Aplia™

Concentrate. Practice. Comprehend.

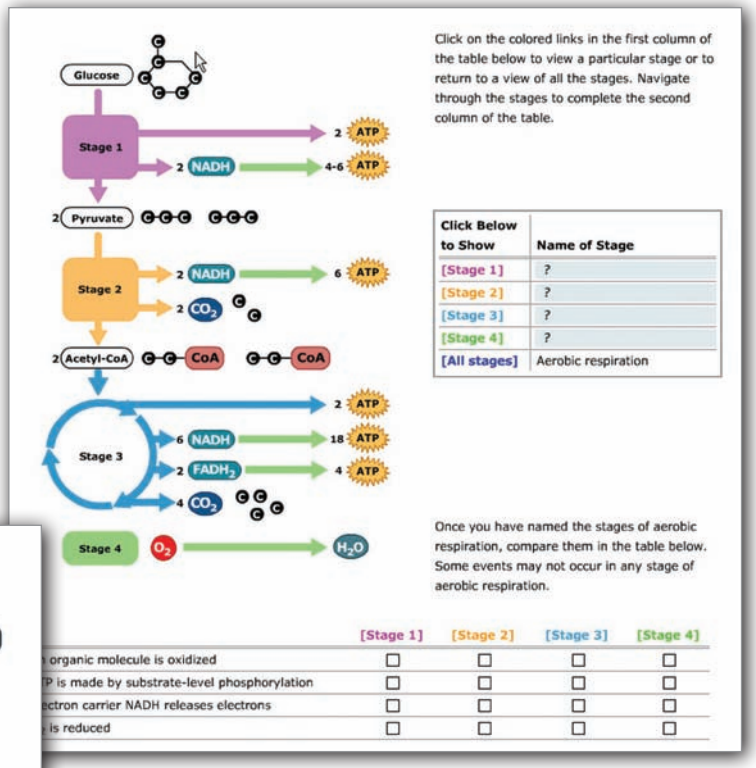
aplia™

Aplia Biology is an interactive online learning solution, designed to work with your text to help you understand complex processes in biology. Work at your own pace, receiving instant, detailed, feedback to ensure that you're never lost. Keep up with **Aplia's** frequent assignments and you'll continue to master concept after concept. More than a million students have succeeded with **Aplia**. Become one of them!

Active Reinforcement

Aplia makes it easy to stay on track throughout the term. **Aplia's** interactive tools help you remain engaged and build an understanding of complex processes.

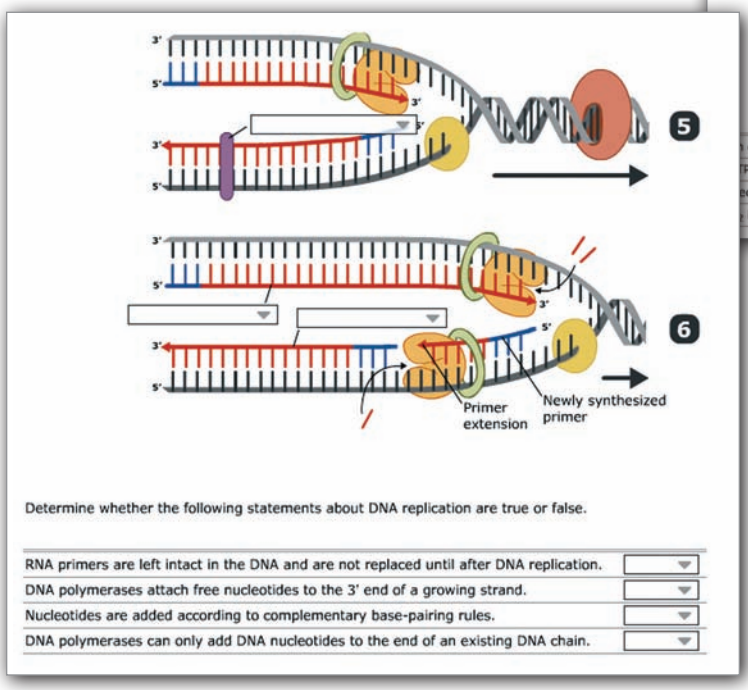
- Practice problems can be repeated so that you understand key concepts.
- Graded problems count toward your final score and are automatically recorded in the instructor's gradebook.



Interactive Figures

Vivid images with related questions help you come to class prepared and ready to participate.

Interactive figures often taken directly from the textbook allow you to focus on sequential processes one step at a time without losing the context of the entire process.



Engaging Videos

Active learning opportunities in the form of short, interactive pieces or videos within an assignment pique your interest and motivate you to learn more about the concept. Aplia integrates your textbook the art, and the media to give you a comprehensive, visual and interactive experience.

Multimedia material reinforces key concepts and ties the homework to the textbook, helping you visualize dynamic biological processes.

Buy or rent the way you want and save! Get the best grade in the shortest possible time!

Cover Image: Leafy sea dragon (*Phycodurus eques*) in Southern Ocean; Michael Aw/Getty Images

The leafy sea dragon inhabits kelp-covered rocky reefs and seaweed beds in the waters off the southern and western coast of Australia. This fish lives in depths from about 3 m to 50 m. It feeds on plankton, mainly tiny crustaceans, and typically grows to a length of about 35 centimeters (14 inches). The leafy sea dragon, with its long leaflike extensions, blends with surrounding seaweed, a striking example of camouflage.

When the male leafy sea dragon is ready to mate, his tail becomes bright yellow. Females then deposit up to 250 bright pink eggs in a spongy brood patch on the underside of the male's tail. The eggs are fertilized during the transfer from the female to the male. The male incubates the eggs for four to six weeks. Then, miniature leafy sea dragons are released into the water.

Leafy sea dragon populations have decreased due to habitat loss, pollution, and collectors who sell them for aquariums. They are currently listed as "near threatened" in the International Union for Conservation of Nature's status list.

ABOUT THE AUTHORS

ELDRA P. SOLOMON has written several leading college-level textbooks in biology and in human anatomy and physiology. Her books have been translated into more than 10 languages. Dr. Solomon earned an M.S. from the University of Florida and an M.A. and Ph.D. from the University of South Florida. Dr. Solomon taught biology and nursing students for more than 20 years.

In addition to being a biologist and science author, Dr. Solomon is a biopsychologist with a special interest in the neuro-physiology of traumatic experience. Her research has focused on the neurological, endocrine, and psychological effects of trauma, including Post-traumatic Stress Disorder and development of maladaptive coping strategies.

Dr. Solomon has presented her research at many national and international conferences, and her work has been published in leading professional journals. Dr. Solomon has been profiled more than 30 times in leading publications, including *Who's Who in America, Who's Who in Science and Engineering, Who's Who in Medicine and Healthcare, Who's Who in American Education, Who's Who of American Women,* and *Who's Who in the World.*

LINDA R. BERG is an award-winning teacher and textbook author. She received a B.S. in science education, an M.S. in botany, and a Ph.D. in plant physiology from the University of Maryland. Her research focused on the evolutionary implications of steroid biosynthetic pathways in various organisms.

Dr. Berg taught at the University of Maryland at College Park for 17 years and at St. Petersburg College in Florida for 8 years. During her career, she taught introductory courses in biology, botany, and environmental science to thousands of students. At the University of Maryland, she received numerous teaching and service awards. Dr. Berg is also the recipient of many national and regional awards, including the National Science Teachers Association Award for Innovations in College Science Teaching, the Nation's Capital Area Disabled Student Services Award, and the Washington Academy of Sciences Award in University Science Teaching.

During her career as a professional science writer, Dr. Berg has authored or co-authored several leading college science textbooks. Her writing reflects her teaching style and love of science.

DIANA W. MARTIN is the Director of General Biology, Division of Life Sciences, at Rutgers University, New Brunswick Campus. She received an M.S. at Florida State University, where she studied the chromosomes of related plant species to understand their evolutionary relationships. She earned a Ph.D. at the University of Texas at Austin, where she studied the genetics of the fruit fly, *Drosophila melanogaster,* and then conducted postdoctoral research at Princeton University. She has taught General Biology and other courses at Rutgers for more than 25 years and has been involved in writing textbooks since 1988. She is immensely grateful that her decision to study biology in college has led to a career that allows her many ways to share her excitement about all aspects of biology.

Table of Contents

Part 1 THE ORGANIZATION OF LIFE 1

1 A View of Life 1

Three Basic Themes 2

Characteristics of Life 2

Organisms are composed of cells 2
Organisms grow and develop 3
Organisms regulate their metabolic processes 3
Organisms respond to stimuli 4
Organisms reproduce 4
Populations evolve and become adapted to the environment 5

Levels of Biological Organization 5

Organisms have several levels of organization 6
Several levels of ecological organization can be identified 6

Information Transfer 6

DNA transmits information from one generation to the next 6
Information is transmitted by chemical and electrical signals 8

The Energy of Life 8

Evolution: The Basic Unifying Concept of Biology 10

Biologists use a binomial system for naming organisms 11
Taxonomic classification is hierarchical 11
The tree of life includes three domains and several kingdoms 11
Species adapt in response to changes in their environment 14
Natural selection is an important mechanism by which evolution proceeds 14
Populations evolve as a result of selective pressures from changes in their environment 15

The Process of Science 15

Science requires systematic thought processes 16
Scientists make careful observations and ask critical questions 16
Chance often plays a role in scientific discovery 17
A hypothesis is a testable statement 17
Many predictions can be tested by experiment 18
Researchers must avoid bias 19
Scientists interpret the results of experiments and make conclusions 19
A theory is supported by tested hypotheses 19
Many hypotheses cannot be tested by direct experiment 19
Paradigm shifts allow new discoveries 21
Systems biology integrates different levels of information 21
Science has ethical dimensions 22

2 Atoms and Molecules: The Chemical Basis of Life 26

Elements and Atoms 27

An atom is uniquely identified by its number of protons 27
Protons plus neutrons determine atomic mass 28
Isotopes of an element differ in number of neutrons 29
Electrons move in orbitals corresponding to energy levels 30

Chemical Reactions 31

Atoms form compounds and molecules 31
Simplest, molecular, and structural chemical formulas give different information 31
One mole of any substance contains the same number of units 31
Chemical equations describe chemical reactions 32

Chemical Bonds 32

In covalent bonds electrons are shared 32
Ionic bonds form between cations and anions 34
Hydrogen bonds are weak attractions 36
van der Waals interactions are weak forces 36

Redox Reactions 36

Water 37

Hydrogen bonds form between water molecules 37
Water molecules interact with hydrophilic substances by hydrogen bonding 38
Water helps maintain a stable temperature 38

Acids, Bases, and Salts 40

pH is a convenient measure of acidity 41
Buffers minimize pH change 42
An acid and a base react to form a salt 42

www.konkur.in

3 The Chemistry of Life: Organic Compounds 46

Carbon Atoms and Organic Molecules 47

Isomers have the same molecular formula but different structures 48

Functional groups change the properties of organic molecules 48

Many biological molecules are polymers 51

Carbohydrates 51

Monosaccharides are simple sugars 52

Disaccharides consist of two monosaccharide units 53

Polysaccharides can store energy or provide structure 53

Some modified and complex carbohydrates have special roles 55

Lipids 56

Triacylglycerol is formed from glycerol and three fatty acids 57

Saturated and unsaturated fatty acids differ in physical properties 57

Phospholipids are components of cell membranes 58

Carotenoids and many other pigments are derived from isoprene units 59

Steroids contain four rings of carbon atoms 59

Some chemical mediators are lipids 59

Proteins 60

Amino acids are the subunits of proteins 60

Peptide bonds join amino acids 61

Proteins have four levels of organization 61

The amino acid sequence of a protein determines its conformation 66

Nucleic Acids 68

Some nucleotides are important in energy transfers and other cell functions 68

Identifying Biological Molecules 69

4 Organization of the Cell 74

The Cell: Basic Unit of Life 75

The cell theory is a unifying concept in biology 75

The organization of all cells is basically similar 75

Cell size is limited 75

Cell size and shape are adapted to function 76

Methods for Studying Cells 77

Light microscopes are used to study stained or living cells 77

Electron microscopes provide a high-resolution image that can be greatly magnified 79

Biologists use biochemical techniques to study cell components 79

Prokaryotic and Eukaryotic Cells 81

Organelles of prokaryotic cells are not surrounded by membranes 81

Membranes divide the eukaryotic cell into compartments 82

The Cell Nucleus 86

Organelles in the Cytoplasm 89

Ribosomes manufacture proteins 89

The endoplasmic reticulum is a network of internal membranes 89

The Golgi complex processes, sorts, and modifies proteins 91

Lysosomes are compartments for digestion 93

Vacuoles are large, fluid-filled sacs with a variety of functions 93

Peroxisomes metabolize small organic compounds 93

Mitochondria and chloroplasts are energy-converting organelles 94

Mitochondria make ATP through cellular respiration 94

Chloroplasts convert light energy to chemical energy through photosynthesis 96

The Cytoskeleton 97

Microtubules are hollow cylinders 97

Centrosomes and centrioles function in cell division 98

Cilia and flagella are composed of microtubules 98

Microfilaments consist of intertwined strings of actin 99

Intermediate filaments help stabilize cell shape 101

Cell Coverings 101

5 Biological Membranes 106

The Structure of Biological Membranes 107

Phospholipids form bilayers in water 107

The fluid mosaic model explains membrane structure 108

Biological membranes are two-dimensional fluids 109

Biological membranes fuse and form closed vesicles 111

Membrane proteins include integral and peripheral proteins 111

Proteins are oriented asymmetrically across the bilayer 113

Overview of Membrane Protein Functions 114

Cell Membrane Structure and Permeability 115

Biological membranes present a barrier to polar molecules 115

Transport proteins transfer molecules across membranes 115

Passive Transport 116

Diffusion occurs down a concentration gradient 116

Osmosis is diffusion of water across a selectively permeable membrane 117

Facilitated diffusion occurs down a concentration gradient 119

Active Transport 121

Active transport systems "pump" substances against their concentration gradients 121

Carrier proteins can transport one or two solutes 123

Cotransport systems indirectly provide energy for active transport 123

Exocytosis and Endocytosis 123

In exocytosis, vesicles export large molecules 123

In endocytosis, the cell imports materials 125

www.konkur.in

Cell Junctions 127

Anchoring junctions connect cells of an epithelial sheet 127

Tight junctions seal off intercellular spaces between some animal cells 128

Gap junctions allow the transfer of small molecules and ions 129

Plasmodesmata allow certain molecules and ions to move between plant cells 129

6 Cell Communication 134

Cell Communication: An Overview 135

Sending Signals 136

Reception 137

Cells regulate reception 138

Three types of receptors occur on the cell surface 139

Some receptors are located inside the cell 141

Signal Transduction 141

Signaling molecules can act as molecular switches 141

Ion channel–linked receptors open or close channels 141

G protein–linked receptors initiate signal transduction 142

Second messengers are intracellular signaling agents 143

Many enzyme-linked receptors activate protein kinase signaling pathways 146

Many activated intracellular receptors are transcription factors 147

Scaffold proteins increase efficiency 147

Signals can be transmitted in more than one direction 147

Responses to Signals 147

Ras pathways involve tyrosine kinase receptors and G proteins 148

The response to a signal is amplified 148

Signals must be terminated 149

Evolution of Cell Communication 150

Part 2 ENERGY TRANSFER THROUGH LIVING SYSTEMS 154

7 Energy and Metabolism 154

Biological Work 155

Organisms carry out conversions between potential energy and kinetic energy 155

The Laws of Thermodynamics 155

The total energy in the universe does not change 155

The entropy of the universe is increasing 156

Energy and Metabolism 156

Enthalpy is the total potential energy of a system 157

Free energy is available to do cell work 157

Chemical reactions involve changes in free energy 157

Free energy decreases during an exergonic reaction 157

Free energy increases during an endergonic reaction 157

Diffusion is an exergonic process 158

Free-energy changes depend on the concentrations of reactants and products 158

Cells drive endergonic reactions by coupling them to exergonic reactions 158

ATP, the Energy Currency of the Cell 159

ATP donates energy through the transfer of a phosphate group 160

ATP links exergonic and endergonic reactions 160

The cell maintains a very high ratio of ATP to ADP 160

Energy Transfer in Redox Reactions 161

Most electron carriers transfer hydrogen atoms 161

Enzymes 162

All reactions have a required energy of activation 162

An enzyme lowers a reaction's activation energy 163

An enzyme works by forming an enzyme–substrate complex 163

Enzymes are specific 164

Many enzymes require cofactors 164

Enzymes are most effective at optimal conditions 165

Enzymes are organized into teams in metabolic pathways 166

The cell regulates enzymatic activity 166

Enzymes are inhibited by certain chemical agents 168

Some drugs are enzyme inhibitors 168

8 How Cells Make ATP: Energy-Releasing Pathways 172

Redox Reactions 173

The Four Stages of Aerobic Respiration 173

In glycolysis, glucose yields two pyruvates 175

Pyruvate is converted to acetyl CoA 177

The citric acid cycle oxidizes acetyl CoA 177

The electron transport chain is coupled to ATP synthesis 177

Inquiring About Electron Transport and Heat 183

Aerobic respiration of one glucose yields a maximum of 36 to 38 ATPs 184

Cells regulate aerobic respiration 186

Energy Yield of Nutrients Other Than Glucose 186

Anaerobic Respiration and Fermentation 187

Alcohol fermentation and lactate fermentation are inefficient 188

www.konkur.in

9 Photosynthesis: Capturing Light Energy 193

Light and Photosynthesis 194

Chloroplasts 195

Chlorophyll is found in the thylakoid membrane 195

Chlorophyll is the main photosynthetic pigment 196

Overview of Photosynthesis 198

ATP and NADPH are the products of the light-dependent reactions: An overview 198

Carbohydrates are produced during the carbon fixation reactions: An overview 199

The Light-Dependent Reactions 199

Photosystems I and II each consist of a reaction center and multiple antenna complexes 200

Noncyclic electron transport produces ATP and NADPH 200

Cyclic electron transport produces ATP but no NADPH 202

ATP synthesis occurs by chemiosmosis 202

The Carbon Fixation Reactions 204

Most plants use the Calvin cycle to fix carbon 204

Photorespiration reduces photosynthetic efficiency 206

The initial carbon fixation step differs in C_4 plants and in CAM plants 206

CAM plants fix CO_2 at night 207

Metabolic Diversity 208

Photosynthesis in Plants and in the Environment 209

Part 3 THE CONTINUITY OF LIFE: GENETICS 213

10 Chromosomes, Mitosis, and Meiosis 213

Eukaryotic Chromosomes 214

DNA is organized into informational units called genes 214

DNA is packaged in a highly organized way in chromosomes 214

Chromosome number and informational content differ among species 215

The Cell Cycle and Mitosis 217

Chromosomes duplicate during interphase 217

During prophase, duplicated chromosomes become visible with the microscope 218

Prometaphase begins when the nuclear envelope breaks down 220

Duplicated chromosomes line up on the midplane during metaphase 220

During anaphase, chromosomes move toward the poles 221

During telophase, two separate nuclei form 221

Cytokinesis forms two separate daughter cells 222

Mitosis produces two cells genetically identical to the parent cell 222

Lacking nuclei, prokaryotes divide by binary fission 222

Regulation of the Cell Cycle 223

Sexual Reproduction and Meiosis 225

Meiosis produces haploid cells with unique gene combinations 227

Prophase I includes synapsis and crossing-over 230

During meiosis I, homologous chromosomes separate 231

Chromatids separate in meiosis II 231

Mitosis and meiosis lead to contrasting outcomes 231

Sexual Life Cycles 233

11 The Basic Principles of Heredity 237

Mendel's Principles of Inheritance 238

Alleles separate before gametes are formed: the principle of segregation 241

Alleles occupy corresponding loci on homologous chromosomes 242

A monohybrid cross involves individuals with different alleles of a given locus 242

A dihybrid cross involves individuals that have different alleles at two loci 245

Alleles on nonhomologous chromosomes are randomly distributed into gametes: the principle of independent assortment 245

Recognition of Mendel's work came during the early 20th century 246

Using Probability to Predict Mendelian Inheritance 247

Inquiring About Solving Genetic Problems 248

The rules of probability can be applied to a variety of calculations 248

Inheritance and Chromosomes 249

Linked genes do not assort independently 249

Calculating the frequency of crossing-over reveals the linear order of linked genes on a chromosome 250

Sex is generally determined by sex chromosomes 251

Extensions of Mendelian Genetics 255

Dominance is not always complete 255

Multiple alleles for a locus may exist in a population 256

A single gene may affect multiple aspects of the phenotype 257

Alleles of different loci may interact to produce a phenotype 257

In polygenic inheritance, the offspring exhibit a continuous variation in phenotypes 257

Genes interact with the environment to shape phenotype 258

12 DNA: The Carrier of Genetic Information 263

Evidence of DNA as the Hereditary Material 264

DNA is the transforming principle in bacteria 264

DNA is the genetic material in certain viruses 265

www.konkur.in

The Structure of DNA 265

Nucleotides can be covalently linked in any order to form long polymers 267

DNA is made of two polynucleotide chains intertwined to form a double helix 268

In double-stranded DNA, hydrogen bonds form between A and T and between G and C 269

DNA Replication 271

Meselson and Stahl verified the mechanism of semiconservative replication 271

Semiconservative replication explains the perpetuation of mutations 273

DNA replication requires protein "machinery" 273

Enzymes proofread and repair errors in DNA 276

Telomeres cap eukaryotic chromosome ends 277

13 Gene Expression 282

Discovery of the Gene–Protein Relationship 283

Beadle and Tatum proposed the one-gene, one-enzyme hypothesis 283

Information Flow from DNA to Protein: An Overview 285

DNA is transcribed to form RNA 285

RNA is translated to form a polypeptide 285

Biologists cracked the genetic code in the 1960s 287

The genetic code is virtually universal 288

The genetic code is redundant 288

Transcription 288

The synthesis of mRNA includes initiation, elongation, and termination 289

Messenger RNA contains base sequences that do not directly code for protein 290

Eukaryotic mRNA is modified after transcription and before translation 291

Translation 293

An amino acid is attached to tRNA before incorporation into a polypeptide 293

The components of the translational machinery come together at the ribosomes 294

Translation begins with the formation of an initiation complex 294

During elongation, amino acids are added to the growing polypeptide chain 295

One of three stop codons signals the termination of translation 296

Variations in Gene Expression 297

Transcription and translation are coupled in bacteria 297

Biologists debate the evolution of eukaryotic gene structure 298

Several kinds of eukaryotic RNA have a role in gene expression 298

The definition of a gene has evolved as biologists have learned more about genes 300

The usual direction of information flow has exceptions 300

Mutations 300

Base-pair substitution mutations result from the replacement of one base pair by another 301

Frameshift mutations result from the insertion or deletion of base pairs 301

Some mutations involve mobile genetic elements 303

Mutations have various causes 303

14 Gene Regulation 307

Gene Regulation in Bacteria and Eukaryotes: An Overview 308

Gene Regulation in Bacteria 309

Operons in bacteria facilitate the coordinated control of functionally related genes 309

Some posttranscriptional regulation occurs in bacteria 313

Gene Regulation in Eukaryotic Cells 314

Eukaryotic transcription is controlled at many sites and by many regulatory molecules 315

The mRNAs of eukaryotes have many types of posttranscriptional control 319

Posttranslational chemical modifications may alter the activity of eukaryotic proteins 320

15 DNA Technology and Genomics 323

DNA Cloning 324

Restriction enzymes are "molecular scissors" 324

Recombinant DNA forms when DNA is spliced into a vector 324

DNA can be cloned inside cells 326

A cDNA library is complementary to mRNA and does not contain introns 329

The polymerase chain reaction amplifies DNA in vitro 329

DNA Analysis 331

Gel electrophoresis is used for separating macromolecules 331

DNA, RNA, and protein blots detect specific fragments 331

Restriction fragment length polymorphisms are a measure of genetic relationships 331

Methods to rapidly sequence DNA have been developed 333

Genomics 335

Identifying protein-coding genes is useful for research and for medical applications 336

One way to study gene function is to silence genes one at a time 336

DNA microarrays are a powerful tool for studying gene expression 336

The Human Genome Project stimulated studies of genome sequencing for other species 338

Several scientific fields—bioinformatics, pharmacogenetics, and proteomics—have emerged 338

www.konkur.in

Applications of DNA Technologies 339
DNA technology has revolutionized medicine 339
DNA fingerprinting has numerous applications 340
Transgenic organisms have foreign DNA incorporated into their cells 340

DNA Technology Has Raised Safety Concerns 343

16 Human Genetics and the Human Genome 347

Studying Human Genetics 348
Human chromosomes are studied by karyotyping 348
Family pedigrees help identify certain inherited conditions 349
The Human Genome Project sequenced the DNA on all human chromosomes 349
Comparative genomics has revealed DNA identical in both mouse and human genomes 351
Researchers use mouse models to study human genetic diseases 351

Abnormalities in Chromosome Number and Structure 351
Down syndrome is usually caused by trisomy 21 352
Most sex chromosome aneuploidies are less severe than autosomal aneuploidies 354
Abnormalities in chromosome structure cause certain disorders 355
Genomic imprinting is determined by whether inheritance is from the male or female parent 356

Genetic Diseases Caused by Single-Gene Mutations 358
Many genetic diseases are inherited as autosomal recessive traits 358
Some genetic diseases are inherited as autosomal dominant traits 360
Some genetic diseases are inherited as X-linked recessive traits 361

Gene Therapy 361
Gene therapy programs are carefully scrutinized 361

Genetic Testing and Counseling 362
Prenatal diagnosis detects chromosome abnormalities and gene defects 362
Genetic screening searches for genotypes or karyotypes 364
Genetic counselors educate people about genetic diseases 364

Human Genetics, Society, and Ethics 365
Genetic discrimination provokes heated debate 365
Many ethical issues related to human genetics must be addressed 366

17 Developmental Genetics 369

Cell Differentiation and Nuclear Equivalence 370
Most cell differences are due to differential gene expression 370
A totipotent nucleus contains all the instructions for development 372
The first cloned mammal was a sheep 373
Stem cells divide and give rise to differentiated cells 373

The Genetic Control of Development 375
A variety of model organisms provide insights into basic biological processes 376
Many genes that control development have been identified in the fruit fly 376
Caenorhabditis elegans has a relatively rigid developmental pattern 381
The mouse is a model for mammalian development 384
Arabidopsis is a model for studying plant development, including transcription factors 386

Cancer and Cell Development 387

Part 4 THE CONTINUITY OF LIFE: EVOLUTION 391

18 Introduction to Darwinian Evolution 391

What Is Evolution? 392

Pre-Darwinian Ideas about Evolution 392

Darwin and Evolution 393
Darwin proposed that evolution occurs by natural selection 395
The modern synthesis combines Darwin's theory with genetics 395
Biologists study the effect of chance on evolution 396

Evidence for Evolution 397
The fossil record provides strong evidence for evolution 397
The distribution of plants and animals supports evolution 400
Comparative anatomy of related species demonstrates similarities in their structures 402
Molecular comparisons among organisms provide evidence for evolution 404
Developmental biology helps unravel evolutionary patterns 406
Evolutionary hypotheses are tested experimentally 407

19 Evolutionary Change in Populations 411

Genotype, Phenotype, and Allele Frequencies 412

The Hardy–Weinberg Principle 412
Genetic equilibrium occurs if certain conditions are met 414
Human MN blood groups are a valuable illustration of the Hardy–Weinberg principle 414

Microevolution 415
Nonrandom mating changes genotype frequencies 415
Mutation increases variation within a population 416
In genetic drift, random events change allele frequencies 416
Gene flow generally increases variation within a population 417
Natural selection changes allele frequencies in a way that increases adaptation 417

www.konkur.in

Genetic Variation in Populations 420

Genetic polymorphism can be studied in several ways 420

Balanced polymorphism exists for long periods 420

Neutral variation may give no selective advantage or disadvantage 422

Populations in different geographic areas often exhibit genetic adaptations to local environments 422

20 Speciation and Macroevolution 426

What Is a Species? 427

The biological species concept is based on reproductive isolation 427

The phylogenetic species concept defines species based on such evidence as molecular sequencing 427

Reproductive Isolation 428

Prezygotic barriers interfere with fertilization 428

Postzygotic barriers prevent gene flow when fertilization occurs 430

Biologists are discovering genes responsible for reproductive isolating mechanisms 430

Speciation 430

Long physical isolation and different selective pressures result in allopatric speciation 432

Two populations diverge in the same physical location by sympatric speciation 434

The study of hybrid zones has made important contributions to what is known about speciation 437

The Rate of Evolutionary Change 438

Macroevolution 439

Evolutionary novelties originate through modifications of pre-existing structures 440

Adaptive radiation is the diversification of an ancestral species into many species 440

Extinction is an important aspect of evolution 441

Is microevolution related to speciation and macroevolution? 442

21 The Origin and Evolutionary History of Life 446

Chemical Evolution on Early Earth 447

Organic molecules formed on primitive Earth 448

The First Cells 449

The origin of a simple metabolism within a membrane boundary may have occurred early in the evolution of cells 449

Molecular reproduction was a crucial step in the origin of cells 450

Biological evolution began with the first cells 451

The first cells were probably heterotrophic 452

Aerobes appeared after oxygen increased in the atmosphere 453

Eukaryotic cells descended from prokaryotic cells 453

The History of Life 455

Rocks from the Ediacaran period contain fossils of cells and simple animals 455

A diversity of organisms evolved during the Paleozoic era 455

Dinosaurs and other reptiles dominated the Mesozoic era 458

Inquiring About The Origin of Flight in Birds 461

The Cenozoic era is the age of mammals 461

22 The Evolution of Primates 465

Primate Adaptations 466

Primate Classification 467

Suborder Anthropoidea includes monkeys, apes, and humans 467

Apes are our closest living relatives 469

Hominin Evolution 471

The earliest hominins may have lived 6 mya to 7 mya 472

Ardipithecus, Australopithecus, and *Paranthropus* are australopithecines, or "southern man apes" 472

Homo habilis is the oldest member of genus *Homo* 474

Homo ergaster may have arisen from *H. habilis* 474

Homo erectus probably evolved from *H. ergaster* 474

Archaic humans date from about 1.2 mya to 200,000 years ago 475

Neandertals appeared approximately 250,000 years ago 475

Inquiring About The Smallest Humans 476

Scientists have reached a near consensus on the origin of modern *Homo sapiens* 476

Cultural Change 478

Development of agriculture resulted in a more dependable food supply 478

Human culture has had a profound impact on the biosphere 478

Part 5 THE DIVERSITY OF LIFE 481

23 Understanding Diversity: Systematics 481

Classifying Organisms 482

Organisms are named using a binomial system 482

Each taxonomic level is more general than the one below it 483

Determining the Major Branches in the Tree of Life 483

Systematics is an evolving science 483

The three domains form the three main branches of the tree of life 485

Some biologists are moving away from Linnaean categories 486

Phylogenetic trees show hypothesized evolutionary relationships 486

Systematists continue to consider other hypotheses 487

www.konkur.in

Reconstructing Evolutionary History 488

Homologous structures are important in determining evolutionary relationships 489

Shared derived characters provide clues about phylogeny 489

Biologists carefully choose taxonomic criteria 489

Molecular homologies help clarify phylogeny 490

Taxa are grouped based on their evolutionary relationships 491

Constructing Phylogenetic Trees 493

Outgroup analysis is used in constructing and interpreting cladograms 493

A cladogram is constructed by considering shared derived characters 494

In a cladogram each branch point represents a major evolutionary step 494

Systematists use the principles of parsimony and maximum likelihood to make decisions 496

24 Viruses and Subviral Agents 501

The Status and Structure of Viruses 502

Viruses are very small 502

A virus consists of nucleic acid surrounded by a protein coat 502

The capsid is a protective protein coat 502

Some viruses are surrounded by an envelope 503

Classification of Viruses 504

Viral Replication 504

Bacteriophages infect bacteria 505

Viruses replicate inside host cells 505

Viral Diseases 506

Viruses cause serious plant diseases 506

Viruses cause serious diseases in animals 507

Inquiring About Influenza and Other Emerging Diseases 509

Evolution of Viruses 512

Subviral Agents 513

Satellites depend on helper viruses 513

Viroids are the smallest known pathogens 513

Prions are protein particles 513

25 Bacteria and Archaea 517

The Structure of Bacteria and Archaea 518

Prokaryotes have several common shapes 518

Prokaryotic cells do not have membrane-enclosed organelles 518

A cell wall protects most prokaryotes 519

Some bacteria produce capsules or slime layers 519

Some prokaryotes have fimbriae or pili 519

Some bacteria survive unfavorable conditions by forming endospores 520

Many types of prokaryotes are motile 520

Prokaryote Reproduction and Evolution 521

Rapid reproduction contributes to prokaryote success 522

Prokaryotes transfer genetic information 522

Evolution proceeds rapidly in bacterial populations 523

Nutritional and Metabolic Adaptations 524

Most prokaryotes require oxygen 524

Some prokaryotes fix and metabolize nitrogen 525

The Phylogeny of the Two Prokaryote Domains 525

Key characters distinguish the three domains 525

Taxonomy of archaea and bacteria continuously changes 526

Many archaea inhabit harsh environments 526

Bacteria are the most familiar prokaryotes 527

Impact on Ecology, Technology, and Commerce 530

Prokaryotes form intimate relationships with other organisms 530

Prokaryotes play key ecological roles 530

Prokaryotes are important in many commercial processes and in technology 531

Bacteria and Disease 532

Many scientists have contributed to our understanding of infectious disease 532

Many adaptations contribute to pathogen success 532

Antibiotic resistance is a major public health problem 534

26 Protists 537

Diversity in the Protists 538

How Did Eukaryotes Evolve? 539

Mitochondria and chloroplasts probably originated from endosymbionts 539

A consensus in eukaryote classification is beginning to emerge 539

Excavates 540

Diplomonads are small, mostly parasitic flagellates 542

Parabasilids are anaerobic endosymbionts that live in animals 542

Euglenoids and trypanosomes have both free-living species and parasites 543

Chromalveolates 544

Most dinoflagellates are a part of marine plankton 545

Apicomplexans are spore-forming parasites of animals 545

Ciliates use cilia for locomotion 547

Water molds produce biflagellate reproductive cells 548

Diatoms have shells composed of two parts 549

Brown algae are multicellular stramenopiles 549

Most golden algae are unicellular biflagellates 550

Rhizarians 551

Forams extend cytoplasmic projections that form a threadlike, interconnected net 551

Actinopods project slender axopods 552

www.konkur.in

Archaeplastids 552

Red algae do not produce motile cells 552

Green algae share many similarities with land plants 553

Unikonts 554

Amoebozoa are unikonts with lobose pseudopodia 555

27 Seedless Plants 561

Adaptations of Plants to Life on Land 562

The plant life cycle alternates between haploid and diploid generations 562

Four major groups of plants exist today 564

Bryophytes 565

Moss gametophytes are differentiated into "leaves" and "stems" 565

Liverwort gametophytes are either thalloid or leafy 567

Hornwort gametophytes are inconspicuous thalloid plants 570

Bryophytes are used for experimental studies 570

Recap: details of bryophyte evolution are based on fossils and on structural and molecular evidence 570

Seedless Vascular Plants 571

Club mosses are small plants with rhizomes and short, erect branches 572

Ferns are a diverse group of spore-forming vascular plants 572

Inquiring About Ancient Plants and Coal Formation 574

Some ferns and club mosses are heterosporous 576

Seedless vascular plants are used for experimental studies 578

Seedless vascular plants arose more than 420 mya 578

28 Seed Plants 582

An Introduction to Seed Plants 583

Gymnosperms 584

Conifers are woody plants that produce seeds in cones 584

Cycads have seed cones and compound leaves 587

Ginkgo biloba is the only living species in its phylum 587

Gnetophytes include three unusual genera 588

Flowering Plants 589

Monocots and eudicots are the two largest classes of flowering plants 590

Sexual reproduction takes place in flowers 590

The life cycle of flowering plants includes double fertilization 592

Seeds and fruits develop after fertilization 594

Flowering plants have many adaptations that account for their success 594

Floral structure provides insights into the evolutionary process 594

The Evolution of Seed Plants 595

Our understanding of the evolution of flowering plants has made great progress in recent years 595

29 The Fungi 601

Characteristics of Fungi 602

Fungi absorb food from the environment 602

Fungi have cell walls that contain chitin 602

Most fungi consist of a network of filaments 602

Fungal Reproduction 603

Many fungi reproduce asexually 603

Most fungi reproduce sexually 604

Fungal Diversity 605

Fungi are assigned to the opisthokont clade 605

Diverse groups of fungi have evolved 605

Chytrids have flagellate spores 606

Zygomycetes reproduce sexually by forming zygospores 607

Microsporidia have been a taxonomic mystery 609

Glomeromycetes are symbionts with plant roots 609

Ascomycetes reproduce sexually by forming ascospores 611

Basidiomycetes reproduce sexually by forming basidiospores 612

Ecological Importance of Fungi 615

Fungi form symbiotic relationships with some animals 615

Mycorrhizae are symbiotic associations between fungi and plant roots 617

A lichen consists of two components: a fungus and a photoautotroph 617

Economic, Biological, and Medical Impact of Fungi 619

Fungi provide beverages and food 619

Fungi are important to modern biology and medicine 620

Fungi are used in bioremediation and to biologically control pests 621

Some fungi cause diseases in humans and other animals 621

Fungi cause many important plant diseases 622

30 An Introduction to Animal Diversity 626

Animal Characters 627

Adaptations to Ocean, Freshwater, and Terrestrial Habitats 627

Marine habitats offer many advantages 627

Some animals are adapted to freshwater habitats 628

Terrestrial living requires major adaptations 628

Animal Evolution 629

Molecular systematics helps biologists interpret the fossil record 629

Biologists develop hypotheses about the evolution of development 630

www.konkur.in

Reconstructing Animal Phylogeny 630

Animals exhibit two main types of body symmetry 630

Animal body plans are linked to the level of tissue development 631

Most bilateral animals have a body cavity lined with mesoderm 632

Bilateral animals form two main clades based on differences in development 633

Biologists have identified major animal clades based on structure, development, and molecular data 633

31 Sponges, Cnidarians, Ctenophores, and Protostomes 640

Sponges, Cnidarians, and Ctenophores: Animals with Asymmetry, Radial, or Biradial Symmetry 641

Sponges have collar cells and other specialized cells 641

Cnidarians have unique stinging cells 643

Comb jellies have adhesive glue cells that trap prey 647

The Lophotrochozoa 648

Flatworms are bilateral acoelomates 648

Nemerteans are characterized by their proboscis 651

Mollusks have a muscular foot, visceral mass, and mantle 652

Annelids are segmented worms 656

The lophophorates are distinguished by a ciliated ring of tentacles 658

Rotifers have a crown of cilia 660

The Ecdysozoa 661

Roundworms are of great ecological importance 661

Arthropods are characterized by jointed appendages and an exoskeleton of chitin 661

32 The Deuterostomes 675

What Are Deuterostomes? 676

Echinoderms 676

Feather stars and sea lilies are suspension feeders 678

Many sea stars capture prey 678

Basket stars and brittle stars make up the largest group of echinoderms 679

Sea urchins and sand dollars have movable spines 679

Sea cucumbers are elongated, sluggish animals 679

The Chordates: Defining Characteristics 680

Invertebrate Chordates 681

Tunicates are common marine animals 681

Lancelets clearly exhibit chordate characteristics 682

Systematists debate chordate phylogeny 682

Introducing the Vertebrates 683

The vertebral column is a derived vertebrate character 683

Vertebrate taxonomy is a work in progress 685

Jawless Fishes 685

Evolution of Jaws and Limbs: Jawed Fishes and Amphibians 687

Most cartilaginous fishes inhabit marine environments 687

The ray-finned fishes gave rise to modern bony fishes 689

Descendants of the lungfishes moved onto the land 690

Amphibians were the first successful land vertebrates 692

Amniotes 693

Our understanding of amniote phylogeny is changing 693

Reptiles have many terrestrial adaptations 694

We can assign extant reptiles to five groups 695

Turtles have protective shells 696

Lizards and snakes are the most common modern reptiles 697

Tuataras superficially resemble lizards 697

Crocodilians have an elongated skull 697

How do we know that birds are really dinosaurs? 697

Modern birds are adapted for flight 699

Mammals have hair and mammary glands 700

New fossil discoveries are changing our understanding of the early evolution of mammals 700

Modern mammals are assigned to three subclasses 701

Part 6 STRUCTURE AND LIFE PROCESSES IN PLANTS 708

33 Plant Structure, Growth, and Development 708

The Plant Body 709

The plant body consists of cells and tissues 709

The ground tissue system is composed of three simple tissues 709

The vascular tissue system consists of two complex tissues 714

The dermal tissue system consists of two complex tissues 717

Plant Meristems 718

Primary growth takes place at apical meristems 719

Secondary growth takes place at lateral meristems 719

Development of Form 720

The plane and symmetry of cell division affect plant form 721

The orientation of cellulose microfibrils affects the direction of cell expansion 721

Cell differentiation depends in part on a cell's location 722

Morphogenesis occurs through pattern formation 724

34 Leaf Structure and Function 728

Leaf Form and Structure 729

Leaf structure is adapted for maximum light absorption 730

www.konkur.in

Stomatal Opening and Closing 734
Blue light triggers stomatal opening 735
Additional factors affect stomatal opening and closing 736

Transpiration and Guttation 736
Some plants exude liquid water 737

Leaf Abscission 738
In many leaves, abscission occurs at an abscission zone near the base of the petiole 738

Modified Leaves 738
Modified leaves of carnivorous plants capture insects 739

35 Stem Structure and Transport 744

Stem Growth and Structure 745
Herbaceous eudicot and monocot stems differ in internal structure 745
Woody plants have stems with secondary growth 746

Water Transport 753
Water and minerals are transported in xylem 753
Water movement can be explained by a difference in water potential 754
According to the tension–cohesion model, water is pulled up a stem 754
Root pressure pushes water from the root up a stem 756

Translocation of Sugar in Solution 756
The pressure–flow model explains translocation in phloem 756

36 Roots and Mineral Nutrition 761

Root Structure and Function 762
Roots have root caps and root hairs 762
The arrangement of vascular tissues distinguishes the roots of herbaceous eudicots and monocots 763
Woody plants have roots with secondary growth 767
Some roots are specialized for unusual functions 767

Root Associations and Interactions 768
Mycorrhizae facilitate the uptake of essential minerals by roots 770
Rhizobial bacteria fix nitrogen in the roots of leguminous plants 771

The Soil Environment 772
Soil is composed of inorganic minerals, organic matter, air, and water 773
Soil organisms form a complex ecosystem 774
Soil pH affects soil characteristics and plant growth 775
Soil provides most of the minerals found in plants 775
Soil can be damaged by human mismanagement 776

37 Reproduction in Flowering Plants 781

The Flowering Plant Life Cycle 782
Flowers develop at apical meristems 782
Each part of a flower has a specific function 782

Pollination 784
Many plants have mechanisms that prevent self-pollination 784
Flowering plants and their animal pollinators have coevolved 784
Some flowering plants depend on wind to disperse pollen 789

Fertilization and Seed/Fruit Development 789
A unique double fertilization process occurs in flowering plants 789
Embryonic development in seeds is orderly and predictable 790
The mature seed contains an embryonic plant and storage materials 790
Fruits are mature, ripened ovaries 793
Seed dispersal is highly varied 794

Germination and Early Growth 796
Some seeds do not germinate immediately 796
Eudicots and monocots exhibit characteristic patterns of early growth 797

Asexual Reproduction in Flowering Plants 797
Apomixis is the production of seeds without the sexual process 799

A Comparison of Sexual and Asexual Reproduction 799
Sexual reproduction has some disadvantages 800

38 Plant Developmental Responses to External and Internal Signals 803

Tropisms 804

Plant Hormones and Development 805
Plant hormones act by signal transduction 805
Auxins promote cell elongation 807
Gibberellins promote stem elongation 809
Cytokinins promote cell division 810
Ethylene promotes abscission and fruit ripening 810
Abscisic acid promotes seed dormancy 811
Brassinosteroids are plant steroid hormones 812
Identification of a universal flower-promoting signal remains elusive 812

Light Signals and Plant Development 813
Phytochrome detects day length 814
Competition for sunlight among shade-avoiding plants involves phytochrome 815
Phytochrome is involved in other responses to light, including germination 816
Phytochrome acts by signal transduction 816
Light influences circadian rhythms 816

www.konkur.in

Responses to Herbivores and Pathogens 817
Jasmonic acid activates several plant defenses 817
Methyl salicylate may induce systemic acquired resistance 818

Part 7 STRUCTURE AND LIFE PROCESSES IN ANIMALS 821

39 Animal Structure and Function: An Introduction 821

Tissues, Organs, and Organ Systems 822
Epithelial tissues cover the body and line its cavities 822
Connective tissues support other body structures 823
Muscle tissue is specialized to contract 828
Nervous tissue controls muscles and glands 829
Tissues and organs make up the organ systems of the body 830

Inquiring About Unwelcome Tissues: Cancers 831

Regulating the Internal Environment 834
Negative feedback systems restore homeostasis 834
A few positive feedback systems operate in the body 835

Thermoregulation 835
Ectotherms absorb heat from their surroundings 836
Endotherms derive heat from metabolic processes 836
Many animals adjust to challenging temperature changes 837

40 Protection, Support, and Movement 842

Epithelial Coverings 843
Invertebrate epithelium may secrete a cuticle 843
Vertebrate skin functions in protection and temperature regulation 843

Skeletal Systems 844
In hydrostatic skeletons, body fluids transmit force 844
Mollusks and arthropods have nonliving exoskeletons 845
Internal skeletons are capable of growth 845
The vertebrate skeleton has two main divisions 846
A typical long bone amplifies the motion generated by muscles 846
Bones are remodeled throughout life 847
Joints are junctions between bones 847

Muscle Contraction 848
Invertebrate muscle varies among groups 848
Insect flight muscles are adapted for rapid contraction 848
Vertebrate skeletal muscles act antagonistically to one another 849
A vertebrate muscle may consist of thousands of muscle fibers 850
Contraction occurs when actin and myosin filaments slide past one another 852
ATP powers muscle contraction 852
The type of muscle fibers determines strength and endurance 855
Several factors influence the strength of muscle contraction 855
Smooth muscle and cardiac muscle are involuntary 856

41 Neural Signaling 860

Neural Signaling: An Overview 861

Neurons and Glial Cells 862
Neurons receive stimuli and transmit neural signals 862
Certain regions of the CNS produce new neurons 862
Axons aggregate to form nerves and tracts 863
Glial cells play critical roles in neural function 863

Transmitting Information along the Neuron 865
Ion channels and pumps maintain the resting potential of the neuron 865
Graded local signals vary in magnitude 867
Axons transmit signals called action potentials 867
The action potential is an all-or-none response 869
An action potential is self-propagating 870

Transmitting Information across Synapses 872
Signals across synapses can be electrical or chemical 872
Neurons use neurotransmitters to signal other cells 872

Inquiring About Alzheimer's Disease 874
Neurotransmitters bind with receptors on postsynaptic cells 875
Activated receptors can send excitatory or inhibitory signals 875

Neural Integration 877
Postsynaptic potentials are summed over time and space 877
Where does neural integration take place? 878

Neural Circuits: Complex Information Signaling 878

42 Neural Regulation 882

Invertebrate Nervous Systems: Trends in Evolution 883

The Vertebrate Nervous System: Structure and Function 884

Evolution of the Vertebrate Brain 886
The hindbrain develops into the medulla, pons, and cerebellum 886
The midbrain is prominent in fishes and amphibians 888
The forebrain gives rise to the thalamus, hypothalamus, and cerebrum 888

The Human Central Nervous System 888
The spinal cord transmits impulses to and from the brain 889
The most prominent part of the human brain is the cerebrum 891

www.konkur.in

The body follows a circadian cycle of sleep and wakefulness 894
The limbic system affects emotional aspects of behavior 897

Inquiring About The Neurobiology of Traumatic Experience 898
Learning and memory involve long-term changes at synapses 899
Language involves comprehension and expression 901

The Peripheral Nervous System 902
The somatic division helps the body adjust to the external environment 902
The autonomic division regulates the internal environment 902

Effects of Drugs on the Nervous System 904

Inquiring About Alcohol: The Most Abused Drug 905

43 Sensory Systems 911

How Sensory Systems Work 912
Sensory receptors receive information 912
Sensory receptors transduce energy 912
Sensory input is integrated at many levels 912
We can classify sensory receptors based on location of stimuli or on the type of energy they transduce 914

Thermoreceptors 915

Electroreceptors and Electromagnetic Receptors 916

Nociceptors 916

Mechanoreceptors 916
Tactile receptors are located in the skin 916
Proprioceptors help coordinate muscle movement 918
Many invertebrates have gravity receptors called statocysts 918
Hair cells are characterized by stereocilia 919
Lateral line organs supplement vision in fishes 919
The vestibular apparatus maintains equilibrium 919
Auditory receptors are located in the cochlea 920

Chemoreceptors 924
Taste receptors detect dissolved food molecules 925
The olfactory epithelium is responsible for the sense of smell 926
Many animals communicate with pheromones 926

Photoreceptors 927
Invertebrate photoreceptors include eyespots, simple eyes, and compound eyes 927
Vertebrate eyes form sharp images 928
The retina contains light-sensitive rods and cones 929
Light activates rhodopsin 930
Color vision depends on three types of cones 932
Integration of visual information begins in the retina 933

44 Internal Transport 937

Types of Circulatory Systems 938
Many invertebrates have an open circulatory system 939
Some invertebrates have a closed circulatory system 939
Vertebrates have a closed circulatory system 940

Vertebrate Blood 940
Plasma is the fluid component of blood 940
Red blood cells transport oxygen 941
White blood cells defend the body against disease organisms 942
Platelets function in blood clotting 943

Vertebrate Blood Vessels 945

Evolution of the Vertebrate Cardiovascular System 946

The Human Heart 946
Each heartbeat is initiated by a pacemaker 948
The cardiac cycle consists of alternating periods of contraction and relaxation 949
The nervous system regulates heart rate 950
Stroke volume depends on venous return 951
Cardiac output varies with the body's need 951

Blood Pressure 951
Blood pressure varies in different blood vessels 953
Blood pressure is carefully regulated 954

The Pattern of Circulation 954
The pulmonary circulation oxygenates the blood 955
The systemic circulation delivers blood to the tissues 955

The Lymphatic System 956
The lymphatic system consists of lymphatic vessels and lymph tissue 956
The lymphatic system plays an important role in fluid homeostasis 957

Cardiovascular Disease 957

45 The Immune System: Internal Defense 963

Evolution of Immune Responses 964
Invertebrates launch nonspecific immune responses 964
Vertebrates launch nonspecific and specific immune responses 965

Nonspecific Immune Responses 966
Physical barriers prevent most pathogens from entering the body 966
Pattern recognition receptors activate nonspecific immune responses 966
Cells of the nonspecific immune system destroy pathogens and produce chemicals 966
Cytokines and complement mediate immune responses 967
Inflammation is a protective response 968

www.konkur.in

Specific Immune Responses 970

Many types of cells are involved in specific immune responses 971

The major histocompatibility complex is responsible for recognition of self 973

Cell-Mediated Immunity 973

Antibody-Mediated Immunity 975

A typical antibody consists of four polypeptide chains 977

Antibodies are grouped in five classes 978

Antigen–antibody binding activates other defenses 978

The immune system responds to millions of different antigens 978

Monoclonal antibodies are highly specific 979

Immunological memory is responsible for long-term immunity 979

Response to Disease, Immune Failures, and Harmful Reactions 982

Cancer cells evade the immune system 982

Immunodeficiency disease can be inherited or acquired 983

HIV is the major cause of acquired immunodeficiency in adults 984

In an autoimmune disease, the body attacks its own tissues 986

Rh incompatibility can result in hypersensitivity 986

Allergic reactions are directed against ordinary environmental antigens 987

Graft rejection is an immune response against transplanted tissue 988

46 Gas Exchange 993

Adaptations for Gas Exchange in Air or Water 994

Types of Respiratory Surfaces 994

The body surface may be adapted for gas exchange 994

Tracheal tube systems deliver air directly to the cells 994

Gills are the respiratory surfaces in many aquatic animals 996

Terrestrial vertebrates exchange gases through lungs 996

The Mammalian Respiratory System 998

The airway conducts air into the lungs 998

Gas exchange occurs in the alveoli of the lungs 1001

Ventilation is accomplished by breathing 1001

The quantity of respired air can be measured 1002

Gas exchange takes place in the alveoli 1002

Gas exchange takes place in the tissues 1003

Respiratory pigments increase capacity for oxygen transport 1003

Carbon dioxide is transported mainly as bicarbonate ions 1004

Breathing is regulated by respiratory centers in the brain 1004

Hyperventilation reduces carbon dioxide concentration 1006

High flying or deep diving can disrupt homeostasis 1006

Some mammals are adapted for diving 1006

Breathing Polluted Air 1007

Inquiring About The Effects of Smoking 1008

47 Processing Food and Nutrition 1012

Nutritional Styles and Adaptations 1013

Animals are adapted to their mode of nutrition 1013

Some invertebrates have a digestive cavity with a single opening 1015

Most animal digestive systems have two openings 1015

The Vertebrate Digestive System 1016

Food processing begins in the mouth 1017

The pharynx and esophagus conduct food to the stomach 1017

Food is mechanically and enzymatically digested in the stomach 1018

Most enzymatic digestion takes place in the small intestine 1020

The liver secretes bile 1021

The pancreas secretes digestive enzymes 1021

Nutrients are digested as they move through the digestive tract 1021

Nerves and hormones regulate digestion 1022

Absorption takes place mainly through the villi of the small intestine 1023

The large intestine eliminates waste 1023

Required Nutrients 1024

Carbohydrates provide energy 1024

Lipids provide energy and are used to make biological molecules 1024

Proteins serve as enzymes and as structural components of cells 1026

Vitamins are organic compounds essential for normal metabolism 1026

Minerals are inorganic nutrients 1026

Antioxidants protect against oxidants 1027

Phytochemicals play important roles in maintaining health 1028

Energy Metabolism 1029

Energy metabolism is regulated by complex signaling 1029

Obesity is a serious nutritional problem 1029

Undernutrition can cause serious health problems 1029

48 Osmoregulation and Disposal of Metabolic Wastes 1034

Maintaining Fluid and Electrolyte Balance 1035

Metabolic Waste Products 1035

Osmoregulation and Excretion in Invertebrates 1036

Nephridial organs are specialized for osmoregulation and/or excretion 1037

Malpighian tubules conserve water 1038

Osmoregulation and Excretion in Vertebrates 1038

Freshwater vertebrates must rid themselves of excess water 1038

Marine vertebrates must replace lost fluid 1039

Terrestrial vertebrates must conserve water 1039

www.konkur.in

The Urinary System 1040

The nephron is the functional unit of the kidney 1042

Urine is produced by filtration, reabsorption, and secretion 1043

Urine becomes concentrated as it passes through the renal tubule 1045

Urine consists of water, nitrogenous wastes, and salts 1046

Hormones regulate kidney function 1046

49 Endocrine Regulation 1052

An Overview of Endocrine Regulation 1053

The endocrine system and nervous system interact to regulate the body 1053

Negative feedback systems regulate endocrine activity 1053

Hormones are assigned to four chemical groups 1054

Types of Endocrine Signaling 1055

Neurohormones are transported in the blood 1055

Some local regulators are considered hormones 1055

Inquiring About Anabolic Steroids and Other Abused Hormones 1056

Mechanisms of Hormone Action 1057

Some hormones enter target cells and activate genes 1057

Many hormones bind to cell-surface receptors 1058

Neuroendocrine Regulation in Invertebrates 1060

Endocrine Regulation in Vertebrates 1060

Homeostasis depends on normal concentrations of hormones 1061

The hypothalamus regulates the pituitary gland 1061

The posterior lobe of the pituitary gland releases hormones produced by the hypothalamus 1061

The anterior lobe of the pituitary gland regulates growth and other endocrine glands 1062

Thyroid hormones increase metabolic rate 1066

The parathyroid glands regulate calcium concentration 1067

The islets of the pancreas regulate glucose concentration 1067

The adrenal glands help the body respond to stress 1071

Many other hormones are known 1073

50 Reproduction 1077

Asexual and Sexual Reproduction 1078

Asexual reproduction is an efficient strategy 1078

Most animals reproduce sexually 1078

Sexual reproduction increases genetic variability 1079

Human Reproduction: The Male 1080

The testes produce gametes and hormones 1080

A series of ducts store and transport sperm 1081

The accessory glands produce the fluid portion of semen 1082

The penis transfers sperm to the female 1083

Testosterone has multiple effects 1083

The hypothalamus, pituitary gland, and testes regulate male reproduction 1084

Human Reproduction: The Female 1084

The ovaries produce gametes and sex hormones 1085

The oviducts transport the secondary oocyte 1086

The uterus incubates the embryo 1087

The vagina receives sperm 1087

The vulva are external genital structures 1088

The breasts function in lactation 1088

The hypothalamus, pituitary gland, and ovaries regulate female reproduction 1089

Inquiring About Breast Cancer 1090

Menstrual cycles stop at menopause 1093

Most mammals have estrous cycles 1093

Fertilization, Pregnancy, and Birth 1093

Fertilization is the fusion of sperm and egg 1093

Inquiring About Novel Origins 1094

Hormones are necessary to maintain pregnancy 1095

The birth process depends on a positive feedback system 1096

Human Sexual Response 1097

Birth Control Methods and Abortion 1098

Many birth control methods are available 1098

Most hormone contraceptives prevent ovulation 1098

Intrauterine devices are widely used 1099

Barrier methods of contraception include the diaphragm and condom 1100

Emergency contraception is available 1100

Sterilization renders an individual incapable of producing offspring 1100

Future contraceptives may control regulatory peptides 1101

Abortions can be spontaneous or induced 1101

Sexually Transmitted Diseases 1101

51 Animal Development 1106

Development of Form 1107

Fertilization 1107

The first step in fertilization involves contact and recognition 1107

Sperm entry is regulated 1108

Fertilization activates the egg 1109

Sperm and egg pronuclei fuse, restoring the diploid state 1109

Cleavage 1109

The pattern of cleavage is affected by yolk 1109

Cleavage may distribute developmental determinants 1111

Cleavage provides building blocks for development 1112

www.konkur.in

Gastrulation 1112
The amount of yolk affects the pattern of gastrulation 1113
Organogenesis 1115
Extraembryonic Membranes 1116
Human Development 1117
The placenta is an organ of exchange 1118
Organ development begins during the first trimester 1118
Development continues during the second and third trimesters 1120
More than one mechanism can lead to a multiple birth 1121
Environmental factors affect the embryo 1121
The neonate must adapt to its new environment 1121
Aging is not a uniform process 1123
Homeostatic response to stress decreases during aging 1123

52 Animal Behavior 1127

Behavior and Adaptation 1128
Behaviors have benefits and costs 1128
Genes interact with environment 1128
Behavior depends on physiological readiness 1130
Many behavior patterns depend on motor programs 1130
Learning: Changing Behavior as a Result of Experience 1131
An animal habituates to irrelevant stimuli 1131
Imprinting occurs during an early critical period 1131
In classical conditioning, a reflex becomes associated with a new stimulus 1132
In operant conditioning, spontaneous behavior is reinforced 1132
Animal cognition is controversial 1133
Play may be practice behavior 1134
Behavioral Responses to Environmental Stimuli 1134
Biological rhythms regulate many behaviors 1134
Environmental signals trigger physiological responses that lead to migration 1135
Foraging Behavior 1136
Costs and Benefits of Social Behavior 1137
Communication is necessary for social behavior 1138
Dominance hierarchies establish social status 1139
Many animals defend a territory 1140
Some insect societies are highly organized 1141
Sexual Selection 1142
Animals of the same sex compete for mates 1142
Animals select quality mates 1143
Sexual selection favors polygynous mating systems 1143
Some animals care for their young 1144
Helping Behavior 1146
Altruistic behavior can be explained by inclusive fitness 1146
Helping behavior may have alternative explanations 1147
Some animals help nonrelatives 1148
Culture in Vertebrate Societies 1148
Some vertebrates transmit culture 1148
Sociobiology explains human social behavior in terms of adaptation 1149

Part 8 THE INTERACTIONS OF LIFE: ECOLOGY 1153

53 Introduction to Ecology: Population Ecology 1153

Features of Populations 1154
Density and dispersion are important features of populations 1154
Changes in Population Size 1156
Dispersal affects the growth rate in some populations 1156
Each population has a characteristic intrinsic rate of increase 1157
No population can increase exponentially indefinitely 1157
Factors Influencing Population Size 1158
Density-dependent factors regulate population size 1158
Density-independent factors are generally abiotic 1160
Life History Traits 1161
Life tables and survivorship curves indicate mortality and survival 1163
Metapopulations 1164
Human Populations 1165
Not all countries have the same growth rate 1167
The age structure of a country helps predict future population growth 1168
Environmental degradation is related to population growth and resource consumption 1169

54 Community Ecology 1173

Community Structure and Functioning 1174
Community interactions are complex and often not readily apparent 1175
The niche is a species' ecological role in the community 1175
Competition is intraspecific or interspecific 1177
Natural selection shapes the bodies and behaviors of both predator and prey 1180
Symbiosis involves a close association between species 1182
Inquiring About Mimicry in Butterflies 1183
Strength and Direction of Community interactions 1185
Other species of a community depend on or are greatly affected by keystone species 1185
Dominant species influence a community as a result of their greater size or abundance 1186
Ecosystem regulation occurs from the bottom up and top down 1186

www.konkur.in

Community Biodiversity 1187

Ecologists seek to explain why some communities have more species than others 1188

Species richness may promote community stability 1190

Community Development 1190

Disturbance influences succession and species richness 1191

Ecologists continue to study community structure 1192

55 Ecosystems and the Biosphere 1196

Energy Flow through Ecosystems 1197

Ecological pyramids illustrate how ecosystems work 1199

Ecosystems vary in productivity 1200

Food chains and poisons in the environment 1202

Cycles of Matter in Ecosystems 1203

Carbon dioxide is the pivotal molecule in the carbon cycle 1203

Bacteria are essential to the nitrogen cycle 1204

The phosphorus cycle lacks a gaseous component 1206

Water moves among the ocean, land, and atmosphere in the hydrologic cycle 1207

Abiotic Factors in Ecosystems 1208

The sun warms Earth 1208

Inquiring About Life without the Sun 1209

The atmosphere contains several gases essential to organisms 1210

The global ocean covers most of Earth's surface 1211

Climate profoundly affects organisms 1212

Fires are a common disturbance in some ecosystems 1213

Studying Ecosystem Processes 1214

56 Ecology and the Geography of Life 1218

Biomes 1219

Tundra is the cold, boggy plains of the far north 1219

Inquiring About The Distribution of Vegetation on Mountains 1220

Boreal forest is the evergreen forest of the north 1221

Temperate rain forest has cool weather, dense fog, and high precipitation 1221

Temperate deciduous forest has a canopy of broad-leaf trees 1222

Temperate grasslands occur in areas of moderate precipitation 1222

Chaparral is a thicket of evergreen shrubs and small trees 1223

Deserts are arid ecosystems 1224

Savanna is a tropical grassland with scattered trees 1225

There are two basic types of tropical forests 1225

Aquatic Ecosystems 1228

Freshwater ecosystems are linked to land and marine ecosystems 1228

Estuaries occur where fresh water and salt water meet 1231

Marine ecosystems dominate Earth's surface 1232

Ecotones 1236

Biogeography 1237

Land areas are divided into six biogeographic realms 1238

57 Biological Diversity and Conservation Biology 1242

The Biodiversity Crisis 1243

Endangered species have certain characteristics in common 1244

Inquiring About Declining Amphibian Populations 1245

Human activities contribute to declining biological diversity 1246

Conservation Biology 1249

In situ conservation is the best way to preserve biological diversity 1249

Ex situ conservation attempts to save species on the brink of extinction 1251

The Endangered Species Act provides some legal protection for species and habitats 1252

International agreements provide some protection of species and habitats 1253

Deforestation 1253

Why are tropical rain forests disappearing? 1254

Why are boreal forests disappearing? 1255

Climate Change 1255

Greenhouse gases cause climate change 1256

What are the probable effects of climate change? 1257

Declining Stratospheric Ozone 1259

Certain chemicals destroy stratospheric ozone 1259

Ozone depletion harms organisms 1260

International cooperation is helping repair the ozone layer 1260

Preface

This ninth edition of Solomon, Berg, Martin *Biology* conveys our vision of the dynamic science of biology and how it affects every aspect of our lives, from our health and behavior to the challenging environmental issues that confront us. New discoveries in the biological sciences continue to increase our understanding of both the unity and diversity of life's processes and adaptations. With this understanding, we become ever more aware of our interdependence with the vast diversity of organisms with which we share planet Earth.

BIOLOGY: THE STUDENT-FRIENDLY BIOLOGY BOOK

We want beginning students to experience learning biology as an exciting journey of discovery. In the ninth edition of *Biology,* we explore Earth's diverse organisms, their remarkable adaptations to the environment, and their evolutionary and ecological relationships. We present the workings of science and the contributions of scientists whose discoveries not only expand our knowledge of biology but also help shape and protect the future of our planet. *Biology* provides insight into what science is, how scientists work, what scientists have contributed, and how scientific knowledge affects daily life.

Since the first edition of *Biology,* we have worked to present the principles of biology in an integrated way that is accurate, interesting, and conceptually accessible to students. In this ninth edition of *Biology,* we continue this tradition. We also continue to present biology in an inquiry-based framework. Some professors interpret inquiry as a learning method that takes place in the laboratory as students perform experiments. Laboratory research is certainly an integral part of inquiry-based learning. But inquiry is also a way of learning in which the student actively pursues knowledge outside the laboratory. In *Biology,* we have always presented the history of scientific advances, including scientific debates, to help students understand that science is a process, that is, a field of investigative inquiry, as well as a body of knowledge (the product of inquiry). In the ninth edition of *Biology,* we make a concerted effort to further integrate inquiry-based learning into the textbook with the introduction of new features and the expansion of several others (discussed in the following sections).

Throughout the text, we stimulate interest by relating concepts to experiences within the student's frame of reference. By helping students make such connections, we facilitate their mastery of general concepts. We hope the combined effect of an engaging writing style and interesting features will motivate and excite students in their study of biology.

THE SOLOMON/BERG/MARTIN LEARNING SYSTEM

In the ninth edition, we have continued to refine our highly successful *Learning System.* This system provides the student with the learning strategies needed to integrate biological concepts and to demonstrate mastery of these concepts. Learning biology is challenging because the subject of biology is filled with so many new terms and so many facts that must be integrated into the framework of general biological principles. To help students focus on important principles and concepts, we provide *Learning Outcomes* for the course and *Learning Objectives* for each major section of every chapter. At the end of each section, we provide *Review Questions* based on the Learning Objectives so students can assess their level of understanding of the material presented in the section. At the end of each chapter, we include a *Summary: Focus on Learning Objectives* that is organized around the *Learning Objectives.* The *Summary* is followed by *Test Your Understanding* questions (including multiple-choice exercises and diagram labeling) and *Critical Thinking* questions.

Throughout the book, students are directed to CengageNOW, a powerful online diagnostic tool that helps students assess their study needs and master the chapter objectives. After taking a pretest on CengageNOW, students receive feedback based on their answers as well as a Personalized Study Plan with links to animations and other resources keyed to their specific learning needs. Selected illustrations in the text are also keyed to *Animated* figures in CengageNOW.

Pedagogical Features

Our *Learning System* includes numerous learning strategies that help students increase their success:

- ***NEW*** An updated and expanded *art program* reinforces concepts discussed in the text, and presents complex processes in clear steps. This edition expands the number of *Key Experiment* figures, which encourage students to evaluate investigative approaches that scientists have taken. *Key Experiment* figures emphasize the scientific process in both classic and modern research; examples include Figures 8-9, 20-13, 22-9, 27-11, and 52-21. Also expanded in this edition are *Key Point* figures, in which important concepts are stated in process diagrams of complex topics; examples include Figures 1-11, 6-6, 8-2, 29-4, and 32-7. Many of the *Key Point* figures have numbered parts that show sequences of events in biological processes or life cycles. Numerous photographs, both alone

www.konkur.in

and combined with line art, help students grasp concepts by connecting the "real" to the "ideal." The line art uses features such as *orientation icons* to help the student put the detailed figures into the broader context. We use symbols and colors consistently throughout the book to help students connect concepts. For example, the same four colors and shapes are used throughout the book to identify guanine, cytosine, adenine, and thymine. Similarly, the same colors are used consistently in illustrations and tables to indicate specific clades of organisms.

- ***NEW*** *Research Method* figures describe why biologists use a particular method and explain how the method is executed. Examples include Figures 12-6, 15-5, and 23-11.
- ***NEW*** *Inquiring About* boxes explore issues of special relevance to students, such as the effects of smoking, how traumatic experiences affect the body, and breast cancer. These boxes also provide a forum for discussing some interesting topics in more detail, such as the smallest ancient humans, ancient plants and coal formation, hydrothermal vent communities, and declining amphibian populations.
- A list of *Key Concepts* at the beginning of each chapter provides a chapter overview and helps the student focus on important principles discussed in the chapter.
- *Learning Objectives* at the beginning of each major section in the chapter indicate, in behavioral terms, what the student must do to demonstrate mastery of the material in that section.
- Each major section of the chapter is followed by a series of *Review* questions that assess comprehension by asking the student to describe, explain, compare, contrast, or illustrate important concepts. The *Review* questions are based on the section Learning Objectives.
- *Concept Statement Subheads* introduce sections, previewing and summarizing the key idea or ideas to be discussed in that section.
- *Sequence Summaries* within the text simplify and summarize information presented in paragraph form. For example, paragraphs describing blood circulation through the body or the steps by which cells take in certain materials are followed by a *Sequence Summary* listing the sequence of structures or steps.
- Numerous *tables,* many illustrated, help the student organize and summarize material presented in the text. Many tables are color-coded.
- A *Summary: Focus on Learning Objectives* at the end of each chapter is organized around the chapter *Learning Objectives.* This summary provides a review of the material, and because selected key terms are boldfaced in the summary, students learn vocabulary words within the context of related concepts.
- End-of-chapter questions provide students with the opportunity to evaluate their understanding of the material in the chapter. *Test Your Understanding* consists of multiple-choice questions, some of which are based on the recall of important terms, whereas others challenge students to integrate their knowledge. Answers to the *Test Your Understanding* questions are provided in Appendix E. Thought-provoking *Critical Thinking* questions encourage the student to apply the concepts just learned to new situations or to make connections among important concepts. Each chapter has one or more *Evolution Link* questions in the *Critical Thinking* section. Many chapters contain one or more *Analyzing Data* questions that require students to actively interpret experimental data presented in the chapter.
- ***NEW*** Many *Critical Thinking* sections also include one or more *Science, Technology, and Society* questions.
- The *Glossary* at the end of the book, the most comprehensive glossary found in any biology text, provides precise definitions of terms. The *Glossary* is especially useful because it is extensively cross-referenced and includes pronunciations for many terms. The vertical blue bar along the margin facilitates rapid access to the *Glossary.* The companion website also includes glossary flash cards with audio pronunciations.

Course Learning Outcomes

At the end of a successful study of introductory biology, the student can demonstrate mastery of biological concepts by responding accurately to the following *Course Learning Outcomes:*

- Design an experiment to test a given hypothesis, using the procedure and terminology of the scientific method.
- Cite the cell theory, and relate the structure of organelles to their functions in both prokaryotic and eukaryotic cells.
- Describe the mechanisms of evolution, explain why evolution is the principal unifying concept in biology, and discuss natural selection as the primary agent of evolutionary change.
- Explain the role of genetic information in all species, and discuss applications of genetics that affect society.
- Describe several mechanisms by which cells and organisms transfer information, including the use of nucleic acids in genetic transmission of information, signal transduction, chemical signals (such as hormones and pheromones), electrical signals (for example, neural transmission), sounds, and visual displays.
- Argue for or against the classification of organisms in three domains and several kingdoms or supergroups, characterizing each of these clades; based on your knowledge of genetics and evolution, give specific examples of the unity and diversity of organisms in different domains and supergroups.
- Compare the structural adaptations, life processes, and life cycles of a prokaryote, protist, fungus, plant, and animal.
- Define *homeostasis,* and give examples of regulatory mechanisms, including feedback systems.
- Trace the flow of matter and energy through a photosynthetic cell and a nonphotosynthetic cell, and through the biosphere, comparing the roles of producers, consumers, and decomposers.
- Describe the study of ecology at the levels of an individual organism, a population, a community, and an ecosystem.

www.konkur.in

WHAT'S NEW: AN OVERVIEW OF *BIOLOGY*, NINTH EDITION

Three themes are interwoven throughout *Biology:* the evolution of life, the transmission of biological information, and the flow of energy through living systems. As we introduce the concepts of modern biology, we explain how these themes are connected and how life depends on them.

Educators present the major topics of an introductory biology course in a variety of orders. For this reason, we carefully designed the eight parts of this book so that they do not depend heavily on preceding chapters and parts. This flexible organization means that an instructor can present the 57 chapters in any number of sequences with pedagogical success. Chapter 1, which introduces the student to the major principles of biology, provides a comprehensive springboard for future discussions, whether the professor prefers a "top-down" or "bottom-up" approach.

In this edition, as in previous editions, we examined every line of every chapter for accuracy and currency, and we made a careful attempt to update every topic and verify all new material. The following brief summary provides a general overview of the organization of *Biology* and some changes made to the ninth edition.

Part 1 The Organization of Life

The six chapters that make up Part 1 provide basic principles of biology and the concepts of chemistry and cell biology that lay the foundation upon which the remaining parts of the book build. We begin Chapter 1 with a discussion of influenza pandemics and how scientists respond to new varieties of pathogens. We then introduce the main themes of the book—evolution, information transfer, and energy transfer. Chapter 1 examines several fundamental concepts in biology and the nature of the scientific process, including a discussion of systems biology. Chapters 2 and 3, which focus on the molecular level of organization, establish the foundations in chemistry necessary for understanding biological processes. Chapters 4, 5, and 6 focus on the cellular level of organization, including cell structure and function, cell membranes, and cell signaling. We have expanded coverage of signaling pathways and the evolution of cell communication. For example, we added a discussion of Ras pathways, as well as a *Key Experiment* on a Ras pathway that regulates reproduction in mammals.

Part 2 Energy Transfer through Living Systems

Because all living cells need energy for life processes, the flow of energy through living systems—that is, capturing energy and converting it to usable forms—is a basic theme of *Biology.* Chapter 7 examines how cells capture, transfer, store, and use energy. Chapters 8 and 9 discuss the metabolic adaptations by which organisms obtain and use energy through cellular respiration and photosynthesis. This section has a new *Key Experiment* figure on the evidence for chemiosmosis. Also, the concept of resonance has been included in the explanation for energy transfer within a photosystem.

Part 3 The Continuity of Life: Genetics

We have updated and expanded the eight chapters of Part 3 for the ninth edition. We begin this unit by discussing mitosis and meiosis in Chapter 10, which includes a new *Key Experiment* on using laser photobleaching to determine how chromosomes are transported toward the spindle poles during anaphase and a new figure on key checkpoints in the cell cycle. Chapter 11, which considers Mendelian genetics and related patterns of inheritance, has new paragraphs on nature versus nurture in human characters and on hydrangea flower color as an illustration of the influence of the environment on the phenotype. We then turn our attention to the structure and replication of DNA in Chapter 12. We include new photographs of Rosalind Franklin, Watson and Crick, phages, DNA replication in *E. coli,* and telomeres. Chapter 13 has a discussion of RNA and protein synthesis, including new information on the contributions of Roger Kornberg, transposons in the human genome, and the percentage of DNA coding for polypeptides versus the percentage of our genome that is expressed. Gene regulation is discussed in Chapter 14, which includes new material on eukaryotic promoters and enhancers and silencers, and on epigenetic inheritance. In Chapter 15, we focus on DNA technology and genomics, including an expanded discussion of engineered strains of *E. coli,* nucleic acid probes, Northern and Western blots, and molecular evolution. These chapters build the necessary foundation for exploring human genetics and the human genome in Chapter 16, which includes new sections on genomic imprinting and on genome-wide association (GWA) scans. In Chapter 17, we introduce the role of genes in development, emphasizing studies on specific model organisms that have led to spectacular advances in this field; changes include new material on induced pluripotent stem (iPS) cells.

Part 4 The Continuity of Life: Evolution

Although we explore evolution as the cornerstone of biology throughout the book, Part 4 discusses evolutionary concepts in depth. We provide the history behind the discovery of the scientific theory of evolution, the mechanisms by which it occurs, and the methods by which it is studied and tested. Chapter 18 introduces the Darwinian concept of evolution and presents several kinds of evidence that support the scientific theory of evolution. In Chapter 19, we examine evolution at the population level. Chapter 20 describes the evolution of new species and discusses aspects of macroevolution. Chapter 21 summarizes the evolutionary history of life on Earth. In Chapter 22, we recount the evolution of the primates, including humans. Many topics and examples have been added to the ninth edition, such as new material on genome sequencing, whale evolution, genetic polymorphism, cichlid evolution, hybrid zones, the metabolism-first hypothesis, and recent discoveries in human evolution, including new material on *Ardipithecus, Homo ergaster,* archaic humans (*H. antecessor* and *H. heidelbergensis*), and Neandertals.

Part 5 The Diversity of Life

Emphasizing the cladistic approach, we use an evolutionary framework to discuss each group of organisms. We present current

www.konkur.in

hypotheses of how groups of organisms are related. Chapter 23 discusses *why* organisms are classified and provides insight into the scientific process of deciding *how* they are classified. New advances have enabled us to further clarify the connection between evolutionary history and systematics in the ninth edition. ***NEW*** Chapter 24 now focuses entirely on the viruses. We added a discussion of polydnaviruses, illustrated by a new *Key Experiment.* We also expanded the discussion of subviral agents. ***NEW*** Chapter 25 is now devoted to the prokaryotes. We added information on the archaea, including a brief discussion of their flagella. The discussion of antibiotic resistance was expanded, and an image of methicillin-resistant *Staphylococcus aureus* (MRSA) was added. Chapter 26, which describes the protists, was completely reorganized and updated to reflect recent evolutionary data; a new color-coded table summarizes the five "supergroups" of eukaryotes. Chapters 27 and 28 present the members of the plant kingdom; Chapter 28 includes new cladograms showing the evolution of land plants and the evolution of seedless vascular plants. Discussion of the origin and early evolution of angiosperms is included in Chapter 28. Chapter 29 describes the fungi. We have added a description of symbiotic relationships among fungi, grasses, and viruses and also a discussion of cell signaling in mycorrhizal fungi between fungi and root cells. In Chapters 30 through 32, we discuss the diversity of animals. We have reorganized some of the discussion and added several tables. We emphasize the cladistic approach, although we continue to include traditional phyla and classes.

Part 6 Structure and Life Processes in Plants

Part 6 introduces students to the fascinating plant world. It stresses relationships between structure and function in plant cells, tissues, organs, and individual organisms. In Chapter 33, we introduce plant structure, growth, and differentiation. Chapter 33 contains a new section on plant form that includes plant aspects of cell division, cell expansion, cell differentiation, tissue culture, morphogenesis, pattern formation, positional information, and *Arabidopsis* mutants. Chapters 34 through 36 discuss the structural and physiological adaptations of leaves, stems, and roots; these chapters include new discussion of the molecular control of plant leaf form, cotransport in phloem loading, and transcription factors that affect root hair development. Chapter 37 describes reproduction in flowering plants, including asexual reproduction, flowers, fruits, and seeds. New to this edition is a spread of photos and a table showing floral characteristics associated with various animal pollinators. Chapter 38 focuses on growth responses and regulation of growth. In the ninth edition, we present the latest findings generated by the continuing explosion of knowledge in plant biology, particularly at the molecular level. New topics include advances in auxin signaling, GA signaling, cytokinin signaling, ethylene signaling, and ABA receptors.

Part 7 Structure and Life Processes in Animals

In Part 7, we provide a strong emphasis on comparative animal physiology, showing the structural, functional, and behavioral adaptations that help animals meet environmental challenges. We use a comparative approach to examine how various animal groups have solved both similar and diverse problems. In Chapter 39, we discuss the basic tissues and organ systems of the animal body, homeostasis, and the ways that animals regulate their body temperature. Chapter 40 focuses on different types of body coverings, skeletons, and muscles, and discusses how they function. In Chapters 41 through 43, we discuss neural signaling, neural regulation, and sensory reception. In Chapters 44 through 51, we compare how different animal groups carry on life processes, such as internal transport, internal defense, gas exchange, digestion, reproduction, and development. Each chapter in this part considers the human adaptations for the life processes being discussed. Part 7 ends with a discussion of behavioral adaptations in Chapter 52. Reflecting recent research findings, we have revised or added new material on many topics, including neurotransmitters, learning, memory, sleep-wake cycles, coevolution of bats and moths, cardiovascular disease, Toll-like receptors, chronic inflammation, and certain hormones. The art program has been updated and improved, and many new photographs and photomicrographs have been added.

Part 8 The Interactions of Life: Ecology

Part 8 focuses on the dynamics of populations, communities, and ecosystems and on the application of ecological principles to disciplines such as conservation biology. Chapters 53 through 56 give the student an understanding of the ecology of populations, communities, ecosystems, and the biosphere, whereas Chapter 57 focuses on global environmental issues. Among the many new topics in this unit are correlations between lemming populations and climate change; a 2006 study by Peter and Rosemary Grant on character displacement in ground finches; evolution in scarlet king snakes away from their model, the coral snake; Paine's classic work with predatory Pisaster sea stars in rocky intertidal communities; ocean acidification; invasion of many of the world's grasslands by woody trees and shrubs; and data on climate change from the Fourth IPCC Assessment.

A COMPREHENSIVE PACKAGE FOR LEARNING AND TEACHING

A carefully designed supplement package is available to further facilitate learning. In addition to the usual print resources, we are pleased to present student multimedia tools that have been developed in conjunction with the text.

Resources for Students

Aplia is an online interactive homework solution that stimulates active learning by increasing student effort and engagement. *Aplia* enables students to optimize the time they spend devoted to coursework. *Aplia* courses are customized to fit with each instructor's syllabus, and provide automatically graded homework with detailed, immediate feedback on every question. *Aplia's* interactive tools also serve to increase student engagement and understanding. The *Aplia* assignments allow students to apply what they learn in the text and in face-to-face instruction directly to their homework.

www.konkur.in

Aplia homework promotes active learning by:

- Leading students through the thought processes of doing science
- Helping students understand the scientific procedures that lead to scientific results covered in the textbook
- Connecting conceptual figures with scientific issues and problems

Aplia Gradebook Analytics show how each student is doing relative to peers in the class. This allows instructors to quickly and easily:

- Review progress student by student, and even drill down to the homework and question level
- Use graphs to monitor student, and class, performance
- Determine in what subject areas students are struggling and need more review

Straightforward language, a simple and intuitive user interface, and online material that reinforces the textbook all combine to make Aplia a solution that makes students think and helps students learn and retain knowledge.

CengageNOW. This updated and expanded online homework and learning tool helps students assess personal study needs and focus their time. By taking a pretest, they are provided with a Personalized Study Plan that directs them to text sections and narrated animations—many new to this edition—that they need to review. If they need to brush up on basic skills, the *How Do I Prepare?* feature walks them through tutorials on basic math, chemistry, study skills, and word roots. Homework and tests can be assigned through *CengageNOW,* with automatic grading for all multiple-choice and true/false questions.

Biology CourseMate. Cengage Learning's *Biology CourseMate* brings course concepts to life with interactive learning, study, and exam preparation tools that support the printed textbook. Watch student comprehension soar as the class works with the printed textbook and the textbook-specific website. *Biology CourseMate* includes:

- An interactive eBook
- Interactive teaching and learning tools including:
  - Quizzes
  - Videos
  - Animations
  - Flash cards
  - And more
- ***Engagement Tracker,*** a first-of-its-kind tool that monitors student engagement in the course

Go to www.cengagebrain.com to access these resources, and look for this icon CourseMate, which denotes a resource available within *CourseMate.*

Study Guide to accompany *Biology,* Ninth Edition, by Jennifer Aline Metzler of Ball State University and Robert Yost of Indiana University and Purdue University, Indianapolis. Updated for this edition, the study guide provides the student with many opportunities to review chapter concepts. Multiple-choice study questions, coloring-book exercises, vocabulary-building exercises, and many other types of active-learning tools are provided to suit different cognitive learning styles.

A Problem-based Guide to Basic Genetics by Donald Cronkite of Hope College. This brief guide provides students with a systematic approach to solving genetics problems, along with numerous solved problems and practice problems.

Spanish Glossary. This Spanish glossary of biology terms is available to Spanish-speaking students.

Audio Study Tools. This edition of *Biology* is accompanied by useful study tools, which contain valuable information such as reviews of important concepts, key terms, questions, and study tips. Students can download the audio study tools.

Virtual Biology Laboratory 4.0. Now with an upgraded user interface, these 14 online laboratory experiments allow students to "do" science by acquiring data, performing simulated experiments, and using data to explain biological concepts. Assigned activities automatically flow to the instructor's grade book. Self-designed activities ask students to plan their procedures around an experimental question and write up their results.

Additional Resources for Instructors

The instructors' examination copy for this edition lists a comprehensive package of print and multimedia supplements, including online resources, available to qualified adopters. Please ask your local sales representative for details.

ACKNOWLEDGMENTS

The development and production of the ninth edition of *Biology* required extensive interaction and cooperation among the authors and many individuals in our family, social, and professional environments. We thank our editors, colleagues, students, family, and friends for their help and support. Preparing a book of this complexity is challenging and requires a cohesive, talented, and hardworking professional team. We appreciate the contributions of everyone on the editorial and production staff at Brooks/Cole–Cengage Learning who worked on this ninth edition of *Biology.* We thank our Publisher Yolanda Cossio for her commitment to *Biology* and for working closely with us throughout the entire process of development and production. We appreciate the help of our Developmental Editor, Christopher Delgado, who diligently kept us on track and coordinated many aspects of this complex project.

We thank Tom Ziolkowski, our Marketing Manager, whose expertise ensured that you would know about our new edition.

We appreciate the help of Senior Content Project Manager Hal Humphrey, who guided overall production of the project.

We thank Editorial Assistants Brandusa Radoias and Joshua Taylor for quickly providing us with resources whenever we needed them.

We thank Creative Director Rob Hugel, Art Director and Cover Designer John Walker, and Text Designer tani hasegawa. We also thank Jean Thompson for developing the instructor's preface.

We appreciate the work of Lauren Oliveira, Media Editor, who coordinated the many high-tech components of the computerized

www.konkur.in

aspects of our *Learning System.* We thank Alexis Glubka, Assistant Editor, for coordinating the print supplements.

We are grateful to our Production Editor, Joan Keyes of Dovetail Publishing Services, for coordinating the many editors involved in the preparation of this edition and bringing together the thousands of complex pieces of the project to produce *Biology,* Ninth Edition. We value the careful work of our Copy Editor, Susan Gall, who patiently helped us maintain consistency and improve the manuscript. We thank Amanda Bickel of Precision Graphics for helping us greatly improve the art program for this book. We also appreciate the efforts of Photo Editor Tim Herzog of Bill Smith Group in helping us find excellent images. We appreciate the help, patience, and hard work of our production team. Our schedule for this project was very demanding. At times, it seemed like the team worked around the clock. When we sent an email at 11 P.M. or during the weekend, we often received an immediate response.

These dedicated professionals and many others on the Brooks/Cole team provided the skill, attention, patience, and good humor needed to produce *Biology,* Ninth Edition. We thank them for their help and support throughout this project.

We thank Dr. Susan Pross, University of South Florida, College of Medicine, for her helpful suggestions for updating the immunology chapter. We appreciate the help of obstetrician/gynecologist Dr. Amy Solomon for her input regarding pregnancy, childbirth, contraception, and sexually transmitted diseases. We appreciate the expert assistance of Mary Kay Hartung, Research and Information Specialist at Florida Gulf Coast University, who we counted on for help whenever we had difficulty finding needed research studies and other information. We thank doctoral student Lois Ball of the University of South Florida, who calculated scale bars for many of the photomicrographs. We are grateful to Mical Solomon for his computer help.

We thank our families and friends for their understanding, support, and encouragement as we struggled through many revisions and intense deadlines. We especially thank Dr. Kathleen M. Heide, Freda Brod, Alan Berg, Jennifer and Pat Roath, Dr. Charles Martin, and Margaret Martin for their support and input.

Our colleagues and students who have used our book have provided valuable input by sharing their responses to past editions of *Biology.* We thank them and ask again for their comments and suggestions as they use this new edition. We can be reached through the Internet via our website at www.CengageBrain.com or through our editors at Brooks/Cole, a division of Cengage Learning.

We express our thanks to the many biologists who have read the manuscript during various stages of its development and provided us with valuable suggestions for improving it. Ninth edition reviewers include the following:

Karl Aufderheide, Texas A & M University
Felicitas Avendano, Grand View College, Iowa
Brian Bagatto, University of Akron
Catherine Black, Idaho State University
Susan Boothe, Alabama Southern Community College
Mark Browning, Purdue University
Jill Buettner, Richland College
Doug Burks, Wilmington College, Ohio
David Byres, Florida Community College at Jacksonville
Geoffrey Church, Fairfield University
Reggie Cobb, Nash Community College
Barbara Collins, California Lutheran University
Karen Curto, University of Pittsburgh
Phillippa Drennan, Loyola Marymount University
James DuMond, Texas Southern University
Wayne Elisens, University of Oklahoma
Cheryld Emmons, Alfred University, New York
Suzanne Gollery, Sierra Nevada College
Jack Holt, Susquehanna University
Ursula Howson, Monmouth University
Ken Klemow, Wilkes University
Paula Lemons, Duke University
Diana Lipscomb, George Washington University
Christopher Loretz, University of Buffalo
Kathi Maleug, University of Colorado at Colorado Springs
Paul Manos, Duke University
Helen McDearman, University of Tennessee at Chattanooga
Virginia McDonough, Hope College
Betsy Morgan, Lonestar College
Dana Nayduch, Georgia Southern University
Onesimus Otieno, Oakwood University
Michael Pallidino, Monmouth College
Craig Peebles, University of Pittsburgh
Ed Perry, Faulkner State Community College
Eric Ribbens, Western Illinois University
Laurel Roberts, University of Pittsburgh
Darrin Rubino, Hanover College, Indiana
Timothy Schuh, St. Cloud State University
Sharon Thoma, University of Wisconsin
Joanne Tillotson, Purchase College, State University of New York
Timothy Tripp, Sam Houston State University
Paul Trombley, Florida State University
Mary Tyler, University of Maine
Fred Wasserman, Boston University
Susan Whittemore, Keene State College
Lawrence Williams, University of Houston
Steven Wilt, Bellarmine College, Kentucky
Robert Yost, Indiana University–Purdue University, Indianapolis
Wendy Zomlefer, University of Georgia

We would also like to thank the hundreds of previous edition reviewers, both professors and students, who are too numerous to mention. They asked thoughtful questions, provided new perspectives, offered alternative wordings to clarify difficult passages, and informed us of possible errors. We are truly indebted to their excellent feedback. Their suggestions have helped us improve each edition of *Biology.*

www.konkur.in

To the Student

Biology is a challenging subject. The thousands of students we have taught have differed in their life goals and learning styles. Some have had excellent backgrounds in science; others, poor ones. Regardless of their backgrounds, it is common for students taking their first college biology course to find that they must work harder than they expected.

The *Learning System* we use in this book is described in the Preface. Using the strategies of the *Learning System* will help you master the language and concepts of biology. You will also want to use the many online tools available to *Biology* students. These tools, also described in the Preface, include *Aplia, CengageNOW,* and *Biology CourseMate.* In addition to these learning strategies, you can make the task of learning biology easier by using approaches that have been successful to a broad range of our students over the years.

Make a Study Schedule

Many college professors suggest that students study 3 hours for every hour spent in class. This major investment in study time is one of the main differences between high school and college. To succeed academically, college students must learn to manage their time effectively. The actual number of hours you spend studying biology will vary depending on how quickly you learn the material, as well as on your course load and personal responsibilities, such as work schedules and family commitments.

The most successful students are often those who are best organized. At the beginning of the semester, make a detailed daily calendar. Mark off the hours you are in each class, along with travel time to and from class if you are a commuter. After you get your course syllabi, add to your calendar the dates of all exams, quizzes, papers, and reports. As a reminder, it also helps to add an entry for each major exam or assignment 1 week before the test or due date. Now add your work schedule and other personal commitments to your calendar. Using a calendar helps you find convenient study times.

Many of our successful biology students set aside 2 hours a day to study biology rather than depend on a weekly marathon session for 8 or 10 hours during the weekend (when that kind of session rarely happens). Put your study hours into your daily calendar, and stick to your schedule.

Determine Whether the Professor Emphasizes Text Material or Lecture Notes

Some professors test almost exclusively on material covered in lecture. Others rely on their students' learning most, or even all, of the content in assigned chapters. Find out what your professor's requirements are, because the way you study will vary accordingly.

How to study when professors test lecture material

If lectures are the main source of examination questions, make your lecture notes as complete and organized as possible. Before going to class, skim over the chapter, identifying key terms and examining the main figures, so that you can take effective lecture notes. Spend no more than 1 hour on this.

Within 24 hours after class, rewrite (or type) your notes. Before rewriting, however, read the notes and make marginal notes about anything that is not clear. Then read the corresponding material in your text. Highlight or underline any sections that clarify questions you had in your notes. Read the entire chapter, including parts that are not covered in lecture. This extra information will give you breadth of understanding and will help you grasp key concepts.

After reading the text, you are ready to rewrite your notes, incorporating relevant material from the text. It also helps to use the Glossary to find definitions for unfamiliar terms. Many students develop a set of flash cards of key terms and concepts as a way to study. Flash cards are a useful tool to help you learn scientific terminology. They are portable and can be used at times when other studying is not possible, for example, when riding a bus.

Flash cards are not effective when the student tries to second-guess the professor. ("She won't ask this, so I won't make a flash card of it.") Flash cards are also a hindrance when students rely on them exclusively. Studying flash cards instead of reading the text is a bit like reading the first page of each chapter in a mystery novel: it's hard to fill in the missing parts, because you are learning the facts in a disconnected way.

How to study when professors test material in the book

If the assigned readings in the text are going to be tested, you must use your text intensively. After reading the chapter introduction, read the list of Learning Objectives for the first section. These objectives are written in behavioral terms; that is, they ask you to "do" something in order to demonstrate mastery. The objectives give you a concrete set of goals for each section of the chapter. At the end of each section, you will find Review questions keyed to the Learning Objectives. Test yourself, going back over the material to check your responses.

Read each chapter section actively. Many students read and study passively. An active learner always has questions in mind and is constantly making connections. For example, there are many processes that must be understood in biology. Don't try to blindly memorize these; instead, think about causes and effects so

www.konkur.in

that every process becomes a story. Eventually, you'll see that many processes are connected by common elements.

You will probably have to read each chapter two or three times before mastering the material. The second and third times through will be much easier than the first, because you'll be reinforcing concepts that you have already partially learned.

After reading the chapter, write a four- to six-page chapter outline by using the subheads as the body of the outline (first-level heads are boldface, in color, and all caps; second-level heads are in color and not all caps). Flesh out your outline by adding important concepts and boldface terms with definitions. Use this outline when preparing for the exam.

Now it is time to test yourself. Answer the Test Your Understanding questions, and check your answers. Write answers to each of the Critical Thinking questions. Finally, review the Learning Objectives in the Chapter Summary, and try to answer them before reading the summary provided. If your professor has told you that some or all of the exam will be short-answer or essay format, write out the answer for each Learning Objective. Remember that this is a self-test. If you do not know an answer to a question, find it in the text. If you can't find the answer, use the Index.

Learn the Vocabulary

One stumbling block for many students is learning the many terms that make up the language of biology. In fact, it would be much more difficult to learn and communicate if we did not have this terminology, because words are really tools for thinking. Learning terminology generally becomes easier if you realize that most biological terms are modular. They consist of mostly Latin and Greek roots; once you learn many of these, you will have a good idea of the meaning of a new word even before it is defined. For this reason, we have included Appendix C, Understanding Biological Terms. To be sure you understand the precise definition of a term, use the Index and Glossary. The more you use biological terms in speech and writing, the more comfortable you will be.

Form a Study Group

Active learning is facilitated if you do some of your studying in a small group. In a study group, the roles of teacher and learner can be interchanged: a good way to learn material is to teach. A study group lets you meet challenges in a nonthreatening environment and can provide some emotional support. Study groups are effective learning tools when combined with individual study of text and lecture notes. If, however, you and other members of your study group have not prepared for your meetings by studying individually in advance, the study session can be a waste of time.

Prepare for the Exam

Your calendar tells you it is now 1 week before your first biology exam. If you have been following these suggestions, you are well prepared and will need only some last-minute reviewing. No all-nighters will be required.

During the week prior to the exam, spend 2 hours each day actively studying your lecture notes or chapter outlines. It helps many students to read these notes out loud (most people listen to what they say!). Begin with the first lecture/chapter covered on the exam, and continue in the order on the lecture syllabus. Stop when you have reached the end of your 2-hour study period. The following day, begin where you stopped the previous day. When you reach the end of your notes, start at the beginning and study them a second time. The material should be very familiar to you by the second or third time around. At this stage, use your textbook only to answer questions or clarify important points.

The night before the exam, do a little light studying, eat a nutritious dinner, and get a full night's sleep. That way, you'll arrive in class on exam day with a well-rested body (and brain) and the self-confidence that goes with being well prepared.

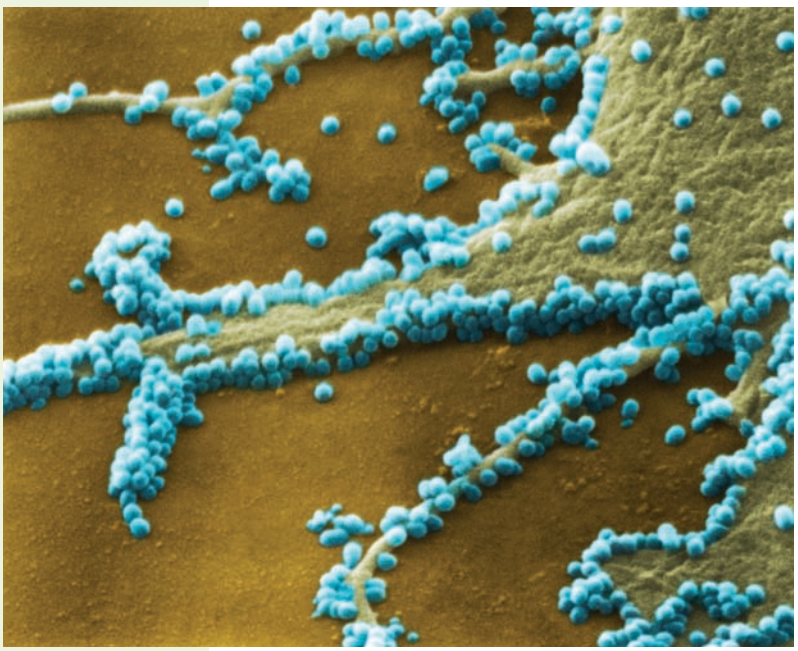
1 A View of Life



NIBSC/Science Photo Library

H1N1, the virus that causes H1N1 influenza (flu). H1N1 virus particles (blue) are visible on a cell (green). When this virus emerged, the human immune system was unfamiliar with its new combination of genes. As a result, the virus spread easily, causing a pandemic. The scanning electron micrograph (SEM) has been color-enhanced.

KEY CONCEPTS

1.1 Basic themes of biology include evolution, information transfer, and energy transfer.

1.2 Characteristics of life include cellular structure, growth and development, self-regulated metabolism, response to stimuli, and reproduction.

1.3 Biological organization is hierarchical and includes chemical, cell, tissue, organ, organ system, and organism levels; ecological organization includes population, community, ecosystem, and biosphere levels.

1.4 Information transfer includes DNA transfer of information from one generation to the next; chemical and electrical signals within and among the cells of every organism; and chemicals, visual displays, and sounds that allow organisms to communicate with one another and to interact with their environment.

1.5 Individual organisms and entire ecosystems depend on a continuous input of energy. Energy is transferred within cells and from one organism to another.

1.6 Evolution is the process by which populations of organisms change over time, adapting to changes in their environment; the tree of life includes three major branches, or domains.

1.7 Biologists ask questions, develop hypotheses, make predictions, and collect data by careful observation and experiment; based on their results, they come to conclusions.

The H1N1 influenza (flu) outbreak became the focus of attention in April 2009. Within a few months, more than 200 countries around the world had reported confirmed cases of this viral disease, and H1N1 had caused thousands of deaths. According to the U.S. Centers for Disease Control and Prevention (CDC), more than 200 known pathogens (disease-causing organisms) have the potential to strike globally. Historically, new viral strains have claimed many human lives. For example, in 1918 an influenza pandemic killed more than 20 million people throughout the world. Epidemiologists warn that even today an influenza pandemic could kill millions of people. Pandemics such as H1N1 have negative global impact. They affect many aspects of life, including the global economy, travel, tourism, and education.

Armed with new technology, biologists work closely with public health and other health-care professionals to prevent dangerous pandemics. When a new disease-causing agent emerges, biologists study its evolutionary relationships to known pathogens. For example, investigators have determined that the 1918 flu pandemic was caused by an influenza A (H1N1) virus that may have mutated and newly emerged from a swine or avian host. The H1N1 strain that was identified in 2009 was related to the 1918 pathogen.

Biologists determined that the 2009 H1N1 strain evolved from a combination of viruses that infected swine, birds, and humans. They found that this strain of H1N1 contains unique combinations of gene segments for which humans do not have preexisting immunity. Knowledge about a

www.konkur.in

virus's origins provides important clues to its structure and behavior, and suggests hypotheses for combating it. Scientists must then test their hypotheses in the laboratory. Researchers were able to determine the antigens (proteins) on the surface of H1N1. These antigens must combine with receptors on human cells in order to infect the cells. Based on careful studies of H1N1, a vaccine was quickly developed.

Pathogens can strike quickly and spread rapidly, and the continuous evolution of drug-resistant pathogens presents a major challenge. New varieties of H1N1 continue to emerge, and investigators must quickly characterize them and assess their potential virulence. Scientists predict that new varieties may show increased drug resistance and may be more virulent. In addition, recently developed vaccines may no longer be effective. Emerging diseases will be discussed further in Chapter 24.

This is an exciting time to study **biology,** the science of life. The remarkable new discoveries biologists are making almost daily affect every aspect of our lives, including our health, food, safety, relationships with humans and other organisms, and the environment of our planet. New knowledge provides new insights into the human species and the millions of other organisms with which we share this planet. Biology affects our personal, governmental, and societal decisions. For example, a combined effort at every level is necessary to provide the resources and knowledge to meet the challenges of global pandemics.

Whatever your college major or career goals, knowledge of biological concepts is a vital tool for understanding our world and for meeting many of the personal, societal, and global challenges that confront us. Among these challenges are the expanding human population, decreasing biological diversity, diminishing natural resources, global climate change, and prevention and cure of diseases, such as heart disease, cancer, diabetes, Alzheimer's disease, acquired immunodeficiency syndrome (AIDS), and influenza. Meeting these challenges will require the combined efforts of biologists and other scientists, health professionals, educators, politicians, and biologically informed citizens.

This book is a starting point for your exploration of biology. It will provide you with the basic knowledge and the tools to become a part of this fascinating science, as well as a more informed member of society.

1.1 THREE BASIC THEMES

LEARNING OBJECTIVE

1 Describe three basic themes of biology.

In this first chapter we introduce three basic themes of biology. These themes are interconnected with one another and with almost every concept that we discuss in this book.

1. **Evolution.** Populations of organisms have evolved through time from earlier forms of life. Scientists have accumulated a wealth of evidence showing that the diverse life-forms on this planet are related and that populations have *evolved,* that is, have changed over time, from earlier forms of life. The process of *evolution* is the framework for the science of biology and is a major theme of this book.
2. **Information transfer.** Information must be transmitted within organisms and among organisms, and organisms must be able to receive information from their environment. The survival and function of every cell and every organism depend on the orderly transmission of information. Evolution depends on the transmission of genetic information from one generation to another.
3. **Energy transfer.** All life processes, including thousands of chemical transactions that maintain life's organization, require a continuous input of energy. Most of the energy for life comes from sunlight. Energy from the sun is transferred through living systems from producers to consumers; decomposers obtain energy as they feed on the dead bodies and wastes of both producers and consumers. Energy is also continuously transferred from one chemical compound to another within every cell.

Evolution, information transfer, and energy transfer are forces that give life its unique characteristics. We begin our study of biology by developing a more precise understanding of the fundamental characteristics of living systems.

Review

- Why are evolution, information transfer, and energy transfer considered basic to life?
- What does the term *evolution* mean as applied to populations of organisms?

1.2 CHARACTERISTICS OF LIFE

LEARNING OBJECTIVE

2 Distinguish between living and nonliving things by describing the features that characterize living organisms.

We easily recognize that a pine tree, a butterfly, and a horse are living things, whereas a rock is not. Despite their diversity, the organisms that inhabit our planet share a common set of characteristics that distinguish them from nonliving things. These features include a precise kind of organization, growth and development, self-regulated metabolism, the ability to respond to stimuli, reproduction, and adaptation to environmental change.

Organisms are composed of cells

Although they vary greatly in size and appearance, all organisms consist of basic units called **cells.** New cells are formed only by the division of previously existing cells. As will be discussed in Chapter 4, these concepts are expressed in the **cell theory,** a fundamental unifying concept of biology.

www.konkur.in

Some of the simplest life-forms, such as protozoa, are **unicellular** organisms, meaning that each consists of a single cell (**FIG. 1-1**). In contrast, the body of a dog or a maple tree is made of billions of cells. In such complex **multicellular** organisms, life processes depend on the coordinated functions of component cells that may be organized to form tissues, organs, and organ systems.

Every cell is enveloped by a protective **plasma membrane** that separates it from the surrounding external environment. The plasma membrane regulates passage of materials between the cell and its environment. Cells have specialized molecules that contain genetic instructions and transmit genetic information. In most cells, the genetic instructions are encoded in deoxyribonucleic acid, more simply known as **DNA.** Cells typically have internal structures called **organelles** that are specialized to perform specific functions.

There are two fundamentally different types of cells: prokaryotic and eukaryotic. **Prokaryotic cells** are exclusive to bacteria and to microscopic organisms called *archaea.* All other organisms are characterized by their **eukaryotic cells.** These cells typically contain a variety of organelles enclosed by membranes, including a **nucleus,** which houses DNA. Prokaryotic cells are structurally simpler; they do not have a nucleus or other membrane-enclosed organelles.

Organisms grow and develop

Biological growth involves an increase in the size of individual cells of an organism, in the number of cells, or in both. Growth may be uniform in the various parts of an organism, or it may be greater in some parts than in others, causing the body proportions to change as growth occurs. Some organisms—most trees, for example—continue to grow throughout their lives. Many animals have a defined growth period that terminates when a characteristic adult size is reached. An intriguing aspect of the growth process is that each part of the organism typically continues to function as it grows.

Living organisms develop as well as grow. **Development** includes all the changes that take place during an organism's life. Like many other organisms, every human begins life as a fertilized egg that then grows and develops. The structures and body form that develop are exquisitely adapted to the functions the organism must perform.

Organisms regulate their metabolic processes

Within all organisms, chemical reactions and energy transformations occur that are essential to nutrition, the growth and repair of cells, and the conversion of energy into usable forms. The sum of all the chemical activities of the organism is its **metabolism.**

Metabolic processes occur continuously in every organism, and they must be carefully regulated to maintain **homeostasis,** an appropriate, balanced internal environment. When enough of a cell product has been made, its manufacture must be decreased or turned off. When a particular substance is required, cell processes that produce it must be turned on. These *homeostatic mechanisms* are self-regulating control systems that are remarkably sensitive and efficient.

Mike Abbey/Visuals Unlimited, Inc.

(a) Unicellular organisms consist of one intricate cell that performs all the functions essential to life. Ciliates, such as this *Paramecium*, move about by beating their hairlike cilia.

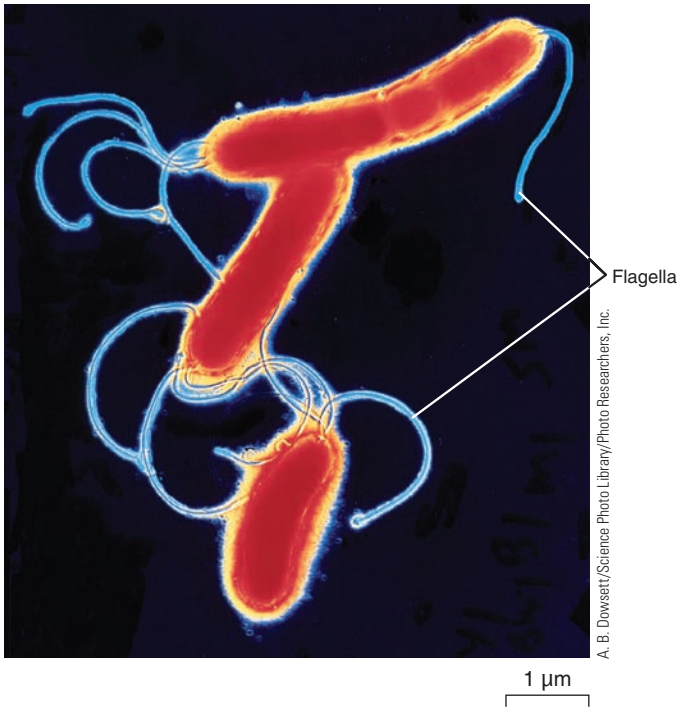
McMurray Photography

(b) Multicellular organisms, such as this African buffalo (*Syncerus caffer*) and the plants on which it grazes, may consist of billions of cells specialized to perform specific functions.

FIGURE 1-1 **Unicellular and multicellular life-forms**

The regulation of glucose (a simple sugar) concentration in the blood of complex animals is a good example of a homeostatic mechanism. Your cells require a constant supply of glucose molecules, which they break down to obtain energy. The circulatory system delivers glucose and other nutrients to all the cells. When the concentration of glucose in the blood rises above normal limits, glucose is stored in the liver and in muscle cells. When you have not eaten for a few hours, the glucose concentration begins to fall. Your body converts stored nutrients to glucose, bringing the glucose concentration in the blood back to normal levels. When the glucose concentration decreases, you also feel hungry and restore nutrients by eating.

www.konkur.in



A. B. Dowsett/Science Photo Library/Photo Researchers, Inc.

FIGURE 1-2 Biological movement

These bacteria (*Helicobacter pylori*), equipped with flagella for locomotion, have been linked to stomach ulcers. The photograph was taken using a scanning electron microscope. The bacteria are not really red and blue. Their color has been artificially enhanced.

Organisms respond to stimuli

All forms of life respond to **stimuli,** physical or chemical changes in their internal or external environment. Stimuli that evoke a response in most organisms are changes in the color, intensity, or direction of light; changes in temperature, pressure, or sound; and changes in the chemical composition of the surrounding soil, air, or water. Responding to stimuli involves movement, though not always locomotion (moving from one place to another).

In simple organisms, the entire individual may be sensitive to stimuli. Certain unicellular organisms, for example, respond to bright light by retreating. In some organisms, locomotion is achieved by the slow oozing of the cell, the process of *amoeboid movement.* Other organisms move by beating tiny, hairlike extensions of the cell called **cilia** or longer structures known as **flagella** (**FIG. 1-2**). Some bacteria move by rotating their flagella.

Most animals move very obviously. They wiggle, crawl, swim, run, or fly by contracting muscles. Sponges, corals, and oysters have free-swimming larval stages, but most are **sessile** as adults, meaning that they do not move from place to place. In fact, they may remain firmly attached to a surface, such as the sea bottom or a rock. Many sessile organisms have cilia or flagella that beat rhythmically, bringing them food and oxygen in the surrounding water. Complex animals, such as grasshoppers, lizards, and humans, have highly specialized cells that respond to specific types of stimuli. For example, cells in the retina of the vertebrate eye respond to light.

Although their responses may not be as obvious as those of animals, plants do respond to light, gravity, water, touch, and other stimuli. For example, plants orient their leaves to the sun and grow toward light. Many plant responses involve different growth rates of various parts of the plant body. A few plants, such as the Venus flytrap of the Carolina swamps, are very sensitive to touch and catch insects (**FIG. 1-3**). Their leaves are hinged along the midrib, and they have a scent that attracts insects. Trigger hairs on the leaf surface detect the arrival of an insect and stimulate the leaf to fold. When the edges come together, they interlock, preventing the insect's escape. The leaf then secretes enzymes that kill and digest the insect. The Venus flytrap usually grows in nitrogen-deficient soil. The plant obtains part of the nitrogen required for its growth from the insects it "eats."

(b) Sexual reproduction. Typically, each of two parents contributes a gamete (sperm or egg). Gametes fuse to produce the offspring, which has a combination of the traits of both parents. A pair of tropical flies are shown mating.

FIGURE 1-4 Asexual and sexual reproduction

of the Nile. Thanks to the work of several scientists, including the Italian physician Francesco Redi in the 17th century and French chemist Louis Pasteur in the 19th century, we know that organisms arise only from previously existing organisms.

Simple organisms, such as amoebas, perpetuate themselves by **asexual reproduction** (FIG. 1-4a). When an amoeba has grown to a certain size, it reproduces by splitting in half to form two new amoebas. Before an amoeba divides, its hereditary material (set of *genes*) is duplicated, and one complete set is distributed to each new cell. Except for size, each new amoeba is similar to the parent cell. The only way that variation occurs among asexually reproducing organisms is by genetic *mutation,* a permanent change in the genes.

In most plants and animals, **sexual reproduction** is carried out by the fusion of an egg and a sperm cell to form a fertilized egg (FIG. 1-4b). The new organism develops from the fertilized egg. Offspring produced by sexual reproduction are the product of the interaction of various genes contributed by the mother and the father. This genetic variation is important in the vital processes of evolution and adaptation.

McMurray Photography

FIGURE 1-5 Adaptations

These Burchell's zebras (*Equus burchelli*), photographed in Tanzania, are behaviorally adapted to position themselves to watch for lions and other predators. Stripes are thought to be an adaptation for visual protection against predators. They serve as camouflage or to break up form when spotted from a distance. The zebra stomach is adapted for feeding on coarse grass passed over by other grazers, an adaptation that helps the animal survive when food is scarce.

Populations evolve and become adapted to the environment

The ability of a population to evolve over many generations and adapt to its environment equips it to survive in a changing world. **Adaptations** are inherited characteristics that enhance an organism's ability to survive in a particular environment. The long, flexible tongue of the frog is an adaptation for catching insects, the feathers and lightweight bones of birds are adaptations for flying, and the thick fur coat of the polar bear is an adaptation for surviving frigid temperatures. Adaptations may be structural, physiological, biochemical, behavioral, or a combination of all four (FIG. 1-5). Every biologically successful organism is a complex collection of coordinated adaptations produced through evolutionary processes.

1.3 LEVELS OF BIOLOGICAL ORGANIZATION

LEARNING OBJECTIVE

3 Construct a hierarchy of biological organization, including levels characteristic of individual organisms and levels characteristic of ecological systems.

www.konkur.in

Whether we study a single organism or the world of life as a whole, we can identify a hierarchy of biological organization (FIG. 1-6). At every level, structure and function are precisely coordinated. One way to study a particular level is by looking at its components. Biologists can gain insights about cells by studying atoms and molecules. Learning about a structure by studying its parts is called **reductionism.** However, the whole is more than the sum of its parts. Each level has **emergent properties,** characteristics not found at lower levels. Populations of organisms have emergent properties such as population density, age structure, and birth and death rates. The *individuals* that make up a population do not have these characteristics. Consider also the human brain. The brain is composed of millions of neurons (nerve cells). However, we could study all of these individual neurons and have no clue about the functional capacities of the brain. Only when the neurons are wired together in precise fashion are the emergent properties, such as the capacity for thought, judgment, and motor coordination, evident.

Organisms have several levels of organization

The chemical level, the most basic level of organization, includes atoms and molecules. An **atom** is the smallest unit of a chemical element that retains the characteristic properties of that element. For example, an atom of iron is the smallest possible amount of iron. Atoms combine chemically to form **molecules.** Two atoms of hydrogen combine with one atom of oxygen to form a single molecule of water. Although composed of two types of atoms that are gases, water can exist as a liquid or solid. The properties of water are very different from those of its hydrogen and oxygen components, an example of emergent properties.

At the cellular level, many types of atoms and molecules associate with one another to form *cells.* However, a cell is much more than a heap of atoms and molecules. Its emergent properties make it the basic structural and functional unit of life, the simplest component of living matter that can carry on all the activities necessary for life.

During the evolution of multicellular organisms, cells associated to form **tissues.** For example, most animals have muscle tissue and nervous tissue. Plants have epidermis, a tissue that serves as a protective covering, and vascular tissues that move materials throughout the plant body. In most complex organisms, tissues organize into functional structures called **organs,** such as the heart and stomach in animals and roots and leaves in plants. In animals, each major group of biological functions is performed by a coordinated group of tissues and organs called an **organ system.** The circulatory and digestive systems are examples of organ systems. Functioning together with great precision, organ systems make up a complex, multicellular **organism.** Again, emergent properties are evident. An organism is much more than its component organ systems.

Several levels of ecological organization can be identified

Organisms interact to form still more complex levels of biological organization. All the members of one species living in the same geographic area at the same time make up a **population.** The populations of various types of organisms that inhabit a particular area and interact with one another form a **community.** A community can consist of hundreds of different types of organisms.

A community together with its nonliving environment is an **ecosystem.** An ecosystem can be as small as a pond (or even a puddle) or as vast as the Great Plains of North America or the Arctic tundra. All of Earth's ecosystems together are known as the **biosphere.** The biosphere includes all of Earth that is inhabited by living organisms—the atmosphere, the hydrosphere (water in any form), and the lithosphere (Earth's crust). The study of how organisms relate to one another and to their physical environment is called **ecology** (derived from the Greek *oikos,* meaning "house").

Review

- What are the levels of organization within an organism?
- What are the levels of ecological organization?

1.4 INFORMATION TRANSFER

LEARNING OBJECTIVE

4 Summarize the importance of information transfer within and between living systems, giving specific examples.

An organism inherits the information it needs to grow, develop, carry on self-regulated metabolism, respond to stimuli, and reproduce. Each organism must also have precise instructions for making the molecules necessary for its cells to communicate. The information an organism requires to carry on these life processes is coded and transmitted in the form of chemical substances and electrical impulses. Organisms must also communicate information to one another.

DNA transmits information from one generation to the next

Humans give birth only to human babies, not to giraffes or rosebushes. In organisms that reproduce sexually, each offspring is a combination of the traits of its parents. In 1953, James Watson and Francis Crick worked out the structure of DNA, the large molecule that makes up the **genes,** the units of hereditary material (FIG. 1-7). A DNA molecule consists of two chains of atoms twisted into a helix. As will be described in Chapter 2, each chain is made up of a sequence of chemical subunits called **nucleotides.** There are four types of nucleotides in DNA; and each sequence of three nucleotides is part of the genetic code.

Watson and Crick's work led to the understanding of this genetic code. The information coded in sequences of nucleotides in DNA transmits genetic information from generation to generation. The code works somewhat like an alphabet. The nucleotides can "spell" an amazing variety of instructions for making organisms as diverse as bacteria, frogs, and redwood trees. The genetic code is universal, that is, virtually identical in all organisms—a dramatic example of the unity of life.

www.konkur.in

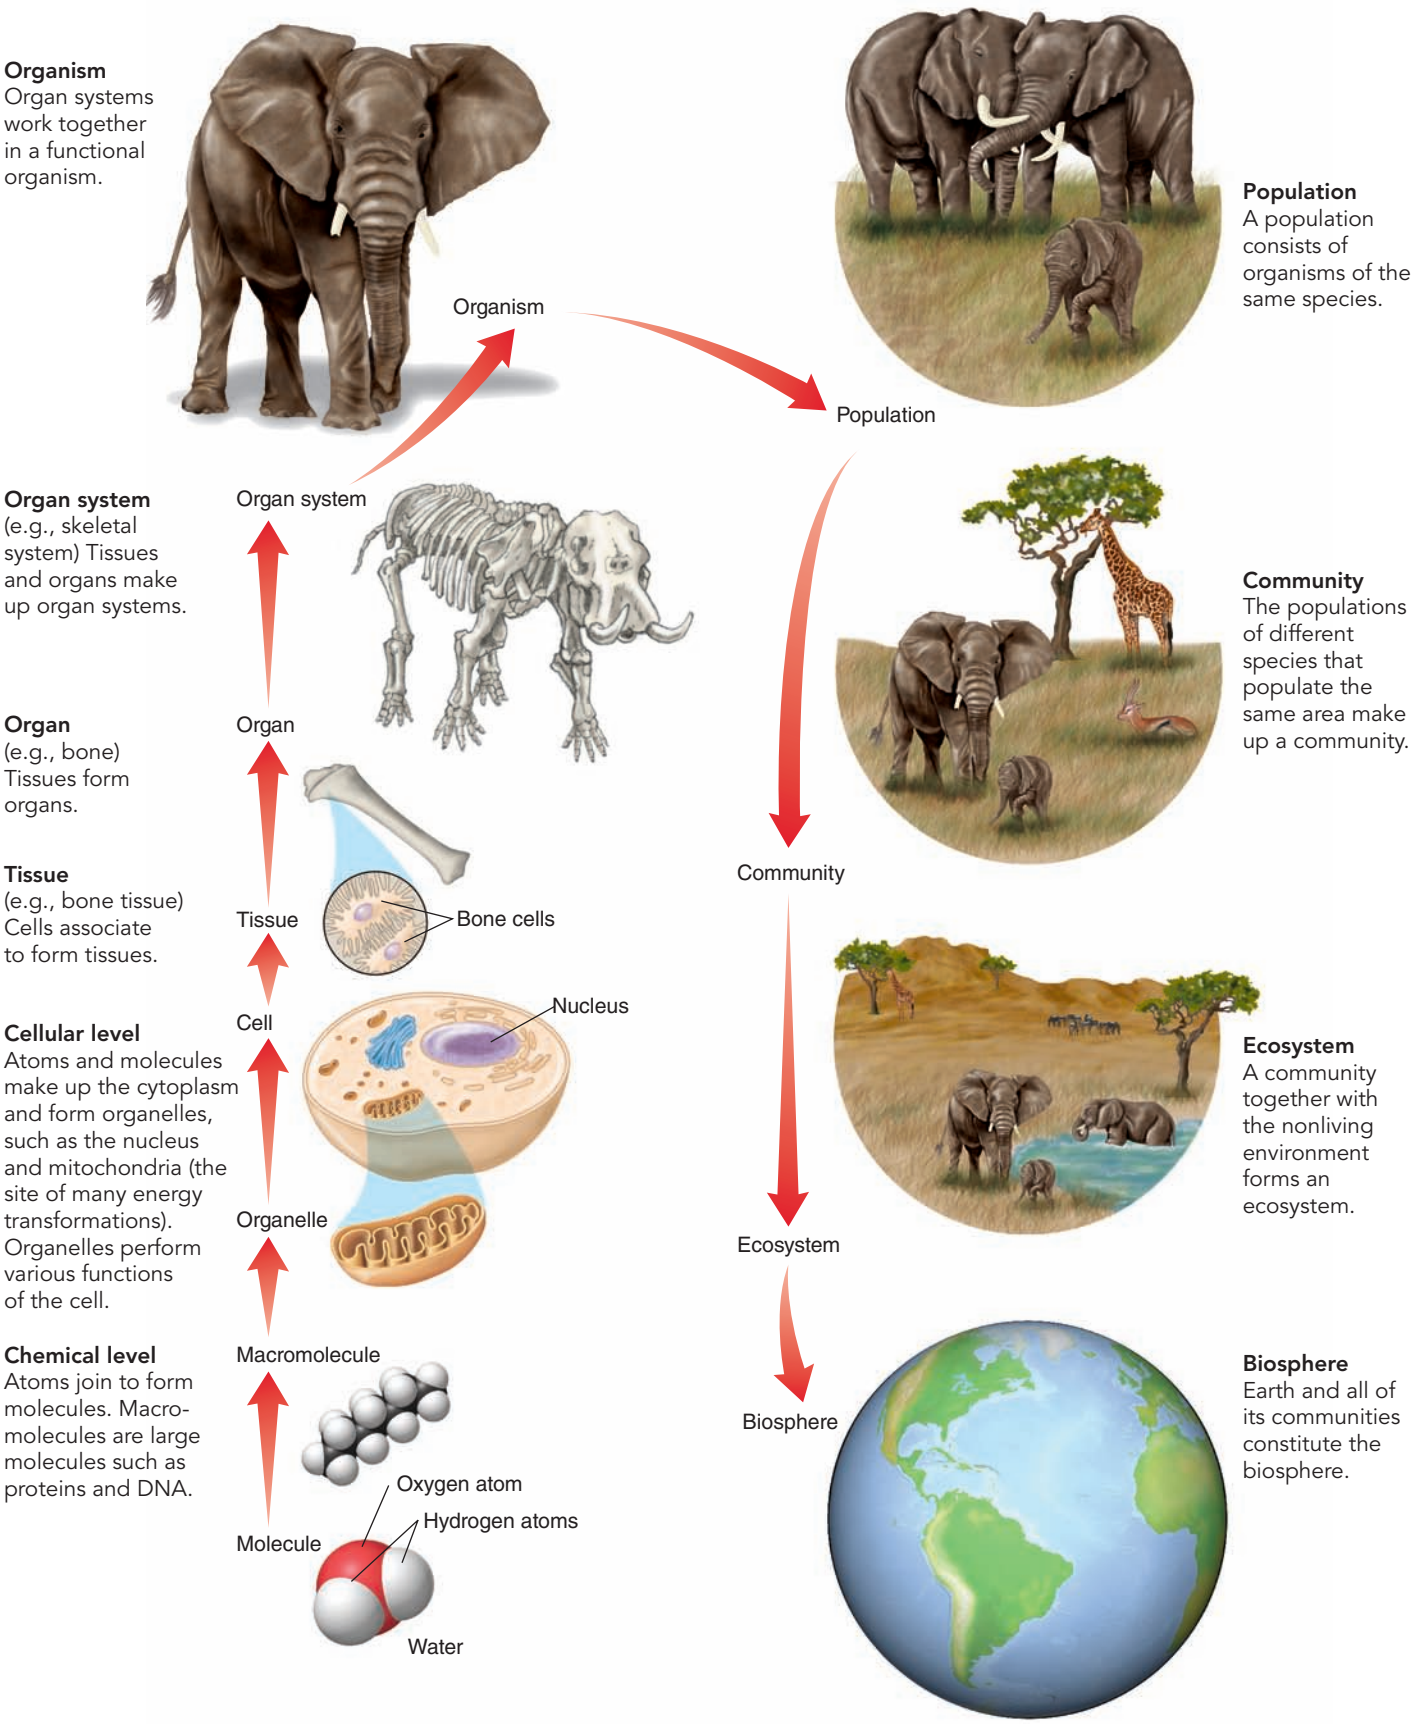

FIGURE 1-6 ***Animated*** The hierarchy of biological organization

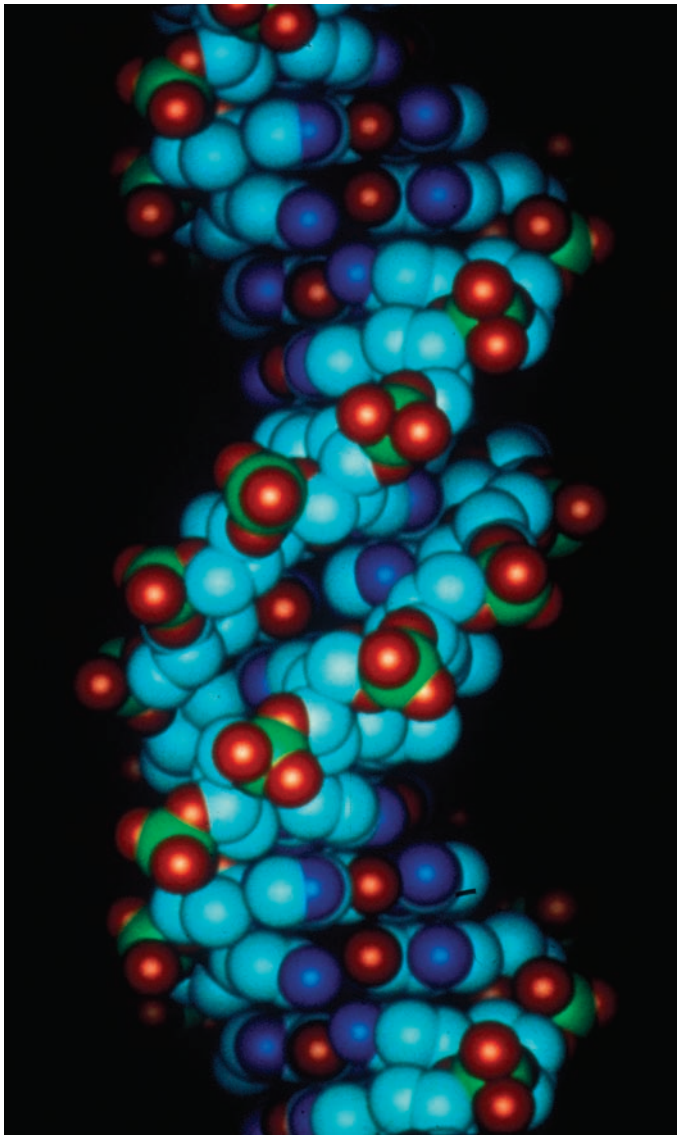
www.konkur.in



Computer image of B-DNA by Geis/Stodola. Not to be reproduced without permission.

FIGURE 1-7 DNA

DNA is the hereditary material that transmits information from one generation to the next. As shown in this model, DNA is a macromolecule that consists of two chains of atoms twisted into a helix. Each chain consists of subunits called nucleotides. The sequence of nucleotides makes up the genetic code.

Information is transmitted by chemical and electrical signals

Genes control the development and functioning of every organism. The DNA that makes up the genes contains the "recipes" for making all the proteins required by the organism. **Proteins** are large molecules important in determining the structure and function of cells and tissues. For example, brain cells differ from muscle cells in large part because they have different types of proteins. Some proteins are important in communication within and among cells. Certain proteins on the surface of a cell serve as markers so that other cells "recognize" them. Some cell-surface proteins serve as receptors that combine with chemical messengers.

Cells use proteins and many other types of molecules to communicate with one another. In a multicellular organism, cells produce chemical compounds, such as **hormones,** that signal other cells. Hormones and other chemical messengers can signal cells in distant organs to secrete a particular required substance or change some metabolic activity. In this way chemical signals help regulate growth, development, and metabolic processes. The mechanisms involved in **cell signaling** often involve complex biochemical processes.

Cell signaling is currently an area of intense research. A major focus has been the transfer of information among cells of the immune system. A better understanding of how cells communicate promises new insights into how the body protects itself against disease organisms. Learning to manipulate cell signaling may lead to new methods of delivering drugs into cells and new treatments for cancer and other diseases.

Some organisms use electrical signals to transmit information. Most animals have nervous systems that transmit information by way of both electrical impulses and chemical compounds known as **neurotransmitters.** Information transmitted from one part of the body to another is important in regulating life processes. In complex animals, the nervous system gives the animal information about its outside environment by transmitting signals from sensory receptors such as the eyes and ears to the brain.

Information must also be transmitted from one organism to another. Mechanisms for this type of communication include the release of chemicals, visual displays, and sounds. Typically, organisms use a combination of several types of communication signals. A dog may signal aggression by growling, using a particular facial expression, and laying its ears back. Many animals perform complex courtship rituals in which they display parts of their bodies, often elaborately decorated, to attract a mate.

1.5 THE ENERGY OF LIFE

LEARNING OBJECTIVE

5 Summarize the flow of energy through ecosystems and contrast the roles of producers, consumers, and decomposers.

Life depends on a continuous input of energy from the sun because every activity of a living cell or organism requires energy. Whenever energy is used to perform biological work, some is converted to heat and dispersed into the environment.

Recall that all the energy transformations and chemical processes that occur within an organism are referred to as its *metabolism.* Energy is necessary to carry on the metabolic activities essential for growth, repair, and maintenance. Each cell of an organism requires nutrients that contain energy. During **cellular respiration,** cells capture energy released by nutrient molecules through a series of carefully regulated chemical reactions (**FIG. 1-8**). The cell can use this energy to do work, including the synthesis of

www.konkur.in

KEY POINT Most of the energy for life is light energy from the sun, which is captured during photosynthesis; some of this energy is stored in the chemical bonds of glucose and other nutrients.

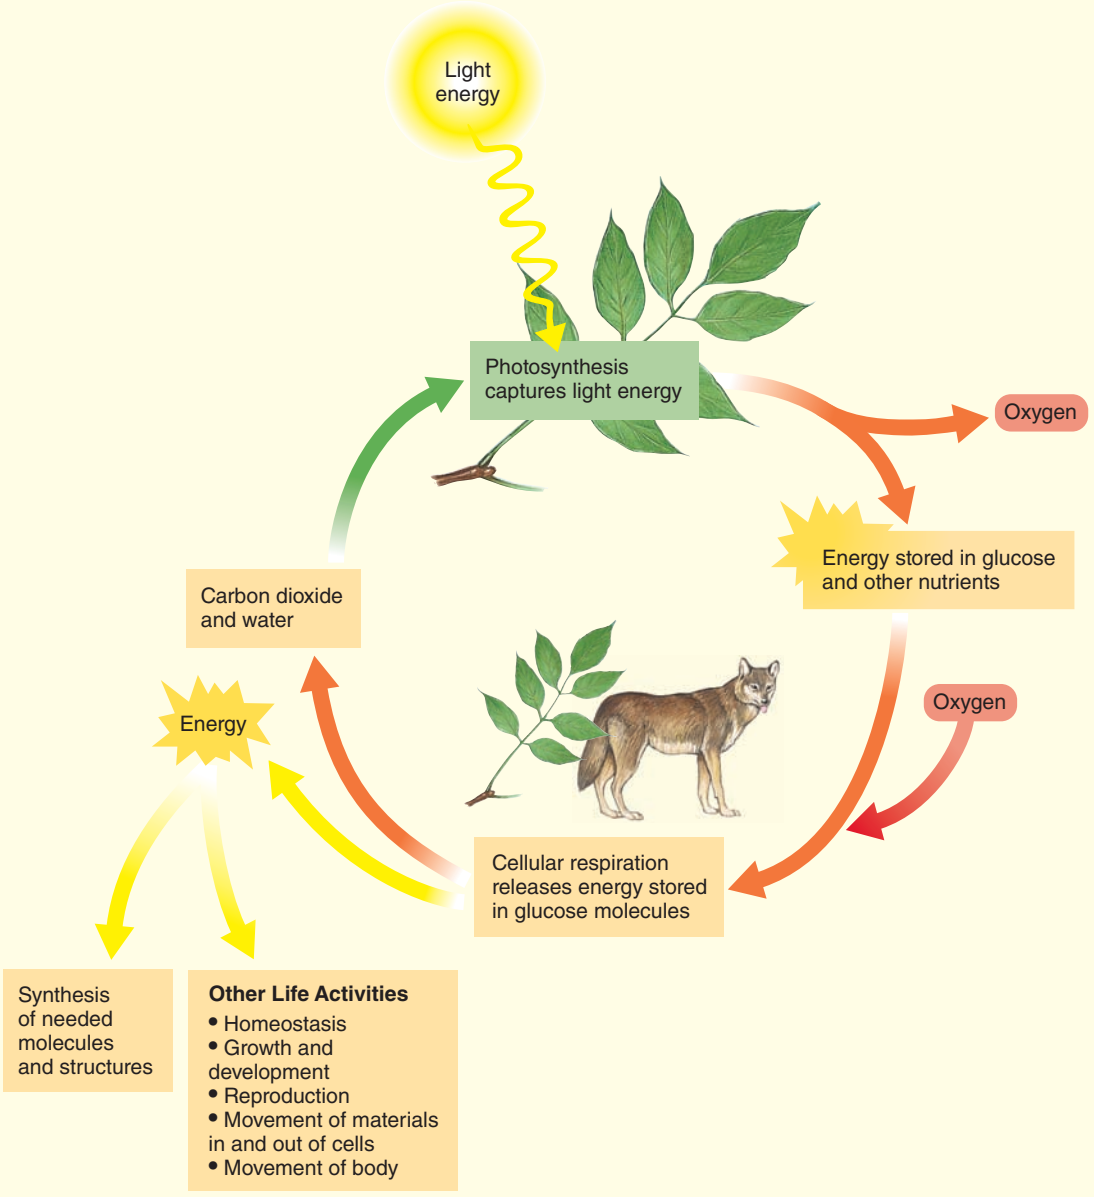

FIGURE 1-8 Energy flow within and among organisms

Algae and certain plant cells carry on photosynthesis, a process that uses light energy to produce glucose from carbon dioxide and water. Energy is stored in the chemical bonds of glucose and other nutrients produced from glucose. Through the process of cellular respiration, cells of all organisms, including algae and plant cells, then break down glucose and other nutrients. The energy released can be used to produce needed molecules and to fuel other life activities.

required materials, such as new cell components. Virtually all cells carry on cellular respiration.

Like individual organisms, ecosystems also depend on a continuous energy input. A self-sufficient ecosystem contains three types of organisms—producers, consumers, and decomposers—and includes a physical environment in which they can survive. These organisms depend on one another and on the environment for nutrients, energy, oxygen, and carbon dioxide. There is a one-way flow of energy through ecosystems. Organisms can neither create energy nor use it with complete efficiency. During every energy transaction, some energy disperses into the environment as heat and is no longer available to the organism (FIG. 1-9).

Plants, algae, and certain bacteria are producers, or **autotrophs,** that produce their own food from simple raw materials.

www.konkur.in

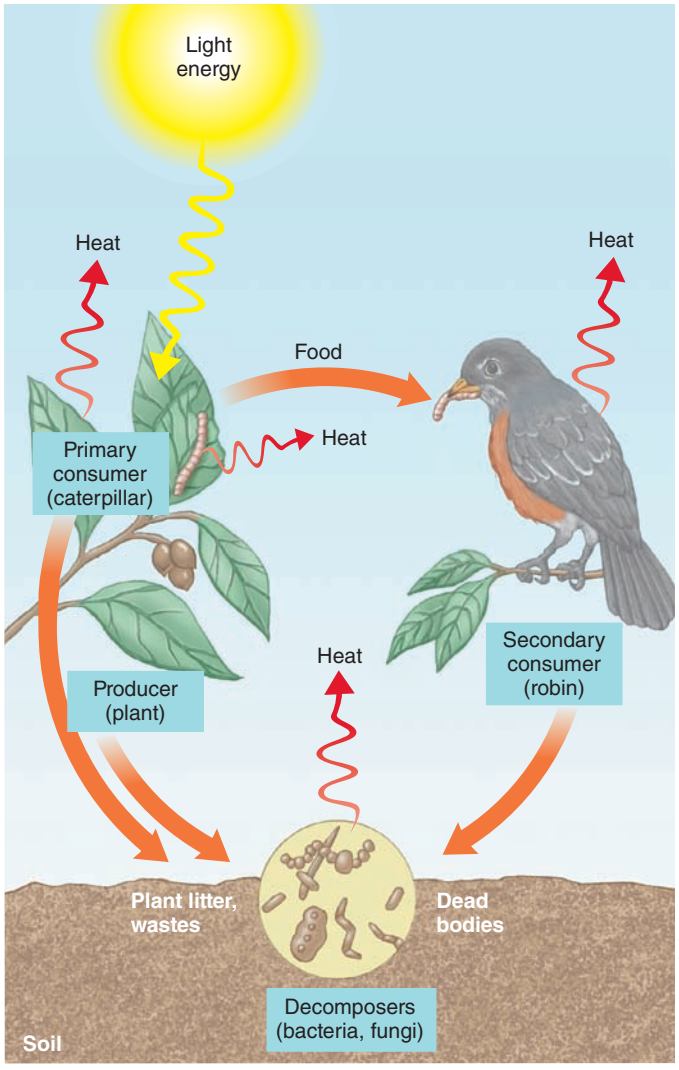

FIGURE 1-9 ***Animated*** **Energy flow through the biosphere**
Continuous energy input from the sun operates the biosphere. During photosynthesis, producers use the energy from sunlight to make complex molecules from carbon dioxide and water. Primary consumers, such as the caterpillar shown here, obtain energy, nutrients, and other required materials when they eat producers. Secondary consumers, such as the robin, obtain energy, nutrients, and other required materials when they eat primary consumers that have eaten producers. Decomposers obtain their energy and nutrients by breaking down wastes and dead organic material. During every energy transaction, some energy is lost to biological systems, dispersing into the environment as heat.

Most of these organisms use sunlight as an energy source and carry on **photosynthesis,** the process during which producers synthesize complex molecules such as glucose (a sugar) from carbon dioxide and water. The light energy is transformed into chemical energy, which is stored within the chemical bonds of the food molecules produced. Oxygen, which is required by the cells of most organisms including plant cells, is produced as a byproduct of photosynthesis:

$$\text{carbon dioxide} + \text{water} + \text{light energy} \longrightarrow \text{glucose} + \text{oxygen}$$

Animals are **consumers,** or **heterotrophs**—that is, organisms that depend on producers for food, energy, and oxygen. **Primary consumers** eat producers, whereas **secondary consumers** eat primary consumers. Consumers obtain energy by breaking down sugars and other food molecules originally produced during photosynthesis. When chemical bonds are broken during this process of cellular respiration, their stored energy is made available for life processes:

$$\text{glucose} + \text{oxygen} \longrightarrow \text{carbon dioxide} + \text{water} + \text{energy}$$

Consumers contribute to the balance of the ecosystem. For example, consumers produce carbon dioxide required by producers. (Note that producers also carry on cellular respiration.) The metabolism of consumers and producers helps maintain the life-sustaining mixture of gases in the atmosphere.

Most bacteria and fungi are **decomposers,** heterotrophs that obtain nutrients by breaking down nonliving organic material such as wastes, dead leaves and branches, and the bodies of dead organisms. In their process of obtaining energy, decomposers make the components of these materials available for reuse. If decomposers did not exist, nutrients would remain locked up in wastes and dead bodies, and the supply of elements required by living systems would soon be exhausted.

1.6 EVOLUTION: THE BASIC UNIFYING CONCEPT OF BIOLOGY

LEARNING OBJECTIVES

6 Demonstrate the binomial system of nomenclature by using specific examples and classify an organism (such as a human) in its domain, kingdom, phylum, class, order, family, genus, and species.

7 Identify the three domains and the kingdoms of living organisms, and give examples of organisms assigned to each group.

8 Give a brief overview of the scientific theory of evolution and explain why it is the principal unifying concept in biology.

9 Apply the theory of natural selection to any given adaptation and suggest a logical explanation of how the adaptation may have evolved.

Evolution is the process by which populations of organisms change over time. Evolutionary theory has become the most important unifying concept of biology. As we will discuss, evolution involves passing genes for new traits from one generation to another, leading to differences in populations. The evolutionary perspective is important in every specialized field within biology. Biologists try to understand the structure, function, and behavior of organisms and their interactions with one another by considering them in light of the long, continuing process of evolution. Although we

www.konkur.in

discuss evolution in depth in Chapters 18 through 22, we present a brief overview here to give you the background necessary to understand other aspects of biology. First, we examine how biologists organize the millions of organisms that have evolved, and then we summarize some of the mechanisms that drive evolution.

Biologists use a binomial system for naming organisms

Biologists have identified about 1.8 million species of extant (currently living) organisms and estimate that several million more remain to be discovered. To study life, we need a system for organizing, naming, and classifying its myriad forms. **Systematics** is the field of biology that studies the diversity of organisms and their evolutionary relationships. **Taxonomy,** a subspecialty of systematics, is the science of naming and classifying organisms. In the 18th century, Carolus Linnaeus, a Swedish botanist, developed a hierarchical system of naming and classifying organisms. Biologists still use this system today, with some modification.

The **species** is a group of organisms with similar structure, function, and behavior. A species consists of one or more populations whose members are capable of breeding with one another; in nature, they do not breed with members of other species. Members of a population contribute to a common **gene pool** (all the genes present in the population) and share a common ancestry. Closely related species are grouped in the next broader category of classification, the **genus** (pl., *genera*).

The Linnaean system of naming species is known as the **binomial system of nomenclature** because each species is assigned a two-part name. The first part of the name is the genus, and the second part, the **specific epithet,** designates a particular species belonging to that genus. The specific epithet is often a descriptive word expressing some quality of the organism. It is always used together with the full or abbreviated generic name preceding it. The generic name is always capitalized; the specific epithet is generally not capitalized. Both names are always italicized or underlined. For example, the domestic dog, *Canis familiaris* (abbreviated *C. familiaris*), and the timber wolf, *Canis lupus* (*C. lupus*), belong to the same genus. The domestic cat, *Felis catus,* belongs to a different genus. The scientific name of the American white oak is *Quercus alba,* whereas the name of the European white oak is *Quercus robur.* Another tree, the white willow, *Salix alba,* belongs to a different genus. The scientific name for our own species is *Homo sapiens* ("wise man").

Taxonomic classification is hierarchical

Just as closely related species may be grouped in a common genus, related genera can be grouped in a more inclusive group, a **family.** Families are grouped into **orders,** orders into **classes,** and classes into **phyla** (sing., *phylum*). Phyla can be assigned to **kingdoms,** and kingdoms are grouped in **domains.** Each formal grouping at any given level is a **taxon** (pl., *taxa*). Note that each taxon is more inclusive than the taxon below it. Together they form a hierarchy ranging from species to domain (**TABLE 1-1** and **FIG. 1-10**).

Consider a specific example. The family Canidae, which includes all doglike carnivores (animals that eat mainly meat), consists of 12 genera and about 34 living species. Family Canidae, along with family Ursidae (bears), family Felidae (catlike animals), and several other families that eat mainly meat, are all placed in order Carnivora. Order Carnivora, order Primates (to which chimpanzees and humans belong), and several other orders belong to class Mammalia (mammals). Class Mammalia is grouped with several other classes that include fishes, amphibians, reptiles, and birds in subphylum Vertebrata. The vertebrates belong to phylum Chordata, which is part of kingdom Animalia. Animals are assigned to domain Eukarya.

The tree of life includes three domains and several kingdoms

Systematics has itself evolved as scientists have developed new techniques for inferring common ancestry among groups of organisms. As we will learn, biologists seek to classify organisms based on evolutionary relationships. These relationships are based on shared characteristics that distinguish a particular group. A group of organisms with a common ancestor is a **clade.** Systematists have developed a **tree of life,** a family tree showing proposed evolutionary relationships among organisms. These relationships are based on shared characteristics, including structural, developmental, behavioral, and molecular similarities, as well as on fossil evidence. **FIGURE 1-11** is a **cladogram,** a branching diagram that depicts the tree of life as it is currently understood. As researchers report new findings, the classification of organisms changes and the branches of the tree of life must be redrawn.

Although the tree of life is a work in progress, most biologists now assign organisms to three domains and to several kingdoms or clades. Bacteria have long been recognized as unicellular prokaryotic cells; they differ from all other organisms (except archaea) in that they are **prokaryotes.** Microbiologist Carl Woese (pronounced "woes") has been a pioneer in developing molecular approaches to systematics. Woese and his colleagues selected a molecule known as small subunit ribosomal RNA (rRNA) that functions in the process of manufacturing proteins in all organisms. Because its molecular structure differs somewhat in various organisms, Woese hypothesized that the molecular composition of rRNA in closely related organisms would be more similar than in distantly related organisms.

Species	*Felis catus*	*Homo sapiens*	*Quercus alba*

www.konkur.in

KEY POINT Biologists use a hierarchical classification scheme with a series of taxonomic categories from species to domain; each category is more general and more inclusive than the one below it.

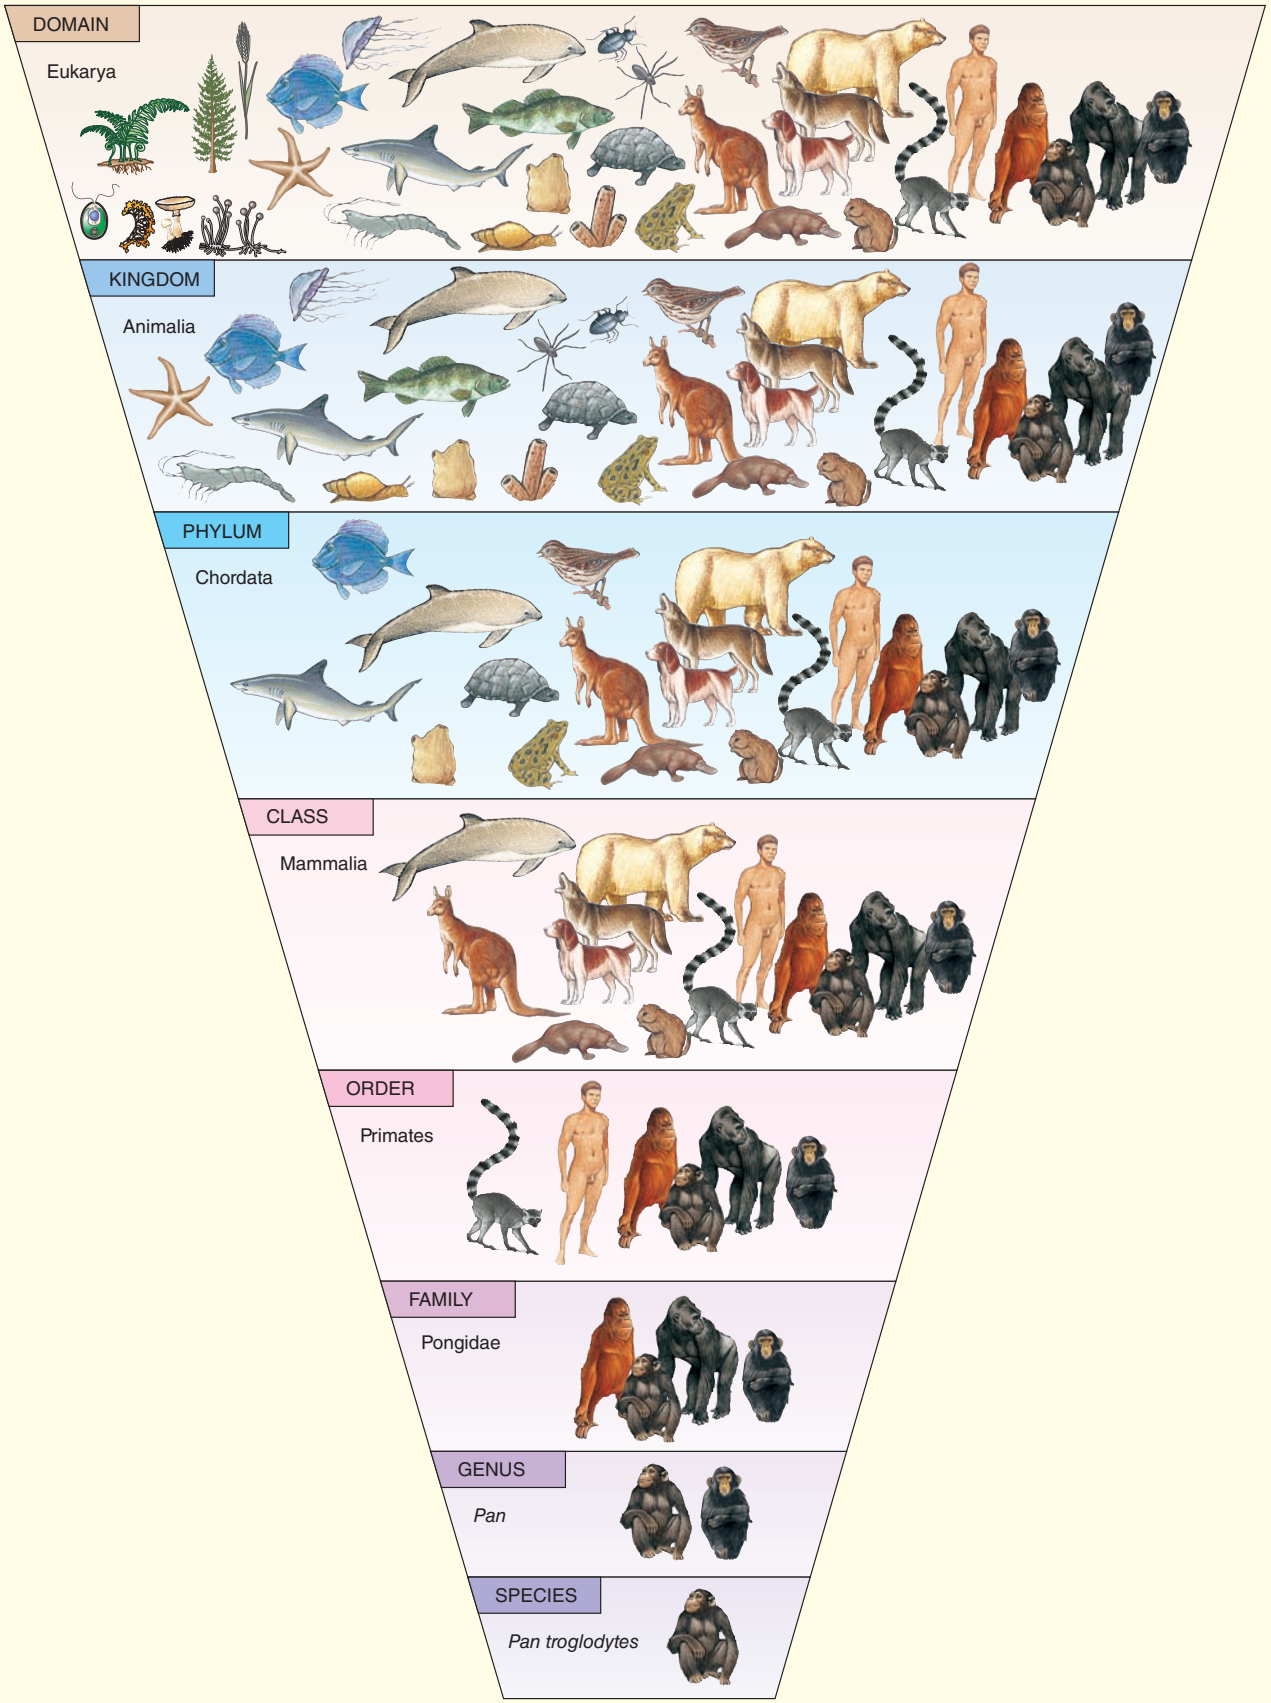

FIGURE 1-10 Classification of the chimpanzee (*Pan troglodytes*)

www.konkur.in

KEY POINT This cladogram illustrates the evolutionary relationships among the three domains and among the major groups of organisms that belong to these domains.

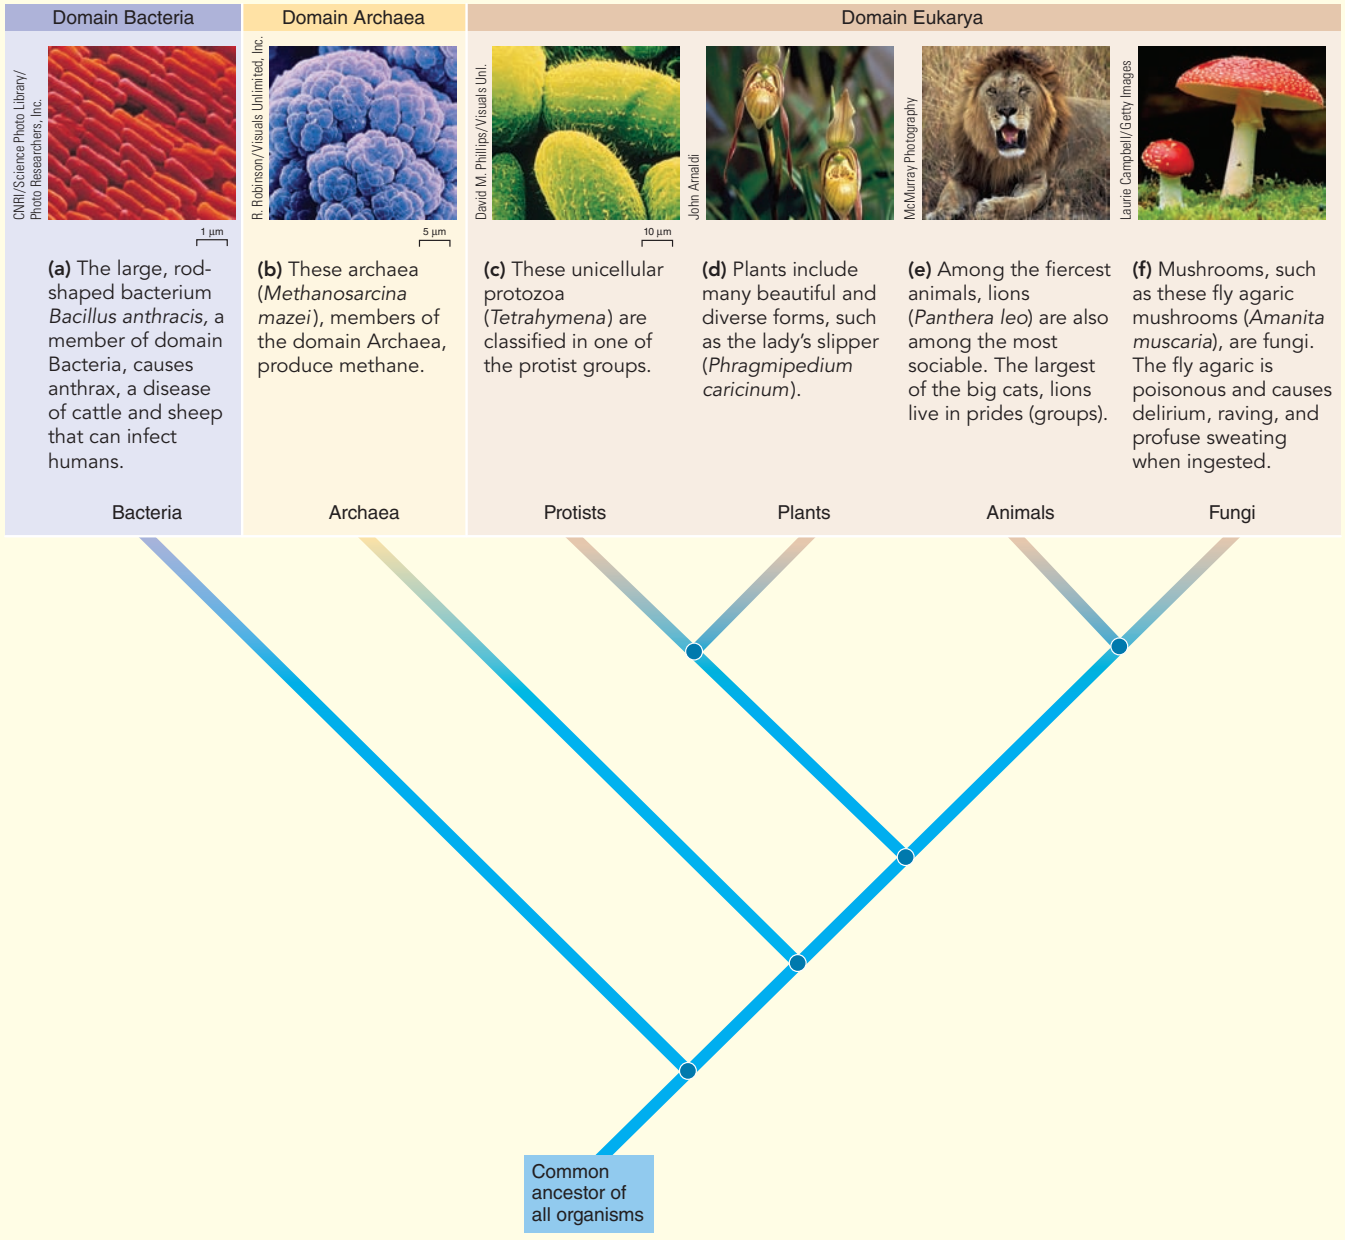

FIGURE 1-11 ***Animated*** **A survey of the three domains of life**

Biologists assign organisms to three domains and to several kingdoms and other groups. The protists do not form a clade and are no longer considered a kingdom. They are assigned to five "supergroups" (not shown).

Woese's findings showed that there are two distinct groups of prokaryotes. He established the domain level of taxonomy and assigned the prokaryotes to two domains: **Bacteria** and **Archaea** (ar'-key-ah). The **eukaryotes,** organisms with eukaryotic cells, are classified in domain **Eukarya.** Woese's work became widely accepted in the mid-1990s.

In the classification system used in this book, each organism is assigned to a domain and to a kingdom or "supergroup." Two kingdoms correspond to the prokaryotic domains: kingdom Archaea corresponds to domain Archaea, and kingdom Bacteria corresponds to domain Bacteria. The remaining kingdoms and groups are assigned to domain Eukarya.

Protists (for example, algae, slime molds, amoebas, and ciliates) are unicellular, colonial, or simple multicellular organisms that have a eukaryotic cell organization. The word *protist,* from the Greek for "the very first," reflects the idea that protists were the first

www.konkur.in

eukaryotes to evolve. Protists are primarily aquatic organisms with diverse body forms, types of reproduction, modes of nutrition, and lifestyles. Some protists are adapted to carry out photosynthesis. Based mainly on molecular data that have clarified many evolutionary relationships among eukaryotes, the protists are no longer considered a kingdom. As we will learn in Chapter 26, several clades of protists have been identified, and many biologists now classify protists into five "supergroups."

Members of kingdom **Plantae** are complex multicellular organisms adapted to carry out photosynthesis. Among characteristic plant features are the *cuticle* (a waxy covering over aerial parts that reduces water loss) and *stomata* (tiny openings in stems and leaves for gas exchange); many plants have multicellular *gametangia* (organs that protect developing reproductive cells). Kingdom Plantae includes both nonvascular plants (mosses) and vascular plants (ferns, conifers, and flowering plants), those that have tissues specialized for transporting materials throughout the plant body. Most plants are adapted to terrestrial environments.

Kingdom **Fungi** is composed of the yeasts, mildews, molds, and mushrooms. Fungi do not photosynthesize. They obtain their nutrients by secreting digestive enzymes into food and then absorbing the predigested food. Kingdom **Animalia** is made up of multicellular organisms that obtain their nutrition by eating other organisms. Most animals exhibit considerable cell and tissue specialization and body organization. These characters have evolved along with complex sense organs, nervous systems, and muscular systems. Most animals reproduce sexually; they have large, nonmotile (do not move from place to place) eggs and small sperm with flagella that propel them in their journey to find the egg.

We have provided an introduction here to the groups of organisms that make up the tree of life. We will refer to them throughout this book, as we consider the many kinds of challenges organisms face and the various adaptations that have evolved in response to them. We discuss the diversity of life in more detail in Chapters 23 through 32, and we summarize classification in Appendix B.

Species adapt in response to changes in their environment

Every organism is the product of numerous interactions between environmental conditions and the genes inherited from its ancestors. If all individuals of a species were exactly alike, any change in the environment might be disastrous to all, and the species would become extinct. Adaptations to changes in the environment occur as a result of evolutionary processes that take place over time and involve many generations.

Natural selection is an important mechanism by which evolution proceeds

Although philosophers and naturalists discussed the concept of evolution for centuries, Charles Darwin and Alfred Wallace first brought a theory of evolution to general attention and suggested a plausible mechanism, **natural selection,** to explain it. In his book *On the Origin of Species by Natural Selection,* published in 1859, Darwin synthesized many new findings in geology and biology. He presented a wealth of evidence supporting his hypothesis that present forms of life descended, with modifications, from previously existing forms. Darwin's book raised a storm of controversy in both religion and science, some of which still lingers.

Darwin's theory of evolution has helped shape the biological sciences to the present day. His work generated a great wave of scientific observation and research that has provided much additional evidence that evolution is responsible for the great diversity of organisms on our planet. Even today, the details of evolutionary processes are a major focus of investigation and discussion.

Darwin based his theory of natural selection on the following four observations:

1. Individual members of a species show some variation from one another.
2. Organisms produce many more offspring than will survive to reproduce (**FIG. 1-12**).
3. Because more individuals are produced than the environment can support, organisms must compete for necessary, but limited, resources such as food, sunlight, and space. Also, some organisms are killed by predators, disease organisms, or unfavorable natural conditions, such as weather changes. Which organisms are more likely to survive?
4. Individuals with characteristics that enable them to obtain and use resources, escape predators, resist disease organisms, and withstand changes in the environment are more likely to survive to reproductive maturity. The survivors that reproduce pass their adaptations for survival on to their offspring. Thus, the best-adapted individuals of a population leave, on average,

J. Serrao/Photo Researchers, Inc.

FIGURE 1-12 Egg masses of the wood frog (*Rana sylvatica*)
Many more eggs are produced than can possibly develop into adult frogs. Random events are largely responsible for determining which of these developing frogs will hatch, reach adulthood, and reproduce. However, certain traits of each organism also contribute to the probability for success in its environment. Not all organisms are as prolific as the frog, but the generalization that more organisms are produced than survive is true throughout the living world.

(c) Palila (*Loxiodes bailleui*) in mamane tree. This finch-billed honeycreeper feeds on immature seeds in pods of the mamane tree. It also eats insects, berries, and young leaves.

FIGURE 1-13 **Adaptation and diversification in Hawaiian honeycreepers**
All three species shown here are endangered, mainly because their habitats have been destroyed by humans or species introduced by humans.

more offspring than do other individuals. Because of this *differential reproduction,* a greater proportion of the population becomes adapted to the prevailing environmental conditions and challenges. The environment *selects* the best-adapted organisms for survival. Note that *adaptation involves changes in populations rather than in individual organisms.*

Darwin did not know about DNA or understand the mechanisms of inheritance. Scientists now understand that most variations among individuals are a result of different varieties of genes that code for each characteristic. The ultimate source of these variations is random **mutations,** chemical or physical changes in DNA that persist and can be inherited. *Mutations modify genes and by this process provide the raw material for evolution.*

Populations evolve as a result of selective pressures from changes in their environment

All the genes present in a population make up its **gene pool.** By virtue of its gene pool, a population is a reservoir of variation. Natural selection acts on individuals within a population. Selection favors individuals with genes specifying traits that allow them to respond effectively to pressures exerted by the environment. These organisms are most likely to survive and produce offspring. As successful organisms pass on their genetic recipe for survival, their traits become more widely distributed in the population. Over time, as populations continue to change (and as the environment itself changes, bringing different selective pressures), the members of the population become better adapted to their environment and less like their ancestors.

As a population adapts to environmental pressures and exploits new opportunities for finding food, maintaining safety, and avoiding predators, the population diversifies and new species may evolve. The Hawaiian honeycreepers, a group of related birds, are a good example. When honeycreeper ancestors first reached Hawaii, few other birds were present, so there was little competition. Genetic variation among honeycreepers allowed some to move into different food zones, and over time, species with various types of bills evolved (**FIG. 1-13**; see also Chapter 20 and Fig. 20-18). Some honeycreepers now have long, curved bills, adapted for feeding on nectar from tubular flowers. Others have short, thick bills for foraging for insects, and still others have adapted for eating seeds.

1.7 THE PROCESS OF SCIENCE

LEARNING OBJECTIVES

10 Design a study to test a given hypothesis, using the procedure and terminology of the scientific method.

11 Compare the reductionist and systems approaches to biological research.

Biology is a science. The word *science* comes from a Latin word meaning "to know." Science is a way of thinking and a method of investigating the natural world in a systematic manner. We test ideas, and based on our findings, we modify or reject these ideas. The **process of science** is investigative, dynamic, and often controversial. The observations made, the range of questions asked, and the design of experiments depend on the creativity of the individual scientist. Science, however, is influenced by cultural, social, historical, and technological contexts, so the process changes over time.

The **scientific method** involves a series of ordered steps. Using the scientific method, scientists make careful observations, ask critical questions, and develop *hypotheses,* which are tentative explanations. Using their hypotheses, scientists make predictions that can be tested by making further observations or by performing experiments. They gather **data,** information that they can analyze, often using computers and sophisticated statistical methods.

www.konkur.in

They interpret the results of their experiments and draw conclusions from them. As we will discuss, scientists pose many hypotheses that cannot be tested by using all of the steps of the scientific method in a rigid way. Scientists use the scientific method as a generalized framework or guide.

Biologists explore every imaginable aspect of life from the structure of viruses and bacteria to the interactions of the communities of our biosphere. Some biologists work mainly in laboratories, and others do their work in the field (**FIG. 1-14**). Perhaps you will decide to become a research biologist and help unravel the complexities of the human brain, discover new hormones that cause plants to flower, identify new species of animals or bacteria, or develop new stem cell strategies to treat cancer, AIDS, or heart disease. Applications of basic biological research have provided the technology to transplant kidneys, livers, and hearts; manipulate genes; treat many diseases; and increase world food production. Biology has been a powerful force in providing the quality of life that most of us enjoy. You may choose to enter an applied field of biology, such as environmental science, dentistry, medicine, pharmacology, or veterinary medicine. Many interesting careers in the biological sciences are discussed in the Careers section on our website.

Science requires systematic thought processes

Science is systematic. Scientists organize and often quantify knowledge, making it readily accessible to all who wish to build on its foundation. In this way, science is both a personal and a social endeavor. Science is not mysterious. Anyone who understands its rules and procedures can take on its challenges. What distinguishes science is its insistence on rigorous methods to examine a problem. Science seeks to give precise knowledge about the natural world; the supernatural is not accessible to scientific methods of inquiry. Science is not a replacement for philosophy, religion, or art. Being a scientist does not prevent one from participating in other fields of human endeavor, just as being an artist does not prevent one from practicing science.

Mark Moffett/Minden Pictures

FIGURE 1-14 Biologist at work

This biologist studying the rainforest canopy in Costa Rica is part of an international effort to study and preserve tropical rain forests. Researchers study the interactions of organisms and the effects of human activities on the rain forests.

Deductive reasoning begins with general principles

Scientists use two types of systematic thought processes: deduction and induction. With **deductive reasoning,** we begin with supplied information, called *premises,* and draw conclusions on the basis of that information. Deduction proceeds from general principles to specific conclusions. For example, if you accept the premise that all birds have wings and the second premise that sparrows are birds, you can conclude deductively that sparrows have wings. Deduction helps us discover relationships among known facts. A **fact** is information or knowledge based on evidence.

Inductive reasoning begins with specific observations

Inductive reasoning is the opposite of deduction. We begin with specific observations and draw a conclusion or discover a general principle. For example, you know that sparrows have wings, can fly, and are birds. You also know that robins, eagles, pigeons, and hawks have wings, can fly, and are birds. You might induce that all birds have wings and fly. In this way, you can use the inductive method to organize raw data into manageable categories by answering this question: What do all these facts have in common?

A weakness of inductive reasoning is that conclusions generalize the facts to all possible examples. When we formulate the general principle, we go from many observed examples to all possible examples. This is known as an *inductive leap.* Without it, we could not arrive at generalizations. However, we must be sensitive to exceptions and to the possibility that the conclusion is not valid. For example, the kiwi bird of New Zealand does *not* have functional wings (**FIG. 1-15**). We can never conclusively prove a universal generalization. The generalizations in inductive conclusions come from the creative insight of the human mind, and creativity, however admirable, is not infallible.

Scientists make careful observations and ask critical questions

In 1928, British bacteriologist Alexander Fleming observed that a blue mold had invaded one of his bacterial cultures. He almost discarded it, but then he noticed that the area contaminated by the mold was surrounded by a zone where bacterial colonies did not grow well. The bacteria were disease organisms of the genus *Staphylococcus,* which can cause boils and skin infections. Anything that could kill them was interesting! Fleming saved the mold, a variety of *Penicillium* (blue bread mold), and isolated the antibiotic penicillin from it. However, he had difficulty culturing it.

Even though Fleming recognized the potential practical benefit of penicillin, he did not develop the chemical techniques needed to purify it, and more than ten years passed before the drug was

www.konkur.in

C. Dani/Peter Arnold

FIGURE 1-15 Is this animal a bird?

The kiwi bird of New Zealand is about the size of a chicken. Its tiny 2-inch wings cannot be used for flight. The survivor of an ancient order of birds, the kiwi has bristly, hairlike feathers and other characteristics that qualify it as a bird.

put to significant use. In 1939, Sir Howard Florey and Ernst Boris Chain developed chemical procedures to extract and produce the active agent penicillin from the mold. Florey took the process to laboratories in the United States, and penicillin was first produced to treat wounded soldiers in World War II. In recognition of their work, Fleming, Florey, and Chain shared the 1945 Nobel Prize in Physiology or Medicine.

Chance often plays a role in scientific discovery

Fleming did not set out to discover penicillin. He benefited from the chance growth of a mold in one of his culture dishes. However, we may wonder how many times the same type of mold grew on the cultures of other bacteriologists who failed to make the connection and simply threw away their contaminated cultures. Fleming benefited from chance, but his mind was prepared to make observations and formulate critical questions, and his pen was prepared to publish them. Significant discoveries are usually made by those who are in the habit of looking critically at nature and recognizing a phenomenon or problem. Of course, the technology necessary for investigating the problem must also be available.

A hypothesis is a testable statement

Scientists make careful observations, ask critical questions, and develop hypotheses. A **hypothesis** is a tentative explanation for observations or phenomena. Hypotheses can be posed as "if . . . then . . ." statements. For example, *if* students taking introductory biology attend classes, *then* they will make a higher grade on the exam than students who do not attend classes.

In the early stages of an investigation, a scientist typically thinks of many possible hypotheses. A good hypothesis exhibits the following characteristics: (1) It is reasonably consistent with well-established facts. (2) It is capable of being tested; that is, it should generate definite predictions, whether the results are positive or negative. Test results should also be repeatable by independent observers. (3) It is falsifiable, which means it can be proven false, as we will discuss in the next section.

After generating hypotheses, the scientist decides which, if any, could and should be subjected to experimental test. Why not test them all? Time and money are important considerations in conducting research. Scientists must establish priority among the hypotheses to decide which to test first.

A falsifiable hypothesis can be tested

In science, a well-stated hypothesis can be tested. If no evidence is found to support it, the hypothesis is rejected. The hypothesis can be shown to be false. Even results that do not support the hypothesis may be valuable and may lead to new hypotheses. If the results do support a hypothesis, a scientist may use them to generate related hypotheses.

Let us consider a hypothesis that we can test by careful observation: female mammals (animals that have hair and produce milk for their young) bear live young. The hypothesis is based on the observations that dogs, cats, cows, lions, and humans all are mammals and all bear live young. Consider further that a new species, species X, is identified as a mammal based on its having hair and producing milk for its young. Biologists predict that females of species X will bear live young. (Is this inductive or deductive reasoning?) If a female of the new species gives birth to live offspring, the hypothesis is supported.

Before the Southern Hemisphere was explored, most people would probably have accepted the hypothesis without question because all known furry, milk-producing animals did, in fact, bear live young. But biologists discovered that two Australian animals (the duck-billed platypus and the spiny anteater) had fur and produced milk for their young—but laid eggs (**FIG. 1-16**). The hypothesis, as stated, was false no matter how many times it had previously been supported. As a result, biologists either had to consider the

Tom McHugh/Photo Researchers, Inc.

FIGURE 1-16 Is this animal a mammal?

The duck-billed platypus (*Ornithorhynchus anatinus*) is classified as a mammal because it has fur and produces milk for its young. However, unlike most mammals, it lays eggs.

www.konkur.in

platypus and the spiny anteater as nonmammals or had to broaden their definition of mammals to include them. (They chose to do the latter.)

A hypothesis is not true just because some of its predictions (the ones people happen to have thought of or have thus far been able to test) have been shown to be true. After all, they could be true by coincidence. In fact, a hypothesis can be supported by data, but it cannot really be *proven* true.

An **unfalsifiable hypothesis** cannot be proven false; in fact, it cannot be scientifically investigated. Belief in an unfalsifiable hypothesis, such as the existence of invisible and undetectable elves, must be rationalized on grounds other than scientific ones.

Models are important in developing and testing hypotheses

Hypotheses have many potential sources, including direct observations or even computer simulations. Increasingly in biology, hypotheses may be derived from **models** that scientists have developed to provide a comprehensive explanation for a large number of observations. Examples of such testable models include the model of the structure of DNA and the model of the structure of the plasma membrane (discussed in Chapter 5).

The best design for an experiment can sometimes be established by performing computer simulations. Virtual testing and evaluation are undertaken before the experiment is performed in the laboratory or field. Modeling and computer simulation save time and money.

Many predictions can be tested by experiment

A hypothesis is an abstract idea, but based on their hypotheses, scientists can make predictions that can be tested. For example, we might predict that biology students who study for ten hours will do better on an exam than students who do not study. As used here, a **prediction** is a deductive, logical consequence of a hypothesis. It does not have to be a future event.

Some predictions can be tested by controlled experiments. Early biologists observed that the nucleus was the most prominent part of the cell, and they hypothesized that cells would be adversely affected if they lost their nuclei. Biologists predicted that if the nucleus were removed from the cell, then the cell would die. They then experimented by surgically removing the nucleus of a unicellular amoeba. The amoeba continued to live and move, but it did not grow, and after a few days it died. These results suggested that the nucleus is necessary for the metabolic processes that provide for growth and cell reproduction.

But, the investigators asked, what if the operation itself, not the loss of the nucleus, caused the amoeba to die? They performed a controlled experiment, subjecting two groups of amoebas to the same operative trauma (**FIG. 1-17**). In the experimental group, the nucleus was removed; in the control group, it was not. Ideally, an **experimental group** differs from a control group only with respect to the variable being studied. In the **control group,** the researcher inserted a microloop into each amoeba and pushed it around inside the cell to simulate removal of the nucleus; then the instrument was withdrawn, leaving the nucleus inside.

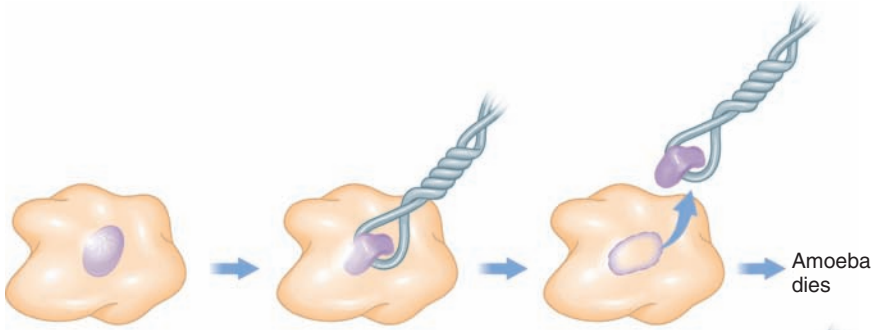
Amoebas treated with such a sham operation recovered and subsequently grew and divided. This experiment showed that the removal of the nucleus, not simply the operation, caused the death

KEY EXPERIMENT

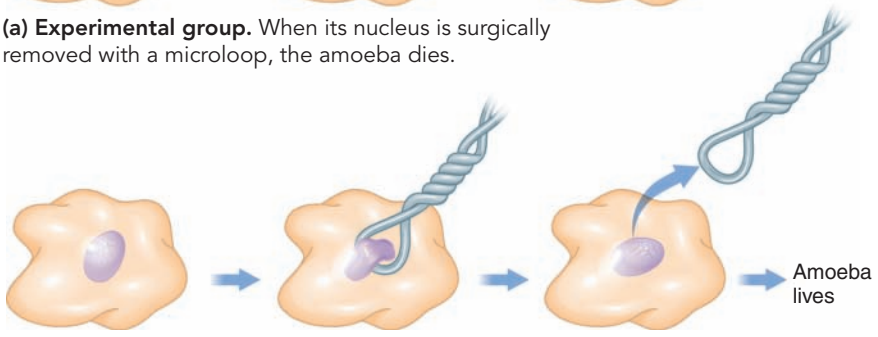
ASK CRITICAL QUESTIONS: Why is the nucleus so large? What is its importance?

DEVELOP HYPOTHESIS: Cells will be adversely affected if they lose their nuclei.

PERFORM EXPERIMENTS: Using a microloop, researchers removed the nucleus from each amoeba in the experimental group. Amoebas in the control group were subjected to the same surgical procedure, but their nuclei were not removed.



(a) Experimental group. When its nucleus is surgically removed with a microloop, the amoeba dies.



(b) Control group. A control amoeba subjected to similar surgical procedures (including insertion of a microloop), but without actual removal of the nucleus, does not die.

RESULTS: Amoebas without nuclei died. Amoebas in the control group lived.

CONCLUSION: Amoebas cannot live without their nuclei. The hypothesis is supported.

FIGURE 1-17 Testing a prediction regarding the importance of the nucleus

Scientists observed that the nucleus was the most prominent part of the cell. They asked critical questions about their observation and developed the hypothesis that cells would be adversely affected if they lost their nuclei. Based on their hypothesis, they made a prediction that could be tested: if the nucleus is removed from an amoeba, the amoeba will die. The investigators then performed experiments to test this prediction. They studied their results and concluded that their hypothesis was supported.

www.konkur.in

of the amoebas. The conclusion is that amoebas cannot live without their nuclei. The results support the hypothesis that if cells lose their nuclei, they are adversely affected. We can conclude that the nucleus is essential for the survival of the cell.

Researchers must avoid bias

In scientific studies, researchers must do their best to avoid bias or preconceived notions of what should happen. For example, to prevent bias, most medical experiments are carried out in a double-blind fashion. When a drug is tested, one group of patients receives the new medication, and a control group of matched patients receives a placebo (a harmless starch pill similar in size, shape, color, and taste to the pill being tested). This is a *double-blind study,* named so because neither the patient nor the physician knows who is getting the experimental drug and who is getting the placebo. The pills or treatments are coded in some way, and the code is broken only after the experiment is over and the results are recorded. Not all experiments can be so neatly designed; for example, it is often difficult to establish appropriate controls.

Scientists interpret the results of experiments and make conclusions

Scientists gather data in an experiment, interpret their results, and then draw conclusions from them. In the amoeba experiment described earlier, investigators concluded that the data supported the hypothesis that the nucleus is essential for the survival of the cell. When the results do support a hypothesis, scientists may use them to generate related hypotheses. Even results that do not support the hypothesis may be valuable and may lead to new hypotheses.

Let us discuss another experiment. Research teams studying chimpanzee populations in Africa have reported that chimpanzees appear to learn specific ways to use tools from one another. Behavior that is learned from others in a population and passed to future generations is what we call "culture." In the past, most biologists have thought that only humans had culture. It has been difficult to test this type of learning in the field, and the idea has been controversial.

Biologists have asked critical questions about whether chimpanzees learned how to use tools by observing one another. Investigators at Yerkes National Primate Research Center in Atlanta developed a hypothesis that chimpanzees can learn particular ways to use tools by observing other chimps. They predicted that if they taught one chimp to use a stick to obtain food from a dispenser, other chimps would learn the technique from the educated one (**FIG. 1-18**). These researchers divided chimpanzees into two experimental groups with 16 in each group. Then they taught a high-ranking female in each group to use a stick to obtain food from an apparatus. The two chimps were taught different methods. One chimp was taught to poke the stick inside the device to free the food. The other was taught to use the stick to lift a hook that removed a blockage, allowing the food to roll forward out of the device.

A third group served as a control group. The chimps in the control group were given access to the sticks and the apparatus with the food inside but none were taught how to use the sticks. All of the control-group chimps manipulated the apparatus with the stick, but none succeeded in releasing food.

When the chimps were returned to their groups, other chimps observed how the educated chimps used the stick, and a large majority began to use sticks in the same way. The chimps in each group learned the specific style of using the stick that their educated chimp had been taught. Most used the stick to obtain food at least 10 times. Two months later, the apparatus was reintroduced to the chimps. Again, most of the chimps used the learned technique for obtaining food. The results of the experiment supported the hypothesis. The researchers concluded that chimpanzees are capable of culturally transmitting learned technology.

Sampling error can lead to inaccurate conclusions

One reason for inaccurate conclusions is *sampling error.* Because not *all* cases of what is being studied can be observed or tested (scientists cannot study every amoeba or every chimpanzee population), scientists must be content with a sample. How can scientists know whether that sample is truly representative of whatever they are studying? If the sample is too small, it may not be representative because of random factors. A study with only two, or even nine, amoebas may not yield reliable data that can be generalized to other amoebas. If researchers test a large number of subjects, they are more likely to draw accurate scientific conclusions (**FIG. 1-19**). The scientist seeks to state with some level of confidence that any specific conclusion has a certain statistical probability of being correct.

Experiments must be repeatable

When researchers publish their findings in a scientific journal, they typically describe their methods and procedures in sufficient detail so that other scientists can repeat the experiments. When the findings are replicated, the conclusions are, of course, strengthened.

A theory is supported by tested hypotheses

Nonscientists often use the word *theory* incorrectly to refer to a hypothesis or even to some untestable idea they wish to promote. A **scientific theory** is actually an integrated explanation of some aspect of the natural world that is based on a number of hypotheses, each supported by consistent results from many observations or experiments. A scientific theory relates data that previously appeared unrelated. A good theory grows, building on additional facts as they become known. It predicts new facts and suggests new relationships among phenomena. It may even suggest practical applications.

A scientific theory, by showing the relationships among classes of facts, simplifies and clarifies our understanding of the natural world. As Einstein wrote, "In the whole history of science from Greek philosophy to modern physics, there have been constant attempts to reduce the apparent complexity of natural phenomena to simple, fundamental ideas and relations." Developing scientific theories is indeed a major goal of science.

Many hypotheses cannot be tested by direct experiment

Some well-accepted theories do not lend themselves to hypothesis testing by ordinary experiments. Often, these theories describe events that occurred in the distant past. We cannot directly observe

www.konkur.in

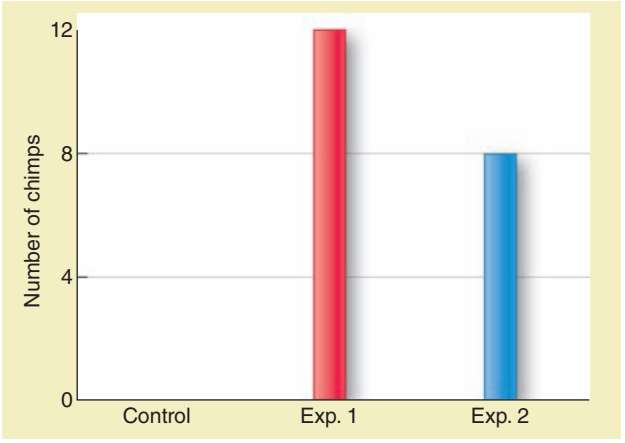
KEY EXPERIMENT

ASK CRITICAL QUESTIONS: Do chimpanzees learn how to use tools by observing one another?

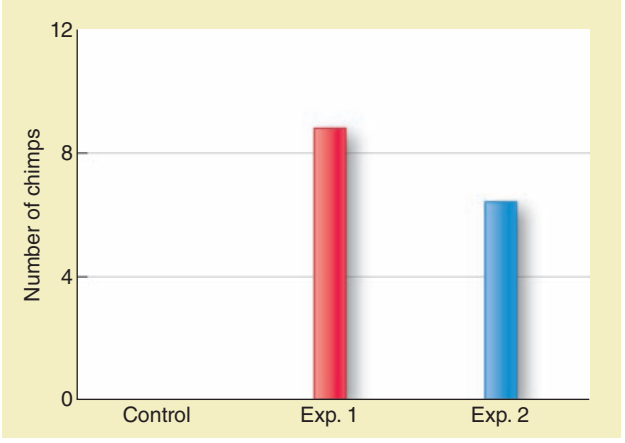
DEVELOP HYPOTHESIS: Chimpanzees can learn particular ways to use tools by observing other chimps.

PERFORM EXPERIMENTS: One female in each of two groups of 16 chimps was educated in a specific way to use a stick to obtain food. The two educated chimps were then returned to their respective groups. Chimpanzees in a control group were not taught how to use a stick.

David Bygott



(a) Number of chimpanzees successfully employing specific method of tool use.



(b) Number of chimpanzees successfully employing learned method of tool use two months later.

RESULTS: Chimpanzees in each experimental group observed the use of the stick by the educated chimp, and a majority began to use the stick in the same way. When tested two months later, many of the chimps in each group continued to use the stick. *The results presented here have been simplified and are based on the number of chimps observed to use the learned method at least 10 times.* All but one chimp in each group learned the technology, but a few used it only a few times. Some chimps taught themselves the alternative method and used that alternative. However, most conformed to the group's use of the method that the investigator taught to the educated chimp.

CONCLUSION: Chimpanzees learn specific ways to use tools by observing other chimps. The hypothesis was supported.

FIGURE 1-18 Testing a prediction about learning in chimpanzee populations

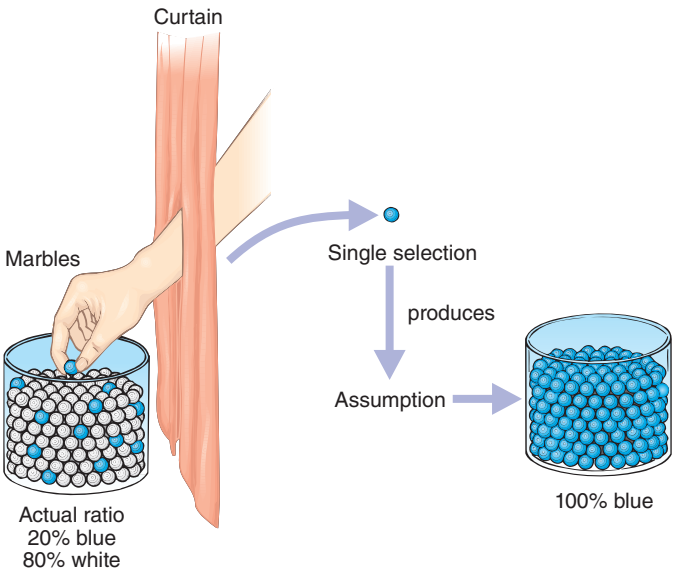
In the photo, wild chimpanzees are shown observing a member of their group using a tool.

the origin of the universe from a very hot, dense state about 13.7 billion years ago (the Big Bang theory). However, physicists and cosmologists have been able to formulate many hypotheses related to the Big Bang and to test many of the predictions derived from these hypotheses.

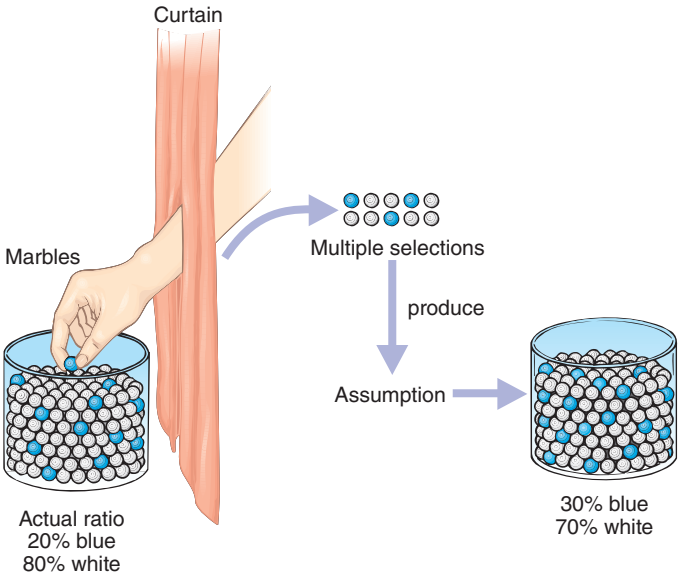
Similarly, humans did not observe the evolution of major groups of organisms because that process took place over millions of years and occurred before humans had evolved. However, many hypotheses about evolution have been posed, and predictions based on them have been tested. For example, if complex organisms evolved from simple life-forms, we would find the fossils of the simplest organisms in the oldest strata (rock layers). As we explore more recent strata, we would expect to find increasingly complex organisms. Indeed, scientists have found this progression of simple to complex fossils.

In addition to fossils, evidence for evolution comes from many sources, including physical and molecular similarities between organisms. Evidence also comes from recent and current studies

www.konkur.in



(a) Taking a single selection can result in sampling error. If the only marble selected is blue, we might assume all the marbles are blue.



(b) The greater the number of selections we take of an unknown, the more likely we can make valid assumptions about it.

FIGURE 1-19 ***Animated*** **Statistical probability**

of evolution in action. Many aspects of ongoing evolution can, in fact, be studied in the laboratory or in the field. The evidence for evolution is so compelling that virtually all scientists today accept evolutionary theory as an integral part of biology.

Paradigm shifts allow new discoveries

A **paradigm** is a set of assumptions or concepts that constitute a way of thinking about reality. For example, from the time of Aristotle to the mid-19th century, biologists thought that organisms were either plants (kingdom Plantae) or animals (kingdom Animalia). This concept was deeply entrenched. However, with the development of microscopes, investigators discovered tiny life-forms—bacteria and protists—that were neither plant nor animal. Biologists had to make a **paradigm shift,** that is, they changed their view of reality, to accommodate this new knowledge. They assigned these newly discovered organisms to new kingdoms. In a more recent paradigm shift, biologists have revised their idea that we are born with all of the brain cells we will ever have. We now understand that certain areas of the brain continue to produce new neurons throughout life.

Systems biology integrates different levels of information

In the *reductionist* approach to biology, researchers study the simplest components of biological processes. Their goal is to synthesize their knowledge of many small parts to understand the whole. Reductionism has been (and continues to be) important in biological research. However, as biologists and their tools have become increasingly sophisticated, huge amounts of data have been generated, bringing the science of biology to a different level.

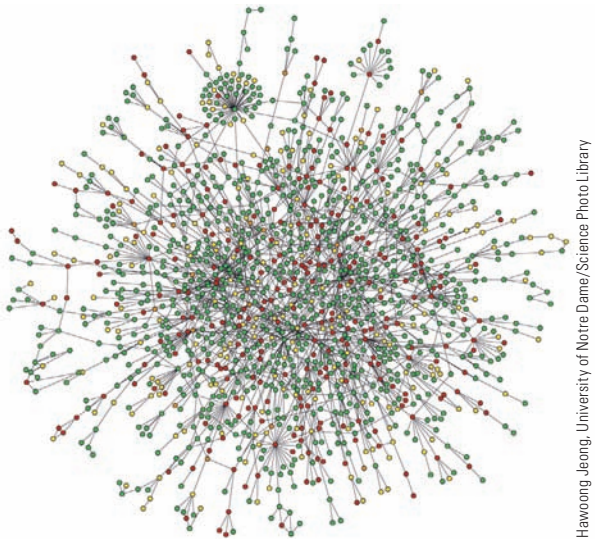
Systems biology is a field of biology that builds on information provided by the reductionist approach and develops large data sets, typically generated by computers. Systems biology is also referred to as *integrative biology.* Reductionism and systems biology are complementary approaches. Using reductionism, biologists have discovered basic information about components, such as molecules, genes, cells, and organs. Systems biologists, who focus on systems as a whole rather than on individual components, need this basic knowledge to study, for example, the *interactions* among various parts and levels of an organism.

Systems biologists integrate data from various levels of complexity with the goal of understanding the big picture—how biological systems function. For example, systems biologists are developing models of different aspects of cell function. Normal cell function depends on the precise actions of hundreds of proteins that relay signals received from other cells. Proteins also relay signals from one part of the cell to another. Researchers are producing detailed maps of the molecular pathways that maintain cell function (**FIG. 1-20**).

One group of researchers has developed a model consisting of nearly 8000 chemical signals involved in a molecular network that leads to programmed cell death. By understanding cell communication, the interactions of genes and proteins in metabolic pathways, and physiological processes, systems biologists hope to eventually develop a model of the whole organism. Systems biology is increasingly used to study disease processes. For example, the interactions between the pathogen and the host cell can be mapped.

The development of systems biology was fueled by the huge amount of data generated by the Human Genome Project. Researchers working on this project identified the DNA sequences that make up the estimated 25,000 genes of the *human genome,* the complete set of genes that make up the human genetic material. Computer software developed for the Human Genome Project can analyze very large data sets. These programs are being used to integrate data about protein interactions and many other aspects of molecular biology. Systems biologists view biology in terms of information systems. Increasingly, they depend on mathematics, statistics, and engineering principles.

www.konkur.in



Hawoong Jeong, University of Notre Dame/Science Photo Library

FIGURE 1-20 Map showing protein interactions in a yeast cell (*Saccharomyces cerevisiae*)

Each dot represents one protein in this single-celled fungus. Lines connect proteins that interact with one another. Highly connected proteins are more critical to cell function. Many of these interactions have also been identified in human cells. Specific proteins were removed by removing the genes that coded for their production. The proteins have been color-coded according to the effect their removal has on the yeast cell: *red*, lethal; *green*, not lethal; *orange*, slower growth; *yellow*, unknown effects.

Science has ethical dimensions

Scientific investigation depends on a commitment to practical ideals, such as truthfulness and the obligation to communicate results. Honesty is particularly important in science. Consider the great (though temporary) damage done whenever an unprincipled or even desperate researcher, whose career may depend on the publication of a research study, knowingly disseminates false data. Until the deception is uncovered, researchers may devote thousands of dollars and hours of precious professional labor to futile lines of research inspired by erroneous reports. Deception can also be dangerous, especially in medical research. Fortunately, science tends to correct itself through consistent use of the scientific process. Sooner or later, someone's experimental results are sure to cast doubt on false data.

Science and technology continuously interact. As scientists doing basic research report new findings, engineers and other inventors develop new products. Many of those products contribute to our quality of life. New technology also provides scientists with more powerful tools for their research and increases the potential for new discoveries. For example, a few years ago determining the genome of any eukaryote required several rooms filled with machines that could sequence the genes. This endeavor also cost millions of dollars. New technologies have revolutionized gene sequencing, allowing complex genomes to be determined quickly, with less equipment, and at far less expense. Plans are under way to determine the genomes of 10,000 vertebrates.

Science and technology continue to change society, and these changes present new challenges. In addition to being ethical about their own work, scientists face many societal and political issues surrounding areas such as genetic research, stem cell research, cloning, and human and animal experimentation. For example, some stem cells that show great potential for treating human disease come from early embryos. The cells can be taken from five- or six-day-old human embryos and then cultured in laboratory glassware. At this stage, the embryo is a group of cells about 0.15 mm long (0.006 in). Such cells could be engineered to treat failing hearts or brains harmed by stroke, injury, Parkinson's disease, or Alzheimer's disease. They could save the lives of burn victims and perhaps be engineered to treat specific cancers. Scientists, and the larger society, will need to determine whether the potential benefits of any type of research outweigh its ethical risks.

The era of the genome brings with it many ethical concerns and responsibilities. How do people safeguard the privacy of genetic information? For example, suppose that you have a family history of breast cancer and learn from genetic testing that you have one of the BRCA mutations. These mutations increase risk for developing breast cancer and certain other cancers. How can you be certain that knowledge of your individual genetic code would not be used against you when you seek employment or health insurance? Scientists must be ethically responsible and must help educate people about their work, including its benefits relative to its risks. It is significant that at the very beginning of the Human Genome Project, part of its budget was allocated for research on the ethical, legal, and social implications of its findings.

Review

- What are the characteristics of a good hypothesis?
- What is meant by a "controlled" experiment?
- What is systems biology?

SUMMARY: FOCUS ON LEARNING OBJECTIVES

1.1 *(page 2)*

1 Describe three basic themes of biology.

- Three basic themes of biology are evolution, transfer of information, and energy transfer. The process of **evolution** results in populations changing over time and explains how the ancestry of organisms can be traced back to earlier forms of life. Information must be transmitted within cells, among cells, among organisms, and from one generation to the next. Life requires continuous input of energy from the sun.

1.2 *(page 2)*

2 Distinguish between living and nonliving things by describing the features that characterize living organisms.

- Every living organism is composed of one or more **cells.** Living things grow by increasing the size and/or number of their cells.
- **Metabolism** includes all the chemical activities that take place in the organism, including the chemical reactions essential to nutrition, growth and repair, and conversion of energy to usable forms. **Homeostasis** refers to the appropriate, balanced internal environment.

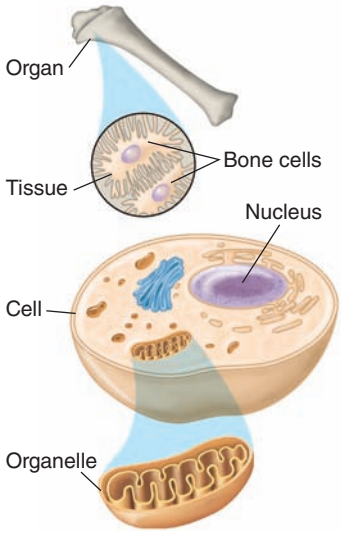
www.konkur.in

- Organisms respond to **stimuli,** physical or chemical changes in their external or internal environment. Responses typically involve movement.
- In **asexual reproduction,** offspring are typically identical to the single parent, except for size; in **sexual reproduction,** offspring are the product of the fusion of gametes, and genes are typically contributed by two parents.
- As populations evolve, they become adapted to their environment. **Adaptations** are traits that increase an organism's ability to survive in its environment.

1.3 *(page 5)*

3 Construct a hierarchy of biological organization, including levels characteristic of individual organisms and levels characteristic of ecological systems.

- Biological organization is hierarchical. A complex organism is organized at the chemical, cell, **tissue, organ, organ system,** and **organism** levels. Cells associate to form tissues that carry out specific functions. In most multicellular organisms, tissues organize to form functional structures called organs. An organized group of tissues and organs form an organ system. Functioning together, organ systems make up a complex, multicellular organism.



- The basic unit of ecological organization is the **population.** Various populations form **communities;** a community and its physical environment are an **ecosystem;** all of Earth's ecosystems together make up the **biosphere.**

CENGAGENOW™ Learn more about biological organization by clicking on the figure in CengageNOW.

1.4 *(page 7)*

4 Summarize the importance of information transfer within and between living systems, giving specific examples.

- Organisms transmit information chemically, electrically, and behaviorally.
- **DNA,** which makes up the **genes,** is the hereditary material. Information encoded in DNA is transmitted from one generation to the next. DNA contains the instructions for the development of an organism and for carrying out life processes. DNA codes for **proteins,** which are important in determining the structure and function of cells and tissues.
- **Hormones,** chemical messengers that transmit messages from one part of an organism to another, are important in **cell signaling.**
- Many organisms use electrical signals to transmit information; most animals have nervous systems that transmit electrical impulses and release **neurotransmitters.**

1.5 *(page 8)*

5 Summarize the flow of energy through ecosystems and contrast the roles of producers, consumers, and decomposers.

- Activities of living cells require energy. Life depends on continuous energy input from the sun. During **photosynthesis,** plants, algae, and certain bacteria use the energy of sunlight to synthesize complex molecules from carbon dioxide and water.
- Virtually all cells carry on **cellular respiration,** a biochemical process in which they capture the energy stored in nutrients by producers. Some of that energy is then used to synthesize required materials or to carry out other cell activities.
- A self-sufficient ecosystem includes **producers,** or **autotrophs,** which make their own food; **primary consumers,** which eat producers, and typically secondary consumers that eat primary consumers; and **decomposers,** which obtain energy by breaking down wastes and dead organisms. Consumers and decomposers are **heterotrophs,** organisms that depend on producers as an energy source and for food and oxygen.

CENGAGENOW™ Learn more about energy flow by clicking on the figure in CengageNOW.

1.6 *(page 10)*

6 Demonstrate the binomial system of nomenclature by using specific examples and classify an organism (such as a human) in its domain, kingdom, phylum, class, order, family, genus, and species.

- Millions of species have evolved. A **species** is a group of organisms with similar structure, function, and behavior that, in nature, breed only with one another. Members of a species contribute to a common **gene pool** and share a common ancestry.
- Biologists use a **binomial system of nomenclature** in which the name of each species includes a **genus** name and a **specific epithet.** Taxonomic classification is hierarchical; it includes species, genus, **family, order, class, phylum, kingdom,** and **domain.** Each grouping is referred to as a **taxon.** A group of organisms with a common ancestor is a **clade.**

7 Identify the three domains and the kingdoms of living organisms, and give examples of organisms assigned to each group.

- Bacteria and archaea have **prokaryotic cells;** all other organisms have **eukaryotic cells.** Prokaryotes make up two of the three domains.
- Organisms are classified in three domains: **Archaea, Bacteria,** and **Eukarya** and several kingdoms: **Archaea, Bacteria, Fungi** (e.g., molds and yeasts), **Plantae,** and **Animalia. Protists** (e.g., algae, water molds, slime molds, and amoebas) are now assigned to five "supergroups."

CENGAGENOW™ Learn more about life's diversity by clicking on the figure in CengageNOW.

8 Give a brief overview of the scientific theory of evolution and explain why it is the principal unifying concept in biology.

- **Evolution** is the process by which populations change over time in response to changes in the environment. Evolutionary theory explains how millions of species came to be and helps us understand the structure, function, behavior, and relationships of organisms.
- **Natural selection,** the major mechanism by which evolution proceeds, favors individuals with traits that enable them to cope with environmental changes. Charles Darwin based his theory of natural selection on his observations that individuals of a species vary; organisms produce more offspring than survive to reproduce; organisms must compete for limited resources; and individuals that are best adapted to their environment are more likely to survive and reproduce, and pass on their hereditary information. Their traits become more widely distributed in the population.
- The source of variation in a population is random **mutation.**

www.konkur.in

9 Apply the theory of natural selection to any given adaptation and suggest a logical explanation of how the adaptation may have evolved.

- When the ancestors of Hawaiian honeycreepers first reached Hawaii, few other birds were present, so there was little competition for food. Through many generations, honeycreepers with longer, more curved bills became adapted for feeding on nectar from tubular flowers. Perhaps those with the longest, most curved bills were best able to survive in this food zone and lived to transmit their genes to their offspring. Those with shorter, thicker bills were more successful foraging for insects and passed their genes to new generations of offspring. Eventually, different species evolved that were adapted to specific food zones.

1.7 *(page 15)*

10 Design a study to test a given hypothesis, using the procedure and terminology of the scientific method.

- The **process of science** is a dynamic approach to investigation. The **scientific method** is a general framework that scientists use in their work; it includes observing, recognizing a problem or stating a critical question, developing a hypothesis, making a prediction that can be tested, making further observations, performing experiments, interpreting results, and drawing conclusions that support or falsify the hypothesis.
- Deductive reasoning and inductive reasoning are two categories of systematic thought used in the scientific method. **Deductive reasoning** proceeds from general principles to specific conclusions and helps us discover relationships among known facts. **Inductive reasoning** begins with specific observations and draws conclusions from them. Inductive reasoning helps us discover general principles.
- A **hypothesis** is a tentative explanation for observations or phenomena. A hypothesis can be tested. If no evidence is found to support it, the hypothesis is rejected.
- A well-designed scientific experiment typically includes both a **control group** and an **experimental group** and must be as free as possible from bias. The control group should be as closely matched to the experimental group as possible. Ideally, the experimental group differs from the control group only with respect to the variable being studied.

CENGAGENOW™ Do your own random sampling by clicking on the figure in CengageNOW.

- A **scientific theory** is an integrated explanation of some aspect of the natural world that is based on a number of hypotheses, each supported by consistent results from many observations or experiments.

11 Compare the reductionist and systems approaches to biological research.

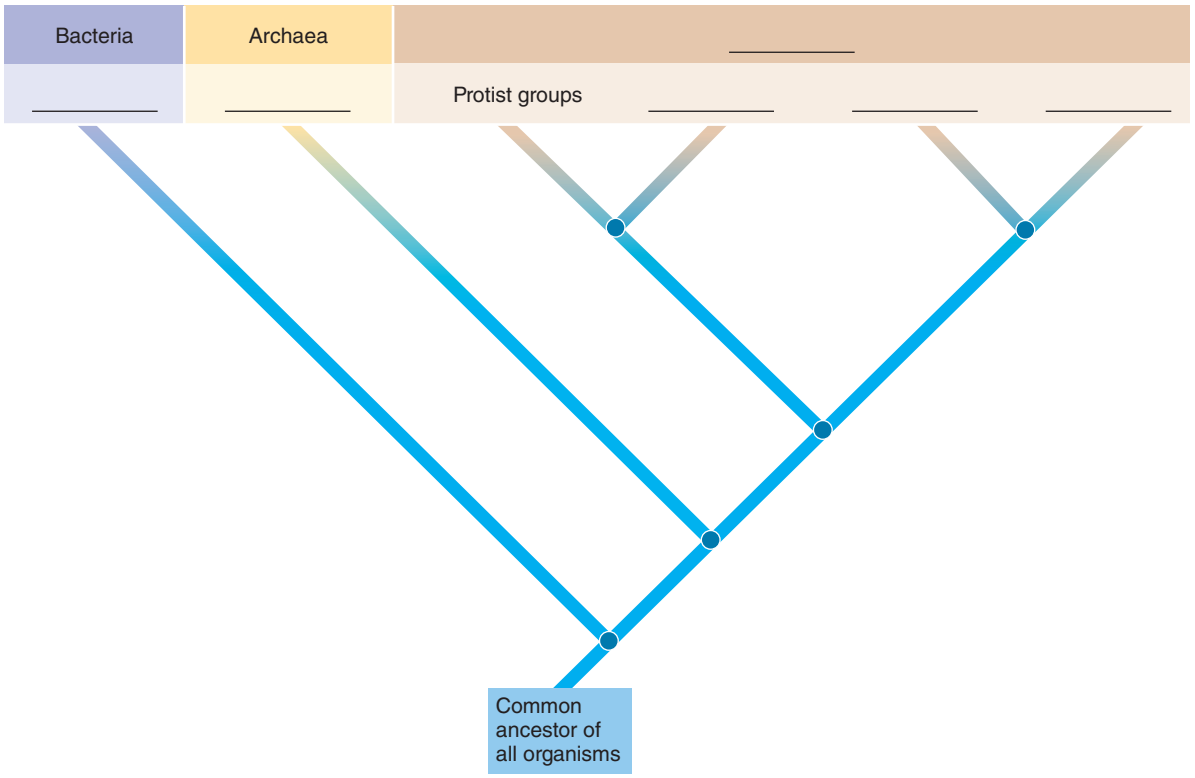
- Using reductionism, researchers study the simplest components of biological processes, for example, molecules or cells. **Systems biology** uses knowledge provided by reductionism. Systems biologists integrate data from various levels of complexity with the goal of understanding how biological systems function.

TEST YOUR UNDERSTANDING

1. Homeostasis (a) is the appropriate, balanced internal environment (b) is the sum of all the chemical activities of an organism (c) is the long-term response of organisms to changes in their environment (d) occurs at the ecosystem level, not in cells or organisms (e) may be sexual or asexual
2. An amoeba splits into two smaller amoebas. This is an example of (a) homeostasis (b) neurotransmission (c) asexual reproduction (d) sexual reproduction (e) metabolism
3. Cells (a) are the building blocks of living organisms (b) always have nuclei (c) are not found among the bacteria (d) a, b, and c (e) a and b
4. Which of the following is a correct sequence of levels of biological organization?
   1. organ system 2. chemical 3. tissue 4. organ 5. cell
   (a) 2, 3, 5, 4, 1 (b) 5, 3, 4, 1, 2 (c) 2, 5, 3, 1, 4 (d) 2, 5, 3, 4, 1 (e) 5, 2, 3, 4, 1
5. Which of the following is a correct sequence of levels of ecological organization?
   1. community 2. organism 3. ecosystem 4. population 5. biosphere
   (a) 5, 3, 1, 4, 2 (b) 2, 4, 1, 3, 5 (c) 2, 1, 4, 3, 5 (d) 4, 2, 1, 3, 5 (e) 2, 4, 3, 1, 5
6. DNA (a) is produced during cellular respiration (b) functions mainly to transmit information from one species to another (c) cannot be changed (d) is a neurotransmitter (e) makes up the genes
7. Cellular respiration (a) is a process whereby sunlight is used to synthesize cell components with the release of energy (b) occurs in heterotrophs only (c) is carried on by both autotrophs and heterotrophs (d) causes chemical changes in DNA (e) occurs in response to environmental changes
8. Fungi are assigned to domain (a) Protista (b) Archaea (c) Bacteria (d) Eukarya (e) Plantae
9. The scientific name for corn is *Zea mays*. *Zea* is the (a) specific epithet (b) genus (c) class (d) kingdom (e) phylum
10. Darwin suggested that evolution takes place by (a) mutation (b) changes in the individuals of a species (c) natural selection (d) interaction of hormones during competition for resources (e) homeostatic responses to each change in the environment
11. Ideally, an experimental group differs from a control group (a) only with respect to the hypothesis being tested (b) because its subjects are more reliable (c) in that it is less subject to bias (d) in that it is less vulnerable to sampling error (e) only with respect to the variable being studied
12. A systems biologist would most likely work on (a) better understanding the components of cells (b) developing a better system of classification of organisms (c) devising a new series of steps for the scientific method (d) researching a series of reactions that communicate information in the cell (e) identifying the connections and interactions of neurons in order to learn about brain function

www.konkur.in

13. Identify the domain and kingdoms by writing the name for each on the blank lines.



CRITICAL THINKING

1. What would happen if a homeostatic mechanism failed? Describe a homeostatic mechanism at work in your body (other than the regulation of glucose cited in the chapter).
2. Contrast the reductionist approach with systems biology. How are the two approaches complementary? Which approach is more likely to consider emergent properties?
3. What are some characteristics of a good hypothesis? Give an example.
4. Make a prediction and devise a suitably controlled experiment to test each of the following hypotheses: (a) A type of mold found in your garden produces an effective antibiotic. (b) The growth rate of a bean seedling is affected by temperature. (c) Estrogen alleviates symptoms of Alzheimer's disease in elderly women.
5. **EVOLUTION LINK.** In what ways does evolution depend on transfer of information? In what ways does transfer of information depend on evolution?
6. **EVOLUTION LINK.** How might an understanding of evolutionary processes help a biologist doing research in (a) animal behavior, for example, the hunting behavior of lions? (b) the development of a new antibiotic to replace one to which bacteria have become resistant? (c) conservation of a specific plant in a rain forest?
7. **ANALYZING DATA.** Compare the two graphs in Figure 1-18. What information does the second graph illustrate? What possible explanation can you give for the differences shown in the two graphs?
8. **SCIENCE, TECHNOLOGY, AND SOCIETY.** New technology is allowing scientists to develop effective gene therapies to treat serious diseases. In the future gene therapy may be used to treat such conditions as addiction or bipolar disorder. What if gene therapy could be used to produce children with athletic ability, artistic ability, or high IQ? Do you have any ethical concerns about these possibilities? If so, where and how would you draw the line?

2 Atoms and Molecules: The Chemical Basis of Life

Frans Lanting/Minden Pictures

Water is a basic requirement for all life. A jaguar (*Panthera onca*), the largest cat in the Western Hemisphere, pauses to drink water from a rainforest stream.

KEY CONCEPTS

2.1 Carbon, hydrogen, oxygen, and nitrogen are the most abundant elements in living things.

2.2 The chemical properties of an atom are determined by its highest-energy electrons, known as valence electrons.

2.3 A molecule consists of atoms joined by covalent bonds. Other important chemical bonds include ionic bonds. Hydrogen bonds and van der Waals interactions are weak attractions.

2.4 The energy of an electron is transferred in a redox reaction.

2.5 Water molecules are polar, having regions of partial positive and partial negative charge that permit them to form hydrogen bonds with one another and with other charged substances.

2.6 Acids are hydrogen ion donors; bases are hydrogen ion acceptors. The pH scale is a convenient measure of the hydrogen ion concentration of a solution.

A knowledge of chemistry is essential for understanding organisms and how they function. This jaguar and the plants of the tropical rain forest, as well as abundant unseen insects and microorganisms, share fundamental similarities in their chemical composition and basic metabolic processes. These chemical similarities provide strong evidence for the evolution of all organisms from a common ancestor and explain why much of what biologists learn from studying bacteria or rats in laboratories can be applied to other organisms, including humans. Furthermore, the basic chemical and physical principles governing organisms are not unique to living things, for they apply to nonliving systems as well.

The success of the Human Genome Project and related studies has relied heavily on biochemistry and **molecular biology,** the chemistry and physics of the molecules that constitute living things. A biochemist may investigate the precise interactions among a cell's atoms and molecules that maintain the energy flow essential to life, and a molecular biologist may study how proteins interact with deoxyribonucleic acid (DNA) in ways that control the expression of certain genes. However, an understanding of chemistry is essential to *all* biologists. An evolutionary biologist may

www.konkur.in

study evolutionary relationships by comparing the DNA of different types of organisms. An ecologist may study how energy is transferred among the organisms living in an estuary or monitor the biological effects of changes in the salinity of the water. A botanist may study unique compounds produced by plants and may even be a "chemical prospector," seeking new sources of medicinal agents.

In this chapter we lay a foundation for understanding how the structure of atoms determines the way they form chemical bonds to produce complex compounds. Most of our discussion focuses on small, simple substances known as **inorganic compounds.** Among the biologically important groups of inorganic compounds are water, many simple acids and bases, and simple salts. We pay particular attention to water, the most abundant substance in organisms and on Earth's surface, and we examine how its unique properties affect living things as well as their nonliving environment. In Chapter 3 we extend our discussion to **organic compounds,** carbon-containing compounds that are generally large and complex. In all but the simplest organic compounds, two or more carbon atoms are bonded to each other to form the backbone, or skeleton, of the molecule.

2.1 ELEMENTS AND ATOMS

LEARNING OBJECTIVES

1. Name the principal chemical elements in living things and provide an important function of each.
2. Compare the physical properties (mass and charge) and locations of electrons, protons, and neutrons. Distinguish between the atomic number and the mass number of an atom.
3. Define the terms *orbital* and *electron shell.* Relate electron shells to principal energy levels.

Elements are substances that cannot be broken down into simpler substances by ordinary chemical reactions. Each element has a **chemical symbol:** usually the first letter or first and second letters of the English or Latin name of the element. For example, O is the symbol for oxygen, C for carbon, H for hydrogen, N for nitrogen, and Na for sodium (from the Latin word *natrium*). Just four elements—oxygen, carbon, hydrogen, and nitrogen—are responsible for more than 96% of the mass of most organisms. Others, such as calcium, phosphorus, potassium, and magnesium, are also consistently present but in smaller quantities. Some elements, such as iodine and copper, are known as *trace elements* because they are required only in minute amounts. **TABLE 2-1** lists the elements that make up organisms and briefly explains the importance of each in typical plants and animals.

An **atom** is defined as the smallest portion of an element that retains its chemical properties. Atoms are much too small to be visible under a light microscope. However, by sophisticated techniques (such as scanning tunneling microscopy, with magnifications as great as 5 million times) researchers have been able to photograph the positions of some large atoms in molecules.

The components of atoms are tiny particles of **matter** (anything that has mass and takes up space) known as subatomic particles. Physicists have discovered a number of subatomic particles, but for our purposes we need consider only three: electrons, protons, and neutrons. An **electron** is a particle that carries a unit of negative electric charge; a **proton** carries a unit of positive charge; and a **neutron** is an uncharged particle. In an electrically neutral atom, the number of electrons is equal to the number of protons.

Clustered together, protons and neutrons compose the **atomic nucleus.** Electrons, however, have no fixed locations and move rapidly through the mostly empty space surrounding the atomic nucleus.

An atom is uniquely identified by its number of protons

Every element has a fixed number of protons in the atomic nucleus, known as the **atomic number.** It is written as a subscript to the left of the chemical symbol. Thus, $_1$H indicates that the hydrogen

TABLE 2-1 Functions of Elements in Organisms

Element* (chemical symbol)	Functions
O Oxygen	Required for cellular respiration; present in most organic compounds; component of water
C Carbon	Forms backbone of organic molecules; each carbon atom can form four bonds with other atoms
H Hydrogen	Present in most organic compounds; component of water; hydrogen ion (H^+) is involved in some energy transfers
N Nitrogen	Component of proteins and nucleic acids; component of chlorophyll in plants
Ca Calcium	Structural component of bones and teeth; calcium ion (Ca^{2+}) is important in muscle contraction, conduction of nerve impulses, and blood clotting; associated with plant cell wall
P Phosphorus	Component of nucleic acids and of phospholipids in membranes; important in energy transfer reactions; structural component of bone
K Potassium	Potassium ion (K^+) is a principal positive ion (cation) in interstitial (tissue) fluid of animals; important in nerve function; affects muscle contraction; controls opening of stomata in plants
S Sulfur	Component of most proteins
Na Sodium	Sodium ion (Na^+) is a principal positive ion (cation) in interstitial (tissue) fluid of animals; important in fluid balance; essential for conduction of nerve impulses; important in photosynthesis in plants
Mg Magnesium	Needed in blood and other tissues of animals; activates many enzymes; component of chlorophyll in plants
Cl Chlorine	Chloride ion (Cl^-) is principal negative ion (anion) in interstitial (tissue) fluid of animals; important in water balance; essential for photosynthesis
Fe Iron	Component of hemoglobin in animals; activates certain enzymes

*Other elements found in very small (trace) amounts in animals, plants, or both include iodine (I), manganese (Mn), copper (Cu), zinc (Zn), cobalt (Co), fluorine (F), molybdenum (Mo), selenium (Se), boron (B), silicon (Si), and a few others.

www.konkur.in

nucleus contains 1 proton, and $_8$O means that the oxygen nucleus contains 8 protons. The atomic number determines an atom's identity and defines the element.

The **periodic table** is a chart of the elements arranged in order by atomic number (**FIG. 2-1** and Appendix A). The periodic table is useful because it lets us simultaneously correlate many of the relationships among the various elements.

Figure 2-1 includes representations of the **electron configurations** of several elements important in organisms. These *Bohr models,* which show the electrons arranged in a series of concentric circles around the nucleus, are convenient to use, but inaccurate. The space outside the nucleus is actually extremely large compared to the nucleus, and as you will see, electrons do not actually circle the nucleus in fixed concentric pathways.

Protons plus neutrons determine atomic mass

The mass of a subatomic particle is exceedingly small, much too small to be conveniently expressed in grams or even micrograms.[1] Such masses are expressed in terms of the **atomic mass unit (amu),** also called the **dalton** in honor of John Dalton, the English

[1]Tables of commonly used units of scientific measurement are printed inside the back cover of this text.

KEY POINT The periodic table provides information about the elements: their compositions, structures, and chemical behavior.

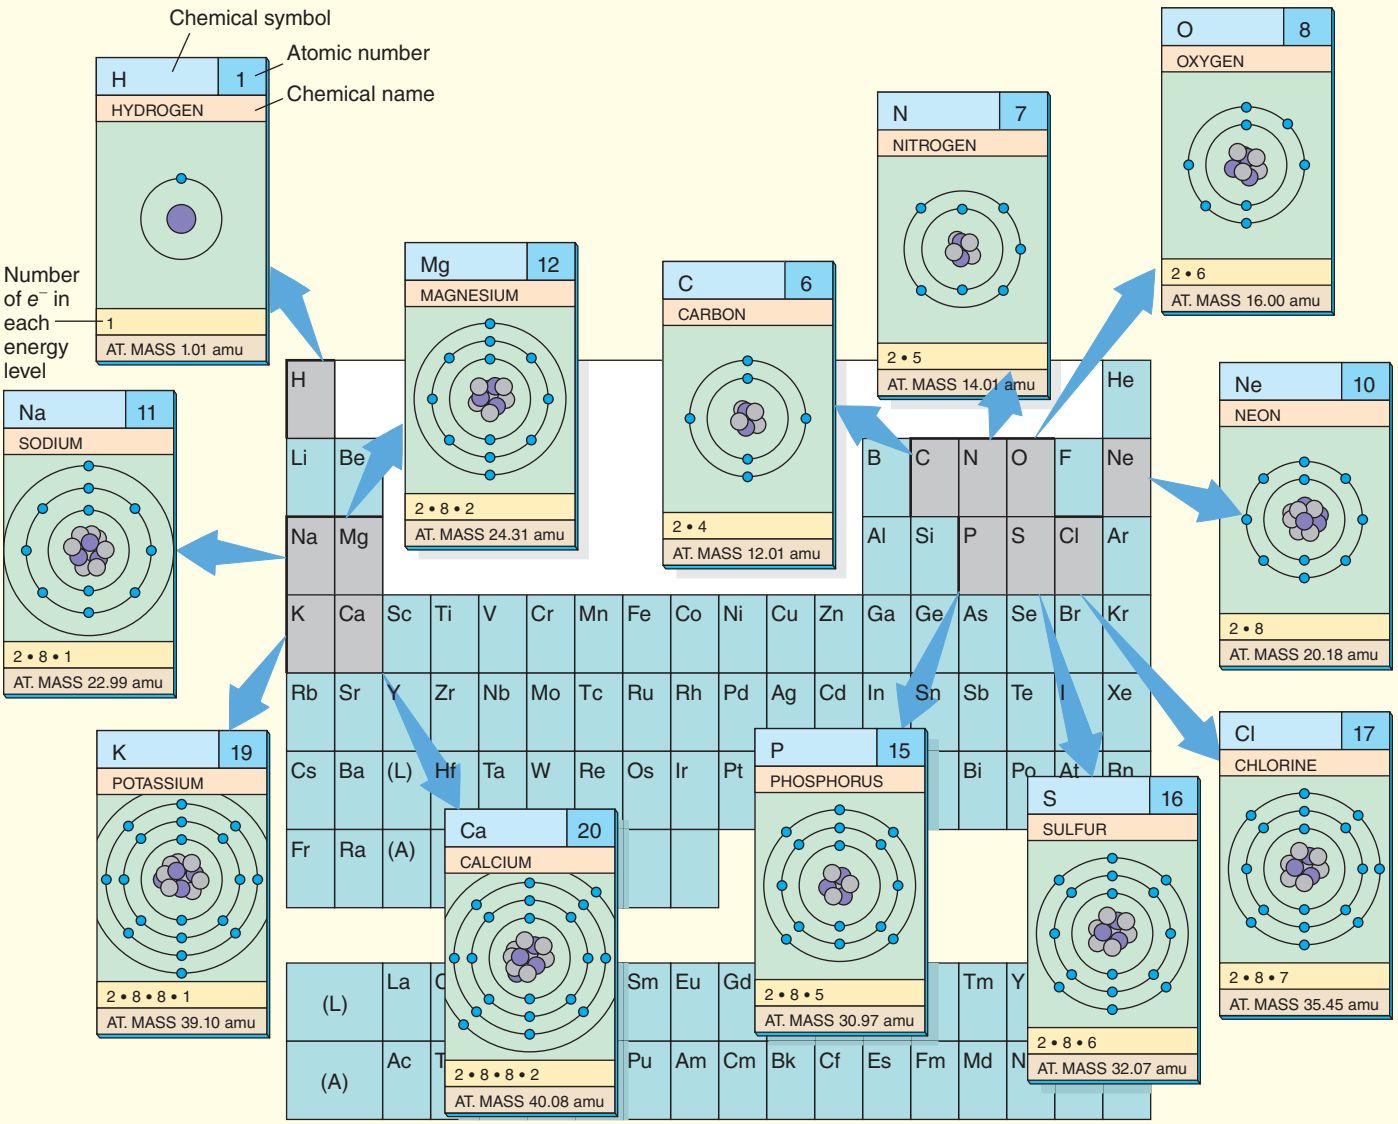

FIGURE 2-1 The periodic table

Note the Bohr models depicting the electron configuration of atoms of some biologically important elements, plus neon, which is unreactive, because its valence shell is full (to be discussed later in the chapter). Although the Bohr model does not depict electron configurations accurately, it is commonly used because of its simplicity and convenience. A complete periodic table is given in Appendix A.

www.konkur.in

chemist who formulated an atomic theory in the early 1800s. One amu is equal to the approximate mass of a single proton or a single neutron. Protons and neutrons make up almost all the mass of an atom. The mass of a single electron is only about 1/1800 the mass of a proton or neutron.

The **atomic mass** of an atom is a number that indicates approximately how much matter it contains compared with another atom. This value is determined by adding the number of protons to the number of neutrons and expressing the result in atomic mass units or daltons.[2] The mass of the electrons is ignored because it is so small. The atomic mass number is indicated by a superscript to the left of the chemical symbol. The common form of the oxygen atom, with 8 protons and 8 neutrons in its nucleus, has an atomic number of 8 and a mass of 16 amu. It is indicated by the symbol $^{16}_{8}O$.

The characteristics of protons, electrons, and neutrons are summarized in the following table:

Particle	Charge	Approximate Mass	Location
Proton	Positive	1 amu	Nucleus
Neutron	Neutral	1 amu	Nucleus
Electron	Negative	Approx. 1/1800 amu	Outside nucleus

Isotopes of an element differ in number of neutrons

Most elements consist of a mixture of atoms with different numbers of neutrons and thus different masses. Such atoms are called **isotopes.** Isotopes of the same element have the same number of protons and electrons; only the number of neutrons varies. The three isotopes of hydrogen, $^{1}_{1}H$ (ordinary hydrogen), $^{2}_{1}H$ (deuterium), and $^{3}_{1}H$ (tritium), contain 0, 1, and 2 neutrons, respectively. **FIGURE 2-2** shows Bohr models of two isotopes of carbon, $^{12}_{6}C$ and $^{14}_{6}C$. The mass of an element is expressed as an average of the masses of its isotopes (weighted by their relative abundance in nature). For example, the atomic mass of hydrogen is not 1.0 amu, but 1.0079 amu, reflecting the natural occurrence of small amounts of deuterium and tritium in addition to the more abundant ordinary hydrogen.

Because they have the same number of electrons, all isotopes of a given element have essentially the same chemical characteristics. However, some isotopes are unstable and tend to break down, or decay, to a more stable isotope (usually becoming a different element); such **radioisotopes** emit radiation when they decay. For example, the radioactive decay of $^{14}_{6}C$ occurs as a neutron decomposes to form a proton and a fast-moving electron, which is emitted from the atom as a form of radiation known as a beta (β) particle. The resulting stable atom is the common form of nitrogen, $^{14}_{7}N$. Using sophisticated instruments, scientists can detect and measure β particles and other types of radiation. Radioactive decay can also be detected by a method known as **autoradiography,** in which radiation causes the appearance of dark silver grains in photographic film (**FIG. 2-3**).

[2]Unlike weight, mass is independent of the force of gravity. For convenience, however, we consider mass and weight equivalent. Atomic weight has the same numerical value as atomic mass, but it has no units.

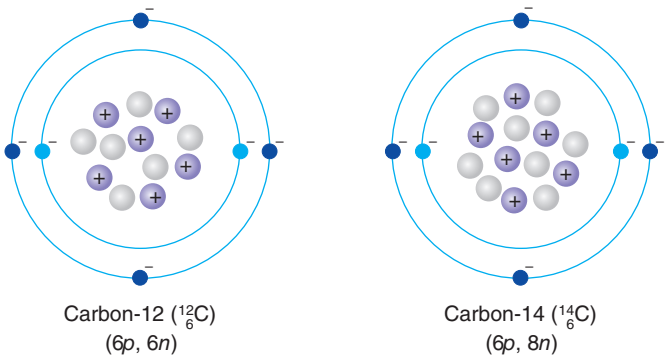

FIGURE 2-2 Isotopes

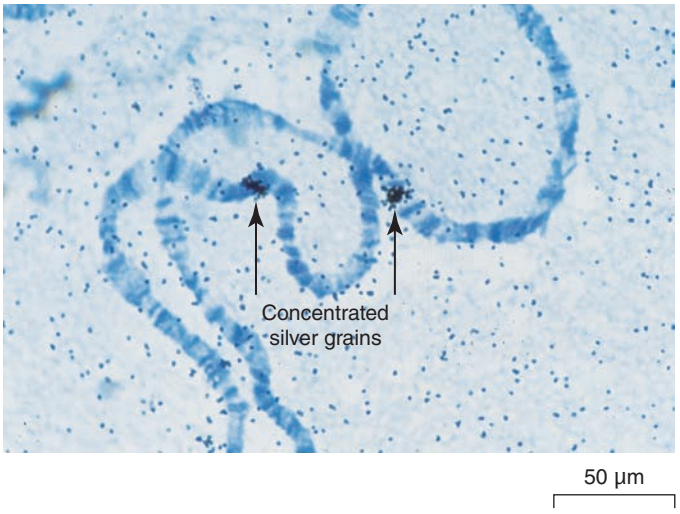
Carbon-12 ($^{12}_{6}C$) is the most common isotope of carbon. Its nucleus contains 6 protons and 6 neutrons, so its atomic mass is 12. Carbon-14 ($^{14}_{6}C$) is a rare radioactive carbon isotope. It contains 8 neutrons, so its atomic mass is 14.

Because the different isotopes of a given element have the same chemical characteristics, they are essentially interchangeable in molecules. Molecules containing radioisotopes are usually metabolized and/or localized in the organism in a similar way to their nonradioactive counterparts, and they can be substituted. For this reason, radioisotopes such as ^{3}H (tritium), ^{14}C, and ^{32}P are extremely valuable research tools used, for example, in dating fossils (see Fig. 18-10), tracing biochemical pathways, determining the sequence of genetic information in DNA (see Fig. 15-10), and understanding sugar transport in plants.

In medicine, radioisotopes are used for both diagnosis and treatment. The location and/or metabolism of a substance such as a hormone or drug can be followed in the body by labeling the substance with a radioisotope such as carbon-14 or tritium. Radioisotopes are used to test thyroid gland function, to provide images of blood flow in the arteries supplying the cardiac muscle, and to



Peter J. Bryant/Biological Photo Service

FIGURE 2-3 Autoradiography

The chromosomes of the fruit fly, *Drosophila melanogaster,* shown in this light micrograph, have been covered with photographic film in which silver grains (*dark spots*) are produced when tritium (^{3}H) that has been incorporated into DNA undergoes radioactive decay. The concentrations of silver grains (*arrows*) mark the locations of specific DNA molecules.

www.konkur.in

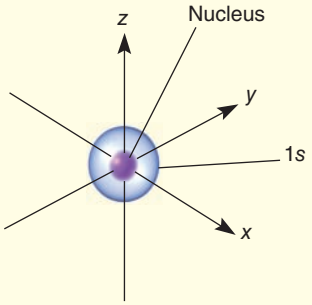
study many other aspects of body function and chemistry. Because radiation can interfere with cell division, radioisotopes have been used therapeutically in treating cancer, a disease often characterized by rapidly dividing cells.

Electrons move in orbitals corresponding to energy levels

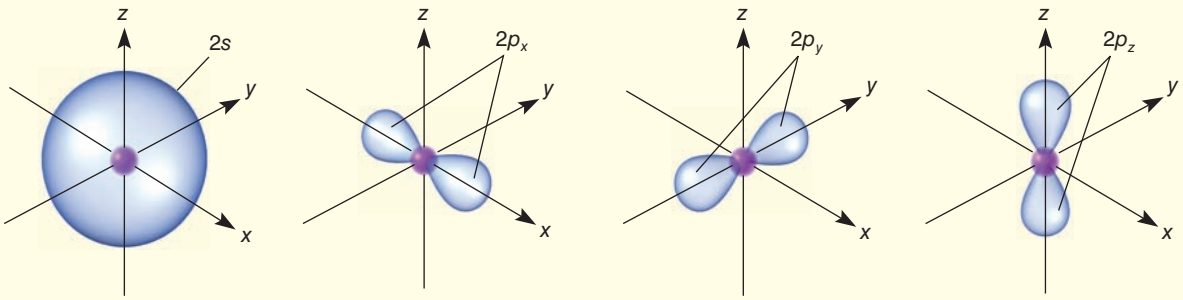
Electrons move through characteristic regions of 3-D space, or **orbitals.** Each orbital contains a maximum of 2 electrons. Because it is impossible to know an electron's position at any given time, orbitals are most accurately depicted as "electron clouds," shaded areas whose density is proportional to the probability that an electron is present there at any given instant. The energy of an electron depends on the orbital it occupies. Electrons in orbitals with similar energies, said to be at the same **principal energy level,** make up an **electron shell** (FIG. 2-4).

In general, electrons in a shell with a greater average distance from the nucleus have greater energy than those in a shell close to the nucleus. The reason is that energy is required to move a nega-

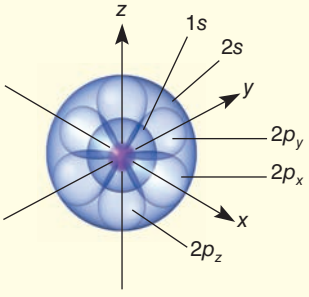
KEY POINT Electrons occupy orbitals corresponding to energy levels.



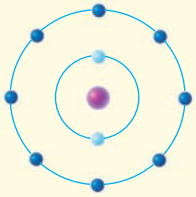
(a) The first principal energy level contains a maximum of 2 electrons, occupying a single spherical orbital (designated 1*s*). The electrons depicted in the diagram could be present anywhere in the blue area.



(b) The second principal energy level includes four orbitals, each with a maximum of 2 electrons: one spherical (2*s*) and three dumbbell-shaped (2*p*) orbitals at right angles to one another.



(c) Orbitals of the first and second principal energy levels of a neon atom are shown superimposed. Note that the single 2*s* orbital plus three 2*p* orbitals make up neon's full valence shell of 8 electrons. Compare this more realistic view of the atomic orbitals with the Bohr model of a neon atom at right.



(d) Neon atom (Bohr model)

FIGURE 2-4 ***Animated*** **Atomic orbitals**
Each orbital is represented as an "electron cloud." The arrows labeled *x*, *y*, and *z* establish the imaginary axes of the atom.

www.konkur.in

tively charged electron farther away from the positively charged nucleus. The most energetic electrons, known as valence electrons, are said to occupy the **valence shell.** The valence shell is represented as the outermost concentric ring in a Bohr model. As we will see in the next sections, it is these valence electrons that play a key role in chemical reactions.

An electron can move to an orbital farther from the nucleus by receiving more energy, or it can give up energy and sink to a lower energy level in an orbital nearer the nucleus. Changes in electron energy levels are important in energy conversions in organisms. For example, during photosynthesis, light energy absorbed by chlorophyll molecules causes electrons to move to a higher energy level (see Fig. 9-3).

Review

- Do all atoms of an element have the same atomic number? the same atomic mass?
- What is a radioisotope? What are some ways radioisotopes are used in biological research?
- How do electrons in different orbitals of the same electron shell compare with respect to their energy?

2.2 CHEMICAL REACTIONS

LEARNING OBJECTIVES

4 Explain how the number of valence electrons of an atom is related to its chemical properties.
5 Distinguish among simplest, molecular, and structural chemical formulas.
6 Explain why the mole concept is so useful to chemists.

The chemical behavior of an atom is determined primarily by the number and arrangement of its **valence electrons.** The valence shell of hydrogen or helium is full (stable) when it contains 2 electrons. The valence shell of any other atom is full when it contains 8 electrons. When the valence shell is not full, the atom tends to lose, gain, or share electrons to achieve a full outer shell. The valence shells of all isotopes of an element are identical; for this reason, they have similar chemical properties and can substitute for one another in chemical reactions (for example, tritium can substitute for ordinary hydrogen).

Elements in the same vertical column (belonging to the same *group*) of the periodic table have similar chemical properties because their valence shells have similar tendencies to lose, gain, or share electrons. For example, chlorine and bromine, included in a group commonly known as the *halogens,* are highly reactive. Because their valence shells have 7 electrons, they tend to gain an electron in chemical reactions. By contrast, hydrogen, sodium, and potassium each have a single valence electron, which they tend to give up or share with another atom. Helium (He) and neon (Ne) belong to a group referred to as the *noble gases.* They are quite unreactive because their valence shells are full. Notice in Figure 2-1 the incomplete valence shells of some of the elements important in organisms, including carbon, hydrogen, oxygen, and nitrogen, and compare them with the full valence shell of neon in Figure 2-4d.

Atoms form compounds and molecules

Two or more atoms may combine chemically. When atoms of *different* elements combine, the result is a chemical compound. A chemical **compound** consists of atoms of two or more different elements combined in a fixed ratio. For example, water is a chemical compound composed of hydrogen and oxygen in a ratio of 2:1. Common table salt, sodium chloride, is a chemical compound made up of sodium and chlorine in a 1:1 ratio.

Two or more atoms may become joined very strongly to form a stable particle called a **molecule.** For example, when two atoms of oxygen combine chemically, a molecule of oxygen is formed. Water is a molecular compound, with each molecule consisting of two atoms of hydrogen and one of oxygen. However, as you will see, not all compounds are made up of molecules. Sodium chloride (common table salt) is an example of a compound that is not molecular.

Simplest, molecular, and structural chemical formulas give different information

A **chemical formula** is a shorthand expression that describes the chemical composition of a substance. Chemical symbols indicate the types of atoms present, and subscript numbers indicate the ratios among the atoms. There are several types of chemical formulas, each providing specific kinds of information.

In a **simplest formula** (also known as an *empirical formula*), the subscripts give the smallest whole-number ratios for the atoms present in a compound. For example, the simplest formula for hydrazine is NH_2, indicating a 1:2 ratio of nitrogen to hydrogen. (Note that when a single atom of a type is present, the subscript number 1 is never written.)

In a **molecular formula,** the subscripts indicate the actual numbers of each type of atom per molecule. The molecular formula for hydrazine is N_2H_4, which indicates that each molecule of hydrazine consists of two atoms of nitrogen and four atoms of hydrogen. The molecular formula for water, H_2O, indicates that each molecule consists of two atoms of hydrogen and one atom of oxygen.

A **structural formula** shows not only the types and numbers of atoms in a molecule but also their arrangement. For example, the structural formula for water is H—O—H. As you will learn in Chapter 3, it is common for complex organic molecules with different structural formulas to share the same molecular formula.

One mole of any substance contains the same number of units

The molecular mass of a compound is the sum of the atomic masses of the component atoms of a single molecule; thus, the molecular mass of water, H_2O, is (hydrogen: 2×1 amu) + (oxygen: 1×16 amu), or 18 amu. (Because of the presence of isotopes, atomic mass values are not whole numbers, but for easy calculation each atomic mass value has been rounded off to a whole number.) Similarly, the molecular mass of glucose ($C_6H_{12}O_6$), a simple sugar that is a key compound in cell metabolism, is (carbon: 6×12 amu) + (hydrogen: 12×1 amu) + (oxygen: 6×16 amu), or 180 amu.

www.konkur.in

The amount of an element or compound whose mass in grams is equivalent to its atomic or molecular mass is 1 **mole (mol).** Thus, 1 mol of water is 18 grams (g), and 1 mol of glucose has a mass of 180 g. The mole is an extremely useful concept because it lets us make meaningful comparisons between atoms and molecules of very different mass. The reason is that *1 mol of any substance always has exactly the same number of units,* whether those units are small atoms or large molecules. The very large number of units in a mole, 6.02×10^{23}, is known as **Avogadro's number,** named for the Italian physicist Amadeo Avogadro, who first calculated it. Thus, 1 mol (180 g) of glucose contains 6.02×10^{23} molecules, as does 1 mol (2 g) of molecular hydrogen (H_2). Although it is impossible to count atoms and molecules individually, a scientist can calculate them simply by weighing a sample. Molecular biologists usually deal with smaller values, either millimoles (mmol, one-thousandth of a mole) or micromoles (μmol, one-millionth of a mole).

The mole concept also lets us make useful comparisons among solutions. A 1 molar solution, represented by 1 *M,* contains 1 mol of that substance dissolved in a total volume of 1 liter (L). For example, we can compare 1 L of a 1 *M* solution of glucose with 1 L of a 1 *M* solution of sucrose (table sugar, a larger molecule). They differ in the mass of the dissolved sugar (180 g and 340 g, respectively), but they each contain 6.02×10^{23} sugar molecules.

Chemical equations describe chemical reactions

During any moment in the life of an organism—a bacterial cell, a mushroom, or a butterfly—many complex chemical reactions are taking place. Chemical reactions, such as the reaction between glucose and oxygen, can be described by means of chemical equations:

$$\underset{\text{Glucose}}{C_6H_{12}O_6} + \underset{\text{Oxygen}}{6\ O_2} \longrightarrow \underset{\text{Carbon dioxide}}{6\ CO_2} + \underset{\text{Water}}{6\ H_2O} + \text{energy}$$

In a chemical equation, the **reactants,** the substances that participate in the reaction, are generally written on the left side, and the products, the substances formed by the reaction, are written on the right side. The arrow means "yields" and indicates the direction in which the reaction proceeds.

Chemical compounds react with one another in quantitatively precise ways. The numbers preceding the chemical symbols or formulas (known as *coefficients*) indicate the relative number of atoms or molecules reacting. For example, 1 mol of glucose burned in a fire or metabolized in a cell reacts with 6 mol of oxygen to form 6 mol of carbon dioxide and 6 mol of water.

Many reactions can proceed simultaneously in the reverse direction (to the left) and the forward direction (to the right). At **dynamic equilibrium,** the rates of the forward and reverse reactions are equal (see Chapter 7). Reversible reactions are indicated by double arrows:

$$\underset{\text{Carbon dioxide}}{CO_2} + \underset{\text{Water}}{H_2O} \rightleftharpoons \underset{\text{Carbonic acid}}{H_2CO_3}$$

In this example, the arrows are drawn in different lengths to indicate that when the reaction reaches equilibrium, there will be more reactants (CO_2 and H_2O) than product (H_2CO_3).

Review

- Why is a radioisotope able to substitute for an ordinary (nonradioactive) atom of the same element in a molecule?
- Which kind of chemical formula provides the most information?
- How many particles would be included in 1 g of hydrogen atoms? in 2 g of hydrogen molecules?

2.3 CHEMICAL BONDS

LEARNING OBJECTIVE

7 Distinguish among covalent bonds, ionic bonds, hydrogen bonds, and van der Waals interactions. Compare them in terms of the mechanisms by which they form and their relative strengths.

Atoms can be held together by forces of attraction called **chemical bonds.** Each bond represents a certain amount of chemical energy. **Bond energy** is the energy necessary to break a chemical bond. The valence electrons dictate how many bonds an atom can form. The two principal types of strong chemical bonds are covalent bonds and ionic bonds.

In covalent bonds electrons are shared

Covalent bonds involve the sharing of electrons between atoms in a way that results in each atom having a filled valence shell. A molecule consists of atoms joined by covalent bonds. A simple example of a covalent bond is the joining of two hydrogen atoms in a molecule of hydrogen gas, H_2. Each atom of hydrogen has 1 electron, but 2 electrons are required to complete its valence shell. The hydrogen atoms have equal capacities to attract electrons, so neither donates an electron to the other. Instead, the two hydrogen atoms share their single electrons so that the 2 electrons are attracted simultaneously to the 2 protons in the two hydrogen nuclei. The 2 electrons whirl around both atomic nuclei, thus forming the covalent bond that joins the two atoms. Similarly, unlike atoms can also be linked by covalent bonds to form molecules; the resulting compound is a **covalent compound.**

A simple way of representing the electrons in the valence shell of an atom is to use dots placed around the chemical symbol of the element. Such a representation is called the *Lewis structure* of the atom, named for G. N. Lewis, an American chemist who developed this type of notation. In a water molecule, two hydrogen atoms are covalently bonded to an oxygen atom:

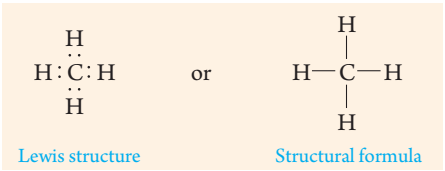
$$H\cdot + H\cdot + \cdot\ddot{O}\cdot \longrightarrow H:\ddot{O}:H$$

Oxygen has 6 valence electrons; by sharing electrons with two hydrogen atoms, it completes its valence shell of 8. At the same time, each hydrogen atom obtains a complete valence shell of 2. (Note that in the structural formula H—O—H, each pair of shared electrons constitutes a covalent bond, represented by a solid line. Unshared electrons are usually omitted in a structural formula.)

The carbon atom has 4 electrons in its valence shell, all of which are available for covalent bonding:

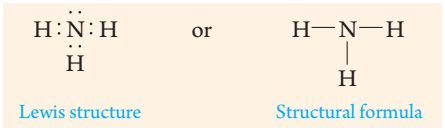
www.konkur.in

When one carbon and four hydrogen atoms share electrons, a molecule of the covalent compound methane, CH_4, is formed:



The nitrogen atom has 5 electrons in its valence shell. Recall that each orbital can hold a maximum of 2 electrons. Usually, 2 electrons occupy one orbital, leaving 3 electrons available for sharing with other atoms:

When a nitrogen atom shares electrons with three hydrogen atoms, a molecule of the covalent compound ammonia, NH_3, is formed:



When one pair of electrons is shared between two atoms, the covalent bond is called a **single covalent bond** (FIG. 2-5a). Two hydrogen atoms share a single pair of electrons. Two oxygen atoms may achieve stability by forming covalent bonds with each other. Each oxygen atom has 6 electrons in its outer shell. To become stable, the two atoms share two pairs of electrons, forming molecular oxygen (FIG. 2-5b). When two pairs of electrons are shared in this way, the covalent bond is called a **double covalent bond,** which is represented by two parallel solid lines. Similarly, a **triple covalent bond** is formed when three pairs of electrons are shared between two atoms (represented by three parallel solid lines).

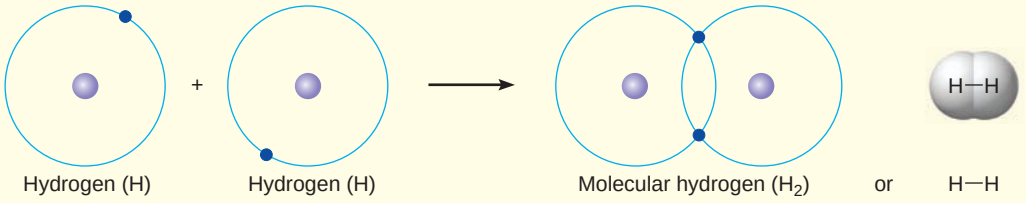
The number of covalent bonds usually formed by the atoms in biologically important molecules is summarized as follows:

Atom	Symbol	Covalent Bonds
Hydrogen	H	1
Oxygen	O	2
Carbon	C	4
Nitrogen	N	3
Phosphorus	P	5
Sulfur	S	2

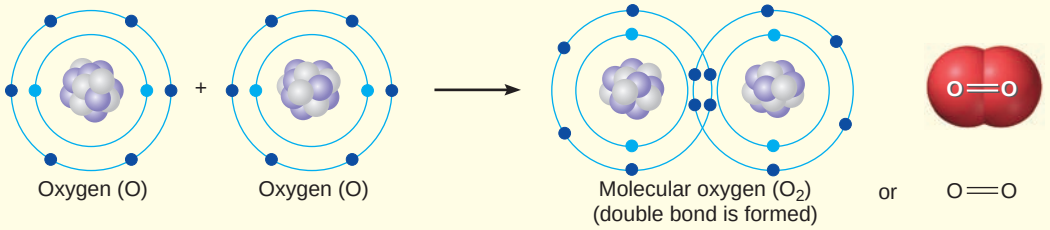
The function of a molecule is related to its shape

In addition to being composed of atoms with certain properties, each kind of molecule has a characteristic size and a general overall shape. Although the shape of a molecule may change (within certain limits), the functions of molecules in living cells are dictated largely by their geometric shapes. A molecule that consists of two atoms is linear. Molecules composed of more than two atoms may

KEY POINT Covalent bonds form when atoms share electrons.



(a) Single covalent bond formation. Two hydrogen atoms achieve stability by sharing a pair of electrons, thereby forming a molecule of hydrogen. In the structural formula on the right, the straight line between the hydrogen atoms represents a single covalent bond.



(b) Double covalent bond formation. In molecular oxygen, two oxygen atoms share two pairs of electrons, forming a double covalent bond. The parallel straight lines in the structural formula represent a double covalent bond.

FIGURE 2-5 Electron sharing in covalent compounds

www.konkur.in

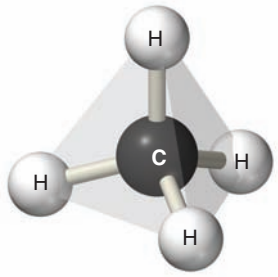


FIGURE 2-6 Orbital hybridization in methane

The four hydrogens are located at the corners of a tetrahedron because of hybridization of the valence shell orbitals of carbon.

have more complicated shapes. The geometric shape of a molecule provides the optimal distance between the atoms to counteract the repulsion of electron pairs.

When an atom forms covalent bonds with other atoms, the orbitals in the valence shell may become rearranged in a process known as **orbital hybridization,** thereby affecting the shape of the resulting molecule. For example, when four hydrogen atoms combine with a carbon atom to form a molecule of methane (CH_4), the hybridized valence shell orbitals of the carbon form a geometric structure known as a *tetrahedron,* with one hydrogen atom present at each of its four corners (**FIG. 2-6**; see also Fig. 3-2a).

We will explore the importance of molecular shape in more detail in Chapter 3 and in our discussion of the properties of water in this chapter.

Covalent bonds can be nonpolar or polar

Atoms of different elements vary in their affinity for electrons. **Electronegativity** is a measure of an atom's attraction for shared electrons in chemical bonds. Very electronegative atoms such as oxygen, nitrogen, fluorine, and chlorine are sometimes called "electron greedy." When covalently bonded atoms have similar electronegativities, the electrons are shared equally and the covalent bond is described as **nonpolar.** The covalent bond of the hydrogen molecule is nonpolar, as are the covalent bonds of molecular oxygen and methane.

In a covalent bond between two different elements, such as oxygen and hydrogen, the electronegativities of the atoms may be different. If so, electrons are pulled closer to the atomic nucleus of the element with the greater electron affinity (in this case, oxygen). A covalent bond between atoms that differ in electronegativity is called a **polar** covalent bond. Such a bond has two dissimilar ends (or poles), one with a partial positive charge and the other with a partial negative charge. Each of the two covalent bonds in water is polar because there is a partial positive charge at the hydrogen end of the bond and a partial negative charge at the oxygen end, where the "shared" electrons are more likely to be.

Covalent bonds differ in their degree of polarity, ranging from those in which the electrons are equally shared (as in the nonpolar hydrogen molecule) to those in which the electrons are much closer to one atom than to the other (as in water). Oxygen is quite electronegative and forms polar covalent bonds with carbon, hydrogen, and many other atoms. Nitrogen is also strongly electronegative, although less so than oxygen.

A molecule with one or more polar covalent bonds can be polar even though it is electrically neutral as a whole. The reason is that a **polar molecule** has one end with a partial positive charge and another end with a partial negative charge. One example is water (**FIG. 2-7**). The polar bonds between the hydrogens and the oxygen are arranged in a V shape, rather than linearly. The oxygen end constitutes the negative pole of the molecule, and the end with the two hydrogens is the positive pole.

Ionic bonds form between cations and anions

Some atoms or groups of atoms are not electrically neutral. A particle with 1 or more units of electric charge is called an ion. An atom becomes an ion if it gains or loses 1 or more electrons. An atom with 1, 2, or 3 electrons in its valence shell tends to lose electrons to other atoms. Such an atom then becomes positively charged because its nucleus contains more protons than the number of electrons orbiting around the nucleus. These positively charged ions are termed **cations.** Atoms with 5, 6, or 7 valence electrons tend to gain electrons from other atoms and become negatively charged **anions.**

The properties of ions are quite different from those of the electrically neutral atoms from which they were derived. For example, although chlorine gas is a poison, chloride ions (Cl^-) are

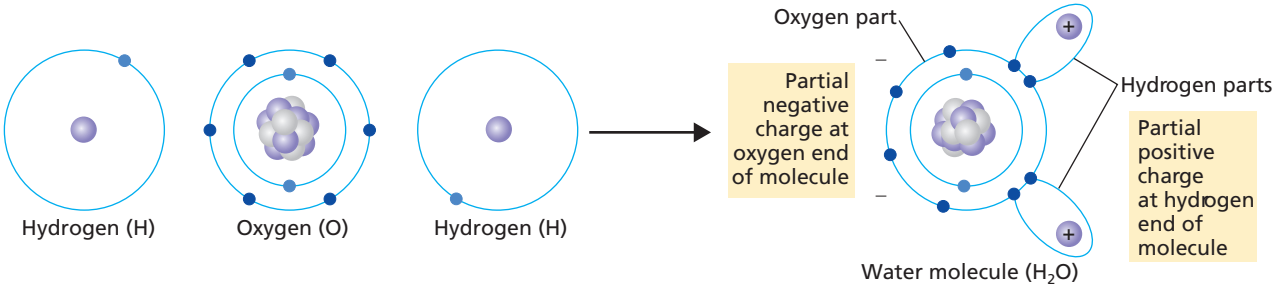

FIGURE 2-7 Water, a polar molecule

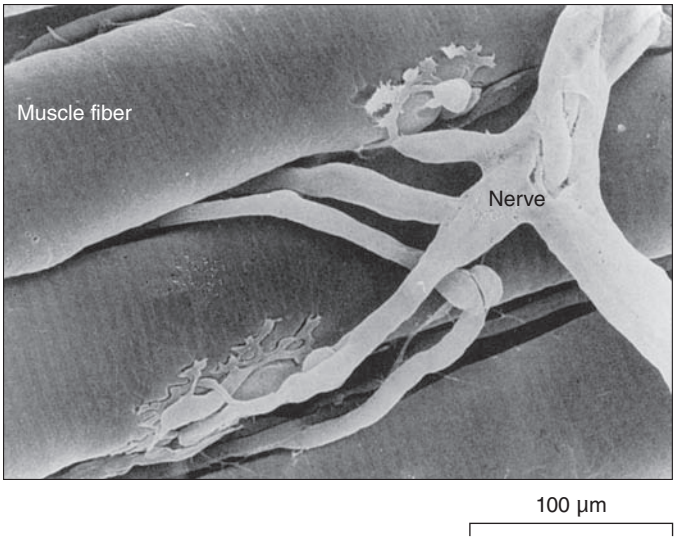
Note that the electrons tend to stay closer to the nucleus of the oxygen atom than to the hydrogen nuclei. This results in a partial negative charge on the oxygen portion of the molecule and a partial positive charge at the hydrogen end. Although the water molecule as a whole is electrically neutral, it is a polar covalent compound.

www.konkur.in



Bloom and Fawcett Textbook of Technology

FIGURE 2-8 Ions and biological processes

Sodium, potassium, and chloride ions are essential for this nerve cell to stimulate these muscle fibers, initiating a muscle contraction. Calcium ions in the muscle cell are required for muscle contraction.

essential to life (see Table 2-1). Because their electric charges provide a basis for many interactions, cations and anions are involved in energy transformations within the cell, the transmission of nerve impulses, muscle contraction, and many other biological processes (**FIG. 2-8**).

A group of covalently bonded atoms can also become an ion (*polyatomic ion*). Unlike a single atom, a group of atoms can lose or gain protons (derived from hydrogen atoms) as well as electrons. Therefore, a group of atoms can become a cation if it loses 1 or more electrons or gains 1 or more protons. A group of atoms becomes an anion if it gains 1 or more electrons or loses 1 or more protons.

An **ionic bond** forms as a consequence of the attraction between the positive charge of a cation and the negative charge of an anion. An **ionic compound** is a substance consisting of anions and cations bonded by their opposite charges.

A good example of how ionic bonds are formed is the attraction between sodium ions and chloride ions. A sodium atom has 1 electron in its valence shell. It cannot fill its valence shell by obtaining 7 electrons from other atoms because it would then have a large unbalanced negative charge. Instead, it gives up its single valence electron to a very electronegative atom, such as chlorine, which acts as an electron acceptor (**FIG. 2-9**). Chlorine cannot give up the 7 electrons in its valence shell because it would then have a large positive charge. Instead, it strips an electron from an electron donor (sodium, in this example) to complete its valence shell.

When sodium reacts with chlorine, sodium's valence electron is transferred completely to chlorine. Sodium becomes a cation, with 1 unit of positive charge (Na^+). Chlorine becomes an anion, a chloride ion with 1 unit of negative charge (Cl^-). These ions attract each other as a result of their opposite charges. This electrical attraction in ionic bonds holds them together to form NaCl, sodium chloride, or common table salt.

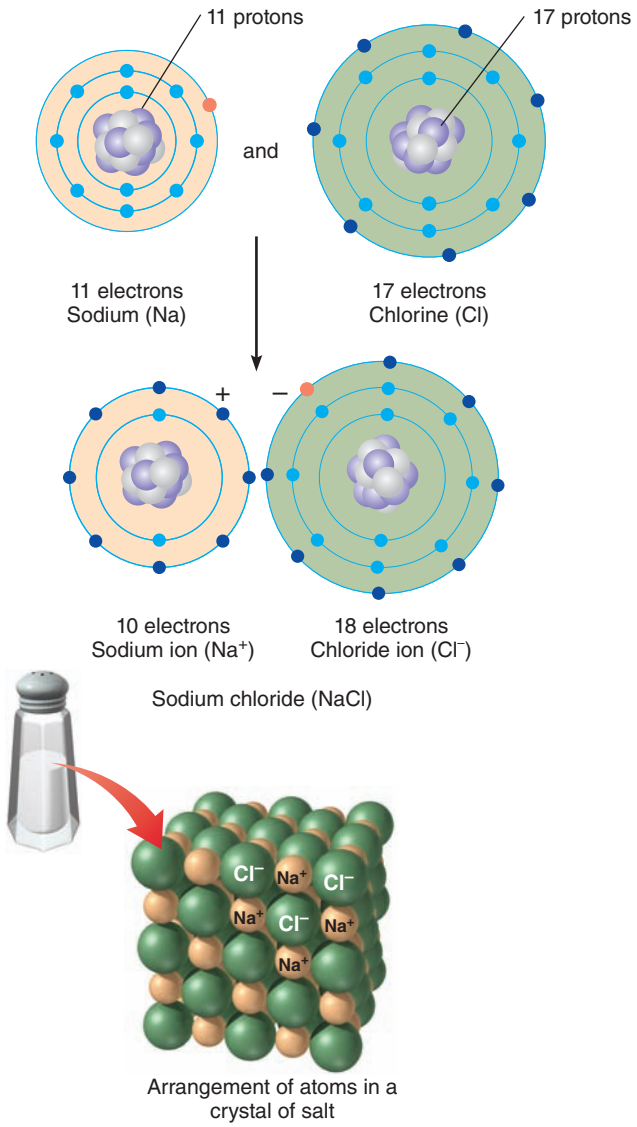


FIGURE 2-9 *Animated* Ionic bonding

Sodium becomes a positively charged ion when it donates its single valence electron to chlorine, which has 7 valence electrons. With this additional electron, chlorine completes its valence shell and becomes a negatively charged chloride ion. These sodium and chloride ions are attracted to one another by their unlike electric charges, forming the ionic compound sodium chloride.

The term *molecule* does not adequately explain the properties of ionic compounds such as NaCl. When NaCl is in its solid crystal state, each ion is actually surrounded by six ions of opposite charge. The simplest formula, NaCl, indicates that sodium ions and chloride ions are present in a 1:1 ratio, but the actual crystal has no discrete molecules composed of one Na^+ and one Cl^- ion.

Compounds joined by ionic bonds, such as sodium chloride, have a tendency to *dissociate* (separate) into their individual ions when placed in water:

$$\underset{\text{Sodium chloride}}{NaCl} \xrightarrow{\text{in } H_2O} \underset{\text{Sodium ion}}{Na^+} + \underset{\text{Chloride ion}}{Cl^-}$$

www.konkur.in

In the solid form of an ionic compound (that is, in the absence of water), ionic bonds are very strong. Water, however, is an excellent **solvent;** as a liquid it is capable of dissolving many substances, particularly those that are polar or ionic, because of the polarity of water molecules. The localized partial positive charge (on the hydrogen atoms) and partial negative charge (on the oxygen atom) on each water molecule attract and surround the anions and cations, respectively, on the surface of an ionic solid. As a result, the solid dissolves. A dissolved substance is referred to as a **solute.** In solution, each cation and anion of the ionic compound is surrounded by oppositely charged ends of the water molecules. This process is known as **hydration** (FIG. 2-10). Hydrated ions still interact with one another to some extent, but the transient ionic bonds formed are much weaker than those in a solid crystal.

Hydrogen bonds are weak attractions

Another type of bond important in organisms is the **hydrogen bond.** When hydrogen combines with oxygen (or with another relatively electronegative atom such as nitrogen), it acquires a partial positive charge because its electron spends more time closer to the electronegative atom. Hydrogen bonds tend to form between an atom with a partial negative charge and a hydrogen atom that is covalently bonded to oxygen or nitrogen (FIG. 2-11). The atoms involved may be in two parts of the same large molecule or in two different molecules. Water molecules interact with one another extensively through hydrogen bond formation.

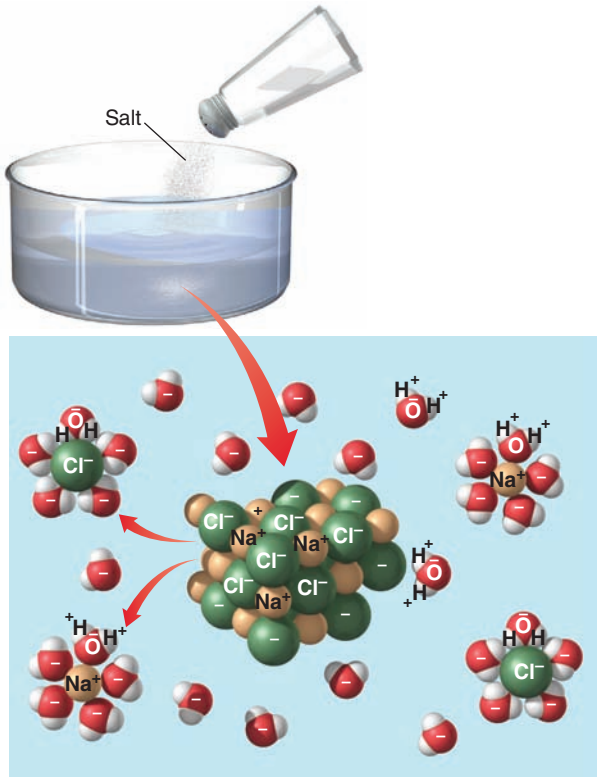

FIGURE 2-10 ***Animated*** **Hydration of an ionic compound**
When the crystal of NaCl is added to water, the sodium and chloride ions are pulled apart. When the NaCl is dissolved, each Na^+ and Cl^- is surrounded by water molecules electrically attracted to it.

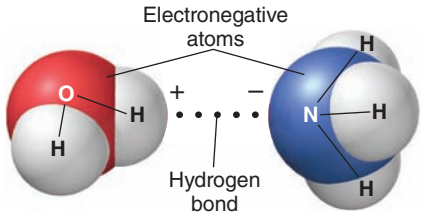

FIGURE 2-11 ***Animated*** **Hydrogen bonding**
A hydrogen bond (*dotted line*) can form between two molecules with regions of unlike partial charge. Here, the nitrogen atom of an ammonia molecule is joined by a hydrogen bond to a hydrogen atom of a water molecule.

Hydrogen bonds are readily formed and broken. Although individually relatively weak, hydrogen bonds are collectively strong when present in large numbers. Furthermore, they have a specific length and orientation. As you will see in Chapter 3, these features are very important in determining the 3-D structure of large molecules such as DNA and proteins.

van der Waals interactions are weak forces

Even electrically neutral, nonpolar molecules can develop transient regions of weak positive and negative charge. These slight charges develop as a consequence of the fact that electrons are in constant motion. A region with a temporary excess of electrons will have a weak negative charge, whereas one with an electron deficit will have a weak positive charge. Adjacent molecules may interact in regions of slight opposite charge. These attractive forces, called **van der Waals interactions,** operate over very short distances and are weaker and less specific than the other types of interactions we have considered. They are most important when they occur in large numbers and when the shapes of the molecules permit close contact between the atoms. Although a single interaction is very weak, the binding force of a large number of these interactions working together can be significant.

Review

- Are all compounds composed of molecules? Explain.
- What are the ways an atom or molecule can become an anion or a cation?
- How do ionic and covalent bonds differ?
- Under what circumstances can weak forces such as hydrogen bonds and van der Waals interactions play significant roles in biological systems?

2.4 REDOX REACTIONS

LEARNING OBJECTIVE

8 Distinguish between the terms *oxidation* and *reduction*, and relate these processes to the transfer of energy.

Many energy conversions that go on in a cell involve reactions in which an electron transfers from one substance to another. The reason is that the transfer of an electron also involves the transfer

www.konkur.in

of the energy of that electron. Such an electron transfer is known as an oxidation–reduction, or **redox reaction.** Oxidation and reduction always occur together. **Oxidation** is a chemical process in which an atom, ion, or molecule *loses* one or more electrons. **Reduction** is a chemical process in which an atom, ion, or molecule *gains* one or more electrons. (The term refers to the fact that the gain of an electron results in the reduction of any positive charge that might be present.)

Rusting—the combining of iron (symbol Fe) with oxygen—is a simple illustration of oxidation and reduction:

$$4\ Fe + 3\ O_2 \longrightarrow 2\ Fe_2O_3$$

Iron (III) oxide

In rusting, each iron atom becomes oxidized as it loses 3 electrons.

$$4\ Fe \longrightarrow 4\ Fe^{3+} + 12e^-$$

The e^- represents an electron; the + superscript in Fe^{3+} represents an electron deficit. (When an atom loses an electron, it acquires 1 unit of positive charge from the excess of 1 proton. In our example, each iron atom loses 3 electrons and acquires 3 units of positive charge.) Recall that the oxygen atom is very electronegative, able to remove electrons from other atoms. In this reaction, oxygen becomes reduced when it accepts electrons from the iron.

$$3\ O_2 + 12e^- \longrightarrow 6\ O^{2-}$$

Redox reactions occur simultaneously because one substance must accept the electrons that are removed from the other. In a redox reaction, one component, the *oxidizing agent,* accepts 1 or more electrons and becomes reduced. Oxidizing agents other than oxygen are known, but oxygen is such a common one that its name was given to the process. Another reaction component, the *reducing agent,* gives up 1 or more electrons and becomes oxidized. In our example, there was a complete transfer of electrons from iron (the reducing agent) to oxygen (the oxidizing agent). Similarly, Figure 2-9 shows that an electron was transferred from sodium (the reducing agent) to chlorine (the oxidizing agent).

Electrons are not easily removed from covalent compounds unless an entire atom is removed. In cells, oxidation often involves the removal of a hydrogen atom (an electron plus a proton that "goes along for the ride") from a covalent compound; reduction often involves the addition of the equivalent of a hydrogen atom (see Chapter 7).

Review

- Why must oxidation and reduction occur simultaneously?
- Why are redox reactions important in some energy transfers?

2.5 WATER

LEARNING OBJECTIVE

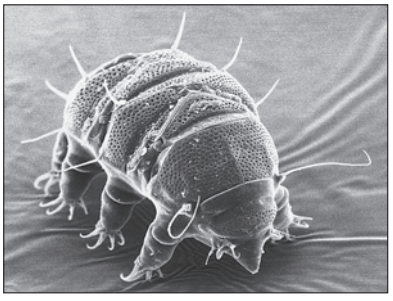
9 Explain how hydrogen bonds between adjacent water molecules govern many of the properties of water.

A large part of the mass of most organisms is water. In human tissues the percentage of water ranges from 20% in bones to 85% in brain cells; about 70% of our total body weight is water. As much as 95% of a jellyfish and certain plants is water. Water is the source, through photosynthesis, of the oxygen in the air we breathe, and its hydrogen atoms become incorporated into many organic compounds. Water is also the solvent for most biological reactions and a reactant or product in many chemical reactions.

Water is important not only as an internal constituent of organisms but also as one of the principal environmental factors affecting them (**FIG. 2-12**). Many organisms live in the ocean or in freshwater rivers, lakes, or puddles. Water's unique combination of physical and chemical properties is considered to have been essential to the origin of life as well as to the continued survival and evolution of life on Earth.

Hydrogen bonds form between water molecules

As discussed, water molecules are polar; that is, one end of each molecule bears a partial positive charge and the other a partial negative charge (see Fig. 2-7). The water molecules in liquid water and in ice associate by hydrogen bonds. The hydrogen atom of one water molecule, with its partial positive charge, is attracted to the oxygen atom of a neighboring water molecule, with its partial negative charge, forming a hydrogen bond. An oxygen atom in a water molecule has two regions of partial negative charge, and each of the two hydrogen atoms has a partial positive charge. Each water molecule can therefore form hydrogen bonds with a maximum of four neighboring water molecules (**FIG. 2-13**).



Diane R. Nelson

100 µm

(a) Commonly known as "water bears," tardigrades, such as these members of the genus *Echiniscus*, are small animals (less than 1.2 mm long) that normally live in moist habitats, such as thin films of water on mosses.

Robert O. Schuster, courtesy of Diane R. Nelson

10 µm

(b) When subjected to desiccation (dried out), tardigrades assume a barrel-shaped form known as a *tun*, remaining in this state, motionless but alive, for as long as 100 years. When rehydrated, they assume their normal appearance and activities.

FIGURE 2-12 The effects of water on an organism

www.konkur.in

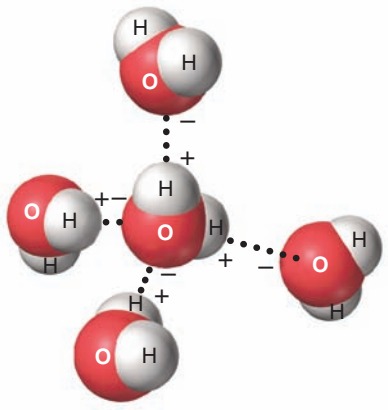


FIGURE 2-13 Hydrogen bonding of water molecules

Each water molecule can form hydrogen bonds (*dotted lines*) with as many as four neighboring water molecules.

Water molecules have a strong tendency to stick to one another, a property known as **cohesion.** This is due to the hydrogen bonds among the molecules. Because of the cohesive nature of water molecules, any force exerted on part of a column of water is transmitted to the column as a whole. The major mechanism of water movement in plants (see Chapter 35) depends on the cohesive nature of water. Water molecules also display **adhesion,** the ability to stick to many other kinds of substances, most notably those with charged groups of atoms or molecules on their surfaces. These adhesive forces explain how water makes things wet.

A combination of adhesive and cohesive forces accounts for **capillary action,** which is the tendency of water to move in narrow tubes, even against the force of gravity (**FIG. 2-14**). For example, water moves through the microscopic spaces between soil particles to the roots of plants by capillary action.

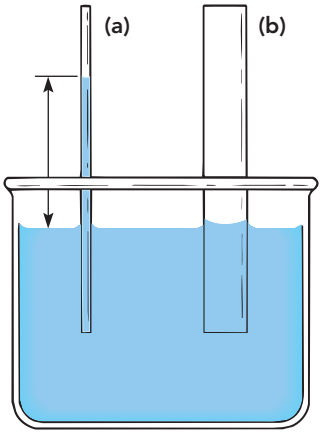

FIGURE 2-14 Capillary action

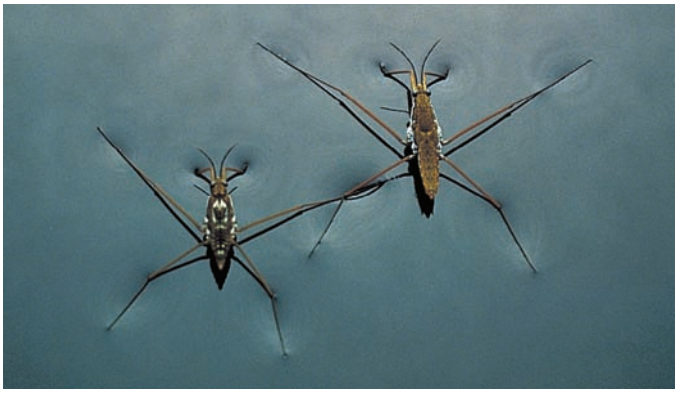
(a) In a narrow tube, there is adhesion between the water molecules and the glass wall of the tube. Other water molecules inside the tube are then "pulled along" because of cohesion, which is due to hydrogen bonds between the water molecules. **(b)** In the wider tube, a smaller percentage of the water molecules line the glass wall. As a result, the adhesion is not strong enough to overcome the cohesion of the water molecules beneath the surface level of the container, and water in the tube rises only slightly.



Dennis Drenner

FIGURE 2-15 Surface tension of water

Hydrogen bonding between water molecules is responsible for the surface tension of water, which causes a dimpled appearance of the surface as these water striders (*Gerris*) walk across it. Fine hairs at the ends of the legs of these insects create highly water-repellent "cushions" of air.

Water has a high degree of **surface tension** because of the cohesion of its molecules, which have a much greater attraction for one another than for molecules in the air. Thus, water molecules at the surface crowd together, producing a strong layer as they are pulled downward by the attraction of other water molecules beneath them (**FIG. 2-15**).

Water molecules interact with hydrophilic substances by hydrogen bonding

Because its molecules are polar, water is an excellent solvent, a liquid capable of dissolving many kinds of substances, especially polar and ionic compounds. Earlier we discussed how polar water molecules pull the ions of ionic compounds apart so that they dissociate (see Fig. 2-10). Because of its solvent properties and the tendency of the atoms in certain compounds to form ions in solution, water plays an important role in facilitating chemical reactions. Substances that interact readily with water are **hydrophilic** ("water-loving"). Examples include table sugar (sucrose, a polar compound) and table salt (NaCl, an ionic compound), which dissolve readily in water. Not all substances in organisms are hydrophilic, however. Many **hydrophobic** ("water-fearing") substances found in living things are especially important because of their ability to form associations or structures that are not disrupted. Hydrophobic interactions occur between groups of nonpolar molecules. Such molecules are insoluble in water and tend to cluster together. This is not due to formation of bonds between the nonpolar molecules but rather to the fact that the hydrogen-bonded water molecules exclude them and in a sense "drive them together." **Hydrophobic interactions** explain why oil tends to form globules when added to water. Examples of hydrophobic substances include fatty acids and cholesterol, discussed in Chapter 3.

Water helps maintain a stable temperature

Hydrogen bonding explains the way water responds to changes in temperature. Water exists in three forms, which differ in their degree of hydrogen bonding: gas (vapor), liquid, and ice, a crystalline

www.konkur.in

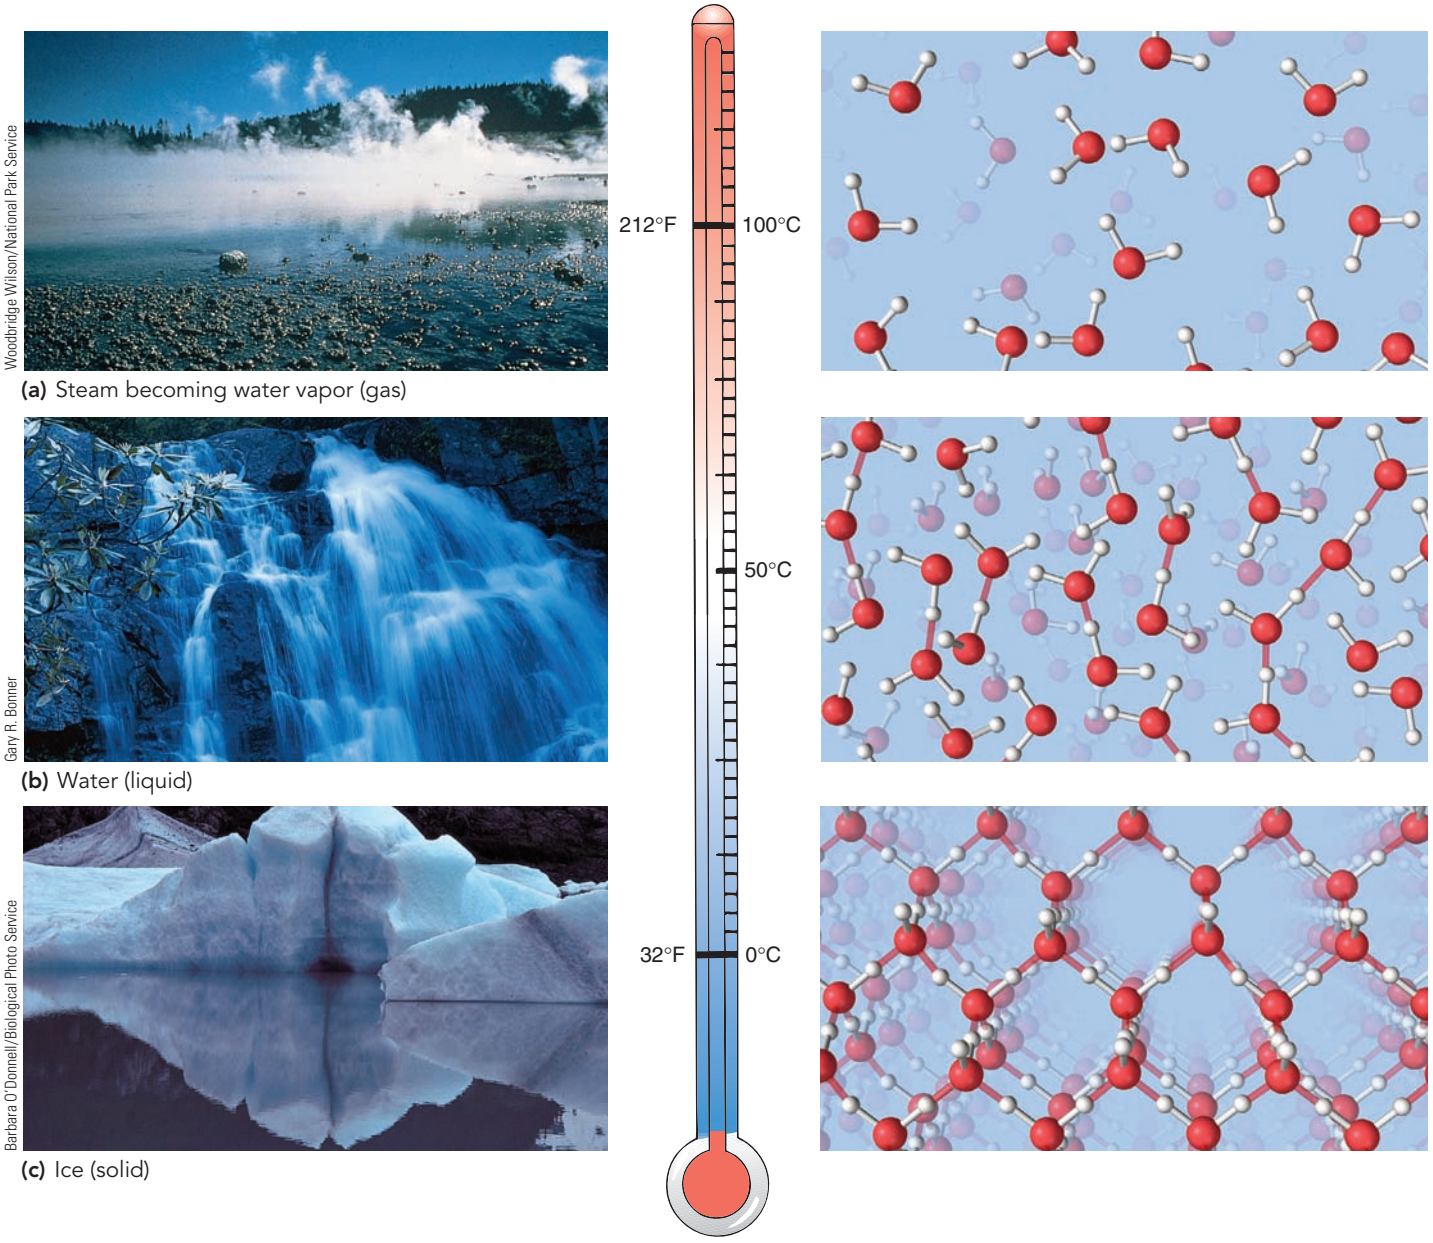


FIGURE 2-16 ***Animated*** **Three forms of water**

(a) When water boils, as in this hot spring at Yellowstone National Park, many hydrogen bonds are broken, causing steam, consisting of minuscule water droplets, to form. If most of the remaining hydrogen bonds break, the molecules move more freely as water vapor (a gas). **(b)** Water molecules in a liquid state continually form, break, and re-form hydrogen bonds with one another. **(c)** In ice, each water molecule participates in four hydrogen bonds with adjacent molecules, resulting in a regular, evenly distanced crystalline lattice structure.

solid (**FIG. 2-16**). Hydrogen bonds are formed or broken as water changes from one state to another.

Raising the temperature of a substance involves adding heat energy to make its molecules move faster, that is, to increase the energy of motion—**kinetic energy**—of the molecules (see Chapter 7). The term **heat** refers to the *total* amount of kinetic energy in a sample of a substance; **temperature** is a measure of the *average* kinetic energy of the particles. For the molecules to move more freely, some of the hydrogen bonds of water must be broken. Much of the energy added to the system is used up in breaking the hydrogen bonds, and only a portion of the heat energy is available to speed the movement of the water molecules, thereby increasing the temperature of the water. Conversely, when liquid water changes to ice, additional hydrogen bonds must be formed, making the molecules less free to move and liberating a great deal of heat into the environment.

Heat of vaporization, the amount of heat energy required to change 1 g of a substance from the liquid phase to the vapor phase,

www.konkur.in

is expressed in units called *calories*. A **calorie (cal)** is the amount of heat energy (equivalent to 4.184 joules [J]) required to raise the temperature of 1 g of water 1 degree Celsius (C). Water has a high heat of vaporization—540 cal—because its molecules are held together by hydrogen bonds. The heat of vaporization of most other common liquid substances is much less. As a sample of water is heated, some molecules are moving much faster than others (they have more heat). These faster-moving molecules are more likely to escape the liquid phase and enter the vapor phase (see Fig. 2-16a). When they do, they take their heat with them, lowering the temperature of the sample, a process called **evaporative cooling.** For this reason, the human body can dissipate excess heat as sweat evaporates from the skin, and a leaf can keep cool in the bright sunlight as water evaporates from its surface.

Hydrogen bonding is also responsible for water's high **specific heat;** that is, the amount of energy required to raise the temperature of water is quite large. The specific heat of water is 1 cal/g of water per degree Celsius. Most other common substances, such as metals, glass, and ethyl alcohol, have much lower specific heat values. The specific heat of ethyl alcohol, for example, is 0.59 cal/g/1°C (2.46 J/g/1°C).

Because so much heat input is required to raise the temperature of water (and so much heat is lost when the temperature is lowered), the ocean and other large bodies of water have relatively constant temperatures. Thus, many organisms living in the ocean are provided with a relatively constant environmental temperature. The properties of water are crucial in stabilizing temperatures on Earth's surface. Although surface water is only a thin film relative to Earth's volume, the quantity is enormous compared to the exposed landmass. This relatively large mass of water resists both the warming effect of heat and the cooling effect of low temperatures.

Hydrogen bonding causes ice to have unique properties with important environmental consequences. Liquid water expands as it freezes because the hydrogen bonds joining the water molecules in the crystalline lattice keep the molecules far enough apart to give ice a density about 10% less than the density of liquid water (see Fig. 2-16c). When ice has been heated enough to raise its temperature above 0°C (32°F), the hydrogen bonds are broken, freeing the molecules to slip closer together. The density of water is greatest at 4°C. Above that temperature water begins to expand again as the speed of its molecules increases. As a result, ice floats on the denser cold water.

This unusual property of water has been important to the evolution of life. If ice had a greater density than water, the ice would sink; eventually, all ponds, lakes, and even the ocean would freeze solid from the bottom to the surface, making life impossible. When a deep body of water cools, it becomes covered with floating ice. The ice insulates the liquid water below it, retarding freezing and permitting organisms to survive below the icy surface.

The high water content of organisms helps them maintain relatively constant internal temperatures. Such minimizing of temperature fluctuations is important because biological reactions can take place only within a relatively narrow temperature range.

Review

- Why does water form hydrogen bonds?
- What are some properties of water that result from hydrogen bonding? How do these properties contribute to the role of water as an essential component of organisms?
- How can weak forces, such as hydrogen bonds, have significant effects in organisms?

2.6 ACIDS, BASES, AND SALTS

LEARNING OBJECTIVES

10 Contrast acids and bases, and discuss their properties.
11 Convert the hydrogen ion concentration (moles per liter) of a solution to a pH value and describe how buffers help minimize changes in pH.
12 Describe the composition of a salt and explain why salts are important in organisms.

Water molecules have a slight tendency to ionize, that is, to dissociate into hydrogen ions (H^+) and hydroxide ions (OH^-). The H^+ immediately combines with a negatively charged region of a water molecule, forming a hydronium ion (H_3O^+). However, by convention, H^+, rather than the more accurate H_3O^+, is used. In pure water, a small number of water molecules ionize. This slight tendency of water to dissociate is reversible as hydrogen ions and hydroxide ions reunite to form water.

$$HOH \rightleftharpoons H^+ + OH^-$$

Because each water molecule splits into one hydrogen ion and one hydroxide ion, the concentrations of hydrogen ions and hydroxide ions in pure water are exactly equal (0.0000001 or 10^{-7} mol/L for each ion). Such a solution is said to be neutral, that is, neither acidic nor basic (alkaline).

An **acid** is a substance that dissociates in solution to yield hydrogen ions (H^+) and anions.

$$\text{Acid} \longrightarrow H^+ + \text{anion}$$

An acid is a proton *donor.* (Recall that a hydrogen ion, or H^+, is nothing more than a proton.) Hydrochloric acid (HCl) is a common inorganic acid.

A **base** is defined as a proton *acceptor.* Most bases are substances that dissociate to yield a hydroxide ion (OH^-) and a cation when dissolved in water.

$$NaOH \longrightarrow Na^+ + OH^-$$
$$OH^- + H^+ \longrightarrow H_2O$$

A hydroxide ion can act as a base by accepting a proton (H^+) to form water. Sodium hydroxide (NaOH) is a common inorganic base. Some bases do not dissociate to yield hydroxide ions directly. For example, ammonia (NH_3) acts as a base by accepting a proton from water, producing an ammonium ion (NH_4^+) and releasing a hydroxide ion.

$$NH_3 + H_2O \longrightarrow NH_4^+ + OH^-$$

www.konkur.in

pH is a convenient measure of acidity

The degree of a solution's acidity is generally expressed in terms of **pH,** defined as the negative logarithm (base 10) of the hydrogen ion concentration (expressed in moles per liter):

$$pH = -\log_{10}[H^+]$$

The brackets refer to concentration; therefore, the term $[H^+]$ means "the concentration of hydrogen ions," which is expressed in moles per liter because we are interested in the *number* of hydrogen ions per liter. Because the range of possible pH values is broad, a logarithmic scale (with a 10-fold difference between successive units) is more convenient than a linear scale.

Hydrogen ion concentrations are nearly always less than 1 mol/L. One gram of hydrogen ions dissolved in 1 L of water (a 1 *M* solution) may not sound impressive, but such a solution would be extremely acidic. The logarithm of a number less than 1 is a negative number; thus, the *negative* logarithm corresponds to a *positive* pH value. (Solutions with pH values less than zero can be produced but do not occur under biological conditions.)

Whole-number pH values are easy to calculate. For instance, consider our example of pure water, which has a hydrogen ion concentration of 0.0000001 (10^{-7}) mol/L. The logarithm is -7. The negative logarithm is 7; therefore, the pH is 7. **TABLE 2-2** shows how to calculate pH values from hydrogen ion concentrations, and the reverse. For comparison, the table also includes the hydroxide ion concentrations, which can be calculated because the product of the hydrogen ion concentration and the hydroxide ion concentration is 1×10^{-14}:

$$[H^+][OH^-] = 1 \times 10^{-14}$$

Pure water is an example of a **neutral solution;** with a pH of 7, it has equal concentrations of hydrogen ions and hydroxide ions (the concentration of each is 10^{-7} mol/L). An **acidic solution** has a hydrogen ion concentration that is higher than its hydroxide ion concentration and has a pH value of less than 7. For example, the hydrogen ion concentration of a solution with pH 1 is 10 times that of a solution with pH 2. A **basic solution** has a hydrogen ion concentration that is lower than its hydroxide ion concentration and has a pH greater than 7.

TABLE 2-2 Calculating pH Values and Hydroxide Ion Concentrations from Hydrogen Ion Concentrations

Substance	$[H^+]$*	log $[H^+]$	pH	$[OH^-]$†
Gastric juice	$0.01, 10^{-2}$	-2	2	10^{-12}

Household ammonia	$0.00000000001, 10^{-11}$	-11	11	10^{-3}

*$[H^+]$ = hydrogen ion concentration (mol/L)

†$[OH^-]$ = hydroxide ion concentration (mol/L)

The pH values of some common substances are shown in **FIGURE 2-17**. Although some very acidic compartments exist within cells (see Chapter 4), most of the interior of an animal or plant cell is neither strongly acidic nor strongly basic but an essentially neutral mixture of acidic and basic substances. Certain bacteria are adapted to life in extremely acidic environments (discussed in Chapter 25), but a substantial change in pH is incompatible with life for most cells. The pH of most types of plant and animal cells (and their environment) ordinarily ranges from around 7.2 to 7.4.

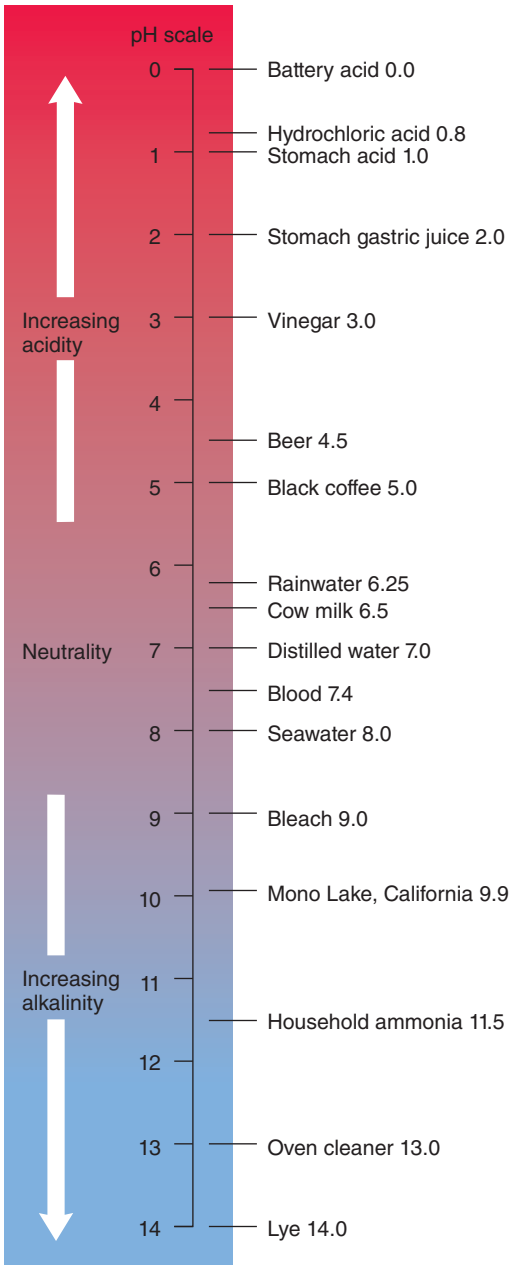

FIGURE 2-17 ***Animated*** **pH values of some common solutions**
A neutral solution (pH 7) has equal concentrations of H^+ and OH^-. Acidic solutions, which have a higher concentration of H^+ than OH^-, have pH values less than 7; pH values greater than 7 characterize basic solutions, which have an excess of OH^-.

www.konkur.in

Buffers minimize pH change

Many homeostatic mechanisms operate to maintain appropriate pH values. For example, the pH of human blood is about 7.4 and must be maintained within very narrow limits. If the blood becomes too acidic (for example, as a result of respiratory disease), coma and death may result. Excessive alkalinity can result in overexcitability of the nervous system and even convulsions. Organisms contain many natural buffers. A **buffer** is a substance or combination of substances that resists changes in pH when an acid or base is added. A buffering system includes a weak acid or a weak base. A weak acid or weak base does not ionize completely. At any given instant, only a fraction of the molecules are ionized; most are not dissociated.

One of the most common buffering systems functions in the blood of vertebrates (see Chapter 46). Carbon dioxide, produced as a waste product of cell metabolism, enters the blood, the main constituent of which is water. The carbon dioxide reacts with the water to form carbonic acid, a weak acid that dissociates to yield a hydrogen ion and a bicarbonate ion. The following expression describes the buffering system:

$$\underset{\text{Carbon dioxide}}{CO_2} + \underset{\text{Water}}{H_2O} \rightleftharpoons \underset{\text{Carbonic acid}}{H_2CO_3} \rightleftharpoons H^+ + \underset{\text{Bicarbonate ion}}{HCO_3^-}$$

As the double arrows indicate, all the reactions are reversible. Because carbonic acid is a weak acid, undissociated molecules are always present, as are all the other components of the system. The expression describes the system when it is at *dynamic equilibrium*, that is, when the rates of the forward and reverse reactions are equal and the relative concentrations of the components are not changing. A system at dynamic equilibrium tends to stay at equilibrium unless a stress is placed on it, which causes it to shift to reduce the stress until it attains a new dynamic equilibrium. A change in the concentration of any component is one such stress. Therefore, the system can be "shifted to the right" by adding reactants or removing products. Conversely, the system can be "shifted to the left" by adding products or removing reactants.

Hydrogen ions are the important products to consider in this system. The addition of excess hydrogen ions temporarily shifts the system to the left, as they combine with the bicarbonate ions to form carbonic acid. Eventually, a new dynamic equilibrium is established. At this point the hydrogen ion concentration is similar to the original concentration, and the product of the hydrogen ion and hydroxide ion concentrations is restored to the equilibrium value of 1×10^{-14}.

If hydroxide ions are added, they combine with the hydrogen ions to form water, effectively removing a product and thus shifting the system to the right. As this occurs, more carbonic acid ionizes, effectively replacing the hydrogen ions that were removed.

Organisms contain many weak acids and weak bases, which allows them to maintain an essential reserve of buffering capacity and helps them avoid pH extremes.

An acid and a base react to form a salt

When an acid and a base are mixed in water, the H^+ of the acid unites with the OH^- of the base to form a molecule of water. The remainder of the acid (an anion) combines with the remainder of the base (a cation) to form a salt. For example, hydrochloric acid reacts with sodium hydroxide to form water and sodium chloride:

$$HCl + NaOH \longrightarrow H_2O + NaCl$$

A **salt** is a compound in which the hydrogen ion of an acid is replaced by some other cation. Sodium chloride, NaCl, is a salt in which the hydrogen ion of HCl has been replaced by the cation Na^+.

When a salt, an acid, or a base is dissolved in water, its dissociated ions can conduct an electric current; these substances are called electrolytes. Sugars, alcohols, and many other substances do not form ions when dissolved in water; they do not conduct an electric current and are referred to as nonelectrolytes.

Cells and extracellular fluids (such as blood) of animals and plants contain a variety of dissolved salts that are the source of the many important mineral ions essential for fluid balance and acid–base balance. Nitrate and ammonium ions from the soil are the important nitrogen sources for plants. In animals, nerve and muscle function, blood clotting, bone formation, and many other aspects of body function depend on ions. Sodium, potassium, calcium, and magnesium are the chief cations present; chloride, bicarbonate, phosphate, and sulfate are important anions. The concentrations and relative amounts of the various cations and anions are kept remarkably constant. Any marked change results in impaired cell functions and may lead to death.

Review

- A solution has a hydrogen ion concentration of 0.01 mol/L. What is its pH? What is its hydroxide ion concentration? Is it acidic, basic, or neutral? How does this solution differ from one with a pH of 1?
- What would be the consequences of adding or removing a reactant or a product from a reversible reaction that is at dynamic equilibrium?
- Why are buffers important in organisms? Why can't strong acids or bases work as buffers?
- Why are acids, bases, and salts referred to as *electrolytes*?

SUMMARY: FOCUS ON LEARNING OBJECTIVES

2.1 *(page 27)*

1 Name the principal chemical elements in living things and provide an important function of each.

- An **element** is a substance that cannot be decomposed into simpler substances by normal chemical reactions. About 96% of an organism's mass consists of carbon, the backbone of organic molecules; hydrogen and oxygen, the components of water; and nitrogen, a component of proteins and nucleic acids.

2 Compare the physical properties (mass and charge) and locations of electrons, protons, and neutrons. Distinguish between the atomic number and the mass number of an atom.

www.konkur.in

- Each **atom** is composed of a nucleus containing positively charged protons and uncharged **neutrons.** Negatively charged **electrons** encircle the nucleus.
- An atom is identified as belonging to a particular element by its number of protons (**atomic number**). The **atomic mass** of an atom is equal to the sum of its protons and neutrons.
- A single proton or a single neutron each has a mass equivalent to one **atomic mass unit (amu).** The mass of a single electron is only about 1/1800 amu.

3 Define the terms *orbital* and *electron shell.* Relate electron shells to principal energy levels.

- In the space outside the nucleus, electrons move rapidly in electron **orbitals.** An **electron shell** consists of electrons in orbitals at the same **principal energy level.** Electrons in a shell distant from the nucleus have greater energy than those in a shell closer to the nucleus.

CENGAGENOW™ Learn more about atomic orbitals by clicking on the figure in CengageNOW.

2.2 *(page 31)*

4 Explain how the number of valence electrons of an atom is related to its chemical properties.

- The chemical properties of an atom are determined chiefly by the number and arrangement of its most energetic electrons, known as **valence electrons.** The valence shell of most atoms is full when it contains 8 electrons; that of hydrogen or helium is full when it contains 2. An atom tends to lose, gain, or share electrons to fill its valence shell.

5 Distinguish among simplest, molecular, and structural chemical formulas.

- Different atoms are joined by chemical bonds to form **compounds.** A **chemical formula** gives the types and relative numbers of atoms in a substance.
- A **simplest formula** gives the smallest whole-number ratio of the component atoms. A **molecular formula** gives the actual numbers of each type of atom in a molecule. A **structural formula** shows the arrangement of the atoms in a molecule.

6 Explain why the mole concept is so useful to chemists.

- One **mole** (the atomic or molecular mass in grams) of any substance contains 6.02×10^{23} atoms, molecules, or ions, enabling scientists to "count" particles by weighing a sample. This number is known as **Avogadro's number.**

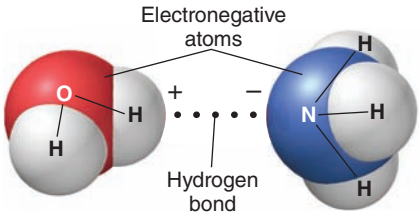
2.3 *(page 32)*

7 Distinguish among covalent bonds, ionic bonds, hydrogen bonds, and van der Waals interactions. Compare them in terms of the mechanisms by which they form and their relative strengths.

- **Covalent bonds** are strong, stable bonds formed when atoms share valence electrons, forming molecules. When covalent bonds are formed, the orbitals of the valence electrons may become rearranged in a process known as **orbital hybridization.** Covalent bonds are **nonpolar** if the electrons are shared equally between the two atoms. Covalent bonds are **polar** if one atom is more **electronegative** (has a greater affinity for electrons) than the other.
- An **ionic bond** is formed between a positively charged **cation** and a negatively charged **anion.** Ionic bonds are strong in the absence of water but relatively weak in aqueous solution.

CENGAGENOW™ Learn more about ionic bonding by clicking on the figure in CengageNOW.

- **Hydrogen bonds** are relatively weak bonds formed when a hydrogen atom with a partial positive charge is attracted to an atom (usually oxygen or nitrogen) with a partial negative charge already bonded to another molecule or in another part of the same molecule.



CENGAGENOW™ Learn more about hydrogen bonding by clicking on the figure in CengageNOW.

- **van der Waals interactions** are weak forces based on fluctuating electric charges.

2.4 *(page 36)*

8 Distinguish between the terms *oxidation* and *reduction,* and relate these processes to the transfer of energy.

- **Oxidation** and **reduction** reactions (**redox reactions**) are chemical processes in which electrons (and their energy) are transferred from a reducing agent to an oxidizing agent. In oxidation, an atom, ion, or molecule loses electrons (and their energy). In reduction, an atom, ion, or molecule gains electrons (and their energy).

2.5 *(page 37)*

9 Explain how hydrogen bonds between adjacent water molecules govern many of the properties of water.

- Water is a **polar molecule** because one end has a partial positive charge and the other has a partial negative charge. Because its molecules are polar, water is an excellent **solvent** for ionic or polar **solutes.**
- Water molecules exhibit the property of **cohesion** because they form hydrogen bonds with one another; they also exhibit **adhesion** through hydrogen bonding to substances with ionic or polar regions.
- Water has a high **heat of vaporization.** Hydrogen bonds must be broken for molecules to enter the vapor phase. These molecules carry a great deal of heat, which accounts for **evaporative cooling.**
- Because hydrogen bonds must be broken to raise its temperature, water has a high **specific heat,** which helps organisms maintain a relatively constant internal temperature; this property also helps keep the ocean and other large bodies of water at a constant temperature.
- The hydrogen bonds between water molecules in ice cause it to be less dense than liquid water. The fact that ice floats makes the aquatic environment less extreme than it would be if ice sank to the bottom.

CENGAGENOW™ Learn more about the three forms of water by clicking on the figure in CengageNOW.

2.6 *(page 40)*

10 Contrast acids and bases, and discuss their properties.

- **Acids** are proton (hydrogen ion, H^+) donors; **bases** are proton acceptors. An acid dissociates in solution to yield H^+ and an anion. Many bases dissociate in solution to yield hydroxide ions (OH^-), which then accept protons to form water.

11 Convert the hydrogen ion concentration (moles per liter) of a solution to a pH value and describe how buffers help minimize changes in pH.

- **pH** is the negative log of the hydrogen ion concentration of a solution (expressed in moles per liter). A **neutral solution** with equal concentrations of H^+ and OH^- (10^{-7} mol/L) has a pH of 7, an **acidic solution** has a pH less than 7, and a **basic solution** has a pH greater than 7.

CENGAGENOW™ Learn more about the pH of common solutions by clicking on the figure in CengageNOW.

www.konkur.in

- A buffering system is based on a weak acid or a weak base. A **buffer** resists changes in the pH of a solution when acids or bases are added.

12 Describe the composition of a salt and explain why salts are important in organisms.

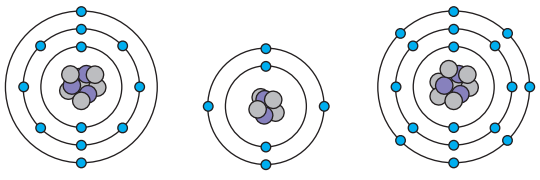
- A **salt** is a compound in which the hydrogen atom of an acid is replaced by some other cation. Salts provide the many mineral ions essential for life functions.

TEST YOUR UNDERSTANDING

1. Which of the following elements is *mismatched* with its properties or function? (a) carbon—forms the backbone of organic compounds (b) nitrogen—component of proteins (c) hydrogen—very electronegative (d) oxygen—can participate in hydrogen bonding (e) all of the above are correctly matched
2. $^{32}_{15}P$, a radioactive form of phosphorus, has (a) an atomic number of 32 (b) an atomic mass of 15 (c) an atomic mass of 47 (d) 32 electrons (e) 17 neutrons
3. Which of the following facts allows you to determine that atom A and atom B are isotopes of the same element? (a) they each have 6 protons (b) they each have 4 neutrons (c) the sum of the electrons and neutrons in each is 14 (d) they each have 4 valence electrons (e) they each have an atomic mass of 14
4. $^{1}_{1}H$ and $^{3}_{1}H$ have (a) different chemical properties because they have different atomic numbers (b) the same chemical properties because they have the same number of valence electrons (c) different chemical properties because they differ in their number of protons and electrons (d) the same chemical properties because they have the same atomic mass (e) the same chemical properties because they have the same number of protons, electrons, and neutrons
5. The orbitals composing an atom's valence electron shell (a) are arranged as concentric spheres (b) contain the atom's least energetic electrons (c) may change shape when covalent bonds are formed (d) never contain more than 1 electron each (e) more than one of the preceding is correct
6. Which of the following bonds and properties are correctly matched? (a) ionic bonds—are strong only if the participating ions are hydrated (b) hydrogen bonds—are responsible for bonding oxygen and hydrogen to form a single water molecule (c) polar covalent bonds—can occur between two atoms of the same element (d) covalent bonds—may be single, double, or triple (e) hydrogen bonds—are stronger than covalent bonds
7. In a redox reaction (a) energy is transferred from a reducing agent to an oxidizing agent (b) a reducing agent becomes oxidized as it accepts an electron (c) an oxidizing agent accepts a proton (d) a reducing agent donates a proton (e) the electrons in an atom move from its valence shell to a shell closer to its nucleus
8. Water has a high specific heat because (a) hydrogen bonds must be broken to raise its temperature (b) hydrogen bonds must be formed to raise its temperature (c) it is a poor insulator (d) it has low density considering the size of the molecule (e) it can ionize
9. A solution at pH 7 is considered neutral because (a) its hydrogen ion concentration is 0 mol/L (b) its hydroxide ion concentration is 0 mol/L (c) the product of its hydrogen ion concentration and its hydroxide ion concentration is 0 mol/L (d) its hydrogen ion concentration is equal to its hydroxide ion concentration (e) it is nonpolar
10. A solution with a pH of 2 has a hydrogen ion concentration that is _____ the hydrogen ion concentration of a solution with a pH of 4. (a) $\frac{1}{2}$ (b) $\frac{1}{100}$ (c) 2 times (d) 10 times (e) 100 times
11. Which of the following cannot function as a buffer? (a) phosphoric acid, a weak acid (b) sodium hydroxide, a strong base (c) sodium chloride, a salt that ionizes completely (d) a and c (e) b and c
12. Which of the following statements is true? (a) the number of individual particles (atoms, ions, or molecules) contained in one mole varies depending on the substance (b) Avogadro's number is the number of particles contained in one mole of a substance (c) Avogadro's number is 10^{23} particles (d) one mole of ^{12}C has a mass of 12 g (e) b and d

CRITICAL THINKING

1. Element A has 2 electrons in its valence shell (which is complete when it contains 8 electrons). Would you expect element A to share, donate, or accept electrons? What would you expect of element B, which has 4 valence electrons, and element C, which has 7?



2. A hydrogen bond formed between two water molecules is only about $\frac{1}{20}$ as strong as a covalent bond between hydrogen and oxygen. In what ways would the physical properties of water be different if these hydrogen bonds were stronger (for example, $\frac{1}{10}$ the strength of covalent bonds)?
3. Consider the following reaction (in water).

$$HCl \longrightarrow H^+ + Cl^-$$

Name the reactant(s) and product(s). Does the expression indicate that the reaction is reversible? Could HCl be used as a buffer?

www.konkur.in

4. **ANALYZING DATA.** Could you safely immerse your hand in a solution containing 0.000,000,000,001 g of H^+ dissolved in 1 L of water?
5. **EVOLUTION LINK.** Initiatives designed to discover evidence for life (biosignatures or biomarkers) in the atmospheres of distant planets have been proposed by the U.S. National Aeronautics and Space Administration (NASA) and the European Space Agency (ESA). If implemented, both the Terrestrial Planet Finder project (NASA) and the Darwin project (ESA) will use special space telescopes to detect atmospheric water vapor, as well as oxygen and carbon dioxide. Which of these biosignatures would you consider the most fundamental indicator that life could have evolved on these planets? Why?

3 The Chemistry of Life: Organic Compounds

© Eastcott/Momatiuk/The Image Works

Humans obtain organic molecules from food. This young girl is using a leaf to feed her baby brother.

KEY CONCEPTS

3.1 Carbon atoms join with one another or other atoms to form large molecules with a wide variety of shapes. Hydrocarbons are nonpolar, hydrophobic molecules; their properties can be altered by adding functional groups: hydroxyl and carbonyl groups (polar), carboxyl and phosphate groups (acidic), and amino groups (basic).

3.2 Carbohydrates are composed of sugar subunits (monosaccharides), which can be joined to form disaccharides, storage polysaccharides, and structural polysaccharides.

3.3 Lipids store energy (triacylglycerols) and are the main structural components of cell membranes (phospholipids).

3.4 Proteins have multiple levels of structure and are composed of amino acid subunits joined by peptide bonds.

3.5 Nucleic acids (DNA and RNA) are informational molecules composed of long chains of nucleotide subunits. ATP and some other nucleotides have a central role in energy metabolism.

3.6 Biological molecules have recognizable attributes that aid in their identification.

Both inorganic and organic forms of carbon occur widely in nature. Many types of organic compounds will become incorporated into the body of the baby in the photograph as he grows. Organic compounds are those in which carbon atoms are covalently bonded to one another to form the backbone of the molecule. Some very simple carbon compounds are considered inorganic if the carbon is not bonded to another carbon or to hydrogen. The carbon dioxide we exhale as a waste product from the breakdown of organic molecules to obtain energy is an example of an inorganic carbon compound. Organic compounds are so named because at one time it was thought that they could be produced only by living (organic) organisms. In 1828, the German chemist Friedrich Wühler synthesized urea, a metabolic waste product. Since that time, scientists have learned to synthesize many organic molecules and have discovered organic compounds not found in any organism.

Organic compounds are extraordinarily diverse; in fact, more than 5 million have been identified. There are many reasons for this diversity. Organic compounds can be produced in a wide variety of three-dimensional (3-D) shapes. Furthermore, the carbon atom forms bonds

www.konkur.in

with a greater number of different elements than does any other type of atom. The addition of chemical groups containing atoms of other elements—especially oxygen, nitrogen, phosphorus, and sulfur—can profoundly change the properties of an organic molecule. Diversity also results from the fact that many organic compounds found in organisms are extremely large *macromolecules,* which cells construct from simpler modular subunits. For example, protein molecules are built from smaller compounds called *amino acids.*

As you study this chapter, you will develop an understanding of the major groups of organic compounds found in organisms, including carbohydrates, lipids, proteins, and nucleic acids (DNA and RNA). Why are these compounds of central importance to all living things? The answer to this question will become more obvious as you study subsequent chapters, in which we explore the evidence that all living things evolved from a common ancestor. Evolution provides a powerful explanation for the similarities of the molecules that constitute the structures of cells and tissues, participate in and regulate metabolic reactions, transmit information, and provide energy for life processes.

3.1 CARBON ATOMS AND ORGANIC MOLECULES

LEARNING OBJECTIVES

1. Describe the properties of carbon that make it the central component of organic compounds.
2. Define the term *isomer* and distinguish among the three principal isomer types.
3. Identify the major functional groups present in organic compounds and describe their properties.
4. Explain the relationship between polymers and macromolecules.

Carbon has unique properties that allow the formation of the carbon backbones of the large, complex molecules essential to life (**FIG. 3-1**). Because a carbon atom has 4 valence electrons, it can complete its valence shell by forming a total of four covalent bonds (see Fig. 2-2). Each bond can link it to another carbon atom or to an atom of a different element. Carbon is particularly well suited to serve as the backbone of a large molecule because carbon-to-carbon bonds are strong and not easily broken. However, they are not so strong that it would be impossible for cells to break them. Carbon-to-carbon bonds are not limited to single bonds (based

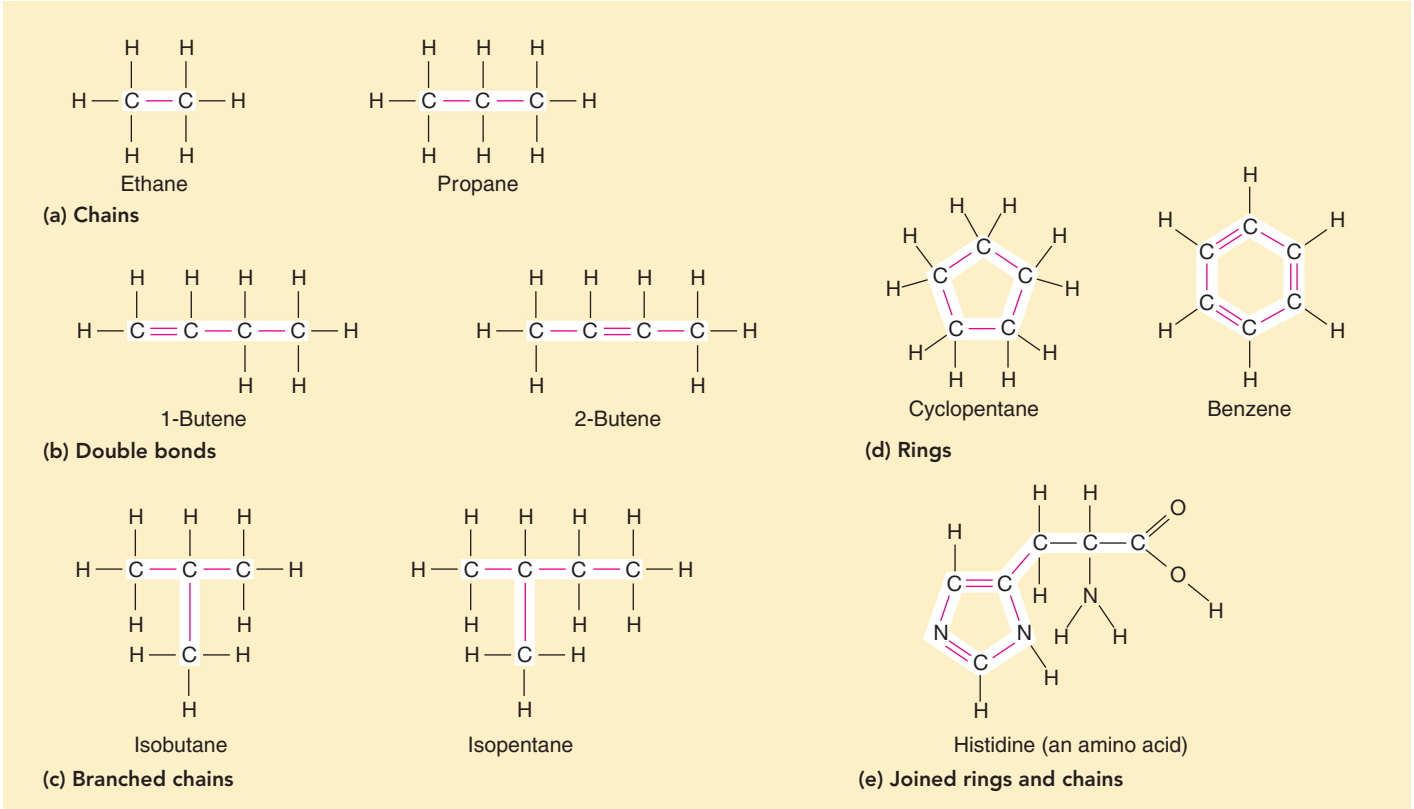

FIGURE 3-1 Organic molecules
Note that each carbon atom forms four covalent bonds, producing a wide variety of shapes.

www.konkur.in

on sharing one electron pair). Two carbon atoms can share two electron pairs with each other, forming double bonds:

$$>C{=}C<$$

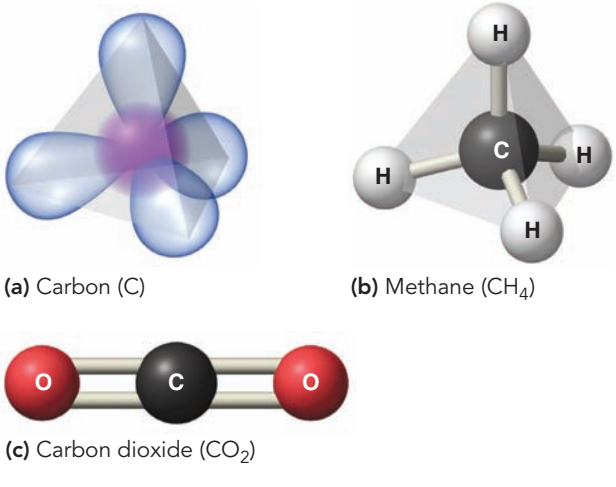
In some compounds, triple carbon-to-carbon bonds are formed:

$$-C{\equiv}C-$$

As shown in Figure 3-1, **hydrocarbons,** organic compounds consisting only of carbon and hydrogen, can exist as unbranched or branched chains, or as rings. Rings and chains are joined in some compounds.

The molecules in the cell are analogous to the components of a machine. Each component has a shape that allows it to fill certain roles and to interact with other components (often with a complementary shape). Similarly, the shape of a molecule is important in determining its biological properties and function. Carbon atoms can link to one another and to other atoms to produce a wide variety of 3-D molecular shapes because the four covalent bonds of carbon do not form in a single plane. Instead, as discussed in Chapter 2, the valence electron orbitals become elongated and project from the carbon atom toward the corners of a tetrahedron (**FIG. 3-2**). The structure is highly symmetrical, with an angle of about 109.5 degrees between any two of these bonds. Keep in mind that for simplicity, many of the figures in this book are drawn as two-dimensional (2-D) graphic representations of 3-D molecules. Even the simplest hydrocarbon chains, such as those in Figure 3-1, are not actually straight but have a 3-D zigzag structure.

Generally, there is freedom of rotation around each carbon-to-carbon single bond. This property permits organic molecules to be flexible and to assume a variety of shapes, depending on the extent to which each single bond is rotated. Double and triple bonds do not allow rotation, so regions of a molecule with such bonds tend to be inflexible.



(a) Carbon (C)

(b) Methane (CH_4)

(c) Carbon dioxide (CO_2)

FIGURE 3-2 Carbon bonding

(a) The 3-D arrangement of the bonds of a carbon atom is responsible for **(b)** the tetrahedral architecture of methane. **(c)** In carbon dioxide, oxygen atoms are joined linearly to a central carbon by polar double bonds.

Isomers have the same molecular formula but different structures

One reason for the great number of possible carbon-containing compounds is the fact that the same components usually can link in more than one pattern, generating an even wider variety of molecular shapes. Compounds with the same molecular formulas but different structures and thus different properties are called **isomers.** Isomers do not have identical physical or chemical properties and may have different common names. Cells can distinguish between isomers. Usually, one isomer is biologically active and the other is not. Three types of isomers are structural isomers, geometric isomers, and enantiomers.

Structural isomers are compounds that differ in the covalent arrangements of their atoms. For example, **FIGURE 3-3a** illustrates two structural isomers with the molecular formula C_2H_6O. Large compounds have more possible structural isomers. There can be up to 366,319 isomers of $C_{20}H_{42}$.

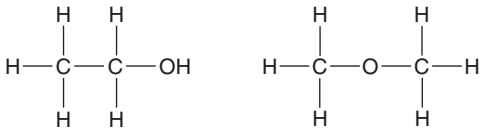
Geometric isomers are compounds that are identical in the arrangement of their covalent bonds but different in the spatial arrangement of atoms or groups of atoms. Geometric isomers are present in some compounds with carbon-to-carbon double bonds. Because double bonds are not flexible, as single bonds are, atoms joined to the carbons of a double bond cannot rotate freely about the axis of the bonds. These *cis–trans* isomers may be represented as shown in **FIGURE 3-3b**. The designation *cis* (Latin, "on this side") indicates that the two larger components are on the same side of the double bond. If they are on opposite sides of the double bond, the compound is designated a *trans* (Latin, "across") isomer.

Enantiomers are isomers that are mirror images of each other (**FIG. 3-3c**). Recall that the four groups bonded to a single carbon atom are arranged at the vertices of a tetrahedron. If the four bonded groups are all different, the central carbon is described as asymmetrical. Figure 3-3c illustrates that the four groups can be arranged around the asymmetrical carbon in two different ways that are mirror images of each other. The two molecules are enantiomers if they cannot be superimposed on each other no matter how they are rotated in space. Although enantiomers have similar chemical properties and most of their physical properties are identical, cells recognize the difference in shape, and usually only one form is found in organisms.

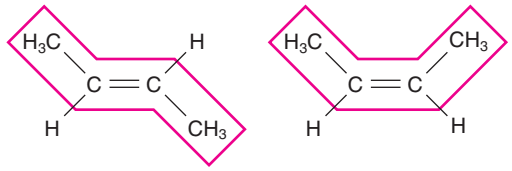
Functional groups change the properties of organic molecules

The existence of isomers is not the only source of variety among organic molecules. The addition of various combinations of atoms generates a vast array of molecules with different properties. Because covalent bonds between hydrogen and carbon are nonpolar, **hydrocarbons** lack distinct charged regions. For this reason, hydrocarbons are insoluble in water and tend to cluster together through **hydrophobic** interactions. "Water fearing," the literal meaning of the term *hydrophobic,* is somewhat misleading. Hydrocarbons interact with water, but much more weakly than the water molecules cohere to one another through hydrogen bonding.

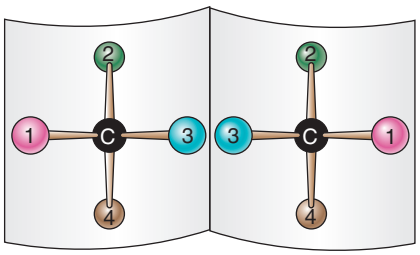
www.konkur.in



(a) Structural isomers. Structural isomers differ in the covalent arrangement of their atoms.



(b) Geometric isomers. Geometric, or *cis–trans*, isomers have identical covalent bonds but differ in the order in which groups are arranged in space.



(c) Enantiomers. Enantiomers are isomers that are mirror images of each other. The central carbon is asymmetrical because it is bonded to four different groups. Because of their 3-D structure, the two figures cannot be superimposed no matter how they are rotated.

FIGURE 3-3 Isomers

Isomers have the same molecular formula, but their atoms are arranged differently.

Hydrocarbons interact weakly with one another, but the main reason for hydrophobic interactions is that they are driven together in a sense, having been excluded by the hydrogen-bonded water molecules.

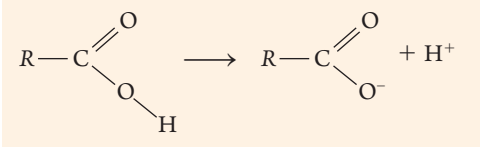
However, the characteristics of an organic molecule can be changed dramatically by replacing one of the hydrogens with one or more **functional groups,** groups of atoms that determine the types of chemical reactions and associations in which the compound participates. Most functional groups readily form associations, such as ionic and hydrogen bonds, with other molecules. Polar and ionic functional groups are **hydrophilic** because they associate strongly with polar water molecules.

The properties of the major classes of biologically important organic compounds—carbohydrates, lipids, proteins, and nucleic acids—are largely a consequence of the types and arrangement of functional groups they contain. When we know what kinds of functional groups are present in an organic compound, we can predict its chemical behavior. Note that the symbol *R* is used to represent the *remainder* of the molecule of which each functional group is a part. For example, the **methyl group,** a common nonpolar hydrocarbon group, is abbreviated *R*—CH_3. As you read the rest of this section, refer to **TABLE 3-1** for the structural formulas of other important functional groups, as well as for additional information.

The **hydroxyl group** (abbreviated *R*—OH) is polar because of the presence of a strongly electronegative oxygen atom. Do not confuse it with the hydroxide ion, OH^-, discussed in Chapter 2. If a hydroxyl group replaces one hydrogen of a hydrocarbon, the resulting molecule can have significantly altered properties. For example, ethane (see Fig. 3-1a) is a hydrocarbon that is a gas at room temperature. If a hydroxyl group replaces a hydrogen atom, the resulting molecule is ethyl alcohol, or ethanol, which is found in alcoholic beverages (see Fig. 3-3a). Ethanol is somewhat cohesive because the polar hydroxyl groups of adjacent molecules interact; it is therefore liquid at room temperature. Unlike ethane, ethyl alcohol dissolves in water because the polar hydroxyl groups interact with the polar water molecules.

The **carbonyl group** consists of a carbon atom that has a double covalent bond with an oxygen atom. This double bond is polar because of the electronegativity of the oxygen; thus, the carbonyl group is hydrophilic. The position of the carbonyl group in the molecule determines the class to which the molecule belongs. An **aldehyde** has a carbonyl group positioned at the end of the carbon skeleton (abbreviated *R*—CHO); a **ketone** has an internal carbonyl group (abbreviated *R*—CO—*R*).

The **carboxyl group** (abbreviated *R*—COOH) in its nonionized form consists of a carbon atom joined by a double covalent bond to an oxygen atom, and by a single covalent bond to another oxygen, which is in turn bonded to a hydrogen atom. Two electronegative oxygen atoms in such close proximity establish an extremely polarized condition, which can cause the hydrogen atom to be stripped of its electron and released as a hydrogen ion (H^+). The resulting ionized carboxyl group has 1 unit of negative charge (R—COO^-):



Carboxyl groups are weakly acidic; only a fraction of the molecules ionize in this way. This group therefore exists in one of

www.konkur.in

TABLE 3-1 Some Biologically Important Functional Groups

Functional Group and Description	Structural Formula	Class of Compound Characterized by Group
Hydroxyl Polar because electronegative oxygen attracts covalent electrons		Alcohols  Example, ethanol
Carbonyl **Aldehydes:** Carbonyl group carbon is bonded to at least one H atom; polar because electronegative oxygen attracts covalent electrons		Aldehydes  Example, formaldehyde
Ketones: Carbonyl group carbon is bonded to two other carbons; polar because electronegative oxygen attracts covalent electrons		Ketones  Example, acetone
Carboxyl Weakly acidic; can release an H^+	 Non-ionized  Ionized	Carboxylic acids (organic acids)  Example, amino acid
Amino Weakly basic; can accept an H^+	 Non-ionized  Ionized	Amines  Example, amino acid
Phosphate Weakly acidic; one or two H^+ can be released	 Non-ionized  Ionized	Organic Phosphates  Example, phosphate ester (as found in ATP)
Sulfhydryl Helps stabilize internal structure of proteins		Thiols  Example, cysteine

two hydrophilic states: ionic or polar. Carboxyl groups are essential constituents of amino acids.

An **amino group** (abbreviated R—NH_2) in its non-ionized form includes a nitrogen atom covalently bonded to two hydrogen atoms. Amino groups are weakly basic because they are able to accept a hydrogen ion (proton). The resulting ionized amino group has 1 unit of positive charge (R—NH_3^+). Amino groups are components of amino acids and of nucleic acids.

A **phosphate group** (abbreviated R—PO_4H_2) is weakly acidic. The attraction of electrons by the oxygen atoms can result in

www.konkur.in

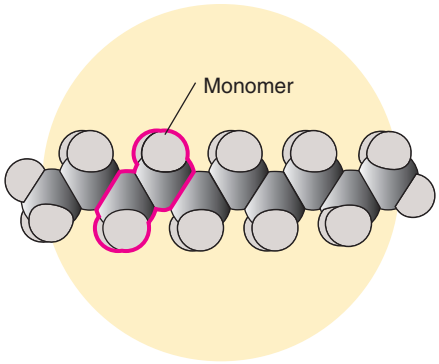


FIGURE 3-4 A simple polymer

This small polymer of polyethylene is formed by linking two-carbon ethylene (C_2H_4) monomers. One such monomer is outlined in red. The structure is represented by a space-filling model, which accurately depicts the 3-D shape of the molecule.

the release of one or two hydrogen ions, producing ionized forms with 1 or 2 units of negative charge. Phosphates are constituents of nucleic acids and certain lipids.

The **sulfhydryl group** (abbreviated *R*—SH), consisting of an atom of sulfur covalently bonded to a hydrogen atom, is found in molecules called *thiols*. As you will see, amino acids that contain a sulfhydryl group can make important contributions to the structure of proteins.

Many biological molecules are polymers

Many biological molecules such as proteins and nucleic acids are very large, consisting of thousands of atoms. Such giant molecules are known as **macromolecules.** Most macromolecules are **polymers,** produced by linking small organic compounds called **monomers** (FIG. 3-4). Just as all the words in this book have been written by arranging the 26 letters of the alphabet in various combinations, monomers can be grouped to form an almost infinite variety of larger molecules. The thousands of different complex organic compounds present in organisms are constructed from about 40 small, simple monomers. For example, the 20 monomers called *amino acids* can be linked end to end in countless ways to form the polymers known as *proteins.*

Polymers can be degraded to their component monomers by **hydrolysis reactions** ("to break with water"). In a reaction regulated by a specific enzyme (biological catalyst), a hydrogen from a water molecule attaches to one monomer, and a hydroxyl from water attaches to the adjacent monomer (FIG. 3-5).

Monomers become covalently linked by **condensation reactions.** Because the *equivalent* of a molecule of water is removed during the reactions that combine monomers, the term *dehydration synthesis* is sometimes used to describe condensation (see Fig. 3-5). However, in biological systems the synthesis of a polymer is not simply the reverse of hydrolysis, even though the net effect is the opposite of hydrolysis. Synthetic processes such as condensation require energy and are regulated by different enzymes.

In the following sections we examine carbohydrates, lipids, proteins, and nucleic acids. Our discussion begins with the smaller, simpler forms of these compounds and extends to the linking of these monomers to form macromolecules.

Review

- What are some of the ways that the features of carbon-to-carbon bonds influence the stability and 3-D structure of organic molecules?
- Draw pairs of simple sketches comparing two (1) structural isomers, (2) geometric isomers, and (3) enantiomers. Why are these differences biologically important?
- Sketch the following functional groups: methyl, amino, carbonyl, hydroxyl, carboxyl, and phosphate. Include both non-ionized and ionized forms for acidic and basic groups.
- How is the fact that a group is nonpolar, polar, acidic, or basic related to its hydrophilic or hydrophobic properties?
- Why is the equivalent of a water molecule important to both condensation reactions and hydrolysis reactions?

3.2 CARBOHYDRATES

LEARNING OBJECTIVE

5 Distinguish among monosaccharides, disaccharides, and polysaccharides; compare storage polysaccharides with structural polysaccharides.

Sugars, starches, and cellulose are **carbohydrates.** Sugars and starches serve as energy sources for cells; cellulose is the main structural component of the walls that surround plant cells. Carbohydrates contain carbon, hydrogen, and oxygen atoms in a ratio of approximately one carbon to two hydrogens to one oxygen $(CH_2O)_n$. The term *carbohydrate,* meaning "hydrate (water) of

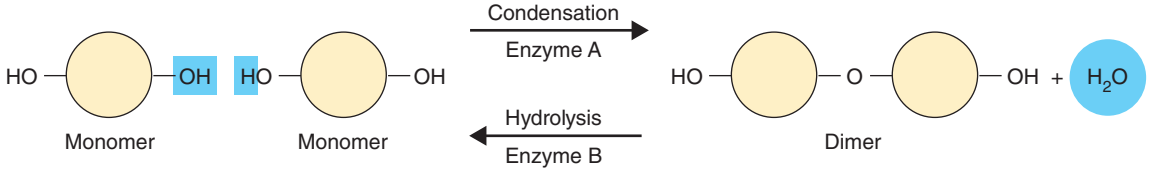

FIGURE 3-5 *Animated* Condensation and hydrolysis reactions

Joining two monomers yields a dimer; incorporating additional monomers produces a polymer. Note that condensation and hydrolysis reactions are catalyzed by different enzymes.

www.konkur.in

carbon," reflects the 2:1 ratio of hydrogen to oxygen, the same ratio found in water (H_2O). Carbohydrates contain one sugar unit (monosaccharides), two sugar units (disaccharides), or many sugar units (polysaccharides).

Monosaccharides are simple sugars

Monosaccharides typically contain from three to seven carbon atoms. In a monosaccharide, a hydroxyl group is bonded to each carbon except one; that carbon is double-bonded to an oxygen atom, forming a carbonyl group. If the carbonyl group is at the end of the chain, the monosaccharide is an aldehyde; if the carbonyl group is at any other position, the monosaccharide is a ketone. (By convention, the numbering of the carbon skeleton of a sugar begins with the carbon at or nearest the carbonyl end of the open chain.)

The large number of polar hydroxyl groups, plus the carbonyl group, gives a monosaccharide hydrophilic properties. **FIGURE 3-6** shows simplified, 2-D representations of some common monosaccharides. The simplest carbohydrates are the three-carbon sugars (trioses): glyceraldehyde and dihydroxyacetone. Ribose and deoxyribose are common pentoses, sugars that contain five carbons; they are components of nucleic acids (DNA, RNA, and related compounds). Glucose, fructose, galactose, and other six-carbon sugars are called hexoses. (Note that the names of carbohydrates typically end in *-ose*.)

Glucose ($C_6H_{12}O_6$), the most abundant monosaccharide, is used as an energy source in most organisms. During cellular respiration (see Chapter 8), cells oxidize glucose molecules, converting the stored energy to a form that can be readily used for cell work. Glucose is also used in the synthesis of other types of compounds

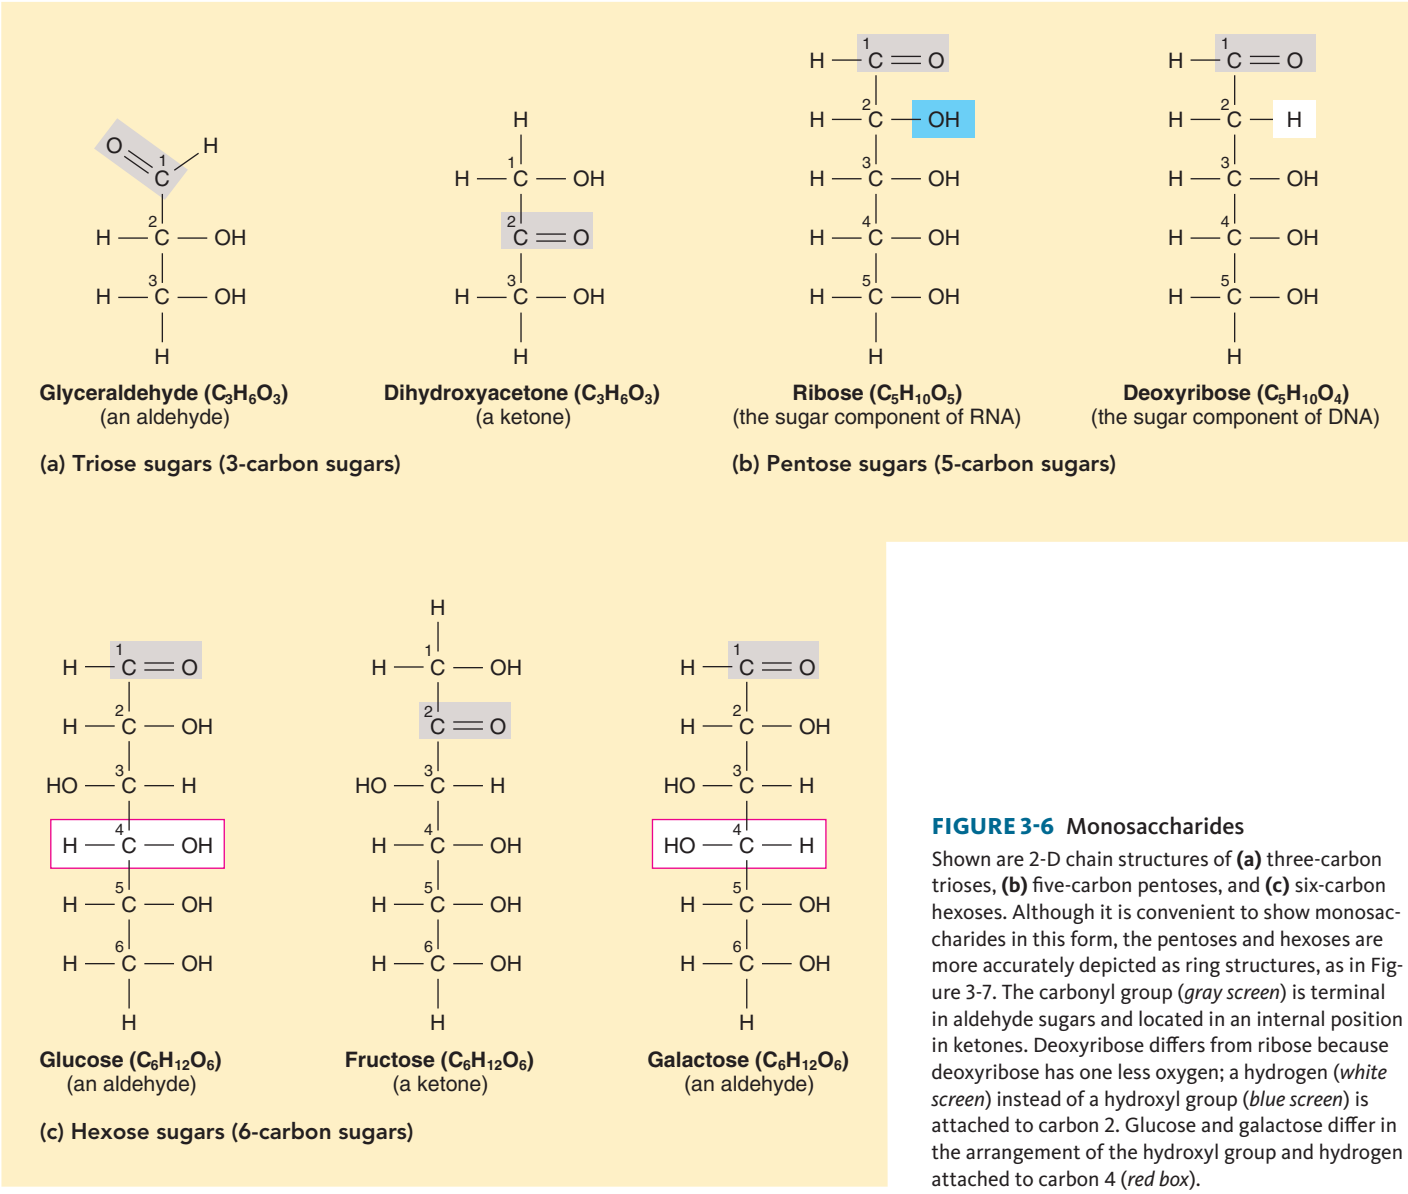

FIGURE 3-6 Monosaccharides

Shown are 2-D chain structures of **(a)** three-carbon trioses, **(b)** five-carbon pentoses, and **(c)** six-carbon hexoses. Although it is convenient to show monosaccharides in this form, the pentoses and hexoses are more accurately depicted as ring structures, as in Figure 3-7. The carbonyl group (*gray screen*) is terminal in aldehyde sugars and located in an internal position in ketones. Deoxyribose differs from ribose because deoxyribose has one less oxygen; a hydrogen (*white screen*) instead of a hydroxyl group (*blue screen*) is attached to carbon 2. Glucose and galactose differ in the arrangement of the hydroxyl group and hydrogen attached to carbon 4 (*red box*).

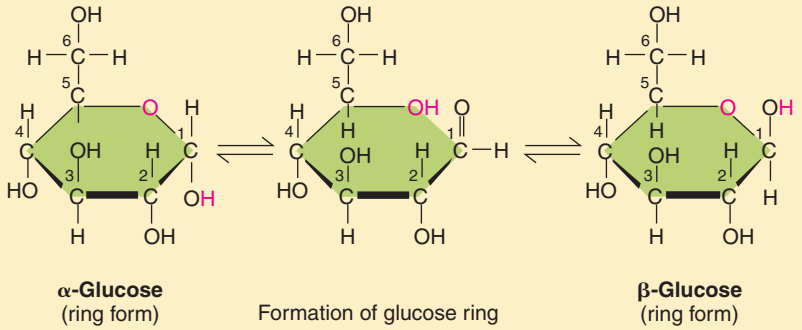
www.konkur.in

such as amino acids and fatty acids. Glucose is so important in metabolism that mechanisms have evolved to maintain its concentration at relatively constant levels in the blood of humans and other complex animals (see Chapter 49).

Glucose and fructose are structural isomers: they have identical molecular formulas, but their atoms are arranged differently. In fructose (a ketone) the double-bonded oxygen is linked to a carbon within the chain rather than to a terminal carbon as in glucose (an aldehyde). Because of these differences, the two sugars have different properties. For example, fructose, found in honey and some fruits, tastes sweeter than glucose.

Glucose and galactose are both hexoses and aldehydes. However, they differ in the arrangement of the atoms attached to asymmetrical carbon atom 4.

The linear formulas in Figure 3-6 give a clear but somewhat unrealistic picture of the structures of some common monosaccharides. As we have mentioned, molecules are not 2-D; in fact, the properties of each compound depend largely on its 3-D structure. Thus, 3-D formulas are helpful in understanding the relationship between molecular structure and biological function.



(a) When dissolved in water, glucose undergoes a rearrangement of its atoms, forming one of two possible ring structures: α-glucose or β-glucose. Although the drawing does not show the complete 3-D structure, the thick, tapered bonds in the lower portion of each ring represent the part of the molecule that would project out of the page toward you.

(b) The essential differences between α-glucose and β-glucose are more readily apparent in these simplified structures. By convention, a carbon atom is assumed to be present at each angle in the ring unless another atom is shown. Most hydrogen atoms have been omitted.

FIGURE 3-7 *α* and *β* forms of glucose

Molecules of glucose and other pentoses and hexoses in solution are actually rings rather than extended straight carbon chains.

Glucose in solution (as in the cell) typically exists as a ring of five carbons and one oxygen. It assumes this configuration when its atoms undergo a rearrangement, permitting a covalent bond to connect carbon 1 to the oxygen attached to carbon 5 (**FIG. 3-7**). When glucose forms a ring, two isomeric forms are possible, differing only in orientation of the hydroxyl (—OH) group attached to carbon 1. When this hydroxyl group is on the same side of the plane of the ring as the —CH_2OH side group, the glucose is designated beta glucose (*β*-glucose). When it is on the side (with respect to the plane of the ring) opposite the —CH_2OH side group, the compound is designated alpha glucose (*α*-glucose). Although the differences between these isomers may seem small, they have important consequences when the rings join to form polymers.

Disaccharides consist of two monosaccharide units

A **disaccharide** (two sugars) contains two monosaccharide rings joined by a glycosidic linkage, consisting of a central oxygen covalently bonded to two carbons, one in each ring (**FIG. 3-8**). The **glycosidic linkage** of a disaccharide generally forms between carbon 1 of one molecule and carbon 4 of the other molecule. The disaccharide maltose (malt sugar) consists of two covalently linked *α*-glucose units. Sucrose, common table sugar, consists of a glucose unit combined with a fructose unit. Lactose (the sugar present in milk) consists of one molecule of glucose and one of galactose.

As shown in Figure 3-8, a disaccharide can be hydrolyzed, that is, split by the addition of water, into two monosaccharide units. During digestion, maltose is hydrolyzed to form two molecules of glucose:

$$\text{maltose} + \text{water} \longrightarrow \text{glucose} + \text{glucose}$$

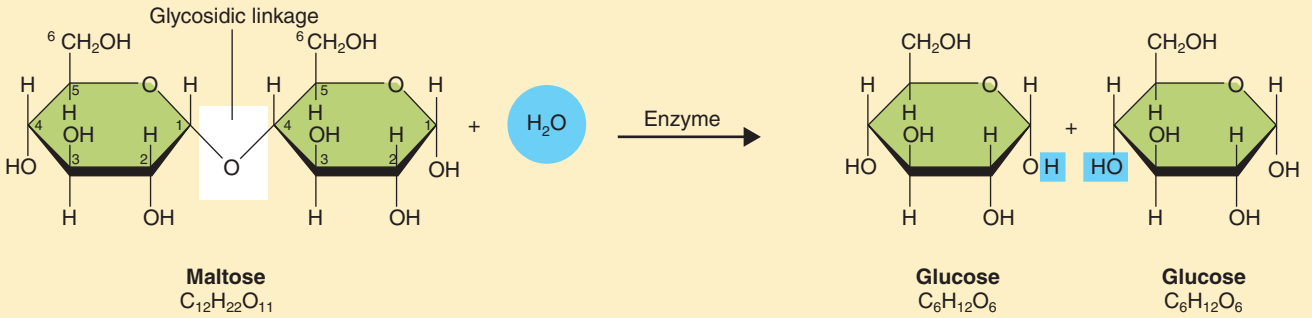
Similarly, sucrose is hydrolyzed to form glucose and fructose:

$$\text{sucrose} + \text{water} \longrightarrow \text{glucose} + \text{fructose}$$

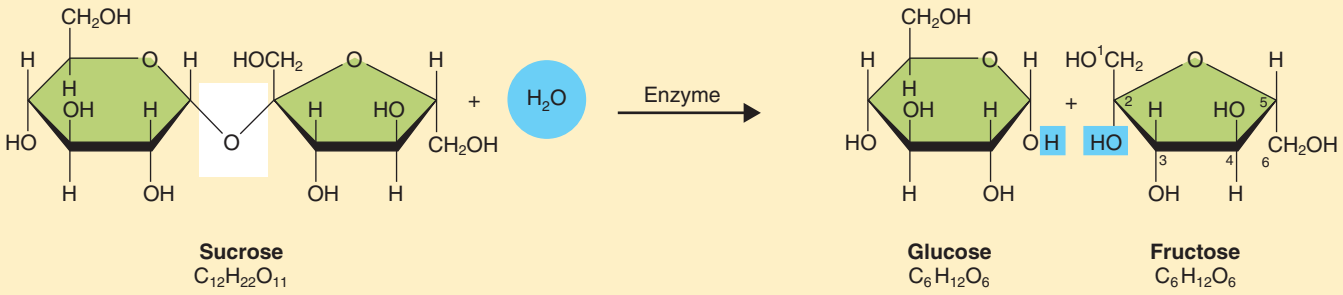
Polysaccharides can store energy or provide structure

A **polysaccharide** is a macromolecule consisting of repeating units of simple sugars, usually glucose. The polysaccharides are the most abundant carbohydrates and include starches, glycogen, and

www.konkur.in



(a) Maltose may be broken down (as during digestion) to form two molecules of glucose.The glycosidic linkage is broken in a hydrolysis reaction, which requires the addition of water.



(b) Sucrose can be hydrolyzed to yield a molecule of glucose and a molecule of fructose.

FIGURE 3-8 Hydrolysis of disaccharides
Note that an enzyme is needed to promote these reactions.

cellulose. Although the precise number of sugar units varies, thousands of units are typically present in a single molecule. A polysaccharide may be a single long chain or a branched chain.

Because they are composed of different isomers and because the units may be arranged differently, polysaccharides vary in their properties. Those that can be easily broken down to their subunits are well suited for energy storage, whereas the macromolecular 3-D architecture of others makes them particularly well suited to form stable structures.

Starch, the typical form of carbohydrate used for energy storage in plants, is a polymer consisting of α-glucose subunits. These monomers are joined by α 1—4 linkages, which means that carbon 1 of one glucose is linked to carbon 4 of the next glucose in the chain (**FIG. 3-9**). Starch occurs in two forms: amylose and amylopectin. Amylose, the simpler form, is unbranched. Amylopectin, the more common form, usually consists of about 1000 glucose units in a branched chain.

Plant cells store starch mainly as granules within specialized organelles called **amyloplasts** (see Fig. 3-9a); some cells, such as those of potatoes, are very rich in amyloplasts. When energy is needed for cell work, the plant hydrolyzes the starch, releasing the glucose subunits. Virtually all organisms, including humans and other animals, have enzymes that can break α 1—4 linkages.

Glycogen (sometimes referred to as *animal starch*) is the form in which glucose subunits, joined by α 1—4 linkages, are stored as an energy source in animal tissues. Glycogen is similar in structure to plant starch but more extensively branched and more water soluble. In vertebrates, glycogen is stored mainly in liver and muscle cells.

Carbohydrates are the most abundant group of organic compounds on Earth, and cellulose is the most abundant carbohydrate; it accounts for 50% or more of all the carbon in plants (**FIG. 3-10**). Cellulose is a structural carbohydrate. Wood is about half cellulose, and cotton is at least 90% cellulose. Plant cells are surrounded by strong supporting cell walls consisting mainly of cellulose.

Cellulose is an insoluble polysaccharide composed of many joined glucose molecules. The bonds joining these sugar units are different from those in starch. Recall that starch is composed of α-glucose subunits, joined by α 1—4 glycosidic linkages. Cellulose contains β-glucose monomers joined by β 1—4 linkages. These bonds cannot be split by the enzymes that hydrolyze the α linkages in starch. Because humans, like other animals, lack enzymes that digest cellulose, we cannot use it as a nutrient. The cellulose found in whole grains and vegetables remains fibrous and provides bulk that helps keep our digestive tract functioning properly.

Some microorganisms digest cellulose to glucose. In fact, cellulose-digesting bacteria live in the digestive systems of cows

www.konkur.in

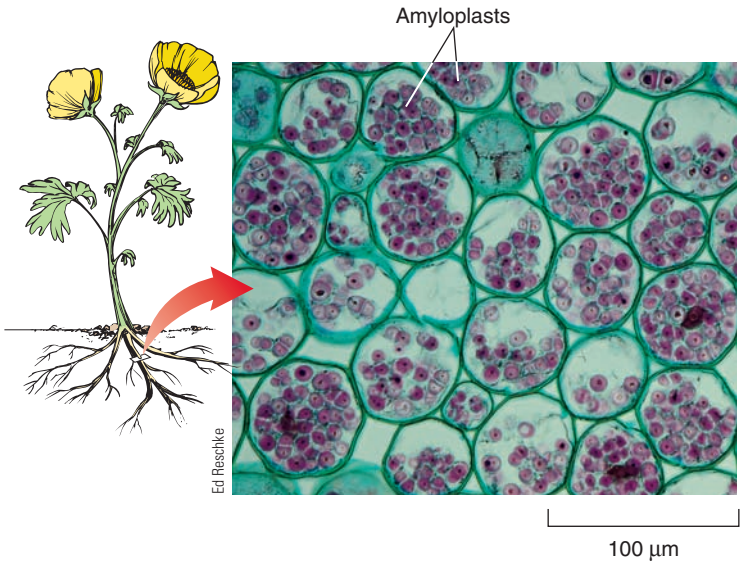
and sheep, enabling these grass-eating animals to obtain nourishment from cellulose. Similarly, the digestive systems of termites contain microorganisms that digest cellulose (see Fig. 26-4b).

Cellulose molecules are well suited for a structural role. The β-glucose subunits are joined in a way that allows extensive hydrogen bonding among different cellulose molecules, and they aggregate in long bundles of fibers (see Fig. 3-10a).

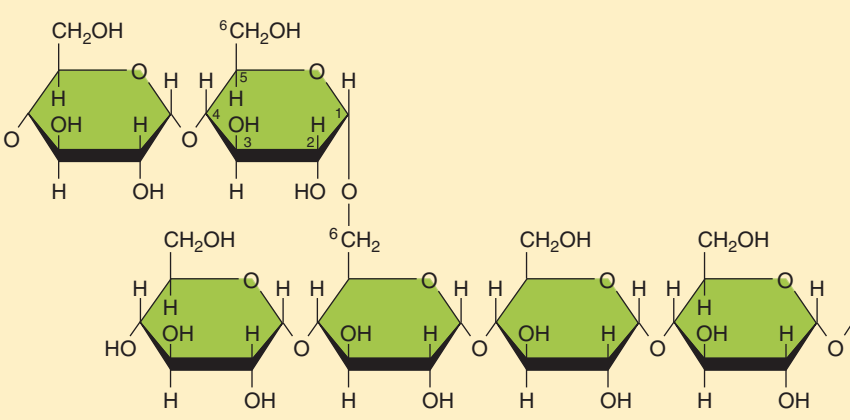
Some modified and complex carbohydrates have special roles

Many derivatives of monosaccharides are important biological molecules. Some form important structural components. The amino sugars galactosamine and glucosamine are compounds in which a hydroxyl group (—OH) is replaced by an amino group ($—NH_2$). Galactosamine is present in cartilage, a constituent of the skeletal system of vertebrates. *N*-acetyl glucosamine (NAG) subunits, joined by glycosidic bonds, compose **chitin,** a main component of the cell walls of fungi and of the external skeletons of insects, crayfish, and other arthropods (**FIG. 3-11**). Chitin forms very tough structures because, as in cellulose, its molecules interact through multiple hydrogen bonds. Some chitinous structures, such as the shell of a lobster, are further hardened by the addition of calcium carbonate ($CaCO_3$), an inorganic form of carbon.

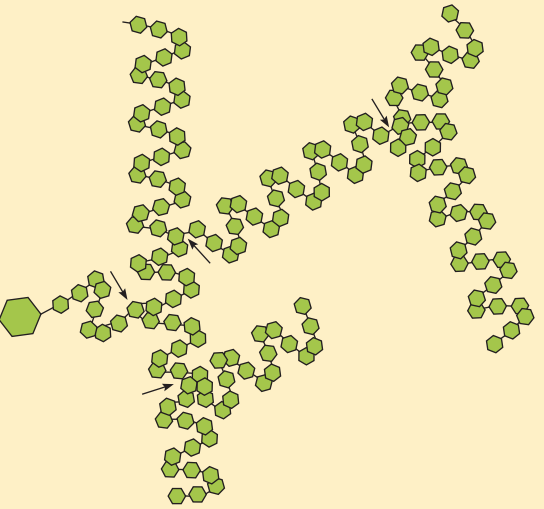
Carbohydrates may also combine with proteins to form **glycoproteins,** compounds present on the outer surface of cells other than bacteria. Some of these carbohydrate chains allow cells to adhere to one another, whereas others provide protection. Most proteins secreted by cells are glycoproteins. These include the major components of mucus, a protective material secreted by the mucous membranes of the respiratory and digestive systems. Carbohydrates combine with lipids to form glycolipids, compounds on the surfaces of animal cells that allow cells to recognize and interact with one another.



(a) Starch (*stained purple*) is stored in specialized organelles, called *amyloplasts,* in these cells of a buttercup root.



(b) Starch is composed of α-glucose molecules joined by glycosidic bonds. At the branch points are bonds between carbon 6 of the glucose in the straight chain and carbon 1 of the glucose in the branching chain.



(c) Starch consists of highly branched chains; the arrows indicate the branch points. Each chain is actually a coil or helix, stabilized by hydrogen bonds between the hydroxyl groups of the glucose subunits.

FIGURE 3-9 Starch, a storage polysaccharide

www.konkur.in

Review

- What features related to hydrogen bonding give storage polysaccharides, such as starch and glycogen, different properties from structural polysaccharides, such as cellulose and chitin?
- Why can't humans digest cellulose?

3.3 LIPIDS

LEARNING OBJECTIVE

6 Distinguish among fats, phospholipids, and steroids, and describe the composition, characteristics, and biological functions of each.

Unlike carbohydrates, which are defined by their structure, **lipids** are a heterogeneous group of compounds that are categorized by the fact that they are soluble in nonpolar solvents (such as ether and chloroform) and are relatively insoluble in water. Lipid molecules have these properties because they consist mainly of carbon and hydrogen, with few oxygen-containing functional groups. Hydrophilic functional groups typically contain oxygen atoms; therefore, lipids, which have little oxygen, tend to be hydrophobic. Among the biologically important groups of lipids are fats, phospholipids, carotenoids (orange and yellow plant pigments), steroids, and waxes. Some lipids are used for energy storage, others serve as structural components of cell membranes, and some are important hormones.

www.konkur.in

Triacylglycerol is formed from glycerol and three fatty acids

The most abundant lipids in living organisms are **triacylglycerols.** These compounds, commonly known as *fats,* are an economical form of reserve fuel storage because, when metabolized, they yield more than twice as much energy per gram as do carbohydrates. Carbohydrates and proteins can be transformed by enzymes into fats and stored within the cells of adipose (fat) tissue of animals and in some seeds and fruits of plants.

A triacylglycerol molecule (also known as a *triglyceride*) consists of glycerol joined to three fatty acids (**FIG. 3-12**). **Glycerol** is a three-carbon alcohol that contains three hydroxyl (—OH) groups, and a **fatty acid** is a long, unbranched hydrocarbon chain with a carboxyl group (—COOH) at one end. A triacylglycerol molecule is formed by a series of three condensation reactions. In each reaction, the equivalent of a water molecule is removed as one of the glycerol's hydroxyl groups reacts with the carboxyl group of a fatty acid, resulting in the formation of a covalent linkage known as an **ester linkage** (see Fig. 3-12b). The first reaction yields a **monoacylglycerol** (*monoglyceride*); the second, a **diacylglycerol** (*diglyceride*); and the third, a triacylglycerol. During digestion, triacylglycerols are hydrolyzed to produce fatty acids and glycerol (see Chapter 47). Diacylglycerol is an important molecule for sending signals within the cell (see Chapters 6 and 49).

Saturated and unsaturated fatty acids differ in physical properties

About 30 different fatty acids are commonly found in lipids, and they typically have an even number of carbon atoms. For example, butyric acid, present in rancid butter, has four carbon atoms. Oleic acid, with 18 carbons, is the most widely distributed fatty acid in nature and is found in most animal and plant fats.

Saturated fatty acids contain the maximum possible number of hydrogen atoms. Palmitic acid, a 16-carbon fatty acid, is a common saturated fatty acid (see Fig. 3-12c). Fats high in saturated fatty acids, such as animal fat and solid vegetable shortening, tend to be solid at room temperature. The reason is that even electrically neutral, nonpolar molecules can develop transient regions of weak positive charge and weak negative charge. This occurs as the constant motion of their electrons causes some regions to have a temporary excess of electrons, whereas others have a temporary electron deficit. These slight opposite charges result in van der Waals interactions between adjacent molecules (see Chapter 2). Although van der Waals interactions are weak attractions, they are strong when many occur among long hydrocarbon chains. These van der Waals interactions tend to make a substance more solid by limiting the motion of its molecules.

Unsaturated fatty acids include one or more adjacent pairs of carbon atoms joined by a double bond. Therefore, they are not fully saturated with hydrogen. Fatty acids with one double bond are **monounsaturated fatty acids,** whereas those with more than one double bond are **polyunsaturated fatty acids.** Oleic acid is a monounsaturated fatty acid, and linoleic acid is a common polyunsaturated fatty acid (see Figs. 3-12d and e). Fats containing a high proportion of monounsaturated or polyunsaturated fatty acids tend to be liquid at room temperature. The reason is that each double bond produces a bend in the hydrocarbon chain that prevents it from aligning closely with an adjacent chain, thereby limiting van der Waals interactions and permitting freer molecular motion.

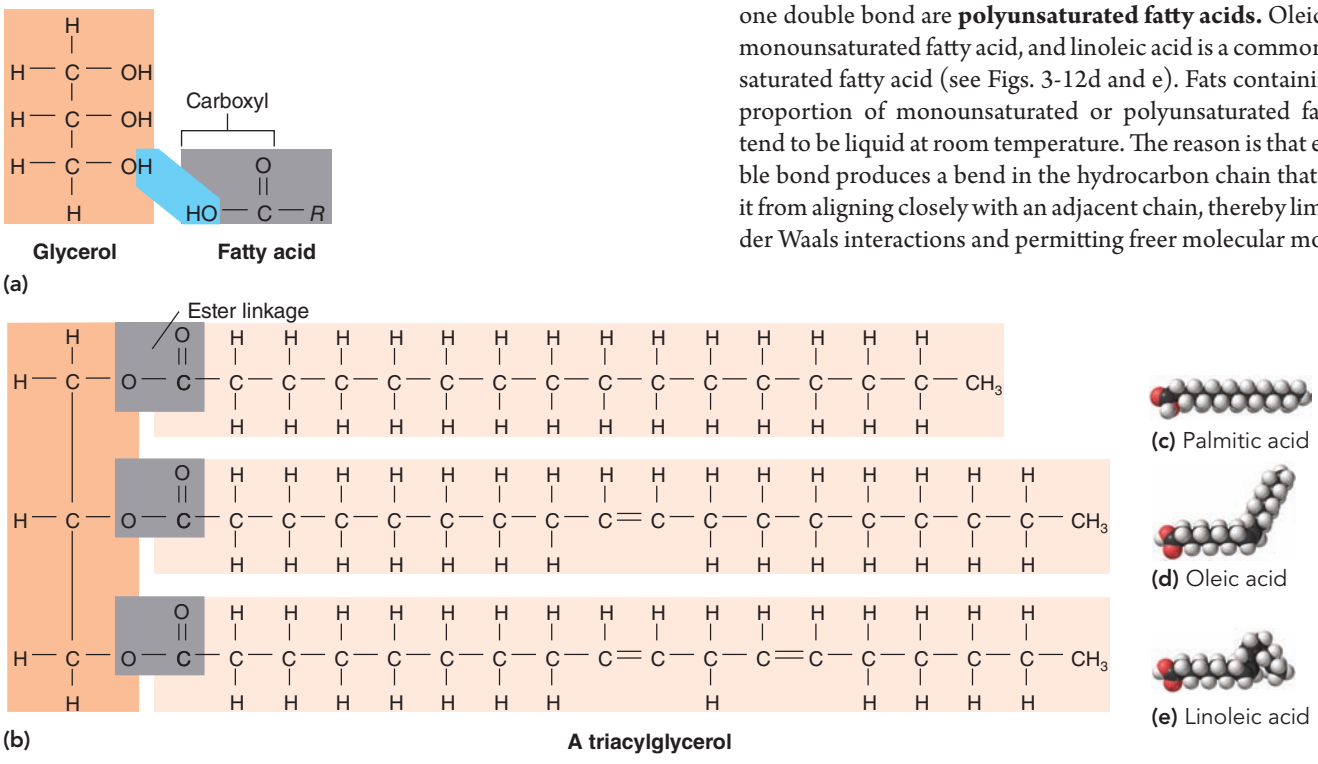

FIGURE 3-12 ***Animated*** **Triacylglycerol, the main storage lipid**

(a) Glycerol and fatty acids are the components of fats. **(b)** Glycerol is attached to fatty acids by ester linkages (*in gray*). The space-filling models show the actual shapes of the fatty acids. **(c)** Palmitic acid, a saturated fatty acid, is a straight chain. **(d)** Oleic acid (monounsaturated) and **(e)** linoleic acid (polyunsaturated) are bent or kinked wherever a carbon-to-carbon double bond appears.

www.konkur.in

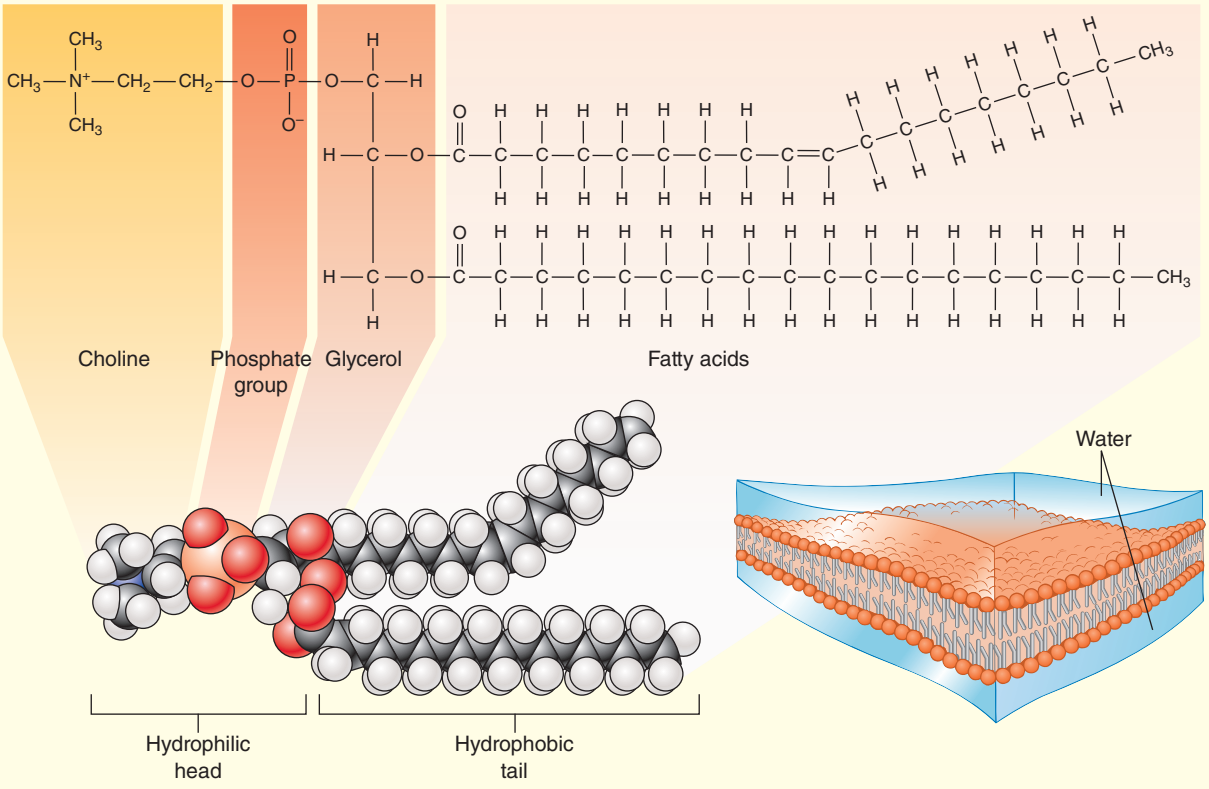
Food manufacturers commonly hydrogenate or partially hydrogenate cooking oils to make margarine and other foodstuffs, converting unsaturated fatty acids to saturated fatty acids and making the fat more solid at room temperature. This process makes the fat less healthful because saturated fatty acids in the diet are known to increase the risk of cardiovascular disease (see Chapter 44). The hydrogenation process has yet another effect. Note that in the naturally occurring unsaturated fatty acids oleic acid and linoleic acid shown in Figure 3-12, the two hydrogens flanking each double bond are on the same side of the hydrocarbon chain (the *cis* configuration). When fatty acids are artificially hydrogenated, the double bonds can become rearranged, resulting in a *trans* configuration, analogous to the arrangement shown in Figure 3-3b. *Trans* fatty acids are technically unsaturated, but they mimic many of the properties of saturated fatty acids. Because the *trans* configuration does not produce a bend at the site of the double bond, *trans* fatty acids are more solid at room temperature; like saturated fatty acids, they increase the risk of cardiovascular disease.

At least two unsaturated fatty acids (linoleic acid and arachidonic acid) are essential nutrients that must be obtained from food because the human body cannot synthesize them. However, the amounts required are small, and deficiencies are rarely seen. There is no dietary requirement for saturated fatty acids.

Phospholipids are components of cell membranes

Phospholipids belong to a group of lipids called **amphipathic lipids,** in which one end of each molecule is hydrophilic and the other end is hydrophobic (**FIG. 3-13**). The two ends of a phospho-

KEY POINT A lipid bilayer forms when phospholipids interact with water.



(a) Phospholipid (lecithin). A phospholipid consists of a hydrophobic tail, made up of two fatty acids, and a hydrophilic head, which includes a glycerol bonded to a phosphate group, which is in turn bonded to an organic group that can vary. Choline is the organic group in lecithin (or phosphatidylcholine), the molecule shown. The fatty acid at the top of the figure is monounsaturated; it contains one double bond that produces a characteristic bend in the chain.

(b) Phospholipid bilayer. Phospholipids form lipid bilayers in which the hydrophilic heads interact with water and the hydrophobic tails are in the bilayer interior.

FIGURE 3-13 ***Animated*** A phospholipid and a phospholipid bilayer

www.konkur.in

lipid differ both physically and chemically. A **phospholipid** consists of a glycerol molecule attached at one end to two fatty acids and at the other end to a phosphate group linked to an organic compound such as choline. The organic compound usually contains nitrogen. (Note that phosphorus and nitrogen are absent in triacylglycerols, as shown in Figure 3-12b.) The fatty acid portion of the molecule (containing the two hydrocarbon "tails") is hydrophobic and not soluble in water. However, the portion composed of glycerol, phosphate, and the organic base (the "head" of the molecule) is ionized and readily water soluble. The amphipathic properties of phospholipids cause them to form lipid bilayers in aqueous (watery) solution. Thus, they are uniquely suited as the fundamental components of cell membranes (discussed in Chapter 5).

Carotenoids and many other pigments are derived from isoprene units

The orange and yellow plant pigments called **carotenoids** are classified with the lipids because they are insoluble in water and have an oily consistency. These pigments, found in the cells of plants, play a role in photosynthesis. Carotenoid molecules, such as β-carotene, and many other important pigments, consist of five-carbon hydrocarbon monomers known as **isoprene units** (FIG. 3-14).

Most animals convert carotenoids to vitamin A, which can then be converted to the visual pigment **retinal.** Three groups of animals—the mollusks, insects, and vertebrates—have eyes that use retinal in the process of light reception.

Notice that carotenoids, vitamin A, and retinal all have a pattern of double bonds alternating with single bonds. The electrons that make up these bonds can move about relatively easily when light strikes the molecule. Such molecules are *pigments;* they tend to be highly colored because the mobile electrons cause them to strongly absorb light of certain wavelengths and reflect light of other wavelengths.

Steroids contain four rings of carbon atoms

A **steroid** consists of carbon atoms arranged in four attached rings; three of the rings contain six carbon atoms, and the fourth contains five (FIG. 3-15). The length and structure of the side chains that extend from these rings distinguish one steroid from another. Like carotenoids, steroids are synthesized from isoprene units.

Among the steroids of biological importance are cholesterol, bile salts, reproductive hormones, and cortisol as well as other hormones secreted by the adrenal cortex. Cholesterol is an essential structural component of animal cell membranes, but when excess cholesterol in blood forms plaques on artery walls, the risk of cardiovascular disease increases (see Chapter 44).

Plant cell membranes contain molecules similar to cholesterol. Interestingly, some of these plant steroids block the intestine's absorption of cholesterol. Bile salts emulsify fats in the intestine so they can be enzymatically hydrolyzed. Steroid hormones regulate certain aspects of metabolism in a variety of animals and plants.

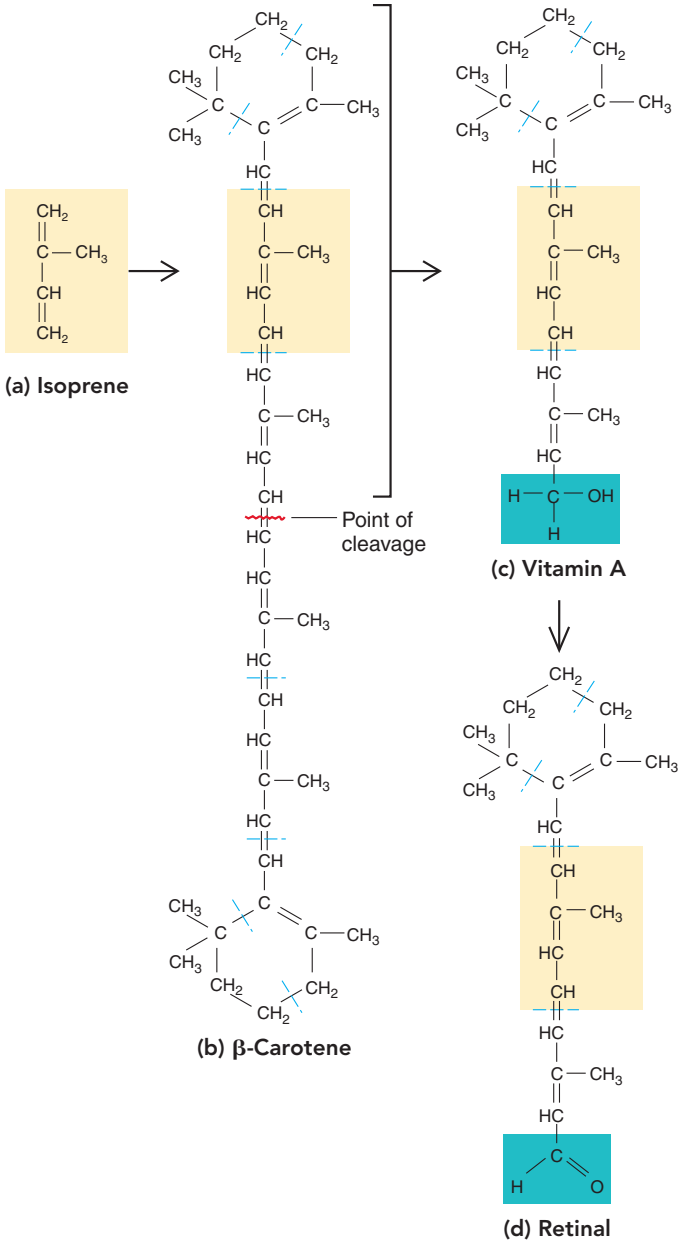


FIGURE 3-14 Isoprene-derived compounds

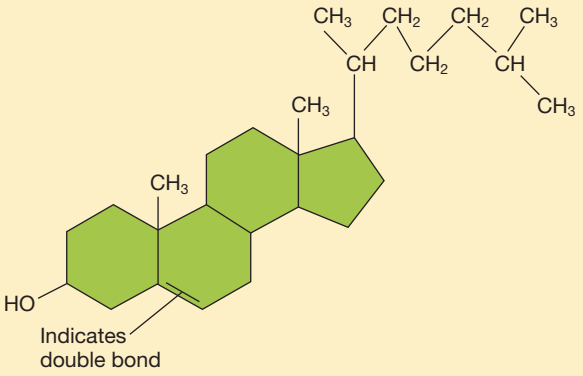
(a) An isoprene subunit. **(b)** β-carotene, with dashed lines indicating the boundaries of the individual isoprene units within. The wavy line is the point at which most animals cleave the molecule to yield two molecules of **(c)** vitamin A. Vitamin A is converted to the visual pigment **(d)** retinal.

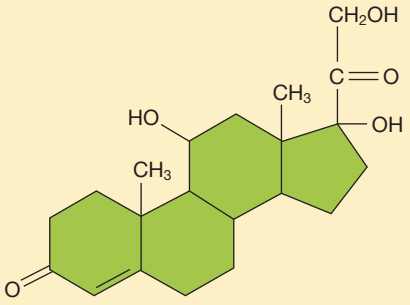
Some chemical mediators are lipids

Animal cells secrete chemicals to communicate with one another or to regulate their own activities. Some chemical mediators are produced by the modification of fatty acids that have been removed from membrane phospholipids. These include *prostaglandins,* which have varied roles, including promoting inflammation and smooth muscle contraction. Certain hormones, such as

www.konkur.in



(a) Cholesterol is an essential component of animal cell membranes.



(b) Cortisol is a steroid hormone secreted by the adrenal glands.

FIGURE 3-15 Steroids

Four attached rings—three six-carbon rings and one with five carbons—make up the fundamental structure of a steroid (*shown in green*). Note that some carbons are shared by two rings. In these simplified structures, a carbon atom is present at each angle of a ring; the hydrogen atoms attached directly to the carbon atoms have not been drawn. Steroids are mainly distinguished by their attached functional groups.

the juvenile hormone of insects, are also fatty acid derivatives (discussed in Chapter 49).

Review

- Why do saturated, unsaturated, and *trans* fatty acids differ in their properties?
- Why do phospholipids form lipid bilayers in aqueous conditions?

3.4 PROTEINS

LEARNING OBJECTIVES

7 Give an overall description of the structure and functions of proteins.
8 Describe the features that are shared by all amino acids and explain how amino acids are grouped into classes based on the characteristics of their side chains.
9 Distinguish among the four levels of organization of protein molecules.

TABLE 3-2 Major Classes of Proteins and Their Functions

Protein Class	Functions and Examples
Enzymes	Catalyze specific chemical reactions
Structural proteins	Strengthen and protect cells and tissues (e.g., collagen strengthens animal tissues)
Storage proteins	Store nutrients; particularly abundant in eggs (e.g., ovalbumin in egg white) and seeds (e.g., zein in corn kernels)
Transport proteins	Transport specific substances between cells (e.g., hemoglobin transports oxygen in red blood cells); move specific substances (e.g., ions, glucose, amino acids) across cell membranes
Regulatory proteins	Some are protein hormones (e.g., insulin); some control the expression of specific genes
Motile proteins	Participate in cellular movements (e.g., actin and myosin are essential for muscle contraction)
Protective proteins	Defend against foreign invaders (e.g., antibodies play a role in the immune system)

Proteins, macromolecules composed of amino acids, are the most versatile cell components. As will be discussed in Chapter 16, scientists have succeeded in sequencing virtually all the genetic information in a human cell, and the genetic information of many other organisms is being studied. Some people might think that the sequencing of genes is the end of the story, but it is actually only the beginning. Much genetic information is used to specify the structure of proteins, and biologists may devote most of the 21st century to understanding these extraordinarily multifaceted macromolecules that are of central importance in the chemistry of life. In a real sense, proteins are involved in virtually all aspects of metabolism because most **enzymes,** molecules that accelerate the thousands of different chemical reactions that take place in an organism, are proteins.

Proteins are assembled into a variety of shapes, allowing them to serve as major structural components of cells and tissues. For this reason, growth and repair, as well as maintenance of the organism, depend on proteins. As shown in **TABLE 3-2**, proteins perform many other functions. Each cell type contains characteristic forms, distributions, and amounts of protein that largely determine what the cell looks like and how it functions. A muscle cell contains large amounts of the proteins myosin and actin, which are responsible for its appearance as well as its ability to contract. The protein hemoglobin, found in red blood cells, is responsible for the specialized function of oxygen transport.

Amino acids are the subunits of proteins

Amino acids, the constituents of proteins, have an amino group ($—NH_2$) and a carboxyl group (—COOH) bonded to the same

www.konkur.in

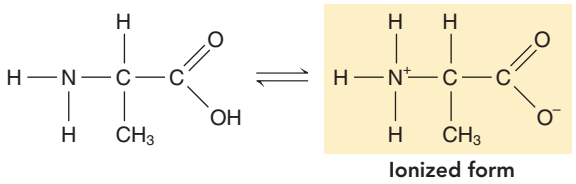


FIGURE 3-16 An amino acid at pH 7
In living cells, amino acids exist mainly in their ionized form, as dipolar ions.

asymmetrical carbon atom, known as the **alpha carbon.** Amino acids in solution at neutral pH are mainly *dipolar ions;* that is, they possess a positive charge at one end and a negative charge at the opposite end. This is generally how amino acids exist at cell pH. Each carboxyl group (—COOH) donates a proton and becomes ionized ($—COO^-$), whereas each amino group ($—NH_2$) accepts a proton and becomes $—NH_3^+$ (FIG. 3-16). Because of the ability of their amino and carboxyl groups to accept and release protons, amino acids in solution resist changes in acidity and alkalinity and therefore are important biological buffers.

Twenty amino acids are commonly found in proteins, each identified by the variable side chain (*R* group) bonded to the α carbon (FIG. 3-17). Glycine, the simplest amino acid, has a hydrogen atom as its *R* group; alanine has a methyl ($—CH_3$) group. The amino acids are grouped in Figure 3-17 by the properties of their side chains. These broad groupings actually include amino acids with a fairly wide range of properties. Amino acids classified as having *nonpolar* side chains tend to have hydrophobic properties, whereas those classified as *polar* are more hydrophilic. An acidic amino acid has a side chain that contains a carboxyl group. At cell pH the carboxyl group is dissociated, giving the *R* group a negative charge. A basic amino acid becomes positively charged when the amino group in its side chain accepts a hydrogen ion. Acidic and basic side chains are ionic at cell pH and therefore hydrophilic.

Some proteins have unusual amino acids in addition to the 20 common ones. These rare amino acids are produced by the modification of common amino acids after they have become part of a protein. For example, after they have been incorporated into collagen, lysine and proline may be converted to hydroxylysine and hydroxyproline. These amino acids can form cross links between the peptide chains that make up collagen. Such cross links produce the firmness and great strength of the collagen molecule, which is a major component of cartilage, bone, and other connective tissues.

With some exceptions, prokaryotes and plants synthesize all their needed amino acids from simpler substances. If the proper raw materials are available, the cells of animals can manufacture some, but not all, of the biologically significant amino acids. **Essential amino acids** are those an animal cannot synthesize in amounts sufficient to meet its needs and must obtain from the diet. Animals differ in their biosynthetic capacities; what is an essential amino acid for one species may not be for another.

The essential amino acids for humans are isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, valine, and histidine. Arginine is added to the list for children because they do not synthesize enough to support growth.

Peptide bonds join amino acids

Amino acids combine chemically with one another by a condensation reaction that bonds the carboxyl carbon of one molecule to the amino nitrogen of another (FIG. 3-18). The covalent carbon-to-nitrogen bond linking two amino acids is a **peptide bond.** When two amino acids combine, a **dipeptide** is formed; a longer chain of amino acids is a **polypeptide.** A protein consists of one or more polypeptide chains. Each polypeptide has a free amino group at one end and a free carboxyl group (belonging to the last amino acid added to the chain) at the opposite end. The other amino and carboxyl groups of the amino acid monomers (except those in side chains) are part of the peptide bonds. The process by which polypeptides are synthesized is discussed in Chapter 13.

A polypeptide may contain hundreds of amino acids joined in a specific linear order. The backbone of the polypeptide chain includes the repeating sequence

plus all other atoms *except those in the* R *groups.* The *R* groups of the amino acids extend from this backbone.

An almost infinite variety of protein molecules is possible, differing from one another in the number, types, and sequences of amino acids they contain. The 20 types of amino acids found in proteins may be thought of as letters of a protein alphabet; each protein is a very long sentence made up of amino acid letters.

Proteins have four levels of organization

The polypeptide chains making up a protein are twisted or folded to form a macromolecule with a specific *conformation,* or 3-D shape. Some polypeptide chains form long fibers. **Globular proteins** are tightly folded into compact, roughly spherical shapes. There is a close relationship between a protein's conformation and its function. For example, a typical enzyme is a globular protein with a unique shape that allows it to catalyze a specific chemical reaction. Similarly, the shape of a protein hormone enables it to combine with receptors on its target cell (the cell on which the hormone acts). Scientists recognize four main levels of protein organization: primary, secondary, tertiary, and quaternary.

Primary structure is the amino acid sequence

The sequence of amino acids, joined by peptide bonds, is the **primary structure** of a polypeptide chain. As discussed in Chapter 13, this sequence is specified by the instructions in a gene. Using analytical methods, investigators can determine the exact sequence of amino acids in a protein molecule. The primary structures of thousands of proteins are known. For example, glucagon, a hormone secreted by the pancreas, is a small polypeptide, consisting of only 29 amino acid units (FIG. 3-19).

Primary structure is always represented in a simple, linear, "beads-on-a-string" form. However, the overall conformation

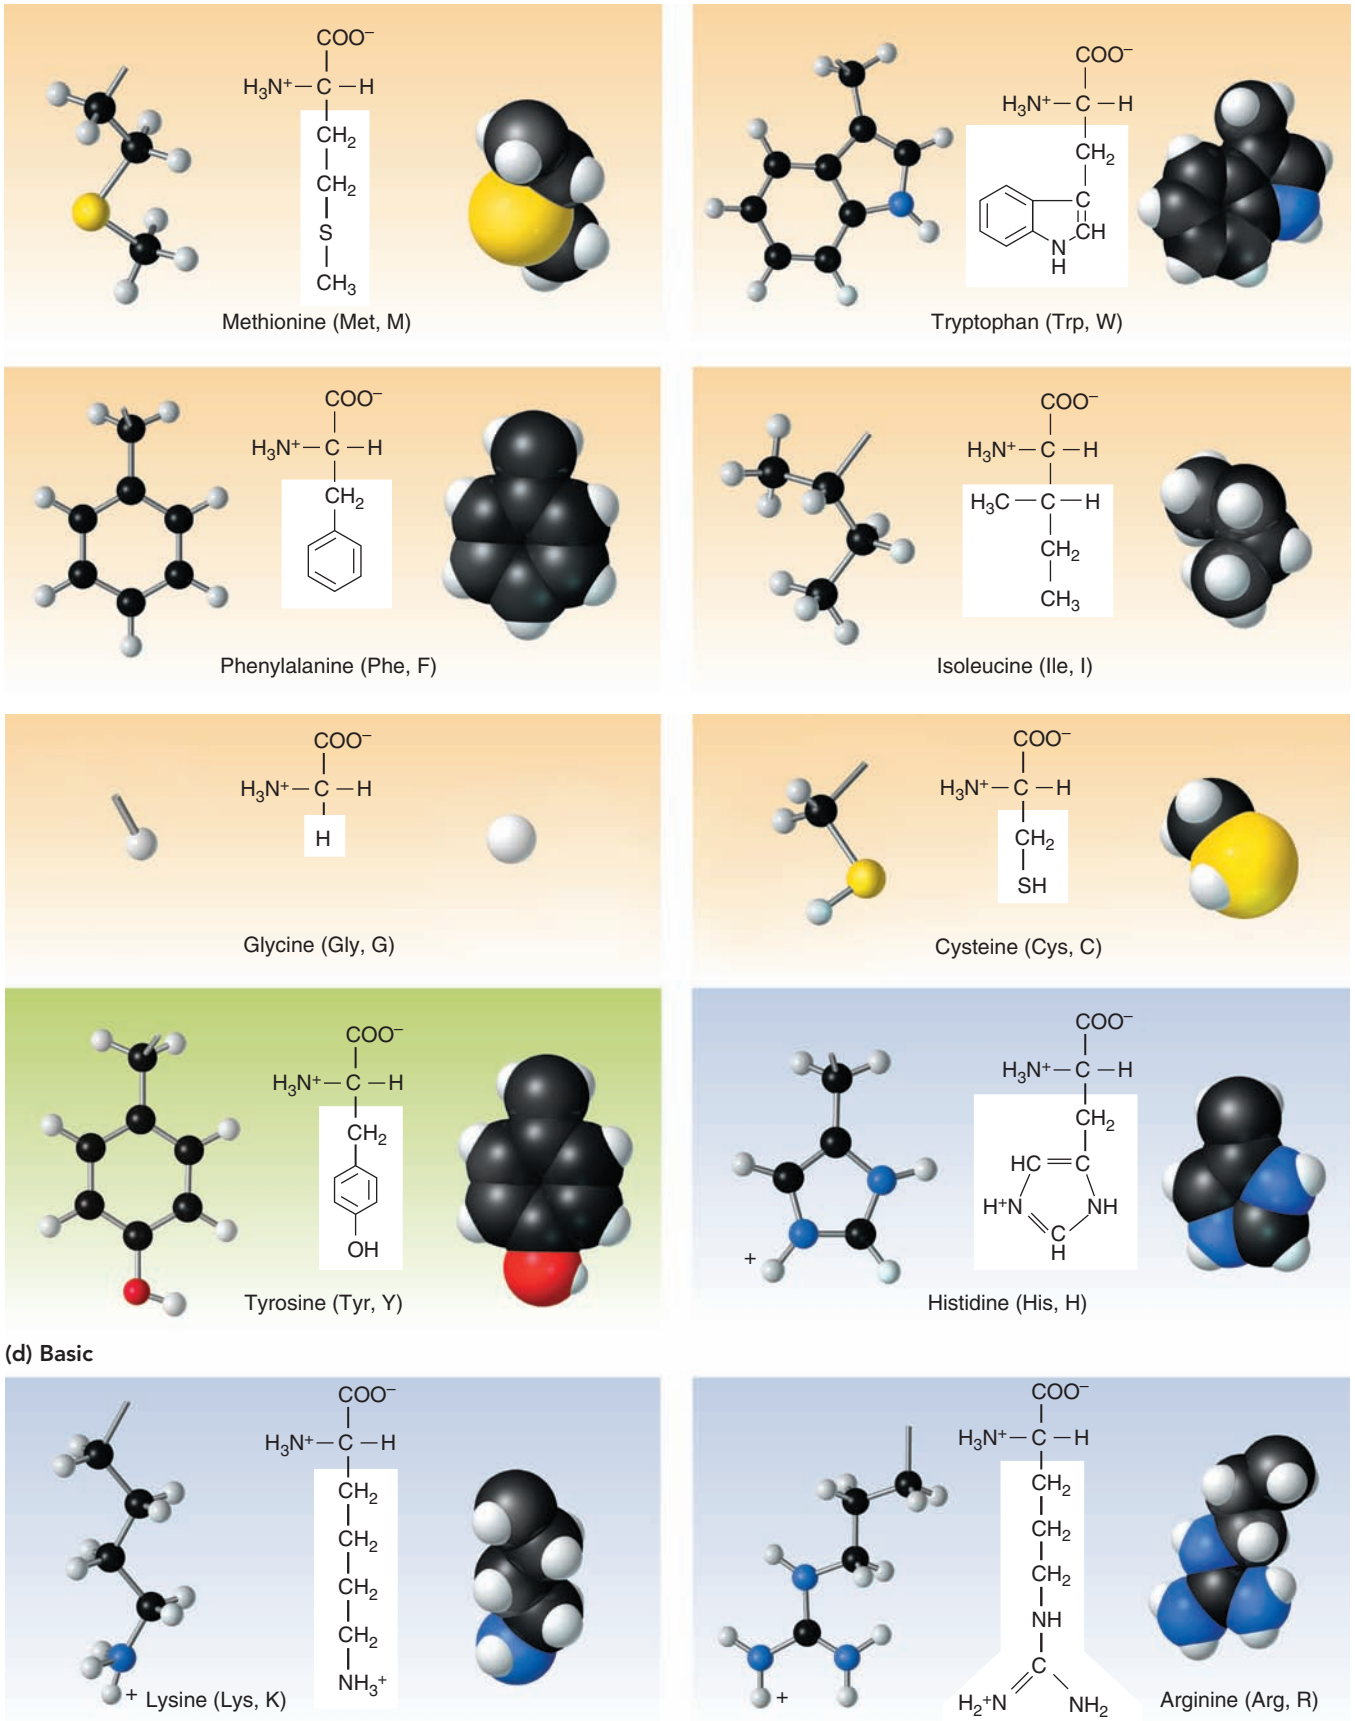

FIGURE 3-17 The 20 common amino acids

(a) Nonpolar amino acids have side chains that are relatively hydrophobic, whereas **(b)** polar amino acids have relatively hydrophilic side chains. Carboxyl groups and amino groups are electrically charged at cell pH; therefore, **(c)** acidic and **(d)** basic amino acids are hydrophilic. The standard three-letter and one-letter

www.konkur.in

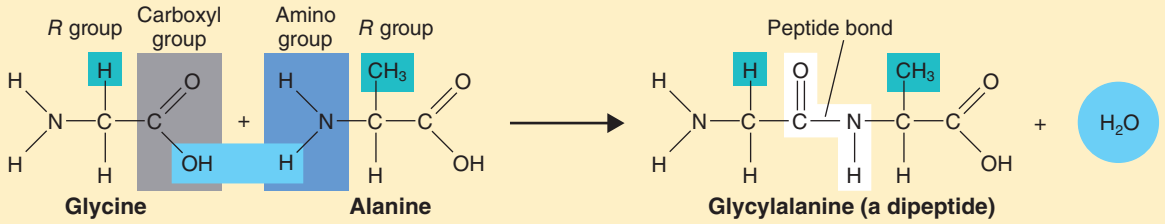

FIGURE 3-18 ***Animated*** **Peptide bonds**

A dipeptide is formed by a condensation reaction, that is, by the removal of the equivalent of a water molecule from the carboxyl group of one amino acid and the amino group of another amino acid. The resulting peptide bond is a covalent, carbon-to-nitrogen bond. Note that the carbon is also part of a carbonyl group and that the nitrogen is also covalently bonded to a hydrogen. Additional amino acids can be added to form a long polypeptide chain with a free amino group at one end and a free carboxyl group at the other.

of a protein is far more complex, involving interactions among the various amino acids that make up the primary structure of the molecule. Therefore, the higher orders of structure—secondary, tertiary, and quaternary—ultimately derive from the specific amino acid sequence (the primary structure).

Secondary structure results from hydrogen bonding involving the backbone

Some regions of a polypeptide exhibit **secondary structure,** which is highly regular. The two most common types of secondary structure are the α-helix and the β-pleated sheet; the designations α and β refer simply to the order in which these two types of secondary structure were discovered. An ***α*-helix** is a region where a polypeptide chain forms a uniform helical coil (**FIG. 3-20a**). The helical structure is determined and maintained by the formation of hydrogen bonds between the backbones of the amino acids in successive turns of the spiral coil.

Each hydrogen bond forms between an oxygen with a partial negative charge and a hydrogen with a partial positive charge. The oxygen is part of the remnant of the carboxyl group of one amino acid; the hydrogen is part of the remnant of the amino group of the fourth amino acid down the chain. Thus, 3.6 amino acids are included in each complete turn of the helix. Every amino acid in an α-helix is hydrogen bonded in this way.

The α-helix is the basic structural unit of some fibrous proteins that make up wool, hair, skin, and nails. The elasticity of these fibers is due to a combination of physical factors (the helical shape) and chemical factors (hydrogen bonding). Although hydrogen bonds maintain the helical structure, these bonds can be broken, allowing the fibers to stretch under tension (like a telephone cord). When the tension is released, the fibers recoil and hydrogen bonds reform. This explains why you can stretch the hairs on your head to some extent and they will snap back to their original length.

The hydrogen bonding in a ***β*-pleated sheet** takes place between different polypeptide chains, or different regions of a polypeptide chain that has turned back on itself (**FIG. 3-20b**). Each chain is fully extended; however, because each has a zigzag structure, the resulting "sheet" has an overall pleated conformation (much like a sheet of paper that has been folded to make a fan). Although the pleated sheet is strong and flexible, it is not elastic, because the distance between the pleats is fixed, determined by the strong covalent bonds of the polypeptide backbones. Fibroin, the protein of silk, is characterized by a β-pleated sheet structure, as are the cores of many globular proteins.

It is not uncommon for a single polypeptide chain to include both α-helical regions and regions with β-pleated sheet conformations. The properties of some biological materials result from such combinations. A spider's web is composed of a material that is extremely strong, flexible, and elastic. Once again we see function and structure working together, as these properties derive from the fact that spider silk is a composite of proteins with α-helical conformations (providing elasticity) and others with β-pleated sheet conformations (providing strength).

Tertiary structure depends on interactions among side chains

The **tertiary structure** of a protein molecule is the overall shape assumed by each individual polypeptide chain (**FIG. 3-21**). This 3-D structure is determined by four main factors that involve interactions among *R* groups (side chains) belonging to the same

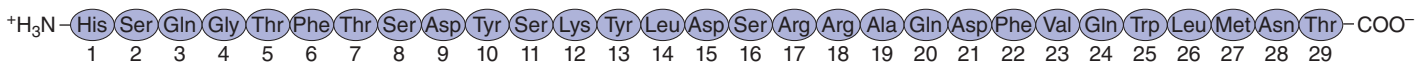

FIGURE 3-19 **Primary structure of a polypeptide**

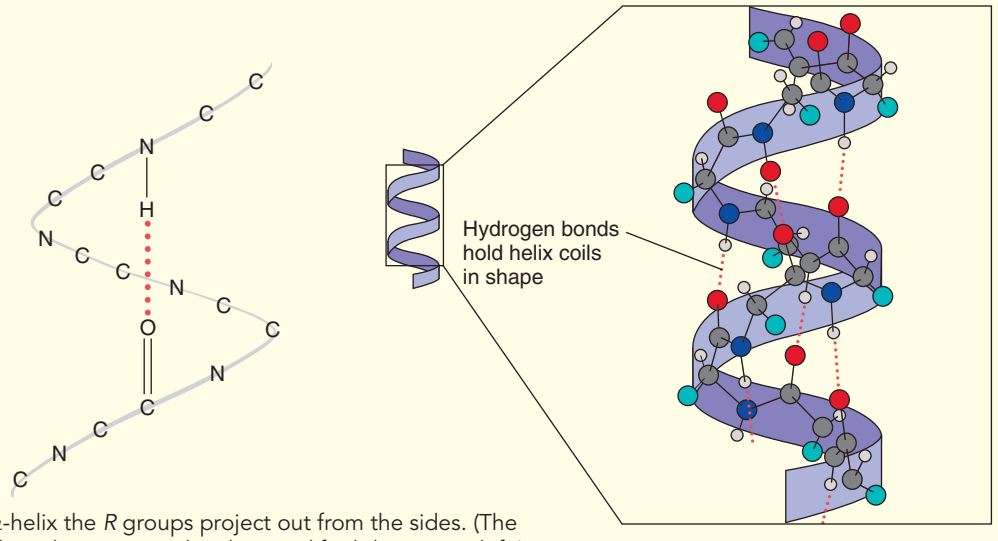
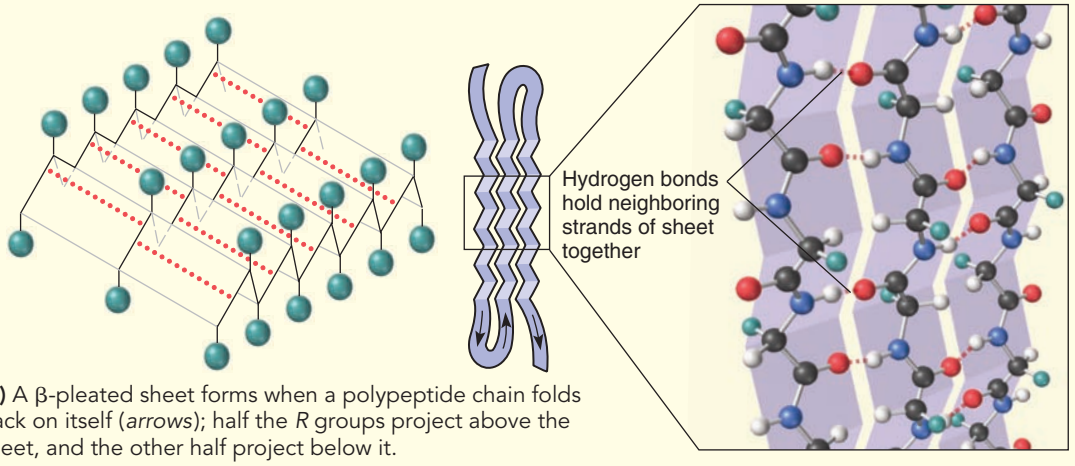
Glucagon is a very small polypeptide made up of 29 amino acids. The linear sequence of amino acids is indicated by ovals containing their abbreviated names (see Fig. 3-17).

www.konkur.in

KEY POINT Secondary structure is highly regular.



(a) In an α-helix the *R* groups project out from the sides. (The R groups have been omitted in the simplified diagram at left.)



(b) A β-pleated sheet forms when a polypeptide chain folds back on itself (*arrows*); half the *R* groups project above the sheet, and the other half project below it.

FIGURE 3-20 ***Animated*** Secondary structure of a protein

polypeptide chain. These include both weak interactions (hydrogen bonds, ionic bonds, and hydrophobic interactions) and strong covalent bonds.

1. Hydrogen bonds form between *R* groups of certain amino acid subunits.
2. An ionic bond can occur between an *R* group with a unit of positive charge and one with a unit of negative charge.
3. Hydrophobic interactions result from the tendency of nonpolar *R* groups to be excluded by the surrounding water and therefore to associate in the interior of the globular structure.
4. Covalent bonds known as *disulfide bonds* or *disulfide bridges* (—S—S—) may link the sulfur atoms of two cysteine subunits belonging to the same chain. A disulfide bridge forms when the sulfhydryl groups of two cysteines react; the two hydrogens are removed, and the two sulfur atoms that remain become covalently linked.

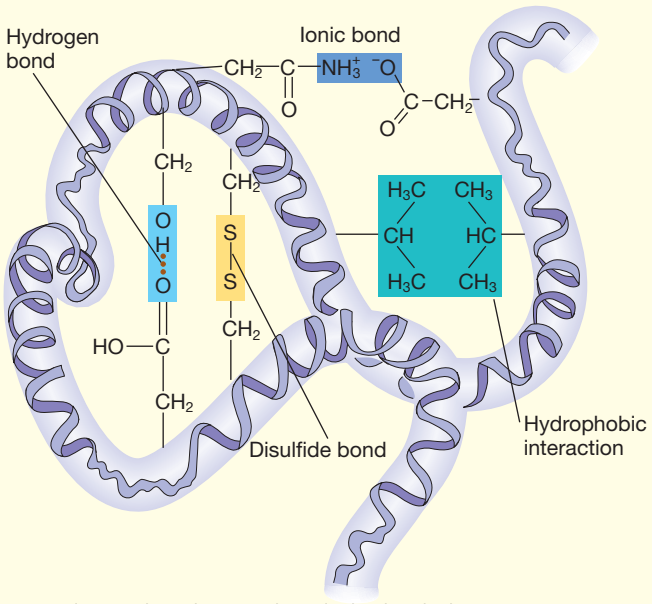
Quaternary structure results from interactions among polypeptides

Many functional proteins are composed of two or more polypeptide chains, interacting in specific ways to form the biologically active molecule. **Quaternary structure** is the resulting 3-D structure. The same types of interactions that produce secondary and tertiary structure also contribute to quaternary structure; these include hydrogen bonding, ionic bonding, hydrophobic interactions, and disulfide bridges.

A functional antibody molecule, for example, consists of four polypeptide chains joined by disulfide bridges (see Chapter 45).

www.konkur.in

KEY POINT Tertiary structure depends on side chain interactions.



(a) Hydrogen bonds, ionic bonds, hydrophobic interactions, and disulfide bridges between *R* groups hold the parts of the molecule in the designated shape.

Jane Richardson

(b) In this drawing, α-helical regions are represented by purple coils, β-pleated sheets by broad green ribbons, and connecting regions by narrow tan ribbons. The interactions among *R* groups that stabilize the bends and foldbacks that give the molecule its overall conformation (tertiary structure) are represented in yellow. This protein is bovine ribonuclease a.

FIGURE 3-21 ***Animated*** Tertiary structure of a protein

Disulfide bridges are a common feature of antibodies and other proteins secreted from cells. These strong bonds stabilize the molecules in the extracellular environment.

Hemoglobin, the protein in red blood cells responsible for oxygen transport, is an example of a globular protein with a quaternary structure (**FIG. 3-22a**). Hemoglobin consists of 574 amino acids arranged in four polypeptide chains: two identical chains called *alpha chains* and two identical chains called *beta chains.*

Collagen, mentioned previously, has a fibrous type of quaternary structure that allows it to function as the major strengthener of animal tissues. It consists of three polypeptide chains wound about one another and bound by cross links between their amino acids (**FIG. 3-22b**).

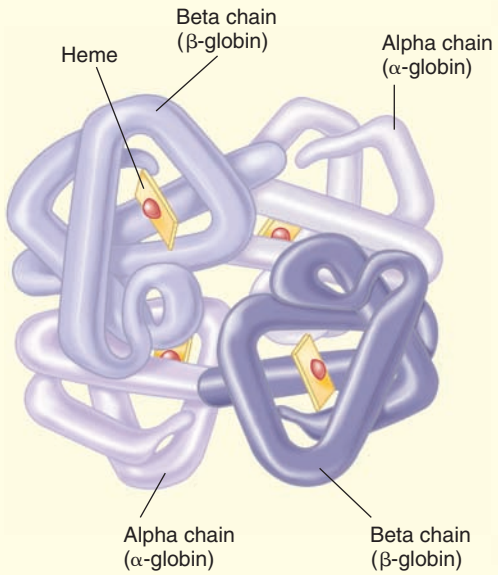
The amino acid sequence of a protein determines its conformation

In 1972, U.S. researcher Christian B. Anfinsen was awarded the Nobel Prize in Chemistry for his studies on protein folding, which demonstrated that, at least under defined experimental conditions *in vitro* (outside a living cell), a polypeptide can spontaneously undergo folding processes that yield its normal, functional conformation. Since Anfinsen's pioneering work, many researchers studying various proteins and using a variety of highly sophisticated approaches have amassed evidence supporting the widely held conclusion that amino acid sequence is the ultimate determinant of protein conformation.

However, because conditions *in vivo* (in the cell) are quite different from defined laboratory conditions, proteins do not always fold spontaneously in the cell. On the contrary, scientists have learned that proteins known as **molecular chaperones** mediate the folding of other protein molecules. Molecular chaperones are thought to make the folding process more orderly and efficient and to prevent partially folded proteins from becoming inappropriately aggregated. However, there is no evidence that molecular chaperones actually dictate the folding pattern. For this reason, the existence of chaperones is not an argument against the idea that amino acid sequence determines conformation.

www.konkur.in

KEY POINT Proteins with two or more polypeptide chains have quaternary structure.



(a) Hemoglobin, a globular protein, consists of four polypeptide chains, each joined to an iron-containing molecule, a heme.

(b) Collagen, a fibrous protein, is a triple helix consisting of three long polypeptide chains.

FIGURE 3-22 Quaternary structure of a protein

Protein conformation determines function

The overall structure of a protein helps determine its biological activity. A single protein may have more than one distinct structural region, called a **domain,** each with its own function. Many proteins are modular, consisting of two or more globular domains, connected by less compact regions of the polypeptide chain.

Each domain may have a different function. For example, a protein may have one domain that attaches to a membrane and another that acts as an enzyme. The biological activity of a protein can be disrupted by a change in amino acid sequence that results in a change in conformation. For example, the genetic disease known as *sickle cell anemia* is due to a mutation that causes the substitution of the amino acid valine for glutamic acid at position 6 (the sixth amino acid from the amino end) in the beta chain of hemoglobin. The substitution of valine (which has a nonpolar side chain) for glutamic acid (which has a charged side chain) makes the hemoglobin less soluble and more likely to form crystal-like structures. This alteration of the hemoglobin affects the red blood cells, changing them to the crescent or sickle shapes that characterize this disease (see Fig. 16-8).

The biological activity of a protein may be affected by changes in its 3-D structure. When a protein is heated, subjected to significant pH changes, or treated with certain chemicals, its structure becomes disordered and the coiled peptide chains unfold, yielding a more random conformation. This unfolding, which is mainly due to the disruption of hydrogen bonds and ionic bonds, is typically accompanied by a loss of normal function. Such changes in shape and the accompanying loss of biological activity are termed *denaturation* of the protein.

For example, a denatured enzyme would lose its ability to catalyze a chemical reaction. An everyday example of denaturation occurs when we fry an egg. The consistency of the egg white protein, known as *albumin,* changes to a solid. Denaturation generally cannot be reversed (you cannot "unfry" an egg). However, under certain conditions, some proteins have been denatured and have returned to their original shape and biological activity when normal environmental conditions were restored.

Protein conformation is studied through a variety of methods

The architecture of a protein can be ascertained directly through various types of analysis, such as the X-ray diffraction studies discussed in Chapter 12. Because these studies are tedious and costly, researchers are developing alternative approaches, which rely heavily on the enormous databases generated by the Human Genome Project and related initiatives.

Today a protein's primary structure can be determined rapidly through the application of genetic engineering techniques (discussed in Chapter 15) or by the use of sophisticated technology such as mass spectrometry. Researchers use these amino acid sequence data to predict a protein's higher levels of structure. As you have seen, side chains interact in relatively predictable ways, such as through ionic and hydrogen bonds. In addition, regions with certain types of side chains are more likely to form α-helices or β-pleated sheets. Computer programs make such predictions, but these are often imprecise because of the many possible combinations of folding patterns.

Computers are an essential part of yet another strategy. Once the amino acid sequence of a polypeptide has been determined, researchers use computers to search databases to find polypeptides with similar sequences. If the conformations of any of those polypeptides or portions have already been determined directly by X-ray diffraction or other techniques, this information can be extrapolated to make similar correlations between amino acid sequence and 3-D structure for the protein under investigation. These predictions are increasingly reliable, as more information is added to the databases every day.

www.konkur.in

Misfolded proteins are implicated in human diseases

Studies on the mechanisms of protein folding, and on the relationship between the activity of a protein and its conformation, are increasingly of medical importance. For example, as discussed in Chapter 24, mad cow disease and related diseases in humans and other animals are caused by misfolded proteins called *prions.* Other serious diseases in which misfolded proteins play an important role include Alzheimer's disease (see Chapter 41) and Huntington's disease (see Chapter 16).

Review

- How does the primary structure of a polypeptide influence its secondary and tertiary structures?

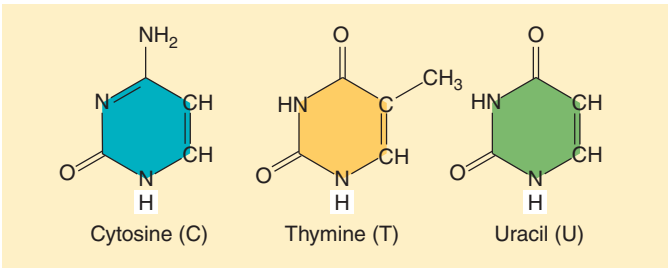
3.5 NUCLEIC ACIDS

LEARNING OBJECTIVE

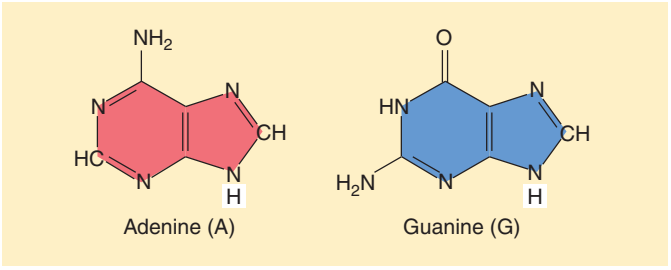
10 Describe the components of a nucleotide. Name some nucleic acids and nucleotides, and discuss the importance of these compounds in living organisms.

Nucleic acids transmit hereditary information and determine what proteins a cell manufactures. Two classes of nucleic acids are found in cells: deoxyribonucleic acid and ribonucleic acid. **Deoxyribonucleic acid (DNA)** composes the genes, the hereditary material of the cell, and contains instructions for making all the proteins, as well as all the RNA the organism needs. **Ribonucleic acid (RNA)** participates in the process in which amino acids are linked to form polypeptides. Some types of RNA, known as **ribozymes,** can even act as specific biological catalysts. Like proteins, nucleic acids are large, complex molecules. The name *nucleic acid* reflects the fact that they are acidic and were first identified, by Swiss biochemist Friedrich Miescher in 1870, in the nuclei of pus cells.

Nucleic acids are polymers of **nucleotides,** molecular units that consist of (1) a five-carbon sugar, either **deoxyribose** (in DNA) or **ribose** (in RNA); (2) one or more phosphate groups, which make the molecule acidic; and (3) a nitrogenous base, a ring compound that contains nitrogen. The nitrogenous base may be either a double-ring **purine** or a single-ring **pyrimidine** (FIG. 3-23). DNA commonly contains the purines **adenine (A)** and **guanine (G),** the pyrimidines **cytosine (C)** and **thymine (T),** the sugar deoxyribose, and phosphate. RNA contains the purines adenine and guanine, and the pyrimidines cytosine and **uracil (U),** together with the sugar ribose, and phosphate. The molecules of nucleic acids are made of linear chains of nucleotides, which are joined by **phosphodiester linkages,** each consisting of a phosphate group and the covalent bonds that attach it to the sugars of adjacent nucleotides (FIG. 3-24). Note that each nucleotide is defined by its particular base and that nucleotides can be joined in any sequence. A nucleic acid molecule is uniquely defined by its specific sequence of nucleotides, which constitutes a kind of code (see Chapter 13). Whereas RNA is usually composed of one nucleotide chain, DNA consists of two nucleotide chains held together by hydrogen bonds and entwined around each other in a double helix (see Fig. 1-7).



(a) Pyrimidines. The three major pyrimidine bases found in nucleotides are cytosine, thymine (in DNA only), and uracil (in RNA only).



(b) Purines. The two major purine bases found in nucleotides are adenine and guanine.

FIGURE 3-23 ***Animated*** **Components of nucleotides**
The hydrogens indicated by the white boxes are removed when the base is attached to a sugar.

Some nucleotides are important in energy transfers and other cell functions

In addition to their importance as subunits of DNA and RNA, nucleotides perform other vital functions in living cells. **Adenosine triphosphate (ATP),** composed of adenine, ribose, and three phosphates (see Fig. 7-5), is of major importance as the primary energy currency of all cells (see Chapter 7). The two terminal phosphate groups are joined to the nucleotide by covalent bonds. These are traditionally indicated by wavy lines, which indicate that ATP can transfer a phosphate group to another molecule, making that molecule more reactive. In this way ATP is able to donate some of its chemical energy. Most of the readily available chemical energy of the cell is associated with the phosphate groups of ATP. Like ATP, **guanosine triphosphate (GTP),** a nucleotide that contains the base guanine, can transfer energy by transferring a phosphate group and also has a role in cell signaling (see Chapter 6).

A nucleotide may be converted to an alternative form with specific cell functions. ATP, for example, is converted to **cyclic adenosine monophosphate (cyclic AMP, or cAMP)** by the enzyme adenylyl cyclase (FIG. 3-25). Cyclic AMP regulates certain

www.konkur.in

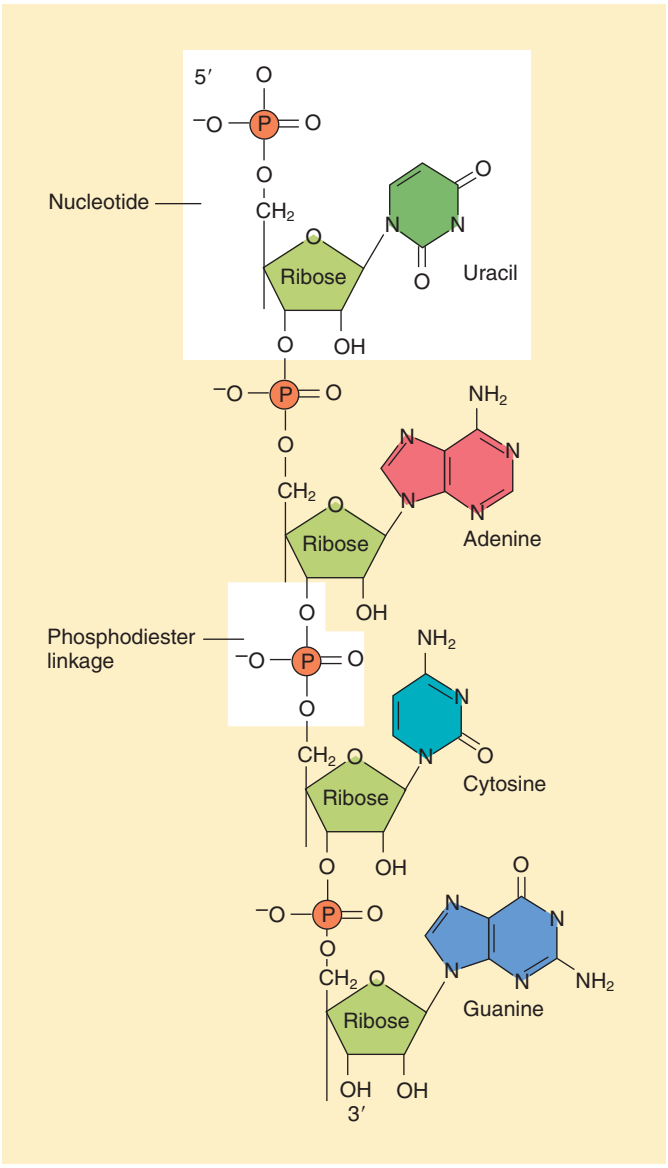


FIGURE 3-24 RNA, a nucleic acid
Nucleotides, each with a specific base, are joined by phosphodiester linkages.

cell functions, such as cell signaling, and is important in the mechanism by which some hormones act. A related molecule, **cyclic guanosine monophosphate (cGMP),** also plays a role in certain cell signaling processes.

Cells contain several dinucleotides, which are of great importance in metabolic processes. For example, as discussed in Chapter 7, **nicotinamide adenine dinucleotide** has a primary role in oxidation and reduction reactions in cells. It can exist in an oxidized form ($\mathbf{NAD^+}$) that is converted to a reduced form (**NADH**) when it accepts electrons (in association with hydrogen; see Fig. 7-7). These electrons, along with their energy, are transferred to other molecules.

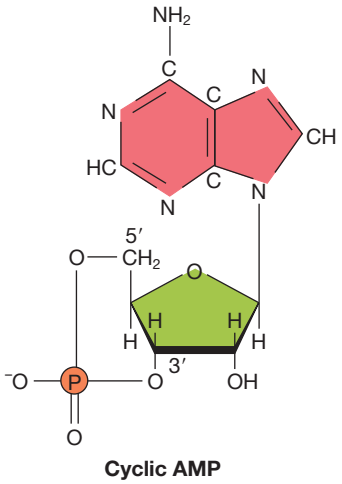

FIGURE 3-25 Cyclic adenosine monophosphate (cAMP)

3.6 IDENTIFYING BIOLOGICAL MOLECULES

LEARNING OBJECTIVE

11 Compare the functions and chemical compositions of the major groups of organic compounds: carbohydrates, lipids, proteins, and nucleic acids.

Although the classes of biological molecules may seem overwhelming at first, you will learn to distinguish them readily by understanding their chief attributes. These are summarized in **TABLE 3-3**.

Review

- How can you distinguish a pentose sugar from a hexose sugar? a disaccharide from a sterol? an amino acid from a monosaccharide? a phospholipid from a triacylglycerol? a protein from a polysaccharide? a nucleic acid from a protein?

www.konkur.in

TABLE 3-3 Classes of Biologically Important Organic Compounds

Class and Component Elements	Description	How to Recognize	Principal Function in Living Systems
Carbohydrates C, H, O	Contain approximately 1 C:2 H:1 O (but make allowance for loss of oxygen when sugar units as nucleic acids and glycoproteins are linked)	Count the carbons, hydrogens, and oxygens.	Cell fuel; energy storage; structural component of plant cell walls; component of other compounds such as nucleic acids and glycoproteins
	1. *Monosaccharides* (simple sugars). Mainly five-carbon (pentose) molecules such as ribose or six-carbon (hexose) molecules such as glucose and fructose	Look for the ring shapes: 	Cell fuel; components of other compounds
	2. *Disaccharides.* Two sugar units linked by a glycosidic bond, e.g., maltose, sucrose	Count sugar units.	Components of other compounds; form of sugar transported in plants
	3. *Polysaccharides.* Many sugar units linked by glycosidic bonds, e.g., glycogen, cellulose	Count sugar units.	Energy storage; structural components of plant cell walls
Lipids C, H, O **(sometimes N, P)**	Contain much less oxygen relative to carbon and hydrogen than do carbohydrates		Energy storage; cellular fuel, components of cells; thermal insulation
	1. *Fats.* Combination of glycerol with one to three fatty acids. Monoacylglycerol contains one fatty acid; diacylglycerol contains two fatty acids; triacylglycerol contains three fatty acids. If fatty acids contain double carbon-to-carbon linkages (C═C), they are unsaturated; otherwise, they are saturated.	Look for glycerol at one end of molecule: 	Cell fuel; energy storage
	2. *Phospholipids.* Composed of glycerol attached to one or two fatty acids and to an organic base containing phosphorus	Look for glycerol and side chain containing phosphorus and nitrogen.	Components of cell membranes
	3. *Steroids.* Complex molecules containing carbon atoms arranged in four attached rings (Three rings contain six carbon atoms each, and the fourth ring contains five.)	Look for four attached rings: 	Some are hormones; others include cholesterol, bile salts, vitamin D; components of cell membranes
	4. *Carotenoids.* Orange and yellow pigments; consist of isoprene units	Look for isoprene units. 	Converted to retinal (important in photoreception) and vitamin A
Proteins C, H, O, N (usually S)	One or more polypeptides (chains of amino acids) coiled or folded in characteristic shapes	Look for amino acid units joined by C—N bonds.	Serve as enzymes; structural components; muscle proteins; hemoglobin
Nucleic Acids C, H, O, N, P	Backbone composed of alternating pentose and phosphate groups, from which nitrogenous bases project. DNA contains the sugar deoxyribose and the bases guanine, cytosine, adenine, and thymine. RNA contains the sugar ribose and the bases guanine, cytosine, adenine, and uracil. Each molecular subunit, called a nucleotide, consists of a pentose, a phosphate, and a nitrogenous base.	Look for a pentose-phosphate backbone. DNA forms a double helix.	Storage, transmission, and expression of genetic information; some important in energy transfers, cell signaling, and other aspects of metabolism.

www.konkur.in

SUMMARY: FOCUS ON LEARNING OBJECTIVES

3.1 *(page 47)*

1 Describe the properties of carbon that make it the central component of organic compounds.

- Each carbon atom forms four covalent bonds with up to four other atoms; these bonds are single, double, or triple bonds. Carbon atoms form straight or branched chains or join into rings. Carbon forms covalent bonds with a greater number of different elements than does any other type of atom.

2 Define the term *isomer* and distinguish among the three principal isomer types.

- **Isomers** are compounds with the same molecular formula but different structures.
- **Structural isomers** differ in the covalent arrangements of their atoms. **Geometric isomers,** or *cis–trans* isomers, differ in the spatial arrangements of their atoms. **Enantiomers** are isomers that are mirror images of each other. Cells can distinguish between these configurations.

3 Identify the major functional groups present in organic compounds and describe their properties.

- **Hydrocarbons,** organic compounds consisting of only carbon and hydrogen, are nonpolar and **hydrophobic.** The **methyl group** is a hydrocarbon group.
- Polar and ionic functional groups interact with one another and are **hydrophilic.** Partial charges on atoms at opposite ends of a bond are responsible for the polar property of a functional group. **Hydroxyl** and **carbonyl groups** are polar.
- **Carboxyl** and **phosphate groups** are acidic, becoming negatively charged when they release hydrogen ions. The **amino group** is basic, becoming positively charged when it accepts a hydrogen ion.

4 Explain the relationship between polymers and macromolecules.

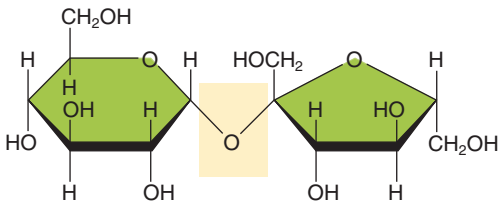
- Long chains of **monomers** (similar organic compounds) linked through **condensation reactions** are called **polymers.** Large polymers such as polysaccharides, proteins, and DNA are referred to as **macromolecules.** They can be broken down by **hydrolysis reactions.**

CENGAGENOW™ Learn more about condensation and hydrolysis reactions by clicking on the figure in CengageNOW.

3.2 *(page 51)*

5 Distinguish among monosaccharides, disaccharides, and polysaccharides. Compare storage polysaccharides with structural polysaccharides.

- **Carbohydrates** contain carbon, hydrogen, and oxygen in a ratio of approximately one carbon to two hydrogens to one oxygen. **Monosaccharides** are simple sugars such as glucose, fructose, and ribose. Two monosaccharides join by a **glycosidic linkage** to form a **disaccharide** such as maltose or sucrose.



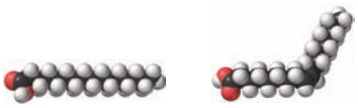
- Most carbohydrates are **polysaccharides,** long chains of repeating units of a simple sugar. Carbohydrates are typically stored in plants as the polysaccharide **starch** and in animals as the polysaccharide **glycogen.** The cell walls of plants are composed mainly of the structural polysaccharide **cellulose.**

CENGAGENOW™ Learn more about starch and cellulose by clicking on the figure in CengageNOW.

3.3 *(page 56)*

6 Distinguish among fats, phospholipids, and steroids, and describe the composition, characteristics, and biological functions of each.

- **Lipids** are composed mainly of hydrocarbon-containing regions, with few oxygen-containing (polar or ionic) functional groups. Lipids have a greasy or oily consistency and are relatively insoluble in water.
- **Triacylglycerol,** the main storage form of fat in organisms, consists of a molecule of **glycerol** combined with three **fatty acids. Monoacylglycerols** and **diacylglycerols** contain one and two fatty acids, respectively. A fatty acid can be either **saturated** with hydrogen or **unsaturated.**



- **Phospholipids** are structural components of cell membranes. A phospholipid consists of a glycerol molecule attached at one end to two fatty acids and at the other end to a phosphate group linked to an organic compound such as choline.
- **Steroid** molecules contain carbon atoms arranged in four attached rings. Cholesterol, bile salts, and certain hormones are important steroids.

CENGAGENOW™ Learn more about triacylglycerol and other lipids by clicking on the figures in CengageNOW.

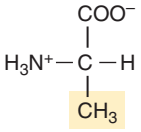
3.4 *(page 60)*

7 Give an overall description of the structure and functions of proteins.

- **Proteins** are complex macromolecules made of simpler subunits, called **amino acids,** joined by **peptide bonds.** Two amino acids combine to form a **dipeptide.** A longer chain of amino acids is a **polypeptide.** Proteins are the most versatile class of biological molecules, serving a variety of functions, such as **enzymes,** structural components, and cell regulators.
- Proteins are composed of various linear sequences of 20 different amino acids.

CENGAGENOW™ Learn more about amino acids and peptide bonds by clicking on the figures in CengageNOW.

8 Describe the features that are shared by all amino acids and explain how amino acids are grouped into classes based on the characteristics of their side chains.



- All amino acids contain an amino group and a carboxyl group. Amino acids vary in their side chains, which dictate their chemical properties—nonpolar, polar, acidic, or basic. Amino acids generally exist as dipolar ions at cell pH and serve as important biological buffers.

www.konkur.in

9 Distinguish among the four levels of organization of protein molecules.

- **Primary structure** is the linear sequence of amino acids in the polypeptide chain.
- **Secondary structure** is a regular conformation, such as an ***α*-helix** or a ***β*-pleated sheet;** it is due to hydrogen bonding between elements of the backbones of the amino acids.
- **Tertiary structure** is the overall shape of the polypeptide chains, as dictated by chemical properties and interactions of the side chains of specific amino acids. Hydrogen bonds, ionic bonds, hydrophobic interactions, and disulfide bridges contribute to tertiary structure.
- **Quaternary structure** is determined by the association of two or more polypeptide chains.

CENGAGENOW™ Learn more about the structure of a protein by clicking on the figure in CengageNOW.

3.5 *(page 68)*

10 Describe the components of a nucleotide. Name some nucleic acids and nucleotides, and discuss the importance of these compounds in living organisms.

- The **nucleic acids DNA** and **RNA,** composed of long chains of nucleotide subunits, store and transfer information that specifies the sequence of amino acids in proteins and ultimately the structure and function of the organism.
- **Nucleotides** are composed of a two-ring **purine** or one-ring **pyrimidine** nitrogenous base, a five-carbon sugar (**ribose** or **deoxyribose**), and one or more phosphate groups.
- **ATP (adenosine triphosphate)** is a nucleotide of special significance in energy metabolism. **NAD^+** is also involved in energy metabolism through its role as an electron (hydrogen) acceptor in biological oxidation and reduction reactions.

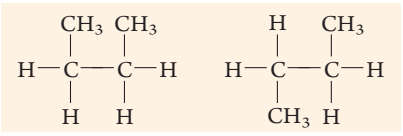
3.6 *(page 69)*

11 Compare the functions and chemical compositions of the major groups of organic compounds: carbohydrates, lipids, proteins, and nucleic acids.

- Review Table 3-3.

TEST YOUR UNDERSTANDING

1. Carbon is particularly well suited to be the backbone of organic molecules because (a) it can form both covalent bonds and ionic bonds (b) its covalent bonds are very irregularly arranged in three-dimensional space (c) its covalent bonds are the strongest chemical bonds known (d) it can bond to atoms of a large number of other elements (e) all the bonds it forms are polar
2. The structures depicted are (a) enantiomers (b) different views of the same molecule (c) geometric (*cis–trans*) isomers (d) both geometric isomers and enantiomers (e) structural isomers



3. Which of the following is a nonpolar molecule? (a) water, H_2O (b) ammonia, NH_3 (c) methane, CH_4 (d) ethane, C_2H_6 (e) more than one of the preceding
4. The synthetic process by which monomers are covalently linked is (a) hydrolysis (b) isomerization (c) condensation (d) glycosidic linkage (e) ester linkage
5. A monosaccharide designated as an aldehyde sugar contains (a) a terminal carboxyl group (b) an internal carboxyl group (c) a terminal carbonyl group (d) an internal carbonyl group (e) a terminal carboxyl group and an internal carbonyl group
6. Structural polysaccharides typically (a) have extensive hydrogen bonding between adjacent molecules (b) are much more hydrophilic than storage polysaccharides (c) have much stronger covalent bonds than do storage polysaccharides (d) consist of alternating α-glucose and β-glucose subunits (e) form helical structures in the cell
7. Saturated fatty acids are so named because they are saturated with (a) hydrogen (b) water (c) hydroxyl groups (d) glycerol (e) double bonds
8. Fatty acids in phospholipids and triacylglycerols interact with one another by (a) disulfide bridges (b) van der Waals interactions (c) covalent bonds (d) hydrogen bonds (e) fatty acids do not interact with one another
9. Which pair of amino acid side groups would be most likely to associate with each other by an ionic bond?
   1. $—CH_3$
   2. $—CH_2—COO^-$
   3. $—CH_2—CH_2—NH_3^+$
   4. $—CH_2—CH_2—COO^-$
   5. $—CH_2—OH$

   (a) 1 and 2 (b) 2 and 4 (c) 1 and 5 (d) 2 and 5 (e) 3 and 4
10. Which of the following levels of protein structure may be affected by hydrogen bonding? (a) primary and secondary (b) primary and tertiary (c) secondary, tertiary, and quaternary (d) primary, secondary, and tertiary (e) primary, secondary, tertiary, and quaternary
11. Which of the following associations between *R* groups are the strongest? (a) hydrophobic interactions (b) hydrogen bonds (c) ionic bonds (d) peptide bonds (e) disulfide bridges
12. Each phosphodiester linkage in DNA or RNA includes a phosphate joined by covalent bonds to (a) two bases (b) two sugars (c) two additional phosphates (d) a sugar, a base, and a phosphate (e) a sugar and a base

www.konkur.in

CRITICAL THINKING

1. Like oxygen, sulfur forms two covalent bonds. However, sulfur is far less electronegative. In fact, it is approximately as electronegative as carbon. How would the properties of the various classes of biological molecules be altered if you were to replace all the oxygen atoms with sulfur atoms?
2. Hydrogen bonds and van der Waals interactions are much weaker than covalent bonds, yet they are vital to organisms. Why?
3. **EVOLUTION LINK.** In what ways are all species alike biochemically? Why? Identify some ways in which species may differ from one another biochemically. Why?
4. **EVOLUTION LINK.** The total number of possible amino acid sequences in a polypeptide chain is staggering. Given that there are 20 amino acids, potentially there could be 20^{100} different amino acid sequences (an impossibly large number), just for polypeptides only 100 amino acids in length. However, the actual number of different polypeptides occurring in organisms is only a tiny fraction of this. Why?
5. **EVOLUTION LINK.** Each amino acid could potentially exist as one of two possible enantiomers, known as the D-form and the L-form (based on the arrangement of the groups attached to the asymmetric α carbon). However, in all organisms, only L-amino acids are found in proteins. What does this suggest about the evolution of proteins?

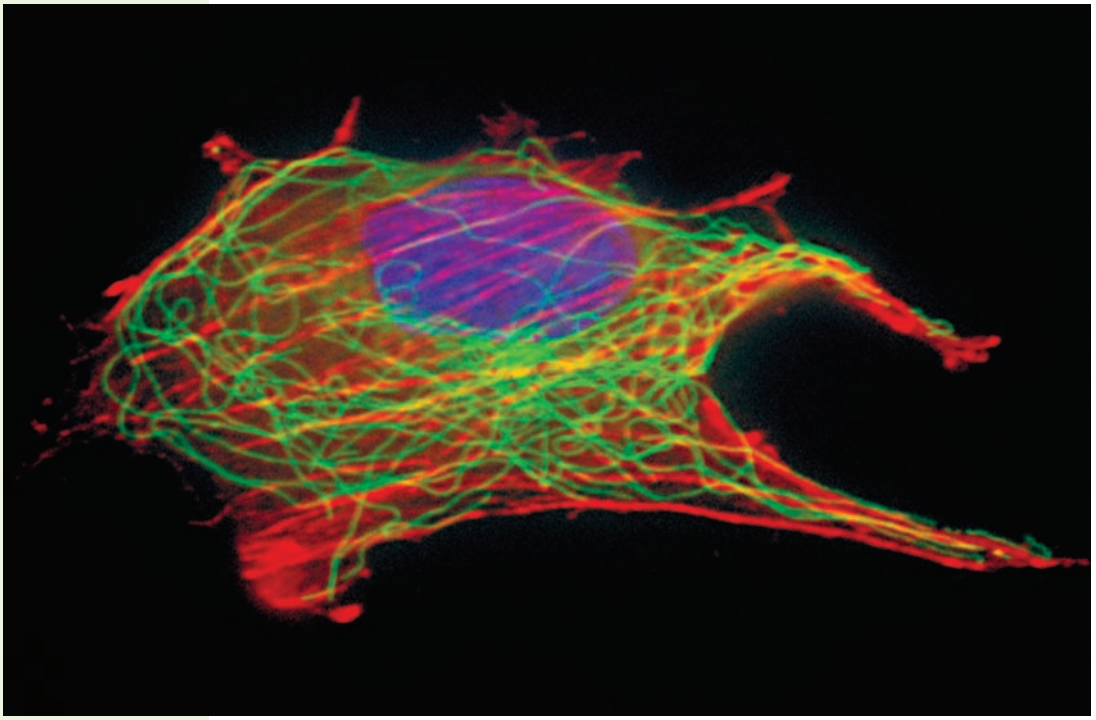
4 Organization of the Cell



Jennifer C. Waters/Photo Researchers, Inc.

The cytoskeleton. The cell shown here was stained with fluorescent antibodies (specific proteins) that bind to proteins associated with DNA (*purple*) and to a protein (tubulin) in microtubules (*green*). Microfilaments (*red*) are also visible. This type of microscopy, known as confocal fluorescence microscopy, shows the extensive distribution of microtubules in this cell.

KEY CONCEPTS

4.1 The cell is the basic unit of life; its organization and size are critical in maintaining homeostasis, and its size and shape are adapted for its function.

4.2 Biologists study cells using microscopes and biochemical techniques such as cell fractionation.

4.3 Unlike prokaryotic cells, eukaryotic cells have internal membranes that divide the cell into compartments, allowing cells to conduct specialized activities within separate, small areas.

4.4 In eukaryotic cells, genetic information coded in DNA is located in the nucleus, which is typically the most prominent organelle in the cell.

4.5 Among the many organelles in the cytoplasm are ribosomes, which synthesize proteins; endoplasmic reticulum and Golgi complexes, which process proteins; and mitochondria and chloroplasts, which convert energy from one form to another.

4.6 The cytoskeleton is a dynamic internal framework that functions in various types of cell movement.

4.7 Most eukaryotic cells are surrounded by a cell coat; in addition, many animal cells are surrounded by an extracellular matrix; cells of most bacteria, archaea, fungi, and plants are surrounded by a cell wall.

The cell is the smallest unit that can carry out all activities we associate with life. When provided with essential nutrients and an appropriate environment, some cells can be kept alive and growing in the laboratory for many years. By contrast, no isolated part of a cell is capable of sustained survival. As you read this chapter, recall the discussion of systems biology in Chapter 1. Even as we describe individual components of cells, we discuss how these components work together, generating complex biological systems within the cell. The cell itself is a highly intricate biological system, and groups of cells make up tissues, organs, and organisms. Each of these is a biological system.

Most prokaryotes and many protists and fungi consist of a single cell. In contrast, most plants and animals are composed of millions of cells. Cells are the building blocks of complex multicellular organisms. Although they are basically similar, cells are also extraordinarily diverse and versatile. They are modified in a variety of ways to carry out specialized functions.

The cell is composed of a vast array of inorganic and organic ions and molecules, including water, salts, carbohydrates, lipids, proteins, and nucleic acids. These molecules are organized to form the structures within the cell and its biochemical pathways. Genetic information is stored in DNA molecules and is faithfully replicated. This information is

www.konkur.in

passed to each new generation of cells during cell division. Information in DNA codes for specific proteins that, in turn, determine cell structure and function.

Cells exchange materials and energy with the environment. All living cells need one or more sources of energy, but a cell rarely obtains energy in a form that is immediately usable. Cells convert energy from one form to another, and that energy is used to carry out various activities, ranging from mechanical work to chemical synthesis. Cells convert energy to a convenient form, usually chemical energy stored in adenosine triphosphate, or ATP (see Chapter 3).

Both the chemical reactions that convert energy from one form to another and the mechanisms of information transfer are essentially the same in all cells, from those in bacteria to those of large, multicellular plants and animals. Such similarities suggest evolutionary relationships.

Thanks to advances in technology, cell biologists use increasingly sophisticated tools in their search to better understand the structure and function of cells. For example, investigation of the cytoskeleton (cell skeleton), currently an active and exciting area of research, has been greatly enhanced by advances in microscopy. In the photomicrograph, we see the extensive distribution of microtubules in cells. Microtubules are key components of the cytoskeleton. They help maintain cell shape, function in cell movement, and facilitate transport of materials within the cell.

4.1 THE CELL: BASIC UNIT OF LIFE

LEARNING OBJECTIVES

1 Describe the cell theory and relate it to the evolution of life.
2 Summarize the relationship between cell organization and homeostasis.
3 Explain the relationship between cell size and homeostasis.

Cells, the building blocks of organisms, are dramatic examples of the underlying unity of all living things.

The cell theory is a unifying concept in biology

Two German scientists, botanist Matthias Schleiden in 1838 and zoologist Theodor Schwann in 1839, used inductive reasoning to conclude that all plants and animals consist of cells. These investigators used their own observations and those of other scientists to reach their conclusions. Later, Rudolf Virchow, another German scientist, observed cells dividing and giving rise to daughter cells. In 1855, Virchow proposed that new cells form only by the division of previously existing cells. The work of Schleiden, Schwann, and Virchow contributed greatly to the development of the **cell theory,** the unifying concept that (1) cells are the basic living units of organization and function in all organisms and (2) that all cells come from other cells.

About 1880, another German biologist, August Weismann, added an important corollary to Virchow's concept by pointing out that the ancestry of all the cells alive today can be traced back to ancient times. Evidence that all living cells have a common origin is provided by the basic similarities in their structures and in the molecules of which they are made. When we examine a variety of diverse organisms, ranging from simple bacteria to the most complex plants and animals, we find striking similarities at the cellular level. Careful studies of shared cell characteristics help us trace the evolutionary history of various organisms and furnish powerful evidence that all organisms alive today had a common origin.

The organization of all cells is basically similar

The organization of cells and their small size allow them to maintain **homeostasis,** an appropriate internal environment. Cells experience constant changes in their environments, such as deviations in salt concentration, pH, and temperature. They must work continuously to restore and maintain the internal conditions that enable their biochemical mechanisms to function.

In order for the cell to maintain homeostasis, its contents must be separated from the external environment. The **plasma membrane** is a structurally distinctive surface membrane that surrounds all cells. By making the interior of the cell an enclosed compartment, the plasma membrane allows the chemical composition of the cell to be different from that outside the cell. The plasma membrane serves as a selective barrier between the cell contents and the outer environment. Cells exchange materials with the environment and can accumulate needed substances and energy stores.

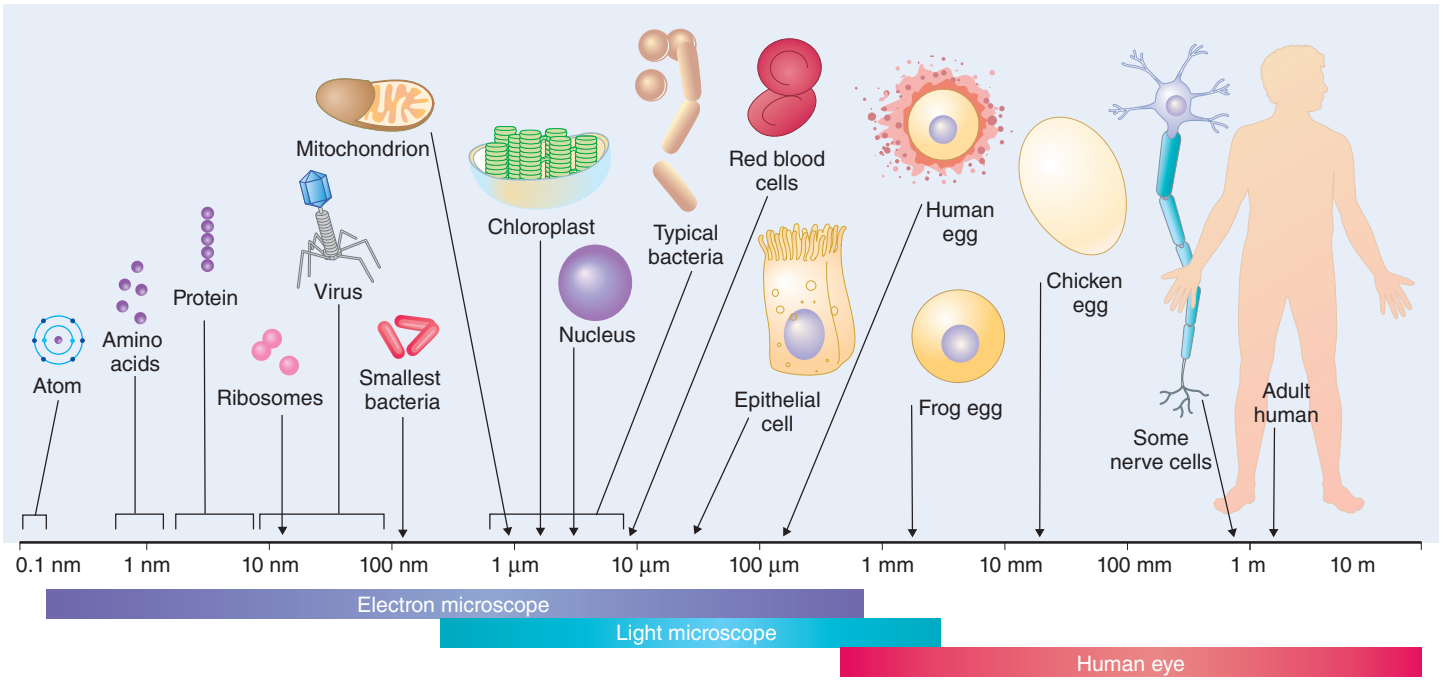
Most cells have internal structures, called **organelles,** that are specialized to carry out metabolic activities, such as converting energy to usable forms, synthesizing needed compounds, and manufacturing structures necessary for functioning and reproduction. Each cell has genetic instructions coded in its DNA, which is concentrated in a limited region of the cell.

Cell size is limited

Although their sizes vary over a wide range (**FIG. 4-1**), most cells are microscopic and must be measured by very small units. The basic unit of linear measurement in the metric system (see inside back cover) is the meter (m), which is just a little longer than a yard. A millimeter (mm) is 1/1000 of a meter and is about as long as the bar enclosed in parentheses (-). The micrometer (μm) is the most convenient unit for measuring cells. A bar 1 μm long is 1/1,000,000 (one millionth) of a meter, or 1/1000 of a millimeter—far too short to be seen with the unaided eye. Most of us have difficulty thinking about units that are too small to see, but it is helpful to remember that a micrometer has the same relationship to a millimeter that a millimeter has to a meter (1/1000).

As small as it is, the micrometer is actually too large to measure most cell components. For this purpose biologists use the nanometer (nm), which is 1/1,000,000,000 (one billionth) of a meter, or 1/1000 of a micrometer. To mentally move down to the world of the nanometer, recall that a millimeter is 1/1000 of a meter, a micrometer is 1/1000 of a millimeter, and a nanometer is 1/1000 of a micrometer.

www.konkur.in



Measurements		
1 meter	=	1000 millimeters (mm)
1 millimeter	=	1000 micrometers (µm)
1 micrometer	=	1000 nanometers (nm)

FIGURE 4-1 Biological size and cell diversity

We can compare relative size from the chemical level to the level of an entire organism by using a logarithmic scale (multiples of 10). The prokaryotic cells of most bacteria range in size from 1 to 10 μm long. Most eukaryotic cells are between 10 and 30 μm in diameter. Mitochondria are about the size of small bacteria, whereas chloroplasts are usually larger, about 5 μm long. Ova (egg cells) are among the largest cells. Although microscopic, some nerve cells are very long. The cells shown here are not drawn to scale.

A few specialized algae and animal cells are large enough to be seen with the naked eye. A human egg cell, for example, is about 130 μm in diameter, or approximately the size of the period at the end of this sentence. The largest cells are birds' eggs, but they are not typical cells because they include large amounts of food reserves—the yolk and the egg white. The functioning part of the cell is a small mass on the surface of the yolk.

Why are most cells so small? If you consider what a cell must do to maintain homeostasis and to grow, it may be easier to understand the reasons for its small size. A cell must take in food and other materials and must rid itself of waste products generated by metabolic reactions. Everything that enters or leaves a cell must pass through its plasma membrane. The plasma membrane contains specialized "pumps" and channels with "gates" that selectively regulate the passage of materials into and out of the cell. The plasma membrane must be large enough relative to the cell volume to keep up with the demands of regulating the passage of materials. Thus, a critical factor in determining cell size is the ratio of its surface area (the plasma membrane) to its volume (**FIG. 4-2**).

As a cell becomes larger, its volume increases at a greater rate than its surface area (its plasma membrane), which effectively places an upper limit on cell size. Above some critical size, the number of molecules required by the cell could not be transported into the cell fast enough to sustain its needs. In addition, the cell would not be able to regulate its concentration of various ions or efficiently export its wastes.

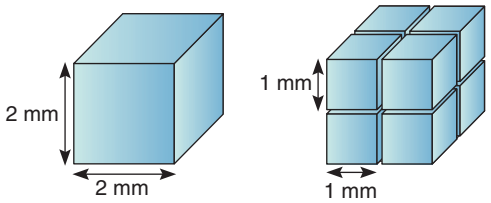
Of course, not all cells are spherical or cuboid. Because of their shapes, some very large cells have relatively favorable ratios of surface area to volume. In fact, some variations in cell shape represent a strategy for increasing the ratio of surface area to volume. For example, many large plant cells are long and thin, which increases their surface area–to-volume ratio. Some cells, such as epithelial cells lining the small intestine, have fingerlike projections of the plasma membrane, called **microvilli,** that significantly increase the surface area for absorbing nutrients and other materials (see Fig. 47-10).

Another reason for the small size of cells is that, once inside, molecules must be transported to the locations where they are converted into other forms. Because cells are small, the distances molecules travel within them are relatively short. Thus, molecules are rapidly available for cell activities.

Cell size and shape are adapted to function

The sizes and shapes of cells are adapted to the particular functions they perform. Some cells, such as amoebas and white blood

www.konkur.in



Surface Area (mm^2)	Surface area = height × width × number of sides × number of cubes	24 (2 × 2 × 6 × 1)	48 (1 × 1 × 6 × 8)
Volume (mm^3)	Volume = height × width × length × number of cubes	8 (2 × 2 × 2 × 1)	8 (1 × 1 × 1 × 8)
Surface Area/ Volume Ratio	Surface area/ volume	3 (24:8)	6 (48:8)

FIGURE 4-2 Surface area–to-volume ratio

The surface area of a cell must be large enough relative to its volume to allow adequate exchange of materials with the environment. Although their volumes are the same, eight small cells have a much greater surface area (plasma membrane) in relation to their total volume than one large cell does. In the example shown, the ratio of the total surface area to total volume of eight 1 mm cubes is double the surface area–to-volume ratio of the single large cube.

cells, change their shape as they move about. Sperm cells have long, whiplike tails, called *flagella,* for locomotion. Nerve cells have long, thin extensions that enable them to transmit messages over great distances. The extensions of some nerve cells in the human body may be as long as 1 meter! Certain epithelial cells are almost rectangular and are stacked much like building blocks to form sheetlike tissues. (Epithelial tissue covers the body and lines body cavities.)

Review

- How does the cell theory contribute to our understanding of the evolution of life?
- How does the plasma membrane help maintain homeostasis?
- Why is the relationship between surface area and volume of a cell important in detemining cell-size limits?

4.2 METHODS FOR STUDYING CELLS

LEARNING OBJECTIVE

4 Describe methods that biologists use to study cells, including microscopy and cell fractionation.

One of the most important tools biologists use for studying cell structures is the microscope. Using a microscope he had made, Robert Hooke, an English scientist, first described cells in 1665 in his book *Micrographia.* Hooke examined a piece of cork and drew and described what he saw. Hooke chose the term *cell* because the tissue reminded him of the small rooms monks lived in. Interestingly, what Hooke saw were not actually living cells but the walls of dead cork cells (**FIG. 4-3a**). Much later, scientists recognized that the interior enclosed by the walls is the important part of living cells.

A few years after Hooke's discovery and inspired by Hooke's work, the Dutch naturalist Antonie van Leeuwenhoek viewed living cells with small lenses that he made. Leeuwenhoek was highly skilled at grinding lenses and was able to magnify images more than 200 times. Among his important discoveries were bacteria, protists, blood cells, and sperm cells. Leeuwenhoek was among the first scientists to report cells in animals. Leeuwenhoek was a merchant and not formally trained as a scientist. However, his skill, curiosity, and diligence in sharing his discoveries with scientists at the Royal Society of London brought an awareness of microscopic life to the scientific world. Unfortunately, Leeuwenhoek did not share his techniques, and it was more than 100 years later, in the late 19th century, before microscopes were sufficiently developed for biologists to seriously focus their attention on the study of cells.

Light microscopes are used to study stained or living cells

The **light microscope (LM),** the type used by most students, consists of a tube with glass lenses at each end. Because it contains several lenses, the modern light microscope is referred to as a *compound microscope.* Visible light passes through the specimen being observed and through the lenses. Light is refracted (bent) by the lenses, magnifying the image. Images obtained with light microscopes are referred to as light micrographs, or **LMs.**

Two features of a microscope determine how clearly a small object can be viewed: magnification and resolving power. **Magnification** is the ratio of the size of the image seen with the microscope to the actual size of the object. The best light microscopes usually magnify an object no more than 2000 times. **Resolution,** or **resolving power,** is the capacity to distinguish fine detail in an image; it is defined as the minimum distance between two points at which they can both be seen separately rather than as a single, blurred point. Resolving power depends on the quality of the lenses and the wavelength of the illuminating light. As the wavelength decreases, the resolution increases.

The visible light used by light microscopes has wavelengths ranging from about 400 nm (violet) to 700 nm (red); this limits the resolution of the light microscope to details no smaller than the diameter of a small bacterial cell (about 0.2 μm). By the early 20th century, refined versions of the light microscope became available.

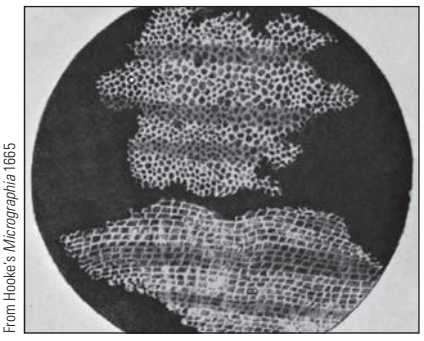
The interior of many cells is transparent and it is difficult to discern specific cell structures. Organic chemists have contributed greatly to light microscopy by developing biological stains that enhance contrast in the microscopic image. Staining has enabled biologists to discover the many different internal cell structures,

www.konkur.in

RESEARCH METHOD

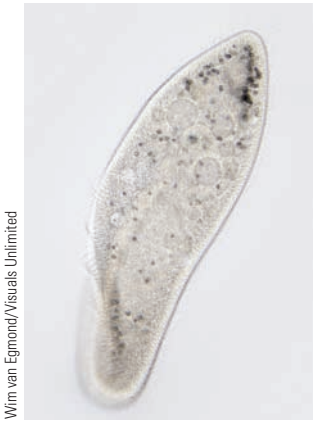
Why Is It Used?

Cells are too small to be studied with the naked eye. Biologists use microscopes to view cells and structures inside cells. Many types of microscopes have been developed. Here we look at photomicrographs of *Paramecia* (a group of ciliated protists) made using several kinds of light microscopes.



From Hooke's *Micrographia* 1665

(a) Robert Hooke's drawing of cork cells.

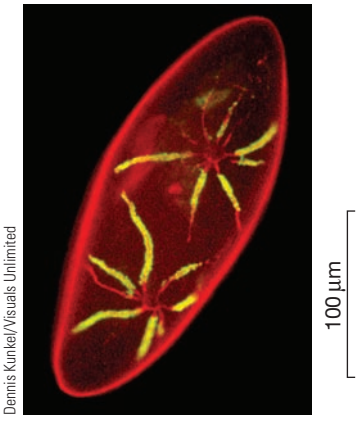


(b) Bright-field (stained).

(c) Dark-field.

(d) Phase contrast.

(e) Differential-interference-contrast (Nomarski).



(f) Confocal. Plasma membrane and contractile vacuoles are stained red. Proton pumps associated with the contractile vacuoles are stained yellow.

How Is It Done?

Using a crude microscope that he constructed, Robert Hooke looked at a thin slice of cork and drew what he saw. Biologists now view cells in more detail using the more sophisticated microscopes and techniques that have been developed. In the light microscope, a beam of light passes through the specimen being observed and through the lenses. The lenses refract the light, which magnifies the image. Bright-field microscopy can be enhanced by staining. The phase contrast and differential-interference-contrast microscopes enhance detail by increasing the differences in optical density in different regions of the cells.

FIGURE 4-3 ***Animated*** Using light microscopy

the organelles. Unfortunately, most methods used to prepare and stain cells for observation also kill them in the process.

Light microscopes with special optical systems now permit biologists to study living cells. In *bright-field microscopy,* an image is formed by transmitting light through a cell (or other specimen) (**FIG. 4-3b**). Because there is little contrast, the details of cell structure are not visible. In *dark-field microscopy,* rays of light are directed from the side, and only light scattered by the specimen enters the lenses. The cell is seen as a bright image against a dark background (**FIG. 4-3c**). The specimen does not need to be stained.

Phase contrast microscopy and *Nomarski differential-interference-contrast microscopy* take advantage of variations in density within the cell (**FIG. 4-3d** and **e**). These variations in density cause differences in the way various regions of the cytoplasm refract (bend)

www.konkur.in

light. Using these microscopes, scientists can observe living cells in action; they can view numerous internal structures that are constantly changing shape and location.

Cell biologists use the *fluorescence microscope* to detect the locations of specific molecules in cells. In the fluorescence microscope, filters transmit light that is emitted by fluorescently stained molecules. Fluorescent stains (like paints that glow under black light) are molecules that absorb light energy of one wavelength and then release some of that energy as light of a longer wavelength. These stains bind specifically to DNA or to specific protein molecules. The molecules absorb ultraviolet light and emit light of a different color. Cells can be stained, and the location of the labeled molecules can be determined, by observing the source of the fluorescent light within the cell. Biologists commonly use a fluorescent molecule known as green fluorescent protein (GFP) that occurs naturally in jellyfish. GFP has been valuable in observing specific proteins in living cells.

Some fluorescent stains chemically bond to *antibodies,* protein molecules important in internal defense. The antibody binds to a highly specific region of a molecule in the cell. A single type of antibody molecule binds to only one type of structure, such as a part of a specific protein or some of the sugars in a specific polysaccharide. Purified fluorescent antibodies known to bind to a specific protein are used to determine where that protein is located within the cell.

Confocal microscopy produces a sharper image than standard fluorescence microscopy (**FIG. 4-3f**). Living cells that have been labeled with fluorescent dye are mounted on a microscope slide. The confocal laser scanning microscope is a computerized microscope. A beam of ultraviolet light from a laser is focused at a specific depth within the cell. The fluorescent label emits visible light, and the investigator can visualize objects in a single plane of focus. The microscope produces optical sections (see the photomicrograph in the chapter introduction). A computer reassembles the images so that a series of optical sections from different planes of the cell can be used to construct a three-dimensional image. Powerful computer-imaging methods greatly improve the resolution of structures labeled by fluorescent dyes.

Electron microscopes provide a high-resolution image that can be greatly magnified

Even with improved microscopes and techniques for staining cells, ordinary light microscopes can distinguish only the gross details of many cell parts (**FIG. 4-4a**). In many cases, you can clearly see only the outline of an organelle. With the development of the **electron microscope (EM),** which came into wide use in the 1950s, researchers could begin to study the fine details, or **ultrastructure,** of cells.

The resolving power for the average human adult eye is about 100 μm. The best light microscopes have a resolving power of about 0.2 μm (200 nm). In comparison, some electron microscopes have resolving powers of just less than 1 nm. This is possible because electrons have very short wavelengths, on the order of about 0.1 to 0.2 nm. Although such resolution is difficult to achieve with biological material, researchers can approach that resolution when examining isolated molecules such as proteins and DNA. This high degree of resolution permits magnifications of more than 1 million times as compared to typical magnifications of no more than 1500 to 2000 times in light microscopy.

The image formed by the electron microscope is not directly visible. The electron beam itself consists of energized electrons, which, because of their negative charge, can be focused by electromagnets just as images are focused by glass lenses in a light microscope (**FIG. 4-4b**). Two main types of electron microscopes are the **transmission electron microscope (TEM)** and the **scanning electron microscope (SEM).** The acronyms TEM and SEM also identify that a micrograph was prepared using a transmission or scanning EM. Electron micrographs are black and white. They are often colorized to highlight various structures.

In transmission electron microscopy, the specimen is embedded in plastic and then cut into extraordinarily thin sections (50 to 100 nm thick) with a glass or diamond knife. A section is then placed on a small metal grid. The electron beam passes through the specimen and then falls onto a photographic plate or a fluorescent screen. When you look at TEMs in this chapter (and elsewhere), keep in mind that each represents only a thin cross section of a cell.

Researchers detect certain specific molecules in electron microscope images by using antibody molecules to which very tiny gold particles are bound. The dense gold particles block the electron beam and identify the location of the proteins recognized by the antibodies as precise black spots on the electron micrograph.

In the scanning electron microscope, the electron beam does not pass through the specimen. Instead, the specimen is coated with a thin film of gold or some other metal. When the electron beam strikes various points on the surface of the specimen, secondary electrons are emitted whose intensity varies with the contour of the surface. The recorded emission patterns of the secondary electrons give a 3-D picture of the surface (**FIG. 4-4c**). The SEM provides information about the shape and external features of the specimen that cannot be obtained with the TEM.

Note that the LM, TEM, and SEM are focused by similar principles. A beam of light or an electron beam is directed by the condenser lens onto the specimen and is magnified by the objective lens and the eyepiece in the light microscope or by the objective lens and the projector lens in the TEM. The TEM image is focused onto a fluorescent screen, and the SEM image is viewed on a type of television screen. Lenses in electron microscopes are actually electromagnets that bend the beam of electrons.

Several other types of microscopes are now available, including two additional kinds of electron microscopes. Digital microscopes that use cameras to send a digital image to a monitor have also been developed.

Biologists use biochemical techniques to study cell components

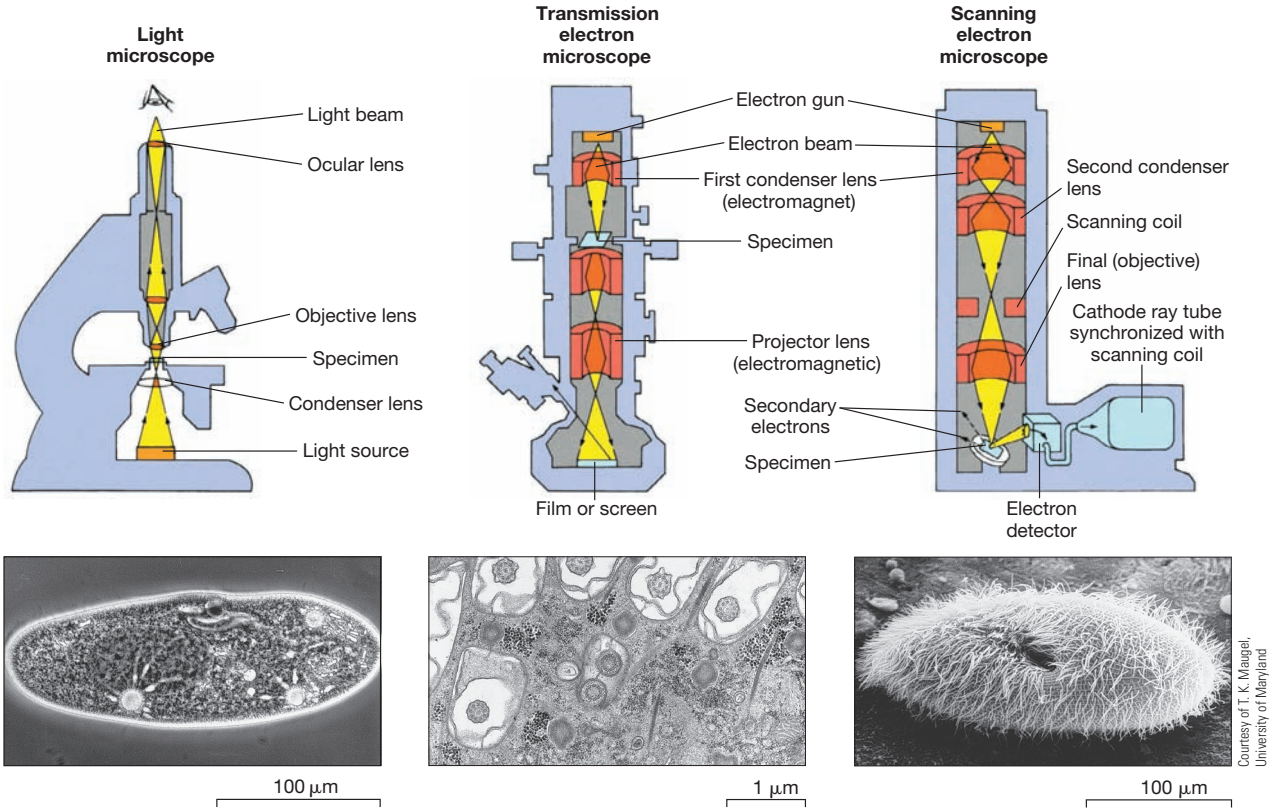
The EM is a powerful tool for studying cell structure, but it has limitations. The methods used to prepare cells for electron microscopy kill them and may alter their structure. Furthermore, electron microscopy provides few clues about the functions of organelles and other cell components. To determine what organelles actually do, researchers use a variety of biochemical techniques.

Cell fractionation is a technique for separating (fractionating) different parts of cells so that they can be studied by physical and chemical methods. Generally, cells are broken apart in a

www.konkur.in

RESEARCH METHOD

Why Is It Used? Electron microscopes have much greater resolving power than light microscopes. Electron microscopes can also magnify images to a much greater extent than light microscopes.



(a) A phase contrast light microscope can be used to view stained or living cells, but at relatively low resolution.

(b) The transmission electron microscope (TEM) produces a high-resolution image that can be greatly magnified. A small part of a thin slice through the *Paramecium* is shown.

(c) The scanning electron microscope (SEM) provides a clear view of surface features.

How Is It Done? In an electron microscope, a beam of electrons is focused on or through the specimen. Instead of glass lenses, electromagnetic lenses are used to form the image. Here we compare images of the protist *Paramecium* made using a phase contrast light microscope with images made using two types of electron microscopes. These three microscopes produce distinctive images of cells.

FIGURE 4-4 ***Animated*** **Using electron microscopes**

blender. The resulting mixture, called the **cell homogenate,** is subjected to centrifugal force by spinning in a **centrifuge** (FIG. 4-5a). The powerful ultracentrifuge can spin at speeds exceeding 100,000 revolutions per minute (rpm), generating a centrifugal force of 500,000 × *G* (a *G* is equal to the force of gravity). Centrifugal force separates the extract into two fractions: a pellet and a supernatant. The *pellet* that forms at the bottom of the tube contains heavier materials, such as nuclei, packed together. The *supernatant,* the liquid above the pellet, contains lighter particles, dissolved molecules, and ions.

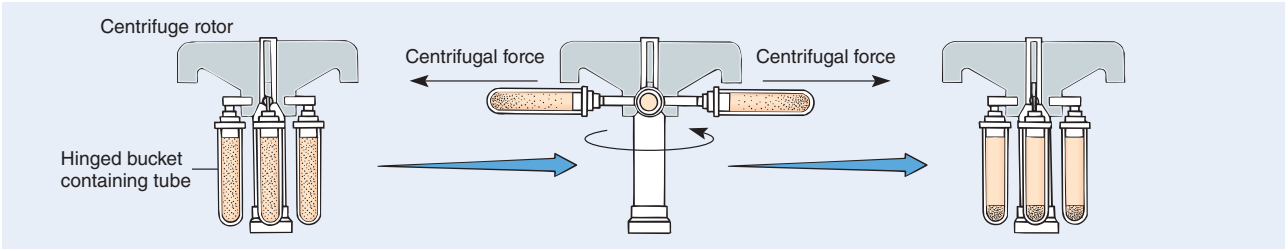
After the pellet is removed, the supernatant can be centrifuged again at a higher speed to obtain a pellet that contains the next-heaviest cell components, for example, mitochondria and chloroplasts. In **differential centrifugation,** the supernatant is spun at successively higher speeds, permitting various cell components to be separated on the basis of their different sizes and densities (FIG. 4-5b).

The pellets can be resuspended and their components can be further purified by **density gradient centrifugation.** In this procedure, the centrifuge tube is filled with a series of solutions of decreasing density. For example, sucrose solutions can be used. The concentration of sucrose is highest at the bottom of the tube and decreases gradually so that it is lowest at the top. The resuspended pellet is placed in a layer on top of the density gradient. Because the densities of organelles differ, each migrates during centrifugation. Each type of organelle forms a band at the position in the gradient where its own density equals that of the sucrose solution (FIG. 4-5c).

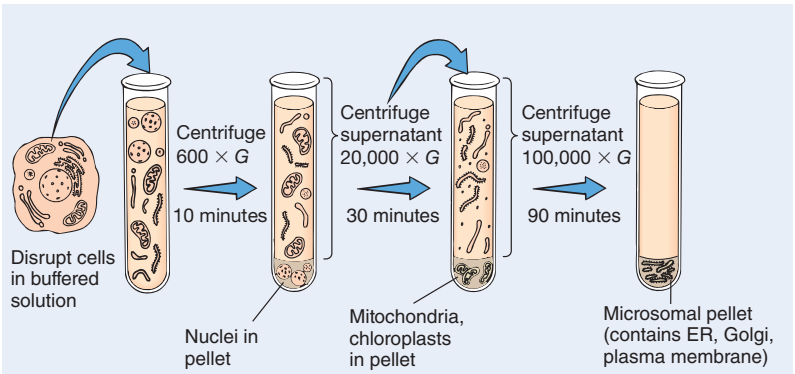
www.konkur.in

RESEARCH METHOD

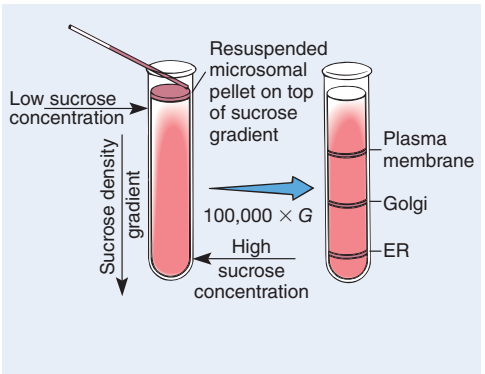
Why Is It Used? Cell fractionation is used to separate (fractionate) cell components according to their size and density.



(a) Centrifugation. Due to centrifugal force, large or very dense particles move toward the bottom of a tube and form a pellet.



(b) Differential centrifugation.



(c) Density gradient centrifugation.

How Is It Done? Cells are broken up in a blender. The cell homogenate (the resulting mixture) is then spun in a centrifuge. As a result of centrifugal force, the heaviest cell components, the nuclei, form a pellet at the bottom of the tube. The supernatant (the liquid above the pellet) can then be spun at a higher speed. The next heaviest component, the mitochondria and chloroplasts, form a pellet, and the supernatant can be spun at a higher speed. This process can be repeated several times. The pellet can be further purified by density gradient centrifugation (see text for further explanation).

FIGURE 4-5 Cell fractionation

Purified organelles can then be studied. For example, they can be examined to determine what kinds of proteins and other molecules they might contain, or what types of chemical reactions take place within them.

Review

- What is the main advantage of the electron microscope? Explain.
- What is cell fractionation? Describe the process.

4.3 PROKARYOTIC AND EUKARYOTIC CELLS

LEARNING OBJECTIVES

5 Compare and contrast the general characteristics of prokaryotic and eukaryotic cells, and contrast plant and animal cells.

6 Describe three functions of cell membranes.

Recall from Chapter 1 that two basic types of cells are known: **prokaryotic cells** and **eukaryotic cells.** Bacteria and archaea are prokaryotic cells. All other known organisms consist of eukaryotic cells.

Organelles of prokaryotic cells are not surrounded by membranes

Prokaryotic cells are typically smaller than eukaryotic cells. In fact, the average prokaryotic cell is only about 1/10 the diameter of the average eukaryotic cell. In prokaryotic cells, the DNA is typically located in a limited region of the cell called a **nuclear area,** or **nucleoid.** Unlike the nucleus of eukaryotic cells, the nuclear area is not enclosed by a membrane (**FIG. 4-6**). The term *prokaryotic,* meaning "before the nucleus," refers to this major difference between prokaryotic and eukaryotic cells. Other types of internal membrane–enclosed organelles are also absent in prokaryotic cells.

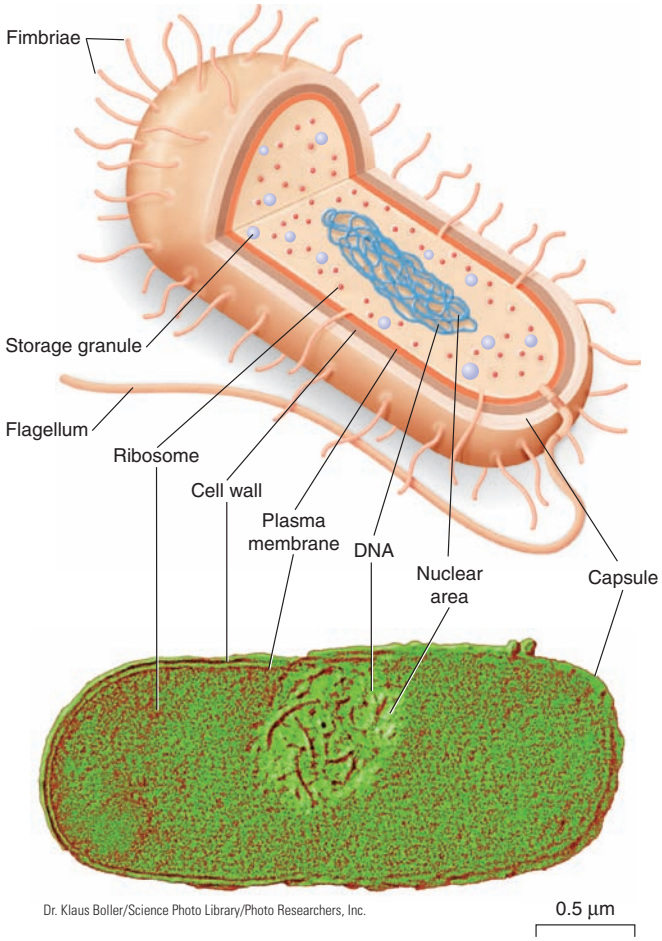
Like eukaryotic cells, prokaryotic cells have a plasma membrane that surrounds the cell. The plasma membrane confines the

www.konkur.in

contents of the cell to an internal compartment. In some prokaryotic cells, the plasma membrane may be folded inward to form a complex of membranes along which many of the cell's metabolic reactions take place. Most prokaryotic cells have **cell walls,** which are extracellular structures that enclose the entire cell, including the plasma membrane.

Many prokaryotes have **flagella** (sing., *flagellum*), long fibers that project from the surface of the cell. Prokaryotic flagella, which operate like propellers, are important in locomotion. Their structure is different from that of flagella found in eukaryotic cells. Some prokaryotes also have hairlike projections called *fimbriae,* which are used to adhere to one another or to attach to cell surfaces of other organisms.

The dense internal material of the bacterial cell contains **ribosomes,** small complexes of ribonucleic acid (RNA) and protein that synthesize polypeptides. The ribosomes of prokaryotic cells are smaller than those found in eukaryotic cells. Prokaryotic cells also contain storage granules that hold glycogen, lipid, or phosphate compounds. This chapter focuses primarily on eukaryotic cells. Prokaryotes are discussed in more detail in Chapter 25.



Dr. Klaus Boller/Science Photo Library/Photo Researchers, Inc.

FIGURE 4-6 ***Animated*** **Structure of a prokaryotic cell**
This colorized TEM shows a thin lengthwise slice through an *Escherichia coli* bacterium. Note the prominent nuclear area containing the genetic material (DNA). *E. coli* is a normal inhabitant of the human intestine, but under certain conditions some strains can cause infections.

Membranes divide the eukaryotic cell into compartments

Eukaryotic cells are characterized by highly organized membrane-enclosed organelles, including a prominent *nucleus,* which contains DNA, the hereditary material. The term *eukaryotic* means "true nucleus." Early biologists thought cells consisted of a homogeneous jelly, which they called *protoplasm.* With the electron microscope and other modern research tools, perception of the environment within the cell has been greatly expanded. We now know that the cell is highly organized and complex (**FIGS. 4-7** through **4-10**). The eukaryotic cell has its own control center, internal transportation system, power plants, factories for making needed materials, packaging plants, and even a "self-destruct" system.

Biologists refer to the part of the cell outside the nucleus as **cytoplasm** and the part of the cell within the nucleus as **nucleoplasm.** Various organelles are suspended within the fluid component of the cytoplasm, which is called the **cytosol.** The term *cytoplasm* includes both the cytosol and all the organelles other than the nucleus.

The many specialized organelles of eukaryotic cells solve some of the problems associated with large size, so eukaryotic cells can be larger than prokaryotic cells. Eukaryotic cells also differ from prokaryotic cells in having a supporting framework, or cytoskeleton, important in maintaining shape and transporting materials within the cell.

Some organelles are present only in specific cells. For example, *chloroplasts,* structures that trap sunlight for energy conversion, are only in cells that carry on photosynthesis, such as certain plant or algal cells. Cells of fungi and plants are surrounded by a *cell wall* external to the plasma membrane. Plant cells also contain a large, membrane-enclosed *vacuole.* We discuss these and other differences among major types of cells throughout this chapter. Plant and animal cells are compared in Figures 4-7 and 4-8 and also in Figures 4-9 and 4-10.

Cell membranes have unique properties that enable membranous organelles to carry out a wide variety of functions. For example, cell membranes never have free ends. As a result, a membranous organelle always contains at least one enclosed internal space or compartment. These membrane-enclosed compartments allow certain cell activities to be localized within specific regions of the cell. Reactants located in only a small part of the total cell volume are far more likely to come in contact, dramatically increasing the rate of the reaction. On the other hand, membrane-enclosed compartments keep certain reactive compounds away from other parts of the cell that they might adversely affect. Compartmentalizing also allows many different activities to go on simultaneously.

Membranes serve as important work surfaces. For example, many chemical reactions in cells are carried out by enzymes that are bound to membranes. Because the enzymes that carry out successive steps of a series of reactions are organized close together on a membrane surface, certain series of chemical reactions occur more rapidly.

Membranes allow cells to store energy. The membrane serves as a barrier that is somewhat analogous to a dam on a river. As we will discuss in Chapter 5, there is both an electric charge difference and a concentration difference on the two sides of the membrane.

www.konkur.in

These differences constitute an *electrochemical gradient*. Such gradients store energy and so have *potential energy* (discussed in Chapter 7). As particles of a substance move across the membrane from the side of higher concentration to the side of lower concentration, the cell can convert some of this potential energy to the chemical energy of ATP molecules. This process of energy conversion (discussed in Chapters 7, 8, and 9) is a basic mechanism that cells use to capture and convert the energy necessary to sustain life.

In a eukaryotic cell, several types of membranes make up the internal membrane system, or **endomembrane system.** In Figures 4-7 and 4-8 (also see Figs. 4-9 and 4-10), notice how membranes divide the cell into many compartments: the nucleus, endoplasmic reticulum (ER), Golgi complex, lysosomes, vesicles, and vacuoles. Although it is not internal, the plasma membrane is also included because it participates in the activities of the endomembrane system. (Mitochondria and chloroplasts are also separate compartments but are not generally considered part of the endomembrane system because they function somewhat independently of other membranous organelles.)

Some organelles have direct connections between their membranes and other compartments. Others transport materials in **vesicles,** small, membrane-enclosed sacs formed by "budding" from

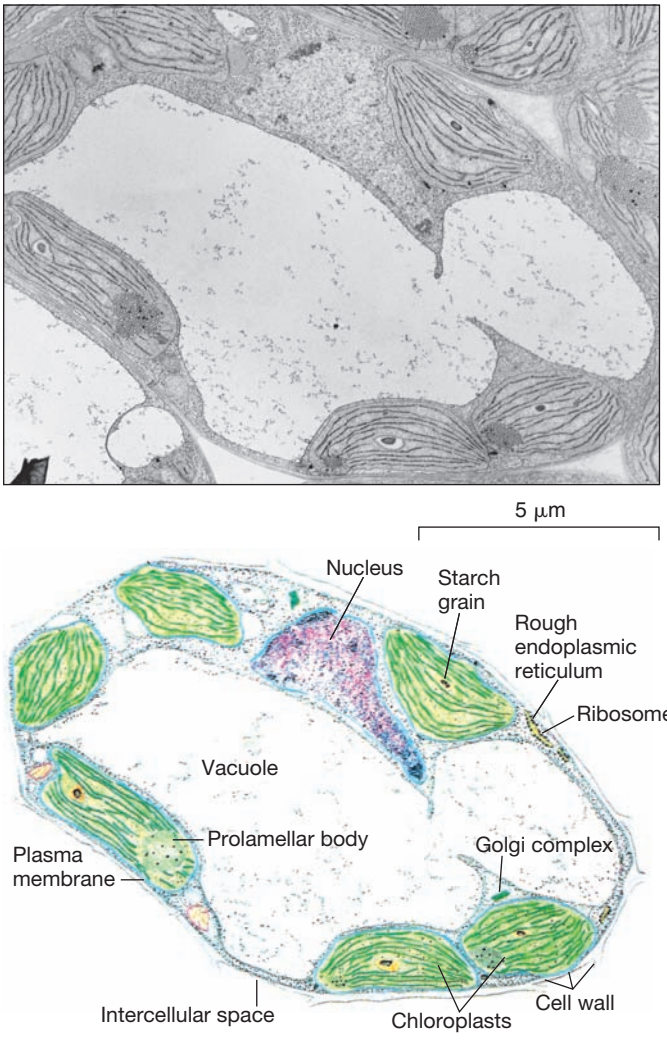


FIGURE 4-7 TEM of a plant cell and an interpretive drawing

Most of this cross section of a cell from the leaf of a young bean plant (*Phaseolus vulgaris*) is dominated by a vacuole. Prolamellar bodies are membranous regions typically seen in developing chloroplasts. Can you label the TEM?

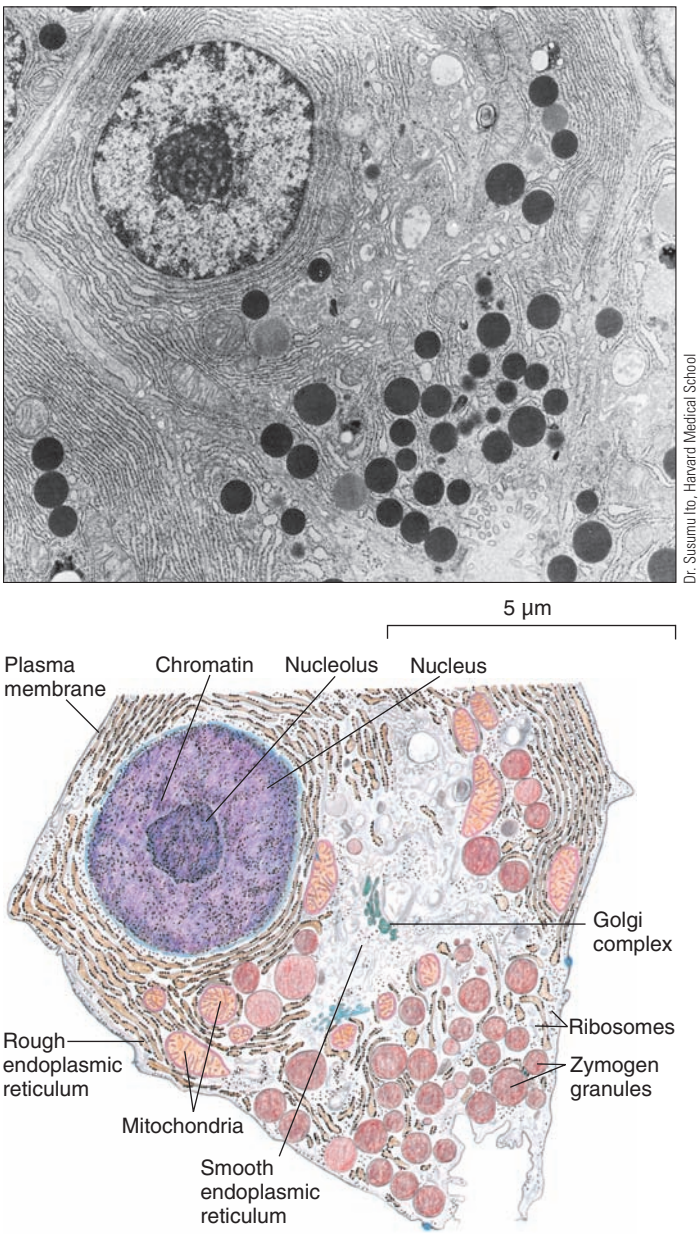

FIGURE 4-8 TEM of a human pancreas cell and an interpretive drawing

Most of the structures of a typical animal cell are present. However, like most cells, this one has certain structures associated with its specialized functions. Pancreas cells such as the one shown here secrete large amounts of digestive enzymes. The large, dark, circular bodies in the TEM and the corresponding structures in the drawing are zymogen granules, which contain inactive enzymes. When released from the cell, the enzymes catalyze chemical reactions such as the breakdown of peptide bonds of ingested proteins in the intestine. Most of the membranes visible in this section are part of the rough endoplasmic reticulum, an organelle specialized to manufacture protein. Can you label the TEM?

www.konkur.in

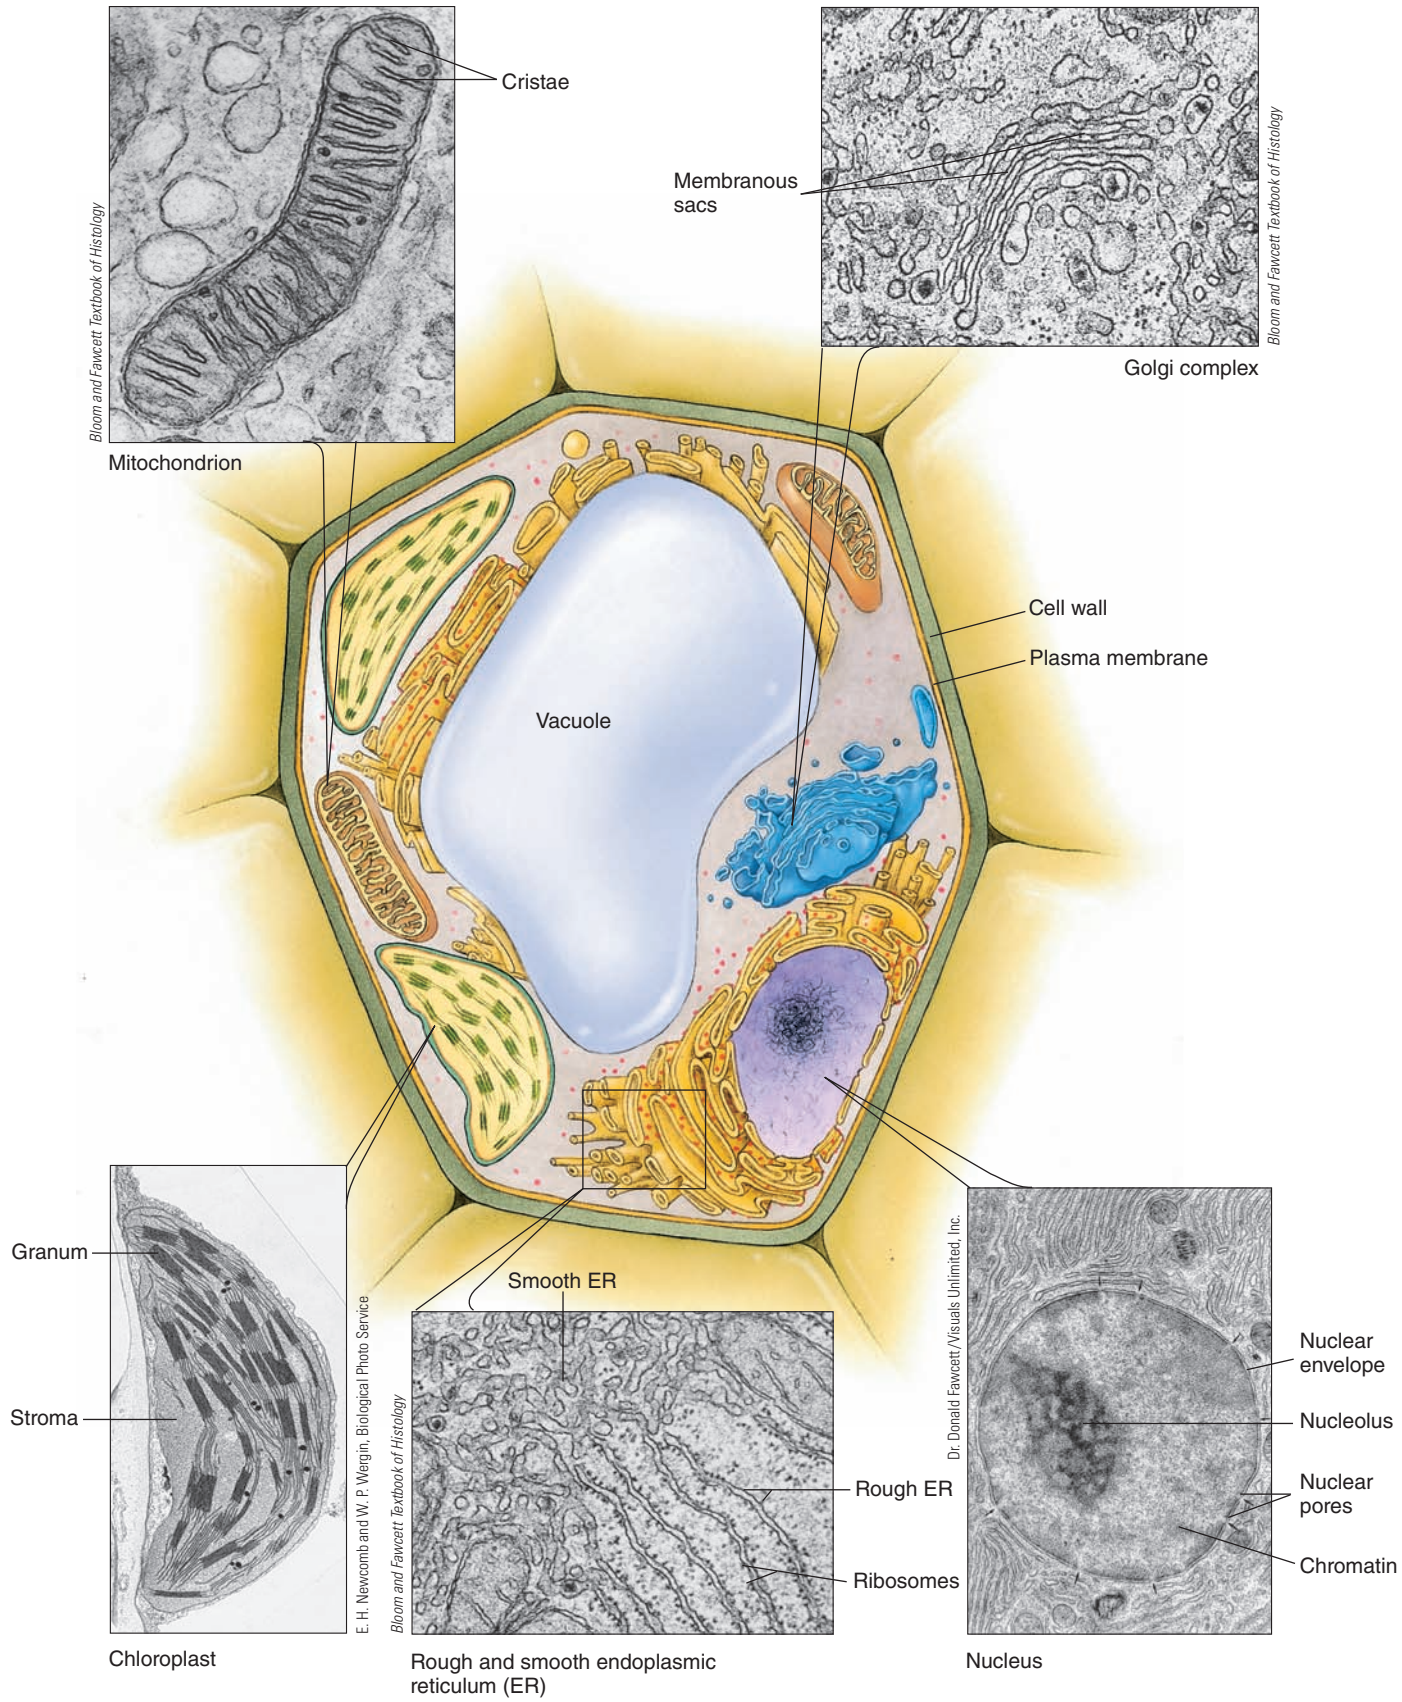

FIGURE 4-9 ***Animated*** **Composite diagram of a plant cell**

Plant cells typically have a cell wall, chloroplasts, and prominent vacuoles. The TEMs show specific structures or areas of the cell. Some plant cells do not have all the organelles shown here. For example, leaf and stem cells that carry on photosynthesis contain chloroplasts, whereas root cells do not. Many of the organelles, such as the nucleus, mitochondria, and endoplasmic reticulum (ER), are characteristic of all eukaryotic cells.

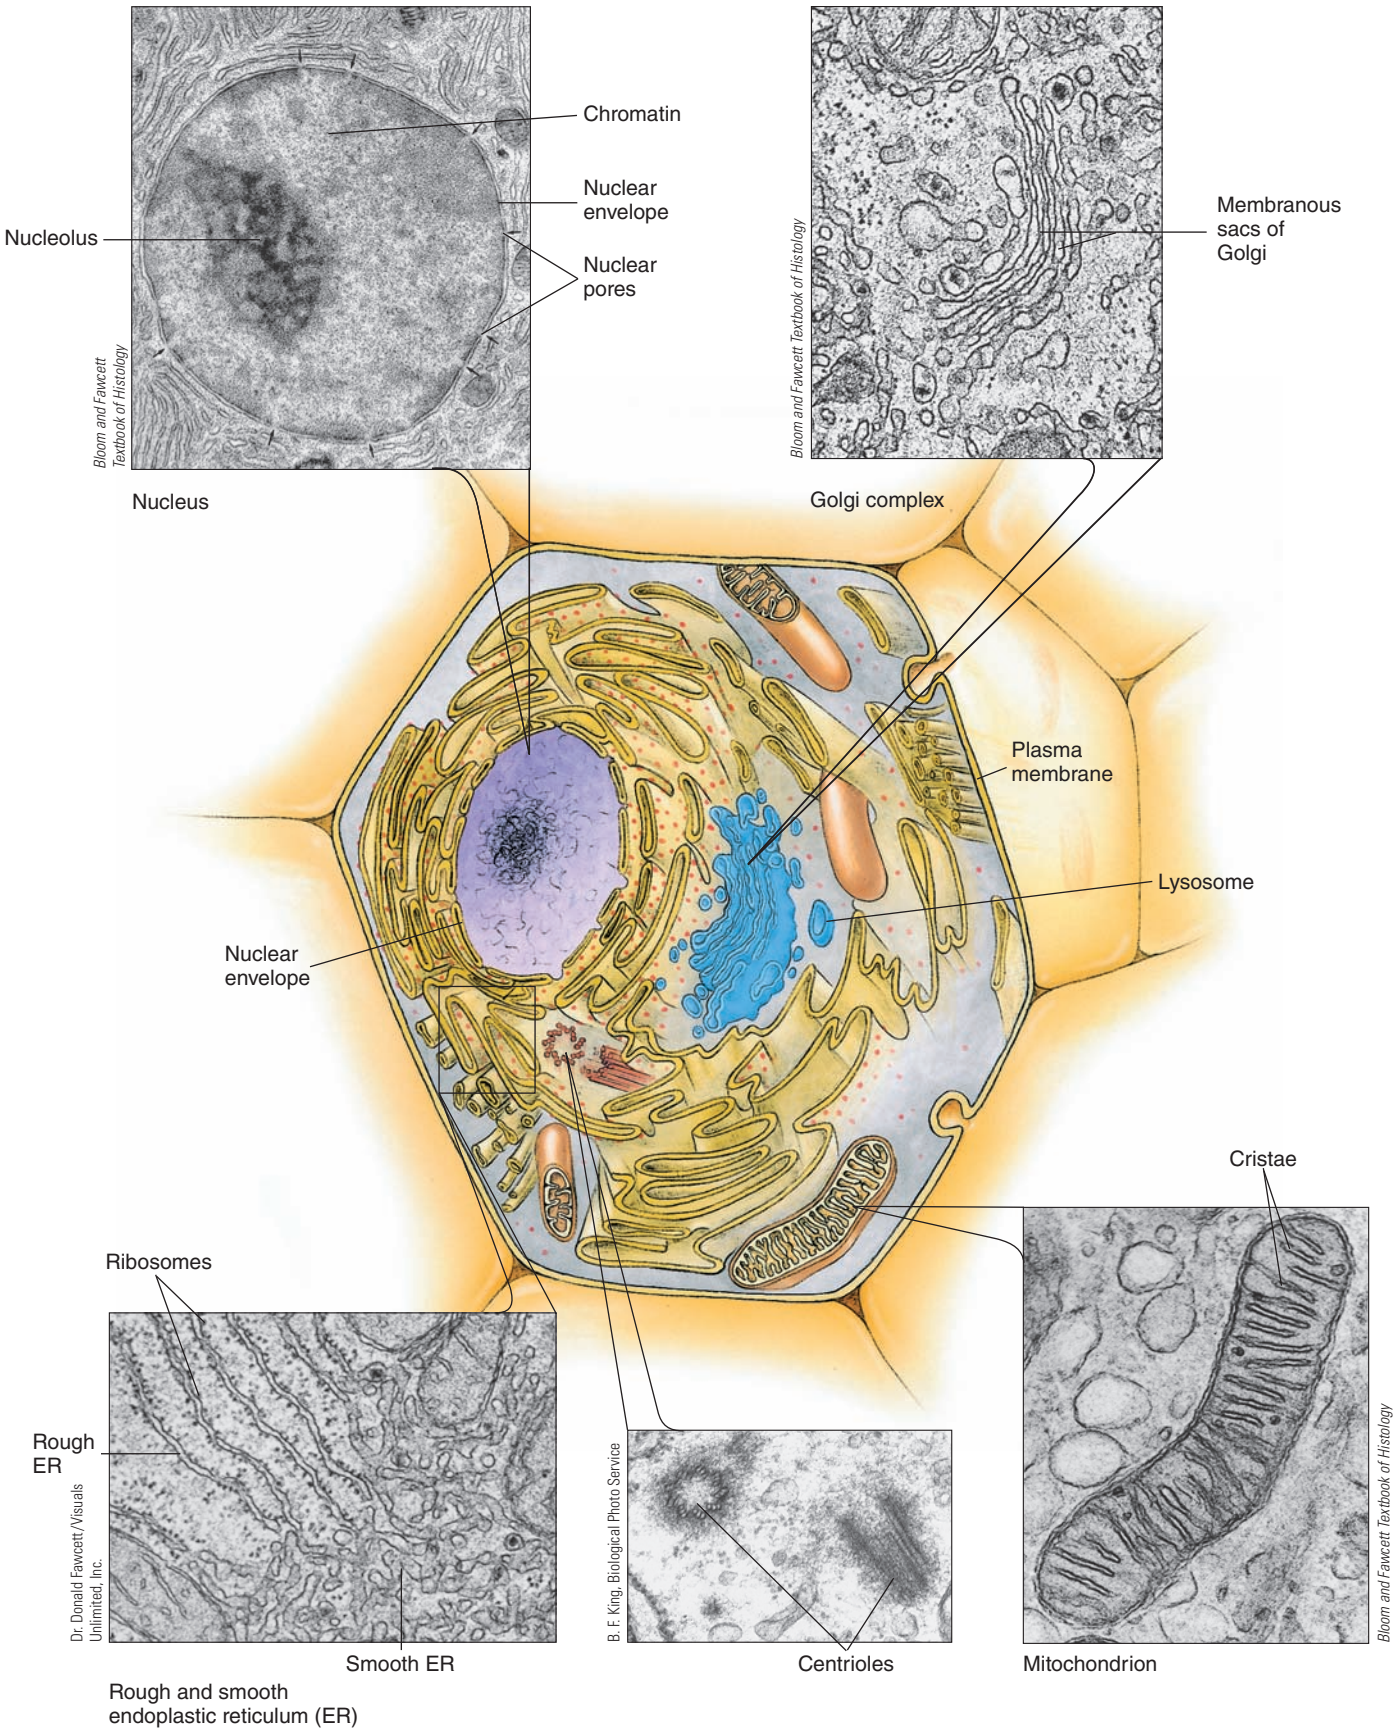

FIGURE 4-10 ***Animated*** **Composite diagram of an animal cell**

This generalized animal cell is shown in a realistic context surrounded by adjacent cells, which cause it to be slightly compressed. The TEMs show the structure of various organelles. Depending on the cell type, certain organelles may be more or less prominent.

www.konkur.in

the membrane of another organelle. Vesicles carry cargo from one organelle to another. A vesicle can form as a "bud" from the membrane of one organelle and then move to another organelle to which it fuses, thus delivering its contents into another compartment.

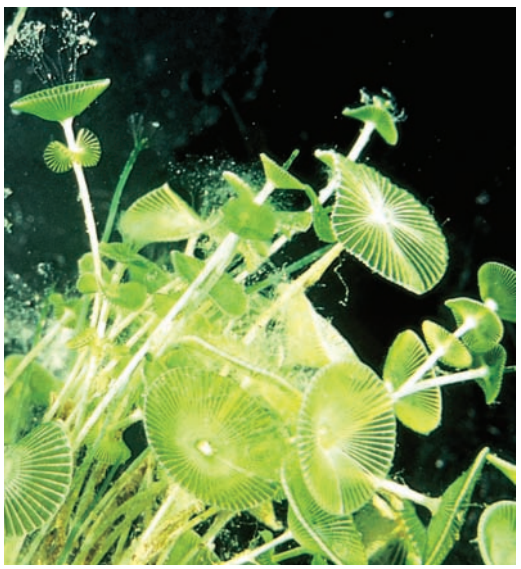
4.4 THE CELL NUCLEUS

LEARNING OBJECTIVE

7 Describe the structure and functions of the nucleus.

Typically, the **nucleus** is the most prominent organelle in the cell. It is usually spherical or oval in shape and averages 5 μm in diameter. Because of its size and the fact that it often occupies a relatively fixed position near the center of the cell, some early investigators guessed long before experimental evidence was available that the nucleus served as the control center of the cell. In the 19th century, biologists discovered that the marine alga *Acetabularia* consists of a single cell (**FIG. 4-11**). At up to 5 cm (2 in) in length, *Acetabularia* is small for a seaweed but gigantic for a cell. It consists of a rootlike holdfast; a long, cylindrical stalk; and a cuplike cap. The nucleus is in the holdfast, about as far away from the cap as it can be. Because it is a single giant cell, *Acetabularia* is easy for researchers to manipulate.

If the cap of *Acetabularia* is removed experimentally, another one grows after a few weeks. Such **regeneration** is common among simple organisms. This fact attracted the attention of investigators, especially Danish biologist J. Hämmerling, who became interested in whether a relationship exists between the nucleus and the physical characteristics of the alga. Hämmerling (during the 1930s to 1950s) performed brilliant experiments that in many ways laid the foundation for much of our modern knowledge of the nucleus. Some of his experiments are summarized in **FIGURE 4-12**. Cell biologists extended these early findings as they developed our modern view of information flow and control in the cell. We now know that the cell stores information in the form of **DNA,** and most of the cell's DNA is located inside the nucleus.



L. Sims/Visuals Unlimited

FIGURE 4-11 LM of *Acetabularia*

To the romantically inclined, the little seaweed *Acetabularia* resembles a mermaid's wineglass, although the literal translation of its name, "vinegar cup," is somewhat less elegant. *Acetabularia,* which consists of a single cell, has been a model organism for investigating the role of the nucleus.

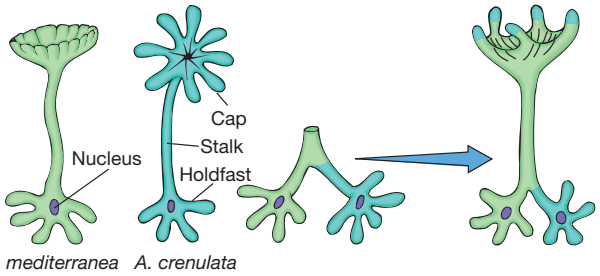
KEY EXPERIMENTS

EXPERIMENT 1

QUESTION: What controls the shape of the cap in *Acetabularia*?

HYPOTHESIS: Something in the stalk or holdfast of *Acetabularia* controls the shape of the cap.

EXPERIMENT: Hämmerling removed the caps from *A. mediterranea* and *A. crenulata*. He then grafted together the two capless algae (**FIG. a**).



(a)

RESULTS AND CONCLUSION: The algae regenerated a common cap with characteristics intermediate between those of the two species involved. This experiment demonstrated that something in the stalk or holdfast controls cap shape.

FIGURE 4-12 *Acetabularia* and the control of cell activities

Biologist J. Hämmerling used two species of the single-celled seaweed *Acetabularia* for most of his experiments: *A. mediterranea,* which has a smooth cap, and *A. crenulata,* which has a cap divided into a series of fingerlike projections. When the cap is removed, the kind of cap that is regenerated depends on the species of *Acetabularia* used in the experiment. As you might expect, *A. crenulata* regenerates a "cren" cap, and *A. mediterranea* regenerates a "med" cap.

The **nuclear envelope** consists of two concentric membranes that separate the nuclear contents from the surrounding cytoplasm (**FIG. 4-13**). These membranes are separated by about 20 to 40 nm. At intervals the membranes come together to form **nuclear pores.** Each nuclear pore consists of a molecular complex made up of many copies of about 30 different proteins. Nuclear pores regulate the passage of materials between nucleoplasm and cytoplasm.

A fibrous network of protein filaments, called the **nuclear lamina,** forms an inner lining for the nuclear envelope. The nuclear

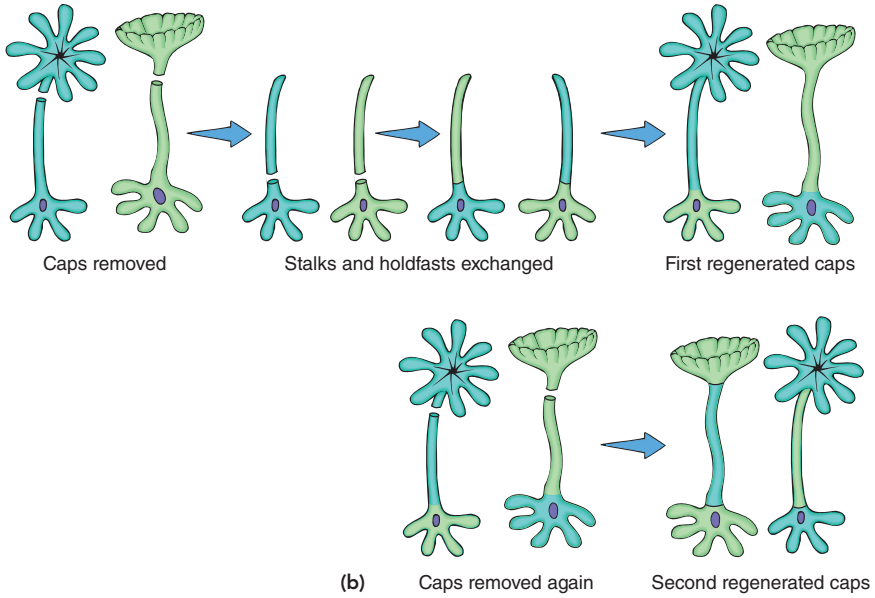
www.konkur.in

EXPERIMENT 2

QUESTION: Does the stalk or the holdfast control the shape of the cap in *Acetabularia?*

HYPOTHESIS: Something in the holdfast of *Acetabularia* controls the shape of the cap.

EXPERIMENT: Hämmerling removed the caps from *A. mediterranea* and *A. crenulata*. Then he severed the stalks from the holdfasts. By telescoping the cell walls of the two species into each other, Hämmerling was able to attach a section of the stalk of one species to a holdfast of the other species (see **FIG. b**).



RESULTS AND CONCLUSION: The results were surprising. The caps that regenerated were characteristic not of the species donating the holdfasts but of those donating the stalks! However, when the caps were removed once again, this time the caps that regenerated were characteristic of the species that donated the holdfasts. This continued to be the case no matter how many more times the regenerated caps were removed.

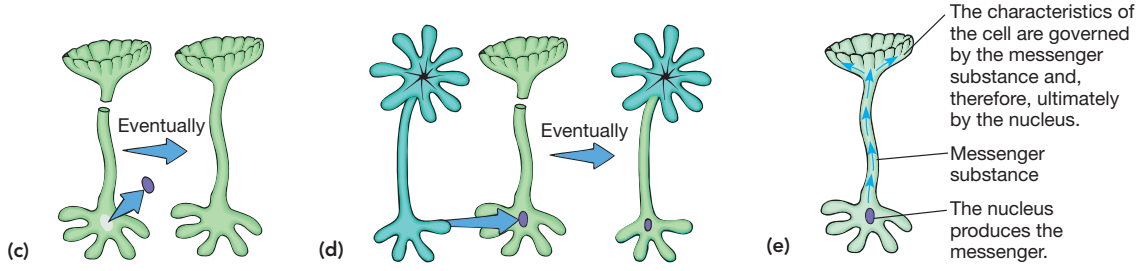
From these results Hämmerling deduced that the ultimate control of the *Acetabularia* cell is associated with the holdfast. Because there is a time lag before the holdfast appears to take over, he hypothesized it produces some temporary cytoplasmic messenger substance whereby it exerts its control. Hämmerling further hypothesized that the grafted stalks initially contain enough of the substance from their former holdfasts to regenerate a cap of the former shape. But this still left the question of how the holdfast exerts its apparent control. An obvious suspect was the nucleus.

EXPERIMENT 3

QUESTION: Does the nucleus in the holdfast control the shape of the cap in *Acetabularia*?

HYPOTHESIS: The nucleus in the holdfast of *Acetabularia* controls the shape of the cap.

EXPERIMENT: Hämmerling removed the nucleus and cut off the cap of *Acetabularia* (**FIG. c**). A new cap typical of the species regenerated. *Acetabularia,* however, can usually regenerate only once without a nucleus. The researcher inserted a nucleus of another species and cut the cap off once again (**FIG. d**).



RESULTS AND CONCLUSION: A new cap regenerated that was characteristic of the species of the nucleus. When two kinds of nuclei were inserted, the regenerated cap was intermediate in shape between those of the species that donated the nuclei.

As a result of these and other experiments, biologists began to develop some basic ideas about the control of cell activities. The holdfast controls the cell because the nucleus is located there. Further, the nucleus is the apparent source of some "messenger substance" that temporarily exerts control but is limited in quantity and cannot be produced without the nucleus (**FIG. e**). This information helped provide a starting point for research on the role of nucleic acids in the control of all cells. Much later, the "messenger substance" was characterized and named messenger RNA (mRNA).

www.konkur.in

KEY POINT The nucleus contains DNA and is the control center of the cell.

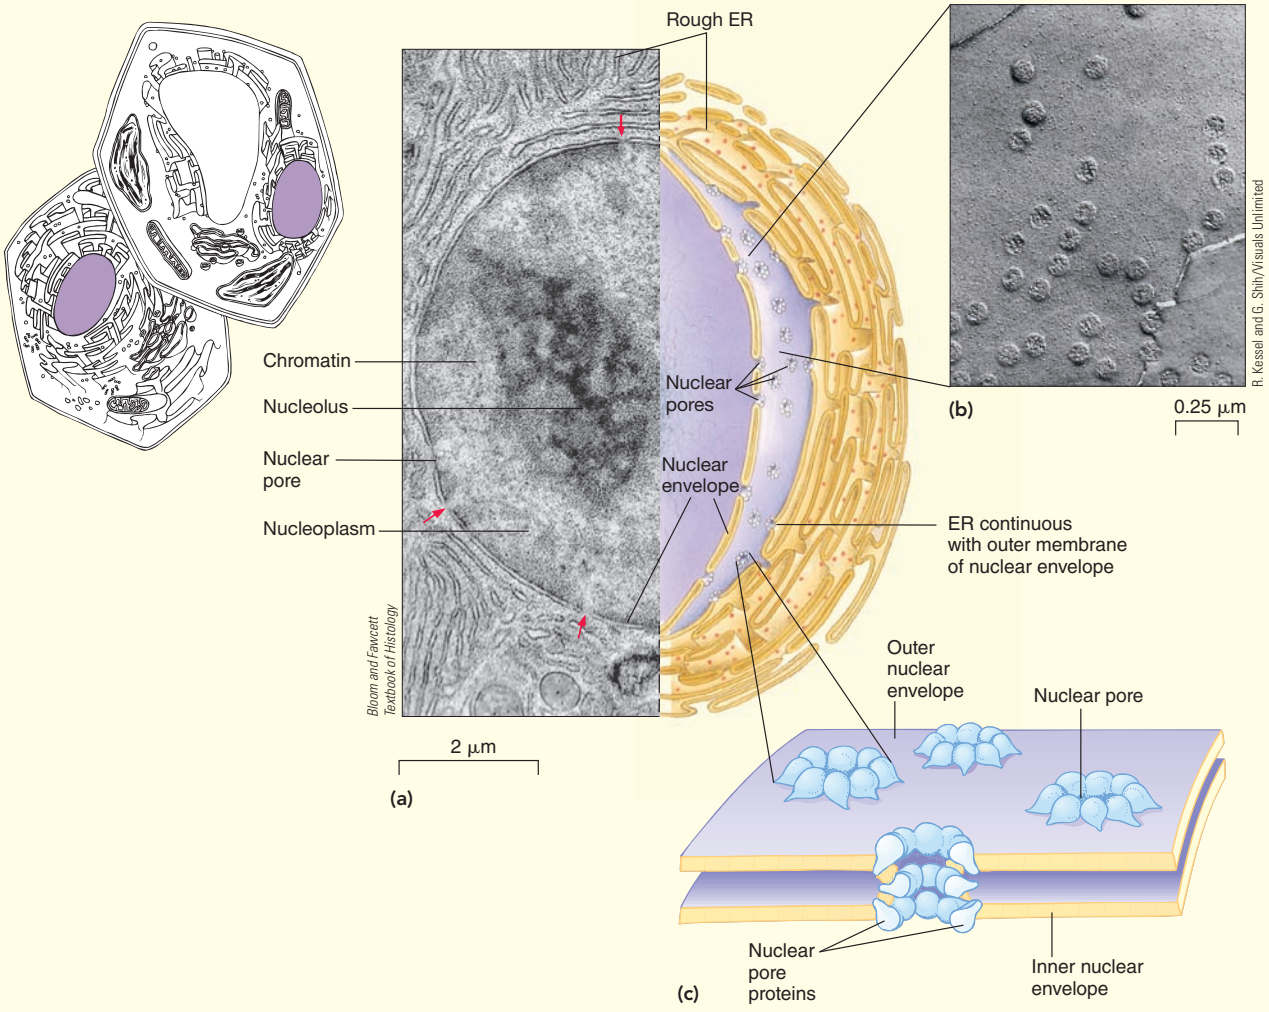


FIGURE 4-13 ***Animated*** **The cell nucleus**

(a) The TEM and interpretive drawing show that the nuclear envelope, composed of two concentric membranes, is perforated by nuclear pores (*red arrows*). The outer membrane of the nuclear envelope is continuous with the membrane of the ER (endoplasmic reticulum). The nucleolus is not bounded by a membrane. **(b)** TEM of nuclear pores. A technique known as freeze-fracture was used to split the membrane. **(c)** The nuclear pores, which are made up of proteins, form channels between the nucleoplasm and cytoplasm.

lamina supports the inner nuclear membrane and helps organize the nuclear contents. It also plays a role in DNA duplication and in regulating the cell cycle. Mutations in genes encoding proteins that make up the nuclear lamina are associated with several human genetic diseases, including muscular dystrophies and premature aging (progeria).

When a cell divides, the information stored in DNA must be reproduced and passed intact to the two daughter cells. DNA has the unique ability to make an exact duplicate of itself through a process called **replication.** DNA molecules include sequences of nucleotides called **genes,** which contain the chemically coded instructions for producing the proteins needed by the cell. The nucleus controls protein synthesis by transcribing its information in **messenger RNA (mRNA)** molecules. Messenger RNA moves into the cytoplasm, where proteins are manufactured.

DNA is associated with RNA and certain proteins, forming a complex known as **chromatin.** This complex appears as a network of granules and strands in cells that are not dividing. Although chromatin appears disorganized, it is not. Because DNA molecules are extremely long and thin, they must be packed inside the nucleus in a regular fashion as part of structures called **chromosomes.** In dividing cells, the chromosomes become visible as distinct thread-like structures. If the DNA in the 46 chromosomes of one human cell could be stretched end to end, it would extend for 2 meters!

www.konkur.in

Most nuclei have one or more compact structures called **nucleoli** (sing., *nucleolus*). A nucleolus, which is *not* enclosed by a membrane, usually stains differently than the surrounding chromatin. Each nucleolus contains a **nucleolar organizer,** made up of chromosomal regions containing instructions for making the type of RNA in ribosomes. This **ribosomal RNA (rRNA)** is synthesized in the nucleolus. The proteins needed to make ribosomes are synthesized in the cytoplasm and imported into the nucleolus. Ribosomal RNA and proteins are then assembled into ribosomal subunits that leave the nucleus through the nuclear pores.

Review

- How does the nucleus store information?
- What is the function of the nuclear envelope?

4.5 ORGANELLES IN THE CYTOPLASM

LEARNING OBJECTIVES

8 Distinguish between smooth and rough endoplasmic reticulum in terms of both structure and function.

9 Trace the path of proteins synthesized in the rough endoplasmic reticulum as they are processed, modified, and sorted by the Golgi complex and then transported to specific destinations.

10 Describe the functions of lysosomes, vacuoles, and peroxisomes.

11 Compare the functions of mitochondria and chloroplasts, and discuss ATP synthesis by each of these organelles.

Cell biologists have identified many types of organelles in the cytoplasm of eukaryotic cells. Among them are the ribosomes, endoplasmic reticulum, Golgi complex, lysosomes, peroxisomes, vacuoles, mitochondria, and chloroplasts. **TABLE 4-1** summarizes eukaryotic cell structures and functions.

Ribosomes manufacture proteins

Ribosomes are tiny particles found free in the cytoplasm or attached to certain membranes. They consist of RNA and proteins and are synthesized by the nucleolus. Ribosomes contain the enzyme necessary to form peptide bonds, which join amino acids to produce polypeptides (see Chapter 3). Each ribosome has two main components: a large subunit and a small subunit. When the two ribosome subunits join, they function as manufacturing plants that assemble polypeptides. Cells that actively produce a lot of proteins may have millions of ribosomes, and the cell can change the number of ribosomes present to meet its metabolic needs. We will discuss much more about ribosomes in Chapter 13.

The endoplasmic reticulum is a network of internal membranes

One of the most prominent features in the electron micrographs in Figures 4-9 and 4-10 is a maze of parallel internal membranes that encircle the nucleus and extend into many regions of the cytoplasm. This complex of membranes, the **endoplasmic reticulum (ER),** forms a network that makes up a significant part of the total volume of the cytoplasm in many cells. A higher-magnification TEM of the ER is shown in **FIGURE 4-14**. Remember that a TEM represents only a thin cross section of the cell, so there is a tendency to interpret the ER as a series of tubes. In fact, many ER membranes consist of a series of tightly packed and flattened, sac-like structures that form interconnected compartments within the cytoplasm.

The internal space the membranes enclose is called the **ER lumen.** In most cells the ER lumen forms a single internal compartment that is continuous with the compartment formed between the outer and inner membranes of the nuclear envelope (see Fig. 4-13). The membranes of other organelles are not directly connected to the ER; they form distinct and separate compartments within the cytoplasm.

The ER membranes and lumen contain enzymes that catalyze many types of chemical reactions. In some cases the membranes serve as a framework for enzymes that carry out sequential biochemical reactions. The two surfaces of the membrane contain different sets of enzymes and represent regions of the cell with different synthetic capabilities, just as different regions of a factory make different parts of a particular product. Still other enzymes are located within the ER lumen.

Two distinct regions of the ER can be distinguished in TEMs: rough ER and smooth ER. Although these regions have different functions, their membranes are connected and their internal spaces are continuous.

Smooth ER synthesizes lipids

Smooth ER has a tubular appearance, and its outer membrane surfaces appear smooth. Enzymes in the membranes of the smooth ER catalyze the synthesis of many lipids and carbohydrates. The smooth ER is the primary site for the synthesis of phospholipids and cholesterol needed to make cell membranes. Smooth ER synthesizes steroid hormones, including reproductive hormones, from cholesterol. In liver cells, smooth ER is important in enzymatically breaking down stored glycogen. (The liver helps regulate the concentration of glucose in the blood.) Smooth ER also stores calcium ions.

Whereas smooth ER may be a minor membrane component in some cells, extensive amounts of smooth ER are present in others. For example, extensive smooth ER is present in human liver cells, where it synthesizes and processes cholesterol and other lipids and serves as a major detoxification site. Enzymes located along the smooth ER of liver cells break down toxic chemicals such as carcinogens (cancer-causing agents) and many drugs, including alcohol, amphetamines, and barbiturates. The cell then converts these compounds to water-soluble products that it excretes. Interestingly, alcohol and many other drugs stimulate liver cells to produce additional smooth ER, increasing the rate that these cells can detoxify the drugs. Alcohol abuse causes liver inflammation that can lead to cirrhosis and eventual liver failure.

Rough ER is important in protein synthesis

The outer surface of the **rough ER** is studded with ribosomes that appear as dark granules. Notice in Figure 4-14 that the lumen side

www.konkur.in

TABLE 4-1 Eukaryotic Cell Structures and Their Functions

Structure	Description	Function
Cell Nucleus		
Nucleus	Large structure surrounded by double membrane; contains nucleolus and chromosomes	Information in DNA is transcribed in RNA synthesis; specifies cell proteins
Nucleolus	Granular body within nucleus; consists of RNA and protein	Site of ribosomal RNA synthesis; ribosome subunit assembly
Chromosomes	Composed of chromatin, a complex of DNA and protein; condense during cell division, becoming visible as rodlike structures	Contain genes (units of hereditary information) that govern structure and activity of cell
Cytoplasmic Organelles		
Plasma membrane	Membrane boundary of cell	Encloses cell contents; regulates movement of materials in and out of cell; helps maintain cell shape; communicates with other cells (also present in prokaryotes)
Ribosomes	Granules composed of RNA and protein; some attached to ER, some free in cytosol	Synthesize polypeptides in both prokaryotes and eukaryotes
Endoplasmic reticulum (ER)	Network of internal membranes extending through cytoplasm	Synthesizes lipids and modifies many proteins; origin of intracellular transport vesicles that carry proteins
Smooth	Lacks ribosomes on outer surface	Lipid synthesis; drug detoxification; calcium ion storage
Rough	Ribosomes stud outer surface	Manufactures proteins
Golgi complex	Stacks of flattened membrane sacs	Modifies proteins; packages secreted proteins; sorts other proteins to vacuoles and other organelles
Lysosomes	Membranous sacs (in animals)	Contain enzymes that break down ingested materials; break down damaged or unneeded organelles and proteins
Vacuoles	Membranous sacs (mostly in plants, fungi, algae)	Store materials, wastes, water; maintain hydrostatic pressure
Peroxisomes	Membranous sacs containing a variety of enzymes	Site of many diverse metabolic reactions; e.g., break down fatty acids
Mitochondria	Sacs consisting of two membranes; inner membrane is folded to form cristae and encloses matrix	Site of most reactions of cellular respiration; transformation of energy originating from glucose or lipids into ATP energy
Plastids (e.g., chloroplasts)	Double-membrane structure enclosing internal thylakoid membrane; chloroplasts contain chlorophyll in thylakoid membrane	Chloroplasts are site of photosynthesis; chlorophyll captures light energy; ATP and other energy-rich compounds are produced and then used to convert CO_2 to carbohydrate
Cytoskeleton		
Microtubules	Hollow tubes made of subunits of tubulin protein	Provide structural support; have role in cell and organelle movement and cell division; components of cilia, flagella, centrioles, basal bodies
Microfilaments	Solid, rodlike structures consisting of actin protein	Provide structural support; play role in cell and organelle movement and cell division
Intermediate filaments	Tough fibers made of protein	Help strengthen cytoskeleton; stabilize cell shape
Centrioles	Pair of hollow cylinders located near nucleus; each centriole consists of nine microtubule triplets (9×3 structure)	Mitotic spindle forms between centrioles during animal cell division; may anchor and organize microtubule formation in animal cells; absent in most plant cells
Cilia	Relatively short projections extending from surface of cell; covered by plasma membrane; made of two central and nine pairs of peripheral microtubules ($9 + 2$ structure)	Movement of some unicellular organisms; used to move materials on surface of some tissues; important in cell signaling
Flagella	Long projections made of two central and nine pairs of peripheral microtubules ($9 + 2$ structure); extend from surface of cell; covered by plasma membrane	Cell locomotion by sperm cells and some unicellular organisms

of the rough ER appears bare, whereas the outer surface (the cytosolic side) looks rough. The ribosomes attached to the rough ER are known as *bound ribosomes; free ribosomes* are suspended in the cytosol.

The rough ER plays a central role in the synthesis and assembly of proteins. Many proteins that are exported from the cell (such as digestive enzymes), and proteins destined for other organelles, are synthesized on ribosomes bound to the ER membrane. The ribosome forms a tight seal with the ER membrane. A tunnel within the ribosome connects to an ER pore. Polypeptides are transported through the tunnel and the pore in the ER membrane into the ER lumen.

In the ER lumen, proteins are assembled and may be modified by enzymes that add carbohydrates or lipids to them. Other enzymes, called **molecular chaperones,** in the ER lumen catalyze the efficient folding of proteins into proper conformations. Pro-

www.konkur.in

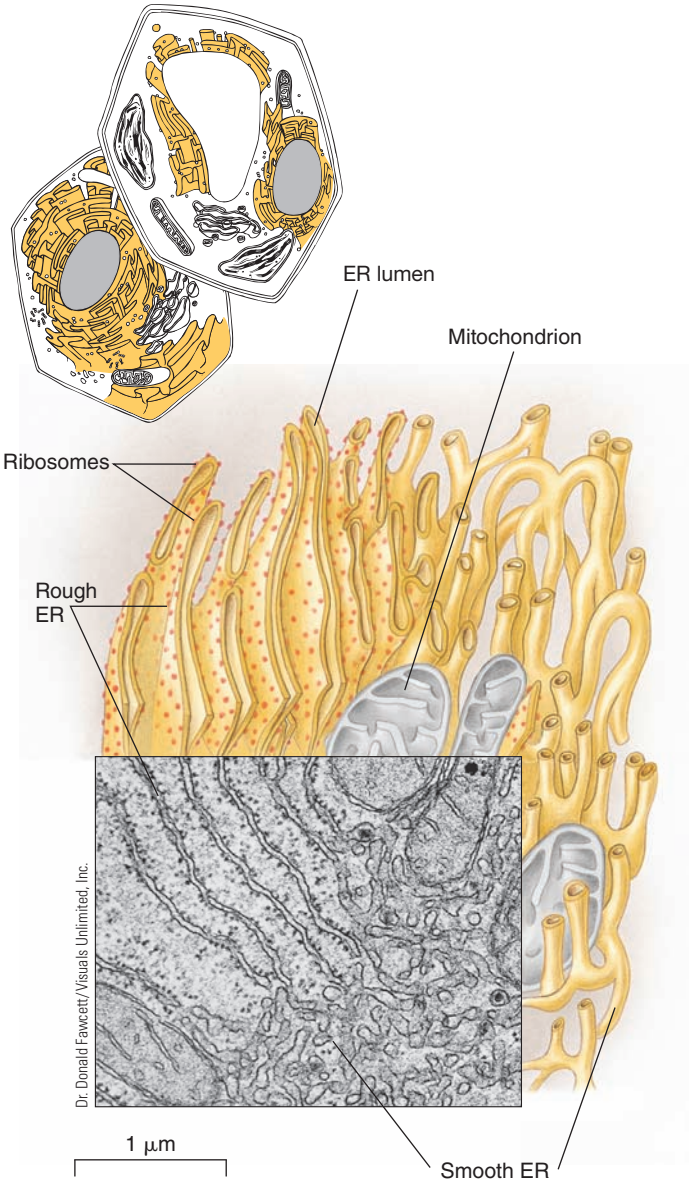

FIGURE 4-14 ***Animated*** **Endoplasmic reticulum (ER)**
The TEM shows both rough and smooth ER in a liver cell.

teins that are not processed correctly, for example, proteins that are misfolded, are transported to the cytosol. There, they are degraded by **proteasomes,** protein complexes in the cytosol that direct the destruction of defective proteins. Properly processed proteins are transferred to other compartments within the cell by small **transport vesicles,** which bud off the ER membrane and then fuse with the membrane of some target organelle.

The Golgi complex processes, sorts, and modifies proteins

The **Golgi complex** (also known as the *Golgi body* or *Golgi apparatus*) was first described in 1898 by the Italian microscopist Camillo Golgi, who found a way to specifically stain this organelle. However, many investigators thought the Golgi complex was an artifact, and its legitimacy as a cell organelle was not confirmed until cells were studied with the electron microscope in the 1950s.

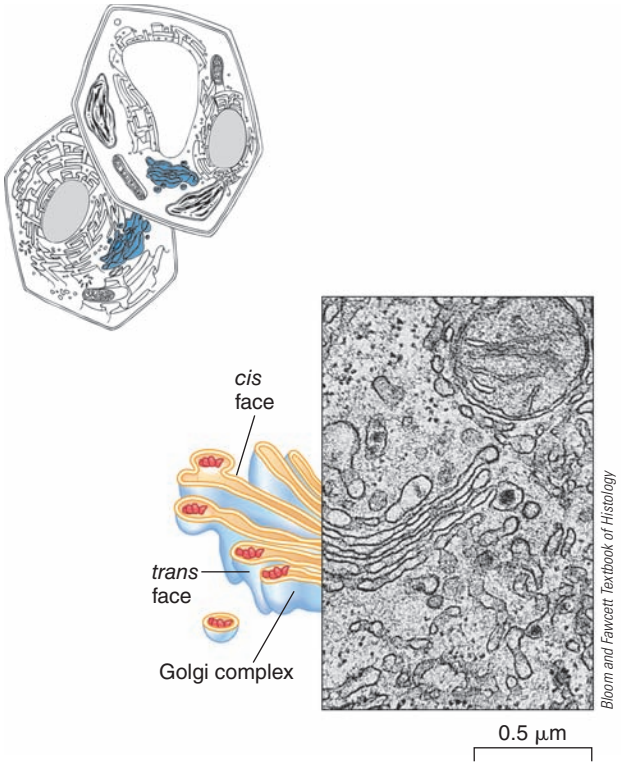

FIGURE 4-15 **TEM and an interpretive drawing of the Golgi complex**

In many cells, the Golgi complex consists of stacks of flattened membranous sacs called **cisternae** (sing., *cisterna*). Each cisterna has an internal space, or lumen (**FIG. 4-15**). In certain regions, cisternae may be distended because they are filled with cell products. The Golgi complex contains a number of separate compartments, as well as some that are interconnected.

Each Golgi stack has three areas, referred to as the *cis face,* the *trans face,* and a *medial region* in between. Typically, the *cis* face (the entry surface) is located nearest the nucleus and receives materials from transport vesicles bringing molecules from the ER. The *trans* face (the exit surface) is closest to the plasma membrane. It packages molecules in vesicles and transports them out of the Golgi.

In a cross-sectional view like that in the TEM in Figure 4-15, many ends of the sheetlike layers of Golgi membranes are distended, an arrangement characteristic of well-developed Golgi complexes in many cells. In some animal cells, the Golgi complex lies at one side of the nucleus; other animal cells and plant cells have many Golgi complexes dispersed throughout the cell.

Cells that secrete large amounts of *glycoproteins* have many Golgi stacks. (Recall from Chapter 3 that a glycoprotein is a protein with a covalently attached carbohydrate.) Golgi complexes of plant cells produce extracellular polysaccharides that are used as components of the cell wall. In animal cells, the Golgi complex manufactures lysosomes.

The Golgi complex processes, sorts, and modifies proteins. Researchers have studied the function of the ER, Golgi complex,

www.konkur.in

KEY POINT After proteins are synthesized, they are transported through a series of compartments where they are successively modified.

1. Polypeptides synthesized on ribosomes are inserted into ER lumen.
2. Sugars are added, forming glycoproteins.
3. Transport vesicles deliver glycoproteins to *cis* face of Golgi.
4. Glycoproteins modified further in Golgi.
5. Glycoproteins move to *trans* face where they are packaged in transport vesicles.
6. Glycoproteins transported to plasma membrane (or other organelle).
7. Contents of transport vesicle released from cell.

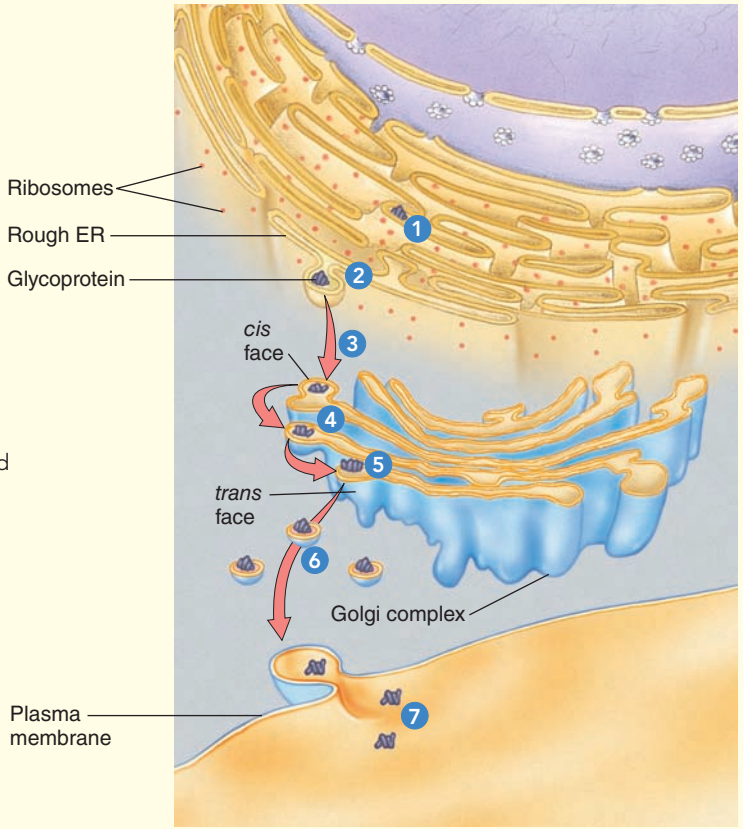

FIGURE 4-16 ***Animated*** **Protein transport within the cell**

Glycoproteins are transported from ribosomes into the ER. They are then transported to the Golgi complex, where they are modified. This diagram shows the passage of glycoproteins through compartments of the endomembrane system of a mucus-secreting goblet cell from the lining of the intestine. Mucus consists of a complex mixture of covalently linked proteins and carbohydrates.

and other organelles by radioactively labeling newly manufactured molecules and observing their movement through the cell. The general pathway is from ribosomes to the lumen of the rough ER to the Golgi complex and then to some final destination (**FIG. 4-16**).

Proteins that are accurately assembled are transported from the rough ER to the *cis* face of the Golgi complex in small transport vesicles formed from the ER membrane. Transport vesicles fuse with one another to form clusters that move along microtubules (part of the cytoskeleton) to the Golgi complex. What happens to glycoprotein molecules released into the Golgi complex? One hypothesis holds that the glycoproteins are enclosed in new vesicles that shuttle them from one compartment to another within the Golgi complex. A competing hypothesis postulates that the cisternae themselves may move from *cis* to *trans* positions. Both hypotheses may be correct: glycoproteins may be transported by both methods.

Regardless of how proteins are moved through the Golgi complex, while there they are modified in different ways, resulting in the formation of complex biological molecules. For example, the carbohydrate part of a glycoprotein (first added to proteins in the rough ER) may be modified. In some cases the carbohydrate component may be a "sorting signal," a cellular zip code that tags the protein, routing it to a specific organelle.

Glycoproteins are packaged in transport vesicles in the *trans* face. These vesicles pinch off from the Golgi membrane and transport their contents to a specific destination. Vesicles transporting products for export from the cell fuse with the plasma membrane. The vesicle membrane becomes part of the plasma membrane, and the glycoproteins are secreted from the cell. Other vesicles may store glycoproteins for secretion at a later time, and still others are routed to various organelles of the endomembrane system. In summary, here is a typical sequence followed by a glycoprotein destined for secretion from the cell:

polypeptides synthesized on ribosomes ⟶ protein assembled and carbohydrate component added in lumen of ER ⟶ transport vesicles move glycoprotein to Golgi (*cis* face) ⟶ glycoprotein further modified in Golgi ⟶ in *trans* face, glycoproteins packaged in transport vesicles ⟶ glycoproteins transported to plasma membrane ⟶ contents released from cell

www.konkur.in

Lysosomes are compartments for digestion

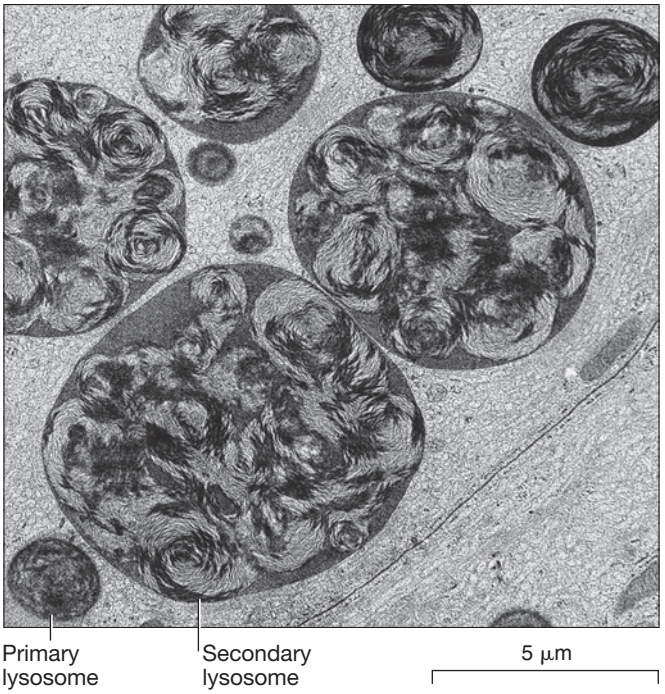
Lysosomes are small sacs of digestive enzymes dispersed in the cytoplasm of most animal cells (**FIG. 4-17**). Researchers have identified about 40 different digestive enzymes in lysosomes.

Because lysosomal enzymes are active under rather acidic conditions, the lysosome maintains a pH of about 5 in its interior. The powerful enzymes and low pH that the lysosome maintains provide an excellent example of the importance of separating functions within the cell into different compartments. Under most normal conditions, the lysosome membrane confines its enzymes and their actions. However, some forms of tissue damage are related to "leaky" lysosomes.

Primary lysosomes are formed by budding from the Golgi complex. Their hydrolytic enzymes are synthesized in the rough ER. As these enzymes pass through the lumen of the ER, sugars attach to each molecule, identifying it as bound for a lysosome. This signal permits the Golgi complex to sort the enzyme to the lysosomes rather than to export it from the cell.

Bacteria (or debris) engulfed by scavenger cells are enclosed in a vesicle formed from part of the plasma membrane. One or more primary lysosomes fuse with the vesicle containing the ingested material, forming a larger vesicle called a *secondary lysosome.* Powerful enzymes in the secondary lysosome come in contact with the ingested molecules and degrade them into their components. Under some conditions, lysosomes break down organelles and allow their components to be recycled or used as an energy source.

In certain genetic diseases of humans, known as *lysosomal storage diseases,* one of the digestive enzymes normally present in lysosomes is absent. Its substrate (a substance the enzyme would normally break down) accumulates in the cell, which eventually interferes with cell activities. An example is Tay-Sachs disease, an inherited disease in which a normal lipid cannot be broken down (discussed in Chapter 16). The accumulation of this lipid in brain cells causes mental retardation, blindness, and death before age 4.



Don Fawcett/Photo Researchers, Inc.

FIGURE 4-17 Lysosomes

The dark vesicles in this TEM are lysosomes, compartments that separate powerful digestive enzymes from the rest of the cell. Primary lysosomes bud off from the Golgi complex. After a lysosome takes in material to be digested, it is known as a secondary lysosome. The large vesicles shown here are secondary lysosomes containing various materials being digested.

Vacuoles are large, fluid-filled sacs with a variety of functions

Although lysosomes have been identified in almost all kinds of animal cells, biologists have not identified them in plant and fungal cells. Many functions carried out in animal cells by lysosomes are performed in plant and fungal cells by a large, single, membrane-enclosed sac called a **vacuole.** The membrane of the vacuole, part of the endomembrane system, is called the **tonoplast.** The term *vacuole,* which means "empty," refers to the fact that these organelles have no internal structure. Although some biologists use the terms *vacuole* and *vesicle* interchangeably, vacuoles are usually larger structures, sometimes produced by the merging of many vesicles.

Vacuoles play a significant role in plant growth and development. Immature plant cells are generally small and contain numerous small vacuoles. As water accumulates in these vacuoles, they tend to coalesce, forming a large central vacuole. A plant cell increases in size mainly by adding water to this central vacuole. As much as 80% of the volume of a plant cell may be occupied by a large central vacuole containing water, stored food, salts, pigments, and metabolic wastes (see Figs. 4-7 and 4-9). The vacuole may serve as a storage compartment for inorganic compounds. In seeds, vacuoles store molecules such as proteins.

Because the vacuole contains a high concentration of solutes (dissolved materials), it takes in water and pushes outward on the cell wall. This hydrostatic pressure, called *turgor pressure,* provides much of the mechanical strength of plant cells. The vacuole is important in maintaining homeostasis. For example, it helps maintain appropriate pH by taking in excess hydrogen ions.

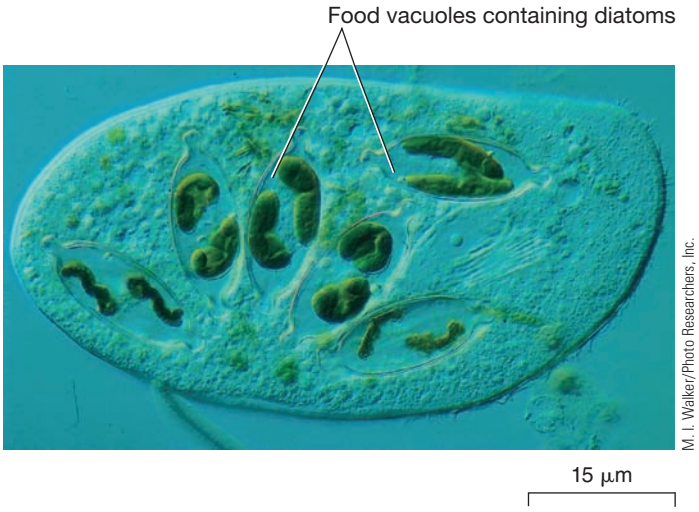
Plants lack organ systems for disposing of toxic metabolic waste products. Plant vacuoles are like lysosomes in that they contain hydrolytic enzymes and break down wastes, as well as unneeded organelles and other cell components. Wastes may be recycled in the vacuole, or they may aggregate and form small crystals inside the vacuole. Compounds that are noxious to herbivores (animals that eat plants) may be stored in some plant vacuoles as a means of defense.

Vacuoles are also present in many types of animal cells and in unicellular protists such as protozoa. Most protozoa have **food vacuoles,** which fuse with lysosomes that digest the food (**FIG. 4-18**). Some protozoa also have **contractile vacuoles,** which remove excess water from the cell (discussed in Chapter 26).

Peroxisomes metabolize small organic compounds

Peroxisomes are membrane-enclosed organelles containing enzymes that catalyze an assortment of metabolic reactions in

www.konkur.in

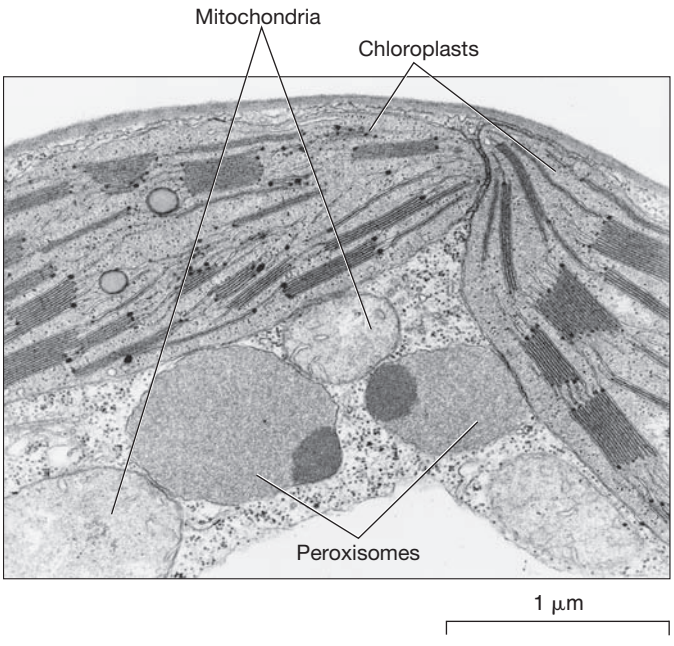


M. I. Walker/Photo Researchers, Inc.

FIGURE 4-18 LM of food vacuoles

This protist, *Chilodonella*, has ingested many small, photosynthetic protists called diatoms (*dark areas*) that have been enclosed in food vacuoles. From the number of diatoms scattered about its cell, one might conclude that *Chilodonella* has a rather voracious appetite.

which hydrogen is transferred from various compounds to oxygen (**FIG. 4-19**). Peroxisomes get their name from the fact that during these oxidation reactions, they produce hydrogen peroxide (H_2O_2). Hydrogen peroxide detoxifies certain compounds; but if this compound were to escape from the peroxisome, it would damage other membranes in the cell. Peroxisomes contain the enzyme



E. H. Newcomb and S. E. Frederick/Biological Photo Service

FIGURE 4-19 Peroxisomes

In this TEM of a tobacco (*Nicotiana tabacum*) leaf cell, peroxisomes are in close association with chloroplasts and mitochondria. These organelles may cooperate in carrying out some metabolic processes.

catalase, which rapidly splits excess hydrogen peroxide to water and oxygen, rendering it harmless.

Peroxisomes are found in large numbers in cells that synthesize, store, or degrade lipids. One of their main functions is to break down fatty acid molecules. Peroxisomes synthesize certain phospholipids that are components of the insulating covering of nerve cells. In fact, certain neurological disorders occur when peroxisomes do not perform this function. Mutations that cause synthesis of abnormal membrane lipids by peroxisomes are linked to some forms of mental retardation.

When yeast cells are grown in an alcohol-rich medium, they manufacture large peroxisomes containing an enzyme that degrades the alcohol. Peroxisomes in human liver and kidney cells detoxify certain toxic compounds, including ethanol, the alcohol in alcoholic beverages.

In plant seeds, specialized peroxisomes, called *glyoxysomes,* contain enzymes that convert stored fats to sugars. The sugars are used by the young plant as an energy source and as a component for synthesizing other compounds. Animal cells lack glyoxysomes and cannot convert fatty acids into sugars.

Mitochondria and chloroplasts are energy-converting organelles

The energy a cell obtains from its environment is usually in the form of chemical energy in food molecules (such as glucose) or in the form of light energy. These types of energy must be converted to forms that cells can use more conveniently. Some energy conversions occur in the cytosol, but other types take place in mitochondria and chloroplasts, organelles specialized to facilitate the conversion of energy from one form to another.

Chemical energy is most commonly stored in ATP. Recall from (Chapter 3) that the chemical energy of ATP can be used to drive a variety of chemical reactions in the cell. **FIGURE 4-20** summarizes the main activities that take place in mitochondria, found in almost all eukaryotic cells, and in chloroplasts, found only in algae and certain plant cells.

Mitochondria and chloroplasts grow and reproduce themselves. They contain small amounts of DNA that code for a small number of the proteins found in these organelles. These proteins are synthesized by mitochondrial or chloroplast ribosomes. Interestingly, these ribosomes are similar to the ribosomes of prokaryotes. The existence of a separate set of ribosomes and DNA molecules in mitochondria and chloroplasts and their similarity in size to many bacteria provide support for **serial endosymbiosis** (discussed in Chapters 21 and 26; see Figs. 21-8 and 26-2). According to this hypothesis, mitochondria and chloroplasts evolved from prokaryotes that took up residence inside larger eukaryotic cells. Eventually, these symbiotic prokaryotes lost the ability to function as autonomous organisms.

Mitochondria make ATP through cellular respiration

Virtually all eukaryotic cells (plant, animal, fungal, and protist) contain complex organelles called **mitochondria** (sing., *mito-*

www.konkur.in

KEY POINT Mitochondria and chloroplasts convert energy into forms that can be used by cells.

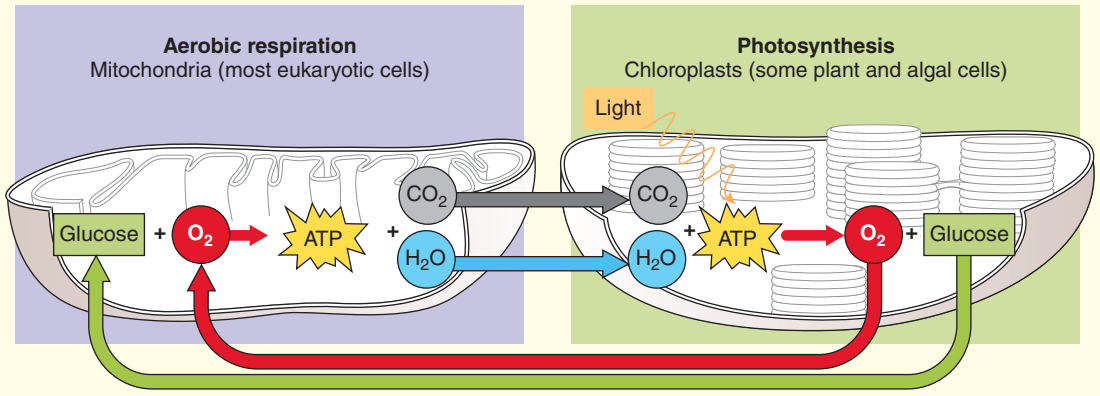


FIGURE 4-20 Cellular respiration and photosynthesis

Cellular respiration takes place in the mitochondria of virtually all eukaryotic cells. In this process, some of the chemical energy in glucose is transferred to ATP. Photosynthesis, which is carried out in chloroplasts in some plant and algal cells, converts light energy to ATP and to other forms of chemical energy. This energy is used to synthesize glucose from carbon dioxide and water.

chondrion). These organelles are the site of **aerobic respiration,** an oxygen-requiring process that includes most of the reactions that convert the chemical energy present in certain foods to ATP (discussed in Chapter 8). During aerobic respiration, carbon and oxygen atoms are removed from food molecules, such as glucose, and converted to carbon dioxide and water.

Mitochondria are most numerous in cells that are very active and therefore have high energy requirements. More than 1000 mitochondria have been counted in a single liver cell! These organelles vary in size, ranging from 2 to 8 μm in length, and change size and shape rapidly. Mitochondria usually give rise to other mitochondria by growth and subsequent division.

Each mitochondrion is enclosed by a double membrane, which forms two *different* compartments within the organelle: the intermembrane space and the matrix (**FIG. 4-21**; we will provide more detailed descriptions of mitochondrial structure in Chapter 8). The **intermembrane space** is the compartment formed between the outer and inner mitochondrial membranes. The **matrix,** the compartment enclosed by the inner mitochondrial membrane, contains enzymes that break down food molecules and convert their energy to other forms of chemical energy.

The **outer mitochondrial membrane** is smooth and allows many small molecules to pass through it. By contrast, the **inner mitochondrial membrane** has numerous folds and strictly regulates the types of molecules that can move across it. The folds, called **cristae** (sing., *crista*), extend into the matrix. Cristae greatly increase the surface area of the inner mitochondrial membrane, providing a surface for the chemical reactions that transform the chemical energy in food molecules into the energy of ATP. The membrane contains the enzymes and other proteins needed for these reactions.

Mitochondria play an important role in programmed cell death, or **apoptosis.** Unlike **necrosis,** which is uncontrolled cell

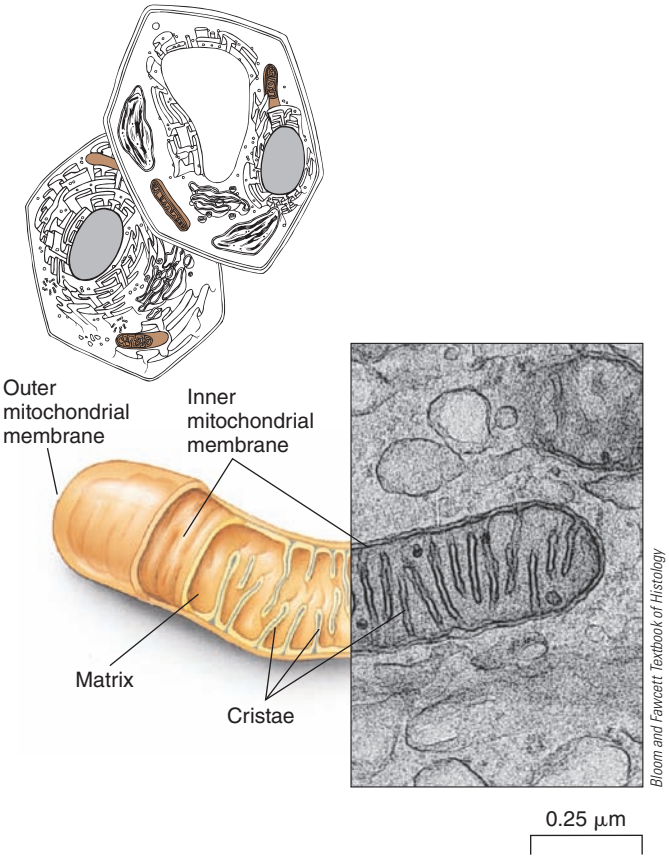

FIGURE 4-21 *Animated* Mitochondria

Aerobic respiration takes place within mitochondria. Cristae are evident in the TEM as well as in the drawing. The drawing shows the relationship between the inner and outer mitochondrial membranes.

www.konkur.in

death that causes inflammation and damages other cells, apoptosis is a normal part of development and maintenance. For example, during the metamorphosis of a tadpole to a frog, the cells of the tadpole tail must die. The hand of a human embryo is webbed until apoptosis destroys the tissue between the fingers. Cell death also occurs in the adult. For example, cells that are no longer functional because they have aged or become damaged are destroyed and replaced by new cells.

Mitochondria initiate cell death in several different ways. For example, they can interfere with energy metabolism or activate enzymes that mediate cell destruction. When a mitochondrion is injured, large pores open in its membrane, and cytochrome *c*, a protein important in energy conversions, is released into the cytoplasm. Cytochrome *c* triggers apoptosis by activating enzymes known as **caspases,** which cut up vital compounds in the cell.

Inappropriate inhibition of apoptosis may contribute to a variety of diseases, including cancer. On the other hand, too much apoptosis may deplete needed cells and lead to death of brain cells associated with Alzheimer's disease, Parkinson's disease, and stroke. Mutations that promote apoptosis may be an important mechanism in mammalian aging. Pharmaceutical companies are developing drugs that block apoptosis. However, cell dynamics are extremely complex, and blocking apoptosis could lead to a worse fate, including necrosis.

Each mitochondrion in a mammalian cell has 5 to 10 identical, circular molecules of DNA, accounting for up to 1% of the total DNA in the cell. Mitochondrial DNA mutates far more frequently than nuclear DNA. Mutations in mitochondrial DNA have been associated with certain genetic diseases, including a form of young adult blindness, and certain types of progressive muscle degeneration. Mitochondria also affect health and aging by leaking electrons. These electrons form **free radicals,** which are toxic, highly reactive compounds with unpaired electrons. The electrons bond with other compounds in the cell, interfering with normal function.

Chloroplasts convert light energy to chemical energy through photosynthesis

Certain plant and algal cells carry out **photosynthesis,** a set of reactions during which light energy is transformed into the chemical energy of glucose and other carbohydrates. **Chloroplasts** are organelles that contain **chlorophyll,** a green pigment that traps light energy for photosynthesis. Chloroplasts also contain a variety of light-absorbing yellow and orange pigments known as **carotenoids** (see Chapter 3). A unicellular alga may have only a single large chloroplast, whereas a leaf cell may have 20 to 100. Chloroplasts tend to be somewhat larger than mitochondria, with lengths usually ranging from about 5 to 10 μm or longer.

Chloroplasts are typically disc-shaped structures and, like mitochondria, have a system of folded membranes (**FIG. 4-22**; we will provide a more detailed description of chloroplast structure in Chapter 9). Two membranes enclose the chloroplast and separate it from the cytosol. The inner membrane encloses a fluid-filled space called the **stroma,** which contains enzymes. These enzymes produce carbohydrates from carbon dioxide and water, using energy trapped from sunlight. A system of internal membranes, which consists of an interconnected set of flat, disclike sacs called **thylakoids,** is suspended in the stroma. The thylakoids are arranged in stacks called **grana** (sing., *granum*).

The thylakoid membrane encloses the innermost compartments within the chloroplast, the **thylakoid lumen.** Chlorophyll is present in the thylakoid membrane, which like the inner mito-

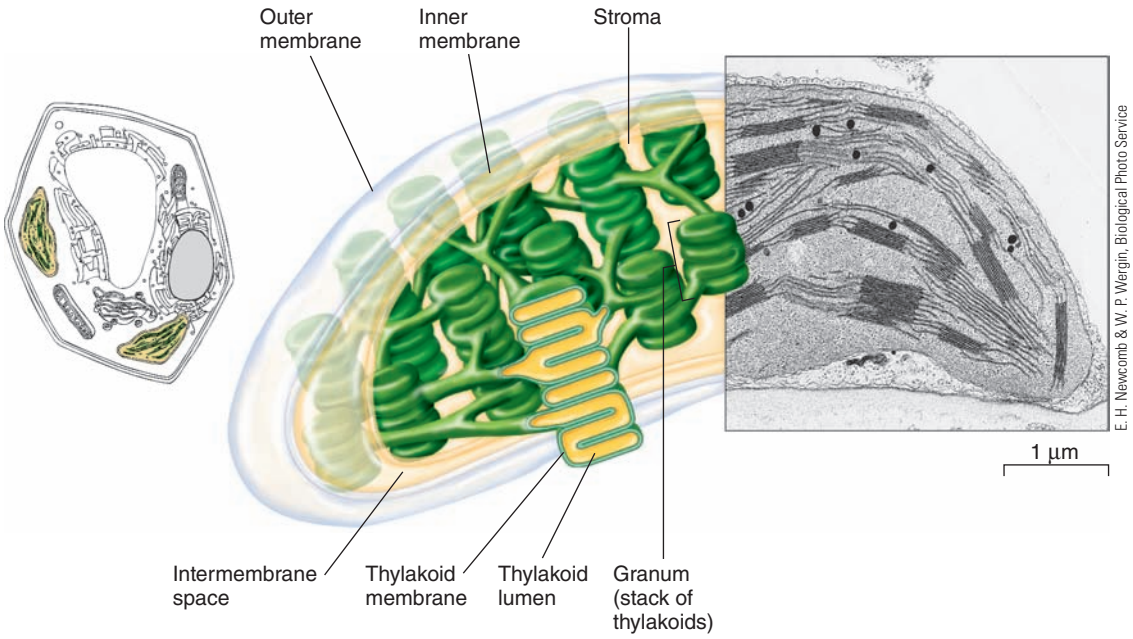

FIGURE 4-22 ***Animated*** **A chloroplast, the organelle of photosynthesis**

The TEM shows part of a chloroplast from a corn leaf cell. Chlorophyll and other photosynthetic pigments are in the thylakoid membranes. One granum is cut open to show the thylakoid lumen. The inner chloroplast membrane may or may not be continuous with the thylakoid membrane (*as shown*).

www.konkur.in

chondrial membranes, is involved in the formation of ATP. Energy absorbed from sunlight by the chlorophyll molecules excites electrons; the energy in these excited electrons is then used to produce ATP and other molecules that transfer chemical energy.

Chloroplasts belong to a group of organelles, known as **plastids,** that produce and store food materials in cells of plants and algae. All plastids develop from **proplastids,** precursor organelles found in less specialized plant cells, particularly in growing, undeveloped tissues. Depending on the specific functions a cell will eventually have, its proplastids can develop into a variety of specialized mature plastids. These are extremely versatile organelles; in fact, under certain conditions even mature plastids can convert from one form to another.

Chloroplasts are produced when proplastids are stimulated by exposure to light. **Chromoplasts** contain pigments that give certain flowers and fruits their characteristic colors; these colors attract animals that serve as pollinators or as seed dispersers. **Leukoplasts** are unpigmented plastids; they include **amyloplasts** (see Fig. 3-9), which store starch in the cells of many seeds, roots, and tubers (such as white potatoes).

4.6 THE CYTOSKELETON

LEARNING OBJECTIVES

12 Describe the structure and functions of the cytoskeleton.
13 Compare cilia and flagella, and describe their functions.

Scientists watching cells growing in the laboratory see that they frequently change shape and that many types of cells move about. The **cytoskeleton,** a dense network of protein fibers, gives cells mechanical strength, shape, and their ability to move (**FIG. 4-23**). The cytoskeleton also functions in cell division and in the transport of materials within the cell.

The cytoskeleton is highly dynamic and constantly changing. Its framework is made of three types of protein filaments: microtubules, microfilaments, and intermediate filaments. Both microfilaments and microtubules are formed from beadlike, globular protein subunits, which can be rapidly assembled and disassembled. Intermediate filaments are made from fibrous protein subunits and are more stable than microtubules and microfilaments.

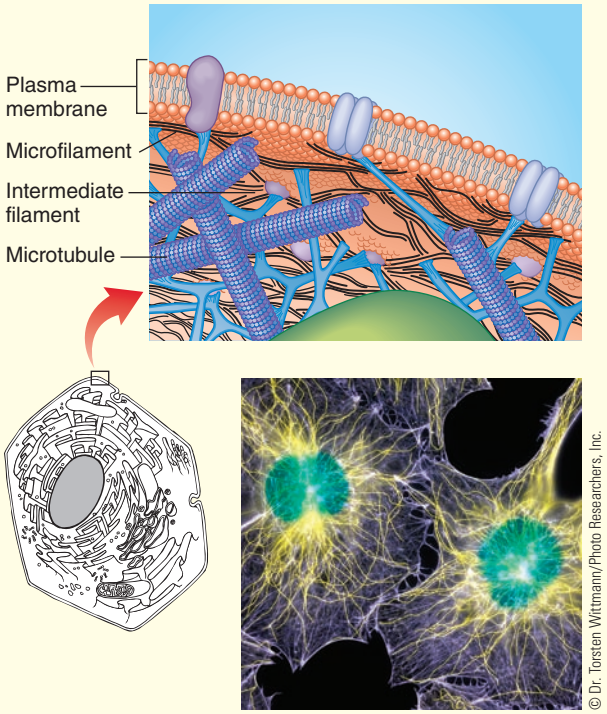
Microtubules are hollow cylinders

Microtubules, the thickest filaments of the cytoskeleton, are rigid, hollow rods about 25 nm in outside diameter and up to several micrometers in length. In addition to playing a structural role in the cytoskeleton, these extremely adaptable structures are involved in the movement of chromosomes during cell division. They serve as tracks for several other kinds of intracellular movement and are the major structural components of cilia and flagella—specialized structures used in some cell movements.

Microtubules consist of two forms of the protein **tubulin:** α-tubulin and β-tubulin. These proteins combine to form a dimer. (Recall from Chapter 3 that a dimer forms from the association of two simpler units, referred to as monomers.) A microtubule elongates by the addition of tubulin dimers (**FIG. 4-24**). Microtubules are disassembled by the removal of dimers, which are recycled to form new microtubules. Each microtubule has polarity, and its two ends are referred to as *plus* and *minus.* The plus end elongates more rapidly.

Other proteins are important in microtubule function. **Microtubule-associated proteins (MAPs)** are classified into two groups: structural MAPs and motor MAPs. *Structural MAPs* may help regulate microtubule assembly, and they cross-link microtubules to other cytoskeletal polymers. *Motor MAPs* use ATP energy to produce movement.

KEY POINT The cytoskeleton consists of networks of several types of fibers that support the cell and are important in cell movement

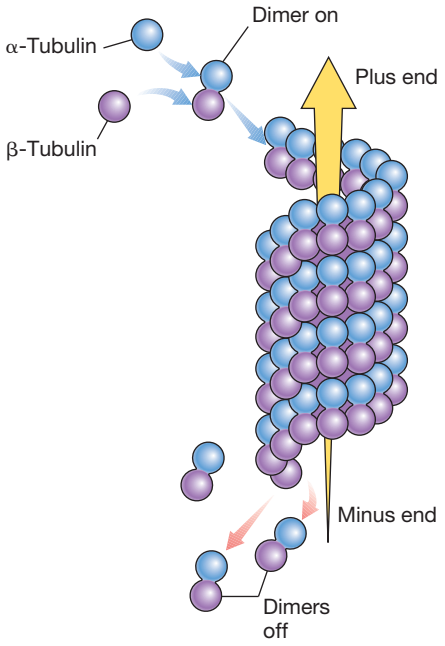


© Dr. Torsten Wittmann/Photo Researchers, Inc.

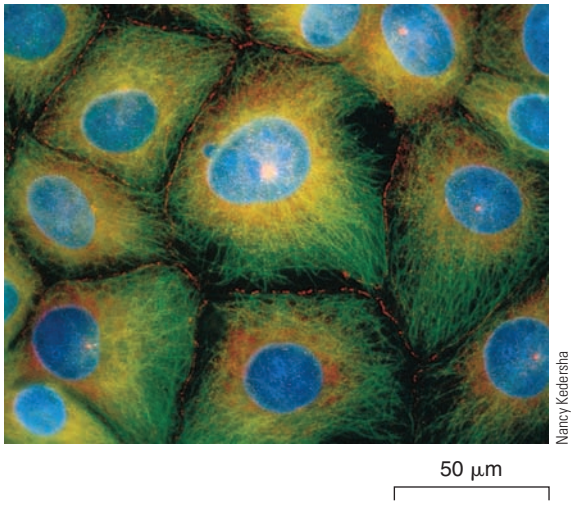
FIGURE 4-23 *Animated* The cytoskeleton

The cytoskeleton of eukaryotic cells consists of networks of several types of fibers, including microtubules, microfilaments, and intermediate filaments. The cytoskeleton contributes to the shape of the cell, anchors organelles, and sometimes rapidly changes shape during cell locomotion. This fluorescent LM shows the cytoskeleton of two fibroblast cells (microtubules, *yellow;* microfilaments, *blue;* nuclei, *green*).

www.konkur.in



(a) Microtubules are manufactured in the cell by adding dimers of α-tubulin and β-tubulin to an end of the hollow cylinder. Notice that the cylinder has polarity. The end shown at the top of the figure is the fast-growing, or plus, end; the opposite end is the minus end. Each turn of the spiral requires 13 dimers.



(b) Fluorescent LM showing microtubules in green. A microtubule-organizing center (*pink dot*) is visible beside or over most of the cell nuclei (*blue*).

FIGURE 4-24 Organization of microtubules

What are the mechanisms by which organelles and other materials move within the cell? Nerve cells typically have long extensions called axons that transmit signals to other nerve cells, muscle cells, or cells that produce hormones. Because of the axon's length and accessibility and because other cells use similar transport mechanisms, researchers have used the axon as a model for studying the transport of organelles within the cell. They have found that many organelles, including mitochondria and transport and secretory vesicles, attach to microtubules. The microtubules serve as tracks along which organelles move to different cell locations.

One motor protein, **kinesin,** moves organelles toward the plus end of a microtubule (FIG. 4-25). **Dynein,** another motor protein, transports organelles in the opposite direction, toward the minus end. This dynein movement is referred to as *retrograde transport.* A protein complex called *dynactin* is also required for retrograde transport. Dynactin is an adapter protein that links dynein to the microtubule and the organelle. At times, for example, during peroxisome transport, kinesins and dyneins may work together.

Centrosomes and centrioles function in cell division

For microtubules to act as a structural framework or participate in cell movement, they must be anchored to other parts of the cell. In nondividing cells, the minus ends of microtubules appear to be anchored in regions called **microtubule-organizing centers (MTOCs).** In animal cells, the main MTOC is the cell center, or **centrosome,** a structure that is important in cell division.

In many cells, including almost all animal cells, the centrosome contains two structures called **centrioles** (FIG. 4-26). These structures are oriented within the centrosome at right angles to each other. They are known as 9×3 *structures* because they consist of nine sets of three attached microtubules arranged to form a hollow cylinder. The centrioles are duplicated before cell division and may play a role in some types of microtubule assembly. Most plant cells and fungal cells have an MTOC but lack centrioles. This suggests that centrioles are not essential to most microtubule assembly processes and that alternative assembly mechanisms are present.

The ability of microtubules to assemble and disassemble rapidly is seen during cell division, when much of the cytoskeleton disassembles (discussed in Chapter 10). At that time tubulin subunits organize into a structure called the **mitotic spindle,** which serves as a framework for the orderly distribution of chromosomes during cell division.

Cilia and flagella are composed of microtubules

Thin, movable structures, important in cell movement, project from surfaces of many cells. If a cell has one, or only a few, of these appendages and if they are long (typically about 200 μm) relative to the size of the cell, they are called **flagella.** If the cell has many short (typically 2 to 10 μm long) appendages, they are called **cilia** (sing., *cilium*).

Cilia and flagella help unicellular and small multicellular organisms move through a watery environment. In animals and certain plants, flagella serve as the tails of sperm cells. In animals, cilia occur on the surfaces of cells that line internal ducts of the body (such as respiratory passageways). Cells use cilia to move liquids and particles across the cell surface. Investigators have shown that cilia also serve as the cell's antenna and play important roles in cell signaling.

Eukaryotic cilia and flagella are structurally alike (but different from bacterial flagella). Each consists of a slender, cylindrical stalk covered by an extension of the plasma membrane. The core

www.konkur.in

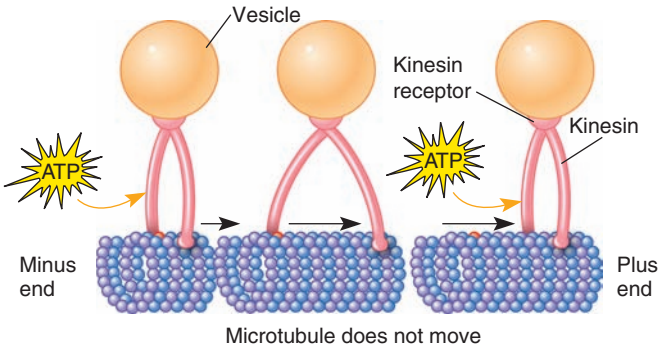


FIGURE 4-25 ***Animated*** **A model of a kinesin motor**

A kinesin molecule attaches to a specific receptor on the vesicle. Energy from ATP powers the kinesin molecule so that it changes its conformation and "walks" along the microtubule, carrying the vesicle along. (Size relationships are exaggerated for clarity.)

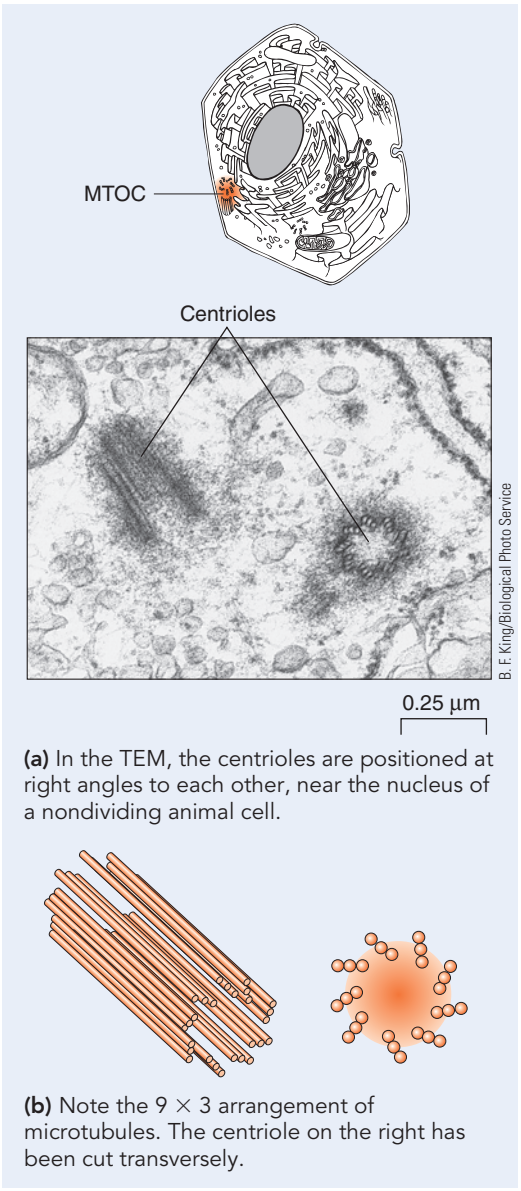
of the stalk contains a group of microtubules arranged so there are nine attached pairs of microtubules around the circumference and two unpaired microtubules in the center (**FIG. 4-27**). This *9 + 2 arrangement* of microtubules is characteristic of virtually all eukaryotic cilia and flagella.

The microtubules in cilia and flagella move by sliding in pairs past each other. The sliding force is generated by dynein proteins, powered by ATP. The dynein "feet" move the microtubule pairs by forming and breaking cross bridges on adjacent pairs of microtubules. Each microtubule pair "walks" along its neighbor. Flexible linking proteins between microtubule pairs prevent microtubules from sliding very far. As a result, the motor action causes the microtubules to bend, resulting in a beating motion (see Fig. 4-27e). Cilia typically move like the arms of a swimmer, alternating a power stroke in one direction with a recovery stroke in the opposite direction. They exert a force that is parallel to the cell surface. In contrast, a flagellum moves like a whip, exerting a force perpendicular to the cell surface.

Each cilium or flagellum is anchored in the cell by a **basal body,** which has nine sets of three attached microtubules in a cylindrical array (*9 × 3 structure*). The basal body appears to be the organizing structure for the cilium or flagellum when it first begins to form. However, experiments have shown that as growth proceeds, the tubulin subunits are added much faster to the tips of the microtubules than to the base.

Basal bodies and centrioles may be functionally related as well as structurally similar. In fact, centrioles are typically found in the cells of eukaryotic organisms that produce flagellated or ciliated cells; these include animals, certain protists, a few fungi, and a few plants. Both basal bodies and centrioles replicate themselves.

Almost every vertebrate cell has a **primary cilium,** a single cilium on the cell surface that serves as a cellular antenna. The primary cilium has receptors on its surface that bind with specific molecules outside the cell or on surfaces of other cells. Recent research indicates that primary cilia play important roles in many signaling pathways that regulate growth and specialization of cells during embryonic development. Primary cilia also help maintain healthy tissues. Malfunction of primary cilia has been associated



(a) In the TEM, the centrioles are positioned at right angles to each other, near the nucleus of a nondividing animal cell.

(b) Note the 9 × 3 arrangement of microtubules. The centriole on the right has been cut transversely.

FIGURE 4-26 **Centrioles**

with several human disorders, including developmental defects, degeneration of the retina, and polycystic kidney disease.

Microfilaments consist of intertwined strings of actin

Microfilaments, also called *actin filaments,* are flexible, solid fibers about 7 nm in diameter. Each microfilament consists of two intertwined polymer chains of beadlike **actin** molecules (**FIG. 4-28**). Microfilaments are linked with one another and with other proteins by linker proteins. They form bundles of fibers that provide mechanical support for various cell structures.

In many cells, a network of microfilaments is visible just inside the plasma membrane, a region called the **cell cortex.** Microfilaments give the cell cortex a gel-like consistency compared to the

www.konkur.in

KEY POINT A cilium consists of a 9 + 2 arrangement of microtubules surrounded by the plasma membrane; dynein proteins move the microtubules by forming and breaking cross bridges on adjacent pairs of microtubules.

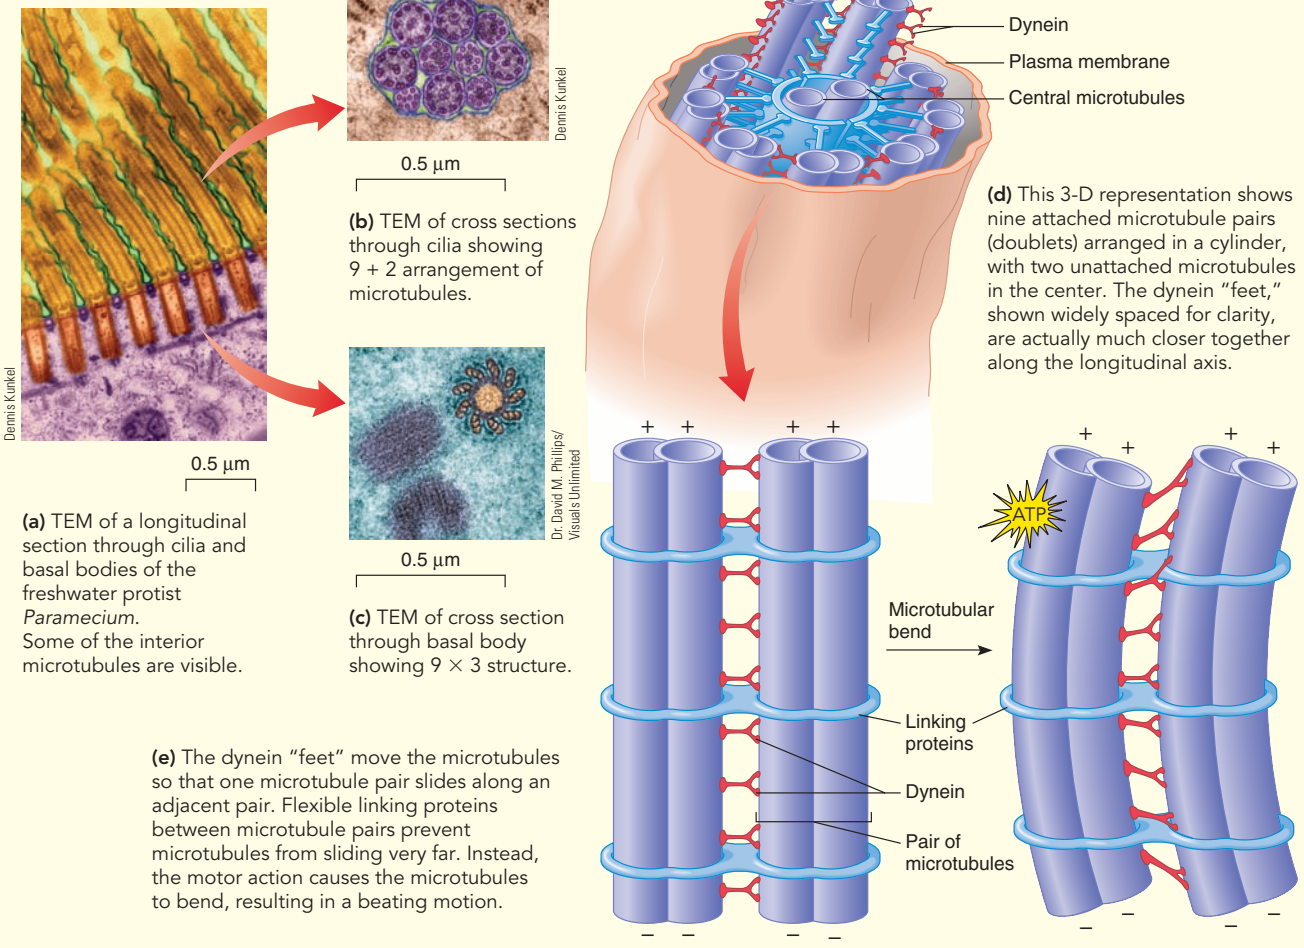


FIGURE 4-27 ***Animated*** Structure and movement of cilia

more fluid state of the cytosol deeper inside the cell. The microfilaments in the cell cortex help determine the shape of the cell and are important in its movement.

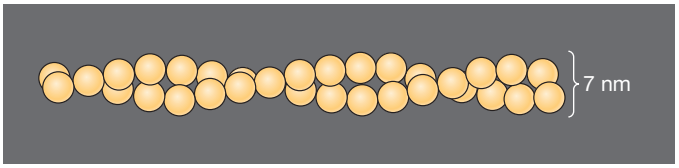
Microfilaments themselves cannot contract, but they can generate movement by rapidly assembling and disassembling. Muscle cells have two types of specialized filaments, one composed mainly of the protein **myosin,** and another composed mainly of the protein actin. ATP bound to myosin provides energy for muscle contraction. When ATP is hydrolyzed to ADP, myosin binds to actin and causes the microfilament to slide. When thousands of filaments slide in this way, the muscle cell shortens. Thus, ATP, actin, and myosin generate the forces that contract muscles (discussed in Chapter 40).

In nonmuscle cells, actin also associates with myosin, forming contractile structures involved in various cell movements. For example, in animal cell division, contraction of a ring of actin associated with myosin constricts the cell, forming two daughter cells (discussed in Chapter 10).

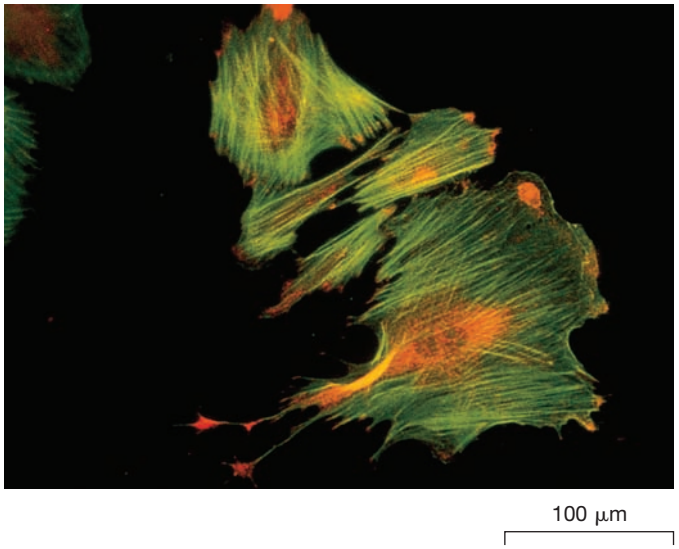
Some cells change their shape quickly in response to changes in the outside environment. Amoebas, human white blood cells, and cancer cells are among the many cell types that can creep along a surface, a process that includes changes in shape. Such responses depend on external signals that affect microfilament, as well as microtubule, assembly. Actin filaments push the plasma membrane outward, forming cytoplasm-filled bulges called **pseudopodia** ("false feet"). The pseudopodia adhere to the surface. Contractions of microfilaments at the opposite end of the cell force the cytoplasm forward in the direction of locomotion. Microtubules, myosin, and other proteins also appear necessary for cell creeping.

As mentioned earlier in the chapter, some types of cells have microvilli, projections of the plasma membrane that increase the surface area of the cell for transporting materials across the plasma

www.konkur.in



(a) A microfilament consists of two intertwined strings of beadlike actin molecules.



(b) Many bundles of microfilaments (*green*) are evident in this fluorescent LM of fibroblasts, cells found in connective tissue.

FIGURE 4-28 Microfilaments

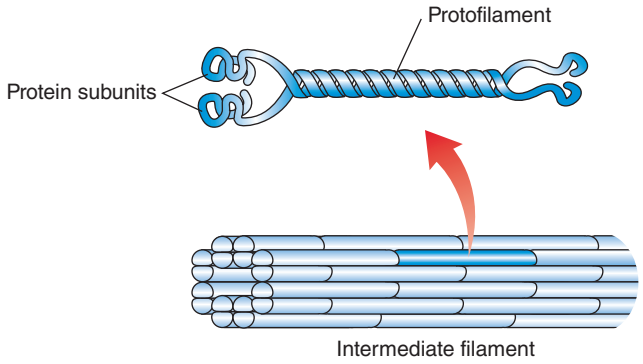
membrane. Composed of bundles of microfilaments, microvilli extend and retract as the microfilaments assemble and disassemble.

Intermediate filaments help stabilize cell shape

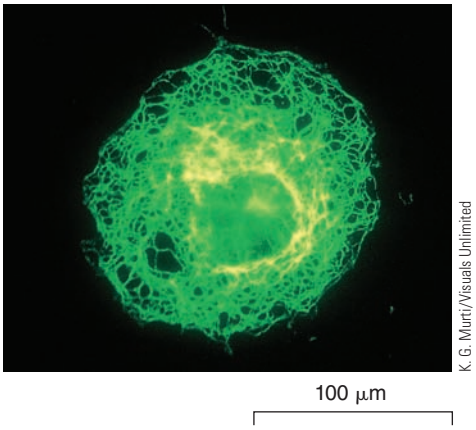
Intermediate filaments are tough, flexible fibers about 10 nm in diameter (**FIG. 4-29**). They provide mechanical strength and help stabilize cell shape. These filaments are abundant in regions of a cell that may be subject to mechanical stress applied from outside the cell. Intermediate filaments prevent the cell from stretching excessively in response to outside forces. Certain proteins cross-link intermediate filaments with other types of filaments and mediate interactions between them.

All eukaryotic cells have microtubules and microfilaments, but only some animal groups, including vertebrates, are known to have intermediate filaments. Even when present, intermediate filaments vary widely in protein composition and size among different cell types and different organisms. Examples of intermediate filaments are the keratins found in the epithelial cells of vertebrate skin and neurofilaments found in vertebrate nerve cells.

Certain mutations in genes coding for intermediate filaments weaken the cell and are associated with several diseases. For example, in the neurodegenerative disease amyotrophic lateral sclerosis (ALS, or Lou Gehrig's disease), abnormal neurofilaments have been identified in nerve cells that control muscles. This condition



(a) Intermediate filaments are flexible rods about 10 nm in diameter. Each intermediate filament consists of components, called protofilaments, composed of coiled protein subunits.



(b) Intermediate filaments are stained green in this human cell isolated from a tissue culture.

FIGURE 4-29 Intermediate filaments

interferes with normal transport of materials in the nerve cells and leads to degeneration of the cells. The resulting loss of muscle function is typically fatal.

Review

- What are the main functions of the cytoskeleton?
- How are microfilaments and microtubules similar? How are they different?
- How are cilia and flagella similar? How are they different?

4.7 CELL COVERINGS

LEARNING OBJECTIVE

14 Describe the glycocalyx, extracellular matrix, and cell wall.

Many cells are surrounded by a **glycocalyx,** or **cell coat,** formed by polysaccharide side chains of proteins and lipids that are part of the plasma membrane. The glycocalyx protects the cell and may help keep other cells at a distance. Certain molecules of the glycocalyx

www.konkur.in

enable cells to recognize one another, to make contact, and in some cases to form adhesive or communicating associations (discussed in Chapter 5). Other molecules of the cell coat contribute to the mechanical strength of multicellular tissues.

Many animal cells are also surrounded by an **extracellular matrix (ECM),** which they secrete. The ECM consists of a gel of carbohydrates and fibrous proteins (**FIG. 4-30**). The main structural protein in the ECM is *collagen,* a protein that forms very tough fibers (see Figure 3-22b). Certain glycoproteins of the ECM, called **fibronectins,** organize the matrix and help cells attach to it. Fibronectins bind to protein receptors that extend from the plasma membrane.

Integrins are receptor proteins in the plasma membrane. They maintain adhesion between the ECM and the intermediate filaments and microfilaments inside the cell. These proteins activate many cell signaling pathways that communicate information from the ECM, and they control signals inside the cell that regulate the differentiation and survival of the cell. When cells are not appropriately anchored, apoptosis is initiated. Integrins are also important in organizing the cytoskeleton so that cells assume a definite shape.

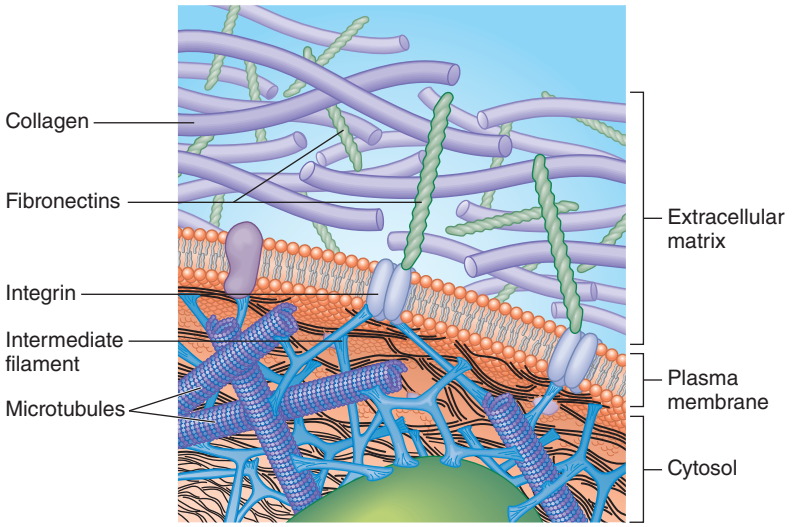


FIGURE 4-30 The extracellular matrix (ECM)
Fibronectins, glycoproteins of the ECM, bind to integrins and other receptors in the plasma membrane.

The cells of most bacteria, archaea, fungi, and plant cells are surrounded by a cell wall. Plant cells have thick cell walls that contain tiny fibers composed of the polysaccharide **cellulose** (see Fig. 3-10). Other polysaccharides in the plant cell wall form cross links between the bundles of cellulose fibers. Cell walls provide structural support, protect plant cells from disease-causing organisms, and keep excess water out of cells so they do not burst.

A growing plant cell secretes a thin, flexible *primary cell wall.* As the cell grows, the primary cell wall increases in size (**FIG. 4-31**). After the cell stops growing, either new wall material is secreted that thickens and solidifies the primary wall, or multiple layers of a *secondary cell wall* with a different chemical composition are formed between the primary wall and the plasma membrane. Wood is made mainly of secondary cell walls. The **middle lamella,** a layer of gluelike polysaccharides called *pectins,* lies between the primary cell walls of adjacent cells. The middle lamella causes the cells to adhere tightly to one another. (For more information on plant cell walls, see the discussion of the ground tissue system in Chapter 33.)

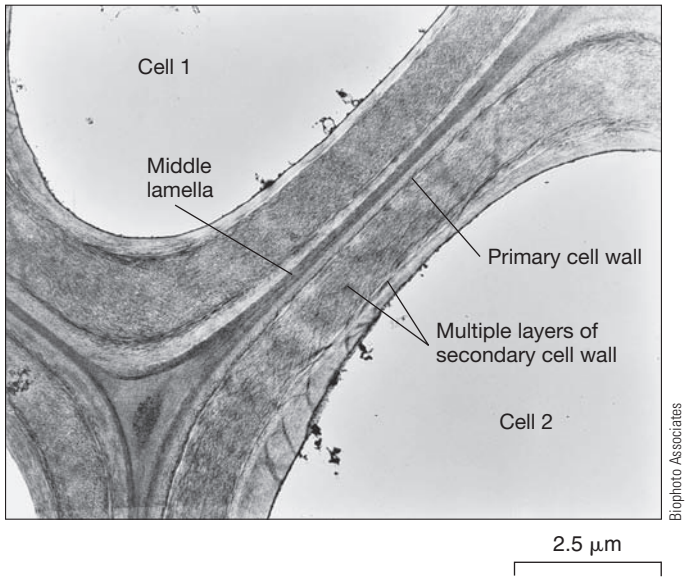

FIGURE 4-31 ***Animated*** Plant cell walls
The cell walls of two adjacent plant cells are labeled in this TEM. The cells are cemented together by the middle lamella, a layer of gluelike polysaccharides called pectins. A growing plant cell first secretes a thin primary wall that is flexible and can stretch as the cell grows. The thicker layers of the secondary wall are secreted inside the primary wall after the cell stops elongating.

Review

- What are the functions of the glycocalyx?
- How do the functions of fibronectins and integrins differ?
- What is the main component of plant cell walls?
- How are plant cell walls formed?

SUMMARY: FOCUS ON LEARNING OBJECTIVES

4.1 *(page 75)*

1 Describe the cell theory and relate it to the evolution of life.

- The **cell theory** holds that (1) cells are the basic living units of organization and function in all organisms and (2) all cells come from other cells. It explains that the ancestry of all the cells alive today can be traced back to ancient times. Evidence that all living cells have evolved from a common ancestor is supported by the basic similarities in their structures and in their molecular composition.

www.konkur.in

2 Summarize the relationship between cell organization and homeostasis.

- The organization of cells is important in maintaining **homeostasis,** an appropriate internal environment.
- Every cell is surrounded by a **plasma membrane** that separates it from its external environment. The plasma membrane allows the cell to maintain internal conditions that may be very different from those of the outer environment. The plasma membrane also allows the cell to exchange materials with its outer environment. Cells have many **organelles,** internal structures that carry out specific functions that help maintain homeostasis.

3 Explain the relationship between cell size and homeostasis.

- A critical factor in determining cell size is the ratio of the plasma membrane (surface area) to the cell's volume. The plasma membrane must be large enough relative to the cell volume to regulate the passage of materials into and out of the cell. For this reason, most cells are microscopic.
- Cell size and shape are related to function and are limited by the need to maintain homeostasis.

4.2 *(page 77)*

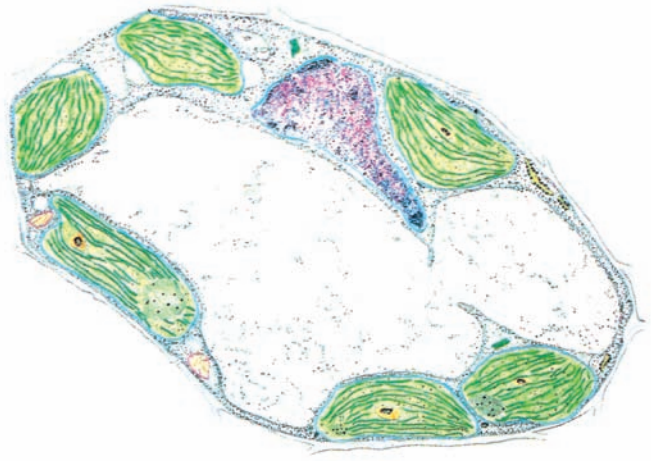
4 Describe methods that biologists use to study cells, including microscopy and cell fractionation.

- Biologists use **light microscopes, electron microscopes,** and a variety of chemical methods to study cells and learn about cell structure. The electron microscope has superior **resolving power,** enabling investigators to see details of cell structures not observable with conventional microscopes.
- Cell biologists use the technique of **cell fractionation** for purifying organelles to gain information about the function of cell structures.

4.3 *(page 81)*

5 Compare and contrast the general characteristics of prokaryotic and eukaryotic cells, and contrast plant and animal cells.

- **Prokaryotic cells** are enclosed by a plasma membrane but have little or no internal membrane organization. They have a **nuclear area** rather than a membrane-enclosed nucleus. Prokaryotic cells typically have a **cell wall** and **ribosomes** and may have propeller-like **flagella.**
- **Eukaryotic cells** have a membrane-enclosed nucleus, and their **cytoplasm** contains a variety of organelles; the fluid component of the cytoplasm is the **cytosol.**
- Plant cells differ from animal cells in that plant cells have rigid cell walls, plastids, and large vacuoles, which are important in plant growth and development. Cells of most plants lack centrioles.



CENGAGENOW™ **Test yourself on the structure of prokaryotic and eukaryotic cells by clicking on the interaction in CengageNOW.**

6 Describe three functions of cell membranes.

- Membranes divide the eukaryotic cell into compartments, allowing it to conduct specialized activities within small areas of the cytoplasm, concentrate reactants, and organize metabolic reactions. Small membrane-enclosed sacs, called **vesicles,** transport materials between compartments.
- Membranes are important in energy storage and conversion.
- A system of interacting membranes forms the **endomembrane system.**

CENGAGENOW™ **Learn more about the endomembrane system by clicking on the figure in CengageNOW.**

4.4 *(page 86)*

7 Describe the structure and functions of the nucleus.

- The **nucleus,** the control center of the eukaryotic cell, contains genetic information coded in DNA. The nucleus is bounded by a **nuclear envelope,** consisting of a double membrane perforated with **nuclear pores** that communicate with the cytoplasm.
- DNA in the nucleus associates with protein to form **chromatin,** which is organized into **chromosomes.** During cell division, the chromosomes condense and become visible as threadlike structures.
- The **nucleolus** is a region in the nucleus that is the site of ribosomal RNA synthesis and ribosome assembly.

4.5 *(page 89)*

8 Distinguish between smooth and rough endoplasmic reticulum in terms of both structure and function.

- The **endoplasmic reticulum (ER)** is a network of folded internal membranes in the cytosol. **Smooth ER** is the site of lipid synthesis, calcium ion storage, and detoxifying enzymes.
- **Rough ER** is studded along its outer surface with **ribosomes** that manufacture polypeptides. Polypeptides synthesized on rough ER may be moved into the ER lumen, where they are assembled into proteins and modified by the addition of a carbohydrate or lipid. These proteins may then be transferred to other compartments within the cell by small transport vesicles that bud off from the ER membrane.

9 Trace the path of proteins synthesized in the rough endoplasmic reticulum as they are processed, modified, and sorted by the Golgi complex and then transported to specific destinations.

- The **Golgi complex** consists of stacks of flattened membranous sacs called **cisternae** that process, sort, and modify proteins synthesized on the ER. The Golgi complex also manufactures lysosomes.
- Glycoproteins are transported from the ER to the *cis* face of the Golgi complex by transport vesicles, which are formed by membrane budding. The Golgi complex modifies carbohydrates and lipids that were added to proteins by the ER and packages them in vesicles.
- Glycoproteins exit the Golgi at its *trans* face. The Golgi routes some proteins to the plasma membrane for export from the cell. Others are transported to lysosomes or other organelles within the cytoplasm.

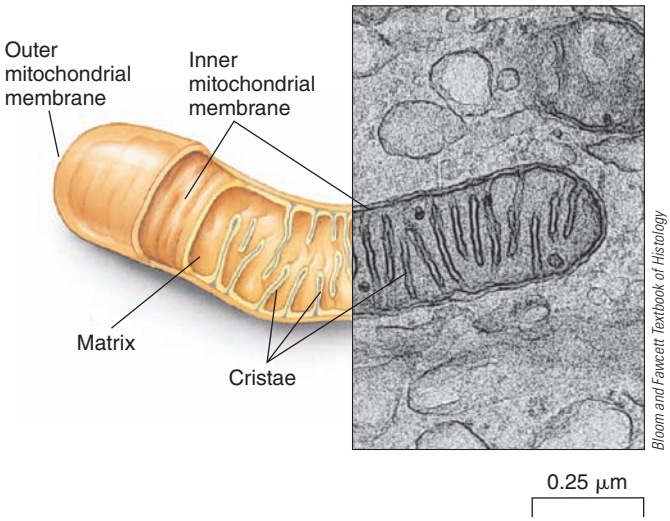
10 Describe the functions of lysosomes, vacuoles, and peroxisomes.

- **Lysosomes** contain enzymes that break down worn-out cell structures, bacteria, and debris taken into cells.
- **Vacuoles** store materials, water, and wastes. They maintain hydrostatic pressure in plant cells.
- **Peroxisomes** are important in lipid metabolism and detoxify harmful compounds such as ethanol. They produce hydrogen peroxide but contain the enzyme catalase, which degrades this toxic compound.

www.konkur.in

11 Compare the functions of mitochondria and chloroplasts, and discuss ATP synthesis by each of these organelles.

- **Mitochondria,** organelles enclosed by a double membrane, are the sites of aerobic respiration. The inner membrane is folded, forming **cristae** that increase its surface area.
- The cristae and the compartment enclosed by the inner membrane, the **matrix,** contain enzymes for the reactions of **aerobic respiration.** During aerobic respiration, nutrients are broken down in the presence of oxygen. Energy captured from nutrients is packaged in ATP, and carbon dioxide and water are produced as byproducts.



- **Plastids** are organelles that produce and store food in the cells of plants and algae.
- **Chloroplasts** are plastids that carry out **photosynthesis.**
- The inner membrane of the chloroplast encloses a fluid-filled space, the **stroma.**
- **Grana,** stacks of interconnected disclike membranous sacs called **thylakoids,** are suspended in the stroma.
- During photosynthesis, **chlorophyll,** the green pigment found in the thylakoid membranes, traps light energy. This energy is converted to chemical energy in ATP and used to synthesize carbohydrates from carbon dioxide and water.

4.6 *(page 97)*

12 Describe the structure and functions of the cytoskeleton.

- The **cytoskeleton** is a dynamic internal framework made of microtubules, microfilaments, and intermediate filaments. The cytoskeleton provides structural support and functions in various types of cell movement, including transport of materials in the cell.
- **Microtubules** are hollow cylinders assembled from subunits of the protein **tubulin.** In cells that are not dividing, the minus ends of microtubules are anchored in **microtubule-organizing centers (MTOCs).** The main MTOC of animal cells is the **centrosome,** which usually contains two centrioles. Each centriole has a 9 × 3 arrangement of microtubules.
- **Microfilaments,** or **actin** filaments, formed from subunits of the protein actin, are important in cell movement.
- **Intermediate filaments** strengthen the cytoskeleton and stabilize cell shape.

CENGAGENOW™ Learn more about the cytoskeleton by clicking on the figure in CengageNOW.

13 Compare cilia and flagella, and describe their functions.

- **Cilia** and **flagella** are thin, movable structures that project from the cell surface and function in movement. Each consists of a 9 + 2 arrangement of microtubules, and each is anchored in the cell by a basal body that has a 9 × 3 organization of microtubules. Cilia are short, and flagella are long.

4.7 *(page 101)*

14 Describe the glycocalyx, extracellular matrix, and cell wall.

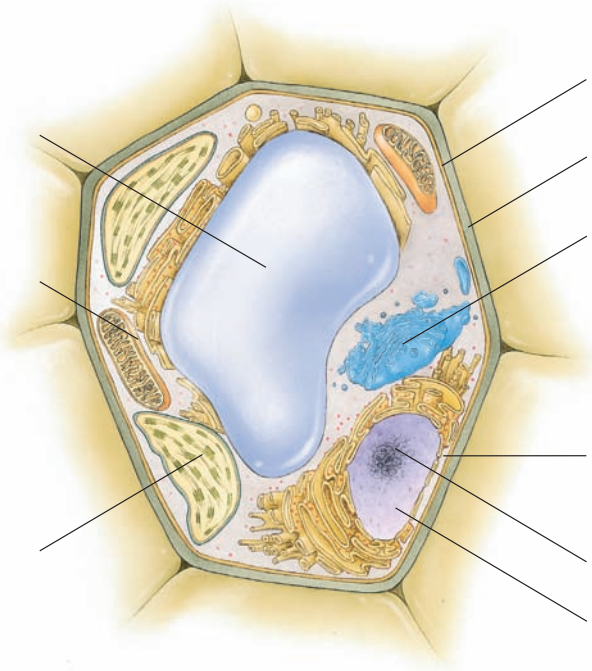
- Most cells are surrounded by a **glycocalyx,** or **cell coat,** formed by polysaccharides extending from the plasma membrane.
- Many animal cells are also surrounded by an **extracellular matrix (ECM)** consisting of carbohydrates and protein. **Fibronectins** are glycoproteins of the ECM that bind to **integrins,** receptor proteins in the plasma membrane.
- Cells of most bacteria, archaea, fungi, and plant cells are surrounded by a cell wall made mainly of carbohydrates. Plant cells secrete **cellulose** and other polysaccharides that form rigid cell walls.

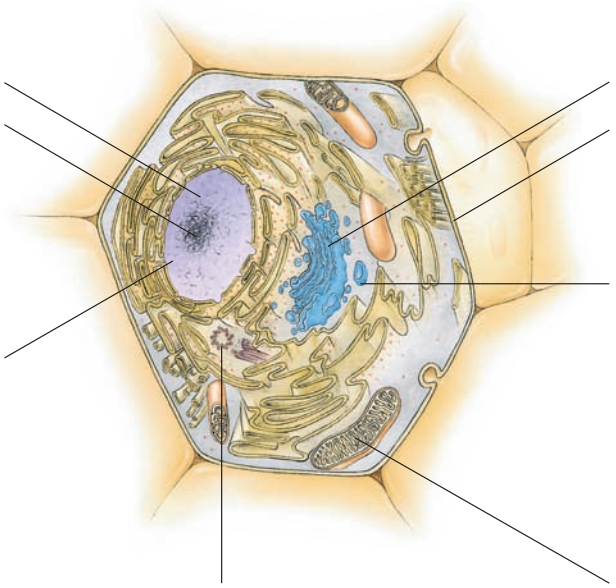
TEST YOUR UNDERSTANDING

1. The ability of a microscope to reveal fine detail is known as (a) magnification (b) resolving power (c) cell fractionation (d) transmission microscopy (e) phase contrast
2. A plasma membrane is characteristic of (a) all cells (b) prokaryotic cells only (c) eukaryotic cells only (d) animal cells only (e) eukaryotic cells except plant cells
3. Detailed information about the shape and external features of a specimen can best be obtained by using a (a) differential centrifuge (b) fluorescence microscope (c) transmission electron microscope (d) scanning electron microscope (e) light microscope
4. Which of the following structures would *not* be found in prokaryotic cells? (a) cell wall (b) ribosomes (c) nuclear area (d) nucleus (e) propeller-like flagellum
5. Which of the following is/are most closely associated with protein synthesis? (a) ribosomes (b) smooth ER (c) mitochondria (d) microfilaments (e) lysosomes
6. Which of the following is/are most closely associated with the breakdown of ingested material? (a) ribosomes (b) smooth ER (c) mitochondria (d) microfilaments (e) lysosomes
7. Which of the following are most closely associated with photosynthesis? (a) basal bodies (b) smooth ER (c) cristae (d) thylakoids (e) MTOCs
8. Use the choices of numbered sequences to select the sequence that most accurately describes information flow in the eukaryotic cell.
   1. DNA in nucleus 2. RNA 3. mitochondria 4. protein synthesis 5. ribosomes
   (a) 1, 2, 5, 4 (b) 3, 2, 5, 1 (c) 5, 2, 3, 1 (d) 4, 3, 2, 1 (e) 1, 2, 3, 4

www.konkur.in

9. Use the choices of numbered sequences to select the sequence that most accurately describes glycoprotein processing in the eukaryotic cell.
   1. ER 2. ribosomes 3. *cis* face of Golgi 4. *trans* face of Golgi 5. transport vesicle 6. grana
   (a) 1, 6, 2, 3, 4 (b) 2, 1, 3, 4, 5 (c) 1, 2, 4, 3, 5 (d) 2, 1, 4, 3, 5 (e) 2, 1, 4, 5, 1
10. Which of the following organelles contain small amounts of DNA and convert energy? (a) microfilaments and microtubules (b) lysosomes and peroxisomes (c) ER and ribosomes (d) nucleus and ribosomes (e) mitochondria and chloroplasts
11. Which of the following function(s) in cell movement? (a) microtubules (b) nucleolus (c) grana (d) smooth ER (e) rough ER
12. Label the diagrams of the animal and plant cells. How is the structure of each organelle related to its function? Use Figures 4-9 and 4-10 to check your answers.





CRITICAL THINKING

1. Why does a eukaryotic cell need both membranous organelles and fibrous cytoskeletal components?
2. Describe a specific example of the correlation between cell structure and function. (*Hint:* Think of mitochondrial structure.)
3. The *Acetabularia* experiments described in this chapter suggest that DNA is much more stable in the cell than is messenger RNA. Is this advantageous or disadvantageous to the cell? Why? *Acetabularia* continues to live for a few days after its nucleus is removed. How can you explain this?
4. **EVOLUTION LINK.** What are the implications of the cell theory for the evolution of organisms?
5. **EVOLUTION LINK.** Biologists use similarities in cells to trace the evolutionary history of various groups of organisms. Explain their rationale. What do such similarities in cell structure and function tell biologists about the common origin of organisms? Explain.

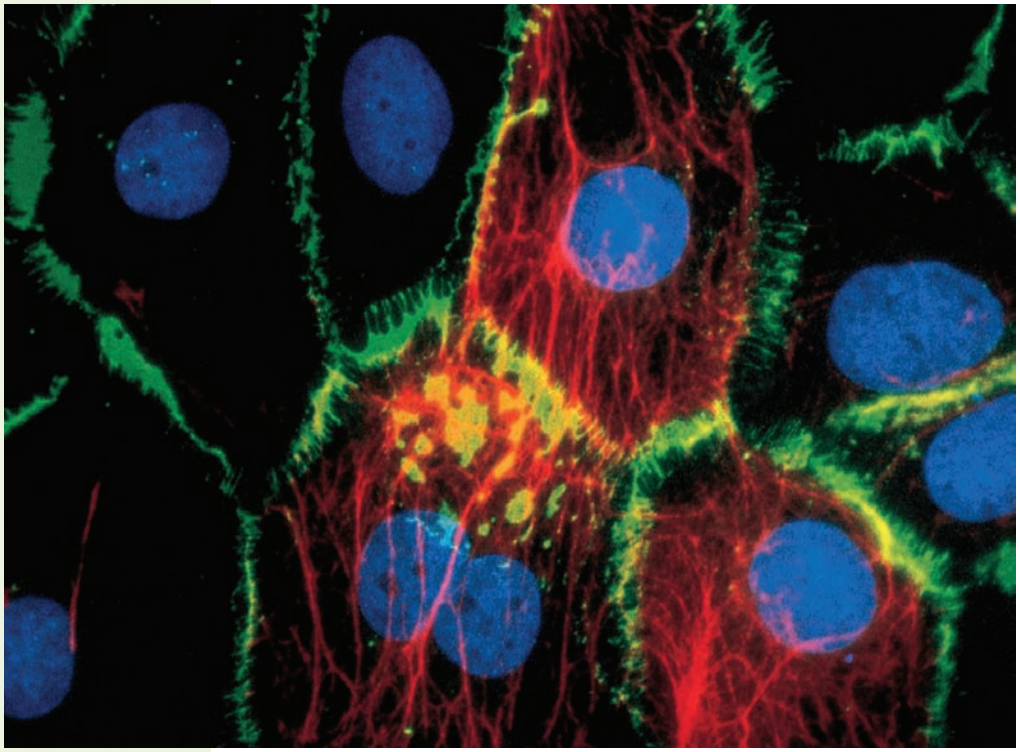
5 Biological Membranes



Nancy Kedersha

Cadherins. The human skin cells shown in this LM were grown in culture and stained with fluorescent antibodies. Cadherins, a group of membrane proteins, are seen as green belts around each cell in this sheet of cells. The nuclei appear as blue spheres; myosin in the cells appears red.

KEY CONCEPTS

5.1 Biological membranes are selectively permeable membranes that help maintain homeostasis in the cell; each cell membrane consists of a fluid bilayer composed of phospholipids in which a variety of proteins are embedded.

5.2 Membrane proteins, and thus membranes, have many functions, including transport of materials, enzymatic activity, transfer of information, and recognition of other cells.

5.3 Transport proteins move ions and small polar molecules through cell membranes.

5.4 Many ions and small molecules move through biological membranes by diffusion, the net movement of particles from a region of higher to a region of lower concentrations.

5.5 Because a cell requires many substances in higher concentrations than their concentrations outside the cell, substances must be actively transported against a concentration gradient; active transport requires a direct expenditure of energy.

5.6 Cells eject products by exocytosis and import materials by endocytosis; both processes require cells to expend energy.

5.7 Cells in close contact may form specialized junctions with one another.

The evolution of biological membranes that separate the cell from its external environment was an essential step in the origin of life. Later, these membranes made the evolution of complex cells possible. The extensive internal membranes of eukaryotic cells form multiple compartments with unique environments that allow highly specialized activities to take place.

Because membrane proteins are critical molecules in cell membrane activities, they are a major focus of cell membrane research. Some proteins associated with the plasma membrane transport materials, whereas others transmit information or serve as enzymes. Still others, known as *cell adhesion molecules,* are important in connecting cells to one another to form tissues. The principal cell adhesion molecules in vertebrates and in many invertebrates are **cadherins.**

The genes that code cadherins are found in choanoflagellates, the closest single-celled relatives of animals. These molecules were probably important in the evolution of animals because they provided a means for cells to adhere to one another and to communicate. Cadherins are responsible for adhesion between cells that form multicellular sheets. For example, these membrane proteins form cell junctions important in

www.konkur.in

maintaining the structure of the epithelium that makes up human skin (see photograph). Cadherins are also important in signaling among cells. An absence of these membrane proteins is associated with the invasiveness of some malignant tumors.

In Chapter 4, we discussed a variety of cell organelles and how they interact to perform cell activities. In this chapter, we focus on the structure and functions of the plasma membrane that surrounds the cell, and on the biological membranes that surround many organelles. We first consider what is known about the composition and structure of biological membranes. Then we provide an overview of the many vital functions of cell membranes, including transport of materials and information transfer. We discuss how cells transport various materials, from ions to complex molecules and even bacteria, across membranes. Finally, we examine specialized structures that allow membranes of different cells to interact. Although much of our discussion centers on the structure and functions of plasma membranes, many of the concepts apply to other cell membranes.

5.1 THE STRUCTURE OF BIOLOGICAL MEMBRANES

LEARNING OBJECTIVES

1. Evaluate the importance of membranes to the homeostasis of the cell, emphasizing their various functions.
2. Describe the fluid mosaic model of cell membrane structure.
3. Relate properties of the lipid bilayer to properties and functions of cell membranes.
4. Describe the ways that membrane proteins associate with the lipid bilayer.

To carry out the many chemical reactions necessary to sustain life, the cell must maintain an appropriate internal environment. Every cell is surrounded by a **plasma membrane** that physically separates it from the outside world and defines it as a distinct entity. By regulating passage of materials into and out of the cell, the plasma membrane helps maintain a life-supporting internal environment. As we discussed in Chapter 4, eukaryotic cells are characterized by numerous organelles that are surrounded by membranes. Some of these organelles—including the nuclear envelope, endoplasmic reticulum (ER), Golgi complex, lysosomes, vesicles, and vacuoles—form the endomembrane system, which extends throughout the cell.

Biological membranes are complex, dynamic structures made of lipid and protein molecules that are in constant motion. The properties of membranes allow them to perform many vital functions. They regulate the passage of materials, divide the cell into compartments, serve as surfaces for chemical reactions, adhere to and communicate with other cells, and transmit signals between the environment and the interior of the cell. Membranes are also an essential part of energy transfer and storage systems. How do the properties of cell membranes enable the cell to carry on such varied functions?

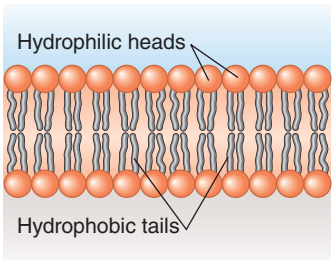
Long before the development of the electron microscope, scientists knew that membranes consist of both lipids and proteins. Work by researchers in the 1920s and 1930s had provided clues that the core of cell membranes consists of lipids, mostly phospholipids (see Chapter 3).

Phospholipids form bilayers in water

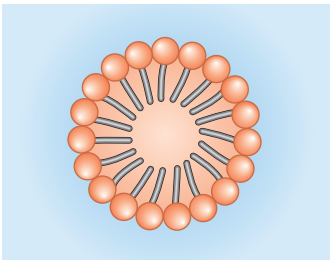
Phospholipids are primarily responsible for the physical properties of biological membranes, because certain phospholipids have unique attributes, including features that allow them to form bilayered structures. A phospholipid contains two fatty acid chains linked to two of the three carbons of a glycerol molecule (see Fig. 3-13). The fatty acid chains make up the nonpolar, *hydrophobic* ("water-fearing") portion of the phospholipid. Bonded to the third carbon of the glycerol is a negatively charged, *hydrophilic* ("water-loving") phosphate group, which in turn is linked to a polar, hydrophilic organic group. Molecules of this type, which have distinct hydrophobic and hydrophilic regions, are called **amphipathic molecules.** All lipids that make up the core of biological membranes have amphipathic characteristics.

Because one end of each phospholipid associates freely with water and the opposite end does not, the most stable orientation for them to assume in water results in the formation of a bilayer structure (**FIG. 5-1a**). This arrangement allows the hydrophilic heads of the phospholipids to be in contact with the aqueous medium while their oily tails, the hydrophobic fatty acid chains, are buried in the interior of the structure away from the water molecules.

Amphipathic properties alone do not predict the ability of lipids to associate as a bilayer. Shape is also important. Phospholipids tend to have uniform widths; their roughly cylindrical shapes, together with their amphipathic properties, are responsible for bilayer formation. In summary, phospholipids form bilayers because the molecules have (1) two distinct regions, one strongly hydrophobic and the other strongly hydrophilic (making them strongly amphipathic) and (2) cylindrical shapes that allow them to associate with water most easily as a bilayer.



(a) Phospholipids in water. Phospholipids associate as bilayers in water because they are roughly cylindrical amphipathic molecules. The hydrophobic fatty acid chains are not exposed to water, whereas the hydrophilic phospholipid heads are in contact with water.

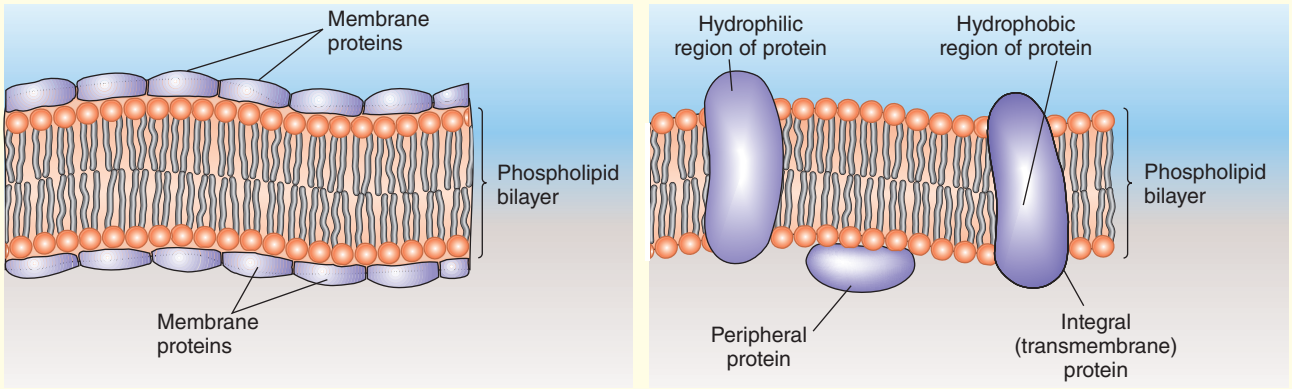


(b) Detergent in water. Detergent molecules are roughly cone-shaped amphipathic molecules that associate in water as spherical structures.

FIGURE 5-1 *Animated* Properties of lipids in water

www.konkur.in

KEY POINT The Davson–Danielli model was the accepted view until about 1970 when advances in biology and chemistry led to new findings about biological membranes that were incompatible with this model. The fluid mosaic model is supported by a large body of data.



(a) The Davson–Danielli model. According to this model, the membrane is a sandwich of phospholipids spread between two layers of protein. Although accepted for many years, this model was shown to be incorrect.

(b) Fluid mosaic model. According to this model, a cell membrane is a fluid lipid bilayer with a constantly changing "mosaic pattern" of associated proteins.

FIGURE 5-2 Two models of membrane structure

Do you know why detergents remove grease from your hands or from dirty dishes? Many common detergents are amphipathic molecules, each containing a single hydrocarbon chain (like a fatty acid) at one end and a hydrophilic region at the other. These molecules are roughly cone-shaped, with the hydrophilic end forming the broad base and the hydrocarbon tail leading to the point. Because of their shapes, these molecules do not associate as bilayers but instead tend to form spherical structures in water (**FIG. 5-1b**). Detergents can "solubilize" oil because the oil molecules associate with the hydrophobic interiors of the spheres.

The fluid mosaic model explains membrane structure

By examining the plasma membrane of mammalian red blood cells and comparing their surface area with the total number of lipid molecules per cell, early investigators calculated that the membrane is no more than two phospholipid molecules thick. In 1935, these findings, together with other data, led Hugh Davson and James Danielli, working at London's University College, to propose a model in which they envisioned a membrane as a kind of "sandwich" consisting of a *lipid bilayer* (a double layer of lipid) between two protein layers (**FIG. 5-2a**). This useful model had a great influence on the direction of membrane research for more than 20 years. Models are important in the scientific process; good ones not only explain the available data but are testable. Scientists use models to help them develop hypotheses that can be tested experimentally (see Chapter 1).

With the development of the electron microscope in the 1950s, cell biologists were able to see the plasma membrane for the first time. One of their most striking observations was how uniform and thin the membranes are. The plasma membrane is no more than 10 nm thick. The electron microscope revealed a three-layered structure, something like a railroad track, with two dark layers separated by a lighter layer (**FIG. 5-3**). Their findings seemed to support the protein–lipid–protein sandwich model.

During the 1960s, a paradox emerged regarding the arrangement of the proteins. Biologists assumed membrane proteins were uniform and had shapes that would allow them to lie like thin sheets on the membrane surface. But when purified by cell fractionation, the proteins were far from uniform; in fact, they varied widely in composition and size. Some proteins are quite large. How could they fit within a surface layer of a membrane less than 10 nm thick?

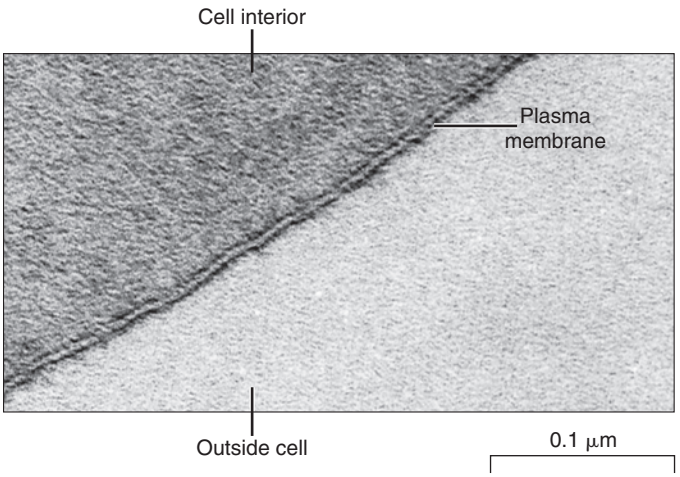


FIGURE 5-3 TEM of the plasma membrane of a mammalian red blood cell

The plasma membrane separates the cytosol (*darker region*) from the external environment (*lighter region*). The hydrophilic heads of the phospholipids are the parallel dark lines, and the hydrophobic tails are the light zone between them.

www.konkur.in

At first, some researchers tried to answer this question by modifying the model with the hypothesis that the proteins on the membrane surfaces were a flattened, extended form, perhaps a β-pleated sheet (see Fig. 3-20b).

Other cell biologists found that instead of having sheetlike structures, many membrane proteins are rounded, or globular. Studies of many membrane proteins showed that one region (or domain) of the molecule could always be found on one side of the bilayer, whereas another part of the protein might be located on the opposite side. Rather than form a thin surface layer, many membrane proteins extended completely through the lipid bilayer. Thus, the evidence suggested that membranes contain different types of proteins of different shapes and sizes that are associated with the bilayer in a mosaic pattern.

In 1972, S. Jonathan Singer and Garth Nicolson of the University of California at San Diego proposed a model of membrane structure that represented a synthesis of the known properties of biological membranes. According to their **fluid mosaic model,** a cell membrane consists of a fluid bilayer of phospholipid molecules in which the proteins are embedded or otherwise associated, much like the tiles in a mosaic picture. This mosaic pattern is not static, however, because the positions of many of the proteins are constantly changing as they move about like icebergs in a fluid sea of phospholipids. This model has provided great impetus to research; it has been repeatedly tested and has been shown to accurately predict the properties of many kinds of cell membranes. **FIGURE 5-2b** depicts the plasma membrane of a eukaryotic cell according to the fluid mosaic model; prokaryotic plasma membranes are discussed in Chapter 25.

Biological membranes are two-dimensional fluids

An important physical property of phospholipid bilayers is that they behave like *liquid crystals.* The bilayers are crystal-like in that the lipid molecules form an ordered array with the heads on the outside and fatty acid chains on the inside; they are liquid-like in that despite the orderly arrangement of the molecules, their hydrocarbon chains are in constant motion. Thus, molecules are free to rotate and can move laterally within their single layer (**FIG. 5-4**). Such movement gives the bilayer the property of a *two-dimensional fluid.* Under normal conditions a single phospholipid molecule can travel laterally across the surface of a eukaryotic cell in seconds.

The fluid qualities of lipid bilayers also allow molecules embedded in them to move along the plane of the membrane (as long as they are not anchored in some way). David Frye and Michael Edidin elegantly demonstrated this in 1970. They conducted experiments in which they followed the movement of membrane proteins on the surface of two cells that had been joined (**FIG. 5-5**). When the plasma membranes of a mouse cell and a human cell are fused, within minutes at least some of the membrane proteins from each

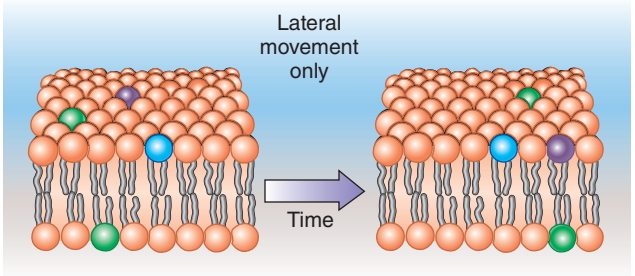

FIGURE 5-4 Membrane fluidity
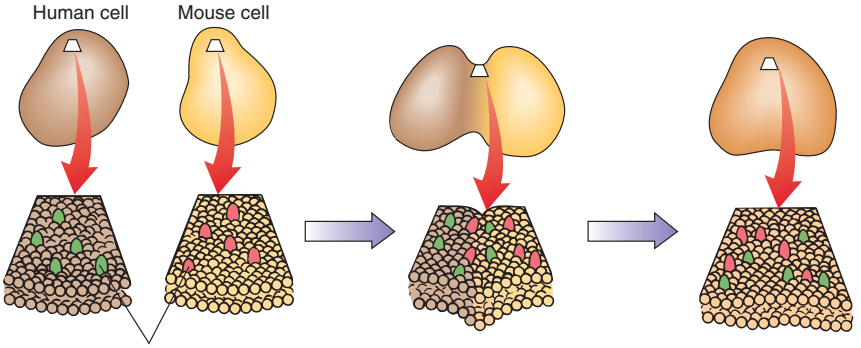
The ordered arrangement of phospholipid molecules makes the cell membrane a liquid crystal. The hydrocarbon chains are in constant motion, allowing each molecule to move laterally on the same side of the bilayer.

KEY EXPERIMENT

QUESTION: Do proteins embedded in a biological membrane move about?

HYPOTHESIS: Proteins are able to move laterally in the plasma membrane.

EXPERIMENT: Larry Frye and Michael Edidin labeled membrane proteins of mouse and human cells using different-colored fluorescent dyes to distinguish between them. Then they fused mouse and human cells to produce hybrid cells.



1 **Labeled membrane proteins.** Membrane proteins of mouse cells and human cells were labeled with fluorescent dye markers in two different colors.

2 **Human-mouse hybrid cell forming.** When plasma membranes of mouse cell and human cell were fused, mouse proteins migrated to the human side and human proteins to the mouse side.

3 **Proteins randomly distributed.** After a short time, mouse and human proteins became randomly distributed through the membrane.

RESULTS AND CONCLUSION: After a brief period of incubation, mouse and human cells intermixed over the surface of the hybrid cells. After about 40 minutes, the proteins of each species had become randomly distributed through the entire hybrid plasma membrane. This experiment demonstrated that proteins in the plasma membrane do move.

FIGURE 5-5 *Animated* Frye and Edidin's experiment

Source: Frye, L. D., and M. Edidin. "The rapid intermixing of cell surface antigens after formation of mouse-human heterokaryons." *Journal of Cell Science,* Vol. 7, 319–335, 1970.

www.konkur.in

cell migrate and become randomly distributed over the single, continuous plasma membrane that surrounds the joined cells. Frye and Edidin showed that the fluidity of the lipids in the membrane allows many of the proteins to move, producing an ever-changing configuration. Occasionally, with the help of enzymes in the cell membrane, phospholipid molecules flip-flop from one layer to the other.

For a membrane to function properly, its lipids must be in a state of optimal fluidity. The membrane's structure is weakened if its lipids are too fluid. However, many membrane functions, such as the transport of certain substances, are inhibited or cease if the lipid bilayer is too rigid. At normal temperatures, cell membranes are fluid, but at low temperatures the motion of the fatty acid chains is slowed. If the temperature decreases to a critical point, the membrane is converted to a more solid gel state.

Certain properties of membrane lipids have significant effects on the fluidity of the bilayer. Recall from Chapter 3 that molecules are free to rotate around single carbon-to-carbon covalent bonds. Because most of the bonds in hydrocarbon chains are single bonds, the chains themselves twist more and more rapidly as the temperature rises.

The fluid state of the membrane depends on its component lipids. You have probably noticed that when melted butter is left at room temperature it solidifies. Vegetable oils, however, remain liquid at room temperature. Recall from our discussion of lipids in Chapter 3 that animal fats such as butter are high in saturated fatty acids that lack double bonds. In contrast, a vegetable oil may be polyunsaturated, with most of its fatty acid chains having two or more double bonds. At each double bond there is a bend in the molecule that prevents the hydrocarbon chains from coming

KEY POINT **According to the fluid mosaic model, a cell membrane is composed of a fluid bilayer of phospholipids in which proteins move about like icebergs in a sea.**

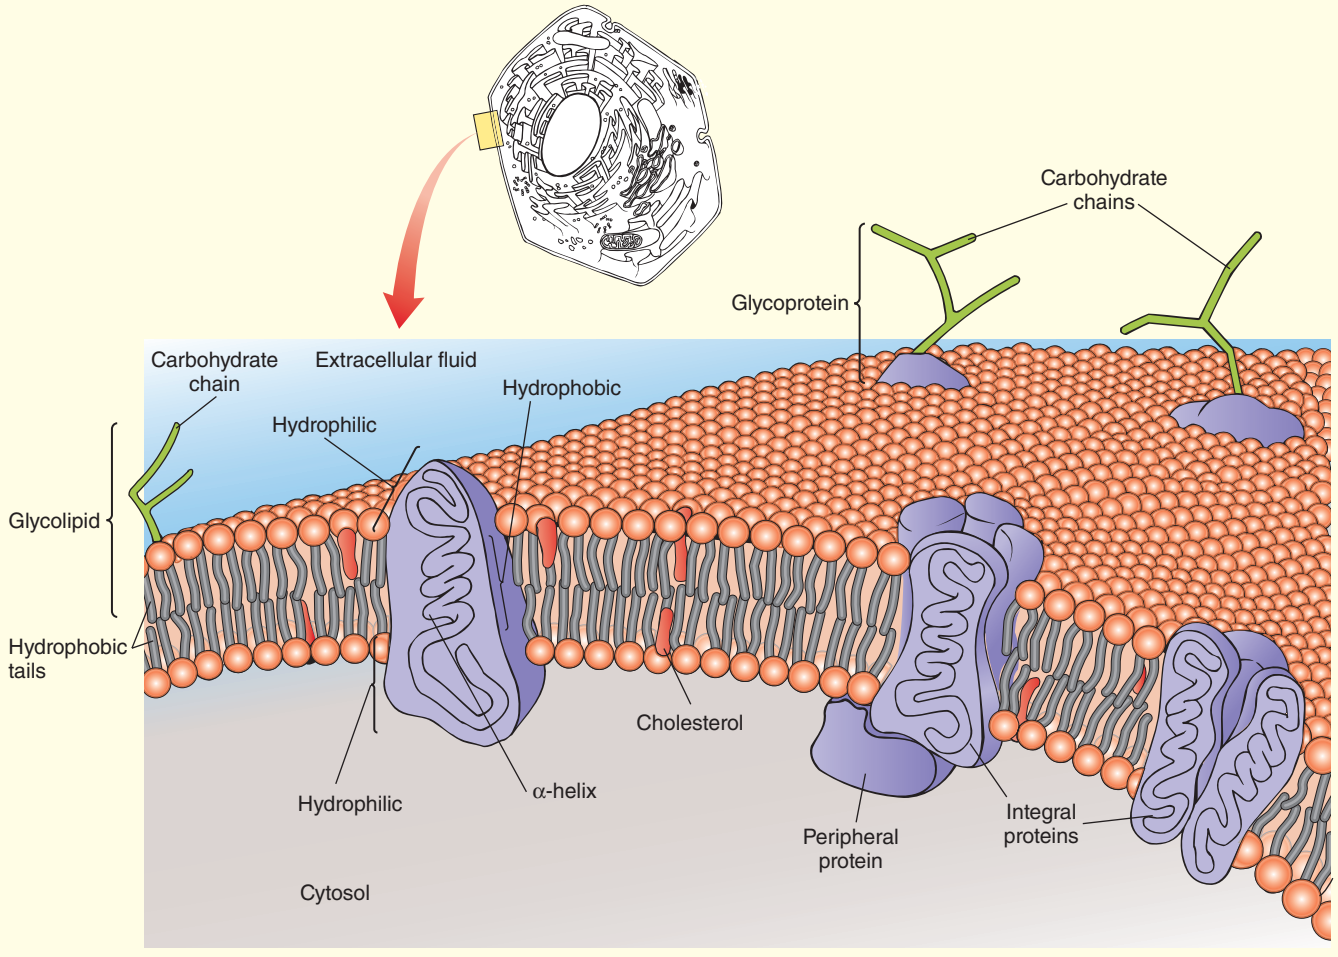


FIGURE 5-6 Detailed structure of the plasma membrane

Although the lipid bilayer consists mainly of phospholipids, other lipids, such as cholesterol and glycolipids, are present. Peripheral proteins are loosely associated with the bilayer, whereas integral proteins are tightly bound. The integral proteins shown here are transmembrane proteins that extend through the bilayer. They have hydrophilic regions on both sides of the bilayer, connected by a membrane-spanning α-helix. Glycolipids (carbohydrates attached to lipids) and glycoproteins (carbohydrates attached to proteins) are exposed on the extracellular surface; they play roles in cell recognition and adhesion to other cells.

www.konkur.in

close together and interacting through van der Waals interactions. In this way, unsaturated fats lower the temperature at which oil or membrane lipids solidify.

Many organisms have regulatory mechanisms for maintaining cell membranes in an optimally fluid state. Some organisms compensate for temperature changes by altering the fatty acid content of their membrane lipids. When the outside temperature is cold, the membrane lipids contain relatively high proportions of unsaturated fatty acids.

Some membrane lipids stabilize membrane fluidity within certain limits. One such "fluidity buffer" is cholesterol, a steroid found in animal cell membranes. A cholesterol molecule is largely hydrophobic but is slightly amphipathic because of the presence of a single hydroxyl group (see Fig. 3-15a). This hydroxyl group associates with the hydrophilic heads of the phospholipids; the hydrophobic remainder of the cholesterol molecule fits between the fatty acid hydrocarbon chains (**FIG. 5-6**).

At low temperatures cholesterol molecules act as "spacers" between the hydrocarbon chains, restricting van der Waals interactions that would promote solidifying. Cholesterol also helps prevent the membrane from becoming weakened or unstable at higher temperatures. The reason is that the cholesterol molecules interact strongly with the portions of the hydrocarbon chains closest to the phospholipid head. This interaction restricts motion in these regions. Plant cells have steroids other than cholesterol that carry out similar functions.

Biological membranes fuse and form closed vesicles

Lipid bilayers, particularly those in the liquid-crystalline state, have additional important physical properties. Bilayers tend to resist forming free ends; as a result, they are self-sealing and under most conditions spontaneously round up to form closed vesicles. Lipid bilayers are also flexible, allowing cell membranes to change shape without breaking. Under appropriate conditions lipid bilayers fuse with other bilayers.

Membrane fusion is an important cell process. When a vesicle fuses with another membrane, both membrane bilayers and their compartments become continuous. Various transport vesicles form from, and also merge with, membranes of the ER and Golgi complex, facilitating the transfer of materials from one compartment to another. A vesicle fuses with the plasma membrane when a product is secreted from the cell.

Membrane proteins include integral and peripheral proteins

The two major classes of membrane proteins, integral proteins and peripheral proteins, are defined by how tightly they are associated with the lipid bilayer (**FIG. 5-7**). **Integral membrane proteins** are firmly bound to the membrane. Cell biologists usually can release them only by disrupting the bilayer with detergents. These proteins are amphipathic. Their hydrophilic regions extend out of the cell or into the cytoplasm, whereas their hydrophobic regions interact with the fatty acid tails of the membrane phospholipids.

Some integral proteins do not extend all the way through the membrane. Many others, called **transmembrane proteins,** extend completely through the membrane. Some span the membrane only once, whereas others wind back and forth as many as 24 times. The most common kind of transmembrane protein is an α-helix (see Chapter 3) with hydrophobic amino acid side chains projecting out from the helix into the hydrophobic region of the lipid bilayer. Some proteins span the membrane in the form of rolled-up β-pleated sheets. These protein formations are barrel-shaped and form pores through which water and other substances can pass.

Peripheral membrane proteins are not embedded in the lipid bilayer. They are located on the inner or outer surface of the plasma

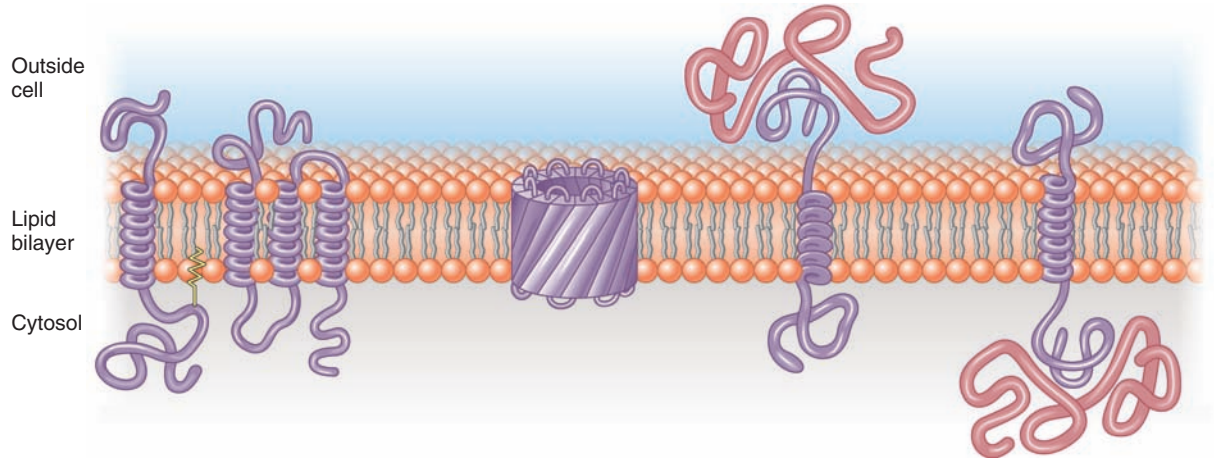

FIGURE 5-7 ***Animated*** **Membrane proteins**

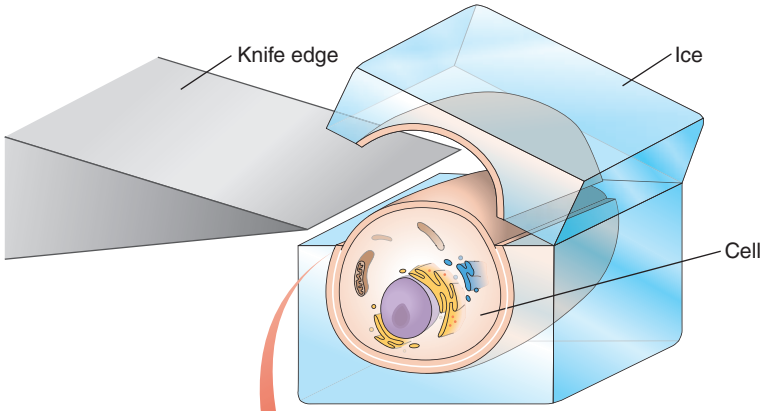
Three transmembrane proteins are shown in **(a), (b),** and **(c).** The rolled-up β-pleated sheet shown in **(c)** forms a pore through the membrane. Water molecules and ions pass through specific types of pores **(d, e).** Peripheral proteins are bound to integral proteins by noncovalent interactions.

www.konkur.in

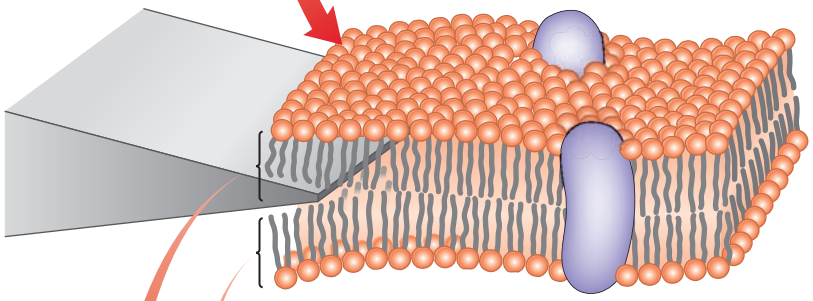
RESEARCH METHOD

Why Is It Used? The freeze-fracture method is used to split the lipid bilayer apart so that its components can be analyzed.

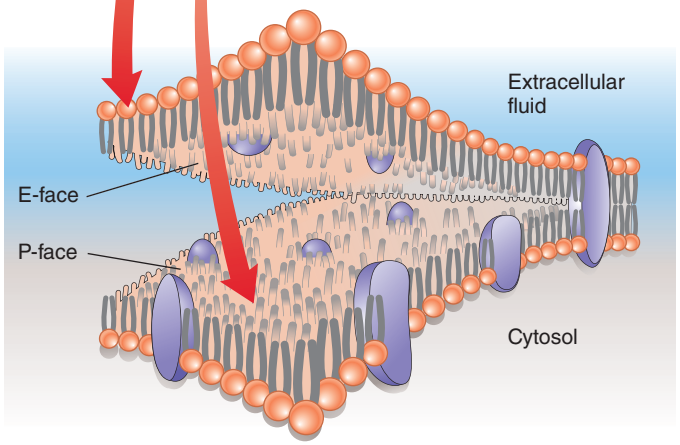
How Is It Done?



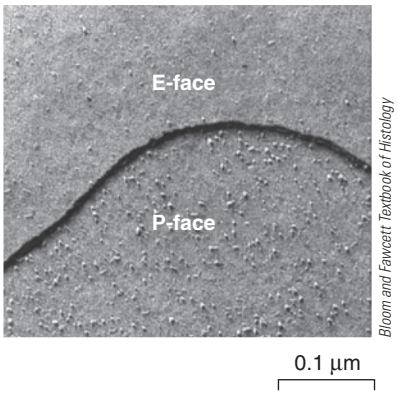
1 Cells are frozen in liquid nitrogen and then fractured with the edge of a knife.



2 The fracture often splits the membrane along the hydrophobic interior of the lipid bilayer.



3 Two complementary fracture faces result. The inner half-membrane presents the P-face (or protoplasmic face), and the outer half-membrane presents the E-face (or external face). Integral proteins, including transmembrane proteins, are inserted through the lipid bilayer.



Bloom and Fawcett Textbook of Histology

4 An electron microscope is used to view the interior surfaces (faces) of the two layers. In this TEM the particles (which appear as bumps) represent large integral proteins.

FIGURE 5-8 Freeze-fracture method

www.konkur.in

membrane, usually bound to exposed regions of integral proteins by noncovalent interactions. Peripheral proteins can be easily removed from the membrane without disrupting the structure of the bilayer.

Proteins are oriented asymmetrically across the bilayer

One of the most remarkable demonstrations that proteins are actually embedded in the lipid bilayer comes from *freeze–fracture* electron microscopy, a technique that splits the membrane into halves. The researcher can literally see the two halves of the membrane from "inside out." When cell biologists examine membranes in this way, they observe numerous particles on the fracture faces (**FIG. 5-8**). The particles are clearly integral membrane proteins, because researchers never see them in freeze-fractured artificial lipid bilayers. These findings profoundly influenced Singer and Nicolson in developing the fluid mosaic model.

Membrane protein molecules are *asymmetrically oriented*. The asymmetry is produced by the highly specific way in which each protein is inserted into the bilayer. Membrane proteins that will become part of the inner surface of the plasma membrane are manufactured by free ribosomes and move to the membrane through the cytoplasm. Membrane proteins that will be associated with the cell's outer surface are manufactured like proteins destined to be exported from the cell.

As discussed in Chapter 4, proteins destined for the cell's outer surface are initially manufactured by ribosomes on the rough ER. They pass through the ER membrane into the ER lumen, where sugars are added, making them **glycoproteins.** However, only a part of each protein passes through the ER membrane, so each completed protein has some regions that are located in the ER lumen and other regions that remain in the cytosol. Enzymes that attach the sugars to certain amino acids on the protein are found only in the lumen of the ER. Thus, carbohydrates can be added only to the parts of proteins located in that compartment.

In **FIGURE 5-9**, follow from top to bottom the vesicle budding and membrane fusion events that are part of the transport process. You can see that the same region of the protein that protruded into

KEY POINT The orientation of a protein in the plasma membrane is determined by the pathway of its synthesis and transport.

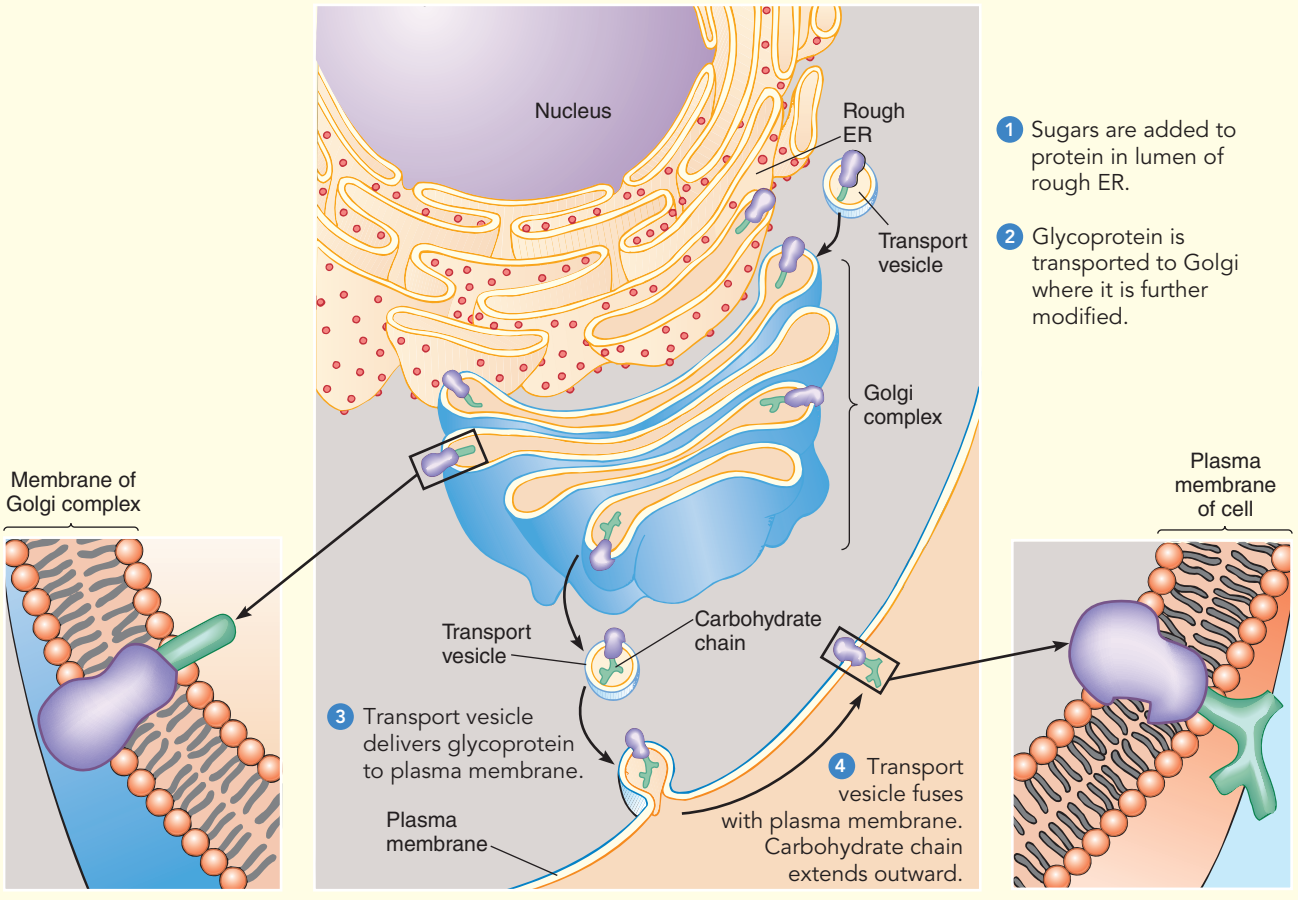


FIGURE 5-9 Synthesis and orientation of a membrane protein

The surface of the rough ER membrane that faces the lumen of the rough ER also faces the lumen of the Golgi complex and vesicles. However, when a vesicle fuses with the plasma membrane, the inner surface of the vesicle becomes the extracellular surface of the plasma membrane.

www.konkur.in

the ER lumen is also transported to the lumen of the Golgi complex. There additional enzymes further modify the carbohydrate chains. Within the Golgi complex, the glycoprotein is sorted and directed to the plasma membrane. The modified region of the protein remains inside the membrane compartment of a transport vesicle as it buds from the Golgi complex. Note that when the transport vesicle fuses with the plasma membrane, the inside layer of the transport vesicle becomes the outside layer of the plasma membrane. The carbohydrate chain extends to the exterior of the cell surface.

In summary, this is the sequence:

> sugar added to protein in ER lumen ⟶ glycoprotein transported to Golgi complex, where it is further modified ⟶ glycoprotein transported to plasma membrane ⟶ transport vesicle fuses with plasma membrane (inside layer of transport vesicle becomes outer layer of plasma membrane)

Review

- What molecules are responsible for the physical properties of a cell membrane?
- How might a transmembrane protein be positioned in a lipid bilayer? How do the hydrophilic and hydrophobic regions of the protein affect its orientation?
- What is the pathway used by cells to place carbohydrates on plasma membrane proteins?

5.2 OVERVIEW OF MEMBRANE PROTEIN FUNCTIONS

LEARNING OBJECTIVE

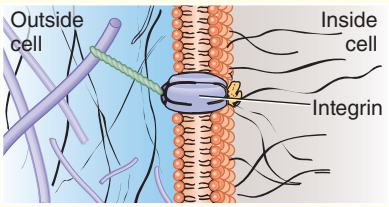
5 Summarize the functions of membrane proteins.

Why does the plasma membrane require so many different proteins? This diversity reflects the multitude of activities that take place in or on the membrane. Proteins associated with the membrane are essential for most of these activities. Generally, plasma membrane proteins fall into several broad functional categories, as shown in **FIGURE 5-10**. Some membrane proteins anchor the cell to its substrate. For example, *integrins,* proteins bound to microfilaments inside the cell, attach the cell to the extracellular matrix (Fig. 5-10a). Integrins also serve as receptors, or docking sites, for proteins of the extracellular matrix (see Fig. 4-30).

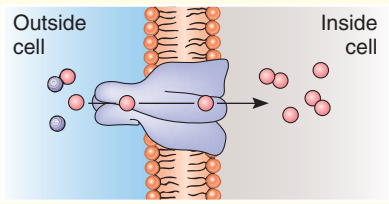
Many membrane proteins are involved in the transport of molecules across the membrane. Some form channels that selectively allow the passage of specific ions or molecules (Fig. 5-10b). Other proteins form pumps that use ATP, or other energy sources, to actively transport solutes across the membrane (Fig. 5-10c).

Certain membrane proteins are enzymes that catalyze reactions near the cell surface (Fig. 5-10d). In mito-

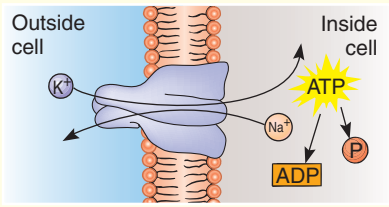
KEY POINT Cell proteins perform many functions, including transporting materials, serving as enzymes for chemical reactions, and transmitting information.



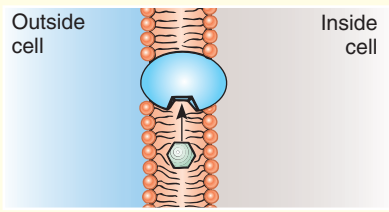
(a) Anchoring. Some membrane proteins, such as integrins, anchor the cell to the extracellular matrix; they also connect to microfilaments within the cell.



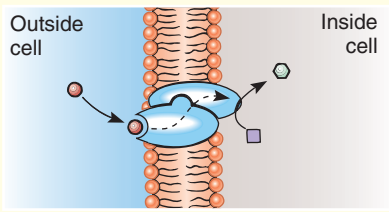
(b) Passive transport. Certain proteins form channels for selective passage of ions or molecules.



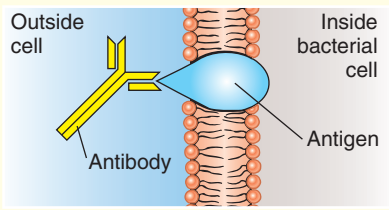
(c) Active transport. Some transport proteins pump solutes across the membrane, which requires a direct input of energy.



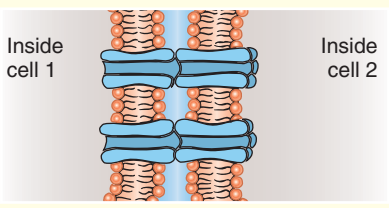
(d) Enzymatic activity. Many membrane-bound enzymes catalyze reactions that take place within or along the membrane surface.



(e) Signal transduction. Some receptors bind with signal molecules such as hormones and transmit information into the cell.



(f) Cell recognition. Some glycoproteins function as identification tags. For example, bacterial cells have surface proteins, or antigens, that human cells recognize as foreign.



(g) Intercellular junction. Cell adhesion proteins attach membranes of adjacent cells.

FIGURE 5-10 Some functions of membrane proteins

www.konkur.in

chondrial or chloroplast membranes, enzymes are organized in sequences that allow the organelle to efficiently regulate series of reactions in cellular respiration or photosynthesis.

Some membrane proteins are receptors that receive information from other cells in the form of chemical or electrical signals. Most vertebrate cells have receptors for hormones released by endocrine glands. Information may be transmitted from proteins in the plasma membrane to the cell interior by *signal transduction* (discussed in Chapter 6; Fig. 5-10e).

Some membrane proteins serve as identification tags that other cells recognize. For example, certain cells recognize the surface proteins, or *antigens,* of bacterial cells as foreign. Antigens stimulate immune defenses that destroy the bacteria (Fig. 5-10f). When certain cells recognize one another, they connect to form tissues. Some membrane proteins form junctions between adjacent cells (Fig. 5-10g). These proteins may also serve as anchoring points for networks of cytoskeletal elements. In the remaining sections of this chapter, we will discuss the functions of cell membrane proteins in transporting material into and out of the cell, and we will discuss junctions between cells. We will discuss other functions of cell membranes in many of the chapters that follow.

Review

- How do proteins function in transporting materials into the cell?
- What role do membrane proteins play in cell recognition?

5.3 CELL MEMBRANE STRUCTURE AND PERMEABILITY

LEARNING OBJECTIVE

6 Describe the importance of selectively permeable membranes and compare the functions of carrier proteins and channel proteins.

A membrane is *permeable* to a given substance if it allows that substance to pass through and impermeable if it does not. The fluid mosaic structure of biological membranes allows them to function as **selectively permeable membranes**—they let some, but not all, substances pass through them. In response to varying environmental conditions or cell needs, a membrane may be a barrier to a particular substance at one time and actively promote its passage at another time. By regulating chemical traffic across its plasma membrane, a cell controls its volume and its internal ionic and molecular composition. This regulation allows the molecular composition of the cell to be quite different from that of its external environment.

Biological membranes present a barrier to polar molecules

In general, biological membranes are most permeable to small nonpolar (hydrophobic) molecules. Such molecules can pass through the hydrophobic lipid bilayer. Gases such as oxygen and carbon dioxide are small, nonpolar molecules that cross the lipid bilayer rapidly. Although they are polar, water molecules are small enough to pass through gaps that occur as a fatty acid chain momentarily moves out of the way. As a result, water molecules slowly cross the lipid bilayer.

The lipid bilayer of the plasma membrane is relatively impermeable to charged ions of any size, so ions and most large polar molecules pass through the bilayer slowly. Ions are important in cell signaling and many other physiological processes. For example, many cell processes, such as muscle contraction, depend on changes in the cytoplasmic concentration of calcium ions. Glucose, amino acids, and most other compounds required in metabolism are polar molecules that also pass through the lipid bilayer slowly. This is advantageous to cells because the impermeability of the plasma membrane prevents them from diffusing out. How then do cells obtain the ions and polar molecules they require?

Transport proteins transfer molecules across membranes

Systems of **transport proteins** that move ions, amino acids, sugars, and other needed polar molecules through membranes apparently evolved very early in the origin of cells. These transmembrane proteins have been found in all biological membranes. Two main types of membrane transport proteins are carrier proteins and channel proteins. Each type of transport protein transports a specific type of ion or molecule or a group of related substances.

Carrier proteins, also called **transporters,** bind the ion or molecule and undergo changes in shape, resulting in movement of the molecule across the membrane. Transfer of solutes by carrier proteins located within the membrane is called **carrier-mediated transport.** As we will discuss, the two forms of carrier-mediated transport—facilitated diffusion and carrier-mediated active transport—differ in their capabilities and energy sources.

ABC transporters make up a large, important group of carrier proteins. The acronym *ABC* stands for ATP-binding cassette. Found in the cell membranes of all species, ABC transporters use energy donated by ATP to transport certain ions, sugars, and polypeptides across cell membranes. Scientists have identified about 48 ABC transporters in human cells. Mutations in the genes encoding these proteins cause or contribute to many human disorders, including cystic fibrosis and certain neurological diseases. ABC transporters transport hydrophobic drugs out of the cell. This response can be a problem clinically because certain transporters remove antibiotics, antifungal drugs, and anticancer drugs.

Channel proteins form tunnels, called pores, through the membrane. Many of these channels are *gated,* which means that they can be opened and closed. Cells regulate the passage of materials through the channels by opening and closing the gates in response to electrical changes, chemical stimuli, or mechanical stimuli. Water and specific types of ions are transported through channels. There are numerous ion channels in every membrane of every cell.

Porins are transmembrane channel proteins that allow various solutes or water to pass through membranes. These channel proteins are rolled-up, barrel-shaped β-pleated sheets that form pores. Researchers Peter Agre of Johns Hopkins School of Medicine in Baltimore, Maryland, and Roderick MacKinnon of the Howard Hughes Medical Institute at Rockefeller University in New York shared the 2003 Nobel Prize in Chemistry for their work on transport proteins. Agre identified transmembrane proteins called **aquaporins** that function as gated water channels.

www.konkur.in

Aquaporins facilitate the rapid transport of water through the plasma membrane. About a billion water molecules per second can pass through an aquaporin! These channels are very selective and do not permit passage of ions and other small molecules. In some cells, such as those lining the kidney tubules of mammals, aquaporins respond to specific signals from hormones. Aquaporins help prevent dehydration by returning water from the kidney tubules into the blood.

5.4 PASSIVE TRANSPORT

LEARNING OBJECTIVES

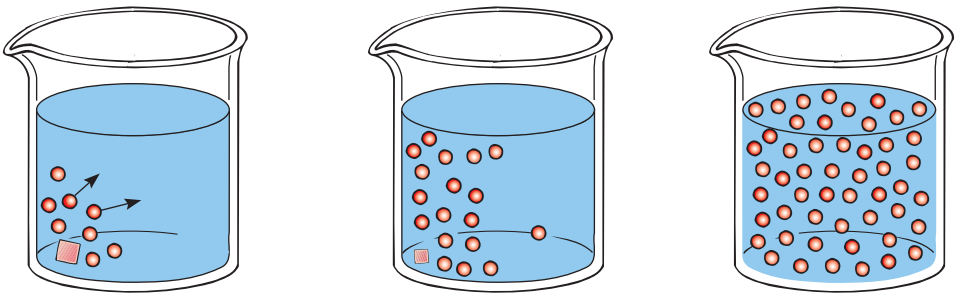
7 Contrast simple diffusion with facilitated diffusion.

8 Define *osmosis* and solve simple problems involving osmosis; for example, predict whether cells will swell or shrink under various osmotic conditions.

Passive transport does not require the cell to expend metabolic energy. Many ions and small molecules move through membranes by *diffusion*. Two types of diffusion are simple diffusion and facilitated diffusion.

Diffusion occurs down a concentration gradient

Some substances pass into or out of cells and move about within cells by **diffusion,** a physical process based on random motion. All atoms and molecules possess kinetic energy, or energy of motion, at temperatures above absolute zero (0 K, −273°C, or −459.4°F). Matter may exist as a solid, liquid, or gas, depending on the freedom of movement of its constituent particles (atoms, ions, or molecules). The particles of a solid are closely packed, and the forces of attraction between them let them vibrate but not move around.



1 When lump of sugar is dropped into beaker of pure water, sugar molecules begin to dissolve and diffuse through water.

2 Sugar molecules continue to dissolve and diffuse through water.

3 Eventually, sugar molecules become distributed randomly throughout water.

FIGURE 5-11 Diffusion

In a liquid the particles are farther apart; the intermolecular attractions are weaker, and the particles move about with considerable freedom. In a gas the particles are so far apart that intermolecular forces are negligible; molecular movement is restricted only by the walls of the container that encloses the gas. Atoms and molecules in liquids and gases move in a kind of "random walk," changing directions as they collide.

Although the movement of individual particles is undirected and unpredictable, we can nevertheless make predictions about the behavior of groups of particles. If the particles are not evenly distributed, then at least two regions exist: one with a higher concentration of particles and the other with a lower concentration. Such a difference in the concentration of a substance from one place to another establishes a **concentration gradient.**

In diffusion, the random motion of particles results in their net movement "down" their own concentration gradient, from the region of higher concentration to the one of lower concentration. This does not mean individual particles are prohibited from moving "against" the gradient. However, because there are initially more particles in the region of high concentration, it logically follows that more particles move randomly from there into the low-concentration region than the reverse (**FIG. 5-11**).

Thus, if a membrane is permeable to a substance, there is net movement from the side of the membrane where it is more highly concentrated to the side where it is less concentrated. Such a gradient across the membrane is a form of stored energy. Stored energy is *potential energy,* which is the capacity to do work as a result of position or state. The stored energy of the concentration gradient is released when ions or molecules move from a region of high concentration to one of low concentration. For this reason, movement down a concentration gradient is spontaneous. (Forms of energy and spontaneous processes are discussed in greater detail in Chapter 7.)

Diffusion occurs rapidly over very short distances. The rate of diffusion is determined by the movement of the particles, which in turn is a function of their size and shape, their electric charges, and the temperature. As the temperature rises, particles move faster and the rate of diffusion increases.

Particles of different substances in a mixture diffuse independently of one another. Diffusion moves solutes toward a state of equilibrium. If particles are not added to or removed from the system, a state of **dynamic equilibrium** is reached. In this condition, the particles are uniformly distributed and there is no net change in the system. Particles continue to move back and forth across the membrane, but they move at equal rates and in both directions.

In organisms, equilibrium is rarely attained. For example, human cells continually produce carbon dioxide as sugars and other molecules are metabolized during aerobic respiration. Carbon dioxide readily diffuses across the plasma

www.konkur.in

membrane but then is rapidly removed by the blood. This limits the opportunity for the molecules to re-enter the cell, so a sharp concentration gradient of carbon dioxide molecules always exists across the plasma membrane.

In **simple diffusion** through a biological membrane, small, nonpolar (uncharged) solute molecules move directly through the membrane down their concentration gradient. Oxygen and carbon dioxide can rapidly diffuse through the membrane. The rate of simple diffusion is directly related to the concentration of the solute; the more concentrated the solute, the more rapid the diffusion.

Osmosis is diffusion of water across a selectively permeable membrane

Osmosis is a special kind of diffusion that involves the net movement of water (the principal *solvent* in biological systems) through a selectively permeable membrane from a region of higher concentration to a region of lower concentration. Water molecules pass freely in both directions, but as in all types of diffusion, *net* movement is from the region where the water molecules are more concentrated to the region where they are less concentrated. Most *solute molecules* (such as sugar and salt) cannot diffuse freely through the selectively permeable membranes of the cell.

The principles involved in osmosis can be illustrated using an apparatus called a U-tube (**FIG. 5-12**). The U-tube is divided into two sections by a selectively permeable membrane that allows solvent (water) molecules to pass freely but excludes solute molecules. A water/solute solution is placed on one side, and pure water is placed on the other. The side containing the solute has a lower effective concentration of water than the pure water side does. The reason is that the solute particles, which are charged (ionic) or polar, interact with the partial electric charges on the polar water molecules. Many of the water molecules are thus "bound up" and no longer free to diffuse across the membrane.

Because of the difference in effective water concentration, there is net movement of water molecules from the pure water side (with a high effective concentration of water) to the water/ solute side (with a lower effective concentration of water). As a result, the fluid level drops on the pure water side and rises on the water/ solute side. Because the solute molecules do not diffuse across the membrane, equilibrium is never attained. Net movement of water continues, and the fluid level rises on the side containing the solute. The weight of the rising column of fluid eventually exerts enough pressure to stop further changes in fluid levels, although water molecules continue to pass through the selectively permeable membrane in both directions.

We define the **osmotic pressure** of a solution as the pressure that must be exerted on the side of a selectively permeable membrane containing the higher concentration of solute to prevent the diffusion of water (by osmosis) from the side containing the lower solute concentration. In the U-tube example, you could measure the osmotic pressure by inserting a piston on the water/solute side of the tube and measuring how much pressure must be exerted by the piston to prevent the rise of fluid on that side of the tube. A solution with a high solute concentration has a low effective water concentration and a high osmotic pressure; conversely, a solution with a low solute concentration has a high effective water concentration and a low osmotic pressure.

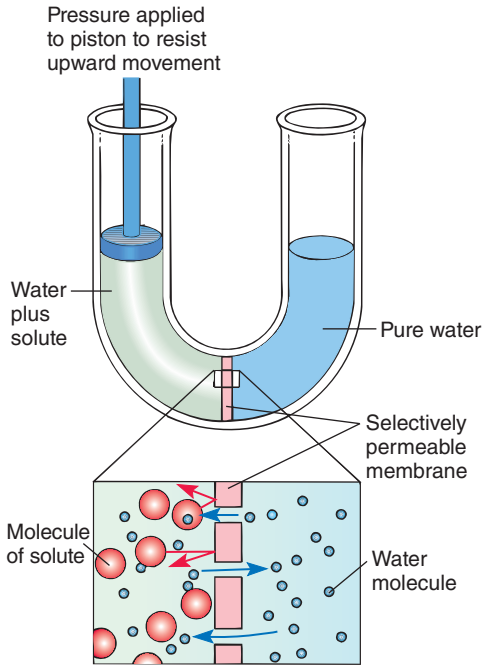


FIGURE 5-12 ***Animated*** **Osmosis**
The U-tube contains pure water on the right and water plus a solute on the left, separated by a selectively permeable membrane. Water molecules cross the membrane in both directions (*blue arrows*). Solute molecules cannot cross (*red arrows*). The fluid level would normally rise on the left and fall on the right because net movement of water would be to the left. However, the piston prevents the water from rising. The force that must be exerted by the piston to prevent the rise in fluid level is equal to the osmotic pressure of the solution.

Two solutions may be isotonic

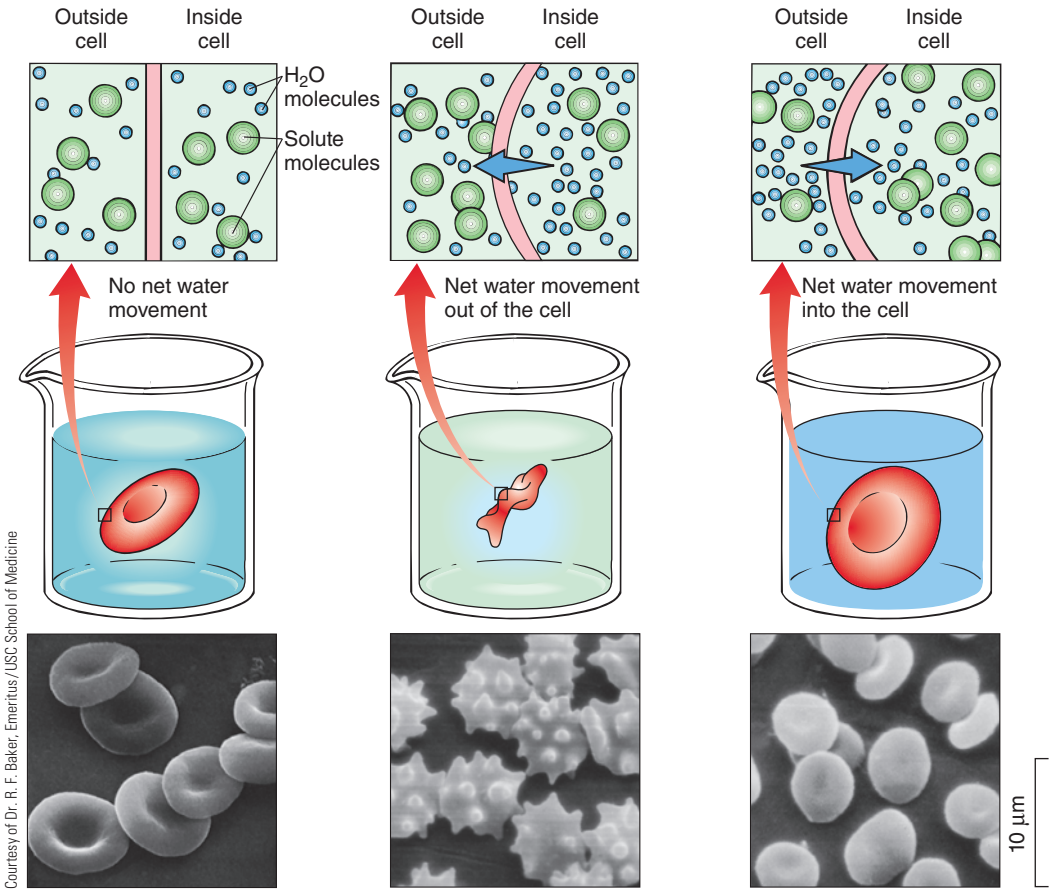
Salts, sugars, and other substances are dissolved in the fluid compartment of every cell. These solutes give the cytosol a specific osmotic pressure. **TABLE 5-1** summarizes the movement of water into and out of a solution (or cell) depending on relative solute concentrations.

When a cell is placed in a fluid with exactly the same osmotic pressure, no net movement of water molecules occurs, either into

TABLE 5-1 Osmotic Terminology

Solute Concentration in Solution A	Solute Concentration in Solution B	Tonicity	Direction of Net Movement of Water
Greater	Less	A hypertonic to B; B hypotonic to A	B to A
Less	Greater	B hypertonic to A; A hypotonic to B	A to B
Equal	Equal	A and B are isotonic to each other	No net movement

www.konkur.in



(a) Isotonic solution. When a cell is placed in an isotonic solution, water molecules pass in and out of the cell, but the net movement of water molecules is zero.

(b) Hypertonic solution. When a cell is placed in a hypertonic solution, there is a net movement of water molecules out of the cell (*blue arrow*). The cell becomes dehydrated and shrunken.

(c) Hypotonic solution. When a cell is placed in a hypotonic solution, the net movement of water molecules into the cell (*blue arrow*) causes the cell to swell or even burst.

FIGURE 5-13 ***Animated*** **The responses of animal cells to osmotic pressure differences**

or out of the cell. The cell neither swells nor shrinks. Such a fluid is of equal solute concentration, or **isotonic,** to the fluid within the cell. Normally, your blood plasma (the fluid component of blood) and all your other body fluids are isotonic to your cells; they contain a concentration of water equal to that in the cells. A solution of 0.9% sodium chloride (sometimes called *physiological saline*) is isotonic to the cells of humans and other mammals. Human red blood cells placed in 0.9% sodium chloride neither shrink nor swell (**FIG. 5-13a**).

One solution may be hypertonic and the other hypotonic

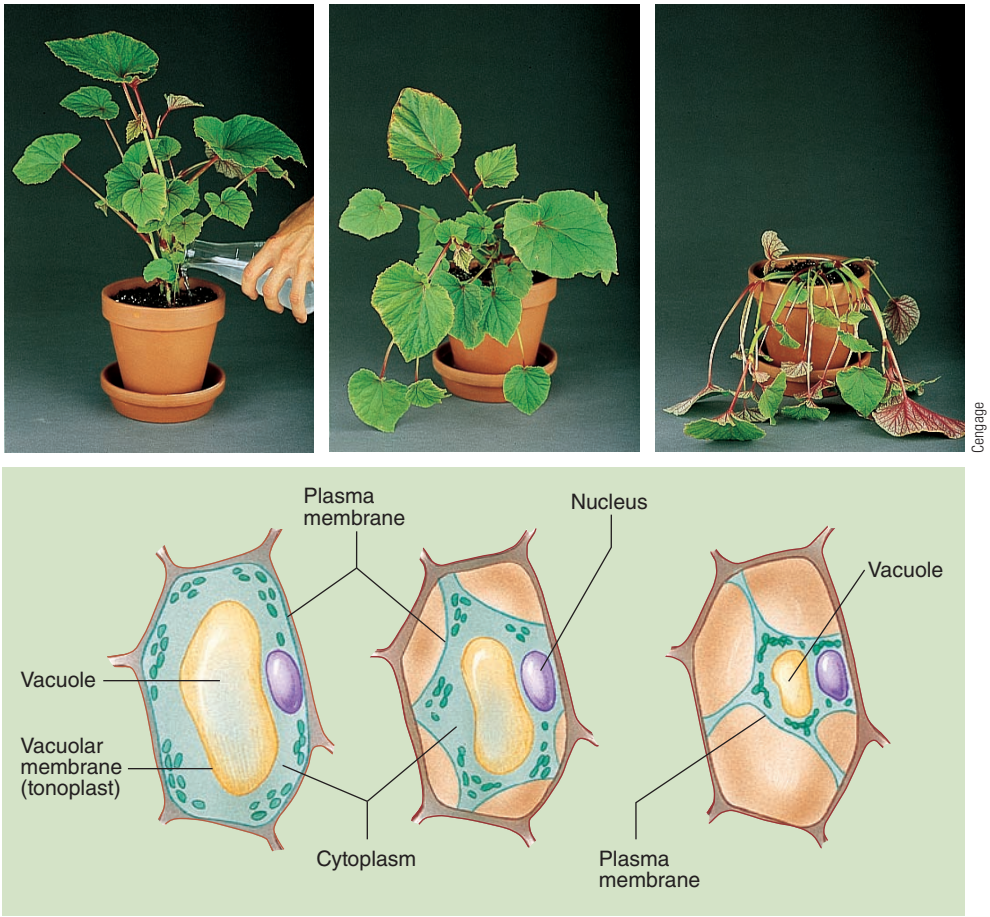
If the surrounding fluid has a concentration of dissolved substances greater than the concentration within the cell, the fluid has a higher osmotic pressure than the cell and is said to be **hypertonic** to the cell. Because a hypertonic solution has a lower effective water concentration, a cell placed in such a solution shrinks as it loses water by osmosis. Human red blood cells placed in a solution of 1.3% sodium chloride shrivel (**FIG. 5-13b**).

If the surrounding fluid contains a lower concentration of dissolved materials than does the cell, the fluid has a lower osmotic pressure and is said to be **hypotonic** to the cell; water then enters the cell and causes it to swell. Red blood cells placed in a solution of 0.6% sodium chloride gain water, swell (**FIG. 5-13c**), and may eventually burst. Many cells that normally live in hypotonic environments have adaptations to prevent excessive water accumulation. For example, *Paramecium* and certain other ciliates (members of the supergroup Chromalveolates) have contractile vacuoles that expel excess water (see Fig. 26-8).

Turgor pressure is the internal hydrostatic pressure usually present in walled cells

The cells of most prokaryotes, algae, plants, and fungi have relatively rigid cell walls. These cells can withstand, without bursting,

www.konkur.in



(a) In hypotonic surroundings, the vacuole of a plant cell fills with water, but the rigid cell walls prevent the cell from expanding. The cells of this healthy begonia plant are turgid.

(b) When the begonia plant is exposed to a hypertonic solution, its cells become plasmolyzed as they lose water.

(c) The plant wilts and eventually dies.

FIGURE 5-14 ***Animated*** **Turgor pressure and plasmolysis**

an external medium that is very dilute, containing only a very low concentration of solutes. Because of the substances dissolved in the cytoplasm, the cells are hypertonic to the outside medium (conversely, the outside medium is hypotonic to the cytoplasm).

Water moves into the cells by osmosis, filling their central vacuoles and distending the cells. The cells swell, building up **turgor pressure** against the rigid cell walls (FIG. 5-14a). The cell walls stretch only slightly, and a steady state is reached when their resistance to stretching prevents any further increase in cell size and thereby halts the *net movement* of water molecules into the cells. (Of course, molecules continue to move back and forth across the plasma membrane.) Turgor pressure in the cells is an important factor in supporting the body of nonwoody plants.

If a cell that has a cell wall is placed in a hypertonic medium, the cell loses water to its surroundings. Its contents shrink, and the plasma membrane separates from the cell wall, a process known as **plasmolysis** (FIGS. 5-14b and 14c). Plasmolysis occurs in plants when the soil or water around them contains high concentrations of salts or fertilizers. It also explains why lettuce becomes limp in a salty salad dressing and why a picked flower wilts from lack of water.

Facilitated diffusion occurs down a concentration gradient

In all processes in which substances move across membranes by diffusion, the net transfer of those molecules from one side to the other occurs as a result of a concentration gradient. We have seen that small, uncharged (nonpolar) solute molecules, such as oxygen and carbon dioxide, move directly through the membrane down their concentration gradient by simple diffusion. In **facilitated diffusion,** a specific transport protein makes the membrane permeable to a particular solute, such as a specific ion or polar molecule. A specific solute can be transported from inside the cell

www.konkur.in

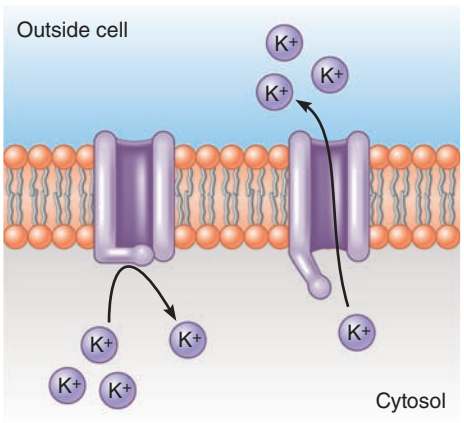


FIGURE 5-15 Facilitated diffusion of potassium ions
In response to an electrical stimulus, the gate of the potassium ion channel opens, allowing potassium to diffuse out of the cell.

to the outside or from the outside to the inside, but net movement is always from a region of higher solute concentration to a region of lower concentration. Channel proteins and carrier proteins facilitate diffusion by different mechanisms.

Channel proteins form hydrophilic channels through membranes

Some channel proteins are porins that form rather large tunnels through which water and solutes pass. However, most channel proteins form narrow channels that transport specific ions down their gradients (**FIG. 5-15**). (As we will discuss, because ions are charged particles, these gradients are electrochemical gradients.) These *ion channels* are referred to as *gated channels* because they can open and close. As many as 100 million ions per second can pass through an open ion channel! Channels can facilitate transport only down a concentration gradient. They cannot actively transport ions from a region of lower concentration to a region of higher concentration.

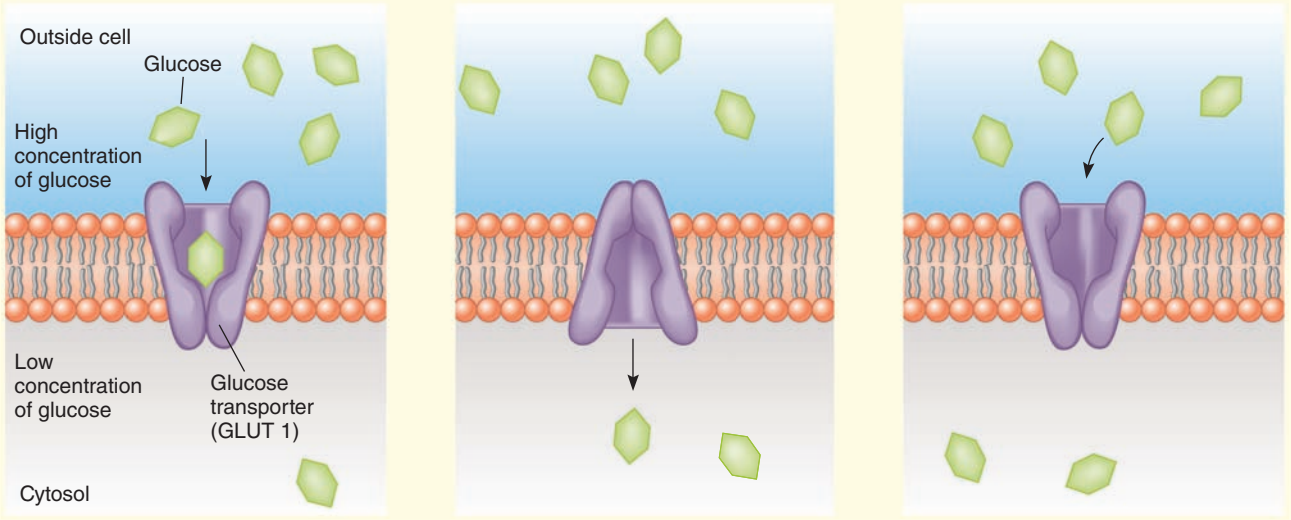
Carrier proteins undergo a change in shape

Transport of solutes through carrier proteins is slower than through channel proteins. The carrier protein binds with one or more solute molecules on one side of the membrane. The protein then undergoes a conformational change (change in shape) that moves the solute to the other side of the membrane.

As an example of facilitated diffusion by a carrier protein, let us consider glucose transport. A carrier protein known as *glucose transporter 1,* or *GLUT 1,* transports glucose into red blood cells (**FIG. 5-16**). The concentration of glucose is higher in the blood plasma than in red blood cells, so glucose diffuses down its concentration gradient into these blood cells. The GLUT 1 transporter facilitates glucose diffusion, allowing glucose to enter the cell about 50,000 times as rapidly as it could by simple diffusion.

Red blood cells keep the internal concentration of glucose low by immediately adding a phosphate group to entering glucose molecules, converting them to highly charged glucose phosphates that cannot pass back through the membrane. Because glucose phosphate is a different molecule, it does not contribute to the glucose concentration gradient. Thus, a steep concentration gradient for glucose is continually maintained, and glucose rapidly diffuses into the

KEY POINT Facilitated diffusion requires the potential energy of a concentration gradient.



1 Glucose binds to GLUT 1.

2 GLUT 1 changes shape and glucose is released inside cell.

3 GLUT 1 returns to its original shape.

FIGURE 5-16 *Animated* Facilitated diffusion of glucose molecules

www.konkur.in

cell, only to be immediately changed to the phosphorylated form. Facilitated diffusion is powered by the concentration gradient.

Researchers have studied facilitated diffusion of glucose using **liposomes,** artificial vesicles surrounded by phospholipid bilayers. The phospholipid membrane of a liposome does not allow the passage of glucose unless a glucose transporter is present in the liposome membrane. Glucose transporters and similar carrier proteins temporarily bind to the molecules they transport. This mechanism appears to be similar to the way an enzyme binds with its substrate, the molecule on which it acts (discussed in Chapter 7). In addition, as in enzyme action, binding apparently changes the shape of the carrier protein. This change allows the glucose molecule to be released on the inside of the cell. According to this model, when the glucose is released into the cytoplasm, the carrier protein reverts to its original shape and is available to bind another glucose molecule on the outside of the cell.

Another similarity to enzyme action is that carrier proteins become saturated when there is a high concentration of the molecule being transported. This saturation may occur because a finite number of carrier proteins are available and they operate at a defined maximum rate. When the concentration of solute molecules to be transported reaches a certain level, all the carrier proteins are working at their maximum rate.

It is a common misconception that diffusion, whether simple or facilitated, is somehow "free of cost" and that only active transport mechanisms require energy. Because diffusion always involves the net movement of a substance down its concentration gradient, we say that the concentration gradient "powers" the process. However, energy is required to do the work of establishing and maintaining the gradient. In our example of facilitated diffusion of glucose, the cell maintains a steep concentration gradient (high outside, low inside) by phosphorylating the glucose molecules once they enter the cell. One ATP molecule is spent for every glucose molecule phosphorylated, and there are additional costs, such as the energy required to make the enzymes that carry out the reaction.

Review

- What would happen if a plant cell were placed in an isotonic solution? a hypertonic environment? a hypotonic environment? How would you modify your predictions for an animal cell?
- What is the immediate source of energy for simple diffusion? For facilitated diffusion?
- In what direction do particles move along their concentration gradient? Would your answers be different for facilitated diffusion compared with simple diffusion?

5.5 ACTIVE TRANSPORT

LEARNING OBJECTIVE

9 Describe active transport, including cotransport.

Although adequate amounts of a few substances move across cell membranes by diffusion, cells must actively transport many solutes *against* a concentration gradient. The reason is that cells require many substances in higher concentrations than their concentration outside the cell.

Both diffusion and active transport require energy. The energy for diffusion is provided by a concentration gradient for the substance being transported. Active transport requires the cell to expend metabolic energy directly to power the process.

An **active transport** system can pump materials from a region of low concentration to a region of high concentration. The energy stored in the concentration gradient not only is unavailable to the system but actually works against it. For this reason, the cell needs some other source of energy. In many cases, cells use ATP energy directly. However, active transport may be coupled to ATP indirectly. In indirect active transport, a concentration gradient provides energy for the cotransport of some other substance, such as an ion.

Active transport systems "pump" substances against their concentration gradients

One of the most striking examples of an active transport mechanism is the **sodium–potassium pump** found in all animal cells (**FIG. 5-17**). The pump is an ABC transporter, a specific carrier protein in the plasma membrane. This transporter uses energy from ATP to pump sodium ions out of the cell and potassium ions into the cell. The exchange is unequal: usually only two potassium ions are imported for every three sodium ions exported. Because these particular concentration gradients involve ions, an electrical potential (separation of electric charges) is generated across the membrane; that is, the membrane is **polarized.**

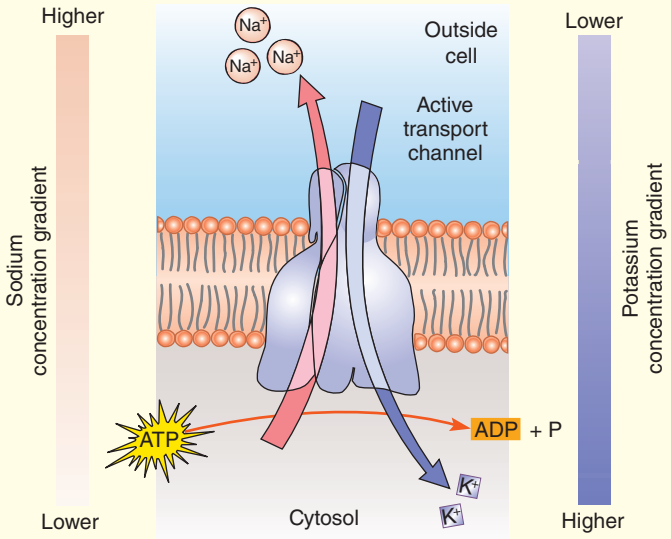
Both sodium and potassium ions are positively charged, but because there are fewer potassium ions inside relative to the sodium ions outside, the inside of the cell is negatively charged relative to the outside. The unequal distribution of ions establishes an **electrical gradient** that drives ions across the plasma membrane. Sodium–potassium pumps help maintain a separation of charges across the plasma membrane. This separation is called a **membrane potential.** Because there is both an electric charge difference and a concentration difference on the two sides of the membrane, the gradient is called an **electrochemical gradient.** Such gradients store energy that is used to drive other transport systems. So important is the electrochemical gradient produced by these pumps that some cells (such as nerve cells) expend more than 25% of their total available energy just to power this one transport system.

Sodium–potassium pumps (as well as all other ATP-driven pumps) are transmembrane proteins that extend entirely through the membrane. By undergoing a series of conformational changes, the pumps exchange sodium for potassium across the plasma membrane. Unlike what occurs in facilitated diffusion, at least one of the conformational changes in the pump cycle requires energy, which is provided by ATP. The shape of the pump protein changes as a phosphate group from ATP first binds to it and is subsequently removed later in the pump cycle.

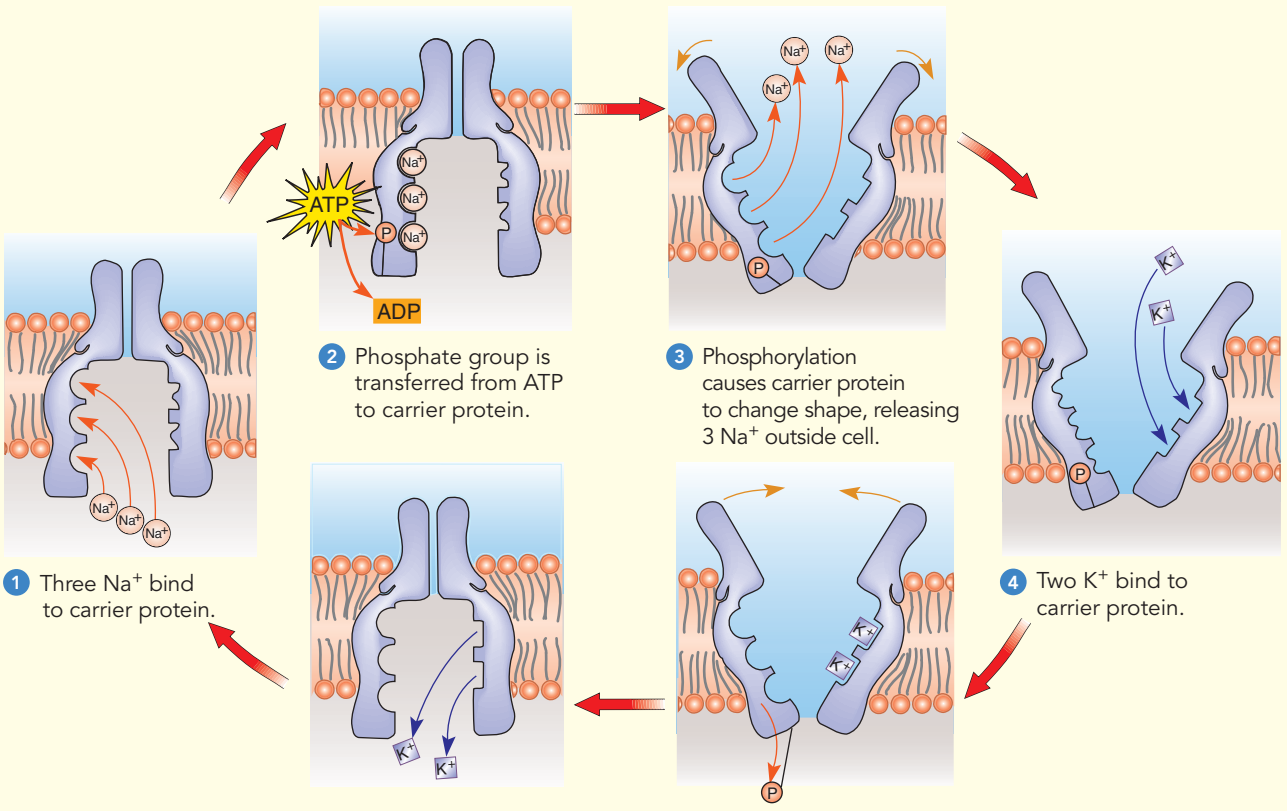
The use of electrochemical potentials for energy storage is not confined to the plasma membranes of animal cells. Cells of bacteria, fungi, and plants use carrier proteins, known as proton pumps, to actively transport hydrogen ions (which are protons) out of the cell. These ATP-driven membrane pumps transfer protons

www.konkur.in

KEY POINT The sodium–potassium pump is a carrier protein that maintains an electrochemical gradient across the plasma membrane.



(a) The sodium–potassium pump is a carrier protein that requires energy from ATP. In each complete pumping cycle, the energy of one molecule of ATP is used to export three sodium ions (Na^+) and import two potassium ions (K^+).



(b) Follow the steps illustrating a model of active transport by the sodium–potassium pump.

FIGURE 5-17 *Animated* A model for the pumping cycle of the sodium–potassium pump

www.konkur.in

from the cytosol to the outside (**FIG. 5-18**). Removal of positively charged protons from the cytoplasm of these cells results in a large difference in the concentration of protons between the outside and inside of the cell. The outside of the cells is positively charged relative to the inside of the plasma membrane. The energy stored in these electrochemical gradients can be used to do many kinds of cell work.

Other proton pumps are used in "reverse" to synthesize ATP. Bacteria, mitochondria, and chloroplasts use energy from food or sunlight to establish proton concentration gradients (discussed in Chapters 8 and 9). When the protons diffuse through the proton carriers from a region of high proton concentration to one of low concentration, ATP is synthesized. These electrochemical gradients form the basis for the major energy conversion systems in virtually all cells.

Ion pumps have other important roles. For example, they are instrumental in the ability of an animal cell to equalize the osmotic pressures of its cytoplasm and its external environment. If an animal cell does not control its internal osmotic pressure, its contents become hypertonic relative to the exterior. Water enters by osmosis, causing the cell to swell and possibly burst (see Fig. 5-13c). By controlling the ion distribution across the membrane, the cell indirectly controls the movement of water, because when ions are pumped out of the cell, water leaves by osmosis.

Carrier proteins can transport one or two solutes

You may have noticed that some carrier proteins, such as proton pumps, transport one type of substance in one direction. These carrier proteins are called **uniporters.** Other carrier proteins, **symporters,** move two types of substances in one direction. For example, a specific carrier protein transports both sodium and glucose into the cell. Still other carrier proteins, **antiporters,** move two substances in opposite directions. Sodium–potassium pumps transport sodium ions out of the cell and potassium ions into the cell. Both symporters and antiporters cotransport solutes.

Cotransport systems indirectly provide energy for active transport

A **cotransport system** moves solutes across a membrane by **indirect active transport.** Two solutes are transported at the same time. The movement of one solute down its concentration gradient provides energy for transport of some other solute up its concentration gradient. However, an energy source such as ATP is required to power the pump that produces the concentration gradient.

Sodium–potassium pumps (and other pumps) generate electrochemical concentration gradients. Sodium is pumped out of the cell and then diffuses back in by moving down its concentration gradient. This process generates sufficient energy to power the active transport of other essential substances. In these systems, a carrier protein *cotransports* a solute *against* its concentration gradient, while sodium, potassium, or hydrogen ions move *down* their gradient. Energy from ATP produces the ion gradient. Then the energy of this gradient drives the active transport of a required substance, such as glucose, against its gradient.

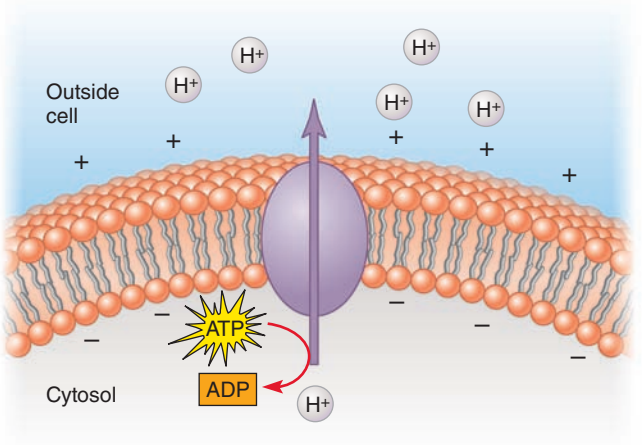


FIGURE 5-18 A model of a proton pump

Proton pumps use the energy of ATP to transport protons (hydrogen ions) across membranes. The energy of the electrochemical gradient established can then be used for other processes.

We have seen how glucose can be moved into the cell by facilitated diffusion. Glucose can also be cotransported into the cell. The sodium concentration inside the cell is kept low by the ATP-requiring sodium–potassium pumps that actively transport sodium ions out of the cell. In glucose cotransport, a carrier protein transports both sodium and glucose (**FIG. 5-19**). As sodium moves into the cell along its concentration gradient, the carrier protein captures the energy released and uses it to transport glucose into the cell. Thus, this indirect active transport system for glucose is "driven" by the cotransport of sodium.

Review

- What is the energy source for active transport?
- What is the energy source for cotransport?

5.6 EXOCYTOSIS AND ENDOCYTOSIS

LEARNING OBJECTIVE

10 Compare exocytotic and endocytotic transport mechanisms.

Individual molecules and ions pass through the plasma membrane by simple and facilitated diffusion and by carrier-mediated active transport. Some larger materials, such as large molecules, particles of food, and even small cells, are also moved into or out of cells. They are transported by exocytosis and endocytosis. Like active transport, these processes require cells to expend energy directly.

In exocytosis, vesicles export large molecules

In **exocytosis,** a cell ejects waste products, or specific products of secretion such as hormones, by the fusion of a vesicle with the

FIGURE 5-21 ***Animated*** **Phagocytosis**
In this type of endocytosis, a cell ingests relatively large solid particles. The white blood cell (a neutrophil) shown in the TEM is phagocytizing bacteria. The vacuoles contain bacteria that have already been ingested. Lysosomes contain digestive enzymes that break down the ingested material. Other bacteria are visible outside the cell.

plasma membrane (**FIG. 5-20**). As the contents of the vesicle are released from the cell, the membrane of the secretory vesicle is incorporated into the plasma membrane. This is the primary mechanism by which plasma membranes grow larger.

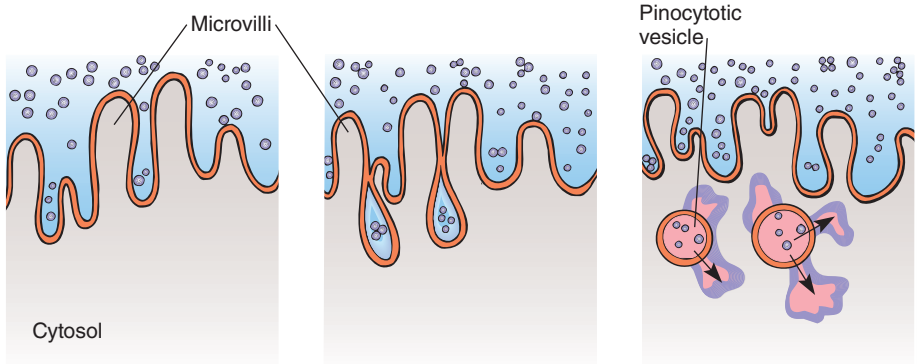
In endocytosis, the cell imports materials

In **endocytosis,** materials are taken into the cell. Several types of endocytotic mechanisms operate in biological systems, including phagocytosis, pinocytosis, and receptor-mediated endocytosis.

In **phagocytosis** (literally, "cell eating"), the cell ingests large solid particles such as food or bacteria (**FIG. 5-21**). Certain protists ingest food by phagocytosis. Some types of vertebrate cells, including certain white blood cells, ingest bacteria and other particles by phagocytosis. During ingestion, folds of the plasma membrane enclose the cell or particle. When the membrane has encircled the particle, the membrane fuses at the point of contact, forming a vacuole. The vacuole may then fuse with lysosomes, which degrade the ingested material.

In **pinocytosis** ("cell drinking"), the cell takes in dissolved materials (**FIG. 5-22**). Tiny droplets of fluid are trapped by folds in the plasma membrane, which pinch off into the cytosol as tiny vesicles. As the liquid contents of these vesicles are slowly transferred into the cytosol, the vesicles become progressively smaller.

In a third type of endocytosis, **receptor-mediated endocytosis,** specific molecules combine with receptor proteins in the plasma membrane. Receptor-mediated endocytosis is the main mechanism by which eukaryotic cells take in macromolecules. As an example, let us look at how mammalian cells take up cholesterol from the blood. Cells use cholesterol as a component of cell membranes and as a precursor of steroid hormones. Cholesterol is transported in the blood as part of particles called *low-density lipoproteins* (*LDLs;* popularly known as "bad cholesterol").



1 Tiny droplets of fluid are trapped by folds of plasma membrane.

2 These pinch off into cytosol as small fluid-filled vesicles.

3 Contents of these vesicles are then slowly transferred to cytosol.

FIGURE 5-22 **Pinocytosis, or "cell drinking"**

www.konkur.in

Much of the receptor-mediated endocytosis pathway was detailed through studies at the University of Texas Health Science Center by Michael Brown and Joseph Goldstein on the LDL receptor. These researchers were awarded the Nobel Prize in Physiology or Medicine in 1985 for their pioneering work. Their findings have important medical implications because cholesterol that remains in the blood instead of entering the cells can be deposited in the artery walls, which increases the risk of cardiovascular disease.

When it needs cholesterol, the cell makes LDL receptors. The receptors are concentrated in *coated pits,* depressed regions on the cytoplasmic surface of the plasma membrane. Each pit is coated by a layer of a protein, called *clathrin,* found just below the plasma membrane. A molecule that binds specifically to a receptor is called a **ligand.** In this case, LDL is the ligand. After the LDL binds with a receptor, the coated pit forms a *coated vesicle* by endocytosis.

FIGURE 5-23 shows the uptake of an LDL particle. Seconds after the vesicle moves into the cytoplasm, the coating dissociates from it, leaving an uncoated vesicle. The vesicles fuse with small compartments called *endosomes.* The LDL and LDL receptors sep-

FIGURE 5-23 ***Animated*** **Receptor-mediated endocytosis**

www.konkur.in

arate, and the receptors are transported to the plasma membrane, where they are recycled. LDL is transferred to a lysosome, where it is broken down. Cholesterol is released into the cytosol for use by the cell. A simplified summary of receptor-mediated endocytosis follows:

> ligand molecules bind to receptors in coated pits of plasma membrane ⟶ coated vesicle forms by endocytosis ⟶ coating detaches from vesicle ⟶ uncoated vesicle fuses with endosome ⟶ ligands separate from receptors which are recycled; endosome fuses with primary lysosome, forming secondary lysosome ⟶ contents of secondary lysosome are digested and released into the cytosol

The recycling of LDL receptors to the plasma membrane through vesicles causes a problem common to all cells that use endocytotic and exocytotic mechanisms: the plasma membrane changes size as the vesicles bud off from it or fuse with it. A type of phagocytic cell known as a *macrophage,* for example, ingests the equivalent of its entire plasma membrane in about 30 minutes, requiring an equivalent amount of recycling or new membrane synthesis for the cell to maintain its surface area. On the other hand, cells that are constantly involved in secretion must return an equivalent amount of membrane to the interior of the cell for each vesicle that fuses with the plasma membrane; if not, the cell surface would continue to expand even though the growth of the cell itself may be arrested.

Review

- How are exocytosis and endocytosis similar?
- How are the processes of phagocytosis and pinocytosis different?
- What is the sequence of events in receptor-mediated endocytosis?

5.7 CELL JUNCTIONS

LEARNING OBJECTIVE

11 Compare the structures and functions of anchoring junctions, tight junctions, gap junctions, and plasmodesmata.

Cells in close contact with one another typically develop specialized intercellular junctions. These structures may allow neighboring cells to form strong connections with one another, prevent the passage of materials, or establish rapid communication between adjacent cells. Several types of junctions connect animal cells, including anchoring junctions, tight junctions, and gap junctions. Plant cells are connected by plasmodesmata.

Anchoring junctions connect cells of an epithelial sheet

Adjacent epithelial cells, such as those found in the outer layer of the mammalian skin, are so tightly bound to each other by **anchoring junctions** that strong mechanical forces are required to separate them. Cadherins, transmembrane proteins shown in the chapter opening photograph, are important components of anchoring junctions. These junctions do not prevent the passage of materials between adjacent cells. Two common types of anchoring junctions are desmosomes and adhering junctions.

Desmosomes are points of attachment between cells (**FIG. 5-24**). They hold cells together at one point as a rivet or a spot weld does. Desmosomes allow cells to form strong sheets, and substances still pass freely through the spaces between the plasma membranes. Each desmosome is made up of regions of dense material associated with the cytosolic sides of the two plasma membranes, plus protein filaments that cross the narrow intercellular space between them. Desmosomes are anchored to systems of

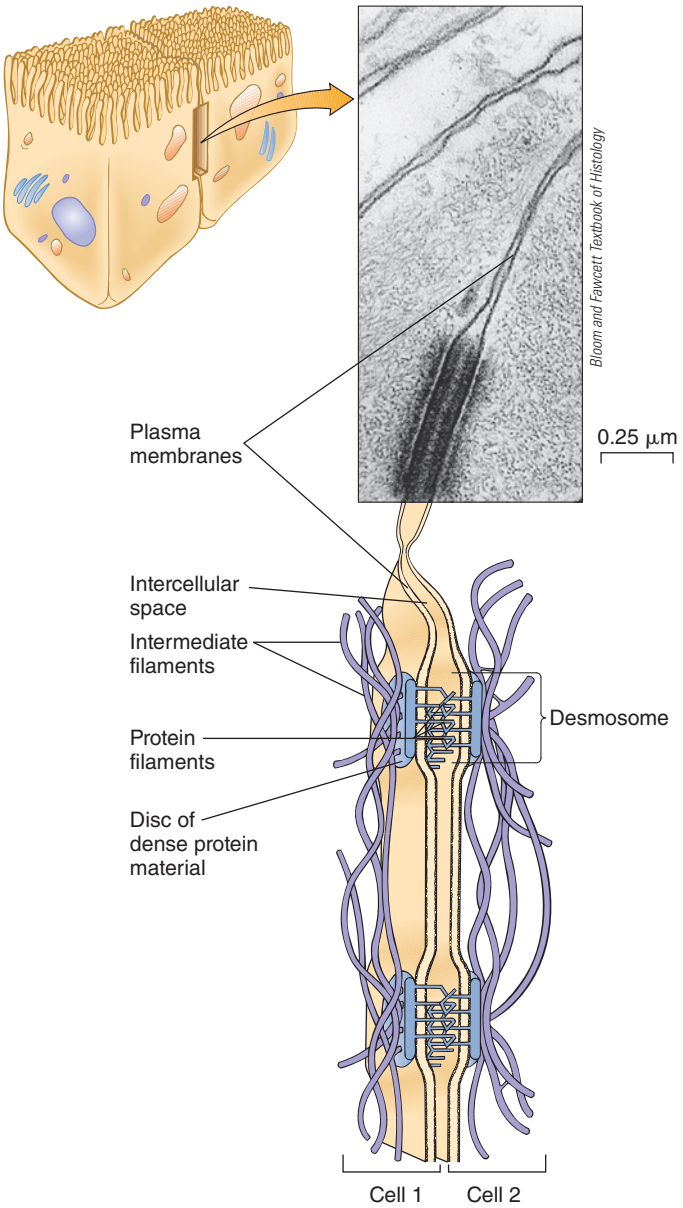

FIGURE 5-24 Desmosomes

The dense structure in the TEM is a desmosome. Each desmosome consists of a pair of buttonlike discs associated with the plasma membranes of adjacent cells, plus the intercellular protein filaments that connect them. Intermediate filaments in the cells are attached to the discs and are connected to other desmosomes.

www.konkur.in

intermediate filaments inside the cells. Thus, the intermediate filament networks of adjacent cells are connected. As a result, mechanical stresses are distributed throughout the tissue.

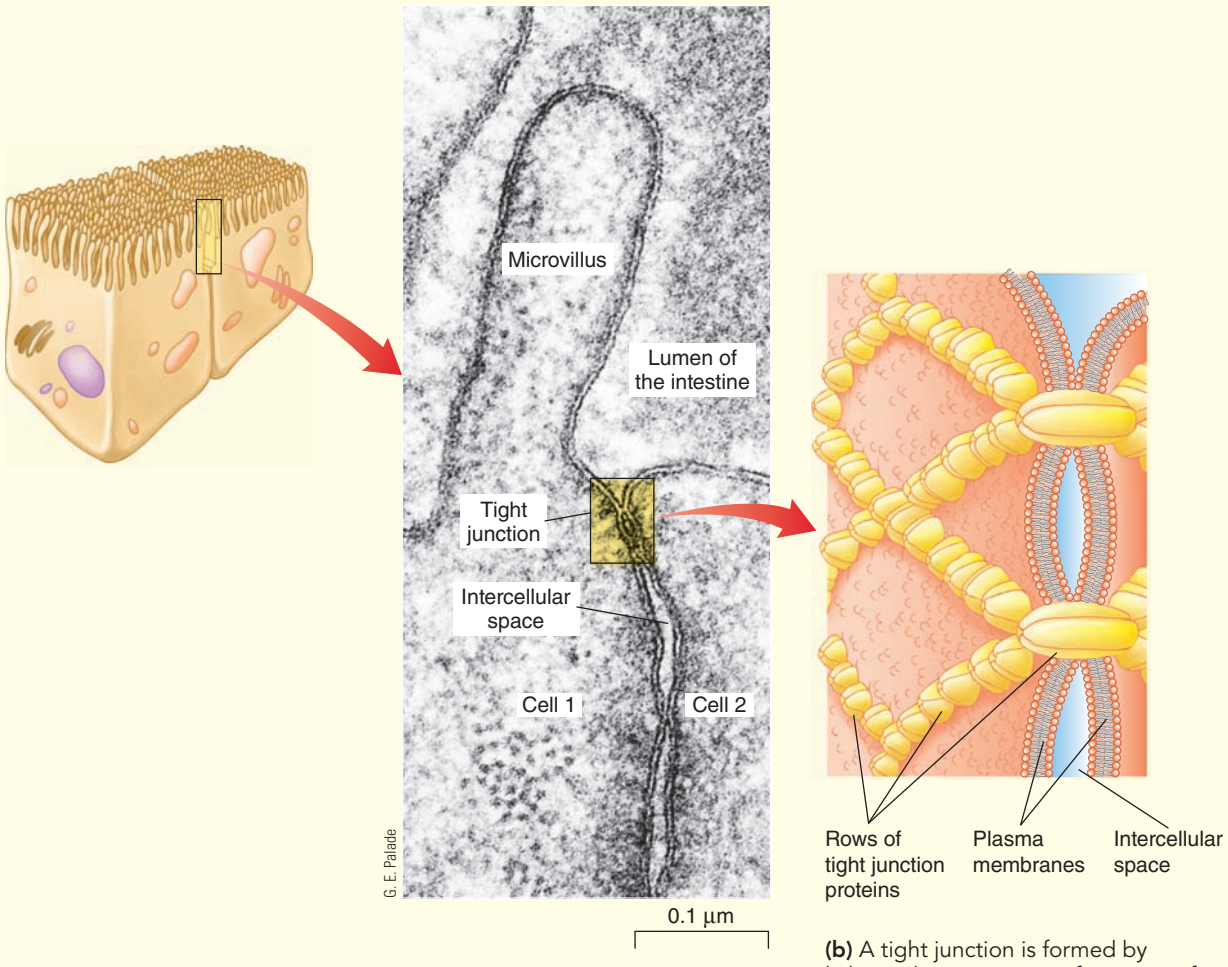
Adhering junctions cement cells together. Cadherins form a continuous adhesion belt around each cell, binding the cell to neighboring cells. These junctions connect to microfilaments of the cytoskeleton. The cadherins of adhering junctions are a potential path for signals from the outside environment to be transmitted to the cytoplasm.

Tight junctions seal off intercellular spaces between some animal cells

Tight junctions are literally areas of tight connections between the membranes of adjacent cells. These connections are so tight that no space remains between the cells and substances cannot leak between them. TEMs of tight junctions show that in the region of the junction the plasma membranes of the two cells are held together by proteins in actual contact with each other. However, as shown in **FIGURE 5-25**, tight junctions are located intermittently. The plasma membranes of the two cells are not fused over their entire surface.

Cells connected by tight junctions seal off body cavities. For example, tight junctions between cells lining the intestine prevent substances in the intestine from passing between the cells and directly entering the blood. The sheet of cells thus acts as a selective barrier. Food substances must be transported across the plasma membranes and *through* the intestinal cells before they enter the blood. This arrangement helps prevent toxins and other unwanted materials from entering the blood and also prevents nutrients

KEY POINT Tight junctions prevent the passage of materials through spaces between cells.



(a) This TEM shows points of fusion between plasma membranes of adjacent cells lining the intestine. One tight junction is marked by the box.

(b) A tight junction is formed by linkages between rows of proteins of adjacent cells. These proteins seal off the intercellular space, preventing passage of materials through spaces between cells.

FIGURE 5-25 *Animated* Tight junctions

www.konkur.in

from leaking out of the intestine. Tight junctions are also present between the cells that line capillaries in the brain. They form the *blood–brain barrier,* which prevents many substances in the blood from passing into the brain.

Gap junctions allow the transfer of small molecules and ions

A **gap junction** is like a desmosome in that it bridges the space between cells; however, the space it spans is somewhat narrower (**FIG. 5-26**). Gap junctions also differ in that they are communicating junctions. They not only connect the plasma membranes but also contain channels connecting the cytoplasm of adjacent cells.

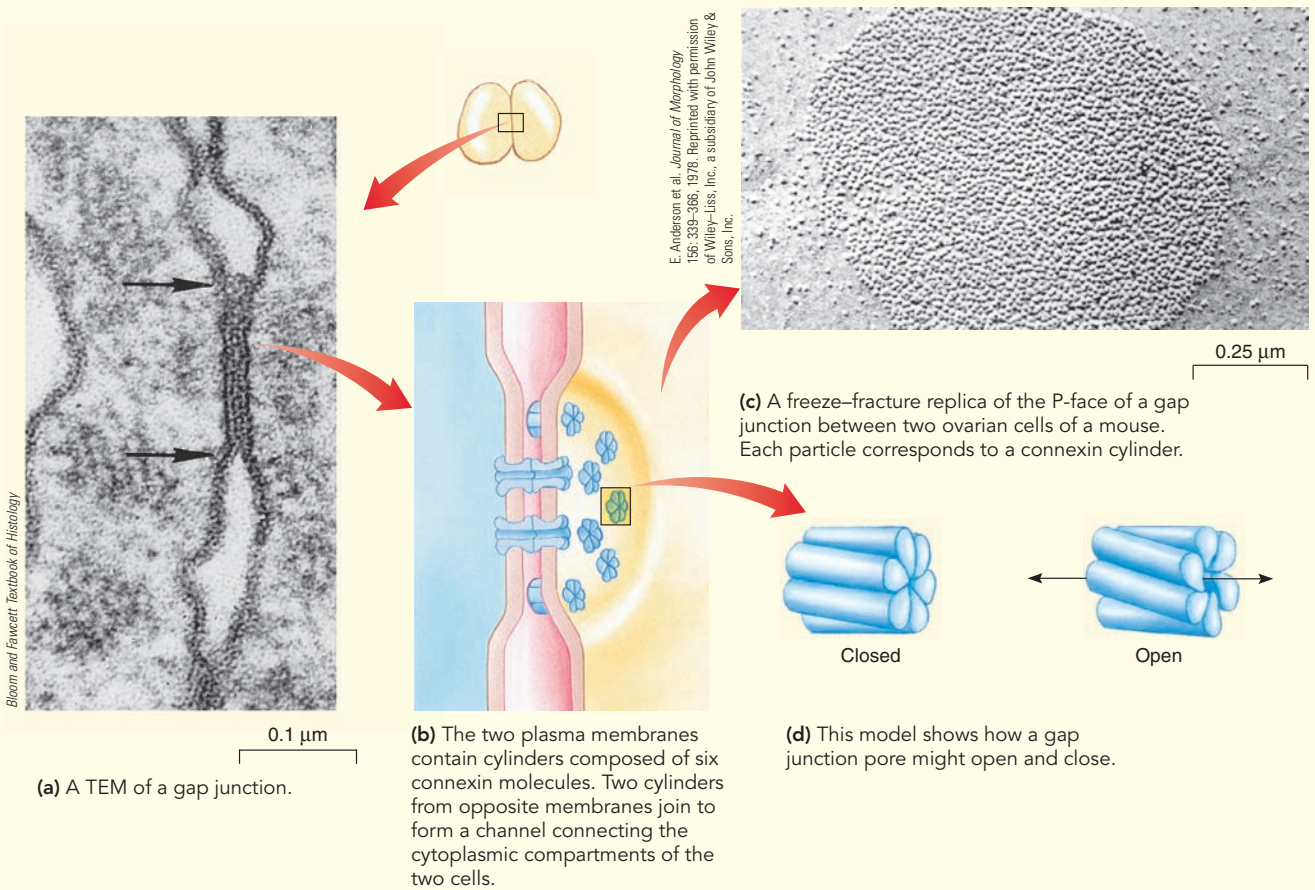
Gap junctions are composed of *connexin,* an integral membrane protein. Groups of six connexin molecules cluster to form a cylinder that spans the plasma membrane. The connexin cylinders on adjacent cells become tightly joined. The two cylinders form a channel, about 1.5 nm in diameter. Small inorganic molecules (such as ions) and some regulatory molecules (such as cyclic AMP, which is illustrated in Figure 3-25) pass through the channels, but larger molecules are excluded. When a marker substance is injected into one of a group of cells connected by gap junctions, the marker passes rapidly into the adjacent cells but does not enter the space between the cells.

Gap junctions provide for rapid chemical and electrical communication between cells. Cells control the passage of materials through gap junctions by opening and closing the channels (see Fig. 5-26d). Cells in the pancreas, for example, are linked by gap junctions in such a way that if one of a group of cells is stimulated to secrete insulin, the signal is passed through the junctions to the other cells in the cluster. This mechanism ensures a coordinated response to the initial signal. Gap junctions allow some nerve cells to be electrically coupled. Cardiac muscle cells are linked by gap junctions that permit the flow of ions necessary to synchronize contractions of the heart.

Plasmodesmata allow certain molecules and ions to move between plant cells

Because plant cells have walls, they do not need desmosomes for strength. Plant cells have connections that are functionally equivalent to the gap junctions of some animal cells. **Plasmodesmata**

KEY POINT Gap junctions allow the transfer of small molecules and ions between adjacent cells.



(a) A TEM of a gap junction.

(b) The two plasma membranes contain cylinders composed of six connexin molecules. Two cylinders from opposite membranes join to form a channel connecting the cytoplasmic compartments of the two cells.

(c) A freeze–fracture replica of the P-face of a gap junction between two ovarian cells of a mouse. Each particle corresponds to a connexin cylinder.

(d) This model shows how a gap junction pore might open and close.

FIGURE 5-26 ***Animated*** **Gap junctions**
The model of a gap junction shown in **(b)** is based on electron microscopic and X-ray diffraction data.

www.konkur.in

(sing., *plasmodesma*) are channels 20 to 40 nm wide that pass through the cell walls of adjacent plant cells, connecting the cytoplasm of neighboring cells (**FIG. 5-27**). The plasma membranes of adjacent cells are continuous with one another through the plasmodesmata. Most plasmodesmata contain a narrow cylindrical structure, called the **desmotubule,** which runs through the channel and connects the smooth ER of the two adjacent cells.

Plasmodesmata generally allow molecules and ions, but not organelles, to pass through the openings from cell to cell. The movement of ions through the plasmodesmata allows for a very slow type of electrical signaling in plants. Whereas the channels of gap junctions have a fixed diameter, plants cells can dilate the plasmodesmata channels. Certain proteins and RNA can pass through plasmodesmata. Some plant viruses spread infection by passing through these junctions.

Review

- How are desmosomes and tight junctions functionally similar? How do they differ?
- What is the justification for considering gap junctions and plasmodesmata to be functionally similar? How do they differ structurally?

KEY POINT Most plant cells have plasmodesmata that connect the cytoplasm of adjacent cells.

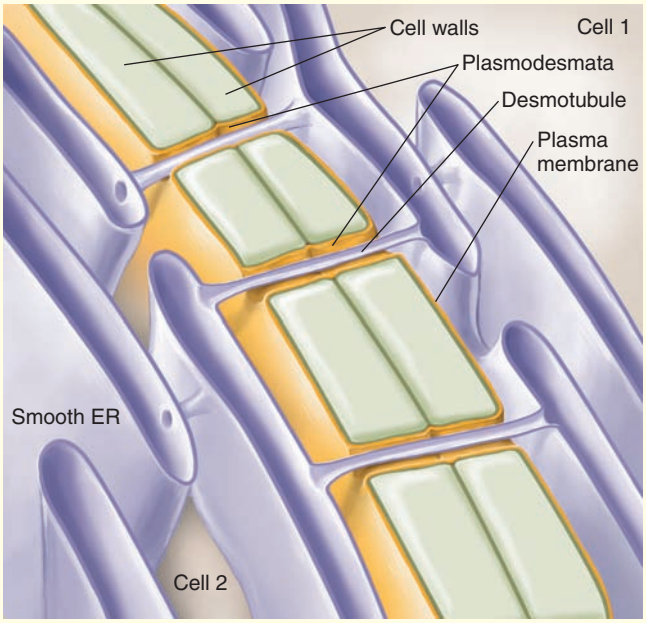


FIGURE 5-27 Plasmodesmata
Cytoplasmic channels through the cell walls of adjacent plant cells allow passage of water, ions, and small molecules. The channels are lined with the fused plasma membranes of the two adjacent cells.

SUMMARY: FOCUS ON LEARNING OBJECTIVES

5.1 *(page 107)*

1 Evaluate the importance of membranes to the homeostasis of the cell, emphasizing their various functions.
- The **plasma membrane** physically separates the interior of the cell from the extracellular environment, receives information about changes in the environment, regulates the passage of materials into and out of the cell, and communicates with other cells.
- Biological membranes form compartments within eukaryotic cells that allow a variety of separate functions. Membranes participate in and serve as surfaces for biochemical reactions.

2 Describe the fluid mosaic model of cell membrane structure.
- According to the **fluid mosaic model,** membranes consist of a fluid phospholipid bilayer in which a variety of proteins are embedded. The phospholipid molecules are **amphipathic:** they have hydrophobic and hydrophilic regions. The hydrophilic heads of the phospholipids are at the two surfaces of the bilayer, and their hydrophobic fatty acid chains are in the interior.

3 Relate properties of the lipid bilayer to properties and functions of cell membranes.
- In almost all biological membranes, the lipids of the bilayer are in a fluid or liquid-crystalline state, which allows the lipid molecules to move rapidly in the plane of the membrane. Proteins also move within the membrane.
- Lipid bilayers are flexible and self-sealing and can fuse with other membranes. These properties allow the cell to transport materials from one region of the cell to another; materials are transported in vesicles that bud from one cell membrane and then fuse with some other membrane.

4 Describe the ways that membrane proteins associate with the lipid bilayer.
- **Integral membrane proteins** are embedded in the bilayer with their hydrophilic surfaces exposed to the aqueous environment and their hydrophobic surfaces in contact with the hydrophobic interior of the bilayer. **Transmembrane proteins** are integral proteins that extend completely through the membrane.
- **Peripheral membrane proteins** are associated with the surface of the bilayer, usually bound to exposed regions of integral proteins, and are easily removed without disrupting the structure of the membrane.

5.2 *(page 114)*

5 Summarize the functions of membrane proteins.
- Membrane proteins anchor cells, transport materials, act as enzymes or receptors, recognize cells and communicate with them, and structurally link cells.

5.3 *(page 115)*

6 Describe the importance of selectively permeable membranes and compare the functions of carrier proteins and channel proteins.
- Biological membranes are **selectively permeable membranes:** they allow the passage of some substances but not others. By regulating

www.konkur.in

passage of molecules that enter and leave the cell and its compartments, the cell controls its volume and the internal composition of ions and molecules.

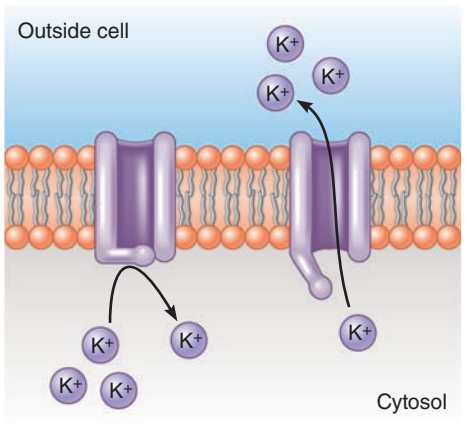
- Membrane **transport proteins** facilitate the passage of certain ions and molecules through biological membranes. **Carrier proteins** are transport proteins that undergo a series of conformational changes as they bind and transport a specific solute. **ABC transporters** are carrier proteins that use energy from ATP to transport solutes.
- **Channel proteins** are transport proteins that form passageways through which water and certain ions travel through the membrane. **Porins** are channel proteins that form relatively large pores through the membrane for passage of water and certain solutes.

CENGAGENOW™ Learn more about the plasma membrane and membrane proteins by clicking on the figures in CengageNOW.

5.4 *(page 116)*

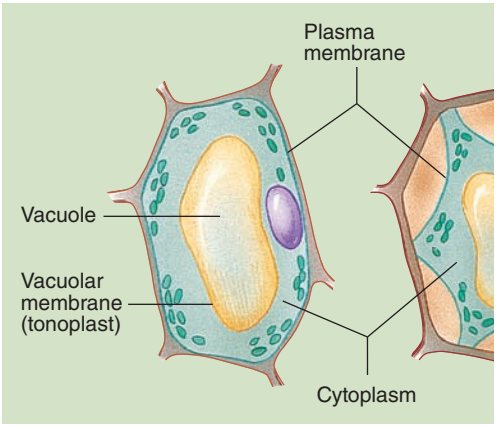
7 Contrast simple diffusion with facilitated diffusion.

- **Diffusion** is the net movement of a substance down its **concentration gradient** from a region of greater concentration to one of lower concentration. Diffusion and osmosis are physical processes that do not require the cell to directly expend metabolic energy.
- In **simple diffusion** through a biological membrane, solute molecules or ions move directly through the membrane down their concentration gradient. **Facilitated diffusion** uses specific transport proteins to move solutes across a membrane. As in simple diffusion, net movement is always from a region of higher to a region of lower solute concentration. Facilitated diffusion cannot work against a concentration gradient.



8 Define *osmosis* and solve simple problems involving osmosis; for example, predict whether cells will swell or shrink under various osmotic conditions.

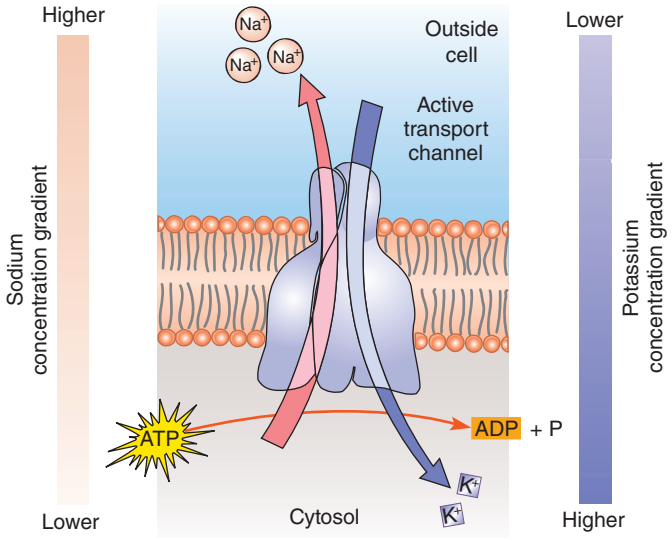
- **Osmosis** is a kind of diffusion in which molecules of water pass through a selectively permeable membrane from a region where water has a higher effective concentration to a region where its effective concentration is lower.
- The concentration of dissolved substances (solutes) in a solution determines its **osmotic pressure.** Cells regulate their internal osmotic pressures to prevent shrinking or bursting.
- An **isotonic** solution has an equal solute concentration compared to that of another fluid, for example, the fluid within the cell.
- When placed in a **hypertonic** solution, one that has a greater solute concentration than that of the cell, a cell loses water to its surroundings; plant cells undergo **plasmolysis,** a process in which the plasma membrane separates from the cell wall.
- When cells are placed in a **hypotonic** solution, one that has a lower solute concentration than the solute concentration of the cell, water enters the cells and causes them to swell.
- Plant cells withstand high internal hydrostatic pressure because their cell walls prevent them from expanding and bursting. Water moves into plant cells by osmosis and fills the central vacuoles. The cells swell, building up **turgor pressure** against the supportive cell walls.



5.5 *(page 121)*

9 Describe active transport, including cotransport.

- In **active transport,** the cell expends metabolic energy to move ions or molecules across a membrane against a concentration gradient. For example, the **sodium–potassium pump** uses ATP to pump sodium ions out of the cell and potassium ions into the cell.



- In **cotransport,** also called **indirect active transport,** two solutes are transported at the same time. An ATP-powered pump maintains a concentration gradient. Then a carrier protein cotransports two solutes. It transports one solute down its concentration gradient and uses the energy released to move another solute against its concentration gradient.

5.6 *(page 123)*

10 Compare exocytotic and endocytotic transport mechanisms.

- The cell expends metabolic energy to carry on exocytosis and endocytosis. In **exocytosis,** the cell ejects waste products or secretes substances such as mucus by fusion of vesicles with the plasma membrane. This process increases the surface area of the plasma membrane.

www.konkur.in

- In **endocytosis,** materials such as food particles are moved into the cell. A portion of the plasma membrane envelops the material, enclosing it in a vesicle or vacuole that is then released inside the cell. This process decreases the surface area of the plasma membrane.
- Three types of endocytosis are phagocytosis, pinocytosis, and receptor-mediated endocytosis.
- In **phagocytosis,** the plasma membrane encloses a large particle such as a bacterium, forms a vacuole around it, and moves it into the cell. In **pinocytosis,** the cell takes in dissolved materials by forming tiny vesicles around droplets of fluid trapped by folds of the plasma membrane.
- In **receptor-mediated endocytosis,** specific receptors in coated pits along the plasma membrane bind **ligand molecules.** These pits, coated by the protein clathrin, form coated vesicles by endocytosis. The vesicles fuse with lysosomes, and their contents are digested and released into the cytosol.

CENGAGENOW™ Learn more about membrane transport by clicking on the figures in CengageNOW.

5.7 *(page 127)*

11 Compare the structures and functions of anchoring junctions, tight junctions, gap junctions, and plasmodesmata.

- Cells in close contact with one another may form intercellular junctions. **Anchoring junctions** include desmosomes and adhering junctions; they are found between cells that form a sheet of tissue. **Desmosomes** spot-weld adjacent animal cells together. **Adhering junctions** are formed by **cadherins, transmembrane proteins** that cement cells together.
- **Tight junctions** seal membranes of adjacent animal cells together, preventing substances from moving through the spaces between the cells.
- **Gap junctions,** composed of the protein connexin, form channels that allow communication between the cytoplasm of adjacent animal cells.
- **Plasmodesmata** are channels connecting adjacent plant cells. Openings in the cell walls allow the plasma membranes and cytosol to be continuous; certain molecules and ions can pass from cell to cell.

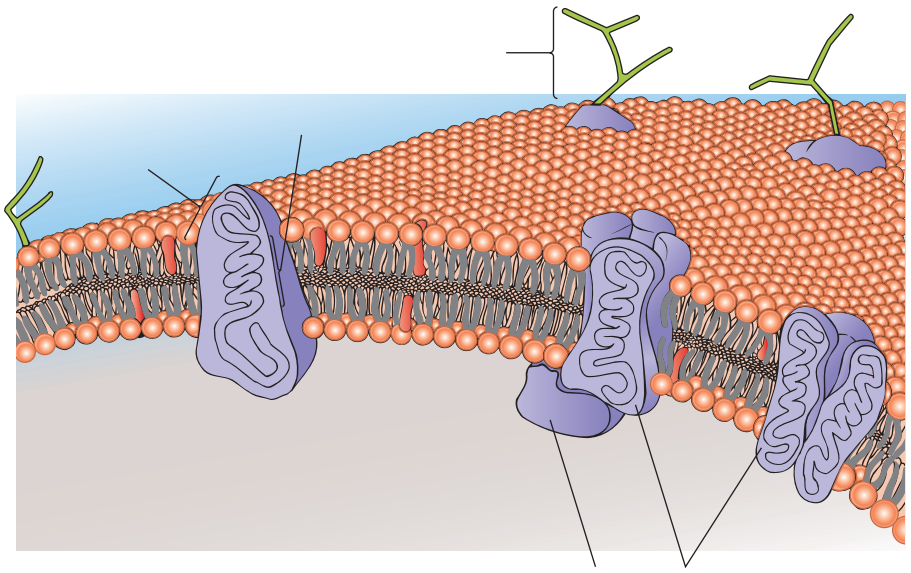
TEST YOUR UNDERSTANDING

1. According to the fluid mosaic model, membranes consist of (a) a lipid–protein sandwich (b) mainly phospholipids with scattered nucleic acids (c) a fluid phospholipid bilayer in which proteins are embedded (d) a fluid phospholipid bilayer in which carbohydrates are embedded (e) a protein bilayer that behaves as a liquid crystal
2. Transmembrane proteins (a) are peripheral proteins (b) are receptor proteins (c) extend completely through the membrane (d) extend along the surface of the membrane (e) are secreted from the cell
3. Which of the following is *not* a function of the plasma membrane? (a) transports materials (b) helps structurally link cells (c) has receptors that relay signals (d) anchors the cell to the extracellular matrix (e) manufactures proteins
4. ABC transporters (a) use the energy of ATP hydrolysis to transport certain ions and sugars (b) are important in facilitated diffusion of certain ions (c) are a small group of channel proteins (d) are found mainly in plant cell membranes (e) permit passive diffusion through their channels
5. When plant cells are in a hypotonic medium, they (a) undergo plasmolysis (b) build up turgor pressure (c) wilt (d) decrease pinocytosis (e) lose water to the environment
6. A laboratory technician accidentally places red blood cells in a hypertonic solution. What happens? (a) they undergo plasmolysis (b) they build up turgor pressure (c) they swell (d) they pump solutes out (e) they become dehydrated and shrunken
7. Which of the following processes requires the cell to expend metabolic energy directly (for example, from ATP)? (a) osmosis (b) facilitated diffusion (c) all forms of carrier-mediated transport (d) active transport (e) simple diffusion
8. Electrochemical gradients (a) power simple diffusion (b) are established by pinocytosis (c) are necessary for transport by aquaporins (d) are established by concentration gradients (e) are a result of both an electric charge difference and a concentration difference between the two sides of the membrane
9. In cotransport (indirect active transport) (a) a uniporter moves a solute across a membrane against its concentration gradient (b) the movement of one solute down its concentration gradient provides energy for transport of some other solute up its concentration gradient (c) a channel protein moves ions by facilitated diffusion (d) osmosis powers the movement of ions against their concentration gradient (e) sodium is directly transported in one direction, and potassium is indirectly transported in the same direction
10. A cell takes in dissolved materials by forming tiny vesicles around fluid droplets trapped by folds of the plasma membrane. This process is (a) indirect active transport (b) pinocytosis (c) receptor-mediated endocytosis (d) exocytosis (e) facilitated diffusion
11. Anchoring junctions that hold cells together at one point as a spot weld does are (a) tight junctions (b) adhering junctions (c) desmosomes (d) gap junctions (e) plasmodesmata

www.konkur.in

12. Junctions that permit the transfer of water, ions, and molecules between adjacent plant cells are (a) tight junctions (b) adhering junctions (c) desmosomes (d) gap junctions (e) plasmodesmata

13. Label the cell membrane. Consult Figure 5-6 to check your answers.



CRITICAL THINKING

1. Why can't larger polar molecules and ions diffuse through the plasma membrane? Would it be advantageous to the cell if they could? Explain.
2. Describe one way that an ion gradient can be established and maintained.
3. Most adjacent plant cells are connected by plasmodesmata, whereas only certain adjacent animal cells are associated through gap junctions. What might account for this difference?
4. **EVOLUTION LINK.** Hypothesis: the evolution of biological membranes was an essential step in the origin of life. Give arguments supporting (or challenging) this hypothesis.
5. **EVOLUTION LINK.** Transport proteins have been found in all biological membranes. What hypothesis could you make regarding whether these molecules evolved early or later in the history of cells? Argue in support of your hypothesis.
6. **SCIENCE, TECHNOLOGY, AND SOCIETY.** Biologists know quite a bit about the components that make up plant cell walls, but they do not have enough data to model the components of the cell wall as a system. Would you be in favor of investing government funds in the research and technology that would allow researchers to model the cell wall? Why or why not? Would your answer be different if you considered that a better understanding of the cell wall might allow biologists to manipulate plant growth, ripening of fruit, and the texture of certain foods?

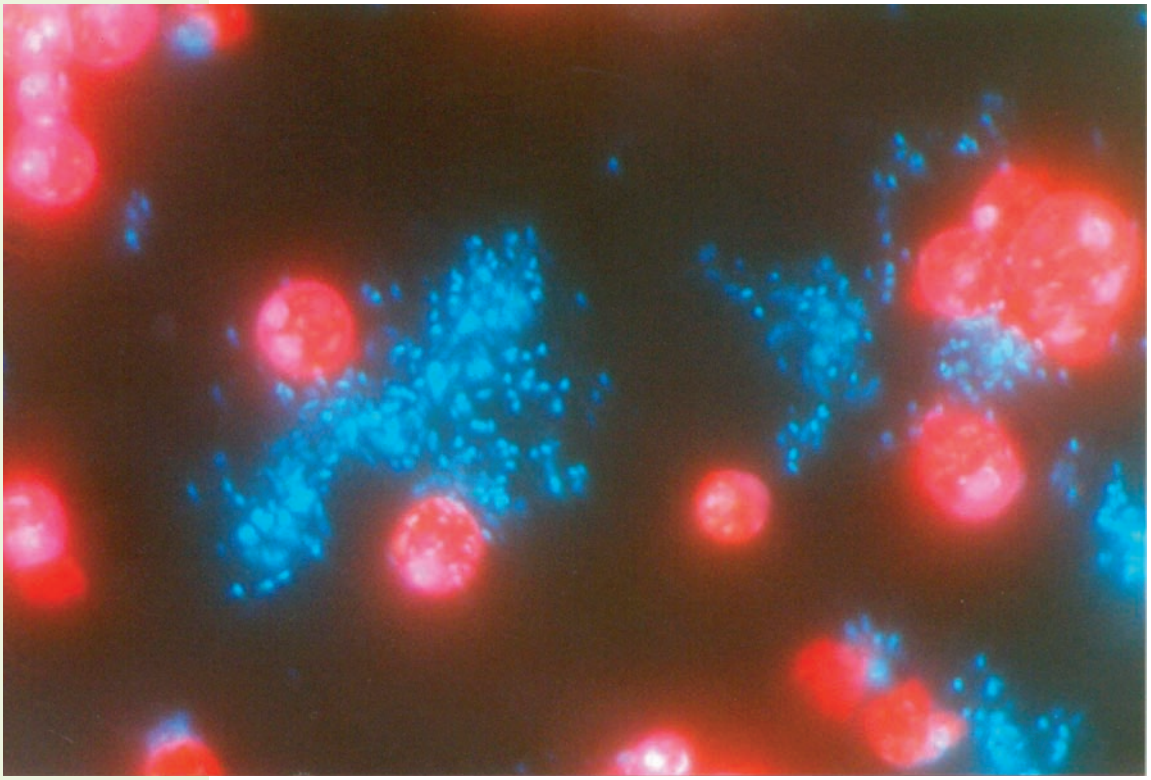
6 Cell Communication



From I. Joint et al., *Science* 298:1207

Cell-to-cell communication across the prokaryote–eukaryote boundary. Spores of the green seaweed *Enteromorpha* (Domain Eukarya) attach to biofilm-forming bacteria (Domain Bacteria) in response to chemical compounds released by the bacteria. The bacteria (*blue*) were stained and visualized with blue light. The spores appear red because of the fluorescence of chlorophyll within them.

KEY CONCEPTS

6.1 Cells communicate by signaling one another, a complex process that involves production of signaling molecules, reception of the signal, signal transduction, and a response.

6.2 Cells signal one another using chemical compounds such as neurotransmitters, hormones, and other signaling molecules.

6.3 A signaling molecule binds to a receptor molecule on the cell surface or inside the target cell.

6.4 In signal transduction, a cell converts an extracellular signal into an intracellular signal and relays the signal, leading to some change in the cell (the response).

6.5 The cell responds to signals by opening or closing ion channels; altering enzyme activity, which leads to metabolic changes and other alterations in cell activity; and by activating or inhibiting specific genes.

6.6 Similarities in cell communication among diverse organisms suggest that the molecules and mechanisms used in information transfer evolved long ago.

To maintain homeostasis, the cells of a multicellular organism must continuously communicate with one another. Many different mechanisms for transmitting information between cells, tissues, and organs have evolved, including electrical signaling and many types of chemical signaling. Organisms also communicate with other members of their species by secreting chemical signals. For example, bacteria release chemical signals that diffuse among nearby bacteria. As the population of bacteria increases, the concentration of the chemical signal increases. Through a process known as *quorum sensing,* the bacteria sense when a certain critical concentration of a signal molecule is reached. The bacteria respond by activating a specific biological process. For example, they may form a **biofilm,** a community of microorganisms attached to a solid surface. Forming a biofilm requires the coordinated activity of numerous bacteria.

Over billions of years, elaborate systems of cell signaling have evolved. Organisms of different species, and even different kingdoms and domains, communicate with one another. For example, the chemical signals released by bacteria can be intercepted by other organisms. During its life cycle, the green seaweed *Enteromorpha* produces spores that move about and temporarily attach to a surface. The spores sense a chemical signal released by bacteria that form biofilms. In response to the chemical

www.konkur.in

signal, the spores move toward the biofilm and attach to individual bacteria that are part of the biofilm surface (see opening photograph).

Thousands of chemical reactions are involved in responding to signal molecules and regulating the communication among molecules necessary to maintain homeostasis. Many researchers are working on the molecular level to understand how proteins receive messages and relay signals. They are learning how proteins act as molecular switches, activating and deactivating molecules in complex signaling pathways.

Some cell biologists are using a systems biology approach to understand the intricate, dynamic interactions involved in cell communication. Biologists, biochemists, physicists, and scientists from many other disciplines are working together to understand how elaborate signaling systems within the cell interact to maintain homeostasis. They are studying how information is transferred between cells at the tissue and organ levels, and throughout the organism. Faulty signaling in cells and between cells can cause a variety of diseases, including cancer and diabetes.

In Chapter 1, we introduced three basic themes of biology. One of these, transmission of information, is the main focus of this chapter. In this chapter, we discuss how cells send and receive signals. We consider how information crosses the plasma membrane and is transmitted through signaling systems. We describe some of the responses that cells make. Finally, we discuss the evolution of cell communication. Increased understanding of the mechanisms of cell communication may suggest new strategies for preventing and treating diseases.

6.1 CELL COMMUNICATION: AN OVERVIEW

LEARNING OBJECTIVE

1 Describe the four main processes essential for cells to communicate.

When food is scarce, the amoeba-like cellular slime mold *Dictyostelium* secretes the compound **cyclic adenosine monophosphate (cAMP).** This chemical compound diffuses through the cell's environment and binds to *receptors* on the surfaces of nearby cells. The activated receptors send signals into the cells that result in movement toward the cAMP. Hundreds of slime molds come together and form a multicellular slug-shaped colony (**FIG. 6-1**; also see Fig. 26-20). (When conditions are favorable, the cells of the slug form a stalked fruiting body with spores at the top; when released, each spore gives rise to an amoeba-like cell.)

Even though they do not move from one place to another, plants also communicate with each other. For example, diseased maple trees send airborne chemical signals that are received by uninfected trees nearby. Cells of the uninfected trees respond by increasing their chemical defenses so that they are more resistant to the disease-causing organisms. Plants also send signals to insects. When tobacco plants are attacked by herbivorous insects, the

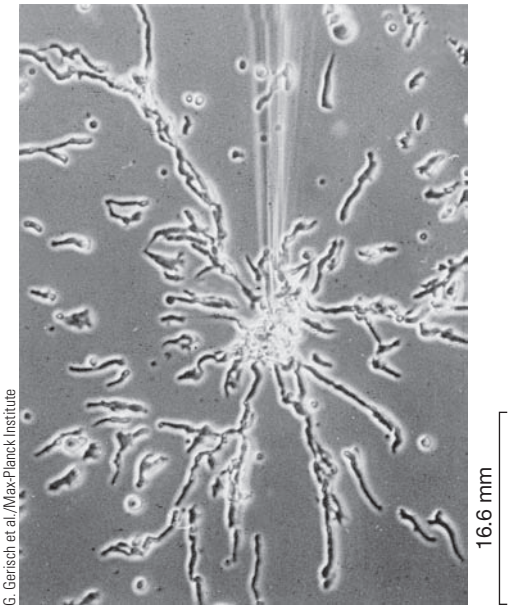


FIGURE 6-1 Cell signaling in cellular slime molds

When food is scarce, the amoeba-like cellular slime mold *Dictyostelium* secretes the chemical compound cyclic AMP (cAMP). The slime molds respond to this chemical signal by aggregating. Converging streams of hundreds of individuals come together and form a multicellular colony.

plants release volatile chemicals. In response to these signals, the insects lay fewer eggs, thus reducing the number of insects feeding on the plants. Predator insects that eat the eggs of the herbivorous insects respond to the plant signals by eating more of the herbivorous insect eggs. Thus, natural selection has resulted in plant signals that herbivorous insects detect and avoid and that carnivorous insects detect and approach. This system of information transfer helps protect plants from herbivorous insects.

To survive, organisms must receive signals from the outside environment and effectively respond to them. In order to grow, develop, and function, the cells of a multicellular organism must also communicate with one another. In plants and animals, *hormones* and other regulatory molecules serve as important chemical signals between various cells and organs. In animals, neurons (nerve cells) transmit information electrically and chemically.

The term **cell signaling** refers to the mechanisms by which cells communicate with one another. If the cells are physically close to one another, a signaling molecule on one cell may combine with a *receptor* (a macromolecule that binds with signaling molecules) on another cell. Most commonly, cells communicate by sending chemical signals over some distance. As we will discuss, cell signaling must be precisely regulated. Cell signaling involves a sequence of four main processes (**FIG. 6-2**). We summarize them here and discuss them in more detail in the following sections of this chapter.

1. **A cell must send a signal.** In chemical signaling, a cell must synthesize and release signaling molecules. For example, specialized cells in the vertebrate pancreas secrete the hormone insulin. If the **target cells,** the cells that can respond to the signal, are not in close proximity, the signal must be transported to them. The circulatory system transports insulin to target cells

www.konkur.in

throughout the body. Next, target cells must receive, relay, and respond to the information signaled.

2. **Reception.** Reception is the process of receiving an incoming signal. **Receptors** are large proteins or glycoproteins that bind with signaling molecules. Many types of signaling molecules do not actually enter the target cell. They bind to specific receptors on the surface of the target cell. Insulin, for example, binds to insulin receptors, which are transmembrane receptors.
3. **Signal transduction** is the process by which a cell converts an extracellular signal into an intracellular signal and relays the signal, leading to a cellular response. Signal transduction typically involves a chain of molecules that relay information. When insulin binds to an insulin receptor, the signal is relayed through several different signaling pathways.
4. **Response.** The final molecule in the signaling pathway converts the signal into a response that alters some cell process. For example, as we will discuss in Chapter 49, insulin stimulates cells to take up glucose from the blood. This response lowers the concentration of glucose in the blood. Insulin also helps regulate fat and protein metabolism. Many signaling molecules stimulate ion channels in the plasma membrane to open or close. Still other signaling molecules activate or inhibit specific genes in the nucleus. These responses can result in changes in cell division and other aspects of cell development.

After a signaling molecule has done its job, its action must be stopped, so during the signaling process, certain mechanisms operate to *terminate the signal.*

KEY POINT When a signaling molecule binds to a receptor molecule on a target cell, the receptor activates a signal transduction pathway, leading to some response in the cell.

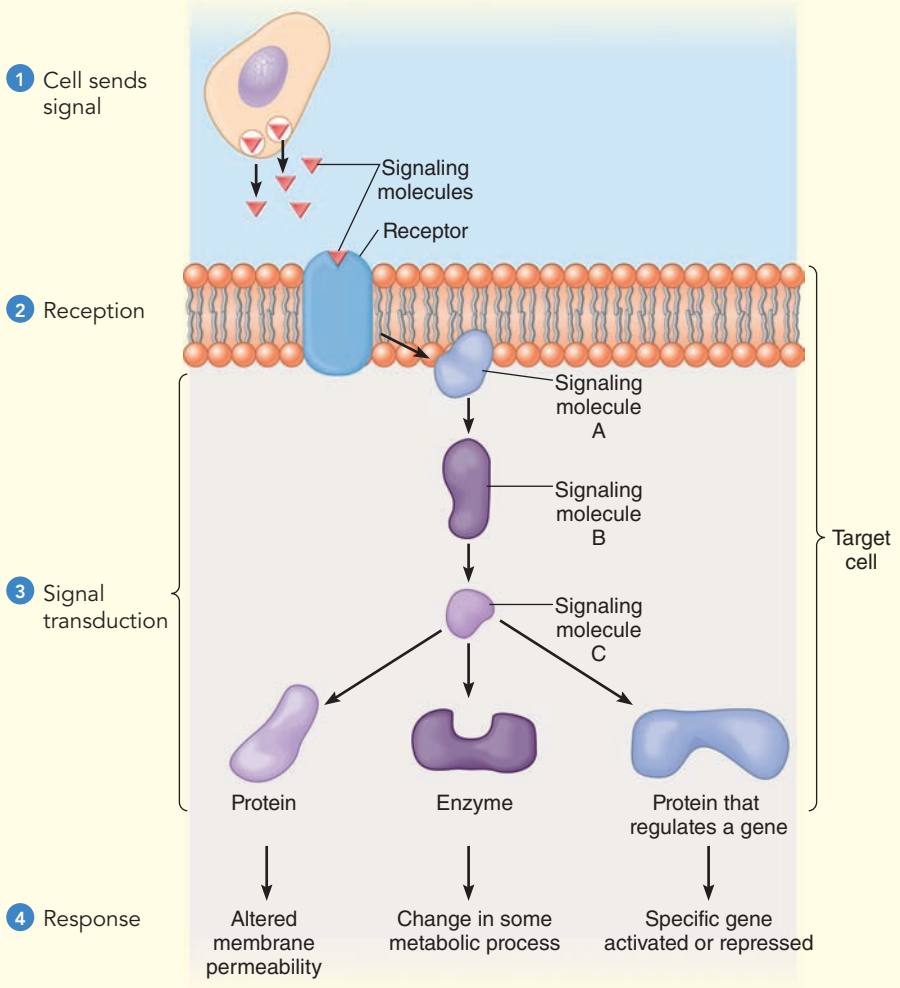

FIGURE 6-2 *Animated* Overview of cell signaling

Review

- What is the sequence of events that takes place in cell signaling? Describe each process.

6.2 SENDING SIGNALS

LEARNING OBJECTIVE

2 Compare three types of signaling molecules: neurotransmitters, hormones, and local regulators.

Cells communicate in several ways, including directly through cell junctions, by way of electrical signals, temporary cell-to-cell contact, and chemical signals. Recall from Chapter 5 that gap junctions in animal cells allow rapid chemical and electrical communication between adjacent cells. For example, the gap junctions between cardiac muscle cells of the heart wall allow the rapid flow of ions necessary for synchronized contraction. Plasmodesmata between adjacent plant cells also allow signal molecules to pass quickly from one cell to another.

Cells that are not directly connected also communicate with one another. In animals, some neurons communicate with electrical signals. Most neurons, however, signal one another by releasing chemical compounds called **neurotransmitters** (FIG. 6-3a). Neurotransmitter molecules diffuse across *synapses,* tiny gaps between neurons. More than 60 different neurotransmitters have been

www.konkur.in

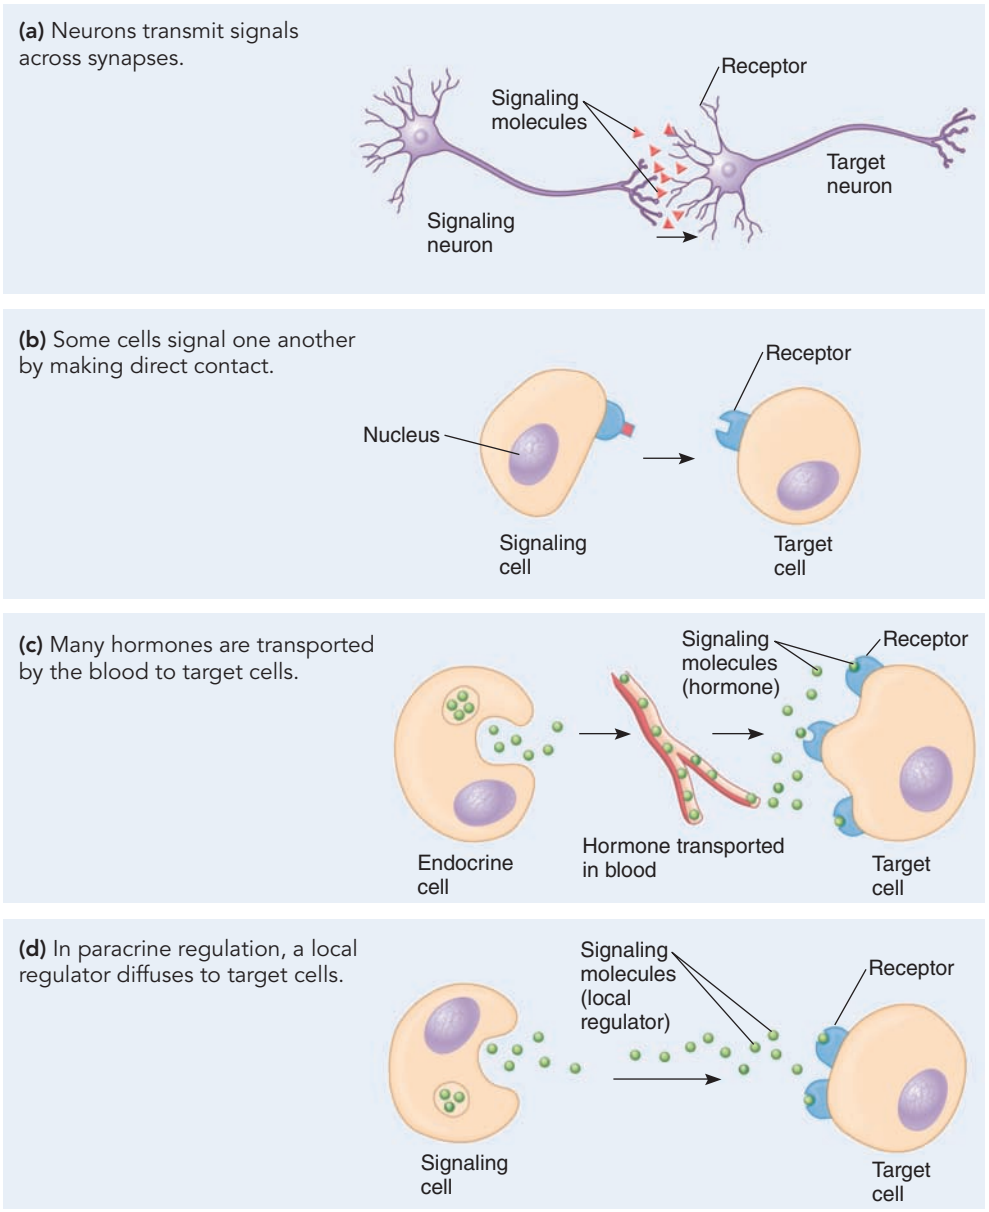

FIGURE 6-3 Some types of cell signaling
Different types of cells may communicate in different ways.

identified, including acetylcholine, norepinephrine, dopamine, serotonin, and several amino acids and peptides.

Cells synthesize many different types of chemical signals and deliver them in various ways. In animals, certain cells in the immune system produce specific chemical compounds that are displayed on the cell surface. These cells recognize the chemical signals and communicate with one another by making direct contact (FIG. 6-3b).

Specialized cells in plants and animals produce signaling molecules called **hormones.** Hormones may be synthesized by neighboring cells or by specialized organs or tissues some distance from the target cells. In animals, many hormones are produced by **endocrine glands.** These glands have no ducts; they secrete their hormones into the surrounding interstitial fluid. Typically, hormones diffuse into capillaries and are transported by the blood to target cells (FIG. 6-3c).

Some cells produce local regulators that signal cells in close proximity. A **local regulator** is a signaling molecule that diffuses through the **interstitial fluid,** the fluid surrounding the cells, and acts on nearby cells. This is called **paracrine regulation** (FIG. 6-3d). Some local regulators are considered hormones. Local regulators include local chemical mediators such as growth factors, histamine, nitric oxide, and prostaglandins. More than 50 **growth factors,** typically peptides, stimulate cell division and normal development in specific types of cells.

Histamine is a local regulator that is stored in certain cells of the immune system and is released in response to allergic reactions, injury, or infection. Histamine causes blood vessels to dilate and capillaries to become more permeable. **Nitric oxide (NO),** another local regulator, is a gas produced by many types of cells, including plant and animal cells. Nitric oxide released by cells lining blood vessels relaxes smooth muscle in the blood vessel walls. As a result, the blood vessels dilate, decreasing blood pressure.

Prostaglandins are local hormones that are paracrine regulators. Prostaglandins modify cAMP levels and interact with other signaling molecules to regulate metabolic activities. For example, some prostaglandins stimulate smooth muscle to contract.

Review

- What are neurotransmitters?
- How are hormones typically transported to target cells?
- What is paracrine regulation?

6.3 RECEPTION

LEARNING OBJECTIVES

3 Identify mechanisms that make reception a highly specific process.
4 Briefly compare ion channel–linked receptors, G protein–linked receptors, enzyme-linked receptors, and intracellular receptors.

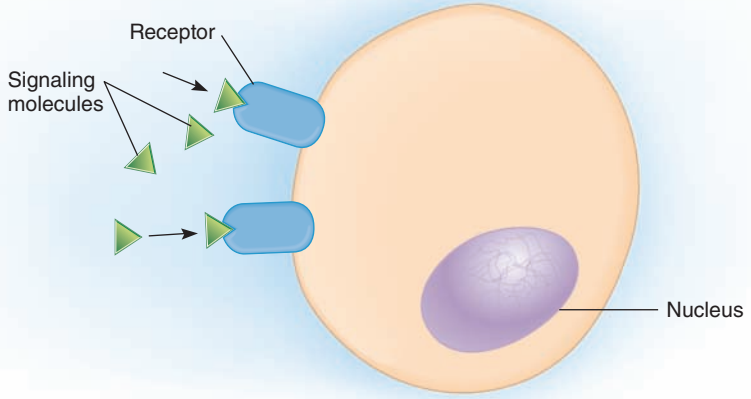
www.konkur.in

Hundreds of different types of signaling molecules are present in the interstitial fluid, the tissue fluid that surrounds the cells of a multicellular organism. How do cells know which messages are for them? The answer is that each type of cell is genetically programmed to receive and respond to specific types of signals. Which signals a cell responds to depends on the specific receptors it is programmed to synthesize.

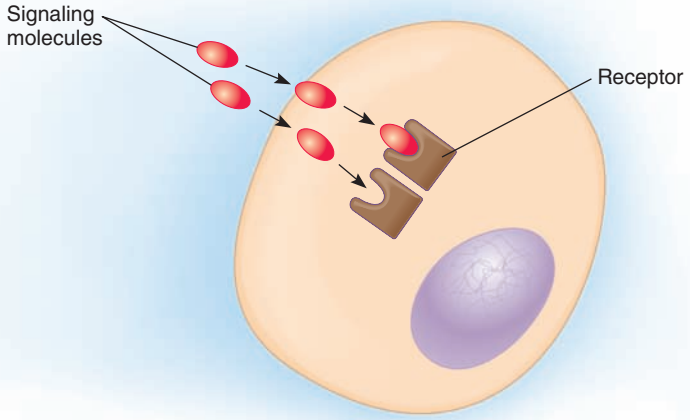
A signaling molecule, such as insulin, that binds to a specific receptor acts as a **ligand.** A ligand is a molecule, other than an enzyme, that binds specifically to a macromolecule (usually a protein), forming a macromolecule-ligand complex. The complex triggers a biological response. Most ligands are hydrophilic molecules that bind to protein receptors on the surface of target cells (**FIG. 6-4a**).

Some signaling molecules are small enough or sufficiently hydrophobic to move through the plasma membrane and enter the cell (**FIG. 6-4b**). These signaling molecules bind with intracellular receptors. Reception occurs when a signaling molecule binds to a specific receptor protein on the surface of, or inside, a target cell. The signaling molecule activates the receptor.

A receptor on the cell surface generally has at least three domains. Recall from Chapter 3 that in biochemistry, the term *domain* refers to a structural and functional region of a protein. The external domain is a docking site for a signaling molecule. A second domain extends through the plasma membrane, and a third domain is a "tail" that extends into the cytoplasm. The tail transmits the signal to a molecule inside the cell.



(a) Hydrophilic signaling molecules bind to receptors in the plasma membrane.



(b) Hydrophobic signaling molecules cross the plasma membrane and bind with receptors inside the cell.

FIGURE 6-4 Cell-surface and intracellular receptors

Hydrophilic (water-soluble) signaling molecules cannot pass through the plasma membrane. They bind to receptors on the cell surface. Hydrophobic (lipid-soluble) signaling molecules pass through the plasma membrane and bind with receptors in the cytosol or nucleus.

Reception is highly selective. Each type of receptor has a specific shape. The receptor binding site is somewhat like a lock, and signaling molecules are like different keys. Only the signaling molecule that fits the specific receptor can influence the metabolic machinery of the cell. Receptors are important in determining the specificity of cell communication.

Different types of cells can produce different types of receptors. Any one cell makes many different receptors. Furthermore, a cell may synthesize different kinds of receptors at different stages in its life cycle or in response to different conditions. Another consideration is that the same signal can have different meanings for various target cells.

Some receptors are specialized to respond to signals other than chemical signals. For example, in the vertebrate eye, a receptor called **rhodopsin** is activated by light. Rhodopsin is part of a signal transduction pathway that leads to vision in dim light. Plants and some algae have **phytochromes,** a family of blue-green pigment proteins that are activated by red light. Activation can lead to changes, such as flowering. Plants, some algae, and at least some animals have **cryptochromes,** pigments that absorb blue light. Cryptochromes play a role in biological rhythms.

Cells regulate reception

An important mechanism that cells use to regulate reception is increasing or decreasing the number of each type of receptor. Depending on the needs of the cell, receptors are synthesized or degraded. For example, when the concentration of the hormone insulin is too high for an extended period, cells decrease the number of their insulin receptors. This process is called **receptor down-regulation.** In the case of insulin, receptor down-regulation suppresses the sensitivity of target cells to the hormone. Insulin stimulates cells to take in glucose by facilitated diffusion, so receptor down-regulation

www.konkur.in

decreases the ability of cells to take in glucose. Receptor down-regulation often involves transporting receptors to lysosomes, where they are destroyed.

Receptor up-regulation occurs in response to low hormone concentrations. A greater number of receptors are synthesized, and their increased numbers on the plasma membrane make it more likely that the signal will be received by a receptor on the cell. Receptor up-regulation thus *amplifies* the signaling molecule's effect on the cell. Receptor up-regulation and down-regulation are controlled in part by signals to genes that code for the receptors.

Three types of receptors occur on the cell surface

Three main types of receptors on the cell surface are ion channel–linked receptors, G protein–linked receptors, and enzyme-linked receptors.

Ion channel–linked receptors convert chemical signals into electrical signals

Ion channel–linked receptors are found in the plasma membrane. These receptors, which have been extensively studied in neurons and muscle cells, convert chemical signals into electrical signals (**FIG. 6-5a**). The receptor itself serves as a channel.

Ion channel–linked receptors are also called **ligand-gated channels,** which means that the ion channel opens or closes in response to the binding of the signaling molecule (ligand). Part of the receptor (protein) that makes up the channel forms the gate. The receptor responds to certain signals by changing its shape, opening or closing the gate. Typically, the gate of an ion channel remains closed until a ligand binds to the receptor.

Neurotransmitters released by neurons in the nervous system are signaling molecules. For example, **acetylcholine** is a neurotransmitter that binds to an acetylcholine receptor. This receptor is a ligand-gated sodium ion channel that is important in muscle contraction. When acetylcholine binds to the receptor, the channel opens, allowing sodium ions to enter the cell. The influx of sodium ions decreases the electric charge difference across the membrane (depolarization), which can lead to muscle contraction. After a brief time, the ligand dissociates from the receptor and the gate closes the channel. As we will discuss in Chapter 41, some ion channels, called voltage-activated channels, are regulated by electrical signals.

G protein–linked receptors link signaling molecules to signal transduction pathways

G protein–linked receptors (also called G protein–coupled receptors) are a large family of transmembrane proteins that loop back and forth through the plasma membrane seven times (**FIG. 6-5b**). The receptor consists of seven transmembrane alpha helices connected by loops that extend into the cytosol or outside the cell. G protein–linked receptors couple certain signaling molecules to various signal transduction pathways inside the cell. The outer part of the receptor has a binding site for a signaling molecule, and the part of the receptor that extends into the cytosol has a binding site for a specific **G protein.**

G proteins bind *guanine nucleotides.* When a signaling molecule binds with a G protein–linked receptor, the receptor changes shape. This change allows the G protein to associate with the receptor.

G protein–linked receptors are found in all eukaryotes. These receptors bind with hundreds of different signaling molecules. Some of the many critical processes that depend on G protein–linked receptors are vision, sense of smell, regulation of mood and behavior, and regulation of the immune system. As you might imagine, understanding how G protein–linked receptors work is medically important. About 60% of prescription medications currently in use act on these receptors. More than 900 G protein–linked receptors have been identified in mammals, and more than 400 of these receptors are potential targets for pharmaceutical interventions.

Enzyme-linked receptors function directly as enzymes or are linked to enzymes

Enzyme-linked receptors are transmembrane proteins with a binding site for a signaling molecule outside the cell and an enzyme component inside the cell. Recall from Chapter 3 that *enzymes* catalyze specific chemical reactions; most enzymes are proteins. Some enzyme-linked receptors do not have an enzyme component but have a binding site for an enzyme. Several groups of enzyme-linked receptors have been identified.

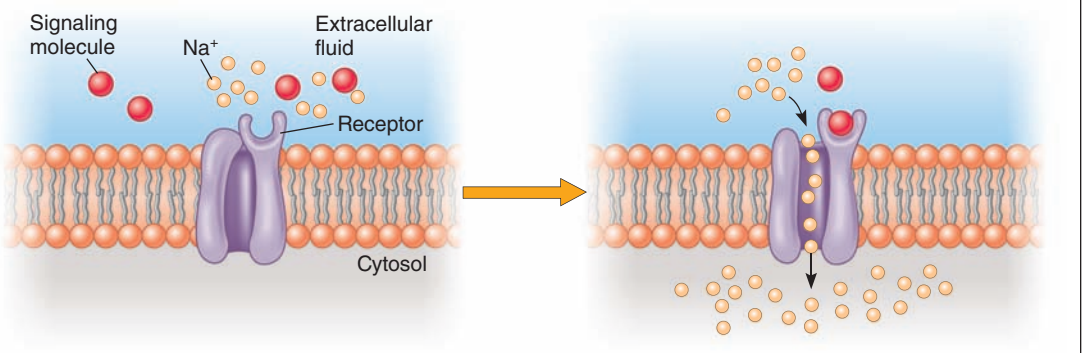
Proteins called *tyrosine kinases* make up a major group of enzyme-linked receptors. A **kinase** is an enzyme that transfers the terminal phosphate group from ATP to a *substrate* (the specific substance on which an enzyme acts). This process is called **phosphorylation.** A **tyrosine kinase** is an enzyme that catalyzes the transfer of phosphate groups from ATP to a specific *tyrosine* that is part of a protein. (Tyrosine is an amino acid.) The tyrosine kinase enzyme part of the receptor is the domain that extends into the cytosol. Tyrosine kinase receptors bind certain hormones, including insulin and *growth factors,* such as nerve growth factor. These receptors regulate many cellular processes and are important in development.

Before the tyrosine kinase can phosphorylate a signaling protein in the cell, it must first be activated. When signal molecules bind to two tyrosine kinase receptors, the receptors move closer together in the plasma membrane and pair, forming a *dimer.* A conformational change (change in shape) takes place, which allows the tyrosine kinase part of each receptor to add a phosphate from an ATP molecule to certain tyrosines on the other member of the dimer (**FIG. 6-5c**). Once activated, tyrosine kinase enzymes can phosphorylate signaling proteins inside the cell (discussed in the next section).

Many plant cell-surface receptors are enzyme-linked receptors. **Brassinosteroids (BRs),** a group of plant steroid hormones, regulate many plant processes, including cell division, cell elongation, and flower development (discussed in Chapter 38). Unlike animal steroid hormones, which typically bind with intracellular receptors, BRs bind with a protein kinase receptor in the plasma membrane. In plant protein kinase receptors, serine and threonine, rather than tyrosine, appear to be the amino acids that are phosphorylated.

The gas **ethylene** is a plant hormone that regulates a variety of processes, including seed germination and ripening of fruit. Ethylene is also important in plant responses to stressors. The ethylene receptor has two components. Each component has a domain that

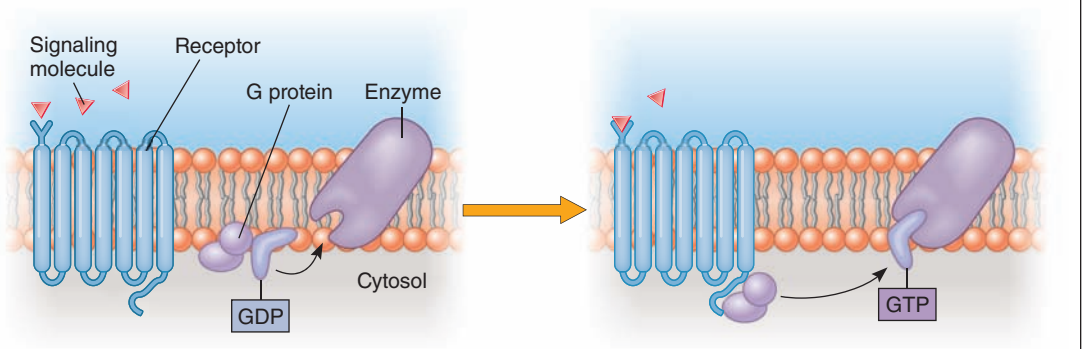
www.konkur.in



1 Ion channel is closed.

2 When signaling molecule binds to receptor, the channel opens. Sodium ions enter cell.

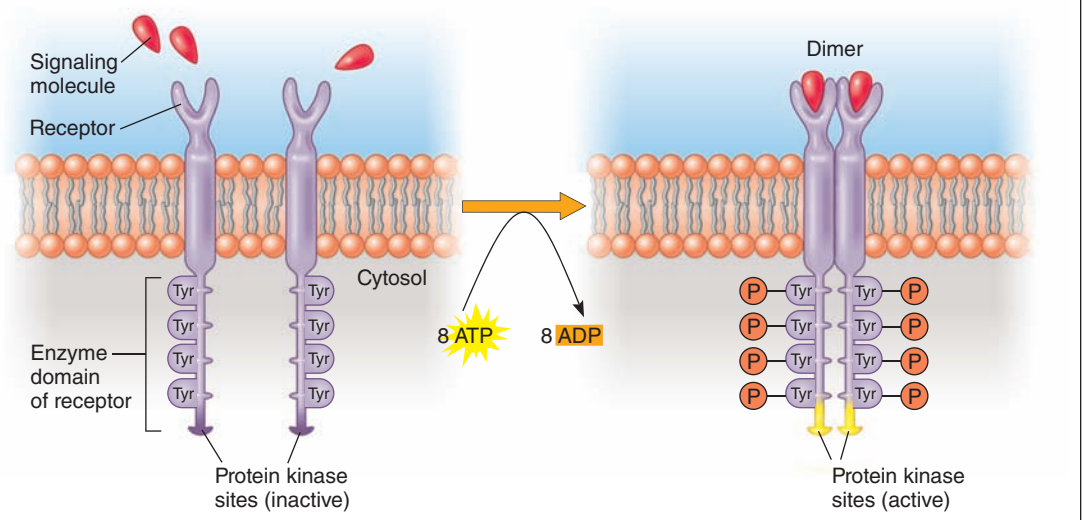
(a) Ion channel–linked receptor



1 In inactive state, the three subunits of G protein are joined.

2 When signaling molecule (ligand) binds to receptor, the ligand–receptor complex associates with G protein. This causes GDP to be replaced with GTP. One subunit of G protein then separates from the other two parts.

(b) G protein–linked receptor



1 Receptors are in inactive state.

2 When signaling molecule (ligand) binds to receptors, receptors are enzymatically phosphorylated. Phosphate comes from ATP.

(c) Enzyme-linked receptors

FIGURE 6-5 Three types of cell-surface receptors

www.konkur.in

is an enzyme, a histidine kinase, that extends into the cell. Receptors with histidine kinase domains are also present in bacterial and yeast cells.

Some receptors are located inside the cell

Certain receptors are found in the cytosol or in the nucleus. Most of these **intracellular receptors** are **transcription factors,** proteins that regulate the expression of specific genes. The signaling molecules that bind with intracellular receptors are small, hydrophobic molecules that can diffuse across the membranes of target cells (see Fig. 6-4b).

In animal cells, most steroid hormones, such as the molting hormone *ecdysone* in insects and *cortisol* in vertebrates, enter target cells and combine with receptor molecules in the cytosol. Vitamins A and D and nitric oxide also bind with intracellular receptors. After binding, the ligand–receptor complex moves into the nucleus. *Thyroid hormones* (which are not steroids) bind to receptors already bound to DNA inside the nucleus.

Review

- How does a receptor "know" which signaling molecules to bind?
- Under what conditions might receptor up-regulation occur? receptor down-regulation?
- What are the three main types of cell-surface receptors? (Briefly describe each.)

6.4 SIGNAL TRANSDUCTION

LEARNING OBJECTIVES

5 Compare the actions of the main types of receptors in signal transduction.

6 Trace the sequence of events in signal transduction for each of the following second messengers: cyclic AMP, inositol trisphosphate, diacylglycerol, and calcium ions.

As we have discussed, many regulatory molecules transmit information to the cell's interior without physically crossing the plasma membrane. Instead, they activate membrane proteins, which then *transduce* the signal. The first component in a signal transduction pathway is typically the receptor, which may be a transmembrane protein with a domain exposed on the extracellular surface. Each type of receptor activates a different signal transduction pathway.

In a typical signaling pathway, a signaling molecule binds with a cell-surface receptor and activates it by changing the shape of the receptor tail that extends into the cytoplasm. The signal may then be relayed through a sequence of proteins that are intracellular signaling molecules. Typically, the proteins in this chain are protein kinases. The chain of signaling molecules in the cell that relays a signal is called a **signaling pathway** or **signaling cascade.** During signal transduction, the original signal is amplified.

More than 3000 signaling proteins have been identified in the cells of mammals alone. Malfunctions in signal transduction pathways have been linked to major diseases, including cancer, heart disease, diabetes, and autoimmune diseases.

Signaling molecules can act as molecular switches

Each component in a signaling pathway acts as a molecular "switch," which can be in an active ("on") state or an inactive ("off") state. When an intracellular signaling molecule receives a signal, it is activated (turned on). Another process then occurs that inactivates (turns off) the signaling molecule. Every activated molecule in a signaling pathway must be inactivated in order to transmit a new signal. Molecular switches are typically regulated by the addition or removal of phosphate groups.

Each time a signal molecule binds to a receptor, a signaling pathway is turned on. As the signal is transmitted to each protein kinase in the chain, the protein is phosphorylated. Recall that in phosphorylation, an enzyme transfers phosphate groups from one molecule to another. As phosphate is transferred, the signal passes from protein kinase 1 to protein kinase 2 to protein kinase 3, and on down the chain (**FIG. 6-6**). Phosphorylation typically activates a protein kinase, although in some cases phosphorylation inhibits its protein kinase activity. A signaling pathway in which a series of protein kinase molecules are phosphorylated is referred to as a **protein kinase cascade.** The last protein kinase in the cascade activates the target protein by phosphorylation. The target protein alters some process in the cell.

After the signal passes from protein kinase 1 to protein kinase 2, protein kinase 1 must be inactivated. Each molecule must be available to transmit a new signal. A **phosphatase** is an enzyme that catalyzes the removal of a phosphate group by hydrolysis; the process is called *dephosphorylation.* Protein phosphatases help regulate protein kinase cascades. Just as a cell contains hundreds of different protein kinases, it also contains many types of protein phosphatases. Rapid removal of phosphate groups by protein phosphatases is an important regulatory mechanism for protein kinase cascades. Such regulation ensures that these pathways operate only in response to the binding of a signal molecule to a receptor.

Ion channel–linked receptors open or close channels

The gates of many ion channels remain closed until a ligand binds to the receptor. For example, when the neurotransmitter acetylcholine binds to an acetylcholine receptor (which is an ion channel–linked receptor), the channel opens, allowing sodium ions to enter the cell (see Fig. 6-5a). Depending on the type of cell, the influx of sodium ions can result in transmission of a neural impulse or in muscle contraction.

Gamma-aminobutyric acid (GABA) is a neurotransmitter that binds to GABA receptors. One class of GABA receptors consists of ligand-gated chloride ion channels. When GABA binds to the receptor, the channel opens. Chloride ions, which are negatively charged, rush out of or into the neuron, depending on the conditions (electrochemical gradient) in the cell. Typically, chloride ions leave the cell, which inhibits transmission of neural impulses. Thus, GABA *inhibits* neural signaling. Barbiturates and benzodiazepine drugs such as Valium bind to GABA receptors. When this occurs, lower amounts of GABA are required to open the chloride channels and inhibit neural impulses. This action results in a tranquilizing effect. (Not all GABA receptors are *themselves* ion

www.konkur.in

KEY POINT Many signaling pathways are protein kinase cascades in which each protein kinase in the pathway is activated by the addition of a phosphate group.

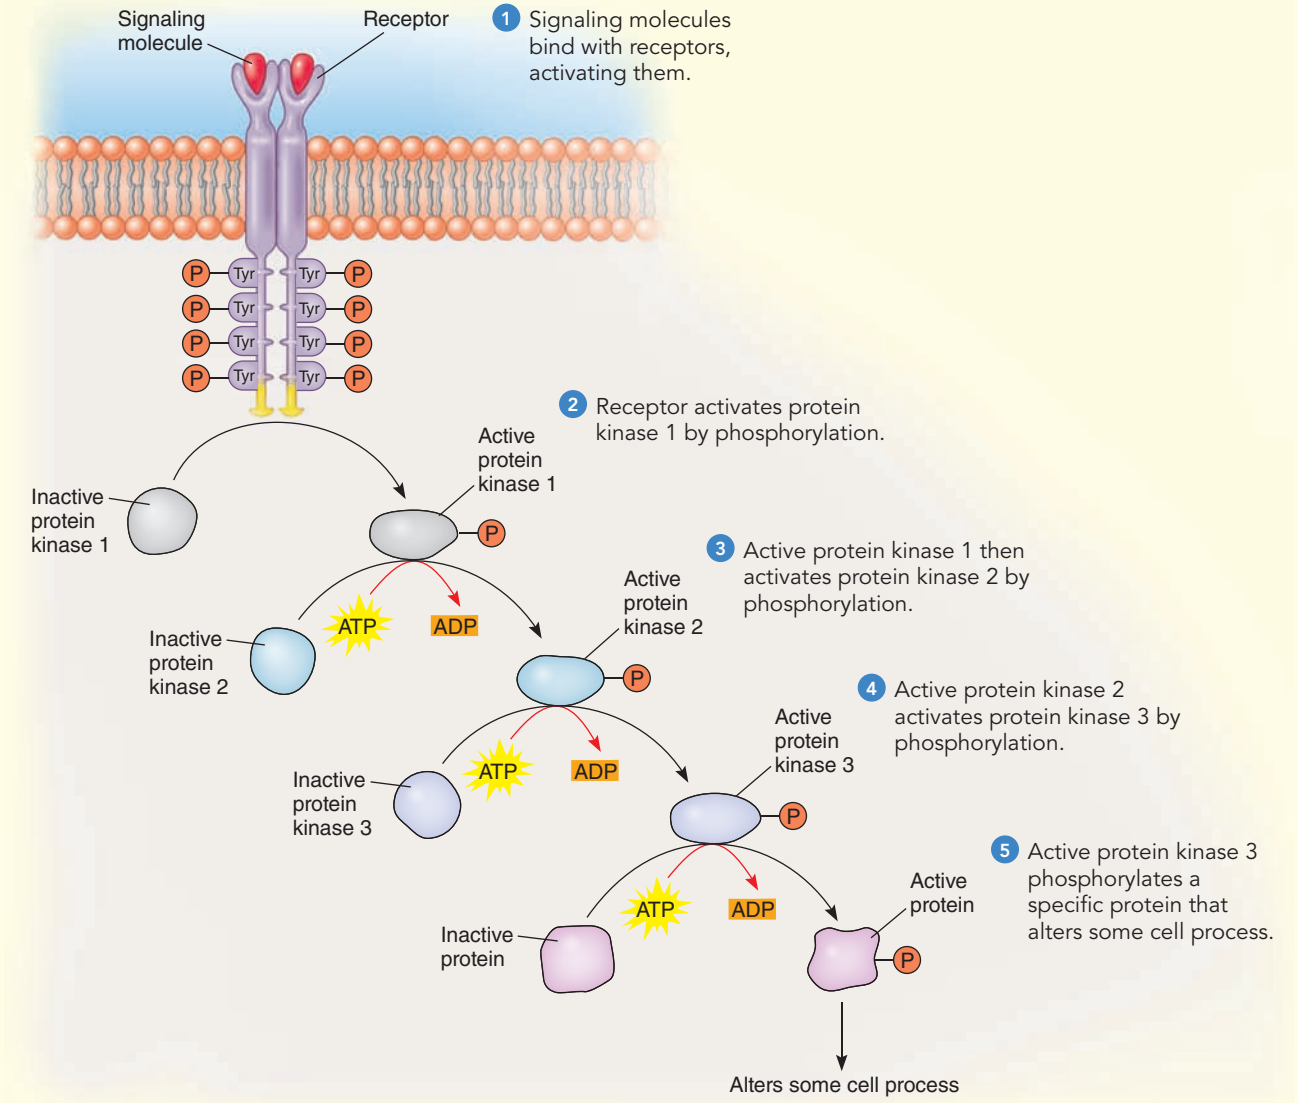


FIGURE 6-6 A phosphorylation cascade

When the receptor is activated, each protein kinase in a signaling pathway activates the next protein kinase in the pathway by phosphorylation. The phosphate group comes from ATP. Addition of a phosphate group typically changes the shape of the molecule. Activation of the last protein in the chain changes some cell process or turns on (or turns off) specific genes. (*P* represents phosphate.) Note that the number of protein kinases varies from pathway to pathway.

channels; some are G-protein–linked receptors or enzyme-linked receptors that trigger a series of reactions resulting in activation of other proteins that serve as ion channels.)

G protein–linked receptors initiate signal transduction

As discussed in the last section, G protein–linked receptors activate G proteins, a group of regulatory proteins important in many signal transduction pathways. These proteins are found in yeasts, protists, plants, and animals. They are involved in the action of some plant and many animal hormones. Some G proteins regulate channels in the plasma membrane, allowing ions to enter or exit the cell. Other G proteins are involved in the perception of sight and smell. In 1994, Alfred G. Gilman of the University of Texas and Martin Rodbell of the National Institute of Environmental Health Sciences were awarded the Nobel Prize in Physiology or Medicine for their groundbreaking research on G proteins.

In its inactive state, the G protein consists of three subunits that are joined (see Fig. 6-5b). One subunit is linked to a molecule of **guanosine diphosphate (GDP),** a molecule similar to ADP but containing the base guanine instead of adenine. When a sig-

www.konkur.in

naling molecule binds with the receptor, the GDP is released and is replaced by **guanosine triphosphate (GTP),** a nucleotide that, like ATP, functions in energy transactions.

The subunit of the G protein that is linked to the GTP separates from the other two subunits. The G protein subunit linked to the GTP is a GTPase, an enzyme that catalyzes the hydrolysis of GTP to GDP. This action, a process that releases energy, deactivates the G protein. Now in its inactive state, the G protein subunit rejoins the other two subunits.

When activated, a G protein initiates signal transduction by binding with a specific protein in the cell. In some cases, G proteins *directly* activate enzymes that catalyze changes in certain proteins. These changes lead to alterations in cell function. More commonly, the signaling molecule serves as the **first messenger,** and information is relayed by way of the G protein to a second messenger.

Second messengers are intracellular signaling agents

Second messengers are ions or small molecules that relay signals inside the cell. More than 15 second messengers have been identified in mammals. When receptors are activated, second messengers are produced in large quantities. Second messengers rapidly diffuse through the cell (or membrane), relaying the signal. Thus, second messengers amplify the signal.

Second messengers pass the signal along to other signaling proteins or target proteins. The signal typically passes through a chain of proteins and other molecules. The last molecule in the sequence activates the final response. Second messengers are not enzymes, but some regulate specific enzymes, such as protein kinases. Others bind to ion channels, opening or closing them.

Cyclic AMP is a second messenger

Most G proteins shuttle a signal between the receptor and a second messenger. In many signaling cascades in prokaryotic and animal cells, the second messenger is cyclic AMP (cAMP) (**FIG. 6-7**). Researcher Earl Sutherland identified cAMP as a second messenger in the 1960s and was awarded the 1971 Nobel Prize in Physiology or Medicine for his pioneering work.

When the G protein undergoes a conformational change (change in shape), it binds with and activates **adenylyl cyclase,** an enzyme on the cytoplasmic side of the plasma membrane. The type of G protein that activates adenylyl cyclase is known as a stimulatory G protein, or G_s. (Some G proteins, denoted as G_i, inhibit enzymes.) Note that the G protein couples the ligand–receptor complex to adenylyl cyclase action (see Fig. 6-7).

When activated, adenylyl cyclase catalyzes the production of cAMP from ATP (**FIG. 6-8**). By coupling the signaling molecule–receptor complex to an enzyme that generates a signal, G proteins amplify the effects of signaling molecules and many second-messenger molecules are rapidly produced. The pathway is regulated, in part, by **phosphodiesterase,** an enzyme that converts cAMP to adenosine monophosphate (AMP). This action is an off switch that rapidly inactivates cAMP when the receptor becomes inactive.

KEY POINT Cyclic AMP (cAMP), a second messenger, relays a signal from the plasma membrane to proteins in the cytosol.

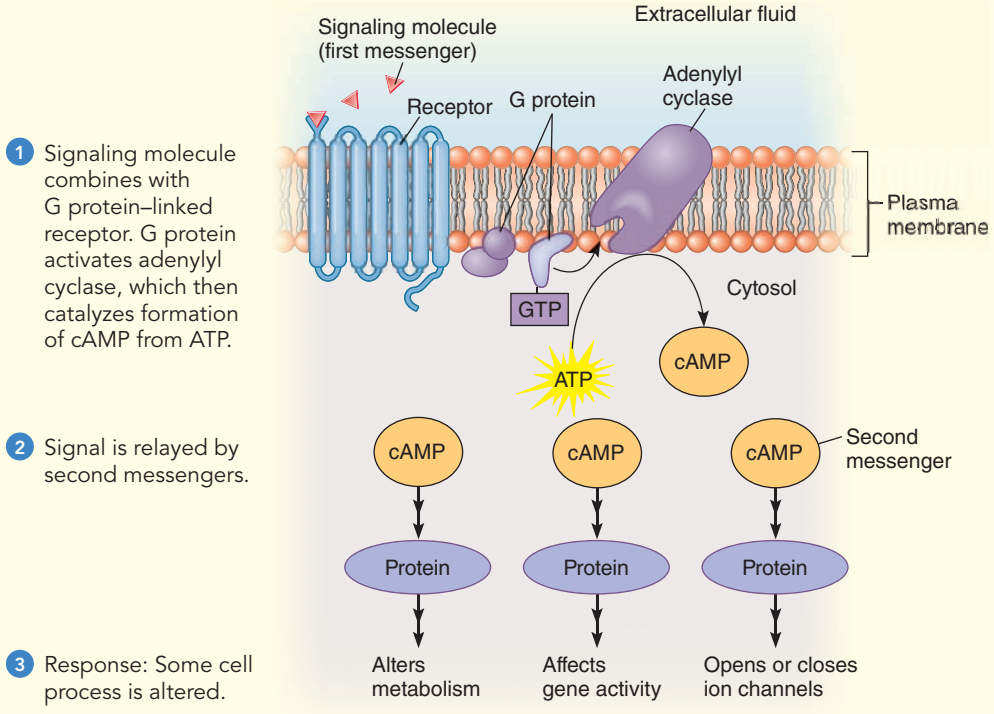

FIGURE 6-7 Signal relay by a second messenger: An overview

www.konkur.in

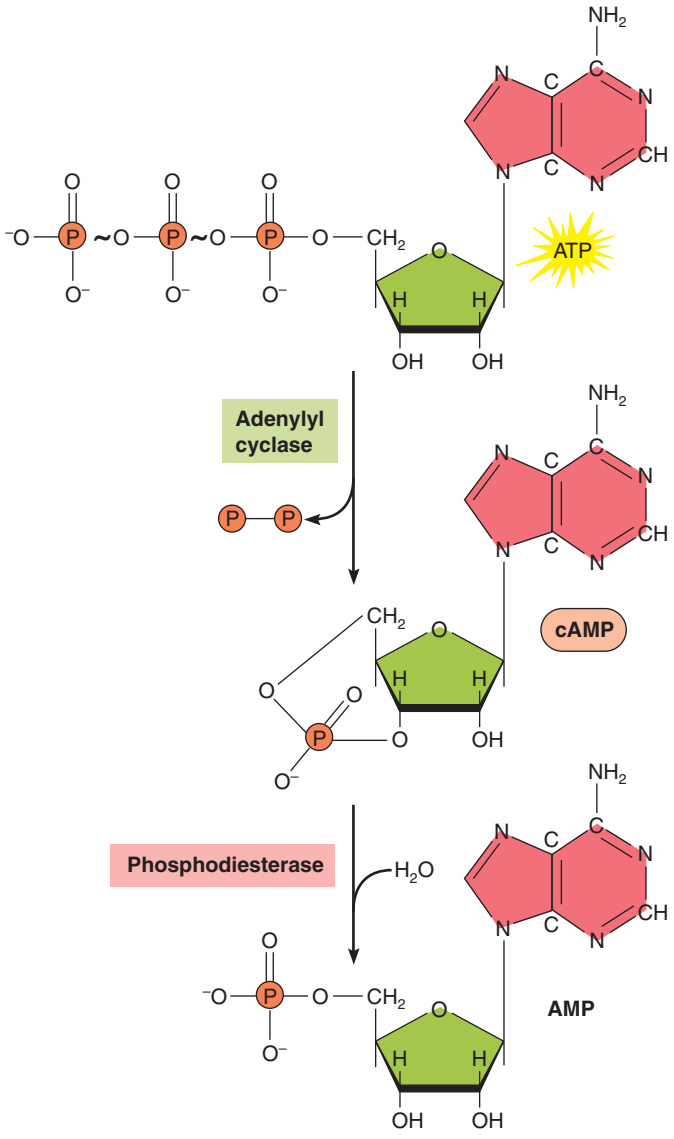

FIGURE 6-8 Synthesis and inactivation of cyclic AMP

Cyclic AMP (cAMP) is a second messenger produced from ATP. The enzyme adenylyl cyclase catalyzes the reaction. Cyclic AMP is inactivated by the enzyme phosphodiesterase, which converts it to adenosine monophosphate (AMP).

FIGURE 6-9 illustrates in more detail the sequence of events in a signaling pathway involving G protein and cyclic AMP. Cyclic AMP activates certain protein kinase enzymes, particularly a group referred to as **protein kinase A.** Recall that protein kinases add phosphate groups to target proteins. When a protein is phosphorylated, its function is altered and it triggers a chain of reactions leading to some response in the cell, such as a metabolic change.

The **substrates,** the substances on which an enzyme acts, for protein kinases are different in various cell types. Consequently, the effect of the enzyme varies depending on the substrate. For example, in skeletal muscle cells, protein kinase A activates enzymes that break down glycogen to glucose, providing the muscle cells with energy. In certain neurons in the brain, the same enzyme acti-

KEY POINT When a signaling molecule binds to a G protein–linked receptor, a G protein is activated; cyclic AMP is produced and activates a signaling pathway, leading to a change in some cell process.

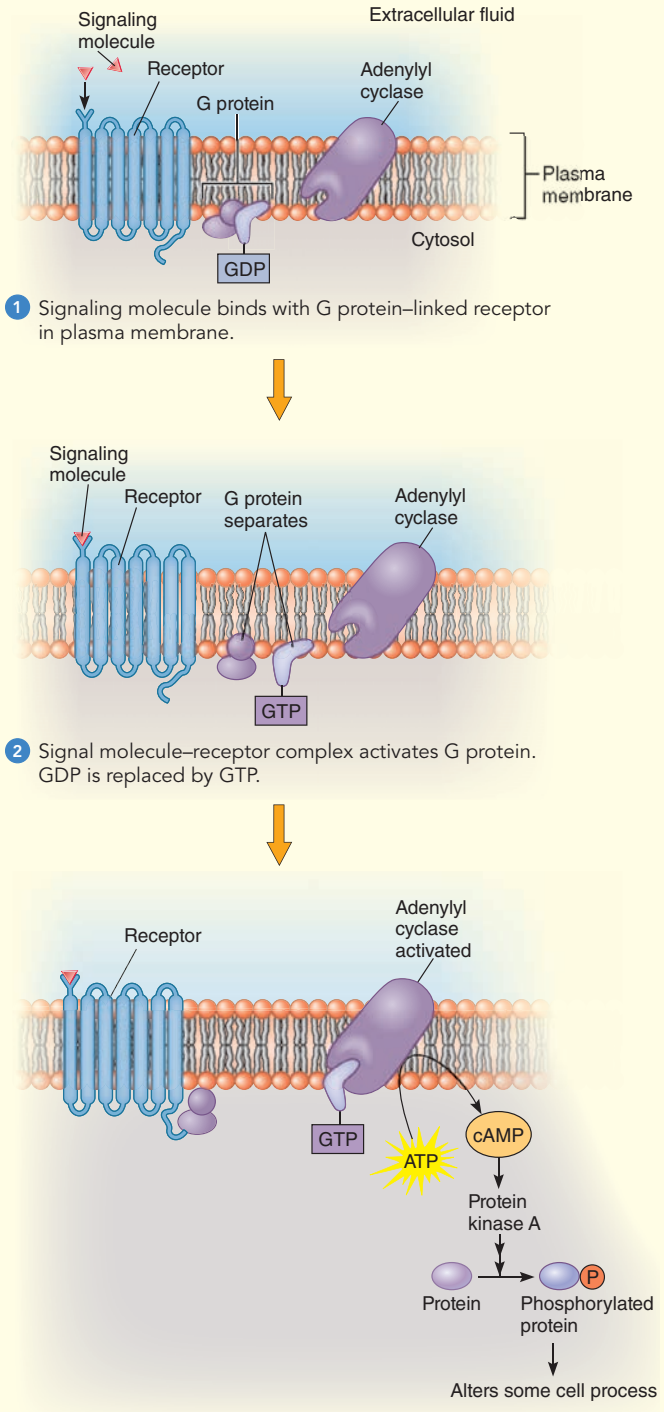

FIGURE 6-9 Signal transduction involving a G protein and cyclic AMP

www.konkur.in

vates the reward system by regulating action of the neurotransmitter dopamine.

We can summarize the sequence of events beginning with the binding of the signaling molecule to the receptor and leading to a change in some cell function:

signaling molecule (first messenger) binds to G protein–linked receptor ⟶ activates G protein ⟶ activates adenylyl cyclase ⟶ catalyzes the formation of cAMP (second messenger) ⟶ activates protein kinase ⟶ phosphorylates proteins ⟶ response in cell

Some G proteins use phospholipids as second messengers

Certain signaling molecule–receptor complexes activate a G protein that then activates the membrane-bound enzyme **phospholipase C** (FIG. 6-10). This enzyme splits a membrane phospholipid, PIP_2 (phosphotidylinositol-4,5-bisphosphate), into two products, **inositol trisphosphate (IP_3)** and **diacylglycerol (DAG).** Both act as second messengers.

DAG remains in the plasma membrane, where in combination with calcium ions, it activates **protein kinase C** enzymes. Depending on the type of cell and the specific protein kinase C, the response of the cell can include growth, a change in cell pH,

KEY POINT **When activated by a G protein, phospholipase C splits the phospholipid PIP_2, producing the second messengers DAG and IP_3.**

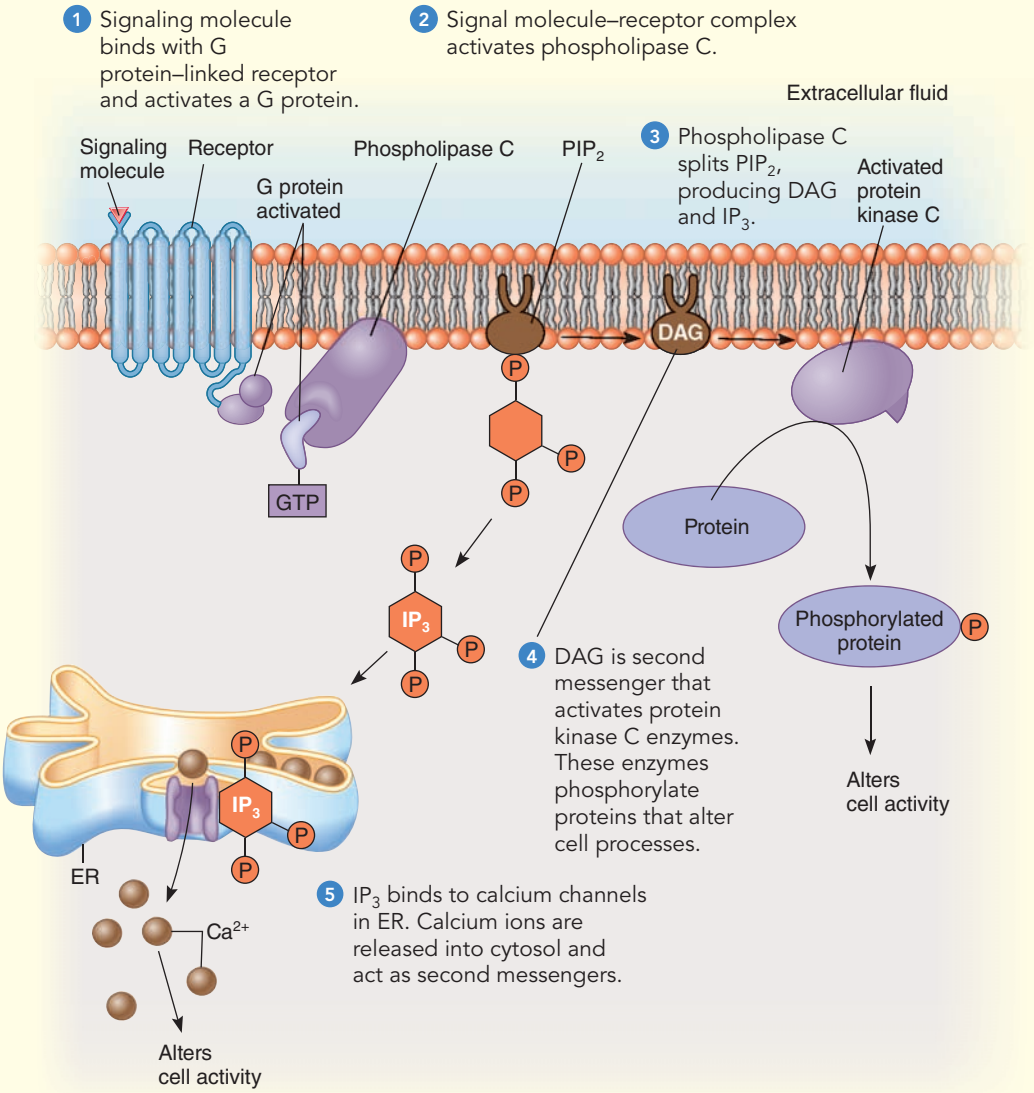

FIGURE 6-10 Phospholipid products as second messengers

An activated G protein activates phospholipase C. This enzyme splits PIP_2, producing two second messengers—IP_3 and DAG. IP_3 binds to calcium channels in the endoplasmic reticulum (ER); calcium ions are released into the cytosol and act as second messengers. DAG activates protein kinase C, a family of enzymes that activates signaling pathways by phosphorylating proteins; calcium ions are needed for the activation of protein kinase C.

www.konkur.in

or regulation of certain ion channels. Protein kinase C stimulates contraction of smooth muscle in the digestive system and in other organs of the body.

IP_3 is a member of a family of inositol phosphate messengers, some of which can donate phosphate groups to proteins. IP_3 binds to calcium channels in the endoplasmic reticulum (ER), causing them to open and release calcium ions into the cytosol. We can summarize this sequence of events as follows:

signaling molecule binds to G protein–linked receptor ⟶ activates G protein ⟶ activates phospholipase ⟶ splits PIP_2 ⟶ inositol trisphosphate (IP_3) + diacylglycerol (DAG)

DAG ⟶ activates protein kinase enzymes ⟶ phosphorylates proteins ⟶ some response in cell

IP_3 ⟶ binds to calcium channels in ER ⟶ calcium ions released into the cytosol ⟶ some response in the cell

Calcium ions are important messengers

Calcium ions (Ca^{2+}) have important functions in many cell processes, including microtubule disassembly, muscle contraction, blood clotting, secretion, and activation of certain cells in the immune system. Calcium ions are critical in neural signaling, including the pathways involved in learning. These ions are also essential in fertilization of an egg and in the initiation of development.

Ion pumps in the plasma membrane normally maintain a low calcium ion concentration in the cytosol compared to its concentration in the extracellular fluid. Calcium ions are also stored in the endoplasmic reticulum. When Ca^{2+} gates open in the plasma membrane or endoplasmic reticulum, the Ca^{2+} concentration rises in the cytosol.

Calcium ions can act alone, but typically they exert their effects by binding to certain proteins. **Calmodulin,** found in all eukaryotic cells, is an important Ca^{2+} binding protein. When four Ca^{2+} bind to a calmodulin molecule, the molecule changes shape and can then activate certain enzymes. Calmodulin combines with a number of different enzymes, including protein kinases and protein phosphatases, and alters their activity. Various types of cells have different calmodulin-binding proteins. How a target cell responds depends on which proteins are present. Calmodulin is important in the regulation of many key processes including metabolism, muscle contraction, memory, inflammation, and apoptosis.

Many enzyme-linked receptors activate protein kinase signaling pathways

Recall that many enzyme-linked receptors are tyrosine kinases, enzymes that phosphorylate the amino acid tyrosine in proteins (see Fig. 6-6). When a signaling molecule, such as a growth factor, binds to an enzyme-linked receptor, sites on the receptor are phosphorylated. Addition of the phosphates activates the enzyme part of the receptor. Once activated, tyrosine kinase enzymes can phosphorylate signaling proteins in the cell. Specific target proteins recognize the phosphorylated tyrosines on the tyrosine kinase receptor molecules. These signaling proteins bind to the phosphorylated sites on the receptor molecules. The signaling proteins are then phosphorylated and can activate specific signaling pathways.

Recall that in many signal transduction pathways, protein kinases form signaling cascades in which the protein kinases are phosphorylated one after another (see Fig. 6-6). Even when the amino acid phosphorylated in the receptor is tyrosine, the amino acids phosphorylated in the protein kinases in the signaling pathway can be serine or threonine, rather than tyrosine. Each reaction in a chain is dependent on the preceding one. Activation of the last protein in

KEY POINT **Many intracellular receptors are transcription factors; when activated, they activate or repress specific genes.**

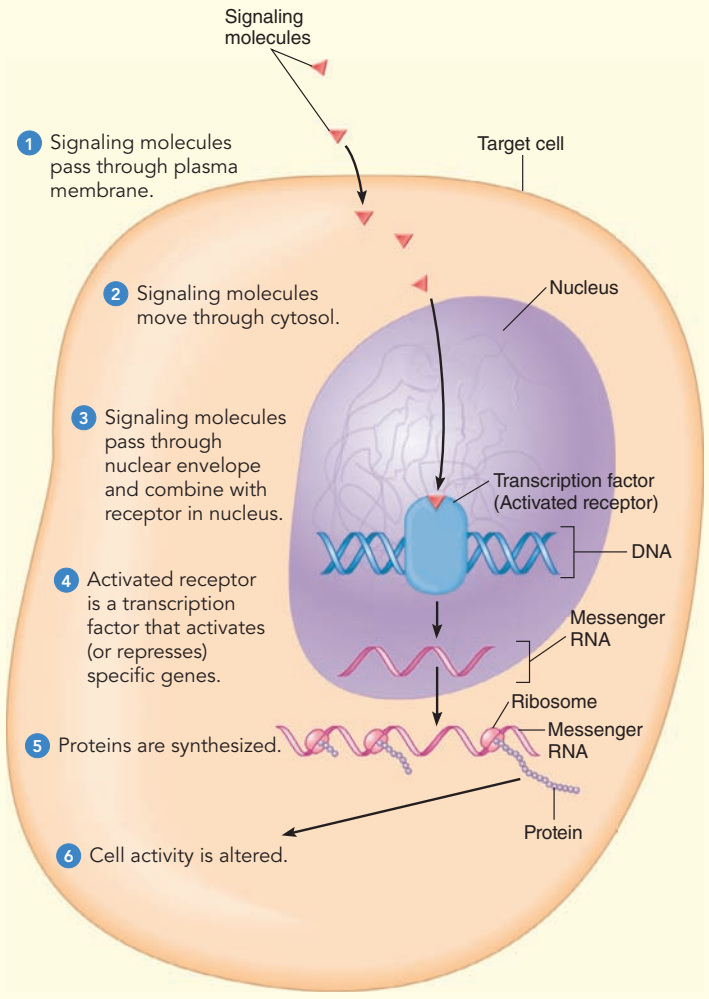

FIGURE 6-11 Intracellular receptors

www.konkur.in

the chain causes a specific cell response. Some cell process is altered.

Many activated intracellular receptors are transcription factors

Some hydrophobic signaling molecules diffuse across the membranes of target cells and bind with intracellular receptors in the cytosol or in the nucleus. For example, cortisol receptors are located in the cytosol. (Cortisol is a steroid hormone produced in the adrenal glands; its structure is shown in Figure 3-15b.) Thyroid hormones pass into the nucleus and bind with receptors that are bound to DNA in the nucleus. Many intracellular receptors are transcription factors that regulate the expression of specific genes. When a signaling molecule binds to a receptor, the receptor is activated. The ligand–receptor complex binds to a specific region of DNA and activates or represses specific genes (**FIG. 6-11**).

Gene activation can take place quickly—within about 30 minutes. Messenger RNA is produced and carries the code for synthesis of a particular protein into the cytoplasm. In combination with ribosomes, messenger RNA manufactures specific proteins that can alter cell activity.

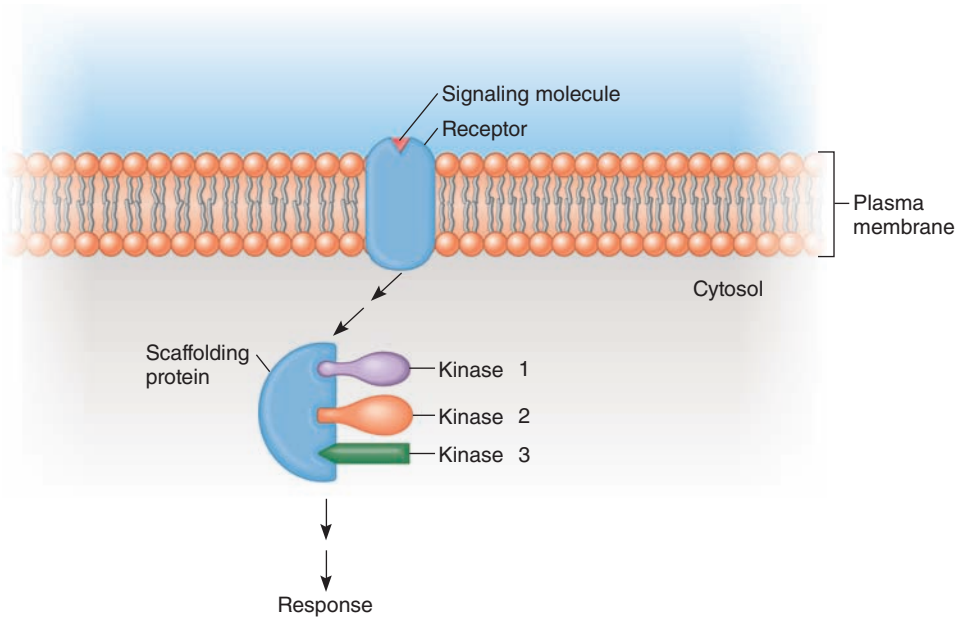

FIGURE 6-12 A scaffold protein

Scaffold proteins organize groups of signaling molecules into a signaling complex, making signal transduction faster, more precise, and more efficient.

Scaffold proteins increase efficiency

Signal transduction is a rapid, precise process. Enzymes must be organized so that they are available as needed for signaling pathways. **Scaffold proteins** organize groups of intracellular signaling molecules into signaling complexes (**FIG. 6-12**). These proteins position enzymes close to the proteins they regulate, increasing the probability that they will react with one another. At the same time, scaffold proteins decrease the chance that enzymes will be co-opted by other pathways. These organizing proteins guide interactions between molecules, reducing cross talk among different signaling pathways. Thus, scaffold proteins ensure that signals are relayed accurately, rapidly, and efficiently.

Scaffold proteins have been identified in many pathways, and similar scaffold proteins have been found in diverse organisms. Both yeasts and mammals have scaffold proteins that bind kinases in MAP kinase pathways (discussed in the next section).

Signals can be transmitted in more than one direction

Integrins, transmembrane proteins that connect the cell to the extracellular matrix, transduce signals in two directions. They transmit signals from outside the cell to the cell interior and also transmit information about the cell interior to the extracellular matrix.

Cell biologists have demonstrated that when certain signaling molecules bind to integrins in the plasma membrane, specific signal transduction pathways are activated. Interestingly, growth factors and certain molecules of the extracellular matrix may modulate one another's messages. Integrins also respond to information received from inside the cell. This *inside-out signaling* affects how selective integrins are with respect to the molecules to which they bind and how strongly they bind to them.

6.5 RESPONSES TO SIGNALS

LEARNING OBJECTIVES

7 Describe three types of responses that cells make to signaling molecules.

8 Contrast signal amplification with signal termination.

As we have learned, signaling molecules activate signal transduction pathways that bring about specific responses in the cell. Most of these responses fall into three categories: ion channels open or close; enzyme activity is altered, leading to metabolic changes and other effects; and specific gene activity may be turned on or off. Various mechanisms and pathways interact to produce specific actions that are responsible for the structure and function of the cell.

www.konkur.in

They are responsible for metabolic activity, movement, growth, cell division, development, and further information transfer.

In animals, neurons release neurotransmitters that excite or inhibit other neurons or muscle cells by affecting ion channels. For example, when acetylcholine binds with a receptor on a target neuron, an ion channel opens and allows passage of sodium and potassium ions. The resulting change in ion permeability can activate the neuron so that it transmits a neural impulse. Serotonin and some other neurotransmitters work indirectly through G proteins and cyclic AMP. In this chain of events, cAMP activates a kinase that phosphorylates a protein which then closes potassium ion channels. This action leads to transmission of a neural impulse. Some G proteins directly open or close ion channels.

Some receptors directly affect enzyme activity, whereas others initiate signal transduction pathways in which enzymes are altered by components of the pathway. When bacteria infect the body, they release certain peptides. Neutrophils, a type of white blood cell, have cell-surface receptors that detect these peptides. When the bacterial peptides bind to a neutrophil's receptors, enzymes are activated that lead to assembly of microfilaments (actin filaments) and microtubules. Contractions of microfilaments at the far end of the neutrophil force the cytoplasm forward. This action allows the neutrophil to move toward the invading bacteria and destroy them. Microtubules and a variety of proteins, including the contractile protein myosin, appear necessary for this movement.

Some signaling molecules affect gene activity. For example, some signaling molecules activate genes that lead to the manufacture of proteins needed for growth and cell division. In both plants and animals, steroid hormones regulate development by causing changes in the expression of specific genes. In animal cells, some steroid hormones bind to nuclear receptors and directly regulate expression of specific target genes. In plant cells, steroid hormones bind to receptors on the cell surface. The signal is then transmitted through a chain of molecules, eventually leading to changes in gene expression. Plant hormones will be discussed in greater detail in Chapter 38, and animal hormones are the focus of Chapter 49.

Ras pathways involve tyrosine kinase receptors and G proteins

Some tyrosine kinase receptors activate G proteins. For example, when growth factors bind to tyrosine kinase receptors, **ras proteins** are activated. Ras proteins are a group of small G proteins that, like other G proteins, are active when bound to GTP. Ras proteins are molecular switches that regulate signaling networks inside the cell. When activated, Ras triggers a cascade of reactions called the Ras pathway. In this pathway, a tyrosine in specific kinase proteins is phosphorylated, leading to critical cell responses.

Ras pathways are important in gene expression, cell division, cell movement, cell differentiation, cell adhesion, embryonic development, and apoptosis. For example, to initiate DNA synthesis, fibroblasts (a type of connective tissue cell) require the presence of two growth factors, epidermal growth factor and platelet-derived growth factor. In one study, investigators injected fibroblasts with antibodies that inactivate Ras proteins by binding to them. The fibroblasts no longer synthesized DNA in response to growth factors. Data from this and similar experiments led to the conclusion that Ras proteins are important in signal transduction involving growth factors.

Ras genes code for Ras proteins. Certain mutations in *Ras* genes result in mutant Ras proteins that bind GTP but cannot hydrolyze it. The mutant Ras proteins are stuck in the "on" state, resulting in unregulated cell division. This condition is associated with several types of human cancer. In fact, mutations in *Ras* genes have been identified in about one-third of all human cancers. Drugs that inhibit specific tyrosine kinase receptors and Ras pathways are being developed to treat cancer.

One Ras pathway that has been extensively studied is the **MAP kinase pathway,** also known as the **ERK pathway;** *MAP* is an acronym for "mitogen-activated protein" (mitogens induce mitosis, the nuclear division associated with eukaryotic cell division). *ERK* is an acronym for "extracellular signal-regulated kinases." Several distinct groups of MAP kinases have been described. The pathway illustrated in **FIGURE 6-13** shows three main MAP protein kinases: Raf, Mek, and ERK. Proteins in the MAP pathway phosphorylate a nuclear protein that combines with other proteins to form a transcription factor. When specific genes are activated, proteins needed for cell growth, cell division, and cell differentiation (specialization) are synthesized. The MAP kinase cascade is the main signaling pathway for cell division and differentiation. As illustrated in **FIGURE 6-14**, the signaling proteins ERK 1 and ERK 2 are important in fertility in mammals.

The response to a signal is amplified

Signaling molecules are typically present in very low concentrations, yet their effects on the cell are often profound. This is possible because the signal is *amplified,* as it is relayed through a signaling pathway. For example, let us examine how the action of a signaling molecule such as the hormone epinephrine is magnified as a signal passes through a series of proteins inside the cell. Epinephrine is released by the adrenal glands in response to danger or other stress. Among its many actions, epinephrine increases heart rate, blood flow to skeletal muscle, and glucose concentration in the blood.

Epinephrine binds to a G protein–linked receptor, causing the receptor to change shape and activate a G protein. A single molecule of a hormone such as epinephrine can activate many G proteins. Each G protein activates an adenylyl cyclase molecule and then returns to its inactive state. Before it becomes inactive, each adenylyl cyclase can catalyze the production of numerous cAMP molecules (**FIG. 6-15**). Then, each cAMP molecule can activate many molecules of a particular protein kinase. That protein kinase can phosphorylate many molecules of the next kinase in the pathway and so on down the cascade.

As a result of **signal amplification,** a single signaling molecule can lead to changes in millions of molecules at the end of a signaling cascade. The response is much greater than would be possible if each signaling molecule acted alone. This process of magnifying the strength of a signaling molecule explains how just a few signaling molecules can lead to major responses in the cell.

www.konkur.in

KEY POINT When growth factors bind to their receptors, they activate the G protein Ras; Ras activates a MAP-kinase signaling pathway, leading to activation (or repression) of specific genes, and ultimately to protein activity that affects some cell process.

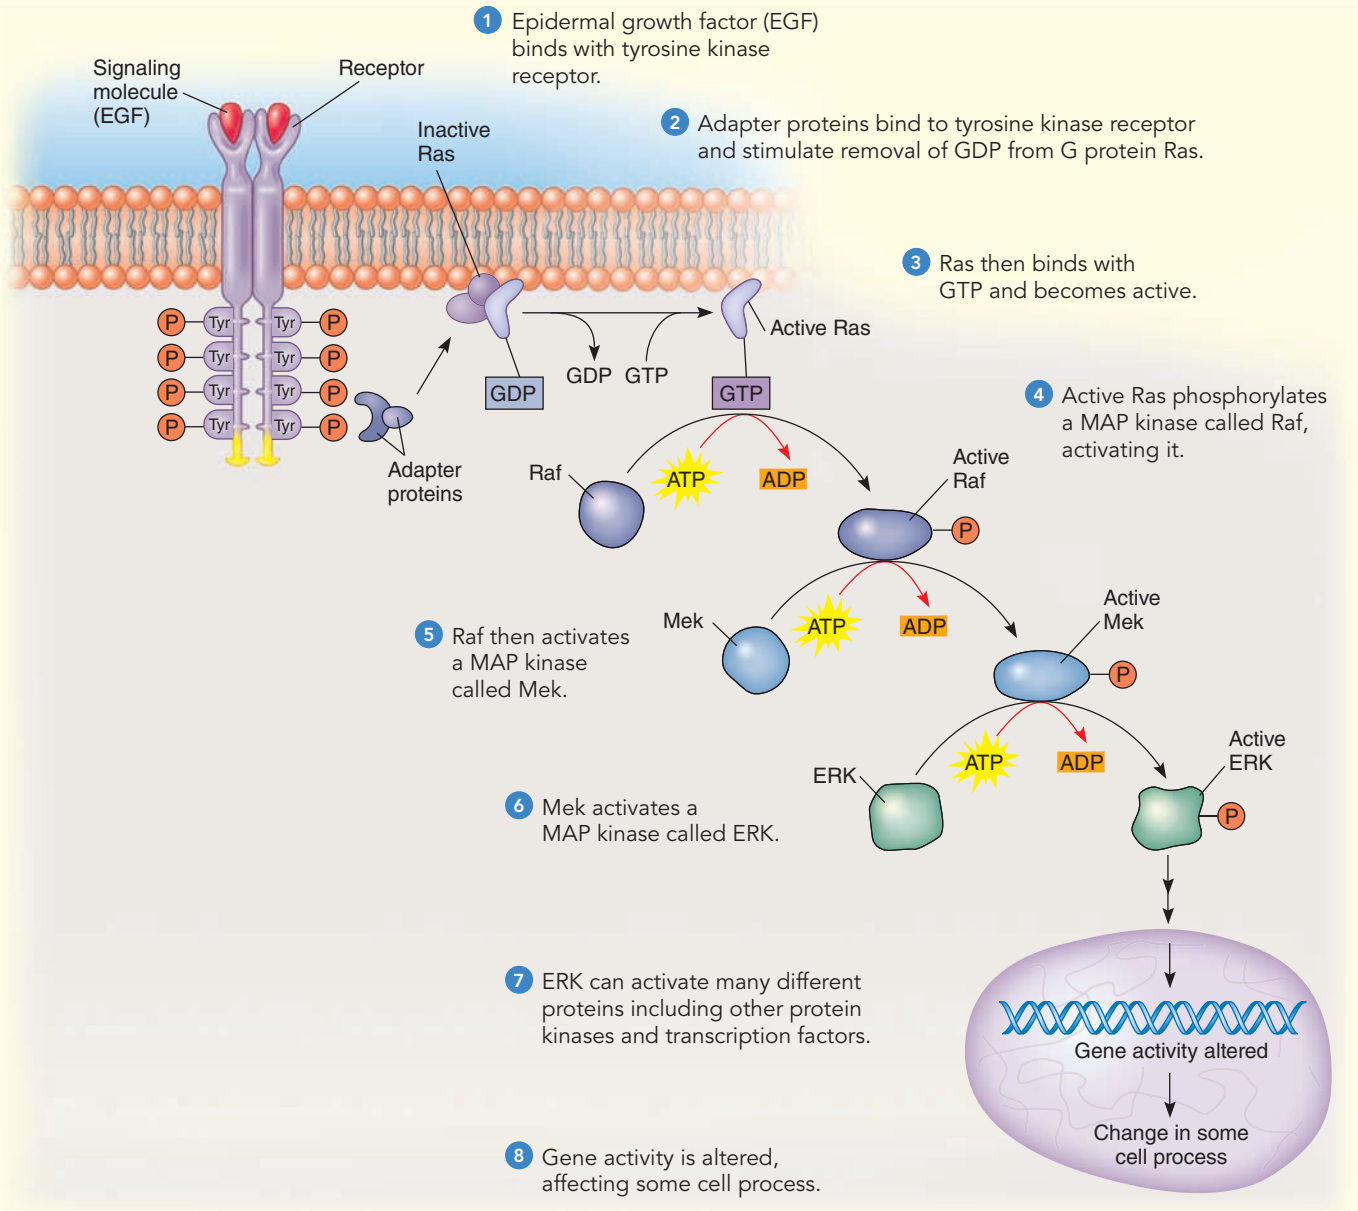

FIGURE 6-13 A highly simplified Ras/MAP kinase signaling pathway

In the pathway illustrated here, epidermal growth factor (EGF) binds with a tyrosine kinase receptor, leading to activation of the small G protein Ras. Then, Ras activates a MAP-kinase signaling pathway. A series of MAP kinases in the pathway are activated by phosphorylation. The final MAP kinase can regulate several transcription factors, leading to changes in gene expression that affect cell processes.

Signals must be terminated

Once a signal has done its job, it must be terminated. **Signal termination** returns the receptor and each of the components of the signal transduction pathway to their inactive states. This action allows the magnitude of the response to reflect the strength of the signal. Molecules in the system must also be ready to respond to new signals.

We have seen that after a G protein is activated, a subunit of the G protein, a GTPase, catalyzes the hydrolysis of GTP to GDP. This action inactivates the G protein. In the cyclic AMP pathway, any increase in cAMP concentration is temporary. Cyclic AMP is rapidly inactivated by a phosphodiesterase, which converts it to adenosine monophosphate (AMP). Thus, the concentration of cAMP

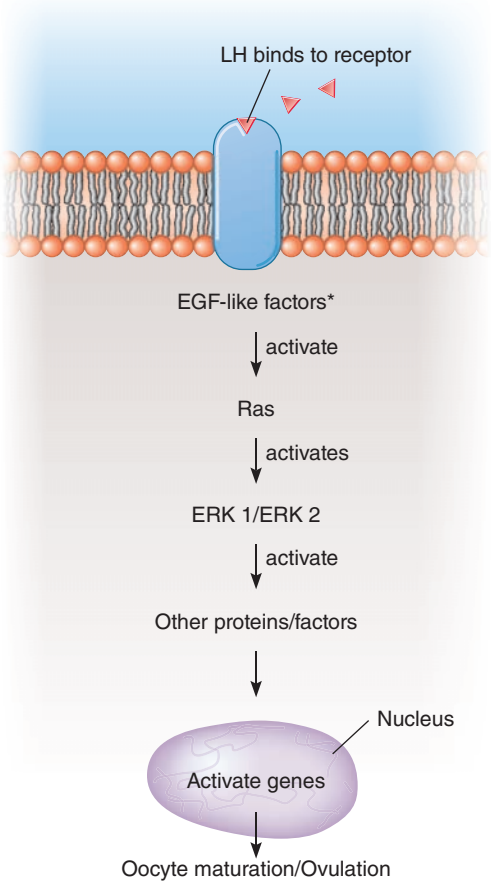
www.konkur.in

KEY EXPERIMENT

QUESTION: Do the signaling molecules ERK 1 and ERK 2 have key functions in signaling pathways leading to maturation of oocytes (eggs) and ovulation (release of a mature egg from the ovary) in mammals?

HYPOTHESIS: The signaling molecules ERK 1 and ERK 2 are key target molecules of the signal sent by the reproductive hormone, luteinizing hormone (LH), and thus are important in oocyte maturation and ovulation in mammals.

EXPERIMENT: The researchers produced a line of mice that were deficient in both ERK 1 and ERK 2. They performed biochemical analyses on the signaling pathway activated by LH. They also examined the ovaries of the mice.



RESULTS AND CONCUSIONS: In mice deficient in both ERK 1 and ERK 2, the signaling pathway from LH was disrupted. As a result, genes regulating oocyte maturation and ovulation were not activated. Oocytes failed to mature and ovulate, and the mice also exhibited reproductive disorders associated with changes in levels of reproductive hormones.

ERK 1 and ERK 2 are key molecules in a signaling pathway that regulates reproduction in mice. These results may lead to greater understanding of certain ovarian disorders that result in infertility in humans.

*EGF = epidermal growth factor

FIGURE 6-14 Identifying key molecules in a signaling pathway that regulates reproduction in mammals

depends on the activity of both adenylyl cyclase, which produces it, and of phosphodiesterase, which breaks it down (see Fig. 6-8). Recall also that in many signaling pathways, each protein kinase activates the next protein kinase in the chain by phosphorylating it; a phosphatase then inactivates it by removing the phosphate group.

Failure to terminate signals can lead to dire consequences. For example, the bacterium that causes cholera is ingested when people drink contaminated water. Cholera is prevalent in areas where water is contaminated with human feces. The cholera bacterium releases a toxin that activates G proteins in the epithelial cells lining the intestine. The toxin chemically changes the G protein so that it no longer switches off. As a result, the G protein continues to stimulate adenylyl cyclase to make cAMP. The cells lining the intestine malfunction, allowing a large flow of chloride ions into the intestine. Water and other ions follow, leading to the severe watery diarrhea that characterizes cholera. The disease is treated by replacing the lost fluid. If untreated, this G protein malfunction can cause death.

Review

- What are some cell responses to signals?
- How do cells amplify signals?
- What is signal termination?

6.6 EVOLUTION OF CELL COMMUNICATION

LEARNING OBJECTIVE

9 Cite evidence supporting a long evolutionary history for cell signaling molecules.

In this chapter, we have examined how the cells of a multicellular organism signal one another and have described a few of the many signal transduction pathways within cells. We have described quorum sensing and other examples of communication between members of a species. We have also discussed communication among members of different species, such as signaling between plants and insects. In our discussion, we have noted many similarities in the types of signals used and in the molecules that cells use to relay signals from the cell surface to the molecules that carry out a specific response. Some signal transduction pathways found in organisms as diverse as yeasts and animals are quite similar.

G proteins, protein kinases, and phosphatases have been highly conserved and are part of signaling pathways in most organisms. Certain disease-causing bacteria have signal transduction pathways similar to those found in eukaryotes. Bacteria may use some of these signal mechanisms to interfere with normal function in the eukaryotic cells they infect. Such similarities in many species suggest evolutionary relationships.

Similarities in cell signaling suggest that the molecules and mechanisms used in cell communication are very old. The evidence suggests that cell communication first evolved in prokaryotes and continued to change over time as new types of organisms evolved. However, the fact that some cell signaling molecules have not

www.konkur.in

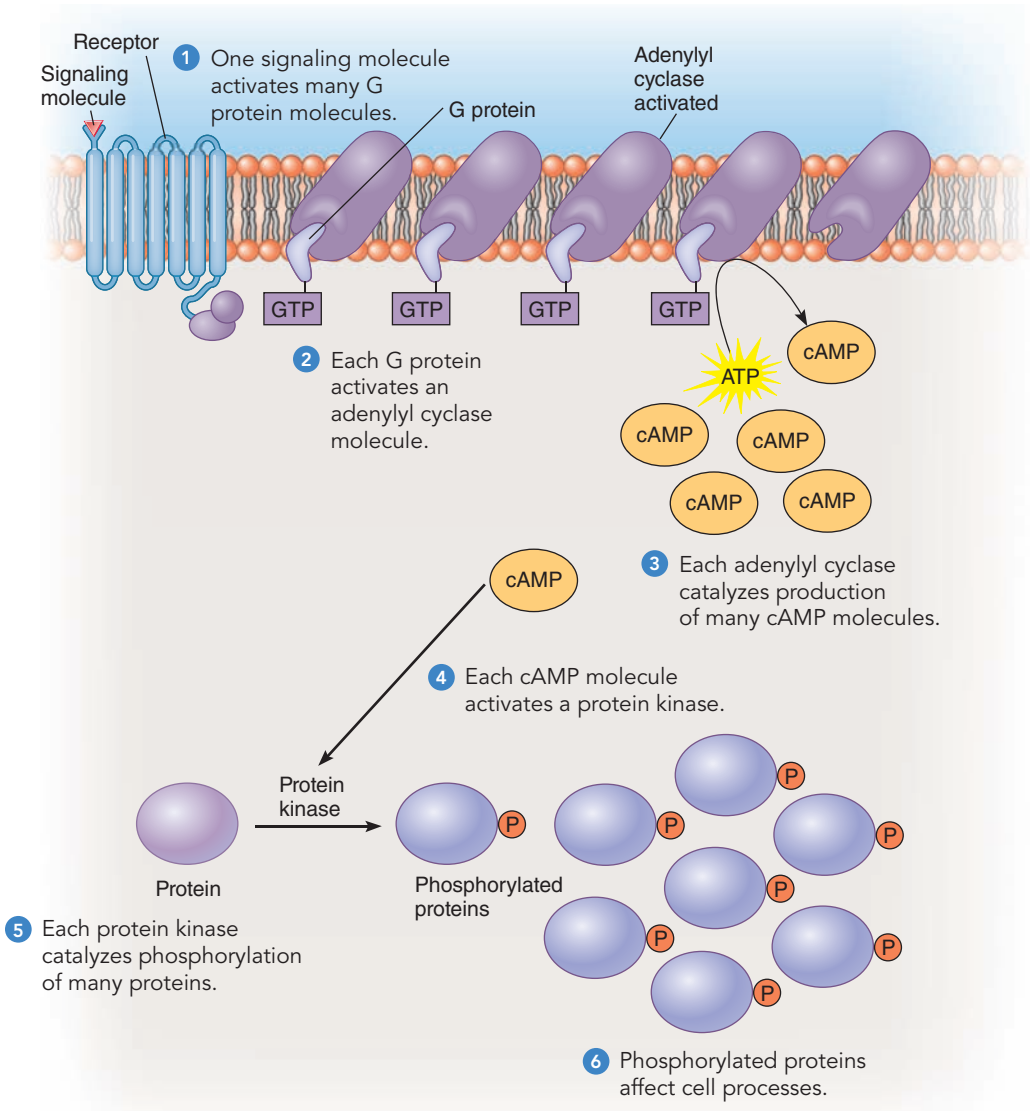

FIGURE 6-15 Signal amplification

The signal is amplified at each step in the pathway so that one activated receptor can give rise to thousands of final products (proteins at the end of the pathway). The response is far greater than what you might expect from a single receptor.

changed very much over time suggests that the importance of these pathways to cell survival has restricted any evolutionary changes that might have made them less effective. Thus, these pathways have weathered the demands of natural selection through millions of years of evolution.

Choanoflagellates, unicellular protists that are thought to be the most recent ancestors of animals, are used as models for studying the early evolution of animals. Choanoflagellates have many of the same proteins found in animals. These tiny organisms have protein kinases similar to those of animals, and a G protein–linked receptor has been identified. These findings indicate that important proteins necessary for cell communication in animals had evolved long before the evolution of animals. As we will discuss in later chapters, similarities and differences in basic molecules, such as G proteins, can be used to trace evolutionary pathways.

Review

- Choanoflagellates and animals have similar protein kinases. What does that suggest about their cell signaling mechanisms?

SUMMARY: FOCUS ON LEARNING OBJECTIVES

6.1 *(page 135)*

1 Describe the four main processes essential for cells to communicate.

- Cells communicate by **cell signaling,** which consists of four main processes: (1) synthesis, release, and transport of signaling molecules; (2) **reception** of information by **target cells;** (3) **signal transduction,** the process in which a receptor converts an extracellular signal into an intracellular signal and relays the signal, leading to a cellular response; and (4) **response** by the cell, for example, some metabolic process may be altered.

6.2 *(page 136)*

2 Compare three types of signaling molecules: neurotransmitters, hormones, and local regulators

- Most neurons (nerve cells) signal one another by releasing chemical compounds called **neurotransmitters.**
- **Hormones** are chemical messengers in plants and animals. In animals, they are secreted by **endocrine glands,** glands that have no ducts. Most hormones diffuse into capillaries and are transported by the blood to target cells.
- **Local regulators** diffuse through the interstitial fluid and act on nearby cells. This is called **paracrine regulation.** Histamine, growth factors, **prostaglandins** (a type of local hormone), and **nitric oxide** (a gaseous signaling molecule that passes into target cells) are examples of local regulators.

6.3 *(page 137)*

3 Identify mechanisms that make reception a highly specific process.

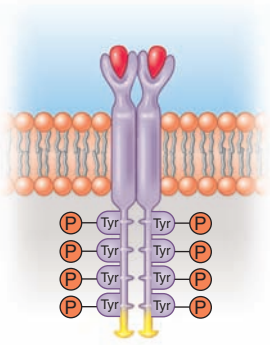
- Each type of receptor has a specific shape, and only the signaling molecule that fits the specific receptor can affect the cell. A cell can have many different types of receptors and can make different

www.konkur.in

receptors at different stages in its life cycle or in response to different conditions. Different types of cells can have different types of receptors.

4 Briefly compare ion channel–linked receptors, G protein–linked receptors, enzyme-linked receptors, and intracellular receptors.

- When a signaling molecule binds to an **ion channel–linked receptor,** the ion channel opens or, in some cases, closes.
- **G protein–linked receptors** are transmembrane proteins that extend into the cytosol or outside the cell. These receptors couple specific signaling molecules to signal transduction pathways inside the cell. The tail of the receptor that extends into the cytosol has a binding site for a specific **G protein,** a regulatory protein that binds to GTP.
- **Enzyme-linked receptors** are transmembrane proteins with a binding site for a signaling molecule outside the cell and a binding site for an enzyme inside the cell. Many enzyme-linked receptors are **tyrosine kinases** in which the enzyme is part of the receptor.



- **Intracellular receptors** are located in the cytosol or in the nucleus. Their ligands are small, hydrophobic molecules that diffuse across the plasma membrane.

6.4 *(page 141)*

5 Compare the actions of the main types of receptors in signal transduction.

- Ion channel–linked receptors convert chemical signals into electrical signals. The gates of many ion channels remain closed until ligands bind to them.
- Many enzyme-linked receptors are tyrosine kinases, enzymes that phosphorylate proteins. Tyrosine kinase receptors activate several different signal transduction pathways. In a **protein kinase cascade,** each molecule in the signaling pathway is phosphorylated by the preceding protein kinase in the chain. The last protein kinase in the cascade activates the target protein by phosphorylation. The target protein alters some process in the cell.
- G protein–linked receptors activate G proteins. A G protein consists of three subunits. It is linked to a molecule of **guanosine diphosphate (GDP),** a molecule similar to ADP but containing the base guanine instead of adenine. When a ligand binds with the receptor, the GDP is released and is replaced by **guanosine triphosphate (GTP).** Then one subunit of the G protein separates from the other two subunits. The activated G protein may initiate a signal transduction pathway by binding with a specific protein in the cell. Some G proteins directly activate enzymes that catalyze changes in certain proteins, leading to changes in cell function.
- Intracellular receptors are located in the cytosol or nucleus. These receptors are **transcription factors** that activate or repress the expression of specific genes.

6 Trace the sequence of events in signal transduction for each of the following second messengers: cyclic AMP, inositol trisphosphate, diacylglycerol, and calcium ions.

- In many signaling systems, the signaling molecule serves as the **first messenger.** Information is relayed by the G protein to a **second messenger,** an intracellular signaling molecule.
- When certain G proteins undergo a conformational change, they bind with and activate **adenylyl cyclase,** an enzyme on the cytoplasmic side of the plasma membrane. Adenylyl cyclase catalyzes the formation of **cyclic AMP (cAMP)** from ATP. Cyclic AMP is a second messenger that activates certain **protein kinase** enzymes that phosphorylate certain proteins. The phosphorylated protein triggers a chain of reactions that lead to some response in the cell.
- Certain G proteins activate the membrane-bound enzyme phospholipase C. This enzyme splits a phospholipid, PIP_2 (phosphotidylinositol-4,5-bisphosphate), into two products, **inositol trisphosphate (IP_3)** and **diacylglycerol (DAG).** IP_3 is a second messenger that can donate phosphate groups to proteins. IP_3 binds to calcium channels in the endoplasmic reticulum, which causes the channels to open and release calcium ions into the cytosol. DAG is a second messenger that activates certain protein kinase enzymes. These enzymes phosphorylate a variety of target proteins.
- Calcium ions can also act as second messengers. They typically combine with the protein **calmodulin,** which then affects the activity of protein kinases and protein phosphatases.

6.5 *(page 147)*

7 Describe three types of responses that cells make to signaling molecules.

- In response to signaling molecules: ion channels open or close; enzyme activity changes leading to metabolic changes and other effects; and specific genes are activated or repressed. These responses can affect cell shape, cell growth, cell division, cell differentiation, and metabolism.

8 Contrast signal amplification with signal termination.

- **Signal amplification** is the process of enhancing the cell's response to a signal as the signal is relayed through a signal transduction pathway. Before it becomes inactive, each enzyme can catalyze the production of numerous product molecules.
- **Signal termination** is the process of inactivating the receptor and each component of the signal transduction pathway once they have done their jobs. Signal termination allows molecules in the system to respond to new signals.

6.6 *(page 150)*

9 Cite evidence supporting a long evolutionary history for cell signaling molecules.

- Molecules important in cell signaling first evolved in prokaryotes. G proteins, protein kinases, and phosphatases have been highly conserved and are part of most signaling pathways.

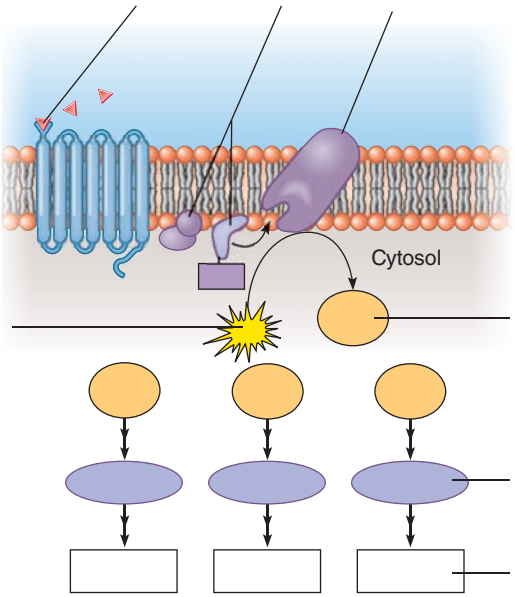
TEST YOUR UNDERSTANDING

1. During signal transduction (a) the cell converts an extracellular signal into an intracellular signal that leads to a change in some cell process (b) a signaling molecule activates or represses several genes (c) each enzyme catalyzes production of one molecule of product (d) relay of the signal is regulated by paracrine regulation (e) the signal is terminated by prostaglandins
2. In paracrine regulation (a) endocrine glands release hormones that are transported by the blood (b) electrical signals are trans-

www.konkur.in

mitted (c) neurotransmitters signal growth factors (d) prostaglandins terminate signals during signal transduction (e) a local regulator signals nearby cells

3. When a signaling molecule binds with a receptor (a) G proteins are inactivated (b) a third messenger is activated (c) cell signaling is terminated (d) the signaling cell is activated (e) the receptor is activated
4. G protein–linked receptors (a) inactivate G proteins (b) activate first messengers (c) consist of 18 transmembrane alpha helices (d) have a tail that extends into the cytosol and a binding site for a G protein (e) are located in the cytoplasm or nucleus
5. An enzyme-linked receptor (a) is an integral membrane protein (b) would not be found on plant cell surfaces (c) forms a dimer with another enzyme-linked receptor when a ligand binds to it (d) is typically an adenylyl cyclase molecule (e) typically activates ion channels
6. G proteins (a) relay a message from an activated receptor to an enzyme that activates a second messenger (b) are GTP molecules (c) terminate cell signaling (d) directly activate protein kinases (e) function as first messengers
7. Which is the correct sequence? 1. protein kinase activated 2. adenylyl cyclase activated 3. cAMP produced 4. proteins phosphorylated 5. G protein activated (a) 1, 2, 3, 5, 4 (b) 5, 3, 2, 1, 4 (c) 5, 2, 3, 4, 1 (d) 5, 2, 3, 1, 4 (e) 2, 3, 1, 4, 5
8. Which is the correct sequence? 1. phospholipase activated 2. G protein activated 3. PIP_2 split 4. proteins phosphorylated 5. DAG produced (a) 1, 2, 5, 3, 4 (b) 2, 1, 3, 5, 4 (c) 4, 2, 3, 1, 5 (d) 5, 2, 3, 1, 4 (e) 2, 3, 5, 4, 1
9. Calcium ions (a) can act as second messengers (b) split calmodulin (c) are kept at higher concentration in the cytosol than in the extracellular fluid (d) are produced in the ER by protein kinases and protein phosphatases (e) typically terminate signaling cascades
10. When growth hormone binds to an enzyme-linked receptor (a) G proteins form a cascade of molecules and are phosphorylated (b) the enzyme portion of the receptor is dephosphorylated (c) the receptor is activated and phorphorylates signaling proteins in the cell (d) an ion channel is opened (e) an immediate signal is sent into the nucleus and specific genes are activated or inhibited
11. Scaffold proteins (a) release kinases and phosphatases into the extracellular fluid (b) increase the probability that an enzyme can be used by several different pathways (c) increase accuracy but slow signaling cascades (d) organize groups of intracellular signaling molecules into signaling complexes (e) are transcription factors found mainly in plant cells
12. Each adenylyl cyclase molecule produces many cAMP molecules. This is an example of (a) receptor up-regulation (b) receptor down-regulation (c) signal amplification (d) scaffold (e) similarities produced by evolution
13. Label the following structures in the diagram: first messenger, G protein, ATP, cAMP (second messenger), protein, cell response. (Consult Fig. 6-7 to check your answers.)



CRITICAL THINKING

1. In many instances, the pathway from signaling molecule to final response in the cell involves complex signaling cascades. Give an example of a complex signaling system, and explain why such complexity may have advantages.
2. More than 500 genes have been identified in the human genome that code for protein kinases. What does this imply regarding protein kinases? Explain your answer.
3. **EVOLUTION LINK.** Cell signaling in plant and animal cells is similar in some ways and different in others. Offer one or more hypotheses for these similarities and differences, and cite specific examples.
4. **EVOLUTION LINK.** Some of the same G protein–linked receptors and signal transduction pathways found in plants and animals have been identified in fungi and algae. What does this suggest about the evolution of these molecules? What does it suggest about these molecules and pathways?
5. **SCIENCE, TECHNOLOGY, AND SOCIETY.** Mutant Ras proteins have been associated with many types of human cancer. Hundreds of millions of dollars are required for the basic research and development of each new drug. As a citizen are you willing to help fund development of new medications to treat cancer through government-sponsored research? Why or why not? If not, what alternatives do you propose?

7 Energy and Metabolism

Karen Su/Corbis

Giant panda (*Ailuropoda melanoleuca*). The chemical energy produced by photosynthesis and stored in bamboo leaves transfers to the panda as it eats.

KEY CONCEPTS

7.1 Energy, the capacity to do work, can be kinetic energy (energy of motion) or potential energy (energy due to position or state).

7.2 Energy cannot be created or destroyed (the first law of thermodynamics), but the total amount of energy available to do work in a closed system decreases over time (the second law of thermodynamics). Organisms do not violate the laws of thermodynamics because, as open systems, they use energy obtained from their surroundings to do work.

7.3 In cells, energy-releasing (exergonic) processes drive energy-requiring (endergonic) processes.

7.4 ATP plays a central role in cell energy metabolism by linking exergonic and endergonic reactions. ATP transfers energy by transferring a phosphate group.

7.5 The transfer of electrons in redox reactions is another way that cells transfer energy.

7.6 As biological catalysts, enzymes increase the rate of specific chemical reactions. The activity of an enzyme is influenced by temperature, pH, the presence of cofactors, and inhibitors and/or activators.

All living things require energy to carry out life processes. It may seem obvious that cells need energy to grow and reproduce, but even nongrowing cells need energy simply to maintain themselves. Cells obtain energy in many forms, but that energy can seldom be used directly to power cell processes. For this reason, cells have mechanisms that convert energy from one form to another. The ordered systems of the cell provide the information that makes these energy transformations possible. Because most components of these energy conversion systems evolved very early in the history of life, many aspects of energy metabolism tend to be similar in a wide range of organisms.

The sun is the ultimate source of almost all the energy that powers life; this *radiant energy* flows from the sun as electromagnetic waves. Plants and other photosynthetic organisms capture about 0.02% of the sun's energy that reaches Earth. As discussed in Chapter 9, photosynthetic organisms convert radiant energy to *chemical energy* in the bonds of organic molecules. This chemical energy becomes available to plants, animals such as the giant panda shown in the photograph, and other organisms through the process of cellular respiration. In cellular respiration, discussed in Chapter 8, organic molecules are broken apart and their energy is converted to more immediately usable forms.

www.konkur.in

This chapter focuses on some of the basic principles that govern how cells capture, transfer, store, and use energy. We discuss the functions of adenosine triphosphate (ATP) and other molecules used in energy conversions, including those that transfer electrons in oxidation–reduction (redox) reactions. We also pay particular attention to the essential role of enzymes in cell energy dynamics. The flow of energy in ecosystems is discussed in Chapter 55.

7.1 BIOLOGICAL WORK

LEARNING OBJECTIVES

1 Define *energy*, emphasizing how it is related to work and to heat.
2 Use examples to contrast potential energy and kinetic energy.

Energy, one of the most important concepts in biology, can be understood in the context of **matter,** which is anything that has mass and takes up space. **Energy** is defined as the capacity to do work, which is any change in the state or motion of matter. Technically, mass is a form of energy, which is the basis behind the energy generated by the sun and other stars. More than 4 billion kilograms of matter per second are converted into energy in the sun.

Biologists generally express energy in units of work—**kilojoules (kJ).** It can also be expressed in units of *heat energy*—**kilocalories (kcal)**—thermal energy that flows from an object with a higher temperature to an object with a lower temperature. One kilocalorie is equal to 4.184 kJ. Heat energy cannot do cell work because a cell is too small to have regions that differ in temperature. For that reason, the unit most biologists prefer today is the kilojoule. However, we will use both units because references to the kilocalorie are common in the scientific literature.

Organisms carry out conversions between potential energy and kinetic energy

When an archer draws a bow, **kinetic energy,** the energy of motion, is used and work is performed (**FIG. 7-1**). The resulting tension in the bow and string represents stored, or potential, energy. **Potential energy** is the capacity to do work as a result of position or state. When the string is released, this potential energy is converted to kinetic energy in the motion of the bow, which propels the arrow.

Most actions of an organism involve a series of energy transformations that occur as kinetic energy is converted to potential energy or as potential energy is converted to kinetic energy. **Chemical energy,** potential energy stored in chemical bonds, is of particular importance to organisms. In our example, the chemical energy of food molecules is converted to kinetic energy in the muscle cells of the archer. The contraction of the archer's muscles, like many of the activities performed by an organism, is an example of *mechanical energy,* which performs work by moving matter.

Review

- You exert tension on a spring and then release it. How do these actions relate to work, potential energy, and kinetic energy?

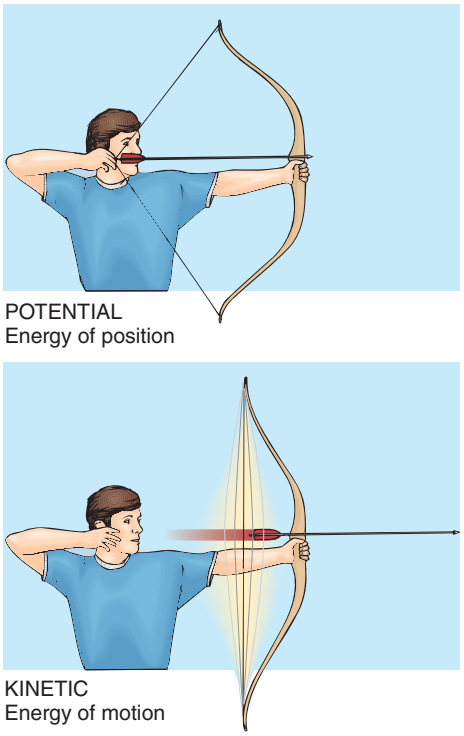

FIGURE 7-1 Potential versus kinetic energy
The potential chemical energy released by cellular respiration is converted to kinetic energy in the muscles, which do the work of drawing the bow. The potential energy stored in the drawn bow is transformed into kinetic energy as the bowstring pushes the arrow toward its target.

7.2 THE LAWS OF THERMODYNAMICS

LEARNING OBJECTIVE

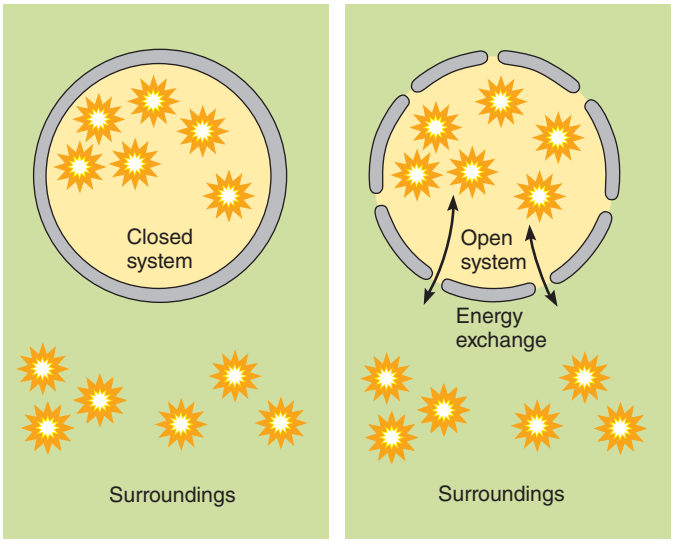
3 State the first and second laws of thermodynamics, and discuss the implications of these laws as they relate to organisms.

Thermodynamics, the study of energy and its transformations, governs all activities of the universe, from the life and death of cells to the life and death of stars. When considering thermodynamics, scientists use the term *system* to refer to an object that they are studying, whether a cell, an organism, or planet Earth. The rest of the universe other than the system being studied constitutes the *surroundings.* A **closed system** does not exchange energy with its surroundings, whereas an **open system** can exchange energy with its surroundings (**FIG. 7-2**). Biological systems are open systems. Two laws about energy apply to all things in the universe: the first and second laws of thermodynamics.

The total energy in the universe does not change

According to the **first law of thermodynamics,** energy cannot be created or destroyed, although it can be transferred or converted from one form to another, including conversions between matter

www.konkur.in



(a) A closed system does not exchange energy with its surroundings.

(b) An open system exchanges energy with its surroundings.

FIGURE 7-2 Closed and open systems

and energy. As far as we know, the total mass-energy present in the universe when it formed, almost 14 billion years ago, equals the amount of energy present in the universe today. This is all the energy that can ever be present in the universe. Similarly, the energy of any system plus its surroundings is constant. A system may absorb energy from its surroundings, or it may give up some energy to its surroundings, but the total energy content of that system plus its surroundings is always the same.

As specified by the first law of thermodynamics, organisms cannot create the energy they require in order to live. Instead, they must capture energy from the environment and transform it to a form that can be used for biological work.

The entropy of the universe is increasing

The **second law of thermodynamics** states that when energy is converted from one form to another, some usable energy—that is, energy available to do work—is converted into heat that disperses into the surroundings (see Fig. 55-1 for an illustration of energy flow through an ecosystem). As you learned in Chapter 2, **heat** is the kinetic energy of randomly moving particles. Unlike *heat energy,* which flows from an object with a higher temperature to one with a lower temperature, this random motion cannot perform work. As a result, the amount of usable energy available to do work in the universe decreases over time.

It is important to understand that the second law of thermodynamics is consistent with the first law; that is, the total amount of energy in the universe is *not* decreasing with time. However, the total amount of energy in the universe that is available to do work is decreasing over time.

Less-usable energy is more diffuse, or disorganized. **Entropy** (***S***) is a measure of this disorder, or randomness; organized, usable energy has a low entropy, whereas disorganized energy, such as heat, has a high entropy.

Entropy is continuously increasing in the universe in all natural processes. Maybe at some time, billions of years from now, all energy will exist as heat uniformly distributed throughout the universe. If that happens, the universe will cease to operate, because no work will be possible. Everything will be at the same temperature, so there will be no way to convert the thermal energy of the universe into usable mechanical energy.

As a consequence of the second law of thermodynamics, no process requiring an energy conversion is ever 100% efficient, because much of the energy is dispersed as heat, increasing entropy. For example, an automobile engine, which converts the chemical energy of gasoline to mechanical energy, is between 20% and 30% efficient. Thus, only 20% to 30% of the original energy stored in the chemical bonds of the gasoline molecules is actually transformed into mechanical energy; the other 70% to 80% dissipates as waste heat. Energy use in your cells is about 40% efficient, with the remaining energy given to the surroundings as heat.

Organisms have a high degree of organization, and at first glance they may appear to refute the second law of thermodynamics. As organisms grow and develop, they maintain a high level of order and do not appear to become more disorganized. However, organisms are open systems; they maintain their degree of order over time only with the constant input of energy from their surroundings. This is why plants must photosynthesize and animals must eat. Although the order within organisms may tend to increase temporarily, the total entropy of the universe (organisms plus surroundings) always increases over time.

Review

- What is the first law of thermodynamics? the second law?
- Life is sometimes described as a constant struggle against the second law of thermodynamics. How do organisms succeed in this struggle without violating the second law?

7.3 ENERGY AND METABOLISM

LEARNING OBJECTIVES

4 Discuss how changes in free energy in a reaction are related to changes in entropy and enthalpy.

5 Distinguish between exergonic and endergonic reactions, and give examples of how they may be coupled.

6 Compare the energy dynamics of a reaction at equilibrium with the dynamics of a reaction not at equilibrium.

The chemical reactions that enable an organism to carry on its activities—to grow, move, maintain and repair itself; reproduce; and respond to stimuli—together make up its metabolism. Recall from Chapter 1 that **metabolism** is the sum of all the chemical activities taking place in an organism. An organism's metabolism consists of many intersecting series of chemical reactions, or pathways. Two main types of metabolism are anabolism and catabolism. **Anabolism** includes the various pathways in which complex molecules are synthesized from simpler substances, such as in the linking of amino acids to form proteins. **Catabolism** includes the pathways in which larger molecules are broken down into smaller ones, such as in the degradation of starch to form monosaccharides.

www.konkur.in

As you will see, these changes involve not only alterations in the arrangement of atoms but also various energy transformations. Catabolism and anabolism are complementary processes; catabolic pathways involve an overall release of energy, some of which powers anabolic pathways, which have an overall energy requirement. In the following sections, we discuss how to predict whether a particular chemical reaction requires energy or releases it.

Enthalpy is the total potential energy of a system

In the course of any chemical reaction, including the metabolic reactions of a cell, chemical bonds break and new and different bonds may form. Every specific type of chemical bond has a certain amount of *bond energy,* defined as the energy required to break that bond. The total bond energy is essentially equivalent to the total potential energy of the system, a quantity known as **enthalpy (H).**

Free energy is available to do cell work

Entropy and enthalpy are related by a third type of energy, termed **free energy (G),** which is the amount of energy available to do work under the conditions of a biochemical reaction. (G, also known as "Gibbs free energy," is named for J. W. Gibbs, a Yale professor who was one of the founders of the science of thermodynamics.) Free energy, the only kind of energy that can do cell work, is the aspect of thermodynamics of greatest interest to a biologist. Enthalpy, free energy, and entropy are related by the following equation:

$$H = G + TS$$

in which H is enthalpy; G is free energy; T is the absolute temperature of the system, expressed in Kelvin units; and S is entropy. Disregarding temperature for the moment, enthalpy (the total energy of a system) is equal to free energy (the usable energy) plus entropy (the unusable energy).

A rearrangement of the equation shows that as entropy increases, the amount of free energy decreases:

$$G = H - TS$$

If we assume that entropy is zero, the free energy is simply equal to the total potential energy (enthalpy); an increase in entropy reduces the amount of free energy.

What is the significance of the temperature (T)? Remember that as the temperature increases, there is an increase in random molecular motion, which contributes to disorder and multiplies the effect of the entropy term.

Chemical reactions involve changes in free energy

Biologists analyze the role of energy in the many biochemical reactions of metabolism. Although the total free energy of a system (G) cannot be effectively measured, the equation $G = H - TS$ can be extended to predict whether a particular chemical reaction will release energy or require an input of energy. The reason is that *changes* in free energy can be measured. Scientists use the Greek capital letter delta (Δ) to denote any change that occurs in the system between its initial state before the reaction and its final state after the reaction. To express what happens with respect to energy in a chemical reaction, the equation becomes

$$\Delta G = \Delta H - T\Delta S$$

Notice that the temperature does not change; it is held constant during the reaction. Thus, the change in free energy (ΔG) during the reaction is equal to the change in enthalpy (ΔH) minus the product of the absolute temperature (T) in Kelvin units multiplied by the change in entropy (ΔS). Scientists express ΔG and ΔH in kilojoules or kilocalories per mole; they express ΔS in kilojoules or kilocalories per Kelvin unit.

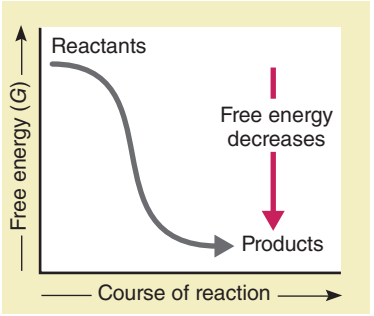
Free energy decreases during an exergonic reaction

An **exergonic reaction** releases energy and is said to be a spontaneous or a "downhill" reaction, from higher to lower free energy (**FIG. 7-3a**). Because the total free energy in its final state is less than the total free energy in its initial state, ΔG is a negative number for exergonic reactions.

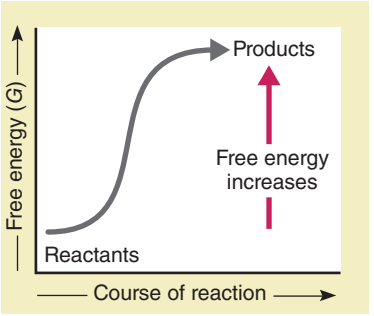
The term *spontaneous* may give the false impression that such reactions are always instantaneous. In fact, spontaneous reactions do not necessarily occur readily; some are extremely slow. The reason is that energy, known as *activation energy,* is required to initiate every reaction, even a spontaneous one. We discuss activation energy later in the chapter.

Free energy increases during an endergonic reaction

An **endergonic reaction** is a reaction in which there is a gain of free energy (**FIG. 7-3b**). Because the free energy of the products is greater than the free energy of the reactants, ΔG has a positive value. Such a reaction cannot take place in isolation. Instead, it must occur in such a way that energy can be supplied from the



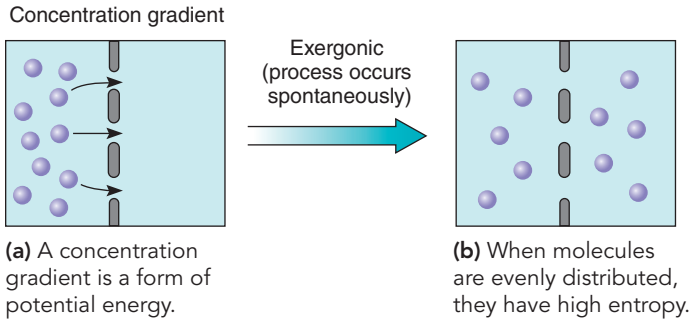
(a) In an exergonic reaction, there is a net loss of free energy. The products have less free energy than was present in the reactants, and the reaction proceeds spontaneously.



(b) In an endergonic reaction, there is a net gain of free energy. The products have more free energy than was present in the reactants.

FIGURE 7-3 ***Animated*** **Exergonic and endergonic reactions**

www.konkur.in



(a) A concentration gradient is a form of potential energy.

(b) When molecules are evenly distributed, they have high entropy.

FIGURE 7-4 Entropy and diffusion

The tendency of entropy to increase can be used to produce work, in this case, diffusion.

surroundings. Of course, many energy-requiring reactions take place in cells, and as you will see, metabolic mechanisms have evolved that supply the energy to "drive" these nonspontaneous cell reactions in a particular direction.

Diffusion is an exergonic process

In Chapter 5, you saw that randomly moving particles diffuse down their own concentration gradient (**FIG. 7-4**). Although the movements of the individual particles are random, net movement of the group of particles seems to be directional. What provides energy for this apparently directed process? A **concentration gradient,** with a region of higher concentration and another region of lower concentration, is an orderly state. A cell must expend energy to produce a concentration gradient. Because work is done to produce this order, a concentration gradient is a form of potential energy. As the particles move about randomly, the gradient becomes degraded. Thus, free energy decreases as entropy increases.

In cellular respiration and photosynthesis, the potential energy stored in a concentration gradient of hydrogen ions (H^+) is transformed into chemical energy in adenosine triphosphate (ATP) as the hydrogen ions pass through a membrane down their concentration gradient. This important concept, known as *chemiosmosis,* is discussed in detail in Chapters 8 and 9.

Free-energy changes depend on the concentrations of reactants and products

According to the second law of thermodynamics, any process that increases entropy can do work. As we have discussed, differences in the concentration of a substance, such as between two different parts of a cell, represent a more orderly state than that when the substance is diffused homogeneously throughout the cell. Free-energy changes in any chemical reaction depend mainly on the difference in bond energies (enthalpy, H) between reactants and products. Free energy also depends on *concentrations* of both reactants and products.

In most biochemical reactions there is little intrinsic free-energy difference between reactants and products. Such reactions are reversible, indicated by drawing double arrows:

$$A \rightleftharpoons B$$

At the beginning of a reaction, only the reactant molecules (A) may be present. As the reaction proceeds, the concentration of the reactant molecules decreases and the concentration of the product molecules (B) increases. As the concentration of the product molecules increases, they may have enough free energy to initiate the reverse reaction. The reaction thus proceeds in both directions simultaneously; if undisturbed, it eventually reaches a state of **dynamic equilibrium,** in which the rate of the reverse reaction equals the rate of the forward reaction. At equilibrium there is no net change in the system; a reverse reaction balances every forward reaction.

At a given temperature and pressure, each reaction has its own characteristic equilibrium. For any given reaction, chemists can perform experiments and calculations to determine the relative concentrations of reactants and products present at equilibrium. If the reactants have much greater intrinsic free energy than the products, the reaction goes almost to completion; that is, it reaches equilibrium at a point at which most of the reactants have been converted to products. Reactions in which the reactants have much less intrinsic free energy than the products reach equilibrium at a point where very few of the reactant molecules have been converted to products.

If you increase the initial concentration of A, then the reaction will "shift to the right," and more A will be converted to B. A similar effect can be obtained if B is removed from the reaction mixture. The reaction always shifts in the direction that reestablishes equilibrium so that the proportions of reactants and products characteristic of that reaction at equilibrium are restored. The opposite effect occurs if the concentration of B increases or if A is removed; here the system "shifts to the left." The actual free-energy change that occurs during a reaction is defined mathematically to include these effects, which stem from the relative initial concentrations of reactants and products. Cells use energy to manipulate the relative concentrations of reactants and products of almost every reaction. Cell reactions are virtually never at equilibrium. By displacing their reactions far from equilibrium, cells supply energy to endergonic reactions and direct their metabolism according to their needs.

Cells drive endergonic reactions by coupling them to exergonic reactions

Many metabolic reactions, such as protein synthesis, are anabolic and endergonic. Because an endergonic reaction cannot take place without an input of energy, endergonic reactions are coupled to exergonic reactions. In **coupled reactions,** the thermodynamically favorable exergonic reaction provides the energy required to drive the thermodynamically unfavorable endergonic reaction. The endergonic reaction proceeds only if it absorbs free energy released by the exergonic reaction to which it is coupled.

Consider the free-energy change, ΔG, in the following reaction:

$$(1)\ A \longrightarrow B \qquad \Delta G = +20.9\ \text{kJ/mol}\ (+5\ \text{kcal/mol})$$

www.konkur.in

Because ΔG has a positive value, you know that the product of this reaction has more free energy than the reactant. This is an endergonic reaction. It is not spontaneous and does not take place without an energy source.

By contrast, consider the following reaction:

(2) C ⟶ D $\Delta G = -33.5$ kJ/mol (−8 kcal/mol)

The negative value of ΔG tells you that the free energy of the reactant is greater than the free energy of the product. This exergonic reaction proceeds spontaneously.

You can sum up reactions 1 and 2 as follows:

(1) A ⟶ B	$\Delta G = +20.9$ kJ/mol (+5 kcal/mol)
(2) C ⟶ D	$\Delta G = -33.5$ kJ/mol (−8 kcal/mol)
Overall	$\Delta G = -12.6$ kJ/mol (−3 kcal/mol)

Because thermodynamics considers the overall changes in these two reactions, which show a net negative value of ΔG, the two reactions taken together are exergonic.

The fact that scientists can write reactions this way is a useful bookkeeping device, but it does not mean that an exergonic reaction mysteriously transfers energy to an endergonic "bystander" reaction. However, these reactions are coupled if their pathways are altered so a common intermediate links them. Reactions 1 and 2 might be coupled by an intermediate (I) in the following way:

(3) A + C ⟶ I	$\Delta G = -8.4$ kJ/mol (−2 kcal/mol)
(4) I ⟶ B + D	$\Delta G = -4.2$ kJ/mol (−1 kcal/mol)
Overall	$\Delta G = -12.6$ kJ/mol (−3 kcal/mol)

Note that reactions 3 and 4 are sequential. Thus, the reaction pathways have changed, but overall the reactants (A and C) and products (B and D) are the same, and the free-energy change is the same.

Generally, for each endergonic reaction occurring in a living cell there is a coupled exergonic reaction to drive it. Often the exergonic reaction involves the breakdown of ATP. Now let's examine specific examples of the role of ATP in energy coupling.

Review

- Consider the free-energy change in a reaction in which enthalpy decreases and entropy increases. Is ΔG zero, or does it have a positive value or a negative value? Is the reaction endergonic or exergonic?
- Why can't a reaction at equilibrium do work?

7.4 ATP, THE ENERGY CURRENCY OF THE CELL

LEARNING OBJECTIVE

7 Explain how the chemical structure of ATP allows it to transfer a phosphate group and discuss the central role of ATP in the overall energy metabolism of the cell.

In all living cells, energy is temporarily packaged within a remarkable chemical compound called **adenosine triphosphate (ATP),** which holds readily available energy for very short periods. We may think of ATP as the energy currency of the cell. When you work to earn money, you might say your energy is symbolically stored in the money you earn. The energy the cell requires for immediate use is temporarily stored in ATP, which is like cash. When you earn extra money, you may deposit some in the bank; similarly, a cell may deposit energy in the chemical bonds of lipids, starch, or glycogen. Moreover, just as you dare not make less money than you spend, the cell must avoid energy bankruptcy, which would mean its death. Finally, just as you probably do not keep money you earn very long, the cell continuously spends its ATP, which must be replaced immediately.

ATP is a nucleotide consisting of three main parts: adenine, a nitrogen-containing organic base; ribose, a five-carbon sugar; and three phosphate groups, identifiable as phosphorus atoms surrounded by oxygen atoms (**FIG. 7-5**). Notice that the phosphate

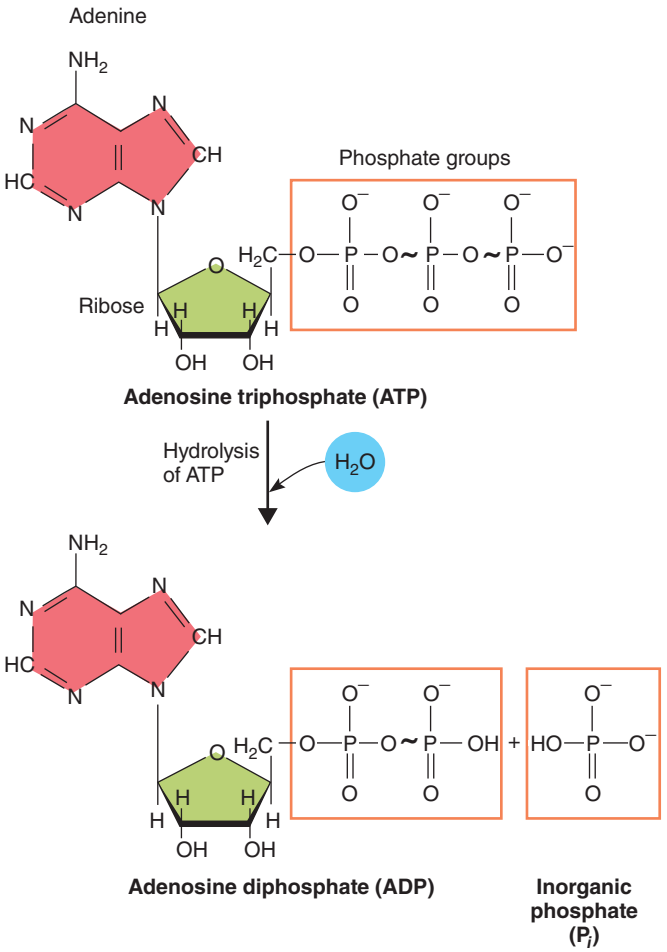


FIGURE 7-5 *Animated* ATP and ADP

ATP, the energy currency of all living things, consists of adenine, ribose, and three phosphate groups. The hydrolysis of ATP, an exergonic reaction, yields ADP and inorganic phosphate. (The black wavy lines indicate unstable bonds. These bonds allow the phosphates to be transferred to other molecules, making them more reactive.)

www.konkur.in

groups are bonded to the end of the molecule in a series, rather like three cars behind a locomotive, and, like the cars of a train, they can be attached and detached.

ATP donates energy through the transfer of a phosphate group

When the terminal phosphate is removed from ATP, the remaining molecule is adenosine diphosphate (ADP) (see Fig. 7-5). If the phosphate group is not transferred to another molecule, it is released as inorganic phosphate (P_i). This is an exergonic reaction with a relatively large negative value of ΔG. (Calculations of the free energy of ATP hydrolysis vary somewhat, but range between about −28 and −37 kJ/mol, or −6.8 to −8.7 kcal/mol.)

(5) $ATP + H_2O \longrightarrow ADP + P_i$
$\Delta G = -32$ kJ/mol (or −7.6 kcal/mol)

Reaction 5 can be coupled to endergonic reactions in cells. Consider the following endergonic reaction, in which two monosaccharides, glucose and fructose, form the disaccharide sucrose.

(6) glucose + fructose $\longrightarrow$ sucrose + H_2O
$\Delta G = +27$ kJ/mol (or +6.5 kcal/mol)

With a free-energy change of −32 kJ/mol (−7.6 kcal/mol), the hydrolysis of ATP in reaction 5 can drive reaction 6, but only if the reactions are coupled through a common intermediate.

The following series of reactions is a simplified version of an alternative pathway that some bacteria use:

(7) glucose + ATP $\longrightarrow$ glucose-P + ADP

(8) glucose-P + fructose $\longrightarrow$ sucrose + P_i

Recall from Chapter 6 that a **phosphorylation reaction** is one in which a phosphate group is transferred to some other compound. In reaction 7 glucose becomes phosphorylated to form glucose phosphate (glucose-P), the intermediate that links the two reactions. Glucose-P, which corresponds to I in reactions 3 and 4, reacts exergonically with fructose to form sucrose. For energy coupling to work in this way, reactions 7 and 8 must occur in sequence. It is convenient to summarize the reactions thus:

(9) glucose + fructose + ATP $\longrightarrow$ sucrose + ADP + P_i
$\Delta G = -5$ kJ/mol (−1.2 kcal/mol)

When you encounter an equation written in this way, remember that it is actually a summary of a series of reactions and that transitory intermediate products (in this case, glucose-P) are sometimes not shown.

ATP links exergonic and endergonic reactions

We have just discussed how the transfer of a phosphate group from ATP to some other compound is coupled to endergonic reactions in the cell. Conversely, adding a phosphate group to adenosine monophosphate, or AMP (forming ADP), or to ADP (forming ATP) requires coupling to exergonic reactions in the cell.

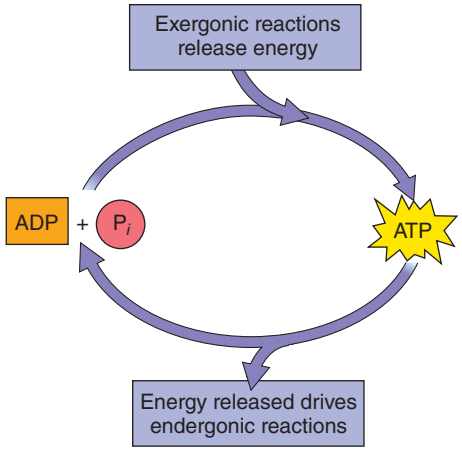

FIGURE 7-6 **ATP links exergonic and endergonic reactions**
Exergonic reactions in catabolic pathways (*top*) supply energy to drive the endergonic formation of ATP from ADP. Conversely, the exergonic hydrolysis of ATP supplies energy to endergonic reactions in anabolic pathways (*bottom*).

$AMP + P_i + \text{energy} \longrightarrow ADP$

$ADP + P_i + \text{energy} \longrightarrow ATP$

Thus, ATP occupies an intermediate position in the metabolism of the cell and is an important link between exergonic reactions, which are generally components of *catabolic pathways,* and endergonic reactions, which are generally part of *anabolic pathways* (**FIG. 7-6**).

The cell maintains a very high ratio of ATP to ADP

The cell maintains a ratio of ATP to ADP far from the equilibrium point. ATP constantly forms from ADP and inorganic phosphate as nutrients break down in cellular respiration or as photosynthesis traps the radiant energy of sunlight. At any time, a typical cell contains more than 10 ATP molecules for every ADP molecule. The fact that the cell maintains the ATP concentration at such a high level (relative to the concentration of ADP) makes its hydrolysis reaction even more strongly exergonic and more able to drive the endergonic reactions to which it is coupled.

Although the cell maintains a high ratio of ATP to ADP, the cell cannot store large quantities of ATP. The concentration of ATP is always very low, less than 1 mmol/L. In fact, studies suggest that a bacterial cell has no more than a 1-second supply of ATP. Thus, it uses ATP molecules almost as quickly as they are produced. A healthy adult human at rest uses about 45 kg (100 lb) of ATP each day, but the amount present in the body at any given moment is less than 1 g (0.035 oz). Every second in every cell, an estimated 10 million molecules of ATP are made from ADP and phosphate, and an equal number of ATPs transfer their phosphate groups, along with their energy, to whatever chemical reactions need them.

Review

- Why do coupled reactions typically have common intermediates?

www.konkur.in

- Give a generalized example of a coupled reaction involving ATP, distinguishing between the exergonic and endergonic reactions.
- Why is the ATP concentration in a cell about 10 times the concentration of ADP?

7.5 ENERGY TRANSFER IN REDOX REACTIONS

LEARNING OBJECTIVE

8 Relate the transfer of electrons (or hydrogen atoms) to the transfer of energy.

You have seen that cells transfer energy through the transfer of a phosphate group from ATP. Energy is also transferred through the transfer of electrons. As discussed in Chapter 2, oxidation is the chemical process in which a substance loses electrons, whereas reduction is the complementary process in which a substance gains electrons. Because electrons released during an oxidation reaction cannot exist in the free state in living cells, every oxidation reaction must be accompanied by a reduction reaction in which the electrons are accepted by another atom, ion, or molecule. Oxidation and reduction reactions are often called redox reactions because they occur simultaneously. The substance that becomes oxidized gives up energy as it releases electrons, and the substance that becomes reduced receives energy as it gains electrons.

Redox reactions often occur in a series, as electrons are transferred from one molecule to another. These electron transfers, which are equivalent to energy transfers, are an essential part of cellular respiration, photosynthesis, and many other chemical processes. Redox reactions, for example, release the energy stored in food molecules so that ATP can be synthesized using that energy.

Most electron carriers transfer hydrogen atoms

Generally, it is not easy to remove one or more electrons from a covalent compound; it is much easier to remove a whole atom. For this reason, redox reactions in cells usually involve the transfer of a hydrogen atom rather than just an electron. A hydrogen atom contains an electron, plus a proton that does not participate in the oxidation–reduction reaction.

When an electron, either singly or as part of a hydrogen atom, is removed from an organic compound, it takes with it some of the energy stored in the chemical bond of which it was a part. That electron, along with its energy, is transferred to an acceptor molecule. An electron progressively loses free energy as it is transferred from one acceptor to another.

One of the most common acceptor molecules in cellular processes is **nicotinamide adenine dinucleotide** ($\mathbf{NAD^+}$). When NAD^+ becomes reduced, it temporarily stores large amounts of free energy. Here is a generalized equation showing the transfer of hydrogen from a compound, which we call X, to NAD^+:

$$XH_2 + NAD^+ \longrightarrow X + NADH + H^+$$

(Oxidized) (Reduced)

Notice that the NAD^+ becomes reduced when it combines with hydrogen. NAD^+ is an ion with a net charge of +1. When 2 electrons and 1 proton are added, the charge is neutralized and the reduced form of the compound, **NADH,** is produced (**FIG. 7-7**). (Although the correct way to write the reduced form of NAD^+

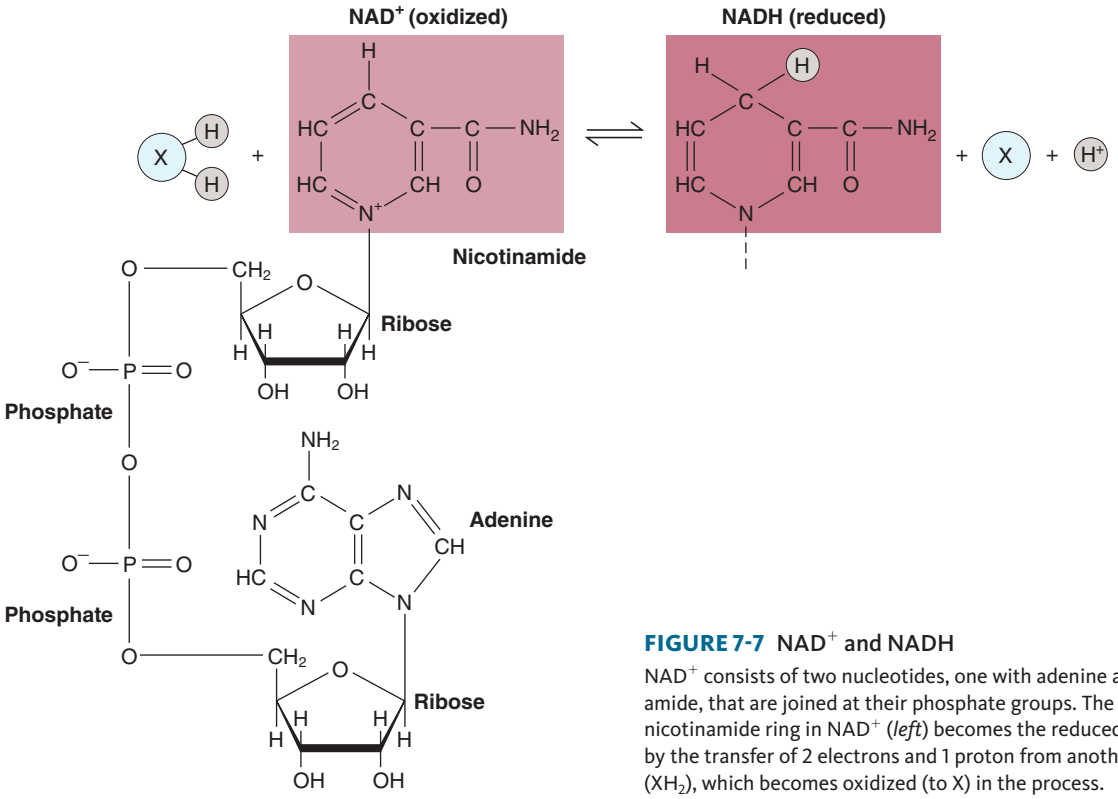

FIGURE 7-7 NAD^+ and NADH

NAD^+ consists of two nucleotides, one with adenine and one with nicotinamide, that are joined at their phosphate groups. The oxidized form of the nicotinamide ring in NAD^+ (*left*) becomes the reduced form in NADH (*right*) by the transfer of 2 electrons and 1 proton from another organic compound (XH_2), which becomes oxidized (to X) in the process.

www.konkur.in

is NADH + H^+, for simplicity we present the reduced form as NADH in this book.) Some energy stored in the bonds holding the hydrogen atoms to molecule X has been transferred by this redox reaction and is temporarily held by NADH. When NADH transfers the electrons to some other molecule, some of their energy is transferred. This energy is usually then transferred through a series of reactions that ultimately result in the formation of ATP (discussed in Chapter 8).

Nicotinamide adenine dinucleotide phosphate ($NADP^+$) is a hydrogen acceptor that is chemically similar to NAD^+ but has an extra phosphate group. Unlike NADH, the reduced form of $NADP^+$, abbreviated **NADPH,** is not involved in ATP synthesis. Instead, the electrons of NADPH are used more directly to provide energy for certain reactions, including certain essential reactions of photosynthesis (discussed in Chapter 9).

Other important hydrogen acceptors or electron acceptors are FAD and the cytochromes. Flavin adenine dinucleotide (FAD) is a nucleotide that accepts hydrogen atoms and their electrons; its reduced form is $FADH_2$. The cytochromes are proteins that contain iron; the iron component accepts electrons from hydrogen atoms and then transfers these electrons to some other compound. Like NAD^+ and $NADP^+$, FAD and the cytochromes are electron transfer agents. Each exists in a *reduced state,* in which it has more free energy, or in an *oxidized state,* in which it has less. Each is an essential component of many redox reaction sequences in cells.

Review

- Which has the most energy, the oxidized form of a substance or its reduced form? Why?

7.6 ENZYMES

LEARNING OBJECTIVES

9 Explain how an enzyme lowers the required energy of activation for a reaction.

10 Describe specific ways enzymes are regulated.

The principles of thermodynamics help us predict whether a reaction can occur, but they tell us nothing about the speed of the reaction. The breakdown of glucose, for example, is an exergonic reaction, yet a glucose solution stays unchanged virtually indefinitely in a bottle if it is kept free of bacteria and molds and not subjected to high temperatures or strong acids or bases. Cells cannot wait for centuries for glucose to break down, nor can they use extreme conditions to cleave glucose molecules. Cells regulate the rates of chemical reactions with **enzymes,** which are biological **catalysts** that increase the speed of a chemical reaction without being consumed by the reaction. Although most enzymes are proteins, scientists have learned that some types of RNA molecules have catalytic activity as well (catalytic RNA is discussed in Chapter 13).

Cells require a steady release of energy, and they must regulate that release to meet metabolic energy requirements. Metabolic processes generally proceed by a series of steps such that a molecule may go through as many as 20 or 30 chemical transformations before it reaches some final state. Even then, the seemingly completed molecule may enter yet another chemical pathway and become totally transformed or consumed to release energy. The changing needs of the cell require a system of flexible metabolic control. The key directors of this control system are enzymes.

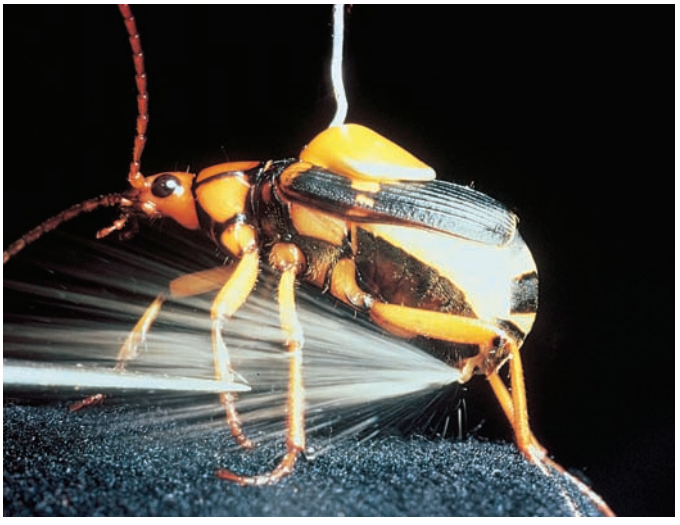
The catalytic ability of some enzymes is truly impressive. For example, hydrogen peroxide (H_2O_2) breaks down extremely slowly if the reaction is uncatalyzed, but a single molecule of the enzyme **catalase** brings about the decomposition of 40 million molecules of hydrogen peroxide per second! Catalase has the highest catalytic rate known for any enzyme. It protects cells by destroying hydrogen peroxide, a poisonous substance produced as a byproduct of some cell reactions. The bombardier beetle uses the enzyme catalase as a defense mechanism (**FIG. 7-8**).

All reactions have a required energy of activation

All reactions, whether exergonic or endergonic, have an energy barrier known as the **energy of activation (E_A),** or **activation energy,** which is the energy required to break the existing bonds and begin the reaction. In a population of molecules of any kind, some have a relatively high kinetic energy, whereas others have a lower energy content. Only molecules with a relatively high kinetic energy are likely to react to form the product.

Even a strongly exergonic reaction, one that releases a substantial quantity of energy as it proceeds, may be prevented from proceeding by the activation energy required to begin the reaction. For example, molecular hydrogen and molecular oxygen can react explosively to form water:

$$2\,H_2 + O_2 \longrightarrow 2\,H_2O$$



Thomas Eisner and Daniel Aneshansley/Cornell University

FIGURE 7-8 Catalase as a defense mechanism

When threatened, a bombardier beetle (*Stenaptinus insignis*) uses the enzyme catalase to decompose hydrogen peroxide. The oxygen gas formed in the decomposition ejects water and other chemicals with explosive force. Because the reaction releases a great deal of heat, the water comes out as steam. (A wire attached by a drop of adhesive to the beetle's back immobilizes it. The researcher prodded its leg with the dissecting needle on the left to trigger the ejection.)

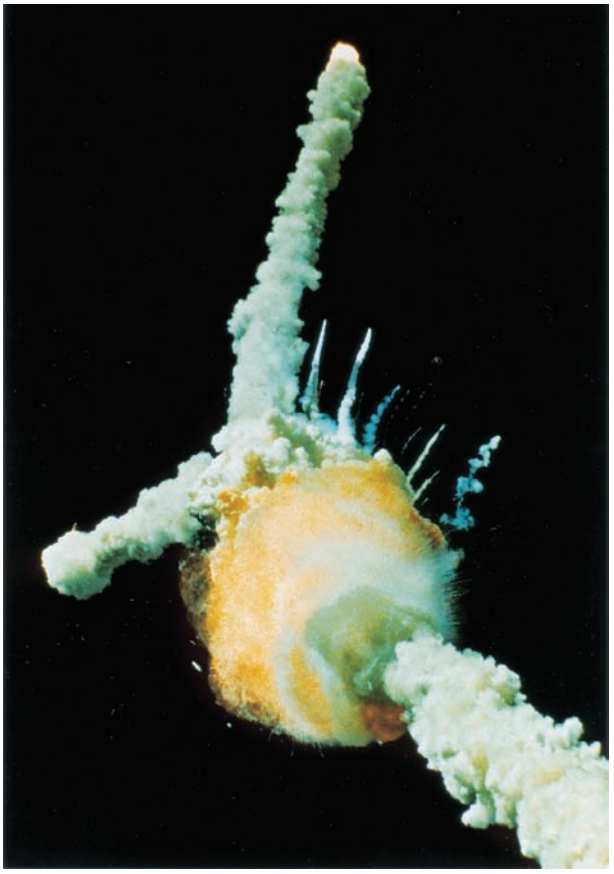
www.konkur.in

This reaction is spontaneous, yet hydrogen and oxygen can be safely mixed as long as all sparks are kept away because the required activation energy for this particular reaction is relatively high. A tiny spark provides the activation energy that allows a few molecules to react. Their reaction liberates so much heat that the rest react, producing an explosion. Such an explosion occurred on the space shuttle *Challenger* on January 28, 1986 (**FIG. 7-9**). The failure of a rubber O-ring to properly seal caused the liquid hydrogen in the tank attached to the shuttle to leak and start burning. When the hydrogen tank ruptured a few seconds later, the resulting force burst the nearby oxygen tank as well, mixing hydrogen and oxygen and igniting a huge explosion.

An enzyme lowers a reaction's activation energy

Like all catalysts, enzymes affect the rate of a reaction by lowering the activation energy (E_A) necessary to initiate a chemical reaction (**FIG. 7-10**). If molecules need less energy to react because the activation barrier is lowered, a larger fraction of the reactant molecules reacts at any one time. As a result, the reaction proceeds more quickly.

Although an enzyme lowers the activation energy for a reaction, it has no effect on the overall free-energy change; that is, an enzyme can promote only a chemical reaction that could proceed without it. If the reaction goes to equilibrium, no catalyst can cause it to proceed in a thermodynamically unfavorable direction or can influence the final concentrations of reactants and products. Enzymes simply speed up reaction rates.



AP/Wide World Photos

FIGURE 7-9 The space shuttle *Challenger* explosion

This disaster resulted from an explosive exergonic reaction between hydrogen and oxygen. All seven crew members died in the accident on January 28, 1986.

KEY POINT An enzyme lowers the activation energy of a reaction but does not alter the free-energy change.

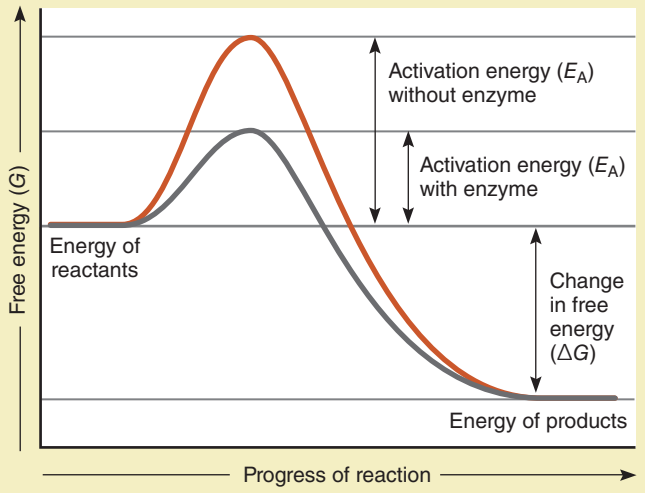


FIGURE 7-10 *Animated* Activation energy and enzymes

An enzyme speeds up a reaction by lowering its activation energy (E_A). In the presence of an enzyme, reacting molecules require less kinetic energy to complete a reaction.

An enzyme works by forming an enzyme–substrate complex

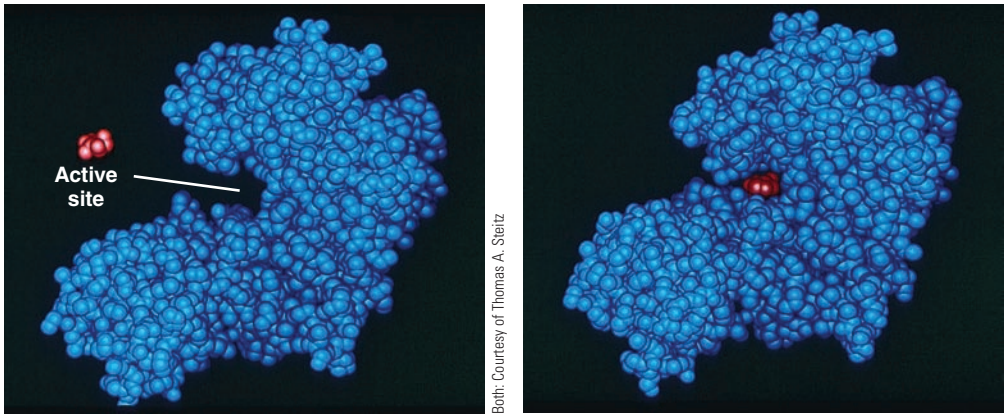
An uncatalyzed reaction depends on random collisions among reactants. Because of its ordered structure, an enzyme reduces this reliance on random events and thereby controls the reaction. The enzyme accomplishes this by forming an unstable intermediate complex with the **substrate,** the substance on which it acts. When the **enzyme–substrate complex,** or **ES complex,** breaks up, the product is released; the original enzyme molecule is regenerated and is free to form a new ES complex:

$$\text{enzyme} + \text{substrate(s)} \longrightarrow \text{ES complex}$$
$$\text{ES complex} \longrightarrow \text{enzyme} + \text{product(s)}$$

The enzyme itself is not permanently altered or consumed by the reaction and can be reused.

As shown in **FIGURE 7-11a**, every enzyme contains one or more **active sites,** regions to which the substrate binds, to form the ES complex. The active sites of some enzymes are grooves or cavities in the enzyme molecule, formed by amino acid side chains. The active sites of most enzymes are located close to the surface. During

www.konkur.in



Both: Courtesy of Thomas A. Steitz

(a) Prior to forming an ES complex, the enzyme's active site is the furrow where the substrate will bind.

(b) The binding of the substrate to the active site induces a change in the conformation of the active site.

FIGURE 7-11 An enzyme–substrate complex
This computer graphic model shows the enzyme hexokinase (*blue*) and its substrate, glucose (*red*).

the course of a reaction, substrate molecules occupying these sites are brought close together and react with one another.

The shape of the enzyme does not seem exactly complementary to that of the substrate. The binding of the substrate to the enzyme molecule causes a change, known as **induced fit,** in the shape of the enzyme (**FIG. 7-11b**). Usually, the shape of the substrate also changes slightly, in a way that may distort its chemical bonds. The proximity and orientation of the reactants, together with strains in their chemical bonds, facilitate the breakage of old bonds and the formation of new ones. Thus, the substrate is changed into a product, which diffuses away from the enzyme. The enzyme is then free to catalyze the reaction of more substrate molecules to form more product molecules.

Enzymes are specific

Enzymes catalyze virtually every chemical reaction that takes place in an organism. Because the shape of the active site is closely related to the shape of the substrate, most enzymes are highly specific. Most catalyze only a few closely related chemical reactions or, in many cases, only one particular reaction. The enzyme urease, which decomposes urea to ammonia and carbon dioxide, attacks no other substrate. The enzyme sucrase splits only sucrose; it does not act on other disaccharides, such as maltose or lactose. A few enzymes are specific only to the extent that they require the substrate to have a certain kind of chemical bond. For example, lipase, secreted by the pancreas, splits the ester linkages connecting the glycerol and fatty acids of a wide variety of fats.

Scientists usually name enzymes by adding the suffix *-ase* to the name of the substrate. The enzyme sucrase, for example, splits sucrose into glucose and fructose. A few enzymes retain traditional names that do not end in *-ase;* some of these end in *-zyme.* For example, lysozyme (from the Greek *lysis,* "a loosening") is an enzyme found in tears and saliva; it breaks down bacterial cell walls. Other examples of enzymes with traditional names are pepsin and trypsin, which break peptide bonds in proteins.

Scientists classify enzymes that catalyze similar reactions into groups, although each particular enzyme in the group may catalyze only one specific reaction. **TABLE 7-1** describes the six classes of enzymes that biologists recognize. Each class is divided into many subclasses. For example, sucrase, mentioned earlier, is called a glycosidase because it cleaves a glycosidic linkage. Glycosidases are a subclass of the hydrolases (see Fig. 3-8b for the hydrolysis of sucrose). Phosphatases, enzymes that remove phosphate groups by hydrolysis, are also hydrolases. Kinases, enzymes that transfer phosphate groups to substrates, are transferases.

Many enzymes require cofactors

Some enzymes consist only of a protein. The enzyme pepsin, which is secreted by the animal stomach and digests dietary protein by breaking certain peptide bonds, is exclusively a protein molecule. Other enzymes have two components: a protein called the *apoenzyme* and an additional chemical component called a **cofactor.** Neither the apoenzyme nor the cofactor alone has catalytic activity; only when the two are combined does the enzyme function. A cofactor may be inorganic, or it may be an organic molecule.

Some enzymes require a specific metal ion as a cofactor. Two very common inorganic cofactors are magnesium ions and calcium ions. Most of the trace elements, such as iron, copper, zinc, and manganese, all of which organisms require in very small amounts, function as cofactors.

An organic, nonpolypeptide compound that binds to the apoenzyme and serves as a cofactor is called a coenzyme. Most coenzymes are carrier molecules that transfer electrons or part of a substrate from one molecule to another. We have already introduced some examples of coenzymes in this chapter. NADH, NADPH, and $FADH_2$ are coenzymes; they transfer electrons.

TABLE 7-1 Important Classes of Enzymes

Enzyme Class	Function
Oxidoreductases	Catalyze oxidation–reduction reactions
Transferases	Catalyze the transfer of a functional group from a donor molecule to an acceptor molecule
Hydrolases	Catalyze hydrolysis reactions
Isomerases	Catalyze conversion of a molecule from one isomeric form to another
Ligases	Catalyze certain reactions in which two molecules become joined in a process coupled to the hydrolysis of ATP
Lyases	Catalyze certain reactions in which double bonds form or break

www.konkur.in

ATP functions as a coenzyme; it is responsible for transferring phosphate groups. Yet another coenzyme, coenzyme A, is involved in the transfer of groups derived from organic acids. Most vitamins, which are organic compounds that an organism requires in small amounts but cannot synthesize itself, are coenzymes or components of coenzymes (see descriptions of vitamins in Table 47-3).

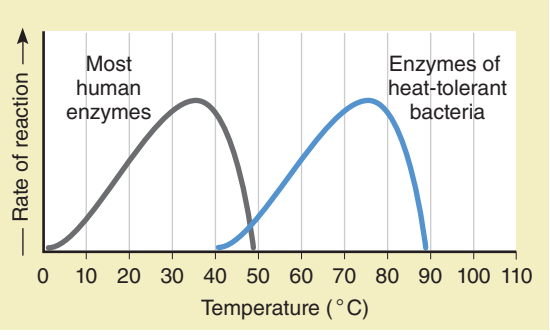
Enzymes are most effective at optimal conditions

Enzymes generally work best under certain narrowly defined conditions, such as appropriate temperature, pH (**FIG. 7-12**), and ion concentration. Any departure from optimal conditions adversely affects enzyme activity.

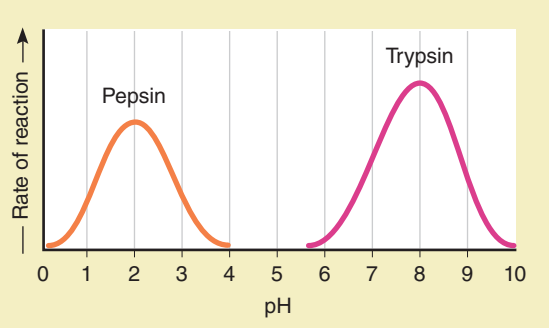
Each enzyme has an optimal temperature

Most enzymes have an optimal temperature, at which the rate of reaction is fastest. For human enzymes, the temperature optima are near the human body temperature (35°C to 40°C). Enzymatic reactions occur slowly or not at all at low temperatures. As the temperature increases, molecular motion increases, resulting in more molecular collisions. The rates of most enzyme-controlled reactions therefore increase as the temperature increases, within limits (see Fig. 7-12a). High temperatures rapidly denature most enzymes. The molecular conformation (3-D shape) of the protein becomes altered as the hydrogen bonds responsible for its secondary, tertiary, and quaternary structures are broken. Because this inactivation is usually not reversible, activity is not regained when the enzyme is cooled.

Most organisms are killed by even a short exposure to high temperature; their enzymes are denatured, and they are unable to continue metabolism. There are a few stunning exceptions to this rule. Certain species of archaea (see Chapter 1 for a description of the archaea) can survive in the waters of hot springs, such as those in Yellowstone Park, where the temperature is almost 100°C; these organisms are responsible for the brilliant colors in the terraces of the hot springs (**FIG. 7-13**). Still other archaea live at temperatures much above that of boiling water, near deep-sea vents, where the extreme pressure keeps water in its liquid state (see Chapter 25 for a discussion of archaea that live in extreme habitats; see also Chapter 55, *Inquiring About: Life without the Sun*).



(a) Generalized curves for the effect of temperature on enzyme activity. As temperature increases, enzyme activity increases until it reaches an optimal temperature. Enzyme activity abruptly falls after it exceeds the optimal temperature because the enzyme, being a protein, denatures.



(b) Enzyme activity is very sensitive to pH. Pepsin is a protein-digesting enzyme in the very acidic stomach juice. Trypsin, secreted by the pancreas into the slightly basic small intestine, digests polypeptides.

FIGURE 7-12 ***Animated*** **The effects of temperature and pH on enzyme activity**

Substrate and enzyme concentrations are held constant in the reactions illustrated.

Each enzyme has an optimal pH

Most enzymes are active only over a narrow pH range and have an optimal pH, at which the rate of reaction is fastest. The optimal pH for most human enzymes is between 6 and 8. Recall from Chapter 2 that *buffers* minimize pH changes in cells so that the pH is maintained within a narrow limit. Pepsin, a protein-digesting enzyme secreted by cells lining the stomach, is an exception; it works only in a very acidic medium, optimally at pH 2 (see Fig. 7-12b). In contrast, trypsin, a protein-splitting enzyme secreted by the pancreas, functions best under the slightly basic conditions found in the small intestine.

FIGURE 7-13 **Grand Prismatic Spring in Yellowstone National Park**

The world's third-largest spring, about 61 m (200 ft) in diameter, the Grand Prismatic Spring teems with heat-tolerant archaea. The rings around the perimeter, where the water is slightly cooler, get their distinctive colors from the various kinds of archaea living there.

www.konkur.in

The activity of an enzyme may be markedly changed by any alteration in pH, which in turn alters electric charges on the enzyme. Changes in charge affect the ionic bonds that contribute to tertiary and quaternary structure, thereby changing the protein's conformation and activity. Many enzymes become inactive, and usually irreversibly denatured, when the medium is made very acidic or very basic.

Enzymes are organized into teams in metabolic pathways

Enzymes play an essential role in reaction coupling because they usually work in sequence, with the product of one enzyme-controlled reaction serving as the substrate for the next. You can picture the inside of a cell as a factory with many different assembly (and disassembly) lines operating simultaneously. An assembly line consists of a number of enzymes. Each enzyme carries out one step, such as changing molecule A into molecule B. Then molecule B is passed along to the next enzyme, which converts it into molecule C, and so on. Such a series of reactions is called a **metabolic pathway.**

$$A \xrightarrow{\text{Enzyme 1}} B \xrightarrow{\text{Enzyme 2}} C$$

Each of these reactions is reversible, despite the fact that an enzyme catalyzes it. An enzyme does not itself determine the direction of the reaction it catalyzes. However, the overall reaction sequence is portrayed as proceeding from left to right. Recall that if there is little intrinsic free-energy difference between the reactants and products for a particular reaction, the direction of the reaction is determined mainly by the relative concentrations of reactants and products.

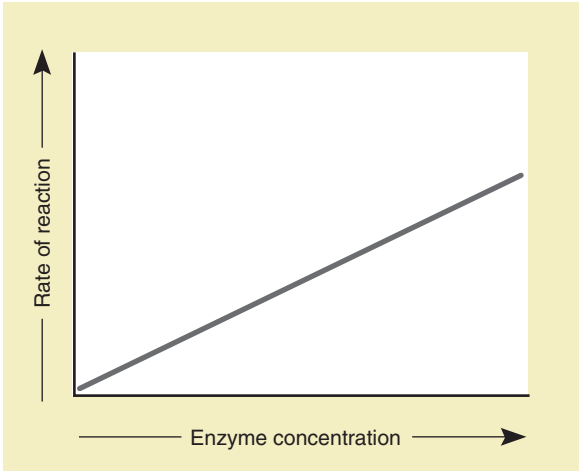
In metabolic pathways, both intermediate and final products are often removed and converted to other chemical compounds. Such removal drives the sequence of reactions in a particular direction. Let us assume that reactant A is continually supplied and that its concentration remains constant. Enzyme 1 converts reactant A to product B. The concentration of B is always lower than the concentration of A because B is removed as it is converted to C in the reaction catalyzed by enzyme 2. If C is removed as quickly as it is formed (perhaps by leaving the cell), the entire reaction pathway is "pulled" toward C.

In some cases the enzymes of a metabolic pathway bind to one another to form a multienzyme complex that efficiently transfers intermediates in the pathway from one active site to another. An example of one such multienzyme complex, pyruvate dehydrogenase, is discussed in Chapter 8.

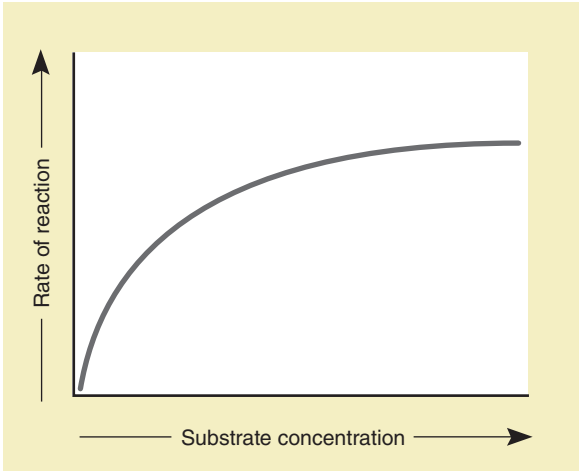
The cell regulates enzymatic activity

Enzymes regulate the chemistry of the cell, but what controls the enzymes? One regulatory mechanism involves controlling the amount of enzyme produced. A specific gene directs the synthesis of each type of enzyme. The gene, in turn, may be switched on by a signal from a hormone or by some other signal molecule. When the gene is switched on, the enzyme is synthesized. The total amount of enzyme present then influences the overall cell reaction rate.

If the pH and temperature are kept constant (as they are in most cells), the rate of the reaction can be affected by the substrate concentration or by the enzyme concentration. If an excess of substrate is present, the enzyme concentration is the rate-limiting factor. The initial rate of the reaction is then directly proportional to the enzyme concentration (**FIG. 7-14a**).



(a) In this example, the rate of reaction is measured at different enzyme concentrations, with an excess of substrate present. (Temperature and pH are constant.) The rate of the reaction is directly proportional to the enzyme concentration.



(b) In this example, the rate of the reaction is measured at different substrate concentrations, and enzyme concentration, temperature, and pH are constant. If the substrate concentration is relatively low, the reaction rate is directly proportional to substrate concentration. However, higher substrate concentrations do not increase the reaction rate because the enzymes become saturated with substrate.

FIGURE 7-14 The effects of enzyme concentration and substrate concentration on the rate of a reaction

www.konkur.in

If the enzyme concentration is kept constant, the rate of an enzymatic reaction is proportional to the concentration of substrate present. Substrate concentration is the rate-limiting factor at lower concentrations; the rate of the reaction is therefore directly proportional to the substrate concentration. However, at higher substrate concentrations, the enzyme molecules become saturated with substrate; that is, substrate molecules are bound to all available active sites of enzyme molecules. In this situation, increasing the substrate concentration does not increase the net reaction rate (**FIG. 7-14b**).

The product of one enzymatic reaction may control the activity of another enzyme, especially in a sequence of enzymatic reactions. For example, consider the following metabolic pathway:

$$A \xrightarrow{\text{Enzyme 1}} B \xrightarrow{\text{Enzyme 2}} C \xrightarrow{\text{Enzyme 3}} D \xrightarrow{\text{Enzyme 4}} E$$

A different enzyme catalyzes each step, and the final product E may inhibit the activity of enzyme 1. When the concentration of E is low, the sequence of reactions proceeds rapidly. However, an increasing concentration of E serves as a signal for enzyme 1 to slow down and eventually to stop functioning. Inhibition of enzyme 1 stops the entire reaction sequence. This type of enzyme regulation, in which the formation of a product inhibits an earlier reaction in the sequence, is called **feedback inhibition** (**FIG. 7-15**).

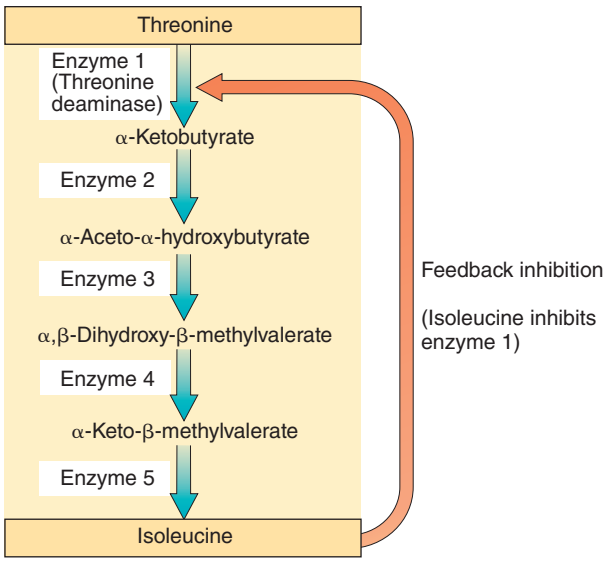


FIGURE 7-15 ***Animated*** **Feedback inhibition**
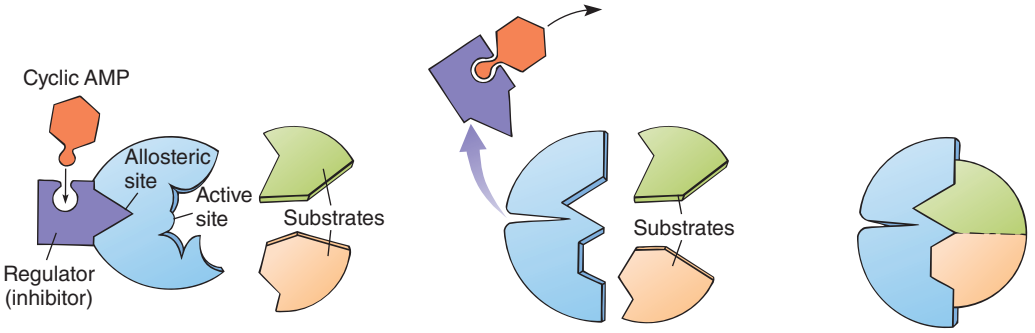
Bacteria synthesize the amino acid isoleucine from the amino acid threonine. The isoleucine pathway involves five steps, each catalyzed by a different enzyme. When enough isoleucine accumulates in the cell, the isoleucine inhibits threonine deaminase, the enzyme that catalyzes the first step in this pathway.

Another method of enzymatic control focuses on the activation of enzyme molecules. In their inactive form, the active sites of the enzyme are inappropriately shaped, so the substrates do not fit. Among the factors that influence the shape of the enzyme are pH, the concentration of certain ions, and the addition of phosphate groups to certain amino acids in the enzyme.

Some enzymes have a receptor site, called an **allosteric site,** on some region of the enzyme molecule other than the active site. (The word *allosteric* means "another space.") When a substance binds to an enzyme's allosteric site, the conformation of the enzyme's active site changes, thereby modifying the enzyme's activity. Substances that affect enzyme activity by binding to allosteric sites are called **allosteric regulators.** Some allosteric regulators are allosteric inhibitors that keep the enzyme in its inactive shape. Conversely, the activities of allosteric activators result in an enzyme with a functional active site.

The enzyme *cyclic AMP-dependent protein kinase* is an allosteric enzyme regulated by a protein that binds reversibly to the allosteric site and inactivates the enzyme. Protein kinase is in this inactive form most of the time (**FIG. 7-16**). When protein kinase activity is



(a) Inactive form of the enzyme. The enzyme protein kinase is inhibited by a regulatory protein that binds reversibly to its allosteric site. When the enzyme is in this inactive form, the shape of the active site is modified so that the substrate cannot combine with it.

(b) Active form of the enzyme. Cyclic AMP removes the allosteric inhibitor and activates the enzyme.

(c) Enzyme–substrate complex. The substrate can then combine with the active site.

FIGURE 7-16 ***Animated*** **An allosteric enzyme**

www.konkur.in

needed, the compound cyclic AMP (cAMP; see Fig. 3-25 for the structure) contacts the enzyme-inhibitor complex and removes the inhibitory protein, thereby activating the protein kinase. Activation of protein kinases by cAMP is an important aspect of the mechanism of cell signaling, including the action of certain hormones (see Chapters 6 and 49 for discussions of cell signaling).

Enzymes are inhibited by certain chemical agents

Most enzymes are inhibited or even destroyed by certain chemical agents. Enzyme inhibition may be reversible or irreversible. **Reversible inhibition** occurs when an inhibitor forms weak chemical bonds with the enzyme. Reversible inhibition can be competitive or noncompetitive.

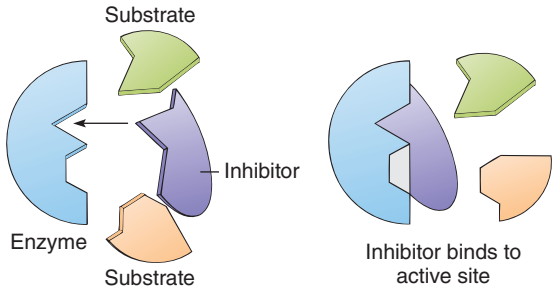
In **competitive inhibition,** the inhibitor competes with the normal substrate for binding to the active site of the enzyme (**FIG. 7-17a**). Usually, a competitive inhibitor is structurally similar to the normal substrate and fits into the active site and combines with the enzyme. However, it is not similar enough to substitute fully for the normal substrate in the chemical reaction, and the enzyme cannot convert it to product molecules. A competitive inhibitor occupies the active site only temporarily and does not permanently damage the enzyme. In competitive inhibition, an active site is occupied by the inhibitor part of the time and by the normal substrate part of the time. If the concentration of the substrate is increased relative to the concentration of the inhibitor, the active site is usually occupied by the substrate. Biochemists demonstrate competitive inhibition experimentally by showing that increasing the substrate concentration reverses competitive inhibition.

In **noncompetitive inhibition,** the inhibitor binds with the enzyme at a site other than the active site (**FIG. 7-17b**). Such an inhibitor inactivates the enzyme by altering its shape so that the active site cannot bind with the substrate. Many important noncompetitive inhibitors are metabolic substances that regulate enzyme activity by combining reversibly with the enzyme. Allosteric inhibition, discussed previously, is a type of noncompetitive inhibition in which the inhibitor binds to a special site, the allosteric site.

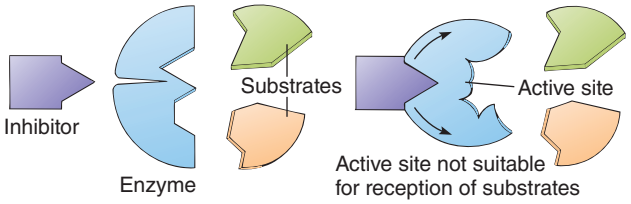
In **irreversible inhibition,** an inhibitor permanently inactivates or destroys an enzyme when the inhibitor combines with one of the enzyme's functional groups, either at the active site or elsewhere. Many poisons are irreversible enzyme inhibitors. For example, heavy metals such as mercury and lead bind irreversibly to and denature many proteins, including enzymes. Certain nerve gases poison the enzyme acetylcholinesterase, which is important for the functioning of nerves and muscles. Cytochrome oxidase, one of the enzymes that transports electrons in cellular respiration, is especially sensitive to cyanide. Death results from cyanide poisoning because cytochrome oxidase is irreversibly inhibited and no longer transfers electrons from its substrate to oxygen.

Some drugs are enzyme inhibitors

Physicians treat many bacterial infections with drugs that directly or indirectly inhibit bacterial enzyme activity. For example, sulfa drugs have a chemical structure similar to that of the nutrient



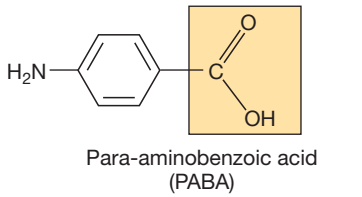
(a) Competitive inhibition. The inhibitor competes with the normal substrate for the active site of the enzyme. A competitive inhibitor occupies the active site only temporarily.



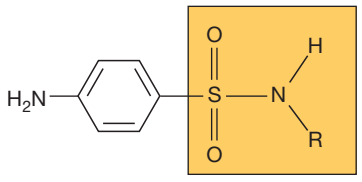
(b) Noncompetitive inhibition. The inhibitor binds with the enzyme at a site other than the active site, altering the shape of the enzyme and thereby inactivating it.

FIGURE 7-17 ***Animated*** **Competitive and noncompetitive inhibition**

para-aminobenzoic acid (PABA) (**FIG. 7-18**). When PABA is available, microorganisms can synthesize the vitamin *folic acid,* which is necessary for growth. Humans do not synthesize folic acid from PABA. For this reason, sulfa drugs selectively affect bacteria. When a sulfa drug is present, the drug competes with PABA for the active site of the bacterial enzyme. When bacteria use the sulfa drug in-



Para-aminobenzoic acid (PABA)



Generic sulfonamide (Sulfa drug)

FIGURE 7-18 **Para-aminobenzoic acid and sulfonamides**

Sulfa drugs inhibit an enzyme in bacteria necessary for the synthesis of folic acid, an important vitamin required for growth. (Note the unusual structure of the sulfonamide molecule; sulfur, which commonly forms two covalent bonds, forms six instead.)

www.konkur.in

stead of PABA, they synthesize a compound that cannot be used to make folic acid. Therefore, the bacterial cells are unable to grow.

Penicillin and related antibiotics irreversibly inhibit a bacterial enzyme called *transpeptidase.* This enzyme establishes some of the chemical linkages in the bacterial cell wall. Bacteria susceptible to these antibiotics cannot produce properly constructed cell walls and are prevented from multiplying effectively. Human cells do not have cell walls and therefore do not use this enzyme. Thus, except for individuals allergic to it, penicillin is harmless to humans. Unfortunately, during the years since it was introduced, resistance to penicillin has evolved in many bacterial strains. The resistant bacteria fight back with an enzyme of their own, penicillinase, which breaks down the penicillin and renders it ineffective. Because bacteria evolve at such a rapid rate, drug resistance is a growing problem in medical practice.

Review

- What effect does an enzyme have on the required activation energy of a reaction?
- How does the function of the active site of an enzyme differ from that of an allosteric site?
- How are temperature and pH optima of an enzyme related to its structure and function?
- Is allosteric inhibition competitive or noncompetitive?

SUMMARY: FOCUS ON LEARNING OBJECTIVES

7.1 *(page 155)*

1 Define *energy,* emphasizing how it is related to work and to heat.

- **Energy** is the capacity to do work (expressed in **kilojoules, kJ**). Energy can be conveniently measured as **heat energy,** thermal energy that flows from an object with a higher temperature to an object with a lower temperature; the unit of heat energy is the **kilocalorie (kcal),** which is equal to 4.184 kJ. Heat energy cannot do cell work.

2 Use examples to contrast potential energy and kinetic energy.

- **Potential energy** is stored energy; **kinetic energy** is energy of motion.
- All forms of energy are interconvertible. For example, photosynthetic organisms capture radiant energy and convert some of it to **chemical energy,** a form of potential energy that powers many life processes, such as muscle contraction.

7.2 *(page 155)*

3 State the first and second laws of thermodynamics, and discuss the implications of these laws as they relate to organisms.

- A **closed system** does not exchange energy with its surroundings. Organisms are **open systems** that do exchange energy with their surroundings.
- The **first law of thermodynamics** states that energy cannot be created or destroyed but can be transferred and changed in form. The first law explains why organisms cannot produce energy; but as open systems, they continuously capture it from the surroundings.
- The **second law of thermodynamics** states that disorder (entropy) in the universe, a closed system, is continuously increasing. No energy transfer is 100% efficient; some energy is dissipated as **heat,** random motion that contributes to **entropy (*S*),** or disorder. As open systems, organisms maintain their ordered states at the expense of their surroundings.

7.3 *(page 156)*

4 Discuss how changes in free energy in a reaction are related to changes in entropy and enthalpy.

- As entropy increases, the amount of **free energy** decreases, as shown in the equation $G = H - TS$, in which G is the free energy, H is the **enthalpy** (total potential energy of the system), T is the absolute temperature (expressed in Kelvin units), and S is entropy.
- The equation $\Delta G = \Delta H - T\Delta S$ indicates that the change in free energy (ΔG) during a chemical reaction is equal to the change in enthalpy (ΔH) minus the product of the absolute temperature (T) multiplied by the change in entropy (ΔS).

5 Distinguish between exergonic and endergonic reactions, and give examples of how they may be coupled.

- An **exergonic reaction** has a negative value of ΔG; that is, free energy decreases. Such a reaction is spontaneous; it releases free energy that can perform work.
- Free energy increases in an **endergonic reaction.** Such a reaction has a positive value of ΔG and is nonspontaneous. In a **coupled reaction,** the input of free energy required to drive an endergonic reaction is supplied by an exergonic reaction.

CENGAGENOW™ Learn more about exergonic and endergonic reactions by clicking on the figure in CengageNOW.

6 Compare the energy dynamics of a reaction at equilibrium with the dynamics of a reaction not at equilibrium.

- When a chemical reaction is in a state of **dynamic equilibrium,** the rate of change in one direction is exactly the same as the rate of change in the opposite direction; the system can do no work because the free-energy difference between the reactants and products is zero.
- When the concentration of reactant molecules is increased, the reaction shifts to the right and more product molecules are formed until equilibrium is re-established.

7.4 *(page 159)*

7 Explain how the chemical structure of ATP allows it to transfer a phosphate group and discuss the central role of ATP in the overall energy metabolism of the cell.

- **Adenosine triphosphate (ATP)** is the immediate energy currency of the cell. It donates energy by means of its terminal phosphate group, which is easily transferred to an acceptor molecule. ATP is formed by the **phosphorylation** of **adenosine diphosphate (ADP),** an endergonic process that requires an input of energy.
- ATP is the common link between exergonic and endergonic reactions and between **catabolism** (degradation of large complex molecules into smaller, simpler molecules) and **anabolism** (synthesis of complex molecules from simpler molecules).

7.5 *(page 161)*

8 Relate the transfer of electrons (or hydrogen atoms) to the transfer of energy.

- Energy is transferred in **oxidation–reduction (redox) reactions.** A substance becomes oxidized as it gives up one or more electrons to another substance, which becomes reduced in the process. Electrons are commonly transferred as part of hydrogen atoms.

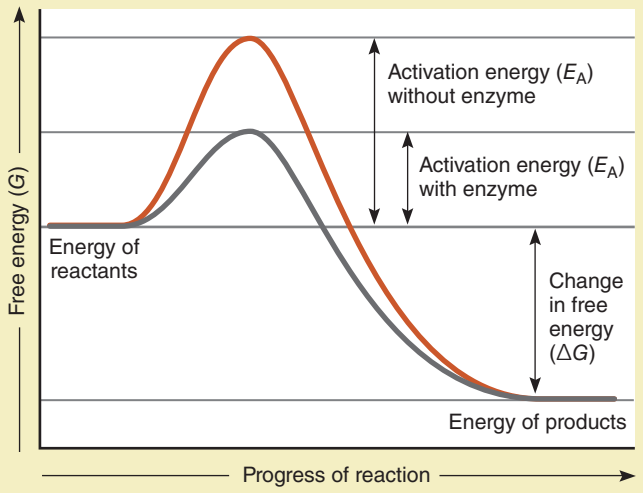
www.konkur.in

- NAD^+ and $NADP^+$ accept electrons as part of hydrogen atoms and become reduced to form **NADH** and **NADPH,** respectively. These electrons (along with some of their energy) can be transferred to other acceptors.

7.6 *(page 162)*

9 Explain how an enzyme lowers the required energy of activation for a reaction.

- An **enzyme** is a biological **catalyst;** it greatly increases the speed of a chemical reaction without being consumed.



- An enzyme works by lowering the **activation energy (E_A),** the energy necessary to get a reaction going. The **active site** of an enzyme is a 3-D region where **substrates** come into close contact and thereby react more readily. When a substrate binds to an active site, an **enzyme–substrate complex** forms in which the shapes of the enzyme and substrate change slightly. This **induced fit** facilitates the breaking of bonds and formation of new ones.

CENGAGENOW™ Learn more about activation energy by clicking on the figure in CengageNOW.

10 Describe specific ways enzymes are regulated.

- Enzymes work best at specific temperature and pH conditions.
- A cell can regulate enzymatic activity by controlling the amount of enzyme produced and by regulating metabolic conditions that influence the shape of the enzyme.
- Some enzymes have **allosteric sites,** noncatalytic sites to which an **allosteric regulator** binds, changing the enzyme's activity. Some allosteric enzymes are subject to **feedback inhibition,** in which the formation of an end product inhibits an earlier reaction in the metabolic pathway.
- **Reversible inhibition** occurs when an inhibitor forms weak chemical bonds with the enzyme. Reversible inhibition may be **competitive,** in which the inhibitor competes with the substrate for the active site, or **noncompetitive,** in which the inhibitor binds with the enzyme at a site other than the active site. **Irreversible inhibition** occurs when an inhibitor combines with an enzyme and permanently inactivates it.

CENGAGENOW™ Learn more about enzymes by clicking on the figures in CengageNOW.

TEST YOUR UNDERSTANDING

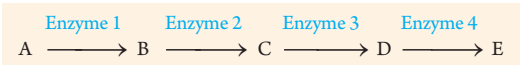
1. Which of the following can do work in a cell? (a) entropy (b) heat (c) heat energy (d) all of the above (e) none of the above
2. In a chemical reaction occurring in a cell, free energy is equivalent to (a) heat energy (b) heat (c) disorder (d) potential energy (e) more than one of the above is true
3. Cells are able to function because they (a) are subject to the laws of thermodynamics (b) have mechanisms that transform energy from the environment into useful forms (c) can use enzymes to convert endergonic reactions into spontaneous reactions (d) all of the above
4. Diffusion is an (a) endergonic process because free energy increases (b) endergonic process because free energy decreases (c) exergonic process because entropy increases (d) exergonic process because entropy decreases (e) more than one of the above
5. A spontaneous reaction is one in which the change in free energy (ΔG) has a _____ value. (a) positive (b) negative (c) positive or negative (d) none of these (ΔG has no measurable value)
6. Healthy living cells maintain (a) ATP and ADP at equilibrium (b) equal concentrations of ATP and ADP (c) an ATP/ADP ratio of at least 10:1 (d) an ATP/ADP ratio of no more than 1:10 (e) most of the cell's stored energy in the form of ATP
7. Which of the following reactions could be coupled to an endergonic reaction with $\Delta G = +3.56$ kJ/mol?
   (a) A $\longrightarrow$ B, $\Delta G = +6.08$ kJ/mol
   (b) C $\longrightarrow$ D, $\Delta G = +3.56$ kJ/mol
   (c) E $\longrightarrow$ F, $\Delta G = 0$ kJ/mol
   (d) G $\longrightarrow$ H, $\Delta G = -1.22$ kJ/mol
   (e) I $\longrightarrow$ J, $\Delta G = -5.91$ kJ/mol
8. Consider this reaction: glucose + 6 O_2 $\longrightarrow$ 6 CO_2 + 6 H_2O ($\Delta G = -2880$ kJ/mol). Which of the following statements about this reaction is *not* true? (a) the reaction is spontaneous in a thermodynamic sense (b) a small amount of energy (activation energy) must be supplied to start the reaction, which then proceeds with a release of energy (c) the reaction is exergonic (d) the reaction can be coupled to an endergonic reaction (e) the reaction must be coupled to an exergonic reaction
9. The required energy of activation of a reaction (a) is fixed, and cannot be altered (b) can be lowered by a specific enzyme (c) can be raised by a specific enzyme (d) b or c, depending on the enzyme (e) none of the above
10. "Induced fit" means that when a substrate binds to an enzyme's active site (a) it fits perfectly, like a key in a lock (b) the substrate and enzyme undergo conformational changes (c) a site other than the active site undergoes a conformational change (d) the substrate and the enzyme become irreversibly bound to each other (e) c and d
11. The function of a biochemical pathway is to (a) supply energy to reactions (b) drive a sequence of reactions in a particular direc-

www.konkur.in

tion (c) maintain chemical equilibrium (d) make energy available to endergonic reactions (e) any of the above, depending on the pathway

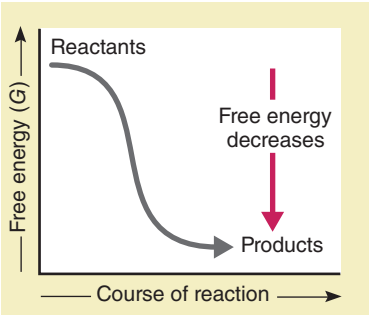
12. In the following reaction series, which enzyme(s) is/are most likely to have an allosteric site to which the end product E binds?

(a) enzyme 1 (b) enzyme 2 (c) enzyme 3 (d) enzyme 4 (e) enzymes 3 and 4



CRITICAL THINKING

1. Given what you have learned in this chapter, explain why an extremely high fever (body temperature above 40°C, or 105°F) can be fatal.
2. **EVOLUTION LINK.** What does the fact that all organisms use ATP/ADP as central links between exergonic and endergonic reactions suggest about the evolution of energy metabolism?
3. **EVOLUTION LINK.** Some have argued that "evolution is impossible because the second law of thermodynamics states that entropy always increases; therefore natural processes cannot give rise to greater complexity." In what ways is this statement a misunderstanding of the laws of thermodynamics?
4. **ANALYZING DATA.** Does the figure illustrate an exergonic reaction or an endergonic reaction? How do you know?



5. **ANALYZING DATA.** Reactions 1 and 2 happen to have the same standard free-energy change: ΔG − 41.8 kJ/mol (−10 kcal/ mol). Reaction 1 is at equilibrium, but reaction 2 is far from equilibrium. Is either reaction capable of performing work? If so, which one?
6. **ANALYZING DATA.** You are performing an experiment in which you are measuring the rate at which succinate is converted to fumarate by the enzyme succinic dehydrogenase. You decide to add a little malonate to make things interesting. You observe that the reaction rate slows markedly and hypothesize that malonate is inhibiting the reaction. Design an experiment that will help you decide whether malonate is acting as a competitive inhibitor or a noncompetitive inhibitor.

8 How Cells Make ATP: Energy-Releasing Pathways

Digital Vision/Getty Images

Grizzly bear (*Ursus arctos*). This grizzly, shown attempting to eat a jumping salmon, may also eat fruit, nuts, roots, insects, and small vertebrates such as mice and ground squirrels.

KEY CONCEPTS

8.1 Aerobic respiration is an exergonic redox process in which glucose becomes oxidized, oxygen becomes reduced, and energy is captured to make ATP.

8.2 Aerobic respiration consists of four stages: glycolysis, formation of acetyl coenzyme A, the citric acid cycle, and the electron transport chain and chemiosmosis.

8.3 Nutrients other than glucose, including many carbohydrates, lipids, and amino acids, can be oxidized by aerobic respiration.

8.4 Anaerobic respiration and fermentation are ATP-yielding redox processes in which glucose becomes oxidized, but oxygen does not become reduced. Instead, these processes involve the reduction of inorganic substances (in anaerobic respiration) or organic substances (in fermentation).

Cells are tiny factories that process materials on the molecular level, through thousands of metabolic reactions. Cells exist in a dynamic state and are continuously building up and breaking down the many different cell constituents. As you learned in Chapter 7, metabolism has two complementary components: **catabolism,** which releases energy by splitting complex molecules into smaller components, and **anabolism,** the synthesis of complex molecules from simpler building blocks. Anabolic reactions produce proteins, nucleic acids, lipids, polysaccharides, and other molecules that help maintain the cell or the organism. Most anabolic reactions are endergonic and require ATP or some other energy source to drive them.

Every organism must extract energy from food molecules that it either manufactures by photosynthesis or obtains from the environment. Grizzly bears, such as the one in the photograph, obtain organic molecules from their varied plant and animal diets. How do they obtain energy from these organic molecules? First, the food molecules are broken down by digestion into simpler components that are absorbed into the blood and transported to all the cells. The catabolic processes that convert the energy in the chemical bonds of nutrients to chemical energy stored in ATP then occur inside cells, usually through a process known as **cellular respiration.**

www.konkur.in

Cellular respiration may be either aerobic or anaerobic. *Aerobic respiration* requires oxygen, whereas *anaerobic pathways*, which include anaerobic respiration and fermentation, do not require oxygen. In the process of *organismal respiration* (discussed in Chapter 46), your lungs provide a steady supply of oxygen that enables your cells to capture energy through aerobic respiration, which is by far the most common pathway and the main subject of this chapter. All three pathways—aerobic respiration, anaerobic respiration, and fermentation—are exergonic and release free energy that can be captured by the cell.

8.1 REDOX REACTIONS

LEARNING OBJECTIVE

1 Write a summary reaction for aerobic respiration that shows which reactant becomes oxidized and which becomes reduced.

Most eukaryotes and prokaryotes carry out **aerobic respiration,** a form of cellular respiration requiring molecular oxygen (O_2). During aerobic respiration, nutrients are catabolized to carbon dioxide and water. Most cells use aerobic respiration to obtain energy from glucose, which enters the cell through a specific transport protein in the plasma membrane (see discussion of facilitated diffusion in Chapter 5). The overall reaction pathway for the aerobic respiration of glucose is summarized as follows:

$$C_6H_{12}O_6 + 6\,O_2 + 6\,H_2O \longrightarrow 6\,CO_2 + 12\,H_2O + \text{energy (in the chemical bonds of ATP)}$$

Note that water is shown on both sides of the equation because it is a reactant in some reactions and a product in others. For purposes of discussion, the equation for aerobic respiration can be simplified to indicate that there is a net yield of water:

$$\underset{\text{Oxidation}}{C_6H_{12}O_6} + 6\,O_2 \rightarrow \underset{\text{Reduction}}{6\,CO_2} + 6\,H_2O + \text{energy (in the chemical bonds of ATP)}$$

If we analyze this summary reaction, it appears that CO_2 is produced by the removal of hydrogen atoms from glucose. Conversely, water seems to be formed as oxygen accepts the hydrogen atoms. Because the transfer of hydrogen atoms is equivalent to the transfer of electrons, this is a **redox reaction** in which glucose becomes **oxidized** and oxygen becomes **reduced** (see discussion of redox reactions in Chapters 2 and 7).

The products of the reaction would be the same if the glucose were simply placed in a test tube and burned in the presence of oxygen. However, if a cell were to burn glucose, its energy would be released all at once as heat, which not only would be unavailable to the cell but also would actually destroy it. For this reason, cells do not transfer hydrogen atoms directly from glucose to oxygen. Aerobic respiration includes a series of redox reactions in which electrons associated with the hydrogen atoms in glucose are transferred to oxygen in a series of steps (**FIG. 8-1**). During this process, the free energy of the electrons is coupled to ATP synthesis.

Review

- In the overall reaction of aerobic respiration, which reactant becomes oxidized and which becomes reduced?
- What is the specific role of oxygen in most cells?

8.2 THE FOUR STAGES OF AEROBIC RESPIRATION

LEARNING OBJECTIVES

2 List and give a brief overview of the four stages of aerobic respiration.

3 Indicate where each stage of aerobic respiration takes place in a eukaryotic cell.

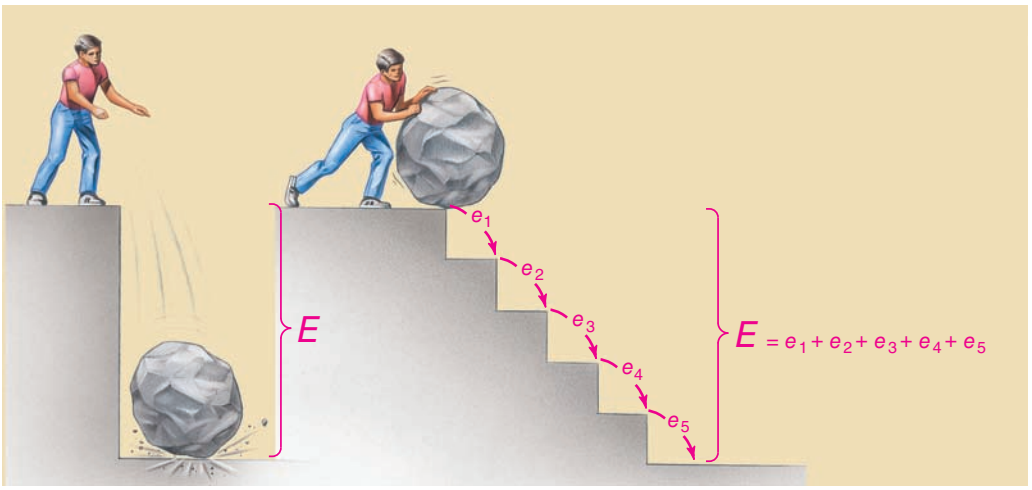

FIGURE 8-1 Changes in free energy

The release of energy from a glucose molecule is analogous to the liberation of energy by a falling object. The total energy released (*E*) is the same whether it occurs all at once or in a series of steps.

www.konkur.in

4 Add up the energy captured (as ATP, NADH, and $FADH_2$) in each stage of aerobic respiration.

5 Define *chemiosmosis* and explain how a gradient of protons is established across the inner mitochondrial membrane.

6 Describe the process by which the proton gradient drives ATP synthesis in chemiosmosis.

The chemical reactions of the aerobic respiration of glucose are grouped into four stages (**FIG. 8-2** and **TABLE 8-1**; see also the summary equations at the end of the chapter). In eukaryotes, the first stage (glycolysis) takes place in the cytosol, and the remaining stages take place inside mitochondria. Most bacteria and archaea also carry out these processes, but because prokaryotic cells lack mitochondria, the reactions of aerobic respiration occur in the cytosol and in association with the plasma membrane.

1. *Glycolysis.* A six-carbon glucose molecule is converted to two three-carbon molecules of pyruvate.[1] Some of the energy of glucose is captured with the formation of two kinds of energy

[1]Pyruvate and many other compounds in cellular respiration exist as anions at the pH found in the cell. They sometimes associate with H^+ to form acids. For example, pyruvate forms pyruvic acid. In some textbooks these compounds are presented in the acid form.

KEY POINT The stages of aerobic respiration occur in specific locations.

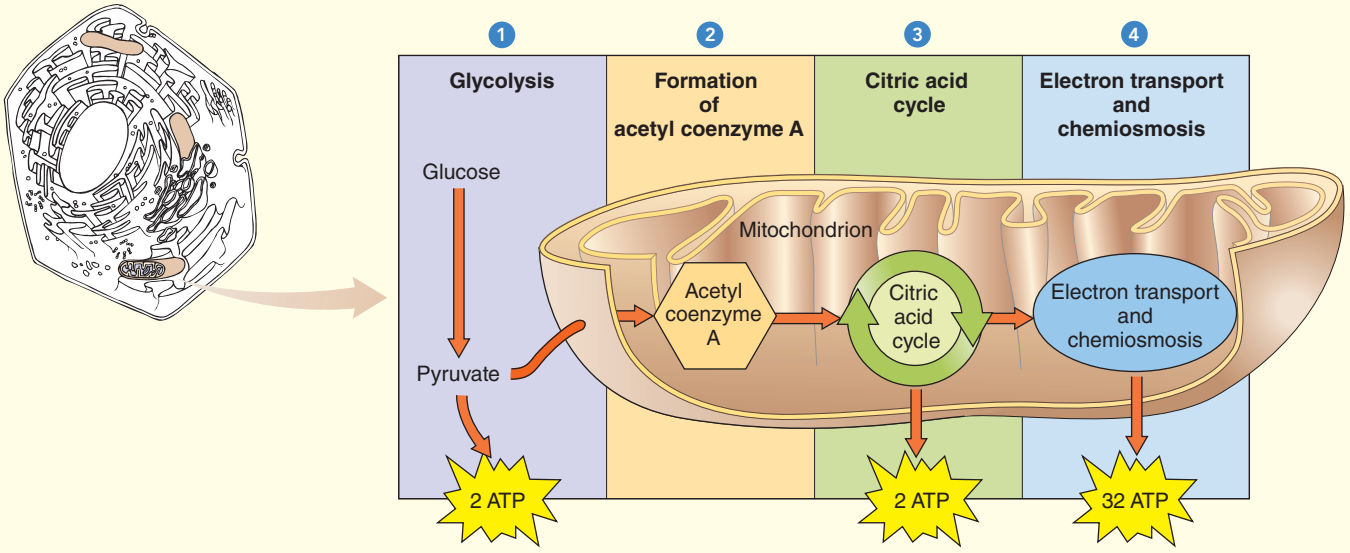

FIGURE 8-2 ***Animated*** **The four stages of aerobic respiration**

Glycolysis, the first stage of aerobic respiration, occurs in the cytosol. Pyruvate, the product of glycolysis, enters a mitochondrion, where cellular respiration continues with the formation of acetyl CoA, the citric acid cycle, and electron transport and chemiosmosis. Most ATP is synthesized by chemiosmosis.

TABLE 8-1 Summary of Aerobic Respiration

Stage	Summary	Some Starting Materials	Some End Products
1. **Glycolysis (in cytosol)**	Series of reactions in which glucose is degraded to pyruvate; net profit of 2 ATPs; hydrogen atoms are transferred to carriers; can proceed anaerobically	Glucose, ATP, NAD^+, ADP, P_i	Pyruvate, ATP, NADH
2. **Formation of acetyl CoA (in mitochondria)**	Pyruvate is degraded and combined with coenzyme A to form acetyl CoA; hydrogen atoms are transferred to carriers; CO_2 is released	Pyruvate, coenzyme A, NAD^+	Acetyl CoA, CO_2, NADH
3. **Citric acid cycle (in mitochondria)**	Series of reactions in which the acetyl portion of acetyl CoA is degraded to CO_2; hydrogen atoms are transferred to carriers; ATP is synthesized	Acetyl CoA, H_2O, NAD^+, FAD, ADP, P_i	CO_2, NADH, $FADH_2$, ATP
4. **Electron transport and chemiosmosis (in mitochondria)**	Chain of several electron transport molecules; electrons are passed along chain; released energy is used to form a proton gradient; ATP is synthesized as protons diffuse down the gradient; oxygen is final electron acceptor	NADH, $FADH_2$, O_2, ADP, P_i	ATP, H_2O, NAD^+, FAD

www.konkur.in

carriers, ATP and NADH.[2] See Chapter 7 to review how ATP transfers energy by transferring a phosphate group (see Figs. 7-5 and 7-6). NADH is a reduced molecule that transfers energy by transferring electrons as part of a hydrogen atom (see Fig. 7-7).

2. *Formation of acetyl coenzyme A.* Each pyruvate enters a mitochondrion and is oxidized to a two-carbon group (acetate) that combines with coenzyme A, forming acetyl coenzyme A. NADH is produced, and carbon dioxide is released as a waste product.
3. *The citric acid cycle.* The acetate group of acetyl coenzyme A combines with a four-carbon molecule (oxaloacetate) to form a six-carbon molecule (citrate). In the course of the cycle, citrate is recycled to oxaloacetate, and carbon dioxide is released as a waste product. Energy is captured as ATP and the reduced, high-energy compounds NADH and $FADH_2$ (see Chapter 7 to review $FADH_2$).
4. *Electron transport and chemiosmosis.* The electrons removed from glucose during the preceding stages are transferred from NADH and $FADH_2$ to a chain of electron acceptor compounds. As the electrons are passed from one electron acceptor to another, some of their energy is used to transport hydrogen ions (protons) across the inner mitochondrial membrane, forming a proton gradient. In a process known as *chemiosmosis* (described later), the energy of this proton gradient is used to produce ATP.

Most reactions involved in aerobic respiration are one of three types: dehydrogenations, decarboxylations, and those we informally categorize as preparation reactions. **Dehydrogenations** are reactions in which two hydrogen atoms (actually, 2 electrons plus 1 or 2 protons) are removed from the substrate and transferred to NAD^+ or FAD. **Decarboxylations** are reactions in which part of a carboxyl group (—COOH) is removed from the substrate as a molecule of CO_2. The carbon dioxide you exhale with each breath is derived from decarboxylations that occur in your cells. The rest of the reactions are preparation reactions in which molecules undergo rearrangements and other changes so that they can undergo further dehydrogenations or decarboxylations. As you examine the individual reactions of aerobic respiration, you will encounter these three basic types.

In following the reactions of aerobic respiration, it helps to do some bookkeeping as you go along. Because glucose is the starting material, it is useful to express changes on a per glucose basis. We will pay particular attention to changes in the number of carbon atoms per molecule and to steps in which some type of energy transfer takes place.

In glycolysis, glucose yields two pyruvates

The word *glycolysis* comes from Greek words meaning "sugar splitting," which refers to the fact that the sugar glucose is metabolized. Glycolysis does not require oxygen and proceeds under aerobic or anaerobic conditions. **FIGURE 8-3** shows a simplified overview of glycolysis, in which a glucose molecule consisting of six carbons is converted to two molecules of **pyruvate,** a three-carbon molecule. Some of the energy in the glucose is captured; there is a net yield of two ATP molecules and two NADH molecules. The reactions of glycolysis take place in the cytosol, where the necessary reactants, such as ADP, NAD^+, and inorganic phosphate, float freely and are used as needed.

The glycolysis pathway consists of a series of reactions, each of which is catalyzed by a specific enzyme (**FIG. 8-4**, pages 178 and 179). Glycolysis is divided into two major phases: the first includes endergonic reactions that require ATP, and the second includes exergonic reactions that yield ATP and NADH.

The first phase of glycolysis requires an investment of ATP

The first phase of glycolysis is sometimes called the "energy investment phase" (see Fig. 8-4, steps l to 5). Glucose is a relatively stable molecule and is not easily broken down. In two separate **phosphorylation reactions,** a phosphate group is transferred from ATP to the sugar. The resulting phosphorylated sugar (fructose-1,6-bisphosphate) is less stable and is broken enzymatically into two three-carbon molecules, dihydroxyacetone phosphate and glyceraldehyde-3-phosphate (G3P). The dihydroxyacetone phosphate is enzymatically converted to G3P, so the products at this point in glycolysis are two molecules of G3P per glucose. We can summarize this portion of glycolysis as follows:

$$\underset{\text{Six-carbon compound}}{\text{glucose}} + 2\ \text{ATP} \longrightarrow \underset{\text{Three-carbon compound}}{2\ \text{G3P}} + 2\ \text{ADP}$$

The second phase of glycolysis yields NADH and ATP

The second phase of glycolysis is sometimes called the "energy capture phase" (see Fig. 8-4, steps 6 to 10). Each G3P is converted to pyruvate. In the first step of this process, each G3P is oxidized by the removal of 2 electrons (as part of two hydrogen atoms). These immediately combine with the hydrogen carrier molecule, NAD^+:

$$\underset{\text{Oxidized}}{NAD^+} + \underset{\text{(From G3P)}}{2\ H} \longrightarrow \underset{\text{Reduced}}{NADH} + H^+$$

Because there are two G3P molecules for every glucose, two NADH are formed. The energy of the electrons carried by NADH is used to form ATP later. This process is discussed in conjunction with the electron transport chain.

In two of the reactions leading to the formation of pyruvate, ATP forms when a phosphate group is transferred to ADP from a phosphorylated intermediate (see Fig. 8-4, steps 7 and l0). This process is called **substrate-level phosphorylation.** Note that in the energy investment phase of glycolysis two molecules of ATP are consumed, but in the energy capture phase four molecules of ATP are produced. Thus, glycolysis yields a net energy profit of *two* ATPs per glucose.

We can summarize the energy capture phase of glycolysis as follows:

$$2\ \text{G3P} + 2\ NAD^+ + 4\ \text{ADP} \longrightarrow 2\ \text{pyruvate} + 2\ \text{NADH} + 4\ \text{ATP}$$

[2]Although the correct way to write the reduced form of NAD^+ is $NADH + H^+$, for simplicity we present the reduced form as NADH throughout the book.

www.konkur.in

KEY POINT Glycolysis includes both energy investment and energy capture.

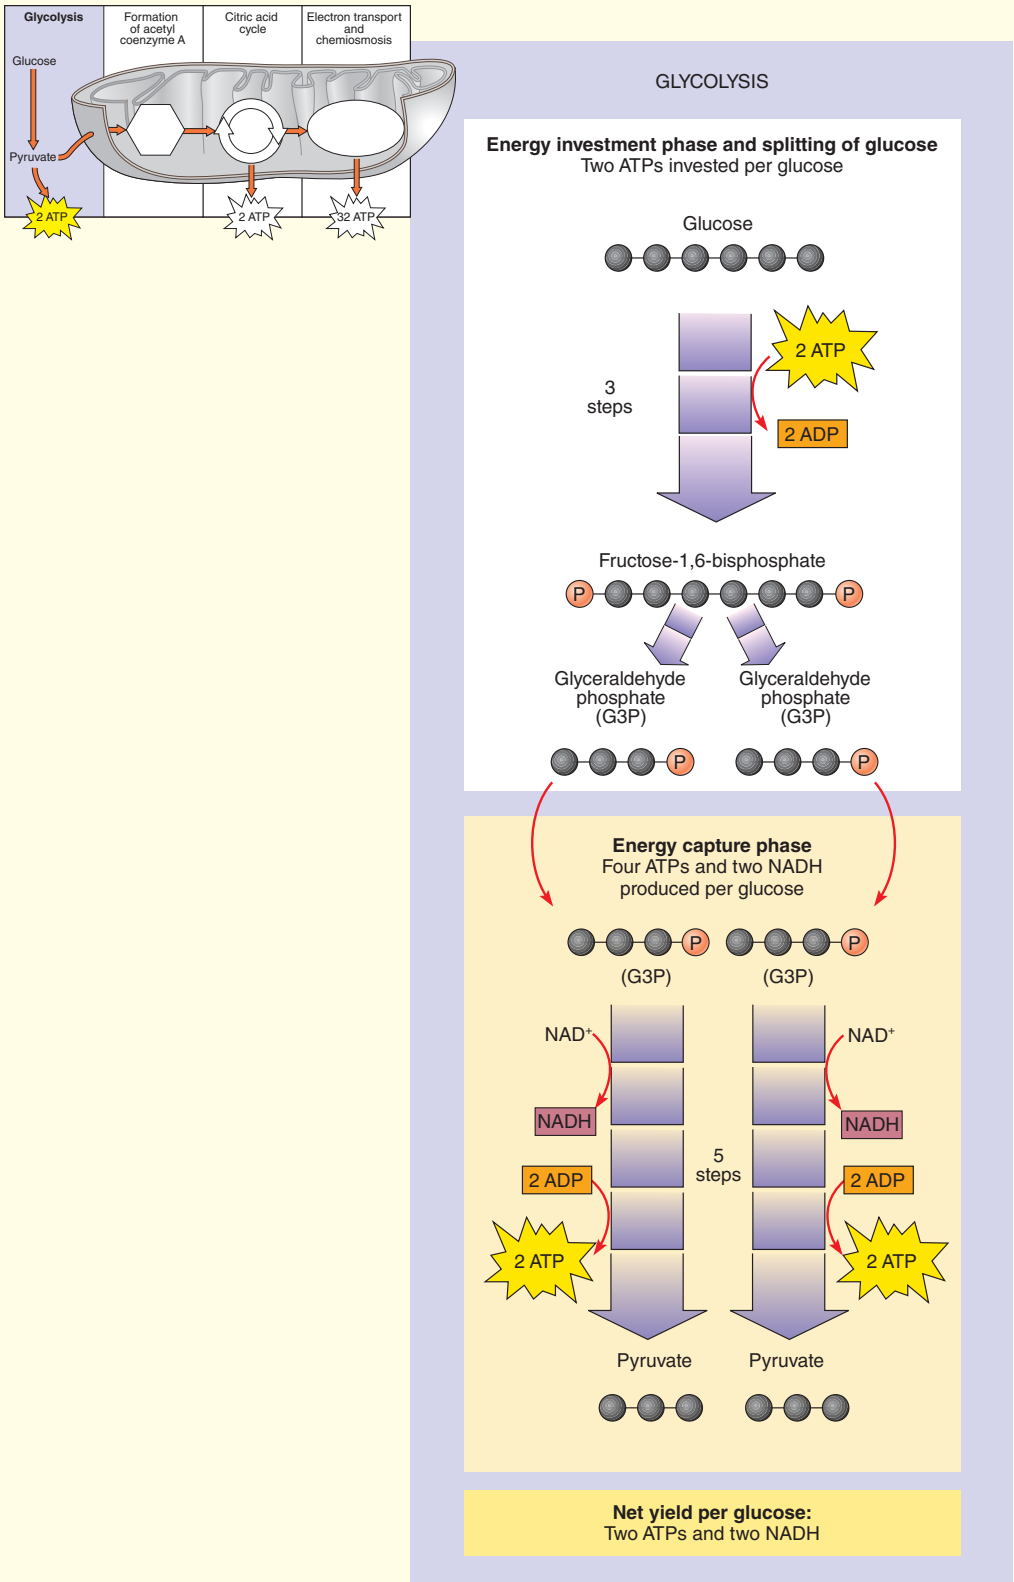

FIGURE 8-3 ***Animated*** **An overview of glycolysis**

The black spheres represent carbon atoms. The energy investment phase of glycolysis leads to the splitting of sugar; ATP and NADH are produced during the energy capture phase. During glycolysis, each glucose molecule is converted to two pyruvates, with a net yield of two ATP molecules and two NADH molecules.

www.konkur.in

Pyruvate is converted to acetyl CoA

In eukaryotes, the pyruvate molecules formed in glycolysis enter the mitochondria, where they are converted to **acetyl coenzyme A (acetyl CoA).** These reactions occur in the cytosol of aerobic prokaryotes. In this series of reactions, pyruvate undergoes a process known as **oxidative decarboxylation.** First, a carboxyl group is removed as carbon dioxide, which diffuses out of the cell (**FIG. 8-5**). Then the remaining two-carbon fragment becomes oxidized, and NAD^+ accepts the electrons removed during the oxidation. Finally, the oxidized two-carbon fragment, an acetyl group, becomes attached to **coenzyme A,** yielding acetyl CoA. *Pyruvate dehydrogenase,* the enzyme that catalyzes these reactions, is an enormous multienzyme complex consisting of 72 polypeptide chains! Recall from Chapter 7 that coenzyme A transfers groups derived from organic acids. In this case, coenzyme A transfers an acetyl group, which is related to acetic acid. Coenzyme A is manufactured in the cell from one of the B vitamins, pantothenic acid.

The overall reaction for the formation of acetyl coenzyme A is:

$$2 \text{ pyruvate} + 2 NAD^+ + 2 \text{ CoA} \longrightarrow 2 \text{ acetyl CoA} + 2 \text{ NADH} + 2 CO_2$$

Note that the original glucose molecule has now been partially oxidized, yielding two acetyl groups and two CO_2 molecules. The electrons removed have reduced NAD^+ to NADH. At this point in aerobic respiration, four NADH molecules have been formed as a result of the catabolism of a single glucose molecule: two during glycolysis and two during the formation of acetyl CoA from pyruvate. Keep in mind that these NADH molecules will be used later (during electron transport) to form additional ATP molecules.

The citric acid cycle oxidizes acetyl CoA

The **citric acid cycle** is also known as the **tricarboxylic acid (TCA) cycle** and the **Krebs cycle,** after Hans Krebs, the German biochemist who assembled the accumulated contributions of many scientists and worked out the details of the cycle in the 1930s. He received a Nobel Prize in Physiology or Medicine in 1953 for this contribution. A simplified overview of the citric acid cycle, which takes place in the matrix of the mitochondria, is given in **FIGURE 8-6**, page 180. The eight steps of the citric acid cycle are shown in **FIGURE 8-7**, page 181. A specific enzyme catalyzes each reaction.

The first reaction of the cycle occurs when acetyl CoA transfers its two-carbon acetyl group to the four-carbon acceptor compound **oxaloacetate,** forming **citrate,** a six-carbon compound.

$$\underset{\text{Four-carbon compound}}{\text{oxaloacetate}} + \underset{\text{Two-carbon compound}}{\text{acetyl CoA}} \longrightarrow \underset{\text{Six-carbon compound}}{\text{citrate}} + \text{CoA}$$

The citrate then goes through a series of chemical transformations, losing first one and then a second carboxyl group as CO_2. One ATP is formed (per acetyl group) by substrate-level phosphorylation. Most of the energy made available by the oxidative steps of the cycle is transferred as energy-rich electrons to NAD^+, forming NADH. For each acetyl group that enters the citric acid cycle, three molecules of NADH are produced (steps 3, 4, and 8). Electrons are also transferred to the electron acceptor FAD, forming $FADH_2$.

In the course of the citric acid cycle, two molecules of CO_2 and the equivalent of eight hydrogen atoms (8 protons and 8 electrons) are removed, forming three NADH and one $FADH_2$. You may wonder why more hydrogen equivalents are generated by these reactions than entered the cycle with the acetyl CoA molecule. These hydrogen atoms come from water molecules that are added during the reactions of the cycle. The CO_2 produced accounts for the two carbon atoms of the acetyl group that entered the citric acid cycle. At the end of each cycle, the four-carbon oxaloacetate has been regenerated, and the cycle continues.

Because two acetyl CoA molecules are produced from each glucose molecule, two cycles are required per glucose molecule. After two turns of the cycle, the original glucose has lost all its carbons and may be regarded as having been completely consumed. To summarize, the citric acid cycle yields four CO_2, six NADH, two $FADH_2$, and two ATPs per glucose molecule.

At this point in aerobic respiration, only four molecules of ATP have been formed per glucose by substrate-level phosphorylation: two during glycolysis and two during the citric acid cycle. Most of the energy of the original glucose molecule is in the form of high-energy electrons in NADH and $FADH_2$. Their energy will be used to synthesize additional ATP through the electron transport chain and chemiosmosis.

The electron transport chain is coupled to ATP synthesis

Let us consider the fate of all the electrons removed from a molecule of glucose during glycolysis, acetyl CoA formation, and the citric acid cycle. Recall that these electrons were transferred as part of hydrogen atoms to the acceptors NAD^+ and FAD, forming NADH and $FADH_2$. These reduced compounds now enter the **electron transport chain,** where the high-energy electrons of their hydrogen atoms are shuttled from one acceptor to another. As the electrons are passed along in a series of exergonic redox reactions, some of their energy is used to drive the synthesis of ATP, which is an endergonic process. Because ATP synthesis (by phosphorylation of ADP) is coupled to the redox reactions in the electron transport chain, the entire process is known as **oxidative phosphorylation.**

The electron transport chain transfers electrons from NADH and $FADH_2$ to oxygen

The electron transport chain is a series of electron carriers embedded in the inner mitochondrial membrane of eukaryotes and in the plasma membrane of aerobic prokaryotes. Like NADH and $FADH_2$, each carrier exists in an oxidized form or a reduced form. Electrons pass down the electron transport chain in a series of redox reactions that works much like a bucket brigade, the old-time chain of people who passed buckets of water from a stream to one another, to a building that was on fire. In the electron transport chain, each acceptor molecule becomes alternately reduced as it accepts electrons and oxidized as it gives them up. The electrons entering the electron transport chain have a relatively high energy content. They lose some of their energy at each step as they pass along the chain of electron carriers (just as some of the water spills out of the bucket as it is passed from one person to another).

www.konkur.in

www.konkur.in

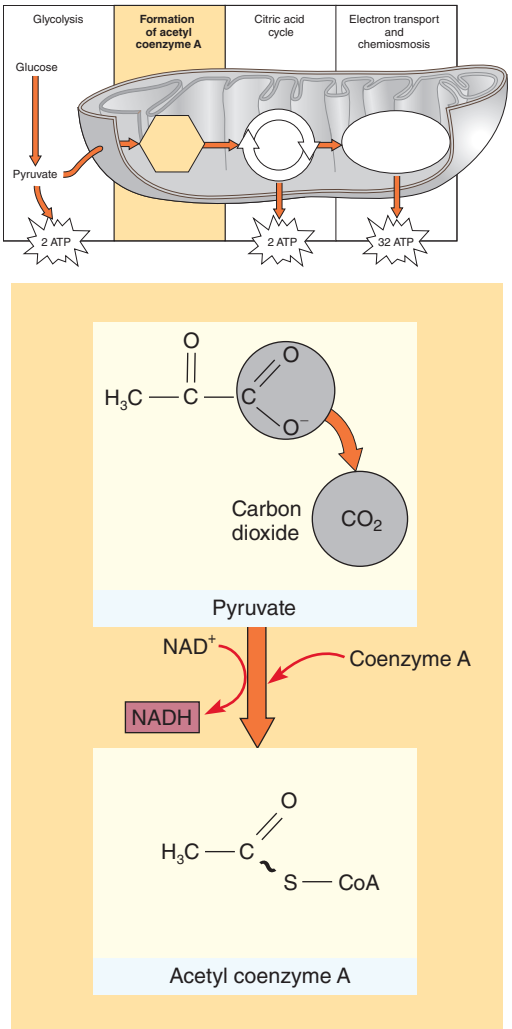

FIGURE 8-5 The formation of acetyl CoA

This series of reactions is catalyzed by the multienzyme complex pyruvate dehydrogenase. Pyruvate, a three-carbon molecule that is the end product of glycolysis, enters the mitochondrion and undergoes oxidative decarboxylation. First, the carboxyl group is split off as carbon dioxide. Then, the remaining two-carbon fragment is oxidized, and its electrons are transferred to NAD^+. Finally, the oxidized two-carbon group, an acetyl group, is attached to coenzyme A. CoA has a sulfur atom that forms a bond, shown as a black wavy line, with the acetyl group. When this bond is broken, the acetyl group can be readily transferred to another molecule.

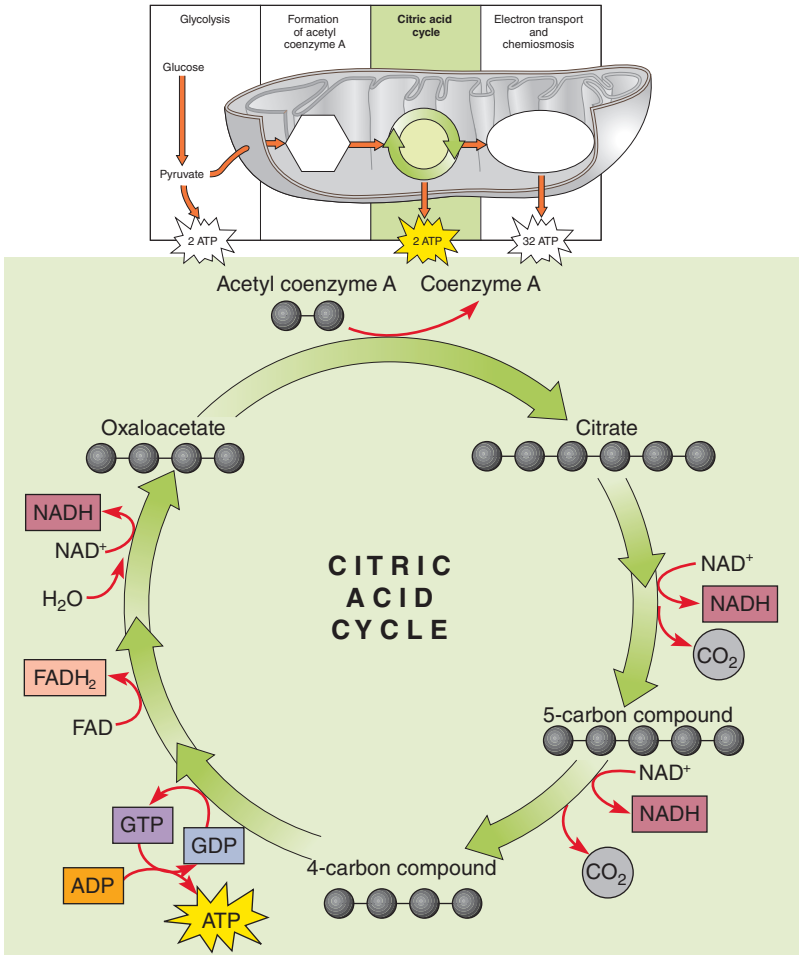

FIGURE 8-6 *Animated* Overview of the citric acid cycle

For every glucose, two acetyl groups enter the citric acid cycle (*top*). Each two-carbon acetyl group combines with a four-carbon compound, oxaloacetate, to form the six-carbon compound citrate. Two CO_2 molecules are removed, and energy is captured as one ATP, three NADH, and one $FADH_2$ per acetyl group (or two ATPs, six NADH, and two $FADH_2$ per glucose molecule).

Members of the electron transport chain include the flavoprotein *flavin mononucleotide (FMN),* the lipid *ubiquinone* (also called *coenzyme Q* or *CoQ*), several *iron–sulfur proteins,* and a group of closely related iron-containing proteins called *cytochromes* (**FIG. 8-8**). Each electron carrier has a different mechanism for accepting and passing electrons. As cytochromes accept and donate electrons, for example, the charge on the iron atom, which is the electron carrier portion of the cytochromes, alternates between Fe^{2+} (reduced) and Fe^{3+} (oxidized).

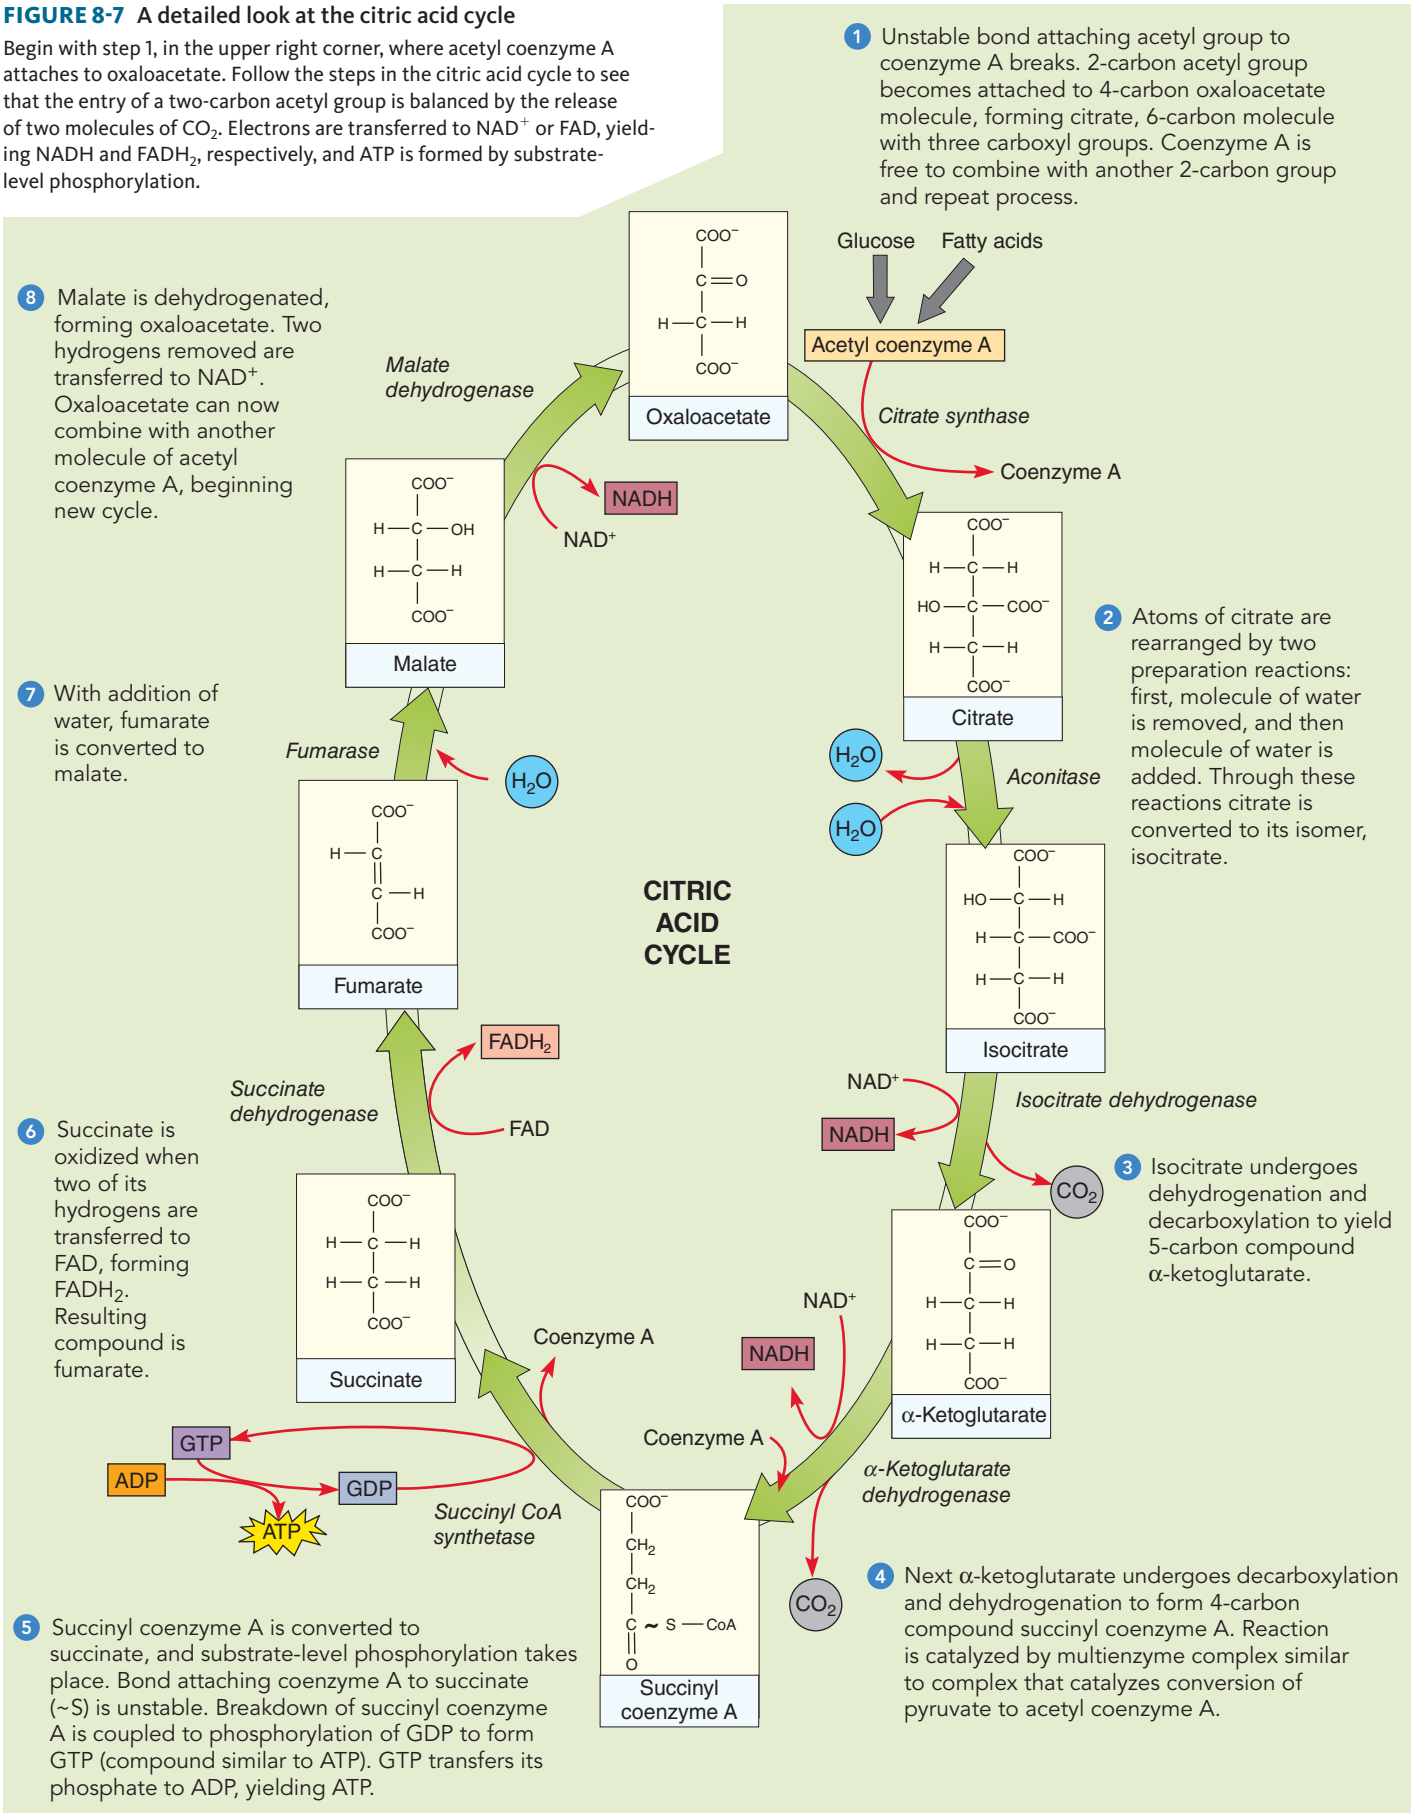
Scientists have extracted and purified the electron transport chain from the inner mitochondrial membrane as four large, distinct protein complexes, or groups, of acceptors. *Complex I (NADH–ubiquinone oxidoreductase)* accepts electrons from NADH molecules that were produced during glycolysis, the formation of acetyl CoA, and the citric acid cycle. *Complex II (succinate–ubiquinone reductase)* accepts electrons from $FADH_2$ molecules that were produced during the citric acid cycle. Complexes I and II both produce the same product, reduced ubiquinone, which is the substrate of *complex III (ubiquinone–cytochrome c oxidoreductase).* That is, complex III accepts electrons from reduced ubiquinone and passes them on to cytochrome *c. Complex IV (cytochrome c oxidase)* accepts electrons from cytochrome *c* and uses these electrons to reduce molecular oxygen, forming water in the process. The electrons simultaneously unite with protons from the surrounding medium to form hydrogen, and the chemical reaction between hydrogen and oxygen produces water.

Because oxygen is the final electron acceptor in the electron transport chain, organisms that respire aerobically require oxygen. What happens when cells that are strict aerobes are deprived of oxygen? The last cytochrome in the chain retains its electrons when no oxygen is available to accept them. When that occurs, each

www.konkur.in

FIGURE 8-7 A detailed look at the citric acid cycle

Begin with step 1, in the upper right corner, where acetyl coenzyme A attaches to oxaloacetate. Follow the steps in the citric acid cycle to see that the entry of a two-carbon acetyl group is balanced by the release of two molecules of CO_2. Electrons are transferred to NAD^+ or FAD, yielding NADH and $FADH_2$, respectively, and ATP is formed by substrate-level phosphorylation.



www.konkur.in

KEY POINT Electron carriers in the mitochondrial inner membrane transfer electrons from NADH and $FADH_2$ to oxygen.

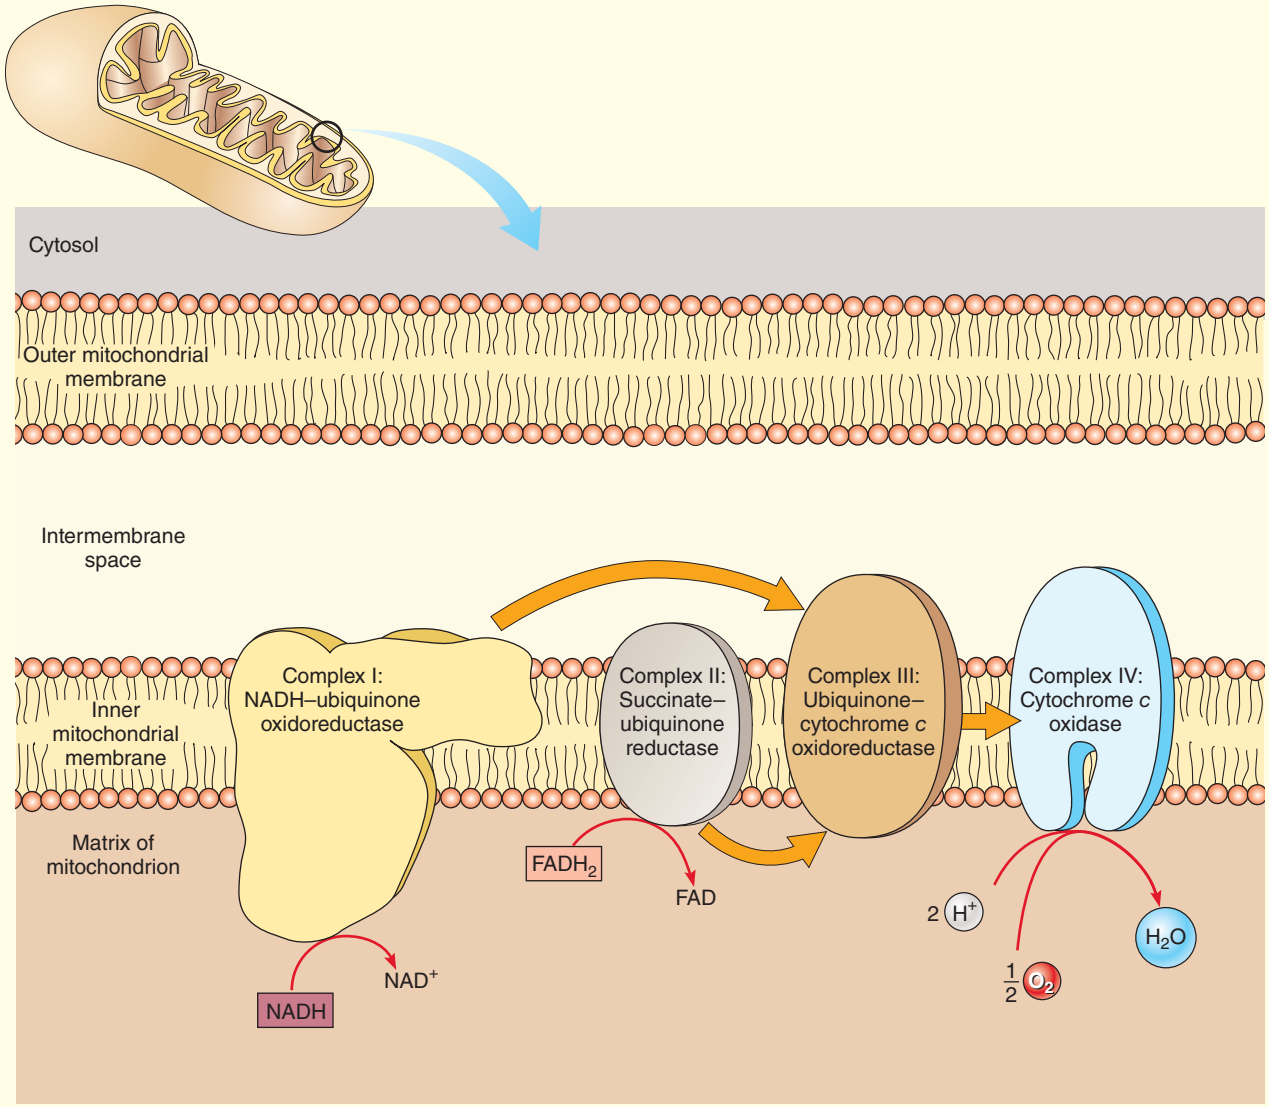


FIGURE 8-8 ***Animated*** **An overview of the electron transport chain**

Electrons fall to successively lower energy levels as they are passed along the four complexes of the electron transport chain located in the inner mitochondrial membrane. (The orange arrows indicate the pathway of electrons.) The carriers within each complex become alternately reduced and oxidized as they accept and donate electrons. The terminal acceptor is oxygen; one of the two atoms of an oxygen molecule (written as $\frac{1}{2}O_2$) accepts 2 electrons, which are added to 2 protons from the surrounding medium to produce water.

acceptor molecule in the chain retains its electrons (each remains in its reduced state), and the entire chain is blocked all the way back to NADH. Because oxidative phosphorylation is coupled to electron transport, no additional ATP is produced by way of the electron transport chain. Most cells of multicellular organisms cannot live long without oxygen because the small amount of ATP they produce by glycolysis alone is insufficient to sustain life processes.

Lack of oxygen is not the only factor that interferes with the electron transport chain. Some poisons, including cyanide, inhibit the normal activity of the cytochromes. Cyanide binds tightly to the iron in the last cytochrome in the electron transport chain, making it unable to transport electrons to oxygen. This blocks the further passage of electrons through the chain, and ATP production ceases.

Although the flow of electrons in electron transport is usually tightly coupled to the production of ATP, some organisms uncouple the two processes to produce heat (see *Inquiring About: Electron Transport and Heat*).

The chemiosmotic model explains the coupling of ATP synthesis to electron transport in aerobic respiration

For decades, scientists were aware that oxidative phosphorylation occurs in mitochondria, and many experiments had shown that the transfer of 2 electrons from each NADH to oxygen (via the

www.konkur.in

Inquiring About

ELECTRON TRANSPORT AND HEAT

What is the source of our body heat? Essentially, it is a byproduct of various exergonic reactions, especially those involving the electron transport chains in our mitochondria. Some cold-adapted animals, hibernating animals, and newborn animals produce unusually large amounts of heat by uncoupling electron transport from ATP production. These animals have adipose tissue (tissue in which fat is stored) that is brown. The brown color comes from the large number of mitochondria found in the brown adipose tissue cells. The inner mitochondrial membranes of these mitochondria contain an uncoupling protein that produces a passive proton channel through which protons flow into the mitochondrial matrix. As a consequence, most of the energy of glucose is converted to heat rather than to chemical energy in ATP.

Certain plants, which are not generally considered "warm" organisms, also have the ability to produce large amounts of heat. Skunk cabbage (*Symplocarpus foetidus*), for example, lives in North American swamps and wet woodlands and generally flowers during February and March when the ground is still covered with snow (see figure). Its uncoupled mitochondria generate large amounts of heat, enabling the plant to melt the snow and attract insect pollinators by vaporizing certain odiferous molecules into the surrounding air. The flower temperature of skunk cabbage is 15° to 22°C (59° to 72°F) when the air surrounding it is −15° to 10°C (5° to 50°F). Skunk cabbage flowers maintain this temperature for two weeks or more. Other plants, such as split leaf philodendron (*Philodendron selloum*) and sacred lotus (*Nelumbo nucifera*), also generate heat when they bloom and maintain their temperatures within precise limits.

Some plants generate as much or more heat per gram of tissue than animals in flight, which have long been considered the greatest heat producers in the living world. The European plant lords-and-ladies (*Arum maculatum*), for example, produces 0.4 J (0.1 cal) of heat per second per gram of tissue, whereas a hummingbird in flight produces 0.24 J (0.06 cal) per second per gram of tissue.

Leonard Lee Rue III/Animals Animals

This plant not only produces a significant amount of heat when it flowers but also regulates its temperature within a specific range.

electron transport chain) usually results in the production of up to three ATP molecules. However, for a long time, the connection between ATP synthesis and electron transport remained a mystery.

In 1961, Peter Mitchell, a British biochemist, proposed the *chemiosmotic model,* which was based on his experiments and on theoretical considerations. One type of experiment involved using bacteria as a model system (**FIG. 8-9**). Because the respiratory electron transport chain is located in the plasma membrane of an aerobic bacterial cell, the bacterial plasma membrane can be considered comparable to the inner mitochondrial membrane. Mitchell demonstrated that if bacterial cells were placed in an acidic environment (that is, an environment with a high hydrogen ion, or proton, concentration), the cells synthesized ATP even if electron transport was not taking place. On the basis of these and other experiments, Mitchell proposed that electron transport and ATP synthesis are coupled by means of a proton gradient across the inner mitochondrial membrane in eukaryotes (or across the plasma membrane in bacteria). His model was so radical that it was not immediately accepted, but by 1978, so much evidence had accumulated in support of **chemiosmosis** that Peter Mitchell was awarded a Nobel Prize in Chemistry.

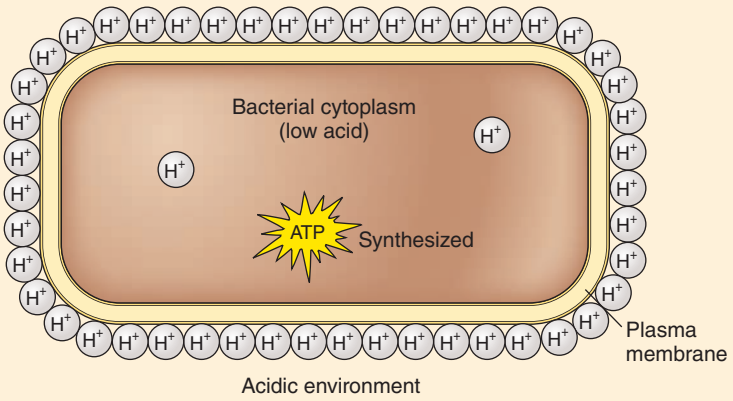
The electron transport chain establishes the proton gradient; some of the energy released as electrons pass down the electron transport chain is used to move protons (H^+) across a membrane. In eukaryotes the protons are moved across the inner mitochondrial membrane into the intermembrane space (**FIG. 8-10**). Hence, the inner mitochondrial

KEY EXPERIMENT

QUESTION: What is the mechanism of oxidative phosphorylation?

HYPOTHESIS: Peter Mitchell proposed that the cell uses energy released during electron transport to create a proton gradient across a membrane. The potential energy inherent in that gradient then drives the synthesis of ATP.

EXPERIMENT: Aerobic bacteria were placed in an acid (high H^+ concentration) environment, thus creating a proton gradient across the plasma membrane. This was done under conditions in which no electron transport was occurring.



RESULTS AND CONCLUSION: The bacteria synthesized ATP in the absence of aerobic respiration. These results supported Mitchell's view that a proton gradient across a membrane is an essential link in the conversion of the electrical energy of the electron transport chain to chemical energy in ATP.

FIGURE 8-9 Evidence for chemiosmosis

www.konkur.in

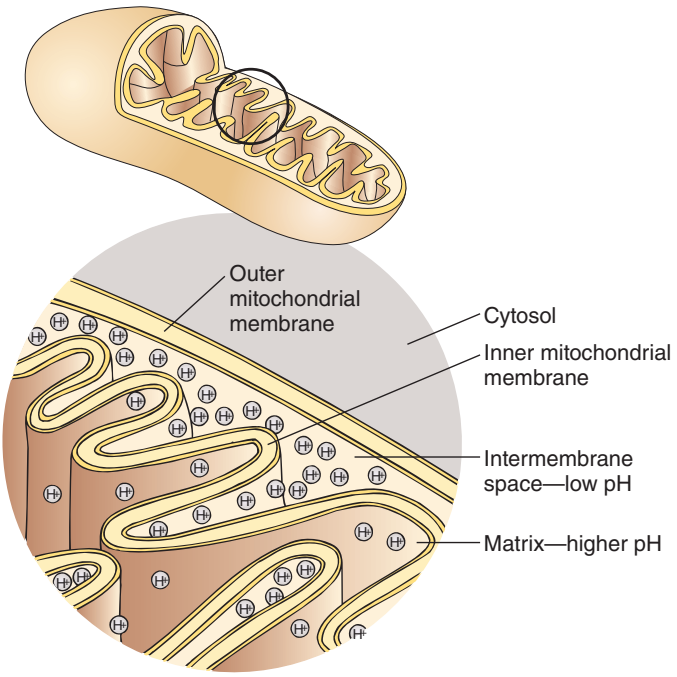


FIGURE 8-10 The accumulation of protons (H^+) within the intermembrane space

As electrons move down the electron transport chain, the electron transport complexes move protons (H^+) from the matrix to the intermembrane space, creating a proton gradient. The high concentration of H^+ in the intermembrane space lowers the pH.

membrane separates a space with a higher concentration of protons (the intermembrane space) from a space with a lower concentration of protons (the mitochondrial matrix).

Protons are moved across the inner mitochondrial membrane by three of the four electron transport complexes (complexes I, III, and IV) (**FIG. 8-11a**). Like water behind a dam, the resulting proton gradient is a form of potential energy that can be harnessed to provide the energy for ATP synthesis.

Diffusion of protons from the intermembrane space, where they are highly concentrated, through the inner mitochondrial membrane to the matrix of the mitochondrion is limited to specific channels formed by a fifth enzyme complex, **ATP synthase,** a transmembrane protein. Portions of these complexes project from the inner surface of the membrane (the surface that faces the matrix) and are visible by electron microscopy (**FIG. 8-11b**). Diffusion of the protons down their gradient, through the ATP synthase complex, is exergonic because the entropy of the system increases. This exergonic process provides the energy for ATP production, although the exact mechanism by which ATP synthase catalyzes the phosphorylation of ADP is still not completely understood.

In 1997, Paul Boyer of the University of California at Los Angeles and John Walker of the Medical Research Council Laboratory of Molecular Biology, Cambridge, England, shared the Nobel Prize in Chemistry for the discovery that ATP synthase functions in an unusual way. Experimental evidence strongly suggests that ATP synthase acts like a highly efficient molecular motor: During the production of ATP from ADP and inorganic phosphate, a central structure of ATP synthase rotates, possibly in response to the force of protons moving through the enzyme complex. The rotation apparently alters the conformation of the catalytic subunits in a way that drives ATP synthesis.

Chemiosmosis is a fundamental mechanism of energy coupling in cells; it allows exergonic redox reactions to drive the endergonic reaction in which ATP is produced by phosphorylating ADP. In photosynthesis (discussed in Chapter 9), ATP is produced by a comparable process.

Aerobic respiration of one glucose yields a maximum of 36 to 38 ATPs

Let us now review where biologically useful energy is captured in aerobic respiration and calculate the total energy yield from the complete oxidation of glucose. **FIGURE 8-12** summarizes the arithmetic involved.

1. In glycolysis, glucose is activated by the addition of phosphates from 2 ATP molecules and converted ultimately to 2 pyruvates + 2 NADH + 4 ATPs, yielding a net profit of 2 ATPs.
2. The 2 pyruvates are metabolized to 2 acetyl CoA + 2 CO_2 + 2 NADH.
3. In the citric acid cycle, the 2 acetyl CoA molecules are metabolized to 4 CO_2 + 6 NADH + 2 $FADH_2$ + 2 ATPs.

Because the oxidation of NADH in the electron transport chain yields up to 3 ATPs per molecule, the total of 10 NADH molecules can yield up to 30 ATPs. The 2 NADH molecules from glycolysis, however, yield either 2 or 3 ATPs each. The reason is that certain types of eukaryotic cells must expend energy to shuttle the NADH produced by glycolysis across the mitochondrial membrane (to be discussed shortly). Prokaryotic cells lack mitochondria; hence, they have no need to shuttle NADH molecules. For this reason, bacteria are able to generate 3 ATPs for every NADH, even those produced during glycolysis. Thus, the maximum number of ATPs formed using the energy from NADH is 28 to 30.

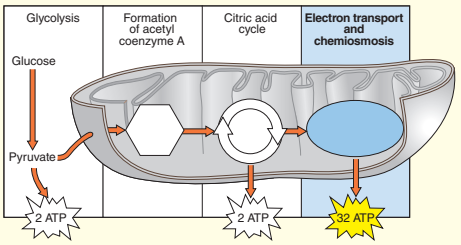
The oxidation of $FADH_2$ yields 2 ATPs per molecule (recall that electrons from $FADH_2$ enter the electron transport chain at a different location than those from NADH), so the 2 $FADH_2$ molecules produced in the citric acid cycle yield 4 ATPs.

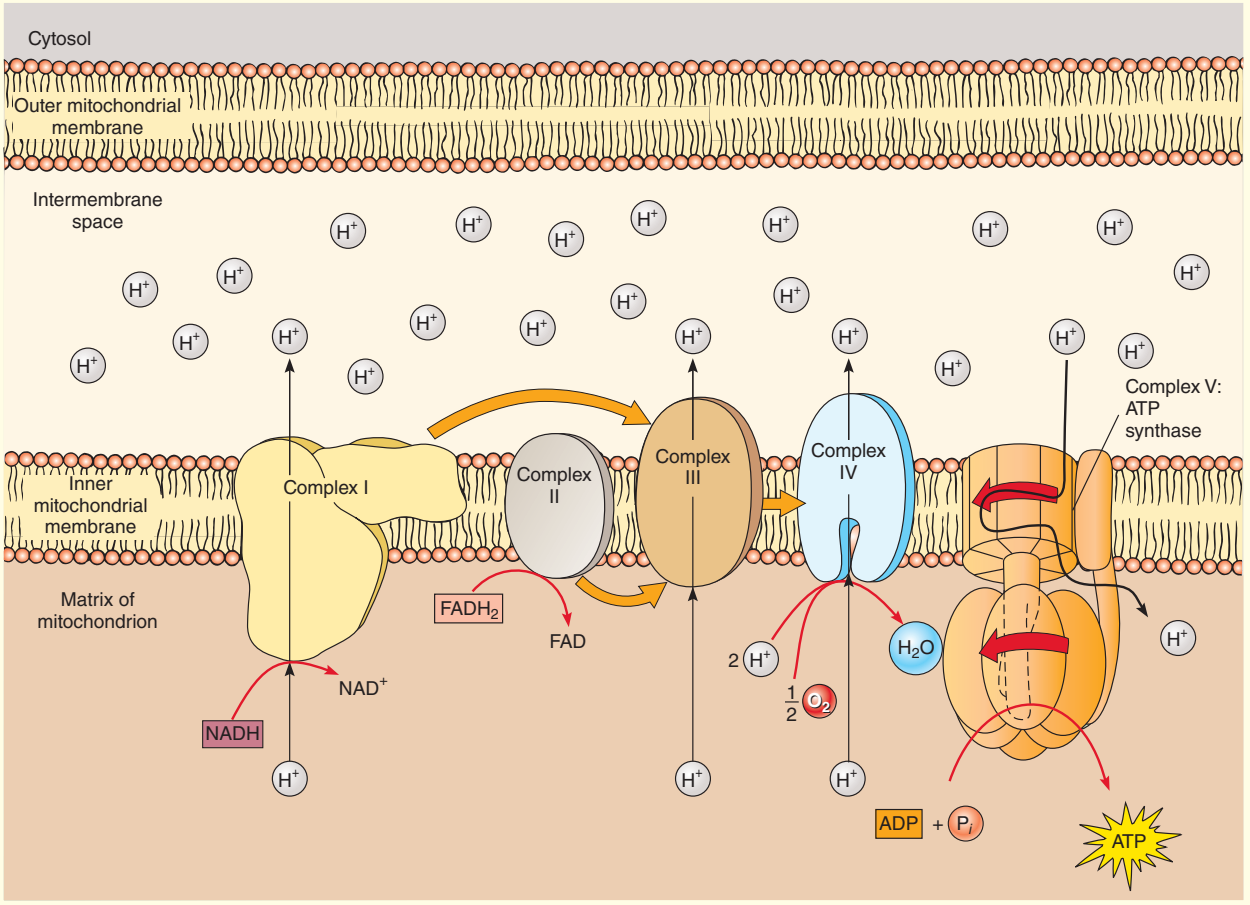
4. Summing all the ATPs (2 from glycolysis, 2 from the citric acid cycle, and 32 to 34 from electron transport and chemiosmosis), you can see that the complete aerobic metabolism of one molecule of glucose yields a maximum of 36 to 38 ATPs. Most ATP is generated by oxidative phosphorylation, which involves the electron transport chain and chemiosmosis. Only 4 ATPs are formed by substrate-level phosphorylation in glycolysis and the citric acid cycle.

We can analyze the efficiency of the overall process of aerobic respiration by comparing the free energy captured as ATP to the total free energy in a glucose molecule. Recall from Chapter 6 that although heat energy cannot power biological reactions, it is convenient to measure energy as heat. This is done through the use of a calorimeter, an instrument that measures the heat of a reaction. A sample is placed in a compartment surrounded by a chamber of water. As the sample burns (becomes oxidized), the temperature of the water rises, providing a measure of the heat released during the reaction.

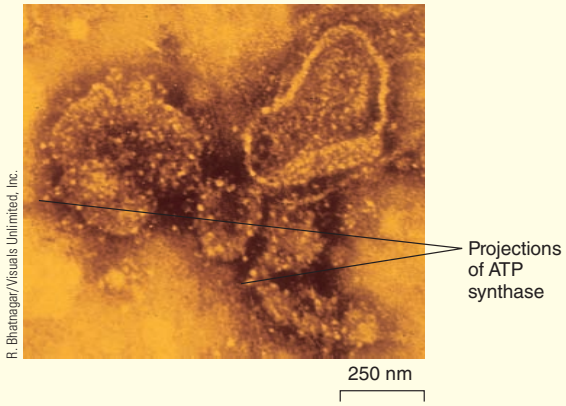
www.konkur.in

KEY POINT The electron transport chain forms a concentration gradient for H^+, which diffuses through ATP synthase complexes, producing ATP.





(a) The electron transport chain in the inner mitochondrial membrane includes three proton pumps that are located in three of the four electron transport complexes. (The orange arrows indicate the pathway of electrons; and the black arrows, the pathway of protons.) The energy released during electron transport is used to transport protons (H^+) from the mitochondrial matrix to the intermembrane space, where a high concentration of protons accumulates. The protons cannot diffuse back into the matrix except through special channels in ATP synthase in the inner membrane. The flow of the protons through ATP synthase provides the energy for generating ATP from ADP and inorganic phosphate (P_i). In the process, the inner part of ATP synthase rotates (thick red arrows) like a motor.



(b) This TEM shows hundreds of projections of ATP synthase complexes along the surface of the inner mitochondrial membrane.

FIGURE 8-11 A detailed look at electron transport and chemiosmosis

www.konkur.in

KEY POINT Most ATP is produced by electron transport and chemiosmosis (oxidative phosphorylation)

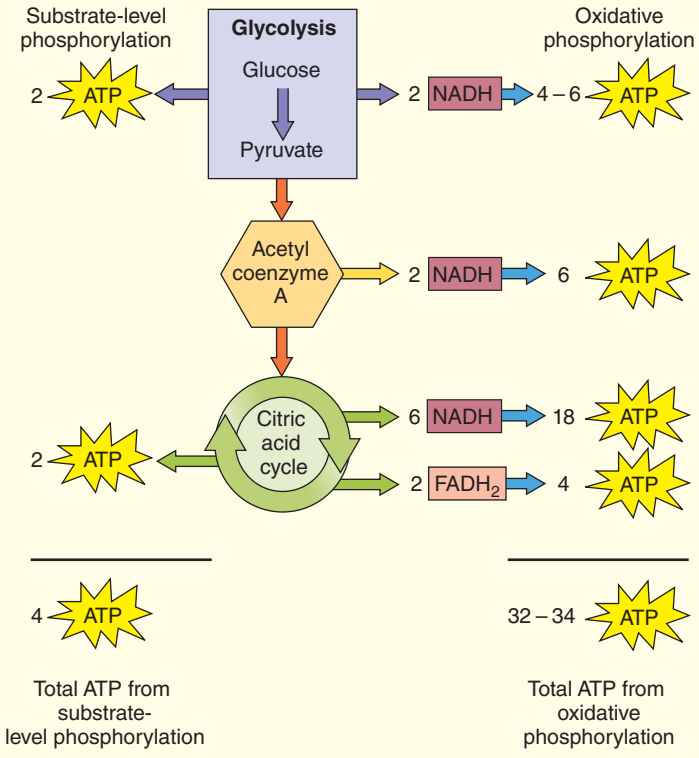


FIGURE 8-12 Energy yield from the complete oxidation of glucose by aerobic respiration

When 1 mol of glucose is burned in a calorimeter, some 686 kcal (2870 kJ) are released as heat. The free energy temporarily held in the phosphate bonds of ATP is about 7.6 kcal (31.8 kJ) per mole. When 36 to 38 ATPs are generated during the aerobic respiration of glucose, the free energy trapped in ATP amounts to 7.6 kcal/mol × 36, or about 274 kcal (1146 kJ) per mole. Thus, the efficiency of aerobic respiration is 274/686, or about 40%. (By comparison, a steam power plant has an efficiency of 35% to 36% in converting its fuel energy into electricity.) The remainder of the energy in the glucose is released as heat.

Mitochondrial shuttle systems harvest the electrons of NADH produced in the cytosol

The inner mitochondrial membrane is not permeable to NADH, which is a large molecule. Therefore, the NADH molecules produced in the cytosol during glycolysis cannot diffuse into the mitochondria to transfer their electrons to the electron transport chain. Unlike ATP and ADP, NADH does not have a carrier protein to transport it across the membrane. Instead, several systems have evolved to transfer just the *electrons* of NADH, not the NADH molecules themselves, into the mitochondria.

In liver, kidney, and heart cells, a special shuttle system transfers the electrons from NADH through the inner mitochondrial membrane to an NAD^+ molecule in the matrix. These electrons are transferred to the electron transport chain in the inner mitochondrial membrane, and up to three molecules of ATP are produced per pair of electrons.

In skeletal muscle, brain, and some other types of cells, another type of shuttle operates. Because this shuttle requires more energy than the shuttle in liver, kidney, and heart cells, the electrons are at a lower energy level when they enter the electron transport chain. They are accepted by ubiquinone rather than by NAD^+ and so generate a maximum of 2 ATP molecules per pair of electrons. For this reason, the number of ATPs produced by aerobic respiration of 1 molecule of glucose in skeletal muscle cells is 36 rather than 38.

Cells regulate aerobic respiration

Aerobic respiration requires a steady input of fuel molecules and oxygen. Under normal conditions these materials are adequately provided and do not affect the rate of respiration. Instead, the rate of aerobic respiration is regulated by how much ADP and phosphate are available, with ATP synthesis continuing until most of the ADP has been converted to ATP. At this point oxidative phosphorylation slows considerably, which in turn slows down the citric acid cycle.

Glycolysis is partly controlled by feedback regulation (see Fig. 7-15 for an illustration of feedback regulation) exerted on the enzyme phosphofructokinase, which catalyzes an early reaction of glycolysis (see Fig. 8-4). The active site of phosphofructokinase binds ATP and fructose-6-phosphate. However, the enzyme has two allosteric sites: an inhibitor site to which ATP binds when present at very high levels, and an activator site to which AMP (adenosine monophosphate, a molecule formed when two phosphates are removed from ATP) binds. Therefore, this enzyme is inactivated when ATP levels are high and activated when they are low. Respiration proceeds when the enzyme becomes activated, thus generating more ATP.

Review

- How much ATP is made available to the cell from a single glucose molecule by the operation of (1) glycolysis, (2) the formation of acetyl CoA, (3) the citric acid cycle, and (4) the electron transport chain and chemiosmosis?
- Why is each of the following essential to chemiosmotic ATP synthesis: (1) electron transport chain, (2) proton gradient, and (3) ATP synthase complex?
- What are the roles of NAD^+, FAD, and oxygen in aerobic respiration?
- What are some of the ways aerobic respiration is controlled?

8.3 ENERGY YIELD OF NUTRIENTS OTHER THAN GLUCOSE

LEARNING OBJECTIVE

7 Summarize how the products of protein and lipid catabolism enter the same metabolic pathway that oxidizes glucose.

www.konkur.in

Many organisms, including humans, depend on nutrients other than glucose as a source of energy. In fact, you usually obtain more of your energy by oxidizing fatty acids than by oxidizing glucose. Amino acids derived from protein digestion are also used as fuel molecules. Such nutrients are transformed into one of the metabolic intermediates that are fed into glycolysis or the citric acid cycle (**FIG. 8-13**).

Amino acids are metabolized by reactions in which the amino group ($—NH_2$) is first removed, a process called **deamination.** In mammals and some other animals, the amino group is converted to urea (see Fig. 48-1 for the biochemical pathway) and excreted, but the carbon chain is metabolized and eventually is used as a reactant in one of the steps of aerobic respiration. The amino acid alanine, for example, undergoes deamination to become pyruvate, the amino acid glutamate is converted to α-ketoglutarate, and the amino acid aspartate yields oxaloacetate. Pyruvate enters aerobic respiration as the end product of glycolysis, and α-ketoglutarate and oxaloacetate both enter aerobic respiration as intermediates in the citric acid cycle. Ultimately, the carbon chains of all the amino acids are metabolized in this way.

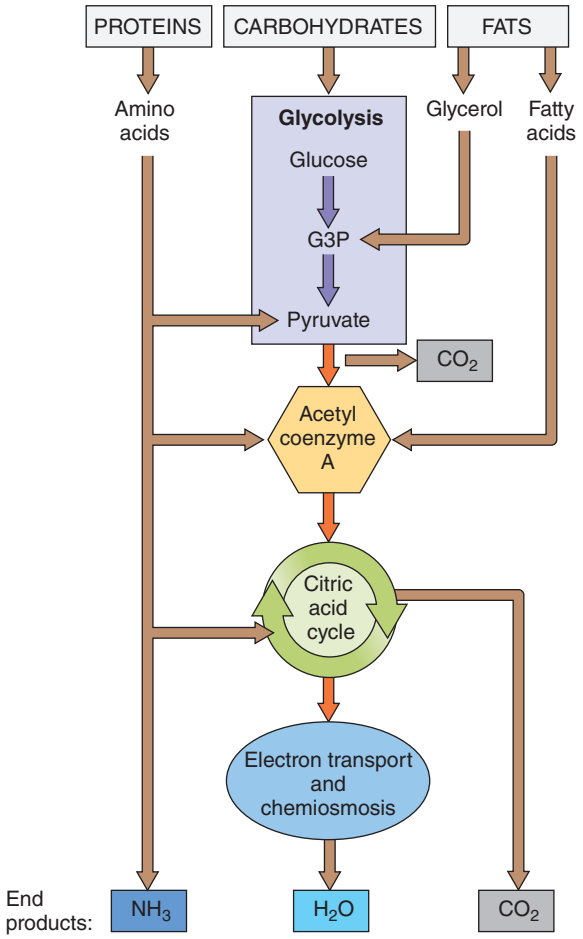

FIGURE 8-13 ***Animated*** **Energy from proteins, carbohydrates, and fats**

Products of the catabolism of proteins, carbohydrates, and fats enter glycolysis or the citric acid cycle at various points. This diagram is greatly simplified and illustrates only a few of the principal catabolic pathways.

Each gram of lipid in the diet contains 9 kcal (38 kJ), more than twice as much energy as 1 g of glucose or amino acids, which have about 4 kcal (17 kJ) per gram. Lipids are rich in energy because they are highly reduced; that is, they have many hydrogen atoms and few oxygen atoms. When completely oxidized in aerobic respiration, a molecule of a six-carbon fatty acid generates up to 44 ATPs (compared with 36 to 38 ATPs for a molecule of glucose, which also has six carbons).

Both the glycerol and fatty acid components of a triacylglycerol (see Figure 3-12 for structures) are used as fuel; phosphate is added to glycerol, converting it to G3P or another compound that enters glycolysis. Fatty acids are oxidized and split enzymatically into two-carbon acetyl groups that are bound to coenzyme A; that is, fatty acids are converted to acetyl CoA. This process, which occurs in the mitochondrial matrix, is called ***β*-oxidation** (beta-oxidation). Acetyl CoA molecules formed by β-oxidation enter the citric acid cycle.

Review

- How can a person obtain energy from a low-carbohydrate diet?
- What process must occur before amino acids enter the aerobic respiratory pathway?
- Where do fatty acids enter the aerobic respiratory pathway?

8.4 ANAEROBIC RESPIRATION AND FERMENTATION

LEARNING OBJECTIVE

8 Compare and contrast anaerobic respiration and fermentation. Include the mechanism of ATP formation, the final electron acceptor, and the end products.

Anaerobic respiration, which does not use oxygen as the final electron acceptor, is performed by some prokaryotes that live in anaerobic environments, such as waterlogged soil, stagnant ponds, and animal intestines. As in aerobic respiration, electrons are transferred in anaerobic respiration from glucose to NADH; they then pass down an electron transport chain that is coupled to ATP synthesis by chemiosmosis. However, an inorganic substance such as nitrate (NO_3^-) or sulfate (SO_4^{2-}) replaces molecular oxygen as the terminal electron acceptor. The end products of this type of anaerobic respiration are carbon dioxide, one or more reduced inorganic substances, and ATP. The following equation summarizes one representative type of anaerobic respiration, which is part of the biogeochemical cycle known as the **nitrogen cycle** (discussed in Chapter 55).

$$C_6H_{12}O_6 + 12\ KNO_3 \longrightarrow$$

Potassium nitrate

$$6\ CO_2 + 6\ H_2O + 12\ KNO_2 + \text{energy}$$

	Aerobic Respiration	Anaerobic Respiration	Fermentation
Immediate fate of electrons in NADH	Transferred to electron transport chain	Transferred to electron transport chain	Transferred to organic molecule
Terminal electron acceptor of electron transport chain	O_2	Inorganic substances such as NO_3^- or SO_4^{2-}	No electron transport chain
Reduced product(s) formed	Water	Relatively reduced inorganic substances	Relatively reduced organic compounds (commonly, alcohol or lactate)
Mechanism of ATP synthesis	Oxidative phosphorylation/ chemiosmosis; also substrate-level phosphorylation	Oxidative phosphorylation/chemiosmosis; also substrate-level phosphorylation	Substrate-level phosphorylation only (during glycolysis)

Certain other bacteria, as well as some fungi, regularly use **fermentation,** an anaerobic pathway that does not involve an electron transport chain. During fermentation only two ATPs are formed per glucose (by substrate-level phosphorylation during glycolysis). One might expect that a cell that obtains energy from glycolysis would produce pyruvate, the end product of glycolysis. However, this cannot happen because every cell has a limited supply of NAD^+, and NAD^+ is required for glycolysis to continue. If virtually all NAD^+ becomes reduced to NADH during glycolysis, then glycolysis stops and no more ATP is produced.

In fermentation, NADH molecules transfer their hydrogen atoms to organic molecules, thus regenerating the NAD^+ needed to keep glycolysis going. The resulting relatively reduced organic molecules (commonly, alcohol or lactate) tend to be toxic to the cells and are essentially waste products.

TABLE 8-2 compares aerobic respiration, anaerobic respiration, and fermentation.

Alcohol fermentation and lactate fermentation are inefficient

Yeasts are **facultative anaerobes** that carry out aerobic respiration when oxygen is available but switch to **alcohol fermentation** when deprived of oxygen (**FIG. 8-14a**). These eukaryotic, unicellular fungi have enzymes that decarboxylate pyruvate, releasing carbon dioxide and forming a two-carbon compound called *acetaldehyde.* NADH produced during glycolysis transfers hydrogen atoms to acetaldehyde, reducing it to *ethyl alcohol* (**FIG. 8-14b**). Alcohol fermentation is the basis for the production of beer, wine, and other alcoholic beverages. Yeast cells are also used in baking to

KEY POINT Fermentation regenerates NAD^+ needed for glycosis.

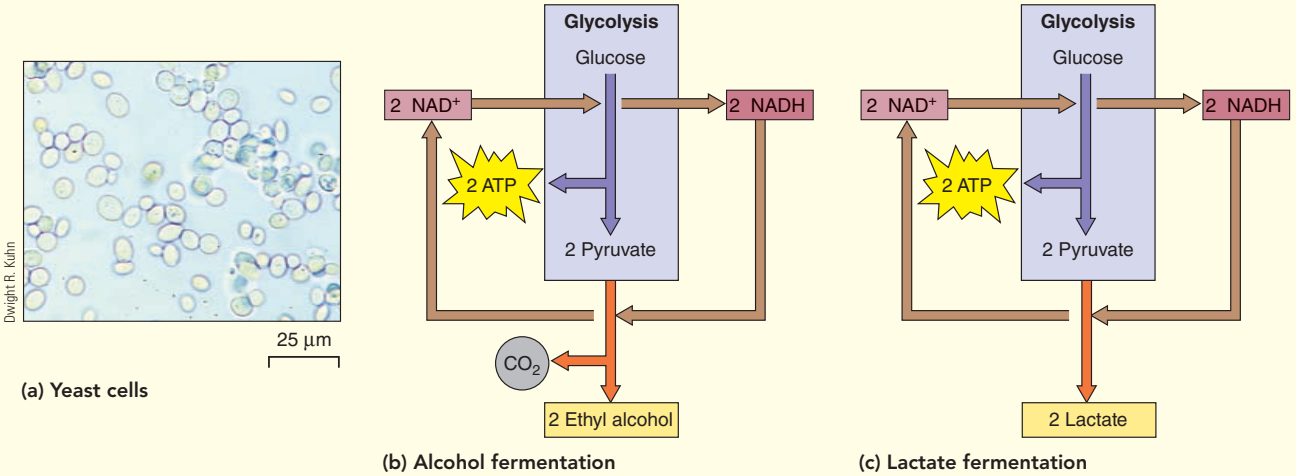

FIGURE 8-14 *Animated* Fermentation

(a) Light micrograph of live brewer's yeast (*Saccharomyces cerevisiae*). Yeast cells have mitochondria and carry on aerobic respiration when O_2 is present. In the absence of O_2, yeasts carry on alcohol fermentation. **(b, c)** Glycolysis is the first part of fermentation pathways. In alcohol fermentation **(b),** CO_2 is split off, and the two-carbon compound ethyl alcohol is the end product. In lactate fermentation **(c),** the final product is the three-carbon compound lactate. In both alcohol and lactate fermentation, there is a net gain of only two ATPs per molecule of glucose. Note that the NAD^+ used during glycolysis is regenerated during both alcohol fermentation and lactate fermentation.

www.konkur.in

produce the carbon dioxide that causes dough to rise; the alcohol evaporates during baking.

Certain fungi and bacteria perform **lactate (lactic acid) fermentation.** In this alternative pathway, NADH produced during glycolysis transfers hydrogen atoms to pyruvate, reducing it to *lactate* (**FIG. 8-14c**). The ability of some bacteria to produce lactate is exploited by humans, who use these bacteria to make yogurt and to ferment cabbage for sauerkraut.

Vertebrate muscle cells also produce lactate. Exercise can cause fatigue and muscle cramps possibly due to insufficient oxygen, the depletion of fuel molecules, and the accumulation of lactate during strenuous activity. This buildup of lactate occurs because muscle cells shift briefly to lactate fermentation if the amount of oxygen delivered to muscle cells is insufficient to support aerobic respiration. The shift is only temporary, however, and oxygen is required for sustained work. About 80% of the lactate is eventually exported to the liver, where it is used to regenerate more glucose for the muscle cells. The remaining 20% of the lactate is metabolized in muscle cells in the presence of oxygen. For this reason, you continue to breathe heavily after you have stopped exercising: the additional oxygen is needed to oxidize lactate, thereby restoring the muscle cells to their normal state.

Although humans use lactate fermentation to produce ATP for only a few minutes, a few animals can live without oxygen for much longer periods. The red-eared slider, a freshwater turtle, remains underwater for as long as two weeks. During this time, it is relatively inactive and therefore does not expend a great deal of energy. It relies on lactate fermentation for ATP production.

Both alcohol fermentation and lactate fermentation are highly inefficient because the fuel is only partially oxidized. Alcohol, the end product of fermentation by yeast cells, can be burned and is even used as automobile fuel; obviously, it contains a great deal of energy that the yeast cells cannot extract using anaerobic methods. Lactate, a three-carbon compound, contains even more energy than the two-carbon alcohol. In contrast, all available energy is removed during aerobic respiration because the fuel molecules become completely oxidized to CO_2. A net profit of only 2 ATPs is produced by the fermentation of one molecule of glucose, compared with up to 36 to 38 ATPs when oxygen is available.

The inefficiency of fermentation necessitates a large supply of fuel. To perform the same amount of work, a cell engaged in fermentation must consume up to 20 times as much glucose or other carbohydrate per second as a cell using aerobic respiration. For this reason, your skeletal muscle cells store large quantities of glucose in the form of glycogen, which enables them to metabolize anaerobically for short periods.

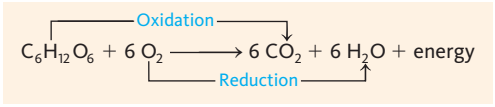
Review

- What is the fate of hydrogen atoms removed from glucose during glycolysis when oxygen is present in muscle cells? How does this compare to the fate of hydrogen atoms removed from glucose when the amount of available oxygen is insufficient to support aerobic respiration?
- Why is the ATP yield of fermentation only a tiny fraction of the yield from aerobic respiration?

SUMMARY: FOCUS ON LEARNING OBJECTIVES

8.1 *(page 173)*

1 Write a summary reaction for aerobic respiration that shows which reactant becomes oxidized and which becomes reduced.



- **Aerobic respiration** is a catabolic process in which a fuel molecule such as glucose is broken down to form carbon dioxide and water. It includes **redox reactions** that result in the transfer of electrons from glucose (which becomes **oxidized**) to oxygen (which becomes **reduced**).
- Energy released during aerobic respiration is used to produce up to 36 to 38 ATPs per molecule of glucose.

8.2 *(page 173)*

2 List and give a brief overview of the four stages of aerobic respiration.

- The chemical reactions of aerobic respiration occur in four stages: glycolysis, formation of acetyl CoA, the citric acid cycle, and the electron transport chain and chemiosmosis.
- During **glycolysis,** a molecule of glucose is degraded to two molecules of **pyruvate.** Two ATP molecules (net) are produced by **substrate-level phosphorylation** during glycolysis. Four hydrogen atoms are removed and used to produce two NADH.

CENGAGENOW™ See the process of glycolysis unfold by clicking on the figure in CengageNOW.

- During the formation of **acetyl CoA,** the two pyruvate molecules each lose a molecule of carbon dioxide, and the remaining acetyl groups each combine with **coenzyme A,** producing two molecules of acetyl CoA; one NADH is produced per pyruvate.
- Each acetyl CoA enters the **citric acid cycle** by combining with a four-carbon compound, **oxaloacetate,** to form **citrate,** a six-carbon compound. Two acetyl CoA molecules enter the cycle for every glucose molecule. For every two carbons that enter the cycle as part of an acetyl CoA molecule, two leave as carbon dioxide. For every acetyl CoA, hydrogen atoms are transferred to three NAD^+ and one FAD; only one ATP is produced by substrate-level phosphorylation.

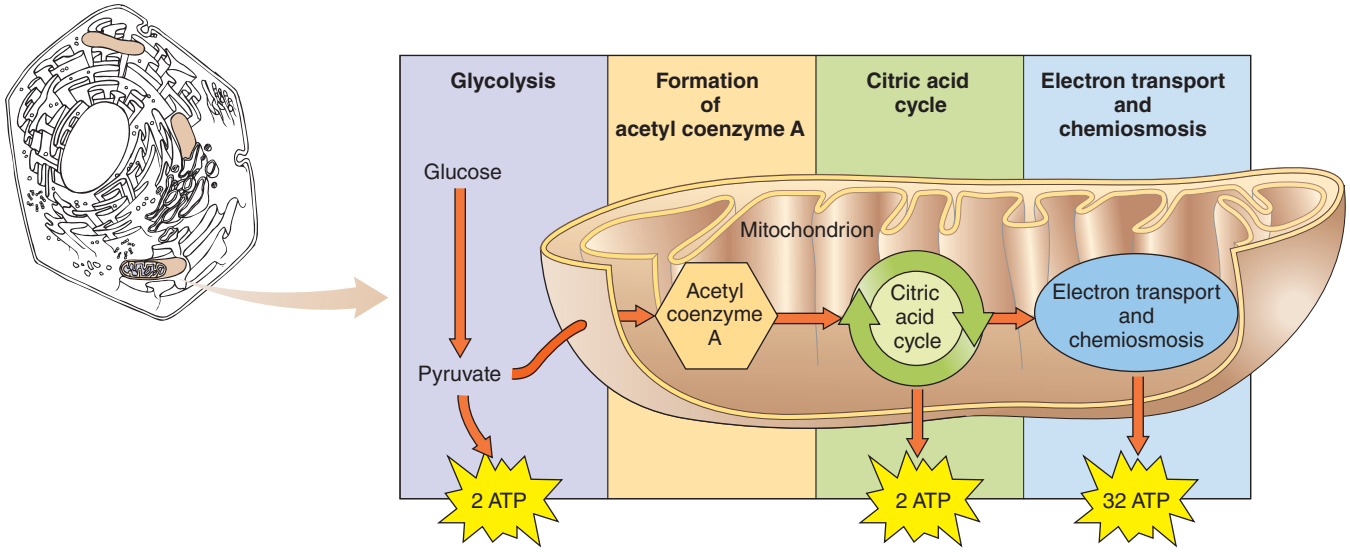
CENGAGENOW™ Interact with the citric acid cycle by clicking on the figure in CengageNOW.

- Hydrogen atoms (or their electrons) removed from fuel molecules are transferred from one electron acceptor to another down an **electron transport chain** located in the mitochondrial inner membrane; ultimately, these electrons reduce molecular oxygen, forming water. In **oxidative phosphorylation,** the redox reactions in the electron transport chain are coupled to synthesis of ATP through the mechanism of **chemiosmosis.**

CENGAGENOW™ See the electron transport chain in action by clicking on the figure in CengageNOW.

3 Indicate where each stage of aerobic respiration takes place in a eukaryotic cell.

www.konkur.in



- Glycolysis occurs in the cytosol, and the remaining stages of aerobic respiration take place in the mitochondria.

4 Add up the energy captured (as ATP, NADH, and $FADH_2$) in each stage of aerobic respiration.

- In glycolysis, each glucose molecule produces 2 NADH and 2 ATPs (net). The conversion of 2 pyruvates to acetyl CoA results in the formation of 2 NADH. In the citric acid cycle, the 2 acetyl CoA molecules are metabolized to form 6 NADH, 2 $FADH_2$, and 2 ATPs. To summarize, we have 4 ATPs, 10 NADH, and 2 $FADH_2$.
- When electrons donated by the 10 NADH and 2 $FADH_2$ pass through the electron transport chain, 32 to 34 ATPs are produced by chemiosmosis. Therefore, each glucose molecule yields a total of up to 36 to 38 ATPs.

5 Define *chemiosmosis* and explain how a gradient of protons is established across the inner mitochondrial membrane.

- In chemiosmosis, some of the energy of the electrons in the electron transport chain is used to pump protons across the inner mitochondrial membrane into the intermembrane space. This pumping establishes a proton gradient across the inner mitochondrial membrane. Protons (H^+) accumulate within the intermembrane space, lowering the pH.

6 Describe the process by which the proton gradient drives ATP synthesis in chemiosmosis.

- The diffusion of protons through channels formed by the enzyme **ATP synthase,** which extends through the inner mitochondrial membrane from the intermembrane space to the mitochondrial matrix, provides the energy to synthesize ATP.

8.3 *(page 186)*

7 Summarize how the products of protein and lipid catabolism enter the same metabolic pathway that oxidizes glucose.

- Amino acids undergo **deamination,** and their carbon skeletons are converted to metabolic intermediates of aerobic respiration.
- Both the glycerol and fatty acid components of lipids are oxidized as fuel. Fatty acids are converted to acetyl CoA molecules by the process of ***β*-oxidation.**

8.4 *(page 187)*

8 Compare and contrast anaerobic respiration and fermentation. Include the mechanism of ATP formation, the final electron acceptor, and the end products.

- In **anaerobic respiration,** electrons are transferred from fuel molecules to an electron transport chain that is coupled to ATP synthesis by chemiosmosis; the final electron acceptor is an inorganic substance such as nitrate or sulfate, not molecular oxygen.
- **Fermentation** is an anaerobic process that does not use an electron transport chain. There is a net gain of only two ATPs per glucose; these are produced by substrate-level phosphorylation during glycolysis. To maintain the supply of NAD^+ essential for glycolysis, hydrogen atoms are transferred from NADH to an organic compound derived from the initial nutrient.
- Yeast cells carry out **alcohol fermentation,** in which ethyl alcohol and carbon dioxide are the final waste products.
- Certain fungi, prokaryotes, and animal cells carry out **lactate (lactic acid) fermentation,** in which hydrogen atoms are added to pyruvate to form lactate, a waste product.

CENGAGENOW™ Learn more about fermentation by clicking on the figure in CengageNOW.

Summary Reactions for Aerobic Respiration

Summary reaction for the complete oxidation of glucose:

$$C_6H_{12}O_6 + 6\,O_2 + 6\,H_2O \longrightarrow 6\,CO_2 + 12\,H_2O + \text{energy (36 to 38 ATP)}$$

Summary reaction for glycolysis:

$$C_6H_{12}O_6 + 2\,ATP + 2\,ADP + 2\,P_i + 2\,NAD^+ \longrightarrow 2\,\text{pyruvate} + 4\,ATP + 2\,NADH + H_2O$$

Summary reaction for the conversion of pyruvate to acetyl CoA:

$$2\,\text{pyruvate} + 2\,\text{coenzyme A} + 2\,NAD^+ \longrightarrow 2\,\text{acetyl CoA} + 2\,CO_2 + 2\,NADH$$

Summary reaction for the citric acid cycle:

$$2\,\text{acetyl CoA} + 6\,NAD^+ + 2\,FAD + 2\,ADP + 2\,P_i + 2\,H_2O \longrightarrow 4\,CO_2 + 6\,NADH + 2\,FADH_2 + 2\,ATP + 2\,CoA$$

www.konkur.in

Summary reactions for the processing of the hydrogen atoms of NADH and $FADH_2$ in the electron transport chain:

$$NADH + 3\ ADP + 3\ P_i + \tfrac{1}{2}\ O_2 \longrightarrow NAD^+ + 3\ ATP + H_2O$$

$$FADH_2 + 2\ ADP + 2\ P_i + \tfrac{1}{2}\ O_2 \longrightarrow FAD^+ + 2\ ATP + H_2O$$

Summary Reactions for Fermentation

Summary reaction for lactate fermentation:

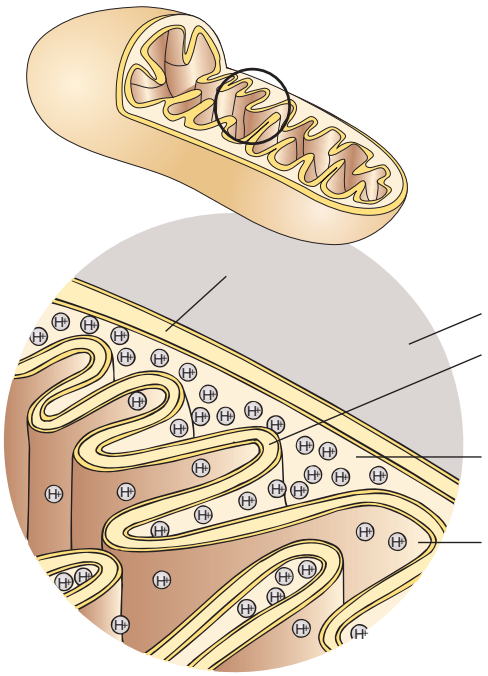
$$C_6H_{12}O_6 \longrightarrow 2\ \text{lactate} + \text{energy (2 ATP)}$$

Summary reaction for alcohol fermentation:

$$C_6H_{12}O_6 \longrightarrow 2\ CO_2 + 2\ \text{ethyl alcohol} + \text{energy (2 ATP)}$$

TEST YOUR UNDERSTANDING

1. A chemical process during which a substance gains electrons and energy is called (a) oxidation (b) oxidative phosphorylation (c) deamination (d) reduction (e) dehydrogenation
2. Which of the following is a correct ranking of molecules with respect to their energy value in glycolysis (*note:* > means "greater than")? (a) two pyruvates > one glucose (b) one glucose > one fructose-1,6-bisphosphate (c) two glyceraldehyde-3-phosphates (G3P) > one glucose (d) two pyruvates > one fructose-1,6-bisphosphate (e) two pyruvates > two glyceraldehyde-3-phosphates (G3P)
3. The reactions of _____ take place within the cytosol of eukaryotic cells. (a) glycolysis (b) oxidation of pyruvate (c) the citric acid cycle (d) chemiosmosis (e) the electron transport chain
4. Before pyruvate enters the citric acid cycle, it is decarboxylated, oxidized, and combined with coenzyme A, forming acetyl CoA, carbon dioxide, and one molecule of (a) NADH (b) $FADH_2$ (c) ATP (d) ADP (e) $C_6H_{12}O_6$
5. In the first step of the citric acid cycle, acetyl CoA reacts with oxaloacetate to form (a) pyruvate (b) citrate (c) NADH (d) ATP (e) CO_2
6. Which of the following is the major source of electrons that flow through the mitochondrial electron transport chain? (a) H_2O (b) ATP (c) NADH (d) ATP synthase (e) coenzyme A
7. The "aerobic" part of aerobic cellular respiration occurs during (a) glycolysis (b) the conversion of pyruvate to acetyl CoA (c) the citric acid cycle (d) electron transport (e) all of the above are aerobic processes
8. Substrate-level phosphorylation (a) occurs through a chemiosmotic mechanism (b) accounts for most of the ATP formed during aerobic cellular respiration (c) occurs during the conversion of pyruvate to acetyl CoA (d) occurs during glycolysis and the citric acid cycle (e) requires high energy electrons from NADH
9. Which of the following is a correct ranking of molecules, according to their energy value in oxidative phosphorylation (*note:* > means "greater than")? (a) ATP = NADH (b) NAD^+ > NADH (c) FAD > $FADH_2$ (d) NADH > ATP
10. A net profit of only 2 ATPs can be produced anaerobically from the _____ of one molecule of glucose, compared with a maximum of 38 ATPs produced in _____. (a) fermentation; anaerobic respiration (b) aerobic respiration; fermentation (c) aerobic respiration; anaerobic respiration (d) dehydrogenation; decarboxylation (e) fermentation; aerobic respiration
11. When deprived of oxygen, yeast cells obtain energy by fermentation, producing carbon dioxide, ATP, and (a) acetyl CoA (b) ethyl alcohol (c) lactate (d) pyruvate (e) citrate
12. Label the figure. Use Figure 8-10 to check your answers.



www.konkur.in

CRITICAL THINKING

1. How are the endergonic reactions of the first phase of glycolysis coupled to the hydrolysis of ATP, which is exergonic? How are the exergonic reactions of the second phase of glycolysis coupled to the endergonic synthesis of ATP and NADH?
2. In what ways is the inner mitochondrial membrane essential to the coupling of electron transport and ATP synthesis? Could the membrane carry out its function if its lipid bilayer were readily permeable to hydrogen ions (protons)?
3. Based on what you have learned in this chapter, explain why a schoolchild can run 17 miles per hour in a 100-yard dash, but a trained athlete can run only about 11.5 miles per hour in a 26-mile marathon.
4. When you lose weight, where does it go?
5. **EVOLUTION LINK.** The reactions of glycolysis are identical in *all* organisms—prokaryotes, protists, fungi, plants, and animals—that obtain energy from glucose catabolism. What does this universality suggest about the evolution of glycolysis?
6. **EVOLUTION LINK.** Molecular oxygen is so reactive that it would not exist in Earth's atmosphere today if it were not constantly replenished by organisms that release oxygen as a waste product of photosynthesis. What does that fact suggest about the evolution of aerobic respiration and oxygen-releasing photosynthetic processes?

9 Photosynthesis: Capturing Light Energy

© tbkmedia.de/Alamy

Photosynthesis. These trees use light energy to power the processes that incorporate CO_2 into organic molecules.

KEY CONCEPTS

9.1 Light energy powers photosynthesis, which is essential to plants and most life on Earth.

9.2 Photosynthesis occurs in chloroplasts and requires the pigment chlorophyll.

9.3 Photosynthesis is a redox process.

9.4 Light-dependent reactions convert light energy to the chemical energy of NADPH and ATP.

9.5 Carbon fixation reactions incorporate CO_2 into organic molecules.

9.6 Most photosynthetic organisms are photoautotrophs.

9.7 Photosynthesis is important to plants and also other organisms.

Look at all the living things that surround you—the trees, your pet goldfish, your own body. Most of that biomass is made up of carbon-based biological molecules. What is the ultimate source of all that carbon? Surprising to some, the source is carbon dioxide from the air. Your cells cannot take carbon dioxide from the air and incorporate it into organic molecules—but some plant cells can. They do this through **photosynthesis,** the sequence of events by which light energy is converted into the stored chemical energy of organic molecules. Photosynthesis is the first step in the flow of energy through most of the living world, capturing the vast majority of the energy that living organisms use. Photosynthesis not only sustains plants (see photograph) and other photosynthetic organisms such as algae and photosynthetic bacteria but also indirectly supports most nonphotosynthetic organisms such as animals, fungi, protozoa, and most bacteria.

Each year photosynthetic organisms convert CO_2 into billions of tons of organic molecules. These molecules have two important roles in both photosynthetic and nonphotosynthetic organisms: they are both the building blocks of cells and, as we saw in Chapter 8, a source of chemical energy that fuels the metabolic reactions that sustain almost all life. Photosynthesis also releases O_2, which is essential to aerobic cellular respiration, the process by which plants, animals, and most other organisms convert this chemical energy to ATP to power cellular processes.

www.konkur.in

In this chapter we first examine how light energy is used in the synthesis of ATP and other molecules that temporarily hold chemical energy but are unstable and cannot be stockpiled in the cell. We then see how their energy powers the anabolic pathway by which a photosynthetic cell synthesizes stable organic molecules from the simple inorganic compounds CO_2 and water. Finally, we explore the role of photosynthesis in plants and in Earth's environment.

9.1 LIGHT AND PHOTOSYNTHESIS

LEARNING OBJECTIVE

1 Describe the physical properties of light and explain the relationship between a wavelength of light and its energy.

Because most life on this planet depends on light, either directly or indirectly, it is important to understand the nature of light and its essential role in photosynthesis. Visible light represents a very small portion of a vast, continuous range of radiation called the *electromagnetic spectrum* (FIG. 9-1). All radiation in this spectrum travels as waves. A **wavelength** is the distance from one wave peak to the next.

At one end of the electromagnetic spectrum are gamma rays, which have very short wavelengths measured in fractions of nanometers, or nm (1 nanometer equals 10^{-9} m, one-billionth of a meter). At the other end of the spectrum are radio waves, with wavelengths so long they can be measured in kilometers. The portion of the electromagnetic spectrum from 380 to 760 nm is called the *visible spectrum* because we humans can see it. The visible spectrum includes all the colors of the rainbow (FIG. 9-2); violet has the shortest wavelength, and red has the longest.

Light is composed of small particles, or packets, of energy called **photons.** The energy of a photon is inversely proportional to its wavelength: shorter-wavelength light has more energy per photon than longer-wavelength light.

Why does photosynthesis depend on light detectable by the human eye (visible light) rather than on some other wavelength of radiation? We can only speculate about the answer. Perhaps the reason is that radiation within the visible-light portion of the spectrum excites certain types of biological molecules, moving electrons into higher energy levels. Radiation with wavelengths longer than those of visible light does not have enough energy to excite these biological molecules. Radiation with wavelengths shorter than those of visible light is so energetic that it disrupts the bonds of many biological molecules. Thus, visible light has just the right amount of energy to cause the kinds of reversible changes in molecules that are useful in photosynthesis.

When a molecule absorbs a photon of light energy, one of its electrons becomes energized, which means that the electron shifts from a lower-energy atomic orbital to a high-energy orbital that is more distant from the atomic nucleus. One of two things then happens to the energized electron, depending on the atom and its

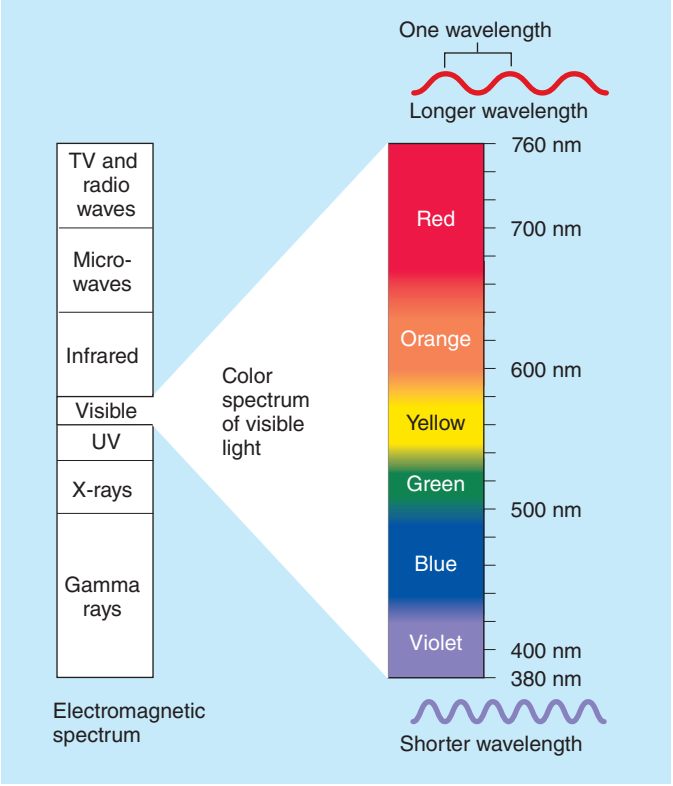

FIGURE 9-1 ***Animated*** **The electromagnetic spectrum**
Waves in the electromagnetic spectrum have similar properties but different wavelengths. Radio waves are the longest (and least energetic) waves, with wavelengths as long as 20 km. Gamma rays are the shortest (and most energetic) waves. Visible light represents a small fraction of the electromagnetic spectrum and consists of a mixture of wavelengths ranging from about 380 to 760 nm. The energy from visible light is used in photosynthesis.

surroundings (FIG. 9-3). The atom may return to its **ground state,** which is the condition in which all its electrons are in their normal, lowest-energy levels. When an electron returns to its ground state, its energy dissipates as heat or as an emission of light of a longer wavelength than the absorbed light; this emission of light is called **fluorescence.** Alternatively, the energized electron may leave the atom and be accepted by an electron acceptor molecule,

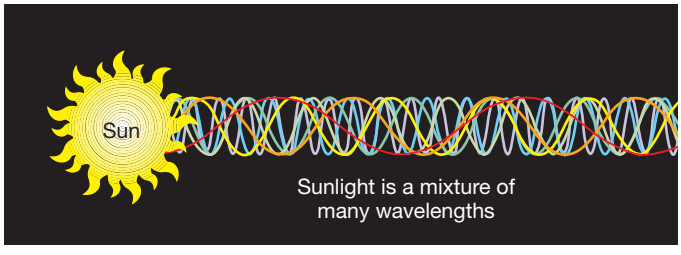

FIGURE 9-2 **Visible radiation emitted from the sun**
Electromagnetic radiation from the sun includes ultraviolet radiation and visible light of varying colors and wavelengths.

www.konkur.in

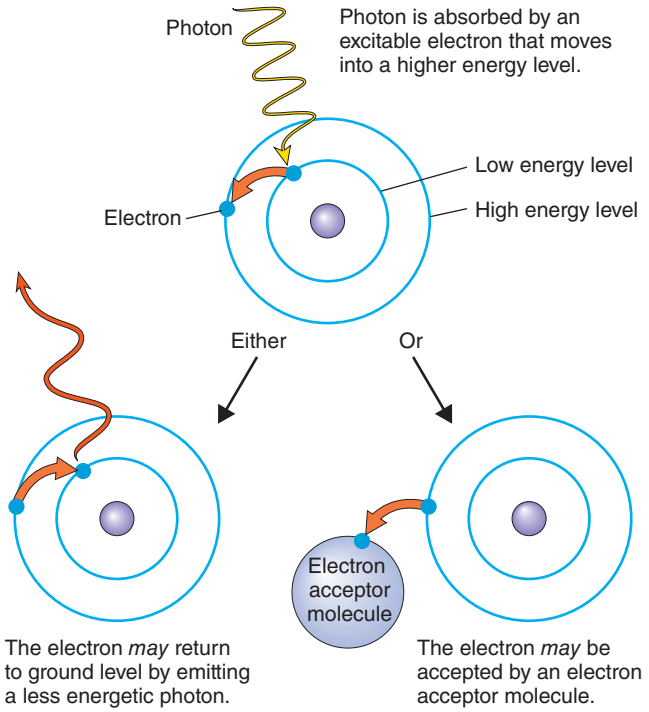

FIGURE 9-3 Interactions between light and atoms or molecules
(*Top*) When a photon of light energy strikes an atom or a molecule of which the atom is a part, the energy of the photon may push an electron to an orbital farther from the nucleus (that is, into a higher energy level). (*Lower left*) If the electron returns to the lower, more stable energy level, the energy may be released as a less energetic, longer-wavelength photon, known as fluorescence (*shown*), or as heat. (*Lower right*) If the appropriate electron acceptors are available, the electron may leave the atom. During photosynthesis, an electron acceptor captures the energetic electron and passes it to a chain of acceptors.

which becomes reduced in the process; this is what occurs in photosynthesis.

Now that you understand some of the properties of light, let us consider the organelles that use light for photosynthesis.

Review

- Why does photosynthesis require visible light?
- Which color of light has the longer wavelength, violet or red?
- Which color of light has the higher energy per photon, violet or red?

9.2 CHLOROPLASTS

LEARNING OBJECTIVES

2 Diagram the internal structure of a chloroplast and explain how its components interact and facilitate the process of photosynthesis.

3 Describe what happens to an electron in a biological molecule such as chlorophyll when a photon of light energy is absorbed.

If you examine a section of leaf tissue in a microscope, you see that the green pigment, chlorophyll, is not uniformly distributed in the cell but is confined to organelles called chloroplasts. In plants, **chloroplasts** lie mainly inside the leaf in the cells of the **mesophyll,** a layer with many air spaces and a very high concentration of water vapor (**FIG. 9-4a**). The interior of the leaf exchanges gases with the outside through microscopic pores, called **stomata** (sing., *stoma*). Each mesophyll cell has 20 to 100 chloroplasts.

The chloroplast, like the mitochondrion, is enclosed by outer and inner membranes (**FIG. 9-4b**). The inner membrane encloses a fluid-filled region called the **stroma,** which contains most of the enzymes required to produce carbohydrate molecules. Suspended in the stroma is a third system of membranes that forms an interconnected set of flat, disklike sacs called **thylakoids.**

The thylakoid membrane encloses a fluid-filled interior space, the **thylakoid lumen.** In some regions of the chloroplast, thylakoid sacs are arranged in stacks called **grana** (sing., *granum*). Each granum looks something like a stack of coins, with each "coin" being a thylakoid. Some thylakoid membranes extend from one granum to another. Thylakoid membranes, like the inner mitochondrial membrane (see Chapter 8), are involved in ATP synthesis. (Photosynthetic prokaryotes have no chloroplasts, but thylakoid membranes are often arranged around the periphery of the cell as infoldings of the plasma membrane.)

Chlorophyll is found in the thylakoid membrane

Thylakoid membranes contain several kinds of *pigments,* which are substances that absorb visible light. Different pigments absorb light of different wavelengths. **Chlorophyll,** the main pigment of photosynthesis, absorbs light primarily in the blue and red regions of the visible spectrum. Green light is not appreciably absorbed by chlorophyll. Plants usually appear green because some of the green light that strikes them is scattered or reflected.

A chlorophyll molecule has two main parts, a complex ring and a long side chain (**FIG. 9-5**). The ring structure, called a *porphyrin ring,* is made up of joined smaller rings composed of carbon and nitrogen atoms; the porphyrin ring absorbs light energy. The porphyrin ring of chlorophyll is strikingly similar to the heme portion of the red pigment hemoglobin in red blood cells. However, unlike heme, which contains an atom of iron in the center of the ring, chlorophyll contains an atom of magnesium in that position. The chlorophyll molecule also contains a long, hydrocarbon side chain that makes the molecule extremely nonpolar and anchors the chlorophyll in the membrane.

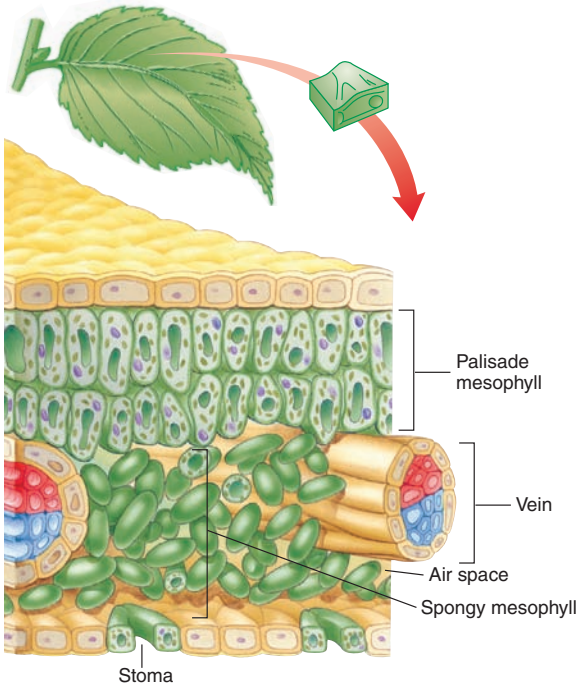
All chlorophyll molecules in the thylakoid membrane are associated with specific *chlorophyll-binding proteins;* biologists have identified about 15 different kinds. Each thylakoid membrane is filled with precisely oriented chlorophyll molecules and chlorophyll-binding proteins that facilitate the transfer of energy from one molecule to another.

There are several kinds of chlorophyll. The most important is **chlorophyll *a*,** the pigment that initiates the light-dependent reactions of photosynthesis. **Chlorophyll *b*** is an accessory pigment that also participates in photosynthesis. It differs from chlorophyll *a* only in a functional group on the porphyrin ring: the methyl group (—CH_3) in chlorophyll *a* is replaced in chlorophyll *b* by a

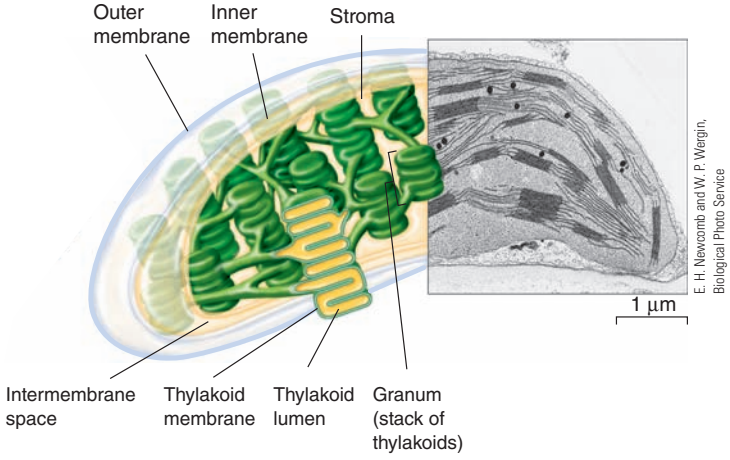
www.konkur.in

terminal carbonyl group (—CHO). This difference shifts the wavelengths of light absorbed and reflected by chlorophyll *b*, making it appear yellow-green, whereas chlorophyll *a* appears bright green.

Chloroplasts have other accessory photosynthetic pigments, such as **carotenoids,** which are yellow and orange (see Fig. 3-14). Carotenoids absorb different wavelengths of light than chlorophyll, thereby expanding the spectrum of light that provides energy for photosynthesis. Chlorophyll may be excited by light directly by energy passed to it from the light source, or indirectly by energy passed to it from accessory pigments that have become excited by light. When a carotenoid molecule is excited, its energy can be transferred to chlorophyll *a*. In addition, carotenoids are antioxidants that inactivate highly reactive forms of oxygen generated in the chloroplasts.



(a) This leaf cross section reveals that the mesophyll is the photosynthetic tissue. CO_2 enters the leaf through tiny pores or stomata, and H_2O is carried to the mesophyll in veins.



(b) In the chloroplast, pigments necessary for the light-capturing reactions of photosynthesis are part of thylakoid membranes, whereas the enzymes for the synthesis of carbohydrate molecules are in the stroma.

FIGURE 9-4 ***Animated*** **The site of photosynthesis**

Chlorophyll is the main photosynthetic pigment

As you have seen, the thylakoid membrane contains more than one kind of pigment. An instrument called a *spectrophotometer* measures the relative abilities of different pigments to absorb different wavelengths of light. The **absorption spectrum** of a pigment is a plot of its absorption of light of different wavelengths. **FIGURE 9-6a** shows the absorption spectra for chlorophylls *a* and *b*.

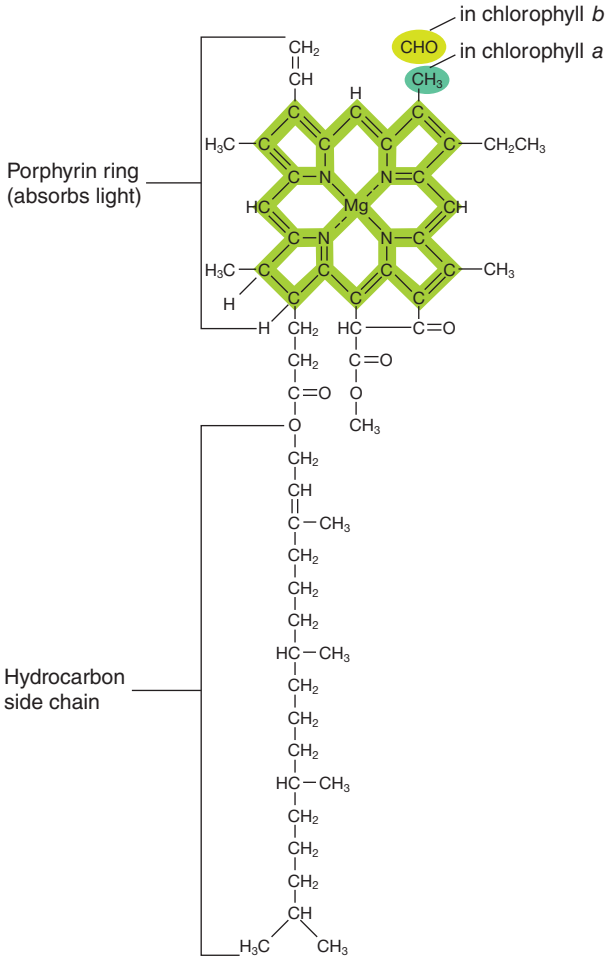


FIGURE 9-5 **The structure of chlorophyll**

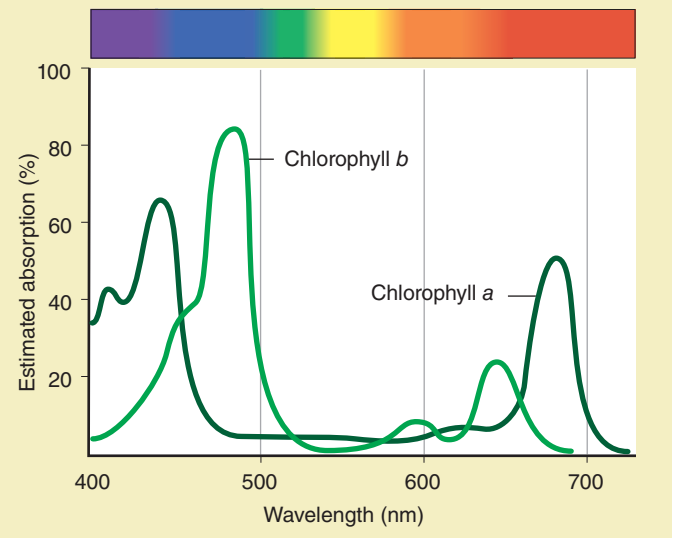
Chlorophyll consists of a porphyrin ring and a hydrocarbon side chain. The porphyrin ring, with a magnesium atom in its center, contains a system of alternating double and single bonds; these are commonly found in molecules that strongly absorb certain wavelengths of visible light and reflect others (chlorophyll reflects green). Notice that at the top right corner of the diagram, the methyl group (—CH_3) distinguishes chlorophyll *a* from chlorophyll *b*, which has a carbonyl group (—CHO) in this position. The hydrophobic hydrocarbon side chain anchors chlorophyll to the thylakoid membrane.

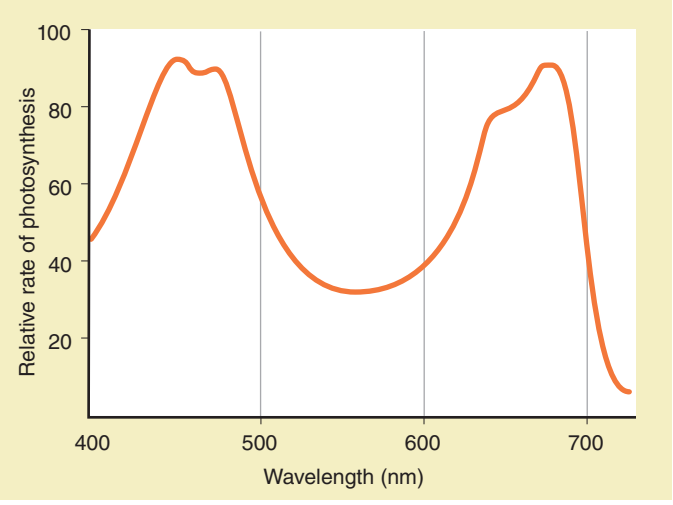
www.konkur.in

An **action spectrum** of photosynthesis is a graph of the relative effectiveness of different wavelengths of light. To obtain an action spectrum, scientists measure the rate of photosynthesis at each wavelength for leaf cells or tissues exposed to monochromatic light (light of one wavelength) (**FIG. 9-6b**).

In a classic biology experiment, the German biologist T. W. Engelmann obtained the first action spectrum in 1883. Engelmann's experiment, described in **FIGURE 9-7**, took advantage of the shape of the chloroplast in a species of the green alga *Spirogyra*. Its long, filamentous strands are found in freshwater habitats, especially slow-moving or still waters. *Spirogyra* cells each contain a long, spiral-shaped, emerald-green chloroplast embedded in the cytoplasm. Engelmann exposed these cells to a color spectrum produced by passing light through a prism. He hypothesized that if chlorophyll were indeed responsible for photosynthesis, the process would take place most rapidly in the areas where the chloroplast was illuminated by the colors most strongly absorbed by chlorophyll.



(a) Chlorophylls *a* and *b* absorb light mainly in the blue (422 to 492 nm) and red (647 to 760 nm) regions.



(b) The action spectrum of photosynthesis indicates the effectiveness of various wavelengths of light in powering photosynthesis. Many plant species have action spectra for photosynthesis that resemble the generalized action spectrum shown here.

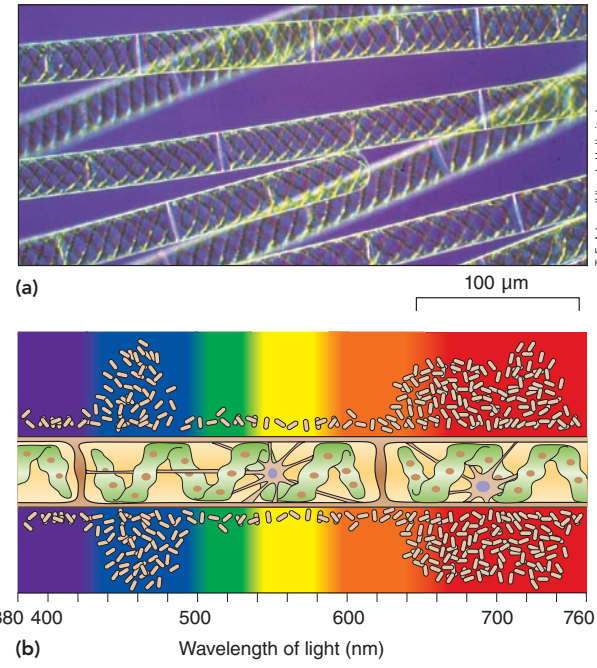
FIGURE 9-6 **A comparison of the absorption spectra for chlorophylls *a* and *b* with the action spectrum for photosynthesis**

KEY EXPERIMENT

QUESTION: Is a pigment in the chloroplast responsible for photosynthesis?

HYPOTHESIS: Engelmann hypothesized that chlorophyll was the main photosynthetic pigment. Accordingly, he predicted that he would observe differences in the amount of photosynthesis, as measured by the amount of oxygen produced, depending on the wavelengths of light used, and that these wavelengths would be consistent with the known absorption spectrum of chlorophyll.

EXPERIMENT: The photograph (a) shows cells of the filamentous alga *Spirogyra*, which has a long spiral-shaped chloroplast. The drawing (b) shows how Engelmann used a prism to expose the cells to light that had been separated into various wavelengths. He estimated the formation of oxygen (which he knew was a product of photosynthesis) by exploiting the fact that certain aerobic bacteria would be attracted to the oxygen. As a control (*not shown*), he also exposed the bacteria to the spectrum of light in the absence of *Spirogyra* cells.



RESULTS AND CONCLUSION: Although the bacteria alone (*control*) showed no preference for any particular wavelength, large numbers were attracted to the photosynthesizing cells in red or blue light, wavelengths that are strongly absorbed by chlorophyll (see Fig. 9-6). Thus, Engelmann concluded that chlorophyll is responsible for photosynthesis.

FIGURE 9-7 ***Animated*** **The first action spectrum of photosynthesis**

www.konkur.in

Yet how could photosynthesis be measured in those technologically unsophisticated days? Engelmann knew that photosynthesis produces oxygen and that certain motile bacteria are attracted to areas of high oxygen concentration. He determined the action spectrum of photosynthesis by observing that the bacteria swam toward the parts of the *Spirogyra* filaments in the blue and red regions of the spectrum. How did Engelmann know bacteria were not simply attracted to blue or red light? Engelmann exposed bacteria to the spectrum of visible light in the absence of *Spirogyra* as a control. The bacteria showed no preference for any particular wavelength of light. Because the action spectrum of photosynthesis closely matched the absorption spectrum of chlorophyll, Engelmann concluded that chlorophyll in the chloroplasts (and not another compound in another organelle) is responsible for photosynthesis. Numerous studies using sophisticated instruments have since confirmed Engelmann's conclusions.

If you examine Figure 9-6 closely, you will observe that the action spectrum of photosynthesis does not parallel the absorption spectrum of chlorophyll exactly. This difference occurs because accessory pigments, such as carotenoids, transfer some of the energy of excitation produced by green light to chlorophyll molecules. The presence of these accessory photosynthetic pigments can be demonstrated by chemical analysis of almost any leaf, although it is obvious in temperate climates when leaves change color in the fall. Toward the end of the growing season, chlorophyll breaks down (and its magnesium is stored in the permanent tissues of the tree), leaving orange and yellow accessory pigments in the leaves.

Review

9.3 OVERVIEW OF PHOTOSYNTHESIS

LEARNING OBJECTIVES

4 Describe photosynthesis as a redox process.
5 Distinguish between the light-dependent reactions and carbon fixation reactions of photosynthesis.

During photosynthesis, a cell uses light energy captured by chlorophyll to power the synthesis of carbohydrates. The overall reaction of photosynthesis can be summarized as follows:

$$6\,CO_2 + 12\,H_2O \xrightarrow[\text{Chlorophyll}]{\text{Light energy}} C_6H_{12}O_6 + 6\,O_2 + 6\,H_2O$$

Carbon dioxide — Water — Glucose — Oxygen — Water

The equation is typically written in the form just given, with H_2O on both sides, because water is a reactant in some reactions and a product in others. Furthermore, all the oxygen produced comes from water, so 12 water molecules are required to produce 12 oxygen atoms. However, because there is no net yield of H_2O, we can simplify the summary equation of photosynthesis for purposes of discussion:

$$6\,CO_2 + 6\,H_2O \xrightarrow[\text{Chlorophyll}]{\text{Light}} C_6H_{12}O_6 + 6\,O_2$$

When you analyze this process, it appears that hydrogen atoms are transferred from H_2O to CO_2 to form carbohydrate, so you can recognize it as a redox reaction. Recall from Chapter 7 that in a redox reaction one or more electrons, usually as part of one or more hydrogen atoms, are transferred from an electron donor (a reducing agent) to an electron acceptor (an oxidizing agent).

$$6\,CO_2 + 6\,H_2O \xrightarrow[\text{Chlorophyll}]{\text{Light}} C_6H_{12}O_6 + 6\,O_2$$

Reduction: $6\,CO_2 \rightarrow C_6H_{12}O_6$ (gains H)
Oxidation: $6\,H_2O \rightarrow 6\,O_2$ (loses H)

When the electrons are transferred, some of their energy is transferred as well. However, the summary equation of photosynthesis is somewhat misleading because no direct transfer of hydrogen atoms actually occurs. The summary equation describes *what* happens but not *how* it happens. The *how* is more complex and involves multiple steps, many of which are redox reactions.

The reactions of photosynthesis are divided into two phases: the light-dependent reactions (the *photo* part of photosynthesis) and the carbon fixation reactions (the *synthesis* part of photosynthesis). Each set of reactions occurs in a different part of the chloroplast: the light-dependent reactions in association with the thylakoids, and the carbon fixation reactions in the stroma (**FIG. 9-8**).

ATP and NADPH are the products of the light-dependent reactions: An overview

Light energy is converted to chemical energy in the **light-dependent reactions,** which are associated with the thylakoids. The light-dependent reactions begin as chlorophyll captures light energy, which causes one of its electrons to move to a higher energy state. The energized electron is transferred to an acceptor molecule and is replaced by an electron from H_2O. When this happens, H_2O is split and molecular oxygen is released (**FIG. 9-9**). Some energy of the energized electrons is used to phosphorylate **adenosine diphosphate (ADP),** forming **adenosine triphosphate (ATP).** In addition, the coenzyme **nicotinamide adenine dinucleotide phosphate ($NADP^+$)** becomes reduced, forming **NADPH.**[1] NADPH is a hydrogen carrier similar to NADH, differing by the addition of a phosphate group. Unlike NADH, which is generally associated with catabolic pathways like aerobic cellular respiration, NADPH has the ability to provide high-energy electrons to power

[1]Although the correct way to write the reduced form of $NADP^+$ is NADPH + H^+, for simplicity's sake we present the reduced form as NADPH throughout the book.

www.konkur.in

KEY POINT The light-dependent reactions in the thylakoids capture energy as ATP and NADPH, which power the carbon fixation reactions in the stroma.

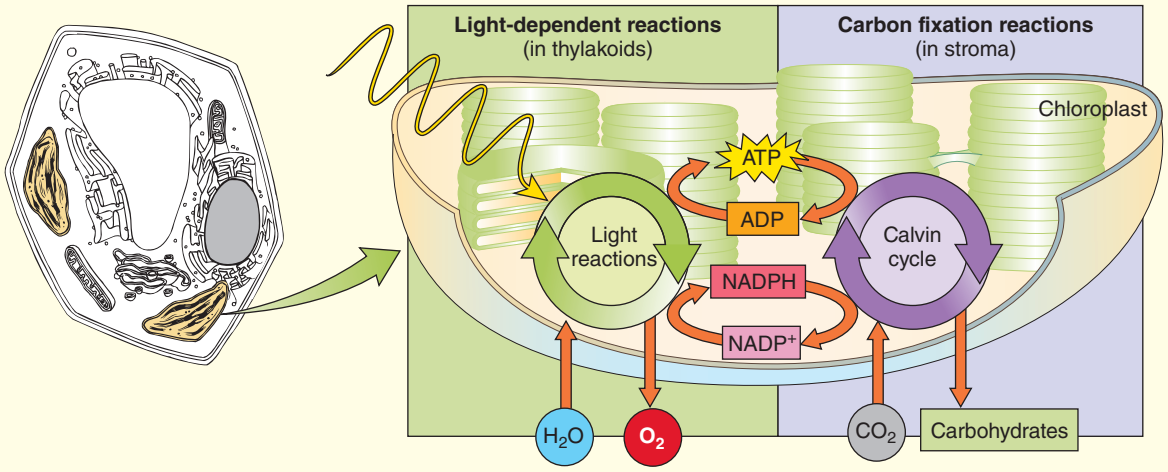

FIGURE 9-8 *Animated* An overview of photosynthesis

certain reactions in anabolic pathways, such as the carbon fixation reactions of photosynthesis. Thus, the products of the light-dependent reactions, ATP and NADPH, are both needed in the energy-requiring carbon fixation reactions.

Carbohydrates are produced during the carbon fixation reactions: An overview

The ATP and NADPH molecules produced during the light-dependent phase are suited for transferring chemical energy but not for long-term energy storage. For this reason, some of their energy is transferred to chemical bonds in carbohydrates, which can be produced in large quantities and stored for future use. Known as **carbon fixation,** these reactions "fix" carbon atoms from CO_2 to existing skeletons of organic molecules. Because the carbon fixation reactions have no direct requirement for light, they were previously referred to as the "dark" reactions. However, they do not require darkness; in fact, many of the enzymes involved in carbon fixation are much more active in the light than in the dark. Furthermore, carbon fixation reactions depend on the products of the light-dependent reactions. Carbon fixation reactions take place in the stroma of the chloroplast.

Now that we have presented an overview of photosynthesis, let us examine the entire process more closely.

- In what ways do the carbon fixation reactions depend on the light-dependent reactions?

9.4 THE LIGHT-DEPENDENT REACTIONS

LEARNING OBJECTIVES

6 Describe the flow of electrons through photosystems I and II in the noncyclic electron transport pathway and the products produced. Contrast this with cyclic electron transport.

7 Explain how a proton (H^+) gradient is established across the thylakoid membrane and how this gradient functions in ATP synthesis.

In the light-dependent reactions, the radiant energy from sunlight phosphorylates ADP, producing ATP, and reduces $NADP^+$, forming NADPH. The light energy that chlorophyll captures is

www.konkur.in

temporarily stored in these two compounds. The light-dependent reactions are summarized as follows:

$$12\,H_2O + 12\,NADP^+ + 18\,ADP + 18\,P_i \xrightarrow[\text{Chlorophyll}]{\text{Light}} 6\,O_2 + 12\,NADPH + 18\,ATP$$

Photosystems I and II each consist of a reaction center and multiple antenna complexes

The light-dependent reactions of photosynthesis begin when chlorophyll *a* and/or accessory pigments absorb light. According to the currently accepted model, chlorophylls *a* and *b* and accessory pigment molecules are organized with pigment-binding proteins in the thylakoid membrane into units called **antenna complexes.** The pigments and associated proteins are arranged as highly ordered groups of about 250 chlorophyll molecules associated with specific enzymes and other proteins. Each antenna complex absorbs light energy and transfers it to the **reaction center,** which consists of chlorophyll molecules and proteins, including electron transfer components, that participate directly in photosynthesis (**FIG. 9-10**). Light energy is converted to chemical energy in the reaction centers by a series of electron transfer reactions.

Two types of photosynthetic units, designated photosystem I and photosystem II, are involved in photosynthesis. Their reaction centers are distinguishable because they are associated with proteins in a way that causes a slight shift in their absorption spectra. Ordinary chlorophyll *a* has a strong absorption peak at about 660 nm. In contrast, the reaction center of **photosystem I** consists of a pair of chlorophyll *a* molecules with an absorption peak at 700 nm and is referred to as **P700.** The reaction center of **photosystem II** is made up of a pair of chlorophyll *a* molecules with an absorption peak of about 680 nm and is referred to as **P680.**

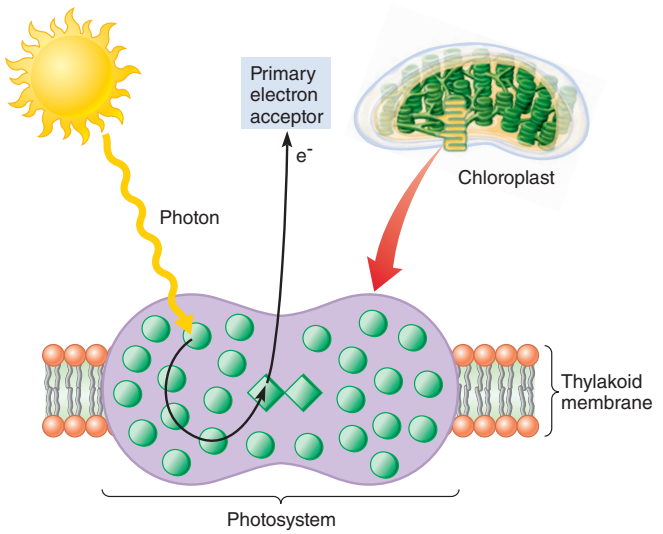

FIGURE 9-10 ***Animated*** **Schematic view of a photosystem**

Chlorophyll molecules (*green circles*) and accessory pigments (*not shown*) are arranged in light-harvesting arrays, or antenna complexes. A portion of one such complex within a photosystem is depicted. Each complex consists of several hundred pigment molecules, in association with special proteins (*not shown*). These proteins hold the pigments in a highly ordered spatial array, such that when a molecule in an antenna complex absorbs a photon, energy derived from that photon is readily passed from one pigment molecule to another (*black arrow*). When this energy reaches one of the two chlorophyll molecules in the reaction center (*green diamonds*), an electron becomes energized and is accepted by a primary electron acceptor.

When a pigment molecule absorbs light energy, that energy is passed, through a process known as *resonance,* directly from one pigment molecule to another within the antenna complex until it reaches the reaction center. When the energy reaches a molecule of P700 (in a photosystem I reaction center) or P680 (in a photosystem II reaction center), an electron is then raised to a higher energy level. As we explain in the next section, this energized electron can be donated to an electron acceptor that becomes reduced in the process.

Noncyclic electron transport produces ATP and NADPH

Let us begin our discussion of **noncyclic electron transport** with the events associated with photosystem I (**FIG. 9-11**). A pigment molecule in an antenna complex associated with photosystem I absorbs a photon of light. The absorbed energy is transferred from one pigment molecule to another until it reaches the reaction center, where it excites an electron in a molecule of P700. This energized electron is transferred to a primary electron acceptor, a special molecule of chlorophyll *a,* which is the first of several electron acceptors in a series. The energized electron is passed along an **electron transport chain** from one electron acceptor to another, until it is passed to *ferredoxin,* an iron-containing protein. Ferredoxin transfers the electron to $NADP^+$ in the presence of the enzyme *ferredoxin–$NADP^+$ reductase.*

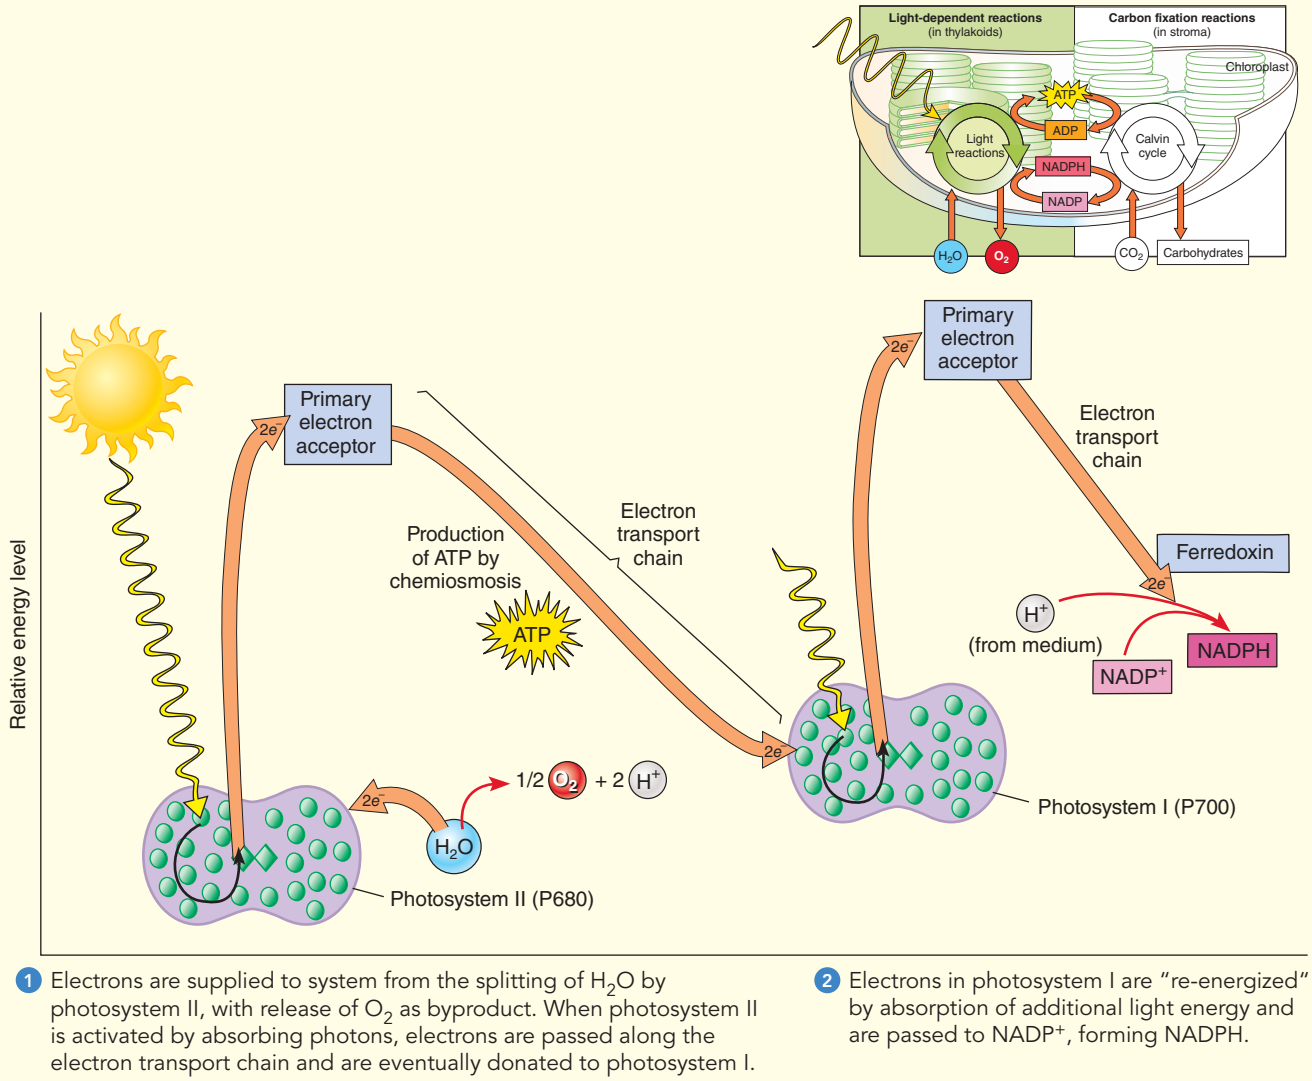
When $NADP^+$ accepts two electrons, they unite with a proton (H^+); thus, the reduced form of $NADP^+$ is NADPH, which is released into the stroma. P700 becomes positively charged when it gives up an electron to the primary electron acceptor; the missing electron is replaced by one donated by photosystem II.

As in photosystem I, photosystem II becomes activated when a pigment molecule in an antenna complex absorbs a photon of light energy. The energy is transferred to the reaction center, where it causes an electron in a molecule of P680 to move to a higher energy level. This energized electron is accepted by a primary electron acceptor (a highly modified chlorophyll molecule known as *pheophytin*) and then passes along an electron transport chain until it is donated to P700 in photosystem I.

How is the electron that has been donated to the electron transport chain replaced? This occurs through **photolysis** (light splitting) of water, a process that not only yields electrons but also is the source of almost all the oxygen in Earth's atmosphere. A molecule of P680 that has given up an energized electron to the primary electron acceptor is positively charged ($P680^+$). $P680^+$ is an oxidizing agent so strong that it pulls electrons away from an oxygen atom that is part of an H_2O molecule. In a reaction catalyzed by a unique, manganese-containing enzyme, water is broken into its components: two electrons, two protons, and oxygen. Each electron is donated to a P680 molecule, which then loses its positive charge; the protons are released into the thylakoid lumen. Because oxygen does not exist in atomic form, the oxygen produced

www.konkur.in

KEY POINT Noncyclic electron transport converts light energy to chemical energy in ATP and NADPH.



1 Electrons are supplied to system from the splitting of H_2O by photosystem II, with release of O_2 as byproduct. When photosystem II is activated by absorbing photons, electrons are passed along the electron transport chain and are eventually donated to photosystem I.

2 Electrons in photosystem I are "re-energized" by absorption of additional light energy and are passed to $NADP^+$, forming NADPH.

FIGURE 9-11 ***Animated*** **Noncyclic electron transport**

In noncyclic electron transport, the formation of ATP is coupled to one-way flow of energized electrons (*orange arrows*) from H_2O (*lower left*) to $NADP^+$ (*far right*). Single electrons actually pass down the electron transport chain; two are shown in this figure because two electrons are required to form one molecule of NADPH.

by splitting one H_2O molecule is written $\frac{1}{2}$ O_2. Two water molecules must be split to yield one oxygen molecule. The photolysis of water is a remarkable reaction, but its name is somewhat misleading because it implies that water is broken by light. Actually, light splits water indirectly by causing P680 to become oxidized.

Noncyclic electron transport is a continuous linear process

In the presence of light, there is a continuous, one-way flow of electrons from the ultimate electron source, H_2O, to the terminal electron acceptor, $NADP^+$. Water undergoes enzymatically catalyzed photolysis to replace energized electrons donated to the electron transport chain by molecules of P680 in photosystem II. These electrons travel down the electron transport chain that connects photosystem II with photosystem I. Thus, they provide a continuous supply of replacements for energized electrons that have been given up by P700.

As electrons are transferred along the electron transport chain that connects photosystem II with photosystem I, they lose energy. Some of the energy released is used to pump protons across the thylakoid membrane, from the stroma to the thylakoid lumen, producing a proton gradient. The energy of this proton gradient is harnessed to produce ATP from ADP by *chemiosmosis,* which we discuss later in the chapter. ATP and NADPH, the products of

www.konkur.in

the light-dependent reactions, are released into the stroma, where both are required by the carbon fixation reactions.

Cyclic electron transport produces ATP but no NADPH

Only photosystem I is involved in **cyclic electron transport,** the simplest light-dependent reaction. The pathway is cyclic because energized electrons that originate from P700 at the reaction center eventually return to P700. In the presence of light, electrons flow continuously through an electron transport chain within the thylakoid membrane. As they pass from one acceptor to another, the electrons lose energy, some of which is used to pump protons across the thylakoid membrane. An enzyme (ATP synthase) in the thylakoid membrane uses the energy of the proton gradient to manufacture ATP. NADPH is not produced, H_2O is not split, and oxygen is not generated. By itself, cyclic electron transport could not serve as the basis of photosynthesis because, as we explain later in the chapter, NADPH is required to reduce CO_2 to carbohydrate.

The significance of cyclic electron transport to photosynthesis in plants is unclear. Cyclic electron transport may occur in plant cells when there is too little $NADP^+$ to accept electrons from ferredoxin. There is evidence that cyclic electron flow may help maintain the optimal ratio of ATP to NADPH required for carbon fixation, as well as provide extra ATP to power other ATP-requiring processes in chloroplasts. Biologists generally agree that ancient bacteria used this process to produce ATP from light energy. A reaction pathway analogous to cyclic electron transport in plants is present in some modern photosynthetic prokaryotes. Noncyclic and cyclic electron transport are compared in **TABLE 9-1**.

ATP synthesis occurs by chemiosmosis

Each member of the electron transport chain that links photosystem II to photosystem I can exist in an oxidized (lower-energy) form and a reduced (higher-energy) form. The electron accepted from P680 by the primary electron acceptor is highly energized; it is passed from one carrier to the next in a series of exergonic redox reactions, losing some of its energy at each step. Some of the energy given up by the electron is not lost by the system, however; it is used to provide energy for ATP synthesis. Because the synthesis of ATP (that is, the phosphorylation of ADP) is coupled to the transport of electrons that have been energized by photons of light, the process is called **photophosphorylation.**

TABLE 9-1 A Comparison of Noncyclic and Cyclic Electron Transport

	Noncyclic Electron Transport	Cyclic Electron Transport
Electron source	H_2O	None—electrons cycle through the system
Oxygen released?	Yes (from H_2O)	No
Terminal electron acceptor	$NADP^+$	None—electrons cycle through the system
Form in which energy is temporarily captured	ATP (by chemiosmosis); NADPH	ATP (by chemiosmosis)
Photosystem(s) required	PS I (P700) and PS II (P680)	PS I (P700) only

The chemiosmotic model explains the coupling of ATP synthesis and electron transport

As discussed earlier, the pigments and electron acceptors of the light-dependent reactions are embedded in the thylakoid membrane. Energy released from electrons traveling through the chain of acceptors is used to pump protons from the stroma, across the thylakoid membrane, and into the thylakoid lumen (**FIG. 9-12**). Thus, the pumping of protons results in the formation of a proton gradient across the thylakoid membrane. Protons also accumulate in the thylakoid lumen as water is split during noncyclic electron transport. Because protons are actually hydrogen ions (H^+), the accumulation of protons causes the pH of the thylakoid interior to fall to a pH of about 5 in the thylakoid lumen, compared to a pH of about 8 in the stroma. This difference of about 3 pH units across the thylakoid membrane means there is an approximately thousand-fold difference in hydrogen ion concentration.

The proton gradient has a great deal of free energy because of its state of low entropy. How does the chloroplast convert that energy to a more useful form? According to the general principles of diffusion, the concentrated protons inside the thylakoid might be expected to diffuse out readily. However, they are prevented from doing so because the thylakoid membrane is impermeable to H^+

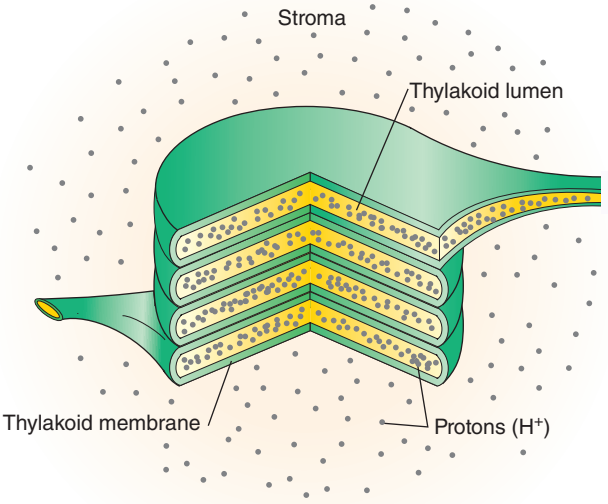


FIGURE 9-12 The accumulation of protons in the thylakoid lumen
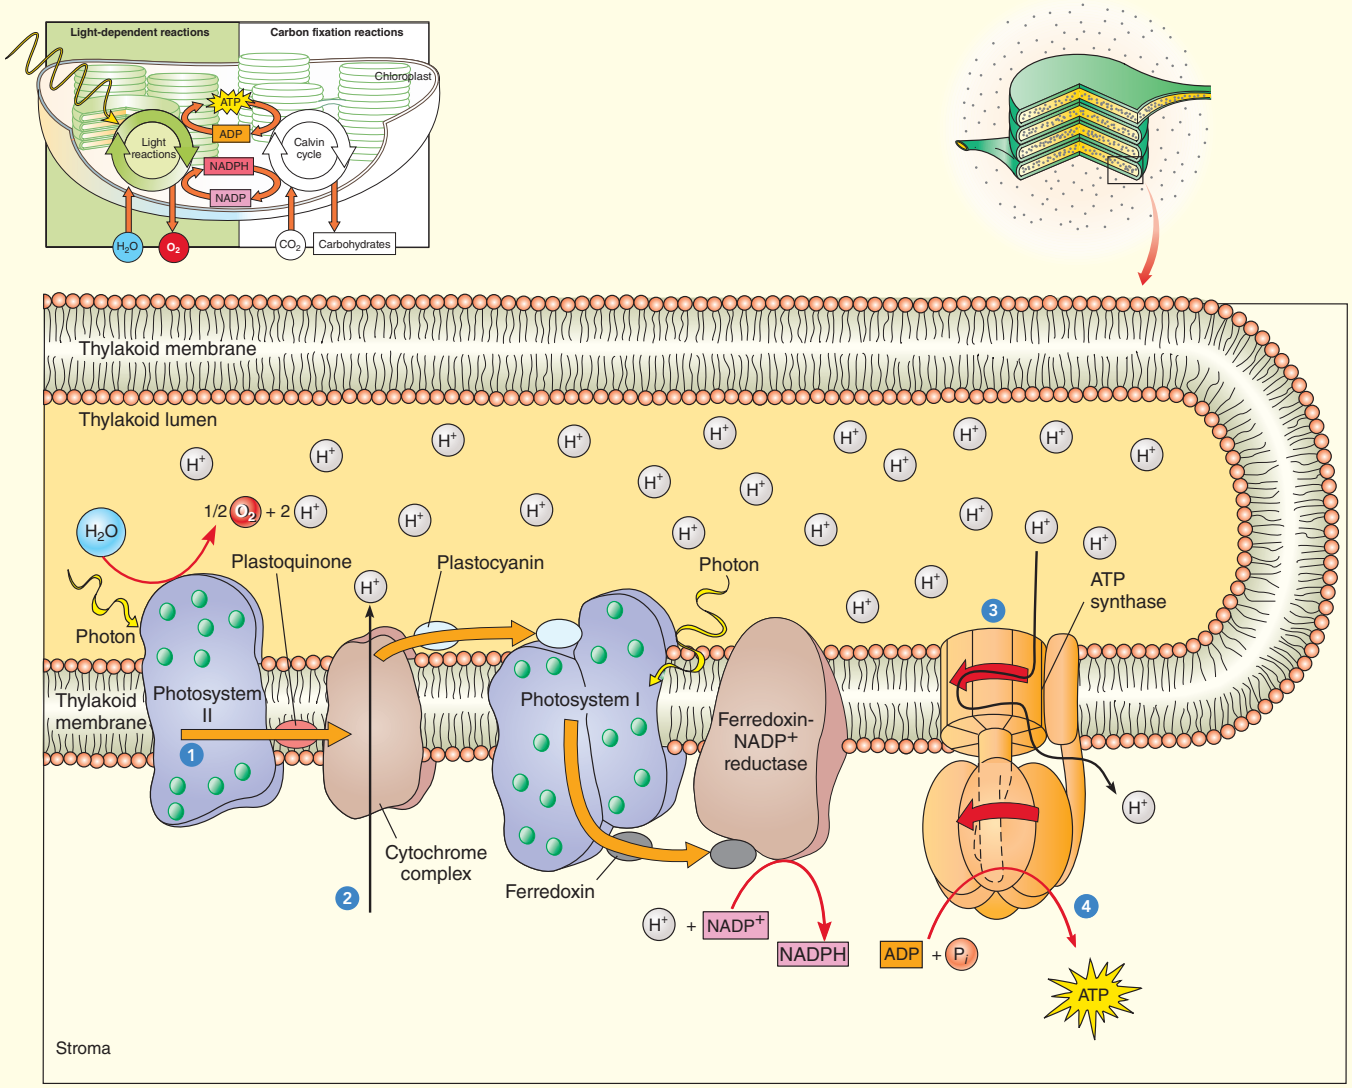
As electrons move down the electron transport chain, protons (H^+) move from the stroma to the thylakoid lumen, creating a proton gradient. The greater concentration of H^+ in the thylakoid lumen lowers the pH.

www.konkur.in

except through certain channels formed by the enzyme **ATP synthase.** This enzyme, a transmembrane protein also found in mitochondria, forms complexes so large they can be seen in electron micrographs (see Fig. 8-11b). ATP synthase complexes project into the stroma. As the protons diffuse through an ATP synthase complex, free energy decreases as a consequence of an increase in entropy. Each ATP synthase complex couples this exergonic process of diffusion down a concentration gradient to the endergonic process of phosphorylation of ADP to form ATP, which is released into the stroma (**FIG. 9-13**). The movement of protons through ATP synthase is thought to induce changes in the conformation of the enzyme that are necessary for the synthesis of ATP. It is estimated that for every four protons that move through ATP synthase, one ATP molecule is synthesized.

The mechanism by which the phosphorylation of ADP is coupled to diffusion down a proton gradient is called **chemiosmosis.** As the essential connection between the electron transport chain and the phosphorylation of ADP, chemiosmosis is a basic

KEY POINT Electron carriers associated with the thylakoid membrane transfer energized electrons from water to $NADP^+$, forming NADPH. ATP is generated by chemiosmosis.



1. Orange arrows indicate pathway of electrons along electron transport chain in thylakoid membrane. Electron carriers within membrane become alternately reduced and oxidized as they accept and donate electrons.
2. Energy released during electron transport is used to transport H^+ from the stroma to the thylakoid lumen, where a high concentration of H^+ accumulates.
3. H^+ are prevented from diffusing back into stroma except through special channels in ATP synthase in the thylakoid membrane.
4. H^+ flows through ATP synthase, generating ATP.

FIGURE 9-13 A detailed look at electron transport and chemiosmosis

TABLE 9-2 A Comparison of Photosynthesis and Aerobic Respiration

	Photosynthesis	Aerobic Respiration
Type of metabolic reaction	Anabolism	Catabolism
Raw materials	CO_2, H_2O	$C_6H_{12}O_6$, O_2
End products	$C_6H_{12}O_6$, O_2	CO_2, H_2O
Which cells have these processes?	Cells that contain chlorophyll (certain cells of plants, algae, and some bacteria)	Every actively metabolizing cell has aerobic respiration or some other energy-releasing pathway
Sites involved (in eukaryotic cells)	Chloroplasts	Cytosol (glycolysis); mitochondria
ATP production	By photophosphorylation (a chemiosmotic process)	By substrate-level phosphorylation and by oxidative phosphorylation (a chemiosmotic process)
Principal electron transfer compound	$NADP^+$ is reduced to form NADPH*	NAD^+ is reduced to form NADH*
Location of electron transport chain	Thylakoid membrane	Mitochondrial inner membrane (cristae)
Source of electrons for electron transport chain	In noncyclic electron transport: H_2O (undergoes photolysis to yield electrons, protons, and oxygen)	Immediate source: NADH, $FADH_2$ Ultimate source: glucose or other carbohydrate
Terminal electron acceptor for electron transport chain	In noncyclic electron transport: $NADP^+$ (becomes reduced to form NADPH)	O_2 (becomes reduced to form H_2O)

*NADPH and NADH are very similar hydrogen (i.e., electron) carriers, differing only in a single phosphate group. However, NADPH generally works with enzymes in anabolic pathways, such as photosynthesis. NADH is associated with catabolic pathways, such as cellular respiration.

mechanism of energy coupling in cells. You may recall from Chapter 8 that chemiosmosis also occurs in aerobic respiration (see **TABLE 9-2**).

Review

- Why is molecular oxygen a necessary byproduct of photosynthesis?
- What process is the actual mechanism of photophosphorylation?
- Why are both photosystems I and II required for photosynthesis? Can cyclic phosphorylation alone support photosynthesis? Explain your answer.

9.5 THE CARBON FIXATION REACTIONS

LEARNING OBJECTIVES

8 Summarize the three phases of the Calvin cycle and indicate the roles of ATP and NADPH in the process.
9 Discuss how photorespiration reduces photosynthetic efficiency.
10 Compare the C_4 and CAM pathways.

In carbon fixation, the energy of ATP and NADPH is used in the formation of organic molecules from CO_2. The carbon fixation reactions may be summarized as follows:

$$12\,NADPH + 18\,ATP + 6\,CO_2 \longrightarrow C_6H_{12}O_6 + 12\,NADP^+ + 18\,ADP + 18\,P_i + 6\,H_2O$$

Most plants use the Calvin cycle to fix carbon

Carbon fixation occurs in the stroma through a sequence of 13 reactions known as the **Calvin cycle.** During the 1950s, University of California researchers Melvin Calvin, Andrew Benson, and others elucidated the details of this cycle. Calvin was awarded a Nobel Prize in Chemistry in 1961.

The 13 reactions of the Calvin cycle are divided into three phases: CO_2 uptake, carbon reduction, and RuBP regeneration (**FIG. 9-14**). All 13 enzymes that catalyze steps in the Calvin cycle are located in the stroma of the chloroplast. Ten of the enzymes also participate in glycolysis (see Chapter 8). These enzymes catalyze reversible reactions, degrading carbohydrate molecules in cellular respiration and synthesizing carbohydrate molecules in photosynthesis.

1. *CO_2 uptake.* The first phase of the Calvin cycle consists of a single reaction in which a molecule of CO_2 reacts with a phosphorylated five-carbon compound, **ribulose bisphosphate (RuBP).** This reaction is catalyzed by the enzyme *ribulose bisphosphate carboxylase/oxygenase,* also known as **rubisco.** The chloroplast contains more rubisco enzyme than any other protein, and rubisco may be one of the most abundant proteins in the biosphere. The product of this reaction is an unstable six-carbon intermediate, which immediately breaks down into two molecules of **phosphoglycerate (PGA)** with three carbons each.

   The carbon that was originally part of a CO_2 molecule is now part of a carbon skeleton; the carbon has been "fixed." The Calvin cycle is also known as the **C_3 pathway** because the product of the initial carbon fixation reaction is a three-carbon compound. Plants that initially fix carbon in this way are called **C_3 plants.**
2. *Carbon reduction.* The second phase of the Calvin cycle consists of two steps in which the energy and reducing power from ATP and NADPH (both produced in the light-dependent reactions) are used to convert the PGA molecules to **glyceraldehyde-3-phosphate (G3P).** As shown in Figure 9-14, for every six carbons that enter the cycle as CO_2, six carbons can leave the system as two molecules of G3P, to be used in car-

www.konkur.in

KEY POINT ATP and NADPH provide the energy that drives carbon fixation in the Calvin cycle.

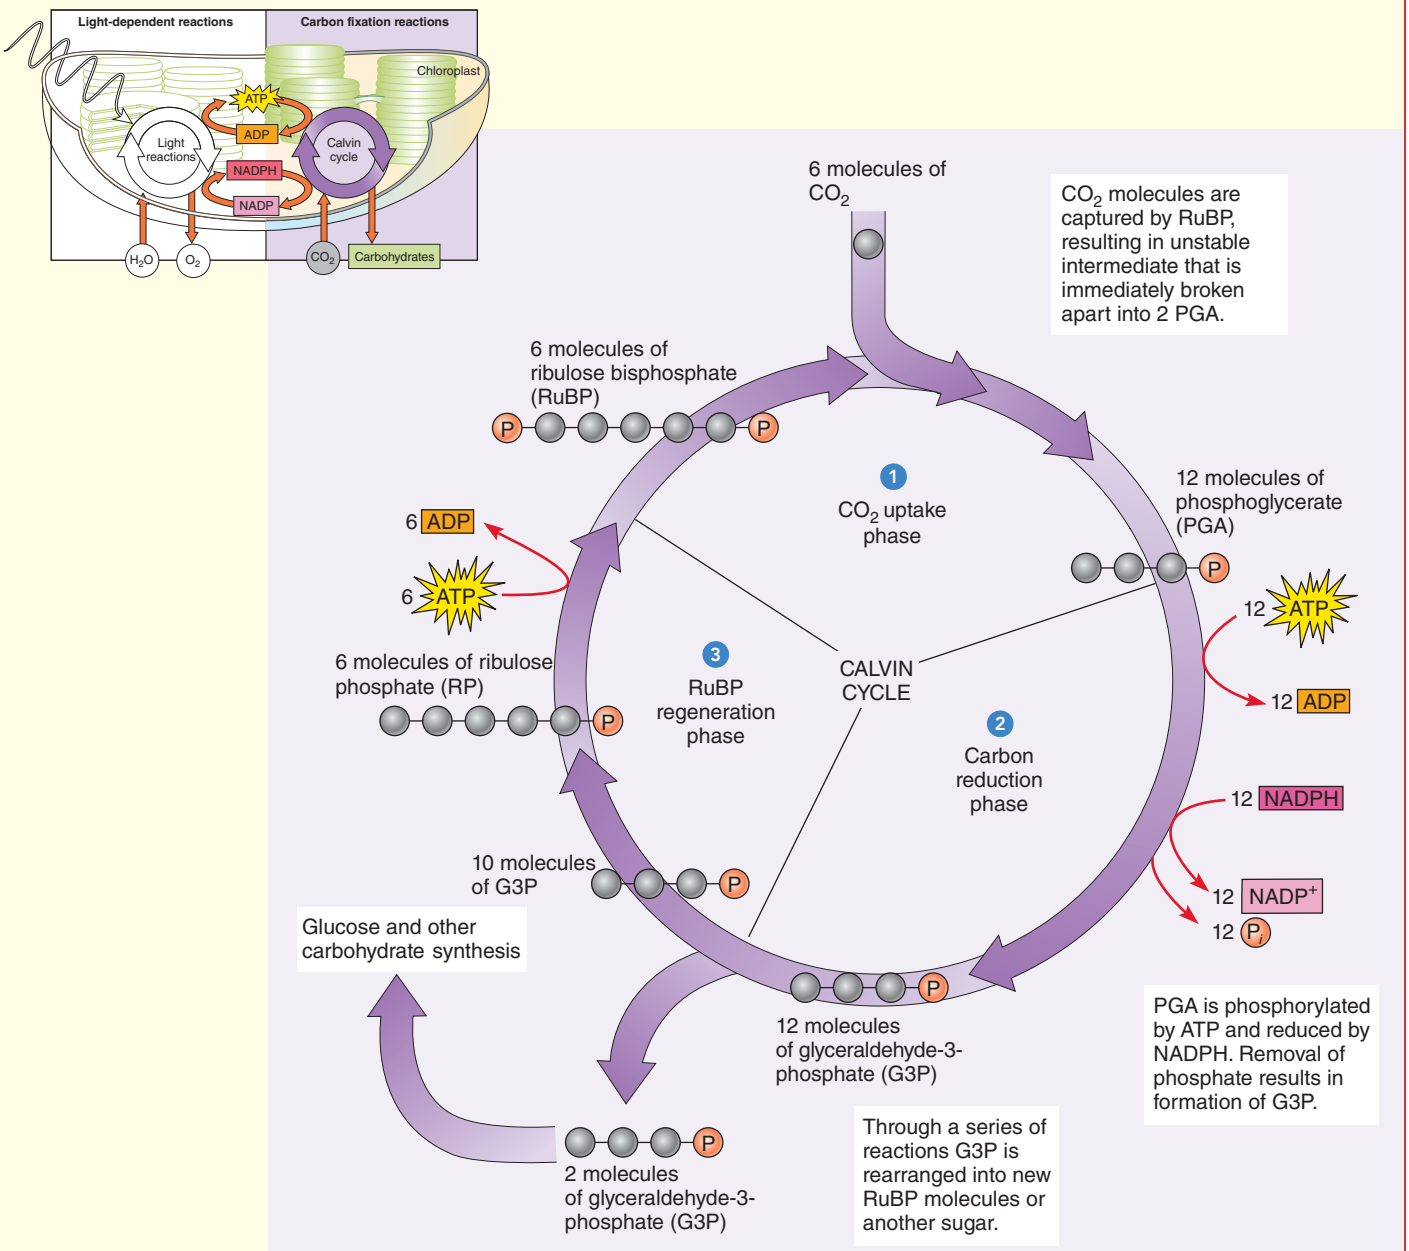

FIGURE 9-14 ***Animated*** **A detailed look at the Calvin cycle**

1 This diagram, in which carbon atoms are black balls, shows that six molecules of CO_2 must be "fixed" (incorporated into pre-existing carbon skeletons) in the CO_2 uptake phase to produce one molecule of a six-carbon sugar such as glucose. 2 Glyceraldehyde-3-phosphate (G3P) is formed in the carbon reduction phase. Two G3P molecules "leave" the cycle for every glucose formed. 3 Ribulose bisphosphate (RuBP) is regenerated, and a new cycle can begin. Although these reactions do not require light directly, the energy that drives the Calvin cycle comes from ATP and NADPH, which are the products of the light-dependent reactions.

bohydrate synthesis. Each of these three-carbon molecules of G3P is essentially half a hexose (six-carbon sugar) molecule. (In fact, you may recall that G3P is a key intermediate in the splitting of sugar in glycolysis; see Figs. 8-3 and 8-4.)

The reaction of two molecules of G3P is exergonic and leads to the formation of glucose or fructose. In some plants, glucose and fructose are then joined to produce sucrose (common table sugar). (Sucrose can be harvested from sugarcane,

www.konkur.in

TABLE 9-3 Summary of Photosynthesis

Reaction Series	Summary of Process	Needed Materials	End Products
Light-dependent reactions (take place in thylakoid membranes)	Energy from sunlight used to split water, manufacture ATP, and reduce $NADP^+$		
Photochemical reactions	Chlorophyll-activated; reaction center gives up photoexcited electron to electron acceptor	Light energy; pigments (chlorophyll)	Electrons
Electron transport	Electrons transported along chain of electron acceptors in thylakoid membranes; electrons reduce $NADP^+$; splitting of water provides some H^+ that accumulates inside thylakoid space	Electrons, $NADP^+$, H_2O, electron acceptors	NADPH, O_2
Chemiosmosis	H^+ permitted to diffuse across the thylakoid membrane down their gradient; they cross the membrane through special channels in ATP synthase complex; energy released is used to produce ATP	Proton gradient, ADP + P_i, ATP synthase	ATP
Carbon fixation reactions (take place in stroma)	Carbon fixation: carbon dioxide used to make carbohydrate	Ribulose bisphosphate, CO_2, ATP, NADPH, necessary enzymes	Carbohydrates, ADP + P_i, $NADP^+$

sugar beets, and maple sap.) The plant cell also uses glucose to produce starch or cellulose.

3. *RuBP regeneration.* Notice that although 2 G3P molecules are removed from the cycle, 10 G3P molecules remain; this represents a total of 30 carbon atoms. Through a series of 10 reactions that make up the third phase of the Calvin cycle, these 30 carbons and their associated atoms become rearranged into six molecules of ribulose phosphate, each of which becomes phosphorylated by ATP to produce RuBP, the five-carbon compound with which the cycle started. These RuBP molecules begin the process of CO_2 fixation and eventual G3P production once again.

In summary, the inputs required for the carbon fixation reactions are six molecules of CO_2 (the source of both the carbons and the oxygens in carbohydrate), phosphates transferred from ATP, and electrons (as hydrogen) provided by NADPH (but ultimately derived from the photolysis of water). In the end, the six carbons from the CO_2 are accounted for by the harvest of a hexose molecule. The remaining G3P molecules are used to synthesize the RuBP molecules with which more CO_2 molecules may combine. **TABLE 9-3** provides a summary of photosynthesis.

Photorespiration reduces photosynthetic efficiency

Many C_3 plants, including certain agriculturally important crops such as soybeans, wheat, and potatoes, do not yield as much carbohydrate from photosynthesis as might be expected, especially during periods of very hot temperature in summer. This phenomenon is a consequence of trade-offs between the plant's need for CO_2 and its need to prevent water loss. Recall that most photosynthesis occurs in mesophyll cells inside the leaf and that the entry and exit of gases from the interior of the leaf are regulated by stomata, tiny pores concentrated on the underside of the leaf (see Fig. 9-4a). On hot, dry days, plants close their stomata to conserve water. Once the stomata close, photosynthesis rapidly uses up the CO_2 remaining in the leaf and produces O_2, which accumulates in the chloroplasts.

Recall that the enzyme RuBP carboxylase/oxygenase (rubisco) catalyzes CO_2 fixation in the Calvin cycle by attaching CO_2 to RuBP. As its full name implies, rubisco acts not only as a carboxylase but also as an oxygenase because high levels of O_2 compete with CO_2 for the active site of rubisco. Some of the intermediates involved in the Calvin cycle are degraded to CO_2 and H_2O in a process that is called **photorespiration** because (1) it occurs in the presence of light; and as in aerobic respiration, (2) it requires oxygen and (3) produces CO_2 and H_2O. However, photorespiration does not produce ATP, and it reduces photosynthetic efficiency because it removes some of the intermediates used in the Calvin cycle.

The reasons for photorespiration are incompletely understood, although scientists hypothesize that it reflects the origin of rubisco at an ancient time when CO_2 levels were high and molecular oxygen levels were low. This view is supported by recent evidence that some amino acid sequences in rubisco are similar to sequences in certain bacterial proteins that apparently evolved prior to the evolution of the Calvin cycle. Genetic engineering to produce plants with rubisco that has a much lower affinity for oxygen is a promising area of research to improve yields of certain valuable crop plants.

The initial carbon fixation step differs in C_4 plants and in CAM plants

Photorespiration is not the only problem faced by plants engaged in photosynthesis. Because CO_2 is not a very abundant gas (composing only 0.038% of the atmosphere), it is not easy for plants to obtain the CO_2 they need. As you have learned, when conditions are hot and dry, the stomata close to reduce the loss of water vapor, greatly diminishing the supply of CO_2. Ironically, CO_2 is potentially less available at the very times when maximum sunlight is available to power the light-dependent reactions.

www.konkur.in

Many plant species living in hot, dry environments have adaptations that facilitate carbon fixation. **C_4 plants** first fix CO_2 into a four-carbon compound, **oxaloacetate. CAM plants** initially fix carbon at night through the formation of oxaloacetate. These special pathways found in C_4 and CAM plants precede the Calvin cycle (C_3 pathway); they do not replace it.

The C_4 pathway efficiently fixes CO_2 at low concentrations

The **C_4 pathway,** in which CO_2 is fixed through the formation of oxaloacetate, occurs not only before the C_3 pathway but also in different cells. Leaf anatomy is usually distinctive in C_4 plants. The photosynthetic mesophyll cells are closely associated with prominent, chloroplast-containing **bundle sheath cells,** which tightly encircle the veins of the leaf (**FIG. 9-15**). The C_4 pathway occurs in the mesophyll cells, whereas the Calvin cycle takes place within the bundle sheath cells.

The key component of the C_4 pathway is a remarkable enzyme that has an extremely high affinity for CO_2, binding it effectively even at unusually low concentrations. This enzyme, **PEP carboxylase,** catalyzes the reaction by which CO_2 reacts with the three-carbon compound **phosphoenolpyruvate (PEP),** forming oxaloacetate (**FIG. 9-16**).

In a step that requires NADPH, oxaloacetate is converted to some other four-carbon compound, usually malate. The malate then passes to chloroplasts within bundle sheath cells, where a different enzyme catalyzes the decarboxylation of malate to yield pyruvate (which has three carbons) and CO_2. NADPH is formed, replacing the one used earlier.

$$\text{malate} + NADP^+ \longrightarrow \text{pyruvate} + CO_2 + NADPH$$

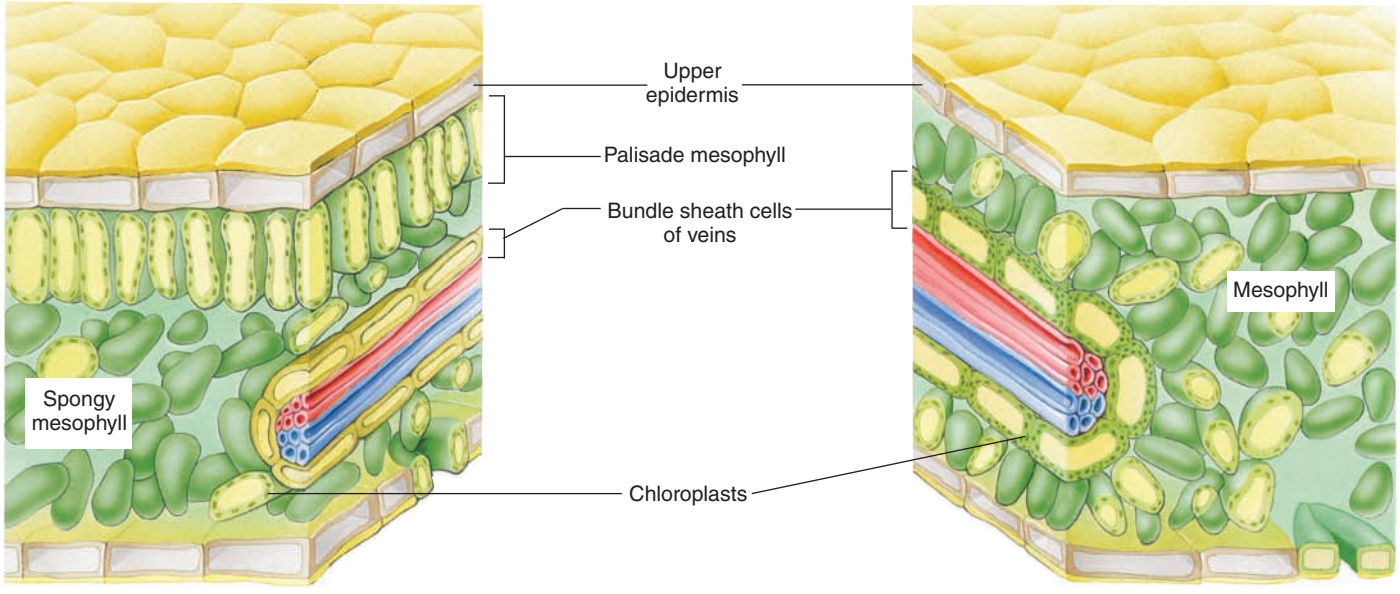
The CO_2 released in the bundle sheath cell combines with ribulose bisphosphate in a reaction catalyzed by rubisco and goes through the Calvin cycle in the usual manner. The pyruvate formed in the decarboxylation reaction returns to the mesophyll cell, where it reacts with ATP to regenerate phosphoenolpyruvate.

Because the C_4 pathway captures CO_2 and provides it to the bundle sheath cells so efficiently, CO_2 concentration within the bundle sheath cells is about 10 to 60 times as great as its concentration in the mesophyll cells of plants having only the C_3 pathway. Photorespiration is negligible in C_4 plants such as crabgrass because the concentration of CO_2 in bundle sheath cells (where rubisco is present) is always high.

The combined C_3–C_4 pathway involves the expenditure of 30 ATPs per hexose, rather than the 18 ATPs used by the C_3 pathway alone. The extra energy expense required to regenerate PEP from pyruvate is worthwhile at high light intensities because it ensures a high concentration of CO_2 in the bundle sheath cells and permits them to carry on photosynthesis at a rapid rate. At lower light intensities and temperatures, C_3 plants are favored. For example, winter rye, a C_3 plant, grows lavishly in cool weather, when crabgrass cannot because it requires more energy to fix CO_2.

CAM plants fix CO_2 at night

Plants living in dry, or *xeric,* conditions have a number of structural adaptations that enable them to survive. Many xeric plants have physiological adaptations as well, including a special carbon fixation pathway, the **crassulacean acid metabolism (CAM) pathway.** The name comes from the stonecrop plant family (the Crassulaceae), which uses the CAM pathway, although the pathway has evolved



(a) In C_3 plants, the Calvin cycle takes place in the mesophyll cells and the bundle sheath cells are nonphotosynthetic.

(b) In C_4 plants, reactions that fix CO_2 into four-carbon compounds take place in the mesophyll cells. The four-carbon compounds are transferred from the mesophyll cells to the photosynthetic bundle sheath cells, where the Calvin cycle takes place.

FIGURE 9-15 C_3 and C_4 plant structure compared

www.konkur.in

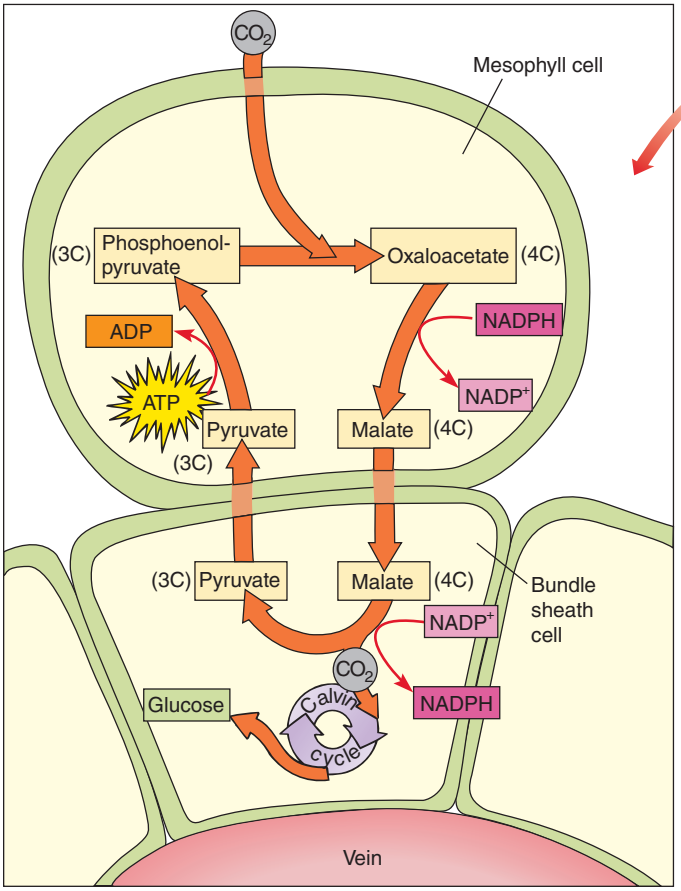


FIGURE 9-16 ***Animated*** **Summary of the C_4 pathway**

CO_2 combines with phosphoenolpyruvate (PEP) in the chloroplasts of mesophyll cells, forming a four-carbon compound that is converted to malate. Malate goes to the chloroplasts of bundle sheath cells, where it is decarboxylated. The CO_2 released in the bundle sheath cell is used to make carbohydrate by way of the Calvin cycle.

Robert W. Domm/Visuals Unlimited

FIGURE 9-17 **A typical CAM plant**

Prickly pear cactus (*Opuntia*) is a CAM plant. The more than 200 species of *Opuntia* living today originated in various xeric habitats in North and South America.

independently in some members of more than 25 other plant families, including the cactus family (Cactaceae), the lily family (Liliaceae), and the orchid family (Orchidaceae) (**FIG. 9-17**).

Unlike most plants, CAM plants open their stomata at night, admitting CO_2 while minimizing water loss. They use the enzyme PEP carboxylase to fix CO_2, forming oxaloacetate, which is converted to malate and stored in cell vacuoles. During the day, when stomata are closed and gas exchange cannot occur between the plant and the atmosphere, CO_2 is removed from malate by a decarboxylation reaction. Now the CO_2 is available within the leaf tissue to be fixed into sugar by the Calvin cycle (C_3 pathway).

The CAM pathway is very similar to the C_4 pathway but with important differences. C_4 plants initially fix CO_2 into four-carbon organic acids in mesophyll cells. The acids are later decarboxylated to produce CO_2, which is fixed by the C_3 pathway in the bundle sheath cells. In other words, the C_4 and C_3 pathways occur in *different locations* within the leaf of a C_4 plant. In CAM plants, the initial fixation of CO_2 occurs at night. Decarboxylation of malate and subsequent production of sugar from CO_2 by the normal C_3 photosynthetic pathway occur during the day. In other words, the CAM and C_3 pathways occur at *different times* within the same cell of a CAM plant.

Although it does not promote rapid growth the way that the C_4 pathway does, the CAM pathway is a very successful adaptation to xeric conditions. CAM plants can exchange gases for photosynthesis and reduce water loss significantly. Plants with CAM photosynthesis survive in deserts where neither C_3 nor C_4 plants can.

- Do C_3, C_4, and CAM plants all have rubisco? PEP carboxylase?

9.6 METABOLIC DIVERSITY

LEARNING OBJECTIVE

11 Contrast photoautotrophs and chemoheterotrophs with respect to their energy and carbon sources.

Land plants, algae, and certain prokaryotes are known as **photoautotrophs.** They are **phototrophs** because they use light energy to make ATP and NADPH, which temporarily hold chemical energy but are unstable and cannot be stockpiled in the cell. They are **autotrophs** (from the Greek *auto,* which means "self," and *trophos,* which means "nourishing") that synthesize complex organic compounds from simpler, inorganic raw materials. The chemical energy of ATP and NADPH then drives carbon fixation, the anabolic pathway in which stable organic molecules are synthesized from CO_2 and water. These organic compounds are used not only as starting

www.konkur.in

materials to synthesize all the other organic compounds the photosynthetic organism needs (such as complex carbohydrates, amino acids, and lipids) but also for energy storage. Glucose and other carbohydrates produced during photosynthesis are relatively reduced compounds that can be subsequently oxidized by aerobic respiration or by some other catabolic pathway (see Chapter 8).

In contrast, animals, fungi, and most bacteria are known as **chemoheterotrophs.** They are **chemotrophs** because they obtain energy from chemicals, typically by redox reactions (see Chapters 7 and 8). They are **heterotrophs** (from the Greek *heter,* which means "other," and *trophos,* which means "nourishing") because they cannot fix carbon; they use organic molecules produced by *other* organisms as the building blocks from which they synthesize the carbon compounds they need.

We are so familiar with plants as photoautotrophs and animals such as ourselves as chemoheterotrophs that we tend to think that all organisms should fit in these two "mainstream" categories. Two other types of nutrition are found in certain bacteria. A few bacteria, known as nonsulfur purple bacteria, are **photoheterotrophs,** able to use light energy but unable to carry out carbon fixation, so they must obtain carbon from organic compounds. Some other bacteria are **chemoautotrophs,** which obtain their energy from the oxidation of reduced inorganic molecules such as hydrogen sulfide (H_2S), nitrite (NO_2^-), or ammonia (NH_3). Some of this captured energy is subsequently used to carry out carbon fixation.

9.7 PHOTOSYNTHESIS IN PLANTS AND IN THE ENVIRONMENT

LEARNING OBJECTIVE

12 State the importance of photosynthesis both in a plant and to other organisms.

Although we characterize plants as photoautotrophs, not all plant cells carry out photosynthesis, and even cells with chloroplasts also possess mitochondria and carry out aerobic respiration. In fact, respiration utilizing the organic molecules the plant has made for itself is the direct source of ATP needed for most plant metabolism.

Several mechanisms regulate the relative activities of photosynthesis and aerobic respiration in plants. Although the enzymes of the Calvin cycle do not require light to function, they are actually regulated by light. As a consequence of the light-requiring reactions, the stroma becomes more basic (approximately pH 8), activating rubisco and other Calvin cycle enzymes. In contrast, light tends to inhibit the enzymes of glycolysis in the cytosol. Hence photosynthesis, not aerobic respiration, is favored in the light. When light is very dim, at a point known as the *light compensation point,* photosynthesis still occurs, but it is not evident because the rate of CO_2 fixation by photosynthesis is equal to the rate of CO_2 release through aerobic respiration. On the other hand, when light is very bright, photorespiration can significantly diminish photosynthetic yields.

As we have seen in this chapter, the reactions of the Calvin cycle provide a net yield of the three-carbon phosphorylated sugar, G3P. What are the various fates of G3P in the plant? Consider a leaf cell actively conducting photosynthesis. A series of enzymes may convert some of the G3P to glucose and then to starch. This starch is stored in starch granules that form inside chloroplasts. It has been recently shown that when this starch is broken down, the disaccharide maltose is typically formed (see Fig. 3-8a). Maltose is transported out of the chloroplast and then cleaved in the cytosol, providing glucose for aerobic respiration. Not all G3P ends up as carbohydrate; some is ultimately converted to amino acids, fatty acids, and other organic molecules needed by the photosynthetic cell.

Some of the G3P is exported to the cytosol, where enzymes convert it to the disaccharide sucrose (see Fig. 3-8b). Sucrose is then actively transported out of the cell, moves through the vascular system of the plant (see Chapter 35 for a discussion of plant transport), and is actively transported into the various cells. Sucrose can be broken down to glucose and fructose, which are used in aerobic respiration or as starting points for the synthesis of the various organic molecules the cells need, such as amino acids, lipids, and carbohydrates. Important carbohydrates include cellulose for cell walls (see Fig. 3-10) and starch, particularly in starch-storing structures such as roots (see Fig. 3-9a) and developing seeds and tubers (such as potatoes).

The benefits of photosynthesis in the environment are staggering. Of course, by fixing carbon, photoautotrophs are the ultimate source of virtually all organic molecules used as energy and carbon sources by chemoheterotrophs such as ourselves (for an exception, see *Inquiring About: Life without the Sun* in Chapter 55). In carrying out carbon fixation, photoautotrophs remove CO_2 from the atmosphere, thereby slowing global warming (see Chapter 57). Also of prime importance is the fact that photolysis of water by photosystem II releases the O_2 that all aerobic organisms require for aerobic respiration. Molecular oxygen is so reactive that it could not be maintained in the atmosphere if it were not constantly replenished in this way.

As discussed in Chapter 21, the evolution of oxygen-producing photosynthesis was a critical event in the history of life on Earth, which not only permitted the evolution of aerobic organisms, but also made terrestrial life possible because in the stratosphere O_2 is converted to ozone (O_3), which shields the planet from damaging ultraviolet light.

www.konkur.in

SUMMARY: FOCUS ON LEARNING OBJECTIVES

9.1 *(page 194)*

1 Describe the physical properties of light and explain the relationship between a wavelength of light and its energy.

- Light consists of particles called **photons** that move as waves.
- Photons with shorter **wavelengths** have more energy than those with longer wavelengths.

9.2 *(page 195)*

2 Diagram the internal structure of a chloroplast and explain how its components interact and facilitate the process of photosynthesis.

- In plants, **photosynthesis** occurs in chloroplasts, which are located mainly within **mesophyll** cells inside the leaf.
- **Chloroplasts** are organelles enclosed by a double membrane; the inner membrane encloses the **stroma** in which membranous, saclike **thylakoids** are suspended. Thylakoids enclose the **thylakoid lumen.** Thylakoids arranged in stacks are called **grana.**
- **Chlorophyll *a*, chlorophyll *b*, carotenoids,** and other photosynthetic pigments are components of the thylakoid membranes of chloroplasts.

3 Describe what happens to an electron in a biological molecule such as chlorophyll when a photon of light energy is absorbed.

- Photons excite biological molecules such as chlorophyll and other photosynthetic pigments, causing one or more electrons to become energized. These energized electrons may be accepted by electron acceptor compounds.
- The combined **absorption spectra** of chlorophylls *a* and *b* are similar to the **action spectrum** for photosynthesis.

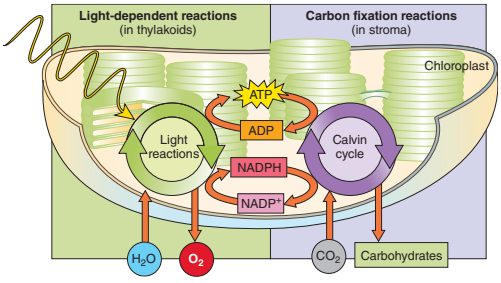
9.3 *(page 198)*

4 Describe photosynthesis as a redox process.

- During photosynthesis, light energy is captured and converted to the chemical energy of carbohydrates; hydrogens from water are used to reduce carbon, and oxygen derived from water becomes oxidized, forming molecular oxygen.

5 Distinguish between the light-dependent reactions and carbon fixation reactions of photosynthesis.

- In the **light-dependent reactions,** electrons energized by light are used to generate **ATP** and **NADPH;** these compounds provide energy for the formation of carbohydrates during the **carbon fixation reactions.**



CENGAGENOW™ Learn more about photosynthesis in plants by clicking on the figures in CengageNOW.

9.4 *(page 199)*

6 Describe the flow of electrons through photosystems I and II in the noncyclic electron transport pathway and the products produced. Contrast this with cyclic electron transport.

- **Photosystems I** and **II** are the two types of photosynthetic units involved in photosynthesis. Each photosystem includes chlorophyll molecules and accessory pigments organized with pigment-binding proteins into **antenna complexes.**
- Only a special pair of chlorophyll *a* molecules in the **reaction center** of an antenna complex give up energized electrons to a nearby electron acceptor. **P700** is in the reaction center for photosystem I; **P680** is in the reaction center for photosystem II.
- During the noncyclic light-dependent reactions, known as **noncyclic electron transport,** ATP and NADPH are formed.
- Electrons in photosystem I are energized by the absorption of light and passed through an **electron transport chain** to $NADP^+$, forming NADPH. Electrons given up by P700 in photosystem I are replaced by electrons from P680 in photosystem II.
- A series of redox reactions takes place as energized electrons are passed along the electron transport chain from photosystem II to photosystem I. Electrons given up by P680 in photosystem II are replaced by electrons made available by the **photolysis** of H_2O; oxygen is released in the process.
- During **cyclic electron transport,** electrons from photosystem I are eventually returned to photosystem I. ATP is produced by **chemiosmosis,** but no NADPH or oxygen is generated.

CENGAGENOW™ Experience the process of noncyclic electron transport by clicking on the figure in CengageNOW.

7 Explain how a proton (H^+) gradient is established across the thylakoid membrane and how this gradient functions in ATP synthesis.

- **Photophosphorylation** is the synthesis of ATP coupled to the transport of electrons energized by photons of light. Some of the energy of the electrons is used to pump protons across the thylakoid membrane, providing the energy to generate ATP by chemiosmosis.
- As protons diffuse through **ATP synthase,** an enzyme complex in the thylakoid membrane, ADP is phosphorylated to form ATP.

9.5 *(page 204)*

8 Summarize the three phases of the Calvin cycle and indicate the roles of ATP and NADPH in the process.

- The carbon fixation reactions proceed by way of the **Calvin cycle,** also known as the **C_3 pathway.**
- In the CO_2 uptake phase of the Calvin cycle, CO_2 is combined with **ribulose bisphosphate (RuBP),** a five-carbon sugar, by the enzyme ribulose bisphosphate carboxylase/oxygenase, commonly known as **rubisco,** forming the three-carbon molecule **phosphoglycerate (PGA).**
- In the carbon reduction phase of the Calvin cycle, the energy and reducing power of ATP and NADPH are used to convert PGA molecules to **glyceraldehyde-3-phosphate (G3P).** For every 6 CO_2 molecules fixed, 12 molecules of G3P are produced, and 2 molecules of G3P leave the cycle to produce the equivalent of 1 molecule of glucose.
- In the RuBP regeneration phase of the Calvin cycle, the remaining G3P molecules are modified to regenerate RuBP.

CENGAGENOW™ See the Calvin cycle in action by clicking on the figure in CengageNOW.

9 Discuss how photorespiration reduces photosynthetic efficiency.

- In **photorespiration,** C_3 plants consume oxygen and generate CO_2 by degrading Calvin cycle intermediates but do not produce ATP. Photorespiration is significant on bright, hot, dry days when plants close their stomata, conserving water but preventing the passage of CO_2 into the leaf.

www.konkur.in

10 Compare the C_4 and CAM pathways.

- In the **C_4 pathway,** the enzyme **PEP carboxylase** binds CO_2 effectively, even when CO_2 is at a low concentration. C_4 reactions take place within mesophyll cells. The CO_2 is fixed in oxaloacetate, which is then converted to malate. The malate moves into a **bundle sheath cell,** and CO_2 is removed from it. The released CO_2 then enters the Calvin cycle.
- The **crassulacean acid metabolism (CAM)** pathway is similar to the C_4 pathway. PEP carboxylase fixes carbon at night in the mesophyll cells, and the Calvin cycle occurs during the day in the same cells.

CENGAGENOW™ See a comparison of the C_3 and C_4 pathways by clicking on the figure in CengageNOW.

9.6 *(page 208)*

11 Contrast photoautotrophs and chemoheterotrophs with respect to their energy and carbon sources.

- **Photoautotrophs** use light as an energy source and are able to incorporate atmospheric CO_2 into preexisting carbon skeletons.
- **Chemoheterotrophs** obtain energy by oxidizing chemicals and obtain carbon as organic molecules from other organisms.

9.7 *(page 209)*

12 State the importance of photosynthesis both in a plant and to other organisms.

- Photosynthesis is the ultimate source of all chemical energy and organic molecules available to photoautotrophs, such as plants, and to virtually all other organisms as well. It also constantly replenishes the supply of oxygen in the atmosphere, vital to all aerobic organisms.

Summary Reactions for Photosynthesis

The light-dependent reactions (noncyclic electron transport):

$$12\ H_2O + 12\ NADP^+ + 18\ ADP + 18\ P_i \xrightarrow[\text{Chlorophyll}]{\text{Light}} 6\ O_2 + 12\ NADPH + 18\ ATP$$

The carbon fixation reactions (Calvin cycle):

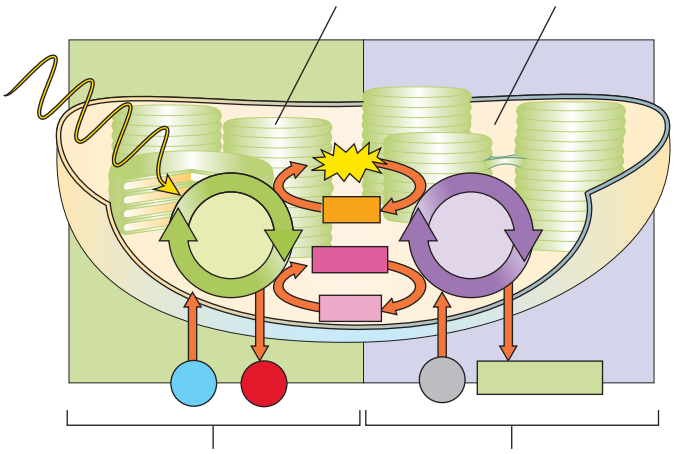
$$12\ NADPH + 18\ ATP + 6\ CO_2 \longrightarrow C_6H_{12}O_6 + 12\ NADP^+ + 18\ ADP + 18\ P_i + 6\ H_2O$$

By canceling out the common items on opposite sides of the arrows in these two coupled equations, we obtain the simplified overall equation for photosynthesis:

$$\underset{\text{Carbon dioxide}}{6\ CO_2} + \underset{\text{Water}}{H_2O} \xrightarrow[\text{Chlorophyll}]{\text{Light energy}} \underset{\text{Glucose}}{C_6H_{12}O_6} + \underset{\text{Oxygen}}{O_2} + \underset{\text{Water}}{6\ H_2O}$$

TEST YOUR UNDERSTANDING

1. Where is chlorophyll located in the chloroplast? (a) thylakoid membranes (b) stroma (c) matrix (d) thylakoid lumen (e) between the inner and outer membranes
2. In photolysis, some of the energy captured by chlorophyll is used to split (a) CO_2 (b) ATP (c) NADPH (d) H_2O (e) both b and c
3. Light is composed of particles of energy called (a) carotenoids (b) reaction centers (c) photons (d) antenna complexes (e) photosystems
4. The relative effectiveness of different wavelengths of light in photosynthesis is demonstrated by (a) an action spectrum (b) photolysis (c) carbon fixation reactions (d) photoheterotrophs (e) an absorption spectrum
5. In plants, the final electron acceptor in noncyclic electron flow is (a) $NADP^+$ (b) CO_2 (c) H_2O (d) O_2 (e) G3P
6. In _____, electrons that have been energized by light contribute their energy to add phosphate to ADP, producing ATP. (a) crassulacean acid metabolism (b) the Calvin cycle (c) photorespiration (d) C_4 pathways (e) photophosphorylation
7. The mechanism by which electron transport is coupled to ATP production by means of a proton gradient is called (a) chemiosmosis (b) crassulacean acid metabolism (c) fluorescence (d) the C_3 pathway (e) the C_4 pathway
8. The Calvin cycle begins when CO_2 reacts with (a) phosphoenolpyruvate (b) glyceraldehyde-3-phosphate (c) ribulose bisphosphate (d) oxaloacetate (e) phosphoglycerate
9. The enzyme directly responsible for almost all carbon fixation on Earth is (a) rubisco (b) PEP carboxylase (c) ATP synthase (d) phosphofructokinase (e) ligase
10. In C_4 plants, C_4 and C_3 pathways occur at different _____; whereas in CAM plants, CAM and C_3 pathways occur at different _____. (a) times of day; locations within the leaf (b) seasons; locations (c) locations; times of day (d) locations; seasons (e) times of day; seasons
11. An organism characterized as a photoautotroph obtains energy from _____ and carbon from _____. (a) light; organic molecules (b) light; CO_2 (c) organic molecules; organic molecules (d) organic molecules; CO_2 (e) O_2; CO_2
12. Label the figure. Use Figure 9-8 to check your answers.



www.konkur.in

CRITICAL THINKING

1. Must all autotrophs use light energy? Explain.
2. Only some plant cells have chloroplasts, but all actively metabolizing plant cells have mitochondria. Why?
3. Explain why the proton gradient formed during chemiosmosis represents a state of low entropy. (You may wish to refer to the discussion of entropy in Chapter 7.)
4. The electrons in glucose have relatively high free energies. How did they become so energetic?
5. **SCIENCE, TECHNOLOGY, AND SOCIETY.** What strategies may be employed in the future to increase world food supply? Base your answer on your knowledge of photosynthesis and related processes.
6. What would life be like for photoautotrophs if there were no chemoheterotrophs? For chemoheterotrophs if there were no photoautotrophs?
7. What might you suspect if scientists learned that a distant planet has an atmosphere that is 15% molecular oxygen?
8. **EVOLUTION LINK.** Propose an explanation for the fact that bacteria, chloroplasts, and mitochondria all have ATP synthase complexes.
9. **ANALYZING DATA.** The figure depicts the absorption spectrum of a plant pigment. What colors/wavelengths does it absorb? What is the color of this pigment?

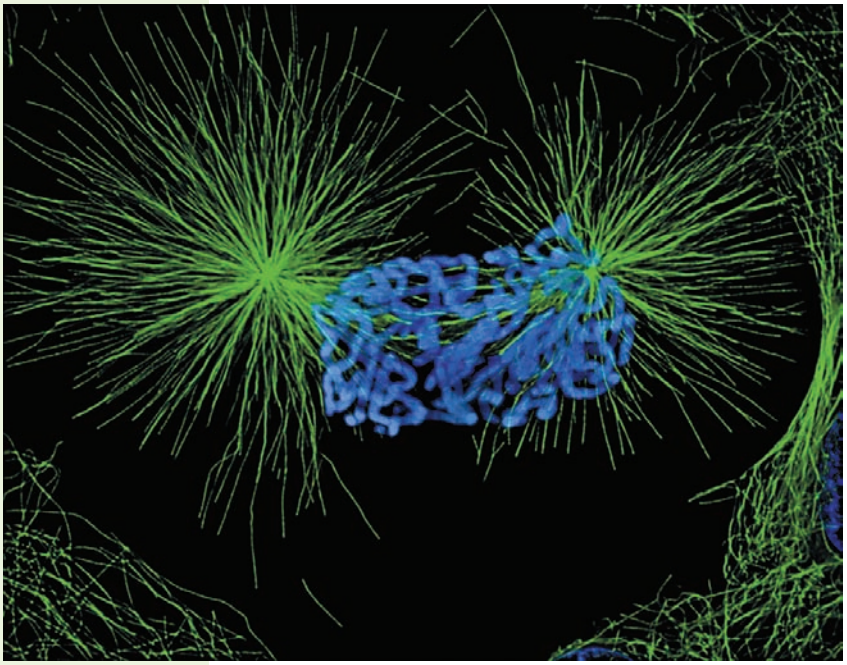
10 Chromosomes, Mitosis, and Meiosis



Alexey Khodjakov, Wadsworth Center, Albany, NY

Fluorescence LM of a cultured newt lung cell in mitosis (early prometaphase). The nuclear envelope has broken down, and the microtubules of the mitotic spindle (*green*) now interact with the chromosomes (*blue*).

KEY CONCEPTS

10.1 In eukaryotic cells, DNA is wound around specific proteins to form chromatin, which in turn is folded and packaged to make individual chromosomes.

10.2 In mitosis, duplicated chromosomes separate (split apart) and are evenly distributed into two daughter nuclei. Mitosis is an important part of the cell cycle, which consists of the successive stages through which a cell passes.

10.3 An internal genetic program interacts with external signals to regulate the cell cycle.

10.4 Meiosis, which reduces the number of chromosome sets from diploid to haploid, is necessary to maintain the normal chromosome number when two cells join during sexual reproduction. Meiosis helps to increase genetic variation among offspring.

10.5 Meiosis and gamete production precede fertilization in the life cycles of sexually reproducing organisms.

Pre-existing cells divide to form new cells. This remarkable process enables an organism to grow, repair damaged parts, and reproduce. Cells serve as the essential link between generations. Even the simplest cell contains a large amount of precisely coded genetic information in the form of deoxyribonucleic acid (DNA). An individual's DNA is organized into informational units called *genes*, which control the activities of the cell and are passed on to its descendants. When a cell divides, the information contained in the DNA must be faithfully replicated and the copies then transmitted to each daughter cell through a precisely choreographed series of steps (see photograph).

DNA is a very long, thin molecule that could easily become tangled and broken, and a eukaryotic cell's nucleus contains a huge amount of DNA. In this chapter we consider how eukaryotes accommodate the genetic material by packaging each DNA molecule with proteins to form a structure called a *chromosome*, each of which contains hundreds or thousands of genes.

We then consider *mitosis*, the highly regimented process that ensures a parent cell transmits one copy of every chromosome to each of its two daughter cells. In this way, the chromosome number is preserved through successive mitotic divisions. Most *somatic cells* (body cells) of eukaryotes divide by mitosis. Mitosis is an active area of biological research, and for good reason: errors in mitosis can result in a host of disorders and diseases

www.konkur.in

such as cancer, a disease condition in which cells divide at an uncontrolled rate and become invasive. Thus, a clearer understanding of mitosis has the potential to improve our treatment of many diseases.

Finally, we discuss *meiosis*, a process that reduces the chromosome number by half. Sexual life cycles in eukaryotes require meiosis. Sexual reproduction involves the fusion of two sex cells, or *gametes*, to form a fertilized egg called a *zygote*. Meiosis makes it possible for each gamete to contain only half the number of chromosomes in the parent cell, thereby preventing the zygotes from having twice as many chromosomes as the parents.

10.1 EUKARYOTIC CHROMOSOMES

LEARNING OBJECTIVES

1 Discuss the significance of chromosomes in terms of their information content.

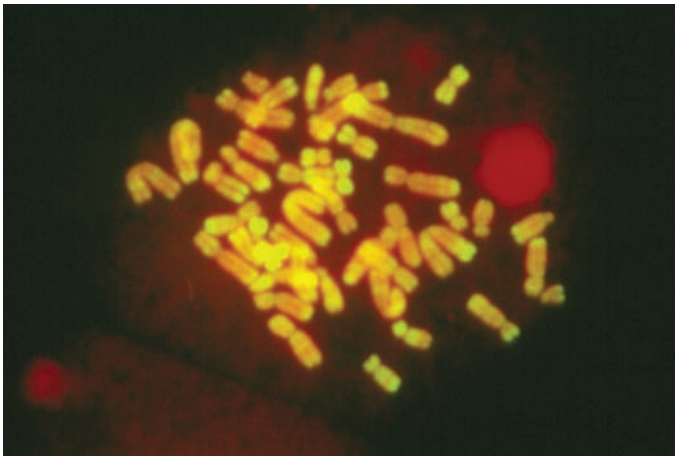
2 Explain how DNA is packed into chromosomes in eukaryotic cells.

The major carriers of genetic information in eukaryotes are the **chromosomes,** which lie within the cell nucleus. Although *chromosome* means "colored body," chromosomes are virtually colorless; the term refers to their ability to be stained by certain dyes. In the 1880s, light microscopes had been improved to the point that scientists such as the German biologist Walther Fleming began to observe chromosomes during cell division. In 1903, American biologist Walter Sutton and German biologist Theodor Boveri noted independently that chromosomes were the physical carriers of genes, the genetic factors Gregor Mendel discovered in the 19th century (discussed in Chapter 11).

Chromosomes are made of **chromatin,** a material consisting of DNA and associated proteins. When a cell is not dividing, the chromosomes are present but in an extended, partially unraveled form. Chromatin consists of long, thin threads that are somewhat aggregated, giving them a granular appearance when viewed with the electron microscope (see Fig. 4-13). During cell division, the chromatin fibers condense and the chromosomes become visible as distinct structures (**FIG. 10-1**).

DNA is organized into informational units called genes

An organism may have thousands of genes. For example, humans have about 20,000 genes that code for proteins. As you will see in later chapters, the concept of the gene has changed considerably since the science of genetics began, but our definitions have always centered on the gene as an informational unit. By providing information needed to carry out one or more specific cell functions, a gene affects some characteristic of the organism. For example, genes govern eye color in humans, wing length in flies, and seed color in peas.



Jan Hinsch/Photo Researchers, Inc.

FIGURE 10-1 Chromosomes
Human chromosomes from an unidentified cell are shown in this fluorescence LM.

DNA is packaged in a highly organized way in chromosomes

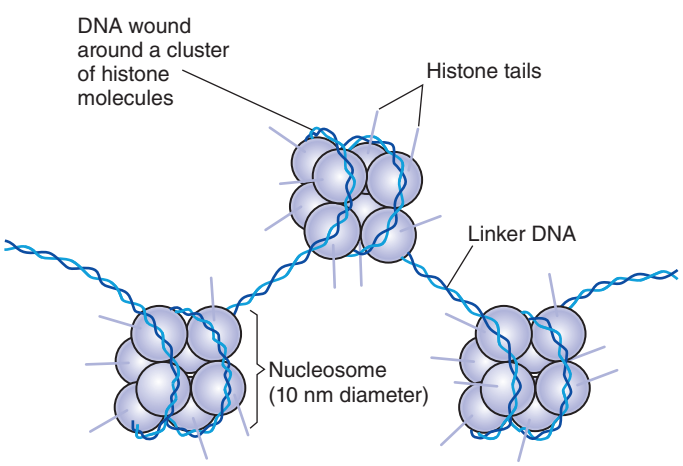
Prokaryotic and eukaryotic cells differ markedly in their DNA content as well as in the organization of DNA molecules. The bacterium *Escherichia coli* normally contains about 4×10^6 base pairs (almost 1.35 mm) of DNA in its single, circular DNA molecule. In fact, the total length of its DNA is about 1000 times as long as the length of the cell itself. Therefore, the DNA molecule is, with the help of proteins, twisted and folded compactly to fit inside the bacterial cell (see Fig. 25-2).

A typical eukaryotic cell contains much more DNA than a bacterium does, and it is organized in the nucleus as multiple chromosomes; these vary widely in size and number among different species. Although a human nucleus is about the size of a large bacterial cell, it contains more than 1000 times the amount of DNA found in *E. coli.* The DNA content of a human sperm cell is about 3×10^9 base pairs; stretched end to end, it would measure almost 1 m long. Remarkably, this DNA fits into a nucleus with a diameter of only 10 μm.

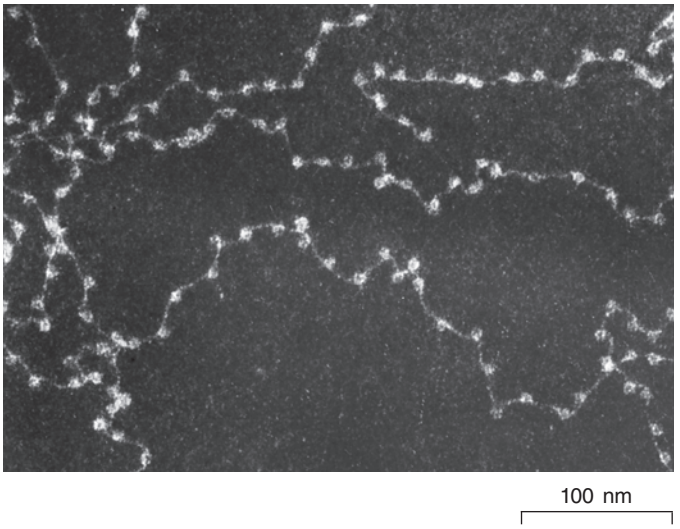
How does a eukaryotic cell pack its DNA into the chromosomes? Chromosome packaging is facilitated by certain proteins known as **histones.**[1] Histones have a positive charge because they have a high proportion of amino acids with basic side chains (see Chapter 3). The positively charged histones associate with DNA, which has a negative charge because of its phosphate groups, to form structures called **nucleosomes.** The fundamental unit of each nucleosome consists of a beadlike structure with 146 base pairs of DNA wrapped around a disc-shaped core of eight histone molecules (two each of four different histone types) (**FIG. 10-2**).

[1]A few types of eukaryotic cells lack histones. Conversely, histones occur in one group of prokaryotes, the archaea (see Chapter 25).

www.konkur.in



(a) A model for the structure of a nucleosome. Each nucleosome bead contains a set of eight histone molecules, forming a protein core around which the double-stranded DNA winds. The DNA surrounding the histones consists of 146 nucleotide pairs; another segment of DNA, about 60 nucleotide pairs long, links nucleosome beads.



(b) TEM of nucleosomes from the nucleus of a chicken cell. Normally, nucleosomes are packed more closely together, but the preparation procedure has spread them apart, revealing the DNA linkers.

FIGURE 10-2 Nucleosomes

Although the nucleosome was originally defined as a bead plus a DNA segment that links it to an adjacent bead, today the term more commonly refers only to the bead itself (that is, the eight histones and the DNA wrapped around them).

Nucleosomes function like tiny spools, preventing DNA from becoming tangled. You can see the importance of this role in **FIGURE 10-3**, which illustrates the enormous length of DNA that unravels from a mouse chromosome after researchers have removed the histones. The role of histones is more than simply structural because their arrangement also affects the activity of the DNA with which they are associated. Histones are increasingly viewed as an important part of the regulation of gene expression—that is, whether genes are turned off or on. We discuss gene regulation by histones in Chapter 14.

The wrapping of DNA into nucleosomes represents the first level of chromosome structure. **FIGURE 10-4** shows the higher-order structures of chromatin leading to the formation of a condensed chromosome. The nucleosomes themselves are 10 nm in diameter. The packed nucleosome state occurs when a fifth type of histone, known as *histone H1,* associates with the linker DNA, packing adjacent nucleosomes together to form a compacted 30 nm chromatin fiber. In extended chromatin, these fibers form large, coiled loops held together by **scaffolding proteins,** nonhistone proteins that help maintain chromosome structure. The loops then interact to form the condensed chromatin found in a chromosome. Cell biologists have identified a group of proteins, collectively called **condensin,** required for chromosome compaction. Condensin binds to DNA and wraps it into coiled loops that are compacted into a mitotic or meiotic chromosome.

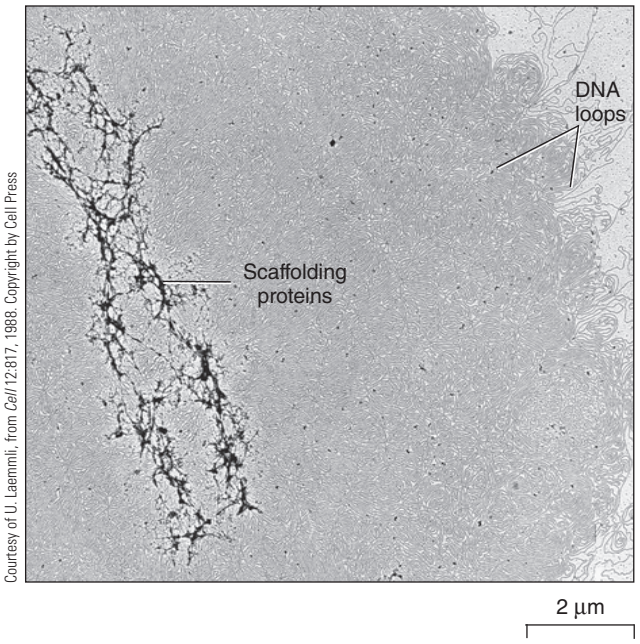


FIGURE 10-3 TEM of a mouse chromosome depleted of histones

Notice how densely packed the DNA strands are, even though they have been released from the histone proteins that organize them into tightly coiled structures.

Chromosome number and informational content differ among species

Every individual of a given species has a characteristic number of chromosomes in the nuclei of its somatic (body) cells. However, it is not the number of chromosomes that makes each species unique but

www.konkur.in

KEY POINT When a cell prepares to divide, its chromosomes become thicker and shorter as their long chromatin fibers are compacted.

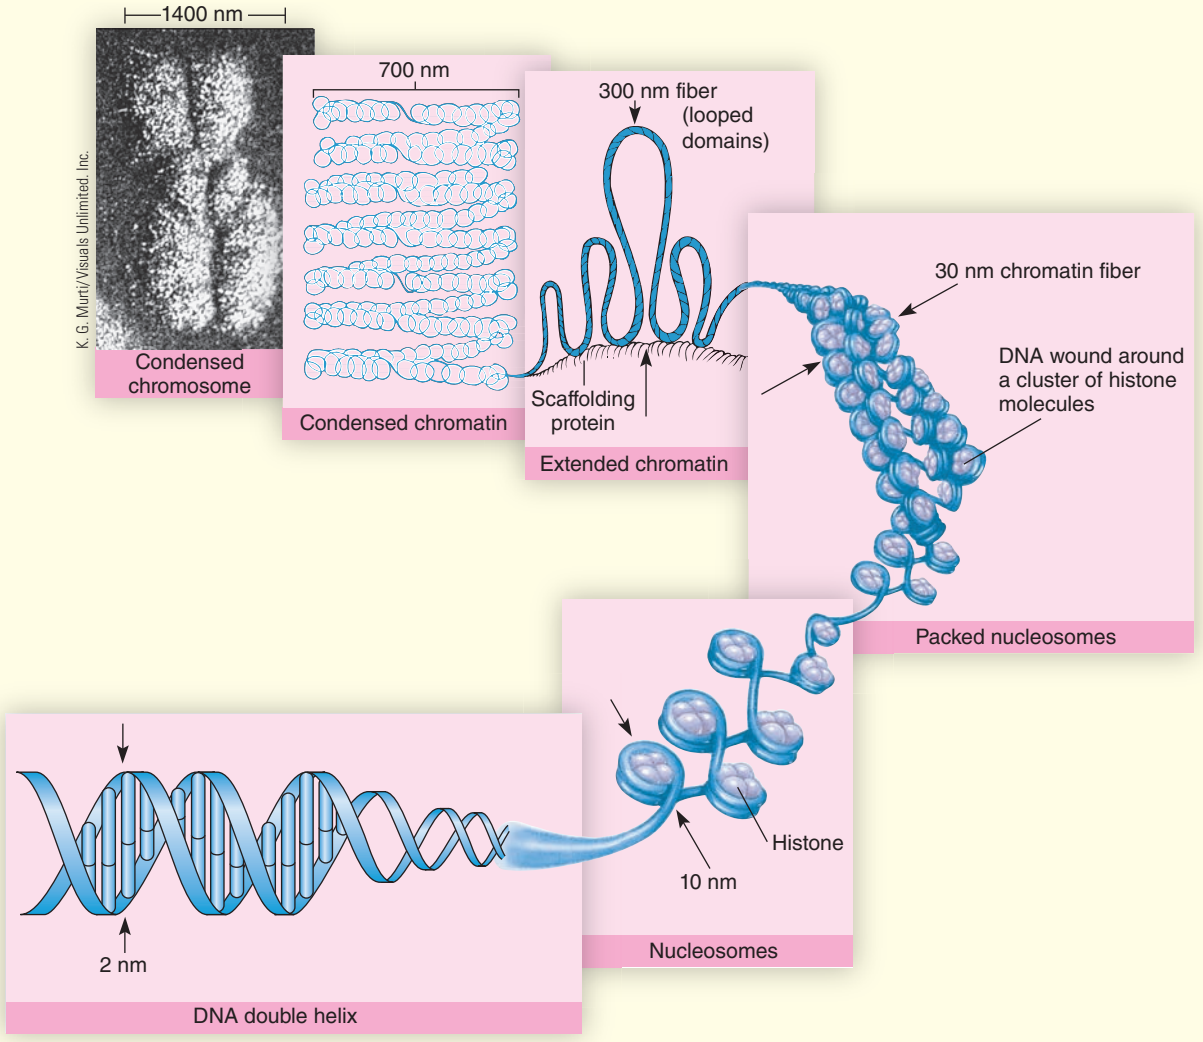

FIGURE 10-4 ***Animated*** **Organization of a eukaryotic chromosome**

This diagram shows how DNA is packaged into highly condensed metaphase chromosomes. First, DNA is wrapped around histone proteins to form nucleosomes. Then, the nucleosomes are compacted into chromatin fibers, which are coiled into looped domains. The looped domains are compacted, ultimately forming chromosomes.

the information the genes specify. Most human somatic cells have exactly 46 chromosomes, but humans are not humans merely because we have 46 chromosomes. Some other species—the olive tree, for example—also have 46. Some humans have an abnormal chromosome composition with more or fewer than 46 (see Fig. 16-4).

Other species have different chromosome numbers. A certain species of roundworm has only 2 chromosomes in each cell, whereas some crabs have as many as 200, and some ferns have more than 1000. Most animal and plant species have between 8 and 50 chromosomes per somatic cell. Numbers above and below these are uncommon. The number of chromosomes a species has does not indicate the species' complexity or its status within a particular domain or kingdom.

Review

- What are the informational units on chromosomes called? Of what do these informational units consist?
- How is the large discrepancy between DNA length and nucleus size addressed in eukaryotic cells?

www.konkur.in

10.2 THE CELL CYCLE AND MITOSIS

LEARNING OBJECTIVES

3 Identify the stages in the eukaryotic cell cycle and describe their principal events.

4 Describe the structure of a duplicated chromosome, including the sister chromatids, centromeres, and kinetochores.

5 Explain the significance of mitosis and describe the process.

When cells reach a certain size, they usually either stop growing or divide. Not all cells divide; some, such as skeletal muscle and red blood cells, do not normally divide once they are mature. Other cells undergo a sequence of activities required for growth and cell division.

The stages through which a cell passes from one cell division to the next are collectively referred to as the **cell cycle.** Timing of the cell cycle varies widely, but in actively growing plant and animal cells, it is about 8 to 20 hours. The cell cycle consists of two main phases, interphase and M phase, both of which can be distinguished under a light microscope (**FIG. 10-5**).

KEY POINT The cell cycle is the successive series of events in the life of a cell.

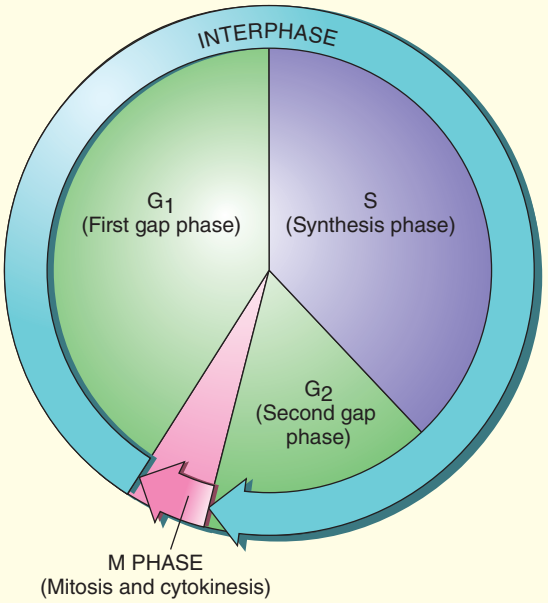

FIGURE 10-5 *Animated* The eukaryotic cell cycle

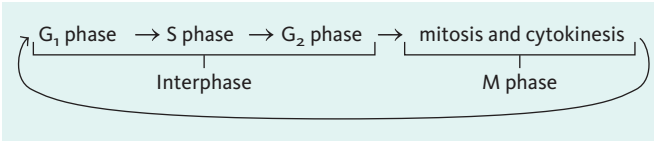
The cell cycle includes interphase (G_1, S, and G_2) and M phase (mitosis and cytokinesis). Proportionate amounts of time spent at each stage vary among species, cell types, and growth conditions. If the cell cycle were a period of 12 hours, G_1 would be about 5 hours, S would be 4.5 hours, G_2 would be 2 hours, and M phase would be 30 minutes.

Chromosomes duplicate during interphase

Most of a cell's life is spent in **interphase,** the time when no cell division is occurring. A cell is metabolically active during interphase, synthesizing needed materials (proteins, lipids, and other biologically important molecules) and growing. Here is the sequence of interphase and M phase in the eukaryotic cell cycle:



The time between the end of mitosis and the beginning of the S phase is termed the **G_1 phase** (*G* stands for *gap,* an interval during which no DNA synthesis occurs). Growth and normal metabolism take place during the G_1 phase, which is typically the longest phase. Cells that are not dividing usually become arrested in this part of the cell cycle and are said to be in a state called G_0. Toward the end of G_1, the enzymes required for DNA synthesis become more active. Synthesis of these enzymes, along with proteins needed to initiate cell division (discussed later in the chapter), enable the cell to enter the S phase.

During the **synthesis phase,** or **S phase,** DNA replicates and histone proteins are synthesized so that the cell can make duplicate copies of its chromosomes. How did researchers identify the S phase of the cell cycle? In the early 1950s, researchers demonstrated that cells preparing to divide duplicate their chromosomes at a relatively restricted time interval during interphase and not during early mitosis, as previously hypothesized. These investigators used isotopes, such as ^3H, to synthesize radioactive thymidine, a nucleotide that is incorporated specifically into DNA as it is synthesized. After radioactive thymidine was supplied for a brief period (such as 30 minutes) to actively growing cells, *autoradiography* (see Fig. 2-3) on exposed film showed that a fraction of the cells had silver grains over their chromosomes. The nuclei of these cells were radioactive because during the experiment DNA had replicated. DNA replication was not occurring in the cells that did not have radioactively labeled chromosomes. Researchers therefore inferred that the proportion of labeled cells out of the total number of cells provides a rough estimate of the length of the S phase relative to the rest of the cell cycle.

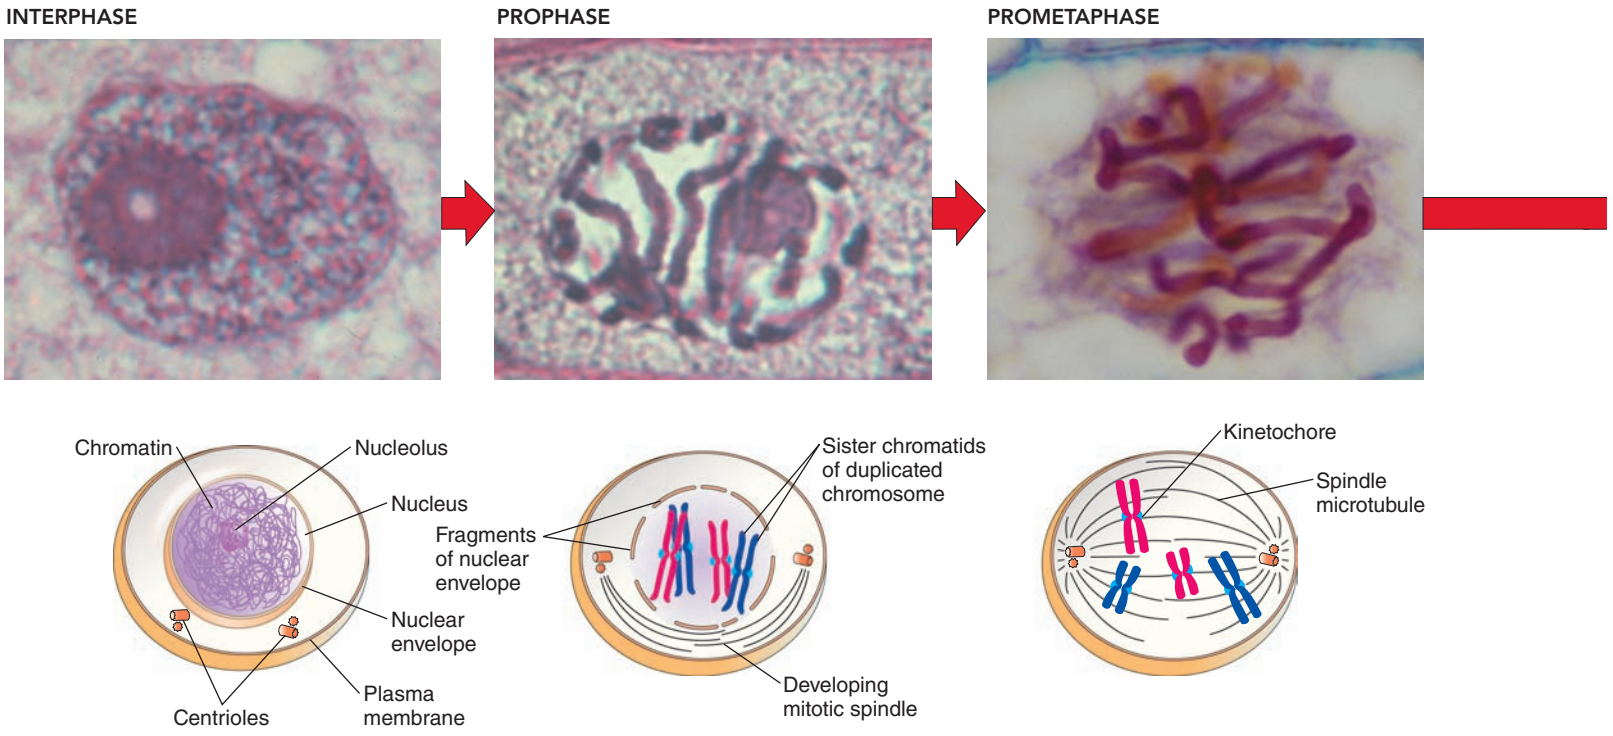
After it completes the S phase, the cell enters a second gap phase, the **G_2 phase.** At this time, increased protein synthesis occurs, as the final steps in the cell's preparation for division take place. For many cells, the G_2 phase is short relative to the G_1 and S phases.

M phase involves two main processes, mitosis and cytokinesis. **Mitosis,** the nuclear division that produces two nuclei containing chromosomes identical to the parental nucleus, begins at the end of the G_2 phase. Cytokinesis, which generally begins before mitosis is complete, is the division of the cell cytoplasm to form two cells.

Mitosis is a continuous process, but for descriptive purposes, it is divided into five stages:

prophase → prometaphase → metaphase → anaphase → telophase

www.konkur.in



(a) Cell carries out normal life activities. Chromosomes become duplicated.

(b) Long fibers of chromatin condense as compact mitotic chromosomes, each consisting of two chromatids attached at their centromeres. Cytoskeleton is disassembled, and mitotic spindle forms between centrioles, which have moved to poles of cell. Nuclear envelope begins to disassemble.

(c) Spindle microtubules attach to kinetochores of chromosomes. Chromosomes begin to move toward cell's midplane.

FIGURE 10-6 ***Animated*** **Interphase and the stages of mitosis**

The LMs show plant cells, which lack centrioles. The drawings depict generalized animal cells with a diploid chromosome number of four; the sizes of the nuclei and chromosomes are exaggerated to show the structures more clearly.

Study **FIGURE 10-6** while you read the following descriptions of these stages as they occur in a typical plant or animal cell.

During prophase, duplicated chromosomes become visible with the microscope

The first stage of mitosis, **prophase,** begins with chromosome compaction, when the long chromatin fibers that make up the chromosomes begin a coiling process that makes them shorter and thicker. The compacted chromatin can then be distributed to the daughter cells with less likelihood of tangling.

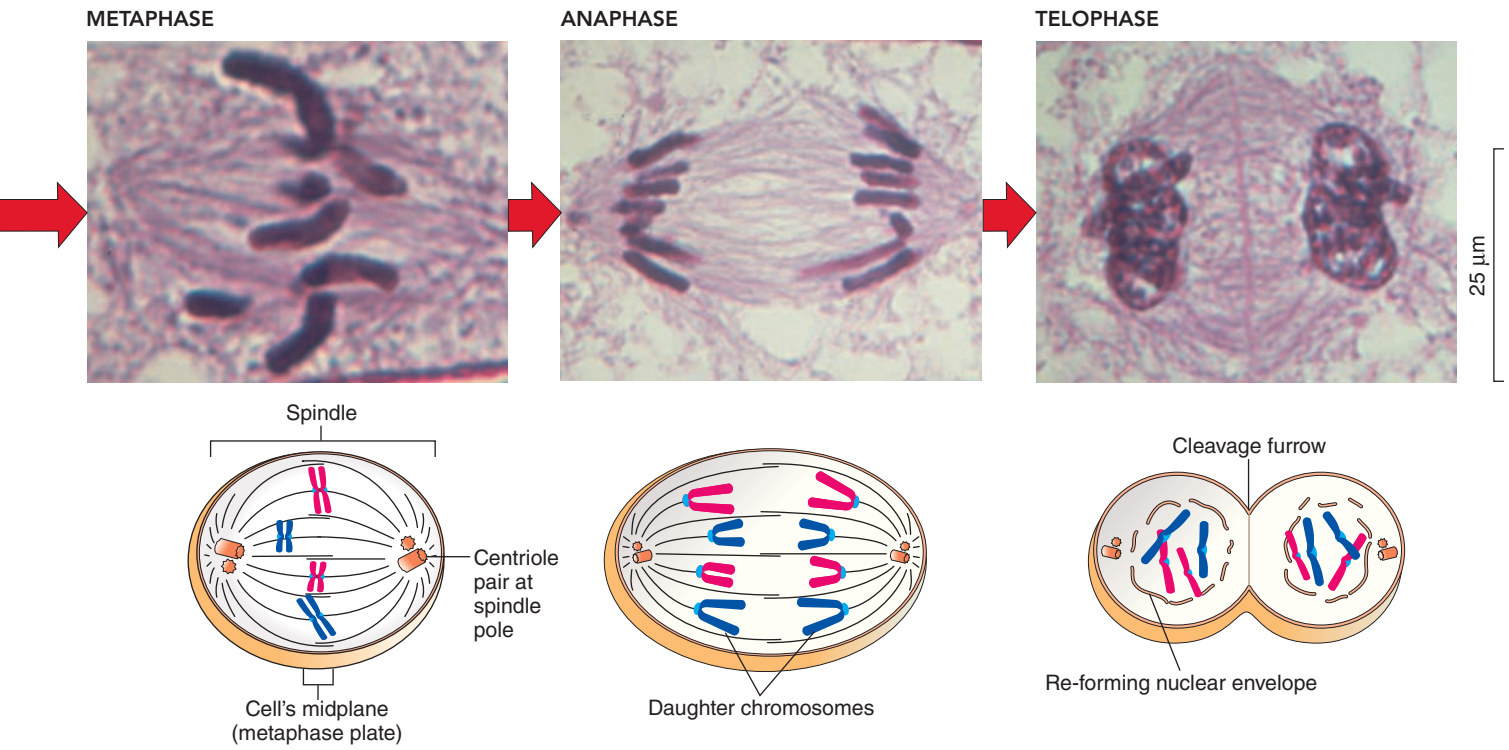
When stained with certain dyes and viewed through the light microscope, chromosomes become visible as darkly stained bodies as prophase progresses. It is now apparent that each chromosome was duplicated during the preceding S phase and consists of a pair of **sister chromatids,** which contain identical, double-stranded DNA sequences. Each chromatid includes a constricted region called the **centromere.** Sister chromatids are tightly associated in the vicinity of their centromeres (**FIG. 10-7**). The chemical basis for this close association at the centromeres consists of precise DNA sequences that are tightly bound to specific proteins.

For example, sister chromatids are physically linked by a ring-shaped protein complex called **cohesin.** Cohesins extend along the length of the sister chromatid arms and are particularly concentrated at the centromere (**FIG. 10-8**). These cohesins, which hold the replicated chromosomes together from their synthesis in S phase onward, help to ensure accurate chromosome segregation during mitosis.

Attached to each centromere is a **kinetochore,** a multiprotein complex to which **microtubules** can bind. These microtubules function in chromosome distribution during mitosis, in which one copy of each chromosome is delivered to each daughter cell.

A dividing cell can be described as a globe, with an equator that determines the midplane (equatorial plane) and two opposite poles. This terminology is used for all cells regardless of their actual shape. Microtubules radiate from each pole, and some of these protein fibers elongate toward the chromosomes, forming the **mitotic spindle,** a structure that separates the duplicated chromosomes

www.konkur.in

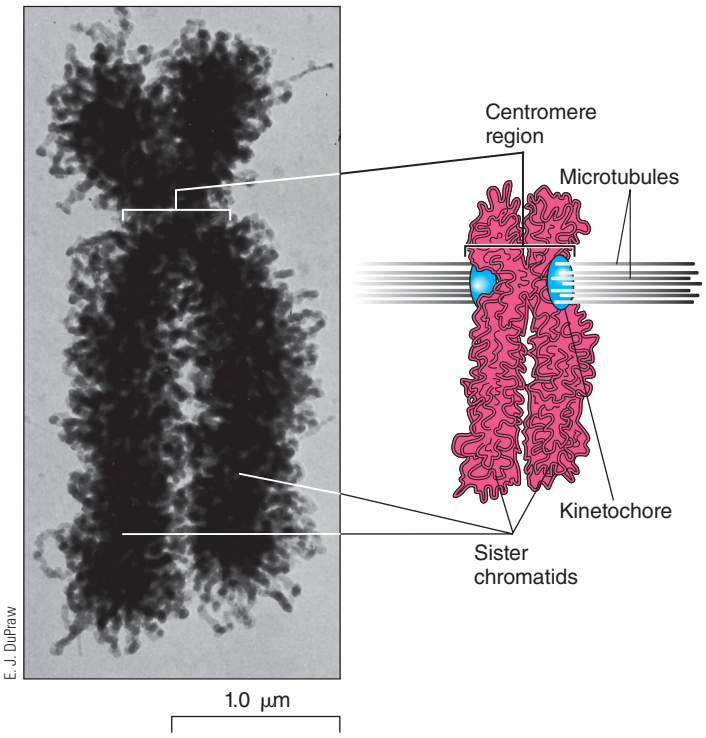


(d) Chromosomes line up along cell's midplane. Spindle microtubules attach each chromosome to both poles.

(e) Sister chromatids separate at their centromeres. One group of chromosomes moves toward each pole of cell. Spindle poles move farther apart.

(f) Chromosomes are grouped at poles. Chromosomes decondense, and nuclear envelopes begin to form. Cytokinesis produces two daughter cells.

▲ **FIGURE 10-6** Continued



◀ **FIGURE 10-7** Sister chromatids and centromeres

The sister chromatids, each consisting of tightly coiled chromatin fibers, are tightly associated at their centromere regions, indicated by the brackets. Associated with each centromere is a kinetochore, which serves as a microtubule attachment site. Kinetochores and microtubules are not visible in this TEM of a metaphase chromosome.

during anaphase (**FIG. 10-9**). The *minus* ends of these microtubules are at the poles, and the *plus* ends extend to the cell's midplane. It might be helpful to review Figure 4-24, which shows the organization of microtubules as linear polymers of the protein *tubulin*. The organization and function of the spindle require the presence of motor proteins and a variety of signaling molecules.

Animal cells differ from plant cells in the details of mitotic spindle formation. In both types of dividing cells, each pole contains a region, the **microtubule-organizing center,** from which extend the microtubules that form the mitotic spindle. The electron microscope shows that microtubule-organizing centers in certain plant cells consist of fibrils with little or no discernible structure.

In contrast, animal cells have a pair of **centrioles** in the middle of each microtubule-organizing center (see Fig. 4-26). The centrioles are surrounded by fibrils that make up the **pericentriolar**

www.konkur.in

KEY POINT When chromosomes duplicate, sister chromatids are initially linked to one another by protein complexes called cohesins. Cohesin linkages are particularly concentrated in the vicinity of the centromere.

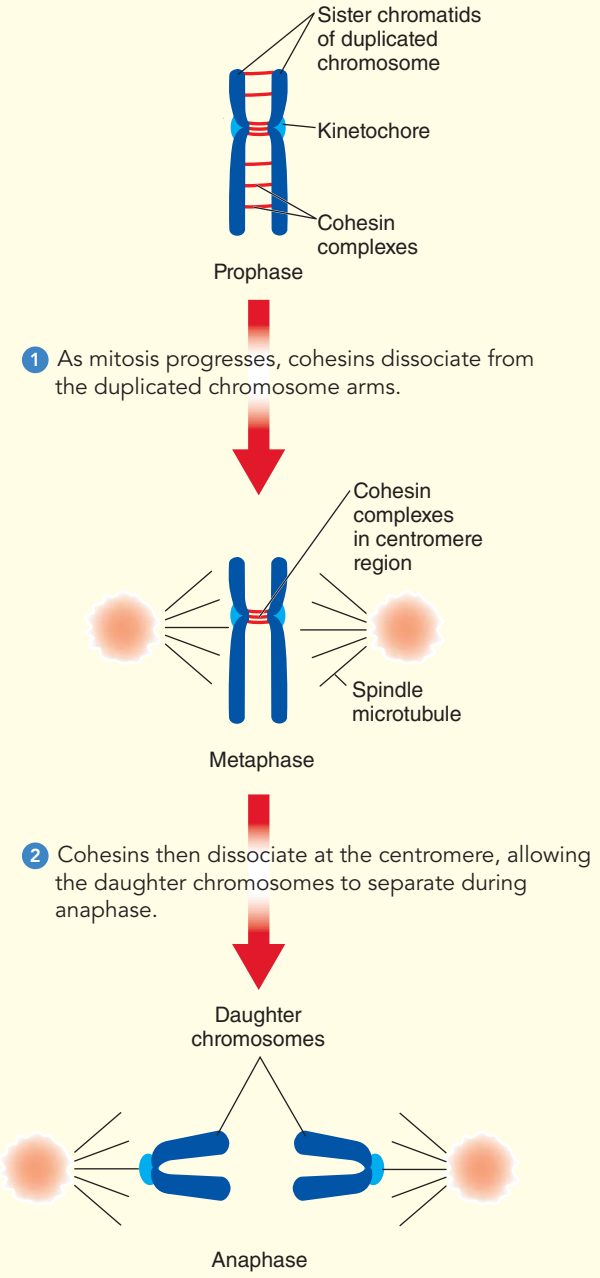


FIGURE 10-8 Cohesins

material. The spindle microtubules terminate in the pericentriolar material, but they do not actually touch the centrioles. Although cell biologists once thought spindle formation in animal cells required centrioles, their involvement is probably coincidental. Current evidence suggests that centrioles organize the pericentriolar material and ensure its duplication when the centrioles duplicate.

Each of the two centrioles is duplicated during the S phase of interphase, yielding two centriole pairs. Late in prophase, microtubules radiate from the pericentriolar material surrounding the centrioles; these clusters of microtubules are called asters. The two asters migrate to opposite sides of the nucleus, establishing the two poles of the mitotic spindle.

Prometaphase begins when the nuclear envelope breaks down

During **prometaphase** the nuclear envelope fragments so that the spindle microtubules come into contact with the chromosomes; units of the disassembled nuclear envelope are sequestered in vesicles to be used later, to assemble nuclear envelopes for the daughter cells. The nucleolus shrinks and usually disappears, and the mitotic spindle is completely assembled. At the start of prometaphase, the duplicated chromosomes are scattered throughout the nuclear region (see the chapter introduction photograph, which shows early prometaphase). The spindle microtubules grow and shrink as they move toward the center of the cell in a "search and capture" process. Their random, dynamic movements give the appearance that they are "searching" for the chromosomes. If a microtubule comes near a centromere, one of the kinetochores of a duplicated chromosome "captures" it. As the now-tethered chromosome continues moving toward the cell's midplane, the unattached kinetochore of its sister chromatid becomes connected to a spindle microtubule from the cell's other pole.

During the chromosomes' movements toward the cell's midplane, long microtubules are shortened by the removal of tubulin subunits, and the short microtubules are lengthened by the addition of tubulin subunits. Evidence indicates that shortening and lengthening occurs at the kinetochore end (the plus end) of the microtubule, not at the spindle pole end (the minus end). This shortening or lengthening occurs while the spindle microtubule remains firmly tethered to the kinetochore. Motor proteins located at the kinetochores may be involved in this tethering of the spindle microtubule. These motor proteins may work in a similar fashion to the kinesin motor shown in Figure 4-25.

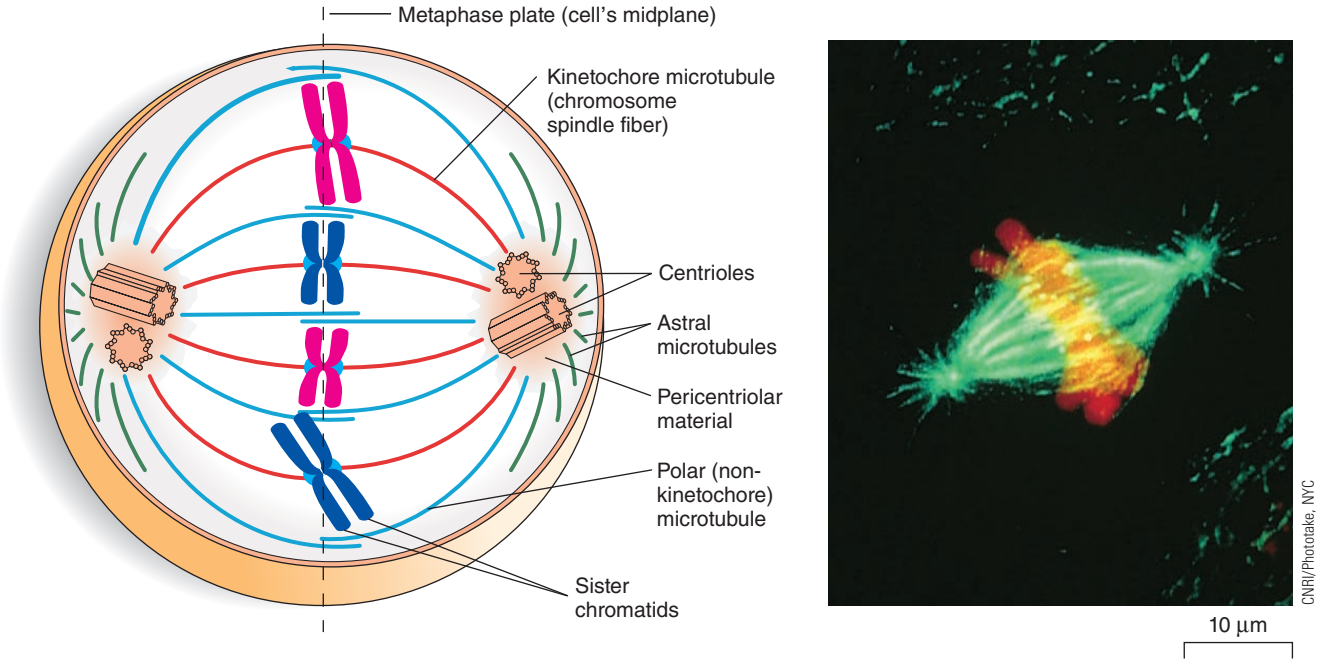
To summarize the events of prometaphase, sister chromatids of each duplicated chromosome become attached at their kinetochores to spindle microtubules extending from opposite poles of the cell, and the chromosomes begin to move toward the cell's midplane. As the cell transitions from prometaphase to metaphase, cohesins dissociate from the sister chromatid arms, freeing them from one another, although some cohesins remain in the vicinity of the centromere.

Duplicated chromosomes line up on the midplane during metaphase

During **metaphase,** all the cell's chromosomes align at the cell's midplane, or **metaphase plate.** As already mentioned, one of the two sister chromatids of each chromosome is attached by its kinetochore to microtubules from one pole, and its sister chromatid is attached by its kinetochore to microtubules from the opposite pole.

The mitotic spindle has three types of microtubules: polar microtubules, kinetochore microtubules, and astral microtubules

www.konkur.in



(a) One end of each microtubule of this animal cell is associated with one of the poles. Astral microtubules (*green*) radiate in all directions, forming the aster. Kinetochore microtubules (*red*) connect the kinetochores to the poles, and polar (nonkinetochore) microtubules (*blue*) overlap at the midplane.

(b) This fluorescence LM of an animal cell at metaphase shows a well-defined spindle and asters (chromosomes, *orange*; microtubules, *green*).

FIGURE 10-9 The mitotic spindle

(see Fig. 10-9). **Polar microtubules,** also known as *nonkinetochore microtubules,* extend from each pole to the equatorial region, where they overlap and interact with nonkinetochore microtubules from the opposite pole. **Kinetochore microtubules** extend from each pole and attach to chromosomes at their kinetochores. **Astral microtubules** are the short microtubules that form asters at each pole.

Each chromatid is completely condensed and appears distinct during metaphase. Because individual chromosomes are more obvious at metaphase than at any other time, the **karyotype,** or chromosome composition, is usually checked at this stage for chromosome abnormalities (see Chapter 16). As the mitotic cell transitions from metaphase to anaphase, the remaining cohesin proteins joining the sister chromatids at their centromere dissociate.

During anaphase, chromosomes move toward the poles

Anaphase begins as the sister chromatids separate. Once the chromatids are no longer attached to their duplicates, each chromatid is called a *chromosome.* The now-separate chromosomes move to opposite poles, using the spindle microtubules as tracks. The kinetochores, still attached to kinetochore microtubules, lead the way, with the chromosome arms trailing behind. Anaphase ends when all the chromosomes have reached the poles.

Cell biologists are making significant progress in understanding the overall mechanism of chromosome movement in anaphase. Chromosome movements are studied in several ways. The number of microtubules at a particular stage or after certain treatments is determined by carefully analyzing electron micrographs. Researchers also physically perturb living cells that are dividing, using microlaser beams or mechanical devices known as *micromanipulators.* A skilled researcher can move chromosomes, break their connections to microtubules, and even remove them from the cell entirely.

Microtubules lack elastic or contractile properties. Then how do the chromosomes move apart? Are they pushed or pulled, or do other forces operate? Microtubules are dynamic structures, with *tubulin* subunits constantly being removed from their ends and others being added. Evidence indicates that during anaphase, kinetochore microtubules shorten, or *depolymerize,* at their *plus* ends, that is, closest toward the midplane of the cell (**FIG. 10-10**). This shortening mechanism pulls the chromosomes toward the poles.

A second mechanism also plays a role in chromosome separation. During anaphase the spindle as a whole elongates, at least partly because polar microtubules originating at opposite poles are associated with motors that let them slide past one another at the midplane. The sliding decreases the degree of overlap, thereby "pushing" the poles apart. This mechanism indirectly causes the chromosomes to move apart because they are attached to the poles by kinetochore microtubules.

During telophase, two separate nuclei form

During the final stage of mitosis, **telophase,** chromosomes arrive at the poles and there is a return to interphase-like conditions. The

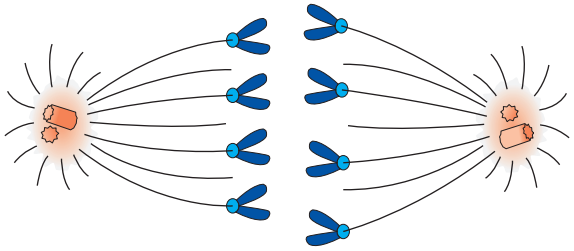
www.konkur.in

KEY EXPERIMENT

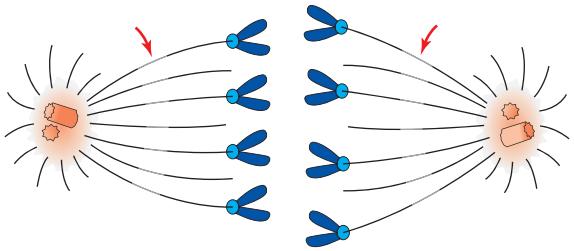
QUESTION: Do spindle microtubules move chromosomes by a shortening (that is, depolymerization) of microtubules at the spindle poles or at the kinetochore ends?

HYPOTHESIS: Spindle microtubules move chromosomes toward the spindle poles by a mechanism in which the spindle microtubules are shortened at their kinetochore ends.

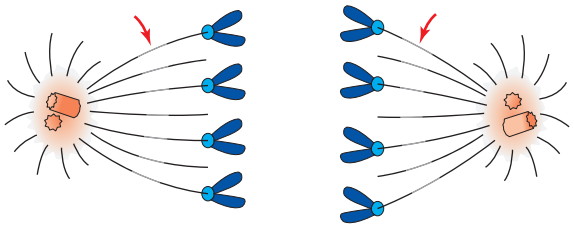
EXPERIMENT: Microtubules in pig kidney cells in early anaphase were labeled with a fluorescent dye that specifically attaches to microtubules.



The researchers marked the microtubules by using a laser microbeam to bleach the dye while keeping the microtubules intact.



RESULTS AND CONCLUSION: The chromosomes moved toward the bleached areas of the spindle microtubules, indicating a shortening of the microtubules on the kinetochore side. The microtubules on the polar ends did not shorten.



Chromosomes moved poleward because they remained anchored to the kinetochore microtubules as tubulin subunits were removed at the kinetochore ends of the microtubules.

FIGURE 10-10 ***Animated*** **Using laser photobleaching to determine how chromosomes are transported toward the spindle poles during anaphase**

chromosomes decondense by partially uncoiling. A new nuclear envelope forms around each set of chromosomes, made at least in part from small vesicles and other components derived from the old nuclear envelope. The spindle microtubules disappear, and the nucleoli reorganize.

Cytokinesis forms two separate daughter cells

Cytokinesis, the division of the cytoplasm to yield two daughter cells, is the last step in M phase and usually overlaps mitosis, generally beginning during telophase. Cytokinesis of an animal or fungal cell (yeast, for example) begins as an *actomyosin contractile ring* is assembled and attached to the plasma membrane. The contractile ring encircles the cell in the equatorial region, at right angles to the spindle (**FIG. 10-11a**). The contractile ring consists of an association between actin and myosin filaments; it is thought that the motor activity of myosin moves actin filaments to cause the constriction, similar to the way actin and myosin cause muscle contraction (see Fig. 40-10). The ring contracts, producing a **cleavage furrow** that gradually deepens and eventually separates the cytoplasm into two daughter cells, each with a complete nucleus. The contractile ring then disassembles.

In plant cells, cytokinesis occurs by forming a **cell plate** (**FIG. 10-11b**), a partition constructed in the equatorial region of the spindle that grows laterally toward the cell wall. The cell plate forms as a line of vesicles originating in the *Golgi complex.* The vesicles contain materials to construct both a primary cell wall for each daughter cell and a middle lamella that cements the primary cell walls together. The vesicle membranes fuse to become the plasma membrane of each daughter cell.

Multinucleated cells form if mitosis is not followed by cytokinesis; this is a normal condition for certain cell types. For example, the body of plasmodial slime molds consists of a multinucleate mass of cytoplasm (see Fig. 26-19a).

Mitosis produces two cells genetically identical to the parent cell

The remarkable regularity of the process of cell division ensures that each daughter nucleus receives exactly the same number and kinds of chromosomes that the parent cell had. Thus, with a few exceptions, every cell of a multicellular organism has the same genetic makeup. If a cell receives more or fewer than the characteristic number of chromosomes through some malfunction of the cell division process, the resulting cell may show marked abnormalities and often cannot survive.

Mitosis provides for the orderly distribution of chromosomes (and of centrioles, if present), but what about the various cytoplasmic organelles? For example, all eukaryotic cells, including plant cells, require mitochondria. Likewise, photosynthetic plant cells cannot carry out photosynthesis without chloroplasts. These organelles contain their own DNA and appear to form by the division of previously existing mitochondria or plastids or their precursors. This nonmitotic division process is similar to prokaryotic cell division (discussed in the next section) and generally occurs during interphase. Because many copies of each organelle are present in each cell, organelles are apportioned with the cytoplasm that each daughter cell receives during cytokinesis.

Lacking nuclei, prokaryotes divide by binary fission

Bacteria and archaea contain much less DNA than do most eukaryotic cells, but precise distribution of the genetic material into two

www.konkur.in

daughter cells is still a formidable process. Prokaryotic DNA usually consists of a single, circular chromosome that is packaged with associated proteins. Although the distribution of genetic material in dividing prokaryotic cells is a simpler process than mitosis, it nevertheless is very precise, to ensure that the daughter cells are genetically identical to the parent cell.

Prokaryotes reproduce asexually, generally by **binary fission,** a process in which one cell divides into two daughter cells (**FIG. 10-12**). The circular DNA molecule replicates, resulting in two identical chromosomes. DNA replication begins at a single site on the bacterial chromosome, termed the *origin of replication.* DNA synthesis proceeds from that point in both directions until they eventually meet (see Fig. 12-16a).

Following replication, the daughter chromosomes separate and move to opposite ends of the elongating cell. Cytokinesis between the daughter chromosomes is controlled by the **Z ring,** a protein scaffold that holds about 10 different proteins around the cell's midsection. There the plasma membrane grows inward between the two DNA copies, dividing the cell's cytoplasm in half, and a new transverse cell wall is synthesized between the two cells. (Bacterial reproduction is described further in Chapter 25.)

Review

- What are the stages of the cell cycle? During which stage does DNA replicate?
- What are the stages of mitosis and what happens in each stage?

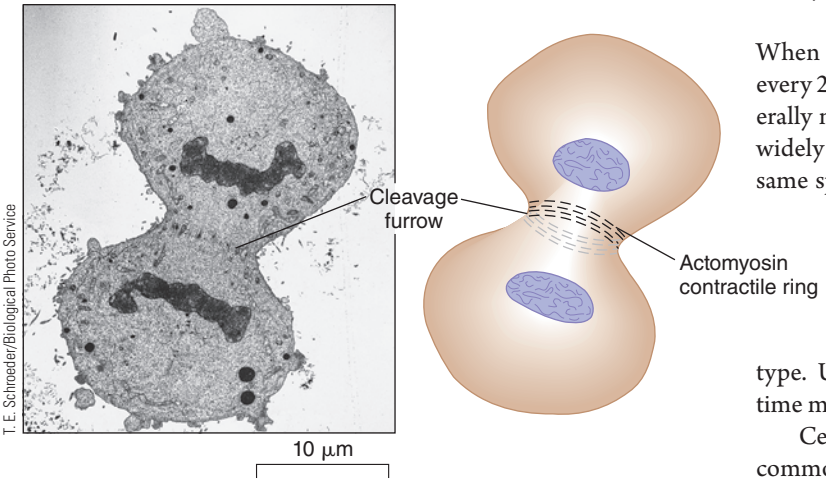
10.3 REGULATION OF THE CELL CYCLE

LEARNING OBJECTIVE

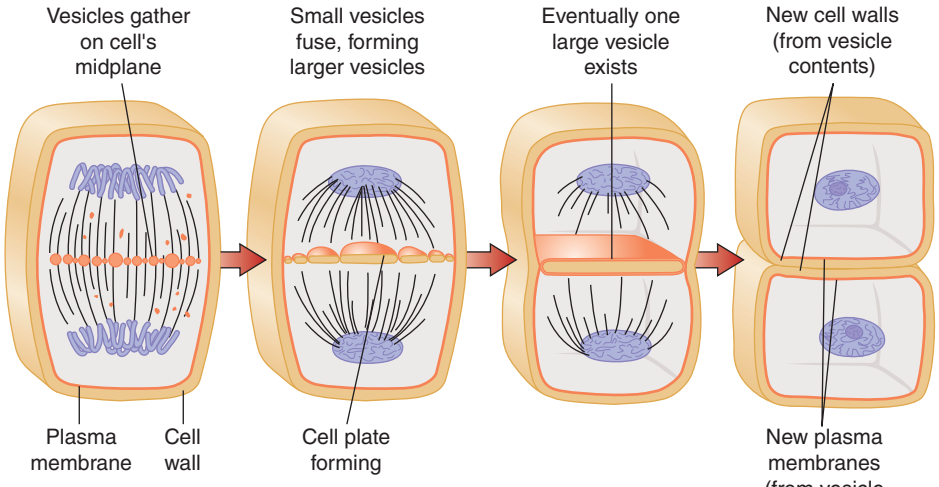
6 Explain some ways in which the cell cycle is controlled.

When conditions are optimal, some prokaryotic cells can divide every 20 minutes. The generation times of eukaryotic cells are generally much longer, although the frequency of cell division varies widely among different species and among different tissues of the same species. Some skeletal muscle cells usually stop dividing after the first few months of life, whereas blood-forming cells, digestive tract cells, and skin cells divide frequently throughout the life of the organism. Under optimal conditions of nutrition, temperature, and pH, the length of the eukaryotic cell cycle is constant for any given cell type. Under less favorable conditions, however, the generation time may be longer.

Certain regulatory molecules that control the cell cycle are common to all eukaryotes. Genetically programmed in the cell's



(a) TEM of the equatorial region of a cultured animal cell undergoing cytokinesis. Note the cleavage furrow. Dividing fungal cells also have a contractile ring that causes cytokinesis.



(b) Cell plate formation during cytokinesis in a plant cell. The TEM shows a maple leaf cell (*Acer saccharinum*) undergoing cytokinesis.

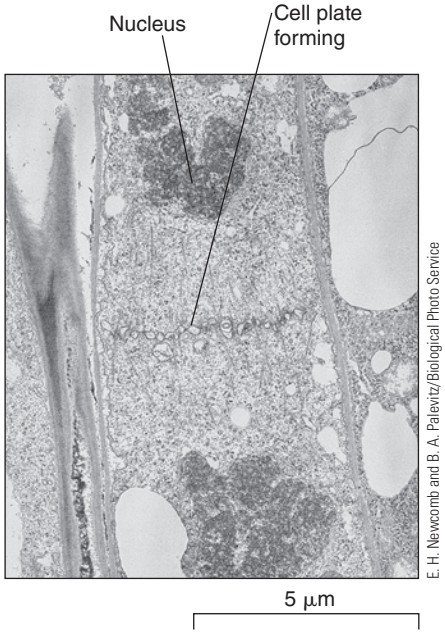


FIGURE 10-11 ***Animated*** **Cytokinesis in animal and plant cells**

The nuclei in both TEMs are in telophase. The drawings show 3-D relationships.

www.konkur.in

KEY POINT Binary fission is a precisely orchestrated sequence of events that ensures each bacterial daughter cell has identical genetic material.

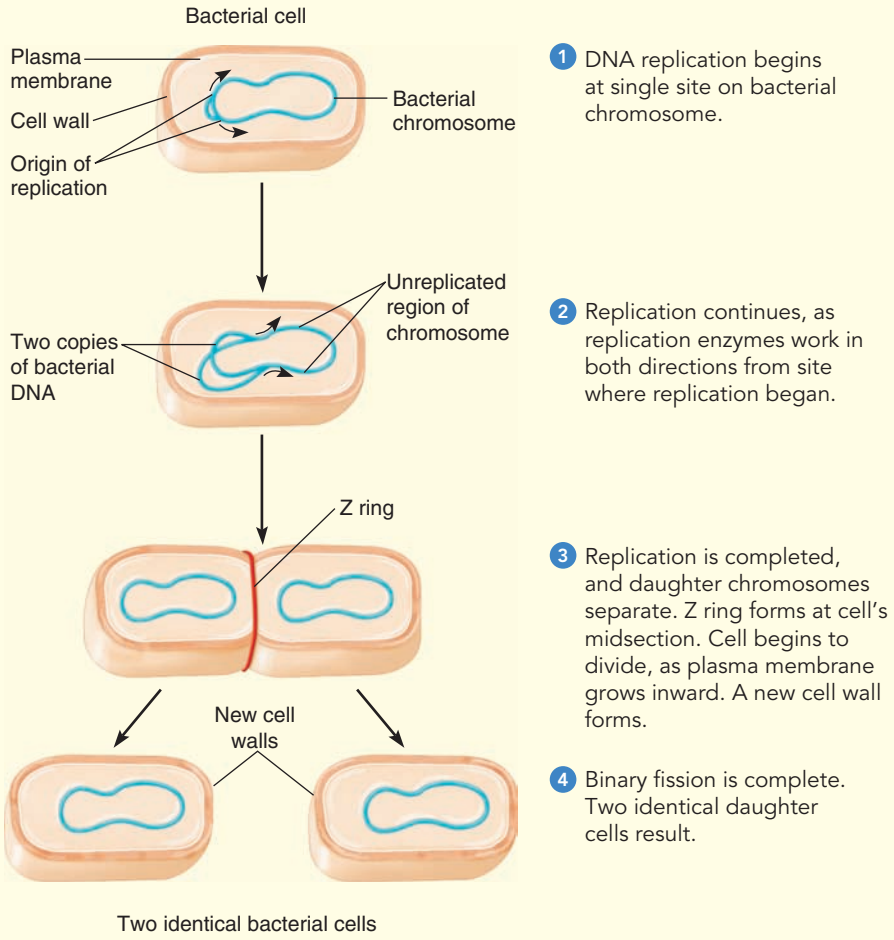

FIGURE 10-12 Binary fission

The bacterial chromosome is much longer than depicted here and is tethered to the plasma membrane at one spot (not shown).

nucleus, these regulatory molecules are components of the *cell cycle control system* found in organisms as diverse as yeast, clams, frogs, humans, and plants. Regulatory molecules trigger a specific sequence of events during the cell cycle.

Because the cell cycle consists of hundreds of sequential events that proceed in an orderly manner, a failure to carefully control these events can have disastrous consequences. Control mechanisms in the genetic program, called **cell-cycle checkpoints,** temporarily block key events from being initiated during the cell cycle. Cell-cycle checkpoints ensure that all the events of a particular stage have been completed before the next stage begins (**FIG. 10-13**). The checkpoints are inactivated after they have done their job so the cell cycle can proceed.

Genes that encode molecules involved in checkpoints are critically important to the cell cycle. If a checkpoint gene is defective, it can result in cancer or other serious diseases. Consider what might happen if the metaphase-anaphase checkpoint molecules were nonfunctional. In this case, anaphase might be initiated too early, before all chromosomes were properly attached to spindle fibers. The resulting daughter cells might have too few or too many chromosomes. An abnormal number of chromosomes is associated with Down syndrome as well as many cancers.

FIGURE 10-14 shows some of the key molecules involved in regulating the cell cycle. Among them are **protein kinases,** enzymes that activate or inactivate other proteins by *phosphorylating* (adding phosphate groups to) them. The protein kinases involved in controlling the cell cycle are **cyclin-dependent kinases (Cdks).** The activity of various Cdks increases and then decreases as the cell moves through the cell cycle. Cdks are active only when they bind tightly to regulatory proteins called **cyclins.** The cyclins are so named because their levels fluctuate predictably during the cell cycle (that is, they "cycle," or are alternately synthesized and degraded as part of the cell cycle).

Three scientists who began their research in the 1970s and 1980s on the roles of protein kinases and cyclins in the cell cycle (Leland Hartwell from the United States, and Paul Nurse and Tim Hunt from Great Britain) were awarded the Nobel Prize in Physiology or Medicine in 2001. Their discoveries were cited as important not only in working out the details of the fundamental cell process of mitosis but also in understanding why cancer cells divide when they should not. For example, cyclin levels are often higher than normal in human cancer cells.

When a specific Cdk associates with a specific cyclin, it forms a **cyclin–Cdk complex.** Cyclin–Cdk complexes phosphorylate enzymes and other proteins. Some of these proteins become activated when they are phosphorylated, and others become inactivated. For example, phosphorylation of the protein **p27,** known to be a major inhibitor of cell division, is thought to initiate degradation of the protein. As various enzymes are activated or inactivated by phosphorylation, the activities of the cell change. Thus, a decrease in a cell's level of p27 causes a nondividing cell to resume division.

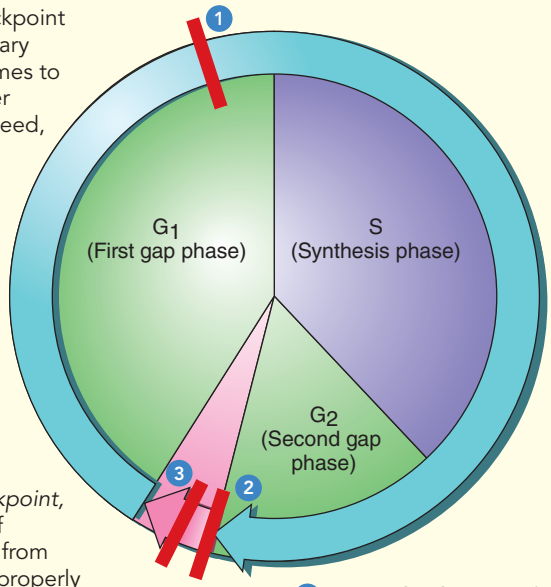
Eukaryotic cells form four major cyclin–Cdk complexes: G_1-Cdk, G_1/S-Cdk, S-Cdk, and M-Cdk. Each cyclin–Cdk complex phosphorylates a different group of proteins. G_1-Cdk prepares the cell to pass from the G_1 phase to the S phase, and then G_1/S-Cdk commits the cell to undergo DNA replication. S-Cdk initiates DNA replication. M-Cdk promotes the events of mitosis, including chromosome condensation, nuclear envelope breakdown, and mitotic spindle formation.

M-Cdk also activates another enzyme complex, the **anaphase-promoting complex (APC),** toward the end of metaphase. APC initiates anaphase by allowing degradation of the cohesins and

www.konkur.in

KEY POINT When a cell has not completed the steps leading to a cell-cycle checkpoint, the checkpoint is active and halts the cell cycle. When the necessary steps are completed, the checkpoint is inactivated, and the cell cycle proceeds.

1 **G_1-S checkpoint:** The first key checkpoint ensures that the cell has the necessary growth factors, nutrients, and enzymes to synthesize DNA. Without the proper signals that the cell is ready to proceed, the checkpoint will not let DNA synthesis begin.



3 **Metaphase-anaphase checkpoint:** Sometimes called the *spindle checkpoint*, this checkpoint occurs at the end of metaphase and prevents anaphase from occurring until all kinetochores are properly attached to spindle fibers along the cell's midplane.

2 **G_2-M checkpoint:** This cell-cycle checkpoint ensures that DNA replication is finished before the cell begins mitosis. If a cell has damaged or unreplicated DNA, the checkpoint will not let the cell undergo mitosis.

FIGURE 10-13 Key checkpoints in the cell cycle

The cell cycle consists of hundreds of sequential events. The red bars show three important checkpoints that determine that previous steps are completed so that the next steps may proceed. Each checkpoint is inactivated after it has performed its function, allowing the cell cycle to continue.

other proteins that hold the sister chromatids together during metaphase. As a result, the sister chromatids separate as two daughter chromosomes. At this point, cyclin is degraded to negligible levels and M-Cdk activity drops, allowing the mitotic spindle to disassemble and the cell to exit mitosis.

Certain drugs can stop the cell cycle at a specific checkpoint. Some of these prevent DNA synthesis, whereas others inhibit the synthesis of proteins that control the cycle or inhibit the synthesis of structural proteins that contribute to the mitotic spindle. Because one of the distinguishing features of most cancer cells is their high rate of cell division relative to that of most normal somatic cells, cancer cells are greatly affected by these drugs. Many side effects of certain anticancer drugs (such as nausea and hair loss) are due to the drugs' effects on normal cells that divide rapidly in the digestive system and hair follicles.

In plant cells, certain hormones stimulate mitosis. These include the **cytokinins,** a group of plant hormones that promote mitosis both in normal growth and in wound healing (see Chapter 38). Similarly, animal hormones, such as certain steroids, stimulate growth and mitosis (see Chapter 49).

Protein **growth factors,** which are active at extremely low concentrations, stimulate mitosis in some animal cells. Of the approximately 50 protein growth factors known, some act only on specific types of cells, whereas others act on a broad range of cell types. For example, the effects of the growth factor *erythropoietin* are limited to cells that will develop into red blood cells, but *epidermal growth factor* stimulates many cell types to divide. Many types of cancer cells divide in the absence of growth factors.

Review

10.4 SEXUAL REPRODUCTION AND MEIOSIS

LEARNING OBJECTIVES

7 Differentiate between asexual and sexual reproduction.
8 Distinguish between haploid and diploid cells, and define *homologous chromosomes.*
9 Explain the significance of meiosis and describe the process.
10 Contrast mitosis and meiosis, emphasizing the different outcomes.

www.konkur.in

KEY POINT Cyclin-dependent kinases (Cdks) control the phosphorylation of other proteins, thereby regulating the transitions between phases of the cell cycle.

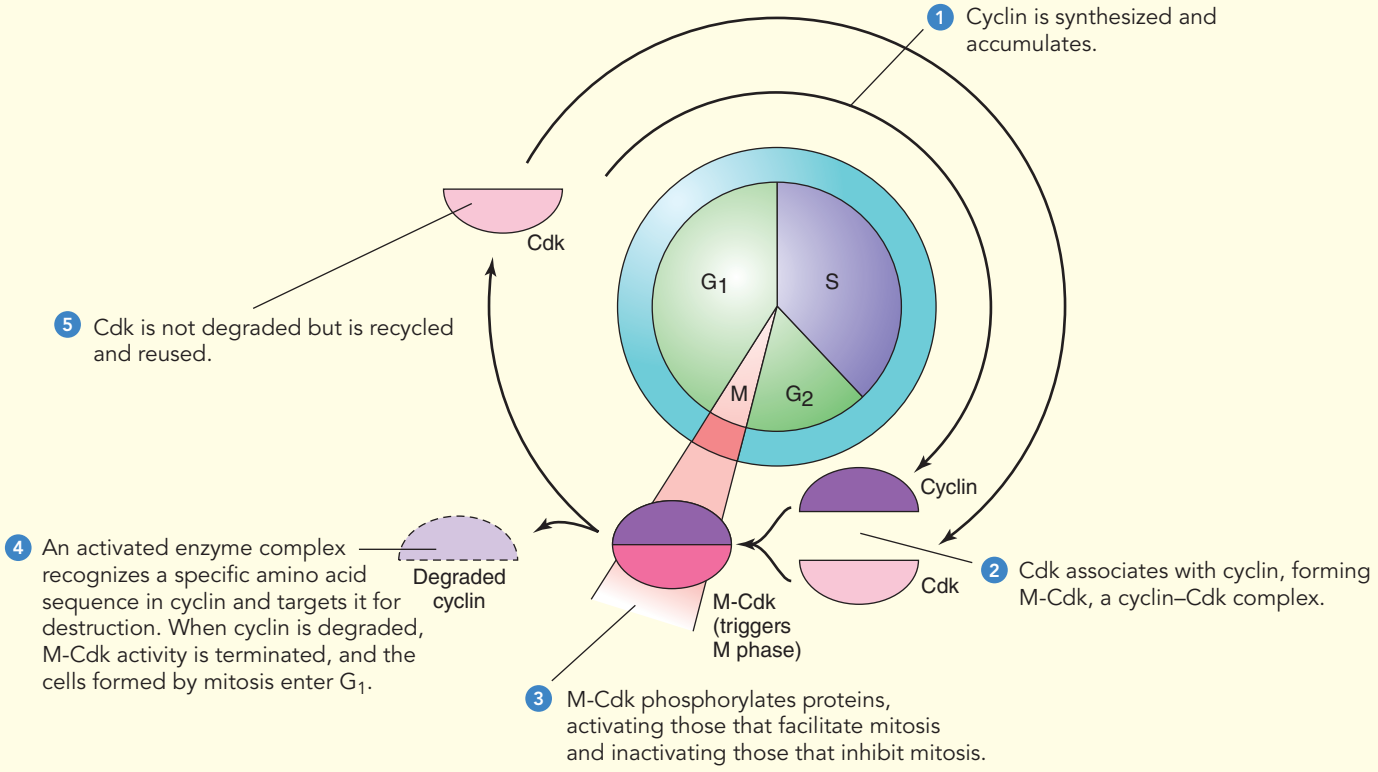

FIGURE 10-14 Molecular control of the cell cycle

This diagram is a simplified view of the control system that triggers the cell to move from G_2 to M phase.

Although the details of the reproductive process vary greatly among different kinds of eukaryotes, biologists distinguish two basic types of reproduction: asexual and sexual. In **asexual reproduction** a single parent splits, buds, or fragments to produce two or more individuals. In most kinds of eukaryotic asexual reproduction, all the cells are the result of mitotic divisions, so their genes and inherited traits are like those of the parent. Such a group of genetically identical organisms is called a **clone.** In asexual reproduction, organisms that are well adapted to their environment produce new generations of similarly adapted organisms. Asexual reproduction occurs rapidly and efficiently, partly because the organism does not need to expend time and energy finding a mate.

In contrast, **sexual reproduction** involves the union of two sex cells, or **gametes,** to form a single cell called a **zygote.** Usually two different parents contribute the gametes, but in some cases a single parent furnishes both gametes. In the case of animals and plants, the egg and sperm cells are the gametes, and the fertilized egg is the zygote.

Sexual reproduction results in genetic variation among the offspring. (*How* this genetic variation arises is discussed later in this chapter and in Chapter 11.) Because the offspring produced by sexual reproduction are not genetically identical to their parents or to each other, some offspring may be able to survive environmental changes better than either parent does. However, one disadvantage of sexual reproduction is that some offspring with a different combination of traits may be less likely to survive than their parents.

There is a potential problem in eukaryotic sexual reproduction: if each gamete had the same number of chromosomes as the parent cell that produced it, then the zygote would have twice as many chromosomes. This doubling would occur generation after generation. How do organisms avoid producing zygotes with ever-increasing chromosome numbers? To answer this question, we need more information about the types of chromosomes found in cells.

Each chromosome in a somatic cell of a plant or animal normally has a partner chromosome. The two partners, known as **homologous chromosomes,** are similar in size, shape, and the position of their centromeres. Furthermore, special chromosome-staining procedures produce a characteristic pattern of bands evident in the members of each chromosome pair. In most species, chromosomes vary enough in their structure that cell biologists can distinguish the different chromosomes and match up the homologous pairs. The 46 chromosomes in human cells constitute 23 homologous pairs.

The most important feature of homologous chromosomes is that they carry information about the same genetic traits, although this information is not necessarily identical. For example, each member of a homologous pair may carry a gene that specifies he-

www.konkur.in

moglobin structure. But one member may have the information for the normal hemoglobin β chain (see Fig. 3-22a), whereas the other may specify the abnormal form of hemoglobin associated with sickle cell anemia (see Chapter 16). Homologous chromosomes can therefore be contrasted with the two members of a pair of sister chromatids, which are precisely identical to each other.

A set of chromosomes has one of each kind of chromosome; in other words, it contains one member of each homologous pair. If a cell or nucleus contains two sets of chromosomes, it is said to have a **diploid** chromosome number. If it has only a single set of chromosomes, it has the **haploid** number.

In humans, the diploid chromosome number is 46 and the haploid number is 23. When a sperm and egg fuse at fertilization, each gamete is haploid, contributing one set of chromosomes; the diploid number is thereby restored in the fertilized egg (zygote). When the zygote divides by mitosis to form the first two cells of the embryo, each daughter cell receives the diploid number of chromosomes, and subsequent mitotic divisions repeat this. Thus, somatic cells are diploid.

An individual whose cells have three or more sets of chromosomes is **polyploid.** Polyploidy is relatively rare among animals but common among plants (see Chapter 20). In fact, polyploidy has been an important mechanism of plant evolution. As many as 80% of all flowering plants are polyploid. Polyploid plants are often larger and hardier than diploid members of the same group. Many commercially important plants, such as wheat and cotton, are polyploid.

The chromosome number found in the gametes of a particular species is represented as *n,* and the zygotic chromosome number is represented as 2*n*. If the organism is not polyploid, the haploid chromosome number is equal to *n,* and the diploid number is equal to 2*n;* thus, in humans, $n = 23$ and $2n = 46$. For simplicity, in the rest of this chapter, the organisms used as examples are not polyploid. We use diploid and 2*n* interchangeably, and haploid and *n* interchangeably, although the terms are not strictly synonymous.

Meiosis produces haploid cells with unique gene combinations

A cell division that reduces chromosome number is called **meiosis.** The term *meiosis* means "to make smaller," and the chromosome number is reduced by one-half. In meiosis a diploid cell undergoes two cell divisions, potentially yielding four haploid cells. It is important to note that haploid cells do not contain just any combination of chromosomes, but one member of each homologous pair.

The events of meiosis are similar to the events of mitosis, with four important differences:

1. Meiosis involves two successive nuclear and cytoplasmic divisions, producing up to four cells.
2. Despite two successive nuclear divisions, the DNA and other chromosome components duplicate only once—during the interphase preceding the first meiotic division.
3. Each of the four cells produced by meiosis contains the haploid chromosome number, that is, only one chromosome set containing only one representative of each homologous pair.
4. During meiosis, each homologous chromosome pair is shuffled, so the resulting haploid cells each have a virtually unique combination of genes.

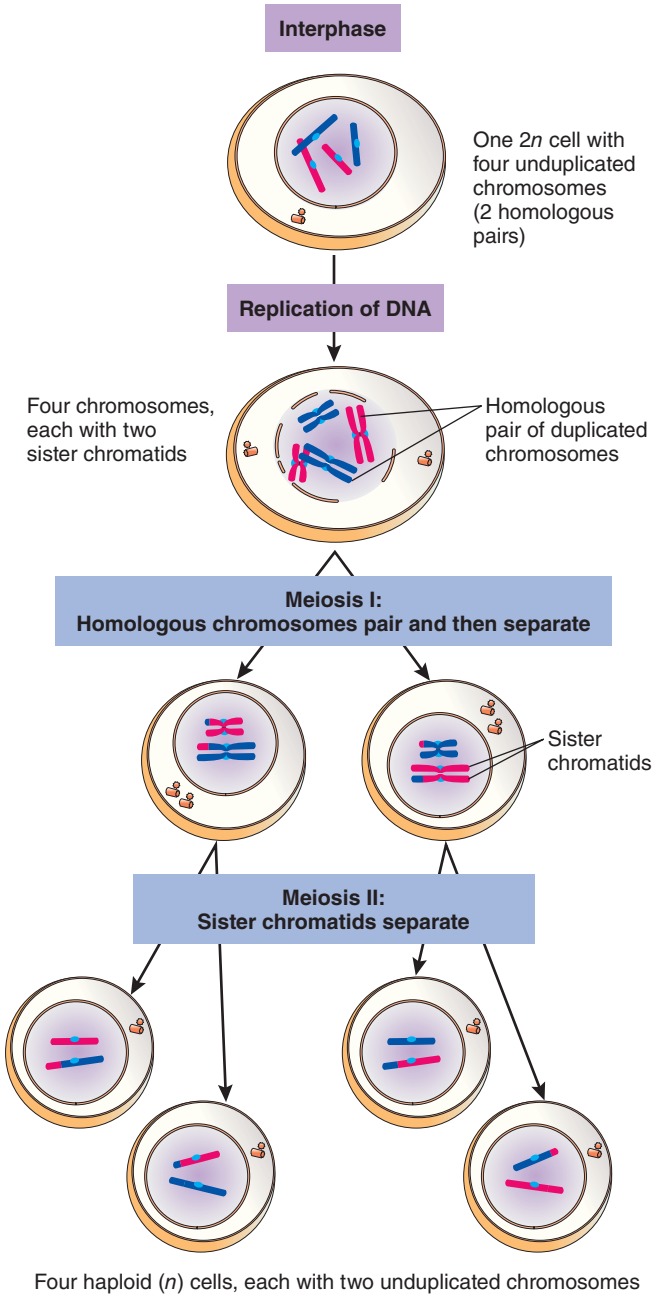

FIGURE 10-15 Overview of meiosis

This figure begins with a diploid cell with four unduplicated chromosomes. The chromosomes derived from one parent are shown in blue, and those from the other parent are red. Homologous pairs are similar in size and shape.

Meiosis typically consists of two nuclear and cytoplasmic divisions, designated the *first* and *second meiotic divisions,* or simply **meiosis I** and **meiosis II** (**FIG. 10-15**). Each includes prophase, metaphase, anaphase, and telophase stages. During meiosis I, the partner homologous chromosomes pair and then separate and move into different nuclei. In meiosis II, the sister chromatids that make up each duplicated chromosome separate from each other and are distributed to two different nuclei. The following discussion describes meiosis in an organism with a diploid chromosome number of 4. Refer to **FIGURE 10-16** as you read.

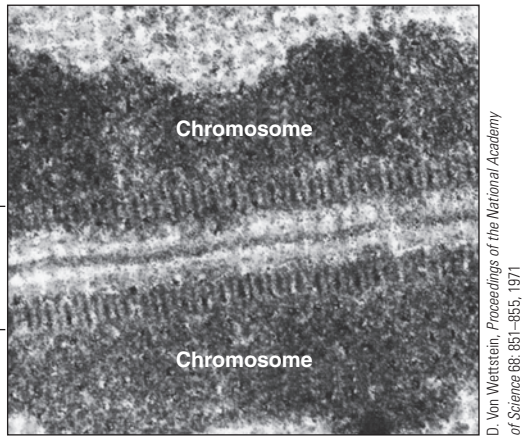
(a) A 3-D model of a tetrad with a complete synaptonemal complex.



(b) TEM of a synaptonemal complex.

FIGURE 10-17 **A synaptonemal complex**

Synapsing homologous chromosomes in meiotic prophase I are held together by a synaptonemal complex, composed mainly of protein.

Prophase I includes synapsis and crossing-over

As occurs during mitosis, the chromosomes duplicate in the S phase of interphase, before the complex movements of meiosis actually begin. Each duplicated chromosome consists of two chromatids, which are linked by cohesins. During **prophase I,** while the chromatids are still elongated and thin, the homologous chromosomes come to lie lengthwise side by side. This process is called **synapsis,** which means "fastening together." For example, in an animal cell with a diploid number of four, synapsis results in two homologous pairs.

One member of each homologous pair is called the **maternal homologue** because it was originally inherited from the female parent; the other member of a homologous pair is the **paternal homologue** because it was inherited from the male parent. Because each chromosome duplicated during interphase and now consists of two chromatids, synapsis results in the association of four chromatids. The resulting association is a **tetrad.** The number of tetrads per prophase I cell is equal to the haploid chromosome number. In an animal cell with a diploid number of 4, there are 2 tetrads (and a total of 8 chromatids); in a human cell at prophase I, there are 23 tetrads (and a total of 92 chromatids).

Homologous chromosomes become closely associated during synapsis. Electron microscopic observations reveal that a characteristic structure, the **synaptonemal complex,** forms along the entire length of the synapsed homologues (**FIG. 10-17**). This proteinaceous structure holds the synapsed homologues together and is thought to play a role in chromosome **crossing-over,** a process in which enzymes break and rejoin DNA molecules, allowing paired homologous chromosomes to exchange genetic material. Crossing-over produces new combinations of genes. The **genetic recombination** from crossing-over greatly enhances the genetic variation—that is, new combinations of traits—among sexually produced offspring. Some biologists think that recombination is the main reason for sexual reproduction in eukaryotes.

In addition to the unique processes of synapsis and crossing-over, events similar to those in mitotic prophase also occur during prophase I. A spindle forms, consisting of microtubules and other components. In animal cells, one pair of centrioles moves to each pole, and astral microtubules form. The nuclear envelope disappears in late prophase I, and in cells with large and distinct chromosomes, the structure of the tetrads can be seen clearly with the microscope.

The sister chromatids remain closely aligned along their lengths. However, the centromeres (and kinetochores) of the homologous chromosomes become separated from one another. In late prophase I, the homologous chromosomes are held together only at specific regions, termed **chiasmata** (sing., *chiasma*). Each chiasma originates at a crossing-over site, that is, a site at which homologous chromatids exchanged genetic material and rejoined, producing an X-shaped configuration (**FIG. 10-18**). At the chiasmata, cohesins hold homologous chromosomes together after the synaptonemal complex has been disassembled. Later, the cohesins dissociate from the chiasmata, freeing the homologous chromo-

The two chiasmata are the result of separate crossing-over events.

some arms from one another. The consequences of crossing-over and genetic recombination are discussed in Chapter 11 (for example, see Fig. 11-12).

During meiosis I, homologous chromosomes separate

Metaphase I occurs when the tetrads align on the midplane. Both sister kinetochores of one duplicated chromosome are attached by spindle fibers to the same pole, and both sister kinetochores of the other duplicated homologous chromosome are attached to the opposite pole. (By contrast, sister kinetochores of each duplicated chromosome are attached to opposite poles in mitosis.)

During **anaphase I,** the paired homologous chromosomes separate, or disjoin, and move toward opposite poles. Each pole receives a random combination of maternal and paternal chromosomes, but only one member of each homologous pair is present at each pole. The sister chromatids remain united at their centromere regions. Again, this differs from mitotic anaphase, in which the sister chromatids separate and move to opposite poles.

During **telophase I,** the chromatids generally decondense somewhat, the nuclear envelope may reorganize, and cytokinesis may take place. Each telophase I nucleus contains the haploid number of chromosomes, but each chromosome is a duplicated chromosome (it consists of a pair of chromatids). In our example, 2 duplicated chromosomes lie at each pole, for a total of 4 chromatids; humans have 23 duplicated chromosomes (46 chromatids) at each pole.

An interphase-like stage called **interkinesis** usually follows. Interkinesis is not a true interphase: there is no S phase and therefore no DNA replication. Interkinesis is brief in most organisms and absent in some.

Chromatids separate in meiosis II

Because the chromosomes usually remain partially condensed between divisions, the prophase of the second meiotic division is brief.

Prophase II is similar to mitotic prophase in many respects. There is no pairing of homologous chromosomes (indeed, only one member of each pair is present in each nucleus) and no crossing-over.

During **metaphase II** the chromosomes line up on the midplanes of their cells. You can easily distinguish the first and second metaphases in diagrams; at metaphase I the chromatids are arranged in bundles of four (tetrads), and at metaphase II they are in groups of two (as in mitotic metaphase). This is not always so obvious in living cells.

During **anaphase II** the chromatids, attached to spindle fibers at their kinetochores, separate and move to opposite poles, just as they would at mitotic anaphase. As in mitosis, each former chromatid is now referred to as a *chromosome.* Thus, at **telophase II** there is one representative for each homologous pair at each pole. Each is an unduplicated (single) chromosome. Nuclear envelopes re-form, the chromosomes gradually elongate to form chromatin fibers, and cytokinesis occurs.

The two successive divisions of meiosis yield four haploid nuclei, each containing *one* of each kind of chromosome. Each resulting haploid cell has a different combination of genes. This genetic variation has two sources: (1) DNA segments are exchanged between maternal and paternal homologues during crossing-over. (2) During meiosis, the maternal and paternal chromosomes of homologous pairs separate independently. The chromosomes are "shuffled" so that each member of a pair becomes randomly distributed to one of the poles at anaphase I.

Mitosis and meiosis lead to contrasting outcomes

Although mitosis and meiosis share many similar features, specific distinctions between these processes result in the formation of different types of cells. Mitosis is a single nuclear division in which sister chromatids separate from each other and are distributed to the two daughter cells, which are genetically identical to each other and to the original cell. A diploid cell that undergoes mitosis produces two diploid cells. Similarly, a haploid cell that

www.konkur.in

KEY POINT Each species has a characteristic number of chromosomes that does not change. In each life cycle, the doubling of chromosomes that occurs during fertilization is compensated for by the reduction in chromosome number that occurs during meiosis.

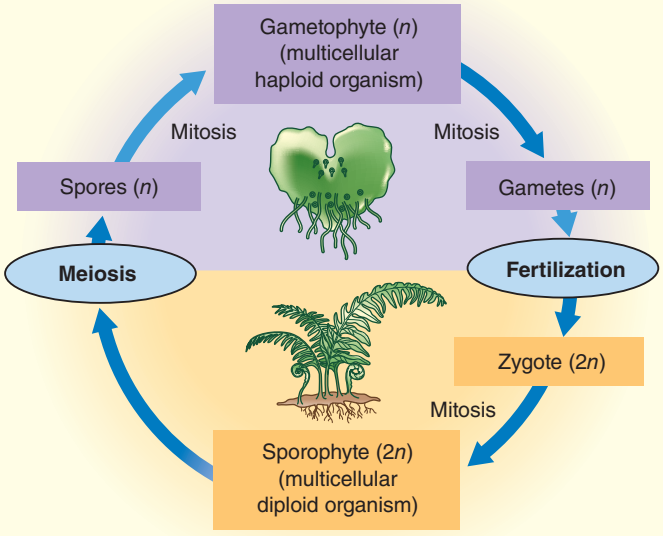
(b) Most fungi and many protists



(c) Plants, some algae, and some fungi

FIGURE 10-19 Representative life cycles

The color code and design here is used throughout the rest of the book. For example, in all life cycles the haploid (*n*) generation is shown in purple, and the diploid (2*n*) generation is gold. The processes of meiosis and fertilization always link the haploid and diploid generations.

www.konkur.in

undergoes mitosis produces two haploid cells. (Some eukaryotic organisms—certain yeasts, for example—are haploid, as are plants at certain stages of their life cycles.) Homologous chromosomes do not associate physically at any time in mitosis.

In meiosis, a diploid cell undergoes two successive nuclear divisions, meiosis I and meiosis II. In prophase I of meiosis, the homologous chromosomes undergo synapsis to form tetrads. Homologous chromosomes separate during meiosis I, and sister chromatids separate during meiosis II. Meiosis ends with the formation of four genetically different, haploid daughter cells. The fates of these cells depend on the type of life cycle; in animals they differentiate as gametes, whereas in plants they become spores.

Review

- Are homologous chromosome pairs present in a diploid cell? Are they present in a haploid cell?
- How does the outcome of meiosis differ from the outcome of mitosis?
- Can haploid cells divide by mitosis? by meiosis?

10.5 SEXUAL LIFE CYCLES

LEARNING OBJECTIVE

11 Compare the roles of mitosis and meiosis in various generalized life cycles.

Because sexual reproduction is characterized by the fusion of two haploid sex cells to form a diploid zygote, it follows that in a sexual life cycle, meiosis must occur before gametes can form. The timing of meiosis in the life cycle varies among species.

In animals and a few other organisms, meiosis leads directly to gamete production (**FIG. 10-19a** on facing page). An organism's somatic cells multiply by mitosis and are diploid; the only haploid cells produced are the gametes. Gametes develop when **germ line cells,** which give rise to the next generation, undergo meiosis.

The formation of gametes is known as **gametogenesis.** Male gametogenesis, termed **spermatogenesis,** forms four haploid sperm cells for each cell that enters meiosis. (See Chapter 50 and Fig. 50-5 for a detailed description of spermatogenesis.)

In contrast, female gametogenesis, called **oogenesis,** forms a single egg cell, or *ovum,* for every cell that enters meiosis. In this process, most of the cytoplasm goes to only one of the two cells produced during each meiotic division. At the end of meiosis I, one nucleus is retained and the other, called the first *polar body,* often degenerates. Similarly, at the end of meiosis II, one nucleus becomes another polar body and the other nucleus survives. In this way, one haploid nucleus receives most of the accumulated cytoplasm and nutrients from the original meiotic cell. (See Chapter 50 and Fig. 50-11 for a detailed description of oogenesis.)

Although meiosis occurs at some point in a sexual life cycle, it does not always *immediately* precede gamete formation. Many eukaryotes, including most fungi and many protists, remain haploid (their cells dividing mitotically) throughout most of their life cycles, with individuals being unicellular or multicellular. Two haploid gametes (produced by mitosis) fuse to form a diploid zygote that undergoes meiosis to restore the haploid state (**FIG. 10-19b**). Examples of these types of life cycles are found in Figures 26-16 and 29-9.

Plants and some algae and fungi have complicated life cycles (**FIG. 10-19c**). These life cycles, characterized by an **alternation of generations,** consist of a multicellular diploid stage, the **sporophyte generation,** and a multicellular haploid stage, the **gametophyte generation.** Sporophyte cells undergo meiosis to form haploid spores, each of which may divide mitotically to produce a multicellular haploid gametophyte. Gametophytes produce gametes by mitosis. The female and male gametes (egg and sperm cells) fuse to form a diploid zygote that divides mitotically to form a multicellular sporophyte. You can find more detailed descriptions of alternation of generations in plants in Chapters 27 and 28.

Review

- In animals, which cells are produced by mitosis? by meiosis?
- Assuming a sexually reproducing organism is haploid, how do meiosis and fertilization maintain the normal chromosome number?

SUMMARY: FOCUS ON LEARNING OBJECTIVES

10.1 *(page 214)*

1 Discuss the significance of chromosomes in terms of their information content.

- Genes, the cell's informational units, are made of DNA. In eukaryotes, DNA associates with protein to form the **chromatin** fibers that make up **chromosomes.**

2 Explain how DNA is packed into chromosomes in eukaryotic cells.

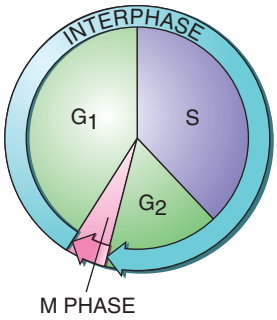
- The organization of eukaryotic DNA into chromosomes allows the DNA to be accurately replicated and sorted into daughter cells without tangling. In eukaryotic cells DNA is associated with **histones** (basic proteins) to form **nucleosomes,** each of which consists of a histone bead with DNA wrapped around it. Nucleosomes are organized into large, coiled loops held together by nonhistone **scaffolding proteins.**

www.konkur.in

10.2 *(page 217)*

3 Identify the stages in the eukaryotic cell cycle and describe their principal events.

- The eukaryotic **cell cycle** is the period from the beginning of one division to the beginning of the next. The cell cycle consists of interphase and M phase.



- **Interphase** consists of the first gap phase (G_1), the synthesis phase (S), and the second gap phase (G_2). During the **G_1 phase,** the cell grows and prepares for the S phase. During the **S phase,** DNA and the chromosome proteins are synthesized, and chromosome duplication occurs. During the **G_2 phase,** protein synthesis increases in preparation for cell division.
- **M phase** consists of **mitosis,** the nuclear division that produces two nuclei identical to the parental nucleus, and **cytokinesis,** the division of the cytoplasm to yield two daughter cells.

CENGAGENOW™ Learn more about the cell cycle by clicking on the figure in CengageNOW.

4 Describe the structure of a duplicated chromosome, including the sister chromatids, centromeres, and kinetochores.

- A duplicated chromosome consists of a pair of **sister chromatids,** which contain identical DNA sequences. Each chromatid includes a constricted region called a **centromere.** Sister chromatids are tightly associated in the region of their centromeres. Attached to each centromere is a **kinetochore,** a protein structure to which microtubules can bind.

5 Explain the significance of mitosis and describe the process.

- Mitosis assures that the chromosome number is preserved when one eukaryotic cell divides to form two. In mitosis, identical chromosomes are distributed to each pole of the cell, and a nuclear envelope forms around each set.
- During **prophase,** the structure of the duplicated chromosomes becomes apparent as the chromatin condenses; each is composed of a pair of identical sister chromatids. The nuclear envelope begins to disassemble, and the **mitotic spindle** begins to form.
- During **prometaphase,** spindle microtubules attach to kinetochores of chromosomes, and chromosomes begin to move toward the cell's midplane.
- During **metaphase,** the chromosomes are aligned on the cell's midplane, or **metaphase plate;** the mitotic spindle is complete, and the kinetochores of the sister chromatids are attached by microtubules to opposite poles of the cell.
- During **anaphase,** the sister chromatids separate and move to opposite poles. Each former chromatid is now a chromosome.
- During **telophase,** a nuclear envelope re-forms around each set of chromosomes, nucleoli become apparent, the chromosomes uncoil, and the spindle disappears. Cytokinesis generally begins in telophase.

CENGAGENOW™ Walk step-by-step through the stages of mitosis by clicking on the figure in CengageNOW.

CENGAGENOW™ Watch cytokinesis unfold by clicking on the figure in CengageNOW.

10.3 *(page 223)*

6 Explain some ways in which the cell cycle is controlled.

- Control mechanisms, called **cell-cycle checkpoints,** temporarily block key events from being initiated during the cell cycle. **Cyclin-dependent kinases (Cdks)** are **protein kinases** involved in regulating the cell cycle. Cdks are active only when they bind tightly to regulatory proteins called **cyclins.** Cyclin levels fluctuate predictably during the cell cycle.

10.4 *(page 225)*

7 Differentiate between asexual and sexual reproduction.

- Offspring produced by **asexual reproduction** usually have hereditary traits identical to those of the single parent. Mitosis is the basis for asexual reproduction in eukaryotic organisms.
- In **sexual reproduction,** two haploid sex cells, or **gametes,** fuse to form a single diploid **zygote.** In a sexual life cycle, meiosis must occur before gametes can be produced.

8 Distinguish between haploid and diploid cells, and define *homologous chromosomes.*

- A **diploid** cell has a characteristic number of chromosome pairs per cell. The members of each pair, called **homologous chromosomes,** are similar in length, shape, and other features and carry genes affecting the same kinds of attributes of the organism.
- A **haploid** cell contains only one member of each homologous chromosome pair.

9 Explain the significance of meiosis and describe the process.

- A diploid cell undergoing **meiosis** completes two successive cell divisions, yielding four haploid cells. Sexual life cycles in eukaryotes require meiosis, which makes it possible for each gamete to contain only half the number of chromosomes in the parent cell.
- **Meiosis I** begins with **prophase I,** in which the members of a homologous pair of chromosomes physically join by the process of **synapsis. Crossing-over** is a process of **genetic recombination** during which homologous (nonsister) chromatids exchange segments of DNA strands.
- At **metaphase I, tetrads**—each consisting of a pair of homologous chromosomes held together by one or more **chiasmata**—line up on the metaphase plate. The members of each pair of homologous chromosomes separate during meiotic **anaphase I** and are distributed to different nuclei. Each nucleus contains the haploid number of chromosomes; each chromosome consists of two chromatids.
- During **meiosis II,** the two chromatids of each chromosome separate, and one is distributed to each daughter cell. Each former chromatid is now a chromosome.

CENGAGENOW™ Walk step-by-step through the stages of meiosis by clicking on the figure in CengageNOW.

10 Contrast mitosis and meiosis, emphasizing the different outcomes.

- Mitosis involves a single nuclear division in which the two daughter cells formed are genetically identical to each other and to the original cell. Synapsis of homologous chromosomes does not occur during mitosis.
- Meiosis involves two successive nuclear divisions and forms four haploid cells. Synapsis of homologous chromosomes occurs during prophase I of meiosis.

CENGAGENOW™ Watch a movie that features living cells undergoing mitosis and meiosis in CengageNOW.

www.konkur.in

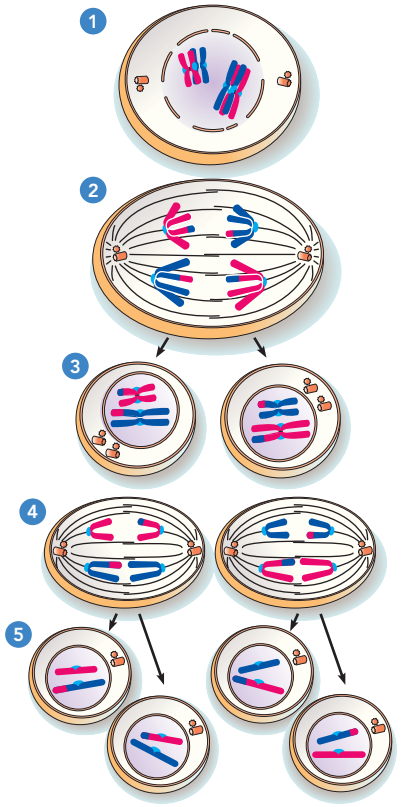
10.5 *(page 233)*

11 Compare the roles of mitosis and meiosis in various generalized life cycles.

- Somatic cells of animals are diploid and are produced by mitosis. The only haploid cells are gametes, produced by **gametogenesis,** which in animals occurs by meiosis.
- Most fungi and many protists are haploid and are produced by mitosis. The only diploid stage is the zygote, which undergoes meiosis to restore the haploid state.
- The life cycle of plants, some algae, and some fungi includes an **alternation of generations.** The multicellular diploid **sporophyte generation** forms haploid spores by meiosis. Each spore divides mitotically to form a multicellular haploid **gametophyte generation,** which produces gametes by mitosis. Two haploid gametes then fuse to form a diploid zygote, which divides mitotically to produce a new sporophyte generation.

TEST YOUR UNDERSTANDING

1. Chromatin fibers include (a) DNA and structural polysaccharides (b) RNA and phospholipids (c) protein and carbohydrate (d) DNA and protein (e) triacylglycerol and steroids
2. A nucleosome consists of (a) DNA and scaffolding proteins (b) scaffolding proteins and histones (c) DNA and histones (d) DNA, histones, and scaffolding proteins (e) histones only
3. The term *S phase* refers to (a) DNA synthesis during interphase (b) synthesis of chromosome proteins during prophase (c) gametogenesis in animal cells (d) synapsis of homologous chromosomes (e) fusion of gametes in sexual reproduction
4. At which of the following stages do human skin cell nuclei have the same DNA content? (a) early mitotic prophase and late mitotic telophase (b) G_1 and G_2 (c) G_1 and early mitotic prophase (d) G_1 and late mitotic telophase (e) G_2 and late mitotic telophase
5. In a cell at _____, each chromosome consists of a pair of attached chromatids. (a) mitotic prophase (b) meiotic prophase II (c) meiotic prophase I (d) meiotic anaphase I (e) all of the preceding
6. The molecular tether that links sister chromatids of a duplicated chromosome to each other is (a) condensin (b) actin (c) myosin (d) cohesin (e) actomyosin
7. In an animal cell at mitotic metaphase, you would expect to find (a) two pairs of centrioles located on the metaphase plate (b) a pair of centrioles inside the nucleus (c) a pair of centrioles within each microtubule-organizing center (d) a centriole within each centromere (e) no centrioles
8. Cell plate formation usually begins during (a) telophase in a plant cell (b) telophase in an animal cell (c) G_2 in a plant cell (d) G_2 in an animal cell (e) a and b
9. A diploid nucleus at early mitotic prophase has _____ set(s) of chromosomes; a diploid nucleus at mitotic telophase has _____ set(s) of chromosomes. (a) 1; 1 (b) 1; 2 (c) 2; 2 (d) 2; 1 (e) not enough information has been given
10. You would expect to find a synaptonemal complex in a cell at (a) mitotic prophase (b) meiotic prophase I (c) meiotic prophase II (d) meiotic anaphase I (e) meiotic anaphase II
11. A chiasma links a pair of (a) homologous chromosomes at prophase II (b) homologous chromosomes at late prophase I (c) sister chromatids at metaphase II (d) sister chromatids at mitotic metaphase (e) sister chromatids at metaphase I
12. Match the following descriptions (a–e) to the steps of meiosis (1–5) in the following figure. (a) haploid cells with unduplicated chromosomes (b) haploid cells with duplicated chromosomes (c) synapsis of homologous chromosomes to form tetrads (d) sister chromatids move to opposite poles (e) homologous chromosomes move to opposite poles



www.konkur.in

CRITICAL THINKING

1. How can two species have the same chromosome number yet have very different attributes?
2. How does the DNA content of the cell change from the beginning of interphase to the end of interphase? Does the number of chromatids change? Explain. Does the number of chromosomes change? Explain.

In questions 3–4, decide whether each is an example of sexual or asexual reproduction, and state why.

3. A diploid queen honeybee produces haploid eggs by meiosis. Some of these eggs are never fertilized and develop into haploid male honeybees (drones).
4. Seeds develop after a flower has been pollinated with pollen from the same plant.
5. **ANALYZING DATA.** In the experiment with spindle microtubules during anaphase (see Fig. 10-10), how would the spindle microtubules have looked during anaphase if they had disassembled at their polar ends instead of their kinetochore ends?
6. **EVOLUTION LINK.** How does mitosis provide evidence for relationships among eukaryotes as diverse as mammals and seaweeds?
7. **EVOLUTION LINK.** Some organisms—for example, certain fungi—reproduce asexually when the environment is favorable and sexually when the environment becomes unfavorable. What might be the evolutionary advantage of sexual reproduction with the associated process of meiosis during unfavorable conditions?

11 The Basic Principles of Heredity

Gregor Mendel. This painting shows Mendel with his pea plants in the monastery garden at Brünn, Austria (now Brüno, Czech Republic).

© Science Source/Photo Researchers, Inc.

KEY CONCEPTS

11.1 The experiments of Gregor Mendel, a pioneer in the field of genetics, revealed the basic principles of inheritance. In Mendel's principle of segregation, members of a gene pair segregate (separate) from one another prior to gamete formation. In the principle of independent assortment, members of different gene pairs assort independently (randomly) into gametes.

11.2 You can use probability to predict Mendelian inheritance: the product rule shows how to combine the probabilities of independent events, and the sum rule shows how to combine the probabilities of mutually exclusive events.

11.3 Chromosome behavior during meiosis helps explain Mendel's principles of inheritance.

11.4 Distinctive inheritance patterns (that is, "extensions" to Mendel's principles) characterize some traits.

Human characters such as eye color and hair color, along with a multitude of other characteristics, are passed on from one generation to another. **Heredity,** the transmission of genetic information from parent to offspring, generally follows predictable patterns in organisms as diverse as humans, penguins, baker's yeast, and sunflowers. **Genetics,** the science of heredity, studies both genetic similarities and **genetic variation,** the differences between parents and offspring or among individuals of a population.

The study of inheritance as a modern branch of science began in the mid-19th century with the work of Gregor Mendel (1822–1884), a monk who bred pea plants (see picture). Mendel was the first scientist to effectively apply quantitative methods to the study of inheritance. He did not merely describe his observations; he planned his experiments carefully,

www.konkur.in

recorded the data, and analyzed the results mathematically. Although unappreciated during his lifetime, his work was rediscovered in 1900.

During the decades following the rediscovery of Mendel's findings, geneticists extended Mendel's principles by correlating the transmission of genetic information from generation to generation with the behavior of chromosomes during *meiosis*. By studying a variety of organisms, geneticists verified Mendel's findings and added a growing list of so-called exceptions to his principles.

Geneticists study not only the transmission of genes but also the expression of genetic information. As you will see in this chapter and those that follow, understanding the relationships between an organism's genes and its characteristics has become increasingly sophisticated as biologists have learned more about the orderly transmission of information in cells from one generation to another.

11.1 MENDEL'S PRINCIPLES OF INHERITANCE

LEARNING OBJECTIVES

1. Define the terms *phenotype, genotype, locus, allele, dominant allele, recessive allele, homozygous,* and *heterozygous.*
2. Describe Mendel's principles of segregation and independent assortment.
3. Distinguish among monohybrid, dihybrid, and test crosses.
4. Explain Mendel's principles of segregation and independent assortment, given what scientists now know about genes and chromosomes.

Gregor Mendel was not the first plant breeder. At the time he began his work, breeders had long recognized the existence of **hybrid** plants and animals, the offspring of two genetically dissimilar parents. When Mendel began his breeding experiments in 1856, two

RESEARCH METHOD

Why Is It Used?

Garden peas normally self-fertilize during reproduction, that is, the male and female gametes are from the same flower. Because pea petals completely enclose the reproductive parts, there is little chance of natural cross-pollination between separate flowers. Cross-pollination enables the researcher to study various patterns of inheritance in peas.

How Is It Done?

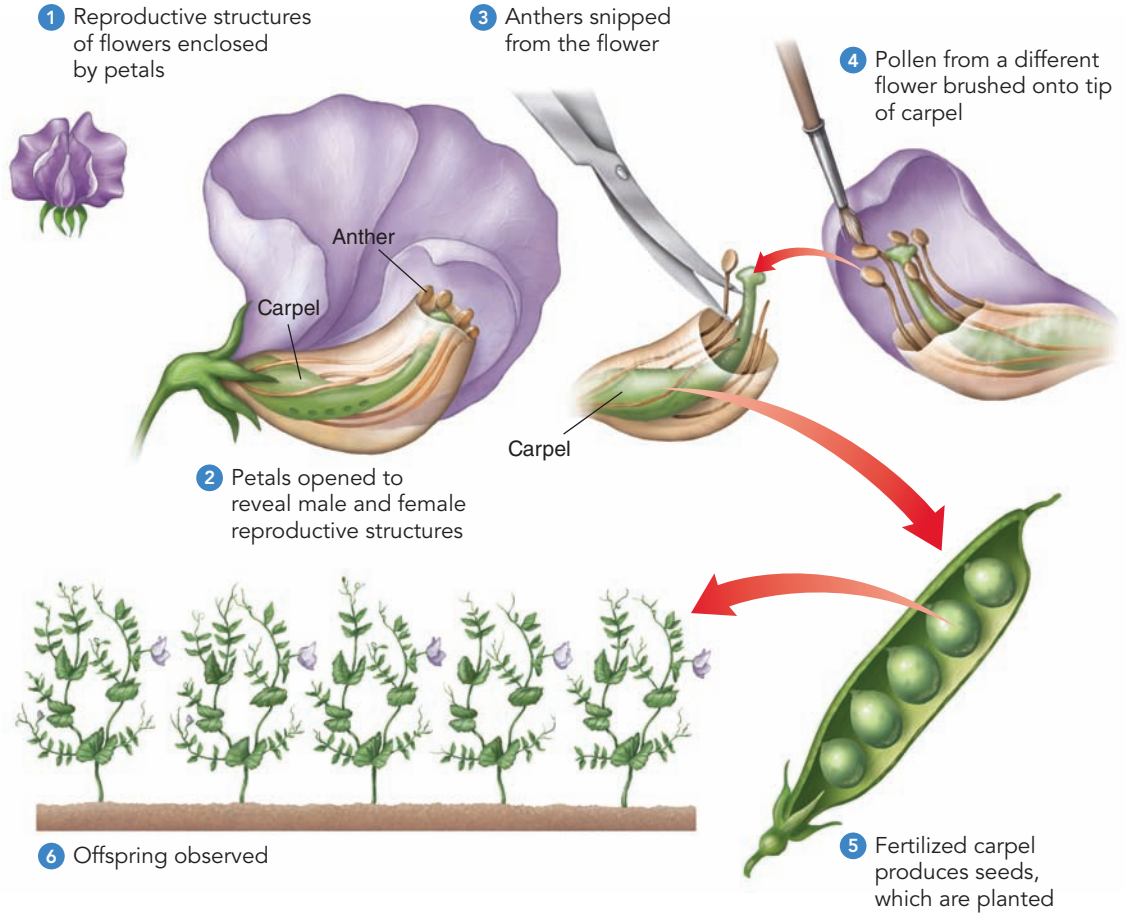

FIGURE 11-1 How garden peas are cross-pollinated

www.konkur.in

main concepts about inheritance were widely accepted: (1) All hybrid plants that are the offspring of genetically pure, or **true-breeding,** parents are similar in appearance. (2) When these hybrids mate with each other, they do not breed true; their offspring show a mixture of traits. Some look like their parents, and some have features like those of their grandparents.

Mendel's genius lay in his ability to recognize a pattern in the way the parental traits reappear in the offspring of hybrids. Before Mendel, no one had categorized and counted the offspring and analyzed these regular patterns over several generations to the extent he did. Just as geneticists do today, Mendel chose the organism for his experiments very carefully. The garden pea, *Pisum sativum,* had several advantages. Pea plants are easy to grow, and many varieties were commercially available. Another advantage of pea plants is that controlled pollinations are relatively easy to conduct. Pea flowers have both male and female parts and naturally self-pollinate. However, the anthers (the male parts of the flower that produce pollen) can be removed to prevent self-fertilization (**FIG. 11-1**). Pollen from a different source can then be applied to the stigma (the receptive surface of the carpel, or female part). Pea flowers are easily protected from other sources of pollen because the petals completely enclose the reproductive structures.

Mendel obtained his original pea seeds from commercial sources and did some important preliminary work before starting his actual experiments. For two years he verified that the varieties were true-breeding lines for various inherited features. Today, scientists use the term **phenotype** to refer to the physical appearance of an organism and **genotype** to refer to the genetic makeup for that organism, which is most often expressed in symbols. A true-breeding line produces only offspring expressing the same phenotype (for example, round seeds or tall plants) generation after generation. During this time Mendel apparently chose those traits of his pea strains that he could study most easily. He probably made the initial observations that later formed the basis of his hypotheses.

Mendel eventually chose strains representing seven **characters,** the attributes (such as seed color) for which heritable differences, or **traits,** are known (such as yellow seeds and green seeds). The characters Mendel selected had clearly contrasting phenotypes (**FIG. 11-2**). Mendel's results were easy to analyze because he chose easily distinguishable phenotypes and limited the genetic variation studied in each experiment.

Mendel began his experiments by crossing plants from two different true-breeding lines with contrasting phenotypes; these genetically pure individuals constituted the **parental generation,** or **P generation.** In every case, the members of the first generation of offspring all looked alike and resembled one of the two parents. For example, when he crossed tall plants with short plants, all the

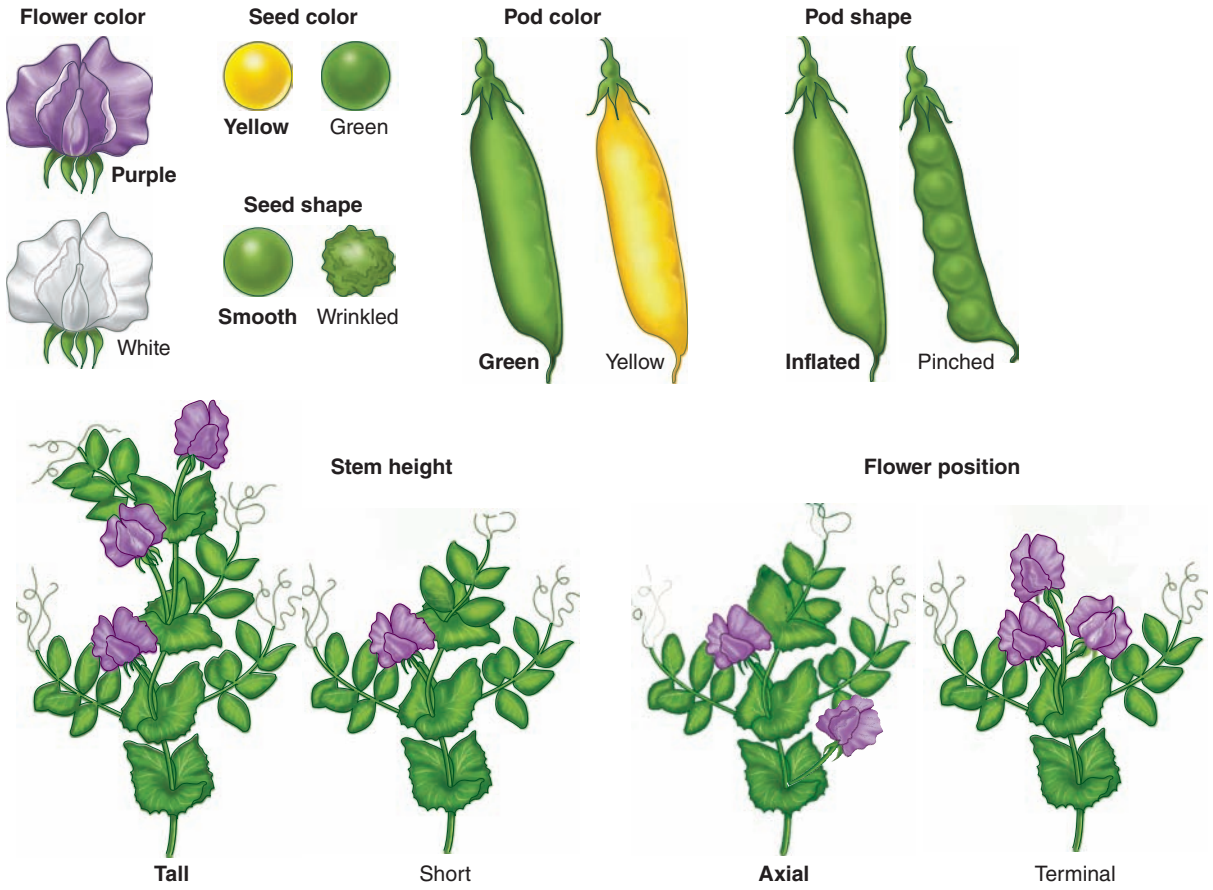

FIGURE 11-2 Seven characters in Mendel's study of pea plants
Each character had two clearly distinguishable phenotypes; the dominant phenotype is boldface.

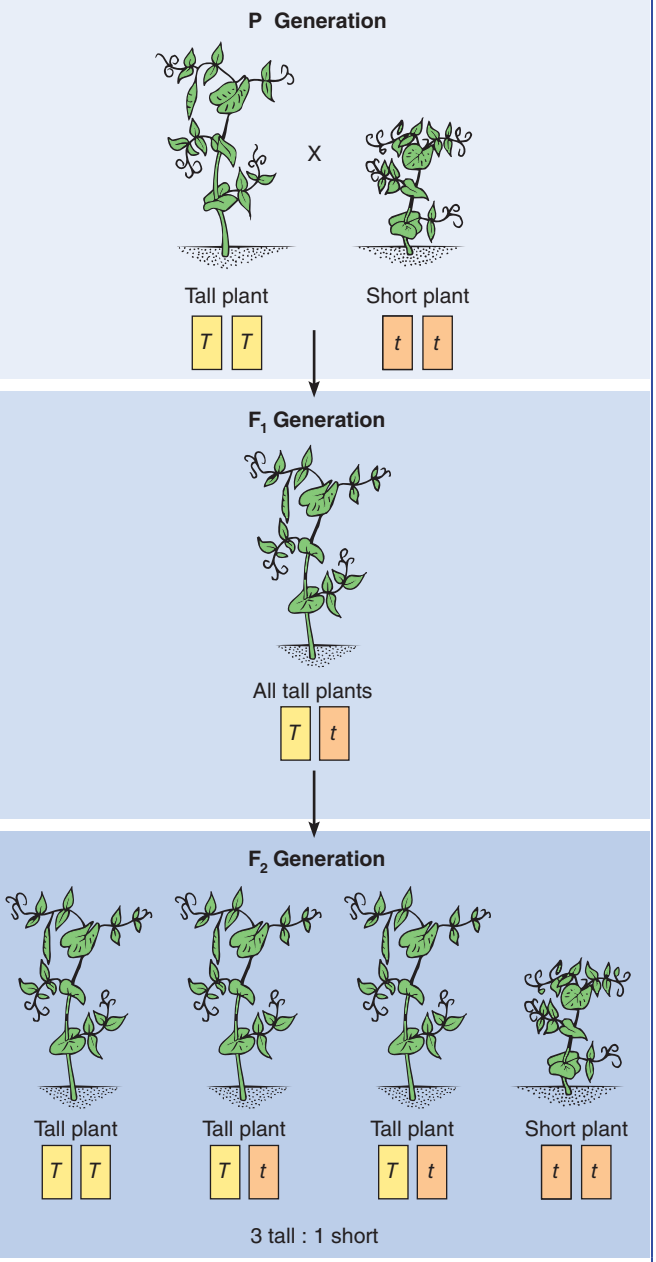
www.konkur.in

KEY EXPERIMENT

QUESTION: When the F_1 generation of tall pea plants is self-pollinated, what phenotypes appear in the F_2 generation?

HYPOTHESIS: Although only the "factor" (gene) for tall height is expressed in the F_1 generation, Mendel hypothesized that the factor for short height is not lost. He predicted that the short phenotype would reappear in the F_2 generation.

EXPERIMENT: Mendel crossed true-breeding tall pea plants with true-breeding short pea plants, yielding only tall offspring in the F_1 generation. He then allowed these F_1 individuals to self-pollinate to yield the F_2 generation.



RESULTS AND CONCLUSION: The F_2 generation included 787 tall and 277 short plants, which resulted in a ratio of about 3:1. Thus, Mendelian traits pass to successive generations in fixed ratios.

FIGURE 11-3 *Animated* One of Mendel's pea crosses

offspring were tall (FIG. 11-3). These offspring were the first filial generation, or the **F_1 generation** (*filial* is from the Latin for "sons and daughters"). The second filial generation, or **F_2 generation,** resulted from a cross between F_1 individuals or by self-pollination of F_1 individuals. Mendel's F_2 generation in this experiment included 787 tall plants and 277 short plants. TABLE 11-1 shows Mendel's experimental results for all seven pea characters.

Most breeders in Mendel's time thought that inheritance involved the blending of traits. In *blending inheritance,* male and female gametes supposedly contained fluids that blended together during reproduction to produce hybrid offspring with features intermediate between those of the mother and father. In fact, some plant breeders had obtained such hybrids.

Although Mendel observed some intermediate types of hybrids, he chose for further study those F_1 hybrids in which "hereditary factors" (as he called them) from one of the parents apparently masked the expression of those factors from the other parent. Other breeders had also observed these types of hybrids, but they had not explained them. Using modern terms, we say that the factor expressed in the F_1 generation (tallness, in our example) is **dominant;** the one hidden in the F_1 (shortness) is **recessive.** Dominant traits mask recessive ones when both are present in the same individual. Although scientists know today that dominance is not always observed, the fact that dominance can occur was not consistent with the notion of blending inheritance.

Mendel's results were inconsistent with the hypothesis of blending inheritance in a more compelling way. Once two fluids have blended, it is very difficult to imagine how they can separate. However, in the preceding example, in the F_1 generation the hereditary factor(s) that controlled shortness clearly was not lost or blended inseparably with the hereditary factor(s) that controlled tallness because shortness reappeared in the F_2 generation. Mendel was very comfortable with the theoretical side of biology because he was also a student of physics and mathematics. He therefore proposed that each kind of inherited feature of an organism is controlled by two factors that behave like discrete particles and are present in every individual.

To Mendel these hereditary factors were abstractions—he knew nothing about chromosomes and DNA. These factors are essentially what scientists today call **genes**—units of heredity that affect an organism's traits. At the molecular level, a gene is a DNA sequence that contains the information to make an RNA or pro-

tein product with a specific function. (Chapter 13 traces the development of ideas regarding the nature of genes.)

Mendel's experiments led to his discovery and explanation of the major principles of heredity, which we now know as the principles of segregation and independent assortment (see **TABLE 11-2** for a summary of Mendel's model of inheritance). We discuss the first principle next and the second later in the chapter.

Alleles separate before gametes are formed: the principle of segregation

Alternative forms of a gene are called **alleles.** In the example in Figure 11-3, each F_1 generation tall plant had two different alleles that control plant height: a **dominant allele** for tallness (which we designate *T*) and a **recessive allele** for shortness (designated *t*). Because the tall allele was dominant, these plants were tall. To explain his experimental results, Mendel proposed an idea now known as the **principle of segregation.** Using modern terminology, the principle of segregation states that before sexual reproduction occurs, the two alleles carried by an individual parent must become separated (that is, segregated).

Recall that during meiosis, homologous chromosomes, and therefore the alleles that reside on them, separate. (You may want to review meiosis in Figure 10-16.) As a result, each sex cell (egg or sperm) formed contains only one allele of each pair. (Later, at the time of fertilization, each haploid gamete contributes one chromosome from each homologous pair and therefore one allele for each gene pair.) An essential feature of meiosis is that the alleles remain intact (one does not mix with or eliminate the other); thus, recessive alleles are not lost and can reappear in the F_2 generation. In our example, before the F_1 plants formed gametes, the allele for tallness segregated from the allele for shortness; so half the gametes contained a *T* allele, and the other half, a *t* allele (**FIG. 11-4**).

The random process of fertilization led to three possible combinations of alleles in the F_2 offspring: one-fourth with two tallness alleles (*TT*), one-fourth with two shortness alleles (*tt*), and one-half with one allele for tallness and one for shortness (*Tt*). Because both *TT* and *Tt* plants are tall, Mendel expected approximately three-fourths (787 of the 1064 plants he obtained) to express the phenotype of the dominant allele (tall) and about one-fourth (277/1064) to express the phenotype of the recessive allele (short). We will explain the mathematical reasoning behind these predictions later in the chapter.

TABLE 11-2 Mendel's Model of Inheritance

1. **Alternative forms of a "factor" (what we now call a *gene*) account for variations in inherited traits.**
   Although Mendel observed only two forms (what we now call *alleles*) for each factor he studied, we now know that many genes have more than two alleles.
2. **Inherited traits pass from parents to offspring as unmodified factors.**
   Mendel did not observe offspring of intermediate appearance, as a hypothesis of blending inheritance would have predicted. Exceptions to this concept are known today.
3. **Each individual has two sets of factors, one of each pair inherited from the mother and one from the father.**
   It does not matter which parent contributes which set of factors.
4. **The paired factors separate during the formation of reproductive cells (the principle of segregation).**
   Because of *meiosis*, which was discovered after Mendel's time, each parent passes one set of factors to each offspring.
5. **Factors may be expressed or hidden in a given generation, but they are never lost.**
   For example, factors not expressed in the F_1 generation reappear in some F_2 individuals.
6. **Each factor is passed to the next generation independently from all other factors (the principle of independent assortment).**
   Research since Mendel's time has revealed that there are exceptions to this principle.

KEY POINT Mendel's principle of segregation is related to the events of meiosis: the separation of homologous chromosomes during meiosis results in the segregation of alleles.

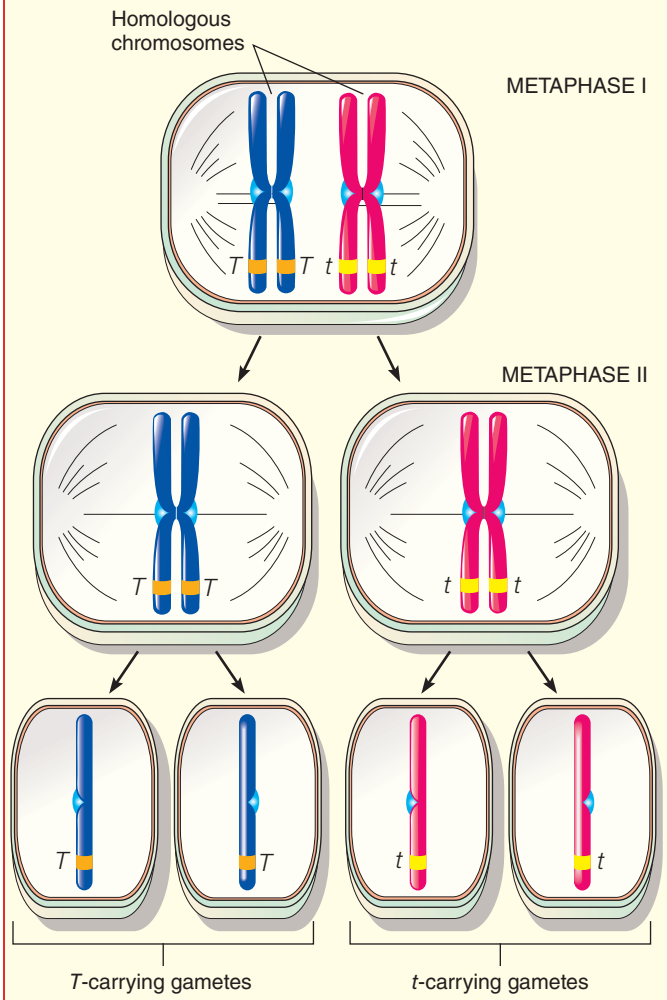

FIGURE 11-4 *Animated* Chromosomes and segregation
Note that half of the gametes carry *T* and half carry *t*.

www.konkur.in

Alleles occupy corresponding loci on homologous chromosomes

Today scientists know that each unduplicated chromosome consists of one long, linear DNA molecule and that each gene is actually a segment of that DNA molecule. We also know that homologous chromosomes not only are similar in size and shape but also usually have the same genes (often with different alleles) located in corresponding positions. The term **locus** (pl., *loci*) originally designated the location of a particular gene on the chromosome (**FIG. 11-5**). We are actually referring to a segment of the DNA that has the information for controlling some aspect of the structure or function of the organism. One locus may govern seed color, another seed shape, another shape of the pods, and so on. Traditional genetic methods can infer the existence of a particular locus only if at least two allelic variants of that locus, producing contrasting phenotypes (for example, yellow peas versus green peas), are available for study. In the simplest cases, an individual can express one (yellow) or the other (green) but not both.

Alleles are, therefore, genes that govern variations of the same character (yellow versus green seed color) and occupy corresponding loci on homologous chromosomes. Geneticists assign each allele of a locus a single letter or group of letters as its symbol.[1]

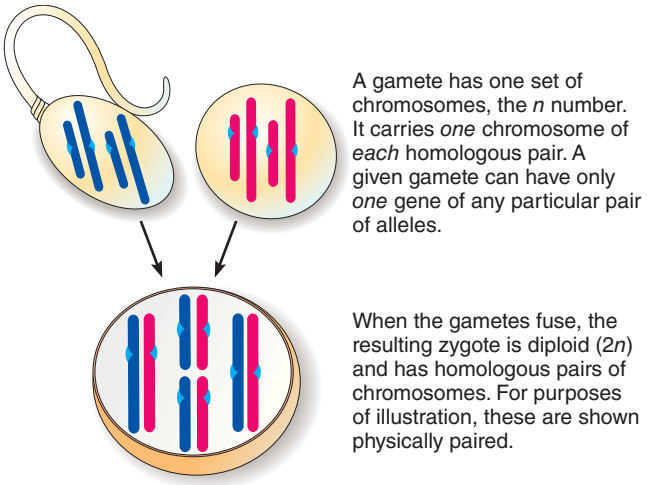
Although geneticists often use more complicated forms of notation, it is customary when working simple genetics problems to indicate a dominant allele with a capital letter and a recessive allele with the same letter in lowercase.

Remember that the term *locus* designates not only a position on a chromosome but also a type of gene controlling a particular character; thus, *Y* (yellow) and *y* (green) represent a specific pair of alleles of a locus involved in determining seed color in peas. Although you may initially be uncomfortable with the fact that geneticists sometimes use the term *gene* to specify a locus and at other times to specify one of the alleles of that locus, the meaning is usually clear from the context.

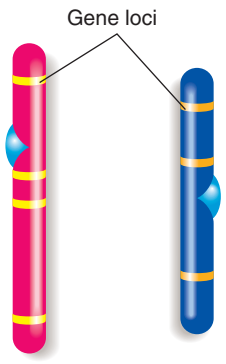
A monohybrid cross involves individuals with different alleles of a given locus

The basic principles of genetics and the use of genetics terms are best illustrated by examples. In the simplest case, a **monohybrid cross,** the inheritance of two different alleles of a single locus, is studied. **FIGURE 11-6** illustrates a monohybrid cross featuring a locus that governs coat color in guinea pigs. The female comes from

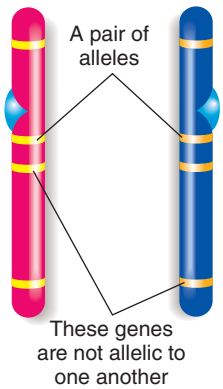
[1]Early geneticists developed their own symbols to represent genes and alleles. Later, groups of scientists met and decided on specific symbols for a given research organism, such as the fruit fly, but each research group had its own rules for assigning symbols. Universally accepted rules for assigning symbols for genes and alleles still do not exist.



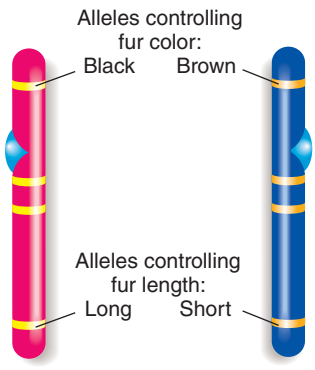
(a) One member of each pair of homologous chromosomes is of maternal origin (*red*), and the other is paternal (*blue*).



(b) These chromosomes are nonhomologous. Each chromosome is made up of hundreds or thousands of genes. A locus is the specific place on a chromosome where a gene is located.



(c) These chromosomes are homologous. Alleles are members of a gene pair that occupy corresponding loci on homologous chromosomes.



(d) Alleles govern the same character but do not necessarily contain the same information.

FIGURE 11-5 ***Animated*** **Gene loci and their alleles**

www.konkur.in

a true-breeding line of black guinea pigs. We say she is **homozygous** for black because the two alleles she carries for this locus are identical. The brown male is also from a true-breeding line and is homozygous for brown. What color would you expect the F_1 offspring to be? Actually, it is impossible to make such a prediction without more information.

In this particular case, the F_1 offspring are black, but they are **heterozygous,** meaning they carry two different alleles for this locus. The brown allele determines coat color only in a homozygous brown individual; it is a recessive allele. The black allele influences coat color in both homozygous black and heterozygous individuals; it is a dominant allele. On the basis of this information, we can use symbols to designate the dominant black allele *B* and the recessive brown allele *b.*

During meiosis in the female parent (*BB*), the two *B* alleles separate according to Mendel's principle of segregation, so each egg has only one *B* allele. In the male (*bb*) the two *b* alleles separate, so each sperm has only one *b* allele. The fertilization of each *B* egg by a *b* sperm results in heterozygous F_1 offspring, each *Bb;* that is, each individual has one allele for brown coat and one for black coat. Because this is the only possible combination of alleles present in the eggs and sperm, all the F_1 offspring are *Bb.* Also, note that it does not make any difference whether the offspring receive the dominant allele from the mother or father guinea pig.

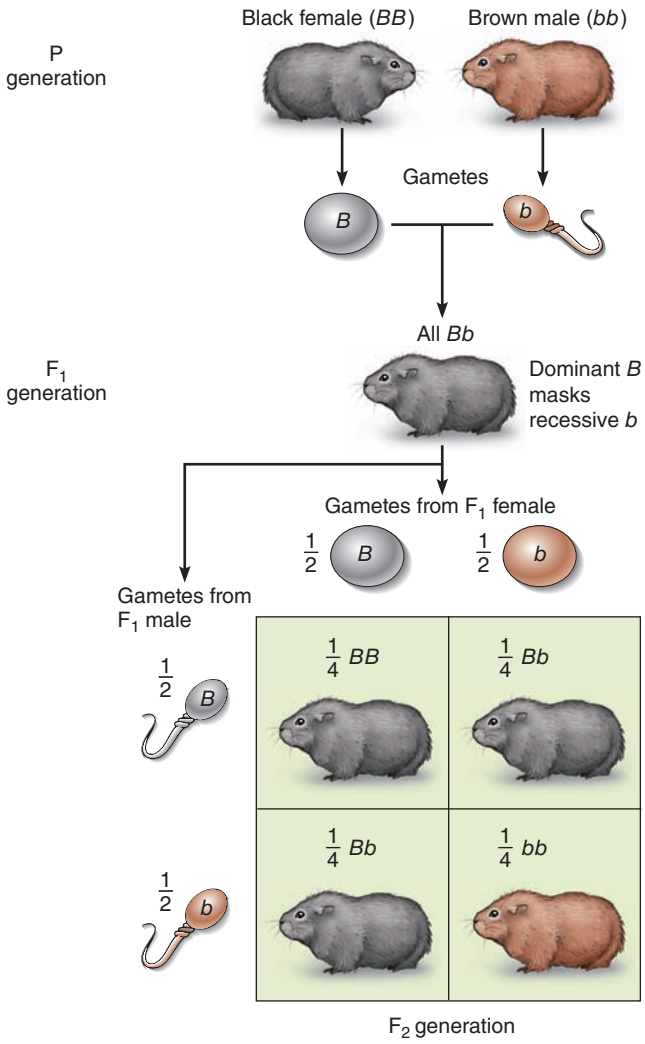


FIGURE 11-6 ***Animated*** **A monohybrid cross in guinea pigs**

In this example, a homozygous black guinea pig is mated with a homozygous brown guinea pig. The F_1 generation includes only black individuals. However, the mating of two of these F_1 offspring yields F_2 generation offspring in the expected ratio of 3 black to 1 brown, indicating that the F_1 individuals are heterozygous.

A Punnett square predicts the ratios of the various offspring of a cross

During meiosis in heterozygous black guinea pigs (*Bb*), the chromosome containing the *B* allele becomes separated from its homologue (the chromosome containing the *b* allele), so each normal sperm or egg contains *B* or *b* but never both. Heterozygous *Bb* individuals form gametes containing *B* alleles and gametes containing *b* alleles in equal numbers. Because no special attraction or repulsion occurs between an egg and a sperm containing the same allele, fertilization is a random process.

As you can see in Figure 11-6, the possible combinations of eggs and sperm at fertilization can be represented in the form of a grid, or **Punnett square,** devised by the early English geneticist Sir Reginald Punnett. The types of gametes (and their expected frequencies) from one parent are listed across the top, and those from the other parent are listed along the left side. The squares are then filled in with the resulting F_2 combinations. Three-fourths of all F_2 offspring have the genetic constitution *BB* or *Bb* and are phenotypically black; one-fourth have the genetic constitution *bb* and are phenotypically brown. The genetic mechanism that governs the approximate 3:1 F_2 ratios obtained by Mendel in his pea-breeding experiments is again evident. These ratios are called *monohybrid F_2 phenotypic ratios.*

The phenotype of an individual does not always reveal its genotype

As mentioned earlier, an organism's phenotype is its appearance with respect to a certain inherited trait. However, because some alleles may be dominant and others recessive, we cannot always determine, simply by examining its phenotype, which alleles are carried by an organism. In the cross we have been considering, the genotype of the female parent is homozygous dominant, *BB,* and her phenotype is black. The genotype of the male parent is homozygous recessive, *bb,* and his phenotype is brown. The genotype of all the F_1 offspring is heterozygous, *Bb,* and their phenotype is black. To prevent confusion, we always indicate the genotype of a heterozygous individual by writing the symbol for the dominant allele first and the recessive allele second (always *Bb,* never *bB*). The expression of dominance partly explains why an individual may resemble one parent more than the other, even though the two parents contribute equally to their offspring's genetic constitution.

Dominance is not predictable—that is, dominance is not an intrinsic part of an allele but is the property of an allele relative to other alleles. Dominance is produced by the mechanism of gene expression and can be determined only by experiment. In one species of animal, black coat may be dominant to brown; in another species, brown may be dominant to black. In a population, the dominant phenotype is not necessarily more common than the recessive phenotype.

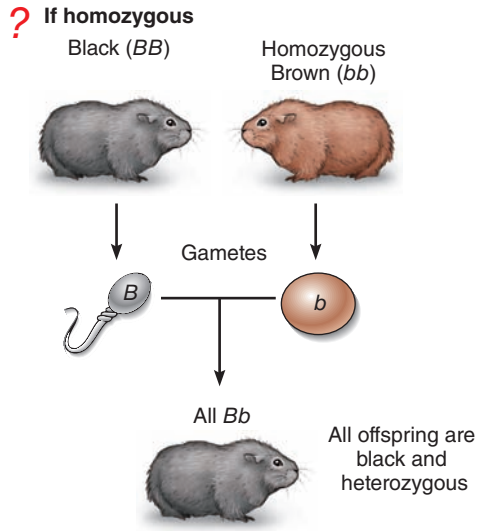
www.konkur.in

KEY EXPERIMENT

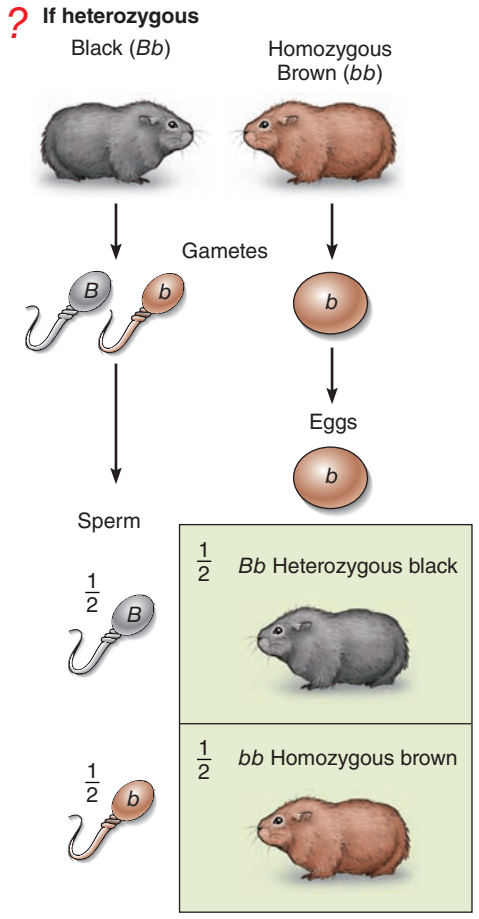
QUESTION: How do you determine the genotype of an individual with a dominant phenotype?

HYPOTHESIS: A test cross between an individual with a dominant phenotype but unknown genotype and an individual that is homozygous recessive for the gene in question yields offspring that provide insight into the genotype of the dominant individual.

EXPERIMENT: Cross a black guinea pig of unknown genotype with a brown guinea pig, which is known to be homozygous recessive.



(a) If a black guinea pig is mated with a brown guinea pig and all the offspring are black, the black parent probably has a homozygous genotype.



(b) If any of the offspring is brown, the black guinea pig must be heterozygous. The expected phenotypic ratio is 1 black to 1 brown.

RESULTS AND CONCLUSION: There are two possible outcomes. If all the offspring are black, the black parent probably has a homozygous genotype. If any of the offspring are brown, the black parent must be heterozygous. The expected ratio is 1 black: 1 brown.

FIGURE 11-7 ***Animated*** A test cross in guinea pigs

A test cross can detect heterozygosity

Guinea pigs with the genotypes *BB* and *Bb* are alike phenotypically; they both have black coats. How, then, can we know the genotype of a black guinea pig? Geneticists accomplish this by performing an experimental cross known as a **test cross,** in which an individual of unknown genotype is crossed with a recessive individual (**FIG. 11-7**). In a test cross, the alleles carried by the gametes from the parent of unknown genotype are never "hidden" in the offspring by dominant alleles contributed by the other parent. Therefore, you can deduce the genotypes of all offspring directly from their phenotypes. If all the offspring were black, what inference would you make about the genotype of the black parent? If any of the offspring were brown, what conclusion would you draw regarding the genotype of the black parent? Would you be more certain about one of these inferences than about the other?[2]

[2]If any of the offspring were brown, the black parent must be heterozygous, *Bb*. If all the offspring were black, you could infer that the black parent is *probably* homozygous, *BB*. (For example, statisticians calculate that if the black parent is heterozygous, the probability of four black offspring, and no brown, is only $\frac{1}{16}$.)

www.konkur.in

Mendel conducted several test crosses; for example, he bred F_1 (tall) pea plants with homozygous recessive (*tt*) short ones. He reasoned that the F_1 individuals were heterozygous (*Tt*) and would be expected to produce equal numbers of *T* and *t* gametes. Because the homozygous short parents (*tt*) were expected to produce only *t* gametes, Mendel hypothesized that he would obtain equal numbers of tall (*Tt*) and short (*tt*) offspring. His results agreed with his hypothesis, providing additional evidence for the hypothesis that there is 1:1 segregation of the alleles of a heterozygous parent. Thus, Mendel's principle of segregation not only explained the known facts, such as the 3:1 monohybrid F_2 phenotypic ratio, but also let him successfully anticipate the results of other experiments—in this case, the 1:1 test-cross phenotypic ratio.

A dihybrid cross involves individuals that have different alleles at two loci

Monohybrid crosses involve a pair of alleles of a single locus. Mendel also analyzed crosses involving alleles of two or more loci. A mating between individuals with different alleles at two loci is called a **dihybrid cross.** Consider the case of two pairs of alleles carried on nonhomologous chromosomes (that is, one pair of alleles is in one pair of homologous chromosomes, and the other pair of alleles is in a different pair of homologous chromosomes). Each pair of alleles is inherited independently; that is, each pair segregates during meiosis independently of the other.

An example of a dihybrid cross carried through the F_2 generation is shown in **FIGURE 11-8.** In this example, black is dominant to brown, and short hair is dominant to long hair. When a homozygous, black, short-haired guinea pig (*BBSS*) and a homozygous, brown, long-haired guinea pig (*bbss*) are mated, the *BBSS* animal produces gametes that are all *BS,* and the *bbss* individual produces gametes that are all *bs.* Each gamete contains one allele for each of the two loci. The union of the *BS* and *bs* gametes yields only individuals with the genotype *BbSs.* All these F_1 offspring are heterozygous for hair color and for hair length, and all are phenotypically black and short-haired.

Each F_1 guinea pig produces four kinds of gametes with equal probability: *BS, Bs, bS,* and *bs.* Hence, the Punnett square has 16 (that is, 4^2) squares representing the F_2 offspring, some of which are genotypically or phenotypically alike. There are 9 chances in 16 of obtaining a black, short-haired individual; 3 chances in 16 of obtaining a black, long-haired individual; 3 chances in 16 of obtaining a brown, short-haired individual; and 1 chance in 16 of obtaining a brown, long-haired individual. This 9:3:3:1 phenotypic ratio is expected in a dihybrid F_2 if the hair color and hair length loci are on nonhomologous chromosomes.

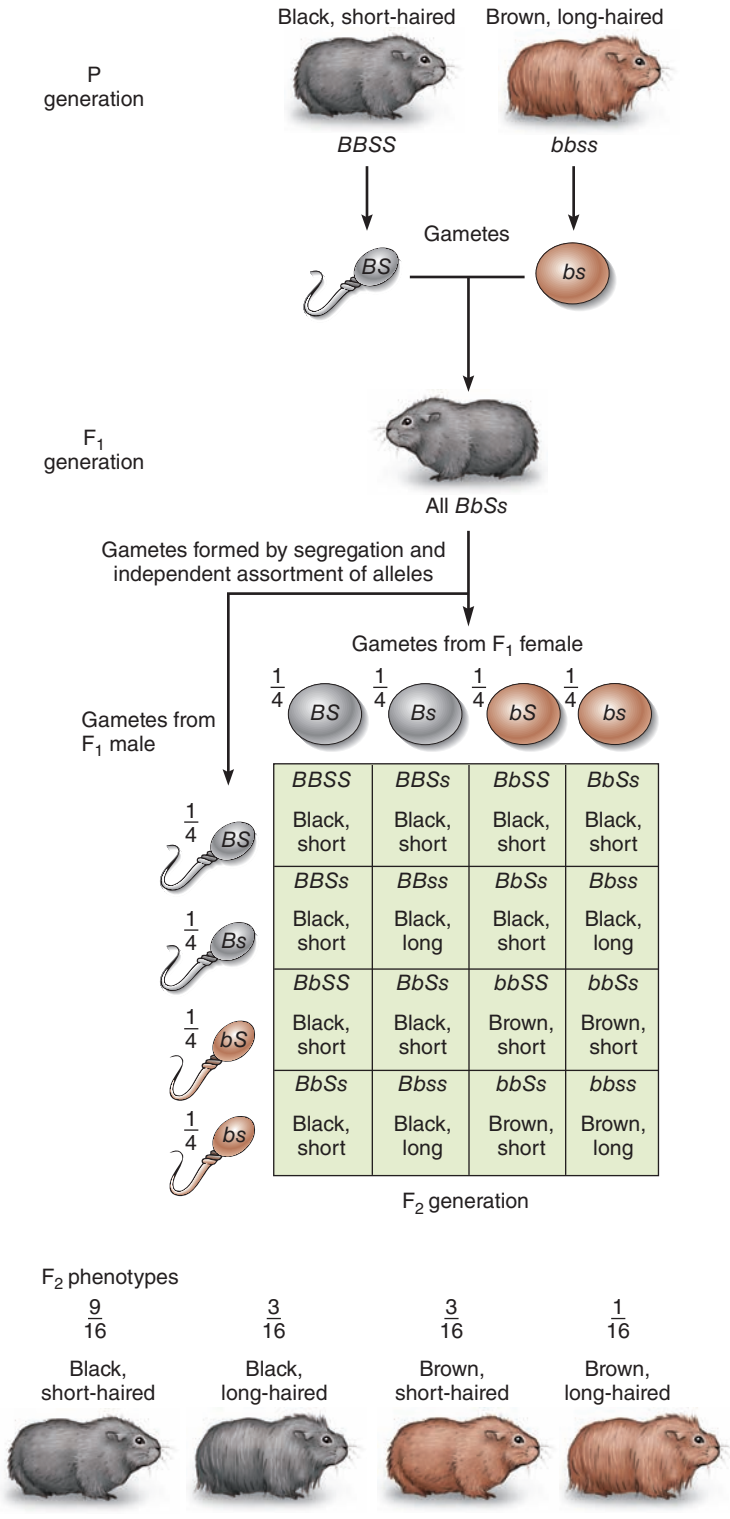


FIGURE 11-8 ***Animated*** **A dihybrid cross in guinea pigs**
When a black, short-haired guinea pig is crossed with a brown, long-haired one, all the offspring are black and have short hair. However, when two members of the F_1 generation are crossed, the ratio of phenotypes is 9:3:3:1.

Alleles on nonhomologous chromosomes are randomly distributed into gametes: the principle of independent assortment

On the basis of results similar to the guinea pig example, Mendel formulated the principle of inheritance, now known as Mendel's **principle of independent assortment,** which states that members of any gene pair segregate from one another independently of the members of the other gene pairs. This mechanism occurs in a regular way to ensure that each gamete contains one allele for each locus, but the alleles of different loci are assorted at random with respect

www.konkur.in

to each other in the gametes. The independent assortment of these alleles can result in **genetic recombination** (or simply **recombination**), the process of assorting and passing alleles to offspring in new combinations that are different from those in the parents.

Today we recognize that independent assortment is related to the events of meiosis. It occurs because two pairs of homologous chromosomes can be arranged in two different ways at metaphase I of meiosis (**FIG. 11-9**). These arrangements occur randomly, with approximately half the meiotic cells oriented one way and half oriented the opposite way. The orientation of the homologous chromosomes on the metaphase plate then determines the way they subsequently separate and disperse into the haploid cells. (As you will soon see, however, independent assortment does not always occur.)

Recognition of Mendel's work came during the early 20th century

Mendel reported his findings at a meeting of the Brünn Society for the Study of Natural Science (in what is now the Czech Republic); he published his results in the society's report in 1866. At that time biology was largely a descriptive science, and biologists had little interest in applying quantitative and experimental methods such as those Mendel had used. Other biologists of the time did not appreciate the importance of his results nor his interpretations of those results. For 34 years his findings were largely neglected.

In 1900, Hugo DeVries in Holland, Carl Correns in Germany, and Erich von Tschermak in Austria recognized Mendel's princi-

KEY POINT Mendel's principle of independent assortment—that factors for different characteristics separate independently of one another prior to gamete formation—is a direct consequence of the events of meiosis.

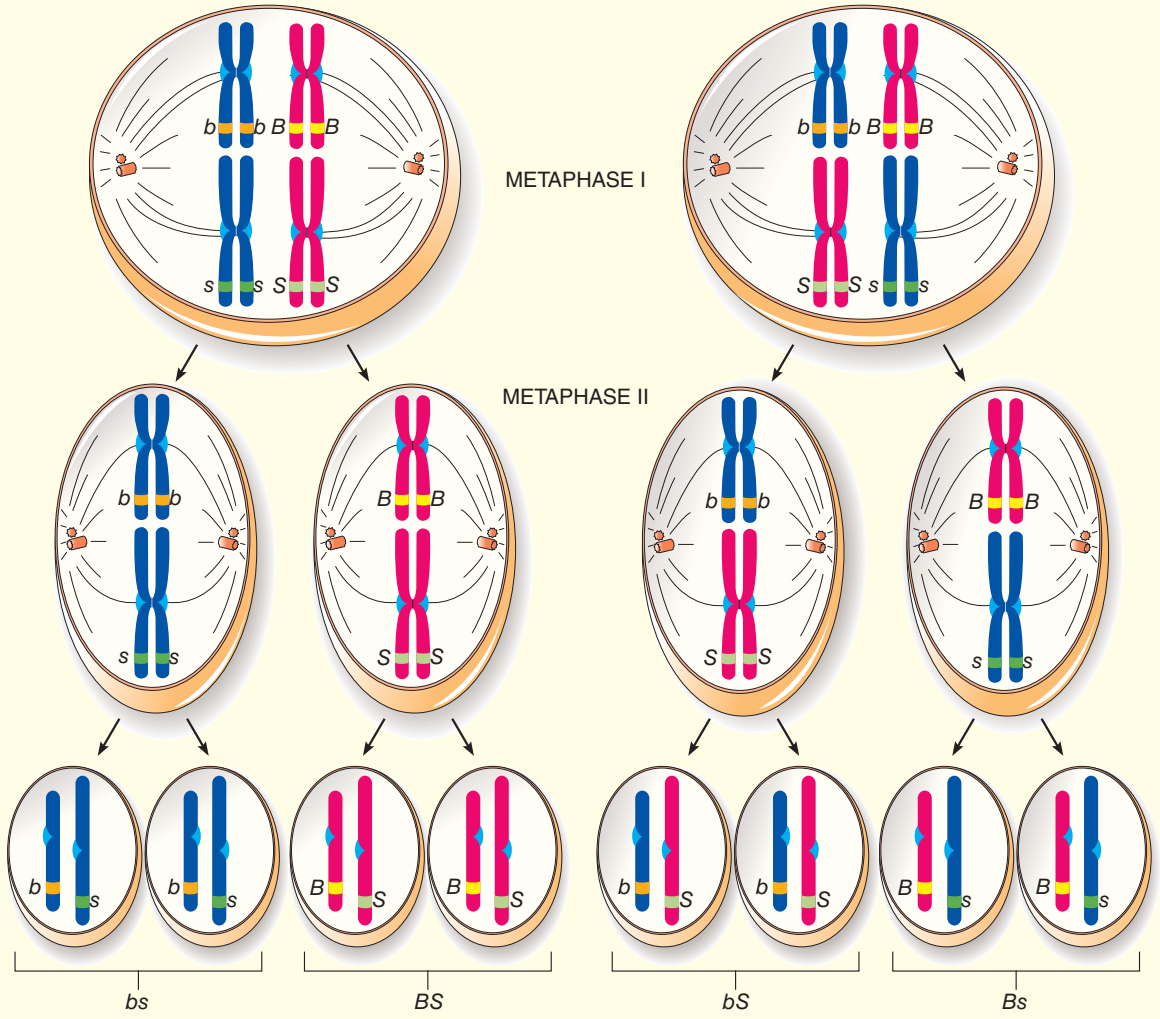

FIGURE 11-9 ***Animated*** Meiosis and independent assortment

Two different pairs of homologous chromosomes can line up two different ways at metaphase I and be subsequently distributed. A cell with the orientation shown at the left produces half *BS* and half *bs* gametes. Conversely, the cell at the right produces half *Bs* and half *bS* gametes. Because approximately half of the meiotic cells at metaphase I are of each type, the ratio of the four possible types of gametes is 1:1:1:1.

www.konkur.in

ples in their own experiments; they later discovered Mendel's paper and found that it explained their own research observations. By this time biologists had a much greater appreciation of the value of quantitative experimental methods. Correns gave credit to Mendel by naming the basic laws of inheritance after him.

Although gametes and fertilization were known at the time Mendel carried out his research, mitosis and meiosis had not yet been discovered. It is truly remarkable that Mendel formulated his ideas mainly on the basis of mathematical abstractions. Today his principles are much easier to understand because we relate the transmission of genes to the behavior of chromosomes.

The details of mitosis and meiosis were described during the late 19th century, and in 1902, American biologist Walter Sutton and German biologist Theodor Boveri independently pointed out the connection between Mendel's segregation of alleles and the separation of homologous chromosomes during meiosis. This connection developed into the **chromosome theory of inheritance,** or the *Sutton–Boveri theory,* which stated that inheritance can be explained by assuming that genes are linearly arranged in specific locations along the chromosomes.

The chromosome theory of inheritance was initially controversial, because at that time there was no direct evidence that genes are found on chromosomes. However, new research provided the findings necessary for wider acceptance and extension of these ideas and their implications. For example, the work of American geneticist Thomas Hunt Morgan in 1910 provided evidence for the location of a particular gene (white eye color) on a specific chromosome (the X chromosome) in fruit flies. Morgan and his graduate students also provided insight into the way genes are organized on chromosomes; we discuss some of Morgan's research contributions later in the chapter.

Review

- What are the relationships among loci, genes, and alleles?
- What is Mendel's principle of segregation?
- What is Mendel's principle of independent assortment?

11.2 USING PROBABILITY TO PREDICT MENDELIAN INHERITANCE

LEARNING OBJECTIVE

5 Apply the product rule and sum rule appropriately when predicting the outcomes of genetic crosses.

All genetic ratios are properly expressed in terms of probabilities. In monohybrid crosses, the expected ratio of the dominant and recessive phenotypes is 3:1. The probability of an event is its expected frequency. Therefore, we can say there are 3 chances in 4 (or $\frac{3}{4}$) that any particular individual offspring of two heterozygous individuals will express the dominant phenotype and 1 chance in 4 (or $\frac{1}{4}$) that it will express the recessive phenotype. Although we sometimes speak in terms of percentages, probabilities are calculated as fractions (such as $\frac{3}{4}$) or decimal fractions (such as 0.75). If an event is certain to occur, its probability is 1; if it is certain *not* to occur, its probability is 0. A probability can be 0, 1, or some number between 0 and 1.

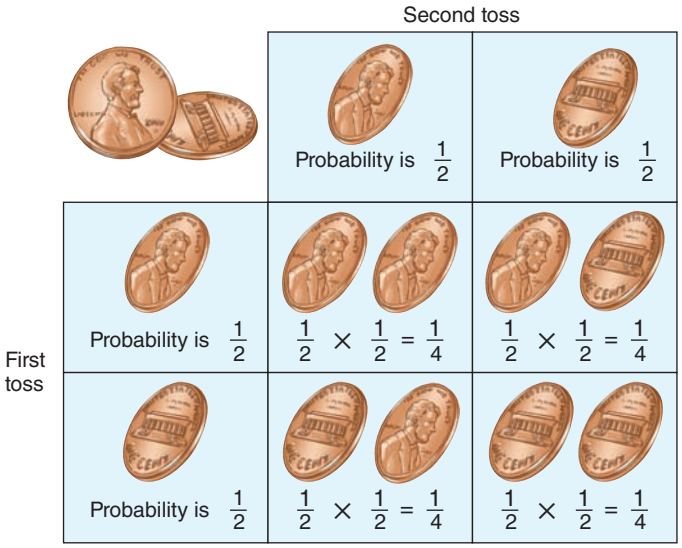

FIGURE 11-10 The rules of probability

For each coin toss, the probability of heads is $\frac{1}{2}$, and the probability of tails is also $\frac{1}{2}$. Because the outcome of the first toss is independent of the outcome of the second, the combined probabilities of the outcomes of successive tosses are calculated by multiplying their individual probabilities (according to the product rule: $\frac{1}{2} \times \frac{1}{2} = \frac{1}{4}$). These same rules of probability predict genetic events.

The Punnett square lets you combine two or more probabilities. When you use a Punnett square, you are following two important statistical principles known as the product rule and the sum rule. The **product rule** predicts the combined probabilities of independent events. Events are *independent* if the occurrence of one does not affect the probability that the other will occur. For example, the probability of obtaining heads on the first toss of a coin is $\frac{1}{2}$; the probability of obtaining heads on the second toss (an independent event) is also $\frac{1}{2}$. If two or more events are independent of each other, the probability of both occurring is the product of their individual probabilities. If this seems strange, keep in mind that when we multiply two numbers that are less than 1, the product is a smaller number. Therefore, the probability of obtaining heads two times in a row is $\frac{1}{2} \times \frac{1}{2} = \frac{1}{4}$, or 1 chance in 4 (**FIG. 11-10**).

Similarly, we can apply the product rule to genetic events. If both parents are *Bb,* what is the probability they will produce a child who is *bb*? For the child to be *bb,* he or she must receive a *b* gamete from each parent. The probability of a *b* egg is $\frac{1}{2}$, and the probability of a *b* sperm is also $\frac{1}{2}$. Like the outcomes of the coin tosses, these probabilities are independent, so we combine them by the product rule ($\frac{1}{2} \times \frac{1}{2} = \frac{1}{4}$). You might like to check this result using a Punnett square.

The **sum rule** predicts the combined probabilities of *mutually exclusive* events. In some cases, there is more than one way to obtain a specific outcome. These different ways are mutually exclusive; if one occurs, the other(s) cannot. For example, if both parents are

www.konkur.in

Inquiring About

SOLVING GENETICS PROBLEMS

How do you solve simple Mendelian genetics problems? Such problems can be fun and easy to work if you follow certain conventions and are methodical in your approach.

1. Always use standard designations for the generations. The generation in which a particular genetic experiment is begun is called the P, or parental, generation. Offspring of this generation are called the F_1, or first filial, generation. The offspring resulting when two F_1 individuals are bred constitute the F_2, or second filial, generation.
2. Write down a key for the symbols you are using for the allelic variants of each locus. Use an uppercase letter to designate a dominant allele and a lowercase letter to designate a recessive allele. Use the same letter of the alphabet to designate both alleles of a particular locus. If you are not told which allele is dominant and which is recessive, the phenotype of the F_1 generation is a good clue.
3. Determine the genotypes of the parents of each cross by using the following types of evidence:
   - Are they from true-breeding lines? If so, they should be homozygous.
   - Can their genotypes be reliably deduced from their phenotypes? This is usually true if they express the recessive phenotype.
   - Do the phenotypes of their offspring provide any information? Exactly how this is done is discussed shortly.
4. Indicate the possible kinds of gametes formed by each of the parents. It is helpful to draw a circle around the symbols for each kind of gamete.
   - If it is a monohybrid cross, we apply the principle of segregation; that is, a heterozygote *Aa* forms two kinds of gametes, *A* and *a*. A homozygote, such as *aa*, forms only one kind of gamete, *a*.
   - If it is a dihybrid cross, we apply the principles of segregation and independent assortment. For example, an individual heterozygous for two loci would have the genotype *AaBb*. Allele *A* segregates from *a*, and *B* segregates from *b*. The assortment of *A* and *a* into gametes is independent of the assortment of *B* and *b*. *A* is equally likely to end up in a gamete with *B* or *b*. The same is true for *a*. Thus, an individual with the genotype *AaBb* produces four kinds of gametes in equal amounts: *AB*, *Ab*, *aB*, and *ab*.
5. Set up a Punnett square, placing the possible types of gametes from one parent down the left side and the possible types from the other parent across the top.
6. Fill in the Punnett square. Avoid confusion by consistently placing the dominant allele first and the recessive allele second in heterozygotes (*Aa*, never *aA*). If it is a dihybrid cross, always write the two alleles of one locus first and the two alleles of the other locus second. It does not matter which locus you choose to write first, but once you have decided on the order, it is crucial to maintain it consistently. This means that if the individual is heterozygous for both loci, you will always use the form *AaBb*. Writing this particular genotype as *aBbA*, or even as *BbAa*, would cause confusion.
7. If you do not need to know the frequencies of all the expected genotypes and phenotypes, you can use the rules of probability as a shortcut instead of making a Punnett square. For example, if both parents are *AaBb*, what is the probability of an *AABB* offspring? To be *AA*, the offspring must receive an *A* gamete from each parent. The probability that a given gamete is *A* is $\frac{1}{2}$, and each gamete represents an independent event, so combine their probabilities by multiplying ($\frac{1}{2} \times \frac{1}{2} = \frac{1}{4}$). The probability of *BB* is calculated similarly and is also $\frac{1}{4}$. The probability of *AA* is independent of the probability of *BB*, so again, use the product rule to obtain their combined probabilities ($\frac{1}{4} \times \frac{1}{4} = \frac{1}{16}$).
8. Very often the genotypes of the parents can be deduced from the phenotypes of their offspring. In peas, for example, the allele for yellow seeds (*Y*) is dominant to the allele for green seeds (*y*). Suppose plant breeders cross two plants with yellow seeds, but you don't know whether the yellow-seeded plants are homozygous or heterozygous. You can designate the cross as: *Y_* × *Y_*. The offspring of the cross are allowed to germinate and grow, and their seeds are examined. Of the offspring, 74 produce yellow seeds, and 26 produce green seeds. Knowing that green-seeded plants are recessive, *yy*, the answer is obvious: Each parent contributed a *y* allele to the green-seeded offspring, so the parents' genotypes must have been *Yy* × *Yy*.

Sometimes it is impossible to determine from the data given whether an individual is homozygous dominant or heterozygous. For example, suppose a cross between a yellow-seeded plant and a green-seeded plant yields offspring that all produce yellow seeds. From the information given about the parents, you can designate the cross as: *Y_* × *yy*. Because all the offspring have yellow seeds, they have the genotype *Yy*. You can deduce this because each parent contributes one allele. (The offspring have yellow seeds, so they must have at least one *Y* allele; however, the green-seeded parent can contribute only a *y* allele to the offspring.) Therefore, the cross is most likely (*YY* × *yy*), but you cannot be absolutely certain about the genotype of the yellow-seeded parent. Further crosses would be necessary to determine this.

Bb, what is the probability that their first child will also have the *Bb* genotype? There are two different ways these parents can have a *Bb* child: either a *B* egg combines with a *b* sperm (probability $\frac{1}{4}$), or a *b* egg combines with a *B* sperm (probability $\frac{1}{4}$).

Naturally, if there is more than one way to get a result, the chances of its being obtained improve; we therefore combine the probabilities of mutually exclusive events by summing (adding) their individual probabilities. The probability of obtaining a *Bb* child in our example is therefore $\frac{1}{4} + \frac{1}{4} = \frac{1}{2}$. (Because there is only one way these heterozygous parents can produce a homozygous recessive child, *bb*, that probability is only $\frac{1}{4}$. The probability of a homozygous dominant child, *BB*, is likewise $\frac{1}{4}$.)

The rules of probability can be applied to a variety of calculations

The rules of probability have wide applications. For example, what are the probabilities that a family with two (and only two) children

www.konkur.in

will have two girls, two boys, or one girl and one boy? For purposes of discussion, let's assume male and female births are equally probable. The probability of having a girl first is $\frac{1}{2}$, and the probability of having a girl second is also $\frac{1}{2}$. These are independent events, so we combine their probabilities by multiplying: $\frac{1}{2} \times \frac{1}{2} = \frac{1}{4}$. Similarly, the probability of having two boys is $\frac{1}{4}$.

In families with both a girl and a boy, the girl can be born first or the boy can be born first. The probability that a girl will be born first is $\frac{1}{2}$, and the probability that a boy will be born second is also $\frac{1}{2}$. We use the product rule to combine the probabilities of these two independent events: $\frac{1}{2} \times \frac{1}{2} = \frac{1}{4}$. Similarly, the probability that a boy will be born first and a girl second is $\frac{1}{4}$. These two kinds of families represent mutually exclusive outcomes, that is, two different ways of obtaining a family with one boy and one girl. Having two different ways of obtaining the desired result improves our chances, so we use the sum rule to combine the probabilities: $\frac{1}{4} + \frac{1}{4} = \frac{1}{2}$.

In working with probabilities, keep in mind a point that many gamblers forget: Chance has no memory. If events are truly independent, past events have no influence on the probability of the occurrence of future events. Probability only has predictive value in the long run, over many trials. (Recall that Mendel counted hundreds of offspring for each cross, and this was one of the reasons for his success.) When working probability problems, common sense is more important than blindly memorizing rules. Examine your results to see whether they appear reasonable; if they don't, re-evaluate your assumptions. (See *Inquiring About: Solving Genetics Problems* for procedures to solve genetics problems, including when to use the rules of probability.)

Review

- Use the rules of probability to answer the following question: In a cross between homozygous pea plants with yellow, round seeds (*YYRR*) and homozygous pea plants with green, wrinkled seeds (*yyrr*), what is the probability of an F_2 plant having yellow, round seeds?
- In the previous question, did you use the product rule or the sum rule? Why?

11.3 INHERITANCE AND CHROMOSOMES

LEARNING OBJECTIVES

6 Define *linkage* and relate it to specific events in meiosis.

7 Show how data from a test cross involving alleles of two loci can be used to distinguish between independent assortment and linkage.

8 Discuss the genetic determination of sex and the inheritance of X-linked genes in mammals.

It is a measure of Mendel's genius that he worked out the principles of segregation and independent assortment without knowing anything about meiosis or the chromosome theory of inheritance. The chromosome theory of inheritance also helps explain certain apparent exceptions to Mendelian inheritance. One of these so-called exceptions involves linked genes.

Linked genes do not assort independently

Beginning around 1910, the research of geneticist Thomas Hunt Morgan and his graduate students extended the concept of the chromosome theory of inheritance. Morgan's research organism was the fruit fly (*Drosophila melanogaster*). Just as the garden pea was an excellent model research organism for Mendel's studies, the fruit fly was perfect for extending general knowledge about inheritance. Fruit flies have a short life cycle—just 14 days—and their small size means that thousands can be kept in a research lab. The large number of individuals increases the chance of identifying mutants. Also, fruit flies have just four pairs of chromosomes, one of which is a pair of sex chromosomes.

By carefully analyzing the results of crosses involving fruit flies, Morgan and his students demonstrated that genes are arranged in a linear order on each chromosome. Morgan also showed that independent assortment does not apply if the two loci lie close together in the same pair of homologous chromosomes. In fruit flies there is a locus controlling wing shape: the dominant allele *V* for normal wings and the recessive allele *v* for abnormally short, or vestigial, wings. Another locus controls body color: the dominant allele *B* for gray body and the recessive allele *b* for black body. If a homozygous *BBVV* fly is crossed with a homozygous *bbvv* fly, the F_1 flies all have gray bodies and normal wings, and their genotype is *BbVv*.

Because these loci happen to lie close to each other in the *same pair* of homologous chromosomes, their alleles do not assort independently; instead, they are **linked genes** that tend to be inherited together. **Linkage** is the tendency for a group of genes on the same chromosome to be inherited together in successive generations. You can readily observe linkage in the results of a test cross in which heterozygous F_1 flies (*BbVv*) are mated with homozygous recessive (*bbvv*) flies (**FIG. 11-11**). Because heterozygous individuals are mated to homozygous recessive individuals, this test cross is similar to the test cross described earlier. However, it is called a **two-point test cross** because alleles of two loci are involved.

If the loci governing these traits were unlinked—that is, on different chromosomes—the heterozygous parent in a test cross would produce four kinds of gametes (*BV, Bv, bV,* and *bv*) in equal numbers. This independent assortment would produce offspring with new gene combinations not present in the parental generation. Recall that any process that leads to new allele combinations is called genetic recombination. In our example, gametes *Bv* and *bV* are **recombinant types.** The other two kinds of gametes, *BV* and *bv,* are **parental types** because they are identical to the gametes produced by the P generation.

Of course, the homozygous recessive parent produces only one kind of gamete, *bv.* Thus, if independent assortment were to occur in the F_1 flies, approximately 25% of the test-cross offspring would be gray-bodied and normal-winged (*BbVv*), 25% black-bodied and normal-winged (*bbVv*), 25% gray-bodied and vestigial-winged (*Bbvv*), and 25% black-bodied and vestigial-winged (*bbvv*). Notice that the two-point test cross lets us determine the genotypes of the offspring directly from their phenotypes.

By contrast, the alleles of the loci in our example do not undergo independent assortment because they are linked. Alleles at different loci but close to one another on a given chromosome

www.konkur.in

KEY EXPERIMENT

QUESTION: How can linkage be recognized in fruit flies?

HYPOTHESIS: Linkage can be recognized when an excess of parental-type offspring and a deficiency of recombinant-type offspring are produced in a two-point test cross.

EXPERIMENT: Fruit flies with gray, normal wings (*BbVv*) are crossed with flies that have black, vestigial wings (*bbvv*). If the alleles for color and wing shape are not linked (i.e., the alleles assort independently), the offspring will consist of an equal number of each of four phenotypes (*bottom row*).

	Gray, normal	Black, vestigial	Gray, vestigial	Black, normal
	BbVv	*bbvv*	*Bbvv*	*bbVv*
Expected results, independent assortment	575	575	575	575
Actual results	965	944	206	185

RESULTS AND CONCLUSION: In the 2300 offspring (*bottom row*) of an actual cross, about 1909 of the offspring belong to each of the two parental types (83% total), and 391 belong to each of the two recombinant types (17% total). Thus, loci for wing length and body color are linked on a homologous chromosome pair.

FIGURE 11-11 A two-point test cross to detect linkage in fruit flies

tend to be inherited together; because chromosomes pair and separate during meiosis as units, the alleles at different loci on a given chromosome tend to be inherited as units. If linkage were complete, only parental-type flies would be produced, with approximately 50% having gray bodies and normal wings (*BbVv*) and 50% having black bodies and vestigial wings (*bbvv*).

However, in our example, the offspring also include some gray-bodied, vestigial-winged flies and some black-bodied, normal-winged flies. These are recombinant flies, having received a recombinant-type gamete from the heterozygous F_1 parent. Each recombinant-type gamete arose by **crossing-over** between these loci in a meiotic cell of a heterozygous female fly. (Fruit flies are unusual in that crossing-over occurs only in females and not in males; it is far more common for crossing-over to occur in both sexes of a species.) When chromosomes pair and undergo synapsis, crossing-over occurs as homologous (nonsister) chromatids exchange segments of chromosome material by a process of breakage and rejoining catalyzed by enzymes (**FIG. 11-12**). Also see the discussion of prophase I in Chapter 10, Section 10.4.

Calculating the frequency of crossing-over reveals the linear order of linked genes on a chromosome

In our fruit fly example (see Fig. 11-11), 391 of the offspring are recombinant types: gray flies with vestigial wings, *Bbvv* (206 of the total); and black flies with normal wings, *bbVv* (185 of the total). The remaining 1909 offspring are parental types. These data can be used to calculate the percentage of crossing-over between the loci (**TABLE 11-3**). You do this by adding the number of individuals in the two recombinant types of offspring, dividing by the *total number of offspring*, and multiplying by 100: $391 \div 2300 = 0.17$; $0.17 \times 100 = 17\%$. Thus, the *V* locus and the *B* locus have 17% recombination between them.

During a single meiotic division, crossing-over may occur at several different points along the length of each homologous chromosome pair. In general, crossing-over is more likely to occur between two loci if they lie far apart on the chromosome and less likely to occur if they lie close together. Because of this rough correlation between the frequency of recombination of two loci and the linear distance between them, a genetic map of the chromosome can be generated by converting the percentage of recombination to **map units.** By convention, 1% recombination between two loci equals a distance of 1 map unit, so the loci in our example are 17 map units apart.

TABLE 11-3 How to Determine Recombination Frequency from a Two-Point Test Cross

	Test-Cross Results (from Fig. 11-11)			
Type of Offspring	Parental Type		Recombinant Type	
Phenotype	Gray, normal	Black, vestigial	Gray, vestigial	Black, normal
Genotype	*BbVv*	*bbvv*	*Bbvv*	*bbVv*
Number of offspring	965	944	206	185
Calculations of recombination frequency	1. Number of parental-type offspring = 1909 2. Number of recombinant-type offspring = 391 3. Total number of offspring = 1909 + 391 = 2300 4. Recombination frequency = 391/2300 × 100 = 17%			

www.konkur.in

KEY POINT The exchange of segments between chromatids of homologous chromosomes is the mechanism of recombination of linked genes.

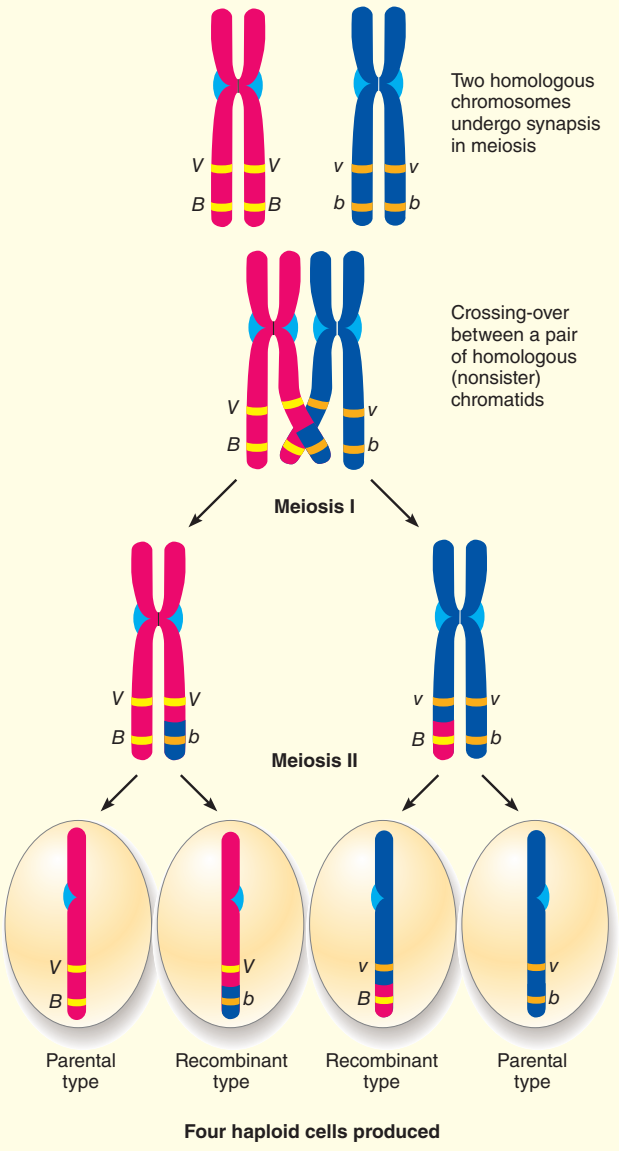

FIGURE 11-12 ***Animated*** Crossing-over

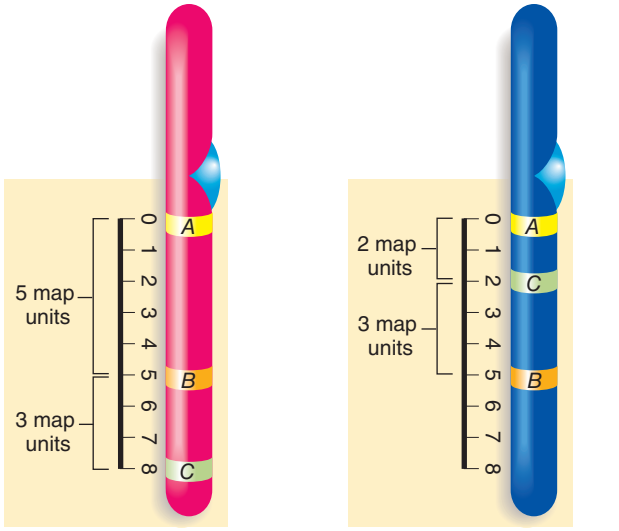
Genes located far apart on a chromosome have a greater probability of being separated by crossing-over than do genes that are closer together.



(a) If the recombination between *A* and *C* is 8% (8 map units), then *B* must be in the middle.

(b) If the recombination between *A* and *C* is 2%, then *C* must be in the middle.

FIGURE 11-13 Gene mapping

Gene order (that is, which locus lies between the other two) is determined by the percentage of recombination between each of the possible pairs. In this hypothetical example, the percentage of recombination between locus *A* and locus *B* is 5% (corresponding to 5 map units) and that between *B* and *C* is 3% (3 map units). There are two alternatives for the linear order of these alleles.

Scientists have determined the frequencies of recombination between specific linked loci in many species. All the experimental results are consistent with the hypothesis that genes are present in a linear order in the chromosomes. **FIGURE 11-13** illustrates the traditional method for determining the linear order of genes in a chromosome.

By putting together the results of numerous crosses, scientists have developed detailed linkage maps for many eukaryotes, including the fruit fly, the mouse, yeast, *Neurospora* (a fungus), and many plants, especially those that are important crops. In addition, researchers have used genetic methods to develop a detailed map for *Escherichia coli,* a bacterium with a single, circular DNA molecule, and many other prokaryotes and viruses. They have made much more sophisticated maps of chromosomes of various species by means of recombinant DNA technology (discussed in Chapter 15). Using these techniques, the *Human Genome Project* has produced detailed maps of human chromosomes (discussed in Chapter 16).

Sex is generally determined by sex chromosomes

In some species, environmental factors exert a large control over an individual's sex. However, genes are the most important sex determinants in most eukaryotic organisms. The major sex-determining genes of mammals, birds, and many insects are carried by **sex chromosomes.** Typically, members of one sex have a pair of similar sex chromosomes and produce gametes that are all identical in sex chromosome constitution. The members of the other sex have two different sex chromosomes and produce two kinds of gametes, each bearing a single kind of sex chromosome.

The cells of female mammals, including humans, contain two **X chromosomes.** In contrast, the males have a single X chromosome and a smaller **Y chromosome** that bears only a few active genes (**FIG. 11-14**). For example, human females have 22 pairs of **autosomes,** which are chromosomes other than the sex chromosomes, plus a pair of X chromosomes; males have 22 pairs of autosomes plus one X chromosome and one Y chromosome. Domestic

www.konkur.in

FIGURE 11-14 SEM of human Y chromosome (left) and X chromosome (right)

Each chromosome is in the duplicated state and consists of two identical chromatids.

cats have 19 pairs of autosomes, to which are added a pair of X chromosomes in females, or an X plus a Y in males. In contrast, sex determination is based on different chromosome systems in animals other than mammals (**TABLE 11-4**).

The Y chromosome determines male sex in most species of mammals

Do male humans have a male phenotype because they have only one X chromosome, or because they have a Y chromosome? Much of the traditional evidence bearing on this question comes from studies of people with abnormal sex chromosome constitutions (see discussion in Chapter 16). A person with an XXY constitution is a nearly normal male in external appearance, although his testes are underdeveloped (Klinefelter syndrome). A person with one X but no Y chromosome has the overall appearance of a female but has defects such as short stature and undeveloped ovaries (Turner syndrome). An embryo with a Y but no X does not survive. Based on these and other observations, biologists concluded that all individuals require at least one X, and the Y is the male-determining chromosome.

Geneticists have identified several genes on the Y chromosome that are involved in determination of the male sex. The *sex reversal on Y (SRY) gene,* the major male-determining gene on the Y chromosome, acts as a "genetic switch" that causes testes to develop in the fetus. The developing testes then secrete the hormone *testosterone,* which causes other male characteristics to develop. Several other genes on the Y chromosome also play a role in sex determination, as do many genes on the X chromosome, which explains why an XXY individual does not have a completely normal male phenotype. Some genes on the autosomes also affect sex development.

Evidence suggests that the X and Y chromosomes of mammals originated as a homologous pair of autosomes. During the evolution of the X and Y chromosomes, almost all of the original functional genes were retained on the X chromosome and lost from the Y chromosome. Today, about 95% of the Y chromosome is male-specific. Either the Y chromosome retained certain genes that coded for proteins that determine maleness, or perhaps mutations occurred in existing genes on the Y chromosome that made it the male-determining chromosome.

Thus, the sex chromosomes are not truly homologous in their present forms because they are not similar in size, shape, or genetic constitution. Nevertheless, the Y chromosome has short, homologous "pairing regions" at its tips that lets it synapse and exchange genetic material with the X chromosome during meiosis.

Half the sperm contain an X chromosome, and half contain a Y chromosome. All normal eggs bear a single X chromosome. Fertilization of an X-bearing egg by an X-bearing sperm results in an XX (female) zygote, or fertilized egg; fertilization by a Y-bearing sperm results in an XY (male) zygote.

You might expect to have equal numbers of X- and Y-bearing sperm and a 1:1 ratio of females to males. However, in humans

TABLE 11-4 Representative Examples of Sex Determination in Animals

X-Y system Mammals, including humans	**X-O system** Certain insects	**Z-W system** Birds, fishes, and some insects	**Haplo-diploid system** Most bees and ants
Male XY Occurs when sperm cell contains a Y chromosome	**Male XO** Occurs when sperm cell contains no sex chromosome	**Male ZW** Occurs when an egg cell contains a W chromosome	**Male Haploid** No sex chromosomes; male develops from unfertilized egg
Female XX Occurs when sperm cell contains an X chromosome	**Female XX** Occurs when sperm cell contains an X chromosome	**Female ZZ** Occurs when an egg cell contains a Z chromosome	**Female Diploid** No sex chromosomes; female develops from fertilized egg

www.konkur.in

more males are conceived than females, and more males die before birth. Even at birth the ratio is not 1:1; about 106 boys are born for every 100 girls. The Y-bearing sperm appear to have a selective advantage, possibly because sperm containing the Y chromosome are smaller and have less mass than sperm containing the X chromosome; it is hypothesized that, on average, the sperm carrying the Y chromosome can swim slightly faster than X-bearing sperm to reach the egg.

X-linked genes have unusual inheritance patterns

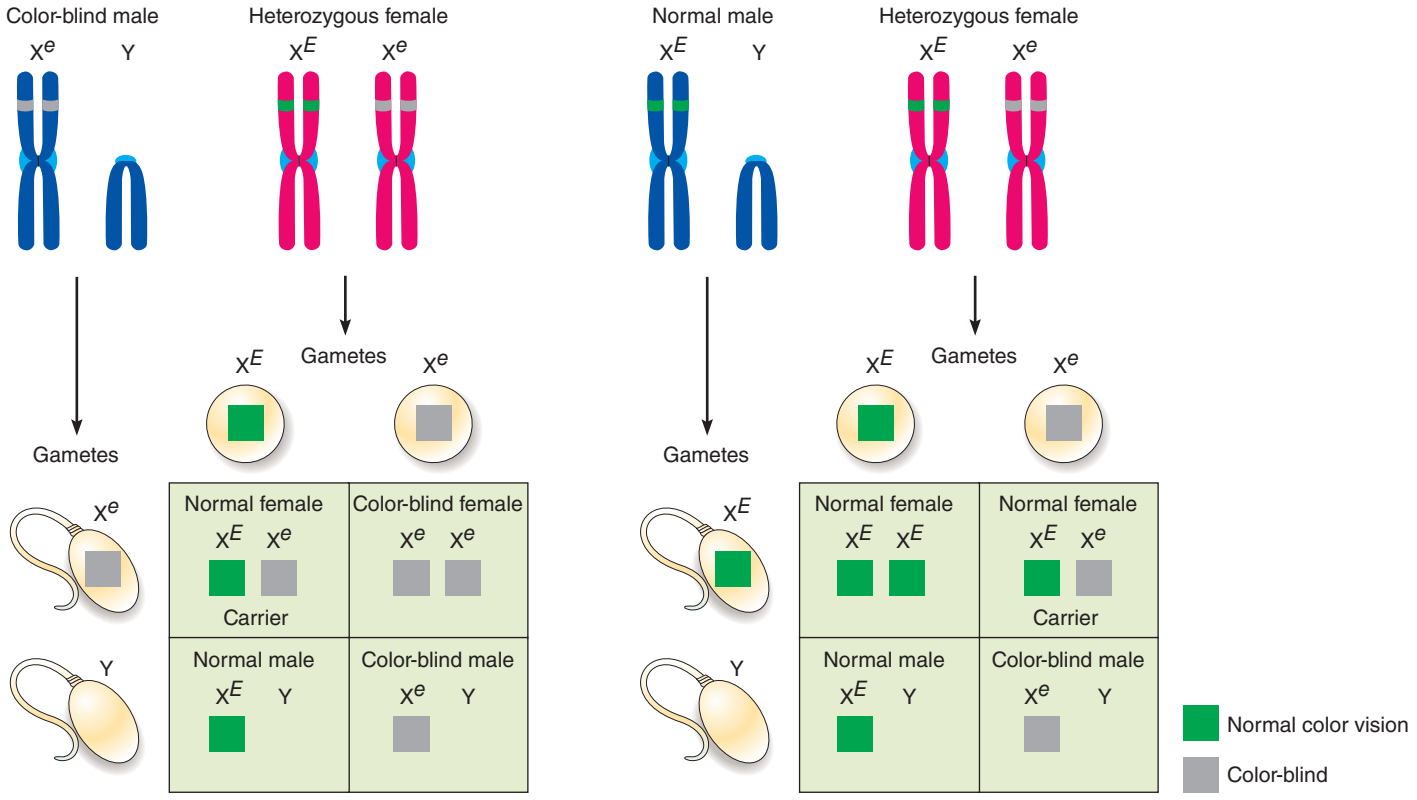
The human X chromosome contains many loci that are required in both sexes. Genes located in the X chromosome, such as those governing color perception and blood clotting, are sometimes called *sex-linked genes.* It is more appropriate, however, to refer to them as **X-linked genes** because they follow the transmission pattern of the X chromosome and, strictly speaking, are not linked to the sex of the organism.

A female receives one X from her mother and one X from her father. A male receives his Y chromosome, which makes him male, from his father. From his mother he inherits a single X chromosome and therefore all his X-linked genes. In the male, every allele present on the X chromosome is expressed, whether that allele was dominant or recessive in the female parent.

A male is neither homozygous nor heterozygous for his X-linked alleles; instead, he is always **hemizygous**—that is, he has only one copy of each X-linked gene. The significance of hemizygosity in males, including human males, is that rare, recessive X-linked genes are expressed, making males more likely to be affected by the many genetic disorders associated with the X chromosome. In comparison only a few genes are located exclusively on the Y chromosome. X and Y chromosomes also have short areas where they carry the same genes, enabling the X and Y to pair during meiosis I.

We will use a simple system of notation for problems involving X linkage, indicating the X chromosome and incorporating specific alleles as superscripts. For example, the symbol X^e signifies a recessive X-linked allele for color blindness and X^E the dominant X-linked allele for normal color vision. The Y chromosome is written without superscripts because it does not carry the locus of interest. Two recessive X-linked alleles must be present in a female for the abnormal phenotype to be expressed (X^eX^e), whereas in the hemizygous male a single recessive allele (X^eY) causes the abnormal phenotype. As a consequence, these abnormal alleles are much more frequently expressed in male offspring. A heterozygous female may be a *carrier,* an individual who possesses one copy of a mutant recessive allele but does not express it in the phenotype (X^EX^e).

To be expressed in a female, a recessive X-linked allele must be inherited from both parents. A color-blind female, for example, must have a color-blind father and a mother who is homozygous or heterozygous for a recessive allele for color blindness (**FIG. 11-15**).



(a) To be color-blind, a female must inherit alleles for color blindness from both parents.

(b) If a normal male mates with a carrier (heterozygous) female, half of their sons would be expected to be color-blind and half of their daughters would be expected to be carriers.

FIGURE 11-15 ***Animated*** **X-linked red–green color blindness**
Note that the Y chromosome does not carry a gene for color vision.

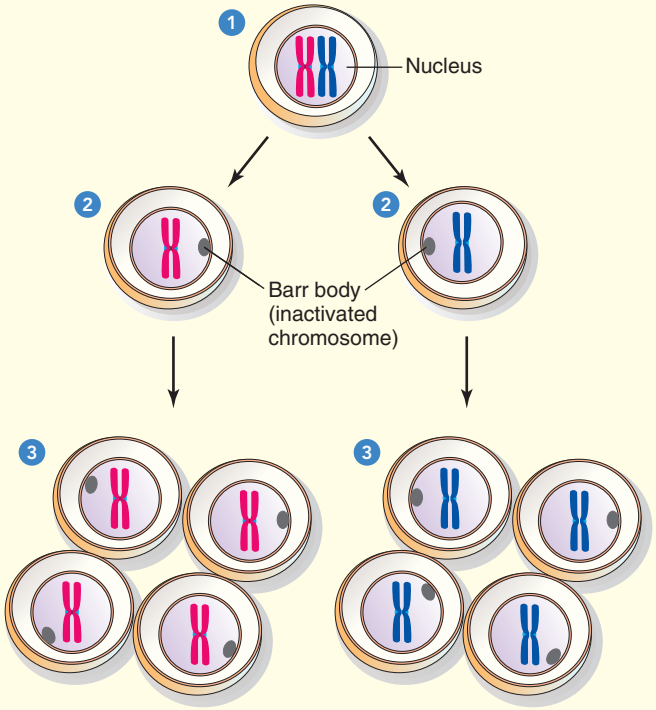
www.konkur.in

The homozygous combination is unusual because the frequency of alleles for color blindness is relatively low. In contrast, a color-blind male need only have a mother who is heterozygous for color blindness; his father can have normal vision. Therefore, X-linked recessive traits are generally much more common in males than in females, a fact that may partially explain why human male embryos are more likely to die.

Dosage compensation equalizes the expression of X-linked genes in males and females

The X chromosome contains numerous genes required by both sexes, yet a normal female has two copies ("doses") for each locus, whereas a normal male has only one. **Dosage compensation** is a mechanism that makes equivalent the two doses in the female and the single dose in the male. Because of dosage compensation,

KEY POINT **In female mammals, one of the two X chromosomes is randomly inactivated during early development, equalizing the level of expression of genes at loci on the X chromosome in males and females.**



1 The zygote and early embryonic cells have two X chromosomes, one from each parent.

2 Random inactivation of one X chromosome occurs early in development. Roughly half the cells inactivate one X chromosome (*left cell*), and the other half inactivate the second X chromosome (*right cell*). The inactive X chromosome is visible as a Barr body near the nuclear envelope.

3 Chromosome inactivation persists through subsequent mitotic divisions, resulting in patches of cells in the adult body.

(a) Inactivation of one X chromosome in female cells.

Eunice Percy/Animals Animals

(b) Persian calico cat. A calico cat has X-linked genes for both black and yellow (or orange) fur. Because of random X chromosome inactivation, black is expressed in some groups of cells and orange is expressed in others. (The patches of white fur are due to the presence of other genes that affect fur color.)

FIGURE 11-16 ***Animated*** Dosage compensation in female mammals

www.konkur.in

males and females produce the same amounts of proteins coded by X-linked genes. Male fruit flies accomplish this by making their single X chromosome more active. In most fly tissues, the metabolic activity of a single male X chromosome is equal to the combined metabolic activity of the two X chromosomes present in the female.

Our understanding of dosage compensation in humans and other mammals is incomplete, but the process generally involves the random inactivation of one of the two X chromosomes in the female (**FIG. 11-16a**). During interphase, a dark spot of chromatin is visible at the edge of the nucleus of each female mammalian cell when stained and observed with a microscope. This dark spot, a **Barr body,** is a dense, metabolically inactive X chromosome. The other X chromosome resembles the metabolically active autosomes; during interphase, it is a greatly extended thread that is not evident in light microscopy. From this and other evidence, the British geneticist Mary Lyon hypothesized in 1961 that in most cells of a female mammal, only one of the two X chromosomes is active; the other is inactive and is condensed as a Barr body. Actually, however, X chromosome inactivation is never complete; as many as 25% of the genes on the inactive chromosome are expressed to some degree.

X chromosome inactivation is a random event in each somatic (body) cell of the female embryo. A female mammal that is heterozygous at an X-linked locus expresses one of the alleles in about half her cells, and the other allele in the other half. X chromosome inactivation is sometimes evident in the phenotype. Mice and cats have several X-linked genes for certain coat colors. Females that are heterozygous for such genes may show patches of one coat color in the middle of areas of the other coat color. This phenomenon, termed **variegation,** is evident in tortoiseshell and calico cats (**FIG. 11-16b**). Early in development, when relatively few cells are present, X chromosome inactivation occurs randomly in each cell. X inactivation is then maintained during all subsequent divisions of that cell line. When any one of these cells divides by mitosis, the cells of the resulting *clone* (a group of genetically identical cells) all have the same active X chromosome, and therefore a patch develops of cells that all express the same color.

You might wonder why variegation is not always apparent in females heterozygous at X-linked loci. The answer is that, although variegation usually occurs, we may need to use special techniques to observe it. For example, color blindness is caused by a defect involving the pigments in the cone cells in the retina of the eye. In at least one type of red–green color blindness, the retina of a heterozygous female actually contains patches of abnormal cones, but the patches of normal cones are enough to provide normal color vision. Variegation can be very hard to observe in cases where cell products become mixed in bodily fluids. For instance, in females heterozygous for the allele that causes hemophilia, only half the cells responsible for producing a specific blood-clotting factor do so, but they produce enough to ensure that the blood clots normally.

11.4 EXTENSIONS OF MENDELIAN GENETICS

LEARNING OBJECTIVES

9 Explain some of the ways genes may interact to affect the phenotype; discuss how a single gene can affect many features of the organism simultaneously.

10 Distinguish among incomplete dominance, codominance, multiple alleles, epistasis, and polygenic inheritance.

11 Describe *norm of reaction* and give an example.

The relationship between a given locus and the trait it controls may or may not be simple. A single pair of alleles of a locus may regulate the appearance of a single trait (such as tall versus short in garden peas). Alternatively, a pair of alleles may participate in the control of several traits, or alleles of many loci may interact to affect the phenotypic expression of a single character. Not surprisingly, these more complex relationships are quite common.

You can assess the phenotype on one or many levels. It may be a morphological trait, such as shape, size, or color. It may be a physiological trait or even a biochemical trait, such as the presence or absence of a specific enzyme required for the metabolism of some specific molecule. In addition, changes in the environmental conditions under which the organism develops may alter the phenotypic expression of genes.

Dominance is not always complete

Studies of the inheritance of many traits in a wide variety of organisms have shown that one member of a pair of alleles may not be completely dominant over the other. In such instances, it is inaccurate to use the terms *dominant* and *recessive.*

The plants commonly called four o'clocks (*Mirabilis jalapa*) may have red or white flowers. Each color breeds true when these plants are self-pollinated. What flower color might you expect in the offspring of a cross between a red-flowering plant and a white-flowering one? Without knowing which is dominant, you might predict that all would have red flowers or all would have white flowers. German botanist Carl Correns, one of the rediscoverers of Mendel's work, first performed this cross and found that all F_1 offspring have pink flowers!

Does this result in any way indicate that the principles of inheritance that Mendel deduced are wrong? Did the parental traits blend inseparably in the offspring? Quite the contrary, for when two of these pink-flowered plants are crossed, red-flowered, pink-flowered, and white-flowered offspring appear in a ratio of 1:2:1 (**FIG. 11-17**). In this instance, as in all other aspects of the scientific process, results that differ from those hypothesized prompt scientists to re-examine and modify their hypotheses to account for the exceptional results. The pink-flowered plants are clearly the heterozygous individuals, and neither the red allele nor the white

www.konkur.in

KEY POINT In incomplete dominance, an F_1 heterozygote has a phenotype intermediate between its parents.

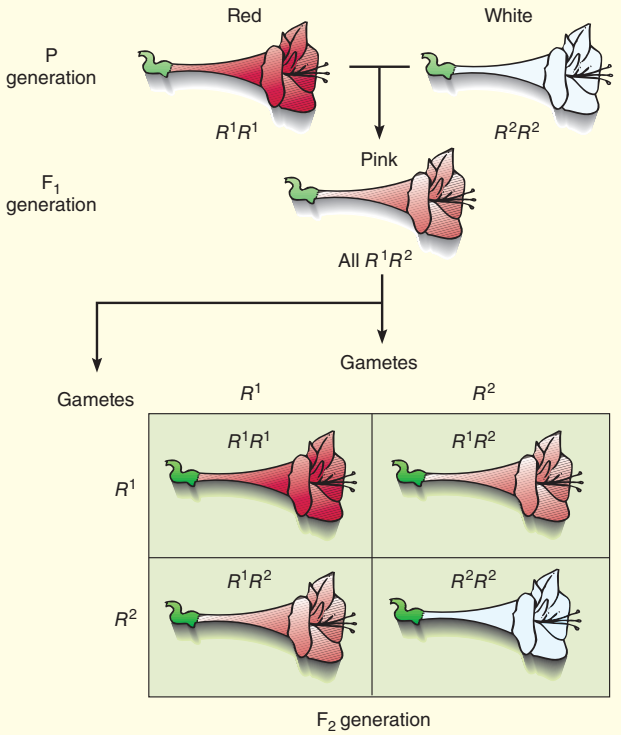

FIGURE 11-17 ***Animated*** **Incomplete dominance in four o'clocks**

Two incompletely dominant alleles, R^1 and R^2, are responsible for red, white, and pink flower colors. Red-flowered plants are R^1R^1, white-flowered plants are R^2R^2, and heterozygotes (R^1R^2) are pink. Note that uppercase letters are used for both alleles because neither is recessive to the other.

allele is completely dominant. When the heterozygote has a phenotype intermediate between those of its two parents, the genes show **incomplete dominance.** In these crosses, the genotypic and phenotypic ratios are identical.

Incomplete dominance is not unique to four o'clocks, and additional examples of incomplete dominance are known in both plants and animals. For example, true-breeding white chickens and true-breeding black chickens produce bluish gray offspring, or Andalusian blues, when crossed.

In both cattle and horses, reddish coat color is not completely dominant to white coat color. Heterozygous individuals have a mixture of reddish hairs and white hairs, which is called *roan.* If you saw a white mare nursing a roan foal, what would you guess was the coat color of the foal's father? Because the reddish and white colors are expressed independently (hair by hair) in the roan heterozygote, scientists sometimes refer to this as a case of **codominance.** Strictly speaking, the term *incomplete dominance* refers to instances in which the heterozygote is intermediate in phenotype, and *codominance* refers to instances in which the heterozygote simultaneously expresses the phenotypes of both types of homozygotes.

TABLE 11-5 ABO Blood Types

Phenotype (blood type)	Genotype	Surface Antigen on RBC	Serum Antibodies to A or B Antigens
A	I^AI^A or I^Ai	A	Anti-B
B	I^BI^B or I^Bi	B	Anti-A
AB	I^AI^B	A, B	None
O	ii	None	Anti-A, anti-B

*This table and the discussion of the ABO system have been simplified somewhat. Note that the body produces antibodies against the antigens *lacking* on its own red blood cells (RBCs). Because of their specificity for the corresponding antigens, these antibodies are used in standard tests to determine blood types.

Humans have four blood types (A, B, AB, and O), collectively called the **ABO blood group.** The human ABO blood group is an excellent example of codominant alleles. Blood types A, B, AB, and O are controlled by three alleles representing a single locus (**TABLE 11-5**). Allele I^A codes for the synthesis of a specific glycoprotein, antigen A, which is expressed on the surface of red blood cells. (Immune responses are discussed in Chapter 45.) *Antigens* are substances capable of stimulating an immune response. Allele I^B leads to the production of antigen *B,* a different but related glycoprotein. Allele i is allelic to I^A and I^B, but it does not code for an antigen.

Individuals with the genotype I^AI^A or I^Ai have blood type A. People with genotype I^BI^B or I^Bi have blood type B. Those with genotype I^AI^B have blood type AB, whereas those with genotype ii have blood type O. These results show that neither allele I^A nor allele I^B is dominant to the other. Both alleles are expressed phenotypically in the heterozygote and are therefore codominant to each other, although each is dominant to allele i.

At one time, determining blood types was used to settle cases of disputed parentage. Although blood-type tests can *exclude* someone as a possible parent of a particular child, they can never prove a certain person is the parent; they only determine he or she *could* be. Could a man with blood type AB be the father of a child with blood type O? Could a woman with blood type O be the mother of a child with blood type AB? Could a type B child with a type A mother have a type A father or a type O father?[3]

Multiple alleles for a locus may exist in a population

Most of our examples so far have dealt with situations in which each locus was represented by a maximum of two allelic variants (three in the example of blood types). It is true that a single diploid individual has a maximum of two different alleles for a particular locus and that a haploid gamete has only one allele for each locus. However, if you survey a population, you may find more than two alleles for a particular locus, as you saw with the ABO blood group (see Table 11-5). If three or more alleles for a given locus exist within the population, that locus has **multiple alleles.**

Research has shown that many loci have multiple alleles. Some alleles can be identified by the activity of a certain enzyme or by

[3]The answer to all these questions is no.

www.konkur.in

some other biochemical feature but do not produce an obvious phenotype. Others produce a readily recognizable phenotype, and certain patterns of dominance can be discerned when the alleles are combined in various ways. In other series of multiple alleles, certain alleles may be codominant and others incompletely dominant. In such cases, the heterozygotes commonly have phenotypes intermediate between those of their parents.

A single gene may affect multiple aspects of the phenotype

In our examples, the relationship between a gene and its phenotype has been direct, precise, and exact, and the loci have controlled the appearance of single traits. However, the relationship of gene to trait may not have such a simple genetic basis. Most genes affect several different characters. The ability of a single gene to have multiple effects is known as **pleiotropy.** Most cases of pleiotropy can be traced to a single fundamental cause. For example, a defective enzyme may affect the functioning of many types of cells. Pleiotropy is evident in many genetic diseases in which a single pair of alleles causes multiple symptoms. For example, people who are homozygous for the recessive allele that causes cystic fibrosis produce abnormally thick mucus in many parts of the body, including the respiratory, digestive, and reproductive systems (cystic fibrosis is discussed in Chapter 16).

Alleles of different loci may interact to produce a phenotype

Several pairs of alleles may interact to affect a single phenotype, or one pair may inhibit or reverse the effect of another pair. One example of gene interaction is illustrated by the inheritance of combs in chickens, where two genes may interact to produce a novel phenotype (**FIG. 11-18**). The allele for a rose comb, *R,* is dominant to that for a single comb, *r.* A second, unlinked pair of alleles governs the inheritance of a pea comb, *P,* versus a single comb, *p.* A single-comb chicken is homozygous for the recessive allele at both loci (*pprr*). A rose comb chicken is either *ppRR* or *ppRr,* and a pea comb chicken is either *PPrr* or *Pprr.* When an *R* and *P* occur in the same individual, the phenotype is neither pea nor rose comb but a completely different type, a walnut comb. The walnut comb phenotype is produced whenever a chicken has one or two *R* alleles, plus one or two *P* alleles (that is, *PPRR, PpRR, PPRr,* or *PpRr*). What would you hypothesize about the types of combs among the offspring of two heterozygous walnut comb chickens, *PpRr*? How does this form of gene interaction affect the ratio of phenotypes in the F_2 generation? Is it the typical Mendelian 9:3:3:1 ratio?[4]

Epistasis is a common type of gene interaction in which the presence of certain alleles of one locus can prevent or mask the expression of alleles of a different locus and express their own phenotype instead. (The term *epistasis* means "standing on.") Unlike the chicken example, no novel phenotypes are produced in epistasis.

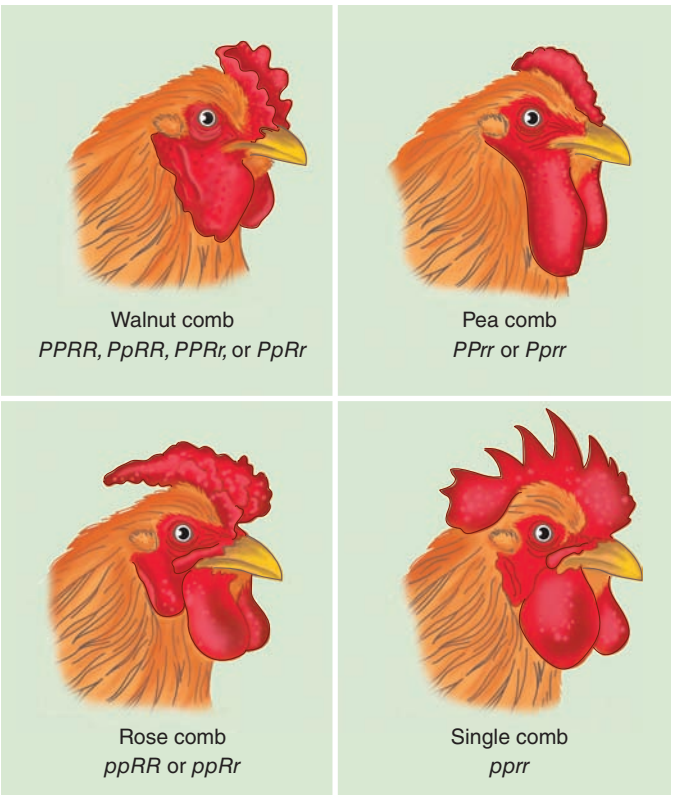

FIGURE 11-18 ***Animated*** **Gene interaction in chickens**
Two gene pairs govern four chicken comb phenotypes. Chickens with walnut combs have the genotype *P_R_*. Chickens with pea combs have the genotype *P_rr,* and those with rose combs have the genotype *ppR_*. Chickens that are homozygous recessive for both loci, *pprr,* have a single comb. (The blanks represent either dominant or recessive alleles.)

Coat color in Labrador retrievers is an example of epistasis that involves a gene for pigment and a gene for depositing color in the coat (**FIG. 11-19**). The two alleles for the pigment gene are *B* for black coat and its recessive counterpart, *b,* for brown coat. The gene for depositing color in the coat has two alleles, *E* for the expression of black and brown coats and *e,* which is epistatic and blocks the expression of the *B/b* gene. The epistatic allele is recessive and therefore is expressed as a yellow coat only in the homozygous condition (*ee*), regardless of the combination of *B* and *b* alleles in the genotype.

In polygenic inheritance, the offspring exhibit a continuous variation in phenotypes

Many human characters—such as height, body form, and skin pigmentation—are not inherited through alleles at a single locus. The same holds true for many commercially important characters in domestic plants and animals, such as milk and egg production. Alleles at several, perhaps many, loci affect each character. The term **polygenic inheritance** is applied when multiple independent pairs of genes have similar and additive effects on the same character.

As many as 60 loci account for the inheritance of skin pigmentation in humans. To keep things simple in this example, we

[4]The offspring of two heterozygous walnut comb chickens will have four genotypes in what appears to be a Mendelian 9:3:3:1 ratio: 9 walnut comb, 3 pea comb, 3 rose comb, and 1 single comb. This example is not a typical Mendelian 9:3:3:1 ratio because it involves a single character (comb shape) coded by alleles at two different loci. In Mendelian inheritance, the 9:3:3:1 ratio involves *two* characters (such as seed color and seed shape) coded by alleles at two loci.

Renee Stockdale/Animals Animals

FIGURE 11-19 ***Animated*** **Epistasis in Labrador retrievers**

Two gene pairs interact to govern coat color in Labrador retrievers. Black Labs have the genotype *B_E_*; yellow Labs have the genotype *B_ee* or *bbee*; and chocolate Labs have the genotype *bbE_*. (The blanks represent either dominant or recessive alleles.)

illustrate the principle of polygenic inheritance in human skin pigmentation with pairs of alleles at three unlinked loci. These can be designated *A* and *a*, *B* and *b*, and *C* and *c*. The capital letters represent incompletely dominant alleles producing dark skin. The more capital letters, the darker the skin because the alleles affect skin pigmentation in an additive fashion. A person with the darkest skin possible would have the genotype *AABBCC*, and a person with the lightest skin possible would have the genotype *aabbcc*. The F_1 offspring of an *aabbcc* person and an *AABBCC* person are all *AaBbCc* and have an intermediate skin color. The F_2 offspring of two such triple heterozygotes (*AaBbCc* × *AaBbCc*) would have skin pigmentation ranging from very dark to very light (**FIG. 11-20**).

Polygenic inheritance is characterized by an F_1 generation that is intermediate between the two completely homozygous parents and by an F_2 generation that shows wide variation between the two parental types. When the number of individuals in a population is plotted against the amount of skin pigmentation and the points are connected, the result is a bell-shaped curve, a *normal distribution curve*. Most of the F_2 generation individuals have one of the intermediate phenotypes; only a few show the extreme phenotypes of the original P generation (that is, the grandparents). On average, only 1 of 64 is as dark as the very dark grandparent, and only 1 of 64 is as light as the very light grandparent. The alleles *A*, *B*, and *C* each produce about the same amount of darkening of the skin; hence, the genotypes *AaBbCc* , *AABbcc*, *AAbbCc*, *AaBBcc*, *aaBBCc*, *AabbCC*, and *aaBbCC* all produce similar intermediate phenotypes.

Genes interact with the environment to shape phenotype

Hydrangeas are shrubs grown for their attractive flowers. The color of certain hydrangea flowers ranges from blue to purple to pink depending on the level of aluminum in the soil before the flowers begin to develop. It is easy to manipulate the level of aluminum by adding alum or aluminum sulfate to the soil or by lowering the soil pH (in acidic soils, aluminum is more soluble). Under these conditions, hydrangea flowers are blue. In alkaline soils (made by adding limestone to the soil), aluminum is less soluble, and the flowers are pink (**FIG. 11-21**).

Another example of the effect of environment on gene expression involves Himalayan rabbits. The phenotype of these rabbits is white fur except for dark patches on the ears, nose, and paws. The local surface temperature of a rabbit's ears, nose, and paws is colder in the rabbit's natural environment, and this temperature difference causes the production of dark fur. If you raise rabbits with the Himalayan genotype at a warm temperature

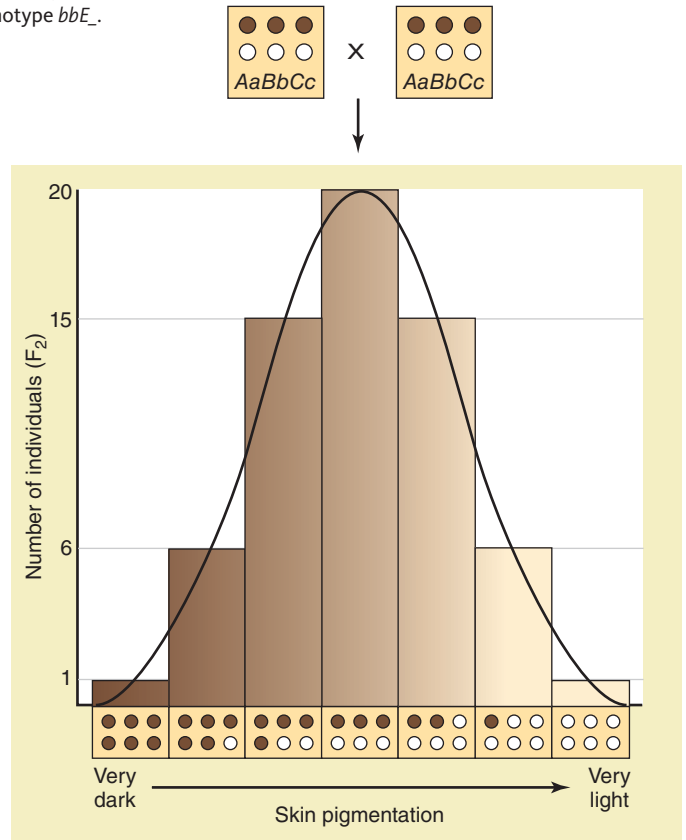

FIGURE 11-20 **Polygenic inheritance in human skin pigmentation**

This simplified example assumes that skin pigmentation in humans is governed by alleles of three unlinked loci. The alleles producing dark skin (*A*, *B*, and *C*) are represented by capital letters, but they are not dominant. Instead, their effects are additive. The number of dark dots, each signifying an allele producing dark skin, is counted to determine the phenotype. A wide range of phenotypes is possible when individuals of intermediate phenotype mate and have offspring (*AaBbCc* × *AaBbCc*). The expected distribution of phenotypes is consistent with the superimposed normal distribution curve.

www.konkur.in

© Wildscape/Alamy

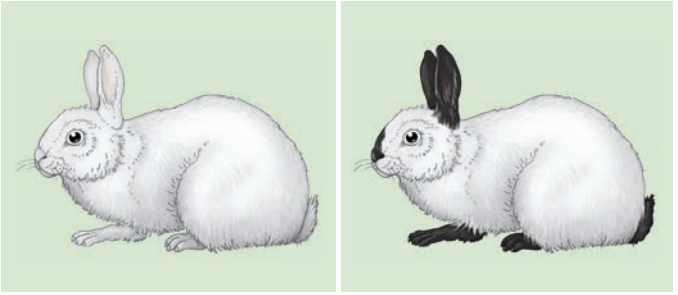
FIGURE 11-21 Influence of the environment on hydrangea flower color

Hydrangea flowers vary in color depending on availability of aluminum, which in turn is dependent on soil pH. Blue flowers develop in a soil pH of 5.5 or less, purple flowers in a soil pH of 5.6 to 6.4, and pink flowers in a soil pH of 6.5 to 7.0.

(30°C), the rabbits are completely white, with no dark patches on the ears, nose, or paws (**FIG. 11-22a**). If you raise Himalayan rabbits at a cooler temperature (25°C), however, they develop the characteristic dark patches of fur (**FIG. 11-22b**). Thus, genes can function differently in different environments.

Now let's examine a human example—height—in the context of genes and the environment. The inheritance of height in humans is polygenic and involves alleles representing ten or more loci. Because many genes are involved and because height is modified by a variety of environmental conditions, such as diet and general health, the height of most adults ranges from 4 ft 2 in (1.25 m) to 7 ft 2 in (2.15 m). The genes that affect height set limits for the phenotype—no human is 12 ft tall, for example—but the environment shapes the phenotype within its genetic limits. The range of phenotypic possibilities that can develop from a single genotype under different environmental conditions is known as the **norm of reaction.** In certain genotypes the norm of reaction is quite limited. In other genotypes, such as those involved in human height, the norm of reaction is quite broad.

Although interactions between genes and the environment influence the phenotypes of many characters, it is difficult to determine the exact contributions of genes and the environment to a given phenotype. In some cases the environment regulates the activity of certain genes, turning them on in some environmental conditions and off in others. Investigators argued for years about



(a) The Himalayan genotype at warm temperatures.

(b) The Himalayan genotype at cold temperatures.

FIGURE 11-22 *Animated* Influence of the environment on rabbit coat color

These rabbits have the same genotype for coat color, but have been exposed to different temperatures.

www.konkur.in

the relative importance of *nature* (genetics/biology) versus *nurture* (environmental influences) regarding such human characters as intelligence, depression, bipolar disorder, and schizophrenia. Studies with identical twins raised in different environments indicate that individuals may inherit genetic potential or vulnerabilities, but environmental conditions may influence the expression of the genotype. Thus, phenotypic expression depends on a combination of nature *and* nuture.

Review

- What is incomplete dominance? codominance?
- What is the difference between multiple alleles and polygenic inheritance?
- What is pleiotropy? epistasis?
- What is a norm of reaction?

SUMMARY: FOCUS ON LEARNING OBJECTIVES

11.1 *(page 238)*

1 Define the terms *phenotype, genotype, locus, allele, dominant allele, recessive allele, homozygous,* and *heterozygous.*

- **Genes** are in chromosomes; the site a gene occupies in the chromosome is its **locus.** Different forms of a particular gene are **alleles;** they occupy corresponding loci on homologous chromosomes.
- An individual that carries two identical alleles is **homozygous** for that locus. If the two alleles are different, that individual is **heterozygous** for that locus.
- One allele, the **dominant allele,** may mask the expression of the other allele, the **recessive allele,** in a heterozygous individual. For this reason two individuals with the same appearance, or **phenotype,** may differ from each other in their genetic makeup (that is, their combination of alleles), or **genotype.**

2 Describe Mendel's principles of segregation and independent assortment.

- According to Mendel's **principle of segregation,** during meiosis the alleles for each locus separate, or segregate, from each other. When haploid gametes are formed, each contains only one allele for each locus.
- According to Mendel's **principle of independent assortment,** alleles of different loci are distributed randomly into gametes. This can result in **genetic recombination,** the production of new allele combinations that were not present in the **parental (P) generation.**

CENGAGENOW™ Learn more about independent assortment by clicking on the figure in CengageNOW.

3 Distinguish among monohybrid, dihybrid, and test crosses.

- A cross between homozygous parents (P generation) that differ from each other with respect to their alleles at one locus is called a **monohybrid cross;** if they differ at two loci, it is called a **dihybrid cross.** The first generation of offspring, called the **F_1 generation,** is heterozygous; the generation produced by a cross of two F_1 individuals is the **F_2 generation.**
- A **test cross** between an individual of unknown genotype and a recessive individual helps determine the unknown genotype.

CENGAGENOW™ Learn more about monohybrid, dihybrid, and test crosses by clicking on the figures in CengageNOW.

4 Explain Mendel's principles of segregation and independent assortment, given what scientists now know about genes and chromosomes.

- Segregation of alleles is a direct result of homologous chromosomes separating during meiosis.
- Independent assortment occurs because there are two ways in which two pairs of homologous chromosomes can be arranged at metaphase I of meiosis. The orientation of homologous chromosomes on the metaphase plate determines the way chromosomes are distributed into haploid cells.

11.2 *(page 247)*

5 Apply the product rule and sum rule appropriately when predicting the outcomes of genetic crosses.

- According to the **product rule,** the probability of two independent events occurring together can be calculated by multiplying the probabilities of each event occurring separately.
- According to the **sum rule,** the probability of an outcome that can be obtained in more than one way can be calculated by adding the separate probabilities.

11.3 *(page 249)*

6 Define *linkage* and relate it to specific events in meiosis.

- **Linkage** is the tendency for a group of genes on the same chromosome to be inherited together. Independent assortment does not apply if two loci are linked close together on the same pair of homologous chromosomes.
- Recombination of linked genes can result from **crossing-over** (breaking and rejoining of homologous chromatids) in meiotic prophase I. (Recall from **Section 11.1** that recombination can also result from independent assortment of unlinked genes.)

7 Show how data from a test cross involving alleles of two loci can be used to distinguish between independent assortment and linkage.

- To distinguish between independent assortment of unlinked genes and linked genes, perform a **two-point test cross** between an individual that is heterozygous at both loci and an individual that is homozygous recessive for both.
- Linkage is recognized when an excess of parental-type offspring and a deficiency of recombinant-type offspring are produced in a two-point test cross.

8 Discuss the genetic determination of sex and the inheritance of X-linked genes in mammals.

- The sex of humans and other mammals is determined by the **X** and **Y chromosomes.** Normal female mammals have two X chromosomes; normal males have one X and one Y. The fertilization of an X-bearing egg by an X-bearing sperm results in a female (XX) zygote. The fertilization of an X-bearing egg by a Y-bearing sperm results in a male (XY) zygote.
- The Y chromosome determines male sex in mammals. The X chromosome contains many important genes unrelated to sex determination that are required by both males and females. A male receives all his **X-linked genes** from his mother. A female receives X-linked genes from both parents.

www.konkur.in

11.4 *(page 255)*

9 Explain some of the ways genes may interact to affect the phenotype; discuss how a single gene can affect many features of the organism simultaneously.

- **Pleiotropy** is the ability of one gene to have several effects on different characters. Most cases of pleiotropy can be traced to a single cause, such as a defective enzyme. Alternatively, alleles of many loci may interact to affect the phenotypic expression of a single character.

10 Distinguish among incomplete dominance, codominance, multiple alleles, epistasis, and polygenic inheritance.

- Dominance does not always apply; some alleles demonstrate **incomplete dominance,** in which the heterozygote is intermediate in phenotype, or **codominance,** in which the heterozygote simultaneously expresses the phenotypes of both homozygotes.
- **Multiple alleles,** three or more alleles that can potentially occupy a particular locus, may exist in a population. A diploid individual has any two of the alleles; a haploid individual or gamete has only one.

- In **epistasis,** an allele of one locus can mask the expression of alleles of a different locus.
- In **polygenic inheritance,** multiple independent pairs of genes may have similar and additive effects on the phenotype.

11 Describe *norm of reaction* and give an example.

- The range of phenotypic possibilities that can develop from a single genotype under different environmental conditions is known as the **norm of reaction.**
- Many genes are involved in the inheritance of height in humans. Also, height is modified by a variety of environmental conditions, such as diet and general health. The genes that affect height set the norm of reaction—that is, the limits—for the phenotype, and the environment molds the phenotype within its norm of reaction.

TEST YOUR UNDERSTANDING

1. One of the autosomal loci controlling eye color in fruit flies has two alleles, one for brown eyes and the other for red eyes. Fruit flies from a true-breeding line with brown eyes were crossed with flies from a true-breeding line with red eyes. The F_1 flies had red eyes. What conclusion can be drawn from this experiment? (a) these alleles underwent independent assortment (b) these alleles underwent segregation (c) these genes are X-linked (d) the allele for red eyes is dominant to the allele for brown eyes (e) all of the preceding are true
2. The F_1 flies described in question 1 were mated with brown-eyed flies from a true-breeding line. What phenotypes would you expect the offspring to have? (a) all red eyes (b) all brown eyes (c) half red eyes and half brown eyes (d) red-eyed females and brown-eyed males (e) brown-eyed females and red-eyed males
3. The type of cross described in question 2 is (a) an F_2 cross (b) a dihybrid cross (c) a test cross (d) a two-point test cross (e) none of these
4. Individuals of genotype *AaBb* were crossed with *aabb* individuals. Approximately equal numbers of the following classes of offspring were produced: *AaBb, Aabb, aaBb,* and *aabb.* These results illustrate Mendel's principle(s) of (a) linkage (b) independent assortment (c) segregation (d) a and c (e) b and c
5. Assume that the ratio of females to males is 1:1. A couple already has two daughters and no sons. If they plan to have a total of six children, what is the probability they will have four more girls? (a) $\frac{1}{4}$ (b) $\frac{1}{8}$ (c) $\frac{1}{16}$ (d) $\frac{1}{32}$ (e) $\frac{1}{64}$
6. Red–green color blindness is an X-linked recessive disorder in humans. Your friend is the daughter of a color-blind father. Her mother had normal color vision, but her maternal grandfather was color-blind. What is the probability your friend is color-blind? (a) 1 (b) $\frac{1}{2}$ (c) $\frac{1}{4}$ (d) $\frac{3}{4}$ (e) 0
7. When two long-winged flies were mated, the offspring included 77 with long wings and 24 with short wings. Is the short-winged condition dominant or recessive? What are the genotypes of the parents?
8. The long hair of Persian cats is recessive to the short hair of Siamese cats, but the black coat color of Persians is dominant to the brown-and-tan coat color of Siamese. Make up appropriate symbols for the alleles of these two unlinked loci. If a pure black, long-haired Persian is mated to a pure brown-and-tan, short-haired Siamese, what will be the appearance of the F_1 offspring? If two of these F_1 cats are mated, what is the chance that a long-haired, brown-and-tan cat will be produced in the F_2 generation? (Use the shortcut probability method to obtain your answer; then, check it with a Punnett square.)
9. Mr. and Mrs. Smith are concerned because their own blood types are A and B, respectively, but their new son, Richard, is blood type O. Could Richard be the child of these parents?
10. A walnut comb rooster is mated to three hens. Hen A, which has a walnut comb, has offspring in the ratio of 3 walnut to 1 rose. Hen B, which has a pea comb, has offspring in the ratio of 3 walnut to 3 pea to 1 rose to 1 single. Hen C, which has a walnut comb, has only walnut comb offspring. What are the genotypes of the rooster and the three hens?
11. Individuals of genotype *AaBb* were mated to individuals of genotype *aabb.* One thousand offspring were counted, with the following results: 474 *Aabb,* 480 *aaBb,* 20 *AaBb,* and 26 *aabb.* What type of cross is this? Are these loci linked? What are the two parental classes and the two recombinant classes of offspring? What is the percentage of recombination between these two loci? How many map units apart are they?
12. Genes *A* and *B* are 6 map units apart, and *A* and *C* are 4 map units apart. Which gene is in the middle if *B* and *C* are 10 map units apart? Which is in the middle if *B* and *C* are 2 map units apart?

www.konkur.in

CRITICAL THINKING

1. Sketch a series of diagrams showing each of the following, making sure to end each series with haploid gametes:
   (a) How a pair of alleles for a single locus segregate in meiosis
   (b) How the alleles of two unlinked loci assort independently in meiosis
   (c) How the alleles of two linked loci undergo genetic recombination
2. Can you always ascertain an organism's genotype for a particular locus if you know its phenotype? Conversely, if you are given an organism's genotype for a locus, can you always reliably predict its phenotype? Explain.
3. Compare the mechanisms of genetic recombination in linked and unlinked genes.
4. **EVOLUTION LINK.** Darwin's theory of evolution by natural selection is based on four observations about the natural world. One of these is that each individual has a combination of traits that makes it uniquely different. Darwin recognized that much of this variation among individuals must be inherited, but he did not know about Mendel's mechanism of inheritance. Based on what you have learned in this chapter, briefly explain the variation among individuals that Darwin observed.
5. **ANALYZING DATA.** Using the graph in Figure 11-20, determine how many offspring were involved in the hypothetical cross studying skin color. What percentage had the lightest skin possible? the darkest skin?
6. **ANALYZING DATA.** The following figure shows a cross between a homozygous black and a homozygous yellow Labrador retriever. What is the phenotype of the F_1 generation? What are the phenotypes and the phenotypic ratio of the F_2 generation? Inheritance of coat color in Labrador retrievers is an example of what type of inheritance pattern?

12 DNA: The Carrier of Genetic Information

Dr. Gopal Murti/Visuals Unlimited

Electron micrograph of DNA replication. During replication, two DNA molecules are synthesized from the original parent molecule. Replication is occurring at the Y-shaped structure, which is called a *replication fork*.

KEY CONCEPTS

12.1 Starting in the 1920s, evidence began to accumulate that DNA is the hereditary material.

12.2 The DNA molecule consists of two strands that wrap around each other to form a double helix; the order of its building blocks provides for the storage of genetic information. The DNA building blocks consist of four different nucleotide subunits, designated T, C, A, and G. The pairing of nucleotide subunits occurs based on precise pairing rules: T pairs with A, and C pairs with G.

12.3 DNA replication, which results in two identical double-stranded DNA molecules, provides the molecular mechanism for passing genetic information from one generation to the next.

After the rediscovery of Mendel's principles in 1900, geneticists conducted experiments to learn how genes are arranged in chromosomes and how they are transmitted from generation to generation. However, basic questions remained unanswered through most of the first half of the 20th century: What are genes made of? How do genes work? The studies of inheritance patterns described in Chapter 11 did not answer these questions. However, they provided a foundation of knowledge that enabled scientists to make predictions about the molecular (chemical) nature of genes and how genes function.

Scientists generally agreed that genes would have to store information in a form that the cell could retrieve and use. But scientists also had to account for other properties of genes. For example, experiments on a variety of organisms had demonstrated that genes are usually stable and passed unchanged from generation to generation. However, occasionally a gene converted to a different form; such genetic changes, called *mutations,* were then transmitted unchanged to future generations.

www.konkur.in

As the science of genetics was developing, biochemists were making a growing effort to correlate the known properties of genes with the nature of various biological molecules. What kind of molecule could store information? How could that information be retrieved and used to direct cell functions? What kind of molecule could be relatively stable but have the capacity to change, resulting in a mutation, under certain conditions?

As they learned more about the central role of proteins in virtually every aspect of cell structure and metabolism, some scientists considered proteins the prime candidates for the genetic material. However, protein did not turn out to be the molecule that governs inheritance. In this chapter we discuss how researchers discovered that **deoxyribonucleic acid (DNA),** a nucleic acid once thought unremarkable, is the molecular basis of inheritance. We explore the unique features of DNA, including its structure and replication (see photograph), that enable it to carry out this role.

12.1 EVIDENCE OF DNA AS THE HEREDITARY MATERIAL

LEARNING OBJECTIVES

1 Summarize the evidence that accumulated during the 1940s and early 1950s demonstrating that DNA is the genetic material.

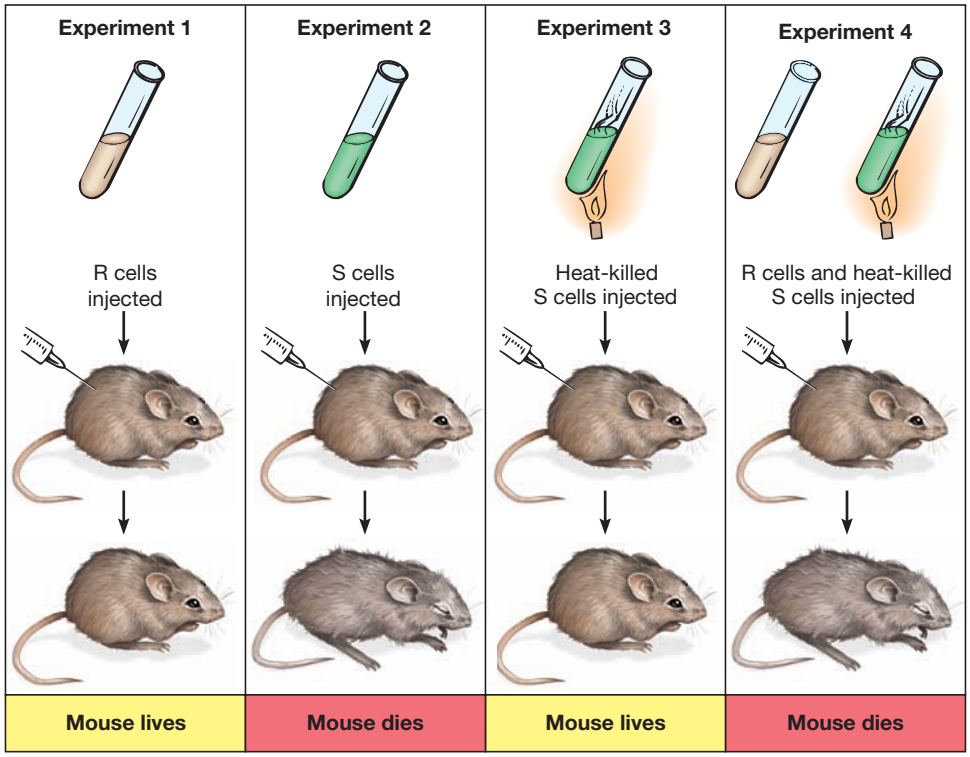
2 State the questions that these classic experiments addressed: Griffith's transformation experiment, Avery's contribution to Griffith's work, and the Hershey–Chase experiments.

KEY EXPERIMENTS

QUESTION: Can a genetic trait be transmitted from one bacterial strain to another?

HYPOTHESIS: The ability of pneumococcus bacteria to cause disease can be transmitted from the virulent strain (smooth, or S cells) to the avirulent strain (rough, or R cells).

EXPERIMENT: Griffith performed four experiments on mice, using the two strains of pneumococci: (1) injection of mice with live rough cells, (2) injection with live smooth cells, (3) injection with heat-killed smooth cells, and (4) injection with both live rough cells and heat-killed smooth cells.



RESULTS AND CONCLUSION: Although neither the rough strain nor the heat-killed smooth strain could kill a mouse, a combination of the two did. Autopsy of the dead mouse showed the presence of living S-strain pneumococci. These results indicated that some substance in the heat-killed S cells had transformed the living R cells into a virulent form.

FIGURE 12-1 *Animated* Griffith's transformation experiments

Griffith was trying to develop a vaccine against pneumonia when he serendipitously discovered the phenomenon of transformation.

During the 1930s and early 1940s, most geneticists paid little attention to DNA, convinced that the genetic material must be protein. Given the accumulating evidence that genes control production of proteins (discussed in Chapter 13), it certainly seemed likely that genes themselves must also be proteins. Scientists knew proteins consisted of more than 20 different kinds of amino acids in many different combinations, which conferred unique properties on each type of protein. Given their complexity and diversity compared with other molecules, proteins seemed to be the "stuff" of which genes are made.

In contrast, scientists had established that DNA and other nucleic acids were made of only four nucleotides, and what was known about their arrangement made them relatively uninteresting to most researchers. For this reason, several early clues to the role of DNA were not widely noticed.

DNA is the transforming principle in bacteria

One of these clues had its origin in 1928, when Frederick Griffith, a British medical officer, made a curious observation concerning two strains of pneumococcus bacteria (**FIG. 12-1**). A smooth (S) strain, named for its formation of smooth colonies on a solid growth medium, exhibited **virulence,**

www.konkur.in

the ability to cause disease, and often death, in its host. When living cells of this strain were injected into mice, the animals contracted pneumonia and died. Not surprisingly, the injected animals survived if the cells were first killed with heat. A related rough (R) strain of bacteria, which forms colonies with a rough surface, exhibited **avirulence,** or inability to produce pathogenic effects; mice injected with either living or heat-killed cells of this strain survived. However, when Griffith injected mice with a mixture of *heat-killed* virulent S cells and *live* avirulent R cells, a high proportion of the mice died. Griffith then isolated living S cells from the dead mice.

Because neither the heat-killed S strain nor the living R strain could be converted to the living virulent form when injected by itself in the control experiments, it seemed that something in the heat-killed cells converted the avirulent cells to the lethal form. This type of permanent genetic change in which the properties of one strain of dead cells are conferred on a different strain of living cells is called **transformation.** Scientists hypothesized that some chemical substance (a *transforming principle,* or *factor*) was transferred from the dead bacteria to the living cells and caused transformation.

In 1944, Oswald T. Avery and his colleagues Colin M. MacLeod and Maclyn McCarty chemically identified Griffith's transforming factor as DNA. They did this through a series of careful experiments in which they lysed (split open) S cells and separated the cell contents into several fractions: lipids, proteins, polysaccharides, and nucleic acids (DNA and RNA). They tested each fraction to see if it could transform living R cells into S cells. The experiments using lipids, polysaccharides, and proteins did not cause transformation. However, when Avery treated living R cells with nucleic acids extracted from S cells, the R cells were transformed into S cells.

Although today scientists consider these results to be the first definitive demonstration that DNA is the genetic material, not all scientists of the time were convinced. Many thought the findings might apply only to bacteria and might not have any relevance for the genetics of eukaryotes. During the next few years, new evidence accumulated that the haploid nuclei of pollen grains and gametes such as sperm contain only half the amount of DNA found in diploid somatic cells of the same species. (*Somatic cells* are body cells and never become gametes.) Because scientists generally accepted that genes are located on chromosomes, these findings correlating DNA content with chromosome number provided strong circumstantial evidence for DNA's importance in eukaryotic inheritance.

DNA is the genetic material in certain viruses

In 1952, geneticists Alfred Hershey and Martha Chase performed a series of elegant experiments on the reproduction of viruses that infect bacteria, known as **bacteriophages** or **phages** (discussed in Chapter 24). When they planned their experiments, they knew that phages reproduce inside a bacterial cell, eventually causing the cell to break open and release large numbers of new viruses. Because electron microscopic studies had shown that only part of an infecting phage actually enters the cell, they reasoned that the genetic material should be included in that portion (**FIG. 12-2**).

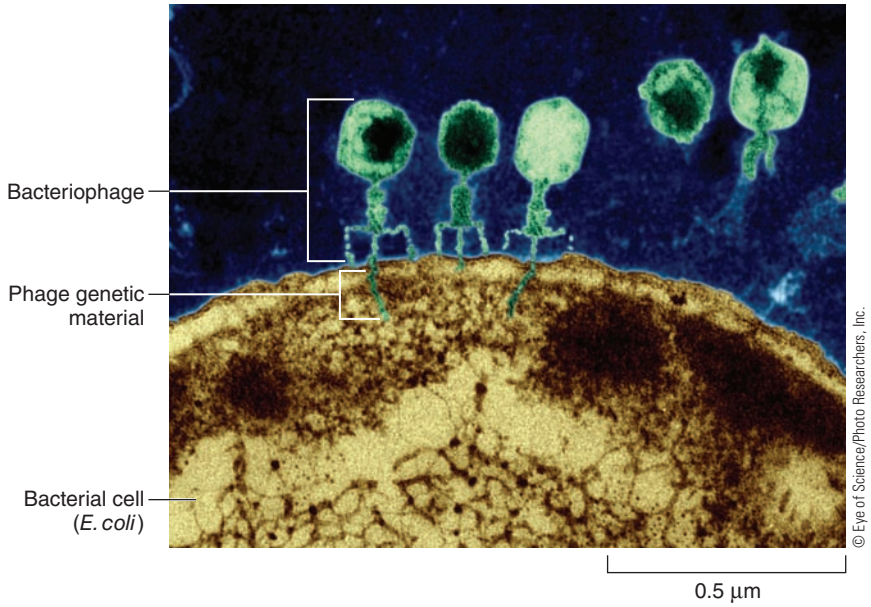


FIGURE 12-2 Bacteriophages on a bacterial cell
This colorized TEM shows several phages attached to the bacterium *Escherichia coli*. Note the viral genetic material being injected into the bacterium.

As shown in **FIGURE 12-3**, they labeled the viral protein of one sample of phages with ^{35}S, a radioactive isotope of sulfur, and the viral DNA of a second sample with ^{32}P, a radioactive isotope of phosphorus. Recall from Chapter 3 that proteins contain sulfur as part of the amino acids cysteine and methionine and that nucleic acids contain phosphate groups. The phages in each sample attached to bacteria, and the researchers shook the phages off by agitating the sample in a blender. Then they centrifuged the samples.

In the sample in which they had labeled the proteins with ^{35}S, they subsequently found radioactivity in the supernatant, indicating that the protein had not entered the cells. In the sample in which they had labeled the DNA with ^{32}P, they found radioactivity associated with the bacterial cells (in the pellet): DNA had actually entered the cells. Hershey and Chase concluded that phages inject their DNA into bacterial cells, leaving most of their protein on the outside. This finding emphasized the significance of DNA in viral reproduction, and many scientists saw it as an important demonstration of DNA's role as the hereditary material.

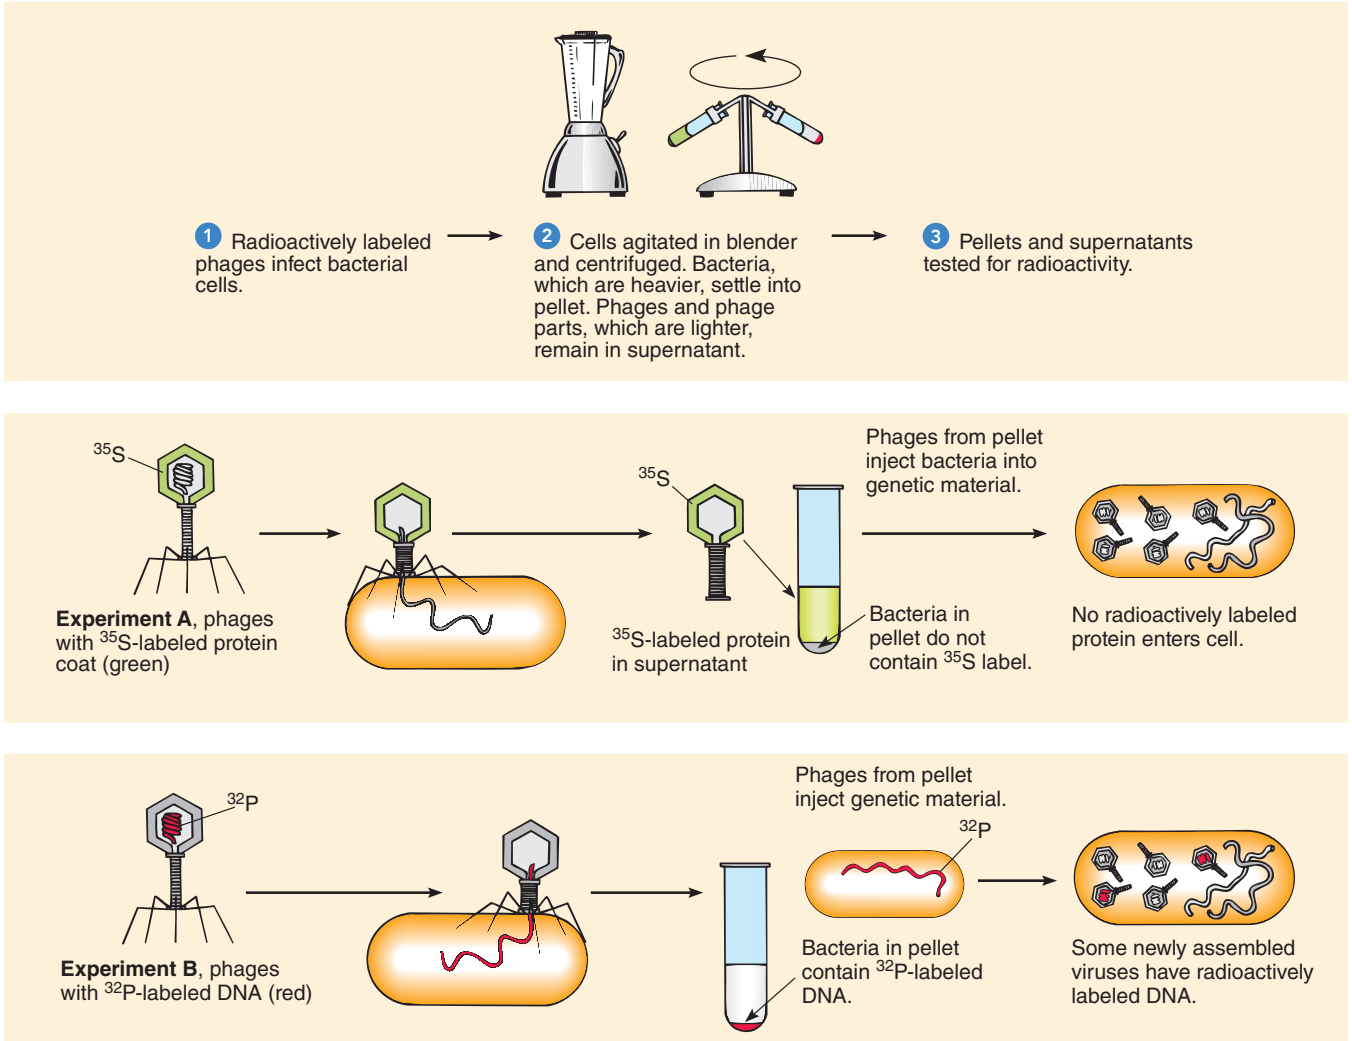
KEY EXPERIMENT

QUESTION: Is DNA or protein the genetic material in bacterial viruses (phages)?

HYPOTHESIS: DNA is the genetic material in bacterial viruses.

EXPERIMENT: Hershey and Chase produced phage populations with either radioactively labeled DNA or radioactively labeled protein. In both cases, they infected bacteria with the phages and then determined whether DNA or protein was injected into bacterial cells to direct the formation of new viral particles.



RESULTS AND CONCLUSION: The researchers could separate phage protein coats labeled with the radioactive isotope ^{35}S from infected bacterial cells without affecting viral reproduction. However, they could not separate viral DNA labeled with the radioactive isotope ^{32}P from infected bacterial cells. This demonstrated that viral DNA enters the bacterial cells and is required for the synthesis of new viral particles. Thus, DNA is the genetic material in phages.

FIGURE 12-3 ***Animated*** **The Hershey–Chase experiments**

Scientists did not generally accept DNA as the genetic material until 1953, when American scientist James Watson and British scientist Francis Crick, both working in England, proposed a model for its structure that had extraordinary explanatory power. The story of how the structure of DNA was figured out is one of the most remarkable chapters in the history of modern biology (**TABLE 12-1**).

As you will see in the following discussion, scientists already knew a great deal about DNA's physical and chemical properties when Watson and Crick became interested in the problem; in fact, they did not conduct any experiments or gather any new data. Their all-important contribution was to integrate all the available information into a model that demonstrated how the molecule can both

TABLE 12-1 A Time Line of Selected Historical DNA Discoveries

Date	Discovery
1871	**Friedrich Miescher** reports discovery of new substance, *nuclein*, from cell nuclei. Nuclein is now known to be a mixture of DNA, RNA, and proteins.
1928	**Frederick Griffith** finds a substance in heat-killed bacteria that "transforms" living bacteria.
1944	**Oswald Avery, Colin MacLeod,** and **Maclyn McCarty** chemically identify Griffith's transforming principle as DNA.
1949	**Erwin Chargaff** reports relationships among DNA bases that provide a clue to the structure of DNA.
1952	**Alfred Hershey** and **Martha Chase** demonstrate that DNA, not protein, is involved in viral reproduction.
1952	**Rosalind Franklin** produces X-ray diffraction images of DNA.
1953	**James Watson** and **Francis Crick** propose a model of the structure of DNA; this contribution is widely considered the start of a revolution in molecular biology that continues to the present.
1958	**Matthew Meselson** and **Franklin Stahl** demonstrate that DNA replication is semiconservative.
1962	**James Watson, Francis Crick,** and **Maurice Wilkins** are awarded the Nobel Prize in Medicine for discoveries about the molecular structure of nucleic acids.*
1969	**Alfred Hershey** is awarded the Nobel Prize in Medicine for discovering the replication mechanism and genetic structure of viruses.

*Rosalind Franklin could not share the prize because she was deceased.

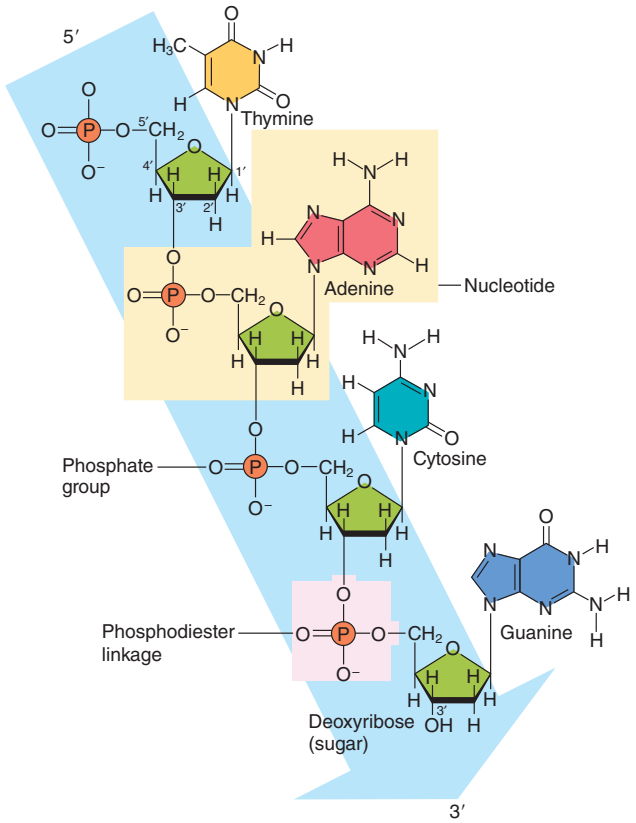

FIGURE 12-4 The nucleotide subunits of DNA

A single strand of DNA consists of a backbone (*superimposed on blue screen*) of phosphate groups alternating with the sugar deoxyribose (*green*). Phosphodiester linkages (*pink*) join sugars of adjacent nucleotides. Linked to the 1′ carbon of each sugar is one of four nitrogenous bases (*top to bottom*): thymine, adenine, cytosine, and guanine. (*The nucleotide containing the base adenine is highlighted yellow.*) Note the polarity of the polynucleotide chain, with the 5′ end at the top of the figure and the 3′ end at the bottom.

carry information for making proteins and serve as its own **template** (pattern or guide) for its duplication.

Nucleotides can be covalently linked in any order to form long polymers

As discussed in Chapter 3, each DNA building block is a **nucleotide** consisting of the pentose sugar **deoxyribose,** a phosphate, and one of four nitrogenous bases (**FIG. 12-4**). It is conventional to number the atoms in a molecule using a system devised by organic chemists. Accordingly, in nucleic acid chemistry the individual carbons in each sugar and each base are numbered. The carbons in a base are designated by numerals, but the carbons in a sugar are distinguished from those in the base by prime symbols, such as 2′. The nitrogenous base is attached to the 1′ carbon of the sugar, and the phosphate is attached to the 5′ carbon. The bases include two **purines, adenine** (**A**) and **guanine** (**G**), and two **pyrimidines, thymine** (**T**) and **cytosine** (**C**).

The nucleotides are linked by covalent bonds to form an alternating sugar–phosphate backbone. The 3′ carbon of one sugar is bonded to the 5′ phosphate of the adjacent sugar to form a 3′, 5′ **phosphodiester linkage.** The result is a polymer of indefinite length, with the nucleotides linked in any order. Scientists now know that most DNA molecules found in cells are millions of bases long. Figure 12-4 also shows that a single polynucleotide chain is directional. No matter how long the chain may be, one end, the **5′ end,** has a 5′ carbon attached to a phosphate and the other, the **3′ end,** has a 3′ carbon attached to a hydroxyl group.

In 1949, Erwin Chargaff and his colleagues at Columbia University had determined the base composition of DNA from several organisms and tissues. They found a simple relationship among the bases that turned out to be an important clue to the structure of DNA. Regardless of the source of the DNA, in Chargaff's words the "ratios of purines to pyrimidines and also of adenine to thymine and of guanine to cytosine were not far from 1" (**TABLE 12-2**).

TABLE 12-2 Base Compositions in DNA from Selected Organisms

	Percentage of DNA Bases				Ratios	
Source of DNA	A	T	G	C	A/T	G/C
E. coli	26.1	23.9	24.9	25.1	1.09	0.99
Yeast	31.3	32.9	18.7	17.1	0.95	1.09

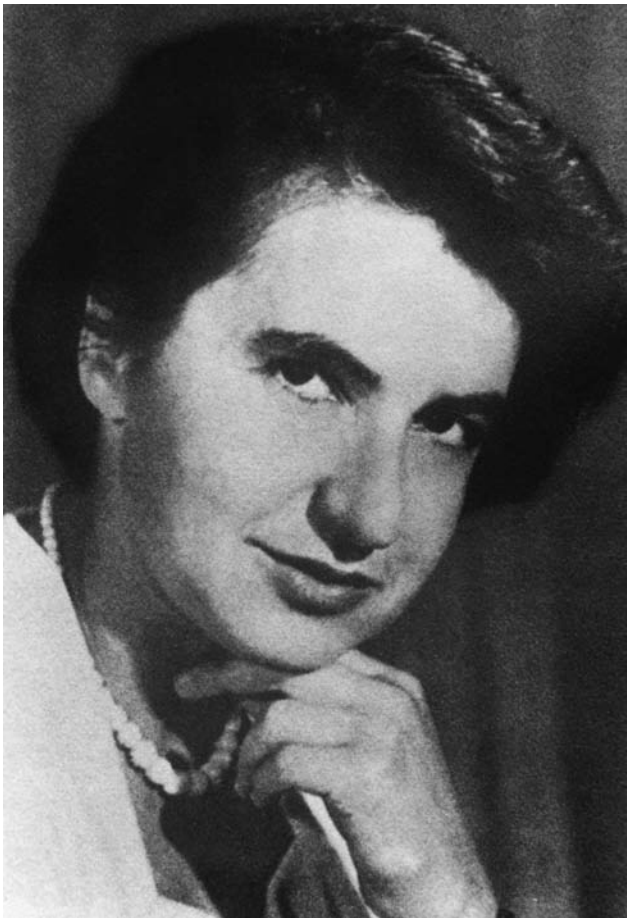
www.konkur.in

In other words, in double-stranded DNA molecules, the number of purines equals the number of pyrimidines, the number of adenines equals the number of thymines (A equals T), and the number of guanines equals the number of cytosines (G equals C). These equalities are called **Chargaff's rules.**

DNA is made of two polynucleotide chains intertwined to form a double helix

Key information about the structure of DNA came from X-ray diffraction studies on crystals of purified DNA, carried out by British scientist Rosalind Franklin at King's College from 1951 to 1953 (**FIG. 12-5**).

X-ray diffraction, a powerful method for determining the 3-D structure of a molecule, can determine the distances between the atoms of molecules arranged in a regular, repeating crystalline structure (**FIG. 12-6**). X-rays have such short wavelengths that they can be scattered by the electrons surrounding the atoms in a molecule. Atoms with dense electron clouds (such as phosphorus and oxygen) tend to deflect electrons more strongly than atoms with lower atomic numbers. Exposing a crystal to an intense beam of X-rays causes the regular arrangement of its atoms to diffract, or scatter,



© Science Source/Photo Researchers, Inc.

FIGURE 12-5 Rosalind Franklin
Franklin was a gifted scientist whose contributions helped elucidate the double helix structure of DNA.

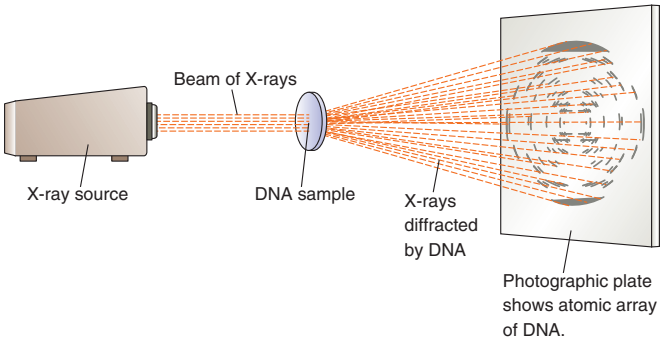
RESEARCH METHOD

Why Is It Used?

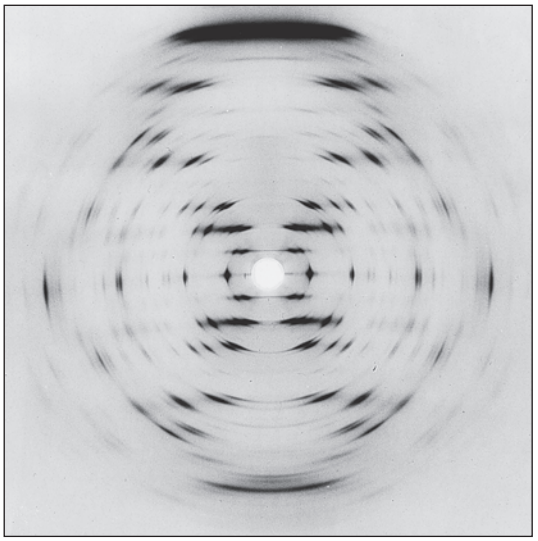
X-ray diffraction can be used to determine the regular array of atoms in a crystalline sample of, for example, DNA. Because each type of crystal has its own characteristic pattern, the three-dimensional structure of the molecule being studied can be deduced.

How Is It Done?

1 Researchers direct a narrow beam of X-rays at a single crystal of DNA. X-rays are diffracted (bent) at specific angles based on the density of electrons of different atoms. Important clues about DNA structure are provided by detailed mathematical analysis of measurements of the spots, which are formed by X-rays hitting the photographic plate



2 X-ray diffraction image of DNA. This diagonal pattern of spots stretching from 11 to 5 and from 1 to 7 (as on a clock face) provides evidence for the helical structure of DNA. The elongated horizontal patterns at the top and bottom indicate that the purine and pyrimidine bases are stacked 0.34 nm apart and are perpendicular to the axis of the DNA molecule.



Dr. S. Dover, Division of Biomolecular Sciences, Kings College, London

FIGURE 12-6 How X-ray diffraction works

www.konkur.in

the X-rays in specific ways. The pattern of diffracted X-rays appears on photographic film as dark spots. Mathematical analysis of the pattern and distances between the spots yields the precise distances between atoms and their orientation within the molecules.

Franklin had already produced X-ray crystallographic films of DNA patterns when Watson and Crick began to pursue the problem of DNA structure. Her pictures clearly showed that DNA has a type of helical structure, and three major types of regular, repeating patterns in the molecule (with the dimensions 0.34 nm, 3.4 nm, and 2.0 nm) were evident. Franklin and colleague Maurice Wilkins had inferred from these patterns that the nucleotide bases (which are flat molecules) are stacked like the rungs of a ladder. Using this information, Watson and Crick began to build scale models of the DNA components and then fit them together to correlate with the experimental data (**FIG. 12-7**).

After several trials, they worked out a model that fit the existing data (**FIG. 12-8**). The nucleotide chains conformed to the dimensions of the X-ray data only if each DNA molecule consisted of *two* polynucleotide chains arranged in a coiled **double helix.** In their model, the sugar–phosphate backbones of the two chains form the outside of the helix. The bases belonging to the two chains associate as pairs along the central axis of the helix. The reasons for the repeating patterns of 0.34 nm and 3.4 nm measurements are readily apparent from the model: each pair of bases is exactly 0.34 nm from the adjacent pairs above and below. Because exactly 10 base pairs are present in each full turn of the helix, each turn constitutes 3.4 nm of length. To fit the data, the two chains must run in opposite directions; therefore, each end of the double helix must have an exposed 5′ phosphate on one strand and an exposed 3′ hydroxyl group (—OH) on the other. Because the two strands run in opposite directions, they are **antiparallel** to each other (**FIG. 12-9a**).

In double-stranded DNA, hydrogen bonds form between A and T and between G and C

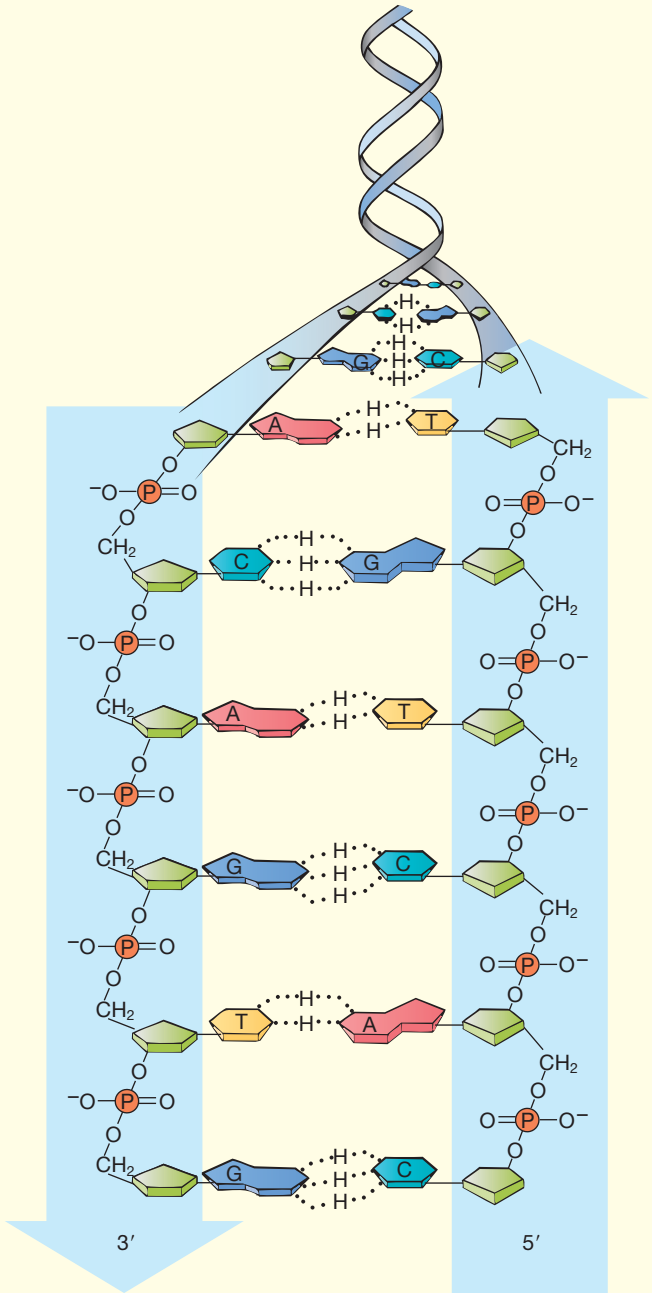
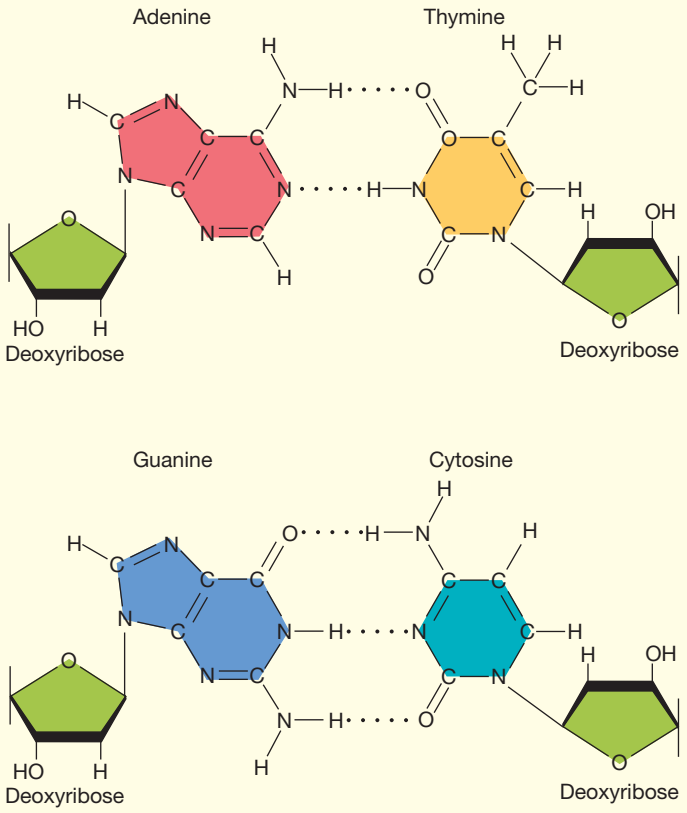
KEY POINT Base pairing and the sequence of bases in DNA provide a foundation for understanding both DNA replication and the inheritance of genetic material.



(a) The two sugar–phosphate chains run in opposite directions. This orientation permits the complementary bases to pair.



(b) Hydrogen bonding between base pairs adenine (A) and thymine (T) (*top*) and guanine (G) and cytosine (C) (*bottom*). The AT pair has two hydrogen bonds; the GC pair has three.

FIGURE 12-9 ***Animated*** **Base pairing and hydrogen bonding**
The two strands of a DNA double helix are hydrogen-bonded between the bases.

X-ray diffraction data. The X-ray diffraction studies indicated that the double helix has a precise and constant width, as shown by the 2.0 nm measurements. This finding is actually consistent with Chargaff's rules. As Figure 12-4 shows, each pyrimidine (cytosine or thymine) contains only one ring of atoms, whereas each purine (guanine or adenine) contains two rings. Study of the models made it clear to Watson and Crick that if each rung of the ladder contained one purine and one pyrimidine, the width of the helix at each base pair would be exactly 2.0 nm. By contrast, the combination of two purines (each of which is 1.2 nm wide) would be wider

www.konkur.in

than 2.0 nm and that of two pyrimidines would be narrower, so the diameter would not be constant. Further examination of the model showed that adenine can pair with thymine (and guanine with cytosine) in such a way that hydrogen bonds form between them; the opposite combinations, cytosine with adenine and guanine with thymine, do not lead to favorable hydrogen bonding.

The nature of the hydrogen bonding between adenine and thymine and between guanine and cytosine is shown in **FIGURE 12-9b**. Two hydrogen bonds form between adenine and thymine, and three between guanine and cytosine. This concept of specific base pairing neatly explains Chargaff's rules. The amount of cytosine must equal the amount of guanine because every cytosine in one chain must have a paired guanine in the other chain. Similarly, every adenine in the first chain must have a thymine in the second chain. The sequences of bases in the two chains exhibit **complementary base pairing**—that is, the sequence of nucleotides in one chain dictates the complementary sequence of nucleotides in the other. For example, if one strand has this sequence,

3′—AGCTAC—5′

then the other strand has the complementary sequence:

5′—TCGATG—3′

The double-helix model strongly suggested that the sequence of bases in DNA provides for the storage of genetic information and that this sequence ultimately relates to the sequences of amino acids in proteins. Although restrictions limit how the bases on opposite strands pair with each other, the number of possible linear sequences of bases in a strand is virtually unlimited. Because a DNA molecule in a cell can be millions of nucleotides long, it can store enormous amounts of information, usually consisting of hundreds of genes.

12.3 DNA REPLICATION

LEARNING OBJECTIVES

6 Cite evidence from Meselson and Stahl's experiment that enabled scientists to differentiate between semiconservative replication of DNA and alternative models.
7 Summarize how DNA replicates and identify some unique features of the process.
8 Explain the complexities of DNA replication that make it (a) bidirectional and (b) continuous in one strand and discontinuous in the other.
9 Discuss how enzymes proofread and repair errors in DNA.
10 Define *telomere*, and describe the possible connections between telomerase and cell aging and between telomerase and cancer.

Two immediately apparent and distinctive features of the Watson–Crick model made it seem plausible that DNA is the genetic material. We have already mentioned that the sequence of bases in DNA can carry coded information. The model also suggested a way in which the sequence of nucleotides in DNA could be precisely copied, a process known as **DNA replication.**

The connection between DNA replication and the behavior of chromosomes in mitosis was obvious to Watson and Crick. A chromosome becomes duplicated so that it consists of two identical sister chromatids that later separate at anaphase; the genetic material must be precisely duplicated and distributed to the daughter cells. They noted, in a classic and now famous understatement at the end of their first brief paper, "It has not escaped our notice that the specific pairing we have postulated immediately suggests a possible copying mechanism for the genetic material."

The model suggested that because the nucleotides pair with each other in complementary fashion, each strand of the DNA molecule could serve as a template for synthesizing the opposite strand. It would simply be necessary for the hydrogen bonds between the two strands to break (recall from Chapter 2 that hydrogen bonds are relatively weak) and the two chains to separate. Each strand of the double helix could then pair with new complementary nucleotides to replace its missing partner. The result would be two DNA double helices, each identical to the original one and consisting of one original strand from the parent molecule and one newly synthesized complementary strand. This type of information copying is called **semiconservative replication** (**FIG. 12-10a**).

Meselson and Stahl verified the mechanism of semiconservative replication

Although the semiconservative replication mechanism suggested by Watson and Crick was (and is) a simple and compelling model, experimental proof was needed to establish that DNA in fact replicates in that manner. Researchers first needed to rule out other possibilities. With *conservative replication,* both parent (or old) strands would remain together, and the two newly synthesized strands would form a second double helix (**FIG. 12-10b**). As a third hypothesis, the parental and newly synthesized strands might become randomly mixed during the replication process—that is, *dispersive replication* (**FIG. 12-10c**). To discriminate among semiconservative replication and the other models, investigators had to distinguish between old and newly synthesized strands of DNA.

One technique is to use a heavy isotope of nitrogen, ^{15}N (ordinary nitrogen is ^{14}N), to label the bases of the DNA strands, making them more dense. Using **density gradient centrifugation,** scientists can separate large molecules such as DNA on the basis of differences in their density (see Fig. 4-5). When DNA is mixed with a solution containing cesium chloride (CsCl) and centrifuged at high speed, the solution forms a density gradient in the centrifuge tube, ranging from a region of lowest density at the top to one of highest density at the bottom. During centrifugation, the DNA molecules migrate to the region of the gradient identical to their own density.

In 1958, Matthew Meselson and Franklin Stahl at the California Institute of Technology grew the bacterium *Escherichia coli* on a medium that contained ^{15}N in the form of ammonium chloride (NH_4Cl). The cells used the ^{15}N to synthesize bases, which then became incorporated into DNA (**FIG. 12-11**). The resulting DNA molecules, which contained heavy nitrogen, were extracted from some of the cells. When the researchers subjected them to density

www.konkur.in

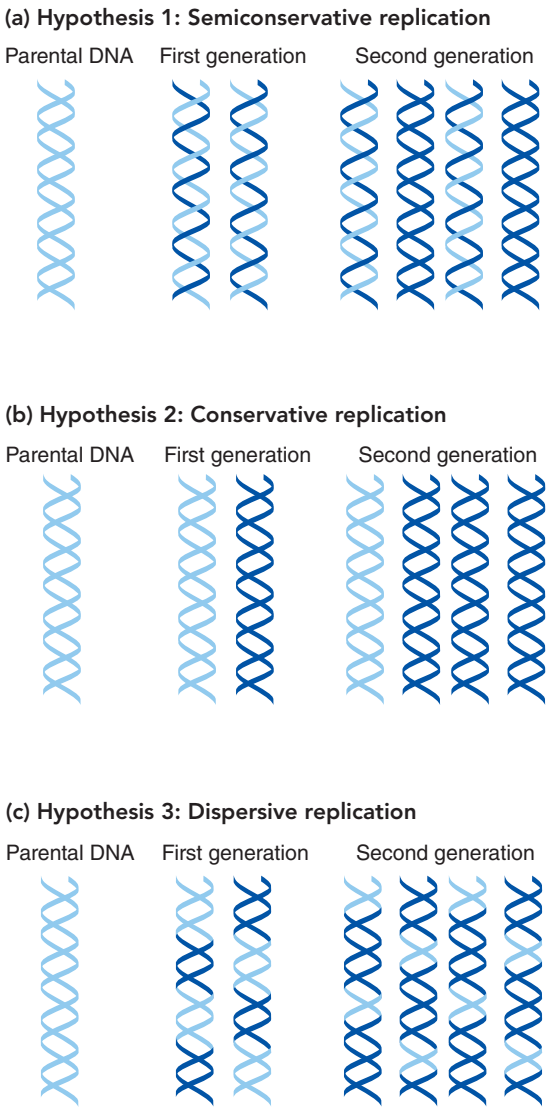

FIGURE 12-10 Alternative models of DNA replication

The hypothesized arrangement of old (*light blue*) and newly synthesized (*dark blue*) DNA strands after one and two generations, according to **(a)** the semiconservative model, **(b)** the conservative model, and **(c)** the dispersive model.

gradient centrifugation, they accumulated in the high-density region of the gradient. The team transferred the rest of the bacteria (which also contained ^{15}N-labeled DNA) to a different growth medium in which the NH_4Cl contained the naturally abundant, lighter ^{14}N isotope and then allowed them to undergo additional cell divisions.

Meselson and Stahl expected the newly synthesized DNA strands to be less dense because they incorporated bases containing the lighter ^{14}N isotope. Indeed, double-stranded DNA from cells isolated after one generation had an intermediate density, indicating they contained half as many ^{15}N atoms as the "parent" DNA. This finding supported the semiconservative replication model, which predicted that each double helix would contain a previously synthesized strand (heavy in this case) and a newly synthesized strand (light in this case). It was also consistent with the dispersive model, which would also yield one class of molecules, all with intermediate density. It was inconsistent with the conservative model, which predicted two classes of double-stranded molecules, those with two heavy strands and those with two light strands.

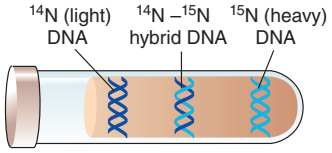
After another cycle of cell division in the medium with the lighter ^{14}N isotope, two types of DNA appeared in the density gradient, exactly as predicted by the semiconservative replication model. One consisted of DNA with a density intermediate between ^{15}N-labeled DNA and ^{14}N-labeled DNA, whereas the other contained only DNA with a density of ^{14}N-labeled DNA. This finding refuted the dispersive model, which predicted that all strands would have an intermediate density.

KEY EXPERIMENT

QUESTION: What is the mechanism of DNA replication?

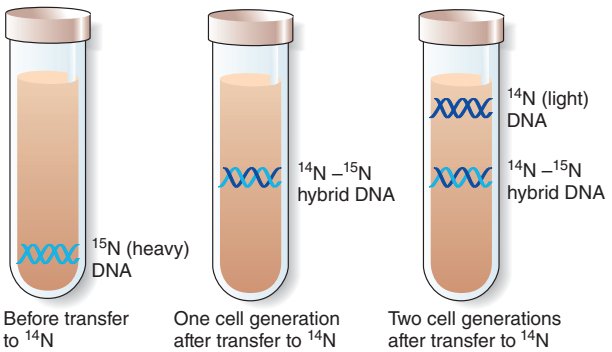
HYPOTHESIS: Figure 12-10 depicts three hypotheses of DNA replication and predicts the arrangement of old and newly synthesized DNA strands after one or two generations according to each hypothesis.

EXPERIMENT: Meselson and Stahl grew bacteria (*E. coli*) in heavy nitrogen (^{15}N) growth medium for many generations so that all the DNA strands would be heavy. Then they transferred some of the cells to light nitrogen (^{14}N) medium so that the newly synthesized strands would be light. They isolated DNA from bacterial cells after 20 minutes (one generation) and 40 minutes (two generations) and centrifuged it to separate DNA into bands based on density.



In density gradient centrifugation, the concentration of CsCl is highest at the bottom of the tube and lowest at the top. DNA molecules move to positions where their density equals that of the CsCl solution in which they are centrifuged.

RESULTS AND CONCLUSION: Based on the observed density of the DNA molecules in each generation, Meselson and Stahl concluded that the semiconservative model accurately predicts the mechanism of DNA replication.



The location of DNA molecules within the centrifuge tube can be determined by UV optics. DNA solutions absorb strongly at 260 nm.

FIGURE 12-11 The Meselson–Stahl experiment

www.konkur.in

Semiconservative replication explains the perpetuation of mutations

The recognition that DNA could be copied by a semiconservative mechanism suggested how DNA could explain a third essential characteristic of genetic material—the ability to mutate. It was long known that **mutations,** or genetic changes, could arise in genes and then be transmitted faithfully to succeeding generations. For example, a mutation in the fruit fly (*Drosophila melanogaster*) produces vestigial wings.

When the double-helix model was proposed, it seemed plausible that mutations could represent a change in the sequence of bases in the DNA. You could predict that if DNA is copied by a mechanism involving complementary base pairing, any change in the sequence of bases on one strand would produce a new sequence of complementary bases during the next replication cycle. The new base sequence would then transfer to daughter molecules by the same mechanism used to copy the original genetic material, as if no change had occurred.

For the example in **FIGURE 12-12**, an adenine base in one of the DNA strands has been changed to guanine. This could occur by a rare error in DNA replication or by one of several other known mechanisms. As discussed later, certain enzymes correct errors when they occur, but not all errors are corrected properly. By one estimate, the rate of uncorrected errors that occur during DNA replication is equal to about one nucleotide in a billion. When the DNA molecule containing an error replicates (left side of Fig. 12-12), one of the strands gives rise to a molecule exactly like its parent strand; the other (mutated) strand gives rise to a molecule with a new combination of bases that is transmitted generation after generation.

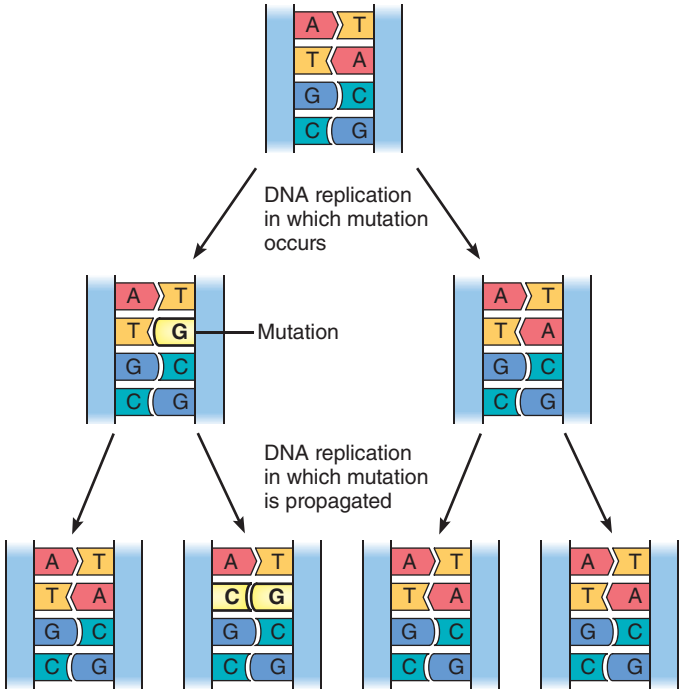


FIGURE 12-12 The perpetuation of a mutation

The process of DNA replication can stabilize a mutation (*bright yellow*) so that it is transmitted to future generations.

DNA replication requires protein "machinery"

Although semiconservative replication by base pairing appears simple and straightforward, the actual process is highly regulated and requires a "replication machine" containing many types of protein and enzyme molecules. Many essential features of DNA replication are common to all organisms, although prokaryotes and eukaryotes differ somewhat because their DNA is organized differently. In most bacterial cells, such as *E. coli,* most or all the DNA is in the form of a single, *circular,* double-stranded DNA molecule. In contrast, each unreplicated eukaryotic chromosome contains a single, *linear,* double-stranded molecule associated with at least as much protein (by mass) as DNA.

We now present DNA replication, based on the current understanding of the process. Although scientists know much about DNA replication, many aspects of the process remain unclear. For example, in the unicellular yeast *Saccharomyces cerevisiae,* which is considered a relatively "simple" eukaryote, 88 genes are involved in DNA replication! Determining the roles and interactions of all those genes will require the efforts of many scientists over a long period.

DNA strands must be unwound during replication

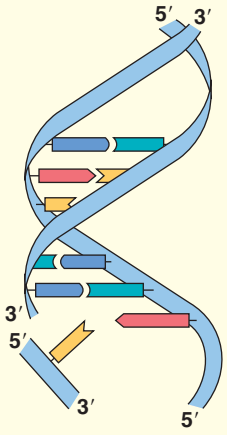
DNA replication begins at specific sites on the DNA molecule, called **origins of replication,** where small sections of the double helix unwind. **DNA helicases** are helix-destabilizing enzymes (several have been identified) that bind to DNA at the origin of replication and break hydrogen bonds, thereby separating the two strands (**TABLE 12-3**). Both DNA strands replicate at the same time at the junction between the separated strands, which is a Y-shaped structure called the **replication fork** (see chapter opener photograph). Helicase travels along the helix, opening the double helix like a zipper during movement of the replication fork.

Once DNA helicases separate the strands, **single-strand binding (SSB) proteins** bind to single DNA strands and stabilize them; this prevents the double helix from re-forming until the strands are replicated. SSB proteins also prevent the hydrolysis of the single-strand regions by other enzymes (*nucleases;* as we discuss later in the chapter, nucleases are involved in DNA repair).

Watson and Crick recognized that in their double-helix model, the two DNA strands wrap around each other like the strands of a rope. If you try to pull the strands apart, the rope must either rotate or twist into tighter coils. You could expect similar results when complementary DNA strands are separated for replication. As the DNA strands unwind to open for replication, torsional strain from supercoiling (excessive twisting) occurs in another part of the DNA molecule. Enzymes called **topoisomerases** produce breaks in the DNA molecules and then rejoin the strands, relieving strain and effectively preventing supercoiling and knot formation during replication. There are two ways that topoisomerases reduce supercoiling. Some topoisomerases produce a temporary break in the polynucleotide backbone of a single strand of DNA, pass that strand through the excessively twisted part, and then reseal the break. Other topoisomerases break both DNA strands, pass some of the helix between the cut ends, and then reseal the break.

www.konkur.in

TABLE 12-3 Proteins Involved in DNA Replication



Enzyme	Function
Helicase	Opens the double helix at replication forks by disrupting the hydrogen bonds that hold the two strands together.
Single-strand binding (SSB) protein	Binds to single strands of DNA and prevents the helix from re-forming before it can be used as a template for replication.
Topoisomerase	Breaks one or both DNA strands, preventing excessive coiling during replication, and then rejoins them in a more relaxed configuration.
DNA polymerase	Links nucleotide subunits to form a new DNA strand from a DNA template.
DNA primase	Synthesizes short RNA primers on the lagging strand. Begins replication of the leading strand.
DNA ligase	Links Okazaki fragments by joining the 3′ end of the new DNA fragment to the 5′ end of the adjoining DNA.

Regardless of their modes of action, topoisomerases give replicating DNA a more relaxed configuration.

DNA synthesis always proceeds in a 5′ ⟶ 3′ direction

The enzymes that catalyze the linking of successive nucleotide subunits are called **DNA polymerases.** They add nucleotides only to the 3′ end of a growing polynucleotide strand, and this strand must be paired with the DNA template strand (**FIG. 12-13**). Nucleotides with three phosphate groups are substrates for the polymerization reaction. As the nucleotides become linked, two of the phosphates are removed. These reactions are strongly exergonic and do not need additional energy. Because the polynucleotide chain is elongated by the linkage of the 5′ phosphate group of the next nucleotide subunit to the 3′ hydroxyl group of the sugar at the end of the existing strand, the new strand of DNA always grows in the 5′ ⟶ 3′ direction. Some DNA polymerases are very efficient in joining nucleotides to the growing polypeptide chain. **DNA Pol III,** which is one of five DNA polymerases that have been identified in the bacterium *E. coli,* can join 1200 nucleotides per minute.

DNA synthesis requires an RNA primer

As mentioned, DNA polymerases add nucleotides only to the 3′ end of an *existing* polynucleotide strand. Then, how is DNA synthesis initiated once the two strands are separated? The answer is that first a short piece of RNA (5 to 14 nucleotides) called an **RNA primer** is synthesized at the point where replication begins (**FIG. 12-14**).

RNA, or **ribonucleic acid** (see Chapters 3 and 13), is a nucleic acid polymer consisting of nucleotide subunits that can associate by complementary base pairing with the single-strand DNA template. The RNA primer is synthesized by **DNA primase,** an enzyme that starts a new strand of RNA opposite a short stretch

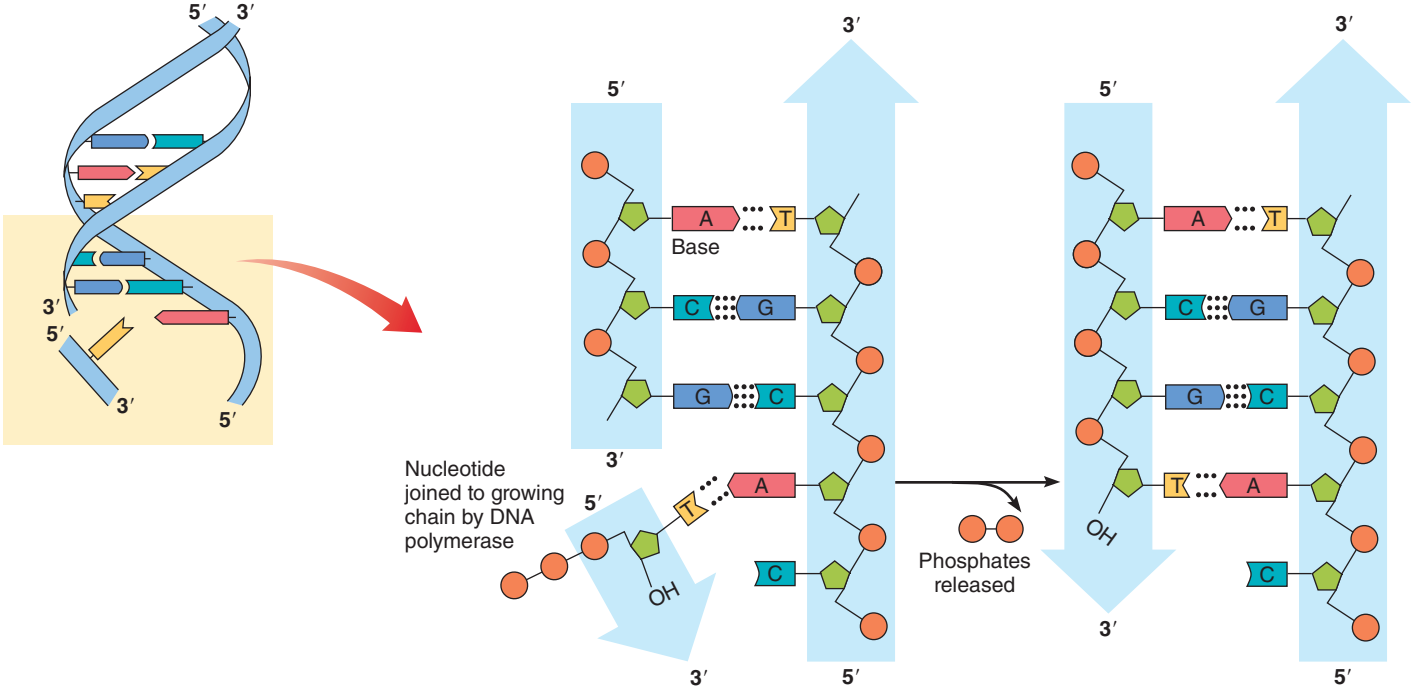


FIGURE 12-13 ***Animated*** **A simplified view of DNA replication**
One nucleotide at a time is added to the 3′ end of a growing chain.

www.konkur.in

KEY POINT DNA replication requires several steps and involves several enzymes, proteins, and RNA primers.

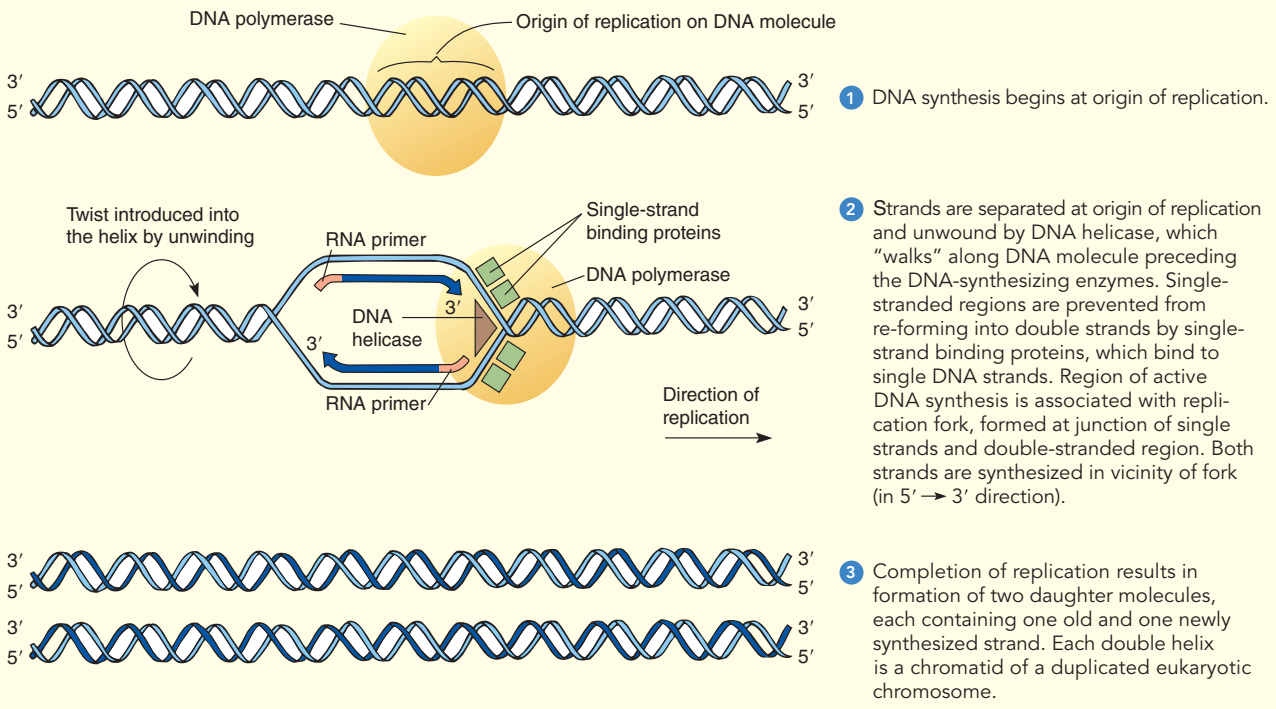

FIGURE 12-14 ***Animated*** An overview of DNA replication

of the DNA template strand. After a few nucleotides have been added, DNA polymerase displaces the primase and subsequently adds subunits to the 3′ end of the short RNA primer. Specific enzymes later degrade the primer (discussed in the next section), and the space fills in with DNA.

DNA replication is discontinuous in one strand and continuous in the other

We mentioned earlier that the complementary DNA strands are antiparallel. DNA synthesis proceeds only in the 5′ ⟶ 3′ direction, which means that the strand being copied is being read in the 3′ ⟶ 5′ direction. Thus, it may seem necessary to copy one of the strands starting at one end of the double helix and the other strand starting at the opposite end. Some viruses replicate their DNA in this way, but this replication method is not workable in the extremely long DNA molecules in eukaryotic chromosomes.

Instead, as previously mentioned, DNA replication begins at origins of replication, and both strands replicate at the same time at a replication fork (**FIG. 12-15**). The position of the replication fork is constantly moving as replication proceeds. Two identical DNA polymerase molecules catalyze replication. One of these adds nucleotides to the 3′ end of the new strand that is always growing *toward* the replication fork. Because this strand is synthesized smoothly and continuously, it is called the **leading strand.**

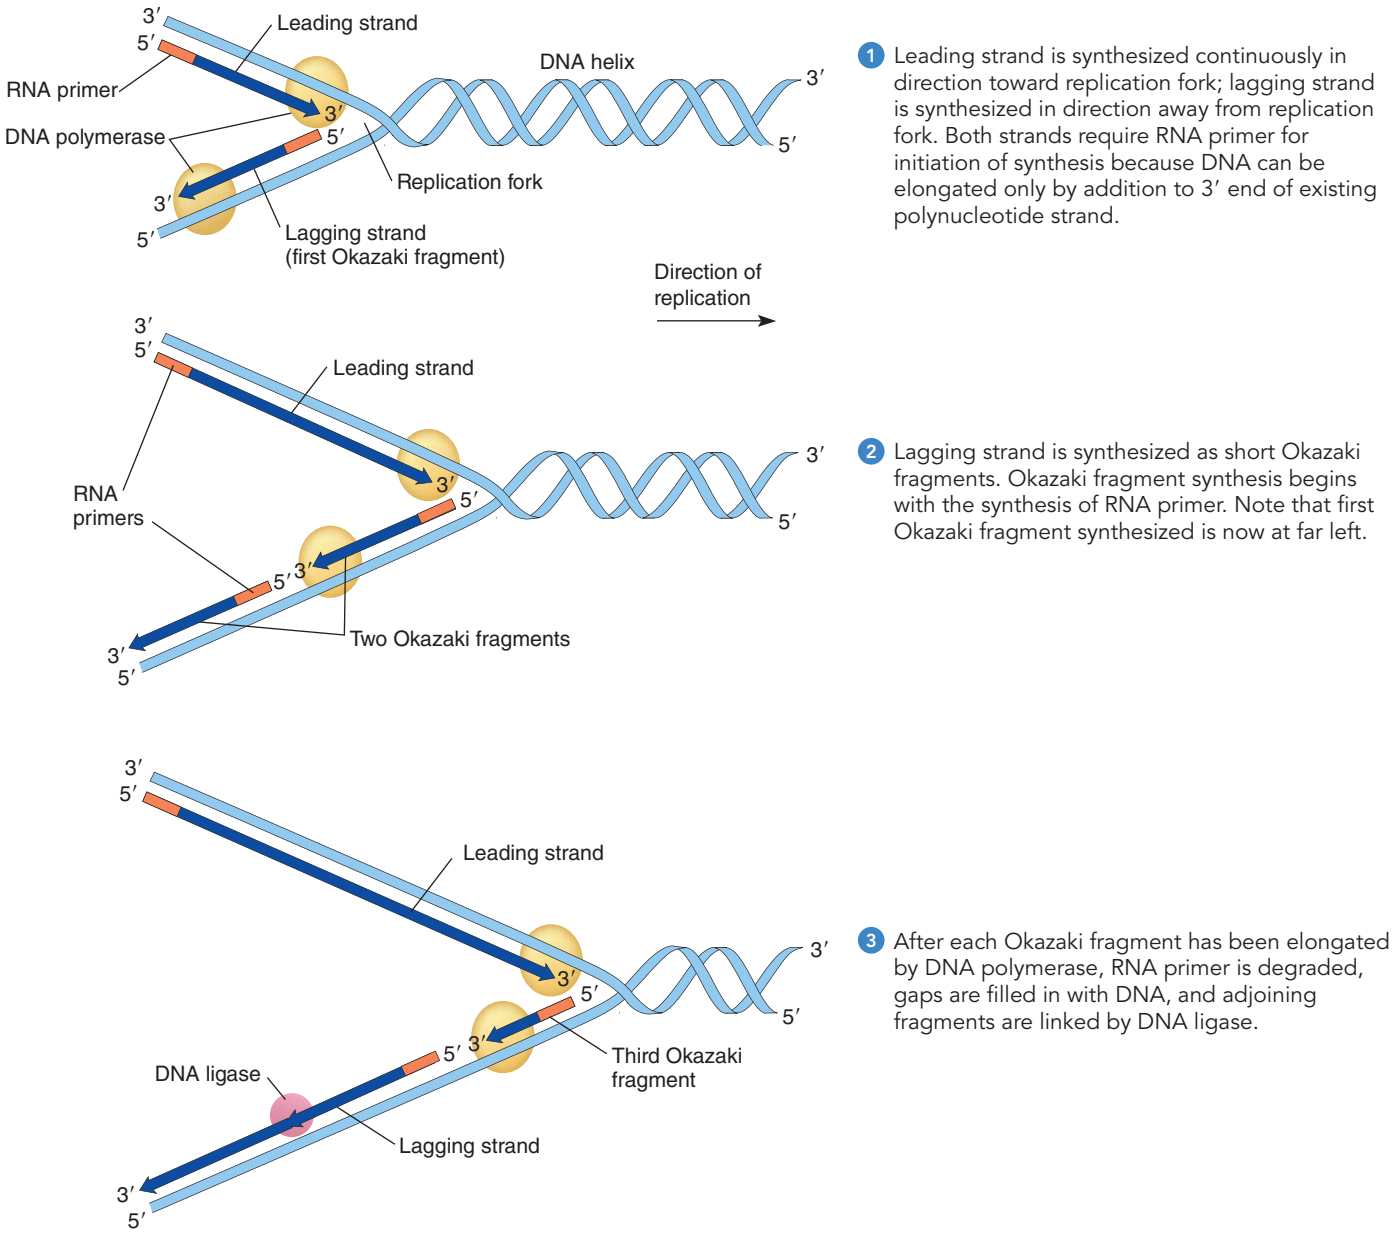
A separate DNA polymerase molecule adds nucleotides to the 3′ end of the other new strand. Called the **lagging strand,** it is always growing *away* from the replication fork. Only short pieces can be synthesized, because if the DNA polymerase were to add continuously to the 3′ end of that strand, it would need to move far from the replication fork. These 100- to 2000-nucleotide pieces are called **Okazaki fragments** after their discoverer, Japanese molecular biologist Reiji Okazaki.

DNA primase periodically catalyzes the synthesis of an RNA primer on the lagging strand. A separate RNA primer initiates each Okazaki fragment, which DNA polymerase then extends toward the 5′ end of the previously synthesized fragment. When the RNA primer of the previously synthesized fragment is reached, DNA polymerase degrades and replaces the primer with DNA. The fragments are then joined by **DNA ligase,** an enzyme that links the 3′ hydroxyl of one Okazaki fragment to the 5′ phosphate of the DNA immediately next to it, forming a phosphodiester linkage. (As you will see later in the chapter, DNA ligase also rejoins broken phosphodiester bonds during DNA repair.)

DNA synthesis is bidirectional

When double-stranded DNA separates, two replication forks form, and the molecule replicates in both directions from the origin of replication. In bacteria, each circular DNA molecule usually has only one origin of replication, so the two replication forks proceed around the circle and eventually meet at the other side to complete the formation of two new DNA molecules. **FIGURE 12-16a** shows a replicating bacterial plasmid. **Plasmids** are small, circular DNA

www.konkur.in



1 Leading strand is synthesized continuously in direction toward replication fork; lagging strand is synthesized in direction away from replication fork. Both strands require RNA primer for initiation of synthesis because DNA can be elongated only by addition to 3′ end of existing polynucleotide strand.

2 Lagging strand is synthesized as short Okazaki fragments. Okazaki fragment synthesis begins with the synthesis of RNA primer. Note that first Okazaki fragment synthesized is now at far left.

3 After each Okazaki fragment has been elongated by DNA polymerase, RNA primer is degraded, gaps are filled in with DNA, and adjoining fragments are linked by DNA ligase.

FIGURE 12-15 Leading and lagging DNA strands

molecules that carry genes separate from those on a bacterial chromosome. Because plasmids are so small compared to the circular bacterial chromosome, they are possible to clearly photograph during replication.

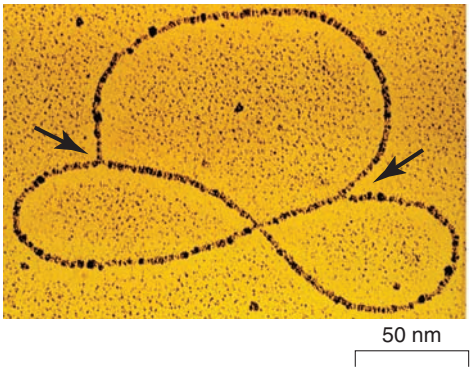
A eukaryotic chromosome consists of one long, linear DNA molecule, so having multiple origins of replication expedites the replication process (**FIG. 12-16b**). Synthesis continues at each replication fork until it meets a newly synthesized strand coming from the opposite direction. This results in a chromosome containing two DNA double helices, each corresponding to a chromatid.

Enzymes proofread and repair errors in DNA

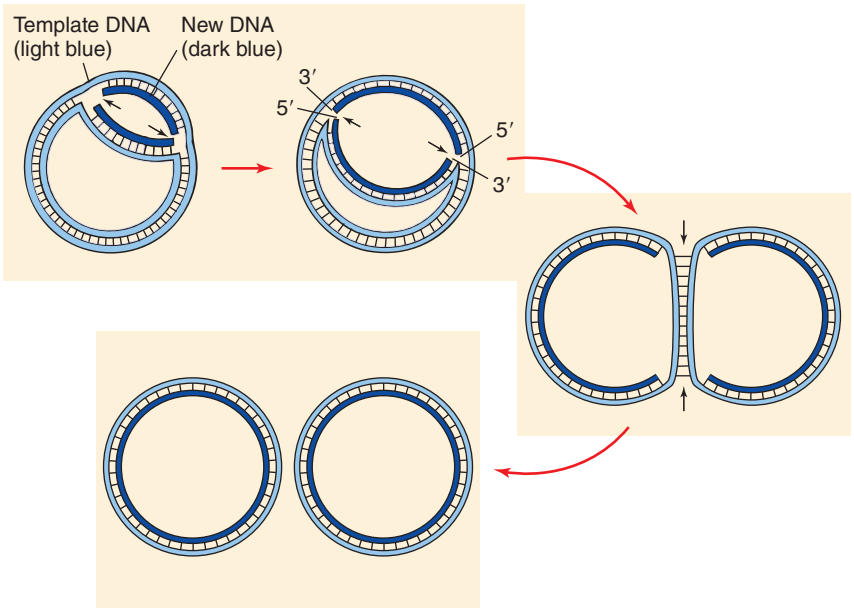
DNA replication occurs only once during each cell generation, and it is important that the process be as accurate as possible to avoid harmful, or possibly even lethal, mutations. Although base pairing during DNA replication is very accurate, errors do occur. Mechanisms have evolved that ensure that errors in replication are corrected. During replication, DNA polymerases proofread each newly added nucleotide against its template nucleotide. When an error in base pairing is found, DNA polymerase immediately removes the incorrect nucleotide and inserts the correct one. A few uncorrected mutations still occur, but they are very infrequent—on the order of one error for every 10^9 or 10^{10} base pairs.

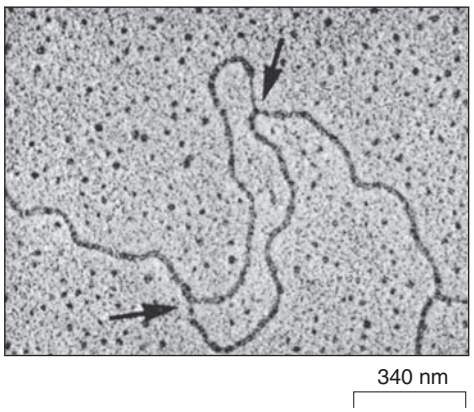
When errors have been left uncorrected by the normal repair activities of DNA polymerase during DNA replication, cells make use of other repair mechanisms (although exactly *how* DNA repair enzymes identify these rare, often-subtle errors in the vast amount of normal DNA is not well understood). In **mismatch repair,** special enzymes recognize the incorrectly paired nucleotides and

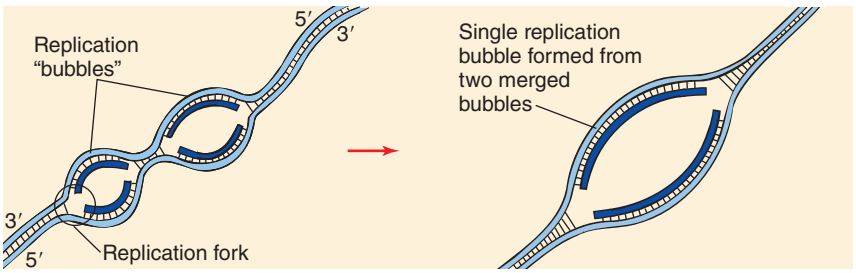
www.konkur.in



(a) TEM (above left) of a replicating plasmid of *E. coli*. Most bacterial plasmids and chromosomes have only one origin of replication. Because DNA synthesis proceeds from that point in both directions, two replication forks form (*black arrows*), travel around the circle, and eventually meet.







(b) TEM (left) of two replication forks (black arrows) in a segment of a eukaryotic chromosome that has partly replicated. Eukaryotic chromosome DNA contains multiple origins of replication. DNA synthesis proceeds in both directions from each origin until adjacent replication "bubbles" eventually merge.

FIGURE 12-16 **Bidirectional DNA replication in bacteria and eukaryotes**
The illustrations do not show leading strands and lagging strands.

remove them; DNA polymerases then fill in the missing nucleotides. The observation that individuals with a hereditary defect in a mismatch repair enzyme are likely to develop a type of colon cancer demonstrates the crucial role of mismatch repair enzymes in ensuring the fidelity of DNA replication from one generation to the next.

In Chapter 13 you will discover that some types of radiation and chemicals, both in the environment and within the cells themselves, cause mutations in DNA. These mutations are almost always harmful, and cells usually correct mutations by using one or more DNA repair enzymes. About 100 kinds of repair enzymes in the bacterium *E. coli* and 130 kinds in human cells have been discovered so far.

One type of DNA repair—**nucleotide excision repair**—is commonly used to repair DNA lesions (deformed DNA) caused by the sun's ultraviolet radiation or by harmful chemicals (**FIG. 12-17**). Three enzymes are involved in nucleotide excision repair—a nuclease to cut out the damaged DNA, a DNA polymerase to add the correct nucleotides, and DNA ligase to close the breaks in the sugar–phosphate backbone. Individuals suffering from the disease *xeroderma pigmentosum* have an inherited defect in a nucleotide excision repair enzyme. Affected individuals develop many skin cancers at an early age because DNA lesions caused by ultraviolet radiation are not repaired.

Telomeres cap eukaryotic chromosome ends

Unlike bacterial DNA, which is circular, eukaryotic chromosomes have free ends. Because DNA replication is discontinuous in the lagging strand, DNA polymerases do not complete replication of the strand neatly. At the end of the DNA, a small portion is left unreplicated, and a small, single-strand segment of the DNA is lost with each cell cycle (**FIG. 12-18a**).

The important genetic information is retained because chromosomes have protective end caps, or telomeres, that do not contain protein-coding genes. **Telomeres** consist of short,

www.konkur.in

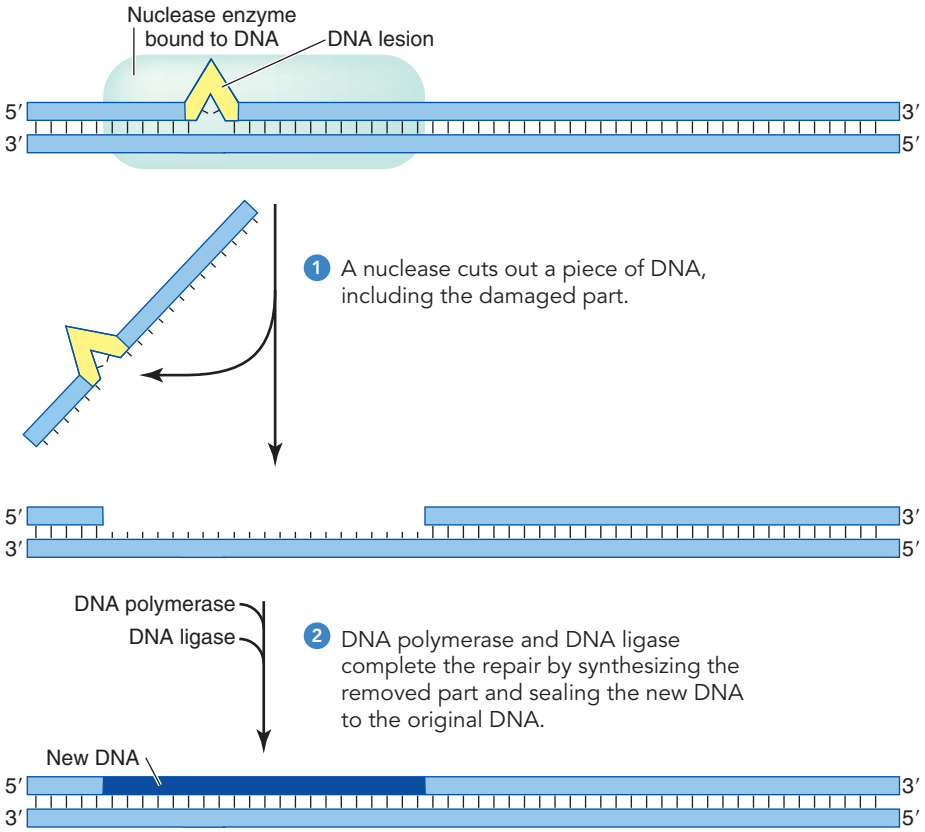


FIGURE 12-17 Nucleotide excision repair of damaged DNA

noncoding, guanine-rich DNA sequences that repeat many times (**FIG. 12-18b**). For example, in human sperm and egg cells, the sequence 5′—TTAGGG—3′ is repeated more than 1000 times at the ends of each chromosome. Therefore, although a small amount of telomeric DNA fails to replicate each time the cell divides, a cell can divide many times before it starts losing essential genetic information.

Telomerase, a special DNA replication enzyme, can lengthen telomeric DNA by adding repetitive nucleotide sequences to the ends of eukaryotic chromosomes. This enzyme, which researchers discovered in 1984, is typically present in cells that divide an unlimited number of times, including protozoa and other unicellular eukaryotes, and most types of **cancer cells.** In humans and other mammals, active telomerase is usually present in germ line cells (which give rise to eggs and sperm) and rapidly dividing cells (such as blood cells, cells lining the intestine, and skin cells) but not in most somatic cells of adult tissues.

When most cells divide for repair or replacement, their chromosome ends shorten. Researchers have demonstrated that in cancer cells of the prostate and pancreas, telomeres are abnormally short: they shorten to a critical point, at which time telomerase is reactivated, which may explain the ability of cancer cells to proliferate in a rapid and uncontrolled manner. Telomere shortening has also been demonstrated in precancerous lesions from the bladder, breast, colon, esophagus, mouth, and cervix.

Research evidence suggests that the shortening of telomeres may contribute to **cell aging** and **apoptosis,** which is programmed cell death. Scientists have analyzed cell aging since the 1960s, following the pioneering studies of American biologist Leonard Hayflick, who showed that when normal somatic cells of the human body are grown in culture, they lose their ability to divide after a limited number of cell divisions. Furthermore, the number of cell divisions is determined by the age of the individual from whom the cells were taken. Cells from a 70-year-old can divide only 20 to 30 times, compared with those from an infant, which can divide 80 to 90 times.

Many investigators have observed correlations between telomerase activity and the ability of cells to undergo unlimited divisions without showing signs of the aging process. However, they could not find evidence of a causal relationship until the early 2000s, when scientists at the Geron Corporation and the University of Texas Southwestern Medical Center conducted a direct test. Using recombinant DNA technology (see Chapter 15), they infected cultured normal human cells with a virus that carried the genetic information coding for the catalytic subunit of telomerase. The infected cells not only produced active telomerase, which elongated the telomeres significantly, but also continued to divide long past the point at which cell divisions would normally cease.

Telomeres and telomerase are an active focus of current research, for both scientific and practical reasons. The ability to give somatic cells telomerase so they can divide many times more than they ordinarily would has many potential therapeutic applications, especially if lost or injured cells must be replaced. However, giving such cells the property of unlimited cell division also has potentially serious consequences. For example, if transplanted into the body, cells with active telomerase might behave like cancer cells.

Cancer cells have the ability to divide hundreds of times in culture; in fact, they are virtually immortal. Most cancer cells, including human cancers of the breast, lung, colon, prostate gland, and pancreas, have telomerase, which allows them to maintain telomere length and possibly to resist apoptosis. Research is underway to develop anticancer drugs that inhibit telomerase activity. An alternative treatment for cancer is also under study—directing the body's immune system to recognize and attack cancer cells that contain telomerase.

Review

- How did Meselson and Stahl verify that DNA replication is semiconservative?
- Why is DNA replication continuous for one strand but discontinuous for the other?
- How does mismatch repair of DNA compare with nucleotide excision repair?

FIGURE 12-18 Telomeres

SUMMARY: FOCUS ON LEARNING OBJECTIVES

12.1 *(page 264)*

1 Summarize the evidence that accumulated during the 1940s and early 1950s demonstrating that DNA is the genetic material.

- Many early geneticists thought genes were made of proteins. They knew proteins were complex and variable, whereas they thought nucleic acids were simple molecules with a limited ability to store information.
- Several lines of evidence supported the idea that **DNA (deoxyribonucleic acid)** is the genetic material. In **transformation** experiments, the DNA of one strain of bacteria can endow related bacteria with new genetic characteristics.
- When a bacterial cell becomes infected with a **bacteriophage** (virus), only the DNA from the virus enters the cell; this DNA is sufficient for the virus to reproduce and form new viral particles.

2 State the questions that these classic experiments addressed: Griffith's transformation experiment, Avery's contribution to Griffith's work, and the Hershey–Chase experiments.

- Griffith's transformation experiment addressed this question: Can a genetic trait be transmitted from one bacterial strain to another? (The answer is yes.)
- Avery's experiments addressed this question: What molecule is responsible for bacterial transformation? (The answer is DNA.)
- The Hershey–Chase experiments addressed this question: Is DNA or protein the genetic material in bacterial viruses (phages)? (The answer is DNA.)

12.2 *(page 265)*

3 Explain how nucleotide subunits link to form a single DNA strand.

- Watson and Crick's model of the structure of DNA demonstrated how information can be stored in the molecule's structure and how DNA molecules can serve as **templates** for their own replication.
- DNA is a polymer of **nucleotides.** Each nucleotide subunit contains a nitrogenous base, which may be one of the **purines** (**adenine** or **guanine**) or one of the **pyrimidines** (**thymine** or **cytosine**). Each base covalently links to a pentose sugar, **deoxyribose,** which covalently bonds to a phosphate group.
- The backbone of each single DNA chain is formed by alternating sugar and phosphate groups, joined by covalent phosphodiester linkages. Each phosphate group attaches to the 5′ carbon of one deoxyribose and to the 3′ carbon of the neighboring deoxyribose.

4 Describe how the two strands of DNA are oriented with respect to each other.

- Each DNA molecule consists of two polynucleotide chains that associate as a **double helix.** The two chains are **antiparallel** (running

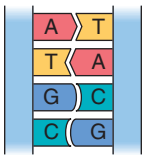
www.konkur.in

in opposite directions); at each end of the DNA molecule, one chain has a phosphate attached to a 5′ deoxyribose carbon, the **5′ end,** and the other has a hydroxyl group attached to a 3′ deoxyribose carbon, the **3′ end.**

CENGAGENOW™ **Interact with the structure of the DNA double helix by clicking on the figures in CengageNOW.**

5 State the base-pairing rules for DNA and describe how complementary bases bind to each other.

- Hydrogen bonding between specific base pairs holds together the two chains of the helix. Adenine (A) forms two hydrogen bonds with thymine (T); guanine (G) forms three hydrogen bonds with cytosine (C).



- **Complementary base pairing** between A and T and between G and C is the basis of Chargaff's rules, which state that A equals T and that G equals C.
- Because complementary base pairing holds together the two strands of DNA, it is possible to predict the base sequence of one strand if you know the base sequence of the other strand.

12.3 *(page 271)*

6 Cite evidence from Meselson and Stahl's experiment that enabled scientists to differentiate between semiconservative replication of DNA and alternative models.

- When *E. coli* cells are grown for many generations in a medium containing heavy nitrogen (^{15}N), they incorporate the ^{15}N into their DNA. When researchers transfer cells from a ^{15}N medium to a ^{14}N medium and isolate them after either one or two generations, the density of the DNA in each group is what would be expected if DNA replication were semiconservative. In **semiconservative replication,** each daughter double helix consists of an original strand from the parent molecule and a newly synthesized complementary strand.

7 Summarize how DNA replicates and identify some unique features of the process.

- During **DNA replication,** the two strands of the double helix unwind. Each strand serves as a template for forming a new, complementary strand. Replication is initiated as **DNA primase** synthesizes a short **RNA primer. DNA polymerase** then adds new nucleotide subunits to the growing DNA strand.
- Additional enzymes and other proteins are required to unwind and stabilize the separated DNA helix. **DNA helicases** open the double helix, and **topoisomerases** prevent tangling and knotting.

8 Explain the complexities of DNA replication that make it (a) bidirectional and (b) continuous in one strand and discontinuous in the other.

- DNA replication is bidirectional, starting at the **origin of replication** and proceeding in both directions from that point. A eukaryotic chromosome may have multiple origins of replication and may be replicating at many points along its length at any one time.
- DNA synthesis always proceeds in a 5′ ⟶ 3′ direction. This requires that one DNA strand, the **lagging strand,** be synthesized discontinuously, as short **Okazaki fragments.** DNA primase synthesizes short RNA primers on the lagging strand, and **DNA ligase** links Okazaki fragments of newly synthesized DNA. The opposite strand, the **leading strand,** is synthesized continuously.

CENGAGENOW™ **Watch the process of replication by clicking on the figure in CengageNOW.**

9 Discuss how enzymes proofread and repair errors in DNA.

- During replication, DNA polymerases proofread each newly added nucleotide against its template nucleotide. When an error in base pairing is found, DNA polymerase immediately removes the incorrect nucleotide and inserts the correct one.
- In **mismatch repair,** enzymes recognize incorrectly paired nucleotides and remove them; DNA polymerases then fill in the missing nucleotides.
- **Nucleotide excision repair** is commonly used to repair DNA lesions caused by the sun's ultraviolet radiation or by harmful chemicals. Three enzymes are involved: a nuclease to cut out the damaged DNA, a DNA polymerase to add the correct nucleotides, and DNA ligase to close the breaks in the sugar–phosphate backbone.

10 Define *telomere,* and describe the possible connections between telomerase and cell aging and between telomerase and cancer.

- Eukaryotic chromosome ends, called **telomeres,** are short, noncoding, repetitive DNA sequences. Telomeres shorten slightly with each cell cycle but can be extended by the enzyme **telomerase.**
- The absence of telomerase activity in certain cells may be a cause of **cell aging,** in which cells lose their ability to divide after a limited number of cell divisions.
- Most **cancer cells,** including human cancers of the breast, lung, colon, prostate gland, and pancreas, have telomerase to maintain telomere length and possibly to resist **apoptosis.**

TEST YOUR UNDERSTANDING

1. When Griffith injected mice with a combination of live rough-strain and heat-killed smooth-strain pneumococci, he discovered that (a) the mice were unharmed (b) the dead mice contained living rough-strain bacteria (c) the dead mice contained living smooth-strain bacteria (d) DNA had been transferred from the smooth-strain bacteria to the mice (e) DNA had been transferred from the rough-strain bacteria to the smooth-strain bacteria
2. Which of the following inspired Avery and his colleagues to perform the experiments demonstrating that the transforming factor in bacteria is DNA? (a) the fact that A is equal to T, and G is equal to C (b) Watson and Crick's model of DNA structure (c) Meselson and Stahl's studies on DNA replication in *E. coli* (d) Griffith's experiments on smooth and rough strains of pneumococci (e) Hershey and Chase's experiments on the reproduction of bacteriophages
3. In the Hershey–Chase experiment with bacteriophages, (a) harmless bacterial cells permanently transformed into virulent cells (b) DNA was shown to be the transforming factor of earlier bacterial transformation experiments (c) the replication of DNA was conclusively shown to be semiconservative (d) viral DNA was shown to enter bacterial cells and cause the production of new viruses within the bacteria (e) viruses injected their proteins, not their DNA, into bacterial cells
4. The two complementary strands of the DNA double helix are held to each other by (a) ionic bonds between deoxyribose molecules (b) ionic bonds between phosphate groups (c) covalent bonds be-

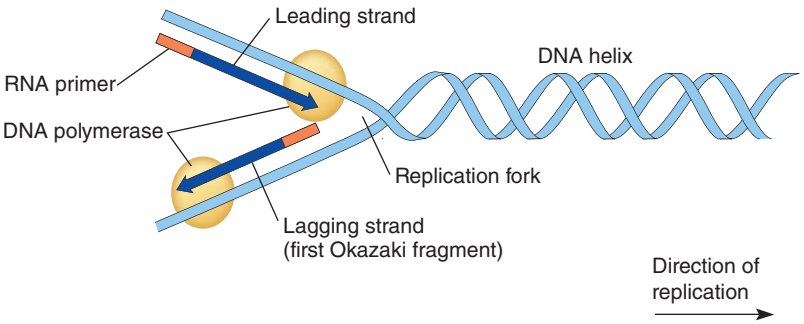
www.konkur.in

tween nucleotide bases (d) covalent bonds between deoxyribose molecules (e) hydrogen bonds between nucleotide bases

5. If a segment of DNA is 5′—CATTAC—3′, the complementary DNA strand is (a) 3′—CATTAC—5′ (b) 3′—GTAATG—5′ (c) 5′—CATTAC—3′ (d) 5′—GTAATG—3′ (e) 5′—CATTAC—5′
6. Each DNA strand has a backbone that consists of alternating (a) purines and pyrimidines (b) nucleotide bases (c) hydrogen bonds and phosphodiester linkages (d) deoxyribose and phosphate (e) phosphate and phosphodiester linkages
7. The experiments in which Meselson and Stahl grew bacteria in heavy nitrogen conclusively demonstrated that DNA (a) is a double helix (b) replicates semiconservatively (c) consists of repeating nucleotide subunits (d) has complementary base pairing (e) is always synthesized in the 5′ ⟶ 3′ direction
8. The statement "DNA replicates by a semiconservative mechanism" means that (a) only one DNA strand is copied (b) first one DNA strand is copied, and then the other strand is copied (c) the two strands of a double helix have identical base sequences (d) some portions of a single DNA strand are old, and other portions are newly synthesized (e) each double helix consists of one old and one newly synthesized strand
9. Topoisomerases (a) synthesize DNA (b) synthesize RNA primers (c) join Okazaki fragments (d) break and rejoin DNA to reduce torsional strain (e) prevent single DNA strands from joining to form a double helix
10. A lagging strand forms by (a) joining primers (b) joining Okazaki fragments (c) joining leading strands (d) breaking up a leading strand (e) joining primers, Okazaki fragments, and leading strands
11. The immediate source of energy for DNA replication is (a) the hydrolysis of nucleotides with three phosphate groups (b) the oxidation of NADPH (c) the hydrolysis of ATP (d) electron transport (e) the breaking of hydrogen bonds
12. Which of the following statements about eukaryotic chromosomes is *false*? (a) eukaryotic chromosomes have free ends (b) telomeres contain protein-coding genes (c) telomerase lengthens telomeric DNA (d) telomere shortening may contribute to cell aging (e) cells with active telomerase may undergo many cell divisions

CRITICAL THINKING

1. What characteristics must a molecule have to function as genetic material?
2. What important features of the structure of DNA are consistent with its role as the chemical basis of heredity?
3. What do telomeres on the ends of chromosomes protect against?
4. **ANALYZING DATA.** In the Hershey–Chase experiment, the radioactive label ^{32}P was present inside bacterial cells (i.e., in the pellet), whereas the radioactive label ^{35}S was present outside bacterial cells (in the supernatant). What would the researchers have concluded had the reverse been true—that is, if the radioactive label ^{35}S was inside the cells and the radioactive label ^{32}P was outside the cells?
5. **ANALYZING DATA.** In the following diagram of DNA replication, label the 3′ and 5′ ends of the leading strand, lagging strand, and the two strands of the DNA double helix.



6. **EVOLUTION LINK.** How does the fact that DNA is the universal molecule of inheritance in all cells support evolutionary theory?

13 Gene Expression

Professor Oscar Miller/Science Photo Library/Photo Researchers, Inc.

Visualizing transcription. In this TEM, RNA molecules (*lateral strands*) are synthesized as complementary copies of a DNA template (*central axis*).

KEY CONCEPTS

13.1 Beadle and Tatum demonstrated the relationship between genes and proteins in the 1940s.

13.2 The transmission of information in cells is typically from DNA to RNA to polypeptide.

13.3 A sequence of DNA base triplets is transcribed into mRNA codons.

13.4 A sequence of mRNA codons is translated into a sequence of amino acids in a polypeptide.

13.5 Bacterial and eukaryotic cells differ in certain details of gene expression.

13.6 Mutations can cause changes in phenotype.

In Chapter 12, we discussed how the cell accurately replicates the nucleotide sequence in DNA to pass the genetic material unaltered to the next generation. Watson and Crick originally described the basic features of the DNA double helix, which scientists now know to be the same in all cells studied to date—from the simplest bacterial cells to intricate human cells.

By the mid-1950s, researchers had determined that the sequence of bases in DNA contains the information that specifies all the proteins the cell needs. However, more than a decade of intense investigation by many scientists preceded a fundamental understanding of how cells convert DNA information into the amino acid sequences of proteins. Much of that understanding came from studying the functions of bacterial genes. After Watson and Crick discovered the structure of DNA, researchers

www.konkur.in

chose bacterial cells as the organisms for these studies because bacteria grow quickly and easily and because they contain the minimal amount of DNA needed for growth and reproduction. As researchers learned that all organisms have fundamental genetic similarities, the validity, as well as the utility, of this approach was repeatedly confirmed.

In this chapter we examine the evidence that accumulated in the first half of the 20th century indicating that most genes specify the structure of proteins. We then consider how DNA affects the phenotype of the organism at the molecular level through the process of gene expression. **Gene expression** involves a series of steps in which the information in the sequence of bases in DNA specifies the makeup of the cell's proteins. The proteins affect the phenotype in some way; these effects range from readily observable physical traits to subtle changes detectable only at the biochemical level. The first major step of gene expression is *transcription*, the synthesis of RNA molecules complementary to the DNA (see photograph). The second major step is *translation*, in which RNA becomes a coded template to direct polypeptide synthesis.

13.1 DISCOVERY OF THE GENE–PROTEIN RELATIONSHIP

LEARNING OBJECTIVES

1 Summarize the early evidence indicating that most genes specify the structure of proteins.

2 Describe Beadle and Tatum's experiments with *Neurospora*.

The idea that genes and proteins are connected originated early in the 20th century, shortly after scientists rediscovered Mendel's principles. In the first edition of his book, *Inborn Errors of Metabolism* (1908), Archibald Garrod, a physician and biochemist, discussed a rare genetic disease called **alkaptonuria,** which scientists hypothesized had a simple recessive inheritance pattern. The condition involves the metabolic pathway that breaks down the amino acid tyrosine, ultimately converting it to carbon dioxide and water. An intermediate in this pathway, homogentisic acid, accumulates in the urine of affected people, turning it black when exposed to air (**FIG. 13-1**). Other symptoms of alkaptonuria include the later development of arthritis and, in men, stones in the prostate gland.

In Garrod's time, scientists knew about enzymes but did not recognize they were proteins. Garrod hypothesized that people with alkaptonuria lack the enzyme that normally oxidizes homogentisic acid. Before the second edition of his book had been published, in 1923, researchers found that affected people do indeed lack the enzyme that oxidizes homogentisic acid. Garrod's hypothesis was correct: a mutation in this gene is associated with the absence of a specific enzyme. Shortly thereafter, in 1926, U.S. biochemist James Sumner purified a different enzyme, urease, and showed it to be a protein. This was the first clear identification of an enzyme as a protein. In 1946, Sumner was awarded the Nobel Prize in Chemistry for being the first to crystallize an enzyme.

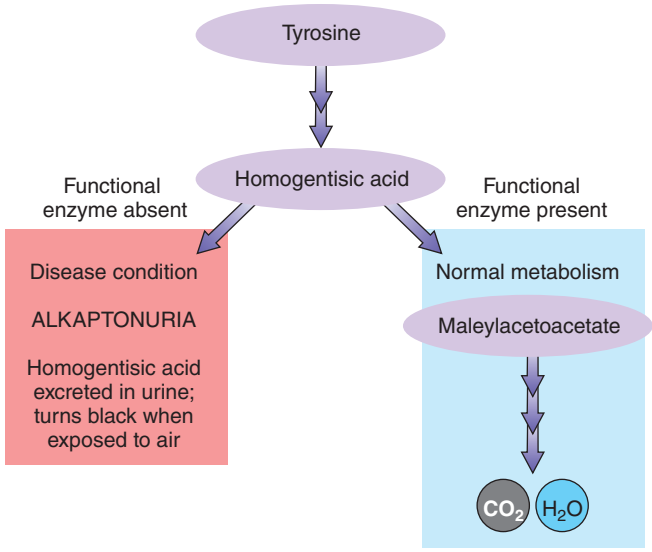

FIGURE 13-1 An "inborn error of metabolism"
Garrod proposed that alkaptonuria is a genetic disease caused by the absence of the enzyme homogentisic acid oxidase, which normally converts homogentisic acid to maleylacetoacetate. Thus, the acid accumulates in the blood and is excreted in the urine, which turns black on contact with the air.

Beadle and Tatum proposed the one-gene, one-enzyme hypothesis

A major advance in understanding the relationship between genes and enzymes came in the early 1940s, when U.S. geneticists George Beadle and Edward Tatum and their associates developed a new approach to the problem. Most efforts until that time had focused on studying known phenotypes, such as eye color in *Drosophila* or pigments in plants, and seeking to determine what biochemical reactions they affected. Researchers found that a series of biosynthetic reactions controls specific phenotypes, but it was not clear whether the genes themselves were acting as enzymes or whether they controlled the workings of enzymes in some indirect way.

Beadle and Tatum decided to take the opposite approach. Rather than try to identify the enzymes affected by single genes, they decided to look for mutations interfering with known metabolic reactions that produce essential molecules, such as amino acids and vitamins. They chose as an experimental organism a fungus, the pink-orange bread mold *Neurospora,* for several important reasons. Wild-type *Neurospora* is easy to grow in culture. (The adjective **wild-type** refers to an individual with the normal phenotype.) *Neurospora* manufactures all its essential biological molecules when grown on a simple growth medium (minimal medium) containing only sugar, salts, and the vitamin biotin. However, a mutant *Neurospora* strain that cannot make a substance such as an amino acid can still grow if that substance is added to the growth medium.

Neurospora is also an ideal experimental organism because it grows primarily as a haploid organism. The haploid condition allows a researcher to immediately identify a recessive mutant allele; there is no homologous chromosome that might carry a dominant allele that would mask its expression.

www.konkur.in

Beadle and Tatum began by exposing thousands of haploid wild-type *Neurospora* asexual spores to X-rays or ultraviolet radiation to produce mutant strains. They first grew each irradiated strain on a complete growth medium, which contained all the amino acids and vitamins normally made by *Neurospora.* Then they tested each strain on the minimal medium described previously. About 1% to 2% of the strains that grew on the complete medium failed to grow after transfer to the minimal medium. Beadle and Tatum reasoned that such strains carried a mutation that prevented the fungus from producing a chemical essential for growth. Further testing of the mutant strain on media containing different combinations of amino acids, vitamins, and other nutrients enabled the investigators to determine the exact compound required (**FIG. 13-2**).

The work on *Neurospora* revealed that each mutant strain had a mutation in only one gene and that each gene affected only one enzyme. Beadle and Tatum stated this one-to-one correspondence between genes and enzymes as the *one-gene, one-enzyme hypothesis.* In 1958, they received the Nobel Prize in Physiology or Medicine for discovering that genes regulate specific chemical events. The work of Beadle, Tatum, and others led to a more precise understanding of what a gene is and to additional predictions about the chemical nature of genes. The idea that a gene encodes the information to produce a single enzyme held for almost a decade, until additional findings required a modification of this definition.

In the late 1940s, researchers began to understand that genes control not only enzymes but other proteins as well. The U.S. chemist Linus Pauling and his colleagues demonstrated in 1949 that a mutation of a single gene alters the structure of hemoglobin. This particular mutant form of hemoglobin is associated with the genetic disease sickle cell anemia (discussed in Chapter 16). British biochemist Vernon Ingram extended Pauling's research in 1957 when he determined that sickle cell hemoglobin and normal hemoglobin differ by only one amino acid.

Studies by other scientists showed that many proteins are constructed from two or more polypeptide chains, each of which is under the control of a different locus. For example, hemoglobin contains two types of polypeptide chains, the α and β subunits. See the structure of hemoglobin in Figure 3-22a. Sickle cell anemia results from a mutation affecting the β subunits.

Scientists therefore extended the definition of a gene to include that one gene is responsible for one polypeptide chain. Even this definition has proved only partially correct, although as you will see later in this chapter, scientists still define a gene in terms of its product.

Although the elegant work of Beadle and Tatum and others demonstrated that genes are expressed in the form of proteins, the mechanism of gene expression was completely unknown. After Watson and Crick's discovery of the structure of DNA, many scientists worked to understand exactly how gene expression takes place. We begin with an overview of gene expression and then consider the various steps in more detail.

Review

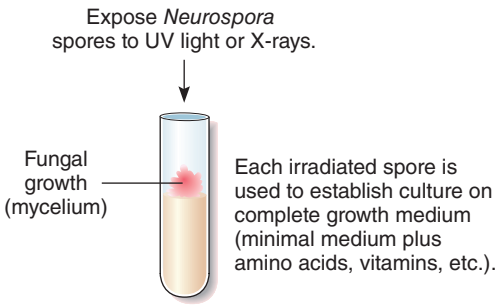
- What is the one-gene, one-enzyme hypothesis?
- What were the contributions of each of the following scientists—Garrod, Beadle and Tatum, and Pauling—to our understanding of the relationship between genes and proteins?

KEY EXPERIMENT

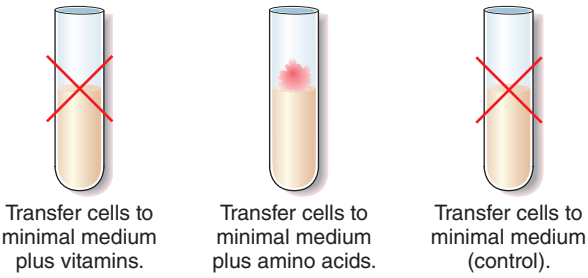
QUESTION: Can genes code for enzymes?

HYPOTHESIS: Mutations induced in *Neurospora,* a type of bread mold, correspond to the absence of functional enzymes.

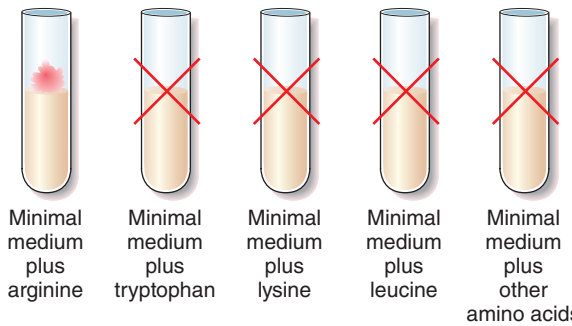
EXPERIMENT: Beadle and Tatum irradiated *Neurospora* spores to induce mutations. They grew cultures derived from these spores on complete growth medium containing all amino acids, vitamins, and other nutrients that *Neurospora* normally makes for itself. They identified nutritional requirements in mutant strains by testing for growth on minimal media supplemented with individual vitamins or amino acids.



RESULTS AND CONCLUSION: They transferred some fungal cells to each of three tubes: one with minimal medium plus vitamins; one with minimal medium plus amino acids; and one with minimal medium (the control). In this example the mutant fungus grew on the minimal medium only if it was supplemented with amino acids.



To determine which amino acid the mutant fungus had lost the ability to synthesize, they transferred the mutant fungus to tubes containing minimal medium and one amino acid only.



In this example, only the medium containing the amino acid arginine supported growth, indicating that the mutation affected some part of arginine's biosynthetic pathway. Beadle and Tatum then identified the enzyme-catalyzed step that was blocked in the synthesis of arginine. On the basis of many similar experiments, they concluded that each gene controls the production of a single enzyme.

FIGURE 13-2 The Beadle–Tatum experiments

13.2 INFORMATION FLOW FROM DNA TO PROTEIN: AN OVERVIEW

LEARNING OBJECTIVES

3 Outline the flow of genetic information in cells, from DNA to RNA to polypeptide.

4 Compare the structures of DNA and RNA.

5 Explain why the genetic code is said to be redundant and virtually universal, and discuss how these features may reflect its evolutionary history.

Although the sequence of bases in DNA determines the sequence of amino acids in polypeptides, cells do not use the information in DNA directly. Instead, a related nucleic acid, **ribonucleic acid (RNA),** links DNA and protein. When a gene that codes for a protein is expressed, first an RNA copy is made of the information in the DNA. It is this RNA copy that provides the information that directs polypeptide synthesis.

Like DNA, RNA is a polymer of nucleotides, but it has some important differences (**FIG. 13-3**). RNA is usually single-stranded, although internal regions of some RNA molecules may have complementary sequences that allow the strand to fold back and pair to form short, double-stranded segments. As shown in Figure 13-3, the sugar in RNA is **ribose,** which is similar to deoxyribose of DNA but has a hydroxyl group at the 2′ position. (Compare ribose with the deoxyribose of DNA, shown in Figure 12-4, which has a hydrogen at the 2′ position.) The base **uracil** substitutes for thymine and, like thymine, is a pyrimidine that can form two hydrogen bonds with adenine. Hence, uracil and adenine are a complementary pair.

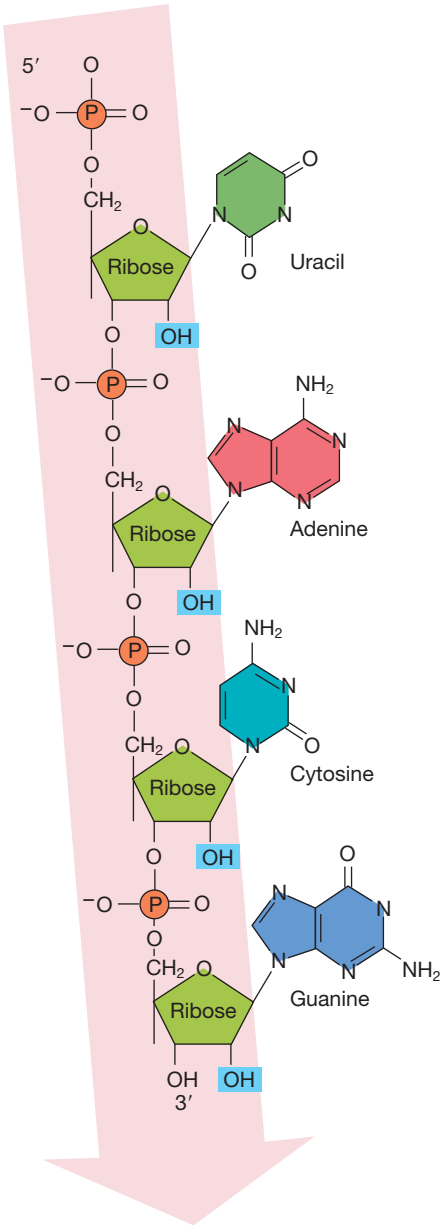

FIGURE 13-3 The nucleotide structure of RNA

The nucleotide subunits of RNA are joined by 5′ ⟶ 3′ phosphodiester linkages, like those found in DNA. Adenine, guanine, and cytosine are present, as in DNA, but the base uracil replaces thymine. All four nucleotide types contain the five-carbon sugar ribose, which has a hydroxyl group (*blue*) on its 2′ carbon atom.

DNA is transcribed to form RNA

The process by which RNA is synthesized resembles DNA replication in that the sequence of bases in the RNA strand is determined by complementary base pairing with one of the DNA strands, the **template strand** (**FIG. 13-4**). Because RNA synthesis takes the information in one kind of nucleic acid (DNA) and copies it as another nucleic acid (RNA), this process is called **transcription** ("copying").

Three main kinds of RNA molecules are transcribed: messenger RNA, transfer RNA, and ribosomal RNA. **Messenger RNA (mRNA)** is a single strand of RNA that carries the information for making a protein. Each of the 45 or so kinds of **transfer RNAs (tRNAs)** is a single strand of RNA that folds back on itself to form a specific shape. Each kind of tRNA bonds with only one kind of amino acid and carries it to the *ribosome.* (Because there are more kinds of tRNA molecules than there are amino acids, many amino acids are carried by two or more kinds of tRNA molecules.) **Ribosomal RNA (rRNA),** which is in a globular form, is an important part of the structure of ribosomes and has catalytic functions needed during protein synthesis.

RNA is translated to form a polypeptide

Following transcription, the transcribed information in the mRNA is used to specify the amino acid sequence of a polypeptide (see Fig. 13-4). This process is called **translation** because it involves conversion of the "nucleic acid language" in the mRNA molecule into the "amino acid language" of protein.

In translation of the genetic instructions to form a polypeptide, a sequence of three consecutive bases in mRNA, called a **codon,** specifies one amino acid. For example, one codon that corresponds to the amino acid phenylalanine is 5′—UUC—3′. Because each codon consists of three nucleotides, the code is described as a **triplet code.** The assignments of codons for amino acids and for start and stop signals are collectively named the **genetic code** (**FIG. 13-5**).

www.konkur.in

KEY POINT Protein synthesis requires two major steps: DNA $\xrightarrow{\text{transcription}}$ RNA $\xrightarrow{\text{translation}}$ protein

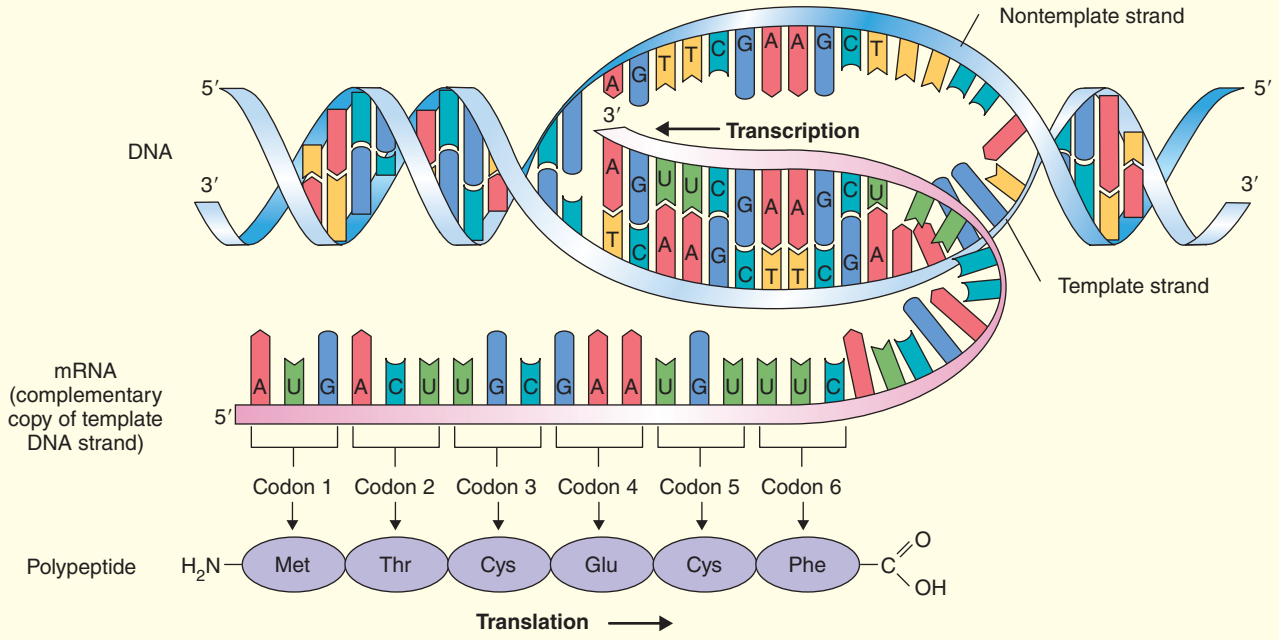

FIGURE 13-4 An overview of transcription and translation

In transcription, messenger RNA is synthesized as a complementary copy of one of the DNA strands, the template strand. Messenger RNA carries genetic information in the form of sets of three bases, or codons, each of which specifies one amino acid. Codons are translated consecutively, thus specifying the linear sequence of amino acids in the polypeptide chain. Translation requires tRNA and ribosomes (*not shown*). The figure depicts transcription and translation in bacteria. In eukaryotes, transcription takes place in the nucleus and translation occurs in the cytosol.

= Stop codon

= Start codon

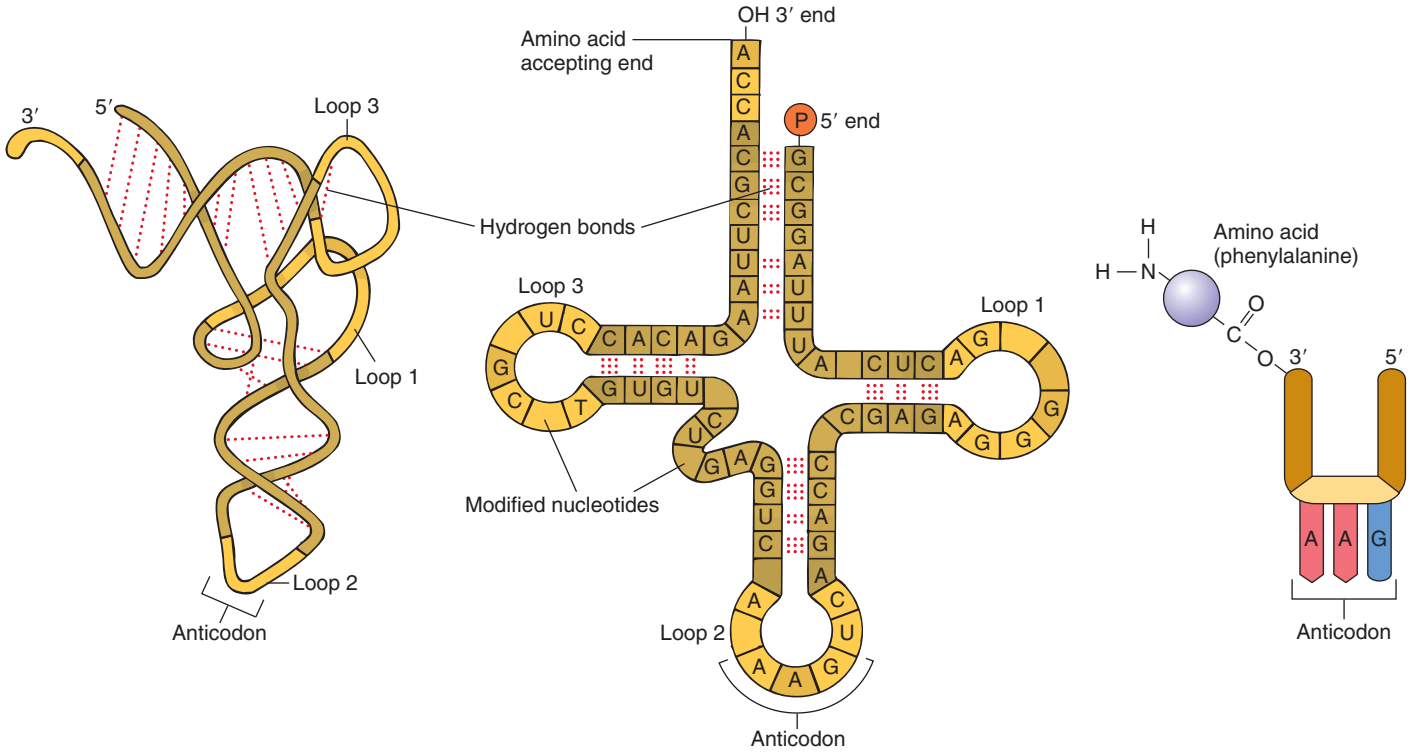
Transfer RNAs are crucial parts of the decoding machinery because they act as "adapters" that connect amino acids and nucleic acids. This mechanism is possible because each tRNA can (1) link with a specific amino acid and (2) recognize the appropriate mRNA codon for that particular amino acid (**FIG. 13-6**). A particular tRNA can recognize a particular codon because it has a sequence of three bases, called the **anticodon,** that hydrogen-bonds with the mRNA codon by complementary base pairing. The exact anticodon that is complementary to the codon for phenylalanine in our example is 3′—AAG—5′.

Translation requires that each tRNA anticodon be hydrogen-bonded to the complementary mRNA codon and that the amino acids carried by the tRNAs be linked in the order specified by the sequence of codons in the mRNA. **Ribosomes,** the site of translation, are organelles composed of two different subunits, each containing protein and rRNA. (The structure and function of ribosomes were introduced in Chapter 4.) Ribosomes attach to the 5′

FIGURE 13-5 The genetic code

The genetic code specifies all possible combinations of the three bases that compose codons in mRNA. Of the 64 possible codons, 61 specify amino acids (see Fig. 3-17 for an explanation of abbreviations). The codon AUG specifies the amino acid methionine and also signals the ribosome to initiate translation ("start"). Three codons—UAA, UGA, and UAG—do not specify amino acids; they terminate polypeptide synthesis ("stop").

www.konkur.in



(a) The 3-D shape of a tRNA molecule is determined by hydrogen bonds formed between complementary bases.

(b) One loop contains the anticodon; these unpaired bases pair with a complementary mRNA codon. The amino acid attaches to the terminal nucleotide at the hydroxyl (OH) 3′ end.

(c) This stylized diagram of an aminoacyl-tRNA shows that the amino acid attaches to tRNA by its carboxyl group, leaving its amino group exposed for peptide bond formation.

FIGURE 13-6 Three representations of a tRNA molecule

end of the mRNA and travel along it, allowing the tRNAs to attach sequentially to the codons of mRNA. In this way the amino acids carried by the tRNAs take up the proper position to be joined by *peptide bonds* in the correct sequence to form a polypeptide.

Biologists cracked the genetic code in the 1960s

Before the genetic code was deciphered, scientists had become interested in how a genetic code might work. The Watson and Crick model of DNA showed it to be a linear sequence of four different nucleotides. If each nucleotide coded for a single amino acid, the genetic code could specify only 4 amino acids, not the 20 found in the vast variety of proteins in the cell.

Scientists saw that the DNA bases could serve as a four-letter "alphabet" and hypothesized that three-letter combinations of the four bases would make it possible to form a total of 64 "words," more than enough to specify all the naturally occurring amino acids. In 1961, Crick and British scientist Sydney Brenner concluded from experimental evidence that the code used nonoverlapping triplets of bases. They predicted that the code is read, one triplet at a time, from a fixed starting point that establishes the **reading frame** for the genetic message.

Marshall Nirenberg, a U.S. biochemist, and his postdoctoral researcher, Heinrich Matthaei, studied protein synthesis outside living cells in purified *cell-free systems* derived from the bacterium *Escherichia coli*. Nirenberg and Matthaei obtained the first experimental evidence indicating the assignment of triplets to specific amino acids. By constructing artificial mRNA molecules with known base sequences, they determined which amino acids would be incorporated into protein. For example, when they added the synthetic mRNA polyuridylic acid (UUUUUUUUU . . .) to a mixture of purified ribosomes, aminoacyl-tRNAs (amino acids linked to their respective tRNAs), and essential cofactors needed to synthesize polypeptide, only phenylalanine was incorporated into the resulting polypeptide chain. The inference was inescapable that the UUU triplet codes for phenylalanine. Similar experiments showed that polyadenylic acid (AAAAAAAAA . . .) codes for a polypeptide of lysine and that polycytidylic acid (CCCCCCCCC . . .) codes for a polypeptide of proline.

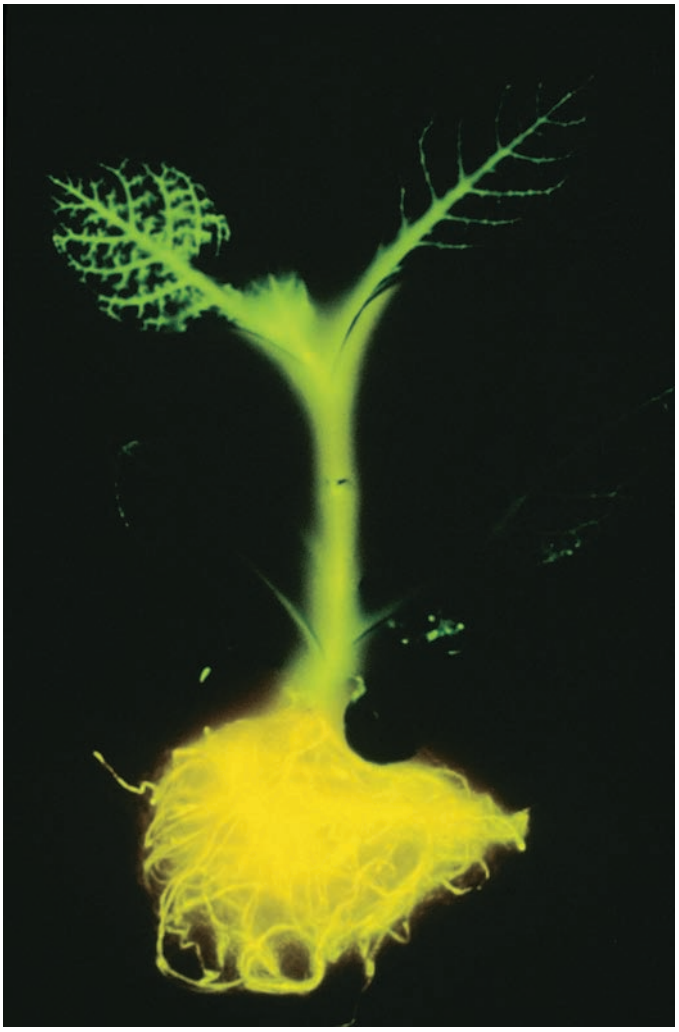
By using mixed nucleotide polymers (such as a random polymer of A and C) as artificial messengers, researchers such as H. Gobind Khorana, then at the University of Wisconsin, assigned the other codons to specific amino acids. However, three of the codons—UAA, UGA, and UAG—did not specify any amino acids. These codons are now known to be the signals that terminate the coding sequence for a polypeptide chain. By 1967, the genetic code was completely "cracked," and scientists had identified the coding assignments of all 64 possible codons shown in Figure 13-5. In 1968, Nirenberg and Khorana received the Nobel Prize in Physiology or Medicine for their work in deciphering the genetic code.

www.konkur.in

Remember that the genetic code is an mRNA code. The tRNA anticodon sequences, as well as the DNA sequence from which the message is transcribed, are complementary to the sequences in Figure 13-5. For example, the mRNA codon for the amino acid methionine is 5′—AUG—3′. It is transcribed from the DNA base sequence 3′—TAC—5′, and the corresponding tRNA anticodon is 3′—UAC—5′.

The genetic code is virtually universal

Perhaps the single most remarkable feature of the code is that it is essentially universal. Over the years, biologists have examined the genetic code in a diverse array of species and found it the same in organisms as different as bacteria, redwood trees, jellyfish, and humans (**FIG. 13-7**). These findings strongly suggest that the code is an ancient legacy that evolved early in the history of life (discussed in Chapter 21).



Keith V. Wood/Visuals Unlimited

FIGURE 13-7 Genetically engineered tobacco plant
This plant glows as it expresses the luciferase gene from a firefly. Luciferase is an enzyme that catalyzes a reaction that produces a flash of light. This classic experiment indicated that animal genes can be expressed in plants.

Scientists have discovered some minor exceptions to the universality of the genetic code. In several unicellular protozoa, UAA and UGA code for the amino acid glutamine instead of functioning as stop signals. Other exceptions are found in mitochondria, which contain their own DNA and protein synthesis machinery for some genes. These slight coding differences vary with the organism, but keep in mind that in each case, all the other coding assignments are identical to those of the standard genetic code.

The genetic code is redundant

Given 64 possible codons and only 20 common amino acids, it is not surprising that more than one codon specifies certain amino acids. This redundancy in the genetic code has certain characteristic patterns. The codons CCU, CCC, CCA, and CCG are "synonymous" in that they all code for the amino acid proline. The only difference among the 4 codons involves the nucleotide at the 3′ end of the triplet. Although the code may be read three nucleotides at a time, only the first two nucleotides seem to contain specific information for proline. A similar pattern can be seen for several other amino acids. Only methionine and tryptophan are specified by single codons. Each of the other amino acids is specified by 2 to 6 different codons.

Crick first proposed this apparent breach of the base-pairing rules as the **wobble hypothesis.** He reasoned that the third nucleotide of a tRNA anticodon (which is the 5′ base of the anticodon sequence) may sometimes form hydrogen bonds with more than one kind of third nucleotide (the 3′ base) of a codon. Investigators later established this experimentally by determining the anticodon sequences of tRNA molecules and testing their specificities in artificial systems. Some tRNAs bond exclusively to one codon, but other tRNA molecules pair with as many as three separate codons that differ in their third nucleotide but that specify the same amino acid. Thus, the wobble hypothesis accounts for the possible variation in base pairing between the third base of a codon and the corresponding base in its anticodon. "Wobble" results in several acceptable forms of base pairing between mRNA and tRNA.

13.3 TRANSCRIPTION

LEARNING OBJECTIVES

6 Compare the processes of transcription and DNA replication, identifying both similarities and differences.
7 Compare bacterial and eukaryotic mRNAs, and explain the functional significance of their structural differences.

Now that we have presented an overview of information flow from DNA to RNA to polypeptide, let us examine the entire pro-

www.konkur.in

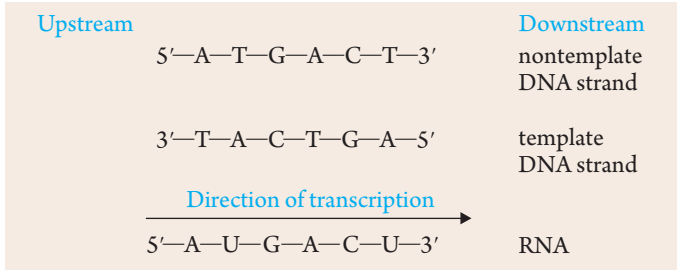
cess more closely. The first stage in the flow of information from DNA to polypeptide is the transcription of a DNA nucleotide sequence into an RNA nucleotide sequence. Stanford University biologist Roger Kornberg painstakingly worked out the details of transcription, for which he was awarded the 2006 Nobel Prize in Chemistry.

In eukaryotic transcription, most RNA synthesis requires one of three **RNA polymerases,** enzymes present in all cells. The three RNA polymerases differ in the kinds of RNA synthesis they catalyze. *RNA polymerase I* catalyzes the synthesis of several kinds of rRNA molecules that are components of the ribosome; *RNA polymerase II* catalyzes the production of the protein-coding mRNA; and *RNA polymerase III* catalyzes the synthesis of tRNA and one of the rRNA molecules.

RNA polymerases require DNA as a template and have many similarities to the DNA polymerases discussed in Chapter 12. Like DNA polymerases, RNA polymerases carry out synthesis in the 5′ ⟶ 3′ direction; that is, they begin at the 5′ end of the RNA molecule being synthesized and then continue to add nucleotides at the 3′ end until the molecule is complete (**FIG. 13-8**). RNA polymerases use nucleotides with three phosphate groups (for example, ATP and GTP) as substrates for the polymerization reaction. As the nucleotides link to the 3′ end of the RNA, two of the phosphates are removed. These reactions are strongly exergonic and do not need the input of additional energy.

Recall from Chapter 12 that whenever nucleic acid molecules associate by complementary base pairing, the two strands are **antiparallel.** Just as the two paired strands of DNA are antiparallel, the template strand of the DNA and the complementary RNA strand are also antiparallel. Therefore, when transcription takes place, as RNA is synthesized in its 5′ ⟶ 3′ direction, the DNA template is read in its 3′ ⟶ 5′ direction.

Scientists conventionally refer to a sequence of bases in a gene or the mRNA sequence transcribed from it as upstream or downstream from some reference point. *Upstream* is toward the 5′ end of the mRNA sequence or the 3′ end of the template DNA strand. *Downstream* is toward the 3′ end of the RNA or the 5′ end of the template DNA strand.



The synthesis of mRNA includes initiation, elongation, and termination

In both bacteria and eukaryotes, the nucleotide sequence in DNA to which RNA polymerase and associated proteins initially bind is called the **promoter.** Because the promoter is not transcribed, RNA polymerase moves past the promoter to begin transcription of the protein-coding sequence of DNA. Different genes may have

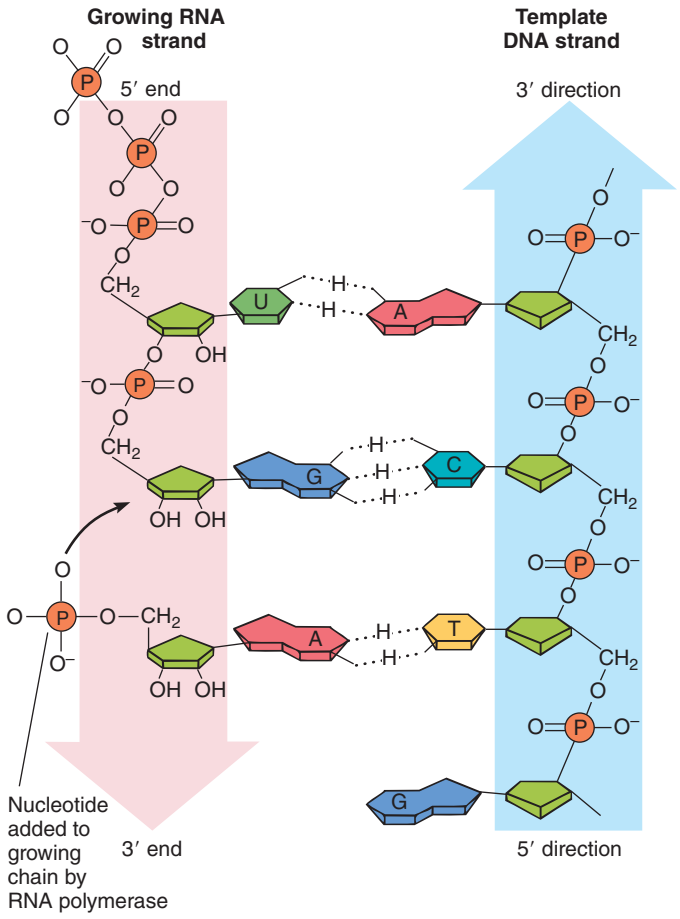


FIGURE 13-8 ***Animated*** **A molecular view of transcription**
Incoming nucleotides with three phosphates pair with complementary bases on the template DNA strand (*right*). RNA polymerase cleaves two phosphates (*not shown*) from each nucleotide and covalently links the remaining phosphate to the 3′ end of the growing RNA chain. Thus, RNA, like DNA, is synthesized in the 5′ ⟶ 3′ direction.

slightly different promoter sequences, so the cell can direct which genes are transcribed at any one time. Bacterial promoters are usually about 40 bases long and lie in the DNA just upstream of the point at which transcription will begin. Once RNA polymerase has recognized the correct promoter, it unwinds the DNA double helix and *initiates* transcription (**FIG. 13-9**). Unlike DNA synthesis, RNA synthesis does not require a primer. However, transcription requires several proteins in addition to RNA polymerase; we discuss these in Chapter 14.

The first nucleotide at the 5′ end of a new mRNA chain initially retains its triphosphate group (see Fig. 13-8). However, during the *elongation* stage of transcription, as each additional nucleotide is incorporated at the 3′ end of the growing RNA molecule, two of its phosphates are removed in an exergonic reaction that leaves the remaining phosphate to become part of the sugar–phosphate backbone (as in DNA replication). The last nucleotide to be incorporated has an exposed 3′-hydroxyl group.

Elongation of RNA continues until *termination,* when RNA polymerase recognizes a termination sequence consisting of a

www.konkur.in

KEY POINT The mRNA is synthesized in the 5′ to 3′ direction as the template strand of the DNA molecule is read in the 3′ to 5′ direction.

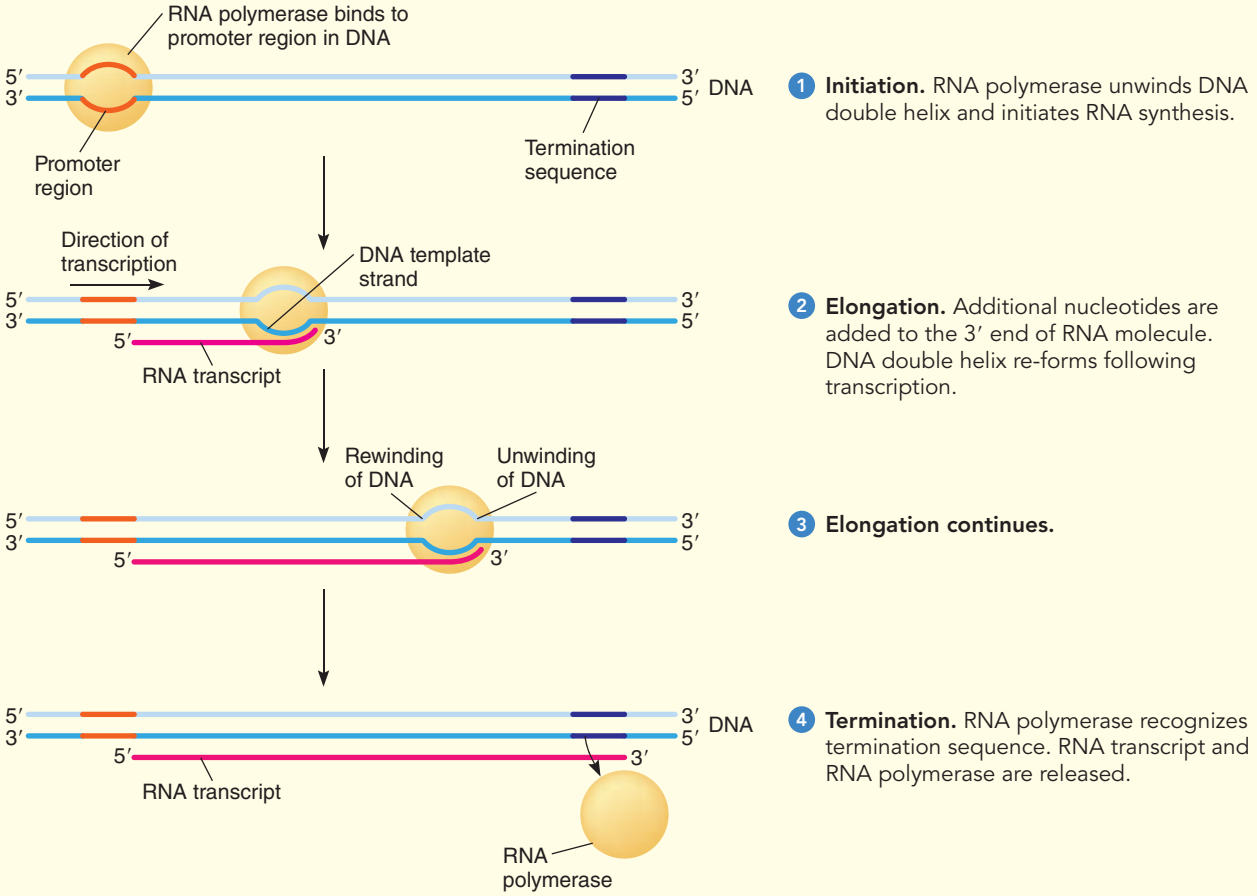

FIGURE 13-9 *Animated* An overview of transcription: initiation, elongation, and termination

specific sequence of bases in the DNA template. This signal leads to a separation of RNA polymerase from the template DNA and the newly synthesized RNA.

Termination of transcription occurs by different mechanisms in bacteria and eukaryotes. In bacteria, transcription stops at the end of the termination sequence. When RNA polymerase comes to the termination sequence, it releases the DNA template and the new RNA strand. In eukaryotic cells, RNA polymerase adds nucleotides to the mRNA molecule after it passes the termination sequence. The 3′ end of the mRNA becomes separated from RNA polymerase about 10 to 35 nucleotides past the termination sequence.

Only one strand in a protein-coding region of DNA is used as a template. For example, consider a segment of DNA that contains the following DNA base sequence in the template strand:

3′—TAACGGTCT—5′

If the complementary DNA strand

5′—ATTGCCAGA—3′

were used as a template, a message would be produced specifying an entirely different (and probably nonfunctional) protein. However, just because one strand is transcribed for a given gene does not mean the same DNA strand is always the template for all genes throughout the length of a chromosome-sized DNA molecule. Instead, a particular strand may serve as the template strand for some genes and the nontemplate strand for others (**FIG. 13-10**).

Messenger RNA contains base sequences that do not directly code for protein

A completed mRNA molecule contains more than the nucleotide sequence that codes for a protein. **FIGURE 13-11** shows a typical bacterial mRNA. (The unique features of eukaryotic mRNA are discussed in the next section.) In both bacteria and eukaryotes, RNA polymerase starts transcription of a gene upstream of the protein-coding DNA sequence. As a result, the mRNA has a noncoding **leader sequence** at its 5′ end. The leader has recognition sites for ribosome binding, which properly position the ribosomes to translate the message. The **start codon** follows the leader sequence and signals the beginning of the **coding sequence** that contains the

www.konkur.in

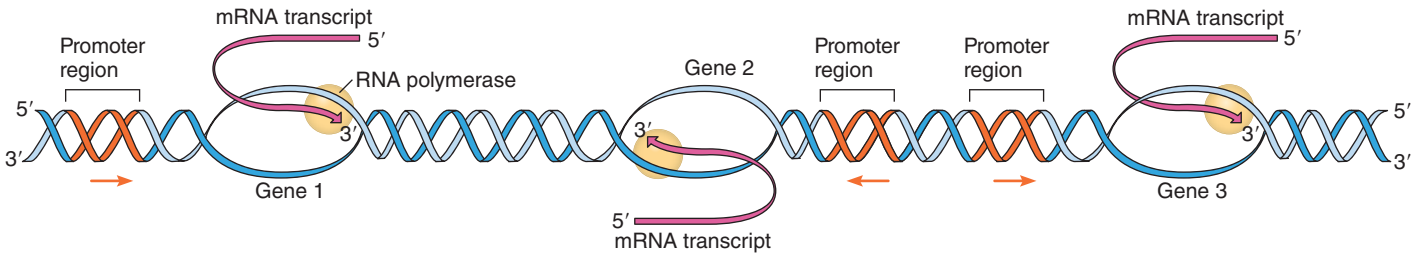

FIGURE 13-10 **The template strand for one gene may be the nontemplate strand for another gene**

Only one of the two strands is transcribed for a given gene, but the opposite strand may be transcribed for a neighboring gene. Each transcript starts at its own promoter region (*orange*). The orange arrow associated with each promoter region indicates the direction of transcription.

actual message for the polypeptide. Unlike coding in eukaryotic cells, in bacterial cells it is common for more than one polypeptide to be encoded by a single mRNA molecule (see Chapter 14). At the end of each coding sequence, a **stop codon** signals the end of the protein. The stop codons—UAA, UGA, and UAG—end both bacterial and eukaryotic messages. They are followed by noncoding 3′ **trailing sequences,** which vary in length.

Eukaryotic mRNA is modified after transcription and before translation

Other differences exist between bacterial and eukaryotic mRNA. Bacterial mRNAs are used immediately after transcription, without further processing. In eukaryotes, the original transcript, called **precursor mRNA,** or **pre-mRNA,** is modified in several ways while it is still in the nucleus. These *posttranscriptional modification and processing* activities produce mature mRNA for transport and translation.

Modification of the eukaryotic message begins when the growing RNA transcript is about 20 to 30 nucleotides long. At that point, enzymes add a **5′ cap** to the 5′ end of the mRNA chain (**FIG. 13-12**). The cap is in the form of an unusual nucleotide, 7-methylguanosine, which is linked to the mRNA transcript by three phosphate groups. Eukaryotic ribosomes cannot bind to an uncapped message.

Capping may also protect the mRNA from certain types of degradation and may therefore partially explain why eukaryotic mRNAs are much more stable than bacterial mRNAs. Eukaryotic mRNAs have half-lives ranging from 30 minutes to as long as 24 hours. The average half-life of an mRNA molecule in a mammalian cell is about 10 hours compared with 2 minutes in a bacterial cell.

A second modification of eukaryotic mRNA, known as **polyadenylation,** may occur at the 3′ end of the molecule. Near the 3′ end of a completed message usually lies a sequence of bases that serves as a signal for adding many adenine-containing nucleotides, known as a **poly-A tail** (for *polyadenylated*). Enzymes in the nucleus recognize the signal for the poly-A tail and cut the mRNA molecule at that site. This process is followed by the enzymatic addition of a string of 100 to 250 adenine nucleotides to the 3′ end. Polyadenylation appears to have several functions: it helps export the mRNA from the nucleus, stabilizes some mRNAs against degradation in the cytosol (the longer the poly-A tail, the longer

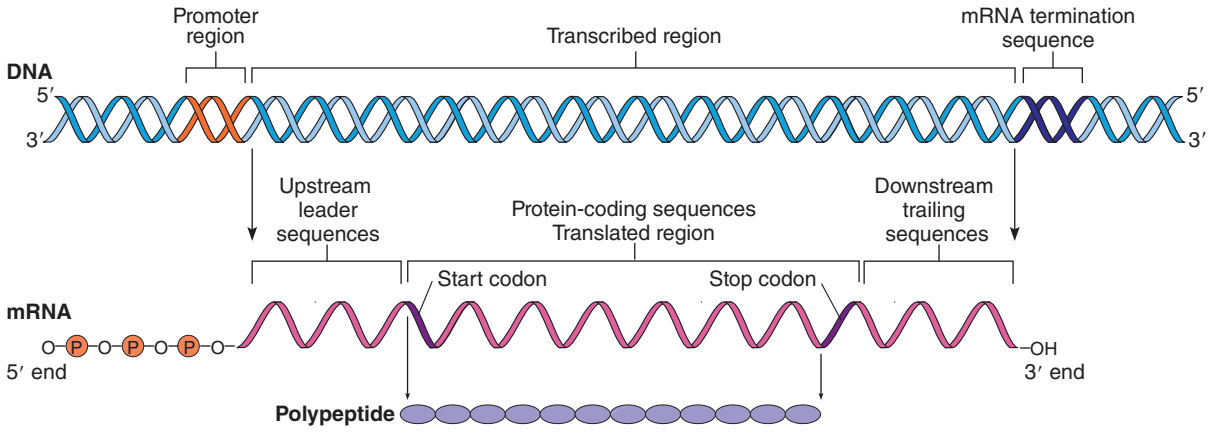

FIGURE 13-11 Bacterial mRNA

This figure compares a bacterial mRNA with the region of DNA from which it was transcribed. RNA polymerase recognizes, but does not transcribe, promoter sequences in the DNA. Initiation of RNA synthesis occurs five to eight bases downstream from the promoter. Ribosome recognition sites are located in the 5′ mRNA upstream leader sequences. Protein-coding sequences begin at a start codon, which follows the leader sequences, and end at a downstream stop codon near the 3′ end of the mRNA molecule. Downstream trailing sequences, which vary in length, follow the polypeptide-coding sequences.

www.konkur.in

KEY POINT After transcription in eukaryotes, pre-mRNA undergoes extensive modification to produce mature, functional mRNA.

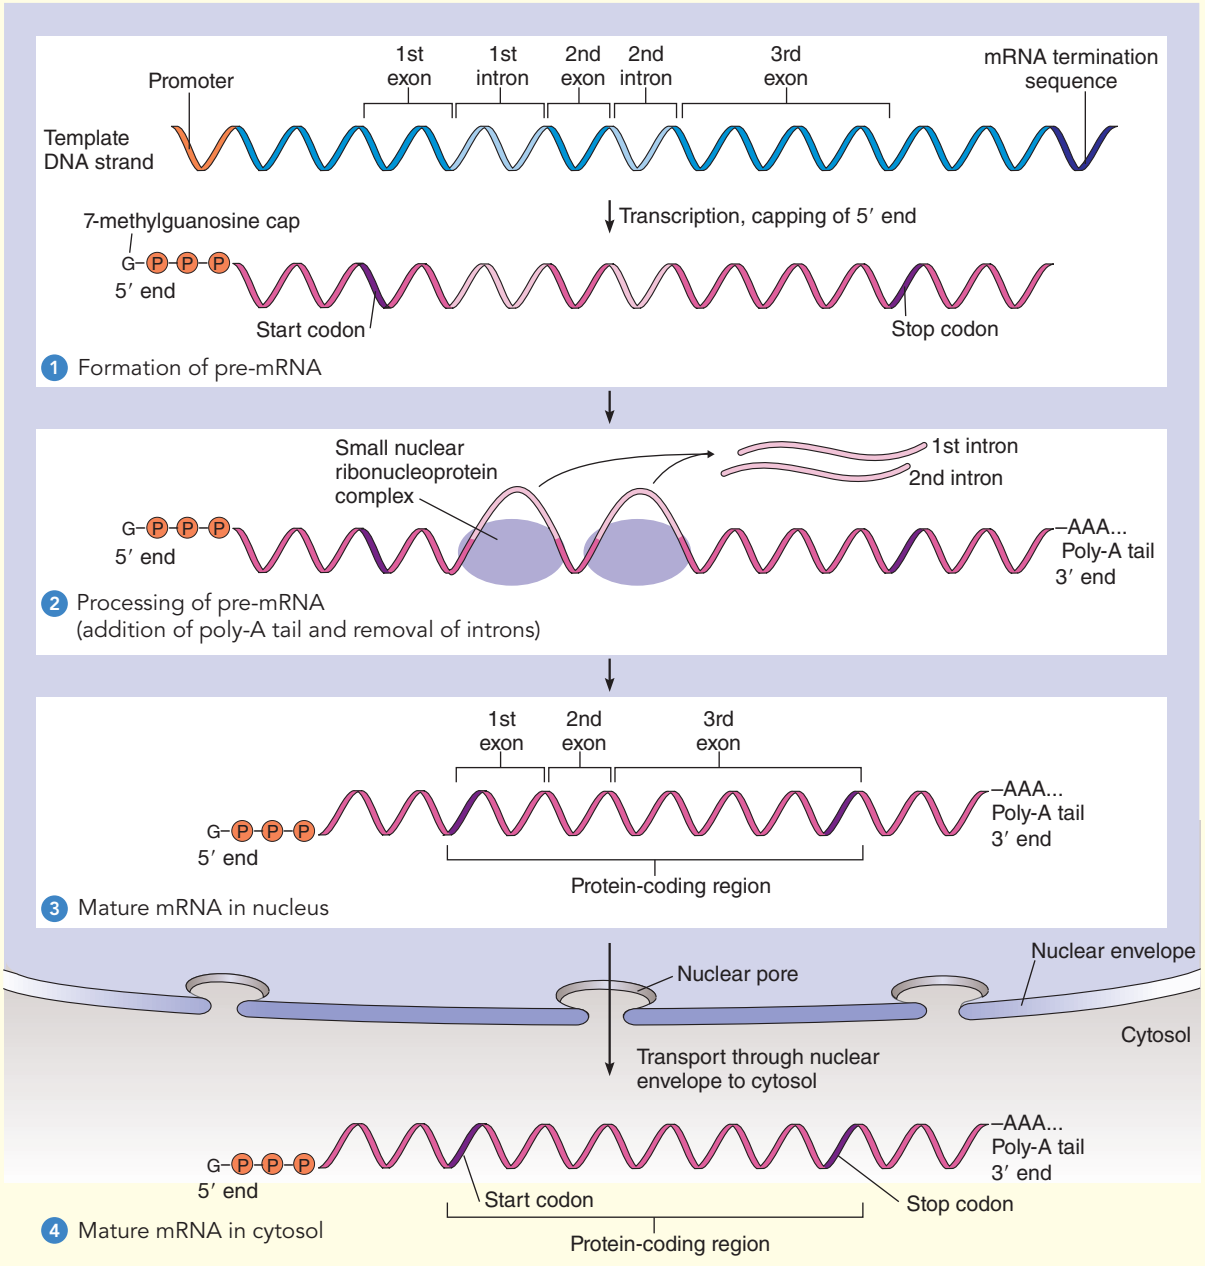

FIGURE 13-12 ***Animated*** **Posttranscriptional modification of eukaryotic messenger RNA**

the molecule persists in the cytosol), and facilitates initiation of translation by helping ribosomes recognize the mRNA.

Both noncoding and coding sequences are transcribed from eukaryotic genes

One of the greatest surprises in the history of molecular biology was the finding that most eukaryotic genes have **interrupted coding sequences:** long sequences of bases within the protein-coding sequences of the gene do not code for amino acids in the final polypeptide product. The noncoding regions within the gene are called **introns** (*in*tervening sequences), as opposed to **exons** (*ex*pressed sequences), which are parts of the protein-coding sequence.

A typical eukaryotic gene may have multiple exons and introns, although the number varies. For example, the human β-globin gene, which produces one component of hemoglobin, contains 2 introns and 3 exons; the human gene for albumin contains 14 introns and 15 exons; and the human gene for titin, the largest protein known, found in muscle cells, contains 233 introns and 234 exons. In many cases, the combined lengths of the intron sequences are much greater than the combined lengths of the exons. For instance,

www.konkur.in

the ovalbumin gene contains about 7700 base pairs, whereas the total of all the exon sequences is only 1859 base pairs.

When a gene that contains introns is transcribed, the entire gene is copied as a large RNA transcript, the pre-mRNA. A pre-mRNA molecule contains both intron and exon sequences. (Note that *intron* and *exon* refer to corresponding nucleotide sequences in both DNA and RNA.) For the pre-mRNA to be made into a functional message, it must be capped and have a poly-A tail added, and the introns must be removed and the exons spliced together to form a continuous protein-coding message.

Splicing itself occurs by several different mechanisms, depending on which type of RNA is involved. In many instances, splicing involves the association of several **small nuclear ribonucleoprotein complexes** (**snRNPs,** pronounced "snurps") to form a large ribonucleoprotein complex called a **spliceosome.** Spliceosomes, which are similar in size to ribosomes, catalyze the reactions that remove introns from pre-mRNA. In other instances the RNA within the intron acts as an RNA catalyst, or **ribozyme,** splicing itself without the use of a spliceosome or protein enzymes.

Posttranscriptional modification in eukaryotes is summarized as follows:

pre-mRNA containing introns and exons ⟶ 5′ end of pre-mRNA capped with modified nucleotide ⟶ poly-A tail added to 3′ end ⟶ introns removed and exons spliced together ⟶ mature mRNA transported into cytosol ⟶ translation at ribosome

Following pre-mRNA processing, the mature mRNA is transported through a nuclear pore into the cytosol to be translated by a ribosome.

13.4 TRANSLATION

LEARNING OBJECTIVES

8 Identify the features of tRNA that are important in decoding genetic information and converting it into "protein language."
9 Explain how ribosomes function in polypeptide synthesis.
10 Describe the processes of initiation, elongation, and termination in polypeptide synthesis.

Translation adds another level of complexity to the process of information transfer because it involves conversion of the triplet nucleic acid code to the 20–amino acid alphabet of polypeptides. Translation requires the coordinated functioning of more than 100 kinds of macromolecules, including the protein and RNA components of the ribosomes, mRNA, and amino acids linked to tRNAs.

Amino acids are joined by *peptide bonds* to form proteins. (See the formation of a peptide bond in Figure 3-18.) This joining links the amino and carboxyl groups of adjacent amino acids. The translation process ensures both that peptide bonds form and that the amino acids link in the correct sequence specified by the codons in the mRNA.

An amino acid is attached to tRNA before incorporation into a polypeptide

How do the amino acids align in the proper sequence so they can link? Crick proposed that a molecule was needed to bridge the gap between mRNA and proteins. This molecule was determined to be tRNA. DNA contains genes that are transcribed to form the tRNAs. Each kind of tRNA molecule binds to a specific amino acid. Amino acids are covalently linked to their respective tRNA molecules by enzymes, called **aminoacyl–tRNA synthetases,** which use ATP as an energy source (**FIG. 13-13**). The resulting complexes, called

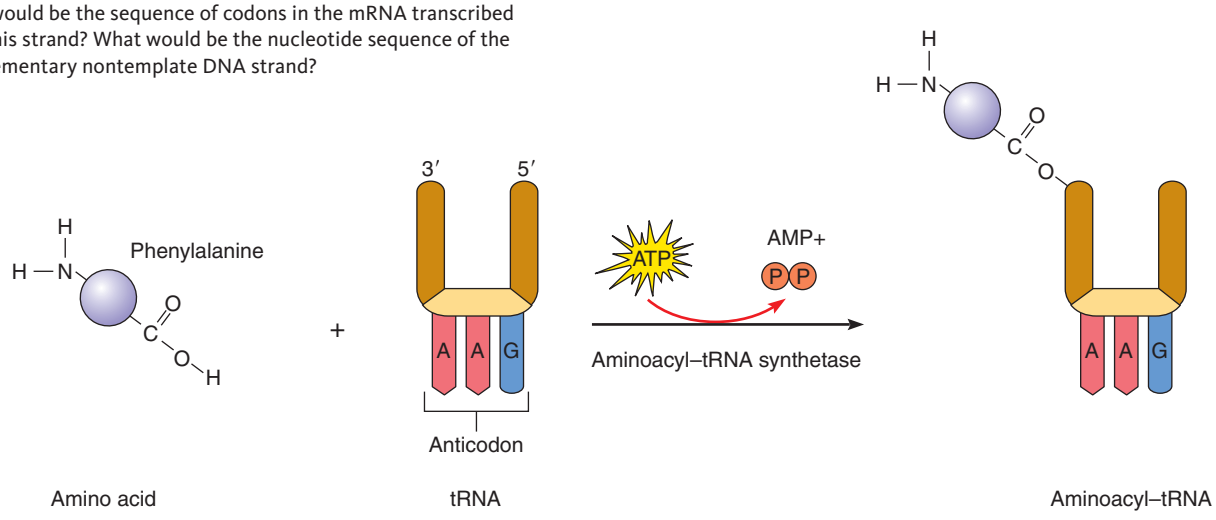

FIGURE 13-13 Linkage of a specific amino acid to the appropriate tRNA
Amino acids are covalently linked to their respective tRNA molecules by aminoacyl–tRNA synthetases, which use ATP as an energy source.

www.konkur.in

aminoacyl–tRNAs, bind to the mRNA coding sequence to align the amino acids in the correct order to form the polypeptide chain.

The tRNAs are polynucleotide chains 70 to 80 nucleotides long, each with several unique base sequences as well as some sequences that are common to all. Although considerably smaller than mRNA or rRNA molecules, tRNA molecules have an intricate structure. A tRNA molecule has several properties essential to its function: (1) it has an anticodon, a complementary binding sequence for the correct mRNA codon; (2) it is recognized by an aminoacyl–tRNA synthetase that adds the correct amino acid; (3) it has an attachment site for the specific amino acid specified by the anticodon (the site lies about 180 degrees from the anticodon); and (4) it is recognized by ribosomes.

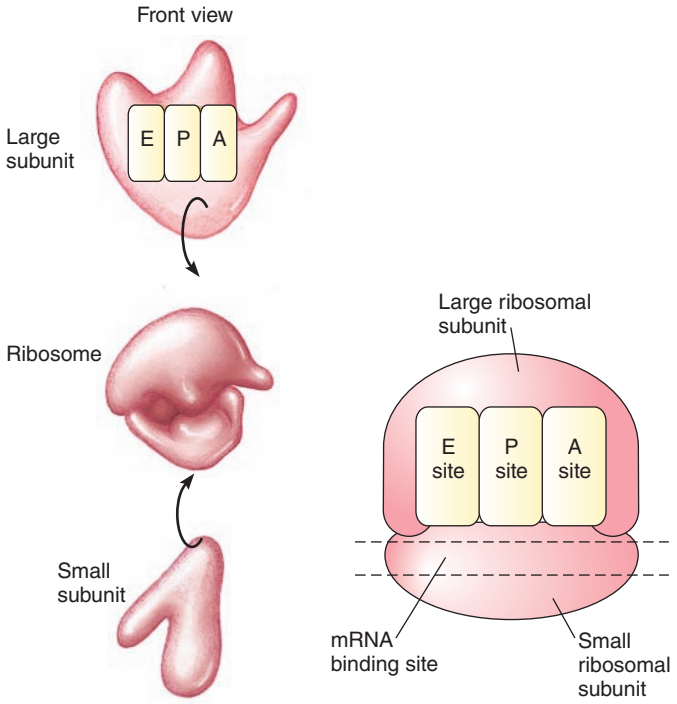
Complementary base pairing within each tRNA molecule causes it to be doubled back and folded. Three or more loops of unpaired nucleotides are formed, one of which contains the anticodon. The amino acid–binding site is at the 3′ end of the molecule. The carboxyl group of the amino acid is covalently bound to the exposed 3′ hydroxyl group of the terminal nucleotide, leaving the amino group of the amino acid free to participate in peptide bond formation. The pattern of folding in tRNAs keeps a constant distance between the anticodon and amino acid, allowing precise positioning of the amino acids during translation.

The components of the translational machinery come together at the ribosomes

The importance of ribosomes and of protein synthesis in cell metabolism is exemplified by a rapidly growing *E. coli* cell, which contains some 15,000 ribosomes—nearly one-third of the total mass of the cell. Although bacterial and eukaryotic ribosomes are not identical, ribosomes from all organisms share many fundamental features and basically work in the same way. Ribosomes consist of two subunits, both made up of protein (about 40% by weight) and rRNA (about 60% by weight). Unlike mRNA and tRNA, rRNA has catalytic functions and does not transfer information. The ribosomal proteins do not appear to be catalytic but instead contribute to the overall structure and stability of the ribosome.

Researchers have isolated each ribosomal subunit intact in the laboratory, then separated each into its RNA and protein constituents. In bacteria, the smaller of these subunits contains 21 proteins and one rRNA molecule, and the larger subunit contains 34 proteins and two rRNA molecules. Under certain conditions researchers can reassemble each subunit into a functional form by adding each component in its correct order. Using this approach, together with sophisticated electron microscopic studies, researchers have determined the 3-D structure of the ribosome (**FIG. 13-14a**), as well as the way it is assembled in the living cell. The large subunit contains a depression on one surface into which the small subunit fits. During translation, the mRNA fits in a groove between the contact surfaces of the two subunits.

The ribosome has four binding sites, one for mRNA and three for tRNAs. Thus, the ribosome holds the mRNA template, the aminoacyl–tRNA molecules, and the growing polypeptide chain in the correct orientation so the genetic code can be read and the next peptide bond formed. Transfer RNA molecules attach to three depressions on the ribosome, the A, P, and E binding sites



(a) A ribosome consists of two subunits, one large and one small. This model of a ribosome is based on a 3-D reconstruction of electron microscopic images.

(b) The mRNA passes through a groove between the two ribosomal subunits. Each ribosome contains three binding sites for tRNA molecules.

FIGURE 13-14 ***Animated*** **Ribosome structure**

(**FIG. 13-14b**). The **P site,** or peptidyl site, is so named because the tRNA holding the growing polypeptide chain occupies the P site. The **A site** is named the aminoacyl site because the aminoacyl–tRNA delivering the next amino acid in the sequence binds at this location. The **E site** (for *exit*) is where tRNAs that have delivered their amino acids to the growing polypeptide chain exit the ribosome.

Translation begins with the formation of an initiation complex

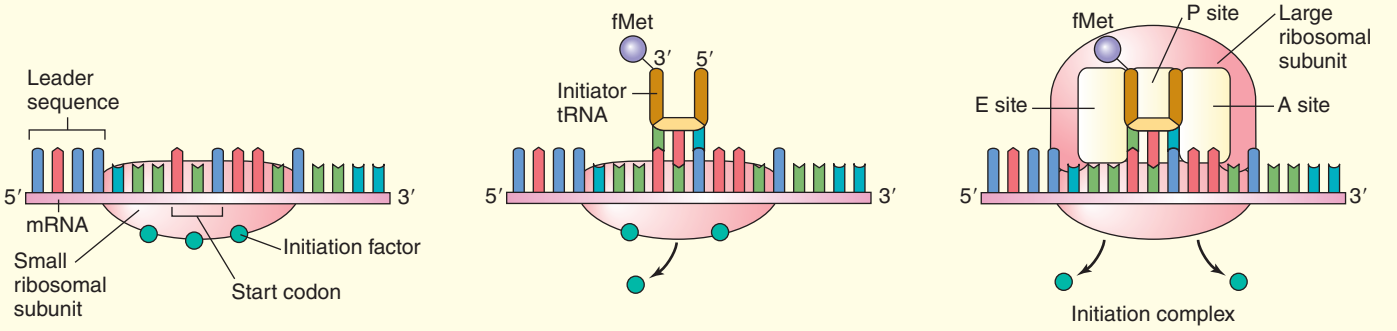
The process of protein synthesis has three distinct stages: initiation, repeating cycles of elongation, and termination. Initiation of protein synthesis is essentially the same in all organisms. Here we describe initiation in bacteria and then briefly discuss some differences between bacterial and eukaryotic initiation.

The **initiation** of translation uses proteins called **initiation factors,** which become attached to the small ribosomal subunit. In bacteria, three different initiation factors attach to the small subunit, which then binds to the mRNA molecule in the region of the AUG start codon (**FIG. 13-15**). A leader sequence upstream (toward the 5′ end) of the AUG helps the ribosome identify the AUG sequence that signals the beginning of the mRNA code for a protein.

The tRNA that bears the first amino acid of the polypeptide is the **initiator tRNA.** The amino acid methionine is bound to the initiator tRNA, and as a result, the first amino acid on new poly-

www.konkur.in

KEY POINT Initiation in bacteria involves a ribosome, an mRNA, an initiator tRNA to which formylated methionine (fMet) is bound, and several protein initiation factors.



1 The small ribosomal subunit binds to the mRNA at the AUG start codon. The leader sequence upstream of the AUG sequence helps the ribosome identify the AUG sequence.

2 The initiator tRNA binds to the start codon, and one of the initiation factors is released.

3 When the large ribosomal subunit binds to the small subunit and the remaining initiation factors are released, the initiation complex is complete.

FIGURE 13-15 The initiation of translation in bacteria

peptides is methionine. (Quite often, the methionine is removed later.) In bacteria, the initiator methionine is modified by the addition of a one-carbon group derived from formic acid and is designated *fMet* for *N*-formylmethionine. The fMet–initiator tRNA, which has the anticodon 3′—UAC—5′, binds to the AUG start codon, releasing one of the initiation factors in the process. The **initiation complex** is complete when the large ribosomal subunit binds to the small subunit and the remaining initiation factors are released.

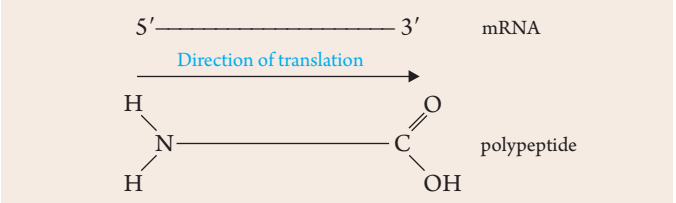
In eukaryotes, initiation of translation differs in three respects. First, the methionine of the initiator tRNA is unmodified. Second, instead of a leader sequence to help identify the start codon on mRNA, the start codon is embedded within a short sequence (such as ACCAUGG) that indicates the site (the underlined AUG) of translation initiation. Third, the initiation complex, which contains perhaps 10 protein factors, is different from that of bacteria.

During elongation, amino acids are added to the growing polypeptide chain

FIGURE 13-16 outlines the four steps in a cycle of **elongation,** the stage of translation in which amino acids are added one by one to the growing polypeptide chain. Elongation is essentially the same in bacteria and eukaryotes. The appropriate aminoacyl–tRNA recognizes the codon in the A site and binds there by base pairing of its anticodon with the complementary mRNA codon. This binding step requires several proteins called **elongation factors.** It also requires energy from **guanosine triphosphate (GTP),** an energy transfer molecule similar to ATP.

The amino group of the amino acid at the A site is now aligned with the carboxyl group of the preceding amino acid attached to the growing polypeptide chain at the P site. A peptide bond forms between the amino group of the new amino acid and the carboxyl group of the preceding amino acid. In this way, the polypeptide is released from tRNA at the P site and attaches to the aminoacyl–tRNA at the A site. This reaction is spontaneous (it does not require additional energy) because ATP transferred energy during formation of the aminoacyl–tRNA. Peptide bond formation does, however, require the enzyme **peptidyl transferase.** Remarkably, this enzyme is not a protein but a ribozyme that is an RNA component of the large ribosomal subunit. Two biochemists, American Thomas Cech (University of Colorado) and Canadian Sidney Altman (Yale University), received a Nobel Prize in Chemistry in 1989 for their independent discovery of ribozymes.

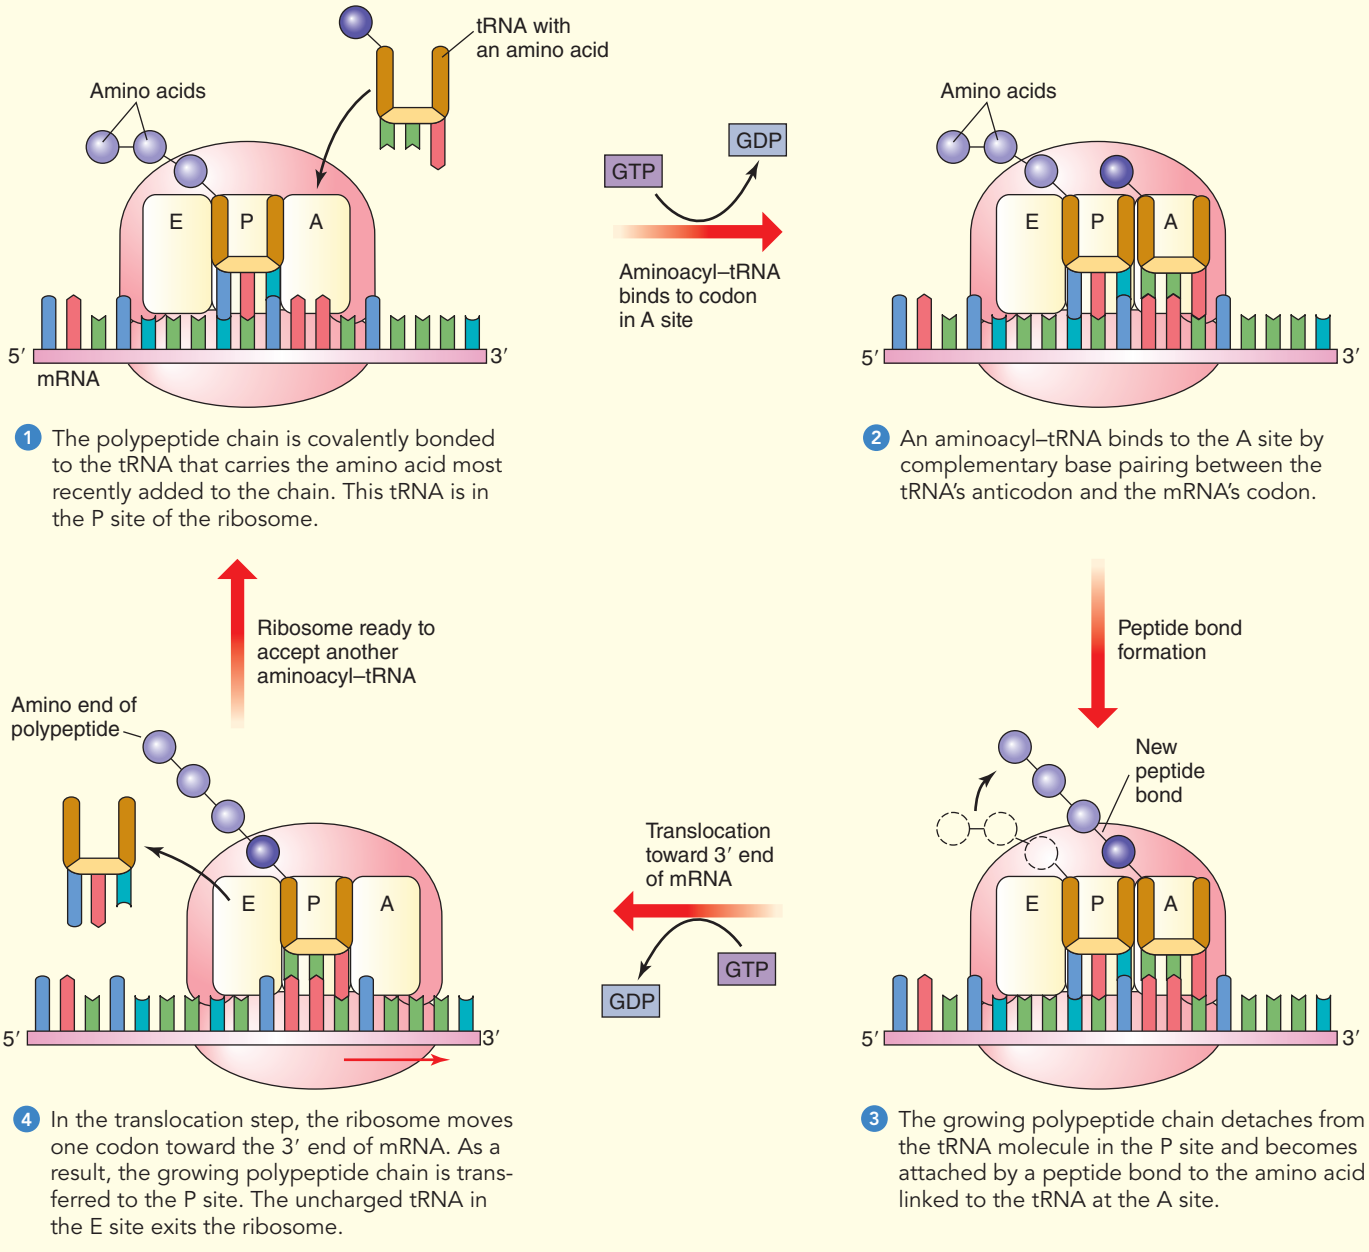
Recall from Chapter 3 that polypeptide chains have direction, or polarity. The amino acid on one end of the polypeptide chain has a free amino group (the amino end), and the amino acid at the other end has a free carboxyl group (the carboxyl end). Protein synthesis always proceeds from the amino end to the carboxyl end of the growing polypeptide chain:



In **translocation,** the ribosome moves down the mRNA by one codon. As a result, the mRNA codon specifying the next amino acid in the polypeptide chain becomes positioned in the unoccupied A site. The translocation process requires energy, which again GTP supplies. The uncharged tRNA—that is, the tRNA without an attached amino acid—is moved from the P site

www.konkur.in

KEY POINT Each repetition of the elongation process adds one amino acid to the growing polypeptide chain.



1 The polypeptide chain is covalently bonded to the tRNA that carries the amino acid most recently added to the chain. This tRNA is in the P site of the ribosome.

2 An aminoacyl–tRNA binds to the A site by complementary base pairing between the tRNA's anticodon and the mRNA's codon.

4 In the translocation step, the ribosome moves one codon toward the 3′ end of mRNA. As a result, the growing polypeptide chain is transferred to the P site. The uncharged tRNA in the E site exits the ribosome.

3 The growing polypeptide chain detaches from the tRNA molecule in the P site and becomes attached by a peptide bond to the amino acid linked to the tRNA at the A site.

FIGURE 13-16 An elongation cycle in translation
This illustration begins after a short chain of amino acids has formed.

to the E site. From there it exits the ribosome and joins the cytosolic pool of tRNAs.

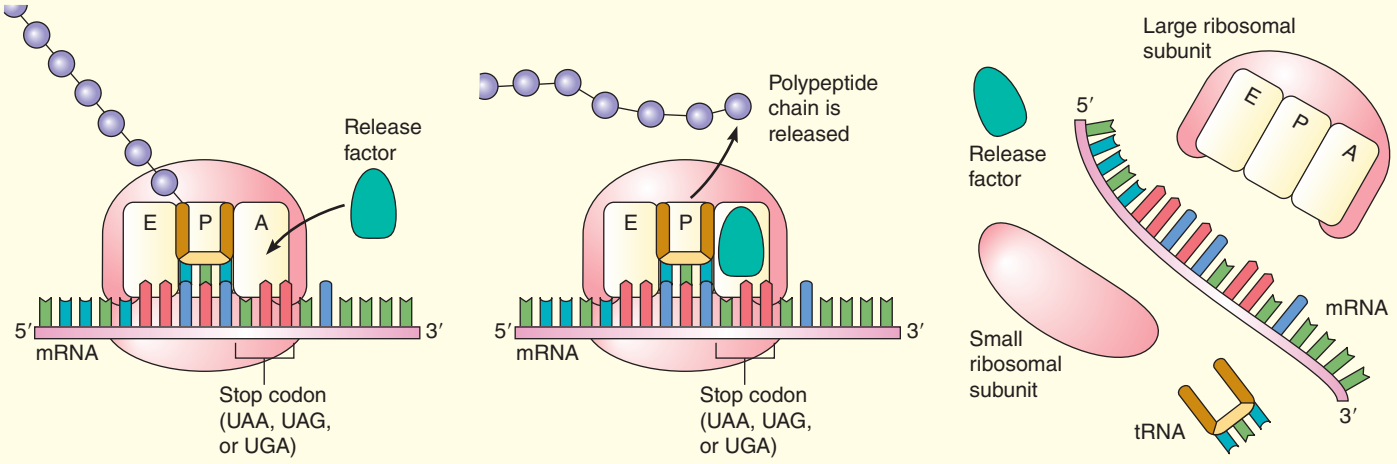
Because translocation involves movement of the ribosome in the 3′ direction along the mRNA molecule, translation always proceeds in the 5′ ⟶ 3′ direction. Each peptide bond forms in a fraction of a second; by repeating the elongation cycle, an average-sized protein of about 360 amino acids is assembled by a bacterium in approximately 18 seconds and by a eukaryotic cell in a little more than 1 minute.

One of three stop codons signals the termination of translation

Termination is the final stage of translation. In termination, the synthesis of the polypeptide chain is terminated by a **release factor,** a protein that recognizes the stop codon at the end of the coding sequence. (Because no tRNA molecule binds to a stop codon, the codon is available for binding by the release factor.) When the release factor binds to the A site, the bond between the tRNA in

www.konkur.in

KEY POINT A stop signal terminates polypeptide synthesis, because no tRNA molecules exist with an anticodon complementary to a stop codon.



1 When the ribosome reaches a stop codon, the A site binds to a protein release factor.

2 The release factor hydrolyzes the bond between the polypeptide chain and the tRNA, causing the release of the polypeptide chain from the tRNA molecule in the P site.

3 The remaining parts of the translation complex dissociate.

FIGURE 13-17 The termination of translation

the P site and the last amino acid of the polypeptide chain breaks (**FIG. 13-17**). This hydrolysis reaction frees the newly synthesized polypeptide and also separates the translation complex into its parts: the mRNA molecule, the release factor, the tRNA molecule in the P site, and the large and small ribosomal subunits. The two ribosomal subunits can be used to form a new initiation complex with another mRNA molecule. Each mRNA is translated only a limited number of times before it is destroyed.

Specialized ribosome-associated proteins, called **molecular chaperones,** assist in the folding of the newly synthesized polypeptide chain into its three-dimensional active shape (see Chapter 3). The sequence of amino acids in the polypeptide chain dictates the shape that it ultimately forms. However, without the molecular chaperone's help, interactions among the various regions of the amino acid chain might prevent the proper folding process from occurring.

Review

- What are ribosomes made of? Do ribosomes carry information to specify the amino acid sequence of proteins?
- What happens in each stage of polypeptide synthesis: initiation, elongation, and termination?
- A certain mRNA strand has the following nucleotide sequence:

  5′—AUG—ACG—UAU—AAC—UUU—3′

  What is the anticodon for each codon? What is the amino acid sequence of the polypeptide? (Use Fig. 13-5 to help answer this question.)

13.5 VARIATIONS IN GENE EXPRESSION

LEARNING OBJECTIVES

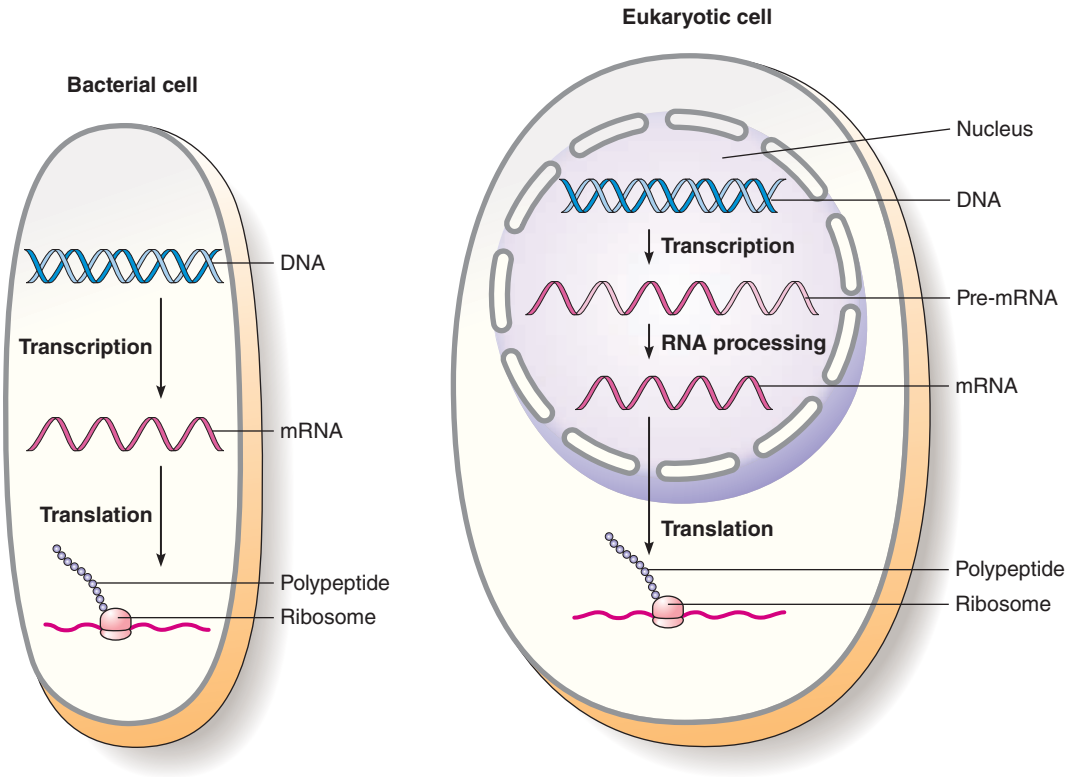
11 Describe a polyribosome in bacterial cells.
12 Briefly discuss RNA interference.
13 Describe retroviruses and the enzyme reverse transcriptase.

You have seen that the basic mechanisms of transcription and translation are quite similar in all organisms. Some significant differences exist between bacteria and eukaryotes (**FIG. 13-18**). Some of these differences result from bacterial versus eukaryotic cell structure. Bacteria lack a nucleus, whereas eukaryotic chromosomes are confined to the cell nucleus and protein synthesis takes place in the cytosol. In eukaryotes, mRNA must move from the nucleus (the site of transcription) to the cytosol (the site of translation, or polypeptide synthesis). Also, as we discussed earlier in the chapter, extensive mRNA processing occurs in eukaryotic cells before translation.

Transcription and translation are coupled in bacteria

In *E. coli* and other bacteria, translation begins very soon after transcription, and several ribosomes are attached to the same mRNA (**FIG. 13-19**). The end of the mRNA molecule synthesized first during transcription is also the first to be translated to form a polypeptide.

www.konkur.in



(a) In a bacterial cell, mRNA is immediately ready for translation by ribosomes.

(b) In a eukaryotic cell, RNA processing occurs in the nucleus before the mRNA exits the nucleus for translation.

FIGURE 13-18 Summary: the flow of genetic information in bacteria and eukaryotes

Ribosomes bind to the 5′ end of the growing mRNA and initiate translation long before the message is fully synthesized. As many as 15 ribosomes may bind to a single mRNA. An mRNA molecule that is bound to clusters of ribosomes constitutes a **polyribosome,** or *polysome.* Polyribosomes also occur in eukaryotic cells, but not while transcription is still occurring.

Although many polypeptide chains can be actively synthesized on a single mRNA at any one time, the half-life of mRNA molecules in bacterial cells is only about 2 minutes. (Half-life is the time it takes for half the molecules to be degraded.) Usually, degradation of the 5′ end of the mRNA begins even before the first polypeptide is complete. Once the ribosome recognition sequences at the 5′ end of the mRNA have been degraded, no more ribosomes attach and initiate protein synthesis.

Biologists debate the evolution of eukaryotic gene structure

The reason for the intricate structure of eukaryotic genes is a matter of ongoing discussion among molecular biologists. Why do introns occur in most eukaryotic nuclear genes but not in the genes of most bacteria (or of mitochondria and chloroplasts)? How did this remarkable genetic system with interrupted coding sequences ("split genes") evolve, and why has it survived? It seems incredible that as much as 75% of the original transcript of a eukaryotic nuclear gene must be *removed* to make a working message.

In the early 1980s, American Walter Gilbert of Harvard University proposed that exons are nucleotide sequences that code for **protein domains,** regions of protein tertiary structure that may have important functions. For example, the active site of an enzyme may compose one domain. A different domain may enable that enzyme to bind to a particular cell structure, and yet another may be a site involved in allosteric regulation (see Chapter 7). Analyses of the DNA and amino acid sequences of many eukaryotic genes have shown that most exons are too small to code for an entire protein domain, although a block of several exons can code for a domain.

Gilbert further postulated that new proteins with new functions emerge rapidly when genetic recombination produces novel combinations of exons that code for different proteins. This hypothesis has become known as *evolution by exon shuffling.* It has been supported by examples such as the low-density lipoprotein (LDL) receptor protein, a protein found on the surface of human cells that binds to cholesterol transport molecules (see Chapter 5). The LDL receptor protein has domains that are related to parts of other proteins with totally different functions. However, many other genes and their corresponding proteins show no evidence of exon shuffling.

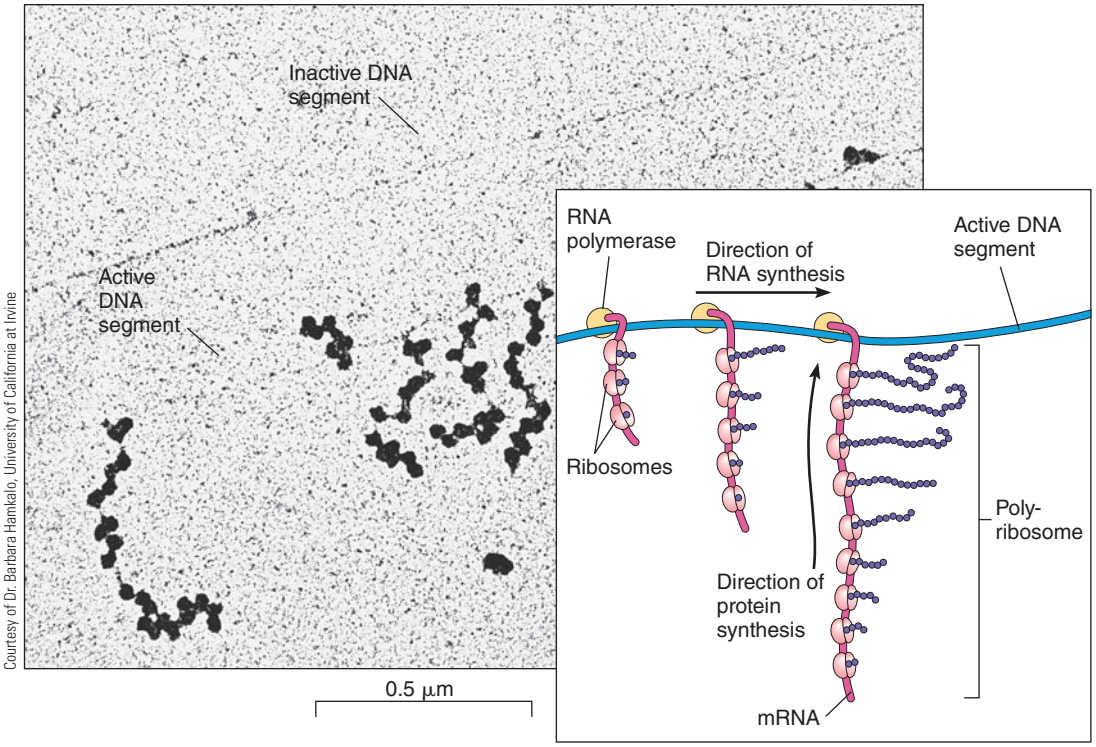
After introns were discovered in a few genes in archaea and bacteria, some biologists hypothesized that introns are relics from the ancient ancestors of all organisms living today. Through billions of years of evolution, the pressure in prokaryotic organisms, which are unicellular, to have a streamlined set of genes may have caused them to lose most of their introns.

Regardless of how split genes originated, intron excision provides one of many ways in which present-day eukaryotes regulate expression of their genes (see Chapter 14). This opportunity for control, together with the fact that eukaryotic RNAs are far more stable than those of bacteria, may balance the energy cost of maintaining a large load of noncoding DNA.

Several kinds of eukaryotic RNA have a role in gene expression

In addition to mRNA, rRNA, and tRNA, eukaryotic cells contain several other kinds of RNA that are an essential part of the complex system that results in protein synthesis (TABLE 13-1). **Small**

www.konkur.in



(a) This TEM shows two strands of *E. coli* DNA, one inactive and the other actively producing mRNA. Protein synthesis begins while the mRNA is being completed.

(b) A sequence (*left to right*) of coupled transcription and translation. Note that several ribosomes translate each mRNA molecule simultaneously.

FIGURE 13-19 Coupled transcription and translation in bacteria

nuclear RNA (snRNA) molecules bind to specific proteins to form a small nuclear ribonucleoprotein complex (snRNP), which in turn combines with other snRNPs to form a spliceosome. (Recall from the discussion earlier in the chapter that a spliceosome catalyzes intron removal.)

Some polypeptides enter the endoplasmic reticulum (ER) as they are being synthesized. **Signal-recognition particle RNA (SRP RNA),** in combination with proteins, directs the ribosome–mRNA–polypeptide complex to the rough ER shortly after translation begins. Translation continues after the complex binds to an integral protein in the ER membrane, and the newly synthesized protein is then distributed to its destination within the cell or outside the cell (for example, as a secretion).

A special group of RNA molecules, known as **small nucleolar RNAs (snoRNAs),** processes pre-rRNA molecules in the nucleolus during ribosome subunit formation. Small nucleolar RNAs bind to complementary regions of pre-rRNA and target sites for cleavage or methylation. A pre-rRNA molecule is larger than the combined size of the three rRNA molecules made from it. In mammalian cells, about 48% of the pre-rRNA molecule is removed during the cleavage steps. Pre-rRNA may have methyl groups added to regions that are to be saved during processing.

The discovery that RNA has the ability to regulate gene expression made big news in biology, both because this phenomenon, known as **RNA interference (RNAi),** is found in many organisms and because it has great potential as a research and medical tool (see Chapters 15 and 17). In RNAi, certain small RNA molecules

TABLE 13-1 Selected Kinds of RNA in Eukaryotic Cells

Kind of RNA	Function
Messenger RNA (mRNA)	Specifies the amino acid sequence of a protein
Transfer RNA (tRNA)	Binds to specific amino acid and serves as adapter molecule when amino acids are incorporated into growing polypeptide chain
Ribosomal RNA (rRNA)	Has both structural and catalytic (ribozyme) roles in ribosome
Small nuclear RNA (snRNA)	Involved in intron removal and regulation of transcription; part of spliceosome particles
Signal-recognition particle RNA (SRP RNA)	Helps direct the ribosome–mRNA–polypeptide complex to the rough ER shortly after translation begins
Small nucleolar RNA (snoRNA)	Processes pre-rRNA in nucleolus during formation of ribosome subunits
Small interfering RNA (siRNA)	Controls transposons and fights viral infections
MicroRNA (miRNA)	Controls expression of genes involved in growth and development by inhibiting the translation of mRNA; involved in several diseases, including prevention of cancer

www.konkur.in

interfere with the expression of genes or their RNA transcripts. RNA interference involves small interfering RNAs, microRNAs, and a few other kinds of short RNA molecules.

Small interfering RNAs (siRNAs) are double-stranded molecules that are 20 to 25 nucleotides in length. These RNA molecules help control damage from transposons (discussed later in the chapter) and viral infections; they also regulate gene expression of protein-coding genes.

MicroRNAs (miRNAs) are single-stranded RNA molecules 20 to 25 nucleotides long that inhibit the translation of mRNAs involved in many biological processes, such as growth and development (**FIG. 13-20**). MicroRNAs are transcribed from genes and then shortened before they are combined with proteins to form a complex that inhibits the expression of mRNA molecules with sequences complementary to the miRNA. More than 200 distinct miRNA genes have been identified in the human genome, but the specifics of how they regulate gene expression by degrading mRNAs and/or preventing mRNAs from being translated into polypeptides are not yet clear. Biologists now recognize that miRNAs have an important role in preventing cancer: cancer cells have measurably lower levels of miRNAs than noncancer cells. A breakdown in miRNA function has also been implicated in heart disease and possibly Parkinson's disease.

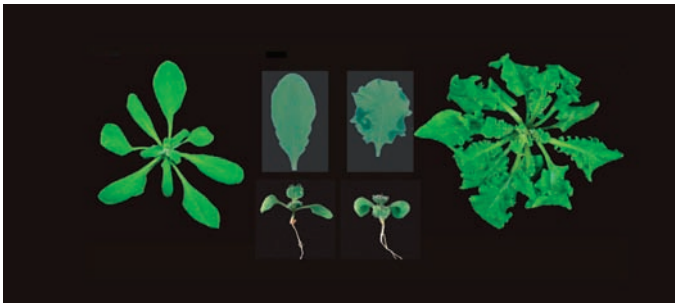
The definition of a gene has evolved as biologists have learned more about genes

At the beginning of this chapter, we traced the development of ideas regarding the nature of the gene. For a time scientists found it useful to define a *gene* as "a sequence of nucleotides that codes for one polypeptide chain." However, as we have learned more about the human genome, research teams have determined that DNA coding for polypeptides makes up about 2% of our genome, whereas about 80% of our genome is expressed; many genes are transcribed to produce the various kinds of RNA molecules (see Table 13-1). Further, as you will see in Chapter 14, studies have shown that in eukaryotic cells, a single gene may produce more than one polypeptide chain by modifications in the way the mRNA is processed.

It is perhaps most useful to define a gene in terms of its product: a **gene** is a DNA nucleotide sequence that carries the information needed to produce a specific RNA or polypeptide product.

The usual direction of information flow has exceptions

For several decades, a central premise of molecular biology was that genetic information always flows from DNA to RNA to protein. Through his studies of viruses, U.S. biologist Howard Temin discovered an important exception to this rule in 1964. Although viruses are not cellular organisms, they contain a single type of nucleic acid and reproduce in a host cell. Temin was studying unusual, cancer-causing tumor viruses that have RNA, rather than DNA, as their genetic material. He found that infection of a host cell by one of these viruses is blocked by inhibitors of DNA synthesis and also by inhibitors of transcription. These findings suggested



Javier F. Palatnik and Detlef Weigel

FIGURE 13-20 The effect of an miRNA molecule on plant growth
A normal *Arabidopsis* plant (*top view, leaf, and side view of seedling*) is shown on the left and serves as a control. Biologists modified an miRNA molecule in the plant on the right, and as a result, it exhibits severe developmental abnormalities, such as curly leaves.

that DNA synthesis and transcription are required for RNA tumor viruses to multiply and that there must be a way for information to flow in the "reverse" direction—from RNA to DNA.

Temin proposed that a **DNA provirus** forms as an intermediary in the replication of RNA tumor viruses. This hypothesis required a new kind of enzyme that would synthesize DNA using RNA as a template. In 1970, Temin and U.S. biologist David Baltimore discovered just such an enzyme, and they shared the Nobel Prize in Physiology or Medicine in 1975 for their discovery. This RNA-directed DNA polymerase, also known as **reverse transcriptase,** is found in all RNA tumor viruses. (Some RNA viruses that do not produce tumors, however, replicate without using a DNA intermediate.) **FIGURE 13-21** shows the steps of RNA tumor virus reproduction. Because they reverse the usual direction of information flow, viruses that require reverse transcriptase are called **retroviruses.** HIV-1, the virus that causes AIDS, is the most widely known retrovirus. As you will see in Chapter 15, the reverse transcriptase enzyme has become an important research tool for molecular biologists.

Review

- What is RNA interference?
- What is a gene?
- How do retroviruses use the enzyme reverse transcriptase?

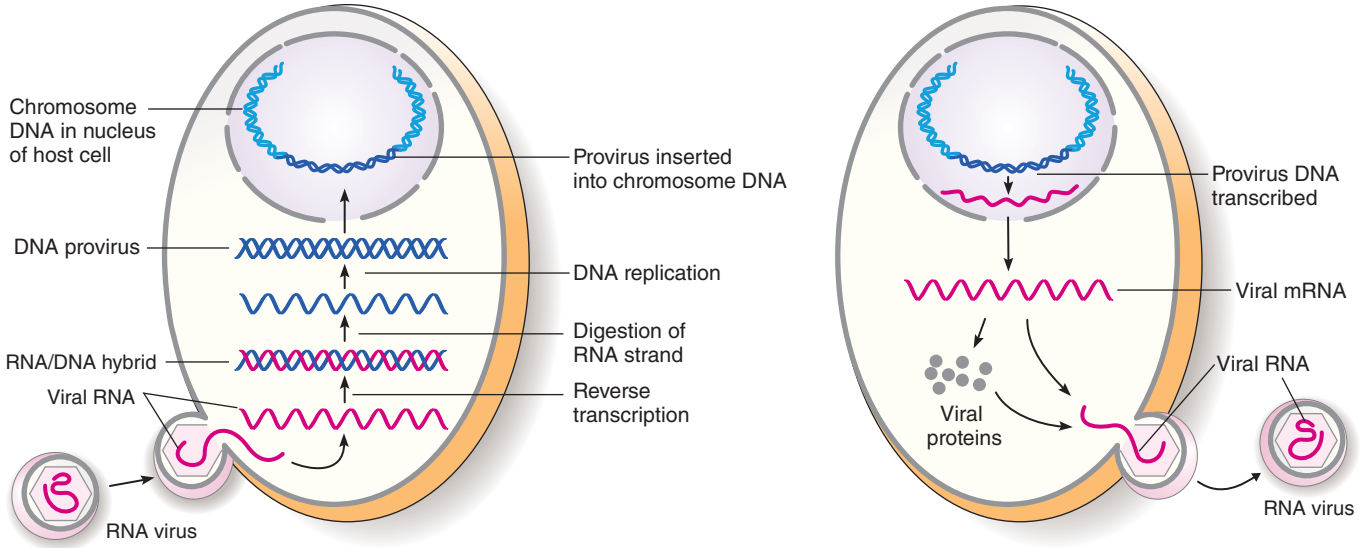
13.6 MUTATIONS

LEARNING OBJECTIVE

14 Give examples of the different classes of mutations that affect the base sequence of DNA and explain the effects that each has on the polypeptide produced.

One of the first major discoveries about genes was that they undergo **mutations,** changes in the nucleotide sequence of the DNA. However, the overall mutation rate is much higher than the frequency of damage to DNA because all organisms have systems of enzymes that repair certain kinds of DNA damage.

www.konkur.in



(a) After an RNA tumor virus enters the host cell, the viral enzyme reverse transcriptase synthesizes a DNA strand that is complementary to the viral RNA. Next, the RNA strand is degraded and a complementary DNA strand is synthesized, thus completing the double-stranded DNA provirus, which is then integrated into the host cell's DNA.

(b) The provirus DNA is transcribed, and the resulting viral mRNA is translated to form viral proteins. Additional viral RNA molecules are produced and then incorporated into mature viral particles enclosed by protein coats.

FIGURE 13-21 The infection cycle of an RNA tumor virus

If a DNA sequence has been changed and not corrected, DNA replication copies the altered sequence just as it would copy a normal sequence, making the mutation stable over an indefinite number of generations. In most cases, the mutant allele has no greater tendency than the original allele to mutate again.

Although most uncorrected mutations are either *silent* (and have no discernible effect) or harmful (such as those that cause inherited diseases and cancer), a few are useful. Because they can be passed to the next generation in cell lines that give rise to gametes, mutations are of vital importance in evolution. Mutations provide the variation among individuals that evolutionary forces act on. Mutations are also useful in research (recall Beadle and Tatum's work with mutations) because they provide the diversity of genetic material that enables researchers to study inheritance and the molecular nature of genes. Scientists now determine where a particular mutation occurs in a gene by using recombinant DNA methods to isolate the gene and determine its sequence of bases (see Chapter 15).

Base-pair substitution mutations result from the replacement of one base pair by another

Mutations can alter genes in several ways. The simplest type of mutation, called a **base-pair substitution,** involves a change in only one pair of nucleotides. Often these mutations result from errors in base pairing during the replication process. For example, a GC, CG, or TA pair might replace an AT base pair. Such a mutation may cause the altered DNA to be transcribed as an altered mRNA. The altered mRNA may then be translated into a polypeptide chain with only one amino acid different from the normal sequence.

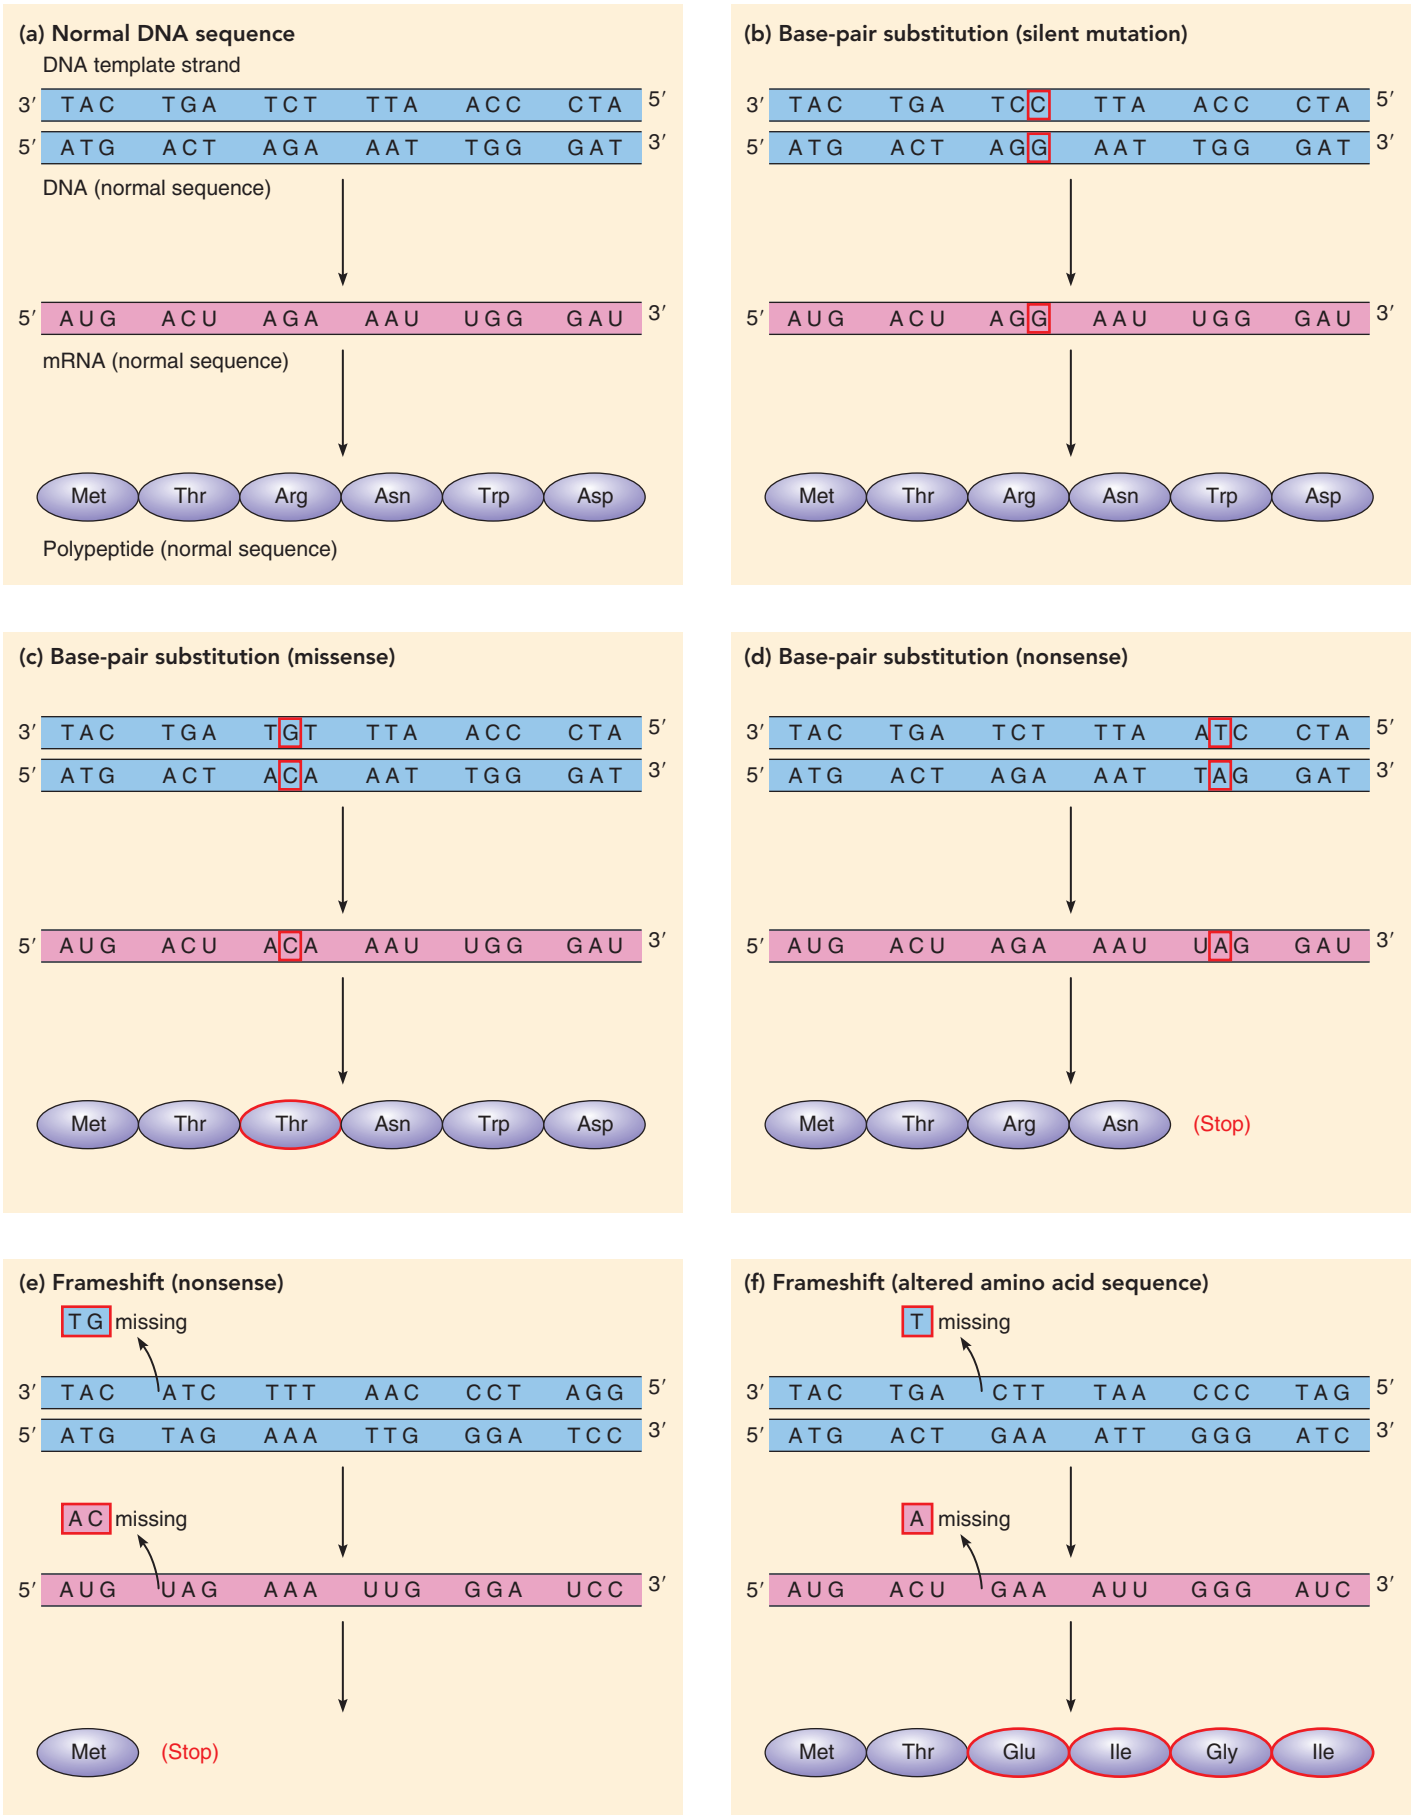
Silent mutations are base-pair substitutions that have no discernible effect—as, for example, a mutation in a protein-coding gene that does not alter the amino acid sequence (**FIGS. 13-22a, b**). Base-pair substitutions that result in replacement of one amino acid by another are sometimes called **missense mutations** (**FIG. 13-22c**). Missense mutations have a wide range of effects. If the amino acid substitution occurs at or near the active site of an enzyme, the activity of the altered protein may decrease or even be destroyed. Some missense mutations involve a change in an amino acid that is not part of the active site. Others may result in the substitution of a closely related amino acid (one with very similar chemical characteristics). Such mutations have no effect on the function of a gene product and may be undetectable. Because these mutations occur relatively frequently, the true number of mutations in an organism is much greater than is actually observed.

Nonsense mutations are base-pair substitutions that convert an amino acid–specifying codon to a stop codon (**FIG. 13-22d**). A nonsense mutation usually destroys the function of the gene product; in the case of a protein-specifying gene, the part of the polypeptide chain that follows the mutant stop codon is missing.

Frameshift mutations result from the insertion or deletion of base pairs

In **frameshift mutations,** one or two nucleotide pairs are inserted into or deleted from the molecule, altering the reading frame. As a result, codons downstream of the insertion or deletion site specify an entirely new sequence of amino acids. Depending on where the insertion or deletion occurs in the gene, different effects are generated. Frameshift mutations may produce a stop

www.konkur.in



www.konkur.in

◀ **FIGURE 13-22** ***Animated*** **Types of mutations**
Compare the normal DNA sequence in part **(a)** with the mutations in parts **(b)** to **(e)**.

codon within a short distance of the mutation (**FIG. 13-22e**). This codon terminates the already altered polypeptide chain. In addition to producing a stop codon, frameshift mutations can result in an altered amino acid sequence immediately after the change (**FIG. 13-22f**). A frameshift mutation in a gene specifying an enzyme usually results in a complete loss of enzyme activity.

Some mutations involve mobile genetic elements

One type of mutation is caused by DNA sequences that "jump" into the middle of a gene. These movable sequences of DNA are known as **mobile genetic elements,** or **transposons.** Mobile genetic elements not only disrupt the functions of some genes but also inactivate some previously active genes. Transposons were discovered in maize (corn) by the U.S. geneticist Barbara McClintock in the 1950s (**FIG. 13-23**). She observed that certain genes appeared to be turned off and on spontaneously. She deduced that the mechanism involved a segment of DNA that moved from one region of a chromosome to another, where it would inactivate a gene. In recognition of her insightful findings, McClintock was awarded the Nobel Prize in Physiology or Medicine in 1983.

Biologists did not appreciate the significance of transposons until the development of recombinant DNA methods and the discovery of transposons in a wide variety of organisms, including humans. We now know that transposons are segments of DNA that range from a few hundred to several thousand bases. In humans, almost half of our genome consists of transposons.

Several kinds of mobile genetic elements have been identified. One of these, called a **DNA transposon,** moves genetic material from one site to another using a "cut-and-paste" method. DNA transposons are common in bacteria and animals, including humans.

Many mobile genetic elements are **retrotransposons,** which replicate by forming an RNA intermediate. Reverse transcriptase converts them into their original DNA sequence before they jump into a gene. Many retrotransposons enlist a host cell's gene expression machinery to produce reverse transcriptase encoded by the retrotransposon. Because retrotransposons use reverse transcriptase, some biologists hypothesize that certain retrotransposons may have evolved from retroviruses, or vice versa. Scientists think that human cells have fewer than 100 retrotransposons actively jumping around. Nevertheless, retrotransposons are extremely important agents of mutation and therefore increase an organism's ability to evolve. By one estimate, retrotransposons are responsible for about 10% of naturally occurring mutations that cause noticeable phenotypic changes.

Mutations have various causes

Most types of mutations occur infrequently but spontaneously from mistakes in DNA replication or defects in the mitotic or meiotic separation of chromosomes. Some regions of DNA, known as *mutational hot spots,* are much more likely than others to undergo mutation. An example is a short stretch of repeated nucleotides, which can cause DNA polymerase to "slip" while reading the template during replication.

Mutations in certain genes increase the overall mutation rate. For example, a mutation in a gene coding for DNA polymerase may make DNA replication less precise, or a mutation in a gene coding for a repair enzyme may allow more mutations to arise as a result of unrepaired DNA damage.

Not all mutations occur spontaneously. **Mutagens,** which cause many of the types of mutations discussed previously, include various types of radiation—such as X-rays, gamma rays, cosmic rays, and ultraviolet rays—and certain chemicals. Some chemical mutagens react with and modify bases in the DNA, leading to mistakes in complementary base pairing when the DNA molecule is replicated. Other chemical mutagens cause nucleotide pairs to be inserted into or deleted from the DNA molecule, changing the normal reading frame during replication.

Despite the presence of enzymes that repair damage to DNA, some new mutations do arise. In fact, each of us has some mutant alleles that neither of our parents had. Although

Jerome Wexler/Visuals Unlimited

FIGURE 13-23 **Transposons in maize**
The white lines and streaks in these kernels are caused by transposons that have moved from one location to another, turning off pigment production in certain cells. The number of cell divisions during the development of the kernel since the transposon turned off the gene determines how much pigment is produced. Some kernels are colorless (unpigmented) because the pigment-producing genes were turned off very early in development.

www.konkur.in

some of these mutations alter the phenotype, most are not noticeable because they are recessive.

Mutations that occur in the cells of the body (somatic cells) are not passed on to offspring. However, these mutations are of concern because somatic mutations and cancer are closely related. Many mutagens are also **carcinogens,** agents that cause cancer.

Review

- What are the main types of mutations?
- What effects does each type of mutation have on the polypeptide product produced?

SUMMARY: FOCUS ON LEARNING OBJECTIVES

13.1 *(page 283)*

1 Summarize the early evidence indicating that most genes specify the structure of proteins.

- Garrod's work on inborn errors of metabolism provided evidence that genes specify proteins. Garrod studied a rare genetic disease called **alkaptonuria** and hypothesized that people with alkaptonuria lack the enzyme that normally oxidizes homogentisic acid.

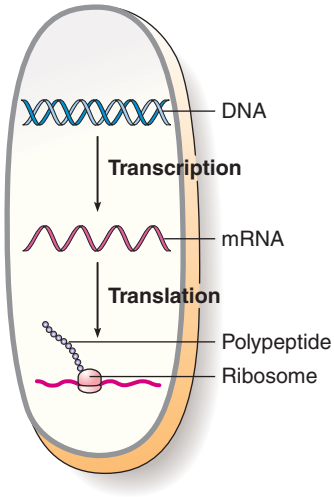
2 Describe Beadle and Tatum's experiments with *Neurospora.*

- Beadle and Tatum exposed *Neurospora* spores to X-rays or ultraviolet radiation to induce mutant strains, and then identified strains that carried a mutation preventing the fungus from producing a chemical essential for growth. Their work revealed that each mutant strain had a mutation in only one gene and that each gene affected only one enzyme.

13.2 *(page 285)*

3 Outline the flow of genetic information in cells, from DNA to RNA to polypeptide.

- The process by which information encoded in DNA specifies the sequences of amino acids in proteins involves transcription and translation. During **transcription,** an RNA molecule complementary to the template DNA strand is synthesized. **Messenger RNA (mRNA)** molecules contain information that specifies the amino acid sequences of polypeptide chains.
- During **translation,** a polypeptide chain specified by the mRNA is synthesized. Each sequence of three nucleotide bases in the mRNA constitutes a **codon,** which specifies one amino acid in the polypeptide chain, or a start or stop signal. Translation requires tRNAs and cell machinery, including ribosomes.



4 Compare the structures of DNA and RNA.

- Like DNA, RNA is formed from nucleotide subunits. However, in RNA each subunit contains the sugar **ribose,** a base (**uracil,** adenine, guanine, or cytosine), and three phosphates. Like DNA, RNA subunits are covalently joined by 5′—3′ linkages to form an alternating sugar–phosphate backbone.

5 Explain why the genetic code is said to be redundant and virtually universal, and discuss how these features may reflect its evolutionary history.

- The **genetic code** is read from mRNA as a series of codons that specify a single sequence of amino acids. The genetic code is redundant because some amino acids are specified by more than one codon. Only a few minor variations are exceptions to the genetic code found in all organisms, strongly suggesting that all organisms are descended from a common ancestor.

13.3 *(page 288)*

6 Compare the processes of transcription and DNA replication, identifying both similarities and differences.

- **RNA polymerases,** involved in RNA synthesis, have many similarities to DNA polymerases involved in DNA replication. Both enzymes carry out synthesis in the 5′ ⟶ 3′ direction. Both use nucleotides with three phosphate groups as substrates, removing two of the phosphates as the nucleotides are covalently linked to the 3′ end of the newly synthesized strand.
- Just as the paired strands of DNA are **antiparallel,** the template strand of the DNA and its complementary RNA strand are antiparallel. As a result, the DNA template strand is read in its 3′ ⟶ 5′ direction as RNA is synthesized in its 5′ ⟶ 3′ direction.
- The same base-pairing rules are followed as in DNA replication, except that uracil is substituted for thymine.

CENGAGENOW™ **Watch transcription unfold by clicking on the figure in CengageNOW.**

7 Compare bacterial and eukaryotic mRNAs, and explain the functional significance of their structural differences.

- Eukaryotic genes and their mRNA molecules are more complicated than those of bacteria. After transcription, a **5′ cap** (a modified guanosine triphosphate) is added to the 5′ end of a eukaryotic mRNA molecule. The molecule also has a **poly-A** tail of adenine-containing nucleotides added at the 3′ end. These modifications may protect eukaryotic mRNA molecules from degradation, giving them a longer lifespan than bacterial mRNA.
- In many eukaryotic genes, the coding regions, called **exons,** are interrupted by noncoding regions, called **introns.** Both exons and introns are transcribed, but the introns are later removed from the original **pre-mRNA,** and the exons are spliced together to produce a continuous polypeptide-coding sequence.

13.4 *(page 293)*

8 Identify the features of tRNA that are important in decoding genetic information and converting it into "protein language."

- **Transfer RNAs (tRNAs)** are the "decoding" molecules in the translation process. Each tRNA molecule is specific for only one amino acid. One part of the tRNA molecule contains an **anticodon** that is

www.konkur.in

complementary to a codon of mRNA. Attached to one end of the tRNA molecule is the amino acid specified by the complementary mRNA codon.

9 Explain how ribosomes function in polypeptide synthesis.

- Each **ribosome** is made of a large and a small subunit; each subunit contains **ribosomal RNA (rRNA)** and many proteins. Ribosomes couple the tRNAs to their proper codons on the mRNA, catalyze the formation of peptide bonds between amino acids, and translocate the mRNA so the next codon can be read.

CENGAGENOW™ Learn more about the structure of ribosomes by clicking on the figure in CengageNOW.

10 Describe the processes of initiation, elongation, and termination in polypeptide synthesis.

- **Initiation** is the first stage of translation. **Initiation factors** bind to the small ribosomal subunit, which then binds to mRNA in the region of AUG, the **start codon.** The **initiator tRNA** binds to the start codon, followed by binding of the large ribosomal subunit.
- **Elongation** is a cyclic process in which amino acids are added one by one to the growing polypeptide chain. Elongation proceeds in the 5′ ⟶ 3′ direction along the mRNA.
- **Termination,** the final stage of translation, occurs when the ribosome reaches one of three **stop codons.** The A site binds to a **release factor,** which triggers the release of the completed polypeptide chain and dissociation of the translation complex.

CENGAGENOW™ Learn more about protein synthesis by clicking on the figure in CengageNOW.

13.5 *(page 297)*

11 Describe a polyribosome in bacterial cells.

- Unlike the processes in eukaryotic cells, transcription and translation are coupled in bacterial cells. Bacterial ribosomes bind to the 5′ end of the growing mRNA and initiate translation before the message is fully synthesized. As many as 15 ribosomes may bind to a single mRNA, forming a **polyribosome.**

12 Briefly discuss RNA interference.

- **RNA interference (RNAi)** occurs when small RNA molecules, such as **small interfering RNAs (siRNAs)** and **microRNAs (miRNAs)** interfere with the expression of genes or their RNA transcripts.

13 Describe retroviruses and the enzyme reverse transcriptase.

- **Retroviruses** are viruses that synthesize DNA from an RNA template. In retroviruses the flow of genetic information is reversed by the enzyme **reverse transcriptase.** HIV-1, the virus that causes AIDS, is a retrovirus.

13.6 *(page 300)*

14 Give examples of the different classes of mutations that affect the base sequence of DNA and explain the effects that each has on the polypeptide produced.

- A **base-pair substitution** is a **mutation** that may alter or destroy the function of a protein if a codon changes so that it specifies a different amino acid (a **missense mutation**) or becomes a stop codon (a **nonsense mutation**).
- The insertion or deletion of one or two base pairs in a gene invariably destroys the function of that protein because it results in a **frameshift mutation,** which changes the codon sequences downstream from the mutation.
- One type of mutation is caused by movable DNA sequences, known as **transposons,** that "jump" into the middle of a gene. Many transposons are **retrotransposons,** which replicate by forming an RNA intermediate; **reverse transcriptase** converts them to their original DNA sequence before they jump into a gene.

CENGAGENOW™ Learn more about mutations by clicking on the figure in CengageNOW.

TEST YOUR UNDERSTANDING

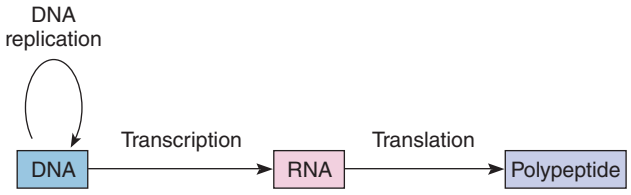
1. Beadle and Tatum (a) predicted that tRNA molecules would have anticodons (b) discovered the genetic disease alkaptonuria (c) showed that the genetic disease sickle cell anemia is caused by a change in a single amino acid in a hemoglobin polypeptide chain (d) worked out the genetic code (e) studied the relationship between genes and enzymes in *Neurospora*
2. What is the correct order of information flow in bacterial and eukaryotic cells? (a) DNA ⟶ mRNA ⟶ protein (b) protein ⟶ mRNA ⟶ DNA (c) DNA ⟶ protein ⟶ mRNA (d) protein ⟶ DNA ⟶ mRNA (e) mRNA ⟶ protein ⟶ DNA
3. During transcription, how many RNA nucleotide bases would usually be encoded by a sequence of 99 DNA nucleotide bases? (a) 297 (b) 99 (c) 33 (d) 11 (e) answer is impossible to determine with the information given
4. The genetic code is defined as a series of _____ in _____. (a) anticodons; tRNA (b) codons; DNA (c) anticodons; mRNA (d) codons; mRNA (e) codons and anticodons; rRNA
5. RNA differs from DNA in that the base _____ is substituted for _____. (a) adenine; uracil (b) uracil; thymine (c) guanine; uracil (d) cytosine; guanine (e) guanine; adenine
6. RNA grows in the _____ direction, as RNA polymerase moves along the template DNA strand in the _____ direction. (a) 5′ ⟶ 3′; 3′ ⟶ 5′ (b) 3′ ⟶ 5′; 3′ ⟶ 5′ (c) 5′ ⟶ 3′; 5′ ⟶ 3′ (d) 3′ ⟶ 3′; 5′ ⟶ 5′ (e) 5′ ⟶ 5′; 3′ ⟶ 3′
7. Which of the following is/are *not* found in a bacterial mRNA molecule? (a) stop codon (b) upstream leader sequences (c) downstream trailing sequences (d) start codon (e) promoter sequences
8. Which of the following is/are typically removed from pre-mRNA during nuclear processing in eukaryotes? (a) upstream leader sequences (b) poly-A tail (c) introns (d) exons (e) all the preceding
9. The role of tRNA is to transport (a) amino acids to the ribosome (b) amino acids to the nucleus (c) initiation factors to the ribosome (d) mRNA to the ribosome (e) release factors to the ribosome
10. Suppose you mix the following components of protein synthesis in a test tube: amino acids from a rabbit; ribosomes from a dog; tRNAs from a mouse; mRNA from a chimpanzee; and necessary enzymes plus an energy source from a giraffe. If protein synthesis occurs, which animal's protein will be made? (a) rabbit (b) dog (c) mouse (d) chimpanzee (e) giraffe

www.konkur.in

11. The _____ catalyzes the excision of introns from pre-mRNA. (a) ribosome (b) spliceosome (c) RNA polymerase enzyme (d) aminoacyl–tRNA synthetase enzyme (e) reverse transcriptase enzyme
12. A nonsense mutation (a) causes one amino acid to be substituted for another in a polypeptide chain (b) results from the deletion of one or two bases, leading to a shift in the reading frame (c) results from the insertion of one or two bases, leading to a shift in the reading frame (d) results from the insertion of a transposon (e) usually results in the formation of an abnormally short polypeptide chain

CRITICAL THINKING

1. Compare and contrast the formation of mRNA in bacterial and eukaryotic cells. How do the differences affect the way in which each type of mRNA is translated? Does one system have any obvious advantage in terms of energy cost? Which system offers greater opportunities for control of gene expression?
2. Biologists hypothesize that transposons eventually lose the ability to replicate and therefore remain embedded in DNA without moving around. Based on what you have learned in this chapter, suggest a possible reason for this loss.
3. How was the genetic code deciphered?
4. Draw an arrow on this figure to show where reverse transcription, catalyzed by the enzyme reverse transcriptase, occurs. Also, show where the enzymes DNA polymerase, RNA polymerase, and peptidyl transferase are involved.



5. **ANALYZING DATA.** You are repeating Beadle and Tatum's classic experiment in biology lab. First, you expose *Neurospora* spores to X-rays, establish a culture from an irradiated spore, and then grow it on (1) a minimal medium plus vitamins, (2) a minimal medium plus amino acids, and (3) a minimal medium. Interpret your results if the fungus grows in *all three* media. Interpret your results if the fungus doesn't grow in *any* of the media.
6. **EVOLUTION LINK.** Because introns are present in all eukaryotes and a few prokaryotes, biologists hypothesize that introns evolved very early in the history of life. If that is true, suggest why the majority of prokaryotes living today lost most of their introns during the course of evolution.

14 Gene Regulation

Courtesy of David J. Goldhamer, University of Connecticut

Specific gene expression in a mouse embryo. This 13.5-day-old mouse embryo has been genetically engineered so that cells that transcribe and express the myogenin gene stain blue. The myogenin gene is expressed only in those cells of the embryo that will give rise to muscle tissue. (The gestation period for a mouse is 18 to 20 days.)

KEY CONCEPTS

14.1 Cells regulate which genes will be expressed and when. Gene regulation in bacteria is primarily in response to stimuli in the environment; gene regulation in eukaryotes helps to maintain homeostasis.

14.2 Gene regulation in bacteria occurs primarily at the level of transcription; regulation of transcription can be either positive or negative.

14.3 Gene regulation in eukaryotes occurs at the levels of transcription, posttranscription, translation, and posttranslation.

Each type of cell in a multicellular organism has a characteristic shape, carries out very specific activities, and makes a distinct set of proteins. Yet with few exceptions, all cells in an organism contain the same genetic information. Why, then, aren't cells identical in structure, molecular composition, and function? Cells differ because gene expression is regulated, and only certain subsets of the total genetic information are expressed in any given cell (see photograph).

What mechanisms control gene expression? Consider a gene coding for a protein that is an enzyme. Expressing that gene involves three basic steps: transcribing the gene to form messenger RNA (mRNA), translating the mRNA into protein, and activating the protein so it can catalyze

www.konkur.in

a specific reaction in the cell. Thus, gene expression results from a series of processes, each of which is regulated in many ways. The control mechanisms use various signals, some originating within the cell and others coming from other cells or from the environment. These signals interact with DNA, RNA, or protein.

Mechanisms that regulate gene expression include control of the amount of mRNA transcribed, of the rate of translation of mRNA, and of the activity of the protein product. These controls are accomplished in several ways. For example, the rate of transcription and the rate of mRNA degradation both control the amount of available mRNA.

Although bacteria are not multicellular, regulation of gene expression is also essential for their survival. Gene regulation in bacteria often involves controlling the transcription of genes whose products are involved in resource use. In eukaryotes, by contrast, fine-tuning the control systems occurs at *all* levels of gene regulation. Involving all levels of gene regulation is consistent with the greater complexity of eukaryotic cells and the need for developmental controls in multicellular organisms.

14.1 GENE REGULATION IN BACTERIA AND EUKARYOTES: AN OVERVIEW

LEARNING OBJECTIVE

1 Explain why bacterial and eukaryotic cells have different mechanisms of gene regulation.

Bacterial and eukaryotic cells use distinctly different mechanisms of gene regulation, based on the specific requirements of the organism. Bacterial cells can exist independently, and each cell performs all its own essential functions. Because they grow rapidly and have relatively short times between cell division events, bacteria carry fewer chemical components.

Expression of bacterial genes occurs when it helps bacteria adjust to their environment, including any food that might be present in the surroundings. The primary requirement of bacterial gene regulation is the production of enzymes and other proteins when needed, and **transcriptional-level control** is the most efficient mechanism.

The organization of related genes into groups that are rapidly turned on and off as units allows the synthesis of only the gene products needed at any particular time. This type of regulation requires rapid turnover of mRNA molecules to prevent messages from accumulating and continuing to be translated when they are not needed. Bacteria rarely regulate enzyme levels by degrading proteins. Once the synthesis of a protein ends, the previously synthesized protein molecules are diluted so rapidly in subsequent cell divisions that breaking them down is usually not necessary. Only when cells are starved or deprived of essential amino acids do protein-digesting enzymes recycle amino acids by breaking down proteins no longer needed for survival.

Eukaryotic cells have different regulatory requirements. Although transcriptional-level control predominates, control at other levels of gene expression is also very important, especially in multicellular organisms, in which groups of cells cooperate with one another in a division of labor. Because a single gene is regulated in different ways in different types of cells, eukaryotic gene regulation is complex.

Eukaryotic cells usually have a long lifespan during which they may need to maintain homeostasis while responding to many different stimuli. New enzymes are not necessarily synthesized each time the cells respond to a stimulus; instead, in many instances pre-formed enzymes and other proteins are rapidly converted from an inactive to an active state. Some cells have a large store of inactive messenger RNA; for example, the mRNA of an egg cell becomes activated when the egg is fertilized.

Much gene regulation in multicellular organisms is focused on the differential expression of genes in the cells in various tissues. Each type of cell has certain genes that are active and other genes that may never be used. For example, developing red blood cells produce the oxygen transport protein hemoglobin, whereas muscle cells never produce hemoglobin but instead produce myoglobin, a related protein coded for by a different gene that stores oxygen in muscle tissues. Apparently, the selective advantages of cell cooperation in multicellular eukaryotes far outweigh the detrimental effects of carrying a load of inactive genes through many cell divisions.

The domesticated pig provides another example of how gene regulation in multicellular organisms affects expression in different tissues. In 2003, biologists reported details of a genetic mutation in pigs that makes them develop more muscle tissue (**FIG. 14-1**). The mutation is in a gene, designated **insulin-like growth factor**

H. Schwind/Okapia/Science Photo Library/Photo Researchers, Inc.

FIGURE 14-1 A lean pig with a mutation in the *IGF2* gene

Years ago, farmers discovered a pig with more muscle and less fat. They selectively bred this pig, and today most commercial pig populations have the mutation that confers this trait. The mutation, which was recently identified as a substitution of a guanine nucleotide for an adenine nucleotide, occurs in a nonprotein-coding region of the *IGF2* gene.

www.konkur.in

2 (*IGF2*), which codes for a protein produced by both muscle and liver tissues. The biologists found that a *base-substitution mutation* (see Chapter 13) in the *IGF2* gene makes the gene 3 times more active in pig muscles, resulting in leaner meat. However, the mutation does not change expression of the gene in liver cells. Interestingly, this mutation is not in the protein-coding portion of the gene but in a nonprotein-coding, and presumably regulatory, region.

Review

- What is the most efficient mechanism of gene regulation in bacteria?
- How would you contrast gene regulation in prokaryotes with that in eukaryotes?

14.2 GENE REGULATION IN BACTERIA

LEARNING OBJECTIVES

2 Define *operon* and explain the functions of the operator and promoter regions.
3 Distinguish among inducible, repressible, and constitutive genes.
4 Differentiate between positive and negative control, and show how both types of control operate in regulating the *lac* operon.
5 Describe the types of posttranscriptional control in bacteria.

The *Escherichia coli* bacterium is common in the intestines of humans and other mammals. It has 4288 genes that code for proteins, approximately 60% of which have known functions. Some of these genes encode proteins that are always needed (such as enzymes involved in glycolysis). These genes, which are constantly transcribed, are **constitutive genes,** and biologists describe them as *constitutively expressed.* Other proteins are needed only when the bacterium is growing under certain conditions.

For instance, bacteria living in the colon of an adult cow are not normally exposed to the milk sugar lactose, a disaccharide. If those cells ended up in the colon of a calf, however, they would have lactose available as a source of energy. This situation presents a dilemma. Should a bacterial cell invest energy and materials to produce lactose-metabolizing enzymes just in case it ends up in the digestive system of a calf? Yet if *E. coli* cells could not produce those enzymes, they might starve in the middle of an abundant food supply. Thus, *E. coli* functions by regulating many enzymes to efficiently use available organic molecules.

Cell metabolic activity is controlled in two ways: by regulating the *activity* of certain enzymes (how effectively an enzyme molecule works) and/or by regulating the *number* of enzyme molecules present in each cell. Some enzymes are regulated in both ways.

An *E. coli* cell growing on glucose needs about 800 different enzymes. Some are present in large numbers, whereas only a few molecules of others are required. For the cell to function properly, the quantity of each enzyme must be efficiently controlled.

Bacteria respond to changing environmental conditions. If lactose is added to a culture of *E. coli* cells, they rapidly synthesize the three enzymes needed to metabolize lactose. Bacteria respond so efficiently because functionally related genes—such as the three genes involved in lactose metabolism—are regulated together in gene complexes called *operons.*

Operons in bacteria facilitate the coordinated control of functionally related genes

The French researchers François Jacob and Jacques Monod are credited with the first demonstration, in 1961, of gene regulation at the biochemical level through their elegant studies on the genes that code for the enzymes that metabolize lactose. In 1965, they received the Nobel Prize in Physiology or Medicine for their discoveries relating to genetic control of enzymes.

To use lactose as an energy source, *E. coli* cells first cleave the sugar into the monosaccharides glucose and galactose, using the enzyme β-galactosidase. Another enzyme converts galactose to glucose, and enzymes in the glycolysis pathway further break down the resulting two glucose molecules (see Chapter 8).

E. coli cells growing on glucose produce very little β-galactosidase enzyme. However, each cell grown on lactose as the sole carbon source has several thousand β-galactosidase molecules, accounting for about 3% of the cell's total protein. Amounts of two other enzymes, lactose permease and galactoside transacetylase, also increase when the cells are grown on lactose. The cell needs permease to transport lactose efficiently across the bacterial plasma membrane; without it, only small amounts of lactose enter the cell. The transacetylase may function in a minor aspect of lactose metabolism, although its role is not clear.

Jacob and Monod identified mutant strains of *E. coli* in which a single genetic defect wiped out all three enzymes. This finding, along with other information, led the researchers to conclude that the DNA coding sequences for all three enzymes are linked as a unit on the bacterial DNA and are controlled by a common mechanism. Each enzyme-coding sequence is a **structural gene.** Jacob and Monod coined the term **operon** for a gene complex consisting of a group of structural genes with related functions plus the closely linked DNA sequences responsible for controlling them. The structural genes of the *lac* operon (lactose operon)—*lacZ, lacY,* and *lacA*—code for β-galactosidase, lactose permease, and transacetylase, respectively (**FIG. 14-2**).

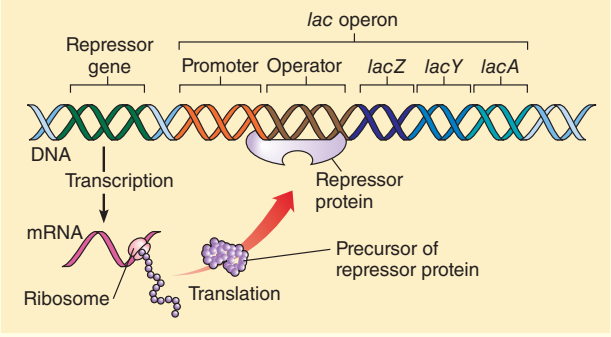
Transcription of the *lac* operon begins as RNA polymerase binds to a single **promoter** region *upstream* from the coding sequences. It then proceeds to transcribe the DNA, forming a single mRNA molecule that contains the coding information for all three enzymes. Each enzyme-coding sequence on this mRNA contains its own start and stop codons; thus, the mRNA is translated to form three separate polypeptides. Because all three enzymes are translated from the same mRNA molecule, their synthesis is coordinated by turning a single molecular "switch" on or off.

The switch that controls mRNA synthesis is the **operator,** which is a sequence of bases upstream from the first structural gene in the operon. In the absence of lactose, a **repressor protein** called the **lactose repressor** binds tightly to the operator. RNA polymerase binds to the promoter but is blocked from transcribing the protein-coding genes of the *lac* operon.

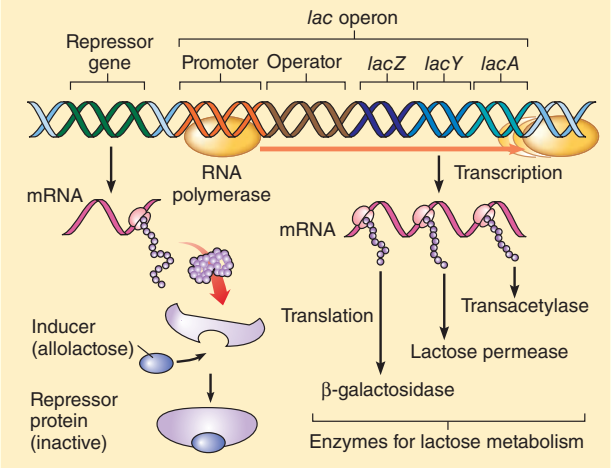
The lactose repressor protein is encoded by a **repressor gene,** which in this case is an adjacent structural gene located upstream

www.konkur.in

KEY POINT The structural genes of the *lac* operon are coordinately controlled and transcribed as a single mRNA.



(a) Lactose absent. In the absence of lactose, a repressor protein, encoded by an adjacent gene, binds to a region known as the operator, thereby blocking transcription of the structural genes.



(b) Lactose present. When lactose is present, it is converted to allolactose, which binds to the repressor at an allosteric site, altering the structure of the protein so it no longer binds to the operator. As a result, RNA polymerase is able to transcribe the structural genes.

FIGURE 14-2 ***Animated*** The *lac* operon

from the promoter site. Unlike the *lac* operon genes, the repressor gene is constitutively expressed and is therefore constantly transcribed; the cell continuously produces small amounts of the repressor protein.

The repressor protein binds specifically to the *lac* operator sequence. When cells grow in the absence of lactose, a repressor molecule nearly always occupies the operator site. When the operator site is briefly free of the repressor, the cell synthesizes a small amount of mRNA. However, the cell synthesizes very few enzyme molecules because *E. coli* mRNA is degraded rapidly (it has a half-life of about 2 to 4 minutes).

Lactose "turns on," or *induces,* the transcription of the *lac* operon because the lactose repressor protein contains a second functional region (an *allosteric site;* see Chapter 7) separate from its DNA-binding site. This allosteric site binds to allolactose, a structural isomer made from lactose. If lactose is in the growth medium, a few molecules enter the cell and are converted to allolactose by the few β-galactosidase molecules present. The binding of a molecule of allolactose to the repressor alters the shape of the protein so that its DNA-binding site no longer recognizes the operator. When the repressor molecules have allolactose bound to them and are therefore inactivated, RNA polymerase actively transcribes the structural genes of the operon.

The *E. coli* cell continues to produce β-galactosidase and the other *lac* operon enzymes until it uses up virtually all the lactose. When the intracellular level of lactose drops, so too does the concentration of allolactose. Therefore, allolactose dissociates from the repressor protein, which then assumes a shape that lets the repressor bind to the operator region and shut down transcription of the operon.

Jacob and Monod isolated genetic mutants to study the *lac* operon

How did Jacob and Monod elucidate the functioning of the *lac* operon? Their approach involved the use of mutant strains, which even today are an essential tool of researchers trying to unravel the components of various regulatory systems. Genetic crosses of mutant strains allow investigators to determine the *map positions* (linear order) of the genes on the DNA and to infer normal gene functions by studying what happens when they are missing or altered. Researchers usually combine this information with the results of direct biochemical studies.

Jacob and Monod divided their mutant strains into two groups, based on whether a particular mutation affected only one enzyme or all three (**FIG. 14-3**). In one group, only one enzyme of the three—β-galactosidase, lactose permease, or galactoside transacetylase—was affected. Subsequent gene-mapping studies showed these were mutations in structural genes located next to each other in a linear sequence.

Jacob and Monod also studied regulatory mutants in which a single mutation affected the expression of all three enzymes. Some of the regulatory mutants transcribed the structural genes of the *lac* operon at a significant rate, even in the absence of lactose, causing the cell to waste energy in producing unneeded enzymes. One group of these gene mutations had map positions just outside the *lac* operon. Jacob and Monod hypothesized the existence of a repressor gene that codes for a repressor molecule (later found to be a protein). Although the specific defect may vary, the members of this group of mutants produce defective repressors; hence, no binding to the *lac* operator and promoter takes place, and the *lac* operon is constitutively expressed.

In contrast, some regulatory mutants failed to transcribe the *lac* operon even when lactose was present. Researchers eventually found that each of these abnormal genes coded for a repressor with an abnormal binding site that prevented allolactose from binding, although the repressor could still bind to the operator. Once bound to the operator, such a mutant repressor remained bound, keeping the operon "turned off."

The genes responsible for another group of regulatory mutants had map positions within the *lac* operon but did not directly involve any of the three structural genes. Jacob and Monod hypothesized that the members of this group produced normal repressor mol-

www.konkur.in

KEY POINT Jacob and Monod analyzed the properties of various mutant strains of *E. coli* to deduce the structure and function of the *lac* operon.

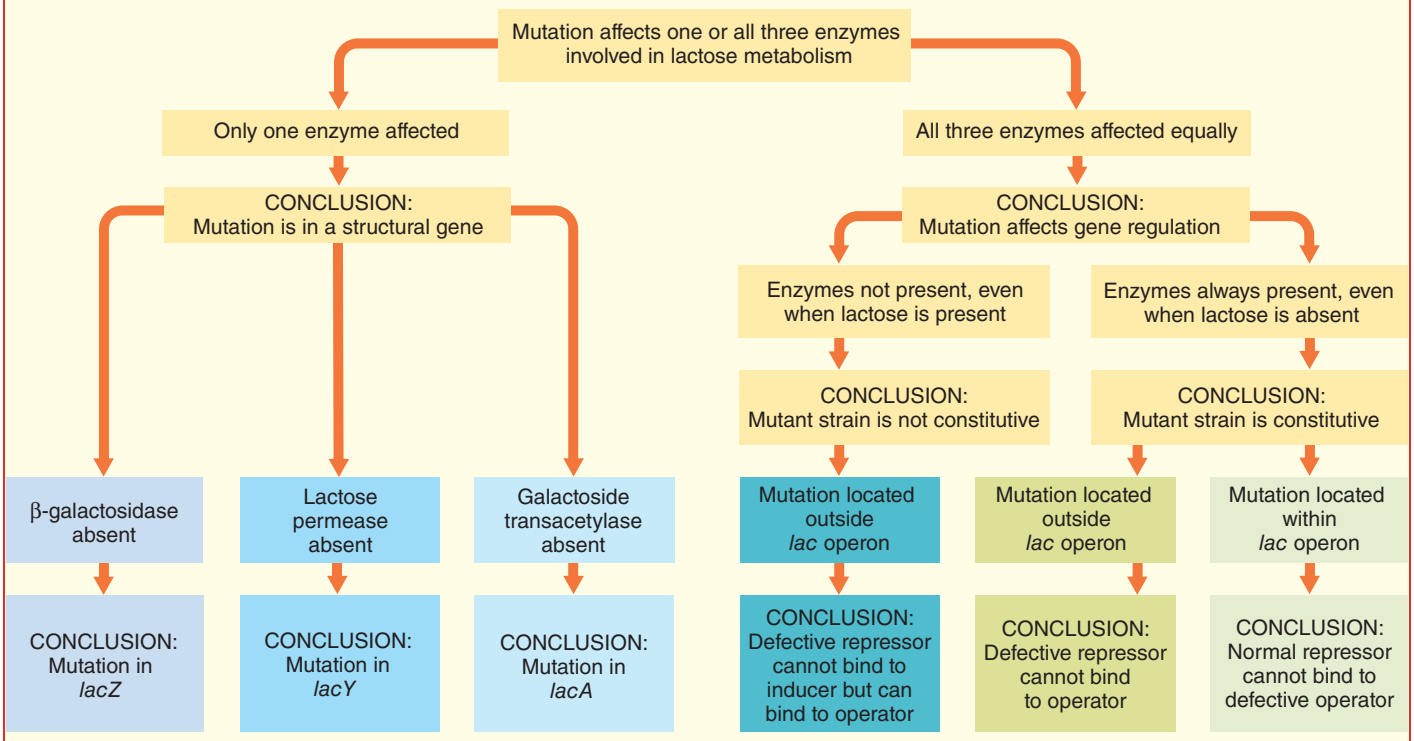


FIGURE 14-3 Genetic and biochemical characterization of the *lac* operon
The diagram shows how Jacob and Monod inferred conclusions based on their experimental results.

ecules but had abnormal operator sequences incapable of binding to the repressor.

An inducible gene is not transcribed unless a specific inducer inactivates its repressor

Geneticists call the *lac* operon an **inducible operon.** A repressor usually controls an inducible gene or operon by keeping it "turned off." The presence of an **inducer** (in this case, allolactose) inactivates the repressor, permitting the gene or operon to be transcribed. Inducible genes or operons usually code for enzymes that are part of catabolic pathways, which break down molecules to provide both energy and components for anabolic reactions. This type of regulatory system lets the cell save the energy cost of making enzymes when no substrates are available on which they can act.

A repressible gene is transcribed unless a specific repressor–corepressor complex is bound to the DNA

Another type of gene regulation system in bacteria is associated mainly with anabolic pathways such as those in which cells synthesize amino acids, nucleotides, and other essential biological molecules from simpler materials. Enzymes coded by repressible genes normally regulate these pathways.

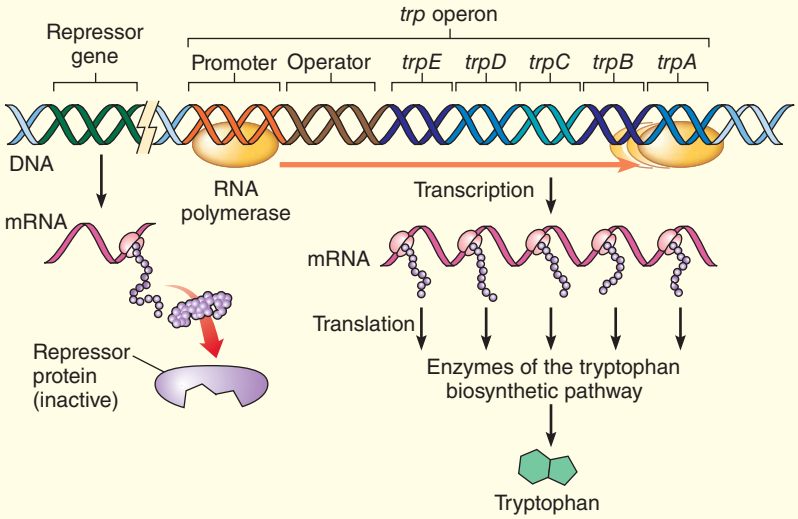
Repressible operons and genes are usually "turned on"; they are turned off only under certain conditions. In most cases the molecular signal for regulating these genes is the end product of the anabolic pathway. When the supply of the end product (such as an amino acid) becomes low, all enzymes in the pathway are actively synthesized. When intracellular levels of the end product rise, enzyme synthesis is repressed. Because the growing cell continuously needs compounds such as amino acids, the most effective mechanism for the cell is to keep the genes that control their production turned on, except when a large supply of the amino acid is available. The ability to turn the genes off prevents cells from overproducing amino acids and other molecules that are essential but expensive to make in terms of energy.

The *trp* operon (tryptophan operon) is an example of a repressible system. In both *E. coli* and a related bacterium, *Salmonella,* the *trp* operon consists of five structural genes that code for the enzymes that the cell needs to synthesize the amino acid tryptophan; these genes are clustered as a transcriptional unit with a single promoter and a single operator (**FIG. 14-4a**). A distant repressor gene codes for a diffusible repressor protein, which differs from the lactose repressor in that the cell synthesizes it in an inactive form that cannot bind to the operator region of the *trp* operon.

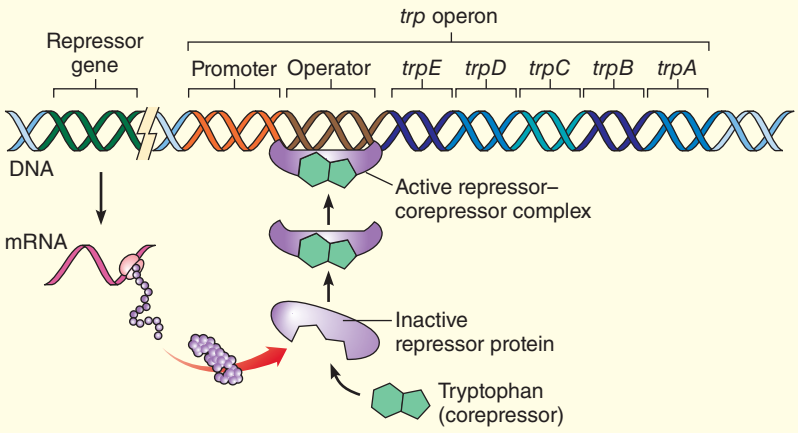
The DNA-binding site of the repressor becomes effective only when tryptophan, its **corepressor,** binds to an allosteric site on the repressor (**FIG. 14-4b**). When intracellular tryptophan levels are low, the repressor protein is inactive and cannot bind to the operator region of the DNA. The enzymes required for tryptophan

www.konkur.in

KEY POINT Structural genes coding for enzymes that synthesize the amino acid tryptophan are organized in a repressible operon.



(a) Low intracellular tryptophan levels. Repressor protein is unable to prevent transcription because it cannot bind to the operator.



(b) High intracellular tryptophan levels. The amino acid tryptophan binds to an allosteric site on the repressor protein, changing its conformation. The resulting active form of the repressor binds to the operator region, blocking transcription of the operon until tryptophan is again required by the cell.

FIGURE 14-4 The *trp* operon

synthesis are produced, and the intracellular concentration of tryptophan increases. Some of it binds to the repressor, altering the repressor's shape so it binds tightly to the operator. This switches the operon off, thereby blocking transcription.

Negative regulators inhibit transcription; positive regulators stimulate transcription

The features of the *lac* and *trp* operons we have described so far are examples of **negative control,** a regulatory mechanism in which the DNA binding regulatory protein is a repressor that turns off transcription of the gene. **Positive control** is regulation by **activator proteins** that bind to DNA and thereby stimulate the transcription of a gene. The *lac* operon is controlled by both a negative regulator (the lactose repressor) and a positively acting activator protein.

Positive control of the *lac* operon requires the cell to recognize the absence of the sugar glucose, which is the initial substrate in the glycolysis pathway. Lactose, like glucose, undergoes stepwise breakdown to yield energy. However, because glucose is a product of the catabolic hydrolysis of lactose, it is most efficient for *E. coli* cells to use the available supply of glucose first, sparing the cell the considerable energy cost of making additional enzymes such as β-galactosidase (**FIG. 14-5a**).

The *lac* operon has a very inefficient promoter element—that is, it has a low affinity for RNA polymerase, even when the repressor protein is inactivated. However, a DNA sequence adjacent to the promoter site is a binding site for another regulatory protein, the **catabolite activator protein (CAP).** When activated, CAP stimulates transcription of the *lac* operon and several other bacterial operons.

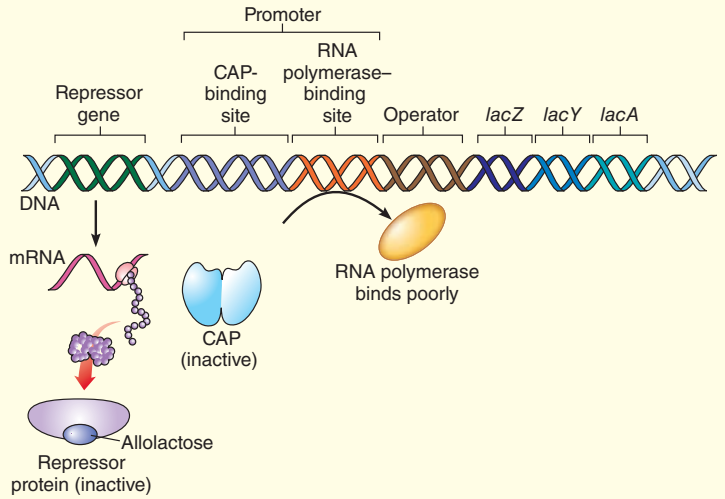
In its active form, CAP is bound by an allosteric site to **cyclic AMP,** or **cAMP,** an alternative form of adenosine monophosphate. Examine Figure 3-25 to see the chemical structure of cAMP. As the cells become depleted of glucose, cAMP levels increase (**FIG. 14-5b**). After the cAMP molecules bind to CAP, the resulting active complex then binds to the CAP-binding site near the *lac* operon promoter. This binding of active CAP bends DNA's double helix (**FIG. 14-6**), strengthening the affinity of the promoter region for RNA polymerase so that the rate of transcriptional initiation accelerates in the presence of lactose. Thus, the *lac* operon is fully active only if lactose is available and intracellular glucose levels are low. **TABLE 14-1** summarizes negative and positive controls in bacteria.

Constitutive genes are transcribed at different rates

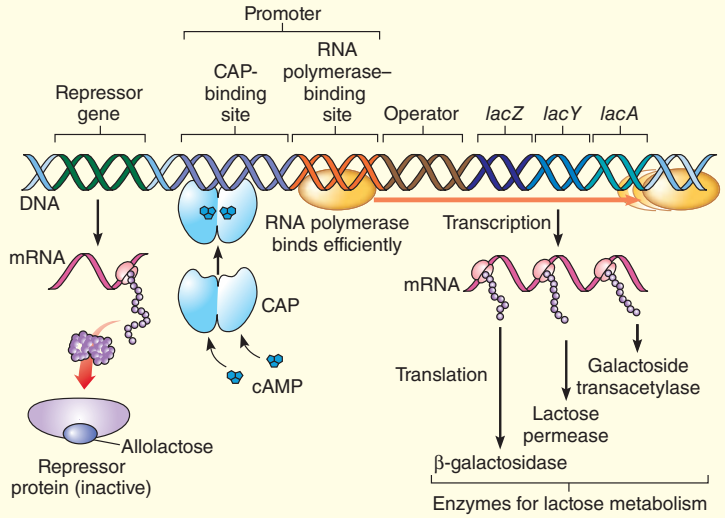
Many gene products encoded by *E. coli* DNA are needed only under certain environmental or nutritional conditions. As you have seen, these genes are generally regulated at the level of transcription. They are turned on and off as metabolic and environmental conditions change. By contrast, constitutive genes are continuously transcribed, but they are not necessarily transcribed (or their mRNAs translated) at the same rate. Some enzymes work more effectively or are more stable than others and thus are present in smaller amounts. Constitutive genes that encode proteins required in large amounts generally have greater expression—that is, are transcribed more rapidly—than genes coding for proteins re-

www.konkur.in

KEY POINT The lactose promoter by itself is weak and binds RNA polymerase inefficiently even when the lactose repressor is inactive.



(a) Lactose high, glucose high, cAMP low. When glucose levels are high, cAMP is low. CAP is in an inactive form and cannot stimulate transcription. Transcription occurs at a low level or not at all.



(b) Lactose high, glucose low, cAMP high. When glucose concentrations are low, each CAP polypeptide has cAMP bound to its allosteric site. The active form of CAP binds to the DNA sequence, and transcription becomes activated.

FIGURE 14-5 Positive control of the *lac* operon

quired in smaller amounts. The promoter elements of these genes control their transcriptional rate. Constitutive genes with efficient ("strong") promoters bind RNA polymerase more frequently and consequently transcribe more mRNA molecules than those with inefficient ("weak") promoters.

Genes coding for repressor or activator proteins that regulate metabolic enzymes are usually constitutive and produce their protein products constantly. Because each cell usually needs relatively few molecules of any specific repressor or activator protein, promoters for those genes tend to be relatively weak.

Some posttranscriptional regulation occurs in bacteria

As you have seen, much of the variability in protein levels in *E. coli* is determined by transcriptional-level control. However, regulatory mechanisms after transcription, known as **posttranscriptional controls,** also occur at various levels of gene expression.

Translational controls are posttranscriptional controls that regulate the rate at which an mRNA molecule is translated. Because the lifespan of an mRNA molecule in a bacterial cell is very short, one that is translated rapidly produces more proteins than one that is translated slowly. Some mRNA molecules in *E. coli* are translated as much as 1000 times faster than other mRNAs. Most of the differences appear to be due to the rate at which ribosomes attach to the mRNA and begin translation.

Posttranslational controls act as switches that activate or inactivate one or more existing enzymes, thereby letting the cell respond to changes in the intracellular concentrations of essential molecules, such as amino acids. A common posttranslational control adjusts the rate of synthesis in a metabolic pathway through **feedback inhibition.** An example of feedback inhibition is diagrammed in Figure 7-15. The end product of a metabolic pathway binds to an allosteric site on the first enzyme in the pathway, temporarily inactivating the enzyme. When the first enzyme in the pathway does not function, all the succeeding enzymes are deprived of substrates. Notice that feedback inhibition differs from the repression caused by tryptophan discussed previously. In that case, the end product of the pathway (tryptophan) prevented the formation of *new* enzymes. Feedback inhibition acts as a fine-tuning mechanism that regulates the activity of the *existing* enzymes in a metabolic pathway.

Review

- What is the function of each of the parts of the *lac* operon (promoter, operator, and structural genes)?
- What structural features does the *trp* operon share with the *lac* operon?
- Why do scientists define the *trp* operon as repressible and the *lac* operon as inducible?
- How is glucose involved in positive control of the *lac* operon?

14.3 GENE REGULATION IN EUKARYOTIC CELLS

LEARNING OBJECTIVES

6 Discuss the structure of a typical eukaryotic gene and the DNA elements involved in regulating that gene.
7 Give examples of some of the ways eukaryotic DNA-binding proteins bind to DNA.
8 Illustrate how a change in chromosome structure may affect the activity of a gene.
9 Explain how a gene in a multicellular organism may produce different products in different types of cells.
10 Identify some of the types of regulatory controls that operate in eukaryotes after mature mRNA is formed.

Like bacterial cells, eukaryotic cells respond to changes in their environment. In addition, multicellular eukaryotes require regulation modes that let individual cells commit to specialized roles and let groups of cells organize into tissues and organs. These processes are accomplished mainly by regulating transcription, but posttranscriptional, translational, and posttranslational controls are also important. In Chapters 12 and 13, we observed that in eukaryotes all aspects of information transfer—including replication, transcription, and translation—are more complicated than in prokaryotes. Not surprisingly, this complexity offers more ways to control gene expression.

Unlike many bacterial genes, eukaryotic genes are not typically arranged in operon-like clusters. (A notable exception is the nematodes, or roundworms, in which some genes are organized into operons.) However, each eukaryotic gene has specific regulatory sequences that are essential in controlling transcription.

Many "housekeeping" enzymes (those needed by virtually all cells) are encoded by constitutive genes, which are expressed in all cells at all times. Some inducible genes have also been found; these respond to environmental threats or stimuli, such as heavy-metal ingestion, viral infection, and heat shock. For example, when a cell is exposed to high temperature, many proteins fail to fold properly. These unfolded proteins elicit a survival response in which *heat-shock genes* are transcribed and heat-shock proteins are synthesized. Although the functions of most heat-shock proteins in eukaryotic cells are unknown, some are **molecular chaperones** that help newly synthesized proteins fold into their proper shape (discussed in Chapters 3 and 13).

Some genes are inducible only during certain periods in the life of the organism; they are controlled by **temporal regulation.** Finally, some genes are under **tissue-specific regulation.** For example, a gene involved in production of a particular enzyme may be regulated by one stimulus (such as a hormone) in muscle tissue, by an entirely different stimulus in pancreatic cells, and by a third stimulus in liver cells. We explore these types of regulation in more detail in Chapters 17 and 49.

FIGURE 14-7 summarizes the regulation of gene expression in eukaryotes. You may want to refer to it as you read the following discussion.

www.konkur.in

Eukaryotic transcription is controlled at many sites and by many regulatory molecules

Like bacterial genes, most genes of multicellular eukaryotes are controlled at the transcriptional level. As you will see, various base sequences in the DNA are important in transcriptional control. In addition, regulatory proteins and the way the DNA is organized in the chromosome affect the rate of transcription.

Chromosome organization affects the expression of some genes

A chromosome is not only a bearer of genes. Various arrangements of a chromosome's ordered components increase or decrease expression of the genes it contains. Figure 10-4 shows the organization of a eukaryotic chromosome. In multicellular eukaryotes, only a subset of the genes in a cell is active at any one time. The inactivated genes differ among cell types and in many cases are irreversibly dormant.

Some of the inactive genes lie in highly compacted chromatin, visible microscopically as densely stained regions of chromosomes during cell division. These regions of chromatin remain tightly coiled and bound to chromosome proteins throughout the cell cycle; even during interphase, they are visible as darkly stained fibers called **heterochromatin** (**FIG. 14-8a**). Evidence suggests that most of the heterochromatin DNA is not transcribed. For example, most of the inactive X chromosome of the two X chromosomes in female mammals is heterochromatic and appears as a *Barr body* (see Fig. 11-16).

Active genes are associated with a more loosely packed chromatin structure called **euchromatin** (**FIG. 14-8b**). The exposure of the DNA in euchromatin lets it interact with *transcription factors* (discussed later in the chapter) and other regulatory proteins.

Cells may have several ways to change chromatin structure from heterochromatin to euchromatin. One way is to chemically modify **histones,** the proteins that associate with DNA to form **nucleosomes.** Each histone molecule has a so-called tail, a string of amino acids that extends from the DNA-wrapped nucleosome (see Fig. 10-2). Methyl groups, acetyl groups, sugars, and even proteins chemically attach to the histone tail and may expose or hide genes, turning them on or off.

Such chemical modifications of histones are the focus of active research because they appear to influence gene expression and therefore offer promise of new approaches to treat cancer and other diseases with a genetic component. Biologists have found general correlations between gene activity and certain chemical groups attached to or absent from histone tails. For example, the genes on DNA in nucleosomes where histone tails are flagged with acetyl groups generally tend to be expressed. Biologists are now trying to determine if specific histone modifications are associated with the activity or inactivity of specific genes within a cell.

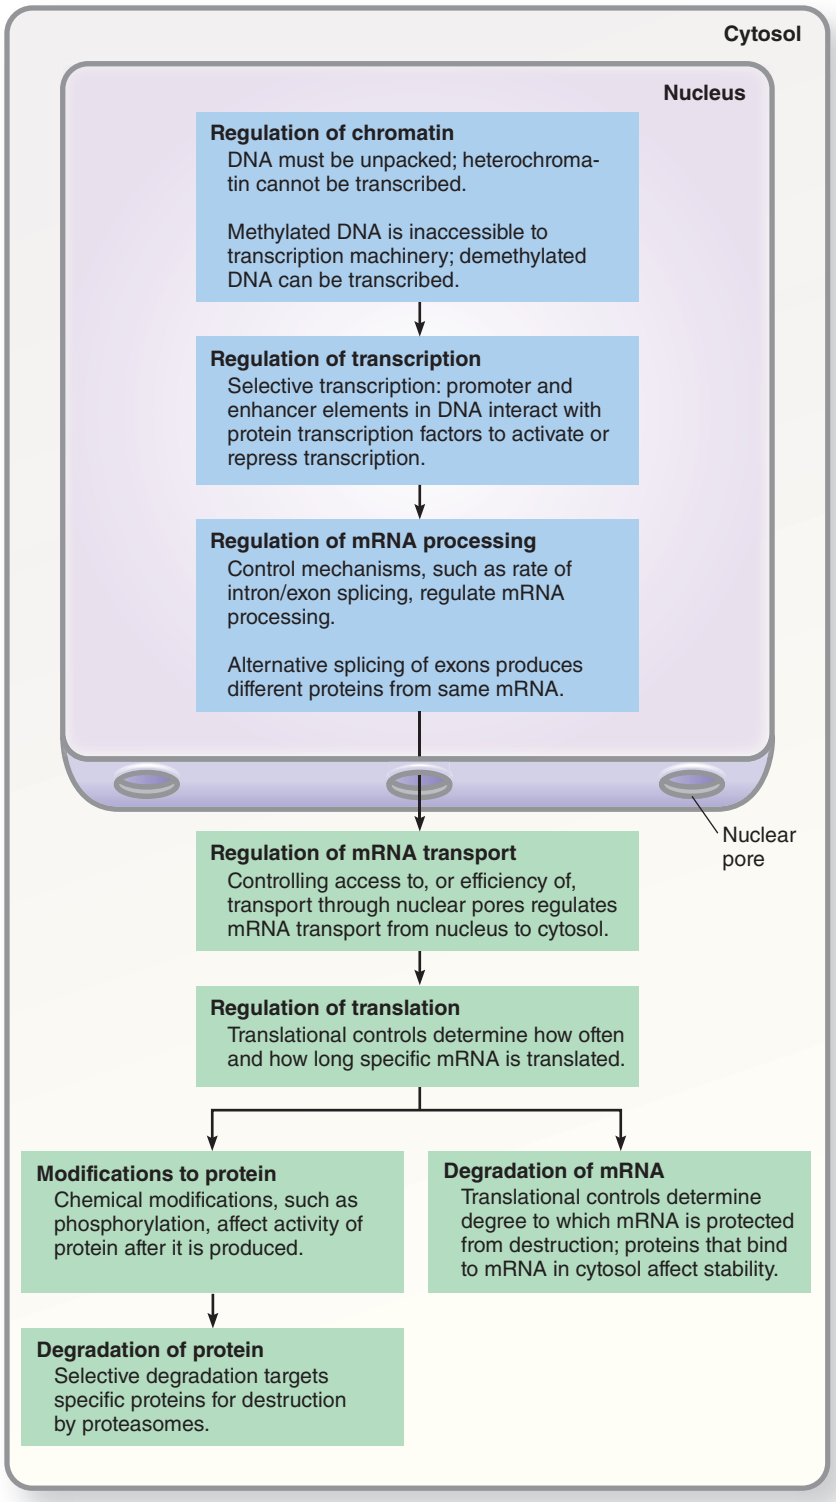

FIGURE 14-7 Gene regulation in eukaryotic cells

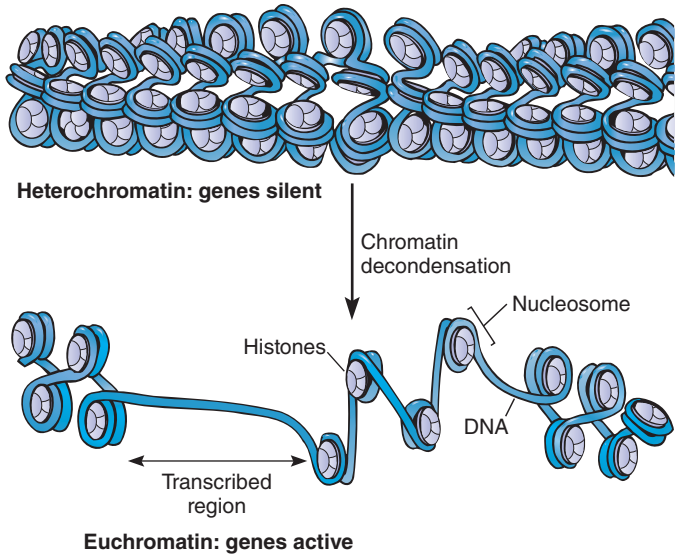
www.konkur.in



(a) Inactive region of DNA. Heterochromatin is organized into tightly associated nucleosomes.

(b) Active region of DNA. Active genes are found in decondensed chromatin called euchromatin. Euchromatin increases the accessibility to RNA polymerase required for transcription. The histones are physically removed from the DNA in the region where transcription occurs.

FIGURE 14-8 Regulation of chromatin: the effect of chromatin structure on transcription

Gene inactivation by DNA methylation is an example of epigenetic inheritance

Inactive genes of vertebrates and some other organisms typically show a pattern of **DNA methylation** in which the DNA has been chemically altered by enzymes that add methyl groups to certain cytosine nucleotides in DNA. (The resulting 5-methylcytosine still pairs with guanine in the usual way.) Evidence indicates that certain regulatory proteins selectively bind to methylated DNA and make it inaccessible to RNA polymerase and other proteins involved in transcription.

DNA methylation, which is found in inactive regions of the cell's genome, probably reinforces gene inactivation rather than serves as the initial mechanism to silence genes. Apparently, once a gene has been turned off by some other means, DNA methylation ensures it will remain inactive. For example, the DNA of the inactive X chromosome of a female mammal becomes methylated after the chromosome has become a condensed Barr body (see Chapter 11). When the DNA replicates in a mitotic cell division, each double strand of DNA has one methylated strand and one unmethylated strand. Methylation enzymes add methyls to the new strand, thereby perpetuating the pre-existing methylation pattern. Hence, the DNA continues to be transcriptionally inactive in all descendants of these cells, often for multiple generations.

In mammals, DNA methylation maintained in this way accounts for **genomic imprinting** (also called *parental imprinting*), in which the phenotypic expression of certain genes is determined by whether a particular allele is inherited from the female or the male parent. Genomic imprinting is associated with some human genetic diseases, such as *Prader–Willi syndrome* and *Angelman syndrome* (both discussed in Chapter 16).

Genomic imprinting is an example of epigenetics. **Epigenetic inheritance** involves changes in how a gene is expressed. In contrast, *genetic inheritance* involves changes in a gene's nucleotide sequence. Because DNA methylation patterns tend to be passed to successive cell generations during cell division, methylation provides a mechanism for epigenetic inheritance. Evidence continues to accumulate that epigenetic inheritance is an important mechanism of gene regulation over the lifetime of an individual. For example, the methylation of genes increases in many people as they age, and decreases in others, perhaps in response to signals from the environment.

New phenotypic traits can arise from epigenetic changes despite the fact that the nucleotide sequence of the gene itself has not changed (**FIG. 14-9**). Epigenetic changes have also been linked to certain human diseases, such as cancer. For example, *tumor suppressor genes* that inhibit cell division (and cancer) are sometimes inactivated epigenetically, resulting in cancer. Chapter 17 discusses cancer and tumor suppressor genes. Thus, some inherited charac-

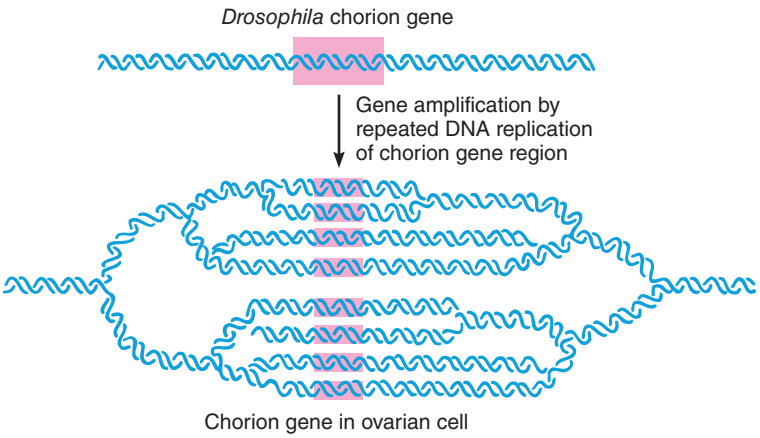

FIGURE 14-10 Regulation of transcription: gene amplification

In *Drosophila*, multiple replications of a small region of the chromosome amplify the chorion (eggshell) protein genes. Replication is initiated at a discrete chromosome origin of replication (*top pink box*) for each copy of the gene that is produced. Replication is randomly terminated, resulting in a series of forked structures in the chromosome.

teristics do not depend exclusively on the sequence of nucleotides in DNA.

Gene amplification increases the number of copies of a gene

A single gene cannot always provide enough copies of its mRNA to meet the cell's needs. The requirement for high levels of certain products is met if multiple copies of the genes that encode them are present in the chromosome. Genes of this type, whose products are essential for all cells, may occur as multiple copies arranged one after another along the chromosome, in **tandemly repeated gene sequences.** Histone genes are usually present as multiple copies of 50 to 500 genes in cells of multicellular organisms. Similarly, multiple copies (150 to 450) of genes for rRNA and tRNA are present in cells.

Other genes, which are required only by a small group of cells, are selectively replicated in those cells in a process called **gene amplification.** For example, the *Drosophila* chorion (eggshell) gene product is a protein made specifically in cells of the female insect's reproductive tract. These cells make massive amounts of the protein that envelops and protects the zygote. Amplifying the chorion protein gene by DNA replication meets the demand for chorion mRNA. In other words, the DNA in that small region of the chromosome is copied many times (**FIG. 14-10**). In other cells of the insect body, however, the gene exists as a single copy in the chromosome.

Eukaryotic promoters vary in efficiency, depending on the presence of functional promoter elements

In eukaryotic as well as bacterial cells, the transcription of any gene requires a base pair where transcription begins, known as the **transcription initiation site,** or *start site,* plus a sequence of bases, the *promoter,* to which RNA polymerase binds. The promoter is a relatively short DNA sequence located adjacent to the gene it regulates.

In almost all multicellular eukaryotes, the promoter contains an element called the TATA box. The **TATA box,** which consists of a sequence of DNA nucleotides such as TATAAA is located about 25 to 30 base pairs upstream from the transcription initiation site (**FIG. 14-11**). Studies show that mutations in the TATA box reduce the rate of transcription.

Some eukaryotic genes have promoter elements in addition to the TATA box. Like the TATA box, these promoter elements have a regulatory function and facilitate the expression of the gene. Many eukaryotic promoters have a promoter element of one or more sequences of nucleotide bases located within a short distance (for example, 80 base pairs) upstream of the RNA polymerase–binding site. Mutations in these elements, like mutations in the TATA box, lower the basic level of transcription.

Enhancers increase the rate of transcription, whereas silencers decrease the rate of transcription

Regulated eukaryotic genes commonly have DNA sequences called **enhancers** that help form an active transcription initiation complex. In this way, enhancers increase the rate of RNA synthesis, often by several orders of magnitude.

Enhancers are remarkable in many ways. Although they are present in all cells, a particular enhancer is functional only in certain types of cells. An enhancer regulates a gene on the same DNA molecule from very long distances—up to thousands of base pairs away from the promoter—and is either upstream or downstream of the promoter it regulates. Furthermore, if an enhancer element is experimentally cut out of the DNA and inverted, it still regulates the gene it normally controls.

Many eukaryotic genes are associated with **silencers,** DNA sequences that can decrease transcription. Like enhancers, silencers are often located long distances from the genes they regulate. As you will see, enhancers and silencers work by interacting with DNA-binding proteins that regulate transcription.

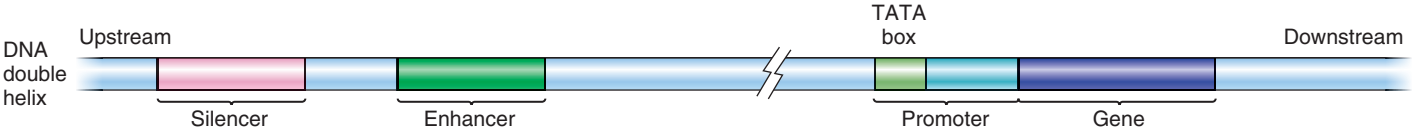

FIGURE 14-11 Regulation of transcription: eukaryotic elements

Eukaryotic regulatory elements include the promoter and various enhancers and silencers. The promoter elements help determine the basic level of transcription that normally occurs, whereas the enhancers (and silencers) have the potential to greatly increase (or decrease) that rate of transcription. (For simplicity, the DNA double helix is represented as a rod.)

www.konkur.in

Transcription factors are regulatory proteins with several functional domains

We previously discussed some DNA-binding proteins that regulate transcription in bacteria. These included the lactose repressor, the tryptophan repressor, and the catabolite activator protein (CAP). Researchers have identified many more DNA-binding proteins that regulate transcription in eukaryotes than in bacteria; these eukaryotic proteins are collectively known as **transcription factors.** Researchers have identified more than 2000 transcription factors in humans.

It is useful to compare regulatory proteins in bacteria and eukaryotes. Many regulatory proteins are modular molecules; that is, they have more than one **domain,** a region with its own tertiary structure and function. Each eukaryotic transcription factor, like the regulatory proteins of bacteria, has a DNA-binding domain plus at least one other domain that is either an activator or a repressor of transcription for a given gene.

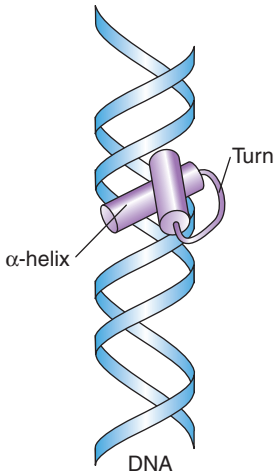
Many transcription factors in eukaryotes (and regulatory proteins in bacteria) have similar DNA-binding domains. One example is the *helix-turn-helix* arrangement, consisting of two α-helical segments. One of these, the recognition helix, inserts into the major groove of the DNA without unwinding the double helix. The other helps hold the first one in place (**FIG. 14-12a**). The "turn" in the helix-turn-helix is a sequence of amino acids that forms a sharp bend in the molecule.

Other transcription factors have DNA-binding domains with multiple "zinc fingers," loops of amino acids held together by zinc ions. Each loop includes an α-helix that fits into a groove of the DNA (**FIG. 14-12b**). Certain amino acid functional groups exposed in each finger have been shown to recognize specific DNA sequences.

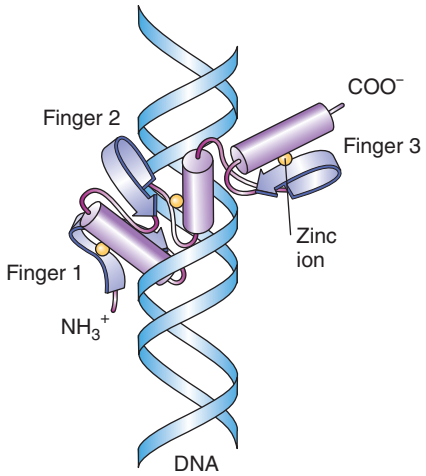
Many transcription factors have DNA-binding domains that function only as pairs, or *dimers.* Many of these transcription factors are known as **leucine zipper proteins** because they are held together by the side chains of leucine and other hydrophobic amino acids (**FIG. 14-12c**). In some cases the two polypeptides that make up the dimer are identical and form a *homodimer.* In other instances they are different, and the resulting *heterodimer* may have very different regulatory properties from those of a homodimer. For a simple and speculative example, let us assume that three regulatory proteins—A, B, and C—are involved in controlling a particular set of genes. These three proteins might associate as dimers in six different ways: three kinds of homodimers (AA, BB, and CC) and three kinds of heterodimers (AB, AC, and BC). Such multiple combinations of regulatory proteins greatly increase the number of possible ways that transcription is controlled.

Transcription in eukaryotes requires multiple regulatory proteins that are bound to different parts of the promoter. The *general transcriptional machinery* is a protein complex that binds to the TATA box of the promoter near the transcription initiation site. That complex is required for RNA polymerase to bind, thereby initiating transcription.

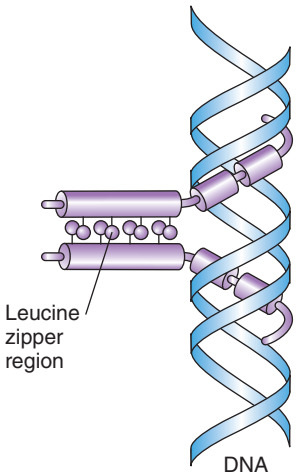
Both enhancers and silencers become functional when specific transcription factors bind to them. **FIGURE 14-13** shows interactions involving an enhancer and a transcription factor that acts as an **activator.** Each activator has at least two functional domains: a DNA recognition site that usually binds to an enhancer and a gene activation site that contacts the target in the general transcriptional machinery. The DNA between the enhancer and promoter



(a) Helix-turn-helix. This portion of a transcription factor (*purple*) contains the helix-turn-helix arrangement. The recognition helix is inserted into the groove of the DNA and is connected to a second helix that helps hold it in place by a sequence of amino acids that form a sharp bend.



(b) Zinc fingers. Regions of certain transcription factors form projections known as "zinc fingers," which insert into the grooves of the DNA and bind to specific base sequences.

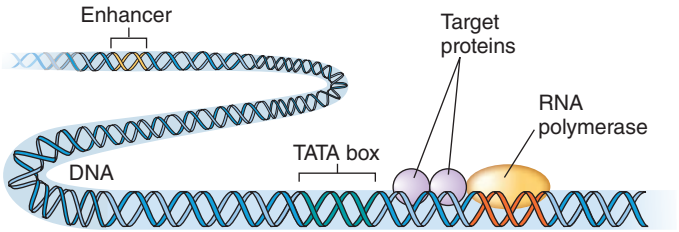


(c) Leucine zipper. This leucine zipper protein is a dimer, held together by hydrophobic interactions involving side chains of leucine and other amino acids.

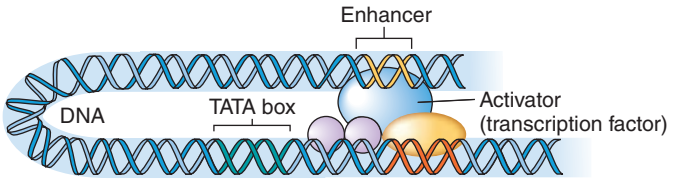
FIGURE 14-12 Regulation of transcription: regulatory proteins

In these illustrations, cylinders represent α-helical regions of regulatory proteins and ribbons represent β-pleated sheets.

www.konkur.in



(a) Low rate of transcription. This gene is transcribed at a basic level when the general transcriptional machinery, including RNA polymerase, is bound to the promoter.



(b) High rate of transcription. A transcription factor that functions as an activator binds to an enhancer. The intervening DNA forms a loop, allowing the transcription factor to contact one or more target proteins in the general transcriptional machinery, thereby increasing the rate of transcription. This diagram is highly simplified, and many more target proteins than the two shown are involved.

FIGURE 14-13 Regulation of transcription: the stimulation of transcription by an enhancer

elements forms a loop that lets an activator bound to an enhancer come in contact with the target proteins associated with the general transcriptional machinery. When this contact occurs, the rate of transcription increases.

The mRNAs of eukaryotes have many types of posttranscriptional control

The half-life of bacterial mRNA is usually minutes long; eukaryotic mRNA, even when it turns over rapidly, is far more stable. Bacterial mRNA is transcribed in a form that is translated immediately. In contrast, eukaryotic mRNA molecules undergo further modification and processing before they are used in protein synthesis. The message is capped, polyadenylated, spliced, and then transported from the nucleus to the cytoplasm to initiate translation (see Fig. 13-12). These events represent potential control points for translation of the message and the production of its encoded protein.

The addition of a **poly-A tail** to eukaryotic mRNA, for example, appears necessary to initiate translation. Researchers have shown that mRNAs with long poly-A tails are efficiently translated, whereas mRNAs with short poly-A tails are essentially dormant. *Polyadenylation,* which commonly occurs in the nucleus, can also take place in the cytosol. When the short poly-A tail of an mRNA is elongated, the mRNA becomes activated and is then translated.

Some pre-mRNAs are processed in more than one way

Investigators have discovered several forms of regulation involving mRNA processing. In some instances, the same gene produces one type of protein in one tissue and a related but somewhat different type of protein in another tissue. This is possible because many genes produce pre-mRNA molecules that have **alternative splicing** patterns; that is, they are spliced in different ways depending on the tissue.

Typically, such a gene includes at least one segment that can be either an **intron** or an **exon** (see Chapter 13). As an intron, the sequence is removed, but as an exon, it is retained. Through alternative splicing, the cells in each tissue produce their own version of mRNA corresponding to the particular gene (**FIG. 14-14**). For example, this mechanism produces different forms of troponin, a protein that regulates muscle contraction, in different muscle tissues.

The stability of mRNA molecules varies

Controlling the lifespan of a particular kind of mRNA molecule permits control over the number of protein molecules translated from it. In some cases, mRNA stability is under hormonal control. This is true for mRNA that codes for vitellogenin, a protein synthesized in the liver of certain female animals, such as frogs and chickens. Vitellogenin is transported to the oviduct, where it is used in forming egg yolk proteins.

The hormone estradiol regulates vitellogenin synthesis. When estradiol levels are high, the half-life of vitellogenin mRNA in frog liver is about 500 hours. When researchers deprive cells of estradiol, the half-life of the mRNA drops rapidly, to less than 165 hours. This quickly lowers cell vitellogenin mRNA levels and decreases synthesis of the vitellogenin protein. In addition to affecting mRNA stability, the hormone seems to control the rate at which the mRNA is synthesized.

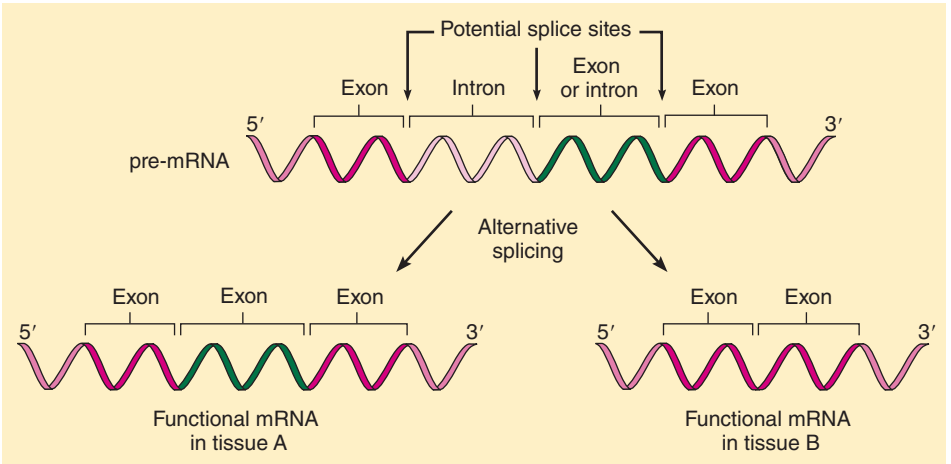


FIGURE 14-14 Regulation of mRNA processing: alternative splicing

In some cases, a pre-mRNA molecule is processed in more than one way to yield two or more mature mRNAs, each of which encodes a related, but different, protein. In this generalized example, the gene contains a segment that can be an exon in tissue A (*left*) but an intron in tissue B (*right*).

www.konkur.in

Posttranslational chemical modifications may alter the activity of eukaryotic proteins

Another way to control gene expression is by regulating the activity of the gene product. Many metabolic pathways in eukaryotes, as in bacteria, contain allosteric enzymes regulated through feedback inhibition. In addition, after they are synthesized, many eukaryotic proteins are extensively modified.

In **proteolytic processing,** proteins are synthesized as inactive precursors, which are converted to an active form by the removal of a portion of the polypeptide chain. For example, proinsulin contains 86 amino acids. Removing 35 amino acids yields the hormone insulin, which consists of two polypeptide chains containing 30 and 21 amino acids, respectively, linked by disulfide bridges.

Chemical modification, by adding or removing functional groups, reversibly alters the activity of an enzyme. One common way to modify the activity of an enzyme or other protein is to add or remove phosphate groups. Enzymes that add phosphate groups are called **kinases;** those that remove them are **phosphatases.** For example, the cyclin-dependent kinases discussed in Chapter 10 help control the cell cycle by adding phosphate groups to certain key proteins, causing them to become activated or inactivated. Chemical modifications such as protein phosphorylation also let the cell respond rapidly to certain hormones, or to fast-changing environmental or nutritional conditions.

Posttranslational control of gene expression can also involve **protein degradation.** The amino acid found at the amino end of a protein correlates with whether the protein is long-lived or short-lived. Some proteins, for example, have a 50% turnover of synthesis and degradation every 3 days. Other proteins, such as proteins in the lens of the human eye, may persist for the entire life of the individual.

Proteins that are selectively targeted for destruction are covalently bonded to **ubiquitin,** a small polypeptide tag that contains 76 amino acids. Additional molecules of ubiquitin are added, forming short chains attached to the soon-to-be degraded protein (**FIG. 14-15**). A protein tagged by ubiquitin is targeted for degradation in a proteasome. **Proteasomes** are large macromolecular structures that recognize the ubiquitin tags. **Proteases** (protein-degrading enzymes) associated with proteasomes hydrolyze some of the peptide bonds, degrading the protein into short, nonfunctional peptide fragments. As the protein is degraded, the ubiquitin molecules are released intact, which allows them to be used again.

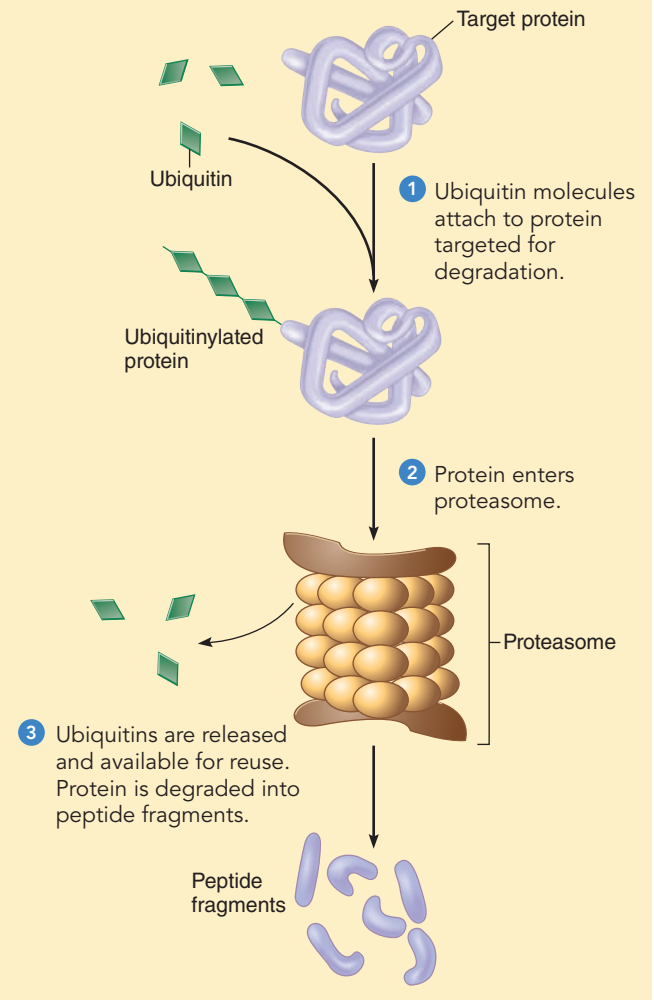

FIGURE 14-15 Degradation of protein: ubiquitin and proteasomes

Review

- How does regulation of eukaryotic genes differ from regulation of bacterial genes?
- Why must certain genes in eukaryotic cells be present in multiple copies?
- How does chromosome structure affect the activity of some eukaryotic genes?
- How does alternative splicing give rise to different proteins?

SUMMARY: FOCUS ON LEARNING OBJECTIVES

14.1 *(page 308)*

1 Explain why bacterial and eukaryotic cells have different mechanisms of gene regulation.

- Bacterial cells grow rapidly and have a relatively short lifespan. **Transcriptional-level control** is the most common way for the prokaryotic cell to regulate gene expression.
- Eukaryotic cells usually have a relatively long lifespan, during which they must maintain homeostasis in response to many different stimuli. Although transcriptional-level control predominates, control at other levels of gene expression is also important.

14.2 *(page 309)*

2 Define *operon* and explain the functions of the operator and promoter regions.

- An **operon** is a gene complex consisting of a group of **structural genes** with related functions plus the closely linked DNA sequences responsible for controlling them.
- Each operon has a single **promoter** region upstream from the protein-coding regions; the promoter is where RNA polymerase first binds to DNA before transcription begins.

www.konkur.in

- The **operator** serves as the regulatory switch for transcriptional-level control of the operon. The binding of a **repressor protein** to the operator sequence prevents transcription; although RNA polymerase binds to the promoter, it is blocked from transcribing the structural genes. When the repressor is not bound to the operator, transcription proceeds.

3 Distinguish among inducible, repressible, and constitutive genes.

- An **inducible operon,** such as the *lac* operon, is normally turned off. The repressor protein is synthesized in an active form that binds to the operator. If lactose is present, it is converted to allolactose, the **inducer,** which binds to the repressor protein. The altered repressor cannot bind to the operator, and the operon is turned on.

CENGAGENOW™ Watch the lactose operon in action by clicking on the figure in CengageNOW.

- A **repressible operon,** such as the *trp* operon, is normally turned on. The repressor protein is synthesized in an inactive form that cannot bind to the operator. A metabolite (usually the end product of a metabolic pathway) acts as a **corepressor.** When corepressor levels are high, a corepressor molecule binds to the repressor, which can now bind to the operator and turn off transcription of the operon.
- **Constitutive genes** are neither inducible nor repressible; they are active at all times. The activity of constitutive genes is controlled by how efficiently RNA polymerase binds to their promoter regions.

4 Differentiate between positive and negative control, and show how both types of control operate in regulating the *lac* operon.

- Repressible and inducible operons are under **negative control.** When the repressor protein binds to the operator, transcription of the operon is turned off.
- Some inducible operons are also under **positive control,** in which an activator protein binds to the DNA and stimulates transcription of the gene. **Catabolite activator protein (CAP)** activates the *lac* operon; CAP binds to the promoter region, stimulating transcription by binding RNA polymerase tightly. To bind, CAP requires **cyclic AMP (cAMP),** which increases in the cell as glucose decreases.

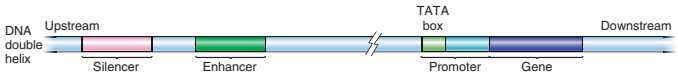
5 Describe the types of posttranscriptional control in bacteria.

- Some **posttranscriptional controls** operate in bacteria. A **translational control** is a posttranscriptional control that regulates the rate of translation of a particular mRNA. **Posttranslational controls** include **feedback inhibition** of key enzymes in some metabolic pathways.

14.3 *(page 314)*

6 Discuss the structure of a typical eukaryotic gene and the DNA elements involved in regulating that gene.

- Eukaryotic genes are not normally organized into operons. Regulation of eukaryotic genes occurs at the levels of transcription, mRNA processing, translation, and modifications of the protein product.
- Transcription of a gene requires a **transcription initiation site,** where transcription begins, plus a promoter to which RNA polymerase binds. In almost all multicellular eukaryotes, the promoter contains an element called the **TATA box** that has a regulatory function and facilitates expression of the gene.
- Some eukaryotic genes have **enhancers** and **silencers** located thousands of bases away from the promoter. These regulatory elements increase or decrease the rate of transcription.



7 Give examples of some of the ways eukaryotic DNA-binding proteins bind to DNA.

- Eukaryotic genes are controlled by DNA-binding proteins called **transcription factors.** Many are transcriptional activators; others are transcriptional repressors.
- Each transcription factor has a DNA-binding **domain.** Some transcription factors have a helix-turn-helix arrangement and insert one of the helices into the DNA. Other transcription factors have loops of amino acids held together by zinc ions; each loop includes an α-helix that fits into the DNA. Some transcription factors are **leucine zipper proteins** that associate as dimers that insert into the DNA.

8 Illustrate how a change in chromosome structure may affect the activity of a gene.

- Densely packed regions of chromosomes, called **heterochromatin,** contain inactive genes. Active genes are associated with a loosely packed chromatin structure called **euchromatin.** Methyl groups, acetyl groups, sugars, and proteins may chemically attach to the **histone** tail, a string of amino acids that extends from the DNA-wrapped **nucleosome,** and may expose or hide genes, turning them on or off.
- **DNA methylation** perpetuates gene inactivation. **Epigenetic inheritance** is an important mechanism of gene regulation that involves changes in how a gene is expressed. Because DNA methylation patterns tend to be repeated in successive cell generations, they provide a mechanism for epigenetic inheritance.
- Some genes whose products are required in large amounts exist as multiple copies in the chromosome. In the process of **gene amplification,** some cells selectively amplify genes by DNA replication.

9 Explain how a gene in a multicellular organism may produce different products in different types of cells.

- As a result of **alternative splicing,** a single gene produces different forms of a protein in different tissues, depending on how the pre-mRNA is spliced. Typically, such a gene contains a segment that can be either an intron or an exon. As an intron, the sequence is removed, and as an exon, the sequence is retained.

10 Identify some of the types of regulatory controls that operate in eukaryotes after mature mRNA is formed.

- Certain regulatory mechanisms increase the stability of mRNA, allowing more protein molecules to be synthesized before mRNA degradation. Sometimes mRNA stability is under hormonal control.
- Posttranslational control of eukaryotic genes occurs by feedback inhibition or by modification of the protein structure. The function of a protein is changed by **kinases** adding phosphate groups or by **phosphatases** removing phosphates.
- Posttranslational control of gene expression also involves **protein degradation.** Proteins targeted for destruction are covalently bonded to **ubiquitin,** which tags it for degradation in a **proteasome,** a large macromolecular structure. **Proteases** associated with proteasomes degrade the protein into short peptide fragments.

TEST YOUR UNDERSTANDING

1. The regulation of most bacterial genes occurs at the level of (a) transcription (b) translation (c) replication (d) posttranslation (e) postreplication

2. The operator of an operon (a) encodes information for the repressor protein (b) is the binding site for the inducer (c) is the binding site for the repressor protein (d) is the binding site for RNA polymerase (e) encodes the information for the CAP

www.konkur.in

3. A mutation that inactivates the repressor gene of the *lac* operon results in (a) the continuous transcription of the structural genes (b) no transcription of the structural genes (c) the binding of the repressor to the operator (d) no production of RNA polymerase (e) no difference in the rate of transcription
4. A repressible operon codes for the enzymes of the following pathway.

$$A \xrightarrow{\text{Enzyme 1}} B \xrightarrow{\text{Enzyme 2}} C \xrightarrow{\text{Enzyme 3}} D$$

Which component of the pathway is most likely to be the corepressor for that operon? (a) substance A (b) substance B or C (c) substance D (d) enzyme 1 (e) enzyme 3

5. Feedback inhibition is an example of control at the level of (a) transcription (b) translation (c) posttranslation (d) replication (e) all the preceding
6. Which of the following is an example of positive control? (a) transcription occurs when a repressor binds to an inducer (b) transcription cannot occur when a repressor binds to a corepressor (c) transcription is stimulated when an activator protein binds to DNA (d) a and b (e) a and c
7. The "zipper" of a leucine zipper protein attaches (a) specific amino acids to specific DNA base pairs (b) two polypeptide chains to each other (c) one DNA region to another DNA region (d) amino acids to zinc atoms (e) RNA polymerase to the operator
8. Inactive genes tend to be found in (a) highly condensed chromatin, known as euchromatin (b) decondensed chromatin, known as euchromatin (c) highly condensed chromatin, known as heterochromatin (d) decondensed chromatin, known as heterochromatin (e) chromatin that is not organized as nucleosomes
9. Which of the following is characteristic of genes and gene regulation in bacteria, but *not* in eukaryotes? (a) presence of enhancers (b) capping of mRNAs (c) many chromosomes per cell (d) binding of DNA to regulatory proteins (e) no requirement for exon splicing
10. Which of the following is characteristic of genes and gene regulation in *both* bacteria and eukaryotes? (a) promoters (b) noncoding DNA within coding sequences (c) enhancers (d) operons (e) DNA located in a nucleus
11. Through alternative splicing, eukaryotes (a) reinforce gene inactivation (b) prevent transcription of heterochromatin (c) produce related but different proteins in different tissues (d) amplify genes to meet the requirement of high levels of a gene product (e) bind transcription factors to enhancers to activate transcription

CRITICAL THINKING

1. Compare the types of bacterial genes associated with inducible operons, those associated with repressible operons, and those that are constitutive. Predict the category into which each of the following would most likely fit: (a) a gene that codes for RNA polymerase, (b) a gene that codes for an enzyme required to break down maltose, (c) a gene that codes for an enzyme used in the synthesis of adenine.
2. The regulatory gene that codes for the tryptophan repressor is not tightly linked to the *trp* operon. Would it be advantageous if it were? Explain your answer.
3. **EVOLUTION LINK.** Suggest why evolution resulted in multiple levels of gene regulation in multicellular eukaryotes.
4. **EVOLUTION LINK.** Comparing DNA sequences in different species indicates that more DNA segments that do not code for protein have been conserved (unchanged) than protein-coding regions. These nonprotein-coding regions are interpreted as gene regulatory elements. Suggest why gene regulatory elements have not undergone many changes during the course of evolution.
5. **ANALYZING DATA.** Develop a simple hypothesis that would explain the behavior of each of the following types of mutants in *E. coli:*

   Mutant a: The map position of this mutation is in the *trp* operon. The mutant cells are constitutive; that is, they produce all the enzymes coded for by the *trp* operon, even if large amounts of tryptophan are present in the growth medium.

   Mutant b: The map position of this mutation is in the *trp* operon. The mutant cells do not produce any enzymes coded for by the *trp* operon under any conditions.

   Mutant c: The map position of this mutation is some distance from the *trp* operon. The mutant cells are constitutive; that is, they produce all the enzymes coded for by the *trp* operon, even if the growth medium contains large amounts of tryptophan.
6. **ANALYZING DATA.** You are studying the rate of transcription of a particular eukaryotic gene. When the DNA located several thousand bases upstream of the gene is removed, the transcription rate of the gene decreases dramatically. How would you interpret these results?

Transgenic fish (GloFish®). These aquarium fish glow green, red, or yellow because researchers inserted a foreign gene encoding a fluorescent protein from either jellyfish or sea corals.

KEY CONCEPTS

15.1 Scientists use DNA technology to produce many copies of specific genes (gene cloning).

15.2 Biologists study DNA using gel electrophoresis, DNA blotting, automated sequencing, and other methods.

15.3 Genomics is an emerging field that comprises the structure, function, and evolution of genomes.

15.4 DNA technology and genomics have wide applications, from medical to forensic to agricultural.

15.5 Scientists must assess the risks of each new recombinant organism.

Beginning in the mid-1970s, the development of new ways to study DNA led to radically new research approaches, such as **recombinant DNA technology,** in which researchers splice together DNA from different organisms in the laboratory. One goal of this technology is to enable scientists to obtain many copies of a specific DNA segment for the purpose of studying it. Because new methods to analyze DNA are continually emerging, we do not attempt to explore them all here. Instead, we discuss some of the major approaches that have provided a foundation for the technologies commonly used by molecular geneticists.

We then consider how studies of DNA sequences have helped scientists understand the organization of genes and the relationship between genes and their products. In fact, most of our current knowledge of the structure and control of eukaryotic genes, and of the roles of genes in development, comes from applying these methods. DNA sequencing has also revolutionized systematics by helping to clarify evolutionary relationships.

This chapter also explores some of the practical applications of DNA technologies. One of the rapidly advancing areas of study is **molecular modification**—altering the DNA of an organism to produce new genes with new traits. Molecular modification, also called *genetic engineering,* can take many forms, ranging from basic research to the production of

www.konkur.in

strains of bacteria that manufacture useful protein products, to the development of plants and animals that express foreign genes (see photograph).

The development of DNA cloning, molecular modification, and related techniques have transformed people's view of **biotechnology,** which is the commercial or industrial use of cells or organisms. Today, biotechnology includes numerous applications in such diverse areas as medicine, foods and agriculture, and forensic science.

15.1 DNA CLONING

LEARNING OBJECTIVES

1. Explain how a typical restriction enzyme cuts DNA molecules and give examples of the ways in which these enzymes are used in recombinant DNA technology.
2. Distinguish among a genomic DNA library, a chromosome library, and a complementary DNA (cDNA) library; explain why one would clone the same eukaryotic gene from both a genomic DNA library and a cDNA library.
3. Explain how researchers use a DNA probe.
4. Describe how the polymerase chain reaction amplifies DNA in vitro.

Recombinant DNA technology was not developed quickly. It actually had its roots in the 1940s with genetic studies of bacteria and **bacteriophages** ("bacteria eaters"), the viruses that infect them. (See Figure 12-2, which shows bacteriophages on the bacterium *Escherichia coli.*) Molecular biologist Paul Berg was the first investigator to construct a recombinant DNA molecule; in 1980, he shared the Nobel Prize in Chemistry for his contributions to recombinant DNA technology. After decades of basic research and the accumulation of extensive knowledge, the technology became feasible and available to the many scientists who now use these methods.

In recombinant DNA technology, scientists use **restriction enzymes** from bacteria to cut DNA molecules only in specific places. Restriction enzymes enable researchers to cut DNA into manageable segments. Each fragment is then incorporated into a suitable **vector** molecule, a carrier capable of transporting the DNA fragment into a cell.

Bacteriophages and DNA molecules called plasmids are two examples of vectors. Bacterial DNA is generally circular; most **plasmids** are separate, much smaller, circular DNA molecules that may be present and replicate inside a bacterial cell, such as *E. coli.* Researchers introduce plasmids into bacterial cells by a method called **transformation,** the uptake of foreign DNA by cells (see Chapter 12). For transformation to be efficient, the researcher alters the cells chemically or by *electroporation*—delivering an electric shock—to make the plasma membrane permeable to the plasmid DNA molecules. Once a plasmid enters a cell, it is replicated and distributed to daughter cells during cell division. When a *recombinant plasmid*—one that has foreign DNA spliced into it—replicates in this way, many identical copies of the foreign DNA are made; in other words, the foreign DNA is **cloned.**

Transposons are an efficient vector for transferring genes into mice and other research organisms. Recall from Chapter 13 that a transposon is a mobile genetic element that can cut itself out of one location in a cell's genome and insert itself into a different location.

Restriction enzymes are "molecular scissors"

Discovering **restriction enzymes** was a major breakthrough in developing recombinant DNA technology. Today, large numbers of different types of restriction enzymes, each with its own characteristics, are readily available to researchers. For example, a restriction enzyme known as *Hin*dIII searches a DNA molecule for the restriction site 5′—AAGCTT—3′, and when it finds that site, it cuts the DNA. (A *restriction site* is a DNA sequence containing the cleavage site that is cut by a particular restriction enzyme.) The sequence 5′—GAATTC—3′ is cut by another restriction enzyme, known as *Eco*RI. The names of restriction enzymes are generally derived from the names of the bacteria from which they were originally isolated. Thus, *Hin*dIII and *Eco*RI are derived from *Hemophilus influenzae* and *E. coli,* respectively.

Why do bacteria produce such enzymes? During infection, a bacteriophage injects its DNA into a bacterial cell. The bacterium can defend itself if it has restriction enzymes that can attack the bacteriophage DNA. The bacterial cell protects its own DNA from breakdown by modifying it after replication. An enzyme adds a methyl group to one or more bases in each restriction site so that the restriction enzyme does not recognize and cut the bacterial DNA.

Restriction enzymes enable scientists to cut DNA from chromosomes into shorter fragments in a controlled way. Many of the restriction enzymes used for recombinant DNA studies cut **palindromic sequences,** which means the base sequence of one strand reads the same as its complement when both are read in the 5′ ⟶ 3′ direction. Thus, in our *Hin*dIII example, both strands read 5′—AAGCTT—3′, which as a double-stranded molecule is diagrammed as follows:

```
5′—AAGCTT—3′
3′—TTCGAA—5′
```

By cutting both strands of the DNA, but in a staggered fashion, these enzymes produce fragments with identical, complementary, single-stranded ends:

```
5′—A        AGCTT—3′
3′—TTCGA        A—5′
```

These ends are called *sticky ends* because they pair by hydrogen bonding with the complementary, single-stranded ends of other DNA molecules that have been cut with the same enzyme (**FIG. 15-1**). Once the sticky ends of two molecules have been joined in this way, they are treated with **DNA ligase,** an enzyme that covalently links the two DNA fragments to form a stable recombinant DNA molecule. (DNA ligase was discussed in the section on DNA replication in Chapter 12.)

Recombinant DNA forms when DNA is spliced into a vector

In recombinant DNA technology, geneticists cut both the DNA to be cloned and plasmid DNA with the same restriction enzyme. The two DNA samples are then mixed under conditions that facilitate hydrogen bonding between the complementary bases of the sticky ends, and the nicks in the resulting recombinant DNA are sealed by DNA ligase (**FIG. 15-2**).

www.konkur.in

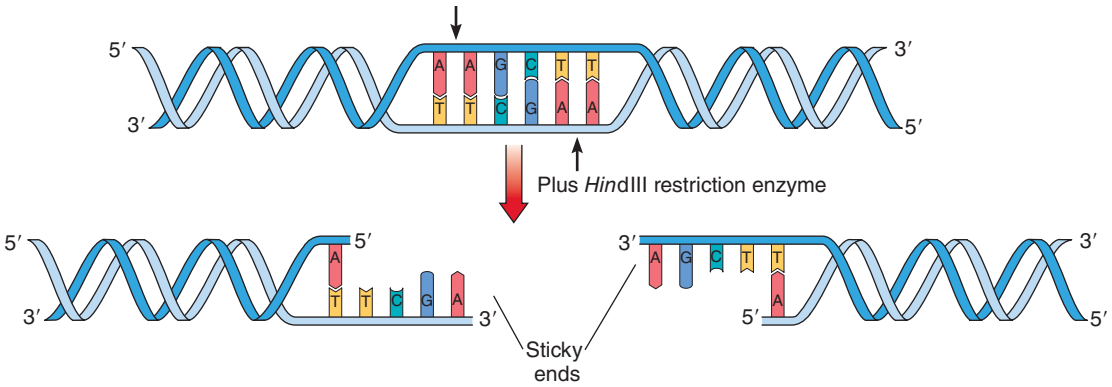

FIGURE 15-1 ***Animated*** **Cutting DNA with a restriction enzyme**

Many restriction enzymes, such as *Hin*dIII, cut DNA at sequences that are palindromic, producing complementary sticky ends. The small black arrows designate the enzyme's cleavage sites.

RESEARCH METHOD

Why Is It Used?

A plasmid carries foreign DNA into a host bacterial cell, where many copies of the gene of interest are made as the bacterial cell divides. These copies are used in many types of research, for example, to make the gene product encoded by the foreign DNA.

How Is It Done?

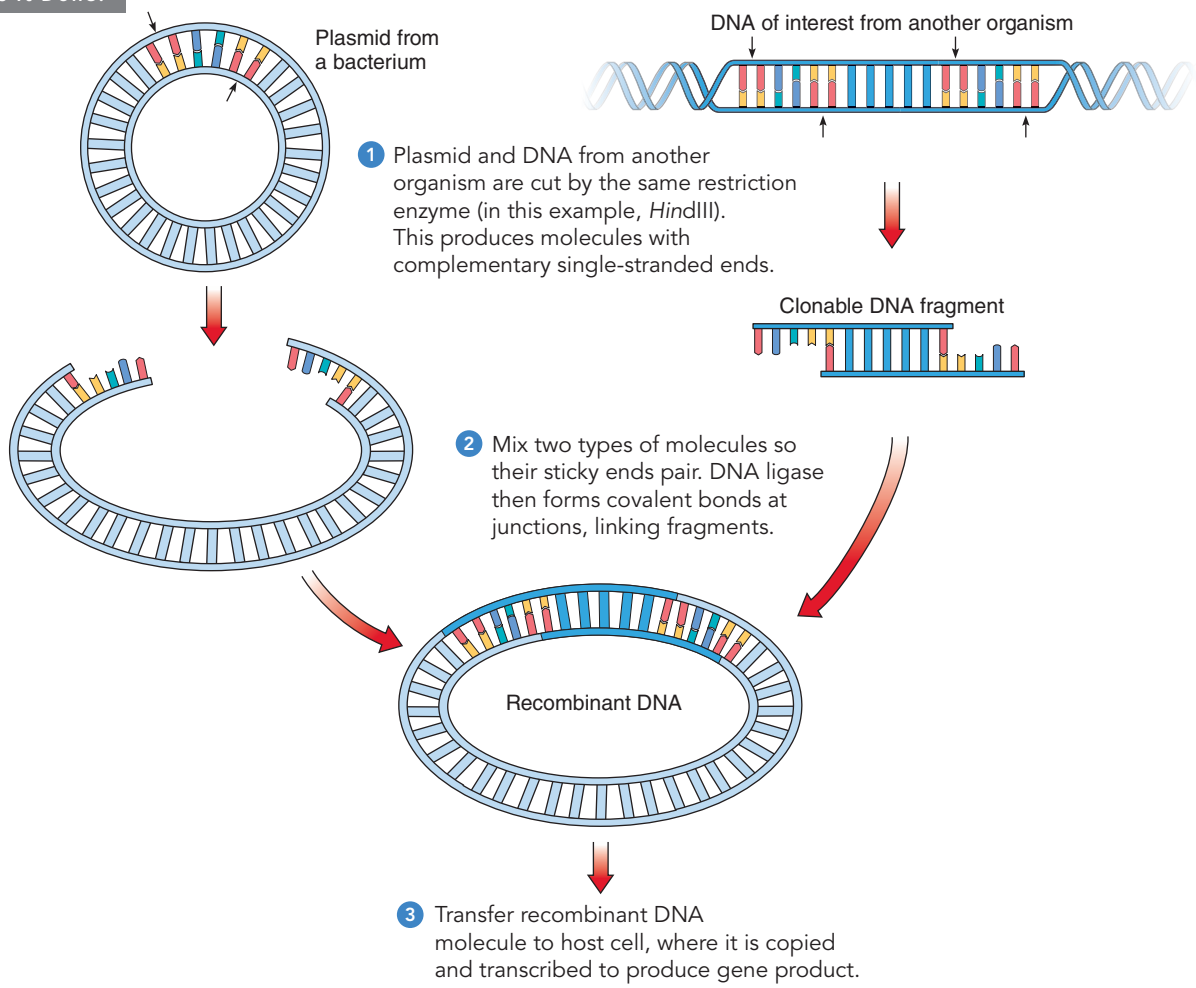

FIGURE 15-2 **Splicing foreign DNA (gene of interest) into a cloning vector (in this example, a bacterial plasmid) to make recombinant DNA**

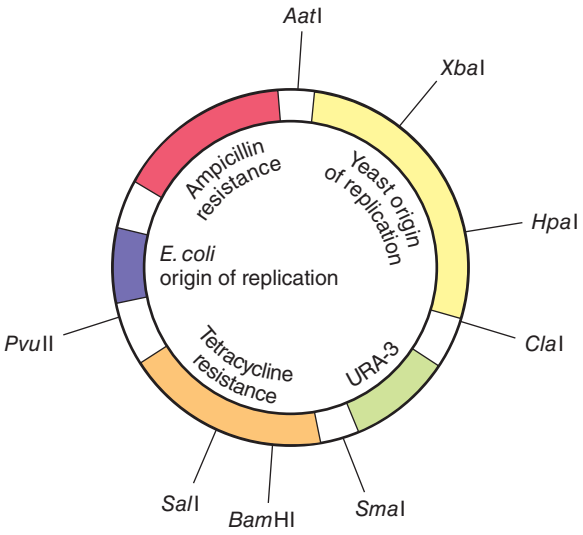
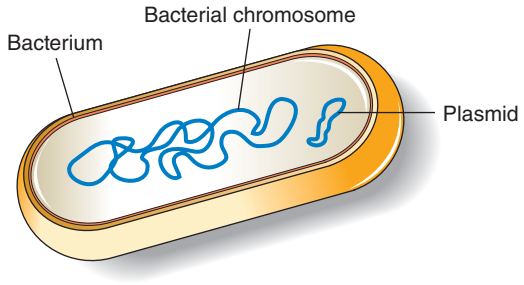
www.konkur.in



(a) This plasmid vector has many useful features. Researchers constructed it from DNA fragments they had isolated from plasmids, *E. coli* genes, and yeast genes. The two origins of replication, one for *E. coli* and one for yeast, *Saccharomyces cerevisiae*, let it replicate independently in either type of cell. Letters on the outer circle designate sites for restriction enzymes that cut the plasmid only at that position. Resistance genes for the antibiotics ampicillin and tetracycline and the yeast *URA-3* gene are also shown. The *URA-3* gene is useful when transforming yeast cells lacking an enzyme required for uracil synthesis. Cells that take up the plasmid grow on a uracil-deficient medium.



(b) The relative sizes of a plasmid and the main DNA of a bacterium.

FIGURE 15-3 Plasmids

The plasmids now used in recombinant DNA work have been extensively manipulated in the laboratory to include features helpful in isolating and analyzing cloned DNA (**FIG. 15-3**). Among these are an origin of replication (see Chapter 12), one or more restriction sites, and genes that let researchers select cells transformed by recombinant plasmids. These genes allow transformed cells to grow under specified conditions that do not allow untransformed cells to grow. In this way, the researchers use features that are also common in naturally occurring plasmids. Typically, plasmids do not contain genes essential to the bacterial cells under normal conditions. However, they often carry genes that are useful under specific environmental conditions, such as genes that confer resistance to particular antibiotics or that let the cells use a specific nutrient. For example, cells transformed with a plasmid that includes a gene for resistance to the antibiotic tetracycline can grow in a medium that contains tetracycline, whereas untransformed cells cannot.

A limiting property of any vector is the size of the DNA fragment it can effectively carry. The size of a DNA segment is often given in kilobases (kb), with 1 kb being equal to 1000 base pairs. Fragments that are smaller than 10 kb are usually inserted into plasmids for use in *E. coli*. However, larger fragments require the use of bacteriophage vectors, which can handle up to 23 kb of DNA. Other vectors are **cosmid cloning vectors,** which are combination vectors with features from both bacteriophages and plasmids, and **bacterial artificial chromosomes (BACs),** which accommodate much larger fragments of DNA. A single BAC can include up to about 200 kb of extra DNA, a feature that made BACs especially useful in the *Human Genome Project,* which is discussed later in the chapter.

Recombinant DNA can also be introduced into cells of eukaryotic organisms. For example, geneticists use modified viruses as vectors in mammal cells. These viruses are disabled so they do not kill the cells they infect. Instead, the viral DNA molecules, as well as any foreign DNA they carry, become incorporated into the cell's chromosomes after infection. As discussed later, other methods do not require a biological vector.

DNA can be cloned inside cells

Because a single gene is only a small part of the total DNA in an organism, isolating the piece of DNA containing that particular gene is like finding a needle in a haystack: a powerful detector is needed. Today, many methods enable biologists to isolate a specific nucleotide sequence from an organism. We start by discussing methods in which DNA is cloned inside bacterial cells. We use the cloning of human DNA as an example, although the procedure is applicable for any organism.

A genomic DNA library contains fragments of all DNA in the genome

The total DNA in a cell is called its **genome.** For example, if DNA is extracted from human cells, we refer to it as human genomic DNA. A **genomic DNA library** is a collection of thousands of DNA fragments that represent all of the DNA in the genome. Each fragment is inserted into a plasmid, which is usually incorporated into a bacterial cell. Thus, a human genomic DNA library is stored in a collection of recombinant bacteria, each with a different fragment of human DNA. Scientists use genomic DNA libraries to isolate and study specific genes. In addition, genomic DNA libraries contain a huge number of sequences that do not code for protein.

Individual chromosomes can also be isolated to make a **chromosome library** containing all the DNA fragments in that specific chromosome. If a gene of interest is known to be associated with a particular chromosome, it is easier to isolate that gene from a chromosome library than from a genomic DNA library.

The basic cloning methods just described are used to make genomic DNA or chromosome libraries. First, the DNA is cut with a restriction enzyme, generating a population of DNA fragments (**FIG. 15-4**). These fragments vary in size and in the genetic information they carry, but they all have identical sticky ends. Ge-

www.konkur.in

RESEARCH METHOD

Why Is It Used?

A genomic library is a collection of all the DNA fragments in an organism's genome; a chromosome library is a collection of all the DNA fragments in a specific chromosome. Each DNA fragment is "stored" in a clone of recombinant bacterial cells. Scientists use genomic and chromosome libraries to isolate and study genes.

How Is It Done?

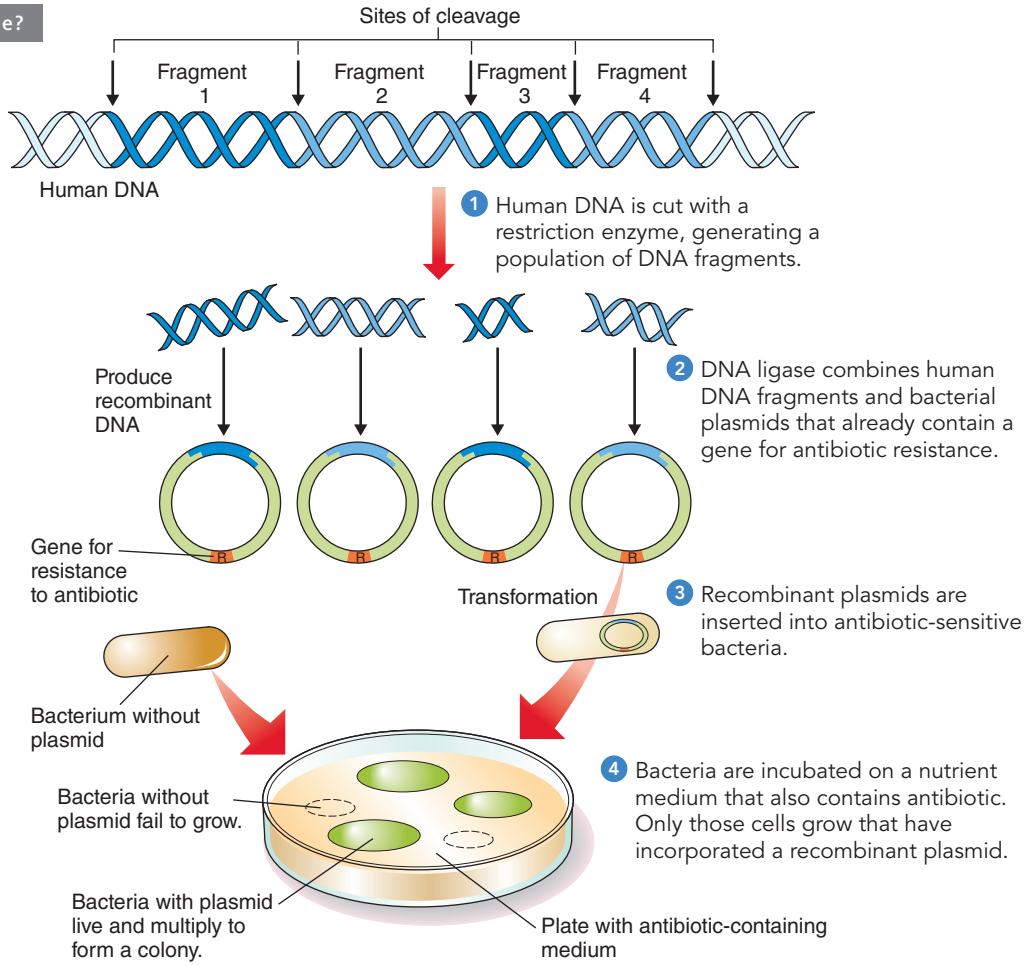


FIGURE 15-4 Producing a genomic DNA library or a chromosome library

neticists treat plasmid DNA that will be used as a vector with the same restriction enzyme, which converts the circular plasmids into linear molecules with sticky ends complementary to those of the human DNA fragments. Recombinant plasmids are produced by mixing the two kinds of DNA (human and plasmid) under conditions that promote hydrogen bonding of complementary bases. Then, DNA ligase is used to covalently bond the paired ends of the plasmid and human DNA, forming recombinant DNA. Unavoidably, nonrecombinant plasmids also form (*not shown in figure*) because some plasmids revert to their original circular shape without incorporating foreign DNA.

The geneticists insert plasmids into antibiotic-sensitive bacterial cells by transformation. Because the ratio of plasmids to cells is kept very low, it is rare for a cell to receive more than one plasmid molecule, and not all cells receive a plasmid. The researchers incubate normally antibiotic-sensitive cells on a nutrient medium that includes antibiotics; the only cells that are able to grow have incorporated a plasmid that contains a gene for antibiotic resistance. In addition, the plasmid has usually been modified in ways that enable researchers to identify those cells containing recombinant plasmids.

Genomic DNA and chromosome libraries contain redundancies; that is, certain human DNA sequences have been inserted into plasmids more than once, purely by chance. However, each individual recombinant plasmid—analogous to a book in the library—contains only a single fragment of the total human genome.

To identify a plasmid containing a sequence of interest, the researcher clones each plasmid until there are millions of copies to work with. This process occurs as the bacterial cells grow and divide. A dilute sample of the bacterial culture is spread on solid growth medium (agar plates), so the cells are widely separated. Each cell divides many times, yielding a visible **colony,** which is a clone of genetically identical cells originating from a single cell.

www.konkur.in

All the cells of a particular colony contain the same recombinant plasmid, so during this process a specific sequence of human DNA is also cloned. The major task is to determine which colony out of thousands contains a cloned fragment of interest. Specific DNA sequences are identified in various ways.

A complementary DNA probe detects a specific DNA sequence

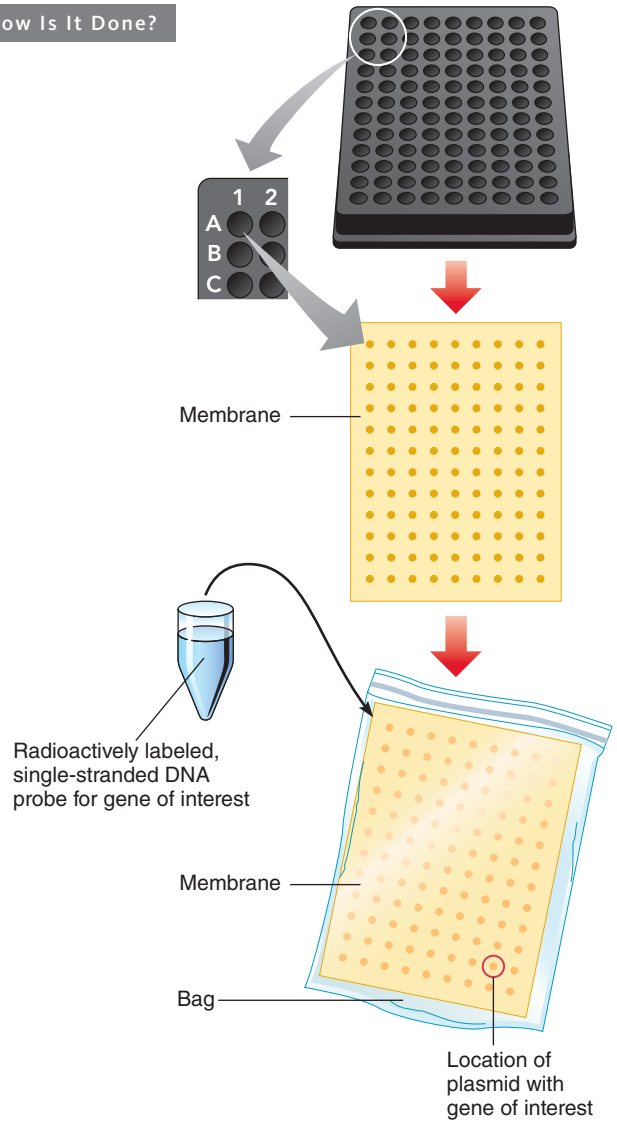
Suppose a researcher wishes to screen the thousands of recombinant DNA molecules in bacterial cells to find the specific DNA sequence of interest. A common approach to detecting a specific DNA sequence involves using a **DNA probe,** which is a segment of DNA that is homologous to part of the sequence of interest. The DNA probe is usually a radioactively labeled segment of single-stranded DNA that can **hybridize**—attach by base pairing—to complementary base sequences in the target DNA.

To find a specific DNA, biologists transfer the genomic library to a nitrocellulose or nylon membrane (**FIG. 15-5**). They treat the cells on the membrane chemically to lyse them, releasing the DNA and making the DNA single-stranded. (Single-stranded DNA

RESEARCH METHOD

Why Is It Used? A radioactive nucleic acid probe reveals the presence of complementary sequences of DNA in a genomic library.

How Is It Done?



1. All clones of the genomic library are stored in multiwell plates. An organism's entire genomic library is stored in many of these plates, which are stacked with a lid on top.
2. Cells from each clone are transferred to a specific location on a nylon or nitrocellulose membrane. The membrane is treated to break open the bacterial cells, releasing plasmids containing DNA fragments.
3. Labeled probe is added to membrane and hybridizes with any DNA with complementary nucleotide sequences (in this case, the gene of interest.)
4. The hybridization is visualized as a dark spot by placing the membrane against X-ray film, which is then developed.

FIGURE 15-5 Identifying a specific DNA sequence in a genomic library by hybridization with a nucleic acid probe

www.konkur.in

binds to the membrane.) Then they incubate the membrane with the radioactive probe mixture to let the probes hybridize with any complementary strands of DNA that may be present. Each spot on the membrane containing DNA that is complementary to that particular probe becomes radioactive and is detected by *autoradiography* (see Chapter 2), using X-ray film. Each spot on the film therefore identifies a colony containing a plasmid that includes the DNA of interest. The biologist then returns to the genomic library and removes cells that contain the cloned sequence of interest. These cells are then grown in culture to produce millions of new bacteria, all containing the recombinant DNA of interest.

A cDNA library is complementary to mRNA and does not contain introns

Researchers frequently wish to clone intact genes while avoiding **introns,** which are regions of eukaryotic genes that do not code for proteins. Scientists also may wish to clone only genes that are expressed in a particular cell type. In such cases, they construct libraries of DNA copies of mature mRNA from which introns have been removed. The copies, known as **complementary DNA (cDNA)** because they are complementary to mRNA, also lack introns. The researchers use the enzyme **reverse transcriptase** (see Chapter 13) to synthesize single-stranded cDNA. DNA polymerase is then used to make the cDNA double-stranded (**FIG. 15-6**). A **cDNA library** is formed using mRNA from a single cell type as the starting material. The double-stranded cDNA molecules are inserted into plasmid or virus vectors, which then multiply in bacterial cells.

Analyzing cDNA clones lets investigators determine certain characteristics of the protein encoded by the gene, including its amino acid sequence. They can also study the structure of the mature mRNA. Because the cDNA copy of the mRNA does not contain intron sequences, comparing the DNA base sequences in cDNA and the DNA in genomic DNA or chromosome libraries reveals the locations of intron and exon coding sequences in the gene.

Cloned cDNA sequences are also useful when geneticists want to produce a eukaryotic protein in bacteria. When they introduce an intron-containing human gene, such as the gene for human growth hormone, into a bacterium, it cannot remove the introns from the transcribed RNA to make a functional mRNA for producing its protein product. If they insert a cDNA clone of the gene into the bacterium, however, its transcript contains an uninterrupted coding region. A functional protein is synthesized if the geneticist inserts the gene downstream of an appropriate bacterial promoter and if he or she places the appropriate bacterial translation initiation sequences in it.

The polymerase chain reaction amplifies DNA in vitro

The methods just described for amplifying, or making multiple copies of, a specific DNA sequence involve cloning DNA in cells, usually those of bacteria. These processes are time consuming and require an adequate DNA sample as the starting material. The **polymerase chain reaction (PCR),** which biochemist Kary Mullis developed in 1985, lets researchers amplify a tiny sample

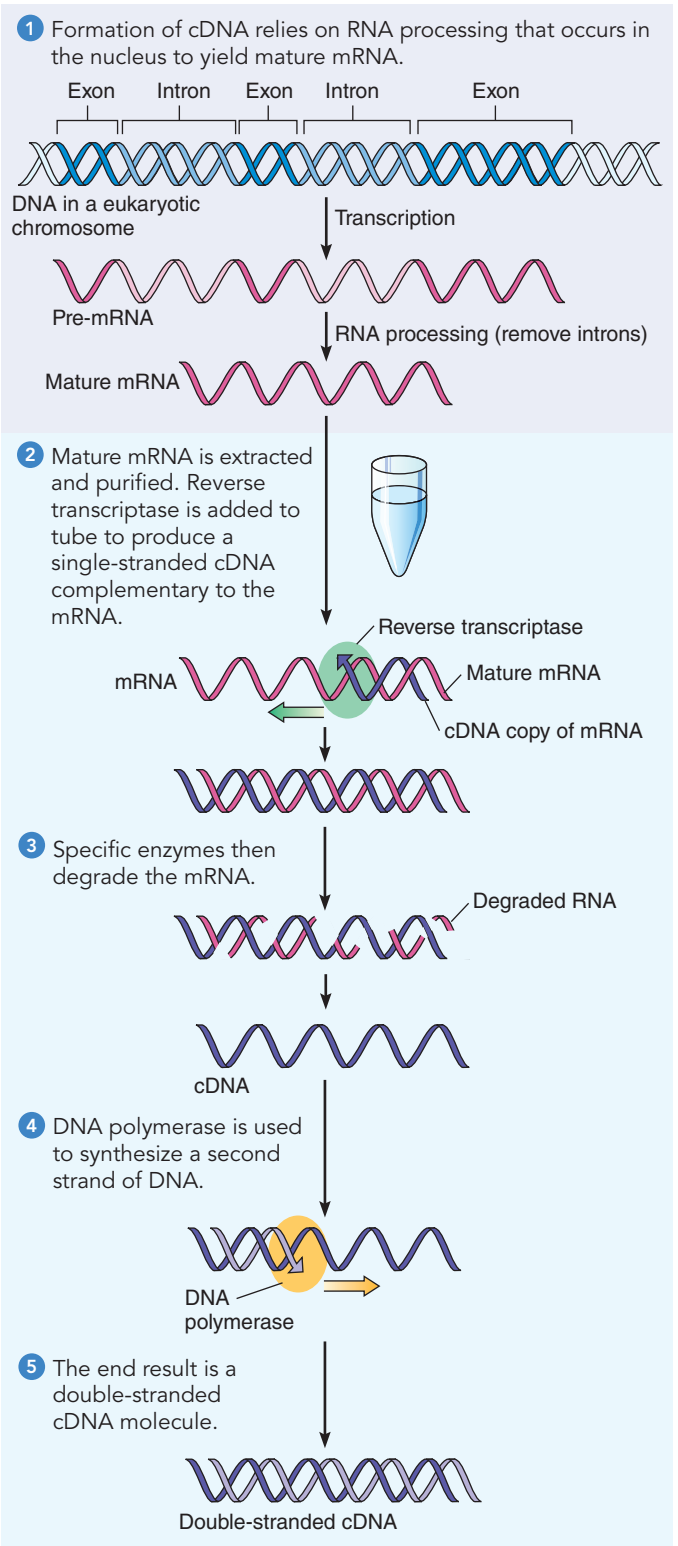


FIGURE 15-6 ***Animated*** **The formation of cDNA**

of DNA *without cloning in a cell.* The DNA is amplified millions of times in a few hours. In 1993, Mullis received the Nobel Prize in Chemistry for his work.

In PCR, DNA polymerase uses nucleotides and primers to replicate a DNA sequence in vitro (outside a living organism),

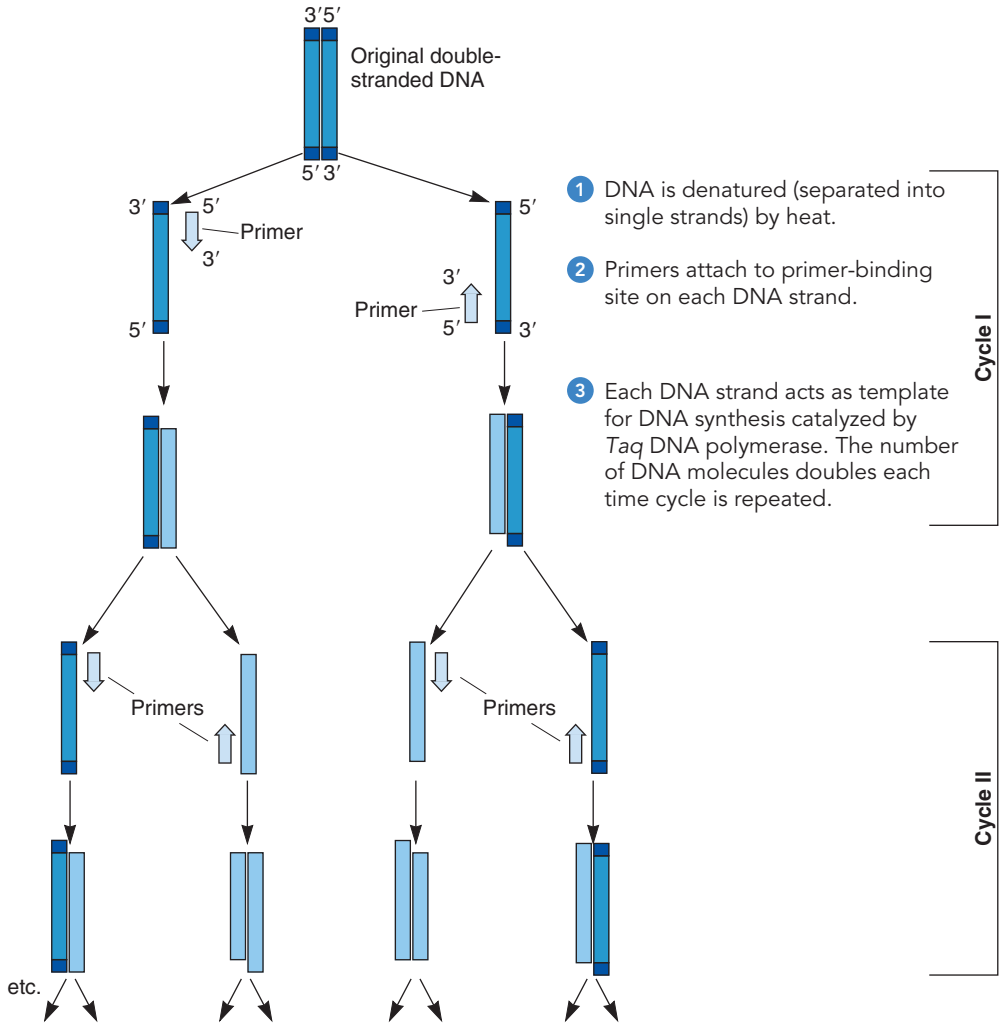
www.konkur.in

thereby producing two DNA molecules (**FIG. 15-7**). Then the researchers denature, or separate by heating, the two strands of each molecule and replicate them again, yielding four double-stranded molecules. After the next cycle of heating and replication, there are eight molecules, and so on, with the number of DNA molecules doubling in each cycle. After only 20 heating and cooling cycles are done using automated equipment, this exponential process yields 2^{20}, or more than 1 million, copies of the target sequence!

Because the reaction can be carried out efficiently only if the DNA polymerase can remain stable through many heating cycles, researchers use a heat-resistant DNA polymerase, known as *Taq* polymerase. The name of this enzyme reflects its source, *Thermus aquaticus,* a bacterium that lives in hot springs in Yellowstone National Park. Because the water in this environment is close to the boiling point, all enzymes in *T. aquaticus* have evolved to be stable at high temperatures. (Recall from Chapter 3 that, when heated, most proteins are irreversibly denatured—they change their overall shape and lose their biological activity.) Bacteria living in deep-sea thermal vents have evolved similar heat-resistant enzymes.

RESEARCH METHOD

Why Is It Used? PCR takes an extremely small sample of DNA and amplifies it to millions of copies in a few hours.



How Is It Done? The initial reaction mixture includes a very small amount of double-stranded DNA, DNA precursors (deoxyribonucleotides), specific nucleic acid primers, and heat-resistant *Taq* DNA polymerase. PCR involves repeated cycles of denaturation, primer attachment, and strand elongation by enzymes using complementary base pairing.

FIGURE 15-7 ***Animated*** **Amplification of DNA by the polymerase chain reaction (PCR)**

www.konkur.in

The PCR technique has virtually limitless applications. It makes cloning easier. It enables researchers to amplify and analyze tiny DNA samples from a variety of sources, ranging from crime scenes to archaeological remains. For example, investigators have used PCR to analyze mitochondrial DNA obtained from the bones of Neandertals (see Chapter 22). Some of the Neandertal genome was sequenced in 2006, enabling researchers to compare it to equivalent parts of the human genome.

A limitation of the PCR technique is that it is almost too sensitive. Even a tiny amount of contaminant DNA in a sample may become amplified if it includes a DNA sequence complementary to the primers, potentially leading to an erroneous conclusion. Researchers take appropriate precautions to avoid this and other technical pitfalls.

15.2 DNA ANALYSIS

LEARNING OBJECTIVES

5 Distinguish among DNA, RNA, and protein blotting.
6 Describe the chain termination method of DNA sequencing.

DNA cloning in cells and the PCR technique have had major impacts on genetic analysis because they provide enough genetic material to address certain fundamental questions about specific genes and their RNA or protein products. For example, when—and how—is a gene expressed? Is a given gene identical from one individual to the next? Is it different from one species to the next? Where is the gene found within the genome? In this and the following section, we consider various techniques that help address these questions. We then examine some of the practical applications of DNA technology in the final section of the chapter.

Gel electrophoresis is used for separating macromolecules

Mixtures of certain macromolecules—proteins, polypeptides, DNA fragments, or RNA—are separated by **gel electrophoresis,** a method that exploits the fact that these molecules carry charged groups that cause them to migrate in an electrical field. **FIGURE 15-8** illustrates gel electrophoresis of DNA molecules. Nucleic acids migrate through the gel toward the positive pole of the electric field because they are negatively charged due to their phosphate groups. Because the gel slows down the large molecules more than the small molecules, the DNA is separated by size. Including DNA fragments of known size as standards ensures accurate measurements of the molecular weights of the unknown fragments. The gel is stained after the DNA fragments are separated to show their number and location.

DNA, RNA, and protein blots detect specific fragments

Geneticists can identify specific DNA fragments that hybridize with a complementary DNA probe. However, it is impossible to hybridize a probe to DNA fragments contained in a gel. For this reason the DNA is usually denatured and then transferred to a nitrocellulose or nylon membrane, which picks up the DNA like a blotter picks up ink. The resulting blot, which is essentially a replica of the gel, is incubated with a DNA probe, which hybridizes with any complementary DNA fragments. If the probe is radioactive, the blot is subjected to autoradiography. The resulting spots on the X-ray film correspond to the locations of the fragments in the gel that are complementary to the probe. Today, many probes are detected by chemical luminescence, which is analyzed by computer scanners, eliminating the need for autoradiography.

This method of detecting DNA fragments—separating them by gel electrophoresis and then transferring them to a nitrocellulose or nylon membrane—is called a **Southern blot,** named for its inventor, Edward M. Southern of Edinburgh University in Scotland (**FIG. 15-9**). The procedure has widespread applications, such as being used to diagnose certain types of genetic disorders. For example, in some cases the DNA of a mutant allele is detected because it migrates differently in the gel than the DNA of its normal counterpart does.

Similar blotting techniques are used to study RNA and proteins. When RNA molecules separated by electrophoresis are transferred to a membrane and detected using a nucleic acid probe, the result is called a **Northern blot** (as a pun on Southern's name being associated with his technique). In the same spirit, the term **Western blot** is applied to a blot consisting of proteins or polypeptides previously separated by gel electrophoresis. (So far, no one has invented a type of blot that could be called an Eastern blot.) In the case of Western blotting, scientists recognize the polypeptides of interest by labeled antibody molecules that bind to them specifically. For example, Western blotting is used diagnostically to detect the presence of proteins specific to HIV-1, the AIDS virus.

Restriction fragment length polymorphisms are a measure of genetic relationships

The variability of genes within a population can be studied in several ways. A traditional approach is based on the premise that no two individuals have the exact same number or position of restriction enzyme cutting sites in the genome: random DNA mutations and recombination may result in individuals with different lengths of fragments produced by a given restriction enzyme. Such **restriction fragment length polymorphisms,** commonly known as **RFLPs,** or "riflips," can be used to determine how closely related different members of a population are. (The term *polymorphism* means "many forms" and refers to inherited differences found within a population.) A **genetic polymorphism** exists if individuals of two or more discrete types, or "morphs," are found in a population.

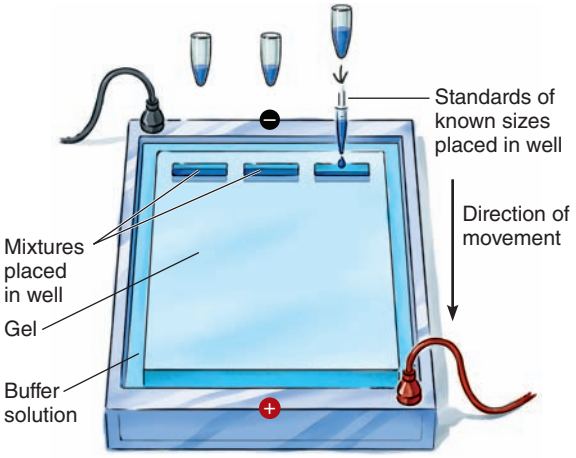
www.konkur.in

RESEARCH METHOD

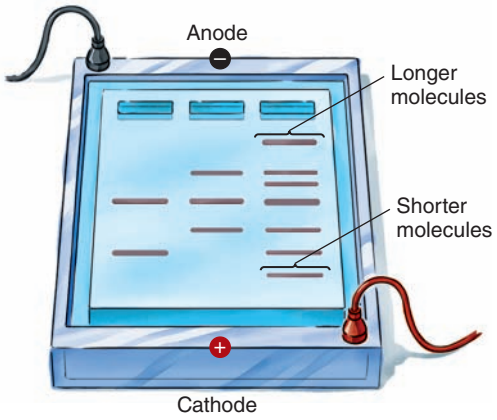
Why Is It Used? Gel electrophoresis separates molecules such as nucleic acids based on their size and charge as they migrate through an electrical field.

How Is It Done?

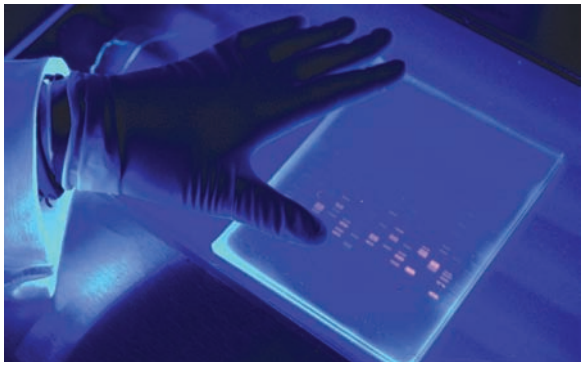
1. A researcher sets up an electrical field in a gel material, consisting of agarose or polyacrylamide, which is poured as a thin slab on a glass or Plexiglas holder. After the gel has solidified, the researcher loads samples containing a mixture of macromolecules (in this case, DNA fragments of different sizes) in wells formed at one end of the gel.



2. When an electrical current is applied, the negatively charged DNA molecules move from the negative pole to the positive pole. The smallest DNA fragments travel the longest distance. The DNA bands are invisible at this point.



3. This gel contains separated DNA fragments. The gel is stained with ethidium bromide, a dye that binds to DNA and is fluorescent under UV light.



Eurelios/Photo Researchers, Inc.

FIGURE 15-8 Gel electrophoresis

Restriction enzymes are used to cut the DNA from two or more individuals, and the fragments are separated by gel electrophoresis, with the DNA from each individual in a separate lane; shorter fragments migrate farther than longer fragments. To visualize the fragments, researchers make a Southern blot of the DNA on the gel, which is then denatured and allowed to hybridize with a DNA probe. The resulting pattern of bands can then be compared.

RFLP analysis has been used when conducting paternity testing and when analyzing evidence found at crime scenes. RFLP analysis has also been used to help map the exact location of gene mutations, such as the mutation that causes cystic fibrosis. Although the RFLP technique has provided useful information in many areas of biology, it is rapidly being replaced by newer methods, such as automated DNA sequencing (discussed in the next section).

www.konkur.in

RESEARCH METHOD

Why Is It Used? The Southern blotting technique allows DNA separated by electrophoresis to be transferred to a filter in the same location as it was on the gel. It can then be hybridized with radioactive complementary probes.

How Is It Done?

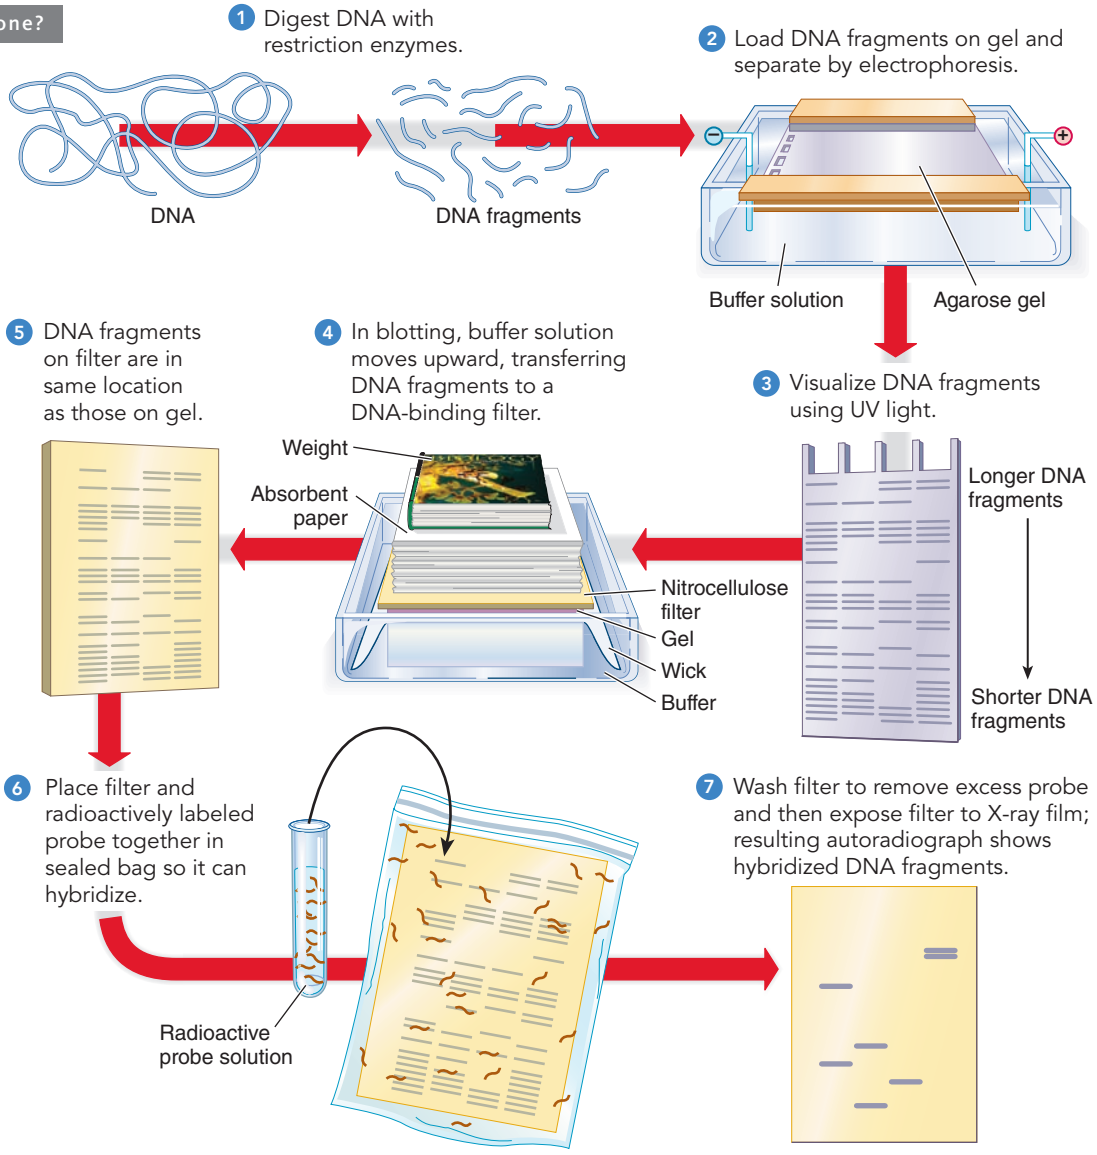


FIGURE 15-9 The Southern blotting technique

Methods to rapidly sequence DNA have been developed

One way to characterize DNA is to determine its sequence of nucleotides. Investigators use a cloned piece of DNA as a research tool for many different applications. For example, they may clone a gene to obtain the encoded protein for some industrial or medical process. Regardless of the particular application, researchers must know a great deal about the gene and how it functions. They usually start by determining the sequence of nucleotides.

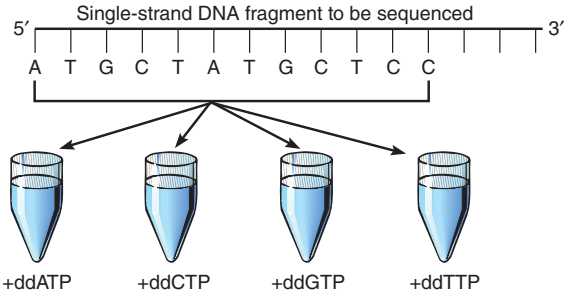
In the 1990s, the advent of automated **DNA-sequencing** machines connected to powerful computers let scientists sequence huge amounts of DNA quickly and reliably. Automated DNA sequencing relies on the **chain termination method** that British biochemist Fred Sanger developed in 1974. In 1980, Sanger shared the Nobel Prize in Chemistry for this contribution. This was Sanger's second Nobel Prize; his first was for his work on the structure of the protein insulin. Although DNA sequencing is now fully automated, many of the automated techniques are still based on Sanger's chain termination method (FIG. 15-10).

www.konkur.in

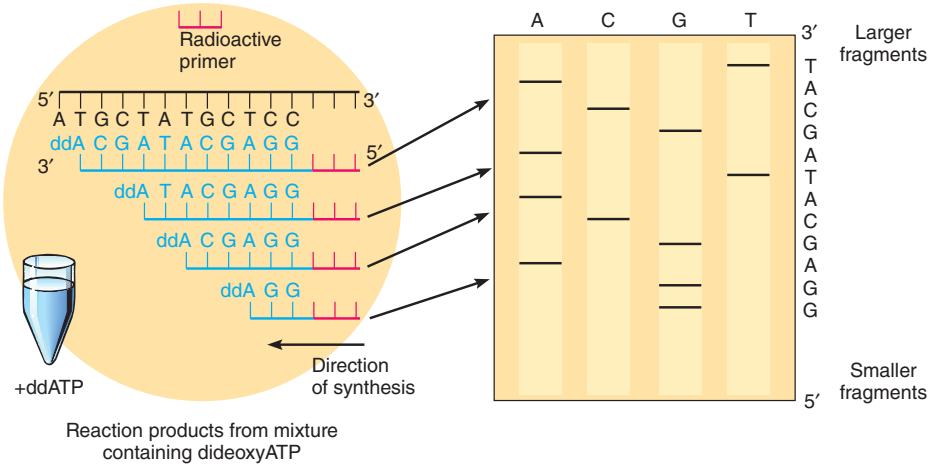
RESEARCH METHOD

Why Is It Used? The dideoxy chain termination method is a rapid, efficient way to sequence DNA.

How Is It Done?

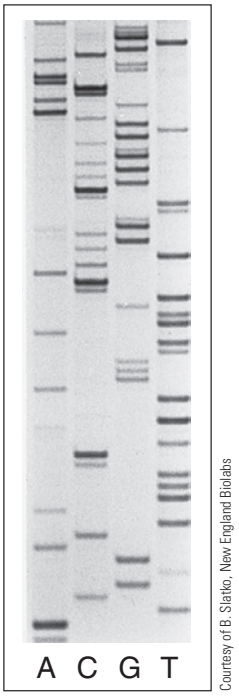


1 Four different reaction mixtures are used to sequence a DNA fragment; each contains a small amount of a single dideoxynucleotide, such as ddATP. Larger amounts of the four normal deoxynucleotides (dATP, dCTP, dGTP, and dTTP) plus DNA polymerase and radioactively labeled primers are also included.



2 The random incorporation of dideoxyATP (ddATP) into the growing chain generates a series of smaller DNA fragments ending at all the possible positions where adenine is found in the newly synthesized fragments. These correspond to positions where thymine occurs in the original template strand.

3 The radioactive products of each reaction mixture are separated by gel electrophoresis and located by exposing the gel to X-ray film. The nucleotide sequence of the newly synthesized DNA is read directly from the film (5′ → 3′). The sequence in the original template strand is its complement (3′ → 5′).



4 An exposed X-ray film of a DNA-sequencing gel. The four lanes represent A, C, G, and T dideoxy reaction mixtures, respectively.

FIGURE 15-10 The dideoxy chain termination method of DNA sequencing

The chain termination method of DNA sequencing is based on the fact that a replicating DNA strand that has incorporated a modified synthetic nucleotide, known as a *dideoxynucleotide,* cannot elongate beyond that point. Unlike a "normal" deoxynucleotide, which has a hydroxyl group on its 3′ carbon, a dideoxynucleotide lacks a hydroxyl group on its 3′ carbon. (Recall from Chapter 12 that a 3′ hydroxyl group reacts each time a phosphodiester linkage is formed.) Thus, dideoxynucleotides terminate elongation during DNA replication.

The researcher prepares four different reaction mixtures. Each contains multiple identical single-stranded copies of the DNA to be sequenced; DNA polymerase; appropriate radioactively labeled primers; and all four deoxynucleotides needed to synthesize DNA—dATP, dCTP, dGTP, and dTTP. Each mixture also includes a small amount of only one of the four dideoxynucleotides: ddATP, ddCTP, ddGTP, or ddTTP. The prefix "dd" refers to dideoxynucleotides, to distinguish them from deoxynucleotides, which are designated "d."

Here's how the reaction proceeds in the mixture that includes ddATP. At each site where adenine is specified, occasionally a growing strand incorporates a ddATP, halting elongation so DNA fragments of varying lengths form in the reaction mixture. Each fragment that contains a ddATP marks a specific location where adenine would normally be found in the newly synthesized strand.

www.konkur.in

Similarly, in the reaction mixture that includes ddCTP, each fragment that contains ddCTP marks the position of a cytosine in the newly synthesized strand, and so on.

The radioactive fragments from each reaction are denatured and then separated by gel electrophoresis, with each reaction mixture, corresponding to A, T, G, or C, occupying its own lane in the gel. The positions of the newly synthesized fragments in the gel can then be determined by autoradiography. Because the high resolution of the gel makes it possible to distinguish between fragments that differ in length by only a single nucleotide, the researcher can read off the sequence in the newly synthesized DNA one base at a time.

The chain termination method is still used in many automated DNA-sequencing machines. However, the method of detection has changed in that the nucleotide sequence is no longer visualized by radioactivity. Instead, researchers label the primer or each of the four ddNTPs with a different-colored fluorescent dye. The computer uses a laser to read the fluorescence of the dye markers as the bases emerge from the end of a lane of electrophoresis medium (**FIG. 15-11**).

Entire genomes have been sequenced using automated DNA sequencing

Sequencing machines today are very powerful and can decode about 1.5 million bases in a 24-hour period. These advances in sequencing technology have made it possible for researchers to study the nucleotide sequences of entire genomes in a wide variety of bacteria, archaea, and eukaryotic organisms.

Much of this research received its initial impetus from the **Human Genome Project,** which began in 1990. The sequencing of the 3 billion base pairs of the human genome was essentially completed in 2001. The genomes of about 800 organisms have been sequenced now, and several hundred more are in various stages of planning or completion. We are in the middle of an extraordinary explosion of gene sequence data, largely due to automated sequencing methods.

DNA sequence information is now kept in large computer databases, many of which are accessed through the Internet. Examples are databases maintained by the National Center for Biotechnology Information and by the Human Genome Organization (HUGO). Geneticists use these databases to compare newly discovered sequences with those already known to identify genes and to access many other kinds of information. By searching for DNA or amino acid sequences in a database, researchers can gain a great deal of insight into the function and structure of the gene product, the evolutionary relationships among genes, and the variability among gene sequences within a population. DNA sequencing of species has added much new information in support of evolution (see Chapter 18).

Review

- What is a Southern blot?
- What technique does automated DNA sequencing use? Outline the basic steps of this method.

15.3 GENOMICS

LEARNING OBJECTIVES

7 Describe three important areas of research in genomics.
8 Explain what a DNA microarray does and give an example of its research and medical potential.
9 Define *pharmacogenetics* and *proteomics*.

Now that we have sequenced the genomes of humans and several hundred other species, what do we do with that information? **Genomics** is the emerging field of biology that studies the entire DNA sequence of an organism's genome to identify all the genes, determine their RNA or protein products, and ascertain how the genes are regulated. As you will see, genomics has important practical applications in addition to answering scientific questions.

The science of genomics has several research areas, including structural genomics, functional genomics, comparative genomics, and metagenomics. *Structural genomics* is concerned with mapping and sequencing genomes. *Functional genomics* deals with the functions of genes and nongene sequences in genomes. *Comparative genomics* involves comparing the genomes of different species to determine what changes in DNA have occurred during the course of evolution. This knowledge furthers our understanding of evolutionary relationships because genes with little or no variation among species are functionally important in the species in which they are found. *Metagenomics* uses the techniques of genomics to analyze communities of microorganisms instead of individual organisms. Metagenomics enables researchers to identify and study all the genes in a community at the same time.

The computer produces the series of peaks shown as it reads the fluorescing bands on the electrophoresis gel. The nucleotide base adenine is shown in green, guanine in black, cytosine in blue, and thymine in red. The DNA sequence assigned by the computer appears at the top of the printout.

www.konkur.in

Identifying protein-coding genes is useful for research and for medical applications

The majority of the human genome contains DNA sequences that do not code for proteins. Although the entire genome is of interest to biologists, the protein-coding regions are of particular interest to medical researchers. Scientists have compiled tens of thousands of short (25 to 30 nucleotides) cDNA sequences, known as **expressed sequence tags (ESTs),** that can help identify protein-coding genes.

A large data set containing thousands of human ESTs is available to scientists via the Internet. Using gene-hunting software, biologists working on a particular DNA sequence can access the data set and match their DNA sequence to a known EST sequence.

Many ESTs in the data set have been identified by comparing them to known DNA sequences from other species. For example, the human telomerase gene *TRT* was identified by matching its human EST sequence to that of a known yeast telomerase sequence. (Recall from Chapter 12 that telomerase adds repetitive nucleotide sequences to the ends, or telomeres, of eukaryotic chromosomes.)

One way to study gene function is to silence genes one at a time

RNA interference (RNAi), first discovered in the mid-1990s, can be used to quickly determine the function of a specific gene. You may recall from Chapter 13 that RNAi is caused by small RNA molecules that interfere with the expression of genes or, more precisely, their mature mRNA transcripts. RNA interference involves small interfering RNAs, microRNAs, and a few other kinds of short RNA molecules. Biologists hypothesize that RNAi, which occurs in many eukaryotic organisms, originally evolved in nature because it protected cells against viruses that have double-stranded RNA molecules.

After a protein-coding gene is identified, perhaps by using ESTs, the function of that gene can be studied by using RNA interference to inactivate the gene. To do this, biologists synthesize a short stretch of RNA that is complementary to part of the DNA sequence of the gene being examined. The RNA is put into cells, and after the gene is silenced, biologists observe any changes in the phenotype to help determine the function of the missing protein.

Gene targeting also reveals gene function

Another research tool that reveals gene function is **gene targeting,** a procedure in which the researcher chooses and "knocks out," or inactivates, a single gene in an organism. *Knockout mice* have been particularly useful in studying the roles of orthologous genes with unknown functions in mammals, including humans. **Orthologous genes** are homologous genes found in different species because they were inherited from a common ancestor. The roles of the inactivated gene are determined by observing the phenotype of the mice bearing the knockout gene. If the gene codes for a protein, for example, studying individuals who lack that protein helps the researcher identify the function of the protein. Because 98% to 99% of the loci of mice are orthologous to human loci, information about knockout genes in mice also provides details about human genes.

Unlike RNA interference, gene targeting is a lengthy procedure. It takes about a year for scientists to develop a new strain of knockout mice through gene targeting. A nonfunctional, or knockout, gene is cloned and introduced into mouse **embryonic stem cells (ES cells)** (also see Chapters 1 and 17). Once inside the ES cells, genes are relatively easy to handle because, like cancer cells, ES cells grow in culture indefinitely. Most important, if placed in a mouse embryo, ES cells divide and produce all the cell types normally found in the mouse. In a tiny fraction of these ES cells, the introduced knockout gene becomes physically associated with the corresponding gene in a chromosome. If this occurs, the gene on the chromosome and the knockout gene tend to exchange DNA segments in a process called *homologous recombination.* In this way, the knockout allele replaces the normal allele in the mouse chromosome.

Researchers inject into early mouse embryos ES cells they think are likely to carry a knockout gene and let the mice develop to maturity. The researchers generally study animals that carry the knockout gene in every cell. However, because many genes are essential to life, researchers have modified the knockout technique to develop strains in which a specific gene is selectively inactivated in only one cell type. Research laboratories around the world have developed thousands of different strains of knockout mice, each displaying its own characteristic phenotype, and the number continues to grow.

Gene targeting in mice is providing answers to basic biological questions relating to the development of embryos, the development of the nervous system, and the normal functioning of the immune system. This technique has great potential for revealing more about various human diseases, especially because many diseases have a genetic component. Geneticists are using gene targeting to study cancer, heart disease, sickle cell anemia, respiratory diseases such as cystic fibrosis, and other disorders.

Mutagenesis screening reveals the genes involved in a particular phenotype

Many large-scale mutagenesis screening projects in mice and other organisms are currently underway. In **mutagenesis screening,** researchers treat male mice with chemical *mutagens* that cause mutations in DNA. They then breed the males with normal females and screen their offspring for unusual phenotypes. Unlike gene targeting, mutagenesis does not necessarily disable a gene completely; instead, it usually causes small, random mutations that change the properties of the proteins that the DNA encodes. The scale of mutagenesis screening is enormous; one screening project in Germany has screened some 28,000 different mouse mutants for changes in phenotypes.

DNA microarrays are a powerful tool for studying gene expression

DNA microarrays provide a way to study patterns of gene expression in a variety of organisms. Each spot in a DNA microarray consists of a single-stranded probe placed on a glass slide or chip (**FIG. 15-12**). First, a mechanical robot prepares the microarray. It spots each location on the grid with thousands to millions of copies of a specific complementary DNA (cDNA) strand. Each spot, known as a *microdot,* contains many copies of a specific single-stranded cDNA molecule. These were synthesized to make a complementary copy of a specific mRNA, which was then amplified by PCR.

www.konkur.in

RESEARCH METHOD

Why Is It Used?

DNA microarray analysis indicates gene expression levels of hundreds or even thousands of specific genes in different cell types. This technique helps scientists understand which genes are active (or inactive) in untreated (control) cells as well as in cells treated with a specific drug.

How Is It Done?

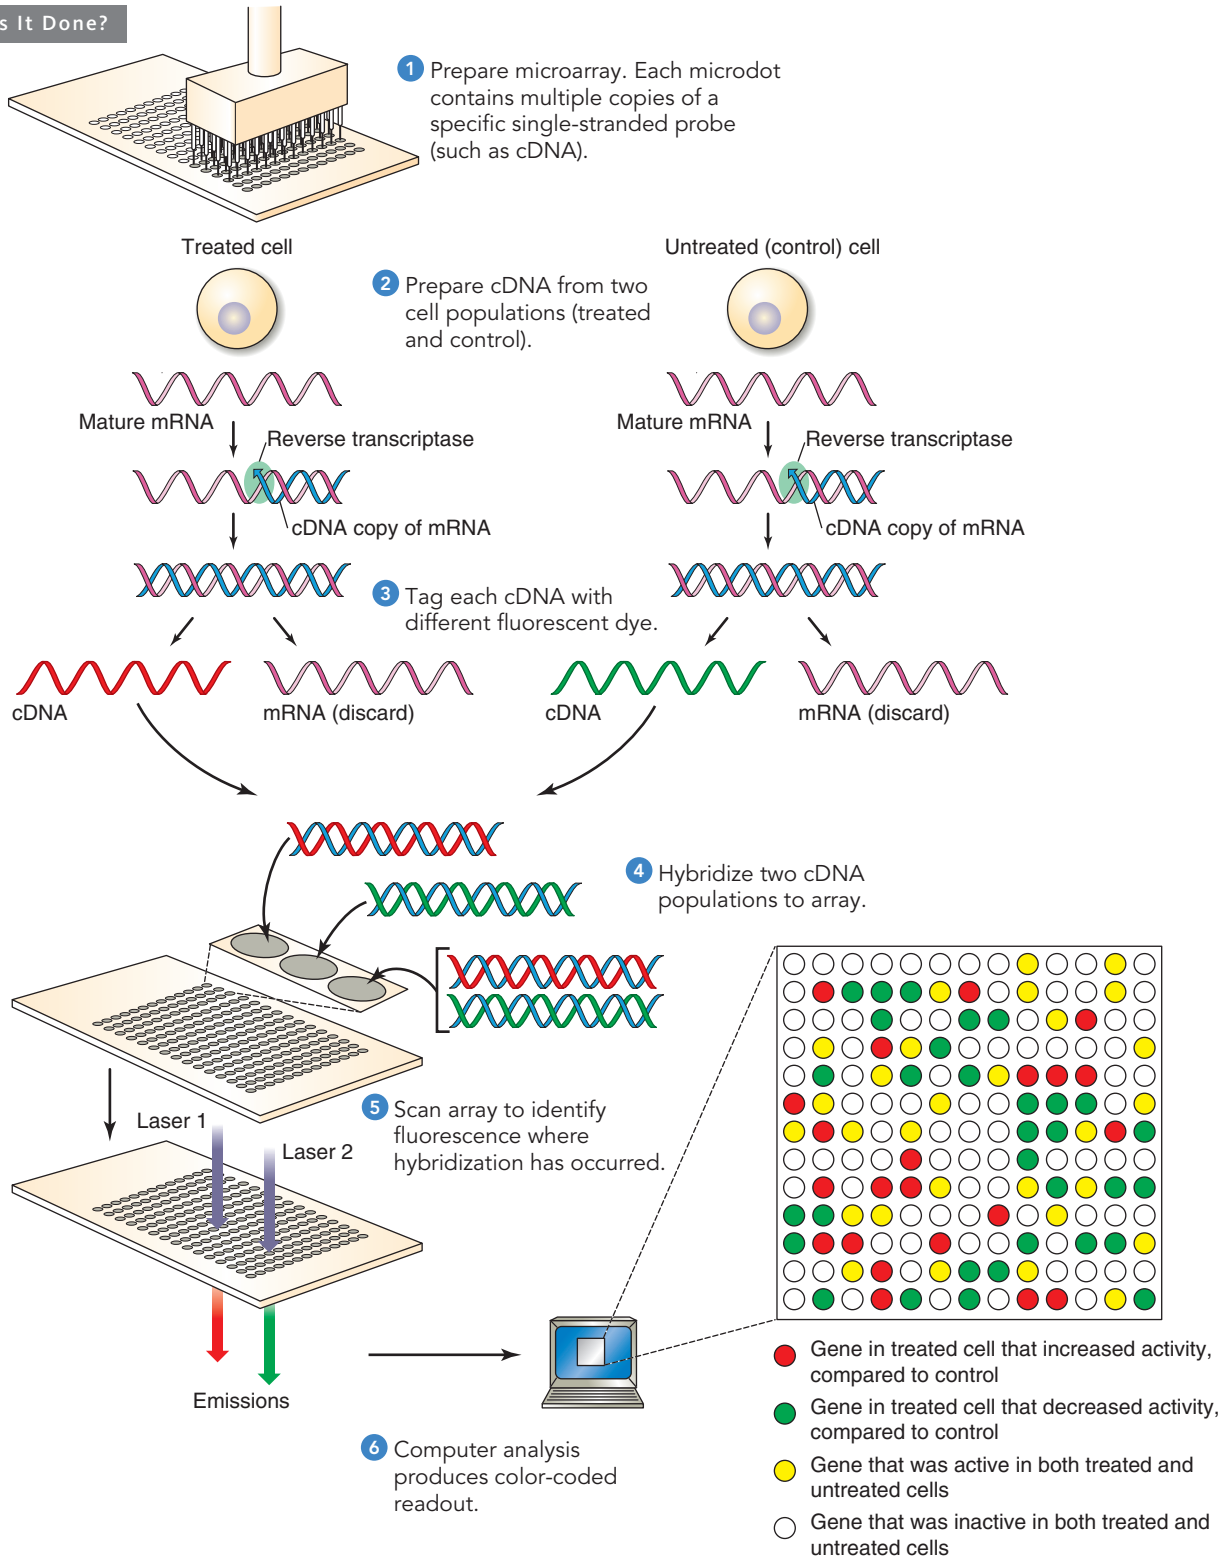

FIGURE 15-12 DNA microarray analysis

www.konkur.in

Researchers then isolate mature mRNA molecules from two cell populations—for example, liver cells treated with a newly developed drug and control liver cells not treated with the drug. Liver cells are often tested because the liver produces many enzymes that metabolize foreign molecules, including drug molecules. Drugs the liver cannot metabolize, or metabolizes weakly, may be too toxic to be used.

Researchers use the isolated mRNA molecules to prepare cDNA molecules for each cell population, which are then tagged with different-colored fluorescent dyes. For example, the treated cells' cDNA molecules might be labeled with red dye and the untreated cells' cDNA molecules with green dye. Then researchers add the two cDNA populations to the array, and some of the cDNA subsequently hybridizes (forms base pairs with) the cDNA on the array.

After washing it to remove any cDNA that has not hybridized to the array, investigators scan the array with lasers to identify red and green fluorescence where hybridization has occurred. Computer analysis of the ratio of red to green fluorescence at each spot in the array produces a color-coded readout that researchers can further analyze. For example, a medical researcher might compare the overall pattern of gene activity in cells treated with an experimental drug with that of cells exposed to known drugs and toxins. If the pattern of gene activity for the treated cells matches that of cells treated with a toxin that damages the liver, the drug will probably not go into clinical trials.

DNA microarrays enable researchers to compare the activities of thousands of genes in cell types from various tissue samples and in normal and diseased cells. Because cancer and other diseases exhibit altered patterns of gene expression, DNA microarrays have the potential to identify disease-causing genes or the proteins they code for, which can then be targeted by therapeutic drugs.

Here's an example of the application. Diffuse large B-cell lymphoma is a cancer of white blood cells that has different subtypes. In 2002, researchers used microarrays to identify 17 genes that are active in various combinations for each subtype. Using DNA microarrays, researchers determined which combination of those 17 genes is active in each subtype of this form of cancer. Armed with the knowledge of which cancer subtype a patient has, physicians can choose the treatment that will probably be most effective for that patient. Examining patterns of gene activity with DNA microarrays also helps medical scientists identify which patients will probably remain free of cancer after treatment and which will probably relapse.

The Human Genome Project stimulated studies of genome sequencing for other species

To aid in analyzing the human genome, investigators carried out comparative genomics by sequencing and mapping studies simultaneously on the mouse and rat genomes. Mice and rats were obvious choices for DNA sequencing because they have been studied for almost a century and much is known about their biology. Mice and rats are sufficiently different from humans that any conserved (that is, identical) sequences found in both rodents and humans are probably functionally important.

In addition, mice are similar enough to humans that both share many physiological traits, including some of the same diseases. To demonstrate the shared similarity between the mouse and human genomes, a consortium of scientists published a study in 2002 that compared the mouse chromosome 16 with the human genome. Only 14 of the 731 known genes on the mouse chromosome had no human counterpart; the remaining 717 genes appeared in one form or another in the human genome.

Comparison of the DNA sequences and chromosome organization of related genes from different species is a powerful tool for identifying the elements essential for their functions. If a human gene has an unknown function, researchers can often deduce clues about its role by studying the equivalent gene in another species, such as a mouse or rat.

Investigators have also sequenced the genomes of other model vertebrate organisms, such as the zebrafish and pufferfish. Biologists have used the zebrafish for many years as a model of vertebrate development because its embryonic stages are transparent and therefore convenient to examine. The pufferfish has the smallest known genome of all vertebrates. By comparing the human genome to that of the pufferfish, researchers have identified shared sequences that have not changed in several hundred million years. Because these sequences have resisted the selective forces of evolution, they may be genes or regulatory elements that direct vertebrate development and are essential in all vertebrates.

Genome analysis of commercially important organisms, such as salmon, chickens, pigs, and rice, is also a priority. For example, scientists have published the rice genome, the genome of the parasite that causes malaria, and the genome of the parasite that causes African sleeping sickness.

One of the most significant genome-sequencing efforts from an evolutionary perspective focuses on nonhuman primates, such as the chimpanzee (whose sequence data were published in 2005). Comparing the DNA sequences of humans and our closest living relatives is helping biologists understand the genetic changes that occurred during human evolution, including which genes govern mental and linguistic capabilities.

Several scientific fields—bioinformatics, pharmacogenetics, and proteomics—have emerged

We have already mentioned that the amount of genomic data now available requires that it be evaluated using powerful computers. The discipline known as **bioinformatics,** or *biological computing*, includes the storage, retrieval, and comparison of nucleotide or amino acid sequences within a given species and among different species. Bioinformatics uses powerful computers and sophisticated software to store, manage, and analyze large amounts of data generated by sequencing and other technologies. For example, as researchers determine new DNA sequences, automated computer programs scan the sequences for patterns typically found in genes. Through comparison of the databases of DNA sequences from different organisms, bioinformatics has already led to insights about gene identification, gene function, and evolutionary relationships.

The new science of gene-based medicine known as **pharmacogenetics** studies how genetic variation among patients affects the action of drugs in individuals. The goal of pharmacogenetics is to customize drugs to match an individual's genetic makeup. Currently, a physician does not know in advance whether a particular medication will benefit a patient or cause severe side effects. An individual's genes, especially those that code for drug-metabolizing

www.konkur.in

enzymes, largely determine that person's response to a specific drug. Pharmacogenetics takes into account the subtle genetic differences among individuals. In as few as 5 to 10 years, patients may take routine genetic screening tests before a physician prescribes a drug.

Pharmacogenetics, like other fields in human genetics, presents difficult ethical questions. The genetic testing that will become an everyday part of pharmacogenetics raises issues of privacy, genetic bias, and potential discrimination. We consider these issues in Chapter 16. Individualized genetic testing may cause people to worry unnecessarily about a genetic disease for which they may never develop symptoms. Most common diseases result from a complex interplay between multiple genes and nongenetic, or environmental, factors. (Recall from Chapter 11 that the environment is an important factor influencing gene expression.) In humans, healthy environmental factors include proper diet, adequate exercise, and not smoking.

The study of all the proteins expressed by a cell at a given time is known as **proteomics.** For example, scientists have identified all the proteins made by a given kind of cell, but the process is much more complicated than sequencing the human genome. Some genes, for example, encode several different proteins. (See Figure 14-14 for an example of alternative splicing.) Also, every somatic cell in the human body has essentially the same genome, but cells in different tissues vary greatly in the kinds of proteins they produce (recall the earlier discussion of DNA microarrays). Protein expression patterns vary not only in different tissues but also at different stages in the development of a single cell.

Scientists want to understand the role of each protein in a cell, the way the various proteins interact, the 3-D structure for each protein, how proteins are spatially arranged within the cell's cytosol and organelles, and protein profiles in diseased cells. While advancing biological knowledge, these goals also promise advances in medicine. If they know the shape of a protein associated with a type of cancer or other disease, scientists may be able to develop drugs that bind to active sites on that protein, turning its activity off. Today, the pharmaceutical industry has drugs that target about 500 proteins in the cell. However, researchers estimate proteomics may yield 10,000 to 20,000 additional protein targets.

- What is a DNA microarray?
- What is pharmacogenetics? proteomics?

15.4 APPLICATIONS OF DNA TECHNOLOGIES

LEARNING OBJECTIVE

10 Describe at least one important application of recombinant DNA technology in each of the following fields: medicine, DNA fingerprinting, and transgenic organisms.

Recombinant DNA technology has provided both a new and unique set of tools for examining fundamental questions about cells and new approaches to applied problems in many other fields. In some areas, the production of genetically modified proteins and organisms has begun to have considerable impact on our lives. The most striking of these has been in medicine.

DNA technology has revolutionized medicine

In increasing numbers of cases, doctors perform **genetic tests** to determine whether an individual has a particular genetic mutation associated with such disorders as Huntington's disease, hemophilia, cystic fibrosis, Tay-Sachs disease, breast cancer, and sickle cell anemia. **Gene therapy,** the use of specific DNA to treat a genetic disease by correcting the genetic problem, is another application of DNA technology that is currently in its infancy. Because genetic testing and gene therapy focus almost exclusively on humans, these applications of DNA technology are discussed in Chapter 16. We focus our discussion here on the use of DNA technology to produce medical products.

Human *insulin* produced by *E. coli* became one of the first genetically modified proteins approved for use by humans. Before the use of recombinant DNA techniques to generate genetically altered bacteria capable of producing the human hormone, insulin was derived exclusively from other animals. Many diabetic patients become allergic to the insulin from animal sources because its amino acid sequence differs slightly from that of human insulin. The ability to produce the human hormone by recombinant DNA methods has resulted in significant medical benefits to insulin-dependent diabetics.

Genetically modified human *growth hormone (GH)* is available to children who need it to overcome growth deficiencies, specifically pituitary dwarfism (see Chapter 49). In the past, human GH was obtainable only from cadavers. Only small amounts were available, and evidence suggested that some of the preparations from human cadavers were contaminated with infectious agents similar to those that cause bovine spongiform encephalopathy, or mad cow disease (discussed in Chapter 24).

The list of products produced by molecular modification is continually growing. For example, *tissue plasminogen activator (TPA),* a protein that prevents or dissolves blood clots, is used to treat cardiovascular disease. If administered shortly after a heart attack, TPA reduces the risk of a subsequent attack. *Tissue growth factor-beta (TGF-β)* promotes the growth of blood vessels and skin, and is used in wound and burn healing. Researchers also use TGF-β in tissue engineering, a developing technology to meet the pressing need for human tissues and, eventually, organs for transplantation by growing them from cell cultures.

The U.S. Food and Drug Administration (FDA) has approved tissue-engineered skin grafts for individuals who have been badly burned, and tissue-engineered cartilage is used for joint repairs. Researchers are investigating the development and use of cardiac cells from ES cells; these cells could be used to repair the heart following heart attacks. Work is also being done on building organs such as bladders and hearts.

Hemophilia A is treated with *human clotting factor VIII.* Before the development of recombinant DNA techniques, factor VIII was available only from human or animal-derived blood, which posed a risk of transmitting infectious agents, such as HIV. *Dornase Alpha (DNase)* improves respiratory function (it helps to liquefy and thin sticky mucus) in people with cystic fibrosis.

www.konkur.in

Recombinant DNA technology is increasingly used to produce vaccines that provide safe and effective immunity against infectious diseases in humans and animals. One way to develop a recombinant vaccine is to clone a gene for a surface protein produced by the disease-causing agent, or pathogen; the researcher then introduces the gene into a nondisease-causing vector. The vaccine, when delivered into the human or animal host, stimulates an immune response to the surface-exposed protein. As a result, if the pathogen carrying that specific surface protein is encountered, the immune system targets it for destruction. Human examples of antiviral recombinant vaccines include vaccines for influenza A, hepatitis B, and polio.

Recombinant vaccines are also being developed against certain bacterial diseases and human cancers. For example, in 2006 the Food and Drug Administration approved a recombinant vaccine against several types of human papillomavirus (HPV). The vaccine, which is administered to females ages 9 to 26, protects against the 70% of cervical cancers caused by HPV.

DNA fingerprinting has numerous applications

The analysis of DNA fragments extracted from an individual, which is unique to that individual, is known as **DNA fingerprinting.** DNA fingerprinting has many applications in humans and other organisms, as in the following examples:

1. Analyzing evidence found at crime scenes (forensic analysis) (**FIG. 15-13**)
2. Identifying mass disaster victims
3. Proving parentage in dogs for pedigree registration purposes
4. Identifying human cancer cell lines
5. Studying endangered species in conservation biology
6. Tracking tainted foods
7. Studying the genetic ancestry of human populations
8. Clarifying disputed parentage
9. Exonerating prisoners wrongfully convicted of a crime

Historically, DNA fingerprinting relied on RFLPs (discussed earlier). Today, many techniques for DNA fingerprinting rely on PCR amplification, restriction enzyme digestion, and Southern blot hybridization to detect molecular markers. The most useful molecular markers are highly polymorphic within the human population (recall our earlier discussion of *polymorphism*). **Short tandem repeats (STRs)** are molecular markers that are short sequences of repetitive DNA—up to 200 nucleotide bases with a simple repeat pattern such as GTGTGTGTGT or CAGCAGCAGCAG. Because they vary in length from one individual to another, STRs are highly polymorphic. This characteristic makes them useful with a high degree of certainty in identifying individuals.

If enough markers are compared, the odds that two people taken at random from the general population would have identical DNA profiles may be as low as one in several billion. The FBI uses a set of STRs from 13 different markers to establish a unique DNA profile for an individual. Such a profile distinguishes that person from every other individual in the United States, except an identical twin.

Recall that DNA is also found in the cell's mitochondria. Whereas nuclear DNA occurs in two copies per cell—one on each of the homologous chromosomes—mitochondrial DNA has as many as 100,000 copies per cell. Therefore, mitochondrial DNA is the molecule of choice for DNA fingerprinting in which biological samples have been damaged—identifying exhumed human remains, for example.

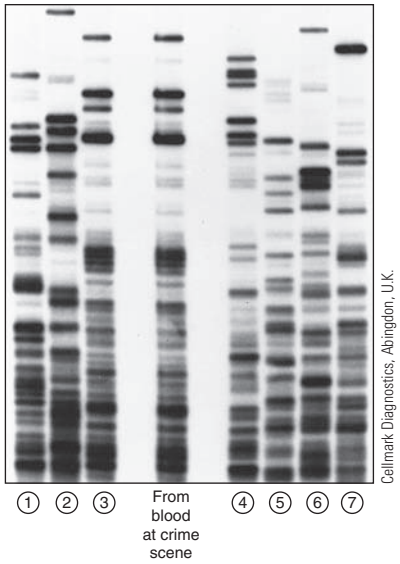

FIGURE 15-13 ***Animated*** **DNA fingerprinting**
These DNA fingerprints show DNA from a crime scene (*in middle*), along with the DNA profiles of seven suspects. Can you pick the suspect whose DNA profile matches blood from the crime scene?

DNA fingerprinting has revolutionized law enforcement. In 1990, the FBI established the Combined DNA Index System (CODIS), consisting of DNA databases from all 50 states. A DNA profile of an unknown suspect can be compared to millions of DNA profiles of convicted offenders in the database, often resulting in identification of the suspect. The DNA from the unknown suspect may come from blood, semen, bones, teeth, hair, saliva, urine, or feces left at the crime scene. Tiny amounts of human DNA have even been extracted from cigarette butts, licked envelopes or postage stamps, dandruff, fingerprints, razor blades, chewing gum, wristwatches, earwax, debris from under fingernails, and toothbrushes.

If applied properly, DNA fingerprinting has the power to identify the guilty and exonerate the innocent. Hundreds of convicted individuals have won new trials and have been subsequently released from incarceration based on correlating DNA profiles with physical evidence from the crime scene. One limitation arises from the fact that the DNA samples are usually small and may have been degraded. Obviously, great care must be taken to prevent contamination of the samples. This is especially crucial if the PCR technique is used to amplify DNA.

Transgenic organisms have foreign DNA incorporated into their cells

Plants and animals in which foreign genes have been incorporated are called **transgenic organisms.** Researchers use varied approaches to insert foreign genes into plant or animal cells. They often use viruses as vectors, although other methods, such as the direct injection of DNA into cells, have also been applied.

www.konkur.in

Transgenic animals are valuable in research

Transgenic animals are usually produced by injecting the DNA of a particular gene into the nucleus of a fertilized egg cell or of ES cells. The researcher then implants the eggs into the uterus of a female and lets them develop. Alternatively, the researcher injects genetically modified ES cells into isolated *blastocysts,* an early stage in embryonic development, and then implants them into a foster mother.

Injecting DNA into cells is not the only way to produce transgenic animals. Researchers may use viruses as recombinant DNA vectors. RNA viruses called **retroviruses** make DNA copies of themselves by reverse transcription. Sometimes the DNA copies become integrated into the host chromosomes, where they are replicated along with host DNA.

Transgenic animals provide valuable applications over a wide range of research areas, such as regulation of gene expression, immune system function, genetic diseases, viral diseases, and genes involved in the development of cancer. The laboratory mouse is a particularly important model organism for these studies.

In a classic study of the control of gene expression, University of Pennsylvania geneticist Ralph L. Brinster in 1983 produced transgenic mice carrying a gene for rat growth hormone (see Fig. 17-18). Brinster and his coworkers wanted to understand the controls that let certain genes be expressed in some tissues and not in others. The pituitary gland of a mouse normally produces small amounts of GH, and these researchers reasoned that other tissues might also be capable of producing the hormone. First they isolated the GH gene from a library of genomic rat DNA. They combined it with the promoter region of a mouse gene that normally produces metallothionein, a protein that is active in the liver and whose synthesis is stimulated by the presence of toxic amounts of heavy metals such as zinc. The researchers used metallothionein regulatory sequences as a switch to turn the production of rat GH on and off at will. After injecting the modified gene into mouse embryo cells, they implanted the embryos into the uterus of a mouse and let them develop.

Because of the difficulty in manipulating the embryos without damaging them, the gene transplant succeeded in only a small percentage of the animals. When exposed to small amounts of zinc, these transgenic mice produced large amounts of growth hormone because the liver is a much larger organ than the pituitary gland. The mice grew rapidly, and one mouse, which developed from an embryo that had received two copies of the GH gene, grew to more than double the normal size (**FIG. 15-14**). As might be expected, such mice often transmit their increased growth capability to their offspring.

Transgenic animals can produce genetically modified proteins

Certain transgenic animal strains produce milk containing foreign proteins of therapeutic or commercial importance. For example, researchers have introduced into sheep the gene for the human protein tissue plasminogen activator (TPA). Producing transgenic livestock (such as pigs, sheep, cows, and goats) that secrete foreign proteins in their milk is known informally as "pharming," a combination of "pharmaceuticals" and "farming" (**FIG. 15-15**).

In pharming, recombinant genes are fused to the regulatory sequences of the milk protein genes, and such genes are therefore activated only in mammary tissues involved in milk production. The advantages of obtaining a protein drug from milk are that

R. L. Brinster, University of Pennsylvania Medical School

FIGURE 15-14 A transgenic mouse

The mouse on the right is normal, whereas the mouse on the left is a transgenic animal that expresses rat growth hormone in large amounts.

FIGURE 15-15 Transgenic "pharm" cows

These cows contain a human gene that codes for lactoferrin, a protein found in human mothers' milk and in secretions such as tears, saliva, bile, and pancreatic fluids. Lactoferrin is one of the immune system's lines of defense against disease-causing organisms. The cows secrete human lactoferrin in their milk.

www.konkur.in

potentially it can be produced in large quantities and that it can be harvested simply by milking the animal. The protein is then purified from the milk. The introduction of the gene does not harm the animals, and because the offspring of the transgenic animal usually produce the recombinant protein, transgenic strains are established.

Transgenic plants are increasingly important in agriculture

People have selectively bred plants for thousands of years. The success of such efforts depends on desirable traits in the variety of plant selected or in closely related wild or domesticated plants whose traits are transferred by crossbreeding. Local varieties or closely related species of cultivated plants often have traits, such as disease resistance, that agriculturalists could advantageously introduce into varieties more useful to modern human needs. If genes are introduced into plants from strains or species with which they do not ordinarily interbreed, the possibilities for improvement increase greatly.

The most widely used vector system for introducing recombinant genes into many types of plant cells is the crown gall bacterium, *Agrobacterium tumefaciens.* This bacterium normally produces plant tumors by introducing a plasmid, called the *Ti plasmid,* into the cells of its host; *Ti* stands for "tumor-inducing." The Ti plasmid induces abnormal growth by forcing the plant cells to produce elevated levels of a plant growth hormone called *cytokinin* (discussed in Chapter 38).

Geneticists "disarm" the Ti plasmid so that it does not induce tumor formation and then use it as a vector to insert genes into plant cells. The cells into which the altered plasmid is introduced are essentially normal except for the inserted genes. Genes placed in the plant genome in this fashion may be transmitted sexually, via seeds, to the next generation, but they can also be propagated asexually, for example, by taking cuttings.

Unfortunately, not all plants take up DNA readily, particularly the cereal grains that are a major food source for humans. One useful approach has been the development of a genetic "shotgun." Researchers coat microscopic gold or tungsten fragments with DNA and then shoot them into plant cells, penetrating the cell walls. Some of the cells retain the DNA, which transforms them. Those cells can then be cultured and used to regenerate an entire plant (see Fig. 17-2). Geneticists have successfully used such an approach to transfer a gene for resistance to a bacterial disease into cultivated rice from one of its wild relatives.

An additional complication of plant genetic modification is that about 120 plant genes lie in the DNA of the chloroplasts; the other 3000 or so genes that plants require to function are in the nucleus. Chloroplasts are essential in photosynthesis, which is the basis for plant productivity. Because great agricultural potential hinges on improving the productivity of photosynthesis, developing methods for changing the part of the plant's DNA within the chloroplast is desirable. Dozens of labs are currently studying methods of chloroplast engineering, although progress has been slow. In 2001, Australian plant physiologists reported that they had altered **rubisco,** the key carbon-fixing enzyme of photosynthesis (see Chapter 9), by changing one of the genes in the chloroplast genome.

The United States is the world's top producer of transgenic crops, also known as **genetically modified (GM) crops.** In 2007, U.S. farmers planted 57.7 hectares (143 million acres) of GM crops. Globally, 51% of the soybean crop, 31% of corn, 13% of cotton, and 5% of canola are GM crops.

Selected Applications of Transgenic Plants Agricultural geneticists are developing GM plants that are resistant to insect pests, viral and fungal diseases, heat, cold, herbicides, salty or acidic soil, and drought. For example, genetically modified papaya trees, which are resistant to the ringspot virus, have been grown in Hawaii for more than 10 years. A variety of corn that has been genetically modified to be resistant to drought is currently being tested in field trials (**FIG. 15-16**).

Courtesy of the Monsanto Corporation

(a) Note the poor yield in genetically unmodified corn plants used as a control.

(b) Genetically modified corn plants withstood drought better than the unmodified corn.

FIGURE 15-16 ***Animated*** **Field test of transgenic corn with resistance to drought**

www.konkur.in

Corn has also been genetically modified to contain the *Bt* gene, a bacterial gene that codes for a protein with insecticidal properties; *Bt* stands for the bacterium's scientific name, *Bacillus thuringiensis*. *Bt* corn, introduced in the United States in 1996, does not need periodic sprays of chemical insecticides to control the European corn borer, the most damaging insect pest of corn in the United States and Canada.

DNA technology also has the potential to develop crops that are more nutritious. For example, in the 1990s geneticists modified rice to produce high quantities of β-carotene, which the human body uses to make vitamin A. In developing countries, vitamin A deficiency is a leading cause of irreversible blindness in children. Vitamin A deficiency also makes children more susceptible to measles and other infectious diseases. Because rice is the staple diet in many countries with vitamin A deficiency, the widespread use of GM rice with β-carotene could help prevent blindness in many of the world's children. However, GM rice is not yet approved for human consumption.

Like some transgenic animals, certain transgenic plants can potentially be "pharmed" to produce large quantities of medically important proteins. Examples include antibodies against the herpes virus and a patient-specific vaccine for lymphoma, a type of cancer.

Some people are concerned about the health effects of consuming foods derived from GM crops and think that such foods should be restricted. For example, critics say that some consumers may develop food allergies. Scientists also recognize this concern and routinely screen new GM crops for allergenicity. There is also an ongoing controversy as to whether GM foods should be labeled. The FDA and most scientists think such labeling would be counterproductive because it would increase public anxiety over a technology that is as safe as traditional breeding methods. In 1996, the U.S. Court of Appeals upheld the FDA position that labeling should not be required.

Review

- In what way has the production of human insulin by recombinant DNA methods had significant medical advantages for diabetics?
- What are short tandem repeats (STRs), and why are they so useful in DNA fingerprinting?
- Why do gene targeting and mutagenesis screening in mice have potential benefits for humans?

15.5 DNA TECHNOLOGY HAS RAISED SAFETY CONCERNS

LEARNING OBJECTIVE

11 Describe at least two safety issues associated with recombinant DNA technology and explain how these issues are being addressed.

When recombinant DNA technology was introduced in the early 1970s, many scientists considered the potential misuses at least as significant as the possible benefits. The possibility that an organism with undesirable environmental effects might be accidentally produced was of great concern. Scientists feared that new strains of bacteria or other organisms, with which the world has no previous experience, might be difficult to control. The scientists who developed the recombinant DNA methods insisted on stringent guidelines for making the new technology safe.

Experiments in thousands of university and industry laboratories over more than 35 years have shown that recombinant DNA manipulations can be carried out safely. Geneticists have produced strains of *E. coli* that cannot survive outside of the laboratory. Researchers carry out experiments that might present unusual risks in facilities designed to hold pathogenic organisms; this precaution ensures that researchers can work with them safely. So far, no evidence suggests that researchers have accidentally cloned hazardous genes or have released dangerous organisms into the environment. However, malicious *intentional* manipulation of dangerous genes certainly remains a concern.

As the safety of the experiments has been established, scientists have relaxed many of the restrictive guidelines for using recombinant DNA. Stringent restrictions still exist, however, in certain areas of recombinant DNA research where there are known dangers or where questions about possible effects on the environment are still unanswered.

These restrictions are most evident in research that proposes to introduce transgenic organisms into the wild, such as agricultural strains of plants whose seeds or pollen might spread in an uncontrolled manner. A great deal of research now focuses on determining the effects of introducing transgenic organisms into a natural environment. Carefully conducted tests have shown that transgenic organisms are not dangerous to the environment simply because they are transgenic.

It is, however, important to assess the risks of each new recombinant organism. Scientists determine whether the organism has characteristics that might cause it to be environmentally hazardous under certain conditions. For example, if geneticists have modified a transgenic crop plant to resist an herbicide, could that gene be transferred, via pollen or some other route, to that plant's weedy relatives, generating herbicide-resistant "superweeds"? In 2003, ecologists at the University of Tennessee, Knoxville, announced the crossing of transgenic oilseed rape plants that contained the *Bt* gene with their wild relative, which is a weed. They crossed the resulting hybrids with the wild relative again and then tested its ability to compete with other weeds in a field of wheat. The transgenic weed was a poor competitor and had less effect on wheat production than its wild relatives in a control field. These results, although encouraging, must be interpreted with care. Scientists must evaluate each transgenic crop plant individually to see if there is gene flow to wild relatives, and if so, what effects might result.

Other concerns relate to plants modified to produce pesticides, such as the *Bt* toxin. The future of the *Bt* toxin in transgenic crops is not secure because low levels of the insecticide could potentially provide ideal conditions for selection for resistant individuals in the insect population. It appears certain insects may evolve genetic resistance to the *Bt* toxin in transgenic plants in the same way they evolve genetic resistance to chemical insecticides.

Another concern is that nonpest species could be harmed. For example, people paid a great deal of attention to the finding that monarch butterfly larvae raised in the laboratory are harmed if they are fed pollen from *Bt* corn plants. However, more recent

www.konkur.in

studies suggest that monarch larvae living in a natural environment do not consume enough pollen to cause damage. Also, evidence indicates that the harm to nonpest species from spraying pesticides is far greater than any harm from transgenic crops.

Environmental concerns about transgenic animals also exist. Several countries are in the process of developing fast-growing transgenic fish, usually by inserting a gene that codes for a growth hormone. Transgenic Atlantic salmon, for example, grow up to six times as fast as nontransgenic salmon grown for human consumption. The transgenic fish do not grow larger than other fish, just faster. The benefits of such genetically enhanced fish include reduced pressure on wild fisheries and less pollution from fish farms. However, if the transgenic fish escaped from the fish farm, what effect would they have on wild relatives? To address this concern, the researchers are developing only nonreproducing female transgenic salmon.

To summarize, DNA technology in agriculture offers many potential benefits, including higher yields by providing disease resistance, more nutritious foods, and the reduced use of chemical pesticides. However, like other kinds of technology, molecular modification poses some risks, such as the risk that genetically modified plants and animals could pass their foreign genes to wild relatives, causing unknown environmental problems. The science of **risk assessment,** which uses statistical methods to quantify risks so they can be compared and contrasted, will help society decide whether to ignore, reduce, or eliminate specific risks of molecularly modified organisms.

Review

- What are some of the environmental concerns regarding transgenic organisms? What kinds of information does society need to determine if these concerns are valid?

SUMMARY: FOCUS ON LEARNING OBJECTIVES

15.1 *(page 324)*

1 Explain how a typical restriction enzyme cuts DNA molecules and give examples of the ways in which these enzymes are used in recombinant DNA technology.

- **Recombinant DNA technology** isolates and amplifies specific sequences of DNA by incorporating them into **vector** DNA molecules. Researchers then **clone**—propagate and amplify—the resulting recombinant DNA in organisms such as *E. coli.*
- Researchers use **restriction enzymes** to cut DNA into specific fragments. Each type of restriction enzyme recognizes and cuts DNA at a highly specific base sequence. Many restriction enzymes cleave DNA sequences to produce complementary, single-stranded sticky ends.

CENGAGENOW™ Learn more about restriction enzymes by clicking on the figure in CengageNOW.

- Geneticists often construct recombinant DNA molecules by allowing the ends of a DNA fragment and a vector, both cut with the same restriction enzyme, to associate by complementary base pairing. Then **DNA ligase** covalently links the DNA strands to form a stable recombinant molecule.

CENGAGENOW™ Learn more about the formation of recombinant DNA by clicking on the figure in CengageNOW.

2 Distinguish among a genomic DNA library, a chromosome library, and a complementary DNA (cDNA) library; explain why one would clone the same eukaryotic gene from both a genomic DNA library and a cDNA library.

- A **genomic DNA library** contains thousands of DNA fragments that represent the total DNA of an organism. A **chromosome library** contains all the DNA fragments from a specific chromosome. Each DNA fragment of a genomic DNA or chromosome library is stored in a specific bacterial strain.
- A **cDNA library** is produced using **reverse transcriptase** to make DNA copies of mature mRNA isolated from eukaryotic cells. These copies, known as **complementary DNA (cDNA),** are then incorporated into recombinant DNA vectors.

CENGAGENOW™ Learn more about the formation of cDNA by clicking on the figure in CengageNOW.

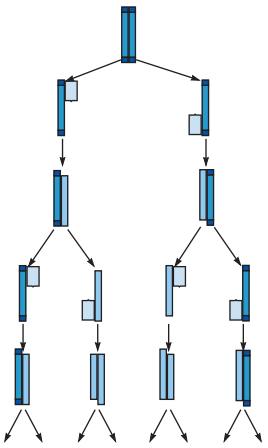
- Genes present in genomic DNA and chromosome libraries from eukaryotes contain **introns,** regions that do not code for protein. Those genes can be amplified in bacteria, but the protein is not properly expressed. Because introns have been removed from mature mRNA molecules, eukaryotic genes in cDNA libraries can be expressed in bacteria to produce functional protein products.

3 Explain how researchers use a DNA probe.

- Researchers use a radioactive DNA sequence as a **DNA probe** to screen thousands of recombinant DNA molecules in bacterial cells to find the colony that contains the DNA of interest.

CENGAGENOW™ Watch the process for using a DNA probe to find bacterial cells with a specific recombinant DNA molecule by clicking on the figure in CengageNOW.

4 Describe how the polymerase chain reaction amplifies DNA in vitro.



- The **polymerase chain reaction (PCR)** is a widely used, automated, in vitro technique in which researchers use specific primers to target a particular DNA sequence and then clone it using a heat-resistant DNA polymerase.
- Using PCR, scientists amplify and analyze tiny DNA samples taken from various sites, from crime scenes to archaeological remains.

CENGAGENOW™ Watch the amplification of DNA by PCR by clicking on the figure in CengageNOW.

www.konkur.in

15.2 *(page 331)*

5 Distinguish among DNA, RNA, and protein blotting.

- A **Southern blot** detects DNA fragments by separating them using gel electrophoresis and then transferring them to a nitrocellulose or nylon membrane. A probe is then **hybridized** by complementary base pairing to the DNA bound to the membrane, and the band or bands of DNA are identified by autoradiography or chemical luminescence.
- When RNA molecules that are separated by electrophoresis are transferred to a membrane, the result is a **Northern blot.**
- A **Western blot** consists of proteins or polypeptides previously separated by gel electrophoresis.

6 Describe the chain termination method of DNA sequencing.

- **DNA sequencing** yields information about the structure of a gene and the probable amino acid sequence of its encoded proteins.
- Automated DNA sequencing is based on the **chain termination method,** which uses dideoxynucleotides, each tagged with a different-colored fluorescent dye, to terminate elongation during DNA replication. Gel electrophoresis separates the resulting fragments, and a laser identifies the nucleotide sequence.

CENGAGENOW™ Learn more about automated DNA sequencing by clicking on the figure in CengageNOW.

15.3 *(page 335)*

7 Describe three important areas of research in genomics.

- **Genomics** is the emerging field of biology that studies the entire DNA sequence of an organism's **genome.** Structural genomics is concerned with mapping and sequencing genomes. Functional genomics deals with the functions of genes and nongene sequences in genomes. Comparative genomics involves comparing the genomes of different species to further our understanding of evolutionary relationships.

8 Explain what a DNA microarray does and give an example of its research and medical potential.

- Many diagnostic tests involve **DNA microarrays,** in which hundreds of different DNA molecules are placed on a glass slide or chip. DNA microarrays enable researchers to compare the activities of thousands of genes in normal and diseased cells from tissue samples. Because cancer and other diseases exhibit altered patterns of gene expression, DNA microarrays have the potential to identify disease-causing genes or the proteins they code for, which can then be targeted by therapeutic drugs.

9 Define *pharmacogenetics* and *proteomics*.

- **Pharmacogenetics,** the new science of gene-based medicine, takes into account the subtle genetic differences among individuals and customizes drugs to match a patient's genetic makeup.
- The study of all the proteins encoded by the human genome and produced in a person's cells and tissues is **proteomics.** Scientists want to identify all the proteins made by a given kind of cell, but the process is much more complicated than sequencing the human genome.

15.4 *(page 339)*

10 Describe at least one important application of recombinant DNA technology in each of the following fields: medicine, DNA fingerprinting, and transgenic organisms.

- Genetically altered bacteria produce many important human protein products, including insulin, growth hormone, tissue plasminogen activator (TPA), tissue growth factor-beta (TGF-β), clotting factor VIII, and Dornase Alpha (DNase).
- **DNA fingerprinting** is the analysis of an individual's DNA. It is based on a variety of **short tandem repeats (STRs),** molecular markers that are highly **polymorphic** within the human population. DNA fingerprinting has applications in areas such as law enforcement, issues of disputed parentage, and tracking tainted foods.

CENGAGENOW™ Solve a murder case with DNA fingerprinting by clicking on the figure in CengageNOW.

- **Transgenic organisms** have foreign DNA incorporated into their genetic material. Transgenic livestock produce foreign proteins in their milk. Transgenic plants have great potential in agriculture.

15.5 *(page 343)*

11 Describe at least two safety issues associated with recombinant DNA technology and explain how these issues are being addressed.

- Some people are concerned about the safety of molecularly modified organisms. To address these concerns, scientists carry out recombinant DNA technology under specific safety guidelines.
- The introduction of transgenic plants and animals into the natural environment, where they may spread in an uncontrolled manner, is an ongoing concern.

TEST YOUR UNDERSTANDING

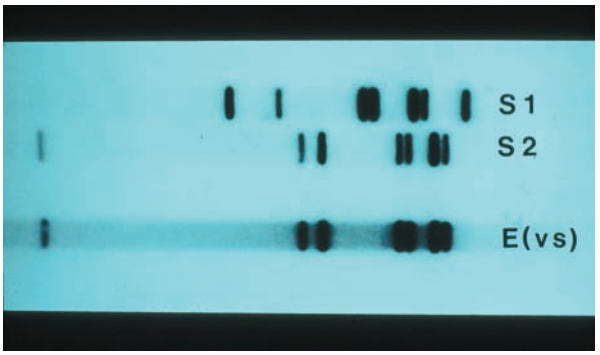
1. A plasmid (a) can be used as a DNA vector (b) is a type of bacteriophage (c) is a type of cDNA (d) is a retrovirus (e) b and c
2. DNA molecules with complementary sticky ends associate by (a) covalent bonds (b) hydrogen bonds (c) ionic bonds (d) disulfide bonds (e) phosphodiester linkages
3. Human DNA and a particular plasmid both have sites that are cut by the restriction enzymes *Hin*dIII and *Eco*RI. To make recombinant DNA, the scientist should (a) cut the plasmid with *Eco*RI and the human DNA with *Hin*dIII (b) use *Eco*RI to cut both the plasmid and the human DNA (c) use *Hin*dIII to cut both the plasmid and the human DNA (d) a or b (e) b or c
4. Which technique rapidly replicates specific DNA fragments without cloning in cells? (a) gel electrophoresis (b) cDNA libraries (c) DNA probe (d) restriction fragment length polymorphism (e) polymerase chain reaction
5. The PCR technique uses (a) heat-resistant DNA polymerase (b) reverse transcriptase (c) DNA ligase (d) restriction enzymes (e) b and c
6. A cDNA clone contains (a) introns (b) exons (c) anticodons (d) a and b (e) b and c
7. The dideoxynucleotides ddATP, ddTTP, ddGTP, and ddCTP are important in DNA sequencing because they (a) cause premature termination of a growing DNA strand (b) are used as primers (c) cause the DNA fragments that contain them to migrate more slowly through a sequencing gel (d) are not affected by high temperatures (e) have more energy than deoxynucleotides
8. In the Southern blot technique, _____ is/are transferred from a gel to a nitrocellulose or nylon membrane. (a) protein (b) RNA (c) DNA (d) bacterial colonies (e) reverse transcriptase

www.konkur.in

9. Gel electrophoresis separates nucleic acids on the basis of differences in (a) length (molecular weight) (b) charge (c) nucleotide sequence (d) relative proportions of adenine and guanine (e) relative proportions of thymine and cytosine
10. A genomic DNA library (a) represents all the DNA in a specific chromosome (b) is made using reverse transcriptase (c) is stored in a collection of recombinant bacteria (d) is a DNA copy of mature mRNAs (e) allows researchers to amplify a tiny sample of DNA
11. Tissue growth factor-beta (a) is a DNA probe for recombinant plasmids (b) is a product of DNA technology used in tissue engineering (c) is necessary to make a cDNA library (d) cannot be synthesized without a heat-resistant DNA polymerase (e) is isolated by the Southern blot technique
12. These highly polymorphic molecular markers are useful in DNA fingerprinting: (a) cosmid cloning vectors (b) cloned DNA sequences (c) palindromic DNA sequences (d) short tandem repeats (e) complementary DNAs

CRITICAL THINKING

1. What are some of the problems that might arise if you were trying to produce a eukaryotic protein in a bacterium? How might using transgenic plants or animals help solve some of these problems?
2. Would molecular modification be possible if we did not know a great deal about the genetics of bacteria? Explain.
3. How is proteomics related to functional genomics?
4. **ANALYZING DATA.** RFLP analysis was performed on blood from a crime scene as well as from two suspects. The crime scene DNA is marked E(vs). Which suspect is probably guilty? Which suspect is definitely innocent?



Leonard Lessin/Peter Arnold, Inc.

5. **EVOLUTION LINK.** DNA technology, such as the production of transgenic animals, is possible only because widely different organisms have essentially identical genetic systems (DNA ⟶ RNA ⟶ protein). What is the evolutionary significance of the universality of genetic systems in organisms as diverse as bacteria and pigs?
6. **SCIENCE, TECHNOLOGY, AND SOCIETY.** What are some ways that recent DNA technologies might affect you personally?

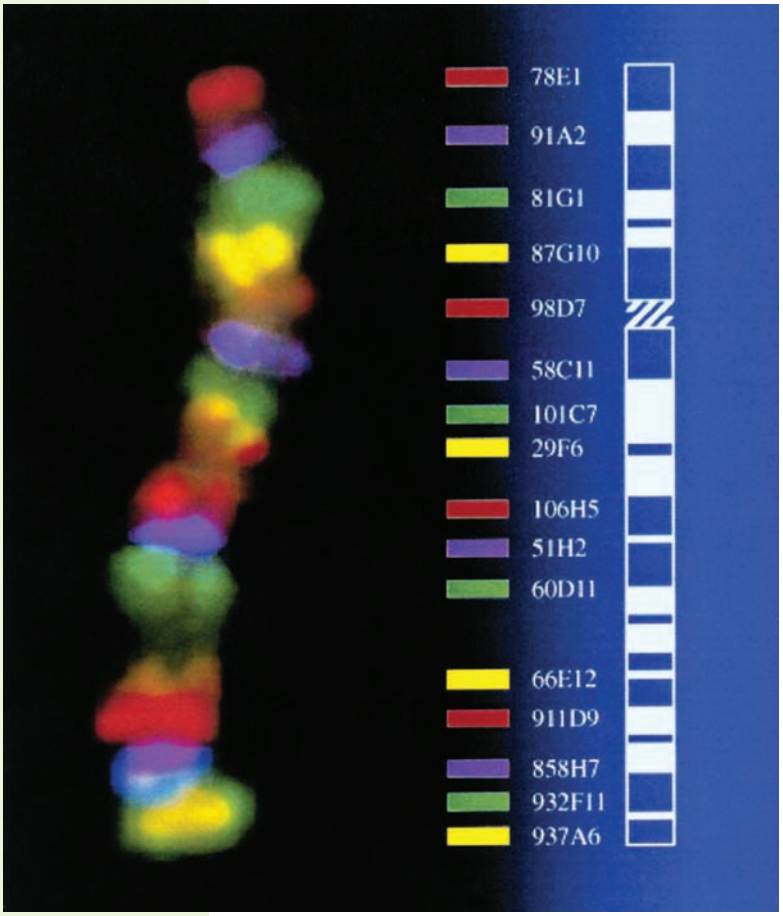
16 Human Genetics and the Human Genome



© Regents of the University of California 2005/Dr. Uli Weier/Photo Researchers, Inc.

Rapid chromosome mapping. This fluorescent LM of human chromosome 10 (*left*) has different-colored fluorescent probes attached to specific DNA sequences. (Loci and key are at *right*.) This technique allows researchers to efficiently determine certain chromosome rearrangements and abnormalities.

KEY CONCEPTS

16.1 Pedigree analysis and karyotype analysis are traditional methods to study human genetics; molecular aspects of the human genome, including genome-wide association scans and comparative genomics, are increasingly used today.

16.2 Chromosome abnormalities such as aneuploidies—the presence or absence of a single chromosome—can cause serious medical conditions.

16.3 Mutations in single genes can produce genetic disorders.

16.4 Researchers are developing gene therapy methods that could potentially correct certain genetic disorders.

16.5 Genetic testing and counseling help individuals make reproductive decisions.

16.6 Certain advances in human genetics raise ethical questions.

The principles of genetics apply to all organisms, including humans. However, important differences separate genetic research on humans and genetic research on other organisms. To study inheritance in other species, geneticists may conduct controlled matings between individuals and raise the offspring under carefully controlled conditions. Of course, setting up experimental matings in humans is unethical and illegal.

An important difference between genetic research in humans and other organisms is that organisms used in genetic research generally produce many offspring and have short generation times between reproductive periods. In contrast, most human families are small, and 20 to 30 years or more elapse between generations.

Despite the inherent difficulties of studying inheritance in humans, **human genetics,** the science of inherited variation in humans, is progressing rapidly (see figure). Researchers conduct population studies of large extended families. Also, the medical attention given to human genetic diseases has expanded our knowledge of human genetics. Genetic studies of other organisms have provided invaluable insights: many

www.konkur.in

human inheritance questions have been explained using model organisms, such as bacteria, yeasts, worms, fruit flies, and mice.

More recently, the **human genome,** which represents the totality of genetic information in human cells, has been mapped and sequenced. In **DNA sequencing,** researchers identify the order of nucleotides in DNA to understand the genetic basis of human similarities and differences.

In this chapter we first examine the methods of human genetics, including new research directions that are developing as a result of the Human Genome Project. Then we discuss a variety of human genetic disorders. We explore the use of gene therapy for some of these disorders, as well as the application of genetic testing, screening, and counseling for families at risk. The chapter concludes with a discussion of ethical issues related to human genetics.

16.1 STUDYING HUMAN GENETICS

LEARNING OBJECTIVES

1 Distinguish between karyotyping and pedigree analysis.
2 Discuss the implications of the Human Genome Project.
3 Discuss the mouse model for studying cystic fibrosis.

Human geneticists use a variety of methods that enable them to help identify genetic defects and to make inferences about a trait's mode of inheritance. We consider three of these methods—the identification of chromosomes by karyotyping, the analysis of family inheritance patterns using pedigrees, and DNA sequencing and mapping of genes by genome projects. Investigators often study human inheritance most effectively by combining these and other approaches.

Human chromosomes are studied by karyotyping

Like Mendel and his pea plants, researchers working with simpler organisms have discovered many of the basic principles of genetics. In such organisms, it is often possible to relate genetic data to the number and structure of specific chromosomes. Some organisms used in genetics, such as the fruit fly *Drosophila melanogaster,* have very few chromosomes; the fruit fly has only four pairs. In *Drosophila* larval salivary glands, the chromosomes are large enough that their structural details are readily evident. (Note the detail shown in the light micrograph of *Drosophila* chromosomes in Figure 2-3.) This organism, therefore, has provided unique opportunities for correlating certain inherited phenotypic changes with alterations in chromosome structure.

The normal number of chromosomes for the human species is 46: 44 **autosomes** (22 pairs) and 2 sex chromosomes (1 pair). A **karyotype** (from Greek, meaning "nucleus") is an individual's chromosome composition, both chromosome number and large structural defects in a chromosome. Until the mid-1950s, when biologists adopted modern methods of karyotyping, the accepted number of chromosomes for the human species was 48, based on a study of human chromosomes published in 1923. The reason researchers counted 48 human chromosomes was the difficulty in separating the chromosomes so they could be accurately counted.

In 1952, University of Texas cell biologist T. C. Hsu treated cells with a hypotonic salt solution by mistake; this caused the cells to swell and the chromosomes to spread apart, thereby making them easier to count. Other techniques were also developed, and in 1956 researchers Joe Hin Tjio and Albert Levan, working in Sweden, reported that humans have 46 chromosomes, not 48. Other researchers subsequently verified this report. The story of the human chromosome number is a valuable example of the "self-correcting" nature of science (although such corrections may take time). The re-evaluation of established facts and ideas, often by using improved techniques or new methods, is an essential part of the scientific process.

Human chromosomes are visible only in dividing cells (see Chapter 10), and it is difficult to obtain dividing cells directly from the human body. Researchers typically use blood because white blood cells can be induced to divide in a culture medium by treating them with certain chemicals. Other sources of dividing cells include skin and, for prenatal chromosome studies, chorionic villi or fetal cells shed into the amniotic fluid (discussed later in the chapter).

In karyotyping, biologists culture dividing human cells and then treat them with the drug *colchicine,* which arrests the cells at mitotic metaphase or late prophase, when the chromosomes are most highly condensed. Next, the researchers put the cells into a hypotonic solution; the cells swell, and the chromosomes spread out so they are easily observed. The investigators then flatten the cells on microscope slides and stain the chromosomes to reveal the patterns of bands, which are unique for each homologous pair. After the microscopic image has been scanned into a computer, the homologous pairs are electronically matched and placed together (**FIG. 16-1**).

By convention, geneticists identify chromosomes by length; position of the centromere; banding patterns, which are produced by staining chromosomes with dyes that produce dark and light crossbands of varying widths; and other features such as *satellites,* tiny knobs of chromosome material at the tips of certain chromosomes. With the exception of the sex chromosomes, all chromosomes but chromosome 21, which is smaller than chromosome 22, are numbered and lined up in order of size. The largest human chromosome (chromosome 1) is about five times as long as the smallest one (chromosome 21), but there are only slight size differences among some of the intermediate-sized chromosomes. The X and Y chromosomes of a normal male are homologous only at their tips; normal females have two X chromosomes and no Y chromosome. Differences from the normal karyotype—that is, deviations in chromosome number or structure—are associated with certain disorders such as Down syndrome (discussed later in the chapter).

Another way to distinguish chromosomes in a karyotype is by **fluorescent in situ hybridization (FISH).** A geneticist tags a DNA strand complementary to DNA in a specific chromosome with a fluorescent dye. The DNA in the chromosome is denatured—that is, the two strands are separated—so the tagged

www.konkur.in

strand can bind to it. A different dye is used for each chromosome, "painting" each with a different color (see karyotype in Fig. 16-1). A chromosome that is multicolored (*not shown*) indicates breakage and fusion of chromosomes, an abnormality associated with certain genetic diseases and many types of cancer.

RESEARCH METHOD

Why Is It Used?

Researchers use karyotypes to screen individuals for chromosome abnormalities.

How Is It Done?

Karyotypes are commonly prepared from cultures of white blood cells. Researchers place prepared cells on a slide, and the chromosomes spill out of the ruptured nuclei. The light microscope under which the slide is viewed is connected to a computer with image analysis software, which helps the biologist match homologous chromosomes and organize them by size. Before computers were used, researchers cut and pasted chromosomes from photographs.

SIU/Peter Arnold, Inc.

These chromosomes have been "painted" by different-colored fluorescent dyes that hybridize to specific pairs of homologous chromosomes. Painting helps the researcher identify chromosomes. A normal human male karyotype is shown.

FIGURE 16-1 Karyotyping

Family pedigrees help identify certain inherited conditions

Early studies of human genetics usually dealt with readily identified pairs of contrasting traits and their distribution among members of a family. A "family tree" that shows inheritance patterns, the transmission of genetic traits within a family over several generations, is known as a **pedigree.** Pedigree analysis remains widely used, even in today's world of powerful molecular genetic techniques, because it helps molecular geneticists determine the exact interrelationships of the DNA molecules they analyze from related individuals. Pedigree analysis is also an important tool of genetic counselors and clinicians. However, because human families tend to be small and information about certain family members, particularly deceased relatives, may not be available, pedigree analysis has limitations.

Pedigrees are produced using standardized symbols. Examine **FIGURE 16-2**, which shows a pedigree for **albinism,** a lack of the pigment melanin in the skin, hair, and eyes. Each horizontal row represents a separate generation, with the earliest generation (Roman numeral I) at the top and the most recent generation at the bottom. Within a given generation, the individuals are usually numbered consecutively, from left to right, using Arabic numerals. A horizontal line connects two parents, and a vertical line drops from the parents to their children. For example, individuals II-3 and II-4 are parents of four offspring (III-1, III-2, III-3, and III-4). Note that individuals in a given generation can be genetically unrelated. For example, II-1, II-2, and II-3 are unrelated to II-4 and II-5. Within a group of siblings, the oldest is on the left, and the youngest is on the right.

The allele for albinism cannot be dominant; if it were, at least one of female III-2's parents would have been an albino. This pedigree is explained if albinism is inherited as an autosomal (not carried on a sex chromosome) recessive allele. In such cases, two phenotypically normal parents could produce an albino offspring because they are heterozygotes and could each transmit a recessive allele.

Studying pedigrees enables human geneticists to predict how phenotypic traits that are governed by the genotype at a single locus are inherited. About 10,000 traits have been described in humans. Pedigree analysis most often identifies three modes of single-locus inheritance: autosomal dominant, autosomal recessive, and X-linked recessive. We define and discuss examples of these inheritance modes later in the chapter.

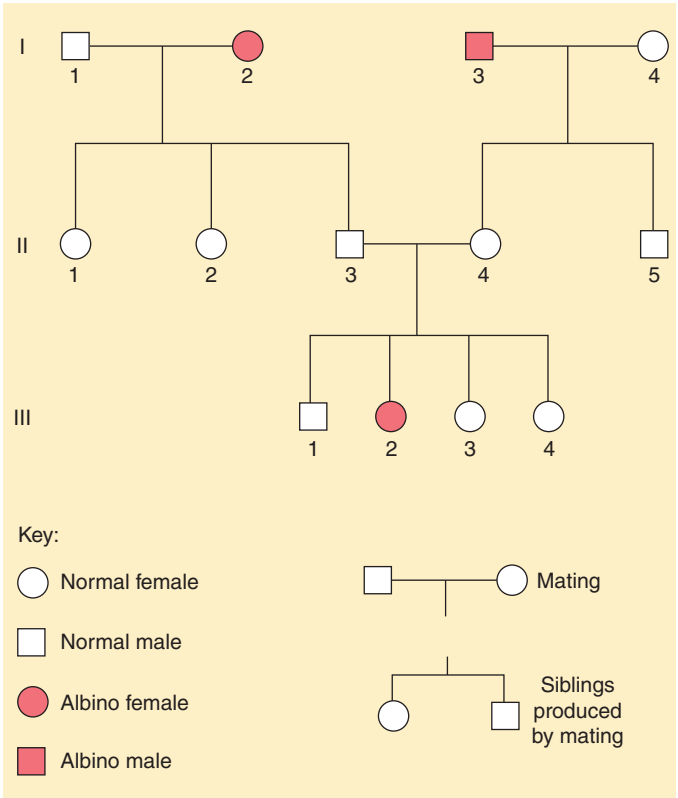
The Human Genome Project sequenced the DNA on all human chromosomes

Scientists working on the **Human Genome Project** sequenced the DNA in the entire nuclear human genome—about 2.9 billion base pairs. (The human mitochondrial genome was sequenced in 1981.) This international undertaking, based on the DNA from 6 to 10 anonymous individuals, was essentially completed in 2001 by hundreds of researchers working in two independent teams, the government-funded International Human Genome Sequencing Consortium and the privately funded company Celera Genomics. The completion of the Human Genome Project in 2003 was a significant milestone in genetics (**TABLE 16-1**).

www.konkur.in

©Mark Eveleigh/Alamy

(a) An albino Cuna Indian girl plays with her friends. Albinism is common among the Cuna people living on the San Blas Islands of Panama.



(b) By studying family histories, a researcher can determine the genetic mechanism of an inherited trait. In this example, III-2 represents an albino girl with two phenotypically normal parents, II-3 and II-4.

FIGURE 16-2 ***Animated*** **A pedigree for albinism**

Scientists hope to eventually identify where all the genes are located in the sequenced DNA. In 2001, the National Human Genome Research Institute (NHGRI) estimated there were 35,000 to 45,000 protein-coding genes in the human genome, but by the end of the decade the estimate had been lowered to 20,000 to 25,000.

TABLE 16-1 Selected Milestones in Genetics

Year	Scientific Advance
1866	Mendel proposed existence of hereditary factors now known as genes
1871	Nucleic acids discovered
1879	Chromosomes identified and observed during cell division
1929	Chemical nature of nucleotides characterized
1953	Double-helix structure of DNA determined
1960s	Genetic code explained (how proteins are made from DNA)
1972	First recombinant DNA molecule produced
1977	DNA sequencing began
1986	DNA sequencing automated
1995	Sequencing of first prokaryotic genome (bacterium *Haemophilus influenzae*) completed
1996	Sequencing of first eukaryotic genome (yeast *Saccharomyces cerevisiae*) completed
1998	Sequencing of first multicellular eukaryotic genome (nematode worm *Caenorhabditis elegans*) completed
2001	Draft sequence of entire human genome published; discovered that 95% of genome is noncoding
2003	Completion of DNA sequencing of human genome

Gene identification represents a formidable challenge. How do you identify a gene in a DNA sequence if you know nothing about it? The human genome is extremely complex. It includes the DNA content of both the nucleus and the mitochondria. However, nuclear DNA accounts for almost all the genetic information in the human genome. Like genomes of other eukaryotic organisms, some (in humans, only about 2%) of the human genome specifies the synthesis of polypeptides, whereas some other segments code only for RNA products.

Most of the human genome consists of noncoding regulatory elements, repetitive sequences (multiple copies) of DNA, and gene segments whose functions remain unknown. Sometimes genes overlap one another, and in other cases a single gene codes for multiple proteins. Relating specific genes to the RNAs and proteins they code for and determining the roles these RNAs and proteins play in the body are some of the avenues of human genetic research that scientists are currently pursuing.

In human chromosome 22, for example, computers scanned DNA sequences for identifying markers such as promoter elements that are typically associated with genes. Using this approach, researchers identified 545 genes. Many of these are "potential" genes in that their messenger RNAs (mRNAs) and protein products have not yet been isolated. Other genes were identified because they code for proteins similar to those previously identified in humans or other organisms. Despite the difficulties, scientists are making

www.konkur.in

progress, and mapping studies will help scientists understand the physical and functional relationships among genes and groups of genes as revealed by their order on the chromosomes.

Now that the human genome has been sequenced, researchers will be busy for many decades analyzing the growing body of human molecular data. In addition to identifying genes, scientists want to understand what each gene's role is, how each gene interacts with other genes, and how the expression of each gene is regulated in different tissues. Eventually, all the thousands of proteins produced in human cells will be identified, their 3-D structures determined, and their properties and functions evaluated.

Genome-wide association scans demonstrate the genetic complexity of major human diseases

Researchers have begun to study sequence variations within the human genome to elucidate differences that might be related to susceptibility to illness or disease. The potential medical applications of the Human Genome Project are extremely promising. Genes on human chromosome 22, for example, are associated with at least 27 diseases known to have a genetic component. The causative genes of many of these disorders have not yet been identified. For example, a gene involved in schizophrenia is strongly linked to human chromosome 22, but scientists do not know its exact location or function.

Genome-wide association (GWA) scans compare the genomes of individuals with a particular disease to healthy individuals without that disease. In 2007, for example, researchers scanned the genomes of more than 16,000 British people to compare genetic patterns in healthy people with those in people with one of seven common diseases: bipolar disorder, coronary artery disease, Crohn's disease, hypertension, rheumatoid arthritis, type 1 diabetes, and type 2 diabetes. These disease phenotypes exhibit complex inheritance patterns, with many different genes contributing to susceptibility. In this particular study, scientists found 24 variations associated with an increased risk of one or more of these diseases. The functions of most of these GWA variations have not yet been determined, but knowing their locations on particular chromosomes will make it easier for researchers to study the genetics of many common human diseases.

Comparative genomics has revealed DNA identical in both mouse and human genomes

About 500 DNA segments longer than 200 base pairs are known to be 100% conserved (that is, identical) between the mouse and human genomes. This remarkable degree of conservation has interesting evolutionary implications because it means that these segments have not mutated during the past 75 million years that mice and humans have shared a common ancestor. During this time, other DNA sections underwent considerable mutation and selection, allowing mice and humans to diverge to their present states. Although the functions of these unchanged elements are not yet determined, they clearly have a vital role. (If they were not essential in their present form, they would have undergone mutation and selection.) Many highly conserved segments appear to contain nonprotein-coding elements that may regulate the expression of other genes.

Researchers use mouse models to study human genetic diseases

Many questions relating to human genetic diseases are difficult to answer because of the ethical issues involved in using humans as test subjects. However, research on any disease is greatly facilitated if an animal model is used for experimentation. A good example is *cystic fibrosis,* a genetic disease caused by a single gene mutation inherited as a recessive allele. In 1994, researchers used **gene targeting** to produce strains of mice that were either homozygous or heterozygous for cystic fibrosis.

The allele that causes cystic fibrosis is a mutant form of a locus involved in controlling the body's water and electrolyte balance. Geneticists have cloned this gene and found that it codes for a protein, the *CFTR protein,* that serves as a chloride ion channel in the plasma membrane. (*CFTR* stands for *cystic fibrosis transmembrane conductance regulator.*) This ion channel transports chloride ions out of the cells lining the digestive tract and the respiratory system. When the chloride ions leave the cells, water follows by osmosis. Thus, the normal secretions of these cells are relatively watery. Because the cells of individuals with cystic fibrosis lack normal chloride ion channels, the individuals' secretions have a low water content and their sweat is very salty. Cells of heterozygous individuals have only half the usual number of functional CFTR ion channels, but these are enough to maintain the normal fluidity of their secretions.

Some researchers are now focusing on understanding the way in which the CFTR channel is activated or inactivated in mice. They hope to use this information to design drugs that enhance chloride transport through the CFTR channels. Such drugs have the potential to treat cystic fibrosis in humans by activating the mutant channels.

Review

- What kinds of information can a human karyotype provide?
- What is pedigree analysis?
- What are two possible benefits scientists hope to obtain by further study of the human genome?
- How does using a mouse model for a genetic disease overcome some of the difficulties in studying human inheritance?

16.2 ABNORMALITIES IN CHROMOSOME NUMBER AND STRUCTURE

LEARNING OBJECTIVES

4 Explain how nondisjunction in meiosis is responsible for chromosome abnormalities such as Down syndrome, Klinefelter syndrome, and Turner syndrome.

5 Distinguish among the following structural abnormalities in chromosomes: translocations, deletions, and fragile sites.

Polyploidy, the presence of multiple sets of chromosomes, is common in plants but rare in animals. It may arise from the failure of chromosomes to separate during meiosis or from the fertilization

www.konkur.in

of an egg by more than one sperm. When it occurs in all the cells of the body, polyploidy is lethal in humans and many other animals. For example, *triploidy* ($3n$) is sometimes found in human embryos that have been spontaneously aborted in early pregnancy.

Abnormalities caused by the presence of a single extra chromosome or the absence of a chromosome—called **aneuploidies**—are more common than polyploidy. **Disomy** is the normal state: two of each kind of chromosome in a cell or individual. In **trisomy,** a cell or individual has two copies of each chromosome except for one, which has three copies; a trisomic chromosome number is designated $2n + 1$. In **monosomy,** an individual lacks one member of a pair of chromosomes; a monosomic chromosome number is designated $2n - 1$. **TABLE 16-2** summarizes some disorders that aneuploidies produce.

Aneuploidies generally arise as a result of an abnormal meiotic (or, rarely, mitotic) division in which chromosomes fail to separate at anaphase. This phenomenon, called **nondisjunction,** can occur with the autosomes or with the sex chromosomes. In meiosis, chromosome nondisjunction may occur during the first or second meiotic division (or both). For example, two X chromosomes that fail to separate at either the first or the second meiotic division may both enter the egg nucleus. Alternatively, the two joined X chromosomes may go into a *polar body,* leaving the egg with no X chromosome. (Recall from Chapter 10 that a polar body is a nonfunctional haploid cell produced during oogenesis; also see Fig. 50-11.)

Nondisjunction of the XY pair during the first meiotic division in the male may lead to the formation of a sperm with both X and Y chromosomes or a sperm with neither an X nor a Y chromosome (**FIG. 16-3**). Similarly, nondisjunction at the second meiotic division can produce sperm with two Xs or two Ys. When an abnormal gamete unites with a normal one, the resulting zygote has a chromosome abnormality that will be present in every cell of the body.

Meiotic nondisjunction results in an abnormal chromosome number at the zygote stage of development, so all cells in the individual have an abnormal chromosome number. In contrast, nondisjunction during a mitotic division occurs sometime later in development and leads to the establishment of a clone of abnormal cells in an otherwise normal individual. Such a mixture of cells with different chromosome numbers may or may not affect somatic (body) or germ line (reproductive) tissues.

Different numbers of chromosomes are common in many cancer cells, particularly those in solid tumors. Whether aneuploidy is a cause or a consequence of cancer, however, is not yet clear.

Recognizable chromosome abnormalities are seen in less than 1% of all live births, but substantial evidence suggests the rate at conception is much higher. At least 17% of pregnancies recognized at 8 weeks will end in spontaneous abortion (miscarriage). Approximately half of these spontaneously aborted embryos have major chromosome abnormalities, including autosomal trisomies (such as trisomy 21), triploidy, tetraploidy, and Turner syndrome (X0), in which the 0 refers to the absence of a second sex chromosome. Autosomal monosomies are exceedingly rare, possibly because they induce a spontaneous abortion very early in the pregnancy, before a woman is even aware she is pregnant. Some investigators give surprisingly high estimates (50% or more) for the loss rate of very early embryos. Chromosome abnormalities probably induce many of these spontaneous abortions.

Down syndrome is usually caused by trisomy 21

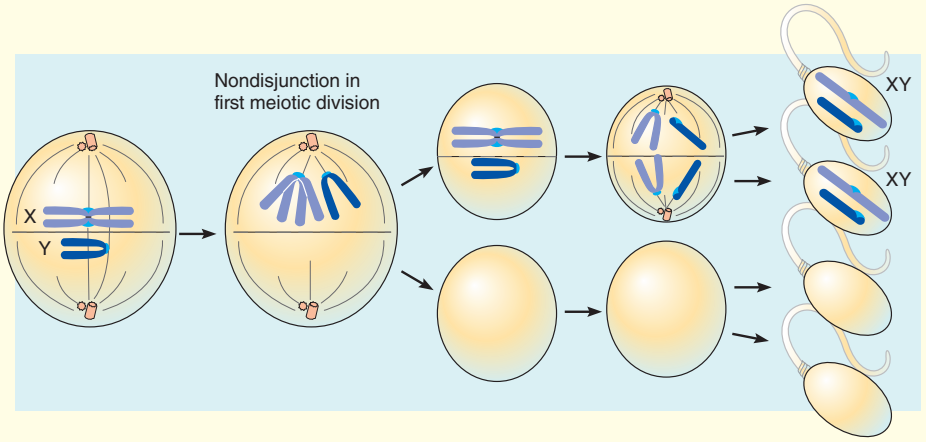
Down syndrome is one of the most common chromosome abnormalities in humans. (The term *syndrome* refers to a set of symptoms that usually occur together in a particular disorder.) It was named after J. Langdon Down, the British physician who in 1866 first described the condition. Affected individuals have abnormalities of the face, eyelids, tongue, hands, and other parts of the body and are mentally retarded (**FIG. 16-4a**). They are also unusually susceptible to certain diseases, such as leukemia and Alzheimer's disease.

TABLE 16-2 Chromosome Abnormalities: Disorders Produced by Aneuploidies

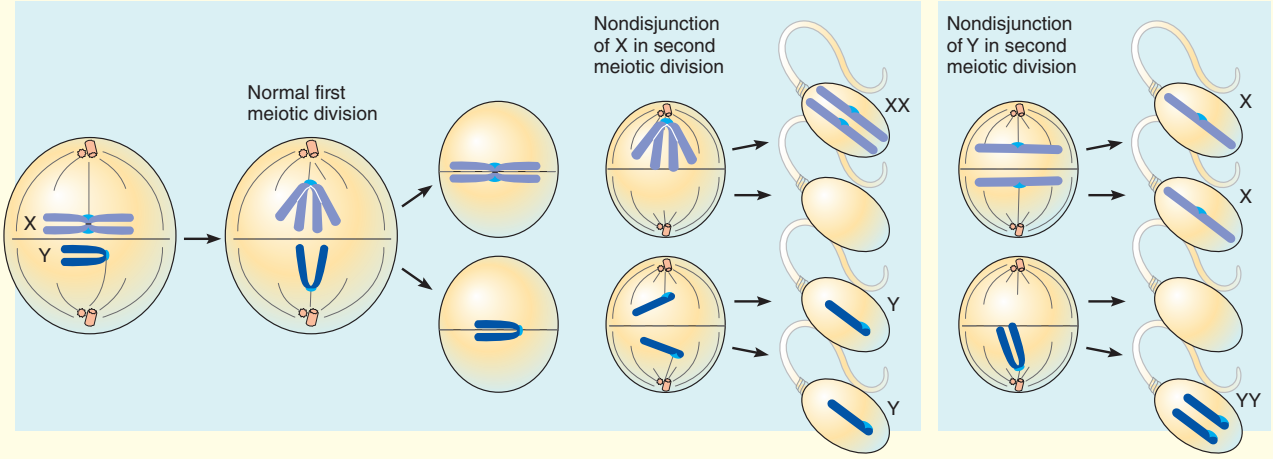
Karyotype	Common Name	Clinical Description
Trisomy 13	Patau syndrome	Multiple defects, with death typically by age 3 months
Trisomy 18	Edwards syndrome	Ear deformities, heart defects, spasticity, and other damage; death typically by age 1 year, but some survive much longer
Trisomy 21	Down syndrome	Overall frequency is about 1 in 800 live births. Most conceptions involving true trisomy occur in older (age 35+) mothers, but translocation resulting in the equivalent of trisomy is not age-related. Trisomy 21 is characterized by a fold of skin above the eye, varying degrees of mental retardation, short stature, protruding furrowed tongue, transverse palmar crease, cardiac deformities, and increased risk of leukemia and Alzheimer's disease.
X0	Turner syndrome	Short stature, webbed neck, sometimes slight mental retardation; ovaries degenerate in late embryonic life, leading to rudimentary sexual characteristics; gender is female; no Barr bodies
XXY	Klinefelter syndrome	Male with slowly degenerating testes, enlarged breasts; one Barr body per cell
XYY	XYY karotype	Many males have no unusual symptoms; others are unusually tall, with heavy acne, and some tendency to mild mental retardation
XXX	Triplo-X	Despite three X chromosomes, usually fertile females with normal intelligence; two Barr bodies per cell

www.konkur.in

KEY POINT Aneuploidy may occur by meiotic nondisjunction, the abnormal segregation of chromosomes during meiosis.



(a) First meiotic division nondisjunction results in two XY sperm and two sperm with neither an X nor a Y.



(b) Second meiotic division nondisjunction of the X chromosome results in one sperm with two X chromosomes, two with one Y each, and one with no sex chromosomes. Nondisjunction of the Y chromosome results in one sperm with two Y chromosomes, two with one X each, and one with no sex chromosome (*box on right*).

FIGURE 16-3 Meiotic nondisjunction

In these examples of nondisjunction of the sex chromosomes in the human male, only the X (*purple*) and Y (*blue*) chromosomes are shown. (The positions of the metaphase chromosomes have been modified to save space.)

Genetic studies have revealed that most people with Down syndrome have 47 chromosomes because of *autosomal trisomy:* this condition is known as **trisomy 21** (FIG. 16-4b). Nondisjunction during meiosis is responsible for the presence of the extra chromosome. Although no genetic information is missing in these individuals, the extra copies of chromosome 21 genes bring about some type of genetic imbalance that causes abnormal physical and mental development. Down syndrome is quite variable in expression, with some individuals far more severely affected than others. Researchers are using DNA technologies to pinpoint genes on chromosome 21 that affect mental development, as well as possible *oncogenes* (cancer-causing genes) and genes that may be involved in Alzheimer's disease. (Like many human conditions, cancer and Alzheimer's disease have both genetic and environmental components.)

Down syndrome occurs in all ethnic groups in about 1 out of 800 live births. Its incidence increases markedly with increasing maternal age. The occurrence of Down syndrome is not affected by the father's age (although other disorders are, including schizophrenia and achondroplasia, the most common form of dwarfism). Down syndrome is 68 times as likely in the offspring of mothers of age 45 than in the offspring of mothers age 20. However, most babies with Down syndrome in the United States are born to mothers younger than 35, in part because these greatly outnumber older mothers, and

www.konkur.in

FIGURE 16-4 Down syndrome

in part because about 90% of older women who undergo prenatal testing terminate the pregnancy if Down syndrome is diagnosed.

The relationship between increased incidence in Down syndrome and maternal age has been studied for decades, but there is no explanation. Scientists have proposed several hypotheses to explain the maternal age effect, but none are supported unequivocally. One explanation is that older women have held eggs in suspended meiosis too long, leading to a deterioration of the meiotic spindle apparatus. (A woman is born with all the oocytes she will ever have; these oocytes remain in prophase I of meiosis until ovulation.) Another possibility is that an aging uterus is less likely to reject an abnormal fetus.

Most sex chromosome aneuploidies are less severe than autosomal aneuploidies

Sex chromosome aneuploidies are tolerated relatively well (see Table 16-2) This is true, at least in part because of the mechanism of **dosage compensation:** mammalian cells compensate for extra X chromosome material by rendering all but one X chromosome inactive. The inactive X is seen as a **Barr body,** a region of darkly stained, condensed chromatin next to the nuclear envelope of an interphase nucleus (see Fig. 11-16). Investigators have used the presence of the Barr body in the cells of normal females as an initial screen to determine whether an individual is genetically female or male. However, as you will see shortly in the context of sex chromosome aneuploidies, the Barr body test has limitations.

Individuals with **Klinefelter syndrome** are males with 47 chromosomes, including two Xs and one Y. They have small testes, produce few or no sperm, and are therefore sterile. The hypothesis that the Y chromosome is the major determinant of the male phenotype has been substantiated by the fact that at least one gene on the Y chromosome acts as a genetic switch, directing male development. Males with Klinefelter syndrome tend to be unusually tall and have female-like breast development. About half show some mental retardation, but many live relatively normal lives. However, each of their cells has one Barr body. On the basis of such a test, they would be erroneously classified as females. About 1 in 1000 live-born males has Klinefelter syndrome.

The sex chromosome composition for **Turner syndrome,** in which an individual has only one sex chromosome, an X chromosome, is designated X0. Because they lack the male-determining effect of the Y chromosome, individuals with Turner syndrome develop as females. However, both their internal and their external genital structures are underdeveloped, and they are sterile. Apparently, a second X chromosome is necessary for normal development of ovaries in a female embryo. Examination of the cells of these individuals reveals no Barr bodies because there is no extra X chromosome to be inactivated. Using the standards of the Barr body test, such an individual would be classified erroneously as a male. About 1 in 2500 live-born females has Turner syndrome.

People with an X chromosome plus two Y chromosomes are phenotypically males, and they are fertile. Other characteristics of these individuals (tall, often with severe acne) hardly qualify as a syndrome; hence the designation **XYY karyotype.** Some years ago, several widely publicized studies suggested that males with this condition are more likely to display criminal tendencies and thus to be imprisoned. However, these studies were flawed because

www.konkur.in

they were based on small numbers of XYY males, without adequate or well-matched control studies of XY males. The prevailing opinion in medical genetics today is that there are many undiagnosed XYY males in the general population who do not have overly aggressive or criminal behaviors and are unlikely to be incarcerated.

Abnormalities in chromosome structure cause certain disorders

Chromosome abnormalities are caused not only by changes in chromosome number but also by distinct changes in the structure of one or more chromosomes. The breakage and rejoining of chromosome parts result in four structural changes within or between chromosomes: duplications, inversions, deletions, and translocations (**FIG. 16-5**). Breaks in chromosomes are the result of errors in replication or recombination. In a **duplication,** a segment of the chromosome is repeated one or more times; these repeats often appear in tandem with one another. The orientation of a chromosome segment is reversed in an **inversion.** In a **deletion,** breakage causes loss of part of a chromosome, along with the genes on that segment. A deletion can occur at the end of a chromosome or on an internal part of the chromosome. In some cases of **translocation,** a chromosome fragment breaks off and attaches to a nonhomologous chromosome. In a **reciprocal translocation,** two nonhomologous chromosomes exchange segments.

Here we consider three simple examples of chromosomal structural changes that result in abnormal phenotypes: translocations, deletions, and *fragile sites,* which are chromosome sites that are susceptible to breakage.

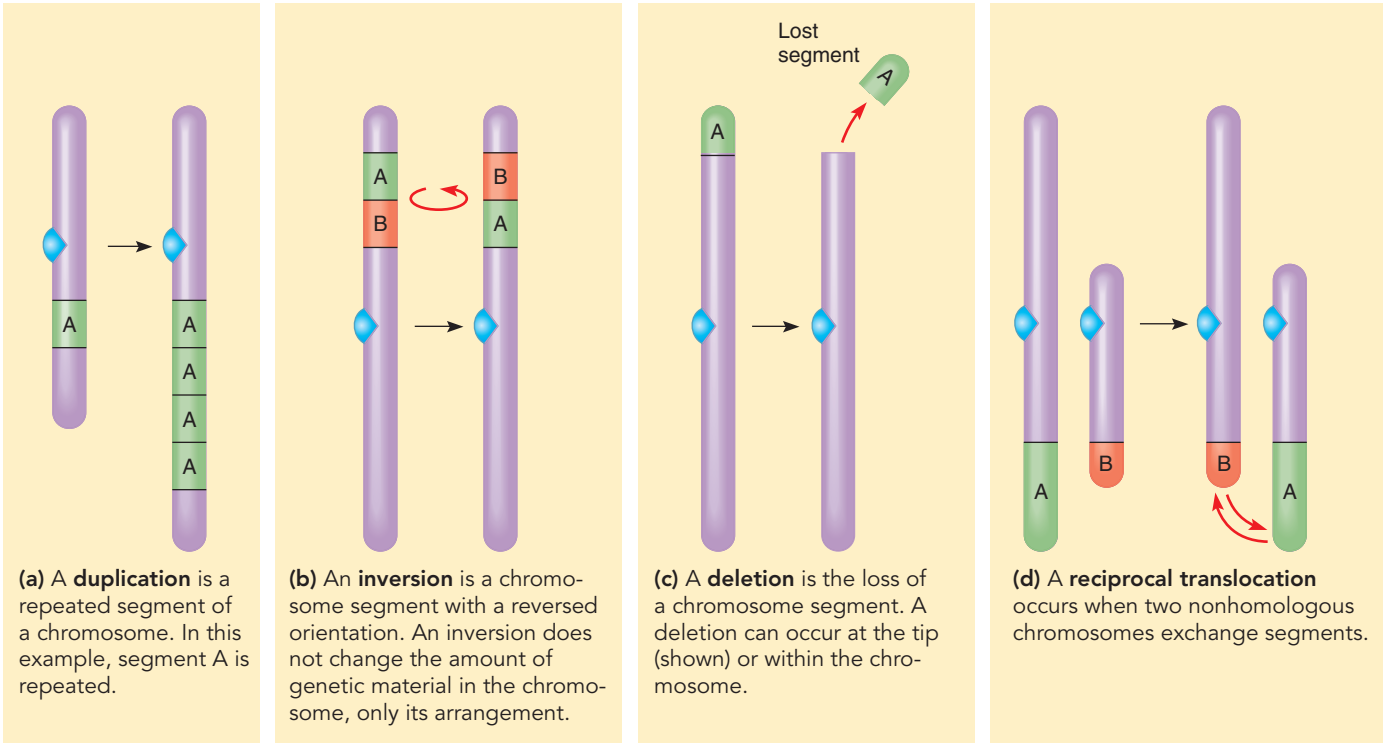
Translocation is the attachment of part of one chromosome to another

The consequences of translocations vary considerably. They include deletions, in which some genes are missing, and duplications, in which extra copies of certain genes are present. In about 4% of individuals with Down syndrome, only 46 chromosomes are present, but one is abnormal. The large arm of chromosome 21 has been translocated to the large arm of another chromosome, usually chromosome 14. Individuals with **translocation Down syndrome** have one chromosome 14, one combined 14/21 chromosome, and two normal copies of chromosome 21. All or part of the genetic material from chromosome 21 is thus present in triplicate. When studying the karyotypes of the parents in such cases, geneticists usually find that either the mother or the father has only 45 chromosomes, although she or he is generally phenotypically normal. The parent with 45 chromosomes has one chromosome 14, one combined 14/21 chromosome, and one chromosome 21; although the karyotype is abnormal, there is no extra genetic material. In contrast to trisomy 21, translocation Down syndrome can run in families, and its incidence is not related to maternal age.

A deletion is the loss of part of a chromosome

Sometimes chromosomes break and fail to rejoin. Such breaks result in deletions of as little as a few base pairs to as much as an entire chromosome arm. As you might expect, large deletions are generally lethal, whereas small deletions may have no effect or may cause recognizable human disorders.

One deletion disorder (1 in 50,000 live births) is **cri du chat syndrome,** in which part of the short arm of chromosome 5 is



(a) A **duplication** is a repeated segment of a chromosome. In this example, segment A is repeated.

(b) An **inversion** is a chromosome segment with a reversed orientation. An inversion does not change the amount of genetic material in the chromosome, only its arrangement.

(c) A **deletion** is the loss of a chromosome segment. A deletion can occur at the tip (shown) or within the chromosome.

(d) A **reciprocal translocation** occurs when two nonhomologous chromosomes exchange segments.

FIGURE 16-5 ***Animated*** Common abnormalities of chromosome structure

www.konkur.in

deleted. As in most deletions, the exact point of breakage in chromosome 5 varies from one individual to another; some cases of cri du chat involve a small loss, whereas others involve a more substantial deletion of base pairs. Infants born with cri du chat syndrome typically have a small head with altered features described as a "moon face" and a distinctive cry that sounds like a kitten mewing. (The name literally means "cry of the cat" in French.) Affected individuals usually survive beyond childhood but exhibit severe mental retardation.

Fragile sites are weak points at specific locations in chromatids

A **fragile site** is a place where part of a chromatid appears to be attached to the rest of the chromosome by a thin thread of DNA. Fragile sites occur at corresponding locations on both chromatids of a chromosome. They have been identified on the X chromosome as well as on certain autosomes. The location of a fragile site is exactly the same in all of an individual's cells, as well as in cells of other family members. Scientists report growing evidence that cancer cells may have breaks at these fragile sites. Whether cancer destabilizes the fragile sites, leading to breakage, or the fragile sites themselves contain genes that contribute to cancer is unknown at this time.

In **fragile X syndrome,** also known as **Martin–Bell syndrome,** a fragile site occurs near the tip of the X chromosome, where the fragile X gene contains a nucleotide triplet CGG that repeats from 200 to more than 1000 times (**FIG. 16-6**). In a normal chromosome, CGG repeats up to 50 times.

Fragile X syndrome is the most common cause of inherited mental retardation. The effects of fragile X syndrome, which are more pronounced in males than in females, range from mild learning and attention deficit disorders to severe mental retardation and hyperactivity. According to the National Fragile X Foundation, about 80% of boys and 35% of girls with fragile X syndrome are at least mildly mentally retarded. Females with fragile X syndrome are usually heterozygous (because their other X chromosome is normal) and are therefore more likely to have normal intelligence.

The discovery of the fragile X gene in 1991 and the development of the first fragile X mouse model in 1994 have provided researchers with ways to develop and test potential treatments, including gene therapy. At the microscopic level, the nerve cells of individuals with fragile X syndrome have malformed dendrites (the part of the nerve cell that receives nerve impulses from other nerve cells). At the molecular level, the triplet repeats associated with fragile X syndrome disrupt the functioning of a gene that codes for a certain protein, designated *fragile X mental retardation protein (FMRP).* In normal cells, FMRP binds to dozens of different mRNA molecules (exactly why it binds is not yet understood), but in cells of individuals with fragile X syndrome the mutated allele does not produce functional FMRP.

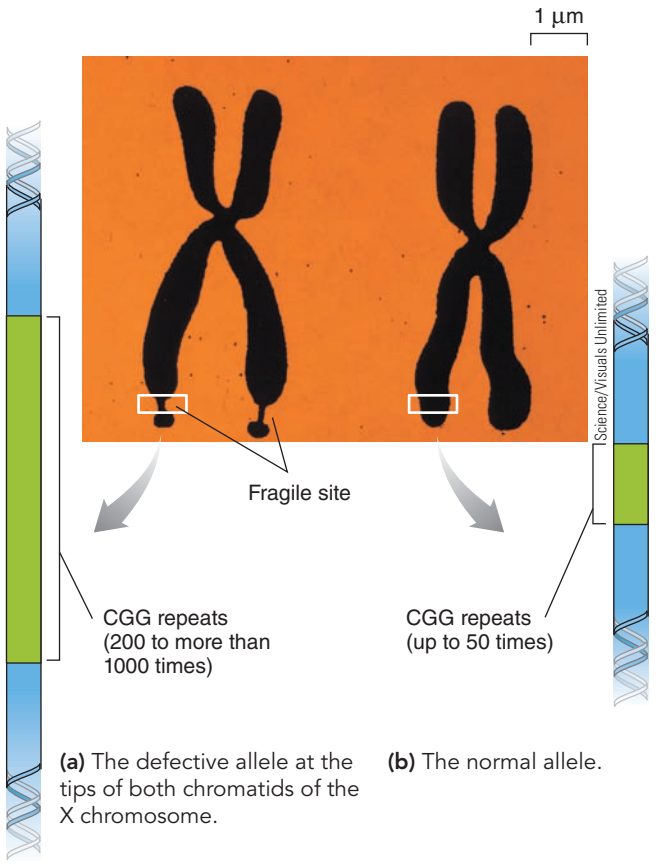


FIGURE 16-6 Fragile X syndrome
This colorized SEM shows an X chromosome with a fragile site and a normal X chromosome.

Genomic imprinting is determined by whether inheritance is from the male or female parent

Some traits are the result of **genomic** or **parental imprinting,** in which the expression of a gene in a given tissue or developmental stage is based on its parental origin—that is, whether the individual inherits the gene from the male or female parent. For some imprinted genes, the paternally inherited allele is always repressed (not expressed); for other imprinted genes, the maternally inherited allele is always repressed. Thus, maternal and paternal genomes have different imprints that result in differential gene expression in the embryo. As discussed in Chapter 14, **epigenetic inheritance** refers to changes in how a gene is expressed without any change in the coding of the DNA bases. Epigenetic inheritance may cause genomic imprinting.

Two rare genetic disorders provide a fascinating demonstration of genomic imprinting. In *Prader-Willi syndrome (PWS),* individuals become compulsive overeaters and obese; they are also short in stature and mildly to moderately retarded. In *Angelman syndrome (AS),* affected individuals are hyperactive, mentally retarded, and unable to speak, and they suffer from seizures. A small *deletion* of several loci from the same region of chromosome 15 causes both PWS and AS (**FIG. 16-7a**). One of these deleted loci is responsible for PWS, another for AS.

Pedigree analysis has shown that when the person inherits the deletion from the father, PWS occurs, whereas when the person inherits the deletion from the mother, AS occurs. This inheritance pattern suggests that the normal PWS gene is expressed only in the paternal chromosome and the normal AS gene is expressed only in the maternal chromosome. PWS occurs because the repressed

16.3 GENETIC DISEASES CAUSED BY SINGLE-GENE MUTATIONS

LEARNING OBJECTIVE

6 State whether each of the following genetic defects is inherited as an autosomal recessive, autosomal dominant, or X-linked recessive: phenylketonuria (PKU), sickle cell anemia, cystic fibrosis, Tay-Sachs disease, Huntington's disease, and hemophilia A.

You have seen that several human disorders involve chromosome abnormalities. Hundreds of human disorders, however, involve enzyme defects caused by mutations of single genes. *Phenylketonuria (PKU)* and *alkaptonuria* (discussed in Chapter 13) are examples of these disorders, each of which is sometimes referred to as an **inborn error of metabolism,** a metabolic disorder caused by the mutation of a gene that codes for an enzyme needed in a biochemical pathway. Both PKU and alkaptonuria involve blocks in the metabolism of specific amino acids.

Many genetic diseases are inherited as autosomal recessive traits

Many human genetic diseases have a simple autosomal recessive inheritance pattern and therefore are expressed only in the homozygous state. Why are these traits recessive? Most recessive mutations result in a mutant allele that encodes a product that no longer works (either there is not enough gene product, or it is a defective gene product). In the heterozygous state, there is one functional copy of the gene and one mutated, nonfunctional copy. The normal copy of the gene generally produces enough protein to meet the cell's needs. In homozygous recessive individuals, *both* alleles of the gene are nonfunctional, and the cell's needs are not met. As a result, the person shows symptoms of disease.

Phenylketonuria results from an enzyme deficiency

Phenylketonuria (PKU), which is most common in individuals of western European descent, is an autosomal recessive disease caused by a defect of amino acid metabolism. It affects about 1 in 10,000 live births in North America. Homozygous recessive individuals lack an enzyme that converts the amino acid phenylalanine to another amino acid, tyrosine. These individuals accumulate high levels of phenylalanine, phenylpyruvic acid, and similar compounds.

The accumulating phenylalanine is converted to phenylketones, which damage the central nervous system, including the brain, in children. The ultimate result in untreated cases is severe mental retardation. An infant with PKU is usually healthy at birth because its mother, who is heterozygous, breaks down excess phenylalanine for both herself and her fetus. However, during infancy and early childhood the accumulation of toxic products eventually causes irreversible damage to the central nervous system.

Beginning in the 1950s, infants with PKU have been identified early and placed on a low-phenylalanine diet, dramatically alleviating their symptoms. The diet is difficult to adhere to because it contains no meat, fish, dairy products, breads, or nuts. Also, individuals with PKU should not consume the sugar substitute aspartame, found in many diet drinks and foods, because it contains phenylalanine. Biochemical tests for PKU have been developed, and screening of newborns through a simple blood test is required in the United States. Because of these screening programs and the availability of effective treatment, thousands of PKU-diagnosed children have not developed severe mental retardation. Most must continue the diet through at least adolescence. Doctors now recommend that patients stay on the diet throughout life because some adults who have discontinued the low-phenylalanine diet experience certain mental problems, such as difficulty in concentration and short-term memory loss.

Ironically, the success of PKU treatment in childhood presents a new challenge today. If a homozygous female who has discontinued the special diet becomes pregnant, the high phenylalanine levels in her blood can damage the brain of the fetus she is carrying, even though that fetus is heterozygous. Therefore, she must resume the diet, preferably before becoming pregnant. This procedure is usually (although not always) successful in preventing the effects of **maternal PKU.** It is especially important for women with PKU to be aware of maternal PKU and to obtain appropriate counseling and medical treatment during pregnancy.

Sickle cell anemia results from a hemoglobin defect

Sickle cell anemia is inherited as an autosomal recessive trait. The disease is most common in people of African descent (approximately 1 in 500 African Americans), and about 1 in 12 African Americans is heterozygous. Under low oxygen conditions, the red blood cells of an individual with sickle cell anemia are shaped like sickles, or half-moons, whereas normal red blood cells are biconcave discs.

The mutation that causes sickle cell anemia was first identified in 1957. The sickled cells contain abnormal hemoglobin molecules, which have the amino acid valine instead of glutamic acid at position 6 (the sixth amino acid from the amino terminal end) in the β-globin chain (see Fig. 3-22a). The substitution of valine for glutamic acid makes the hemoglobin molecules stick to one another to form fiberlike structures that change the shape of some of the red blood cells. This sickling occurs in the veins after the oxygen has been released from the hemoglobin. The blood cells' abnormal sickled shape slows blood flow and blocks small blood

www.konkur.in

vessels (**FIG. 16-8**), resulting in tissue damage from lack of oxygen and essential nutrients and in episodes of pain. Because sickled red blood cells also have a shorter lifespan than normal red blood cells, many affected individuals have severe anemia.

Treatments for sickle cell anemia include pain-relief measures, transfusions, and, more recently, medicines such as hydroxyurea, which activates the gene for the production of normal fetal hemoglobin (this gene is generally not expressed after birth). The presence of normal fetal hemoglobin in the red blood cells dilutes the sickle cell hemoglobin, thereby minimizing the painful episodes and reducing the need for blood transfusions. The long-term effects of hydroxyurea are not known at this time, but there are concerns that it may induce tumor formation.

Ongoing research is directed toward providing gene therapy for sickle cell anemia. The development of a mouse model for studying sickle cell anemia has enabled researchers to test gene therapy. The first gene therapy treatments in mice used a mouse retrovirus as a **vector,** a carrier that transfers the genetic information. However, the retrovirus did not effectively transport the normal gene for hemoglobin into the bone marrow, where stem cells produce new blood cells. In 2001, researchers cured sickle cell anemia in mice using a modified HIV as a vector. Before this treatment can be tested in humans, however, researchers must demonstrate that the HIV vector is safe. Bone marrow transplants are also a promising future treatment for seriously ill individuals.

The reason the sickle cell allele occurs at a higher frequency in parts of Africa and Asia is well established. Individuals who are heterozygous (Hb^AHb^S) and carry alleles for both normal hemoglobin (Hb^A) and sickle cell hemoglobin (Hb^S) are more resistant to the malarial parasite, *Plasmodium falciparum,* which causes a severe, often fatal, form of malaria. The malarial parasite, which spends part of its life cycle inside red blood cells, does not thrive when sickle cell hemoglobin is present. (An individual heterozygous for sickle cell anemia produces both normal and sickle cell hemoglobin.) Areas in Africa where *falciparum* malaria occurs correlate well with areas in which the frequency of the sickle cell allele is more common in the human population. Thus, Hb^AHb^S individuals, possessing one copy of the mutant sickle cell allele, have a selective advantage over both types of homozygous individuals, Hb^AHb^A (who may die of malaria) and Hb^SHb^S (who may die of sickle cell anemia). This phenomenon, known as **heterozygote advantage,** is discussed further in Chapter 19 (see Fig. 19-7).

Cystic fibrosis results from defective ion transport

Cystic fibrosis is the most common autosomal recessive disorder in children of European descent (1 in 2500 births). About 1 in 25 individuals in the United States is a heterozygous carrier of the mutant cystic fibrosis allele. Abnormal secretions characterize this disorder. The most severe effect is on the respiratory system, where abnormally viscous mucus clogs the airways. The cilia that line the bronchi cannot easily remove the mucus, and it becomes a growth medium for dangerous bacteria. These bacteria or their toxins attack the surrounding tissues, leading to recurring pneumonia and other complications. The heavy mucus also occurs elsewhere in the body, causing digestive difficulties and other effects.

As discussed earlier, the gene responsible for cystic fibrosis codes for CFTR, the protein that regulates the transport of chloride ions across cell membranes. The defective protein, found in plasma membranes of epithelial cells lining the passageways of the lungs, intestines, pancreas, liver, sweat glands, and reproductive organs, results in the production of an unusually thick mucus that eventually leads to tissue damage. Although many forms of cystic fibrosis exist that vary somewhat in the severity of symptoms, the disease is almost always serious.

Antibiotics are used to control bacterial infections, and daily physical therapy is required to clear mucus from the respiratory system (**FIG. 16-9**). Treatment with *Dornase Alpha (DNase),* an enzyme produced by recombinant DNA technology, helps break down the mucus. Without treatment, death would occur in infancy. With treatment, the average life expectancy for individuals with cystic fibrosis is about 38 years. Because of the serious limitations of available treatments, gene therapy for cystic fibrosis is under development.

The most severe mutant allele for cystic fibrosis predominates in northern Europe, and another, somewhat less serious, mutant allele is more prevalent in southern Europe. Presumably, these mutant alleles are independent mutations that have been maintained by natural selection. Some experimental evidence supports the

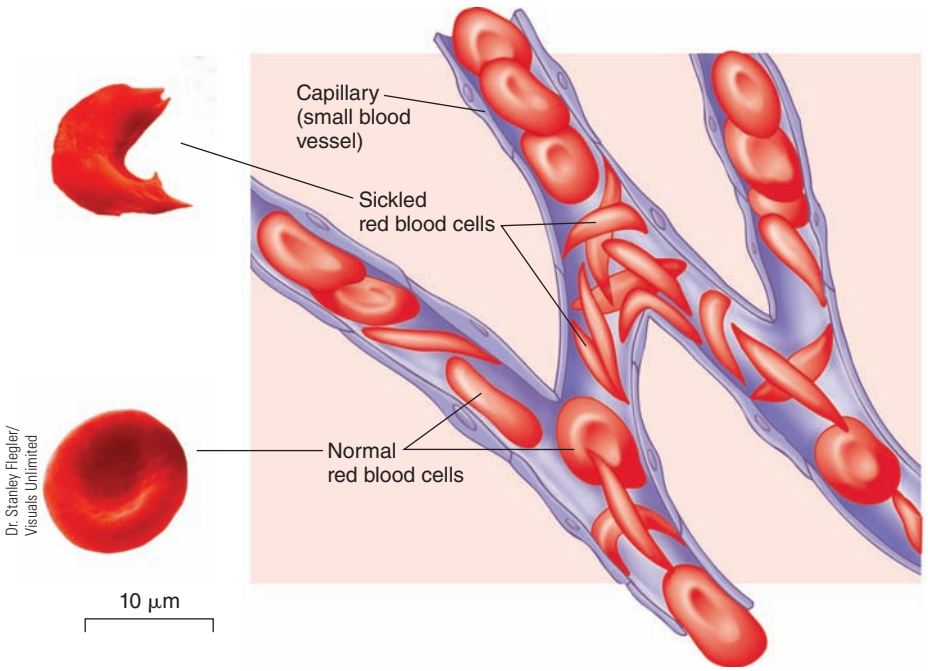

FIGURE 16-8 Sickle cell anemia

Sickled red blood cells do not pass through small blood vessels as easily as unsickled red blood cells do. The sickled cells can cause blockages that prevent oxygen from being delivered to tissues.

www.konkur.in

FIGURE 16-9 Treating cystic fibrosis

One traditional treatment for cystic fibrosis is chest percussion, or gentle pounding on the chest, to clear mucus from clogged airways in the lungs. This technique is typically done after nebulizer therapy, which loosens the mucus.

hypothesis that heterozygous individuals are less likely to die from infectious diseases that cause severe diarrhea, such as cholera, another possible example of heterozygote advantage.

Tay-Sachs disease results from abnormal lipid metabolism in the brain

Tay-Sachs disease is an autosomal recessive disease that affects the central nervous system and results in blindness and severe mental retardation. The symptoms begin within the first year of life and result in death before the age of 5 years. Because of the absence of an enzyme, a normal membrane lipid in brain cells fails to break down properly and accumulates in intracellular organelles called *lysosomes* (discussed in Chapter 4). The lysosomes swell and cause nerve cells to malfunction. Although research is ongoing, no effective treatment for Tay-Sachs disease is available at this time. However, an effective treatment strategy in a mouse model was reported in 1997: oral administration of an inhibitor reduced the synthesis of the lipid that accumulates in the lysosomes. This treatment offers the hope of future breakthroughs to deal more effectively with Tay-Sachs disease in humans.

The abnormal allele is especially common in the United States among Jewish individuals whose ancestors came from eastern and central Europe (Ashkenazi Jews). In contrast, Jewish individuals whose ancestors came from the Mediterranean region (Sephardic Jews) have a very low frequency of the allele.

Some genetic diseases are inherited as autosomal dominant traits

Huntington's disease (HD), named after George Huntington, the U.S. physician who first described it in 1872, is caused by a rare autosomal dominant allele that affects the central nervous system. The disease causes severe mental and physical deterioration, uncontrollable muscle spasms, and personality changes; death ultimately results. No effective treatment has been found. Every child of an affected individual has a 50% chance of also being affected (and, if affected, of passing the abnormal allele to his or her offspring). Ordinarily, we would expect a dominant allele with such devastating effects to occur only as a new mutation and not to be transmitted to future generations. Because HD symptoms typically do not appear until relatively late in life (most people do not develop the disease until they are in their forties), affected individuals are likely to produce children before the disease develops (**FIG. 16-10**). In North America, HD occurs in 1 in 20,000 live births.

The gene responsible for HD is located on the short end of chromosome 4. The mutation is a nucleotide triplet (CAG) that is repeated many times; the normal allele repeats CAG from 6 to 35 times, whereas the mutant allele repeats CAG from 40 to more than 150 times. Because CAG codes for the amino acid glutamine, the resulting protein, called "huntingtin," has a long strand of glutamines. The number of nucleotide triplet repeats seems to be important in determining the age of onset and the severity of the disease; larger numbers of repeats correlate with an earlier age of onset and greater severity.

Much research now focuses on how the mutation is linked to neurodegeneration in the brain. A mouse model of HD is providing valuable clues about the development of the disease. Using this model, researchers have demonstrated that the defective version of huntingtin binds to enzymes called *acetyltransferases* in brain cells,

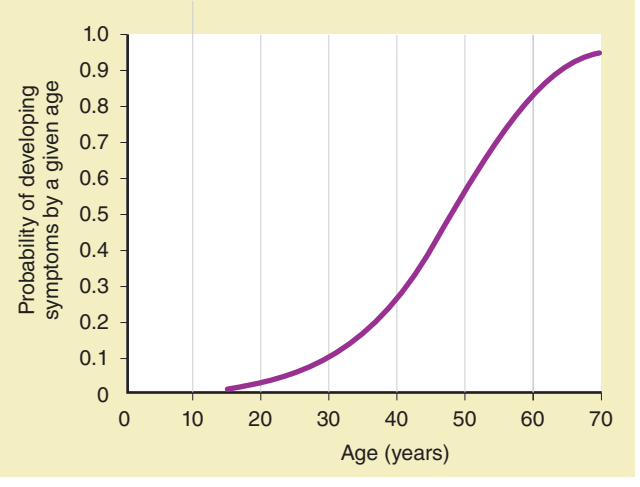

FIGURE 16-10 Age of onset of Huntington's disease

The graph shows the cumulative probability that an individual carrying a Huntington's disease allele will have developed symptoms at a given age. (Adapted from Harper, P. S., *Genetic Counseling*, 5th ed., Butterworth-Heinemann, Oxford, 1998.)

www.konkur.in

blocking their action. Acetyltransferases are involved in turning genes on for expression, so in the brain cells of HD individuals, much of normal transcription cannot occur. Once neurologists better understand HD's mechanism of action on nerve cells, it may be possible to develop effective treatments to slow the progression of the disease.

Cloning of the HD allele became the basis for tests that allow those at risk to learn presymptomatically if they carry the allele. The decision to be tested for any genetic disease is understandably a highly personal one. The information is, of course, invaluable for those who must decide whether or not to have children. However, someone who tests positive for the HD allele must then live with the virtual certainty of eventually developing this devastating and incurable disease. Researchers hope that information from affected individuals who choose to be identified before the onset of symptoms may ultimately contribute to the development of effective treatments.

Some genetic diseases are inherited as X-linked recessive traits

Hemophilia A was once referred to as a disease of royalty because of its high incidence among male descendants of Queen Victoria, but it is also found in many nonroyal pedigrees. Caused by the absence of a blood-clotting protein called factor VIII, hemophilia A is characterized by severe internal bleeding in the head, joints, and other areas from even a slight wound. The mode of inheritance is X-linked recessive. Thus, affected individuals are almost exclusively male, having inherited the abnormal allele on the X chromosome from their heterozygous carrier mothers. (For a female to be affected by an X-linked trait, she would have to inherit the defective allele from both parents, whereas an affected male need only inherit one defective allele from his mother.)

Treatments for hemophilia A consist of blood transfusions and the administration of clotting factor VIII (the missing gene product) by injection. Unfortunately, these treatments are costly. During the 1980s, many clotting factor VIII preparations made from human plasma were unknowingly contaminated with HIV, and many men with hemophilia subsequently died from AIDS. Since 1992, virus-free clotting factor VIII has been available from both human plasma and recombinant DNA technology.

Geneticists are beginning to unravel X-linked genes affecting intelligence

The X chromosome contains a disproportionate number of the more than 200 genes identified so far that affect cognitive abilities, for example, by coding for proteins required for the brain to function normally. Not surprisingly, many kinds of mental impairment are linked to defects in genes on the X chromosome. By one count, the human X chromosome contains less than 4% of the human genome, yet 10% of the genes in which defects are known to cause some form of mental retardation are found on the X chromosome. Because males have only one X chromosome, more boys than girls have some form of mental impairment, a fact that has been observed for more than a century.

Review

- Which of the following genetic diseases is/are inherited as an autosomal recessive: phenylketonuria, Huntington's disease, Tay-Sachs disease?
- Which of the following genetic diseases is/are inherited as an autosomal dominant: sickle cell anemia, hemophilia A, Huntington's disease?
- Which of the following genetic diseases is/are inherited as an X-linked recessive: hemophilia A, cystic fibrosis, Tay-Sachs disease?

16.4 GENE THERAPY

LEARNING OBJECTIVE

7 Briefly discuss the process of gene therapy, including some of its technical challenges.

Because serious genetic diseases are difficult to treat, scientists have dreamed of developing actual cures. Today, advances in genetics are bringing these dreams closer to reality. One strategy is **gene therapy,** which aims to compensate for a defective, mutant allele by adding a normal, therapeutic allele (and its expressed protein) to certain cells. The rationale is that although a particular allele may be present in all cells, it is expressed only in some. Expression of the normal allele in only the cells that require it may be sufficient to yield a normal phenotype (**FIG. 16-11**).

This approach presents several technical problems. The solutions to these problems must be tailored to the nature of the gene itself, as well as to its product and the types of cells in which it is expressed. First, the gene is cloned and the DNA is introduced into the appropriate cells.

One of the most successful techniques is packaging the normal allele in a viral vector, a virus that moves the normal allele into target cells that currently have a mutant allele. Ideally, the virus should infect a high percentage of the cells. Most important, the virus should do no harm, especially over the long term. Early gene therapy trials used an adenovirus, which causes the common cold. However, some individuals had a strong immune reaction to the virus, so many current trials use an adeno-associated virus that does not cause side effects.

To date, gene therapy has had a greater than 90% success rate in restoring the immune systems of 30 children with *severe combined immunodeficiency (SCID).* (SCID is a group of inherited disorders that seriously compromise the immune system.) This success rate is significantly better than the 50% success rate of the older therapy involving bone marrow transplants.

Although many obstacles must be overcome, gene therapies for several other genetic diseases are under development or are being tested on individuals in clinical trials. Scientists are currently addressing some of the unique problems presented by each disease.

Gene therapy programs are carefully scrutinized

Until recently, major technical advances caused the number of clinical studies involving gene therapy to grow dramatically. However, the death of a young man in a gene therapy trial in 1999, and five more recent cases of cancer (leukemia) in children, one of whom

www.konkur.in

RESEARCH METHOD

Why Is It Used?

Mice are a model system for the development of gene therapy, the use of normal genes to correct or alleviate the symptoms of a genetic disease caused by defective copies of a particular gene. This procedure is performed on humans for certain types of genetic disease.

How Is It Done?

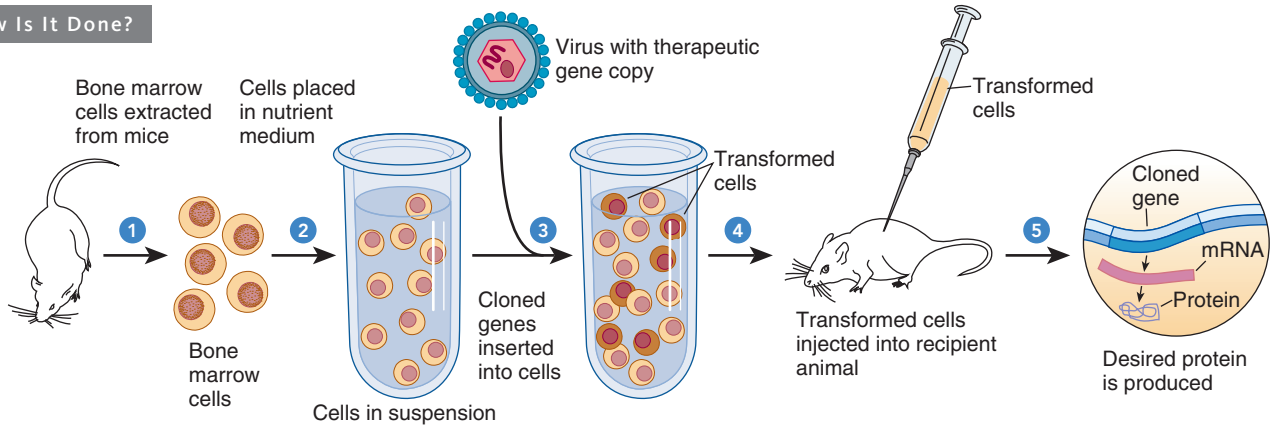

FIGURE 16-11 Gene therapy in bone marrow cells of a mouse

died, led to a shutdown of many trials, pending the outcome of investigations about health risks. The main safety concern in these inquiries is the potential toxicity of viral vectors. The vector used in the young man who died was an adenovirus that was required in large doses to transfer enough copies of the normal alleles for effective therapy. Unfortunately, the high viral doses triggered a fatal immune response in the patient's body. The children who developed leukemia were being treated for SCID. The vector in these cases was a retrovirus that inserted itself into and activated an oncogene that can cause childhood leukemia.

Performing clinical trials on humans always has inherent risks. Researchers carefully select patients and thoroughly explain the potential benefits and risks, as far as they are known, so the patient—or, in the case of children, the parents—can give informed consent for the procedure. However, the problems in gene therapy trials in recent years have researchers busy developing safer alternatives to viral vectors.

- Why are viral vectors of potential concern in human gene therapy?

16.5 GENETIC TESTING AND COUNSELING

LEARNING OBJECTIVES

8 State the relative advantages and disadvantages of amniocentesis, chorionic villus sampling, and preimplantation genetic diagnosis in the prenatal diagnosis of human genetic abnormalities.

9 Distinguish between genetic screening programs for newborns and adults, and discuss the scope and implications of genetic counseling.

Geneticists have made many advances in detecting genetic disorders in individuals in recent years, including in prenatal diagnosis and genetic screening. With these advances comes increased information for couples at risk of having children with genetic diseases. Helping couples understand and deal with the genetic information now available is part of the rapidly expanding field of genetic counseling.

Prenatal diagnosis detects chromosome abnormalities and gene defects

Health-care professionals are increasingly successful at diagnosing genetic diseases prenatally. In the diagnostic technique called **amniocentesis,** a physician obtains a sample of the *amniotic fluid* surrounding the fetus by inserting a needle through the pregnant woman's abdomen, into the uterus, and then into the amniotic sac surrounding the fetus. Some of the amniotic fluid is withdrawn from the amniotic cavity into a syringe (**FIG. 16-12**). The fetus is normally safe from needle injuries because **ultrasound imaging** helps determine the positions of the fetus, placenta, and the needle. (Figure 51-18 shows an ultrasound of a human fetus.) However, there is a 0.5%, or 1 in 200, chance that amniocentesis will induce a miscarriage.

Amniotic fluid contains living cells sloughed off the body of the fetus and hence genetically identical to the cells of the fetus. After cells grow for about 2 weeks in culture in the lab, technicians karyotype dividing cells to detect chromosome abnormalities. Other DNA tests have also been developed to identify most chromosome abnormalities. Amniocentesis, which has been per-

www.konkur.in

KEY POINT In amniocentesis, the fluid surrounding the developing fetus is sampled, usually during the 16th week of pregnancy, to detect genetic and developmental disorders.

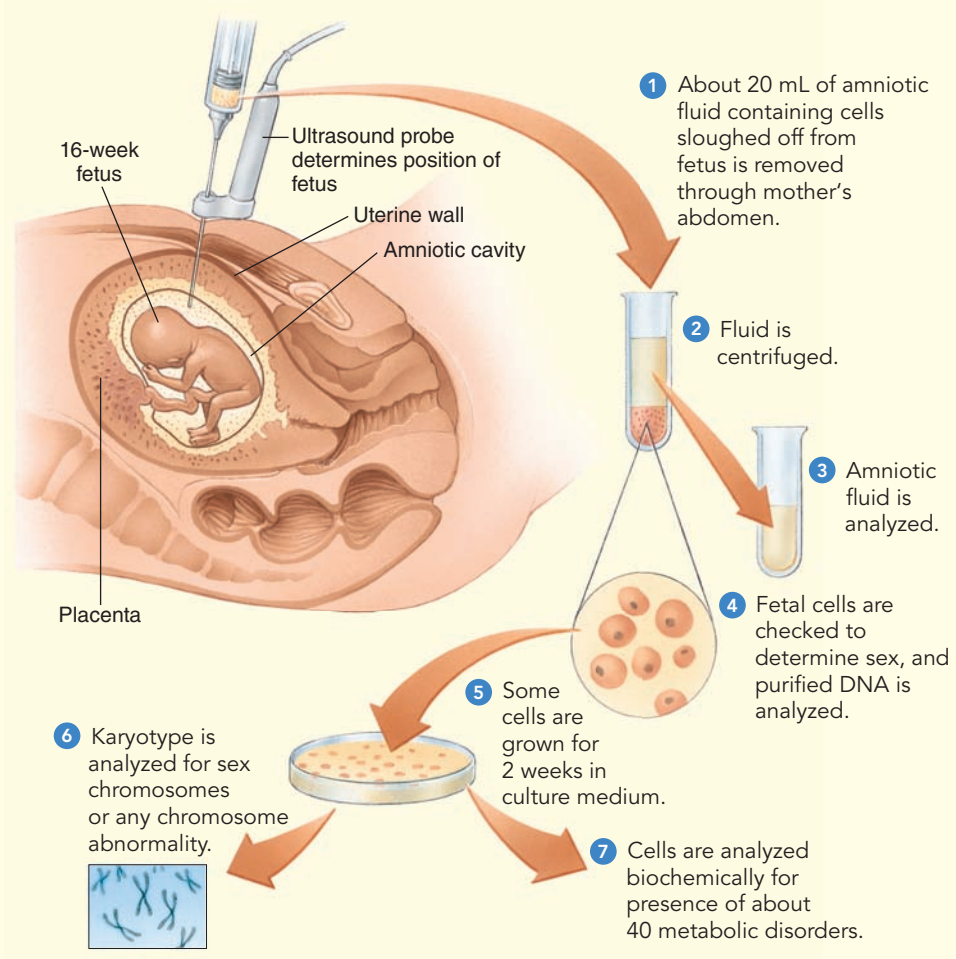

FIGURE 16-12 ***Animated*** **Amniocentesis**
Certain genetic diseases and other abnormal conditions are diagnosed prenatally by amniocentesis.

formed since the 1960s, is routinely offered for pregnant women older than age 35 because their fetuses have a higher-than-normal risk of Down syndrome.

Researchers have developed prenatal tests to detect many genetic disorders with a simple inheritance pattern, but these disorders are rare enough that physicians usually order the tests performed only if they suspect a particular problem. Enzyme deficiencies can often be detected by incubating cells recovered from amniotic fluid with the appropriate substrate and measuring the product; this technique has been useful in prenatal diagnosis of disorders such as Tay-Sachs disease. The tests for several other diseases, including sickle cell anemia, Huntington's disease, and cystic fibrosis, involve directly testing the individual's DNA for the mutant allele.

Amniocentesis is also useful in detecting a condition known as *spina bifida,* in which the spinal cord does not close properly during development. A relatively common malformation (about 1 in 300 births), this birth defect is associated with abnormally high levels of a normally occurring protein, *α-fetoprotein,* in the amniotic fluid. Some of this protein crosses the placenta into the mother's blood, which is tested for *maternal serum α-fetoprotein (MSAFP)* as a screen for spinal cord defects. If an elevated level of MSAFP is detected, the physician performs diagnostic tests, such as ultrasound imaging and amniocentesis. (Interestingly, abnormally *low* levels of MSAFP are associated with Down syndrome and other trisomies.)

One problem with amniocentesis is that most of the conditions it detects are unpreventable and incurable, and the results are generally not obtained until well into the second trimester, when terminating the pregnancy is both psychologically and medically more difficult than earlier. Therefore, researchers have developed tests that yield results earlier in the pregnancy. **Chorionic villus sampling (CVS)** involves removing and studying cells that will form the fetal contribution to the placenta (**FIG. 16-13**). CVS, which has been performed in the United States since about 1983, is associated with a slightly greater risk of infection or miscarriage than amniocentesis, but its advantage is that results are obtained earlier in the pregnancy than in amniocentesis, usually within the first trimester.

A relatively new embryo-screening process, known as **preimplantation genetic diagnosis (PGD),** is available for couples who carry alleles for Tay-Sachs disease, hemophilia, sickle cell anemia, and dozens of other inherited genetic conditions. PGD is an adjunct to assisted reproductive technology. Conception is by **in vitro fertilization (IVF),** in which gametes are collected, eggs are fertilized in a dish in the laboratory, and the resulting embryo is then implanted in the uterus for development (see *Inquiring About: Novel Origins,* in Chapter 50). Prior to implantation, the physician screens single cells of early embryos for one or more genetic diseases before placing a healthy embryo into the woman's uterus. PGD differs from amniocentesis and CVS in that the test is performed *before* a woman is pregnant, so it eliminates the decision of whether or not to terminate the pregnancy if an embryo has a genetic abnormality. However, PGD is not as accurate as amniocentesis or CVS, and it is more expensive. Moreover, PGD is sometimes controversial because some couples use it to choose the gender of their offspring, not to screen for genetic diseases.

www.konkur.in

KEY POINT In chorionic villus sampling, chorionic cells genetically identical to the embryo are sampled, usually during the eighth or ninth week of pregnancy, to detect genetic disorders.

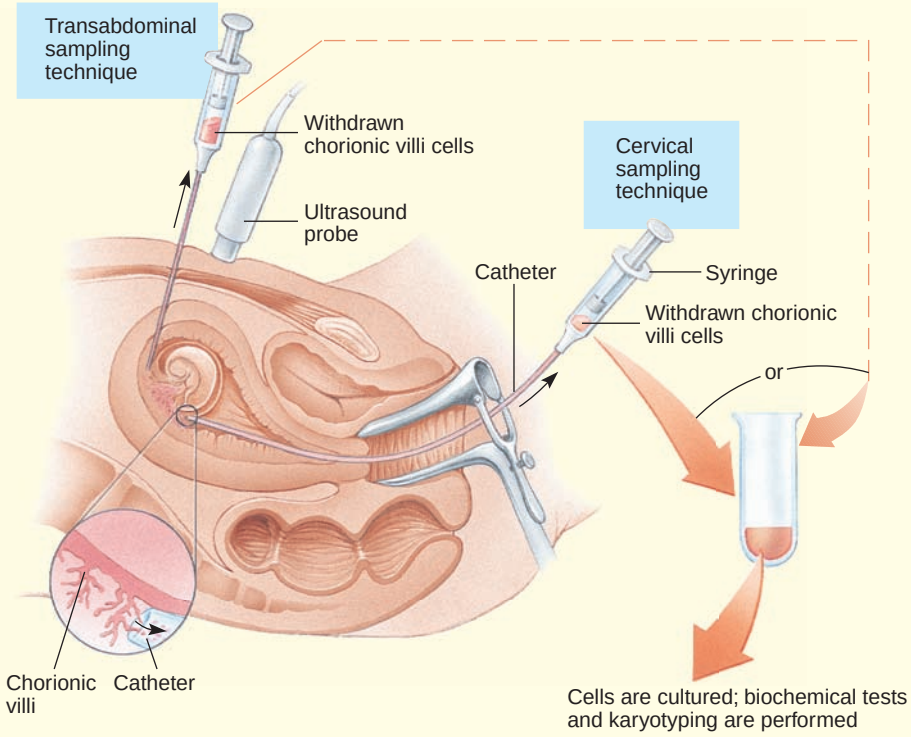

FIGURE 16-13 Chorionic villus sampling (CVS)
This test allows the early diagnosis of some genetic abnormalities. Samples may be obtained by inserting a needle through the uterine wall or the cervical opening.

Although using amniocentesis, CVS, and PGD can help physicians diagnose certain genetic disorders with a high degree of accuracy, the tests are not foolproof, and many disorders cannot be diagnosed at all. Therefore, the lack of an abnormal finding is no guarantee of a normal baby.

Genetic screening searches for genotypes or karyotypes

Genetic screening is a systematic search through a population for individuals with a genotype or karyotype that might cause a serious genetic disease in themselves or their offspring. There are two main types of genetic screening, for newborns and for adults, and each serves a different purpose. Newborns are screened primarily as the first step in preventive medicine, and adults are screened to help them make informed reproductive decisions.

Newborns are screened to detect and treat certain genetic diseases before the onset of serious symptoms. The routine screening of infants for PKU began in 1962 in Massachusetts. Laws in all 50 states of the United States, as well as in many other countries, currently require PKU screening. Sickle cell anemia is also more effectively treated with early diagnosis. Screening newborns for sickle cell anemia reduces infant mortality by about 15% because doctors can administer daily doses of antibiotics, thereby preventing bacterial infections common to newborns with the disease. The number of genetic disorders that can be screened in newborns is rapidly increasing, and the March of Dimes currently recommends screening newborns for 29 disorders, most of which are genetic.

Genetic screening of adults identifies carriers (heterozygotes) of recessive genetic disorders. If both prospective parents are heterozygous, the carriers are counseled about the risks involved in having children. Since the 1970s, about 1 million young Jewish adults in the United States, Israel, and other countries have been screened voluntarily for Tay-Sachs disease, and about 1 in 30 has been identified as a carrier. Tay-Sachs screening programs have reduced the incidence of Tay-Sachs disease to almost zero.

Genetic counselors educate people about genetic diseases

Couples who are concerned about the risk of abnormality in their children, because they have either an abnormal child or a relative affected by a hereditary disease, may seek **genetic counseling** for medical and genetic information as well as support and guidance. Genetic clinics, available in most major metropolitan centers, are usually affiliated with medical schools.

Genetic counselors, who have received training in counseling, medicine, and human genetics, provide people with the information they need to make reproductive decisions. They offer advice, tempered with respect and sensitivity, in terms of risk estimates—that is, the *probability* that any given offspring will inherit a particular condition. The counselor uses the complete family histories of both the man and the woman, and a clinical geneticist (a physician who specializes in genetics) may screen for the detection of heterozygous carriers of certain conditions.

When a disease involves only a single gene locus, probabilities can usually be easily calculated. For example, if one prospective parent is affected with a trait that is inherited as an autosomal dominant disorder, such as Huntington's disease, the probability that any given child will have the disease is 0.5, or 50%. The birth to phenotypically normal parents of a child affected with an autosomal recessive trait, such as albinism or PKU, establishes that both parents are heterozygous carriers, and the probability that any subsequent child will be affected is therefore 0.25, or 25%. For a disease inherited through a recessive allele on the X chromo-

www.konkur.in

some, such as hemophilia A, a normal woman and an affected man will have daughters who are carriers and sons who are normal. The probability that the son of a carrier mother and a normal father will be affected is 0.5, or 50%; the probability that their daughter will be a carrier is also 0.5, or 50%.

It is important for identified carriers to receive appropriate genetic counseling. A genetic counselor is trained not only to provide information pertaining to reproductive decisions but also to help individuals understand their situation and avoid feeling stigmatized.

- What is the purpose of genetic screening for newborns?
- What is the purpose of genetic screening for adults?

16.6 HUMAN GENETICS, SOCIETY, AND ETHICS

LEARNING OBJECTIVE

10 Discuss the controversies of genetic discrimination.

Many misconceptions exist about genetic diseases and their effects on society. Some people erroneously think of certain individuals or populations as genetically unfit and thus responsible for many of society's ills. They argue, for example, that medical treatment of people affected with genetic diseases, especially those who reproduce, increases the frequency of abnormal alleles in the population. However, such notions are incorrect. Genetic disorders are so rare that modern medical treatments will have only a negligible effect on their incidence.

Recessive mutant alleles are present in *all* individuals and *all* ethnic groups; no one is exempt. According to one estimate, each of us is heterozygous for several (3 to 15) harmful recessive alleles, any of which could cause debilitating illness or death in the homozygous state. Why, then, are genetic diseases relatively uncommon? Each of us has many thousands of essential genes, any of which can be mutated. It is very unlikely that the abnormal alleles that one individual carries are also carried by that individual's mate. Of course, this possibility is more likely if the harmful allele is a relatively common one, such as the one responsible for cystic fibrosis.

Relatives are more likely than nonrelatives to carry the same harmful alleles, having inherited them from a common ancestor. A greater-than-normal frequency of a particular genetic disease among offspring of **consanguineous matings,** matings between genetically related individuals, is often the first clue that the mode of inheritance is autosomal recessive. The offspring of consanguineous matings have a small but significantly increased risk of genetic disease. In fact, they account for a disproportionately high percentage of those individuals in the population with autosomal recessive disorders. Because of this perceived social cost, marriages of close relatives, including first cousins, are prohibited by about half the states in the United States. However, consanguineous marriages are still relatively common in many other countries.

Genetic discrimination provokes heated debate

One of the fastest-growing areas of medical diagnostics is genetic screening and testing, and new genetic tests that screen for diseases such as cystic fibrosis, sickle cell anemia, Huntington's disease, colon cancer, and breast cancer increase each year. However, genetic testing raises many social, ethical, and legal issues that we as a society must address.

One of the most difficult issues is whether genetic information should be available to health insurance and life insurance companies. Many people think genetic information should not be given to insurance companies, but others, including employers, insurers, and many organizations representing people affected by genetic disorders, say such a view is unrealistic. If people use genetic tests to help them decide when to buy insurance and how much, then insurers insist they should also have access to this information. Insurers say they need access to genetic data to help calculate equitable premiums (insurance companies average risks over a large population). However, some are concerned that insurers might use the results of genetic tests to discriminate against people with genetic diseases or to deny them coverage.

Physicians argue that people at risk for a particular genetic disease might delay being tested because they fear genetic discrimination from insurers and employers. **Genetic discrimination** is discrimination against an individual or family members because of differences from the "normal" genome in that individual. The perception of genetic discrimination already exists in society. A 1996 study found that 25% of 332 people with family histories of one or more genetic disorders thought they had been refused life insurance, 22% thought they had been refused health insurance, and 13% thought they had been denied employment because of genetic discrimination. In a 1998 survey by the National Center for Genetic Resources, 63% of respondents said they probably or definitely would not take a genetic test if the results could be disclosed to either their employers or insurers.

Complicating the issue even more, genetic tests are sometimes difficult to interpret, in part because of the many complex interactions between genes and the environment. If a woman tests positive for an allele that has been linked to breast cancer, for example, she is at significant risk, but testing positive does not necessarily mean she will develop breast cancer. These uncertainties also make it hard to decide what form of medical intervention, from frequent mammograms to surgical removal of healthy breasts, is appropriate.

The Ethical, Legal, and Social Implications (ELSI) Research Program of the National Human Genome Research Institute has developed principles designed to protect individuals against genetic discrimination. In 2008 the **Genetic Information Nondiscrimination Act (GINA)** extended significant protection against workplace and health discrimination. This law prohibits employers and insurance companies from discriminating on the basis of information derived from genetic tests. For example, neither employers nor insurance companies are permitted to request a genetic test. Employers cannot base employment decisions on

www.konkur.in

genetic information. Also, insurance companies cannot cancel or deny coverage or increase the price of premiums based on genetic information.

Many ethical issues related to human genetics must be addressed

Genetic discrimination is only one example of ethical issues arising from our expanding knowledge of human genetics. Consider the following questions, all of which deal with the broad ethical issue of individual rights: What is the youngest age at which genetic testing should be permitted for adult-onset diseases, such as Huntington's disease? What are the emotional and psychological effects on individuals who are told they have tested positive for an incurable genetic disease? Should testing be performed when some family members want testing and others do not? Should parents be able to test their minor children? Should access to genetic test data be permitted in cases of paternity or kinship testing? Should states be able to collect genetic data on their residents? Should school administrators or law enforcement agencies have access to genetic data? These questions are only a sample of the many issues that both ethicists and society must consider now and in the future. As human genetics assumes an increasingly important role in society, issues of genetic privacy and the confidentiality of genetic information must be addressed.

Review

- Why is it incorrect to assume that certain individuals or populations carry most of the abnormal alleles found in humans?
- To be expressed, an autosomal recessive genetic disease must be homozygous. What relationship does this fact have to consanguineous matings?
- Why do health and life insurance companies want genetic information about their clients?

SUMMARY: FOCUS ON LEARNING OBJECTIVES

16.1 *(page 348)*

1 Distinguish between karyotyping and pedigree analysis.

- Studies of an individual's **karyotype,** the number and kinds of chromosomes present in the nucleus, enable researchers to identify various chromosome abnormalities.
- A **pedigree** is a "family tree" that shows the transmission of genetic traits within a family over several generations. Pedigree analysis is useful in detecting autosomal dominant mutations, autosomal recessive mutations, X-linked recessive mutations, and defects due to **genomic imprinting,** which is the expression of a gene based on its parental origin.

CENGAGENOW™ Learn more about pedigrees by clicking on the figure in CengageNOW.

2 Discuss the implications of the Human Genome Project.

- The **human genome** is the total genetic information in human cells. The **Human Genome Project** sequenced the DNA in the nuclear human genome. Now that the human genome has been sequenced, researchers will be busy for decades identifying genes and understanding what each gene's role is, how each gene interacts with other genes, and how the expression of each gene is regulated in different tissues. For example, researchers have begun to use **genome-wide association (GWA) scans** to identify genetic variations associated with complex human diseases.

3 Discuss the mouse model for studying cystic fibrosis.

- The use of animal models greatly helps researchers investigate human disease. Researchers used **gene targeting** to produce strains of mice that are either homozygous or heterozygous for cystic fibrosis. Results from these studies may yield more effective drugs for treating the disease.

16.2 *(page 351)*

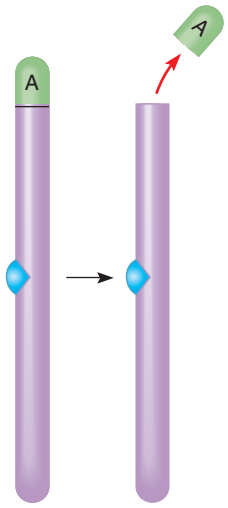
4 Explain how nondisjunction in meiosis is responsible for chromosome abnormalities such as Down syndrome, Klinefelter syndrome, and Turner syndrome.

- In **aneuploidy,** there are either missing or extra copies of certain chromosomes. Aneuploidies include **trisomy,** in which an individual's cells contain an extra chromosome, and **monosomy,** in which one member of a pair of chromosomes is missing.
- **Trisomy 21,** the most common form of **Down syndrome,** and **Klinefelter syndrome** (XXY) are examples of trisomy. **Turner syndrome** (X0) is an example of monosomy.
- Trisomy and monosomy are caused by meiotic **nondisjunction,** in which sister chromatids or homologous chromosomes fail to move apart properly during meiosis.

CENGAGENOW™ Learn more about karyotypes by clicking on the figure in CengageNOW.

5 Distinguish among the following structural abnormalities in chromosomes: translocations, deletions, and fragile sites.

- In a **translocation,** part of one chromosome becomes attached to another. About 4% of individuals with Down syndrome have a translocation in which the long arm of chromosome 21 is attached to the long arm of one of the larger chromosomes, such as chromosome 14.
- A **deletion** can result in chromosome breaks that fail to rejoin. The deletion may range in size from a few base pairs to an entire chromosome arm. One deletion disorder in humans is **cri du chat syndrome,** in which part of the short arm of chromosome 5 is deleted.



www.konkur.in

- **Fragile sites** may occur at specific locations on both chromatids of a chromosome. In **fragile X syndrome,** a fragile site occurs near the tip on the X chromosome, where the nucleotide triplet CGG is repeated many more times than is normal. Fragile X syndrome is the most common cause of inherited mental retardation.

16.3 *(page 358)*

6 State whether each of the following genetic defects is inherited as an autosomal recessive, autosomal dominant, or X-linked recessive: phenylketonuria (PKU), sickle cell anemia, cystic fibrosis, Tay-Sachs disease, Huntington's disease, and hemophilia A.

- Most human genetic diseases that show a simple inheritance pattern are transmitted as autosomal recessive traits. **Phenylketonuria (PKU)** is an autosomal recessive disorder in which toxic phenylketones damage the developing nervous system. **Sickle cell anemia** is an autosomal recessive disorder in which abnormal hemoglobin (the protein that transports oxygen in the blood) is produced. **Cystic fibrosis** is an autosomal recessive disorder in which abnormal secretions are produced primarily in organs of the respiratory and digestive systems. **Tay-Sachs disease** is an autosomal recessive disorder caused by abnormal lipid metabolism in the brain.
- **Huntington's disease** is an autosomal dominant inheritance pattern that results in mental and physical deterioration, usually beginning in adulthood.
- **Hemophilia A** is an X-linked recessive disorder that results in a defect in a blood component required for clotting.

16.4 *(page 361)*

7 Briefly discuss the process of gene therapy, including some of its technical challenges.

- In **gene therapy,** the normal allele is cloned and the DNA is introduced into certain human cells where its expression may be sufficient to yield a normal phenotype.
- One technical challenge in gene therapy is finding a safe, effective **vector,** usually a virus, to deliver the gene of interest into the cells.

16.5 *(page 362)*

8 State the relative advantages and disadvantages of amniocentesis, chorionic villus sampling, and preimplantation genetic diagnosis in the prenatal diagnosis of human genetic abnormalities.

- In **amniocentesis,** a physician samples the amniotic fluid surrounding the fetus and cultures and screens the fetal cells suspended in the fluid for genetic defects. Amniocentesis provides results in the second trimester of pregnancy.

CENGAGENOW™ Learn more about amniocentesis by clicking on the figure in CengageNOW.

- In **chorionic villus sampling (CVS),** a physician removes and studies some of the fetal cells. CVS provides results in the first trimester of pregnancy but is associated with a slightly greater risk of infection and miscarriage than amniocentesis.
- Couples who conceive by in vitro fertilization may elect to have **preimplantation genetic diagnosis (PGD).** A physician screens the embryos for one or more genetic diseases before placing a healthy embryo into the woman's uterus. PGD is not as accurate as amniocentesis or CVS, and it is more expensive.

9 Distinguish between genetic screening programs for newborns and adults, and discuss the scope and implications of genetic counseling.

- **Genetic screening** identifies individuals who might carry a serious genetic disease. Screening of newborns is the first step in preventive medicine, and screening of adults helps them make informed reproductive decisions.
- Couples who are concerned about the risk of abnormality in their children may seek **genetic counseling.** A genetic counselor provides medical and genetic information pertaining to reproductive decisions and helps individuals understand their situation and avoid feeling stigmatized.

16.6 *(page 365)*

10 Discuss the controversies of genetic discrimination.

- **Genetic discrimination** is discrimination against an individual or family member because of differences from the "normal" genome in that individual.
- One of the most difficult issues in avoiding genetic discrimination is whether genetic information should be available to employers and to health and life insurance companies. The **Genetic Information Nondiscrimination Act (GINA)** prohibits employers and insurance companies from discriminating on the basis of information derived from genetic tests.

TEST YOUR UNDERSTANDING

1. A diagram of a pedigree shows (a) controlled matings between members of different true-breeding strains (b) the total genetic information in human cells (c) a comparison of DNA sequences among genomes of humans and other species (d) the subtle genetic differences among unrelated people (e) the expression of genetic traits in the members of two or more generations of a family
2. Which pattern of inheritance is associated with a trait that (1) is not usually expressed in the parents, (2) is expressed in about one-fourth of the children, and (3) is expressed in both male and female children? (a) autosomal recessive (b) autosomal dominant (c) X-linked recessive (d) X-linked dominant (e) Y-linked
3. An abnormality in which there is one more or one fewer than the normal number of chromosomes is called (a) a karyotype (b) a fragile site (c) an aneuploidy (d) trisomy (e) a translocation
4. The failure of chromosomes to separate normally during cell division is called (a) a fragile site (b) an inborn error of metabolism (c) a satellite knob (d) a translocation (e) nondisjunction
5. The chromosome composition of an individual or cell is called its (a) karyotype (b) nucleotide triplet repeat (c) pedigree (d) DNA microarray (e) translocation
6. An inherited disorder caused by a defective or absent enzyme is called (a) a karyotype (b) trisomy (c) a reciprocal translocation (d) an inborn error of metabolism (e) an aneuploidy
7. In _____, a genetic mutation codes for an abnormal hemoglobin molecule that is less soluble than usual and more likely than normal to deform the shape of the red blood cell. (a) Down syndrome (b) Tay-Sachs disease (c) sickle cell anemia (d) PKU (e) hemophilia A

www.konkur.in

8. During this procedure, a sample of the fluid that surrounds the fetus is obtained by inserting a needle through the walls of the abdomen and uterus. (a) DNA marking (b) chorionic villus sampling (c) ultrasound imaging (d) preimplantation genetic diagnosis (e) amniocentesis

9–11. Examine the following pedigrees and decide on the most likely mode of inheritance of each disorder. (a) autosomal recessive (b) autosomal dominant (c) X-linked recessive (d) a, b, or c (e) a or c

9. 
10. 
11. 
CRITICAL THINKING

1. **SCIENCE, TECHNOLOGY, AND SOCIETY.** Imagine that you are a genetic counselor. What advice or suggestions might you give in the following situations?
   a. A couple has come for advice because the woman had a sister who died of Tay-Sachs disease.
   b. A young man and woman who are not related are engaged to be married. However, they have learned that the man's parents are first cousins, and they are worried about the possibility of increased risk of genetic defects in their own children.
   c. A young woman's paternal uncle (her father's brother) has hemophilia A. Her father is free of the disease, and there has never been a case of hemophilia A in her mother's family. Should she be concerned about the possibility of hemophilia A in her own children?
   d. A 20-year-old man is seeking counseling because his father was recently diagnosed with Huntington's disease.
   e. A 45-year-old woman has just been diagnosed with Huntington's disease. She says she will not tell her college-age sons because of the burden it will place on them. Given that the woman, not her sons, is your client, do you have a duty to inform the sons? Explain your reasoning.
2. A common belief about human genetics is that an individual's genes alone determine his or her destiny. Explain why this is a misconception.
3. Is a chromosome deletion equivalent to a frameshift mutation (discussed in Chapter 13)? Why or why not?
4. **EVOLUTION LINK.** Explain some of the evolutionary implications that one can conclude from the fact that mice and humans have about 500 DNA segments that are completely identical.
5. **ANALYZING DATA.** Examine Figure 16-10, and estimate the age at which half of individuals carrying a Huntington's disease allele will have developed symptoms. At what age will three-fourths of these individuals have symptoms?

CENGAGENOW™ Additional questions are available in CengageNOW at www.cengage.com/login.

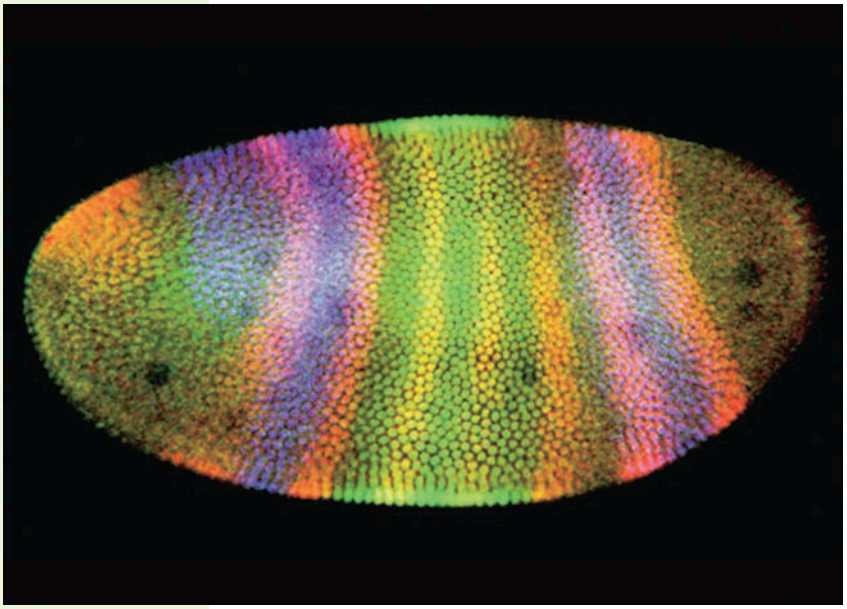
17 Developmental Genetics



Stephen W. Paddock

Differential gene expression in the model organism *Drosophila melanogaster.*

KEY CONCEPTS

17.1 Differential gene expression controls the development of specialized tissues and organs.

17.2 Many genes that regulate development are quite similar in a wide range of organisms, from fruit flies to humans. Mutations in genes that regulate development have provided insights into how those genes function.

17.3 Mutations in oncogenes and tumor suppressor genes may lead to cancer.

Developmental genetics is the study of the genes involved in cell differentiation and development of an organism. Until the late 1970s, biologists knew little about how genes interact to control development. Unraveling the genetic interactions that take place during development was an intractable problem using traditional methods. However, rapid progress in recombinant DNA research led scientists to search for developmental mutants and to apply sophisticated techniques to study them. (A *mutant* is an individual with an abnormal phenotype caused by a gene mutation.)

The organism in the photograph is a developing embryo of the fruit fly *Drosophila melanogaster.* Geneticists used **immunofluorescence,** in which a fluorescent dye is joined to an antibody that binds to a specific protein to localize the protein. In this case researchers bound three different antibodies—one red, one blue, and one yellow—to three specific proteins. The patterns of colored bands indicate that different cells of the embryo have *differential gene expression*—that is, different genes are active at the same time.

Work with *Drosophila* and other organisms has profound implications for understanding both normal human development (including aging) and malfunctions that lead to birth defects and cancer. Striking similarities among genes that govern development in widely different species suggest that developmentally important genetic mechanisms are deeply rooted in the evolutionary history of multicellular organisms. There are

www.konkur.in

also differences in species' developmental patterns that reflect their separate evolutionary paths. As you will learn in Chapter 18, developmental genes have played a role in reshaping organisms during the course of their evolution.

Biologists are now studying how genes are activated, inactivated, and modified to control development. Eventually, scientists expect to understand how a single cell—a fertilized egg—develops into a multicellular organism as complex as a human.

17.1 CELL DIFFERENTIATION AND NUCLEAR EQUIVALENCE

LEARNING OBJECTIVES

1. Distinguish between cell determination and cell differentiation, and between nuclear equivalence and totipotency.
2. Describe the classic experiments of Steward, Gurdon, and Wilmut.
3. Define *stem cells*, distinguish between embryonic stem cells and pluripotent stem cells, and describe some of the promising areas of research involving stem cells.

The study of **development,** broadly defined as all the changes that occur in the life of an individual, encompasses some of the most fascinating and difficult problems in biology today. Of particular interest is the process by which cells specialize and organize into a complex organism. During the many cell divisions required for a single cell to develop into a multicellular organism, groups of cells become gradually committed to specific patterns of gene activity through the process of **cell determination.** As cell determination proceeds, it restricts an embryonic cell's developmental pathway so that its fate becomes more and more limited. The final step leading to cell specialization is **cell differentiation.** A differentiated cell, which has a characteristic appearance and characteristic activities, appears to be irreversibly committed to its fate.

Another intriguing part of the developmental puzzle is the building of the body. In **morphogenesis,** the development of form, cells in specific locations differentiate and become spatially organized into recognizable structures. Morphogenesis proceeds through the multistep process of **pattern formation,** the organization of cells into three-dimensional structures. Pattern formation includes signaling between cells, changes in cell shapes, and cell migrations. Depending on their location, cells are exposed to different concentrations of signaling molecules that specify positional information. Thus, *where* a given cell is located often determines *what* it will become when it matures.

The human body, like that of other vertebrates, contains about 250 recognizably different types of cells (**FIG. 17-1**). Combinations of these specialized cells, known as **differentiated cells,** are organized into diverse and complex structures—such as the eye, hand, and brain—each capable of carrying out many sophisticated activities. Most remarkable of all is the fact that all the structures of the body and the different cells within them descend from a unicellular **zygote,** a fertilized egg.

All multicellular organisms undergo complex patterns of development. The root cells of plants, for example, have structures and functions very different from those of the various types of cells located in leaves. Diversity is also found at the molecular level; most strikingly, each type of plant or animal cell makes a highly specific set of proteins. In some cases, such as the protein hemoglobin in red blood cells, one cell-specific protein may make up more than 90% of the cell's total mass of protein. Other cells may have a complement of many cell-specific proteins, each of which is present in small amounts but still plays an essential role. However, because certain proteins are required in every type of cell (all cells, for example, require the same enzymes for glycolysis), cell-specific proteins usually make up only a fraction of the total number of different kinds of proteins.

When researchers first discovered that each type of differentiated cell makes a unique set of proteins, some scientists hypothesized that each group of cells loses the genes it does not need and retains only those required. However, this does not generally seem true. According to the principle of **nuclear equivalence,** the nuclei of essentially all differentiated adult cells of an individual are genetically (though not necessarily metabolically) identical to one another and to the nucleus of the zygote from which they descended. This means that virtually all *somatic cells* in an adult have the same genes. However, different cells express different subsets of these genes.

Somatic cells are all the cells of the body other than **germ line cells,** which ultimately give rise to a new generation. In animals, germ line cells—whose descendants ultimately undergo meiosis and differentiate into gametes—are generally set aside early in development. In plants, the difference between somatic cells and germ line cells is not as distinct, and the determination that certain cells undergo meiosis is made much later in development.

The evidence for nuclear equivalence comes from cases in which differentiated cells or their nuclei have been found to retain the potential of directing the development of the entire organism. Such cells or nuclei are said to exhibit **totipotency.**

Most cell differences are due to differential gene expression

Because genes do not seem to be lost regularly during development (and thus nuclear equivalence is present in different cell types), differences in the molecular composition of cells must be regulated by the activities of different genes. The process of developmental gene regulation is often referred to as **differential gene expression.**

As discussed in Chapter 14, the expression of eukaryotic genes is regulated in many ways and at many levels. For example, a particular enzyme may be produced in an inactive form and then be activated later. However, much of the regulation that is important in development occurs at the transcriptional level. The transcription of certain sets of genes is repressed, whereas that of other sets is activated. Even the expression of genes that are *constitutive*—that is, constantly transcribed—is regulated during development so that the *quantity* of each product varies from one tissue type to another.

www.konkur.in

KEY POINT As development proceeds, somatic cells that previously had the potential to develop into a variety of cells become increasingly committed to a specific fate.

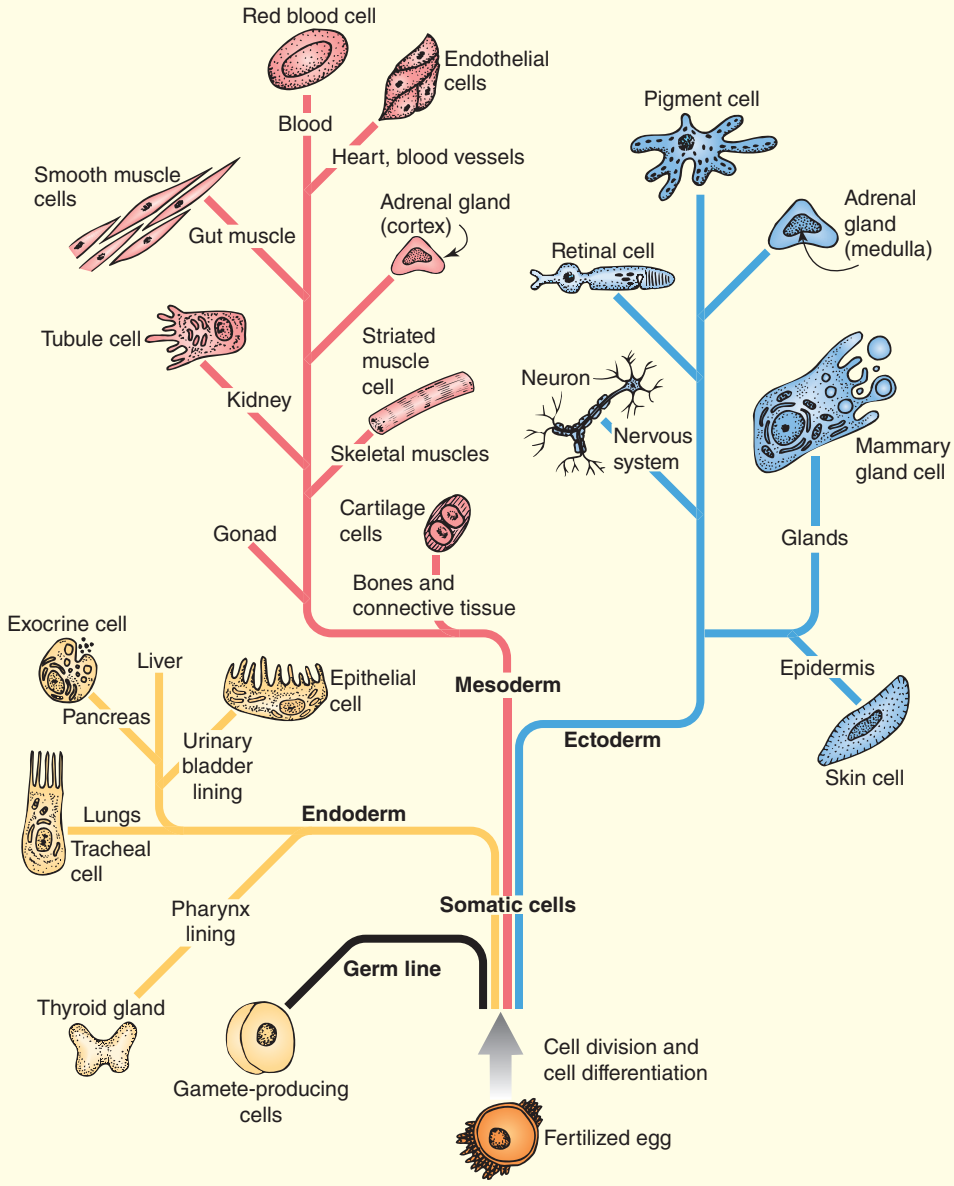


FIGURE 17-1 Vertebrate cell lineages

Repeated divisions of the fertilized egg (*bottom*) result in the establishment of tissues containing groups of specialized cells. Germ line cells (cells that produce the gametes) are set aside early in development. Somatic cells progress along various developmental pathways undergoing a series of commitments that progressively determine their fates.

We can think of differentiation as a series of pathways leading from a single cell to cells in each of the different specialized tissues, arranged in an appropriate pattern. At times a cell makes genetic commitments to the developmental path its descendants will follow. These commitments gradually restrict the development of the descendants to a limited set of final tissue types. Determination, then, is a progressive fixation of the fate of a cell's descendants.

As the development of a cell becomes determined along a differentiation pathway, its physical appearance may or may not change significantly. Nevertheless, when a stage of determination is complete, the changes in the cell usually become self-perpetuating and are not easily reversed. Cell differentiation is usually the last stage in the developmental process. At this stage, a precursor cell becomes structurally and functionally recognizable as a bone cell,

www.konkur.in

for example, and its pattern of gene activity differs from that of a neuron (nerve cell) or any other cell type.

A totipotent nucleus contains all the instructions for development

In plants, some differentiated cells can be induced to become the equivalent of embryonic cells. Biologists use *tissue culture techniques* to isolate individual cells from certain plants and to allow them to grow in a nutrient medium.

In the 1950s, F. C. Steward and his coworkers at Cornell University conducted some of the first experiments investigating cell totipotency in plants (**FIG. 17-2**). **Totipotent cells** have the potential to give rise to all parts of an organism because they contain a complete set of genetic instructions required to direct the normal development of an entire organism. Steward and his colleagues induced root cells from a carrot to divide in a liquid nutrient medium, forming groups of cells called *embryoid* (embryo-like) *bodies.* These clumps of dividing cells were then transferred to an agar medium, which provided nutrients and a solid supporting structure for the developing plant cells. Some of the cells of the embryoid bodies gave rise to roots, stems, and leaves. The resulting small plants, called *plantlets* to distinguish them from true seedlings, were then transplanted to soil, where they ultimately developed into adult plants capable of producing flowers and viable seeds.

Because these plants are all derived from the same parent plant, they are genetically alike and therefore constitute a clone. As mentioned in Chapter 15, a **clone** consists of individual organisms, cells, or DNA molecules that are genetically identical to another individual, cell, or DNA molecule, from which it was derived. The methods of plant tissue culture are now extensively used to produce genetically engineered plants because they enable researchers to regenerate whole plants from individual cells that have incorporated recombinant DNA molecules (see Chapter 38).

In the 1950s, researchers began testing whether steps in the process of determination are reversible in animal cells by transplanting the *nucleus* of a cell in a relatively late stage of development into an egg cell that had been *enucleated* (that is, its own nucleus had been destroyed). Robert Briggs and Thomas J. King of the Institute for Cancer Research in Pennsylvania pioneered *nuclear transplantation experiments.* They transplanted nuclei from frog cells at different stages of development into egg cells whose nuclei had been removed. Some of the transplants proceeded normally through several developmental stages, and a few even developed into normal tadpoles. As a rule, the nuclei transplanted from cells at earlier stages were most likely to support development to the tadpole stage. As the fate of the cells became more and more determined, the probability quickly declined that a transplanted nucleus could control normal development.

British biologist John B. Gurdon carried out experiments on nuclear transplantation in frogs during the 1960s. In a few cases he demonstrated that nuclei isolated from the intestinal epithelial cells of a tadpole directed development up to the tadpole stage (**FIG. 17-3**). This result occurred infrequently (about 1.5% of the time); however, in these kinds of experiments success counts more than failure. Therefore, he could safely conclude that at least some nuclei of differentiated animal cells are in fact totipotent.

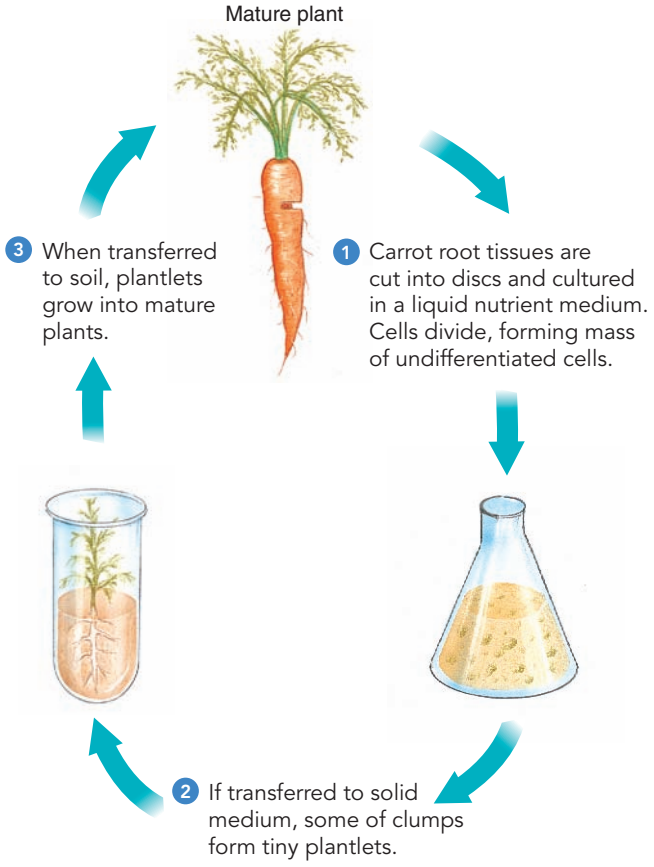
For many years, because these successes with frogs could not be repeated with mammalian embryos, many developmental biologists concluded that some fundamental feature of mammalian reproductive biology might be an impenetrable barrier to mammalian cloning. This perception changed markedly in 1996 and 1997 with the first reports of the birth of cloned mammals.

KEY EXPERIMENT

QUESTION: Are differentiated somatic plant cells totipotent?

HYPOTHESIS: Differentiated somatic carrot cells can be induced to develop into an entire plant.

EXPERIMENT: F. C. Steward and his coworkers cultured carrot root tissues in a liquid nutrient medium. These cells divided to form clumps of undifferentiated cells. The clumps were then transferred to a solid growth medium.



RESULTS AND CONCLUSION: The development of a complete carrot plant from differentiated somatic cells demonstrated the totipotency of these cells.

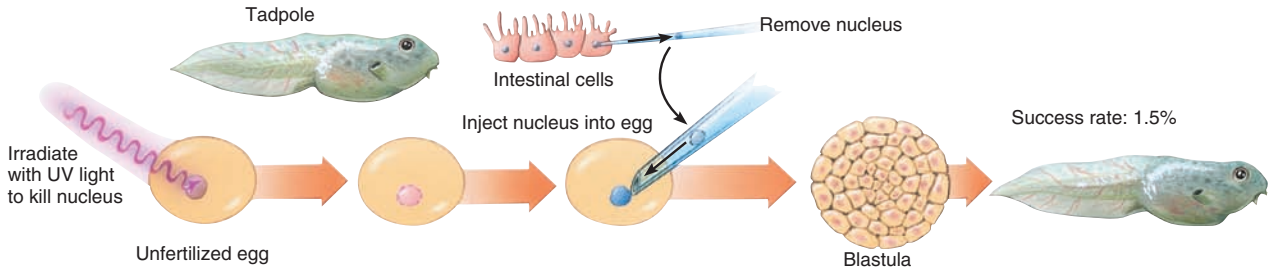
KEY EXPERIMENT

QUESTION: Are nuclei in differentiated animal cells totipotent?

HYPOTHESIS: Nuclei from differentiated cells contain the information required for normal development.

EXPERIMENT: John Gurdon injected the nuclei of differentiated cells (tadpole intestinal cells) into eggs whose own nuclei were destroyed by ultraviolet radiation.



RESULTS AND CONCLUSION: Normal development proceeded to the tadpole stage in about 1.5% of trials, indicating that the genes for programming development up to that point were still present and could be appropriately activated.

Source: Gurdon, J. B. "The Developmental Capacity of Nuclei Taken from Intestinal Epithelium Cells of Feeding Tadpoles." *Journal of Embryology and Experimental Morphology* Vol. 10, Dec. 1962.

FIGURE 17-3 Gurdon's experiment on nuclear totipotency in frogs

The first cloned mammal was a sheep

In 1996, Ian Wilmut, Keith Campbell, and their coworkers at the Roslin Institute in Edinburgh, Scotland, reported that they had succeeded in cloning sheep by using nuclei from an early stage of sheep embryos (the *blastocyst* stage; see Chapter 51). These scientists received worldwide attention in early 1997 when they announced the birth of a lamb named Dolly (after the singer Dolly Parton). Dolly's genetic material was derived from a cultured sheep mammary gland cell that was fused with an enucleated sheep's egg. The resulting cell divided and developed into an embryo that was then cultured in vitro until it reached a stage at which it could be transferred to a host mother (**FIG. 17-4**). Not surprisingly, the overall success rate was low: of 277 fused cells, only 29 developed into embryos that could be transferred, and Dolly was the only live lamb produced.

Why did Wilmut's team succeed when so many other researchers had failed? Applying the basic principles of cell biology, they recognized that the **cell cycles** (see Chapter 10) of the egg cytoplasm and the donor nucleus were not synchronous. The egg cell is arrested at metaphase II of meiosis, whereas the actively growing donor somatic cell is usually in the DNA synthesis phase (S), or in G_2. By withholding certain nutrients from the mammary gland cells used as donors, the researchers caused these cells to enter a nondividing state referred to as G_0. This had the effect of synchronizing the cell cycles of the donor nucleus and the egg. They then used an electric shock to fuse the donor cell with the egg and initiate embryo development.

Although an extremely high level of technical expertise is required, these and other researchers have modified and extended these techniques to produce cloned calves, pigs, horses, rats, mice, dogs, and cats, among others. The list of mammalian species successfully cloned continues to grow. However, the success rate for each set of trials is low, around 1% to 2%, and the incidence of genetic defects is high. Dolly was euthanized at age 6 because she was suffering from a virus-induced lung cancer that infected several sheep where she was housed. However, she developed arthritis at 5½ years, which is relatively young for a sheep to have this degenerative disease. Some biologists speculate that using adult genetic material to produce a clone might produce an animal with prematurely old cells (see discussion of telomeres and cell aging in Chapter 12). Further research may provide some answers to this potential problem.

The main focus of cloning research is the production of **transgenic** organisms, in which foreign genes have been incorporated (see Chapter 15). Researchers are actively pursuing new techniques to improve the efficiency of the cloning process. Only then will it be possible to produce large numbers of cloned transgenic animals for a variety of uses, such as increasing the populations of endangered species. For example, the first healthy clone of an endangered species, a wild relative of cattle known as a *banteng*, was born in 2003. The nucleus for this clone came from a frozen skin cell of a banteng that died in 1980 at the San Diego Zoo.

Stem cells divide and give rise to differentiated cells

Stem cells are undifferentiated cells that can divide to produce differentiated descendants yet retain the ability to divide to maintain the stem cell population. When a stem cell divides, its daughter cells can remain stem cells or differentiate into specialized cells such as muscle cells, neurons, or blood cells. What happens depends on the presence or absence of an array of biochemical signals. One of

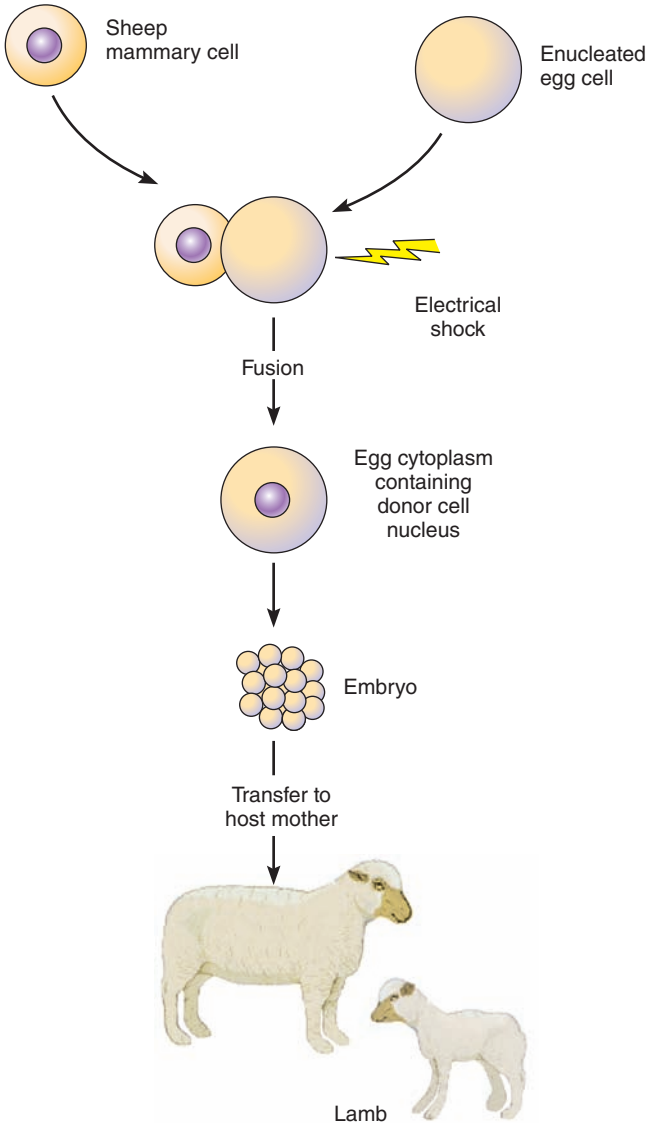
www.konkur.in

KEY EXPERIMENT

QUESTION: Are nuclei in differentiated mammalian cells totipotent?

HYPOTHESIS: The nucleus of a differentiated cell from an adult mammal fused with an enucleated egg can provide the genetic information to direct normal development.

EXPERIMENT: Ian Wilmut and his colleagues produced a sheep embryo by fusing a cultured adult sheep mammary cell with an enucleated sheep's egg. He then implanted the embryo into the uterus of a host mother.



RESULTS AND CONCLUSION: Normal development proceeded, and a female lamb—the world's first cloned mammal—was born. To provide additional evidence that the cloned sheep was fully functioning, when she matured, she was bred and gave birth to a normal offspring.

FIGURE 17-4 ***Animated*** **Wilmut's experiment on mammalian cloning**

the most challenging areas of stem cell research today involves determining the identity, order, and amounts of the chemical signals that will result in a specific type of cell differentiation.

The most versatile stem cells—zygotes—are totipotent and have the potential to give rise to all tissues of the body and placenta. Stem cells can also be derived from embryos or adult cells. (The term *adult* is somewhat misleading because **adult stem cells** can be harvested from umbilical cord tissue, infants, and children as well as adults.) Embryonic and adult stem cells are known as **pluripotent stem cells** because they can give rise to many, but not all, of the types of cells in an organism. **Embryonic stem cells (ES cells),** formed after a zygote has undergone several rounds of cell division to form a 5- or 6-day-old blastocyst, are more versatile than adult stem cells (**FIG. 17-5**). For example, ES cells are pluripotent and have the potential to develop into any type of cell in the body; ES cells are not totipotent because they cannot form cells of the placenta.

Adult stem cells have been found in the human brain, retina, heart, bone marrow, dental pulp, intestines, and other sites. Adult neural stem cells in the brain are pluripotent and differentiate to form neurons and glial cells. Adult stem cells in the bone marrow form both red blood cells and the various types of white blood cells of the immune system. The range of cells that adult stem cells can differentiate into is more limited than that of ES cells. However, recent studies suggest that even specialized stem cells may be more versatile than once thought. For example, adult neural stem cells form blood cells when transplanted into bone marrow.

Stem cells are potential sources for cell transplantation into patients to treat serious degenerative conditions. For example, Parkinson's disease results from a progressive loss of cells that produce the neurotransmitter dopamine in a specific region of the brain. Transplantation of stem cells that have been induced to differentiate as dopamine-producing cells holds great promise as an effective long-term treatment. Similarly, stem cells may become a source of insulin-producing cells for transplantation into the pancreas of individuals with diabetes mellitus. Stem cells might also provide replacement neurons in people with spinal cord injury or other types of neurological damage.

Researchers ultimately hope to establish lines of human pluripotent stem cells that can grow indefinitely in culture, be induced to differentiate under controlled conditions and stably maintain their differentiated state, and be manipulated genetically. They particularly want to develop ES cell lines from patients with cancer, diabetes, cardiovascular disease, and neurogenerative disorders (such as Parkinson's disease); such cell lines would be invaluable in research on these disorders. Although work on stem cells in mice and other mammals has been conducted for many years, similar studies in humans have progressed slowly, despite the great promise of stem cells as a therapeutic tool.

Thus far, the only known source of ES cells is early human embryos left over from **in vitro fertilization** (see Chapter 50). Some countries have government restrictions on public funding due to ethical considerations related to the origins of ES cells. Other countries, notably some Asian countries, have no restrictions on this type of research. In the United States, the Obama administration lifted restrictions on stem cell research that were established during the George W. Bush administration, and public funding became available in 2009.

www.konkur.in

FIGURE 17-5 Human embryonic stem (ES) cells

Induced pluripotent stem (iPS) cells may eventually replace ES cells

In 2007 and 2008, scientists at several research labs were able to produce **induced pluripotent stem (iPS) cells** by introducing a few key **transcription factors** into mature mouse and human cells such as fibroblasts and skin cells. (Recall from Chapter 14 that transcription factors are DNA-binding proteins that regulate gene transcription in eukaryotic cells.)

The transcription factors reprogrammed the developmental state of the mature cells so they became pluripotent embryonic cells, but the mechanism by which they accomplished this is currently unknown. The transcription factors may have removed methyl groups from key genes that are normally turned off in adult cells but turned on in embryonic cells. (Recall from Chapter 14 that epigenetic inheritance consists of gene inactivation, for example, by DNA methylation.) For genes that are inactivated by methylation, removing the methyl groups would reactivate the genes.

Scientists must learn more about iPS cells before they can be used to replace embryonic stem cells in research. It does not appear that there is any difference between iPS cells and ES cells. If this is the case, then the ethical concerns that make ES cells controversial (discussed in the next section) may soon not matter because scientists will not need to use ES cells.

Ethical questions exist relating to human cloning

Cloning research continues to fuel an ongoing debate regarding the potential for human cloning and its ethical and religious implications. In the United States, the National Bioethics Advisory Commission has been established to study this and other questions. In considering these issues, it is important to recognize that *cloning* is a broad term that includes several different processes involved in producing biological cells, tissues, organs, or organisms.

Human reproductive cloning has the goal of producing a newborn human that is genetically identical to another, usually adult, human. It would involve placing a human embryo produced by a process other than fertilization into a woman's body. Many countries are opposed to human reproductive cloning.

In contrast, **human therapeutic cloning** would involve duplication of human ES cells or iPS cells for scientific study or medical purposes; no newborn human would develop. These cells would provide a supply of replacement tissues, such as heart muscle or nervous tissue, for revolutionary medical procedures.

Many people support research in therapeutic cloning because of the potential benefits in curing disease. Other people have ethical or religious objections if ES cells are used.

- What are stem cells?

17.2 THE GENETIC CONTROL OF DEVELOPMENT

LEARNING OBJECTIVES

4 Indicate the features of *Drosophila melanogaster*, *Caenorhabditis elegans*, *Mus musculus*, and *Arabidopsis thaliana* that have made these organisms valuable models in developmental genetics.

5 Distinguish among maternal effect genes, segmentation genes, and homeotic genes in *Drosophila*.

6 Explain the relationship between transcription factors and genes that control development.

7 Define *induction* and *apoptosis*, and give examples of the roles they play in development.

Development has been an important area of research for many years, and biologists have spent considerable time studying the development of invertebrate and vertebrate animals. By investigating

www.konkur.in

patterns of morphogenesis in different species, researchers have identified both similarities and differences in the basic plan of development from a zygote to an adult in organisms ranging from the sea urchin to mammals (see Chapter 51).

In addition to descriptive studies, many classic experiments have demonstrated how groups of cells differentiate and undergo pattern formation. Researchers have developed elaborate screening programs to detect mutations that let them identify many developmental genes in both plants and animals. They then use molecular genetic techniques and other sophisticated methodologies to determine how those genes work and how they interact to coordinate developmental processes.

A variety of model organisms provide insights into basic biological processes

In studies of the genetic control of development, the choice of organism to use as an experimental model is important. A **model organism** is a species chosen for biological studies because it has characteristics that allow for the efficient analysis of biological processes. Because most model organisms are small organisms with short generation times, they are easy to grow and study under controlled conditions. For example, mice are a better model organism than kangaroos.

One of the most powerful approaches in developmental genetics involves isolating mutants of a model organism with abnormal development. Not all organisms have useful characteristics that allow researchers to isolate and maintain developmental mutants for future study. Geneticists so thoroughly understand the genetics of the fruit fly, *Drosophila melanogaster,* that this organism has become one of the most important systems for such studies. Other organisms—the yeast *Saccharomyces cerevisiae;* the nematode worm, *Caenorhabditis elegans;* the zebrafish, *Danio rerio;* the laboratory mouse, *Mus musculus;* and certain plants, including *Arabidopsis thaliana,* a tiny weed—have also become important models in developmental genetics. Each of these organisms has attributes that make it particularly useful for examining certain aspects of development (**FIG. 17-6**).

In the 1990s, developmental geneticists working on *C. elegans* discovered RNA interference, which has become a powerful research tool. In **RNA interference (RNAi)** certain small RNA molecules interfere with the expression of genes or their RNA transcripts (see Chapter 13). One way these molecules work is to silence genes by selectively cleaving mRNA molecules that have base sequences complementary to the small RNA molecules. The use of RNAi makes it possible to knock out the expression of a specific gene in an organism during its development, thereby deducing the purpose of the gene.

Many genes that control development have been identified in the fruit fly

The fruit fly (*Drosophila*) genome sequence, which was completed in late 1999, includes about 13,600 protein-coding genes. At least 1200 of these are essential for embryonic development.

Two of the traditional advantages of *Drosophila* as a research organism are the abundance of mutant alleles, including those of developmental genes, available for study and the relative ease with which a new mutation is mapped on the chromosomes. U.S. biologist Edward B. Lewis (1918–2004), a pioneering developmental geneticist, began working with *Drosophila* mutants in the 1940s. The work of German researcher Christiane Nüsslein-Volhard and American Eric Wieschaus extended our understanding of development in fruit flies. Lewis, Nüsslein-Volhard, and Wieschaus shared the 1995 Nobel Prize in Physiology or Medicine for their decades of painstaking research on the genetics of *Drosophila* development. Many of the genes they discovered in the fruit fly are now known to be important in the growth and development of all animals.

The *Drosophila* life cycle includes egg, larval, pupal, and adult stages

Development in *Drosophila* consists of several distinct stages (**FIG. 17-7**). After the egg is fertilized, a period of embryogenesis occurs during which the zygote develops into a sexually immature form known as a **larva** (pl., *larvae*). After hatching from the egg, each larva undergoes several molts (shedding of the external covering, or cuticle). The periods between molts are called *instars.* Each molt results in a size increase until the larva is ready to become a **pupa.** Pupation involves a molt and the hardening of the new external cuticle so that the pupa is completely encased. The insect then undergoes **metamorphosis,** a complete change in form. During that time, most of the larval tissues degenerate and other tissues differentiate to form the body parts of the sexually mature adult fly.

The larvae are wormlike in appearance and look nothing like the adult flies. However, very early in embryogenesis of the developing larvae, precursor cells of many of the adult structures are organized as relatively undifferentiated, paired structures called **imaginal discs.** The name comes from *imago,* the adult form of the insect. Each imaginal disc occupies a definite position in the larva and will form a specific structure, such as a wing or a leg, in the adult body (**FIG. 17-8**). The discs are formed by the time embryogenesis is complete and the larva is ready to begin feeding. In some respects the larva is a developmental stage that feeds and nurtures the precursor cells that give rise to the adult fly, which is the only form that reproduces.

The organization of the precursors of the adult structures, including the imaginal discs, is under genetic control. Thus far, more than 50 genes have been identified that specify the formation of the imaginal discs, their positions within the larva, and their ultimate functions within the adult fly. Those genes were identified through mutations that either prevent certain discs from forming or alter their structure or ultimate fate.

Drosophila developmental mutations affect the body plan

Scientists have identified many developmental mutations in *Drosophila.* Researchers have examined their effects on development in various combinations and have studied them extensively at the molecular level. In our discussion we pay particular attention to mutations that affect the segmented body plan of the organism, in both the larva and the adult.

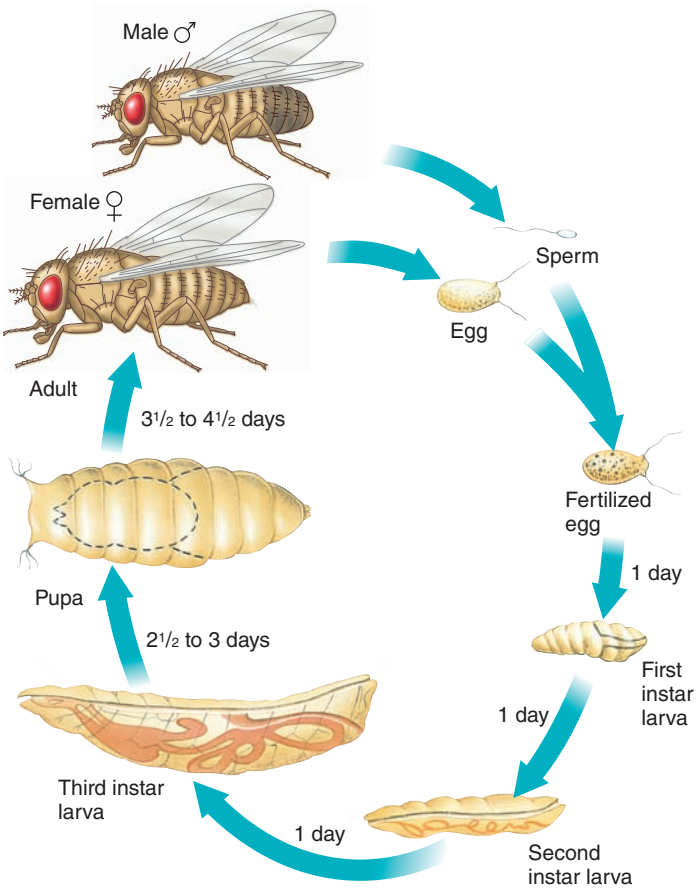

FIGURE 17-7 The life cycle of *Drosophila*

As it develops from a zygote to a sexually mature adult fly, a fruit fly passes through several stages. It takes about 12 days, at 25°C, to complete the life cycle. The dotted lines within the pupa represent the animal undergoing metamorphosis.

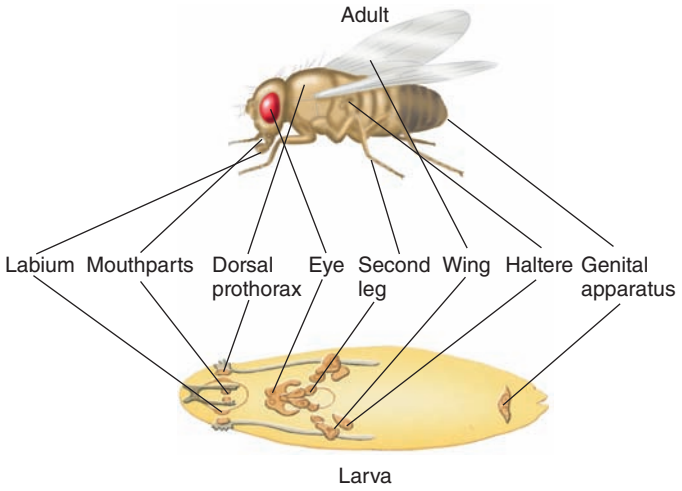

FIGURE 17-8 The location of imaginal discs

Each pair of discs in a *Drosophila* larva (*bottom*) develops into a specific pair of structures in the adult fly.

In early development of *Drosophila,* the structure of the egg becomes organized as it develops in the ovary of the female. Stores of mRNA, along with yolk proteins and other cytoplasmic molecules, pass from the surrounding maternal cells into the egg. Immediately after fertilization, the zygote nucleus divides, beginning a series of 13 mitotic divisions.

Each division takes only 5 or 10 minutes, which means that the DNA in the nuclei replicates constantly and at a very rapid rate. During that time, the nuclei do not synthesize RNA. Cytokinesis does not take place, and the nuclei produced by the first seven divisions remain at the center of the embryo until the eighth division occurs. At that time, most of the nuclei migrate out from the center and become localized at the periphery of the embryo. This is known as the *syncytial blastoderm* stage because the nuclei are not surrounded by individual plasma membranes. (A *syncytium* is a structure containing many nuclei residing in a common cytoplasm.) Subsequently, plasma membranes form, and the embryo becomes known as a *cellular blastoderm.*

Maternal Effect Genes The genes that organize the structure of the egg cell are called **maternal effect genes.** These genes in the surrounding maternal tissues are transcribed to produce mRNA molecules that are transported into the developing egg. Analysis of mutant flies with defective maternal effect genes has revealed that many of these genes are involved in establishing the polarity of the embryo—such as which part of the embryo will become the head. Polarity dictates those parts of the egg that are dorsal or ventral and those that are anterior or posterior (see Chapter 30); thus, these genes are known as *egg polarity genes.*

FIGURE 17-9a illustrates concentration gradients for two specific maternal mRNA molecules in the very early embryo. These mRNA transcripts of some of the maternal effect genes are identified by their ability to hybridize with radioactive DNA probes derived from cloned genes (discussed in Chapter 15). Alternatively, researchers use fluorescently tagged antibodies (as in the chapter opening photograph) to bind to specific protein products of the maternal effect genes. These protein gradients organize the early pattern of development in the embryo by determining anterior and posterior regions.

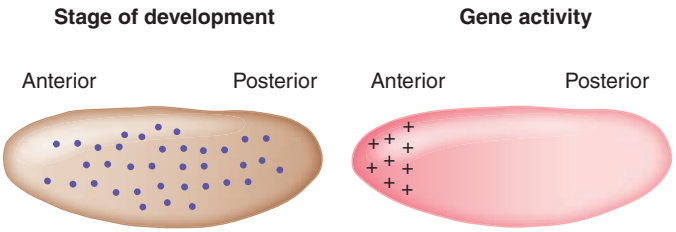
A combination of protein gradients may provide positional information that specifies the fate—that is, the developmental path—of each nucleus within the embryo. For example, mutations in certain maternal effect genes result in an embryo with two heads or two posterior ends.

In many cases, injecting normal maternal mRNA into the mutant embryo reverses the phenotype associated with a mutation in a given maternal effect gene. The fly subsequently develops normally, indicating that the gene product is needed only for a short time in the earliest stages of development.

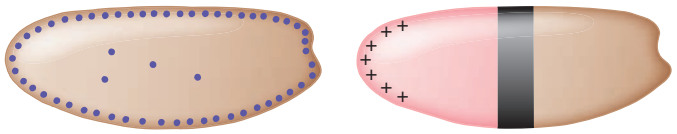
Segmentation Genes As the nuclei start to migrate to the periphery of the embryo, **segmentation genes** in those nuclei begin to produce embryonic mRNA. Thus far, geneticists have identified at least 24 segmentation genes that are responsible for generating a repeating pattern of body segments within the embryo and adult fly. Based on the study of mutant phenotypes, researchers group the segmentation genes into three classes—gap genes, pair–rule genes, and segment polarity genes.

Gap genes are the first set of segmentation genes to act. These genes interpret the maternal anterior-posterior information in the

www.konkur.in



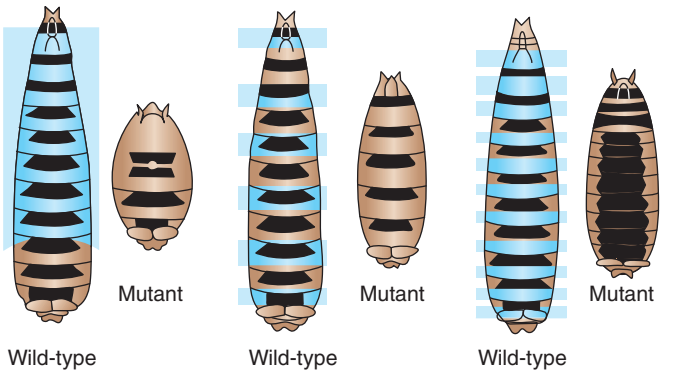
(a) At 1.25 hours after fertilization, the embryo consists of a common cytoplasm with about 128 nuclei (*purple circles*). Maternal effect genes divide the embryo into anterior and posterior sections. The crosses in the anterior region represent mRNA molecules transcribed from one maternal effect gene. The pink shading represents a different maternal mRNA molecule that is more concentrated in the anterior region.



(b) At 2 hours after fertilization, about 1500 nuclei have migrated into the periphery of the embryo and started to make their own mRNA molecules. The gap genes divide the embryo into anterior, middle, and posterior sections. The maternal RNA (shown in pink) is now transcribed from segmentation genes (*crosses*) in nuclei in the anterior region. The mRNA from another gap gene is transcribed in the middle of the embryo (*black region*).

FIGURE 17-9 Early development in *Drosophila*

Longitudinal sections on the left show two early stages of development of the *Drosophila* embryo. These are matched with the simplified patterns of gene activity at each stage on the right. (Adapted from Akam, M. E., "The Molecular Basis for Metameric Pattern in the Drosophila Embryo," *Development*, Vol. 101, 1987.)



(a) Gap genes (b) Pair–rule genes (c) Segment polarity genes

FIGURE 17-10 A comparison of mutations in *Drosophila* segmentation genes

Gap genes, pair–rule genes, and segment polarity genes control the pattern of body segments in a *Drosophila* embryo. The blue bands mark the regions in which the protein products of these genes are normally expressed in wild-type embryos. These same regions are absent in embryos in which the gene is mutated—that is, the mutant lacks the blue-shaded parts. The resulting phenotype is characteristic of the class to which the gene belongs. (Adapted from Nusslein-Volhard, C., and E. Wieschaus, "Mutations Affecting Segment Number and Polarity in Drosophila," *Nature*, Vol. 287, 1980.)

egg and begin organization of the body into anterior, middle, and posterior regions (FIG. 17-9b). A mutation in one of the gap genes usually causes the absence of one or more body segments in an embryo (FIG. 17-10a).

The other two classes of segmentation genes do not act on small groups of body segments; instead, they affect all segments. Mutations in **pair–rule genes** delete every other segment, producing a larva with half the normal number of segments (FIG. 17-10b and FIG. 17-11). Mutations in **segment polarity genes** produce segments in which one part is missing and the remaining part is duplicated as a mirror image (FIG. 17-10c). The effects of the different classes of mutants are summarized in TABLE 17-1.

Each segmentation gene has distinctive times and places in the embryo in which it is most active. The observed pattern of expression of maternal effect genes and segmentation genes indicates that a progressive series of developmental events determines cells destined to form adult structures. First, maternal effect genes that form gradients of morphogens in the egg determine the anterior-posterior (head-to-tail) axis and the dorsal and ventral regions of the embryo. A **morphogen** is a chemical agent that affects the differentiation of cells and the development of form. Morphogen gradients are signals that help cells determine their location within the embryo and promote their eventual differentiation into specialized tissues and organs.

TABLE 17-1 Classes of Genes Involved in Establishing Segmented Body Plan in *Drosophila*

Class of Gene	Site of Gene Activity	Functions of Genes
Maternal effect genes	Maternal tissues surrounding egg	Initiate anterior-posterior regions in embryo and regulate expression of segmentation genes
Segmentation genes		
Gap genes	Embryo	Divide embryo into broad regions and influence activity of pair–rule genes
Pair–rule genes	Embryo	Divide embryo into strips, each about two segments wide, and influence activity of segment polarity genes
Segment polarity genes	Embryo	Define all segments of body, and divide each segment into anterior and posterior halves
Homeotic genes	Embryo	Control identities of segments; expression of homeotic gene is controlled by segmentation genes

www.konkur.in

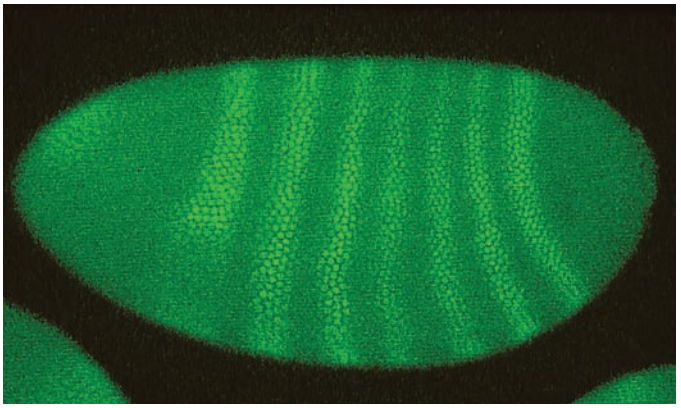


FIGURE 17-11 Segmentation gene activity

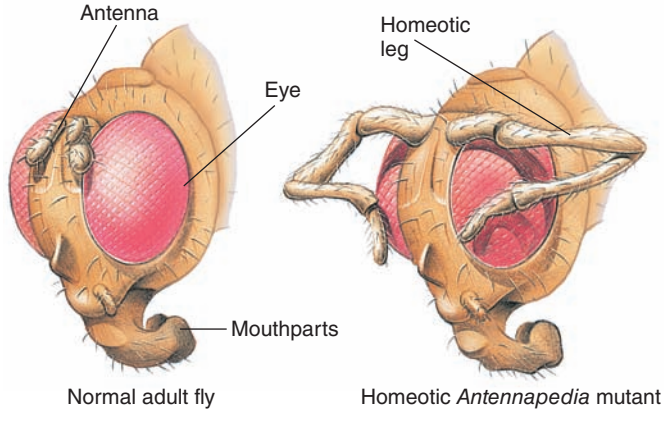
The bright bands in this fluorescence LM reveal the presence of mRNA transcribed from one of the pair–rule genes known as *fushi tarazu* (Japanese for "not enough segments"). When this locus is mutated, the segments of the larva that are normally derived from these bands are absent.

Next, segmentation genes respond to the morphogens at each location to regulate the production of segments from the head to the posterior region. Within each segment, other genes are then activated to specify which body part that segment will become. Every cell's position is further specified with a specific "address" designated by combinations of the activities of the regulatory genes.

The segmentation genes act in sequence, with the gap genes acting first, then the pair–rule genes, and finally the segment polarity genes. In addition, the genes of the three groups interact. Each time a new group of genes acts, cells for that group become more determined in their development. As the embryo develops, each region is progressively subdivided into smaller regions.



(a) The head of a normal fly and a fly with an *Antennapedia* mutation.

Most segmentation genes code for transcription factors. For example, some segmentation genes code for a "zinc-finger" type of DNA-binding regulatory protein. (See Figure 14-12b to review zinc fingers.) *Homeotic genes,* discussed next, also code for transcription factors. The fact that many of the genes involved in controlling developmental processes code for transcription factors indicates that those proteins act as genetic switches to regulate the expression of other genes.

Once researchers have identified proteins that function as transcription factors, they can use the purified proteins to determine the DNA target sequences to which the proteins bind. This approach has been increasingly useful in identifying additional parts of the regulatory pathway involved in different stages of development. Transcription factors also play a role in cancer (discussed later in the chapter).

Homeotic Genes After segmentation genes have established the basic pattern of segments in the fly body, **homeotic genes** specify the developmental plan for each segment. Mutations in homeotic genes cause one body part to be substituted for another and therefore produce some peculiar changes in the adult. A striking example is the *Antennapedia* mutant fly, which has legs that grow from the head where the antennae would normally be (**FIG. 17-12**).

Homeotic genes in *Drosophila* were originally identified by the altered phenotypes produced by mutant alleles. When geneticists

(b) SEM of the head of a fly with an *Antennapedia* mutation.

FIGURE 17-12 The *Antennapedia* locus

Antennapedia mutations cause homeotic transformations in *Drosophila* in which legs or parts of legs replace the antennae.

www.konkur.in

analyzed the DNA sequences of several homeotic genes, they discovered a short DNA sequence of approximately 180 base pairs, which characterizes many homeotic genes as well as some other genes that play a role in development. This DNA sequence is called the **homeobox.** Each homeobox codes for a protein functional region called a **homeodomain,** consisting of 60 amino acids that form four α-helices. One of these serves as a recognition helix that binds to specific DNA sequences and thereby affects transcription. Thus, the products of homeotic genes, like those of the earlier-acting segmentation genes, are transcription factors. In fact, some segmentation genes also contain homeoboxes.

Studies of ***Hox* genes,** clusters of homeobox-containing genes that specify the anterior-posterior axis during development, provide insights about evolutionary relationships. *Hox* genes were initially discovered in *Drosophila,* where they are arranged in two adjacent groups on the chromosome: the *Antennapedia complex* and the *bithorax complex.* As *Hox* genes have been identified in other animals, such as other arthropods, sea anemones, annelids (segmented worms), roundworms, and vertebrates, researchers have found that these genes are also clustered and that their organization is remarkably similar to that in *Drosophila.*

FIGURE 17-13 compares the organization of the *Hox* gene clusters of the fruit fly and mouse. The fruit fly and mouse *Hox* genes are located in the same order along the chromosome. Moreover, the linear order of the genes on the chromosome reflects the order of the corresponding regions they control, from anterior to posterior, in the animal. This organization apparently reflects the need for these genes to be transcribed in a specific temporal sequence.

Drosophila has only one *Antennapedia–bithorax* complex. However, mice, humans, and many other vertebrates have four similar *Hox* gene clusters, each located in a different chromosome. These complexes probably arose through gene duplication. The fact that extra copies of these genes are present helps explain why mutations causing homeotic-like transformations are seldom seen in vertebrate animals. One does not see an extra eye growing where a mouse leg should be, for example. However, one particular type of *Hox* mutation that has been described in both mice and humans causes abnormalities in the limbs and genitalia. The involvement of the genitalia provides a further explanation for the rarity of these mutant alleles because affected individuals are unlikely to reproduce.

The fact that very similar developmental controls are seen in organisms as diverse as insects and vertebrates (including humans) indicates that the basic mechanism evolved early and has been highly conserved in all animals that have an anterior-posterior axis, even those that are not segmented. Clearly, once a successful way of regulating groups of genes and integrating their activities evolved, it was retained, although it has apparently been modified to provide alterations of the body plan.

The finding of homeobox-like genes in plants suggests these genes originated early during eukaryotic evolution. With further investigations, researchers hope to develop an overall model of how the rudiments of morphogenesis are controlled in all multicellular eukaryotes. These systems of master genes that regulate development are a rich source of "molecular fossils" that are illuminating evolutionary history in new and exciting ways. These kinds of studies have led to an ongoing synthesis of evolution and developmental biology that has come to be known as **Evo Devo.**

KEY POINT *Hox* genes are arranged in the same order on the chromosome as they are expressed along the anterior-posterior axis of the embryo.

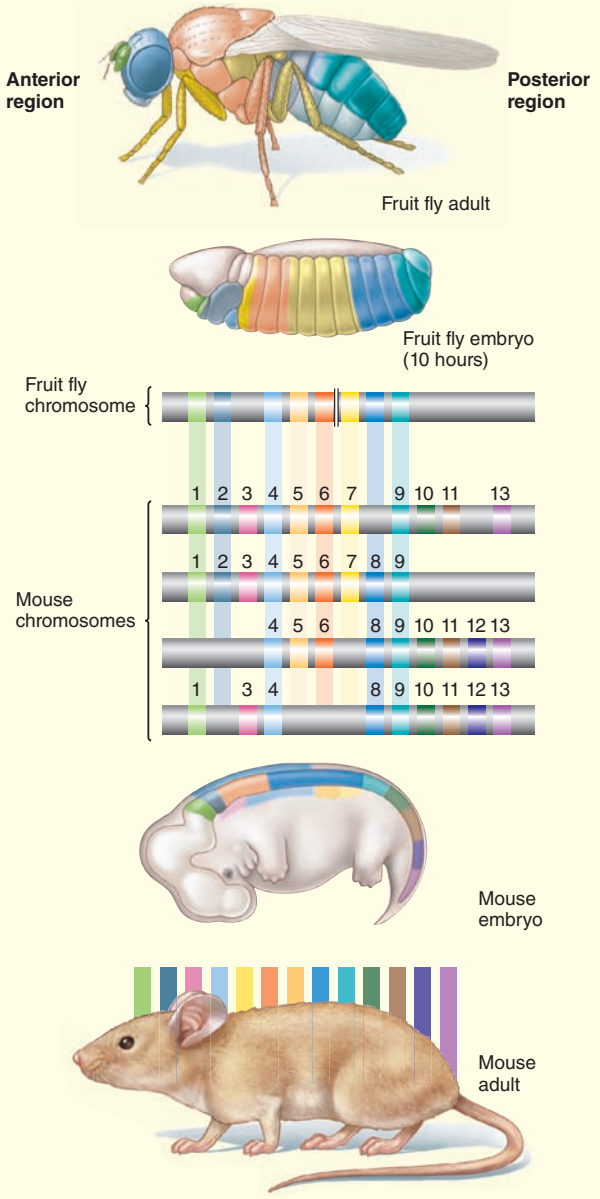


FIGURE 17-13 *Hox* gene clusters

Clusters of *Hox* genes are found in all animal groups except sponges. Note that in each organism, the linear sequence of these developmental genes (*color-coded bands*) on the chromosome(s) reflects their spatial order of expression in the embryo.

Caenorhabditis elegans has a relatively rigid developmental pattern

The nematode worm *C. elegans* is an ideal model organism because its system for the genetic control of development is relatively easy to study. Sydney Brenner, a British molecular geneticist, began studying molecular development in this animal at Cambridge

www.konkur.in

University in the 1960s. He selected *C. elegans* because it is small, has a short life cycle (its normal lifespan is about 3 weeks), and is genetically well characterized. Consisting of about 19,700 protein-coding genes, it was the first animal genome sequenced. Today, *C. elegans* is an important tool for answering basic questions about the development of individual cells within a multicellular organism.

When an adult, *C. elegans* is only 1.5 mm long and contains only 959 somatic cells (**FIG. 17-14**). Individuals are either males or **hermaphrodites,** organisms with both sexes in the same individual. Hermaphroditic *C. elegans* are capable of self-fertilization, which makes it easy to obtain offspring that are homozygous for newly induced recessive mutations. The availability of males that can reproduce sexually with the hermaphrodites makes it possible to perform genetic crosses as well.

Because the worm's body is transparent, researchers can follow the development of literally every one of its somatic cells using a Nomarski differential interference microscope, which provides contrast in transparent specimens. As a result of efforts by several research teams, the lineage of each somatic cell in the adult has been determined. Those studies have shown that the nematode has a very rigid, or fixed, developmental pattern. After fertilization, the egg undergoes repeated divisions, producing about 550 cells that make up the small, sexually immature larva. After the larva hatches from the egg case, further cell divisions give rise to the adult worm.

The lineage of each somatic cell in the adult can be traced to a single cell in a small group of **founder cells,** which are formed early in development (**FIG. 17-15a**). If a particular founder cell is destroyed or removed, the adult structures that would normally develop from that cell are missing. Such a rigid developmental pattern, in which the fates of the cells become restricted early in development, is referred to as **mosaic development.** Each cell has a specific fate in the embryo, just as each tile in a mosaic design forms part of the pattern.

Scientists initially hypothesized that every organ system in *C. elegans* might be derived from only one founder cell. Detailed analysis of cell lineages, however, reveals that many of the structures found in the adult, such as the nervous system and the musculature, are in fact derived from more than one founder cell (**FIG. 17-15b**). A few lineages have been identified in which a neuron and a muscle cell are derived from the division of a single cell.

A researcher who uses microscopic laser beams small enough to destroy individual cells can determine the influence one cell has on the development of a neighboring cell. Consistent with the rigid pattern of cell lineages, the destruction of an individual cell in *C. elegans* results, in most cases, in the absence of all of the structures derived from that cell but with the normal differentiation of all the neighboring somatic cells. This observation suggests that development in each cell is regulated through its own internal program.

However, the developmental pattern of *C. elegans* is not entirely mosaic. In some cases, cell differentiation is influenced by interactions with particular neighboring cells, a phenomenon known as **induction.** One example is the formation of the vulva (pl., *vulvae*), the reproductive structure through which the eggs are laid. A single nondividing cell, called the *anchor cell,* is a part of the ovary, the structure in which the germ line cells undergo meiosis to produce the eggs. The anchor cell attaches to the ovary and to a point on the outer surface of the animal, triggering the formation of a passage through which the eggs pass to the outside. When the anchor cell is present, it induces cells on the surface to form the vulva and its opening. If the anchor cell is destroyed by a laser beam, however, the vulva does not form, and the cells that would normally form the vulva remain as surface cells (**FIG. 17-16**).

The analysis of worm mutations has contributed to our understanding of inductive interactions. For example, several types of mutations cause more than one vulva to form. In such mutant animals, multiple vulvae form even if the anchor cell is destroyed. Thus, the mutant cells do not require an inductive signal from an anchor cell to form a vulva. Evidently, in these mutants the gene or genes responsible for vulva formation are constitutive. Conversely, mutants lacking a vulva are also known. In some of these, the cells that would normally form the vulva apparently do not respond to the inducing signal from the anchor cell.

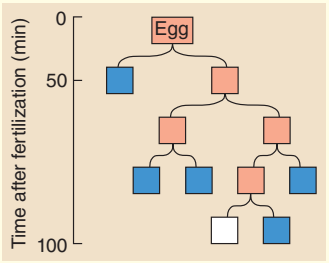
C. elegans is a model system to study apoptosis

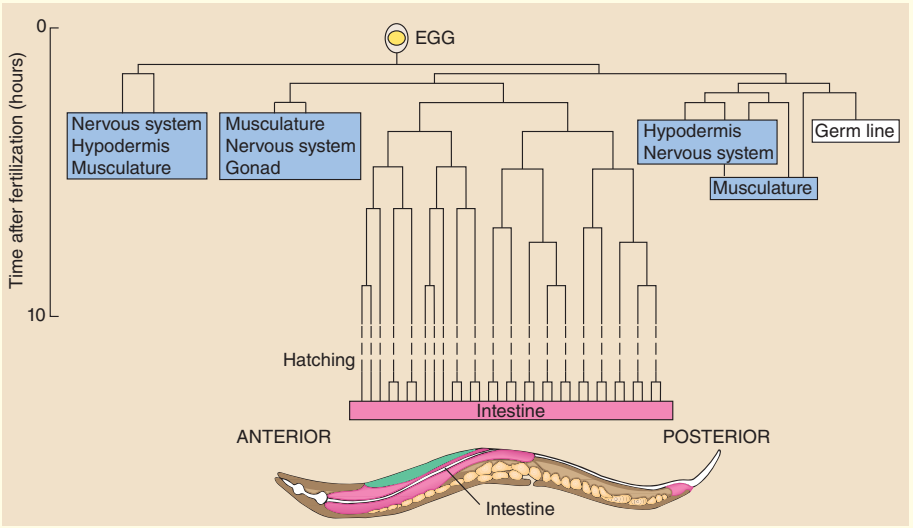
During normal development in *C. elegans,* there are instances in which cells are destined to die shortly after they are produced. **Apoptosis,** or genetically programmed cell death, has been observed in a wide variety of organisms, both plant and animal. For example, the human hand is formed as a webbed structure, but

www.konkur.in

KEY POINT The nematode worm *C. elegans* has a fixed developmental pattern in which the fate of each adult cell can be traced to one of several founder cells in the embryo.



(a) All somatic cells of *C. elegans* are derived from five somatic founder cells (*shown in blue*) produced during the early cell divisions of the embryo. The cell shown in white gives rise to germ line cells.



(b) The nervous system, hypodermis, and musculature derive from several founder cells. This lineage map traces the development of the cells that form the intestine. (The dashed lines represent many cell divisions of a particular lineage.)

FIGURE 17-15 Cell lineages of *Caenorhabditis elegans*

the fingers become individualized when the cells between them undergo apoptosis. In *C. elegans,* as in other organisms, apoptosis is under genetic control. The worm embryos undergo mitosis to produce a total of 1090 cells, but 131 of these undergo apoptosis during development, resulting in adult worms with 959 cells.

In 1986, U.S. molecular geneticist Robert Horvitz discovered several mutant worms that were defective in some way relating to apoptosis. He characterized the mutations and the genes responsible for them at the molecular level. For example, one of the genes codes for a protein that regulates the release from mitochondria of molecules that trigger apoptosis (mitochondria are now known to have a crucial role in apoptosis in animals ranging from *C. elegans* to humans). Other genes were identified that code for a family of proteins known as **caspases,** proteolytic enzymes active in the early stages of apoptosis. Homologous genes were subsequently identified in other organisms, including humans; some of these loci in mammals also code for caspases. The molecular events that trigger apoptosis remain an area of intense research interest, the results of which will shed considerable light on the general processes of cell aging and cancer.

Robert Horvitz and British scientists Sydney Brenner and John Sulston shared the Nobel Prize in Physiology or Medicine in 2002 for their work on the genetic regulation of organ development and apoptosis in *C. elegans.* Sulston was one of Brenner's

students. He traced the lineage of how a single zygote gives rise to the 959 cells in the nematode adult and also observed that some cells die during normal development. Continuing Sulston's work on apoptosis, Horvitz, as mentioned earlier, was the first to discover genes involved in apoptosis.

The mouse is a model for mammalian development

Mammalian embryos develop in markedly different ways from the embryos of *Drosophila* and *C. elegans.* The laboratory mouse, *Mus musculus,* is the best-studied example of mammalian development. Researchers have identified numerous genes affecting development in the mouse. The mouse genome sequence, which was published in 2002, contains 27,000 to 30,000 genes, similar to the number of protein-coding genes in the human genome. Indeed, 99% of the genes in the mouse have counterparts in humans.

The early development of the mouse and other mammals is similar in many ways to human development. During the early developmental period, the embryo lives free in the reproductive tract of the female. It then implants in the wall of the uterus, after which the mother meets its nutritional and respiratory needs. Consequently, mammalian eggs are very small and contain little in the way of food reserves. Almost all research on mouse development has concentrated on the stages leading to implantation because in those stages the embryo is free-living and can be experimentally manipulated. During that period, developmental commitments that have a significant effect on the future organization of the embryo take place.

After fertilization, a series of cell divisions gives rise to a loosely packed group of cells. Research shows that all cells are equivalent in the very early mouse embryo. For example, at the two-cell stage of mouse embryogenesis, if researchers destroy one cell and implant the remaining cell into the uterus of a surrogate mother, a normal mouse usually develops.

Conversely, if two embryos at the eight-cell stage of development are fused and implanted into a surrogate mother, a normal-sized mouse develops (**FIG. 17-17**). By using two embryos with different genetic characters, such as coat color, researchers demonstrated that the resulting mouse has four genetic parents. These chimeric mice have fur with patches of different colors derived from clusters of genetically different cells. A **chimera** is an organism containing two or more kinds of genetically dissimilar cells arising from different zygotes. (The term is derived from the name of a mythical beast that was said to have the head of a lion, the body of a goat, and a snakelike tail.) Chimeras let researchers use genetically marked cells to trace the fates of certain cells during development.

The responses of mouse embryos to such manipulations contrast with the mosaic or predetermined nature of early *C. elegans* development, in which destroying one of the founder cells results in the loss of a significant portion of the embryo. For this reason, biologists say that the mouse has highly **regulative development**—the early embryo acts as a self-regulating whole that accommodates missing or extra parts.

Transgenic mice are used in studies of developmental regulation

In transformation experiments, foreign DNA injected into fertilized mouse eggs is incorporated into the chromosomes and expressed (**FIG. 17-18**). (Also see Figure 15-14 for an example of a transgenic mouse.) The resulting transgenic mice provide insights

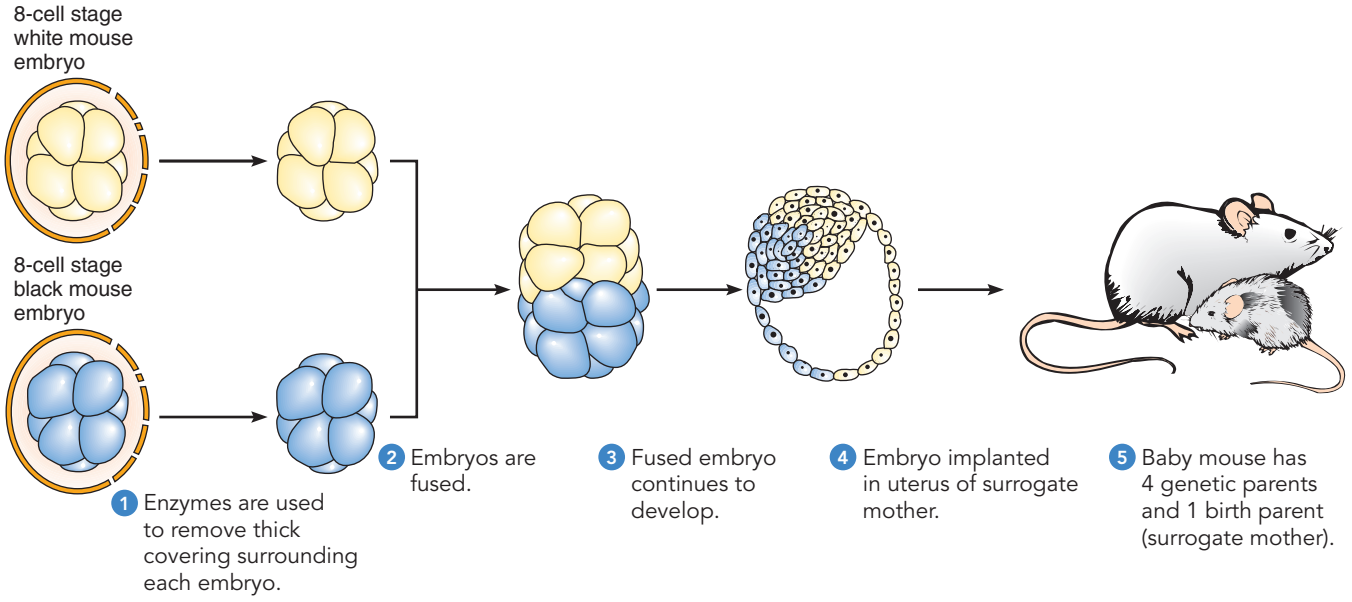

FIGURE 17-17 Chimeric mouse

Researchers remove embryos from females of two different strains and combine the cells in vitro. The resulting aggregate embryo continues to develop and is implanted in the uterus of a surrogate mother. The offspring has four different genetic parents. Although the surrogate mother is the birth mother, she is not genetically related.

www.konkur.in

into how genes are activated during development. Scientists can identify a *transgene* (foreign gene) that has been introduced into a mouse and determine whether it is active by marking the gene in several ways. Sometimes a similar gene from a different species is used; its protein is distinguished from the mouse protein by specific antibodies.

It is also possible to construct a hybrid gene consisting of the regulatory elements of a mouse gene and part of another, non-mouse, gene that codes for a "reporter" protein. For example, the reporter protein could be an enzyme not normally found in mice. Such studies have been important in showing which DNA sequences of a mouse homeobox gene determine where the gene is expressed in the embryo.

Many developmentally controlled genes introduced into mice have yielded important information about gene regulation. When researchers introduce developmentally controlled genes from other species, such as humans or rats, into mice, the genes are regulated the same way they normally are in the donor animal. When introduced into the mouse, for example, human genes encoding insulin, globin, and crystallin—which are normally expressed in cells of the pancreas, blood, and eye lens, respectively—are expressed only in those same tissues in the mouse. That these genes are correctly expressed in their appropriate tissues indicates that the signals for tissue-specific gene expression are highly conserved through evolution. Information on the regulation of genes controlling development in one organism can have valuable applications to other organisms, including humans.

RESEARCH METHOD

Why Is It Used?

This method is used to establish a transgenic line of mice that contain genes with useful traits for scientific and medical research.

How Is It Done?

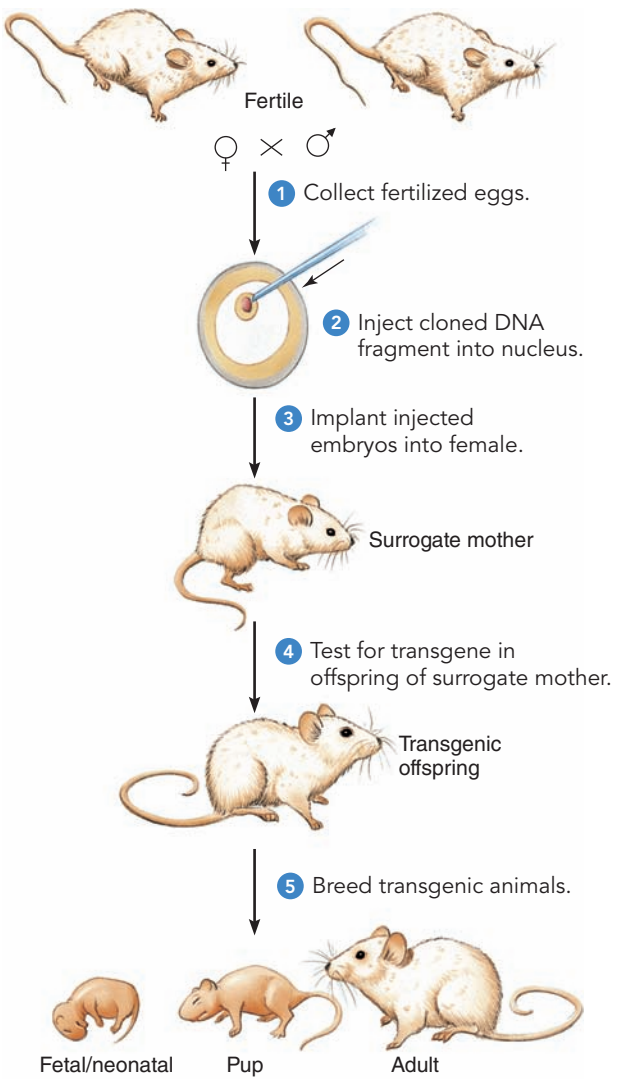

FIGURE 17-18 Producing a transgenic mouse

Mice and other model organisms are providing insights into the aging process

Aging, which is defined as a progressive decline in the performance of various parts of the body, is an important field of developmental biology. The study of aging has great practical potential because age-related diseases represent one of the biggest challenges of biomedical research today. Scientists have demonstrated that many environmental factors influence aging. For example, severe calorie restriction in rodents and other mammals delays aging. However, how the human genome interacts with the cell environment during the aging process is not well understood.

Researchers working with model organisms, such as *Drosophila* and *C. elegans,* have found that more than 1000 protein-coding genes affect aging to variable degrees. In the nematode worm *C. elegans,* most aging genes are under the control of three genes (ELT-3, ELT-5, and ELT-6), all of which code for transcription factors.

Many of the genes that slow aging in organisms as diverse as yeasts, nematodes, and mammals are associated with cells' responses to nutrients. Dietary restrictions are known to extend lifespan for many organisms, from yeasts to dogs and possibly even to primates. Two genes (the PHA-4 gene and the SKN-1 gene) that extend survival in *C. elegans* code for transcription factors.

One of the most potent lifespan-extending genes, present in *C. elegans,* codes for a protein similar to the membrane receptor that allows cells to respond to the peptide **insulin-like growth factor (IGF)** in humans and other mammals. The binding of IGF to its receptor triggers **signal transduction** within the cell, which regulates the expression of many genes.

Researchers wondered if the IGF receptor influences aging in mammals, including humans. To test this hypothesis, they produced *knockout mice* with an inactivated gene for the insulin-like growth factor receptor (IGF-1R). (Knockout mice were first discussed in Chapter 15.) Because mice are diploid organisms, they have two copies of the gene, designated *igf1r.* When both alleles of *igf1r* are inactivated, the mice develop many abnormalities and die at birth. However, when one allele of *igf1r* is inactivated and the other is left in its normal state, the mice thrive and live about 25% longer than control mice. In all other respects, the heterozygous mice are normal. They are virtually indistinguishable from control

www.konkur.in

mice in their rate of development, metabolic rate, ability to reproduce, and body size. Mice heterozygous at the *igf1r* locus produce fewer IGF receptors, and therefore the cells are not exposed to as much signaling from IGF.

Research on the IGF receptor and aging in mice suggests that some of the hundreds of other mutant genes associated with aging in *C. elegans* may also be involved in mammalian aging. Thus, the genetic control of mammalian aging has enough research topics to occupy molecular geneticists for many years.

Arabidopsis is a model for studying plant development, including transcription factors

Mouse-ear cress (*Arabidopsis thaliana*), the organism most widely used to study the genetic control of development in plants, is a member of the mustard family. Although *Arabidopsis* itself is a weed of no economic importance, it has several advantages for research. The plant completes its life cycle in just a few weeks and is small enough to be grown in a petri dish, yielding thousands of individuals in limited space. Botanists use chemical mutagens to produce mutant strains and have isolated many developmental mutants. When they insert cloned foreign genes into *Arabidopsis* cells, the genes integrate into the chromosomes and are expressed. The researchers then induce these transformed cells to differentiate into transgenic plants.

In 2000, the *Arabidopsis* genome became the first plant genome sequenced. Although its genome is relatively small (the rice genome is about four times larger), it includes about 26,000 protein-coding genes. In comparison, *Drosophila* has about 13,600 genes and *C. elegans* about 19,700. Many genes in *Arabidopsis* are functionally equivalent to genes in *Drosophila, C. elegans,* and other animal species.

Of particular importance to development are the more than 1500 genes that code for transcription factors in *Arabidopsis* (compared to 635 at last count for *Drosophila*). Not surprisingly, many genes known to specify identities of parts of the *Arabidopsis* flower code for transcription factors. During the development of *Arabidopsis* flowers, four distinct flower parts differentiate: sepals, petals, stamens, and carpels (**FIG. 17-19a**; also see Fig. 33-1). Sepals cover and protect the flower when it is a bud, petals help attract animal pollinators to the flower, stamens produce pollen grains, and the carpel produces ovules, which develop into seeds following fertilization (discussed in Chapter 28).

The **ABC model** explains how three classes of homeotic genes control the development of the four floral organs; this model may help explain the thousands of different forms of flowers that have evolved. Class *A* genes are needed to specify sepals; both *A* and *B* genes are needed to specify petals; both *B* and *C* genes are needed to specify stamens; and class *C* genes are needed to specify the carpel. Mutations in the *A, B,* or *C* organ-identity genes, all of which code for transcription factors, cause one flower part to be substituted for another. For example, class *C* homeotic mutants (which have an inactive *C* gene) have petals in place of stamens and sepals in place of the carpel. Therefore, the entire flower consists of only sepals and petals. **FIGURES 17-19b, c,** and **d** shows three homeotic mutants of *Arabidopsis.*

The ABC model is not the entire explanation for floral development. Another class of genes, designated *SEPALLATA,* interacts with the *B* and *C* genes to specify the development of petals, stamens, and carpels. Remarkably, when *SEPALLATA* genes are turned on permanently in *Arabidopsis,* the resulting plants have white petals growing where the leaves should be. (Because these plants do not photosynthesize, they are grown on a nutrient medium.)

These findings in *Arabidopsis* vastly increase the number of molecular probes available in plants. Researchers use these probes to identify other genes that control development in various plant species and to compare them with genes from a wide range of organisms. The success of the *Arabidopsis* sequencing project led to an international initiative by plant biologists to understand the functions of all genes in *Arabidopsis.* This functional genomic information will lead to a far deeper understanding of plant development and evolutionary history.

Review

- What are the relative merits of *Drosophila*, *C. elegans*, *M. musculus*, and *Arabidopsis* as model organisms for the study of development?
- What are transcription factors, and how do they influence development?
- What role does induction play in development?
- What is apoptosis?

17.3 CANCER AND CELL DEVELOPMENT

LEARNING OBJECTIVE

8 Discuss the relationship between cancer and mutations that affect cell developmental processes.

Cancer cells lack normal biological inhibitions. Normal cells are tightly regulated by control mechanisms that prompt them to divide when necessary and prevent them from growing and dividing inappropriately. Cells of many tissues in the adult are normally prevented from dividing; they reproduce only to replace a neighboring cell that has died or become damaged. Cancer cells have escaped such controls and can divide continuously.

As a consequence of their abnormal growth pattern, some cancer cells eventually form a mass of tissue called a **tumor,** or *neoplasm.* If the tumor remains at the spot where it originated, it can usually be removed by surgery. One of the major problems with certain forms of cancer is that the cells can escape from the controls that maintain them in one location. **Metastasis** is the spreading of cancer cells to different parts of the body. Cancer cells invade other tissues and form multiple tumors. Lung cancer, for example, is particularly deadly because its cells are highly metastatic; they enter the bloodstream, spread, and form tumors in other parts of the lungs and in other organs, such as the liver and the brain.

Biologists now know that cancer is caused by the altered expression of specific genes critical for cell division. Using recombinant DNA methods, researchers have identified many of the genes that when functioning abnormally transform normal cells into cancer cells. The traits of each kind of cancer cell come from at least one, and probably several, **oncogenes,** or cancer-causing genes. Oncogenes arise from changes in the expression of certain genes called **proto-oncogenes,** which are *normal* genes found in all cells and are involved in the control of growth and development.

Investigators first discovered oncogenes in viruses that infect mammalian cells and transform them into cancer cells, in a process known as *malignant transformation.* Such viruses have oncogenes as part of their genomes. When these viruses infect a cell, the viral oncogenes are expressed, causing the cell to divide.

A proto-oncogene in a cell that has not been infected by a virus can also mutate and become an oncogene. One of the first oncogenes researchers identified was isolated from a tumor in a human urinary bladder. In the cell that gave rise to the tumor, a proto-oncogene had undergone a single base-pair mutation; the result was that the amino acid valine replaced the amino acid glycine in the protein product of the gene. This subtle change was apparently a critical factor in converting the normal cell into a cancer cell.

Some of the control mechanisms of cell growth are illustrated in greatly simplified form in **FIGURE 17-20**. One or more external signal molecules trigger the growth and division of cells. Some of these substances are **growth factors** that bind to specific **growth factor receptors** associated with the cell surface, initiating a cascade of events inside the cell. Often the growth factor receptor complex acts as a **protein kinase,** an enzyme that phosphorylates proteins, which then phosphorylate specific amino acids of several cytoplasmic proteins. This posttranslational modification usually results in the activation of previously inactive enzymes. These activated enzymes then catalyze the activation of certain nuclear proteins, many of which are transcription factors. Activated transcription factors bind to their DNA targets and stimulate the transcription of specific sets of genes that initiate growth and cell division.

Even in the simplified scenario presented in the figure, it is evident that multiple steps are required to control cell proliferation. Researchers have identified the proto-oncogenes that encode the products responsible for many of these steps. The current list

KEY POINT **Growth factors are signaling proteins that stimulate cell division in specific target cells.**

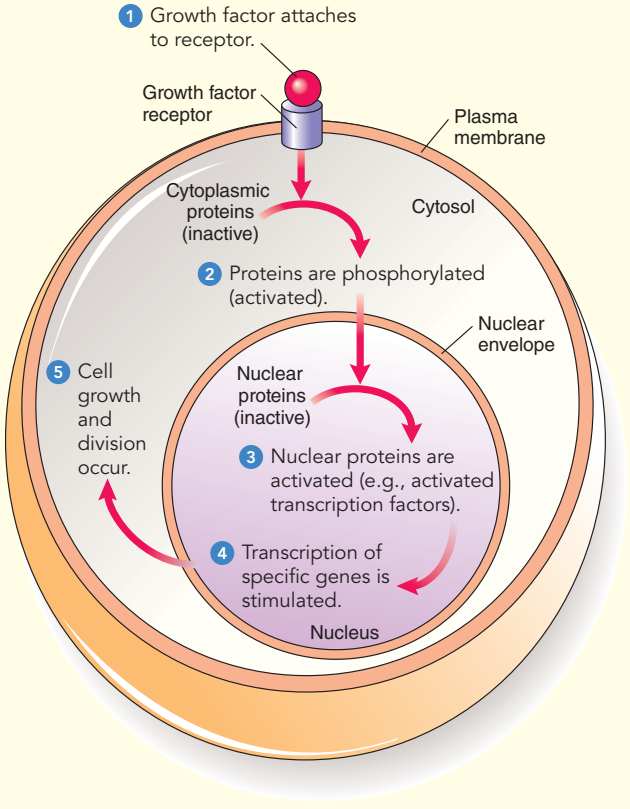

FIGURE 17-20 A cell growth control cascade

In this example, a growth factor stimulates cell growth. Proto-oncogenes code for the growth factor receptor and some of the other components of the system. When a proto-oncogene mutates, becoming an oncogene, the cell grows and divides even in the absence of the growth factor.

www.konkur.in

of known proto-oncogenes includes genes that code for various growth factors or growth factor receptors and genes that respond to stimulation by growth factors, including many transcription factors. When a proto-oncogene mutates or is expressed inappropriately (i.e., when it becomes an oncogene), the cell may misinterpret the signal and respond by growing and dividing. For example, in some cases a proto-oncogene encoding a growth factor receptor mutates in a way that compromises regulation of the receptor. It is always switched "on," even in the absence of the growth factor that normally controls it.

Not all genes that cause cancer when mutated are proto-oncogenes. About half of all cancers are caused by a mutation in a **tumor suppressor gene.** These genes, also known as *anti-oncogenes,* normally interact with growth-inhibiting factors to block cell division. When mutated, they lose their ability to "put on the brakes," and uncontrolled growth ensues.

Currently, more than 100 oncogenes and 15 tumor suppressor genes have been identified, and many more probably remain to be identified. A change in a single proto-oncogene is usually insufficient to cause a cell to become malignant. The development of cancer is usually a multistep process involving both mutations that activate oncogenes and mutations that inactivate tumor suppressor genes.

Additional factors, such as chromosome translocations (see Chapter 16) or the inappropriate activation of the enzyme responsible for the maintenance of telomeres (see Chapter 12), may also play a role in the development of cancer. The Cancer Genome Project, a long-term international initiative based in Great Britain, is currently examining every human gene for cancer-related mutations. As more of these genes are discovered and their interactions are unraveled, we will gain a fuller understanding of the control of growth and development. This understanding will improve the diagnosis and treatments of various types of cancer.

Some researchers view cancer as a stem cell disease because cancer cells are propagated by a small number of cells that have many properties of stem cells. However, the propagation of normal stem cells is tightly regulated, so the question that some biologists are pursuing is how cell mechanisms that regulate stem cell self-renewal are changed to cause cancer cell proliferation. It is possible that the relatively long life of stem cells allows them to accumulate mutations that cause the cells to proliferate in an uncontrolled fashion. Although this line of research is promising, it should be emphasized that the validity of cancer as a stem cell disease remains to be demonstrated for most kinds of cancer.

Review

- How are oncogenes and tumor suppressor genes related to genes involved in the control of normal growth and development?
- How is a growth factor involved in a typical growth control cascade?

SUMMARY: FOCUS ON LEARNING OBJECTIVES

17.1 *(page 370)*

1 Distinguish between cell determination and cell differentiation, and between nuclear equivalence and totipotency.

- An organism contains many types of cells that are specialized to carry out specific functions. These cells are the product of a process of gradual commitment, called **cell determination,** which ultimately leads to the final step in cell specialization, called **cell differentiation.**
- **Nuclear equivalence** is the concept that, with a few exceptions, all the nuclei of the differentiated **somatic cells** of an organism are identical to one another and to the nucleus of the single cell from which they descended. **Totipotency** is the capability of cells to direct the development of an entire organism.

2 Describe the classic experiments of Steward, Gurdon, and Wilmut.

- Steward induced mature carrot root cells to de-differentiate and express their totipotency, forming an entire plant.

- Gurdon injected nuclei from tadpole intestinal cells into enucleated eggs; a small fraction of these developed into tadpoles, demonstrating the totipotency of the injected nucleus.
- Wilmut fused a differentiated cell from an adult sheep cell with an enucleated egg and implanted it into the uterus of a host mother, where it developed into a normal lamb.

CENGAGENOW™ Learn more about sheep cloning by clicking on the figure in CengageNOW.

3 Define *stem cells,* distinguish between embryonic stem cells and pluripotent stem cells, and describe some of the promising areas of research involving stem cells.

- **Stem cells** can divide to produce differentiated descendants yet retain the ability to divide to maintain the stem cell population. Totipotent stem cells give rise to all cell types of the body and placenta, whereas **pluripotent stem cells** give rise to many, but not all, types of cells in an organism.
- **Embryonic stem (ES) cells,** formed after a zygote has undergone several rounds of cell division to become a 5- or 6-day-old blastocyst, are pluripotent and have the potential to develop into any type of cell in the body; ES cells are not totipotent because they cannot form cells of the placenta.
- Stem cells show promise in treating diseases, such as Parkinson's disease and diabetes mellitus.

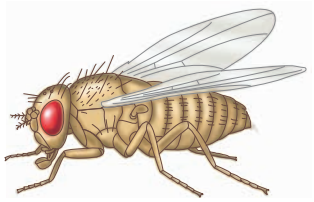
17.2 *(page 375)*

4 Indicate the features of *Drosophila melanogaster, Caenorhabditis elegans, Mus musculus,* and *Arabidopsis thaliana* that have made these organisms valuable models in developmental genetics.

- Developmental mutations have been identified in the fruit fly, *Drosophila,* many of which affect the organism's segmented body plan. Many developmental genes discovered in the fruit fly are

www.konkur.in

now known to be important in the growth and development of all animals.



- *C. elegans* is a roundworm with **mosaic development,** a rigid developmental pattern in which the fates of cells are restricted early in development. The lineage of every somatic cell in the adult is known, and each can be traced to a single **founder cell** in the early embryo.
- The laboratory mouse, *M. musculus,* is extensively used in studies of mammalian development. The mouse shows **regulative development;** the very early embryo is a self-regulating whole and can develop normally even if it has extra or missing cells. **Transgenic** mice, in which foreign genes have been incorporated, have helped researchers determine how genes are activated and regulated during development.
- Genes affecting development have also been identified in certain plants, such as *A. thaliana.* The **ABC model** of interactions among three kinds of genes hypothesizes how floral organs develop in *Arabidopsis.* Mutations in these homeotic genes cause one flower part to be substituted for another.

5 Distinguish among maternal effect genes, segmentation genes, and homeotic genes in *Drosophila.*

- The earliest developmental events to operate in the egg are established by **maternal effect genes** in the surrounding maternal tissues, which are active prior to fertilization. Some produce gradients of **morphogens,** chemical agents that affect the differentiation and development of form. Maternal effect genes establish polarity in the embryo.
- **Segmentation genes** generate a repeating pattern of body segments within the embryo. **Gap genes** are segmentation genes that begin organizing the body into anterior, middle, and posterior regions; **pair–rule genes** and **segment polarity genes** affect all segments.
- The later-acting **homeotic genes** are responsible for specifying the identity of each segment.

6 Explain the relationship between transcription factors and genes that control development.

- **Transcription factors** are DNA-binding proteins that regulate transcription in eukaryotes. Some genes that code for transcription factors contain a DNA sequence called a **homeobox,** which codes for a protein with a DNA-binding region called a **homeodomain.**
- Some homeobox genes are organized into complexes that appear to be systems of master genes specifying an organism's body plan. Parallels exist between the homeobox complexes of *Drosophila* and those of other animals.

7 Define *induction* and *apoptosis,* and give examples of the roles they play in development.

- **Induction** is developmental interactions with neighboring cells. During development in *C. elegans,* the anchor cell induces cells on the surface to organize to form the vulva, the structure through which the eggs are laid.
- **Apoptosis** is programmed cell death. During human development, the human hand forms as a webbed structure, but the fingers become individualized when the cells between them die.

17.3 *(page 387)*

8 Discuss the relationship between cancer and mutations that affect cell developmental processes.

- The traits of cancer cells are due to cancer-causing **oncogenes.** Oncogenes arise from changes in the expression of normal genes called **proto-oncogenes,** which exist in all cells and are involved in the control of growth and development.
- Known proto-oncogenes include genes that code for various **growth factors** or **growth factor receptors** and genes that respond to stimulation by growth factors, including many transcription factors. When a proto-oncogene is expressed inappropriately (i.e., becomes an oncogene), the cell may misinterpret the signal and respond by growing and dividing.
- **Tumor suppressor genes** normally interact with growth-inhibiting factors to block cell division. A mutation in a tumor suppressor gene may inactivate it and thereby lead to cancer.

TEST YOUR UNDERSTANDING

1. Morphogenesis occurs through the multistep process of (a) differentiation (b) determination (c) pattern formation (d) totipotency (e) selection
2. The cloning experiments carried out on frogs demonstrated that (a) all differentiated frog cells are totipotent (b) some differentiated frog cells are totipotent (c) all nuclei from differentiated frog cells are totipotent (d) some nuclei from differentiated frog cells are totipotent (e) cell differentiation always requires the loss of certain genes
3. The anterior-posterior axis of a *Drosophila* embryo is first established by certain (a) homeotic genes (b) maternal effect genes (c) segmentation genes (d) proto-oncogenes (e) pair–rule genes
4. You discover a new *Drosophila* mutant in which mouth parts are located where the antennae are normally found. You predict that the mutated gene is most likely a (a) homeotic gene (b) gap gene (c) pair–rule gene (d) maternal effect gene (e) segment polarity gene
5. Most segmentation genes code for (a) transfer RNAs (b) enzymes (c) transcription factors (d) histones (e) transport proteins
6. Homeobox genes (a) are found in fruit flies but no other animals (b) tend to be expressed in the order that they appear on a chromosome (c) contain a characteristic DNA sequence (d) b and c (e) a, b, and c
7. The developmental pattern of *C. elegans* is said to be mosaic because (a) development is controlled by gradients of morphogens (b) part of the embryo fails to develop if a founder cell is destroyed (c) some individuals are self-fertilizing hermaphrodites (d) all development is controlled by maternal effect genes (e) apoptosis never occurs

www.konkur.in

8. Which of the following illustrates the regulative nature of early mouse development? (a) the mouse embryo is free-living prior to implantation in the uterus (b) it is possible to produce a transgenic mouse (c) it is possible to produce a mouse in which a specific gene has been knocked out (d) genes related to *Drosophila* homeotic genes have been identified in mice (e) a chimeric mouse can be produced by fusing two mouse embryos
9. *Arabidopsis* is useful as a model organism for the study of plant development because (a) it is of great economic importance (b) it has a very long generation time (c) many developmental mutants have been isolated (d) it contains a large amount of DNA per cell (e) it has a rigid developmental pattern
10. Pluripotent stem cells (a) lose genetic material during development (b) give rise to many, but not all, types of cells in an organism (c) organize into recognizable structures through pattern formation (d) cannot grow in tissue culture (e) have been used to clone a sheep and several other mammals
11. Which of the following statements about cancer is *false*? (a) oncogenes arise from mutations in proto-oncogenes (b) tumor suppressor genes normally interact with growth-inhibiting factors to block cell division (c) more than 100 oncogenes and 15 tumor suppressor genes have been identified (d) oncogenes were first discovered in mouse models for cancer (e) the development of cancer is usually a multistep process involving both oncogenes and mutated tumor suppressor genes
12. Proto-oncogenes code for (a) morphogens (b) antibodies for immune responses (c) growth factor receptors and other components of the growth control cascade (d) enzymes such as reverse transcriptase (e) ES cells

CRITICAL THINKING

1. Why is an understanding of gene regulation in eukaryotes crucial to an understanding of developmental processes?
2. Why do scientists study development in more than one type of organism?
3. Could a gene be involved in the growth of both stem cells and some kinds of cancer? Explain your answer.
4. **EVOLUTION LINK.** How are the striking similarities among genes that govern development in widely differing species strong evidence for evolution?
5. **EVOLUTION LINK.** What is the common ground between evolutionary biologists and developmental biologists who have adopted the perspective known as Evo Devo?
6. **ANALYZING DATA.** Flower parts are arranged in four concentric circles: sepals, petals, stamens, and carpel. According to the ABC model of floral organ development in *Arabidopsis,* class *A* genes are needed to specify sepals, the *A* and *B* genes to specify petals, the *B* and *C* genes to specify stamens, and class *C* genes to specify the carpel. If a mutation occurs in one of the *B* genes, rendering it inactive, what will the resulting flowers consist of?

18 Introduction to Darwinian Evolution

Science Source/Photo Researchers, Inc.

Charles Darwin. This portrait was made shortly after Darwin returned to England from his voyage around the world.

KEY CONCEPTS

18.1 Evolution is the accumulation of inherited changes within populations over time.

18.2 Ideas about evolution originated long before Darwin's time.

18.3 Darwin's scientific theory of evolution, natural selection, explained how natural forces in the environment could cause evolution. Natural selection occurs because individuals with traits that make them better adapted to local conditions are more likely to survive and produce offspring than are individuals that are not as well adapted. The modern synthesis combines Darwin's theory with genetics.

18.4 The evidence that evolution has taken place and is still occurring is overwhelming. This evidence includes fossils, biogeography, comparative anatomy, molecular biology, developmental biology, and evolutionary experiments with living organisms.

A great deal of evidence suggests that the biological diversity represented by the millions of species currently living on our planet evolved from a single ancestor during Earth's long history. Thus, organisms that are radically different from one another are in fact distantly related, linked through numerous intermediate ancestors to a single, common ancestor. The British naturalist Charles Darwin (1809–1882) developed a simple, scientifically testable mechanism to explain the relationship among Earth's diversity of organisms. He argued persuasively that all the species that exist today, as well as the countless extinct species that existed in the past, arose from earlier ones by a process of gradual *divergence* (splitting into separate evolutionary pathways), or *evolution*.

The concept of evolution is the cornerstone of biology because it links all fields of the life sciences into a unified body of knowledge. As stated by U.S. geneticist Theodosius Dobzhansky, "Nothing in biology makes sense except in the light of evolution."[1] Biologists seek to understand both the remarkable variety and the fundamental similarities of organisms within the context of evolution. The science of evolution allows biologists to

[1] *American Biology Teacher,* Vol. 35, No. 125 (1973).

www.konkur.in

compare common threads among organisms as seemingly different as bacteria, whales, lilies, slime molds, and tapeworms. Animal behavior, developmental biology, genetics, evolutionary ecology, systematics, and molecular evolution are examples of some of the biological disciplines that are grounded in evolution.

This chapter discusses Charles Darwin and the development of his evolutionary theory by natural selection. It also presents evidence that supports evolution, including fossils, biogeography, comparative anatomy, molecular biology, developmental biology, and experimental studies of ongoing evolutionary change in both the laboratory and nature.

18.1 WHAT IS EVOLUTION?

LEARNING OBJECTIVE

1 Define *evolution*.

In beginning our study of evolution, we define **evolution** as the accumulation of genetic changes within populations over time. A **population** is a group of individuals of one species that live in the same geographic area at the same time. Just as the definition of a *gene* changed as you studied genetics, you will find that the definition of *evolution* will become more precise in later chapters.

The term *evolution* does not refer to changes that occur in an individual within its lifetime. Instead, it refers to changes in the characteristics of populations over the course of generations. These changes may be so small that they are difficult to detect or so great that the population differs markedly from its ancestral population.

Eventually, two populations may diverge to such a degree that we refer to them as different species. The concept of species is developed extensively in Chapter 20. For now, a simple working definition is that a **species** is a group of organisms, with similar structure, function, and behavior, that are capable of interbreeding with one another.

Evolution has two main perspectives—the minor evolutionary changes of populations usually viewed over a few generations (*microevolution,* discussed in Chapter 19) and the major evolutionary events usually viewed over a long period, such as formation of different species from common ancestors (*macroevolution,* discussed in Chapter 20).

Evolution has important practical applications. Agriculture must deal with the evolution of pesticide resistance in insects and other pests. Likewise, medicine must respond to the rapid evolutionary potential of disease-causing organisms such as bacteria and viruses (**FIG. 18-1**). (Significant evolutionary change occurs in a very short time period in insects, bacteria, and other organisms with short lifespans.) Medical researchers use evolutionary principles to predict which flu strains are evolving more quickly, information that scientists need to make the next year's flu vaccine. Also, researchers developing effective treatment strategies for the human immunodeficiency virus (HIV) must understand its evolution, both within and among hosts.

The conservation management of rare and endangered species makes use of the evolutionary principles of population genetics. The rapid evolution of bacteria and fungi in polluted soils is used in the field of **bioremediation,** in which microorganisms are employed to clean up hazardous-waste sites. Evolution even has applications beyond biology. For example, certain computer applications make use of algorithms that mimic natural selection in biological systems.

18.2 PRE-DARWINIAN IDEAS ABOUT EVOLUTION

LEARNING OBJECTIVE

2 Discuss the historical development of evolutionary theory.

Although Darwin is universally associated with evolution, ideas of evolution predate Darwin by centuries. Aristotle (384–322 BCE) saw much evidence of natural affinities among organisms. This led him to arrange all the organisms he knew in a "scale of nature" that extended from the exceedingly simple to the most complex. Aristotle visualized organisms as being imperfect but "moving toward a more perfect state." Some scientific historians have interpreted this idea as the forerunner of evolutionary theory, but Aristotle was vague on the nature of this "movement toward perfection" and certainly did not propose that natural processes drove the process of evolution. Furthermore, modern evolutionary theory now recognizes that evolution does not move toward more "perfect" states or even necessarily toward greater complexity.

Long before Darwin's time, fossils had been discovered embedded in rocks. Some of these corresponded to parts of famil-

www.konkur.in

iar species, but others were strangely unlike any known species. Fossils were often found in unexpected contexts; for example, marine invertebrates (sea animals without backbones) were sometimes discovered in rocks high on mountains. Leonardo da Vinci (1452–1519) was among the first to correctly interpret these unusual finds as the remains of animals that had existed in previous ages but had become extinct.

The French naturalist Jean Baptiste de Lamarck (1744–1829) was the first scientist to propose that organisms undergo change over time as a result of some natural phenomenon rather than divine intervention. According to Lamarck, a changing environment caused an organism to alter its behavior, thereby using some organs or body parts more and others less. Over several generations, a given organ or body part would increase in size if it was used a lot, or shrink and possibly disappear if it was used less. His hypothesis required that organisms pass traits they acquired during their lifetimes to their offspring. For example, Lamarck suggested that the long neck of the giraffe developed when a short-necked ancestor stretched its neck to browse on the leaves of trees. Its offspring inherited the longer neck, which stretched still further as they ate. This process, repeated over many generations, resulted in the long necks of modern giraffes. Lamarck also thought that all organisms were endowed with a vital force that drove them to change toward greater complexity and "perfection" over time.

Lamarck's proposed mechanism of evolution is quite different from the mechanism later proposed by Darwin. However, Lamarck's hypothesis remained a reasonable explanation for evolution until Mendel's basis of heredity was rediscovered at the beginning of the 20th century. At that time, Lamarck's ideas were largely discredited.

18.3 DARWIN AND EVOLUTION

LEARNING OBJECTIVES

3 Explain the four premises of evolution by natural selection as proposed by Charles Darwin.

4 Compare the modern synthesis with Darwin's original evolutionary theory.

Darwin, the son of a prominent physician, was sent at the age of 15 to study medicine at the University of Edinburgh. Finding himself unsuited for medicine, he transferred to Cambridge University to study theology. During that time, he became the protégé of the Reverend John Henslow, who was a professor of botany. Henslow encouraged Darwin's interest in the natural world. Shortly after receiving his degree, Darwin embarked on the HMS *Beagle,* which was taking a 5-year exploratory cruise around the world to prepare navigation charts for the British navy.

The *Beagle* left Plymouth, England, in 1831 and cruised along the east and west coasts of South America (**FIG. 18-2**). While other members of the crew mapped the coasts and harbors, Darwin spent many weeks ashore studying the animals, plants, fossils, and geologic formations of both coastal and inland regions, areas that had not been extensively explored. He collected and cataloged thousands of plant and animal specimens and kept notes of his observations, information that became essential in the development of his theory.

The *Beagle* spent almost 2 months at the Galápagos Islands, 965 km (600 mi) west of Ecuador, where Darwin continued his observations and collections. He compared the animals and plants of the Galápagos with those of the South American mainland. He was particularly impressed by their similarities and wondered why the organisms of the Galápagos should resemble those from South America more than those from other islands in different parts of the world. Moreover, although there were similarities between Galápagos and South American species, there were also distinct

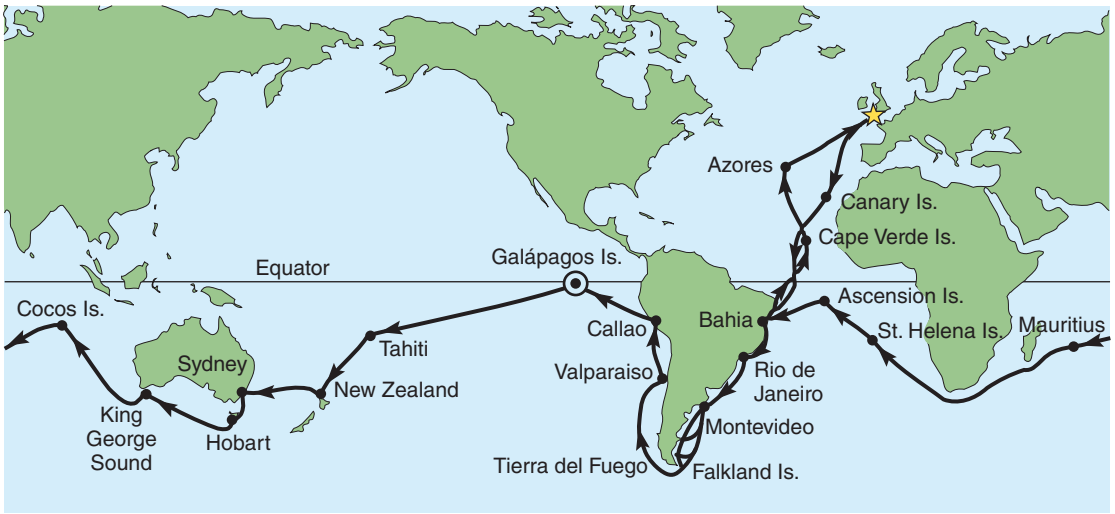

FIGURE 18-2 ***Animated*** **The voyage of HMS *Beagle***

The 5-year voyage began in Plymouth, England (*star*), in 1831. Observations made in the Galápagos Islands (*bull's-eye*) off the western coast of South America helped Darwin develop a satisfactory mechanism to explain how a population of organisms could change over time.

www.konkur.in

differences. There were even recognizable differences in the reptiles and birds from one island to the next. Darwin wondered why these remote islands should have such biological diversity. After he returned home, Darwin pondered these observations and attempted to develop a satisfactory explanation for the distribution of species among the islands.

Darwin drew on several lines of evidence when considering how species might have originated. Despite the work of Lamarck, the general notion in the mid-1800s was that Earth was too young for organisms to have changed significantly since they had first appeared. During the early 19th century, however, geologists advanced the idea that mountains, valleys, and other physical features of Earth's surface did not originate in their present forms. Instead, these features developed slowly over long periods by the geologic processes of volcanic activity, uplift, erosion, and glaciation. On his voyage Darwin took with him *Principles of Geology,* published by English geologist Charles Lyell in 1830, and studied it carefully. Lyell provided an important concept for Darwin—that the slow pace of geologic processes, which still occur today, indicated that Earth was extremely old.

Other important evidence that influenced Darwin was the fact that breeders and farmers could develop many varieties of domesticated animals in just a few generations. They did so by choosing certain traits and breeding only individuals that exhibited the desired traits, a procedure known as **artificial selection.** Breeders, for example, have produced numerous dog varieties—such as bloodhounds, dalmatians, Airedales, border collies, and Pekinese—by artificial selection.

Many plant varieties were also produced by artificial selection. For example, cabbage, broccoli, brussels sprouts, cauliflower, collard greens, kale, and kohlrabi are distinct vegetable crops that are all members of the same species, *Brassica oleracea* (**FIG. 18-3**). Selective breeding of the colewort, or wild cabbage, a leafy plant native to Europe and Asia, produced all seven vegetables. Beginning more than 4000 years ago, some farmers artificially selected wild cabbage plants that formed overlapping leaves. Over time, these leaves became so prominent that the plants, which resembled modern cabbages, became recognized as separate and distinct from their wild cabbage ancestor. Other farmers selected different features of the wild cabbage, giving rise to the other modifications. For example, kohlrabi was produced by selection for an enlarged storage stem, and brussels sprouts by selection for enlarged axillary buds. Thus, humans are responsible for the evolution of *B. oleracea* into seven distinct vegetable crops. Darwin was impressed by the changes induced by artificial selection and hypothesized that a similar selective process occurred in nature. Darwin therefore used artificial selection as a model when he developed the concept of natural selection.

The ideas of Thomas Malthus (1766–1834), a British clergyman and economist, were another important influence on Darwin. In *An Essay on the Principle of Population as It Affects the Future Improvement of Society,* published in 1798, Malthus noted that population growth is not always desirable—a view contrary to the beliefs of his day. He observed that populations have the capacity to increase geometrically ($1 \longrightarrow 2 \longrightarrow 4 \longrightarrow 8 \longrightarrow 16$) and thus outstrip the food supply, which only has the capacity to increase arithmetically ($1 \longrightarrow 2 \longrightarrow 3 \longrightarrow 4 \longrightarrow 5$). In the case of humans, Malthus suggested that the conflict between population growth and food supply generates famine, disease, and war, which serve as inevitable brakes on population growth.

FIGURE 18-3 Artificial selection in *Brassica oleracea*
An enlarged terminal bud (the "head") was selected in cabbage (*lower left*), flower clusters in broccoli (*upper left*) and cauliflower (*middle right*), axillary buds in brussels sprouts (*bottom middle*), leaves in collards (*upper right*) and kale (*lower right*), and stems in kohlrabi (*middle*).

Malthus's idea that there is a strong and constant check on human population growth strongly influenced Darwin's explanation of evolution. Darwin's years of observing the habits of animals and plants had introduced him to the struggle for existence described by Malthus. It occurred to Darwin that in this struggle, inherited variations favorable to survival would tend to be preserved, whereas unfavorable ones would be eliminated.

The result would be **adaptation,** an evolutionary modification that improves the chances of survival and reproductive success in a given environment. Eventually, the accumulation of modifications might result in a new species. Time was the only thing required for new species to originate, and the geologists of the era, including Lyell, had supplied evidence that Earth was indeed old enough to provide adequate time.

Darwin had at last developed a workable scientific explanation of evolution, that of **natural selection,** in which better adapted organisms are more likely to survive and become the parents of the next generation. As a result of natural selection, the population changes over time; the frequency of favorable traits increases in successive generations, whereas less favorable traits become scarce or disappear. Darwin spent the next 20 years formulating his arguments for natural selection, accumulating an immense body of evidence to support his theory, and corresponding with other scientists.

As Darwin was pondering his ideas, Alfred Russel Wallace (1823–1913), a British naturalist who studied the plants and animals of the Malay Archipelago for 8 years, was similarly struck by the diversity of species and the peculiarities of their distribution. He wrote a brief essay on this subject and sent it to Darwin, by then a world-renowned biologist, asking his opinion. Darwin rec-

www.konkur.in

ognized his own theory and realized Wallace had independently arrived at the same conclusion—that evolution occurs by natural selection. Darwin's colleagues persuaded him to present Wallace's manuscript along with an abstract of his own work, which he had prepared and circulated to a few friends several years earlier. Both papers were presented in July 1858 at a London meeting of the Linnaean Society. Darwin's monumental book, *On the Origin of Species by Natural Selection; or, The Preservation of Favored Races in the Struggle for Life,* was published in 1859. In 1870, Wallace's book, *Contributions to the Theory of Natural Selection,* was published, 8 years after he returned from the Malay Archipelago.

Darwin proposed that evolution occurs by natural selection

Darwin's mechanism of evolution by natural selection consists of observations on four aspects of the natural world: variation; overproduction; limits on population growth, or a struggle for existence; and differential reproductive success.

1. *Variation.* The individuals in a population exhibit variation (**FIG. 18-4**). Each individual has a unique combination of traits, such as size, color, ability to tolerate harsh environmental conditions, and resistance to certain parasites or infections. Some traits improve an individual's chances of survival and reproductive success, whereas others do not. Remember that the variation necessary for evolution by natural selection must be inherited. Although Darwin recognized the importance to evolution of inherited variation, he did not know the mechanism of inheritance.
2. *Overproduction.* The reproductive ability of each species has the potential to cause its population to geometrically increase over time. A female frog lays about 10,000 eggs, and a female cod produces perhaps 40 million eggs! In each case, however, only about two offspring survive to reproduce. Thus, in every generation each species has the capacity to produce more offspring than can survive.
3. *Limits on population growth, or a struggle for existence.* There is only so much food, water, light, growing space, and other resources available to a population, so organisms compete with one another for these limited resources. Because there are more individuals than the environment can support, not all survive to reproduce. Other limits on population growth include predators, disease organisms, and unfavorable weather conditions.
4. *Differential reproductive success.* Those individuals that have the most favorable combination of characteristics (those that make individuals better adapted to their environment) are more likely to survive and reproduce. Offspring tend to resemble their parents because the next generation inherits the parents' genetically based traits. Successful reproduction is the key to natural selection: the best-adapted individuals produce the most offspring, whereas individuals that are less well adapted die prematurely or produce fewer or inferior offspring.

FIGURE 18-4 Genetic variation in emerald tree boas

These snakes, all of the same species (*Corallus caninus*), were caught in a small section of forest in French Guiana. Many snake species exhibit considerable variation in their coloration and patterns.

Over time, enough changes may accumulate in geographically separated populations (often with slightly different environments) to produce new species. Darwin noted that the Galápagos finches appeared to have evolved in this way. The 14 species are closely related. All descended from a common ancestor—a single species that found its way from the South American mainland 2 million to 3 million years ago. (The closest genetic relatives of the Galápagos finches are small seed-eating birds known as grassquits that live in western South America.)

During this 2-million to 3-million year period, the number of islands increased, the climate changed, and the plant life and food supply changed. The different islands of the Galápagos kept the finches isolated from one another, thereby allowing them to diverge into separate species in response to varying conditions (**FIG. 18-5**).

Peter Grant, Rosemary Grant, and colleagues have documented natural selection in the Galápagos finches in their natural environment since the early 1970s. As an example of the evolutionary process in action, consider the sharp-beaked ground finch (*Geospiza difficilis*). This species lives on several different islands, and each population has evolved different beak shapes and sizes depending on the diet available on the island where it lives.

We revisit the Galápagos finches in later chapters. Some long-term research by Peter Grant, Rosemary Grant, and colleagues on the microevolution of Galápagos finches when droughts affect the food supply is described in Chapter 19; these studies have demonstrated that environmental change can drive natural selection. *Character displacement,* an aspect of evolutionary ecology, is described in Galápagos finches in Chapter 54.

The modern synthesis combines Darwin's theory with genetics

One of the premises on which Darwin based his scientific theory of evolution by natural selection is that individuals transmit traits to the next generation. However, Darwin was unable to explain *how* this occurs or *why* individuals vary within a population. As discussed in Chapter 11, Gregor Mendel elucidated the basic patterns of inheritance. Darwin, who was a contemporary of Mendel, was apparently not acquainted with Mendel's work. Indeed, the scientific community did not recognize Mendel's work until the early part of the 20th century.

(d) The woodpecker finch (*Camarhynchus pallidus*) digs insects out of bark and crevices by using spines, twigs, or even dead leaves.

FIGURE 18-5 ***Animated*** **Galápagos finches**

Darwin inferred that these birds are derived from a common ancestral population of seed-eating birds from South America. Variation in their beaks is the result of adaptation to the availability of different kinds of food.

Beginning in the 1930s and 1940s, biologists experienced a conceptual breakthrough when they combined the principles of Mendelian inheritance with Darwin's theory of natural selection. The result was a unified explanation of evolution known as the **modern synthesis.** In this context, *synthesis* refers to combining parts of several theories to form a unified whole. Some of the founders of the modern synthesis were U.S. geneticist Theodosius Dobzhansky, British geneticist and statistician Ronald Fisher, British geneticist J. B. S. Haldane, British biologist Julian Huxley, U.S. biologist Ernst Mayr, U.S. paleontologist George Gaylord Simpson, U.S. botanist G. Ledyard Stebbins, and U.S. geneticist Sewell Wright.

Today, the modern synthesis incorporates our expanding knowledge in genetics, which on its own makes an irrefutable case for evolution, systematics, paleontology, developmental biology, behavior, and ecology. The modern synthesis explains Darwin's observation of variation among offspring in terms of **mutation,** or changes in DNA, such as nucleotide substitutions. Mutations provide the genetic variability on which natural selection acts during evolution. The modern synthesis, which emphasizes the genetics of populations as the central focus of evolution, has held up well since it was developed. It has dominated the thinking and research of biologists working in many areas and has resulted in an enormous accumulation of new discoveries that validate evolution by natural selection.

Most biologists not only accept the basic principles of the modern synthesis but also try to better understand the causal processes of evolution. For example, what is the role of chance in evolution? How rapidly do new species evolve? These and other questions have arisen in part from a re-evaluation of the fossil record and in part from new discoveries in molecular aspects of inheritance. Such critical analyses are an integral part of the scientific process because they stimulate additional observation and experimentation, along with re-examination of previous evidence. Science is an ongoing process, and information obtained in the future may require modifications to certain parts of the modern synthesis.

We now consider one of the many evolutionary questions currently being addressed by biologists: the relative effects of chance and natural selection on evolution.

Biologists study the effect of chance on evolution

Biologists have wondered whether we would get the same results if we were able to repeat evolution by starting with similar organisms exposed to similar environmental conditions. That is, would the same kinds of changes evolve, as a result of natural selection? Or would the organisms be quite different as a result of random events? Several recently reported examples of evolution in action suggest that chance may not be as important as natural selection, at least at the population level.

A fruit fly species (*Drosophila subobscura*) native to Europe inhabits areas from Denmark to Spain. Biologists noted that the northern flies have larger wings than southern flies (**FIG. 18-6**). The same fly species was accidentally introduced to North America in the late 1970s. Ten years after its introduction, biologists determined that no statistically significant changes in wing size had occurred in the different regions of North America. However, 20 years after its introduction, the fruit flies in North America exhibited the same type of north–south wing changes as in Europe. (It is not known why larger wings evolve in northern areas and smaller wings in southern climates.)

A study of the evolution of fishes known as *sticklebacks* in three coastal lakes of western Canada yielded intriguingly similar results to the fruit fly study. Molecular evidence indicates that when the lakes first formed several thousand years ago, they were populated with the same ancestral species. (Analysis of the mitochondrial DNA of sticklebacks in the three lakes supports the hypothesis of a common ancestor.) In each lake, the same two species have evolved from the common ancestral fish. One species is large and consumes invertebrates along the bottom of the lake, whereas the other species is smaller and consumes plankton at the lake's surface.

www.konkur.in

George Gilchrist

FIGURE 18-6 Wing size in female fruit flies

In Europe, female fruit flies (*Drosophila subobscura*) in northern countries have larger wings than flies in southern countries. Shown are two flies: one from Denmark (*right*) and the other from Spain (*left*). The same evolutionary pattern emerged in North America after the accidental introduction of *D. subobscura* to the Americas.

Members of the two species within a single lake do not interbreed with each other, but individuals of the larger species from one lake interbreed in captivity with individuals of the larger species from the other lakes. Similarly, smaller individuals from one lake interbreed in captivity with smaller individuals from the other lakes.

In these examples, natural selection appears to be a more important agent of evolutionary change than chance. If chance were the most important factor influencing the direction of evolution, then fruit fly evolution would not have proceeded the same way on two different continents, and stickleback evolution would not have proceeded the same way in three different lakes. However, just because we have many examples of the importance of natural selection in evolution, it does not necessarily follow that random events should be discounted as a factor in directing evolutionary change. Proponents of the role of chance think that chance is more important in the evolution of major taxonomic groups (macroevolution) than in the evolution of populations (microevolution). It also may be that random events take place but their effects on evolution are harder to demonstrate than natural selection.

Review

- What is natural selection?
- Why are only inherited variations important in the evolutionary process?
- What part of Darwin's theory was he unable to explain? How does the modern synthesis fill this gap?

18.4 EVIDENCE FOR EVOLUTION

LEARNING OBJECTIVES

5 Summarize the evidence for evolution obtained from the fossil record.

6 Define *biogeography* and describe how the distribution of organisms supports evolution.

7 Describe the evidence for evolution derived from comparative anatomy.

8 Briefly explain how molecular biology and developmental biology provide insights into the evolutionary process.

9 Give an example of how evolutionary hypotheses are tested experimentally.

A vast body of scientific evidence supports evolution, including observations from the fossil record, biogeography, comparative anatomy, molecular biology, and developmental biology. In addition, evolutionary hypotheses are increasingly being tested experimentally. Taken together, this evidence confirms the scientific theory that life unfolded on Earth by the process of evolution.

The fossil record provides strong evidence for evolution

Perhaps the most direct evidence for evolution comes from the discovery, identification, and interpretation of **fossils,** which are the remains or traces typically left in sedimentary rock by previously existing organisms. (The term *fossil* comes from the Latin word *fossilis,* meaning "something dug up.") Sedimentary rock forms by the accumulation and solidification of particles (pebbles, sand, silt, or clay) produced by the weathering of older rocks, such as volcanic rocks. The sediment particles, which are usually deposited on a riverbed, lake bottom, or the ocean floor, accumulate over time and exhibit distinct layers (**FIG. 18-7**). In an undisturbed rock sequence, the oldest layer is at the bottom, and upper layers are successively younger. The study of sedimentary rock layers, including their composition, arrangement, and similarity from one location to another, enables geologists to place events recorded in rocks in their correct sequence.

The fossil record shows a progression from the earliest unicellular organisms to the many unicellular and multicellular organisms living today (see Table 21-1). The fossil record therefore demonstrates that life has evolved through time. To date, paleontologists (scientists who study extinct species) have described and named about 300,000 fossil species, and others are still being discovered.

Although most fossils are preserved in sedimentary rock, some more recent remains have been exceptionally well preserved in bogs, tar, amber (ancient tree resin), or ice (**FIG. 18-8**). For example, the remains of a woolly mammoth deep-frozen in Siberian ice for more than 25,000 years were so well preserved that part of its DNA could be analyzed.

Few organisms that die become fossils. The formation and preservation of a fossil require that an organism be buried under conditions that slow or prevent the decay process. This is most likely to occur if an organism's remains are covered quickly by a sediment of fine soil particles suspended in water. In this way the remains of aquatic organisms may be trapped in bogs, mudflats, sandbars, or deltas. Remains of terrestrial organisms that lived on a floodplain may also be covered by waterborne sediments or, if the organism lived in an arid region, by windblown sand. Over time, the sediments harden to form sedimentary rock, and minerals usually replace the organism's remains so that many details of its structure, even cellular details, are preserved.

The fossil record is not a random sample of past life but instead is biased toward aquatic organisms and those living in the

FIGURE 18-7 Exposed layers of sedimentary rock at the Burgess shale fossil bed

This site, located in the Canadian Rockies, was formed about 500 million years ago when an avalanche of mud buried and preserved diverse and unusual marine animals.

few terrestrial habitats conducive to fossil formation. Relatively few fossils of tropical rainforest organisms have been found, for example, because their remains decay extremely rapidly on the forest floor, before fossils can develop. Another reason for bias in the fossil record is that organisms with hard body parts such as bones and shells are more likely to form fossils than are those with soft body parts. Also, rocks of different ages are unequally exposed at Earth's surface; some rocks of certain ages are more accessible to paleontologists for fossil study than are rocks of other ages.

Because of the nature of the scientific process, each fossil discovery represents a separate "test" of evolutionary theory. If any of the tests fail, the theory would have to be modified to fit the existing evidence. The verifiable discovery, for example, of fossil remains of modern humans (*Homo sapiens*) in Precambrian rocks, which are more than 570 million years old, would falsify evolutionary theory as currently proposed. However, Precambrian rocks examined to date contain only fossils of simple organisms, such as algae and small, soft-bodied animals, that evolved early in the history of life. The earliest fossils of *H. sapiens* with anatomically modern features do not appear in the fossil record until approximately 195,000 years ago (see Chapter 22).

Fossils provide a record of ancient organisms and some understanding of where and when they lived. Using fossils of organisms from different geologic ages, scientists can sometimes infer the lines of descent (evolutionary relationships) that gave rise to modern-day organisms. In many instances, fossils provide direct evidence of the origin of new species from pre-existing species, including many transitional forms.

Transitional fossils document whale evolution

Over the past century, biologists have found evidence suggesting that whales and other cetaceans (an order of marine mammals) evolved from land-dwelling mammals. During the 1980s and 1990s, paleontologists discovered several fossil intermediates in whale evolution that help document the whales' transition from land to water.

Fossils of *Ambulocetus natans,* a 50-million-year-old transitional form discovered in Pakistan, have many features of modern whales but also possess hind limbs and feet (**FIG. 18-9a**). (Modern whales do not have hind limbs, although *vestigial* pelvic and hind-limb bones persist. Vestigial structures are discussed later in the chapter.) The vertebrae of *Ambulocetus*'s lower back were very flexible, allowing the back to move dorsoventrally (up and down) during swimming and diving, as with modern whales. This ancient whale could swim but also moved about on land, perhaps as sea lions do today.

Rodhocetus is a fossil whale found in more recent rocks in Pakistan (**FIG. 18-9b**). The vertebrae of *Rodhocetus* were even more flexible than those found in *Ambulocetus.* The flexible vertebrae allowed *Rodhocetus* a more powerful dorsoventral movement during swimming. *Rodhocetus* may have been totally aquatic.

By 40 million years ago (mya), the whale transition from land to ocean was almost complete. Egyptian fossils of *Basilosaurus* show a whale with a streamlined body and front flippers for steering, like those of modern-day whales (**FIG. 18-9c**). *Basilosaurus* retained vestiges of its land-dwelling ancestors—a pair of reduced hind limbs that were disjointed from the backbone and probably not used in locomotion. Reduction in the hind limbs continued to the present. The modern blue whale has vestigial pelvis and femur bones embedded in its body (**FIG. 18-9d**).

Various methods determine the age of fossils

Because layers of sedimentary rock occur naturally in the sequence of their deposition, with the more recent layers on top of the older, earlier ones, most fossils are dated by their relative position in sedimentary rock. However, geologic events occurring after the rocks were initially formed have occasionally changed the relationships of some rock layers. Geologists identify specific sedimentary rocks not only by their positions in layers but also by features such as mineral content and by the fossilized remains of certain organisms, known as **index fossils,** that characterize a specific layer over large geographic areas. Index fossils are fossils of organisms that existed for a relatively short geologic time but were preserved as fossils in large numbers. With this information, geologists can arrange rock layers and the fossils they contain in chronological order and identify comparable layers in widely separated locations.

Radioactive isotopes, also called **radioisotopes,** present in a rock provide a means to accurately measure its age (see Chapter 2). Radioisotopes emit invisible radiations. As radiation is emitted, the nucleus of a radioisotope changes into the nucleus of a different element; this process is known as **radioactive decay.** The radioactive nucleus of uranium-235, for example, decays into lead-207.

Each radioisotope has its own characteristic rate of decay. The time required for one half of the atoms of a radioisotope to change into a different atom is known as its **half-life** (**FIG. 18-10**). Radioisotopes differ significantly in their half-lives. For example,

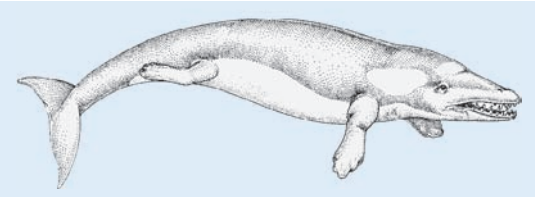
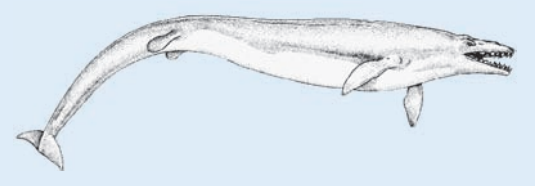
(a) *Ambulocetus natans,* a transitional form between modern whale descendants and their terrestrial ancestors, possessed several recognizable whale features. It retained the hind limbs of its four-legged ancestors, however.



(b) The more recent *Rodhocetus* had flexible vertebrae that permitted a powerful dorsoventral movement during swimming.



(c) *Basilosaurus* was more streamlined and possessed tiny nonfunctional hind limbs.

(d) *Balaenoptera,* the modern blue whale, contains vestiges of pelvis and leg bones embedded in its body.

FIGURE 18-9 Fossil intermediates in whale evolution

Biologists hypothesize that the ancestors of whales had four legs, as shown in these reconstructions of whale intermediates based on fossil evidence. Fossils indicate that ankle bones in whale intermediates match those found in present-day hippos, cows, pigs, and camels. Figures are not drawn to scale. (**a–c:** Adapted with permission from Futuyma, D. J., *Science on Trial: The Case for Evolution,* Fig. 2, pp. 260–261, Sinauer Associates, Sunderland, MA, 1995.)

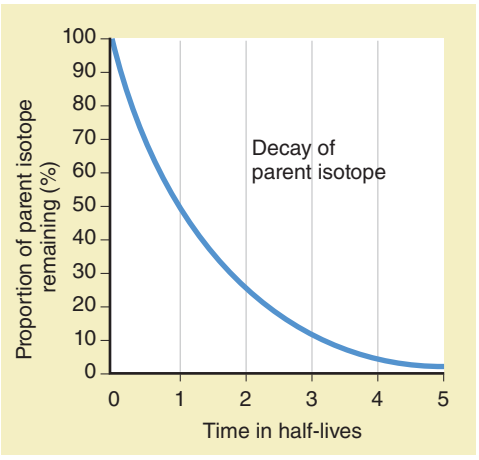


FIGURE 18-10 *Animated* Radioisotope decay

At time zero, the sample is composed entirely of the radioisotope and the radioactive clock begins ticking. After one half-life, only 50% of the original radioisotope remains. During each succeeding half-life, half of the remaining radioisotope is converted to decay product(s).

the half-life of iodine-132 is only 2.4 hours, whereas the half-life of uranium-235 is 704 million years. The half-life of a particular radioisotope is constant and does not vary with temperature, pressure, or any other environmental factor.

The age of a fossil in sedimentary rock is usually estimated by measuring the relative proportions of the original radioisotope and its decay product in volcanic rock intrusions that penetrate the sediments. For example, the half-life of potassium-40 is 1.3 billion years, meaning that in 1.3 billion years half of the radioactive potassium will have decayed into its decay product, argon-40. The radioactive clock begins ticking when the magma solidifies into volcanic rock. The rock initially contains some potassium but no argon. Because argon is a gas, it escapes from hot rock as soon as it forms, but when potassium decays in rock that has cooled and solidified, the argon accumulates in the crystalline structure of the rock. If the ratio of potassium-40 to argon-40 in the rock being tested is 1:1, the rock is 1.3 billion years old.

Several radioisotopes are commonly used to date fossils. Three of these are potassium-40 (half-life 1.3 billion years), uranium-235 (half-life 704 million years), and carbon-14 (half-life 5730 years). Radioisotopes other than carbon-14 are used to date the *rock* in which fossils are found, whereas carbon-14 is used to date the *carbon remains* of anything that was once living, such as wood, bones, and shells. Whenever possible, the age of a fossil is independently verified using two or more different radioisotopes.

Carbon-14, which is continuously produced in the atmosphere from nitrogen-14 (by cosmic radiation), subsequently decays to nitrogen-14. Because the formation and the decay of carbon-14 occur at constant rates, the ratio of carbon-14 to carbon-12 (a more abundant, stable isotope of carbon) is constant in the atmosphere. Organisms absorb carbon from the atmosphere either directly (by photosynthesis) or indirectly (by consuming photosynthetic organisms). Because each organism absorbs carbon from the atmosphere, its ratio of carbon-14 to carbon-12 is the same as that in the atmosphere. When an organism dies, however, it no longer absorbs carbon, and the proportion of carbon-14 in its remains declines as carbon-14 decays to nitrogen-14. Because of its relatively short half-life, carbon-14 is useful for dating fossils that are 50,000 years old or less. It is particularly useful for dating archaeological sites.

The distribution of plants and animals supports evolution

The study of the past and present geographic distribution of organisms is called **biogeography.** The geographic distribution of

www.konkur.in

organisms affects their evolution. Darwin was interested in biogeography, and he considered why the species found on ocean islands tend to resemble species of the nearest mainland, even if the environment is different. He also observed that species on ocean islands do not tend to resemble species on islands with similar environments in other parts of the world.

Darwin studied the plants and animals of two sets of arid islands—the Cape Verde Islands, nearly 640 km (400 mi) off western Africa, and the Galápagos Islands, about 960 km (600 mi) west of Ecuador, South America. On each group of islands, the plants and terrestrial animals were indigenous (native), but those of the Cape Verde Islands resembled African species and those of the Galápagos resembled South American species. The similarities of Galápagos species to South American species were particularly striking considering that the Galápagos Islands are dry and rocky and the nearest part of South America is humid and has a lush tropical rain forest. Darwin concluded that species from the neighboring continent migrated or were carried to the islands, where they subsequently adapted to the new environment and, in the process, evolved into new species.

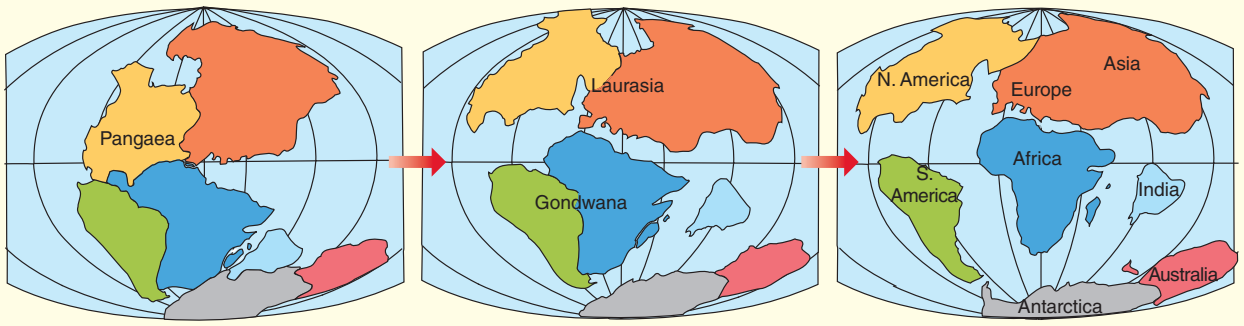
If evolution were not a factor in the distribution of species, we would expect to find a given species everywhere that it could survive. However, the actual geographic distribution of organisms makes sense in the context of evolution. For example, Australia, which has been a separate landmass for millions of years, has distinctive organisms. Australia has populations of egg-laying mammals (monotremes) and pouched mammals (marsupials) not found anywhere else. Two hundred million years ago, Australia and the other continents were joined in a major landmass. Over the course of millions of years, the Australian continent gradually separated from the others. The monotremes and marsupials in Australia continued to thrive and diversify. The isolation of Australia also prevented placental mammals, which arose elsewhere at a later time, from competing with its monotremes and marsupials. In other areas of the world where placental mammals evolved, most monotremes and marsupials became extinct.

We now consider how Earth's dynamic geology has affected biogeography and evolution.

Biogeography and evolution are related to Earth's geologic history

In 1915, the German scientist Alfred Wegener, who had noted a correspondence between the geographic shapes of South America and Africa, proposed that all the landmasses had at one time been joined into one huge supercontinent, which he called Pangaea (**FIG. 18-11a**). He further suggested that Pangaea had subsequently broken apart and that the various landmasses had separated in a process known as **continental drift.** Wegener did not know of any

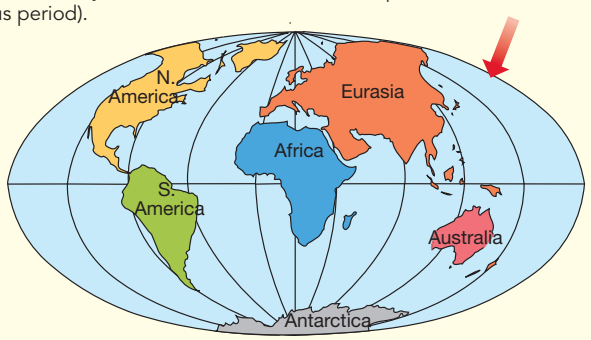
KEY POINT Geologists hypothesize that the breakup of Pangaea is only the latest in a series of continental breakups and collisions that have taken place since early in Earth's history.



(a) The supercontinent Pangaea, about 240 mya (Triassic period).

(b) Breakup of Pangaea into Laurasia (Northern Hemisphere) and Gondwana (Southern Hemisphere) began about 180 mya. The landmasses looked this way about 120 mya (Cretaceous period).

(c) Further separation of landmasses, 60 mya (early Paleogene period). Note that Europe and North America were still joined and that India was a separate landmass.



(d) The continents today.

FIGURE 18-11 *Animated* Continental drift

www.konkur.in

mechanism that could have caused continental drift, so his idea, although debated initially, was largely ignored.

In the 1960s, scientific evidence provided the explanation for continental drift. Earth's crust is composed of seven large plates (plus a few smaller ones) that float on the mantle, which is the mostly solid layer of Earth lying beneath the crust and above the core. (Because of its hotter temperature, the solid rock of the mantle is more plastic than the solid rock of the crust above it.)

The landmasses are situated on some of these plates. As the plates move, the continents change their relative positions (**FIGS. 18-11b, c,** and **d**). The movement of the crustal plates is termed **plate tectonics.**

Any area where two plates meet is a site of intense geologic activity. Earthquakes and volcanoes are common in such a region. Both San Francisco, noted for its earthquakes, and the Mount Saint Helens volcano are situated where two plates meet. If landmasses lie on the edges of two adjacent plates, mountains may form. The Himalayas formed when the plate carrying India rammed into the plate carrying Asia. When two plates grind together, one of them is sometimes buried under the other in a process known as *subduction*. When two plates move apart, a ridge of lava forms between them. The Atlantic Ocean is increasing in size because of the expanding zone of lava along the Mid-Atlantic Ridge, where two plates are separating.

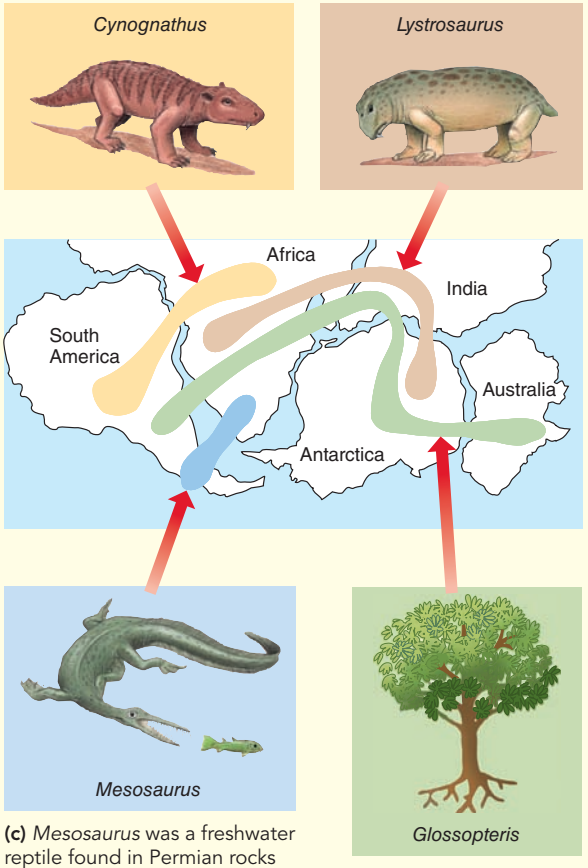
Knowledge that the continents were at one time connected and have since drifted apart is useful in explaining certain aspects of biogeography (**FIG. 18-12**). Likewise, continental drift has played a major role in the evolution of different organisms. When Pangaea originally formed during the late Permian period, it brought together terrestrial species that had evolved separately from one another, leading to competition and some extinction. Marine life was adversely affected, in part because, with the continents joined as one large mass, less coastal area existed. (Shallow coastal areas contain a greater diversity of marine species than deep-water environments.)

Pangaea separated into several landmasses approximately 180 mya. As the continents began to drift apart, populations became geographically isolated, were exposed to different environmental conditions, and began to diverge along separate evolutionary pathways. As a result, the plants, animals, and other organisms of previously connected continents—South America and Africa, for example—differ. Continental drift also caused gradual changes in ocean and atmospheric currents that have profoundly influenced the biogeography and evolution of organisms. (Biogeography is discussed further in Chapter 56.)

KEY POINT **Knowledge that the continents were united at one time explains the unique distribution of certain fossil plants and animals.**

(a) *Cynognathus* was a carnivorous reptile found in Triassic rocks in South America and Africa.

(b) *Lystrosaurus* was a herbivorous reptile found in Triassic rocks in Africa, India, and Antarctica.



(c) *Mesosaurus* was a freshwater reptile found in Permian rocks in South America and Africa.

(d) *Glossopteris* was a seed-bearing tree found in Permian rocks in South America, Africa, India, Antarctica, and Australia.

FIGURE 18-12 Distribution of fossils on continents that were joined during the Permian and Triassic periods (286 mya to 213 mya)

Comparative anatomy of related species demonstrates similarities in their structures

Comparing the structural details of features found in different but related organisms reveals a basic similarity. Such features that are derived from the same structure in a common ancestor are termed **homologous features;** the condition is known as **homology.** For example, consider the limb bones of mammals. A human arm, a cat forelimb, a whale front flipper, and a bat wing, although quite different in appearance, have strikingly similar arrangements of bones, muscles, and nerves. **FIGURE 18-13** shows a comparison of their skeletal structures. Each has a single bone (the humerus) in the part of the limb nearest the trunk of the body, followed by the two bones (radius and ulna) of the forearm, a group of bones (carpals) in the wrist, and a variable number of digits (metacarpals and phalanges). This similarity is particularly striking because arms, forelimbs, flippers, and wings are used for different types of locomotion, and there is no overriding mechanical reason for them to be so similar structurally. Similar arrangements of parts of the forelimb are evident in ancestral birds, reptiles, and amphibians and even in the first fishes that came out of water onto land hundreds of millions of years ago (see Fig. 32-17).

www.konkur.in

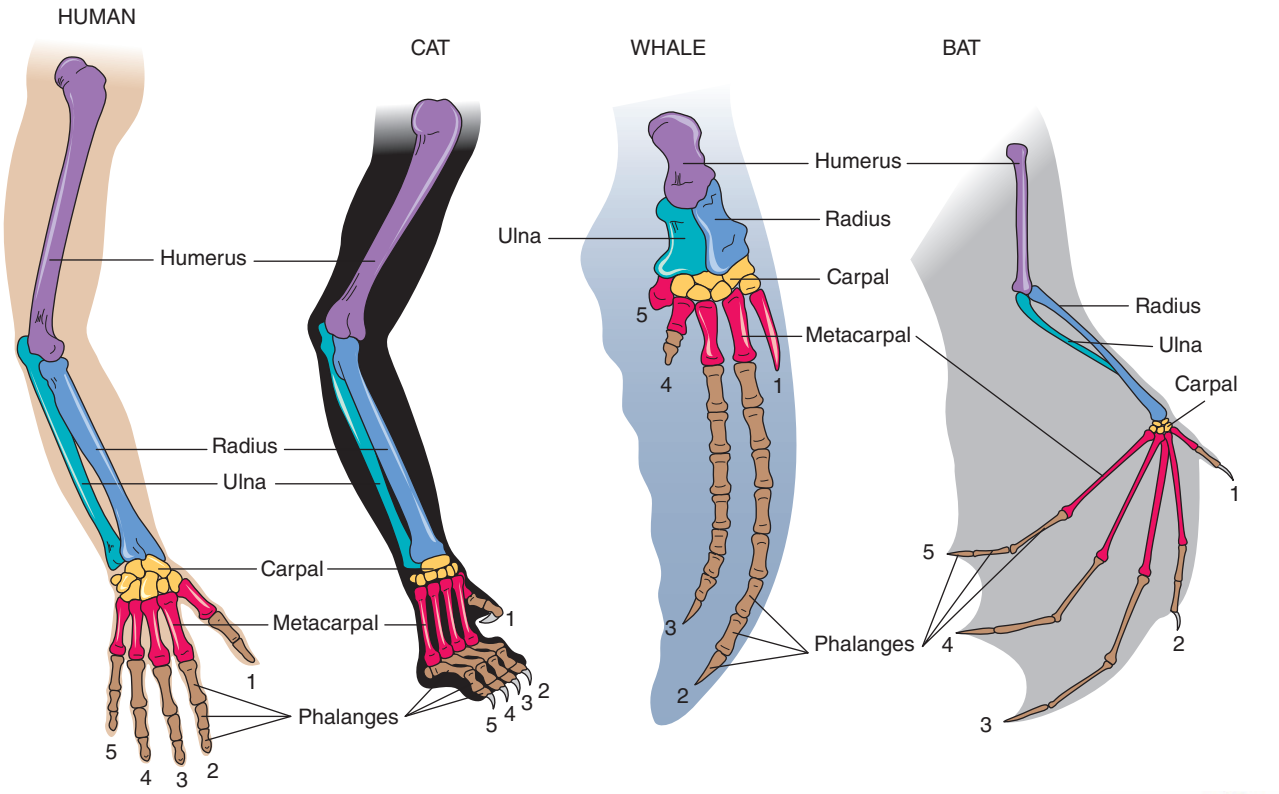

FIGURE 18-13 ***Animated*** **Structural homology in vertebrates**
The human arm, cat forelimb, whale flipper, and bat wing have a basic underlying similarity of structure because they are derived from a common ancestor. The five digits are numbered in each drawing.

Leaves provide an example of homology in plants. In many plant species, leaves have been modified for functions other than photosynthesis. A cactus spine and a pea tendril, although quite different in appearance, are homologous because both are modified leaves (**FIG. 18-14**). The spine protects the succulent stem tissue of the cactus, whereas the tendril, which winds around a small object once it makes contact, helps support the climbing stem of the pea plant. Such modifications in organs used in different ways are the expected outcome of a common evolutionary origin. The basic structure present in a common ancestor was modified in different ways for different functions as various descendants subsequently evolved.

Not all species with "similar" features have descended from a recent common ancestor, however. Sometimes similar environmental conditions result in the evolution of similar adaptations. Such independent evolution of similar structures in distantly related organisms is known as **convergent evolution.** Aardvarks, anteaters, and pangolins are an excellent example of convergent evolution (**FIG. 18-15**). They resemble one another in lifestyle and certain structural features. All have strong, sharp claws to dig open ant and termite mounds and elongated snouts with long, sticky tongues to catch these insects. Yet aardvarks, anteaters, and pangolins evolved from three distantly related orders of mammals. (See Figure 32-28, which shows several examples of convergent evolution in placental and marsupial mammals.)

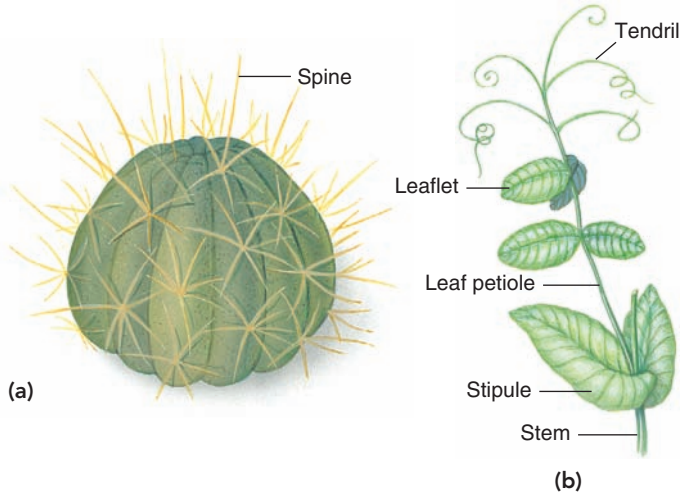

FIGURE 18-14 **Homology in plants**
(a) The spines of the fishhook cactus (*Ferocactus wislizenii*) are modified leaves, as are **(b)** the tendrils of the garden pea (*Pisum sativum*). Leaves of the garden pea are compound, that is, they are divided into smaller components called leaflets. The terminal leaflets are modified into tendrils that are frequently branched.

Structurally similar features that are not homologous but have similar functions that evolved independently in distantly related organisms are said to be **homoplastic features.** Such similarities in different species that are independently acquired by convergent evolution and not by common descent are called **homoplasy.**[2]

[2]An older, less precise term that some biologists still use for nonhomologous features with similar functions is *analogy.*

(c) The pangolin (*Manis crassicaudata*) is native to Africa and to southern and southeastern Asia.

FIGURE 18-15 Convergent evolution

Three distantly related mammals adapted independently to eat ants and termites in similar grassland/forest environments in different parts of the world.

For example, the wings of various distantly related flying animals, such as insects and birds, resemble one another superficially; they are homoplastic features that evolved over time to meet the common function of flight, although they differ in more fundamental aspects. Bird wings are modified forelimbs supported by bones, whereas insect wings may have evolved from gill-like appendages present in the aquatic ancestors of insects.

Spines, which are modified leaves, and thorns, which are modified stems, are an example of homoplasy in plants. Spines and thorns resemble one another superficially but are homoplastic features that evolved independently to solve the common need for protection from herbivores (**FIG. 18-16**).

Like homology, homoplasy offers crucial evidence of evolution. Homoplastic features are of evolutionary interest because they demonstrate that organisms with separate ancestries may adapt in similar ways to similar environmental demands.

Comparative anatomy also reveals the existence of **vestigial structures.** Many organisms contain organs or parts of organs that are seemingly nonfunctional and degenerate, often undersized or lacking some essential part. Vestigial structures are remnants of more developed structures that were present and functional in ancestral organisms. In the human body, more than 100 structures are considered vestigial, including the coccyx (fused tailbones), third molars (wisdom teeth), and the muscles that move our ears. Whales and pythons have vestigial hind-limb bones (**FIG. 18-17**); pigs have vestigial toes that do not touch the ground; wingless birds such as the kiwi have vestigial wing bones; and many blind, burrowing, or cave-dwelling animals have nonfunctioning, vestigial eyes.

The occasional presence of a vestigial structure is to be expected as a species adapts to a changing mode of life. Some structures become much less important for survival and may end up as vestiges. When a structure no longer confers a selective advantage, it may become smaller and lose much or all of its function with the passage of time. Because the presence of the vestigial structure is usually not harmful to the organism, however, selective pressure for completely eliminating it is weak, and the vestigial structure is found in many subsequent generations.

Molecular comparisons among organisms provide evidence for evolution

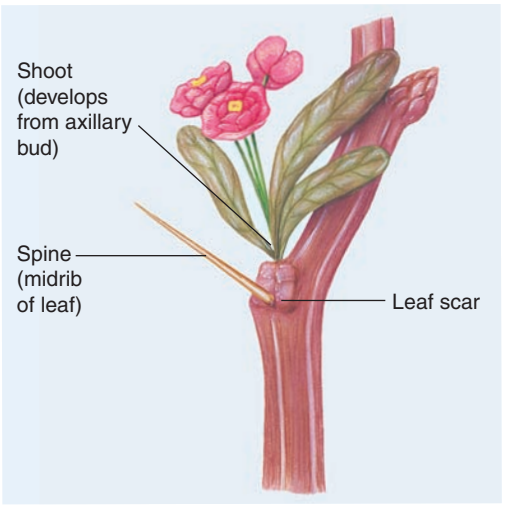
Fossils, biogeography, and comparative anatomy provided Darwin with important clues about the evolutionary history of life. Today, similarities and differences in the biochemistry and molecular biology of various organisms provide additional compelling evidence for evolutionary relationships. Molecular evidence for evolution includes the universal genetic code and the conserved sequences of amino acids in proteins and of nucleotides in DNA.

The genetic code is virtually universal

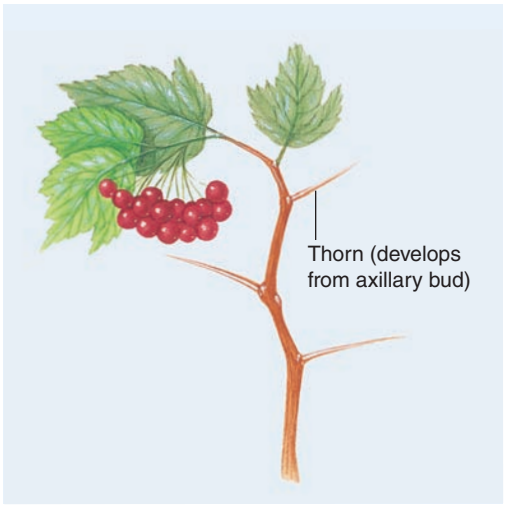
Organisms owe their characteristics to the types of proteins they possess, which in turn are determined by the sequence of nucleotides in their messenger ribonucleic acid (mRNA), as specified by the order of nucleotides in their DNA. Evidence that all life is related comes from the fact that all organisms use a genetic code that is virtually identical. (There is some minor variation in the genetic code. For example, some mitochondria have several deviations from the standard code.)

Recall from Chapter 13 that the genetic code specifies a triplet (a sequence of three nucleotides in DNA) that codes for a particular codon (a sequence of three nucleotides in mRNA). The codon then codes for a particular amino acid in a polypeptide chain. For example, "AAA" in DNA codes for "UUU" in mRNA, which codes for the amino acid phenylalanine in organisms as diverse as

www.konkur.in



(a) A spine of Japanese barberry (*Berberis thunbergii*) is a modified leaf. (In this example, the spine is actually the midrib of the original leaf, which has been shed.)



(b) Thorns of downy hawthorn (*Crataegus mollis*) are modified stems that develop from axillary buds.

FIGURE 18-16 Homoplasy in plants

shrimp, humans, bacteria, and tulips. In fact, "AAA" codes for phenylalanine in all organisms examined to date.

The universality of the genetic code—no other code has been found in any organism—is convincing evidence that all organisms arose from a common ancestor. The genetic code has been maintained and transmitted through all branches of the evolutionary tree since its origin in some extremely early (and successful) organism.

Proteins and DNA contain a record of evolutionary change

Researchers have carried out thousands of comparisons of protein and DNA sequences from various species during the past 30 years or so. Moreover, the recent explosion in DNA sequencing information (more than 1000 species have now had their genomes sequenced) is beginning to provide a wealth of evolutionary data as these genomes are compared. Sequence-based relationships generally agree with earlier studies, which based evolutionary relationships on similarities in structure among living organisms and on fossil data of extinct organisms.

Investigations of the sequence of amino acids in proteins that play the same roles in many species have revealed both great similarities and certain specific differences. Even organisms that are only remotely related share some proteins, such as cytochrome *c,* which is part of the electron transport chain in aerobic respiration. To survive, all aerobic organisms need a respiratory protein with the same basic structure and function as the cytochrome *c* of their common ancestor. Consequently, not all amino acids that confer the structural and functional features of cytochrome *c* are free to change. Any mutations that changed the amino acid sequence at structurally important sites of the cytochrome *c* molecule would have been harmful, and natural selection would have prevented such mutations from being passed to future generations. However, in the course of the long, independent evolution of different organisms, mutations have resulted in the substitution of many amino acids at less important locations in the cytochrome *c* molecule. The greater the differences in the amino acid sequences of their cytochrome *c* molecules, the longer it has been since two species diverged.

Because a protein's amino acid sequences are coded in DNA, the differences in amino acid sequences indirectly reflect the nature and number of underlying DNA base-pair changes that must have occurred during evolution. Of course, not all DNA codes for proteins (witness introns and transfer RNA genes). **DNA sequencing**—that is, determining the order of nucleotide bases in DNA—of both protein-coding DNA and nonprotein-coding DNA—is useful in determining evolutionary relationships.

Generally, the more closely species are considered related on the basis of other scientific evidence, the greater the percentage of nucleotide sequences that their DNA molecules have in common. By using the DNA sequence data in **FIGURE 18-18**, for example, you can conclude that the closest living relative of humans is the chimpanzee (because its DNA has the lowest percentage of differences in the sequence examined). (Primate evolution is discussed in Chapter 22.)

In some cases, molecular evidence challenges traditional evolutionary ideas that were based on structural comparisons among living species and/or on studies of fossil skeletons. Consider even-toed hoofed mammals such as pigs, camels, deer, antelope, cattle, and hippos. Whales lack toes and were traditionally not classified as close relatives of hoofed mammals.

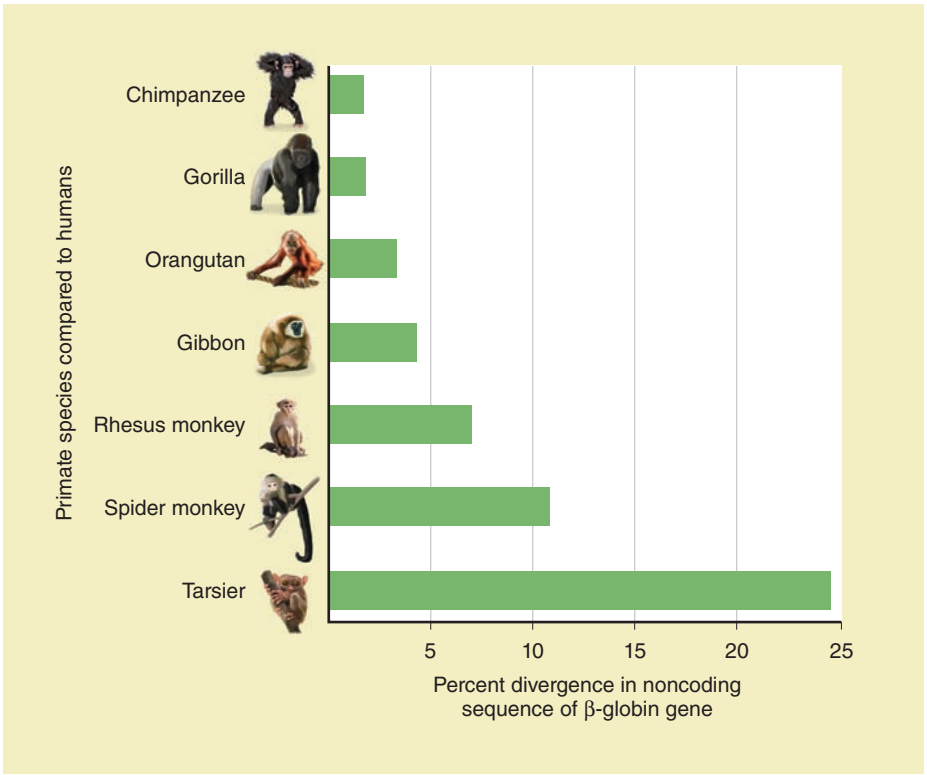

FIGURE 18-18 Differences in DNA nucleotide sequences as evidence of evolutionary relationships

Comparing the same gene in different organisms provides a window into evolution. Here the differences in the noncoding region of the β-globin gene are compared between humans and other primates. Evolutionary biologists are beginning to expand such studies from comparing one or several genes to comparing entire genomes.

FIGURE 18-19 depicts a **cladogram,** or **phylogenetic tree,** based on molecular data for whales and selected hoofed mammals. Such cladograms—diagrams showing lines of descent—can be derived from differences in a given DNA nucleotide sequence. This diagram indicates that whales are more closely related to hippos than to any other hoofed mammal. The branches representing whales and hippos probably diverged relatively recently because of the close similarity of DNA sequences in these species. In contrast, camels, which have DNA sequences that are less similar to those of whales, diverged much earlier. The molecular evidence indicates that whales and hippos share a recent common ancestor.

The molecular evidence linking whales and even-toed hoofed mammals has led to a reexamination of early fossil whales. Like today's hoofed mammals, early fossil whales had an even number of toes on their appendages. Fossil whales also had the same type of specialized ankle bone (called a double pulley) as hippos and other hoofed mammals.

Developmental biology helps unravel evolutionary patterns

As early as 1975, biologists were suggesting that regulatory changes in gene expression, particularly of genes involved in development, were responsible for many differences between closely related species. Today much evidence supports the idea that regulatory changes—how genes are switched on and off during development—help explain the diversity of form in species with similar genes. Mutations in genes that regulate development often result in dramatically different structures (see Fig. 17-12).

Increasingly, developmental biology, particularly at the molecular level, is providing answers to such questions as how snakes became elongated and lost their limbs. In many cases, evolutionary changes such as the loss of limbs in snakes occur as a result of changes in genes that regulate the orderly sequence of events that occurs during development. In pythons, for example, the loss of forelimbs and elongation of the body are linked to mutations in several *Hox* genes that affect the expression of body patterns and limb formation in a wide variety of animals. (See the discussion of *Hox* gene clusters in Chapter 17.) The hind limbs may not develop because python embryonic tissue does not respond to internal signals that trigger leg elongation.

Developmental geneticists at Harvard Medical School and Princeton University are studying the developmental basis for the different beak shapes of the Galápagos finches. They have determined that a gene that codes for an important signaling molecule, bone morphogenic protein 4 (BMP4), affects the development of the birds' craniofacial skeletons. The gene for BMP4 is turned on earlier in development and has a higher level of expression in finch species with larger, thicker beaks than in finches with smaller beaks.

Scientific evidence overwhelmingly demonstrates that development in different animals is controlled by the same kinds of genes; these genetic similarities in a wide variety of organisms reflect a shared evolutionary history. For example, vertebrates have similar patterns of embryological development that indicate they share a common ancestor. All vertebrate embryos have segmented muscles, pharyngeal (throat) pouches, a tubular heart without left and right sides, a system of arteries known as *aortic arches* in the pharyngeal region, and many other shared features. All these structures are necessary and functional in the developing fish. The small, segmented muscles of the fish embryo give rise to the segmented muscles used by the adult fish in swimming. The pharyngeal pouches break through to the surface as gill slits. The adult fish heart remains undivided and pumps blood forward to the gills that develop in association with the aortic arches.

Because none of these embryonic features persists in the adults of reptiles, birds, or mammals, why are these fishlike structures present in their embryos? Evolution is a conservative process, and natural selection builds on what has come before rather than starting from scratch. The evolution of new features often does not require the evolution of new developmental genes but instead depends on a modification in developmental genes that already exist (see discussion of pre-adaptations in Chapter 20). KEY POINT This branching diagram, called a *cladogram*, shows hypothetical evolutionary relationships. The organisms depicted here share a common ancestor.

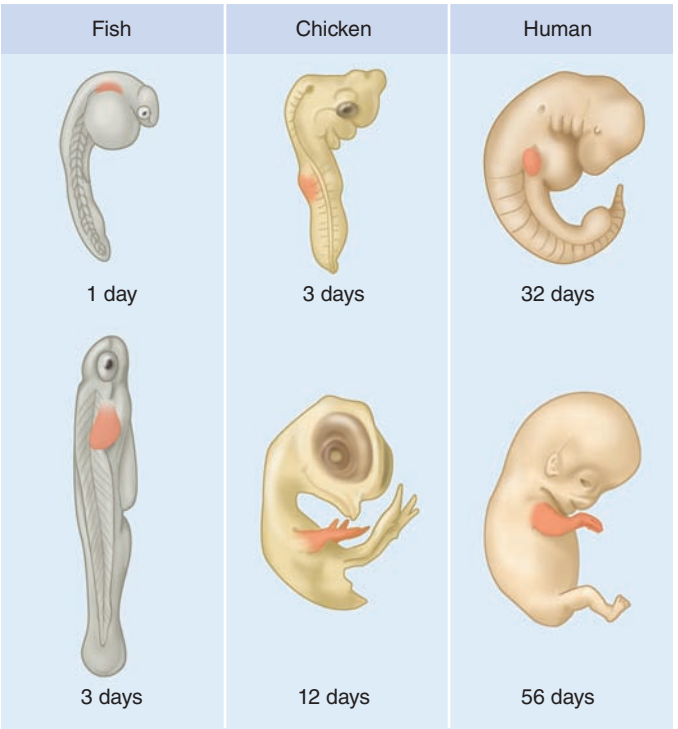
Adapted from Nikaido, M., et al., "Phylogenetic Relationships among Cetartiodactyls Based on Insertions of Short and Long Interspersed Elements: Hippopotamuses Are the Closest Extant Relatives of Whales," *Proceedings of the National Academy of Sciences*, Vol. 96, Aug. 31, 1999.

FIGURE 18-19 Cladogram of whales and their closest living relatives

DNA sequence differences among selected mammals suggest that hoofed mammals such as hippos and giraffes are the closest living relatives of whales. The hippopotamus is probably the closest living relative of whales and other cetaceans. The nodes (*circles*) represent branch points where a species splits into two or more lineages. (Ruminants are mammals such as cows, sheep, and giraffes that have a multichambered stomach and chew regurgitated plant material to make it more digestible.)



John Burgoyne/National Geographic Image Collection

FIGURE 18-20 Development of fish fins, chicken wings, and human limbs

Fish, chickens, and humans are vertebrates with strikingly similar genes. Although the early embryos of these organisms are much alike, the areas colored orange follow different developmental pathways, resulting in fins, wings, or limbs. (Figures are not to scale.)

tebrates are thought to have evolved from fishlike ancestors; therefore, they share some of the early stages of development still found in fishes today. The accumulation of genetic changes over time in these vertebrates has modified the basic body plan laid out in fish development (**FIG. 18-20**).

Evolutionary hypotheses are tested experimentally

Increasingly, biologists are designing imaginative experiments, often in natural settings, to test evolutionary hypotheses. David Reznick from the University of California at Santa Barbara and John Endler from James Cook University in Australia have studied evolution in guppy populations in Venezuela and in Trinidad, a small island in the southern Caribbean.

Reznick and Endler observed that different streams have different kinds and numbers of fishes that prey on guppies. Predatory fishes that prey on larger guppies are present in all streams at lower elevations; these areas of intense predation pressure are known as *high-predation habitats.* Predators are often excluded from tributaries or upstream areas by rapids and waterfalls. The areas above such barriers are known as *low-predation habitats* because they contain only one species of small predatory fish that occasionally eats smaller guppies.

Differences in predation are correlated with many differences in the guppies, such as male coloration, behavior, and attributes known as *life history traits* (discussed in more detail in Chapter 53). These traits include age and size at sexual maturity, the number of offspring per reproductive event, the size of the offspring, and the frequency of reproduction. For example, guppy adults are larger in streams found at higher elevations and smaller in streams found at lower elevations.

Do predators actually cause these differences to evolve? Reznick and colleagues tested this evolutionary hypothesis by conducting field experiments in Trinidad. Taking advantage of waterfalls that prevent the upstream movement of guppies, guppy predators, or both, they moved either guppies or guppy predators over such barriers. For example, guppies from a high-predation habitat were introduced into a low-predation habitat by moving them over a barrier waterfall into a section of stream that was free of guppies and large predators. The only fish species that lived in this section of stream before the introduction was the small predatory fish.

www.konkur.in

Eleven years later, the researchers captured adult females from the introduction site (low-predation habitat) and the control site below the barrier waterfall (high-predation habitat). They bred these females in their laboratory and compared the life history traits of succeeding generations. The descendants of guppies introduced into the low-predation habitat matured at a larger size than did the descendants of guppies from the control site below the waterfall (**FIG. 18-21**). They also produced fewer, but larger, offspring. The introduced fish populations had evolved to have life histories similar to those of fishes typically found in such low-predation habitats. Similar studies have demonstrated that predators have played an active role in the evolution of other traits, such as the average number of offspring produced during the lifetime of an individual female (fecundity), male coloration, and behavior.

Rapid evolution on a scale of years has also been observed in organisms as diverse as marine snails, mussels, soapberry bugs, mayflies, anole lizards, ʻiʻiwis (scarlet honeycreepers), and wild rabbits. These and other experiments and observations demonstrate not only that evolution is real but also that it is occurring now, driven by selective environmental forces, such as predation, that can be experimentally manipulated. Darwin incorrectly assumed evolution to be so gradual that humans cannot observe it. As Jonathan Weiner, author of *The Beak of the Finch: A Story of Evolution in Our Time,* notes, "Darwin did not know the strength of his own theory. He vastly underestimated the power of natural selection. Its action is neither rare nor slow. It leads to evolution daily and hourly, all around us, and we can watch."

Review

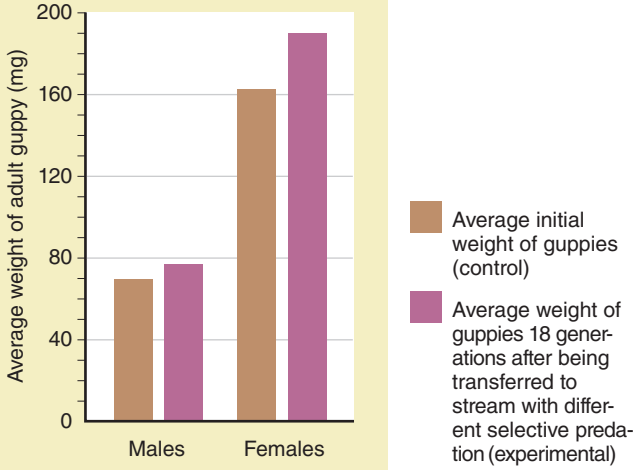
- How do scientists date fossils?
- How can we explain that fossils of *Mesosaurus*, an extinct reptile that could not swim across open water, are found in the southern parts of both Africa and South America?
- How do homologous and homoplastic features provide evidence of evolution?
- How does developmental biology provide evidence of a common ancestry for vertebrates as diverse as reptiles, birds, pigs, and humans?
- How do predator preferences drive the evolution of size in guppies?

KEY EXPERIMENT

QUESTION: Can natural selection be observed in a natural population?

HYPOTHESIS: A natural population will respond adaptively to environmental change.

EXPERIMENT: Male and female guppies from a stream in which the predators preferred large adult guppies as prey (*brown bars*) were transferred to a stream in which the predators preferred juveniles and small adults.



RESULTS AND CONCLUSION: After 11 years, the descendants of the transferred guppies (*pink bars*) were measurably larger than their ancestors, indicating that larger guppies had a selective advantage in the new environment.

Data used with permission from Reznick, D. N., et al., "Evaluation of the Rate of Evolution in Natural Populations of Guppies [*Poecilia reticulata*]," *Science*, Vol. 275, Mar. 28, 1997.

FIGURE 18-21 D. N. Reznick's experiment in guppy evolution

SUMMARY: FOCUS ON LEARNING OBJECTIVES

18.1 *(page 392)*

1 Define *evolution*.

- **Evolution** is the accumulation of inherited changes within a **population** over time. Evolution is the unifying concept of biology because it links all fields of the life sciences into a coherent body of knowledge.

18.2 *(page 392)*

2 Discuss the historical development of evolutionary theory.

- Jean Baptiste de Lamarck was the first scientist to propose that organisms undergo change over time as a result of some natural phenomenon rather than divine intervention. Lamarck thought organisms were endowed with a vital force that drove them to change toward greater complexity over time. He thought organisms could pass traits acquired during their lifetimes to their offspring.
- Charles Darwin's observations while voyaging on the HMS *Beagle* were the basis for his evolutionary theory. Darwin tried to explain the similarities between animals and plants of the arid Galápagos Islands and the humid South American mainland.
- Darwin was influenced by **artificial selection,** in which breeders develop many varieties of domesticated plants and animals in just a few generations. Darwin applied Thomas Malthus's ideas on the natural increase in human populations to natural populations. Darwin was influenced by the idea that Earth was extremely old, an idea promoted by Charles Lyell and other geologists.

18.3 *(page 393)*

3 Explain the four premises of evolution by natural selection as proposed by Charles Darwin.

- Charles Darwin and Alfred Wallace independently proposed evolution by **natural selection,** which is based on four observations.

www.konkur.in

First, genetic variation exists among the individuals in a population. Second, the reproductive ability of each species causes its populations to have the potential to geometrically increase in number over time. Third, organisms compete with one another for the resources needed for life, such as food, living space, water, and light. Fourth, offspring with the most favorable combination of inherited characteristics are most likely to survive and reproduce, passing those genetic characteristics to the next generation.

- Natural selection results in **adaptations,** evolutionary modifications that improve the chances of survival and reproductive success in a particular environment. Over time, enough changes may accumulate in geographically separated populations to produce new species.

CENGAGENOW™ **Learn more about the Galápagos Islands and the Galápagos Island finches by clicking on the figures in CengageNOW.**

4 Compare the modern synthesis with Darwin's original evolutionary theory.

- The **modern synthesis** combines Darwin's evolutionary theory by natural selection with modern genetics to explain why individuals in a population vary and how species adapt to their environment.
- **Mutation** provides the genetic variability that natural selection acts on during evolution.

18.4 *(page 397)*

5 Summarize the evidence for evolution obtained from the fossil record.

- Direct evidence of evolution comes from **fossils,** the remains or traces of ancient organisms. Layers of sedimentary rock normally occur in their sequence of deposition, with the more recent layers on top of the older, earlier ones. **Index fossils** characterize a specific layer over large geographic areas. **Radioisotopes** present in a rock provide a way to accurately measure the rock's age.

CENGAGENOW™ **Learn more about fossil intermediates by clicking on the figure in CengageNOW.**

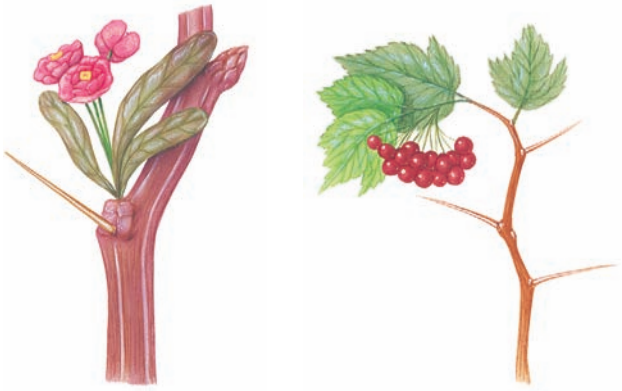
6 Define *biogeography* and describe how the distribution of organisms supports evolution.

- **Biogeography,** the geographic distribution of organisms, affects their evolution. Areas that have been separated from the rest of the world for a long time contain organisms that have evolved in isolation and are therefore unique to those areas.
- At one time the continents were joined to form a supercontinent. **Continental drift,** which caused the various landmasses to break apart and separate, has played a major role in evolution.

CENGAGENOW™ **Watch continental drift by clicking on the figure in CengageNOW.**

7 Describe the evidence for evolution derived from comparative anatomy.

- **Homologous features** have basic structural similarities, even though the structures may be used in different ways because homologous features derive from the same structure in a common ancestor. Evolutionary affinities exist among the organisms that have homologous features.
- **Homoplastic features** evolved independently to have similar functions in distantly related organisms. Homoplastic features demonstrate **convergent evolution,** in which organisms with separate ancestries adapt in similar ways to comparable environmental demands.



- **Vestigial structures** are nonfunctional or degenerate remnants of structures that were present and functional in ancestral organisms. Structures occasionally become vestigial as species adapt to different modes of life.

CENGAGENOW™ **Learn more about vestigial structures by clicking on the figure in CengageNOW.**

8 Briefly explain how molecular biology and developmental biology provide insights into the evolutionary process.

- Molecular evidence for evolution includes the universal genetic code and the conserved sequences of amino acids in proteins and of nucleotides in DNA.
- Evolutionary changes are often the result of mutations in genes that affect the orderly sequence of events during development. Development in different animals is controlled by the same kinds of genes, which indicates these animals have a shared evolutionary history.
- The accumulation of genetic changes since organisms diverged, or took separate evolutionary pathways, has modified the pattern of development in more complex vertebrate embryos.

9 Give an example of how evolutionary hypotheses are tested experimentally.

- Reznick and Endler have studied the effects of predation intensity on the evolution of guppy populations in the laboratory and in nature. Such experiments are a powerful way for investigators to test the underlying processes of natural selection.

TEST YOUR UNDERSTANDING

1. Evolution is based on which of the following concepts? (a) organisms share a common origin (b) over time, organisms have diverged from a common ancestor (c) an animal's body parts can change over its lifetime, and these acquired changes are passed to the next generation (d) a and b (e) a, b, and c
2. Evolution is the accumulation of genetic changes within _____ over time. (a) individuals (b) populations (c) communities (d) a and b (e) a and c
3. Charles Darwin proposed that evolution could be explained by the differential reproductive success of organisms that resulted from their naturally occurring variation. Darwin called this process (a) coevolution (b) convergent evolution (c) natural selection (d) artificial selection (e) homoplasy
4. Which of the following is *not* part of Darwin's mechanism of evolution? (a) differential reproductive success (b) variation

www.konkur.in

in a population (c) inheritance of acquired (nongenetic) traits (d) overproduction of offspring (e) struggle for existence

5. The modern synthesis (a) is based on the sequence of fossils in rock layers (b) uses genetics to explain the source of hereditary variation that is essential to natural selection (c) was first proposed by ancient Greek scholars (d) considers the influence of the geographic distribution of organisms on their evolution (e) is reinforced by homologies that are explained by common descent
6. The evolution of beak size in the various species of Galápagos finches is associated with their (a) songs (b) diets (c) body sizes (d) predators (e) none of the preceding
7. The fossil record (a) usually occurs in sedimentary rock (b) sometimes appears fragmentary (c) is relatively complete for tropical rainforest organisms but incomplete for aquatic organisms (d) a and b (e) a, b, and c
8. In _____, the selecting agent is the environment, whereas in _____, the selecting agent is humans. (a) natural selection; convergent evolution (b) mutation; artificial selection (c) homoplasy; homology (d) artificial selection; natural selection (e) natural selection; artificial selection
9. Aardvarks, anteaters, and pangolins are only distantly related but are similar in structure and form as a result of (a) homology (b) convergent evolution (c) biogeography (d) vestigial structures (e) artificial selection
10. The species of the Galápagos Islands (a) are similar to those on other islands at the same latitude (b) are similar to those on the South American mainland (c) are identical to those on other islands at the same latitude (d) are identical to those on the South American mainland (e) are similar to those on both the African and South American mainlands
11. Changes in just a few genes that regulate _____ are often responsible for the evolution of new anatomical features in a population. (a) fossil formation (b) vestigial structures (c) development (d) biogeography (e) adaptation

CRITICAL THINKING

1. **EVOLUTION LINK.** The use of model organisms such as the mouse for research and biomedical testing of human diseases is based on the assumption that all organisms share a common ancestor. On what evidence is this assumption based?
2. **EVOLUTION LINK.** What adaptations must an animal possess to swim in the ocean? Why are such genetically different organisms as porpoises, which are mammals, and sharks, which are fish, so similar in form?
3. **EVOLUTION LINK.** The human fetus grows a coat of fine hair (the lanugo) that is shed before or shortly after birth. Fetuses of chimpanzees and other primates also grow coats of hair, but they are not shed. Explain these observations based on what you have learned in this chapter.
4. **EVOLUTION LINK.** Charles Darwin once said, "It is not the strongest of the species that survive, nor the most intelligent, but the one most responsive to change." Explain what he meant.
5. **EVOLUTION LINK.** Write short paragraphs explaining each of the following statements:
   a. Natural selection chooses from among the individuals in a population those most suited to *current* environmental conditions. It does not guarantee survival under future conditions.
   b. Individuals do not evolve, but populations do.
   c. The organisms that exist today do so because their ancestors had traits that allowed them and their offspring to thrive.
   d. At the molecular level, evolution can take place by the replacement of one nucleotide by another.
   e. Evolution is said to have occurred within a population when measurable genetic changes are detected.
6. **EVOLUTION LINK.** Although most salamanders have four legs, a few species that live in shallow water lack hind limbs and have extremely tiny forelimbs (*see photograph*). Develop a hypothesis to explain how limbless salamanders came about according to Darwin's mechanism of evolution by natural selection. How could you test your hypothesis?

Suzanne L. Collins and Joseph T. Collins/Photo Researchers, Inc.

The narrow-striped dwarf siren (*Pseudobranchus striatus axanthus*) is an aquatic salamander that resembles an eel. It is native to Florida.

7. **ANALYZING DATA.** Which of the primates in Figure 18-18 is the most distantly related to humans? Explain your answer.
8. **SCIENCE, TECHNOLOGY, AND SOCIETY.** Farmers often face a predicament, known as the pesticide treadmill, in which the cost of applying pesticides increases because the pesticides have to be applied more frequently or in larger doses, while their effectiveness decreases. Based on what you have learned in this chapter, offer an explanation for why the pesticides lose their effectiveness.

19 Evolutionary Change in Populations

G. I. Bernard/Animals Animals

Genetic variation in snail shells. Shown are the shell patterns and colors in a single snail species (*Cepaea nemoralis*), native to Scotland. Variation in shell color may have adaptive value in these snails because some colors predominate in cooler environments whereas other colors are more common in warmer habitats.

KEY CONCEPTS

19.1 The genotype, phenotype, and allele frequencies of a population's gene pool (all alleles of all loci) can be calculated.

19.2 The Hardy–Weinberg principle predicts allele and genotype frequencies for a population that is not evolving.

19.3 Natural selection, as well as nonrandom mating, mutation, genetic drift, and gene flow are forces that drive changes in a population's gene pool over successive generations (microevolution). Modes of natural selection include stabilizing selection, directional selection, and disruptive selection.

19.4 Populations typically exhibit genetic variation, which may include genetic polymorphism, balanced polymorphism, or geographic variation.

As you learned in Chapter 18, evolution occurs in populations, not individuals. Although natural selection acts on individuals, causing differential survival and reproduction, individuals themselves do not evolve during their lifetimes. Evolutionary change, which includes modifications in structure, physiology, ecology, and behavior, is inherited from one generation to the next. Although Darwin recognized that evolution occurs in populations, he did not understand how the attributes of organisms are passed to successive generations. One of the most significant advances in biology since Darwin's time has been the demonstration of the genetic basis of evolution.

Recall from Chapter 18 that a **population** consists of all individuals of the same species that live in a particular place at the same time. Individuals within a population vary in many recognizable characters. A population of snails, for example, may vary in shell size, weight, or color (see photograph). Some of this variation is due to heredity, and some is due to environment (nonheritable variation), such as the individual differences observed in the pink color of flamingos, which is partly attributable to differences in diet.

Biologists study variation in a particular character (characteristic) by taking measurements of that character in a population. By comparing the character in parents and offspring, it is possible to estimate the amount of observed variation that is genetic, as represented by the number, frequency, and kinds of alleles in a population. (Recall from

www.konkur.in

Chapter 11 that an **allele** is one of two or more alternate forms of a gene. Alleles occupy corresponding positions, or **loci,** on homologous chromosomes.)

This chapter will help you develop an understanding of the importance of genetic variation as the raw material for evolution and of the basic concepts of **population genetics,** the study of genetic variability within a population and of the evolutionary forces that act on it. Population genetics represents an extension of Gregor Mendel's principles of inheritance (see Chapter 11). You will learn how to distinguish genetic equilibrium from evolutionary change and to assess the roles of the five factors responsible for evolutionary change: nonrandom mating, mutation, genetic drift, gene flow, and natural selection.

19.1 GENOTYPE, PHENOTYPE, AND ALLELE FREQUENCIES

LEARNING OBJECTIVES

1 Define what is meant by a population's gene pool.
2 Distinguish among genotype, phenotype, and allele frequencies.

Each population possesses a **gene pool,** which includes all the alleles for all the loci present in the population. Because diploid organisms have a maximum of two different alleles at each genetic locus, a single individual typically has only a small fraction of the alleles present in a population's gene pool. The genetic variation that is evident among individuals in a given population indicates that each individual has a different subset of the alleles in the gene pool.

The evolution of populations is best understood in terms of genotype, phenotype, and allele frequencies. Suppose, for example, that all 1000 individuals of a hypothetical population have their genotypes tested, with the following results:

Genotype	Number	Genotype Frequency
AA	490	0.49
Aa	420	0.42
aa	90	0.09
Total	1000	1.00

Each **genotype frequency** is the proportion of a particular genotype in the population. Genotype frequency is usually expressed as a decimal fraction, and the sum of all genotype frequencies is 1.0 (somewhat like probabilities, which were discussed in Chapter 11). For example, the genotype frequency for the *Aa* genotype is $420 \div 1000 = 0.42$.

A **phenotype frequency** is the proportion of a particular phenotype in the population. If each genotype corresponds to a specific phenotype, then the phenotype and genotype frequencies are the same. If allele *A* is dominant over allele *a,* however, the phenotype frequencies in our hypothetical population would be the following:

Phenotype	Number	Phenotype Frequency
Dominant	910	0.91
Recessive	90	0.09
Total	1000	1.00

In this example, the dominant phenotype is the sum of two genotypes, *AA* and *Aa,* so the number 910 is obtained by adding $490 + 420$.

An **allele frequency** is the proportion of a specific allele (that is, of *A* or *a*) in a particular population. As mentioned earlier, each individual, being diploid, has two alleles at each genetic locus. Because we started with a population of 1000 individuals, we must account for a total of 2000 alleles. The 490 *AA* individuals have 980 *A* alleles, whereas the 420 *Aa* individuals have 420 *A* alleles, making a total of 1400 *A* alleles in the population. The total number of *a* alleles in the population is $420 + 90 + 90 = 600$. Now it is easy to calculate allele frequencies:

Allele	Number	Allele Frequency
A	1400	0.7
a	600	0.3
Total	2000	1.0

Review

- Does the term *gene pool* apply to individuals, populations, or both?
- Can the frequencies of all genotypes in a population be determined directly with respect to a locus that has only two alleles, one dominant and the other recessive?
- In a human population of 1000, 840 are tongue rollers (*TT* or *Tt*), and 160 are not tongue rollers (*tt*). What is the frequency of the dominant allele (*T*) in the population?

19.2 THE HARDY–WEINBERG PRINCIPLE

LEARNING OBJECTIVES

3 Discuss the significance of the Hardy–Weinberg principle as it relates to evolution and list the five conditions required for genetic equilibrium.
4 Use the Hardy–Weinberg principle to solve problems involving populations.

In the example just discussed, we observe that only 90 of the 1000 individuals in the population exhibit the recessive phenotype characteristic of the genotype *aa.* The remaining 910 individuals exhibit the dominant phenotype and are either *AA* or *Aa.* You might assume that after many generations, genetic recombination during sexual reproduction would cause the dominant allele to become more common in the population. You might also assume that the recessive allele would eventually disappear altogether. These were common assumptions of many biologists early in the 20th century. However, these assumptions are incorrect because the frequencies of alleles and genotypes do not change from generation to generation unless influenced by outside factors (discussed later in the chapter).

www.konkur.in

A population whose allele and genotype frequencies do not change from generation to generation is said to be at **genetic equilibrium.** Such a population, with no net change in allele or genotype frequencies over time, is not undergoing evolutionary change. A population that is at genetic equilibrium is not evolving with respect to the locus being studied. However, if allele frequencies change over successive generations, evolution is occurring.

The explanation for the stability of successive generations in populations at genetic equilibrium was provided independently by Godfrey Hardy, an English mathematician, and Wilhelm Weinberg, a German physician, in 1908. They pointed out that the expected frequencies of various genotypes in a population can be described mathematically. The resulting **Hardy–Weinberg principle** shows that if the population is large, the process of inheritance does not by itself cause changes in allele frequencies. It also explains why dominant alleles are not necessarily more common than recessive ones. The Hardy–Weinberg principle represents an ideal situation that seldom occurs in the natural world. However, it is useful because it provides a model to help us understand the real world. Knowledge of the Hardy–Weinberg principle is essential to understanding the mechanisms of evolutionary change in sexually reproducing populations.

We now expand our original example to illustrate the Hardy–Weinberg principle. Keep in mind as we go through these calculations that in most cases we know only the phenotype frequencies. When alleles are dominant and recessive, it is usually impossible to visually distinguish heterozygous individuals from homozygous dominant individuals. The Hardy–Weinberg principle lets us use phenotype frequencies to calculate the expected genotype frequencies and allele frequencies, assuming we have a clear understanding of the genetic basis for the character under study.

As mentioned earlier, the frequency of either allele, *A* or *a,* is represented by a number that ranges from 0 to 1. An allele that is totally absent from the population has a frequency of zero. If all the alleles of a given locus are the same in the population, then the frequency of that allele is 1.

Because only two alleles, *A* and *a,* exist at the locus in our example, the sum of their frequencies must equal 1. If we let p represent the frequency of the dominant (A) allele in the population, and q the frequency of the recessive (a) allele, then we can summarize their relationship with a simple binomial equation, $p + q = 1$. When we know the value of either p or q, we can calculate the value of the other: $p = 1 - q$, and $q = 1 - p$.

Squaring both sides of $p + q = 1$ results in $(p + q)^2 = 1$. This equation can be expanded to describe the relationship of the allele frequencies to the genotypes in the population. When it is expanded, we obtain the frequency of the offspring genotypes:

$$\underset{\text{Frequency of } AA}{p^2} + \underset{\text{Frequency of } Aa}{2pq} + \underset{\text{Frequency of } aa}{q^2} = \underset{\text{All individuals in the population}}{1}$$

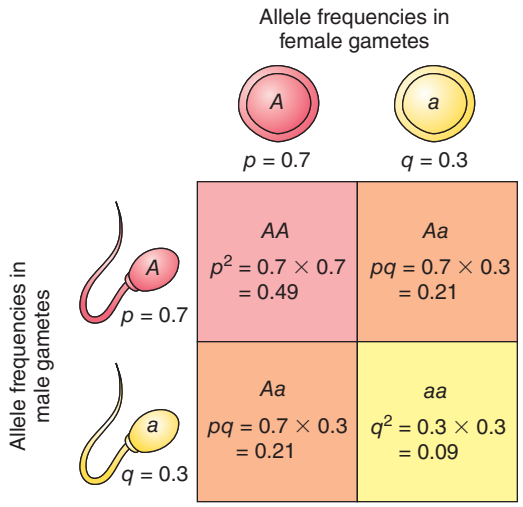
We always begin Hardy–Weinberg calculations by determining the frequency of the homozygous recessive genotype. From the fact that we had 90 homozygous recessive individuals in our population of 1000, we infer that the frequency of the *aa* genotype, q^2, is 90/1000, or 0.09. Because q^2 equals 0.09, q (the frequency of the recessive *a* allele) is equal to the square root of 0.09, or 0.3. From the relationship between p and q, we conclude that the frequency of the dominant *A* allele, p, equals $1 - q = 1 - 0.3 = 0.7$.

Given this information, we can calculate the frequency of homozygous dominant (AA) individuals: $p^2 = 0.7 \times 0.7 = 0.49$ (**FIG. 19-1**). The expected frequency of heterozygous individuals (Aa) would be $2pq = 2 \times 0.7 \times 0.3 = 0.42$. Thus, approximately 490 individuals are expected to be homozygous dominant, and 420 are expected to be heterozygous. Note that the sum of homozygous dominant and heterozygous individuals equals 910, the number of individuals showing the dominant phenotype with which we started.

Any population in which the distribution of genotypes conforms to the relation $p^2 + 2pq + q^2 = 1$, whatever the absolute values for p and q may be, is at genetic equilibrium. The Hardy–Weinberg principle allows biologists to calculate allele frequencies in a given population if we know the genotype frequencies, and vice versa. These values provide a basis of comparison with a

Genotypes	*AA*	*Aa*	*aa*
Frequency of genotypes in population	0.49	0.42 (0.21 + 0.21)	0.09
Frequency of alleles in gametes	*A* = 0.49 + 0.21 = 0.7		*a* = 0.21 + 0.09 = 0.3

(a) Genotype and allele frequencies. The figure illustrates how to calculate frequencies of the alleles *A* and *a* in the gametes produced by each genotype.



(b) Segregation of alleles and random fertilization. When eggs and sperm containing *A* or *a* alleles unite randomly, the frequency of each of the possible genotypes (*AA, Aa, aa*) among the offspring is calculated by multiplying the frequencies of the alleles *A* and *a* in eggs and sperm.

FIGURE 19-1 ***Animated*** **The Hardy–Weinberg principle**

www.konkur.in

population's allele or genotype frequencies in succeeding generations. During that time, if the allele or genotype frequencies deviate from the values predicted by the Hardy–Weinberg principle, then the population is evolving.

Genetic equilibrium occurs if certain conditions are met

The Hardy–Weinberg principle of genetic equilibrium tells us what to expect when a sexually reproducing population is not evolving. The relative proportions of alleles and genotypes in successive generations will always be the same, provided the following five conditions are met:

1. *Random mating.* In unrestricted random mating, each individual in a population has an equal chance of mating with any individual of the opposite sex. In our example, the individuals represented by the genotypes *AA, Aa,* and *aa* must mate with one another at random and must not select their mates on the basis of genotype or any other factors that result in nonrandom mating.
2. *No net mutations.* There must be no mutations that convert *A* into *a,* or vice versa. That is, the frequencies of *A* and *a* in the population must not change because of mutations.
3. *Large population size.* Allele frequencies in a small population are more likely to change by random fluctuations (that is, by genetic drift, which is discussed later) than are allele frequencies in a large population.
4. *No migration.* There can be no exchange of alleles with other populations that might have different allele frequencies. In other words, there can be no migration of individuals into or out of a population.[1]
5. *No natural selection.* If natural selection is occurring, certain phenotypes (and their corresponding genotypes) are favored over others. These more successful genotypes are said to have greater **fitness,** which is the relative ability to make a genetic contribution to subsequent generations. Consequently, the allele frequencies will change, and the population will evolve.

Human MN blood groups are a valuable illustration of the Hardy–Weinberg principle

Humans have dozens of antigens on the surfaces of their blood cells. (An *antigen* is a molecule, usually a protein or carbohydrate, that is recognized as foreign by cells of another organism's immune system.) One group of antigens, designated the MN blood group, stimulates the production of antibodies when injected into rabbits or guinea pigs. However, humans do not produce antibodies for M and N, so the MN blood group is not medically important, for example, when giving blood transfusions. (Recall the discussion of the medically important ABO alleles in Chapter 11.) The MN blood group is of interest to population geneticists because the alleles for the MN blood group, usually designated *M* and *N,* are codominant (genotype *MM* produces antigen M only, genotype *NN* produces antigen N only, and the heterozygous genotype *MN* produces both antigens). This allows population geneticists to directly observe all three possible genotype frequencies and compare them with calculated frequencies. The following data are typical of the MN blood group in people in the United States:

Genotype	Observed
MM	320
MN	480
NN	200
Total	1000

Because 1000 diploid individuals are in the sample, there are a total of 2000 alleles. The frequency of *M* alleles in the population $= p = (2 \times 320 + 480) \div 2000 = 0.56$. The frequency of *N* alleles in the population $= q = (2 \times 200 + 480) \div 2000 = 0.44$. As a quick check, the sum of the frequencies should equal 1. Does it?

If this population is in genetic equilibrium, then the expected *MM* genotype frequency $= p^2 = (0.56)^2 = 0.31$. The expected *MN* genotype frequency $= 2pq = 2 \times 0.56 \times 0.44 = 0.49$. The expected *NN* genotype frequency $= q^2 = (0.44)^2 = 0.19$. As a quick check, the sum of the three genotype frequencies should equal 1. Does it? You can use the calculated genotype frequencies to determine how many individuals in a population of 1000 should have the expected genotype frequencies. By comparing the expected numbers with the actual results observed, you see how closely the population is to genetic equilibrium. Simply multiply each genotype frequency by 1000:

Genotype	Observed	Expected
MM	320	313.6
MN	480	492.8
NN	200	193.6
Total	1000	1000.0

The expected numbers closely match the observed numbers, indicating that the *MN* blood groups in the human population are almost at genetic equilibrium. This is not surprising because the lack of medical significance suggests that the *MN* characteristic is not subject to natural selection and that it does not produce a visible phenotype that might affect random mating.

Review

- In a population at genetic equilibrium, the frequency of the homozygous recessive genotype (*tt*) is 0.16. What are the allele frequencies of *T* and *t*, and what are the expected frequencies of the *TT* and *Tt* genotypes?
- In a population at genetic equilibrium, the frequency of the dominant phenotype is 0.96. What are the frequencies of the dominant (*A*) and recessive (*a*) alleles, and what are the expected frequencies of the *AA*, *Aa*, and *aa* genotypes?
- The genotype frequencies of a population are determined to be 0.6 *BB*, 0.0 *Bb*, and 0.4 *bb*. Is it likely that this population meets all the conditions required for genetic equilibrium?

[1]Note that evolutionary biologists use the term *migration,* not in its ordinary sense of periodic or seasonal movement of individuals from one location to another but in reference to a movement of individuals that results in a transfer of alleles from one population to another.

www.konkur.in

19.3 MICROEVOLUTION

LEARNING OBJECTIVES

5 Define *microevolution.*

6 Discuss how each of the following microevolutionary forces alters allele frequencies in populations: nonrandom mating, mutation, genetic drift, gene flow, and natural selection.

7 Distinguish among stabilizing selection, directional selection, and disruptive selection.

Evolution represents a departure from the Hardy–Weinberg principle of genetic equilibrium. The degree of departure between the observed allele or genotype frequencies and those expected by the Hardy–Weinberg principle indicates the amount of evolutionary change. This type of evolution—generation-to-generation changes in allele or genotype frequencies *within* a population—is sometimes referred to as **microevolution** because it often involves relatively small or minor changes, usually over a few generations.

Changes in the allele frequencies of a population result from five microevolutionary processes: nonrandom mating, mutation, genetic drift, gene flow, and natural selection. These microevolutionary processes are the opposite of the conditions that must be met if a population is in genetic equilibrium. When one or more of these processes acts on a population, allele or genotype frequencies change from one generation to the next.

Nonrandom mating changes genotype frequencies

When individuals select mates on the basis of phenotype (thereby selecting the corresponding genotype), they bring about evolutionary change in the population. Two examples of nonrandom mating are inbreeding and assortative mating.

In many populations, individuals mate more often with close neighbors than with more distant members of the population. As a result, neighbors tend to be more closely related—that is, genetically similar—to one another. The mating of genetically similar individuals who are more closely related than if they had been chosen at random from the entire population is known as **inbreeding.** Although inbreeding does not change the overall allele frequency, the frequency of homozygous genotypes increases with each successive generation of inbreeding. The most extreme example of inbreeding is self-fertilization, which is particularly common in certain plants.

Inbreeding does not appear to be detrimental in some populations, but in others it causes **inbreeding depression,** in which inbred individuals have lower fitness than those not inbred. **Fitness** is usually measured as the average number of surviving offspring of one genotype compared to the average number of surviving offspring of competing genotypes. Inbreeding depression, as evidenced by fertility declines and high juvenile mortality, is thought to be caused by the expression of harmful recessive alleles as homozygosity increases with inbreeding.

Several studies in the 1990s provided direct evidence of the deleterious consequences of inbreeding in nature. For example, white-footed mice (*Peromyscus leucopus*) were taken from a field and used to develop both inbred and non-inbred populations in the laboratory. When these laboratory-bred populations were returned to nature, their survivorship was estimated from release–recapture data. The non-inbred mice had a statistically significant higher rate of survival (**FIG. 19-2**). It is not known why the inbred mice had a lower survival rate. Some possibilities include higher disease susceptibility, poorer ability to evade predators, less ability to find food, and less ability to win fights with other white-footed mice.

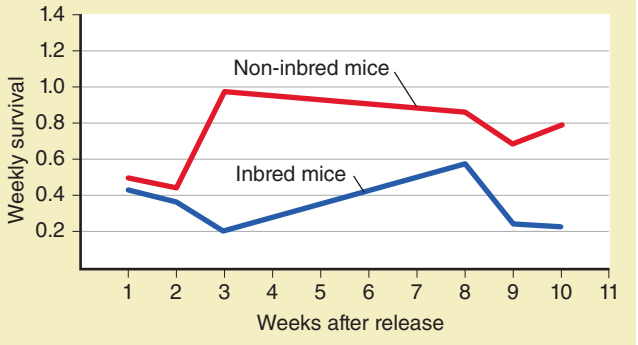
Assortative mating, in which individuals select mates by their phenotypes, is another example of nonrandom mating. For example, biologists selected two phenotypes—high bristle number and low bristle number—in a fruit fly (*Drosophila melanogaster*) population. Although the researchers made no effort to control mating, they observed that the flies preferentially mated with those of similar phenotypes. Females with high bristle number tended to mate with males with high bristle number, and females with low bristle number tended to mate with males with low bristle number. Such

KEY EXPERIMENT

QUESTION: Does inbreeding affect survival?

HYPOTHESIS: Non-inbred white-footed mice (*Peromyscus leucopus*) will have a survival advantage over inbred mice in a natural environment.

EXPERIMENT: Field-captured mice were used to establish inbred and non-inbred laboratory populations. The mice were marked and then released back into the field population. The population was then sampled by capturing mice, noting the number of inbred and non-inbred mice, and re-releasing the mice. The *x*-axis represents the 10-week period during which the samples were collected. Values on the *y*-axis are the estimated proportion of mice that survived from one week to the next. For example, the value of 0.2 in week 3 for the inbred mice means that 20% of the inbred mice that were alive at the beginning of the week survived through that week.



RESULTS AND CONCLUSION: Non-inbred mice (*red*) had a consistently higher survival rate than inbred mice (*blue*). Thus, inbreeding had a negative effect on survival in this species in nature.

FIGURE 19-2 Survival of inbred and non-inbred mice

www.konkur.in

selection of mates with the same phenotype is known as *positive assortative mating* (as opposed to the less common phenomenon, *negative assortative mating*, in which mates with opposite phenotypes are selected).

Positive assortative mating is practiced in many human societies, in which men and women tend to marry individuals like themselves in such characteristics as height or intelligence. Like inbreeding, assortative mating usually increases homozygosity at the expense of heterozygosity in the population and does not change the overall allele frequencies in the population. However, assortative mating changes genotype frequencies only at the loci involved in mate choice, whereas inbreeding affects genotype frequencies in the entire genome.

Mutation increases variation within a population

Variation is introduced into a population through **mutation,** which is an unpredictable change in deoxyribonucleic acid (DNA). As discussed in Chapter 13, mutations, which are the source of all new alleles, result from (1) a change in the nucleotide base pairs of a gene, (2) a rearrangement of genes within chromosomes so that their interactions produce different effects, or (3) a change in chromosome structure. Mutations occur unpredictably and spontaneously. A particular locus may have a DNA sequence that causes certain types of mutations to occur more frequently than others. The rate of mutation appears relatively constant for a particular locus but may vary by several orders of magnitude among genes within a single species and among different species.

Not all mutations pass from one generation to the next. Those occurring in somatic (body) cells are not inherited. When an individual with such a mutation dies, the mutation is lost. Some mutations, however, occur in reproductive cells. These mutations may or may not overtly affect the offspring because most of the DNA in a cell is "silent" and does not code for specific polypeptides or proteins that are responsible for physical characteristics. Even if a mutation occurs in the DNA that codes for a polypeptide, it may still have little effect on the structure or function of that polypeptide (we discuss such *neutral variation* later in the chapter). However, when a polypeptide is sufficiently altered to change its function, the mutation is usually harmful. By acting against seriously abnormal phenotypes, natural selection eliminates or reduces to low frequencies the most harmful mutations. Mutations with small phenotypic effects, even if slightly harmful, have a better chance of being incorporated into the population, where at some later time, under different environmental conditions, they may produce phenotypes that are useful or adaptive.

The "needs" of a population do not determine what mutations will occur. Consider a population living in an increasingly dry environment. A mutation producing a new allele that helps an individual adapt to dry conditions is no more likely to occur than one for adapting to wet conditions or one with no relationship to the changing environment. The production of new mutations simply increases the genetic variability that is acted on by natural selection and, therefore, increases the potential for new adaptations.

Mutation by itself causes small deviations in allele frequencies from those predicted by the Hardy–Weinberg principle. Although allele frequencies may be changed by mutation, these changes are typically several orders of magnitude smaller than changes caused by other evolutionary forces, such as genetic drift. Mutation is usually negligible as an evolutionary force, but it is essential to the evolutionary process because it is the ultimate source of genetic variation.

In genetic drift, random events change allele frequencies

The size of a population has important effects on allele frequencies because random events, or chance, tend to cause changes of relatively greater magnitude in a small population. If a population consists of only a few individuals, an allele present at a low frequency in the population could be completely lost by chance. Such an event would be unlikely in a large population. For example, consider two populations, one with 10,000 individuals and one with 10 individuals. If an uncommon allele occurs at a frequency of 10%, or 0.1, in both populations, then 1900 individuals in the large population have the allele.[2] That same frequency, 0.1, in the smaller population means that only about 2 individuals have the allele.[3] From this exercise, it is easy to see that there is a greater likelihood of losing the rare allele from the smaller population than from the larger one. Predators, for example, might happen to kill one or two individuals possessing the uncommon allele in the smaller population purely by chance, so these individuals would leave no offspring.

The production of random evolutionary changes in small breeding populations is known as **genetic drift.** Genetic drift results in changes in allele frequencies in a population from one generation to another. One allele may be eliminated from the population purely by chance, regardless of whether that allele is beneficial, harmful, or of no particular advantage or disadvantage. Thus, genetic drift decreases genetic variation *within* a population, although it tends to increase genetic differences *among* different populations.

When bottlenecks occur, genetic drift becomes a major evolutionary force

Because of fluctuations in the environment, such as depletion in food supply or an outbreak of disease, a population may rapidly and markedly decrease from time to time. The population is said to go through a bottleneck during which genetic drift can occur in the small population of survivors. As the population again increases in size, many allele frequencies may be quite different from those in the population preceding the decline.

Scientists hypothesize that genetic variation in the cheetah was considerably reduced by a bottleneck at the end of the last Ice Age, some 10,000 years ago (see Fig. 52-9). Cheetahs nearly became extinct, perhaps from overhunting by humans. The few surviving cheetahs had greatly reduced genetic variability, and as a result, the cheetah population today is so genetically uniform that unrelated cheetahs can accept skin grafts from one another. (Normally, only identical twins accept skin grafts so readily.)

[2] $2pq + q^2 = 2(0.9)(0.1) + (0.1)^2 = 0.18 + 0.01 = 0.19$; $0.19 \times 10{,}000 = 1900$

[3] $0.19 \times 10 = 1.9$

www.konkur.in

The founder effect occurs when a few "founders" establish a new colony

When one or a few individuals from a large population establish, or found, a colony (as when a few birds separate from the rest of the flock and fly to a new area), they bring with them only a small fraction of the genetic variation present in the original population. As a result, the only alleles among their descendants will be those of the colonizers. Typically, the allele frequencies in the newly founded population are quite different from those of the parent population. The genetic drift that results when a small number of individuals from a large population found a new colony is called the **founder effect.**

The Finnish people may illustrate the founder effect (**FIG. 19-3**). Geneticists who sampled DNA from Finns and from the European population at large found that Finns exhibit considerably less genetic variation than other Europeans. This evidence supports the hypothesis that Finns are descended from a small group of people who settled about 4000 years ago in the area that is now Finland and, because of the geography, remained separate from other European societies for centuries. The subpopulation in eastern Finland is especially homogeneous because it existed in relative isolation after being established by only several hundred founders in the 1500s.

The founder effect and population bottlenecks have also apparently affected the genetic composition of the population of Iceland. Iceland's 275,000 citizens are descended from a small group of Norse and Celtic people who settled that island in the ninth century. Isolation and population bottlenecks due to disease and natural disasters have contributed to the relative genetic homogeneity of the Icelandic people.

The founder effect can be of medical importance. For example, by chance one of the approximately 200 founders of the Amish population of Pennsylvania carried a recessive allele that, when homozygous, is responsible for a form of dwarfism, Ellis–van Creveld syndrome. Although this allele is rare in the general population (frequency about 0.001), today it is relatively common in the Amish population (frequency about 0.07).

Yann Arthus Bertrand/Corbis

FIGURE 19-3 Finns and the founder effect

The Finnish people are thought to have descended from a small founding population that remained separate from the rest of Europe for centuries.

The Finnish and Icelandic populations, as well as certain Amish populations, are being studied by researchers in the quest to identify genetic contributions to a large number of diseases. The task is simplified in these studies because confounding factors such as variability in the rest of the genome and differences in such environmental factors as nutrition, access to medical care, and exposure to pollutants are relatively controlled.

Gene flow generally increases variation within a population

Individuals of a species tend to be distributed in local populations that are genetically isolated to some degree from other populations. For example, the bullfrogs of one pond form a population separated from those in an adjacent pond. Some exchanges occur by migration between ponds, but the frogs in one pond are much more likely to mate with those in the same pond. Because each population is isolated to some extent from other populations, each has distinct genetic traits and gene pools.

The migration of breeding individuals between populations causes a corresponding movement of alleles, or **gene flow,** that has significant evolutionary consequences. As alleles flow from one population to another, they usually increase the amount of genetic variability within the recipient population. If sufficient gene flow occurs between two populations, they become more similar genetically. Because gene flow reduces the amount of variation between two populations, it tends to counteract the effects of natural selection and genetic drift, both of which often cause populations to become increasingly distinct.

If migration by members of a population is considerable and if populations differ in their allele frequencies, then significant genetic changes occur in local populations. For example, by 10,000 years ago modern humans occupied almost all of Earth's major land areas except a few islands. Because the population density was low in most locations, the small, isolated human populations underwent random genetic drift and natural selection. More recently (during the past 300 years or so), major migrations have increased gene flow, significantly altering allele frequencies within previously isolated human populations.

Natural selection changes allele frequencies in a way that increases adaptation

Natural selection is the mechanism of evolution first proposed by Darwin in which members of a population that are more successfully adapted to the environment have greater fitness—that is, they are more likely to survive and reproduce (see Chapter 18). Over successive generations, the proportion of favorable alleles increases in the population. In contrast with other microevolutionary processes (nonrandom mating, mutation, genetic drift, and gene flow), natural selection leads to adaptive evolutionary change. Natural selection not only explains why organisms are well adapted to the environments in which they live but also helps account for the remarkable diversity of life. Natural selection enables populations to change, thereby adapting to different environments and different ways of life.

www.konkur.in

Natural selection results in the differential reproduction of individuals with different traits, or phenotypes (and therefore different genotypes), in response to the environment. Natural selection preserves individuals with favorable phenotypes and eliminates those with unfavorable phenotypes. Individuals that survive and produce fertile offspring have a selective advantage.

The mechanism of natural selection does not develop a "perfect" organism. Rather, it weeds out those individuals whose phenotypes are less adapted to environmental challenges, while allowing better-adapted individuals to survive and pass their alleles to their offspring. By reducing the frequency of alleles that result in the expression of less favorable traits, the probability is increased that favorable alleles responsible for an adaptation will come together in the offspring.

Natural selection operates on an organism's phenotype

Natural selection does not act directly on an organism's genotype. Instead, it acts on the phenotype, which is, at least in part, an expression of the genotype. The phenotype represents an interaction between the environment and all the alleles in the organism's genotype. It is rare that alleles of a single locus determine the phenotype, as Mendel originally observed in garden peas. Much more common is the interaction of alleles of several loci for the expression of a single phenotype. Many plant and animal characteristics are under this type of *polygenic* control (see Chapter 11).

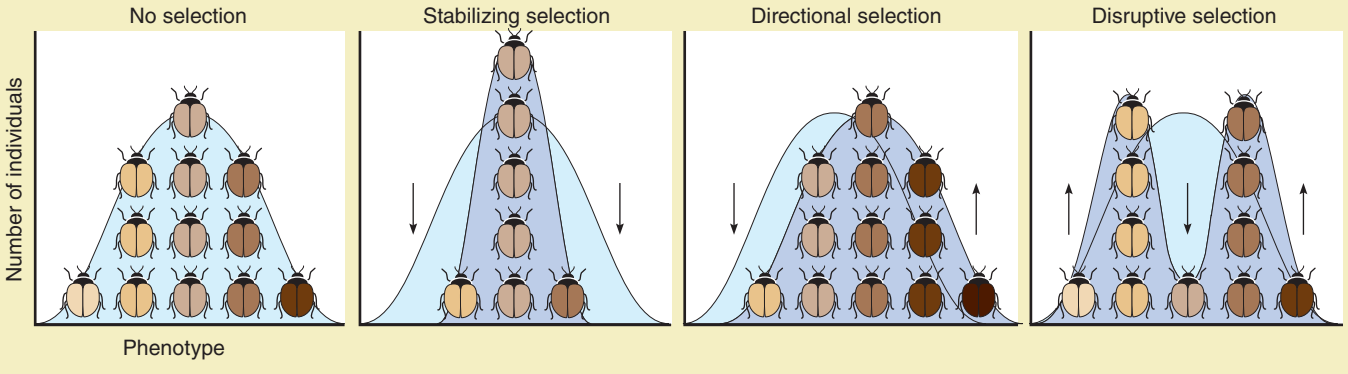
When characters are under polygenic control (as is human height), a range of phenotypes occurs, with most of the population located in the median range and fewer at either extreme. This is a normal distribution or standard bell curve (**FIG. 19-4a**; see also Fig. 11-20). Three kinds of selection cause changes in the normal distribution of phenotypes in a population: stabilizing, directional, and disruptive selection. Although we consider each process separately, in nature their influences generally overlap.

Stabilizing Selection The process of natural selection associated with a population well adapted to its environment is known as **stabilizing selection.** Most populations are probably influenced by stabilizing forces most of the time. Stabilizing selection selects against phenotypic extremes. In other words, individuals with average, or intermediate, phenotypes are favored.

Because stabilizing selection tends to decrease variation by favoring individuals near the mean of the normal distribution at the expense of those at either extreme, the bell curve narrows (**FIG. 19-4b**). Although stabilizing selection decreases the amount of variation in a population, variation is rarely eliminated by this process because other microevolutionary processes act against a decrease in variation. For example, mutation is slowly but continually adding to the genetic variation within a population.

One of the most widely studied cases of stabilizing selection involves human birth weight, which is under polygenic control and is also influenced by environmental factors. Extensive data from hospitals have shown that infants born with intermediate weights are most likely to survive (**FIG. 19-5**). Infants at either extreme (too small or too large) have higher rates of mortality. When newborn infants are too small, their body systems are immature, and when they are too large, they have difficult deliveries because they cannot pass as easily through the cervix and vagina. Stabilizing selec-

KEY POINT **Stabilizing, directional, and disruptive selection can change the distribution of phenotypes in a population.**



(a) A character that is under polygenic control (in this example, wing colors in a hypothetical population of beetles) exhibits a normal distribution of phenotypes in the absence of selection.

(b) As a result of stabilizing selection, which trims off extreme phenotypes, variation about the mean is reduced.

(c) Directional selection shifts the curve in one direction, changing the average value of the character.

(d) Disruptive selection, which trims off intermediate phenotypes, results in two or more peaks.

FIGURE 19-4 ***Animated*** **Modes of selection**

The blue screen represents the distribution of individuals by phenotype (in this example, color variation) in the original population. The purple screen represents the distribution by phenotype in the evolved population. The arrows represent the pressure of natural selection on the phenotypes.

www.konkur.in

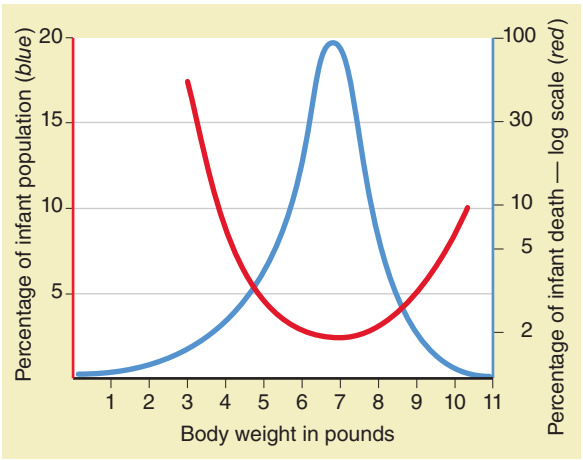


FIGURE 19-5 Stabilizing selection

The blue curve shows the distribution of birth weights in a sample of 13,730 infants. The red curve shows mortality (death) at each birth weight. Infants with very low or very high birth weights have higher death rates than infants of average weight. The optimum birth weight, that is, the one with the lowest mortality, is close to the average birth weight (about 7 lb). (Adapted from Cavalli-Sforza, L. L., and W. F. Bodmer, *The Genetics of Human Populations*, W. H. Freeman and Company, San Francisco, 1971.)

tion operates to reduce variability in birth weight so it is close to the weight with the minimum mortality rate.

Directional Selection If an environment changes over time, **directional selection** may favor phenotypes at one of the extremes of the normal distribution (FIG. 19-4c). Over successive generations, one phenotype gradually replaces another. So, for example, if greater size is advantageous in a new environment, larger individuals will become increasingly common in the population. However, directional selection occurs only if alleles favored under the new circumstances are already present in the population.

Darwin's Galápagos finches provide an excellent example of directional selection. Since 1973, Peter Grant and Rosemary Grant of Princeton University have studied the Galápagos finches. The Grants did a meticulous analysis of finch eating habits and beak sizes on Isla Daphne Major during three extended droughts (1977–1978, 1980, and 1982), one of which was followed by an extremely wet El Niño event (1983). During the droughts, the number of insects and small seeds declined, and large, heavy seeds became the finches' primary food source.

Many finches died during this time, and most of the survivors were larger birds whose beaks were larger and deeper. In a few generations, these larger birds became more common in the population (TABLE 19-1). After the El Niño event, however, smaller seeds became the primary food source, and smaller finches with average-sized beaks were favored. In this example, natural selection is directional: during the drought, natural selection operated in favor of the larger phenotype; whereas after the wet period, selection occurred in the opposite direction, favoring the smaller phenotype. The guppy populations studied in Venezuela and Trinidad (see Chapter 18) are another example of directional selection.

Directional selection by hunters has been observed in bighorn sheep (*Ovis canadensis*) in Canada. Sport hunters target large rams with rapidly growing horns for their trophy value (FIG. 19-6).

TABLE 19-1 Population Changes in *Geospiza fortis* before and after the 1976–1977 Drought

Character	Average before Drought (634)*	Average after Drought (135)*	Difference
Weight (g)	16.06	17.13	+1.07
Wing length (mm)	67.88	68.87	+0.99
Tarsus (leg, just above the foot) length (mm)	19.08	19.29	+0.21
Bill length (mm)	10.63	10.95	+0.32
Bill depth (mm)	9.21	9.70	+0.49
Bill width (mm)	8.58	8.83	+0.25

FIGURE 19-6 Bighorn sheep

This ram exhibits the massive horns that characterize this species.

Because these rams are typically killed prior to reaching their full reproductive potential, they contribute less to the gene pool; the result has been a 25% decline in average ram weight and horn length over a period of 30 years. Paradoxically, the rams that would

www.konkur.in

normally have the greatest fitness because of their size and ability to use their horns in competition with other males for mates become less fit when these attributes cause them to be singled out by hunters.

Disruptive Selection Sometimes extreme changes in the environment may favor two or more different phenotypes at the expense of the mean. That is, more than one phenotype may be favored in the new environment. **Disruptive selection** is a special type of directional selection in which there is a trend in several directions rather than just one (**FIG. 19-4d**). It results in a divergence, or splitting apart, of distinct groups of individuals within a population. Disruptive selection, which is relatively rare, selects against the average, or intermediate, phenotype.

Limited food supply during a severe drought caused a population of finches on another island in the Galápagos to experience disruptive selection. The finch population initially exhibited a variety of beak sizes and shapes. Because the only foods available on this island during the drought were wood-boring insects and seeds from cactus fruits, natural selection favored birds with beaks suitable for obtaining these types of food. Finches with longer beaks survived because they could open cactus fruits, and those with wider beaks survived because they could strip off tree bark to expose insects. However, finches with intermediate beaks could not use either food source efficiently and had a lower survival rate.

Natural selection induces change in the types and frequencies of alleles in populations only if there is pre-existing inherited variation. Genetic variation is the raw material for evolutionary change because it provides the diversity on which natural selection acts. Without genetic variation, evolution cannot occur. In the next section we explore the genetic basis for variation that is acted on by natural selection.

Review

- Which microevolutionary force leads to adaptive changes in allele frequencies?
- Why is mutation important to evolution if it is the microevolutionary force that generally has the smallest effect on allele frequencies?
- Which microevolutionary forces are most associated with an increase in variation within a population? among populations?
- Which microevolutionary force typically changes genotype frequencies without changing allele frequencies? Explain.

19.4 GENETIC VARIATION IN POPULATIONS

LEARNING OBJECTIVE

8 Describe the nature and extent of genetic variation, including genetic polymorphism, balanced polymorphism, neutral variation, and geographic variation.

Populations contain abundant genetic variation that was originally introduced by mutation. Sexual reproduction, with its associated crossing-over, independent assortment of chromosomes during meiosis, and random union of gametes, also contributes to genetic variation. The sexual process allows the variability introduced by mutation to be combined in new ways, which may be expressed as new phenotypes.

Genetic polymorphism can be studied in several ways

Genetic polymorphism, which is genetic variation among individuals in a population, is extensive in populations, although many of the genetic variants are present at low frequencies. Much of genetic polymorphism is not evident because it does not produce distinct phenotypes.

One way biologists estimate the total amount of genetic polymorphism in populations is by comparing the different forms of a particular protein. Each form consists of a slightly different amino acid sequence that is coded for by a different allele. For example, tissue extracts containing a particular enzyme may be analyzed for different individuals by gel electrophoresis. In *gel electrophoresis,* the enzymes are placed in slots on an agarose gel and an electric current is applied, causing each enzyme to migrate across the gel (see Fig. 15-8). Slight variations in amino acid sequences in the different forms of a particular enzyme cause each to migrate at a different rate, which can be detected using special stains or radioactive labels. Depending on the species studied, the percentage of enzymes that are polymorphic can range from about 15% to as much as 70%. In general, polymorphism of enzyme-coding loci tends to be greater in plants than in animals.

Determining the sequence of nucleotides in DNA from individuals in a population provides a *direct* estimate of genetic polymorphism that is sensitive enough to detect alleles that differ by only one nucleotide (**single nucleotide polymorphisms, SNPs**). (DNA sequencing is shown in Figures 15-10 and 15-11.) DNA sequencing of specific alleles in an increasing number of organisms, including humans, indicates that SNPs are common in most populations.

Recent studies have revealed that genetic changes in which segments of DNA have been gained or lost (compared to a reference genome) are common in model organisms such as mice and *Drosophila,* as well as humans. These **copy number variations,** or **CNVs,** can involve DNA segments that range from as few as 500 to 1000 base pairs up to about two million base pairs. It is currently estimated that the average human may have a dozen or more CNVs in their genome. In most cases, there does not appear to be an associated phenotype, or the phenotype is benign, such as an effect on eye color. However, as more sophisticated technologies have been developed to support ongoing research, evidence is accumulating that links specific CNVs to increased risk for certain medically important conditions, such as autism, Alzheimer's disease, and susceptibility to HIV infection.

Balanced polymorphism exists for long periods

Balanced polymorphism is a special type of genetic polymorphism in which two or more alleles persist in a population over many generations as a result of natural selection. Heterozygote advantage and frequency-dependent selection are mechanisms that preserve balanced polymorphism.

www.konkur.in

Genetic variation may be maintained by heterozygote advantage

We have seen that natural selection often eliminates unfavorable alleles from a population, whereas favorable alleles are retained. However, natural selection sometimes helps maintain genetic diversity. In some cases natural selection may even maintain a population's alleles that are unfavorable in the homozygous state. This happens, for example, when the heterozygote *Aa* has a higher degree of fitness than either homozygote *AA* or *aa*. This phenomenon, known as **heterozygote advantage,** is demonstrated in humans by the selective advantage of heterozygous carriers of the sickle cell allele.

The mutant allele (Hb^S) for sickle cell anemia produces an altered hemoglobin that deforms or sickles the red blood cells, making them more likely to form dangerous blockages in capillaries and to be destroyed in the liver, spleen, or bone marrow (discussed in Chapter 16). People who are homozygous for the sickle cell allele (Hb^SHb^S) usually die at an early age if medical treatment is not available.

Heterozygous individuals carry alleles for both normal (Hb^A) and sickle cell hemoglobin. The heterozygous condition (Hb^AHb^S) makes a person more resistant to a type of severe malaria (caused by the parasite *Plasmodium falciparum*) than people who are homozygous for the normal hemoglobin allele (Hb^AHb^A). In a heterozygous individual, each allele produces its own specific kind of hemoglobin, and the red blood cells contain the two kinds in roughly equivalent amounts. Such cells sickle much less readily than cells containing only the Hb^S allele. They are more resistant to infection by the malaria-causing parasite, which lives in red blood cells, than are the red blood cells containing only normal hemoglobin.

Where malaria is a problem, each of the two types of homozygous individuals is at a disadvantage. Those homozygous for the sickle cell allele are likely to die of sickle cell anemia, whereas those homozygous for the normal allele may die of malaria. The heterozygote is therefore more fit than either homozygote. In parts of Africa, the Middle East, and southern Asia where falciparum malaria is prevalent, heterozygous individuals survive in greater numbers than either homozygote (**FIG. 19-7**). The Hb^S allele is maintained at a high frequency in the population, even though the homozygous recessive condition is almost always lethal.

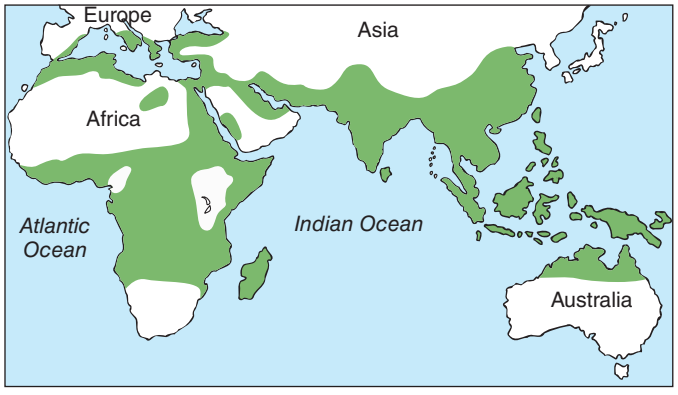
What happens to the frequency of Hb^S alleles in Africans and others who possess it when they migrate to the United States and other countries with few cases of malaria? As might be expected, the frequency of the Hb^S allele gradually declines in such populations, possibly because it confers a selective disadvantage by causing sickle cell anemia in homozygous individuals but no longer confers a selective advantage by preventing malaria in heterozygous individuals. The Hb^S allele never disappears from the population, however, because it is "hidden" from selection in heterozygous individuals and because it is reintroduced into the population by gene flow from the African population.

Genetic variation may be maintained by frequency-dependent selection

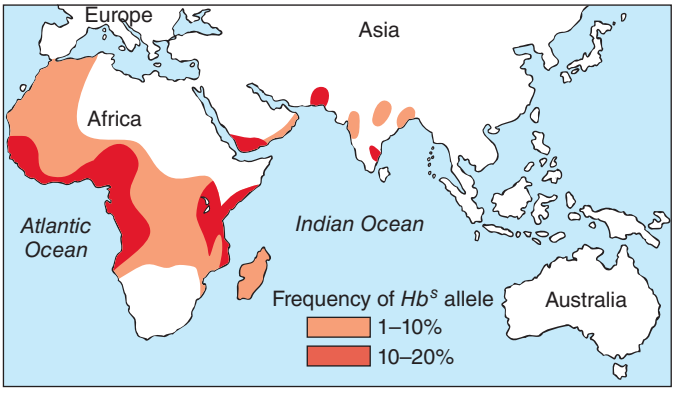
Thus far in our discussion of natural selection, we have assumed that the fitness of particular phenotypes (and their corresponding genotypes) is independent of their frequency in the population. However, in cases of **frequency-dependent selection,** the fitness of a particular phenotype depends on how frequently it appears in the population. Often a phenotype has a greater selective value when rare than when common in the population. Such phenotypes lose their selective advantage as they become more common.

Frequency-dependent selection often acts to maintain genetic variation in populations of prey species. In this case, the predator catches and consumes the more common phenotype but may ignore the rarer phenotypes. Consequently, the less common phenotype produces more offspring and therefore makes a greater relative contribution to the next generation.

Frequency-dependent selection is demonstrated in scale-eating fish (cichlids of the species *Perissodus microlepsis*) from Lake



(a) The geographic distribution of falciparum malaria (*green*).



(b) The distribution of the sickle cell anemia allele (*red and orange*).

FIGURE 19-7 Heterozygote advantage

Over large geographic areas, the distribution of individuals heterozygous for the sickle cell (Hb^S) allele is similar to the distribution of falciparum malaria. This evidence for greater fitness of heterozygous individuals in malarial regions supports the hypothesis of heterozygote advantage. (Adapted from Allison, A. C., "Protection Afforded by Sickle-Cell Traits against Subtertian Malarial Infection," *British Medical Journal,* Vol. 1, 1954.)

www.konkur.in

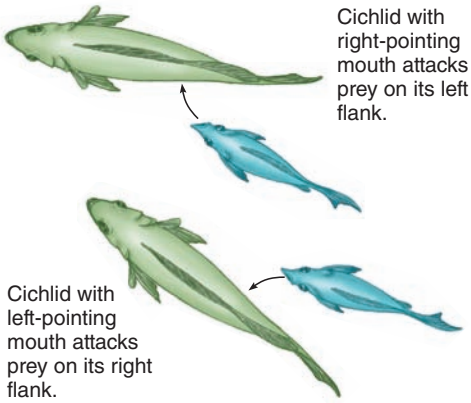
Tanganyika in Africa (**FIG. 19-8**). The scale-eating fish, which obtain food by biting scales off other fish, have either left-pointing or right-pointing mouths. A single locus with two alleles determines this characteristic; the allele for right-pointing mouth is dominant over the allele for left-pointing mouth. These fish attack their prey from behind and from a single direction, depending on mouth morphology. Those with left-pointing mouths always attack the right flanks of their prey, whereas those with right-pointing mouths always attack the left flanks.

The prey species are more successful at evading attacks from the more common form of scale-eating fish. For example, if the cichlids with right-pointing mouths are more common than those with left-pointing mouths, the prey are attacked more often on their left flanks. They therefore become more wary against such attacks, conferring a selective advantage to the less common cichlids with left-pointing mouths. The cichlids with left-pointing mouths would be more successful at obtaining food and would therefore have more offspring. Over time, the frequency of fish with left-pointing mouths would increase in the population, until their abundance causes frequency-dependent selection to work against them and confer an advantage on the now less common fish with right-pointing mouths. Thus, frequency-dependent selection maintains both populations of fish at approximately equal numbers.

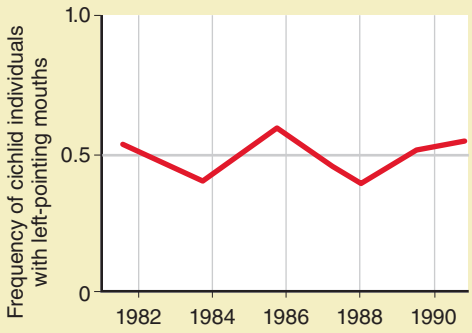
KEY EXPERIMENT

QUESTION: Can evidence for frequency-dependent selection be found in natural populations?

HYPOTHESIS: Equal proportions of scale-eating cichlids with right-pointing mouths vs. left-pointing mouths in a population are maintained by frequency-dependent selection.



EXPERIMENT: The relative frequencies of scale-eating cichlids with left-pointing and right-pointing mouths in Lake Tanganyika in Africa were monitored over a 10-year period.



RESULTS AND CONCLUSION: Relative frequencies of left-pointing and right-pointing cichlids varied slightly from year to year, but remained close to 0.5. This approximate 1:1 ratio is consistent with frequency-dependent selection because prey fish become especially wary to attacks by the cichlid type that is currently most common; therefore either type is at a selective disadvantage if its frequency rises above 0.5.

FIGURE 19-8 Frequency-dependent selection in scale-eating cichlids

Neutral variation may give no selective advantage or disadvantage

Some of the genetic variation observed in a population may confer no apparent selective advantage or disadvantage in a particular environment. For example, random changes in DNA that do not alter protein structure usually do not affect the phenotype. Variation that does not alter the ability of an individual to survive and reproduce and is, therefore, not adaptive is called **neutral variation.**

The extent of neutral variation in organisms is difficult to determine. It is relatively easy to demonstrate that an allele is beneficial or harmful if its effect is observable. But the variation in alleles that involves only slight differences in the proteins they code for may or may not be neutral. These alleles may be influencing the organism in subtle ways that are difficult to measure or assess. Also, an allele that is neutral in one environment may be beneficial or harmful in another.

Populations in different geographic areas often exhibit genetic adaptations to local environments

In addition to the genetic variation among individuals within a population, genetic differences often exist among different populations within the same species, a phenomenon known as **geographic variation.** One type of geographic variation is a **cline,** which is a gradual change in a species's phenotype and genotype frequencies through a series of geographically separate populations as a result of an environmental gradient. A cline exhibits variation in the expression of such attributes as color, size, shape, physiology, or behavior. Clines are common among species with continuous ranges over large geographic areas. For example, the body sizes of many widely distributed birds and mammals increase gradually as the latitude increases, presumably because larger animals are better able to withstand the colder temperatures of winter.

The common yarrow (*Achillea millefolium*), a wildflower that grows in a variety of North American habitats from lowlands to

www.konkur.in

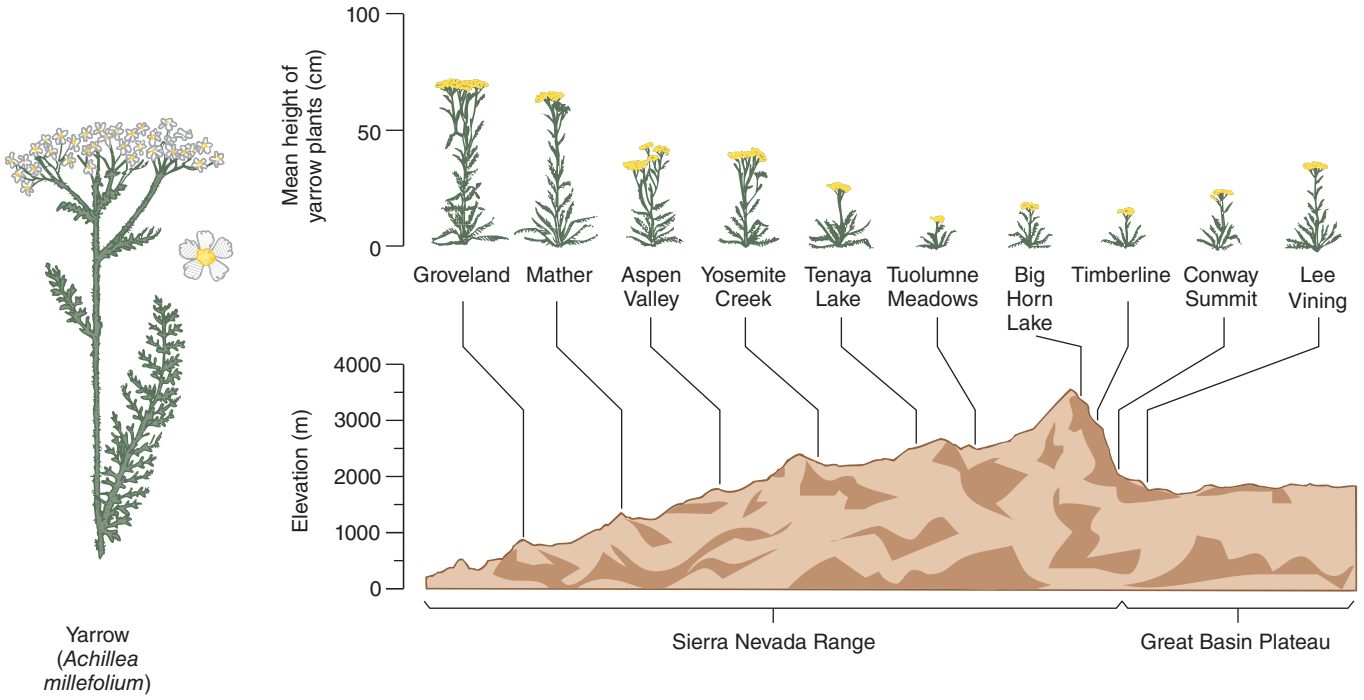

FIGURE 19-9 Clinal variation in yarrow (*Achillea millefolium*)

(After J. Clausen, D. D. Keck, and W. M. Hiesey, "Experimental Studies on the Nature of Species: III. Environmental Responses of Climatic Races of *Achillea*," Carnegie Institute Washington Publication, Vol. 58, 1948.)

mountain highlands, exhibits clinal variation in height in response to different climates at different elevations. Although substantial variation exists among individuals within each population, individuals in populations at higher elevations are, on average, shorter than those at lower elevations. The genetic basis of these clinal differences was experimentally demonstrated in a set of classical experiments in which series of populations from different geographic areas were grown in the same environment (**FIG. 19-9**). Despite being exposed to identical environmental conditions, each experimental population exhibited the traits characteristic of the elevation from which it was collected.

Review

- How does the sickle cell allele illustrate heterozygote advantage?
- How does frequency-dependent selection affect genetic variation within a population over time?
- How can researchers test the hypothesis that clinal variation among populations of a particular species has a genetic basis?

SUMMARY: FOCUS ON LEARNING OBJECTIVES

19.1 *(page 412)*

1 Define what is meant by a population's gene pool.

- All the individuals that live in a particular place at the same time make up a **population.** Each population has a **gene pool,** which includes all the **alleles** for all the **loci** present in the population.
- **Population genetics** is the study of genetic variability within a population and of the forces that act on it.

2 Distinguish among genotype, phenotype, and allele frequencies.

- A **genotype frequency** is the proportion of a particular genotype in the population. A **phenotype frequency** is the proportion of a particular phenotype in the population. An **allele frequency** is the proportion of a specific allele of a given genetic locus in the population.

19.2 *(page 412)*

3 Discuss the significance of the Hardy–Weinberg principle as it relates to evolution and list the five conditions required for genetic equilibrium.

- The **Hardy–Weinberg principle** states that allele and genotype frequencies do not change from generation to generation (no evolution is occurring) in a population at **genetic equilibrium.**
- The Hardy–Weinberg principle applies only if mating is random in the population, there are no net mutations that change the allele frequencies, the population is large, individuals do not migrate between populations, and natural selection does not occur.

4 Use the Hardy–Weinberg principle to solve problems involving populations.

- In the Hardy–Weinberg equation, p = the frequency of the dominant allele, q = the frequency of the recessive allele: $p + q = 1$.
- The genotype frequencies of a population are described by the relationship $p^2 + 2pq + q^2 = 1$, where p^2 is the frequency of the homozygous dominant genotype, $2pq$ is the frequency of the heterozygous genotype, and q^2 is the frequency of the homozygous recessive genotype.

CENGAGENOW™ **Interact with the Hardy–Weinberg principle by clicking on the figure in CengageNOW.**

www.konkur.in

19.3 *(page 415)*

5 Define *microevolution.*

- **Microevolution** is a change in allele or genotype frequencies within a population over successive generations.

6 Discuss how each of the following microevolutionary forces alters allele frequencies in populations: nonrandom mating, mutation, genetic drift, gene flow, and natural selection.

- In nonrandom mating, individuals select mates on the basis of phenotype, indirectly selecting the corresponding genotype(s). **Inbreeding** is the mating of genetically similar individuals that are more closely related than if they had been chosen at random from the entire population. Inbreeding in some populations causes **inbreeding depression,** in which inbred individuals have lower **fitness** (relative ability to make a genetic contribution to the next generation) than non-inbred individuals. In **assortative mating** individuals select mates by their phenotypes. Both inbreeding and assortative mating increase the frequency of homozygous genotypes.
- **Mutations,** unpredictable changes in DNA, are the source of new alleles. Mutations increase the genetic variability acted on by natural selection.
- **Genetic drift** is a random change in the allele frequencies of a small population. Genetic drift decreases genetic variation within a population, and the changes caused by genetic drift are usually not adaptive. A sudden decrease in population size caused by adverse environmental factors is known as a bottleneck. The **founder effect** is genetic drift that occurs when a small population colonizes a new area.
- **Gene flow,** a movement of alleles caused by the migration of individuals between populations, causes changes in allele frequencies.
- **Natural selection** causes changes in allele frequencies that lead to adaptation. Natural selection operates on an organism's phenotype, but it changes the genetic composition of a population in a favorable direction for a particular environment.

7 Distinguish among stabilizing selection, directional selection, and disruptive selection.

- **Stabilizing selection** favors the mean at the expense of phenotypic extremes. **Directional selection** favors one phenotypic extreme over another, causing a shift in the phenotypic mean. **Disruptive selection** favors two or more phenotypic extremes.

CENGAGENOW™ **Watch natural selection in action by clicking on the figure in CengageNOW.**

19.4 *(page 420)*

8 Describe the nature and extent of genetic variation, including genetic polymorphism, balanced polymorphism, neutral variation, and geographic variation.

- **Genetic polymorphism** is the presence of genetic variation within a population.
- **Balanced polymorphism** is a special type of genetic polymorphism in which two or more alleles persist in a population over many generations as a result of natural selection.
- **Heterozygote advantage** occurs when the heterozygote exhibits greater fitness than either homozygote. In **frequency-dependent selection,** a genotype's selective value varies with its frequency of occurrence.
- **Neutral variation** is genetic variation that confers no detectable selective advantage.
- **Geographic variation** is genetic variation that exists among different populations within the same species. A **cline** is a gradual change in a species's phenotype and genotype frequencies through a series of geographically separate populations.

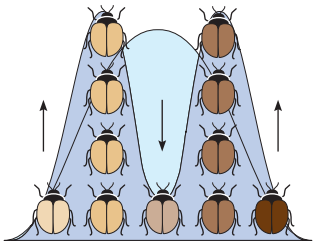
TEST YOUR UNDERSTANDING

1. The genetic description of an individual is its genotype, whereas the genetic description of a population is its (a) phenotype (b) gene pool (c) genetic drift (d) founder effect (e) changes in allele frequencies
2. In a diploid species, each individual possesses (a) one allele for each locus (b) two alleles for each locus (c) three or more alleles for each locus (d) all the alleles found in the gene pool (e) half of the alleles found in the gene pool
3. The MN blood group is of interest to population geneticists because (a) people with genotype *MN* cannot receive blood transfusions from either *MM* or *NN* people (b) the *MM, MN,* and *NN* genotype frequencies can be observed directly and compared with calculated expected frequencies (c) the *M* allele is dominant to the *N* allele (d) people with the *MN* genotype exhibit frequency-dependent selection (e) people with the *MN* genotype exhibit heterozygote advantage
4. If all copies of a given locus have the same allele throughout the population, then the allele frequency is (a) 0 (b) 0.1 (c) 0.5 (d) 1.0 (e) 10.0
5. If a population's allele and genotype frequencies remain constant from generation to generation, (a) the population is undergoing evolutionary change (b) the population is said to be at genetic equilibrium (c) microevolution has taken place (d) directional selection is occurring, but only for a few generations (e) genetic drift is a significant evolutionary force
6. Analysis of DNA sequences for a particular locus among individuals within a population provides biologists with one way to estimate (a) genetic drift (b) genetic polymorphism (c) gene flow (d) heterozygote advantage (e) frequency-dependent selection
7. The continued presence of the allele that causes sickle cell anemia in areas where falciparum malaria is prevalent demonstrates which of the following phenomena? (a) inbreeding depression (b) frequency-dependent selection (c) heterozygote advantage (d) genetic drift (e) a genetic bottleneck
8. According to the Hardy–Weinberg principle, (a) allele frequencies are not dependent on dominance or recessiveness but remain essentially unchanged from generation to generation (b) the sum of allele frequencies for a given locus is always greater than 1 (c) if a

www.konkur.in

locus has only one allele, the frequency of that allele is zero (d) allele frequencies change from generation to generation (e) the process of inheritance, by itself, causes changes in allele frequencies

9. The Hardy–Weinberg principle may be applicable if (a) population size is small (b) migration occurs only at the beginning of the breeding season (c) mutations occur at a constant rate (d) matings occur exclusively between individuals of the same genotype (e) natural selection does not occur
10. Mutation (a) leads to adaptive evolutionary change (b) adds to the genetic variation of a population (c) is the result of genetic drift (d) almost always benefits the organism (e) a and b
11. Which of the following is *not* true of natural selection? (a) natural selection acts to preserve favorable traits and eliminate unfavorable traits (b) the offspring of individuals that are better adapted to the environment will make up a larger proportion of the next generation (c) natural selection directs the course of evolution by preserving the traits acquired during an individual's lifetime (d) natural selection acts on a population's genetic variability, which arises through mutation (e) natural selection may result in changes in allele frequencies in a population
12. The distribution of phenotypes shown in the figure is most consistent with (a) no selection (b) stabilizing selection (c) directional selection (d) disruptive selection (e) genetic equilibrium



CRITICAL THINKING

1. **EVOLUTION LINK.** Why are mutations almost always neutral or harmful? If this is true, why are mutations nevertheless essential to evolution?
2. **EVOLUTION LINK.** Explain this apparent paradox: scientists discuss evolution in terms of *genotype* fitness (the selective advantage that a particular genotype confers on an individual), yet natural selection acts on an organism's *phenotype.*
3. **EVOLUTION LINK.** Why is it easier for researchers to study the genetic contribution to disease in the populations of Finland or Iceland, as opposed to those of the United States?
4. **EVOLUTION LINK.** Evolution is sometimes characterized as "survival of the fittest." Is this consistent with an evolutionary biologist's definitions of *fitness* and *natural selection*? Is this a good way to think about evolution, or a poor one?
5. **ANALYZING DATA.** Recall that the allele for right-pointing mouth in cichlids (*A*) is dominant over that for left-pointing mouth (*a*). Use the Hardy–Weinberg principle to calculate the allele frequencies that would correspond to equal frequencies of the two phenotypes. Which allele has the higher frequency? Why? How are these scale-eating fish an example of balanced polymorphism?
6. **ANALYZING DATA.** The recessive allele that causes Ellis–van Creveld syndrome when homozygous has a frequency of about 0.07 in the Amish population of Pennsylvania, although its frequency is only about 0.001 in the general population. How many persons out of 1000 in the Amish population would be expected to have the disease? How many out of a million in the general population?
7. **ANALYZING DATA.** You study males in populations of a certain species of minnows in a series of lakes at different latitudes. You find that they exhibit clinal variation in average weight at maturity and hypothesize that the weight differences are due to genetic factors. You predict that the average weights at maturity of representatives of each population reared in aquaria will differ in ways that are consistent with the differences you observed among the wild populations. However, when you conduct the experiment, you find no differences among the population averages. What is your conclusion?
8. **SCIENCE, TECHNOLOGY, AND SOCIETY.** Automated techniques are being developed that will provide new information on the extent of genetic polymorphism among humans, particularly with respect to single nucleotide polymorphisms (SNPs) and copy number variations (CNVs). In what ways might this information prove useful? In what ways might it present challenges?

Blue-footed booby. Blue-footed boobies are large sea birds that nest on the Galápagos Islands and several other arid islands in the eastern Pacific Ocean. Male and female pairs are monogamous and typically nest on black lava. The largest blue-footed booby breeding population is found in the Galápagos Islands.

KEY CONCEPTS

20.1 According to the biological species concept, a species consists of individuals that can successfully interbreed with one another but not with individuals from other species.

20.2 The evolution of different species begins with reproductive isolation, in which two populations are no longer able to interbreed successfully.

20.3 In allopatric speciation, populations diverge into different species due to geographic isolation, or physical separation. In sympatric speciation, populations become reproductively isolated from one another despite living in the same geographic area.

20.4 Speciation may require millions of years but sometimes occurs much more quickly.

20.5 The evolution of species and higher taxa is known as macroevolution.

A Brazilian rain forest contains thousands of species of insects, amphibians, reptiles, birds, and mammals. The Great Barrier Reef off the coast of Australia has thousands of species of sponges, corals, mollusks, crustaceans, sea stars, and fishes. The various environments on Earth abound in rich assemblages of species. Scientists have currently named about 1.8 million species.

We do not know exactly how many species exist today, but many biologists estimate the number to be on the order of 4 million to 100 million! Often this diversity has been portrayed as many twig tips on a "tree of life." As one follows the twigs from the tips toward the main body of the tree, they form connections that represent common ancestors that are now extinct. Indeed, more than 99.9% of all species that ever existed are now extinct. Tracing the branches of the tree of life to larger and larger connections eventually leads to a single trunk that represents the few simple unicellular organisms that evolved early in Earth's history and became the ancestors of all species living today.

www.konkur.in

Thus, life today is the product of 3 billion to 4 billion years of evolution. How did all these species diversify throughout Earth's history? Darwin's studies led him to conclude that the Galápagos Islands were the birthplace of many new species (see photograph). Our understanding of how species evolve has advanced significantly since Darwin published *On the Origin of Species*.

In this chapter we consider the reproductive barriers that isolate species from one another and the possible evolutionary mechanisms that explain how the millions of species that live today or lived in the past originated from ancestral species. We then examine the rate of evolutionary change and the evolution of higher taxonomic categories (species, genus, family, order, class, and phylum), which is the focus of macroevolution.

20.1 WHAT IS A SPECIES?

LEARNING OBJECTIVE

1 Describe the biological species concept and list two potential problems with the concept.

The concept of distinct kinds of organisms, known as **species** (from Latin, meaning "kind"), is not new. However, there are several different definitions of species, and every definition has some sort of limitation. Linnaeus was the 18th-century biologist who founded modern taxonomy—the science of naming, describing, and classifying organisms. He classified plants and other organisms into separate species based on their visible structural differences, such as feathers or number of flower parts. This method, known as the *morphological species concept,* is still used to help characterize species, but structural differences alone are not adequate to explain what constitutes a species.

The biological species concept is based on reproductive isolation

Population genetics did much to clarify the concept of species. According to the **biological species concept,** first expressed by evolutionary biologist Ernst Mayr in 1942, a species consists of one or more populations whose members interbreed in nature to produce fertile offspring and do not interbreed with—that is, are reproductively isolated from—members of different species. Gene flow occurs between individuals of a given species when they mate, but reproductive barriers restrict individuals of one species from interbreeding, or exchanging genes, with members of other species. As a result, reproductive barriers keep a given species genetically distinct from other species. An extension of the biological species concept holds that new species evolve when formerly interbreeding populations become reproductively isolated from one another.

The biological species concept is currently the most widely accepted definition of species, but it has several shortcomings. One problem with the biological species concept is that it applies only to sexually reproducing organisms. Bacteria reproduce asexually,

FIGURE 20-1 Bdelloid rotifer (*Philodina roseola*)
Bdelloid rotifers are all females. Because they do not reproduce sexually, it is difficult to classify these small marine animals as species under the biological species concept.

although they may have considerable exchange of genetic material by means of *horizontal gene transfer* among bacterial individuals that are classified as different species. Thus, reproductive isolation is not a good criterion for defining species of bacteria.

Small marine organisms known as bdelloid rotifers are an example of animals that reproduce asexually (**FIG. 20-1**). All bdelloid rotifers are females, and they produce offspring without needing males. These organisms and also extinct organisms must be classified based on their structural and biochemical characteristics; the biological species concept does not apply to them.

Another potential problem with the biological species concept is that although individuals assigned to different species do not normally interbreed, they may *sometimes* successfully interbreed. For example, where their ranges overlap, some coyotes have been known to mate with wolves. As a result, some wolves carry coyote genes and vice versa. Yet, most biologists agree that wolves and coyotes are separate species.

The phylogenetic species concept defines species based on such evidence as molecular sequencing

Some biologists prefer the **phylogenetic species concept,** also called the *evolutionary species concept,* in which a population is

www.konkur.in

declared a separate species if it has undergone evolution long enough for statistically significant differences in diagnostic traits to emerge. If a population has a unique diagnostic trait—a set of spines running down the back, for example—that can be demonstrated to be inherited, then this population is considered a separate species. This approach has the advantage of being testable by comparing gene sequences between two groups. However, many biologists do not want to abandon the biological species concept, in part because the phylogenetic species concept cannot be applied if the evolutionary history (as determined by DNA sequencing) of a taxonomic group has not been carefully studied; most groups have not been rigorously analyzed. Also, if the phylogenetic species concept were universally embraced, the number of named species would probably double. This increase would occur because many closely related populations that are classified as **subspecies** (a taxonomic subdivision of a species) under the biological species concept would fit the requirements of separate species under the phylogenetic species concept.

Thus, the exact definition of a species remains fuzzy. Unless we clearly state otherwise, when we mention *species* in this text, we are referring to the biological species concept.

Review

- What is a species, according to the biological species concept? What are some of the limitations of this definition?

20.2 REPRODUCTIVE ISOLATION

LEARNING OBJECTIVE

2 Explain the significance of reproductive isolating mechanisms and distinguish among the various prezygotic and postzygotic barriers.

Various **reproductive isolating mechanisms** prevent interbreeding between two different species whose *ranges* (areas where each lives) overlap. These mechanisms preserve the genetic integrity of each species because gene flow between the two species is prevented.

Most species have two or more mechanisms that block a chance occurrence of individuals from two closely related species overcoming a single reproductive isolating mechanism. Although most mechanisms operate before mating or fertilization occurs (*prezygotic*), others work after fertilization has taken place (*postzygotic*).

Prezygotic barriers interfere with fertilization

Prezygotic barriers are reproductive isolating mechanisms that prevent fertilization from taking place. Because male and female gametes never come into contact, an *interspecific zygote*—that is, a fertilized egg formed by the union of an egg from one species and a sperm from another species—is never produced. Prezygotic barriers include temporal isolation, habitat isolation, behavioral isolation, mechanical isolation, and gametic isolation.

Sometimes genetic exchange between two groups is prevented because they reproduce at different times of the day, season, or year. Such examples demonstrate **temporal isolation.** For example, two very similar species of fruit flies, *Drosophila pseudoobscura* and *D. persimilis,* have ranges that overlap to a great extent, but they do not interbreed. *Drosophila pseudoobscura* is sexually active only in the afternoon; and *D. persimilis,* only in the morning. Similarly, two frog species have overlapping ranges in eastern Canada and the United States. The wood frog (*Rana sylvatica*) usually mates in late March or early April, when the water temperature is about 7.2°C (45°F), whereas the northern leopard frog (*R. pipiens*) usually mates in mid-April, when the water temperature is 12.8°C (55°F) (**FIG. 20-2**).

Although two closely related species may be found in the same geographic area, they usually live and breed in different habitats in that area. This provides **habitat isolation** between the two species. For example, the five species of small birds known as flycatchers are nearly identical in appearance and have overlapping ranges in the eastern part of North America. They exhibit habitat isolation because during the breeding season, each species stays in a particular habitat within its range, so potential mates from different species do not meet. The least flycatcher (*Empidonax minimus*)

L. & D. Klein/Photo Researchers, Inc.

(a) The wood frog (*Rana sylvatica*) mates in early spring, often before the ice has completely melted in the ponds.

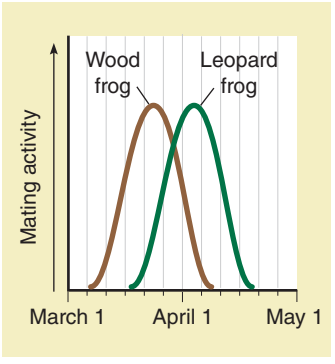
(b) The leopard frog (*Rana pipiens*) typically mates a few weeks later.



(c) Graph of peak mating activity in wood and leopard frogs. In nature, wood and leopard frogs do not interbreed.

FIGURE 20-2 ***Animated*** **Temporal isolation in wood and leopard frogs**

www.konkur.in

R. Brown/VIREO

FIGURE 20-3 Behavioral isolation in bowerbirds

Each bowerbird species has highly specialized courtship patterns that prevent its mating with another species. The male satin bowerbird (*Ptilonorhynchus violacens*) constructs an enclosed place, or bower, of twigs to attract a female. (The bower is the dark "tunnel" on the left.) Note the white flowers and blue decorations, including human-made objects such as bottle caps, that he has arranged at the entrance to his bower.

frequents open woods, farms, and orchards; whereas the acadian flycatcher (*E. virescens*) is found in deciduous forests, particularly in beech trees, and swampy woods. The alder flycatcher (*E. alnorum*) prefers wet thickets of alders, the yellow-bellied flycatcher (*E. flaviventris*) nests in conifer woods, and the willow flycatcher (*E. traillii*) frequents brushy pastures and willow thickets.

Many animal species exchange a distinctive series of signals before mating. Such courtship behaviors illustrate **behavioral isolation** (also known as **sexual isolation**). Bowerbirds, for example, exhibit species-specific courtship patterns. The male satin bowerbird of Australia constructs an elaborate bower of twigs, adding decorative blue parrot feathers and white flowers at the entrance (**FIG. 20-3**). When a female approaches the bower, the male dances around her, holding a particularly eye-catching decoration in his beak. While dancing, he puffs his feathers, extends his wings, and sings a courtship song that consists of a variety of sounds, including loud buzzes and hoots. These specific courtship behaviors keep closely related bird species reproductively isolated from the satin bowerbird. If a male and female of two different bowerbird species begin courtship, it stops when one member does not recognize or respond to the signals of the other.

Another example of behavioral isolation involves the wood frogs and northern leopard frogs just discussed as an example of temporal isolation. Males of these two species have very specific vocalizations to attract females of their species for breeding. These vocalizations reinforce each species's reproductive isolation.

Sometimes members of different species court and even attempt copulation, but the incompatible structures of their genital organs prevent successful mating. Structural differences that inhibit mating between species produce **mechanical isolation.** For example, many flowering plant species have physical differences in their flower parts that help them maintain their reproductive isolation from one another. In such plants, the flower parts are adapted for specific insect pollinators. Two species of sage, for example, have overlapping ranges in southern California. Black sage (*Salvia mellifera*), which is pollinated by small bees, has a floral structure different from that of white sage (*S. apiana*), which is pollinated by large carpenter bees (**FIG. 20-4**). Interestingly, black sage and white sage are also prevented from mating by a temporal barrier: black sage flowers in early spring, and white sage flowers in late spring and early summer. Presumably, mechanical isolation prevents insects from cross-pollinating the two species should they happen to flower at the same time.

If mating takes place between two species, their gametes may still not combine. Molecular and chemical differences between species cause **gametic isolation,** in which the egg and sperm of different species are incompatible. In aquatic animals that release their eggs and sperm into the surrounding water simultaneously, interspecific fertilization is extremely rare. The surface of the egg contains specific proteins that bind only to complementary molecules on the surface of sperm cells of the same species (see Chapter 51). A similar type of molecular recognition often occurs between pollen grains and the stigma (receptive surface of the

(a) The petal of the black sage functions as a landing platform for small bees. Large bees cannot fit on this platform.

(b) The larger landing platform and longer stamens of white sage allow pollination by larger California carpenter bees (a different species). If smaller bees land on white sage, their bodies do not brush against the stamens. (In the figure, the upper part of the white sage flower has been removed.)

FIGURE 20-4 Mechanical isolation in black sage and white sage

The differences in their floral structures allow black sage and white sage to be pollinated by different insects. Because the two species exploit different pollinators, they cannot interbreed.

www.konkur.in

female part of the flower) so that pollen does not germinate on the stigma of a different plant species.

Postzygotic barriers prevent gene flow when fertilization occurs

Fertilization sometimes occurs between gametes of two closely related species despite the existence of prezygotic barriers. When this happens, **postzygotic barriers** that increase the likelihood of reproductive failure come into play. Generally, the embryo of an interspecific hybrid spontaneously aborts. **Development,** the orderly sequence of events that occurs as an organism grows and matures, is a complex process requiring the precise interaction and coordination of many genes. Apparently, the genes from parents belonging to different species do not interact properly in regulating the mechanisms for normal development. In this case, reproductive isolation occurs by **hybrid inviability.** For example, in crosses between different species of irises the embryos die before reaching maturity. Similarly, nearly all the hybrids die in the embryonic stage when the eggs of a bullfrog are fertilized artificially with sperm from a leopard frog.

If an interspecific hybrid does live, it may not reproduce, for several reasons. Hybrid animals may exhibit courtship behaviors incompatible with those of either parental species, and as a result they will not mate. More often, **hybrid sterility** occurs when problems during meiosis cause the gametes of an interspecific hybrid to be abnormal. Hybrid sterility is particularly common if the two parental species have different chromosome numbers. For example, a mule is the offspring of a female horse ($2n = 64$) and a male donkey ($2n = 62$) (**FIG. 20-5**). This type of union almost always results in sterile offspring ($2n = 63$) because synapsis (the pairing of homologous chromosomes during meiosis) and segregation of chromosomes cannot occur properly.

Occasionally, a mating between two F_1 hybrids produces a second hybrid generation (F_2). The F_2 hybrid may exhibit **hybrid breakdown,** the inability of a hybrid to reproduce because of some defect. For example, hybrid breakdown in the F_2 generation of a cross between two sunflower species was 80%. In other words, 80% of the F_2 generation were defective in some way and could not reproduce successfully. Hybrid breakdown also occurs in the F_3 and later generations.

TABLE 20-1 summarizes the various prezygotic and postzygotic barriers that prevent interbreeding between two species.

Biologists are discovering genes responsible for reproductive isolating mechanisms

Progress has been made in identifying some of the genes involved in reproductive isolation. For example, scientists have determined the genetic basis for prezygotic isolation in species of abalone, large mollusks found along the Pacific coast of North America. In abalone, the fertilization of eggs by sperm requires *lysin,* a sperm protein that attaches to a lysin receptor protein located on the egg envelope. After attachment, the lysin produces a hole in the egg envelope that permits the sperm to penetrate the egg. Scientists cloned the lysin receptor gene and demonstrated that this gene varies among abalone species. Differences in the lysin receptor protein in various abalone species determine sperm compatibility with the egg. Sperm of one abalone species do not attach to a lysin receptor protein of an egg of a different abalone species.

Other genes related to reproductive isolating mechanisms—loosely referred to as "speciation genes"—have been identified in a diverse group of organisms, such as Florida beach mice, cactus finches, fruit fly (*Drosophila*) species, and flycatcher birds in the South Pacific.

Review

- What barriers prevent wood frogs and leopard frogs from interbreeding in nature?
- How is temporal isolation different from behavioral isolation?
- How is mechanical isolation different from gametic isolation?
- Of which postzygotic barrier is the mule an example?

FIGURE 20-5 Hybrid sterility in mules

Mules are interspecific hybrids formed by mating a female horse (*left*) with a male donkey (*right*). Although the mule (*center*) exhibits valuable characteristics of each of its parents, it is sterile.

20.3 SPECIATION

LEARNING OBJECTIVES

3 Explain the mechanism of allopatric speciation and give an example.

4 Explain the mechanisms of sympatric speciation and give both plant and animal examples.

We are now ready to consider how entirely new species may arise from previously existing ones. The evolution of a new species is called **speciation.** The formation of two species from a single species occurs when a population becomes reproductively isolated from other populations of the species and the **gene pools** of the two separated populations begin to diverge in genetic composition. When a population is sufficiently different from its ancestral species that there is no genetic exchange between them, we consider speciation to have occurred. Speciation happens in two ways: allopatric speciation and sympatric speciation.

www.konkur.in

TABLE 20-1 ***Animated*** **Reproductive Isolating Mechanisms**

Mechanism	How It Works		Example
Prezygotic barriers prevent fertilization			
Temporal isolation	Similar species reproduce at different times		Two species of fruit flies of the genus *Drosophila* live in the same geographic area, but one is sexually active only in the afternoon and the other only in the morning.
Habitat isolation	Similar species reproduce in different habitats		Several flycatcher species of the genus *Empidonax* live in the same geographic area but in different habitats; for example, the least flycatcher in open woods, farms, and orchards, and the acadian flycatcher in deciduous forests and swampy woods.
Behavioral isolation	Similar species have distinctive courtship behaviors		The male satin bowerbird of Australia constructs an elaborate bower, dances around the female, and sings a specific courtship song that keeps closely related bowerbird species reproductively isolated from the satin bowerbird.
Mechanical isolation	Similar species have structural differences in their reproductive organs		Black sage (genus *Salvia*) is pollinated by small bees, whereas white sage is pollinated by large carpenter bees. Because of differences in the flower structures, neither type of bee can successfully pollinate the other sage species.
Gametic isolation	Gametes of similar species are chemically incompatible		In aquatic animals such as sponges that release their eggs and sperm into the water simultaneously, interspecific fertilization rarely occurs because the egg surface is compatible only with the sperm surface of the same species.
Postzygotic barriers reduce viability or fertility of hybrid			
Hybrid inviability	Interspecific hybrid dies at early stage of embryonic development		In crosses between different species of irises (genus *Iris*), fertilization occurs but the embryos in the seeds die before reaching maturity.
Hybrid sterility	Interspecific hybrid survives to adulthood but is unable to reproduce successfully		A mule, the offspring of a female horse and a male donkey, has sterile offspring because synapsis and segregation of chromosomes do not occur properly during gamete formation.
Hybrid breakdown	Offspring of interspecific hybrid are unable to reproduce successfully		In a cross between two sunflower species, most of the F_2 generation are defective in some way and cannot reproduce successfully. Hybrid breakdown also occurs in later generations.

www.konkur.in

Long physical isolation and different selective pressures result in allopatric speciation

Speciation that occurs when one population becomes geographically separated from the rest of the species and subsequently evolves by natural selection and/or genetic drift is known as **allopatric speciation** (from the Greek *allo,* "different," and *patri,* "native land"). Recall from Chapter 18 that *natural selection* occurs as individuals that possess favorable adaptations to the environment survive and become parents of the next generation. *Genetic drift* is a random change in allele frequency resulting from the effects of chance on the survival and reproductive success of individuals in a small breeding population (see Chapter 19). Both natural selection and genetic drift result in changes in allele frequencies in a population, but only in natural selection is the change in allele frequency adaptive.

Allopatric speciation is the most common method of speciation and accounts for almost all evolution of new animal species. The geographic isolation required for allopatric speciation may occur in several ways. Earth's surface is in a constant state of change. Such change includes rivers shifting their courses; glaciers migrating; mountain ranges forming; land bridges forming that separate previously united aquatic populations; and large lakes diminishing into several smaller, geographically separated pools.

What may be an imposing geographic barrier to one species may be of no consequence to another. Birds and cattails, for example, do not become isolated when a lake subsides into smaller pools; birds easily fly from one pool to another, and cattails disperse their pollen and fruits by air currents. Fishes, in contrast, usually cannot cross the land barriers between the pools and so become reproductively isolated.

In the Death Valley region of California and Nevada, large interconnected lakes formed during wetter climates of the last Ice Age. These lakes were populated by one or several species of pupfishes. Over time, the climate became drier, and the large lakes dried up, leaving isolated pools. Presumably, each pool contained a small population of pupfish that gradually diverged from the common ancestral species by genetic drift and natural selection in response to habitat differences—the high temperatures, high salt concentrations, and low oxygen levels characteristic of desert springs. Today, there are 20 or so distinct species, subspecies, and populations in the area of Death Valley, California, and Ash Meadows, Nevada (**FIG. 20-6**). Many, such as the Devil's Hole pupfish and the Owens pupfish, are restricted to one or two isolated springs.

Allopatric speciation also occurs when a small population migrates or is dispersed (such as by a chance storm) and colonizes a new area away from the range of the original species. This colony is geographically isolated from its parental species, and the small *microevolutionary* changes that accumulate in the isolated gene pool over many generations may eventually be sufficient to form a new species. Because islands provide the geographic isolation required for allopatric speciation, they offer excellent opportunities to study this evolutionary mechanism. A few individuals of a few species probably colonized the Galápagos Islands and the Hawaiian Islands, for example. The hundreds of unique species presently found on each island presumably descended from these original colonizers (**FIG. 20-7**).

Speciation is more likely to occur if the original isolated population is small. Recall from Chapter 19 that genetic drift, including the founder effect, is more consequential in small populations. Genetic drift tends to result in rapid changes in allele frequencies in a small, isolated population. The different selective pressures of the new environment to which the population is exposed further accentuate the divergence caused by genetic drift.

The Kaibab squirrel is an example of allopatric speciation in progress

About 10,000 years ago, when the American Southwest was less arid, the ponderosa pine forests in the area supported a tree squir-

FIGURE 20-7 Allopatric speciation of the Hawaiian goose (the nene)

Nene (pronounced "nay-nay"; *Branta sandvicensis*) are geese originally found only on volcanic mountains on the geographically isolated islands of Hawaii and Maui, which are some 4200 km (2600 mi) from the nearest continent. Compared with those of other geese, the feet of Hawaiian geese are not completely webbed, their toenails are longer and stronger, and their foot pads are thicker; these adaptations enable Hawaiian geese to walk easily on lava flows. Nenes probably evolved from a small population of geese that originated in North America. Photographed in Hawaii Volcanoes National Park, Hawaii.

rel with conspicuous tufts of hair sprouting from its ears. A small tree squirrel population living on the Kaibab Plateau of the Grand Canyon became geographically isolated when the climate changed, thus causing areas to the north, west, and east to become desert. Just a few miles to the south lived the rest of the squirrels, which we know as Abert squirrels, but the two groups were separated by the Grand Canyon. With changes over time in both its appearance and its ecology, the Kaibab squirrel is on its way to becoming a new species.

During its many years of geographic isolation, the small population of Kaibab squirrels has diverged from the widely distributed Abert squirrels in several ways. Perhaps most evident are changes in fur color. The Kaibab squirrel now has a white tail and a gray belly, in contrast to the gray tail and white belly of the Abert squirrel (**FIG. 20-8**). Biologists think these striking changes arose in Kaibab squirrels as a result of genetic drift.

Scientists have not reached a consensus about whether the two squirrel populations are separate species, and most biologists today consider the Kaibab squirrel (*Sciurus aberti ssp. kaibabensis*) and the Abert squirrel (*Sciurus aberti*) as distinct subspecies. Because the Kaibab and Abert squirrels remain reproductively isolated from each other, it is assumed that they will continue to evolve into separate species.

Porto Santo rabbits diverged rapidly from European rabbits

Allopatric speciation has the potential to occur quite rapidly. Early in the 15th century, a small population of rabbits was released on Porto Santo, a small island off the coast of Portugal. Because there were no other rabbits or competitors and no predators on the island, the rabbits thrived. By the 19th century, these rabbits were markedly different from their European ancestors. They were only half as large (weighing slightly more than 500 g, or 1.1 lb), with a different color pattern and a more nocturnal lifestyle. More significant, attempts to mate Porto Santo rabbits with mainland European rabbits failed. Many biologists concluded that within 400 years, an extremely brief period in evolutionary history, a new species of rabbit had evolved.

Not all biologists agree that the Porto Santo rabbit is a new species. The objection stems from a more recent breeding experiment and is based on biologists' lack of a consensus about the definition of a species. In the experiment, foster mothers of the wild Mediterranean rabbit raised newborn Porto Santo rabbits. When they reached adulthood, these Porto Santo rabbits mated successfully with Mediterranean rabbits to produce healthy, fertile offspring. To some biologists, this experiment clearly demonstrated that Porto Santo rabbits are not a separate species but a subspecies. These biologists cite the Porto Santo rabbits as an example of speciation in progress, much like the Kaibab squirrels just discussed.

Many other biologists think the Porto Santo rabbit is a separate species because it does not interbreed with the other rabbits under natural conditions. They point out that the breeding experiment was successful only after the baby Porto Santo rabbits were raised under artificial conditions that probably modified their natural behavior.

Two populations diverge in the same physical location by sympatric speciation

Although geographic isolation is an important factor in many cases of evolution, it is not an absolute requirement. In **sympatric speciation** (from the Greek *sym,* "together," and *patri,* "native land"), a new species evolves within the same geographic region as the parental species. The divergence of two populations in the same geographic range occurs when reproductive isolating mechanisms evolve at the *start* of the speciation process. Sympatric speciation is especially common in plants. The role of sympatric speciation in animal evolution is probably much less important than allopatric speciation; until recently, sympatric speciation in animals has been difficult to demonstrate in nature.

Sympatric speciation occurs in at least two ways: a change in **ploidy** (the number of chromosome sets making up an organism's genome) and a change in ecology. We now examine each of these mechanisms.

Allopolyploidy is an important mechanism of sympatric speciation in plants

As a result of reproductive isolating mechanisms discussed earlier, the union of two gametes from different species rarely forms viable offspring; if offspring are produced, they are usually sterile. Synapsis cannot usually occur in interspecific hybrid offspring because not all the chromosomes are homologous. However, if the chromosome number doubles *before* meiosis, then homologous chromosomes can undergo synapsis. Although not common, this spontaneous doubling of chromosomes has been documented in a variety of plants and a few animals. It produces nuclei with multiple sets of chromosomes.

Polyploidy, the possession of more than two sets of chromosomes, is a major factor in plant evolution. Reproductive isolation occurs in a single generation when a polyploid species with multiple sets of chromosomes arises from diploid parents. There are two kinds of polyploidy: autopolyploidy and allopolyploidy. An **autopolyploid** contains multiple sets of chromosomes from a single species, and an **allopolyploid** contains multiple sets of chromosomes from two or more species. We discuss only allopolyploidy because it is much more common in nature.

Allopolyploidy occurs in conjunction with **hybridization,** which is sexual reproduction between individuals from closely related species. Allopolyploidy produces a fertile interspecific hybrid because the polyploid condition provides the homologous chromosome pairs necessary for synapsis during meiosis. As a result, gametes may be viable (**FIG. 20-9**). An allopolyploid—that is, an interspecific hybrid produced by allopolyploidy—reproduces with itself (self-fertilization) or with a similar individual. However, allopolyploids are reproductively isolated from both parents because their gametes have a different number of chromosomes from those of either parent.

If a population of allopolyploids (that is, a new species) becomes established, selective pressures cause one of three outcomes. First, the new species may not compete successfully against species that are already established, so it becomes extinct. Second, the allopolyploid individuals may assume a new role in the environment and so coexist with both parental species. Third, the new species may successfully compete with either or both of its parental species. If it has a combination of traits that confers greater fitness than one or both parental species for all or part of the original range of the parent(s), the hybrid species may replace the parent(s).

Although allopolyploidy is extremely rare in animals, it is significant in the evolution of flowering plant species. As many as 80% of all flowering plant species are polyploids, and most of these are allopolyploids. Moreover, allopolyploidy provides a mechanism

KEY POINT Changes in chromosome number have often led to speciation in plants.

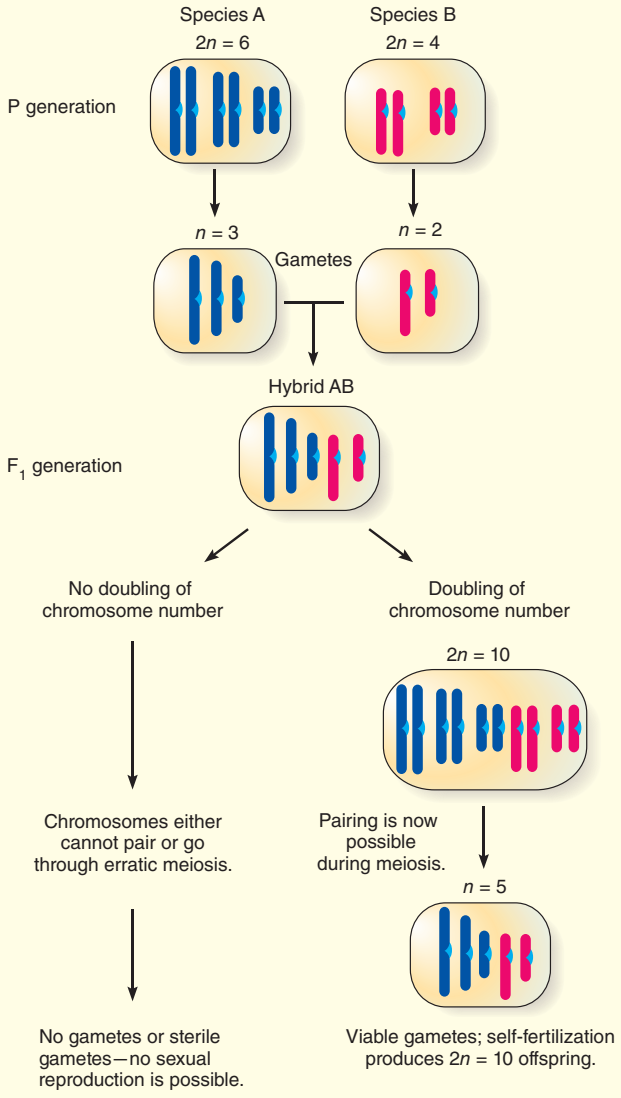

FIGURE 20-9 Sympatric speciation by allopolyploidy in plants

When two species (designated the P generation) successfully interbreed, the interspecific hybrid offspring (the F_1 generation) are almost always sterile (*bottom left*). If the chromosomes double, proper synapsis and segregation of the chromosomes can occur and viable gametes may be produced (*bottom right*). (Unduplicated chromosomes are shown for clarity.)

www.konkur.in

for extremely rapid speciation. A single generation is all that is needed to form a new, reproductively isolated species. Allopolyploidy may explain the rapid appearance of many flowering plant species in the fossil record and their remarkable diversity today (at least 300,000 species).

The kew primrose (*Primula kewensis*) is an example of sympatric speciation that was documented at the Royal Botanic Gardens at Kew, England, in 1898 (**FIG. 20-10**). Plant breeders developed *P. kewensis* as an interspecific hybrid of two primrose species, *P. floribunda* ($2n = 18$) and *P. verticillata* ($2n = 18$). *Primula kewensis* had a chromosome number of 18 but was sterile. Then, at three different times, it was reported to have spontaneously formed a fertile branch, which was an allopolyploid ($2n = 36$) that produced viable seeds of *P. kewensis.*

The mechanism of sympatric speciation has been experimentally verified for many plant species. One example is a group of species, collectively called *hemp nettles,* that occur in temperate parts of Europe and Asia. One hemp nettle, *Galeopsis tetrahit* ($2n = 32$), is a naturally occurring allopolyploid hypothesized to have formed by the hybridization of two species, *G. pubescens* ($2n = 16$) and *G. speciosa* ($2n = 16$). This process occurred in nature but was experimentally reproduced. *Galeopsis pubescens* and *G. speciosa* were crossed to produce F_1 hybrids, most of which were sterile. Nevertheless, both F_2 and F_3 generations were produced. The F_3 generation included a polyploid plant with $2n = 32$ that self-fertilized to yield fertile F_4 offspring that could not mate with either of the parental species. These allopolyploid plants had the same appearance and chromosome number as the naturally occurring *G. tetrahit.* When the experimentally produced plants were crossed with the naturally occurring *G. tetrahit,* a fertile F_1 generation was formed. Thus, the experiment duplicated the speciation process that occurred in nature.

Changing ecology causes sympatric speciation in animals

Biologists have observed the occurrence of sympatric speciation in animals, but its significance—how often it happens and under what conditions—is still debated. Many examples of sympatric speciation in animals involve parasitic insects and rely on genetic mechanisms other than polyploidy. For example, in the 1860s in the Hudson River Valley of New York, a population of fruit maggot flies (*Rhagoletis pomonella*) parasitic on the small red fruits of native hawthorn trees was documented to have switched to a new host, domestic apples, which had been introduced from Europe. Although the sister populations (hawthorn maggot flies and apple maggot flies) continue to occupy the same geographic area, no gene flow occurs between them because they eat, mate, and lay their eggs on different hosts (**FIG. 20-11**). In other words, because the hawthorn and apple maggot flies have diverged and are reproductively isolated from each other, they have effectively become separate species. Most entomologists, however, still recognize hawthorn and apple maggot flies as a single species because their appearance is virtually identical.

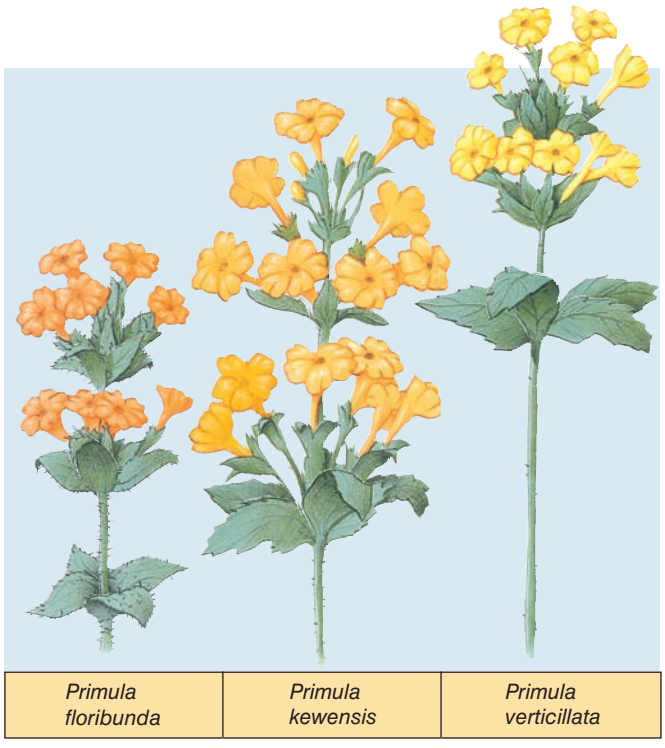

FIGURE 20-10 ***Animated*** **Sympatric speciation of a primrose**
A new species of primrose, *Primula kewensis*, arose in 1898 as an allopolyploid derived from the interspecific hybridization of *P. floribunda* and *P. verticillata*. Today, *P. kewensis* is a popular houseplant.

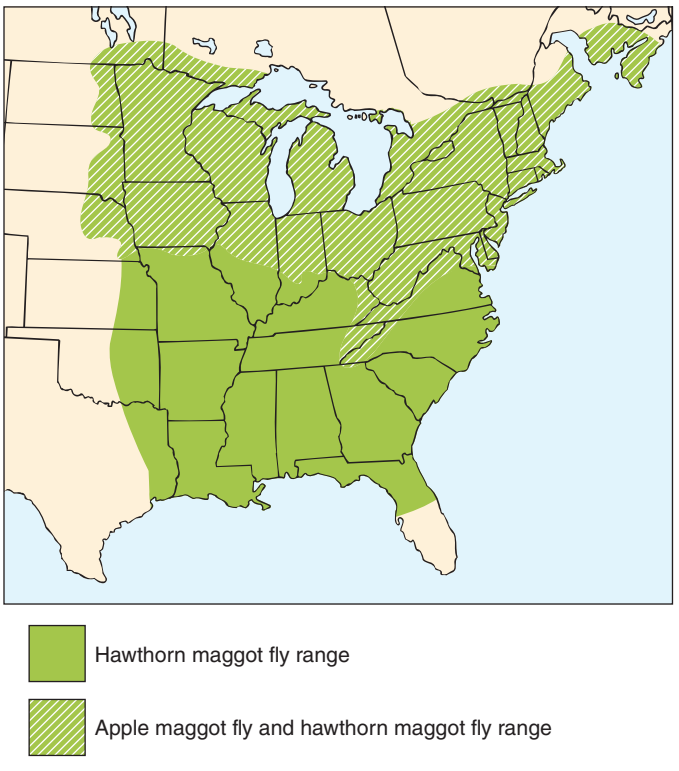

FIGURE 20-11 **Ranges of apple and hawthorn maggot flies**
Apple and hawthorn maggot flies are sympatric throughout the northern half of the hawthorn maggot fly's range. (Adapted from G. L. Bush, "Sympatric Host Race Formation and Speciation in Frugivorous Flies of the Genus *Rhagoletis* [Diptera, Tephritidae]," *Evolution*, Vol. 23, No. 2, June 1969.)

www.konkur.in

In situations such as that of the fruit maggot flies, a mutation arises in an individual and spreads through a small group of insects by sexual reproduction. The particular mutation leads to *disruptive selection* (see Chapter 19), in which both the old and new phenotypes are favored. Selection is disruptive because the original population is still favored when it parasitizes the original host, and the mutants are favored by a new ecological opportunity—in this case, to parasitize a different host species. Additional mutations may occur that cause the sister populations to diverge even further.

Cichlids in East Africa intrigue evolutionary biologists

Biologists have studied the speciation of colorful fishes known as *cichlids* (pronounced "sik-lids") in several East African lakes. The different species of cichlids in a given lake have remarkably different eating habits, which are reflected in the shapes of their jaws and teeth. Some graze on algae; some consume dead organic material at the bottom of the lake; and others are predatory and eat plankton (microscopic aquatic organisms), insect larvae, the scales off fish, or even other cichlid species. In some cichlids, food preferences are related to size (smaller cichlids consume plankton), which in turn is related to mating preference (small, plankton-eating cichlids mate only with other small, plankton-eating cichlids).

In other cichlids, related species do not differ in size but only in color and mating habits. Each species has a distinct male coloration, which matches the preferences of females of that species in choosing mates (**FIG. 20-12**).

Charles Darwin called choosing a mate based on its color or some other characteristic **sexual selection.** He recognized that female preference for showy colors or elaborate ornaments on males, if it was based on *inherited* variation, could result in these male sexual traits becoming more common and more pronounced over time. Female preference for a particular male trait confers a selective advantage to the males exhibiting that trait because they have an improved chance to mate and pass on their genes. Darwin suggested that sexual selection, like natural selection, could eventually result in the evolution of new species. (Sexual selection is discussed in greater detail in Chapter 52.)

DNA sequence data indicate that the cichlid species within a single lake are more closely related to one another than to fishes in nearby lakes or rivers. These molecular data suggest that cichlid species evolved sympatrically, or at least within the confines of a lake, rather than by repeated colonizations by fish populations in nearby rivers.

How rapidly did sympatric speciation occur in cichlids? Seismic and drill core data provide evidence that Lake Victoria dried up completely during the Late Pleistocene, when much of north and equatorial Africa was arid. The diverse cichlid species may have arisen after the climate became wetter and Lake Victoria refilled. Further, the more than 500 **endemic** (found nowhere else) cichlid species in Lake Victoria may have evolved from one or a few common ancestors in a remarkably short period—as little as 12,000 years. Other biologists have offered competing hypotheses about the timing and geographic origin of Lake Victoria's cichlids. Regardless of the uncertainties of certain details, Lake Victoria's cichlids are widely recognized as exemplifying the fastest rate of evolution known for such a large group of vertebrate species.

Loss of Cichlid Diversity in Lake Victoria. In recent years, many of the cichlid species living in Lake Victoria have become extinct. The Nile perch, a voracious predator that was deliberately introduced into the lake in 1960 to stimulate the local fishing economy and whose population exploded in the 1980s, has been blamed for the extinction of most of the cichlid species that have disappeared.

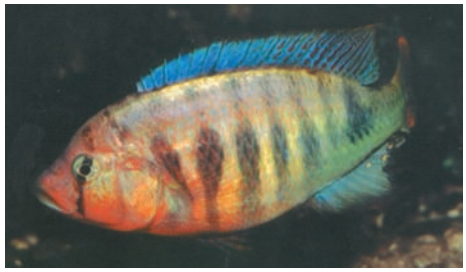
Biologists from the University of Leiden in the Netherlands observed, however, that species were also disappearing in habitats in the lake where the Nile perch is known to have little or no impact. Ole Seehausen and his colleagues measured environmental features at 22 localities with such habitats and found strong correlations between bright and diverse male colors and clear, well-lit water. Each species has its own distinct male coloration, which is used by females of that species to choose mates. In clear water, members of each species do not interbreed with members of other species.

As nearby forests have been cut, soil erosion has made the water of Lake Victoria more turbid (cloudy). Agricultural practices in the area have also contributed fertilizer and sediment pollution. Seehausen demonstrated that as the water became more turbid from pollution, light could not penetrate effectively. He hypothesized that as a result, females could not distinguish males of their own species from males of closely related species.

As already discussed, cichlids have evolved during the past 12,000 years. Their relative youth as species means they may not

(a) *Pundamilia pundamilia* males have bluish-silver bodies.

(b) *Pundamilia nyererei* males have red backs.



(c) *Pundamilia* "red head" males have a red "chest." (The "red head" species has not yet been scientifically named.)

a–c: Ole Seehausen, University of Bern

FIGURE 20-12 Color variation in Lake Victoria cichlids

Some evidence suggests that changes in male coloration may be the first step in speciation of Lake Victoria cichlids. Later, other traits, including ecological characteristics, diverge. Female cichlids generally have cryptic coloration; their drab colors help them blend into their surroundings.

www.konkur.in

yet have evolved additional reproductive isolating mechanisms other than mate preference based on color. It also means that closely related species can be expected to interbreed without loss of fertility. With increasing turbidity, males lose their bright colors because they are no longer favored by sexual selection, and females have mated with males of other species (**FIGURE 20-13**). Thus, many species are being replaced with a few hybrids.

The study of hybrid zones has made important contributions to what is known about speciation

When two populations have significantly diverged as a result of geographic separation, there is no easy way to determine if the speciation process is complete (recall the disagreement about whether Porto Santo rabbits are a separate species or a subspecies). If such populations, subspecies, or species come into secondary contact before strong prezygotic isolating mechanisms have evolved, they may hybridize, producing fertile offspring, where they meet. A **hybrid zone** is an area of overlap between two recently diverged populations in which interbreeding takes place and hybrid offspring are common. Hybrid zones are typically narrow, presumably because the hybrids are not well adapted for either parental environment. The hybrid population is typically very small compared with the parental populations.

On the Great Plains of North America, red-shafted and yellow-shafted flickers (types of woodpeckers) meet and interbreed. The red-shafted flicker, named for the male's red underwings and tail, is found in the western part of North America, from the Great Plains to the Pacific Ocean. Yellow-shafted flicker males, which have yellow underwings and tails, range east of the Rockies. Hybrid flickers, which form a stable hybrid zone from Texas to southern Alaska, are varied in appearance, although many have orange underwings and tails.

According to the biological species concept, if red-shafted and yellow-shafted flickers are two species, they should maintain their reproductive isolation. Because a hybrid zone has formed, most biologists think the red-shafted and yellow-shafted flickers are geographic subspecies instead of separate species; red-shafted, yellow-shafted, and hybrid flickers are collectively called northern flickers.

Three evolutionary processes may occur in hybrid zones

When two diverging populations or closely related species come into contact and form a hybrid zone, one of three possibilities can occur: reinforcement, which helps maintain two separate species; fusion of the two species into one; or stability of the hybrid zone (**FIG. 20-14**). **Reinforcement** occurs when the hybrids in the hybrid zone are less fit than the two parental populations. Reinforcement is the increase in reproductive isolation that often occurs over time in a hybrid zone—that is, natural selection strengthens and increases the number of prezygotic barriers between the two species. As a result, fewer and fewer hybrids are formed, and the hybrid zone gradually disappears.

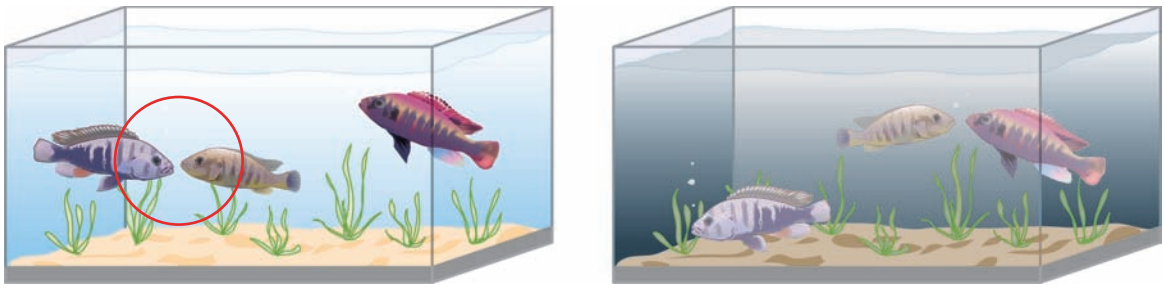
In **fusion,** the hybrids in a hybrid zone are as fit as either of the parental populations. Over time, differences in the reproductive barriers between the two parental populations weaken, and the hybrid zone enlarges. The eventual result is a fusing of two species (or subspecies) into one. Hybridization of the Lake Victoria cichlids (discussed earlier in the chapter) is an example of species loss due to fusion.

KEY EXPERIMENT

QUESTION: Why is cichlid diversity declining in Lake Victoria?

HYPOTHESIS: Cichlids are disappearing from Lake Victoria because of changes in their habitat.

EXPERIMENT: Seehausen and colleagues took field measurements in 22 different locations in Lake Victoria and later verified these field observations with laboratory experiments in which two cichlid species were placed in aquaria that were either well-lit or not.



RESULTS AND CONCLUSION: When aquaria were well-lit (left), females of two closely related cichlid species (one red, the other blue) consistently chose mates of their own species (circled area) over those of other species. When light was blocked to simulate turbid conditions found in parts of Lake Victoria (right), females often chose males of other species.

Thus, increasing turbidity of Lake Victoria's water is preventing females of cichlid species from using color to select mates of their own species. As a result, females are interbreeding with males of other species, and the number of cichlid species is declining as the distinctive gene pools of different species are merging.

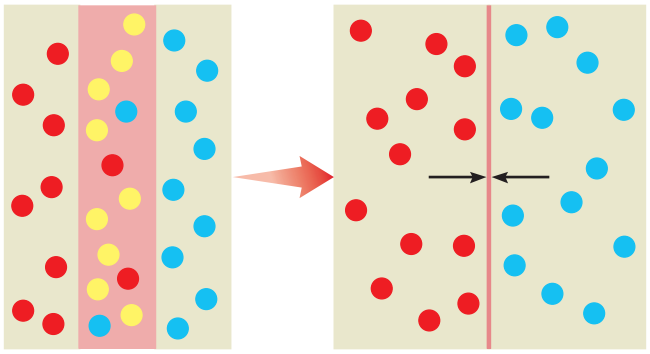
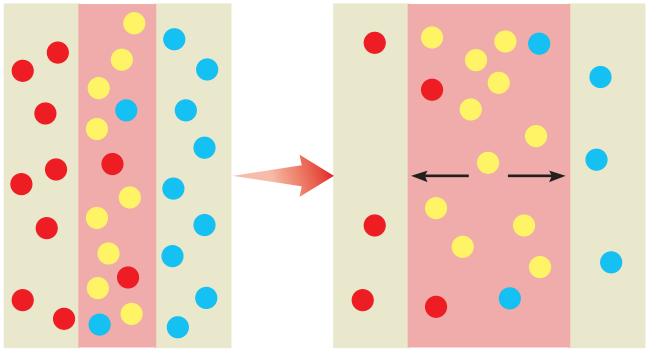
FIGURE 20-13 Explaining the rapid loss of cichlid diversity in Lake Victoria

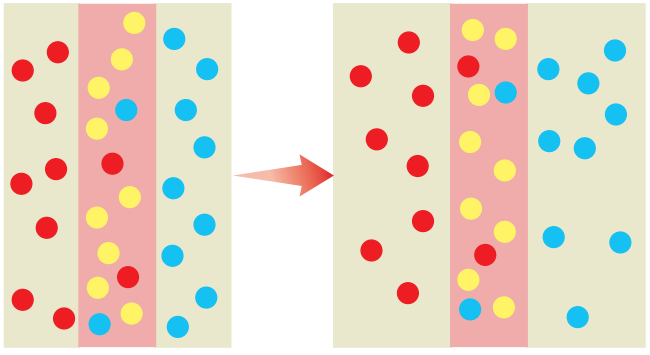
www.konkur.in



(a) Reinforcement. Hybrids are not as fit as the parents. Over time, the differences between the two parental populations increase, and hybrids are no longer produced. As the hybrid zone shrinks, the resulting outcome is two species.



(b) Fusion. Hybrids are as fit as the two parental populations. Over time, differences between the two parental populations weaken and the hybrid zone enlarges. The essential result is a single species.



(c) Stability. Hybrids are more fit than either parental population. The fitness of the hybrids results in a stable hybrid zone. Eventually, a third species may form in the hybrid zone.

FIGURE 20-14 How hybrid zones between two closely related species or diverging populations can change over time

Stability is an evolutionary process in which the hybrids are more fit than either parental population. Hybrids continue to be formed, resulting in a stable hybrid zone. Stable hybrid zones often occur in **ecotones,** areas of transition between two different environments. In this case, the two incipient species are adapted to two different communities, and the hybrids' combination of characters from both parental populations allows them to flourish in the ecotone. Eventually, a third species may form in such a hybrid zone. (Ecotones are discussed further in Chapter 56.)

In the example of the flicker hybrid zone, reinforcement does not appear to be occurring. At the same time, the two kinds of flickers are not fusing together into one distinct group. The flicker hybrid zone has not expanded; the two types of flickers have maintained their distinctiveness and have not rejoined into a single, freely interbreeding population. Thus, at this time, flicker hybrids have formed a stable hybrid zone.

Review

- What are five geographic barriers that might lead to allopatric speciation?
- How do hybridization and polyploidy cause a new plant species to form in as little as one generation?
- What is the likely mechanism of speciation for pupfishes? for cichlids?

20.4 THE RATE OF EVOLUTIONARY CHANGE

LEARNING OBJECTIVE

5 Discuss the pace of evolution by describing punctuated equilibrium and phyletic gradualism.

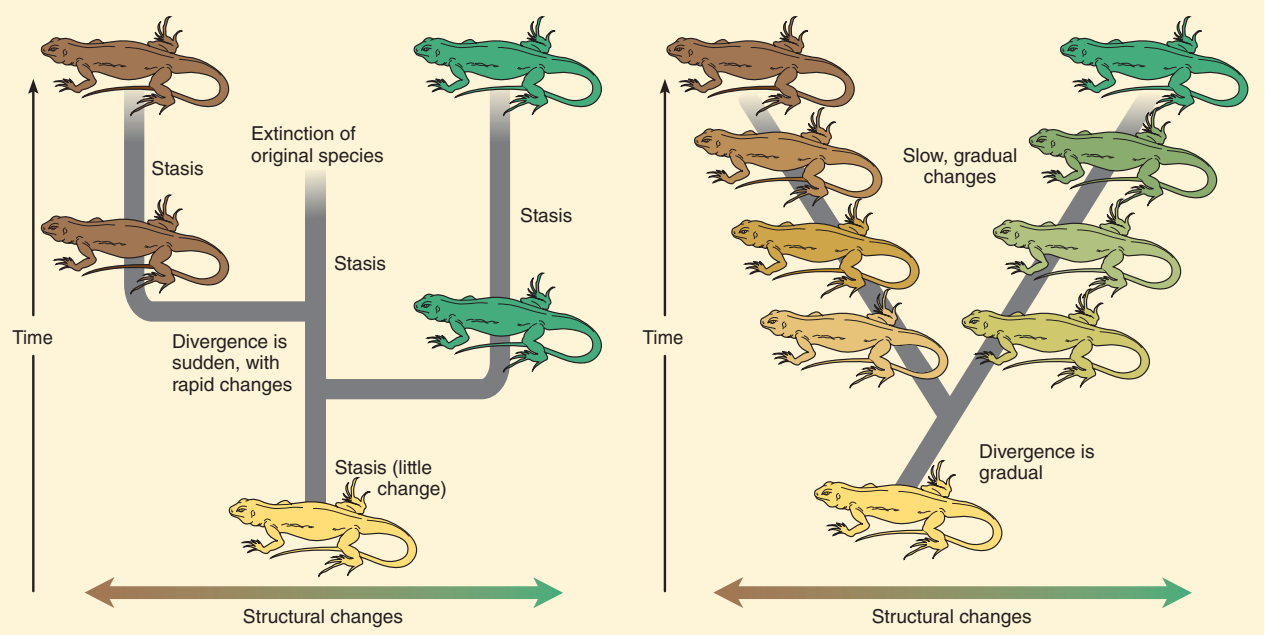
We have seen that speciation is hard for us to directly observe as it occurs. Does the fossil record provide clues about how rapidly new species arise? Biologists have long recognized that the fossil record lacks many transitional forms; the starting points (ancestral species) and the end points (new species) are present, but the intermediate stages in the evolution from one species to another are often lacking. This observation has traditionally been explained by the incompleteness of the fossil record, although scientists have sometimes made new fossil discoveries that fill in the missing parts.

Two different models—punctuated equilibrium and phyletic gradualism—explain evolution as observed in the fossil record (**FIG. 20-15**). The **punctuated equilibrium** model was proposed by paleontologists who questioned whether the fossil record really is as incomplete as it initially appeared. In the history of a species, long periods of **stasis** (little or no evolutionary change) appeared to be punctuated, or interrupted, by short periods of rapid speciation that were perhaps triggered by changes in the environment—that is, periods of great evolutionary stress. Thus, speciation proceeded in "spurts." These relatively short periods of active evolution (perhaps 100,000 years) were followed by long periods (perhaps 2 million years) of stability.

Punctuated equilibrium accounts for the abrupt appearance of a new species in the fossil record, with little or no evidence of intermediate forms. Proponents hypothesize that few transitional forms appear in the fossil record because few transitional forms occurred during speciation.

www.konkur.in

KEY POINT Punctuated equilibrium and phyletic gradualism represent opposite ends of a spectrum of speciation patterns. Speciation often proceeds in an intermediate or mixed pattern.



(a) In **punctuated equilibrium**, long periods of stasis are interrupted by short periods of rapid speciation.

(b) In **phyletic gradualism**, a slow, steady change in species occurs over time.

FIGURE 20-15 Punctuated equilibrium and gradualism
In this figure, structural changes in the lizards are represented by changes in skin color.

In contrast, the traditional Darwinian view of evolution espouses the **phyletic gradualism** model, in which evolution proceeded continuously over long periods. Gradualism is rarely observed in the fossil record because the record is incomplete. (Recall from Chapter 18 that precise conditions are required for fossil formation. Most organisms leave no trace of their existence because they decompose when they die.) Occasionally, a complete fossil record of transitional forms has been discovered and cited as a strong case for gradualism. The gradualism model maintains that populations slowly diverge from one another by the gradual accumulation of adaptive characteristics within each population. These adaptive characteristics accumulate as a result of different selective pressures encountered in different environments.

Scientists supporting phyletic gradualism maintain that any periods of stasis evident in the fossil record are the result of *stabilizing selection* (see Chapter 19). They also emphasize that stasis in fossils is deceptive because fossils do not reveal all aspects of evolution. Although fossils display changes in external structure and skeletal structure, other genetic changes—in physiology, internal structure, resistance to infection, and behavior—all of which also represent evolution, are not evident. Gradualists recognize rapid evolution only when strong *directional selection* occurs.

Many biologists today embrace both models to explain the fossil record. They contend that the pace of evolution may be abrupt in certain instances and gradual in others and that neither punctuated equilibrium nor gradualism exclusively characterizes the changes associated with evolution. Many biologists do not view the distinction between punctuated equilibrium and phyletic gradualism as real. They suggest that genetic changes occur gradually and at a roughly constant pace and that the majority of these mutations do not cause speciation. When the mutations that do cause speciation occur, they are dramatic and produce a pattern consistent with the punctuated equilibrium model.

- Are the phyletic gradualism and punctuated equilibrium models mutually exclusive? Explain your answer.

20.5 MACROEVOLUTION

LEARNING OBJECTIVES

6 Define *macroevolution.*
7 Discuss macroevolution in the context of novel features, including preadaptations, allometric growth, and paedomorphosis.
8 Discuss the macroevolutionary significance of adaptive radiation and extinction.

Macroevolution is large-scale phenotypic changes in populations that generally warrant their placement in taxonomic groups at the

www.konkur.in

species level and higher—that is, new species, genera, families, orders, classes, and even phyla, kingdoms, and domains. One concern of macroevolution is to explain evolutionary novelties, which are large phenotypic changes such as the appearance of jointed limbs during the evolution of arthropods (crustaceans, insects, and spiders). These phenotypic changes are so great that the new species possessing them are assigned to different genera or higher taxonomic categories. Studies of macroevolution also seek to discover and explain major changes in species diversity through time such as occur during *adaptive radiation,* when many species appear, and *mass extinction,* when many species disappear. Thus, evolutionary novelties, adaptive radiation, and mass extinction are important aspects of macroevolution.

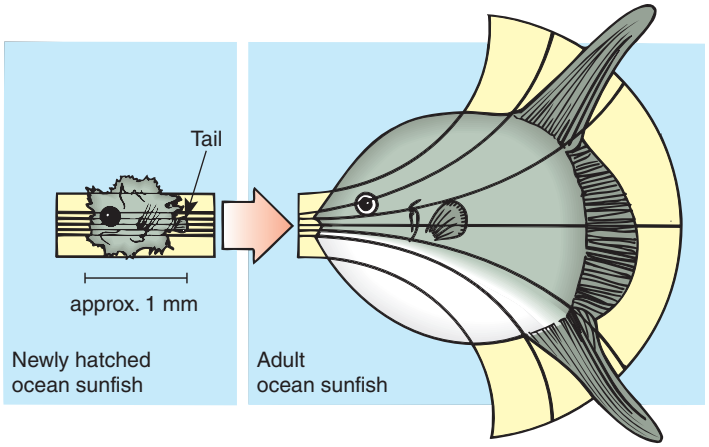
Evolutionary novelties originate through modifications of pre-existing structures

New designs arise from structures already in existence. A change in the basic pattern of an organism produces something unique, such as wings on insects, flowers on plants, and feathered wings on birds. Usually, these evolutionary novelties are variations of some pre-existing structures, called **preadaptations,** that originally fulfilled one role but subsequently changed in a way that was adaptive for a different role. Feathers, which evolved from reptilian scales and may have originally provided thermal insulation in primitive birds and some dinosaurs, represent a preadaptation for flight. With gradual modification, feathers evolved to function in flight as well as to fulfill their original thermoregulatory role. (Interestingly, a few feather-footed bird species exist; this phenotype is the result of a change in gene regulation that alters scales, normally found on bird feet, into feathers.)

How do such evolutionary novelties originate? Many are probably due to changes during development. *Regulatory genes* exert control over hundreds of other genes during development, and very slight genetic changes in regulatory genes could ultimately cause major structural changes in the organism (see Chapters 17 and 18).

For example, during development most organisms exhibit varied rates of growth for different parts of the body, known as **allometric growth** (from the Greek *allo,* "different," and *metr,* "measure"). The size of the head in human newborns is large in proportion to the rest of the body. As a human grows and matures, the torso, hands, and legs grow more rapidly than the head. Allometric growth is found in many organisms, including the male fiddler crab with its single, oversized claw, and the ocean sunfish with its enlarged tail (**FIG. 20-16**). If growth rates are altered even slightly, drastic changes in the shape of an organism may result, changes that may or may not be adaptive. For example, allometric growth may help explain the extremely small and relatively useless forelegs of the dinosaur *Tyrannosaurus rex,* compared with those of its ancestors.

Sometimes novel evolutionary changes occur when a species undergoes changes in the *timing* of development. Consider, for example, the changes that would occur if juvenile characteristics were retained in the adult stage, a phenomenon known as **paedomorphosis** (from the Greek *paed,* "child," and *morph,* "form"). Adults of some salamander species have external gills and tail fins, features found only in the larval (immature) stages of other salamanders.



(a) A newly hatched ocean sunfish, only 1 mm long, has an extremely small tail.

(b) This allometric transformation is visualized by drawing rectangular coordinate lines through a picture of the juvenile fish and then changing the coordinate lines mathematically.

Richard Herrmann

(c) An ocean sunfish swims off the coast of southern California. The adult ocean sunfish may reach 4 m (13 ft) and weigh about 1500 kg (3300 lb).

FIGURE 20-16 **Allometric growth in the ocean sunfish**
The tail end of an ocean sunfish (*Mola mola*) grows faster than the head end, resulting in the unique shape of the adult.

Retention of external gills and tail fins throughout life obviously alters the salamander's behavioral and ecological characteristics (**FIG. 20-17**). Perhaps such salamanders succeeded because they had a selective advantage over "normal" adult salamanders; that is, by remaining aquatic, they did not have to compete for food with the terrestrial adult forms of related species. The paedomorphic forms also escaped the typical predators of terrestrial salamanders (although they had other predators in their aquatic environment). Studies suggest that paedomorphosis in salamanders is probably the result of mutations in genes that block the production of hormones that stimulate metamorphic changes. When paedomorphic salamanders receive hormone injections, they develop into adults lacking external gills and tail fins.

www.konkur.in

Stephen Dalton/Photo Researchers, Inc.

FIGURE 20-17 Paedomorphosis in a salamander

An adult axolotl salamander (*Ambystoma mexicanum*) retains the juvenile characteristics of external gills (feathery structures protruding from the neck) and a tail fin (*not visible*). Paedomorphosis allows the axolotl to remain permanently aquatic and to reproduce without developing typical adult characteristics.

Adaptive radiation is the diversification of an ancestral species into many species

Some ancestral species have given rise to far more species than have other evolutionary lineages. **Adaptive radiation** is the evolutionary diversification of many related species from one or a few ancestral species in a relatively short period.

Evolutionary innovations such as those we considered in the last section may trigger an adaptive radiation. Alternatively, an adaptive radiation may occur because the ancestral species happens to have been in the right place at the right time to exploit numerous ecological opportunities.

Biologists developed the concept of adaptive zones to help explain this type of adaptive radiation. **Adaptive zones** are new ecological opportunities that were not exploited by an ancestral organism. At the species level, an adaptive zone is essentially identical to one or more similar *ecological niches* (the functional roles of species within a community; see Chapter 54). Examples of adaptive zones include nocturnal flying to catch small insects, grazing on grass while migrating across a savanna, and swimming at the ocean's surface to filter out plankton. When many adaptive zones are empty, as they were in Lake Victoria when it refilled some 12,000 years ago (discussed earlier in the chapter), colonizing species such as the cichlids may rapidly diversify and exploit them.

Because islands have fewer species than do mainland areas of similar size, latitude, and topography, vacant adaptive zones are more common on islands than on continents. Consider the Hawaiian honeycreepers, a group of related birds found in the Hawaiian Islands. When the honeycreeper ancestors reached Hawaii, few other birds were present. The succeeding generations of honeycreepers quickly diversified into many new species and, in the process, occupied the many available adaptive zones that on the mainland are occupied by finches, honeyeaters, treecreepers, and woodpeckers. The diversity of their bills is a particularly good illustration of adaptive radiation (**FIG. 20-18**). Some honeycreeper bills are curved to extract nectar out of tubular flowers, whereas others are short and thick for ripping away bark in search of insects.

Another example of vacant adaptive zones involves the Hawaiian silverswords, 28 species of closely related plants found only in the Hawaiian Islands. When the silversword ancestor, a California plant related to daisies, reached the Hawaiian Islands, many diverse environments, such as cool, arid mountains; exposed lava flows; dry woodlands; shady, moist forests; and wet bogs were present and more or less unoccupied. The succeeding generations of silverswords quickly diversified in structure and physiology to occupy the many adaptive zones available to them. The diversity in their leaves, which changed during the course of natural selection as different populations adapted to various levels of light and moisture, is a particularly good illustration of adaptive radiation (**FIG. 20-19**). Leaves of silverswords that are adapted to shady, moist forests are large, for example, whereas those of silverswords living in arid areas are small. The leaves of silverswords living on exposed volcanic slopes are covered with dense, silvery hairs that may reflect some of the intense ultraviolet radiation off the plant.

Adaptive radiation appears more common during periods of major environmental change, but it is difficult to determine how these changes are related to adaptive radiation. It is possible that major environmental change indirectly affects adaptive radiation by increasing the extinction rate. Extinction produces empty adaptive zones, which provide new opportunities for species that remain. Mammals, for example, diversified and exploited a variety of adaptive zones relatively soon after the dinosaurs' extinction. Flying bats, running gazelles, burrowing moles, and swimming whales all originated from early mammals that had coexisted with reptiles for millions of years.

Extinction is an important aspect of evolution

Extinction, the end of a lineage, occurs when the last individual of a species dies. The loss is permanent, for once a species is extinct, it never reappears. Extinctions have occurred continually since the origin of life; by one estimate, only 1 species is alive today for every 2000 that have become extinct. Extinction is the eventual fate of all species, in the same way that death is the eventual fate of all individual organisms.

Although extinction has a negative short-term impact on the number of species, it facilitates evolution over a period of thousands to millions of years. As mentioned previously, when species become extinct, their adaptive zones become vacant. Consequently, surviving species are presented with new evolutionary opportunities and may diverge, filling in some of the unoccupied zones. In other words, the extinct species may eventually be replaced by new species.

During the long history of life, extinction appears to have occurred at two different rates. The continuous, low-level extinction of species is sometimes called **background extinction.** In contrast, five or possibly six times during Earth's history, **mass extinctions** of numerous species and higher taxonomic groups have taken place in both terrestrial and marine environments. The most recent mass extinction, which occurred about 65 million years ago (mya), killed off many marine organisms, terrestrial plants, and

www.konkur.in

KEY POINT Adaptive radiation occurs when a single ancestral species diversifies into a variety of species, each adapted to a different ecological niche.

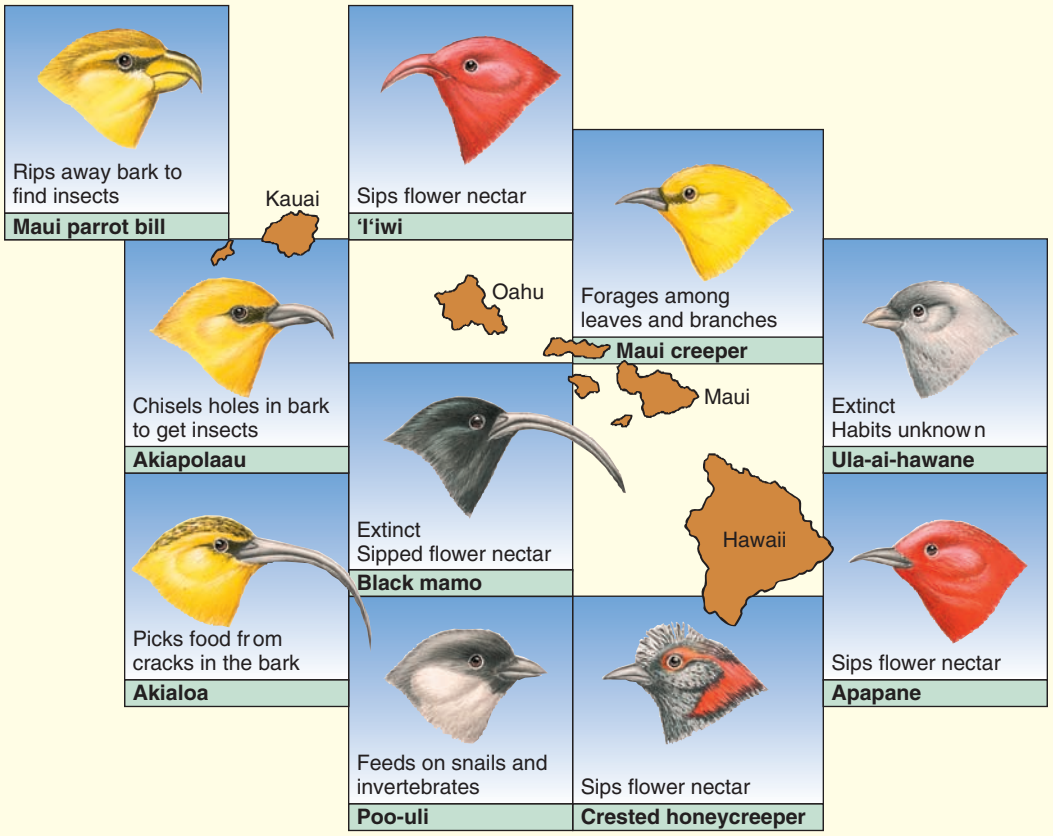


FIGURE 20-18 Adaptive radiation in Hawaiian honeycreepers

Compare the various beak shapes and methods of obtaining food. Many honeycreeper species are now extinct or nearing extinction as a result of human activities, including the destruction of habitat and the introduction of predators such as rats, dogs, and pigs.

vertebrates, including the last of the dinosaurs. The time span over which a mass extinction occurs may be several million years, but that is relatively short compared with the 3.5 billion years or so of Earth's history of life. Each period of mass extinction has been followed by a period of adaptive radiation of some of the surviving groups.

The causes of past episodes of mass extinction are not well understood. Both environmental and biological factors seem to have been involved. Major changes in climate could have adversely affected those plants and animals that lacked the genetic flexibility to adapt. Marine organisms, in particular, are adapted to a steady, unchanging climate. If Earth's temperature were to increase or decrease by just a few degrees overall, many marine species would probably perish.

It is also possible that past mass extinctions were due to changes in the environment induced by catastrophes. If a large comet or small asteroid collided with Earth, the dust ejected into the atmosphere on impact could have blocked much of the sunlight. In addition to disrupting the food chain by killing many plants (and therefore terrestrial animals), this event would have lowered Earth's temperature, leading to the death of many marine organisms. Evidence exists that the extinction of dinosaurs was caused by an extraterrestrial object's collision with Earth (see Chapter 21).

Biological factors also trigger extinction. Competition among species may lead to the extinction of species that cannot compete effectively. The human species, in particular, has had a profound impact on the rate of extinction. The habitats of many animal and plant species have been altered or destroyed by humans, and habitat destruction can result in a species's extinction. Some biologists think we have entered the greatest mass extinction episode in Earth's history. (Extinction is discussed further in Chapter 57.)

Is microevolution related to speciation and macroevolution?

The concepts presented in Chapters 18 and 19 represent the **modern synthesis,** in which mutation provides the genetic variation on which natural selection acts. The modern synthesis combines

The 28 silversword species, which are classified in three closely related genera, live in a variety of habitats.

Darwin's theory with important aspects of genetics. Many aspects of the modern synthesis have been tested and verified at the population and subspecies levels. Many biologists contend that microevolutionary processes explain macroevolution. They assert that natural selection, mutation, genetic drift, and gene flow account for not only the genetic variation within populations but also the origin of new species and higher taxa as well.

A considerable body of data from many fields supports the modern synthesis as it relates to speciation and macroevolution. Consider, for example, the *fish–tetrapod transition* (the evolution of four-legged amphibians from fishes), which was a major macroevolutionary event in the history of vertebrates (see Chapter 32). The fish–tetrapod transition is well documented in the fossil record. Studies of fossil intermediates show that the transition from aquatic fishes to terrestrial amphibians occurred as evolutionary novelties, such as changes in the limbs and skull roof, were added. These novelties accumulated as a succession of small changes over a period of 9 million to 14 million years. This time scale is sufficient to have allowed natural selection and other microevolutionary processes to produce the novel characters.

Although few biologists doubt the role of natural selection and microevolution in generating specific adaptations, some question the *extent* of microevolution's role in the overall pattern of life's history. These biologists ask whether speciation and macroevolution have been dominated by microevolutionary processes or by external, chance events, such as an impact by an asteroid. Chance events do not "care" about adaptive superiority but instead lead to the random extinction or survival of species. In the case of an asteroid impact, for example, certain species may survive because they were "lucky" enough to be in a protected environment at the time of impact. If chance events have been the overriding factor during life's history, then microevolution cannot be the exclusive explanation for the biological diversity present today (see discussion of the role of chance in evolution in Chapter 18).

Review

- Why are evolutionary novelties important to scientists studying macroevolution?
- What is a preadaptation? What is paedomorphosis?
- What roles do extinction and adaptive radiation play in macroevolution?

www.konkur.in

SUMMARY: FOCUS ON LEARNING OBJECTIVES

20.1 *(page 427)*

1 Describe the biological species concept and list two potential problems with the concept.

- According to the **biological species concept,** a species consists of one or more populations whose members interbreed in nature to produce fertile offspring and do not interbreed with members of different species.
- One problem with the biological species concept is that it applies only to sexually reproducing organisms. Also, although individuals assigned to different species do not normally interbreed, they may occasionally successfully interbreed.

20.2 *(page 428)*

2 Explain the significance of reproductive isolating mechanisms and distinguish among the various prezygotic and postzygotic barriers.

- **Reproductive isolating mechanisms** restrict gene flow between species.
- **Prezygotic barriers** are reproductive isolating mechanisms that prevent fertilization from taking place. **Temporal isolation** occurs when two species reproduce at different times of the day, season, or year. In **habitat isolation,** two closely related species live and breed in different habitats in the same geographic area. In **behavioral isolation,** distinctive courtship behaviors prevent mating between species. **Mechanical isolation** is due to incompatible structural differences in the reproductive organs of similar species. In **gametic isolation,** gametes from different species are incompatible because of molecular and chemical differences.

- **Postzygotic barriers** are reproductive isolating mechanisms that prevent gene flow after fertilization has taken place. **Hybrid inviability** is the death of interspecific embryos during development. **Hybrid sterility** prevents interspecific hybrids that survive to adulthood from reproducing successfully. **Hybrid breakdown** prevents the offspring of hybrids that survive to adulthood and successfully reproduce from reproducing beyond one or a few generations.

CENGAGENOW™ Explore reproductive isolation by clicking on the figures in CengageNOW.

20.3 *(page 430)*

3 Explain the mechanism of allopatric speciation and give an example.

- **Speciation** is the evolution of a new species from an ancestral population. **Allopatric speciation** (for example, in Death Valley pupfishes) occurs when one population becomes geographically isolated from the rest of the species and subsequently diverges. Speciation is more likely to occur if the original isolated population is small because genetic drift is more significant in small populations.

CENGAGENOW™ Explore allopatric speciation by clicking on the figures in CengageNOW.

4 Explain the mechanisms of sympatric speciation and give both plant and animal examples.

- **Sympatric speciation** does not require geographic isolation. In plants, sympatric speciation can result from **allopolyploidy,** in which a **polyploid** individual (one with more than two sets of chromosomes) is a hybrid derived from two species. One example of sympatric speciation by allopolyploidy is the hemp nettle.
- Sympatric speciation occurs in animals, such as fruit maggot flies and cichlids, but how often it occurs and under what conditions remain to be determined.

CENGAGENOW™ Explore sympatric speciation by clicking on the figure in CengageNOW.

20.4 *(page 438)*

5 Discuss the pace of evolution by describing punctuated equilibrium and phyletic gradualism.

- According to the **punctuated equilibrium** model, evolution of species proceeds in spurts. Short periods of active speciation are interspersed with long periods of **stasis.** According to the **phyletic gradualism** model, populations slowly diverge from one another by the accumulation of adaptive characteristics within a population.

20.5 *(page 439)*

6 Define *macroevolution.*

- **Macroevolution** is large-scale phenotypic changes in populations that typically warrant the placement of the populations in taxonomic groups at the species level and higher—that is, new species, genera, families, orders, classes, and even phyla, kingdoms, and domains.

7 Discuss macroevolution in the context of novel features, including preadaptations, allometric growth, and paedomorphosis.

- Evolutionary novelties may be due to changes during **development,** the orderly sequence of events that occurs as an organism grows and matures. Slight genetic changes in regulatory genes could cause major structural changes in an organism.
- Evolutionary novelties may originate from **preadaptations,** structures that originally fulfilled one role but changed in a way that was adaptive for a different role. Feathers are an example of a preadaptation.
- **Allometric growth,** varied rates of growth for different parts of the body, results in overall changes in the shape of an organism. Examples include the expanded tail region of the ocean sunfish and the enlarged claw of the male fiddler crab.
- **Paedomorphosis,** the retention of juvenile characteristics in the adult, occurs because of changes in the timing of development. Adult axolotl salamanders, with external gills and tail fins, are an example of paedomorphosis.

8 Discuss the macroevolutionary significance of adaptive radiation and extinction.

- **Adaptive radiation** is the process of diversification of an ancestral species into many new species. **Adaptive zones** are new ecological opportunities that were not exploited by an ancestral organism. When many adaptive zones are empty, colonizing species may rapidly diversify and exploit them. Hawaiian honeycreepers and silverswords both underwent adaptive radiation after their ancestors colonized the Hawaiian Islands.

www.konkur.in

- **Extinction** is the death of a species. When species become extinct, the adaptive zones that they occupied become vacant, allowing other species to evolve and fill those zones. **Background extinction** is the continuous, low-level extinction of species. **Mass extinction** is the extinction of numerous species and higher taxonomic groups in both terrestrial and marine environments.

TEST YOUR UNDERSTANDING

1. A prezygotic barrier prevents (a) the union of egg and sperm (b) reproductive success by an interspecific hybrid (c) the development of the zygote into an embryo (d) allopolyploidy from occurring (e) changes in allometric growth
2. The reproductive isolating mechanism in which two closely related species live in the same geographic area but reproduce at different times is (a) temporal isolation (b) behavioral isolation (c) mechanical isolation (d) gametic isolation (e) hybrid inviability
3. Interspecific hybrids, if they survive, are (a) always sterile (b) always fertile (c) usually sterile (d) usually fertile (e) never sterile
4. The first step leading to allopatric speciation is (a) hybrid inviability (b) hybrid breakdown (c) adaptive radiation (d) geographic isolation (e) paedomorphosis
5. The pupfishes in the Death Valley region are an example of which evolutionary process? (a) background extinction (b) allopatric speciation (c) sympatric speciation (d) allopolyploidy (e) paedomorphosis
6. Which of the following evolutionary processes is associated with allopolyploidy? (a) gradualism (b) allometric growth (c) sympatric speciation (d) mass extinction (e) preadaptation
7. According to the punctuated equilibrium model, (a) populations slowly diverge from one another (b) the evolution of species occurs in spurts interspersed with long periods of stasis (c) evolutionary novelties originate from preadaptations (d) reproductive isolating mechanisms restrict gene flow between species (e) the fossil record, being incomplete, does not accurately reflect evolution as it actually occurred
8. The evolutionary conversion of reptilian scales into feathers is an example of (a) allometric growth (b) paedomorphosis (c) gradualism (d) hybrid breakdown (e) a preadaptation
9. Adaptive radiation is common following a period of mass extinction, probably because (a) the survivors of a mass extinction are remarkably well adapted to their environment (b) the unchanging environment following a mass extinction drives the evolutionary process (c) many adaptive zones are empty (d) many ecological niches are filled (e) the environment induces changes in the timing of development for many species
10. The Hawaiian silverswords are an excellent example of which evolutionary process? (a) allometry (b) preadaptation (c) microevolution (d) adaptive radiation (e) extinction

CRITICAL THINKING

1. **EVOLUTION LINK.** Why is allopatric speciation more likely to occur if the original isolated population is small?
2. **EVOLUTION LINK.** The photograph shows a "zebrass," a sterile hybrid produced on a Texas ranch by a cross between a zebra and a donkey. Based on what you have learned about prezygotic and postzygotic isolating mechanisms, which reproductive isolating mechanism(s) would you say is/are probably at work here? How would you test your hypothesis?

Harry Engels/Photo Researchers, Inc.

3. **EVOLUTION LINK.** Could hawthorn and apple maggot flies be considered an example of assortative mating, which was discussed in Chapter 19? Explain your answer.
4. **EVOLUTION LINK.** Because mass extinction is a natural process that may facilitate evolution during the period of thousands to millions of years that follow it, should humans be concerned about the current mass extinction that we are causing? Why or why not?
5. **ANALYZING DATA.** Examine Figure 20-2c, and predict which date is likeliest for researchers to have collected wood and leopard frogs and interbred them in the lab: March 10, April 1, or April 15. Explain your answer.

21 The Origin and Evolutionary History of Life

© Phil Degginger/Carnegie Museum/Alamy

Fossil of an Early Permian reptile. This well-preserved fossil of *Orobates pabsti* was matched to well-preserved fossil footprints found nearby. Although the limbs are spread out in death, *Orobates* walked with an upright gait with its limbs under its body. Discovered and photographed in Germany.

KEY CONCEPTS

21.1 Although there is no direct fossil evidence of the origin of life, biochemical experiments have demonstrated how the complex organic molecules that are found in all living organisms may have formed.

21.2 The first cells were probably heterotrophic, anaerobic, and prokaryotic. Photosynthesis, aerobic respiration, and eukaryotic cell structure represent several major advances that occurred during the early history of life.

21.3 The fossil record tells us much of what we know about the history of life, such as what kinds of organisms existed and where and when they lived. Scientists identify and demonstrate relationships among fossils in rock layers from different periods of geologic time.

The preceding three chapters were concerned with biological evolution. However, we have not dealt with what many regard as a fundamental question: How did life begin? Although biologists generally accept the hypothesis that life developed from nonliving matter, exactly how this process, called **chemical evolution,** occurred is not certain. Current models suggest that small organic molecules first formed spontaneously and accumulated over time. Large organic macromolecules such as proteins and nucleic acids could have then assembled from the smaller molecules.

The macromolecules interacted, combining into more complicated structures that could eventually metabolize and replicate, passing their genetic information on to their descendants, which eventually became the first true cells. After the first cells originated, they diverged over several billion years into the rich biological diversity that characterizes our planet today.

Initially, unicellular prokaryotes (archaea and bacteria) predominated, followed by unicellular eukaryotes. The first multicellular eukaryotes were soft-bodied marine animals that did not leave many fossils.

www.konkur.in

Shelled animals and other marine invertebrates (animals without backbones) appeared next, as exemplified by trilobites, primitive aquatic arthropods. Marine invertebrates were followed by the first vertebrates (animals with backbones). The first fishes with jaws appeared and diversified. Some of these gave rise to amphibians, the first vertebrates with limbs that were capable of moving about on land. Amphibians gave rise to reptiles, which diversified and populated the land (see photograph). Reptiles, in turn, gave rise independently to birds and to mammals. Plants underwent a comparable evolutionary history and diversification.

In this chapter we survey life over a vast span of time, starting when our planet was relatively young. We first examine proposed models about how life began and then trace life's long evolutionary history.

21.1 CHEMICAL EVOLUTION ON EARLY EARTH

LEARNING OBJECTIVES

1 Describe the conditions that scientists think existed on early Earth.
2 Contrast the prebiotic soup hypothesis and the iron–sulfur world hypothesis.

Scientists generally agree that life's beginnings occurred under environmental conditions quite different from those of today. Therefore, we must examine the conditions of early Earth to understand the origin of life. Evidence from many sources provides us with clues that help us formulate plausible scenarios of the steps in which life originated. Study of the origin of life is an active area of scientific research today, and many important contributions are adding to our understanding of how life began.

Astrophysicists and geologists estimate that Earth is about 4.6 billion years old. The atmosphere of early Earth apparently included carbon dioxide (CO_2), water vapor (H_2O), carbon monoxide (CO), and nitrogen (N_2). It may also have contained some ammonia (NH_3), hydrogen sulfide (H_2S), and methane (CH_4), although ultraviolet radiation from the sun most likely broke these reduced molecules down rapidly. The early atmosphere probably contained little or no free oxygen (O_2).

Four requirements must have existed for the chemical evolution of life: little or no free oxygen, a source of energy, the availability of chemical building blocks, and time. First, life could have begun only in the absence of free oxygen. Oxygen is quite reactive and would have oxidized the organic molecules that are necessary building blocks in the origin of life. Earth's early atmosphere was probably strongly reducing, which means that any free oxygen would have reacted with other elements to form oxides. Thus, oxygen would have been tied up in compounds.

The origin of life would also have required energy to do the work of building biological molecules from simple inorganic chemicals. Early Earth was a place of high energy with violent thunderstorms; widespread volcanic activity; bombardment from meteorites and other extraterrestrial objects; and intense radiation, including ultraviolet radiation from the sun (**FIG. 21-1**). The young

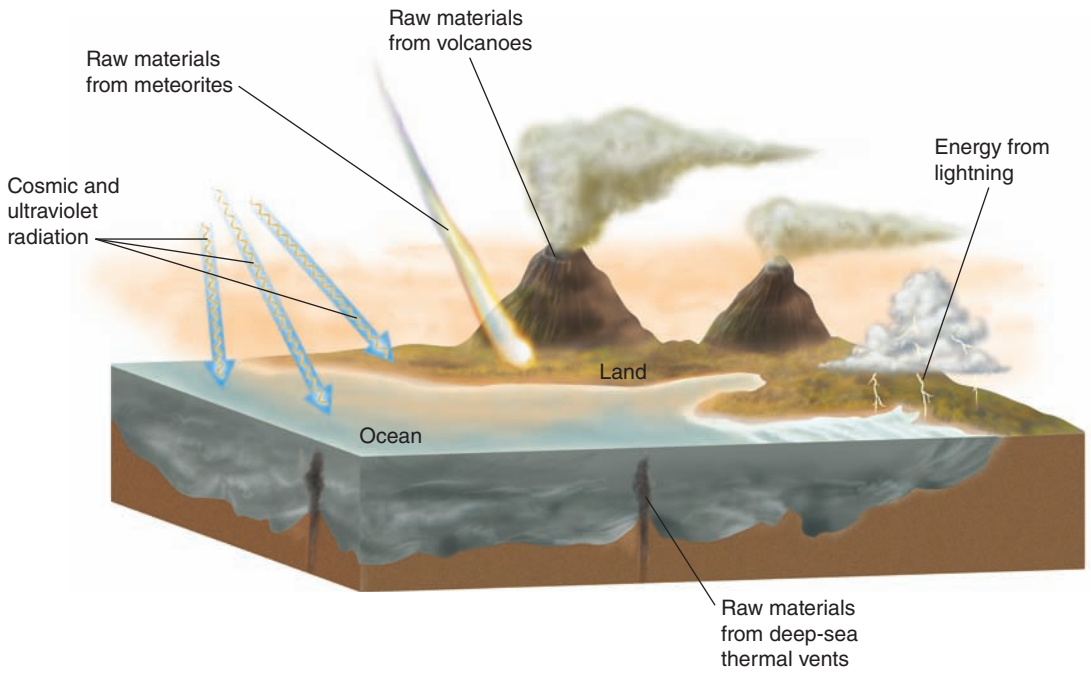

FIGURE 21-1 Conditions on early Earth

Volcanoes erupted, spewing gases that contributed to the atmosphere, and violent thunderstorms triggered torrential rainfall that washed molecules out of the atmosphere and eroded the land. Meteorites and other extraterrestrial objects bombarded Earth, cataclysmically changing the crust, ocean, and atmosphere. Deep-sea thermal vents, heated by Earth's internal heat, spewed forth chemicals. High-energy radiation from cosmic and ultraviolet rays blasted the planet.

www.konkur.in

sun probably produced more ultraviolet radiation than it does today, and ancient Earth had no protective ozone layer to filter it.

A third requirement would have been the presence of the chemical building blocks needed for chemical evolution. These included water, dissolved inorganic minerals (present as ions), and the gases present in the early atmosphere. A final requirement for the origin of life was time for molecules to accumulate and react with one another. Earth is approximately 4.6 billion years old, and evidence suggests that life arose early in Earth's history.

Organic molecules formed on primitive Earth

Because organic molecules are the building materials for organisms, it is reasonable to first consider how they may have originated. Two main models seek to explain how the organic precursors of life originated: the **prebiotic soup hypothesis** proposes that these molecules formed near Earth's surface, whereas the **iron–sulfur world hypothesis** proposes that organic precursors formed at cracks in the ocean's floor.

Organic molecules may have been produced at Earth's surface

The concept that simple organic molecules such as sugars, nucleotide bases, and amino acids could form spontaneously from simpler raw materials was first advanced in the 1920s by two scientists working independently: A. I. Oparin, a Russian biochemist, and J. B. S. Haldane, a Scottish physiologist and geneticist.

Their hypothesis was tested in the 1950s by U.S. biochemists Stanley Miller and Harold Urey, who designed a closed apparatus that simulated conditions that presumably existed on early Earth (**FIG. 21-2**). They exposed an atmosphere rich in H_2, CH_4, H_2O, and NH_3 to an electric discharge that simulated lightning. Their analysis of the chemicals produced during one week revealed that amino acids and other organic molecules had formed. Although more recent data suggest that Earth's early atmosphere was not rich in methane, ammonia, or hydrogen, similar experiments using different combinations of gases have produced a wide variety of organic molecules that are important in contemporary organisms. These include all 20 amino acids, several sugars, lipids, the nucleotide bases of RNA and DNA, and ATP (when phosphate is present). Thus, before life began, its chemical building blocks were probably accumulating as a necessary step in chemical evolution.

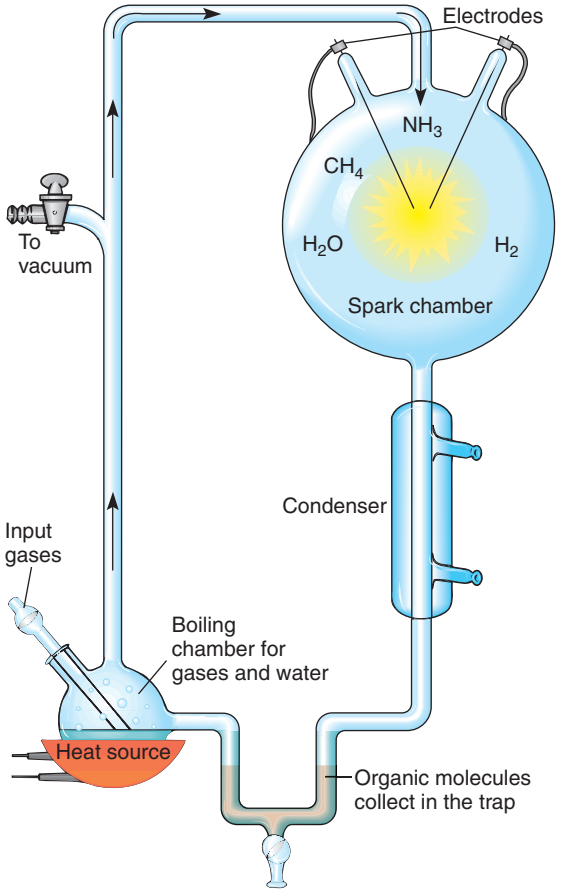
Oparin envisioned that the organic molecules would, over vast spans of time, accumulate in the shallow seas to form a "sea of organic soup." He envisioned smaller organic molecules (monomers) combining to form larger ones (polymers) under such conditions. Evidence gathered since Oparin's time indicates that organic polymers may have formed and accumulated on rock or clay surfaces rather than in the primordial seas. Clay, which consists of microscopic particles of weathered rock, is particularly intriguing as a possible site for early polymerizations because it binds organic monomers and contains zinc and iron ions that may have served as catalysts. Laboratory experiments have confirmed that organic polymers form spontaneously from monomers on hot rock or clay surfaces.

KEY EXPERIMENT

QUESTION: Could organic molecules have formed in the conditions of early Earth?

HYPOTHESIS: Organic molecules can form in a reducing atmosphere similar to that thought to be present on early Earth.

EXPERIMENT: The apparatus that Miller and Urey used to simulate the reducing atmosphere of early Earth contained hydrogen, methane, ammonia, and water. An electrical spark was produced in the upper right flask to simulate lightning.



RESULTS AND CONCLUSION: The gases present in the flask reacted together, and in one week a variety of simple organic compounds, such as amino acids, accumulated in the trap at the bottom. Thus, the formation of organic molecules—the first step in the origin of life—can be produced from simple precursors.

Organic molecules may have formed at hydrothermal vents

Some biologists hypothesize that early polymerizations leading to the origin of life may have occurred in cracks in the deep-ocean floor where hot water, carbon monoxide, and minerals such as sulfides of iron and nickel spew forth—the iron–sulfur world hypoth-

www.konkur.in

esis. Such **hydrothermal vents** would have been better protected than Earth's surface from the catastrophic effects of meteorite bombardment.

Today, these anaerobic hot springs produce precursors of biological molecules and of energy-rich "food," including the highly reduced compounds hydrogen sulfide and methane. These chemicals support a diverse community of microorganisms, clams, crabs, tube worms, and other animals (see *Inquiring About: Life without the Sun,* in Chapter 55).

Testing the iron–sulfur world hypothesis at hydrothermal vents is difficult, but laboratory experiments simulating the high pressures and temperatures at the vents have yielded intriguing results. For example, iron and nickel sulfides catalyze reactions between carbon monoxide and hydrogen sulfide, producing acetic acid and other simple organic compounds. Also, experiments show that ammonia, one of the precursors of proteins and nucleic acids, is produced in abundance, suggesting that vents were ammonia-rich environments in the prebiotic world and that the earliest organisms could have formed in this seemingly inhospitable environment.

Review

- What are the four requirements for chemical evolution, and why is each essential?
- What is the prebiotic soup hypothesis?
- How does the iron–sulfur world hypothesis differ from the prebiotic soup hypothesis?

21.2 THE FIRST CELLS

LEARNING OBJECTIVES

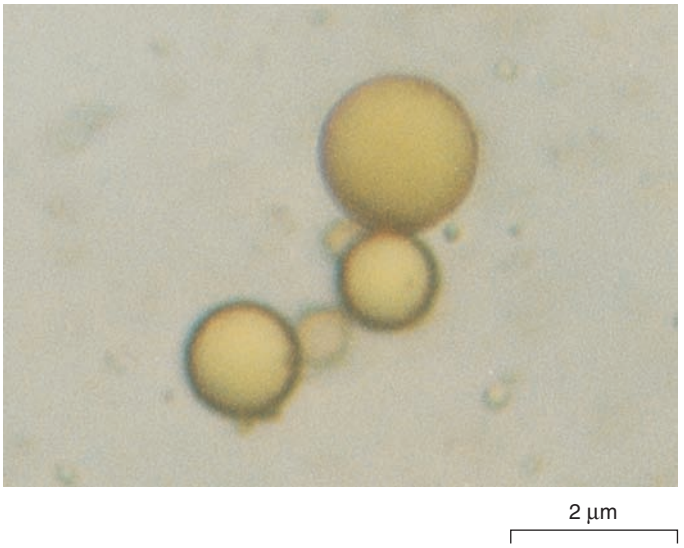
3 Outline the major steps hypothesized to have occurred in the origin of cells.

4 Explain how the evolution of photosynthetic autotrophs affected both the atmosphere and other organisms.

5 Describe the hypothesis of serial endosymbiosis.

After the first polymers formed, could they have assembled spontaneously into more complex structures with an outer membranous boundary? Scientists have synthesized several different **protobionts,** which are vesicle-like assemblages of abiotically produced (that is, not produced by organisms) organic polymers. These protobionts resemble living cells in several ways, thus providing clues as to how aggregations of complex nonliving molecules took that "giant leap" and became living cells. These protobionts exhibit many functional and structural attributes of living cells. They often divide in half (binary fission) after they have sufficiently "grown." Protobionts maintain an internal chemical environment that is different from the external environment (homeostasis), and some of them show the beginnings of metabolism (catalytic activity). They are highly organized, considering their relatively simple composition.

Microspheres are a type of protobiont formed by adding water to abiotically formed polypeptides (**FIG. 21-3**). Some microspheres are excitable: they produce an electrical potential across their surfaces, reminiscent of electrochemical gradients in cells. Microspheres can also absorb materials from their surroundings



Steven Brooke and Richard LeDuc

FIGURE 21-3 Microspheres

(selective permeability) and respond to changes in osmotic pressure as though membranes enveloped them, even though they contain no lipid.

In 2008, scientists constructed protobionts in which membranes of fatty acids and monoglycerides surround larger DNA-like molecules. These protobionts are impermeable to the genetic molecules but allow smaller organic molecules—that is, "nutrients"—to enter. This study is significant because it suggests how early cells could have held on to their "genes" and absorbed needed nutrients from their environment without the sophisticated membrane structure associated with contemporary cells.

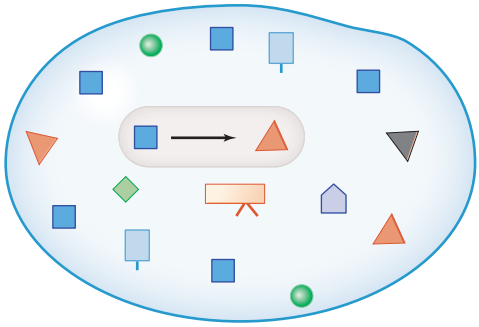
The study of protobionts shows that relatively simple nonliving structures have some of the properties of life. However, it is a major step (or several steps) to go from simple molecular aggregates such as protobionts to living cells.

The origin of a simple metabolism within a membrane boundary may have occurred early in the evolution of cells

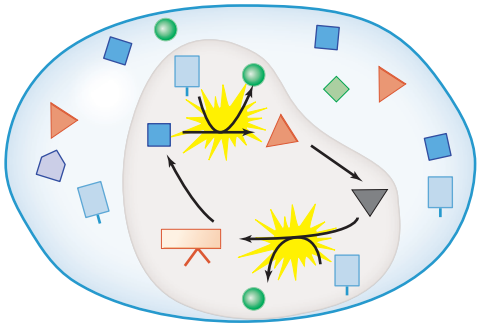
Although we have learned many things about how organic molecules may have formed on primitive Earth, the problem of how pre-cells evolved into living cells remains to be solved. Let's examine one possible scenario—the **metabolism first hypothesis**—supported by chemist Robert Shapiro at New York University and many others. Shapiro envisions life beginning as a self-sustaining, organized system consisting of chemical reactions between simple molecules that are enclosed within a boundary—that is, separated from the external environment (**FIG. 21-4a**).

A source of energy must be available to drive these chemical reactions (thereby maintaining an internal organization different from the external environment). To be self-sustaining, the energy source must be coupled to the chemical reaction sequence (**FIG. 21-4B**). (Recall how ATP links exergonic and endergonic reactions, shown in Figure 7-6.)

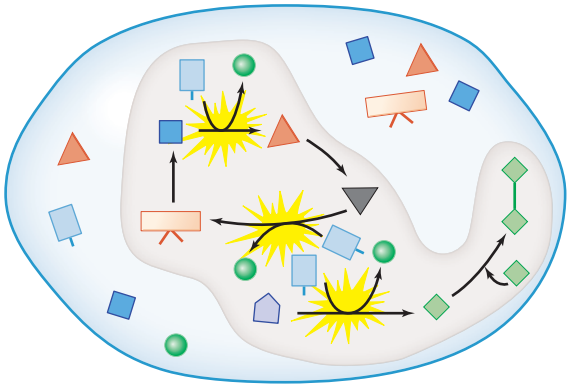
www.konkur.in



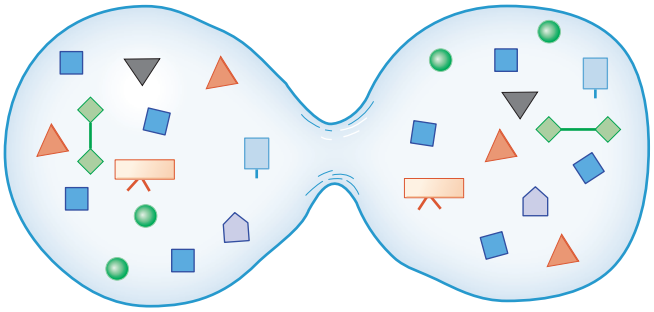
(a) Within a membranous boundary, chemical reactions occur among simple molecules.



(b) A source of energy is coupled to the chemical reaction sequence.



(c) As the pre-cell system continues to evolve, its size and organization increase.



(d) The pre-cell system develops the ability to reproduce.

FIGURE 21-4 Origin of life: the metabolism first scenario

As the pre-cells continue to evolve, their organization increases (**FIG. 21-4c**). Finally, to survive, the pre-cell system must grow and reproduce. One of the most significant parts of the origin of living cells from pre-cells was the evolution of molecular reproduction (**FIG. 21-4d**).

Molecular reproduction was a crucial step in the origin of cells

In living cells, genetic information is stored in the nucleic acid DNA, which is transcribed into messenger RNA (mRNA), which in turn is translated into the proper amino acid sequence in proteins. All three macromolecules in the DNA ⟶ RNA ⟶ protein sequence contain precise information. Of these, only DNA and RNA are capable of self-replication (although only in the presence of the proper enzymes in cells today). Because both RNA and DNA can form spontaneously on clay in much the same way that other organic polymers do, the question becomes, which molecule, DNA or RNA, first appeared in the prebiotic world?

Many scientists have suggested that RNA was the first informational molecule to evolve in the progression toward a self-sustaining, self-reproducing cell and that proteins and DNA came along later. According to a model known as the **RNA world,** the chemistry of prebiotic Earth gave rise to self-replicating RNA molecules that functioned as both enzymes and substrates for their own replication. We represent the replication of RNA in the RNA world scenario as a circular arrow:

RNA often has catalytic properties; such enzymatic RNAs are called **ribozymes.** Before the evolution of true cells, ribozymes may have catalyzed their own replication in the clays, shallow rock pools, or hydrothermal vents where life originated. When RNA strands are added to a test tube containing RNA nucleotides but no enzymes, the nucleotides combine to form short RNA molecules.

The occurrence of an RNA world early in the history of life can never be proven, but experiments with **in vitro evolution,** also called **directed evolution,** have shown it is feasible. These experiments address an important question about the RNA world, namely, could RNA molecules have catalyzed the many different chemical reactions needed for life? In directed evolution, a large pool of RNA molecules with different sequences is mixed, and molecules are selected for their ability to catalyze a single biologically important reaction (**FIG. 21-5**). Those molecules that have at least some catalytic ability are selected by researchers, who then amplify them into many copies. The researchers use certain chemicals to cause mutations, and then expose the molecules to another round of selection. After this cycle is repeated several times, the RNA molecules at the end of the selection process function efficiently as catalysts for the reaction. In vitro evolution studies have shown that RNA has a large functional repertoire—that is, RNA can catalyze a variety of biologically important reactions.

Biologists hypothesize that in the RNA world, ribozymes initially catalyzed protein synthesis and other important biological reactions; only later did protein enzymes catalyze these reactions.

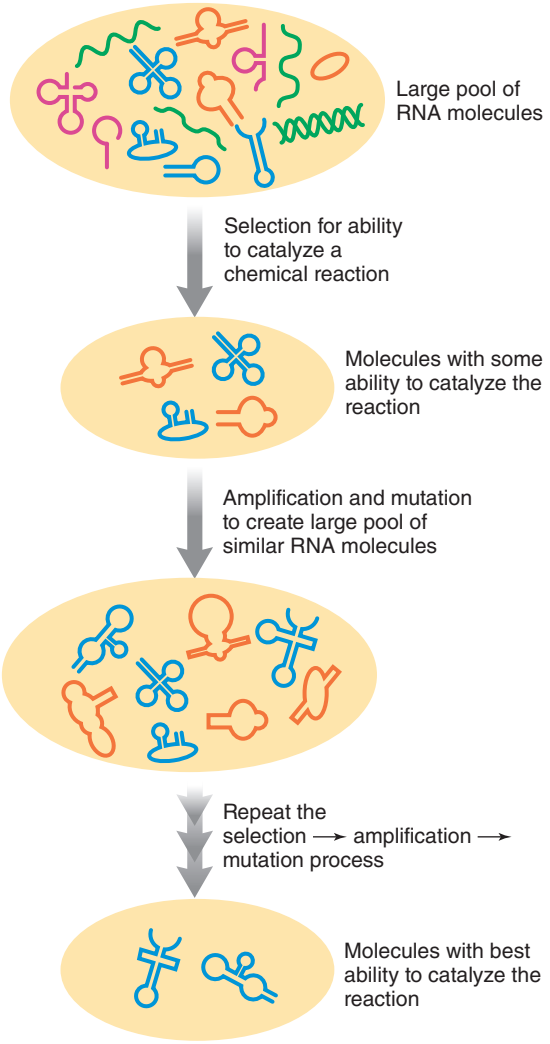
KEY EXPERIMENT

QUESTION: Can in vitro natural selection result in chemical evolution of catalysts?

HYPOTHESIS: Self-replicating RNA molecules can undergo changes that make them more efficient catalysts.

EXPERIMENT: RNA molecules are selected from a large pool, based on their ability to catalyze a specific reaction, then amplified and mutated (*see figure*). This process is repeated 7 to 20 additional times.



RESULTS AND CONCLUSION: The final group of RNA molecules is the most efficient at catalyzing the chemical reaction selected for. Scientists have developed more than two dozen synthetic RNA catalysts by in vitro evolution.

FIGURE 21-5 In vitro evolution of RNA molecules

RNA → protein

Interestingly, in test tube experiments, RNA molecules have evolved that direct protein synthesis by catalyzing peptide bond formation. Some single-stranded RNA molecules fold back on themselves as a result of interactions among the nucleotides composing the RNA strand. Sometimes the conformation (shape) of the folded RNA molecule is such that it weakly binds to an amino acid (see discussion of peptidyl transferase in Chapter 13). Amino acids held close to one another by RNA molecules may bond, forming a polypeptide.

We have considered how the evolution of informational molecules may have given rise to RNA and later to proteins. If a self-replicating RNA capable of coding for proteins appeared prior to DNA, how did DNA, the universal molecule of heredity in cells, become involved? Perhaps RNA made double-stranded copies of itself that eventually evolved into DNA.

DNA ⟵ RNA ⟶ protein

The incorporation of DNA into the information transfer system was advantageous because the double helix of DNA is more stable (less reactive) than the single strand of RNA. Such stability in a molecule that stores genetic information would have provided a decided advantage in the prebiotic world (as it does today).

Thus, in the DNA/RNA/protein world, DNA became the information storage molecule, RNA remained involved in protein synthesis, and protein enzymes catalyzed most cell reactions, including DNA replication and RNA synthesis.

DNA → RNA → protein
