance be used. The operator should always keep in mind that a functional appliance is primarily an interceptive device, seldom capable of achieving full correction and complete dental detailing. The appliance is a first-phase attack on the total problem. The argument of one-phase versus two-phase treatment will not be settled here. Distinguished proponents ascribe to both approaches. However, with proper case selection, proper wear, and proper patient compliance, the author's firm conviction, based on thousands of treated cases, good and bad, is that

[†] References 26, 38, 57, 141, 143–147.

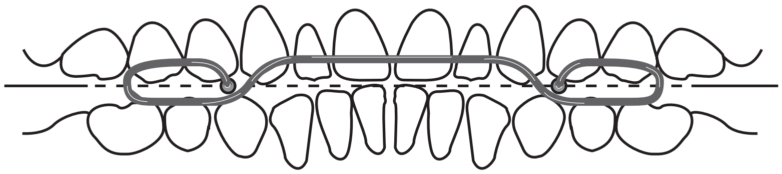

FIGURE 35-18 End-to-end construction bite and configuration of 0.9-mm stainless steel labial and buccal screening wire extends to the distal of the second deciduous molars. The wire has no contact with teeth. Fränkel added acrylic to the posterior aspect of the screening wire to make more effective buccal shields.

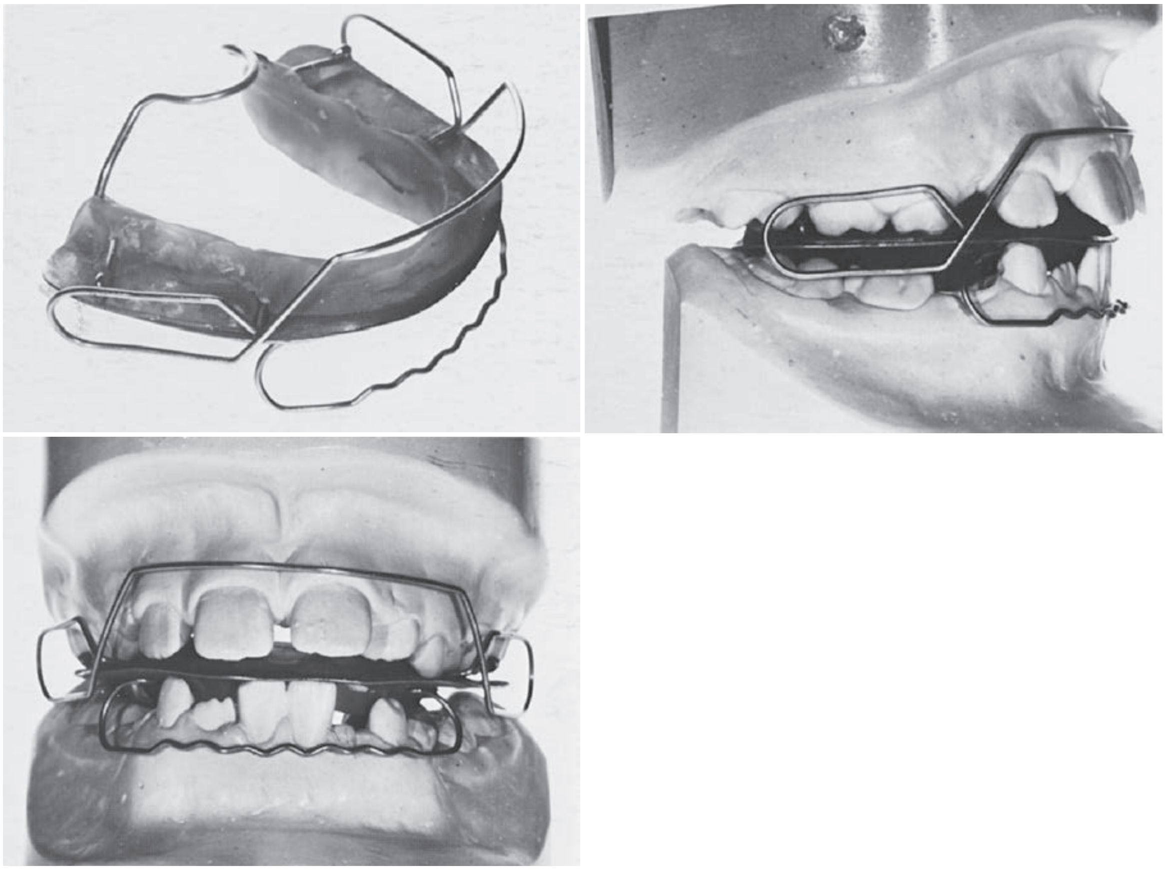

FIGURE 35-19 Fleischer Bio-Bionator is placed on working models in construction bite relationship. A lower screening wire has been added to prevent a lower lip trap and to allow the tongue to procline lingually malposed lower incisors. This arrangement is similar to the lip shields of the Fränkel function regulator.

skeletal and neuromuscular changes can be attained with functional appliances in first-phase therapy that cannot be duplicated with single-phase treatment. No patents or commercial ties exist to influence this observation.

In this short survey chapter, the concern is for Class II malocclusion, the most frequent challenge and the one with the greatest potential for therapeutic success. For a fuller discussion of techniques and appliances and for Class III and open bite problems, see Chapter 13 in *Dentofacial Orthopedics with Functional Appliances*, 2nd ed., by Graber and associates.[10]

Anterior Mandibular Posturing

In the past, if the sagittal discrepancy was not too great, the forward posturing of the mandible was such that the upper and lower incisors contacted in an end-to-end relationship (see Fig. 35-19). However, the patient's adjustment to the mandibular protrusion is easier if the advancement is made in 3-mm increments. Evidence exists that this method is more successful, despite the added work. Usually adjustment can be done with a 12- to 16-week interval in the sequential advancement. Procumbency of the lower incisors is less likely with sequential advancement, and patient compliance is better. As Petrovic and colleagues[10,86,133] have shown, tissue reaction is also more favorable, and Rabie and colleagues[75,149,150] conclusively demonstrated this on treated cases. Case selection will help determine the decision. Lingually inclined lower incisors, as with a lower lip trap problem, may respond better with a 5- to 6-mm advancement. As a general rule, the anterior advancement should be 3 mm or more from the most posterior condylar position in the fossa. Paulsen concurs.[73]

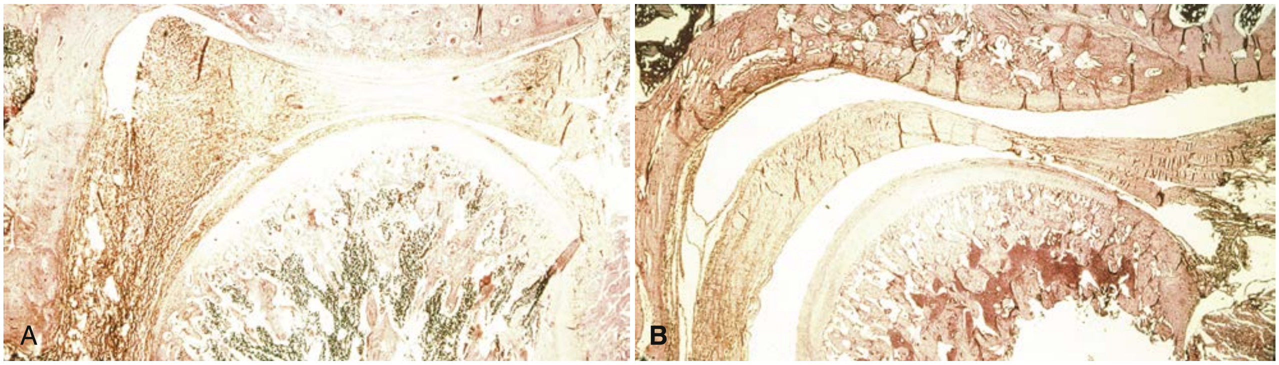

FIGURE 35-20 Cryogenic primate specimens. **A,** Control shows normal morphologic and positional relationships of the condyle, disk, eminence, and retrodiskal attachment. **B,** Significant change is visible in only 6 weeks of wear of a retrusive splint. Dramatic diminution of disk and retrodiskal tissue has occurred. Clearly, forced retrusion has the potential to damage retrodiskal tissue and reduce metabolism, that is, growth and development. (**A,** Courtesy Isberg; from Graber TM. The unique nature of the temporomandibular joint metabolism; the clinical implications. In: Rabie AM, Urist MR, eds. *Bone Formation and Repair.* Amsterdam: Elsevier; 1997:143–157.)

A good technique is to have the patient move the mandible forward as far as possible and then drop back 3 to 4 mm. If a functional shift to one side or the other occurs because of a narrow maxillary arch and convenience swing to one side, then lining up the maxillary and mandibular midlines with the construction bite can eliminate this shift. Rakosi, with his tremendous experience with functional and fixed appliances through the years, has carefully described the construction bite technique, with detailed illustrations and descriptions, to ensure the best possible results, in his chapter in *Dentofacial Orthopedics with Functional Appliances*, 2nd ed., by Graber and associates.[10]

Because the maxillary incisors are initially and frequently tipped labially and are often spaced, using an active plate for a short period or limited fixed appliances to retract and rotate maxillary incisors before placing the functional appliance may be preferable to reduce the magnitude of initial mandibular protraction and to enhance patient compliance. What should be made clear is that modern orthodontics is not an either/or therapy. Mixing fixed and functional appliances is easy and often desirable with modern bonding techniques, and functional appliances are not the "easy and cheap" alternative to classic full-mouth fixed hardware. Bonding anterior brackets and placing molar bands on the maxillary arch is a ½-hour time investment with major returns in better functional appliance retention and control of maxillary incisors, rather than resorting merely to tipping them lingually with the labial bow of the removable appliance.

Despite the controversy that still exists over the idea of the existence of posterior condylar displacement in some Class II deep bite malocclusions, seminal research by Dayton Blume and Vernon Boman demonstrates this phenomenon in selected cases. Some patients with TMJ sequelae are relieved only by forward posturing of the mandible (see Fig. 35-52, which shows research findings of Blume and Boman). This possibility should be checked with the diagnostic functional analysis. Tomographic radiographs and scintigraphy, such as that used by Paulsen,[108] Ruf and Pancherz,[53,54] and Pancherz,[47] show this positional status, taking a postural resting position and maximal occlusion lateral views. However, the astute clinician can see the same by observation and palpation. Recent research by Isberg and Isaacson,[139] Kantomaa and Pirttiniemi,[34] and Pirttiniemi and colleagues,[51] as well as the author of this text,[65] shows that retrusive forces on the condyle in the TMJ can impinge on the retrodiskal pad, reducing the metabolic exchange and the potential nutrient elements for TMJ and condylar growth (Fig. 35-20). Definite reduction in the collagen and proteoglycan content of the condyle shows the effect of reduced anabolic and greater catabolic activity.[51] Condylar advancement enhances metabolic activity.[65] As previously noted, the vertical opening is within the limits of the freeway space. Elevator and protractor muscles are activated, and a greater hyoid group compensation or retracting force occurs, which is distributed against the maxillary arch. This action only slightly inhibits maxillary downward and forward relocation, as studies by McNamara and colleagues demonstrate[39–42,134,151] (see also Chapter 16). Biting into the appliance and swallowing enhance the neuromuscular and osseous adaptation (both fossa and condyle) to the new posture.

Hamilton Expansion Activator

The Hamilton expansion activator is a variant of the traditional monobloc. David Hamilton was often called "the thinking man's orthodontist." The first generation of such appliances was removable and yet achieved stable correction. Current bonded appliances reduce the need for patient compliance and have a high level of success (Figs. 35-21 to 35-24). The simultaneous use of two palatal jackscrews permits differential expansion control, which is highly desirable. Too often, a single palatal expansion screw does not provide the varying need of expansion in anterior and posterior maxillary buccal segments. The Hamilton philosophy and appliances are described in detail in *Dentofacial Orthopedics with Functional* Appliances, 2nd ed., by Graber and associates.[10] Hamilton[113] points out, as do Graber,[122] Gianelly and associates,[112] and others, that most patients with these functional appliances need concurrent partial fixed appliances, transverse correction, or a second period of therapy to complete the required detailing. This fact is vital to orthodontists' understanding of the multiple challenges of correcting a large variety of malocclusions, depending on a multiplicity of causative factors, sexual dimorphism, and when the orthodontist first sees the patient.

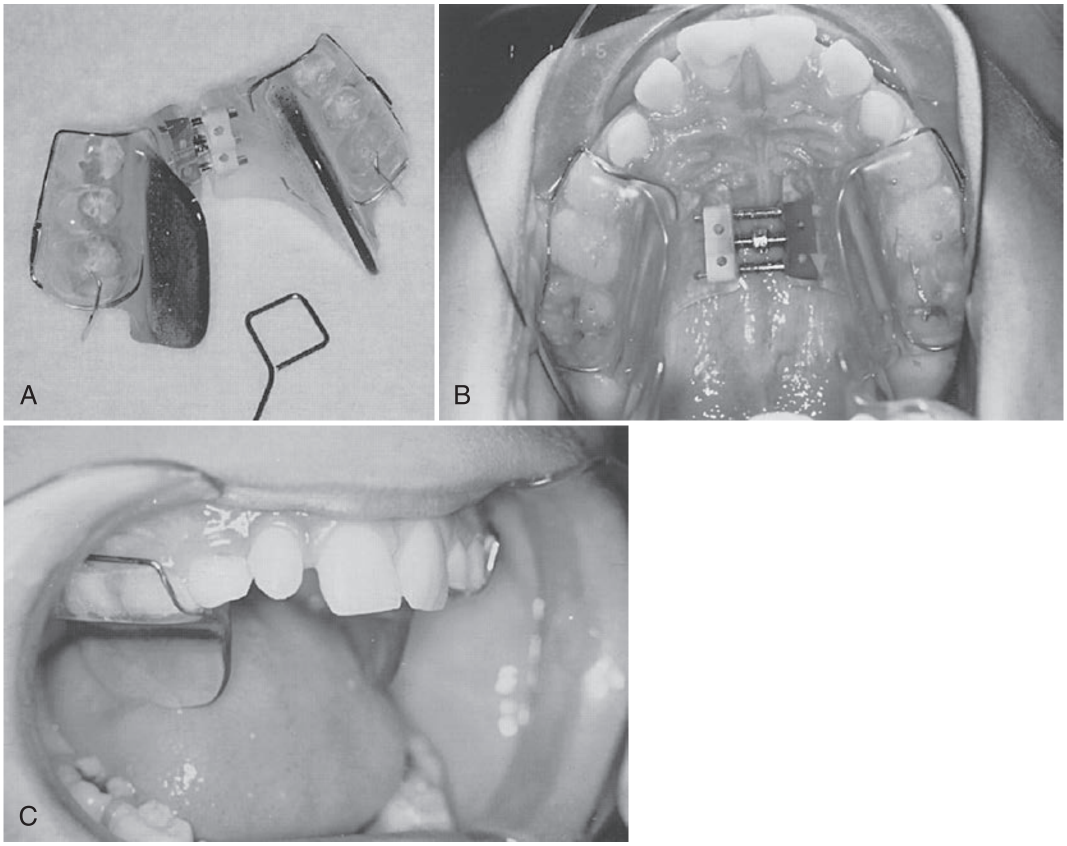

FIGURE 35-21 Early version of Hamilton bonded activator (from mandibular aspect). **A,** The palatal jackscrew is partly open. (Later versions have two palatal expansion screws for more effective localized expansion.) The dark lingual flanges extend toward the viewer. Impressions of the lower posterior teeth are embedded in the occlusal acrylic in the forward postural relationship. **B,** The Hamilton appliance is bonded to the maxillary arch; again, the lingual flanges vertically extend toward the viewer. **C,** Lateral view shows the lingual flanges of the bonded appliance. These lingual flanges guide the mandible into its correct anterior construction bite via proprioception.

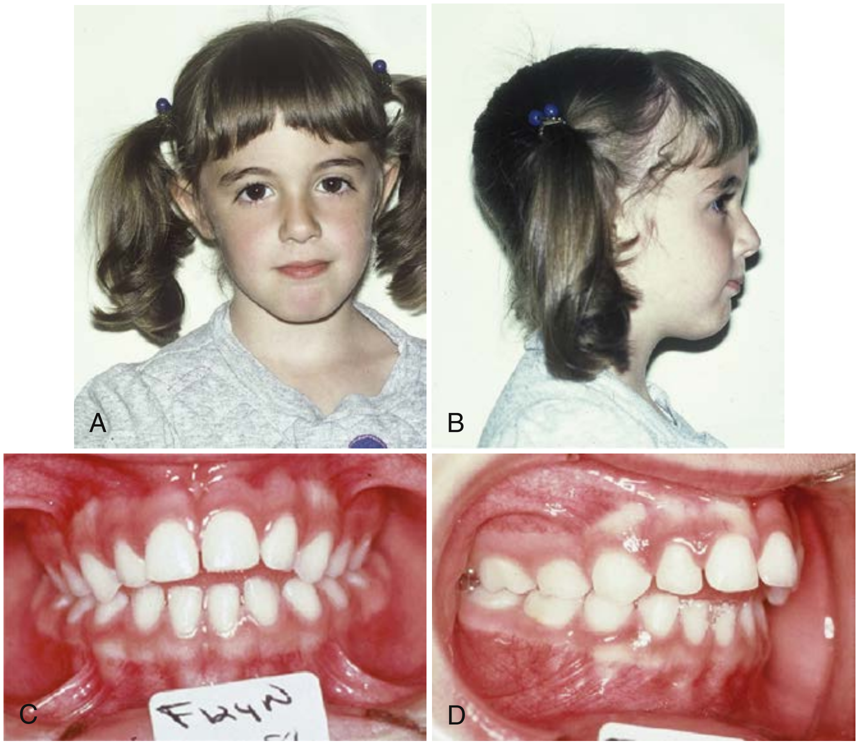

FIGURE 35-22 **A, B,** Initial facial and profile views show a female patient with a Class II, Division 1 malocclusion with anterior open bite, no interocclusal clearance, excessive overjet, a constricted maxilla, and narrow and retruded mandibular arch. **C, D,** All of these characteristics cause compensatory and deforming perioral neuromuscular activity.

FIGURE 35-22, cont'd **E–H,** Posttreatment frontal and lateral facial and intraoral views show significant facial sagittal jaw improvement. **I,** A twin-screw palatal expansion appliance provides selective buccal segment expansion. This appliance was worn for 8 weeks and was followed by a Hamilton bonded activator (see Figs. 35-21 and 35-23). **J–M,** Intraoral views of the patient at age 11 years and 6 months indicate that minimum fixed appliance treatment will be required to finish tooth minor alignment and to establish a normal overbite. This is a classic example of a proper two-stage orthopedic appliance management for the twenty-first century.

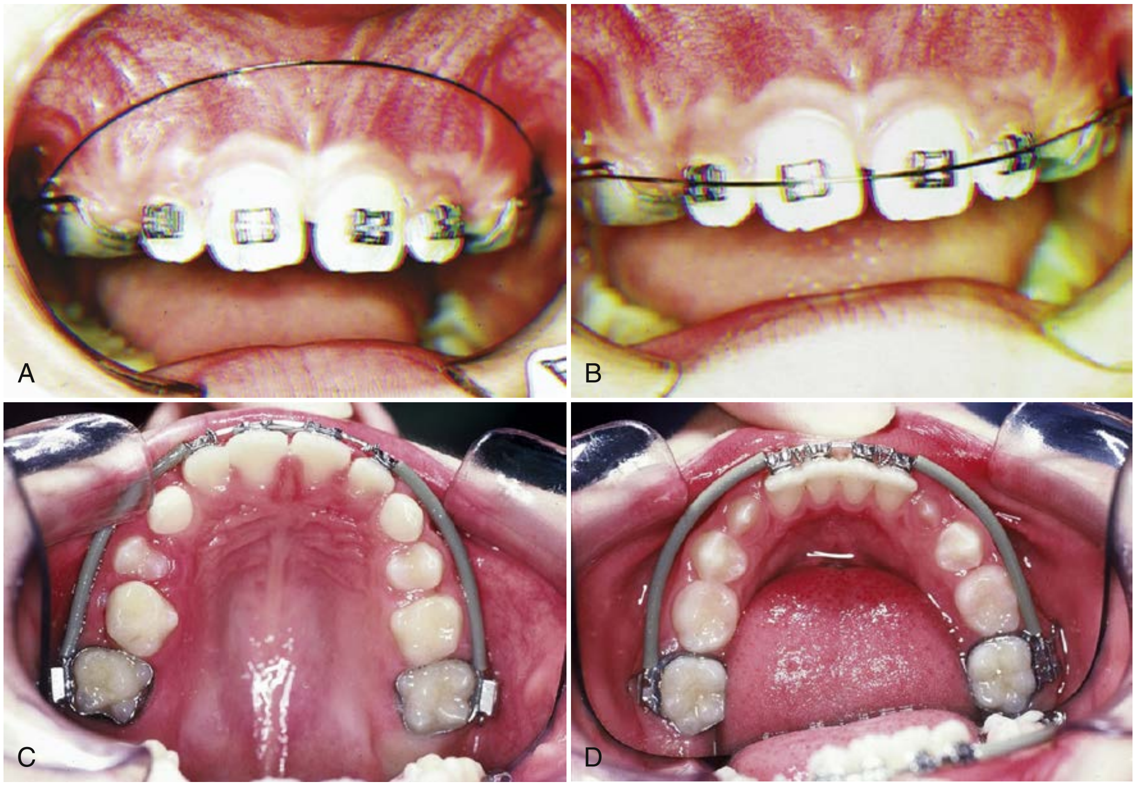

FIGURE 35-23 A, B, Molars and incisors are usually bonded, and light arch wire force quickly aligns malposed teeth and corrects any vertical discrepancies. C, D, Buccal tubes have been added on first molars to align the incisors with the bonded brackets.

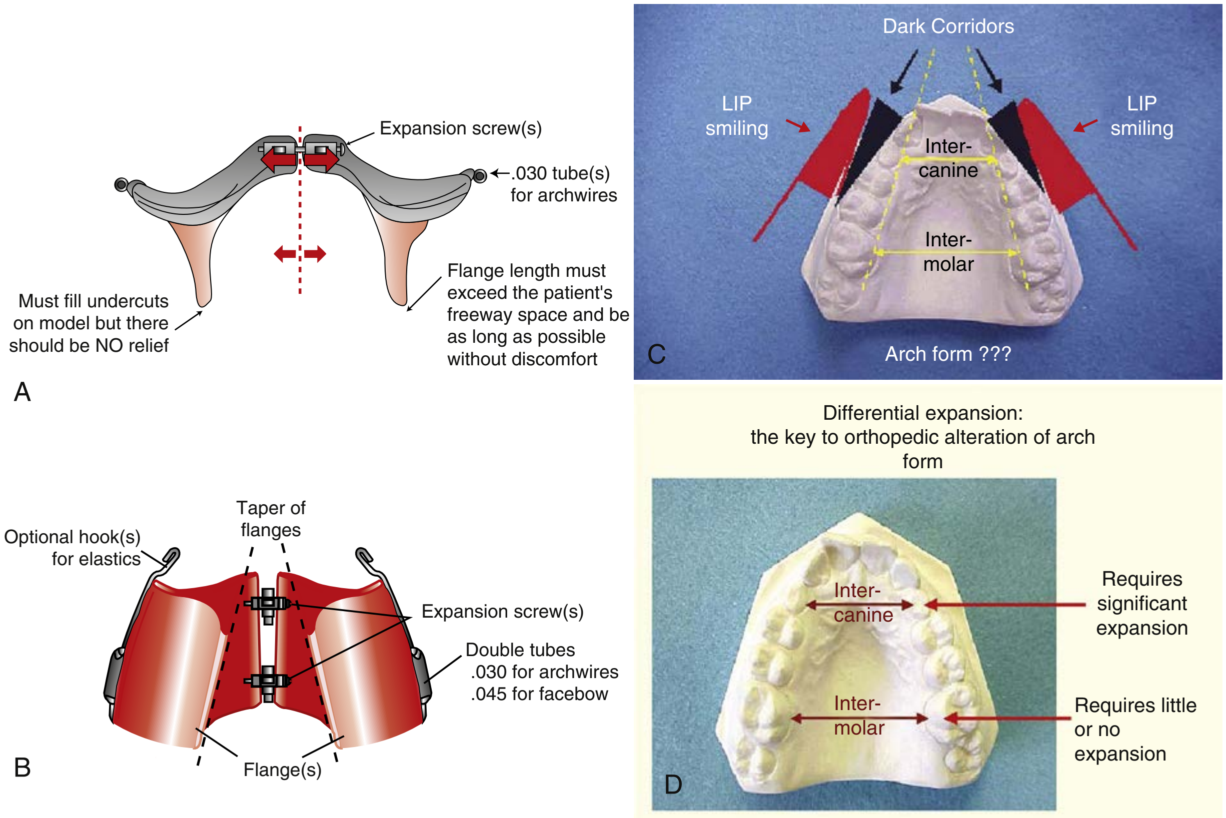

FIGURE 35-24 Hamilton dual arch expansion appliance; it can be removable or bonded to the maxillary arch. A, Note the length of the lingual mandibular flanges. One or two expansion screws can be used. Buccal tubes may be added for headgear or arch wire use. B, Drawing shows palatal view with lingual flanges extending toward the viewer. Note the double buccal tubes and twin expansion screws. Lingual extensions guide the mandible forward by proprioceptive contact with mandibular lingual mucosa. A maxillary labial arch may be added, as well as an acrylic cap for the lower incisors. This expansion/functional appliance is similar to the Balters' Bionator. The maxillary expansion screw void can be filled with acrylic after the desired expansion is achieved. C, Original maxillary narrow arch form is demonstrated with the canine dark corridors highlighted. D, Final arch form is natural.

Fränkel Appliance

Rolf Fränkel[93] probably did more to interest American orthodontists in functional appliances than any single clinician. His outstanding long-term three-dimensional results, the spectacular improvements that have stood the test of time and were done with the highest integrity, showed what can be done with carefully selected patients, properly designed appliances, an exercise routine (oral gymnastics), and maximal patient compliance. His impeccably researched clinical results are still the gold standard for all functional appliances, fixed and removable[106] (Figs. 35-25 and 35-26). Fränkel's insistence on full-time wear and on making the appliance (the functional regulator) an exercise device with oral gymnastics during the day demonstrates the significant role of function, per se. His requirement for anchoring the appliance at the maxillary first molar–second deciduous molar embrasure emphasizes the need for this or a similar design to maximize withholding the horizontal growth of the maxillary arch. The use of buccal shields to screen off potentially narrowing muscle forces and of lip pads in the lower labial vestibule to prevent abnormal perioral muscle function and lingualizing forces makes eminently good sense (see Fig. 35-25). Enlow and colleagues,[138] Moffett,[152] Graber,[30,121,153] and others[88,134,141] validate the fact that periosteal pull (i.e., viscoelastic stretch), as created by the Fränkel buccal shields, has the potential to stimulate bone growth (i.e., expansion of the transverse dimension) and is so well illustrated in cases treated with the functional regulator (see Fig. 35-30). Fränkel's step-by-step advancement, so easily achieved by the unique appliance design, has proved to provide the best and most stable results, and these results are applicable to other functional appliances.

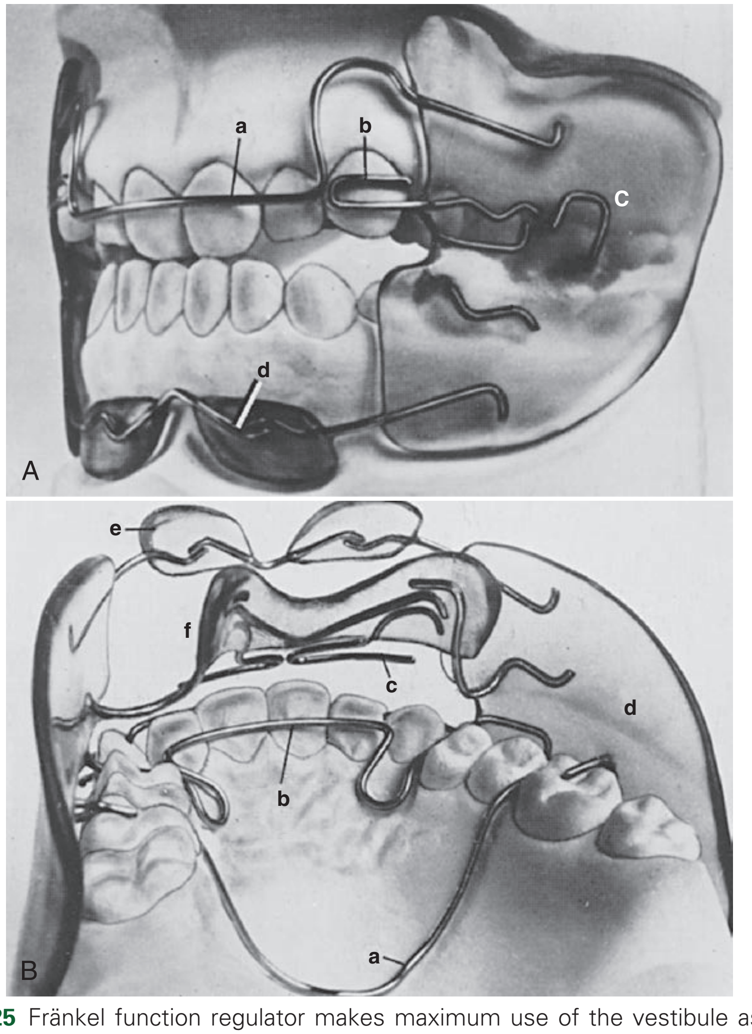

FIGURE 35-25 Fränkel function regulator makes maximum use of the vestibule as an area of operation, screening away abnormal lip and cheek pressures. **A,** Labial and buccal views. The wire assembly anchors the appliance on the maxillary arch at the mesial first molar embrasure. (*a*) Labial bow; (*b*) canine loop; (*c*) buccal shields; (*d*) lip pads (pelots). **B,** No interocclusal acrylic is used, and no interference with eruption of mandibular teeth occurs. A lingual acrylic pad or plate is the only contact with the lower arch, maintaining it in a protrusive relationship in the trough provided by the lingual acrylic pad and the lip pads. Sagittal advancement is usually accomplished in two steps of 3 mm each, with a simple advancement of the posturing trough. Less than full-time wear (except at mealtimes) diminishes the effectiveness of the appliance. (*a*) Cross-palatal stabilizing wire on the maxillary arch; (*b*) maxillary looped lingual arch or protrusion bow; (*c*) lower lingual wires; (*d*) buccal shield; (*e*) lip pads; (*f*) lower lingual pad or plate.

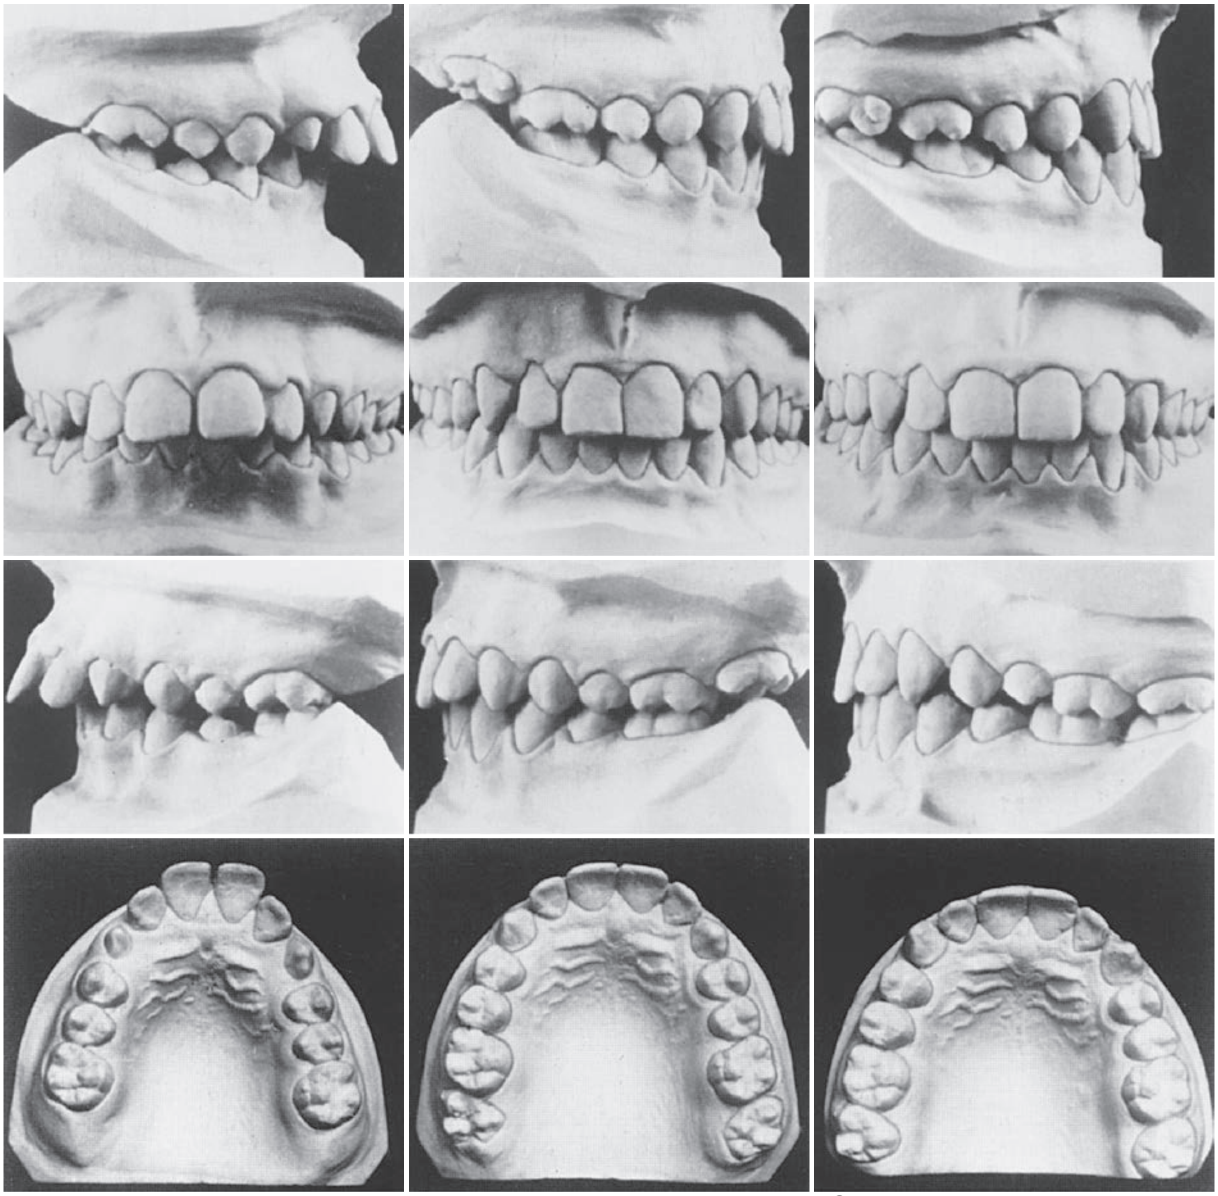

A B C

Note the autonomous arch expansion. (Courtesy Rolf Fränkel.)

Unlike the activator, however, which can be modified in many ways and still produce an acceptable result, the Fränkel appliance demands a rigid discipline of design, fit, and use, as well as proper treatment timing and case selection. Patient daytime wear is a motivational challenge for the orthodontist and has been an Achilles' heel in that too many clinicians have not been able to replicate Fränkel's spectacular results.[154,155] This failure is partly because of deficiencies in appliance construction and a lack of experience on the part of the clinician; primarily, however, failure is the result of the lack of sufficient compliance on the part of too many patients (i.e., full-time wear). Of all the appliances, the functional regulator is the one that mostly depends on function, proper fabrication, sufficient length of wear, and cooperation. Some of its features have been incorporated into modifications of fixed functional appliances and activators with beneficial results. However, the popularity of the pure functional regulator has waned, not because of questions about the validity of the philosophy, but because of pragmatic use, more demanding laboratory procedures, and compliance demands. (For a full discussion of this approach, see *Dentofacial Orthopedics with Functional Appliances*, 2nd ed., by Graber and associates.[10])

Double Plates

Martin Schwarz[131,156] recognized early that a monobloc was bulky and difficult to wear. Therefore he introduced the double plate functional approach. Upper and lower removable appliances were held in place by wire appurtenances. Opposing occlusal guiding ramps postured the mandible forward as the jaws were closed. Daytime wear and patient compliance were significantly improved. The Schwarz plate was the historical precursor of William Clark's twin block appliance, which has now become the most widely used functional appliance in the world.[126]

Clark Twin Block Appliance

The Clark twin block appliance is a modern, highly successful functional appliance approach modeled after the Schwarz double plate.[37,44,126,157] William Clark has developed this combination of upper and lower appliances to a high degree of efficiency. His book describes all the technical features in detail and shows many examples of successfully treated cases of all categories.[126] Occlusal guide planes, selective grinding, guided eruption, and a midpalatal jackscrew allow for three-dimensional control.

Using wire appurtenances and a jackscrew with the upper and lower inclined planes, the clinician has three-dimensional control (Figs. 35-27 to 35-35). Ease of full-time wear and selective guidance of eruption are attractive features. Similar to Hamilton, McNamara, and others, Clark recognizes the need to restore normal maxillary width and accomplishes this in his active arch development stage of treatment. Some clinicians modify the Clark maxillary component with two expansion screws for differential expansion, similar to Hamilton (see Chapter 16). As with other functional appliances, this modification may also be made ahead of time for transverse deficiencies. The twin block appliances can also be bonded, as with the Hamilton expansion activator. If desired, rare earth magnets in an attraction mode can be incorporated into the guide planes, as Moss[142] has done with his functional appliance design. The magnets stimulate repetitive functional activity and TMJ metabolism and optimize response, similar to the Vardimon magnetic appliance discussed later in this chapter.[60,158,159]

The orthopedic phase with the twin blocks recognizes the need for eruption of lower molars to eliminate excessive overbite and deficient vertical dimension. Because the mandibular molars are not covered, they are free to erupt in an upward and forward vector, aiding in the Class II sagittal correction (see Fig. 35-29). Of course, in open bite cases, the molars are covered to prevent eruption and to close down the bite.

Functional appliances resort to reciprocal Class II dental correction in a noninvasive manner, avoiding the potential iatrogenic sequelae of periodontal involvement, gingival inflammation, crestal bone loss, and root resorption or dilaceration. This reciprocal upper and lower dental adjustment must be

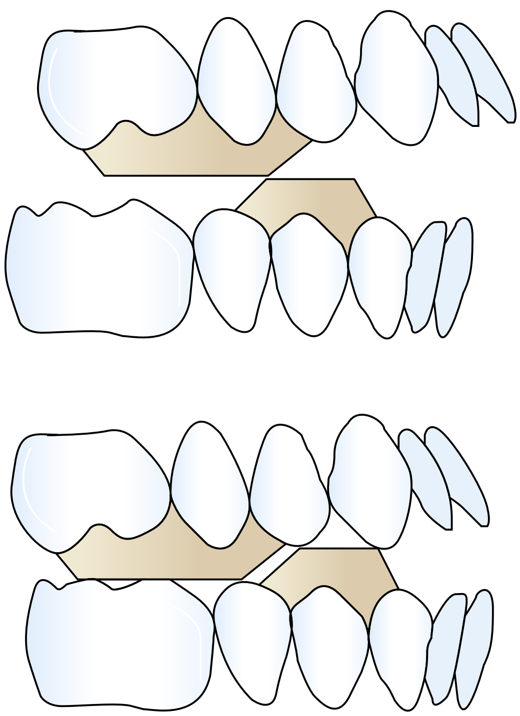

FIGURE 35-27 Clark twin blocks are modified double plates with occlusal inclined planes. They were introduced by Martin Schwarz to reduce the bulkiness of the traditional monobloc. The twin blocks meet at approximately 70 degrees, with the lower inclined plane mesial in a Class II correction.

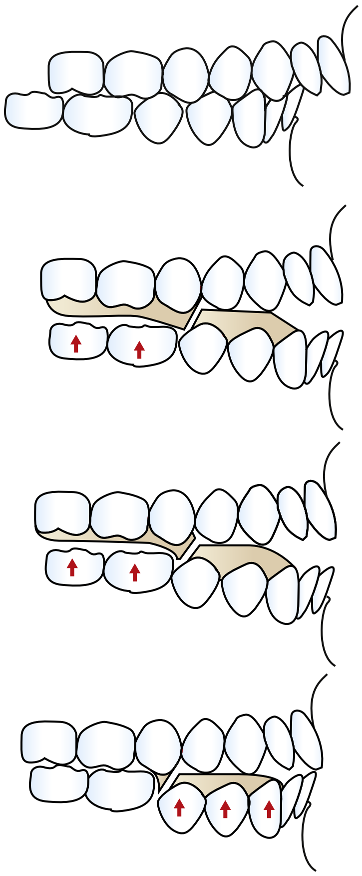

FIGURE 35-28 Twin block occlusal relief used to expedite eruption of lower molars and reduce overbite.

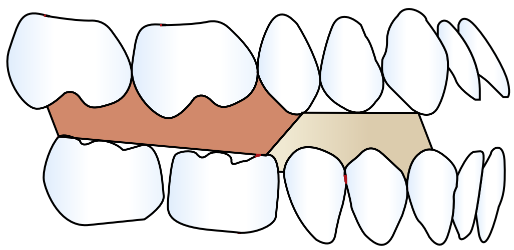

FIGURE 35-29 In patients with open bites, occlusal cover is maintained over posterior teeth to achieve all possible depression of the upper and lower molars.

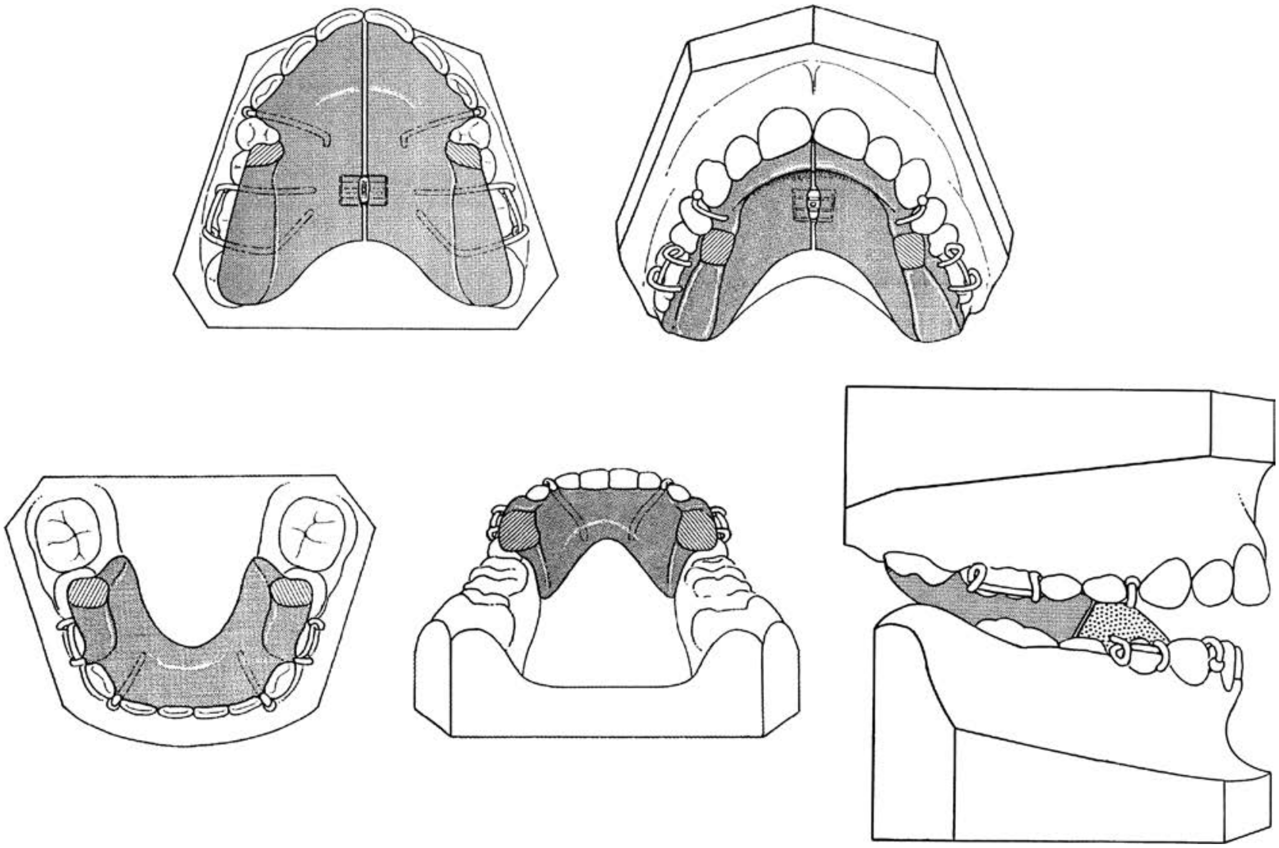

FIGURE 35-30 Standard Clark twin blocks. Hash marks denote the occlusal inclined guiding planes. (Courtesy of W. Brudon and J.A. McNamara Jr, University of Michigan. IN Clark WJ: Twin block functional therapy, ed. 2, London, 2002, Elsevier, Ltd)

controlled, of course. Too often, conventional functional appliances do not control mandibular incisors, which become excessively proclined during treatment. To obtain dental correction with biocompatible measures is not maltreatment, however. For example, lower incisors that are initially lingually inclined as the result of a perverted lip trap can be greatly improved. Acrylic capping of lower incisors also reduces the tendency to procumbency. In any event, Hansen and Pancherz[31] note considerable recovery from lower incisor proclination after treatment in their long-term studies.

If rare earth magnets are used for phase I of twin block therapy, then they are embedded in attraction mode on the 70-degree inclined planes of upper and lower appliances. Functional activity and interarch contact are thus enhanced. If the appliance is not bonded, then the patient is instructed to wear it all the time, removing it only for cleaning. Moss[160] has reported using repelling rare earth magnets in a different configuration, again to assist in forward posturing of the mandible. A thin layer of acrylic covers opposing magnetic surfaces to prevent breaking the parylene seal and thus fostering corrosion. After the rapid and desired sagittal correction has been achieved, the twin blocks are worn for an additional 2 to 3 months to stabilize the occlusion and to allow for needed dental compensation (e.g., posterior eruption, which occurs more slowly). Compensation is a common problem for all functional appliances because sagittal correction is achieved before vertical treatment objectives are reached. The acrylic is trimmed away from the contiguous maxillary occlusal surfaces to allow for unimpeded molar and premolar eruption. As Buschang and Santos-Pinto[24] note, nine times as much vertical growth as sagittal growth occurs in the human face. The lower appliance is usually discontinued unless arch length has been gained, and an inclined plane is added to the maxillary appliance, which serves as an active or short-term retainer for phase II during the continued eruption of posterior teeth as they lock into correct interdigitation. Many studies emphasize the importance of a *locked occlusion* to prevent sagittal relapse.[*]

Magnetic Appliances

Blechman,[163,164] Bondemark and Kurol,[165] and Vardimon and colleagues,[60,159] as well as Darendelilier and associates[166] and Joho and Darendelilier,[167] have been aware of the potential for using rare earth magnets in orthodontics and dentofacial orthopedics for some time. Blechman,[168] the true pioneer, has been intimately involved in the medical and dental use of rare earth magnets. Recent medical research corroborates his observations that static magnet fields may have an electric field effect that potentiates tissue response.[65,168,169] Despite widespread and increasing use of magnetic adjuncts in general orthopedic problems, in vitro orthodontic research has produced mixed

* References 20, 31, 37, 44, 47, 53, 54, 57, 60, 159, 161, 162.

FIGURE 35-31 Deforming perioral muscle function is noted in an 8-year-old boy before twin block treatment.

results thus far. Is it a question of not knowing what to look for? Heightened blood flow is clearly evident, and the alignment of blood cells is influenced by rare earth magnets, but the magnitude or character of force, its duration, and whether continuous or intermittent force is applied are questions currently being addressed, particularly in medical orthopedics, in which considerable improvement has been noted in specific types of problems, such as back and joint disorders, fracture nonunion, and pain threshold management. The clinical use of magnets in such cases is widespread.

In orthodontics, Vardimon and colleagues[170] have demonstrated the clinical use of magnets for the deimpaction of maxillary canines, which can achieve the desired result in as little as one third of the time required by conventional traction technique. The article received the B.F. Dewel Award in 1992 as the best article in the *American Journal of Orthodontics and Dentofacial Orthopedics* the previous year. With the magnetic deimpaction, the tissue attachments and alveolar bone height are normal rather than the compromised gingival margins observed in conventional *expose and pull* techniques. No evidence of root resorption was seen.

Despite the increased exercise effect of magnets incorporated into functional appliances, which enhances the TMJ–condylar growth metabolism, no compelling evidence currently exists of a significantly enhanced localized tissue effect. This lack of evidence may be because the magnets are not contiguous to the tissues but are separated from them by acrylic barriers. At this time, magnetic functional appliances do not appear to be much more effective than nonmagnetic designs in a nongrowing child. Improper case selection, improper design, and injudicious use can cause unwanted lower incisor proclination, as with any other functional appliance. Incorporating Fränkel-type buccal

FIGURE 35-32 The patient in Fig. 35-31 is seen after 14 months of twin block treatment. Note the use of a biteplate during this support phase to stimulate posterior eruption because vertical dimension improvement often takes longer than sagittal correction.

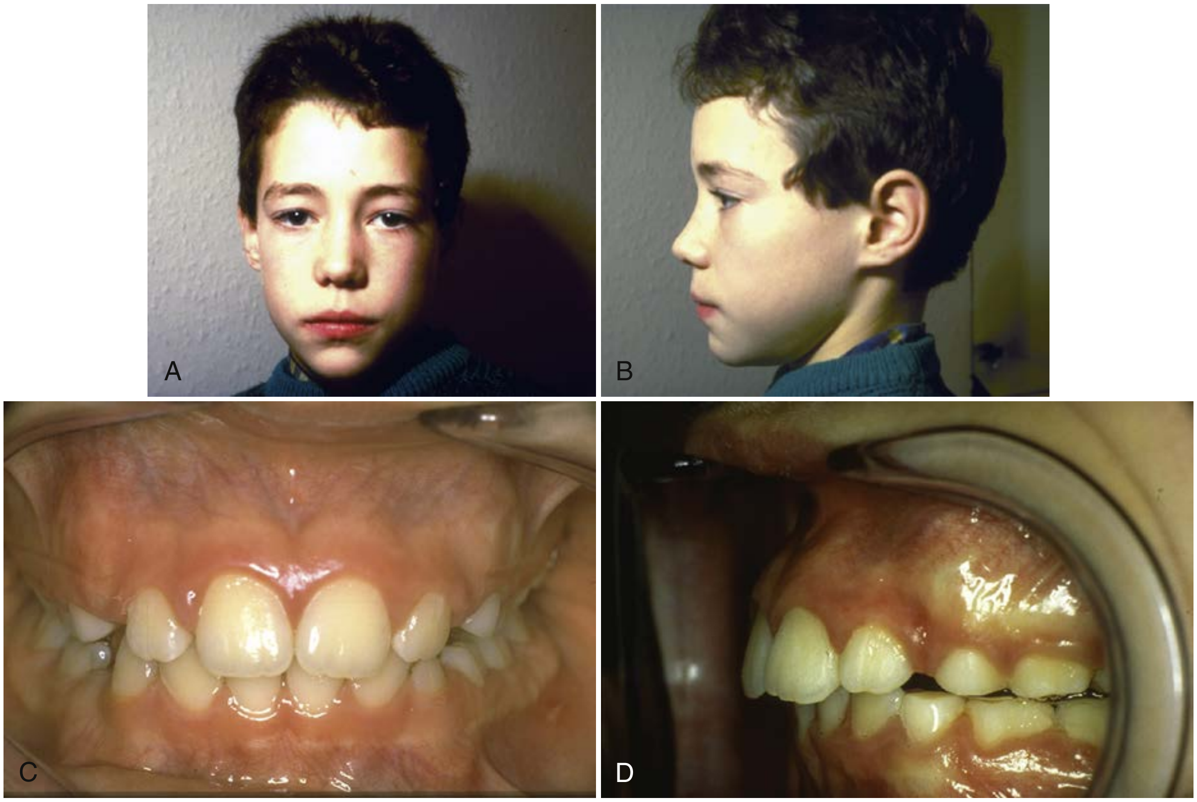

FIGURE 35-33 Facial and intraoral views depicts the patient in Figs. 35-31 and 35-32.

(Courtesy Andy Vardimon.)

shields or the buccal loops of the Bionator appliance in patients with narrow maxillary arches or perverted perioral muscle function may be beneficial in magnetic and other types of functional appliances, replacing the jackscrew. The functional appliance, as with any other mechanism, should be *the thinking orthodontist's approach* and not a procrustean bed or mechanical straitjacket for all patients.

Vardimon and associates have had significant success with magnetic functional appliances (Figs. 35-36 and 35-37). A report in the *American Journal of Orthodontics and Dentofacial Orthopedics* highlights the uniform success achieved.[76] Two case reports are shown in Figures 35-38 and 35-39 to demonstrate Vardimon's success with magnetic appliances.

Stöckli-Teuscher Combined Activator-Headgear Orthopedics

Long-term research with even the most efficient removable functional appliances demonstrates a minimal distalizing effect on the maxillary complex.[23,42,100,158,171] A withholding of the anterior component of maxillary change is probably the most that can be expected. Fixed functional appliances such as the Pancherz modification of the Herbst appliance, the Jasper Jumper, and the De Vincenzo Eureka Spring, all described in this book, can definitely distalize the maxillary molars and may also have some effect on the maxillary downward and forward growth pattern with possible enhancement of horizontal mandibular growth.

Traditionally, despite the mandibular underdevelopment in most Class II malocclusions, American orthodontists have attacked the maxilla with extraoral force, producing a compromise result to fit the maxilla to the deficient mandible. Calling it *camouflage treatment* does not make it any more legitimate. Because the classic activator is primarily directed against the mandible, what is needed in the best of all worlds is a device that affects a correction using significant changes in both the maxillary and the mandibular basal structures (i.e., growth patterns), plus dentoalveolar compensatory changes. Thus the mechanotherapy must adapt treatment to dentofacial growth in an optimal manner, eliminating three-dimensional malocclusion problems.

Normally, the sagittal and vertical growth of the condyles and change in the TMJ glenoid fossa position and morphologic structure are balanced by the downward and forward growth of the maxilla. The great anatomist Harry Sicher attributed the bulk of maxillary basal change to sutural growth.[10] As Coben[172] emphasizes, however, growth of the sphenooccipital synchondrosis is a significant factor in both a lengthening of the cranial base and the sagittal midface development, as well as influencing the position of the glenoid fossa (Figs. 35-40 to 35-43). This critical area has been largely ignored in orthodontic research and diagnosis.

If the magnitude and nature of the growth processes are such that the vertical component is dominant, then the mandibular symphysis will move more vertically. If the horizontal vector is greater, then the chin point will move more sagittally. Functional appliances, alone, actually attack only part of the problem. Korkhaus noted, referring to functional orthopedics, "We effect the correction of distoclusion exclusively through the mesial development of the entire lower jaw."[173] However, is this enough, particularly when definite limitations exist on the therapeutic change of the mandibular position and morphologic structure?

Stöckli and Teuscher persuasively argue in the second and third editions of this text that a combined assault against the maxilla using a functional appliance and extraoral force produces a more dramatic and stable correction skeletally, cosmetically, and functionally. Figures 35-41 to 35-44 illustrate the challenges. Figure 35-41 shows average natural growth and displacement of the maxilla and mandible. The result is harmonious downward and forward growth. If mandibular growth is deficient, then a more horizontal lower jaw vector must be stimulated to compensate for the sagittal discrepancy, essentially producing the entire correction with mandibular basal change and stable dental compensation (see Fig. 35-42). Research shows that solely skeletal correction is not possible in many cases with functional or conventional fixed appliances.[174] The orthognathic surgeon recognizes the problem and can effect such a skeletal change through surgical repositioning or distraction osteogenesis. However, this procedure is beyond the domain of conventional orthodontics and this chapter. Figure 35-43 shows the potential of combined assault on the maxillary and mandibular sagittal discrepancy. A more realistic orthopedic possibility is combined maxillary withholding, plus mandibular and fossa forward displacement, plus vertical control of dental and skeletal spatial relationships. Neither functional appliances nor extraoral force alone can routinely

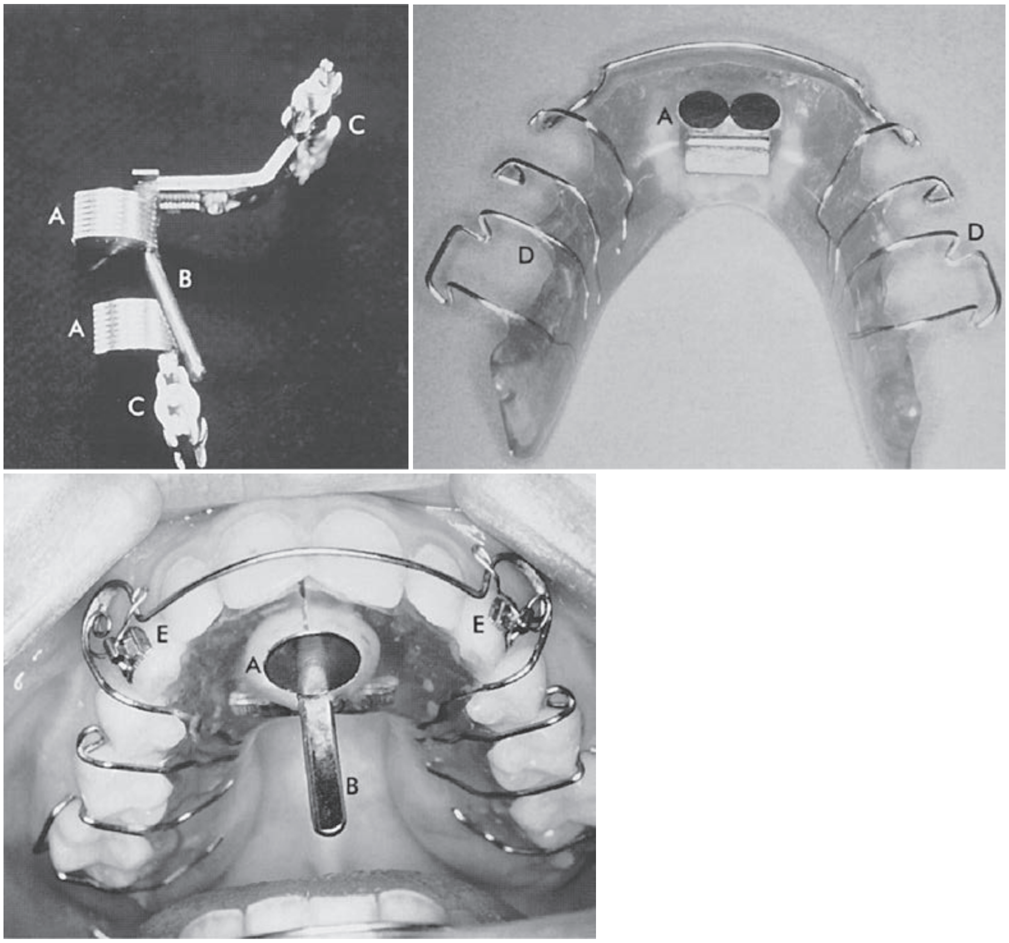

FIGURE 35-37 Vardimon functional magnetic appliance. Upper and lower modified Schwarz plates, similar to the Clark twin block appliances, are used. Instead of bilateral-angled magnetic inclines, lingual rare earth magnets are buried in the acrylic at the midline. A maxillary guiding prong that slides on the lingual acrylic of the lower appliance during closure brings the mandible forward into the desired protrusive relationship as the attractive magnets contact. This unloads the condyle in much the same way as other functional appliances, except that the functional stimulus occurs more often with the *make-and-break* magnetic contact. Temporomandibular joint metabolism is enhanced in this manner. Patient compliance is apparently improved. Transverse control can be achieved by incorporating palatal jackscrews if needed. The upper and lower magnets have not been incorporated into the acrylic; rather, they are positioned to show the glide path as they approach each other. Magnetic attraction exists as far as 2 cm (*top views*). Small elastics hooked above bonded canine brackets to enhance retention of the maxillary functional magnetic appliance (*middle view*). *A,* Magnets; *B,* guidance prong; *C,* metal tags for incorporation of upper and lower appliances into the acrylic; *D,* retention clasps; *E,* elastics hooked over bonded brackets.

FIGURE 35-38 Patient FN was 11 years, 3 months old when functional magnetic system (FMS) treatment was initiated. His Class II malocclusion was due to prognathic maxilla and mild retrognathic mandible (McNamara analysis: Point A to Nasion Perpendicular line = 4mm, Pogonion to Nasion Perpendicular line = −8mm. Retrognathic mandible according to Steiner analysis: SNA angle = 80 degrees, SNB angle = 72 degrees.) Pretreatment records: **A,** Profile. **B,** 3/4 Profile,. **C,** Overjet. **D,** Frontal view with excessive overjet; **E,** Left occlusion. First FMS treatment stage lasted 9 months. A full Class I molar relationship was established, with the canine in almost a Class I relationship, which resulted in overjet remnant. **F,** Upper FMS appliance. **G,** Lower FMS appliance. **H, I,** Increased bite clearance with the FMS. **J,** End of FMS treatment. **K, L,** Second edgewise treatment stage: during treatment. **M, N,** Posttreatment profile and smile. **O,** Schematic illustration provides the percentage correction of each component. Without taking growth into account, major treatment changes occurred in the mandible (75%) and the upper molar (75%). However, after subtracting growth, the mandibular skeletal contribution dropped to 12.3% and the maxillary dental contribution (molar distalization) increased to 92%. *OLp,* Occlusal line perpendicular. FIGURE 35-41 Average natural displacement pattern of the maxilla (Point A) and the mandible (pogonion), relative to the anterior cranial base. The horizontal and vertical vectors (*white*) and the resultant vector of displacement are shown. In an average facial growth pattern, the forward component of the mandibular symphysis displacement is slightly greater than that of the anterior apical base of the maxilla. The difference is marked at the bottom. Of course, as Coben points out, if superimposition occurred on the entire cranial base, including the sphenooccipital synchondrosis, then the result would be different.

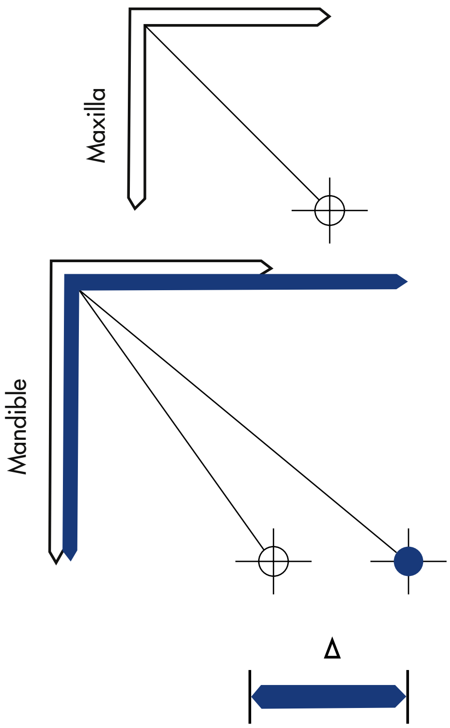

FIGURE 35-42 The concept of stimulating specific forward growth, with mandibular displacement (*black*) to bring about the so-called jumping of the bite in Class II treatment with functional orthopedics, can be an unfulfilled orthodontic "dream" because the actual change that occurs without appliance interference cannot be measured at the same time. The morphogenetic pattern, treatment timing, appliance used, and patient compliance are important determining factors. For these reasons, forecasting is a difficult, if not impossible, task.

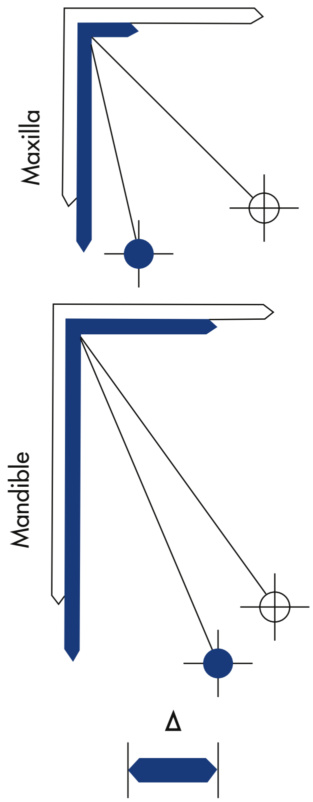

FIGURE 35-43 Reduction of the sagittal component of maxillary skeletal and dentoalveolar structures (*black*) is compared with the average values. Stöckli and Teuscher believe that this possibility is more realistic with functional appliances, despite the research of McNamara and others, which shows little effect of functional appliances on the maxilla. The use of an extraoral appliance (headgear) does enhance sagittal withholding or a distalizing effect on the maxilla, hence the justification for combined functional appliances and headgear. In many cases, however, rotational and elongating reactions by the maxilla and dentoalveolar structures create additional vertical demands and reduce the potential sagittal correction, causing an opening mandibular rotation that exacerbates the apical base discrepancy (*lower diagram*). Because of dominant vertical growth, as shown by Buschang, appliance control of this vector is essential (i.e., vertical growth is much greater than sagittal growth).

provide the desired correction.* A study by Altenburger and Ingervall,[100] comparing combination headgear-activator results with the results achieved using an activator alone, still does not show a significant distalizing effect with combination therapy. However, in a more recent study, Du, Hagg, and Rabie[27] show significant molar distalization when incorporating a headgear with the Herbst appliance.

Again, the reader is referred to the excellent chapter by Stöckli and Teuscher in the second edition of this book for techniques and treatment.[173] Figures 35-44 and 35-45 illustrate the activator-headgear appliance. Proper construction implies that the extraoral force component considers any possible rotational effect from extraoral force, which must pass as close as possible through the maxillary center of resistance.

Perhaps the best compromise, ensuring optimal stability of the functional appliance when the headgear is worn, is to place first molar bands and buccal tubes, insert the occipital pull extraoral force arms into the buccal tubes, and have the wire clasps of the functional appliance snap above the buccal tubes to give maximal retention for day and night wear of the functional appliance. Three-dimensional control of molar anchor teeth is a top priority, preventing unwanted opening of the bite. This two-jaw approach enhances anchorage and dentoalveolar compensation and provides optimal growth guidance. Various functional appliances can be used—a Bionator, twin block, or monobloc appliance—but with reduced bulk to permit full-time wearing.

Fixed Functional Appliances

Herbst Appliance

At the International Dental Congress of 1909 in Berlin, Emil Herbst presented a fixed bite-jumping device called Scharnier, or joint[179] (Figs. 35-46 to 35-48). The idea of continually keeping the mandible forward and eliminating the need for patient compliance, as is required with removable functional appliances, appealed to clinicians. In 1934, Herbst and Martin Schwarz wrote a series of articles describing their case selection,

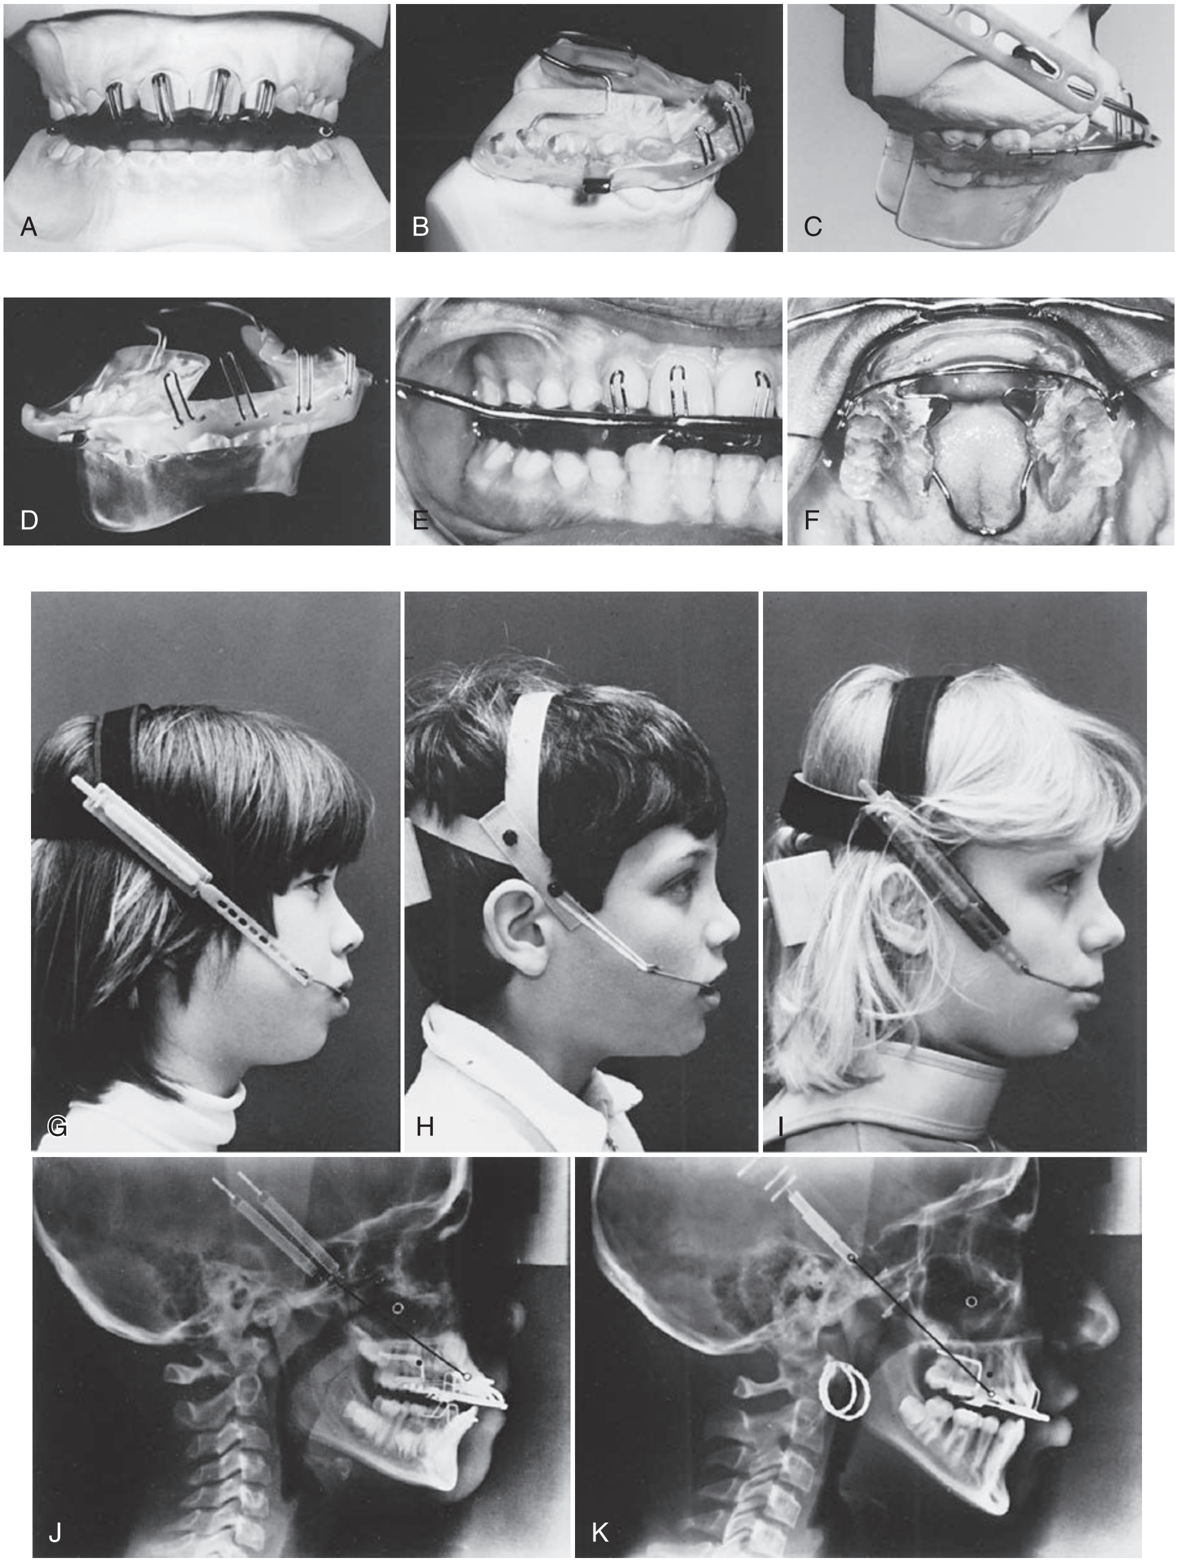

FIGURE 35-44 Activator-headgear appliance and extraoral attachments. **A,** Vestibular extensions and torquing springs are demonstrated. **B,** The appliance is placed on the lower cast. Note the anterior area with torquing springs, palatal extension of acrylic, and transpalatal wire. **C,** The appliance is placed on the upper cast with the facebow inserted. Note the lower lingual flange extension for engaging the mandibular arch, similar to the Hamilton appliance. **D,** Appliance view again shows the transpalatal bar, torquing springs, and lingual extensions. **E,** The activator-facebow is in place. **F,** The activator is in place on the lower arch, showing the insertion of the facebow. Note the tongue against the transpalatal Coffin spring. In this construction, labial and lingual wires are used instead of torquing springs. **G,** An anteriorly placed force vector is estimated in this case to pass just anterior to the center of resistance of the maxilla. Some anterior rotation of the dentition must be expected, and ample condylar growth is required. **H,** Average steepness of the force vector is estimated to pass slightly superior to the center of resistance of the upper dentition. The posterior rotational effect on the maxilla and the anterior rotational effect on the dentition should neutralize each other to ensure that no change is expected in the inclination of the occlusal plane. **I,** The posteriorly placed force vector is estimated in this case to pass just inferior to the center of resistance of the dentition. Posterior rotation of the maxilla and dentition must be anticipated. This setup is used for patients with an open bite tendency or when the prognosis of condylar growth is poor. **J, K,** Lateral cephalograms are provided to check force vectors (*line connecting the circle at the end of the outer arms of the facebow and the circle at the springs of the headcap*) to the centers of resistance of the maxilla (*white circle*) and upper dentition (*black dot*).

experiences, problems, and solutions.[180] Patients with retrognathic mandibles and TMJ problems responded best. Breakage had been reduced by some design changes of the tube and plunger assembly. However, after this, little appeared in the literature until the concept was resurrected by Hans Pancherz.[107] In 1979, Pancherz's article in the *American Journal of Orthodontics* called attention to the possible stimulation of mandibular growth. Subsequent articles have elaborated on modifications and the short- and long-term effects on jaw relationship, occlusion, and masticatory efficiency.[31,50,114,181] Ruf and Pancherz's long-term research[53,54] and clinical use have prompted others to use this approach or modify the appliance (e.g., Jasper Jumper, Eureka Spring).[182]

The Herbst appliance can be compared with an artificial joint between the maxilla and mandible. The bilateral telescopic mechanism maintains the protracted position of the mandible,

even during function (see Fig. 35-48). This appliance and its use are fully described by Hans Pancherz in an extensive chapter in *Dentofacial Orthopedics with Functional Appliances*, 2nd ed., by Graber and associates.[10] Each device consists of a tube, a plunger, two pivots, and two locking screws that prevent the telescoping elements from slipping past the pivots (see Figs. 35-46 and 35-47). The pivot for the tube is usually soldered to the maxillary first molar band, and the pivot for the plunger is attached to the mandibular first premolar band. Pancherz found that waiting until the premolars erupted before starting therapy still allows enough time for harnessing adequate remaining growth, particularly in boys.

Generally, the protraction of the mandible for the Herbst appliance is similar to that for the Bionator, with the incisors in an end-to-end relationship, although the incremental advancement approach can be used in large sagittal discrepancies (Fig. 35-49). Du, Hagg, and Rabie[27] prefer incremental advancement and show significant benefit with this method, duplicating the research of Petrovic and Stutzmann on rats.

The length of the tube-plunger assembly determines the amount of advancement. Although conventional orthodontic bands can be used, Pancherz prefers his current approach of casting splints of chromium-cobalt alloy that incorporate molars and premolars and are cemented as units with glass ionomer cement (see Fig. 35-48, *C*). This method saves chair time and causes few clinical problems. For patients with narrow arches, a first-phase expansion can be done with a palatal expansion appliance (one or two expansion screws), or a quad helix appliance can be incorporated into the maxillary appliance (Fig. 35-50). Construction details, per-visit tasks, and the effects of Herbst therapy are thoroughly described in *Dentofacial Orthopedics with Functional Appliances*, 2nd ed., by Graber and associates[10] and in the periodical literature.

The Herbst appliance is a powerful and effective functional system in the treatment of Class II malocclusions.[53] As with other functional appliances, viscoelastic stretch is important. Normalization of occlusion is generally accomplished in 6 to 8 months. Overcorrection of sagittal arch relationships and incomplete cuspal interdigitation, resulting from slower eruption of posterior teeth, are to be expected as settling occurs. Skeletal and dental changes contribute to the treatment result.[54,127,183] Fränkel[93] was critical of the short duration of Herbst appliance wear and recommended prolonged active removable appliance retention and myofunctional exercises during the growth period, as do orthopedic surgeons for growth guidance problems. This practice takes advantage of continued jaw growth. The author of this chapter supports this concept. The downside is that prolonged patient compliance is more difficult.

Sagittal Changes

Figure 35-51 illustrates the restraint of the maxillary arch and the stimulation of mandibular growth.[10] Bone remodeling processes are clearly evident on the lower border of the mandible. Histologic studies confirm these observations.[1] The ultimate condylar position in the fossa is unaffected by Herbst appliance therapy, unless the original problem was a Class II, Division 2 malocclusion. However, and this is again emphasized, modification of the TMJ fossa itself occurs during the growth period. The lower incisors are proclined, and the maxillary molars are posteriorly moved, as with a high-pull headgear.[31] During the first year after treatment, the occlusion settles and the sagittal relationships recover approximately 30% of their previous dimensions. Approximately 90% of the posttreatment occlusal changes occur during the first 6 months and are primarily of dental origin. Lower incisor procumbency rebounds to a significant degree. Lower molars and upper molars tend to move posteriorly and anteriorly, respectively, after treatment.[53]

An unfavorable maxillomandibular growth relationship contributes to early posttreatment changes only to a minor degree. A catch-up in maxillary growth and a minor reduction in mandibular growth increments are apparent in patients treated with the Herbst appliance.[31,54] Again, continued functional retention may enhance stability.

Vertical Changes

In Class II malocclusions with deep bites, overbite may be significantly reduced with Herbst therapy.[31,53] The change primarily results from eruption of lower molars and the intrusion of

the lower incisors. As previously noted, proclination of lower incisors contributes to the seeming intrusion of these teeth. Nevertheless, the appliance has a limited effect on the maxillary and mandibular jaw positions, as expressed by the palatal plane angle and the mandibular plane angle. One must stress again that part of the change is an improvement in the glenoid fossa position and morphologic structure, a change long overlooked until the seminal research of Peter Buschang[24] and Hans Ullrich Paulsen.[49,50]

Long-Term Posttreatment Changes

Several effects have been observed 5 to 10 years after treatment in patients treated with the Herbst appliance. A Class I dental arch relationship is maintained by a stable cuspal interdigitation of the upper and lower arches, whereas relapse tends to occur in cases with unstable occlusal conditions.[54] Teeth locked in a proper relationship are more likely to transfer continuing maxillary growth forces to the mandible. Pancherz emphasized a functionally stable occlusion as possibly more important than posttreatment growth increments. The most common combination of factors leading to varying degrees of relapse are too early treatment, mixed dentition treatment, persistent lip or tongue dysfunction habits, unstable posttreatment occlusion, and insufficient length of appliance wear and retention measures. However, in Pancherz's view, unfavorable posttreatment growth is not a significant factor for occlusal relapse.

Although too early treatment is often associated with relapse, it actually may not be responsible for relapse. More likely, in the mixed dentition, a solid Class I interdigitation is not possible with the deciduous molars. Pancherz believes therefore that the unstable occlusion, not the timing, is responsible.[53] Pancherz notes, however, that the most favorable time to initiate treatment is during the peak pubertal growth period.

Pancherz is totally objective in his intensive and impressive long-term studies. In addition, Pancherz notes from his own and a number of other studies that the basal skeletal relationship is improved but not totally normalized, whereas the occlusal relationship is essentially normalized.[31,46] The implication is that the Herbst appliance is capable of producing sagittal changes that can partially compensate for aberrant skeletal relationships.

A recent study by Ruf and Pancherz[54] assesses the TMJ adaptation through prospective magnetic resonance imaging and roentgenographic techniques. A similar paper was accepted for publication in the *American Journal of Orthodontics and Dentofacial Orthopedics* in 1999. Both papers clearly show significant remodeling with Herbst fixed functional treatment. Strangely enough, comprehensive, long-term studies of the modification of temporomandibular morphologic structure and position in the growing face have yet to be done for fixed appliances, although Paulsen and colleagues[49,50] show convincing evidence of fossa remodeling with sophisticated tomography for short-term Herbst treatment. This long-overlooked phenomenon has been emphasized in this chapter, and references to the seminal work done by Bierbaek and colleagues,[66] Buschang and Santos-Pinto,[24] Decrue and Weislander,[69] Droel and Isaacson,[70] Hotz,[83] Ikai and associates,[32] Kantomaa and Pirttiniemi,[34] Pancherz,[47] and Paulsen[49] clearly indicate the tissue changes, as demonstrated by the Buschang study of changes in the position of the glenoid fossa during growth. It is only logical, then, that the same implications should apply for conventional removable functional appliances. Buschang and Santos-Pinto[24] show the significant potential to affect the changing position of the membranous bone TMJ elements, both fossa and articular eminence. Nature already has pointed the way to this possibility by showing adaptations to deep bite (deep fossa, steep eminence) and Class III malocclusions (shallow fossa, eminently shallow curve).[29]

In another provocative unpublished study that the author directed some years ago at Northwestern University by Dayton Blume and Vernon Boman, postural resting and habitual occlusion condylar and fossa relations were measured in samples of Class I and Class II malocclusions. A significantly higher percentage of condylar retrusion was noted in the Class II sample (Fig. 35-52). Knowing what orthodontists now know about the potentially deleterious effects of condylar retrusion, the logical question may be, "How much of the underdeveloped mandible resulted from interference with metabolism, as dramatically illustrated by Graber,[65] Isberg,[139] Jasper and McNamara,[140] Ward and associates,[80] and others?" (See Fig. 35-20.)

The effects on the facial profile have also been studied by Pancherz and associates.[45,48,114] In patients who were treated for 7 to 8 months and reexamined 5 to 10 years after treatment, a general reduction of hard and soft tissue profile convexity was noted (Fig. 35-53). The upper lip becomes less protrusive, whereas the lower lip remains almost unchanged. However, considerable individual variations were noted (Fig. 35-54).

Overall, the following long-term posttreatment changes can be expected:

- Reduction of the soft tissue profile convexity (excluding the nose), with an increase in mandibular prognathism (see Fig. 35-53)

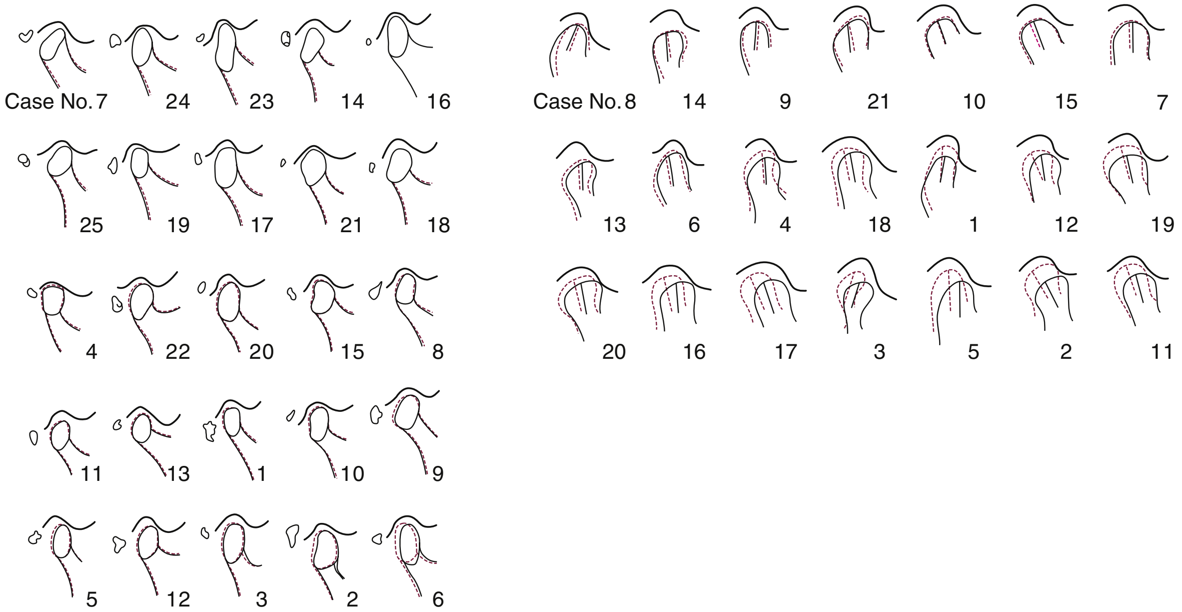

FIGURE 35-52 Unpublished radiographic research by Dayton Blume and Vernon Boman show the path of closure from the postural resting position (*black solid line*) to habitual occlusion (*red dotted line*) in normal patients (*left*) and those with a Class II malocclusion (*right*). This evidence indicates significantly more translatory action (functional retrusion) with an upward and backward path of closure for Class II malocclusions. Normally, condylar movement is essentially rotary from postural rest to maximal intercuspation (*left*). (From Graber TM. Anatomische und physiologische aspekte bei der behandlung von kiefergelenksstörungen [The anatomical and physiological aspects in the treatment of temporomandibular joint disorders]. *Fortschr Kieferorthop* 1991;52:126–132.)

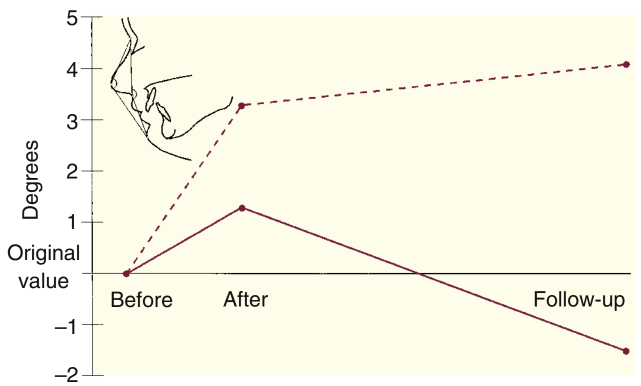

FIGURE 35-53 Mean changes in the soft tissue facial profile angles, excluding the nose (*dotted line*) and including the nose (*solid line*), in 49 subjects treated with the Herbst appliance. Positive values imply profile convexity reduction. Negative values imply profile convexity increase. Measurements were taken before treatment (original value of 0), after 7 months of appliance wear, when the appliance was removed, and at follow-up 5 to 10 years after treatment. (Data from Pancherz H, Fischer S. Amount and direction of temporomandibular joint growth changes in Herbst treatment: a cephalometric long-term investigation. *Angle Orthod* 2003;73:493–501.)

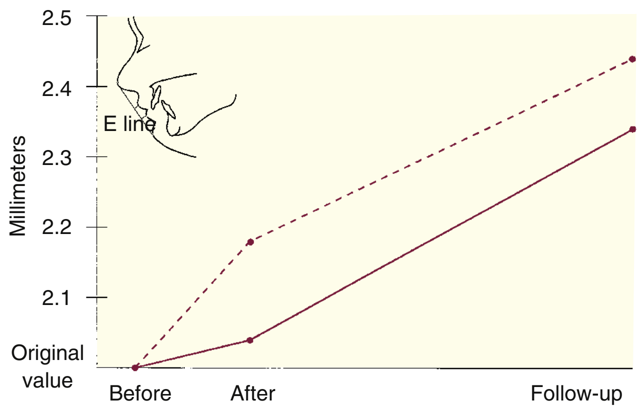

FIGURE 35-54 Mean changes in the position of the upper lip (*dotted line*) and the lower lip (*solid line*) in relation to the aesthetic line in 49 subjects treated with the Herbst appliance. Negative values imply lip retrusion. Measurements were taken before treatment, when the appliance was removed, after 7 months of appliance wear, and 5 to 10 years after treatment. (Data from Pancherz H, Fischer S. Amount and direction of temporomandibular joint growth changes in Herbst treatment: a cephalometric long-term investigation. *Angle Orthod* 2003;73:493–501.)

- Increase in the soft tissue profile convexity (including the nose), largely because of normal nasal growth (see Fig. 35-53)
- Retrusion of the upper and lower lips in relation to the aesthetic line because of normal nose and chin growth (see Fig. 35-54)

Jasper Jumper

The popular Jasper Jumper is a modification of the Herbst appliance just described. The interarch flexible force module of the Jasper Jumper allows the patient greater freedom of movement (Fig. 35-55). As with the Pancherz version of the Herbst appliance, the Jasper Jumper resorts to pushing forces, in contrast to conventional intermaxillary elastics (Figs. 35-56 to 35-59). Repetitive forward posturing is the key element. Metabolism, again, is stimulated to provide the achievable optimum result.

McNamara[41] notes that the treatment response of the Jasper Jumper is almost equally divided between basal and dental effects.[10] On average, a 2-mm increase in mandibular length occurs. Little maxillary skeletal change has been noted. As with all functional appliances, the potential for modification of the fossa in position and morphologic structure exists in the growing individual. One must analyze this using reliable three-dimensional landmarks rather than conventional two-dimensional radiographic, cephalometrically constructed measure points and line and angular reconstructions (cephalometric tracings).[140,184–186]

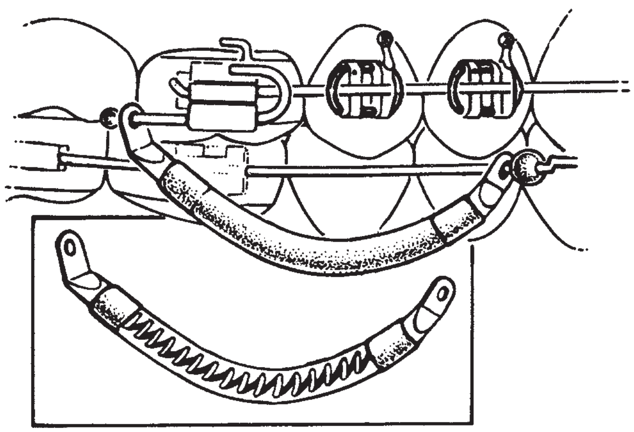

FIGURE 35-55 Jasper Jumper essentials. The distal end of the force module is attached to the maxillary dental arch by means of a ball pin and double molar tubes. The appliance can be activated by anteriorly moving the ball pin. The alignment of the spring within the jumper mechanism is shown in the inset.

According to McNamara,[116] the most pronounced dentoalveolar change with the Jasper Jumper and similar appliances, is a relative posterior movement of the maxillary buccal segments of approximately 2.5 mm. Proclination of the lower incisors is also reported, as with the conventional Herbst appliance.*

As with the Pancherz version of the Herbst appliance, the Jasper Jumper has the advantage of a shorter active treatment time, which is a double-edged sword because less time is available to harness growth increments. Patient compliance needs are minimal. The appliance is less rigid than the classic Herbst device and uses a flexible pushing device, also enlisting the buccinator mechanism (buccal muscle forces) (see Figs. 35-55 to 35-59). In addition to sagittal forces, the Jasper Jumper has a transverse expansion vector acting on the maxillary molars, which must be watched. A transpalatal arch counteracts unwanted buccal malposition of the upper first molars. The use of a lower lingual arch enhances mandibular anchorage (see Fig. 35-59).[10,152,184]

Most of the Pancherz team's observations concerning the conventional Herbst appliance apply to the Jasper Jumper, although some clinicians believe that the magnitude of change is less with the Jasper Jumper. John DeVincenzo has designed several fixed functional appliance modifications that could be used, including his own effective Eureka Spring. DeVincenzo[69,143] attributes the bulk of change to dentoalveolar compensation, with minimal skeletal reaction.

Detailed treatment adjustments are presented in Chapter 17 of *Dentofacial Orthopedics with Functional Appliances*, 2nd ed., by Graber and associates.[10] The reader is strongly advised to read Part 2 of that chapter on asymmetric dentofacial orthopedics. A significant number of Class II malocclusions are not bilateral mirror images. Barry Mollenhauer's discussion applies not only to the Jasper Jumper but also to all fixed functional appliance modifications.[10,63,184,188]

FIGURE 35-56 Outriggers (auxiliary arch wires) are used to anchor the force module. **A,** The rectangular auxiliary wire is anteriorly looped over the main archwire and is posteriorly cinched back through the auxiliary tube. **B,** A ball pin is inserted through the distal hole of the jumper module, anteriorly placed through the face-bow tube on the upper first molar band, and cinched forward to activate the module.

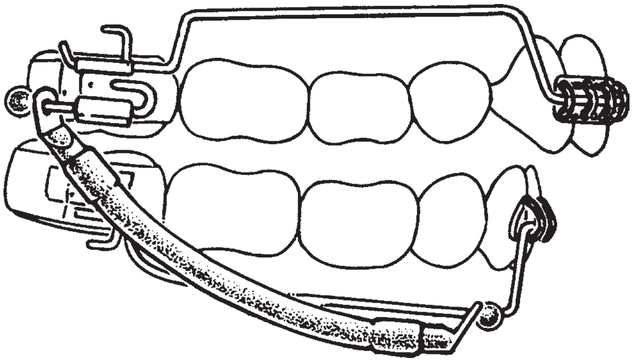

FIGURE 35-57 The force module is used in a patient with mixed dentition. In this instance, a bayonet bend is distally placed to the canine, and a Lexan ball anteriorly acts as a stop for the force module. In this example, the upper and lower rectangular utility arches connect the anterior and posterior teeth.

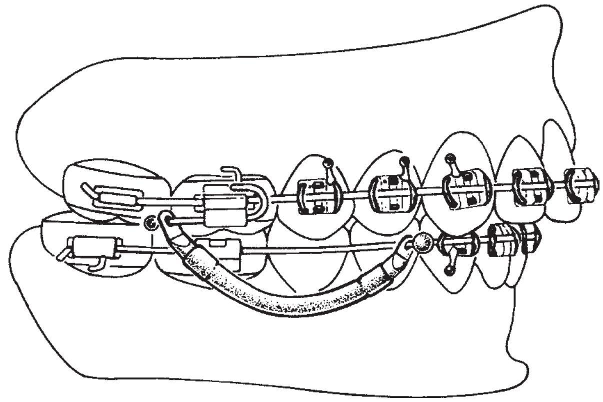

FIGURE 35-58 Maximal anchorage is set up for the force module. The maxillary and mandibular archwires extend to the second molars and are posteriorly cinched back. Tiebacks can also be used. The offset bend in the main archwire (see Fig. 35-59) is obscured by the Lexan ball.

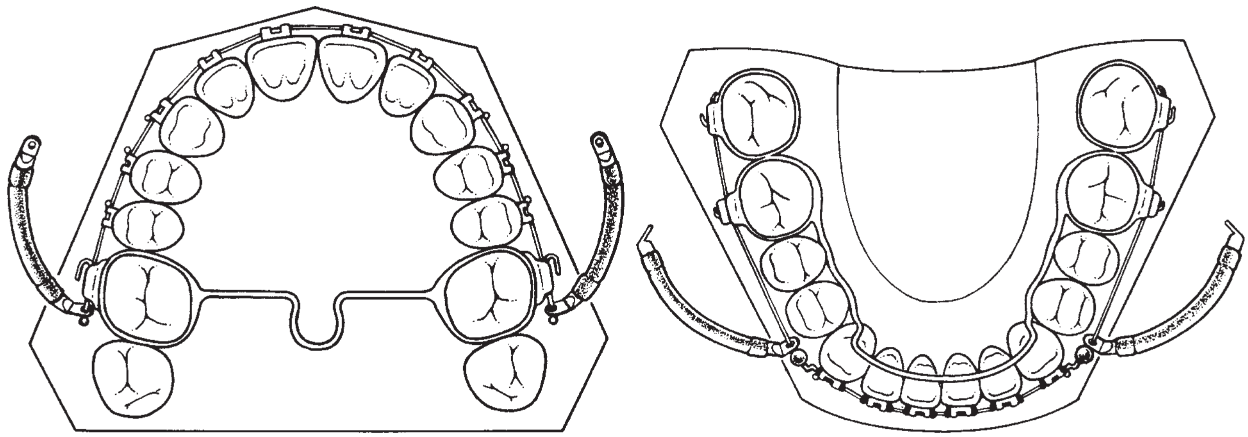

A B

FIGURE 35-59 **A,** The transpalatal arch, combined with fixed appliances, is used to enhance maxillary anchorage. **B,** A lower lingual arch, combined with fixed appliances, enhances mandibular anchorage.

SUMMARY

The author of this chapter hopes that this overview of the biologic approach—enlisting the patient's own muscles, function, growth pattern, optimal metabolic stimulation, and compliance—will excite the reader enough to stimulate, the reading of the accompanying list of references. Functional appliances do not replace fixed attachments. Indeed, the combined use of brackets, bands, and extraoral force has the potential for the best possible and most stable long-term results. Treatment timing and length of treatment are important considerations for growth guidance as orthopedic surgeons show. The ultimate goal of all orthodontists is to be applied biologists.

Treatment of the Face with Biocompatible Orthodontics

Dwight Damon

OUTLINE

THE DAMON SYSTEM CONCEPT

The philosophy underlying the intended use of the Damon System (Ormco Corporation, Orange, CA) is to approximate biologically induced, tooth-moving forces in each phase of orthodontic treatment. The Damon System achieves this goal by means of a passive, virtually friction-free, self-locking, fixed-appliance conduit that maximizes the full potential of today's high-tech archwires. By doing so, the Damon System provides a reliable and simple means of achieving the best possible facial balance for each patient through the use of light forces that foster corrective functional adaptation of the archform while maximizing patient comfort during treatment. This functional adaptation is similar to the *Fränkel effect* in its posterior arch-widening results. Traditional treatment planning has long been based on maintaining the original archform for stability. In patients with muscle imbalance and collapsed archforms, tooth mass often had to be eliminated. Extensive clinical results indicate that clinicians can now maintain most complete dentitions, even in severely crowded arches, by using very light–force, high-tech archwires in the passive Damon appliance that alter the balance of forces among the lips, tongue, and muscles of the face. This alteration creates a new force equilibrium that allows the archform to reshape itself to accommodate the teeth; the body, not the clinician, determines where the teeth should be positioned. The author refers to this phenomenon as "physiologically determined" tooth positioning. Computed tomographic (CT) scans taken of patients just debonded and those in retention for longer than 5 years demonstrate that using light forces in a passive tube with a small wire-to-lumen ratio enables teeth to be bodily moved, without excessive tipping, in all planes of space and that alveolar bone will follow. This compelling research calls for a significant shift in thinking and treatment planning, reducing and even eliminating the need for molar distalization, extractions (excluding those deemed appropriate for bimaxillary protrusive cases), and rapid palatal expansion.

Practicing orthodontist Alan Pollard describes the Damon appliance system as unique in offering "rapid alignment with gentle forces, functional adaptation and accurate, predictable tooth positioning with micro precision." He continues, "It provides a well-documented means, a virtually friction-free tube, by which the most advanced wire technologies can work to their maximum advantage, an aim most of us have aspired to but have not been able to achieve in conventionally ligated edgewise systems."[1]

Pollard refers to the Damon appliance as a *tube*. Tube is a useful and accurate geometric description of this passive appliance. The appliance is a tube with tie-wings rather than a bracket and, as such, has a static facial wall when its locking mechanism is closed. To emphasize the important difference between this passive appliance and active self-locking brackets, the Damon bracket appliance is referred to as a tube throughout this discussion.

This chapter presents documentation that substantiates existing clinical findings on patients treated with extremely light forces via the Damon System. Before doing so, the author reviewed the early observations he made in using the system and the two important governing principles (achieving facial harmony and using nonextraction therapy where possible, about which most orthodontists agree today) and their close alignment with Damon System principles. Review of these principles leads to a systematic discussion of the vascularity of the periodontal ligament and alveolar complex. CT scans of various types of cases demonstrate stable and even improved alveolar bone formation after bodily tooth movement with light forces via the Damon System. Treatment results of a wide range of malocclusions demonstrate the application and versatility of the system. After these presentations, the section, "Damon System Essentials," touches on torque selection, the Damon archform and archwire sequencing, interarch elastic configurations, and the use of the retention splint.

EARLY OBSERVATIONS OF DAMON SYSTEM TREATMENT

When the author first started using this new passive tube technology in the mid-1990s, it became obvious that alveolar bone, tissue, and teeth responded differently from those treated with conventional high-force mechanics. The following observations were made from some of the earliest cases treated with the first Damon SL tubes. These observations totally changed the author's treatment planning and have led to improvements in bracket-tube geometries and materials. Most of the photographs in this section exhibit much earlier and larger iterations of the Damon tube appliance.

1. *The system offers minimal negative impact on the archform when aligning severely malpositioned teeth.* When using conventionally tied appliances and engaging a high upper canine, the expected impact would be for the adjacent lateral incisor and first premolar to intrude or superiorly move with the incisors anteriorly flaring. With this tube technology and low-force, low-friction mechanics, these adverse responses are minimized or eliminated (Fig. 36-1).
2. *The appropriate force and wire-to-lumen ratio produces a Fränkel-type, arch-widening effect in the posterior, whereas lower canine width stays approximately the same.* The action of the small round archwire (0.014 inch) in the large lumen produces posterior transverse arch-widening that accommodates most complete dentitions, even in severely crowded arches and without the use of high-force palatal expansion (Fig. 36-2, *A* and *B*). Usually minimal change occurs in lower incisor position on the composite head film tracing (Fig. 36-2, *C*). (The only exception is when the canines are severely positioned anteriorly or lingually to the lateral incisors, which is consistent with other types of clinical mechanics with or without extractions.) Establishing the appropriate force and wire-to-lumen ratio in the initial phase of treatment is critical for the orthodontist. The initial archwire (Ni-Ti Align SE or Damon Copper Ni-Ti (Ormco Corporation, Orange, CA) must not exceed 0.014 inch in diameter and must remain an adequate time to allow its full expression (Fig. 36-3). Moving too quickly or forcing archwire changes through the Ni-Ti Align SE or the Damon Copper Ni-Ti phases may disrupt the adaptation process, totally altering the impact on the face, bone, muscles, and soft tissues.
3. *The orbicularis oris and mentalis muscles create a lip bumper effect, which minimizes anterior movement of the incisors.* Based on experience with conventional mechanics, orthodontists expect to see labial movement of anterior teeth when trying to accommodate teeth in a crowded arch without making room for them via extractions. In

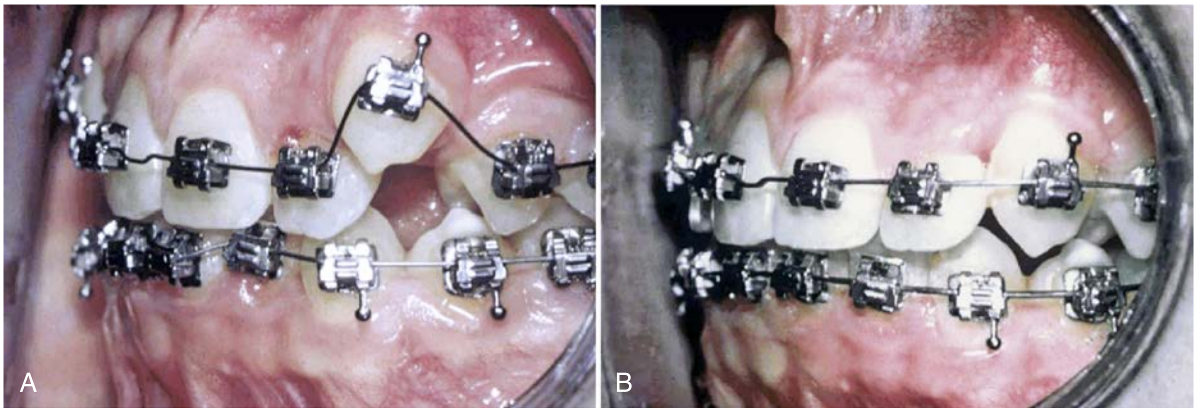

FIGURE 36-1 A, B, When bringing a high canine into position, light-force tube technology produces minimal impact on the adjacent teeth and little flaring of the incisors.

using the tube system, the author noticed that the anterior movement of the incisors was minimal, and the lips and muscles of the face become powerful allies with this low-force system. The patient in Figure 36-4, *A* and *B*, is an early example of this phenomenon. Because of her flat midface, treating this patient without extractions was essential. With a minimal incisor inclination change, treatment brought a pleasing dental result (Fig. 36-4, *C-H*). The composite head film shows minimal anterior movement of the incisors (see Fig. 36-4, *D*). The patient also had excellent tissue and periodontal response (see Fig. 36-4, *E*) 3½ years in retention.

4. *In cases treated with nonextraction, as the arch widens in the posterior, the tongue usually lifts and moves forward, creating a new force equilibrium between it and the lips and muscles of the face.* This phenomenon provides the muscles of the face and tongue a second chance to balance themselves and for the archform to continue to reshape itself to accommodate the teeth (Fig. 36-5).
5. *In bimaxillary protrusive cases treated through extraction therapy, treatment mechanics are greatly simplified with the lip bumper or headgear effect of the facial muscles, thus minimizing the demand on posterior anchorage.* The crowded anterior teeth, engaged with an archwire no stronger than 0.014-inch Ni-Ti or Copper Ni-Ti, take the path of least resistance into the extraction site (Fig. 36-6).

CONTEMPORARY ORTHODONTIC PHILOSOPHIES

Achieve Facial Harmony via Facially Driven Treatment Planning

Most contemporary clinicians have expanded their primary focus toward creating beautiful and handsome faces, with "putting plaster on the table" filling a vital but contributory role. Treatment planning is now concentrated on developing a result that is conducive, rather than detrimental, to long-term maturation of the face; that is, treating the 13-year-old patient with the future 50-year-old adult in mind.

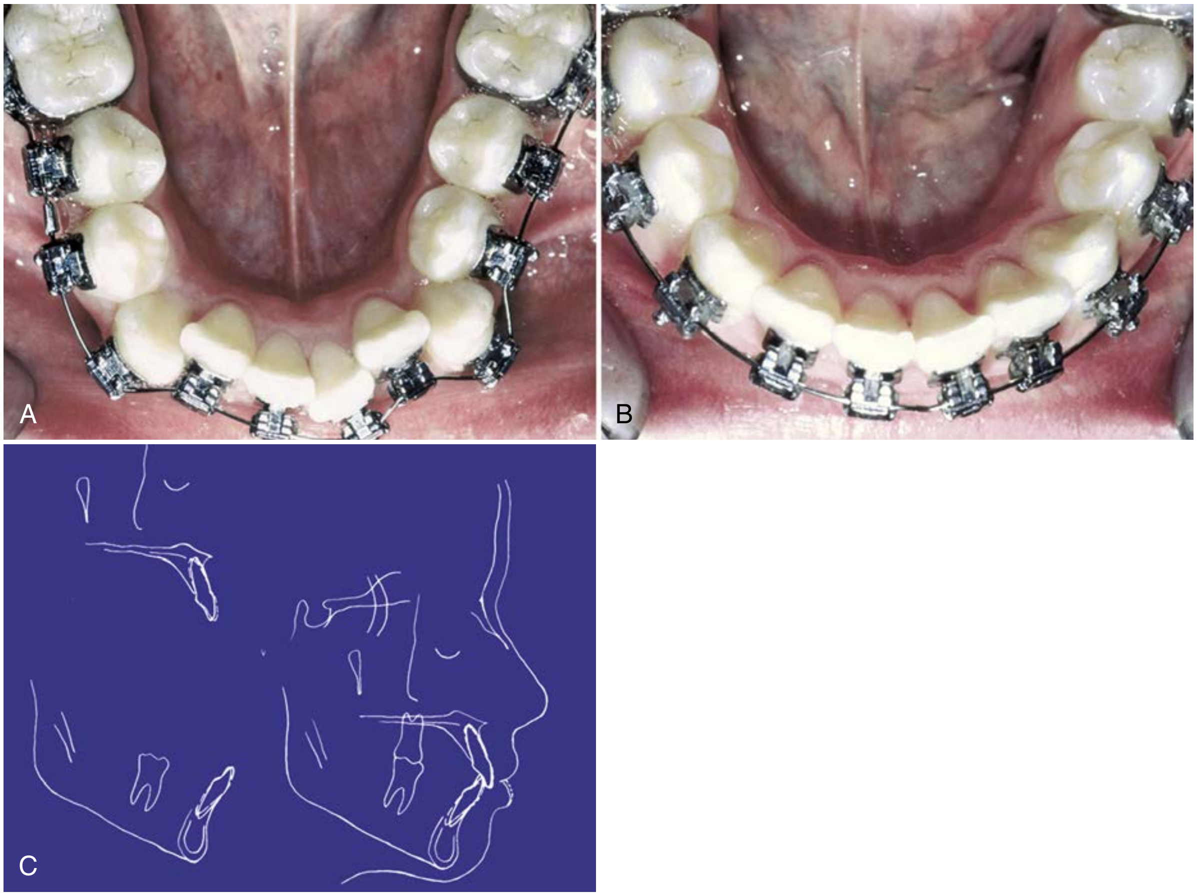

FIGURE 36-2 A, B, The action of the small round archwire (0.014 inch) in the large lumen of the Damon System tube appliance produces a Fränkel-type arch-widening effect in the posterior, usually with minimal change in the lower incisor position on the composite head film tracing (C).

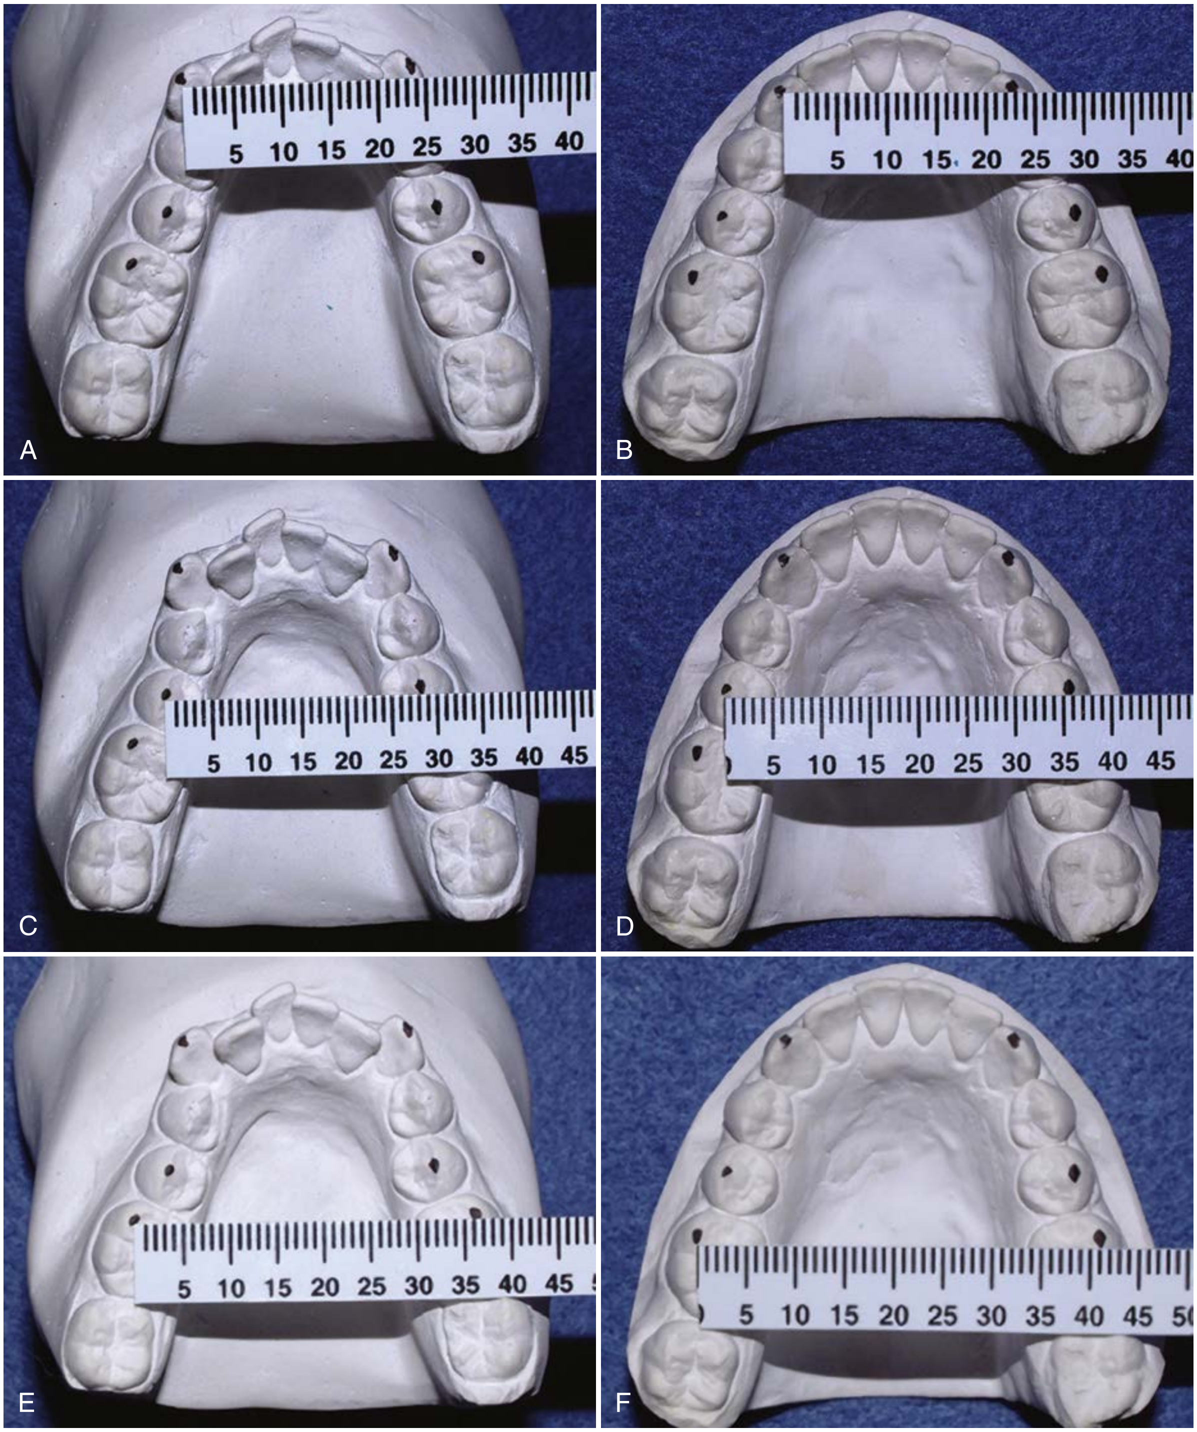

FIGURE 36-3 Lower canine width stays approximately the same if the initial nickel-titanium (Ni-Ti) archwire does not exceed 0.014 inch in size. This early case demonstrates a −1-mm change in canine width, an 8-mm change in first premolar width, and a 5-mm change in first molar width. **A,** Pretreatment. Canines: 23.5 mm. **B,** Posttreatment. Canines: 22.5 mm; change: −1 mm. **C,** Pretreatment. First premolars: 28 mm. **D,** Posttreatment. First premolars: 36 mm; change: 8 mm. **E,** Pretreatment. First molars: 36 mm. **F,** Posttreatment. First molars: 41 mm; change: 5 mm.

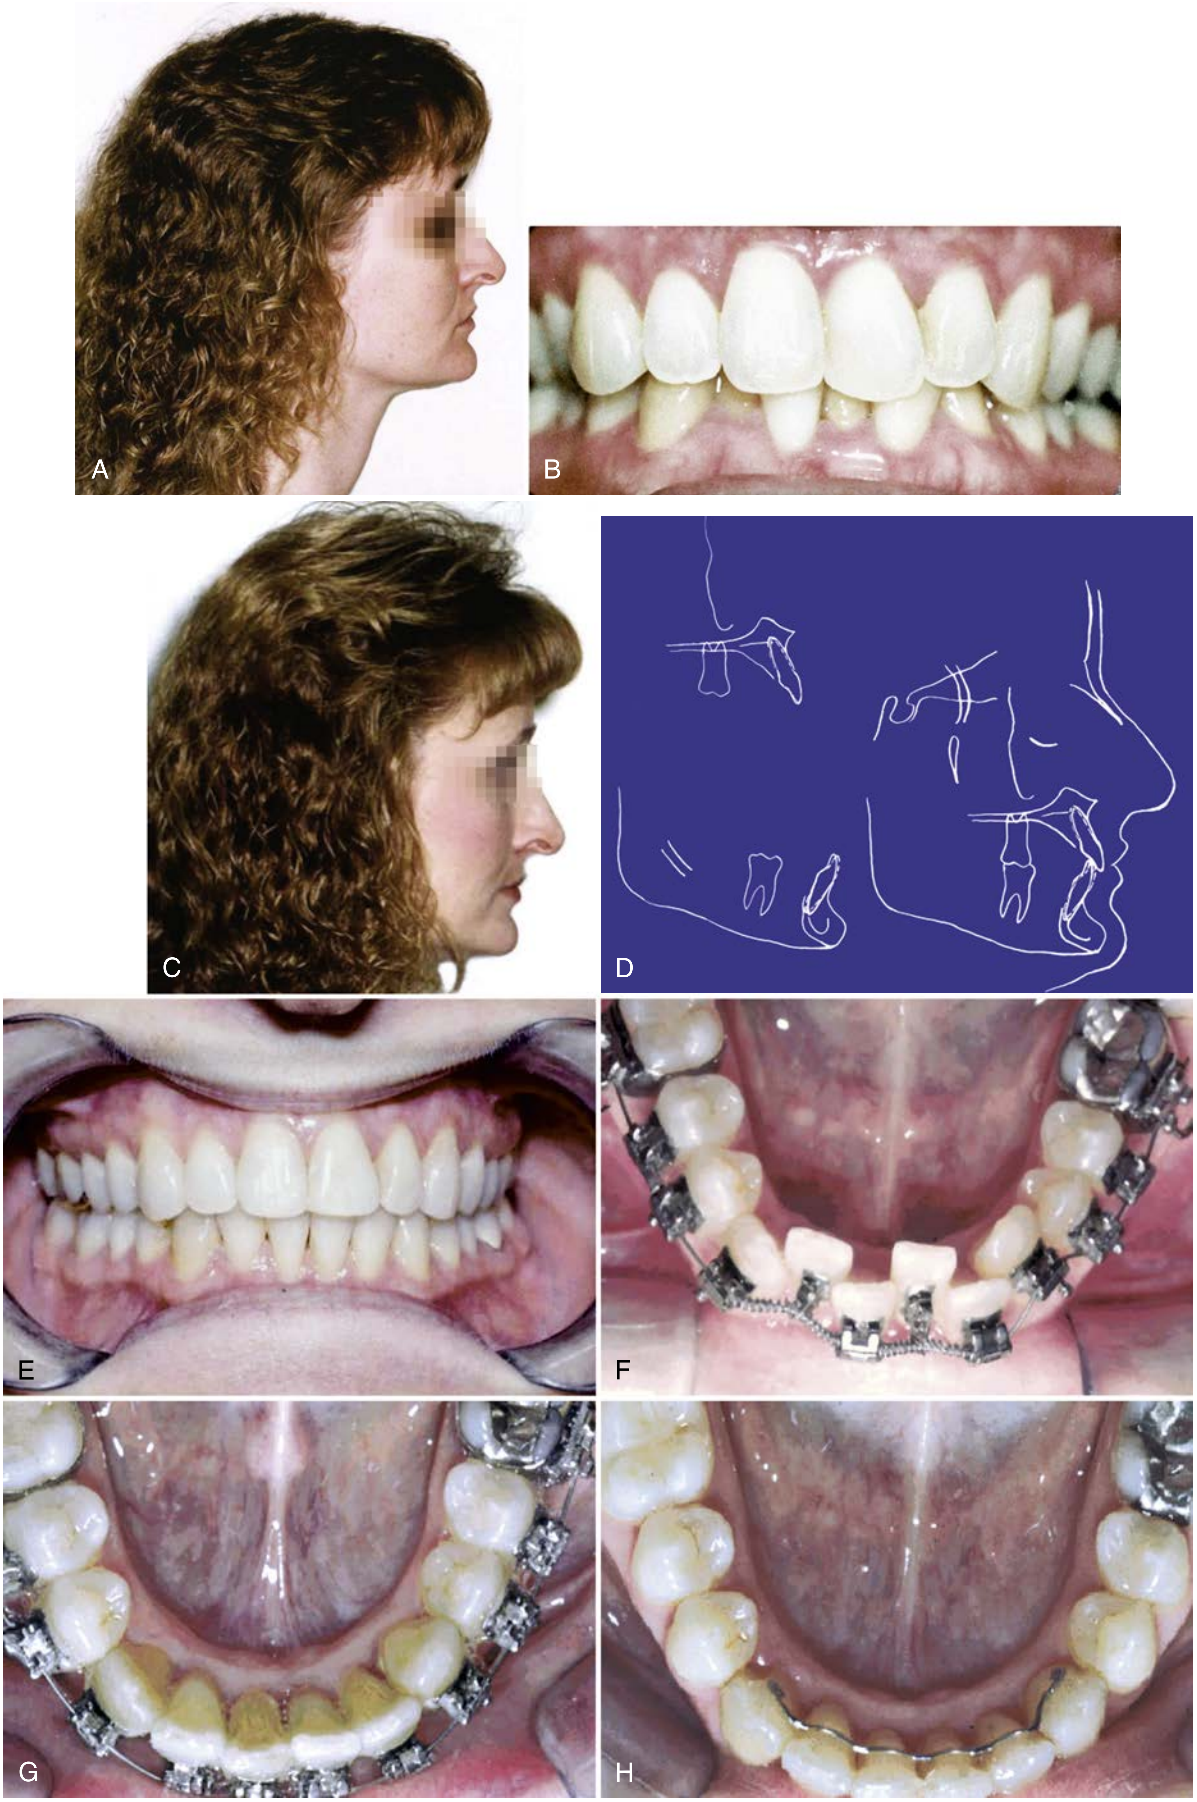

FIGURE 36-4 The lip bumper effect of the orbicularis oris and mentalis muscles precludes dumping of the incisors. **A, B,** Pretreatment records. **C-E,** Posttreatment records. **F,** Pretreatment lower arch. **G,** Third appointment after 3½ months of treatment. **H,** Retention record at 3½ years.

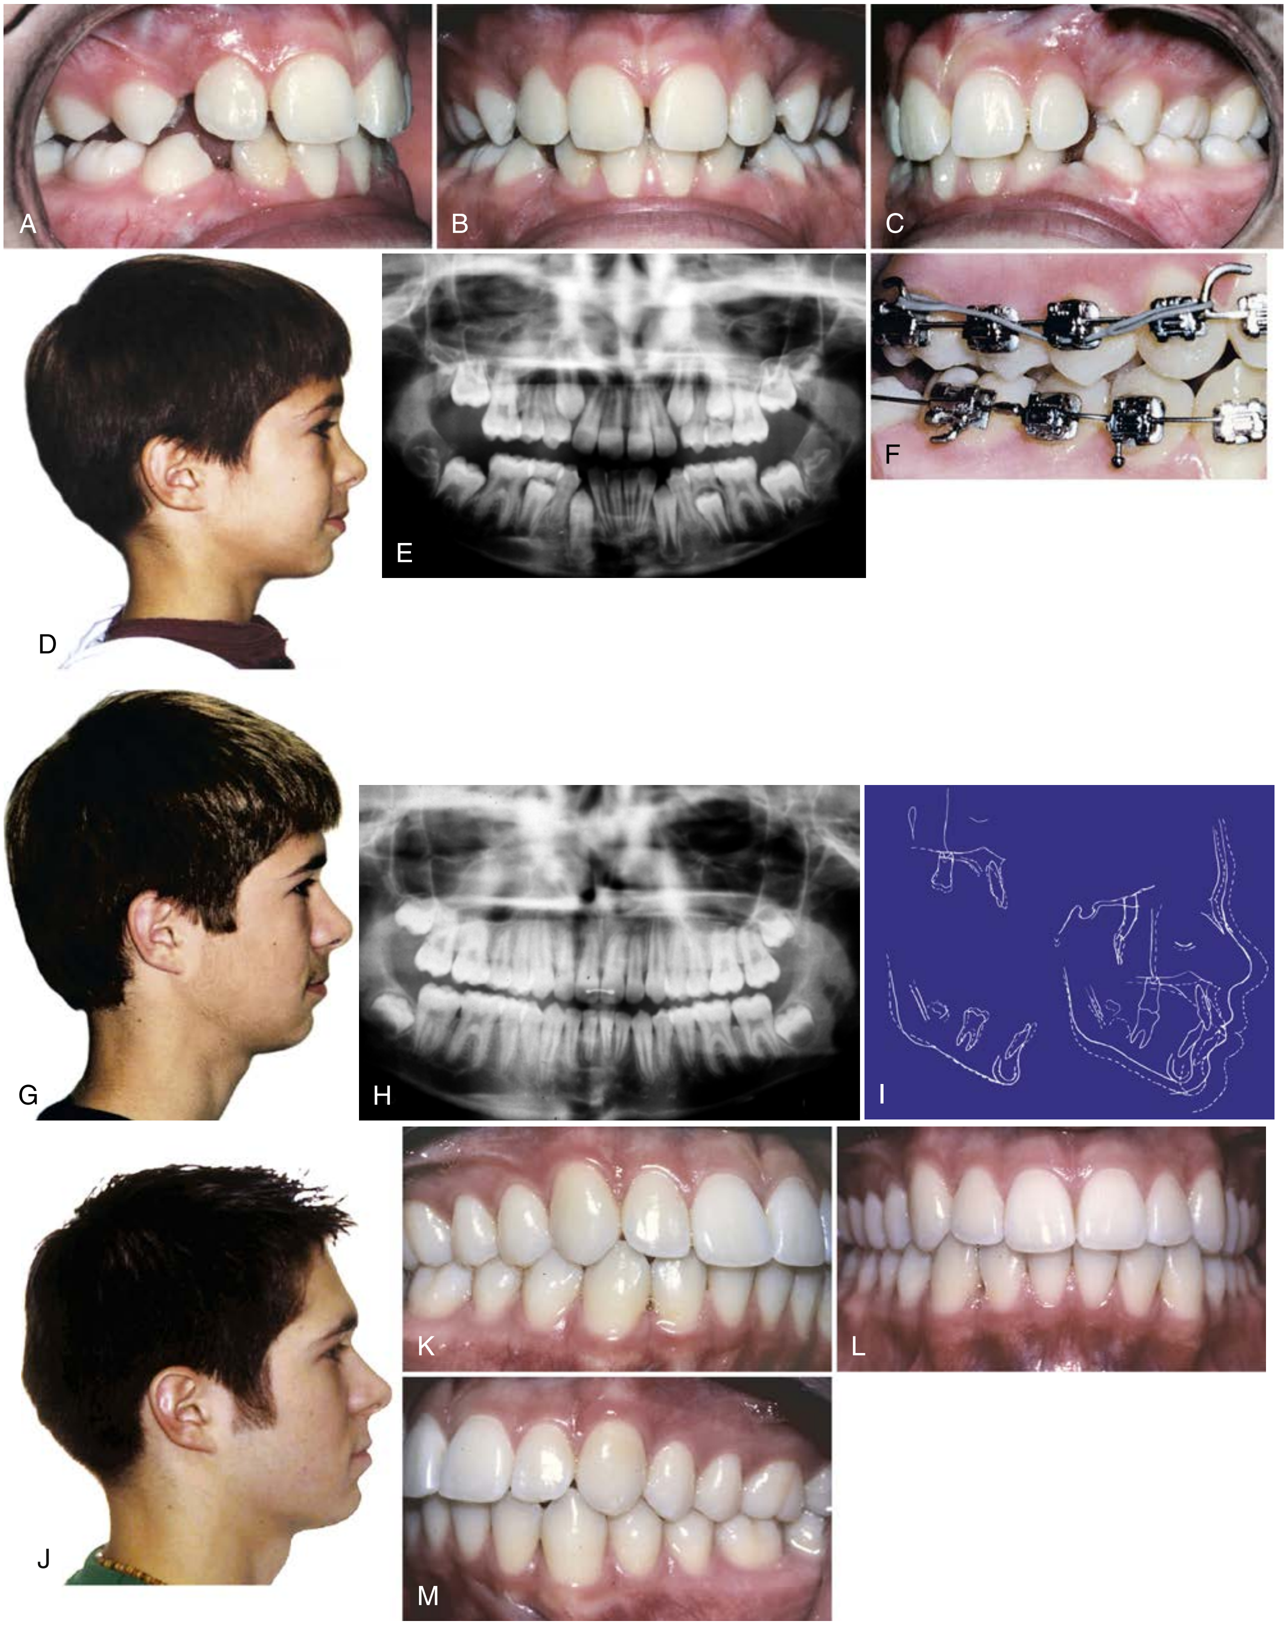

FIGURE 36-5 In cases treated with nonextraction, as the arch widens in the posterior, the tongue lifts and moves forward, creating a new force equilibrium between it and the lips and muscles of the face. **A-E,** Pretreatment. **F,** Tongue responds to the change in the posterior arch width and lifts into new position, often creating a posterior open bite. **G-I,** Posttreatment. **J-M,** Results after 4 years and 3 months in retention with no retainer wear for the last 2 years.

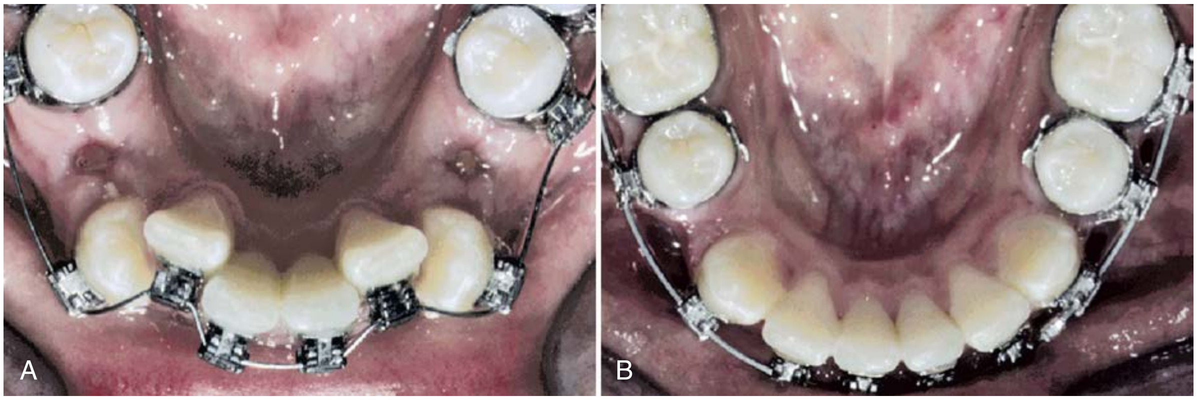

FIGURE 36-6 Bimaxillary protrusive extraction case. Treatment mechanics were greatly simplified with the lip bumper or headgear effect of the facial muscles minimizing the demand on posterior anchorage. As the crowded teeth aligned, they took the path of least resistance, which was into the extraction space. **A,** Pretreatment. **B,** At 6 months, 2 weeks.

CASE STUDY 36-1 Achieving Facial Harmony with Facially Driven Treatment Planning

Case 1 (CB) demonstrates a good prospect for this method of treatment planning, which provides expanded options for extremely low-force mechanics. CB exhibits a Class I face (Class II dentally on the right) with severe crowding in both arches and a unilateral posterior crossbite. His canines were totally blocked and had erupted labially to the lateral incisors in both arches with minimal bone and thin labial tissue (Fig. 36-7). The upper second premolars were erupting toward the palate. CB resembles his father, who is tall with a strong nose and chin, so one can assume that his well-proportioned nose and chin buttons will dramatically change as his face matures. He lacks facial support laterally; his midface is somewhat concave with an obtuse nasolabial angle. Along with a thinning of the lips, such common facial traits are prevalent in patients with collapsed and crowded dental arches.

The treatment objectives were as follows:

1. Gain maxillary and mandibular arch length to achieve facial balance with a positive impact on patient profile.
2. Establish upper and lower incisor position to provide lip support.
3. Establish maxillary and mandibular posterior arch width to support midface.
4. Establish ideal maxillary lip-to-tooth relationship.
5. Design treatment mechanics to eliminate the need for high-force rapid palatal expansion.
6. With low-force mechanics working with the orofacial muscle complex, bone, and tissue, establish a physiologically determined tooth position.

Conventional treatment planning would suggest that four first premolars should be extracted, and early in the author's career, the extractions would have been done without thinking about the long-term impact on this young man's profile. The long-term result of many such treatment plans produced flat or dished-in faces. In this case, evaluating where this profile could be at 30 years of age is absolutely critical. Even with extractions, a lower bonded retainer would still have been necessary to maintain lower incisor position over the long term. If lower bonded retainers are required for stability, then why not treat the face using light-force archwires in a passive tube system to gain arch length, especially when one can do so with far less trauma than higher force extraction therapy?

Box 36-1 outlines the treatment sequence of the case. Special torques were selected for this case: +7 degrees for the upper central incisors and +3 degrees for the upper lateral incisors. The torque used on the lower central incisors and lateral incisors was −6 degrees. Before beginning orthodontic treatment, the author prescribed that the patient have his primary second molars extracted. Because of the severe labial position of the canines, extraction was necessary to gain space immediately; consequently, the author began treatment in the maxilla with a rectangular wire (0.014- × 0.025-inch Ni-Ti Align SE) with medium-light Ni-Ti springs activated 1.5 to 2.0 times the width of a bracket (Fig. 36-8). Beginning treatment with a rectangular Ni-Ti wire is not a recommended treatment protocol for Damon System mechanics; but, in this case, the upper anterior teeth were well aligned and the canines were rapidly erupting through the cortical plate. The author needed to apply the gentle space-opening mechanism of Ni-Ti coil springs from the four anterior teeth to the molars to gain arch length and transverse arch width, making room for the canines to descend into their normal position. The protocol mandates a 0.014-inch Ni-Ti archwire as the initial archwire; however, because of the interbracket distance and the need to engage a Ni-Ti coil spring, the case required the stability of a rectangular wire. As the space became available, the canines came down naturally and were not bracketed until they were well-positioned in the archform. A mandibular 0.014-inch Ni-Ti Align SE sectional archwire was placed in the more crowded lower arch only lateral to lateral incisor because, with a span so great, the archwire would have disengaged had the wire engaged the first molars (Fig. 36-9 to Fig. 36-11; see also Fig. 36-8).

Given the opportunity, this case should have been started long before the canines erupted through the tissue; however, it does provide an excellent example of why orthodontists should design treatment mechanics that do not overpower the biologic system. At the beginning of treatment, the canines are labial to the lateral incisors in both arches. With conventional mechanics, the challenge is gaining room for them to be included in the arch without negatively affecting the lateral roots. With light-force tube mechanics, the orbicularis oris and mentalis muscles minimize the anterior flaring of the incisors but also encourage the distal positioning of the canines as space is gained in the arch with posterior adaptation. Using this treatment protocol for 8 years, the author has not observed a negative impact on the roots of the lateral incisors.

The Damon System treated this patient to a dentally and facially pleasing result without extractions or other high-force mechanics (Fig. 36-12). One should think how differently this 18-year-old's profile, and indeed his entire face, would have looked had four premolars been removed. Figure 36-13 tracks the maturation of the profile of this patient from 13 years, 4 months to 20 years, 8 months of age, clearly demonstrating how well this system served him in precluding extraction therapy.

Years after this case was completed, the author decided that taking CT scans of patients after treatment would be helpful in demonstrating the health of the bony architecture when treated with low-force tube mechanics. Figures 36-14 and 36-15 compare plaster models of the upper and lower arches taken initially and on the day of debonding with CT scans taken 5 or more years after treatment. Without high-force rapid palatal

CASE STUDY 36-1 Achieving Facial Harmony with Facially Driven Treatment Planning—cont'd

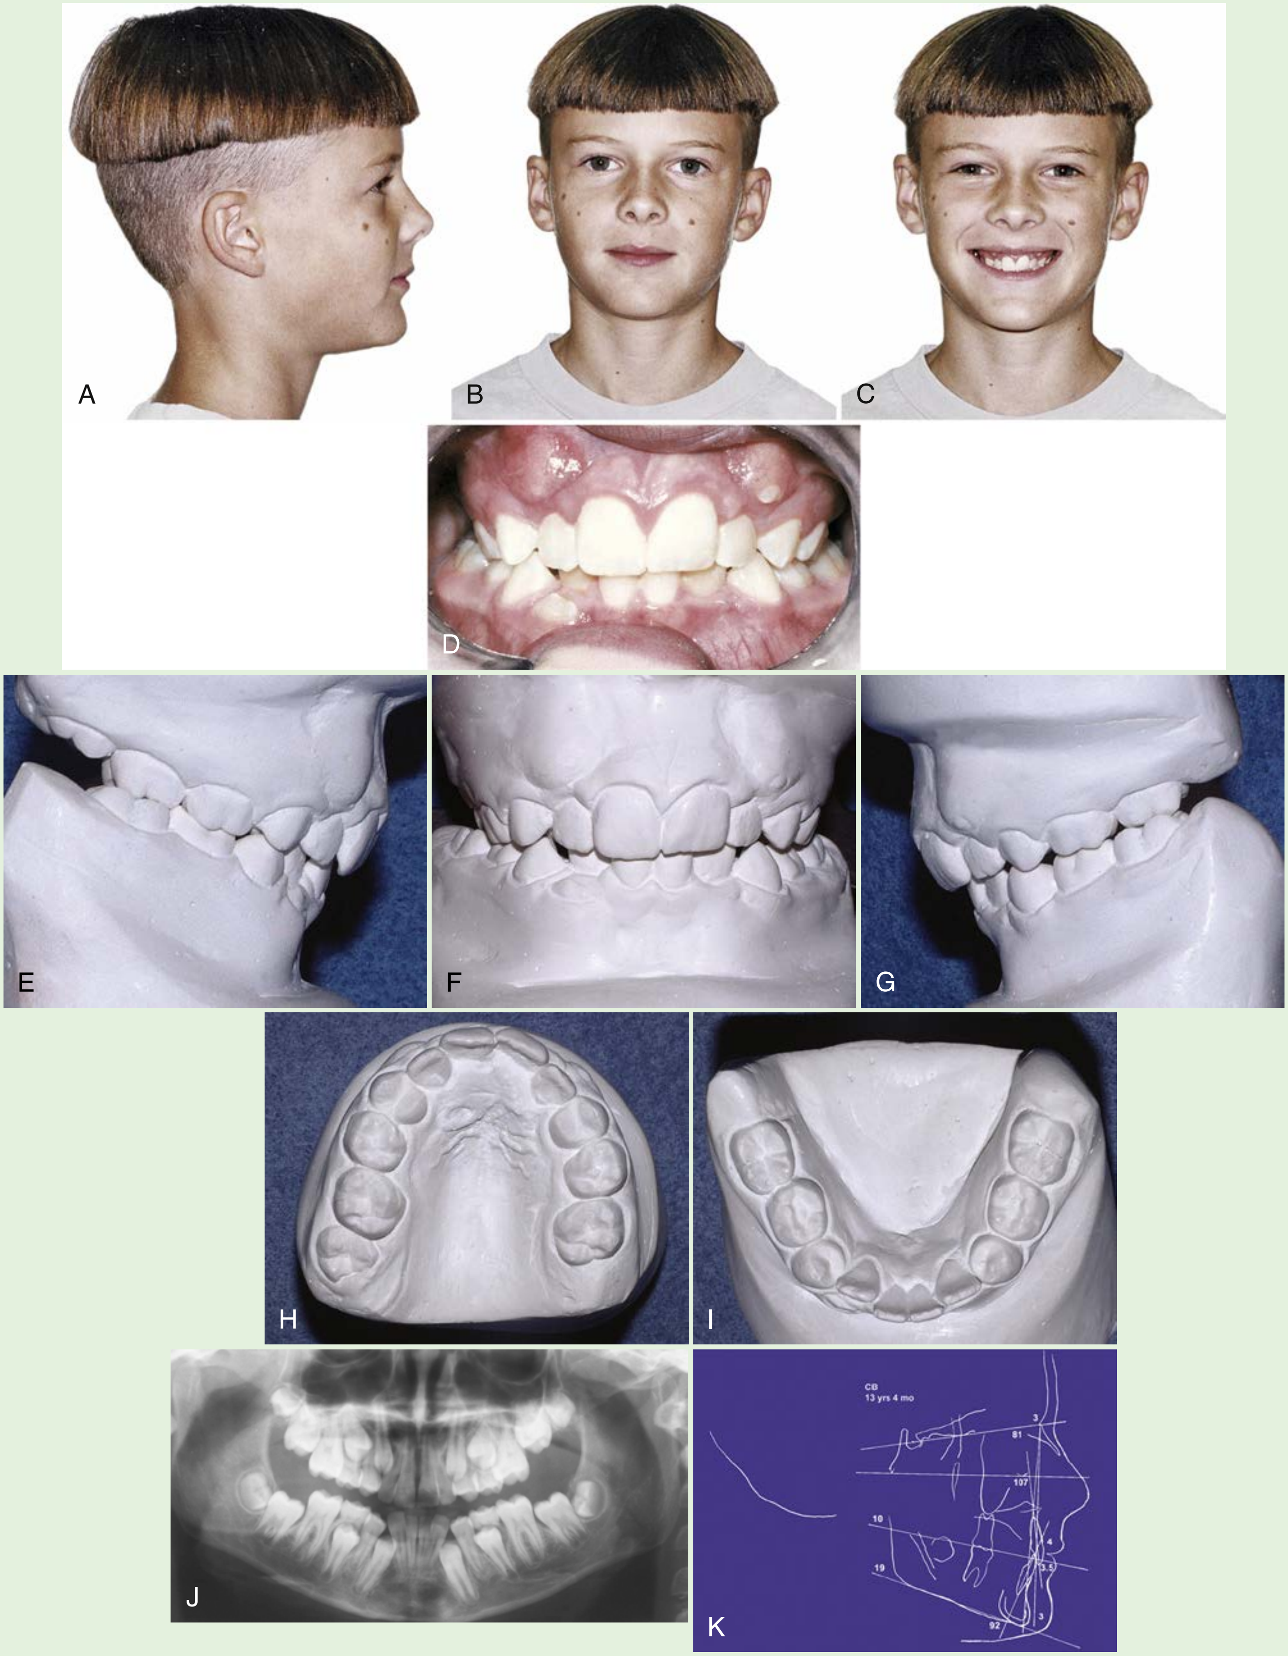

FIGURE 36-7 **A-K,** Pretreatment records for case 1 (CB, age 13 years, 6 months). Diagnosis: Class I face (Class II dentally on the right) with severe crowding in both arches and a unilateral posterior crossbite. The canines are totally blocked to the labial of the lateral incisors in both arches with thin bone and tissue surrounding them. The upper second premolars are erupting toward the palate. CB laterally lacks facial support; his midface is somewhat concave with an obtuse nasolabial angle.

Continued

CASE STUDY 36-1 Achieving Facial Harmony with Facially Driven Treatment Planning—cont'd

BOX 36-1 Case 1 (CB) Treatment Sequence

First appointment: Banded maxillary and mandibular first molars. Bonded central and lateral incisors (see Fig. 36-8). Because of the severe labial position of the canines, it was necessary to gain space, therefore began treatment with a maxillary rectangular wire (0.014- × 0.025-inch Ni-Ti Align SE) with medium-light Ni-Ti springs activated 1.5 to 2.0 times the width of a bracket. Placed mandibular 0.014-inch Ni-Ti Align SE sectional archwire.

Second appointment at 2 months, 1 week: Placed maxillary and mandibular 0.016- × 0.025-inch Ni-Ti Align SE. Activated Ni-Ti springs 1.5 width of the bracket.

Third appointment at 4 months, 1 week: Checked only the status (see Fig. 36-9).

Fourth appointment at 6 months, 1 week: Activated the springs.

Fifth appointment at 8 months: Placed maxillary and mandibular 0.019- × 0.025-inch stainless steel arch wire (see Fig. 36-10). Took a panoramic radiograph to evaluate the position of erupting permanent teeth.

Sixth appointment at 10 months, 2 weeks: Adjusted the maxillary archwire.

Seventh appointment at 12 months, 2 weeks: Bonded maxillary canines and first and second premolars. Placed continuous 0.014-inch Ni-Ti Align SE in the maxillary arch.

Eighth appointment at 14 months, 3 weeks: Repositioned maxillary left lateral. Waiting on the eruption of the permanent teeth. Patient did not keep appointments for the next 5 months.

Ninth appointment at 19 months, 3 weeks: Bonded mandibular canines and first and second premolars. Placed continuous mandibular 0.014-inch Ni-Ti Align SE. Placed maxillary 0.016- × 0.025-inch Ni-Ti Align SE.

Tenth appointment at 22 months, 1 week: Placed maxillary 0.019- × 0.025-inch stainless steel posted archwire. Placed mandibular 0.016- × 0.025-inch Ni-Ti Align SE. Took head film.

Eleventh appointment at 24 months, 3 weeks: Took panoramic radiograph to evaluate root position (see Fig. 36-11). Adjusted maxillary archwire.

Twelfth appointment (at 26 months, 2 weeks): Bonded mandibular second molars. Placed 0.016-inch Ni-Ti Align SE overlay to engage mandibular second molars.

Thirteenth appointment at 29 months: Bonded upper second molars. Placed maxillary 0.016-inch Ni-Ti SE overlay. Placed crimpable hooks on 0.016- × 0.025-inch Ni-Ti Align SE. Started full-time bilateral V-elastics and anterior trapezoid elastics.

Fourteenth appointment at 30 months, 3 weeks: Adjusted maxillary archwire. Placed mandibular 0.016- × 0.025-inch posted stainless steel archwire in lower arch because additional play between archwire and bracket slot was needed for settling. Continued bilateral V-elastics full time.

Fifteenth appointment at 32 months, 1 week: Adjusted maxillary and mandibular archwires. Continued V-elastics full time.

Sixteenth appointment at 33 months, 2 weeks: Debonded both arches, and placed retention wires. Bonded 0.016- × 0.022-inch Bond-a-Braid braided wire to the maxillary arch lateral to lateral incisor. Placed 0.026-inch round stainless steel wire on the mandibular arch canine to canine, bonding only the canines (see Fig. 36-12). Prescribed upper and lower slipcover retainers for night wear only.

expansion, the maxillary first premolar width increased by 11 mm and the maxillary first molars increased by 14 mm with desired tipping. An estimation of the second premolar change is 12 to 13 mm. The lower first premolar width increased by 11 mm, and the lower first molar width increased by 5 mm. Canines had erupted high through the cortical plate in both arches and could not be measured.

The plaster models and the horizontal CT scans of the upper arch (Fig. 36-16) demonstrate that the majority of tooth movement occurred with minimal tipping, resulting in a well-shaped archform. Figure 36-17 demonstrates that the arch length gain was in the transverse and was achieved through bodily movement of teeth and desirable tipping of posterior teeth. In addition, the palatal anatomic improvement is also evident. Figure 36-18 shows vertical CT scans of the upper second premolars and upper second molars. All the vertical CT scans illustrate excellent tooth position and health of the surrounding bone structure that resulted from bodily tooth movement without high-force rapid palatal expansion. Moreover, the scans illustrate the delicacy of the bony architecture in this area and should challenge all clinicians to consider lowering forces and using an alternative to rapid palatal expansion.

Orthodontists can make a number of interesting observations from the CT scans. The vertical CT scan of the lower second molar (Fig. 36-19) was eye opening for the author. Before using low-force tube mechanics, the author had always assumed that in trying to gain lower arch length, conventional mechanics caused the second molars to erupt lingually; however, in looking at the CT scans, the author came to another conclusion. In crowded cases, the tongue is more passive than normal and typically does not lift or function into the palate. In swallowing at least 1000 times a day and articulating sounds, a normally functioning tongue continually moves up and down in the palate, thus shaping the architecture of the lingual cortical plate, especially in the lower second molar area. In a normal functioning case, the lingual cortical plate is more upright than in crowded cases where the tongue is passive, sitting low in the mouth; thus in such cases, the cortical plate is lingually inclined in the second molar area. The net result is that as the second molar erupts, its crown follows the path of least resistance between the buccal and lingual cortical plate, which usually results in a lingually tipped clinical crown. A second observation is that on nearly all CT scans taken, the apex of the lower second molar root is usually positioned within the lingual cortical plate. This observation supports the recommended treatment protocol of the system to cut the stainless steel working archwire between the first and second molars when applying Class II elastic mechanics. Because the apex of the second molar is sitting in cortical bone, which has low vascularity, orthodontists only need to engage it in cases of maximum anchorage. Ricketts spoke of the anchorage value present when tipping the lower roots against or into the buccal cortical plate.

The horizontal CT scan of the lower arch (Fig. 36-20) offers an important vantage point when considering orthodontic force. The bony contours on the labial, buccal, and lingual sides are demonstrated. Much of the tooth structure normally sits within the thin-layer, low-vascular cortical bone, which supports the concept of using extremely low forces. The scan lends support to the idea that in using low-force mechanics, cortical bone will follow tooth movement in all planes of space. The author believes that when orthodontists can simulate the forces of natural tooth movement—as orthodontists have done over the years with the Fränkel appliance—the body has an incredible ability to adapt. An interesting analogy is how the cortical plate adapts (Fig. 36-21) around a horizontally impacted tooth as it slowly develops. Figure 36-22 shows records taken after 5 years, 3 months in retention. Despite the fact that CB had not worn his retainers for more than 4 years, the dentition remained stable.

Use of Nonextraction Therapy Where Possible and Light-Force Mechanics

A second trend—toward nonextraction therapy—is an admirable orthodontic goal. The principle means of achieving nonextraction, however, negates another important biologically sound principle: that of using low-force orthodontic mechanics. Heretofore, other than the Fränkel and similar appliances that have proved difficult to apply and to clinically manage, the principal means of orthodontically gaining arch length were distalizing molars or using high-force rapid palatal expansion devices. Each of these methods has its drawbacks because the forces are high when one considers the fragile vascular architecture (illustrated later in Fig. 36-28). CBCT scans of the midface after rapid palatal expansion show wide ranging effects on skeletal and dental structures. Distalizing molars is also time consuming. Although Damon System practitioners are sometimes reluctant to relinquish their rapid palatal expanders, the author believes that their use has an unnecessarily detrimental effect on the biologic structure and function of the entire dentofacial system. Rather than causing patients to suffer the trauma of opening the palatal sutures, distalizing the molars, or extractions (and the subsequent closure of the extraction sites and adding treatment length), clinicians can now maintain many complete dentitions by using very light-force, high-tech archwires in passive tubes, thus gaining arch length.

FORCE MANAGEMENT

Achieving Extremely Light-Force Mechanics: A Passive Tube

The author has spent nearly 20 years carefully evaluating the rationale for his clinical mechanics. Early on, it became apparent that using a force system was not “biologically sensible.” To use a bracket system to move teeth along an archwire that was tightly tied and nearly locked the wire to the base of the bracket slot made little sense. To reach orthodontic goals, orthodontists are challenged to use forces that are consistent with biologically sound principles of tooth movement.

The author believed that an appliance capable of accommodating a biologically attuned system might best be developed by looking into the field of self-locking brackets. Orthodontic history indicates that, from its early years, clinicians perceived the advantages of engaging archwires in tubes rather than ligating them into brackets. One of the earliest tube systems, the twin-wire cap-and-channel appliance, possessed some of the attributes of current self-locking systems but was limited by hard-to-place caps and the absence of space-age wires, preadjusted slots, and modern mechanics. In 1966, the Snap Ring appliance was introduced (3M Unitek, Monrovia, CA). This appliance was not self-locking in today’s sense of the term, but it simulated the concept.[2] A staple applicator attached a metal C-ring that locked over the outer portion of a round bracket. The system was limited by the large bracket size and the same shortcomings of the earlier cap-and-channel system.

A later example was the Edgelok bracket (Ormco Corporation, Orange, CA), which was introduced in the late 1960s (Fig. 36-23). Craig Andreiko, director of research and development at Ormco, described the bracket as the “first true self-ligating tube-type appliance.” He went on to explain that, “It was comfortable, had a positive-seating mechanism that formed the facial wall that was easy to open and close. It had the misfortune of being introduced around the same time as

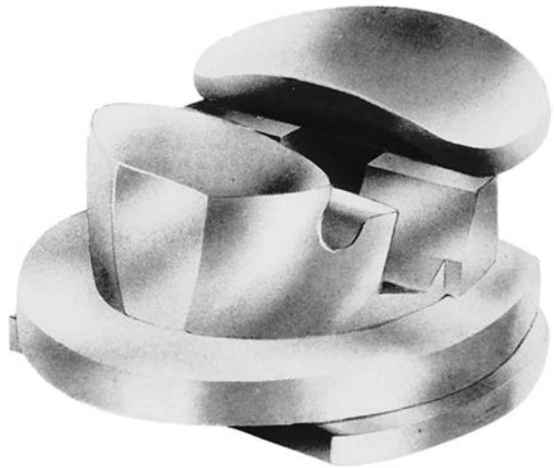

FIGURE 36-23 The Ormco Edgelok self-ligating bracket was introduced in the late 1960s.

the StraightWire appliance from ‘A’ Company. It also suffered from the prevailing edgewise treatment sentiment of the time that dictated an archwire selection and timing that stifled the effectiveness of even the more resilient and efficient archwires that were becoming available; nevertheless, it enjoyed widespread usage for a number of years, waning as preadjusted appliances took hold in the marketplace.”[3]

Another major advancement of that era was the SPEED appliance (Strite Industries, Cambridge, Canada), an active self-ligating appliance. The use of the SPEED appliance has been shown to reduce archwire changing chair time to as little as 25% of that of conventional twin brackets. The evolution of self-locking appliances greatly accelerated after 1995 with the introduction of active and passive appliances, including the Damon System.

Coinciding with the advances in self-locking appliances has been the evolution of the space-age nickel-titanium wires introduced by George Andreasen and the University of Iowa in cooperation with 3M Unitek. Although the profession widely recognized this development as a landmark advance in providing appropriate, light, continuous orthodontic force, it has been slow to realize its full potential. Ray Morrow, former 3M Unitek research and development project manager for Nitinol wire, related the early problems with usage of the archwires that are analogous with today’s failures to take full advantage of their remarkable potential: “Initially, just as they were accustomed to using stainless steel archwires, many clinicians tried to place bends in the wires, so many complaints were received about breakage from what actually was the result of improper usage of the early, somewhat brittle wires. In response, Unitek altered its manufacturing process in order to produce less elastic wires that permitted more bending without breaking. It was some time before proper usage of the wires ended the complaints, even as wires with greater elasticity and resistance to bending were introduced by Unitek and, later, by other companies.”[4]

The author has included this bit of history because, even today, the ultimate clinical benefits attainable with the remarkable space-age wires are being severely limited. Steel and elastomeric ligations are primary causes of this problem because they create binding and friction; active self-locking appliances provide a significant improvement but still exert facial-side pressure in many phases of treatment that limit the freedom of

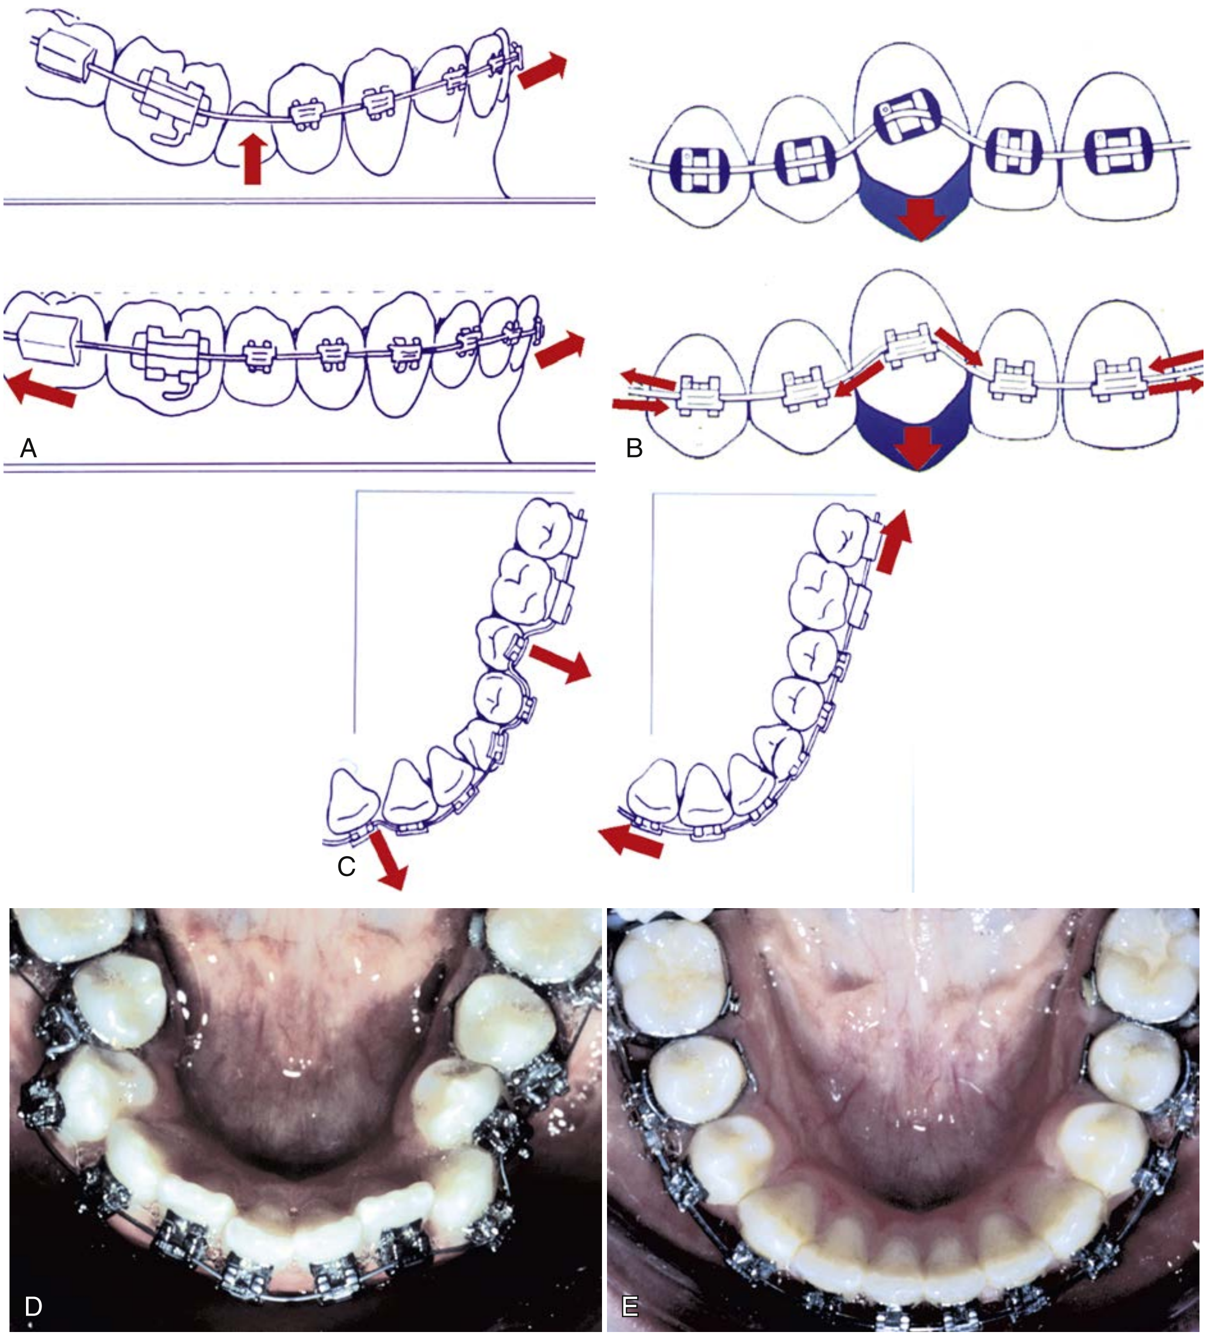

FIGURE 36-24 Sliding mechanics is involved with (A) leveling the arch, (B) aligning high canines, (C) correcting tooth rotations, and (D, E) changing archform.

the archwire to perform. Maximizing treatment results requires a passive self-locking appliance (tube), combined with careful selection of archwires (allowing plenty of play in early treatment and in midtreatment) and timing (allowing the wires to work and fully express their potential). The Damon System meets these demands to reach the optimal force range that stimulates cellular activity without occluding blood flow in the periodontium.

A Look at Sliding Mechanics

Many types of space-closure mechanics that require sliding the brackets along the wire as they start to level and align have been used for years, so achieving space closure with the Damon tube is easy for clinicians to visualize and accept. Over the past 30 years, clinicians have moved away from starting cases with multiloop stainless steel archwires in favor of using high-tech continuous wires free of any loops or bends. For teeth to align in the early phases of treatment, sliding mechanics must take place. Leveling the arch, aligning high canines, correcting tooth rotations, and changing archform (Fig. 36-24) are good examples of the use of sliding mechanics. Orthodontists have accepted and used tubes on molars for many years with great success. Passive self-ligation gives the clinician the opportunity to have a tube on every tooth, enhancing the performance of low-force high-tech archwires with low-friction sliding mechanics.

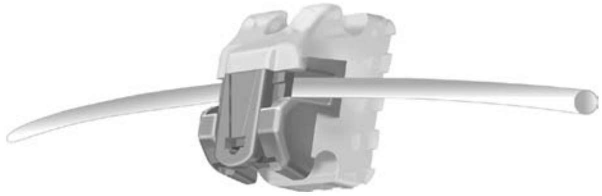

FIGURE 36-25 The passive Damon System 3 tube and bracket from Ormco.

The Damon System (Fig. 36-25) has been developed to align each phase of treatment with these natural force systems of normal growth and development. It became apparent that the application of biologically appropriate forces at each stage of treatment is essential for a long-term favorable outcome. As previously mentioned, the Damon appliance is commonly referred to as a bracket, but the term *tube* is a more useful description for this passive appliance. The appliance is a tube with tie-wings rather than a conventional bracket and, as such, has a static facial wall when the self-locking slide is closed. Vourdouris[5] compared the friction produced by passive and active conventional and self-locking brackets. With the use of a 0.019- × 0.025-inch stainless steel archwire, conventional brackets with elastomeric ties showed 400 (125.42 g/cm^2) to more than 600 (152.30 g/cm^2) times greater friction; steel ties showed 400 (97.07 g/cm^2) times greater friction; and active self-ligating brackets showed 216 (54.12 g/cm^2) times the friction of the *passive* self-ligating Damon tube (0.25 g/cm^2). With conventionally tied fixed appliances and active self-ligating brackets, the archwire is totally seated against the base of the bracket slot during some or all phases of treatment. The resulting binding and friction make closing spaces, leveling, archform changes, and closing of open bites, as well as the finishing, settling, and detailing of the occlusion, far more challenging. Passive self-ligation maintains play in the mechanical system during all stages of treatment. Figure 36-26 illustrates the degree of freedom of the initial round wire in a Damon tube. The small wire-to-lumen ratio is essential to leveling, aligning, and arch adaptation in a friction-free environment but *initially* limits rotational control. Rotational control is primarily achieved with the second, larger archwire, but the lack of friction and binding enables the overall correction to proceed faster. The short treatment times in the illustrative cases typify results obtained with consistent, biologically sensible forces. Figure 36-27 demonstrates that accurate tooth positioning, including rotational control, requires a full-depth archwire to fill the slot in a passive system. The play in the system when using 0.014- × 0.025-inch, 0.016- × 0.025-inch, 0.017- × 0.025-inch, and 0.019- × 0.025-inch rectangular wires in a 0.022-inch slot provides the needed rotational control and allows for 7 to 10 degrees of torque play in both directions with excellent rotational control later in the wire progression.

One must think of this new therapy as a complete system and not simply a new passive self-ligating bracket. With this new low-force, low-friction technology (tubes on each tooth instead of brackets with ligature ties and elastomerics), the clinician can apply very light forces that closely match normal biologic tooth-moving forces. *These properly attuned forces, not the clinician, allow the muscles of the face and tongue, bone, and soft tissue to determine the archform.*

An examination of what is known about the fragility of the vascular system and the bony architecture that support the dental arches is a necessary consideration for any orthodontic treatment.

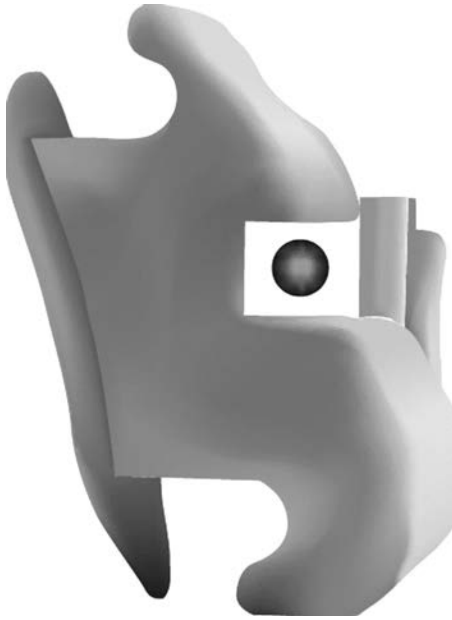

FIGURE 36-26 The small wire-to-lumen ratio of the Damon tube is essential to leveling, aligning, and arch adaptation in a friction-free environment.

FIGURE 36-27 With larger archwires, the Damon conduit provides excellent torque and rotational control without lodging the system.

Case for Using Extremely Light Forces in Passive Tubes

Using scanning electron microscopy and the corrosion resin cast method, Brazilian researchers M.C. Kronka, I. Watanabe, and M.C. Pereira da Silva[6] have published images of the angioarchitecture of the palatine gingival in young rabbits. These photographs clearly illustrate the fragility of the vascular architecture entering the alveolar bone on one side of the periodontal space (Fig. 36-28, *A*) and the lacelike network on the root of the tooth on the other side (Fig. 36-28, *B*). Figure 36-28, *C*, illustrates an even closer view of the vascular network of the

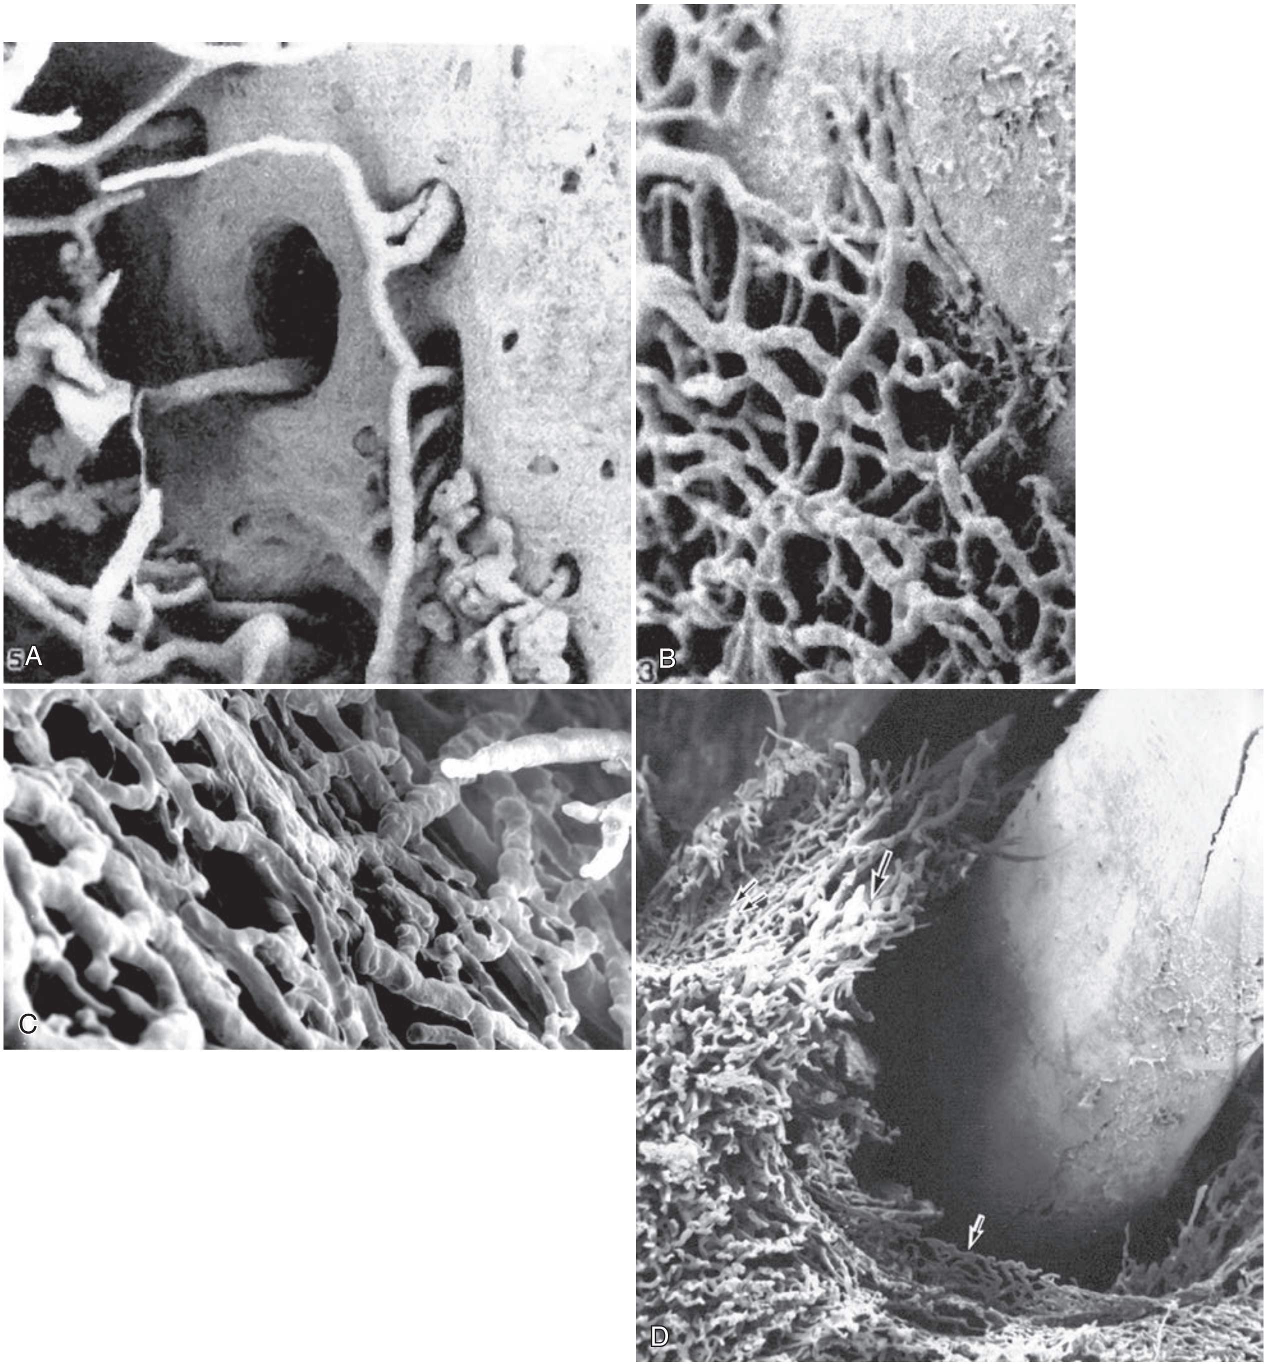

FIGURE 36-28 **A,** Lacelike vascular architecture of the tooth of a young rabbit reveals its fragility and susceptibility to destruction by high forces. **B,** Blood vessels are shown entering the alveolar bone. **C,** Image is a close up of the network. **D,** Tooth, sulcus, and vascular network are visualized.

periodontal ligament, with Figure 36-28, *D*, showing the tooth, sulcus, and vascular network. Such images should challenge all orthodontists to reevaluate their clinical force systems. Clinical mechanics and force systems are too often based on patient tolerance rather than on their impact on the periodontium and cellular biologic structure. Orthodontists continually ask the question, "What is the largest archwire I can get in?" If teeth do not move, then often orthodontists simply apply more force, yet they recognize the detrimental effects of excessive force on vascularity of the dentoalveolar complex. The cellular structure of orthodontically induced tooth movement is complex, and researchers are still challenged to unravel all the cellular mechanisms in play.

The modeling events of tooth movement are commonly referred to as areas of compression and tension within the periodontal ligament. Simply put, membranous bone growth is appositional with alveolar bone being resorbed on the moving front and new bone being laid down on the trailing side. Just more than 100 years ago, Carl Sandstedt[7] discovered the different responses of tissue to heavy and light orthodontic forces. He determined that on the tension side of the tooth, the responses to strong and weak orthodontic forces were similar. Bone deposition occurred with spicules forming along the direction of the strained periodontal fibers. The old bone was unchanged in appearance, whereas the new bone growth was easy to recognize. Responses on the pressure side of the tooth varied significantly, however, between light and heavy forces. No root resorption occurred with light forces because new bone was equally resorbed along the entire socket surface. The response to heavy forces was notably different, which led Sandstedt to coin the often-heard phrase "undermining resorption." The underlying bone was not resorbed in areas where the periodontal ligament was overcompressed. Rather, active resorption of bone and tooth root took place in the still vital areas surrounding the damaged membrane. Sandstedt's findings have been well recognized in academia and in the literature but have been widely ignored in the clinic for more than a century.

In 1932, A.M. Schwarz[8] found that very light forces of 20 to 26 g/cm^2, the same pressure in the capillaries of the periodontal ligaments, afforded safe and effective tooth movement. The obvious conclusion is to not exceed the outward pressure of the blood vessel if one does not wish to collapse it. Anything greater strangles the capillaries and generates necrotic tissue at the pressure sites.

Perhaps the greatest contributions to understanding the mechanisms of structural changes and tissue behavior caused by excessive orthodontic forces were produced by K. Reitan.[9-13] His publications from the late 1940s through the early 1970s revealed the strangulation of periodontal ligament capillaries, damage to the tissues, and resulting necrosis of the periodontal ligament and root resorption caused by conventional orthodontic forces.

In 1973, P. Rygh[14,15] summed up the consequences of the conventional orthodontics (high force) of the day: With conventional forces, this destructive process occurs at each appointment, and the wire is activated through a distance wider than the periodontal ligament space. At each wire change, teeth slam against the wall of the socket, and the intricate network of blood vessels is crushed yet again. Each time this trauma occurs, it takes weeks for the periodontal ligament to revascularize at the cellular level.

In 1992, Tuncay and colleagues[16] observed that oxygen is the trigger mechanism for remodeling the periodontium. If vascularity is interrupted in the periodontal space between bone and teeth, then oxygen is no longer available and cellular activity is slowed or stopped. In 1993, W.R. Proffit and H.W. Fields[17] advocated that, "Optimum force levels for orthodontic tooth movement should be just high enough to stimulate cellular activity without completely occluding blood vessels in the periodontal ligament." The author has named this threshold force the *biozone* or *optimal force zone*. Proffit[9] also stated, "If the applied force is great enough to totally occlude blood vessels and cut off the blood supply, a hyalinized avascular necrotic area is formed. This area must revascularize before teeth start to move."

Regarding Rygh's and Reitan's findings, Bob Borkowski[18] stated, "This healing time is, in essence, a big timeout in the progress of treatment. Understanding this phenomenon makes me wonder if this healing time isn't the reason why, in conventional mechanics, adult treatment takes longer than adolescent treatment." Borkowski postulated that this difference is due to children healing from their wounds faster than adults.

The issue of oxygen supply raises questions about what is happening with the use of light, high-tech archwires in a passive tube where play between the wire and the lumen size of the tubes is considerable. The response to very light, high-tech wire used in low-friction, passive tubes is different from the use of the same high-tech wires in conventionally ligated or active self-ligating appliances. Certainly the adaptation phenomenon is occurring at the cellular level, and perhaps this phenomenon has something to do with oxygen supply. At this stage, the phenomenon is not clear. What orthodontists can verify is that the response is similar to that seen in patients treated with the Fränkel appliance.

Patients such as CB (see Case Study 36-1) have always prompted the author to question the cause of crowding. Given the cause, orthodontists can better assess what methods to use to stimulate the best possible resolution. As in most such cases, the shape and size of the body of the mandible is normal, but the alveolar process is severely constricted. The author's opinion is that this condition often results from lips and muscles of the face being out of balance with the tongue. The tongue is passive or sitting too low in its cavity, and without the exertion of the strong outward force of the tongue on the arches, the muscles of the face dominate, thus constricting the lower arch and allowing the maxilla to collapse inward. Fränkel[19] capably demonstrated that keeping the buccal tissues away from the dental arches fosters a redistribution of forces between the lips and muscles of the face and the tongue, generating greater arch length. Fränkel used buccal shields to increase arch width. The absence of cheek forces enabled the tongue to generate buccal drift of posterior teeth. Long-term studies on patients undergoing treatment with the Fränkel appliance have proved the results to be stable.

The Damon System, when properly applied, provides patients with the physiologic improvements possible with the Fränkel appliance and other muscular imbalance corrective appliances, plus the precision finishing attainable with preadjusted edgewise appliances. Because form follows function, the author considers many malocclusions to be *functional abnormalities*. Light wires acting in an almost friction-free environment in the Damon tube appear to be able to correct the functional imbalance and allow the alveolar process to create a new, individualized archform. The author's explanation for this phenomenon is that the friction and binding of the archwire in conventionally ligated appliances (and *active* self-ligating appliances) preclude functional adaptation. Orthodontists recognize the power of sliding mechanics to close space, with buccal tubes being essential to this process. Sliding mechanics also offers the most efficient means of aligning and leveling teeth in the early phases of treatment. Clinicians often use edgewise wires to unravel and level malposed teeth. Minimal play exists between the archwire and the bracket slot, and the wire becomes bound up in a tightly ligated system. In a nearly friction-free environment with the appropriate amount of play between the archwires (a 0.014-inch round nickel-titanium wire is essential to this process) and the passive bracket tube, teeth begin to level and unravel, and the arch begins to widen in the transverse. Alan Bagden[20] suggests that this beginning adaptation "wakes up the tongue." This phenomenon allows the tongue to seek a higher level in the oral cavity, thus instigating a new force interplay among the tongue, cheeks, and lips. With this gentle force of a small round wire in large fixed passive tubes, transverse arch adaptation occurs similar to the Fränkel effect. Although the technique is too new to substantiate improved long-term stability, results to date have been encouraging. Apparently, moving teeth with high-tech archwires in passive self-locking tubes generates a healthy alveolar bone and periodontium support that is not as susceptible to relapse as the typical repositioning of the dentition with more traumatic forces.

After treating several thousand patients with this low-force tube system, the author noted the significant variation in the rate of tooth movement from patient to patient. In most patients the rapid rate of tooth movement with such light forces is impressive. Using high-force conventional mechanics for years, the author found the response among patients to be approximately the same, with the greatest variable being between adults and children. Now the slowest and most challenging cases are in those who have had previous extractions and conventional higher-force orthodontics. The alveolar bone appears to have been altered, which affects subsequent treatment planning and length of treatment.

COMPUTED TOMOGRAPHIC SCANS DEMONSTRATE HEALTHY BONE STRUCTURE AFTER TREATMENT WITH THE LOW-FORCE DAMON TUBE SYSTEM

Over the years, the author has observed that the kindest movers of teeth are normally functioning muscles of the face and tongue. Orthodontists have recognized the Fränkel effect in first-phase treatment using the 2 × 4 method (with fixed appliances only on the four anterior teeth and molars), which alters the impact of the facial musculature, allowing the premolars to move laterally. The author's experience has been that over several months, premolar width usually increases 6 to 8 mm with little tipping. This same type of bodily movement of teeth with extremely light, high-tech archwires in the passive Damon tube appliance has been verified on CT scans of patients who experienced posterior width change. The scans also document that the bone development tracked with the teeth movement and arch adaptation. Rather than using high-force expansion, this research suggests that trying to match this *natural force* adaptation with all clinical mechanics makes sense.

Until now, orthodontic research has been primarily limited to clinical observations and long-term retention studies, with conventional radiographs and periodontal findings serving as the evaluation technologies. With the technical advancements of three-dimensional CT scans for the midface, orthodontists now have the means to determine the posttreatment health of the alveolar bone. The author has spent hundreds of hours evaluating CT scans taken on 13 patients treated with low-force mechanics in a passive tube system where functional adaptation accommodated teeth in a crowded arch using nonextraction therapy. These findings are encouraging and should challenge clinicians everywhere to reevaluate their management of clinical forces and stimulate them to consider a paradigm shift of their treatment planning. These CT scans were taken on young and adult patients, from those just debonded to one patient in retention for longer than 5 years.

Most clinicians have believed that with clinical mechanics, at best, teeth can be tipped only in the transverse, not bodily moved as well. These CT scans conclusively show that alveolar bone can be altered and reshaped with low clinical forces. This low-force and passive tube technology and the clinical research that substantiates it call for changes in treatment planning and the mechanics of tooth movement. Other findings from the CT scans demonstrate how thin the alveolar bone is on the labial, buccal, and lingual aspects of the teeth that orthodontists are trying to move. These CT scans make it apparent that every effort should be made to take great care of the thin cortical plate. In viewing the scans of patients in long-term retention, the reader will note that the architecture and thickness of the alveolar bone appears to improve over time after low-force orthodontics. Recognizing that low-force orthodontics can have a *positive* impact on the periodontium is encouraging. The reason bone may regenerate in some areas of the mouth in periodontally challenged patients and not in others is not understood. The periodontist who conducted connective tissue grafts on patients during or after treatment with low-force and passive tube technology commented on observing an improved vascular environment. After having evaluated CT scans of several crowded cases in retention, the author recommends that orthodontists make every effort for early tooth guidance in children to keep permanent teeth from erupting through the labial, lingual, and buccal cortical plates. Obviously, teeth erupting in the center of the alveolar ridge usually have far improved bone on the labial and buccal aspects.

CASE PRESENTATIONS AND CLINICAL ANALYSES

The following cases graphically demonstrate how facial treatment planning should and can be the primary focus. The dentitions of these patients are obviously crowded. The dentitions beg the question, "Why are these patients so crowded?" Are the bones of the midface and body of the mandible smaller than normal, or has there been an adaptation of the alveolar process because of abnormal muscle forces affecting arch development? Most orthodontists have been trained to evaluate the patients only from head films. As mentioned in the case of CB, early in the author's career, extraction therapy would have been used to treat CB, despite the body of his mandible being exactly the same size as the author's, which is an exceedingly wide archform. To see that more and more orthodontists around the world realizing the impact that treatment decisions have on the maturing profile, for good or for ill, is exciting. With improvements in technique and technology, orthodontists now can plan and execute treatment by evaluating its long-term implications on profile (lateral view) and arch width and facial support (frontal view). In the author's estimation, designing treatment mechanics that *do not overpower the biologic system in any phase of treatment is critical*, and doing so requires the use of low-force archwires in a passive tube. In reviewing these case studies, the reader should note that great care has been given to using treatment forces that are "just high enough to stimulate cellular activity without overpowering the periodontium and orofacial muscular complex."[17] *If orthodontists maintain force levels in the optimal force zone, the alveolar bone and tissue can be moved with teeth*. With the Damon System, the art of clinical orthodontics is to match treatment mechanics with the natural low-force systems of the body and to learn how to read and react to how the alveolar process and muscles adapt.

CASE STUDY 36-2 Treatment with Nonextraction Therapy

Case 2 (AH) provides another example of how the transverse dimension and severe upper anterior crowding can be satisfactorily treated with simple low-force and tube mechanics. This case is a good example of facially driven treatment achieved by converting anterior crowding into posterior adaptation of bone, muscle, and soft tissues. Arch length gain is illustrated along with the correction of the Class II dentition. At 16 years, 5 months of age, AH had a Class II dental bilateral posterior crossbite and crowded maxillary arch. She was midface deficient but with a good profile and an aesthetically pleasing obtuse nasolabial angle.

The treatment objectives were as follows:

1. Gain maxillary arch width to support the midface.
2. Correct midface deficiency.
3. Maintain nasolabial angle while improving the midface.
4. Develop an ideal tooth-to-lip relationship.
5. Transpose the malpositioned upper right canine distolingually without damaging the root of the lateral directly lingual to the canine root.

Pretreatment records (Fig. 36-29) demonstrate the substantial Class II arch relationship and severely crowded maxillary dentition. Only low-force Damon System mechanics were used throughout treatment. No palatal expanders, distalizers, headgear, implants, lingual holding arches, or removable appliances were used. Using low-force mechanics, the result was far superior patient comfort throughout treatment and improved bone and tissue at the end of treatment.

Tom Pitts, a former member of Robert Ricketts' Bioprogressive Study Club, reported that in a study of the relationship between tooth-to-tooth gain in arch width and overall increase in arch length, Ricketts found specific

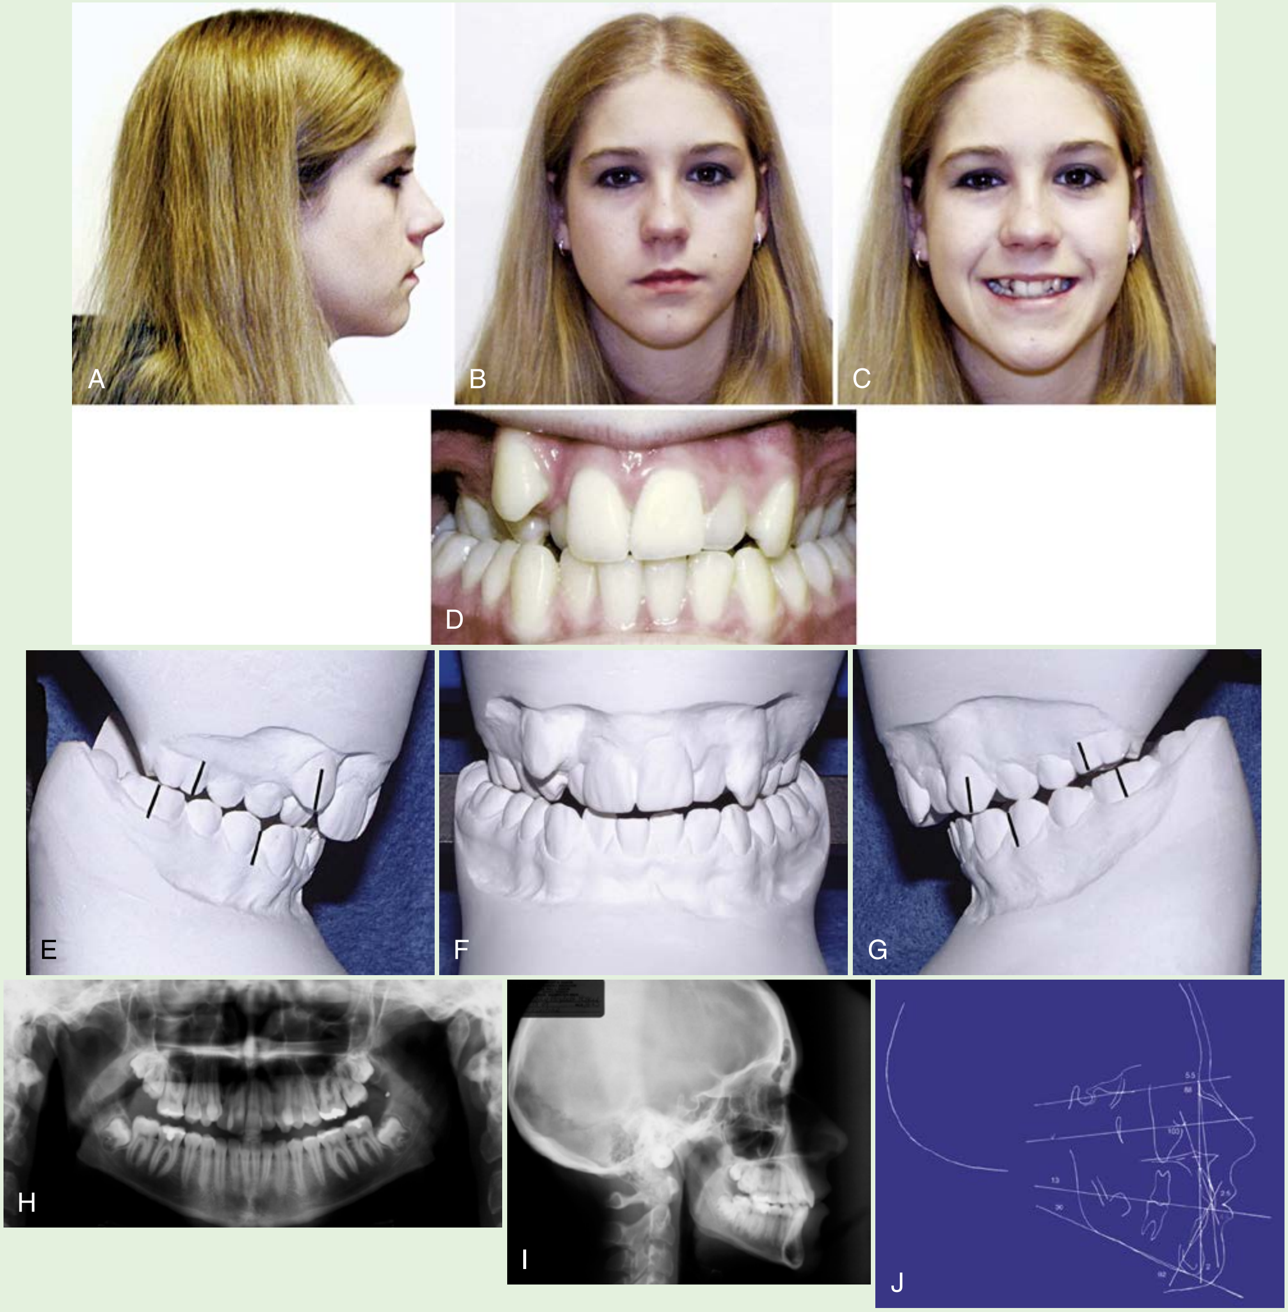

FIGURE 36-29 A-J, Pretreatment records for case 2 (AH, age 16 years, 5 months). Diagnosis: Class II with bilateral posterior crossbite and crowded maxillary arch and midface deficiency but good profile and obtuse nasolabial angle.

Continued

CASE STUDY 36-2 Treatment with Nonextraction Therapy—cont'd

ratios occurred with changing archform and orthodontic treatment.[21] This research indicates that a 1-mm gain in canine width, a 1.5-mm gain in first premolar width, a 2-mm gain in second premolar width, or a 4-mm gain in molar width each yields a 1-mm increase in arch length. The light-force Damon System maximizes the potential of each individual's anatomic and physiologic structure in delivering a natural archform. The system provides nature a second chance to correct inherent or habit-generated deficiencies. The crowding in this case indicates a tongue trapped low in the mouth and unable to provide the necessary facial thrust for normal maxillary arch formation (Fig. 36-30). The Damon System helps correct nature's muscle imbalances with gentle forces. The long intervals between appointments allow the light archwires to work to their full potential in the almost friction- and binding-free tubes.

Posttreatment records (Fig. 36-31) were taken after 22 months, 3 weeks of treatment in 11 appointments. Figure 36-32 shows that bodily tooth movement along with minimal corrective tipping created a 9- to 12-mm upper arch width adaptation and tremendous palatal change. The patient was happy to report that she could now breathe through her nose and sleep with her mouth closed. The intraoral photographs reveal healthy bone and tissue with significant alveolar improvement. Figure 36-33 compares the plaster models of the upper arches taken initially and the day of debonding with the CT scans taken 7 months after treatment. Initial and final comparisons of the plaster models clearly reveal the posterior arch widening, anterior unscrambling, and arch shape improvements. CT scans demonstrate healthy alveolar bone in all areas. Unfettered light wires worked to develop what nature and a trapped, underactive tongue failed to produce; that is, an appropriate archform for AH and a pleasing final result.

Archwires adapted to the initial and final upper archforms (Fig. 36-34) make apparent what happened to the anterior crowding. Adapting the final archwire to the initial archform demonstrates an arch length gain of 13 mm, yet the measurement distal of the first molars to the labial of the incisors at the beginning and end of treatment is only 1 mm, which explains why the existing attractive profile was maintained while the midface deficiency was improved. These measurements indicate that the anterior crowding was accommodated by transverse posterior adaptation. An observation in other patients is that a change in the posterior arch width of only 1 or 2 mm can have a favorable impact on the midface. The horizontal CT scans (Fig. 36-35) illustrate that the pleasant midface change is not simply a result of the expansion of the dental arch but the entire alveolar process high in the vestibule, which provides improved facial support.

Initial and final comparisons of the plaster models of the lower arch demonstrate the minimal change (0 to 2.5 mm) in posterior arch width (Fig. 36-36). The horizontal CT scan taken 7 months in retention (Fig. 36-37) demonstrates how the roots of the lower teeth sit in the cortical plate. Considering that the change in the lower arch width or anteroposterior tooth movement was small, it is interesting to note in the CT scans that so much of the tooth structure is sitting in cortical bone with low vascularity, again supporting Rygh's notion of low-force mechanics.

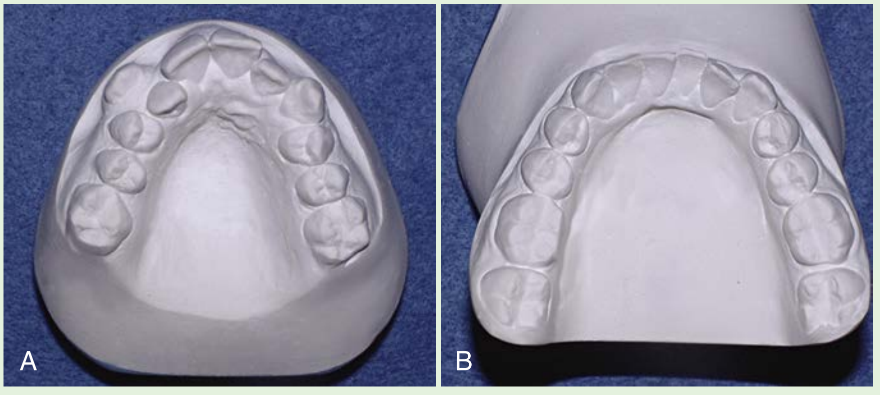

FIGURE 36-30 A, B, The trapped tongue is unable to normalize posterior maxillary arch width. The lower arch shape indicates low tongue posture.

CASE STUDY 36-2 **Treatment with Nonextraction Therapy—cont'd**

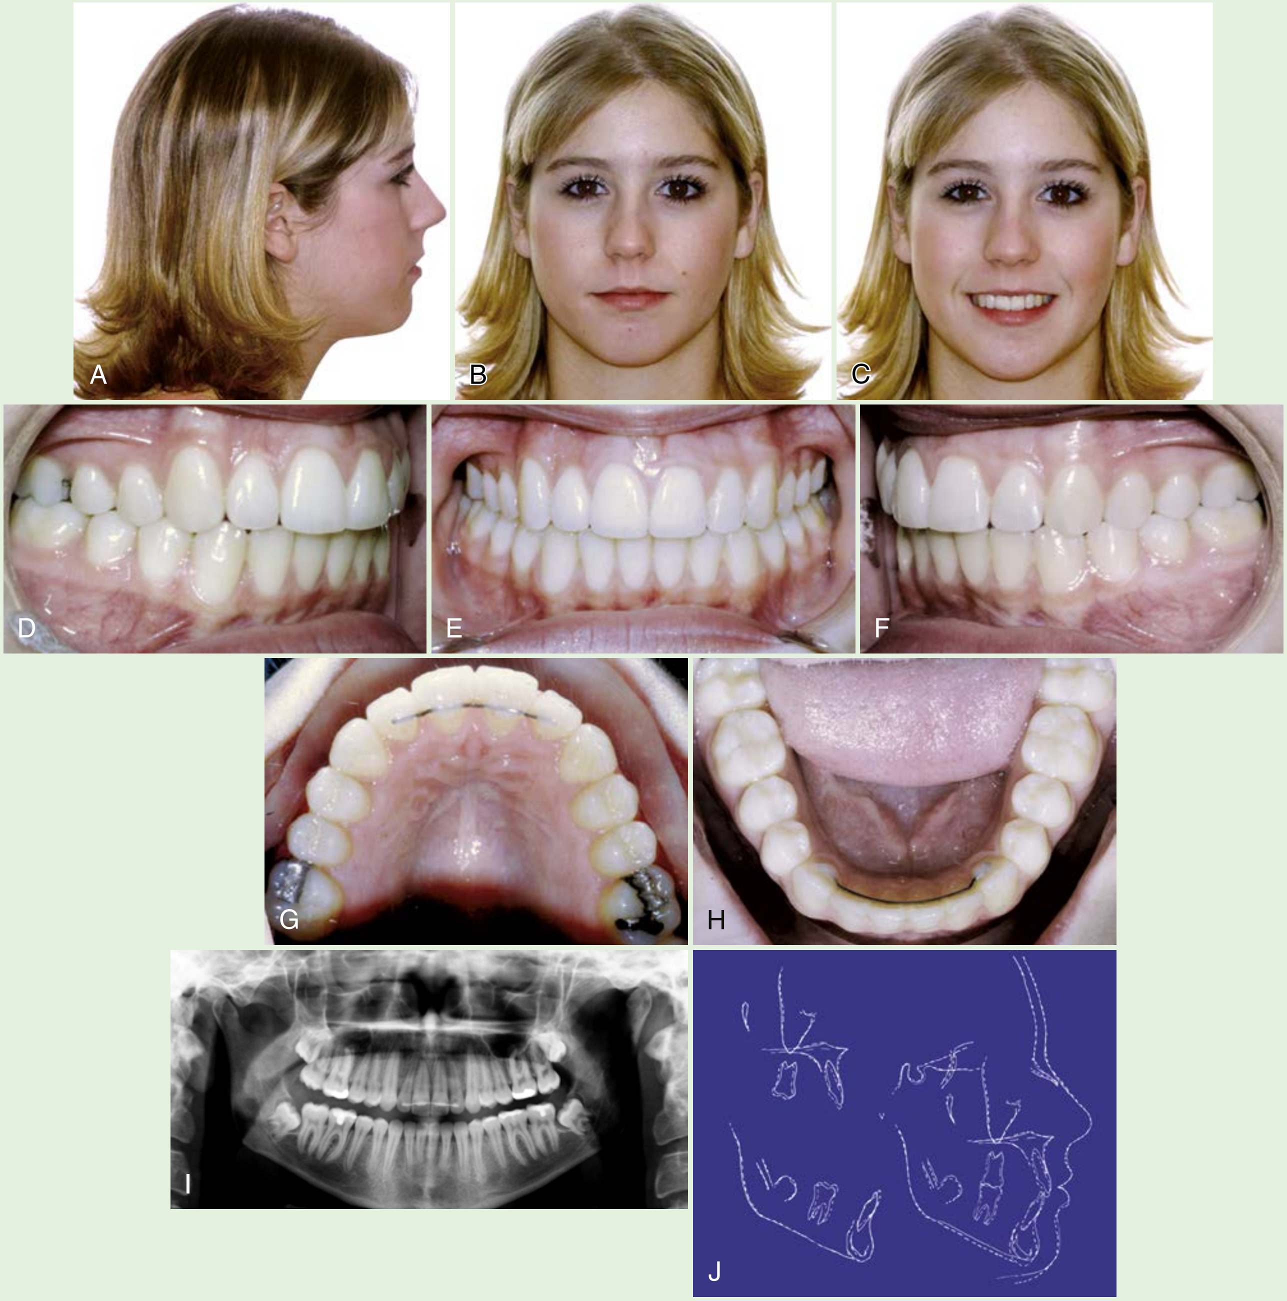

FIGURE 36-31 A-J, Posttreatment records of AH. Total treatment time: 22 months, 3 weeks with 11 appointments. Midfacial aesthetics improved while maintaining favorable profile. Minimal tipping with 9- to 12-mm upper posterior adaptation and improved tongue position are evident.

FIGURE 36-32 The pretreatment and posttreatment plaster models of AH demonstrate bodily tooth movement and tremendous palatal change with minimal corrective tipping that resulted in a significant improvement of articulation and easier breathing.

Canines: 27 mm; first premolars: 34 mm; second premolars: 40 mm; first molars: 46.5 mm. **B,** Posttreatment. Canines: 27 mm; first premolars: 36.5 mm; second premolars: 42 mm; first molars: 47 mm.

CASE STUDY 36-2 Treatment with Nonextraction Therapy—cont'd

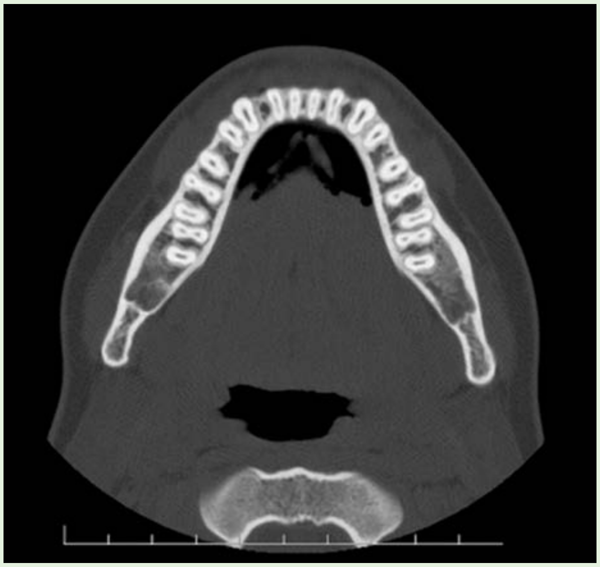

FIGURE 36-37 Horizontal computed tomographic scan of AH's lower arch taken at 7 months into retention shows healthy labial and buccal bone with minimal change in tooth position. The fact that so much tooth structure sits in cortical bone with low vascularity supports Rygh's notion of low-force mechanics.

CASE STUDY 36-3 Treatment with Extraction Therapy

Despite orthodontists' desire to treat with nonextraction therapy, it should be strongly emphasized that certain types of cases warrant extraction therapy. The philosophy of the Damon System is not founded on the idea of nonextraction therapy at any cost. The intent of the system is to achieve pleasing facial symmetry with a long-term healthy periodontium. Bimaxillary protrusive cases with full lip posture require extractions. In addition, on rare occasions, patients may not have the lip competence to keep the dentition from flaring forward with nonextraction therapy because the system heavily counts on the lip bumper or headgear effect. This lack of muscle competence must be recognized early in treatment, and extractions are recommended to avoid round tripping of the anterior teeth.

Case 3 (KH) was selected to demonstrate how the face determines treatment planning and that there is a time to extract. KH was 9 years, 8 months of age when she exhibited a Class II, Division 1 protrusive dentition with a severely deficient mandible, disproportionate lower facial height, and petite facial features. She had a small nose and a lack of lip seal. Her genetic potential was greatly limited from significant growth, the father's height being 5 feet 4 inches and the mother's height at 5 feet 1 inch. Both parents displayed refined features. Her dentition evaluation noted generalized spacing in the maxillary arch. Upper incisors were labially inclined, and the central incisors were large. She also had a significant overjet with a normal overbite.

The treatment objectives were as follows:

1. Achieve a Class I face, and then reevaluate protrusion and profile in an attempt to create facial balance and symmetry.
2. Anticipate the impact of treatment on the patient's maturing profile.
3. Leave the Herbst appliance on at least 16 to 18 months because of the severity of the Class II and the petite size of the slow-growing patient.
4. If necessary, extract four premolars before initiating phase 2 to achieve the best possible facial aesthetics.

Pretreatment records, which are shown in Figure 36-38, include tomograms taken before initiating phase 1 Herbst appliance treatment. In accord with the author's Herbst philosophy of slowly activating over a long time, the initial advancement was limited to 4 mm. The Herbst appliance treatment sequence (Box 36-2) reveals the small advancements that work along with the facial muscles in developing lateral upper arch expansion. Tomograms were taken again at the seventh appointment to check the condylar position. The Herbst appliance was removed on the eighth appointment, completing 18 months of functional Herbst appliance therapy. Progress records were taken at this time (Fig. 36-39). A comparison of the pre-Herbst and post-Herbst cephalometric tracings and facial photographs revealed an ANB (A point–nasion–B point) change of 3 degrees. Although the chin position improved with Herbst appliance treatment, this petite girl was still protrusive, and it continued to be a challenge for her to fit her lips over her teeth. In view of her genetic growth potential and the refined features of her parents, the girl was scheduled for four first premolar extractions.

The patient waited 5 months before starting phase 2 treatment. After the premolar extractions, the upper and lower arches were bonded 6 to 6 (second molars had not erupted). A special prescription of +7 degrees of torque was selected for the upper and lower canines, which is strongly recommended on all extraction cases to prevent lingual tipping of the clinical crowns during space closure. Maxillary and mandibular 0.014-inch Ni-Ti Align SE archwires were placed. Bonded treatment required 11 appointments and 21 months; the treatment sequence is shown in Box 36-3.

Figure 36-40 shows the placement of the 0.019- × 0.025-inch stainless steel archwires with Ni-Ti springs hooked on them distal to the first molars. The distal eyelets were bent 90 degrees before placing over the distal ends of the cut archwires. To avoid flaring the second molars to the buccal, springs were not attached to the second molar hooks. The preceding procedure should be followed in cases of minimum anchorage. In cases of maximum anchorage retraction, ligation of the first and second molars together while attaching the springs to the hooks of the first molars is recommended (Fig. 36-41).

KH demonstrates how simple mechanics work at their best in an unbound mechanical system with light application of force. Archwire posts evenly

BOX 36-3 Case 3 (KH) Treatment Sequence: Phase 2 Post-Herbst Appliance

Start: Extracted upper and lower first premolars.

First appointment: Bonded upper and lower arches 6 to 6. Used +7-degree torque on upper and lower canines. Placed 0.014-inch Ni-Ti Align SE maxillary and mandibular archwires.

Second appointment at 2 months 2 weeks: Placed maxillary and mandibular 0.016- × 0.025-inch Ni-Ti Align SE archwires.

Third appointment at 5 months: Placed maxillary and mandibular posted 0.019- × 0.025-inch stainless steel archwires with Ni-Ti closing springs hooked onto archwire distal to first molars(see Fig. 36-40).

Fourth appointment at 7 months, 1 week: Activated Ni-Ti springs, and clipped archwires distal to first molars (see Fig. 36-41).

Fifth appointment at 9 months, 3 weeks: Activated Ni-Ti springs, and started Class II elastics (Fig. 36-42).

Sixth appointment at 12 months: Bonded upper and lower second molars. Placed 0.016-inch Ni-Ti Align SE overlay archwire.

Seventh appointment at 14 months, 2 weeks: Adjusted maxillary archwire, and continued Class II elastics (night only), including anterior trapezoid.

Eighth appointment at 16 months: Adjusted both archwires. Started nighttime V-elastics and continued trapezoid elastics.

Ninth appointment at 17 months, 2 weeks: Adjusted maxillary archwire and continued V-elastics and anterior trapezoid elastics full time.

Tenth appointment at 19 months: Adjusted both archwires and continued V-elastics and anterior trapezoid elastics.

Eleventh appointment at 20 months, 2 weeks: Adjusted maxillary archwire. Continued V-elastics and anterior trapezoid elastics, and scheduled debonding.

Twelfth appointment at 21 months, 2 weeks: Debonded both arches (see Fig. 36-43). Bonded 0.016-× 0.022-inch Bond-a-Braid braided wire onto the maxillary teeth lateral to lateral incisor. Bonded 0.026-inch stainless steel round wire onto the mandibular teeth canine to canine.

FIGURE 36-41 **A,** In minimum anchorage retraction cases, cutting the archwire distal to the first molar and attaching the spring to the distal end of the first molar tube are recommended. **B,** In maximum anchorage retraction cases, ligating the first and second molars together while attaching the spring to the hook of the first molar is recommended.

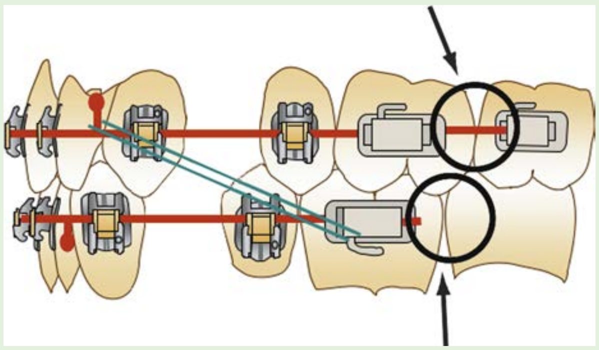

FIGURE 36-42 Tenth appointment at 19 months for KH. V-elastics and anterior trapezoid elastics are configured.

distribute forces over all teeth. Eliminating bracket hooks keeps the appliance clean and promotes healthy tissue response and patient comfort.

Posttreatment records were taken at 21 months, 2 weeks (Fig. 36-43). Figure 36-44 provides a summary of the wire progression of phase 2 treatment. The author does not see how this favorable of a result could have been achieved without the premolar extractions. Maxillary retention was achieved with 0.016-× 0.022-inch Bond-a-Braid braided wire (Reliance Orthodontic Products, Itasca, IL) bonded to each tooth lateral to lateral incisor. Mandibular retention was achieved with 0.026-inch stainless steel wire placed canine to canine and bonded to only the canines. Clear slipcover retainers were made for both arches to help hold the extraction sites closed while the Class II splint was being fabricated (Fig. 36-45). To retain the Class II correction, the splint was worn nightly for 1 year, after which time the patient began wearing the slipcover retainers again only at night.

CASE STUDY 36-4 Treatment with Elastics of Nongrowing Patients with Class II and III Dentitions

One of the greatest challenges in clinical orthodontics is planning the treatment of nongrowing patients with a Class II dentition. So often, these cases have significant overbite or overjet in which the profile and lateral facial support will be greatly affected by treatment planning decisions. Most adults seeking orthodontic treatment desire far more than simply straight teeth. They are keenly aware of what the aging process is doing to their bite and face. With this system, the clinician now has many more opportunities to meet this challenge without negatively affecting the profile and lateral facial support and can, in fact, sometimes improve it.

Some clinicians consider dental correction of Class II and III cases with nothing more than elastics impossible, but with the use of the tube system and high-tech archwires, orthodontists around the world are able to treat certain patients with Class II and III elastics that conventional mechanics precludes. Case 4 (TBM) was selected to demonstrate how the Damon System and Class II elastics can correct a nongrowing patient with a Class II dentition if certain principles are followed. Using a Herbst appliance attached to the archwire was obviously the author's first treatment choice, but the patient preferred to use elastics.

Patient TBM illustrates a combination of factors: a full Class II, Division 2 dentition; the necessity to level the curve of Spee; and moderate anterior crowding. Orthodontists using conventional mechanics would be necessarily apprehensive about treating such a case with Class II elastics for fear of severely dumping the lower anteriors. With traditional mechanics, the archwire is securely tied into each bracket and acts like a bridge beam. Each arch operates as a rigid unit against the other; any interference significantly slows anteroposterior correction. The Damon System functions similar to multiloop archwires, given the play between the archwire and the tube. With independent movement at every bracket, slight interferences do not shut down anteroposterior correction with Class II elastics. At the same time, using very low forces allows the lips and muscles of the face to act as a lip bumper, which precludes dumping the anteriors. Moreover, because second molars sit in cortical bone, the archwire is clipped distal to the first molars, allowing the second molars to drift independently. The gain in the transverse arch width not only helps accommodate the crowding, but it also helps correct the Class II dentition.

TBM was a 40-year-old patient exhibiting a Class II, Division 2 dentition with a pleasing upper lip–to–nose relationship and a strong chin button (Fig. 36-46). She had a 100% overbite with overerupted incisors with the upper central incisors too upright and labially inclined lower anterior teeth. The lower lip was slightly everted because of the position of the anterior dentition. She exhibited moderate crowding of both arches and a significant curve of Spee. Her lower left second premolar was congenitally missing, with a retained second primary molar occupying its space. Third molars had been extracted before treatment. The upper right central and lower right first molar had full porcelain crowns. Earlier in the author's career, the author would have tried to distalize the molars or would have extracted upper first premolars. Either of these treatment options would have had a significant detrimental impact on the profile with the loss of upper lip support.

The treatment objectives were as follows:

1. Correct Class II molar and canine, eliminate crowding, and level the curve of Spee without further dumping of the lower incisors.
2. Eliminate the option of extracting maxillary first premolars because of the negative impact on the face.
3. Establish archform to give lateral facial support.
4. Control torque of maxillary and mandibular anterior segments.
5. Maintain attractive nose-to-lip relationship.
6. Minimize everting of lower lip.

Box 36-4 outlines the treatment sequence. With this low-force and tube technology, the overbite and torque were corrected with the selection of high-torque anterior brackets and tubes and a reverse curve Ni-Ti archwire with 20 degrees of torque. These appliance choices saved considerable time and allowed the clinician to start Class II elastics as soon as a 0.019- × 0.025-inch stainless steel wire is placed in the upper arch. This size of stainless steel archwire is strongly recommended to maintain the vertical dimension in the maxillary arch when pulling Class II elastics. Figure 36-50 provides a summary of the wire progression. Correcting the Class II molar and canine relationships, eliminating the crowding in both arches, and leveling the curve of Spee without severely dumping the lower incisors were encouraging results. In this case, the lower incisors actually uprighted slightly with only minimal anterior bodily movement. Cutting the lower archwire distal to the first molars before placing Class II elastics is always important (see Case Study 3). In some cases, the patient will position the jaw forward when sleeping, minimizing the effect of elastic wear. If so, then instructing the patient to wear two elastics on each side during sleep is important.

CASE STUDY 36-4 Treatment with Elastics of Nongrowing Patients with Class II and III Dentitions—cont'd

Figure 36-51 illustrates comparisons of pretreatment and posttreatment upper arch plaster models, which show 3.5-mm change in canine width, 2-mm change in first premolar width, and 2.5-mm change in first molar width. Figure 36-52 illustrates comparisons of pretreatment and posttreatment models of lower arch plaster models, which show 1.5-mm change in canine width, 1.5-mm change in first premolar width, and 1.0-mm change in first molar width.

To be able to exceed this patient's expectations for orthodontics by completing treatment in 18 months, 1 week and with only 11 total appointments was gratifying (see Fig. 36-49). With such treatment, outstanding patient cooperation is obviously required. Figure 36-53 shows the facial and intraoral results taken 19 months into retention that illustrate excellent stability.

FIGURE 36-46 **A-K,** Pretreatment records for case 4 (TBM, age 40 years). Diagnosis: Class II, Division 2 dentally; pleasing upper lip–to–nose relationship and strong chin button; 100% overbite, overerupted incisors, upper central incisors too upright, and labially inclined lower incisors with everted lower lip; moderate crowding in both arches and significant curve of Spee; lower left second premolar congenitally missing with retained second primary molar. Upper right central and lower right first molar had full porcelain crowns. Third molars were extracted before treatment.

CASE STUDY 36-4 Treatment with Elastics of Nongrowing Patients with Class II and III Dentitions—cont'd

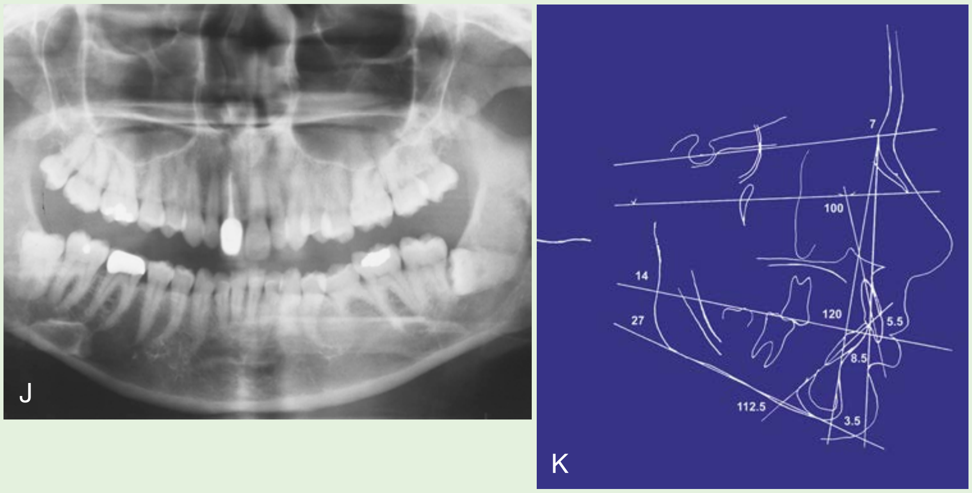

FIGURE 36-46, cont'd

BOX 36-4 Case 4 (TBM) Treatment Sequence

First appointment: Because this patient elected to wear Class II elastics rather than a Herbst appliance, she wore them for an extended period; consequently, high-torque brackets on the upper incisors (+17 degrees on the upper central incisors and +12 degrees on the upper lateral incisors) were selected to prevent the central incisors from uprighting too much. Low-torque brackets were selected for the lower incisors (−6 degrees) to keep them from flaring during extended Class II elastics wear. Bonded upper and lower arches 7 to 7, except for broken-down lower left first molar where a band was placed for support. Placed separators for band. Placed a 0.014-inch Ni-Ti Align SE archwire in the upper arch and a 0.014-inch Ni-Ti Align SE sectional archwire in the lower arch (the lower left first molar was not bondable). Made night-time soft splint for lower arch.

Second appointment at 2 months, 2 weeks: Placed a 0.017- × 0.025-inch Ni-Ti reverse curve with 20-degree torque in the upper arch. Banded lower left first molar. Placed a 0.016-inch Ni-Ti Align SE in the lower arch.

Third appointment at 5 months: Inserted a 0.018- × 0.025-inch Ni-Ti Align SE in the maxilla as a transitional wire between the 0.017- × 0.025-inch Ni-Ti reverse curve and the 0.019- × 0.025-inch stainless steel finishing archwire. Without this transitional wire, going from the reverse curve to the finishing archwire would have been too uncomfortable for the patient. (The reverse curve with +20-degree torque placed at the previous appointment worked exceptionally well in this instance. Sometimes a 0.019- × 0.025-inch reverse curve with torque is needed.) Placed a 0.016- × 0.025-inch Ni-Ti Align SE in the mandible.

Fourth appointment at 7 months, 1 week: Placed a 0.019- × 0.025-posted stainless steel archwire in both arches. Took panoramic radiograph. Started full-time Class II elastics ($\frac{5}{16}$-inch, 6-oz) wear. Clipped lower archwire distal to lower first molars. Doing so is critically important to be able to correct Class II dentitions with elastics because the second molar roots are usually positioned in cortical bone of low vascularity.

Fifth appointment at 9 months, 1 week: Continued Class II elastics. Recommend two elastics on each side at bedtime if patient postured mandible forward while sleeping.

Sixth appointment at 10 months, 3 weeks: Checked patient. Continued Class II elastics.

Seventh appointment at 12 months, 1 week: Adjusted maxillary archwire with tiebacks (Fig. 36-47). Continued Class II elastics.

Eighth appointment at 14 months: Placed a 0.014- × 0.025-inch Ni-Ti Align SE in the mandible with tiebacks. Used a 0.014- × 0.025-inch Ni-Ti Align SE to incorporate second molars. Left for one appointment. Continued Class II elastics.

Ninth appointment at 15 months, 2 weeks: Maintained the 0.019- × 0.025-inch posted stainless steel archwires in the maxilla. Placed a 0.016- × 0.025-inch posted stainless steel archwire in the mandible for desired play between the archwire and the bracket lumen to improve settling and finishing. Began full-time V-elastics. Changed Class II elastics wear from full time to night only.

Tenth appointment at 17 months: Adjusted maxillary and mandibular archwires (Fig. 36-48). Maintained same elastic wear. Prepared to debond.

Eleventh appointment at 18 months, 1 week: Debonded both arches and placed retention wires (Fig. 36-49). Bonded a 0.016- × 0.022-inch Bond-a-Braid braided wire onto the maxillary teeth lateral to lateral incisor. Bonded 0.026-inch stainless steel round wire onto the mandibular teeth canine to canine. Prescribed the Damon splint be worn nightly for 10 to 12 months (length of time prescribed for each patient depends on the severity of the case). Also prescribed regular slipcover retainers in addition to splint.

CASE STUDY 36-5 Treatment of a Nongrowing Patient with a Class III Severe Posterior Crossbite and Anterior Open Bite

Case 5 (AB) was selected to show how low-force and tube treatment mechanics affect alveolar bone. The patient strongly opposed the surgical options presented. Before the advent of the Damon System technology, this patient could only have been treated surgically. CT scans taken the day of debonding clearly illustrate that if forces are biologically sensible, then the alveolar bone will follow the bodily movement of the teeth. AB was nearly 37 years old when he sought treatment after observing the results his brother experienced in the author's practice. He had Class III dentition with a severe open bite and a bilateral posterior crossbite (Fig. 36-54). He complained of airway problems and said he was challenged to enunciate clearly when making presentations. Both brothers were severe tongue thrusters, and to close the right posterior open bite was challenging for both of them. He is a vertical grower with a long lower facial height, long tooth roots, and midface deficiency. His upper and lower midline was off when placing the mandible in centric relation.

The treatment objectives were as follows:

1. Using low-force, low-friction mechanics, allow the orofacial musculature, bone, and soft tissue to establish a new physiologically determined tooth position that allows more room for the tongue.
2. Correct Class III molar relationship and bilateral posterior crossbite.
3. Increase maxillary posterior arch width to accommodate crowding.
4. Improve midface support by moving maxillary dentition forward.
5. Improve cant of occlusal plane, if possible.
6. Correct anterior open bite. Retain case to preclude tongue thrust from reopening bite.

Box 36-5 outlines the treatment sequence for this patient. Special torques were selected: +17 degrees for the upper central incisors, +10 degrees for the upper lateral incisors, and +7 degrees for the upper and lower canines. Figure 36-56 compares the plaster models of the upper arches taken initially and on the day of debonding with vertically cut

BOX 36-5 Case 5 (AB) Treatment Sequence

First appointment: Bonded maxillary and mandibular arches 7 to 7. Placed 0.014-inch Ni-Ti Align SE in both arches.

Second appointment at 2 months, 2 weeks: Rebonded lower right lateral and replaced 0.014-inch Ni-Ti Align SE. Placed maxillary 0.014- × 0.025-inch Ni-Ti Align SE.

Third appointment at 4 months, 1 week: Placed mandibular 0.016-inch Ni-Ti Align SE. Patient missed appointments for the next several months.

Fourth appointment at 8 months 2 weeks: Placed maxillary 0.016- × 0.025-inch Ni-Ti Align SE. Placed mandibular 0.014- × 0.025-inch Ni-Ti Align SE.

Fifth appointment at 10 months, 2 weeks: Placed maxillary 0.019- × 0.025-inch posted stainless steel. Placed mandibular 0.016- × 0.025-inch stainless steel. Bonded lingual buttons to upper first molars. Started full-time posterior cross elastics and full-time Class III $\frac{5}{16}$-inch, 6-oz elastics.

Sixth appointment at 13 months: Adjusted upper and lower archwire. Continued full-time wear of Class III elastics. Changed posterior cross elastics to nighttime wear.

Seventh appointment at 14 months, 2 weeks: Adjusted maxillary archwire. Started full-time $\frac{5}{16}$-inch, 6-oz posterior V-elastics and anterior trapezoid elastics.

Eighth appointment at 16 months: Adjusted maxillary archwire. Continued same elastics wear.

Ninth appointment at 17 months, 3 weeks: Adjusted maxillary and mandibular archwires. Continued same elastics wear.

Tenth appointment at 19 months, 1 week: Adjusted maxillary and mandibular archwire. Continued same elastics wear.

Eleventh appointment at 20 months, 3 weeks (Fig. 36-55): Debonded both arches. Bonded 0.016- × 0.022-inch Bond-a-Braid braided wire onto the maxillary teeth lateral to lateral incisor. Bonded 0.026-inch stainless steel round wire onto the mandibular teeth canine to canine. Fabricated slipcover retainers for upper and lower arches. Fabricated Damon splint for nighttime wear.

CT scans also taken the day of debonding. The maxillary canine width increased 3 mm, the first premolar width increased 8 mm, the second premolar width increased 5 mm, and the first molar width increased 4.5 mm. The CT scans show positive alveolar bone response to significant lateral and vertical tooth movement, once again demonstrating that using biologically sensible forces will cause the alveolar bone to follow the movement of teeth in all planes of space with minimal tipping. (Note that the cut of the horizontal CT scans are tipped toward the anterior segment of the arch.) Using simple mechanics, this patient was treated in 20 months, 3 weeks with 11 office visits (see Fig. 36-55). Retaining these types of complex cases with a night muscle-training splint and lingually bonded wires on both the upper and lower anteriors is essential. Despite significant tooth movement, the photographs taken the day of debonding show a positive tissue response. The horizontal CT scan of the upper arch taken at debonding (Fig. 36-57) illustrates the well-shaped archform.

Treatment with the Herbst Appliance of Growing Patients with Skeletal Class II Dentition

This section includes some of the author's findings with the Herbst appliance after using it for longer than 24 years, treating more than 3000 patients, and following many of these patients for a number of years. Obviously, improvement in the technology continues to affect how orthodontists use and apply any appliance system. The author intends to give an overview of how this technology is used to treat some of the most challenging cases. (See also Chapter 16.)

The Herbst appliance is one of the most powerful treatment options in orthodontics. Combining the low-force and tube system with the Herbst appliance gives the clinician the opportunity to convert complex and long-term treatment situations into straightforward treatment using noncompliance mechanics for superior clinical results. After having the opportunity to lecture around the world, the author has found that many clinicians have a negative view of the Herbst appliance and its clinical application. Many of these views are justified when discussions center only around its impact on the A point–nasion–B point (ANB) angle. The author has observed great variation in what *does or does not happen* to the ANB angle with the use of the Herbst appliance. The author's interest in using the appliance focuses far more on its functional impact on the entire orofacial complex rather than its effect on the ANB. Although a positive response in the ANB angle is helpful, the ANB simply does not change in some cases. Although the ANB angle may not be positively affected, so many positive things do happen when the patient is given a second chance for the entire dentofacial complex to function in a more normal manner. If the mandible is slowly advanced over an extended period, then the impact can be dramatic *in growing and nongrowing patients*. Orthodontists have seen patients who had a narrow upper arch and a severe Class II skeletal pattern. This situation is an example of a functional adaptation of the alveolar process and dentition reacting to the musculature altered by the anteroposterior position of the mandible. If the mandibular position is slowly normalized, then clinicians often observe teeth and alveolar process responses even without orthodontic intervention.

Clinical Principles for Using the Herbst Appliance

Orthodontists know that growth of young patients occurs over a long period. Recognizing that the body needs time to react to a given functional change has always seemed logical. The form-follows-function adage is appropriate when using the Herbst appliance. The author's favorite time to start Herbst appliance treatment is when the young patient's growth starts to accelerate. Some exceptions are severe cases and those patients with self-esteem and special growth issues. The average Herbst appliance starting age for girls is 10½ to 11 years; boys are later at 11 to 11½ years of age.

The author strongly recommends advancing the Herbst appliance only 4.0 to 4.5 mm at the beginning of treatment. Slowly activating the appliance over a long period has many advantages. The author prefers not to advance the condyle more than two thirds of the way down the articular eminence. This small advancement of the mandible lessens the Class II elastic effect on the musculature and thereby minimizes the forward proclination (dumping) of the lower incisors. With this small advancement, the author relies on the functional effect of the Herbst appliance and muscles to initiate lateral upper arch adaptation naturally, *negating the need for high-force palatal expansion before placing the Herbst appliance*. As the Herbst appliance advances the mandible, the combined impact of the V-shape of the mandible, the usual presence of an upper archwire connecting the four anteriors to the molars, and the Herbst rods foster a slow and natural lateral change in the maxilla with little dental tipping. *Surprisingly, this lateral adaptation of the palate is not age specific.*

The second Herbst appliance advancement of approximately 3 mm is performed 5 to 6 months into treatment. Once again, the activation is allowed an interval of approximately 5 months for the muscles to adapt. Using the same principles, activations thereafter are applied according to each patient's specific needs for skeletal correction. In most cases, activation is terminated when the upper and lower anterior teeth are end to end. The average length of treatment is 14 to 16 months. (In severe applications, treatment time is extended to 2 years or longer.) If a patient relapses during the full-bonded phase of treatment, then the author gives the Herbst appliance a second opportunity to work directly on the archwire. Some of the most successful cases the author has treated have resulted from more than one application of the Herbst appliance.

Patients treated with the Herbst appliance require special retention that is critical to long-term success. The length of time specified for a nightly splint to be worn after debonding in the case studies is an example. The activator-type retainer is most important to the success of this type of treatment.

Working together, the low-force and tube technology and the Herbst appliance provide a powerful combination that allows the clinician to simplify treatment mechanics and convert the most challenging cases to routine clinical orthodontics. Slowly advancing the Herbst appliance, allowing it work for a long period, and retaining it with a night splint are the key elements for success. Most of the Herbst appliance research to date has been on patients who have been rapidly activated, treated over a significantly shorter period, and released without anteroposterior retention.

Clinical Application of the Herbst Appliance

The author uses the Herbst appliance in several different ways in timing and treatment application:

- Mixed dentition Herbst appliance therapy with and without anterior brackets
- Archwire Herbst appliance therapy in patients with full dentition
- Archwire Herbst appliance therapy for patients with temporomandibular joint problems
- Archwire Herbst appliance therapy with coil springs as a supplement for Class II elastics

The following two cases demonstrate Herbst application in the author's practice.

CASE STUDY 36-6 Youth with Herbst Appliance Treatment Demonstrates Typical Response

Case 6 (KP) 12 years, 5 months of age was selected to demonstrate the typical response to standard Herbst appliance treatment. Pretreatment records (Fig. 36-58) indicate her to be a Class II, Division 1 case with a retrusive mandible and narrow midface. She exhibited a good chin button but with poor tissue contour under her chin. She demonstrated a moderate overeruption of lower incisors, flared upper incisors, and lingually inclined upper and lower canines with the typical narrowing of the anterior maxillary arch in patients with a Class II dentition.

The treatment objectives were as follows:

1. Achieve facial balance and symmetry of nose, lips, and chin.
2. Create maxillary and mandibular posterior arch width to support midface with low-force mechanics.
3. Establish maxillary and mandibular incisor position to give natural lip-to-tooth relationship.
4. Exert a positive impact on the archwires.

The pretreatment profile makes it apparent that the mandible is growing slower than the maxilla. Treatment plans that attempt to move the maxilla or dentition distally to meet a deficient mandible often leave patients with a prominent nose, lack of upper lip support, and a weak chin. In such cases, the author has always found it more conducive to create an environment for mandibular change. Box 36-6 outlines the phase 1 Herbst appliance treatment sequence. The impact Herbst appliance treatment had on this patient's facial balance and dentition is positive. Using Herbst appliance therapy before bonding means that the orthodontic treatment is initiated on a simple Class I case with the increased maxillary arch width, eliminating the need for high-force palatal expansion (see Fig. 36-61). An interesting note is that this patient's upper first premolar width change was less than is normally observed with Herbst appliance treatment. The tongue did not completely reposition itself until after fully bonded treatment was started, which added an additional 5-mm width gain after Herbst appliance treatment. Combining the Damon System with Herbst appliance therapy simplifies treatment planning, minimizes the need for patient cooperation, and yields rewarding results. Box 36-7 outlines the phase 2 posttreatment Herbst appliance sequence.

The combination of Herbst appliance therapy and Damon System mechanics achieved excellent facial balance (see Fig. 36-64). Figure 36-65 outlines the posttreatment sequence with the Herbst appliance archwire. Figure 36-66 illustrates the comparisons of the initial and final models of upper arch, which show 5.5-mm change in canine width, 10.5-mm change in first premolar width, and 7-mm change in first molar width. Figure 36-67 illustrates the comparisons of the initial and final models of lower arch, which show 0.5-mm change in canine width, 2-mm change in first premolar width, and 0.5-mm change in first molar width. One-year retention records illustrate good stability (Fig. 36-68). CT scans taken 2 years, 6 months into retention (Fig. 36-69) signify healthy alveolar bone and good archform.

CASE STUDY 36-6 Youth with Herbst Appliance Treatment Demonstrates Typical Response—cont'd

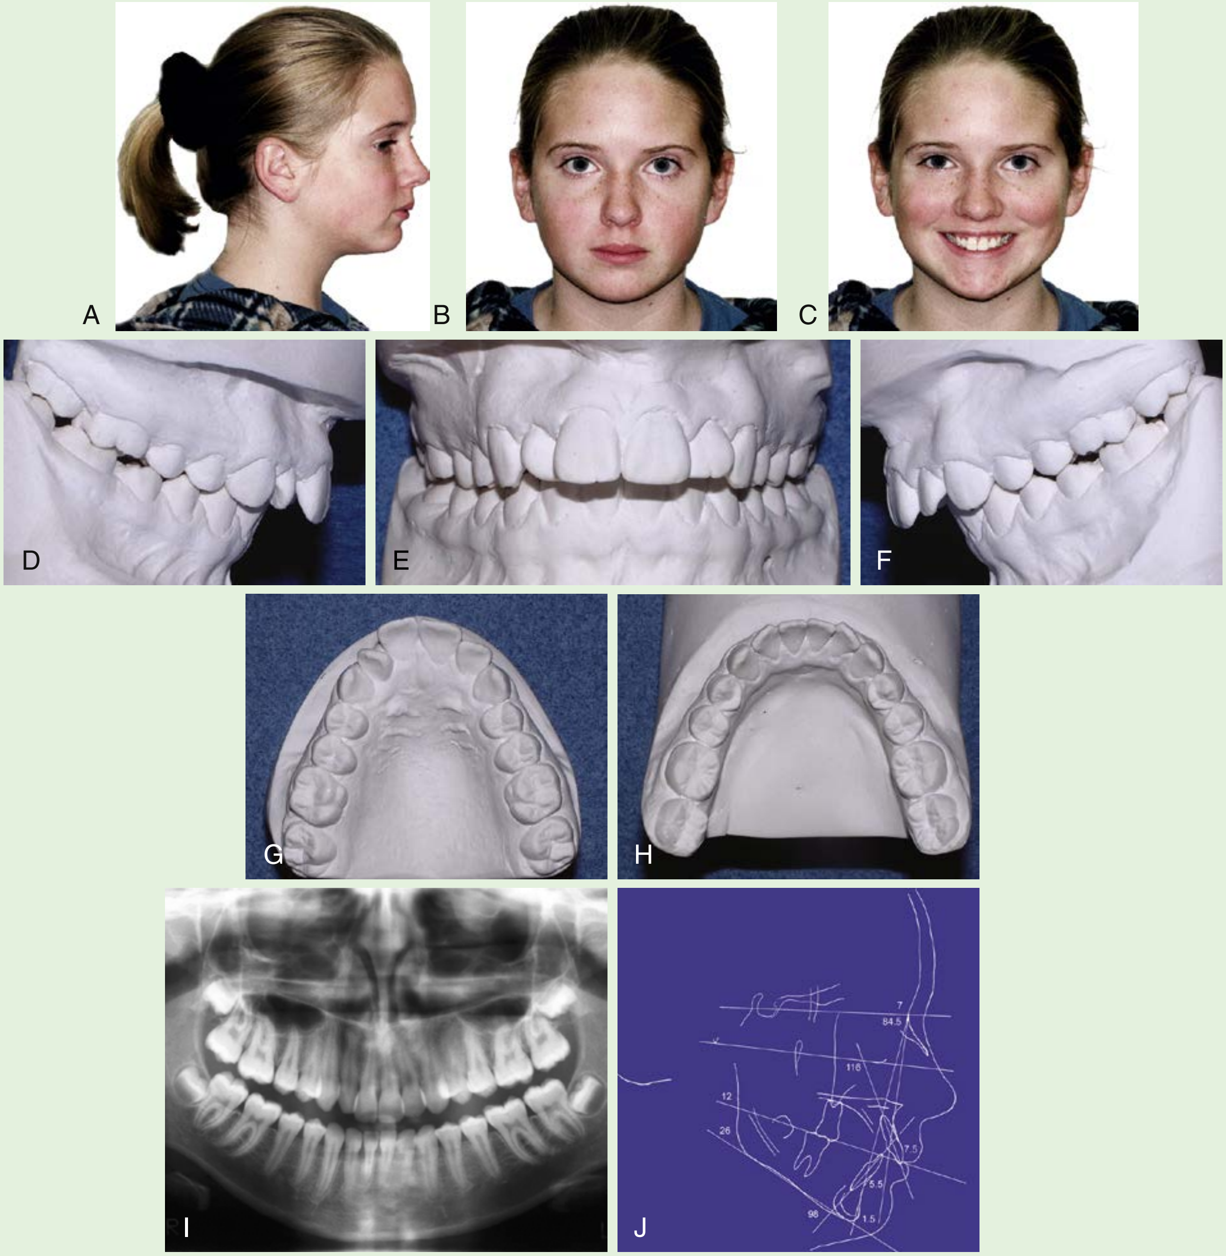

FIGURE 36-58 **A-L,** Pretreatment records for case 6 (KP, age 12 years, 5 months). Diagnosis: Class II, Division 1 with retrusive mandible, narrow midface, a good chin button but with excessive tissue under her chin; moderate over-eruption of lower incisors, flared upper incisors, and lingually inclined upper and lower canines with the narrowing of anterior maxillary arch that is typical in patients with Class II dentition.

CASE STUDY 36-6 Youth with Herbst Appliance Treatment Demonstrates Typical Response—cont'd

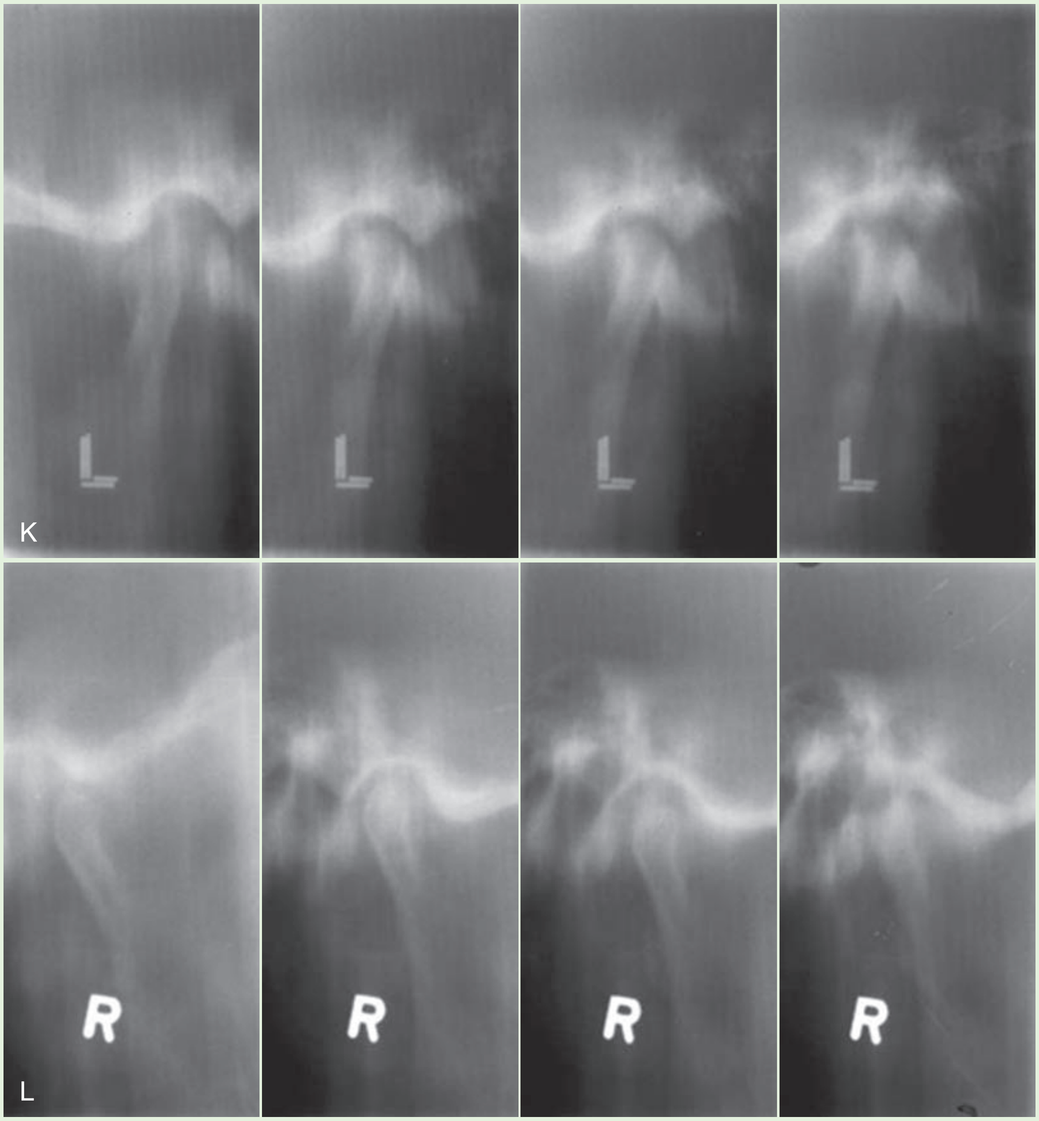

FIGURE 36-58, cont'd

BOX 36-6 Case 6 (KP) Treatment Sequence: Phase 1 Herbst Appliance

Start: Took tomograms.

First appointment: Placed Flip-Lock Herbst appliance (TP Orthodontics, Inc., La Porte, IN) (Fig. 36-59). Selected special high torques for upper central incisors (+17 degrees) and lateral incisors (+12 degrees). Bonded upper central and lateral incisors. Placed sectional 0.014-inch Ni-Ti Align SE extending from maxillary right canine to maxillary left lateral incisor with the ends of the wire heat treated and bent for comfort, leaving enough room for the anterior teeth to align. Initially activated Herbst appliance 4.5 mm.

Second appointment at 2 months, 3 weeks: Placed maxillary and mandibular 0.017- × 0.025-inch titanium molybdenum alloy (TMA) archwire with moderate intrusive bends anterior to the molar tubes. This wire was inserted in tubes soldered to the first molar Herbst crowns.

Third appointment at 6 months: Placed maxillary and mandibular 0.019- × 0.025-inch TMA archwire with moderate intrusive bends to intrude anterior teeth. This wire was inserted in the tubes of the first molar Herbst appliance crown. Added 2-mm shims.

Fourth appointment at 8 months, 2 weeks: Adjusted maxillary archwire. Added 1-mm shim.

Fifth appointment at 10 months, 3 weeks: Checked Herbst appliance.

Sixth appointment at 13 months, 2 weeks: Took tomograms and evaluated progress (Fig. 36-60). Scheduled HERBST appliance removal.

Seventh appointment at 16 months: Removed Herbst appliance (Fig. 36-61). Took progress records. First premolar width change with the Herbst appliance was 5.5 mm.

CASE STUDY 36-6 Youth with Herbst Appliance Treatment Demonstrates Typical Response—cont'd

FIGURE 36-59 Flip-Lock Herbst appliance used to treat KP.

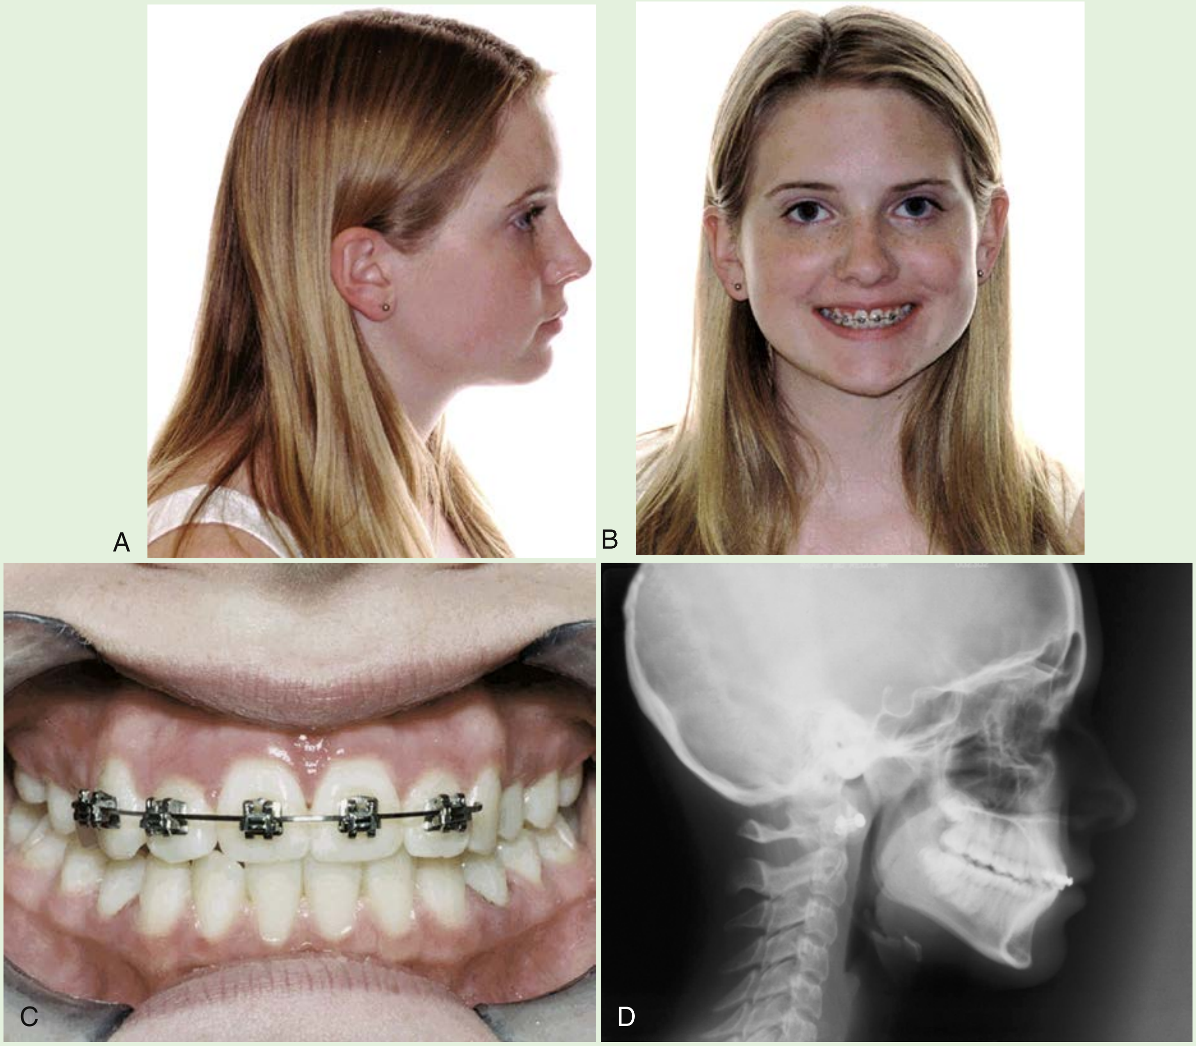

FIGURE 36-61 A-D, Phase 1 posttreatment records of KP with Herbst appliance (Herbst appliance treatment time: 16 months with seven appointments). Records taken after Herbst appliance treatment demonstrate Class I dentition and improved facial symmetry.

BOX 36-7 Case 6 (KP) Treatment Sequence: Phase 2 Posttreatment Herbst Appliance

This patient's canines were slightly toed in. Selected special torques (+7 degrees) for upper and lower canines to help upright them.

First appointment: Bonded maxillary and mandibular 7 to 7. Placed continuous maxillary and mandibular 0.014-inch Ni-Ti Align SE archwires with crimpable stops.

Second appointment at 2 months, 2 weeks: Placed upper 0.016- × 0.025-inch Ni-Ti Align SE. Placed lower 0.014- × 0.025-inch Ni-Ti Align SE.

Third appointment at 4 months, 3 weeks: Took panoramic radiograph to evaluate root angulations and bracket positions (Fig. 36-62).

Fourth appointment at 7 months, 2 weeks: Placed maxillary 0.019- × 0.025-inch posted stainless steel archwire with tiebacks. Placed mandibular 0.016- × 0.025-inch posted stainless steel archwire with tiebacks, which kept the play in the bracket tube to help eliminate binding and help close the posterior occlusion when trying to close the bite vertically. Started bilateral V-elastics.

Fifth appointment at 9 months, 3 weeks: Adjusted upper and lower archwires. Continued full-time V-elastics. Added Class II elastics for night wear only.

Sixth appointment at 12 months: Adjusted maxillary and mandibular archwires. Posterior occlusion was hard to close because of tongue repositioning.

Seventh appointment at 13 months, 2 weeks: Checked occlusion. Continued full-time elastics.

Eighth appointment at 15 months, 1 week: Adjusted maxillary and mandibular archwires. Continued full-time elastics.

Ninth appointment at 17 months: Debonded arches (Fig. 36-64). Initiated fixed retention by bonding 0.016- × 0.022-inch Bond-a-Braid braided wire onto the maxillary teeth lateral to the lateral incisor and bonding 0.026-inch stainless steel round wire onto the mandibular teeth canine to canine because of the severity of the initial crowding. The patient was instructed to wear clear plastic overlay retainers for upper and lower arches and the Damon splint for night retention for an activator type of effect until patient is finished growing.

CASE STUDY 36-7 Youth with Herbst Appliance Treatment Demonstrates the Definitive Response

This case was selected because it definitively demonstrates what the Damon System has to offer: a gold standard for gaining space in a full Class II occlusion. By simply normalizing the position of the mandible, the muscles of the face and tongue have a completely different impact on the surrounding structures, which gives the patient a second chance for normal physiologic adaptation to take place. This case is also a great example of form after function. What is exciting is that with a little time and effort, using simple mechanics, and allowing physiologic adaptation to occur, the patient can be treated with respect for the maturing face and profile.

Case 7 (KR) was 11 years, 6 months of age with a Class II, Division 2 crowded dentition (Fig. 36-70). She had a prominent nose but a good chin button. She lacked lateral facial support and arch length and width in both

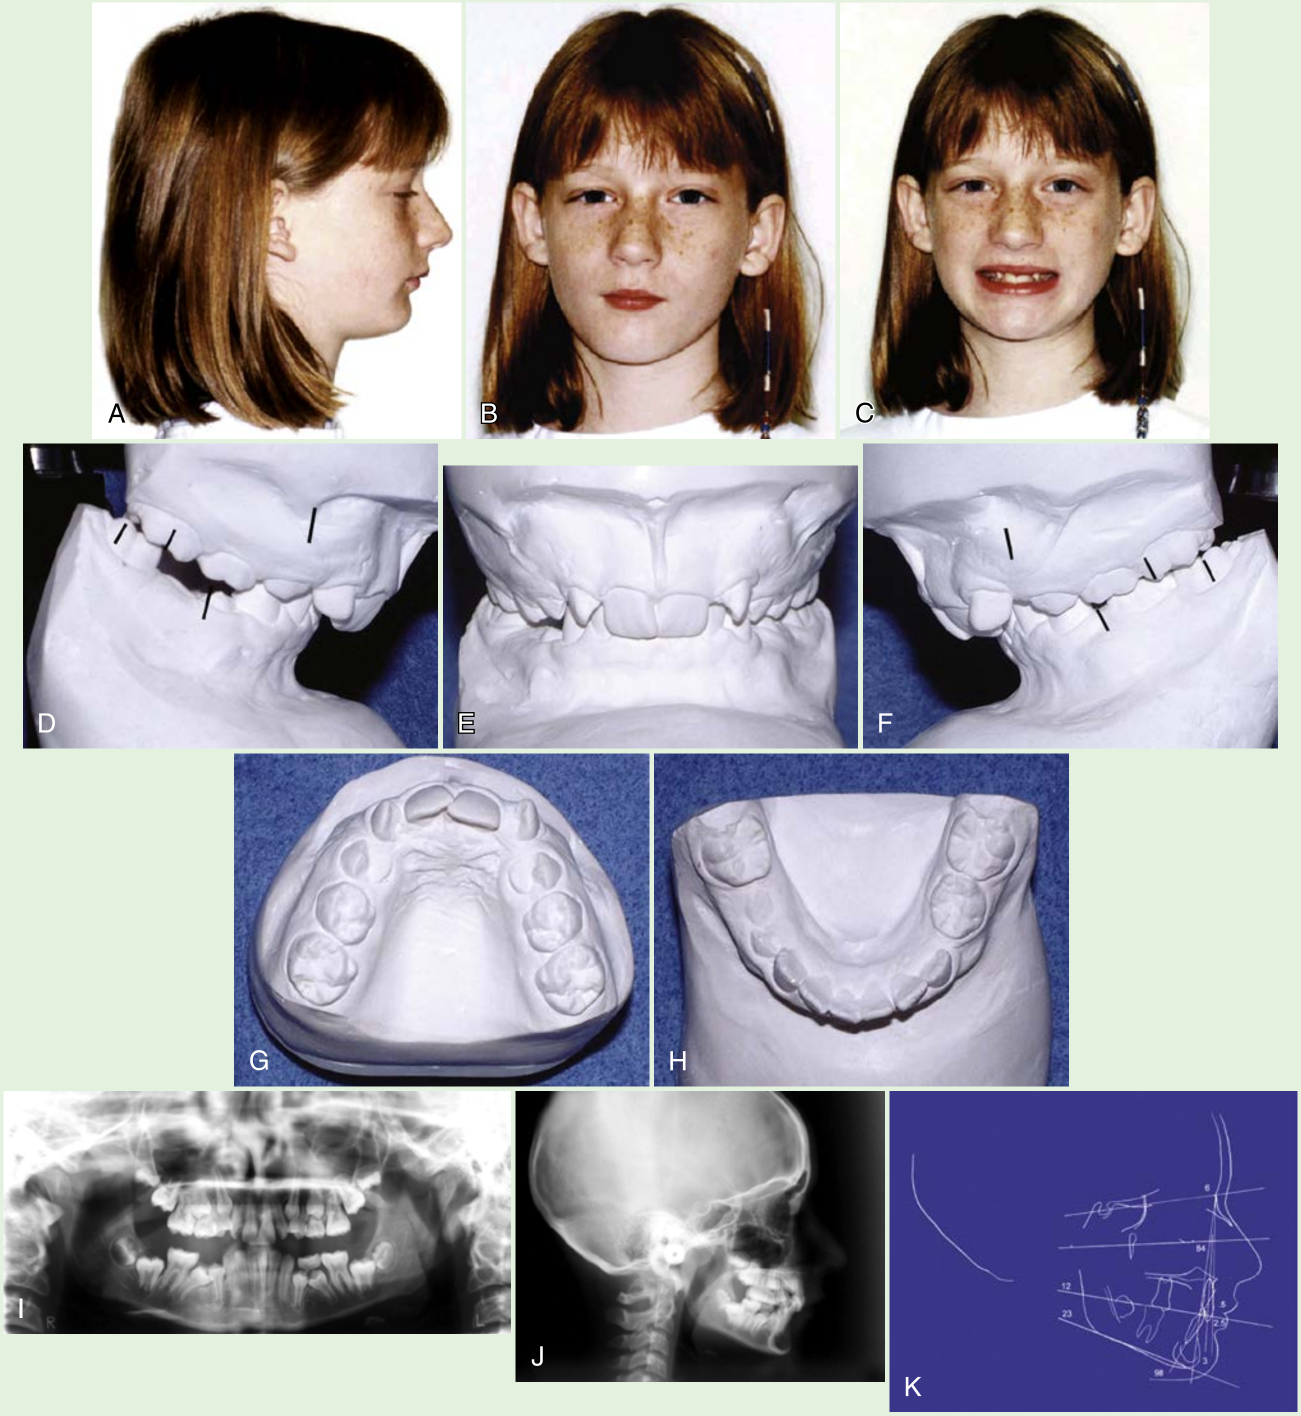

FIGURE 36-70 A-M, Pretreatment records for case 7 (KR, age 12 years, 5 months). Diagnosis: Class II, Division 2 crowded dentition; retrusive mandible and lacking lateral facial support, arch length and arch width in both arches; 100% overbite, overerupted upper and lower incisors; prominent nose and good chin button.

CASE STUDY 36-7 Youth with Herbst Appliance Treatment Demonstrates the Definitive Response—cont'd

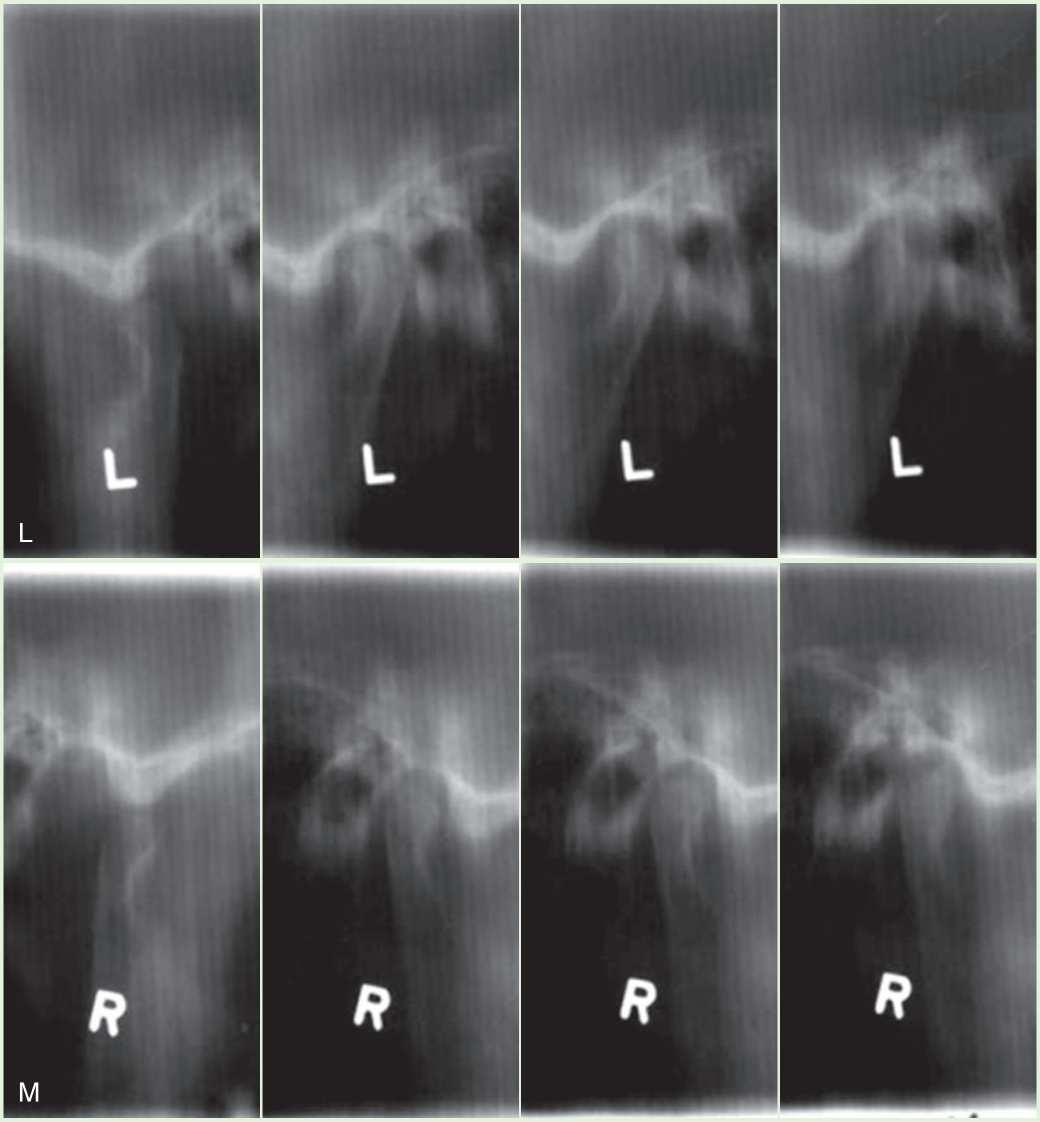

FIGURE 36-70, cont'd

arches. She had 100% overbite with overerupted upper and lower central and lateral incisors. Her retrusive mandible was likely to become more pronounced with maturity. What happens long-term to the maturing profile is well documented. This anticipated profile change calls for treatment mechanics that will move the upper incisors forward, giving increased dental support to the upper lip and, at the same time, helping minimize the prominence of the nose. As the nasolabial angle decreases, room is being made for the erupting upper canines. This anterior dental movement also allows room for Herbst appliance therapy to slowly position the mandible forward into a more normal anteroposterior position. In other words, the lower arch is fitted to the upper as much as growth and development will allow.

The treatment objectives were as follows:

1. Design treatment mechanics in anticipation of the long-term impact on the patient's face and profile.
2. Achieve facial balance and symmetry.
3. Establish maxillary anteroposterior position and posterior width to support the midface.
4. Gain maxillary arch length.
5. Establish ideal maxillary tooth-to-lip relationship.
6. Achieve physiologically sound tooth position.
7. Design treatment mechanics to position the deficient mandible to the maxilla as growth and development permit.

Tomograms were taken before starting phase 1 Herbst appliance therapy. Special high-torque central incisors (17 degrees) and lateral incisors (10 degrees) were selected. These central torques are selected for Division 2 cases. High torques are also the choice for central and lateral incisors for cases requiring Class II elastics to prevent loss of torque control from the elastic wear; they also are suitable for most extraction cases to prevent loss of torque control when retracting anterior teeth. At the start of treatment, a maxillary 0.014-inch Ni-Ti Align SE sectional archwire was placed lateral to lateral incisor, and the Herbst appliance was placed

Continued

CASE STUDY 36-7 Youth with Herbst Appliance Treatment Demonstrates the Definitive Response—cont'd

and advanced just short of the incisors. At the second appointment (2 months, 2 weeks), a 0.017- × 0.025-inch TMA archwire (Ormco Corporation, Orange, CA) with light intruding bends was placed. Light intrusion bends were used to minimize molar tube binding, and medium-light Ni-Ti coil springs were placed on the wire (engaging the molars) and activated twice the width of the bracket. Light C-chains were placed lateral to lateral incisor to consolidate space. Box 36-8 presents the phase 1 Herbst appliance treatment sequence.

Phase 1 therapy was completed in 18 months with nine appointments. KR had responded well with impressive lateral arch development resulting from the Fränkel effect of the Herbst appliance and archwire —a natural expander without force. Initial and after treatment, Herbst appliance upper model comparisons (see Fig. 36-74) reveal increases of 8 mm in first premolar width and 6 mm in first molar width, with Figure 36-75 illustrating the posttreatment Herbst appliance cephalometric tracing composite. Before the use of the Herbst appliance and tube technology, the author's usual treatment options were headgear, upper first premolar extractions, or distalizing upper molars to make room for blocked-out canines. These types of treatment had a detrimental long-term impact on the nasolabial angle and profile of the maturing face.

BOX 36-8 Case 7 (KR) Treatment Sequence: Phase 1 Herbst Appliance

Start: Took tomograms.

First appointment: Placed Herbst appliance, and bonded upper central and lateral incisors (high torques). Placed 0.014-inch Ni-Ti Align SE sectional archwire lateral to lateral incisor. Advanced Herbst appliance just short of incisors (Fig. 36-71).

Second appointment at 2 months, 2 weeks: Placed maxillary 0.017- × 0.025-inch TMA archwire with light intruding bends. Placed medium-light Ni-Ti coil springs and activated 2 times width of bracket. Placed light C-chain lateral to lateral incisor to consolidate space (Fig. 36-72).

Third appointment at 5 months: Activated Herbst appliance with shims just short of anterior teeth. Placed maxillary 0.019- × 0.025-inch TMA archwire with light intruding bends. Activated medium-light Ni-Ti coil springs.

Fourth appointment at 7 months, 2 weeks: Added 3-mm shims, and checked length of archwire in molar tube.

Fifth appointment at 10 months: Replaced maxillary 0.019 × 0.025 TMA with a longer one.

Sixth appointment at 12 months, 2 weeks: Added 3-mm shims.

Seventh appointment at 15 months: Checked appliance and increased intrusion bends in upper archwire.

Eighth appointment at 16 months, 2 weeks: Took tomograms and added 1-mm shims (Fig. 36-73).

Ninth appointment at 18 months: Removed Herbst appliance, took progress records (Figs. 36-74 and 36-75), conducted progress consultation, and arranged for full bonding.

Phase 2 treatment was immediately initiated after phase 1, with full bonding of upper and lower arches and placement of 0.014-inch Ni-Ti Align SE archwires. Phase 2 treatment was completed in 14 months, 2 weeks with eight appointments. Box 36-9 shows the phase 2 Herbst appliance posttreatment sequence. Posttreatment records (see Fig. 36-76) include a cephalometric tracing composite and a panoramic radiograph. Comparing these records with pretreatment records reveals a pleasing result that accommodated the maturing profile changes seen in retention. Initial and final upper model comparisons (Fig. 36-77) reveal increases of 11 mm in first premolar width, 10 mm in second premolar width, and 7.5 mm in first molar width. Bodily movement and limited corrective tipping are apparent. Lower model comparisons (Fig. 36-78) show a 0.5-mm arch width increase in the canines and 5-mm width increase in the first molars.

With the Damon System, teeth can be moved and bone will follow; however, the muscles must be given time to adapt, which is why a splint was required for retention. The Damon splint (See Finishing Phase discussion) is made for nightly wear to provide an activator-type effect until the patient has completed growing. The author uses splints in 30% of all cases, 100% of Herbst appliance and Class II elastic cases, and for anyone with muscle dysfunction or temporomandibular joint problems. KR wore her splint at night for 12 months after debonding.

Maxillary retention was achieved with 0.016- × 0.022-inch Bond-a-Braid braided wire bonded to each tooth lateral to lateral incisor and left in place for approximately 2 years. Permanent mandibular retention was achieved with 0.026-inch stainless steel wire placed canine to canine and bonded to only the canines. Clear slipcover retainers were fabricated for use after nightly splint wear. Figure 36-79 shows facial photographs 20 months in retention. Horizontal CT scans of upper and lower arches (Fig. 36-80) were taken 3 years in retention. The healthy alveolar bone and excellent archforms are evident.

FIGURE 36-71 First appointment. Herbst appliance disarticulated and bonded upper anteriors are used to start KR in phase 1 treatment.

FIGURE 36-75 Cephalometric tracing composite at posttreatment with Herbst appliance for KR.

BOX 36-9 Case 7 (KR) Treatment Sequence: Phase 2 After Herbst Appliance Treatment

First appointment: Fully bonded upper and lower arches, and placed 0.014-inch Ni-Ti Align SE archwires.

Second appointment at 2 months, 2 weeks: Placed maxillary 0.016- × 0.025-inch and mandibular 0.014- × 0.025-inch Ni-Ti Align SE archwires.

Third appointment at 5 months: Placed maxillary 0.019- × 0.025-inch posted stainless steel archwire and mandibular 0.018- × 0.025-inch Ni-Ti Align SE archwire. Took panoramic radiograph and checked root position and bracket placement.

Fourth appointment at 7 months, 2 weeks: Placed mandibular 0.019- × 0.025-inch posted stainless steel archwire, and started full time Class II elastics.

Fifth appointment at 10 months: Adjusted maxillary archwire, and continued full time Class II elastics.

Sixth appointment at 11 months, 2 weeks: Adjusted archwires, and cut Class II elastic wear to half time.

Seventh appointment at 13 months: Adjusted maxillary archwire torque, and added bilateral V-elastics.

Eighth appointment at 14 months, 2 weeks: Debonded both arches. Bonded 0.016- × 0.022-inch Bond-a-Braid braided wire onto the maxillary teeth lateral to lateral incisor and placed a 0.026-inch stainless steel wire onto the mandibular teeth canine to canine, bonding only the canines. Made upper and lower slipcover retainers for full-time wear and Damon splint for nightly wear (Fig. 36-76).

DAMON SYSTEM ESSENTIALS

Damon System Appliance

The preadjusted Damon appliance (Fig. 36-81) is available in 0.022- and 0.018-inch slots. The author prefers the 0.022-inch dimension because the larger slot allows greater flexibility in the selection of archwire sizes and materials. Considering the archwire progression possibilities for each size, the author believes that the 0.022-inch slot maximizes the potential for keeping forces in the optimal force zone. A small wire in a large lumen is most favorable for tooth movement because it diminishes the divergence of angles in the archwire slot, allowing freer movement. Those who prefer the 0.018-inch slot to work with lighter forces will find that with the Damon System, the 0.022-inch slot affords that advantage. When used with the recommended archwire progression, the greater play allows faster, unrestricted tooth movement and a more comfortable patient.

The Damon tube is manufactured by metal injection molding, which is the most precise process today to manufacture metal brackets and tubes. The metal injection molding process makes it possible to manufacture exceedingly small, accurate parts that allow movement of the slide and to provide the close tolerances of the archwire slot. Opening the slide in the latest D3 version is achieved with an opening tool, whereas closing requires only finger pressure. Upper tubes open incisally and lower tubes open gingivally to provide the best visibility when checking archwire placement.

Damon Standard Prescription

The Damon standard prescription is recommended for all molars and premolars, all incisors and canines in good position, and labially inclined canines (Table 36-1). Careful selection of specific torque prescriptions is strongly encouraged before starting treatment.

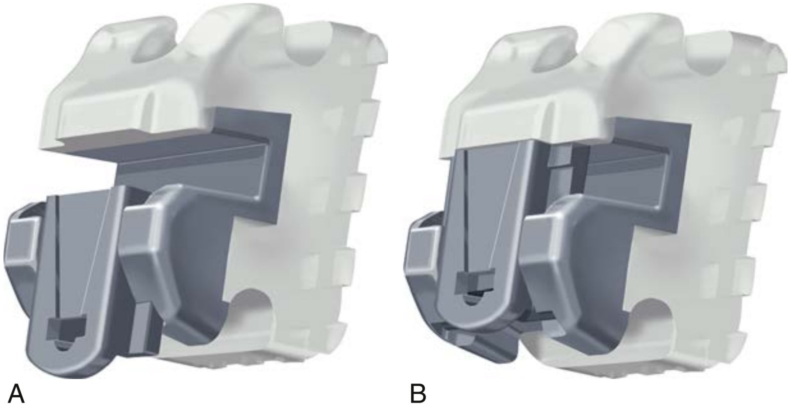

FIGURE 36-81 The Damon 3 tube and bracket in the (A) open and (B) closed positions.

TABLE 36-1 Standard Torques for the Damon Prescription

	Torque (in degrees)	Tip (in degrees)	Rotation (in degrees)
Upper Arch			
Central incisors	+12	+5	0
Lateral incisors	+8	+9	0
Canines	0	+6	0
First premolars	−7	+2	0
Second premolars	−7	+2	0
First molars	−9	0	10
Second molars	−9	0	5
Lower Arch			
Central incisors	−1	+2	0
Lateral incisors	−1	+2	0
Canines	0	+5	0
First premolars	−12	+2	0
Second premolars	−17	+2	0
First molars	−30	+2	0
Second molars	−10	0	5

High-Torque and Low-Torque Alternatives to the Damon Standard Prescription

Incisors and canines are available with torque variances for specific malalignments to shorten treatment times through greater torque control.

Upper central incisors

- +17-degree torque, +5-degree tip, 0-degree rotation: Division 2 cases, cases requiring extensive Class II elastics, and most extraction cases
- +7-degree torque, +5-degree tip, 0-degree rotation: central incisors requiring extensive uprighting, cases requiring extensive Class III elastics, extremely crowded cases combined with anterior tongue thrusting or thumb or finger habit, and when extensive arch length needs to be gained and the incisors have near normal angulation

Upper lateral incisors

- +10-degree torque, +9-degree tip, 0-degree rotation: Division 2 cases, cases requiring extensive Class II elastics, and most extraction cases
- +3-degree torque, +9-degree tip, 0-degree rotation: lateral incisors requiring extensive uprighting, blocked lateral incisors in lingual crossbite that will have too much torque from standard prescription as they move into normal position, cases needing extensive Class III elastics, extremely crowded cases combined with anterior tongue thrusting or thumb/finger habit, and where extensive arch length needs to be gained and the incisors have near normal angulation

Upper and lower canines

- +7-degree torque, +6-degree tip, 0-degree rotation: canines needing coronal uprighting and most extraction cases requiring first premolar space closure

Lower central and lateral incisors

- −6-degree torque, +2-degree tip, 0-degree rotation: extreme crowding in lower anterior segment, cases needing extensive Class II elastics, any lower incisor initially positioned lingual with labial root position, and cases needing a Herbst appliance on the archwire

Damon System Archwires and Archwire Sequencing

The Damon System has been carefully designed and developed to take advantage of play in the mechanical system and yet maintain superb control of teeth in the working and finishing stages of treatment. The amount of play between the bracket tube and archwire is critical and must be understood to take advantage of this new technology. Archwire sequencing is a critical element in managing clinical forces. In the early aligning phase, minimization of binding and friction is important and accomplished by placing a small high-tech archwire in a large lumen or tube of the bracket. This method is particularly significant in the lower anterior segment where teeth are usually crowded and the interbracket distance is minimal. The applied force can be less if the divergence of the bracket slots is minimized when a small flexible archwire is positioned on either side of the large bracket tubes. This concept is similar to driving a car down a winding highway by using both sides of the road to minimize the curves and to allow for faster travel. This mechanical advantage allows the clinician significant advantages to apply a force just high enough to stimulate cellular activity without crushing the lacelike network of blood vessels around the roots in the periodontal ligament and surrounding alveolar bone. One of the key mistakes clinicians make when starting to use this technology is not allowing enough time for

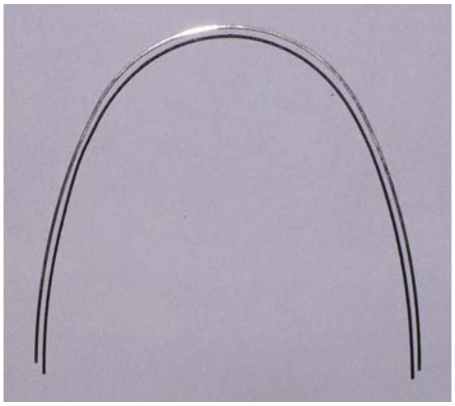

FIGURE 36-82 The shape of the working and final archform are copied in stainless steel from the lower archform that results from the high-tech archwire edgewise phase of treatment.

FIGURE 36-83 Examples of two cases treated with the same high-tech archform.

these light archwires to work. The author encourages clinicians to resist the temptation to change archwires constantly. Proffit stated, "Activating an appliance too frequently, short circuiting the repair process, can produce damage to the teeth or bone that a longer appointment cycle would have prevented or at least minimized."[17] Observing the root proximity in or adjacent to the alveolar cortical plate on lower CT scans makes a strong case for using biologically sensible forces and paying close attention to how forces are applied. Most clinicians using traditional mechanics select archwires based on patient tolerance rather than selecting forces based on biologic principles. Those clinicians who use conventional archwire sequencing or force archwire changes in the bracket tubes *severely compromise the clinical response of this new technology.*

The Damon archform has been developed over many years but is used in a single form and size only during the first two phases of high-tech archwires. The first two high-tech archwire phases are intended to give the body a second chance to find a new physiologically determined tooth position and archform dictated by the muscles of the face and tongue, bone, and soft tissue. This is a functional or natural archform, not a forced archform. The art of new clinical orthodontics is to learn how to read and react to how the body responds to these very light forces. The teeth are not being driven into a predetermined archform. *The shape of the working and final archform is copied from the lower arch after the high-tech edgewise phase* (Fig. 36-82). *Instead of treating to a small, medium, and large archform, each archform is patient specific* (Fig. 36-83). *After using this new technology for more than 8 years, the author realized that predicting the shape and size of the final archform is impossible before treatment.* This is a significant advantage over traditional mechanics and other current treatment techniques. (Note that the Ni-Ti wires specified throughout the cases presented are Ni-Ti Align SE wires. The author has worked with Ormco to develop Copper Ni-Ti archwires for the initial light round wire and high-tech edgewise phases that the author now uses.)

Light Round Wire Phase

By the end of the light round wire phase, the orthodontist will have achieved significant leveling and aligning, begun rotational control, and begun arch development.

The orthodontist should consider the following:

- Use a 0.014-inch Copper Ni-Ti initial archwire to start tooth movement, level, begin archform development, and prepare for the next archwire.
- Use a 0.016-inch Copper Ni-Ti archwire for a second archwire in severely crowded adult patients who are not ready for the second phase archwire.

High-Tech Edgewise Phase

By the end of the high-tech edgewise phase, the orthodontist will have completed leveling and aligning, completed rotational control, begun torque control, begun space consolidation, and continued arch development.

The orthodontist should consider the following:

- Place 0.016- × 0.025-inch Copper Ni-Ti wires in primarily young patients with well-prepared upper arches.
- Place 0.014- × 0.025-inch Copper Ni-Ti when archwire is too difficult to engage in the upper arch. In all lower arches, because of interbracket distance, 0.014- × 0.025-inch Copper Ni-Ti is strongly recommended. In all adults, 0.014- × 0.025-inch Copper Ni-Ti is recommended as the second archwire in upper and lower arches. Space is consolidated in the anterior segments.
- Use a 0.018- × 0.025-inch Copper Ni-Ti archwire after a 0.014- × 0.025-inch Copper Ni-Ti archwire. The archwire is well suited for preparing for the insertion of the working stainless steel wire.
- A 20-degree pretorqued reverse curve 0.017- × 0.025-inch Copper Ni-Ti archwire serves well as a Division 2 second wire. Use the same wire without the torque if only intrusion is needed. A 0.019- × 0.025-inch version of the same wire is available for more challenging cases or a follow-up archwire.
- Take a panoramic radiograph, and assess root positions after the use of high-tech edgewise wire to determine the need to reposition brackets.

Major Mechanics Phase

By the end of the major mechanics phase, the orthodontist will have completed or nearly completed torque control, completed space consolidation, corrected buccolingual discrepancies, and finalized the patient-specific archform.

A 0.019- × 0.025-inch posted stainless steel archwire is used to maintain arch integrity and should be used during anteroposterior correction and closure and also to maintain the anterior vertical and posterior buccolingual.

Finishing Phase

By the end of the finishing phase, the orthodontist will have conducted final detailing.

In most cases the working archwires are kept in place to finish the case. If more bending or torquing of archwires is needed to finish, then the orthodontist should use 0.019- × 0.025-inch or 0.017- × 0.025-inch TMA archwire.

Tieback Usage with the Damon System

Once all the spaces are closed, modules, elastic chains, or ligature wires are typically used in the major mechanics and final stages of treatment to keep all spaces closed. Available in a variety of sizes and strengths, tieback modules are extended intraarch from the posted hook on a 0.019- × 0.025-inch archwire, occlusally passing beneath the first premolar tie-wings to the hook of the first molar in the same arch. Tiebacks are strongly recommended in this low-force, low-friction system because space easily opens.

Using Elastics with the Damon System

Many ways exist to achieve good clinical results with elastic wear. The elastics most frequently used in the author's clinic have proved effective in the passive self-locking system. The author keeps treatment mechanics simple and has been impressed with what can be achieved with elastic wear when biologically sensible forces are applied to a mechanical system with greatly reduced friction and binding. Posts on the archwires used for elastic wear are preferred so as to evenly distribute force over all teeth. Eliminating bracket hooks keeps the appliance clean and more comfortable and promotes healthy tissue response. Because the bracket is self-ligating, the tie-wings are free for elastic attachment.

Lingual Retainer Wire and Splint Retainer

Using this tube technology and low-force, low-friction mechanics, clinicians now are able to treat many patients who, in the past, would have been scheduled for surgery. To retain these challenging patients who have had severe muscle imbalances, the author strongly recommends the placement of temporary upper and permanent lower lingual retainer wires and nightly use of a splint.

As an outstanding muscle trainer, the splint not only maintains the alignment of teeth and dental arches, but it also helps maintain the orientation of the occlusion. Approximately 30% of the author's patients today are retained with this special splint for at least 1 year or longer. *Without the use of the splint, the long-term stability of many cases would be compromised.* Surprisingly, patients adapt well to splints, and many mention an improvement in nightly sleep patterns.

Splints are recommended in patients with:

1. Severe muscle dysfunction (buccolingual coordination challenges)
2. Herbst appliance
3. Severe posterior crossbite
4. Lateral tongue-thrust
5. Severe Class II or III dentitions corrected with elastics
6. Temporomandibular joint disorders
7. Some sleep apnea

For maximum retention, the orthodontist places lingual retention wires after debonding and bonds a 0.016- × 0.025-inch Bond-a-Braid braided wire to each upper tooth lateral to lateral incisor. (The orthodontist removes the upper retention wire 2 to 3 years into retention, depending on the severity of the original anterior tooth position and patient stability in retention.) The orthodontist takes an impression of the lower arch. The orthodontist fabricates a canine-to-canine lingual retainer on the model with a 0.026-inch round stainless steel wire. In normal cases the orthodontist bonds the retainer to only the canines. In severe cases the orthodontist bonds the retainer to each tooth canine to canine. (The lower lingual retainer is permanently left in.)

After the lingual bonded retainers are in place, the orthodontist takes impressions of the upper and lower dental arches. Thick pink base plate wax is heated in a hot water bath and folded end to end twice to create four thicknesses of wax. (The orthodontist must make certain that the wax is soft to prevent distortion of the condyle when taking a bite registration.) The orthodontist instructs the patient to bite slowly into the wax, carefully aligning the midlines and leaving 3 to 4 mm of bite opening for airway and thickness of the upper and lower retainer materials. In all Class II retention cases, the orthodontist takes the bite registration in a slightly overcorrected mandibular position. Figure 36-84 illustrates the fabrication and seating of this valuable retention splint.

FIGURE 36-84 Fabrication of the splint retainer. **A,** Trim models and remove any occlusal bubbles. Cut groove in base of models with acrylic bur in alveolar ridge area *(arrows)*. **B,** Apply sticky wax to the models together with three toothpicks. Paint Al-Cote separating agent (Dentsply, York, PA) on both model bases. **C,** Mount upper and lower models on simple articulator. **D,** Carefully separate models from their bases at the separating agent joint. **E,** Remove plaster from the center of both models, and use vacuum application of Essex A+ (Raintree Essix, Metairie, LA) or Biocryl (Great Lakes Orthodontics, Tonawanda, NY). Block out undercuts with Wonderfill (Dental Creations, Waco, TX). **F,** Trim retainer material on the model, and place the models back on the articulator with sticky wax. **G,** Mix acrylic, and place it between the models from middle canine to posterior canine on the buccal and lingual aspects. **H,** Leave airway in anterior area canine to canine. Amount of airway is determined by the needs of the patient. **I,** Place acrylic beyond the tip of the upper canine. Leave it short of the cusp tip *(arrow)*. A fracture line sets up if patients clench their teeth. **J,** Relieve any undercuts with acrylic bur on upper canine. **K,** Note how tongue is contained *(arrows)*.

SUMMARY

The philosophy underlying the intended use of the Damon System is to approximate the forces that normal functioning muscles have on tooth position and the developing archform. The system is a blend of high-technology archwires and passive self-ligating tubes (brackets) carefully matched to produce great finishes while maintaining an appreciable amount of play in the mechanical system, especially in the initial stages of treatment. This new way of thinking about clinical mechanics is based on trying to achieve the following two clinical principles:

1. Do not overpower the biologic system with high-force mechanics during any phase of treatment.
2. Work with the orofacial musculature, allowing it to determine the new physiologically based tooth position and archform balanced among the facial muscles, tongue, bone, and soft tissue.

For many years, clinicians have based most of their treatment planning decisions on maintaining the patient's original archform. Determining the appropriate force level was often based on patient tolerance rather than its impact on the biologic cellular composition of bone and tissue. Conventional thinking also ascribed stable results to the elimination of tooth mass to maintain the original archform. Long-term retention studies have not shown a statistically significant correlation between tooth extraction and stability. For years, orthodontists have observed that many malocclusions are simply the result of functional abnormalities. With muscle-imbalance corrective appliances, Fränkel demonstrated that the posterior archform could be altered long-term stability. The reason why the Damon System appears to have an effect similar to the Fränkel effect with its concomitant impact on the physiologic adaptation of the muscles is not completely understood. With the use of very light, biologically sensible forces to start to unravel crowding, the changing archform appears to "wake up the tongue" and, in most patients, creates a new balance of the orofacial musculature. This newly created balance of the muscles, bone, and soft tissue is what determines the new tooth position and archform. With the Damon System and the philosophy of low-force mechanics, the art of clinical orthodontics is learning how to read and react to what the body determines for each individual patient. Extensive clinical results indicate that complete dentitions can be maintained, even in many crowded arches. In most cases, the body—not the clinician—determines the final archform.

The most significant impact of this new, passive technology is the myriad of additional options available to the clinician for facially driven treatment planning. Clinicians around the world are acutely aware of the long-term impact of traditional extraction therapy on the maturing face. (The philosophy of the Damon System still strongly recommends extraction therapy in bimaxillary protrusive cases.) By designing new treatment mechanics that consider the biologic impact of low-force treatment over the lifetime of a patient, orthodontists now have the opportunity to consider what the patient will look like at 50 years of age and design treatment plans in which most complete dentitions are preserved.

CT scans taken of patients just debonded and compared with scans taken 5 years and longer in retention show promising results from the low-force therapy offered via the Damon System and its underlying treatment philosophy. The following observations were made from studying the results of Damon System therapy on 13 patients ranging in ages from 13 years, 6 months to 56 years of age:

1. Alveolar bone can be altered and reshaped with low clinical forces.
2. With low-force, low-friction orthodontics via the Damon System, the alveolar bone will allow the movement of teeth with minimal tipping in all planes of space.
3. Alveolar bone is exceedingly thin on the labial, buccal, and lingual aspects of teeth that clinicians are trying to move. This observation calls for low-force therapy that respects the delicate nature of this bony architecture.
4. In many lower arches, pretreatment roots are routinely positioned within the cortical plate. This observation mandates the deployment of extremely low clinical force systems that take into account the low vascularity of cortical plate.
5. The architecture and thickness of alveolar bone appears to improve over time in retention after low-force orthodontics.
6. The low-force mechanics used through the Damon System indicate improved bone response for teeth that have not been allowed to erupt through the facial or lingual cortical plate. For this reason, early tooth guidance is strongly encouraged.
7. Low-force orthodontics *can* have a positive impact on the bone of periodontal patients.
8. Several hundred thousand patients have now been treated worldwide with the Damon System technology. In compromised dentitions, periodontists following complex cases treated with this light-force system have been impressed with the positive bone and tissue response. Although the clinical results are promising, further research and long-term retention studies are encouraged.

Acknowledgment

The author would like to acknowledge Robert Borkowski for his input about the physiologic functioning of tooth movement and contribution to this chapter in that regard, much of which comes from his postgraduate orthodontic thesis.
