Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

TERMS OF USE

Neither McGraw-Hill nor its licensors shall be liable to you or anyone else for any inaccuracy, error or omission, regardless of cause, in the work or for any damages resulting therefrom. McGraw-Hill has no responsibility for the content of any information accessed through the work. Under no circumstances shall McGraw-Hill and/or its licensors be liable for any indirect, incidental, special, punitive, consequential or similar damages that result from the use of or inability to use the work, even if any of them has been advised of the possibility of such damages. This limitation of liability shall apply to any claim or cause whatsoever whether such claim or cause arises in contract, tort or otherwise.

Contents

Authors
Preface

Section I. Reproduction Basics

1. Anatomy of the Female Reproductive System
Ryan J. Heitmann

2. Embryology of the Urogenital System & Congenital Anomalies of the Genital Tract
Catherine M. DeUgarte

3. Genetic Disorders & Sex Chromosome Abnormalities
Somjate Manipalviratn, Bradley Trivax, & Andy Huang

4. Physiology of Reproduction in Women
Connie Alford & Sahadat Nurudeen

5. The Breast
Amer Karam

Section II. Normal Obstetrics

6. Normal Pregnancy
Helene B. Bernstein & George VanBuren

7. Normal & Abnormal Labor & Delivery
Carol L. Archie & Ashley S. Roman

8. Maternal Physiology During Pregnancy & Fetal & Early Neonatal Physiology
Amy A. Flick & Daniel A. Kahn

9. Normal Newborn Assessment & Care
Elisabeth L. Raab & Lisa K. Kelly

0. The Normal Puerperium
Caroline Pessel & Ming C. Tsai

1. Imaging in Obstetrics
Simi Gupta & Ashley S. Roman

Section III. Pregnancy at Risk

2. Assessment of At-Risk Pregnancy
Shobha H. Mehta & Robert J. Sokol

3. Early Pregnancy Risks
Ann-Marie Surette & Samantha M. Dunham

4. Late Pregnancy Complications
Ashley S. Roman

5. Congenital Fetal Infections
Unzila Nayeri & Stephen Thung

6. Disproportionate Fetal Growth
Jeannine Rahimian

7. Multiple Gestation
Melissa C. Bush & Martin L. Pernoll

8. Third-Trimester Vaginal Bleeding
Sarah A. Wagner

9. Malpresentation & Cord Prolapse
Karen Kish

0. Operative Delivery
Marc H. Incerpi

1. Postpartum Hemorrhage & the Abnormal Puerperium
Sarah B.H. Poggi

2. Neonatal Resuscitation
Elisabeth L. Raab & Lisa K. Kelly

3. Critical Care Obstetrics
Nathan S. Fox, Johanna Weiss Goldberg, & Ramada S. Smith

4. Obstetric Analgesia & Anesthesia
John S. McDonald, Biing-Jaw Chen, & Wing-Fai Kwan

Section IV. Surgical & Medical Complications of Pregnancy

5. Surgical Disorders in Pregnancy
Ella Speichinger & Christine H. Holschneider

6. Hypertension in Pregnancy

David A. Miller

7. Cardiac & Pulmonary Disorders in Pregnancy
Afshan B. Hameed & Martin N. Montoro

8. Renal & Urinary Tract Disorders in Pregnancy
Nathan S. Fox & Andrei Rebarber

9. Gastrointestinal Disorders in Pregnancy
Chad K. Klauser & Daniel H. Saltzman

0. Dermatologic Disorders in Pregnancy
Abigail Ford Winkel

1. Diabetes Mellitus & Pregnancy
Aisling Murphy, Carla Janzen, Stacy L. Strehlow, Jeffrey S. Greenspoon, & Sue M. Palmer

2. Thyroid & Other Endocrine Disorders During Pregnancy
Cynthia Gyamfi Bannerman

3. Nervous System & Autoimmune Disorders in Pregnancy
Laura Kalayjian, T. Murphy Goodwin, & Richard H. Lee

4. Hematologic Disorders in Pregnancy
Christina Arnett, Jeffrey S. Greenspoon, & Ashley S. Roman

Section V. General Gynecology

5. Gynecologic History, Examination, & Diagnostic Procedures
Charles Kawada & Drorith Hochner-Celnikier

6. Imaging in Gynecology
Micah J. Hill & Alan H. DeCherney

7. Pediatric & Adolescent Gynecology
Dvora Bauman

8. Complications of Menstruation & Abnormal Uterine Bleeding
Asher Shushan

9. Benign Disorders of the Vulva & Vagina
Jacob Bornstein

0. Benign Disorders of the Uterine Cervix
Izabella Khachikyan & Pamela Stratton

1. Benign Disorders of the Ovaries & Oviducts
Ofer Lavie

2. Urinary Incontinence & Pelvic Floor Disorders
Christopher M. Tarnay

3. Sexually Transmitted Diseases & Pelvic Infections
Gillian Mackay

4. Antimicrobial Chemotherapy
Shmuel Benenson, Lisa Green, & Alan H. DeCherney

5. Perioperative, Intraoperative, & Postoperative Complications in Gynecologic Surgery
Cecilia K. Wieslander & Danielle D. Marshall

6. Therapeutic Gynecologic Procedures
Cecilia K. Wieslander & Keri S. Wong

Section VI. Gynecologic Oncology

7. Premalignant & Malignant Disorders of the Vulva & Vagina
Amer Karam

8. Premalignant & Malignant Disorders of the Uterine Cervix
Christine H. Holschneider

9. Premalignant & Malignant Disorders of the Uterine Corpus
Nicole D. Fleming & Oliver Dorigo

0. Premalignant & Malignant Disorders of the Ovaries & Oviducts
Gary Levy & Karen Purcell

1. Gestational Trophoblastic Diseases
Paola Aghajanian

2. Radiation and Chemotherapy for Gynecologic Cancers
Wafic M. ElMasri & Oliver Dorigo

Section VII. Reproductive Endocrinology & Infertility

3. Infertility
Shahin Ghadir, Gayane Ambartsumyan, & Alan H. DeCherney

4. Amenorrhea
Alex Simon, Wendy Y. Chang, & Alan H. DeCherney

5. Hirsutism
Ariel Revel

6. Endometriosis
Susan Sarajari, Kenneth N. Muse, Jr., & Michael D. Fox

7. Assisted Reproductive Technologies: In Vitro Fertilization & Related Techniques
Konstantinos G. Michalakis, Alan H. DeCherney, & Alan S. Penzias

8. Contraception & Family Planning
Ronald T. Burkman & Amnon Brzezinski

9. Menopause & Postmenopause
Lauren Nathan

Section VIII. Psychological & Social Issues

0. Domestic Violence & Sexual Assault
Michael C. Lu, Jessica S. Lu, & Vivian P. Halfin

Index

Authors

Therapeutic Gynecologic Procedures

Preface

As in the previous editions, this text is a single-source reference for practitioners in both the inpatient and outpatient setting focusing on the practical aspects of clinical diagnosis and patient management.

Contained within the text is a thorough review of all of obstetrics and gynecology, including medical advances up to the time of publication. More than 1000 diseases and disorders are included.

A continued emphasis on disease prevention and evidence-based medicine remains paramount. In addition to diagnosis and treatment of disease, pathophysiology is a major area of focus. The concise format facilitates quick access.

A new and improved layout will certainly be appreciated, with more than 500 anatomic drawings, imaging studies, and diagrams as part of the basic text.

Medical students will find *Current Diagnosis & Treatment: Obstetrics & Gynecology* to be an authoritative introduction to the specialty and an excellent source for reference and review. House officers will welcome the concise practical information for commonly encountered health problems. Practicing obstetricians and gynecologists, family physicians, internists, nurse practitioners, nurse midwives, physician assistants, and other health care providers whose practice includes women’s health can use the book to answer questions that arise in the daily practice of obstetrics and gynecology.

Medicine, including obstetrics and gynecology, is undergoing rapid change, and every attempt has been made to keep the Lange Series current. A great deal of effort has gone into checking the sources to make sure that this book presents standards of care and acceptable modes of treatment and diagnosis.

Everything that lies between the covers of the eleventh edition of *Current Diagnosis & Treatment: Obstetrics & Gynecology* has been updated, modified, and modernized from the tenth edition.

Section I. Reproduction Basics

1
Anatomy of the Female Reproductive System

Ryan J. Heitmann, DO

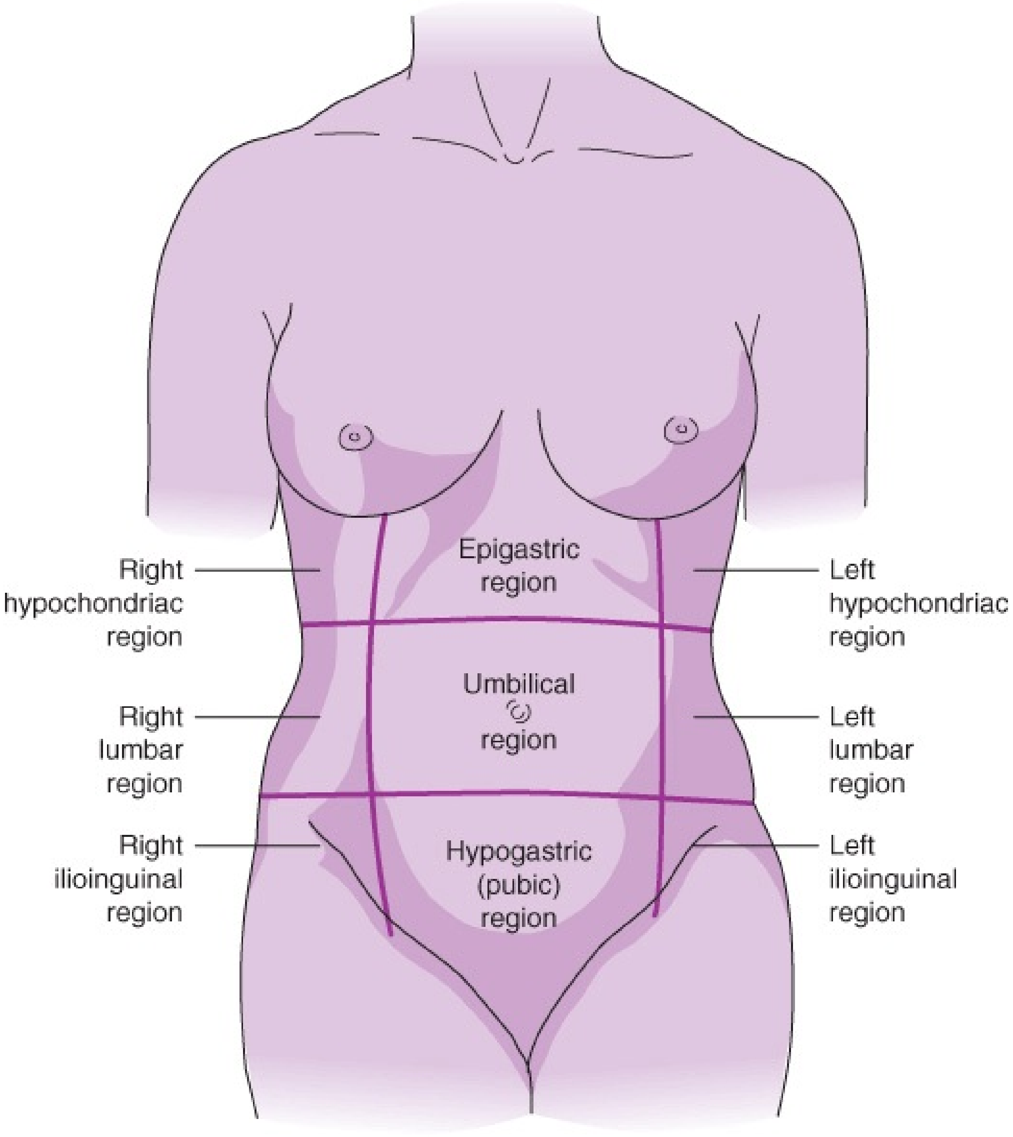
Understanding human and pelvic anatomy is essential to the fundamental knowledge of an obstetrician/gynecologist. The basic facts and anatomic structures do not change, but our knowledge and understanding of relationships and function continues to increase. Advances in surgical techniques continue to place more importance on a physician's understanding of surgical landmarks. There can be significant variation in surgical anatomy, so the practitioner should be well versed in "normal" anatomy and prepared for the "nontextbook" cases.

ABDOMINAL WALL

Topographic Anatomy

The anterior abdominal wall is divided into sections for descriptive purposes and to allow the physician to outline relationships of the viscera in the abdominal cavity. The center point of reference is the sternoxiphoid process, which is in the same plane as the 10th thoracic vertebra. The upper 2 sections are formed by the subcostal angle; the lower extends from the lower ribs to the crest of the ilium and forward to the anterior superior iliac spines. The base is formed by the inguinal ligaments and the symphysis pubica.

The viscera are located by dividing the anterolateral abdominal wall into regions. One line is placed from the level of each ninth costal cartilage to the iliac crests. Two other lines are drawn from the middle of the inguinal ligaments to the cartilage of the eighth rib. The 9 regions formed (Fig. 1–1) are the epigastric, umbilical, hypogastric, and right and left hypochondriac, lumbar, and ilioinguinal.

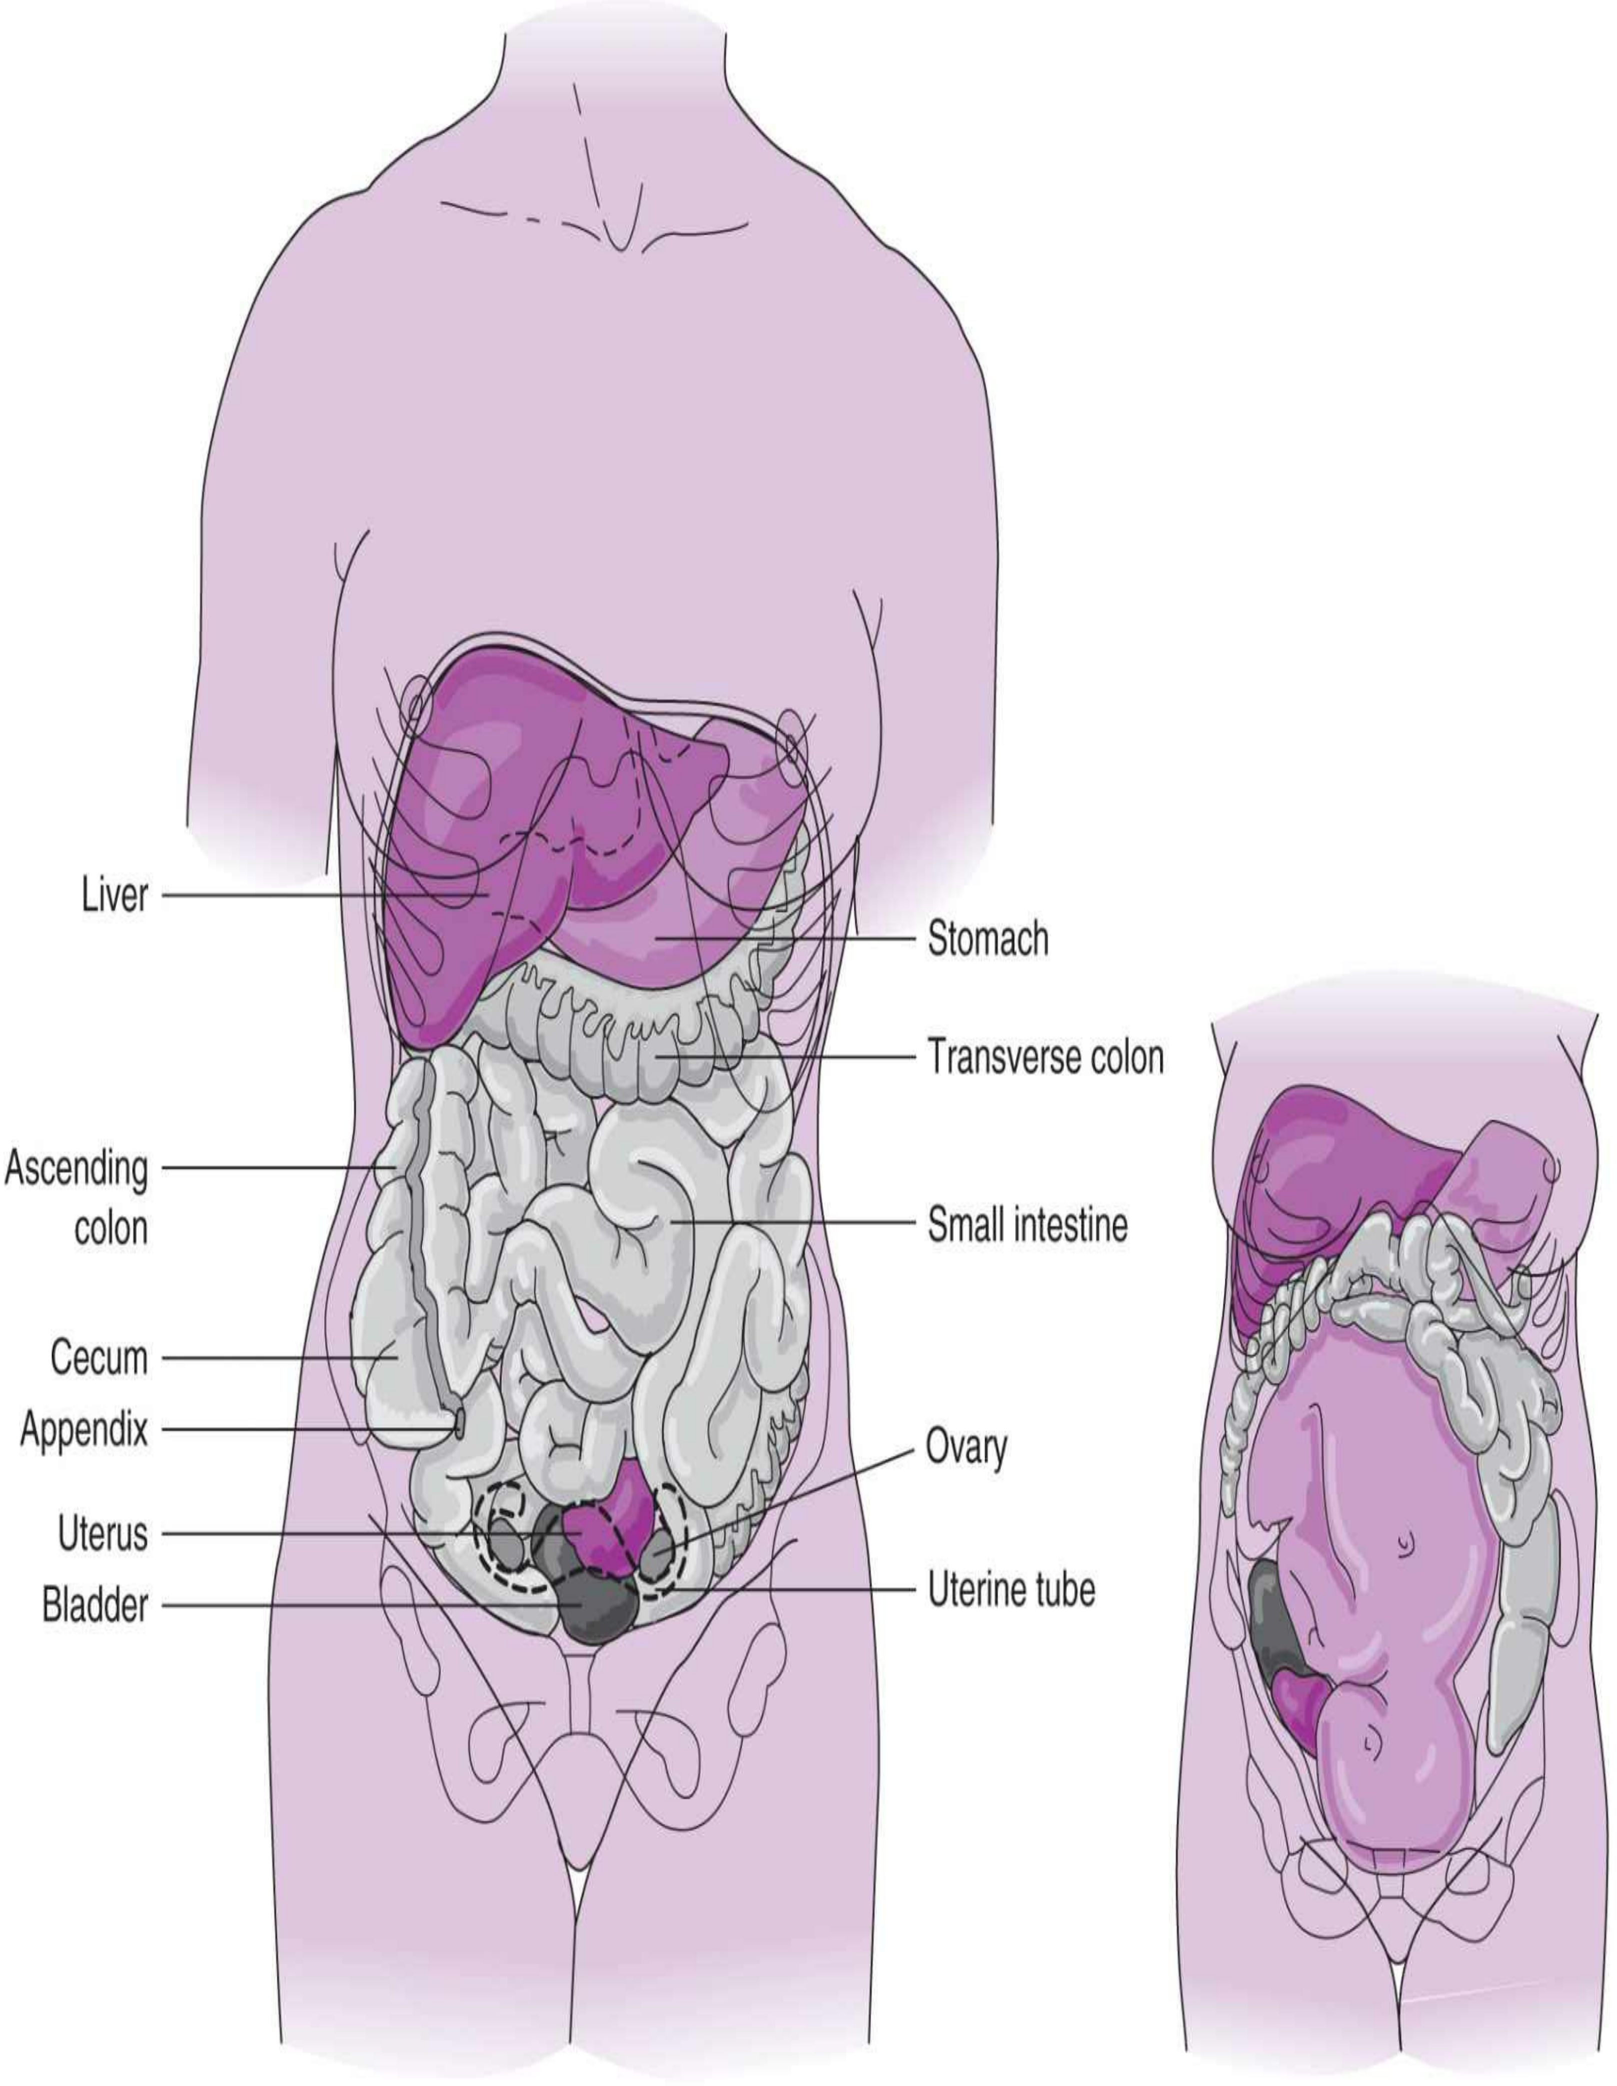


Right hypochondriac region
Epigastric region
Left hypochondriac region
Right lumbar region
Umbilical region
Left lumbar region
Right ilioinguinal region
Hypogastric (pubic) region
Left ilioinguinal region

Figure 1–1. Regions of the abdomen.

Within the right hypochondriac zone are the right lobe of the liver, the gallbladder at the anterior inferior angle, part of the right kidney deep within the region, and, occasionally, the right colic flexure.

The epigastric zone contains the left lobe of the liver and part of the right lobe, the stomach, the proximal duodenum, the pancreas, the suprarenal glands, and the upper poles of both kidneys (Fig. 1–2).



Liver
Ascending colon
Cecum
Appendix
Uterus
Bladder
Stomach
Transverse colon
Small intestine
Ovary
Uterine tube

Figure 1–2. Abdominal viscera in situ. Inset shows projection of fetus in situ.

The left hypochondriac region marks the situation of the spleen, the fundus of the stomach, the apex of the liver, and the left colic flexure.

Within the right lumbar region are the ascending colon, coils of intestine, and, frequently, the inferior border of the lateral portion of the right kidney.

The central umbilical region contains the transverse colon, the stomach, the greater omentum, the small intestine, the second and third portions of the duodenum, the head of the pancreas, and parts of the medial aspects of the kidneys.

Located in the left lumbar region are the descending colon, the left kidney, and the small intestine. Within the limits of the right ilioinguinal region are the cecum and appendix, part of the ascending colon, the small intestine, and, occasionally, the right border of the greater omentum.

The hypogastric region includes the greater omentum, loops of small intestine, the pelvic colon, and often part of the transverse colon.

The left ilioinguinal region encloses the sigmoid colon, part of the descending colon, loops of small intestine, and the left border of the greater omentum.

There is considerable variation in the position and size of individual organs due to differences in body size, conformation, and disease processes. Throughout life, variations in the positions of organs are dependent not only on gravity but also on the movements of the hollow viscera, which induce further changes in shape when filling and emptying. The need to recognize the relationships of the viscera to the abdominal regions becomes most apparent when taking into account the distortion that occurs during pregnancy. For example, the appendix lies in the right ilioinguinal region (right lower quadrant) until the 12th week of gestation. At 16 weeks, it is at the level of the right iliac crest. At 20 weeks, it is at the level of the umbilicus, where it will remain until after delivery. Because of this displacement, the symptoms of appendicitis will be different during the 3 trimesters. Similarly, displacement will also affect problems involving the bowel.

Skin, Subcutaneous Tissue, & Fascia

The abdominal skin is smooth, fine, and very elastic. It is loosely attached to underlying structures except at the umbilicus, where it is firmly adherent. Langer’s lines are lines of tension based on the orientation of dermal fibers in the skin. On the anterior abdominal wall, these lines are arranged mostly in a transverse fashion. As a consequence, vertical incisions heal under more tension and therefore have a propensity to develop into wider scars. This is more noticeable in those patients who tend to form keloids. Conversely, transverse incisions, like a Pfannenstiel, heal with a much better cosmetic appearance.

Beneath the skin is the superficial fascia (tela subcutanea). This fatty protective fascia covers the entire abdomen. Below the navel, it consists principally of 2 layers: Camper’s fascia, the more superficial layer containing most of the fat; and Scarpa’s fascia (deep fascia), the fibroelastic membrane firmly attached to midline aponeuroses and to the fascia lata.

Arteries

Arteries of the Upper Abdomen

The lower 5 intercostal arteries (Fig. 1–3) and the subcostal artery accompany the thoracic nerves. Their finer, terminal branches enter the rectus sheath to anastomose with the superior and inferior epigastric arteries. The superior epigastric artery is the direct downward prolongation of the internal mammary artery. This artery descends between the posterior surface of the rectus muscle and its sheath to form an anastomosis with the inferior epigastric artery upon the muscle.

Musculophrenic artery
Inferior epigastric artery (medial border of inguinal trigone)
Superficial epigastric vein
Femoral artery
Femoral vein

Figure 1–3. Superficial veins and arteries of abdomen.

The inferior epigastric artery, a branch of the external iliac artery, usually arises just above the inguinal ligament and passes on the medial side of the round ligament to the abdominal inguinal ring. From there, it ascends in a slightly medial direction, passing above and lateral to the subcutaneous inguinal ring, which lies between the fascia transversalis and the peritoneum. Piercing the fascia transversalis, it passes in front of the linea semicircularis, turns upward between the rectus and its sheath, enters the substance of the rectus muscle, and meets the superior epigastric artery. The superior epigastric supplies the upper central abdominal wall, the inferior supplies the lower central part of the anterior abdominal wall, and the deep circumflex supplies the lower lateral part of the abdominal wall.

Arteries of the Lower Abdomen

The deep circumflex iliac artery is also a branch of the external iliac artery, arising from its side either opposite the epigastric artery or slightly below the origin of that vessel. It courses laterally behind the inguinal ligament lying between the fascia transversalis and the peritoneum. The deep circumflex artery perforates the transversus near the anterior superior spine of the ilium and continues between the transversus and internal oblique along and slightly above the crest of the ilium, finally running posteriorly to anastomose with the iliolumbar artery. A branch of the deep circumflex iliac artery is important to the surgeon because it forms anastomoses with branches of the inferior epigastric.

The various incisions on the abdomen encounter some muscle planes and vasculature of clinical significance. The McBurney incision requires separation of the external and internal oblique muscles and splitting of the transversus. The deep circumflex artery may be frequently encountered. The paramedian incision is made in the right or left rectus. Below the arcuate line, the fascia of the external and internal oblique, as well as the transversus muscles when present, goes over the rectus abdominis; above the arcuate line, the transversus and part of the internal oblique go under the rectus. The vasculature is primarily perforators and frequently the thoracoabdominal vein. Inferiorly, the superficial epigastric may be encountered.

In the Pfannenstiel or low transverse incision, the fascia of the external and internal oblique goes over the rectus muscle as well as the transversus muscle when present. After the fascia over the rectus is incised, the muscles can be separated. The superficial epigastric artery and vein are encountered in Camper’s fascia. Laterally, the superficial and deep circumflex iliac arteries may be at the margin of the incision. Lying under the transversus muscle and entering the rectus approximately halfway to the umbilicus is the inferior epigastric artery.

In the Cherney incision, care should be taken to avoid the inferior epigastric artery, which is the primary blood supply to the rectus abdominis. Abdominal incisions are shown in Figure 1–4. The position of the muscles influences the type of incision to be made. The aim is to adequately expose the operative field, avoiding damage to parietal structures, blood vessels, and nerves. Low transverse incisions ideally do not extend past the lateral edges of the rectus muscles to avoid damage to the inferior epigastric vessels.

Veins

The superficial veins are more numerous than the arteries and form more extensive vascular networks. Above the level of the umbilicus, blood returns through the anterior cutaneous and the paired thoracoepigastric veins, the superficial epigastric veins, and the superficial circumflex iliac veins in the tela subcutanea. A cruciate anastomosis exists, therefore, between the femoral and axillary veins.

The deep veins correspond in name with the arteries they accompany. Below the umbilicus, these veins run caudally and medially to the external iliac vein; above that level, they run cephalad and laterally into the intercostal veins. Lymphatic drainage in the deeper regions of the abdominal wall follows the deep veins directly to the superficial inguinal nodes.

Lymphatics

The lymphatic drainage of the lower abdominal wall (Fig. 1–5) is primarily to the superficial inguinal nodes, 10–20 in number, which lie in the area of the inguinal ligament. These nodes may be identified by dividing the area into quadrants by intersecting horizontal and vertical lines that meet at the saphenofemoral junction. The lateral abdominal wall drainage follows the superficial circumflex iliac vein and drains to the lymph nodes in the upper lateral quadrant of the superficial inguinal nodes. The drainage of the medial aspect follows the superficial epigastric vein primarily to the lymph nodes in the upper medial quadrant of the superficial inguinal nodes. Of major clinical importance are the frequent anastomoses between the lymph vessels of the right and left sides of the abdomen.

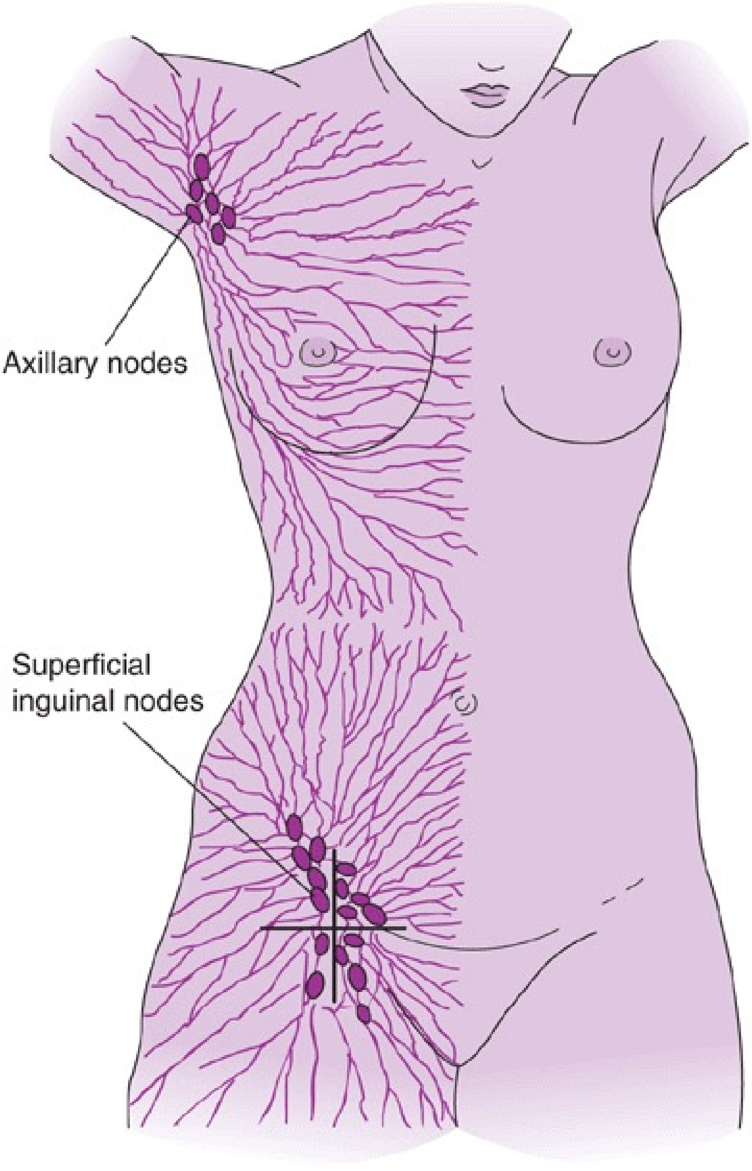

Figure 1–5. Lymphatics of abdominal wall. Only one side is shown, but contralateral drainage occurs (ie, crosses midline to the opposite side).

Abdominal Nerves

The lower 6 thoracic nerves align with the ribs and give off lateral cutaneous branches (Fig. 1–6). The intercostal nerves pass deep to the upturned rib cartilages and enter the abdominal wall. The main trunks of these nerves run forward between the internal oblique and the transversus. The nerves then enter the rectus sheaths and the rectus muscles, and the terminating branches emerge as anterior cutaneous nerves.

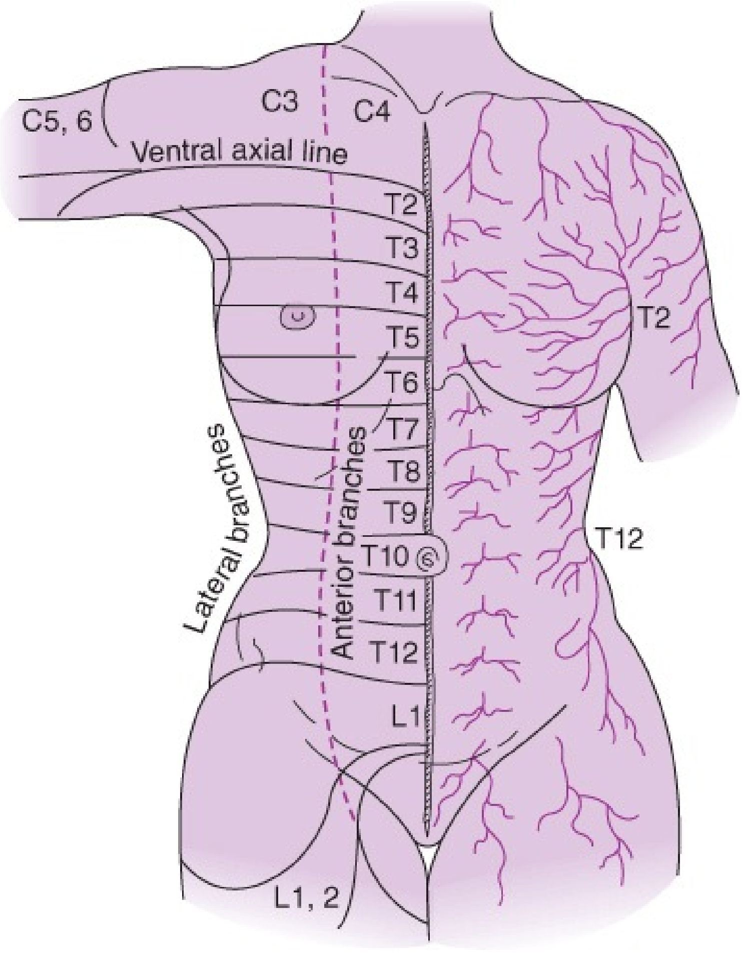

Figure 1–6. Cutaneous innervation of the abdominal wall.

The iliohypogastric nerve springs from the first lumbar nerve after the latter has been joined by the communicating branch from the last (12th) thoracic nerve. It pierces the lateral border of the psoas and crosses anterior to the quadratus lumborum muscle but posterior to the kidney and colon. At the lateral border of the quadratus lumborum, it pierces the aponeurosis of origin of the transversus abdominis and enters the areolar tissue between the transversus and the internal oblique muscle. Here, it frequently communicates with the last thoracic nerve and with the ilioinguinal nerve, which also originates from the first lumbar and last thoracic nerves.

The iliohypogastric divides into 2 branches. The iliac branch pierces the internal and external oblique muscles, emerging through the latter above the iliac crest and supplying the integument of the upper and lateral part of the thigh. The hypogastric branch, as it passes forward and downward, gives branches to both the transversus abdominis and internal oblique. It communicates with the ilioinguinal nerve and pierces the internal oblique muscle near the anterior superior spine. The hypogastric branch proceeds medially beneath the external oblique aponeurosis and pierces it just above the subcutaneous inguinal ring to supply the skin and symphysis pubica.

Similarly as with arteries and veins, care should be taken to avoid any nerve damage when performing surgery. With a low transverse incision, the iliohypogastric and ilioinguinal nerves are commonly encountered. Risk of damage or entrapment increases the more lateral an incision is made. When repairing the fascial layers, to help avoid entrapment of the iliohypogastric or ilioinguinal nerve, one should be careful not to place stitches lateral to the angle/apex of fascial incisions.

Abdominal Muscles & Fascia

The muscular wall that supports the abdominal viscera (Fig. 1–7) is composed of 4 pairs of muscles and their aponeuroses. The 3 paired lateral muscles are the external oblique, the internal oblique, and the transversus. Their aponeuroses interdigitate at the midline to connect opposing lateral muscles, forming a thickened band at this juncture, the linea alba, which extends from the xiphoid process to the pubic symphysis. Anteriorly, a pair of muscles—the rectus abdominis, with the paired pyramidalis muscles at its inferior border with its sheath—constitutes the abdominal wall.

Function of Abdominal Muscles

In general, the functions of the abdominal muscles are 3-fold: (1) support and compression of the abdominal viscera by the external oblique, internal oblique, and transversus muscles; (2) depression of the thorax in conjunction with the diaphragm by the rectus abdominis, external oblique, internal oblique, and transversus muscles, as evident in respiration, coughing, vomiting, defecation, and parturition; and (3) assistance in bending movements of the trunk through flexion of the vertebral column by the rectus abdominis, external oblique, and internal oblique muscles. There is partial assistance in rotation of the thorax and upper abdomen to the same side when the pelvis is fixed by the internal oblique and by the external oblique to the opposite side. In addition, the upper external oblique serves as a fixation muscle in abduction of the upper limb of the same side and adduction of the upper limb of the opposite side. The pyramidalis muscle secures the linea alba in the median line.

External Oblique Muscle

The external oblique muscle consists of 8 pointed digitations attached to the lower 8 ribs. The lowest fibers insert into the anterior half of the iliac crest and the inguinal ligament. At the linea alba, the muscle aponeurosis interdigitates with that of the opposite side and fuses with the underlying internal oblique.

Internal Oblique Muscle

The internal oblique muscle arises from thoracolumbar fascia, the crest of the ilium, and the inguinal ligament. Going in the opposite oblique direction, the muscle inserts into the lower 3 costal cartilages and into the linea alba on either side of the rectus abdominis. The aponeurosis helps to form the rectus sheath both anteriorly and posteriorly. The posterior layer extends from the rectus muscle rib insertions to below the umbilicus.

Transversus Muscle

The transversus muscle, the fibers of which run transversely and arise from the inner surfaces of the lower 6 costal cartilages, the thoracolumbar fascia, the iliac crest, and the inguinal ligament, lies beneath the internal oblique. By inserting into the linea alba, the aponeurosis of the transversus fuses to form the posterior layer of the posterior rectus sheath. The termination of this layer is called the arcuate line, and below it lies the transversalis fascia, preperitoneal fat, and peritoneum. Inferiorly, the thin aponeurosis of the transversus abdominis becomes part of the anterior rectus sheath.

Rectus Muscles

The rectus muscles are straplike and extend from the thorax to the pubis. They are divided by the linea alba and outlined laterally by the linea semilunaris. Three tendinous intersections cross the upper part of each rectus muscle, and a fourth may also be present below the umbilicus. The pyramidalis muscle, a vestigial muscle, is situated anterior to the lowermost part of the rectus muscle. It arises from and inserts into the pubic periosteum. Beneath the superficial fascia and overlying the muscles is the thin, semitransparent deep fascia. Its extensions enter and divide the lateral muscles into coarse bundles.

Special Structures

There are several special anatomic structures in the abdominal wall, including the umbilicus, linea alba, linea semilunaris, and rectus sheath.

Umbilicus

The umbilicus is positioned opposite the disk space between the third and fourth lumbar vertebrae, approximately 2 cm below the midpoint of a line drawn from the sternoxiphoid process to the top of the pubic symphysis. The umbilicus is a dense, wrinkled mass of fibrous tissue enclosed by and fused with a ring of circular aponeurotic fibers in the linea alba. Normally, it is the strongest part of the abdominal wall. It also represents the shortest distance between the skin and the abdominal cavity, and it is the most common place to enter the abdomen with the primary trochar when performing laparoscopic surgery.

Linea Alba

The linea alba, a fibrous band formed by the fusion of the aponeuroses of the muscles of the anterior abdominal wall, marks the medial side of the rectus abdominis; the linea semilunaris forms the lateral border, which courses from the tip of the ninth costal cartilage to the pubic tubercle. The linea alba extends from the xiphoid process to the pubic symphysis, represented above the umbilicus as a shallow median groove on the surface.

Rectus Sheath & Aponeurosis of the External Oblique

The rectus sheath serves to support and control the rectus muscles. It contains the rectus and pyramidalis muscles, the terminal branches of the lower 6 thoracic nerves and vessels, and the inferior and superior epigastric vessels. Cranially, where the sheath is widest, its anterior wall extends upward onto the thorax to the level of the fifth costal cartilage and is attached to the sternum. The deeper wall is attached to the xiphoid process and the lower borders of the seventh to ninth costal cartilages and does not extend upward onto the anterior thorax. Caudally, where the sheath narrows considerably, the anterior wall is attached to the crest and the symphysis pubica. Above the costal margin on the anterior chest wall, there is no complete rectus sheath (Fig. 1–8). Instead, the rectus muscle is covered only by the aponeurosis of the external oblique. In the region of the abdomen, the upper two-thirds of the internal oblique aponeurosis split at the lateral border of the rectus muscle into anterior and posterior lamellas. The anterior lamella passes in front of the external oblique and blends with the external oblique aponeurosis.

Figure 1–8. Formation of rectus sheath.

The posterior wall of the sheath is formed by the posterior lamella and the aponeurosis of the transversus muscle. The anterior and posterior sheaths join at the midline. The lower third of the internal oblique aponeurosis is undivided. Together with the aponeuroses of the external oblique and transversus muscles, it forms the anterior wall of the sheath. The posterior wall is occupied by transversalis fascia, which is spread over the interior surfaces of both the rectus and the transversus muscles, separating them from peritoneum and extending to the inguinal and lacunar ligaments. The transition from aponeurosis to fascia usually is fairly sharp, marked by a curved line called the arcuate line.

Variations of Abdominal Muscles

Variations have been noted in all of the abdominal muscles.

Rectus Muscle

The rectus abdominis muscle may differ in the number of its tendinous inscriptions and the extent of its thoracic attachment. Aponeurotic slips or slips of muscle on the upper part of the thorax are remnants of a more primitive state in which the muscle extended to the neck. Absence of part or all of the muscle has been noted. The pyramidalis muscle may be missing, only slightly developed, double, or extend upward to the umbilicus.

External Oblique Muscle

The external oblique muscle varies in the extent of its origin from the ribs. Broad fascicles may be separated by loose tissue from the main belly of the muscle, either on its deep or on its superficial surface. The supracostalis anterior is a rare fascicle occasionally found on the upper portion of the thoracic wall. Transverse tendinous inscriptions may also be found.

Internal Oblique Muscle

The internal oblique deviates at times, both in its attachments and in the extent of development of the fleshy part of the muscle. Occasionally, tendinous inscriptions are present, or the posterior division forms an extra muscle 7–7.5 cm wide and separated from the internal oblique by a branch of the iliohypogastric nerve and a branch of the deep circumflex iliac artery.

Transversus Muscle

The transversus muscle fluctuates widely in the extent of its development but is rarely absent. Rarely, it extends as far inferiorly as the ligamentum teres uteri (round ligament), and infrequently, it is situated superior to the anterior superior spine. However, it generally occupies an intermediate position.

BONY PELVIS

The pelvis (Fig. 1–9) is a basin-shaped ring of bones that marks the distal margin of the trunk. The pelvis rests on the lower extremities and supports the spinal column. It is composed of 2 innominate bones, one on each side, joined anteriorly and articulated with the sacrum posteriorly. The 2 major pelvic divisions are the pelvis major (upper or false pelvis) and the pelvis minor (lower or true pelvis). The pelvis major consists primarily of the space superior to the iliopectineal line, including the 2 iliac fossae and the region between them. The pelvis minor, located below the iliopectineal line, is bounded anteriorly by the pubic bones, posteriorly by the sacrum and coccyx, and laterally by the ischium and a small segment of the ilium.

Innominate Bone

The innominate bone is composed of 3 parts: ilium, ischium, and pubis.

Ilium

The ilium consists of a bladelike upper part or ala (wing) and a thicker, lower part called the body.

The body forms the upper portion of the acetabulum and unites with the bodies of the ischium and pubis. The medial surface of the ilium presents as a large concave area: The anterior portion is the iliac fossa; the smaller posterior portion is composed of a rough upper part, the iliac tuberosity; and the lower part contains a large surface for articulation with the sacrum. At the inferior medial margin of the iliac fossa, a rounded ridge, the arcuate line, ends anteriorly in the iliopectineal eminence. Posteriorly, the arcuate line is continuous with the anterior margin of the ala of the sacrum across the anterior aspect of the sacroiliac joint. Anteriorly, it is continuous with the ridge or pecten on the superior ramus of the pubis.

The lateral surface or dorsum of the ilium is traversed by 3 ridges: the posterior, anterior, and inferior gluteal lines. The superior border is called the crest, and at its 2 extremities are the anterior and posterior superior iliac spines. The principal feature of the anterior border of the ilium is the heavy anterior inferior iliac spine. Important aspects of the posterior border are the posterior superior and the inferior iliac spines and, below the latter, the greater sciatic notch, the inferior part of which is bounded by the ischium. The inferior border of the ilium participates in the formation of the acetabulum.

The main vasculature (Fig. 1–10) of the innominate bone appears where the bone is thickest. Blood is supplied to the inner surface of the ilium through twigs of the iliolumbar, deep circumflex iliac, and obturator arteries by foramens on the crest, in the iliac fossa, and below the terminal line near the greater sciatic notch. The outer surface of the ilium is supplied mainly below the inferior gluteal line through nutrient vessels derived from the gluteal arteries. The inferior branch of the deep part of the superior gluteal artery forms the external nutrient artery of the ilium and continues in its course to anastomose with the lateral circumflex artery. Upon leaving the pelvis below the piriformis muscle, it divides into a number of branches, a group of which passes to the hip joint.

Ischium

The ischium is composed of a body, superior and inferior rami, and a tuberosity. The body is the heaviest part of the bone and is joined with the bodies of the ilium and pubis to form the acetabulum. It presents 3 surfaces. (1) The smooth internal surface is continuous above with the body of the ilium and below with the inner surface of the superior ramus of the ischium. Together, these parts form the posterior portion of the lateral wall of the pelvis minor. (2) The external surface of the ischium is the portion that enters into the formation of the acetabulum. (3) The posterior surface is the area between the acetabular rim and the posterior border. It is convex and is separated from the ischial tuberosity by a wide groove. The posterior border, with the ilium, forms the bony margin of the greater sciatic notch. The superior ramus of the ischium descends from the body of the bone to join the inferior ramus at an angle of approximately 90 degrees.

The large ischial tuberosity and its inferior portion are situated on the convexity of this angle. The inferior portion of the tuberosity forms the point of support in the sitting position. The posterior surface is divided into 2 areas by an oblique line. The lesser sciatic notch occupies the posterior border of the superior ramus between the spine and the tuberosity. The inferior ramus, as it is traced forward, joins the inferior ramus of the pubis to form the arcus pubis (ischiopubic arch).

The ischium is supplied with blood from the obturator medial and lateral circumflex arteries. The largest vessels are situated between the acetabulum and the sciatic tubercle.

Pubis

The pubis is composed of a body and 2 rami, superior and inferior. The body contributes to the formation of the acetabulum, joining with the body of the ilium at the iliopectineal eminence and with the body of the ischium in the region of the acetabular notch. The superior ramus passes medially and forward from the body to meet the corresponding ramus of the opposite side at the symphysis pubica. The medial or fore portion of the superior ramus is broad and flattened anteroposteriorly. Formerly called "the body," it presents an outer and an inner surface, the symphyseal area, and an upper border or "crest."

Approximately 2 cm from the medial edge of the ramus and in line with the upper border is the prominent pubic tubercle, an important landmark. Below the crest are the anterior surface and the posterior or deep surface. The medial portion of the superior ramus is continuous below with the inferior ramus, and the lateral part presents a wide, smooth area anterosuperiorly, behind which is an irregular ridge, the pecten ossis pubis. The pecten pubis forms the anterior part of the linea terminalis. In front of and below the pectineal area is the obturator crest, passing from the tubercle to the acetabular notch. On the inferior aspect of the superior ramus is the obturator sulcus. The inferior ramus is continuous with the superior ramus and passes downward and backward to join the inferior ramus of the ischium, forming the "ischiopubic arch." The pubis receives blood from the pubic branches of the obturator artery and from branches of the medial and lateral circumflex arteries.

Pubic Symphysis

The pubic symphysis is a synarthrodial joint of the symphyseal surfaces of the pubic bones. The ligaments associated with it are (1) the interpubic fibrocartilage, (2) the superior pubic ligament, (3) the anterior pubic ligament, and (4) the arcuate ligament. The interpubic fibrocartilage is thicker in front than behind and projects beyond the edges of the bones, especially on the posterior aspect, blending intimately with the ligaments at its margins. Sometimes it is woven throughout, but often the interpubic fibrocartilage presents an elongated, narrow fissure with fluid in the interspace, partially dividing the cartilage into 2 plates.

The interpubic cartilage is intimately adherent to the layer of hyaline cartilage that covers the symphyseal surface of each pubic bone. The superior pubic ligament extends laterally along the crest of the pubis on each side to the pubic tubercle, blending in the middle line with the interpubic cartilage. The thick and strong anterior pubic ligament is closely connected with the fascial covering of the muscles arising from the conjoined rami of the pubis. It consists of several strata of thick, decussating fibers of different degrees of obliquity, the superficial being the most oblique and extending lowest over the joint. The arcuate ligament is a thick band of closely connected fibers that fills the angle between the pubic rami to form a smooth, rounded top to the pubic arch. Both on the anterior and posterior aspects of the joint, the ligament gives off decussating fibers that, interlacing with one another, strengthen the joint.

Sacrum

The sacrum is formed in the adult by the union of 5 or 6 sacral vertebrae; occasionally, the fifth lumbar vertebra is partly fused with it. The process of union is known as "sacralization" in the vertebral column. The sacrum constitutes the base of the vertebral column. As a single bone, it is considered to have a base, an apex, 2 surfaces (pelvic and dorsal), and 2 lateral portions. The base faces upward and is composed principally of a central part, formed by the upper surface of the body of the first sacral vertebra, and 2 lateral areas of alae. The body articulates by means of a fibrocartilage disk with the body of the fifth lumbar vertebra. The alae represent the heavy transverse processes of the first sacral vertebra that articulate with the 2 iliac bones. The anterior margin of the body is called the promontory and forms the sacrovertebral angle with the fifth lumbar vertebra. The rounded anterior margin of each ala constitutes the posterior part (pars sacralis) of the linea terminalis.

The pelvic surface of the sacrum is rough and convex. In the midline is the median sacral crest (fused spinal processes), and on either side is a flattened area formed by the fused laminae of the sacral vertebrae. The laminae of the fifth vertebra and, in many cases, those of the fourth and occasionally of the third are incomplete (the spines also are absent), thus leaving a wide opening to the dorsal wall of the sacral canal known as the sacral hiatus. Lateral to the laminae are the articular crests (right and left), which are in line with the paired superior articular processes above. The lateral processes articulate with the inferior articular processes of the fifth lumbar vertebra. The inferior extensions of the articular crests form the sacral cornua that bind the sacral hiatus laterally and are attached to the cornua of the coccyx. The cornua can be palpated in life and are important landmarks indicating the inferior opening of the sacral canal (for sacral-caudal anesthesia).

The lateral portions of the sacrum are formed by the fusion of the transverse processes of the sacral vertebrae. They form dorsally a line of elevations called the lateral sacral crests. The parts corresponding to the first 3 vertebrae are particularly massive and present a large area facing laterally called the articular surface, which articulates with the sacrum. Posterior to the articular area, the rough bone is called the sacral tuberosity. It faces the tuberosity of the ilium. The apex is the small area formed by the lower surface of the body of the fifth part of the sacrum. The coccyx is formed by 4 (occasionally 3 or 5) caudal or coccygeal vertebrae. The second, third, and fourth parts are frequently fused into a single bone that articulates with the first by means of a fibrocartilage. The entire coccyx may become ossified and fused with the sacrum (the sacrococcygeal joint).

The sacrum receives its blood supply from the middle sacral artery, which extends from the bifurcation of the aorta to the tip of the coccyx, and from the lateral sacral arteries that branch either as a single artery that immediately divides or as 2 distinct vessels from the hypogastric artery. The lowest lumbar branch of the middle sacral artery ramifies over the lateral parts of the sacrum, passing back between the last vertebra and the sacrum to anastomose with the lumbar arteries above and the superior gluteal artery below. The lateral sacral branches (usually 4) anastomose anteriorly to the coccyx with branches of the inferior lateral sacral artery that branch from the hypogastric artery. They give off small spinal branches that pass through the sacral foramens and supply the sacral canal and posterior portion of the sacrum.

Sacroiliac Joint

The sacroiliac joint is a diarthrodial joint with irregular surfaces. The articular surfaces are covered with a layer of cartilage, and the cavity of the joint is a narrow cleft. The cartilage on the sacrum is hyaline in its deeper parts but much thicker than that on the ilium. A joint capsule is attached to the margins of the articular surfaces, and the bones are held together by the anterior sacroiliac, long and short posterior sacroiliac, and interosseous ligaments. In addition, there are 3 ligaments (Fig. 1–11), classed as belonging to the pelvic girdle itself, which also serve as accessory ligaments to the sacroiliac joint: the iliolumbar, sacrotuberous, and sacrospinous ligaments.

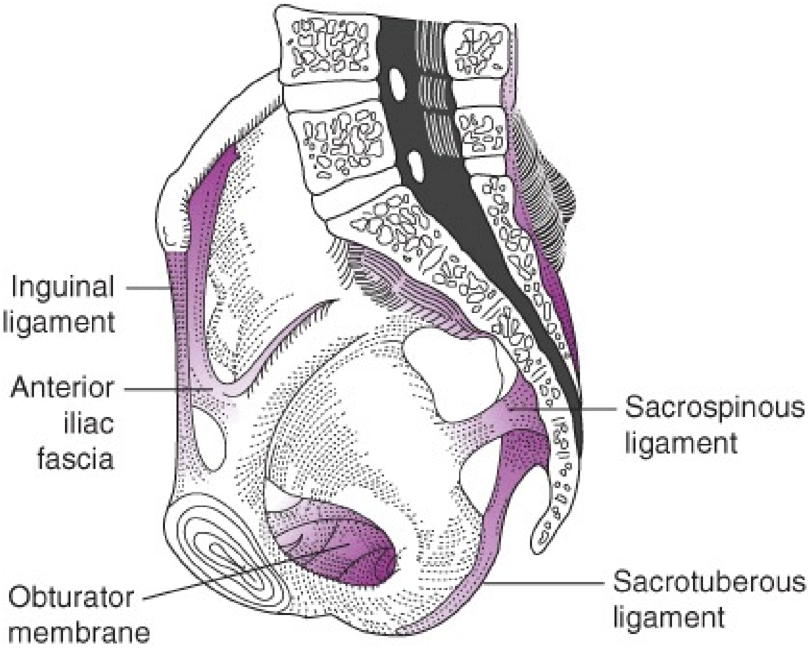

Figure 1–11. Ligaments of the pelvis.

The anterior sacroiliac ligaments unite the base and the lateral part of the sacrum to the ilium, blending with the periosteum of the pelvic surface and, on the ilium, reaching the arcuate line to attach in the paraglenoid grooves. The posterior sacroiliac ligament is extremely strong and consists essentially of 2 sets of fibers, deep and superficial, forming the short and long posterior sacroiliac ligaments, respectively. The short posterior sacroiliac ligament passes inferiorly and medially from the tuberosity of the ilium, behind the articular surface and posterior interior iliac spine, to the back of the lateral portion of the sacrum and to the upper sacral articular process, including the area between it and the first sacral foramen.

The long posterior sacroiliac ligament passes inferiorly from the posterior superior iliac spine to the second, third, and fourth articular tubercles on the back of the sacrum. It partly covers the short ligament and is continuous below with the sacrotuberous ligament. The interosseous ligaments are the strongest of all and consist of fibers of different lengths passing in various directions between the 2 bones. They extend from the rough surface of the sacral tuberosity to the corresponding surface on the lateral aspect of the sacrum, above and behind the articular surface.

Ligaments

The sacrotuberous ligament, in common with the long posterior sacroiliac ligament, is attached above to the crest of the ilium and posterior iliac spine and to the posterior aspect of the lower 3 sacral vertebrae. Below, it is attached chiefly to the medial border of the ischial tuberosity. Some of the fibers at the other end extend forward along the inner surface of the ischial ramus, forming the falciform process. Other posterior fibers continue into the tendons of the hamstrings.

The sacrospinous ligament is triangular and thin, extending from the lateral border of the sacrum and coccyx to the spine of the ischium. It passes medially (deep) to the sacrotuberous ligament and is partly blended with it along the lateral border of the sacrum.

The iliolumbar ligament connects the fourth and fifth lumbar vertebrae with the iliac crest. It originates from the transverse process of the fifth lumbar vertebra, where it is closely woven with the sacrolumbar ligament. Some of its fibers spread downward onto the body of the fifth vertebra, and others ascend to the disk above. It is attached to the inner lip of the crest of the ilium for approximately 5 cm. The sacrolumbar ligament is generally inseparable from the iliolumbar ligament and is regarded as part of it.

Foramens

Several foramens are present in the bony pelvis. The sacrospinous ligament separates the greater from the lesser sciatic foramen. These foramens are subdivisions of a large space intervening between the sacrotuberous ligament and the femur. The piriformis muscle passes out of the pelvis into the thigh by way of the greater sciatic foramen, accompanied by the gluteal vessels and nerves. The internal pudendal vessels, the pudendal nerve, and the nerve to the obturator internus muscle also leave the pelvis by this foramen, after which they enter the perineal region through the lesser sciatic foramen. The obturator internus muscle passes out of the pelvis by way of the lesser sciatic foramen.

The obturator foramen is situated between the ischium and the pubis. The obturator membrane occupies the obturator foramen and is attached continuously to the inner surface of the bony margin except above, where it bridges the obturator sulcus, converting the latter into the obturator canal, which provides passage for the obturator nerve and vessels.

On either side of the central part of the pelvic surface of the sacrum are 4 anterior sacral foramens that transmit the first 4 sacral nerves. Corresponding to these on the dorsal surface are the 4 posterior sacral foramens for transmission of the small posterior rami of the first 4 sacral nerves.

TYPES OF PELVES

Evaluation of the pelvis is best achieved by using the criteria set by Caldwell and Moloy, which are predicated upon 4 basic types of pelves: (1) the gynecoid type (from Greek *gyne* meaning woman); (2) the android type (from Greek *aner* meaning man); (3) the anthropoid type (from Greek *anthropos* meaning human); and (4) the platypelloid type (from Greek *platys* meaning broad and *pella* meaning bowl) (Fig. 1–12).

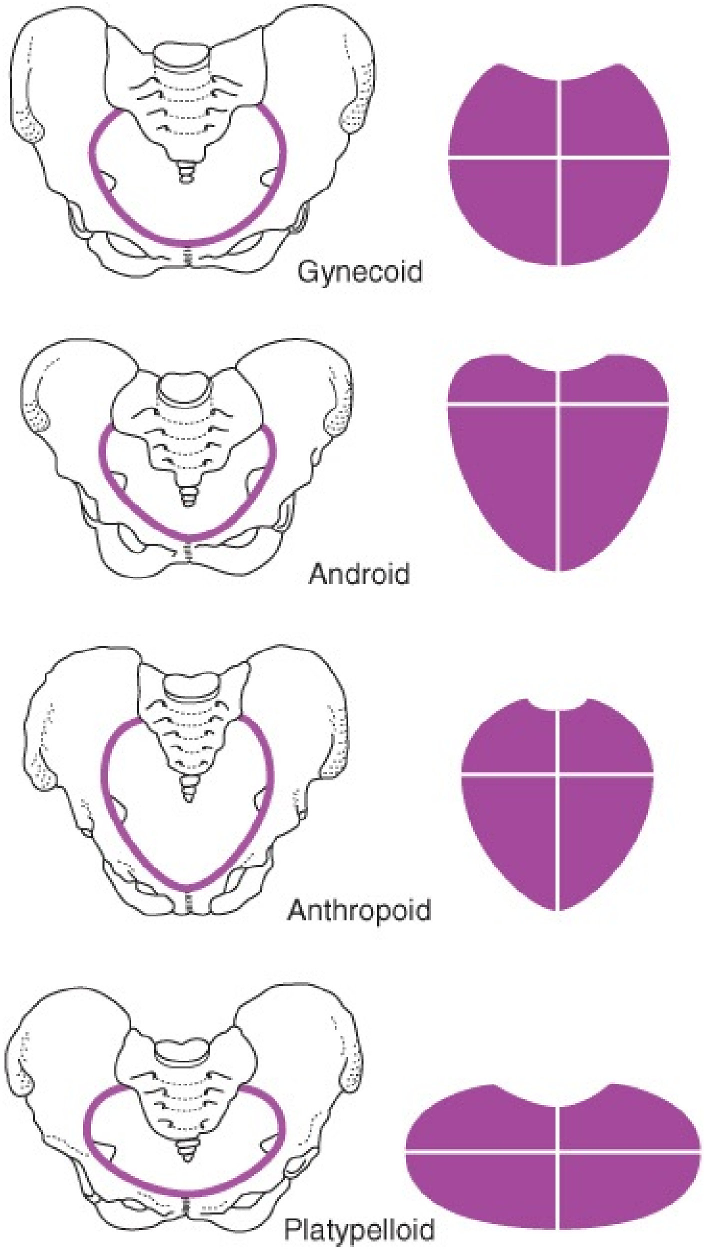

Figure 1–12. Types of pelves. White lines in the diagrams at right (after Steele) show the greatest diameters of the pelves at left. (Reproduced, with permission, from Benson RC. *Handbook of Obstetrics & Gynecology*. 8th ed. Los Altos, CA: Lange; 1983.)

Gynecoid

In pure form, the gynecoid pelvis provides a rounded, slightly ovoid, or elliptical inlet with a well-rounded forepelvis (anterior segment). This type of pelvis has a well-rounded, spacious posterior segment, an adequate sacrosciatic notch, a hollow sacrum with a somewhat backward sacral inclination, and a Norman-type arch of the pubic rami. The gynecoid pelvis has straight side walls and wide interspinous and intertuberous diameters. The bones are primarily of medium weight and structure.

Android

The android pelvis has a wedge-shaped inlet, a narrow fore-pelvis, a flat posterior segment, and a narrow sacrosciatic notch, with the sacrum inclining forward. The side walls converge, and the bones are medium to heavy in structure.

Anthropoid

The anthropoid pelvis is characterized by a long, narrow, oval inlet; an extended and narrow anterior and posterior segment; a wide sacrosciatic notch; and a long, narrow sacrum, often with 6 sacral segments. The subpubic arch may be an angled Gothic type or rounded Norman type. Straight side walls are characteristic of the anthropoid pelvis, whose interspinous and intertuberous diameters are less than those of the average gynecoid pelvis. A medium bone structure is usual.

Platypelloid

The platypelloid pelvis has a distinct oval inlet with a very wide, rounded retropubic angle and a wider, flat posterior segment. The sacrosciatic notch is narrow and has a normal sacral inclination, although it is often short. The subpubic arch is very wide, and the side walls are straight, with wide interspinous and intertuberous diameters.

The pelvis in any individual case may be one of the 4 “pure” types or a combination of mixed types. When one discusses the intermediate pelvic forms, the posterior segment with its characteristics generally is described first and the anterior segment with its characteristics next (eg, anthropoid-gynecoid, android-anthropoid, or platypelloid-gynecoid). It is impossible to have a platypelloid-anthropoid pelvis or a platypelloid-android pelvis.

Pelvic Relationships

Several important relationships should be remembered, beginning with those at the inlet of the pelvis. The transverse diameter of the inlet is the widest diameter, where bone is present for a circumference of 360 degrees. This diameter stretches from pectineal line to pectineal line and denotes the separation of the posterior and anterior segments of the pelvis. In classic pelves (gynecoid), a vertical plane dropped from the transverse diameter of the inlet passes through the level of the interspinous diameter at the ischial spine.

These relationships may not hold true, however, in combination or intermediate (mixed type) pelves. The anterior transverse diameter of the inlet reaches from pectineal prominence to pectineal prominence; a vertical plane dropped from the anterior transverse passes through the ischial tuberosities. For good function of the pelvis, the anterior transverse diameter should never be more than 2 cm longer than the transverse diameter (Fig. 1–13).

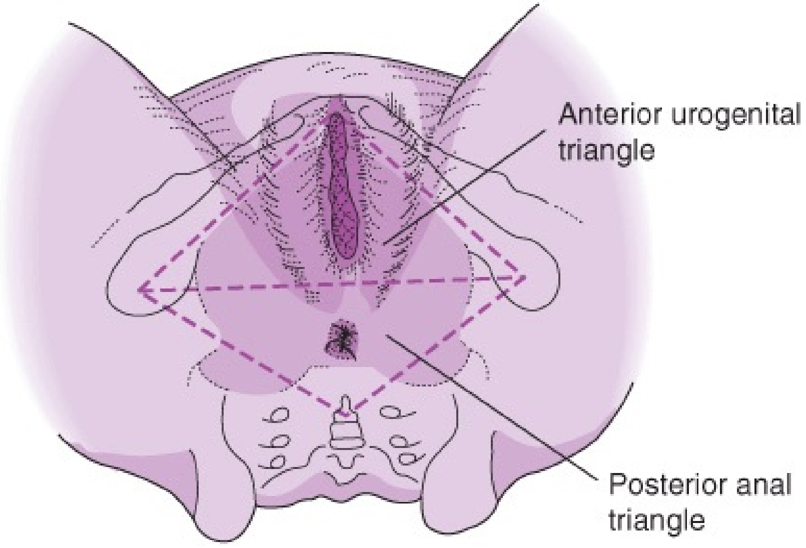

Figure 1–13. Urogenital and anal triangles.

Obstetric Conjugate

The obstetric conjugate differs from both the diagonal conjugate and the true conjugate. It is represented by a line drawn from the posterior superior portion of the pubic symphysis (where bone exists for a circumference of 360 degrees) toward intersection with the sacrum. This point need not be at the promontory of the sacrum. The obstetric conjugate is divided into 2 segments: (1) the anterior sagittal, originating at the intersection of the obstetric conjugate with the transverse diameter of the inlet and terminating at the symphysis pubica; and (2) the posterior sagittal, originating at the transverse diameter of the inlet to the point of intersection with the sacrum.

Interspinous Diameter

A most significant diameter in the midpelvis is the interspinous diameter. It is represented by a plane passing from ischial spine to ischial spine. The posterior sagittal diameter of the midpelvis is a bisecting line drawn at a right angle from the middle of the interspinous diameter, in the same plane, to a point of intersection with the sacrum. This is the point of greatest importance in the midpelvis. It is sometimes said that the posterior sagittal diameter should be drawn from the posterior segment of the intersecting line of the interspinous diameter, in a plane from the inferior surface of the symphysis, through the interspinous diameter to the sacrum. However, this configuration often places the posterior sagittal diameter lower in the pelvis than the interspinous diameter. It is the interspinous diameter, together with the posterior sagittal diameter of the midpelvis, that determines whether or not there is adequate room for descent and extension of the head during labor.

Intertuberous Diameter

The intertuberous diameter of the outlet will reflect the length of the anterior transverse diameter of the inlet (ie, the former cannot be larger than the latter if convergent or straight side walls are present). Therefore, the intertuberous diameter determines the space available in the anterior segment of the pelvis at the inlet, and, similarly, the degree of convergence influences the length of the biparietal diameter at the outlet.

Posterior Sagittal Diameter

The posterior sagittal diameter of the outlet is an intersecting line drawn from the middle of the intertuberous diameter to the sacrococcygeal junction and reflects the inclination of the sacrum toward the outlet for accommodation of the head at delivery. It should be noted that intricate measurements of the pelvis are significant only at minimal levels. Evaluation of the pelvis for a given pregnancy, size of the fetus for a given pelvis, and conduct of labor engagement are far more important.

Outlets of the True Pelvis

The true pelvis is said to have an upper “inlet” and a lower “outlet.” The pelvic inlet to the pelvis minor is bounded, beginning posteriorly, by (1) the promontory of the sacrum; (2) the linea terminalis, composed of the anterior margin of the ala sacralis, the arcuate line of the ilium, and the pecten ossis pubis; and (3) the upper border or crest of the pubis, ending medially at the symphysis. The conjugate or the anteroposterior diameter is drawn from the center of the promontory to the symphysis pubica, with 2 conjugates recognized: (1) the true conjugate, measured from the promontory to the top of the symphysis; and (2) the diagonal conjugate, measured from the promontory to the bottom of the symphysis.

The transverse diameter is measured through the greatest width of the pelvic inlet. The oblique diameter runs from the sacroiliac joint of one side to the iliopectineal eminence of the other. The pelvic outlet, which faces downward and slightly backward, is very irregular. Beginning anteriorly, it is bounded by (1) the arcuate ligament of the pubis (in the midline), (2) the ischiopubic arch, (3) the ischial tuberosity, (4) the sacrotuberous ligament, and (5) the coccyx (in mid-line). Its anteroposterior diameter is drawn from the lower border of the symphysis pubica to the tip of the coccyx. The transverse diameter passes between the medial surfaces of the ischial tuberosities.

INGUINAL REGION

The inguinal region of the abdominal wall is bounded by the rectus abdominis muscle medially, the line connecting the anterior superior iliac spines superiorly, and the inguinal ligament inferiorly. The region contains 8 layers of abdominal wall. These layers, from the most superficial inward, are (1) the skin, (2) the tela subcutanea (subcutaneous tissue), (3) the aponeurosis of the external oblique muscle, (4) the internal oblique muscle, (5) the transversus abdominis muscle (below the free border, the layer is incomplete), (6) the transversalis fascia, (7) the subperitoneal fat and connective tissue, and (8) the peritoneum. The tela subcutanea consists of the superficial fatty Camper’s fascia, which is continuous with the tela subcutanea of the whole body, and the deeper membranous Scarpa’s fascia, which covers the lower third of the abdominal wall and the medial side of the groin, both joining below the inguinal ligament to form the fascia lata of the thigh.

Subcutaneous (External) Inguinal Ring

A triangular evagination of the external oblique aponeurosis, the subcutaneous inguinal ring (external abdominal ring), is bounded by an aponeurosis at its edges and by the inguinal ligament inferiorly. The superior or medial crus is smaller and attaches to the symphysis pubica. The inferior or lateral crus is stronger and blends with the inguinal ligament as it passes to the pubic tubercle. The sharp margins of the ring are attributed to a sudden thinning of the aponeurosis. In the female, the ligamentum teres uteri (round ligament) pass through this ring. The subcutaneous inguinal ring is much smaller in the female than in the male, and the abdominal wall is relatively stronger in this region.

Abdominal (Internal) Inguinal Ring

The abdominal inguinal ring (internal abdominal ring) is the rounded mouth of a funnel-shaped expansion of transversalis fascia that lies approximately 2 cm above the inguinal ligament and midway between the anterior superior iliac spine and the symphysis pubica. Medially, it is bounded by the inferior epigastric vessels; the external iliac artery is situated below. The abdominal inguinal ring represents the area where the round ligament emerges from the abdomen. The triangular area medial to the inferior epigastric artery, bounded by the inguinal ligament below and the lateral border of the rectus sheath, is known as the trigonum inguinale (Hesselbach’s triangle), the site of congenital direct hernias.

Inguinal Canal

The inguinal canal in the female is not well demarcated, but it normally gives passage to the round ligament of the uterus, a vein, an artery from the uterus that forms a cruciate anastomosis with the labial arteries, and extraperitoneal fat. The fetal ovary, like the testis, is an abdominal organ and possesses a gubernaculum that extends from its lower pole downward and forward to a point corresponding to the abdominal inguinal ring, through which it continues into the labia majora.

The processus vaginalis is an evagination of peritoneum at the level of the abdominal inguinal ring occurring during the third fetal month. In the male, the processus vaginalis descends with the testis. The processus vaginalis of the female is rudimentary, but occasionally a small diverticulum of peritoneum is found passing partway through the inguinal region; this diverticulum is termed the processus vaginalis peritonei (canal of Nuck). Instead of descending, as does the testis, the ovary moves medially, where it becomes adjacent to the uterus.

The intraabdominal portion of the gubernaculum ovarii becomes attached to the lateral border of the developing uterus, evolving as the ligament of the ovary and the round ligament of the uterus. The extra-abdominal portion of the round ligament of the uterus becomes attenuated in the adult and may appear as a small fibrous band. The inguinal canal is an intermuscular passageway that extends from the abdominal ring downward, medially, and somewhat forward to the subcutaneous inguinal ring (about 3–4 cm). The canal is roughly triangular in shape, and its boundaries are largely artificial. The lacunar and inguinal ligaments form the base of the canal. The anterior or superficial wall is formed by the external oblique aponeurosis, and the lowermost fibers of the internal oblique muscle add additional strength in its lateral part. The posterior or deep wall of the canal is formed by transversalis fascia throughout and is strengthened medially by the falx inguinalis.

Abdominal Fossae

The abdominal fossae in the inguinal region consist of the foveae inguinalis lateralis and medialis. The fovea inguinalis lateralis lies lateral to a slight fold, the plica epigastrica, formed by the inferior epigastric vessels, and just medial to the abdominal inguinal ring, which slants medially and upward toward the rectus muscle. From the lateral margin of the tendinous insertion of the rectus muscle, upward toward the umbilicus, and over the obliterated artery extends a more accentuated fold, the plica umbilicalis lateralis. The fovea inguinalis medialis lies between the plica epigastrica and the plica umbilicalis lateralis, with the bottom of the fossa facing the trigonum inguinale (Hesselbach’s triangle). This region is strengthened by the interfoveolar ligament at the medial side of the abdominal inguinal ring and the conjoined tendon lateral to the rectus muscle; however, these bands vary in width and thus are supportive.

Ligaments & Spaces

The falx inguinalis or conjoined tendon is formed by the aponeurosis of the transversus abdominis and internal oblique muscles. These fibers arise from the inguinal ligament and arch downward and forward to insert on the pubic crest and pecten ossis pubis, behind the inguinal and lacunar ligaments. The interfoveolar ligament is composed partly of fibrous bands from the aponeurosis of the transversalis muscle of the same and opposite sides. Curving medial to and below the internal abdominal ring, they attach to the lacunar ligament and pectineal fascia.

The inguinal ligament itself forms the inferior thickened border of the external oblique aponeurosis, extending from the anterior superior iliac spine to the pubic tubercle. Along its inferior border, it becomes continuous with the fascia lata of the thigh. From the medial portion of the inguinal ligament, a triangular band of fibers attaches separately to the pecten ossis pubis. This band is known as the lacunar (Gimbernat’s) ligament. The reflex inguinal ligament (ligament of Colles or triangular fascia) is represented by a small band of fibers, often poorly developed, and derived from the superior crus of the subcutaneous inguinal ring and the lower part of the linea alba. These fibers cross to the opposite side to attach to the pecten ossis pubis. The inguinal ligament forms the roof of a large osseoligamentous space leading from the iliac fossa to the thigh. The floor of this space is formed by the superior ramus of the pubis medially and by the body of the ilium laterally.

The iliopectineal ligament extends from the inguinal ligament to the iliopectineal eminence, dividing this area into 2 parts. The lateral, larger division is called the muscular lacuna and is almost completely filled by the iliopsoas muscle, along with the femoral nerve medially and the lateral femoral cutaneous nerves laterally. The medial, smaller division is known as the vascular lacuna and is traversed by the external iliac (femoral) artery, vein, and lymphatic vessels, which do not completely fill the space. The anterior border of the vascular lacuna is formed by the inguinal ligament and the transversalis fascia. The posterior boundary is formed by the ligamentum pubicum superius (Cooper's ligament), a thickening of fascia along the public pecten where the pectineal fascia and iliopectineal ligament meet.

The transversalis fascia and iliac fascia are extended with the vessels, forming a funnel-shaped fibrous investment, the femoral sheath. The sheath is divided into 3 compartments: (1) the lateral compartment, containing the femoral artery; (2) the intermediate compartment, containing the femoral vein; and (3) the medial compartment or canal, containing a lymph node (nodi lymphatici inguinales profundi [node of Rosenmüller or Cloquet]) and the lymphatic vessels that drain most of the leg, groin, and perineum.

The femoral canal also contains areolar tissue, which frequently condenses to form the "femoral septum." Because of the greater spread of the pelvis in the female, the muscular and vascular lacunae are relatively large spaces. The upper or abdominal opening of the femoral canal is known as the femoral ring and is covered by the parietal peritoneum.

Arteries

In front of the femoral ring, the arterial branches of the external iliac artery are the inferior epigastric and the deep circumflex iliac. The inferior epigastric artery arises from the anterior surface of the external iliac, passing forward and upward on the anterior abdominal wall between peritoneum and transversalis fascia. It pierces the fascia just below the arcuate line, entering the rectus abdominis muscle or coursing along its inferior surface to anastomose with the superior epigastric from the internal thoracic. The inferior epigastric artery forms the lateral boundary of the trigonum inguinale (Hesselbach's triangle). At its origin, it frequently gives off a branch to the inguinal canal, as well as a branch to the pubis (pubic artery), which anastomoses with twigs of the obturator artery. The pubic branch of the inferior epigastric often becomes the obturator artery.

The deep circumflex iliac artery arises laterally and traverses the iliopsoas to the anterior superior iliac spine, where it pierces the transversus muscle to course between the transversus and the internal oblique, sending perforators to the surface. It often has anastomoses with penetrating branches of the inferior epigastric via its perforators through the rectus abdominis. The veins follow a similar course.

As the external iliac artery passes through the femoral canal, which underlies the inguinal ligament, it courses medial to the femoral vein and nerve, resting in what is termed the femoral triangle (Scarpa's triangle). The femoral sheath is a downward continuation of the inguinal ligament anterior to the femoral vessel and nerve.

The branches of the femoral artery supplying the groin are (1) the superficial epigastric, (2) the superficial circumflex iliac, (3) the superficial external pudendal, and (4) the deep external pudendal. The superficial epigastric artery passes upward through the femoral sheath over the inguinal ligament, to rest in Camper's fascia on the lower abdomen. The superficial circumflex iliac artery arises adjacent to the superior epigastric, piercing the fascia lata and running parallel to the inguinal ligament as far as the iliac crest. It then divides into branches that supply the integument of the groin, the superficial fascia, and the lymph glands, anastomosing with the deep circumflex iliac, the superior gluteal, and the lateral femoral circumflex arteries.

The superficial external pudendal artery arises from the medial side of the femoral artery, close to the preceding vessels. It pierces the femoral sheath and fascia cribrosa, coursing medially across the round ligament to the integument on the lower part of the abdomen and the labium majus, anastomosing with the internal pudendal. The deep external pudendal artery passes medially across the pectineus and adductor longus muscles, supplying the integument of the labium majus and forming, together with the external pudendal artery, a rete with the labial arteries.

Hernias

A hernia (Fig. 1–14) is a protrusion of any viscus from its normal enclosure, which may occur with any of the abdominal viscera, especially the jejunum, ileum, and greater omentum. A hernia may be due to increased pressure, such as that resulting from strenuous exercise, lifting heavy weights, tenesmus, or increased expiratory efforts, or it may result from decreased resistance of the abdominal wall (congenital or acquired), such as occurs with debilitating illness or old age, prolonged distention from ascites, tumors, pregnancy, corpulence, emaciation, injuries (including surgical incisions), congenital absence, or poor development. Hernias are likely to occur where the abdominal wall is structurally weakened by the passage of large vessels or nerves and developmental peculiarities. Ventral hernias occur through the linea semilunaris or the linea alba.

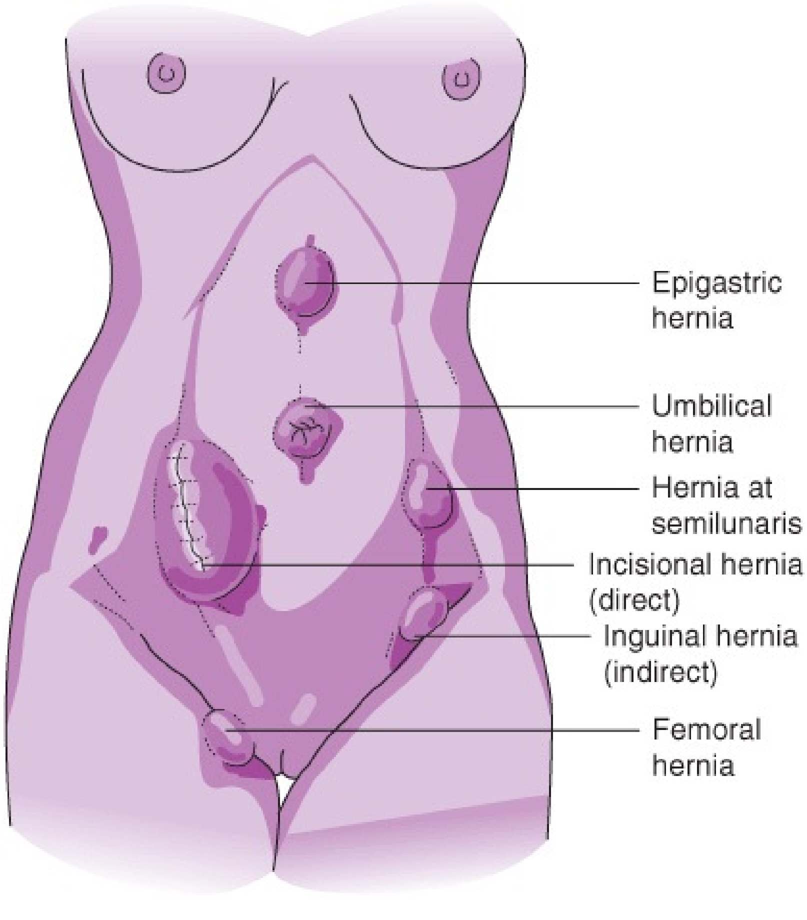

Figure 1–14. Hernia sites.

During early fetal development, portions of the mesentery and a loop of the intestine pass through the opening to occupy a part of the body cavity (the umbilical coelom) situated in the umbilical cord. Normally, the mesentery and intestine later return to the abdominal cavity. If they fail to do so, a congenital umbilical hernia results. Infantile umbilical hernias occur if the component parts fail to fuse completely in early postnatal stages. The unyielding nature of the fibrous tissue forming the margin of the ring predisposes to strangulation.

NERVES OF THE PELVIS

The pelvic autonomic system can be divided into the superior hypogastric plexus (the presacral plexus and the uterinus magnus), the middle hypogastric plexus, and the inferior hypogastric plexus. The superior hypogastric plexus begins just below the inferior mesenteric artery. It is composed of 1–3 intercommunicating nerve bundles connected with the inferior mesenteric ganglia, but no ganglia are an integral part of the plexus. The intermesenteric nerves receive branches from the lumbar sympathetic ganglia.

Superior Hypogastric Plexus

The superior hypogastric plexus continues into the mid-hypogastric plexus. The presacral nerves spread out into a latticework at the level of the first sacral vertebra, with connecting rami to the last of the lumbar ganglia. The greater part of the superior mid-hypogastric plexus may be found to the left of the midline.

Inferior Hypogastric Plexus

At the first sacral vertebra, this plexus divides into several branches that go to the right and left sides of the pelvis. These branches form the beginning of the right and left inferior hypogastric plexus. The inferior hypogastric plexus, which is the divided continuation of the mid-hypogastric plexus, the superior hypogastric plexus, the presacral nerve, and the uterinus magnus, is composed of several parallel nerves on each side. This group of nerves descends within the pelvis in a position posterior to the common iliac artery and anterior to the sacral plexus, curves laterally, and finally enters the sacrouterine fold or ligaments. The medial section of the primary division of the sacral nerves sends fibers (nervi erigentes) that enter the pelvic plexus in the sacrouterine folds. The plexus now appears to contain both sympathetic (inferior hypogastric plexus) and parasympathetic (nervi erigentes) components.

Nervi Erigentes

The sensory components, which are mostly visceral, are found in the nervi erigentes; however, if one takes into account the amount of spinal anesthetic necessary to eliminate uterine sensation, one must assume that there are a number of sensory fibers in the sympathetic component.

Common Iliac Nerves

The common iliac nerves originate separately from the superior hypogastric plexus and descend on the surface of the artery and vein, one part going through the femoral ring and the remainder following the internal iliac, finally rejoining the pelvic plexus.

Hypogastric Ganglion

On either side of the uterus, in the base of the broad ligament, is the large plexus described by Lee and Frankenhäuser, the so-called hypogastric ganglion. The plexus actually consists of ganglia and nerve ramifications of various sizes, as well as branches of the combined inferior hypogastric plexus and the nervi erigentes. It lies parallel to the lateral pelvic wall, its lateral surface superficial to the internal iliac and its branches; the ureter occupies a position superficial to the plexus. The middle vesical artery perforates and supplies the plexus, its medial branches supplying the rectal stalk. The greater part of the plexus terminates in large branches that enter the uterus in the region of the internal os, while another smaller component of the plexus supplies the vagina and the bladder. The branches of the plexus that supply the uterus enter the isthmus primarily through the sacrouterine fold or ligament.

In the isthmus, just outside the entrance to the uterus, ascending rami pass out into the broad ligament to enter the body of the uterus at higher levels—besides supplying the uterine tubes. A part of the inferior hypogastric plexus may pass directly to the uterus without involvement in the pelvic plexus.

Ganglia are in close proximity to the uterine arteries and the ureters, in the adventitia of the bladder and vagina, and in the vesicovaginal septum. The nerve bundles entering the ganglia contain both myelinated and unmyelinated elements. Corpuscula lamellosa (Vater-Pacini corpuscles) may be found within the tissues and are often observed within nerve bundles, especially within those in the lower divisions of the plexus. Both myelinated and unmyelinated nerves are present within the uterus. The nerves enter along the blood vessels, the richest supply lying in the isthmic portion of the uterus. The fibers following the blood vessels gradually diminish in number in the direction of the fundus, where the sparsest distribution occurs. The fibers run parallel to the muscle bundles, and the nerves frequently branch to form a syncytium before terminating on the sarcoplasm as small free nerve endings.

Sensory Corpuscles

Vater-Pacini corpuscles (corpuscula lamellosa) are present outside the uterus. Dogiel and Krause corpuscles (corpuscula bulboidea) appear in the region of the endocervix. They may also be found in the broad ligament along with Vater-Pacini corpuscles and at the juncture of the uterine arteries with the uterus. These corpuscles may act to modulate the stretch response that reflexively stimulates uterine contractions during labor.

The innervation of the cervix shows occasional free endings entering papillae of the stratified squamous epithelium of the pars vaginalis. The endocervix contains a rich plexus of free endings that is most pronounced in the region of the internal os. The endocervix and the isthmic portion of the uterus in the nonpregnant state both contain the highest number of nerves and blood vessels of any part of the uterus. The presence here of a lamellar type of corpuscle has already been noted.

Nerves pass through the myometrium and enter the endometrium. A plexus with penetrating fibers involving the submucosal region is present in the basal third of the endometrium, with branches terminating in the stroma, in the basilar arterioles, and at the origin of the spiral arterioles. The outer two-thirds of the endometrium are devoid of nerves.

STRUCTURES LINING THE PELVIS

The walls of the pelvis minor are made up of the following layers: (1) the peritoneum, (2) the subperitoneal or extraperitoneal fibroareolar layer, (3) the fascial layer, and (4) the muscular layer. The anatomy of the floor of the pelvis is comparable to that of the walls except for the absence of an osseoligamentous layer.

Peritoneum

The peritoneum presents several distinct transverse folds that form corresponding fossae on each side. The most anterior is a variable fold, the transverse vesical, extending from the bladder laterally to the pelvic wall. It is not the superficial covering of any definitive structure. Behind it lies the broad ligament, which partially covers and aids in the support of the uterus and adnexa.

Ligaments

The broad ligament extends from the lateral border on either side of the uterus to the floor and side walls of the pelvis. It is composed of 2 layers, anterior and posterior, the anterior facing downward and the posterior facing upward, conforming to the position of the uterus. The inferior or “attached” border of the broad ligament is continuous with the parietal peritoneum on the floor and on the side walls of the pelvis. Along this border, the posterior layer continues laterally and posteriorly in an arc to the region of the sacrum, forming the uterosacral fold. Another fold—the rectouterine fold—frequently passes from the posterior surface of the cervix to the rectum in the midline.

The anterior layer of the broad ligament is continuous laterally along the inferior border with the peritoneum of the paravesical fossae and continuous medially with peritoneum on the upper surface of the bladder. Both layers of the attached border continue up the side walls of the pelvis to join with a triangular fold of peritoneum, reaching to the brim of the pelvis to form the suspensory ligament of the ovary or infundibular ligament. This ligament contains the ovarian vessels and nerves. The medial border of the broad ligament on either side is continuous with the peritoneal covering on both uterine surfaces. The 2 layers of the ligament separate to partially contain the uterus, and the superior or “free” border, which is laterally continuous with the suspensory ligament of the ovary, envelops the uterine tube.

The broad ligament can be divided into regions as follows: (1) a larger portion, the mesometrium, which is associated especially with the lateral border of the uterus; (2) the mesovarium, the fold that springs from the posterior layer of the ovary; and (3) the thin portion, the mesosalpinx, which is associated with the fallopian tube in the region of the free border. The superior lateral corner of the broad ligament has been referred to as the suspensory ligament of the ovary, or infundibulopelvic ligament, because it suspends the infundibulum as well as the ovary.

Fossae & Spaces

Corresponding to the peritoneal folds are the peritoneal fossae. The prevesical or retropubic space is a potential space that is crossed by the transverse vesical fold. It is situated in front of the bladder and behind the pubis. When the bladder is displaced posteriorly, it becomes an actual space, anteriorly continuous from side to side and posteriorly limited by a condensation of fatty areolar tissue extending from the base of the bladder to the side wall of the pelvis.

The vesicouterine pouch is a narrow cul-de-sac between the anterior surface of the body of the uterus and the upper surface of the bladder when the uterus is in normal ante-flexed position. In the bottom of this pouch, the peritoneum is reflected from the bladder onto the uterus at the junction of the cervix and corpus. Therefore, the anterior surface of the cervix is below the level of the peritoneum and is connected with the base of the bladder by condensed areolar tissue.

The peritoneum on the posterior surface of the body of the uterus extends downward onto the cervix and onto the posterior fornix of the vagina. It is then reflected onto the anterior surface of the rectum to form a narrow cul-de-sac continuous with the pararectal fossa of either side. The entire space, bounded anteriorly by the cervix and by the fornix in the midline, the uterosacral folds laterally, and the rectum posteriorly, is the rectouterine pouch or cul-de-sac (pouch of Douglas).

Subperitoneal & Fascial Layers

The subperitoneal layer consists of loose, fatty areolar tissue underlying the peritoneum. External to the subperitoneal layer, a layer of fascia lines the wall of the pelvis, covering the muscles and, where these are lacking, blending with the periosteum of the pelvic bones. This layer is known as the parietal pelvic fascia and is subdivided into the obturator fascia, the fascia of the urogenital diaphragm, and the fascia of the piriformis.

The obturator fascia is of considerable thickness and covers the obturator internus muscle. Traced forward, it partially blends with the periosteum of the pubic bone and assists in the formation of the obturator canal. Traced upward, it is continuous at the arcuate line with the iliac fascia. Inferiorly, it extends nearly to the margin of the ischiopubic arch, where it is attached to the bone. In this lower region, it also becomes continuous with a double-layered triangular sheet of fascia, the fasciae of the urogenital diaphragm, passing across the anterior part of the pelvic outlet. A much thinner portion of the parietal pelvic fascia covers the piriformis and coccygeus muscles in the posterior pelvic wall. Medially, the piriformis fascia blends with the periosteum of the sacrum around the margins of the anterior sacral foramens and covers the roots and first branches of the sacral plexus.

Visceral pelvic fascia denotes the fascia in the bottom of the pelvic bowl, which invests the pelvic organs and forms a number of supports that suspend the organs from the pelvic walls. These supports arise in common from the obturator part of the parietal fascia, along or near the arcus tendineus. This arc or line extends from a point near the lower part of the symphysis pubica to the root of the spine of the ischium. From this common origin, the fascia spreads inward and backward, dividing into a number of parts classified as either investing (endopelvic) fascia or suspensory and diaphragmatic fascia.

Muscular Layer

The muscles of the greater pelvis are the psoas major and iliacus. Those of the lesser pelvis are the piriformis, obturator internus, coccygeus, and levator ani; they do not form a continuous layer.

Greater Pelvis

Psoas Major

The fusiform psoas major muscle originates from the 12th thoracic to the fifth lumbar vertebrae. Parallel fiber bundles descend nearly vertically along the side of the vertebral bodies and extend along the border of the minor pelvis, beneath the inguinal ligament, and on toward insertion in the thigh. The medial border inserts into the lesser trochanter, whereas the lateral border shares its tendon with the iliacus muscle. Together with the iliacus, it is the most powerful flexor of the thigh, acting as a lateral rotator of the femur when the foot is off the ground and free and as a medial rotator when the foot is on the ground and the tibia is fixed. The psoas component flexes the spine and the pelvis and abducts the lumbar region of the spine. The psoas, having longer fibers than the iliacus, gives a quicker but weaker pull.

Iliacus

The fan-shaped iliacus muscle originates from the iliac crest, the iliolumbar ligament, the greater part of the iliac fossa, the anterior sacroiliac ligaments, and frequently the ala of the sacrum. It also originates from the ventral border of the ilium between the 2 anterior spines. It is inserted in an oblique manner on the lateral surface of the tendon that emerges from the psoas above the inguinal ligament and directly on the femur immediately distal to the lesser trochanter. The lateral portion of the muscle arising from the ventral border of the ilium is adherent to the direct tendon of the rectus femoris and the capsule of the hip joint.

Lesser Pelvis

Piriformis

The piriformis has its origin from the lateral part of the ventral surface of the second, third, and fourth sacral vertebrae, from the posterior border of the greater sciatic notch, and from the deep surface of the sacrotuberous ligament near the sacrum. The fiber bundles pass through the greater sciatic foramen to insert upon the anterior and inner portion of the upper border of the greater trochanter. The piriformis acts as an abductor, lateral rotator, and weak extensor of the thigh.

Obturator Internus

The obturator internus arises from the pelvic surface of the pubic rami near the obturator foramen, the pelvic surface of the ischium between the foramen and the greater sciatic notch, the deep surface of the obturator internus fascia, the fibrous arch that bounds the canal for the obturator vessels and nerves, and the pelvic surface of the obturator membrane. The fiber bundles converge toward the lesser sciatic notch, where they curve laterally to insert into the trochanteric fossa of the femur. The obturator internus is a powerful lateral rotator of the thigh. When the thigh is bent at a right angle, the muscle serves as an abductor and extensor.

Coccygeus

The coccygeus muscle runs from the ischial spine and the neighboring margin of the greater sciatic notch to the fourth and fifth sacral vertebrae and the coccyx. A large part of the muscle is aponeurotic. It supports the pelvic and abdominal viscera and possibly flexes and abducts the coccyx.

Levator Ani

The levator ani muscle forms the floor of the pelvis and the roof of the perineum. It is divisible into 3 portions: (1) the iliococcygeus, (2) the pubococcygeus, and (3) the puborectalis.

1. Iliococcygeus—The iliococcygeus arises from the arcus tendineus, which extends from the ischial spine to the superior ramus of the pubis near the obturator canal and for a variable distance downward below the obturator canal. Its insertion is into the lateral aspect of the coccyx and the raphe that extends from the tip of the coccyx to the rectum. Many fiber bundles cross the median line.

2. Pubococcygeus—The pubococcygeus arises from the inner surface of the os pubis, the lower margin of the symphysis pubica to the obturator canal, and the arcus tendineus as far backward as the origin of the iliococcygeus. It passes backward, downward, and medially past the urogenital organs and the rectum, inserting into the anterior sacrococcygeal ligament, the deep part of the anococcygeal raphe, and each side of the rectum. The pubococcygeus lies to some extent on the pelvic surface of the insertion of the iliococcygeus.

3. Puborectalis—The puborectalis arises from the body and descending ramus of the pubis beneath the origin of the pubococcygeus, the neighboring part of the obturator fascia, and the fascia covering the pelvic surface of the urogenital diaphragm. Many of the fiber bundles interdigitate with those of the opposite side, and they form a thick band on each side of the rectum behind which those of each side are inserted into the anococcygeal raphe.

The levator ani serves to slightly flex the coccyx, raise the anus, and constrict the rectum and vagina. It resists the downward pressure that the thoracoabdominal diaphragm exerts on the viscera during inspiration.

Pelvic Diaphragm

The pelvic diaphragm (Fig. 1–15) extends from the upper part of the pelvic surface of the pubis and ischium to the rectum, which passes through it. The pelvic diaphragm is formed by the levator ani and coccygeus muscles and covering fasciae. The diaphragmatic fasciae cloaking the levator ani arise from the parietal pelvic fascia (obturator fascia), the muscular layer lying between the fasciae. As viewed from above, the superior fascia is the best developed and is reflected onto the rectum, forming the “rectal sheath.” The coccygeus muscle forms the deeper portion of the posterolateral wall of the ischiorectal fossa, helping to bind the pelvic outlet. The diaphragm presents a hiatus anteriorly, occupied by the vagina and urethra. The pelvic diaphragm is the main support of the pelvic floor; it suspends the rectum and indirectly supports the uterus.

Arteries & Veins

The blood supply to the muscles lining the pelvis is primarily from branches of the hypogastric artery, accompanied by contributions from the external iliac artery. The iliolumbar branch of the hypogastric artery runs upward and laterally beneath the common iliac artery, then beneath the psoas muscle to the superior aperture of the pelvis minor, where it divides into iliac and lumbar branches. The iliac supplies both the iliacus and psoas muscles. It passes laterally beneath the psoas and the femoral nerve and, perforating the iliacus, ramifies in the iliac fossa between the muscle and the bone. It supplies a nutrient artery to the bone and then divides into several branches that can be traced as follows: (1) upward toward the sacroiliac synchondrosis to anastomose with the last lumbar artery, (2) laterally toward the crest of the ilium to anastomose with the lateral circumflex and gluteal arteries, and (3) medially toward the pelvis minor to anastomose with the deep circumflex iliac from the external iliac. The lumbar branch ascends beneath the psoas and supplies that muscle along with the quadratus lumborum. It then anastomoses with the last lumbar artery.

Another branch of the hypogastric artery, the lateral sacral artery, may be represented as 2 distinct vessels. It passes medially in front of the sacrum and turns downward to run parallel with the sympathetic trunk. Crossing the slips of origin of the piriformis muscle, it sends branches to that muscle. On reaching the coccyx, it anastomoses in front of the bone with the middle sacral artery and with the inferior lateral sacral artery of the opposite side. The obturator artery usually arises from the hypogastric, but occasionally it may stem from the inferior epigastric or directly from the external iliac artery. It runs forward and downward slightly below the brim of the pelvis, lying between the peritoneum and endopelvic fascia. Passing through the obturator canal, it emerges and divides into anterior and posterior branches that curve around the margin of the obturator foramen beneath the obturator externus muscle.

When the obturator artery arises from the inferior epigastric or external iliac artery, its proximal relationships are profoundly altered, the vessel coursing near the femoral ring where it may be endangered during operative procedures. The anterior branch of the obturator artery runs around the medial margin of the obturator foramen and anastomoses with both of its posterior branch and the medial circumflex artery. It supplies branches to the obturator muscles. The internal pudendal artery is a terminal branch of the hypogastric artery that arises opposite the piriformis muscle and accompanies the inferior gluteal artery downward to the lower border of the greater sciatic foramen. It leaves the pelvis between the piriformis and coccygeus muscles, passing over the ischial spine to enter the ischiorectal fossa through the small sciatic foramen. Then, running forward through the canalis pudendalis (Alcock’s canal) in the obturator fascia, it terminates by dividing into the perineal artery and the artery of the clitoris.

Within the pelvis, the artery lies anterior to the piriformis muscle and the sacral plexus of nerves, lateral to the inferior gluteal artery. Among the small branches that it sends to the gluteal region are those that accompany the nerve to the obturator internus. Another of its branches, the inferior hemorrhoidal artery, arises at the posterior part of the ischiorectal fossa. Upon perforating the obturator fascia, it immediately breaks up into several branches. Some of them run medially toward the rectum to supply the levator ani muscle. The superior gluteal artery originates as a short trunk from the lateral and back part of the hypogastric artery, associated in origin with the iliolumbar and lateral sacral and sometimes with the inferior gluteal or with the inferior gluteal and the internal pudendal. It leaves the pelvis through the greater sciatic foramen above the piriformis muscle, beneath its vein and in front of the superior gluteal nerve. Under cover of the gluteus maximus muscle, it breaks into a superficial and a deep division.

The deep portion further divides into superior and inferior branches. The inferior branch passes forward between the gluteus medius and minimus toward the greater trochanter, where it anastomoses with the ascending branch of the lateral circumflex. It supplies branches to the obturator internus, the piriformis, the levator ani, and the coccygeus muscles and to the hip joint. The deep circumflex iliac artery arises from the side of the external iliac artery either opposite the epigastric or a little below the origin of that vessel. It courses laterally behind the inguinal ligament, lying between the fascia transversalis and the peritoneum or in a fibrous canal formed by the union of the fascia transversalis with the iliac fascia. It sends off branches that supply the psoas and iliacus muscles, as well as a cutaneous branch that anastomoses with the superior gluteal artery.

VULVA

The vulva consists of the mons pubis, the labia majora, the labia minora, the clitoris, and the glandular structures that open into the vestibulum vaginae (Fig. 1–16). The size, shape, and coloration of the various structures, as well as the hair distribution, vary among individuals and racial groups. Normal pubic hair in the female is distributed in an inverted triangle, with the base centered over the mons pubis. Nevertheless, in approximately 25% of normal women, hair may extend upward along the linea alba. The type of hair is dependent, in part, on the pigmentation of the individual. It varies from heavy, coarse, crinkly hair in black women to sparse, fairly fine, lanugo-type hair in Asian women. The length and size of the various structures of the vulva are influenced by the pelvic architecture, as is the position of the external genitalia in the perineal area. The external genitalia of the female have their exact counterparts in the male.

Labia Majora

Superficial Anatomy

The labia majora are comprised of 2 rounded mounds of tissue, originating in the mons pubis and terminating in the perineum. They form the lateral boundaries of the vulva and are approximately 7–9 cm long and 2–4 cm wide, varying in size with height, weight, race, age, parity, and pelvic architecture. Embryologically, these permanent folds of skin are homologous to the scrotum of the male. Hair is distributed over their surfaces, extending superiorly in the area of the mons pubis from one side to the other. The lateral surfaces are adjacent to the medial surface of the thigh, forming a deep groove when the legs are together. The medial surfaces of the labia majora may oppose each other directly or may be separated by protrusion of the labia minora. The cleft that is formed by this opposition anteriorly is termed the anterior commissure. Posteriorly, the cleft is less clearly defined and termed the posterior commissure. The middle portion of the cleft between the 2 labia is the rima pudendi.

Deep Structures

Underlying the skin is a thin, poorly developed muscle layer called the tunica dartos labialis, the fibers of which course, for the most part, at right angles to the wrinkles of the surface, forming a crisscross pattern. Deep to the dartos layer is a thin layer of fascia, most readily recognizable in the old or the young because of the large amount of adipose and areolar tissue. Numerous sweat glands are found in the labia majora, with the greater number on the medial aspect. In the deeper substance of the labia majora are longitudinal bands of muscle that are continuous with the ligamentum teres uteri (round ligament) as it emerges from the inguinal canal. Occasionally, a persistent processus vaginalis peritonei (canal of Nuck) may be seen in the upper region of the labia. This can occasionally fill with fluid causing a cyst in the canal of Nuck to be present in the labia majora. Complete surgical obliteration of this persistent tract will solve this problem.

Arteries

The arterial supply into the labia majora comes from the internal and external pudendals, with extensive anastomoses. Within the labia majora is a circular arterial pattern originating inferiorly from a branch of the perineal artery, from the external pudendal artery in the anterior lateral aspect, and from a small artery of the ligamentum teres uteri superiorly. The inferior branch from the perineal artery, which originates from the internal pudendal as it emerges from the canalis pudendalis (Alcock’s canal), forms the base of the rete with the external pudendal arteries. These arise from the medial side of the femoral and, occasionally, from the deep arteries just beneath the femoral ring, coursing medially over the pectineus and adductor muscles, to which they supply branches. They terminate in a circular rete within the labium majus, penetrating the fascia lata adjacent to the fossa ovalis and passing over the round ligament to send a branch to the clitoris.

Veins

The venous drainage is extensive and forms a plexus with numerous anastomoses. In addition, the veins communicate with the dorsal vein of the clitoris, the veins of the labia minora, and the perineal veins, as well as with the inferior hemorrhoidal plexus. On each side, the posterior labial veins connect with the external pudendal vein, terminating in the great saphenous vein (saphena magna) just prior to its entrance (saphenous opening) in the fossa ovalis. This large plexus is frequently manifested by the presence of large varicosities during pregnancy.

Lymphatics

The lymphatics of the labia majora are extensive and utilize 2 systems, one lying superficially (under the skin) and the other deeper, within the subcutaneous tissues. From the upper two-thirds of the left and right labia majora, superficial lymphatics pass toward the symphysis and turn laterally to join the medial superficial inguinal nodes. These nodes drain into the superficial inguinal nodes overlying the saphenous fossa. The drainage flows into and through the femoral ring (fossa ovalis) to the nodi lymphatici inguinales profundi (nodes of Rosenmüller or Cloquet; deep subinguinal nodes), connecting with the external iliac chain.

The superficial subinguinal nodes, situated over the femoral trigone, also accept superficial drainage from the lower extremity and the gluteal region. This drainage may include afferent lymphatics from the perineum. In the region of the symphysis pubica, the lymphatics anastomose in a plexus between the right and left nodes. Therefore, any lesion involving the labia majora allows direct involvement of the lymphatic structures of the contralateral inguinal area. The lower part of the labium majus has superficial and deep drainage that is shared with the perineal area. The drainage passes, in part, through afferent lymphatics to superficial subinguinal nodes; from the posterior medial aspects of the labia majora, it frequently enters the lymphatic plexus surrounding the rectum.

Nerves

The innervation of the external genitalia has been studied by many investigators. The iliohypogastric nerve originates from T12 and L1 and traverses laterally to the iliac crest between the transversus and internal oblique muscles, at which point it divides into 2 branches: (1) the anterior hypogastric nerve, which descends anteriorly through the skin over the symphysis, supplying the superior portion of the labia majora and the mons pubis; and (2) the posterior iliac, which passes to the gluteal area.

The ilioinguinal nerve originates from L1 and follows a course slightly inferior to the iliohypogastric nerve, with which it may frequently anastomose, branching into many small fibers that terminate in the upper medial aspect of the labium majus.

The genitofemoral nerve (L1–L2) emerges from the anterior surface of the psoas muscle to run obliquely downward over its surface, branching in the deeper substance of the labium majus to supply the dartos muscle and that vestige of the cremaster present within the labium majus. Its lumboinguinal branch continues downward onto the upper part of the thigh.

From the sacral plexus, the posterior femoral cutaneous nerve, originating from the posterior divisions of S1 and S2 and the anterior divisions of S2 and S3, divides into several rami that, in part, are called the perineal branches. They supply the medial aspect of the thigh and the labia majora. These branches of the posterior femoral cutaneous nerve are derived from the sacral plexus. The pudendal nerve, composed primarily of S2, S3, and S4, often with a fascicle of S1, sends a small number of fibers to the medial aspect of the labia majora. The pattern of nerve endings is illustrated in Table 1–1.

Table 1–1. Quantitative distribution of nerve endings in selected regions of the female genitalia.

[3] Also called corpuscula bulboidea.

Labia Minora

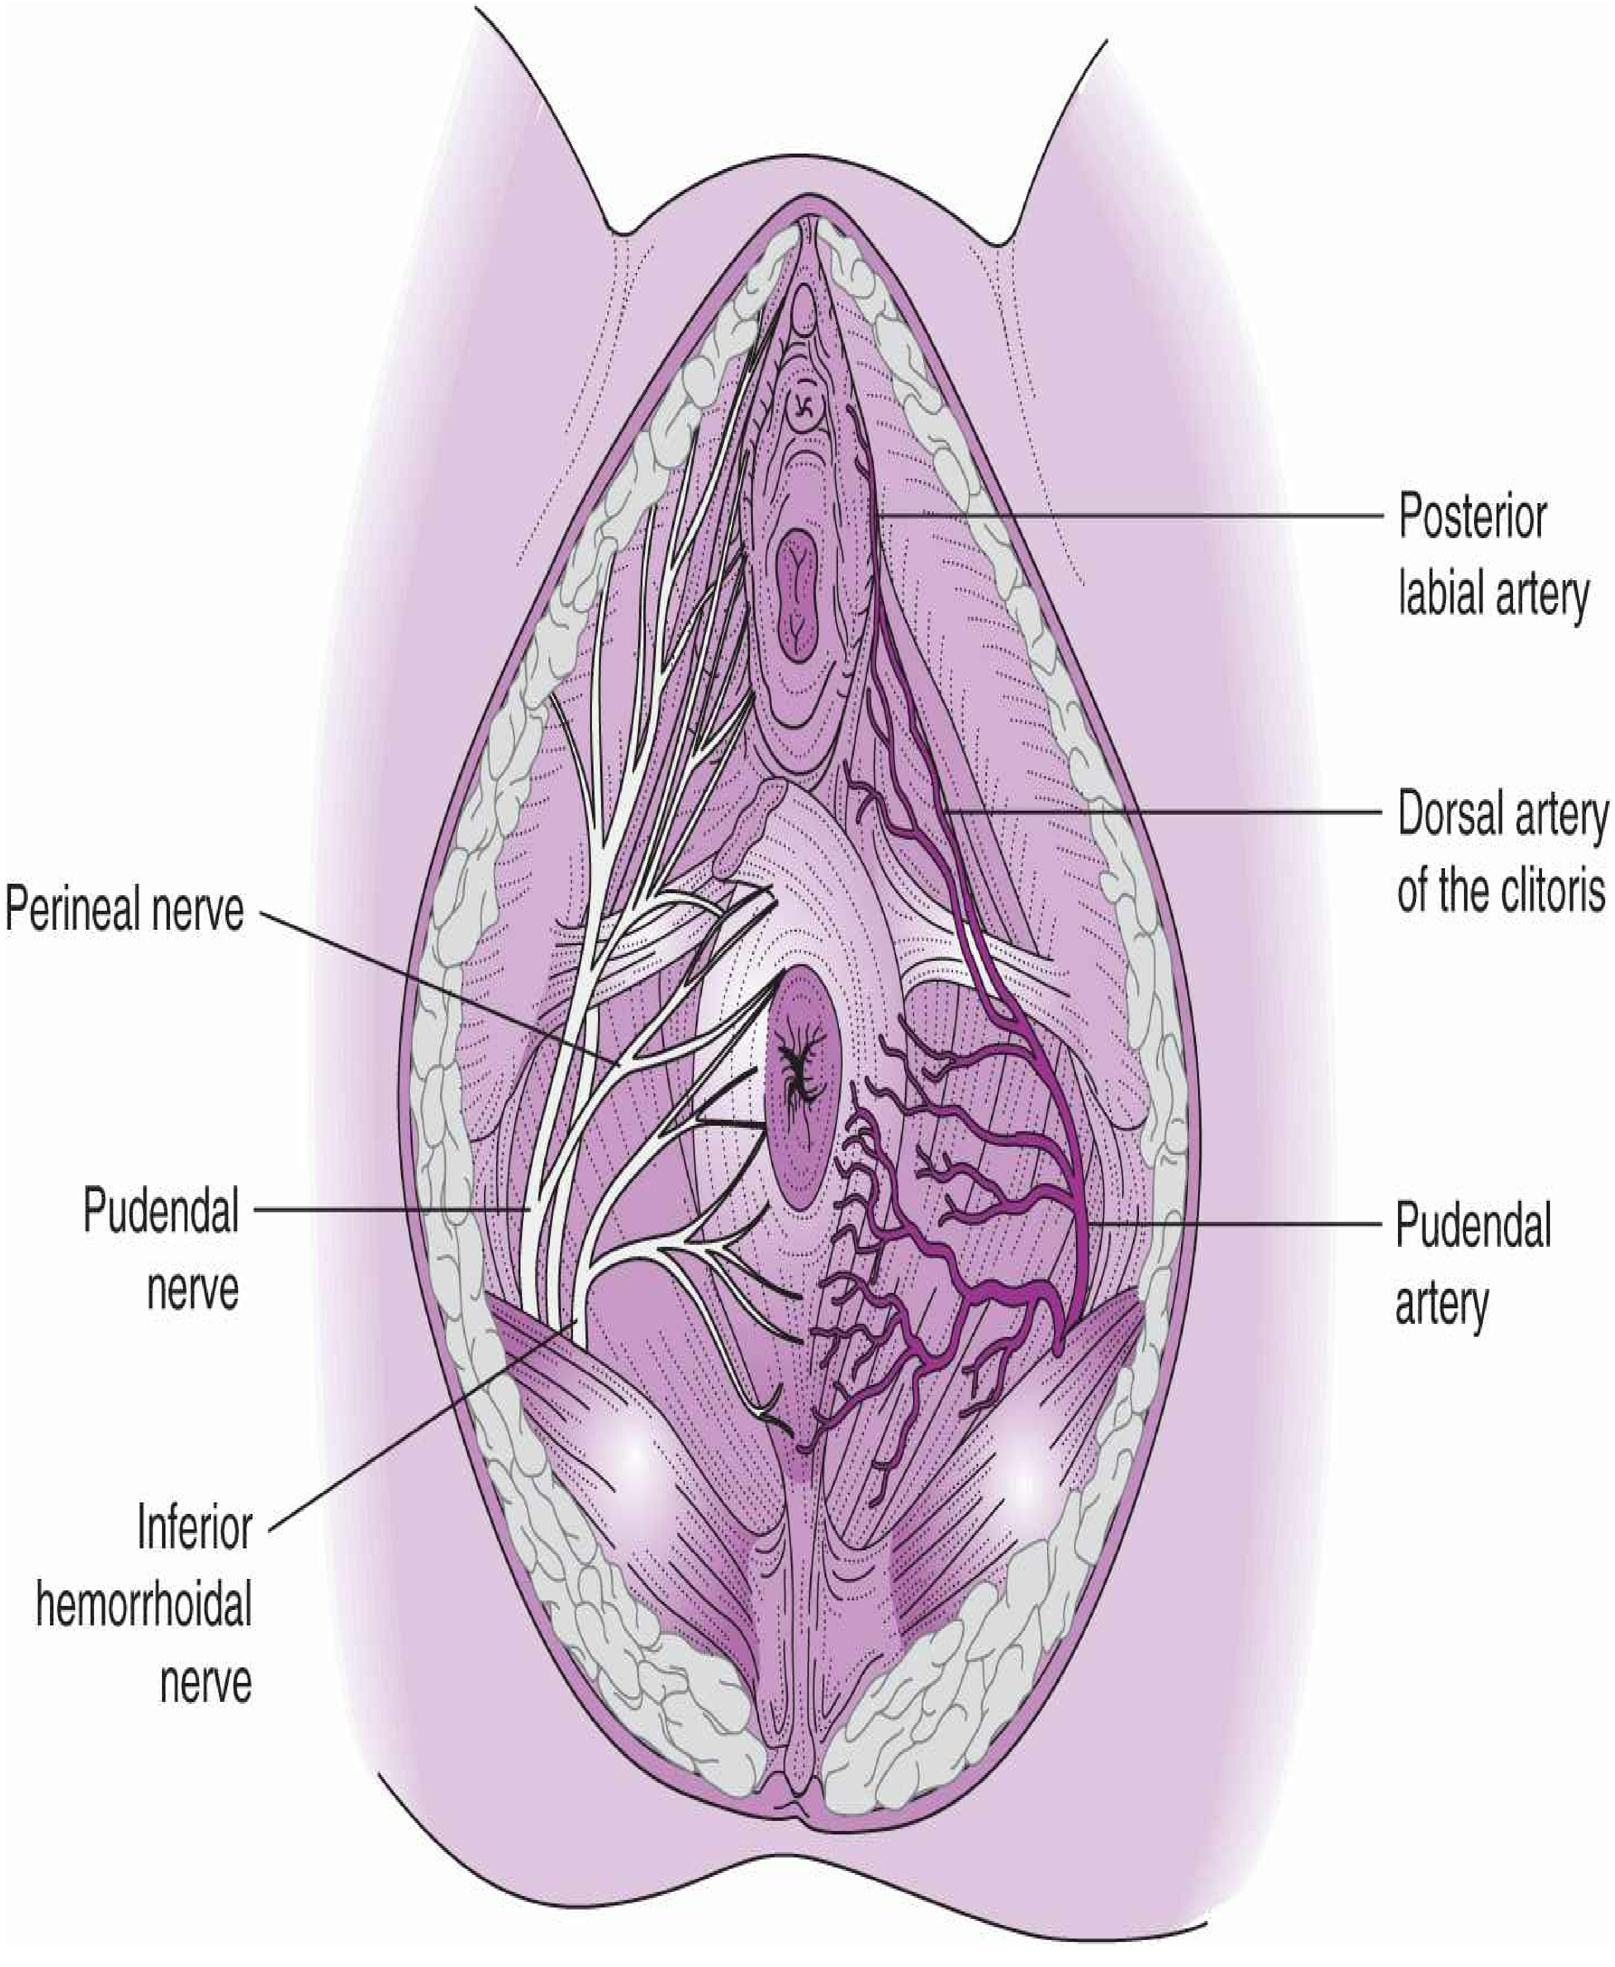
Superficial Anatomy

The labia minora are 2 folds of skin that lie within the rima pudendi and measure approximately 5 cm in length and 0.5–1 cm in thickness. The width varies according to age and parity, measuring 2–3 cm at its narrowest diameter to 5–6 cm at its widest, with multiple corrugations over the surface. The labia minora begin at the base of the clitoris, where fusion of the labia is continuous with the prepuce, extending posteriorly and medially to the labia majora at the posterior commissure. On their medial aspects superiorly beneath the clitoris, they unite to form the frenulum adjacent to the urethra and vagina, terminating along the hymen on the right and left sides of the fossa navicularis and ending posteriorly in the frenulum of the labia pudendi, just superior to the posterior commissure. A deep cleft is formed on the lateral surface between the labium majus and the labium minus.

The skin on the labia minora is smooth, pigmented, and hairless. The color and distention vary, depending on the level of sexual excitement and the pigmentation of the individual. The glands of the labia are homologous to the glandulae preputiales (glands of Littre) of the penile portion of the male urethra.

Arteries

The main source of arterial supply (Fig. 1–17) occurs through anastomoses from the superficial perineal artery, branching from the dorsal artery of the clitoris, and from the medial aspect of the rete of the labia majora. Similarly, the venous pattern and plexus are extensive.



Posterior labial artery
Dorsal artery of the clitoris
Perineal nerve
Pudendal nerve
Pudendal artery
Inferior hemorrhoidal nerve

Figure 1–17. Arteries and nerves of perineum.

Veins

The venous drainage is to the medial vessels of the perineal and vaginal veins, directly to the veins of the labia majora, to the inferior hemorrhoidals posteriorly, and to the clitoral veins superiorly.

Lymphatics

The lymphatics medially may join those of the lower third of the vagina superiorly and the labia majora laterally, passing to the superficial subinguinal nodes and to the deep subinguinal nodes. In the midline, the lymphatic drainage coincides with that of the clitoris, communicating with that of the labia majora to drain to the opposite side.

Nerves

The innervation of the labia minora originates, in part, from fibers that supply the labia majora and from branches of the pudendal nerve as it emerges from the canalis pudendalis (Alcock's canal) (Fig. 1–17). These branches originate from the perineal nerve. The labia minora and the vestibule area are homologous to the skin of the male urethra and penis. The short membranous portion, approximately 0.5 cm of the male urethra, is homologous to the midportion of the vestibule of the female.

Clitoris

Superficial Anatomy

The clitoris is about 2 cm in length and is a homologue to the dorsal part of the penis. It consists of 2 small erectile cavernous bodies, terminating in a rudimentary glans clitoridis. The erectile body, the corpus clitoridis, consists of the 2 crura clitoridis and the glans clitoridis, with overlying skin and prepuce, a miniature homologue of the glans penis. The crura extend outward bilaterally to their position in the anterior portion of the vulva. The cavernous tissue, homologous to the corpus spongiosum penis of the male, appears in the vascular pattern of the labia minora in the female.

At the lower border of the pubic arch, a small triangular fibrous band extends onto the clitoris (suspensory ligament) to separate the 2 crura, which turn inward, downward, and laterally at this point, close to the inferior rami of the pubic symphysis. The crura lie inferior to the ischiocavernosus muscles and bodies. The glans is situated superiorly at the fused termination of the crura. It is composed of erectile tissue and contains an integument, hoodlike in shape, termed the prepuce. On its ventral surface, there is a frenulum clitoridis, the fused junction of the labia minora.

Arteries

The blood supply to the clitoris is from its dorsal artery, a terminal branch of the internal pudendal artery, which is the terminal division of the posterior portion of the internal iliac (hypogastric) artery. As it enters the clitoris, it divides into 2 branches, the deep and dorsal arteries. Just before entering the clitoris itself, a small branch passes posteriorly to supply the area of the external urethral meatus.

Veins

The venous drainage of the clitoris begins in a rich plexus around the corona of the glans, running along the anterior surface to join the deep vein and continuing downward to join the pudendal plexus from the labia minora, labia majora, and perineum, forming the pudendal vein.

Lymphatics

The lymphatic drainage of the clitoris coincides primarily with that of the labia minora, the right and left sides having access to contralateral nodes in the superficial inguinal chain. In addition, its extensive network provides further access downward and posteriorly to the external urethral meatus toward the anterior portion of the vestibule.

Nerves

The innervation of the clitoris is through the terminal branch of the pudendal nerve, which originates from the sacral plexus as previously discussed. It lies on the lateral side of the dorsal artery and terminates in branches within the glans, corona, and prepuce. The nerve endings in the clitoris vary from a total absence within the glans to a rich supply primarily located within the prepuce (Table 1–1). A total absence of endings within the clitoris itself takes on clinical significance when one considers the emphasis placed on the clitoris in discussing problems of sexual gratification in women.

Vestibule

Superficial Anatomy

The area of the vestibule is bordered by the labia minora laterally, by the frenulum labiorum pudendi (or posterior commissure) posteriorly, and by the urethra and clitoris anteriorly. Inferiorly, it is bordered by the hymenal ring. The opening of the vagina or junction of the vagina with the vestibule is limited by a membrane stretching from the posterior and lateral sides to the inferior surface of the external urethral orifice. This membrane is termed the hymen. Its shape and openings vary and depend on age, parity, and sexual experience. The form of the opening may be infantile, annular, semilunar, cribriform, septate, or vertical; the hymen may even be imperforate. In parous women and in the postcoital state, the tags of the hymenal integument are termed carunculae myrtiformes.

The external urethral orifice, which is approximately 2–3 cm posterior to the clitoris, on a slightly elevated and irregular surface with depressed areas on the sides, may appear to be stellate or crescentic in shape. It is characterized by many small mucosal folds around its opening. Bilaterally and on the surface are the orifices of the paraurethral and periurethral glands (ductus paraurethrales [ducts of Skene and Astruc]).

At approximately the 5 and 7 o’clock positions, just external to the hymenal rings, are 2 small papular elevations that represent the orifices of the ducts of the glandulae vestibulares majores or larger vestibular glands (Bartholin) of the female (bulbourethral gland of the male). The fossa navicularis lies between the frenulum labiorum pudendi and the hymenal ring. The skin surrounding the vestibule is stratified squamous in type, with a paucity of rete pegs and papillae.

Arteries

The blood supply to the vestibule is an extensive capillary plexus that has anastomoses with the superficial transverse perineal artery. A branch comes directly from the pudendal anastomosis with the inferior hemorrhoidal artery in the region of the fossa navicularis. The blood supply of the urethra anteriorly, a branch of the dorsal artery of the clitoris and the azygos artery of the anterior vaginal wall, also contributes.

Veins

Venous drainage is extensive, involving the same areas described for the arterial network.

Lymphatics

The lymphatic drainage has a distinct pattern. The anterior portion, including that of the external urethral meatus, drains upward and outward with that of the labia minora and the clitoris. The portion next to the urethral meatus may join that of the anterior urethra, which empties into the vestibular plexus to terminate in the superficial inguinal nodes, the superficial subinguinal nodes, the deep subinguinal nodes, and the external iliac chain. The lymphatics of the fossa navicularis and the hymen may join those of the posterior vaginal wall, intertwining with the intercalated lymph nodes along the rectum, which follow the inferior hemorrhoidal arteries. This pattern becomes significant with cancer. Drainage occurs through the pudendal and the hemorrhoidal chain and through the vestibular plexus onto the inguinal region.

Nerves

The innervation of the vestibular area is primarily from the sacral plexus through the perineal nerve. The absence of the usual modalities of touch is noteworthy. The vestibular portion of the hymenal ring contains an abundance of free nerve endings (pain).

Vestibular Glands

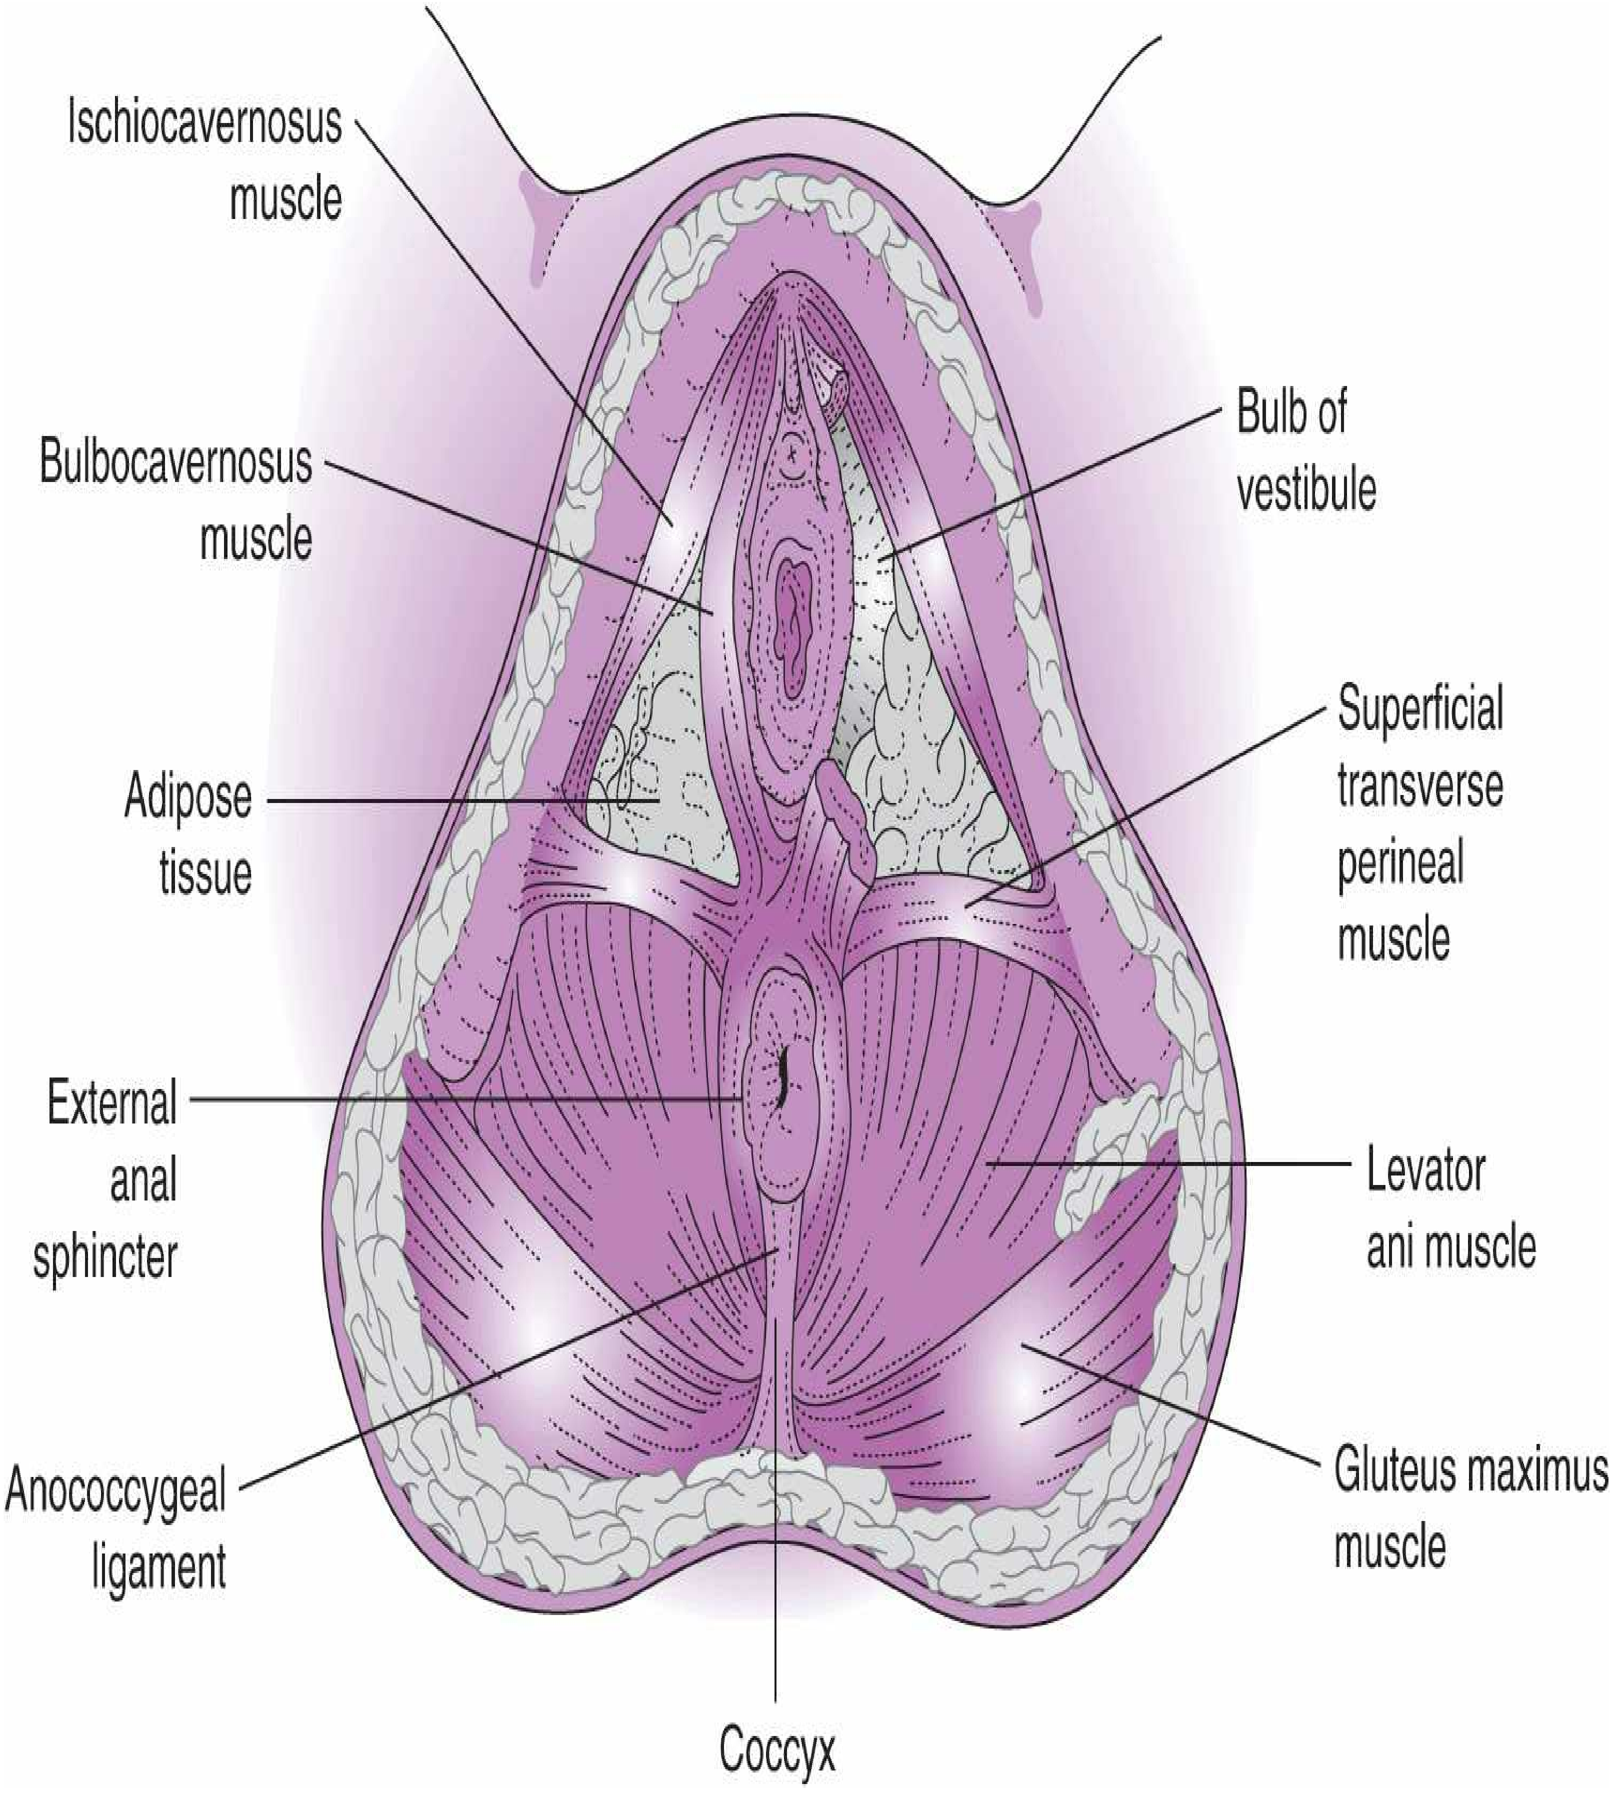
The glandulae vestibulares majores (larger vestibular glands or Bartholin glands) have a duct measuring approximately 5 mm in diameter. The gland itself lies just inferior and lateral to the bulbocavernosus muscle. The gland is tubular and alveolar in character, with a thin capsule and connective tissue septa dividing it into lobules in which occasional smooth muscle fibers are found. The epithelium is cuboid to columnar and pale in color, with the cytoplasm containing mucigen droplets and colloid spherules with acidophilic inclusions. The epithelium of the duct is simple in type, and its orifice is stratified squamous like the vestibule. The secretion is a clear, viscid, and stringy mucoid substance with an alkaline pH. Secretion is active during sexual activity.

The greater vestibular gland is homologous to the bulbourethral gland (also known as Cowper’s glands, Duverney’s glands, Tiedemann’s glands, or the Bartholin glands of the male). If the opening to the gland becomes clogged, then a painful Bartholin’s cyst can develop.

The arterial supply to the greater vestibular gland comes from a small branch of the artery on the bulbocavernosus muscle, penetrating deep into its substance. Venous drainage coincides with the drainage of the bulbocavernosus body. The lymphatics drain directly into the lymphatics of the vestibular plexus, having access to the posterior vaginal wall along the inferior hemorrhoidal channels. They also drain via the perineum into the inguinal area. Most of this minor drainage is along the pudendal vessels in the canalis pudendalis and explains, in part, the difficulty in dealing with cancer involving the gland. The innervation of the greater vestibular gland is from a small branch of the perineal nerve, which penetrates directly into its substance.

Muscles of External Genitalia

The muscles (Fig. 1–18) of the external genitalia and cavernous bodies in the female are homologous to those of the male, although they are less well developed.



Ischiocavernosus muscle
Bulbocavernosus muscle
Adipose tissue
External anal sphincter
Anococcygeal ligament
Bulb of vestibule
Superficial transverse perineal muscle
Levator ani muscle
Gluteus maximus muscle
Coccyx

Figure 1–18. Pelvic musculature (inferior view).

Bulbocavernosus Muscle

The bulbocavernosus muscle and deeper bulbus vestibuli or cavernous tissues arise in the midline from the posterior part of the central tendon of the perineum, where each opposes the fibers from the opposite side. Each ascends around the vagina, enveloping the bulbus vestibuli (the corpus cavernosum bodies of the male) to terminate in 3 heads: (1) the fibrous tissue dorsal to the clitoris, (2) the tunica fibrosa of the corpus cavernosa overlying the crura of the clitoris, and (3) decussating fibers that join those of the ischiocavernosus to form the striated sphincter of the urethra at the junction of its middle and lower thirds.

The blood supply is derived from the perineal branch of the internal pudendal artery as it arises in the anterior part of the ischiorectal fossa. Deep to the fascia diaphragmatis urogenitalis inferior (Colles' fascia) and crossing between the ischiocavernosus and bulbocavernosus muscles, the pudendal artery sends 1–2 branches directly into the bulbocavernosus muscle and vestibular body, continuing anteriorly to terminate in the dorsal artery of the clitoris.

The venous drainage accompanies the pudendal plexus. In addition, it passes posteriorly with the inferior hemorrhoidal veins and laterally with the perineal vein, a branch of the internal pudendal vein. The lymphatics run primarily with those of the vestibular plexus, with drainage inferiorly toward the intercalated nodes of the rectum and anteriorly and laterally with the labia minora and majora to the superficial inguinal nodes. Contralateral drainage in the upper portion of the muscle and body is evident.

Ischiocavernosus Muscle

The ischiocavernosus muscle and its attendant cavernous tissue arise from the ischial tuberosity and inferior ramus to the ischium. It envelops the crus of its cavernous tissue in a thin layer of muscle ascending toward and over the medial and inferior surfaces of the symphysis pubica to terminate in the anterior surface of the symphysis at the base of the clitoris. It then sends decussating fibers to the region of the upper and middle thirds of the urethra, forming the greater part of the organ's voluntary sphincter. The blood supply is through perforating branches from the perineal artery as it ascends between the bulbocavernosus and ischiocavernosus muscles to terminate as the dorsal artery of the clitoris. The innervation stems from an ischiocavernosus branch of the perineal division of the pudendal nerve.

Transversus Muscle

The transversus perinei superficialis muscle arises from the inferior ramus of the ischium and from the ischial tuberosity. The fibers of the muscle extend across the perineum and are inserted into its central tendon, meeting those from the opposite side. Frequently, the muscle fibers from the bulbocavernosus, the puborectalis, the superficial transverse perinei, and occasionally the external anal sphincter will interdigitate. The blood supply is from a perforating branch of the perineal division of the internal pudendal artery, and the nerve supply is from the perineal division of the pudendal nerve.

Inferior Layer of Urogenital Diaphragm

The inferior layer of urogenital diaphragm is a potential space depending upon the size and development of the musculature, the parity of the female, and the pelvic architecture. It contains loose areolar connective tissue interspersed with fat. The bulbocavernosus muscles, with the support of the superficial transverse perinei muscles and the puborectalis muscles, act as a point of fixation on each side for support of the vulva, the external genitalia, and the vagina.

Surgical Considerations

A midline episiotomy is most effective to minimize trauma to vital supports of the vulva, bulbocavernosus, and superficial transverse perinei muscles. Overdistention of the vagina caused by the presenting part and body of the infant forms a temporary sacculation. If distention occurs too rapidly or if dilatation is beyond the resilient capacity of the vagina, rupture of the vaginal musculature may occur, often demonstrated by a cuneiform groove on the anterior wall and a tonguelike protrusion on the posterior wall of the vagina. Therefore, return of the vagina and vulva to the nonpregnant state is dependent upon the tonus of the muscle and the degree of distention of the vagina during parturition.

Special and deliberate consideration should be paid to the repair of the perineal body, the external anal sphincter, and the rectal mucosa. Whether created spontaneously or iatrogenically with episiotomy, lack of proper repair and attention to return of proper anatomic function will result in long-term morbidity with dyspareunia or anal incontinence.

CONTENTS OF THE PELVIC CAVITY

The organs that occupy the female pelvis (Figs. 1–19 to 1–21) are the bladder, the ureters, the urethra, the uterus, the uterine (fallopian) tubes or oviducts, the ovaries, the vagina, and the rectum.* With the exception of the inferior portion of the rectum and most of the vagina, all lie immediately beneath the peritoneum. The uterus, uterine tubes, and ovaries are almost completely covered with peritoneum and are suspended in peritoneal ligaments. The remainder are partially covered. These organs do not completely fill the cavity; the remaining space is occupied by ileum and sigmoid colon.

Bladder

Anatomy

The urinary bladder is a muscular, hollow organ that stores urine and lies posterior to the pubic bones and anterior to the uterus and broad ligament. Its form, size, and position vary with the amount of urine it contains. When empty, it takes the form of a somewhat rounded pyramid, having a base, a vertex (or apex), a superior surface, and a convex inferior surface that may be divided by a median ridge into 2 inferolateral surfaces.

Relationships

The superior surface of the bladder is covered with peritoneum that is continuous with the medial umbilical fold, forming the paravesical fossae laterally. Posteriorly, the peritoneum passes onto the uterus at the junction of the cervix and corpus, continuing upward on the anterior surface to form the vesicouterine pouch. When the bladder is empty, the normal uterus rests upon its superior surface. When the bladder is distended, coils of intestine may lie upon its superior surface. The base of the bladder rests below the peritoneum and is adjacent to the cervix and the anterior fornix of the vagina. It is separated from these structures by areolar tissue containing plexiform veins. The area over the vagina is extended as the bladder fills. The inferolateral surfaces are separated from the wall of the pelvis by the potential prevesical space, containing a small amount of areolar tissue but no large vessels. This surface is nonperitoneal and thus suitable for operative procedures. Posterolateral to the region facing the symphysis, each of the inferolateral surfaces is in relation to the fascia of the obturator internus, the obturator vessels and nerve, the obliterated umbilical artery above, and the fascia of the levator ani below. Posteriorly and medially, the inferior surface is separated from the base by an area called the urethrovesical junction, the most stationary portion of the bladder.

Fascia, Ligaments, & Muscle

The bladder is enclosed by a thin layer of fascia, the vesical sheath. Two thickenings of the endopelvic fascia, the medial and lateral pubovesical or puboprostatic ligaments, extend at the vesicourethral junction abutting the levator ani muscle from the lower part of the anterior aspect of the bladder to the pubic bones. Similar fascial thickenings, the lateral true ligaments, extend from the sides of the lower part of the bladder to the lateral walls of the pelvis. Posteriorly, the vesicourethral junction of the bladder lies directly against the anterior wall of the vagina.

A fibrous band, the urachus or medial umbilical ligament, extends from the apex of the bladder to the umbilicus. This band represents the remains of the embryonic allantois. The lateral umbilical ligaments are formed by the obliterated umbilical arteries and are represented by fibrous cords passing along the sides of the bladder and ascending toward the umbilicus. Frequently, the vessels will be patent, thus forming the superior vesical arteries. The peritoneal covering of the bladder is limited to the upper surface. The reflections of the peritoneum to the anterior abdominal wall and the corresponding walls of the pelvis are sometimes described as the superior, lateral, and posterior false ligaments. The muscle (smooth) of the bladder is represented by an interdigitated pattern continuous with and contiguous to the inner longitudinal and anterior circumferential muscles of the urethra. No distinct muscle layers are apparent.

Mucous Membrane

The mucous membrane is rose-colored and lies in irregular folds that become effaced by distention. The 3 angles of the vesical trigone are represented by the orifices of the 2 ureters and the internal urethral orifice. This area is redder in color and free from plication. It is bordered posteriorly by the plica interureterica, a curved transverse ridge extending between the orifices of the ureters. A median longitudinal elevation, the uvula vesicae, extends toward the urethral orifice. The internal urethral orifice is normally situated at the lowest point of the bladder, at the junction of the inferolateral and posterior surfaces. It is surrounded by a circular elevation, the urethral annulus, approximately level with the center of the symphysis pubica. The epithelial lining of the bladder is transitional in type. The mucous membrane rests on the submucous coat, composed of areolar tissue superficial to the muscular coat. There is no evidence of a specific smooth muscle sphincter in the vesical neck.

Arteries, Veins, & Lymphatics

The blood supply to the bladder comes from branches of the hypogastric artery. The umbilical artery, a terminal branch of the hypogastric artery, gives off the superior vesical artery prior to its obliterated portion. It approaches the bladder (along with the middle and inferior vesical arteries) through a condensation of fatty areolar tissue, limiting the prevesical “space” posterosuperiorly, to branch out over the upper surface of the bladder. It anastomoses with the arteries of the opposite side and the middle and inferior vesical arteries below. The middle vesical artery may arise from one of the superior vessels, or it may come from the umbilical artery, supplying the sides and base of the bladder. The inferior vesical artery usually arises directly from the hypogastric artery—in common with or as a branch of the uterine artery—and passes downward and medially, where it divides into branches that supply the lower part of the bladder. The fundus may also receive small branches from the middle hemorrhoidal, uterine, and vaginal arteries. The veins form an extensive plexus at the sides and base of the bladder from which stems pass to the hypogastric trunk.

The lymphatics, in part, accompany the veins and communicate with the hypogastric nodes. They also communicate laterally with the external iliac glands, and some of those from the fundus pass to nodes situated at the promontory of the sacrum. The lymphatics of the bladder dome are separate on the right and left sides and rarely cross, but extensive anastomoses are present among the lymphatics of the base, which also involve those of the cervix.

Nerves

The nerve supply to the bladder is derived partly from the hypogastric sympathetic plexus and partly from the second and third sacral nerves (the nervi erigentes).

Ureters

Anatomy & Relationships

The ureter is a slightly flattened tube that extends from the termination of the renal pelvis to the lower outer corner of the base of the bladder, a distance of 26–28 cm. It is partly abdominal and partly pelvic and lies entirely behind the peritoneum. Its diameter varies from 4–6 mm, depending on distention, and its size is uniform except for 3 slightly constricted portions.

The first of 3 constrictions is found at the junction of the ureter with the renal pelvis and is known as the upper isthmus. The second constriction—the lower isthmus—is at the point where the ureter crosses the brim of the pelvis minor. The third (intramural) constriction is at the terminal part of the ureter as it passes through the bladder wall.

The pelvic portion of the ureter begins as the ureter crosses the pelvic brim beneath the ovarian vessels and near the bifurcation of the common iliac artery. It conforms to the curvature of the lateral pelvic wall, inclining slightly laterally and posteriorly until it reaches the pelvic floor. The ureter then bends anteriorly and medially at about the level of the ischial spine to reach the bladder. In its upper portion, it is related posteriorly to the sacroiliac articulation; then, lying upon the obturator internus muscle and fascia, it crosses the root of the umbilical artery, the obturator vessels, and the obturator nerve.

In its anterior relationship, the ureter emerges from behind the ovary and under its vessels to pass behind the uterine and superior and middle vesical arteries. Coursing anteriorly, it comes into close relation with the lateral fornix of the vagina, passing 8–12 mm from the cervix and vaginal wall before reaching the bladder. When the ureters reach the bladder, they are about 5 cm apart. The ureters open into the bladder by 2 slitlike apertures, the urethral orifices, about 2.5 cm apart when the bladder is empty.

Wall of Ureter

The wall of the ureter is approximately 3 mm thick and is composed of 3 coats: connective tissue, muscle, and mucous membrane. The muscular coat has an external circular and an internal longitudinal layer throughout its course and an external longitudinal layer in its lower third. The mucous membrane is longitudinally plicated and covered by transitional epithelium. The intermittent peristaltic action of the ureteral musculature propels urine into the bladder in jets. The oblique passage of the ureter through the bladder wall tends to constitute a valvular arrangement, but no true valve is present. The circular fibers of the intramural portion of the ureter possess a sphincter like action. Still, under some conditions of overdistention of the bladder, urine may be forced back into the ureter.

Arteries, Veins, & Lymphatics

The pelvic portion of the ureter receives its blood supply from a direct branch of the hypogastric artery, anastomosing superiorly in its adventitia with branches from the iliolumbar and inferiorly with branches from the inferior vesical and middle hemorrhoidal arteries. Lymphatic drainage passes along the hypogastric vessels to the hypogastric and external iliac nodes, continuing up the ureters to their middle portion where drainage is directed to the periaortic and interaorticocaval nodes.

Nerves

The nerve supply is provided by the renal, ovarian, and hypogastric plexuses. The spinal level of the afferents is approximately the same as the kidney (T12, L1, L2). The lower third of the ureter receives sensory fibers and postganglionic parasympathetic fibers from the Frankenhäuser plexus and sympathetic fibers through this plexus as it supplies the base of the bladder. These fibers ascend the lower third of the ureter, accompanying the arterial supply. The middle segment appears to receive postganglions of sympathetic and parasympathetic fibers through and from the middle hypogastric plexus. The upper third is supplied by the same innervation as the kidney.

Urethra

Anatomy & Relationships

The female urethra is a canal 2.5–4 cm long. It extends downward and forward in a curve from the neck of the bladder (internal urethral orifice), which lies nearly opposite the symphysis pubica. Its termination, the external urethral orifice, is situated inferiorly and posteriorly from the lower border of the symphysis. Posteriorly, it is closely applied to the anterior wall of the vagina, especially in the lower two-thirds, where it actually is integrated with the wall, forming the urethral carina. Anteriorly, the upper end is separated from the prevesical “space” by the pubovesical (puboprostatic) ligaments, abutting against the levator ani and vagina and extending upward onto the pubic rami.

Anatomy of Walls

The walls of the urethra are very distensible, composed of spongy fibromuscular tissue containing cavernous veins and lined by submucous and mucous coats. The mucosa contains numerous longitudinal lines when undistended, the most prominent of which is located on the posterior wall and termed the crista urethralis. Also, there are numerous small glands (the homologue of the male prostate, paraurethral and periurethral glands of Astruc, ducts of Skene) that open into the urethra. The largest of these, the paraurethral glands of Skene, may open via a pair of ducts beside the external urethral orifice in the vestibule. The epithelium begins as transitional at the upper end and becomes squamous in the lower part.

External to the urethral lumen is a smooth muscle coat composed of an outer circular layer and an inner longitudinal layer in the lower two-thirds. In the upper third, the muscle bundles of the layers interdigitate in a basketlike weave to become continuous with and contiguous to those of the bladder. The entire urethral circular smooth muscle acts as the involuntary sphincter. In the region of the juncture of the middle and lower thirds of the urethra, decussating fibers (striated in type) form the middle heads of the bulbocavernosus and ischiocavernosus muscles and encircle the urethra to form the sphincter urethrae (voluntary sphincter).

Arteries & Veins

The arterial supply is intimately involved with that of the anterior vaginal wall, with cruciate anastomoses to the bladder. On each side of the vagina are the vaginal arteries, originating in part from the coronary artery of the cervix, the inferior vesical artery, or a direct branch of the uterine artery. In the midline of the anterior vaginal wall is the azygos artery, originating from the coronary or circular artery of the cervix. Approximately 5 branches traverse the anterior vaginal wall from the lateral vaginal arteries to the azygos in the midline, with small sprigs supplying the urethra. A rich anastomosis with the introitus involves the clitoral artery (urethral branches) as the artery divides into the dorsal and superficial arteries of the clitoris, a terminal branch of the internal pudendal artery. The venous drainage follows the arterial pattern, although it is less well defined. In the upper portion of the vagina, it forms an extensive network called the plexus of Santorini.

Nerves

The nerve supply is parasympathetic, sympathetic, and spinal. The parasympathetic and sympathetic nerves are derived from the hypogastric plexus; the spinal supply is via the pudendal nerve.

Uterus

Anatomy

The uterus is a pear-shaped, thick-walled, muscular organ, situated between the base of the bladder and the rectum. Covered on each side by the 2 layers of the broad ligament, it communicates above with the uterine tubes and below with the vagina. It is divided into 2 main portions, the larger portion or body above and the smaller cervix below, connected by a transverse constriction, the isthmus. The body is flattened so that the side-to-side dimension is greater than the anteroposterior dimension and larger in women who have borne children. The anterior or vesical surface is almost flat; the posterior surface is convex. The fallopian tubes join the uterus at the superior (lateral) angles. The round portion that extends above the plane passing through the points of attachment of the 2 tubes is termed the fundus. This portion is the region of greatest breadth.

The cavity of the body, when viewed from the front or back, is roughly triangular with the base up. The communication of the cavity below with the cavity of the cervix corresponds in position to the isthmus and forms the internal orifice (internal os uteri). The cervix, also called the portio vaginalis, is somewhat barrel-shaped and is 2–4 cm in length, its lower end joining the vagina at an angle varying from 45–90 degrees. It projects into the vagina and is divided into a supravaginal and a vaginal portion by the line of attachment. About one fourth of the anterior surface and half of the posterior surface of the cervix belong to the vaginal portion. At the extremity of the vaginal portion is the opening leading to the vagina, the external orifice (external os uteri), which is round or oval before parturition but takes the form of a transverse slit in women who have borne children. The cavity of the cervix is fusiform in shape, with longitudinal folds or furrows, and extends from the internal to the external orifice. The endocervical canal is composed of columnar, mucus-secreting cells, whereas the external cervix is lined by nonkeratinizing squamous epithelium. The junction between these 2 areas is called the squamocolumnar junction or transitional zone.

The size of the uterus varies, under normal conditions, at different ages and in different physiologic states. In the adult woman who has never borne children, it is approximately 7–8 cm long, 4–5 cm at its widest point, and 30–40 g in weight. In the prepubertal period, it is considerably smaller. In women who have borne children, it is larger. Its shape, size, and characteristics in the pregnant state become considerably modified depending on the stage of gestation.

Layers of Uterine Wall

The wall of the uterus is very thick and consists of 3 layers: serous, muscular, and mucous. The serous layer (perimetrium) is simply the peritoneal covering. It is thin and firmly adherent over the fundus and most of the body, and then thickens posteriorly and becomes separated from the muscle by the parametrium. The muscular layer (myometrium) is extremely thick at about 1.5–2.5 cm and continuous with that of the tubes and vagina. It also extends into the ovarian and round ligaments, into the cardinal ligaments at the cervix, and minimally into the uterosacral ligaments. Two principal layers of the muscular coat can be distinguished: (1) the outer layer, which is weaker and composed of longitudinal fibers; and (2) a stronger inner layer, the fibers of which are interlaced and run in various directions, having intermingled within them large venous plexuses. The muscle layer hypertrophies with the internal os to form a sphincter.

The cervix, from the internal os distally, progressively loses its smooth muscle, finally to be entirely devoid of smooth muscle and elastic in its distal half. It is, in fact, the “dead-end tendon” of the uterus, at which point, during the active component of labor, both the uterus and the vagina direct their efforts. The mucous layer (endometrium) is soft and spongy, composed of tissue resembling embryonic connective tissue. The surface consists of a single layer of ciliated columnar epithelium. The tissue is rather delicate and friable and contains many tubular glands that open into the cavity of the uterus.

Position & Axis Direction

The direction of the axis of the uterus varies greatly. Normally, the uterus forms a sharp angle with the vagina so that its anterior surface lies on the upper surface of the bladder and the body is in a horizontal plane when the woman is standing erect. There is a bend in the area of the isthmus, at which the cervix then faces downward. This position is the normal anteversion or angulation of the uterus, although it may be placed backward (retroversion), without angulation (military position), or to one side (lateral version). The forward flexion at the isthmus is referred to as anteflexion, or there may be a corresponding retroflexion or lateral flexion. There is no sharp line between the normal and pathologic state of anterior angulation.

Relationships

Anteriorly, the body of the uterus rests upon the upper and posterior surfaces of the bladder, separated by the uterovesical pouch of the peritoneum. The whole of the anterior wall of the cervix is below the floor of this pouch, and it is separated from the base of the bladder only by connective tissue. Posteriorly, the peritoneal covering extends down as far as the uppermost portion of the vagina; therefore, the entire posterior surface of the uterus is covered by peritoneum, and the convex posterior wall is separated from the rectum by the rectouterine pouch (cul-de-sac or pouch of Douglas). Coils of intestine may rest upon the posterior surface of the body of the uterus and may be present in the rectouterine pouch.

Laterally, the uterus is related to the various structures contained within the broad ligament: the uterine tubes, the round ligament and the ligament of the ovary, the uterine artery and veins, and the ureter. The relationships of the ureters and the uterine arteries are very important surgically. The ureters, as they pass to the bladder, run parallel with the cervix for a distance of 8–12 mm. The uterine artery crosses the ureter anterosuperiorly near the cervix, about 1.5 cm from the lateral fornix of the vagina. In effect, the ureter passes under the uterine artery “as water flows under a bridge.”

Ligaments

Although the cervix of the uterus is fixed, the body is free to rise and fall with the filling and emptying of the bladder. The so-called ligaments supporting the uterus consist of the uterosacral ligaments, the transverse ligaments of the cervix (cardinal ligaments, cardinal supports, ligamentum transversum colli, ligaments of Mackenrodt), the round ligaments, and the broad ligaments. The cervix is embedded in tissue called the parametrium, containing various amounts of smooth muscle. There are 2 pairs of structures continuous with the parametrium and with the wall of the cervix: the uterosacral ligaments and the transverse (cardinal) ligament of the neck, the latter of which is the chief means of support and suspends the uterus from the lateral walls of the pelvis minor. The uterosacral ligaments are, in fact, the inferior posterior folds of peritoneum from the broad ligament. They consist primarily of nerve bundles from the inferior hypogastric plexus and contain preganglionic and postganglionic fibers and C fibers of the sympathetic lumbar segments, parasympathetic in part from sacral components and in part from sensory or C fibers of the spinal segments.

The cardinal ligaments are composed of longitudinal smooth muscle fibers originating superiorly from the uterus and inferiorly from the vagina, fanning out toward the fascia visceralis to form, with the internal os of the cervix, the primary support of the uterus. There is a natural defect in the muscle at its sides (hilum of the uterus) and at the cervical isthmus (internal os), where the vasculature and nerve supply enter the uterus.

The round ligaments of the uterus, although forming no real support, may assist in maintaining the body of the uterus in its typical position over the bladder. They consist of fibrous cords containing smooth muscle (longitudinal) from the outer layer of the corpus. From a point of attachment to the uterus immediately below that of the ovarian ligament, each round ligament extends downward, laterally, and forward between the 2 layers of the mesometrium, toward the abdominal inguinal ring that it traverses and the inguinal canal, to terminate in a fanlike manner in the labia majora and become continuous with connective tissue. The round ligament is the gubernaculum (ligamentum teres uteri), vestigial in the female. It is accompanied by a funicular branch of the ovarian artery, by a branch from the ovarian venous plexus, and, in the lower part of its course, by a branch from the inferior epigastric artery (Sampson’s artery), over which it passes as it enters the inguinal ring. Through the inguinal canal, it is accompanied by the ilioinguinal nerve and the external spermatic branch of the genitofemoral nerve.

The broad ligament, consisting of a transverse fold of peritoneum that arises from the floor of the pelvis between the rectum and the bladder, provides minimal support. In addition to the static support of these ligaments, the pelvic diaphragm (levator ani) provides an indirect and dynamic support. These muscles do not actually come in contact with the uterus, but they aid in supporting the vagina and maintain the entire pelvic floor in resisting downward pressure. The effectiveness of these muscles depends on an intact perineum (perineal body, bulbocavernosus muscle and body), for if it is lacerated or weakened the ligaments will gradually stretch and the uterus will descend. The uterus and its components and the vagina are, in fact, one continuous unit.

Arteries

The blood supply to the uterus is from the uterine and ovarian arteries. As a terminal branch of the hypogastric artery, the uterine artery runs downward and medially to cross the ureter near the cervix. It then ascends along the lateral border of the uterus in a tortuous course through the parametrium, giving off lateral branches to both uterine surfaces. Above, it anastomoses to join with the ovarian artery in the mesometrium, which creates the main accessory source of blood. The uterine arteries within the uterus form a series of arches over the fundus, creating cruciate anastomoses with the opposite side.

Branches of the arcuate arteries (radial) penetrate the myometrium at right angles to terminate in the basilar arterioles for the basilar portion of the endometrium and in the spinal arteries of the endometrium. The spinal arteries are tortuous in structure, not because of endometrial growth but because, ontogenically, an organ carries its arterial supply with it as it changes size and position. Therefore, the spiral arteries are able to maintain adequate arterial flow to the placenta while it is attached within the uterus.

On the other hand, the veins of the endometrium are a series of small sinusoids that connect to the larger sinusoids of the myometrium, the latter coalescing into the larger veins of the uterine complex. It is useful here to note the significance of the muscular role of the uterus in helping to control venous bleeding during parturition.

The arterial supply to the cervix is primarily through the cervical branches of the right and left uterine arteries, which form a rete around the cervix (coronary artery), creating the azygos artery in the midline anteriorly and posteriorly. Anastomoses between this artery and the vaginal artery on both sides afford cruciate flow on the anterior wall, whereas on the posterior wall of the vagina, anastomoses occur with the right and left middle hemorrhoidal arteries as they supply the wall and the rectum.

Veins

The veins form a plexus and drain through the uterine vein to the hypogastric vein. There are connections with the ovarian veins and the inferior epigastric by way of the vein accompanying the round ligament.

Lymphatics

Lymphatic drainage involves several chains of lymph nodes. From the subperitoneal plexus, the collecting trunks of the lower uterine segment may drain by way of the cervix to the external iliac chain or by way of the isthmus to the lateral sacral nodes. Drainage along the round ligament progresses to the superficial inguinal nodes, then to the femoral, and finally to the external iliac chain. Drainage laterally to the suspensory ligament of the ovary involves the lumbar pedicle and progresses in a retroperitoneal manner across and anteriorly to the ureter, to the lumbar nodes (interaorticocaval) that lie along the aorta, and inferiorly to the kidney.

Fallopian Tubes (Uterine Oviducts)

Anatomy

The fallopian tubes serve to convey the ova (eggs) to the uterus. They extend from the superior angles of the uterus to the region of the ovaries, running in the superior border of the broad ligament (mesosalpinx). The fallopian tubes and ovaries are collectively referred to as the adnexa. The course of each tube is nearly horizontal at first and slightly backward. Upon reaching the lower (uterine) pole of the ovary, the tube turns upward, parallel with the anterior (mesovarian) border, then arches backward over the upper pole and descends posteriorly to terminate in contact with the medial surface. Each tube is 7–12 cm long and may be divided into 4 parts: isthmus, ampulla, infundibulum, and interstitial.

The isthmus is the narrow and nearly straight portion immediately adjoining the uterus. It has a rather long intramural course, and its opening into the uterus, the uterine ostium, is approximately 1 mm in diameter. Following the isthmus is the wider, more tortuous ampulla. It terminates in a funnel-like dilatation, the infundibulum. The margins of the infundibulum are fringed by numerous diverging processes, the fimbriae, the longest of which, the fimbria ovarica, is attached to the ovary. The funnel-shaped mouth of the infundibulum, the abdominal ostium, is about 3 mm in diameter and actually leads into the peritoneal cavity, although it probably is closely applied to the surface of the ovary during ovulation. The interstitial is the portion of the tube that lies within the uterine wall. The innermost portion is seen from the uterine cavity as the tubal ostea.

Layers of Wall

The wall of the tube has 4 coats: serous (peritoneal), subserous or adventitial (fibrous and vascular), muscular, and mucous. Each tube is enclosed within a peritoneal covering except along a small strip on its lower surface, where the mesosalpinx is attached. At the margins of the infundibulum and the fimbriae, this peritoneal covering becomes directly continuous with the mucous membrane lining the interior of the tube. The subserous tissue is lax in the immediate vicinity of the tube. The blood and nerve supply is found within this layer. The muscular coat has an outer longitudinal and an inner circular layer of smooth muscle fibers, more prominent and continuous with that of the uterus at the uterine end of the tube. The mucous coat is ciliated columnar epithelium with coarse longitudinal folds, simple in the region of the isthmus but becoming higher and more complex in the ampulla. The epithelial lining extends outward into the fimbriae. The ciliary motion is directed toward the uterus.

Arteries & Veins

The blood supply to the tubes is derived from the ovarian and uterine arteries. The tubal branch of the uterine artery courses along the lower surface of the uterine tube as far as the fimbriated extremity and may also send a branch to the ligamentum teres. The ovarian branch of the uterine artery runs along the attached border of the ovary and gives off a tubal branch. Both branches form cruciate anastomoses in the mesosalpinx. The veins accompany the arteries.

Lymphatics

The lymphatic drainage occurs through trunks running retroperitoneally across and anterior to the ureter, into the lumbar nodes along the aorta, and inferior to the kidney.

Ovaries

Anatomy

The ovaries are paired organs situated close to the wall on either side of the pelvis minor, a little below the brim. Each measures 2.5–5 cm in length, 1.5–3 cm in breadth, and 0.7–1.5 cm in width, weighing about 4–8 g. The ovary has 2 surfaces, medial and lateral; 2 borders, anterior or mesovarian and posterior or free; and 2 poles, upper or tubal and lower or uterine. When the uterus and adnexa are in the normal position, the long axis of the ovary is nearly vertical, but it bends somewhat medially and forward at the lower end so that the lower pole tends to point toward the uterus. The medial surface is rounded and, posteriorly, may have numerous scars or elevations that mark the position of developing follicles and sites of ruptured ones.

Structure of Ovary

The ovary is covered by cuboid or low columnar epithelium and consists of a cortex and a medulla. The medulla is made up of connective tissue fibers, smooth muscle cells, and numerous blood vessels, nerves, lymphatic vessels, and supporting tissue. The cortex is composed of a fine areolar stroma, with many vessels and scattered follicles of epithelial cells within which are the definitive ova (oocytes) in various stages of maturity. The more mature follicles enlarge and project onto the free surface of the ovary, where they are visible to the naked eye. These are called graafian follicles. When fully mature, the follicle bursts, releasing the ovum and becoming transformed into a corpus luteum. The corpus luteum, in turn, is later replaced by scar tissue, forming a corpus albicans if pregnancy is not achieved that particular menstrual cycle.

Relationships

The upper portion of this surface is overhung by the fimbriated end of the uterine tube, and the remainder lies in relation to coils of intestine. The lateral surface is similar in shape and faces the pelvic wall, where it forms a distinct depression, the fossa ovarica. This fossa is lined by peritoneum and is bounded above by the external iliac vessels and below by the obturator vessels and nerve; its posterior boundary is formed by the ureter and uterine artery and vein, and the pelvic attachment of the broad ligament is located anteriorly.

The mesovarian or anterior border is fairly straight and provides attachment for the mesovarium, a peritoneal fold by which the ovary is attached to the posterosuperior layer of the broad ligament. Because the vessels, nerves, and lymphatics enter the ovary through this border, it is referred to as the hilum of the ovary.

Mesovarium

The ovary is suspended by means of the mesovarium, the suspensory ligament of the ovary (infundibulopelvic [IP] ligament), and the ovarian ligament. The mesovarium consists of 2 layers of peritoneum, continuous with both the epithelial coat of the ovary and the posterosuperior layer of the broad ligament. It is short and wide and contains branches of the ovarian and uterine arteries, with plexuses of nerves, the pampiniform plexus of veins, and the lateral end of the ovarian ligament. The suspensory ligament of the ovary is a triangular fold of peritoneum and is actually the upper lateral corner of the broad ligament, which becomes confluent with the parietal peritoneum at the pelvic brim. It attaches to the mesovarium as well as to the peritoneal coat of the infundibulum medially, thus suspending both the ovary and the tube. It contains the ovarian artery, veins, and nerves after they pass over the pelvic brim and before they enter the mesovarium.

The ovarian ligament is a band of connective tissue, with numerous small muscle fibers, that lies between the 2 layers of the broad ligament on the boundary line between the mesosalpinx and the mesometrium, connecting the lower (uterine) pole of the ovary with the lateral wall of the uterus. It is attached just below the uterine tube and above the attachment of the round ligament of the uterus and is continuous with the latter.

Arteries

The ovarian artery is the chief source of blood for the ovary. Though both arteries may originate as branches of the abdominal aorta, the left frequently originates from the left renal artery; the right, less frequently. The vessels diverge from each other as they descend. Upon reaching the level of the common iliac artery, they turn medially over that vessel and ureter to descend tortuously into the pelvis on each side between the folds of the suspensory ligament of the ovary into the mesovarium. An additional blood supply is formed from anastomosis with the ovarian branch of the uterine artery, which courses along the attached border of the ovary. Blood vessels that enter the hilum send out capillary branches centrifugally.

The veins follow the course of the arteries and, as they emerge from the hilum, form a well-developed plexus (the pampiniform plexus) between the layers of the mesovarium. Smooth muscle fibers occur in the meshes of the plexus, giving the whole structure the appearance of erectile tissue.

Lymphatics

Lymphatic channels drain retroperitoneally, together with those of the tubes and part of those from the uterus, to the lumbar nodes along the aorta inferior to the kidney. The distribution of lymph channels in the ovary is so extensive that it suggests the system may also provide additional fluid to the ovary during periods of preovulatory follicular swelling.

Nerves

The nerve supply of the ovaries arises from the lumbosacral sympathetic chain and passes to the gonad along with the ovarian artery.

Vagina

Anatomy

The vagina is a strong, hollow, fibromuscular canal approximately 7–9 cm long that extends from the uterus to the vestibule of the external genitalia, where it opens to the exterior. Its long axis is almost parallel with that of the lower part of the sacrum, and it meets the cervix of the uterus at an angle of 45–90 degrees. Because the cervix of the uterus projects into the upper portion, the anterior wall of the vagina is 1.5–2 cm shorter than the posterior wall. The circular cul-de-sac formed around the cervix is known as the fornix and is divided into 4 regions: the anterior fornix, the posterior fornix, and 2 lateral fornices. Toward its lower end, the vagina pierces the urogenital diaphragm and is surrounded by the 2 bulbocavernosus muscles and bodies, which act as a sphincter (sphincter vaginae).

Wall Structure

The vaginal wall is composed of a mucosal layer and a muscular layer. The smooth muscle fibers are indistinctly arranged in 3 layers: an outer longitudinal layer, circumferential layer, and a poorly differentiated inner longitudinal layer. In the lower third, the circumferential fibers envelop the urethra. The submucous area is abundantly supplied with a dense plexus of veins and lymphatics. The mucous layer shows many transverse and oblique rugae, which project inward to such an extent that the lumen in transverse section resembles an H-shaped slit. On the anterior and posterior walls, these ridges are more prominent, and the anterior column forms the urethral carina at its lower end, where the urethra slightly invaginates the anterior wall of the vagina. The mucosa of the vagina is lined throughout by nonkeratinized squamous epithelium. Even though the vagina has no true glands, there is a secretion present. It consists of cervical mucus, desquamated epithelium, and, with sexual stimulation, a direct transudate.

Relationships

Anteriorly, the vagina is in close relationship to the bladder, ureters, and urethra in succession. The posterior fornix is covered by the peritoneum of the rectovaginal pouch, which may contain coils of intestine. Below the pouch, the vagina rests almost directly on the rectum, separated from it by a thin layer of areolar connective tissue. Toward the lower end of the vagina, the rectum turns back sharply, and the distance between the vagina and rectum greatly increases. This space, filled with muscle fibers, connective tissue, and fat, is known as the perineal body. The lateral fornix lies just under the root of the broad ligament and is approximately 1 cm from the point where the uterine artery crosses the ureter.

The remaining lateral vaginal wall is related to the edges of the anterior portion of the levator ani. The vagina is supported at the introitus by the bulbocavernosus muscles and bodies, in the lower third by the levator ani (puborectalis), and superiorly by the transverse (cardinal) ligaments of the uterus. The ductus epoophori longitudinalis (duct of Gartner), the remains of the lower portion of the wolffian duct (mesonephric duct), may often be found on the sides of the vagina as a minute tube or fibrous cord. These vestigial structures often become cystic and appear as translucent areas.

Arteries & Veins

The chief blood supply to the vagina is through the vaginal branch of the uterine artery. After forming the coronary or circular artery of the cervix, it passes medially, behind the ureter, to send 5 main branches onto the anterior wall to the midline. These branches anastomose with the azygos artery (originating midline from the coronary artery of the cervix) and continue downward to supply the anterior vaginal wall and the lower two-thirds of the urethra. The uterine artery eventually anastomoses to the urethral branch of the clitoral artery. The posterior vaginal wall is supplied by branches of the middle and inferior hemorrhoidal arteries, traversing toward the midline to join the azygos artery from the coronary artery of the cervix. These branches then anastomose on the perineum to the superficial and deep transverse perineal arteries. The veins follow the course of the arteries.

Lymphatics

The lymphatics are numerous mucosal plexuses, anastomosing with the deeper muscular plexuses. The superior group of lymphatics joins those of the cervix and may follow the uterine artery to terminate in the external iliac nodes or form anastomoses with the uterine plexus. The middle group of lymphatics, which drain the greater part of the vagina, appears to follow the vaginal arteries to the hypogastric channels. In addition, there are lymph nodes in the rectovaginal septum that are primarily responsible for drainage of the rectum and part of the posterior vaginal wall. The inferior group of lymphatics forms frequent anastomoses between the right and left sides and either courses upward to anastomose with the middle group or enters the vulva and drains to the inguinal nodes.

Nerves

The innervation of the vagina contains both sympathetic and parasympathetic fibers. Only occasional free nerve endings are seen in the mucosa; no other types of nerve endings are noted.

SUMMARY

Even though the basic anatomy and structure of the human body is not changing, the evolution of surgical approaches and technologies is. This constantly ever-changing field requires the gynecologic surgeon to be well versed in female pelvic anatomy by constantly reviewing and studying its contents. Being knowledgeable and current with the female pelvis will allow even the most experienced, senior surgeon to adjust to situations where anatomy is altered secondary to disease processes, congenital malformation, or other unknown complications.

Embryology of the Urogenital System & Congenital Anomalies of the Genital Tract

Catherine M. DeUgarte, MD

In the urogenital system, knowledge of the embryology is crucial in understanding the functions and interconnections between the reproductive and urologic systems. The adult genital and urinary systems are distinct in both function and anatomy, with the exception of the male urethra, where the 2 systems are interconnected. During development, these 2 systems are closely associated. The initial developmental overlap of these systems occurs 4–12 weeks after fertilization. The complexity of developmental events in these systems is evident by the incomplete separation of the 2 systems found in some congenital anomalies. For the sake of clarity, this chapter describes the embryology of each system separately, rather than following a strict developmental chronology.

In view of the complexity and duration of differentiation and development of the genital and urinary systems, it is not surprising that the incidence of malformations involving these systems is one of the highest (10%) of all body systems. Etiologies of congenital malformations are sometimes categorized on the basis of genetic, environmental, or genetic-plus-environmental (so-called polyfactorial inheritance) factors. Known genetic and inheritance factors reputedly account for about 20% of anomalies detected at birth, aberration of chromosomes for nearly 5%, and environmental factors for nearly 10%. The significance of these statistics must be viewed against reports that (1) an estimated one-third to one-half of human zygotes are lost during the first week of gestation and (2) the cause of possibly 70% of human anomalies is unknown. Even so, congenital malformations remain a matter of concern because they are detected in nearly 3% of infants, and 20% of perinatal deaths are purportedly due to congenital anomalies.

The inherent pattern of normal development of the genital system can be viewed as one directed toward somatic "femaleness," unless development is directed by factors for "maleness." The presence and expression of a Y chromosome (and its testis-determining genes) in a normal 46,XY karyotype of somatic cells directs differentiation toward a testis, and normal development of the testis makes available hormones for the selection and differentiation of the genital ducts. When male hormones are present, the mesonephric (wolffian) system persists; when male hormones are not present, the "female" paramesonephric (müllerian) ducts persist. Normal feminization or masculinization of the external genitalia is also a result of the respective timely absence or presence of androgen.

An infant usually is reared as female or male according to the appearance of the external genitalia. However, genital sex is not always immediately discernible, and the choice of sex of rearing can be an anxiety-provoking consideration. Unfortunately, even when genital sex is apparent, later clinical presentation may unmask disorders of sexual differentiation that can lead to problems in psychological adjustment. Whether a somatic disorder is detected at birth or later, investigative backtracking through the developmental process is necessary for proper diagnosis and treatment.

Overview of the First 4 Weeks of Development*

Transformation of the bilaminar embryonic disk into a trilaminar disk composed of **ectoderm, mesoderm**, and **endoderm** (the 3 embryonic germ layers) occurs during the third week by a process called **gastrulation** (Fig. 2–1). During this process, a specialized thickening of epiblast, the **primitive**

streak, elongates through the midline of the disk. Some epiblastic cells become **mesoblastic cells**, which migrate peripherally between the epiblast and hypoblast, forming a middle layer of **embryonic mesoderm**. Other mesoblastic cells migrate into the hypoblastic layer and form **embryonic endoderm**, which displaces the hypoblastic cells. The remaining overlying epiblast becomes the **embryonic ectoderm**.

Numbers indicate the weeks after fertilization when the indicated developmental change occurs. GI, gastrointestinal.

By the end of the third week, 3 clusters of mesoderm are organized on both sides of the midline neural tube. From medial to lateral, these clusters are **paraxial mesoderm**, which forms much of the axial skeleton; **intermediate mesoderm**, which is the origin of the **urogenital ridge** and, hence, much of the reproductive and excretory systems (Fig. 2–2); and **lateral plate mesoderm**, which splits and takes part in body cavity formation. The **intermediate mesoderm** is located between the paraxial and lateral plate mesoderm and is the origin of the **urogenital ridge** and, hence, much of the reproductive and excretory systems (Fig. 2–2). The primitive streak regresses after the fourth week. Rarely, degeneration of the streak is incomplete, and presumptive remnants form a teratoma in the sacrococcygeal region of the fetus (more common in females than in males).

Figure 2–2. Schematic drawing of formation of the definitive kidney and its collecting ducts. The pronephric duct is probably the only structure that participates in all 3 urinary systems, as its caudal portion continues to grow and is called the mesonephric duct when the mesonephric system develops. (Explanatory symbols are given in Fig. 2–1.)

Weeks 4 through 8 of development are called the **embryonic period** (the **fetal period** is from week 9 to term) because formation of all major internal and external structures, including the 2 primary forerunners of the urogenital system (urogenital ridge and urogenital sinus), begins during this time. During this period the embryo is most likely to develop major congenital or acquired morphologic anomalies in response to the effects of various agents. During the fourth week, the shape of the embryo changes from that of a trilaminar disk to that of a crescentic cylinder. The change results from “folding,” or flexion, of the embryonic disk in a ventral direction through both its transverse and longitudinal planes. Flexion occurs as midline structures (neural tube and somites) develop and grow at a faster pace than more lateral tissues (ectoderm, 2 layers of lateral plate mesoderm enclosing the coelom between them, and endoderm). Thus, during transverse folding, the lateral tissues on each side of the embryo curl ventromedially and join the respective tissues from the other side, creating a midline ventral tube (the endoderm-lined **primitive gut**), a mesoderm-lined coelomic cavity (the **primitive abdominopelvic cavity**), and the incomplete ventral and lateral body wall. Concurrent longitudinal flexion ventrally of the caudal region of the disk establishes the pouchlike distal end, or **cloaca**, of the primitive gut as well as the distal attachment of the cloaca to the yolk sac through the allantois of the sac (Fig. 2–3).

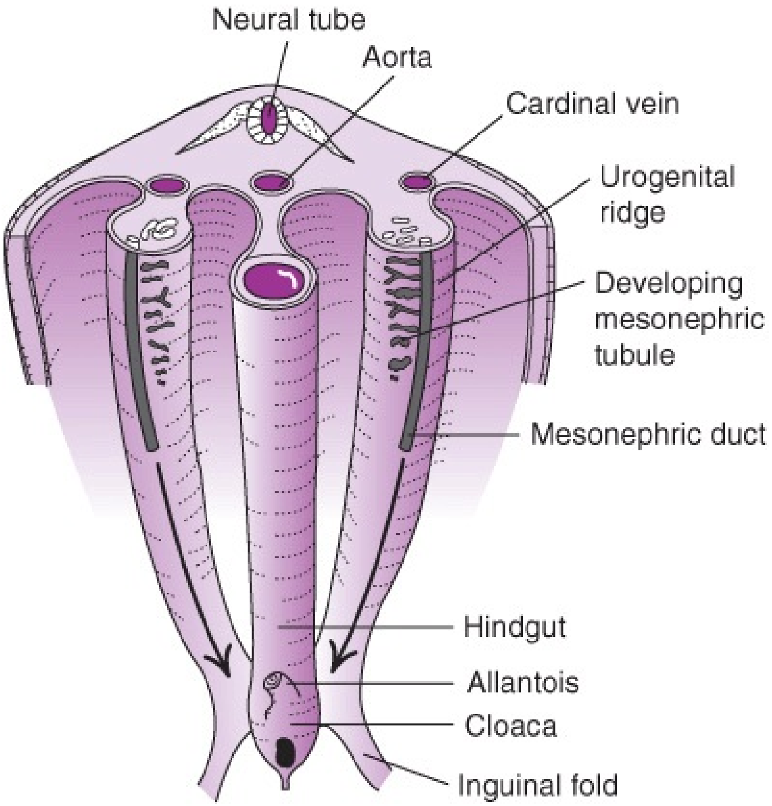

Figure 2–3. Early stage in the formation of the mesonephric kidneys and their collecting ducts in the urogenital ridge. The central tissue of the ridge is the nephrogenic cord, in which the mesonephric tubules are forming. The mesonephric ducts grow toward (arrows) and will open into the cloaca. About 5 weeks’ gestation.

A noteworthy point (see The Gonads) is that the primordial germ cells of the later-developing gonad initially are found close to the allantois and later migrate to the gonadal primordia. Subsequent partitioning of the cloaca during the sixth week results in formation of the anorectal canal and the **urogenital sinus**, the progenitor of the urinary bladder, urethra, vagina, and other genital structures (Fig. 2–1 and Table 2–1; see Subdivision of the Cloaca & Formation of the Urogenital Sinus).

Embryonic folding also moves the intermediate mesoderm—the forerunner of the **urogenital ridge**—to its characteristic developmental locations as bilateral longitudinal bulges in the dorsal wall of the new body cavity and lateral to the dorsal mesentery of the new gut tube. By the end of the fourth week of development, the principal structures (urogenital ridge and cloaca) and tissues that give rise to the urogenital system are present.

Tables 2–1 and 2–2 provide a general overview of urogenital development.

Table 2–2. Developmental chronology of the human urogenital system.

Age in Weeks[1]	Size (C-R) in mm	Urogenital System
2.5	1.5	Allantois present.
3.5	2.5	All pronephric tubules formed. Pronephric duct growing caudad as a blind tube. Cloaca and cloacal membrane present.
4	5	Primordial germ cells near allantois. Pronephros degenerated. Pronephric (mesonephric) duct reaches cloaca. Mesonephric tubules differentiating rapidly. Metanephric bud pushes into secretory primordium.
5	8	Mesonephros reaches its caudal limit. Ureteric and pelvic primordia distinct.
6	12	Cloaca subdividing into urogenital sinus and anorectal canal. Sexless gonad and genital tubercle prominent. Paramesonephric duct appearing. Metanephric collecting tubules begin branching.
7	17	Mesonephros at peak of differentiation. Urogenital sinus separated from anorectal canal (cloaca subdivided). Urogenital and anal membranes rupturing.
8	23	Earliest metanephric secretory tubules differentiating. Testis (8 weeks) and ovary (9–10 weeks) identifiable as such. Paramesonephric ducts, nearing urogenital sinus, are ready to unite a uterovaginal primordium. Genital ligaments indicated.

10	40	Kidney able to excrete urine. Bladder expands as sac. Genital duct of opposite sex degenerating. Bulbourethral and vestibular glands appearing. Vaginal bulbs forming.
12	56	Kidney in lumbar location. Early ovarian folliculogenesis begins. Uterine horns absorbed. External genitalia attain distinctive features. Mesonephros and rete tubules complete male duct. Prostate and seminal vesicle appearing. Hollow viscera gaining muscular walls.
16	112	Testis at deep inguinal ring. Uterus and vagina recognizable as such. Mesonephros involuted.
20–38 (5–9 months)	160–350	Female urogenital sinus becoming a shallow vestibule (5 months). Vagina regains lumen (5 months). Uterine glands begin to appear (5 months). Scrotum solid until sacs and testes descend (7–8 months). Kidney tubules cease forming at birth.

THE URINARY SYSTEM

Three excretory “systems” form successively, with temporal overlap, during the embryonic period. Each system has a different excretory “organ,” but the 3 systems share anatomic continuity through development of their excretory ducts. The 3 systems are mesodermal derivatives of the urogenital ridge (Figs. 2–2 and 2–3), part of which becomes a longitudinal mass, the **nephrogenic cord**. The **pronephros**, or organ of the first system, exists rudimentarily, is nonfunctional, and regresses during the fourth week. However, the developing pronephric ducts continue to grow and become the mesonephric ducts of the subsequent kidney, the **mesonephros**. The paired mesonephroi exist during 4–8 weeks as simplified morphologic versions of the third, or permanent, set of kidneys, and they may have transient excretory function. Although the mesonephroi degenerate, some of their tubules, called **epigenital mesonephric tubules**, persist to participate in formation of the gonad and male ductuli efferentes (Fig. 2–4). The permanent kidney, the **metanephros**, begins to form in response to an inductive influence of a diverticulum of the mesonephric ducts during the fifth week and becomes functional at 10–13 weeks.

Figure 2–4. Schematic drawing of the formation of the gonads and genital ducts.

Differentiation of the caudal segment of the mesonephric ducts results in (1) incorporation of part of the ducts into the wall of the urogenital sinus (early vesicular trigone, see following text), and (2) formation of a ductal diverticulum, which plays an essential role in formation of the definitive kidney. If male sex differentiation occurs, the major portion of each duct becomes the epididymis, ductus deferens, and ejaculatory duct. Only small vestigial remnants of the duct sometimes persist in the female (**Gartner's duct; duct of the epoophoron**).

Metanephros (Definitive Kidney)

A. Collecting Ducts

By the end of the fifth week, a **ureteric bud**, or metanephric diverticulum, forms on the caudal part of the mesonephric duct close to the cloaca. The bud gives rise to the collecting tubules, calices, renal pelvis, and ureter (Fig. 2–2). The stalk of the elongating bud will become the **ureter** when the ductal segment between the stalk and the cloaca becomes incorporated into the wall of the urinary bladder (which is a derivative of the partitioned cloaca, see text that follows; Figs. 2–5 to 2–8). The expanded tip, or **ampulla**, of the bud grows into the adjacent metanephric mesoderm (**blastema**) and subdivides successively into 12–15 generations of buds, or eventual **collecting tubules**. From weeks 10–14, dilatation of the early generations of tubular branches successively produces the **renal pelvis**, the **major calices**, and the **minor calices**, while the middle generations form the medullary collecting tubules. The last several generations of collecting tubules grow centrifugally into the cortical region of the kidney between weeks 24 and 36.

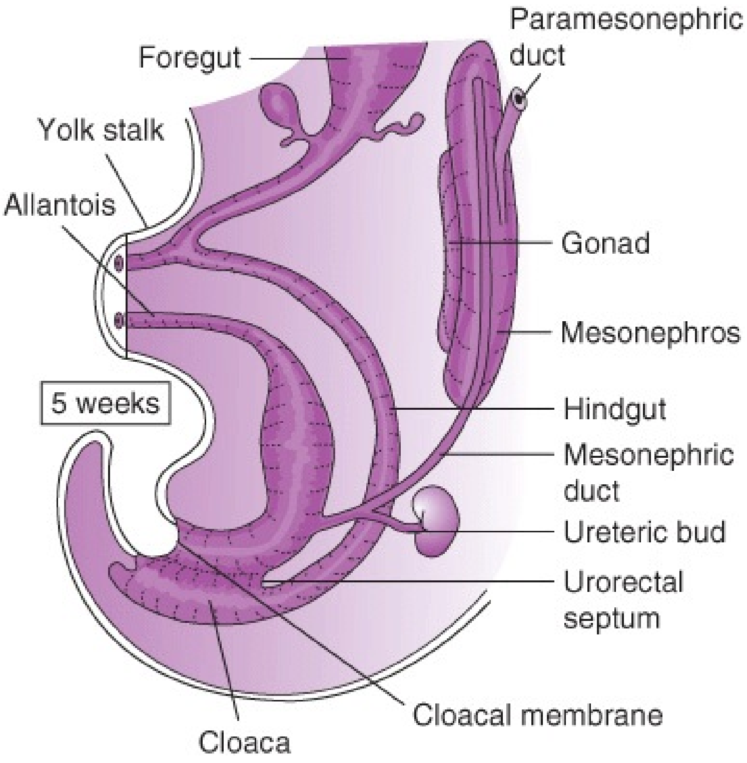

Figure 2–5. Left-side view of urogenital system and cloacal region prior to subdivision of cloaca by urorectal septum (Tourneux and Rathke folds). Position of future paramesonephric duct is shown (begins in the sixth week). Gonad is in the indifferent stage (sexually undifferentiated).

B. Nephrons

Continued maintenance of the intimate relationship of the metanephric blastema and ampulla is necessary for normal formation of the definitive excretory units (nephrons), which starts at about the eighth week. Formation of urine purportedly begins at about weeks 10–13, when an estimated 20% of the nephrons are morphologically mature.

The last month of gestation is marked by interstitial growth, hypertrophy of existing components of uriniferous tubules, and the disappearance of bud primordia for collecting tubules. Opinions differ about whether formation of nephrons ceases prenatally at about 28 or 32 weeks or postnatally during the first several months. If the ureteric bud fails to form, undergoes early degeneration, or fails to grow into the nephrogenic mesoderm, aberrations of nephrogenesis result. These may be nonthreatening (**unilateral renal agenesis**), severe, or even fatal (**bilateral renal agenesis, polycystic kidney**).

C. Positional Changes

Figure 2–9 illustrates relocation of the kidney to a deeper position within the posterior body wall, as well as the approximately 90-degree medial rotation of the organ on its longitudinal axis. Rotation and lateral positioning probably are facilitated by the growth of midline structures (axial skeleton and muscles). The “ascent” of the kidney between weeks 5 and 8 can be attributed largely to differential longitudinal growth of the rest of the lumbosacral area and to the reduction of the rather sharp curvature of the caudal region of the embryo. Some migration of the kidney may also occur. Straightening of the curvature also may be attributable to relative changes in growth, especially the development of the infraumbilical abdominal wall. As the kidney moves into its final position (lumbar 1–3 by the 12th week), its arterial supply shifts to successively higher aortic levels. Ectopic kidneys can result from abnormal “ascent.” During the seventh week, the “ascending” metanephroi closely approach each other near the aortic bifurcation. The close approximation of the 2 developing kidneys can lead to fusion of the lower poles of the kidneys, resulting in formation of a single **horseshoe kidney**, the ascent of which would be arrested by the stem of the interior mesenteric artery. Infrequently, a **pelvic kidney** results from trapping of the organ beneath the umbilical artery, which restricts passage out of the pelvis.

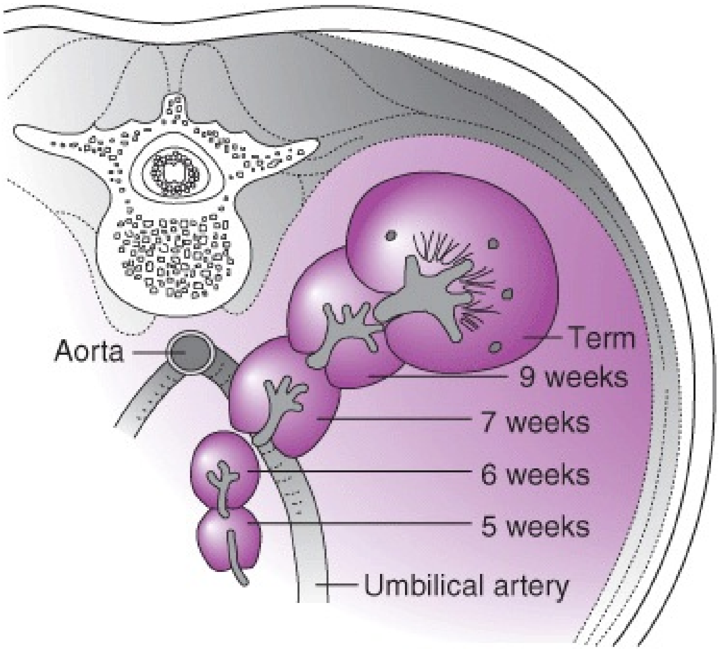

Figure 2–9. Positional changes of the definitive kidney at 5 different stages but projected on one cross-sectional plane.

THE GENITAL SYSTEM

Sexual differentiation of the genital system occurs in a basically sequential order: genetic, gonadal, ductal, and genital. **Genetic sex** is determined at fertilization by the complement of sex chromosomes (ie, XY specifies a genotypic male and XX a female). However, early morphologic indications of the sex of the developing embryo do not appear until about the eighth or ninth week after conception. Thus, there is a so-called **indifferent stage**, when morphologic identity of sex is not clear or when preferential differentiation for one sex has not been imposed on the sexless primordia. This is characteristic of early developmental stages for the gonads, genital ducts, and external genitalia. When the influence of genetic sex has been expressed on the indifferent gonad, **gonadal sex** is established. The **SRY (sex-determining region of the Y chromosome**) gene in the short arm of the Y chromosome of normal genetic males is considered the best candidate for the gene encoding for the **testis-determining factor (TDF**). TDF initiates a chain of events that results in differentiation of the gonad into a testis with its subsequent production of antimüllerian hormone and testosterone, which influences development of somatic “maleness” (see Testis). Normal genetic females do not have the SRY gene, and the early undifferentiated medullary region of their presumptive gonad does not produce the TDF (see Ovary).

The testis and ovary are derived from the same primordial tissue, but histologically visible differentiation toward a testis occurs sooner than that toward an ovary. An “ovary” is first recognized by the absence of testicular histogenesis (eg, thick tunica albuginea) or by the presence of germ cells entering meiotic prophase between the 8th and about the 11th week. The different primordia for male and female genital ducts exist in each embryo during overlapping periods, but establishment of male or female **ductal sex** depends on the presence or absence, respectively, of testicular products and the sensitivity of tissues to these products. The 2 primary testicular products are androgenic steroids (**testosterone** and nonsteroidal **antimüllerian hormone**) (see Testis). Stimulation by testosterone influences the persistence and differentiation of the "male" mesonephric ducts (**wolffian ducts**), whereas antimüllerian hormone influences regression of the "female" paramesonephric ducts (**müllerian ducts**). Absence of these hormones in a nonaberrant condition specifies persistence of müllerian ducts and regression of wolffian ducts (ie, initiation of development of the uterus and uterine tubes). **Genital sex** (external genitalia) subsequently develops according to the absence or presence of androgen. Thus, *the inherent pattern of differentiation of the genital system can be viewed as one directed toward somatic "femaleness" unless the system is dominated by certain factors for "maleness" (eg, gene expression of the Y chromosome, androgenic steroids, and antimüllerian hormone*).

THE GONADS

Indifferent (Sexless) Stage

Gonadogenesis temporally overlaps metanephrogenesis and interacts with tissues of the mesonephric system. Formation of the gonad is summarized schematically in Figure 2–4. Around the fifth week, the midportion of each urogenital ridge thickens as cellular condensation forms the **gonadal ridge**. For the next 2 weeks, this ridge is an undifferentiated cell mass, lacking either testicular or ovarian morphology. As shown in Figure 2–4, the cell mass consists of (1) **primordial germ cells**, which translocate into the ridge, and a mixture of **somatic cells** derived by (2) proliferation of the coelomic epithelial cells, (3) condensation of the **underlying mesenchyme** of part of the urogenital ridge, and (4) ingrowth of **mesonephric-derived cells**.

The end of the gonadal indifferent stage in the male is near the middle of the seventh week, when a basal lamina delineates the coelomic epithelium and the developing tunica albuginea separates the coelomic epithelium from the developing testicular cords. The indifferent stage in the female ends around the ninth week, when the first oogonia enter meiotic prophase.

Primordial germ cells, presumptive progenitors of the gametes, become evident in the late third to early fourth week in the dorsocaudal wall of the yolk sac and the mesenchyme around the allantois. The **allantois** is a caudal diverticulum of the yolk sac that extends distally into the primitive umbilical stalk and, after embryonic flexion, is adjacent proximally to the cloacal hindgut. The primordial germ cells are translocated from the allantoic region (about the middle of the fourth week) to the urogenital ridge (between the middle of the fifth week and late in the sixth week). It is not known whether primordial germ cells must be present in the gonadal ridge for full differentiation of the gonad to occur. The initial stages of somatic development appear to occur independently of the germ cells. Later endocrine activity in the testis, but not in the ovary, is known to occur in the absence of germ cells. The germ cells appear to have some influence on gonadal differentiation at certain stages of development.

Testis

During early differentiation of the testis, there are condensations of germ cells and somatic cells, which have been described as platelike groups, or sheets. These groups are at first distributed throughout the gonad and then become more organized as primitive **testicular cords**. The cords begin to form centrally and are arranged somewhat perpendicular to the long axis of the gonad. In response to TDF, these cords differentiate into Sertoli cells. The first characteristic feature of male gonadal sex differentiation is evident around week 8, when the **tunica albuginea** begins to form in the mesenchymal tissue underlying the coelomic epithelium. Eventually, this thickened layer of tissue causes the developing testicular cords to be separated from the surface epithelium and placed deeper in the central region of the gonad. The surface epithelium reforms a basal lamina and later thins to a mesothelial covering of the gonad. The testicular cords coil peripherally and thicken as their cellular organization becomes more distinct. A basal lamina eventually develops in the testicular cords, although it is not known if the somatic cells, germ cells, or both are primary contributors to the lamina.

Throughout gonadal differentiation, the developing testicular cords appear to maintain a close relationship to the basal area of the mesonephric-derived cell mass. An interconnected network of cords, **rete cords**, develops in this cell mass and gives rise to the **rete testis**. The rete testis joins centrally with neighboring epigenital mesonephric tubules, which become the **efferent ductules** linking the rete testis with the epididymis, a derivative of the mesonephric duct. With gradual enlargement of the testis and regression of the mesonephros, a cleft forms between the 2 organs, slowly creating the mesentery of the testis, the **mesorchium**.

The differentiating testicular cords are made up of primordial germ cells (primitive spermatogonia) and somatic "supporting" cells (**sustentacular cells**, or **Sertoli cells**). Some precocious meiotic activity has been observed in the fetal testis. Meiosis in the germ cells usually does not begin until puberty; the cause of this delay is unknown. Besides serving as "supporting cells" for the primitive spermatogonia, Sertoli cells also produce the glycoprotein **antimüllerian hormone** (also called **müllerian-inhibiting substance**). Antimüllerian hormone causes regression of the paramesonephric (müllerian) ducts, apparently during a very discrete period of ductal sensitivity in male fetuses. At puberty, the seminiferous cords mature to become the seminiferous tubules, and the Sertoli cells and spermatogonia mature.

Shortly after the testicular cords form, the steroid-producing **interstitial (Leydig) cells** of the extracordal compartment of the testis differentiate from stromal mesenchymal cells, probably due to antimüllerian hormone. Mesonephric-derived cells may also be a primordial source of Leydig cells. Steroidogenic activity of Leydig cells begins near the 10th week. High levels of testosterone are produced during the period of differentiation of external genitalia (weeks 11–12) and maintained through weeks 16–18. Steroid levels then rise or fall somewhat in accordance with changes in the concentration of Leydig cells. Both the number of cells and the levels of testosterone decrease around the fifth month.

Ovary

A. Development

In the normal absence of the Y chromosome or the sex-determining region of the Y chromosome (SRY gene; see The Genital System), the somatic sex cords of the indifferent gonad do not produce TDF. In the absence of TDF, differentiation of the gonad into a testis and its subsequent production of antimüllerian hormone and testosterone do not occur (see Testis). The indifferent gonad becomes an ovary. Complete ovarian differentiation seems to require two X chromosomes (XO females exhibit ovarian dysgenesis, in which ovaries have precociously degenerated germ cells and no follicles and are present as gonadal "streaks"). The first recognition of a developing ovary around weeks 9–10 is based on the temporal absence of testicular-associated features (most prominently, the tunica albuginea) and on the presence of early meiotic activity in the germ cells.

Early differentiation toward an ovary involves mesonephric-derived cells "invading" the basal region (adjacent to mesonephros) and central region of the gonad (central and basal regions represent the primitive “medullary” region of the gonad). At the same time, clusters of germ cells are displaced somewhat peripherally into the “cortical” region of the gonad. Some of the central mesonephric cells give rise to the rete system that subsequently forms a network of cords (**intraovarian rete cords**) extending to the primitive cortical area. As these cords extend peripherally between germ clusters, several epithelial cell proliferations extend centrally, and some mixing of these somatic cells apparently takes place around the germ cell clusters. These early cordlike structures are more irregularly distributed than early cords in the testis and not distinctly outlined. The cords open into clusters of germ cells, but all germ cells are not confined to cords. The first oogonia that begin meiosis are located in the innermost part of the cortex and are the first germ cells to contact the intraovarian rete cords.

Folliculogenesis begins in the innermost part of the cortex when the central somatic cells of the cord contact and surround the germ cells while an intact basal lamina is laid down. These somatic cells are morphologically similar to the mesonephric cells that form the intraovarian rete cords associated with the oocytes and apparently differentiate into the presumptive granulosa cells of the early follicle. Folliculogenesis continues peripherally. Between weeks 12 and 20 of gestation, proliferative activity causes the surface epithelium to become a thickened, irregular multilayer of cells. In the absence of a basal lamina, the cells and apparent epithelial cell cords mix with underlying tissues. These latter cortical cords often retain a connection to and appear similar to the surface epithelium. The epithelial cells of these cords probably differentiate into granulosa cells and contribute to folliculogenesis, although this occurs after the process is well under way in the central region of the gonad. Follicles fail to form in the absence of oocytes or with precocious loss of germ cells, and oocytes not encompassed by follicular cells degenerate.

Stromal mesenchymal cells, connective tissue, and somatic cells of cords not participating in folliculogenesis form the **ovarian medulla** in the late fetal ovary. Individual **primordial follicles** containing diplotene oocytes populate the inner and outer cortex of this ovary. The rete ovarii may persist, along with a few vestiges of mesonephric tubules, as the vestigial epoophoron near the adult ovary. Finally, similar to the testicular mesorchium, the **mesovarium** eventually forms as a gonadal mesentery between the ovary and old urogenital ridge. Postnatally, the epithelial surface of the ovary consists of a single layer of cells continuous with peritoneal mesothelium at the ovarian hilum. A thin, fibrous connective tissue, the tunica albuginea, forms beneath the surface epithelium and separates it from the cortical follicles.

B. Anomalies of the Ovaries

Anomalies of the ovaries encompass a broad range of developmental errors from complete absence of the ovaries to supernumerary ovaries. The many variations of gonadal disorders usually are subcategorized within classifications of disorders of sex determination. Unfortunately, there is little consensus for a major classification, although most include pathogenetic consideration. Extensive summaries of the different classifications are offered in the references to this chapter.

Congenital absence of the ovary (no gonadal remnants found) is very rare. Two types have been considered, agenesis and agonadism. By definition, **agenesis** implies that the primordial gonad did not form in the urogenital ridge, whereas **agonadism** indicates the absence of gonads that may have formed initially and subsequently degenerated. It can be difficult to distinguish one type from the other on a practical basis. For example, a patient with female genital ducts and external genitalia and a 46,XY karyotype could represent either gonadal agenesis or agonadism. In the latter condition, the gonad may form but undergo early degeneration and resorption before any virilizing expression is made. *Whenever congenital absence of the ovaries is suspected, careful examination of the karyotype, the external genitalia, and the genital ducts must be performed*.

Descriptions of agonadism usually have indicated that the external genitalia are abnormal (variable degree of fusion of labioscrotal swellings) and that either very rudimentary ductal derivatives are present or there are no genital ducts. The cause of agonadism is unknown, although several explanations have been suggested, such as (1) failure of the primordial gonad to form, along with abnormal formation of ductal anlagen, and (2) partial differentiation and then regression and absorption of testes (accounting for suppression of müllerian ducts but lack of stimulation of mesonephric, or wolffian, ducts). Explanations that include teratogenic effects or genetic defects are more likely candidates in view of the associated incidence of nonsexual somatic anomalies with the disorder. The **streak gonad** is a product of primordial gonadal formation and subsequent failure of differentiation, which can occur at various stages. The gonad usually appears as a fibrouslike cord of mixed elements (lacking germ cells) located parallel to a uterine tube. Streak gonads are characteristic of **gonadal dysgenesis** and a 45,XO karyotype (**Turner's syndrome;** distinctions are drawn between Turner's syndrome and **Turner's stigmata** when consideration is given to the various associated somatic anomalies of gonadal dysgenesis). However, streak gonads may be consequent to genetic mutation or hereditary disease other than the anomalous karyotype.

Ectopic ovarian tissue occasionally can be found as **accessory ovarian tissue** or as **supernumerary ovaries**. The former may be a product of disaggregation of the embryonic ovary, and the latter may arise from the urogenital ridge as independent primordia.

SUBDIVISION OF THE CLOACA & FORMATION OF THE UROGENITAL SINUS

The endodermally lined urogenital sinus is derived by partitioning of the endodermal cloaca. It is the precursor of the urinary bladder in both sexes and the urinary and genital structures specific to each sex (Fig. 2–1). The cloaca is a pouchlike enlargement of the caudal end of the hindgut and is formed by the process of "folding" of the caudal region of the embryonic disk between 4 and 5 weeks' gestation (see Overview of the First 4 Weeks of Development; Figs. 2–1 and 2–3). During the "tail-fold" process, the posteriorly placed allantois, or allantoic diverticulum of the yolk sac, becomes an anterior extension of the cloaca (Figs. 2–3 and 2–5). Soon after the cloaca forms, it receives posterolaterally the caudal ends of the paired mesonephric ducts and hence becomes a junctional cistern for the allantois, the hindgut, and the ducts. A **cloacal membrane**, composed of ectoderm and endoderm, is the caudal limit of the primitive gut and temporarily separates the cloacal cavity from the extraembryonic confines of the amniotic cavity (Fig. 2–5).

Between weeks 5 and 7, 3 wedges of splanchnic mesoderm, collectively called the **urorectal septum**, proliferate in the coronal plane in the caudal region of the embryo to eventually subdivide the cloaca (Figs. 2–5 to 2–8). The superior wedge, called the **Tourneux fold**, is in the angle between the allantois and the primitive hindgut, and it proliferates caudally into the superior end of the cloaca (Fig. 2–5). The other 2 mesodermal wedges, called the **Rathke folds**, proliferate in the right and left walls of the cloaca. Beginning adjacent to the cloacal membrane, these laterally placed folds grow toward each other and the Tourneux fold. With fusion of the 3 folds creating a urorectal septum, the once single chamber is subdivided into the primitive **urogenital sinus** (ventrally) and the **anorectal canal** of the hindgut (dorsally; Figs. 2–6 to 2–8). The mesonephric ducts and allantois then open into the sinus. The uterovaginal primordium of the fused paramesonephric ducts will contact the sinusal wall between the mesonephric ducts early in the ninth week of development. However, it can be noted that the junctional point of fusion of the cloacal membrane and urorectal septum forms the **primitive perineum** (later differentiation creates the so-called perineal body of tissue) and subdivides the cloacal membrane into the **urogenital membrane** (anteriorly) and the **anal membrane** (posteriorly; Figs. 2–5, 2–8, and 2–10; see also Fig. 2–20).

THE GENITAL DUCTS

Indifferent (Sexless) Stage

Two pairs of genital ducts are initially present in both sexes: (1) the **mesonephric (wolffian) ducts**, which give rise to the male ducts and a derivative, the seminal vesicles; and (2) the **paramesonephric (müllerian) ducts**, which form the oviducts, uterus, and part of the vagina. When the adult structures are described as derivatives of embryonic ducts, this refers to the epithelial lining of the structures. Muscle and connective tissues of the differentiating structures originate from splanchnic mesoderm and mesenchyme adjacent to ducts. Mesonephric ducts are originally the excretory ducts of the mesonephric "kidneys" (see previous text), and they develop early in the embryonic period, about 2 weeks before development of paramesonephric ducts (weeks 6–10). The 2 pairs of genital ducts share a close anatomic relationship in their bilateral course through the urogenital ridge. At their caudal limit, both sets contact the part of the cloaca that is later separated as the urogenital sinus (Figs. 2–5, 2–6, and 2–10). *Determination of the ductal sex of the embryo (ie, which pair of ducts will continue differentiation rather than undergo regression) is established initially by the gonadal sex and later by the continuing influence of hormones*.

Figure 2–10. Diagrammatic comparison between male and female differentiation of internal genitalia.

Formation of each paramesonephric duct begins early in the sixth week as an invagination of coelomic epithelium in the lateral wall of the cranial end of the urogenital ridge and adjacent to each mesonephric duct. The free edges of the invaginated epithelium join to form the duct except at the site of origin, which persists as a funnel-shaped opening, the future **ostium of the oviduct**. At first, each paramesonephric duct grows caudally through the mesenchyme of the urogenital ridge and laterally parallel to a mesonephric duct. More inferiorly, the paramesonephric duct has a caudomedial course, passing ventral to the mesonephric duct. As it follows the ventromedial bend of the caudal portion of the urogenital ridge, the paramesonephric duct then lies medial to the mesonephric duct, and its caudal tip lies in close apposition to its counterpart from the opposite side (Fig. 2–10). At approximately the eighth week, the caudal segments of the right and left ducts fuse medially and their lumens coalesce to form a single cavity. This conjoined portion of the Y-shaped paramesonephric ducts becomes the uterovaginal primordium, or canal.

Male: Genital Ducts

A. Mesonephric Ducts

The mesonephric ducts persist in the male and, under the stimulatory influence of testosterone, differentiate into the internal genital ducts (epididymis, ductus deferens, and ejaculatory ducts). Near the cranial end of the duct, some of the mesonephric tubules (epigenital mesonephric tubules) of the mesonephric kidney persist lateral to the developing testis. These tubules form a connecting link, the **ductuli efferentes**, between the duct and the rete testis (Fig. 2–10). The cranial portion of each duct becomes the convoluted **ductus epididymis**. The **ductus deferens** forms when smooth muscle from adjacent splanchnic mesoderm is added to the central segment of the mesonephric duct. The seminal vesicle develops as a lateral bud from each mesonephric duct just distal to the junction of the duct and the urogenital sinus (Fig. 2–7). The terminal segment of the duct between the sinus and seminal vesicle forms the **ejaculatory duct**, which becomes encased by the developing prostate gland early in the 12th week (see Differentiation of the Urogenital Sinus). A vestigial remnant of the duct may persist cranially near the head of the epididymis as the **appendix epididymis**, whereas remnants of mesonephric tubules near the inferior pole of the testis and tail of the epididymis may persist as the **paradidymis** (Fig. 2–10).

B. Paramesonephric Ducts

The paramesonephric ducts begin to undergo morphologic regression centrally (and progress cranially and caudally) about the time they meet the urogenital sinus caudally (approximately the start of the ninth week). Regression is effected by nonsteroidal antimüllerian hormone produced by the differentiating Sertoli cells slightly before androgen is produced by the Leydig cells (see Testis). Antimüllerian hormone is produced from the time of early testicular differentiation until birth (ie, not only during the period of regression of the paramesonephric duct). However, ductal sensitivity to antimüllerian hormone in the male seems to exist for only a short “critical” time preceding the first signs of ductal regression. Vestigial remnants of the cranial end of the ducts may persist as the **appendix testis** on the superior pole of the testis (Fig. 2–10). Caudally, a ductal remnant is considered to be part of the prostatic utricle of the seminal colliculus in the prostatic urethra.

C. Relocation of the Testes & Ducts

Around weeks 5–6, a bandlike condensation of mesenchymal tissue in the urogenital ridge forms near the caudal end of the mesonephros. Distally, this gubernacular precursor tissue grows into the area of the undifferentiated tissue of the anterior abdominal wall and toward the genital swellings. Proximally, the **gubernaculum** contacts the mesonephric duct when the mesonephros regresses and the gonad begins to form. By the start of the fetal period, the mesonephric duct begins differentiation and the gubernaculum adheres indirectly to the testis via the duct, which lies in the mesorchium of the testis. The external genitalia differentiate over the seventh to about the 19th week. By the 12th week, the testis is near the deep inguinal ring, and the gubernaculum is virtually at the inferior pole of the testis, proximally, and in the mesenchyme of the scrotal swellings, distally.

Although the testis in early development is near the last thoracic segment, it is still close to the area of the developing deep inguinal ring. With rapid growth of the lumbar region and “ascent” of the metanephric kidney, the testis remains relatively immobilized by the gubernaculum, although there is the appearance of a lengthy transabdominal “descent” from an upper abdominal position. The testis descends through the inguinal canal around the 28th week and into the scrotum about the 32nd week. Testicular blood vessels form when the testis is located on the dorsal body wall and retain their origin during the transabdominal and pelvic descent of the testis. The mesonephric duct follows the descent of the testis and hence passes anterior to the ureter, which follows the retroperitoneal ascent of the kidney (Fig. 2–10).

Female: Uterus & Uterine Tubes

A. Mesonephric Ducts

Virtually all portions of these paired ducts degenerate in the female embryo, with the exception of the most caudal segment between the ureteric bud and the cloaca, which is later incorporated into the posterior wall of the urogenital sinus (Figs. 2–5 and 2–6) as the **trigone of the urinary bladder**. Regression begins just after gonadal sex differentiation and is finished near the onset of the third trimester. Cystlike or tubular vestiges of mesonephric duct (Fig. 2–11) may persist to variable degrees parallel with the vagina and uterus (**Gartner’s cysts**). Other mesonephric remnants of the duct or tubules may persist in the broad ligament (**epoophoron**).

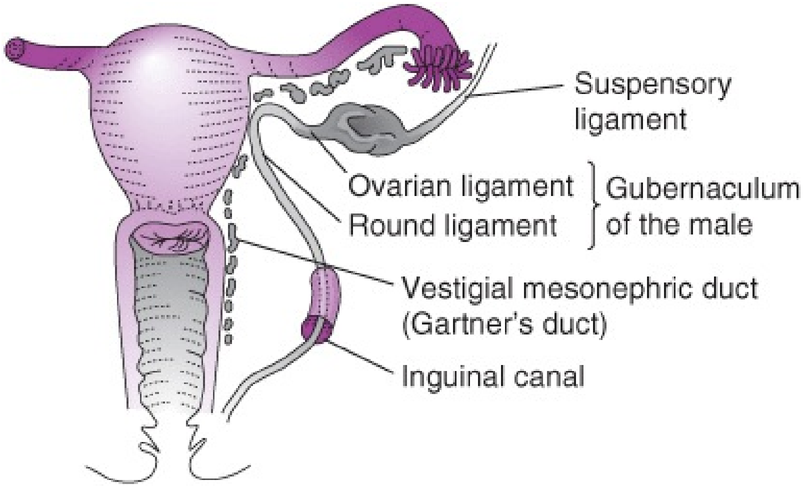

Figure 2–11. Female genital tract. Gubernacular derivatives and mesonephric vestiges are shown.

B. Paramesonephric Ducts

Differentiation of müllerian ducts in female embryos produces the uterine tubes, uterus, and probably the fibromuscular wall of the vagina. In contrast to the ductal/gonadal relationship in the male, ductal differentiation in the female does not require the presence of ovaries. Formation of the bilateral paramesonephric ducts during the second half of the embryonic period has been described [see Indifferent (Sexless) Stage]. By the onset of the fetal period, the 2 ducts are joined caudally in the midline, and the fused segment of the new Y-shaped ductal structure is the **uterovaginal primordium** (Fig. 2–8). The nonfused cranial part of each paramesonephric duct gives rise to the **uterine tubes** (oviducts), and the distal end of this segment remains open and will form the **ostium of the oviduct**.

Early in the ninth week, the uterovaginal primordium contacts medianly the dorsal wall of the urogenital sinus. This places the primordium at a median position between the bilateral openings of the mesonephric ducts, which joined the dorsal wall during the fifth week before subdivision of the urogenital sinus from the cloaca occurred (Figs. 2–8 and 2–9). A ventral protrusion of the dorsal wall of the urogenital sinus forms at the area of contact of the uterovaginal primordium with the wall and between the openings of the mesonephric ducts. In reference to its location, this protrusion is called the **sinusal tubercle (sinus tubercle, paramesonephric tubercle, müllerian tubercle**). This tubercle may consist of several types of epithelia derived from the different ducts as well as from the wall of the sinus.

Shortly after the sinusal tubercle forms, midline fusion of the middle and caudal portions of the paramesonephric ducts is complete, and the vertical septum (apposed walls of the fused ducts) within the newly established uterovaginal primordium degenerates, creating a single cavity or canal (Fig. 2–12). The solid tip of this primordium continues to grow caudally, while a mesenchymal thickening gradually surrounds the cervical region of the uterovaginal primordium. The primordium gives rise to the fundus, body, and isthmus of the uterus, specifically the endometrial epithelium and glands of the uterus. The endometrial stroma and smooth muscle of the myometrium are derived from adjacent splanchnic mesenchyme. The epithelium of the cervix forms from the lower aspect of the primordium. Development of the various components of the uterus covers the 3 trimesters of gestation. The basic structure is generated during the latter part of the first trimester. The initial formation of glands and muscular layer occurs near midgestation, whereas mucinous cells in the cervix appear during the third trimester.

The formation of the vagina is discussed in Differentiation of the Urogenital Sinus, even though the question of whether the vaginal epithelium is a sinusal or paramesonephric derivative (or both) has not been resolved. The fibromuscular wall of the vagina is generally considered to be derived from the uterovaginal primordium (Fig. 2–13).

C. Relocation of the Ovaries & Formation of Ligaments

Transabdominal “descent” of the ovary, unlike that of the testis, is restricted to a relatively short distance, presumably (at least partly) because of attachment of the gubernaculum to the paramesonephric duct. Hence, relocation of the ovary appears to involve both (1) a passive rotatory movement of the ovary as its mesentery is drawn by the twist of the developing ductal mesenteries and (2) extensive growth of the lumbosacral region of the fetus. The ovarian vessels (like the testicular vessels) originate or drain near the point of development of the gonad, the arteries from the aorta just inferior to the renal arteries and the veins to the left renal vein or to the vena cava from the right gonad.

Initial positioning of the ovary on the anteromedial aspect of the urogenital ridge is depicted in Figure 2–10, as is the relationship of the paramesonephric duct lateral to the degenerating mesonephros, the ovary, and the urogenital mesentery. The urogenital mesentery between the ridge and the dorsal body wall represents the first mesenteric support for structures developing in the ridge.

Alterations within the urogenital ridge eventually result in formation of contiguous double-layered mesenteries supporting the ovary and segments of the paramesonephric ducts. Enlargement of the ovary and degeneration of the adjacent mesonephric tissue bring previously separated layers of coelomic mesothelium into near apposition, establishing the mesentery of the ovary, the **mesovarium**. Likewise, mesonephric degeneration along the region of differentiation of the unfused cranial segment of the paramesonephric ducts establishes the **mesosalpinx**. Caudally, growth and fusion ventromedially of these bilateral ducts “sweep” the once medially attached mesenteries of the ducts toward the midline. These bilateral mesenteries merge over the fused uterovaginal primordium and extend laterally to the pelvic wall to form a continuous double-layered “drape,” the **mesometrium of the broad ligament**, between the upper portion of the primordium and the posterolateral body wall. This central expanse of mesentery creates the rectouterine and vesicouterine pouches. The midline caudal fusion of the ducts also alters the previous longitudinal orientation of the upper free segments of the ducts (the oviducts) to a near transverse orientation. During this alteration, the attached mesovarium is drawn from a medial relationship into a posterior relationship with the paramesonephric mesentery of the mesosalpinx and the mesometrium.

The **suspensory ligament of the ovary**, through which the ovarian vessels, nerves, and lymphatics traverse, forms when cranial degeneration of the mesonephric tissue and regression of the urogenital ridge adjacent to the ovary reduce these tissues to a peritoneal fold.

The **round ligament of the uterus** and the **proper ovarian ligament** are both derivatives of the **gubernaculum**, which originates as a mesenchymal condensation at the caudal end of the mesonephros and extends over the initially short distance to the anterior abdominal wall (see Relocation of the Testes and Ducts). As the gonad enlarges and the mesonephric tissue degenerates, the cranial attachment of the gubernaculum appears to “shift” to the inferior aspect of the ovary. Distally, growth of the fibrous gubernaculum continues into the inguinal region. However, the midportion of the gubernaculum becomes attached, inexplicably, to the paramesonephric duct at the uterotubal junction. Formation of the uterovaginal primordium by caudal fusion of the paramesonephric ducts apparently carries the attached gubernaculum medially within the cover of the encompassing mesentery of the structures (ie, the parts of the developing broad ligament). This fibrous band of connective tissue eventually becomes 2 ligaments.

Cranially, the band is the proper ligament of the ovary, extending between the inferior pole of the ovary and the lateral wall of the uterus just inferior to the oviduct. Caudally, it continues as the uterine round ligament from a point just inferior to the proper ovarian ligament and extending through the inguinal canal to the labium majus.

D. Anomalies of the Uterine Tubes (Oviducts, Fallopian Tubes)

The uterine tubes are derivatives of the cranial segments of the paramesonephric (müllerian) ducts, which differentiate in the urogenital ridge between the sixth and ninth weeks (Fig. 2–10). Ductal formation begins with invagination of the coelomic epithelium in the lateral coelomic bay. The initial depression remains open to proliferate and differentiate into the ostium (Fig. 2–10). Variable degrees of **duplication of the ostium** sometimes occur; in such cases, the leading edges of the initial ductal groove presumably did not fuse completely or anomalous proliferation of epithelium around the opening occurred.

Absence of a uterine tube is very rare when otherwise normal ductal and genital derivatives are present. This anomaly has been associated with (1) ipsilateral absence of an ovary and (2) ipsilateral unicornuate uterus (and probable anomalous broad ligament). Bilateral absence of the uterine tubes is most frequently associated with lack of formation of the uterus and anomalies of the external genitalia. Interestingly, absence of the derivatives of the lower part of the müllerian ducts with persistence of the uterine tubes occurs more frequently than the reverse condition. This might be expected, as the müllerian ducts form in a craniocaudal direction.

Partial absence of a uterine tube (middle or caudal segment) also has been reported. The cause of partial absence is unknown, although several theories have been advanced. One theory holds that when the unilateral anomaly coincides with ipsilateral ovarian absence, a “vascular accident” might occur following differentiation of the ducts and ovaries. Obviously, various factors resulting in somewhat localized atresia could be proposed. From a different perspective, bilateral absence of the uterine tubes as an associated disorder in a female external phenotype is characteristic of **testicular feminization syndrome or androgen insensitivity syndrome** (nonpersistence of the rest of the paramesonephric ducts, anomalous external genitalia, hypoplastic male genital ducts, and testicular differentiation with usual ectopic location).

E. Anomalies of the Uterus

The epithelium of the uterus and cervix and the fibromuscular wall of the vagina are derived from the paramesonephric (müllerian) ducts, the caudal ends of which fuse medially to form the uterovaginal primordium. Most of the primordium gives rise to the uterus (Fig. 2–13). Subsequently, the caudal tip of the primordium contacts the pelvic part of the urogenital sinus, and the interaction of the sinus (sinovaginal bulbs) and primordium leads to differentiation of the vagina. Various steps in this sequential process can go awry, such as (1) complete or partial failure of one or both ducts to form (agenesis), (2) lack of or incomplete fusion of the caudal segments of the paired ducts (abnormal uterovaginal primordium), or (3) failure of development *after* successful formation (aplasia or hypoplasia). Many types of anomalies may occur because of the number of sites for potential error, the complex interactions necessary for the development of the müllerian derivatives, and the duration of the complete process.

Complete **agenesis of the uterus** is very rare, and associated vaginal anomalies are usually expected. Also, a high incidence of associated structural or positional abnormalities of the kidney has been reported; there has been speculation that the initial error in severe cases may be in the development of the urinary system and then in the formation of the paramesonephric ducts.

Aplasia of the paramesonephric ducts (**müllerian aplasia**) is more common than agenesis and could occur after formation and interaction of the primordium with the urogenital sinus. A rudimentary uterus or a vestigial uterus (ie, varying degrees of fibromuscular tissue present) is most frequently accompanied by partial or complete absence of the vagina. As in uterine agenesis, ectopic kidney or absence of a kidney is frequently associated with uterine aplasia (in about 40% of cases). **Uterine hypoplasia** variably yields a rudimentary or infantile uterus and is associated with normal or abnormal uterine tubes and ovaries. Unilateral agenesis or aplasia of the ducts gives rise to **uterus unicornis**, whereas unilateral hypoplasia may result in a rudimentary horn that may or may not be contiguous with the lumen of the “normal” horn (**uterus bicornis unicollis** with one unconnected rudimentary horn; Fig. 2–14). The status of the rudimentary horn must be considered for potential hematometra, or blood in the uterus that cannot exit, at puberty.

Figure 2–14. Uterine anomalies. (*Redrawn and reproduced, with permission, from Toaff R. A major genital malformation: communicating uteri. *Obstet Gynecol* 1974;43:221.)

Anomalous **unification** caudally of the paramesonephric ducts results in many uterine malformations (Fig. 2–14). The incidence of defective fusion is estimated to be 0.1–3% of females. Furthermore, faulty unification of the ducts has been cited as the primary error responsible for most anomalies of the female genital tract. Partial or complete retention of the apposed walls of the paired ducts can produce slight (**uterus subseptus unicollis**) to complete (**uterus bicornis septus**) septal defects in the uterus. Complete failure of unification of the paramesonephric ducts can result in a double uterus (**uterus didelphys**) with either a single or double vagina.

F. Anomalies of the Cervix

Because the cervix forms as an integral part of the uterus, cervical anomalies are often the same as uterine anomalies. Thus, absence or hypoplasia of the cervix is rarely found with a normal uterovaginal tract. The cervix appears as a fibrous juncture between the uterine corpus and the vagina.

DIFFERENTIATION OF THE UROGENITAL SINUS

Until differentiation of the genital ducts begins, the urogenital sinus appears similar in both sexes during the middle and late embryonic period. For purposes of describing the origin of sinusal derivatives, the sinus can be divided into 3 parts: (1) the **vesical part**, or the large dilated segment superior to the entrance of the mesonephric ducts; (2) the **pelvic part**, or the narrowed tubular segment between the level of the mesonephric ducts and the inferior segment; and (3) the **phallic part**, often referred to as the definitive urogenital sinus (the anteroposteriorly elongated, transversely flattened inferiormost segment) (Fig. 2–8). The **urogenital membrane** temporarily closes the inferior limit of the phallic part. The superior limit of the vesical part becomes delimited by conversion of the once tubular allantois to a thick fibrous cord, the **urachus**, by about 12 weeks. After differentiation of the vesical part of the sinus to form the epithelium of the **urinary bladder**, the urachus maintains its continuity between the apex of the bladder and the umbilical cord and is identified postnatally as the **median umbilical ligament**. Various anomalies of urachal formation can present as **urachal fistula, cyst**, or **sinus**, depending on the degree of patency that persists during obliteration of the allantois.

In both sexes, the caudal segments of each mesonephric duct between the urogenital sinus and the level of the ureter of the differentiating metanephric diverticulum (or ureteric bud) become incorporated into the posterocaudal wall of the vesical part (ie, urinary bladder) of the sinus (Figs. 2–5 and 2–6). As the dorsal wall of the bladder grows and “absorbs” these caudal segments, the ureters are gradually “drawn” closer to the bladder and eventually open directly and separately into it, dorsolateral to the mesonephric ducts (Figs. 2–6 and 2–7). The mesodermal segment of mesonephric duct incorporated into the bladder defines the epithelium of the **trigone of the bladder**, although this mesodermal epithelium is secondarily replaced by the endodermal epithelium of the sinusal bladder. After formation of the trigone, the remainder of each mesonephric duct (ie, the portion that was cranial to the metanephric diverticulum) is joined to the superior end of the pelvic part of the urogenital sinus. Thereafter, the ducts either degenerate (in females) or undergo differentiation (in males).

Male: Urinary Bladder, Urethra, & Penis (Fig. 2–15)

The urogenital sinus gives rise to the endodermal epithelium of the **urinary bladder**, the prostatic and membranous urethra, and most of the spongy (penile) urethra (except the glandular urethra). Outgrowths from its derivatives produce epithelial parts of the prostate and bulbourethral glands (Fig. 2–15). The **prostatic urethra** receives the ejaculatory ducts (derived from the mesonephric ducts) and arises from 2 parts of the urogenital sinus. The portion of this urethral segment superior to the ejaculatory ducts originates from the inferiormost area of the vesical part of the sinus. The lower portion of the prostatic urethra is derived from the pelvic part of the sinus near the entrance of the ducts and including the region of the sinusal tubercle—the latter apparently forming the seminal colliculus. Early in the 12th week, endodermal outgrowths of the prostatic urethra form the prostatic anlage, the **prostatic buds**, from which the glandular epithelium of the **prostate** will arise. Differentiation of splanchnic mesoderm contributes other components to the gland (smooth muscle and connective tissue), as is the case for mesodermal parts of the urinary bladder. The pelvic part of the sinus also gives rise to the epithelium of the **membranous urethra**, which later yields endodermal buds for the **bulbourethral glands**. The phallic, or inferior, part of the urogenital sinus proliferates anteriorly as the external genitalia form (during weeks 9–12) and results in incorporation of this phallic part as the endodermal epithelium of the **spongy (penile) urethra** (the distal glandular urethra is derived from ectoderm).

Figure 2–15. Schematic drawing of male differentiation of the urogenital sinus; formation of urinary bladder and urethra. (Explanatory symbols are given in Fig. 2–1.)

Early masculinization of the undifferentiated or indifferent genitalia takes place during the first 3 weeks of the fetal period (weeks 9–12) and is caused by androgenic stimulation. The phallus and urogenital folds gradually elongate to initiate development of the **penis**. The subjacent endodermal lining of the inferior part (phallic) of the urogenital sinus extends anteriorly along with the urogenital folds, creating an endodermal plate, the **urethral plate**. The plate deepens into a groove, the **urethral groove**, as the urogenital folds (now called **urethral folds**) thicken on each side of the plate. The urethral groove extends into the ventral aspect of the developing penis, and the bilateral urethral folds slowly fuse in a posterior to anterior direction over the urethral groove to form the **spongy (penile) urethra**, thereby closing the urogenital orifice (Fig. 2–15; see also Fig. 2–20). The line of fusion becomes the **penile raphe** on the ventral surface of the penis.

As closure of the urethral folds approaches the glans, the external urethral opening on this surface is eliminated. Concurrently, an **ectodermal glandular plate** invaginates the tip of the penis. Canalization of the plate forms the distal end of the penile urethra, the **glandular urethra**. Thus, the external urethral meatus becomes located at the tip of the glans when closure of the urethral folds is completed (see Fig. 2–20). The **prepuce** is formed slightly later by a circular invagination of ectoderm at the tip of the **glans penis**. This cylindric ectodermal plate then cleaves to leave a double-layered fold of skin extending over the glans.

While the cloacal folds and phallic urogenital sinus were differentiating into the penis and the urethra, the **genital (labioscrotal)** swellings of the undifferentiated stage were enlarging lateral to the cloacal folds. Medial growth and fusion of the scrotal swellings to form the **scrotum** and **scrotal raphe** around the 12th week virtually complete the differentiation of the male external genitalia (see Figs. 2–20 and 2–22).

Female: Urinary Bladder, Urethra, & Vagina

A. Development

Differentiation of the female sinus is schematically presented in Figure 2–13 and illustrated in Figures 2–8, 2–12, 2–16, and 2–17. In contrast to sinusal differentiation in the male, the vesical part of the female urogenital sinus forms the epithelium of the **urinary bladder** and entire **urethra**. Derivatives of the pelvic part of the sinus include the epithelium of the **vagina**, the **greater vestibular glands**, and the **hymen**. Controversy exists about how the vagina is formed, mainly because of a lack of consensus about the origin and degree of inclusion of its precursory tissues (mesodermal paramesonephric duct, endodermal urogenital sinus, or even mesonephric duct). The most common theory is that 2 endodermal outgrowths, the **sinovaginal bulbs**, of the dorsal wall of the pelvic part of the urogenital sinus form bilateral to and join with the caudal tip of the uterovaginal primordium (fused paramesonephric ducts) in the area of the sinusal tubercle (Fig. 2–12). This cellular mass at the end of the primordium occludes the inferior aspect of the canal, creating an endodermal **vaginal plate** within the mesodermal wall of the uterovaginal primordium. Eventually, the vaginal segment grows, approaching the vestibule of the vagina. The process of growth has been described either as “downgrowth” of the vaginal segment away from the uterine canal and along the urogenital sinus or, more commonly, as “upgrowth” of the segment away from the sinus and toward the uterovaginal canal. In either case, the vaginal segment is extended between the paramesonephric-derived cervix and the sinus-derived vestibule (Figs. 2–12, 2–16, and 2–17). Near the fifth month, the breakdown of cells centrally in the vaginal plate creates the vaginal lumen, which is delimited peripherally by the remaining cells of the plate as the epithelial lining of the vagina. The solid vaginal fornices become hollow soon after canalization of the vaginal lumen is complete. The upper one-third to four-fifths of the vaginal epithelium has been proposed to arise from the uterovaginal primordium, whereas the lower two-thirds to one-fifth has been proposed as a contribution from the sinovaginal bulbs.

Figure 2–17. Sagittal cutaway view of differentiated urogenital sinus and precanalization stage of vaginal development. The drawing depicts one of several theories about the relative contributions of paramesonephric ducts and sinovaginal bulbs to the vagina.

The fibromuscular wall of the vagina is derived from the uterovaginal primordium. The cavities of the vagina and urogenital sinus are temporarily separated by the thin **hymen**, which probably is a mixture of tissue derived from the vaginal plate and the remains of the sinusal tubercle. With concurrent differentiation of female external genitalia, inferior closure of the sinus does not occur during the 12th week of development, as it does in the male. Instead, the remainder of the pelvic part and all of the inferior phallic part of the urogenital sinus expand to form the **vestibule of the vagina**. Presumably, the junctional zone of pigmentation on the labia minora represents the distinction between endodermal derivation from the urogenital sinus (medially) and ectodermal skin (laterally).

B. Anomalies of the Vagina

The vagina is derived from interaction between the uterovaginal primordium and the pelvic part of the urogenital sinus (Fig. 2–13; see Development). The causes of vaginal anomalies are difficult to assess because integration of the uterovaginal primordium and the urogenital sinus in the *normal* differentiation of the vagina remains a controversial subject. Furthermore, an accurate breakdown of causes of certain anomalous vaginal presentations, as with many anomalies of the external genitalia, would have to include potential moderating factors of endocrine and genetic origin as well.

The incidence of absence of the vagina due to suspected **vaginal agenesis** is about 0.025%. Agenesis may be due to failure of the uterovaginal primordium to contact the urogenital sinus. The uterus is usually absent (Fig. 2–18). Ovarian agenesis is not usually associated with vaginal agenesis. The presence of greater vestibular glands has been reported with presumed vaginal agenesis; their presence emphasizes the complexity of differentiation of the urogenital sinus.

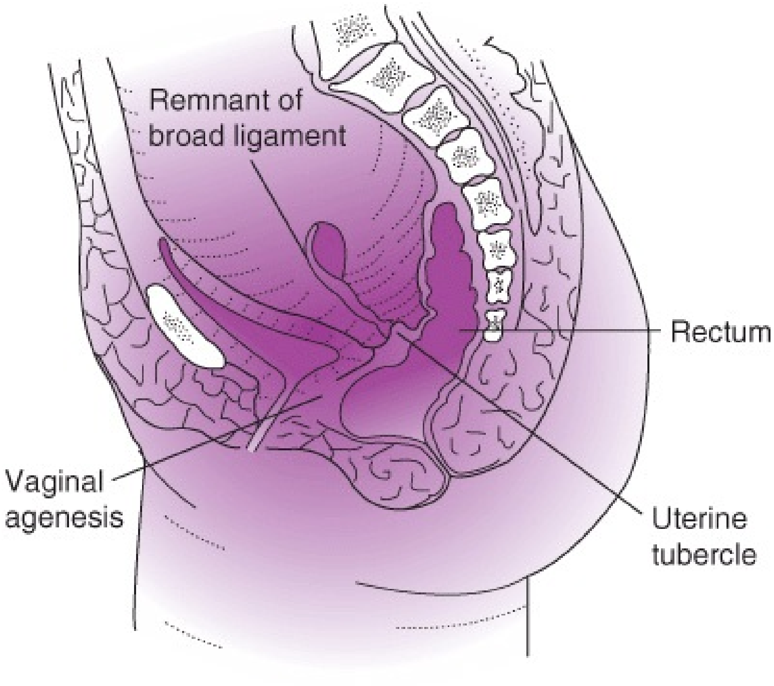

Figure 2–18. Midsagittal view of vaginal agenesis and uterine agenesis with normal ovaries and oviducts.

Vaginal atresia, on the other hand, is considered when the lower portion of the vagina consists merely of fibrous tissue while the contiguous superior structures (the uterus, in particular) are well differentiated (perhaps because the primary defect is in the sinusal contribution to the vagina). In **müllerian aplasia** almost all of the vagina and most of the uterus are absent (Rokitansky-Küster-

Hauser syndrome, with a rudimentary uterus of bilateral, solid muscular tissue, was considered virtually the same as this aplasia). Most women with absence of the vagina (and normal external genitalia) are considered to have müllerian aplasia rather than vaginal atresia.

Other somatic anomalies are sometimes associated with müllerian aplasia, suggesting multiple malformation syndrome. Associated vertebral anomalies are much more prevalent than middle ear anomalies, eg, müllerian aplasia associated with **Klippel-Feil syndrome** (fused cervical vertebrae) is more common than müllerian aplasia associated with Klippel-Feil syndrome plus middle ear anomalies ("conductive deafness"). **Winter's syndrome**, which is thought to be autosomal recessive, is evidenced by middle ear anomalies (somewhat similar to those in the triad above), renal agenesis or hypoplasia, and vaginal atresia (rather than aplasia of the paramesonephric ducts). **Dysgenesis** (partial absence) of the vagina and **hypoplasia** (reduced caliber of the lumen) have also been described.

Transverse vaginal septa (Fig. 2–19) are probably not the result of vaginal atresia but rather of incomplete canalization of the vaginal plate or discrete fusion of sinusal and primordial (ductal) derivatives. Alternative explanations are likely because the histologic composition of septa is not consistent. A rare genetic linkage has been demonstrated. A single septum or multiple septa can be present, and the location may vary in upper or lower segments of the lumen. **Longitudinal vaginal septa** can also occur. A variety of explanations have been advanced, including true duplication of vaginal primordial tissue, anomalous differentiation of the uterovaginal primordium, abnormal variation of the caudal fusion of the müllerian ducts, persistence of vaginal plate epithelium, and anomalous mesodermal proliferation. Septa may be imperforate or perforated. A transverse septum creates the potential for various occlusive manifestations (eg, hydrometrocolpos, hematometra, or hematocolpos), depending on the composition and location of the trapped fluid.

Hematocolpos
Complete occlusion of lower vagina by transverse septum or imperforate hymen

Figure 2–19. Transverse vaginal septa.

Abnormalities of the vagina are often associated with anomalies of the urinary system and the rectum because differentiation of the urogenital sinus is involved in formation of the bladder and urethra as well as the vagina and vestibule. Furthermore, if partitioning of the cloaca into the sinus and anorectal canal is faulty, then associated rectal defects can occur. Compound anomalies may affect the urinary tract or rectum. The urethra may open into the vaginal wall; even a single vesicovaginal cavity has been described. On the other hand, the vagina can open into a persistent urogenital sinus, as in certain forms of female pseudohermaphroditism. Associated rectal abnormalities include vaginorectal fistula, vulvovaginal anus, rectosigmoidal fistula, and vaginosigmoidal cloaca in the absence of the rectum (see Cloacal Dysgenesis).

C. Anomalies of the Hymen

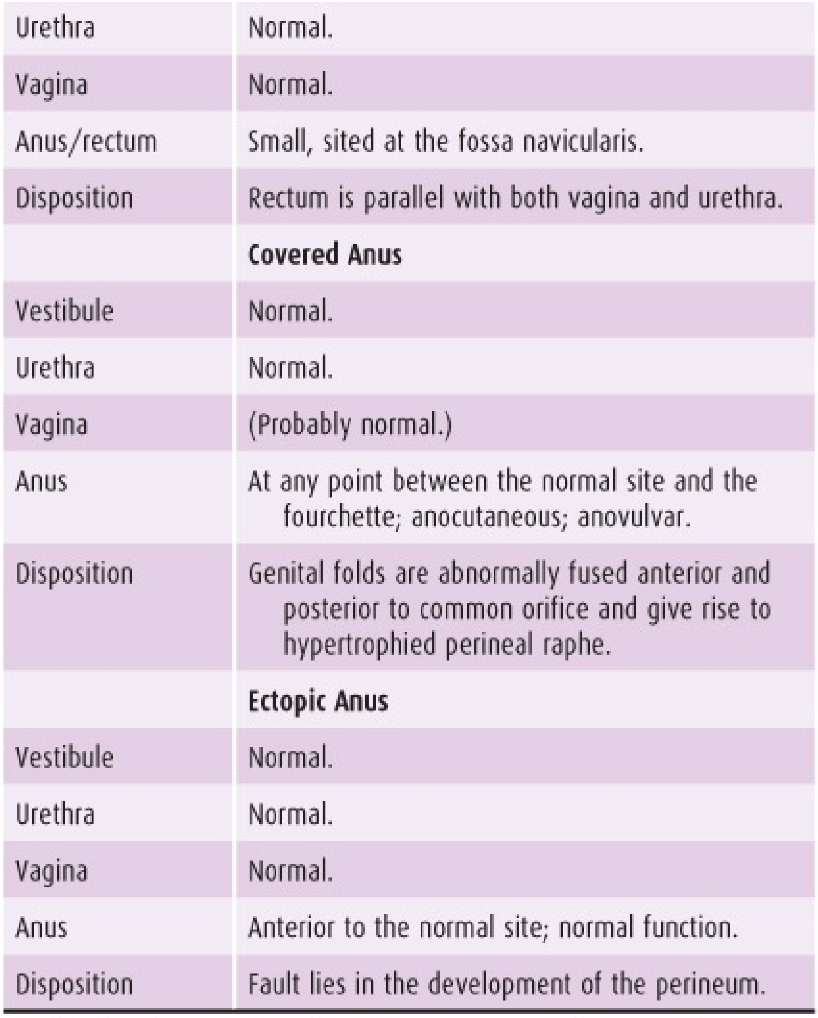
The hymen is probably a mixture of tissue derived from remains of the sinusal tubercle and the vaginal plate. Usually, the hymen is patent, or perforate, by puberty, although an **imperforate hymen** is not rare. The imperforate condition can be the result of a congenital error of lack of central degeneration or the result of inflammatory occlusion after perforation. Obstruction of menstrual flow at puberty may be the first sign (Fig. 2–19).

D. Cloacal Dysgenesis (Including Persistence of the Urogenital Sinus)

Anomalous partitioning of the cloaca by abnormal development of the urorectal septum is rare, at least based on reported cases in the literature. As anticipated from a developmental standpoint, the incidence of associated genitourinary anomalies is high. Five types of cloacal or anorectal malformations are summarized in Table 2–3.

Table 2–3. Cloacal malformations.

	Rectocloacal Fistula
Vestibule	Deformed; flanked by labia; clitoris in front, fourchette behind; anterior vestibule short, shallow, and moist; single external orifice in posterior half of vestibule (common conduit for urine, cervical mucus, and feces).
Bladder/urethra	Anterior; directed cranially and ventrally.
Vagina	Opens into the vault of cloaca.
Anus/rectum	Enters at highest and most posterior point; orifice is in midline and stenotic.
Disposition	Lengths of urethra and vagina are inversely proportionate to length of cloacal canal.
	Rectovaginal Fistula
Vestibule	Normal anatomy (2 orifices: urethral and vaginal).
Bladder/urethra	Normal.
Vagina	May be septate or normal.
Anus/rectum	Internal in the midposterior vaginal wall.
Disposition	Anus absent from perineum.
	Rectovestibular Fistula
Vestibule	Contains rectum, otherwise normal.



Urethra	Normal.
Vagina	Normal.
Anus/rectum	Small, sited at the fossa navicularis.
Disposition	Rectum is parallel with both vagina and urethra.
	Covered Anus
Vestibule	Normal.
Urethra	Normal.
Vagina	(Probably normal.)
Anus	At any point between the normal site and the fourchette; anocutaneous; anovulvar.
Disposition	Genital folds are abnormally fused anterior and posterior to common orifice and give rise to hypertrophied perineal raphe.
	Ectopic Anus
Vestibule	Normal.
Urethra	Normal.
Vagina	Normal.
Anus	Anterior to the normal site; normal function.
Disposition	Fault lies in the development of the perineum.

Modified and reproduced, with permission, from Okonkwo JEN, Crocker KM. Cloacal dysgenesis. *Obstet Gynecol* 1977;50:97–101.

Rectocloacal fistula with a persistent cloaca provides a common canal or outlet for the urinary, genital, and intestinal tracts. The distinction between a canal and an outlet is one of depth (deep versus very shallow, respectively) of the persistent lower portion of the cloaca and, thus, the length of the individual urethral and vaginal canals emptying into the cloaca. The inverse relationship between depth (or length) of the cloaca and length of the vaginal and urethral canals is probably a reflection of the time when arrest of formation of the urorectal septum occurs. Although the bladder, the vagina, and the rectum can empty into a common cloaca as just described, other unusual variations of persistent cloaca can also occur.

For example, the vagina and rectum develop, but the urinary bladder does not develop as a separate entity from the cloaca. Instead, the vagina and rectum open separately into a “urinary bladder,” which has ureters entering posterolaterally to the vagina (vaginal orifice is in the “anatomic trigone” of the bladderlike structure). The external orifice from the base of this cloacal “bladder” is a single narrow canal. One explanation for this variant might be that arrest of formation of the urorectal septum occurs much earlier than does the separate development of distal portions of the 3 tracts (urethra, vagina, and anorectum) to a more advanced (but still incomplete) stage before urorectal septal formation ceases. The anomaly is probably rare.

With a **rectovaginal fistula**, the vestibule may appear anatomically normal, but the anus does not appear in the perineum. The defect probably results from anorectal agenesis due to incomplete subdivision of the cloaca (similar agenesis in the male could result in a rectourethral fistula). The development of the anterior aspect of the vagina completes the separation of the urethra from the vagina, so there is not a persistent urogenital sinus. **Anorectal agenesis** is reputedly the most common type of anorectal malformation, and usually a fistula occurs. Rectovaginal, anovestibular (or rectovestibular; Table 2–3), and anoperineal fistulas account for most anorectal malformations.

In the absence of the anorectal defect (normal anal presentation) but presence of a **persistent urogenital sinus** with a single external orifice, various irregularities of the urethra and genitalia can appear. The relative positions of urethral and vaginal orifices in the sinus can even change as the child grows. In the discussion of anomalies of the labia majora, there may be a persistent urogenital sinus in female pseudohermaphroditism due to congenital adrenal hyperplasia. The vagina opens into the persisting pelvic part of the sinus, which extends with the phallic part of the sinus to the external surface at the urogenital opening. The sinus can be deep and narrow in the neonate, approximating the size of a urethra, or it can be relatively shallow.

Urinary tract disorders associated with persistent urogenital sinus include duplication of the ureters, unilateral ureteral and renal agenesis or atresia, and lack of or abnormal ascent of the kidneys. Variations in the anomalies of derivatives of the urogenital sinus appear to be related in part to the time of arrest of normal differentiation and development of the urogenital sinus, as well as to the impact of other factors associated with abnormal sexual differentiation, such as the variable degrees of response to adrenal androgen in congenital adrenal hyperplasia.

THE EXTERNAL GENITALIA

Undifferentiated Stage

The external genitalia begin to form early in the embryonic period, shortly after development of the cloaca. The progenitory tissues of the genitalia are common to both sexes, and the early stage of development is virtually the same in females and males. Although differentiation of the genitalia can begin around the onset of the fetal period if testicular differentiation is initiated, definitive genital sex is usually not clearly apparent until the 12th week. Formation of external genitalia in the male involves the influence of androgen on the interaction of subepidermal mesoderm with the inferior parts of the endodermal urogenital sinus. In the female, this androgenic influence is absent.

The external genitalia form within the initially compact area bounded by the umbilical cord (anteriorly), the developing limb buds (laterally), the embryonic tail (posteriorly), and the cloacal membrane (centrally). Two of the primordia for the genitalia first appear bilaterally adjacent to the cloacal membrane (a medial pair of cloacal folds and a lateral pair of genital [labioscrotal] swellings). The **cloacal folds** are longitudinal proliferations of caudal mesenchyme located between the ectodermal epidermis and the underlying endoderm of the phallic part of the urogenital sinus. Proliferation and bilateral anterior fusion of these folds create the **genital tubercle**, which protrudes near the anterior edge of the cloacal membrane by the sixth week (Figs. 2–20 to 2–22). Extension of the tubercle forms the phallus, which at this stage is the same size in both sexes.

Anus

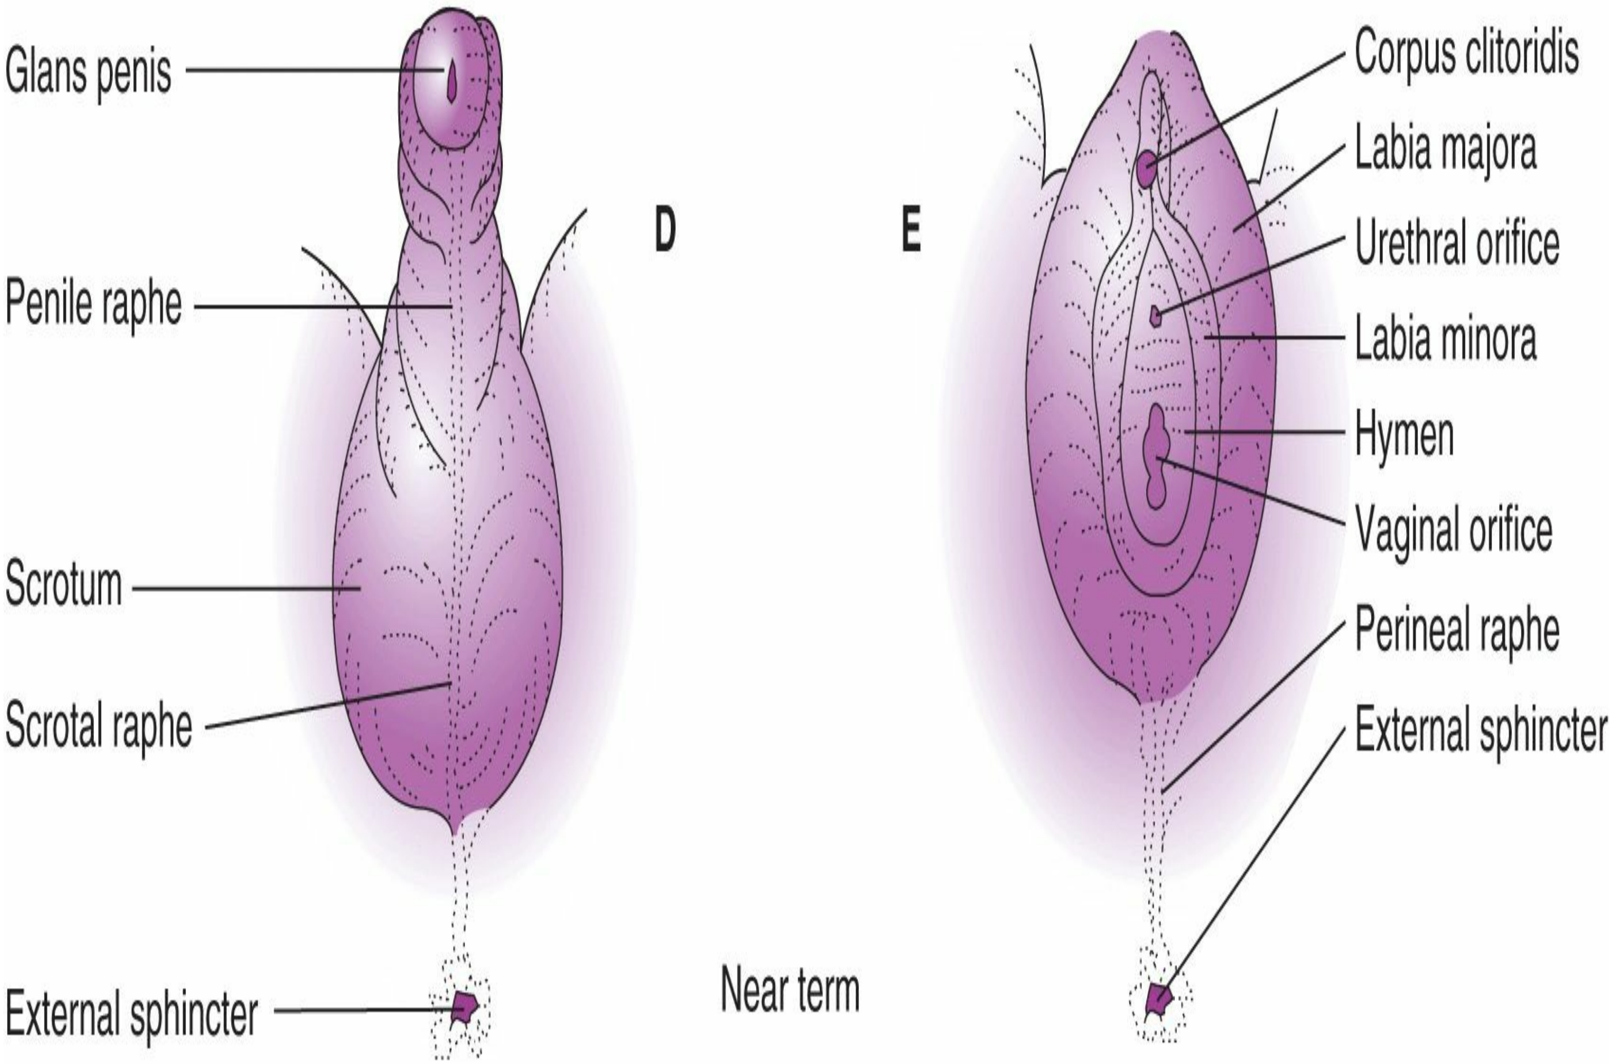

Figure 2–22. Development of external genitalia. **A**: Before sexual differentiation and just after the urorectal septum divides the cloacal membrane. **B** and **D:** Male differentiation at about 10 weeks and near term, respectively. The urogenital folds fuse ventrally over the urethral groove to form the spongy urethra and close the inferior phallic part of the urogenital sinus. The glandular urethra forms by canalization of invaginated ectoderm from the tip of the glans. **C** and **E**: Female differentiation at about 10 weeks and near term, respectively. Until about 12 weeks, there is little difference in the appearance of female and male external genitalia. The urogenital folds fuse only at their anterior and posterior extremes, while the unfused remainder differentiates into the labia minor. (See also Figs. 2–20 and 2–21.)

By the seventh week, the urorectal septum subdivides the bilayered (ectoderm and endoderm) cloacal membrane into the **urogenital membrane** (anteriorly) and the **anal membrane** (posteriorly). The area of fusion of the urorectal septum and the cloacal membrane becomes the **primitive perineum**, or **perineal body**. With formation of the perineum, the cloacal folds are divided transversely as **urogenital folds** adjacent to the urogenital membrane and **anal folds** around the anal membrane. As the mesoderm within the urogenital folds thickens and elongates between the perineum and the phallus, the urogenital membrane sinks deeper into the fissure between the folds. Within a week, this membrane ruptures, forming the **urogenital orifice** and, thus, opening the urogenital sinus to the exterior. Similar thickening of the anal folds creates a deep anal pit, in which the anal membrane breaks down to establish the **anal orifice** of the anal canal (Figs. 2–20 and 2–21).

Subsequent masculinization or feminization of the external genitalia is a consequence of the respective presence or absence of androgen and the androgenic sensitivity or insensitivity of the tissues. The significance of both of these factors (availability of hormone and sensitivity of target tissue) is exemplified by the rare condition (about 1 in 50,000 “females”) of **testicular feminization**, wherein testes are present (usually ectopic) and produce testosterone and antimüllerian hormone. The antimüllerian hormone suppresses formation of the uterus and uterine tubes (from the paramesonephric ducts), whereas testosterone supports male differentiation of the mesonephric ducts to form the epididymis and ductus deferens. The anomalous feminization of the external genitalia is considered to be due to androgenic insensitivity of the precursor tissues consequent to an abnormal androgen receptor or postreceptor mechanism set by genetic inheritance.

Female

A. Development of External Genitalia

Feminization of the external genitalia proceeds in the absence of androgenic stimulation (or nonresponsiveness of the tissue). The 2 primary distinctions in the general process of feminization versus masculinization are (1) the lack of continued growth of the phallus and (2) the near absence of fusion of the urogenital folds and the labioscrotal swellings. Female derivatives of the indifferent sexual primordia for the external genitalia are virtually homologous counterparts of the male derivatives. Formation of the female genitalia is schematically presented in Figure 2–21.

The growth of the phallus slows relative to that of the urogenital folds and labioscrotal swellings and becomes the diminutive **clitoris**. The anterior extreme of the urogenital folds fuses superior and inferior to the clitoris, forming the **prepuce** and **frenulum of the clitoris**, respectively. The mid-portions of these folds do not fuse but give rise to the **labia minora**. Lack of closure of the folds leaves the urogenital orifice patent and results in formation of the **vestibule of the vagina** from the inferior portion of the pelvic part and the phallic part of the urogenital sinus at about the fifth month (Fig. 2–21). Derivatives of the vesical part of the sinus (the **urethra**) and the superior portion of the pelvic part of the sinus (**vagina** and **greater vestibular glands**) then open separately into the vestibule. The **frenulum of the labia minora** is formed by fusion of the posterior ends of the urogenital folds. The mesoderm of the labioscrotal swellings proliferates beneath the ectoderm and remains virtually unfused to create the **labia majora** lateral to the labia minora. The swellings blend together anteriorly to form the **anterior labial commissure** and the tissue of the **mons pubis**, while the swellings posteriorly less clearly define a **posterior labial commissure**. The distal fibers of the round ligament of the uterus project into the tissue of the labia majora.

B. Anomalies of the Labia Minora

In otherwise normal females, 2 somewhat common anomalies occur—labial fusion and labial hypertrophy. True labial fusion as an early developmental defect in the normally unfused midportions of the urogenital folds is purportedly less frequent than “fusion” due to inflammatory-type reactions. **Labial hypertrophy** can be unilateral or bilateral and may require surgical correction in extreme cases.

C. Anomalies of the Labia Majora

The labia majora are derived from the bilateral genital (labioscrotal) swellings, which appear early in the embryonic period and remain unfused centrally during subsequent sex differentiation in the fetal period. Anomalous conditions include **hypoplastic** and **hypertrophic labia** as well as different gradations of fusion of the labia majora. Abnormal fusion (masculinization) of labioscrotal swellings in genetic females is most commonly associated with ambiguous genitalia of female pseudohermaphroditism consequent to **congenital adrenal hyperplasia (adrenogenital syndrome**). Over 90% of females with congenital adrenal hyperplasia have a steroid 21-hydroxylase deficiency (autosomal recessive), resulting in excess adrenal androgen production. This enzyme deficiency has been reported to be “the most common cause of ambiguous genitalia in genetic females.” Associated anomalies include clitoral hypertrophy and persistent urogenital sinus. Formation of a penile urethra is extremely rare.

D. Anomalies of the Clitoris

Clitoral agenesis is extremely rare and is due to lack of formation of the genital tubercle during the sixth week. Absence of the clitoris could also result from **atresia** of the genital tubercle. The tubercle forms by fusion of the anterior segments of the cloacal folds. Very rarely, these anterior segments fail to fuse, and a **bifid clitoris** forms. This anomaly also occurs when unification of the anterior parts of the folds is restricted by exstrophy of the cloaca or bladder. Duplication of the genital tubercle with consequent formation of a **double clitoris** is equally rare. **Clitoral hypertrophy** alone is not common but may be associated with various intersex disorders.

E. Anomalies of the Perineum

The primitive perineum originates at the area of contact of the mesodermal urorectal septum and the endodermal dorsal surface of the cloacal membrane (at 7 weeks). During normal differentiation of the external genitalia in the fetal period, the primitive perineum maintains the separation of the urogenital folds and ruptured urogenital membrane from the anal folds and ruptured anal membrane, and later develops the perineal body. Malformations of the perineum are rare and usually associated with malformations of cloacal or anorectal development consequent to abnormal development of the urorectal septum. Imperforate anus has an incidence of about 0.02%. The simplest form (rare) is a thin membrane over the anal canal (the anal membrane failed to rupture at the end of the embryonic period). Anal stenosis can arise by posterior deviation of the urorectal septum as the septum approaches the cloacal membrane, causing the anal membrane to be smaller (with a relatively increased anogenital distance through the perineum). Anal agenesis with a fistula detected as an ectopic anus is considered to be a urorectal septal defect. The incidence of agenesis with a fistula is only slightly less than that without a fistula. In females, the fistula commonly may be located in the perineum (perineal fistula) or may open into the posterior aspect of the vestibule of the vagina (anovestibular fistula; see Cloacal Dysgenesis).

GENETIC DISORDERS

MENDELIAN LAWS OF INHERITANCE

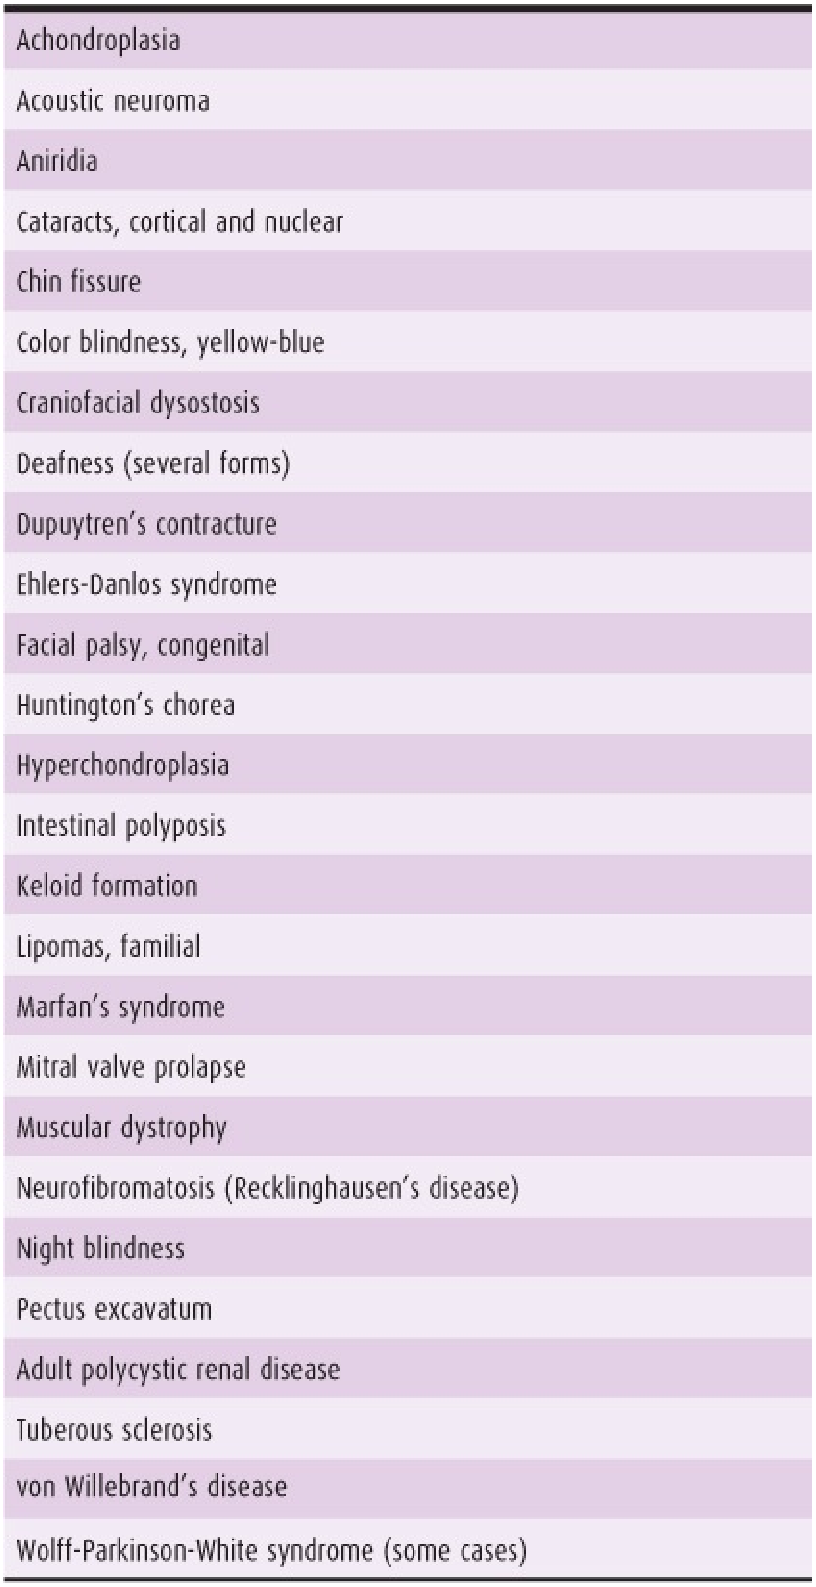
1. Types of Inheritance

Autosomal Dominant

In autosomal dominant inheritance, it is assumed that a mutation has occurred in 1 gene of an allelic pair and that the presence of this new gene produces enough of the changed protein to give a different phenotypic effect. Environment must also be considered because the effect may vary under different environmental conditions. The following are characteristic of autosomal dominant inheritance:

1. The trait appears with equal frequency in both sexes.
2. For inheritance to take place, at least 1 parent must have the trait unless a new mutation has just occurred.
3. When a homozygous individual is mated to a normal individual, all offspring will carry the trait. When a heterozygous individual is mated to a normal individual, 50% of the offspring will show the trait.
4. If the trait is rare, most persons demonstrating it will be heterozygous (Table 3–1).

Table 3–1. Examples of autosomal dominant conditions and traits.



Achondroplasia
Acoustic neuroma
Aniridia
Cataracts, cortical and nuclear
Chin fissure
Color blindness, yellow-blue
Craniofacial dysostosis
Deafness (several forms)
Dupuytren's contracture
Ehlers-Danlos syndrome
Facial palsy, congenital
Huntington's chorea
Hyperchondroplasia
Intestinal polyposis
Keloid formation
Lipomas, familial
Marfan's syndrome
Mitral valve prolapse
Muscular dystrophy
Neurofibromatosis (Recklinghausen's disease)
Night blindness
Pectus excavatum
Adult polycystic renal disease
Tuberous sclerosis
von Willebrand's disease
Wolff-Parkinson-White syndrome (some cases)

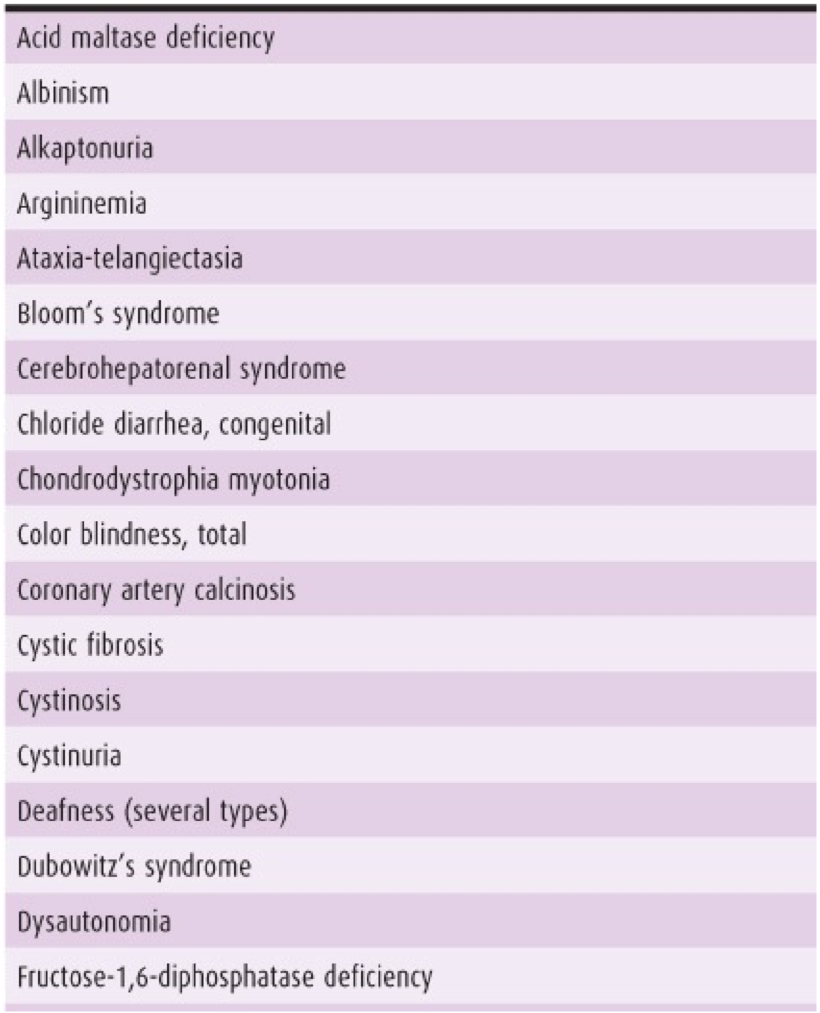
Autosomal Recessive

The mutant gene will not be capable of producing a new characteristic in the heterozygous state in this circumstance under customary environmental conditions—ie, with 50% of the genetic material producing the new protein, the phenotypic effect will not be different from that of the normal trait. When the environment is manipulated, the recessive trait occasionally becomes dominant. The characteristics of this form of inheritance are as follows:

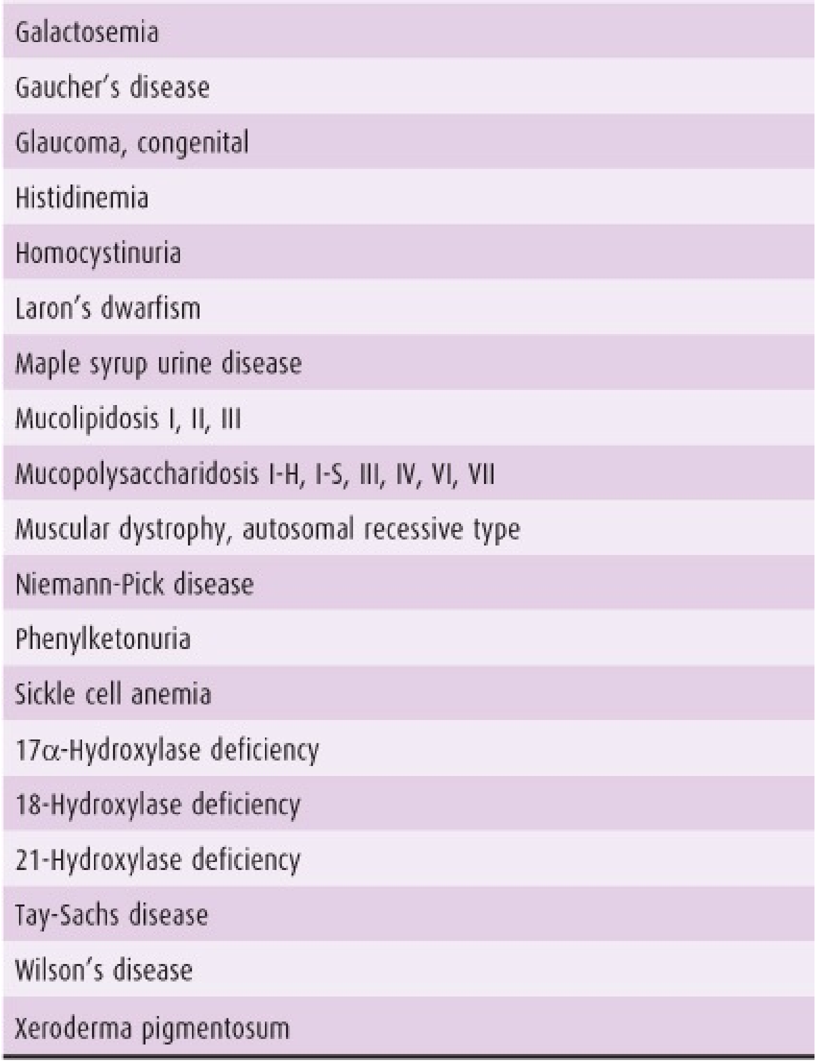
1. The characteristic will occur with equal frequency in both sexes.
2. For the characteristic to be present, both parents must be carriers of the recessive trait.

3. If both parents are homozygous for the recessive trait, all offspring will have it.
4. If both parents are heterozygous for the recessive trait, 25% of the offspring will have it.
5. In pedigrees showing frequent occurrence of individuals with rare recessive characteristics, consanguinity is often present (Table 3–2).

Table 3–2. Examples of autosomal recessive conditions and traits.



Acid maltase deficiency
Albinism
Alkaptonuria
Argininemia
Ataxia-telangiectasia
Bloom's syndrome
Cerebrohepatorenal syndrome
Chloride diarrhea, congenital
Chondrodystrophia myotonia
Color blindness, total
Coronary artery calcinosis
Cystic fibrosis
Cystinosis
Cystinuria
Deafness (several types)
Dubowitz's syndrome
Dysautonomia
Fructose-1,6-diphosphatase deficiency



Galactosemia
Gaucher's disease
Glaucoma, congenital
Histidinemia
Homocystinuria
Laron's dwarfism
Maple syrup urine disease
Mucolipidosis I, II, III
Mucopolysaccharidosis I-H, I-S, III, IV, VI, VII
Muscular dystrophy, autosomal recessive type
Niemann-Pick disease
Phenylketonuria
Sickle cell anemia
17α-Hydroxylase deficiency
18-Hydroxylase deficiency
21-Hydroxylase deficiency
Tay-Sachs disease
Wilson's disease
Xeroderma pigmentosum

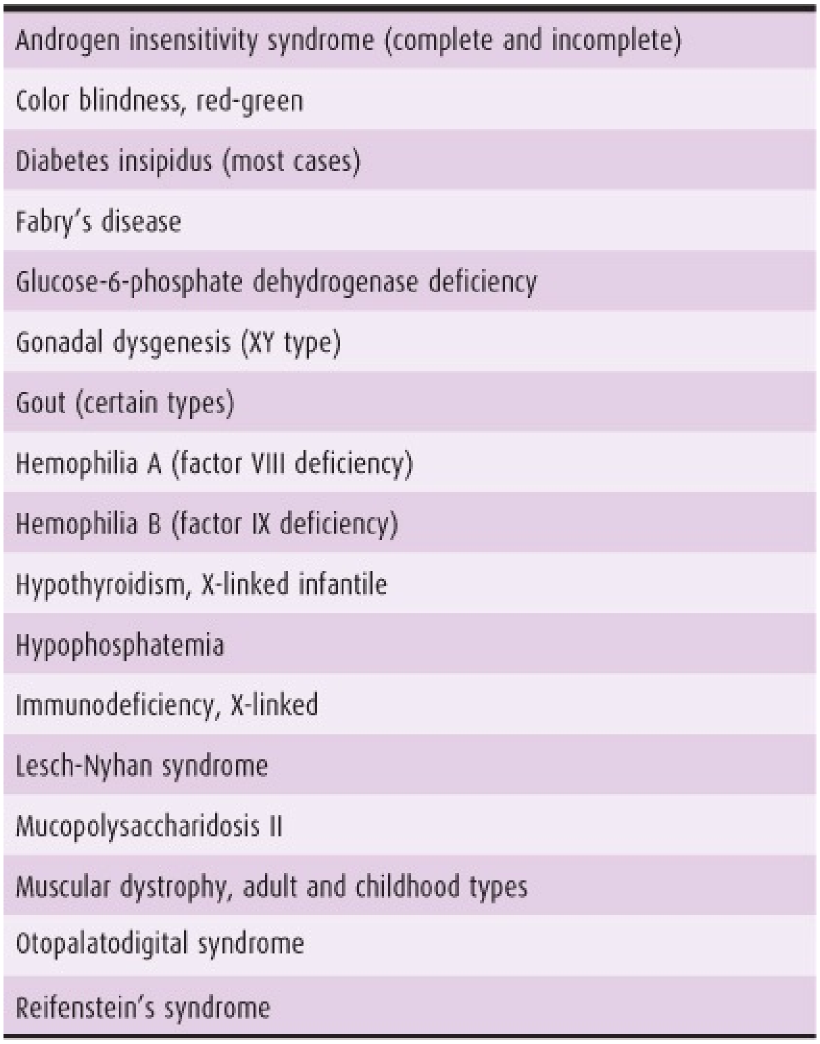
X-Linked Recessive

This condition occurs when a gene on the X chromosome undergoes mutation and the new protein formed as a result of this mutation is incapable of producing a change in phenotype characteristic in the heterozygous state. Because the male has only 1 X chromosome, the presence of this mutant will allow for expression should it occur in the male. The following are characteristic of this form of inheritance:

1. The condition occurs more commonly in males than in females.
2. If both parents are normal and an affected male is produced, it must be assumed that the mother is a carrier of the trait.
3. If the father is affected and an affected male is produced, the mother must be at least heterozygous for the trait.
4. A female with the trait may be produced in 1 of 2 ways. (A) She may inherit a recessive gene from both her mother and her father; this suggests that the father is affected and the mother is heterozygous. (B) She may inherit a recessive gene from 1 of her parents and may express the recessive characteristic as a function of the Lyon hypothesis; this assumes that all females are mosaics for their functioning X chromosome. It is theorized that this occurs because at about the time of implantation, each cell in the developing female embryo selects 1 X chromosome as its functioning X and that all progeny cells thereafter use this X chromosome as their functioning X chromosome. The other X chromosome becomes inactive. Because this selection is done on a random basis, it is conceivable that some females will be produced who will be using primarily

the X chromosome bearing the recessive gene. Thus, a genotypically heterozygous individual may demonstrate a recessive characteristic phenotypically on this basis (Table 3–3).

Table 3–3. Examples of X-linked recessive conditions and traits.



Androgen insensitivity syndrome (complete and incomplete)
Color blindness, red-green
Diabetes insipidus (most cases)
Fabry's disease
Glucose-6-phosphate dehydrogenase deficiency
Gonadal dysgenesis (XY type)
Gout (certain types)
Hemophilia A (factor VIII deficiency)
Hemophilia B (factor IX deficiency)
Hypothyroidism, X-linked infantile
Hypophosphatemia
Immunodeficiency, X-linked
Lesch-Nyhan syndrome
Mucopolysaccharidosis II
Muscular dystrophy, adult and childhood types
Otopalatodigital syndrome
Reifenstein's syndrome

X-Linked Dominant

In this situation, the mutation will produce a protein that, when present in the heterozygous state, is sufficient to cause a change in characteristic. The following are characteristic of this type of inheritance:

1. The characteristic occurs with the same frequency in males and females.
2. An affected male mated to a normal female will produce the characteristic in 50% of the offspring.
3. An affected homozygous female mated to a normal male will produce the affected characteristic in all offspring.
4. A heterozygous female mated to a normal male will produce the characteristic in 50% of the offspring.
5. Occasional heterozygous females may not show the dominant trait on the basis of the Lyon hypothesis (Table 3–4).

Table 3–4. Examples of X-linked dominant conditions and traits.

Acro-osteolysis, dominant type
Cervico-oculo-acoustic syndrome
Hyperammonemia
Orofaciodigital syndrome I

2. Applications of Mendelian Laws

Identification of Carriers

When a recessive characteristic is present in a population, carriers may be identified in a variety of ways. If the gene is responsible for the production of a protein (eg, an enzyme), the carrier often possesses 50% of the amount of the substance present in homozygous normal persons. Such a circumstance is found in galactosemia, where the carriers will have approximately half as much galactose-1-phosphate uridyltransferase activity in red cells as do noncarrier normal individuals.

At times, the level of the affected enzyme may be only slightly below normal, and a challenge with the substance to be acted upon may be required before the carrier can be identified. An example is seen in carriers of phenylketonuria, in whom the deficiency in phenylalanine hydroxylase is in the liver cells, and serum levels may not be much lower than normal. Nonetheless, when the individual is given an oral loading dose of phenylalanine, plasma phenylalanine levels may remain high because the enzyme is not present in sufficient quantities to act upon this substance properly.

In still other situations where the 2 alleles produce different proteins that can be measured, a carrier state will have 50% of the normal protein and 50% of the other protein. Such a situation is seen in sickle cell trait, where 1 gene is producing hemoglobin A and the other hemoglobin S. Thus, the individual has half the amount of hemoglobin A as a normal person and half the hemoglobin S of a person with sickle cell anemia. An interesting but important problem involves the detection of carriers of cystic fibrosis. This is the most common autosomal recessive disease in Caucasian populations of European background, occurring in 1 in 2500 births in such populations but found in the carrier state in 1 in 25 Americans. By 1990, over 230 alleles of the single gene responsible have been discovered. The gene is known as the cystic fibrosis transmembrane conductance regulator (CFTR), and the most common mutation, delta F508, accounts for about 70% of all mutations, with 5 specific point mutations accounting for over 85% of cases. Because so many alleles are present, population screening poses logistical problems that have yet to be worked out. Most programs screen for the most common mutations using DNA replication and amplification studies.

3. Polygenic Inheritance

Polygenic inheritance is defined as the inheritance of a single phenotypic feature as a result of the effects of many genes. Most physical features in humans are determined by polygenic inheritance. Many common malformations are determined in this way also. For example, cleft palate with or without cleft lip, clubfoot, anencephaly, meningomyelocele, dislocation of the hip, and pyloric stenosis each occur with a frequency of 0.5–2 per 1000 in white populations. Altogether, these anomalies account for slightly less than half of single primary defects noted in early infancy. They are present in siblings of affected infants—when both parents are normal—at a rate of 2–5%. They are also found more commonly among relatives than in the general population. The increase in incidence is not environmentally induced because the frequency of such abnormalities in monozygotic twins is 4–8 times that of dizygotic twins and other siblings. The higher incidence in monozygotic twins is called concordance.

Sex also plays a role. Certain conditions appear to be transmitted by polygenic inheritance and are passed on more frequently by the mother who is affected than by the father who is affected. Cleft lip occurs in 6% of the offspring of women with cleft lip, as opposed to 2.8% of offspring of men with cleft lip.

Many racial variations in diseases are believed to be transmitted by polygenic inheritance, making racial background a determinant of how prone an individual will be to a particular defect. In addition, as a general rule, the more severe a defect, the more likely it is to occur in subsequent siblings. Thus, siblings of children with bilateral cleft lip are more likely to have the defect than are those of children with unilateral cleft lip.

Environment undoubtedly plays a role in polygenic inheritance, because seasonal variations alter some defects and their occurrence rate from country to country in similar populations.

EPIGENETIC

Epigenetic is the regulation of gene expression not encoded in the nucleotide sequence of the gene. Gene expression can either be turned on or off by DNA methylation or histone modification (methylation, acetylation, phosphorylation, ubiquitination, or ADP-ribosylation). Epigenetic can subsequently be inherited by its descendants.

Genomic Imprinting

Genomic imprinting is an epigenetic process by which the male and female genomes are differently expressed. The imprinting mark on genes is either by DNA methylation or histone modification. The imprinting patterns are different according to the parental origin of the genes. Genomic imprints are erased in primordial germ cells and reestablished again during gametogenesis. The imprinting process is completed by the time of round spermatids formation in males and at ovulation of metaphase-II oocytes in females. The imprinted genes survive the global waves of DNA demethylation and remethylation during early embryonic development. In normal children, 1 set of chromosomes is derived from the father and the other from the mother. If both sets of chromosomes are from only 1 parent, the imprinted gene expression will be unbalanced. Prader-Willi syndrome and Angelman syndrome are examples of imprinting disorders. In Prader-Willi syndrome, both 15q13 regions are from the father, whereas in Angelman syndrome, both 15q13 regions are from the mother.

CYTOGENETICS

1. Identification of Chromosomes

In 1960, 1963, 1965, and 1971, international meetings were held in Denver, London, Chicago, and Paris, respectively, for the purpose of standardizing the nomenclature of human chromosomes. These meetings resulted in a decision that all autosomal pairs should be numbered in order of decreasing size from 1 to 22. Autosomes are divided into groups based on their morphology, and these groups are labeled by the letters A–G. Thus, the A group is comprised of pairs 1–3; the B group, pairs 4 and 5; the C group, pairs 6–12; the D group, pairs 13–15; the E group, pairs 16–18; the F group, pairs 19 and 20; and the G group, pairs 21 and 22. The sex chromosomes are labeled X and Y, the X chromosome being similar in size and morphology to the number 7 pair and thus frequently included in the C group (C-X) and the Y chromosome being similar in morphology and size to the G group (G-Y) (Fig. 3–1).

Figure 3–1. Karyotype of a normal male demonstrating R banding.

The short arm of a chromosome is labeled p and the long arm q. If a translocation occurs in which the short arm of a chromosome is added to another chromosome, it is written p +. If the short arm is lost, it is p−. The same can be said for the long arm (q+ and q−).

It has been impossible to separate several chromosome pairs from one another on a strictly morphologic basis because the morphologic variations have been too slight. However, there are other means of identifying each chromosome pair in the karyotype. The first of these is the incorporation of ^{3}H-thymidine, known as the autoradiographic technique. This procedure involves the incorporation of radioactive thymidine into growing cells in tissue culture just before they are harvested. Cells that are actively undergoing DNA replication will pick up the radioactive thymidine, and the chromosomes will demonstrate areas of activity. Each chromosome will incorporate thymidine in a different pattern, and several chromosomes can therefore be identified by their labeling pattern. Nonetheless, with this method it is not possible to identify each chromosome, although it is possible to identify chromosomes involved in pathologic conditions, eg, D_1 trisomy and Down syndrome.

Innovative staining techniques have made it possible to identify individual chromosomes in the karyotype and to identify small anomalies that might have evaded the observer using older methods. These involve identification of chromosome banding by a variety of staining techniques, at times with predigestion with proteolytic agents. Some of the more commonly used techniques are the following:

Q banding: Fixed chromosome spreads are stained without any pretreatment using quinacrine mustard, quinacrine, or other fluorescent dyes and observed with a fluorescence microscope.

G banding: Preparations are incubated in a variety of saline solutions using any 1 of several pretreatments and stained with Giemsa's stain.

R banding: Preparations are incubated in buffer solutions at high temperatures or at special pH and stained with Giemsa's stain. This process yields the reverse bands of G banding (Fig. 3–1).

C banding: Preparations are either heated in saline to temperatures just below boiling or treated with certain alkali solutions and then stained with Giemsa's stain. This process causes prominent bands to develop in the region of the centromeres.

2. Cell Division

Each body cell goes through successive stages in its life cycle. As a landmark, cell division can be considered as the beginning of a cycle. Following this, the first phase, which is quite long but depends on how rapidly the particular cell is multiplying, is called the G_1 stage. During this stage, the cell is primarily concerned with carrying out its function. Following this, the S stage, or period of DNA synthesis, takes place. Next there is a somewhat shorter stage, the G_2 stage, during which time DNA synthesis is completed and chromosome replication begins. Following this comes the M stage, when cell division occurs.

Somatic cells undergo division by a process known as **mitosis** (Fig. 3–2). This is divided into 4 periods. The first is **prophase**, during which the chromosome filaments shorten, thicken, and become visible. At this time they can be seen to be composed of 2 long parallel spiral strands lying adjacent to one another and containing a small clear structure known as the **centromere**. As prophase continues, the strands continue to unwind and may be recognized as chromatids. At the end of prophase, the nuclear membrane disappears and **metaphase** begins. This stage is heralded by the formation of a spindle and the lining up of the chromosomes in pairs on the spindle. Following this, **anaphase** occurs, at which time the centromere divides and each daughter chromatid goes to 1 of the poles of the spindle. **Telophase** then ensues, at which time the spindle breaks and cell cytoplasm divides. A nuclear membrane now forms, and mitosis is complete. Each daughter cell has received chromosome material equal in amount and identical to that of the parent cell. Because each cell contains 2 chromosomes of each pair and a total of 46 chromosomes, a cell is considered to be **diploid**. Occasionally, an error takes place on the spindle, and instead of chromosomes dividing, with identical chromatids going to each daughter cell, an extra chromatid goes to 1 daughter cell and the other lacks that particular member. After completion of cell division, this leads to a trisomic state (an extra dose of that chromosome) in 1 daughter cell and a monosomic state (a missing dose of the chromosome) in the other daughter cell. Any chromosome in the karyotype may be involved in such a process, which is known as mitotic nondisjunction. If these cells thrive and produce their own progeny, a new cell line is established within the individual. The individual then has more than 1 cell line and is known as a **mosaic**. A variety of combinations and permutations have occurred in humans.

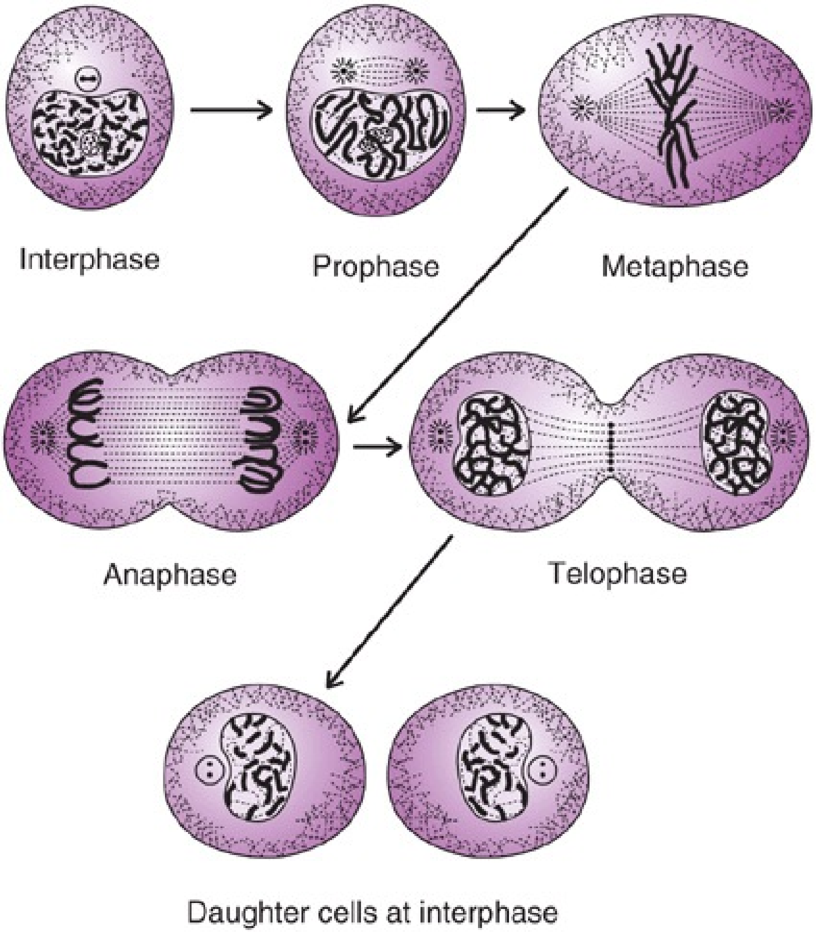

Figure 3–2. Mitosis of a somatic cell.

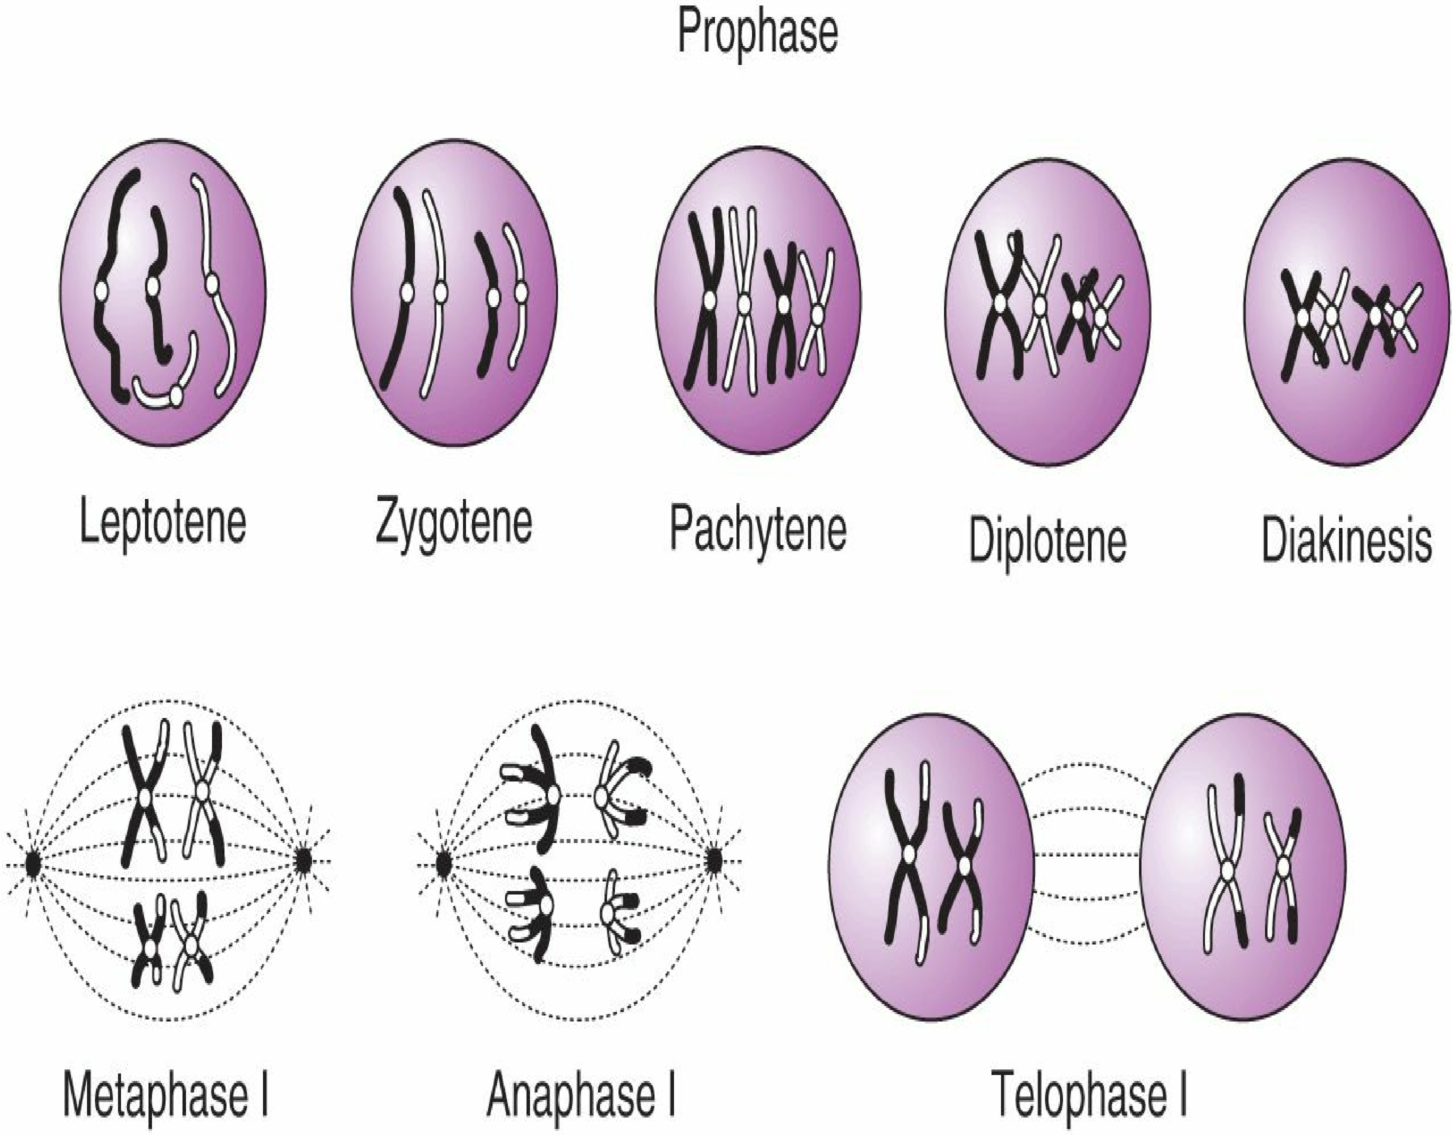
Germ cells undergo division for the production of eggs and sperm by a process known as **meiosis**. In the female it is known as oogenesis and in the male as spermatogenesis. The process that produces the egg and the sperm for fertilization essentially reduces the chromosome number from 46 to 23 and changes the normal diploid cell to an aneuploid cell, ie, a cell that has only 1 member of each chromosome pair. Following fertilization and the fusion of the 2 pronuclei, the diploid status is reestablished.

Meiosis can be divided into several stages (Fig. 3–3). The first is **prophase I**. Early prophase is known as the **leptotene stage**, during which chromatin condenses and becomes visible as a single elongated threadlike structure. This is followed by the **zygotene stage**, when the single threadlike chromosomes migrate toward the equatorial plate of the nucleus. At this stage, homologous chromosomes become arranged close to one another to form **bivalents** that exchange materials at several points known as **synapses**. In this way, genetic material located on 1 member of a pair is exchanged with similar material located on the other member of a pair. Next comes the **pachytene stage** in which the chromosomes contract to become shorter and thicker. During this stage, each chromosome splits longitudinally into 2 chromatids united at the centromere. Thus, the bivalent becomes a structure composed of 4 closely opposed chromatids known as a **tetrad**. The human cell in the pachytene stage demonstrates 23 tetrads. This stage is followed by the **diplotene stage**, in which the chromosomes of the bivalent are held together only at certain points called bridges or chiasms. It is at these points that crossover takes place. The sister chromatids are joined at the centromere so that crossover can only take place between chromatids of homologous chromosomes and not between identical sister chromatids. In the case of males, the X and Y chromosomes are not involved in crossover. This stage is followed by the last stage of prophase, known as **diakinesis**. Here the bivalents contract, and the chiasms move toward the end of the chromosome. The homologs pull apart, and the nuclear membrane disappears. This is the end of prophase I.

FIRST MEIOTIC DIVISION



Prophase
Leptotene
Zygotene
Pachytene
Diplotene
Diakinesis
Metaphase I
Anaphase I
Telophase I

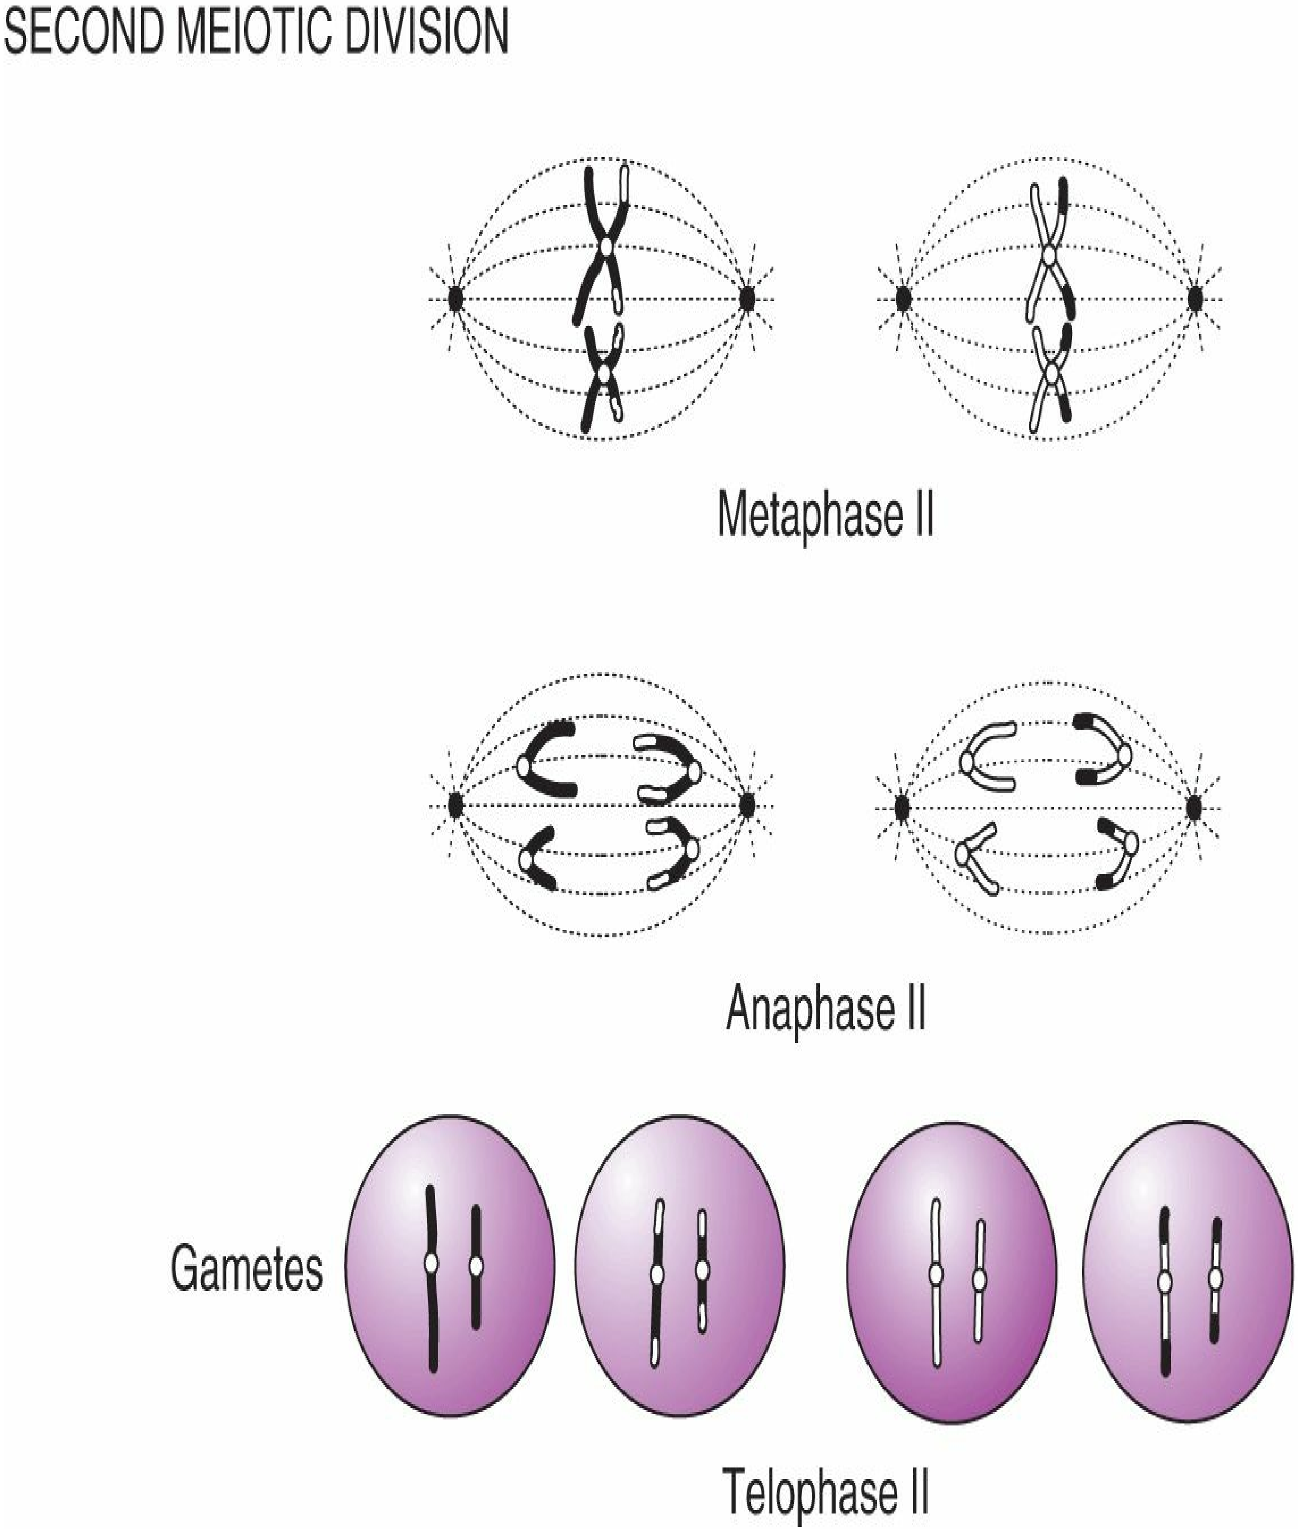


Figure 3–3. Meiosis in the human.

Metaphase I follows. At this time, the bivalents are now highly contracted and align themselves along the equatorial plate of the cell. Paternal and maternal chromosomes line up at random. This stage is then followed by **anaphase I** and **telophase I**, which are quite similar to the corresponding events in mitosis. However, the difference is that in meiosis the homologous chromosome of the bivalent pair separates and not the sister chromatids. The homologous bivalents pull apart, 1 going to each pole of the spindle, following which 2 daughter cells are formed at telophase I.

Metaphase, anaphase, and telophase of meiosis II take place next. A new spindle forms in metaphase, the chromosomes align along the equatorial plate, and, as anaphase occurs, the chromatids pull apart, 1 each going to a daughter cell. This represents a true division of the centromere. Telophase then supervenes, with reconstitution of the nuclear membrane and final cell division. At the end, a haploid number of chromosomes is present in each daughter cell (Fig. 3–3). In the case of spermatogenesis, both daughter cells are similar, forming 2 separate sperms. In the case of oogenesis, only 1 egg is produced, the nuclear material of the other daughter cell being present and intact but with very little cytoplasm, this being known as the **polar body**. A polar body is formed at the end of meiosis I and the end of meiosis II. Thus, each spermatogonium produces 4 sperms at the end of meiosis, whereas each oogonium produces 1 egg and 2 polar bodies.

Nondisjunction may also occur in meiosis. When it does, both members of the chromosome pair go to 1 daughter cell and none to the other. If the daughter cell that receives the entire pair is the egg, and fertilization ensues, a triple dose of the chromosome, or trisomy, will occur. If the daughter cell receiving no members of the pair is fertilized, a monosomic state will result. In the case of autosomes, this is lethal, and a very early abortion will follow. In the case of the sex chromosome, the condition may not be lethal, and examples of both trisomy and monosomy have been seen in humans. Any chromosome pair may be involved in trisomic or monosomic conditions.

3. Abnormalities in Chromosome Morphology & Number

As has been stated, nondisjunction may give rise to conditions of trisomy. In these cases, the morphology of the chromosome is not affected, but the chromosome number is. Be this as it may, breaks and rearrangements in chromosomes may have a variety of results. If 2 chromosomes undergo breaks and exchange chromatin material between them, the outcome is 2 morphologically new chromosomes known as **translocations**. If a break in a chromosome takes place and the fragment is lost, **deletion** has occurred. If the deletion is such that the cell cannot survive, the condition may be lethal. Nonetheless, several examples of deleted chromosomes in individuals who have survived have been identified. If a break takes place at either end of a chromosome and the chromosome heals by having the 2 ends fuse together, a ring chromosome is formed. Examples of these have been seen clinically in all of the chromosomes of the karyotype, and generally they exhibit a variety of phenotypic abnormalities.

At times a chromosome will divide by a horizontal rather than longitudinal split of the centromere. This leaves each daughter cell with a double dose of 1 of the arms of the chromosome. Thus, 1 daughter cell receives both long arms and the other both short arms of the chromosome. Such a chromosome is referred to as an **isochromosome**, the individual being essentially trisomic for 1 arm and monosomic for the other arm of the chromosome. Examples of this abnormality have been seen in humans.

Another anomaly that has been recognized is the occurrence of 2 breaks within the chromosome and rotation of the center fragment 180 degrees. Thus, the realignment allows for a change in morphology of the chromosome, although the original number of genes is preserved. This is called an **inversion**. At meiosis, however, the chromosome has difficulty in undergoing chiasm formation, and abnormal rearrangements of this chromosome, leading to partial duplications and partial losses of chromatin material, do take place. This situation may lead to several bizarre anomalies. If the centromere is involved in the inversion, the condition is called a **pericentric inversion**.

Breaks occasionally occur in 2 chromosomes, and a portion of 1 broken chromosome is inserted into the body of another, leading to a grossly abnormal chromosome. This is known as an **insertion** and generally leads to gross anomalies at meiosis.

4. Methods of Study

Sex Chromatin (X-Chromatin) Body (Barr Body)

The X-chromatin body was first seen in the nucleus of the nerve cell of a female cat in 1949 by Barr and Bertram. It has been found to be the constricted, nonfunctioning X chromosome. As a general rule, only 1 X chromosome functions in a cell at a given time. All other X chromosomes present in a cell may be seen as X-chromatin bodies in a resting nucleus. Thus, if one knows the number of X chromosomes, one can anticipate that the number of Barr bodies will be 1 less. If one counts the number of Barr bodies, the number of X chromosomes can be determined by adding 1.

Drumsticks on Polymorphonuclear Leukocytes

Small outpouchings of the lobes of nuclei in polymorphonuclear leukocytes of females have been demonstrated to be the X-chromatin body in this particular cell. Hence, leukocyte preparations may be used to detect X-chromatin bodies in much the same way as buccal cells are used.

Chromosome Count

In the karyotypic analysis of a patient, it is the usual practice to count 20–50 chromosome spreads for chromosome number. The purpose of this practice is to determine whether mosaicism exists because if a mosaic pattern does exist, there will be at least 2 cell lines of different counts. Photographs are made of representative spreads, and karyotypes are constructed so that the morphology of each chromosome can be studied.

Banding Techniques

As previously described, it is possible after appropriate pretreatment to stain metaphase spreads with special stains and construct a karyotype that demonstrates the banding patterns of each chromosome. In this way, it is possible to identify with certainty every chromosome in the karyotype. This is of value with problems such as translocations and trisomic conditions. Another use depends on the fact that most of the long arm of the Y chromosome is heterochromic and stains deeply with fluorescent stains. Thus, the Y chromosome can be identified at a glance, even in the resting nucleus.

APPLIED GENETICS & TERATOLOGY

1. Chromosomes & Spontaneous Abortion

An entirely new approach to reproductive biology problems became available with the advent of tissue culture and cytologic techniques that made it possible to culture cells from any tissue of the body and produce karyotypes that could be analyzed. In the early 1960s, investigators in a number of laboratories began to study chromosomes of spontaneous abortions and demonstrated that the earlier the spontaneous abortion occurred, the more likely it was due to a chromosomal abnormality. It is now known that in spontaneous abortions occurring in the first 8 weeks, the fetuses have about a 50% incidence of chromosome anomalies.

Of abortuses that are abnormal, approximately one-half are trisomic, suggesting an error of meiotic nondisjunction. One-third of abortuses with trisomy have trisomy 16. Although this abnormality does not occur in liveborn infants, it apparently is a frequent problem in abortuses. The karyo-type 45,X occurs in nearly one-fourth of chromosomally abnormal abortuses. This karyotype occurs about 24 times more frequently in abortuses than in liveborn infants, a fact that emphasizes its lethal nature. Over 15% of chromosomally abnormal abortuses have polyploidy (triploidy or tetraploidy). These lethal conditions are seen only in abortuses except in extremely rare circumstances and are due to a variety of accidents, including double fertilization and a number of meiotic errors. Finally, a small number of chromosomally abnormal abortuses have unbalanced translocations and other anomalies.

Recurrent Pregnancy Loss

Couples who experience habitual abortion constitute about 0.5% of the population. The condition is defined as 2 or more spontaneous abortions. Several investigators have studied groups of these couples using banding techniques and have found that 10–25% of them have a chromosome anomaly in either the male or female partner. Those seen are 47,XXX, 47,XYY, and a variety of balanced translocation carriers. Those with sex chromosome abnormalities frequently demonstrate other nondisjunctional events. Chromosome anomalies are thus a major cause of habitual abortion, and the incorporation of genetic evaluation into such a work-up is potentially fruitful.

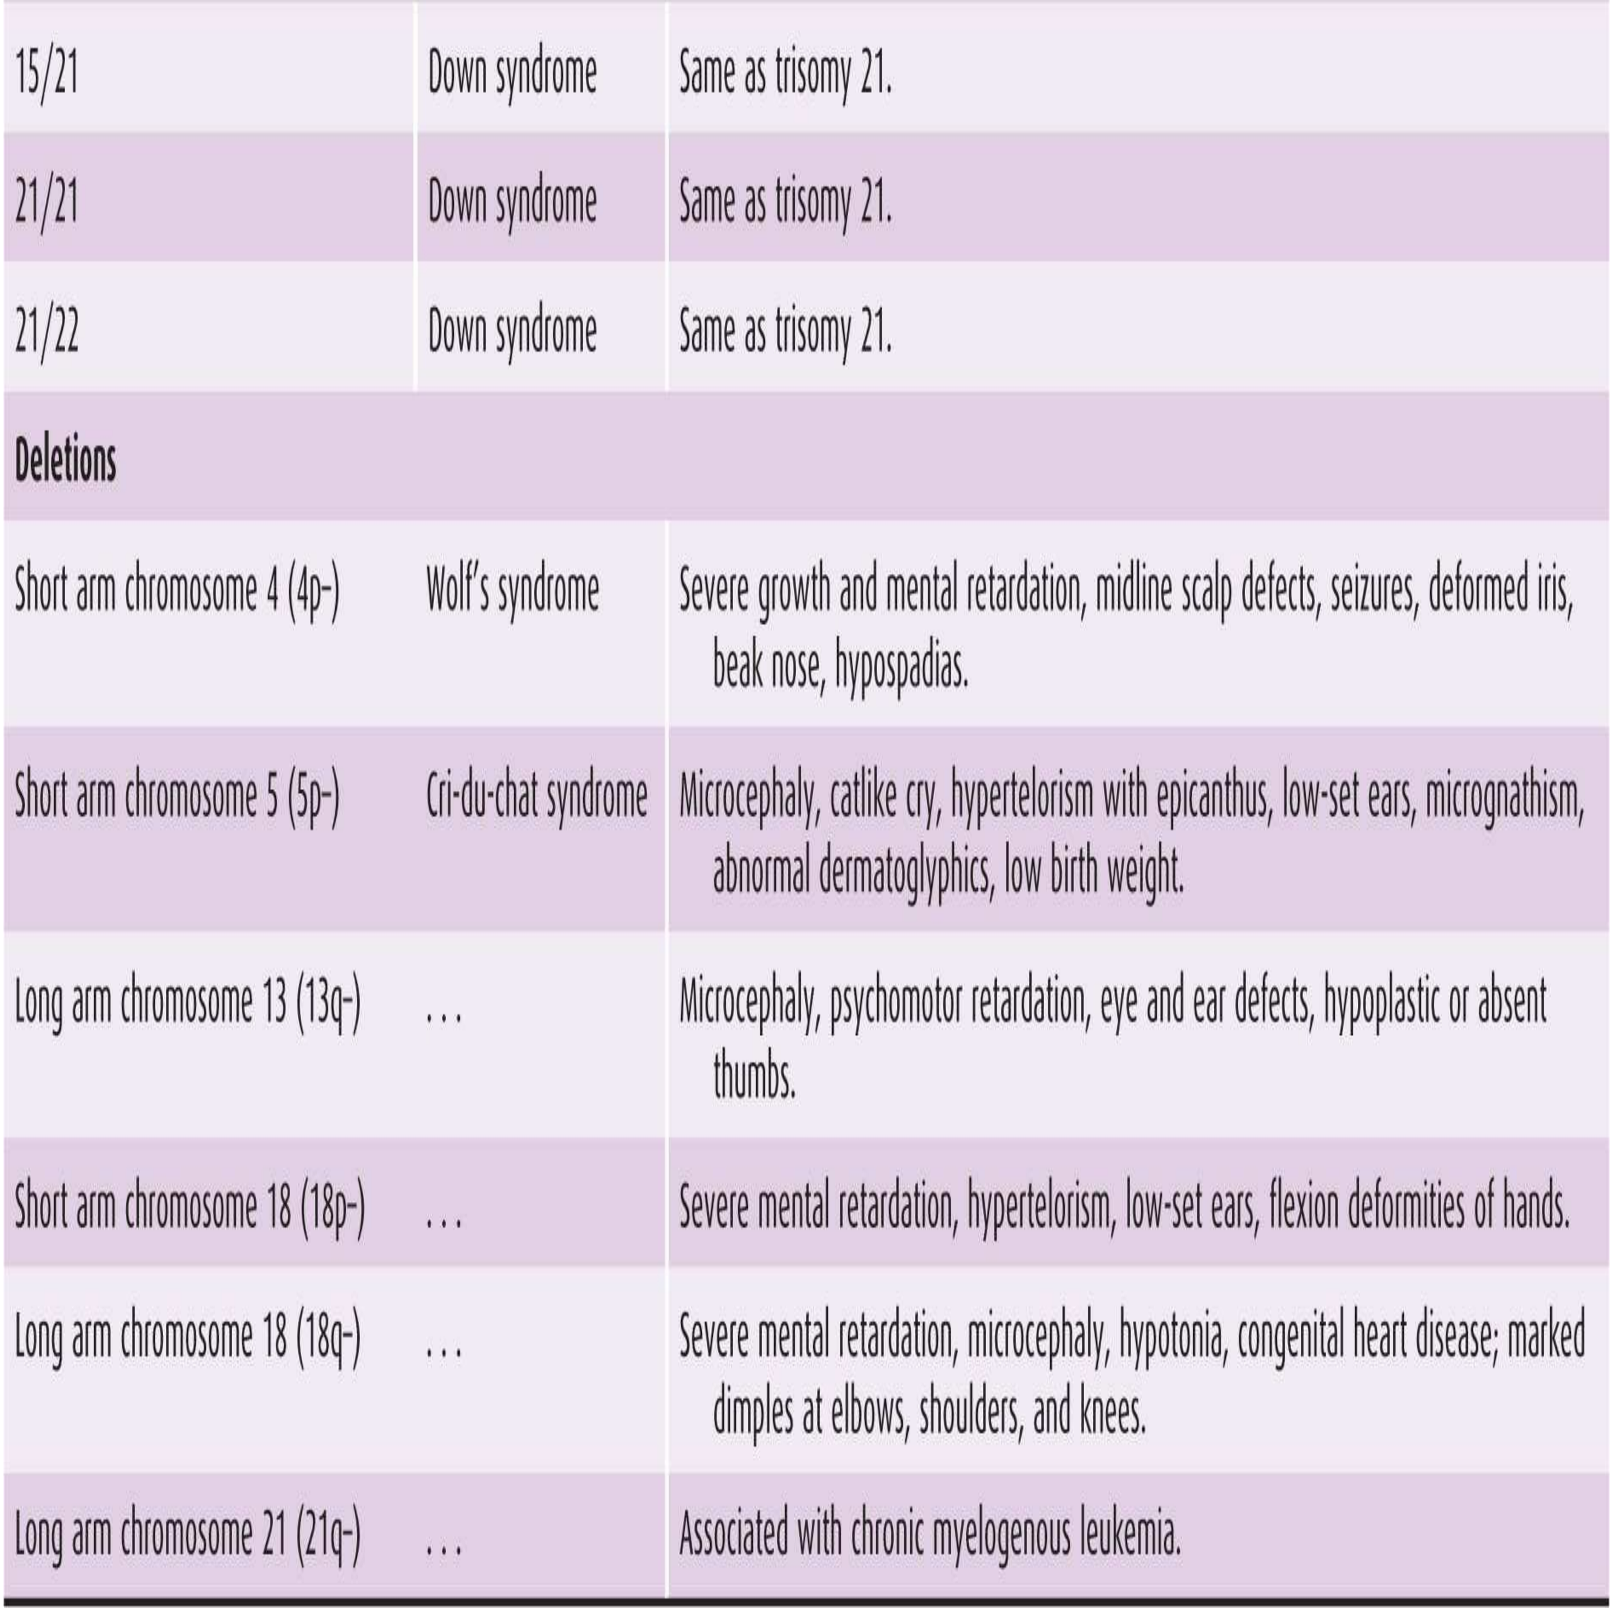
Lippman-Hand and Bekemans reviewed the world literature and studied the incidence of balanced translocation carriers among 177 couples who had 2 or more spontaneous abortions. These studies suggest that in 2–3% of couples experiencing early fetal loss, 1 partner will have balanced translocations. This percentage is not markedly increased when more than 2 abortions occur. Females had a somewhat higher incidence of balanced translocations than did males.

2. Chromosomal Disorders

This section is devoted to a brief discussion of various autosomal abnormalities. Table 3–5 summarizes some of the autosomal abnormalities that have been diagnosed. They are represented as syndromes, together with some of the signs typical of these conditions. In general, autosomal monosomy is so lethal that total loss of a chromosome is rarely seen in an individual born alive. Only a few cases of monosomy 21–22 have been reported to date, which attests to the rarity of this disorder. Trisomy may occur with any chromosome. The 3 most common trisomic conditions seen in living individuals are trisomies 13, 18, and 21. Trisomy of various C group chromosomes has been reported sporadically. The most frequently reported is trisomy 8. Generally, trisomy of other chromosomes must be assumed to be lethal, because they occur only in abortuses, not in living individuals. To date, trisomy of every autosome except chromosome 1 has been seen in abortuses.

Table 3–5. Autosomal disorders.

Type	Synonym	Signs
Monosomy		
Monosomy 21–22		Moderate mental retardation, antimongoloid slant of eyes, flared nostrils, small mouth, low-set ears, spade hands.
Trisomy		
Trisomy 13	Trisomy D: the "D$_1$" syndrome	Severe mental retardation, congenital heart disease (77%), polydactyly, cerebral malformations (especially aplasia of olfactory bulbs), eye defects, low-set ears, cleft lip and palate, low birth weight. Characteristic dermatoglyphic pattern.
Trisomy 18	Trisomy E: the "E" syndrome, Edward's syndrome	Severe mental retardation, long narrow skull with prominent occiput, congenital heart disease, flexion deformities of fingers, narrow palpebral fissures, low-set ears, harelip and cleft palate. Characteristic dermatoglyphics, low birth weight.
Trisomy 21	Down syndrome	Mental retardation, brachycephaly, prominent epicanthal folds. Brushfield spots, poor nasal bridge development, congenital heart disease, hypotonia, hypermobility of joints, characteristic dermatoglyphics.
Translocations		



15/21	Down syndrome	Same as trisomy 21.
21/21	Down syndrome	Same as trisomy 21.
21/22	Down syndrome	Same as trisomy 21.
Deletions		
Short arm chromosome 4 (4p-)	Wolf's syndrome	Severe growth and mental retardation, midline scalp defects, seizures, deformed iris, beak nose, hypospadias.
Short arm chromosome 5 (5p-)	Cri-du-chat syndrome	Microcephaly, catlike cry, hypertelorism with epicanthus, low-set ears, micrognathism, abnormal dermatoglyphics, low birth weight.
Long arm chromosome 13 (13q-)	…	Microcephaly, psychomotor retardation, eye and ear defects, hypoplastic or absent thumbs.
Short arm chromosome 18 (18p-)	…	Severe mental retardation, hypertelorism, low-set ears, flexion deformities of hands.
Long arm chromosome 18 (18q-)	…	Severe mental retardation, microcephaly, hypotonia, congenital heart disease; marked dimples at elbows, shoulders, and knees.
Long arm chromosome 21 (21q-)	…	Associated with chronic myelogenous leukemia.

Translocations can occur between any 2 chromosomes of the karyotype, and a variety of phenotypic expressions may be seen after mediocre arrangements. Three different translocation patterns have been identified in Down syndrome: 15/21, 21/21, and 21/22.

Deletions may also occur with respect to any chromosome in the karyotype and may be brought about by a translocation followed by a rearrangement in meiosis, which leads to the loss of chromatin material, or by a simple loss of the chromatin material following a chromosome break. Some of the more commonly seen deletion patterns are listed in Table 3–5.

The most frequent abnormality related to a chromosome abnormality is Down syndrome. Down syndrome serves as an interesting model for the discussion of autosomal diseases. The 21 trisomy type is the most common form and is responsible for approximately 95% of Down syndrome patients. There is a positive correlation between the frequency of Down syndrome and maternal age. Babies with Down syndrome are more often born to teenage mothers and even more frequently to mothers over 35. Although the reason for these findings is not entirely clear, it may be that, in older women at least, the egg has been present in prophase of the first meiotic division from the time of fetal life and that, as the egg ages, there is a greater tendency for nondisjunction to occur, leading to trisomy. A second theory is that coital habits are more erratic in both the very young and the older mothers, and this may lead to an increased incidence of fertilization of older eggs. This theory maintains that these eggs may be more likely to suffer nondisjunction or to accept abnormal sperm. Be this as it may, the incidence of Down syndrome in the general population is approximately 1 in 600 deliveries and at age 40 approximately 1 in 100 deliveries. At age 45, the incidence is approximately 1 in 40 deliveries (Table 3–6). The other 5% of Down syndrome patients are the result of translocations, the most common being the 15/21 translocation, but examples of 21/21 and 21/22 have been noted. In the case of 15/21, the chance of recurrence in a later pregnancy is theoretically 25%. In practice, a rate of 10% is observed if the mother is the carrier. When the father is the carrier, the odds are less because there may be a selection not favoring the sperm carrying both the 15/21 translocation and the normal 21 chromosome. In the case of 21/21 translocation, there is no chance for formation of a normal child because the carrier will contribute either both 21s or no 21 and, following fertilization, will produce either a monosomic 21 or trisomic 21. With regard to 21/22 translocation, the chance of producing a baby with Down syndrome is 1 in 2.

Table 3–6. Estimates of rates per thousand of chromosome abnormalities in live births by single-year interval.

[1] XXX is excluded.

[2] Calculation of the total at each age assumes rate for autosomal aneuploidies is at the midpoints of the ranges given.

[3] No range may be constructed for those under 20 years by the same methods as for those 20 and over.

Reproduced, with permission, from Hook EB. Rates of chromosome abnormalities at different maternal ages. *Obstet Gynecol* 1981;58: 282–285.

In general, other trisomic states occur with greater frequency in older women, and the larger the chromosome involved, the more severe the syndrome. Because trisomy 21 involves the smallest of the chromosomes, the phenotypic problems of Down syndrome are the least severe, and a moderate life expectancy may be anticipated. Even these individuals will be grossly abnormal, however, because of mental retardation and defects in other organ systems. The average life expectancy of patients with Down syndrome is much lower than for the general population.

3. Prenatal Diagnosis

Currently the most common use for applied genetics in obstetrics and gynecology is in prenatal counseling, screening, and diagnosis. Prenatal diagnosis first came into use in 1977 with the discovery of the significance of serum α fetoprotein (AFP). The United Kingdom Collaboration Study found that elevated AFP in maternal serum drawn between 16 and 18 weeks of gestation correlated with an increased incidence of neural tube defects (NTDs). Since that time, much research effort has been aimed at perfecting the technique. We now can screen not only for NTDs but also for trisomy 21 and trisomy 18. In addition, cystic fibrosis, sickle cell disease, and Huntington’s disease, as well as many inborn errors of metabolism and other genetic disorders, can now be identified prenatally.

Neural Tube Disease

Most neural tube diseases, eg, anencephaly, spina bifida, and meningomyelocele, are associated with a multifactorial inheritance pattern. The frequency of their occurrence varies in different populations (eg, rates as high as 10 per 1000 births in Ireland and as low as 0.8 per 1000 births in the western United States). Ninety percent are index cases, ie, they occur spontaneously without previous occurrence in a family. In general, if a couple has a child with such an anomaly, the chance of producing another affected child is 2–5%. If they have had 2 such children, the risk can be as high as 10%. However, other diagnostic possibilities involving different modes of inheritance should be considered. Siblings also run greater risks of having affected children, with the highest risk being to female offspring of sisters and the lowest to male offspring of brothers. Maternal serum screening is now available to all mothers between 16 and 20 weeks of gestation. If an elevation of 2.5 or more standard deviations above the mean is noted, amniocentesis for AFP should be done along with a careful ultrasound study of the fetus for structural anomalies. Evidence for an NTD noted on ultrasound and suspected by amniotic fluid AFP elevation of 3.0 or more standard deviations indicates a diagnosis of an NTD and allows for appropriate counseling and decision making for the parents.

Maternal serum AFP screening detects about 85% of all open NTDs, thus allowing detection of 80% of all open NTDs and 90% of all anencephalic infants. Serum AFP screening does not detect skin-covered lesions or the closed form of NTDs. Thus, most encephaloceles may be missed.

Approximately 5–5.5% of women screened will have abnormally elevated values (≥ 2.5 times the mean). Most of these will be false-positive results (a repeat test should determine this) due to inaccurate dating of gestational age, multiple gestation, fetal demise or dying fetus, or a host of other structural abnormalities. In most cases, repeat AFP testing and ultrasound examination will identify the problem. If the serum AFP level remains elevated and ultrasound examination does not yield a specific diagnosis, amniotic fluid AFP levels should be measured as well as amniotic fluid acetylcholinesterase levels. Further testing and counseling may be necessary before a final diagnosis can be made. When the correct gestational age is used, the false-positive rate for second-trimester maternal screening is 3–4%.

Chromosomal Abnormalities

In 1984, maternal serum AFP levels were found to be lower in patients who delivered infants with Down syndrome. Using the AFP value with maternal age, 25–30% of fetuses with Down syndrome were detected prenatally. In 1988, 2 additional tests were added to the maternal AFP: human chorionic gonadotropin (hCG) and unconjugated estriol (uE_3). Using the “triple screen,” a 60% detection rate for Down syndrome was accomplished. In addition, the use of uE_3 allowed for detection of trisomy 18.

Fetuses with Down syndrome have low maternal AFP, low uE_3, and high hCG. Fetuses with trisomy 18 have low values across all of the serum markers. The false-positive rate for women less than 35 years of age is 5%. Above this age cutoff, the false-positive rate is increased. The definitive diagnosis of a chromosomal abnormality must be confirmed with a fetal karyotype.

The risk of fetal trisomies increases with increasing maternal age. At age 35 the risk of a trisomy is approximately 1 in 200. At age 40 the risk is 1 in 20 (Table 3–6). Prior to the discovery of serum markers, advanced maternal age was used to guide which women received fetal karyotyping. Trisomies, however, are not the only abnormality increased in this population of women. Sex chromosome aneuploidies (47,XXY and 47,XXX) also occur at an increased rate in women 35 years of age and older. Despite the advances in serum screening, fetal karyotyping continues to be the gold standard for prenatal testing in this group of women. The use of maternal serum screening in this subset of women is hindered by a high false-positive rate, less than 100% detection rate for trisomy 18 and 21, and the lack of ability to screen for the sex chromosome aneuploidies.

Cystic Fibrosis

Cystic fibrosis affects 1 in 3300 individuals of European descent in the United States. The carrier frequency is 1 in 29 for North Americans of European descent and Ashkenazi Jewish descent and 1 in 60 for African Americans. A deletion of phenylalanine at position 508 of the CFTR gene on chromosome 7 leads to the disease. All individuals with a family history of cystic fibrosis or a high carrier frequency should be offered carrier testing. For couples who are both carriers of the defective allele, fetal testing may be provided.

Future Advances in Prenatal Screening

In the detection of certain trisomies, the triple-marker screen provides better sensitivity than any single marker alone. Nonetheless, the detection rate for trisomy 18 and trisomy 21 still remains quite low. According to the Serum Urine and Ultrasound Screening Study (SURUSS), integration of nuchal translucency measurement and pregnancy-associated plasma protein-A (PAPP-A) in the first trimester improves screening. This information in conjunction with early second-trimester measurement of AFP, uE_3, free β-hCG (or total hCG), and inhibin-A with maternal age provides the most effective method for screening of Down syndrome, with an 85% detection rate and 0.9% false-positive rate. As the field of prenatal diagnostics continues to evolve, higher detection rates with lower false-positive rates can be expected. With continued research and advancing technology, prenatal screening may move into the first trimester. It may involve new markers (proform of eosinophil major basic protein [proMBP], nasal bone) and may even involve markers taken in both the first and second trimesters.

Fetal Karyotyping

A. Amniocentesis

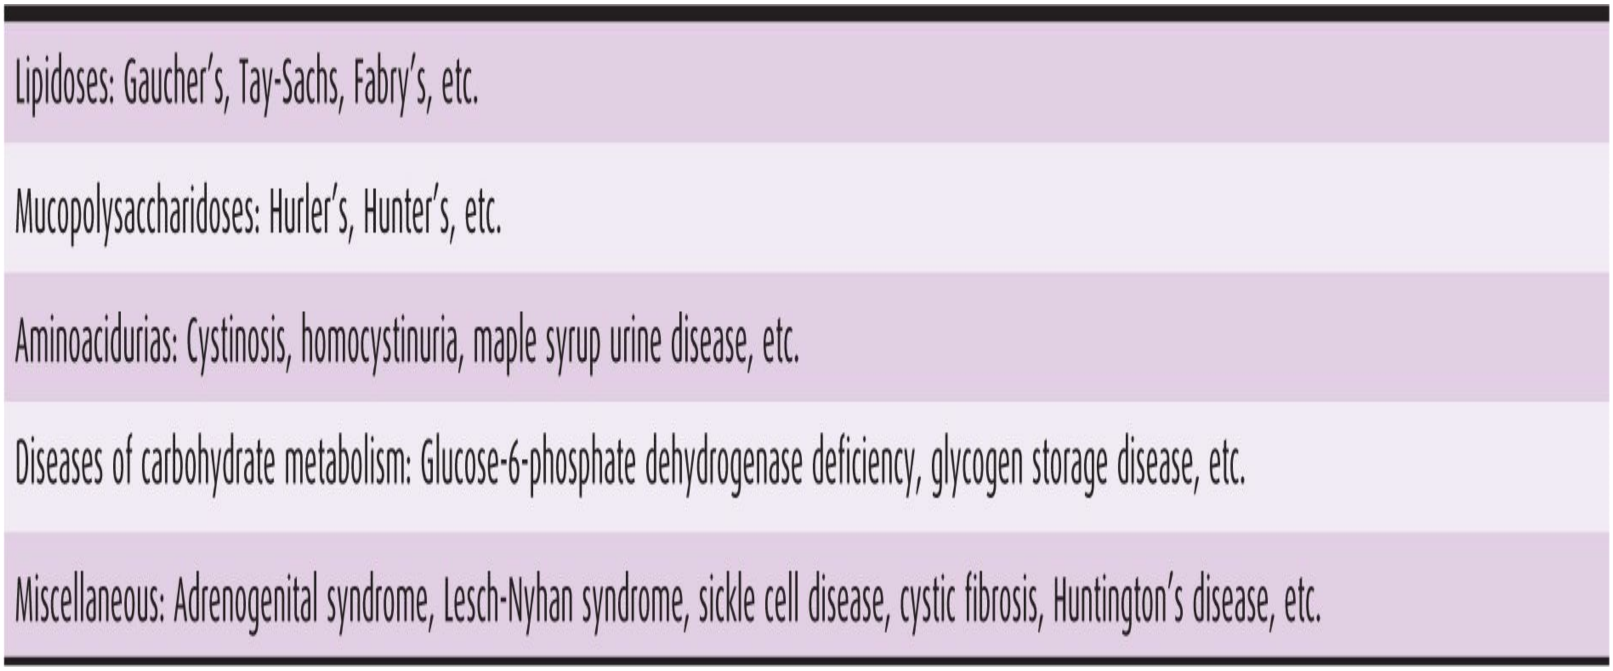
Amniocentesis for prenatal diagnosis of genetic diseases is an extremely useful tool in the following circumstances or classes of patients:

1. Maternal age 35 years or above
2. Previous chromosomally abnormal child
3. Three or more spontaneous abortions
4. Patient or husband with chromosome anomaly
5. Family history of chromosome anomaly
6. Possible female carrier of X-linked disease
7. Metabolic disease risk (because of previous experience or family history)
8. NTD risk (because of previous experience or family history)
9. Positive second-trimester maternal serum screen

Currently, so many metabolic diseases can be diagnosed prenatally by amniocentesis that when the history elicits the possible presence of a metabolic disease, it is prudent to check with a major center to ascertain the availability of a diagnostic method.

Amniocentesis generally is carried out at 15 to 17 weeks of gestation but can be offered earlier (12–14 weeks). The underlying risk of amniocentesis when performed at 15 weeks of gestation and beyond is increased risk of miscarriage. This risk is estimated at 1 in 200 (0.5%), which is approximately the risk of Down syndrome in a 35-year-old woman. When amniocentesis is performed prior to 15 weeks, the miscarriage rate is slightly increased. Table 3–7 lists some of the conditions that now can be diagnosed prenatally by biochemical means.

Table 3–7. Examples of hereditary diseases diagnosable prenatally.



Lipidoses: Gaucher’s, Tay-Sachs, Fabry’s, etc.
Mucopolysaccharidoses: Hurler’s, Hunter’s, etc.
Aminoacidurias: Cystinosis, homocystinuria, maple syrup urine disease, etc.
Diseases of carbohydrate metabolism: Glucose-6-phosphate dehydrogenase deficiency, glycogen storage disease, etc.
Miscellaneous: Adrenogenital syndrome, Lesch-Nyhan syndrome, sickle cell disease, cystic fibrosis, Huntington’s disease, etc.

B. Chorionic Villus Sampling

Chorionic villus sampling (CVS) is a technique used in the first trimester to obtain villi for cytogenetic testing. Most commonly, it is performed transcervically; however, transabdominal routes may also be attempted. The value of CVS is that it can be performed earlier in the pregnancy, and thus the decision of pregnancy termination can be made earlier. The downfall of CVS, however, is a slightly higher miscarriage rate of 1–5% and an association with distal limb defects. These risks appear to be dependent on operator experience, and lower numbers have been reported when CVS is performed between 10 and 12 weeks of gestation.

Karyotyping & Fluorescence In Situ Hybridization Analysis

Once the fetal cells are obtained, they must be processed. Formal karyotyping should be performed on all specimens. This involves culturing the cells, replication, and eventually karyotyping. The entire process often takes 10–14 days until the final report becomes available. Fortunately, a quicker analysis can be obtained for some of the most common chromosomal anomalies.

The fluorescence in situ hybridization (FISH) study is a rapid assay for the detection of specific chromosomal aneuploidies using fluorescent-labeled DNA probes. Currently, probes exist for chromosomes 13, 18, 21, and 22, as well as the X and Y sex chromosomes among others. The average time to obtain a result is 24 hours. However, certain chromosomal probes may return as quickly as 4 hours. The more rapid turnaround time can be attained because the probes are mixed with uncultured amniocytes obtained from amniotic fluid or cells from CVS. If a patient is late in gestation or if the ultrasound is highly suggestive of a certain chromosomal composite, FISH analysis may be an appropriate study. With the development of multicolor FISH, all human chromosomes are painted in 24 different colors, allowing identification of chromosome rearrangement.

Single Gene Defects

If 1 parent is affected and the condition is caused by an autosomal dominant disorder, the chances are 1 in 2 that a child will be affected. If both parents are carriers of an autosomal recessive condition, the chances are 1 in 4 that the child will be affected and 1 in 2 that the child will be a carrier. Carrier status of both parents can be assumed if an affected child has been produced or if a carrier testing program is available and such testing determines that both parents are carriers. Tay-Sachs disease and sickle cell disease detection programs are examples of the latter possibility.

When carrier testing is available and the couple is at risk, as with Tay-Sachs disease in Jewish couples and sickle cell disease in blacks, the physician should order these carrier tests before pregnancy is undertaken, or immediately if the patient is already pregnant. When parents are carriers and pregnancy has been diagnosed, prenatal diagnostic testing is indicated if a test is available. If a physician does not know whether or not a test exists or how to obtain the test, the local genetic counseling program, local chapter of the National Foundation/March of Dimes, or state health department should be called for consultation. These sources may be able to inform the physician about new research that may have produced a prenatal test. A new test may be likely because this area of research is very dynamic. If genetic counseling services are readily available, patients with specific problems should be referred to those agencies for consultation. It is impossible for a physician to keep track of all of the current developments in the myriad conditions caused by single gene defects.

X-linked traits are frequently amenable to prenatal diagnostic testing. When such tests are not available, the couple has the option of testing for the sex of the fetus. If a fetus is noted to be a female, the odds are overwhelming that it will not be affected, although a carrier state may be present. If the fetus is a male, the chances are 1 in 2 that it will be affected. With this information, the couple can decide whether or not to continue the pregnancy in the case of a male fetus. Again, checking with genetic counseling agencies may reveal a prenatal diagnostic test that has only recently been described or information such as gene linkage studies that may apply in the individual case.

All options should be presented in a nonjudgmental fashion with no attempt to persuade, based on the best information available at the time. The couple should be encouraged to decide on a course of action that suits their particular needs. If the decision is appropriate, it should be supported by the physician and the genetic counselor. Very rarely, the patient will make a decision the physician regards as unwise or unrealistic. Such a decision may be based on superstition, religious or mystical beliefs, simple naiveté, or even personality disorder. The physician should make every attempt to clarify the issues for the patient. Rarely, other resources such as family members or spiritual leaders may be consulted in strict confidence. The physician and the genetic counselor must clearly set forth the circumstances of the problem in the record, in case the patient undertakes a course of action that ends in tragedy and perhaps attempts to blame the professional counselors for not preventing it.

Genetic Counseling

Genetic counseling involves interaction between the physician, the family, and the genetic counselor. It is the physician’s responsibility to utilize the services of the genetic consultant in the best interest of the patient. The genetic counselor will take a formal family history and construct a family tree (Fig. 3–4). The assessment of the underlying general population risk of a disease and the specific family risk should be provided. When a specific diagnosis is known in the proband and the relatives are dead or otherwise not available, the counselor may ask to see photographs, which may show characteristics of the suspected condition. In many cases, when the pedigree is constructed, the inheritance pattern can be determined. If this can be done, the relative risks that future progeny will be affected can be estimated. This pedigree information is also useful in discussing the case with a genetic counselor.

THE CHROMOSOMAL BASIS OF SEX DETERMINATION

Syngamy

The sex of the fetus normally is determined at fertilization. The cells of normal females contain 2 X chromosomes; those of normal males contain 1 X and 1 Y. During meiotic reduction, half of the male gametes receive a Y chromosome and the other half an X chromosome. Because the female has 2 X chromosomes, all female gametes contain an X chromosome. If a Y-bearing gamete fertilizes an ovum, the fetus is male; conversely, if an X-bearing gamete fertilizes an ovum, the fetus is female.

Arithmetically, the situation described previously should yield a male/female sex ratio of 100—the sex ratio being defined as 100 times the number of males divided by the number of females. However, for many years, the male/female sex ratio of the newborns in the white population has been approximately 105. Apparently the sex ratio at fertilization is even higher than at birth; most data on the sex of abortuses indicate a preponderance of males.

Abnormalities of Meiosis and Mitosis

The discussion in this section is limited to anomalies of meiosis and mitosis that result in some abnormality in the sex chromosome complement of the embryo.

Chromosome studies in connection with various clinical conditions suggest that errors in meiosis and mitosis do indeed occur. These errors result in any of the following principal effects: (1) an extra sex chromosome, (2) an absent sex chromosome, (3) 2 cell lines having different sex chromosomes and arising by mosaicism, (4) 2 cell lines having different sex chromosomes and arising by chimerism, (5) a structurally abnormal sex chromosome, and (6) a sex chromosome complement inconsistent with the phenotype.

By and large, an extra or a missing sex chromosome arises as the result of an error of disjunction in meiosis I or II in either the male or the female. In meiosis I, this means that instead of each of the paired homologous sex chromosomes going to the appropriate daughter cell, both go to 1 cell, leaving that cell with an extra sex chromosome and the daughter cell with none. Failure of disjunction in meiosis II simply means that the centromere fails to divide normally.

A variation of this process, known as anaphase lag, occurs when 1 of the chromosomes is delayed in arriving at the daughter cell and thus is lost. Theoretically, chromosomes may be lost by failure of association in prophase and by failure of replication, but these possibilities have not been demonstrated.

Persons who have been found to have 2 cell lines apparently have experienced problems in mitosis in the very early stage of embryogenesis. Thus, if there is nondisjunction or anaphase lag in an early (first, second, or immediately subsequent) cell division in the embryo, mosaicism may be said to exist. In this condition, there are 2 cell lines; 1 has a normal number of sex chromosomes, and the other is deficient in a sex chromosome or has an extra number of sex chromosomes. A similar situation exists in chimerism, except that there may be a difference in the sex chromosome: 1 may be an X and 1 may be a Y. This apparently arises by dispermy, by the fertilization of a double oocyte, or by the fusion, very early in embryogenesis, of 2 separately fertilized oocytes. Each of these conditions has been produced experimentally in animals.

Structural abnormalities of the sex chromosomes—deletion of the long or short arm or the formation of an isochromosome (2 short arms or 2 long arms)—result from injury to the chromosomes during meiosis. How such injuries occur is not known, but the results are noted more commonly in sex chromosomes than in autosomes—perhaps because serious injury to an autosome is much more likely to be lethal than injury to an X chromosome, and surviving injured X chromosomes would therefore be more common.

The situation in which there is a sex chromosome complement with an inappropriate genotype arises in special circumstances of true hermaphroditism and XX males (see later sections).

The X Chromosome in Humans

At about day 16 of embryonic life, there appears on the undersurface of the nuclear membrane of the somatic cells of human females a structure 1 μm in diameter known as the X-chromatin body. There is genetic as well as cytogenetic evidence that this is 1 of the X chromosomes (the only chromosome visible by ordinary light microscopy during interphase). In a sense, therefore, all females are hemizygous with respect to the X chromosome. However, there are genetic reasons for believing that the X chromosome is not entirely inactivated during the process of formation of the X-chromatin body. In normal females, inactivation of the X chromosome during interphase and its representation as the X-chromatin body are known as the Lyon phenomenon (for Mary Lyon, a British geneticist). This phenomenon may involve, at random, either the maternal or the paternal X chromosome. Furthermore, once the particular chromosome has been selected early in embryogenesis, it is always the same X chromosome that is inactivated in the progeny of that particular cell. Geneticists have found that the ratio of maternal to paternal X chromosomes inactivated is approximately 1:1.

The germ cells of an ovary are an exception to the X inactivation concept in that X inactivation does not characterize the meiotic process. Apparently, meiosis is impossible without 2 genetically active X chromosomes. Although random structural damage to 1 of the X chromosomes seems to cause meiotic arrest, oocyte loss, and therefore failure of ovarian development, an especially critical area necessary for oocyte development has been identified on the long arm of the X. This essential area involves almost all of the long arm and has been specifically located from Xq13 to Xq26. If this area is broken in 1 of the X chromosomes as in a deletion or translocation, oocyte development does not occur. However, a few exceptions to this rule have been described.

It is a curious biologic phenomenon that if 1 of the X chromosomes is abnormal, it is always this chromosome that is genetically inactivated and becomes the X-chromatin body, regardless of whether it is maternal or paternal in origin. Although this general rule seems to be an exception to the randomness of X inactivation, this is more apparent than real. Presumably, random inactivation does occur, but the disadvantaged cells—ie, those left with a damaged active X—do not survive. Consequently, the embryo develops only with cells with a normal active X chromosome (X-chromatin body) (Fig. 3–5).

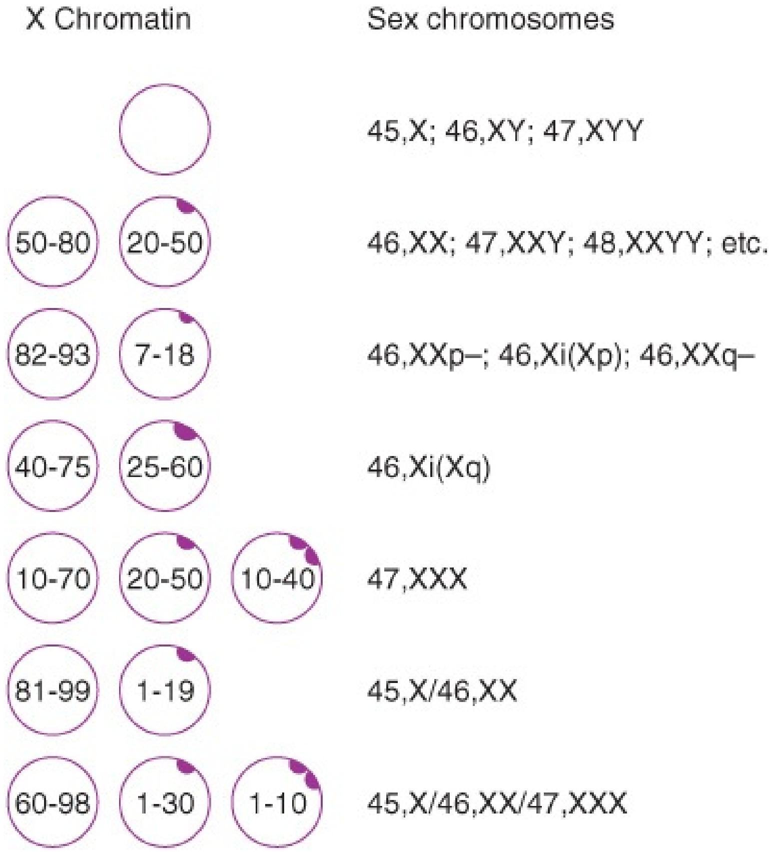

Figure 3–5. Relation of X-chromatin body to the possible sex chromosome components.

If there are more than 2 X chromosomes, all X chromosomes except 1 are genetically inactivated and become X-chromatin bodies; thus, in this case, the number of X-chromatin bodies will be equal to the number of X chromosomes minus 1. This type of inactivation applies to X chromosomes even when a Y chromosome is present, eg, in Klinefelter's syndrome.

Although the X chromosomes are primarily concerned with the determination of femininity, there is abundant genetic evidence that loci having to do with traits other than sex determination are present on the X chromosome. Thus, in the catalog of genetic disorders given in the 10th edition of *Mendelian Inheritance in Man*, 320 traits are listed as more or less definitely X-linked. Substantial evidence for X linkage has been found for about 160 of these traits; the rest are only suspected of having this relationship. Hemophilia, color blindness, childhood muscular dystrophy (Duchenne's dystrophy), Lesch-Nyhan syndrome, and glucose-6-phosphate dehydrogenase deficiency are among the better known conditions controlled by loci on the X chromosome. These entities probably arise from the expression of a recessive gene due to its hemizygous situation in males.

X-linked dominant traits are infrequent in humans. Vitamin D-resistant rickets is an example.

At least 1 disorder can be classified somewhere between a structural anomaly of the X chromosome and a single gene mutation. X-linked mental retardation in males is associated with a fragile site at q26, but a special culture medium is required for its demonstration. Furthermore, it has been shown that heterozygote female carriers for this fragile site have low IQ test scores.

The Y Chromosome in Humans

Just as the X chromosome is the only chromosome visible by ordinary light microscopy during interphase, the Y chromosome is the only chromosome visible in interphase, after exposure to quinacrine compounds, by fluorescence microscopy. This is a very useful diagnostic method.

In contrast to the X chromosome, few traits have been traced to the Y chromosome except those having to do with testicular formation and those at the very tip of the short arm, homologous with those at the tip of the short arm of the X. Possession of the Y chromosome alone, ie, without an X chromosome, apparently is lethal, because such a case has never been described.

Present on the Y chromosome is an area that produces a factor that allows for testicular development. This factor is termed testis-determining factor (TDF). Without the presence of TDF, normal female anatomy will develop. When TDF is present, testicular development occurs with subsequent differentiation of Sertoli cells. The Sertoli cells in turn produce a second factor central to male differentiation, müllerian-inhibiting factor (MIF), also termed antimüllerian factor (AMF). The presence of MIF causes the regression of the müllerian ducts and thereby allows for the development of normal internal male anatomy.

Y-Chromosome Microdeletion

In addition to sex determination function, human Y chromosome also has a role in spermatogenesis controlled by multiple genes along proximal Yq. The locus for spermatogenesis is on the euchromatic part of Yq (Yq11) called azoospermic factor (AZF). The AZF region is divided into three nonoverlapping regions AZFa, AZFb, and AZFc. The term “microdeletion” means that the size of the deleted segment is not visualized on karyotyping but must be discerned through molecular biology technique. There is no specific phenotype–genotype correlation between the degree of spermatogenic failure and type of Yq microdeletion. Complete deletion of AZFa and AZFb regions is associated with Sertoli cell-only syndrome and spermatogenic arrest, respectively. However, partial deletions of AZFa or AZFb or complete/partial deletions of AZFc are associated with a variable degree of spermatogenic failure ranging from oligozoospermia to Sertoli cell-only syndrome. There are reports of progressive impairment of spermatogenesis over time in patient with AZFc deletion. The fourth AZFd region, which was earlier proposed, does not exist based on the Y chromosome sequencing. There are many candidate genes within the deleted regions that are responsible for impaired spermatogenesis. The extensively studied genes are DAZ on AZFc region, RBMY1A1 on AZFb region, and USP9Y, DBY, and UTY on AZFa region. Because the deleted genes are expressed mainly in testes, men carrying the deletions have no abnormalities other than spermatogenic failure.

The incidence of Yq microdeletions in infertile men varies from 1–55% depending on study design. The most frequently deleted region is AZFc (~60%), whereas the deletion of the AZFa region is extremely rare (5%). The identification of Yq microdeletion has a prognostic value for the chance of successful testicular sperm retrieval. Men with complete deletion of AZFa and AZFb regions have almost no chance of having sperm recovered from surgical testicular sperm retrieval procedure, and no treatment is presently available for their fertility problem besides the use of donor sperm.

In the past, the majority of cases of Yq microdeletions have been de novo in infertile men during embryogenesis or from meiotic error in the germline of the fertile father. However, with the advent of assisted reproductive technologies, these infertile men can conceive genetic offspring with intracytoplasmic sperm injection (ICSI) technique, so Yq microdeletion can pass from generation to generation. A few studies show that when a Yq microdeletion is present in infertile men, ICSI-derived sons will inherit the same deletion. In view of genetic counseling, although Yq microdeletion is transmitted to the male offspring, the phenotype of male offspring regarding the degree of spermatogenesis is unpredictable due to the influence of the presence or absence of environmental factors that could affect spermatogenesis and the period of lifetime when spermatogenesis is assessed.

ABNORMAL DEVELOPMENT

1. Ovarian Agenesis–Dysgenesis

In 1938, Turner described 7 girls 15–23 years of age with sexual infantilism, webbing of the neck, cubitus valgus, and retardation of growth. A survey of the literature indicates that “Turner’s syndrome” means different things to different writers. After the later discovery that ovarian streaks are characteristically associated with the clinical entity described by Turner, “ovarian agenesis” became a synonym for Turner’s syndrome. After discovery of the absence of the X-chromatin body in such patients, the term ovarian agenesis gave way to “gonadal dysgenesis,” “gonadal agenesis,” or “gonadal aplasia.”

Meanwhile, some patients with the genital characteristics mentioned previously were shown to have a normally positive X-chromatin count. Furthermore, a variety of sex chromosome complements have been found in connection with streak gonads. As if these contradictions were not perplexing enough, it has been noted that streaks are by no means confined to patients with Turner’s original tetrad of infantilism, webbing of the neck, cubitus valgus, and retardation of growth but may be present in girls with sexual infantilism only. Since Turner’s original description, a host of additional somatic anomalies (varying in frequency) have been associated with his original clinical picture; these include shield chest, overweight, high palate, micrognathia, epicanthal folds, low-set ears, hypoplasia of nails, osteoporosis, pigmented moles, hypertension, lymphedema, cutis laxa, keloids, coarctation of the aorta, mental retardation, intestinal telangiectasia, and deafness.

For our purposes, the eponym Turner’s syndrome will be used to indicate sexual infantilism with ovarian streaks, short stature, and 2 or more of the somatic anomalies mentioned earlier. In this context, terms such as ovarian agenesis, gonadal agenesis, and gonadal dysgenesis lose their clinical significance and become merely descriptions of the gonadal development of the person. At least 21 sex chromosome complements have been associated with streak gonads (Fig. 3–6), but only about 9 sex chromosome complements have been associated with Turner’s syndrome. However, approximately two-thirds of patients with Turner’s syndrome have a 45,X chromosome complement, whereas only one-fourth of patients without Turner’s syndrome but with streak ovaries have a 45,X chromosome complement.

Figure 3–6. The 21 sex chromosome complements that have been found in patients with streak gonads.

Karyotype–phenotype correlations in the syndromes associated with ovarian agenesis are not completely satisfactory. Nonetheless, if gonadal development is considered as 1 problem and if the somatic difficulties associated with these syndromes are considered as a separate problem, one can make certain correlations.

With respect to failure of gonadal development, it is important to recall that diploid germ cells require 2 normal active X chromosomes. This is in contrast to the somatic cells, where only 1 sex chromosome is thought to be genetically active, at least after day 16 of embryonic life in the human, when the X-chromatin body first appears in the somatic cells. It is also important to recall that in 45,X persons no oocytes persist, and streak gonads are the rule. From these facts, it can be inferred that failure of gonadal development is not the result of a specific sex chromosome defect but rather of the absence of 2 X chromosomes with the necessary critical zones.

Karyotype–phenotype correlations with respect to somatic abnormalities are even sketchier than the correlations with regard to gonadal development. However, good evidence shows that monosomy for the short arm of the X chromosome is related to somatic difficulties, although some patients with long-arm deletions have somatic abnormalities.

History of Gonadal Agenesis

The histologic findings in these abnormal ovaries in patients with gonadal streaks are essentially the same regardless of the patient's cytogenetic background (Fig. 3–7).

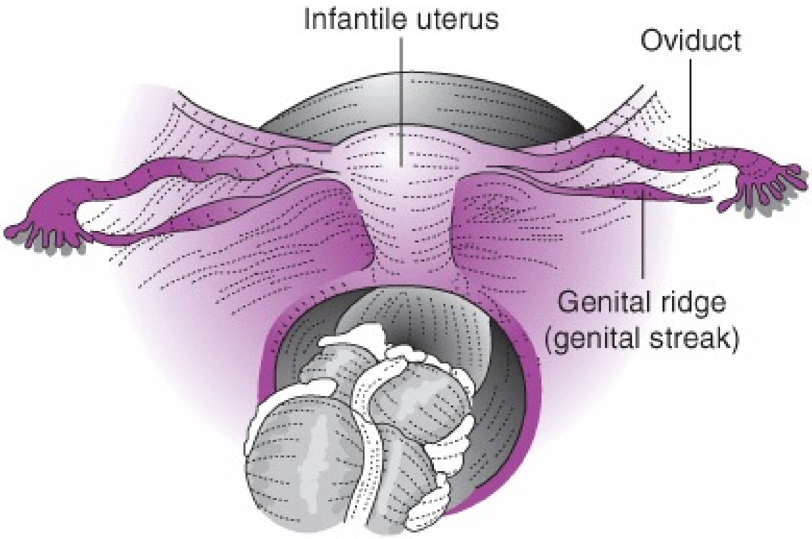

Figure 3–7. Gonadal streaks in a patient with the phenotype of Turner's syndrome. (Redrawn and reproduced, with permission, from Jones HW Jr, Scott WW. *Hermaphroditism, Genital Anomalies and Related Endocrine Disorders*. 2nd ed. Philadelphia, PA: Williams & Wilkins; 1971.)

Fibrous tissue is the major component of the streak. It is indistinguishable microscopically from that of the normal ovarian stroma. The so-called germinal epithelium, on the surface of the structure, is a layer of low cuboid cells; this layer appears to be completely inactive.

Tubules of the ovarian rete are invariably found in sections taken from about the midportion of the streak.

In all patients who have reached the age of normal puberty, hilar cells are also demonstrated. The number of hilar cells varies among patients. In those with some enlargement of the clitoris, hilar cells are present in large numbers. These developments may be causally related. Nevertheless, hilar cells are also found in many normal ovaries. The origin of hilar cells is not precisely known, but they are associated with development of the medullary portion of the gonad. Their presence lends further support to the concept that in ovarian agenesis the gonad develops along normal lines until just before the expected appearance of early oocytes. In all cases in which sections of the broad ligament have been available for study, it has been possible to identify the mesonephric duct and tubules—broad ligament structures found in normal females.

Clinical Findings

A. Symptoms & Signs

1. In newborn infants—The newborn with streak ovaries often shows edema of the hands and feet. Histologically, this edema is associated with large dilated vascular spaces. With such findings, it is obviously desirable to obtain a karyotype. However, some children with streak ovaries—particularly those who have few or no somatic abnormalities—cannot be recognized at birth.

2. In adolescents—The arresting and characteristic clinical finding in many of these patients is their short stature. Typical patients seldom attain a height of 1.5 m (5 ft) (Fig. 3–8). In addition, sexual infantilism is a striking finding. As mentioned earlier, a variety of somatic abnormalities may be present; by definition, if 2 or more of these are noted, the patient may be considered to have Turner's syndrome. Most of these patients have only 1 normal X chromosome, and two-thirds of them have no other sex chromosome. Patients of normal height without somatic abnormalities may also have gonadal streaks. Under these circumstances, there is likely to be a cell line with 2 normal sex chromosomes but often a second line with a single X. The internal findings are exactly the same as in patients with classic Turner's syndrome, however.

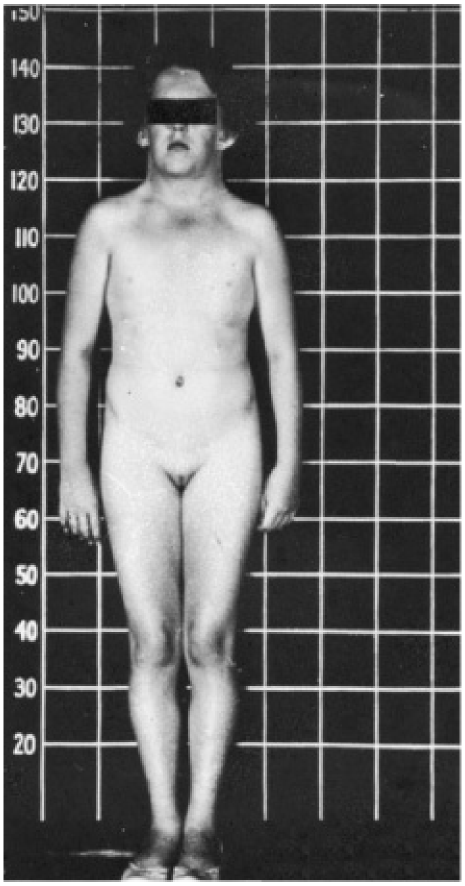

Figure 3–8. Patient with Turner's syndrome. (*Reproduced, with permission, from Jones HW Jr, Scott WW. Hermaphroditism, Genital Anomalies and Related Endocrine Disorders*. 2nd ed. Philadelphia, PA: Williams & Wilkins; 1971.)

B. Laboratory Findings

An important finding in patients of any age—but especially after expected puberty, ie, about 12 years—is elevation of total gonadotropin production. From a practical point of view, ovarian failure in patients over age 15 cannot be considered a diagnostic possibility unless the serum follicle-stimulating hormone level is more than 50 mIU/mL and luteinizing hormone level is more than 90 mIU/mL.

Nongonadal endocrine functions are normal. Urinary excretion of estrogens is low, and the maturation index and other vaginal smear indices are shifted well to the left.

Treatment

Substitution therapy with estrogen is necessary for development of secondary characteristics.

Therapy with growth hormone will increase height. Whether ultimate height will be greater than it otherwise would be is uncertain, but current evidence suggests that it will be.

The incidence of malignant degeneration is increased in the gonadal streaks of patients with a Y chromosome, as compared with normal males. Surgical removal of streaks from all patients with a Y chromosome is recommended.

2. True Hermaphroditism

By classic definition, true hermaphroditism exists when both ovarian and testicular tissue can be demonstrated in 1 patient. In humans, the Y chromosome carries genetic material that normally is responsible for testicular development; this material is active even when multiple X chromosomes are present. Thus, in Klinefelter's syndrome, a testis develops with up to 4 Xs and only 1 Y. Conversely (with rare exceptions), a testis has not been observed to develop in the absence of the Y chromosome. The exceptions are found in true hermaphrodites and XX males, in whom testicular tissue has developed in association with an XX sex chromosome complement.

Clinical Findings

A. Symptoms & Signs

No exclusive features clinically distinguish true hermaphroditism from other forms of intersexuality. Hence, the diagnosis must be entertained in an infant with any form of intersexuality, except only those with a continuing virilizing influence, eg, congenital adrenal hyperplasia. Firm diagnosis is possible after the onset of puberty, when certain clinical features become evident, but the diagnosis can and should be made in infancy.

In the past, most true hermaphrodites have been reared as males because they have rather masculine-appearing external genitalia (Fig. 3–9). Nevertheless, with early diagnosis, most should be reared as females.

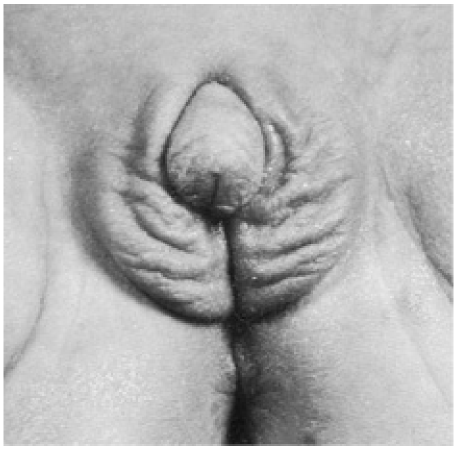

Figure 3–9. External genitalia of a patient with true hermaphroditism. (Reproduced, with permission, from Jones HW Jr, Scott WW. *Hermaphroditism, Genital Anomalies and Related Endocrine Disorders*. 2nd ed. Philadelphia, PA: Williams & Wilkins; 1971.)

Almost all true hermaphrodites develop female-type breasts. This helps to distinguish male hermaphroditism from true hermaphroditism, because few male hermaphrodites other than those with familial feminizing hermaphroditism develop large breasts.

Many true hermaphrodites menstruate. The presence or absence of menstruation is partially determined by the development of the uterus; many true hermaphrodites have rudimentary or no development of the müllerian ducts (Fig. 3–10).

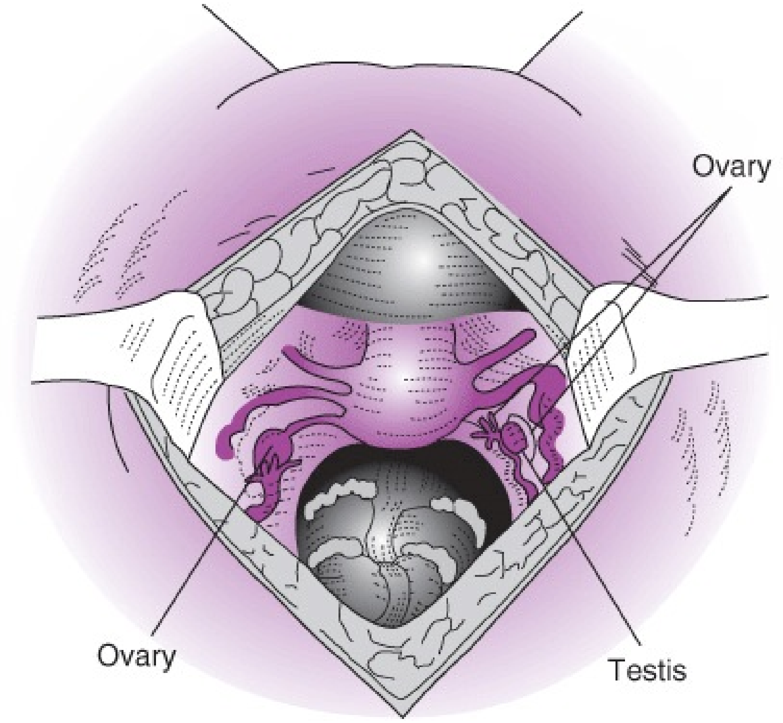

Figure 3–10. Internal genitalia of a patient with true hermaphroditism. (Reproduced, with permission, from Jones HW Jr, Scott WW. *Hermaphroditism, Genital Anomalies and Related Endocrine Disorders*. 2nd ed. Philadelphia, PA: Williams & Wilkins; 1971.)

A few patients who had a uterus and menstruated after removal of testicular tissue have become pregnant and delivered normal children.

B. Sex Chromosome Complements

Most true hermaphrodites have X-chromatin bodies and karyotypes that are indistinguishable from those of normal females. In contrast to these, a few patients who cannot be distinguished clinically from other true hermaphrodites have been reported to have a variety of other karyotypes—eg, several chimeric persons with karyotypes of 46,XX/46,XY have been identified.

In true hermaphrodites, the testis is competent in its müllerian-suppressive functions, but an ovotestis may behave as an ovary insofar as its müllerian-suppressive function is concerned. The true hermaphroditic testis or ovotestis is as competent to masculinize the external genitalia as is the testis of a patient with the virilizing type of male hermaphroditism. This is unrelated to karyotype.

Deletion mapping by DNA hybridization has shown that most (but not all) XX true hermaphrodites have Y-specific sequences. Abnormal crossover of a portion of the Y chromosome to the X in meiosis may explain some cases. This latter statement is further supported by the finding of a positive H-Y antigen assay in some patients with 46,XX true hermaphroditism.

In general, the clinical picture of true hermaphroditism is not compatible with the clinical picture in other kinds of gross chromosomal anomalies. For example, very few true hermaphrodites have associated somatic anomalies, and mental retardation almost never occurs.

Treatment

The principles of treatment of true hermaphroditism do not differ from those of the treatment of hermaphroditism in general. Therapy can be summarized by stating that surgical removal of contradictory organs is indicated, and the external genitalia should be reconstructed in keeping with the sex of rearing. The special problem in this group is how to establish with certainty the character of the gonad. This is particularly difficult in the presence of an ovotestis, because its recognition by gross characteristics is notoriously inaccurate, and one must not remove too much of the gonad for study. In some instances, the gonadal tissue of 1 sex is completely embedded within a gonadal structure primarily of the opposite sex.

3. Klinefelter's Syndrome

This condition, first described in 1942 by Klinefelter, Reifenstein, and Albright, occurs only in apparent males. As originally described, it is characterized by small testes, azoospermia, gynecomastia, relatively normal external genitalia, and otherwise average somatic development. High levels of gonadotropin in urine or serum are characteristic.

Clinical Findings

A. Symptoms & Signs

By definition, this syndrome applies only to persons reared as males. The disease is not recognizable before puberty except by routine screening of newborn infants. Most patients come under observation at 16–40 years of age.

Somatic development during infancy and childhood may be normal. Growth and muscular development may also be within normal limits. Most patients have a normal general appearance and no complaints referable to this abnormality, which is often discovered during the course of a routine physical examination or an infertility study.

In the original publication by Klinefelter and coworkers, gynecomastia was considered an essential part of the syndrome. Since then, however, cases without gynecomastia have been reported.

The external genitalia are perfectly formed and in most patients are quite well developed. Erection and intercourse usually are satisfactory.

There is no history of delayed descent of the testes in typical cases, and the testes are in the scrotum. Neither is there any history of testicular trauma or disease. Although a history of mumps orchitis is occasionally elicited, this disease has not been correlated with the syndrome. However, the testes are often very small in contrast to the rest of the genitalia (about 1.5 × 1.5 cm).

Psychological symptoms are often present. Most studies of this syndrome have been performed in psychiatric institutions. The seriousness of the psychological disturbance seems to be partly related to the number of extra X chromosomes—eg, it is estimated that about one-fourth of XXY patients have some degree of mental retardation.

B. Laboratory Findings

One of the extremely important clinical features of Klinefelter's syndrome is the excessive amount of pituitary gonadotropin found in either urine or serum assay.

The urinary excretion of neutral 17-ketosteroids varies from relatively normal to definitely subnormal levels. There is a rough correlation between the degree of hypoleydigism as judged clinically and a low 17-ketosteroid excretion rate.

C. Histologic & Cytogenetic Findings

Klinefelter's syndrome may be regarded as a form of primary testicular failure.

Several authors have classified a variety of forms of testicular atrophy as subtypes of Klinefelter's syndrome. Be this as it may, Klinefelter believed that only those patients who have a chromosomal abnormality could be said to have this syndrome. Microscopic examination of the adult testis shows that the seminiferous tubules lack epithelium and are shrunken and hyalinized. They contain large amounts of elastic fibers, and Leydig cells are present in large numbers.

Males with positive X-chromatin bodies are likely to have Klinefelter's syndrome. The nuclear sex anomaly reflects a basic genetic abnormality in sex chromosome constitution. All cases studied have had at least 2 X chromosomes and 1 Y chromosome. The most common abnormality in the sex chromosome constitution is XXY, but the literature also records XXXY, XXYY, XXXXY, and XXXYY, and mosaics of XX/XXY, XY/XXY, XY/XXXY, and XXXY/XXXXY. In all examples except the XX/XXY mosaic, a Y chromosome is present in all cells. From these patterns, it is obvious that the Y chromosome has a very strong testis-forming impulse, which can operate in spite of the presence of as many as 4 X chromosomes.

Thus, patients with Klinefelter's syndrome will have not only a positive X-chromatin body but also a positive Y-chromatin body.

The abnormal sex chromosome constitution causes differentiation of an abnormal testis, leading to testicular failure in adulthood. At birth or before puberty, such testes show a marked deficiency or absence of germinal cells.

By means of nursery screening, the frequency of males with positive X-chromatin bodies has been estimated to be 2.65 per 1000 live male births.

Treatment

There is no treatment for the 2 principal complaints of these patients: infertility and gynecomastia. No pituitary preparation has been effective in the regeneration of the hyalinized tubular epithelium or the stimulation of gametogenesis. Furthermore, no hormone regimen is effective in treating the breast hypertrophy. When the breasts are a formidable psychological problem, surgical removal may be a satisfactory procedure. In patients who have clinical symptoms of hypoleydigism, substitution therapy with testosterone is an important physiologic and psychological aid. Donor sperm may be offered for treatment of infertility.

4. Double-X Males

A few cases of adult males with a slightly hypoplastic penis and very small testes but no other indication of abnormal sexual development have been reported. These males are sterile. Unlike those with Klinefelter's syndrome, they do not have abnormal breast development. They are clinically very similar to patients with Del Castillo's syndrome (testicular dysgenesis). Nevertheless, the XX males have a positive sex chromatin and a normal female karyotype. These may be extreme examples of the sex reversal that usually is partial in true hermaphroditism.

5. Multiple-X Syndromes

The finding of more than 1 X-chromatin body in a cell indicates the presence of more than 2 X chromosomes in that particular cell. In many patients, such a finding is associated with mosaicism, and the clinical picture is controlled by this fact—eg, if 1 of the strains of the mosaicism is 45,X, gonadal agenesis is likely to occur. There also are persons who do not seem to have mosaicism but do have an abnormal number of X chromosomes in all cells. In such persons, the most common complement is XXX (triplo-X syndrome), but XXXX (tetra-X syndrome) and XXXXX (penta-X syndrome) have been reported.

An additional X chromosome does not seem to have a consistent effect on sexual differentiation.

The body proportions of these persons are normal, and the external genitalia are normally female. A number of such persons have been examined at laparotomy, and no consistent abnormality of the ovary has been found. In a few cases, the number of follicles appeared to be reduced, and in at least 1 case the ovaries were very small and the ovarian stroma poorly differentiated. About 20% of postpubertal patients with the triplo-X syndrome report various degrees of amenorrhea or some irregularity in menstruation. For the most part, however, these patients have a normal menstrual history and are of proved fertility.

Almost all patients known to have multiple-X syndromes have some degree of mental retardation. A few have mongoloid features. (The mothers of these patients tended to be older than the mothers of normal children, as is true with Down syndrome.) Perhaps these findings are in part circumstantial, as most of these patients were discovered during surveys in mental institutions. The important clinical point is that mentally retarded infants should have chromosomal study.

Uniformly, the offspring of triplo-X mothers have been normal. This is surprising, because theoretically in such cases meiosis should produce equal numbers of ova containing 1 or 2 X chromosomes, and fertilization of the abnormal XX ova should give rise to XXX and XXY individuals. Nevertheless, the triplo-X condition seems selective for normal ova and zygotes.

The diagnosis of this syndrome is made by identifying a high percentage of cells with double X-chromatin bodies in the buccal smear and by finding 47 chromosomes with a karyotype showing an extra X chromosome in all cells cultured from the peripheral blood. It should be noted that in the examination of the buccal smear, some cells have a single X-chromatin body. Hence, based on the chromatin examination, one might suspect XX/XXX mosaicism. Actually, in triplo-X patients, only a single type of cell can be demonstrated in cultures of cells from the peripheral blood. The absence of the second X-chromatin body in some of the somatic cells may result from the time of examination of the cell (during interphase) and from the spatial orientation, which could have prevented visualization of the 2 X-chromatin bodies (adjacent to the nuclear membrane). In this syndrome, the number of cells containing either 1 or 2 X-chromatin bodies is very high—at least 60–80%, as compared with an upper limit of about 40% in normal females.

6. Female Hermaphroditism due to Congenital Adrenal Hyperplasia

ESSENTIALS OF DIAGNOSIS

- Female pseudohermaphroditism, ambiguous genitalia with clitoral hypertrophy, and, occasionally, persistent urogenital sinus.
- Early appearance of sexual hair; hirsutism, dwarfism.
- Urinary 17-ketosteroids elevated; pregnanetriol may be increased.
- Elevated serum 17-hydroxyprogesterone level.
- Occasionally associated with water and electrolyte imbalance—particularly in the neonatal period.

General Considerations

Female hermaphroditism due to congenital adrenal hyperplasia is a clearly delineated clinical syndrome. The syndrome has been better understood since the discovery that cortisone may successfully arrest virilization. The problem usually is due to a deficiency of a gene required for 21-hydroxylation in the biosynthesis of cortisol.

If the diagnosis is not made in infancy, an unfortunate series of events ensues. Because the adrenals secrete an abnormally large amount of virilizing steroid even during embryonic life, these infants are born with abnormal genitalia (Fig. 3–11). In extreme cases, there is fusion of the scrotolabial folds and, in rare instances, even formation of a penile urethra. The clitoris is greatly enlarged so that it may be mistaken for a penis (Fig. 3–12). No gonads are palpable within the fused scrotolabial folds, and their absence has sometimes given rise to the mistaken impression of male cryptorchidism. Usually, there is a single urinary meatus at the base of the phallus, and the vagina enters the persistent urogenital sinus as noted in Figure 3–13.

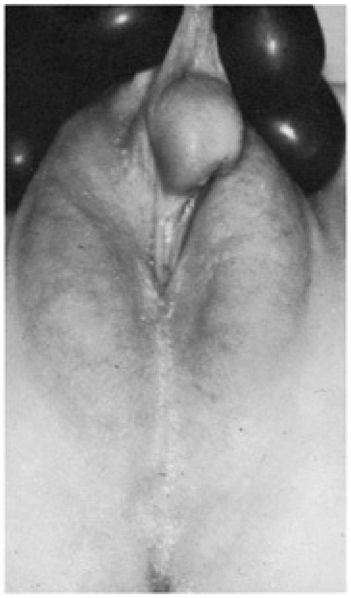

Figure 3–11. External genitalia of a female patient with congenital virilizing adrenal hyperplasia. Compare with Figure 3–12. (Reproduced, with permission, from Jones HW Jr, Scott WW. *Hermaphroditism, Genital Anomalies and Related Endocrine Disorders*. 2nd ed. Philadelphia, PA: Williams & Wilkins; 1971.)

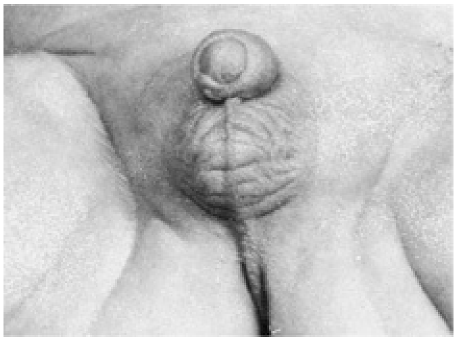

Figure 3–12. External genitalia of a female patient with congenital virilizing adrenal hyperplasia. This is a more severe deformity than that shown in Figure 3–11.

(Redrawn and reproduced, with permission, from Verkauf BS, Jones HW Jr. Masculinization of the female genitalia in congenital adrenal hyperplasia. *South Med J* 1970;63:634–

638.)

During infancy, provided there are no serious electrolyte disturbances, these children grow more rapidly than normal. For a time, they greatly exceed the average in both height and weight. Unfortunately, epiphyseal closure occurs by about age 10, and as a result, these people are much shorter than normal as adults (Fig. 3–14).

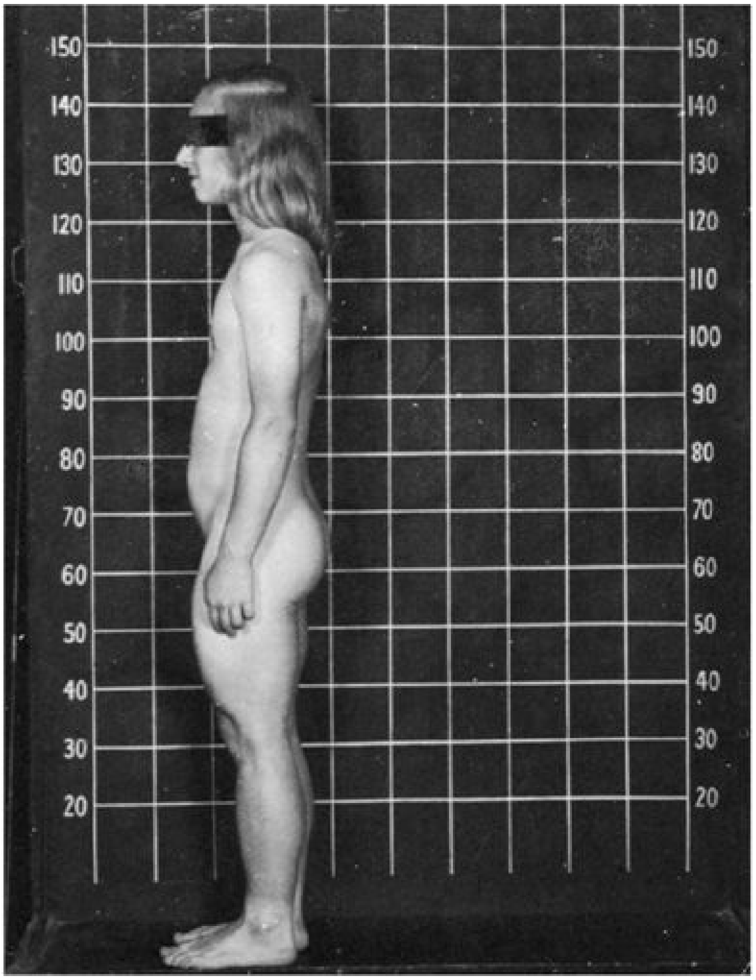

Figure 3–14. Untreated adult with virilizing adrenal hyperplasia. Note the short stature and the relative shortness of the limbs. (Reproduced, with permission, from Jones HW Jr, Scott WW. *Hermaphroditism, Genital Anomalies and Related Endocrine Disorders*. 2nd ed. Philadelphia, PA: Williams & Wilkins; 1971.)

The process of virilization begins at an early age. Pubic hair may appear as early as age 2 years but usually somewhat later. This is followed by growth of axillary hair and finally by the appearance of body hair and a beard, which may be so thick as to require daily shaving. Acne may develop early. Puberty never ensues. There is no breast development. Menstruation does not occur. During the entire process, serum adrenal androgens and 17-hydroxyprogesterone levels are abnormally high.

Although our principal concern here is with this abnormality in females, it must be mentioned that adrenal hyperplasia of the adrenogenital type may also occur in males, in whom it is called macrogenitosomia precox. Sexual development progresses rapidly, and the sex organs attain adult size at an early age. Just as in the female, sexual hair and acne develop unusually early, and the voice becomes deep. The testes are usually in the scrotum; however, in early childhood they remain small and immature, although the genitalia are of adult dimensions. In adulthood, the testes usually enlarge and spermatogenesis occurs, allowing impregnation rates similar to those of a control population.

Somatic development in the male corresponds to that of the female; as a child, the male exceeds the average in height and strength, but (if untreated) as an adult he is stocky, muscular, and well below average height.

Both the male and the female with this disorder—but especially the male—may have the complicating problem of electrolyte imbalance. In infancy, it is manifested by vomiting, progressive weight loss, and dehydration and may be fatal unless recognized promptly. The characteristic findings are an exceedingly low serum sodium level, low CO_2-combining power level, and high potassium level. The condition is sometimes misdiagnosed as congenital pyloric stenosis.

A few of these patients have a deficiency in 11-hydroxylation that is associated with hypertension in addition to virilization.

Adrenal Histology

The adrenal changes center on a reticular hyperplasia, which becomes more marked as the patient grows older. In some instances, the glomerulosa may participate in the hyperplasia, but the fasciculata is greatly diminished in amount or entirely absent. Lipid studies show absence of fascicular and glomerular lipid but an abnormally strong lipid reaction in the reticularis (Fig. 3–15).

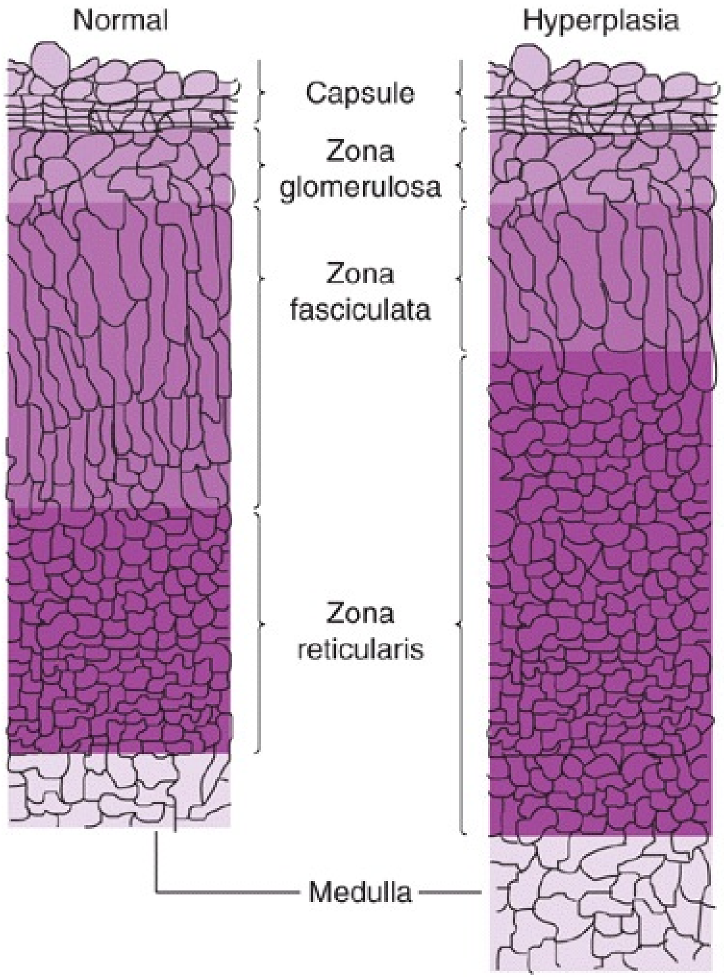

Figure 3–15. Normal adrenal architecture and adrenal histology in congenital virilizing adrenal hyperplasia. Note the great relative increase in the zona reticularis.

Ovarian Histology

The ovarian changes can be summarized by stating that in infants, children, and teenagers, there is normal follicular development to the antrum stage but no evidence of ovulation. With increasing age, less and less follicular activity occurs, and primordial follicles disappear. This disappearance must not be complete, however, because cortisone therapy, even in adults, usually results in ovulatory menstruation after 4–6 months of treatment.

Developmental Anomalies of the Genital Tubercle & Urogenital Sinus Derivatives

The phallus is composed of 2 lateral corpora cavernosa, but the corpus spongiosum is normally absent. The external urinary meatus is most often located at the base of the phallus (Fig. 3–11). An occasional case may be seen in which the urethra does extend to the end of the clitoris (Fig. 3–12). The glans penis and the prepuce are present and indistinguishable from these structures in the male. The scrotolabial folds are characteristically fused in the midline, giving a scrotum-like appearance with a median perineal raphe; however, they seldom enlarge to normal scrotal size. No gonads are palpable within the scrotolabial folds. When the anomaly is not severe (eg, in patients with postnatal virilization), fusion of the scrotolabial folds is not complete, and by gentle retraction it is often possible to locate not only the normally located external urinary meatus but also the orifice of the vagina.

An occasional patient has no communication between the urogenital sinus and the vagina. In no case does the vagina communicate with that portion of the urogenital sinus that gives rise to the female urethra or the prostatic urethra. Instead, the vaginal communication is via caudal urogenital sinus derivatives; thus, fortunately, the sphincter mechanism is not involved, and the anomalous communication is with that portion of the sinus that develops as the vaginal vestibule in the female and the membranous urethra in the male. From the gynecologist’s point of view, it is much more meaningful to say that the vagina and (female) urethra enter a persistent urogenital sinus than to say that the vagina enters the (membranous [male]) urethra. This conclusion casts some doubt on the embryologic significance of the prostatic utricle, which is commonly said to represent the homologue of the vagina in the normal male.

Hormone Changes

Important and specific endocrine changes occur in congenital adrenal hyperplasia of the adrenogenital type. The ultimate diagnosis depends on demonstration of these abnormalities.

A. Urinary Estrogens

The progressive virilization of female hermaphrodites caused by adrenal hyperplasia would suggest that estrogen secretion in these patients is low, and this hypothesis is further supported by the atrophic condition of both the ovarian follicular apparatus and the estrogen target organs. Actually, the determination of urinary estrogens, both fluorometrically and biologically, indicates that it is elevated.

B. Serum Steroids

The development of satisfactory radioimmunoassay techniques for measuring steroids in blood serum has resulted in an increased tendency to measure serum steroids rather than urinary metabolites in diagnosing the condition and monitoring therapy. Serum steroid profiles of many patients with this disorder show that numerous defects in the biosynthesis of cortisol may occur. The most common defect is at the 21-hydroxylase step. Less frequent defects are at the 11-hydroxylase step and the 3β-ol-dehydrogenase step. Rarely, the defect is at the 17-hydroxylase step. In the most common form of the disorder—21-hydroxylase deficiency—the serum 17-hydroxyprogesterone level and, to a lesser extent, the serum progesterone level are elevated. This is easily understandable when it is recalled that

17-hydroxyprogesterone is the substrate for the 21-hydroxylation step (Fig. 3–16). Likewise, in the other enzyme defects, the levels of serum steroid substrates are greatly elevated.

Figure 3–16. Enzymatic steps in cortisol synthesis. Localization of defects in congenital adrenal hyperplasia.

Pathogenesis of Virilizing Adrenal Hyperplasia

The basic defects in congenital virilizing adrenal hyperplasia are 1 or more enzyme deficiencies in the biosynthesis of cortisol (Fig. 3–16). With the reduced production of cortisol, normal feedback to the hypothalamus fails, with the result that increased amounts of adrenocorticotropic hormone (ACTH) are produced. This excess production of ACTH stimulates the deficient adrenal gland to produce relatively normal amounts of cortisol—but also stimulates production of abnormally large amounts of estrogen and androgens by the zona reticularis. In this overproduction, a biologic preponderance of androgens causes virilization. These abnormal sex steroids suppress the gonadotropins so that untreated patients never reach puberty and do not menstruate.

Therefore, the treatment of this disorder consists in part of the administration of sufficient exogenous cortisol to suppress ACTH production to normal levels. This in turn should reduce overstimulation of the adrenal so that the adrenal will cease to produce abnormally large amounts of estrogen and androgen. The gonadotropins generally return to normal levels, with consequent feminization of the patient and achievement of menstruation.

The pathogenesis of the salt-losing type of adrenal hyperplasia involves a deficiency in aldosterone production.

Diagnosis

Hermaphroditism due to congenital adrenal hyperplasia must be suspected in any infant born with ambiguous or abnormal external genitalia. It is exceedingly important that the diagnosis be made at a very early age if undesirable disturbances of metabolism are to be prevented.

All patients with ambiguous external genitalia should have an appraisal of their chromosomal characteristics. In all instances of female pseudohermaphroditism due to congenital hyperplasia, the chromosomal composition is that of a normal female. A pelvic ultrasound in the newborn to determine the presence of a uterus is very helpful and, if positive, strongly suggests a female infant.

The critical determinations are those of the urinary 17-ketosteroid and serum 17-hydroxyprogesterone levels. If these are elevated, the diagnosis must be either congenital adrenal hyperplasia or tumor. In the newborn, the latter is very rare, but in older children and adults with elevated 17-ketosteroids, the possibility of tumor must be considered. One of the most satisfactory methods of making this different diagnosis is to attempt to suppress the excess androgens by administration of dexamethasone. In an adult or an older child, a suitable test dose of dexamethasone is 1.25 mg/45 kg (100 lb) body weight, given orally for 7 consecutive days. In congenital adrenal hyperplasia, there should be suppression of the urinary 17-ketosteroids on the seventh day of the test to less than 1 mg/24 h; in the presence of tumor, either there will be no effect or the 17-ketosteroid levels will rise.

Determination of urinary dehydroepiandrosterone (DHEA) or serum dehydroepiandrosterone sulfate (DHEAS) levels can also be helpful in differentiating congenital adrenal hyperplasia from an adrenal tumor. Levels in patients with congenital adrenal hyperplasia may be up to double the normal amount, whereas an adrenal tumor is usually associated with levels that are much higher than double the normal level.

Determination of the serum sodium and potassium levels and CO_2-combining power is also important to ascertain whether electrolyte balance is seriously disturbed.

Treatment

The treatment of female hermaphroditism due to congenital adrenal hyperplasia is partly medical and partly surgical. Originally, cortisone was administered; today, it is known that various cortisone derivatives are at least as effective. It is most satisfactory to begin treatment with relatively large doses of hydrocortisone divided in 3 doses orally for 7–10 days to obtain rapid suppression of adrenal activity. In young infants, the initial dose is about 25 mg/d; in older patients, 100 mg/d. After the output of 17-ketosteroids has decreased to a lower level, the dose should be reduced to the minimum amount required to maintain adequate suppression. This requires repeated measurements of plasma 17α-hydroxyprogesterone in order to individualize the dose.

It has been found that even with suppression of the urinary 17-ketosteroids to normal levels, the more sensitive serum 17-hydroxyprogesterone level may still be elevated. It seems difficult and perhaps undesirable to suppress the serum 17-hydroxyprogesterone values to normal because to do so may require doses of hydrocortisone that tend to cause cushingoid symptoms.

In the treatment of newborns with congenital adrenal hyperplasia who have a defect of electrolyte regulation, it is usually necessary to administer sodium chloride in amounts of 4–6 g/d, either orally or parenterally, in addition to cortisone. Furthermore, fludrocortisone acetate usually is required initially. The dose is entirely dependent on the levels of the serum electrolytes, which must be followed serially, but it is generally 0.05–0.1 mg/d.

In addition to the hormone treatment of this disorder, surgical correction of the external genitalia is usually necessary.

During acute illness or other stress, as well as during and after an operation, additional hydrocortisone is indicated to avoid the adrenal insufficiency of stress. Doubling the maintenance dose is usually adequate in such circumstances.

7. Female Hermaphroditism without Progressive Masculinization

Females with no adrenal abnormality may have fetal masculinization of the external genitalia with the same anatomic findings as in patients with congenital virilizing adrenal hyperplasia. Unlike patients with adrenogenital syndrome, patients without adrenal abnormality do not have elevated levels of serum steroids or urinary 17-ketosteroids, nor do they show precocious sexual development or the metabolic difficulties associated with adrenal hyperplasia as they grow older. At onset of puberty, normal feminization with menstruation and ovulation may be expected.

The diagnosis of female hermaphroditism not due to adrenal abnormality depends on the demonstration of a 46,XX karyotype and the finding of normal levels of serum steroids or normal levels of 17-ketosteroids in the urine. If fusion of the scrotolabial folds is complete, it is necessary to determine the exact relationship of the urogenital sinus to the urethra and vagina and to demonstrate the presence of a uterus by rectal examination or ultrasonography or endoscopic observation of the cervix. When there is a high degree of masculinization, the differential diagnosis between this condition and true hermaphroditism may be very difficult; an exploratory laparotomy may be required in some cases.

Classification

Patients with this problem may be seen because of a variety of conditions.

1. Exogenous androgen:
    a. Maternal ingestion of androgen
    b. Maternal androgenic tumor
    c. Luteoma of pregnancy
    d. Adrenal androgenic tumor
2. Idiopathic: No identifiable cause.
3. Special or nonspecific: The same as condition 2 except that it is associated with various somatic anomalies and with mental retardation.
4. Familial: A very rare anomaly.

8. Male Hermaphroditism

Persons with abnormal or ectopic testes may have external genitalia so ambiguous at birth that the true sex is not identifiable (Fig. 3–17). At puberty, these persons tend to become masculinized or feminized depending on factors to be discussed. Thus, the adult habitus of these persons may be typically male, ie, without breasts, or typically female, with good breast development. In some instances, the external genitalia may be indistinguishable from those of a normal female; in others, the clitoris may be enlarged; and in still other instances, there may be fusion of the labia in the midline, resulting in what seems to be a hypospadiac male. A deep or shallow vagina may be present. A cervix, a uterus, and uterine tubes may be developed to varying degrees; however, müllerian structures are often absent. Mesonephric structures may be grossly or microscopically visible. Body hair may be either typically feminine in its distribution and quantity or masculine in distribution and of sufficient quantity as to require plucking or shaving if the person is reared as a female. In a special group, axillary and pubic hair is congenitally absent. Although there is a well-developed uterus in some instances, all patients so far reported have been amenorrheic—in spite of the interesting theoretic possibility of uterine bleeding from endometrium stimulated by estrogen of testicular origin. There is no evidence of adrenal malfunction. In the feminized group, and less frequently in the nonfeminized group, there is a strong familial history of the disorder. Male hermaphrodites reared as females may marry and be well adjusted to their sex role. Others, especially when there has been equivocation regarding sex of rearing in infancy, may be less than attractive as women because of indecisive therapy. Psychiatric studies indicate that the best emotional adjustment comes from directing endocrine, surgical, and psychiatric measures toward improving the person’s basic characteristics. Fortunately, this is consonant with the surgical and endocrine possibilities for those reared as females, because current operative techniques can produce more satisfactory feminine than masculine external genitalia. Furthermore, the testes of male hermaphrodites are nonfunctional as far as spermatogenesis is concerned. Only about one-third of male hermaphrodites are suitable for rearing as males.

Classification

Since about 1970, considerable progress has been made in identifying specific metabolic defects that are etiologically important for the various forms of male hermaphroditism. Details are beyond the scope of this text. Nevertheless, it is important to point out that all cases of male hermaphroditism have a defect in either the biologic action of testosterone or the MIF of the testis. Furthermore, it now seems apparent that nearly all—if not all—of these defects have a genetic or cytogenetic background.

The causes and pathogenetic mechanisms of these defects may vary, but the final common pathway is 1 of the 2 problems just mentioned; in the adult a study of the serum gonadotropins and serum steroids, including the intermediate metabolites of testosterone, can often pinpoint a defect in the biosynthesis of testosterone. In other cases, the end-organ action of testosterone may be defective. In children, the defect is sometimes more difficult to determine before gonadotropin levels rise at puberty, but one may suspect a problem by observing abnormally high levels of steroids that act as substrates in the metabolism of testosterone. A working classification of male hermaphroditism is as follows:

- I. Male hermaphroditism due to a central nervous system defect
  - A. Abnormal pituitary gonadotropin secretion
  - B. No gonadotropin secretion
- II. Male hermaphroditism due to a primary gonadal defect
  - A. Identifiable defect in biosynthesis of testosterone
    - 1. Pregnenolone synthesis defect (lipoid adrenal hyperplasia)
    - 2. 3β-Hydroxysteroid dehydrogenase deficiency
    - 3. 17α-Hydroxylase deficiency
    - 4. 17,20-Desmolase deficiency
    - 5. 17β-Ketosteroid reductase deficiency
  - B. Unidentified defect in androgen effect
  - C. Defect in duct regression (Figs. 3–18 and 3–19)

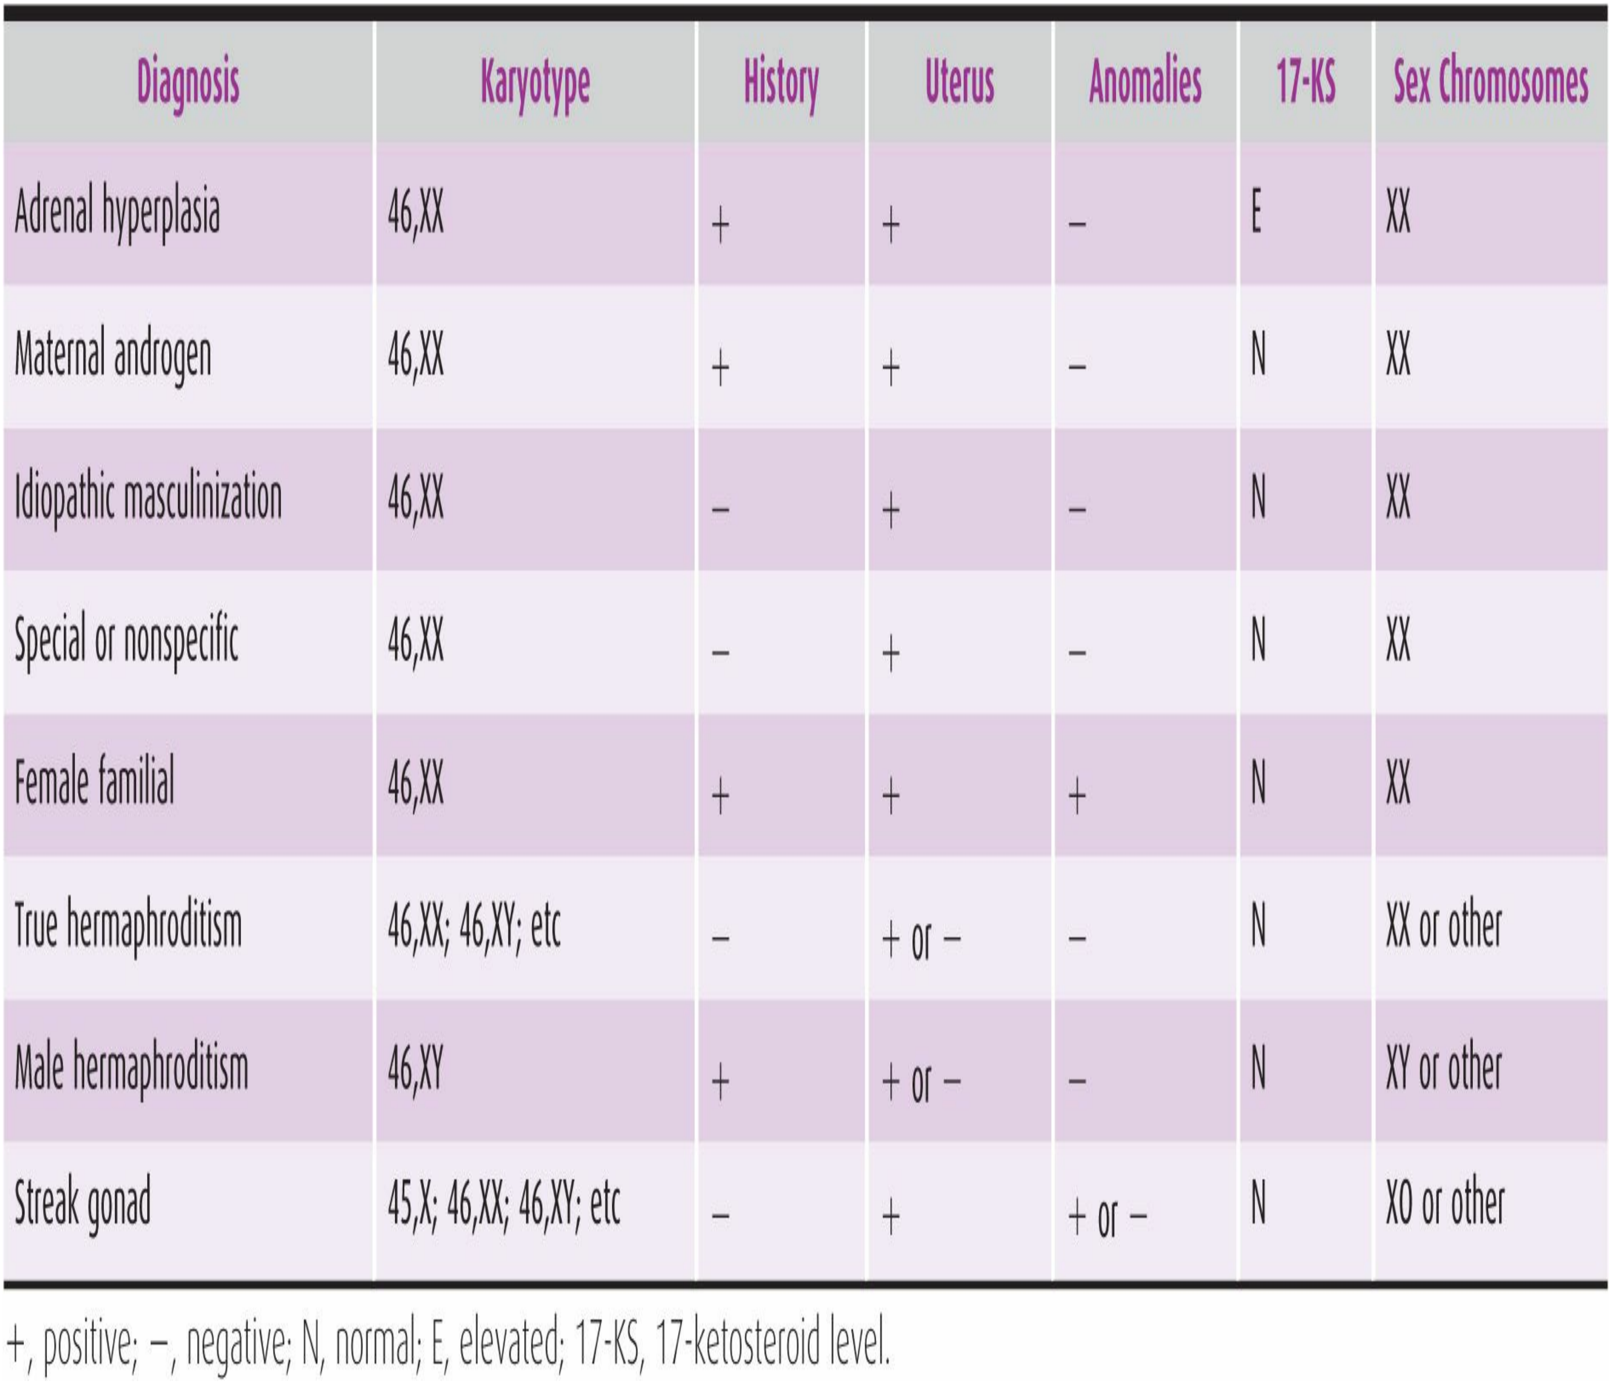
9. Differential Diagnosis in Infants with Ambiguous Genitalia

Accurate differential diagnosis is possible in most patients with ambiguous genitalia (Table 3–8). This requires a complex history of the mother's medication use, a complex sex chromosome study, rectal examination for the presence or absence of a uterus, measurement of serum steroid levels, pelvic ultrasonography, and information about other congenital anomalies. The following disorders, however, do not yield to differentiation by the parameters given in Table 3–8: (1) idiopathic masculinization, (2) the "special" forms of female hermaphroditism, (3) 46,XX true hermaphroditism, and, occasionally, (4) the precise type of male hermaphroditism. For these differentiations, laparotomy may be necessary for diagnosis and for therapy.

Table 3–8. Differential diagnosis of ambiguous external genitalia.



Diagnosis	Karyotype	History	Uterus	Anomalies	17-KS	Sex Chromosomes
Adrenal hyperplasia	46,XX	+	+	−	E	XX
Maternal androgen	46,XX	+	+	−	N	XX
Idiopathic masculinization	46,XX	−	+	−	N	XX
Special or nonspecific	46,XX	−	+	−	N	XX
Female familial	46,XX	+	+	+	N	XX
True hermaphroditism	46,XX; 46,XY; etc	−	+ or −	−	N	XX or other
Male hermaphroditism	46,XY	+	+ or −	−	N	XY or other
Streak gonad	45,X; 46,XX; 46,XY; etc	−	+	+ or −	N	XO or other

+, positive; −, negative; N, normal; E, elevated; 17-KS, 17-ketosteroid level.

10. Treatment of Hermaphroditism

The sex of rearing is much more important than the obvious morphologic signs (external genitalia, hormone dominance, gonadal structure) in forming the gender role. Furthermore, serious psychological consequences may result from changing the sex of rearing after infancy. Therefore, it is seldom proper to advise a change of sex after infancy to conform to the gonadal structure of the external genitalia. Instead, the physician should exert efforts to complete the adjustment of the person to the sex role already assigned. Fortunately, most aberrations of sexual development are discovered in the newborn period or in infancy, when reassignment of sex causes few problems.

Regardless of the time of treatment (and the earlier the better), the surgeon should reconstruct the external genitalia to correspond to the sex of rearing. Any contradictory sex structures that may function to the patient’s disadvantage in the future should be eradicated. Specifically, testes should always be removed from male hermaphrodites reared as females, regardless of hormone production. In cases of testicular feminization, orchiectomy is warranted because a variety of tumors may develop in these abnormal testes if they are retained, but the orchiectomy may be delayed until after puberty in this variety of hermaphroditism.

In virilized female hermaphroditism due to adrenal hyperplasia, suppression of adrenal androgen production by the use of cortisone from an early age will result in completely female development. It is no longer necessary to explore the abdomen and the internal genitalia in this well-delineated syndrome. The surgical effort should be confined to reconstruction of the external genitalia along female lines.

Patients with streak gonads or Turner's syndrome, who are invariably reared as females, should be given exogenous estrogen when puberty is expected. Those hermaphrodites reared as females who will not become feminized also require estrogen to promote the development of the female habitus, including the breasts. In patients with a well-developed system, cyclic uterine withdrawal bleeding can be produced even though reproduction is impossible. Estrogen should be started at about age 12 and may be given as conjugated estrogens, 1.5 mg/d orally (or its equivalent). In some patients, after a period of time, this dosage may have to be increased for additional breast development. In patients without ovaries who have uteri and in male hermaphrodites in the same condition, cyclic uterine bleeding can often be induced by the administration of estrogen for 3 weeks of each month. In other instances, this may be inadequate to produce a convincing "menstrual" period; if so, the 3 weeks of estrogen can be followed by 3–4 days of progestin (eg, medroxyprogesterone acetate) orally or a single injection of progesterone. Prolonged estrogen therapy increases the risk of subsequent development of adenocarcinoma of the corpus, so periodic endometrial sampling is mandatory in such patients.

Reconstruction of Female External Genitalia

The details of the operative reconstruction of abnormal external genitalia are beyond the scope of this chapter. However, it should be emphasized that the procedure should be carried out at the earliest age possible so as to enhance the desired psychological, social, and sexual orientation of the patient and to facilitate adjustment by the parents. Sometimes the reconstruction can be done during the neonatal period. In any case, operation should not be delayed beyond the first several months of life. From a technical point of view, early operation is possible in all but the most exceptional circumstances.

Physiology of Reproduction in Women

Connie Alford, MD
Sahadat Nurudeen, MD

This chapter is concerned with the function of the female reproductive system from birth, through puberty and adulthood, and finally to menopause.

After birth, the gonads are quiescent until they are activated by gonadotropins from the pituitary to bring about the final maturation of the reproductive system. This period of final maturation is known as adolescence. It is often called puberty, although strictly defined, puberty is the period when the endocrine and gametogenic functions of the gonads first develop to the point where reproduction is possible.

After sexual maturity, there are regular periodic changes of the adult female reproductive system, each in preparation for pregnancy. The cyclic changes are primarily divided into the ovarian and uterine cycle, though changes can also be seen in the uterine cervix, vagina, and breasts. Control of the cycle is exerted through the regulation of hypothalamic, pituitary, and ovarian hormones.

With advancing age, these cycles become irregular and eventually cease in the period known as menopause. The ovarian follicles are less responsive to central regulation, and there is an acute decrease in estrogen levels, which may lead to vasomotor symptoms, labile mood, and many changes in the female reproductive tract.

PUBERTY

The age at the time of puberty is variable. In Europe and the United States, it has been declining at the rate of 1–3 months per decade for more than 175 years. In the United States in recent years, puberty has generally been occurring between the ages of 8 and 13 in girls and 9 and 14 in boys depending on ethnic background.

Another event that occurs in humans at the time of puberty is an increase in the secretion of adrenal androgens (Fig. 4–1). The onset of this increase is called **adrenarche**. It typically happens in males and females before the onset of puberty occurring at age 8–10 years in girls and 10–12 years in boys. Dehydroepiandrosterone (DHEA) values peak at about 25 years of age and are slightly higher in boys. They then decline slowly to low values after the age of 60.

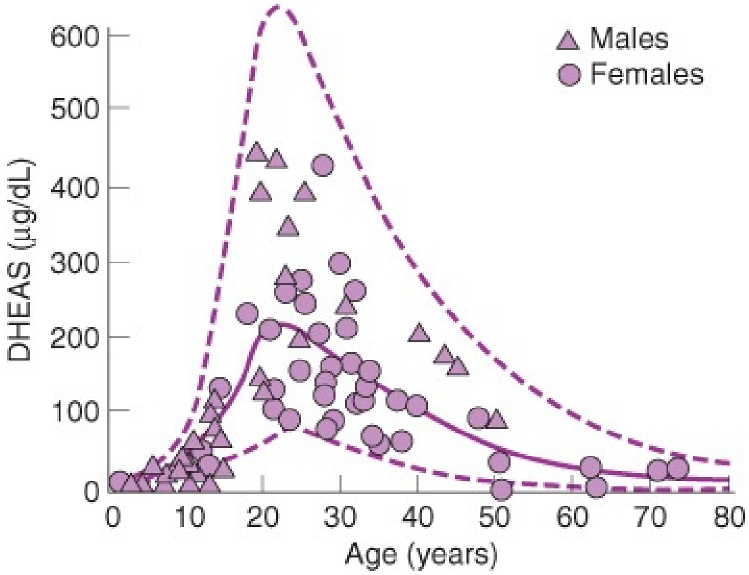

Figure 4–1. Change in serum dehydroepiandrosterone sulfate (DHEAS) with age. The middle line is the mean, and the dashed lines identify ±1.96 standard deviations. (Reproduced with permission from Smith MR, Rudd BT, Shirley A, et al. A radioimmunoassay for the estimation of serum dehydroepiandrosterone sulfate in normal and pathological sera. *Clin Chim Acta* 1975;65:5.)

The increase in adrenal androgen secretion at adrenarche occurs without any changes in the secretion of cortisol or adrenocorticotropic hormone (ACTH). Adrenarche is probably due to a rise in the lyase activity of a 17α-hydroxylase. Thereafter, there is a gradual decline in this activity as plasma adrenal androgen secretion declines to low levels in old age.

In girls, the first event of puberty is **thelarche**, the development of breasts. The breasts develop under the influence of the ovarian hormones estradiol and progesterone, with estradiol primarily responsible for the growth of ducts and progesterone primarily responsible for the growth of lobules and alveoli. Thelarche is then followed by **pubarche**, the development of axillary and pubic hair. The adrenal androgens contribute significantly to the growth of axillary and pubic hair. Finally there is **menarche**, the first menstrual period. The initial periods are generally anovulatory with regular ovulation beginning about 1 year later.

The sequence of changes that occur at puberty in girls is summarized in Figure 4–2.

Figure 4–2. Sequence of events at adolescence in girls. **A**: Stage 1: Preadolescent; elevation of breast papillae only. Stage 2: Breast bud stage (may occur between ages 8 and 13); elevation of breasts and papillae as small mounds, with enlargement of areolar diameter. Stage 3: Enlargement and elevation of breasts and areolas with no separation of contours. Stage 4: Areolas and papillae project from breast to form a secondary mound. Stage 5: Mature; projection of papillae only, with recession of areolas into general contour of breast. **B**: Stage 1: Preadolescent; no pubic hair. Stage 2: Sparse growth along labia of long, slightly pigmented, downy hair that is straight or slightly curled (may occur between ages 8 and 14). Stage 3: Darker, coarser, more curled hair growing sparsely over pubic area. Stage 4: Resembles adult in type but covers smaller area. Stage 5: Adult in quantity and type. (Redrawn, with permission, from Tanner JM. *Growth at Adolescence*. 2nd ed. New York, NY: Blackwell; 1962.)

Control of the Onset of Puberty

In general, many factors can influence the timing of the initiation of puberty including general health, genetic influences, nutrition, and exercise. However, a neural mechanism is thought to be predominantly responsible for the onset of puberty. It depends on normal functioning of the hypothalamic-pituitary-gonadal axis. In children, the gonads can be stimulated by gonadotropins, the pituitary contains gonadotropins, and the hypothalamus contains gonadotropin-releasing hormone (GnRH). However, the gonadotropins are not secreted. In immature monkeys, normal menstrual cycles can be brought on by pulsatile injection of GnRH, and the cycles persist as long as the pulsatile injection is continued. In addition, GnRH is secreted in a pulsatile fashion in adults. Thus, it seems clear that during the period from birth to puberty, a neural mechanism is operating to prevent the normal pulsatile release of GnRH. The nature of the mechanism inhibiting the GnRH pulse generator is unknown. Several theories have been suggested about this mechanism, including a recent study involving humans and mice, providing evidence that GPR54, a gene for a G protein–coupled receptor, is involved in the regulation of the processing or secretion of GnRH by the hypothalamus.

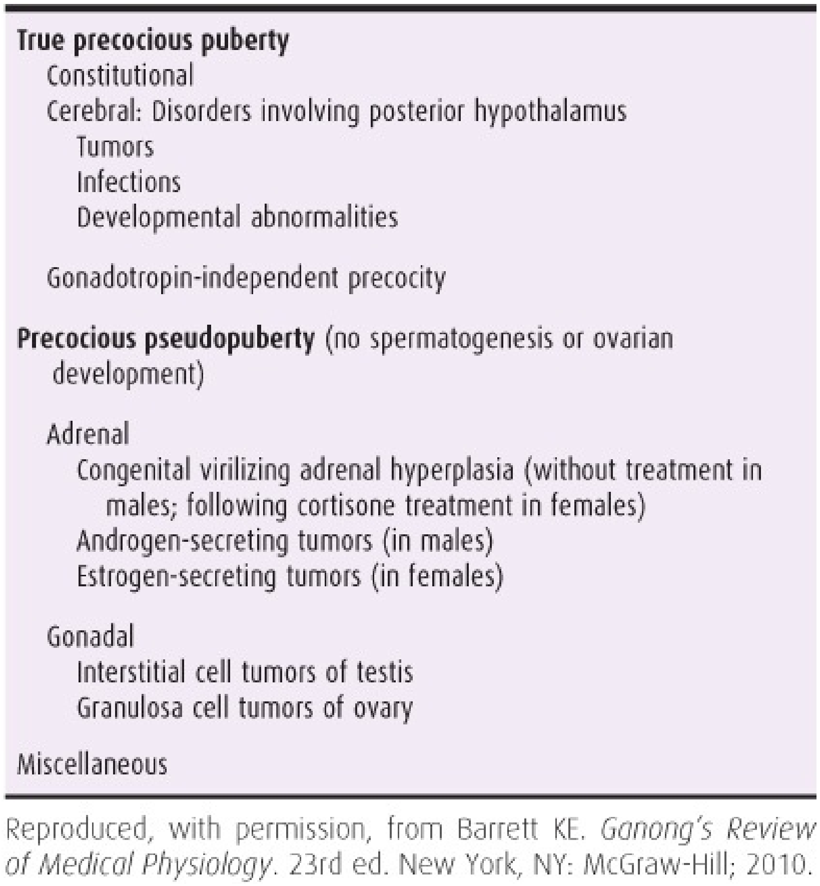
Relation to Leptin

It has been argued for some time that normally a critical body weight must be reached for puberty to occur. Thus, for example, young women who engage in strenuous athletics lose weight and stop menstruating. The same is seen in girls with anorexia nervosa. If these girls start to eat and gain weight, they menstruate again, ie, they “go back through puberty.” It now appears that leptin, the satiety-producing hormone secreted by fat cells, may be the link between body weight and puberty. Leptin treatment has been shown to induce precocious puberty in immature female mice. However, more recent studies have suggested leptin to have a more permissive role for the onset of puberty rather than being a trigger. Observations of recombinant leptin administration in older, but not younger, children with leptin deficiency resulted in increased gonadotropin pulsatility. The role of leptin in the control of pubarche remains to be determined.

Sexual Precocity

Sexual precocity is pubertal development occurring before the age of 8 years in girls, and before the age of 9 years in boys. The major causes of precocious sexual development in humans are listed in Table 4–1. Early development of secondary sexual characteristics without gametogenesis is caused by abnormal exposure of immature males to androgen or females to estrogen. This syndrome should be called **precocious pseudopuberty** to distinguish it from true precocious puberty due to an early, but otherwise normal pubertal pattern of gonadotropin secretion from the pituitary (Fig. 4–3).

Table 4–1. Classification of the causes of precocious sexual development in humans.



True precocious puberty
- Constitutional
- Cerebral: Disorders involving posterior hypothalamus
  - Tumors
  - Infections
  - Developmental abnormalities

- Gonadotropin-independent precocity

Precocious pseudopuberty (no spermatogenesis or ovarian development)

- Adrenal
  - Congenital virilizing adrenal hyperplasia (without treatment in males; following cortisone treatment in females)
  - Androgen-secreting tumors (in males)
  - Estrogen-secreting tumors (in females)

- Gonadal
  - Interstitial cell tumors of testis
  - Granulosa cell tumors of ovary

Miscellaneous

Reproduced, with permission, from Barrett KE. *Ganong's Review of Medical Physiology*. 23rd ed. New York, NY: McGraw-Hill; 2010.

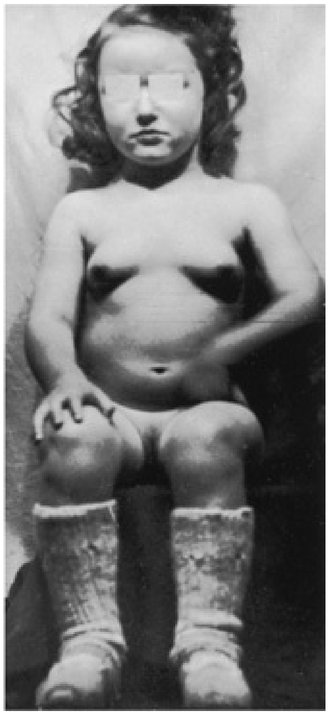


Figure 4–3. Constitutional precocious puberty in a 3½-year-old girl. The patient developed pubic hair and started to menstruate at the age of 17 months.

In 1 large series of cases, precocious puberty was the most frequent endocrine symptom of hypothalamic disease. It is interesting that in experimental animals and humans, lesions of the ventral hypothalamus near the infundibulum cause precocious puberty. The effect of the lesions may be due to an interruption of neural pathways that produce inhibition of the GnRH pulse generator or a local release of factors causing premature activation of the GnRH pulse generator. Pineal tumors are sometimes associated with precocious puberty, but there is evidence that these tumors are related only when there is secondary damage to the hypothalamus. Precocity due to this and other forms of hypothalamic damage probably occurs with equal frequency in both sexes, although the constitutional form of precocious puberty is more common in girls. In addition, it has now been proven that precocious gametogenesis and steroidogenesis can occur without the pubertal pattern of gonadotropin secretion (gonadotropin-independent precocity). At least in some cases of the condition, the sensitivity of luteinizing hormone (LH) receptors to gonadotropins is increased because of an activating mutation in the G protein that couples receptors to adenylyl cyclase.

Recent observational studies have proposed a link between low birth weight, increased weight gain during childhood, changes in insulin sensitivity, and subsequent hormonal changes, such as early pubarche. Although the association remains speculative, these studies suggest a programmed adaptation to improved postnatal nutritional status triggering a pathway of rapid growth and secondary sexual development.

Delayed or Absent Puberty

The normal variation in the age at which adolescent changes occur is so wide that puberty cannot be considered to be pathologically delayed until the absence of secondary sexual development by age 14 in girls or until the failure of menarche by the age of 17. Failure of maturation due to panhypopituitarism is associated with dwarfing and evidence of other endocrine abnormalities. Patients with the XO chromosomal pattern and gonadal dysgenesis are also dwarfed. In some individuals, puberty is delayed and menarche does not occur (primary amenorrhea), even though the gonads are present and other endocrine functions are normal.

REPRODUCTIVE FUNCTION AFTER SEXUAL MATURITY

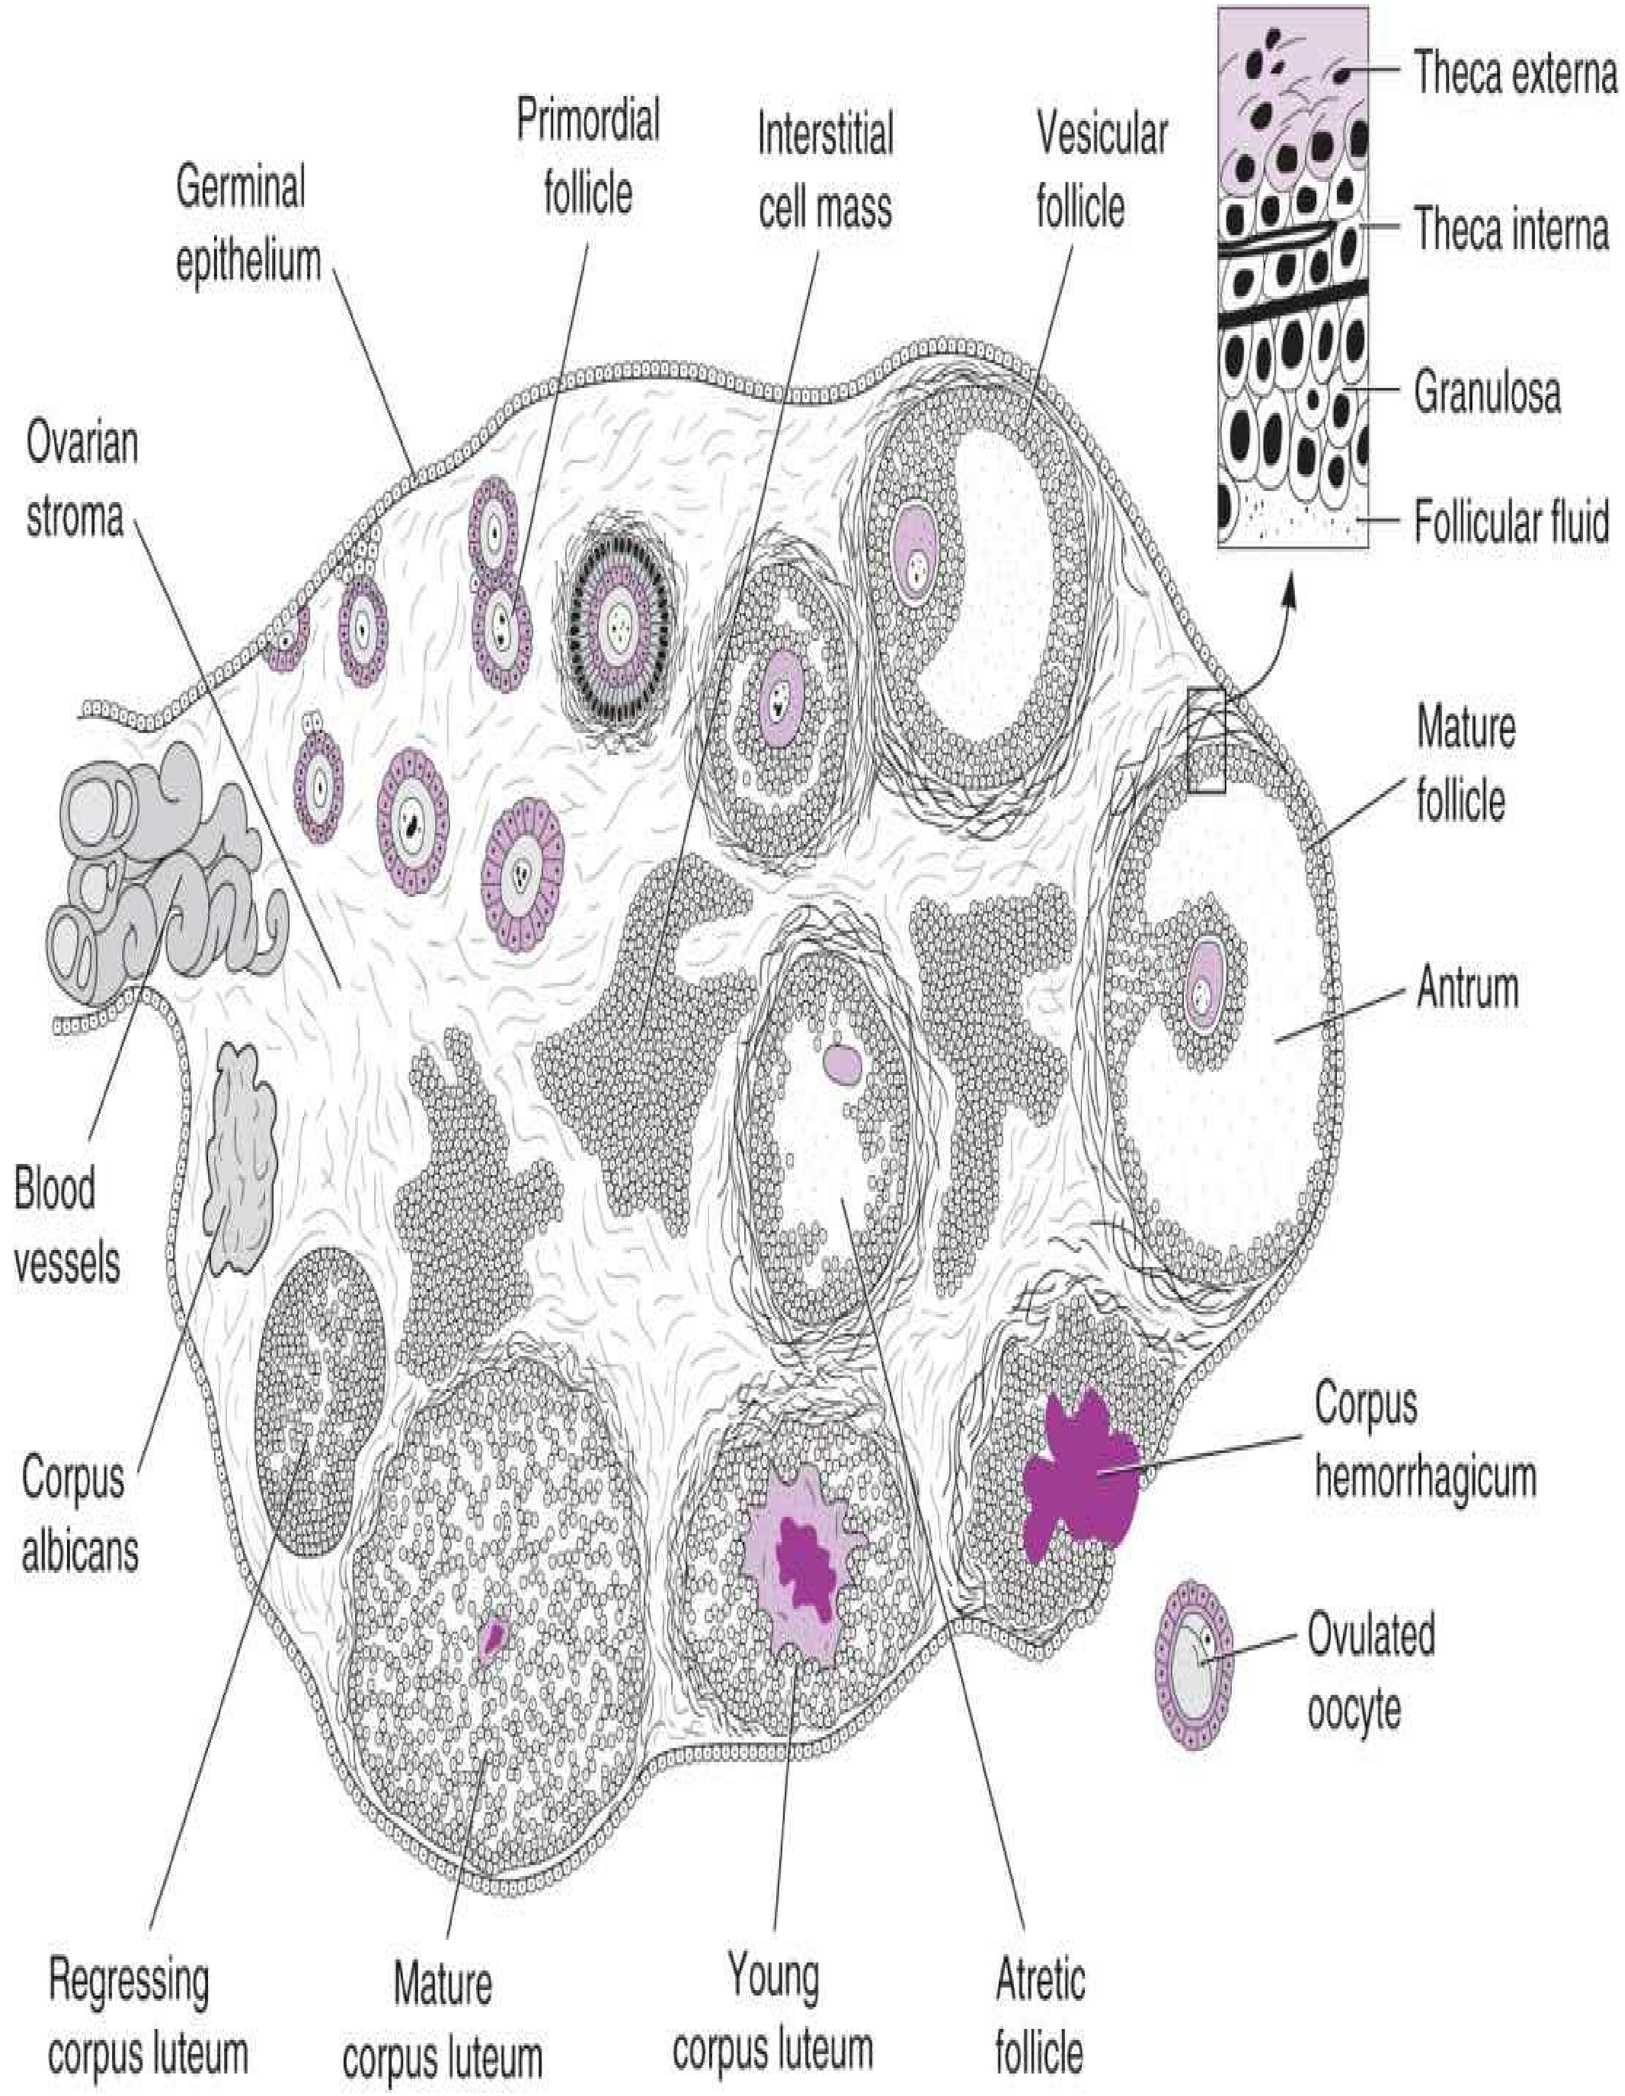
Menstrual Cycle

The anatomy of the reproductive system of adult women is described in Chapter 1. Unlike the reproductive system of men, this system shows regular cyclic changes that teleologically may be regarded as periodic preparation for fertilization and pregnancy. In primates, the cycle is a **menstrual cycle**, and its most conspicuous feature is the cyclic vaginal bleeding that occurs with shedding of the uterine mucosa (**menstruation**). The length of the cycle is notoriously variable, but the average figure is 28 days from the start of one menstrual period to the start of the next. By common usage, the days of the cycle are identified by number, starting with the first day of menstruation.

Ovarian Cycle

From the time of birth, there are many **primordial follicles** under the ovarian capsule. Each contains an immature ovum (Fig. 4–4). At the start of each cycle, several of these follicles enlarge and a cavity forms around the ovum (antrum formation). This cavity is filled with follicular fluid. In humans, 1 of the follicles in 1 ovary starts to grow rapidly on about the sixth day and becomes the **dominant follicle**. The others regress, forming **atretic follicles**. It is not known how 1 follicle is singled out for development during this **follicular phase** of the menstrual cycle, but it seems to be related to the follicle's ability to produce estrogen, which is necessary for final maturation. The secretion of estrogen, in animal models, has been demonstrated even before the dominant follicle has emerged as morphologically dominant. Theoretically, depending on the position of the follicle to the blood supply, there is a gradient of exposure to different amounts of hormones, growth factors, and other signaling molecules. Therefore, the follicle most responsive to follicle-stimulating hormone (FSH) is likely to be the first to produce estradiol.

The structure of a mature ovarian follicle (**graafian follicle**) is shown in Figure 4–4. The cells of the **theca interna** of the follicle are the primary source of circulating estrogens. The follicular fluid has a high estrogen content, and much of this estrogen comes from the **granulosa cells**.



Theca externa
Theca interna

Ovulated oocyte
Regressing corpus luteum
Mature corpus luteum
Young corpus luteum
Atretic follicle

Figure 4–4. Diagram of a mammalian ovary, showing the sequential development of a follicle, formation of a corpus luteum, and, in the center, follicular atresia. A section of the wall of a mature follicle is enlarged at the upper right. The interstitial cell mass is not prominent in primates.

At about the 14th day of the cycle, the distended follicle ruptures, and the ovum is extruded into the abdominal cavity. This is the process of **ovulation**. The ovum is picked up by the fimbriated ends of the uterine tubes (oviducts) and transported to the uterus. Unless fertilization occurs, the ovum degenerates or passes on through the uterus and out of the vagina.

The follicle that ruptures at the time of ovulation promptly fills with blood, forming what is sometimes called a **corpus hemorrhagicum**. Minor bleeding from the follicle into the abdominal cavity may cause peritoneal irritation and fleeting lower abdominal pain (“mittelschmerz”). The granulosa and theca cells of the follicle lining promptly begin to proliferate, and the clotted blood is rapidly replaced with yellowish, lipid-rich **luteal cells**, forming the **corpus luteum**. This is the **luteal phase** of the menstrual cycle, during which the luteal cells secrete estrogen and progesterone. Growth of the corpus luteum depends on its developing an adequate blood supply. There is evidence that vascular endothelial growth factor (VEGF) is essential for this process through regulation by the transcription factor, HIF-1α, under hypoxic conditions or by gonadotropin-stimulated conditions. If pregnancy occurs, the corpus luteum persists, and there are usually no more menstrual cycles until after delivery. If there is no pregnancy, the corpus luteum begins to degenerate about 4 days before the next menses (day 24 of the cycle) and is eventually replaced by fibrous tissue, forming a **corpus albicans**.

In humans, no new ova are formed after birth. During fetal development, the ovaries contain over 7 million germ cells; however, many undergo involution before birth, and others are lost after birth. At the time of birth, there are approximately 2 million primordial follicles containing ova, but approximately 50% of these are atretic. The remaining million ova undergo the first meiotic division at this time and arrest in prophase until adulthood. Atresia continues during development, and the number of ova in both the ovaries at the time of puberty is less than 300,000 (Fig. 4–5). Normally, only 1 of these ova per cycle (or about 400–500 in the course of a normal reproductive life) is stimulated to mature; the remainder degenerate. Just before ovulation, the first meiotic division is completed. One of the daughter cells, the **secondary oocyte**, receives most of the cytoplasm, while the other, the **first polar body**, fragments and disappears. The secondary oocyte immediately begins the second meiotic division, but this division stops at metaphase and is completed only when a sperm penetrates the oocyte. At that time, the **second polar body** is cast off, and the fertilized ovum proceeds to form a new individual.

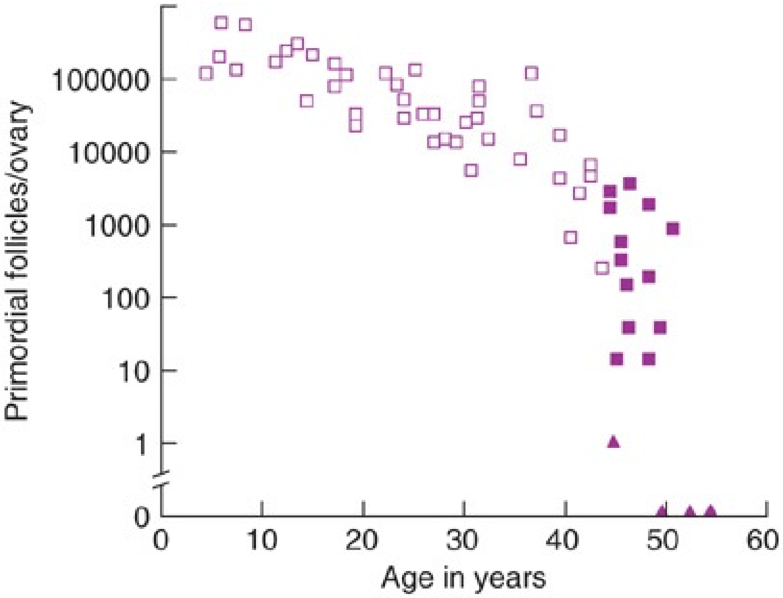

Figure 4–5. Number of primordial follicles per ovary in women at various ages. □, premenopausal women (regular menses); ■, perimenopausal women (irregular menses for at least 1 year); ▲, postmenopausal women (no menses for at least 1 year). Note that the vertical scale is a log scale and that the values are from 1 rather than 2 ovaries. (Reproduced, with permission, from Richardson SJ, Senikas V, Nelson JF. Follicular depletion during the menopausal transition: evidence for accelerated loss and ultimate exhaustion. *J Clin Endocrinol Metab* 1987;65:1231.)

Uterine Cycle

The events that occur in the uterus during the menstrual cycle terminate with the menstrual flow. By the end of each menstrual period, all but the deep layer of the endometrium has sloughed. Under the influence of estrogen secreted from the developing follicles, the endometrium regenerates from the deep layer and increases rapidly in thickness during the period from the fifth to 16th days of the menstrual cycle. As the thickness increases, the uterine glands are drawn out so that they lengthen (Fig. 4–6), but they do not become convoluted or secrete to any degree. These endometrial changes are called proliferative, and this part of the menstrual cycle is sometimes called the **proliferative phase**. It is also called the preovulatory or follicular phase of the cycle. After ovulation, the endometrium becomes more highly vascularized and slightly edematous under the influence of estrogen and progesterone from the corpus luteum. The glands become coiled and tortuous (Fig. 4–6), and they begin to secrete clear fluid. Consequently, this phase of the cycle is called the **secretory** or **luteal phase**. Late in the luteal phase, the endometrium, like the anterior pituitary, produces prolactin. The function of this endometrial prolactin has yet to be determined, though it has been suggested that prolactin may play a role in implantation.

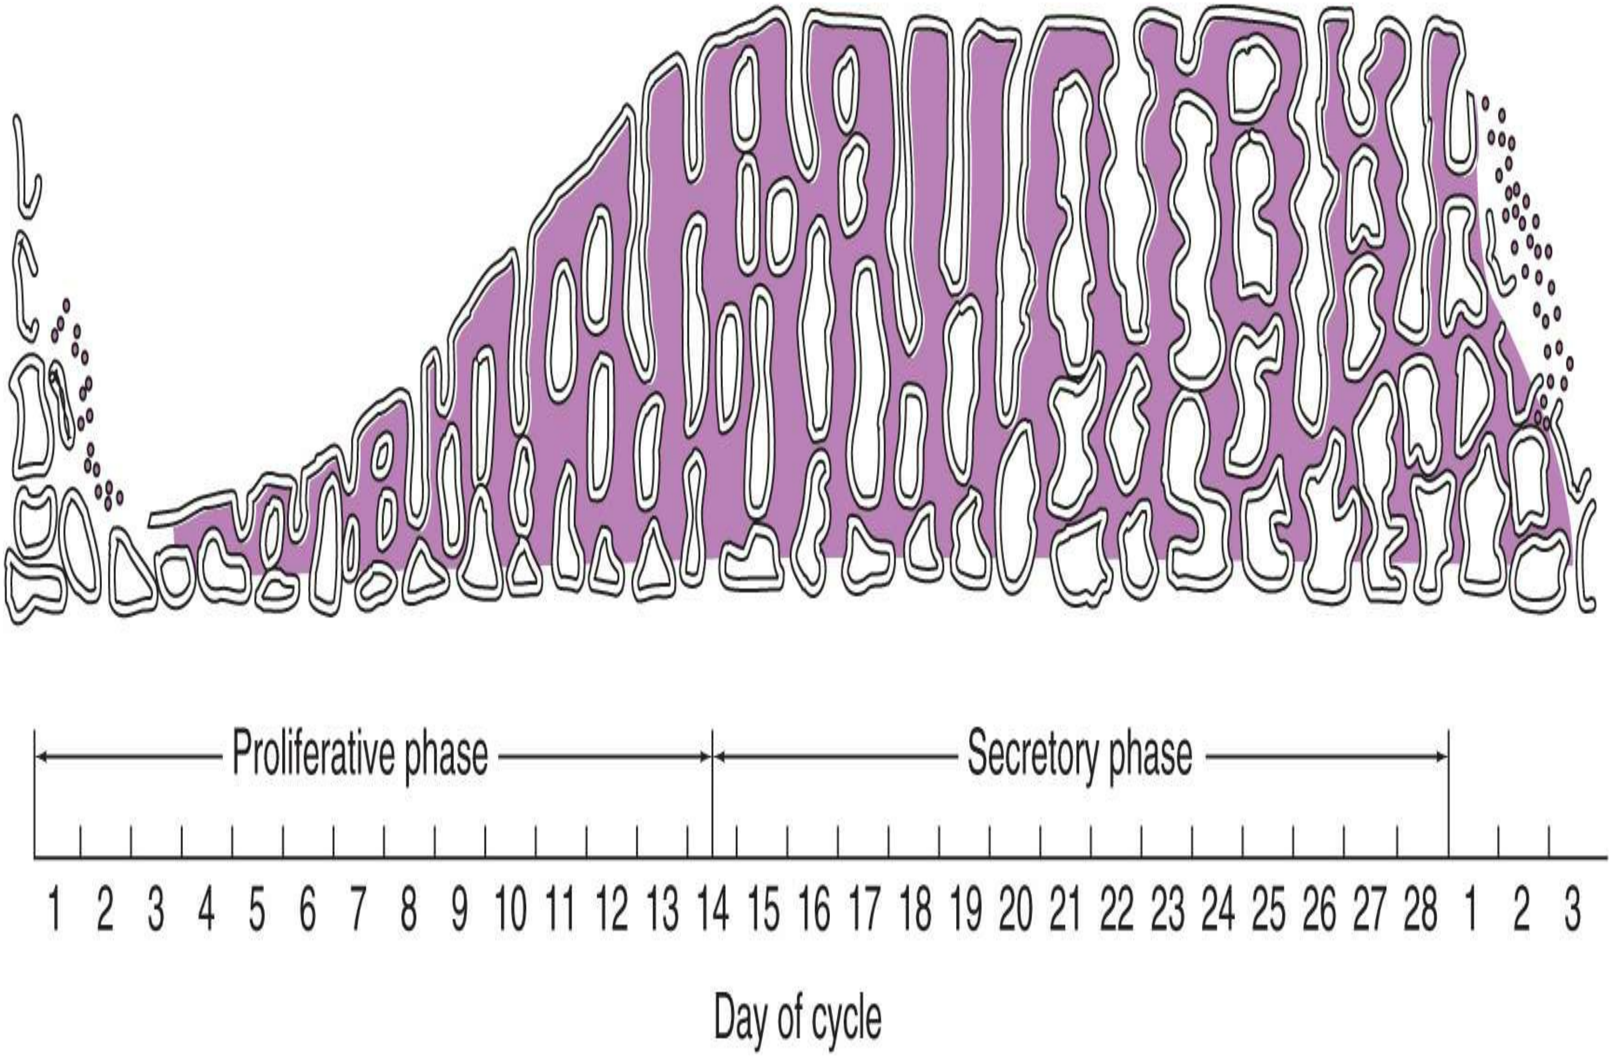

Figure 4–6. Changes in the endometrium during the menstrual cycle. (Reproduced, with permission, from Ganong WF. *Review of Medical Physiology*. 22nd ed. New York, NY: McGraw-Hill; 2005.)

The endometrium is supplied by 2 types of arteries. The superficial two-thirds of the endometrium, the stratum functionale, is shed during menstruation and is supplied by the long, coiled spiral arteries. The deep layer, which is not shed, is called the stratum basale and is supplied by short, straight basilar arteries.

When the corpus luteum regresses, hormonal support for the endometrium is withdrawn, causing vascular spasms in the spiral artery, ultimately leading to endometrial ischemia. The endometrium becomes thinner, which adds to the coiling of the spiral arteries. Leukocyte infiltration into the endometrial stroma initiates the breakdown of the extracellular matrix in the functionalis layer. Foci of necrosis appear in the endometrium and walls of the spiral arteries, which coalesce and lead to spotty hemorrhages that become confluent and ultimately produce menstrual flow.

Spiral artery vasospasm serves to limit blood loss during menstruation and probably is produced by locally released prostaglandins. There are large quantities of prostaglandins in the secretory endometrium and in menstrual blood. Infusions of prostaglandin F_{2a} (PGF_{2a}) produce endometrial necrosis and bleeding. One theory of the onset of menstruation holds that in necrotic endometrial cells, lysosomal membranes break down and release proteolytic enzymes that foster the formation of prostaglandins from cellular phospholipids while promoting further local tissue destruction.

From the point of view of endometrial function, the proliferative phase of the menstrual cycle represents the restoration of the epithelium from the preceding menstruation, while the secretory phase represents the preparation of the uterus for implantation of the fertilized ovum. The length of the secretory phase is remarkably constant, about 14 days. The variations seen in the length of the menstrual cycle are mostly due to variations in the length of the proliferative phase. When fertilization fails to occur during the secretory phase, the endometrium is shed, and a new cycle begins.

Normal Menstruation

Menstrual blood is predominantly arterial, with only 25% of the blood being of venous origin. It contains tissue debris, prostaglandins, and relatively large amounts of fibrinolysin from the endometrial tissue. The fibrinolysin lyses clots, so menstrual blood does not normally contain clots unless the flow is excessive.

The usual duration of the menstrual cycle is 3–5 days, but flow as short as 1 day and as long as 8 days can occur in normal women. The average amount of blood loss is 30 mL but normally may range from slight spotting to 80 mL. Loss of more than 80 mL is abnormal. Obviously, the amount of flow can be affected by various factors, including not only the thickness of the endometrium, but also the medications and diseases that affect clotting mechanisms. After menstruation, the endometrium regenerates from the stratum basale.

Anovulatory Cycles

In some instances, ovulation fails to occur during the menstrual cycle. Such anovulatory cycles are common for the first 12–18 months after menarche and again before the onset of menopause. When ovulation does not occur, no corpus luteum is formed, and the effects of progesterone on the endometrium are absent. Estrogens continue to cause growth, however, and the proliferative endometrium becomes thick enough to break down and begin to slough. The time it takes for bleeding to occur is variable, but it usually occurs less than 28 days from the last menstrual period. The flow is also variable and ranges from scanty to relatively profuse.

Cyclic Changes in the Uterine Cervix

Although it is contiguous with the body of the uterus, the cervix of the uterus is different in a number of ways. The mucosa of the uterine cervix does not undergo cyclic desquamation, but there are regular changes in the cervical mucus. Estrogen makes the mucus much thinner and more alkaline, changes that promote the survival and transport of sperm. Progesterone makes it thick, tenacious, and cellular. The mucus is thinnest at the time of ovulation, and its elasticity, or **spinnbarkeit**, increases so that by midcycle a drop can be stretched into a long, thin thread that may be 8–12 cm or more in length. In addition, it dries in an arborizing, fernlike pattern when a thin layer is spread on a slide (Fig. 4–7). After ovulation and during pregnancy, it becomes thick and fails to form the fern pattern.

Figure 4–7. Patterns formed when cervical mucus is smeared on a slide, permitted to dry, and examined under the microscope. Progesterone makes the mucus thick and cellular. In the smear from a patient who failed to ovulate (**bottom**), there is no progesterone to inhibit the estrogen-induced fern pattern. (Reproduced, with permission, from Barrett KE. *Ganong's Review of Medical Physiology*. 23rd ed. New York, NY: McGraw-Hill; 2010.)

Vaginal Cycle

Under the influence of estrogens, the vaginal epithelium becomes cornified, and these cornified epithelial cells can be identified in a vaginal smear. Under the influence of progesterone, a thick mucus is secreted, and the epithelium proliferates and becomes infiltrated with leukocytes. The cyclic changes in the vaginal smear in rats are particularly well known. The changes in humans and other species are similar but unfortunately not so clear-cut. However, the increase in cornified epithelial cells is apparent when a vaginal smear from an adult woman in the follicular phase of the menstrual cycle is compared, for example, with a smear taken from a prepubescent female.

Cyclic Changes in the Breasts

Although lactation normally does not occur until the end of pregnancy, there are cyclic changes in the breasts during the menstrual cycle. Estrogens cause proliferation of mammary ducts, whereas progesterone causes growth of lobules and alveoli (see Actions of Progesterone). The breast swelling, tenderness, and pain experienced by many women during the 10 days preceding menstruation probably are due to distention of the ducts, hyperemia, and edema of the interstitial tissue of the breasts. All of these changes regress, along with the symptoms, during menstruation.

Cyclic Changes in Other Body Functions

In addition to cyclic breast swelling and tenderness, there is usually a small increase in body temperature during the luteal phase of the menstrual cycle. This change in body temperature (see Indicators of Ovulation) probably is due to the thermogenic effect of progesterone.

Changes During Sexual Intercourse

During sexual excitation, the vaginal walls become moist as a result of transudation of fluid through the mucus membrane. A lubricating mucus is secreted by the vestibular glands. The upper part of the vagina is sensitive to stretch, while tactile stimulation from the labia minora and clitoris adds to the sexual excitement. The stimuli are reinforced by tactile stimuli from the breasts and, as in men, by visual, auditory, and olfactory stimuli. Eventually, the crescendo or climax known as orgasm may be reached. During orgasm, there are autonomically mediated rhythmic contractions of the vaginal wall. Impulses also travel via the pudendal nerves and produce rhythmic contractions of the bulbocavernosus and ischiocavernosus muscles. The vaginal contractions may aid in the transport of spermatozoa but are not essential for it, as fertilization of the ovum is not dependent on orgasm.

Indicators of Ovulation

Knowing when during the menstrual cycle ovulation occurs is important in increasing fertility or, conversely, in contraception. A convenient, but retrospective, indicator of the time of ovulation is a rise in the basal body temperature (Fig. 4–8). Accurate temperatures can be obtained by using a thermometer that is able to measure temperature precisely between 96 and 100°F. The woman should take her temperature orally, vaginally, or rectally in the morning before getting out of bed. The cause of temperature change at the time of ovulation is unknown but probably is due to the increase in progesterone secretion, as progesterone is thermogenic. A rise in urinary LH occurs during the rise in circulating LH that causes ovulation. This increase can be measured and used as another indicator of ovulation. Kits using dipsticks or simple color tests for detection of urinary LH are available for home use.

Ovulation normally occurs about 9 hours after the peak of the LH surge at midcycle (Fig. 4–8). The ovum lives approximately 72 hours after it is extruded from the follicle but probably is fertilizable for less than half this time. In a study of the relationship of isolated intercourse to pregnancy, 36% of women had a detected pregnancy following intercourse on the day of ovulation, but with intercourse on days after ovulation, the percentage was zero. Isolated intercourse of the first and second days before ovulation led to pregnancy in about 36% of the women. A few pregnancies resulted from isolated intercourse on day 3, 4, or 5 before ovulation, although the percentage was much lower, ie, 8% on day 5 before ovulation. Thus, some sperm can survive in the female genital tract and produce fertilization for up to 120 hours before ovulation, but the most fertile period is clearly the 48 hours before ovulation. However, for those interested in the “rhythm method” of contraception, if should be noted that there are rare but documented cases of pregnancy resulting from isolated coitus on every day of the cycle.

OVARIAN HORMONES

Chemistry, Biosynthesis, & Metabolism of Estrogens

The naturally occurring estrogens are **17β-estradiol, estrone**, and **estriol** (Fig. 4–9). They are C_{18} steroids, ie, they do not have an angular methyl group attached to the 10 position or a Δ^4-3-keto configuration in the A ring. They are secreted primarily by the granulosa and thecal cells of the ovarian follicles, the corpus luteum, and the placenta. The biosynthetic pathway involves their aromatization from androgens. Aromatase (CYP19) is the enzyme that catalyzes the conversion of androstenedione to estrone (Fig. 4–9). It also catalyzes the conversion of testosterone to estradiol.

Theca interna cells have many LH receptors, and LH acts on them via cyclic adenosine 3′,5′-monophosphate (cAMP) to increase conversion of cholesterol to androstenedione. Some of the androstenedione is converted to estradiol, which enters the circulation. The theca interna cells also supply androstenedione to granulosa cells. The granulosa cells only make estradiol when provided with androgens (Fig. 4–10), and they secrete the estradiol that they produce into the follicular fluid. They have many FSH receptors, and FSH facilitates the secretion of estradiol by acting via cAMP to increase the aromatase activity in these cells. Mature granulosa cells also acquire LH receptors, and LH stimulates estradiol production.

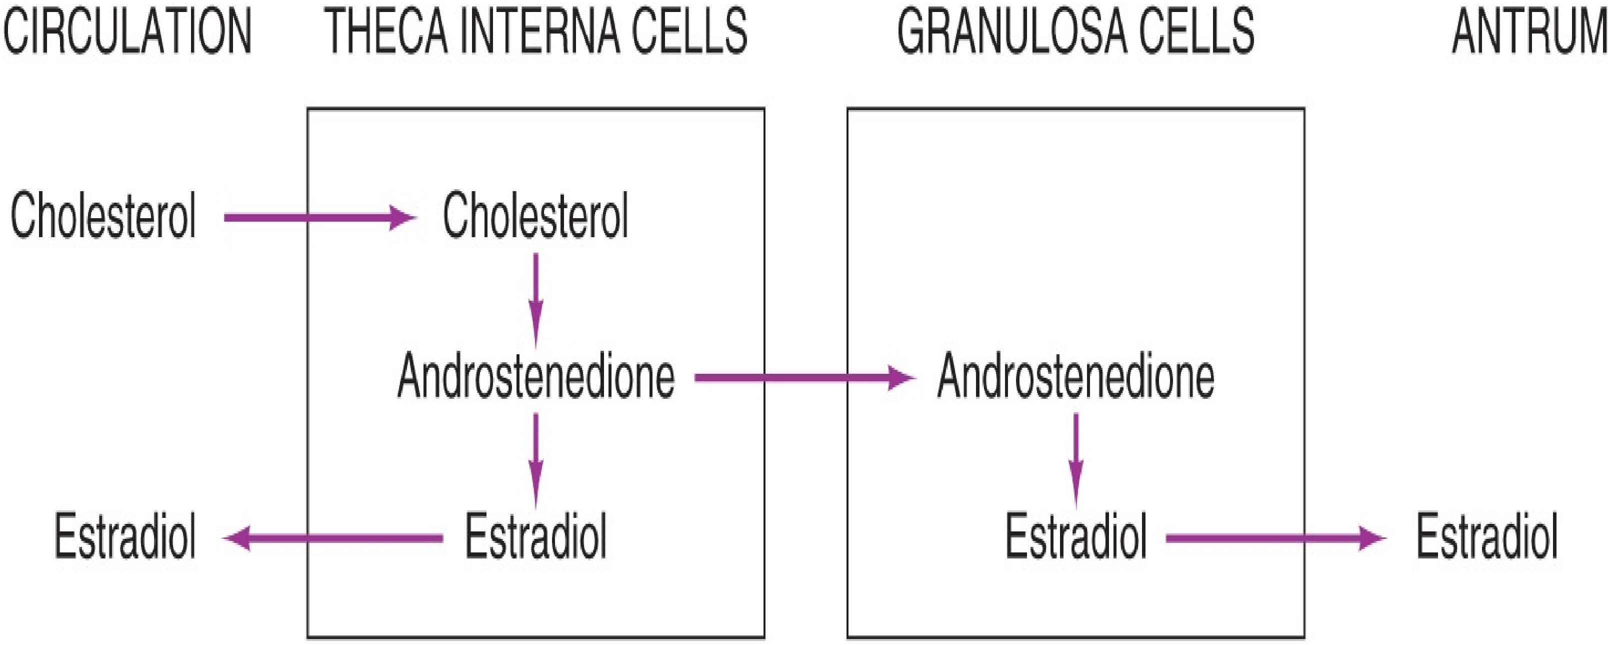

Figure 4–10. Interactions between theca and granulosa cells in estradiol synthesis and secretion. (Reproduced, with permission, from Barrett KE. *Ganong's Review of Medical Physiology*. 23rd ed. New York, NY: McGraw-Hill; 2010.)

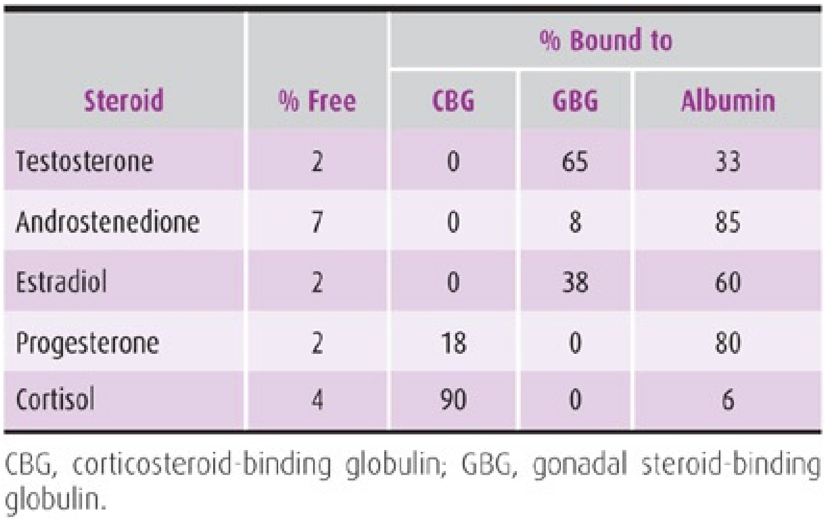
The stromal tissue of the ovary also has the potential to produce androgens and estrogens. However, it probably does so in insignificant amounts in normal premenopausal women. 17β-Estradiol, the major secreted estrogen, is in equilibrium in the circulation with estrone. Estrone is further metabolized to **estriol** (Fig. 4–9), probably mainly in the liver. Estradiol is the most potent estrogen of the three, and estriol is the least potent.

Two percent of the circulating estradiol is free. The remainder is bound to protein: 60% to albumin and 38% to the same gonadal steroid-binding globulin (GBG) that binds testosterone (Table 4–2).

Table 4–2. Distribution of gonadal steroids and cortisol in plasma.



Steroid	% Free	% Bound to		
		CBG	GBG	Albumin
Testosterone	2	0	65	33
Androstenedione	7	0	8	85
Estradiol	2	0	38	60
Progesterone	2	18	0	80
Cortisol	4	90	0	6

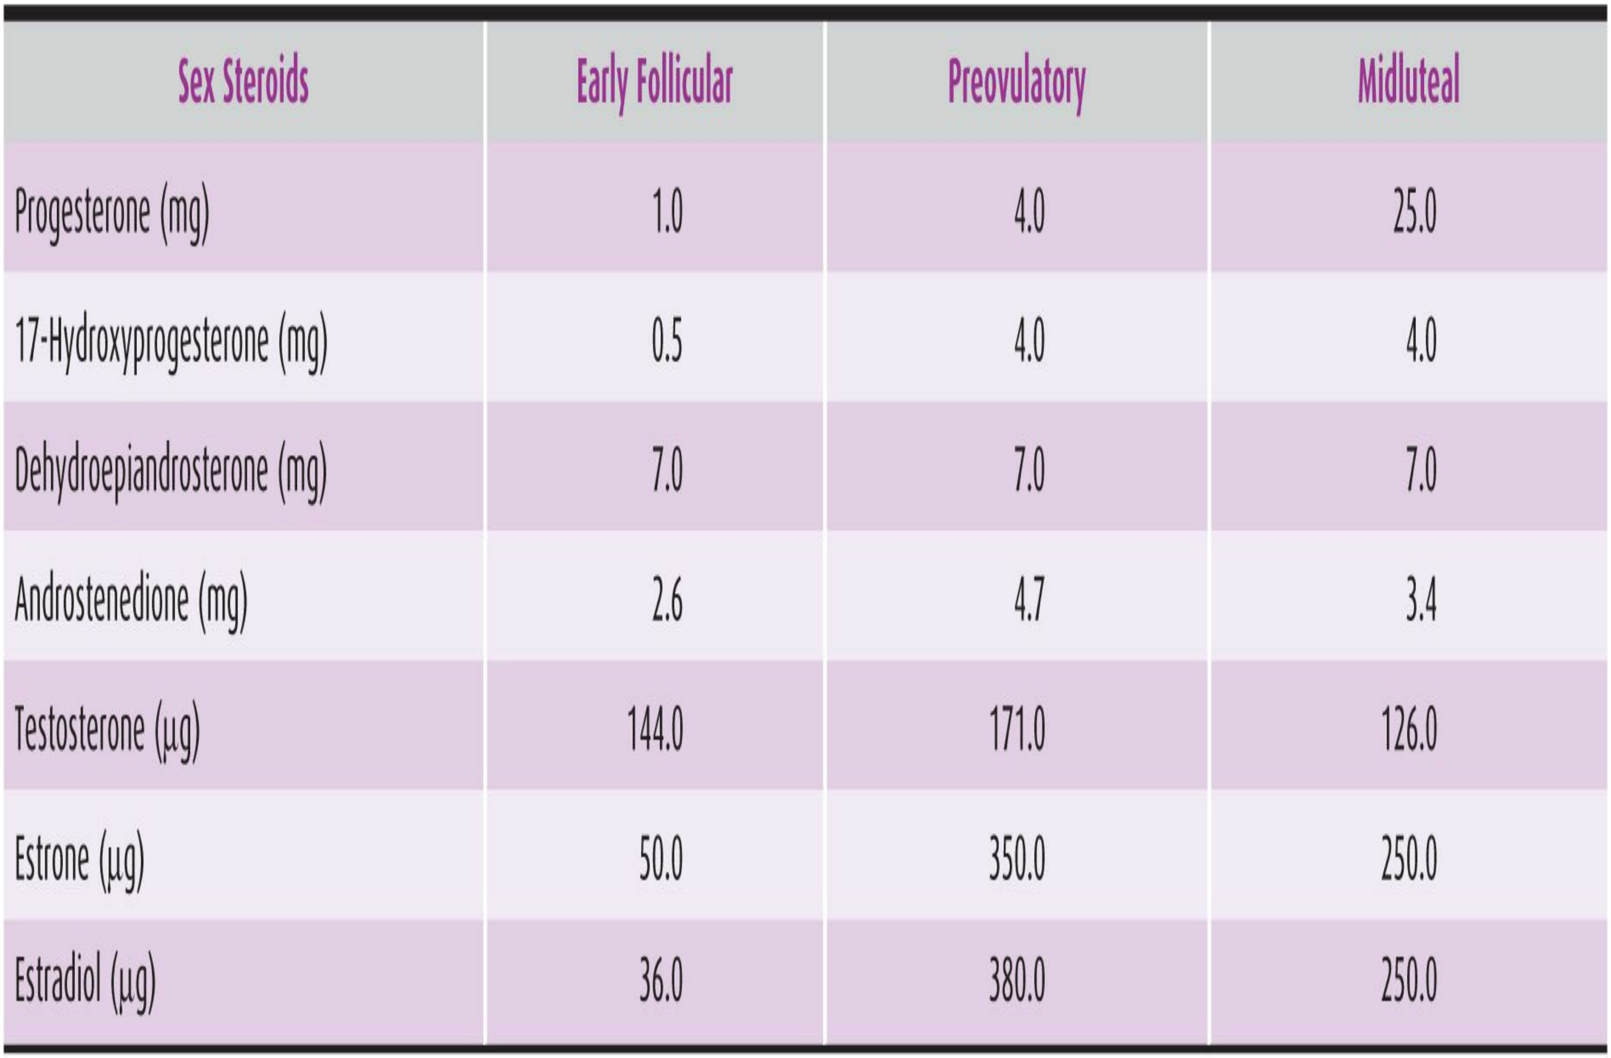
CBG, corticosteroid-binding globulin; GBG, gonadal steroid-binding globulin.

In the liver, estrogens are oxidized or converted to glucuronide and sulfate conjugates. Appreciable amounts are secreted in the bile and reabsorbed in the bloodstream (enterohepatic circulation). There are at least 10 different metabolites of estradiol in human urine.

Secretion of Estrogens

The concentration of estradiol in plasma during the menstrual cycle is shown in Figure 4–8. Almost all of the estrogen comes from the ovary. There are 2 peaks of secretion: one just before ovulation and one during the midluteal phase. The estradiol secretion rate is 36 µg/d (133 nmol/d) in the early follicular phase, 380 µg/d just before ovulation, and 250 µg/d during the midluteal phase (Table 4–3). After menopause, estrogen secretion declines to low levels. For comparison, the estradiol production rate in men is about 50 µg/d (184 nmol/d).

Table 4–3. Twenty-four–hour production rates of sex steroids in women at different stages of the menstrual cycle.



Sex Steroids	Early Follicular	Preovulatory	Midluteal
Progesterone (mg)	1.0	4.0	25.0
17-Hydroxyprogesterone (mg)	0.5	4.0	4.0
Dehydroepiandrosterone (mg)	7.0	7.0	7.0
Androstenedione (mg)	2.6	4.7	3.4
Testosterone (μg)	144.0	171.0	126.0
Estrone (μg)	50.0	350.0	250.0
Estradiol (μg)	36.0	380.0	250.0

Effects on Female Genitalia

Estrogens facilitate the growth of the ovarian follicles and increase the motility of the uterine tubes. Their role in the cyclic changes in the endometrium, cervix, and vagina is discussed earlier. They increase uterine blood flow and have important effects on the smooth muscle of the uterus. In immature and ovariectomized females, the uterus is small and the myometrium atrophic and inactive. Estrogens increase the amount of uterine muscle and its content of contractile proteins. Under the influence of estrogens, the myometrium becomes more active and excitable, and action potentials in the individual muscle fibers are increased. The “estrogen-dominated” uterus is also more sensitive to oxytocin.

Prolonged treatment with estrogens causes endometrial hypertrophy. When estrogen therapy is discontinued, there is some sloughing and **withdrawal bleeding**. Some “breakthrough” bleeding may also occur during prolonged treatment with estrogens.

Effects on Endocrine Organs

Estrogens decrease FSH secretion. In some circumstances, estrogens inhibit LH secretion (negative feedback); in others, they increase LH secretion (positive feedback). Estrogens also increase the size of the pituitary. Women are sometimes given large doses of estrogens for 4–6 days to prevent conception during the fertile period (postcoital or “morning-after” contraception). In this instance, pregnancy probably is prevented by interference with implantation of the fertilized ovum rather than by changes in gonadotropin secretion.

Estrogens cause increased secretion of angiotensinogen and thyroid-binding globulin. They also cause epiphyseal closure in humans. In livestock, they exert an important protein anabolic effect, possibly by stimulating the secretion of androgens from the adrenal; estrogens have been used commercially to increase the weight of domestic animals.

Effects on the Central Nervous System

Estrogens are responsible for estrus behavior in animals, and they may increase libido in humans. They apparently exert this action by a direct effect on certain neurons in the hypothalamus (Fig. 4–11).

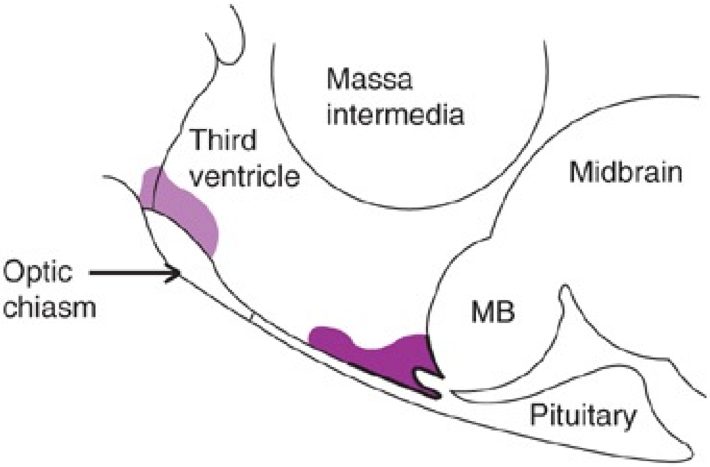

Figure 4–11. Loci where implantations of estrogen in the hypothalamus affect ovarian weight and sexual behavior in rats, projected on a sagittal section of the hypothalamus. The implants that stimulate sex behavior are located in the suprachiasmatic area above the optic chiasm, whereas ovarian atrophy is produced by implants in the arcuate nucleus and surrounding ventral hypothalamus just above the pituitary stalk. MB, mamillary body. (Reproduced, with permission, from Barrett KE. *Ganong's Review of Medical Physiology*. 23rd ed. New York, NY: McGraw-Hill; 2010.)

Estrogens increase the proliferation of dendrites on neurons and the number of synaptic knobs in rats. In humans, they have been reported to slow the progression of Alzheimer's disease, but this role of estrogen remains controversial.

Effects on the Breasts

Estrogens produce duct growth in the breasts and are largely responsible for breast enlargement at puberty in girls. Breast enlargement that occurs when estrogen-containing skin creams are applied locally is primarily due to systemic absorption of the estrogen, although a slight local effect is also produced. Estrogens are responsible for the pigmentation of the areolas. Pigmentation usually becomes more intense during the first pregnancy than it does at puberty.

Effects on Female Secondary Sex Characteristics

The body changes that develop in girls at puberty—in addition to enlargement of the breasts, uterus, and vagina—are due in part to estrogens, which are the "feminizing hormones," and in part simply to the absence of testicular androgens. Women have narrow shoulders, broad hips, thighs that converge, and arms that diverge (wide **carrying angle**). This body configuration, plus the female distribution of fat in the breasts and buttocks, is also seen in castrated males. In women, the larynx retains its prepubertal proportions, and the voice is high-pitched. There is less body hair and more scalp hair, and the pubic hair generally has a characteristic flattop pattern (**female escutcheon**). Growth of pubic and axillary hair in the female is due primarily to androgens rather than estrogens, although estrogen treatment may cause some hair growth. The androgens are produced by the adrenal cortex and, to a lesser extent, by the ovaries.

Other Actions of Estrogens

Normal women retain salt and water and gain weight just before menstruation. Estrogens can cause some degree of salt and water retention. However, aldosterone secretion is slightly elevated in the luteal phase, and this also contributes to premenstrual fluid retention.

Estrogens make sebaceous gland secretions more fluid and thus counter the effect of testosterone and inhibit formation of comedones ("blackheads") and acne. The liver palms, spider angiomas, and slight breast enlargement seen in advanced liver disease are due to increased circulating estrogens. The increase appears to be due to decreased hepatic metabolism of androstenedione, making more of this androgen available for conversion to estrogens.

Estrogens have a significant plasma cholesterol-lowering action. They produce vasodilatation and inhibit vascular smooth muscle proliferation, possibly by increasing the local production of nitric oxide (NO). Estrogen has also been shown to prevent expression of factors important in the initiation of atherosclerosis. These actions may account for the low incidence of myocardial infarction and other complications of atherosclerotic-vascular disease in premenopausal women. There is considerable evidence that small doses of estrogen may reduce the incidence of cardiovascular disease after menopause. However, some recently published data do not support this conclusion, and additional research is needed. Large doses of oral estrogen also promote thrombosis, apparently because the high concentrations of estrogen that reach the liver in the portal blood alter hepatic production of clotting factors.

Mechanism of Action

The 2 principal types of nuclear estrogen receptors are estrogen receptor-α (ER-α), which is encoded by a gene on chromosome 6, and estrogen receptor-β (ER-β), which is encoded by a gene on chromosome 14. Both are members of the nuclear receptor superfamily, which includes receptors for many different steroids. After binding estrogen, the nuclear receptors dimerize and bind to DNA, altering its transcription (Fig. 4–12). Some tissues contain one type or the other, but there is also overlap, with some tissues containing both ER-α and ER-β. ER-α is found primarily in the uterus, kidneys, liver, and heart; whereas ER-β is found primarily in the ovaries, prostate, lung, gastrointestinal tract, hemopoietic system, and central nervous system. The receptors also form heterodimers, with ER-α binding to ER-β. Male and female mice in which the gene for ER-α has been knocked out are sterile, develop osteoporosis, and continue to grow because their epiphyses do not close. ER-β female knockouts are infertile, but ER-β male knockouts are fertile even though they have hyperplastic prostates and loss of fat. Thus, the actions of the estrogen receptors are complex, multiple, and varied. However, this is not surprising because it is now known that both receptors exist in various isoforms and, like thyroid receptors, can bind to various activating and stimulating factors.

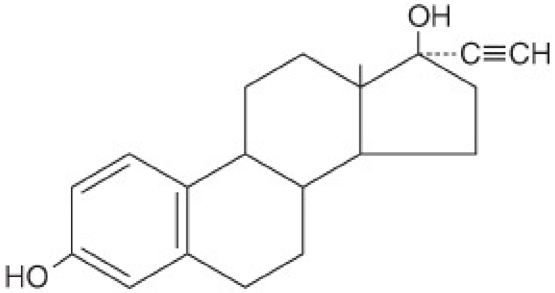
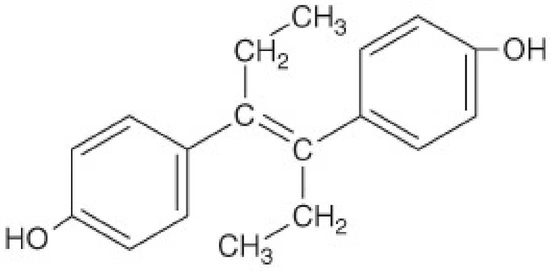
Most of the actions of estrogens are genomic, ie, mediated by actions of the nucleus. However, some effects are so rapid that it is difficult to believe they are mediated via increased expression of mRNAs. These include effects on neuronal discharge in the brain and possibly feedback effects on gonadotropin secretion. Their existence has led to the hypothesis that, in addition to genomic actions, there are nongenomic effects of estrogens that are presumably mediated by membrane receptors. Similar rapid effects of progesterone, testosterone, and aldosterone may also be produced by membrane receptors.

Synthetic Estrogen

The ethinyl derivative of estradiol (Fig. 4–13) is a potent estrogen. Unlike naturally occurring estrogens, it is relatively active when given orally because it has an ethinyl group in position 17, which makes it resistant to hepatic metabolism. Naturally occurring hormones have low activity when given orally because the portal venous drainage of the intestine carries them to the liver, where they are largely inactivated before they can reach the general circulation. Some nonsteroidal substances and a few compounds found in plants have estrogenic activity. Plant estrogens rarely affect humans but may cause undesirable effects in farm animals. Diethylstilbestrol (Fig. 4–13) and a number of related compounds are strongly estrogenic, possible because they are converted to steroid-like ring structures in the body.



Ethinyl estradiol



Diethylstilbestrol

Estradiol reduces the hot flashes and other symptoms of the menopause, and it prevents the development of osteoporosis. It may reduce the initiation and progression of atherosclerosis and the incidence of myocardial infarctions. However, it also stimulates the growth of the endometrium and the breast, and it can lead to cancer of the uterus and possibly the breast. Therefore, there has been an active search for “tailor-made” estrogens that have the bone and cardiovascular effects of estradiol but lack its growth-stimulating effects on the uterus and the breast. Two of the selective estrogen receptor modulators (SERMs), **tamoxifen** and **raloxifene**, show promise in this regard. Neither combats the symptoms of menopause, but both have the bone-preserving effects of estradiol. They may also have cardioprotective effects, but the clinical relevance of these effects has not been established. In addition, tamoxifen does not stimulate the breast, and raloxifene does not stimulate the breast or uterus. The clinical uses of the 2 drugs are discussed elsewhere in this book.

Chemistry, Biosynthesis, & Metabolism of Progesterone

Progesterone (Fig. 4–14) is a C_{21} steroid secreted in large amounts by the corpus luteum and the placenta. It is an important intermediate in steroid biosynthesis in all tissues that secrete steroid hormones, and small amounts enter the circulation from the testes and adrenal cortex. The 20α- and 20β-hydroxy derivatives of progesterone are formed in the corpus luteum. About 2% of the progesterone in the circulation is free (Table 4–2), whereas 80% is bound to albumin and 18% is bound to corticosteroid-binding globulin. Progesterone has a short half-life and is converted in the liver to pregnanediol, which is conjugated to glucuronic acid and excreted in the urine (Fig. 4–14).

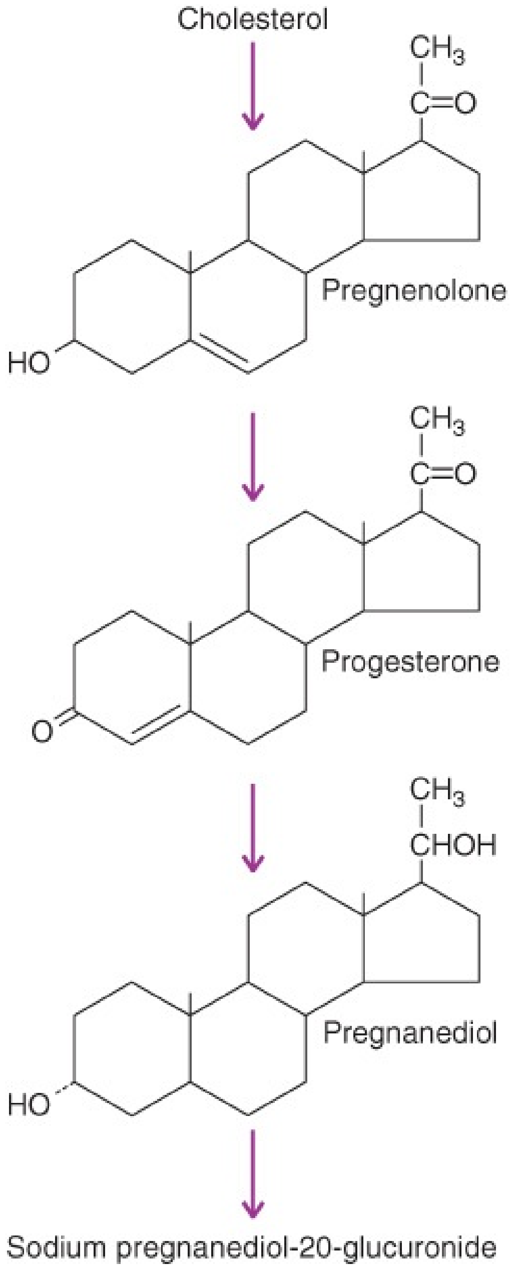

Figure 4–14. Biosynthesis of progesterone and major pathway for its metabolism. Other metabolites are also formed. (Reproduced, with permission, from Barrett KE. *Ganong's Review of Medical Physiology*. 23rd ed. New York, NY: McGraw-Hill; 2010.)

Secretion of Progesterone

The plasma progesterone level in women during the follicular phase of the menstrual cycle is approximately 0.9 ng/mL (3 nmol/L), whereas the level in men is approximately 0.3 ng/mL (1 nmol/L). The difference is due to secretion of small amounts of progesterone by cells in the ovarian follicle. During the luteal phase, the large amounts secreted by the corpus luteum cause ovarian secretion to increase about 20-fold. The result is an increase in plasma progesterone to a peak value of approximately 18 ng/mL (60 nmol/L) (Fig. 4–8).

The stimulating effect of LH on progesterone secretion by the corpus luteum is due to activation of adenylyl cyclase and involves a subsequent step that is dependent on protein synthesis.

Actions of Progesterone

The principal target organs of progesterone are the uterus, the breasts, and the brain. Progesterone is responsible for the progestational changes in the endometrium and the cyclic changes in the cervix and vagina described earlier. It has antiestrogenic effects on the myometrial cells, decreasing their excitability, their sensitivity to oxytocin, and their spontaneous electrical activity, while increasing their membrane potential. Progesterone decreases the number of estrogen receptors in the endometrium and increases the rate of conversion of 17β-estradiol to less active estrogens.

In the breast, progesterone stimulates the development of lobules and alveoli. It induces differentiation of estrogen-prepared ductal tissue and supports the secretory function of the breast during lactation.

The feedback effects of progesterone are complex and are exerted at both the hypothalamic and the pituitary level. Large doses of progesterone inhibit LH secretion and potentiate the inhibitory effects of estrogens, preventing ovulation.

Progesterone is thermogenic and probably is responsible for the rise in basal body temperature at the time of ovulation (Fig. 4–8). Progesterone stimulates respiration, and the fact that alveolar partial pressure of carbon dioxide (Pco_2) in women during the luteal phase of the menstrual cycle is lower than that in men is attributed to the action of secreted progesterone. In pregnancy, alveolar Pco_2 falls as progesterone secretion rises.

Large doses of progesterone produce natriuresis, probably by blocking the action of aldosterone on the kidney. The hormone does not have significant anabolic effect.

Mechanism of Action

The effects of progesterone, like those of other steroids, are brought about by an action on DNA to initiate synthesis of new mRNA. The progesterone receptor is bound to a heat shock protein in the absence of the steroid, and progesterone binding releases the heat shock protein, exposing the DNA-binding domain of the receptor. The synthetic steroid **mifepristone (RU-486**) binds to the receptor but does not release the heat shock protein, and it blocks the binding of progesterone. As the maintenance of early pregnancy depends on the stimulatory effect of progesterone on endometrial growth and its inhibition of uterine contractility, mifepristone causes absorption. In some countries, mifepristone combined with a prostaglandin is used to produce elective abortions.

Two isoforms of the progesterone receptor are produced by differential processing from a single gene on chromosome 11. Progesterone receptor A (PR_A) is a truncated form that when activated is capable of inhibiting some of the actions of progesterone receptor B (PR_B). A third isoform has been identified in humans, PR_C, which is thought to modulate the transcriptional activity of PR_A and PR_B. However, although the physiologic significance of the existence of the isoforms remains to be determined, it has been suggested that they have distinct tissue-specific responses to progesterone.

Substances that mimic the action of progesterone are sometimes called **progestational agents, gestagens**, or **progestins**. They are used along with synthetic estrogens as oral contraceptive agents.

RELAXIN

Relaxin is a polypeptide hormone that is secreted by the corpus luteum in women and by the prostate in men. During pregnancy, it relaxes the pubic symphysis and other pelvic joints while softening and dilating the uterine cervix, thus facilitating delivery. It also inhibits uterine contractions and may play a role in the development of the mammary glands. In nonpregnant women, relaxin is found in the corpus luteum and the endometrium during the secretory but not the proliferative phase of the menstrual cycle. Its function in non-pregnant women is unknown, but it is postulated that relaxin may play a role in follicular development, ovulation, and/or implantation. There is currently no evidence that endogenous relaxin contributes to reproductive processes in any species.

In most species, there is only 1 relaxin gene, but in humans there are 2 genes on chromosome 9 that code for 2 structurally different polypeptides with relaxin activity. However, only 1 of these genes is active in the ovary and the prostate. The structure of the polypeptide produced in these 2 tissues is shown in Figure 4–15.

INHIBINS & ACTIVINS

Both the ovaries and testes produce polypeptides called **inhibins** that inhibit FSH secretion. There are 2 inhibins, and they are formed from 3 polypeptide subunits: a glycosylated α subunit with a molecular weight of 18,000, and 2 nonglycosylated β subunits, β_A and β_B, each with a molecular weight of 14,000. The subunits are formed from precursor proteins (Fig. 4–16). The α subunit combines with β_A to form a heterodimer and with β_B to form another heterodimer, with the subunits linked by disulfide bonds. Both $\alpha\beta_A$ (inhibin A) and $\alpha\beta_B$ (inhibin B) inhibit FSH secretion by a direct action on the pituitary, although it now appears that inhibin B is the FSH-regulating hormone in adults. Inhibins are produced by Sertoli cells in males and by granulosa cells in females.

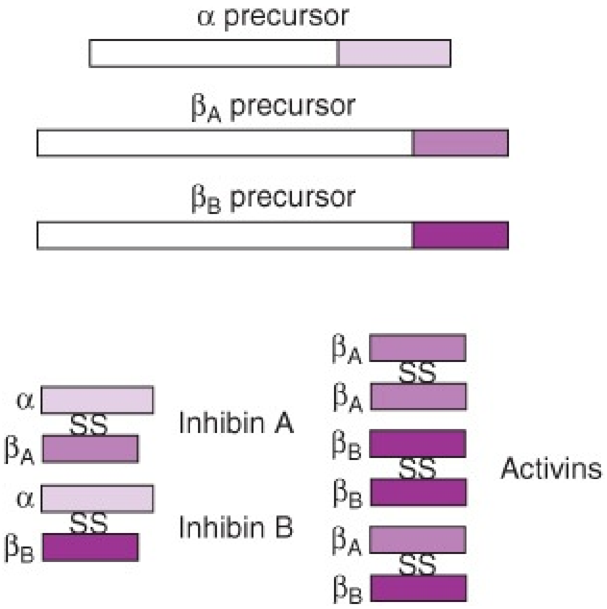

Figure 4–16. Inhibin precursor proteins and the various inhibins and activins that are formed from them. SS, disulfide bonds. (Reproduced, with permission, from Ganong WF. *Review of Medical Physiology*. 22nd ed. New York, NY: McGraw-Hill; 2005.)

The heterodimer, $\beta_A\beta_B$, and the homodimers, $\beta_A\beta_A$ and $\beta_B\beta_{B,}$ stimulate rather than inhibit FSH secretion and consequently are called **activins**. Their function in reproduction is unsettled. However, the inhibins and activins are members of the transforming growth factor-β superfamily of dimeric growth factors. Also included in this superfamily is the müllerian inhibitory substance (MIS), which is important in embryonic development of the gonads. Two **activin receptors** have been cloned, and both appear to be serine kinases. Inhibins and activins are found not only in the gonads, but also in the brain and many other tissues. In the bone marrow, activins are involved in the development of white blood cells. In embryonic life, activins are involved in the formation of mesoderm. All mice with a targeted deletion of the α-inhibin gene initially grew in a normal fashion but then developed gonadal stromal tumors, thus elucidating the role of the α-inhibin gene as a tumor suppressor gene.

In plasma, α_2-macroglobulin binds activins and inhibins. In tissues, activins bind to a family of 4 glycoproteins called **follistatins**. Binding of the activins inactivates their biologic activity, which may involve regulation of FSH production from gonadotropes in the anterior pituitary. However, the relation of follistatins to inhibin and their physiologic function remain unsettled.

PITUITARY HORMONES

Ovarian secretion depends on the action of hormones secreted by the anterior pituitary gland. The anterior pituitary gland secretes 6 established hormones: ACTH, growth hormone, thyroid-stimulating hormone (TSH), FSH, LH, and prolactin (Fig. 4–17). It also secretes 1 putative hormone: β-lipotrophic hormone (β-LPH).

Figure 4–17. Anterior pituitary hormones. In women, follicle-stimulating hormone (FSH) and luteinizing hormone (LH) act in sequence on the ovary to produce growth of the ovarian follicle, which secretes estrogen, then ovulation, followed by formation and maintenance of the corpus luteum, which secretes estrogen and progesterone. In men, FSH and LH control the functions of the testes. Prolactin stimulates lactation. β-LPH, β-lipotropic hormone; ACTH, adrenocorticotropic hormone; TSH, thyroid-stimulating hormone. (Reproduced, with permission, from Ganong WF. *Review of Medical Physiology*. 22nd ed. New York, NY: McGraw-Hill; 2005.)

The posterior pituitary differs from the anterior pituitary in that its hormones, oxytocin and arginine vasopressin, are secreted by neurons directly into the systemic circulation.

GONADOTROPINS

The gonadotropins, FSH and LH, act in concert to regulate the cyclic secretion of the ovarian hormones. They are glycoproteins made up of α and β subunits. The α subunits have the same amino acid composition as the α subunits in the glycoproteins, TSH and human chorionic gonadotropin (hCG). The specificity of these 4 glyco-protein hormones is imparted by the different structures of their β subunits. The carbohydrates in the gonadotropin molecules increase the potency of the hormones by markedly slowing their metabolism. The half-life of human FSH is about 170 minutes; the half-life of LH is about 60 minutes.

The receptors for FSH and LH are serpentine receptors coupled to adenylyl cyclase through G_S. In addition, each has an extended, glycosylated extracellular domain.

HYPOTHALAMIC HORMONES

Secretion of the anterior pituitary hormones is regulated by the hypothalamic hypophysiotropic hormones. These substances are produced by neurons and enter the portal hypophysial vessels (Fig. 4–18), a special group of blood vessels that transmit substances directly from the hypothalamus to the anterior pituitary gland. The actions of these hormones are summarized in Figure 4–19. The structures of 6 established hypophysiotropic hormones are known (Fig. 4–20). No single prolactin-releasing hormone has been isolated and identified. However, several polypeptides that are found in the hypothalamus can increase prolactin secretion, and 1 or more of these may stimulate prolactin secretion under physiologic conditions.

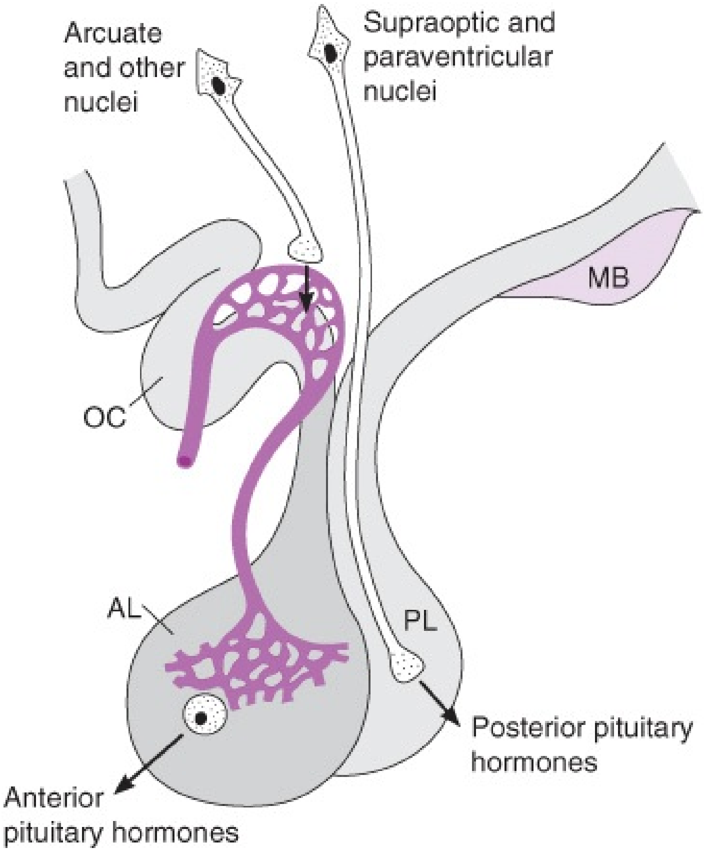

Figure 4–18. Secretion of hypothalamic hormones. The hormones of the posterior lobe (PL) are released into the general circulation from the endings of supraoptic and paraventricular neurons, whereas hypophysiotropic hormones are secreted into the portal hypophysial circulation from the endings of arcuate and other hypothalamic neurons. The posterior pituitary hormones are produced in the cell bodies of neurons located in the supraoptic and paraventricular nuclei of the hypothalamus and transported down the axons of these neurons to their endings in the posterior lobe of the pituitary. The hormones are released from the endings into the circulation when action potentials pass down the axons and reach their endings. The structures of the hormones are shown in Figure 4–21.

CONTROL OF OVARIAN FUNCTION

FSH from the pituitary is responsible for the early maturation of the ovarian follicles, while FSH and LH together are responsible for the final maturation. A burst of LH secretion (Fig. 4–8) triggers ovulation and the initial formation of the corpus luteum. There is also a smaller midcycle burst of FSH secretion, the significance of which is uncertain. LH stimulates the secretion of estrogen and progesterone from the corpus luteum.

Hypothalamic Components

The hypothalamus occupies a key role in the control of gonadotropin secretion. Hypothalamic control is exerted by GnRH secreted into the portal hypophysial vessels. GnRH stimulates the secretion of both FSH and LH. It is unlikely that there is an additional separate follicle-stimulating hormone-releasing hormone (FRH).

GnRH is normally secreted in episodic bursts (**circhoral secretion**). These bursts are essential for normal secretion of gonadotropins, which are also exerted in a pulsatile fashion (Fig. 4–22). If GnRH is administered by constant infusion, the number of GnRH receptors in the anterior pituitary decreases (**downregulation**) and LH secretion falls to low levels. However, if GnRH is administered episodically at a rate of 1 pulse per hour, LH secretion is stimulated. This is true even when endogenous GnRH secretion has been prevented by a lesion of the ventral hypothalamus.

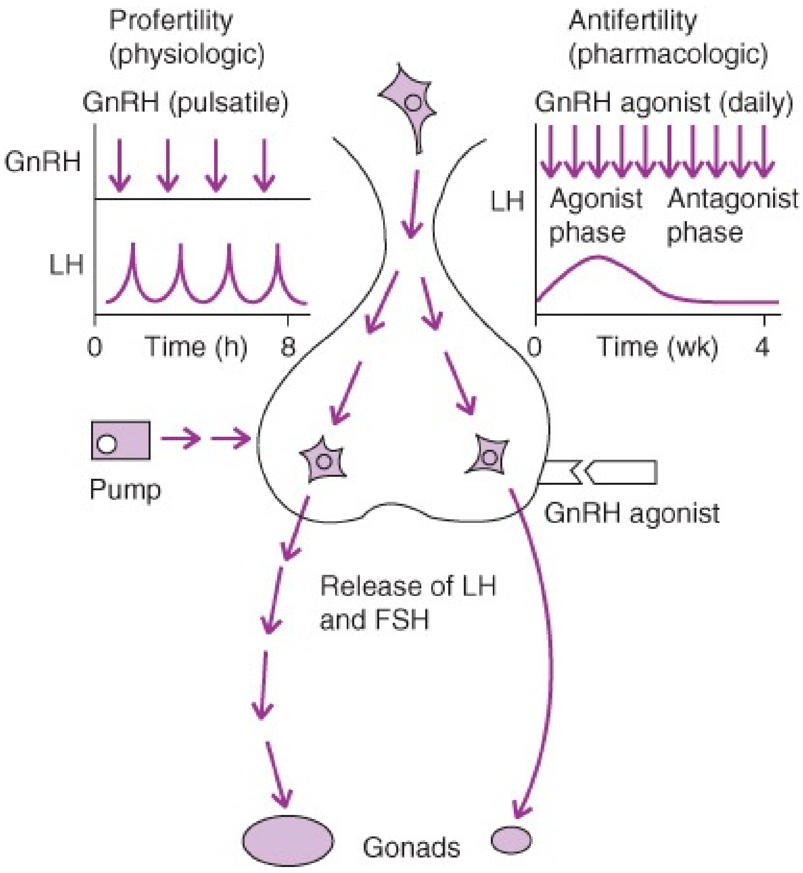

Figure 4–22. Profertility and antifertility actions of gonadotropin-releasing hormone (GnRH) and its agonists. The normal secretion of GnRH is pulsatile, occurring at 30- to 60-minute intervals. This mode, which can be mimicked by timed injections, produces circhoral peaks of luteinizing hormone

(LH) and follicle-stimulating hormone (FSH) secretion and promotes fertility. If GnRH is administered by continuous infusion or if 1 of its long-acting synthetic agonists is injected, there is initial stimulation of the pituitary receptors. However, this stimulation lasts for only a few days and is followed by receptor downregulation with inhibition of gonadotropin secretion (antifertility effect). (Reproduced, with permission, from Conn PM, Crowley WF Jr. Gonadotropin-releasing hormone and its analogues. *N Engl J Med* 1991;324:93.)

It is clear that, not only is this episodic nature of secretion of GnRH an important phenomenon, but that fluctuations in the frequency and amplitude of these GnRH bursts are also important in generating the other hormonal changes that are responsible for the menstrual cycle. Frequency is increased by estrogens and decreased by progesterone and testosterone. The frequency increases late in the follicular phase of the cycle, culminating in the LH surge. During the secretory phase, the frequency decreases as a result of the action of progesterone, but when estrogen and progesterone secretion decrease at the end of the cycle, frequency once again increases.

At the time of the midcycle LH surge, the sensitivity of the gonadotropes to GnRH is greatly increased because of their exposure to GnRH pulses of the frequency that exist at this time. This self-priming effect of GnRH is important in producing a maximum LH response.

The nature and the exact location of the GnRH pulse generator in the hypothalamus are still unsettled. However, it is known that norepinephrine and possibly epinephrine increase GnRH pulse frequencies. Conversely, opioid peptides, such as the enkephalins and β-endorphin, reduce the frequency of GnRH pulses.

The downregulation of pituitary receptors and the consequent decrease in LH secretion produced by constantly elevated levels of GnRH has led to the use of long-acting GnRH agonists to inhibit LH secretion in precocious puberty, endometriosis, leiomyomas, and cancer of the prostate.

Feedback Effects

Changes in plasma levels of LH, FSH, sex steroids, and inhibin B during the menstrual cycle are shown in Figure 4–8, and their feedback relations are diagrammed in Figure 4–23. At the start of the follicular phase, the inhibin B level is low and the FSH level is modestly elevated, fostering follicular growth. LH secretion is held in check by the negative feedback effect of the rising plasma estrogen level. At 36–48 hours before ovulation, the estrogen feedback effect becomes positive, which initiates the burst of LH secretion (LH surge) that produces ovulation. Ovulation occurs about 9 hours after the LH peak. FSH secretion also peaks, despite a small rise in inhibin B level, probably because of the strong stimulation of gonadotropes by GnRH. During the luteal phase, secretion of LH and FSH is low because of the elevated levels of estrogen, progesterone, and inhibin B.

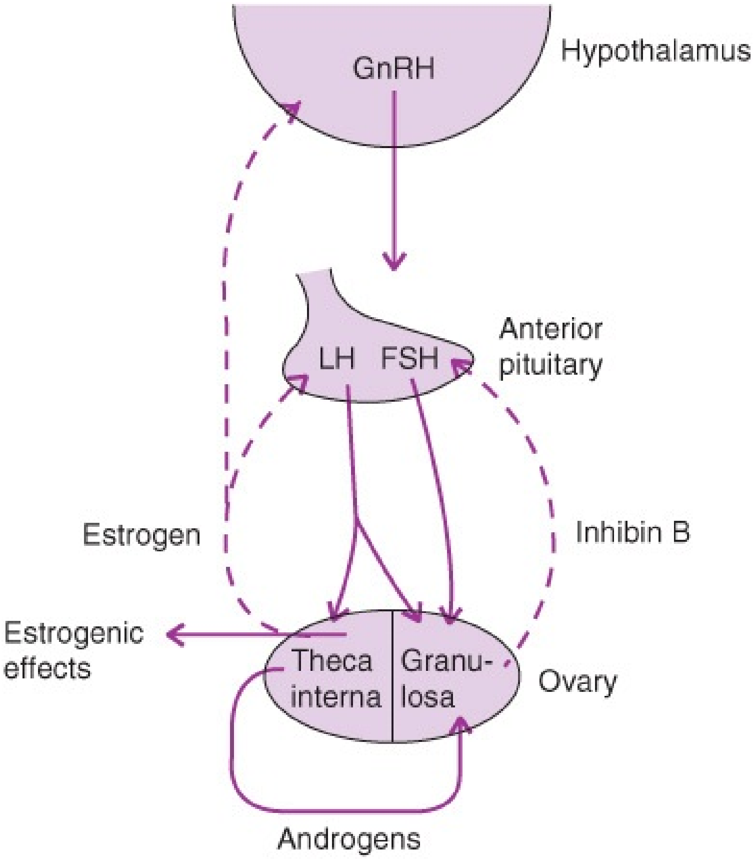

Figure 4–23. Feedback regulation of ovarian function. The cells of the theca interna provide androgens to the granulosa cells, and the thecal cells produce the circulating estrogens, which inhibit the secretion of luteinizing hormone (LH), gonadotropin-releasing hormone (GnRH), and follicle-stimulating hormone (FSH). Inhibin B from the granulosa cells also inhibits FSH secretion. LH regulates thecal cells, whereas the granulosa cells are regulated by both LH and FSH. The dashed arrows indicate inhibition, and the solid arrows indicate stimulation. (Reproduced, with permission, from Ganong WF. *Review of Medical Physiology*. 22nd ed. New York, NY: McGraw-Hill; 2005.)

It should be emphasized that a moderate, constant level of circulating estrogen exerts a negative feedback effect on LH secretion, whereas an elevated estrogen level exerts a positive feedback and stimulates LH secretion. It has been demonstrated in monkeys that there is also a minimum time that estrogen levels must be elevated to produce a positive feedback. When the circulating estrogen level was increased about 300% for 24 hours, only negative feedback was seen; but when it was increased about 300% for 36 hours or more, a brief decline in secretion was followed by a burst of LH secretion that resembled the midcycle surge. When circulating levels of progesterone were high, the positive feedback effect of estrogen was inhibited. There is evidence in primates that both the negative and the positive feedback effects of estrogen are exerted in the medio-basal hypothalamus via the ER-α receptors. The mechanism of the “switch” between negative and positive feedback remains unknown.

Control of Menstrual Cycle

In an important sense, regression of the corpus luteum (**luteolysis**) starting 3–4 days before menses is the key to the menstrual cycle. PGF_{2a} appears to be a physiologic luteolysin, but this prostaglandin is only active when endothelial cells producing endothelin-1 (ET-1) are present. Therefore, it appears that, at least in some species, luteolysis is produced by the combined action of PGF_{2a} and ET-1. In some domestic animals, oxytocin secreted by the corpus luteum appears to exert a local luteolytic effect, possibly by causing the release of prostaglandins. Once luteolysis begins, the estrogen and progesterone levels fall, followed by increased secretion of FSH and LH. A new crop of follicles develops, and then a single dominant follicle matures as a result of the action of FSH and LH. Near midcycle, there is a rise in estrogen secretion from the follicle. This rise augments the responsiveness of the pituitary to GnRH and triggers a burst of LH secretion. The resulting ovulation is followed by formation of a corpus luteum. There is a drop in estrogen secretion at first, but progesterone and estrogen levels then rise together, along with inhibin B. The elevated levels inhibit FSH and LH secretion for a while, but luteolysis again occurs and a new cycle begins.

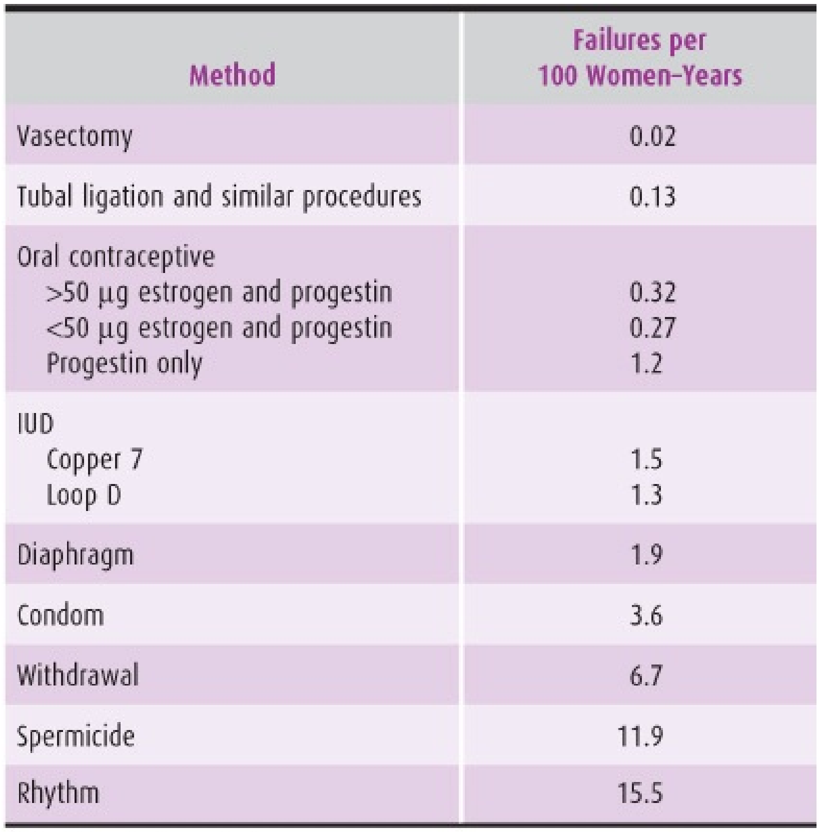
Reflex Ovulation

Female cats, rabbits, mink, and certain other animals have long periods of **estrus**, or heat, during which they ovulate only after copulation. Such **reflex ovulation** is brought about by afferent impulses from the genitalia and the eyes, ears, and nose that converge on the ventral hypothalamus and provoke an ovulation-inducing release of LH from the pituitary. In species such as rats, monkeys, and humans, ovulation is a spontaneous periodic phenomenon, but afferent impulses converging on the hypothalamus can also exert effects. Ovulation can be delayed for 24 hours in rats by administering pentobarbital or other neurally active drugs 12 hours before the expected time of follicle rupture. In women, menstrual cycles may be markedly influenced by emotional stimuli.

Contraception

Methods commonly used to prevent conception, along with their failure rates, are listed in Table 4–4. Contraception is considered in detail in Chapter 58. It is briefly reviewed here because the techniques used are excellent examples of the practical application of the physiologic principles discussed in this chapter.

Table 4–4. Relative effectiveness of frequently used contraceptive methods.



Method	Failures per 100 Women-Years
Vasectomy	0.02
Tubal ligation and similar procedures	0.13
Oral contraceptive	
>50 μg estrogen and progestin	0.32
<50 μg estrogen and progestin	0.27
Progestin only	1.2
IUD

Loop D	1.3
Diaphragm	1.9
Condom	3.6
Withdrawal	6.7
Spermicide	11.9
Rhythm	15.5

IUD, intrauterine device.

Data from Vessey M, Lawless M, Yeates D. Efficacy of different contraceptive methods. *Lancet* 1982;1:841. Reproduced with permission.

Among the most extensively used contraceptives are estrogens and/or progestins in varying doses and combinations. They interfere with gonadotropic secretion or implantation, and in some cases, inhibit the union of sperm with ova.

Once conception has occurred, abortion can be produced by progesterone antagonists such as mifepristone.

Implantation of foreign bodies in the uterus causes changes in the duration of the sexual cycle in a number of mammalian species. In humans, such foreign bodies do not alter the menstrual cycle, but they act as effective contraceptive devices. The 2 **intrauterine devices (IUDs**) available in the United States are T-shaped devices that contain copper or progestin. There is production of a local, sterile, inflammatory reaction secondary to the presence of the foreign body in the uterine cavity, which is thought to act as a spermicide inhibiting sperm capacitation, penetration, and survival. The progestin IUD thickens cervical mucus and may cause endometrial alterations that prevent implantation.

Implants made up primarily of progestins are now being increasingly used in some parts of the world. The implants are inserted under the skin and remain effective for 3 years. The 2 primary mechanisms of action include inhibition of ovulation and restriction of sperm penetration through cervical mucus. They often produce amenorrhea but otherwise appear to be well tolerated. Spontaneous breakthrough bleeding is, however, a common side effect.

PROLACTIN

Chemistry of Prolactin

Prolactin is another anterior pituitary hormone that has important functions in reproduction and pregnancy. The human prolactin molecule contains 199 amino acid residues and 3 disulfide bridges

(Fig. 4–24) and has considerable structural similarity to human growth hormone and human chorionic somatomammotropin (hCS). The half-life of prolactin, like that of growth hormone, is about 20 minutes. Structurally similar prolactins are secreted by the endometrium and by the placenta.

Figure 4–24. Structure of human prolactin. (Reproduced, with permission, from Bondy PK, Rosenberg LE. *Metabolic Control and Disease*. 8th ed. New York, NY: Saunders; 1980.)

Receptors

The human prolactin receptor resembles the growth hormone receptor. It is one of the superfamily of receptors that includes the growth hormone receptor and receptors for many cytokines and hematopoietic growth factors. It dimerizes and activates the JAK-STAT and other intracellular enzymes cascades.

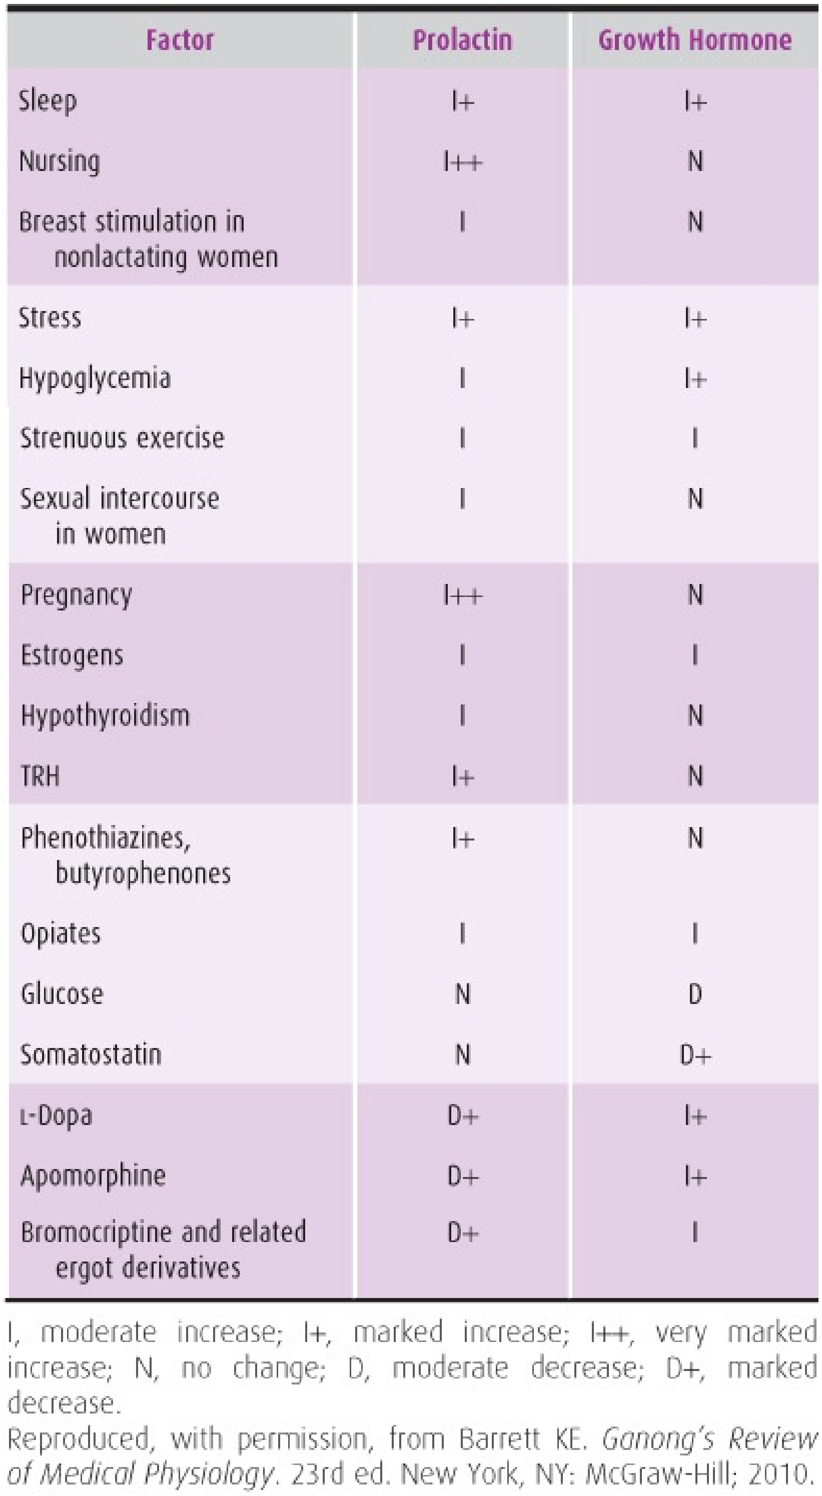
Actions

Prolactin causes milk secretion from the breast after estrogen and progesterone priming. Its effect on the breast causes increased production of casein and lactalbumin. However, the action of the hormone is not exerted on the cell nucleus and is prevented by inhibitors of microtubules. Prolactin also inhibits the effects of gonadotropins, possibly by an action at the level of the ovary. Consequently, it is a “natural contraceptive” that spaces pregnancies by preventing ovulation in lactating women. The function of prolactin in normal males is unsettled, but excess prolactin in normal males causes impotence. An action of prolactin that has been used in the past as the basis for a bioassay to assess this hormone is stimulation of the growth and “secretion” of the crop sacs in pigeons and other birds. The paired crop sacs are outpouchings of the esophagus that form, by desquamation of their inner cell layers, a nutritious material (“milk”) that the birds feed to their young. However, prolactin, FSH, and LH are now regularly measured by radioimmunoassay.

Regulation of Prolactin Secretion

The normal plasma prolactin concentration is approximately 5 ng/mL in men and 8 ng/mL in women. Secretion is tonically inhibited by the hypothalamus, and a section of the pituitary stalk leads to an increase in circulating prolactin. Thus, the effect of the hypothalamic prolactin-inhibiting hormone (PIH), dopamine, is greater than the effect of the putative prolactin-releasing hormone. In humans, prolactin secretion is increased by stimulation of the nipple, exercise, and surgical or psychological stress (Table 4–5). The plasma prolactin level rises during sleep, with the rise starting after the onset of sleep and persisting throughout the sleep period. Secretion is increased during pregnancy, reaching a peak at the time of parturition. After delivery, the plasma concentration falls to nonpregnant levels in about 8 days. Suckling produces a prompt increase in secretion, but the magnitude of this rise gradually declines after a woman has been nursing for more than 3 months.

Table 4–5. Factors affecting the secretion of human prolactin and growth hormone.



Factor	Prolactin	Growth Hormone
Sleep	I+	I+
Nursing	I++	N
Breast stimulation in nonlactating women	I	N
Stress	I+	I+
Hypoglycemia	I	I+
Strenuous exercise	I	I
Sexual intercourse in women	I	N
Pregnancy	I++	N
Estrogens	I	I
Hypothyroidism	I	N
TRH	I+	N
Phenothiazines, butyrophenones	I+	N
Opiates	I	I
Glucose	N	D
Somatostatin	N	D+
L-Dopa	D+	I+
Apomorphine	D+	I+
Bromocriptine and related ergot derivatives	D+	I

I, moderate increase; I+, marked increase; I++, very marked increase; N, no change; D, moderate decrease; D+, marked decrease.

Reproduced, with permission, from Barrett KE. *Ganong's Review of Medical Physiology*. 23rd ed. New York, NY: McGraw-Hill; 2010.

L-Dopa decreases prolactin secretion by increasing formation of dopamine. Bromocriptine and other dopamine agonists inhibit secretion because they stimulate dopamine receptors. Chlorpromazine and related drugs that block dopamine receptors increase prolactin secretion. Thyroid-releasing hormone (TRH) stimulates the secretion of prolactin in addition to TSH, plus there are additional prolactin-releasing polypeptides in hypothalamic tissue. Estrogens produce a slowly developing increase in prolactin secretion as a result of a direct action on the lactotropes.

It has not been established that prolactin facilitates the secretion of dopamine in the median eminence. Thus, prolactin acts in the hypothalamus in a negative feedback fashion to inhibit its own secretion.

Hyperprolactinemia

Up to 70% of patients with chromophobe adenomas of the anterior pituitary have elevated plasma prolactin levels. In some instances, the elevation may be due to damage to the pituitary stalk, but in most cases, the tumor cells are actually secreting the hormone. The hyperprolactinemia may cause galactorrhea, but in many individuals, there are no demonstrable abnormalities. Indeed, most women with galactorrhea have normal prolactin levels; definite elevations are found in less than one-third of patients with this condition.

Another interesting observation is that 15–20% of women with secondary amenorrhea have elevated prolactin levels, and when prolactin secretion is reduced, normal menstrual cycles and fertility return. It appears that prolactin may produce amenorrhea by blocking the action of gonadotropins on the ovaries, but definitive proof of this hypothesis must await further research. The hypogonadism produced by prolactinomas is associated with osteoporosis due to estrogen deficiency.

Hyperprolactinemia in men is associated with impotence and hypogonadism that disappear when prolactin secretion is reduced.

MENOPAUSE

The human ovary gradually becomes unresponsive to gonadotropins with advancing age, and its function declines so that sexual cycles and menstruation disappear (menopause). This unresponsiveness is associated with and is probably caused by a decline in the number of primordial follicles (Fig. 4–5). The ovaries no longer secrete progesterone and 17β-estrodiol in appreciable quantities. Estrone is formed by aromatization of androstenedione in fat and other tissues, but the amounts are normally small. The uterus and vagina gradually become atrophic. As the negative feedback effect of the estrogens and progesterone is reduced, secretion of FSH and LH is increased, and plasma FSH and LH rise to high levels. Old female mice and rats have long periods of diestrus and increased levels of gonadotropin secretion, but a clear-cut “menopause” has apparently not been described in experimental animals.

In women, the menses usually become irregular and cease between the age of 45 and 55. The average age at onset of menopause has increased since the turn of the century and is currently about 51 years.

Sensation of warmth spreading from the trunk to the face (“hot flushes,” also called hot flashes), night sweats, and various mood fluctuations are common after ovarian function has ceased. Hot flushes are said to occur in 75% of menopausal women and may last as long as 40 years. They are prevented by administration of estrogen. These vasomotor symptoms are not always specific to menopause; they also occur in premenopausal women and men whose gonads are removed surgically or destroyed by disease. Thus, the vasomotor symptoms result from acute estrogen withdrawal. However, it has been demonstrated that they coincide with surges of LH secretion. LH is secreted in episodic bursts at intervals of 30–60 minutes or more (circhoral secretion), and in the absence of gonadal hormones, these bursts are large. Each hot flush begins with the start of a burst. However, LH itself is not responsible for the symptoms, as they can continue after removal of the pituitary. Instead, it appears that some event in the hypothalamus initiates both the release of LH and the episode of flushing. Menopause and the clinical management of patients with menopausal symptoms are discussed in more detail in Chapter 59.

5
The Breast

Amer Karam, MD

ANATOMY OF THE FEMALE BREAST

The breasts are secondary reproductive glands of ectodermal origin. They are frequently referred to as modified sweat glands. Each breast lies on the superior aspect of the chest wall. In women, the breasts are the organs of lactation, whereas in men, the breasts are normally functionless and undeveloped.

HISTOLOGY

The adult female breast contains glandular and ductal elements, stroma consisting of fibrous tissue that binds the individual lobes together and adipose tissue within and between the lobes.

Each breast consists of 12–20 conical lobes. The base of each lobe is in close proximity to the ribs. The apex, which contains the major excretory duct of the lobe, is deep to the areola and nipple. In turn, each lobe consists of a group of lobules. The lobules have several lactiferous ducts, which unite to form a major duct that drains the lobes as they course toward the nipple–areolar complex. Each of the major ducts widens to form an ampulla as they travel toward the areola and then narrow at its individual opening in the nipple. The lobules are held in place by a meshwork of loose, fatty areolar tissue. The fatty tissue increases toward the periphery of the lobule and gives the breast its bulk and hemispheric shape.

Approximately 80–85% of the normal breast is adipose tissue. The breast tissues are joined to the overlying skin and subcutaneous tissue by fibrous strands.

In the nonpregnant, nonlactating breast, the alveoli are small and tightly packed. During pregnancy, the alveoli hypertrophy, and their lining cells proliferate in number. During lactation, the alveolar cells secrete proteins and lipids, which comprise breast milk.

The deep surface of the breast lies on the fascia that covers the chest muscles. The fascial stroma, derived from the superficial fascia of the chest wall, is condensed into multiple bands that run from the breast into the subcutaneous tissues and the corium of the skin overlying the breast. These fascial bands—Cooper’s ligaments—support the breast in its upright position on the chest wall. These bands may be distorted by a tumor, resulting in pathologic skin dimpling.

HISTOLOGIC CHANGES IN THE FEMALE BREAST DURING THE LIFE SPAN

In response to multiglandular stimulation during puberty, the female breast starts to enlarge and eventually assumes its conical or spherical shape. Growth is the result of an increase in acinar tissue, ductal size and branching, and deposits of adipose, the main factor in breast enlargement. Also during puberty, the nipple and areola enlarge. Smooth muscle fibers surround the base of the nipple, and the nipple becomes more sensitive to touch.

Once menses is established, the breast undergoes a periodic premenstrual phase during which the acinar cells increase in number and size, the ductal lumens widen, and breast size and turgor increase slightly. Many women have breast tenderness during this phase of the menstrual cycle. Menstrual bleeding is followed by a postmenstrual phase, characterized by a decrease in size and turgor, reduction in the number and size of the breast acini, and a decrease in diameter of the lactiferous ducts. Cyclic hormonal influences to the breast are quite variable.

In response to progesterone during pregnancy, breast size and turgidity increase considerably. These changes are accompanied by deepening pigmentation of the nipple–areolar complex, nipple enlargement, areolar widening, and an increase in the number and size of the lubricating glands in the areola. The breast ductal system branches markedly, and the individual ducts widen. The acini increase in number and size. In late pregnancy, the fatty tissues of the breasts are almost completely replaced by cellular breast parenchyma. After delivery with the rapid drop in progesterone and estrogen levels, the breasts, now fully mature, start to secrete milk. With cessation of nursing or administration of estrogens, which inhibit lactation, the breast rapidly returns to its prepregnancy state, with marked diminution of cellular elements and an increase in adipose deposits.

Following menopause, which typically occurs during the fifth decade of life, the breast undergoes a gradual process of atrophy and involution. There is a decrease in the number and size of acinar and ductal elements, so that the breast tissue regresses to an almost infantile state. Adipose tissue may or may not atrophy, with disappearance of the parenchymal elements.

GROSS ANATOMY (Fig. 5–1)

The adult female breast mound characteristically forms a near hemispheric contour on each side of the chest wall, usually extending from just below the level of the second rib inferiorly to the sixth or seventh rib. The breast mound is usually situated between the lateral sternal border and the anterior axillary fold. The breast tissue extends over a larger anatomic area than the more obvious breast mound. The superior portion of the breast tissue emerges gradually from the chest wall inferior to the clavicle, whereas the lateral and inferior borders are better defined. The major portion of the breast tissue is located superficial to the pectoralis major muscle and projects laterally and ventrally toward the tail of Spence. Smaller portions of breast tissue extend laterally and inferiorly to lie superficial to the serratus anterior and external oblique muscles and as far caudad as the rectus abdominis. The tail of Spence is a triangular tongue-shaped portion of breast tissue that extends superiorly and laterally toward the axilla, perforating the deep axillary fascia, and enters the axilla, where it terminates in close proximity to the axillary lymph nodes and vessels as well as the axillary blood vessels and nerves.

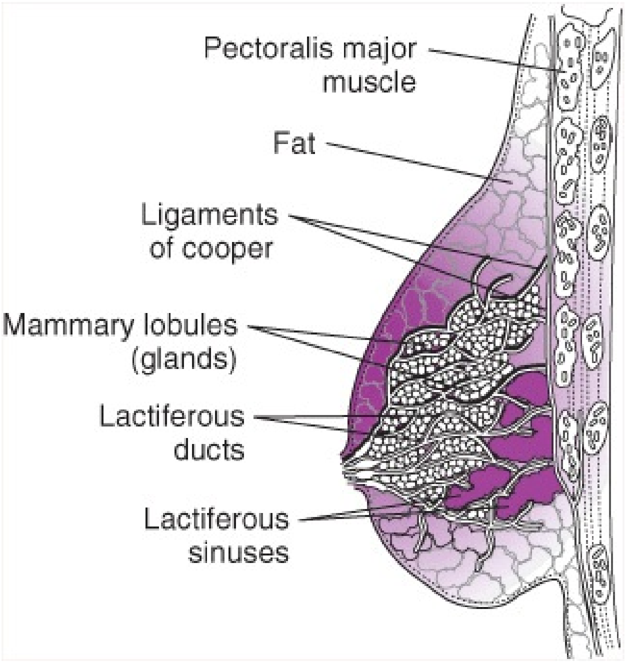

Figure 5–1. Sagittal section of mammary gland.

The Nipple & Areola

The areola is a circular pigmented zone 2–6 cm in diameter at the tip of the breast. Its color varies from pale pink to deep brown depending on age, parity, and skin pigmentation. The skin of the areola contains multiple small, elevated nodules beneath which are located the sebaceous glands of Montgomery. The glands are responsible for lubrication of the nipple and help prevent cracks and fissures in the nipple–areolar complex that occur during breastfeeding. During the third trimester of pregnancy, the sebaceous glands of Montgomery markedly hypertrophy.

A circular smooth muscle band surrounds the base of the nipple. Longitudinal smooth muscle fibers branch out from this ring of circular smooth muscle to encircle the lactiferous ducts as they converge toward the nipple. The many small punctate openings at the superior aspect of the nipple represent the terminals of the major lactiferous ducts. As discussed earlier, the ampullae of the lactiferous ducts are deep to the nipple and the areola.

Blood Vessels, Lymphatics, & Nerves

A. Arteries (Fig. 5–2)

The breast has a rich blood supply with multiple arteries and veins. Perforating branches from the internal thoracic/mammary artery that penetrate the second to the fifth intercostal interspaces supply blood to the medial half of the breast. These arteries perforate the intercostal muscles and the anterior intercostal membrane to supply both the breast and the pectoralis major and minor muscles. During pregnancy, and not infrequently in advanced breast disease, the intercostal perforators may enlarge from engorgement. Small branches from the anterior intercostal arteries also supply the medial aspect of the breast. Laterally, the pectoral branch of the thoracoacromial branch of the axillary artery and the external mammary branch of the lateral thoracic artery, which also is a branch of the second segment of the axillary artery, supply the breast. The external mammary artery passes along the lateral free edge of the pectoralis major muscle to reach the lateral half of the breast. The artery usually is located medial to the long thoracic nerve.

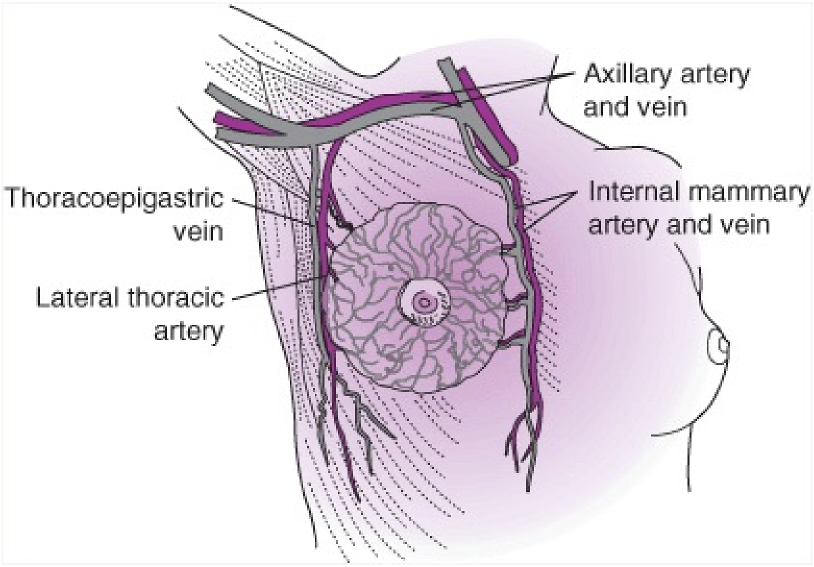

Figure 5–2. Arteries and veins of the breast.

The medial and lateral arteries, as they reach the breast, tend to arborize mainly in the supra-areolar area; consequently, the arterial supply to the upper half of the breast is almost twice that of the lower half.

B. Veins

Venous return from the breast closely follows the routes of the arterial system. Blood returns to the superior vena cava via the axillary and internal thoracic veins. It also returns via the vertebral venous plexuses, which are fed by the intercostal and azygos veins. Through the azygos veins, there is also some minor flow into the portal system. A rich anastomotic plexus of superficial breast veins is located in the subareolar region. In thin-skinned, fair individuals, these veins are normally visible, and they are almost always visible during pregnancy. Their presence makes for marked vascularity of sub- and para-areolar incisions. Venous return flow is greater in the superior quadrants than in the inferior quadrants of the breast.

C. Lymphatics (Fig. 5–3)

A thorough knowledge of the lymphatic drainage of the breast is of critical importance to the clinician. This is true because the lymphatic drainage has significant implications in several disease etiologies, including breast cancer. To a large extent, modern, less invasive surgical management techniques such as sentinel lymph node biopsy are based on a solid understanding of the pattern of lymphatic drainage in the breast.

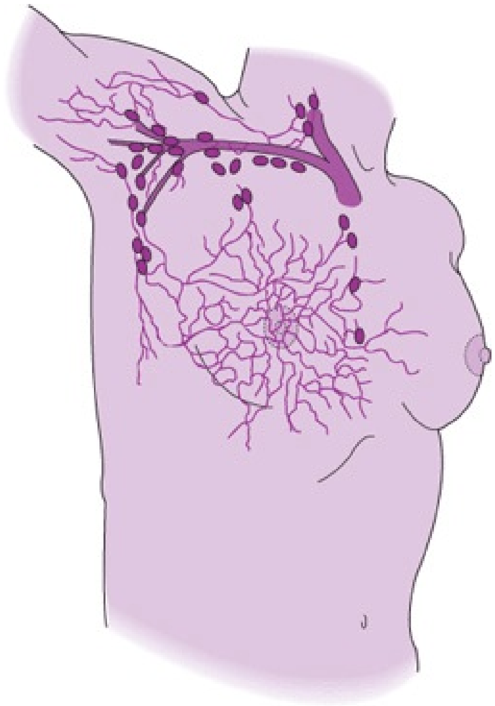

Figure 5–3. Lymphatics of the breast and axilla.

Lymphatic drainage in the breast may be divided into 2 main categories: superficial (including cutaneous) drainage and deep parenchymatous drainage.

1. Superficial drainage—A large lymphatic plexus exists in the subcutaneous tissues of the breast deep to the nipple–areolar complex. This plexus drains the areola and nipple regions, including the cutaneous and subcutaneous tissues adjacent to the nipple–areolar complex. In addition, the superficial plexus drains the deep central parenchymatous region of the breast.

2. Deep parenchymatous drainage—The deep parenchymatous lymph vessels drain the remainder of the breast as well as some portion of the skin and subcutaneous tissues of the nipple–areolar complex not served by the superficial plexus. Small periductal and periacinal lymph vessels collect parenchymal lymph and deliver it to the larger interlobar lymphatics. Lymph from the cutaneous and nipple–areolar regions may drain either directly into the subareolar plexus or deeply into the parenchymatous lymph system. Once in the deep parenchymatous drainage, the lymph is delivered to the subareolar plexus for efferent transport.

The majority of lymphatic drainage from both the retroareolar and the deep interlobar lymphatics of the breast travel to the ipsilateral axillary lymph nodes. The route of drainage to the highest axillary node or nodes is not reproducible from patient to patient. In general, however, the drainage of the breast is to the anterior axillary or subpectoral nodes, which are located deep to the lateral border of the pectoralis major muscle, close to the lateral thoracic artery. From these nodes, lymph travels to nodes in close proximity to the lateral portion of the axillary vein. The lymph then passes superiorly, via the axillary chain of lymph vessels and nodes. Eventually, the drainage reaches the highest nodes of the axilla. Although this is the most regular pattern of lateral and superior breast lymphatic drainage, other paths are common, particularly when the lateral and superiorly directed channels are obstructed, for example, by tumor masses.

Surgeons usually classify the axillary lymph nodes in levels according to their relationship with the pectoralis minor muscle. Thus, lymph nodes located lateral or below the pectoralis minor muscle are classified as level I lymph nodes. Lymph nodes located deep to the pectoralis minor muscle constitute level II lymph nodes. Finally, lymph nodes located medially or superiorly to the upper margin of the pectoralis minor muscle constitute level III lymph nodes.

D. Nerves Encountered During Axillary Dissection

The lateral and anterior cutaneous branches of T4–6 supply the cutaneous tissues covering the breasts. Two major nerves and 2 smaller groups of nerves are in close proximity to the breast area and thus assume importance in breast surgery:

1. The **thoracodorsal nerve**, a branch of the posterior cord of the brachial plexus (C5–7), runs inferiorly along with the subscapular artery lying close to the posterior axillary wall and the ventral surface of the subscapular muscle. The nerve innervates the superior half of the latissimus dorsi muscle and is usually surrounded by a large venous plexus that drains into the subscapular veins.
2. The **long thoracic nerve** (nerve of Bell) arises from the anterior primary divisions of C5–7 at the level of the lower half of the anterior scalene muscle. In the neck, the nerve descends dorsal to the trunks of the brachial plexus on the inferior segment of the middle scalene muscle. Further descent places it dorsal to the clavicle and the axillary vessels. On the lateral thoracic wall, it descends on the external surface of the serratus anterior muscle along the anterior axillary line. The long thoracic nerve supplies filaments to each of the digitations of the serratus anterior muscle. Injury to this nerve results in a “winged” scapula.
3. The **intercostal brachial nerves** are 3 relatively minor cutaneous nerves that supply the skin of the medial surface of the upper arm. They transverse the lateral chest wall to the upper inner surface of the arm, passing across the base of the axilla.
4. The **medial and lateral pectoral nerves** supply the 2 pectoral muscles and pass from the axilla to the lateral chest wall. The lateral pectoral nerve, which arises from the lateral cord of the plexus, pierces the clavipectoral fascia membrane together with the thoracoacromial artery and supplies the pectoralis major muscle. The medial pectoral nerve, which arises from the medial cord of the brachial plexus but ends up being lateral to the lateral pectoral nerve, pierces the clavipectoral fascia and supplies the pectoralis minor muscle.

DISEASES OF THE BREAST

FIBROCYSTIC BREAST CHANGES

ESSENTIALS OF DIAGNOSIS

- Painful, often multiple, usually bilateral mobile masses in the breast.
- Rapid fluctuation in the size of the masses is common.
- Frequently, pain occurs or increases, as does size during the premenstrual phase of the cycle.
- Most common age is 30–50 years; occurrence is rare in postmenopausal women.

Pathogenesis

Fibrocystic breast changes, formerly known as fibrocystic disease, chronic cystic mastitis, or mammary dysplasia, are the most common cause of cyclic breast pain or mastalgia in reproductive age women. The term is imprecise and encompasses a wide spectrum of pathologic entities. The lesions are always associated with benign changes in the breast epithelium, some of which are found so frequently in normal breasts that they are probably variants of normal breast histology, but have, unfortunately, been termed a “disease.” From a clinical standpoint, this entity is best described as nodular, sensitive breast.

Clinical Findings

Fibrocystic changes are common and affect more than 50% of women of reproductive age. These changes are thought to be the result of a hormonal imbalance that may produce asymptomatic breast lumps that are discovered by palpation. Cyclical breast pain or tenderness is often the presenting symptom and calls attention to the mass. The pain is caused by the proliferation of normal glandular breast tissue with estrogen stimulating the ductal elements and progesterone stimulating the stroma. There may be nonbloody, green or brown discharge from the nipple. In many cases, discomfort occurs or is increased during the premenstrual phase of the cycle. Fluctuations in size and rapid appearance or disappearance of a breast mass are common in cystic changes. In many women, caffeine seems to potentiate these symptoms. However, the role of caffeine as a direct cause of these symptoms has never been proven. Pain, fluctuation in size, and multiplicity of lesions are the features most helpful in differentiation from carcinoma. However, if a dominant mass is present, it should be evaluated by biopsy. Pathologists refer to a variety of histologic findings associated with fibrocystic changes including fibrosis, ductal hyperplasia, and adenosis.

Differential Diagnosis

Pain, fluctuation in size, and multiplicity of lesions help to differentiate these lesions from carcinoma and the benign entity of fibroadenoma. Final diagnosis often rests on biopsy and pathologic determination. Ultrasonography may be helpful in the diagnosis; mammography is usually not indicated for women under the age of 30 as the breast tissue in these young women may be too radiodense to allow a meaningful evaluation. Aspiration and/or sonography may be useful in differentiating a cystic from a solid mass.

Treatment

Once a benign diagnosis or normal findings have been established by biopsy or on clinical or imaging findings, simple reassurance will provide many patients with adequate relief.

For those patients who still seek treatment, symptomatic relief by avoiding trauma and by wearing a bra with adequate support can be very helpful. The role of caffeine consumption in the development and treatment of fibrocystic change has never been proven; however, many patients report relief of symptoms after abstinence from coffee, tea, and chocolate. Similarly, observational studies have suggested that low-fat diets can provide some relief. The data regarding the utility of vitamin E supplementation and evening primrose oil are controversial. Mild analgesics such as acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs) can be used to relieve breast pain. For more symptomatic women, danazol and tamoxifen have been found to be effective, although their significant side effects have limited their acceptability and utility.

Prognosis

Exacerbations of pain, tenderness, and cyst formation may occur at any time until menopause, when symptoms subside. Patients should be reassured that single nonproliferative lesions like fibrocystic changes are not associated with an increased risk of breast cancer. On the other hand, the presence of multiple nonproliferative lesions or proliferative lesions (florid hyperplasia, sclerosing adenosis, and intraductal papillomas), particularly those with atypia (atypical lobular or ductal hyperplasia), is associated with an increased risk of subsequent breast cancer.

FIBROADENOMA OF THE BREAST

Pathogenesis

This common, benign neoplasm occurs most frequently in young women, usually within 20 years after puberty. It is somewhat more frequent and tends to occur at an earlier age in black women than in white women. The etiology of fibroadenomas is not known, but a hormonal relationship is likely since they can increase in size during pregnancy or with estrogen therapy and usually regress after menopause. Multiple tumors in 1 or both breasts are found in 10–15% of patients.

Clinical Findings

The typical fibroadenoma is a round, firm, discrete, relatively movable, nontender mass 1–5 cm in diameter. The tumor is usually discovered accidentally. Clinical diagnosis in young patients is generally not difficult. Fibroadenomas typically present as well-defined solid masses with benign imaging features on ultrasound and can be managed with core needle biopsy or short-term (3–6 months) follow-up with a repeat ultrasound and breast examination.

Differential Diagnosis

Definitive diagnosis can only be confirmed with a core biopsy or excision if the patient is symptomatic or wishes the mass to be excised. Cryoablation is an alternative to surgical excision of fibroadenomas, but should only be considered after a core biopsy diagnosis of fibroadenoma has been made.

Rapid growth sometimes raises the suspicion for a phyllodes tumor and can mandate an excision to confirm the diagnosis and rule out a malignancy.

Simple fibroadenomas do not raise the subsequent risk of breast cancer, although the presence of adjacent proliferative changes or a complex fibroadenoma is associated with a slightly increased risk.

Phyllodes tumors of the breast (previously called cystosarcoma phyllodes) are fibroepithelial tumors that tend to grow rapidly and may sometimes be confused with benign fibroadenomas. This tumor may reach a large size and, if inadequately excised, will recur locally. The lesion can be, but rarely is, malignant.

Treatment

Treatment is by local excision of the mass with a margin of surrounding normal breast tissue. The treatment of malignant phyllodes tumors is more controversial but generally involves wide local excision with appropriate margins. The role of radiation and chemotherapy is controversial. Breast conservation even for large tumors may not compromise cancer-specific survival.

NIPPLE DISCHARGE

Pathogenesis

Nipple discharge is usually characterized as normal lactation, galactorrhea or benign physiologic nipple discharge, and pathologic nipple discharge.

The most common causes of pathologic nipple discharge are intraductal papillomas and, less frequently, carcinoma and fibrocystic change with ectasia of the ducts. The discharge is usually unilateral, emanating from a single duct, and can be serous, bloody, or serosanguineous.

Clinical Findings

The important characteristics of the discharge and some other factors to be evaluated by history and physical examination are as follows:

1. Nature of discharge (serous, bloody, or other)
2. Association with or without a mass
3. Unilateral or bilateral
4. Single duct or multiple duct discharge

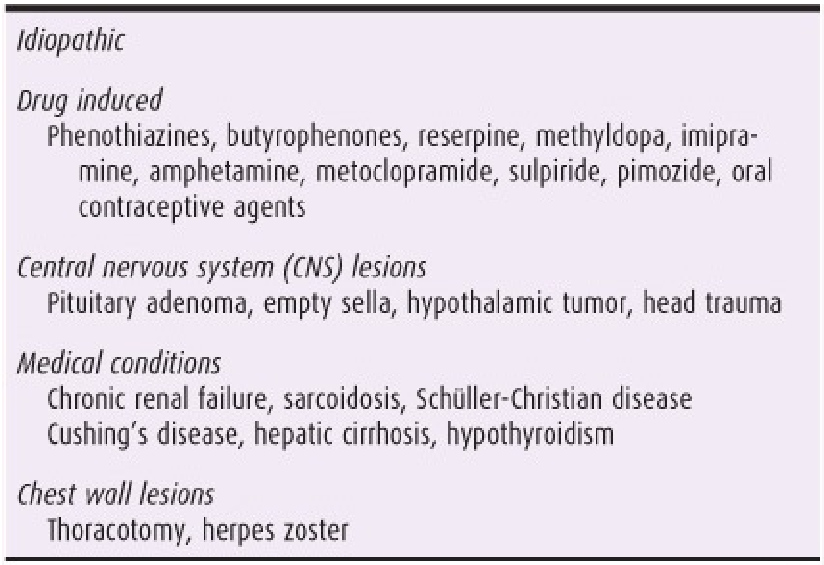
5 Discharge that is spontaneous, persistent or intermittent, or must be expressed

6. Discharge produced by pressure at a single site or by general pressure on the breast
7. Relation to menses
8. Premenopausal or postmenopausal
9. History of oral contraceptive use or estrogen replacement for postmenopausal symptoms

Differential Diagnosis

Galactorrhea or physiologic nipple discharge is frequently the result of hyperprolactinemia secondary to medications such as phenothiazines, endocrine tumors such as lactotroph adenomas, or endocrine abnormalities such as hypothyroidism and pituitary or hypothalamic disease (Table 5–1). Galactorrhea usually manifests as bilateral multiductal milky nipple discharge in the nonlactating breast. If the physical examination is otherwise normal, imaging is negative, and the discharge is multiductal and nonbloody, a pregnancy test, prolactin levels, renal and thyroid function tests, and appropriate endocrinologic follow-up may be necessary with appropriate treatment of the underlying cause.

Table 5–1. Causes of galactorrhea.



Idiopathic

Drug induced
- Phenothiazines, butyrophenones, reserpine, methyldopa, imipramine, amphetamine, metoclopramide, sulpiride, pimozide, oral contraceptive agents

Central nervous system (CNS) lesions
- Pituitary adenoma, empty sella, hypothalamic tumor, head trauma

Medical conditions
- Chronic renal failure, sarcoidosis, Schüller-Christian disease
- Cushing's disease, hepatic cirrhosis, hypothyroidism

Chest wall lesions
- Thoracotomy, herpes zoster

Reproduced, with permission, from Hindle WH. *Breast Disease for Gynecologists*. New York, NY: Appleton & Lange; 1990.

Pathologic nipple discharge is usually unilateral, spontaneous serous or serosanguineous from a single duct and is usually caused by an intraductal papilloma or, more infrequently, by an intraductal malignancy. In either case, a palpable mass may not be present. The involved duct may be identified by pressure at different sites around the nipple at the margin of the areola. Bloody discharge is more suggestive of cancer but is usually caused by a benign papilloma in the duct. Cytologic examination is rarely helpful because negative findings do not rule out cancer, which is more likely in women older than age 50 years. Imaging modalities such as mammography and/or ultrasonography may reveal underlying abnormalities in the duct. Ductography can be used to delineate an intraductal filling defect, which may be causing the nipple discharge.

Treatment

In any case, surgical excision of the involved duct should be performed once the workup has ruled out additional breast findings that need to be addressed.

Purulent discharge can originate in a subareolar abscess and may require excision of the abscess and related lactiferous sinus.

FAT NECROSIS

Fat necrosis is a benign condition of the breast but is of clinical importance because it produces a mass, often accompanied by skin or nipple retraction, that is clinically indistinguishable from carcinoma. Trauma and surgery are the presumed etiology, although only about half of patients recall a history of injury to the breast. Ecchymosis is occasionally observed in conjunction with the mass. Tenderness may or may not be present. If untreated, the mass associated with fat necrosis gradually disappears. Should the mass not resolve after several weeks, a biopsy should be considered. Once the diagnosis is established, surgical excision is usually not necessary.

BREAST ABSCESS

During lactation and nursing, an area of redness, tenderness, and induration may develop in the breast. In its early stages, the infection can often be resolved while continuing nursing with the affected breast and administering an antibiotic. If the lesion progresses to form a palpable mass with local and systemic signs of infection, an abscess has developed and needs to be drained. Even in this setting breastfeeding or pumping can help in controlling the pain and discomfort associated with the infection as well as shorten the duration of the infection.

Less frequently, a subareolar abscess may develop in young or middle-age women who are not lactating. These infections tend to recur after simple incision and drainage unless the area is explored in a quiescent interval with excision of the involved lactiferous duct or ducts at the base of the nipple. Except for the subareolar type of abscess, infection in the breast is very rare unless the patient is lactating.

If a patient with a suspected breast infection does not respond to treatment, inflammatory breast cancer should be suspected especially when associated with axillary lymphadenopathy.

MALFORMATION OF THE BREAST

Many women consult their physicians for abnormalities in either the size or the symmetry of their breasts. Difference in size between the 2 breasts is common. If extreme, however, these differences may be corrected by cosmetic surgery, although the breast tissue in these individuals is otherwise normal.

Similarly, woman may complain of overly large breasts (macromastia). Studies fail to show any endocrinologic or pathologic abnormalities, and these patients may also be considered candidates for cosmetic surgery such as breast-reduction mammoplasty.

Less common malformations of the breast include amastia, complete absence of 1 or both breasts, or the presence of accessory nipples (polythelia) and breast tissue (polymastia) along the embryologic milk line, which occurs in 1–2% of whites.

PUERPERAL MASTITIS

See Chapter 10.

CARCINOMA OF THE FEMALE BREAST

ESSENTIALS OF DIAGNOSIS

- Early findings: Single, nontender, firm to hard mass with ill-defined margins; mammographic abnormalities and no palpable mass.
- Later findings: Skin or nipple retraction; axillary lymphadenopathy; breast enlargement, redness, edema, brawny induration, peau d'orange, pain, fixation of mass to skin or chest wall.
- Late findings: Ulceration; supraclavicular lymphadenopathy; edema of arm; bone, lung, liver, brain, or other distant metastases.

General Considerations

Cancer of the breast is the most common cancer in women, excluding nonmelanoma skin cancers. After lung cancer, it is the second most common cause of cancer death for women. The American Cancer Society estimates that over 210,000 new cases of cancer of the breast will be diagnosed in 2010, resulting in over 40,000 deaths. These figures include male breast cancer, which accounts for less than 1% of annual breast cancer incidence. The yearly breast cancer incidence has steadily decreased from 1999 to 2006. Similarly, the mortality from breast cancer has been decreasing since 1975, which is attributed to better screening and advances in treatment modalities. On average, the breast cancer death rate decreased by 2.3% per year from 1990 to 2001. The probability of developing the disease increases throughout life. The mean and median age of women with breast cancer is 60–61 years, and breast cancer is the main cause of death for women between the ages of 40 and 59.

At the present rate of incidence, a woman's risk of developing invasive breast cancer in her lifetime from *birth* to *death* is 1 in 8. This figure is from the Surveillance, Epidemiology, and End Results Program (SEER) of the National Cancer Institute (NCI) and is often cited but needs clarification. The data include all age groups in 5-year intervals with an open-ended interval at 85 years and above. When calculating risk, each age interval is weighted to account for the increasing risk of breast cancer with increasing age. A woman's risk of being diagnosed with invasive breast cancer by age is as follows:

- By age 30: 1 in 2000
- By age 40: 1 in 233
- By age 50: 1 in 53
- By age 60: 1 in 22
- By age 70: 1 in 13
- By age 80: 1 in 9
- In a lifetime: 1 in 8

In the United States, breast cancer is the most common cancer among women of all ethnic groups, although the incidence of the disease is highest among white patients. In general, rates reported from developing countries are lower than those reported from developed countries, with the notable exception of Japan. Some of the variability may be a result of underreporting, but lifestyle, sociodemographic, and environmental factors such as diet, exercise, parity, breastfeeding, and body weight are implicated as possible causes for this observed difference.

Women with a family history of breast cancer are more likely to develop the disease than controls. The risk of being diagnosed with breast cancer for a patient with 1 affected first-degree relative (mother or sister) is increased by almost 2-fold. With 2 affected first-degree relatives, the increased risk is almost 3-fold. The risk is even higher if those relatives were diagnosed at a young age. A family history of breast cancer is, however, only reported by 15–20% of patients with breast cancer. Inherited specific genetic mutations that predispose patients to breast cancer such as, BRCA1 and BRCA2 gene mutations, are rare, accounting for approximately 5% of all breast cancers. BRCA mutations place affected women at a significantly increased lifetime risk, up to a 70%, of being diagnosed with breast cancer.

Nulliparous women and women whose first full-term pregnancy was after age 30 years have a slightly higher incidence of breast cancer than multiparous women. Late menarche and artificial menopause are associated with a lower incidence of breast cancer, whereas early menarche (before age 12 years) and late natural menopause (after age 50 years) are associated with a slight increase in risk of developing breast cancer. The bulk of the currently available evidence supports a causal relationship between the use of postmenopausal combination hormone therapy and breast cancer, predominantly hormone receptor–positive breast cancer. On the other hand, a clear association has not been consistently established between oral contraceptive use and the risk of breast cancer.

Fibrocystic changes of the breast and other nonproliferative breast lesions are not associated with an increased risk of breast cancer. However, the presence of multiple nonproliferative lesions and the presence of proliferative changes, especially those associated with cytologic atypia, are associated with an increased incidence of cancer. Correspondingly, a personal history of breast cancer is the greatest risk factor for subsequent breast cancer events. In addition, a woman who has had cancer in 1 breast is at increased risk of not only a recurrence but also of a second primary in the ipsilateral breast, as well as in the contralateral breast. Women with cancer of the uterine corpus have a breast cancer risk significantly higher than that of the general population, and women with breast cancer have a comparably increased risk of endometrial cancer.

Women who are at greater-than-normal risk of developing breast cancer should be identified by their physicians and followed carefully. Screening programs involve periodic physical examination and screening mammography; screening magnetic resonance imaging of the breasts for those asymptomatic patients at highest risk may increase the detection rate of breast cancer and may improve the survival rate, although this has not yet been demonstrated. Unfortunately, more than 50% of women who develop breast cancer do not have significant identifiable risk factors.

Staging

The physical examination of the breast and additional pre-operative studies are used to determine the clinical stage of a breast cancer. Clinical staging is based on the TNM (tumor, node, metastasis) system of the International Union Against Cancer. This classification considers tumor size, clinical assessment of axillary nodes, and the presence or absence of distant metastases. The assessment of the clinical stage is important in planning therapy. Histologic (or pathologic) staging is determined following surgery and along with clinical staging helps determine prognosis.

Clinical Findings

The majority of patients with breast cancer are diagnosed as a result of an abnormal mammogram and less often because of a palpable mass. The initial evaluation should include assessment of the local lesion, including a bilateral mammogram, if not previously performed, and breast ultrasound as indicated. The initial workup should include laboratory tests such as a complete blood count, liver function tests, and alkaline phosphatase. The search for distant spread should only be reserved for locally advanced breast cancers or if signs/symptoms of distant spread are present.

A. Symptoms

When the history is taken, special note should be made of the onset and duration of menarche, pregnancies, parity, artificial or natural menopause, date of last menstrual period, previous breast lesions and/or biopsies, hormonal supplementation, radiation exposure, and a family history of breast cancer. Back or other bone pain may be the result of osseous metastases. Systemic complaints or weight loss should raise the question of metastases, which may involve any organ but most frequently involve the bones, liver, and lungs. The more advanced the cancer in terms of aggressive histologic features, size of primary lesion, local invasion, and extent of regional node involvement, the higher is the incidence of metastatic spread to distant sites. Lymph node involvement is the single most significant prognostic feature and increases with increasing tumor size and aggressive histologic features such as pathologic grade.

Most patients with palpable breast cancers present with painless masses in the breast, most of which are discovered by the patient herself. Less frequent symptoms are breast pain; nipple discharge; erosion, retraction, enlargement, or itching of the nipple; and redness, generalized hardness, enlargement, or shrinking of the breast. Rarely, an axillary mass, swelling of the arm, or bone pain (from metastases) may be the first symptoms. Because of organized screening programs, fewer than 10% of breast cancers are detected solely on physical examination, and more than 90% are detected as a result of an abnormal mammogram

B. Signs

Inspection of the breast is the first step in physical examination and should be carried out with the patient sitting, arms at sides and then overhead. Abnormal variations in breast size and contour, minimal nipple retraction, and slight edema, redness, or retraction of the skin can be identified. Asymmetry of the breasts and retraction or dimpling of the skin can often be accentuated by having the patient raise her arms overhead or press her hands on her hips in order to contract the pectoralis muscles. Axillary and supraclavicular areas should be thoroughly palpated for enlarged nodes with the patient sitting (Fig. 5–4). Palpation of the breast for masses or other changes should be performed with the patient both seated and supine with the arm abducted (Fig. 5–5).

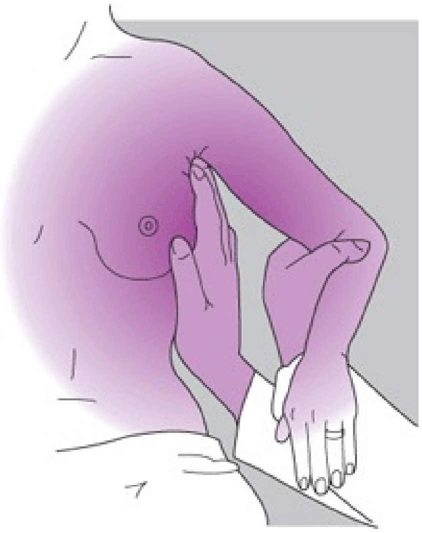


Figure 5–4. Palpation of axillary region for enlarged lymph nodes.

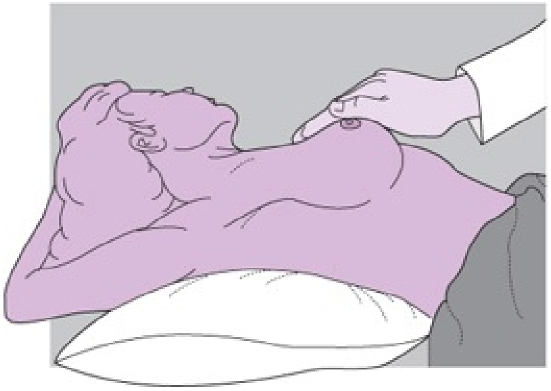

Figure 5–5. Palpation of breasts. Palpation is performed with the patient supine and the arm abducted.

Breast cancer usually consists of a nontender, firm or hard lump with poorly delineated margins generally caused by local infiltration. Slight skin or nipple retraction is an important sign as it may affect staging. Minimal asymmetry of the breast may be noted. Very small (1–2-mm) erosions of the nipple epithelium may be the only manifestation of Paget’s carcinoma. Watery, serous, or bloody discharge from the nipple is an occasional early sign but is more often associated with benign disease, as discussed earlier.

A lesion smaller than 1 cm in diameter may be difficult or impossible for a clinical examiner to feel and yet may be discovered by the patient's self-examination. During the premenstrual phase of the cycle, increased innocuous nodularity may suggest neoplasm or may obscure an underlying lesion. If there is any question regarding the nature of an abnormality under these circumstances, the patient should be asked to return after her period.

The following are characteristic of advanced carcinoma: edema, redness, nodularity, or ulceration of the skin; the presence of a large primary tumor (>5 cm); fixation to the chest wall; enlargement, shrinkage, or retraction of the breast; marked axillary lymphadenopathy; edema of the ipsilateral arm; supraclavicular lymphadenopathy; and distant metastases.

Most frequently, metastases initially tend to involve regional lymph nodes first, which may be clinically palpable, before spreading to distant sites. The axillary lymph nodes receive more than 85% of the lymphatic drainage from the breast. One or 2 movable, nontender, not particularly firm axillary lymph nodes 5 mm or less in diameter are frequently present and are generally of no clinical significance. Any firm or hard nodes larger than 5 mm in diameter are highly suspicious for nodal metastases. Axillary nodes that are matted or fixed to skin or deep structures indicate locally advanced disease (at least stage III). Histologic studies show that microscopic metastases are present in approximately 40% of patients with clinically negative nodes. Conversely, if the examiner believes that the axillary nodes are involved, this is confirmed in approximately 85% of cases on pathologic examination. The incidence of positive axillary nodes increases with the size of the primary tumor, the degree of local invasiveness of the neoplasm, and certain aggressive histologic features such as tumor grade.

Usually no nodes are palpable in the supraclavicular fossa. Firm or hard nodes of any size in this location or just beneath the clavicle (infraclavicular nodes) are indicative of locally advanced disease and suggest the strong possibility of distant metastatic sites of cancer. Biopsy or fine-needle aspiration to confirm nodal involvement in these areas is paramount. Ipsilateral supraclavicular nodes containing cancer indicate that the patient is in an advanced stage of the disease (stage IIIC). Edema of the ipsilateral arm, commonly caused by metastatic infiltration of regional lymphatics, is also a sign of advanced cancer.

C. Special Clinical Forms of Breast Carcinoma

1. Paget's disease of the breast—Paget's disease of the breast refers to the eczematoid eruption and ulceration that arises from the nipple, can spread to the areola, and is associated with an underlying carcinoma. An underlying mass is palpable in about 50% of patients with Paget's disease. Of these masses, 95% are found to be an invasive cancer, mostly infiltrating ductal. For patients with Paget's disease and no underlying palpable mass, a noninvasive breast cancer or ductal carcinoma in situ is found in 75% of cases. Pain, itching, and/or burning are often the presenting symptoms, along with a superficial erosion or ulceration. Less frequently, a bloody discharge and nipple retraction are observed. The diagnosis is established most often by full-thickness biopsy of the lesion, which reveals the pathognomonic intraepithelial adenocarcinoma cells or Paget cells within the epidermis of the nipple. In 12–15% of patients with Paget's disease of the breast, no associated underlying intraparenchymal breast cancer is found.

Paget's disease is uncommon, accounting for approximately 1% of all breast cancers. It is frequently misdiagnosed and treated as dermatitis or bacterial infection, leading to an unfortunate delay in detection. Mastectomy has traditionally been the mainstay of therapy, although breast conservation followed by whole breast radiation can be attempted if nipple, areola, and wide local excision of the palpable mass or area of mammographic abnormality can be performed with an acceptable cosmetic result and negative margins. As for other forms of breast cancer, patients with only in situ disease need not have axillary evaluation, which is reserved for patients with an underlying palpable mass/invasive carcinoma or if a mastectomy is planned.

2. Inflammatory carcinoma—Inflammatory carcinoma is an aggressive form of breast cancer that is characterized by diffuse, brawny edema of the skin of the breast with an erysipeloid border, usually without an underlying palpable mass. Generally, this is a clinical diagnosis with pathologic confirmation of tumor embolization in the dermal lymphatics by biopsy of the overlying skin and should not be confused with noninflammatory locally advanced breast cancer. Inflammatory breast cancer is an aggressive but rare form of breast cancer representing less than 5% of cases. At presentation, nearly 35% of patients with inflammatory breast cancer have evidence of metastases. The inflammatory component, often mistaken for an infectious process, is caused by the blockage of dermal lymphatics by tumor emboli, which results in lymphedema and hyperemia. If a suspected skin infection does not rapidly respond (1–2 weeks) to a course of antibiotics, biopsy must be performed. Treatment usually consists of several cycles of neoadjuvant chemotherapy followed by surgery and/or radiotherapy depending on tumor response. A modified radical mastectomy is usually recommended for locoregional control as long as a complete resection of the tumor can be accomplished.

3. Occurrence during pregnancy or lactation—Pregnancy-associated breast cancer is defined as breast cancer that is diagnosed during pregnancy, in the first postpartum year, or anytime during lactation. The frequency of breast cancer during pregnancy or lactation ranges between 1:3000 and 1:10,000. The association of pregnancy and breast cancer presents a diagnostic and therapeutic dilemma for the patient and the physician. Women with breast cancer diagnosed during pregnancy or lactation tend to present at a later stage due in part to diagnostic delays. In the past, pregnancy-associated breast cancer was thought to lead to a worse outcome for the patient. More recent studies, however, have reported similar outcomes for women with breast cancer diagnosed during pregnancy and lactation when compared with nonpregnant breast cancer patients after controlling for stage, age, and other prognostic factors. Termination of the pregnancy, formerly performed routinely in the first two trimesters, has not been demonstrated to improve outcome. In most instances, modified radical mastectomy in pregnancy is the minimal treatment of choice, with the possible exception of the latter part of the third trimester, wherein breast-conservation therapy followed by postpartum radiotherapy may be considered. Most women with breast cancer diagnosed during pregnancy or lactation will be candidates for systemic chemotherapy. In general, the risk of fetal teratogenicity is highest during the first trimester and period of organogenesis. In the second or third trimester, chemotherapy is associated with a much lower risk or fetal toxicity but has been significantly linked to an increased risk of prematurity and growth retardation. In general, antimetabolites such as methotrexate, targeted antibodies such as trastuzumab, taxanes, and endocrine therapy should be avoided during pregnancy. Delivery of the infant should be delayed for a few weeks after the last dose of chemotherapy in order to minimize the risk of neutropenia in the fetus and infectious complication. The use of radiotherapy during pregnancy is contraindicated because of the potential for fetal damage. The decision to proceed with pregnancy termination should be individualized and based on the willingness of the patient to accept the potential teratogenic risk incurred by her breast cancer therapy.

4. Bilateral breast cancer—Clinically evident simultaneous bilateral breast cancer occurs in less than 1% of cases, but there is a 5–8% incidence of later occurrence of cancer in the second breast. Bilaterality occurs more often in women younger than age 50 years and is more frequently associated with a lobular carcinoma and in patients with hereditary breast cancer syndromes such as Li-Fraumeni syndrome. The incidence of second breast cancers increases directly with the length of time the patient is alive after her first cancer and is approximately 1.0% per year and is significantly higher in patients with hereditary breast cancer syndromes.

In patients with breast cancer, careful screening of the contralateral breast at the time of initial diagnosis and at regular intervals thereafter is warranted. Routine biopsy of the opposite breast is usually not indicated.

D. Mammography

Mammography is the breast imaging modality of choice and the only screening method that has been consistently found to decrease mortality of breast cancer. Some breast cancers can be identified by mammography as early as 2 years before reaching a size detectable by palpation.

Although false-positive and false-negative results are occasionally obtained with mammography, the experienced radiologist can interpret mammograms correctly in approximately 90% of cases. Ultrasound and magnetic resonance imaging (MRI) are not recommended for screening the general population, and their primary role is as adjuncts to an abnormal mammogram. For women at high risk for developing breast cancer, the addition of MRI and ultrasound to screening mammograms may be contemplated.

Because up to 15% of cancers that are detected on clinical exams are not seen on mammograms, a negative mammogram should preclude further intervention in patients with a dominant or suspicious mass. The use of a targeted ultrasound can help decrease the false-negative rate of mammograms and evaluate the mammographically occult palpable breast mass.

E. Cytology

Cytologic examination of nipple discharge or cyst fluid may be helpful on rare occasions. As a rule, mammography and breast biopsy are required when nipple discharge or cyst fluid is bloody or cytologically equivocal.

F. Biopsy

The diagnosis of breast cancer depends ultimately on examination of tissue removed by biopsy. Treatment should never be undertaken without an unequivocal histologic diagnosis of cancer. The safest course is biopsy examination of all suspicious masses found on physical examination and, in the absence of a mass, of suspicious lesions demonstrated by mammography. Approximately 30% of lesions thought to be definitely cancer prove on biopsy to be benign, and approximately 15% of lesions believed to be benign are found to be malignant. These findings demonstrate the fallibility of clinical judgment and the necessity for biopsy.

The simplest method is by fine-needle aspiration (FNA). This method is, however, limited by its inability to distinguish invasive from noninvasive breast cancers and the relatively high rate of nondiagnostic studies, especially for nonpalpable abnormalities and with less experienced practitioners.

In many centers, core needle biopsies, most often with image guidance, have replaced open surgical biopsies. Core needle biopsies offer the advantage of a more definitive histologic diagnosis, minimize the risk of inadequate samples, and allow the distinction between invasive and noninvasive breast cancers. Open surgical biopsies, often with wire localization, should be reserved for those lesions that are technically unattainable with core needle biopsies or in the event of core needle biopsy results that do not correlate with the imaging findings (discordant results).

In general, outpatient biopsy followed by definitive surgery at a later date gives patients time to adjust to the diagnosis of cancer, meet with members of the multidisciplinary team involved with managing breast cancer, and consider a second opinion as well as alternative forms of treatment. Studies show no adverse effects from the short (1–2 weeks) delay of the 2-step procedure, and this is the current recommendation of the NCI.

At the time of the initial biopsy of breast cancer, the specimen can also be analyzed with immunohistochemical staining for hormone and growth factor (eg, HER-2-Neu) receptors. Tumor analysis using reverse transcriptase polymerase chain reaction (RT-PCR) technology from pathologic specimens to assess the tumor recurrence risk is now available. Such tests can aid the patient and physician in the decision for further adjuvant therapy or not. At the time of pathologic confirmation of a breast cancer diagnosis, patients on hormone replacement therapy (HRT) should be instructed to stop hormone use until counseled by an oncologist.

G. Laboratory Findings

A complete blood cell count (CBC), chemistry panel including liver function tests (LFTs), and a β-human chorionic gonadotropin (β-hCG) in premenopausal patients should be obtained as part of the initial evaluation. An elevation in alkaline phosphatase or liver function may be an indication of distant metastatic disease and warrants further investigation. Hypercalcemia may be seen in advanced cases of metastatic cancer.

H. Imaging Studies

Most systematic reviews have concluded that the routine radiologic evaluation for metastatic disease is unnecessary in the majority of patients since the overall yield is low. In general, the prevalence of metastatic disease increases with the clinical stage of the disease. The Cancer Care Ontario Practice Guidelines Initiative recommends against routine staging for clinical stage I disease, whereas they recommend routine staging in patients with stage III disease and radio-nuclide bone scanning in patients with stage II disease. In general, imaging studies should be limited to patients with higher pretest probability of distant metastases, such as those with signs, symptoms, or laboratory abnormalities suggestive of distant metastases and those with locally advanced breast cancer.

The imaging modality of choice has not been standardized, although computed tomography (CT) scanning of chest, abdomen, and pelvis offers a more sensitive and attractive 1-visit option at the price of a higher risk of false-positive results, cost, and radiation exposure. In addition, evaluation for skeletal metastases with radionuclide bone scans would still be required.

The combination of positron emission tomography (PET) and CT scans is a promising tool in the staging and metastatic evaluation of breast cancer because it allows for the evaluation of visceral and bony metastases. However, data regarding its routine use in the metastatic workup of patients with breast cancer are lacking.

The American Society of Clinical Oncology has found that there is insufficient evidence to support the routine use of tumor markers such as CA 15-3, CA 27.29, and carcinoembryonic antigen (CEA). In general, assessment of myocardial function should be reserved for patients at high risk of cardiotoxicity (age >65 years or underlying heart disease) prior to initiating treatment with anthracyclines and in all patients scheduled to receive trastuzumab.

Early Detection

A. Screening Programs

Mammography remains the single best screening procedure for the early detection of breast cancer.

The majority of breast cancers in the United States are detected as a result of an abnormal screening study. In general, depending on a woman's age and the density of her breasts, the sensitivity of mammography is 70–90%, and its specificity is greater than 90%. Yearly mammogram screening among women continues to increase, so that in 1997, roughly 85% of women had had a mammogram at least once previously. This was an increase of 15% from 1990 and of 47% from 1987. In 2008, the proportion of US women age 50–74 years who reported that they had a screening mammogram in the preceding 2 years was 81.1%. Lack of insurance coverage and lower socioeconomic status were associated with significantly lower prevalence of up-to-date mammography.

Despite a consensus on the importance of mammographic screening, mammography has still not been demonstrated unequivocally to decrease breast cancer mortality across all age groups. In women between 50 and 69 years of age, there is reasonable evidence, based largely on 8 randomized controlled trials, that screening mammography is beneficial. In elderly patients over the age of 70 years, however, the optimal frequency of screening is still unknown because they have not generally been included in most large cooperative screening trials and because of their limited life expectancy, which can affect gains in breast mortality. For younger women, the evidence is also not entirely clear. For women age 40–49 years, there appears to be a small benefit, which comes at the price of a higher number of patients in that age group who need to be screened. These results may be due to the lower prevalence of the disease and decreased sensitivity of mammograms in this age group as well as the possibility that younger women have faster growing tumors, which may be more readily missed at one screening and become clinically apparent before the subsequent screening. Nevertheless, in the Health Insurance Plan of Greater New York screening study from the United States, which with 18 years has the longest follow-up of any randomized mammography screening study, there was a 30% reduction in mortality in women older than 50 years of age. Despite academic debate and challenges and controversy in the news media, the consensus that screening mammography saves lives has been upheld.

Current screening recommendations from the American College of Radiology, the American Cancer Society, and the American Medical Association call for annual mammograms starting at age 40 years. The American College of Obstetricians and Gynecologists calls for screening mammography every 1–2 years for women age 40–49 and annually thereafter. There is no recommendation for a "baseline" examination prior to age 40 years, nor is there any evidence to support this practice in women younger than this age. Women with a genetic predisposition to breast cancer should be screened using a combination of screening mammography and MRI beginning at age 25 or based on the age of earliest onset breast cancer in the family. For women with a family history of breast cancer but without a genetic mutation, some authorities have suggested initiating screening with mammography before age 40, although data from randomized controlled trials on the efficacy of this approach is lacking.

B. Breast Examination

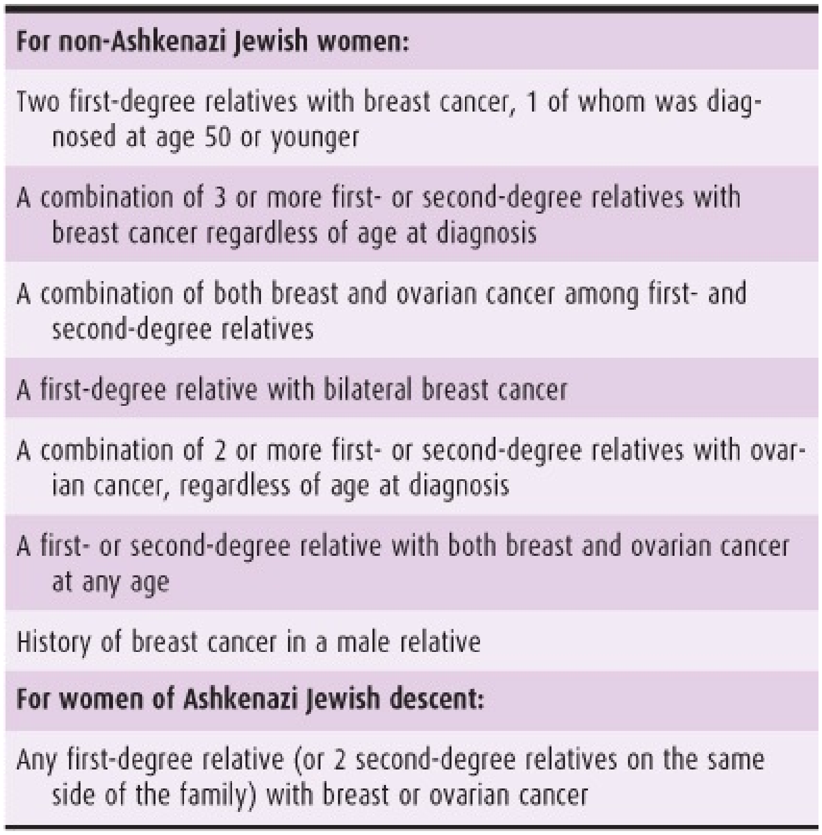
Even though several randomized controlled trials included clinical breast examination with mammography, the utility of clinical breast exams remains debatable. From these studies, it appears that mammography detected approximately 90% of breast cancers and clinical breast exams detected approximately 50% with significant but not total overlap. A recent review of the literature concluded that the effectiveness of clinical breast examination has yet to be proven. It also appears that sensitivity of clinical breast examination in the community setting is lower than that reported in the randomized trials due to a lack of standardization and procedural and examiner variability. Clinical breast examination remains an attractive and useful option in developing countries where screening mammography programs are prohibitively expensive, in the event of mammographically occult breast cancer, and in older women who are no longer being screened regularly.

The few randomized controlled trials that have examined breast self-examination have similarly failed to show a benefit in the rates of breast cancer diagnosis and mortality, suggesting that breast self-examination only be offered as an adjunct to regular screening and patients be educated about its limitations.

C. Genetic Testing

A positive family history of breast cancer is recognized as a risk factor for the subsequent development of breast cancer. With the discovery of 2 major breast cancer predisposition genes, BRCA1 (17q21) and BRCA2 (13q12-13), there has been increasing interest in genetic testing. Mutations in these 2 genes are associated with an elevated risk for breast cancer, as well as ovarian, colon, prostate, and pancreatic cancers. Of all women with breast cancer, approximately 5–10% may have mutations in BRCA1 or BRCA2. The estimated risk of a patient developing cancer with a BRCA1 or BRCA2 mutation is believed to be between 40% and 85%. Particular mutations may be more common in specific ethnic groups like the Ashkenazi Jewish population. Genetic testing is available and may be considered for members of high-risk families. The US Preventive Task Force, Kaiser Permanente, and the National Cancer Center Network have developed BRCA testing guidelines (Table 5–2). Because of the complexities of genetic testing, genetic counseling before and after testing is necessary.

Table 5–2. Recommendations from the US Preventive Services Task Force on who should be offered genetic testing for BRCA mutations.

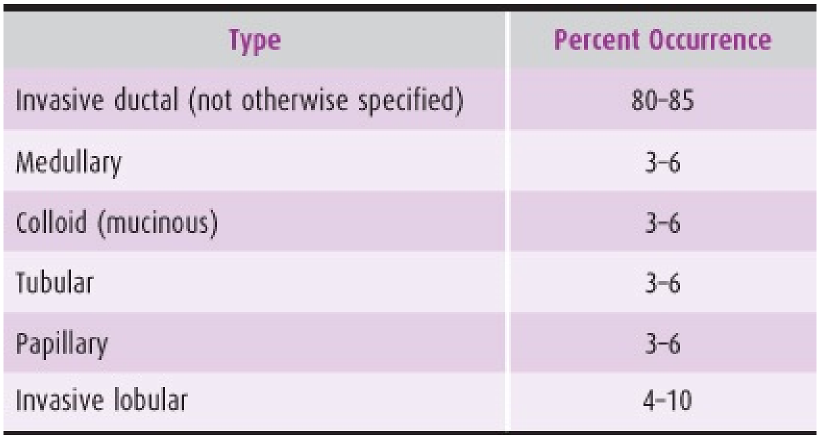


For non-Ashkenazi Jewish women:
Two first-degree relatives with breast cancer, 1 of whom was diagnosed at age 50 or younger
A combination of 3 or more first- or second-degree relatives with breast cancer regardless of age at diagnosis
A combination of both breast and ovarian cancer among first- and second-degree relatives
A first-degree relative with bilateral breast cancer
A combination of 2 or more first- or second-degree relatives with ovarian cancer, regardless of age at diagnosis
A first- or second-degree relative with both breast and ovarian cancer at any age
History of breast cancer in a male relative
For women of Ashkenazi Jewish descent:
Any first-degree relative (or 2 second-degree relatives on the same side of the family) with breast or ovarian cancer

Pathologic Types

Numerous pathologic subtypes of breast cancer can be identified histologically (Table 5–3). More than 95% of breast malignancies arise from the epithelial elements of the breast. These pathologic types are distinguished by the histologic appearance and growth pattern of the tumor. In general, breast cancer arises either from the epithelial lining of the large or intermediate-sized ducts (ductal) or from the epithelium of the terminal ducts of the lobules (lobular). The cancer may be invasive or in situ. Most breast cancers arise from the intermediate ducts and are invasive (invasive ductal or infiltrating ductal), and most histologic types are merely subtypes of invasive ductal cancer with unusual growth patterns (colloid, medullary, tubular, etc).

Table 5–3. Histologic types of breast cancer.



Type	Percent Occurrence
Invasive ductal (not otherwise specified)	80–85
Medullary	3–6
Colloid (mucinous)	3–6
Tubular	3–6
Papillary	3–6
Invasive lobular	4–10

The histologic subtypes have only slight bearing on prognosis when outcomes are compared after accurate staging. Colloid (mucinous), medullary, papillary, adenoid cystic, and tubular histologies are generally believed to have a more favorable prognosis. Other histologic criteria have been studied in an attempt to substratify patients based on features such as tumor differentiation, lymphovascular space invasion, and tumor necrosis. Although these characteristics are important, stage is predominant and paramount in predicting outcome.

The noninvasive cancers by definition lack the ability to spread. However, in patients whose biopsies show noninvasive intraductal cancer, associated invasive ductal cancers are present in 1–3% of cases. Lobular carcinoma in situ is considered by some to be a premalignant lesion that by itself is not a true cancer. It lacks the ability to spread but is associated with the subsequent development of invasive ductal cancer in 25–30% of cases within 15 years.

Hormone Receptor Sites

The presence or absence of estrogen and/or progesterone receptors in the nucleus of tumor cells is of critical importance in managing patients with initial, recurrent, and metastatic disease. Both estrogen receptors (ERs) and progesterone receptors (PRs) are nuclear hormone receptors. After binding their respective hormones in the cytoplasm of the target cell, the DNA-binding sites on the receptor are unmasked, and the activated complex migrates into the nucleus in order to bind to their respective hormone-responsive DNA elements. The responsiveness of breast cancer to hormonal therapy is best predicted by tumor expression of the ER and/or PR, and ER/PR-negative tumors are unlikely to benefit from endocrine therapy and would be better treated with systemic chemotherapy. Conversely, the magnitude of benefit from adjuvant endocrine therapy is directly related to the amount of ER.

ERs may be of prognostic significance, but current evidence is still unclear. For small node-negative tumors, the presence of ER is associated with lower likelihood of recurrence at 5 years when compared to ER-poor tumors. With longer follow-up, however, this initial advantage disappears primarily due to late recurrences. ER positivity is associated with a number of prognostic indicators, such as tumor grade and ploidy, but not with nodal metastases, and ER-positive tumors are more likely to metastasize to bone, soft tissue, and genital organs than are ER-negative tumors, which are more likely to spread to the liver, lung, and brain.

The Oxford Overview conducted by the Early Breast Cancer Trialists' Collaborative Group analyzed the data on each woman randomized to all trials of the treatment of operable breast cancer. In their last round of analysis published in 2005, the group showed that treatment with 5 years of tamoxifen when compared to no adjuvant endocrine therapy was associated with a 41% reduction in the annual risk of relapse and a 34% reduction in the annual death rate for women with ER-positive breast cancer.

It is advisable to obtain an ER assay for every breast cancer at the time of initial diagnosis. Receptor status may change after hormonal therapy, radiotherapy, or chemotherapy. The specimen requires special handling, and the laboratory should be prepared to process the specimen correctly.

HER2 & Response to Therapy

The HER2 gene encodes for a transmembrane glycoprotein that belongs to the epidermal growth factor receptor (EGFR) family of receptors, which play a key role in signal transduction controlling growth, differentiation, and possibly angiogenesis. Overexpression of the glycoprotein and/or amplification of its encoding gene is noted in 18–20% of breast cancer patients. HER2 overexpression/amplification is associated with an increased risk of recurrence and breast cancer death in the absence of systemic/targeted therapy and is also associated with resistance to endocrine therapy. However, HER2 overexpression/overamplification helps identify patients who benefit from the addition of agents that target the protein such as trastuzumab, a humanized monoclonal mouse antibody that binds the HER2 protein, and lapatinib, an oral tyrosine kinase inhibitor that blocks HER2. At least 4 large randomized controlled trials have shown that the addition of 1 year of trastuzumab to adjuvant therapy in patients with HER2-positive breast cancer significantly improves their disease-free and overall survival.

Curative Treatment

All oncologic treatment may be classified as curative or palliative. Curative treatment intent is advised for early-stage and locally advanced disease (clinical stages I to IIIC disease). Treatment intent is palliative for patients with stage IV disease and for previously treated patients who develop distant metastases or unresectable local recurrence.

A. Therapeutic Options

1. Radical mastectomy—Historically, Halsted is credited with performing the first modern radical mastectomy in 1882 in the United States. This surgical procedure was the en bloc removal of the breast, pectoral muscles, and axillary lymph nodes. It was the standard surgical procedure performed for breast cancer in the United States from the turn of the 20th century until the 1950s. During the 1950s, emerging information about lymph node drainage patterns prompted surgeons to undertake the extended radical mastectomy, which is a radical mastectomy and the removal of the internal mammary lymph nodes. It was postulated that a more extensive dissection of the draining lymphatics would improve control rates and translate into improved survival. A randomized trial, however, proved no benefit to the extended radical mastectomy versus the radical mastectomy, and the former was abandoned. Moreover, the failure of the extended radical mastectomy underscored the complications and morbidity of breast cancer surgery. This morbidity coupled with inadequate disease control led surgeons to explore less invasive and disfiguring techniques. Currently, radical mastectomy is rarely indicated or performed. Even in settings where radical resection may be entertained, such as invasion of the pectoralis muscles or large tumors, less invasive surgery coupled with neoadjuvant chemotherapy is preferred.

2. Modified radical mastectomy—Replacing radical mastectomy, the modified radical mastectomy (MRM) is the removal of the breast and underlying pectoralis major fascia, but not the muscle, and evaluation of selected axillary lymph nodes. Variations of this procedure include sacrificing the pectoralis minor muscle or not, and retracting, splitting, or transecting the pectoralis major to access the apex of the axilla for dissection. Because it is less invasive and less disfiguring, MRM provides a better cosmetic and functional result than radical mastectomy. Two prospective randomized trials, single-institution data, and several retrospective studies all demonstrate no difference in disease-free or overall survival rates between radical mastectomy and MRM for early-stage breast cancer. Until the early 1980s and the emergence of breast-conservation therapy (BCT), MRM was the standard treatment available to women for early-stage cancer. For locally advanced breast cancer and when the patient is not a candidate for BCT, or if the patient is not motivated for breast conservation, MRM remains a valid treatment option. A total mastectomy (simple mastectomy) is the removal of the whole breast, like an MRM, without the axillary dissection.

3. Breast-conservation therapy—BCT involves a surgical procedure such as a lumpectomy—an excision of the tumor mass with a negative surgical margin—an axillary evaluation, and postoperative irradiation. Several other operations, more limited in the scope of surgical dissection than MRM, such as segmental mastectomy, partial mastectomy, and quadrantectomy, are also used in conjunction with radiation and are part of the surgical component of BCT. As a result of 6 prospective randomized trials that showed no significant difference in local relapse, distant metastases, or overall survival between conservative surgery with radiation and mastectomy, BCT has gained increasing acceptance as a treatment option for stage I and II and selected stage III breast cancers.

B. Choice of Local Therapy

Breast cancer is a multidisciplinary disease in which surgeons, medical and radiation oncologists, radiologists, pathologists, nurses, and psychosocial support staff all play fundamental roles. Working with the patient, this team recommends the most appropriate treatment strategy. Clinical and pathologic stage, as well as biologic aggressiveness, are the principal determinants guiding local therapy, treatment strategy, and, ultimately, outcome. For early-stage breast cancer, including node-positive cases, much of the decision for initial local therapy rests with the patient. MRM is always a valid choice for addressing the local treatment of breast cancer. A patient’s decision to undergo MRM does not necessarily obviate the role of radiation in the further management of breast cancer, and postmastectomy irradiation may still be recommended in approximately 20–25% of cases. To be a candidate for BCT, the patient must not be pregnant and cannot have multicentric breast cancer (evidence of cancer in >1 quadrant of the breast), locally advanced disease, diffuse microcalcifications on mammogram, or a prior history of ipsilateral breast irradiation. Relative contraindications are collagen-vascular disorders that could lead to a poor cosmetic outcome with irradiation and breast implants or psychiatric issues that would make close follow-up and surveillance difficult. These restrictions are only a portion of the decision-making process that must be completed before embarking on BCT.

Perhaps most importantly, the patient must be motivated and desire to maintain her breast in the face of a cancer diagnosis. This may entail some degree of physical, emotional, and psychological distress. For example, a patient may have to endure multiple re-excisions to obtain a negative surgical margin on the lumpectomy specimen. A patient may also experience resistance to BCT in areas where it is not commonly offered and where a multidisciplinary approach to breast cancer is not practiced. It has been shown that the surgical management of breast cancer differs considerably based on geographic location in the United States, independent of patient and tumor characteristics. Nevertheless, both physicians and patients pursue BCT because it allows the patient to preserve her breast without any decrement to survival, and the vast majority of women are pleased with the cosmetic result.

Because the treatment options for locally advanced and inflammatory breast cancers are in some ways less flexible than those for early-stage breast cancer, it is even more critical to engage the patient in the decision-making process for the choice of initial therapy. Many different strategies, which include mastectomy and less invasive surgeries, with or without neoadjuvant chemotherapy and adjuvant chemotherapy, radiation, and further maintenance interventions, are commonly used. In many settings, protocol therapy may be the most desirable treatment option.

Mastectomy

For about three-quarters of a century, radical mastectomy was considered standard therapy for breast cancer. The procedure was designed to remove the primary lesion, the breast in which it arose, the underlying muscle, and, by dissection in continuity, the axillary lymph nodes, which are most often the first site of regional spread beyond the breast. When radical mastectomy was introduced by Halsted, the average patient presented for treatment with locally advanced disease, and a relatively extensive procedure was often necessary just to remove all gross cancer. This is no longer the case. Patients now present with much smaller, less locally advanced lesions. Most of the patients in Halsted’s original series would now be considered incurable by surgery alone, because they had extensive involvement of the chest wall, skin, and supraclavicular regions. Since the 1960s, MRM has supplanted the radical mastectomy because of its comparable disease control and a substantial decrease in morbidity and disfiguration.

In many cases, adjuvant therapy after MRM (eg, radiation) can even further reduce the incidence of local recurrence in certain patients with unfavorable tumor characteristics. In addition, 3 recent randomized trials of postmastectomy radiation, which confirmed a local control advantage, demonstrated an overall survival benefit in certain subsets of both pre- and postmenopausal women. For patients with ≥4 positive lymph nodes or large tumors ≥5 cm in diameter, postmastectomy radiation is strongly recommended. The role of postmastectomy radiation in patients with 1–3 positive nodes is more controversial. However, with increasing duration of follow-up, there is emerging evidence in favor of postmastectomy radiation for patients with 1–3 positive lymph nodes. Therefore, when deciding on initial local therapy, a patient must keep in mind that choosing MRM does not necessarily exclude a recommendation for adjuvant radiation.

Breast-Conservation Therapy

Because studies comparing radical mastectomy and MRM demonstrated no decrement in local control or survival, radical mastectomy has given way to MRM. In the 1980s, 6 prospective randomized trials were conducted worldwide that showed no significant difference in locoregional relapse or overall survival between breast-conserving surgery and radiation versus MRM for early-stage invasive breast cancer. In addition, an overview analysis showed equivalent survival with BCT as compared to mastectomy. Two of these studies included patients with node-positive breast cancer. With the addition of radiation to breast-conserving surgery techniques such as lumpectomy with an axillary evaluation, local failure is reduced to rates comparable to MRM with no compromise to overall survival.

There are a few absolute contraindications to BCT, which are mainly related to increased rates of in-breast recurrences or preclusion of use of radiation. These include persistently positive surgical margins, multicentric disease present in more than 1 quadrant of the breast, diffuse malignant-appearing calcifications throughout the breast precluding adequate resection, history of prior radiation therapy to the breast, and pregnancy. Other relative contraindications include a history of scleroderma due to an increased risk of skin toxicity associated with radiation and the large size of the tumor relative to the size of the breast, resulting in an unacceptable cosmetic outcome. Factors that are not contraindications to breast conservation include nodal metastases, tumor location, tumor subtype, and a family history of breast cancer.

Unfortunately, no subgroup of patient with breast cancer undergoing breast conservation has a low enough risk of recurrence to justify the elimination of adjuvant therapy. Some investigators are currently examining alternative strategies of delivering radiotherapy such partial breast irradiation and shortened courses of whole breast radiation in select patients with node-negative disease.

Axillary Evaluation

It is important to recognize that axillary evaluation is valuable both in planning therapy and in staging of the cancer. Axillary lymph node dissection has long been the mainstay for axillary staging in the treatment of patients with breast cancer. Although the removal of even occult cancer in axillary lymph nodes generally does not translate into an improvement in overall survival rates, regional failures will be lower. Axillary lymph node dissection is generally safe but may result in nerve damage and lymphedema, especially in patients receiving postoperative radiotherapy. Because of the potential for major morbidity associated with the procedure and questions regarding any survival advantage it would offer, some investigators examined the use of sentinel lymph node biopsy (SLNB) as an alternative to formal axillary dissection for the pathologic assessment of the clinically negative axilla. This procedure uses a tracer material that is injected into the tumor bed to map the tumor drainage to the primary or “sentinel” axillary lymph node(s). The sentinel lymph node is excised and pathologically examined. If the sentinel lymph node is found to harbor metastatic disease, a subsequent formal dissection is done. Conversely, if the sentinel lymph node is negative, no further surgical evaluation need be performed. Although this procedure relies heavily on the surgeon’s expertise with a new technique and has some inherent limitations, when performed by an experienced team, a negative result carries a negative predictive value of 94–96%. Potential side effects and complications are minimized, and recovery is quick without sacrificing diagnostic or therapeutic results. A practical example of the benefits of SLNB is that, when used in conjunction with BCT, reported rates of lymphedema are lower than with axillary dissection.

Adjuvant Systemic Therapy

A. Hormonal Therapy

Adjuvant hormonal therapy or manipulation is recommended for all women whose breast cancer expresses hormone receptors. Even if the tumor does not express estrogen hormone receptor protein but only progesterone, hormonal therapy may be beneficial. This recommendation is made regardless of age, menopausal status, involvement or number of positive lymph nodes, or tumor size. The benefit of adjuvant hormonal therapy is seen across all subgroups of breast cancer patients, with both invasive and in situ lesions. Although the absolute decrease in recurrence, second primary breast cancer, and death may vary from group to group, there is a firmly established role for adjuvant hormonal intervention.

Until recently, 5 years of tamoxifen was considered to be the adjuvant hormonal therapy regimen of choice and remains a valuable option for both premenopausal and post-menopausal women with ER-positive tumors. Randomized trials support the 5-year duration, which is superior to shorter courses and does not expose the patient to the increased risk of adverse effects associated with longer use. Furthermore, use longer than 5 years does not appear to enhance the long-term benefit seen with just 5 years of use. Although tamoxifen carries an increased risk of endometrial cancer and venous thromboembolism, the benefits outweigh the risks for the vast number of patients. Surveillance screening procedures such as transvaginal ultrasound and endometrial biopsy are not necessary in asymptomatic patients on tamoxifen.

More recently, aromatase inhibitors (AI) such as anastrozole have been shown to be as effective if not more effective than tamoxifen in postmenopausal women with early-stage, invasive breast cancer. In fact, in at least 2 large trials, anastrozole and letrozole were found to be superior to tamoxifen in terms of disease-free survival, time to recurrence, and the incidence of contralateral breast cancer, although no significant difference in overall survival was seen. The toxicity profile of AIs is also different, making them useful for women who would like to avoid the tamoxifen-related side effects. Compared to tamoxifen, the use of AIs confers a smaller risk of endometrial cancer, venous thromboembolic events, and hot flashes. However, AIs are associated with a higher risk of musculoskeletal disorders, osteoporosis, and cardiac events when compared to tamoxifen. AIs are not typically used in premenopausal patients because the reduced estrogen feedback on the hypothalamus results in an increase in gonadotropin release, which paradoxically stimulates the ovary to produce more aromatase and androgen substrate.

B. Chemotherapy

Cytotoxic chemotherapy is commonly offered to women as adjuvant treatment for both early-stage and locally advanced breast cancer. The goal of adjuvant chemotherapy is to eliminate occult microscopic metastases that are often responsible for late recurrences. Cytotoxic chemotherapy offers benefits to the many early and the majority of locally advanced breast cancer patients, although the magnitude of benefit is more pronounced in premenopausal and node-positive patients. Cytotoxic chemotherapy is also considered by many to be the standard of care for patients with ER-negative tumors who are candidates for adjuvant systemic therapy because of adverse prognostic indicators such as tumor size >1 cm, positive lymph nodes, and high-grade disease.

The benefit of adding chemotherapy to endocrine therapy for patients with ER-positive tumors is more controversial, especially for patients with negative lymph nodes. The Oncotype DX 21-gene recurrence score assay is a potentially useful tool that could help predict patients with node-negative ER-positive tumors who have the lowest risk of distant recurrence, enough to justify elimination of chemotherapy.

Polychemotherapy (≥2 agents) is superior to single-agent chemotherapy. Duration for 3–6 months or 4–6 cycles appears to offer optimal benefit without subjecting the patient to undue toxicity associated with more prolonged treatment, which adds little benefit in terms of overall outcome. Cytotoxic chemotherapy with an anthracycline-based (doxorubicin or epirubicin) regimen is favored, because a small but statistically significant improvement in survival has been demonstrated compared with nonanthracycline-containing regimens. The cardiac toxicity caused by anthracyclines is not considered detrimental in women without significant cardiac disease but does occur in 1% of cases or less. Several trials have also demonstrated a survival advantage for regimens that include a taxane in addition to an anthracycline, particularly in node-positive tumors and other higher risk tumors. Alterations in dose schedule (eg, “dose-dense” regimens) also offer advantages over other combinations and administrations of chemotherapy for well-defined patient populations. As previously mentioned, several trials have shown that the addition of trastuzumab offers an overall and recurrence-free survival advantage in all but the most favorable HER2-positive tumors at the price of a small but significant increase in cardiac events, particularly for patients receiving an anthracycline-containing regimen. However, emerging data suggest the equivalence of taxane-based combinations with trastuzumab and those combinations containing anthracyclines with less cardiac toxicity. The choice of adjuvant chemotherapy is complex. The medical oncologist must consider multiple tumor and patient features and individualize treatment for breast cancer patients.

Several areas concerning chemotherapy have generated considerable interest but lack conclusive evidence. For instance, high-dose chemotherapy with bone marrow or stem cell rescue is not recommended. There is no evidence that high-dose regimens are superior to standard-dose polychemotherapy. Stem cell support or bone marrow transplant should be offered only on protocol. Further investigation is also needed to clarify the role of other biologic agents and dosing schedules. Trials need to enroll more patients older than age 70 years to assess the benefits and toxicities of adjuvant chemotherapy in this population. Finally, studies designed to measure quality of life need to be done to place the benefits versus toxicity question of adjuvant therapies into context.

The use of systemic therapy prior to surgery has become the mainstay of therapy for patients with locally advanced or inflammatory breast cancer but is increasingly being offered to patients with early-stage breast cancer to facilitate BCT instead of mastectomy.

Follow-Up Care

After primary treatment, breast cancer patients should be followed for life because of the long, insidious natural history of breast cancer. The goals of close breast cancer follow-up are to detect recurrences and second primaries after treatment in the ipsilateral breast and to detect new cancers in the contralateral breast. The risk of a second primary in the contralateral breast of a patient with a history of breast cancer is believed to be roughly 0.5–1% per year. Although there are no universally accepted guidelines, several consensus conferences have met to establish recommendations. After the completion of treatment, it is recommended that the patient undergo a physical examination every 4 months for the first 2 years, then every 6 months until year 5, and annually thereafter. A mammogram should be obtained annually for all patients and no less than 6 months after the completion of radiation therapy. For patients who received irradiation, a chest radiograph is also obtained yearly. Routine laboratory tests including CBC, chemistry profile, and LFTs can be ordered yearly, especially if the patient received chemotherapy, or else as needed. There is no role for routine bone scans or additional imaging unless the patient is symptomatic or there is clinical suspicion of an abnormality. Patients taking tamoxifen should have annual pelvic examinations and be counseled to report any irregular vaginal bleeding. Patients on AIs need periodic bone density studies and lipid panels to assess their cardiovascular risk factors.

A. Local Recurrence

The development of local recurrence correlates with stage and thus tumor size as well as the presence and number of positive axillary lymph nodes, margin status, nuclear grade, and histologic type. The median time to recurrence is roughly 4 years, with a 1–2% risk per year for the first 5 years and a 1% risk per year thereafter. Late failures occurring 15–20 years or more after treatment, however, do occur. The risk of local recurrence after BCT or MRM is generally <15%, 20 years after treatment. Positive axillary lymph nodes are prognostic for local failure at the chest wall after MRM, but they are not prognostic for a local failure after BCT.

The treatment of local recurrences depends on the initial local therapy. In the breast, failures after BCT can be treated with salvage mastectomy with salvage rates of approximately 50%. In general, there is no difference in overall survival for an isolated breast recurrence successfully treated with salvage mastectomy. Node failures are more ominous. Axillary failures have roughly a 50% 3- to 5-year disease-free survival, and supraclavicular failures have a 0–20% 3-year disease-free survival. All chest wall abnormalities should be biopsied to rule out recurrence and resected with a wide local excision if possible. Adjuvant salvage therapies such as radiation, cytotoxic chemotherapy, and hormonal therapy may also be instituted.

Local recurrence may signal the presence of widespread disease and is an indication for bone and liver scans, posteroanterior and lateral chest x-rays, and other examinations as needed to search for evidence of distant metastases. When there is no evidence of metastases beyond the chest wall and regional nodes, radical irradiation for cure and complete local excision can be attempted. Many patients with locally recurrent tumors will develop distant metastases within 2 years. For this reason, most physicians use systemic therapy for treatment of patients with local recurrence.

B. Edema of the Arm

Lymphedema of the arm is a significant and often dreaded complication of breast cancer treatment. Lymphedema occurs as a result of lymphatic disruption and insult caused primarily by local treatment modalities like surgery and radiation. Although each of these modalities carries its own risk with respect to arm edema, a combined-modality approach further increases this risk. With a typical level I/II axillary lymph node dissection and radiation, the risk of lymphedema is roughly <10%. This risk approached 30% when a more aggressive level III dissection was more commonly performed in the past. The rates of clinically significant lymphedema—that is, edema that affects function and is not merely detectable with sophisticated measurement tools—are generally considered to be much lower. With the advent of SLNB, lymphedema rates are expected to continue to improve.

Late or secondary edema of the arm may develop years after MRM, as a result of axillary recurrence or of infection in the hand or arm, with obliteration of lymphatic channels. Interestingly, there is frequently no obvious initiating event causing late arm swelling in a patient with a history of breast cancer treatment.

C. Breast Reconstruction

Breast reconstruction, with the implantation of a prosthesis or autologous tissue such as transverse rectus abdominis myocutaneous flap (TRAM), is now commonly offered following mastectomy and can be very frequently performed immediately after surgery. Therefore, reconstruction should be discussed with patients prior to mastectomy and is not an obstacle to the diagnosis of recurrent cancer.

Prognosis

The stage of breast cancer is the single most reliable indicator of prognosis. Patients with disease localized to the breast and no evidence of regional spread after microscopic examination of the lymph nodes have by far the most favorable prognosis. ERs and PRs appear to be an important prognostic variable because patients with hormone receptor–negative tumors and no evidence of metastases to the axillary lymph nodes have a much higher recurrence rate than do patients with hormone receptor-positive tumors and no regional metastases. The histologic subtype of breast cancer (eg, medullary, lobular, comedo) seems to have little significance in prognosis once these tumors are truly invasive.

Many patients who develop breast cancer will ultimately die of breast cancer. The mortality rate of breast cancer patients exceeds that of age-matched normal controls for nearly 20 years. Thereafter, the mortality rates are equal, although deaths that occur among the breast cancer patients are often directly the result of tumor. Five-year statistics do not accurately reflect the final outcome of therapy.

When cancer is localized to the breast, with no evidence of regional spread after pathologic examination, the clinical cure rate with most accepted methods of therapy is 75–80%. Exceptions to this may be related to the hormonal receptor content of the tumor, tumor size, host resistance, or associated illness. Patients with small ER- and PR-positive tumors and no evidence of axillary spread probably have a 5-year survival rate of nearly 90%. When the axillary lymph nodes are involved with the tumor, the survival rate drops to 50–60% at 5 years, and probably to less than 25% at 10 years. In general, breast cancer appears to be somewhat more aggressive in younger than in older women, which may be related to the fact that relatively fewer younger women have ER-positive tumors.

PALLIATIVE TREATMENT OF RECURRENT AND METASTATIC BREAST CANCER

This section discusses palliative therapy of disseminated disease incurable by surgery (stage IV).

Local Therapy

Patients with metastatic breast cancer are unlikely to be cured of their disease, and for many, the goals of care shift from cure to palliation, symptom control, and improved quality of life. In general, local therapy, such as palliative radiotherapy or surgery when technically feasible, should be reserved for patients in order to control their symptoms and minimize the risk of complications. As part of multimodality treatment, surgery for patients with metastatic breast cancer should be reserved for patients with a good performance status, minimal organ involvement, prolonged disease-free interval, or indolent disease growth when the likelihood of achieving complete resection of the tumor or metastasis is reasonable. A subset of these patients may achieve long-term survival as a result of surgery, although confirmatory data are still lacking. Palliative irradiation is also of value in the treatment of certain bone or soft tissue metastases to control pain or avoid pathologic fracture. Radiotherapy is especially useful in the treatment of the isolated bony metastasis and chest wall recurrences.

Hormonal Therapy

Disseminated disease may respond to prolonged endocrine therapy such as ovarian ablation or administration of drugs that block hormone receptor sites or that block hormone synthesis or production. Hormonal manipulation is usually more successful in postmenopausal women. A favorable response to hormonal manipulation occurs in about one-third of patients with metastatic breast cancer. In patients whose tumors contain ERs, the response is approximately 60%, and perhaps as high as 80% for patients whose tumors contain PRs as well. Tumors negative for both ERs and PRs have response rates to hormonal therapy that are 10% or less.

Because the quality of life during a remission induced by endocrine manipulation is usually superior to a remission after cytotoxic chemotherapy, it may be best to try endocrine manipulation as a first-line systemic treatment for tumor recurrence or palliation. However, it is better to forgo endocrine therapy in patients with rapidly growing visceral metastases in whom a period of ineffective therapy may lead to a significant decline in organ function and performance status. Thus, salvage endocrine therapy is best reserved for patients with minimal symptoms, no visceral involvement, and slow-growing tumors.

As a general rule, only 1 type of systemic therapy should be given at a time. The systemic modality may be given in combination with a local or regional treatment if symptomatic lesions develop. For instance, it may be necessary to irradiate a destructive lesion of weight-bearing bone while the patient is taking a hormonal agent or chemotherapy. The palliative systemic regimen should be changed only if the disease is clearly progressing but not if disease appears stable. This is especially important for patients with destructive bone metastases, because minor changes in the status of these lesions are difficult to determine radiographically. A plan of therapy that would simultaneously minimize toxicity and maximize benefits is often best achieved by hormonal manipulation.

The choice of endocrine therapy depends on the menopausal status of the patient. Women within 1 year of their last menstrual period are considered to be premenopausal, whereas women whose menstruation ceased more than 1 year ago are usually classified as postmenopausal. In the past, ovarian ablation, usually by bilateral surgical oophorectomy, or radiation was the standard method of hormone manipulation used in premenopausal women with advanced breast cancer. However, it has subsequently become clear that tamoxifen is equally effective and has none of the attendant risks of surgical ablation of the ovaries. Tamoxifen is recommended as the treatment of choice for hormonal therapy in the premenopausal woman with advanced breast cancer. For postmenopausal patients, AIs and tamoxifen are the initial therapy of choice for metastatic breast cancer amenable to endocrine manipulation, and a favorable response to initial hormonal therapy with tamoxifen is predictive of future responses to hormonal maneuvers.

The use of AIs, which work by blocking the conversion of testosterone to estradiol and androstenedione to estrogen both in the adrenal cortex and in peripheral tissue, including breast cancers themselves, is effective in postmenopausal patients.

Other hormonal agents have been found to be effective in premenopausal patients. Gonadotropin-releasing hormone (GnRH) agonists that act on the pituitary to eventually suppress follicle-stimulating hormone (FSH) and luteinizing hormone (LH) and the pituitary–ovarian axis, thereby decreasing estrogen production, have been used since the 1980s. They are an alternative to oophorectomy if used alone or can be combined with tamoxifen or AIs.

Progestins, megestrol acetate, and medroxyprogesterone acetate are alternative agents reserved mainly for cases resistant to tamoxifen and AIs.

Chemotherapy

Cytotoxic drugs should be considered for the treatment of metastatic breast cancer in the following instances: (1) if visceral metastases are present (especially brain or lymphangitic pulmonary spread), (2) if hormonal treatment is unsuccessful or the disease has progressed after an initial response to hormonal manipulation, or (3) if the tumor is ER and PR negative. With response rates of 35–55% in many series, the taxanes are quickly eclipsing the anthracyclines as the single most useful agents in the treatment of hormone-refractory metastatic breast cancer. Where once doxorubicin could achieve response rates of 40–50%, in some trials, the taxanes seem to offer a small overall survival advantage. In addition, they are generally well tolerated with an acceptable side effect profile. Questions about dosing, schedule of administration, and use with other agents, however, still have to be thoroughly answered.

Combination chemotherapy using multiple agents is appealing because, theoretically, the risk of drug resistance and cumulative toxicity is decreased. When compared to single-agent doxorubicin therapy, combination chemotherapy provides higher response rates and longer intervals until first progression. Nevertheless, the use of combination chemotherapy has never been shown to decrease drug resistance or toxicity in breast cancer. When combination chemotherapy has been compared to single-agent taxane therapy, although response rates were slightly lower, quality-of-life measurements were higher for the single agent. Thus, either a single-agent taxane or an anthracycline-containing combination regimen is frequently used as a first-line treatment. The use of cytotoxic chemotherapy or any other treatment modality should always be highly individualized, especially in the palliative setting.

Bisphosphonate Therapy

Bone is the most common site of metastatic disease at initial presentation and at the time of breast cancer recurrence. Bone metastases are often detected with a bone scan obtained in the staging of locally advanced cases or obtained because of clinical suspicion in the previously treated patient. Confirmation with plain radiographs, MRI, and/or CT is frequently needed because nearly 10% of lytic lesions may not be detected with a nuclear medicine scan. These other radiographic studies also help to delineate the extent of the metastatic disease. After bone metastases are confirmed, bisphosphonate therapy has been shown to diminish pain and decrease the rate of skeletal events and complications related to the bone metastases.

Bisphosphonate therapy should be administered with other palliative systemic treatments such as hormonal manipulation or chemotherapy. It is typically given intravenously every 3–4 weeks and continued indefinitely even though long-term studies are lacking. Regular dental exams, laboratory monitoring, and creatinine and renal function, as well as evaluation of calcium and vitamin D levels, are also recommended due to the risk of osteonecrosis of the jaw, renal insufficiency, and hypocalcemia associated with prolonged therapy.

Section II. Normal Obstetrics

6
Normal Pregnancy and Prenatal Care

Helene B. Bernstein, MD, PhD George VanBuren, MD

NORMAL PREGNANCY

Pregnancy (gestation) is the physiologic process of a developing fetus within the maternal body. Several terms are used to define the developmental stage of human conception and the duration of pregnancy. For obstetric purposes, the gestational age or menstrual age is the time elapsed since the first day of the last normal menstrual period (LNMP), which actually precedes the time of oocyte fertilization. The gestational age is expressed in completed weeks. The start of the gestation (based on the LNMP) is usually 2 weeks before ovulation, assuming a 28-day regular menstrual cycle. The developmental or fetal age is the age of the conception calculated from the time of implantation, which is 4 to 6 days after ovulation is completed. The menstrual gestational age of pregnancy is calculated at 280 days or 40 completed weeks. The estimated due date (EDD) may be estimated by adding 7 days to the first day of the last menstrual period and subtracting 3 months plus 1 year (Naegele's rule).

The period of gestation can be divided into units consisting of 3 calendar months each or 3 trimesters. The first trimester can be subdivided into the embryonic and fetal periods. The embryonic period starts at the time of fertilization (developmental age) or at 2 through 10 weeks' gestational age. The embryonic period is the stage at which organogenesis occurs and the time period during which the embryo is most sensitive to teratogens. The end of the embryonic period and the beginning of the fetal period occurs 8 weeks after fertilization (developmental age) or 10 weeks after the onset of the last menstrual period.

Definitions

The term **gravid** means "pregnant"; gravida is the total number of pregnancies that a women has had, regardless of the outcome. **Parity** is the number of births, both before and after 20 weeks' gestation, and comprises 4 components:

1. Full-term births
2. Preterm births: having given birth to an infant (alive or deceased) weighing 500 g or more, or at or beyond 20 completed weeks (based on the first day of the last menstrual period)
3. Abortions: pregnancies ending before 20 weeks, either induced or spontaneous
4. Living children

When gravidity and parity are calculated as part of the obstetric history, multiple births are designated as a single gravid event, and each infant is included as part of the parity total.

Live birth is the delivery of any infant (regardless of gestational age) that demonstrates evidence of life (eg, a heartbeat, umbilical cord pulsation, voluntary or involuntary movement), independent of whether the umbilical cord has been cut or the placenta detached. An **infant** is a live-born human from the moment of birth until the completion of 1 year of life (365 days).

A **preterm infant** is defined as one born between 20 weeks and 37 completed weeks of gestation (259 days). A **term infant** is one born between 37 0/7 and 40 0/7 weeks gestation (280 days). At term, a fetus usually weighs more than 2500 g. Depending on maternal factors such as obesity and diabetes, amniotic fluid volume, and genetic and racial factors, the baby may be larger or smaller than expected; therefore, the clinician must rely on objective data to determine fetal maturity. Fetal lung maturity is assumed after 39 weeks' gestation but can be verified at an earlier gestational age by analysis of amniotic fluid by amniocentesis.

A **postterm infant** is born after 42 weeks' gestation (294 days). A prolonged pregnancy may result in an excessive-size infant with diminished placental capacity. A postmature infant may exhibit characteristic cutaneous changes, including a loss of subcutaneous fat, wrinkled skin, and fine long hair on the arms. Predicting the end of a pregnancy is a difficult problem for prenatal care providers. Prenatal mortality rates increase as gestation advances past the due date (EDD) and accelerates sharply after 42 weeks' gestation. It is not uncommon to offer induction of labor after 41 completed weeks, or 7 days past the due date. (See Chapter 14 on Late Pregnancy Complications.) Estimated gestational age can be determined by methods outlined later for ascertaining fetal age and EDD.

Increased morbidity and mortality may be associated with a **macrosomic infant** or a **large for gestational age** (LGA) fetus. This is defined as a fetus with an estimated fetal weight at or beyond the 90th percentile at any gestational age. At term, approximately 10% of newborn infants weigh more than 4000 g, and the weight of 1.5% of newborns is in excess of 4500 g. Excessive fetal size should be suspected in women with a previous macrosomic fetus or those with diabetes mellitus. A **low-birth-weight infant** is any live birth for which the infant's weight is less than or equal to 2500 g. An infant with fetal growth restriction is defined as one at or below the 10th percentile at any gestational age.

Using a system based on the duration of gestational age or fetal weight, an **abortion** is the expulsion or extraction of part (incomplete) or all (complete) of the placenta or membranes without an identified fetus or with a fetus (alive or deceased) weighing less than 500 g or with an estimated gestational age of less than 20 completed weeks or 139 days from the last menstrual period, if fetal weight is unknown.

A. Birth Rate & Fertility Rate

Birth rate is defined as the number of live births per 1000 population. The **fertility rate** is expressed as the number of live births per 1000 women ages 15–44 years (sexually active population group). The current birth rate is 13.83 per 1000 population in 2010, whereas the general fertility rate is 66.7 per 1000 women ages 15–44 years.

B. Neonatal & Perinatal Periods

The **neonatal** period is defined as birth until 28 days of life; during this interval, the infant is designated as a newborn or neonate. The **perinatal period** is the time from 28 weeks' gestation to the first 7 days of life; this also includes the late fetal and early neonatal period.

The **prenatal mortality rate** is the sum of late fetal deaths plus early neonatal deaths (death in the first 7 days of life). The **neonatal mortality rate** (NMR) is infant death from birth to within 28 days of life. The NMR is calculated as the number of neonatal deaths during a year, divided by the number of live births during the same year, expressed per 1000 live births.

ESSENTIALS OF DIAGNOSIS

- Diagnosis is made on the basis of amenorrhea and a positive pregnancy test.
- It is crucial to diagnose pregnancy as soon as possible in order to initiate appropriate prenatal care, avoid teratogen (an agent that can cause a deleterious fetal effect) exposure, and diagnose nonviable or ectopic pregnancies.

Clinical Findings

A. Symptoms & Signs

A number of clinical signs and symptoms may presumptively indicate pregnancy.

1. Amenorrhea—Cessation of menses is caused by hormones (estrogen and progesterone) produced by the corpus luteum. The abrupt cessation of menses in a healthy reproductive-aged female with predictable cycles is highly suggestive of pregnancy.

2. Nausea & vomiting—This is a common symptom (50% of pregnancies) that begins as early as 2 weeks' gestational age and customarily resolves at between 13 and 16 weeks' gestation. Hyperemesis gravidarum is an extreme form of nausea and vomiting and is characterized by dehydration, weight loss (up to 5%), and ketonuria. In extreme cases of hyperemesis gravidarum, hospitalization, intravenous therapy, antiemetics, and, if needed, parenteral nutrition are given. Uncomplicated nausea and vomiting is treated with frequent small meals, a dry diet, and emotional support. (See Chapter 29 on Gastrointestinal Disorders in Pregnancy for more discussion.)

3. Breast changes

A. MASTODYNIA—Breast tenderness may range from tingling to pain caused by hormonal changes affecting the mammary duct and alveolar system.

B. BREAST ENGORGEMENT—Breast engorgement and periareolar venous prominences are also seen early in pregnancy, especially in primiparous patients. **Montgomery's tubercles** are the portion of the areolar glands visible on the skin surface. These tubercles can be more pronounced during pregnancy secondary to hormonal changes occurring as early as 6–8 weeks' gestation.

C. COLOSTRUM SECRETION—Protein and antibody production may occur during pregnancy as early as 16 weeks' gestation. This secretion is not associated with preterm delivery.

D. DEVELOPMENT OF SECONDARY BREAST TISSUE—Development of secondary breast tissue may occur across the nipple line. Hypertrophy of secondary breast tissue may occur in the axilla and cause a symptomatic mass.

4. Fetal movement—The initial perception of fetal movement occurs at 18–20 weeks' gestation in primiparous patients and as early as 14 weeks' gestation in multiparous patients. Maternal perception of movement is called **quickening**, but this is not a dependable sign of pregnancy.

5. Elevated basal body temperature—Progesterone produces a 0.5°F increase in the basal body temperature, which persists after the missed menses. The rise in temperature occurs within the luteal phase of the menstrual cycle.

6. Skin changes

A. CHLOASMA—The mask of pregnancy is skin darkening of the forehead, bridge of the nose, or cheek bones. This pregnancy-associated change is linked to genetic predisposition and usually occurs after 16 weeks' gestation. Chloasma is exacerbated by sunlight.

B. LINEA NIGRA—Melanocyte-stimulating hormone increases, causing darkening of the nipples and the lower midline from the umbilicus to the pubis (linea nigra). This skin change is genetically based; skin lightens slightly after delivery of the fetus.

C. STRIAE—Striae marks of the breast and abdomen appear as irregular scars. The striae appear late in pregnancy and are caused by collagen separation.

D. SPIDER TELANGIECTASIA—These are common skin lesions of pregnancy that result from elevated plasma estrogen. Both the vascular stellate skin lesions as well as palmar erythema may be seen in pregnancy and also occur in patients with liver failure.

7. Pelvic organ changes

A. CHADWICK'S SIGN—Congestion of the pelvic vasculature causes bluish discoloration of the vagina and the cervix. This is a presumptive sign of pregnancy.

B. HEGAR'S SIGN—There is widening and softening of the body or isthmus of the uterus. This occurs at 6–8 weeks' menstrual age or gestational age. Estrogen and progesterone cause increased cervical softening and dilation at the external os.

C. LEUKORRHEA—There is an increase in vaginal discharge, containing epithelial cells and cervical mucous, secondary to hormonal changes.

D. PELVIC LIGAMENTS—There is relaxation of the sacroiliac and pubic symphysis during pregnancy. Relaxation is pronounced at the pelvic symphysis.

E. ABDOMINAL ENLARGEMENT—There is progressive abdominal enlargement with growth of uterus during pregnancy. From 18 to 34 weeks there is a good correlation between the uterine fundal measurement in centimeters and the gestational age in weeks.

F. UTERINE CONTRACTIONS—Painless uterine contractions (**Braxton Hick's contractions**) are felt as tightening or pressure. They usually begin at approximately 28 weeks' gestation and increase in regularity with advancing gestational age. These contractions usually disappear with walking or exercise, whereas true labor contractions become more intense.

DIAGNOSIS

A. Fetal Heart Tones

Fetal heart tones (FHTs) are detectable by handheld Doppler (after 10 weeks' gestation) or by fetoscope (after 18–20 weeks' gestation). The normal heart rate is 110–160 beats per minute, with a higher fetal heart rate observed early in pregnancy.

B. Uterine Size/Fetal Palpation

Uterine size can be used to diagnose pregnancy secondary to uterine enlargement. Later in pregnancy, the fetus can be palpated through the maternal abdominal wall (after 22 weeks), and the position can be determined by Leopold's maneuvers.

C. Imaging Studies

Sonography is one of the most useful technical aids in diagnosing and monitoring pregnancy. Cardiac activity is discernible at 5–6 weeks via transvaginal sonogram, limb buds at 7–8 weeks, and finger and limb movements at 9–10 weeks. At the end of the embryonic period (10 weeks by LNMP), the embryo has a human appearance. The gestational age can be determined by the crown rump length between 6 and 13 weeks' gestation, with a margin of error of approximately 8% or 3–5 days.

D. Pregnancy Tests

Sensitive, early pregnancy tests measure changes in the level of human chorionic gonadotropin (hCG). There is a small degree of cross-reactivity between luteinizing hormone, follicle-stimulating hormone, and thyrotropin, which all share an α subunit with hCG. The β submit of hCG is produced by the syncytiotrophoblast 8 days after fertilization and may be detected in the maternal serum 8–11 days after conception or as early as 21–22 days after the LNMP. β-hCG levels peak at 10–12 weeks' gestation and decrease afterward. The half-life of hCG is 1.5 days. Generally, serum and urine levels return to normal (<5 mIU/mL), 21–24 days after delivery or after a fetal loss.

1. Home pregnancy test—hCG is a qualitative test that is performed on the first voided morning urine sample. A positive test is usually indicated by a color change. Because the accuracy of the home pregnancy test depends on technique and interpretation, it should always be repeated in the office.

2. Urine pregnancy test—An antibody assay recognizing the β-hCG subunit is the initial lab test performed in the office to diagnose pregnancy. The test is reliable, rapid (1–5 minutes), and inexpensive, with a positive test threshold between 5 and 50 mIU/mL, characterized by a color change. This is the most common method to confirm pregnancy.

3. Serum pregnancy test—β-hCG can be detected within 7 days after conception or at a menstrual age of 21 days' gestation. The threshold for a positive test can be as low as 2–4 mIU/mL. Serial quantitative tests of β-hCG are be used to evaluate threatened abortion, ectopic pregnancy, or a molar pregnancy.

GESTATIONAL AGE DETERMINATION

The EDD (estimated date of delivery) and gestational age should be established based on the LNMP and Naegele's rule. Clinical parameters, discussed later, should be used as an adjunct to confirm or establish dating as needed.

Pregnancy Calendar or Calculator

Normally, human pregnancy lasts 280 days or 40 weeks (9 calendar months or 10 lunar months) from the LNMP. This may also be calculated as 266 days or 38 weeks from the last ovulation in a normal 28-day cycle. The easiest method of determining gestational age is with a pregnancy calendar or calculator. The EDD can be determined mathematically using Naegele's rule: subtract 3 months from the month of the LNMP and add 7 to the first day of the LNMP. Example: With an LNMP of July 14, the EDD is April 21.

CLINICAL PARAMETERS

Ultrasound

Ultrasound is used routinely to determine viability, estimate gestational age, screen for aneuploidy, and evaluate fetal anatomy and well-being. From 13 to 20 weeks, the most accurate parameter for gestational age assessment is the biparietal diameter, although this measurement is often used together with the head circumference, abdominal circumference, and femur length, with a margin of error (secondary to measurement) of 8% or approximately 7 days. After 24 weeks' gestation, the accuracy of ultrasound to estimate gestational age is diminished and is best used to assess growth or the estimated fetal weight.

Indications for ultrasound are as follows:

1. Dating.
2. Aneuploidy assessment—Discussed in Screening section (later).
3. Anatomical survey—A comprehensive anatomical survey can be performed as early as 16–18 weeks' gestation.
4. Cervical length assessment.
5. Fetal well-being can be monitored by ultrasound using the biophysical profile.

Uterine Size

An early first-trimester examination usually correlates well with the estimated gestational age. The uterus is palpable just at the pubic symphysis at 8 weeks. At 12 weeks, the uterus becomes an abdominal organ, and at 16 weeks, it is usually at the midpoint between the pubic symphysis and the umbilicus. Between 18 and 34 weeks' gestation, the uterus size or fundal height is measured in centimeters from the pubic symphysis to the upper edge of the uterine corpus, and the measurement correlates well with the gestational age in weeks (Fig. 6–1). The uterus is palpable at 20 weeks at the umbilicus. After 36 weeks, the fundal height may decrease as the fetal head descends into the pelvis.

Figure 6–1. Height of fundus at various times during pregnancy.

Quickening

Maternal perception of fetal movement occurs between 18 and 20 weeks in the primiparous patient and at 14–18 weeks in the multigravida. The perceived fetal movement, or quickening, is often described as a butterfly-like movement rather than a kick.

Fetal Heart Tones

FHTs may be heard by a fetoscope at 18–20 weeks and by Doppler ultrasound as early as 10 weeks' gestation.

PREGNANCY FAILURE

Early

A. Diagnosis

The gold standard for diagnosis of early pregnancy failure is ultrasound. Definitive diagnosis requires recognition of a fetus in the absence of cardiac activity.

B. Laboratory Findings

In cases where ultrasound findings are equivocal, serial measurements of serum β-hCG levels with a failure to demonstrate an appropriate increase are helpful.

Late

C. Signs and Symptoms

In late pregnancy, the first sign of fetal demise is usually the absence of fetal movement as noted by the mother.

D. Diagnosis

If FHT cannot be appreciated, real-time ultrasonography is virtually 100% accurate in describing the absence of fetal heart motion.

E. Complications

Disseminated intravascular coagulopathy is a rare sequelae occurring after an intrauterine fetal demise (IUFD). Coagulation studies may be started 2 weeks after the demise of one twin, and delivery can be undertaken if serial serum fibrinogen levels fall below 200 mg/dL. In a singleton IUFD, coagulation studies including fibrinogen are done immediately after the diagnosis is made, and delivery is initiated promptly.

PRENATAL CARE

Pregnancy is a normal physiologic process; however, complications that increase the mortality or morbidity to the mother and/or fetus occur in 5–20% of pregnancies. Our present system of prenatal care focuses on prevention.

Prenatal care providers must be familiar with the normal changes of pregnancy and the possible pathologic changes that may occur so that therapeutic measures can be initiated to reduce any risks to the mother or fetus. The purpose of prenatal care is to ensure a successful pregnancy outcome when possible, including the delivery of a live, healthy fetus. It’s proven that mothers receiving prenatal care have a lower risk of complications, and one of the principal aims of prenatal care is the identification and special treatment of the high-risk patient—the one whose pregnancy, because of some factor in her medical history or an issue that develops during pregnancy, is likely to have a poor outcome.

Ideally, a woman planning pregnancy should have a medical evaluation before conception; this allows the physician to determine whether any risk factors will complicate a pregnancy in the context of a complete history and physical examination, along with prenatal laboratory studies. During the medical evaluation, the risks of cigarette smoking, alcohol and drug use, and exposure to known teratogens are discussed. Instructions on nutrition, exercise, and vitamins can be provided before pregnancy. For example, folic acid taken 3 months before conception may be beneficial in decreasing the incidence of open neural tube defects and cardiac anomalies.

Most women do not have a preconception evaluation, and the first prenatal visit may be scheduled well into the first and occasionally in the second or third trimester. Factors for delayed medical care should be reviewed with the patient, and any barriers—whether social, financial, or cultural—may be addressed for this and future pregnancies.

INITIAL OFFICE VISIT

The purpose of the first office visit is to identify any risk factors influencing the mother and/or fetus. A plan of care for a high-risk pregnancy may be established at the first prenatal visit, including pertinent consultations of subspecialists.

HISTORY

A. Obstetric History

The interview should include a discussion of current symptoms; this is also an ideal time to discuss any perceptions regarding childbearing (including potential birth plans) and the effect of the pregnancy on the patient’s life.

Outcomes of all previous pregnancies provide important information for the current pregnancy; the following information should be obtained: length of gestation, birth weight, length of labor, type of delivery, fetal/neonatal outcome, anesthesia, and any complications occurring in previous pregnancies, including pregnancies ending before 20 weeks’ gestation. If a caesarean section was performed, an operative report detailing the type of incision and any intraoperative complications should be obtained.

B. Medical History

Pregnancy may influence a number of maternal organ systems, and preexisting conditions may be exacerbated during pregnancy. Many cardiovascular, gastrointestinal, and endocrine disorders require careful evaluation and consultation regarding effects on the mother. For example, a prior blood transfusion may increase the risk of hemolytic disease of the newborn because of maternal antibodies produced secondary to a minor blood group mismatch. Medical conditions of particular relevance to pregnancy include diabetes and other endocrine diseases, hypertension, epilepsy, and autoimmune diseases.

C. Surgical History

A history of previous gynecologic, abdominal, or uterine surgery may necessitate a caesarean section. In addition, a history of cervical surgery, multiple induced abortions, or recurrent fetal losses may suggest cervical incompetence. Patients with a previous caesarean section may be candidates for vaginal delivery if they are adequately counseled and meet established guidelines.

D. Family History

A family history of diabetes mellitus should alert the clinician about an increased risk of gestational diabetes, especially if the patient has a history of a large infant or a previous birth defect, or an unexplained fetal demise. Glucose testing should be performed at the initial prenatal visit if there is a strong suspicion of undiagnosed pregestational diabetes rather than waiting until 24–28 weeks' gestation.

Awareness of familial disorders is also important in pregnancy management. Thus a brief, 3-generation pedigree is useful. Antenatal screening tests are available for many hereditary diseases. A history of twinning is important, because dizygotic twinning (polyovulation) may be a maternally inherited trait.

E. Social History

The prenatal history should include documentation of tobacco and alcohol use, any contact with intravenous drugs or drug users, or other drug use. Exposures (workplace and otherwise) should be evaluated.

Physical Examination

A complete physical examination should be performed at the first obstetric or prenatal visit; the pelvic examination is of special importance for the obstetrician, nurse, or midwife.

1. Bony pelvis—The configuration should be evaluated to determine whether the patient is at risk for cephalopelvic disproportion, which may lead to an operative delivery. Pelvimetry has been largely replaced, however, by clinical evaluation of the pelvis ("trial of labor").

A. Pelvic inlet—The anteroposterior diameter or diagonal conjugate may be estimated at the time of the initial pelvic examination. For this measurement, the index and middle finger are inserted into the vagina, the middle finger reaches the sacral promontory, and the tissue between the examiners' index and thumb is pushed against the patient's pubic symphysis. The distance between the tip of the examiner's finger and pubic symphysis pressure on the thumb measures the diagonal conjugate; the anterior diameter of the pelvic inlet is estimated by subtracting 1.5 cm from the measured diagonal conjugate (Fig. 6–2).

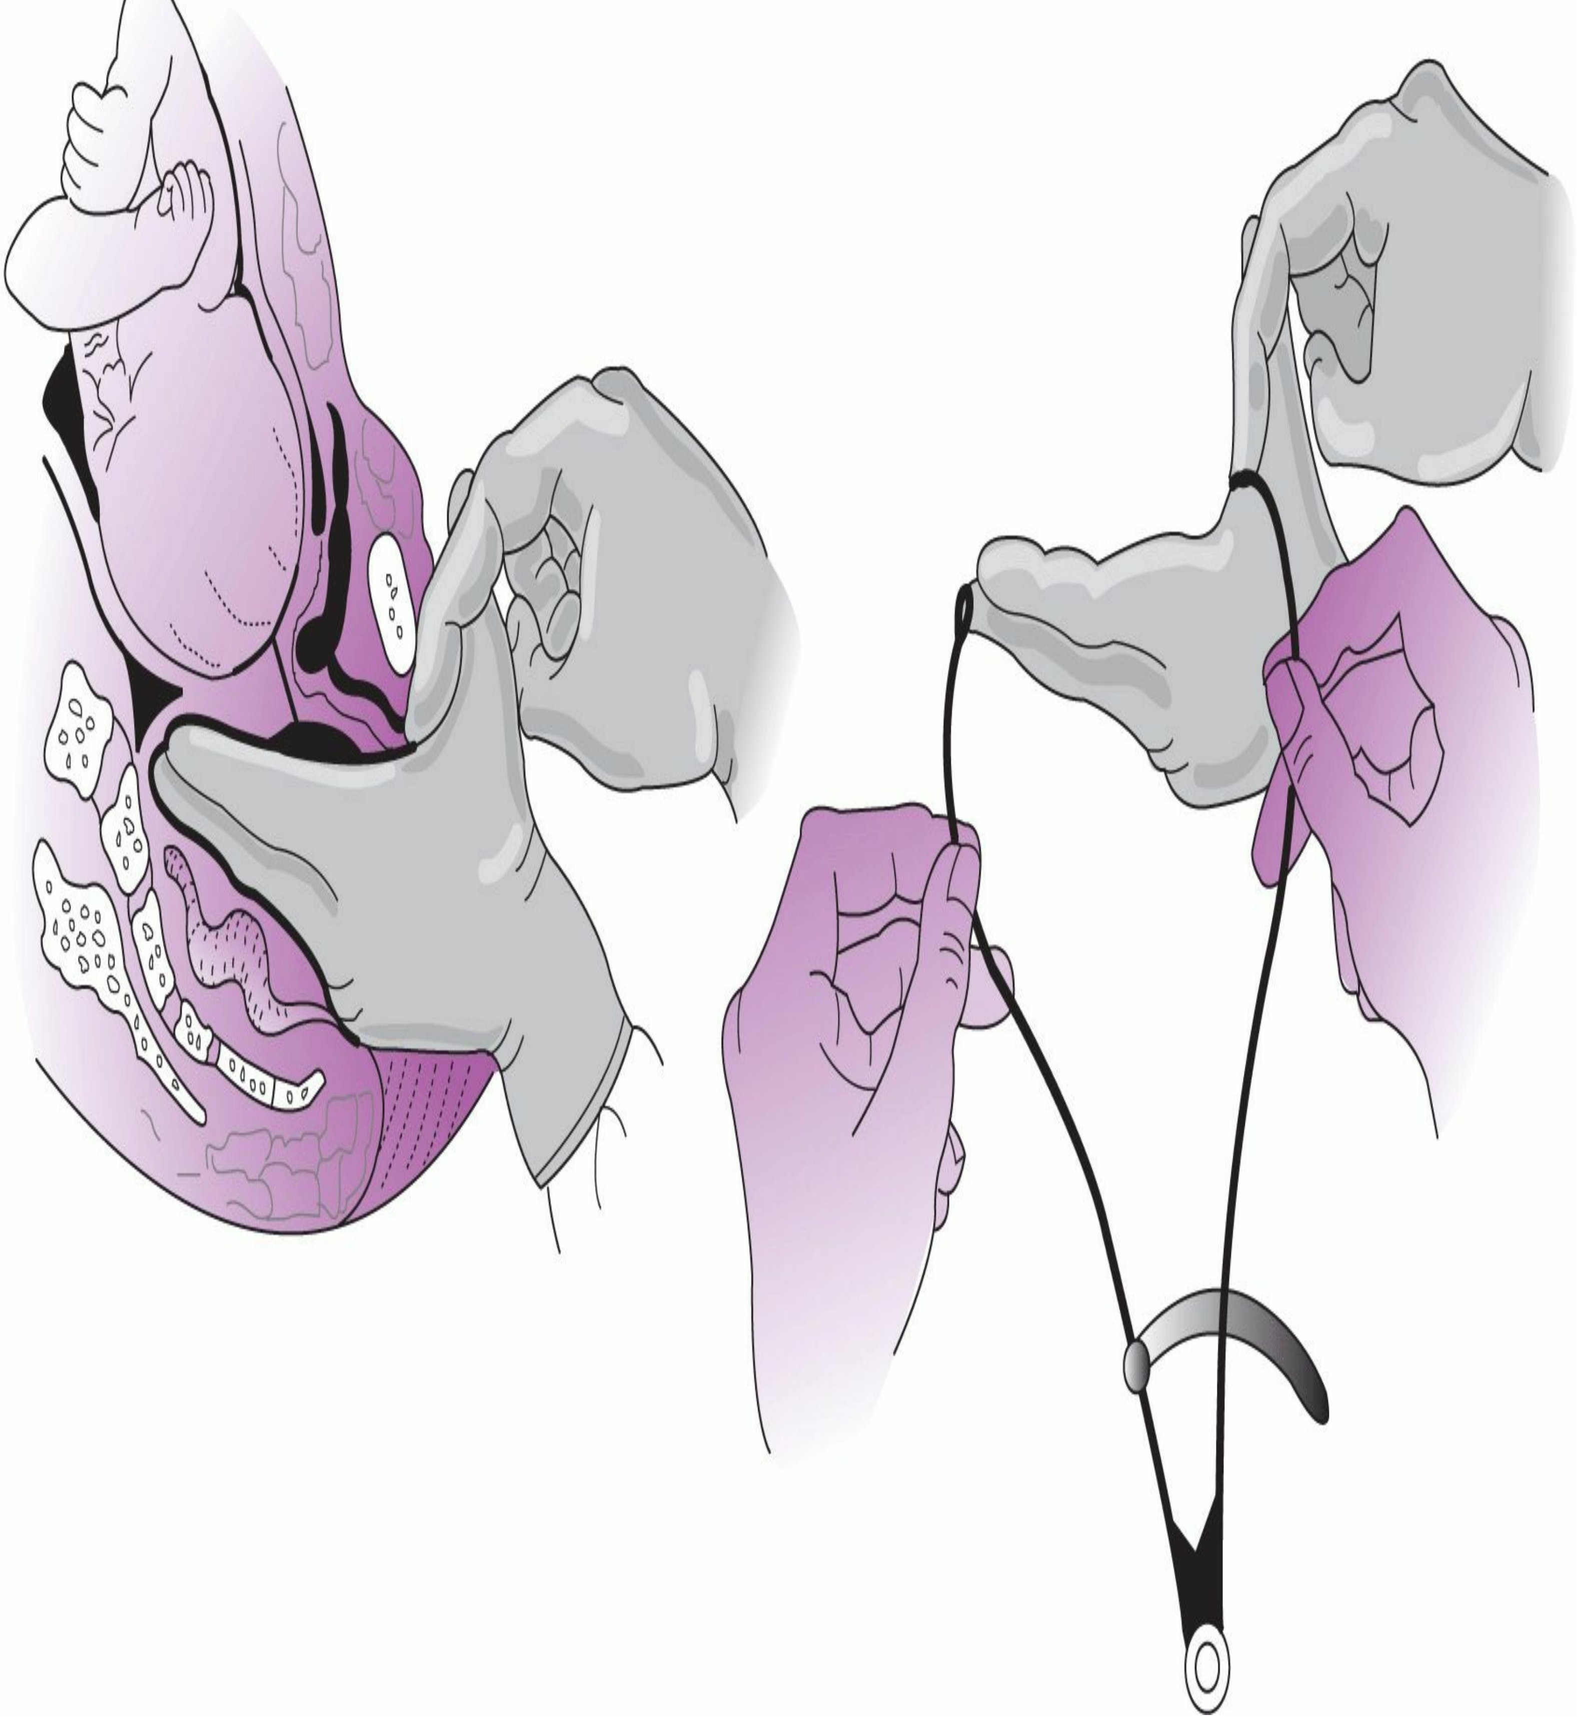

Figure 6–2. Measurement of the diagonal conjugate (conjugata diagonalis). (Reproduced, with permission, from Benson RC. *Handbook of Obstetrics & Gynecology*. 8th ed. Los Altos, CA: Lange; 1983.)

B. MIDPELVIS—The midpelvic space can be estimated by noting the prominence and closeness of the ischial spines. If the walls of the pelvis converge, and if the curve of the sacrum is straight/shallow, or if the sacrosciatic notches are narrowed, the midpelvis may be inadequate for a vaginal delivery.

c. Pelvic outlet—In contrast to the midpelvis, the pelvic outlet can be estimated by a physical examination. The shape of the outlet can be determined by palpitation of the pubic rami from the symphysis to the ischial tuberosities with an estimation of the angle of the rami. A subpubic angle of less than 90 degrees suggests an inadequate pelvic outlet. A prominent coccyx decreases the anterior posterior diameter of the outlet and may further diminish the pelvic outlet.

2. Uterus—The uterus can be used to confirm gestational age in the first half of pregnancy. As the uterus enlarges, it becomes globular and often rotates to the right.

3. Cervical length—A nulliparous woman who has not undergone a vaginal delivery will have a closed external cervical os. A multiparous patient may have a greater opening or dilation of the external os. The average cervical length by bimanual examination in women averages between 3 and 4 cm. Women with a previous history of spontaneous preterm birth may undergo a transvaginal sonogram (TVS) during the second trimester to evaluate her risk of recurrent preterm birth. Serial TVS exams may be necessary if there is any evidence of cervical dilation or cervical shortening on the initial sonogram.

4. Adnexal exam—During the pelvic exam, a bimanual examination is performed, and the cervical length and evaluation of both ovaries (the adnexa) can be performed.

Laboratory Tests

A. Initial Blood Tests

At the first prenatal visit, a number of screening tests are performed, including a complete blood count (hemoglobin, hematocrit, and platelets), blood group and Rh typing (ABO/Rh), screen for antibodies against blood group antigens, VDRL (Venereal Disease Research Laboratory) or RPR (rapid plasma reagent) for syphilis, hepatitis B surface antigen, and serology to detect antibodies against rubella and HIV. Women with a history of gestational diabetes are given a glucose challenge test (GCT) with oral ingestion of a solution containing 50 g of glucose. The venous glucose level is checked 1 hour after glucose ingestion.

B. Genetic Screening and Testing

1. Screening—First-trimester screening using a combination of a fetal nuchal translucency measurement and maternal serum analysis of pregnancy-associated plasma protein A (PAPP-A) and free or total β-hCG is used to screen for trisomy (21, 18, and 13). The detection rate of aneuploidy is between 85% and 87%, with a false-positive rate of less than 5%. With the use of first-trimester screening, maternal serum α fetoprotein (AFP) should be drawn at 15–18 weeks' gestation to screen for open neural tube defects.

For patients desiring aneuploidy assessment who did not receive first-trimester screening, a second trimester maternal serum quad screen is offered between 15 and 20 weeks' gestation (ideally at 16–18 weeks) to screen for neural tube defects and aneuploidy (chromosomal abnormalities). Analytes studied include serum β-hCG, unconjugated estriol, AFP, and inhibin. The detection rate of a quad screen is between 65% and 75% for trisomy 21, 18, and 13 and between 80% and 85% for open neural tube defects. The false-positive rate is approximately 5%.

Additional genetic testing includes hemoglobin electrophoresis to screen for hemoglobinopathies (including sickle cell disease risk) and cystic fibrosis screening, which has been added to prenatal screening at many institutions.

2. Invasive genetic testing—Invasive genetic testing must be offered to all women, especially those who will be 35 years of age or older at the time of delivery or who have a history of an abnormal pedigree or risk factors for inherited diseases. Chorionic villous sampling is performed between 9 and 13 weeks' gestation by either transabdominal or transvaginal technique. Amniocentesis is usually offered at between 15 and 20 weeks' gestation. The complication rate of these procedures is less than 1%, and the detection rate for aneuploidy is greater than 99%.

C. Urine Testing

At the initial prenatal visit, urinalysis and culture is performed. Approximately 2–12% of pregnant women have an asymptomatic urinary tract infection. If the bacterial count is greater than 10^5/mL, expressed as colony-forming units (CFU) on a voided specimen, then antibiotic sensitivity is performed.

Testing for urinary protein, glucose, and ketones is performed at each prenatal visit. Proteinuria of greater than or equal to 2+ on a standard dipstick (which correlates to greater than 300 mg/24 hours on a timed urine collection) may indicate renal disease or the onset of preeclampsia. The presence of glucosuria signifies that glucose transport to the kidney exceeds the transport capacity of the kidneys. This generally does not have clinical significance unless carbohydrate intolerance or gestational diabetes is present. During pregnancy in a known diabetic patient, the presence of urinary ketones usually indicates inadequate carbohydrate intake. In this case, the patient's diet should be reevaluated to ensure adequate carbohydrate intake.

D. Papanicolaou Smear (PAP)

Cervical cancer screening is performed at the initial prenatal visit unless there has been a normal exam within the past year.

E. Tuberculin Skin Test

A tuberculin skin test (**purified protein derivative**) is appropriate for high-risk patients.

E. Sexually Transmitted Diseases

1. Syphilis—Tests performed at the initial prenatal visit such as VDRL and the RPR screen in a sensitive, nonspecific manner for *Treponema pallidum.* A treponemal antibody test (FTA-ABS) is used to confirm syphilis infection after a positive VDRL or RPR screen in the absence of confirmed prior infection. Penicillin is the treatment of choice in pregnancy because of the ability of the agent to cross the placenta and treat the fetus as well as the mother. Erythromycin or ceftriaxone are alternative treatments outside of pregnancy, but penicillin is the treatment of choice for pregnant women. Because of the risk of treatment failure with secondary agents and congenital syphilis infection, penicillin desensitization is indicated in the setting of anaphylactic allergy. Monthly serologic tests (VDRL or RPR) are followed to assess treatment success of syphilis. These tests can remain positive after treatment; however, their titer should decrease substantially. The FTA-ABS will remain positive even after successful treatment.

2. Chlamydia—Screening consists of a DNA probe, which has a 90% specificity and sensitivity. An endocervical sample or urine sample can be used for diagnosis of chlamydia (CT). The agent of choice is azithromycin (1 g oral dose). Amoxicillin (500 mg oral dose three times a day for 7 days) is an alternative treatment. A test of cure is performed 2–3 weeks after completion of treatment. Screening for gonorrhea (GC) and CT are routinely performed at the time of PAP smear. In a high-risk population, these cultures are repeated at the third trimester (35–37 weeks' EGA).

3. Gonorrhea—GC can be detected by culture of the organism in Thayer-Morton agar or by a DNA probe as part of a combined GC/CT. GC may be transmitted to the infant and cause ophthalmic injury. Infection may be associated with preterm labor, preterm premature rupture of membranes, and intrapartum as well as postpartum infection. The drug of choice is ceftriaxone (125 mg intramuscularly [IM] onetime dose or 1 g intravenously every 24 hours for disseminated disease) secondary to prevalent penicillin-resistant strains. Patients with an allergy to penicillin are treated with a 2-g IM dose of spectinomycin.

4. Herpes simplex virus—Tissue culture or DNA polymerase chain reaction are used to detect active herpetic infections; serology can be used to assess a history of exposure. Oral acyclovir is used for primary and recurrent outbreaks. Prophylactic treatment at 36 weeks' gestation for women with documented genital herpes and recurrent outbreaks is recommended to reduce the chance of the patient having an active outbreak when she presents in labor. Regimens commonly used are acyclovir 400 mg twice daily or valacyclovir 1000 mg daily. When a patient is admitted for delivery, she should be asked about prodromal symptoms and examined for lesions of the cervix, vagina, and perineum. If no lesions or symptoms are present, vaginal delivery is permitted.

5. HIV—All obstetric patients should undergo HIV screening on an "opt out" basis at the first prenatal visit. The initial HIV screening test is an enzyme-linked immunosorbent assay (ELISA) followed by a confirmatory Western blot or immunofluorescence assay for patients with ELISA-positive tests.

If a woman has not had prenatal HIV testing (or care), a rapid HIV test is offered at the time of hospital admission. The goal of prenatal care and treatment of the HIV-positive pregnant patient is to appropriately treat the mother, reduce viral load, and minimize perinatal HIV transmission by providing antiretroviral prophylaxis intrapartum and to the infant. Treatment regimens should include prenatal highly active anti-retroviral therapy and intrapartum infusion of azidothymidine. Ongoing assessment of an HIV-infected pregnant woman involves serial measurements of the viral load and CD4 T-cell count. Cesarean delivery is recommended only for patients with high viral load (>1000 copies/mL); otherwise, mode of delivery is dictated by obstetric indications.

6. Other infections

A. TRICHOMONAS—*Trichomonas vaginalis* can be identified in 20–30% of pregnant patients, but only 5–10% of patients are symptomatic (itching, burning, or discharge). *T vaginalis* is a flagellated ovoid organism seen under magnification in warm normal saline solution. The discharge is described as foamy green and malodorous. Metronidazole has an efficacy of approximately 95% against *T vaginalis*. Metronidazole may be given as a single oral dose of 2 g, 500 mg twice daily for 7 days, or 250 mg 3 times daily for 7 days.

B. CANDIDIASIS—*Candida albicans* can be cultured from the vagina of many immunocompromised women (HIV, insulin-dependent diabetes mellitus, or pregnant). Symptoms of vaginal candidiasis include vaginal burning, itching, and a thick, white, curd-like discharge. Marked inflammation of the vagina and perineum may be noted, but fewer than 50% of women have symptoms.

The confirmatory test for candida is microscopic detection of hyphae or yeast buds on a KOH preparation. For uncomplicated candida yeast infections, topical therapy may be given for 3–7 days with agents such as miconazole, terconazole, clotrimazole, and butoconazole. In refractory cases, administration of systemic agents may be considered. Fluconazole (150-mg single oral dose) is the preferred agent in pregnancy.

C. BACTERIAL VAGINOSIS—Bacterial vaginosis (BV) is responsible for a large percentage of vaginitis during pregnancy. BV is a polymicrobial infection that is associated with many complications of pregnancy, including preterm labor, preterm premature rupture of membranes, chorioamnionitis, and endometritis.

SUBSEQUENT VISITS

The frequency of office visits is dependent on the gestational age, maternal condition, and any fetal complications. The standard schedule for prenatal office visits in uncomplicated patients is every 4 weeks from 0 to 32 weeks' gestation, every 2 weeks from 32 to 36 weeks' gestation, and weekly visits after 36 weeks' gestation.

At each visit, maternal weight, uterine fundal height, maternal blood pressure, and urinalysis by dipstick are documented. The FHTs should be documented. All findings should be recorded and compared with those from previous visits.

Maternal Weight Gain

The prepregnancy weight and the amount of weight gain during pregnancy are important. Maternal weight gain during pregnancy is due to a number of factors. The fetus (on average, 3500 g at term), the placenta (650 g) amniotic fluid (800 mg), breast enlargement (400 g) and uterus (970 g) are factors, as well as increased interstitial fluid and blood volume, which results in an additional 1200–1800 g of weight gain.

A woman who is 15% or more below ideal body weight or of short stature has a risk for a small for gestational age (SGA) infant and preterm delivery. A pregnant adolescent may have maternal compromise, as well as fetal jeopardy, if her diet is inadequate to meet her own growth requirements as well as that of the fetus. Inadequate maternal weight gain may reflect poor nutrition, inadequate nutrition absorption, or maternal illness, predisposing the mother to an inadequate volume expansion and the fetus to growth restriction. The American College of Obstetrics and Gynecology recommend a weight gain of 11.5–16 kg (25–35 lb) during a singleton pregnancy. Underweight women should gain more weight (12.5–18 kg or 28–40 lb), whereas obese women should gain less than 7–11.5 kg or 15–25 lbs.

Obese women (>30 body mass index [BMI]) and those with excessive maternal weight gain during pregnancy are more likely to have a macrosomic infant when compared with women with a normal BMI and appropriate weight gain during pregnancy.

Blood Pressure

The blood pressure tends to decrease 5–7 mm (both systolic and diastolic components) early in the second trimester, but the blood pressure measurement returns to normal levels in the third trimester. Blood pressure changes may provide a subtle sign of vascular compromise. Elevation of blood pressure may precede an increase in proteinuria seen with hypertension in pregnancy. Blood pressure is most accurately measured in a sitting position (with the arm at the level of the heart).

Fundal Height

There is a connection between the uterine size or fundal height (in centimeters) and the gestational age (in weeks) between 18 and 34 weeks. Measurement is made from the pubic symphysis to the top of the uterus (McDonald's technique). Fundal height is measured at each visit after 20 weeks' gestation. If the fundal height is discordant from the estimated gestational age by more than 2 (centimeters or weeks), further evaluation of fetal size and amniotic fluid via ultrasound is warranted.

Fetal Heart Tones

FHTs can be auscultated by 10–12 weeks' gestation using a handheld Doppler device; while in use, attention should be paid to the rate, rhythm, and presence of any irregularity of heart rate, as well as accelerations or decelerations. Abnormalities in rate or rhythm should be evaluated by ultrasound, electronic fetal heart rate monitoring, or even a fetal echocardiogram.

Edema

At each prenatal visit, findings should be noted, including transient episodes of general edema or swelling. Lower extremity edema in late pregnancy is a natural consequence of hydrostatic changes in lower body circulation. Edema of the upper body (eg, face and hands), especially in association with relative or absolute increases in blood pressure, may be the first sign of preeclampsia, although edema is not part of the current diagnostic criteria. A moderate rise in blood pressure without excessive fluid retention may suggest a predisposition to chronic hypertension.

Fetal Size & Position

Manual assessment of fetal size and position is always indicated after approximately 26 weeks' gestation. The fetus may assume a number of positions before late gestation, but persistence of an abnormal lie into late pregnancy suggests abnormal placentation, uterine anomalies, or other problems that should be investigated by ultrasound. If an abnormal lie persists, consider external version after 37 weeks' gestation.

Laboratory Evaluations

A. Third-Trimester Laboratory Studies

1. Gestational diabetes screening—A 1-hour GCT, with a 50-g glucose load, is given between 24 and 28 weeks' gestation. If the 1-hour glucose test is abnormal, a 3-hour glucose tolerance test is performed. A 100-g glucose load is ingested after obtaining a fasting glucose level. Venous glucose levels are then measured at 1, 2, and 3 hours after the glucose load.

2. Complete blood count—This is normally repeated at the beginning of the third trimester to evaluate for anemia.

3. Group B streptococcus—The current recommendation is to perform routine screening for group B streptococcus (GBS) between 35 and 37 weeks' gestation. If the patient has a positive GBS culture at 35–37 weeks, or a positive urine culture for GBS anytime during the pregnancy, the patient is treated with penicillin (the drug of choice in the absence of allergy) at the time of admission in labor, decreasing the risk of early-onset group B streptococcal sepsis in the newborn.

COMMON COMPLAINTS

Ptyalism

Excessive salivation may be a complaint in a small percentage of pregnant women. The cause is unknown but may be associated with nausea and vomiting.

Pica

Pica is the ingestion of substances with no nutritive value; some common examples are ingestion of clay or laundry starch. Pica is harmful, as nutrition may be inadequate with the ingestion of nonnutritious bulk.

Urinary Frequency & Renal Function

Urinary frequency is a common complaint throughout pregnancy. Late in pregnancy, the enlarging uterus and fetus decrease bladder capacity, leading to frequency. The glomerular filtration rate increases 50% during pregnancy, and the serum creatinine decreases to a level of 0.4–0.6 mg/dL. Both the altered bladder and kidney function result from hormonal changes associated with pregnancy. Dysuria or hematuria may be a sign of infection. Approximately 2–12% of pregnant women have a urinary tract infection without symptoms. Diagnosis of a urinary tract infection will require a urinalysis as well as a urine culture with bacterial sensitivity.

Varicose Veins

Pressure by the enlarging uterus, which reduces venous return, as well as the relaxation of vascular smooth muscle by progesterone may result in enlargement of the peripheral veins in the lower extremities and development of varicosities. Specific therapy includes elevation of the lower extremities and the use of thigh-high compression stockings. These measures may reduce the degree of lower extremity edema and varicosity. Superficial varicosity is not evidence of deepvenous thrombosis.

Joint & Back Pain

During pregnancy, relaxation may result in a small degree of separation or mobility at the pubic symphysis and sacroiliac articulations. The pregnant patient may experience an unstable pelvis, which results in pain. A pelvic girdle or maternity sling with bed rest may partially relieve the pelvic pain. The increasingly protuberant maternal abdomen results in lordosis. The patient may compensate the lordosis with backward thrust of the shoulders and forward thrust of the head. The corrective position may result in an exaggerated curvature of the maternal spine. A maternity girdle and low-heeled support shoes may reduce the back pain. Exercise and physical therapy may be helpful.

Leg Cramps/Numbness

Leg cramps are a common complaint with an unknown etiology. Theories for leg cramps include a reduced level of serum calcium or magnesium. Treatments include nutritional supplementation of calcium carbonate or calcium lactate. Magnesium citrate (300 mg per day) has also been used for leg cramps. Other therapies include local heat, massage, or flexion of the feet.

Breast Soreness

Physiologic breast engorgement may cause discomfort, especially during early and late pregnancy. A well-fitting brassiere worn 24 hours a day affords relief. Ice bags are temporarily effective. Hormone therapy is of no value.

Discomfort in the Hands

Acrodysesthesia of the hands consists of periodic numbness and tingling of the fingers (the feet are never involved). It affects at least 5% of pregnant women. In some cases it is thought to be a brachial plexus traction syndrome caused by drooping of the shoulders during pregnancy; carpal tunnel syndrome is a common cause of a similar symptom complex. The discomfort is most common at night and early in the morning. It may progress to partial anesthesia and impairment of manual proprioception. The condition is apparently not serious, but it may persist after delivery as a consequence of lifting and carrying the baby.

OTHER ISSUES RELATED TO PRENATAL CARE

Bathing

Bath water generally does not enter the vagina. Swimming and bathing are not contraindicated during pregnancy. However, in the third trimester, a patient may have impaired balance and is at risk for a fall.

Dental Care

There may be gum hypertrophy and gingival bleeding during pregnancy. Interdental papillae (epulis) may form in the upper gingiva and may have to be surgically removed. Normal dental procedures such as prophylaxis (cleaning), cavity restoration (filling), and periodontal restoration may be performed under local anesthesia. Antibiotics may be given for dental abscesses. Periodontal disease has been associated with an increased risk of preterm delivery in some studies.

Douching

Douching, which is seldom necessary, may be harmful during pregnancy and should be avoided.

Drugs, Nicotine, & Alcohol

1. Drugs—A **teratogen** is a toxin, drug, or a biologic agent that causes a harmful effect on a fetus. The US Food and Drug Administration has a classification system for drugs during pregnancy and lactation. The greatest effect of a drug is normally during the period of organogenesis (weeks 2–10 after LNMP). Drugs with the potential for addiction such as heroin, methadone, and benzodiazepines can cause major problems for the neonate, including withdrawal.

2. Nicotine & cigarette smoking—There is an increased risk of low-birth-weight infants with cigarette smoking by pregnant women. Smoking during pregnancy is associated with an increased risk of intrauterine growth restriction, placenta previa, placenta abruption, preterm birth, low birth weight, and perinatal mortality. Pregnant women should be urged not to smoke; but, if cessation is not possible, a reduction of the number of cigarettes smoked per day is encouraged. Pharmacologic agents may be offered to assist with smoking cessation.

3. Alcohol—The precise level of alcohol consumption that is safe during pregnancy cannot be determined. A fetal alcohol syndrome (FAS) after maternal ingestion (>2 oz daily) has been described, with an incidence from 1 in 600 to 1 in 1500 live births. The major features of FAS include pre- and postnatal growth restriction, cranial–facial dysmorphology (including microcephalus and microphthalmia), mental retardation, cardiac defects, and behavioral abnormalities. Infants whose mothers consume alcohol during pregnancy can have FAS or fetal alcohol effects (FAEs) or be normal. Pregnant women should be encouraged to avoid alcohol during pregnancy.

Exercise

Pregnant women should incorporate 30 minutes or more of moderate-intensity physical activity. Activities with risk of maternal injury, especially abdominal trauma, should be avoided. Aerobic and exercise classes have been designed for pregnant women. Pregnancy yoga classes are also available for women. Routines in yoga classes are designed for flexibility and joint protection.

Immunization

Killed virus, toxoid, or recombinant vaccines may be given during pregnancy. The American College of Obstetrics and Gynecology recommends that all pregnant women should receive the injectable influenza vaccine during the season (October–March). The “flu shot” is safe when given in any trimester. Furthermore, if administered during pregnancy, the vaccine appears to reduce the risk of infant respiratory disease within the first 6 months of life. Diphtheria and tetanus toxoid, hepatitis B vaccine series, and killed polio vaccine may be administered during pregnancy to women at risk.

Live attenuated vaccines (varicella, measles, mumps, polio, and rubella) should be given 3 months before pregnancy or postpartum. Live virus vaccines are contra-indicated in pregnancy secondary to the potential risk of fetal infection. Viral shedding occurs in children receiving vaccination, but they do not transmit the virus; consequently, vaccination may be safely given to the children of pregnant women.

Secondary prophylaxis with immune globulin is recommended for pregnant women exposed to measles, hepatitis A, hepatitis B, tetanus, chicken pox, or rabies.

Intercourse

No adverse outcome can be directly attributed to sexual intercourse during pregnancy. If cramping, spotting, or bright red bleeding follows coitus, sexual activity should not occur until the patient is evaluated by her clinician. A patient with preterm labor or vaginal bleeding should not have coitus until evaluated by her clinician.

Nutritional Requirements

The mother’s nutrition from the moment of conception is an important factor in the development of the infant’s metabolic pathways and future well-being. The pregnant woman should be encouraged to eat a balanced diet and should be made aware of special needs for iron, folic acid, calcium, and zinc. The average woman weighing 58 kg (127 lb) has a normal dietary intake of 2300 kcal/d. An additional 300 kcal/d is needed during pregnancy, and an additional 500 kcal/d is needed during breastfeeding (Table 6–1). Consumption of fewer calories could result in inadequate intake of essential nutrients.

A. Protein

Protein needs in pregnancy are 1 g per kilogram per day plus 20 g per day in the second half of pregnancy (60–80 g per day for the average woman). Protein intake is crucial for embryonic development, and consumption of lean animal foods (chicken or fish), low-fat dairy products, and vegetable proteins such as legumes should be encouraged.

B. Calcium

Calcium intake should be 1200 mg per day during pregnancy and lactation. Calcium intake is of special concern for the pregnant adolescent and lactating woman. Low calcium intake is defined as less than 600 mg per day; should calcium intake be deficient during pregnancy, demineralization of the maternal skeleton may occur.

C. Iron

Every pregnant woman should have adequate iron intake for the increased red blood cell production that starts at approximately 6 weeks' gestation. In addition, women should have supplementation of 30 g per day of elemental iron during the second and third trimester. If iron deficiency anemia is diagnosed, the elemental iron dose may be increased to 60–120 mg per day.

D. Vitamins/Minerals

A well-balanced diet is critical to the nutrition of any pregnant woman. Folic acid has been shown to reduce the risk of neural tube defects (NTDs). A daily dose of 4 mg of folic acid is recommended for patients who have had a previous pregnancy affected by an NTD. Folic acid should be initiated a minimum of 1 month before conception and continued for the first 3 months after pregnancy. The recurrence risk of NTD is reduced by 70% with prenatal use of folic acid.

For all other women, a daily intake of at least 0.4 mg of folic acid before conception and through the first 3 months of pregnancy is recommended. Patients with insulin-dependent diabetes mellitus and those with seizure disorders treated with valproic acid and carbamazepine are at increased risk of an NTD (1%) and should receive at least 1 mg per day of folic acid. Vitamin B_{12} supplements are also desirable for strict vegetarian patients as well as those with megaloblastic anemia.

Travel

Travel (by automobile, train, or plane) does not adversely affect a pregnancy, but separation from the physician may be of concern.

Preparation for Labor

As term approaches, the patient must be instructed on the physiologic changes associated with labor. She is usually admitted to the hospital when contractions occur at 5- to 10-minute intervals. She should be told to seek medical advice for any of the following danger signals: (1) rupture of membranes, (2) vaginal bleeding, (3) decreased fetal movement, (4) evidence of preeclampsia (eg, marked swelling of the hands and face, blurring of vision, headache, epigastric pain, convulsions), (5) chills or fever, (6) severe or unusual abdominal or back pain, or (7) any other severe medical problems.

Normal & Abnormal Labor & Delivery

Carol L. Archie, MD
Ashley S. Roman, MD, MPH

LABOR AND DELIVERY

ESSENTIALS OF DIAGNOSIS

- Labor is a sequence of uterine contractions that results in effacement and dilatation of the cervix and voluntary bearing-down efforts, leading to the expulsion per vagina of the products of conception.
- Delivery is the mode of expulsion of the fetus and placenta.

Pathogenesis

Labor and delivery is a normal physiologic process that most women experience without complications. The goal of the management of this process is to foster a safe birth for mothers and their newborns. Additionally, the staff should attempt to make the patient and her support person(s) feel welcome, comfortable, and informed throughout the labor and delivery process. Physical contact between the newborn and the parents in the delivery room should be encouraged. Every effort should be made to foster family interaction and to support the desire of the family to be together. The role of the obstetrician/midwife and the labor and delivery staff is to anticipate and manage complications that may occur that could harm the mother or the fetus. When a decision is made to intervene, it must be considered carefully, because each intervention carries both potential benefits and potential risks. The best management in the majority of cases may be close observation and, when necessary, cautious intervention.

Physiologic Preparation for Labor

Before the onset of true labor, several preparatory physiologic changes commonly occur. The settling of the fetal head into the brim of the pelvis, known as **lightening**, usually occurs 2 or more weeks before labor in first pregnancies. In women who have had a previous delivery, lightening often does not occur until early labor. Clinically, the mother may notice a flattening of the upper abdomen and increased pressure in the pelvis. This descent of the fetus is often accompanied by a decrease in discomfort associated with crowding of the abdominal organs under the diaphragm (eg, heartburn, shortness of breath) and an increase in pelvic discomfort and frequency of urination.

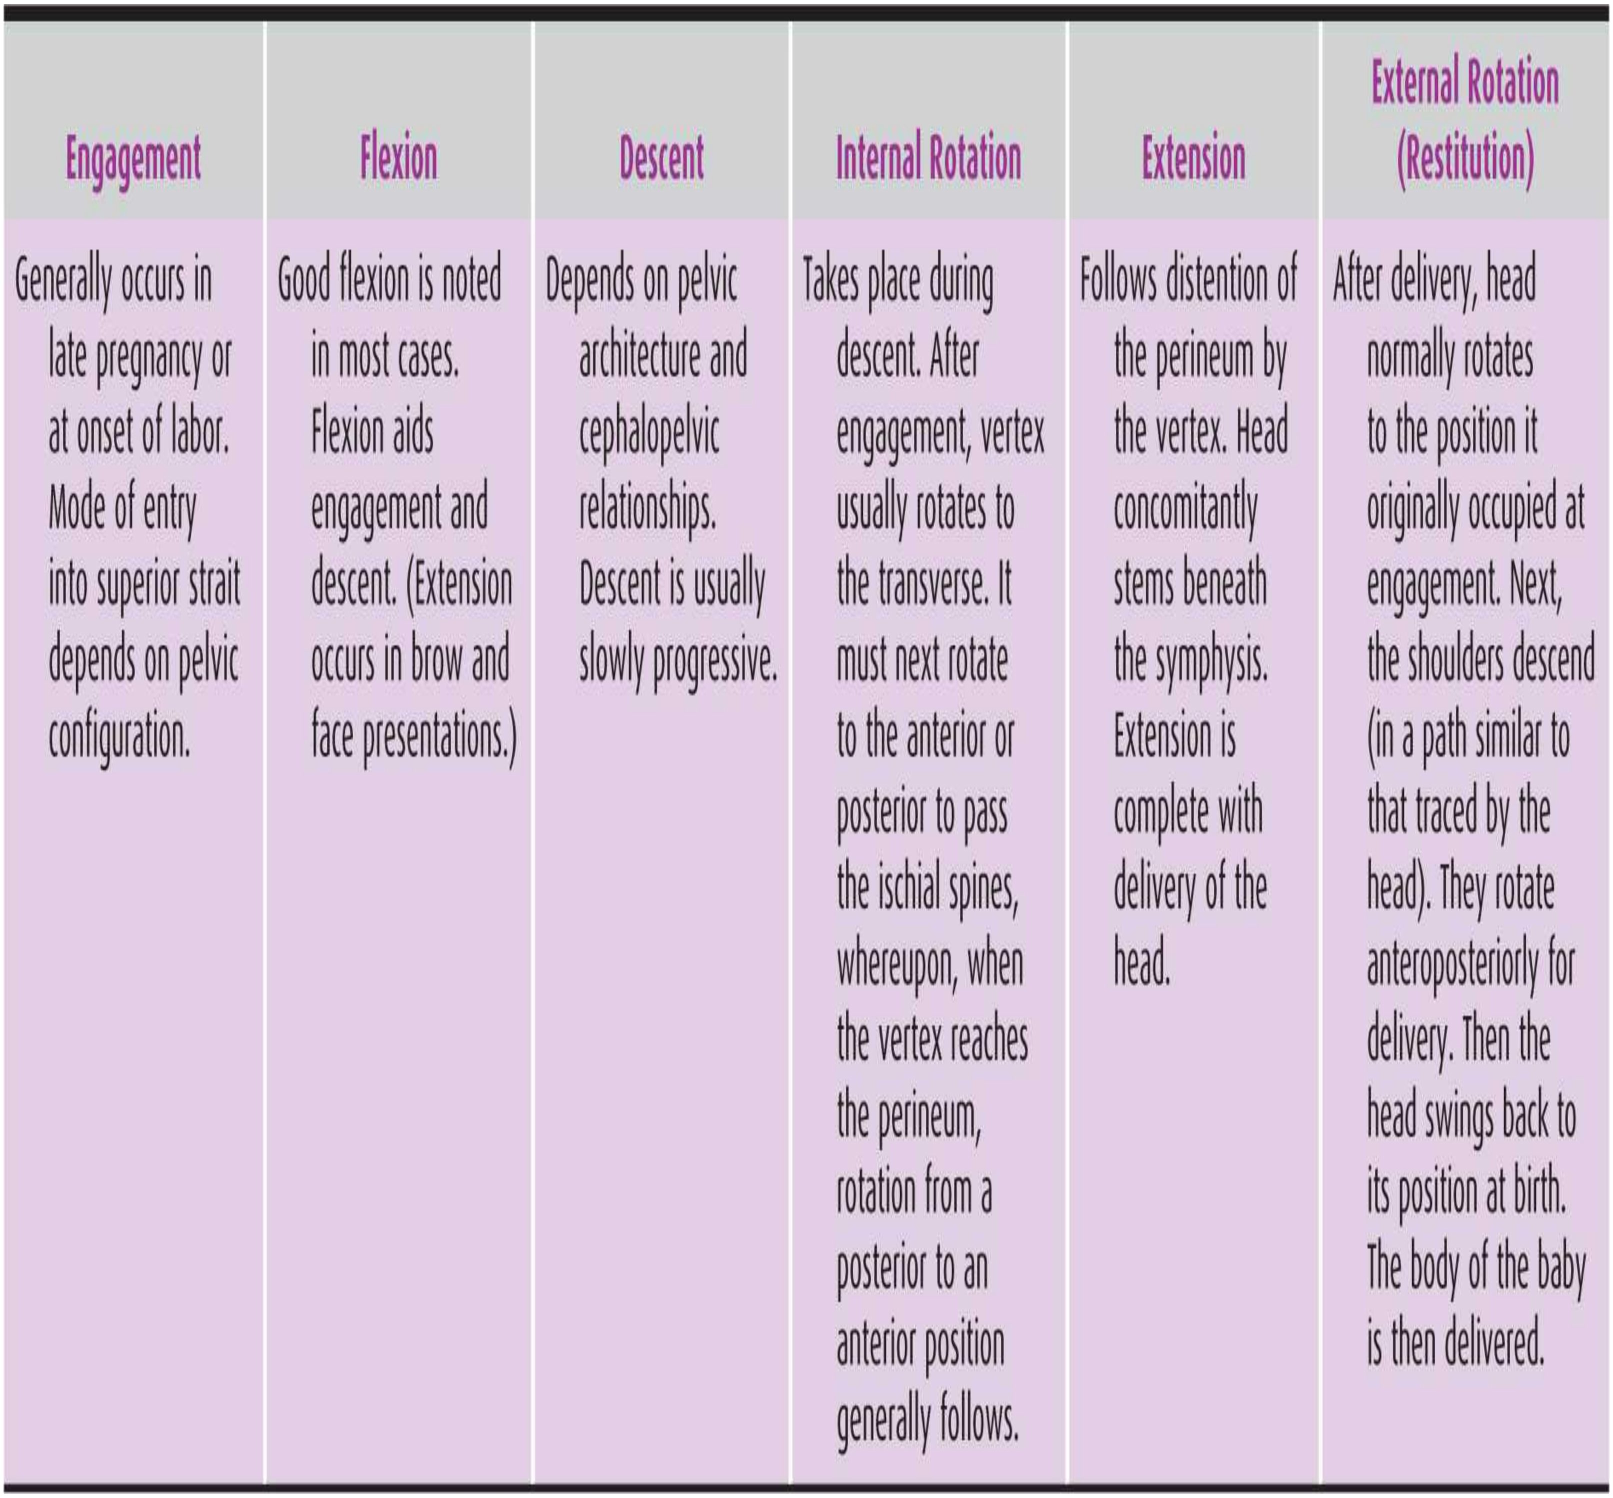
During the last 4–8 weeks of pregnancy, irregular, generally painless uterine contractions occur with slowly increasing frequency. These contractions, known as **Braxton Hicks contractions**, may occur more frequently, sometimes every 10–20 minutes, and with greater intensity during the last weeks of pregnancy. When these contractions occur early in the third trimester, they must be distinguished from true preterm labor. Later, they are a common cause of “false labor,” which is distinguished by the lack of cervical change in response to the contractions.

During the course of several days to several weeks before the onset of true labor, the cervix begins to soften, efface, and dilate. In many cases, when labor starts, the cervix is already dilated 1–3 cm in diameter. This is usually more pronounced in the multiparous patient, the cervix being relatively more firm and closed in nulliparous women. With cervical effacement, the mucus plug within the cervical canal may be released. When this occurs, the onset of labor is sometimes marked by the passage of a small amount of blood-tinged mucus from the vagina known as **bloody show**.

Mechanism of Labor

The mechanism of labor in the vertex position consists of engagement of the presenting part, flexion, descent, internal rotation, extension, external rotation, and expulsion (Table 7–1). The progress of labor is dictated by the pelvic dimensions and configuration, the size of the fetus, and the strength of the contractions. In essence, delivery proceeds along the line of least resistance, that is, by adaptation of the smallest achievable diameters of the presenting part to the most favorable dimensions and contours of the birth canal.

Table 7–1. Mechanisms of labor: vertex presentation.

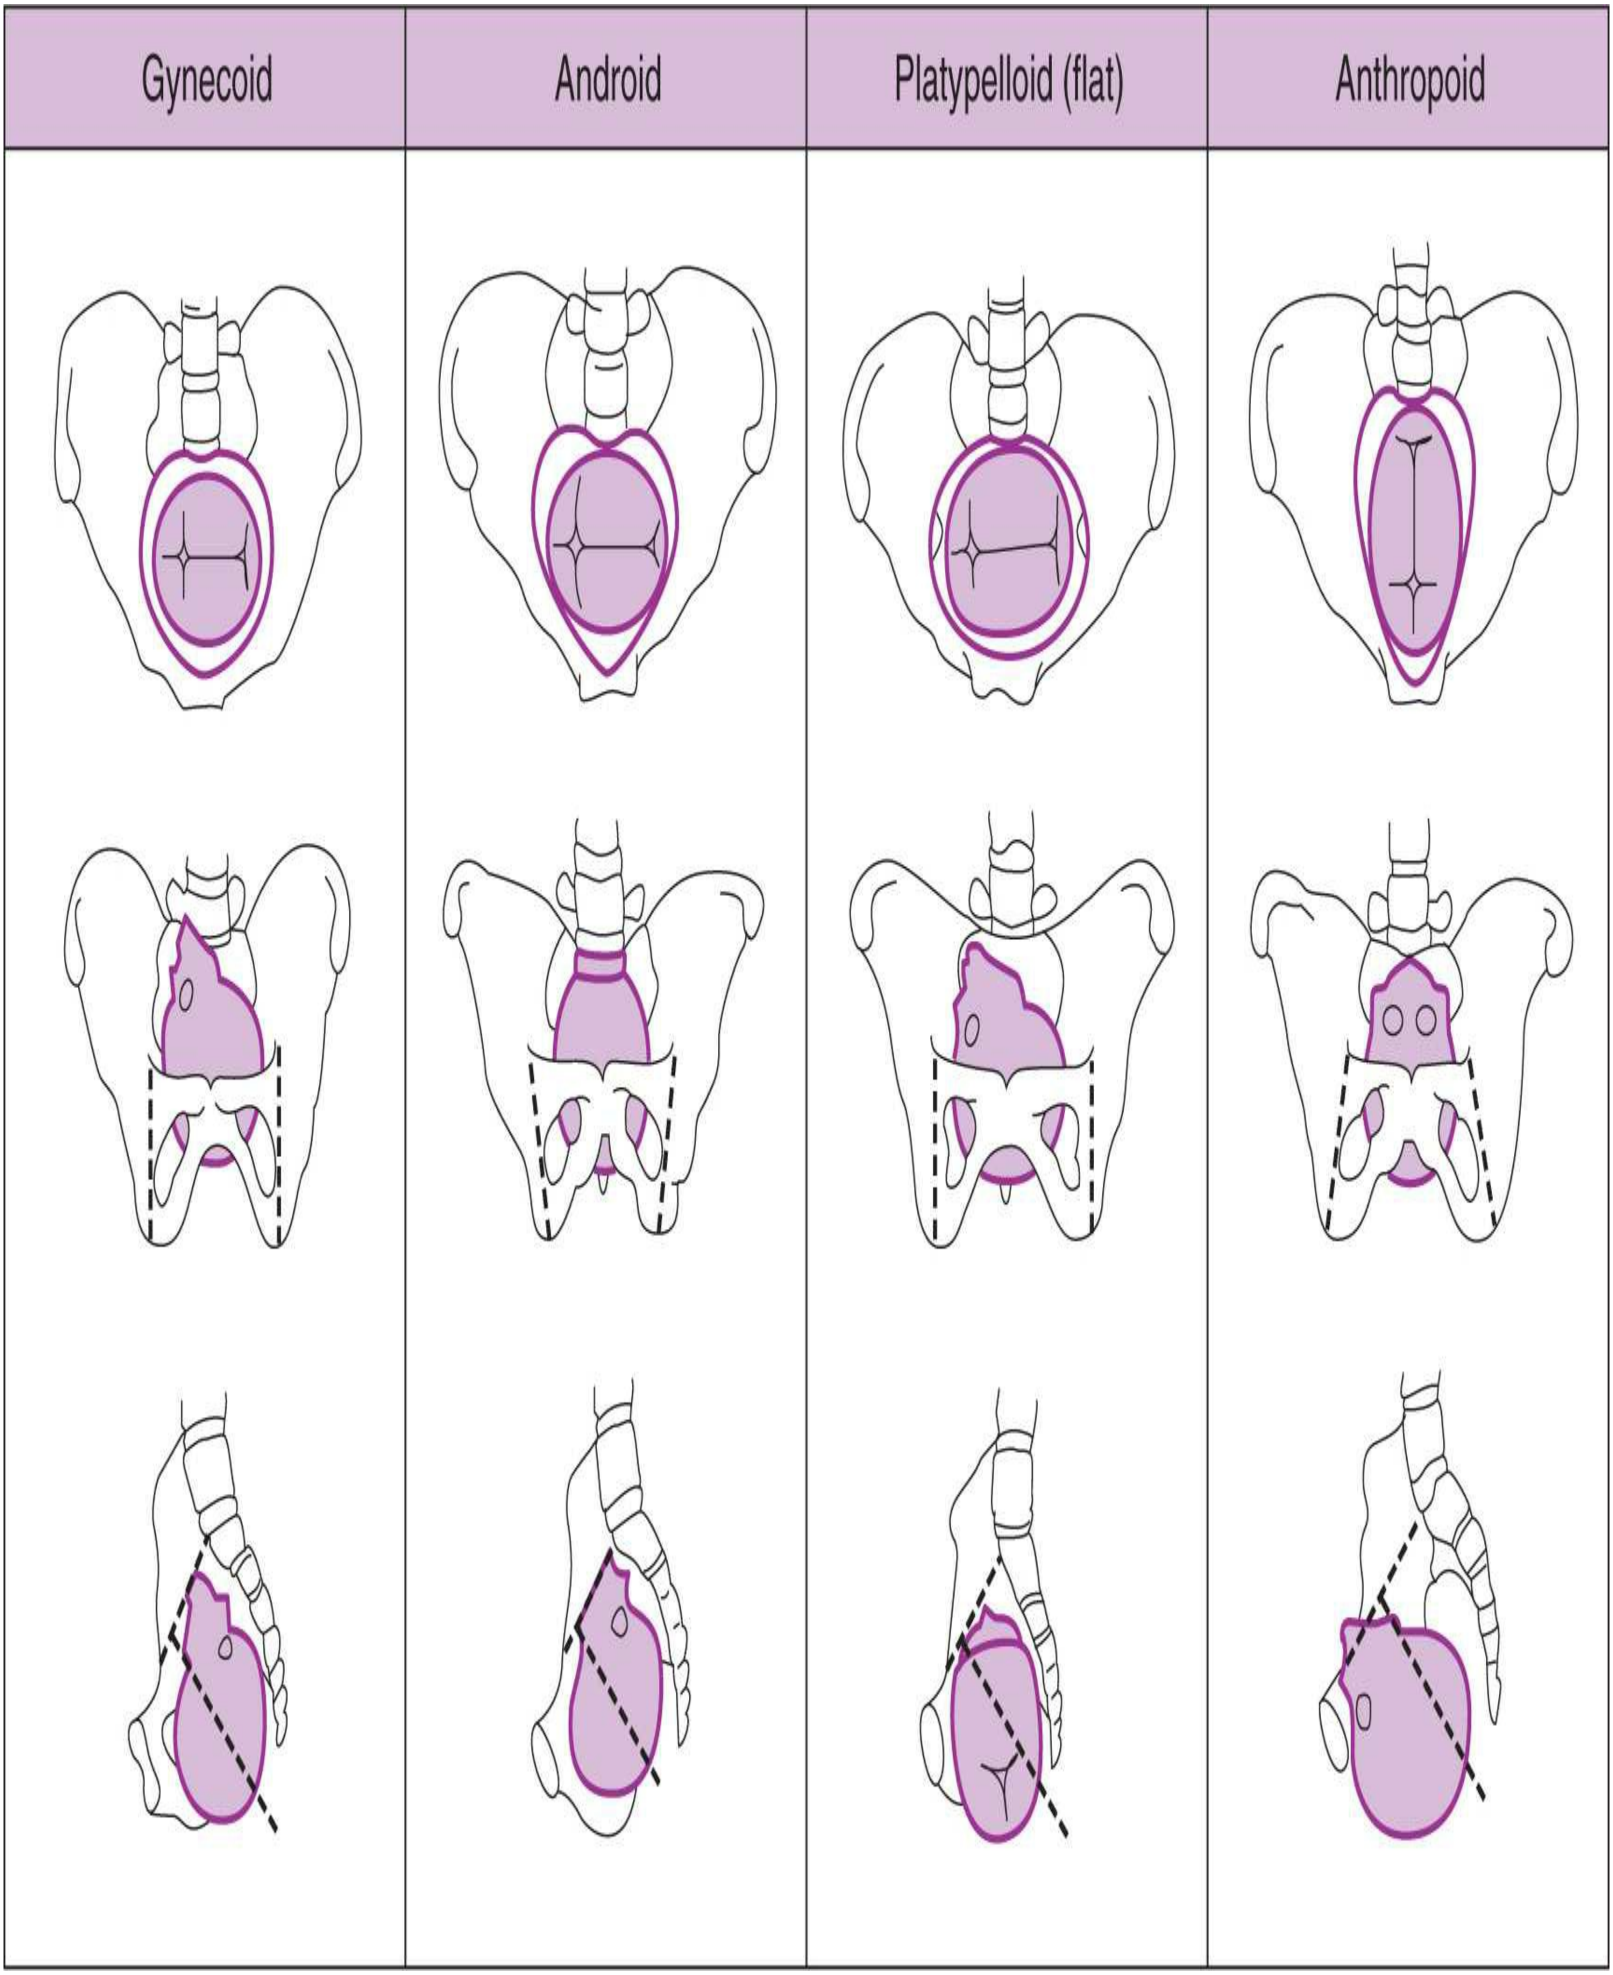


Engagement	Flexion	Descent	Internal Rotation	Extension	External Rotation (Restitution)
Generally occurs in late pregnancy or at onset of labor. Mode of entry into superior strait depends on pelvic configuration.	Good flexion is noted in most cases. Flexion aids engagement and descent. (Extension occurs in brow and face presentations.)	Depends on pelvic architecture and cephalopelvic relationships. Descent is usually slowly progressive.	Takes place during descent. After engagement, vertex usually rotates to the transverse. It must next rotate to the anterior or posterior to pass the ischial spines, whereupon, when the vertex reaches the perineum, rotation from a posterior to an anterior position generally follows.	Follows distention of the perineum by the vertex. Head concomitantly stems beneath the symphysis. Extension is complete with delivery of the head.	After delivery, head normally rotates to the position it originally occupied at engagement. Next, the shoulders descend (in a path similar to that traced by the head). They rotate anteroposteriorly for delivery. Then the head swings back to its position at birth. The body of the baby is then delivered.

The sequence of events in vertex presentation is as follows:

A. Engagement

This usually occurs late in pregnancy in the primigravida, commonly in the last 2 weeks. In the multiparous patient, engagement usually occurs with the onset of labor. The head enters the superior strait in the occiput transverse position in 70% of women with a gynecoid pelvis (Figs. 7–1 and 7–2).



Gynecoid

Danforth DN, Ellis AH. Midforceps delivery: A vanishing art? *Am J Obstet Gynecol* 1963;86:29–37.)

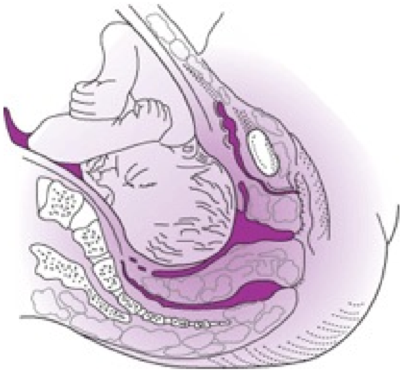

Figure 7–2. Left occipitoanterior engagement.

B. Flexion

In most cases, flexion is essential for both engagement and descent. This will vary, of course, if the head is small in relation to the pelvis or if the pelvis is unusually large. When the head is improperly fixed—or if there is significant narrowing of the pelvic strait (as in the platypelloid type of pelvis)—there may be some degree of deflexion, if not actual extension. Such is the case with a brow (deflexion) or face (extension) presentation.

C. Descent

Descent is gradually progressive and is affected by the forces of labor and thinning of the lower uterine segment. Other factors also play a part (eg, pelvic configuration and the size and position of the presenting part). The greater the pelvic resistance or the poorer the contractions, the slower the descent. Descent continues progressively until the fetus is delivered; the other movements are superimposed on it (Fig. 7–3).

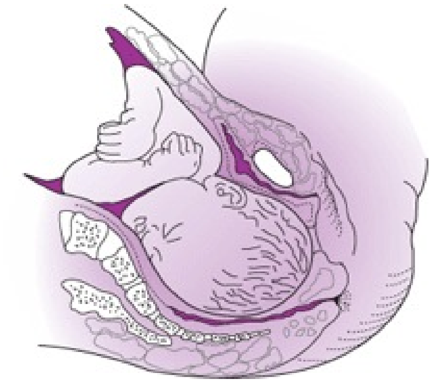

Figure 7–3. Descent in left occipitoanterior position.

D. Internal rotation

With the descent of the head into the midpelvis, rotation occurs so that the sagittal suture occupies the anteroposterior diameter of the pelvis. Internal rotation normally begins with the presenting part at the level of the ischial spines. The levator ani muscles form a V-shaped sling that tends to rotate the vertex anteriorly. In cases of occipitoanterior vertex, the head has to rotate 45 degrees, and in occipitoposterior vertex, 135 degrees, to pass beneath the pubic arch (Fig. 7–4).

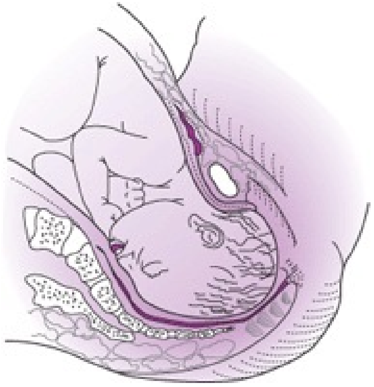

Figure 7–4. Anterior rotation of head.

E. Extension

Because the vaginal outlet is directed upward and forward, extension must occur before the head can pass through it. As the head continues its descent, there is a bulging of the perineum, followed by crowning. Crowning occurs when the largest diameter of the fetal head is encircled by the vulvar ring (Fig. 7–5). At this time, spontaneous delivery is imminent.

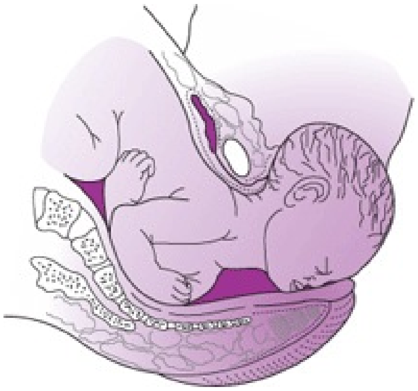

Figure 7–5. Extension of the head.

F. External rotation

External rotation (restitution) follows delivery of the head when it rotates to the position it occupied at engagement. After this, the shoulders descend in a path similar to that traced by the head. The anterior shoulder rotates internally approximately 45 degrees to come under the pubic arch for delivery (Fig. 7–6). As this occurs, the head swings back to its position at birth.

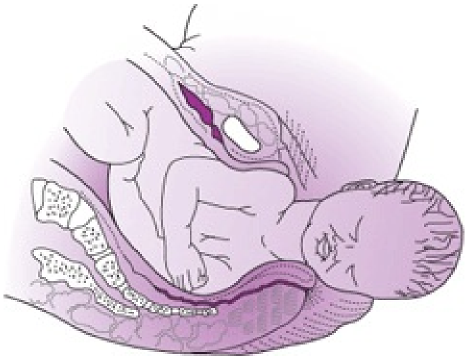

Figure 7–6. External rotation of the head.

Clinical Findings

In true labor, the woman is usually aware of her contractions during the first stage. The intensity of pain depends on the fetal/pelvic relationships, the quality and strength of uterine contractions, and the emotional and physical status of the patient. Few women experience no discomfort during the first stage of labor. Some women describe slight low back pain that radiates around to the lower abdomen. Each contraction starts with a gradual build-up of intensity, and dissipation of discomfort promptly follows the climax. Normally, the contraction will be at its height well before discomfort is reported. Dilatation of the lower birth canal and distention of the perineum during the second stage of labor will almost always cause discomfort.

Normal labor is a continuous process that has been divided into **three stages** for purposes of study, with the first stage further subdivided into two phases, the latent phase and the active phase.

- The first stage of labor is the interval between the onset of labor and full cervical dilatation.
- The second stage is the interval between full cervical dilatation and delivery of the infant.
- The third stage of labor is the period between the delivery of the infant and the delivery of the placenta.

In his classic studies of labor in 1967, Friedman presented data describing the process of spontaneous labor over time. The duration of the first stage of labor in primipara patients is noted to range from 6–18 hours, whereas in multiparous patients, the range is reported to be 2–10 hours. The lower limit of normal for the rate of cervical dilatation during the active phase is 1.2 cm per hour in first pregnancies and 1.5 cm per hour in subsequent pregnancies. The duration of the second stage in the primipara is 30 minutes to 3 hours and is 5–30 minutes for multiparas. For both, the duration of the third stage was reported to be 0–30 minutes for all pregnancies. These data, although extremely helpful as guidelines, should not be used as strict deadlines that trigger interventions if not met. Even if a numerical (statistical) approach is used to define “abnormal,” the cutoff figure would not be the average range, but the 5th percentile numbers (eg, 25.8 hours for the first stage of labor in a primipara). The course that is more appropriate is to consider the overall clinical presentation and use the progress of labor to estimate the likelihood that successful vaginal delivery will occur.

The first stage of labor is evaluated by the rate of change of cervical effacement, cervical dilatation, and descent of the fetal head. The frequency and duration of uterine contractions alone is not an adequate measure of labor progress. The second stage of labor begins after full cervical dilatation. The progress of this stage is measured by the descent, flexion, and rotation of the presenting part.

Treatment

Women most likely to have a normal labor and delivery have had adequate prenatal care without significant maternal or fetal complications and are at 36 weeks’ gestation or beyond. Whenever a pregnant woman is evaluated for labor, the following factors should be assessed and recorded:

- Time of onset and frequency of contractions, status of membranes, any history of bleeding, and any fetal movement.
- History of allergies, use of medication, and time, amount, and content of last oral intake.
- Prenatal records with special attention to prenatal laboratory results that impact intrapartum and immediate postpartum management (eg, HIV and hepatitis B status).
- Maternal vital signs, urinary protein and glucose, and uterine contraction pattern.

- Fetal heart rate, presentation, and clinical estimated fetal weight.
- Status of the membranes, cervical dilatation and effacement (unless contraindicated, eg, by placenta previa), and station of the presenting part.

If no complications are detected during the initial assessment and the patient is found to be in prodromal labor, admission for labor and delivery may be deferred. When a patient is admitted, a hematocrit or hemoglobin measurement should be obtained and a blood clot should be obtained in the event that a cross-match is needed. A blood group, Rh type, and antibody screen should also be done.

The First Stage of Labor

In the first stage of normal labor, the pregnant woman may be allowed to ambulate or sit in a comfortable chair as desired. When the patient is lying in bed, the supine position should be discouraged. Patients in active labor should avoid ingestion of solid food. Clear liquids, ice chips, or preparations for moistening the mouth and lips should be allowed. When significant amounts of fluids and calories are required because of long labor, they should be given intravenously.

Maternal pulse and blood pressure should be recorded at least every 2–4 hours in normal labor and more frequently if indicated. Maternal fluid balance (ie, urine output and intravenous and oral intake) should be monitored, and both dehydration and fluid overload should be avoided.

Management of discomfort and pain during labor and delivery is a necessary part of good obstetric practice. A patient’s request is sufficient justification for providing pain relief during labor. Specific analgesic and anesthetic techniques are discussed in Chapter 24. Some patients tolerate the pain of labor by using techniques learned in childbirth preparation programs. Common methods of preparation include Lamaze, Bradley, Read, hypnotherapy, and prenatal yoga. Although specific techniques vary, these classes usually teach relief of pain through the application of principles of education, emotional support, touch, relaxation, paced breathing, and mental focus. The staff at the bedside should be knowledgeable about these pain-management techniques and should be supportive of the patient’s decision to use them. When such methods fail to provide adequate pain relief, some patients will ask for medical assistance, and such requests should be respected. Indeed, the use of appropriate medical analgesic techniques should be explained to the patient and her labor partner and their use encouraged when medically indicated.

Reassurance of fetal well-being is sought through fetal monitoring. Fetal monitoring may be performed intermittently or continuously, depending on the presence or absence of risk factors for adverse perinatal outcome. In patients with no significant obstetric risk factors, either continuous or intermittent monitoring is acceptable. If the fetus is monitored intermittently, then the fetal heart rate should be auscultated or the electronic monitor tracing should be evaluated at least every 30 minutes in the active phase of the first stage of labor and at least every 15 minutes in the second stage of labor. In patients with obstetric risk factors such as hypertension, intrauterine fetal growth restriction, diabetes, or multiple gestations, continuous fetal monitoring is recommended.

Uterine contractions may be monitored by palpation, by tocodynamometer, or by internal pressure catheter. If monitored by palpation, the patient’s abdomen should be palpated every 30 minutes to assess contraction frequency, duration, and intensity. For at-risk pregnancies, uterine contractions should be monitored continuously along with the fetal heart rate. This can be achieved by using either an external tocodynamometer or an internal pressure catheter in the amniotic cavity. The latter method is particularly useful when abnormal progression of labor is suspected or when the patient requires oxytocin for augmentation of labor.

The progress of labor is monitored by examination of the cervix. During the latent phase, especially when the membranes are ruptured, vaginal examinations should be done sparingly to decrease the risk of intrauterine infection. In the active phase, the cervix should be assessed approximately every 2 hours. The cervical effacement and dilatation and the station and position of the fetal head should be recorded (Fig. 7–7). Additional examinations to determine whether full dilation has occurred may be required if the patient reports the urge to push, or to search for prolapse of the umbilical cord or perform fetal scalp stimulation if a significant fetal heart rate deceleration is detected.

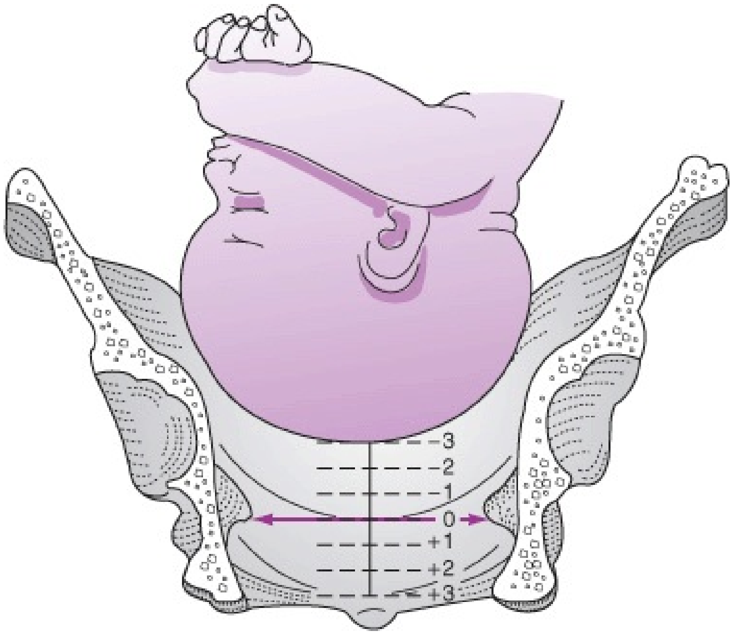

Figure 7–7. Stations of the fetal head. (Reproduced, with permission, from Benson RC. *Handbook of Obstetrics & Gynecology*. 8th ed. Los Altos, CA: Lange; 1983.)

The therapeutic rupture of fetal membranes (amniotomy) has been largely discredited as a means of induction when used alone. Moreover, artificial rupture of the membranes increases the risk of chorioamnionitis and the need for antibiotics (especially if labor is prolonged), as well as the risk of cord prolapse if the presenting part is not engaged. Amniotomy may, however, provide information on the volume of amniotic fluid and the presence of meconium. In addition, rupture of the membranes may cause an increase in uterine contractility. Amniotomy should not be performed routinely. It should be used when internal fetal or uterine monitoring is required and may be helpful when enhancement of uterine contractility in the active phase of labor is indicated. Care should be taken to palpate for the umbilical cord and to avoid dislodging the fetal head. The fetal heart rate should be recorded before, during, and immediately after the procedure.

The Second Stage of Labor

At the beginning of the second stage of labor, the mother usually feels a desire to bear down with each contraction. This abdominal pressure, together with the force of the uterine contractions, expels the fetus. During the second stage of labor. the descent of the fetal head is measured to assess the progress of labor. The descent of the fetus is evaluated by measuring the relationship of the bony portion of the fetal head to the level of the maternal ischial spines (station) (Fig. 7–7). When the leading portion of the fetal skull is at the level of the ischial spines, the station is “0.” The American College of Obstetricians and Gynecologists–endorsed method for describing station is to estimate the number of centimeters from the ischial spines. For instance, when the leading portion of the head is 2 cm above the ischial spines, this is reported as −2 station; when the leading portion of the skull is 3 cm below the ischial spines, this is reported as +3. Some practitioners find it useful to refer to station in estimated thirds of the maternal pelvis. An approximate correlation of these two methods would be as follows: $2\text{ cm} = +1$, $4\text{ cm} = +2$, and $6\text{ cm} = +3$.

The second stage generally takes from 30 minutes to 3 hours in primigravid women and from 5–30 minutes in multigravid women. The median duration is 50 minutes in a primipara and 20 minutes in a multipara. These times may vary depending on the pushing efforts of the mother, the quality of the uterine contractions, and the type of analgesia.

Delivery

When the fetal head is noted to crown, delivery is imminent. Careful management by the practitioner with controlled efforts of the mother will minimize perineal trauma. Routine episiotomy is unnecessary and is associated with increased maternal blood loss, increased risk of disruption of the anal sphincter (third-degree extension) and rectal mucosa (fourth-degree extension), and delay in the patient's resumption of sexual activity. Further extension follows extrusion of the head beyond the introitus. Once the head is delivered, the airway is cleared of blood and amniotic fluid using a bulb suction device. The oral cavity is cleared initially, followed by clearing of the nares.

After the airway is cleared, an index finger is used to check whether the umbilical cord encircles the neck. If so, the cord can usually be slipped over the infant's head. If the cord is too tight, it can be cut between two clamps.

Delivery of the anterior shoulder is aided by gentle downward traction on the externally rotated head (Fig. 7–8). The posterior shoulder is then delivered by gentle upward traction on the head (Fig. 7–9). The brachial plexus may be injured if excessive force is used. After these maneuvers, the body, legs, and feet are delivered with gentle traction on the shoulders.

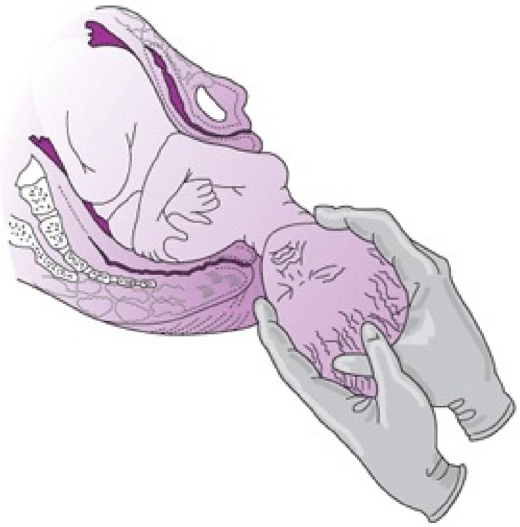

Figure 7–8. Delivery of anterior shoulder.

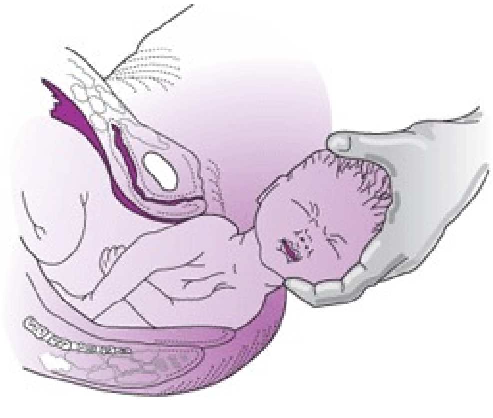

Figure 7–9. Delivery of posterior shoulder.

After delivery, blood will be infused from the placenta into the newborn if the baby is held below the mother’s introitus. Delayed cord clamping can result in neonatal hyperbilirubinemia as additional blood is transferred to the newborn infant. Generally, a vigorous newborn can be delivered directly from the introitus to the abdomen and waiting arms of a healthy, alert mother. Placing the child skin to skin (abdomen to abdomen) results in optimum warmth for the newborn. Then the cord, which has been doubly clamped, may be cut between the clamps by either the practitioner, the mother, or her partner.

Third Stage of Labor

Immediately after the baby is delivered, the cervix and vagina should be inspected for actively bleeding lacerations and surgical repair should be performed as needed. Repair of vaginal lacerations should be performed using absorbable suture material, either 2-0 or 3-0. The inspection and repair of the cervix, vagina, and perineum is often easier prior to the separation of the placenta before uterine bleeding obscures visualization.

Separation of the placenta generally occurs within 2–10 minutes of the end of the second stage, but it may take 30 minutes or more to spontaneously separate. Signs of placental separation are as follows: (1) a fresh show of blood appears from the vagina, (2) the umbilical cord lengthens outside the vagina, (3) the fundus of the uterus rises up, and (4) the uterus becomes firm and globular. When these signs appear, it is safe to place traction on the cord. The gentle traction, with or without counterpressure between the symphysis and fundus to prevent descent of the uterus, allows delivery of the placenta.

After the delivery of the placenta, attention is turned to prevention of excessive postpartum bleeding. Uterine contractions that reduce this bleeding may be enhanced with uterine massage and/or the infusion of a dilute solution of oxytocin. The placenta should be examined to ensure complete removal and to detect placental abnormalities.

Puerperium

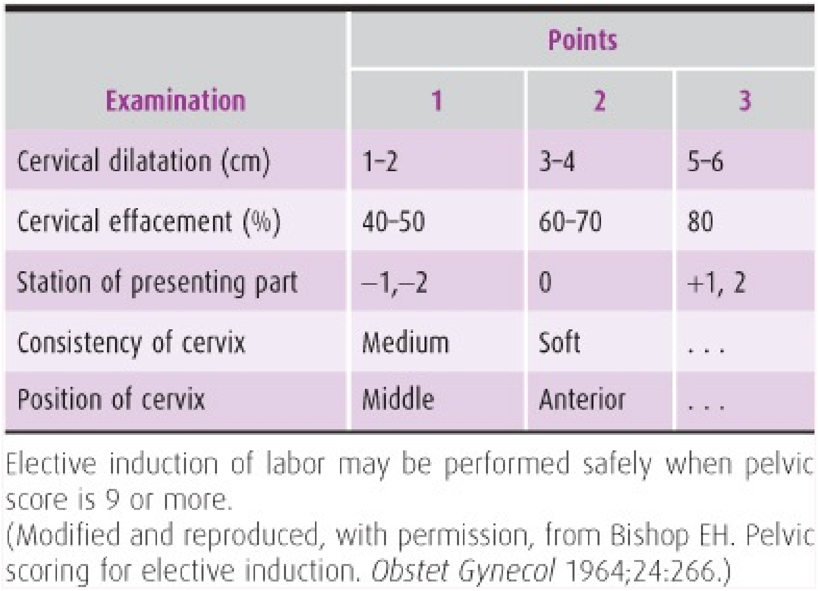
The puerperium consists of the period after the delivery of the baby and placenta to approximately 6 weeks postpartum. The immediate postpartum period (within the first hour of delivery) is a critical time for both maternal and neonatal physiologic and emotional adjustment. During that hour, the maternal blood pressure, pulse rate, and uterine blood loss must be monitored closely. It is during this time that most postpartum hemorrhage usually occurs, largely as a result of uterine relaxation, retained placental fragments, or unrepaired lacerations. Occult bleeding (eg, vaginal wall hematoma formation) may manifest as increasing pelvic pain.

At the same time, maternal bonding to the newborn is evolving, and ideally breastfeeding is initiated. Early initiation of breastfeeding is beneficial to the health of both the mother and the newborn. Both benefit because babies are extremely alert and programmed to latch onto the breast during this period. Mother–infant pairs that begin breastfeeding early are most able to continue breastfeeding for longer periods of time. For the mother, nursing accelerates the involution of the uterus, thereby reducing blood loss by increasing uterine contractions. For the newborn, there are important immunologic advantages. For example, various maternal antibodies are present in breast milk, which provide the newborn with passive immunity against certain infections. Also immunoglobulin (Ig) A, a secretory immunoglobulin present in significant amounts in breast milk, protects the infant’s gut by preventing attachment of harmful bacteria to cells of the gut mucosal surface. It is also believed that maternal lymphocytes pass through the infant’s gut wall and initiate immunologic processes that are not yet fully understood. In addition to the immunologic benefits, breast milk is the ideal nutritional source for the newborn. Moreover, it is inexpensive and is usually in good supply. Given all the advantages (the preceding is only a partial list of the benefits), encouraging successful breastfeeding is an important health goal.

Induction and Augmentation of Labor

Induction of labor is the process of initiating labor by artificial means; augmentation is the artificial stimulation of labor that has begun spontaneously. Labor induction should be performed only after appropriate assessment of the mother and fetus. Additionally, the risks, benefits, and alternatives to induction in each case must be evaluated and explained to the patient. In the absence of medical indications for induction, fetal maturity must be confirmed by either exact pregnancy dating, first-trimester ultrasound measurements, and/or amniotic fluid analysis. Evaluation of the cervical status in terms of effacement and softening is important in predicting success of induction and is highly recommended before any elective induction (Table 7–2). Generally, induction should be done in response to specific indications and should not be done electively prior to 39 weeks gestational age.

Table 7–2. Bishop method of pelvic scoring for elective induction of labor.



Examination	Points		
	1	2	3
Cervical dilatation (cm)	1–2	3–4	5–6
Cervical effacement (%)	40–50	60–70	80
Station of presenting part	−1,−2	0	+1, 2
Consistency of cervix	Medium	Soft	. . .
Position of cervix	Middle	Anterior	. . .

Elective induction of labor may be performed safely when pelvic score is 9 or more.
(Modified and reproduced, with permission, from Bishop EH. Pelvic scoring for elective induction. *Obstet Gynecol* 1964;24:266.)

A. Indications

The following are common indications for induction of labor:

1. Maternal—Preeclampsia, diabetes mellitus, heart disease.

2. Fetal—Prolonged pregnancy, Rh incompatibility, fetal abnormality, chorioamnionitis, premature rupture of membranes, placental insufficiency, suspected intrauterine growth restriction.

B. Contraindications

Absolute contraindications to induction of labor include contracted pelvis; placenta previa; uterine scar because of previous classical caesarean section, myomectomy entering the endometrium, hysterotomy, or unification surgery; and transverse lie.

Labor induction should be carried out with caution in the following situations: breech presentation, oligohydramnios, multiple gestation, grand multiparity, previous caesarean section with transverse scar, prematurity, suspected fetal macrosomia.

Complications of Induction of Labor

A. For the mother

In many cases, induction of labor exposes the mother to more distress and discomfort than judicious delay and subsequent vaginal or caesarean delivery. The following hazards must be kept in mind: (1) failure of induction with increased risk of caesarean delivery; (2) uterine inertia and prolonged labor; (3) tumultuous labor and tetanic contractions of the uterus, causing premature separation of the placenta, rupture of the uterus, and laceration of the cervix; (4) intrauterine infection; and (5) postpartum hemorrhage.

B. For the fetus

An induced delivery exposes the infant to the risk of prematurity if the estimated date of conception has been inaccurately calculated. Precipitous delivery may result in physical injury. Prolapse of the cord may follow amniotomy. Injudicious administration of oxytocin or inadequate observation during induction could lead to fetal heart rate abnormalities or delivery of a baby with poor Apgar scores.

Methods of Cervical Ripening

Cervical ripening before induction of labor could facilitate the onset and progression of labor and increase the chance of vaginal delivery, particularly in primigravid patients.

A. Prostaglandin

Two forms of prostaglandins are commonly used for cervical ripening before induction at term: misoprostol (PGE_1) and dinoprostone (PGE_2). Although only dinoprostone, commercially available as prostaglandin gel, is currently Food and Drug Administration–approved for this use, off-label use of misoprostol for cervical ripening is widely practiced. Indeed, although both misoprostol and dinoprostone applied locally intravaginally can provide significant improvement in the Bishop score, a meta-analysis of randomized, controlled trials focusing on cervical ripening and induction of labor found the time to delivery was shorter and the rate of caesarean delivery was lower in the misoprostol group.

Dinoprostone comes prepackaged in a single-dose syringe containing 0.5 mg of PGE_2 in 2.5 mL of a viscous gel of colloidal silicon dioxide in triacetin. The syringe is attached to a soft-plastic catheter for intracervical administration, and the catheter is shielded to help prevent application above the internal cervical os. Misoprostol is manufactured in 100-μg unscored and 200-μg scored tablets that can be administered orally, vaginally, and rectally. PGE_2 should not be used in patients with a history of asthma, glaucoma, or myocardial infarction. Unexplained vaginal bleeding, chorioamnionitis, ruptured membranes, and previous caesarean section are relative contraindications to the use of prostaglandins for cervical ripening.

For cervical ripening and induction at term, misoprostol is given vaginally at a dose of 25 μg every 4–6 hours. With dinoprostone, usually 12 hours should be allowed for cervical ripening, after which oxytocin induction should be started. PGE_1 and PGE_2 have similar side-effect and risk profiles, including fetal heart rate deceleration, fetal distress, emergency caesarean section, uterine hypertonicity, nausea, vomiting, fever, and peripartum infection. However, a current literature review does not indicate any significant differences in reported side effects between control and treatment groups with prostaglandin cervical ripening.

B. Balloon catheter

A Foley catheter with a 25- to 50-mL balloon is passed into the endocervix above the internal os using tissue forceps. The balloon is then inflated with sterile saline, and the catheter is withdrawn gently to the level of internal cervical os. This method should induce cervical ripening over 8–12 hours. The cervix will be dilated 2–3 cm when the balloon falls out, which will make amniotomy possible, but effacement may be unchanged.

C. Hygroscopic dilators

Laminaria tents are made from desiccated stems of the cold-water seaweed *Laminaria digitata* or *L japonica*. When placed in the endocervix for 6–12 hours, the laminaria increases in diameter 3- to 4-fold by extracting water from cervical tissues, gradually swelling and expanding the cervical canal. Synthetic dilators like lamicel, a polyvinyl alcohol polymer sponge impregnated with 450 mg of magnesium sulfate, and dilapan, which is made from a stable nontoxic hydrophilic polymer of polyacrylonitrile, are also noted to be highly effective in mechanical cervical dilation.

Methods of Induction of Labor

A. Oxytocin

Intravenous administration of a very dilute solution of oxytocin is the most effective medical means of inducing labor. Oxytocin exaggerates the inherent rhythmic pattern of uterine motility, which often becomes clinically evident during the last trimester and increases as term is approached.

The dosage must be individualized. The administration of oxytocin is determined with a biologic assay: The smallest possible effective dose must be determined for each patient and then used to initiate and maintain labor. Constant observation by qualified attendants is required when this method is used.

In most cases it is sufficient to add 1 mL of oxytocin (10 units of oxytocin to 1 L of 5% dextrose in water [1 mU/mL]). One acceptable oxytocin infusion regimen is to begin induction or augmentation at 1 mU/min, preferably with an infusion pump or other accurate delivery system, and increase oxytocin in 2-mU increments at 15-minute intervals.

When contractions of 50–60 mm Hg (per the internal monitor pressure) or lasting 40–60 seconds (per the external monitor) occur at 2.5- to 4-minute intervals, the oxytocin dose should be increased no further. Oxytocin infusion is discontinued whenever hyperstimulation or fetal distress is identified, but can be restarted when reassuring fetal heart rate and uterine activity patterns are restored.

B. Amniotomy

Early and variable decelerations of the fetal heart rate are noted to be relatively common with amniotomy. Nonetheless, amniotomy may be an effective way to induce labor in carefully selected cases with high Bishop scores. Release of amniotic fluid shortens the muscle bundles of the myometrium; the strength and duration of the contractions are thereby increased, and a more rapid contraction sequence follows. The membranes should be ruptured with an amniohook. Make no effort to strip the membranes, and do not displace the head upward to drain off amniotic fluid. Because amniotomy has not been proven effective in augmenting labor uniformly, it is recommended that the active phase of labor be entered before performing amniotomy for augmentation. Amniotomy in selected cases, although slightly increasing the risk of infectious morbidity, could shorten the course of labor without increasing or reducing the incidence of operative delivery.

Maternal Physiology During Pregnancy & Fetal & Early Neonatal Physiology

Amy A. Flick, MD
Daniel A. Kahn, MD, PhD

Pregnancy involves a number changes in anatomy, physiology, and biochemistry, which can challenge maternal reserves. A basic knowledge of these adaptations is critical for understanding normal laboratory measurements, knowing the drugs likely to require dose adjustments, and recognizing women who are predisposed to medical complications during pregnancy.

CARDIOVASCULAR SYSTEM

Anatomic Changes

With uterine enlargement and diaphragmatic elevation, the heart rotates on its long axis in a left-upward displacement. As a result of these changes, the apical beat (point of maximum intensity) shifts laterally. Overall, the heart size increases by approximately 12%, which results from both an increase in myocardial mass and intracardiac volume (approximately 80 mL). Vascular changes include hypertrophy of smooth muscle and a reduction in collagen content.

Blood Volume

Blood volume expansion begins early in the first trimester, increases rapidly in the second trimester, and plateaus at about the 30th week (Fig. 8–1). The approximately 50% elevation in plasma volume, which accounts for most of the increment, results from a cascade of effects triggered by pregnancy hormones. For example, increased estrogen production by the placenta stimulates the renin–angiotensin system, which, in turn, leads to higher circulating levels of aldosterone. Aldosterone promotes renal Na^+ reabsorption and water retention. Progesterone also participates in plasma volume expansion through a poorly understood mechanism; increased venous capacitance is another important factor. Human chorionic somatomammotropin, progesterone, and perhaps other hormones promote erythropoiesis, resulting in the approximately 30% increase in red cell mass.

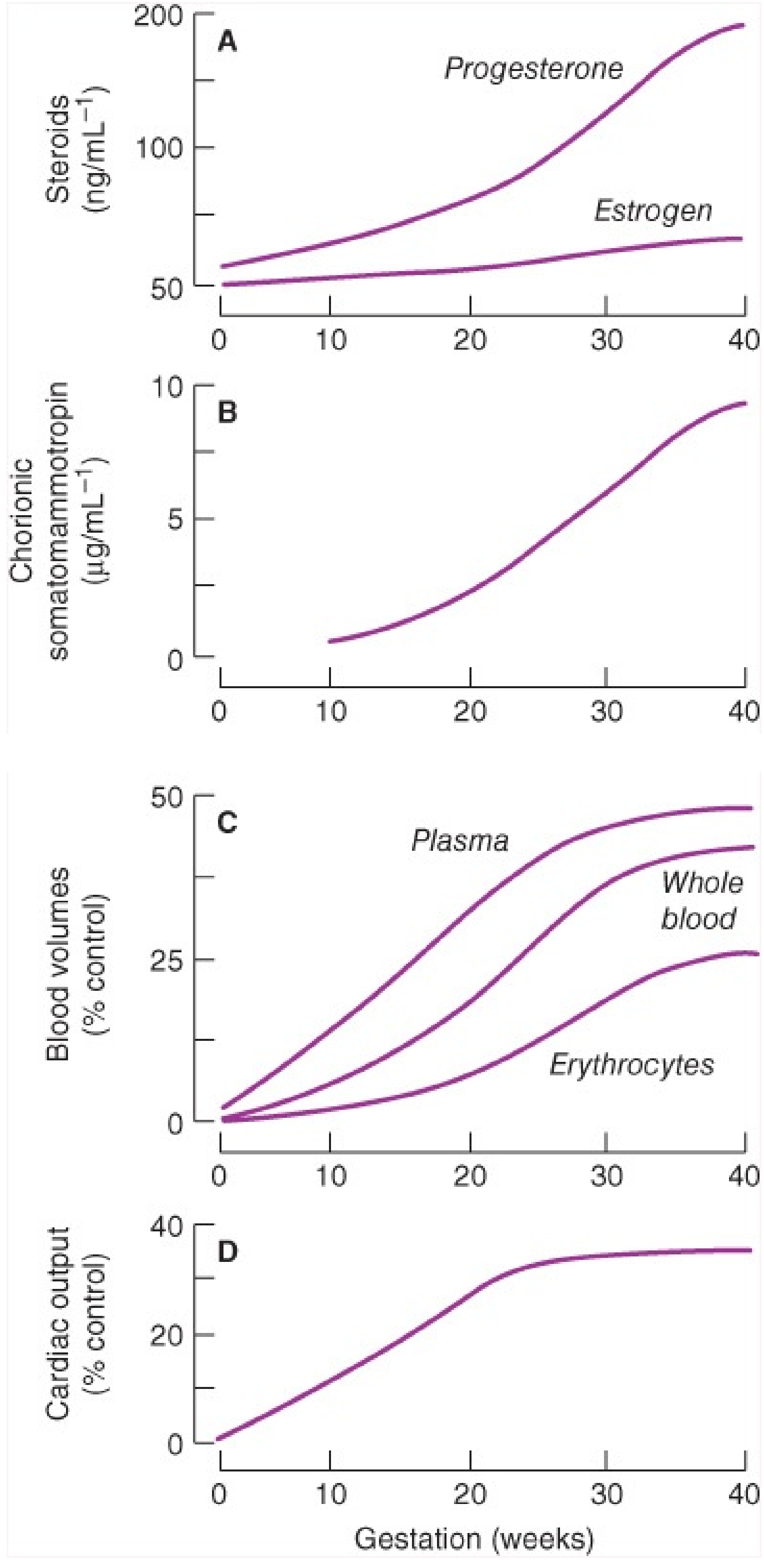

Figure 8–1. Increases in maternal hormones (**A, B**), blood volume (**C**), and cardiac output (**D**) over gestation. % control represents the increment relative to nonpregnant values. (Modified, with permission, from Longo LD. Maternal blood volume and cardiac output during pregnancy: A hypothesis of endocrinologic control. *Am J Physiol* 1983;245:R720.)

The magnitude of the increase in blood volume varies according to the size of the woman, the number of prior pregnancies, and the number of fetuses she is carrying. This hypervolemia of pregnancy compensates for maternal blood loss at delivery, which averages 500–600 mL for vaginal and 1000 mL for caesarean delivery.

Cardiac Output

Cardiac output increases approximately 40% during pregnancy, with maximum values achieved at 20–24 weeks' gestation. This rise in cardiac output is thought to result from the hormonal changes of pregnancy, as well as the arteriovenous-shunt effect of uteroplacental circulation.

Stroke volume increases 25–30% during pregnancy, reaching peak values at 12–24 weeks' gestation (Fig. 8–2). Thus elevations in cardiac output after 20 weeks of gestation depend critically on the rise in heart rate. Maximum cardiac output is associated with a 24% increase in stroke volume and a 15% rise in heart rate. Cardiac output increases in labor in association with painful contractions, which increase venous return and activate the sympathetic nervous system. Cardiac output is further increased, albeit transiently, at delivery.

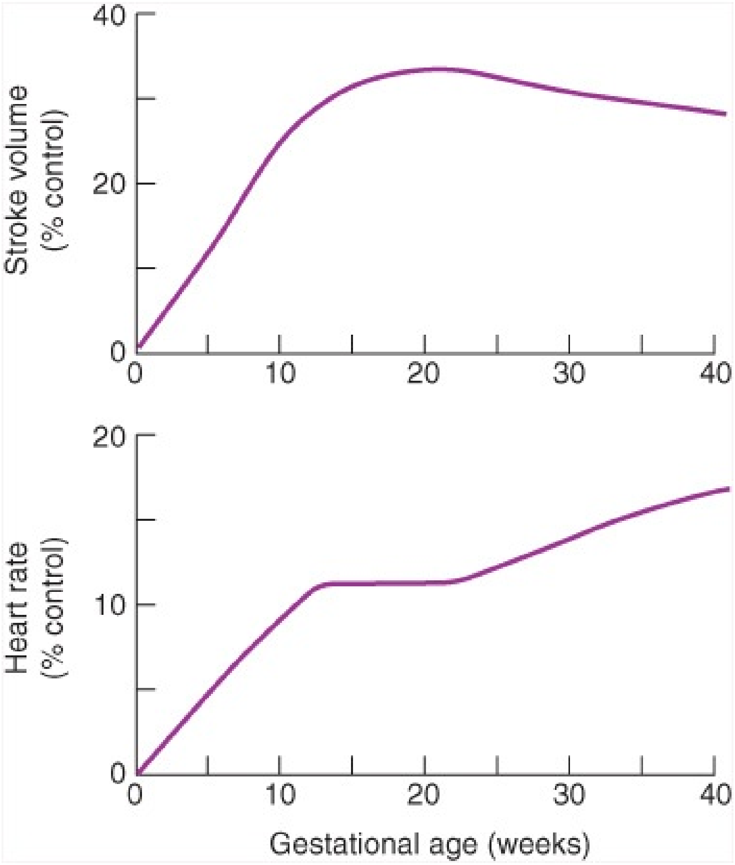

Figure 8–2. Increases in maternal stroke volume and heart rate. The % control represents increment relative to measurements in patients who are not pregnant. (Reproduced, with permission, from Koos BJ. Management of uncorrected, palliated, and repaired cyanotic congenital heart disease in pregnancy. *Prog Ped Cardiol* 2004;19:250.)

Stroke volume is sensitive to maternal position. In lateral recumbency, stroke volume remains roughly the same from 20 weeks' gestation until term, but in the supine position stroke volume decreases after 20 weeks and can even decrease to nonpregnant levels by 40 weeks' gestation.

The resting maternal heart rate, which progressively increases over the course of gestation, averages at term approximately 15 beats/min more than the nonpregnant rate (Fig. 8–2). Of course, exercise, emotional stress, heat, drugs, and other factors can further increase heart rate.

Multiple gestations have even more profound effects on the maternal cardiovascular system. In twin pregnancies, cardiac output is approximately 20% greater than for singletons, because of greater stroke volume (15%) and heart rate (3.5%). Other differences include greater left ventricular end-diastolic dimensions and muscle mass.

Cardiac output is generally resistant to postural stress. For example, the decrease in cardiac output that develops immediately after standing does not occur in the middle of the third trimester, although some reduction can occur earlier in pregnancy. In the third trimester, the supine position can reduce cardiac output and arterial pressure caused by compression of the vena cava by the gravid uterus with an associated reduction in venous return to the heart. Approximately 10% of gravidas will develop supine hypotensive syndrome, characterized by hypotension, bradycardia, and syncope. These women are particularly sensitive to caval compression because of reduced capacitance in venous collaterals. Shifting the gravida to a right or left lateral recumbent position will alleviate caval compression, increase blood return to the heart, and restore cardiac output and arterial pressure.

Blood Pressure

Systemic arterial pressure declines slightly during pregnancy, reaching a nadir at 24–28 weeks of gestation. Pulse pressure widens because the fall is greater for diastolic than for systolic pressures (Fig. 8–3). Systolic and diastolic pressures (and mean arterial pressure) increase to prepregnancy levels by approximately 36 weeks.

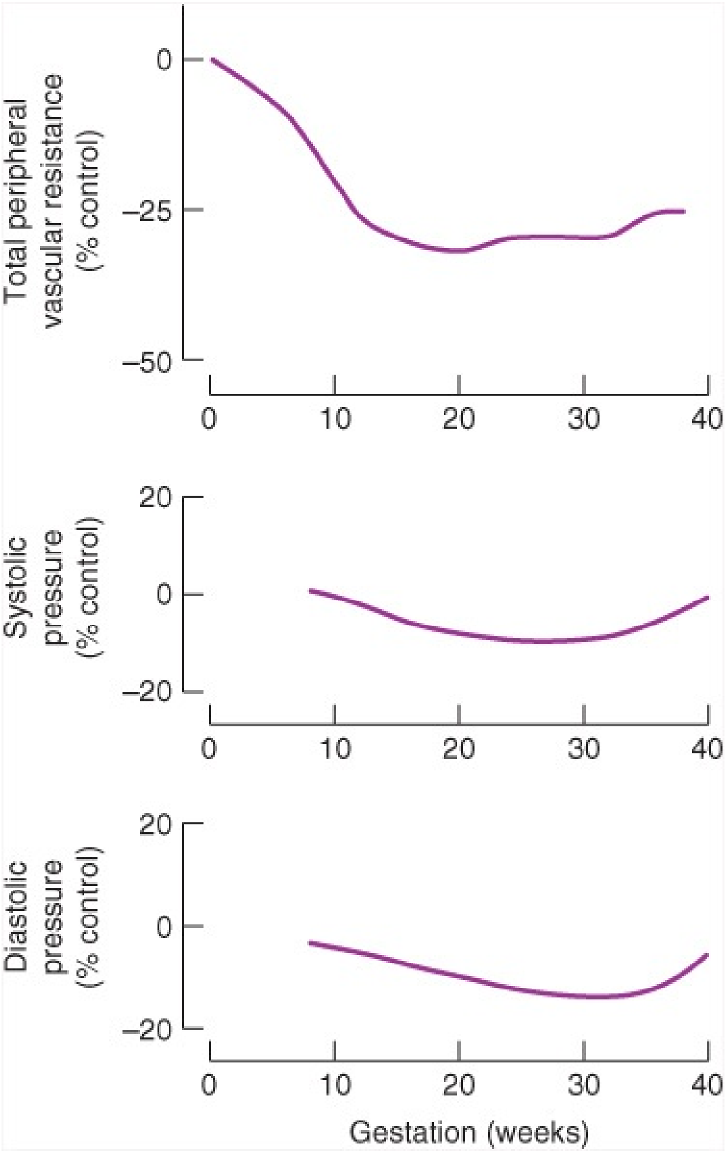

Figure 8–3. Changes in maternal peripheral vascular resistance and arterial pressures over gestation. Pressures were measured in the left lateral recumbent position. The % control represents the relative change from nonpregnant values. (Modified, with permission, from Thornburg KL, Jacobson SL, Giraud GD, Morton MJ. Hemodynamic changes in pregnancy. *Semin Perinatol* 2000;24:11–14; Wilson M, Morganti AA, Zervoudakis I, et al. Blood pressure, the renin-aldosterone system and sex

steroids throughout normal pregnancy. *Am J Med* 1980;68:97–104.)

Venous pressure progressively increases in the lower extremities, particularly when the patient is supine, sitting, or standing. The rise in venous pressure, which can cause edema and varicosities, results from compression of the inferior vena cava by the gravid uterus and possibly from the pressure of the fetal presenting part on the common iliac veins. Lying in lateral recumbency minimizes changes in venous pressure. As expected, venous pressure in the lower extremities falls immediately after delivery. Venous pressure in the upper extremities is unchanged by pregnancy.

Peripheral Vascular Resistance

Vascular resistance decreases in the first trimester, reaching a nadir of approximately 34% below nonpregnancy levels by 14 to 0 weeks of gestation with a slight increase toward term (Fig. 8–3). The hormonal changes of pregnancy likely trigger this fall in vascular resistance by enhancing local vasodilators, such as nitric oxide, prostacyclin, and possibly adenosine. Delivery is associated with nearly a 40% decrease in peripheral vascular resistance, although mean arterial pressure is generally maintained because of the associated rise in cardiac output.

Blood Flow Distribution

In absolute terms, blood flow increases to the uterus, kidneys, skin, breast, and possibly other maternal organs; the total augmented organ flow reflects virtually the entire increment in maternal cardiac output. However, when expressed as a percentage of cardiac output, blood flow in some of these organs may not be elevated compared with the nonpregnant state.

Blood flow to the uterus increases in a gestational age-dependent manner. Uterine blood flow can be as high as 800 mL/min, which is approximately 4 times the nonpregnant value. The increased flow during pregnancy results from the relatively low resistance in the uteroplacental circulation.

Renal blood flow increases approximately 400 mL/min above nonpregnant levels, and blood flow to the breasts increases approximately 200 mL/min. Blood flow to the skin also increases, particularly in the hands and feet. The increased skin blood flow helps dissipate heat produced by metabolism in the mother and fetus.

Strenuous exercise, which diverts blood flow to large muscles, has the potential to decrease uteroplacental perfusion and thus O_2 delivery to the fetus. Women who are already adapted to an exercise routine can generally continue the program in pregnancy; however, pregnant women should discuss their exercise plans with the physician managing the pregnancy.

HEART MURMURS & RHYTHM

The physiologic changes of pregnancy alter several clinical findings. For example, systolic ejection murmurs, which result from increased cardiac output and decreased blood viscosity, can be detected in 90% or more gravidas. Thus caution should be exercised in interpreting systolic murmurs in pregnant women.

The first heart sound may be split, with increased loudness of both portions, and the third heart sound may also be louder. Continuous murmurs or bruits may be heard at the left sternal edge, which arise from the internal thoracic (mammary) artery.

Pregnancy decreases the threshold for reentrant supraventricular tachycardia. Normal pregnancy can also be accompanied by sinus tachycardia, sinus bradycardia, and isolated atrial and ventricular premature contractions.

Electrocardiographic changes can include a 15- to 20-degree shift to the left in the electrical axis. Changes in ventricular repolarization can result in ST-segment depression or T-wave flattening. However, pregnancy does not alter the amplitude and duration of the P wave, QRS complex, or T wave.

PULMONARY SYSTEM

Anatomic Changes

Pregnancy alters the circulation of a number of tissues involved in respiration. For example, capillary dilatation leads to engorgement of the nasopharynx, larynx, trachea, and bronchi. Prominent pulmonary vascular markings observed on x-ray are consistent with increased pulmonary blood volume.

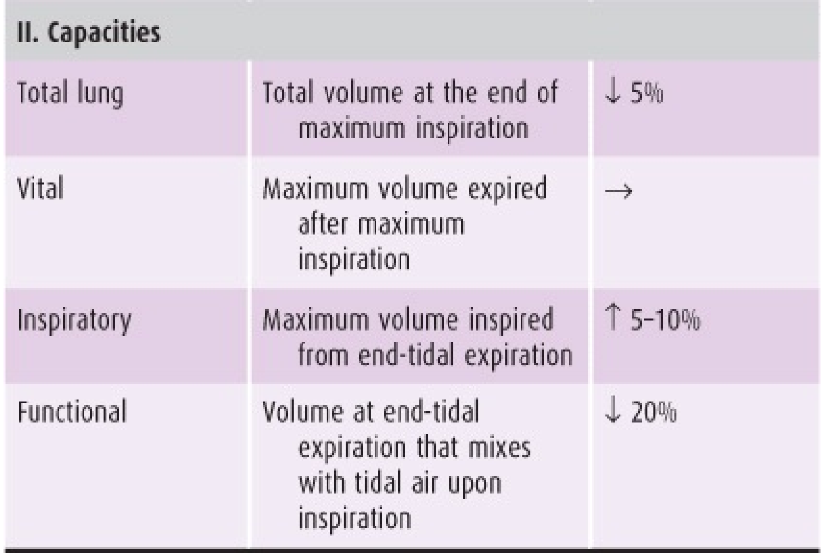
As the uterus enlarges, the diaphragm is elevated by as much as 4 cm. The rib cage is displaced upward, increasing the angle of the ribs with the spine. These changes increase the lower thoracic diameter by approximately 2 cm and the thoracic circumference by up to 6 cm. Elevation of the diaphragm does not impair its function. Abdominal muscles have less tone and activity during pregnancy, causing respiration to be more diaphragm dependent.

Lung Volumes and Capacities

Several lung volumes and capacities are altered by pregnancy (Table 8–1). Dead space volume increases because of relaxation of the musculature of conducting airways. Tidal volume and inspiratory capacity increase. Elevation of the diaphragm is associated with reduction in total lung capacity and functional residual capacity. The latter involves a decrease in both expiratory reserve and residual volumes.

Table 8–1. Effects of pregnancy on lung volumes and capacities.

	Definition	Change
I. Volumes		
Tidal	Volume inspired and expired with each normal respiratory cycle	↑ 35–50%
Inspiratory reserve	Maximum volume that can be inspired over normal end-tidal inspiration	↓
Expiratory reserve	Maximum volume that can be expired from resting end-tidal expiration	↓ 20%
Residual	Volume remaining in the lungs after maximum expiration	↓ 20%



II. Capacities		
Total lung	Total volume at the end of maximum inspiration	↓ 5%
Vital	Maximum volume expired after maximum inspiration	→
Inspiratory	Maximum volume inspired from end-tidal expiration	↑ 5–10%
Functional	Volume at end-tidal expiration that mixes with tidal air upon inspiration	↓ 20%

Respiration

Pregnancy has little effect on respiratory rate. Thus the increase in minute ventilation (approximately 50%) results from the rise in tidal volume. This increment in minute ventilation is disproportionately greater than the rise (approximately 20%) in total oxygen consumption in maternal muscle tissues (cardiac, respiratory, uterine, skeletal) and in the products of the fetal genome (placenta, fetus). This hyperventilation, which decreases maternal arterial PCO_2 to approximately 27–32 mm Hg, results in a mild respiratory alkalosis (blood pH of 7.4–7.5). The hyperventilation and hyperdynamic circulation slightly increase arterial PO_2.

Increased levels of progesterone appear to have a critical role in the hyperventilation of pregnancy, which develops early in the first trimester. As in the luteal phase of the menstrual cycle of nonpregnant women, the increased ventilation appears to be caused by the action of progesterone on central neurons involved in respiratory regulation. The overall respiratory effect appears to be a decrease in the threshold and an increase in the sensitivity of central chemoreflex responses to CO_2. Maternal hyperventilation may be protective in that that it prevents the fetus from being exposed to high CO_2 tensions, which might adversely affect the development of respiratory control and other critical regulatory mechanisms.

Functional measurement of ventilation can also change according to posture and duration of pregnancy. For example, the peak expiratory rate, which declines throughout gestation in the sitting and standing positions, is particularly compromised in the supine position.

RENAL SYSTEM

Anatomic Changes

During pregnancy, the length of the kidneys increases by 1–1.5 cm, with a proportional increase in weight. The renal calyces and pelves are dilated in pregnancy, with the volume of the renal pelvis increased up to 6-fold compared with the nonpregnant value of 10 mL. The ureters are dilated above the brim of the bony pelvis, with more prominent effects on the right. The ureters elongate, widen, and become more curved. The entire dilated collecting system may contain up to 200 mL of urine, which predisposes to ascending urinary infections. Urinary tract dilatation disappears in virtually all women by postpartum day 4.

Several factors likely contribute to the hydronephrosis and hydroureter of pregnancy: (1) Pregnancy hormones (eg, progesterone) may cause hypotonia of ureteral smooth muscle. Against this possibility is the observation that high progesterone levels in nonpregnant women do not cause hydroureter. (2) Enlargement of the ovarian vein complex in the infundibulopelvic ligament may compress the ureter at the brim of the bony pelvis. (3) Hyperplasia of smooth muscle in the distal one-third of the ureter may cause reduction in luminal size, leading to dilatation in the upper two-thirds. (4) The sigmoid colon and dextrorotation of the uterus likely reduce compression (and dilatation) of the left ureter relative to the right.

Renal Function

Renal plasma flow increases 50–85% above nonpregnant values during the first half of pregnancy, with a modest decrease in later gestation. The changes in renal plasma flow reflect decreases in renal vascular resistance, which achieves lowest values by the end of the first trimester. Elevated renal perfusion is the principal factor involved in rise in glomerular filtration rate (GFR), which is increased by approximately 25% in the second week after conception. GFR reaches a peak increment of 40–65% by the end of the first trimester and remains high until term (Fig. 8–4). The fraction of renal plasma flow that passes through the glomerular membrane (filtration fraction) decreases during the first 20 weeks of gestation, which subsequently rises toward term.

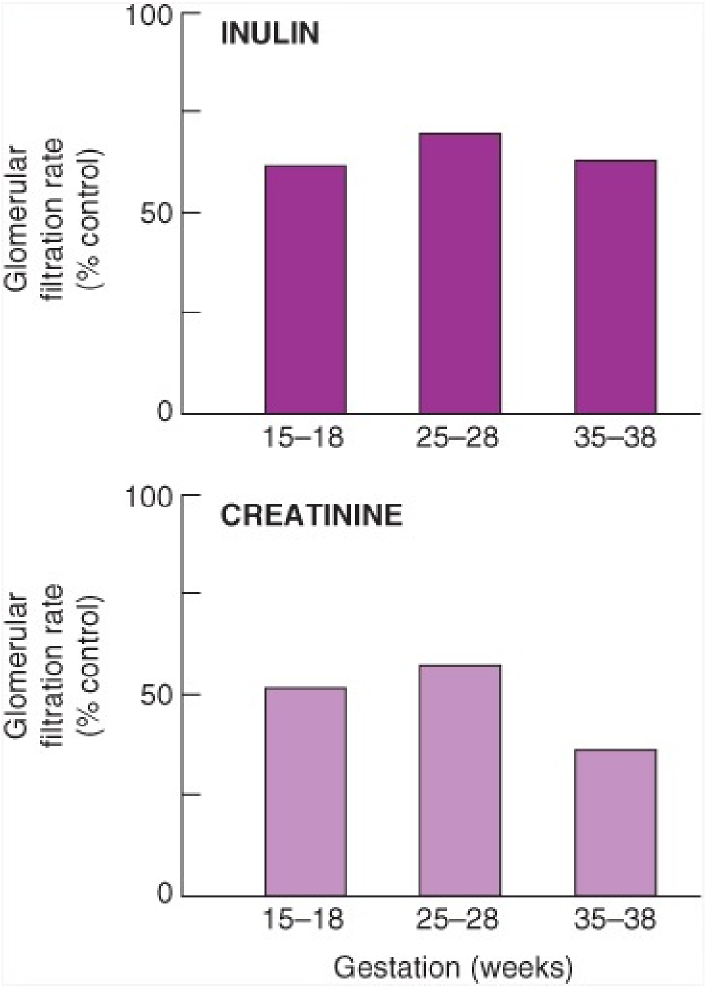


Figure 8–4. Increases in glomerular filtration over gestation as reflected by changes in inulin and endogenous creatinine clearances. The % control represents relative change from postpartum values. (Data from Davison JM, Hytten FE. Glomerular filtration during and after pregnancy. *J Obstet Gynaecol Br Commonw* 1974;81:558.)

Hormones involved in these changes in renal vascular resistance may include progesterone and relaxin (via upregulation of vascular matrix metalloproteinase-2). Agents elaborated by the endothelium, such as endothelin (ET) (via activation of $\mathrm{ET_B}$ receptor subtype) and nitric oxide (via increased cyclic guanosine –3’,5’-monophosphate), are likely to be critically involved in the reduction of renal vascular resistance. An additional factor is the increased cardiac output, which permits increased renal perfusion without depriving other organs of blood flow.

Urinary flow and sodium excretion rates in late pregnancy are increased 2-fold in lateral recumbency compared with the supine position. Thus measurements of urinary function must take into account maternal posture. Collection periods should be at least 12–24 hours to allow for errors caused by the large urinary dead space. However, reasonable estimates of urinary excretion of a particular substance over shorter time periods generally can be calculated by referencing the level to the creatinine concentration in the same sample of urine (substance/creatinine ratio) with the assumption that a pregnant woman excretes 1 g of creatinine per day. Creatinine production (0.7–1.0 g/day) by skeletal muscle is virtually unchanged by pregnancy.

Up to 80% of the glomerular filtrate is reabsorbed by the proximal tubules, a process that is independent of hormonal control. Aldosterone regulates sodium reabsorption in the distal tubules, whereas arginine vasopressin activity, which regulates free water clearance, determines the ultimate urine concentration. Pregnancy is associated with increased circulating concentrations of aldosterone. Even though the GFR increases dramatically during gestation, the volume of urine excreted per day is unchanged.

Renal clearance of creatinine increases as the GFR rises, with maximum clearances approximately 50% more than nonpregnant levels. The creatinine clearance decreases somewhat after approximately 30 weeks of gestation. The rise in GFR lowers mean serum creatinine concentrations (pregnant, 0.46 ± 0.13 mg/100 mL; nonpregnant, 0.67 ± 0.14 mg/100 mL) and blood urea nitrogen (pregnant, 8.17 ± 1.5 mg/100 mL; nonpregnant, 13 ± 3 mg/100 mL) concentrations.

Increased GFR with saturation of tubular resorption capacity for filtered glucose can result in glucosuria. In fact, more than 50% of women have glucosuria sometime during pregnancy. Increased urinary glucose levels contribute to increased susceptibility of pregnant women to urinary tract infection.

Urinary protein loss normally does not exceed 300 mg over 24 hours, which is similar to the nonpregnant state. Thus proteinuria of more than 300 mg over 24 hours suggests a renal disorder.

Renin activity increases early in the first trimester and continues to rise until term. This enzyme is critically involved in the conversion of angiotensinogen to angiotensin I, which subsequently forms the potent vasoconstrictor angiotensin II. Angiotensin II levels also increase in pregnancy, but the vasoconstriction and hypertension that might be expected do not occur. In fact, normal pregnant women are very resistant to the pressor effects of elevated levels of angiotensin II and other vasopressors; this effect is likely mediated by increased vascular synthesis of nitric oxide and other vasodilators.

Angiotensin II is also a potent stimulus for adrenocortical secretion of aldosterone, which, in conjunction with arginine vasopressin, promotes salt and water retention in pregnancy. The net effect is a decrease in plasma sodium concentrations by approximately 5 mEq/L and a fall in plasma osmolality by nearly 10 mOsm/kg. These effects on electrolyte homeostasis likely involve a resetting of the pituitary osmostat. In pregnancy, the increased pituitary secretion of vasopressin is largely balanced by placental production of vasopressinase. Pregnant women who are unable to sufficiently augment vasopressin secretion can develop a diabetes insipidus–like condition characterized by massive diuresis and profound hypernatremia. Cases have been described with maternal sodium levels reaching 170 mEq/L.

Bladder

As the uterus enlarges, the urinary bladder is displaced upward and flattened in the anteroposterior diameter. One of the earliest symptoms of pregnancy is increased urinary frequency, which may be related to pregnancy hormones. In later gestation, mechanical effects of the enlarged uterus may contribute to the increased frequency. Bladder vascularity increases and muscle tone decreases, which increases bladder capacity up to 1500 mL.

GASTROINTESTINAL SYSTEM

Anatomic Changes

As the uterus grows, the stomach is pushed upward and the large and small bowels extend into more rostrolateral regions. Historically, it has been believed that the appendix is displaced superiorly in the right flank area. Recent literature has called this, and other common assumptions regarding pregnancy-associated changes, in to question. It is clear that organs return to their normal positions in the early puerperium.

Oral Cavity

Salivation appears to increase, although this may be caused in part by swallowing difficulty associated with nausea. Pregnancy does not predispose to tooth decay or to mobilization of bone calcium.

The gums may become hypertrophic and hyperemic; often, they are so spongy and friable that they bleed easily. This may be caused by increased systemic estrogen because similar problems sometimes occur with the use of oral contraceptives.

Esophagus & Stomach

Reflux symptoms (heartburn) affect 30–80% of pregnant women. Gastric production of hydrochloric acid is variable and sometimes exaggerated but more commonly reduced. Pregnancy is associated with greater production of gastrin, which increases stomach volume and acidity of gastric secretions. Gastric production of mucus also may be increased. Esophageal peristalsis is decreased. Most women first report symptoms of reflux in the first trimester (52% vs. 24% in the second trimester vs. 8.8% in the third trimester), although the symptoms can become more severe with advanced gestation.

The underlying predisposition to reflux in pregnancy is related to hormone-mediated relaxation of the lower esophageal sphincter (Fig. 8–5). With advancing gestation, the lower esophageal sphincter has decreased pressure as well as blunted responses to sphincter stimulation. Thus decreased motility, increased acidity of gastric secretions, and reduced function of the lower esophageal sphincter contribute to the increased gastric reflux. The increased prevalence of gastric reflux and delayed gastric emptying of solid food make the gravida more vulnerable to regurgitation and aspiration with anesthesia. The rate of gastric emptying of solid foods is slowed in pregnancy, but the rate for liquids remains generally the same as in the nonpregnant state.

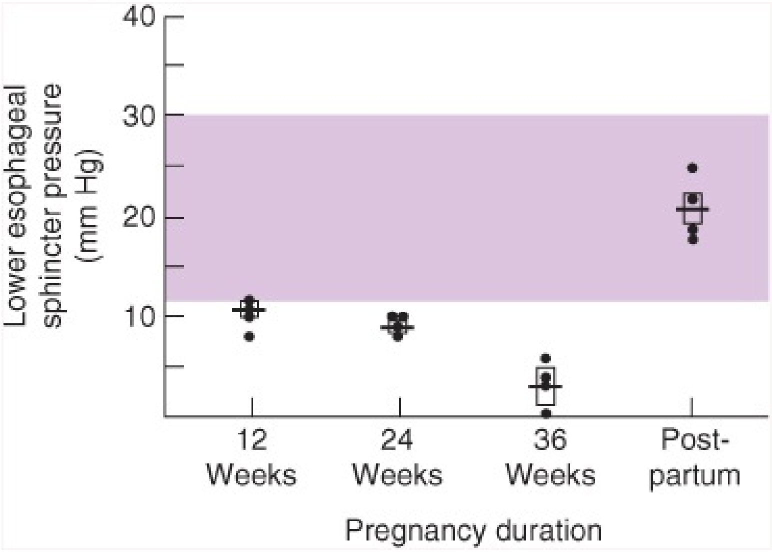

Figure 8–5. Lower esophageal sphincter pressures for 3 periods of pregnancy and the postpartum state. The shaded area represents the normal range in nonpregnant women. The horizontal bars show the mean ± SE for measurements in 4 women. The rectangles show the mean ± SE for each gestational age. (Modified, with permission, from Van Theil DH, Gravaler JS, Joshi SN, et al. Heartburn in pregnancy. *Gastroenterology* 1977;72:666.)

Intestines

Intestinal transit times are decreased in the second and third trimesters (Fig. 8–6), whereas first-trimester and postpartum transit times are similar. Transit times return to normal within 2–4 days postpartum.

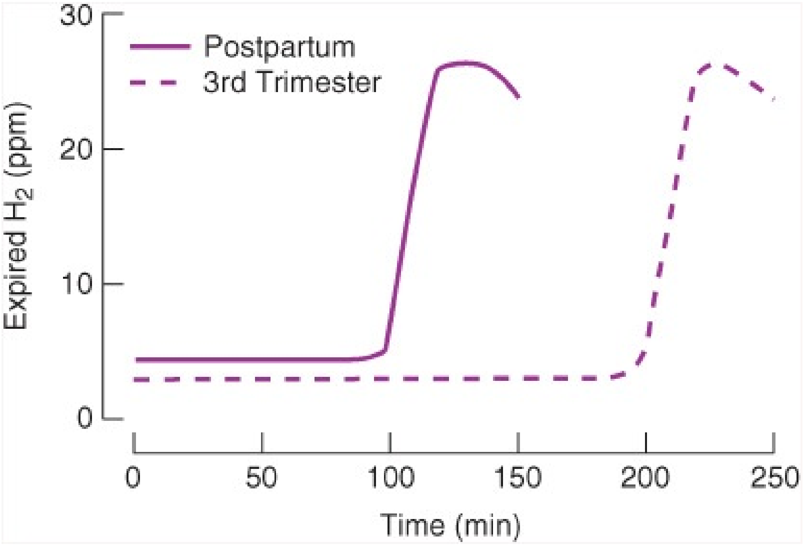

Figure 8–6. Small-bowel transit times measured by the lactulose hydrogen breath method in a single woman in the third trimester and postpartum. Hydrogen concentrations in maternal breath were determined after administration of a lactulose meal. Hydrogen is released when bacteria in the colon break down lactulose. (Modified, with permission, from Wald A, Van Thiel DH, Hoeschstetter L, et al. Effect of pregnancy on gastrointestinal transit. *Dig Dis Sci* 1982;27:1015.)

The reduced gastrointestinal motility during pregnancy has been thought to be caused by increased circulating concentrations of progesterone. However, experimental evidence suggests that elevated estrogen concentrations are critically involved through an enhancement of nitric oxide release from the nonadrenergic, noncholinergic nerves that modulate gastrointestinal motility. Other factors may also be involved.

The slow transit time of food through the gastrointestinal tract potentially enhances water absorption, predisposing to constipation. However, diet and cultural expectations may be more important factors in this disorder.

Gallbladder

The emptying of the gallbladder is slowed in pregnancy and often incomplete. When visualized at caesarean delivery, the gallbladder commonly appears dilated and atonic. Bile stasis of pregnancy increases the risk for gallstone formation, although the chemical composition of bile is not appreciably altered.

Liver

Liver morphology does not change in normal pregnancy. Plasma albumin levels are reduced to a greater extent than the slight decrease in plasma globulins. This fall in the albumin/globulin ratio mimics liver disease in nonpregnant individuals. Serum alkaline phosphatase activity can double as the result of alkaline phosphatase isozymes produced by the placenta.

HEMATOLOGIC SYSTEM

Red Blood Cells

The red cell mass expands by approximately 33%, or by approximately 450 mL of erythrocytes for the average pregnant woman (Fig. 8–1). The increase is greater with iron supplementation. The greater increase in plasma volume accounts for the anemia of pregnancy. For example, maternal hemoglobin levels average 10.9 ± 0.8 (SD) g/dL in the second trimester and 12.4 ± 1.0 g/dL at term.

Iron

The enhanced erythropoiesis of pregnancy increases utilization of iron, which can reach 6–7 mg per day in the latter half of pregnancy. Many women begin pregnancy in an iron-deficient state, making them vulnerable to iron deficiency anemia. Thus supplemental iron is commonly given to pregnant women. Because the placenta actively transports iron from the mother to the fetus, the fetus generally is not anemic even when the mother is severely iron deficient.

White Blood Cells

The total blood leukocyte count increases during normal pregnancy from a prepregnancy level of 4300–4500/μL to 5000–12,000/μL in the last trimester, although counts as high as 16,000/μL have been observed in the last trimester. Counts in the 20,000–25,000/μL range can occur during labor. The cause of the rise in the leukocyte count, which primarily involves the polymorphonuclear forms, has not been established.

Polymorphonuclear leukocyte chemotaxis may be impaired in pregnancy, which appears to be a cell-associated defect. Reduced polymorphonuclear leukocyte adherence has been reported in the third trimester. These observations may predispose pregnant women to infection. Basophil counts decrease slightly as pregnancy advances. Eosinophil counts, although variable, remain largely unchanged.

Platelets

Some studies have reported increased production of platelets (thrombocytopoiesis) during pregnancy that is accompanied by progressive platelet consumption. Platelet counts fall below 150,000/μL in 6% of gravidas in the third trimester. This *pregnancy-associated thrombocytopenia*, which appears to be caused by increased peripheral consumption, resolves with delivery and is of no pathologic significance. Levels of prostacyclin (PGI_2), a platelet aggregation inhibitor, and thromboxane A_2, an inducer of platelet aggregation and a vasoconstrictor, increase during pregnancy.

Clotting Factors

Circulating levels of several coagulation factors increase in pregnancy. Fibrinogen (factor I) and factor VIII levels increase markedly, whereas factors VII, IX, X, and XII increase to a lesser extent.

Plasma fibrinogen concentrations begin to increase from nonpregnant levels (1.5–4.5 g/L) during the third month of pregnancy and progressively rise by nearly 2-fold by late pregnancy (4–6.5 g/L). The high estrogen levels of pregnancy may be involved in the increased fibrinogen synthesis by the liver.

Prothrombin (factor II) is only nominally affected by pregnancy. Factor V concentrations are mildly increased. Factor XI decreases slightly toward the end of pregnancy, and factor XIII (fibrin-stabilizing factor) is appreciably reduced, up to 50% at term. The free form of protein S declines in the first and second trimesters and remains low for the rest of gestation.

Fibrinolytic activity is depressed during pregnancy through a poorly understood mechanism. Plasminogen concentrations increase concomitantly with fibrinogen, but there is still a net procoagulant effect of pregnancy.

Coagulation and fibrinolytic systems undergo major alterations during pregnancy. Understanding these physiologic changes is critical for the management of some of the more serious pregnancy disorders, including hemorrhage and thromboembolic disease.

SKIN

Anatomic Changes

Hyperpigmentation is one of the well-recognized skin changes of pregnancy, which is manifested in the linea nigra and melasma, the *mask of pregnancy*. The latter, which is exacerbated by sun exposure, develops in up to 70% of pregnancies and is characterized by an uneven darkening of the skin in the centrofacial-malar area. The hyperpigmentation is probably because of the elevated concentrations of melanocyte-stimulating hormone and/or estrogen and progesterone effects on the skin. Similar hyperpigmentation of the face can be seen in nonpregnant women who are taking oral contraceptives.

Striae gravidarum consist of bands or lines of thickened, hyperemic skin. These “stretch marks” begin to appear in the second trimester on the abdomen, breasts, thighs, and buttocks. Decreased collagen adhesiveness and increased ground substance formation are characteristically seen in this skin condition. A genetic predisposition appears to be involved because not every gravida develops these skin changes. Effective treatment (preventive or therapeutic) has yet to be found.

Other common cutaneous changes include spider angiomas, palmar erythema, and cutis marmorata (mottled appearance of skin secondary to vasomotor instability). The development or worsening of varicosities accompanies nearly 40% of pregnancies. Compression of the vena cava by the gravid uterus increases venous pressures in the lower extremities, which dilates veins in the legs, anus (hemorrhoids), and vulva.

The nails and hair also undergo changes. Nails become brittle and can show horizontal grooves

(Beau's lines). Thickening of the hair during pregnancy is caused by an increased number of follicles in anagen (growth) phase, and generalized hirsutism can worsen in women who already have hair that is thick or has a male pattern of distribution. The thickening of the hair ends 1–5 months postpartum with the onset of the telogen (resting) phase, which results in excessive shedding and thinning of hair. Normal hair growth returns within 12 months.

METABOLISM

Pregnancy increases nutritional requirements, and several maternal alterations occur to meet this demand. Pregnant women tend to rest more often, which conserves energy and thereby enhances fetal nutrition. The maternal appetite and food intake usually increase, although some have a decreased appetite or experience nausea and vomiting (see Chapter 6). In rare instances, women with pica may crave substances such as clay, cornstarch, soap, or even coal.

Pregnancy is associated with profound changes in structure and metabolism. The most obvious physical changes are weight gain and altered body shape. Weight gain results not only from the uterus and its contents, but also from increased breast tissue, blood volume, and water volume (approximately 6.8 L) in the form of extravascular and extracellular fluid. Deposition of fat and protein and increased cellular water are added to maternal stores. The average weight gain during pregnancy is 12.5 kg (27.5 lb).

Protein accretion accounts for approximately 1 kg of maternal weight gain, which is evenly divided between the mother (uterine contractile protein, breast glandular tissue, plasma protein, and hemoglobin) and the fetoplacental unit.

Total body fat increases during pregnancy, but the amount varies with the total weight gain. During the second half of pregnancy, plasma lipids increase (plasma cholesterol increases 50%, plasma triglyceride concentration may triple), but triglycerides, cholesterol, and lipoproteins decrease soon after delivery. The ratio of low-density lipoproteins to high-density lipoproteins increases during pregnancy. It has been suggested that most fat is stored centrally during midpregnancy and that as the fetus extracts more nutrition in the latter months, fat storage decreases.

Metabolism of carbohydrates and insulin during pregnancy is discussed in Chapter 31. Pregnancy is associated with insulin resistance, which can lead to hyperglycemia (gestational diabetes) in susceptible women. This metabolic disorder usually disappears after delivery, but may arise later in life as type 2 diabetes.

Maternal–Placental–Fetal Unit

Fetal genetics, physiology, anatomy, and biochemistry can now be studied with ultrasonography, fetoscopy, chorionic villus sampling, amniocentesis, and fetal cord and scalp blood sampling. Embryology and fetoplacental physiology must now be considered when providing direct patient care. Currently, some medical centers measure fetal pulse oximetry, fetal electroencephalograms, and fetal heart rate monitoring in determining the oxygenation status of the fetus. As the technology improves, we are reaching further into the early perinatal period to determine abnormal physiology and growth.

THE PLACENTA

A **placenta** may be defined as any intimate apposition or fusion of fetal organs to maternal tissues for physiologic exchange. The basic parenchyma of all placentas is the **trophoblast**; when this becomes a membrane penetrated by fetal **mesoderm**, it is called the **chorion**.

In the evolution of viviparous species, the yolk sac presumably is the most archaic type of placentation, having developed from the egg-laying ancestors of mammals. In higher mammals, the **allantoic sac** fuses with the chorion, forming the chorioallantoic placenta, which has mesodermal vascular villi. When the trophoblast actually invades the maternal endometrium (which in pregnancy is largely composed of decidua), a deciduate placenta results. In humans, maternal blood comes into direct contact with the fetal trophoblast.

DEVELOPMENT OF THE PLACENTA

Soon after ovulation, the endometrium develops its typical secretory pattern under the influence of progesterone from the corpus luteum. The peak of development occurs at approximately 1 week after ovulation, coinciding with the expected time for implantation of a fertilized ovum.

The first cleavage occurs during the next 36 hours after the cellular union of the egg and sperm. As the conceptus continues to divide and grow, the peristaltic activity of the uterine tube slowly transports it to the uterus, a journey that requires 6–7 days. Concomitantly, a series of divisions creates a hollow ball, the **blastocyst**, which then implants within the endometrium. Most cells in the wall of the blastocyst are trophoblastic; only a few are destined to become the embryo.

Within a few hours after implantation, the trophoblast invades the endometrium and begins to produce **human chorionic gonadotropin (hCG**), which is thought to be important in converting the normal corpus luteum into the corpus luteum of pregnancy. As the cytotrophoblasts (**Langhans' cells**) divide and proliferate, they form transitional cells that are the likely source of hCG. Next, these transitional cells fuse, lose their individual membranes, and form the multinucleated **syncytiotrophoblast**. Mitotic division then ceases. Thus the syncytial layer becomes the front line of the invading fetal tissue. Maternal capillaries and venules are tapped by the invading fetal tissue to cause extravasation of maternal blood and the formation of small lakes (lacunae), the forerunners of the intervillous space. These lacunae fill with maternal blood by reflux from previously tapped veins. An occasional maternal artery then opens, and a sluggish circulation is established (hemato-tropic phase of the embryo).

The lacunar system is separated by trabeculae, many of which develop buds or extensions. Within these branching projections, the cytotrophoblast forms a mesenchymal core.

The proliferating trophoblast cells then branch to form secondary and tertiary villi. The **mesoblast**, or central stromal core, also formed from the original trophoblast, invades these columns to form a supportive structure within which capillaries are formed. The **embryonic body stalk** (later to become the umbilical cord) invades this stromal core to establish the fetoplacental circulation. If this last step does not occur, the embryo will die. Sensitive tests for hCG suggest that at this stage, more embryos die than live.

Where the placenta is attached, the branching villi resemble a leafy tree (the **chorion frondosum**), whereas the portion of the placenta covering the expanding conceptus is smoother (**chorion laeve**). When the latter is finally pushed against the opposite wall of the uterus, the villi atrophy, leaving the amnion and chorion to form the 2-layered sac of fetal membranes.

At approximately 40 days after conception, the trophoblast has invaded approximately 40–60 spiral arterioles, of which 12–15 may be called major arteries. The pulsatile arterial pressure of blood that spurts from each of these major vessels pushes the chorionic plate away from the decidua to form 12–15 "tents," or maternal **cotyledons**. The remaining 24–45 tapped arterioles form minor vascular units that become crowded between the larger units. As the chorionic plate is pushed away from the basal plate, the anchoring villi pull the maternal basal plate up into septa (columns of fibrous tissue that virtually surround the major cotyledons). Thus at the center of each maternal vascular unit there is 1 artery that terminates in a thin-walled sac, but there are numerous maternal veins that open through the basal plate at random. The human placenta has no peripheral venous collecting system. Within each maternal vascular unit is the fetal vascular “tree,” with the tertiary free-floating villi (the major area for physiologic exchange) acting as thousands of baffles that disperse the maternal bloodstream in many directions.

FUNCTIONS OF THE MATERNAL– PLACENTAL–FETAL UNIT

The placenta is a complex organ of internal secretion, releasing numerous hormones and enzymes into the maternal bloodstream. In addition, it serves as the organ of transport for all fetal nutrients and metabolic products as well as for the exchange of oxygen and CO_2. Although fetal in origin, the placenta depends almost entirely on maternal blood for its nourishment.

The arterial pressure of maternal blood (60–70 mm Hg) causes it to pulsate toward the chorionic plate into the low-pressure (20 mm Hg) intervillous space. Venous blood in the placenta tends to flow along the basal plate and out through the venules directly into maternal veins. The pressure gradient within the fetal circulation changes slowly with the mother’s posture, fetal movements, and physical stress. The pressure within the placental intervillous space is approximately 10 mm Hg when the pregnant woman is lying down. After a few minutes of standing, this pressure exceeds 30 mm Hg. In comparison, the fetal capillary pressure is 20–40 mm Hg.

Clinically, placental perfusion can be altered by many physiologic changes in the mother or fetus. When a precipitous fall in maternal blood pressure occurs, increased plasma volume improves placental perfusion. Increasing the maternal volume with saline infusion increases the fetal oxygen saturation. An increased rate of rhythmic uterine contractions benefits placental perfusion, but tetanic labor contractions are detrimental to placental and fetal circulation as they do not allow a resting period in which normal flow resumes to the fetus. An increased fetal heart rate tends to expand the villi during systole, but this is a minor aid in circulatory transfer.

Circulatory Function

A. Uteroplacental Circulation

The magnitude of the uteroplacental circulation is difficult to measure in humans. The consensus is that total uterine blood flow near term is 500–700 mL/min. Not all of this blood traverses the intervillous space. It is generally assumed that approximately 85% of the uterine blood flow goes to the cotyledons and the rest to the myometrium and endometrium. One may assume that blood flow in the placenta is 400–500 mL/min in a patient near term who is lying quietly on her side and is not in labor.

As the placenta matures, thrombosis decreases the number of arterial openings into the basal plate. At term, the ratio of veins to arteries is 2:1 (approximately the ratio found in other mature organs).

Near their entry into the intervillous spaces, the terminal maternal arterioles lose their elastic reticulum. Because the distal portions of these vessels are lost with the placenta, bleeding from their source can be controlled only by uterine contraction. Thus uterine atony causes postpartum hemorrhage.

B. Plasma Volume Expansion & Spiral Artery Changes

Structural alterations occur in the human uterine spiral arteries found in the decidual part of the placental bed. As a consequence of the action of cytotrophoblast on the spiral artery vessel wall, the normal musculoelastic tissue is replaced by a mixture of fibrinoid and fibrous tissue. The small spiral arteries are converted to large tortuous channels, creating low-resistance channels or arteriovenous shunts.

In early normal pregnancy, there is an early increase in plasma volume and resulting physiologic anemia as the red blood cell mass slowly expands. Immediately after delivery, with closure of the placental shunt, diuresis and natriuresis occur. When the spiral arteries fail to undergo these physiologic changes, fetal growth retardation often occurs with preeclampsia. "Evaluating uterine arteries, which serve the spiral arteries and the placenta in the pregnant women, offers an indirect method of monitoring the spiral arteries." Fleischer and colleagues (1986) reported that normal pregnancy is associated with a uterine artery Doppler velocimetry systolic/diastolic ratio of less than 2:6. With a higher ratio and a notch in the waveform, the pregnancy is usually complicated by stillbirth, premature birth, intrauterine growth retardation, or preeclampsia.

C. Fetoplacental Circulation

At term, a normal fetus has a total umbilical blood flow of 350–400 mL/min. Thus the maternoplacental and fetoplacental flows have a similar order of magnitude.

The villous system is best compared with an inverted tree. The branches pass obliquely downward and outward within the intervillous spaces. This arrangement probably permits preferential currents or gradients of flow and undoubtedly encourages intervillous fibrin deposition, commonly seen in the mature placenta.

Cotyledons (subdivisions of the placenta) can be identified early in placentation. Although they are separated by the placental septa, some communication occurs via the subchorionic lake in the roof of the intervillous spaces.

Before labor, placental filling occurs whenever the uterus contracts (*Braxton Hicks contractions*). At these times, the maternal venous exits are closed, but the thicker-walled arteries are only slightly narrowed. When the uterus relaxes, blood drains out through the maternal veins. Hence blood is not squeezed out of the placental lake with each contraction, nor does it enter the placental lake in appreciably greater amounts during relaxation.

During the height of an average first-stage contraction, most of the cotyledons are devoid of any flow and the remainder are only partially filled. Thus, intermittently—for periods of up to a minute—maternoplacental flow virtually ceases. Therefore, it should be evident that any extended prolongation of the contractile phase, as in uterine tetany, could lead to fetal hypoxia.

Endocrine Function

A. Secretions of the Maternal– Placental–Fetal Unit

The placenta and the maternal–placental–fetal unit produce increasing amounts of steroids late in the first trimester. Of greatest importance are the steroids required in fetal development from 7 weeks' gestation through parturition. Immediately after conception and until 12–13 weeks' gestation, the principal source of circulating gestational steroids (progesterone is the major one) is the corpus luteum of pregnancy.

After 42 days, the placenta assumes an increasingly important role in the production of several steroid hormones. Steroid production by the embryo occurs even before implantation is detectable in utero. Before implantation, production of progesterone by the embryo may assist ovum transport.

Once implantation occurs, trophoblastic hCG and other pregnancy-related peptides are secreted. A more sophisticated array of fetoplacental steroids is produced during organogenesis and with the development of a functioning hypothalamic–pituitary–adrenal axis. Adenohypophyseal basophilic cells first appear at approximately 8 weeks in the development of the fetus and indicate the presence of significant quantities of adrenocorticotropic hormone (ACTH). The first adrenal primordial structures are identified at approximately 4 weeks, and the fetal adrenal cortex develops in concert with the adenohypophysis.

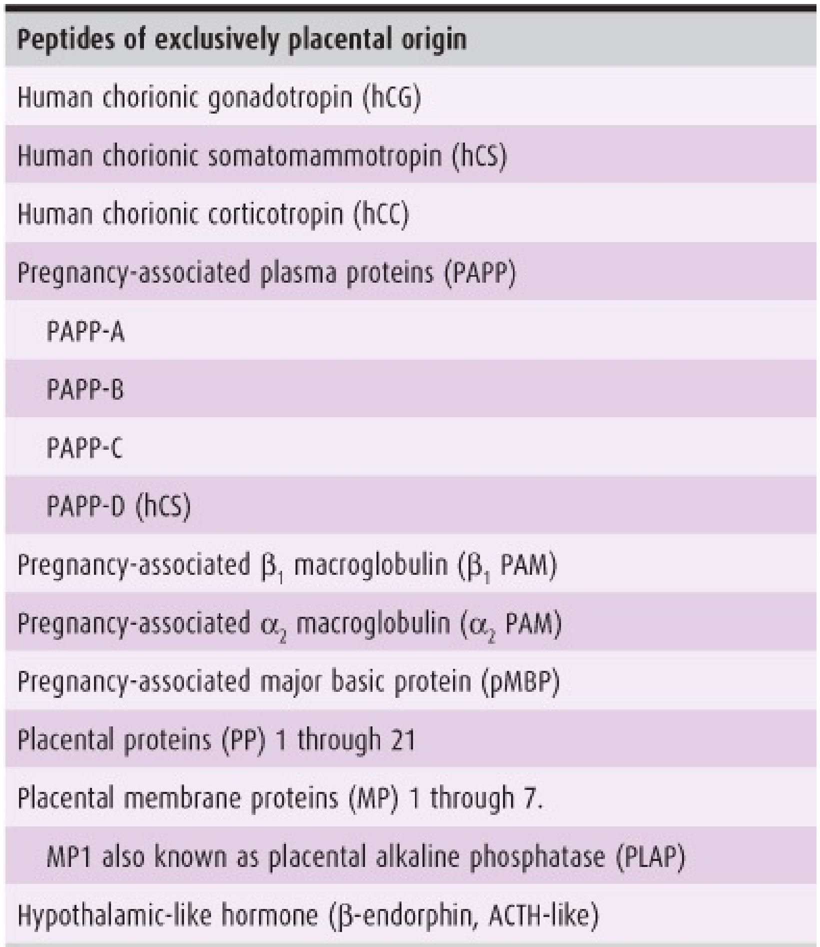
The fetus and the placenta acting in concert are the principal sources of steroid hormones controlling intrauterine growth, maturation of vital organs, and parturition. The fetal adrenal cortex is much larger than its adult counterpart. From midtrimester until term, the large inner mass of the fetal adrenal gland (80% of the adrenal tissue) is known as the **fetal zone**. This tissue is supported by factors unique to the fetal status and regresses rapidly after birth. The outer zone ultimately becomes the bulk of the postnatal and adult cortex.

The trophoblastic mass increases exponentially through the seventh week, after which time the growth velocity gradually increases to an asymptote close to term. The fetal zone and placenta exchange steroid precursors to make possible the full complement of fetoplacental steroids. Formation and regulation of steroid hormones also take place within the fetus itself.

In addition to the steroids, another group of placental hormones unique to pregnancy are the polypeptide hormones, each of which has an analogue in the pituitary. These placental protein hormones include hCG and human chorionic somatomammotropin. The existence of placental human chorionic corticotropin also has been suggested.

A summary of the hormones produced by the maternal–placental–fetal unit is shown in Table 8–2.

Table 8–2. Summary of maternal–placental–fetal endocrine-paracrine functions.



Peptides of exclusively placental origin
Human chorionic gonadotropin (hCG)
Human chorionic somatomammotropin (hCS)
Human chorionic corticotropin (hCC)
Pregnancy-associated plasma proteins (PAPP)
PAPP-A
PAPP-B
PAPP-C
PAPP-D (hCS)
Pregnancy-associated β_1 macroglobulin (β_1 PAM)
Pregnancy-associated α_2 macroglobulin (α_2 PAM)
Pregnancy-associated major basic protein (pMBP)
Placental proteins (PP) 1 through 21
Placental membrane proteins (MP) 1 through 7.
MP1 also known as placental alkaline phosphatase (PLAP)
Hypothalamic-like hormone (β-endorphin, ACTH-like)

Steroid of mainly placental origin
Progesterone
Hormones of maternal–placental–fetal origin
Estrone
Estradiol 50% from maternal androgens
Hormone of placental–fetal origin
Estriol
Hormone of corpus luteum of pregnancy
Relaxin
Fetal hormones
Thyroid hormone
Fetal adrenal zone hormones
α-Melanocyte-stimulating hormone
Corticotropin intermediate lobe peptide
Anterior pituitary hormone
Adrenocorticotropic hormone (ACTH)
Tropic hormones for fetal zone of placenta
β-Endorphin
β-Lipotropin

B. Placental Secretions

1. Human chorionic gonadotropin—hCG was the first of the placental protein hormones to be described. It is a glycoprotein that has biologic and immunologic similarities to the luteinizing hormone (LH) from the pituitary. Recent evidence suggests that hCG is produced by the syncytiotrophoblast of the placenta. hCG is elaborated by all types of trophoblastic tissue, including that of hydatidiform moles, chorioadenoma destruens, and choriocarcinoma. As with all glycoprotein hormones (LH, follicle-stimulating hormone, thyroid-stimulating hormone [TSH]), hCG is composed of 2 subunits, α and β. The α subunit is common to all glycoproteins, and the β subunit confers unique specificity to the hormone.

Antibodies have been developed to the β subunit of hCG. This specific reaction allows for differentiation of hCG from pituitary LH. hCG is detectable 9 days after the midcycle LH peak, which occurs 8 days after ovulation and only 1 day after implantation. This measurement is useful because it can detect pregnancy in all patients on day 11 after fertilization. Concentrations of hCG rise exponentially until 9–10 weeks' gestation, with a doubling time of 1.3–2 days.

Concentrations peak at 60–90 days' gestation. Afterward, hCG levels decrease to a plateau that is maintained until delivery. The half-life of hCG is approximately 32–37 hours, in contrast to that of most protein and steroid hormones, which have half-lives measured in minutes. Structural characteristics of the hCG molecule allow it to interact with the human TSH receptor in activation of the membrane adenylate cyclase that regulates thyroid cell function. The finding of hCG-specific adenylate stimulation in the placenta may mean that hCG provides "order regulation" within the cell of the trophoblast.

2. Human chorionic somatomammotropin—Human chorionic somatomammotropin (hCS), previously referred to as designated **human placental lactogen**, is a protein hormone with immunologic and biologic similarities to the pituitary growth hormone. It is synthesized in the syncytiotrophoblastic layer of the placenta. It can be found in maternal serum and urine in both normal and molar pregnancies. However, it disappears so rapidly from serum and urine after delivery of the placenta or evacuation of the uterus that it cannot be detected in the serum after the first postpartum day. The somatotropic activity of hCS is 3%, which is less than that of human growth hormone (hGH). In vitro, hCS stimulates thymidine incorporation into DNA and enhances the action of hGH and insulin. It is present in microgram-per-milliliter quantities in early pregnancy, but its concentration increases as pregnancy progresses, with peak levels reached during the last 4 weeks. Prolonged fasting at midgestation and insulin-induced hypoglycemia are reported to raise hCS concentrations. hCS may exert its major metabolic effect on the mother to ensure that the nutritional demands of the fetus are met.

It has been suggested that hCS is the “growth hormone” of pregnancy. The in vivo effects of hCS owing to its growth hormonelike and anti-insulin characteristics result in impaired glucose uptake and stimulation of free fatty acid release, with resultant decrease in insulin effect.

3. Placental proteins—A number of proteins thought to be specific to the pregnant state have been isolated. The most commonly known are the 4 pregnancy-associated plasma proteins (PAPPs) designated as PAPP-A, PAPP-B, PAPP-C, and PAPP-D. PAPP-D is the hormone hCS (described earlier). All these proteins are produced by the placenta and/or decidua. The physiologic role of these proteins, except for PAPP-D, are at present unclear. Numerous investigators have postulated various functions, ranging from facilitating fetal “allograft” survival and the regulation of coagulation and complement cascades to the maintenance of the placenta and the regulation of carbohydrate metabolism in pregnancy. In vitro studies of PAPP-A in knockout mouse models show it functioning as a regulator of local insulin-like growth factor bioavailability.

C. Fetoplacental Secretions

The placenta may be an incomplete steroid-producing organ that must rely on precursors reaching it from the fetal and maternal circulations (an integrated-maternal–placental–fetal unit). The adult steroid-producing glands can form progestins, androgens, and estrogens, but this is not true of the placenta. Estrogen production by the placenta is dependent on precursors reaching it from both the fetal and maternal compartments. Placental progesterone formation is accomplished in large part from circulating maternal cholesterol.

In the placenta, cholesterol is converted to pregnenolone and then rapidly and efficiently to progesterone. Production of progesterone approximates 250 mg per day by the end of pregnancy, at which time circulating levels are on the order of 130 mg/mL. To form estrogens, the placenta, which has an active aromatizing capacity, uses circulating androgens obtained primarily from the fetus but also from the mother. The major androgenic precursor is **dehydroepiandrosterone sulfate (DHEAS**). This compound comes from the fetal adrenal gland. Because the placenta has an abundance of sulfatase (sulfate-cleaving) enzyme, DHEAS is converted to free unconjugated DHEA when it reaches the placenta, then to androstenedione, testosterone, and finally estrone and 17β-estradiol.

The major estrogen formed in pregnancy is estriol; however, its functional value is not well understood. It appears to be effective in increasing uteroplacental blood flow, as it has a relatively weak estrogenic effect on other organ systems. Ninety percent of the estrogen in the urine of pregnant women is estriol.

Circulating progesterone and estriol are thought to be important during pregnancy because they are present in such large amounts. Progesterone may play a role in maintaining the myometrium in a state of relative quiescence during much of pregnancy. A high local (intrauterine) concentration of progesterone may block cellular immune responses to foreign antigens. Progesterone appears to be essential for maintaining pregnancy in almost all mammals examined. This suggests that progesterone may be instrumental in conferring immunologic privilege to the uterus.

Placental Transport

The placenta has a high rate of metabolism, with consumption of oxygen and glucose occurring at a faster rate than in the fetus. Presumably, this high metabolism requirement is caused by multiple transport and biosynthesis activities.

The primary function of the placenta is the transport of oxygen and nutrients to the fetus and the reverse transfer of CO_2, urea, and other catabolites back to the mother. In general, those compounds that are essential for the minute-by-minute homeostasis of the fetus (eg, oxygen, CO_2, water, sodium) are transported very rapidly by diffusion. Compounds required for the synthesis of new tissues (eg, amino acids, enzyme cofactors such as vitamins) are transported by an active process. Substances such as certain maternal hormones, which may modify fetal growth and are at the upper limits of admissible molecular size, may diffuse very slowly, whereas proteins such as IgG immunoglobulins probably reach the fetus by the process of pinocytosis. This transfer takes place by at least 5 mechanisms: simple diffusion, facilitated diffusion, active transport, pinocytosis, and leakage.

A. Mechanisms of Transport

1. Simple diffusion—Simple diffusion is the method by which gases and other simple molecules cross the placenta. The rate of transport depends on the chemical gradient, the diffusion constant of the compound in question, and the total area of the placenta available for transfer (Fick's law). The chemical gradient (ie, the differences in concentration in fetal and maternal plasma) is in turn affected by the rates of flow of uteroplacental and umbilical blood. Simple diffusion is also the method of transfer for exogenous compounds such as drugs.

2. Facilitated diffusion—The prime example of a substance transported by facilitated diffusion is glucose, the major source of energy for the fetus. Presumably, a carrier system operates *with* the chemical gradient (as opposed to active transport, which operates *against* the gradient) and may become saturated at high glucose concentrations. In the steady state, the glucose concentration in fetal plasma is approximately two-thirds that of the maternal concentration, reflecting the rapid rate of fetal utilization. Substances of low molecular weight, minimal electric charge, and high lipid solubility diffuse across the placenta with ease.

3. Active transport—Selective transport of specific essential nutrients and amnio acids are accomplished by enzymatic mechanisms.

4. Pinocytosis—Electron microscopy has shown pseudo-podial projections of the syncytiotrophoblastic layer that reach out to surround minute amounts of maternal plasma. These particles are carried across the cell virtually intact to be released on the other side, whereupon they promptly gain access to the fetal circulation. Certain other proteins (eg, foreign antigens) may be immunologically rejected. This process may work both to and from the fetus, but the selectivity of the process has not been determined. Complex proteins, small amounts of fat, some immunoglobulins, and even viruses may traverse the placenta in this way. For the passage of complex proteins, highly selective processes involving special receptors are involved. For example, maternal antibodies of the IgG class are freely transferred, whereas other antibodies are not.

5. Leakage—Gross breaks in the placental membrane may occur, allowing the passage of intact cells. Despite the fact that the hydrostatic pressure gradient is normally from fetus to mother, tagged red cells and white cells have been found to travel in either direction. Such breaks probably occur most often during labor or with placental disruption (abruptio placentae, placenta previa, or trauma), caesarean section, or intrauterine fetal death. It is at these times that fetal red cells can most often be demonstrated in the maternal circulation. This is the mechanism by which the mother may become sensitized to fetal red cell antigens such as the D (Rh) antigen.

B. Placental Transport of Drugs

The placental membranes are often referred to as a “barrier” to fetal transfer, but there are few substances (eg, drugs) that will not cross the membranes at all. A few compounds, such as heparin and insulin, are of sufficiently large molecular size or charge that minimal transfer occurs. This lack of transfer is almost unique among drugs. Most medications are transferred from the maternal to the fetal circulation by simple diffusion, the rate of which is determined by the respective gradients of the drugs.

These diffusion gradients are influenced in turn by a number of serum factors, including the degree of drug-protein binding (eg, sex hormone binding globulin). Because serum albumin concentration is considerably lower during pregnancy, drugs that bind almost exclusively to plasma albumin (eg, warfarin, salicylates) may have relatively higher unbound concentrations and, therefore, an effectively higher placental gradient. By contrast, a compound such as carbon monoxide may attach itself so strongly to the increased total hemoglobin that there will be little left in the plasma for transport.

The placenta also acts as a lipoidal resistance factor to the transfer of water-soluble foreign organic chemicals; as a result, chemicals and drugs that are readily soluble in lipids are transferred much more easily across the placental barrier than are water-soluble drugs or molecules. Ionized drug molecules are highly water soluble and are therefore poorly transmitted across the placenta. Because ionization of chemicals depends in part on their pH-pK relationships, multiple factors determine this “simple diffusion” of drugs across the placenta. Obviously, drug transfer is not simple, and one must assume that some amount of almost any drug will cross the placenta.

ANATOMIC DISORDERS OF THE PLACENTA

Observation of structural alterations within the placenta may indicate fetal and maternal disease that otherwise might go undetected.

Twin-Twin Transfusion Syndrome

Nearly all monochorionic twin placentas show an anastomosis between the vessels of the 2 umbilical circulations, but differ in number, direction, and size of the anastomoses. These usually involve the major branches of the arteries and veins in the placental surface. Artery-to-artery communications are found in 75% of the monochorionic twin placentas. Less frequently found are vein-to-vein and artery-to-vein anastomoses. Of great pathologic significance are deep arteriovenous communications between the 2 circulations. This occurs when there are shared lobules supplied by an umbilical arterial branch from one fetus and drained by an umbilical vein branch of the other fetus. This is found in approximately half of all monochorionic twin placentas. Fortunately, one-way flow to the shared lobule may be compensated for by reverse flow through a superficial arterioarterial or venovenous anastomosis, if they coexist.

Twin-twin transfusion syndrome (TTS) arises when shared lobules causing blood flow from one twin to the other are not compensated for by the presence of superficial anastomosis or by shared lobules, causing flow in the opposite direction. This syndrome occurs in 15–20% of cases of monochorial placentation The twin receiving the transfusion is plethoric and polycythemic and may show cardiomegaly. The donor twin is pale and anemic and may have organ weights similar to those seen in the intrauterine malnutrition form of small for gestational age.

Placental Infarction

A placental infarct is an area of ischemic necrosis of placental villi resulting from obstruction of blood flow through the spiral arteries as a result of thrombosis. The lesions have a lobular distribution. However, the spiral arteries are not true end arteries, and if there is adequate flow through the arteries supplying adjacent lobules, sufficient circulation will be maintained to prevent necrosis. Thus ischemic necrosis of one placental lobule probably indicates not only that the spiral artery supplying the infarcted lobule is thrombosed, but that flow through adjacent spiral arteries is severely impaired. Placental infarction may serve as a mechanism allowing the fetus to redistribute blood flow to those placental lobules that are adequately supplied by the maternal circulation. Although often seen in mature placentas at low levels, the infarct must be extensive before the fetus is physiologically impaired.

Chorioangioma of the Placenta

A benign neoplasm occurring in approximately 1% of placentas and composed of fetoplacental capillaries may occur within the placenta. It is grossly visible as a purplered, apparently encapsulated mass, variable in size, and occasionally multicentered. Placental hemangiomas, or “chorioangiomas,” that measure 5 cm or more may be linked with maternal, fetal, and neonatal complications due to arteriovenous shunting of blood away from the fetus. Many placental tumors are accompanied by hydramnios, hemorrhage, preterm delivery, and fetal growth restriction.

Amniotic Bands

Close inspection of the fetal membranes, particularly near the umbilical cord insertion, may reveal band or stringlike membrane segments that are easily lifted above the placental surface. The origin of amniotic bands is unclear. Proposed mechanism include tearing in the amnion early in pregnancy as well as inherited developmental abnormality. They may cause constriction of the developing limbs or other digits. Amputation has been known to result. Syndactyly, clubfoot, and fusion deformities of the cranium and face may also be explained in certain instances on the basis of amniotic bands.

Placental Pathology

Any infant born with a complication may benefit from histologic evaluation of the placenta and umbilical cord. Histopathologic features of a placenta with uteroplacental insufficiency include nonmarginal infarcts, shrunken placental villi, increased syncytial knots, increased perivillous fibrin, and multifocal and diffuse fibrin deposition. Similarly, if the ratio of nucleated red blood cells to leukocytes exceeds 2:3, this indicates fetal hypoxic stress. Chorangiosis is a pathologic change that indicates long-standing placental hypoperfusion or low-grade tissue hypoxia.

The presence of meconium and its location can also give insight into the possible time of the presumed insult. Under gross observation, meconium will stain the placenta and cord after 1–3 hours of exposure. Stained infant fingernails indicate meconium exposure for at least 6 hours. Stained vernix equates with exposure of meconium for 15 hours or longer.

Microscopic evaluation also sheds light on the timing of the release of meconium. Meconium-laden macrophages at the chorionic surface of the placenta can be seen when meconium has been present for 2–3 hours. When these macrophages are found deep within the extraplacental membranes, meconium has been present for at least 6–12 hours.

Lastly, when evaluation of the umbilical cord demonstrates necrobiotic and necrotic arterial media with surrounding meconium-laden macrophages, the release of meconium occurred more than 48 hours before delivery.

Abnormalities of Placental Implantation

Normally the placenta selects a location on the endometrium that benefits the growing fetus. However, there are numerous instances when the placental implantation site is not beneficial.

Placenta previa, or the implantation of the placenta over the cervical os, is the most common. The incidence at 12 weeks' gestation is approximately 6% because of the advancement of transvaginal imaging. Fortunately, most cases of placenta previa resolve by the time of delivery (reported incidence of 5/1000 births). A marginal placenta previa occurs when the edge of the placenta lies within 2–3 cm of the cervical os; the prevalence ranges from 10–45% when the less accurate abdominal ultra-sonogram is used.

Associated consequences of these abnormal placentation sites include increased risk for bleeding, both for the mother and the fetus, increased need for caesarean delivery, and possible risk of placenta accreta and increta or percreta, abruption, and growth restriction. Once the placental edge moves beyond 2–3 cm from the cervical os, these risks are minimized.

Placenta accreta is the most dangerous consequence of placenta previa. It involves abnormal trophoblastic invasion beyond the Nitabuch's layer. Placenta increta is the term used to describe invasion into the myometrium. Placenta percreta describes invasion through the serosa with possible invasion into surrounding tissues such as the bladder. Placenta accreta is associated with life-threatening postpartum hemorrhage and increased need for immediate hysterectomy.

The risk factors for placenta previa and placenta accreta are similar. Advanced maternal age, increased parity, and prior uterine surgery are common risk factors for both entities. The strongest correlation appears to exist with prior uterine surgeries. The prevalence of placenta previa after 1 prior caesarean delivery reaches 0.65% versus 0.26% in the unscarred uterus. However, after 4 or more caesarean deliveries the prevalence reaches 10%. Similarly, the frequency of accreta in the presence of placenta previa increases as the number of uterine surgeries increases. In patients with 1 prior uterine surgery, accreta occurs in 24% of placenta previas, whereas after 4 or more surgeries, the frequency of placenta accreta may be as high as 67%.

Placenta accreta may be suspected with certain ultrasound findings such as loss of the hypoechoic retroplacental myometrial zone, thinning or disruption of the hyperechoic uterine serosa-bladder interface, or with visualization of an exophytic mass. In all cases of placenta previa, and especially if placenta accreta is suspected, the patient must be counseled that hysterectomy may be needed to control excessive bleeding after delivery. Blood products must be available before delivery of the infant to ensure prompt replacement.

THE UMBILICAL CORD

Development

In the early stages, the embryo has a thick embryonic stalk containing 2 umbilical arteries, 1 large umbilical vein, the allantois, and the primary mesoderm. The arteries carry blood from the embryo to the chorionic villi, and the umbilical vein returns blood to the embryo. The umbilical vein and 2 arteries twist around one another.

In the fifth week of gestation, the amnion expands to fill the entire extraembryonic coelom. This process forces the yolk sac against the embryonic stalk and covers the entire contents with a tube of amniotic ectoderm, forming the umbilical cord. The cord is narrower in diameter than the embryonic stalk and rapidly increases in length. The connective tissue of the umbilical cord is called **Wharton's jelly** and is derived from the primary mesoderm. The umbilical cord can be found in loops around the baby's neck in approximately 23% of normal spontaneous vertex deliveries.

At birth, the mature cord is approximately 50–60 cm in length and 12 mm in diameter. A long cord is defined as more than 100 cm, and a short cord as less than 30 cm. There may be as many as 40 spiral twists in the cord, as well as false knots and true knots. When umbilical blood flow is interrupted at birth, the intraabdominal sections of the umbilical arteries and vein gradually become fibrous cords. The course of the umbilical vein is discernible in the adult as a fibrous cord from the umbilicus to the liver (ligamentum teres) contained within the falciform ligament. The umbilical arteries are retained proximally as the internal iliac arteries and give off the superior vesicle arteries and the medial umbilical ligaments within the medial umbilical folds to the umbilicus. When the umbilical cord is cut and the end examined at the time of delivery, the vessels ordinarily are collapsed.

Analysis of the Umbilical Cord in Fetal Abnormalities

A segment of umbilical cord should be kept available as a source of umbilical cord blood for blood gas measurements at the time of delivery. Cord blood gases are a more objective measure of oxygenation than Apgar scores.

ABNORMALITIES OF THE UMBILICAL CORD

Velamentous Insertion

In velamentous insertion, the umbilical vessels divide to course through the membranes before reaching the chorionic plate. Velamentous insertion occurs in approximately 1% of placentas in singleton pregnancies, with multiple gestations having a 6–9 times higher incidence. When these vessels present themselves ahead of the fetus (vasa previa), they may rupture during labor or before to cause fetal exsanguination. When painless vaginal bleeding occurs, the blood may be tested to determine whether it is of fetal origin (Apt test). In practical terms, a high index of suspicion for vasa previa is needed because the time to fetal collapse with bleeding from vasa previa is often too rapid to allow test interpretation.

Short Umbilical Cord

It appears from indirect evidence in the human fetus that the length of the umbilical cord at term is determined by the amount of amniotic fluid present during the first and second trimesters and by the mobility of the fetus. If oligohydramnios, amniotic bands, or limitation of fetal motion occur for any reason, the umbilical cord will not develop to an average length. Amniocentesis performed to produce oligohydramnios in pregnant rats at 14–16 days results in significant reduction of umbilical cord length. The length of the umbilical cord does not vary with fetal weight, presentation, or placental size. Simple mechanical factors may determine the eventual length of the cord.

Knots in the Umbilical Cord

True knots occur in the cord in 1% of deliveries, leading to a perinatal loss of 6.1% in such cases. False knots are developmental variations with no clinical importance.

Loops of the Umbilical Cord

Twisting of the cord about the fetus may be the reason for excessive cord length. One loop of cord is present about the neck in 21% of deliveries, 2 loops in 2.5%, and 3 loops in 0.2%. The presence of loops increases as the amount of amniotic fluid increases, as the length of the umbilical cord increases and as fetal movement increases. When 3 loops are present, the cord is usually longer than 70 cm. One study of 1000 consecutive deliveries found 1 or more loops of cord around the neck in approximately 24% of cases. Retrospective studies suggest that neither single nor multiple loops are associated with adverse fetal outcomes.

Torsion of the Umbilical Cord

Torsion of the cord occurs counterclockwise in most cases. If twisting is extreme, fetal asphyxia may result.

Single Artery

A 2-vessel cord (absence of 1 umbilical artery) occurs in approximately 0.2–11% pregnancies, with risks depending on multiple gestation, ethnicity, maternal age, fetal sex, and smoking. The cause may be aplasia or atrophy of the missing vessel. The presence of single umbilical artery increases the risk for congenital and chromosomal anomalies. Associated malformations include neural tube defects, cardiac defects, genitourinary malformations, gastrointestinal malformations, and respiratory malformations. Acardiac twinning has also been documented. Level III ultrasound should be preformed.

Normal Newborn Assessment & Care

Elisabeth L. Raab, MD, MPH
Lisa K. Kelly, MD

A full-term newborn is a baby born at 37 weeks’ or more gestation. Term newborns are evaluated in the delivery room immediately after birth to assure that they do not require respiratory or circulatory support, have no birth-related trauma or congenital anomalies requiring immediate intervention, and are transitioning as expected to extrauterine life. Approximately 97% of newborns are healthy and require only routine care in the nursery after birth. In the nursery, newborns receive a thorough evaluation to determine maturity, evaluate growth and development, and identify those with signs of acute illness or underlying congenital disease.

DELIVERY ROOM MANAGEMENT

At every delivery there should be at least 1 person whose primary responsibility is attending to the newborn. Although approximately 90% of the time no resuscitation will be required, the attendant must be able to recognize signs of distress in a newborn and carry out a skilled resuscitation.

After the umbilical cord is cut, newborns should be placed in a warm environment. They may be placed on the mother’s chest, skin-to-skin, or they may be brought to a radiant warmer. Early skin-to-skin contact increases the likelihood and duration of breastfeeding, decreases infant crying, and facilitates bonding and is therefore encouraged when possible. However, it should only be done when the newborn is crying/breathing and has good tone and when there are no risk factors that increase the likelihood that resuscitation will be required (eg, prematurity). The infant is dried with prewarmed towels to prevent heat loss and the airway is positioned and cleared to ensure patency. The airway may be cleared by suctioning the mouth and nares with a bulb syringe or a suction catheter connected to mechanical suction. If the newborn is well-appearing and not at increased risk, the airway can be cleared simply by wiping the mouth and nose with a towel.

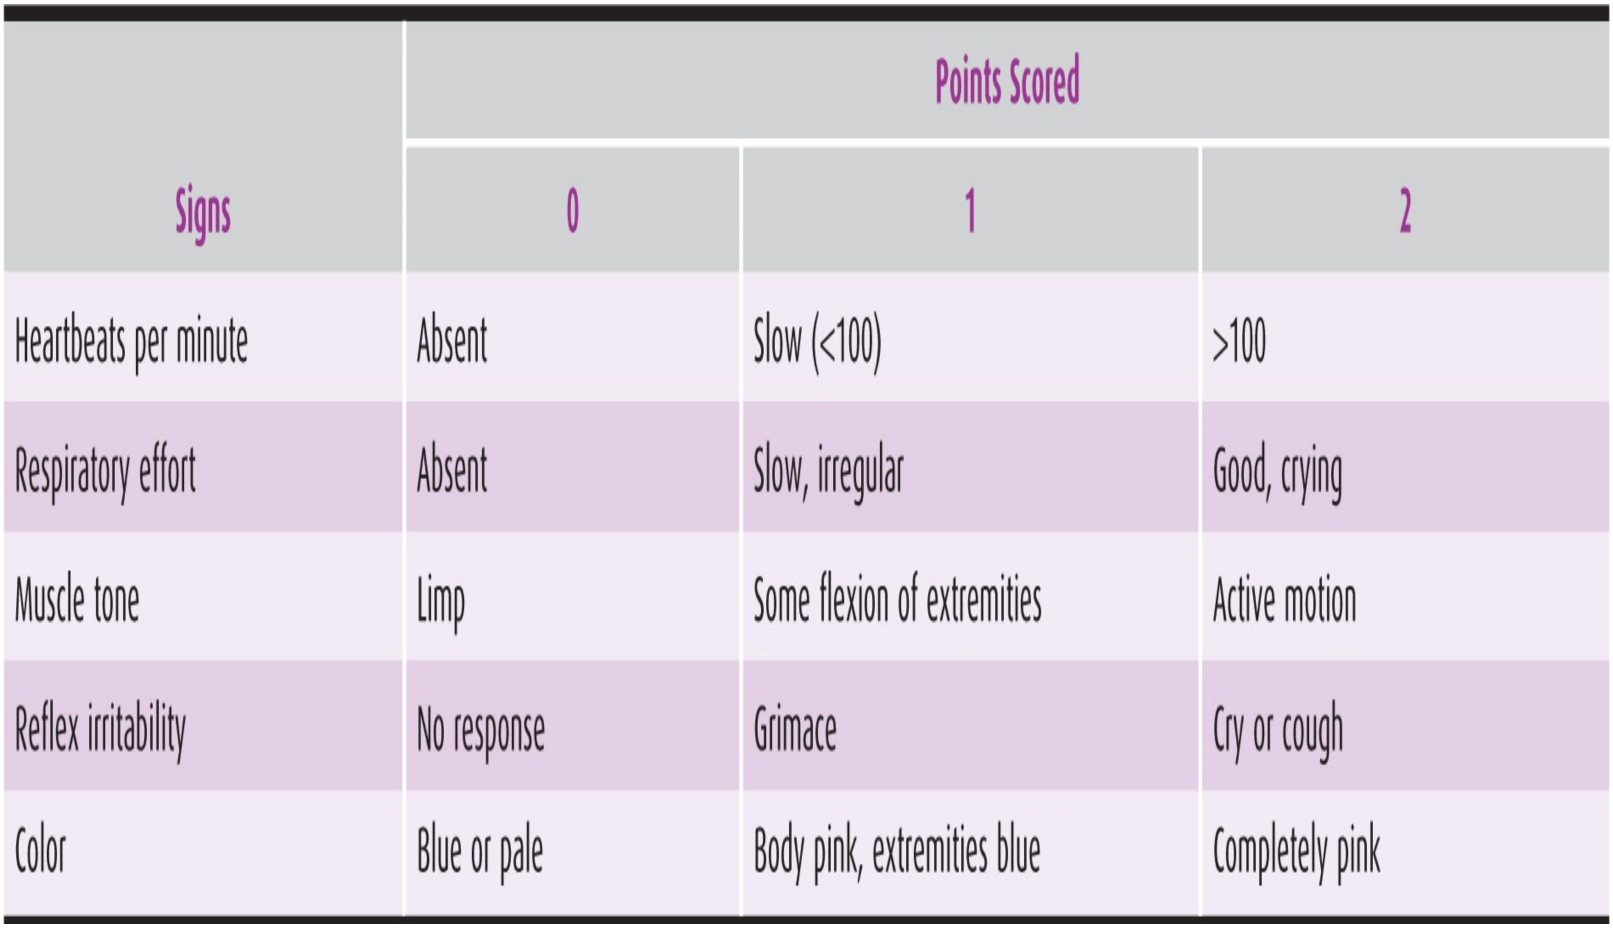
During this initial postpartum period, the newborn’s respiratory effort, heart rate, color, and activity are evaluated to determine the need for intervention. If drying and suctioning do not provide adequate stimulus, it is appropriate to flick the soles or rub the back to stimulate breathing. It is important to note the presence of meconium in the amniotic fluid or on the newborn’s skin. Although not contraindicated, it is no longer recommended that the obstetrician routinely suction the oropharynx of an infant born with meconium-stained amniotic fluid upon delivery of the head. If a newborn is in distress or has depressed respiratory effort after delivery and there is evidence that meconium was passed in utero, it is appropriate to intubate and suction the trachea before stimulating the baby in any way. Meconium can block the airway, preventing the newborn lungs from filling with oxygen, a vital step in normal transitioning. However, if the attempted intubation is prolonged or repeatedly unsuccessful, it may be appropriate to omit tracheal suctioning in favor of initiating positive pressure ventilation (PPV) in a depressed infant. Tracheal suctioning has not been shown to decrease the incidence of meconium aspiration syndrome or mortality rates in depressed infants born through meconium-stained fluid. An active, crying, well-appearing newborn does not require endotracheal intubation, regardless of the presence of meconium staining or the thickness of the meconium.

If a newborn remains apneic despite drying, suctioning, and stimulation, or if there are signs of distress such as grunting, central cyanosis, or bradycardia, resuscitation should quickly be initiated. PPV should be initiated in response to gasping, apnea and/or a heart rate below 100 beats/min and the decision to initiate PPV should ideally be made within the first 30–60 seconds after birth.

The Assignment of Apgar Scores

The Apgar score was introduced by Virginia Apgar in 1952 to quantitatively evaluate the newborn's condition after birth (Table 9–1). Scores between 0 and 2 in each of 5 different categories are assigned at 1 and 5 minutes of life. The score reflects the cardiorespiratory and neurologic status at those time points. If the score is <7 at 5 minutes, scores should be assigned every 5 minutes until the baby has a score of 7 or greater or has reached 20 minutes of life. The Apgar score is not what determines the need for resuscitation. Although scores are based on the same elements used to evaluate the newborn's status, the assessment of the need for intervention with PPV should ideally already have been made by the time the 1-minute Apgar score is assigned. Studies do not show a correlation between a low 1-minute Apgar score and outcome. However, the change between the scores at 1 and 5 minutes is a meaningful measure of the effectiveness of the resuscitation efforts, and a 5-minute score of 0–3 is associated with increased mortality in both preterm and full-term infants. It is important to know that factors such as prematurity, maternal medications, and congenital disease can adversely affect scores.

Table 9–1. Apgar scoring.



Signs	Points Scored		
	0	1	2
Heartbeats per minute	Absent	Slow (<100)	>100
Respiratory effort	Absent	Slow, irregular	Good, crying
Muscle tone	Limp	Some flexion of extremities	Active motion
Reflex irritability	No response	Grimace	Cry or cough
Color	Blue or pale	Body pink, extremities blue	Completely pink

The Importance of the Prenatal & Intrapartum History

Knowledge of the prenatal and intrapartum history is essential for adequate care of the newborn. The history should be reviewed before delivery (if possible), as it may alter care in the immediate postpartum period. For example, information about the use of certain anesthetic drugs during labor and delivery alerts those attending the delivery to the possibility of newborn respiratory depression and allows them to anticipate a role for the use of naloxone in the resuscitation. Other important pieces of information are the presence of chronic disease in the mother (eg, diabetes mellitus, Grave’s disease, or systemic lupus erythematosus), maternal illicit or prescription drug use, prenatal ultrasound findings, maternal screening laboratory test results, and the presence of risk factors for neonatal infection. All of these will affect how the newborn is monitored during the nursery admission and in the first few weeks of life, and adequate care is not possible without them.

A. The Initial Exam

Although a complete and detailed physical exam is delayed until the newborn is admitted to the nursery and has had time to transition to extrauterine life, a brief examination should be done shortly after delivery to rule out any problems that require immediate attention.

1. Airway—The airway should be evaluated for patency. A suction catheter may be passed through each naris if needed to remove secretions from the nasopharynx or if there is concern about the possibility of choanal atresia, but is not necessary if adequate clearance of secretions is achieved with a bulb syringe and the newborn is breathing comfortably. Although a suction catheter is an effective means of removing secretions, it should be used cautiously because it can induce bradycardia and cause trauma and edema to the mucous membranes.

2. Chest—The chest should be examined to determine the adequacy of the respiratory effort. One should assess chest wall movement, respiratory rate, and breathing pattern and look for signs of distress, such as retractions. Crackles are often audible initially, but should clear over time as fetal lung fluid is resorbed and the lungs inflate with air. Decreased or asymmetric breath sounds may result from pneumonia, atelectasis, a pneumothorax, mass, or effusion. Heart rate and rhythm should be evaluated, and the presence or absence of a murmur noted. The heart rate should be >100 beats/min.

3. Abdomen—The abdomen should be soft and nondistended. A distended, firm abdomen may indicate a bowel obstruction, pneumoperitoneum, or intraabdominal mass. A scaphoid abdomen, when accompanied by respiratory distress, should raise the examiner’s suspicion of a diaphragmatic hernia. The umbilical stump should be examined and the number of blood vessels noted. A single umbilical artery may be a clue to the presence of other anomalies, renal anomalies in particular.

4. Skin—The skin color should be evaluated. Although acrocyanosis, bluish discoloration of the hands and feet, may be seen in well newborns, central cyanosis of the trunk may be a sign that the newborn is not receiving sufficient oxygen. Cyanosis and pallor can result from a wide variety of causes such as sepsis, anemia, respiratory insufficiency with or without abnormally elevated cardiac vascular resistance, congenital heart disease, and hypoxic-ischemic injury with cardiac dysfunction; the pre- and intrapartum history is often useful in determining the etiology. Pulse oximetry is useful to help determine the oxygen saturation in the event of cyanosis. A cyanotic infant with a normal heart rate and respiratory effort may be given free-flow 100% oxygen by face mask or tubing held close to the nose and should be observed for improvement in skin coloring. If the skin does not become pink, the patient may require PPV to achieve improved oxygenation.

5. Genitalia—It is important to closely evaluate the genitalia before pronouncing the sex of the newborn. If there is ambiguity of the genitalia, the situation must be explained to the parents, and a full evaluation, including karyotyping and consultation with a pediatric endocrinologist and urologist, should be done before gender assignment.

5. General—Alertness, activity, tone, and movement of the extremities should be noted. The face and extremities should be evaluated for evidence of congenital anomalies or birth trauma. The most common birth-related injuries are nerve injuries (facial and brachial nerve palsies) and fractures (primarily clavicular). Unilateral peripheral facial nerve palsy should be suspected when the newborn has normal movement of the forehead, but difficulty closing the eye and flattening of the nasolabial folds on the affected side and an asymmetric facial expression with crying (the unaffected side will go down). Peripheral facial nerve injury is thought to result from compression of the nerve against the maternal sacrum during delivery and is not associated with the use of forceps in delivery. The risk of brachial plexus injury is increased when there is shoulder dystocia or the baby is large for gestational age (LGA). Erb's palsy (C5–C6 injury) manifests as an inability to externally rotate or abduct the shoulder; the affected arm is held adducted and internally rotated and is extended and pronated at the elbow ("waiter-tip" position). If the C5–T1 nerve roots are all affected, the function of the hand will be affected as well.

CARE & OBSERVATION IN THE FIRST FEW HOURS OF LIFE

A single 1-mg intramuscular injection of vitamin K is recommended for all newborns to prevent bleeding as a result of vitamin K deficiency. Vitamin K prophylaxis has been standard of care since 1961, when it was first recommended by the American Academy of Pediatrics (AAP). Standard newborn care also includes applying either 0.5% erythromycin ointment, 1% silver nitrate solution, or 1% tetracycline ointment to the infant's eyes shortly after birth to prevent infectious neonatal conjunctivitis.

The well newborn may remain with the mother after birth and attempt an initial feed. There should be continued intermittent assessment to assure that there is no cardiorespiratory distress, temperature instability, altered level of activity, or other signs of distress. It is important that care-givers are aware that babies that require resuscitation after birth are at increased risk of difficulties with transitioning and must be monitored closely.

NEWBORN NURSERY CARE

Vital Signs

Vital signs should be recorded by the nursing staff for all newborns admitted to the nursery. Body temperature is typically measured in the axilla. Fever, defined as a temperature ≥38.0° Celsius (or 100.4° Fahrenheit), is often caused by excessive environmental heat or overbundling when it occurs shortly after birth. Hypothermia may result if newborns are left in the delivery room unbundled and off the radiant warmer. A newborn with hypothermia or hyperthermia whose temperature fails to normalize in response to appropriate environmental measures should be evaluated for possible sepsis and central nervous system pathology.

A normal respiratory rate for a newborn is typically between 40 and 60 breaths per minute. A normal heart rate for a newborn is generally 100–160 beats/min, but varies considerably with sleep and activity level. If measured, pulse oximetry should be >95% in the term infant. However, it is important to realize that oxygen saturations may remain low for several minutes after birth. Data indicate that it takes approximately 8 minutes on average for pulse oxygen saturations to rise above 90%. Neonatal resuscitation guidelines published by the AAP in 2010 target a preductal saturation of >80% by 5 minutes of life and 85–95% by 10 minutes of life in both term and preterm infants. Blood pressure varies with gestation and birth weight. There is still debate regarding what constitutes an abnormal blood pressure in a neonate, but hypotension in the first 12–24 hours of life is typically defined as a mean blood pressure less than the gestational age. Hypertension in the full-term newborn is defined as a systolic blood pressure >90 mm Hg and diastolic blood pressure >60 mm Hg and a mean blood pressure >70 mm Hg. Blood pressures should be measured in all 4 extremities if there is any suspicion of cardiac disease. Coarctation of the aorta is characterized by elevated blood pressure in the upper extremities and decreased pressure in the lower extremities.

Growth and Development

Weight, length, and head circumference should be measured and plotted on curves to assess intrauterine growth (Fig. 9–1). Newborns that are small for gestational age (SGA), historically defined as less than the 10th percentile on the growth curve, may warrant evaluation for congenital infections, chromosomal syndromes, or other causes if there is no identifiable cause for the growth retardation, such as multiple pregnancy or preeclampsia or other evidence of placental insufficiency. Infants that are SGA or LGA should be treated similarly to the infants of diabetic mothers and should be monitored for hypoglycemia in the first few hours of life.

Figure 9–1. Classification of newborns based on gestational age plotted against head circumference, length, and weight. AGA, appropriate for gestational age; LGA, large for gestational age; SGA, small for gestational age.

Although gestational age is usually estimated before delivery by prenatal ultrasound (preferably early on in the pregnancy) or the mother’s last menstrual period, information is sometimes unavailable or inaccurate, and maturity should be reassessed postnatally. There are measures, such as Ballard’s modified version of the Dubowitz exam (Table 9–2), that incorporate multiple elements of the physical exam and may be useful at 12–24 hours of life to help determine gestational age.

Table 9–2. Newborn maturity rating and classification.

	0	1	2	3	4	5
Neuromuscular maturity						
Posture						Square window (wrist)	 90°	 60°	 45°	 30°	 0°	
Arm recoil	 180°		 100°–180°	 90°–100°	 < 90°	
Popliteal angle	 180°	 160°	 130°	 110°	 90°	 < 90°
Scarf sign						
Heel to ear						

Physical maturity						
Skin	Gelatinous, red, transparent	Smooth, pink; visible veins	Superficial peeling and/or rash; few veins	Cracking, pale area; rare veins	Parchment, deep cracking; no vessels	Leathery, cracked, wrinkled
Lanugo	None	Abundant	Thinning	Bald areas	Mostly bald	
Plantar creases	No crease	Faint red marks	Anterior transverse crease only	Creases anterior two-thirds	Creases cover entire sole	
Breast	Barely perceptible	Flat areola; no bud	Stippled areola; bud, 1-2 mm	Raised areola; bud, 3-4 mm	Full areola; bud, 5-10 mm	
Ear	Pinna flat; stays folded	Slightly curved pinna; soft; slow recoil	Well-curved pinna; soft; ready recoil	Formed and firm; instant recoil	Thick cartilage; ear stiff	
Genitalia (male)	Scrotum empty; no rugae		Testes descending; few rugae	Testes down; good rugae	Testes pendulous; deep rugae	
Genitalia (female)	Prominent clitoris and labia minora		Majora and minora equally prominent	Majora large; minora small	Clitoris and minora completely covered	

The following information should be recorded: Birth date and Apgar score at 1 and 5 minutes. Two separate examinations should be made within the first 24 hours to determine the estimated gestational age according to maturity rating. Each examination and the age of the infant at each examination should be noted. Maturity rating:

Score	5	10	15	20	25	30	35	40	45	50
Weeks	26	28	30	32	34	36	38	40	42	44

Physical Exam

A physician should perform a complete physical exam of the newborn within the first 24 hours of life.

A. Skin

As on the initial brief examination, the color of the skin should be evaluated and the presence of cyanosis, pallor, or jaundice noted. The healthy newborn should be pink. Postterm infants often have dry, cracked skin. Clinical jaundice is rare in the first 24 hours of life and should trigger an evaluation. Plethora, often seen in infants of diabetic mothers, may indicate significant polycythemia. Practice varies, but most neonatologists consider a hematocrit >70% in an asymptomatic newborn and 65% in a symptomatic newborn grounds for a partial exchange transfusion. Symptoms of hyperviscosity include hypoxia, hypoglycemia, increased work of breathing, and seizures. Neurologic sequelae can be serious. Petechiae are often present over the face and upper torso, particularly when a nuchal cord is present. When present below the nipple line, petechiae should raise concern about the possibility of sepsis or platelet dysfunction. Bruising occurs frequently, especially with breech presentation, but should be noted because it may lead to excessive hemolysis and hyperbilirubinemia when extensive. Mongolian spots are dark purple-blue hyperpigmented areas usually over the back and buttocks that look like bruising, but are clusters of melanocytes deep within the dermis. They are present in a majority of black and Asian newborns and fade over time. Dermal sinuses, dimples, and cysts should be noted; they may indicate underlying defects or pose a risk for infection.

The most common newborn rash is erythema toxicum, which presents at 24–48 hours of life in almost half of all newborns as erythematous papular-pustular lesions that tend to spare the palms and soles. Other frequently seen benign rashes include milia, small white papules typically around the nares, and transient neonatal pustular melanosis, small vesicles or pustules present at birth that leave pigmented macules surrounded by scale when they disappear.

Hemangiomas and vascular malformations may be present at birth. Hemangiomas are benign tumors of vascular endothelium and are often not present at birth, but may be noted soon after. They eventually involute without therapy, but only after an initial period of growth, usually of 6–12 months. If present near the eyes or airways, they may require early intervention to prevent visual or airway compromise. In contrast, vascular malformations such as port-wine stains and salmon patches are always present at birth. Developmental anomalies composed of 1 or more types of vessels, they typically grow as the child grows and do not resolve spontaneously.

B. Head, Face, & Neck

The head should be evaluated for any asymmetry. The suture lines may be open or slightly overriding, but premature fusion requires intervention, as it presents a constraint to brain growth. The anterior fontanelle should be soft, not tense or bulging, when the newborn is calm. It is typically 1–4 cm in size and may be enlarged with hypothyroidism or increased intracranial pressure. The posterior fontanelle is typically <1 cm and may not be palpable.

Scalp edema (caput succedaneum) can most easily be differentiated from a cephalohematoma (a localized collection of blood under the dura mater) by noting whether or not the swelling crosses suture lines; cephalohematoma is typically confined by suture lines. A cephalohematoma should raise awareness of the possible development of hyperbilirubinemia as the collection of blood is broken down and resorbed. Skull fractures can occur, and the skull should be palpated carefully.

The face should be evaluated for dysmorphic features, malformations, and asymmetries. Micrognathia may cause significant airway compromise in the neonate and is associated with various syndromes. The palate should be palpated to ensure that it is not high-arched or clefted. A naris is patent if there is air movement through it (demonstrated by holding cotton in front of it) when the mouth and other naris are closed. Subconjunctival hemorrhages are a common finding as a result of the birth process. An absent red reflex should prompt an immediate ophthalmologic evaluation to rule out a congenital cataract, retinoblastoma, or glaucoma. Pupils should be equal and reactive. Abnormalities of the positioning or formation of the eyes, nose, or ears may suggest specific syndromes or chromosomal defects. Although preauricular tags and pits have been associated with renal malformations, there is no current evidence to suggest that their presence, when an isolated finding, is sufficient to warrant a renal ultrasound. The neck should be examined for masses, cysts, and webbing. The clavicles should be palpated for crepitus, swelling, and tenderness, which would suggest an underlying fracture. Although not usually detected until several weeks of age, torticollis may occur as a result of ischemia within, or hemorrhage into, the sternocleidomastoid muscle at birth. It manifests as a head tilt with or without a fibrous mass palpable in the muscle. Surgery is rarely necessary; the overwhelming majority of cases are managed with a home stretching regimen or physical therapy.

C. Chest

The chest should be evaluated for deformities such as widely spaced or accessory nipples and pectus excavatum. Breast buds may be present in both sexes and are normal, a product of exposure to circulating maternal hormones in utero.

The respiratory effort and rate should be evaluated, looking for signs of respiratory distress. Early on, tachypnea may be the only sign of pathologic processes as varied as pneumonia, amniotic fluid and/or meconium aspiration syndrome, sepsis, or congenital heart disease (CHD). Breath sounds are auscultated, paying attention to the quality of the breath sounds, the air entry, and any asymmetry that is present across the lung fields. Asymmetry of the breath sounds may indicate an area of consolidation from atelectasis or infection, a pneumothorax, effusion, or mass. Upper airway sounds, such as congestion or stridor, are often mistaken for abnormal breath sounds on exam. The listener can usually distinguish noises of upper airway origin from those of intrathoracic origin by listening for the presence of the sounds over the patient’s neck. Respiratory distress or an abnormal lung exam should be evaluated with a chest radiograph. In an emergency situation in which a pneumothorax is suspected, a transilluminator may be used. Transillumination is increased over the side of a pneumothorax, but it is sometimes difficult to assess accurately and should be confirmed by chest radiograph when possible before needle aspiration or chest tube placement.

A hyperdynamic precordium may indicate underlying heart disease with volume overload to one or both ventricles. The heart is auscultated to evaluate the heart rate and rhythm and characterize the heart sounds. A split-second heart sound can assure the examiner that both the aortic and pulmonary valves are present. A murmur should be described by where it is heard, what it sounds like, if it occurs in systole or diastole, and how loud it is. Murmurs are often audible in the newborn and are frequently innocent. Innocent murmurs are often attributed to a closing ductus arteriosus or foramen ovale, but the most commonly heard innocent murmur in the neonate is produced by peripheral pulmonic stenosis (PPS). PPS murmurs occur during systole and are best heard over the back or axillae.

Murmurs may or may not be present in newborns with CHD. Ventricular septal defects, the most common form of CHD, have a characteristic harsh, systolic murmur associated with them. However, the pressures in the newborn pulmonary system are still high (roughly equal to systemic pressures), and thus there is usually no flow gradient across a large ventricular defect to produce a murmur in the first few days of life. Complex CHD typically presents as cyanosis, tachypnea, or shock and will rarely present as an asymptomatic murmur. Signs may develop quickly with closure of the ductus arteriosus if the lesion has ductal-dependent pulmonary or systemic flow. The initial steps in evaluating a stable patient for suspected CHD include 4-extremity blood pressure measurements, measurement of pre- and postductal saturations, electrocardiogram, chest radiography, and a hyperoxia test. The diagnosis of CHD is usually established by echocardiogram.

D. Abdomen

The examiner should listen for bowel sounds and palpate the abdomen for masses, organomegaly, or abnormal musculature. The liver is easily palpable in the newborn and the inferior edge is usually 1–2 cm below the right costal margin. It is often possible to palpate the kidneys and spleen. Absence of the abdominal musculature may be associated with significant urinary tract abnormalities. The umbilical stump should be assessed for redness or induration that may suggest the presence of an infection. Umbilical hernias are common and typically require no intervention in infancy. Omphalocele and gastroschisis are major abdominal wall defects and require emergent surgical evaluation. Omphalocele is a midline abdominal wall defect. Bowel, and often liver, herniate through the defect, and the umbilicus is typically on the anterior aspect of the omphalocele. Unless ruptured, an omphalocele is covered by a membrane. Omphalocele is associated with aneuploidies, certain genetic syndromes such as pentalogy of Cantrell, and other congenital structural malformations. The defect in gastroschisis is typically to the right of the umbilicus on the abdominal wall, and the etiology of the defect is thought to be due to vascular interruption. The entire bowel may be externalized, but the liver typically remains internal. Unlike omphaloceles, the externalized bowel is not covered by a membrane. Other bowel abnormalities such as bowel atresias and malrotation of the bowel may be present in infants with gastroschisis. Fetuses with gastroschisis are also at increased risk of developing intrauterine growth restriction.

E. Genitalia

The penile length and clitoral size should be inspected to rule out ambiguous genitalia. The labia majora should cover the labia minora and clitoris in a term female. White mucouslike discharge from the vagina is often present and is physiologic.

The scrotum should be evaluated for hernias or masses and descent of the testicles. Transillumination of the scrotum will help to distinguish a hydrocele from an inguinal hernia. The position of the urethral meatus is important to note, as the presence of hypospadias should preclude routine circumcision to allow for optimal surgical correction of the hypospadias.

F. Anus

The rectum should be evaluated for patency and position. An anteriorly displaced rectum may be associated with a rectogenital fistula.

G. Musculoskeletal System

The extremities, spine, and hips are examined for signs of fracture, malformation, or deformation. Range of motion of the joints is assessed. Arthrogryposis, contractures of the joints, may be seen with neuromuscular disease or oligohydramnios as a result of decreased or limited movement in utero. Abnormalities of the extremities, such as polydactyly or syndactyly, are seen in different chromosomal abnormalities and syndromes and may help in making the diagnosis. Particular attention should be paid to the examination of the hips (despite the fact that a dislocation may not be detectable in the first weeks of life) because developmental dysplasia of the hip (DDH) can cause permanent damage if left undetected throughout the first year of life. Either the Barlow or Ortolani test may be used to determine whether a dislocation is present. The Barlow test involves positioning the patient on the back, bringing the knees together at midline, and then pushing down and out on the upper inner thighs. The Ortolani test involves pushing downward on the femurs while abducting the hips. With both maneuvers the dislocation is detected as a clunk as the femoral head is dislocated from the acetabulum (posteriorly with the Barlow, laterally with the Ortolani). Asymmetry of the gluteal folds and skin creases of the legs is another clue to the presence of DDH.

H. Neurologic System

Observing the activity level, alertness, and positioning of the newborn provides a tremendous amount of information about the overall state of health. A healthy, full-term newborn at rest should lie with the extremities flexed. Decreased tone may be a sign of neuromuscular or systemic illness such as sepsis. There should be spontaneous intermittent movement of all 4 limbs, and the baby should be alert during at least portions of the examination. Pupil size and symmetry should be noted. Primitive reflexes such as the Moro, grasp, suck, and tonic neck reflex should all be present at birth. To elicit the Moro reflex, the newborn is supported with a hand under the back and then rapidly dropped a few centimeters back toward the examination bed. The full Moro reflex consists of extension and then flexion and adduction of the arms (“embrace”), opening of the eyes, and a cry. Reflexes are elicited by tapping a finger over the appropriate tendon. Significant clonus may be a sign of central nervous system injury. A sacral dimple or tuft of hair over the sacral spine may indicate spina bifida occulta and should be evaluated with a spinal ultrasound; if the findings of the ultrasound are equivocal, a magnetic resonance imaging scan should be done at approximately 3 months of age.

Feeding

The benefits of breastfeeding on everything from the strength of the immune system to developmental outcomes and IQ have been well documented. Human milk is the most easily digested form of infant nutrition, and its caloric value is superior to formula. Mothers should be counseled prenatally about the benefits of breastfeeding and encouraged by their obstetric caregivers to consider breastfeeding. Contraindications to breastfeeding include HIV infection, active tuberculosis infection, and the use of certain medications. Maternal hepatitis C virus (HCV) infection is not a contraindication to breastfeeding. Transmission of HCV via breastmilk is not documented in the absence of coexisting maternal infection with HIV. Nevertheless, infected mothers should be informed that transmission via breastmilk is theoretically possible.

Breastfeeding may be difficult and frustrating for new mothers. It is important that the newborn nursery staff work to provide mothers with the support and knowledge they need to make breastfeeding a positive experience. It is also important that mothers of newborns who require bottle supplementation (eg, a dehydrated, jaundiced infant) are reassured that their efforts at breastfeeding will not be derailed by exposure to the bottle during a limited, medically necessary period, and that breastfeeding can still ultimately succeed.

Regardless of the overwhelming literature to support the value of breast milk, many mothers in the United States choose to bottle-feed their children. Selection of the formula given to the newborn is often based on what formula is available in the nursery or by the mother’s preference. Standard-term infant formula contains iron supplementation and provides 20 kcal/oz. No one formula is better than another for healthy term infants. Mothers with a family history of lactose intolerance sometimes request soy formula, and standard soy formula will provide adequate nutrition for growth and development. Formulas such as Alimentum and Nutramigen are available for infants with more significant protein allergy. Premature infant formulas contain 24 kcal/oz and provide higher amounts of protein, medium-chain triglycerides, and vitamins and minerals (eg, calcium and phosphorous) than standard formulas. The AAP currently recommends formula for the first year of life.

Voiding and Stooling

Voiding should be monitored closely in the nursery. Changes in the baby’s weight and the frequency of urination can be used to assess the hydration status and adequacy of intake in a breastfeeding baby. The time of the first void of urine and stool should be documented. Failure to void in the first 24 hours of life should prompt an evaluation of renal function and hydration status. Failure to pass stool in the first 48 hours of life should prompt an evaluation for possible bowel obstruction; 94% of normal term newborns will pass meconium in the first 24 hours of life. Obstruction can result from conditions such as bowel atresia or stenosis, Hirschsprung’s disease, and meconium ileus.

American Academy of Pediatrics and American Heart Association. *Textbook of Neonatal Resuscitation*. 5th ed. Dallas, TX: American Academy of Pediatrics; 2006.

NEWBORN SCREENING & PROPHYLAXIS

The initial newborn exam may be normal despite the presence of serious occult illness. Signs of complex congenital heart disease, sepsis, gastrointestinal obstruction, significant jaundice, inborn errors of metabolism, and other illnesses may not be present until the second or third day of life at the earliest: shortly before, and at times after, the baby’s discharge. Screening is done in the hopes of detecting disease before a patient becomes symptomatic and is usually reserved for processes that have a worse prognosis if not detected early and for which there is effective therapy. The maternal medical history, the obstetric and perinatal history, and state laws determine what screening is done on any given baby.

Standard newborn screening tests have traditionally screened for the following:

1. Phenylketonuria by Guthrie’s test for phenylalanine level
2. Congenital hypothyroidism by thyroid function testing
3. Congenital syphilis by either rapid plasma reagent (RPR) or Venereal Disease Research Laboratory (VDRL) test (whichever test was performed on the mother)
4. ABO incompatibility using infant blood type and direct Coombs’ test (standard if mother has O blood type, done at many institutions for all newborns)
5. Hearing loss (evaluated by auditory brainstem response or otoacoustic emissions)

Using tandem mass spectrometry, it is now possible to screen for as many as 50 congenital conditions from a single blood sample. Although it has been standard in many states for years now, expanded newborn screening was only adopted as a national standard in the United States in the spring of 2010.

Additional targeted screening often includes evaluation for infection, illicit drug exposure, hyperbilirubinemia, and hypoglycemia when there are risk factors that increase the yield of the testing. A history of rupture of amniotic membranes for >18 hours before delivery, maternal intrapartum fever, chorioamnionitis, and a positive maternal group B streptococcus culture without adequate treatment before delivery are all risk factors for newborn sepsis. A history of any of these risk factors warrants a screening evaluation of the asymptomatic newborn for laboratory evidence of infection. Screening is routinely done for hypoglycemia in infants of diabetic mothers as well as for SGA and LGA babies. At many institutions, infants of diabetic mothers are screened for polycythemia as well.

Information about maternal hepatitis B, HIV, herpes simplex virus (HSV), chlamydia, and syphilis status is essential to newborn care. Adequate prophylaxis for hepatitis B can prevent transmission in 95% of infants born to hepatitis B surface antigen–positive (HBsAg+) mothers. A baby born to a mother who is HBsAg+ should receive the hepatitis B vaccine and hepatitis B immune globulin (HBIG) within the first 12 hours of life to prevent hepatitis B virus transmission. If the mother's status is unknown, the newborn should receive the vaccine within 12 hours of birth, and every effort should be made to determine the mother's status. If the baby weighs more than 2 kg, HBIG can be given as late as 7 days of life if maternal status is positive or still unknown and still provide effective postexposure prophylaxis. However, a baby who weighs <2 kg at birth should receive HBIG by 12 hours of postnatal life to receive adequate prophylaxis. Appropriate screening and treatment for infants born to mothers with a history of infection with HIV, chlamydia, HSV, or syphilis are detailed in the AAP's *Red Book*.

CIRCUMCISION

Routine circumcision is not currently recommended by the AAP. Although there is evidence that supports some medical benefits of circumcision (eg, decreased incidence of urinary tract infections during infancy, sexually transmitted disease, and penile cancer), the data are insufficient for the AAP to recommend the procedure for all newborn males, given concerns about the impossibility of informed consent in an infant and evidence of the pain and stress caused by the procedure. Parents should be provided with unbiased information about the procedure, and the decision to proceed should be left to them. If circumcision is performed, analgesia, either topical or by nerve block, should be given.

DISCHARGE PLANNING

The physician should complete another thorough examination on the day of discharge to reevaluate the overall health of the newborn. Anticipatory guidance should be given to parents to help them care for their newborns and recognize signs of illness and distress. Safety issues, such as the use of car seats, should be addressed. Parents should be alerted to problems such as fever, lethargy, and poor feeding that should prompt them to see a physician. They should be taught about expected newborn behavior, adequate feeding, monitoring of voiding and stooling, and umbilical cord care.

Anticipatory guidance is particularly important now that hospital stays after delivery are often only 36–48 hours. Criteria for newborn discharge at <48 hours of life are outlined in a 2004 AAP policy statement. Newborns discharged before 48 hours of life must be examined by a health care professional within 72 hours of the discharge, preferably within 48 hours. The plan for the newborn's first visit to the physician and any necessary follow-up laboratory testing or nursing visits to the home should be clearly established at the time of discharge, and parents should be able to demonstrate skill and comfort with feeding and tending to the baby's basic needs.

10
The Normal Puerperium

Caroline Pessel, MD
Ming C. Tsai, MD

The puerperium, or postpartum period, generally lasts 6 weeks and is the period of adjustment after delivery when the anatomic and physiologic changes of pregnancy are reversed, and the body returns to the normal, nonpregnant state. The postpartum period has been arbitrarily divided into the immediate puerperium, or the first 24 hours after parturition, when acute postanesthetic or postdelivery complications may occur; the early puerperium, which extends until the first week postpartum; and the remote puerperium, which includes the period of time required for involution of the genital organs and return of menses, usually approximately 6 weeks.

ANATOMIC & PHYSIOLOGIC CHANGES DURING THE PUERPERIUM

Uterine Involution

The uterus increases markedly in size and weight during pregnancy (approximately 10 times the nonpregnant weight, reaching a crude weight of 1000 g) but involutes rapidly after delivery to the nonpregnant weight of 50–100 g. The gross anatomic and histologic characteristics of this process have been studied through autopsy, hysterectomy, and endometrial specimens. In addition, the decrease in size of the uterus and cervix has been demonstrated by magnetic resonance imaging, sonography, and computed tomography.

Immediately after delivery, the uterus weighs approximately 1 kg, and its size approximates that of a 20-week pregnancy (at the level of the umbilicus). At the end of the first postpartum week, it normally will have decreased to the size of a 12-week gestation and is palpable at the symphysis pubis (Fig. 10–1). In case of abnormal uterine involution, infection and retained products of conception should be ruled out.

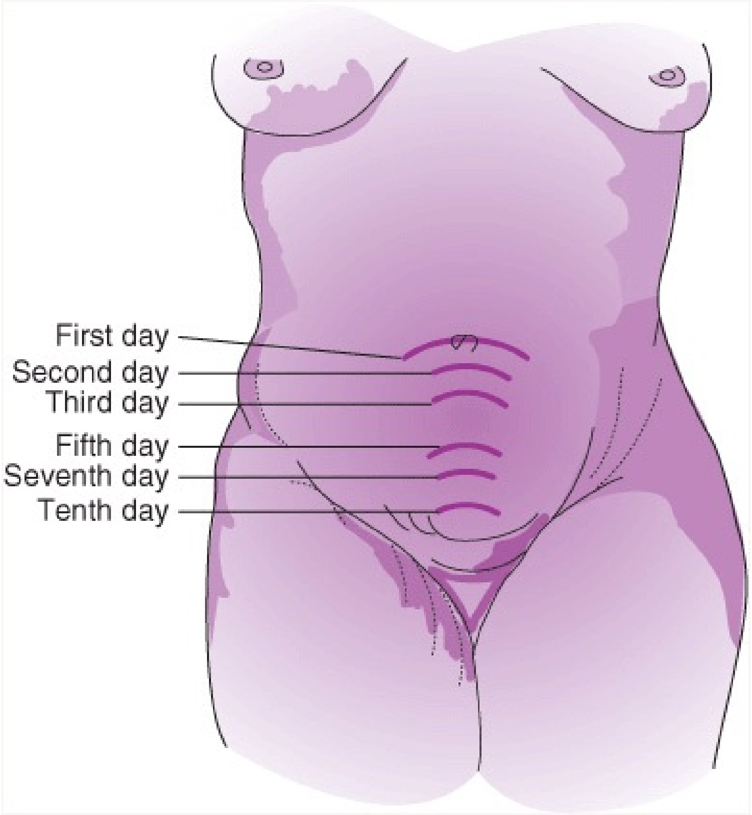

Figure 10–1. Involutional changes in the height of the fundus and the size of the uterus during the first 10 days postpartum.

Myometrial contractions, or **afterpains,** assist in involution. These contractions occur during the first 2–3 days of the puerperium and produce more discomfort in multiparas than in primiparas. Such pains are accentuated during nursing as a result of oxytocin release from the posterior pituitary. During the first 12 hours postpartum, uterine contractions are regular, strong, and coordinated (Fig. 10–2). The intensity, frequency, and regularity of contractions decrease after the first postpartum day as involutional changes proceed. Uterine involution is nearly complete by 6 weeks, at which time the organ weighs less than 100 g. The increase in the amount of connective tissue, elastin in the myometrium and blood vessels, and the increase in numbers of cells are permanent to some degree, so the uterus is slightly larger after pregnancy.

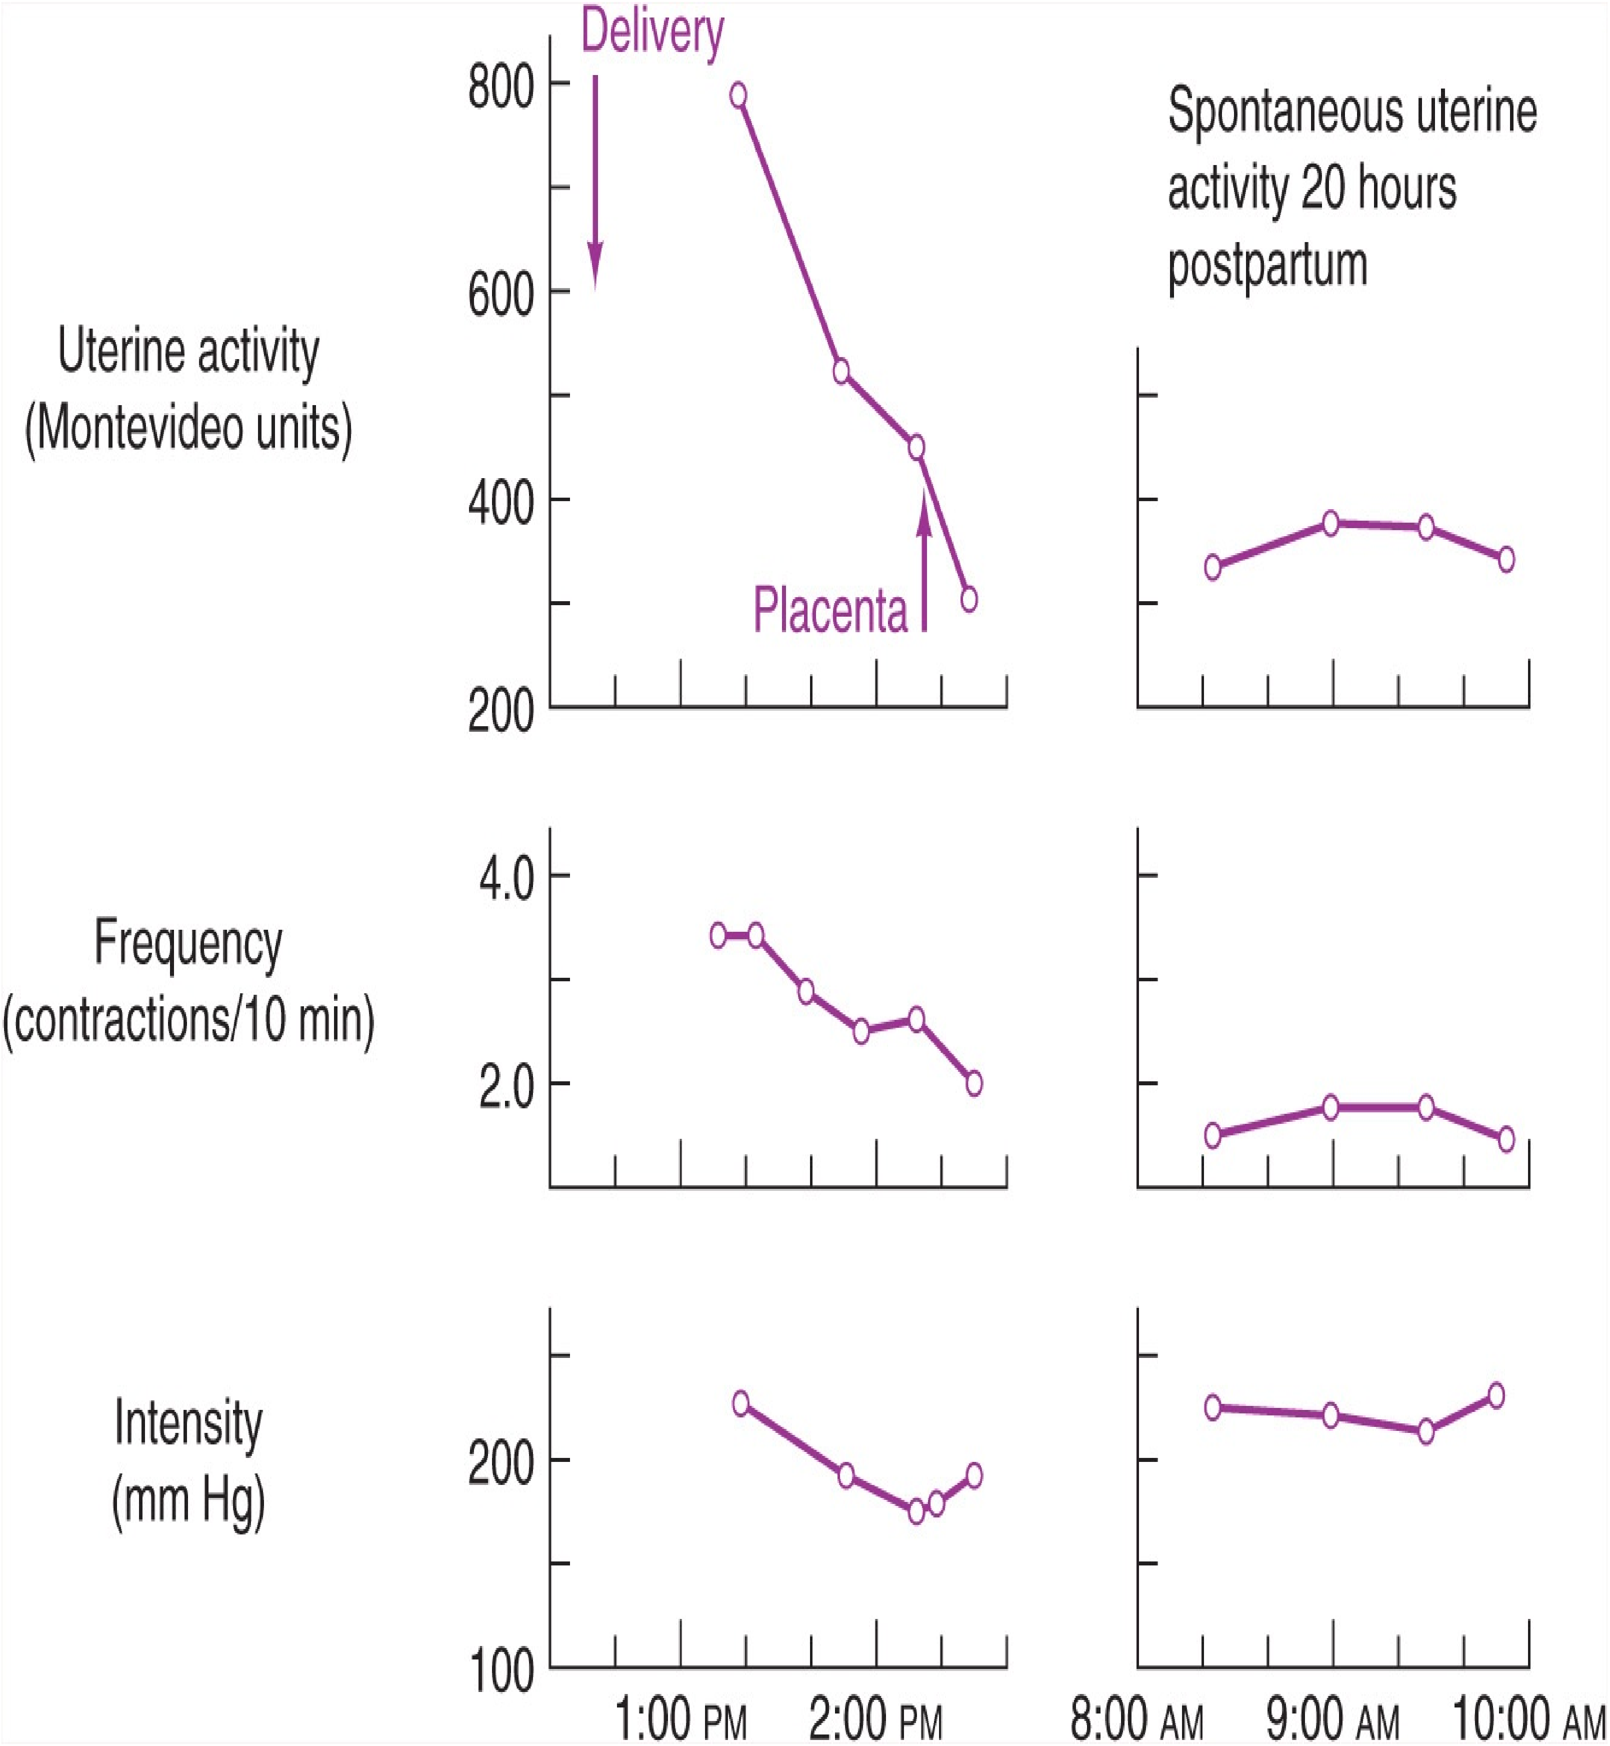

Figure 10–2. Uterine activity during the immediate puerperium (**left**) and at 20 hours postpartum (**right**).

Changes in the Placental Implantation Site

After delivery of the placenta, there is immediate contraction of the placental site to a size less than half the diameter of the original placenta. This contraction, as well as arterial smooth muscle contractions, leads to hemostasis. Involution occurs by means of the extension and down growth of marginal endometrium and by endometrial regeneration from the glands and stroma in the decidua basalis.

By day 16, placental site, endometrial, and superficial myometrial infiltrates of granulocytes and mononuclear cells are seen. Regeneration of endometrial glands and endometrial stroma has also begun. Endometrial regeneration at the placental site is not complete until 6 weeks postpartum. In the disorder termed **subinvolution of the placental site,** complete obliteration of the vessels in the placental site fails to occur. Patients with this condition have persistent lochia and are subject to brisk hemorrhagic episodes. This condition usually can be treated with utero-tonics. In the rare event that uterine curettage is performed, partly obliterated hyalinized vessels can be seen on the histologic specimen.

Normal postpartum discharge begins as **lochia rubra,** containing blood, shreds of tissue, and decidua. The amount of discharge rapidly tapers and changes to a reddish-brown color over the next 3–4 days. It is termed **lochia serosa** when it becomes serous to mucopurulent, paler, and often malodorous. During the second or third postpartum week, the **lochia alba** becomes thicker, mucoid, and yellowish-white, coincident with a predominance of leukocytes and degenerated decidual cells. Typically during the fifth or sixth week postpartum, the lochial secretions cease as healing nears completion.

Changes in the Cervix, Vagina, & Muscular Walls of the Pelvic Organs

The cervix gradually closes during the puerperium; at the end of the first week, it is little more than 1 cm dilated. The external os is converted into a transverse slit, thus distinguishing the parous woman who delivered vaginally from the nulliparous woman or from one who delivered by caesarean section. Cervical lacerations heal in most uncomplicated cases, but the continuity of the cervix may not be restored, so the site of the tear may remain as a scarred notch.

After vaginal delivery, the overdistended and smooth-walled vagina gradually returns to its antepartum condition by about the third week. Thickening of the mucosa, cervical mucus production, and other estrogenic changes may be delayed in a lactating woman. The torn hymen heals in the form of fibrosed nodules of mucosa, the **carunculae myrtiformes**.

Two weeks after delivery, the fallopian tube reflects a hypoestrogenic state marked by atrophy of the epithelium. Fallopian tubes removed between postpartum days 5 and 15 demonstrate acute inflammatory changes that have not been correlated with subsequent puerperal fever or salpingitis. Normal changes in the pelvis after uncomplicated term vaginal delivery include widening of the symphysis and sacroiliac joints. Gas may be seen by ultrasonography in the endometrial cavity a few days after an uncomplicated vaginal delivery. This sonographic observation is more often seen after caesarean section and after manual evacuation of placenta, and it does not necessarily indicate the presence of endometritis. Ovulation occurs as early as 27 days after delivery, with a mean time of 70–75 days in nonlactating women and 6 months in lactating women. In lactating women the duration of anovulation ultimately depends on the frequency of breastfeeding, duration of each feed, and proportion of supplementary feeds. Ovulation suppression is due to high prolactin levels, which remain elevated until approximately 3 weeks after delivery in nonlactating women and 6 weeks in lactating women. However, estrogen levels fall immediately after delivery in all mothers and remain suppressed in lactating mothers. Menstruation returns as soon as 7 weeks in 70% and by 12 weeks in all nonlactating mothers, and as late as 36 months in 70% of breastfeeding mothers.

The voluntary muscles of the pelvic floor and the pelvic supports gradually regain their tone during the puerperium. Tearing or overstretching of the musculature or fascia at the time of delivery predisposes to genital prolapse and genital hernias (cystocele, rectocele, and enterocele). Overdistention of the abdominal wall during pregnancy may result in rupture of the elastic fibers of the cutis, persistent striae, and diastasis of the rectus muscles. Involution of the abdominal musculature may require 6–7 weeks, and vigorous exercise is not recommended until after that time.

Urinary System

In the immediate postpartum period, the bladder mucosa is edematous as a result of labor and delivery. In addition, bladder capacity is increased. Overdistention and incomplete emptying of the bladder with the presence of residual urine are therefore common problems. The decreased bladder sensibility induced by intrapartum regional analgesia may lead to postpartum urinary retention; however, it is reversible and usually not detrimental to later urinary function. Nearly 50% of patients have a mild proteinuria for 1–2 days after delivery. Ultrasonographic examination demonstrates resolution of collecting system dilatation by 6 weeks postpartum in most women. Urinary stasis, however, may persist in more than 50% of women at 12 weeks postpartum. The incidence of urinary tract infection is generally higher in women with persistent dilatation. Significant renal enlargement may persist for many weeks postpartum.

Pregnancy is accompanied by an estimated increase of approximately 50% in the glomerular filtration rate. These values return to normal or less than normal during the eighth week of the puerperium. Endogenous creatinine clearance similarly returns to normal by 8 weeks. Renal plasma flow, which increased during pregnancy by 25% in the first trimester, falls in the third trimester and continues to fall to below normal levels for up to 24 months. Normal levels return slowly over 50–60 weeks. The glucosuria induced by pregnancy disappears. The blood urea nitrogen rises during the puerperium; at the end of the first week postpartum, values of 20 mg/dL are reached, compared with 15 mg/dL in the late third trimester.

Fluid Balance & Electrolytes

An average decrease in maternal weight of 10–13 lb occurs intrapartum and immediately postpartum due to the loss of amniotic fluid and blood as well as delivery of the infant and placenta. The average patient may lose an additional 4 kg (9 lb) during the puerperium and over the next 6 months as a result of excretion of the fluids and electrolytes accumulated during pregnancy. Contrary to widespread belief, breastfeeding has minimal effects on hastening weight loss postpartum. The magnitude of weight gain during pregnancy has impact on the postpartum weight retention. Women who gain more weight than the recommended range during the pregnancy tend to be heavier at 3 years postpartum than women who gained weight within recommended range during pregnancy, and this applies to both obese and nonobese patients.

There is an average net fluid loss of at least 2 L during the first week postpartum and an additional loss of approximately 1.5 L during the next 5 weeks. The water loss in the first week postpartum represents a loss of extracellular fluid. A negative balance must be expected of slightly more than 100 mEq of chloride per kilogram of body weight lost in the early puerperium. This negative balance probably is attributable to the discharge of maternal extracellular fluid. The puerperal losses of salt and water are generally larger in women with preeclampsia or eclampsia.

The changes occurring in serum electrolytes during the puerperium indicate a general increase in the numbers of cations and anions compared with antepartum values. Although total exchangeable sodium decreases during the puerperium, the relative decrease in body water exceeds the sodium loss. The diminished aldosterone antagonism due to falling plasma progesterone concentrations may partially explain the rapid rise in serum sodium. Cellular breakdown due to tissue involution may contribute to the rise in plasma potassium concentration noted postpartum. The mean increase in cations, chiefly sodium, amounts to 4.7 mEq/L, with an equal increase in anions. Consequently, the plasma osmolality rises by 7 mOsm/L at the end of the first week postpartum. In keeping with the chloride shift, there is a tendency for the serum chloride concentration to decrease slightly postpartum as serum bicarbonate concentration increases.

Metabolic & Chemical Changes

Total fatty acids and nonesterified fatty acids return to non-pregnant levels on about the second day of the puerperium. Both cholesterol and triglyceride concentrations decrease significantly within 24 hours after delivery, and this change is reflected in all lipoprotein fractions. Plasma triglycerides continue to fall and approach nonpregnant values 6–7 weeks postpartum. By comparison, the decrease in plasma cholesterol levels is slower; low-density lipoprotein cholesterol remains above nonpregnant levels for at least 7 weeks postpartum. Lactation does not influence lipid levels, but, in contrast to pregnancy, the postpartum hyperlipidemia is sensitive to dietary manipulation.

During the early puerperium, blood glucose concentrations (both fasting and postprandial) tend to fall below the values seen during pregnancy and delivery. This fall is most marked on the second and third postpartum days. Accordingly, the insulin requirements of diabetic patients are lower. Reliable indications of the insulin sensitivity and the blood glucose concentrations characteristic of the non-pregnant state can be demonstrated only after the first week postpartum. Thus a glucose tolerance test performed in the early puerperium may be interpreted erroneously if nonpuerperal standards are applied to the results.

The concentration of free plasma amino acids increases postpartum. Normal nonpregnant values are regained rapidly on the second or third postpartum day and are presumably a result of reduced utilization and an elevation in the renal threshold.

Cardiovascular Changes

A. Blood Coagulation

The production of both prostacyclin (prostaglandin I_2 [PGI_2]), an inhibitor of platelet aggregation, and thromboxane A_2, an inducer of platelet aggregation and a vasoconstrictor, is increased during pregnancy and the puerperium. Possibly, the balance between thromboxane A_2 and PGI_2 is shifted to the side of thromboxane A_2 dominance during the puerperium because platelet reactivity is increased at this time. Rapid and dramatic changes in the coagulation and fibrinolytic systems occur after delivery (Table 10–1). A decrease in the fibrinogen concentration begins during labor and reaches its lowest point during the first day postpartum. Thereafter, rising plasma fibrinogen levels reach prelabor values by the third or fifth day of the puerperium. This secondary peak in fibrinogen activity is maintained until the second postpartum week, after which the level of activity slowly returns to normal nonpregnant levels during the following 7–10 days. A similar pattern occurs with respect to factor VIII and plasminogen. Circulating levels of antithrombin III are decreased in the third trimester of pregnancy. Patients with a congenital deficiency of antithrombin III (an endogenous inhibitor of factor X) have recurrent venous thromboembolic disease, and a low level of this factor has been associated with a hypercoagulable state.

Table 10–1. Changes in blood coagulation and fibrinolysis during the puerperium.

	Time Postpartum				
	1 Hour	1 Day	3-5 Days	1st Week	2nd Week
Platelet count	↓	↑	↑↑	↑↑	↑
Platelet adhesiveness	↑	↑↑	↑↑↑	↑	0
Fibrinogen	↓	↓	↑	0	↓
Factor V		↑	↑↑	↑	0
Factor VIII	↓	↓	↑	↑	↓
Factors II, VII, X		↓	↓	↓↓	↓↓
Plasminogen	↓	↓↓	0	↓	↓
Plasminogen activator	↑↑↑	↑↑	0		
Fibrinolytic activity	↑	↑↑	↑↑	↑	
Fibrin split products	↑	↑↑	↑↑		

The arrows indicate the direction and relative magnitude of change compared with the late third trimester or antepartum values. Zero indicates a return to antepartum but not necessarily nonpregnant values.

(Data from Manning FA, et al. *Am J Obstet Gynecol* 1971;110:900; Bonnar J, et al. *Br Med J* 1970;2:200; Ygg J. *Am J Obstet Gynecol* 1969;104:2; and Shaper AG, et al. *J Obstet Gynaecol Br Commonw* 1968;75:433.)

The fibrinolytic activity of maternal plasma is greatly reduced during the last months of pregnancy but increases rapidly after delivery. In the first few hours postpartum, an increase in tissue plasminogen activator (t-PA) activity develops, together with a slight prolongation of the thrombin time, a decrease in plasminogen activator inhibitors, and a significant increase in fibrin split products. Protein C is an important coagulation inhibitor that requires the nonenzymatic cofactor protein S (which exists as a free protein and as a complex) for its activity. The level of protein S, both total and free, increases on the first day after delivery and gradually returns to normal levels after the first week postpartum.

The increased concentration of clotting factors normally seen during pregnancy can be viewed as important reserve to compensate for the rapid consumption of these factors during delivery and in promoting hemostasis after parturition. Nonetheless, extensive activation of clotting factors, together with immobility, sepsis, or trauma during delivery, may set the stage for later thromboembolic complications (see Chapter 27). The secondary increase in fibrinogen, factor VIII, or platelets (which remain well above nonpregnant values in the first week postpartum) also predisposes to thrombosis during the puerperium. The abrupt return of normal fibrinolytic activity after delivery may be a protective mechanism to combat this hazard. A small percentage of puerperal women who show a diminished ability to activate the fibrinolytic system appear to be at high risk for the development of postpartum thromboembolic complications.

B. Blood Volume Changes

The total blood volume normally decreases from the antepartum value of 5–6 L to the nonpregnant value of 4 L by the third week after delivery. One-third of this reduction occurs during delivery and soon afterward, and a similar amount is lost by the end of the first postpartum week. Additional variation occurs with lactation. The volume expansion with increased water retention in the extracellular space during pregnancy may be viewed as a protective mechanism that allows most women to tolerate considerable blood loss during parturition. Normal vaginal delivery of a single fetus entails an average blood loss of approximately 400 mL, whereas caesarean section leads to a blood loss of nearly 1 L. If total hysterectomy is performed in addition to caesarean section delivery, the mean blood loss increases to approximately 1500 mL. Delivery of twins and triplets entails blood losses similar to those of operative delivery, but a compensatory increase in maternal plasma volume and red blood cell mass may be exacerbated in mothers carrying multiple gestations.

Dramatic and rapid readjustments occur in the maternal vasculature after delivery so that the response to blood loss during the early puerperium is different from that occurring in the nonpregnant woman. Delivery leads to obliteration of the low-resistance uteroplacental circulation and results in a 10–15% reduction in the size of the maternal vascular bed. Loss of placental endocrine function also removes a stimulus to vasodilatation.

A declining blood volume with a rise in hematocrit is usually seen 3–7 days after vaginal delivery (Fig. 10–3). In contrast, serial studies of patients after caesarean section indicate a more rapid decline in blood volume and hematocrit and a tendency for the hematocrit to stabilize or even decline in the early puerperium. Hemoconcentration occurs if the loss of red cells is less than the reduction in vascular capacity. Hemodilution takes place in patients who lose 20% or more of their circulating blood volume at delivery. In patients with preeclampsia–eclampsia, resolution of peripheral vasoconstriction and mobilization of excess extracellular fluid may lead to significant expansion of vascular volume by the third postpartum day. Plasma atrial natriuretic peptide levels nearly double during the first days postpartum in response to atrial stretch caused by blood volume expansion and may have relevance for postpartum natriuresis and diuresis. Occasionally, a patient sustains minimal blood loss at delivery. In such a patient, marked hemoconcentration may occur in the puerperium, especially if there has been a preexisting polycythemia or a considerable increase in the red cell mass during pregnancy.

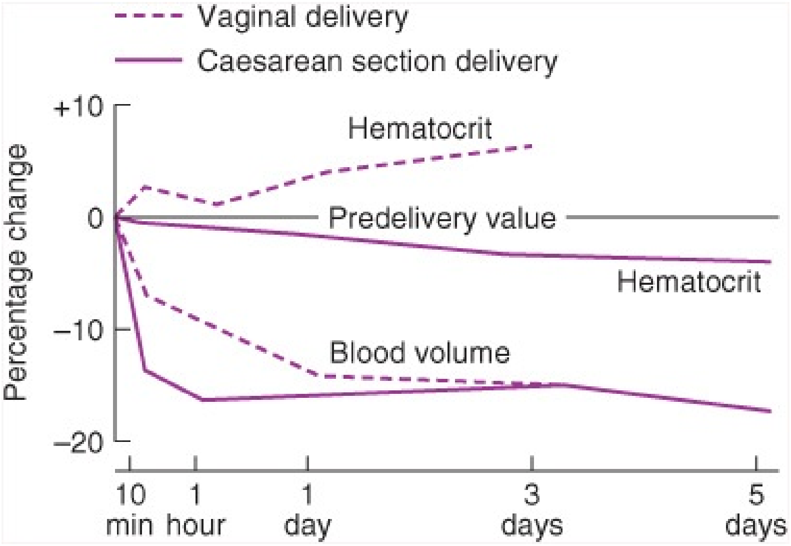

Figure 10–3. Postpartum changes in hematocrit and blood volume in patients delivered vaginally and by caesarean section. Values are expressed as the percentage change from the predelivery hematocrit or blood volume. (Data from Ueland K, et al. Maternal cardiovascular dynamics. 1. Cesarean section under subarachnoid block anesthesia. *Am J Obstet Gynecol* 1968;100:42; PMID 5634434; and Ueland K, Hansen J. Maternal cardiovascular dynamics. 3. Labor and delivery under local and caudal analgesia. *Am J Obstet Gynecol* 1969;103: 8; PMID: 5761783.)

C. Hematopoiesis

The red cell mass increases by about 25% during pregnancy, whereas the average red cell loss at delivery is approximately 14%. Thus the mean postpartum red cell mass level should be about 15% above nonpregnant values. The sudden loss of blood at delivery, however, leads to a rapid and short-lived reticulocytosis (with a peak on the fourth postpartum day) and moderately elevated erythropoietin levels during the first week postpartum.

The bone marrow in pregnancy and in the early puerperium is hyperactive and capable of delivering a large number of young cells to the peripheral blood. Prolactin may play a minor role in bone marrow stimulation.

A striking leukocytosis occurs during labor and extends into the early puerperium. In the immediate puerperium, the white blood cell count may be as high as 25,000/mL, with an increased percentage of granulocytes. The stimulus for this leukocytosis is not known, but it probably represents a release of sequestered cells in response to the stress of labor.

The serum iron level is decreased and the plasma iron turnover is increased between the third and fifth days of the puerperium. Normal values are regained by the second week postpartum. The shorter duration of ferrokinetic changes in puerperal women compared with the duration of changes in nonpregnant women who have had phlebotomy is due to the increased erythroid marrow activity and the circulatory changes described previously.

Most women who sustain an average blood loss at delivery and who received iron supplementation during pregnancy show a relative erythrocytosis during the second week postpartum. Because there is no evidence of increased red cell destruction during the puerperium, any red cells gained during pregnancy will disappear gradually according to their normal life span. A moderate excess of red blood cells after delivery, therefore, may lead to an increase in iron stores. Iron supplementation is not necessary for normal postpartum women if the hematocrit or hemoglobin concentration 5–7 days after delivery is equal to or greater than a normal predelivery value. In the late puerperium, there is a gradual decrease in the red cell mass to nonpregnant levels as the rate of erythropoiesis returns to normal.

D. Hemodynamic Changes

The hemodynamic adjustments in the puerperium depend largely on the conduct of labor and delivery (eg, maternal position, method of delivery, mode of anesthesia or analgesia, and blood loss). Cardiac output increases progressively during labor in patients who have received only local anesthesia. The increase in cardiac output peaks immediately after delivery, at which time it is approximately 80% above the prelabor value. During a uterine contraction there is a rise in central venous pressure, arterial pressure, and stroke volume—and, in the absence of pain and anxiety, a reflex decrease in the pulse rate. These changes are magnified in the supine position. Only minimal changes occur in the lateral recumbent position because of unimpaired venous return and absence of aortoiliac compression by the contracting uterus (Poseiro's effect). Epidural anesthesia can interfere with the hemodynamic change by attenuating the progressive rise in cardiac output during labor and reduces the absolute increase observed immediately after delivery, probably by limiting pain, anxiety, and oxygen consumption.

Although major hemodynamic readjustments occur during the period immediately after delivery, there is a return to nonpregnant conditions in the early puerperium. A trend for normal women to increase their blood pressure slightly in the first 5 days postpartum reflects an increased uterine vascular resistance and a temporary surplus in plasma volume. A small percentage will have diastolic blood pressures of 100 mm Hg. Cardiac output (measured by Doppler and cross-sectional echocardiography) declines 28% within 2 weeks postpartum from peak values observed at 38 weeks' gestation. This change is associated with a 20% reduction in stroke volume and a smaller decrease in myocardial contractility indices. Postpartum resolution of pregnancy-induced ventricular hypertrophy takes longer than the functional postpartum changes (Fig. 10–4). In fact, limited data support a slow return of cardiac hemodynamics to prepregnancy levels over a 1-year period. There are no hemodynamic differences between lactating and nonlactating mothers.

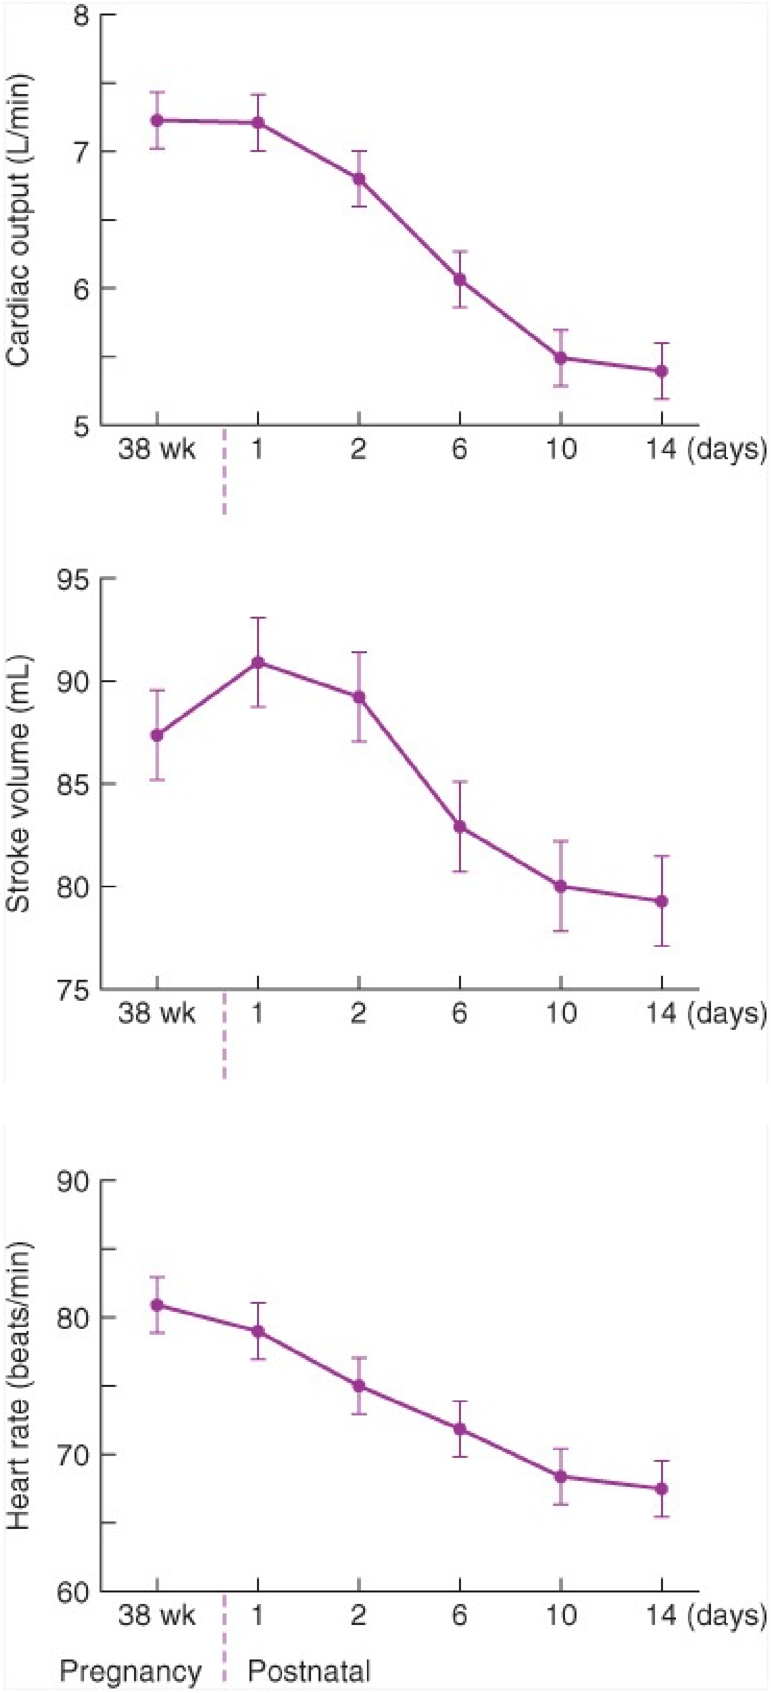

Figure 10–4. Changes in cardiac output, stroke volume, and heart rate during the puerperium after normal delivery. (Reproduced, with permission, from Hunter S, Robson SC. Adaptation of the maternal heart in pregnancy. *Br Heart J* 1992;68:540.)

Respiratory Changes

The pulmonary functions that change most rapidly are those influenced by alterations in abdominal contents and thoracic cage capacity. Lung volumes change in the puerperium and gradually return to the nonpregnant states. The total lung capacity increases after delivery due to decreased intraabdominal pressure on the diaphragm. An increase in resting ventilation and oxygen consumption and a less efficient response to exercise may persist during the early postpartum weeks. Comparisons of aerobic capacity before pregnancy and again postpartum indicate that lack of activity and weight gain contribute to a generalized detraining effect 4–8 weeks postpartum.

Changes in acid–base status generally parallel changes in respiratory function. The state of pregnancy is characterized by respiratory alkalosis and compensated metabolic acidosis, whereas labor represents a transitional period. A significant hypocapnia (<30 mm Hg), a rise in blood lactate, and a fall in pH are first noted at the end of the first stage of labor and extend into the puerperium. Within a few days, a rise toward the normal nonpregnant values of PCO_2 (35–40 mm Hg) occurs. Progesterone influences the rate of ventilation by means of a central effect, and rapidly decreasing levels of this hormone are largely responsible for the increased PCO_2 seen in the first week postpartum. An increase in base excess and plasma bicarbonate accompanies the relative postpartum hypercapnia. A gradual increase in pH and base excess occurs until normal levels are reached at approximately 3 weeks postpartum.

The resting arterial PO_2 and oxygen saturation during pregnancy are higher than those in nonpregnant women. During labor, the oxygen saturation may be depressed, especially in the supine position, probably as a result of a decrease in cardiac output and a relative increase in the amount of intrapulmonary shunting. However, a rise in the arterial oxygen saturation to 95% is noted during the first postpartum day. An apparent oxygen debt incurred during labor extends into the immediate puerperium and appears to depend on the length and severity of the second stage of labor. Many investigators have commented on the continued elevation of the basal metabolic rate for a period of 7–14 days after delivery. The increased resting oxygen consumption in the early puerperium has been attributed to mild anemia, lactation, and psychologic factors.

Pituitary–Ovarian Relationships

The plasma levels of placental hormones decline rapidly after delivery. Human placental lactogen has a half-life of 20 minutes and reaches undetectable levels in maternal plasma during the first day after delivery. Human chorionic gonadotropin (hCG) has a mean half-life of approximately 9 hours. The concentration of hCG in maternal plasma falls below 1000 mU/mL within 48–96 hours postpartum and falls below 100 mU/mL by the seventh day. Highly specific and sensitive radioimmunoassay for the subunit of hCG indicates virtual disappearance of hCG from maternal plasma between the 11th and 16th days after normal delivery. The regressive pattern of hCG activity is slower after first-trimester abortion than it is after term delivery and even more prolonged in patients who have undergone suction curettage for molar pregnancy.

Within 3 hours after removal of the placenta, the plasma concentration of 17β-estradiol falls to 10% of the antepartum value. The lowest levels are reached by the seventh postpartum day. Plasma estrogens do not reach follicular phase levels (>50 pg/mL) until 19–21 days postpartum in nonlactating women. The return to normal plasma levels of estrogens is delayed in lactating women. Lactating women who resume spontaneous menses achieve follicular-phase estradiol levels (>50 pg/mL) during the first 60–80 days postpartum. Lactating amenorrheic persons are markedly hypoestrogenic (plasma estradiol <10 pg/mL) during the first 180 days postpartum. The onset of breast engorgement on days 3–4 of the puerperium coincides with a significant fall in estrogen levels and supports the view that high estrogen levels suppress lactation.

The metabolic clearance rate of progesterone is high, and, as with estradiol, the half-life is calculated in minutes. By the third day of the puerperium, the plasma progesterone concentrations are below luteal phase levels (<1 ng/mL).

Prolactin levels in maternal blood rise throughout pregnancy to reach concentrations of 200 ng/mL or more. After delivery, prolactin declines in erratic fashion over a period of 2 weeks to the nongravid range in nonlactating women (Fig. 10–5). In women who are breastfeeding, basal concentrations of prolactin remain above the nongravid range and increase dramatically in response to suckling. As lactation progresses, the amount of prolactin released with each suckling episode declines. If breastfeeding occurs only 1–3 times each day, serum prolactin levels return to normal basal values within 6 months postpartum; if suckling takes place more than 6 times each day, high basal concentrations of prolactin will persist for more than 1 year. The diurnal rhythm of peripheral prolactin concentrations (a daytime nadir followed by a nighttime peak) is abolished during late pregnancy but is re-established within 1 week postpartum in non-nursing women.

Figure 10–5. Serum concentrations of prolactin, follicle-stimulating hormone (FSH), luteinizing hormone (LH), estradiol, and progesterone in a lactating and nonlactating woman during the puerperium. The hatched bars for the prolactin data represent the normal nongravid range. To convert the FSH and LH to milli-international units per milliliter, divide the FSH values by 2 and multiply the LH values by 4.5. (Reproduced, with permission, from Reyes FI, Winter JS, Faiman C. Pituitary-ovarian interrelationships during the puerperium. *Am J Obstet Gynecol* 1972;114:589.)

Serum follicle-stimulating hormone (FSH) and luteinizing hormone (LH) concentrations are very low in all women during the first 10–12 days postpartum, whether or not they lactate. The levels increase over the subsequent days and reach follicular-phase concentrations during the third week postpartum (Fig. 10–5). At this time, marked LH pulse amplification occurs during sleep but disappears as normal ovulatory cycles are established. In this respect, the transition from postpartum amenorrhea to cyclic ovulation is reminiscent of puberty, when gonadotropin secretion increases during sleep. There is a preferential release of FSH over LH postpartum during spontaneous recovery or after stimulation by exogenous gonadotropin-releasing hormone (GnRH). In the early puerperium, the pituitary is relatively refractory to GnRH, but 4–8 weeks postpartum, the response to GnRH is exaggerated. The low levels of FSH and LH postpartum are most likely related to insufficient endogenous GnRH secretion during pregnancy and the early puerperium, resulting in depletion of pituitary gonadotropin stores. The high estrogen and progesterone milieu of late pregnancy is associated with increased endogenous opioid activity, which may be responsible for suppression of GnRH activity in the puerperium. Resumption of FSH and LH secretion can be accelerated by administering a long-acting GnRH agonist during the first 10 days postpartum.

Because ovarian activity normally resumes upon weaning, either the suckling stimulus itself or the raised level of prolactin is responsible for suppression of pulsatile gonadotropin secretion. Hyperprolactinemia may not entirely account for the inhibition of gonadotropin secretion during lactation, as bromocriptine treatment abolishes the hyperprolactinemia of suckling but not the inhibition of gonadotropin secretion. Sensory inputs associated with suckling (if sufficiently intense), as well as oxytocin and endogenous opioids that are released during suckling, may affect the hypothalamic control of gonadotropin secretion, possibly by inhibiting the pulsatile secretion of GnRH. It appears that by 8 weeks after delivery, although ovarian activity still remains suppressed in fully breastfeeding women, pulsatile secretion of LH has resumed at a low and variable frequency in most women. However, the presence or absence of GnRH or LH pulses at 8 weeks does not predict the time of resumption of ovarian activity.

The time of appearance of the first ovulation is variable, and it is delayed by breastfeeding. Approximately 10–15% of non-nursing mothers ovulate by the time of the 6-week postpartum examination, and approximately 30% ovulate within 90 days postpartum. An abnormally short luteal phase is noted in 35% of first ovulatory cycles. The earliest reported time of ovulation as determined by endometrial biopsy is 33 days postpartum. Patients who have had a first-trimester abortion or ectopic pregnancy generally ovulate sooner after termination of pregnancy (as early as 14 days) than do women who deliver at term. Moreover, the majority of these women do ovulate before the first episode of postabortal bleeding—in contrast to women who have had a term pregnancy.

Endometrial biopsies in lactating women do not show a secretory pattern before the seventh postpartum week. Provided that nursing is in progress and that menstruation has not returned, ovulation before the tenth week postpartum is rare. In well-nourished women who breastfed for an extended period of time, fewer than 20% had ovulated by 6 months postpartum. Much of the variability in the resumption of menstruation and ovulation observed in lactating women may be due to individual differences in the strength of the suckling stimulus and to partial weaning (formula supplementation). This emphasizes the fact that suckling is not a reliable form of birth control. Because the period of lactational infertility is relatively short in Western societies, some form of contraception must be used if pregnancy is to be prevented. Among women who have unprotected intercourse only during lactational amenorrhea but adopt other contraceptive measures when they resume menstruation, only 2% will become pregnant during the first 6 months of amenorrhea. In underdeveloped countries, lactational amenorrhea and infertility may persist for 1–2 years owing to frequent suckling and poor maternal nutrition. When maternal dietary intake is improved, menstruation resumes at least 6 months earlier.

Other Endocrine Changes

Progressive enlargement of the pituitary gland occurs during pregnancy, with a 30–100% increase in weight achieved at term. Magnetic resonance imaging shows a linear gain in pituitary gland height of approximately 0.08 mm/wk during pregnancy. An additional increase in size occurs during the first week postpartum. Beyond the first week postpartum, however, the pituitary gland returns rapidly to its normal size in both lactating and nonlactating women.

The physiologic hypertrophy of the pituitary gland is associated with an increase in the number of pituitary lactotroph cells at the expense of the somatotropic cell types. Thus growth hormone secretion is depressed during the second half of pregnancy and the early puerperium. Because levels of circulating insulin-like growth factor (IGF)-1 increase throughout pregnancy, a placental growth hormone has been postulated and recently identified. Maternal levels of IGF-1 correlate highly with this distinct placental growth hormone variant, but not with placental lactogen during pregnancy and in the immediate puerperium.

Late pregnancy and the early puerperium are also characterized by pituitary somatotroph hyporesponsiveness to growth hormone-releasing hormone and to insulin stimulation. Whatever the inhibitory mechanism may be (possibly increased somatostatin secretion), it persists during the early postpartum period.

The rapid disappearance of placental lactogen and the low levels of growth hormone after delivery lead to a relative deficiency of anti-insulin factors in the early puerperium. It is not surprising, therefore, that low fasting plasma glucose levels are noted at this time and that the insulin requirements of diabetic patients usually drop after delivery. Glucose tolerance tests performed in women with gestational diabetes demonstrate that only 30% have abnormal test results 3–5 days after delivery, and 20% have abnormal glucose tolerance at 6 weeks postpartum. Because the early puerperium represents a transitional period in carbohydrate metabolism, the results of glucose tolerance tests may be difficult to interpret.

Evaluation of thyroid function is also difficult in the period immediately after birth because of rapid fluctuations in many indices. Characteristically, the plasma thyroxine level and other indices of thyroid function are highest at delivery and in the first 12 hours thereafter. A decrease to antepartum values is seen on the third or fourth day after delivery. Reduced available estrogens postpartum lead to a subsequent decrease in circulating thyroxine-binding globulin and a gradual diminution in bound thyroid hormones in serum. Serum concentrations of thyroid-stimulating hormone (TSH) are not significantly different postpartum from those of the pregnant or nonpregnant state. Administration of thyroid-releasing hormone in the puerperium results in a normal increase in both TSH and prolactin, and the response is similar in lactating and nonlactating patients. Because pregnancy is associated with some immunosuppressive effects, hyperthyroidism or hypothyroidism may recur postpartum in autoimmune thyroid disease. Failure of lactation and prolonged disability may be the result of hypothyroidism postpartum. In Sheehan's syndrome of pituitary infarction, postpartum cachexia and myxedema are seen secondary to anterior hypophyseal insufficiency.

Maternal concentrations of total and unbound (free) plasma cortisol, adrenocorticotropic hormone (ACTH), immunoreactive corticotropin-releasing hormone (CRH), and β-endorphin rise progressively during pregnancy and increase further during labor. Plasma 17-hydroxycorticosteroid levels increase from a concentration of 4–14 μg/dL at 40 weeks' gestation. A 2- to 3-fold increase is seen during labor. ACTH, CRH, and β-endorphin decrease rapidly after delivery and return to nonpregnant levels within 24 hours. Prelabor cortisol values are regained on the first day postpartum, but a return to normal, nonpregnant cortisol and 17-hydroxycorticosteroid levels is not reached until the end of the first week postpartum.

Much of the rise in total cortisol (but not in the unbound fraction) can be explained by the parallel increase in corticosteroid-binding globulin (CBG) during pregnancy. Displacement of cortisol from CBG by high concentrations of progesterone cannot account for the increased free cortisol levels because saliva progesterone levels (a measure of the unbound hormone) do not fluctuate, whereas a normal diurnal rhythm of saliva cortisol is maintained during pregnancy and postpartum. An extrapituitary source of ACTH, a progesterone-modulated decrease in the hypothalamic–pituitary sensitivity to glucocorticoid feedback inhibition, and an extrahypothalamic (eg, placental) source of CRH have been suggested as explanations for elevated plasma ACTH levels and the inability of dexamethasone to completely suppress ACTH in pregnant women.

In the third trimester, the placenta produces large amounts of CRH, which is released into the maternal circulation and may contribute to the hypercortisolemia of pregnancy. Present evidence suggests that it stimulates the maternal pituitary to produce ACTH while desensitizing the pituitary to further acute stimulation with CRH. Maternal hypothalamic control of ACTH production is retained (perhaps mediated by vasopressin secretion); this permits a normal response to stress and a persistent diurnal rhythm.

Overall, it is most likely that under the influence of rising estrogens and progesterone, there is a resetting of the hypothalamic–pituitary sensitivity to cortisol feedback during pregnancy, which persists for several days postpartum. Several studies have suggested a relationship between peripartum alterations in maternal levels of cortisol and β-endorphin and the development of postnatal mood disturbances.

The excretion of urinary 17-ketosteroids is elevated in late pregnancy as a result of an increase in androgenic precursors from the fetoplacental unit and the ovary. An additional increase of 50% in excretion occurs during labor. Excretion of 17-ketosteroids returns to antepartum levels on the first day after delivery and to the nonpregnant range by the end of the first week. The mean levels of testosterone during the third trimester of pregnancy range from 3 to 7 times the mean values for nonpregnant women. The elevated levels of testosterone decrease after parturition parallel with the gradual fall in sex hormone-binding globulin (SHBG). Androstenedione, which is poorly bound to SHBG, falls rapidly to nonpregnant values by the third day postpartum. Conversely, the postpartum plasma concentration of dehydroepiandrosterone sulfate remains lower than that of nonpregnant women, because its metabolic clearance rate continues to be elevated in the early puerperium. Persistently elevated levels of 17-ketosteroids or androgens during the puerperium are an indication for investigation of ovarian abnormalities. Plasma renin and angiotensin II levels fall during the first 2 hours postpartum to levels within the normal nonpregnant range. This suggests that an extra-renal source of renin has been lost with the expulsion of the fetus and placenta.

There is little direct information about the puerperal changes in numerous other hormones, including aldosterone, parathyroid hormone, and calcitonin. More research should be done on these important endocrine relationships in the puerperium.

CONDUCT AND MANAGEMENT OF THE PUERPERIUM

Most patients will benefit from 2–4 days of hospitalization after delivery. Only 3% of women with a vaginal delivery and 9% of women having a caesarean section have a childbirth-related complication requiring prolonged postpartum hospitalization or readmission. Although a significant amount of symptomatic morbidity may exist postpartum (painful perineum, breastfeeding difficulties, urinary infections, urinary and fecal incontinence, and headache), most women can return home safely 2 days after normal vaginal delivery if proper education and instructions are given, if confidence exists with infant care and feeding, and if adequate support exists at home. Earlier discharge is acceptable in select mothers and infants who have had uncomplicated labors and deliveries. Discharge criteria should be met and follow-up care provided. Optimal care includes home nursing visits through the fourth postpartum day.

Disadvantages of early discharge are the increased risks of rehospitalization of some neonates for hyperbilirubinemia and neonatal infection (eg, from group B streptococci).

Activities & Rest

The policy of early ambulation after delivery benefits the patient. Early ambulation provides a sense of well-being, hastens involution of the uterus, improves uterine drainage, and lessens the incidence of postpartum thromboembolic event. If the delivery has been uncomplicated, the patient may be out of bed as soon as tolerated. Early ambulation does not mean immediate return to normal activity or work. Commonly mothers complain of lethargy and fatigue. Therefore, rest is essential after delivery, and the demands on the mother should be limited to allow for adequate relaxation and adjustment to her new responsibilities. It is helpful to set aside a few hours each day for rest periods. Many mothers do not sleep well for several nights after delivery, and it is surprising how much of the day is occupied with the care of the newborn.

In uncomplicated deliveries, more vigorous activity, climbing stairs, lifting of heavy objects, riding in or driving a car, and performing muscle toning exercises may be resumed without delay. Specific recommendations should be individualized. Current American College of Obstetricians and Gynecologists committee opinions support gradual resumption of exercise routines as soon as medically and physically safe, as detraining may have occurred during pregnancy. No known maternal complications are associated with resumption of exercise, even in women who choose to resume an exercise routine within days. Exercise postpartum does not compromise lactation or neonatal weight gain. It may be beneficial in decreasing anxiety levels and decreasing the incidence of postpartum depression.

Diet

A regular diet is permissible as soon as the patient wishes in the absence of complication. Protein-rich foods, fruits, vegetables, milk products, and a high fluid intake are recommended, especially for nursing mothers. It is estimated that women will need approximately 500 kcal per day more than the recommended level for nonpregnant and nonlactating women. It may be advisable to continue the daily vitamin–mineral supplement during the early puerperium. Lactating women are advised to maintain calcium intake of 1000 mg per day and should be encouraged to drink plenty of fluids to maintain adequate hydration. After caesarean section, there is no evidence supporting compromised safety or comfort from the introduction of solid foods early and allowing the patient to decide when to eat postoperatively. In fact, early feeding as tolerated by the patient has been shown to be safe, to enhance patient satisfaction, to minimize hospital stay, and to facilitate a more rapid return to normal diet and bowel function.

Care of the Bladder

Most women empty the bladder during labor or have been catheterized at delivery. Even so, serious bladder distention may develop within 12 hours. A prolonged second stage of labor or operative delivery may traumatize the base of the bladder and interfere with normal voiding and is significantly associated with protracted urinary retention beyond the third postpartum day. In some cases, overdistention of the bladder may be related to pain or regional anesthesia. Mechanical bladder outlet obstruction may develop secondary to edema or local hematoma, functional obstruction may be secondary to pain, and detrusor underactivity may be due to bladder overdistention during labor. The marked polyuria noted for the first few days postpartum causes the bladder to fill in a relatively short time. Hence obstetric patients require catheterization more frequently than most surgical patients. The patient should be catheterized every 6 hours after delivery if she is unable to void or empty her bladder completely. Intermittent catheterization is preferable to an indwelling catheter because the incidence of urinary tract infection is lower. However, if the bladder fills to more than 1000 mL, 1–2 days of decompression by a retention catheter usually is required to establish voiding without significant residual urine. Postpartum voiding dysfunction is common but usually self-limited and spontaneously resolves within 3 days.

The incidence of true asymptomatic bacteriuria is approximately 5% in the early puerperium. Postpartum patients with a history of previous urinary tract infection, conduction anesthesia, and catheterization during delivery and operative delivery should have a bacterial culture of a midstream urine specimen. In cases of confirmed bacteriuria, antibiotic treatment should be given; otherwise, bacteriuria will persist in nearly 30% of patients. Three days of therapy is sufficient and avoids prolonged antibiotic exposure to the lactating mother.

Bowel Function

Pregnancy itself is associated with increased gastric emptying, but gastrointestinal motility is commonly delayed after labor and delivery. The mild ileus that follows delivery, together with perineal discomfort and postpartum fluid loss by other routes, predisposes to constipation during the puerperium. Milk of magnesia, 15–20 mL orally on the evening of the second postpartum day, usually stimulates a bowel movement by the next morning. If not, a rectal suppository, such as bisacodyl or a small tap water or oil retention enema, may be given. Less bowel stimulation will be needed if the diet contains sufficient roughage. Stool softeners, such as dioctyl sodium sulfosuccinate, may ease the discomfort of early bowel movements. Hemorrhoidal discomfort is a common complaint postpartum and usually responds to conservative treatment with compresses, suppositories containing corticosteroids, local anesthetic sprays or emollients, and sitz baths. Surgical treatment of hemorrhoids postpartum is rarely necessary unless thrombosis is extensive.

Operative vaginal delivery and lacerations involving the anal sphincter increase a woman’s risk for anal incontinence. However, 5% of pregnant women overall have some degree of anal incontinence at 3 months postpartum. Complaints of fecal incontinence are often delayed because of embarrassment. Most cases are transient; however, cases persisting beyond 6 months require investigation and probable treatment.

Bathing

As soon as the patient is ambulatory, she may take a shower. Sitz or tub baths probably are safe if performed in a clean environment. Most patients prefer showers to tub baths because of the profuse flow of lochia immediately postpartum; however, sitz baths may be beneficial for perineal pain relief. Vaginal douching is contraindicated in the early puerperium. Tampons may be used whenever the patient is comfortable.

Care of the Perineum

Postpartum perineal care, even in the patient with an uncomplicated and satisfactorily repaired episiotomy or laceration, usually requires no more than routine cleansing with a bath or shower and analgesia.

Immediately after delivery, cold compresses (usually ice) applied to the perineum decrease traumatic edema and discomfort. The perineal area should be gently cleansed with plain soap at least once or twice per day and after voiding or defecation. If the perineum is kept clean, healing should occur rapidly. Cold or iced sitz baths, rather than hot sitz baths, may provide additional perineal pain relief for some patients. The patient should be put in a lukewarm tub to which ice cubes are added for 20–30 minutes. The cold promotes pain relief by decreasing the excitability of nerve endings and slowing nerve conduction, and by local vasoconstriction, which reduces edema, inhibits hematoma formation, and decreases muscle irritability and spasm. Episiotomy pain is easily controlled with nonsteroidal anti-inflammatory agents, which appear to be superior to acetaminophen or propoxyphene.

An episiotomy or repaired lacerations should be inspected daily. A patient with mediolateral episiotomy, a third- or fourth-degree laceration or extension, or extensive bruising or edema may experience severe perineal pain. In the case of persistent or unusual pain, a vaginal and/or rectal examination should be performed to identify a hematoma, perineal infection, or potentially fatal conditions, such as angioedema, necrotizing fasciitis, or perineal cellulitis. Episiotomy wounds rarely become infected, which is remarkable considering the difficulty of preventing contamination of the perineal area. In the event of infection, local heat and irrigation should cause the infection to subside. Appropriate antibiotics may be indicated if an immediate response to these measures is not observed. In rare instances, the wound should be opened widely and sutures removed for adequate drainage.

Uterotonic Agents

Prophylactic administration of oxytocin after the second stage of labor and/or after placental delivery is beneficial in preventing postpartum hemorrhage and the need for therapeutic uterotonics. The routine use of ergot preparations or prostaglandins may be as effective as oxytocin but has significantly more side effects. There appear to be no data supporting the prophylactic use of uterotonic agents beyond the immediate puerperium. These agents should be limited to patients with specific indications, such as postpartum hemorrhage or uterine atony.

Emotional Reactions

Several basic emotional responses occur in almost every woman who has given birth to a normal baby. A woman's first emotion is usually one of extreme relief, followed by a sense of happiness and gratitude that the new baby has arrived safely. A regular pattern of behavior occurs in the human mother immediately after birth of the infant. Touching, holding, and grooming of the infant under normal conditions rapidly strengthen maternal ties of affection. However, not all mothers react in this way, and some may even feel detached from the new baby. These reactions range from the common, physiologic, relatively mild, and transient "maternity blues," which affect some 50–70% of postpartum women, to more severe reactions including depression and rare puerperal psychosis.

Postpartum blues or maternity blues occur in up to 70% of postpartum women and appear to be a normal psychologic adjustment or response. It is generally characterized by tearfulness, anxiety, irritation, and restlessness. This symptomatology can be quite diverse and may include depression, feelings of inadequacy, elation, mood swings, confusion, difficulty concentrating, headache, forgetfulness, insomnia, depersonalization, and negative feelings toward the baby. These transient symptoms usually occur within the first few days after delivery and cease by postpartum day 10, although bouts of weeping may occur for weeks after delivery. The blues are self-limiting, but the distress can be diminished by physical comfort and reassurance. Evidence suggests that rooming-in during the hospital stay reduces maternal anxiety and results in more successful breastfeeding.

Prematurity or illness of the newborn delays early intimate maternal–infant contact and may have an adverse effect on the rapid and complete development of normal mothering responses. Stressful factors during the puerperium (eg, marital infidelity or loss of friends as a result of the necessary confinement and preoccupation with the new baby) may leave the mother feeling unsupported and may interfere with the formation of a maternal bond with the infant.

When a baby dies or is born with a congenital defect, the obstetrician should inform the mother and father about the problem together, if possible. The baby's normal, healthy features and potential for improvement should be emphasized, and positive statements should be made about the present availability of corrective treatment and the promises of ongoing research. In the event of a perinatal loss, parents should be assisted in the grieving process. They should be encouraged to see and touch the baby at birth or later, even if maceration or anomalies are present. Mementos such as footprints, locks of hair, or a photograph can be a solace to the parents after the infant has been buried. During the puerperium, the obstetrician has an important opportunity to help the mother whose infant has died work through her period of mourning or discouragement and to assess abnormal reactions of grief that suggest a need for psychiatric assistance. Pathologic grief is characterized by the inability to work through the sense of loss within 3–4 months, with subsequent feelings of low self-esteem.

Sexual Activity During the Postpartum Period

Establishment of normal prepregnancy sexual response patterns is delayed after delivery. However, it is safe to resume sexual activity when the woman's perineum is comfortable and bleeding is diminished. Although the median time for resumption of intercourse after delivery is 6 weeks and the normal sexual response returns at 12 weeks, sexual desire and activity vary tremendously among women. Sexual function significantly declines during the third trimester of pregnancy. This dysfunction peaks approximately 3 months postpartum and tends to improve within 6 months after delivery. During pregnancy women report lack of information and concerns about possible adverse outcomes for the pregnancy as reasons for their decreased sexual activity. Physical manifestations such as weight gain, breast tenderness, anxiety, and fatigue likely also contribute to avoidance of intercourse as the pregnancy progresses.

After delivery most women report low or absent sexual desire during the early puerperium and attribute this to fatigue, weakness, dyspareunia, vaginal dryness, urinary or fecal incontinence, irritative vaginal discharge, or fear of injury to the healing perineum. Early pelvic-floor muscle exercise appears to have positive effects on restoration of female sexual function. Significant predictors of dyspareunia at 6 months vary by study but have included breastfeeding, vacuum delivery, greater than first-degree lacerations, fecal incontinence, and history of previous dyspareunia. Approximately 90% of women restart sexual activity within 6 months after delivery, depending on the site and state of perineal or vaginal healing, return of libido, and vaginal atrophy resulting from breastfeeding. There is a gradual and steady recovery of sexual function postpartum, and by 12 months 80–85% of patients consider their sex lives unchanged and only 10–15% consider it worsened. The mode of delivery alone does not appear to have significant effect on sexual function 12–18 months after childbirth, as no difference in satisfaction or complications was found between women who delivered vaginally without episiotomy, heavy perineal laceration, or secondary operative interventions and women who underwent elective caesarean section.

Sexual counseling is indicated before the mother is discharged from the hospital. A discussion of the normal fluctuations of sexual interest during the puerperium is appropriate, as are suggestions for noncoital sexual options that enhance the expression of mutual pleasure and affection. The importance of sleep and rest and of the partner’s emotional and physical support is emphasized. If milk ejection during sexual relations is a concern, nursing the baby before sexual intimacy can help. Sexual relations can generally be resumed by the third week postpartum, if desired. A water-soluble lubricant or vaginal estrogen cream is especially helpful in lactating amenorrheic mothers in whom vaginal atrophy occurs, usually because of low circulating estrogen levels. Patients should be informed that at least 50% of women engaging in sexual intercourse by 6 weeks will experience dyspareunia, which may persist up to 1 year. Dyspareunia also occurs in women with caesarean sections and in women using oral contraceptives who are not breastfeeding.

Postpartum Immunization

A. Prevention of Rh Isoimmunization

The postpartum injection of Rh_o (D) immunoglobulin[*] has been shown to prevent sensitization in the Rh-negative woman who has had fetal-to-maternal transfusion of Rh-positive fetal red cells. The risk of maternal sensitization rises with the volume of fetal transplacental hemorrhage. The usual amount of fetal blood that enters the maternal circulation is <0.5 mL. The usual dose of 300 μg of Rh_o (D) immunoglobulin is in excess of the dose generally required. Three hundred grams will neutralize approximately 30 mL of whole fetal blood (or 15 mL of Rh+ fetal red blood cells). If neonatal anemia or other clinical symptoms suggest the occurrence of a large transplacental hemorrhage, the amount of fetal blood in the maternal circulation can be estimated by the Kleihauer-Betke smear and the amounts of Rh_o (D) immunoglobulin to be administered adjusted accordingly.

Rh_o (D) immunoglobulin is administered after abortion without qualifications or after delivery to women who meet all of the following criteria: (1) The mother must be Rh_o (D)-negative without Rh antibodies, (2) the baby must be Rh (D)+ or Rh (D)-/Du-positive, and (3) the cord blood must be Coombs-negative. If these criteria are met, a 1:1000 dilution of Rh_o (D) immunoglobulin is cross-matched to the mother's red cells to ensure compatibility, and 1 mL (300 μg) is given intramuscularly to the mother within 72 hours after delivery. If the 72-hour interval has been exceeded, it is advisable to give the immunoglobulin rather than withhold it because it may still protect against sensitization 14–28 days after delivery, and the time required to mount a response varies among cases. The 72-hour time limit for administration of Rh immunoglobulin was a study limitation in a study in which patients in prison were allowed to be visited only every 3 days; thus the use of Rh immunoglobulin past the 3-day interval was never studied. Rh_o (D) immunoglobulin should also be given after delivery or abortion when serologic tests of maternal sensitization to the Rh factor are questionable.

The average risk of maternal sensitization after abortion is approximately half the risk incurred by full-term pregnancy and delivery; the latter has been estimated at 11%. Women with pregnancy losses up to 12 weeks may receive a smaller dose of Rh immunoglobulin, as the 50-μg dose is sufficient to protect against 2.5 mL of Rh-positive fetal red blood cells. Even though mothers have received Rh_o (D) immunoglobulin, they should be screened with each subsequent pregnancy because postpartum prophylaxis failures still exist. Failures are related to inadequate Rh_o (D) immunoglobulin administration postpartum, an undetected very low titer in the previous pregnancy, and inexcusable oversights. Routine use of postpartum screening protocols to identify excess fetomaternal hemorrhage and strict adherence to recommended protocols for the management of unsensitized Rh-negative women will prevent most of these postpartum sensitizations.

B. Rubella Vaccination

A significant number of women of childbearing age estimated at 10–20% have never been immunized or exposed to rubella infection. The appropriate test for assessing rubella immunity is the immunoglobulin G serology. Women who are susceptible to rubella can be vaccinated safely and effectively with a live attenuated rubella virus vaccine (RA 27/3 strain) during the immediate puerperium. It is more immunogenic than earlier forms of the vaccine and is available in monovalent, bivalent (measles-rubella [MR]), and trivalent (measles-mumps-rubella [MMR]) forms. Seroconversion occurs in approximately 95% of women vaccinated postpartum. There is no contraindication to giving MMR vaccination while breastfeeding, and it is not associated with viral transmission to newborns. Women who receive rubella vaccinations are not contagious and cannot transmit infection to other susceptible children or adults. In addition, the serologic response against rubella is satisfactory when given concomitantly with other immunoglobulins such as Rh-immunoglobulin. Vaccinated patients should be informed that transient side effects can result from rubella vaccination. Mild symptoms such as low-grade fever and malaise may occur in fewer than 25% of patients and arthralgias and rash in fewer than 10%; rarely, overt arthritis may develop. Among adult women there is a 10–15% incidence of acute polyarthritis after immunization. In 2001, the US Centers for Disease Control and Prevention (CDC) changed the safe pregnancy interval after receiving the rubella vaccine from 3 months to 1 month. The receipt of vaccination during the pregnancy is not an indication for termination. The maximum theoretical risk of congenital rubella resulting from vaccination during early pregnancy is 1–2%.

C. Postpartum Tdap (Tetanus, Diphtheria, Pertussis) Vaccination

With the incidence of pertussis growing among adults and adolescents in the United States, there is a concomitant increased risk of transmission to susceptible populations, including infants. Infants do not have full immunity against pertussis until they have received at least 3 doses of pertussis-containing vaccine, making infants younger than 6 months the most susceptible. Pertussis is preventable through vaccination; however, immunity from childhood pertussis vaccines wanes after 5–10 years, making adolescent and adult populations again susceptible to pertussis. Infants under 12 months of age comprised 19% of cases and 92% of pertussis deaths in the United States from 2000–2004. Of those with pertussis, 63% required hospitalization, and 13% were diagnosed with pneumonia. The use of Tdap vaccine in the postpartum woman can provide protection to infants.

The Advisory Committee on Immunization Practices (ACIP) recommends routine postpartum Tdap for those pregnant women who previously have not received a dose of Tdap (including women who are breastfeeding) before discharge from the hospital or birthing center. If Tdap cannot be administered before discharge, it should be given as soon as it is feasible. The dose of Tdap replaces the next decennial dose of Td. Providers who choose to administer Tdap to pregnant women should discuss the lack of safety data with the pregnant patient.

D. Postpartum Influenza Vaccination

The ACIP recommends universal flu vaccination in the United States. Pregnant women are characterized by the CDC as a high-risk population because having the flu would place these women and their fetuses at increased risk of complications. The “flu shot” should thus be offered to these women as soon as flu season begins in September. This intramuscular form of the vaccine contains killed inactivated virus and is safe in pregnancy. The nasal-spray flu vaccine is not a safe option for pregnant women because it contains live albeit weakened flu viruses. If a pregnant woman does not receive the flu shot during pregnancy, then she should be given the vaccine in the immediate postpartum period. The ACIP strongly recommends that household contacts and caregivers of children younger than 6 months receive the flu shot, because children this young are at high risk for complications from the flu and are too young to be vaccinated themselves. Women in this postpartum period are eligible for either the flu shot or nasal-spray vaccine.

Contraception & Sterilization

The immediate puerperium has long been recognized as a convenient time for the discussion of family planning, although these discussions ideally should begin during prenatal care. Pregnancy prevention and birth control decisions should be made before discharge with a qualified nurse, physician, or physician’s assistant or with the aid of educational tools. Anovulatory infertility lasts approximately 5 weeks in nonlactating women and >8 weeks in fully lactating women. The lactational pregnancy rate is approximately 1–2% at 1 year postpartum.

Tubal sterilization is the most common method of contraception used in the United States. It is the procedure of choice for women desiring permanent sterilization. It can be performed easily at the time of caesarean section or within 48 hours postpartum after vaginal delivery in uncomplicated patients without prolonging hospitalization or significantly increasing morbidity. Sterilization may not be advisable in women younger than 30 years, those of low parity, or when the neonatal outcome is in doubt and survival of the infant is not assured. Postponing tubal sterilization 6–8 weeks postpartum is desirable for many couples, as it allows time to ensure that the infant is healthy, to fully understand the implications of permanent sterilization, and, according to the US Collaborative Review on Sterilization, to decrease feelings of guilt and regret. It also allows for different surgical approaches to be discussed, including the hysteroscopic Essure device (Conceptus, Mountain View, CA), which has the benefit of avoiding abdominal incisions.

Appropriate counseling regarding risks of failure, permanence of the procedure, the medical risks, and the potential psychosocial reactions to the procedure should be discussed with the patient. Patient ambivalence at the last minute is not unusual, in which case it is advisable to defer the procedure until after the puerperium. The 10-year failure rate of postpartum sterilization ranges from 1–3% and varies with type of procedure performed. The risks of postpartum or interval tubal ligation are infrequent, and deaths from the procedure occur in 2–12 per 100,000 cases. Long-term complications, such as the posttubal syndrome (irregular menses and increased menstrual pain) have been reported in some 10–15% of women; however, well-controlled prospective studies have failed to confirm that these symptoms occur more frequently with sterilization than in controls.

Use of lactational amenorrhea for family planning in exclusively breastfeeding mothers provides 98% contraceptive protection for up to 6 months according to some studies; however, concurrent use of progestin-only pill is advisable to increase the contraceptive efficacy. When menses return, natural family planning may begin. This method, which has pregnancy rates comparable to those of barrier methods, uses detection of the periovulatory period by evaluating cervical mucus changes and/or basal body temperature changes. Patients should be aware that the natural method is not always reliable and can potentially increase the chance of pregnancy, especially in those women with irregular cycles.

Use of spermicides, a condom, or both may be prescribed until the postpartum examination; these methods carry a failure rate of 1.6–21 per 100 woman-years. Fitting of a diaphragm is not practical until involution of the reproductive organs has taken place and may be more difficult in lactating women with vaginal dryness. It should always be used in conjunction with a spermicidal lubricant containing nonoxynol-9. The failure rate for the diaphragm varies from 2.4–19.6 per 100 woman-years, with the lowest failure rates (comparable to the intrauterine device [IUD]) occurring in women who are older, motivated, experienced, or familiar with the technique.

Combined hormonal contraception, including the pill, patch, or ring, functions by suppressing ovulation, increasing cervical mucus viscosity, and lowering the receptivity of the endometrium to implantation. Oral contraception should be deferred until 6 weeks postpartum because of concerns about the postpartum hypercoagulable state. Of note, the vaginal ring produces the lowest estrogen levels of any combined hormonal contraceptive available. The typical use failure rate for combined hormonal contraception is 7–8% due primarily to missed pills or failure to resume therapy after the 7-day pill-free interval. Studies are inconclusive regarding estrogen’s effect on milk letdown, and several studies have shown no deleterious effect of oral contraceptive pills on the breastfed infant. Progestin-only oral contraceptive (norethindrone 0.35 mg/d) has proven to be a safe option that does not suppress lactation and in fact may actually enhance lactation. Its contraceptive efficacy is maximum with exclusive breastfeeding, and additional or alternative contraceptive methods are advisable when breastfeeding frequency is decreased. The use of a long-acting progestin such as depot medroxyprogesterone acetate (Depo-Provera; Pfizer, New York, NY), 150 mg administered intramuscularly or 104 mg administered subcutaneously every 3 months, provides effective contraception (>99% contraceptive efficacy) for the lactating woman without increasing the risk of maternal thromboembolism or decreasing milk yield. However, concerns related to prolonged amenorrhea, prolonged return to fertility, the inconvenience of unscheduled bleeding, weight gain, skin changes, and reversible bone density reduction and lipid metabolism changes are potential reasons for discontinuation. On the other hand, the level of progestin in depot medroxyprogesterone acetate raises the seizure threshold and is the contraceptive of choice for women with seizure disorders.

Levonorgestrel implants placed after establishment of lactation (immediately postpartum or by 6 weeks) provide acceptable contraception with no effect on lactation or infant growth. They have gained little favor, probably because of irregular bleeding, high cost, and difficulty in insertion and removal.

Insertion of an IUD (copper-containing TCu 380 Ag) (Eurim-Pharm Vertriebs GmbH & Co KG, Austria) and ParaGard T380A (Duramed Pharmaceuticals Inc. Pomona, NY, USA), progesterone-releasing Progestasert (Janssen Pharmaceuticals Inc. Titusville, NJ, USA), or levonorgestrel-releasing Mirena (Bayer Healthcare Pharmaceuticals inc. Wayne, NJ, USA)) is highly effective in preventing pregnancy (<2–3 pregnancies per 100 woman-years) and is not considered an abortifacient. Ideally, an IUD should be placed at the first postpartum visit; however, it may be placed as early as immediately postpartum. In this latter case, the incidence of expulsion appears higher than with interval insertion. The main side effects include <1% risk of pelvic infection in the first 2 weeks after insertion, uterine perforation (<1%), expulsion (<3%), and abnormal uterine bleeding. The risk of ectopic pregnancy is lower among women with the Mirena or ParaGard compared with women using no contraception. The risk of uterine perforation during IUD insertion is higher in lactating women, probably because of the accelerated rate of uterine involution. Of note, the risk of expulsion is not increased in these lactating women. Uterine perforation is highest when insertion is performed in the first 1–8 weeks after delivery. The levonorgestrel IUD in particular has added noncontraceptive benefits, including an 80% rate of amenorrhea after 1 year, improvements in dysmenorrhea and endometriosis, and management of endometrial hyperplasia in poor surgical candidates.

Discharge Examination & Instructions

Before the patient’s hospital discharge, the breasts and abdomen should be examined. The degree of uterine involution and tenderness should be noted. The calves and thighs should be palpated to rule out thrombophlebitis. The characteristics of the lochia are important and should be observed. The episiotomy wound should be inspected to see whether it is healing satisfactorily. A blood sample should be obtained for hematocrit or hemoglobin determination. Unless the patient has an unusual pelvic complaint, there is little need to perform a vaginal examination. The obstetrician should be certain that the patient is voiding normally, has normal bowel function, and is physically able to assume her new responsibilities at home.

The patient will require some advice on what she is allowed to do when she arrives home. Hygiene is essentially the same as practiced in the hospital, with a premium on cleanliness. Upon discharge from the hospital, the patient should be instructed to rest for at least 2 hours during the day, and her usual household activities should be curtailed. Activities, exercise, and return to work will be individualized. Accepted disability after delivery is 6 weeks. Various forms of social support are critical for mothers, especially those employed outside the home: available, high-quality day care; parental leave for both mothers and fathers; and support provided by the workplace such as flexible hours, the opportunity to breastfeed, on-site day care, and care for sick children. The patient who has had frequent prenatal visits to her obstetrician may feel cut off from the doctor during the interval between discharge and the first postpartum visit. She will feel reassured in this period if she receives thoughtful advice on what she is allowed to do and what she can expect when she arrives home. She should be instructed to notify the physician or nurse in the event of fever, vaginal bleeding, or back pain that does not resolve with over-the-counter pain medication. At the time of discharge, the patient should be informed that she will note persistent but decreasing amounts of vaginal lochia for approximately 3 weeks and possibly for a short period during the fourth or fifth week after delivery.

Postpartum Visit Examination

At the postpartum visit—4–6 weeks after discharge from the hospital—the patient’s weight and blood pressure should be recorded. Most patients retain approximately 60% of any weight in excess of 11 kg (24 lb) that was gained during pregnancy. A suitable diet may be prescribed if the patient has not returned to her approximate prepregnancy weight. If the patient was anemic upon discharge from the hospital or has been bleeding during the puerperium, a complete blood count should be determined. Persistence of uterine bleeding demands investigation and definitive treatment.

The breasts should be examined, and the adequacy of support, abnormalities of the nipples or lactation, and the presence of any masses should be noted. The patient should be instructed concerning self-examination of the breasts. A complete rectovaginal evaluation is required.

Nursing mothers may show a hypoestrogenic condition of the vaginal epithelium. Prescription of a vaginal estrogen cream to be applied at bedtime should relieve local dryness and coital discomfort without the side effects of systemic estrogen therapy. The cervix should be inspected and a Papanicolaou (Pap) smear obtained. Women whose prenatal smears are normal are still at risk for an abnormal Pap smear at their postpartum visit.

The episiotomy incision and repaired lacerations must be examined and the adequacy of pelvic and perineal support noted. Bimanual examination of the uterus and adnexa is indicated. At the time of the postpartum examination, most patients have some degree of retrodisplacement of the uterus, but this may soon correct itself. If marked uterine descensus is noted, or if the patient develops stress incontinence or symptomatic cystocele or rectocele, surgical correction should be considered if childbearing has been completed. Hysterectomy or vaginal repair is best postponed for at least 3 months after delivery to allow maximal restoration of the pelvic supporting structures.

The patient may resume full activity or employment if her course to this point has been uneventful. Once again, the patient should be advised regarding family planning and contraceptive practices. The postnatal visit is an important opportunity to consider general disorders such as backache and depression and to discuss infant feeding and immunization. Review of medical complications during the pregnancy and potential long-term impact of those pathologies should be discussed. Documentation of blood pressure should demonstrate normalization in women who experienced gestational hypertension or preeclampsia. Postpartum glucose tolerance testing and counseling of women with a history of gestational diabetes is also recommended. The rapport established between the obstetrician and the patient during the prenatal and postpartum periods provides a unique opportunity to establish a preventive health program in subsequent years.

LACTATION

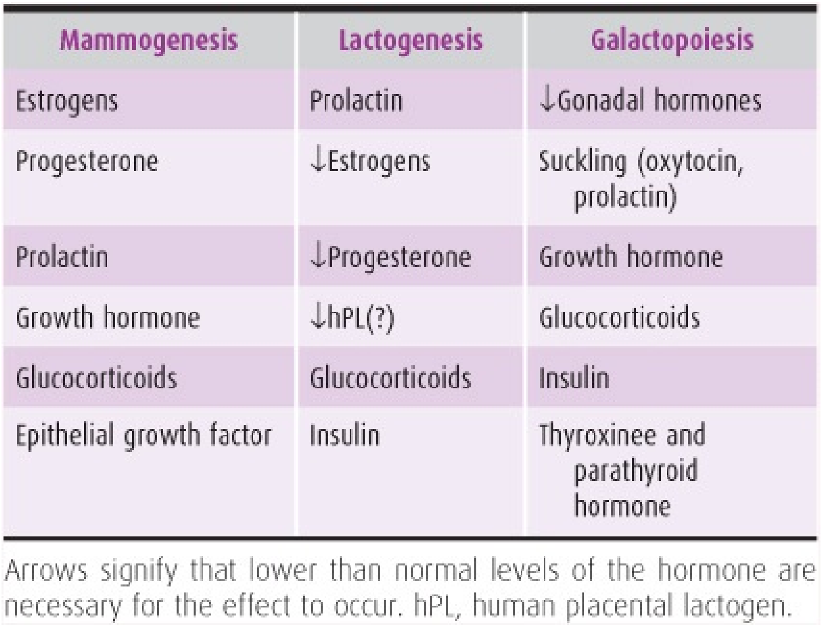
Physiology

The mammary glands are modified exocrine glands that undergo dramatic anatomic and physiologic changes during pregnancy and in the immediate puerperium. Their role is to provide nourishment for the newborn and to transfer antibodies from mother to infant.

During the first half of pregnancy, proliferation of alveolar epithelial cells, formation of new ducts, and development of lobular architecture occur. Later in pregnancy, proliferation declines, and the epithelium differentiates for secretory activity. At the end of gestation, each breast will have gained approximately 400 g. Factors contributing to increase in mammary size include hypertrophy of blood vessels, myoepithelial cells, and connective tissue; deposition of fat; and retention of water and electrolytes. Blood flow is almost double that of the nonpregnant state.

Lactation depends on a delicate balance of several hormones. An intact hypothalamic–pituitary axis is essential to the initiation and maintenance of lactation. Lactation can be divided into 3 stages: (1) mammogenesis, or mammary growth and development; (2) lactogenesis, or initiation of milk secretion; and (3) galactopoiesis, or maintenance of established milk secretion (Table 10–2). Estrogen is responsible for the growth of ductal tissue and alveolar budding, whereas progesterone is required for optimal maturation of the alveolar glands. Glandular stem cells undergo differentiation into secretory and myoepithelial cells under the influence of prolactin, growth hormone, insulin, cortisol, and an epithelial growth factor. Although alveolar secretory cells actively synthesize milk fat and proteins from midpregnancy onward, only small amounts are released into the lumen. However, lactation is possible if pregnancy is interrupted during the second trimester.

Table 10–2. Multihormonal interaction in mammary growth and lactation.



Mammogenesis	Lactogenesis	Galactopoiesis
Estrogens	Prolactin	↓Gonadal hormones
Progesterone	↓Estrogens	Suckling (oxytocin, prolactin)
Prolactin	↓Progesterone	Growth hormone
Growth hormone	↓hPL(?)	Glucocorticoids
Glucocorticoids	Glucocorticoids	Insulin
Epithelial growth factor	Insulin	Thyroxinee and parathyroid hormone

Arrows signify that lower than normal levels of the hormone are necessary for the effect to occur. hPL, human placental lactogen.

Prolactin is a necessary hormone for milk production, but lactogenesis also requires a low-estrogen environment. Although prolactin levels continue to rise as pregnancy advances, placental sex steroids block prolactin-induced secretory activity of the glandular epithelium. It appears that sex steroids and prolactin are synergistic in mammogenesis but antagonistic in galactopoiesis. Therefore, lactation is not initiated until plasma estrogens, progesterone, and human placental lactogen levels fall after delivery. Progesterone inhibits the biosynthesis of lactose and α-lactalbumin; estrogens directly antagonize the lactogenic effect of prolactin on the mammary gland by inhibiting α-lactalbumin production. Human placental lactogen may also exert a prolactin-antagonist effect through competitive binding to alveolar prolactin receptors.

The maintenance of established milk secretion requires periodic suckling and the actual emptying of ducts and alveoli. Growth hormone, cortisol, thyroxine, and insulin exert a permissive effect.

Prolactin is required for galactopoiesis, but high basal levels are not mandatory, because prolactin concentrations in the nursing mother decline gradually during the late puerperium and approach that of the non-pregnant state. However, if a woman does not breastfeed her baby, her serum prolactin concentration will return to nonpregnant values within 2–3 weeks. If the mother suckles twins simultaneously, the prolactin response is about double that when 1 baby is fed at a time, illustrating an apparent synergism between the number of nipples stimulated and the frequency of suckling. The mechanism by which suckling stimulates prolactin release probably involves the inhibition of dopamine, which is thought to be the hypothalamic prolactin-inhibiting factor.

Nipple stimulation by suckling or other physical stimuli evokes a reflex release of oxytocin from the neurohypophysis. Because retrograde blood flow can be demonstrated within the pituitary stalk, oxytocin may reach the adenohypophysis in very high concentrations and affect pituitary release of prolactin independently of any effect on dopamine. The release of oxytocin is mediated by afferent fibers of the fourth to sixth intercostal nerves via the dorsal roots of the spinal cord to the midbrain.

The paraventricular and supraoptic neurons of the hypothalamus make up the final afferent pathway of the milk ejection reflex. The central nervous system can modulate the release of oxytocin by either stimulating or inhibiting the hypothalamus to increase or decrease prolactin-inhibiting factor (dopamine) and thus the release of oxytocin from the posterior pituitary. Thus positive senses related to nursing and crying of infant and positive attitudes in pregnancy and toward breastfeeding can improve milk yield and the ultimate success of breastfeeding. Likewise, the expectation of nursing is sufficient to release oxytocin before milk letdown but is not effective in releasing prolactin in the absence of suckling. Contrarily, negative stimuli, such as pain, stress, fear, anxiety, insecurity, or negative attitudes, may inhibit the letdown reflex. Oxytocin levels may rise during orgasm, and sexual stimuli may trigger milk ejection.

Synthesis of Human Milk

Prolactin ultimately promotes milk production by inducing the synthesis of mRNAs for the production of milk enzymes and milk proteins at the membrane of mammary epithelial cells (alveolar cells). Milk synthesis and secretion are then initiated via four major transcellular and paracellular pathways. The substrates for milk production are primarily derived from the maternal gut or produced in the maternal liver. The availability of these substrates is aided by a 20–40% increased blood flow to the mammary gland, gastrointestinal tract, and liver, as well as increased cardiac output during breastfeeding. The principal carbohydrate in human milk is lactose. Glucose metabolism is a key function in human milk production, because lactose is derived from glucose and galactose; the latter originates from glucose-6-phosphate. A specific protein, α-lactalbumin, catalyzes lactose synthesis. This rate-limiting enzyme is inhibited by gonadal hormones during pregnancy. Prolactin and insulin, which enhance the uptake of glucose by mammary cells, also stimulate the formation of triglycerides. Fat synthesis takes place in the endoplasmic reticulum. Most proteins are synthesized de novo in the secretory cells from essential and nonessential plasma amino acids. The formation of milk protein and mammary enzymes is induced by prolactin and enhanced by cortisol and insulin.

Mature human milk contains 7% carbohydrate as lactose, 3–5% fat, 0.9% protein, and 0.2% mineral constituents expressed as ash. Its energy content is 60–75 kcal/dL. Approximately 25% of the total nitrogen of human milk represents nonprotein compounds (eg, urea, uric acid, creatinine, and free amino acids). The principal proteins of human milk are casein, α-lactalbumin, lactoferrin, immunoglobulin (Ig) A, lysozyme, and albumin. Milk also contains a variety of enzymes that may contribute to the infant's digestion of breast milk (eg, amylase, catalase, peroxidase, lipase, xanthine oxidase, and alkaline and acid phosphatase). The fatty acid composition of human milk is rich in palmitic and oleic acids and varies somewhat with the diet. The major ions and mineral constituents of human milk are Na^+, K^+, Ca^{2+}, Mg^{2+}, Cl^-, phosphorus, sulfate, and citrate. Calcium concentrations vary from 25–35 mg/dL and phosphorus concentrations from 13–16 mg/dL. Iron, copper, zinc, and trace metal contents vary considerably. All the vitamins except vitamin K are found in human milk in nutritionally adequate amounts. The composition of breast milk is not greatly affected by race, age, parity, normal diet variations, moderate postpartum dieting, weight loss, or aerobic exercise. Volume and caloric density may be reduced in extreme scenarios, such as developing countries where starvation or daily caloric intake is <1600 kcal/d. In addition, milk composition does not differ between the 2 breasts unless 1 breast is infected. However, the volume and concentration of constituents varies during the day. The volume per feed increases in the late afternoon and evening. Nitrogen peaks in the late afternoon. Fat concentrations peak in the morning and are lowest at night. Lactose levels remain fairly constant.

Colostrum, the premilk secretion, is a yellowish alkaline secretion that may be present in the last months of pregnancy and for the first 2–3 days after delivery. It has a higher specific gravity (1.040–1.060); a higher protein, vitamin A, immunoglobulin, and sodium and chloride content; and a lower carbohydrate, potassium, and fat content than mature breast milk. Colostrum has a normal laxative action and is an ideal natural starter food.

Ions and water pass the membrane of the alveolar cell in both directions. Human milk differs from the milk of many other species by having a lower concentration of monovalent ions and a higher concentration of lactose. The aqueous phase of milk is isosmotic with plasma; thus the higher the lactose, the lower the ion concentration. The ratio of potassium/sodium is 3:1 in both milk and mammary intracellular fluid. Because milk contains approximately 87% water and lactose is the major osmotically active solute, it follows that milk yield is largely determined by lactose production.

Immunologic Significance of Human Milk

The neonate's secretory immune system and cellular responses are immature. In particular, the IgM and IgA responses are poor, and cellular immunity is impaired for several months. Maternal transfer of immunoglobulins through breast milk provides support for the infant's developing immune system and thereby enhances neonatal defense against infection. All classes of immunoglobulins are found in milk, but IgA constitutes 90% of immunoglobulins in human colostrum and milk. The output of immunoglobulins by the breast is maximal in the first week of life and declines thereafter as the production of milk-specific proteins increases. Lacteal antibodies against enteric bacteria and their antigenic products are largely of the IgA class. IgG and IgA lacteal antibodies provide short-term systemic and long-term enteric humoral immunity to the breastfed neonate. IgA antipoliomyelitis virus activity present in breastfed infants indicates that at least some transfer of milk antibodies into serum does occur. However, maternal lacteal antibodies are absorbed systemically by human infants for only a very short time after birth. Long-term protection against pathogenic enteric bacteria is provided by the absorption of lacteal IgA to the intestinal mucosa. In addition to providing passive immunity, there is evidence that lacteal immunoglobulins can modulate the immunocompetence of the neonate, but the exact mechanisms have not been described. For instance, the secretion of IgA into the saliva of breastfed infants is enhanced in comparison with bottle-fed controls.

Breast milk is highly anti-infective, containing more than 4000 cells/mm^3, the majority of which are leukocytes. The total cell count is even higher in colostrum. In human milk, the leukocytes are predominantly mononuclear cells and macrophages. Both T and B lymphocytes are present. During maternal infection, antigen-specific lymphocytes can migrate to the breast mucosa or produce immunoglobulins, both of which are key in the fight against infection. Fully functional immunoglobulins are present, primarily as IgA, IgG, and IgM. Polymeric secretory IgA is easily transported across the mucous membrane of the breast, blocking the mucosal receptors of infectious agents.

Elements in breast milk other than immunoglobulins and cells have prophylactic value against infections. The marked difference between the intestinal flora of breastfed and bottle-fed infants is due to a dialyzable nitrogen-containing carbohydrate (bifidus factor) that supports the growth of *Lactobacillus bifidus* in breastfed infants. The stool of bottle-fed infants is more alkaline and contains predominantly coliform organisms and *Bacteroides* spp. *L bifidus* inhibits the growth of *Shigella* spp, *Escherichia coli*, and yeast. Human milk also contains a nonspecific antimicrobial factor, lysozyme (a thermostable, acid-stable enzyme that cleaves the peptidoglycans of bacteria), and a “resistance factor,” which protect the infant against staphylococcal infection. Lactoferrin, an iron chelator, exerts a strong bacteriostatic effect on staphylococci and *E coli* by depriving the organisms of iron. Both C3 and C4 components of complement and antitoxins for neutralizing *Vibrio cholerae* are found in human milk. Unsaturated vitamin B_{12}–binding protein in milk renders the vitamin unavailable for utilization by *E coli* and *Bacteroides*. Finally, interferon in milk may provide yet another nonspecific anti-infection factor.

Human milk may also have prophylactic value in childhood food allergies. During the neonatal period, permeability of the small intestine to macromolecules is increased. Secretory IgA in colostrum and breast milk reduces the absorption of foreign macromolecules until the endogenous IgA secretory capacity of the newborn intestinal lamina propria and lymph nodes develops at 2–3 months of age. Protein of cow’s milk can be highly allergenic in the infant predisposed by heredity. The introduction of cow’s milk–free formulas has considerably reduced the incidence of milk allergy. Thus comparative studies on the incidence of allergy, bacterial and viral infections, severe diarrhea, necrotizing enterocolitis, tuberculosis, and neonatal meningitis in breastfed and bottle-fed infants support the concept that breast milk fulfills a protective function.

Advantages & Disadvantages of Breastfeeding

A. For the Mother

1. Advantages—Breastfeeding is convenient, economical, and emotionally satisfying to most women. It helps to contract the uterus and accelerates the process of uterine involution in the postpartum period, including decreased maternal blood loss. It promotes mother–infant bonding and self-confidence. Maternal gastrointestinal motility and absorption are enhanced. Ovulatory cycles are delayed with exclusive breastfeeding. According to epidemiologic studies, breastfeeding may help to protect against premenopausal cancer and ovarian cancer. American College of Obstetrics and Gynecologists recommends that exclusive breastfeeding be continued until the infant is at least 6 months old.

2. Disadvantages—Regular nursing restricts activities and may be perceived by some mothers as an inconvenience. Twins can be nursed successfully, but few women are prepared for the first weeks of almost continual feeding. Caesarean section may necessitate modifications of early breastfeeding routines. Difficulties such as nipple tenderness and mastitis may develop. Compared with nonlactating women, breastfeeding women have a significant decrease (mean 6.5%) in bone mineral content at 6 months postpartum, but there is “catch-up” remineralization after weaning.

There are few absolute contraindications to breastfeeding (see Disadvantages and Contraindications for the Infant).

A. For the Infant

1. Advantages—Breast milk is digestible, of ideal composition, available at the right temperature and the right time, and free of bacterial contamination. Infants of breastfed mothers have a decreased incidence of all of the following: diarrhea, lower respiratory tract infection, otitis media, pneumonia, urinary tract infections, necrotizing enterocolitis, invasive bacterial infection, and sudden infant death. Breastfed infants may have a decreased risk of developing insulin-dependent diabetes, Crohn's disease, ulcerative colitis, lymphoma, and allergic diseases later in life. Breastfed infants are less likely to become obese later in life. Suckling promotes infant–mother bonding. Cognitive development and intelligence may be improved.

2. Disadvantages and Contraindications—Absolute contraindications to breastfeeding include the use of street drugs or excess alcohol; human T-cell leukemia virus type 1; breast cancer; active herpes simplex infection of the breast; active pulmonary tuberculosis or human T-cell lymphotropic virus type I or II positive in the mother; galactosemia in the infant; and maternal intake of cancer chemotherapeutic agents, recent diagnostic or therapeutic radioactive isotopes, or recent exposure to radioactive materials. Specific precautions for individual medications should be reviewed when prescribing drugs to lactating women. HIV infection in the United States is also a contraindication to breastfeeding because it has been recognized as a mode of HIV transmission. Breastfeeding might pose an additional risk of vertical transmission (approximately 15%) above that present from the antepartum and intrapartum periods. The risk of HIV transmission through breast milk is substantially higher among women who become infected during the postpartum lactation period. Most mothers in developed countries who know of their seropositivity choose not to breastfeed; in underdeveloped countries where lactation is critical to infant survival, breastfeeding is recommended even among HIV-infected mothers.

Breastfeeding is not contraindicated for mothers who are hepatitis B surface antigen positive, or mothers who are infected with hepatitis C virus (positive hepatitis C virus antibody or virus-RNA–positive blood). The presence of fever or seropositivity for chronic exposure to cytomegalovirus (CMV) are also not contraindications to breastfeeding. Caution should be exercised in low-birth-weight babies where potential risk of transmission must be balanced against nutritional benefit. Freezing and pasteurization can decrease the CMV viral load in the mother's milk.

The milk of a nursing mother with cystic fibrosis is high in sodium and places the infant at risk for hypernatremia. A woman with clinically infectious varicella should be isolated from the infant and should neither breastfeed nor bottle-feed. Once the infant has received varicella zoster immune globulin and there are no skin lesions on the mother's breast, she may provide expressed milk for her infant. A small number of otherwise healthy breastfed infants develop unconjugated hyperbilirubinemia (sometimes exceeding 20 mg/dL) during the first few weeks of life because of the higher than normal glucuronyl transferase inhibitory activity of the breast milk. The inhibitor may be a pregnanediol, although increased milk lipase activity and free fatty acids are likely the critical factors.

Breastfeeding is not usually possible for weak, ill, or very premature infants or for infants with cleft palate, choanal atresia, or phenylketonuria. It is common practice in many nurseries to feed premature infants human milk collected fresh from their mothers or processed from donors. The effects of processing and storage on the persistence of viral agents are not well studied. CMV transmission through breast milk has been documented and may pose a significant hazard for preterm infants. It is recommended that seronegative preterm infants receive milk from seronegative donors only. Because maternal antibodies are present in breast milk, an otherwise healthy term infant may do better if breastfed.

Breastfeeding is not contraindicated in women who have undergone breast augmentation with saline implants. Many women with breast implants breastfeed successfully, but reduction mammoplasty involving nipple autotransplantation severs the lactiferous ducts and precludes nursing. The success rate of breastfeeding decreases approximately 25% and the need to supplement with formula increases 19% in women after augmentation. When nipple sensation is lost as a result of breast surgery, breastfeeding is not possible. Other postoperative factors, such as breast pain, capsular contracture, and pressure on the breast from the implant, may compromise a woman's ability to exclusively breastfeed. Finally, the psychologic concern that breastfeeding may compromise the results of a cosmetic surgery may interfere with breastfeeding attempts.

Principles & Techniques of Breastfeeding

In the absence of anatomic or medical complications, the timing of the first feeding and the frequency and duration of subsequent feedings largely determine the outcome of breastfeeding. Infants and mothers who are able to initiate breastfeeding within 1–2 hours of delivery are more successful than those whose initial interactions are delayed for several hours. Lactation is established most successfully if the baby remains with the mother and she can feed on demand for adequate intervals throughout the first 24-hour period. The initial feeding should last 5 minutes at each breast in order to condition the letdown reflex. At first, the frequency of feedings may be very irregular (8–10 times per day), but after 1–2 weeks a fairly regular 4- to 6-hour pattern will emerge.

When the milk "comes in" abruptly on the third or fourth postpartum day, there is an initial period of discomfort caused by vascular engorgement and edema of the breasts. The baby does not nurse so much by developing intermittent negative pressure as by a rhythmic grasping of the areola; the infant "works" the milk into its mouth. Little force is required in nursing because the breast reservoirs can be emptied and refilled without suction. Nursing mothers notice a sensation of drawing and tightening within the breast at the beginning of suckling after the initial breast engorgement disappears. They are thus conscious of the milk ejection reflex, which may even cause milk to spurt or run out.

Some women expend a great deal of emotion on the subject of breastfeeding, and a few are almost overwhelmed by fear of being unable to care for their babies in this way. If attendants are sympathetic and patient, however, a woman who wants to nurse usually can do so. Attendants must be certain that the baby "latches" on (actually over) the nipple and the areola so as to feed properly without causing pain for the mother.

The baby should nurse at both breasts at each feeding, because overfilling of the breasts is the main deterrent to the maintenance of milk secretion. Nursing at only 1 breast at each feeding inhibits the reflex that is provoked simultaneously in both breasts. Thus nursing at alternate breasts from 1 feeding to the next may increase discomfort due to engorgement and reduce milk output. It is helpful for the mother to be taught to empty the breasts after each feeding; a sleepy baby may not have accomplished this. The use of supplementary formula or other food during the first 6–8 weeks of breastfeeding can interfere with lactation and should be avoided except when absolutely necessary. The introduction of an artificial nipple, which requires a different sucking mechanism, will weaken the sucking reflex required for breastfeeding. Some groups, such as the La Leche League, recommend that other fluids be given by spoon or dropper rather than by bottle.

In preparing to nurse, the mother should (1) wash her hands with soap and water, (2) clean her nipples and breasts with water, and (3) assume a comfortable position, preferably in a rocking or upright chair with the infant and mother chest-to-chest. If the mother is unable to sit up to nurse her baby because of painful perineal sutures, she may feel more comfortable lying on her side. An alternative position is the football hold. A woman with large pendulous breasts may find it difficult to manage both the breasts and the baby. If the baby lies on a pillow, the mother will have both hands free to guide the nipple.

Each baby nurses differently; however, the following procedure is generally successful:

1. Allow the normal newborn to nurse at each breast on demand or approximately every 3–4 hours, for 5 minutes per breast per feeding the first day. Over the next few days, gradually increase feeding time to initiate the letdown reflex, but do not exceed 10–15 minutes per breast. Suckling for longer than 15 minutes may cause maceration and cracking of the nipples and thus lead to mastitis.
2. Stimulating the cheek or lateral angle of the baby’s mouth should precipitate a reflex turn to the nipple and opening of the mouth. The infant is brought firmly to the breast, and the nipple and areola are placed into the mouth as far as the nipple–areola line. Slight negative pressure holds the teat in place, and milk is obtained with a peristaltic motion of the tongue. Compressing the periareolar area and expressing a small amount of colostrum or milk for the baby to taste may stimulate the baby to nurse.
3. Try to keep the baby awake by moving or patting, but do not snap its feet, work its jaw, push its head, or press its cheeks.
4. Before removing the infant from the breast, gently open its mouth by lifting the outer border of the upper lip to break the suction.

After nursing, gently wipe the nipples with water and dry them.

Milk Yield

The prodigious energy requirements for lactation are met by mobilization of elements from maternal tissues and from dietary intake. Physiologic fat stores laid down during pregnancy are mobilized during lactation, and the return to prepregnancy weight and figure is promoted. A variety of studies suggest that a lactating woman should increase her normal daily food intake by 500 kcal/d, but intakes of 2000–2300 calories are sufficient for lactating women. The recommended daily dietary increases for lactation are 20 g of protein; a 20% increase in all vitamins and minerals except folic acid, which should be increased by 50%; and a 33% increase in calcium, phosphorus, and magnesium. There is no evidence that increasing fluid intake will increase milk volume. Fluid restriction also has little effect because urine output will diminish in preference to milk output.

With nursing, average milk production on the second postpartum day is approximately 120 mL. The amount increases to about 180 mL on the third postpartum day and to as much as 240 mL on the fourth day. In time, milk production reaches approximately 300 mL/d.

A good rule of thumb for the calculation of milk production for a given day in the week after delivery is to multiply the number of the postpartum day by 60. This gives the approximate number of milliliters of milk secreted in that 24-hour period.

If all goes well, sustained production of milk will be achieved by most patients after 10–14 days. A yield of 120–180 mL per feeding is common by the end of the second week. When free secretion has been established, marked increases are possible.

Early diminution of milk production often is due to failure to empty the breasts because of weak efforts by the baby or ineffectual nursing procedures; emotional problems, such as aversion to nursing; or medical complications, such as mastitis, debilitating systemic disease, or Sheehan’s syndrome. Late diminution of milk production results from too generous complementary feedings of formula, emotional or other illness, and pregnancy.

Adequate rest is essential for successful lactation. Sometimes it is difficult to ensure an adequate milk yield if the mother is working outside the home. If it is not possible to rearrange the nursing schedule to fit the work schedule or vice versa, it may be necessary to empty the breasts manually or by pump. Milk output can be estimated by weighing the infant before and after feeding. If there has been a bowel movement during feeding, the baby should be weighed before the diaper is changed.

It may be necessary to substitute bottle-feeding for breastfeeding if the mother’s supply continues to be inadequate (<50% of the infant’s needs) after 3 weeks of effort, if nipple or breast lesions are severe enough to prevent pumping, or if the mother is either pregnant or severely (physically or mentally) ill. Nourishment from the inadequately lactating breast can be augmented with the Lact-Aid Nursing Trainer (Lact-Aid International, Athens, TN), a device that provides a supplemental source of milk via a plastic capillary tube placed beside the breast and suckled simultaneously with the nipple. Disposable plastic bags serve as reservoirs, and the supplemental milk is warmed by hanging the bag next to the mother. The Lact-Aide supplementer has also been used to help nurse premature infants and to re-establish lactation after untimely weaning due to illness. The long-term success of breastfeeding is increased by a structured home support system of postnatal visits by allied health personnel or experienced volunteers.

Disorders of Lactation

A. Painful Nipples

Tenderness of the nipples, a common symptom during the first days of breastfeeding, generally begins when the baby starts to suck. As soon as milk begins to flow, nipple sensitivity usually subsides. If maternal tissues are unusually tender, dry heat may help between feedings. Nipple shields should be used only as a last resort because they interfere with normal sucking. Glass or plastic shields with rubber nursing nipples are preferable to shields made entirely of rubber.

Nipple fissures cause severe pain and prevent normal letdown of milk. Local infection around the fissure can lead to mastitis. The application of vitamin A and D ointment or hydrous lanolin, which does not have to be removed, is often effective. To expedite healing, the following steps are recommended. Apply dry heat for 20 minutes 4 times per day with a 60-watt bulb held 18 inches away from the nipple. Conduct prefeeding manual expression. Begin nursing on the side opposite the fissure with the other breast exposed to air to allow the initial letdown to occur atraumatically. Apply expressed breast milk to nipples and let it dry in between feedings. If necessary, use a nipple shield while nursing, and take ibuprofen or acetaminophen with or without codeine just after nursing. On rare occasions, it may be necessary to stop nursing temporarily on the affected side and to empty the breast either manually or by gentle pumping. Commercially available hydrogel pad is another alternative to treat sore nipple. It is designed to be worn inside the bra to prevent and soothe painful, cracked, or bleeding nipples and contribute to the healing process. The hydro-gel pad contains a low water/high glycerin content, which provides natural moisture to the area without causing skin maceration. Recent studies have shown that by retaining the internal natural moisture level of the skin, nipple trauma improves more quickly.

A cause of chronic severe sore nipples without remarkable physical findings is candidal infection. Prompt relief is provided by topical nystatin cream. Thrush or candidal diaper rash or maternal candidal vaginitis must be treated as well.

B. Engorgement

Engorgement of the breasts occurs in the first week postpartum and is due to vascular congestion and accumulation of milk. Vascularity and swelling increase on the second day after delivery, and the areola or breast may become engorged. Prepartum breast massage and around-the-clock demand feedings help to prevent engorgement in these patients. When the areola is engorged, the nipple is occluded and proper grasping of the areola by the infant is not possible. With moderately severe engorgement, the breasts become firm and warm, and the lobules may be palpable as tender, irregular masses. Considerable discomfort and often a slight fever can be expected.

Mild cases may be relieved by acetaminophen or other analgesics, cool compresses, and partial expression of the milk before nursing. In severe cases, the patient should empty the breasts manually or with an electric pump. Alternative treatments for breast engorgement include acupuncture, cabbage leaves, cold gel packs, pharmacologic treatments, and ultrasound, but none of them have proven to be superior for symptom relief.

C. Mastitis

Mastitis occurs most frequently in primiparous nursing patients and usually is caused by coagulase-positive *Staphylococcus aureus*. High fever should never be ascribed to simple breast engorgement alone. Inflammation of the breast seldom begins before the fifth day postpartum. Most frequently, symptoms of a painful erythematous lobule in an outer quadrant of the breast are noted during the second or third week of the puerperium. Inflammation may occur with weaning when the flow of milk is disrupted, or the nursing mother may acquire the infection during her hospital stay and then transmit it to the infant. Demonstration of antibody-coated bacteria in the milk indicates the presence of infectious mastitis. Many infants harbor an infection and, in turn, infect the mother’s breast during nursing. Neonatal streptococcal infection should be suspected if mastitis is recurrent or bilateral.

Infection may be limited to the subareolar region but more frequently involves an obstructed lactiferous duct and the surrounding breast parenchyma. If cellulitis is not properly treated, a breast abscess may develop. When only mastitis is present, it is best to prevent milk stasis by continuing breastfeeding or by using a breast pump. Apply local heat, provide a well-fitted bra, and institute appropriate antibiotic treatment. Cephalosporins, methicillin sodium, and dicloxacillin sodium are the antibiotics of choice to combat penicillinase-producing bacteria.

The presence of pitting edema over the inflamed area and any degree of fluctuation suggest abscess formation. It is necessary to incise and open loculated areas and provide wide drainage. Although correct breastfeeding techniques and alternation of breast may decrease the formation of nipple crack and mastitis, there is currently insufficient evidence to show effectiveness of any of the interventions, including breastfeeding education, pharmacologic treatments, and alternative therapies, regarding the occurrence of mastitis.

D. Miscellaneous Complications

A galactocele, or milk-retention cyst, is caused by blockage of a milk duct. It usually will resolve with warm compresses and continuation of breastfeeding. Sometimes the infant will reject one or both breasts. Strong foods such as beans, cabbage, turnips, broccoli, onions, garlic, and rhubarb may cause aversion to milk or neonatal colic. A common cause of nursing problems is maternal fatigue.

Inhibition & Suppression of Lactation

Despite a recent upsurge in breastfeeding in Western countries, many women will not or cannot breastfeed, and others will fail in the attempt. Lactation inhibition is desirable in the event of fetal or neonatal death as well.

The oldest and simplest method of suppressing lactation is to stop nursing, to avoid nipple stimulation, to refrain from expressing or pumping the milk, and to wear a supportive bra. Analgesics are also helpful. Patients will complain of breast engorgement (45%), pain (45%), and leaking breasts (55%). Although the breasts will become considerably engorged and the patient may experience discomfort, the collection of milk in the duct system will suppress its production, and reabsorption will occur. After approximately 2–3 days, engorgement will begin to recede, and the patient will be comfortable again. Medical suppression of lactation with estrogens or bromocriptine is no longer recommended due to undesired side effect and medical complications.

Imaging in Obstetrics

Simi Gupta, MD
Ashley S. Roman, MD, MPH

Technology for imaging in obstetrics has advanced a great deal over the past decade, but the purpose remains the same: to evaluate the anatomy and well-being of the fetus and the mother. The primary imaging modality in obstetrics is the 2-dimensional (2D) ultrasound because it is safe and widely available. Three- and 4-dimensional (3D/4D) ultrasound and magnetic resonance imaging (MRI) are also being used in certain situations to enhance imaging techniques, but the cost of these modalities limits their widespread use. Finally, computed tomography (CT) scan has limited utility because of safety issues but may be necessary in evaluating certain maternal conditions.

ULTRASOUND IMAGING

Ultrasound evaluation uses sound waves at a frequency greater than that which the human ear can hear (>20,000 cycles per second or Hertz [Hz]) to obtain images. An ultrasound examination is performed in real time with images or video clips stored for review. Ultrasound probes contain a transducer that creates the ultrasound waves at different frequencies. Higher frequency transducers provide better resolution but have less tissue penetrations, whereas low-frequency transducers have lower resolution but better tissue penetration.

In obstetrics and gynecology, ultrasound imaging is generally performed 1 of 2 ways: either with a transvaginal probe or transabdominal probe. The choice of which probe to use generally depends on the structure of interest and its distance from the probe. For instance, imaging of the cervix or an early gestation is generally best achieved with a transvaginal probe, whereas evaluation of the fetus in the third trimester of pregnancy is best accomplished with transabdominal imaging.

Ultrasound during pregnancy when performed for medical indications is considered to be safe. There are no documented harmful effects to the fetus from diagnostic ultrasound. Ultrasound waves, however, are a form of energy and have been shown to raise tissue temperature with high energy output or prolonged exposure. To minimize this risk, it is recommended that energy output, as measured by the Mechanical Index, be kept less than 1.0 and that ultrasound be used for diagnostic purposes only (ie, not for entertainment purposes). Imaging of the fetus can be divided into ultrasound evaluations in the first trimester and evaluations in the second and third trimesters. In each trimester, the goals and the ability to evaluate the fetal anatomy differ.

First-Trimester Ultrasound Examination

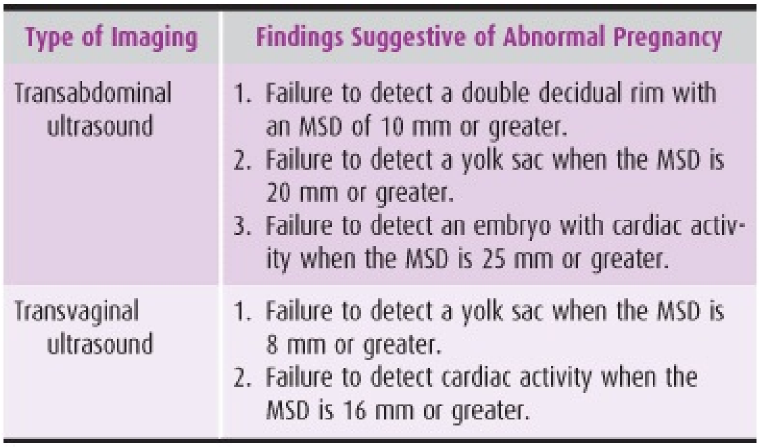
There are a number of indications to perform first-trimester ultrasound. They include confirmation of an intrauterine pregnancy, assessment of pelvic pain and vaginal bleeding, estimation of gestational age, confirmation of viability, evaluation of number of gestations, genetic screening, evaluation of basic anatomy, and assessment of uterine and adnexal anomalies and pathology.

To begin with, a first-trimester ultrasound can be used to confirm an early pregnancy by documenting the location of a gestational sac and the presence or absence of a yolk sac and fetal pole.

However, one should use caution in determining the location of a pregnancy based solely on the presence of a gestational sac because sometimes an intrauterine fluid collection could be a pseudogestational sac from an ectopic pregnancy and not a normal gestational sac. Please see Chapter 13 for a more thorough discussion of using ultrasound to evaluate for ectopic pregnancy.

An ultrasound in the first trimester can also be used to determine the gestational age and viability of a pregnancy by the presence or absence of cardiac activity. Gestational age should be determined by measuring the length of the fetal pole. If there is no fetal pole noted, the gestational age can be estimated by measuring the mean sac diameter of the gestational sac. To assess for viability, cardiac activity should be noted by transvaginal ultrasound when the fetal pole measures 4–5 mm, which corresponds to a gestational age of 6.0–6.5 weeks. Using transabdominal ultrasound, cardiac activity should be noted when the fetal pole corresponds with a gestational age of 8 weeks. Table 11–1 includes some guidelines for evaluation of an abnormal pregnancy. However, there are exceptions to the guidelines, so a follow-up ultrasound may be considered in order not to terminate a normal pregnancy.

Table 11–1. Guidelines for evaluation of an abnormal pregnancy.



Type of Imaging	Findings Suggestive of Abnormal Pregnancy
Transabdominal ultrasound	1. Failure to detect a double decidual rim with an MSD of 10 mm or greater. 2. Failure to detect a yolk sac when the MSD is 20 mm or greater. 3. Failure to detect an embryo with cardiac activity when the MSD is 25 mm or greater.
Transvaginal ultrasound	1. Failure to detect a yolk sac when the MSD is 8 mm or greater. 2. Failure to detect cardiac activity when the MSD is 16 mm or greater.

MSD, mean sac diameter.

The first trimester is also the best time to determine the number of gestations and to evaluate the chorionicity and amnionicity of multifetal pregnancies. An ultrasound will be able to show the number of gestational sacs, number of yolk sacs, and the number of fetal poles with cardiac activity. In cases of multifetal pregnancies, an ultrasound will also show the location of the placenta or placentas, the number of yolk sacs, and the presence or absence of a dividing membrane or membranes. In monochorionic-monoamniotic twins, there will be no dividing membrane between the fetuses, and there will be a single yolk sac (Fig. 11–1).

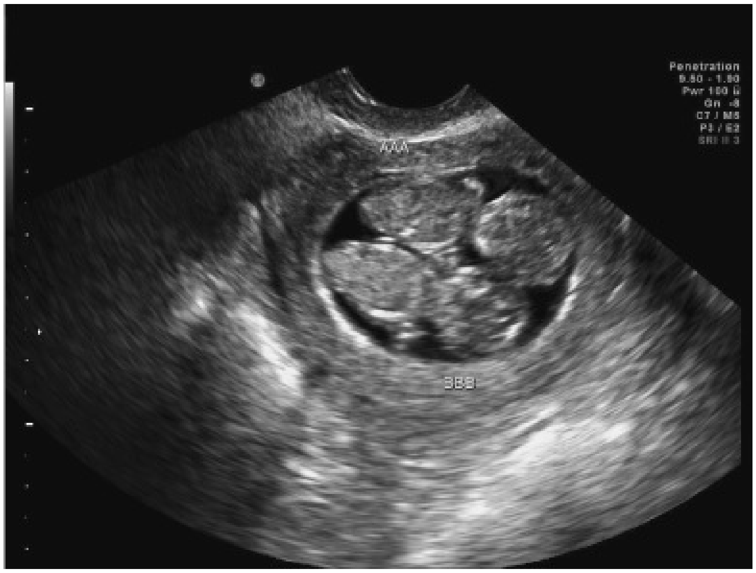


Figure 11–1. Monochorionic monoamniotic twin gestation at 10 weeks’ gestation. Note the lack of a dividing membrane and the close proximity of the fetuses. A single yolk sac was also noted.

Monochorionic, diamniotic pregnancies in the early first trimester are characterized by a single chorion with 2 yolk sacs visualized. In many cases, the amnion may not be visible until approximately 8 weeks’ gestation, at which time thin amniotic sacs may be seen surrounding each embryo (Fig. 11–2). By 10 weeks, monochorionic-diamniotic pregnancies are characterized by the T-sign on ultrasound, which represents a single placenta with 2 amnions. This is in contrast to dichorionic-diamniotic pregnancies, which will either show 2 separate placentas or show the classic lambda or twin-peak sign if there are fused placentas (Fig. 11–3). Conjoined twins can also be diagnosed during the first trimester based on ultrasound findings demonstrating a single amnion, chorion, and yolk sac and 2 fetal poles that are fused (Fig. 11–4).

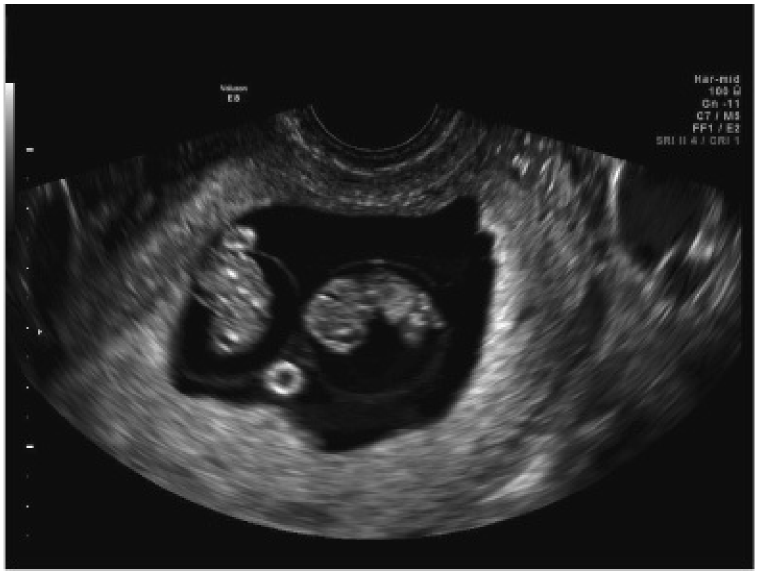

Figure 11–2. Monochorionic diamniotic twin gestation at 9 weeks’ gestation. Note the thin amnion surrounding each fetus and the 2 yolk sacs, both characteristic of the monochorionic diamniotic twin pregnancy at this early gestational age.

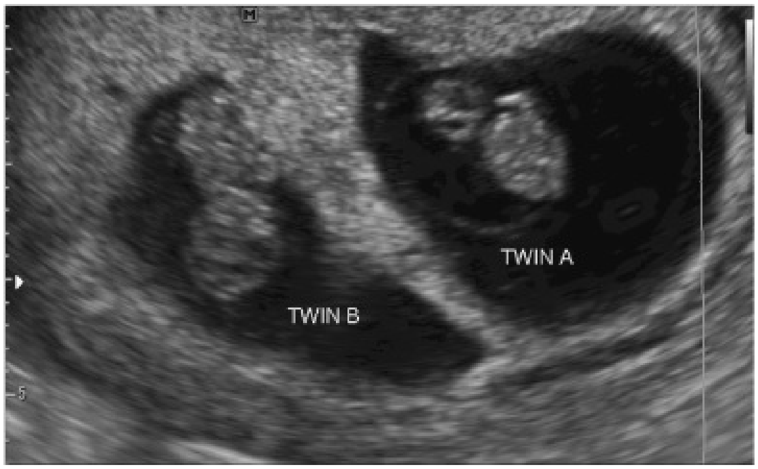

Figure 11–3. Dichorionic diamniotic twin gestation at 8 weeks' gestation. Note the thick dividing membrane and wedge-shaped "lambda sign," the area at the top of the image, which represents the junction of the 2 placentas.

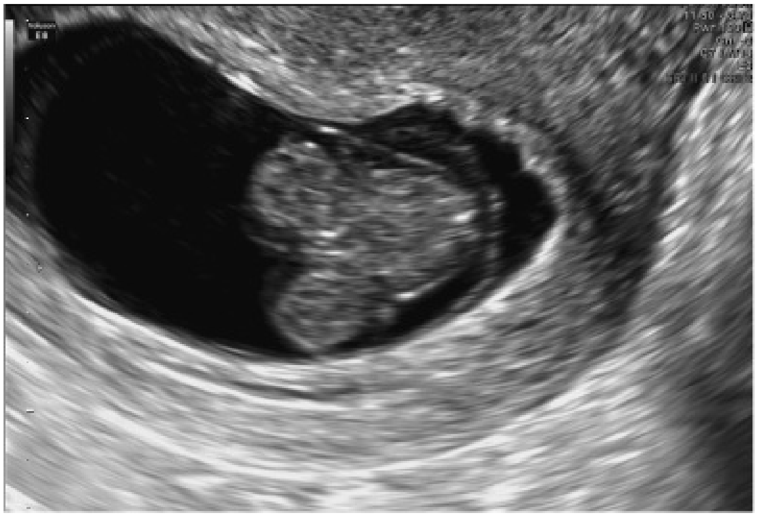

Figure 11–4. Conjoined twin pregnancy at 9 weeks' gestation. Note the 2 fetal heads and apparent fusion at the thorax and abdomen. In this image, there is also a single amnion and chorion identified.

In the last 20 years, extensive research has shown that first-trimester ultrasound can also be used as a screening test for Down syndrome, trisomy 18, and trisomy 13. This is performed by measuring the nuchal translucency, or area of fluid that accumulates behind the fetal neck (Fig. 11–5). The combination of this measurement with maternal β human chorionic gonadotropin and pregnancy-associated plasma protein-A levels provides a patient-specific risk that the patient can use to determine whether she wants definitive testing for fetal chromosomal abnormalities with either chorionic villus sampling or an amniocentesis. More recently, research has shown that by incorporating the presence or absence of the nasal bone on ultrasound into the algorithm, the detection rate for Down syndrome in the first trimester is 94%, with a false-positive rate of 5%. Some institutions are also looking at impedance to flow in the ductus venosus and tricuspid regurgitation as markers of genetic abnormalities early in pregnancy.

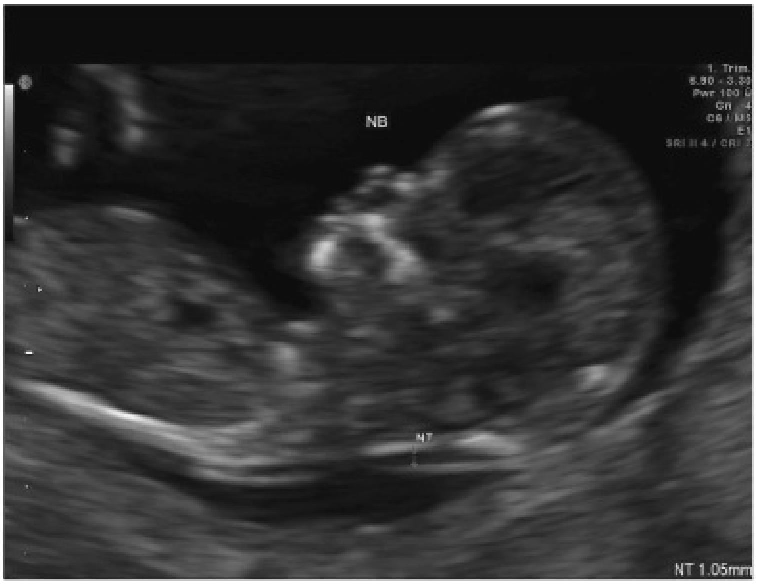

Figure 11–5. Fetal nuchal translucency measurement at 12 weeks' gestation. The nuchal translucency refers to the echolucent space underneath the skin at the back of the neck. In this case, the nuchal translucency measurement was normal. In this figure, also note that the nasal bone is imaged. It is seen as a line underneath and parallel to the skin that is of equal or greater echogenicity than the skin.

Finally, with improvements in ultrasound technology and implementation of first-trimester screening for aneuploidy, more attention has been paid to the fetal anatomical survey in the first trimester. Although there are no official guidelines regarding what constitutes a fetal anatomical survey in the first trimester, it is possible to evaluate the fetal brain, spine, stomach, bladder, kidneys, abdominal cord insertion, and extremities during this period. Anatomical survey in the first trimester can currently detect a number of fetal anomalies, and surely as experience continues to grow, the number and type of anomalies detected will also increase. However, there are many structures that cannot be adequately evaluated in the first trimester, and there are many fetal anomalies that do not manifest on ultrasound until later in pregnancy. Therefore, an additional ultrasound is recommended in the second trimester.

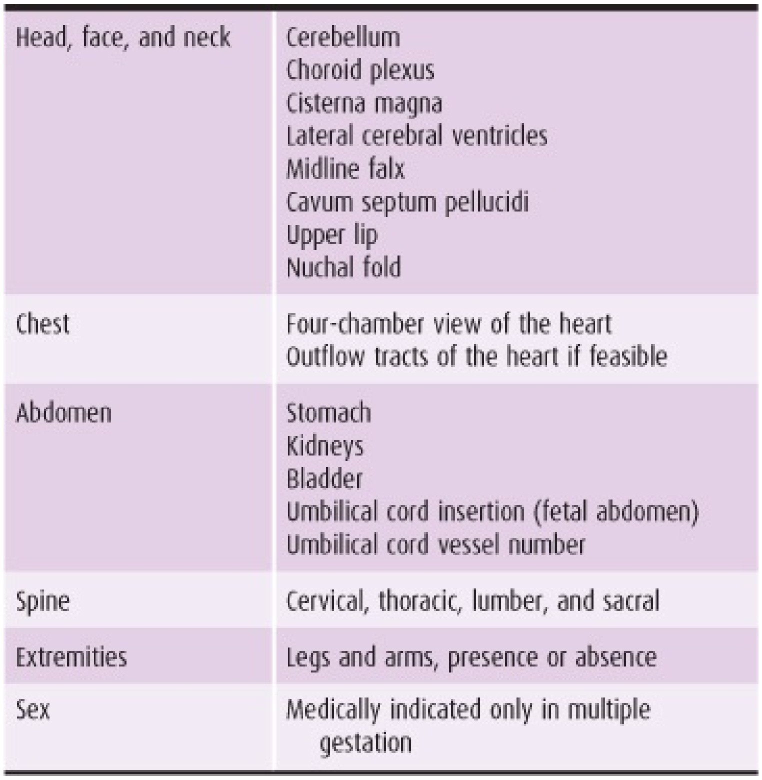
Second- and Third-Trimester Ultrasound Examination

In the second and third trimesters, transvaginal and transabdominal ultrasound can be used for screening for chromosomal and nonchromosomal fetal anomalies, fetal growth, fetal well-being, fetal lie and presentation, placental anomalies, and cervical insufficiency. Additionally, it can be used for evaluating for gestational age, number of gestations, and viability if a first-trimester ultrasound was not performed.

A. Anatomy

The fetal anatomical evaluation recommended in current guidelines can be adequately assessed transabdominally after approximately 18 weeks of gestation and detects approximately 70% of major anatomical anomalies. However, the majority of the anatomy can be seen as early as 16 weeks transabdominally and even as early as 14 weeks transvaginally. If a patient is going to have a single second-trimester ultrasound to evaluate the basic fetal anatomy, it should be performed after 18 weeks' gestation. This is with the understanding that she may need to have a follow-up ultrasound after 20 weeks if further imaging of the brain and/or the heart is recommended. Some structures that are not required in current guidelines but that can be assessed (eg, the corpus callosum in the brain) cannot be reliably viewed until approximately 20 weeks' gestation. Therefore, some experts recommend 2 anatomy ultrasounds during pregnancy; the first can be performed at approximately 14–16 weeks' gestation to allow for early diagnosis of major structural malformations and the second after 20 weeks' gestation to optimize evaluation of the heart and brain. Table 11–2 includes a guideline for fetal structures that should be assessed during a second-trimester anatomy ultrasound.

Table 11–2. AIUM guidelines for the fetal anatomical ultrasound.



Head, face, and neck	Cerebellum Choroid plexus Cisterna magna Lateral cerebral ventricles Midline falx Cavum septum pellucidi Upper lip Nuchal fold
Chest	Four-chamber view of the heart Outflow tracts of the heart if feasible
Abdomen	Stomach Kidneys Bladder Umbilical cord insertion (fetal abdomen) Umbilical cord vessel number
Spine	Cervical, thoracic, lumber, and sacral
Extremities	Legs and arms, presence or absence
Sex	Medically indicated only in multiple gestation

The second-trimester ultrasound can also be used as a genetic sonogram because major structural anomalies that can be seen are often associated with a chromosomal anomaly. Trisomy 13 and trisomy 18 fetuses have major structural anomalies that are identifiable by ultrasound in more than 80% of cases. However, fetuses with Down syndrome have major ultrasound-identifiable anomalies in only 25% of cases. These include certain cardiac anomalies, duodenal atresia, and ventriculomegaly. Ultrasound can also detect "soft" markers, which are variations in normal anatomy that are usually not clinically significant but can be associated with aneuploidy. Soft markers of Down syndrome include short femur or humerus length, renal pyelectasis, echogenic intracardiac foci, ventriculomegaly, or hyperechoic bowel. According to clinical studies, if the ultrasound does not reveal any soft markers, the risk of Down syndrome is reduced approximately 50–80%. A normal second-trimester genetic sonogram, however, does not eliminate the possibility of Down syndrome.

B. Growth

Ultrasound in the second and third trimester can also be used to evaluate fetal growth. Measurements of the biparietal diameter, head circumference, abdominal circumference or average abdominal diameter, and femoral diaphysis length can be calculated to determine an estimated fetal weight. This estimated fetal weight can be compared with the estimated fetal weights in published nomograms at each gestational age to evaluate the growth of the fetus. Indications for a fetal growth scan include measurement of fundal height less than expected based on gestational age, inability to measure fundal height because of fibroids or maternal obesity, multiple gestations, or maternal or fetal complications of pregnancy that are associated with fetal growth restriction.

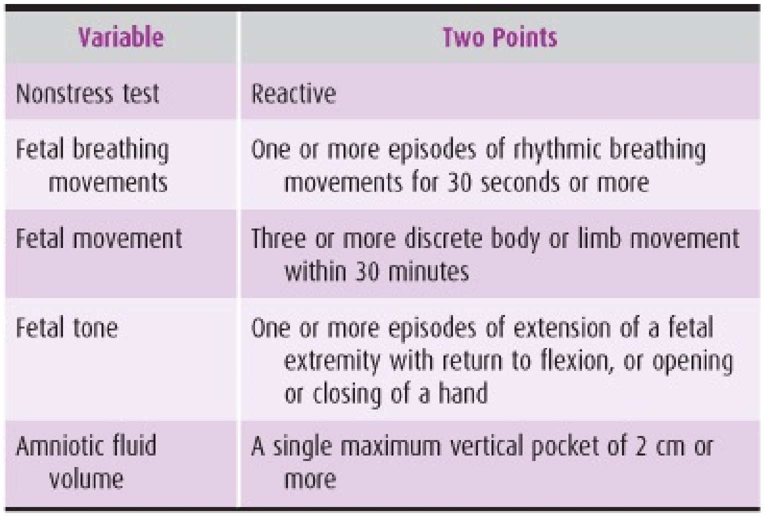
The purpose of performing fetal growth scans is to identify fetal growth abnormalities (ie, fetal growth restriction and macrosomia). Intrauterine growth restriction is usually defined as an estimated gestational age less than the 10%. It can be associated with chromosomal and nonchromosomal anomalies, infection, and placental insufficiency. Identification of these fetuses is important because growth restriction is associated with fetal demise, and increased surveillance of the growth restricted fetuses may decrease this risk. Macrosomia can be defined as an estimated fetal weight greater than 4000 or 4500 g. Identification of these fetuses can be useful because of the association of macrosomia with postpartum hemorrhage, caesarean delivery, and shoulder dystocia. However, ultrasound is not a perfect estimate of fetal growth. The error rate can be as high as 15–20% depending on the gestational age and certain maternal characteristics such as body habitus and abdominal scar tissue. Also, if ultrasounds for growth are performed more often than every 2 weeks, the margin of error may be too great to determine whether appropriate growth has occurred. (See Chapter 16 on Disproportionate Fetal Growth for more detail.)

C. Evaluation of Fetal Well-Being

The purpose of using ultrasound for fetal surveillance is to identify fetuses that are at risk for intrauterine death or severe morbidity. Ideally, this will allow interventions such as early delivery in order to prevent these complications. Patients that may benefit from fetal surveillance include those with complaints such as decreased fetal movements, who carry fetuses with intrauterine growth restriction, or with medical or fetal complications that put them at risk for intrauterine death or severe morbidity. The 2 main methods of fetal surveillance are the biophysical profile or modified biophysical profile and Doppler ultrasound.

1. Biophysical profile—The biophysical profile (BPP) was first introduced in 1980. It consists of using 4 ultrasound parameters and a nonstress test to assign a score that gives a fetus's risk of hypoxia or intrauterine death. Table 11–3 shows the scoring of the fetal BPP. A score of 8 or 10 (of a possible score of 10) is considered normal. A score of 6 is considered equivocal, and a score of 4 or less is considered abnormal. Oligohydramnios, regardless of the composite score, warrants further evaluation.

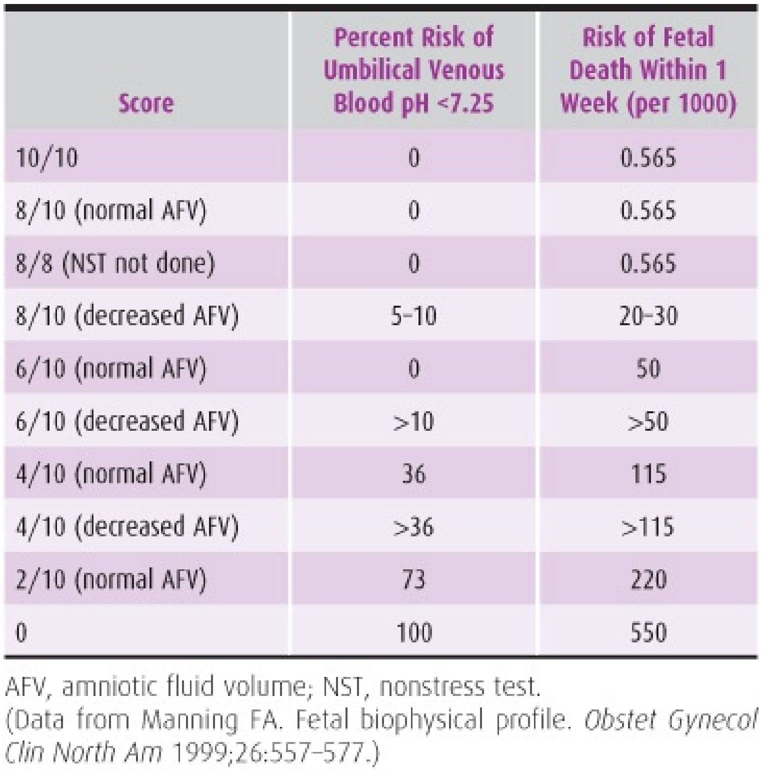
Table 11–3. Parameters of the biophysical profile.



Variable	Two Points
Nonstress test	Reactive
Fetal breathing movements	One or more episodes of rhythmic breathing movements for 30 seconds or more
Fetal movement	Three or more discrete body or limb movement within 30 minutes
Fetal tone	One or more episodes of extension of a fetal extremity with return to flexion, or opening or closing of a hand
Amniotic fluid volume	A single maximum vertical pocket of 2 cm or more

The modified BPP consists of performing a nonstress test with only an evaluation of the amniotic fluid volume as measured by the amniotic fluid index (AFI). The AFI is calculated by dividing the uterus into 4 quadrants and measuring the maximum vertical pocket of amniotic fluid in each quadrant. The theory for this is based on the idea that the nonstress test is a measure of short-term fetal status, and the AFI is a measure of long-term fetal status. The AFI can measure long-term status because placental dysfunction can cause decreased renal perfusion, which can lead to oligohydramnios. If either the nonstress test is not reactive or the amniotic fluid index is less than 5 cm, the test is considered nonreactive. The stillbirth rate within a week of testing for a normal BPP or modified BPP is approximately 0.6–0.8 per 1000, giving a negative predictive value of greater than 99.9% for both tests. Risk of adverse pregnancy outcome as correlated with BPP score is shown in Table 11–4.

Table 11–4. Interpretation of biophysical profile.



Score	Percent Risk of Umbilical Venous Blood pH <7.25	Risk of Fetal Death Within 1 Week (per 1000)
10/10	0	0.565
8/10 (normal AFV)	0	0.565
8/8 (NST not done)	0	0.565
8/10 (decreased AFV)	5-10	20-30
6/10 (normal AFV)	0	50
6/10 (decreased AFV)	>10	>50
4/10 (normal AFV)	36	115
4/10 (decreased AFV)	>36	>115
2/10 (normal AFV)	73	220
0	100	550

AFV, amniotic fluid volume; NST, nonstress test.
(Data from Manning FA. Fetal biophysical profile. *Obstet Gynecol Clin North Am* 1999;26:557–577.)

2. Fetal Doppler evaluation—Doppler ultrasound is emerging as a newer method to evaluate fetal well-being. Christian Doppler first described the Doppler effect in the 1800s as a way of describing the variation in the frequency of a light or sound wave as the source of that wave moves from a fixed point. In medicine, Doppler ultrasound is used as a measure of the speed at which blood is moving within a vessel. The 3 most common fetal arterial Dopplers are measured in the umbilical artery, middle cerebral artery, and uterine artery, whereas the most common fetal venous Doppler is measured in the ductus venosus. Umbilical artery Dopplers are a reflection of the placental circulation. As diseases begin to affect the placenta and increase resistance within the placenta, the end-diastolic flow in the umbilical artery begins to slow and eventually may become absent or even reversed.

Middle cerebral artery Dopplers work on a different principle (Fig. 11–6). In the presence of fetal hypoxemia, blood flow is redistributed to the brain, known as the brain-sparing effect. As a result, in worsening disease states, blood flow increases in the middle cerebral artery. This measurement can be used both for a general assessment of fetal well-being as well as an assessment for fetal anemia. Finally, ductus venosus Dopplers reflect cardiac compliance and cardiac afterload, which may increase with disease states that affect the placenta. Therefore, evaluation of the ductus venosus waveform can be used to assess fetal well-being.

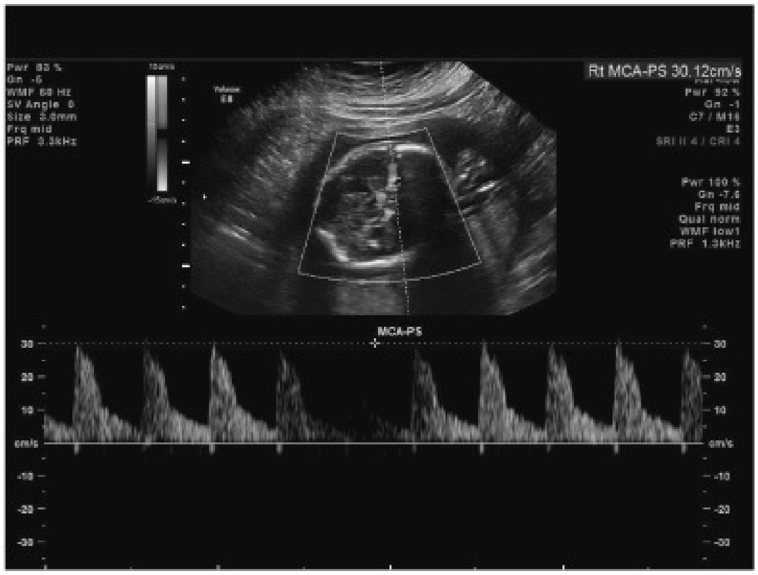


Figure 11–6. Middle cerebral artery Dopplers to screen for fetal anemia. Color Doppler is used to identify the circle of Willis. The Doppler calipers are placed on the proximal third of the middle cerebral artery at a 0-degree angle (ie, dotted line overlaps the length of the middle cerebral artery). The peak systolic velocity is measured by measuring the peak of the waveforms.

D. Placental Location

In addition to the fetus, ultrasound in the second and third trimester can be used to evaluate the placenta for placental anomalies. It is standard to evaluate the placental location during the anatomy scan or third-trimester growth ultrasound, but if there is vaginal bleeding, one may also evaluate for placental abruption.

The placenta is usually described by its location, its relationship to the internal cervical os, and its appearance. Specifically, it is important to evaluate the placenta for any evidence of placenta previa. The distance of the lower edge of the placenta is measured in relation to the internal cervical os. Using ultrasound, the relationship of the placenta to the cervix can be described in 1 of 3 ways: complete previa, marginal previa, and no evidence of previa. If the placenta or placental edge covers the internal os, it is considered a complete placenta previa. A marginal placenta previa occurs when the placental edge is within 2 cm of the internal os but does not cover it. This is clinically significant because a placenta previa is associated with antenatal and intrapartum vaginal bleeding, and it is recommended that patients with a placenta previa have a caesarean section for delivery to decrease their risk of experiencing hemorrhage.

The placenta may also be evaluated for the presence of placenta accreta, which is most commonly associated with prior uterine surgery. A placenta accreta refers to trophoblastic villi that penetrate the decidua but not the myometrium and thus result in an abnormally adherent placenta. Other abnormalities of placental attachment include placenta increta, in which the trophoblastic villi penetrate the myometrium, and placenta percreta, in which the trophoblastic villi penetrate the myometrium and uterine serosa. On ultrasound, a placenta accreta can be suspected when there are placental lacunae, thinning of the myometrium over the placenta, and loss of the retroplacental hypoechoic space among other findings. Clinically, this is relevant because a placenta accreta can prevent separation of the placenta from the uterus after delivery of the fetus. Antenatal identification of placenta accreta can be used to ensure a planned delivery with the appropriate resources, which can reduce maternal morbidity and mortality.

Finally, ultrasound of the placenta can be used to evaluate for vaginal bleeding in the pregnant patient. The most concerning causes of third-trimester vaginal bleeding are placenta previa and placental abruption. Placenta previa may be suspected in the clinical scenario of painless vaginal bleeding and as noted before can be diagnosed by ultrasound. Placental abruption is often suspected when there is painful vaginal bleeding, but the sensitivity of ultrasound in diagnosing placental abruption is low. Ultrasound can only visualize hemorrhage in approximately 50% of cases of clinical placental abruption.

Maternal Evaluation

Ultrasound is also used in pregnancy to evaluate for maternal pathology, such as uterine fibroids and ovarian cysts or masses. However, imaging of certain maternal structures also has implications for obstetrical outcomes.

A. Cervical Evaluation

Ultrasound can be used to evaluate the cervix in the pregnant patient, as the shape and length of the cervix has been shown to correlate with preterm delivery. The best way to evaluate the cervix is by using transvaginal ultrasound. The most clinically applicable measurement is that of the cervical length. This is the distance of the closed cervix from the external os along the endocervical canal to the innermost closed portion of the cervix. It is also often standard to report the presence or absence of funneling or opening of the internal os. It is also important that approximately 3–5 minutes be spent evaluating the cervix because of the potential for dynamic changes. The shortest cervical length should be reported and used for clinical management.

The specific uses of cervical length measurements are rapidly evolving, but it is important to understand some basic principles for the use of these measurements. A normal cervical length measures between 25 and 50 mm from the mid-second trimester until the third trimester. A cervical length less than or equal to 25 mm at these gestational ages can be considered abnormal or “short.” In the third trimester, there is physiologic shortening of the cervix, making the distinction between normal and abnormal more difficult. The earlier in gestation and the shorter the cervical length, the higher is the risk of preterm delivery. In Table 11–5, the risk of preterm birth by cervical length at 24 weeks is shown.

Table 11–5. Sensitivity, specificity, and predictive value of cervical length at 24 weeks of gestation for preterm birth before 35 weeks of gestation.

	Cervical Length ≤ 20 mm	Cervical Length ≤ 25 mm	Cervical Length ≤ 30 mm
Sensitivity	23.0%	37.3%	54.0%
Specificity	97.0%	92.2%	76.3%
Positive predictive value	25.7%	17.8%	9.3%
Negative predictive value	96.5%	97.0%	97.4%

(Data modified from Iams J, Goldenberg R, Meis P. The length of the cervix and the risk of spontaneous premature delivery. *N Engl J Med* 1996;334:567–572.)

Cervical length measurements can be used in the second trimester in both low- and high-risk women to evaluate the risk for preterm birth. There are now many studies evaluating different treatment options, such as progesterone or cerclage, to help prevent preterm delivery based on the length of the cervix. In the late second and third trimester, cervical length can also be assessed in the symptomatic patient to help guide the need for hospitalization or the administration of steroids.

B. Maternal Doppler Evaluation

Uterine artery Dopplers are based on the theory that the spiral arterioles of the uterine arteries are meant to be maximally dilated to ensure adequate blood flow to the uterus. Worsening disease states are associated with a waveform notch and low end-diastolic velocity from high impedance circulation in the uterine artery. There have been a number of studies that have evaluated first- and second-trimester uterine artery Dopplers as a predictor of preeclampsia and intrauterine growth restriction. The studies have shown that in combination with abnormal maternal serum analytes, uterine artery Dopplers have a high sensitivity for prediction of these outcomes. Additional research is still being conducted to identify more accurately which patients to screen and with which combination of uterine artery Dopplers and serum analytes. Currently, besides close monitoring, aspirin is the only intervention that has been shown to decrease the risk of developing these adverse outcomes. Again, however, additional research is needed to determine which patients would benefit from this therapy.

3D/4D ULTRASOUND

Up to this point, the discussion on imaging in obstetrics has been limited to 2D ultrasound. However, as technology is improving, the clinical uses of 3D and 4D ultrasound have started to be evaluated. The benefits of 3D ultrasound include improved evaluation of fetal anomalies, the ability to store information for reevaluation at a later time or by a different clinician, and improved maternal–fetal bonding. Specific fetal anomalies that have been studied with 3D include the fetal face, skeleton, neuroanatomy, and heart. 3D ultrasound not only helps to confirm a suspected anomaly seen in 2D ultrasound, but it also can help to explain findings to the parents. Figures 11–7 and 11–8 demonstrate 3D images of the fetal face. Figure 11–7 represents a normal fetal face, whereas Figure 11–8 demonstrates a fetus affected by unilateral cleft lip. Furthermore, 4D ultrasound can be used to evaluate fetal anomalies that may affect fetal movement.

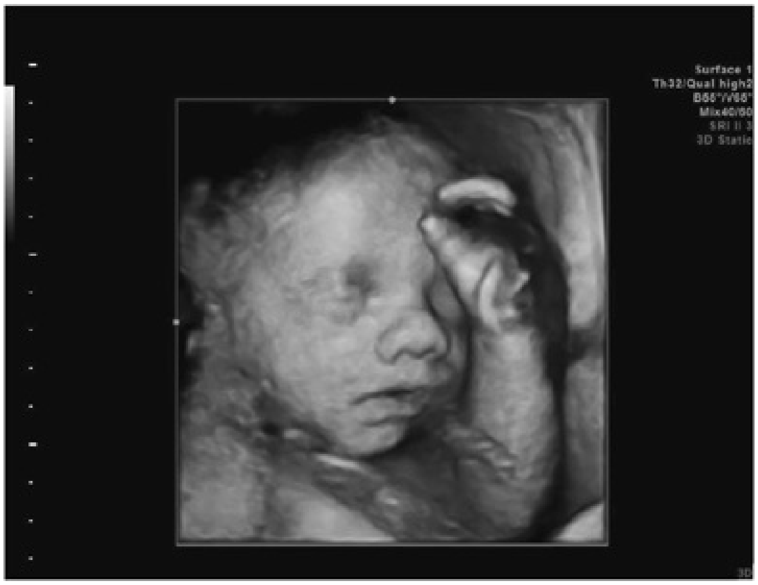

Figure 11–7. 3D ultrasound image of normal fetal face at 29 weeks' gestation. Note the intact, smooth contour of the upper lip and symmetry of the nostrils.

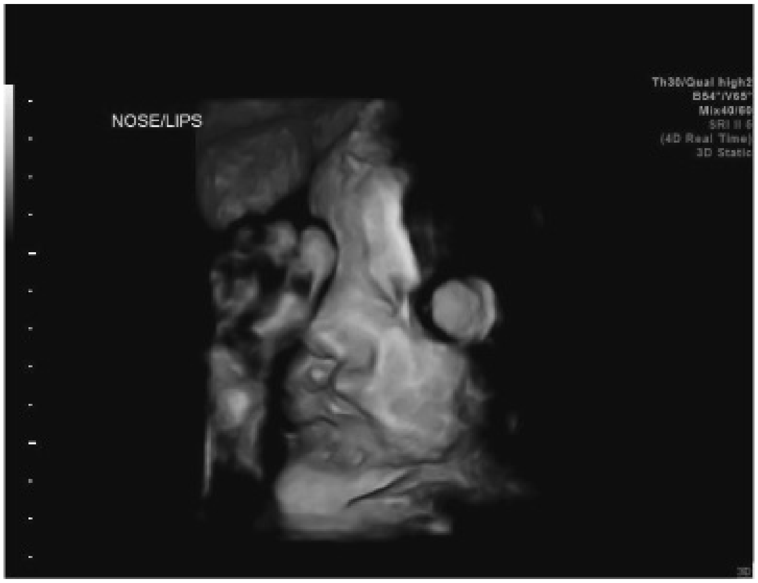

Figure 11–8. 3D ultrasound image of fetal face affected by unilateral cleft lip at 35 weeks' gestation. Note the unilateral defect in the contour of the upper lip.

MAGNETIC RESONANCE IMAGING

Although ultrasound is the primary imaging modality used in obstetrics, MRI can be beneficial in certain cases. In the second trimester, obtaining or ascertaining a diagnosis is usually the purpose of the MRI, whereas in the third trimester, delivery planning is the goal. Abnormal fetal neuroanatomy, specifically ventriculomegaly, is the most common indication for a fetal MRI. MRI has been shown to alter the diagnosis or improve the accuracy of the diagnosis in up to 50% of studies performed for suspected fetal central nervous system anomalies. MRI can also be used to evaluate other fetal anomalies, such as genitourinary, gastrointestinal, cardiac, and musculoskeletal anomalies. For example, genitourinary anomalies are often associated with oligohydramnios, which can affect the imaging quality of ultrasound. MRI, on the other hand, is not dependent on the surrounding tissue, so it can be beneficial in these cases. In addition to fetal imaging, MRI has also been shown to be helpful in evaluating the placenta. In cases of suspected placenta accreta, increta, and percreta, where ultrasound findings are equivocal or a posterior placenta limits ultrasound evaluation, MRI can be used to more accurately diagnose the suspected abnormality.

Finally, although the safety of ultrasound in obstetrics has been well established, the safety of MRI is sometimes questioned. There have been no studies linking MRI to any teratogenic effects on the fetus. However, gadolinium use is not recommended during pregnancy. Although limited studies have not shown any adverse effect on the fetus, gadolinium has been shown to cross the placenta and may have a long half-life in the fetal compartment. For these reasons, it should not be used unless the potential benefit outweighs the potential risk of unknown fetal harm.

Section III. Pregnancy at Risk

12
Assessment of At-Risk Pregnancy

Shobha H. Mehta, MD
Robert J. Sokol, MD

ESSENTIALS OF DIAGNOSIS

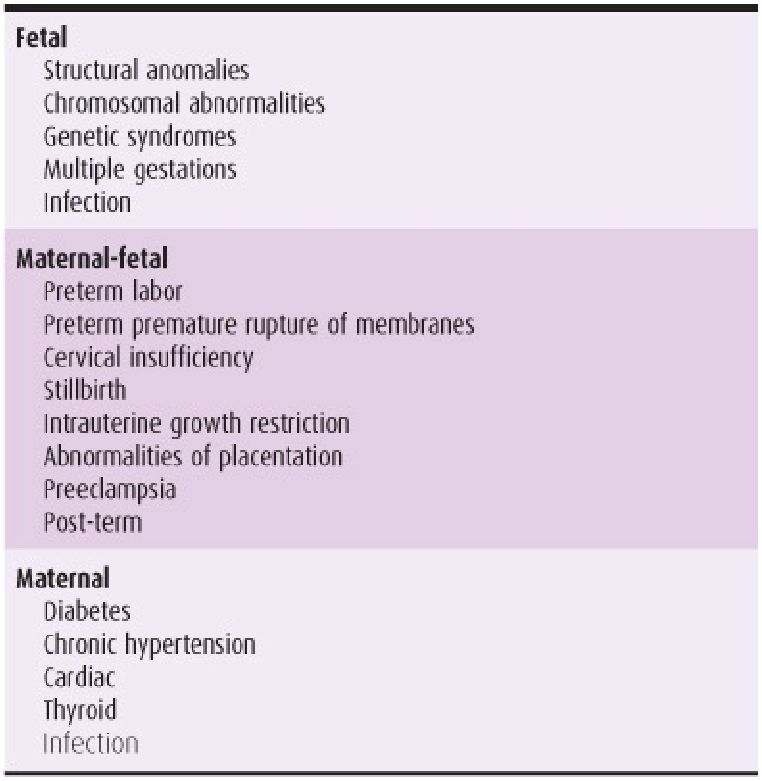
- A careful history to reveal specific risk factors
- A maternal physical examination organized to identify or exclude risk factors
- Routine maternal laboratory screening for common disorders
- Special maternal laboratory evaluations for disorders suggested by any evaluative process
- Comprehensive fetal assessment by an assortment of techniques over the entire course of the pregnancy

---

OVERVIEW

High-risk pregnancy is broadly defined as one in which the mother, fetus, or newborn is, or may possibly be, at increased risk of morbidity or mortality before, during, or after delivery. Factors that may lead to this increased risk include maternal health, obstetric abnormalities, and fetal disease. Table 12–1 provides an overview of some major categories that comprise a high-risk pregnancy.

Table 12–1. Major categories of high-risk pregnancies.



Fetal
Structural anomalies
Chromosomal abnormalities
Genetic syndromes
Multiple gestations
Infection
Maternal-fetal
Preterm labor
Preterm premature rupture of membranes
Cervical insufficiency
Stillbirth
Intrauterine growth restriction
Abnormalities of placentation
Preeclampsia
Post-term
Maternal
Diabetes
Chronic hypertension
Cardiac
Thyroid
Infection

The purpose of this chapter is to outline basic and essential aspects of diagnostic modalities available for determination of pregnancies at risk that can be used in practice in a rational manner.

The incidence of high-risk pregnancy varies according to the criteria used to define it. A great many factors are involved, and the effects of any given factor differ from patient to patient. Outcomes can include mortality of the mother and/or the fetus/neonate. Leading causes of maternal death include thromboembolic disease, hypertensive disease, hemorrhage, infection, and ectopic pregnancy. The leading causes of infant mortality (death from birth to 1 year of age) are congenital malformations and prematurity-related conditions. Although there is variation in definition depending on the resource, a perinatal death is one that occurs at any time after 28 weeks' gestation through the first 7 days after delivery. The perinatal mortality rate is the number of perinatal deaths per 1000 live births. Preterm birth is the leading cause of perinatal morbidity and neonatal mortality.

In assessing pregnancies to determine risk, several key concepts may offer tremendous insight. Human reproduction is a complex social, biochemical, and physiologic process that is not as successful as once thought. Approximately half of all conceptions are lost before pregnancy is even recognized. Another 15–20% are lost in the first trimester. Of this latter group, more than half have abnormal karyotypes and defy current methodologies for prevention of loss. However, many other causes of reproductive loss are amenable to diagnosis and treatment. In this chapter we discuss the indications and justifications for antepartum care and intrapartum management.

PRECONCEPTION CARE

Preconception evaluation and counseling of women of reproductive age has gained increasing acceptance as an important component of women's health. Care given in family planning and gynecology centers provides a potential opportunity to maximize maternal and fetal health benefits before conception. Issues of potential consequence to a pregnancy, such as medical problems, lifestyle (eg, substance abuse, weight, exercise), or genetic issues should be investigated and interventions devised before pregnancy. Specific recommendations include folic acid for the prevention of fetal neural tube defects (0.4 mg/d), strict blood sugar control in diabetic women, general management of any medical problems in the mother, avoidance of known teratogenic medications, and smoking cessation.

PRENATAL PERIOD

Initial Screening

The initial prenatal visit is important in evaluation and assessment of risk during the pregnancy and should take place as early in the pregnancy as possible, preferably in the first trimester. Information of vital importance includes maternal medical and obstetric history, physical examination, and key laboratory findings.

A. Maternal Age

Extremes of maternal age increase risks of maternal or fetal morbidity and mortality. Adolescents are at increased risk for preeclampsia–eclampsia, intrauterine growth restriction, and maternal malnutrition.

Women of increasing age at the time of delivery are at higher risk for preeclampsia, diabetes, and obesity, as well as other medical conditions. An increased risk of caesarean section, stillbirth, and placenta accreta are noted in women with advanced maternal age.

The risk of fetal aneuploidy increases with increasing age; the American College of Obstetricians and Gynecologists (ACOG), however, has recommended that maternal age of 35 years no longer be used as a cutoff to determine who is offered screening and who is offered invasive testing. Instead, patient counseling regarding options followed by maternal serum screening, ultrasound, and/or invasive testing, depending on patient’s wishes, should occur.

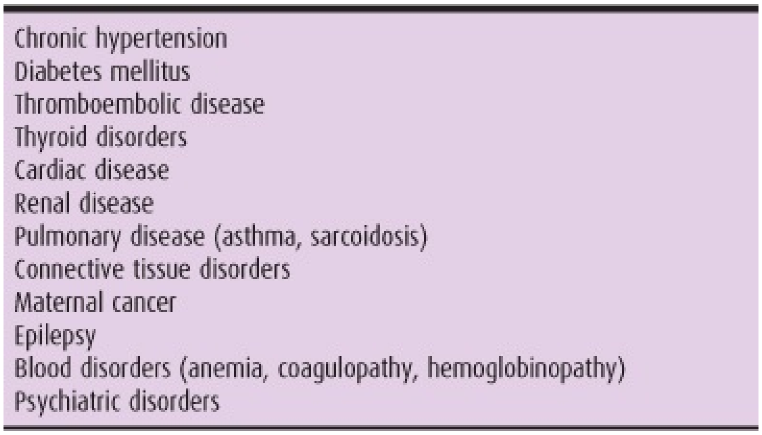
B. Modality of Conception

It is important to differentiate spontaneous pregnancy from that resulting from assisted reproductive technologies (ART). Use of ART increases the risks of perinatal mortality (both stillbirths and early neonatal deaths), multifetal gestation, preterm birth (both singletons and multiples), congenital anomalies, and low birth weight.

C. Past Medical History

Many medical disorders can complicate the pregnancy course for the mother and thus the fetus. It is important that these diseases and their severity be addressed before conception if possible. During pregnancy, the patient may require aggressive management and additional visits and testing to follow the course of the disease, in addition to possible consultation or management of a high-risk specialist. Table 12–2 lists some of the most important disorders that may complicate pregnancy.

Table 12–2. Some maternal diseases, disorders, and other complications of pregnancy.



Chronic hypertension
Diabetes mellitus
Thromboembolic disease
Thyroid disorders
Cardiac disease
Renal disease
Pulmonary disease (asthma, sarcoidosis)
Connective tissue disorders
Maternal cancer
Epilepsy
Blood disorders (anemia, coagulopathy, hemoglobinopathy)
Psychiatric disorders

D. Family History

A detailed family history is helpful in determining any increased risk of heritable disease states (eg, Tay-Sachs, cystic fibrosis, sickle cell disease) that may affect the mother or fetus during the pregnancy or the fetus after delivery. Other relevant findings includes family history of thromboembolism, birth defects (particularly cardiac anomalies), and medical history of first-degree relatives (particularly diabetes).

E. Ethnic Background

Population screening for certain inheritable genetic diseases is not cost effective because of the relative rarity of those genes in the general population. However, many genetic diseases affect certain ethnicities in disproportionate amounts, allowing cost-effective screening of those particular groups. Table 12–3 lists several common inheritable genetic diseases for which screening is possible. It includes the group at risk as well as the method of screening.

Table 12–3. Common inheritable genetic diseases.

Disease	Population at Increased Risk	Method of Testing
Alpha thalassemia	Chinese, Southeast Asian, African	CBC Hemoglobin electrophoresis Mutation analysis
β thalassemia	Chinese, Southeast Asians, Mediterraneans, Pakistanis, Bangladeshis, Middle Easterners, African	CBC Hemoglobin electrophoresis
Bloom's syndrome	Ashkenazi Jews	Mutation analysis
Canavan's disease	Ashkenazi Jews	Mutation analysis
Cystic fibrosis	North American Caucasians of European ancestry, Ashkenazi Jews	Mutation analysis
Familial dysautonomia	Ashkenazi Jews	Mutation analysis
Fanconi's anemia	Ashkenazi Jews	Mutation analysis
Gaucher's disease	Ashkenazi Jews	Mutation analysis
Niemann-Pick disease	Ashkenazi Jews	Mutation analysis
Sickle cell disease and other structural hemoglobinopathies	African Americans, Africans, Hispanics, Mediterranean, Middle Easterners, Caribbean Indians	CBC Hemoglobin electrophoresis
Tay-Sachs	Ashkenazi Jews, French Canadians, Cajuns	Enzyme and mutation analysis

CBC, complete blood cell count.

F. Past Obstetric History

1. Recurrent abortion—A diagnosis of recurrent abortion is made after 3 or more consecutive spontaneous losses of a pregnancy before 20 weeks' gestation. Recurrent abortion is best investigated before another pregnancy occurs; workup can be initiated after 2 losses. If the patient is currently pregnant, however, as much of the workup as possible should be performed.

- Karyotype of abortus specimen
- Parental karyotype
- Survey for cervical and uterine anomalies
- Screening for hormonal abnormalities (ie, hypothyroidism)
- Infectious disease evaluation of the genital tract

The association between inherited thrombophilias and recurrent pregnancy loss is unclear; thus the testing for these is currently not recommended in the clinical setting. Screening for antiphospholipid antibodies (acquired thrombophilia) may be appropriate.

2. Previous stillbirth or neonatal death—A history of previous stillbirth or neonatal death should trigger an immediate investigation regarding the conditions or circumstances surrounding the event. If the demise was the result of a nonrecurring event, such as cord prolapse or traumatic injury, then the present pregnancy has a risk approaching the background risk. However, stillbirth or neonatal death may suggest a cytogenetic abnormality, structural malformation syndrome, or fetomaternal hemorrhage. Review of records, including autopsy, placental pathology, and karyotype if obtained, is vital. As with fetal loss, the association of unexplained stillbirth with inherited thrombophilias is unclear and testing is not recommended, although a maternal thrombophilia workup may be considered with stillbirth in the setting of severe placental thrombosis or infarcts, significant fetal growth restriction, or in the patient with a history of thrombosis.

3. Previous preterm delivery—A history of preterm birth confers an increased risk of early delivery in subsequent pregnancies. Furthermore, the risk of a subsequent pre-term birth increases as the number of prior preterm births increases, and the risk decreases with each subsequent birth that is not preterm. The recurrence risk also rises as the gestational age of the previous preterm delivery decreases. Despite intense investigation, the incidence of preterm delivery has slightly increased in the United States, due in large measure to medical intervention producing indicated preterm deliveries. Eighty-five percent of preterm deliveries occur between 32 and 36 6/7 weeks, and they carry minimal fetal or neonatal morbidity. The remaining 15% of preterm deliveries, however, account for nearly all of the perinatal morbidity and mortality. Common causes of perinatal morbidity in premature infants include respiratory distress syndrome, intraventricular hemorrhage, bronchopulmonary dysplasia, necrotizing enterocolitis, sepsis, apnea, retinopathy of prematurity, and hyperbilirubinemia. Preterm deliveries can be divided into 2 types: spontaneous and indicated, with indicated preterm deliveries caused by medical or obstetric disorders that place the mother and/or fetus at risk. The clinical risk factors most often associated with spontaneous preterm birth include history of previous preterm birth, genital tract infection, nonwhite race, multiple gestation, bleeding in the second trimester, and low prepregnancy weight. Recent multicenter trials have shown that progesterone in the form of 17α-hydroxyprogesterone caproate, given as weekly injections of 250 mg beginning in the second trimester, can decrease the risk of preterm delivery in patients with a history of prior spontaneous preterm delivery.

4. Rh alloimmunization or ABO incompatibility—All pregnant patients should undergo an antibody screen at the first prenatal visit. Those patients who are Rh (D)–negative with no evidence of anti-D alloimmunization should receive Rh (D) immunoglobulin (RhoGAM; Ortho-Clinical Diagnostics, Rochester, NY) 300 μg at 28 weeks of gestation. Patients who are Rh (D) sensitized can be followed with maternal titers and/or amniocentesis for fetal blood typing, followed by either serial amniocentesis for ΔOD_{450} or serial middle cerebral artery peak systolic velocity measurements, as well as fetal blood sampling via cordocentesis.

5. Previous preeclampsia–eclampsia—Previous preeclampsia–eclampsia increases the risk for hypertension in the current pregnancy, especially if underlying chronic hypertension or renal disease is present.

6. Previous infant with genetic disorder or congenital anomaly—A woman with a previous history of a fetus with a chromosomal abnormality is a frequent indication of cytogenetic testing, although this may be preceded by first- or second-trimester screening and anatomy ultrasound (US). The rate of recurrence depends on the abnormality.

7. Teratogen exposure—A teratogen is any substance, agent, or environmental factor that has an adverse effect on the developing fetus. Whereas malformations caused by teratogen exposure are relatively rare, knowledge of exposure can aid in the diagnosis and management.

A. DRUGS—Alcohol, antiseizure medications (phenytoin, valproic acid, etc.), lithium, mercury, thalidomide, diethylstilbestrol (DES), warfarin, isotretinoin, and so forth.

B. INFECTIOUS AGENTS—Cytomegalovirus, *Listeria*, rubella, toxoplasmosis, varicella, *Mycoplasma*, and so forth.

C. RADIATION—It is believed that medical diagnostic radiation delivering less than 0.05 Gy (5 rad) to the fetus has no teratogenic risk.

Physical Examination

Physical examination is important not only during the initial visit, but also throughout the pregnancy. Collection of maternal height and weight information allows for calculation of maternal body mass index, useful in risk assessment for many pregnancy abnormalities. In addition, weight gain is followed throughout the pregnancy, also a useful parameter for several risk factors in pregnancy. Vital sign abnormalities can lead to the diagnosis of many key obstetric complications. Fever, defined as a temperature of 100.4°F or greater, can be a sign of chorioamnionitis. Signs or symptoms of chorioamnionitis should be assessed, and, if chorioamnionitis is suspected, amniocentesis for microscopy and culture should be considered. Depending on clinical correlation, delivery may be necessary. Maternal tachycardia can be a sign of infection, anemia, or both. Isolated mild tachycardia (>100 beats/min) should be evaluated and followed up, as should maternal tachyarrhythmias. Maternal heart rate is noted to increase normally in pregnancy, however. The normal pattern of maternal blood pressure readings is a decrease from baseline during the first trimester, reaching its nadir in the second trimester, and slightly rising in the third trimester, although not as high as the baseline levels. Repeated blood pressure readings of 140/90 mm Hg taken 6 hours apart should be considered evidence of preeclampsia or gestational hypertension. Increases in systolic and diastolic blood pressure, although no longer part of the definition, may also be an indication of development of pregnancy-related hypertensive disease. The rest of the physical examination should be performed during the initial visit and focused examination during each visit. Fundal height measurements and fetal heart tone checks should also be performed.

Urinalysis

At the first prenatal visit, a clean-catch urine culture and sensitivity should be performed. Any growth should be treated with the appropriate antibiotics. At all subsequent visits, urine dipstick testing to screen for protein, glucose, leukocyte esterase, blood, or any combination of markers is useful in identifying patients with a change in baseline urinary composition.

Screening Tests

Screening tests during the initial visit include testing for rubella, rapid plasma reagin, hepatitis B, blood type, HIV, gonorrhea, and *Chlamydia*, and Pap smear.

ANTEPARTUM MANAGEMENT

Genetic Testing

A. First-Trimester Screening

Nuchal translucency, measured between 11(0/7) and 13(6/7) weeks, combined with maternal serum free β-human chorionic gonadotropin (β-hCG) and pregnancy-associated plasma protein-A levels, has been found to have 87.0% sensitivity for detection of trisomy 21, with a 5% false-positive rate. In the absence of chromosomal abnormalities, an increased nuchal translucency is associated with an increased risk of structural cardiac abnormalities and skeletal dysplasias, and so forth. Further US findings in the first trimester, including absence of nasal bone and abnormal ductus venosus Doppler findings, may further improve the detection rate for aneuploidy but require a high level of sonographic skill. Patients with an abnormal screening result can be offered invasive testing such as chorionic villus sampling for more accurate detection of fetal aneuploidy. The advantage of the first-trimester screen (as opposed to second-trimester maternal screening, discussed next) is that it allows for earlier detection of aneuploidy.

B. Second-Trimester Maternal Serum Screening

Frequently known as the "triple screen," this test includes maternal serum α-fetoprotein (MSAFP), β-hCG, and estriol. In some institutions, only the MSAFP is used, whereas in other institutions, a fourth test for inhibin is included, making it a "quad test." The usefulness of this screen is its ability to identify pregnancies at increased risk for open neural tube defects, as well as for certain chromosomal abnormalities, especially trisomy 21 (70% sensitivity for Down syndrome detection). This test is effective at 15–22 weeks' gestation and therefore can identify an at-risk pregnancy in time to pursue more definitive diagnosis, if desired. It is important to note, however, that maternal serum screening is not a definitive test and must be followed by invasive testing (discussed later) for karyotype determination.

The first- and second-trimester screen should not both be ordered independently during a pregnancy; this approach leads to unacceptably high false-positive rates for aneuploidy. Approaches have been developed, however, that allow for both tests to be used in combination to determine aneuploidy risk. One such approach is integrated aneuploidy screening, in which a single risk assessment is calculated using all 6 analytes after completion of both tests. Integrated screening has a Down syndrome detection rate of 95%, with a 5% false-positive rate. One major drawback is the withholding of information until the second trimester, precluding the benefits of early diagnosis and chorionic villus sampling. Another approach is stepwise sequential screening, which presents patients with risk-assessment results after completion of the first-trimester component and then again after the second-trimester blood draw. With this test, the detection rate for Down syndrome is 95%, with a 5% false-positive rate. Combined sequential screening is similar, but patients with a very low first-trimester risk do not have second-trimester analysis performed.

C. Screening for Carriers of Genetic Disease

Screening for sickle cell disease should be offered to individuals of African and African American descent and those from the Mediterranean basin, the Middle East, and India. Hemoglobin electrophoresis is the definitive test to determine the carrier status of sickle cell disease as well as other hemoglobinopathies.

Cystic fibrosis carrier screening should be discussed with all patients. Carrier rates, however, are highest in Caucasians, including parents of Eastern European Jewish (or Ashkenazi Jewish) descent. Furthermore, the detection rate of known mutations is highest in these groups and is lower in other groups. For instance, Asian Americans have a cystic fibrosis carrier rate of 1 in 94, and the detection rate of testing in this population is 49%. Current guidelines recommend offering information regarding testing to all groups but counseling lower-risk groups of the limitations of the testing.

Given the higher prevalence of other recessive genetic diseases among individuals of Ashkenazi Jewish descent, carrier screening should be offered for Tay-Sachs disease, Canavan's disease, and familial dysautonomia. Screening is also available for mucolipidosis IV, Niemann-Pick disease type A, Fanconi's anemia group C, Bloom's syndrome, and Gaucher's disease and may be considered in this population.

Preterm Labor Detection

Many patients present throughout pregnancy with signs and symptoms of preterm labor, specifically uterine contractions. Although the cost of missing true preterm labor is high, many patients are not in true labor, and the financial cost of aggressive management of these patients is also high. The accurate diagnosis of preterm labor may be aided by 2 screening tests: cervical length measurement and fetal fibronectin.

Gestational Diabetes Screening

Although recent consensus groups have recommended screening for gestational diabetes based on risk factors, many studies have shown this to be inadequate for detecting patients with gestational screening versus universal screening.

Routine screening consists of performing a glucose challenge test between 24 and 28 weeks. The test consists of a 50-g oral glucose load with a plasma glucose level drawn exactly 1 hour after. If the value is 140 mg/dL or over, a more specific glucose tolerance test (GTT) should be performed (the cutoff may be lowered to 130 mg/dL to improve sensitivity). The GTT involves obtaining a fasting plasma glucose level, giving a 100-g oral glucose load, then drawing plasma levels at 1 hour, 2 hours, and 3 hours after the glucose load. A test is considered positive for gestational diabetes if 2 of the 4 values are elevated. The thresholds proposed by Carpenter and Coustan are currently favored (fasting >95 mg/dL, 1 hour >180 mg/dL, 2 hour >155 mg/dL, 3 hour >140 mg/dL).

Group B Streptococcus

Group B streptococcus (GBS) asymptomatically colonizes between 10% and 30% of pregnant women, but perinatal transmission can result in a severe and potentially fatal neonatal infection. The current GBS testing protocol emphasizes the importance of culture screening and treatment over risk factor–based screening. For this reason, patients should be screened with a rectovaginal culture at 35–37 weeks. If the culture is positive, patients should be treated with intrapartum antibiotics. Intrapartum antibiotic prophylaxis has been shown to decrease the risk of perinatal GBS transmission. If the culture result is unknown, patients should be treated if in preterm labor, with rupture of membranes greater than or equal to 18 hours, or maternal fever greater than 100.4°F during labor. All patients with GBS bacteriuria during the pregnancy or a previous neonate with GBS sepsis should be treated with intrapartum antibiotics.

FETAL ASSESSMENT

Performed during all trimesters, the techniques used are diverse, and the information obtained varies according to the quality of imaging, depth of investigation, and gestational age of pregnancy.

Ultrasound

Ultrasound (US) has evolved continuously over the last 30 years, with better equipment produced each year. Real-time sonography allows a 2-dimensional (2-D) image to demonstrate fetal anatomy, as well as characteristics such as fetal weight, movement, volume of amniotic fluid, and structural anomalies, such as myomas or placenta previa that may affect the pregnancy. Three-dimensional sonography allows volume to be ascertained, creating a 3-D–appearing image on the 2-D screen, which assists in identifying and clarifying certain anatomic anomalies. Most recently, 4-D machines have been developed, which produce 3-D video in real time. As the machines become more technically advanced and the computers that run them become faster, the images obtained will continue to improve and push the boundaries of sonographic prenatal diagnosis.

Diagnostic US is widely used in the assessment of the pregnancy and the fetus and offers a more than 80% detection rate of anomalies in experienced centers. The benefits and limitations of US should be discussed with all patients, and the decision to perform a US rests jointly with the physician and the patient.

A **standard** US examination should provide information such as fetal number, presentation, documentation of fetal viability, assessment of gestational age, amniotic fluid volume, placental location, fetal biometry, and an anatomic survey of the fetus(es). A **limited** US examination is a goal-directed search for a suspected problem or finding. A limited US can be used for guidance during procedures such as amniocentesis or external cephalic version, assessment of fetal well-being, or documentation of presentation or placental location intrapartum. A **specialized** US examination is performed when an anomaly is suspected based on history, biochemical abnormalities, or results of either the limited or standard scan. Other specialized examinations include fetal Doppler, biophysical profile (BPP), fetal echo-cardiogram, or additional biometric studies.

US evaluation of fetal anatomy may detect major structural anomalies. Gross malformations such as anencephaly and hydrocephaly are commonly diagnosed and rarely missed; however, more subtle anomalies such as facial clefts, diaphragmatic hernias, and cardiac defects are more commonly reported to have been missed by US. The basic fetal anatomy survey should include visualization of the cerebral ventricles, 4-chamber view of the heart, and examination of the spine, stomach, urinary bladder, umbilical cord insertion site, and renal region. Any indication of an anomaly should be followed by a more comprehensive sonogram. Typically, the fetal anatomic survey is performed at 17–20 weeks; however, there is controversy regarding the potential benefits of an earlier sonogram at 14–16 weeks using the transvaginal probe. The earlier scan allows earlier detection of anomalies that are almost always present by the second trimester, as well as allowing greater detailed viewing of the fetal anatomy by using the higher resolution vaginal transducers.

Aneuploidy Screening

Multiple second-trimester sonographic findings associated with aneuploidy or "markers" of aneuploidy have been identified. The presence of single or multiple markers adjusts the patient's age-related risk of aneuploidy based on the particular markers present. Such sonographic findings include, but are not limited to:

- Echogenic intracardiac focus
- Choroid plexus cysts
- Pyelectasis
- Echogenic bowel
- Short femur
- Increased nuchal fold

Chorionic Villus Sampling

Chorionic villus sampling (CVS) is an invasive test performed between 9 and 13 weeks' gestation and can be performed either transcervically or transabdominally. CVS is performed under sonographic guidance with the passing of a sterile catheter or needle into the placental site. Chorionic villi are aspirated and undergo cytogenetic analysis. The benefit of CVS over amniocentesis is its availability earlier in pregnancy. The overall pregnancy loss rate is higher than that of midtrimester amniocentesis, likely as a result of the increased background rate of spontaneous pregnancy loss between 9 and 16 weeks; limited data suggest that procedure-related loss rate for CVS appears to approach the rate of midtrimester amniocentesis. One disadvantage of CVS is that, unlike amniocentesis, it does not allow diagnosis of neural tube defects.

Amniocentesis

Amniocentesis is also performed under the guidance of ultrasonography. A needle is inserted transcutaneously through the maternal abdominal wall into the amniotic cavity, and fluid is removed. There are many uses for this amniotic fluid. In the early second trimester, these include AFP evaluation for neural tube defect assessment and the most common indication of cytogenetic analysis. In this case, amniocentesis is often performed between 15 and 20 weeks' gestation, and fetal cells from the amniotic fluid are obtained. Risks associated with the procedure are considered to be very low, with the risk of abortion as a result of amniocentesis considered to be between 1 in 200 to 1 in 450 amniocenteses.

Amniocentesis also provides a useful tool later in pregnancy, at low risk, for diagnosis of intra-amniotic inflammation and infection as a risk factor for preterm labor and adverse outcome, as well as documentation of fetal lung maturity.

Fetal Blood Sampling

Also referred to as cordocentesis or percutaneous umbilical blood sampling, fetal blood sampling is an option for chromosomal or metabolic analysis of the fetus. Benefits of the procedure include a rapid result turnaround and the ability to perform the procedure in the second and third trimesters. Intravascular access to the fetus is useful for assessment and treatment of certain fetal conditions such as Rh sensitization and alloimmune thrombocytopenia. However, there is a higher risk of fetal death compared with the other methods. Fetal loss rates are approximately 2%, but can vary depending on the fetal condition involved.

ANTEPARTUM FETAL TESTING

Fetal Movement Assessment

A decrease in maternal perception of fetal movement can precede fetal death, sometimes by several days. Perception of 10 distinct movements in a period of up to 2 hours is considered reassuring; if fewer, patients are often advised to undergo further testing.

Nonstress Test

Fetal movements associated with accelerations of fetal heart rate (FHR) provide reassurance that the fetus is not acidotic or neurologically depressed. A reactive and therefore reassuring nonstress test (NST) is defined as 2 or more FHR accelerations, at least 15 beats/min above the baseline and lasting at least 15 seconds within a 20-minute period. Vibroacoustic stimulation can elicit FHR accelerations that can reduce overall testing time without compromising detection of an acidotic fetus. In the case of a nonreassuring NST, further evaluation or delivery depends on the clinical context. In a patient at term, delivery is warranted. Pregnancy remote from term poses a more challenging dilemma to the clinician. If resuscitative efforts are not successful in restoring reactivity to the NST, then ancillary tests or testing techniques may prove useful in avoiding a premature iatrogenic delivery for nonreassuring FHR patterns, as the false-positive rate may be as high as 50–60%.

Biophysical Profile

The biophysical profile (BPP) is another way to assess fetal well-being. The BPP is composed of 5 components: NST, fetal breathing movements (30 seconds or more in 30 minutes), fetal movement (3 or more in 30 minutes), fetal tone (extension/flexion of an extremity), and amniotic fluid volume (vertical pocket of 2 cm or more). Each component is worth 2 points; a score of 8 or 10 is normal, 6 is equivocal, and 4 or less is abnormal. A BPP score of 10/10 or 8/10 with normal amniotic fluid volume is associated with a low risk of fetal asphyxia in the following week (approximately 1 per 1000).

Modified Biophysical Profile

Modified BPP combines NST, a short-term indicator of fetal acid–base status, with amniotic fluid index (AFI), a long-term indicator of placental function. AFI is measured by dividing the uterus into 4 equal quadrants and measuring the largest vertical pocket in each quadrant; the results are then summed and expressed in millimeters. The modified BPP has become a primary mode of antepartum fetal surveillance; a nonreactive NST or an AFI less than 50 mm (oligohydramnios) requires further fetal assessment or intervention.

Contraction Stress Test

The contraction stress test (CST) is based on the response of FHR to uterine contractions, with the premise that fetal oxygenation will be worsened during contractions. This can result in late decelerations in an already suboptimally oxygenated fetus. The test requires 3 contractions in 10 minutes to be adequate for interpretation. A positive or abnormal test is defined as late decelerations occurring with more than half of the contractions. A test is considered to be suspicious or equivocal if any late decelerations are seen (with fewer than 50% of contractions) and negative with no late decelerations. Contraindications to CST include any contraindications to labor, such as placenta previa or prior classic caesarean section. This test is now rarely used.

Growth Ultrasound

Growth US studies, performed every 3–4 weeks, are useful for assessment of fetuses that may be at risk for growth restriction secondary to medical conditions of pregnancy or fetal abnormalities.

Doppler Studies

Fetal Doppler studies initially were used to assess the placenta by evaluation of umbilical artery outflow. They have since evolved to a more comprehensive multivessel evaluation of fetal status. Doppler studies can be used to assess a compromised fetus (particularly the growth-restricted fetus) and may function as a diagnostic tool that alerts the clinician to the need for further intervention, including BPP, continuous fetal monitoring, or possibly delivery. In addition, the peak systolic velocity of the middle cerebral artery is used to assess fetal anemia in cases of alloimmunization and parvo-virus infection.

Fetal Maturity Tests

A. Indications for Assessing Fetal Lung Maturity

ACOG has recommended that fetal pulmonary maturity should be confirmed before elective delivery before 39 weeks' gestation unless fetal maturity can be inferred from any of these criteria: fetal heart tones have been documented for 20 weeks by nonelectronic fetoscope or for 30 weeks by Doppler; 36 weeks have elapsed since a serum or urine hCG-based pregnancy test was reported to be positive; US measurement of crown–rump length at 6–11 weeks of gestation or measurements at 12–20 weeks support a gestational age equal to or greater than 39 weeks. For those patients for whom delivery is mandated by fetal or maternal indications, testing of fetal lung maturity should not be performed, nor does a mature fetal lung maturity result before 39 weeks' gestation indicate delivery in the absence of appropriate clinical circumstances

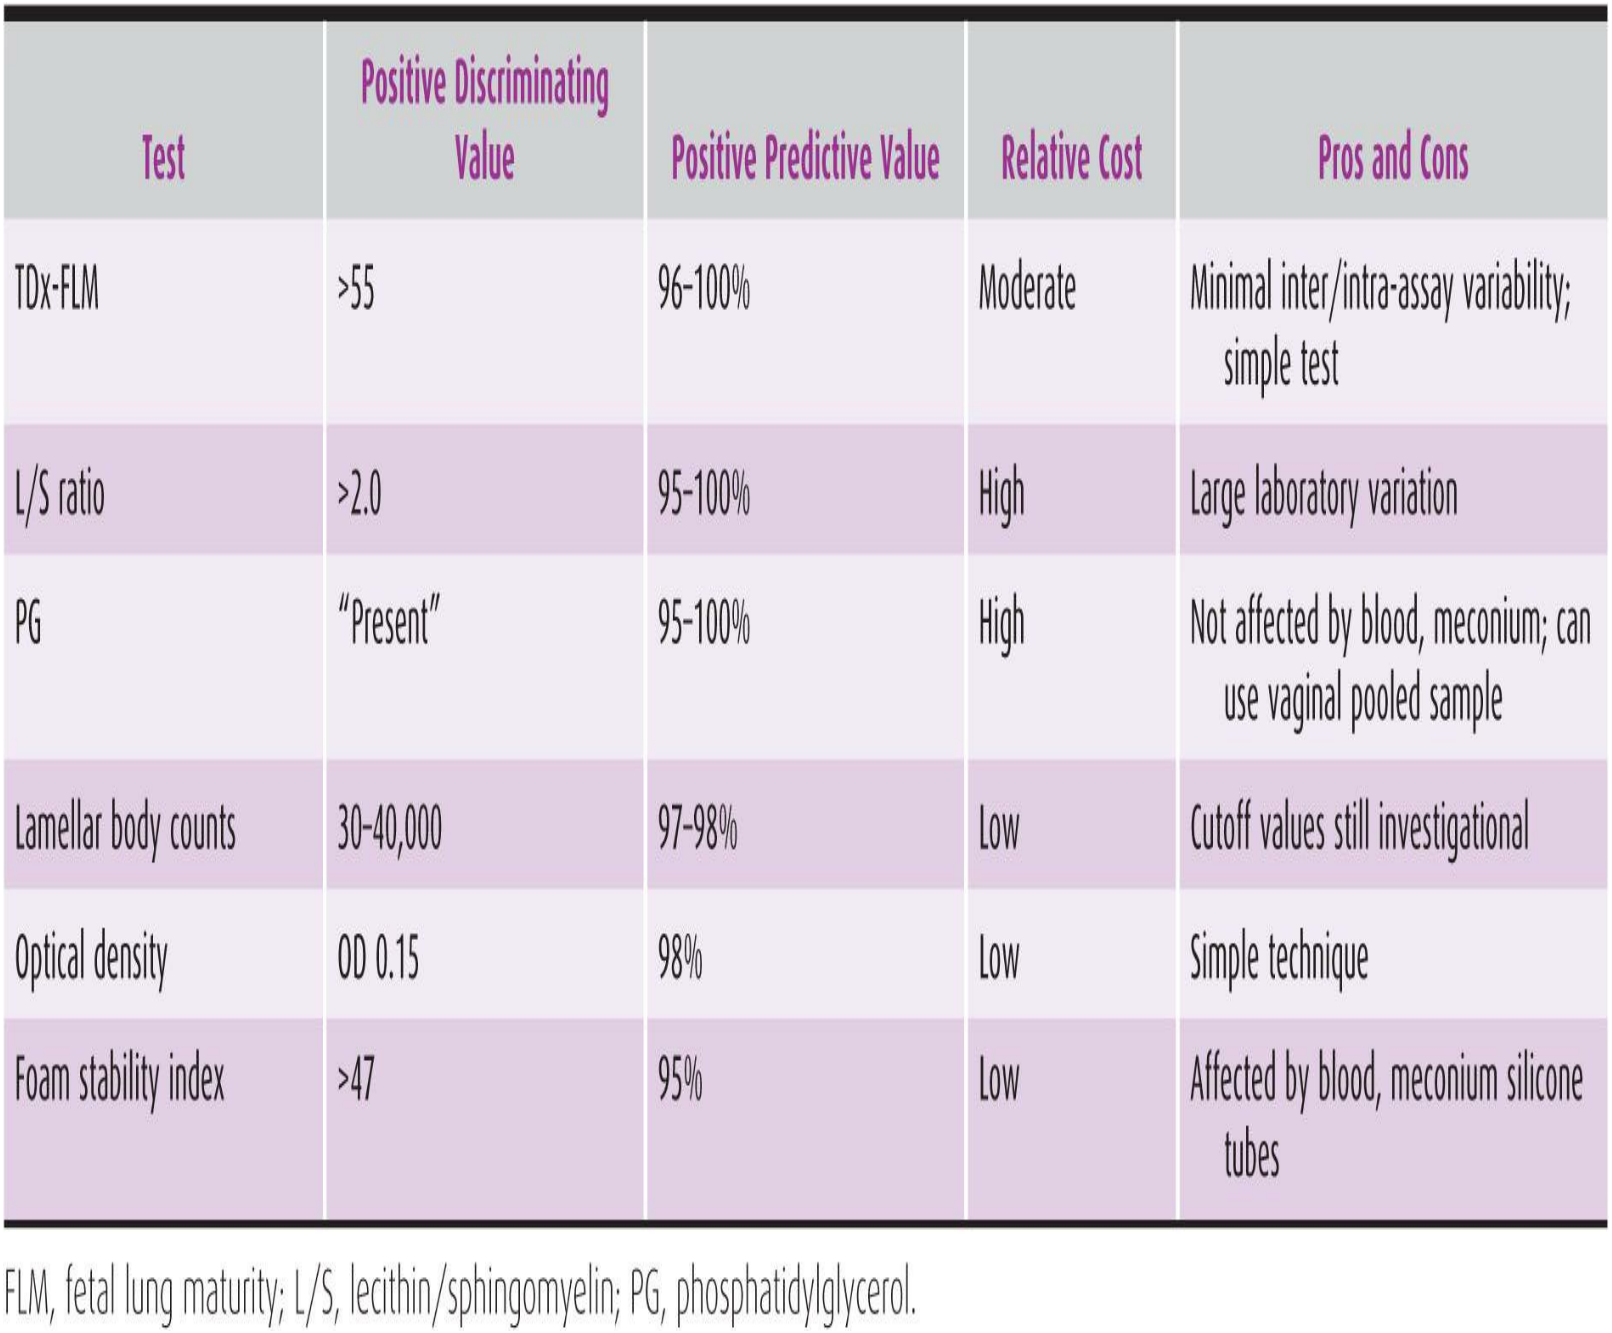
1. Lecithin/sphingomyelin ratio—The lecithin/sphingomyelin (L/S) ratio for assessment of fetal pulmonary maturity was first introduced by Gluck and colleagues in 1971. The test depends on outward flow of pulmonary secretions from the lungs into the amniotic fluid, thereby changing the phospholipid composition of the latter and permitting measurement of the L/S ratio in a sample of amniotic fluid. In the absence of complications, the ratio of these 2 components reaches 2.0 at approximately 35 weeks. The presence of blood or meconium may interfere with test interpretation.

2. Phosphatidylglycerol—Phosphatidylglycerol (PG) is a minor constituent of surfactant. It begins to increase appreciably in amniotic fluid several weeks after the rise in lecithin. Its presence is more indicative of fetal lung maturity because PG enhances the spread of phospholipids on the alveoli.

3. Fluorescence polarization—The fluorescence polarization test, currently the most widely used test, uses polarized light to quantitate the competitive binding of a probe to both albumin and surfactant in amniotic fluid; thus it is a true direct measurement of surfactant concentration. It reflects the ratio of surfactant to albumin and is measured by an automatic analyzer, such as the TDx-FLM. An elevated ratio has been correlated with the presence of fetal lung maturity; the threshold for maturity is 55 mg of surfactant per gram of albumin.

Table 12–4 lists all fetal maturity tests available, discriminating levels, and specific characteristics of the tests.

Table 12–4. Fetal maturity tests.



Test	Positive Discriminating Value	Positive Predictive Value	Relative Cost	Pros and Cons
TDx-FLM	>55	96-100%	Moderate	Minimal inter/intra-assay variability; simple test
L/S ratio	>2.0	95-100%	High	Large laboratory variation
PG	"Present"	95-100%	High	Not affected by blood, meconium; can use vaginal pooled sample
Lamellar body counts	30-40,000	97-98%	Low	Cutoff values still investigational
Optical density	OD 0.15	98%	Low	Simple technique
Foam stability index	>47	95%	Low	Affected by blood, meconium silicone tubes

FLM, fetal lung maturity; L/S, lecithin/sphingomyelin; PG, phosphatidylglycerol.

INTRAPARTUM MANAGEMENT

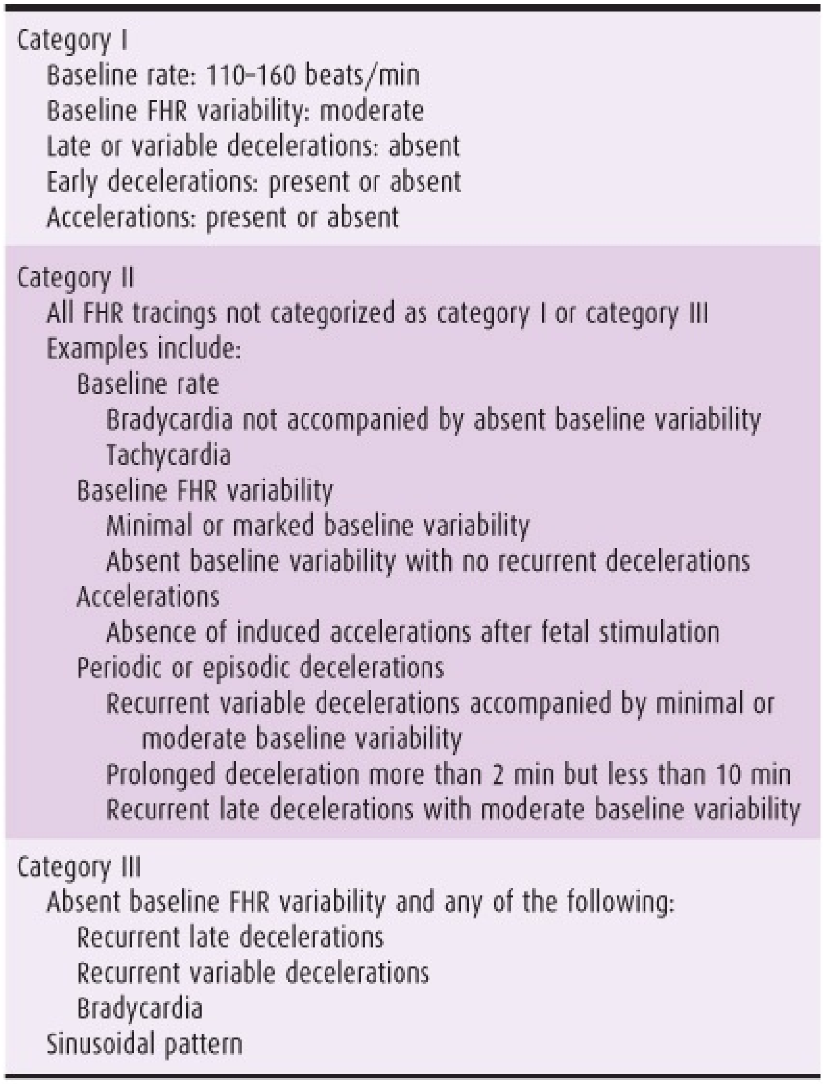
Fetal Heart Rate Monitoring

Use of electronic fetal monitoring (EFM) has been increasing over the last several decades, up to 85%

in 2002. No randomized controlled trials have compared the benefits of EFM versus no form of monitoring during labor. Randomized clinical trials comparing EFM with intermittent auscultation showed an increase in caesarean section rate, caesarean section rate for fetal distress, and operative vaginal delivery rate, with no reduction in overall perinatal mortality, but possibly a decrease in perinatal mortality from fetal hypoxia. Given these findings, ACOG has stated that either EFM or intermittent auscultation is acceptable, given that guidelines for intermittent auscultation are met. Intermittent auscultation may not, however, be acceptable in high-risk patients.

Despite its widespread use, EFM suffers from poor interobserver and intraobserver reliability, uncertain efficacy, and a high false-positive rate. In 2008, a workshop sponsored by ACOG, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), and the Society of Maternal-Fetal Medicine recommended an EFM interpretive system based on a three-tiered approach (Table 12–5). Utility of this approach remains to be seen.

Table 12–5. Three-tiered fetal heart rate interpretation system.



- Category I
  - Baseline rate: 110–160 beats/min
  - Baseline FHR variability: moderate
  - Late or variable decelerations: absent
  - Early decelerations: present or absent
  - Accelerations: present or absent
- Category II
  - All FHR tracings not categorized as category I or category III
  - Examples include:
    - Baseline rate
      - Bradycardia not accompanied by absent baseline variability
      - Tachycardia
    - Baseline FHR variability
      - Minimal or marked baseline variability
      - Absent baseline variability with no recurrent decelerations
    - Accelerations
      - Absence of induced accelerations after fetal stimulation
    - Periodic or episodic decelerations
      - Recurrent variable decelerations accompanied by minimal or moderate baseline variability
      - Prolonged deceleration more than 2 min but less than 10 min
      - Recurrent late decelerations with moderate baseline variability
- Category III
  - Absent baseline FHR variability and any of the following:
    - Recurrent late decelerations
    - Recurrent variable decelerations
    - Bradycardia
  - Sinusoidal pattern

FHR, fetal heart rate.

Fetal Heart Rate Definitions

The baseline is the mean FHR rounded to increments of 5 beats/min, at least 2 minutes in any 10-minute segment. Normal baseline is between 110 and 160 beats/min. Baseline FHR below 110 is defined as *bradycardia*; baseline FHR above 160 is defined as *tachycardia*. Either bradycardia (particularly when the new baseline is less than 80 beats/min) or tachycardia (particularly when associated with a decrease in variability or repetitive late or severe variable decelerations) suggests a nonreassuring fetal status. *Accelerations* (at 32 weeks or greater) are defined as elevations above the baseline of 15 beats/min lasting 15 seconds or longer; less than 32 weeks it is defined by elevations of 10 beats/min lasting at least 10 seconds. Two or more accelerations in a 20-minute interval are reassuring; this defines reactivity in an NST. *Variability* is defined by fluctuations in the FHR of 2 cycles per minute or greater and can range from absent to marked. Decelerations are categorized as early, late, and variable. *Early decelerations* generally mirror contractions in timing and shape and are generally not ominous, often representing head compression. *Late decelerations* are smooth falls in the FHR beginning after the contraction has started and ending after the contraction has ended. They are associated with fetal hypoxemia and a potential for perinatal morbidity and mortality. *Variable decelerations* are abrupt in decline and return to baseline, vary in timing with the contraction, and usually represent cord compression. These are most ominous when repetitive and severe (below 60 beats/min). A *prolonged deceleration* is a decrease of 15 beats/min below the baseline lasting between 2 and 10 minutes.

Ancillary Tests

A. Fetal Scalp Blood Sampling

In the presence of a nonreassuring FHR pattern, a scalp blood sample for determination of pH or lactate can be considered. Although the specificity is high (normal values rule out asphyxia), the sensitivity and positive predictive value of a low scalp pH in identifying a newborn with hypoxic–ischemic encephalopathy is low. For these reasons, in addition to the technical skill and expense of the procedure, fetal scalp pH is no longer used in many institutions.

B. Vibroacoustic Stimulation/Scalp Stimulation

The presence of an acceleration after a vaginal examination in which the examiner stimulates the fetal vertex with the examining finger or after vibroacoustic stimulation (as described earlier under “Nonstress Test”) confirms the absence of acidosis (pH >7.2). Some clinicians prefer these methods over fetal scalp blood sampling because they are less invasive.

C. Fetal Pulse Oximetry

Fetal pulse oximetry, the measure of the fetus’ oxygenation during labor, was developed with the goal of improving the specificity of FHR monitoring and decreasing the number of caesarean sections secondary to nonreassuring fetal status. It has not been demonstrated to be a clinically useful test in evaluating fetal status and is not recommended.

D. ST-Segment Analysis During Labor

ST-segment analysis via computerized real-time analysis of the ST-segment interval of the fetal electrocardiogram has been shown in initial studies to, in combination with intrapartum monitoring with EFM, increase the ability of obstetricians to identify compromised fetuses and to intervene more appropriately. A large multicenter randomized controlled trial is currently underway in the United States.

CONCLUSION

Assessing pregnancy to determine risk, as well as careful monitoring of pregnancies with a recognized risk, begins early in the gestation. Preconception counseling of patients with known medical or genetic disorders helps to optimize outcomes. Early and frequent prenatal care allows the care provider to screen his or her patient population to identify pregnancies at risk and act accordingly. Additionally, pregnancies identified as complicated by 1 or more issues can be followed by assortments of maternal and fetal surveillance techniques to maximize therapeutic treatment.

As technology advances and our ability to both diagnose and treat improve, the methods for assessment and care of the pregnancy at risk will be a constantly changing field.

Early Pregnancy Risks

Ann-Marie Surette, MD
Samantha M. Dunham, MD

SPONTANEOUS ABORTION

ESSENTIALS OF DIAGNOSIS

- Suprapubic pain, uterine cramping, and/or back pain
- Vaginal bleeding
- Cervical dilation
- Passage of products of conception
- Quantitative β-human chorionic gonadotropin that is falling or not adequately rising
- Abnormal ultrasound findings (eg, empty gestational sac, lack of fetal growth or fetal cardiac activity)

General Considerations

Spontaneous abortion is the most common complication of pregnancy and is defined as the passing of a pregnancy at less than 20 weeks of gestation. It implies the spontaneous loss of an embryo or fetus weighing less than 500 g. **Threatened abortion** is bleeding arising from within the uterus that occurs before the 20th completed week in a viable pregnancy. The patient may or may not experience pain or cramping; however, there is no passage of products of conception and no cervical dilation. **Complete abortion** is the expulsion of all of the products of conception before the 20th completed week of gestation, whereas **incomplete abortion** is the expulsion of some, but not all, of the products of conception. **Inevitable abortion** refers to bleeding from within the uterus before the 20th week, with dilation of the cervix but without expulsion of the products of conception. The term **missed abortion** describes a nonviable pregnancy that has been retained in the uterus without cervical dilation and without the spontaneous passage of products of conception. In **septic abortion**, embryonic or fetal demise has occurred, and intrauterine infection has developed, which has the potential risk of spreading systemically.

Although the true incidence of spontaneous abortion is unknown, approximately 15% of clinically evident pregnancies and up to 50% of chemically evident pregnancies end in spontaneous abortion. Eighty percent of spontaneous abortions occur before 12 weeks' gestation.

The incidence of abortion is influenced by the age of the mother and by a number of pregnancy-related factors, including the number of previous spontaneous abortions, a previous intrauterine fetal demise, and a previous infant born with malformations or known genetic defects. Additionally, chromosomal abnormalities in either parent, such as balanced translocations, and medical comorbidities, such as thyroid disease and diabetes mellitus, may influence the rate of spontaneous abortion.

Pathogenesis

An abnormal karyotype is present in as many as 50% of spontaneous abortions occurring during the first trimester. The incidence decreases to 20–30% of second-trimester losses and to 5–10% of third-trimester losses. The majority of chromosome abnormalities are trisomies (56%), followed by polyploidy (20%) and monosomy X (18%).

Other suspected causes of spontaneous abortion are less common, and these include infection, anatomic defects, endocrine factors, immunologic factors, and exposure to toxic substances. In a significant percentage of spontaneous abortions, the etiology is unknown, even with genetic testing.

A. Genetic Abnormalities

Aneuploidy, an abnormal chromosomal number, is the most common genetic abnormality, accounting for up to 50% of clinical miscarriages. Monosomy X or Turner's syndrome is the single most common aneuploidy, comprising approximately 18% of these gestations. As a group, the autosomal trisomies account for more than half of aneuploid losses, with trisomy 16 being the most common. Autosomal trisomies have been noted for every chromosome except chromosome number 1. Most trisomic pregnancies end in miscarriage. The exceptions are trisomy 21, 18, and 13, which have survival to birth rates of 22%, 5%, and 3%, respectively.

Polyploidy, usually in the form of triploidy, is found in approximately 20% of all miscarriages. Polyploid conceptions typically result in an anembryonic gestation. Occasionally, these pregnancies will develop into partial hydatidiform moles.

The remaining half of early abortuses appear to have normal chromosomes. Of these, 20% have other genetic abnormalities that may account for the loss. Mendelian or polygenic factors resulting in anatomic defects may play a role. These factors tend to be more common in later fetal losses.

B. Maternal Factors

1. Systemic disease

A. MATERNAL INFECTIONS—Organisms such as *Toxoplasma gondii*, herpes simplex virus, cytomegalovirus, and *Listeria monocytogenes* have been implicated in spontaneous abortion. Although these agents, as well as *Chlamydia trachomatis*, have been found in women with first-trimester losses, a causal relationship has not been established.

B. OTHER DISEASES—Endocrine disorders such as hypothyroidism, hyperthyroidism, hyperprolactinemia, and poorly controlled diabetes mellitus; cardiovascular disorders, such as hypertensive or renal disease; and autoimmune disorders, such as systemic lupus erythematosus and antiphospholipid syndrome, are associated with spontaneous abortion. At less than 10 weeks, the association between antiphospholipid syndrome and early pregnancy loss is controversial and less well established.

2. Uterine and cervical factors—Congenital anomalies that distort or reduce the size of the uterine cavity, such as unicornuate, bicornuate, or septate uterus, are associated with poor pregnancy outcomes (Fig. 13–1). There is an increased risk of miscarriage, as well as placental abruption, intrauterine growth restriction, and preterm labor. Of all uterine anomalies, septate uterus is the most common and can be removed by hysteroscopic resection, resulting in higher pregnancy and live birth rates (Fig. 13–2). Upper and lower genital tract structural changes have been observed in 25–33% of women whose mothers took diethylstilbestrol (DES) during pregnancy. Uterine anomalies, such as a T-shaped or hypoplastic uterus, carry an increased risk of miscarriage. DES was banned from use in pregnant women in 1971. As a result, pregnancy complications in DES daughters are less and less common, as these women are now 40 years and older. Acquired anomalies, such as fibroids (especially submucosal) and endometrial polyps, have been associated with spontaneous abortions as well.

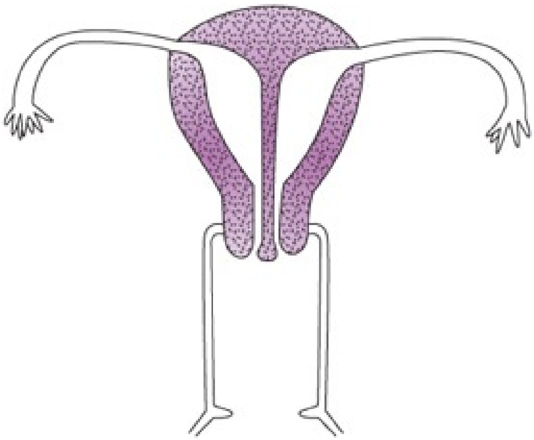

Figure 13–1. Complete bicornuate uterus. (Reproduced, with permission, from Reichman DE, Laufer MR. Congenital uterine anomalies affecting reproduction. *Best Pract Res Clin Obstet Gynaecol* 2010;24:193. PMID: 19897423.)

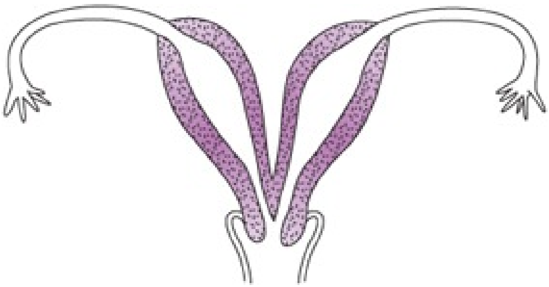

Figure 13–2. Septate uterus. (Reproduced, with permission, from Reichman DE, Laufer MR. Congenital uterine anomalies affecting reproduction. *Best Pract Res Clin Obstet Gynaecol* 2010;24:193. PMID: 19897423.)

The formation of scar tissue, or synechiae, within the uterine cavity that leads to problems such as infertility or recurrent miscarriage is known as Asherman’s syndrome. These intrauterine adhesions or fibrosis are most commonly found after dilation and curettage (D&C) of the gravid uterus, either for spontaneous miscarriage, termination, or treatment of postpartum hemorrhage. Diagnosis is often confirmed with hysterosalpingogram, saline infusion sonogram, or hysteroscopy. Treatment is by resection of the adhesions using hysteroscopy.

Cervical insufficiency (previously known as cervical incompetence) is painless cervical shortening or dilation in the second or early third trimester, up to 28 weeks, resulting in preterm birth. Congenital uterine anomalies and DES anomalies are associated with cervical insufficiency. Procedures to treat dysplasia of the cervix such as cervical conization appear to increase the risk for cervical insufficiency.

C. Toxic Factors

Exposure to antineoplastic drugs, anesthetic gases, alcohol, nicotine, or cocaine can result in spontaneous abortion. Other substances such as lead, ethylene oxide, and formaldehyde have also been associated with subsequent miscarriage.

D. Trauma

Direct trauma, such as a penetrating injury to the uterus, or indirect trauma, such as surgical removal of an ovary containing the corpus luteum, may result in spontaneous abortion. Amniocentesis or chorionic villus sampling are associated with a risk of pregnancy loss.

Pathology

In spontaneous abortion, hemorrhage into the decidua basalis often occurs. Necrosis and inflammation appear at the area of implantation. The pregnancy then becomes partially or entirely detached. Uterine contractions and dilation of the cervix result in expulsion of part or all of the products of conception.

Prevention

Some miscarriages can be prevented by early obstetric care and even preconception care, with adequate treatment of maternal comorbidities such as diabetes and hypertension, and by protection of pregnant women from environmental hazards and exposure to infectious diseases.

Clinical Findings

A. Threatened Abortion

Approximately 25% of pregnant women experience first-trimester bleeding. In most cases, this bleeding is caused by implantation into the endometrium. The cervix remains closed, and slight bleeding with or without cramping may be noted. Resolution of the bleeding and cramping carries a favorable prognosis; however, these women are at increased risk for subsequent miscarriage. First-trimester bleeding has also been associated with preterm premature rupture of membranes and preterm labor. Other causes, such as ectopic pregnancy and molar gestation, should also be considered.

B. Inevitable Abortion

Bleeding with cervical dilation, often with back or abdominal pain, indicate impending abortion. Unlike an incomplete abortion, the products of conception have not passed from the uterine cavity.

C. Incomplete Abortion

Incomplete abortion (Fig. 13–3) is defined as the passage of some but not all of the products of conception from the uterine cavity. Bleeding and cramping usually continue until all products of conception have been expelled. In general, severe pain and heavy bleeding occur and often require medical evaluation.

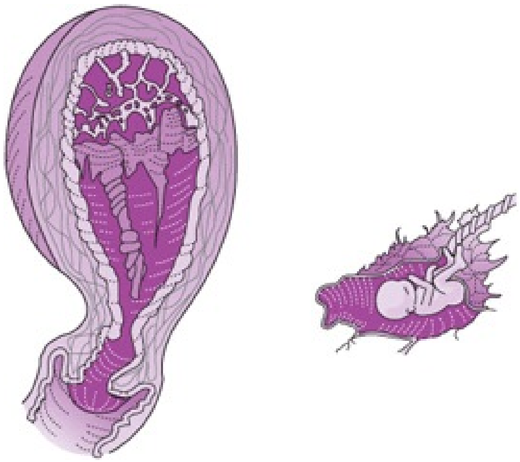

Figure 13–3. Incomplete abortion. **Right:** Product of incomplete abortion. (Reproduced, with permission, from Benson RC. *Handbook of Obstetrics & Gynecology*. 8th ed. Los Altos, CA: Lange; 1983.)

D. Complete Abortion

In a complete abortion (Fig. 13–4), all of the products of conception have passed from the uterine cavity and the cervix is closed. Slight bleeding and mild cramping may continue for several weeks.

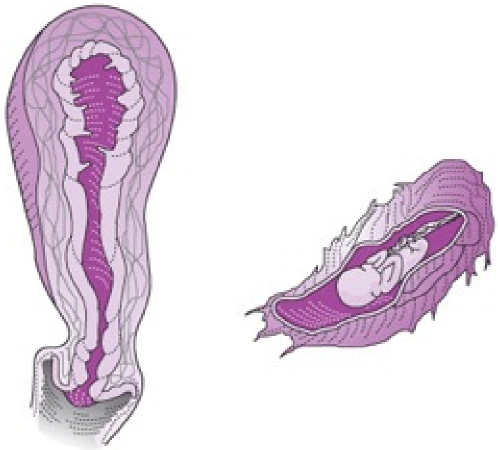

Figure 13–4. Complete abortion. **Right:** Product of complete abortion. (Reproduced, with permission, from Benson RC. *Handbook of Obstetrics & Gynecology*. 8th ed. Los Altos, CA: Lange; 1983.)

E. Missed Abortion

Missed abortion is defined as a pregnancy that has been retained within the uterus after embryonic or fetal demise. Cramping or bleeding may be present, but often there are no symptoms. The cervix is closed, and the products of conception remain in situ.

F. Anembryonic Pregnancy

Anembryonic pregnancy (previously called *blighted ovum*) is an ultrasound diagnosis. It is a pregnancy in which the embryo fails to develop or is resorbed after loss of viability. On ultrasound, an empty gestational sac is seen without a fetal pole (Fig. 13–5). Clinical presentation is similar to that of a missed or threatened abortion: Mild pain or bleeding may be present; however, the cervix is closed, and the nonviable pregnancy is retained in the uterus.

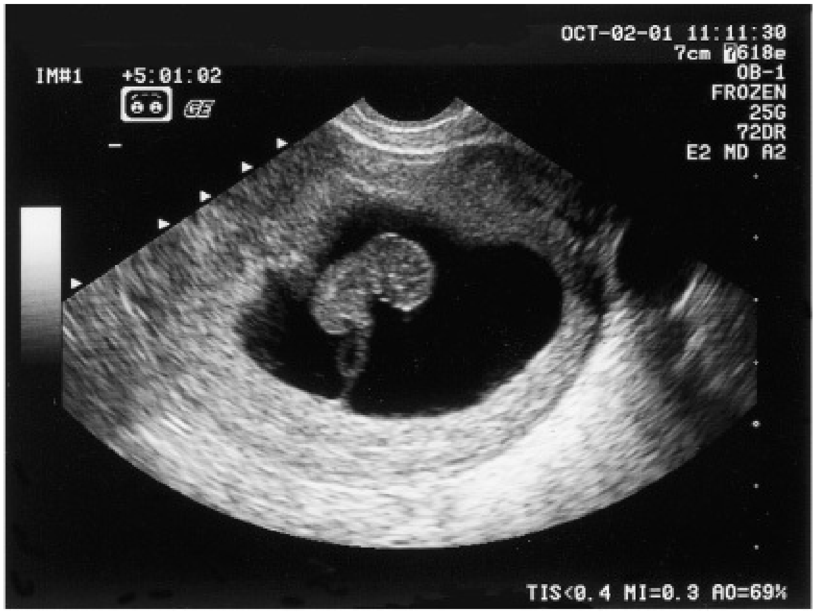

Figure 13–5. Anembryonic pregnancy: large, irregular gestational sac without an embryo.

Laboratory Findings

A. Complete Blood Count

If significant bleeding has occurred, the patient will be anemic. Both the white blood cell count and the sedimentation rate may be elevated, even without the presence of infection.

B. Pregnancy Tests

Falling or abnormally rising serum levels of β-human chorionic gonadotropin (hCG) are diagnostic of an abnormal pregnancy, either a failed intrauterine gestation or an ectopic pregnancy.

Ultrasound Findings

Transvaginal ultrasound is an essential diagnostic tool in diagnosing early normal and abnormal pregnancies. As early as 4–5 weeks of gestation, a gestational sac may be visualized in the uterus. In a normal intrauterine pregnancy, the sac is spherical and is eccentrically placed within the endometrium. At 5–6 weeks' gestation, a yolk sac will be present. In general, a gestational sac with a mean sac diameter (MSD) of ≥8 mm should contain a yolk sac. Similarly, a gestational sac with an MSD of >16 mm should also contain an embryo (Fig. 13–6). Pregnancies with a large gestational sac and no embryo are typically anembryonic gestations and are managed in a similar manner as a missed abortion (Fig. 13–5). Fetal heart motion is expected in embryos with a crown to rump length of >5 mm or at 6–7 weeks' gestation. If a repeat ultrasound in 1 week does not show embryonic cardiac activity, the diagnosis of embryonic demise is made.

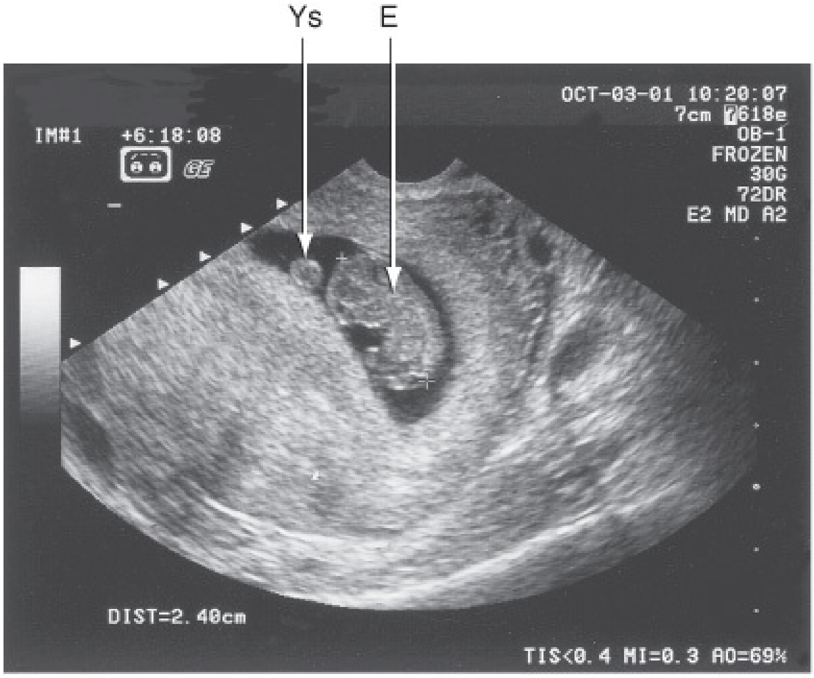

Figure 13–6. Intrauterine pregnancy with gestational sac, yolk sac, and embryo.

In threatened abortion, ultrasound will reveal a normal gestational sac and a viable embryo. However, a large or irregular sac, an eccentric fetal pole, and/or a slow fetal heart rate (<85 beats/min) carry a poor prognosis. Miscarriage becomes increasingly less likely the further the gestation progresses. If a viable fetus of 6 weeks or less is seen on ultrasound, the risk of miscarriage is approximately 15–30%. The risk decreases to 5–10% at 7–9 weeks' gestation and to less than 5% after 9 weeks' gestation.

In an incomplete abortion, the gestational sac usually is irregularly shaped. Heterogenous, echogenic material representing retained products of conception is seen within the uterus. Endometrial thickness can be helpful in diagnosing an incomplete abortion; however, there is no consensus on a cutoff value to distinguish complete miscarriage from incomplete miscarriage. Color Doppler can be used to assess for flow within the tissue and can help differentiate retained products of conception that remain implanted within the uterus from tissue or blood that is in the process of expulsion. Thus, a combination of clinical and ultrasound findings must be used to determine management.

The diagnosis of complete abortion is also based on clinical findings. On ultrasound, the endometrial lining appears thin, and no products of conception are visible within the cavity. Importantly, a complete abortion is only diagnosed with certainty if a previous intrauterine gestation was documented on ultrasound. Otherwise, hCG levels must be followed to confirm the absence of ectopic pregnancy.

Ectopic pregnancy may cause similar symptoms of miscarriage, such as bleeding and abdominal or pelvic pain. An adnexal mass may or may not be present. The presence of an ectopic pregnancy is exceedingly rare if an intrauterine pregnancy (gestational sac plus yolk sac) is seen on ultrasound. The chance of a simultaneous intrauterine and extrauterine pregnancy (heterotopic pregnancy) is approximately 1 in 3900, including spontaneous pregnancies and those conceived with assisted reproductive technology (ART).

Hydatidiform molar pregnancies usually end in miscarriage before the fifth month of gestation. Theca lutein cysts are present in 50% of cases and appear as bilateral, large, multiseptated ovarian cysts. These cysts are caused by excessive production of hCG by the abnormal trophoblastic tissue. The uterus may also be unusually large and contain a heterogenous endometrial mass classically described on ultrasound as a “swiss cheese” or “snowstorm” pattern. An early molar gestation may present simply as an anembryonic gestation or spontaneous abortion. Only partial molar gestations will contain fetal parts.

When findings on ultrasound are nonspecific, correlation with hCG levels can improve the ability to distinguish normal and abnormal pregnancies. In a normal pregnancy, the minimal rise in hCG is 53% over 48 hours. hCG values that rise slower than expected may be consistent with a failed intrauterine or ectopic pregnancy. Decreasing levels of hCG are also diagnostic of an abnormal pregnancy. In spontaneous abortion, the hCG values are expected to drop 21–35% in 2 days (depending on the initial hCG value). A slower decline is suggestive of an ectopic pregnancy.

Complications

Severe or persistent bleeding during or after spontaneous abortion may be life-threatening. The more advanced the gestation, the greater the likelihood of excessive blood loss. Infection, intrauterine adhesions (Asherman’s syndrome), and infertility are other complications of abortion.

Perforation of the uterus may occur during procedures to remove retained products of conception, namely D&C. The rate of perforation during the first and second trimesters is approximately 0.5% for both induced and spontaneous abortions. Uterine perforation is more common during D&C performed in pregnancy because of the soft uterine wall and may be accompanied by injury to the bowel and bladder, hemorrhage, and infection. Surgical evacuation may also lead to cervical trauma and subsequent cervical insufficiency.

Treatment of Abortions

Successful management of spontaneous abortion depends on early diagnosis. Every patient should have a complete history taken and a physical examination performed. Laboratory studies include a complete blood count, blood type, and cervical cultures to determine pathogens in case of infection.

If the diagnosis of threatened abortion is made, pelvic rest can be recommended, although it has not been shown to prevent subsequent miscarriage. Prognosis is good when bleeding and/or cramping resolve.

If the diagnosis of a missed or incomplete abortion is made, options include surgical, medical, or expectant management. In the past, surgery was the standard of care because of concern that medical or expectant management would lead to higher rates of retained pregnancy tissue and subsequent infection. More recently, expectant or medical management are acceptable alternatives and have even shown lower rates of infection despite their higher rates of retained products of conception. These patients also avoid the risks of surgery, including uterine perforation, intrauterine adhesions, and cervical insufficiency. The advantages of performing a D&C include convenient timing and low rates of retained products of conception.

Expectant management allows the spontaneous passage of products of conception and avoids risks of surgery. Risks and side effects include unpredictable timing until the abortion is completed with the possibility of significant pain and bleeding, occasionally requiring emergent D&C. Expectant management also has the highest rates of retained pregnancy tissue, necessitating treatment with misoprostol (prostaglandin E1) or D&C.

Patients who choose medical management are given misoprostol, a drug that induces uterine contractions and expulsion of the products of conception. The risk of retained products is lower than with expectant management; however, repeat doses of medication may be needed to complete the abortion. As with expectant management, timing can be unpredictable, and symptoms of pain and/or bleeding may necessitate emergent D&C. Expectant or medical management of abortion assumes that prompt medical evaluation is available. Those options should not be considered if medical care is not easily accessible.

If the diagnosis of complete abortion is made, the patient should be observed for further bleeding. If bleeding is minimal, no further treatment is necessary. All products of conception should be examined and sent for pathologic examination to confirm an intrauterine pregnancy. If an intrauterine pregnancy was not previously seen on ultrasound and no pathology specimen is available, serial hCG levels are followed to confirm spontaneous abortion. If hCG levels decline more slowly than expected (eg, <21–35%), an ectopic pregnancy or retained products of conception must be considered. Molar gestation is also a possible diagnosis if hCG levels plateau or rise abnormally without an intrauterine pregnancy.

If a complete or partial hydatidiform molar pregnancy is diagnosed, surgical evacuation with suction D&C should be performed. As long as hCG levels are decreasing and remain undetectable after molar evacuation, there is no need for chemotherapy. However, if hCG levels start rising, plateau, or are persistent for more than 6 months, evaluation for malignant postmolar gestational trophoblastic disease is indicated.

Treatment of Complications

Uterine perforation may result in intraperitoneal bleeding, as well as injury to the bladder and/or bowel. In many cases, uterine perforation is asymptomatic and goes unrecognized. When perforation and bowel or bladder injury is suspected or when heavy bleeding is encountered, laparoscopy and/or laparotomy are indicated to determine the extent of the perforation and to evaluate for injury to other adjacent organs.

RECURRENT PREGNANCY LOSS

ESSENTIALS OF DIAGNOSIS

- Three or more consecutive pregnancy losses before 20 weeks of gestation

General Considerations

Recurrent miscarriage is defined as 3 or more consecutive pregnancy losses before 20 weeks of gestation, each with a fetus weighing less than 500 g. Recurrent pregnancy loss affects up to 5% of couples, often with no identifiable cause. The prognosis for a successful subsequent pregnancy correlates with the number of previous miscarriages. The risk of spontaneous abortion in a first pregnancy is approximately 15%, and this risk is at least doubled in women experiencing recurrent pregnancy loss.

Overall, the prognosis after repeated losses is good, with most couples having an approximately 60% chance of a viable pregnancy.

Pathogenesis & Treatment

Determining the etiology of recurrent miscarriage involves a comprehensive workup. This evaluation can be divided into 6 categories of possible causes: genetic, immunologic, endocrinologic, anatomic, microbiologic, and thrombophilic.

Table 13–1 summarizes a diagnostic workup and possible therapies for recurrent abortion.

Table 13–1. Evaluation and management of recurrent early pregnancy loss.

Factor	Diagnostic Evaluation	Treatment
Genetic factors	Parental cytogenetics Three-generation pedigree	Genetic counseling Donor egg/sperm PGD
Anatomic factors	Ultrasound, hysterosalpingogram, hysteroscopy	Hysteroscopic metroplasty Lysis of adhesions Hysteroscopic myomectomy/polypectomy Cervical cerclage
Endocrine fctors	Midluteal progesterone level TSH level Prolactin level Fasting insulin and glucose, glucose tolerance test	Progesterone supplementation Synthroid Bromocriptine, cabergoline Metformin, insulin
Immunologic factors	Lupus anticoagulant Anticardiolipin IgG/IgM	ASA, heparin
Thrombophilic factors	Factor V Leiden Prothrombin gene mutation Fasting homocysteine Protein S/protein C activity Antithrombin activity	Heparin (insufficient data to routinely recommend)
Exogenous agents	Evaluate for tobacco, alcohol, drug use	Eliminate exposure

ASA, acetylsalicylic acid; Ig, immunoglobulin; PGD, preimplant genetic diagnosis; TSH, thyroid-stimulating hormone.

Data from Stephenson MD. Evaluation and management of recurrent early pregnancy loss. *Clin Obstet Gynecol* 2007;50:132.

A. Genetic Errors

Genetic errors associated with recurrent pregnancy loss include maternal and paternal karyotype abnormalities and recurrent aneuploidy.

A structural genetic factor is found in either partner in up to 8% of couples with recurrent miscarriage. Of these, balanced translocations are the most common and are found more frequently in the female partner. Less frequent findings include chromosome insertions, deletions, and inversions. When a karyotypic abnormality is found, genetic counseling should be provided because the likelihood of a subsequent healthy birth depends on the chromosome(s) involved and the type of rearrangement. Although couples affected by a structural genetic defect are more likely to have a miscarriage, the subsequent live birth rate can be as high as 70%. Despite the good prognosis, some patients opt for treatment with ART. If the defect is paternal, artificial insemination by a donor is available. For a maternal defect, a donor egg may be fertilized by the husband’s sperm. Preimplantation genetic diagnosis is also available for parents who wish to use their own gametes.

In couples with normal karyotypes, recurrent fetal aneuploidy can be the cause of miscarriage. The most common aneuploidies found are the trisomies. Although miscarriages caused by trisomies are usually random events, the frequency of such events increases with advancing maternal age. In the general reproductive population, however, a trisomic miscarriage does not increase the risk of having a similar outcome in the next pregnancy. As a result, recurrent pregnancy loss with normal fetal chromosomes carries an overall higher recurrence risk, as this subset is presumably caused by maternal or paternal etiologies.

B. Uterine & Cervical Abnormalities

Anatomic abnormalities were the first described causes of recurrent miscarriage and account for up to 15% of recurrent pregnancy losses. Defects include congenital uterine anomalies, cervical insufficiency, submucosal leiomyomas and endometrial polyps, malformations from DES exposure in utero, and Asherman’s syndrome.

The most common uterine malformation is a uterine septum. This anomaly is associated with first-trimester losses, presumably because of implantation failure on the relatively avascular septum. Other müllerian fusion abnormalities such as bicornuate and unicornuate uterus are less common and are more likely to cause second-trimester miscarriage or preterm delivery. Similarly, anomalies caused by DES exposure (eg, T-shaped uterus) can lead to second-trimester loss.

Structural defects such as submucosal leiomyomas and endometrial polyps likely interfere with implantation. In Asherman’s syndrome, implantation is impeded by the presence of intrauterine adhesions and fibrosis. This scarring can also impair adequate blood supply to the endometrium. Diagnosis of uterine defects is usually accomplished with transvaginal ultrasound. A specific type of transvaginal ultrasound, in which saline is infused into the endometrial cavity (eg, saline infusion sonography), can help delineate defects such as leiomyomas, polyps, and intrauterine adhesions. Hysterosalpingogram or magnetic resonance imaging can detect uterine malformations. Treatment is primarily surgical, and minimally invasive procedures using hysteroscopy can be performed in many cases.

Cervical insufficiency classically presents in the second trimester with painless cervical dilation. Although no definite cause is found in many patients, cervical insufficiency has been associated with congenital uterine anomalies, trauma from procedures that dilate the cervix (eg, D&C), and excisional procedures such as a loop electrosurgical excision procedure or cold-knife conization.

If other causes of recurrent pregnancy loss are excluded and the presumed etiology is cervical insufficiency, a cervical cerclage is recommended between 13 and 16 weeks’ gestation. Success rates with cerclage are 85–90%. Complications include bleeding, infection, rupture of membranes, and miscarriage. Contraindications to cerclage placement include bleeding of unknown etiology, infection, labor, ruptured membranes, and known fetal anomalies.

C. Endocrine Factors

Possible endocrine causes of recurrent miscarriage include thyroid disorders, hyperprolactinemia, poorly controlled diabetes mellitus, and luteal phase defect (eg, progesterone insufficiency).

Luteal phase defect (LPD) is thought to result from a deficiency in progesterone; however, the diagnosis remains controversial. Critics of this diagnosis note intraobserver and interobserver variations in biopsy results, the presence of LPD in normal women, and inconsistent results in women diagnosed with LPD. Furthermore, controlled studies demonstrating an improvement in pregnancy outcome with progesterone treatment are lacking. For these reasons, many experts are skeptical about the importance of LPD as an etiology of recurrent pregnancy loss.

The proposed mechanism in LPD is a relative lack of progesterone that causes a delay in endometrial development, preventing normal implantation. Inadequate hormonal support of the embryo may also be involved. In the past, the diagnosis of LPD was made by luteal phase endometrial biopsies that showed a lag in endometrial development when compared with the current day of the cycle. More recently, midluteal progesterone levels of <10 ng/mL have been used to diagnose an inadequate luteal phase. LPD is treated with supplemental progesterone.

Untreated hypothyroidism increases the risk of miscarriage. Hypothyroidism is diagnosed with a sensitive thyroid-stimulating hormone test, and patients should be euthyroid before attempting pregnancy. Hyperprolactinemia may be associated with recurrent pregnancy loss by competing with the hypothalamic–pituitary–ovarian axis, resulting in insufficient folliculogenesis, oocyte maturation, and/or a LPD. Treatment of hyperprolactinemia with a dopamine agonist may improve pregnancy outcomes. Patients with poorly controlled diabetes mellitus can similarly have an increased risk of miscarriage. These risks for recurrent pregnancy loss highlight the importance of diagnosing and treating underlying medical problems.

D. Infection

Infections such as *Toxoplasma gondii*, *Listeria monocytogenes*, herpes simplex, and cytomegalovirus have been implicated in spontaneous abortion, although a causal relationship has not been defined. No infectious agents have been clearly linked to recurrent pregnancy loss.

E. Immunologic Factors

Antiphospholipid syndrome is an autoimmune disorder defined by the presence of characteristic clinical features and antiphospholipid antibodies (lupus anticoagulant and/or anticardiolipin antibodies). The most common and serious complications of this disorder are venous and arterial thrombosis, in which the majority of thrombotic events are venous. The risk of thrombosis is significantly increased during pregnancy. Although the exact mechanism is unclear, the increased thrombotic potential in women with antiphospholipid syndrome is associated with recurrent pregnancy loss after 10 weeks’ gestation. Therapy with aspirin with or without heparin has been shown to reduce pregnancy loss.

Women with systemic lupus erythematosus (SLE) have a higher rate of miscarriage and pregnancy loss in all trimesters. The prevalence of antiphospholipid antibodies in patients with SLE is estimated at 37%, and such antibodies are the most sensitive indicator of poor pregnancy outcomes.

Previously, the sharing of human leukocyte antigens between partners was thought to be associated with recurrent pregnancy loss. More recent studies, including a large, randomized controlled trial, do not support this theory. Despite the lack of diagnostic tests to identify an alloimmune factor associated with early pregnancy loss, there is evidence that there are immunologic interactions between the mother and her allogeneic pregnancy. Investigation is currently underway looking at the efficacy of active and passive immunotherapy in preventing recurrent miscarriage.

F. Thrombophilia

Certain inherited or acquired thrombophilic factors are associated with an increased risk of venous thromboembolism. These include a group of inherited gene mutations that predispose to arterial and/or venous thrombosis: factor V Leiden mutation, prothrombin gene mutation, hyperhomocysteinemia, methylenetetrahydrofolate reductase polymorphisms, and deficiencies in protein S, protein C, and antithrombin III. Despite the association between inherited thrombophilias and venous thromboembolism, a definitive causal link cannot be made between these diseases and uteroplacental thrombosis leading to adverse pregnancy outcomes.

Testing for maternal inherited thrombophilia may be considered when there is a personal history of thromboembolism in the absence of other risk factors such as surgery or prolonged immobilization. Testing is also indicated when a first-degree relative has a history of a high-risk thrombophilia or venous thromboembolism before age 50 years in the absence of risk factors. Currently, recurrent pregnancy loss is not an indication to screen for thrombophilias, with the exception of antiphospholipid antibodies. Likewise, there are insufficient data that treatment with heparin or other anticoagulant therapies improves pregnancy outcomes in women with inherited thrombophilia and recurrent pregnancy loss.

SEPTIC ABORTION

ESSENTIALS OF DIAGNOSIS

- Intrauterine infection involving the endometrium and products of conception

---

GENERAL CONSIDERATIONS

Mortality from abortion is rare in developed countries such as the United States, where induced abortions are legal. Abortion continues to be a leading cause of maternal death in countries where abortion remains illegal. These abortion-related deaths are primarily from sepsis as a result of unsterile instruments and poor surgical technique. Hemorrhage also accounts for a proportion of these deaths.

In septic abortion, infection usually begins as endometritis involving the endometrium and any retained products of conception. These patients present with fevers, chills, abdominal pain, vaginal bleeding, and malodorous vaginal discharge. Without treatment, endometritis may spread beyond the uterus, leading to peritonitis, bacteremia, and sepsis.

The 2 most common causes of septic abortion are retained products of conception and bacteria that have been introduced into the uterus via ascending infection. Pathogens that cause septic abortion are usually those seen in normal vaginal flora as well as sexually transmitted bacteria. Before performing D&C, screening for sexually transmitted infections is essential.

In evaluating septic abortion, a complete blood count, urinalysis, endocervical cultures, blood cultures, and abdominal x-ray to rule out uterine perforation should be obtained. Ultrasound should be performed to look for retained products of conception.

Treatment

Treatment of septic abortion involves hospitalization and intravenous antibiotic therapy. Selection of antibiotic agents should provide for both anaerobic and aerobic coverage. If retained products of conception are diagnosed, a D&C is indicated.

ECTOPIC PREGNANCY

ESSENTIALS OF DIAGNOSIS

- Pregnancy implanted outside the endometrial cavity.
- The most common site of ectopic pregnancy is a fallopian tube.

Pathogenesis

In ectopic pregnancy, a fertilized ovum implants outside the endometrial cavity (Fig. 13–7). Nearly all ectopic pregnancies (>95%) occur in the fallopian tube (**tubal pregnancy**); however, an ectopic pregnancy may also be found implanted within the endocervical canal (**cervical pregnancy**), on or in the ovary (**ovarian pregnancy**), within a scar from a prior caesarean delivery (**caesarean scar pregnancy**), or within the peritoneal cavity (**abdominal pregnancy**).

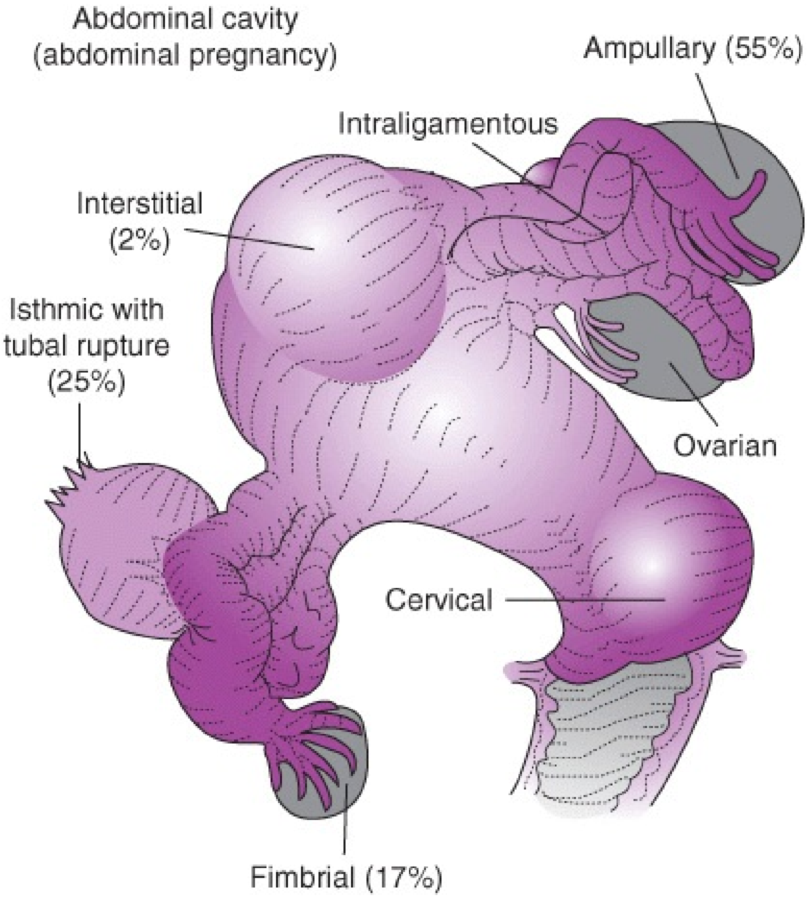

Figure 13–7. Locations of ectopic pregnancies. (Reproduced, with permission, from: Benson RC. *Handbook of Obstetrics & Gynecology*. 8th ed. Los Altos, CA: Lange; 1983.)

Ectopic pregnancy occurs in approximately 1.5–2.0% of all pregnancies. The incidence has increased from 4.5 per 1000 in 1970 to 19.7 per 1000 in 1992, the last time data were reported by the US Centers for Disease Control and Prevention. This may be due, at least in part, to a higher incidence of pelvic inflammatory disease, use of assisted reproductive technology, and higher rates of tubal sterilization.

The morbidity and mortality associated with ectopic pregnancy has decreased dramatically, mainly because of earlier diagnosis with ultrasound and hCG levels and subsequent treatment before rupture. Nevertheless, ectopic pregnancy is the leading cause of pregnancy-related death in the first trimester and accounts for 4–10% of all pregnancy-related deaths.

Classification & Incidence

Ectopic pregnancy can be classified as follows (Fig. 13–7).

1. Tubal (>95%)—Includes ampullary (70%), isthmic (12%), fimbrial (11%), and interstitial (2%).

2. Other (<5%)—Includes cervical, ovarian, caesarean scar, and abdominal. Primary abdominal pregnancies have been reported, but most abdominal pregnancies result from tubal abortion or rupture with subsequent implantation in the bowel, omentum, or mesentery. Caesarean scar pregnancy is becoming an increasingly recognized clinical entity, with its incidence presumably paralleling the rise in caesarean section rates.

3. Heterotopic pregnancy—An ectopic pregnancy that occurs in combination with an intrauterine pregnancy. The risk of a heterotopic pregnancy is <1 in 30,000 of spontaneous pregnancies. The incidence ranges from 1 in 100 to 1 in 500 with assisted reproductive technologies.

There are many known risk factors for ectopic pregnancy, such as previous pelvic inflammatory disease, current and past smoking, and the presence of an intrauterine device (IUD). Despite our knowledge of these predisposing factors, up to one-third of ectopic pregnancies occur in women without any apparent risk factors.

A. Tubal Factors

Damage to the fallopian tube from a number of factors increases the risk of ectopic pregnancy. In pelvic inflammatory disease (PID), microorganisms ascend from the lower genital tract, infecting and causing inflammation of the uterus, fallopian tubes, and ovaries. Salpingitis can result in damage to fallopian tube cilia and blockage or closure of the tube. PID can also lead to adhesion formation among pelvic organs.

Other causes of distorted tubal anatomy leading to an increased risk of ectopic pregnancy include previous tubal surgery, endometriosis, uterine leiomyomas, and developmental abnormalities of the tube or abnormal tubal anatomy from in utero DES exposure. Up to one-third of pregnancies after tubal ligation and approximately 7% of pregnancies after sterilization reversal are ectopic. Additionally, one-third of pregnancies after an ectopic pregnancy are also ectopic implantations.

B. Assisted Reproductive Technology (ART)

The rate of ectopic pregnancy with ART ranges from 2.1% to as high as 8.6% of all clinical pregnancies. The etiology of ectopic pregnancy in patients undergoing ART and in vitro fertilization (IVF) is not completely understood, but several theories are currently under investigation.

Medications used to increase ovarian follicle production result in high levels of progesterone and estradiol that may affect tubal peristalsis and uterine relaxation. Women with tubal factor infertility undergoing IVF have even higher rates of ectopic pregnancy, and most physicians will recommend removal of diseased tubes before IVF. Ectopic pregnancy rates are associated with the number of transferred embryos as well as placement of the embryos.

C. Other Factors

Pregnancy is uncommon in women who use an IUD for contraception. However, approximately 5% of pregnancies that do occur in women using an IUD are ectopic pregnancies. Nevertheless, women with an IUD are overall less likely to develop an ectopic pregnancy than women who do not use contraception. Smoking also significantly increases the risk of ectopic pregnancy, likely because cigarette smoke affects cilia and smooth muscle function in the fallopian tube.

Timing of Rupture

Rupture of an ectopic pregnancy is usually spontaneous. Isthmic pregnancies tend to rupture earliest, at 6–8 weeks’ gestation, because of the small diameter of this portion of the tube. Ampullary pregnancies rupture later, generally at 8–12 weeks. Interstitial pregnancies are the last to rupture, usually at 12–16 weeks, as the myometrium allows more room for the ectopic to grow. Interstitial rupture is quite dangerous because its proximity to uterine and ovarian vessels can result in massive hemorrhage.

Prevention

Prevention and early treatment of sexually transmitted diseases is important to prevent tubal damage and subsequent ectopic pregnancy. Smoking cessation can also help reduce the risk of ectopic pregnancy. Smoking decreases the motility of the fallopian tube cilia and makes a fertilized egg less likely to traverse the tube normally. Unfortunately, other known risk factors are more difficult to control, and up to one-third of ectopic pregnancies occur without any associated risk factors.

Clinical Findings

No specific symptoms or signs are pathognomonic for ectopic pregnancy, and many disorders can present similarly. Normal pregnancy, threatened or incomplete abortion, ovarian cyst rupture, ovarian torsion, gastroenteritis, and appendicitis can all be confused with ectopic pregnancy. Because early diagnosis is crucial, a high index of suspicion should be maintained when any pregnant woman in the first trimester presents with bleeding and/or abdominal pain.

A. Symptoms

The following symptoms may assist in the diagnosis of ectopic pregnancy.

1. Pain—Pelvic or abdominal pain is present in almost 100% of cases. Pain can be unilateral or bilateral, localized or generalized. The presence of subdiaphragmatic or shoulder pain is suggestive of intraabdominal bleeding. In tubal ectopic pregnancy, implantation typically occurs in the wall of the tube, in the connective tissue beneath the serosa. There may be little or no decidual reaction within the tube and minimal defense against the permeating trophoblast. The trophoblast invades blood vessels, causing local hemorrhage. A hematoma in the subserosal space enlarges as the pregnancy grows, and progressive distention of the tube eventually leads to pain and rupture.

2. Bleeding—Abnormal uterine bleeding occurs in roughly 75% of cases and represents decidual sloughing. Bleeding usually presents as intermittent, light spotting; however, bleeding may be heavier. A decidua cast is passed in 5–10% of ectopic pregnancies and may be mistaken for products of conception. Vaginal bleeding is of endometrial origin and results when the decidua breaks down from lack of progesterone support, a hallmark of an abnormal pregnancy. Occasionally the entire decidua may be shed in one or more large pieces as a decidual cast of the endometrial cavity. On pathologic examination, only decidua is seen, whereas chorionic villi are notably absent.

3. Amenorrhea—Secondary amenorrhea is variable. Approximately half of women with ectopic pregnancies have some bleeding at the time of their expected menses and may not realize they are pregnant.

4. Syncope—Dizziness, lightheadedness, and/or syncope may be part of the initial presentation and should raise suspicion for intraabdominal bleeding from a ruptured ectopic pregnancy.

B. Signs

On examination, the following signs are important in the diagnosis of ectopic gestation.

1. Tenderness—Diffuse or localized abdominal tenderness is present in the majority of patients with ectopic pregnancies. Adnexal and/or cervical motion tenderness is also a common finding.

2. Adnexal Mass—A unilateral adnexal mass is palpated in one-third to one-half of patients. More often, unilateral adnexal fullness rather than a discrete mass is appreciated. Occasionally, a cul-de-sac mass is noted.

3. Uterine changes—The uterus may undergo the typical changes of pregnancy, including softening and a slight increase in size.

4. Hemodynamic instability—Vital signs will reflect the hemodynamic status of patients with tubal rupture and intraabdominal bleeding.

C. Laboratory Findings

1. Hematocrit—The hematocrit is an important initial test that indirectly assesses the hemodynamic status of the patient and reflects the amount of intraabdominal bleeding.

2. β-hCG—The qualitative serum or urine hCG assay is positive in virtually 100% of ectopic pregnancies. A positive result, however, does not help distinguish an intrauterine from ectopic pregnancy. More helpful is a quantitative hCG value that, in conjunction with transvaginal ultrasound, can often make the diagnosis. If ultrasound is nondiagnostic (eg, in an early ectopic, early normal pregnancy, or early failed pregnancy), serial hCG values can be followed. The hCG level should rise at a minimum of 53% over 48 hours in a normal pregnancy. An inappropriate rise in hCG has a sensitivity of 99% for an abnormal gestation. Of note, two-thirds of ectopic pregnancies have abnormally rising values, whereas the remaining third show a normal progression.

3. Progesterone—Serum progesterone levels may help confirm an ectopic pregnancy diagnosis. Serum progesterone values are independent of hCG levels. A serum progesterone level less than 5 ng/mL has a 100% specificity for identifying an abnormal pregnancy, but does not identify the location of the pregnancy. Progesterone levels greater than 20 ng/mL are associated with normal intrauterine pregnancies. All values in between 5 and 20 ng/mL are equivocal.

C. Diagnostic Tests

1. Ultrasound—Ultrasound is an essential part of the evaluation for an ectopic pregnancy. An initial transvaginal ultrasound can be used to visualize an intrauterine pregnancy or a definite ectopic gestation. If neither diagnosis is made, the patient is considered to have a “pregnancy of unknown location.” Approximately 25–50% of women with an ectopic pregnancy initially present in this manner. An intrauterine pregnancy may not be visualized because the gestational sac has not yet developed or has collapsed. Likewise, an early ectopic pregnancy may be too small to be detected by ultrasound. When a diagnosis cannot be made, the patient is then followed with serial hCG levels and ultrasound until either an ectopic pregnancy, intrauterine gestation, or early pregnancy failure is confirmed.

In general, ultrasound should detect an intrauterine gestation when the hCG value falls within or surpasses the “discriminatory zone,” defined as an hCG value between 1500 and 2000 mIU/mL. If the hCG level is higher than the discriminatory zone, and the transvaginal ultrasound is nondiagnostic, ectopic pregnancy or early abnormal pregnancy is likely. Caution should be used when interpreting hCG values because they may be falsely elevated in a pregnancy with multiple gestations.

A normal intrauterine sac appears regular and well defined on ultrasound. It has been described as an echolucent area having a “double ring” or “double decidual” sign, which represents the decidual lining and the chorion around the early gestational sac. In ectopic pregnancy, ultrasound may reveal only a thickened, decidualized endometrium. Decidual sloughing results in intracavitary fluid or blood and creates the so-called pseudogestational sac, a small and irregular structure that may be confused with an intrauterine gestational sac.

The presence of an adnexal mass with an empty uterus raises the suspicion for an ectopic pregnancy, especially if the hCG titers are above the discriminatory zone. Visualization of a gestational sac with a yolk sac or embryo within the adnexa confirms the diagnosis; however, it is more common to find a hyperechoic “tubal ring” or complex mass within the adnexae (Fig. 13–8). If rupture has occurred, anechoic or echogenic free fluid in the cul-de-sac may be visualized.

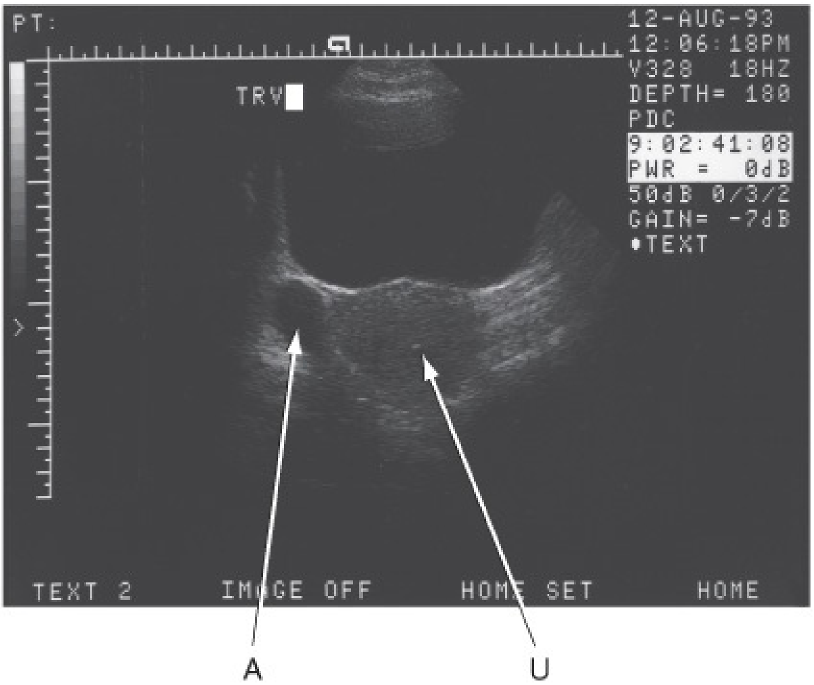

Figure 13–8. Empty uterus (U) with an adnexal mass (A) suspicious for an ectopic pregnancy.

Ultrasound is increasingly being relied on to differentiate several less common types of ectopic pregnancies. Both interstitial tubal and caesarean section scar pregnancies can be difficult to distinguish from intrauterine gestations because of their proximity to the intrauterine cavity.

The most likely alternative diagnosis of an adnexal mass in early pregnancy is a corpus luteum cyst, which can also rupture and bleed, thus making its distinction from an ectopic pregnancy challenging.

2. Laparoscopy—In the past, laparoscopy was often used to diagnosis ectopic pregnancy. In current practice, however, transvaginal ultrasound has replaced laparoscopy as the preferred diagnostic tool. Compared with laparoscopy, ultrasound is equally effective in confirming the presence or absence of ectopic pregnancy. Ultrasound also has the advantages of being both cost-effective and noninvasive. In terms of surgical treatment for ectopic pregnancy, laparoscopy is the standard method, assuming the patient is hemo-dynamically stable.

3. D&C—D&C can be performed to confirm or exclude intrauterine pregnancy. D&C is usually performed when an early ectopic or abnormal intrauterine gestation is suspected based on hCG levels and ultrasound. D&C should not be performed if a pregnancy is desired because it may remove a normal, early intrauterine gestation. If chorionic villi are seen on pathology examination of the D&C specimen, an intrauterine pregnancy is confirmed. On the other hand, if only decidua is obtained on D&C, ectopic pregnancy is highly likely.

4. Laparotomy—Immediate surgery is indicated in the hemodynamically unstable patient with a presumed ectopic pregnancy. Laparoscopy is generally the preferred surgical method for evaluation of suspected ectopic pregnancy in the stable patient; however, exploratory laparotomy can provide rapid access to control intraabdominal hemorrhage. Laparotomy also may be performed if the laparoscopic approach does not allow adequate visualization or if scar tissue from previous surgeries makes the laparoscopic approach too difficult.

5. Culdocentesis—Culdocentesis, the vaginal passage of a needle into the posterior cul-de-sac, was once used to confirm the presence of hemoperitoneum. This technique has now been replaced by transvaginal ultrasound and is rarely performed in modern medicine.

6. Magnetic resonance imaging—Magnetic resonance imaging is a useful adjunct to ultrasound in cases in which an unusual ectopic location is suspected. The location of the ectopic pregnancy and recognition of cervical, caesarean scar, or interstitial pregnancy determines the options for treatment and management. In these types of ectopic pregnancy, conservative treatment with methotrexate is often preferred and usually attempted before surgery to avoid the potential catastrophic hemorrhage associated with surgical management in these cases.

Treatment

A. Expectant Management

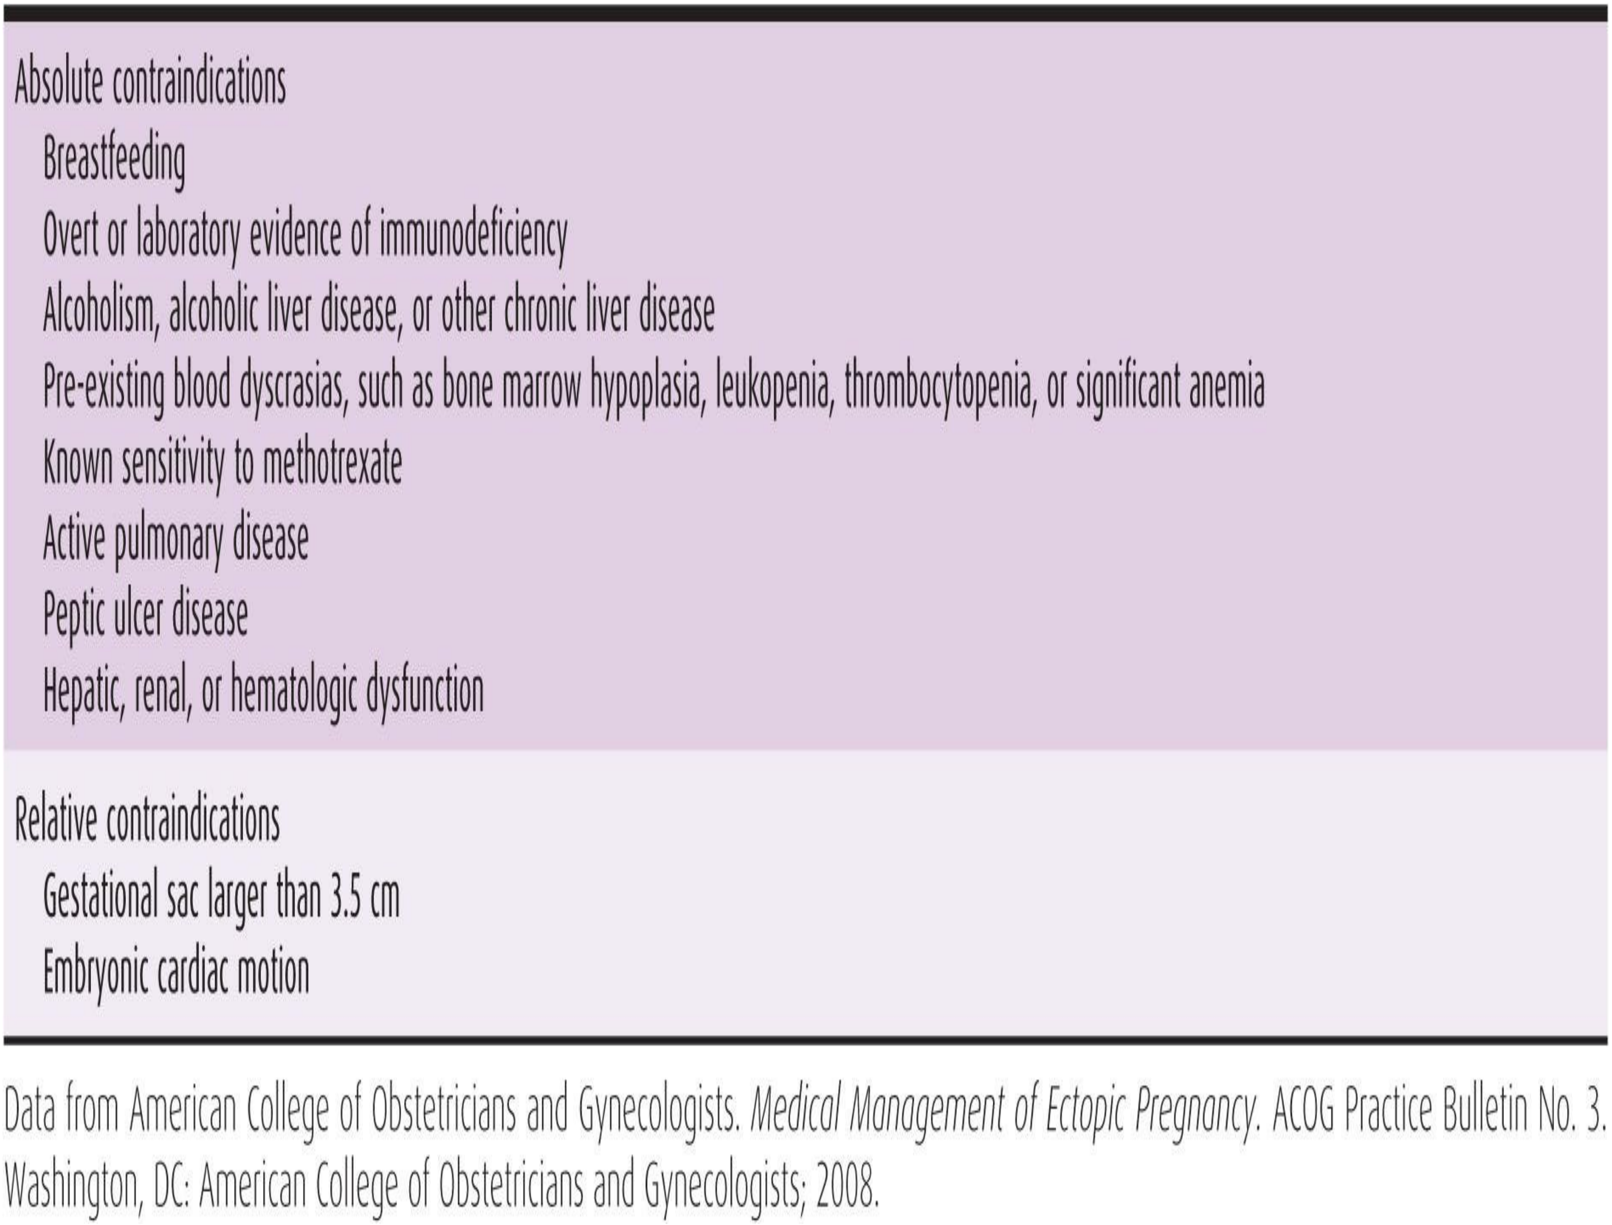
Expectant management is appropriate and can be successful in a select population of patients. In general, these women should be asymptomatic, with lower starting hCG levels and evidence that the ectopic pregnancy is spontaneously resolving (eg, decreasing hCG levels). If the initial hCG level is less than 200 mU/mL, 88% of patients experience resolution with expectant management. These women should be educated about the potential risks of tubal rupture, intraabdominal bleeding, and the need for emergent surgery.

B. Medical Management

Methotrexate (MTX) is a drug that inhibits the action of dihydrofolate reductase, thereby inhibiting DNA synthesis. MTX affects actively proliferating tissues such as bone marrow, intestinal mucosa, malignant cells, and trophoblastic tissue. This antimetabolite can be considered for women who are hemodynamically stable with a confirmed ectopic pregnancy or if clinical suspicion is high for an ectopic pregnancy. Although treatment of early ectopic pregnancy with MTX has significantly decreased the number of women who need surgery, there are several contraindications to its use.

Embryonic cardiac motion or the presence of a gestational sac larger than 3.5 cm are relative contraindications to MTX due to the higher rate of treatment failure in patients with either one of these findings. The level of hCG is also predictive of MTX success. With hCG values greater than 5000 mIU/mL, the failure rate is 14% with a single dose of MTX compared with 3.7% with a multiple-dose regimen. Because MTX affects rapidly dividing tissues within the body, it should not be given to women with blood dyscrasias or active gastrointestinal or respiratory disease. MTX is toxic to hepatocytes and is cleared by the kidneys; thus serum creatinine level and liver transaminases should be normal before administration. Patients must also be considered reliable for follow-up (Table 13–2).

Table 13–2. Contraindications to methotrexate in treatment of ectopic pregnancy.



Absolute contraindications
- Breastfeeding
- Overt or laboratory evidence of immunodeficiency
- Alcoholism, alcoholic liver disease, or other chronic liver disease
- Pre-existing blood dyscrasias, such as bone marrow hypoplasia, leukopenia, thrombocytopenia, or significant anemia
- Known sensitivity to methotrexate
- Active pulmonary disease
- Peptic ulcer disease
- Hepatic, renal, or hematologic dysfunction

Relative contraindications
- Gestational sac larger than 3.5 cm
- Embryonic cardiac motion

Data from American College of Obstetricians and Gynecologists. *Medical Management of Ectopic Pregnancy*. ACOG Practice Bulletin No. 3. Washington, DC: American College of Obstetricians and Gynecologists; 2008.

There are three different regimens for giving MTX: single dose, two-dose, and a fixed multidose protocol. The single 50 mg/m^2 dose of MTX is most commonly used, given as an intramuscular injection. hCG levels are measured at 4 and 7 days posttreatment with an expected 15% decrease from day 4 to day 7. Weekly hCG levels are then checked until zero. If hCG levels do not drop appropriately, a second MTX dose or surgical intervention is advised. Overall, the fixed multidose regimen has been shown to be the most effective regimen, especially in treating more advanced gestations and those with embryonic cardiac activity. However, these patients may experience more side effects, and adherence to the treatment plan may be more difficult.

It is not unusual for women given MTX to have an increase in abdominal pain 2–3 days after administration, likely from the effect of the drug on trophoblast tissue and tubal distention or tubal abortion. Despite this common finding, monitoring for tubal rupture during MTX therapy is extremely important, and worsening pain should prompt immediate evaluation.

C. Surgical Treatment

Once the mainstay of therapy for ectopic pregnancy, surgical treatment is now mainly reserved for patients with contraindications to medical management and for those with evidence of tubal rupture. Despite declining rates of surgical management, surgery remains the most definitive treatment for ectopic pregnancies.

In a hemodynamically stable patient, laparoscopy is the standard approach for surgical management of a known or suspected ectopic pregnancy that is not amenable to medical treatment. In some instances, previous surgeries with subsequent intraabdominal adhesions makes laparotomy the preferred approach. Tubal pregnancies can be treated with either linear salpingostomy or salpingectomy. The decision to perform either procedure depends on the patient's desire for future fertility as well as the appearance of the contralateral tube. If the contralateral tube appears abnormal and fertility is desired, a linear salpingostomy can be performed, and future fertility seems to be improved. In this technique, an incision is made along the fallopian tube, proximal to the ectopic pregnancy. The gestational tissue is gently removed from the tube with an effort to remove the ectopic in one piece. Patients who undergo linear salpingostomy are at risk for having persistent trophoblastic tissue and must be evaluated with weekly hCG levels until undetectable. hCG levels may remain elevated in up to 20% of patients who have undergone salpingostomy. In these cases, MTX is given, with high rates of resolution. Linear salpingostomy also increases the risk of a second ectopic pregnancy occurring in this tube, with rates up to 15%. In general, if the contralateral tube is normal, salpingectomy should be performed to reduce the risk of subsequent ectopic pregnancy.

Salpingectomy (removal of the fallopian tube) is preferred if the patient has completed child bearing, if the affected tube appears damaged, or if salpingostomy has already been performed on that tube. Salpingectomy is a simpler technique and carries minimal risk of retained trophoblastic tissue and postoperative tubal bleeding.

Interstitial pregnancies are uncommon, accounting for only 2–4% of all ectopic pregnancies. MTX and surgery can be offered to these patients. Expectant management is currently not recommended because it has not been well studied in these patients and the risks are considered greater than for tubal ectopics. Interstitial pregnancies implant into the vascular uterine cornua, and subsequent rupture can cause significant bleeding. MTX is a reasonable first-line therapy for the treatment of asymptomatic patients with an unruptured interstitial pregnancy, with reported success rates of >80%. Similar to MTX treatment of tubal pregnancies, close follow-up and patient education are necessary. Surgery is an option for patients who desire definitive management. Laparotomy was once the standard surgical approach; however, several laparoscopic techniques have now been described. Earlier diagnosis has allowed for management of interstitial pregnancies with less invasive surgical procedures.

D. Emergency Treatment

Immediate surgery is indicated when the diagnosis of a ruptured ectopic pregnancy is made. Blood products should be requested immediately because transfusion is often necessary. There is no place for conservative management in a patient with a ruptured ectopic. Even patients who initially present with normal vital signs can quickly become hemodynamically unstable. Rh_o (D) immunoglobulin should be given to any Rh-negative mother with the diagnosis of ectopic pregnancy because sensitization may occur.

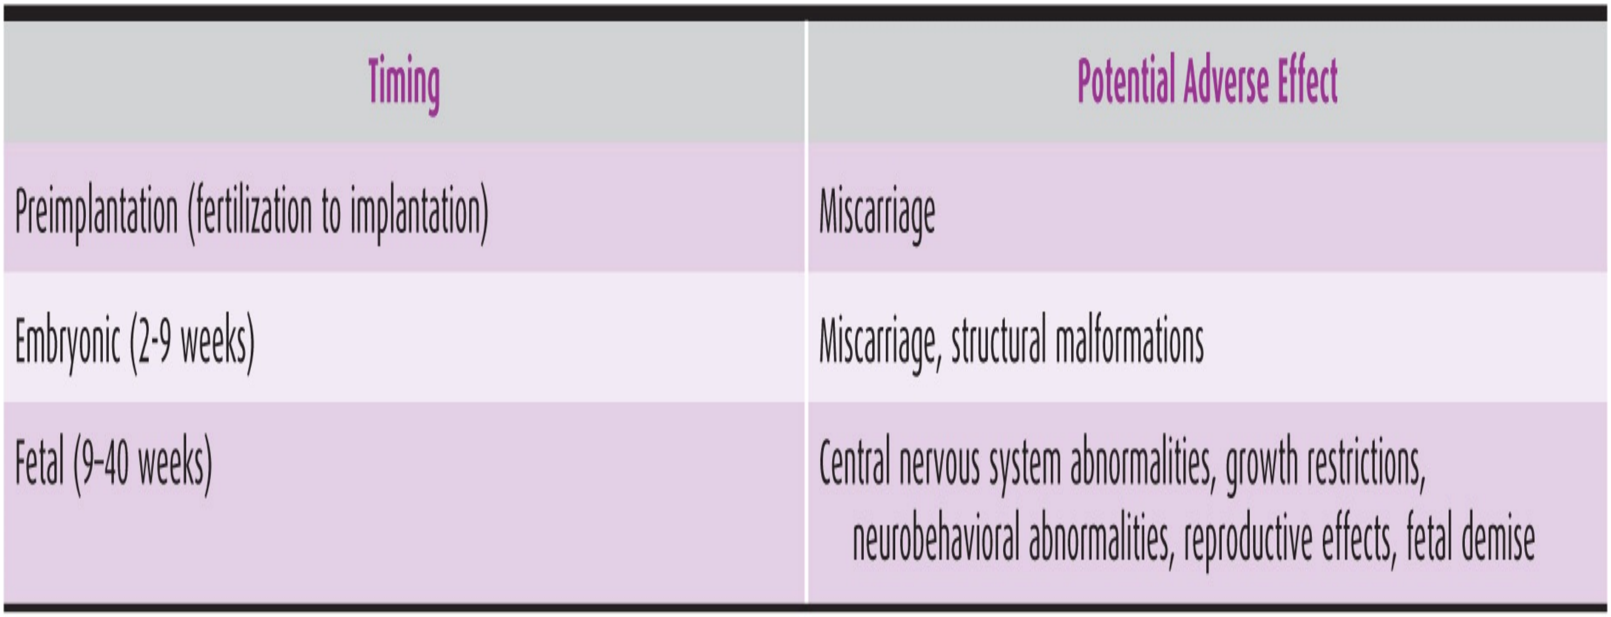
EXPOSURE TO FETOTOXIC AGENTS

Many harmful agents are responsible for altering the biologic process of human development. Recognized teratogens include viruses (eg, rubella, cytomegalovirus, congenital lymphocytic choriomeningitis virus), environmental factors (eg, hyperthermia, irradiation), chemicals (eg, mercury, alcohol), and therapeutic drugs (eg, inhibitors of the renin–angiotensin system, thalidomide, isotretinoin, warfarin, valproic acid, carbamazepine).

Evaluation

When evaluating exposure to teratogens, it is important to consider gestational age at the time of exposure. Fetal development is most vulnerable during organogenesis (2–8 weeks postconception). Also important is the route of administration and dose of a particular medication, the length of exposure, and maternal and placental clearance. Passage into the placental circulation is necessary for a drug to cause a teratogenic effect. Table 13–3 lists some of the potential adverse effects related to the timing of exposure.

Table 13–3. Potential adverse effects of fetotoxic exposure at selected stages of development.

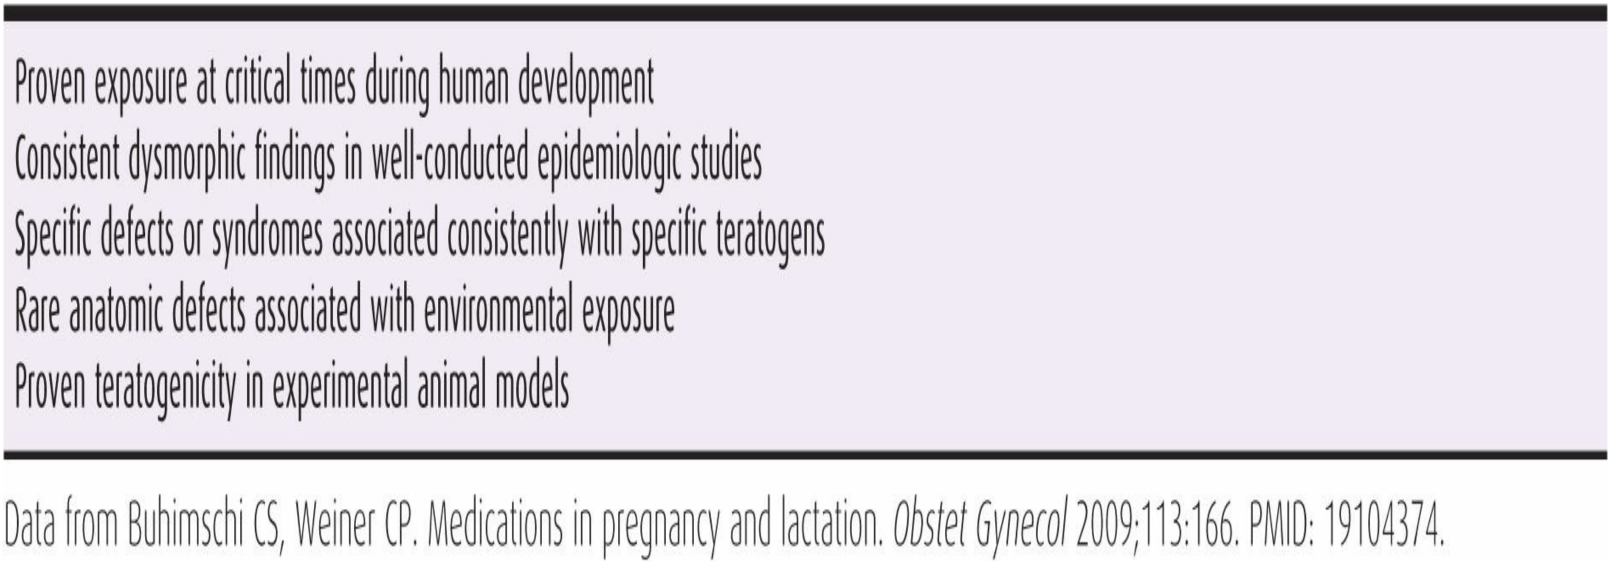


Timing	Potential Adverse Effect
Preimplantation (fertilization to implantation)	Miscarriage
Embryonic (2-9 weeks)	Miscarriage, structural malformations
Fetal (9-40 weeks)	Central nervous system abnormalities, growth restrictions, neurobehavioral abnormalities, reproductive effects, fetal demise

Data from Buhimschi CS, Weiner CP. Medications in pregnancy and lactation. *Obstet Gynecol* 2009;113:166. PMID: 19104374.

Evaluation of studies examining toxic exposures is difficult because of the large number of possible fetotoxic agents and the complex interaction between these agents, the presence or absence of influences that may alter the effects of an agent, and the presence or absence of certain genotypes that might alter an individual’s susceptibility. Therefore, specific criteria for recognizing teratogens in humans have been defined (Table 13–4). Table 13–5 lists common teratogens and their potential fetotoxic effects.

Table 13–4. Criteria used to define human teratogens.



Proven exposure at critical times during human development
Consistent dysmorphic findings in well-conducted epidemiologic studies
Specific defects or syndromes associated consistently with specific teratogens
Rare anatomic defects associated with environmental exposure
Proven teratogenicity in experimental animal models

Data from Buhimschi CS, Weiner CP. Medications in pregnancy and lactation. *Obstet Gynecol* 2009;113:166. PMID: 19104374.

Table 13–5. Common teratogens and their potential fetotoxic effects.

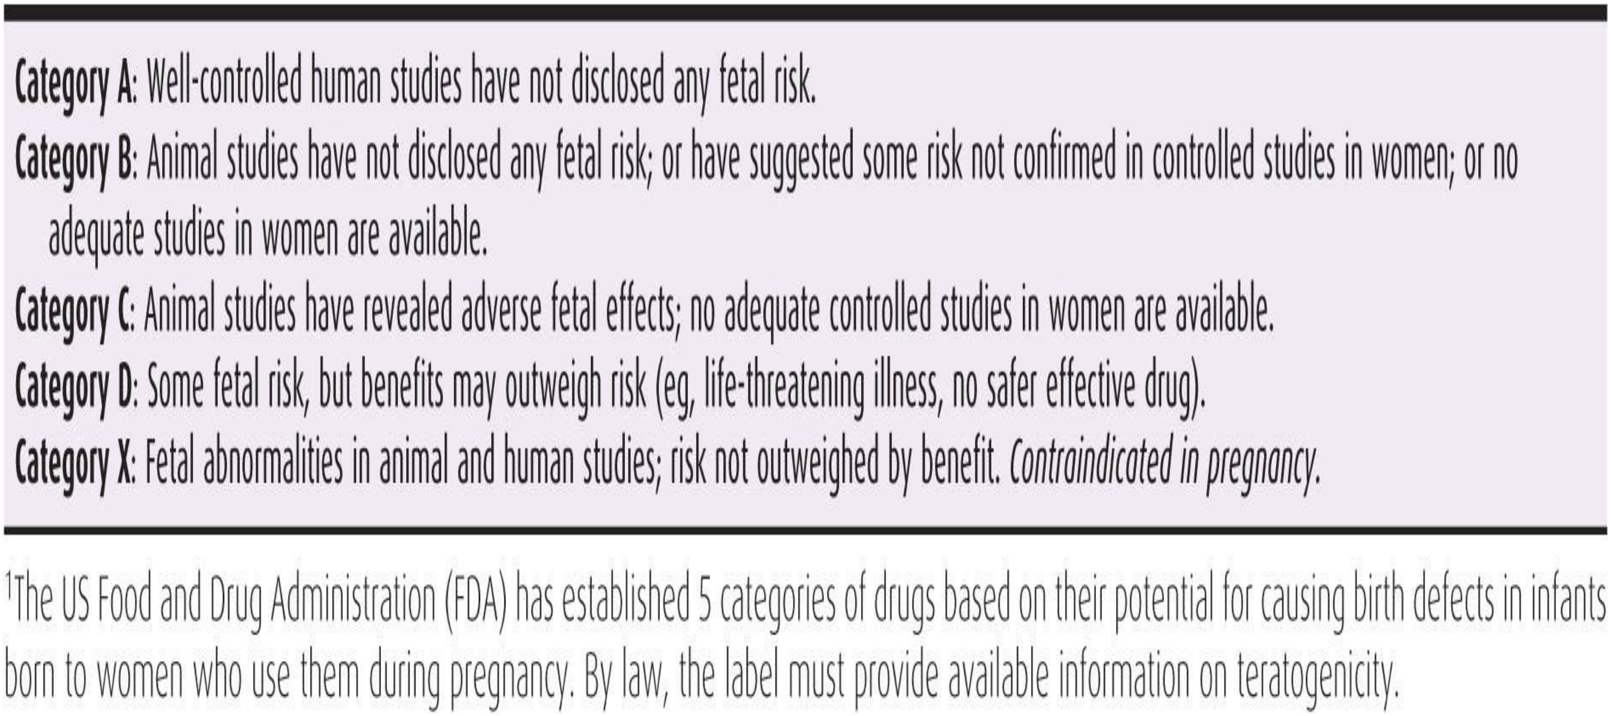
Teratogen	Potential Effects
Angiotensin-converting enzyme (ACE) inhibitors	**First-trimester exposure** Cardiovascular/CNS malformations **Second-trimester exposure** Oligohydramnios, anuria, renal failure, limb contractures, pulmonary hypoplasia
Selective serotonin reuptake inhibitors (SSRIs)	**Sertraline**: Increased risk of omphalocele, atrial, and ventricular septal defects **Paroxetine**: 1.5 to 2-fold increased risk of congenital cardiac malformations, anencephaly, omphalocele **All SSRIs**: Late exposure associated with transient neonatal respiratory distress
Anticonvulsants	**Valproic acid**: distinct craniofacial appearance, limb abnormalities, heart defects, CNS dysfunction **Carbamazepine**: facial dysmorphism, developmental delay, spina bifida, distal phalange, and fingernail hypoplasia **Phenytoin**: congenital heart defects, cleft palate
Anxiolytics (benzodiazepines)	Neonatal withdrawal, hypotonia, cyanosis, “floppy infant” syndrome
Alkylating agents	**Cyclophosphamide**: growth restriction, high-arched palate, microcephaly, flat nasal bridge, syndactyly, finger hypoplasia
Hormones/androgens	**Medroxyprogesterone acetate**: increased risk of hypospadias in male fetuses **Danazol**: androgenic effect on female fetuses
Antimetabolites (methotrexate)	Craniofacial, axial skeletal, cardiopulmonary, gastrointestinal malformations
Antithyroids	**Propylthiouracil**: fetal hypothyroidism, aplasia cutis **Methimazole**: fetal goiter, aplasia cutis, esophageal atresia, choanal atresia
Coumarin derivatives	**Warfarin**: nasal hypoplasia, microphthalmia, hypoplasia of the extremities, growth restriction, heart disease, scoliosis, deafness, CNS malformations, mental retardation
Lithium	Fetal and neonatal cardiac arrhythmias, hypoglycemia, nephrogenic diabetes insipidus, Ebstein’s anomaly, polyhydramnios
Retinoids (isotretinoin)	Severe CNS, cardiovascular, endocrine malformations, mental retardation

Data from Buhimschi CS, Weiner CP. Medications in pregnancy and lactation. *Obstet Gynecol* 2009;113:166.

Counseling of parents should include review of the exposure history and discussion of the particular agent involved, as well as possible sequelae. In some cases, intervention may be possible. In other cases, if a pregnancy is found to develop abnormally, the parents may elect to abort an affected fetus. Effective counseling should provide the best information available to assist parents in what can be a very difficult decision.

The United States Food and Drug Administration standards for drug labeling with regard to teratogenicity are listed in Table 13–6.

Table 13–6. Teratogenicity drug labeling required by the FDA.[1]



Category A: Well-controlled human studies have not disclosed any fetal risk.

Category B: Animal studies have not disclosed any fetal risk; or have suggested some risk not confirmed in controlled studies in women; or no adequate studies in women are available.

Category C: Animal studies have revealed adverse fetal effects; no adequate controlled studies in women are available.

Category D: Some fetal risk, but benefits may outweigh risk (eg, life-threatening illness, no safer effective drug).

Category X: Fetal abnormalities in animal and human studies; risk not outweighed by benefit. *Contraindicated in pregnancy.*

[1] The US Food and Drug Administration (FDA) has established 5 categories of drugs based on their potential for causing birth defects in infants born to women who use them during pregnancy. By law, the label must provide available information on teratogenicity.

Late Pregnancy Complications

Ashley S. Roman, MD, MPH

PRETERM LABOR

ESSENTIALS OF DIAGNOSIS

- Estimated gestational age of greater than 20 0/7 weeks and less than 37 0/7 weeks
- Regular uterine contractions at frequent intervals
- Documented cervical change or appreciable cervical dilatation or effacement

---

Pathogenesis

Labor is the process of coordinated uterine contractions leading to progressive cervical effacement and dilatation by which the fetus and placenta are expelled. **Preterm labor** is defined as labor occurring after 20 weeks' but before 37 weeks' gestation. Although there is no strict definition in the literature regarding the amount of uterine contractions required for preterm labor, there is consensus that contractions need to be regular and at frequent intervals. Generally, more than 4 contractions per hour are needed to cause cervical change. The uterine contractions need not be painful to cause cervical change and may manifest themselves as abdominal tightening, lower back pain, or pelvic pressure. In addition, there must be demonstrated cervical effacement or dilatation to meet a diagnosis of preterm labor.

It is important to distinguish preterm labor from other similar clinical entities, such as cervical incompetence (cervical change in the absence of uterine contractions) and preterm uterine contractions (regular contractions in the absence of cervical change) because the treatment for these situations differs. Cervical incompetence may require cerclage placement, and preterm uterine contractions without cervical change is generally a self-limited phenomenon that resolves spontaneously and requires no intervention. If ruptured membranes accompany preterm labor, these cases are classified as preterm premature rupture of membranes (for discussion of diagnosis see Premature Rupture of Membranes).

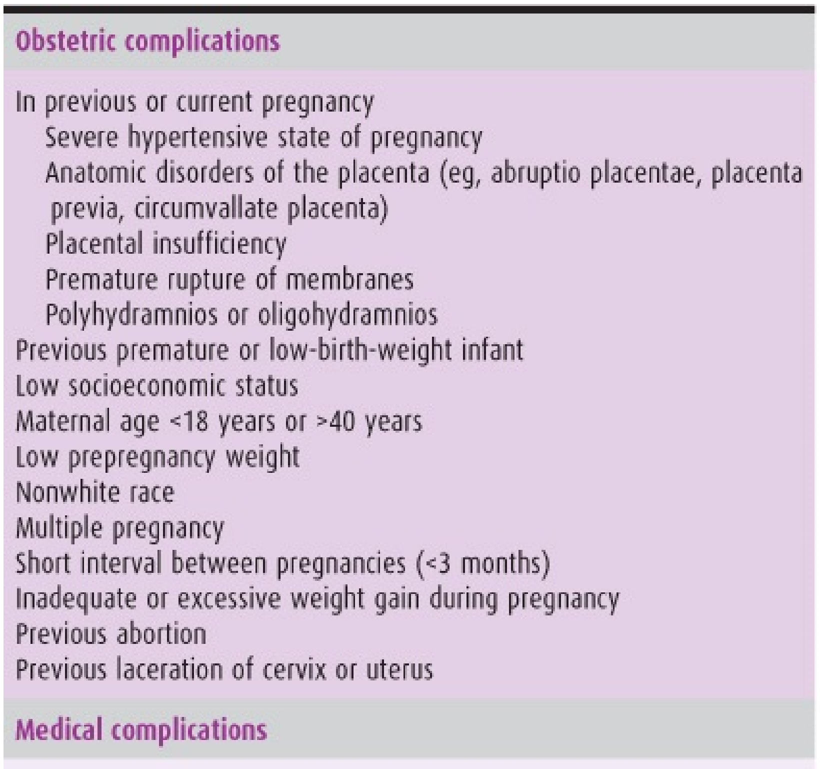
Preterm birth complicates approximately 12% of all pregnancies in the United States. It is the number one cause of neonatal morbidity and mortality and causes 75% of neonatal deaths that are not due to congenital anomalies.

Thirteen percent of all infants are classified as low birth weight (<2500 g), of whom 25% are mature low-birth-weight infants and approximately 75% are truly premature. The latter group accounts for nearly two-thirds of infant deaths (approximately 25,000 annually in the United States). Approximately 30% of premature births are due to miscalculation of gestational age or to medical intervention required by the mother or fetus.

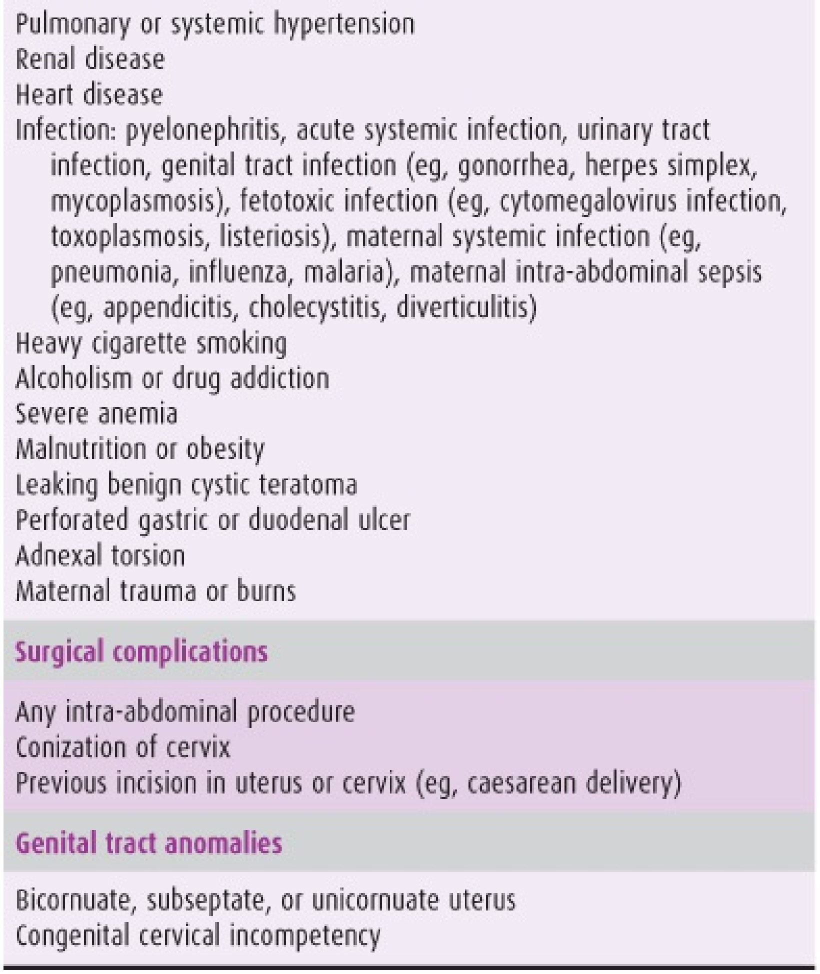
The care of premature infants is costly. Compared with term infants, those born prematurely suffer greatly increased morbidity and mortality (eg, functional disorders, abnormalities of growth and development). Thus every effort is made to prevent or inhibit preterm labor. If preterm labor cannot be inhibited or is best allowed to continue, it should be conducted with the least possible trauma to the mother and infant.

Many obstetric, medical, and anatomic disorders are associated with preterm labor. Some of the risk factors are listed in Table 14–1. Detailed discussions of these conditions are given in other chapters. The cause of preterm labor in 50% of pregnancies, however, is idiopathic. Although several prospective risk-scoring tools are in use, they have not been convincingly demonstrated to be of value.

Table 14–1. Risk factors associated with preterm labor.



Obstetric complications
In previous or current pregnancy
Severe hypertensive state of pregnancy
Anatomic disorders of the placenta (eg, abruptio placentae, placenta previa, circumvallate placenta)
Placental insufficiency
Premature rupture of membranes
Polyhydramnios or oligohydramnios
Previous premature or low-birth-weight infant
Low socioeconomic status
Maternal age <18 years or >40 years
Low prepregnancy weight
Nonwhite race
Multiple pregnancy
Short interval between pregnancies (<3 months)
Inadequate or excessive weight gain during pregnancy
Previous abortion
Previous laceration of cervix or uterus
Medical complications



Pulmonary or systemic hypertension Renal disease Heart disease Infection: pyelonephritis, acute systemic infection, urinary tract infection, genital tract infection (eg, gonorrhea, herpes simplex, mycoplasmosis), fetotoxic infection (eg, cytomegalovirus infection, toxoplasmosis, listeriosis), maternal systemic infection (eg, pneumonia, influenza, malaria), maternal intra-abdominal sepsis (eg, appendicitis, cholecystitis, diverticulitis) Heavy cigarette smoking Alcoholism or drug addiction Severe anemia Malnutrition or obesity Leaking benign cystic teratoma Perforated gastric or duodenal ulcer Adnexal torsion Maternal trauma or burns
Surgical complications
Any intra-abdominal procedure Conization of cervix Previous incision in uterus or cervix (eg, caesarean delivery)
Genital tract anomalies
Bicornuate, subseptate, or unicornuate uterus Congenital cervical incompetency

Prevention

Unfortunately, there are few interventions known to prevent preterm labor. For women with a history of a prior spontaneous preterm birth, there is evidence indicating that progestin administered via either vaginal suppositories of progesterone or weekly intramuscular injections of 17-α hydroxyprogesterone caproate starting at 16–20 weeks until approximately 36–37 weeks reduces the risk of recurrent preterm birth by approximately 30%. Furthermore, vaginal progesterone may also reduce the risk of preterm birth in women found to have a short cervix on transvaginal ultrasound in the midtrimester. But, aside from these specific interventions, there is little we can do to prevent preterm labor.

Clinical Findings

A. Symptoms and Signs

1. Uterine contractions—Regular uterine contractions at frequent intervals as documented by tocometer or uterine palpation, generally more than 2 in one-half hour.

2. Dilation and effacement of cervix—This can be established by clinical examination or by transvaginal ultrasound. Documented cervical change in dilation or effacement of at least 1 cm or a cervix that is well effaced and dilated (at least 2 cm) on admission is considered diagnostic. On transvaginal ultrasound, a cervical length less than the 10th percentile (generally ≤2.5 cm) is also suggestive of cervical effacement.

3. Other signs—Many patients present with bloody mucous vaginal discharge, or “bloody show.” More significant vaginal bleeding should be evaluated for abruptio placentae or placenta previa.

Additionally, patients may report an increase in vaginal discharge or passage of their mucus plug.

B. Evaluation

Evaluation should include determination of the following:

1. Gestational age—Gestational age must be between 20 0/7 and 37 0/7 weeks' estimated gestational age (EGA), which should be calculated based on the patient's last menstrual period (LMP) or date of conception, if known, or the previous sonographic estimation if these dates are uncertain.

2. Fetal weight—Care must be taken to determine fetal size by ultrasonography.

3. Presenting part—The presenting part must be noted because abnormal presentation is more common in earlier stages of gestation.

4. Fetal monitoring—Continuous fetal monitoring should be performed to ascertain fetal well-being.

5. Tocodynamometry—Tocodynamometry should be performed to confirm the presence and frequency of contractions.

6. Physical examination—Physical examination should be performed to assess for cervical dilation, ruptured membranes (see section on Premature Rupture of Membranes), fundal tenderness, vaginal bleeding, and fever.

C. Laboratory Studies

1. Complete blood count with differential.
2. Urine obtained by catheter for urinalysis, culture, and sensitivity testing.
3. Ultrasound examination for fetal size, position, and placental location.
4. Amniocentesis may be useful to ascertain fetal lung maturity in instances in which EGA is uncertain, the size of the fetus is in conflict with the estimated date of conception (too small, suggesting intrauterine growth restriction, or too large, suggesting more advanced EGA), or the fetus is more than 34 weeks' EGA. Specifically, the amniotic fluid can be tested for lecithin/sphingomyelin (L/S) ratio, the presence of phosphatidylglycerol, fluorescence polarization assay, or lamellar body count. Amniocentesis should also be performed in instances in which chorioamnionitis is suspected; the fluid should be tested for Gram's stain, bacterial culture, glucose levels, cell count, and, if available, interleukin-6 level.
5. Speculum examination should be performed. Cervical cultures should be sent for gonorrhea and chlamydia. A wet mount should be performed to look for signs of bacterial vaginosis. Group B streptococcus (GBS) cultures should be taken from the vaginal and rectal mucosa. A swab may also be used to test any fluid in the vaginal to see if it is amniotic fluid (see section on Premature Rupture of Membranes).
6. Hematologic workup in cases associated with vaginal bleeding (see Chapter 18).
7. Fetal fibronectin testing kits have been approved by the Food and Drug Administration (FDA) as a means to assess the risk of preterm birth in patients with preterm labor. A cervicovaginal swab is taken to look for the presence of fetal fibronectin. A negative test is effective at identifying women at low risk of imminent delivery (within 2 weeks). A positive test result, however, is less sensitive at predicting preterm birth. The test may be helpful in identifying patients at low risk of preterm birth who can be managed on an outpatient basis.

Differential Diagnosis

The differential diagnosis includes preterm contractions without labor (ie, without cervical change) and cervical insufficiency (ie, cervical dilation without uterine contractions). However, clinical examination and signs can help distinguish among these entities.

Complications

The primary complication of preterm labor is preterm birth and the resulting prematurity of the infant. Treatment is directed toward reducing the likelihood of preterm birth and reducing the risk of prematurity-related complications in the infant, such as respiratory distress syndrome and neurologic injury.

Treatment

Decisions regarding management are made based on EGA, estimated weight of the fetus, and existence of contraindications to suppressing preterm labor. Table 14–2 lists factors indicating that preterm labor should be allowed to continue. Once the patient is determined to not have any of these contraindications, the management of preterm labor depends on fetal gestational age. Generally, management falls into 1 of 2 categories: expectant management (observation) or intervention. For pregnancies between 24 0/7 and 34 0/7 weeks' EGA, intervention with corticosteroids has been shown to be of benefit in reducing neonatal morbidity and mortality rates. Although the efficacy of tocolysis has been much debated, it is generally accepted that a delay in delivery of 48 hours may be achieved at a minimum. Because this window can be used for corticosteroid administration, tocolysis is favored in many centers.

Table 14–2. Some cases in which preterm labor should not be suppressed.

Maternal factors
Severe hypertensive disease (eg, acute exacerbation of chronic hypertension, eclampsia, severe preeclampsia)
Pulmonary or cardiac disease (eg, pulmonary edema, adult respiratory distress syndrome, valvular disease, tachyarrhythmias)
Advanced cervical dilatation (>4 cm)
Maternal hemorrhage (eg, abruptio placentae, placenta previa, disseminated intravascular coagulation)
Fetal factors
Fetal death or lethal anomaly
Fetal distress
Intrauterine infection (chorioamnionitis)
Therapy adversely affecting the fetus (eg, fetal distress due to attempted suppression of labor)
Estimated fetal weight ≥2500 g
Erythroblastosis fetalis or fetal hydrops
Severe intrauterine growth retardation

Extremes of preterm gestational age pose special problems. Fetuses of very preterm pregnancies (20–23 weeks; EGA or estimated fetal weight [EFW] less than 550 g) are generally not considered to be viable. If these pregnancies can be continued for several more weeks, the fetuses will become viable, but have a high risk for significant morbidity if they are born in this periviable period and survive. Furthermore, intervention carries significant risks to the mother, including the risks of prolonged bed rest and side effects of tocolysis. Given these risks, expectant management is an acceptable and, in certain instances, preferable alternative to intervention. Mothers who choose intervention as opposed to expectant management should be extensively counseled by a multidisciplinary team, including the neonatologist, obstetrician, and social worker.

Conversely, once a pregnancy has continued beyond 34–37 weeks' EGA or EFW greater than 2500 g, the fetal survival rate is within 1% of the survival rate at 37 weeks. Fetal morbidity is less severe and is rarely a cause of long-term sequelae. Furthermore, corticosteroids have not been shown to be of benefit in fetuses of this age or size. Therefore, expectant management is usually the recommended course of action. Several factors should be considered when deciding between intervention and expectant management, including the certainty of the patient's dates, EFW, presence of maternal problems that could delay fetal lung maturity such as diabetes mellitus, and family history of late-onset respiratory distress syndrome (RDS).

There are other cases in which maternal or fetal factors indicate that preterm labor should be allowed to continue regardless of gestational age. Table 14–2 lists cases in detail.

The following is a protocol for management of pregnancies with preterm labor between 24 and 34 weeks' gestation.

A. Bed Rest

The role of bed rest in the management of preterm labor is controversial. Meta-analyses have failed to demonstrate prolongation of pregnancy. Bed rest is associated with an increased risk of maternal thromboembolism. At minimum, bed rest may be advised particularly during the initial evaluation of an episode of preterm labor to allow for close fetal and maternal monitoring.

B. Corticosteroids

The administration of corticosteroids to accelerate fetal lung maturity has become the standard of care in the United States for all women between 24 and 34 weeks' EGA at risk of preterm delivery within the following 7 days. It has been shown to decrease the incidence of neonatal respiratory distress, intraventricular hemorrhage, and neonatal mortality. Steroids can be given according to 1 of 2 protocols: (1) betamethasone 12 mg intramuscularly (IM) every 24 hours for a total of 2 doses; or (2) dexamethasone 6 mg IM every 12 hours for a total of 4 doses.

The optimal benefits of antenatal corticosteroids are seen 24 hours after administration, peak at 48 hours, and continue for at least 7 days. If therapy for preterm labor is successful and the pregnancy continues beyond 2 weeks, there are data suggesting that a single repeat course of steroids may be beneficial if the risk of preterm birth remains high and the patient is <33 weeks. More than 2 courses, however, may be associated with fetal growth abnormalities and delayed psychomotor development in the infant. In terms of safety of 1 or 2 courses of antenatal steroids, there does not appear to be an increased risk of infection or suppression of the fetal adrenal glands with steroid administration, and long-term follow-up of fetuses who received 1 or 2 courses of antenatal steroids shows no sequelae that can be attributed directly to steroid administration.

C. Tocolysis

If the patient continues to contract and falls into a high-risk group based on a history of preterm birth, positive fibronectin, short cervix on transvaginal sonography, or changing dilatation on cervical examination, tocolytic therapy may be initiated. When using tocolysis to treat preterm labor, it is important to keep the following goals in mind. The short-term goal is to continue the pregnancy for 48 hours after steroid administration, after which the maximum effect of the steroids can be achieved. The long-term goal is to continue the pregnancy beyond 34–36 weeks (depending on the institution), at which point fetal morbidity and mortality are dramatically reduced, and tocolysis can be discontinued.

Tocolytic therapy should be considered in the patient with cervical dilatation less than 5 cm. Successful tocolysis is generally considered fewer than 4–6 uterine contractions per hour without further cervical change.

The beta-mimetics and nifedipine are the most commonly used tocolytic agents. The decision to use a specific tocolytic should be carefully considered because of contraindications and side effects associated with each agent (Table 14–3).

Table 14–3. Side effects and complications of common tocolytics.

Tocolytic	Maternal Effects	Fetal/Neonatal Effects
Beta-mimetics (ritodrine, terbutaline)	Pulmonary edema Hypotension Tachycardia Nausea/vomiting Hyperglycemia Hypokalemia Cardiac arrhythmias	Tachycardia Hyperglycemia Hypoglycemia Ileus Possible increased risk for intraventricular hemorrhage
Magnesium sulfate	Flushing Nausea/vomiting Headache Generalized muscle weakness Shortness of breath Diplopia Pulmonary edema Chest pain Hypotension Tetany Respiratory depression	Lethargy Hypotonia Respiratory depression
Indomethacin	Gastrointestinal effects: Nausea/vomiting, heartburn, bleeding Coagulation disturbances Thrombocytopenia Renal failure Hepatitis Elevated blood pressure in hypertensive patients	Renal dysfunction Oligohydramnios Pulmonary hypertension Postpartum patent ductus arteriosus Premature constriction of ductus arteriosus in utero Increased risk for necrotizing enterocolitis and intraventricular hemorrhage
Nifedipine	Hypotension Tachycardia Headache Flushing Dizziness Nausea/vomiting	Tachycardia Hypotension

1. Beta-mimetic adrenergic agents—Beta-mimetic adrenergic agents act directly on beta receptors (β_2) to relax the uterus. Their use is limited by dose-related cardiovascular side effects, including pulmonary edema, adult RDS, elevated systolic blood pressure and reduced diastolic blood pressure, and both maternal and fetal tachycardia. Other dose-related effects are decreased serum potassium level and increased blood glucose and plasma insulin levels and lactic acidosis. Maternal medical contraindications to the use of β-adrenergic agents include cardiac disease, hyperthyroidism, uncontrolled hypertension or pulmonary hypertension, asthma requiring sympathomimetic drugs or corticosteroids for relief, uncontrolled diabetes, and chronic hepatic or renal disease. Commonly observed effects during intravenous administration are palpitations, tremors, nervousness, and restlessness. The beta-mimetic in common use is terbuta-line. Although it has been used in the past, ritodrine is no longer commercially available. Because of the side effects, beta-mimetic tocolysis in the United States is now limited almost exclusively to subcutaneous intermittent injections as a method of temporizing and triaging patients before definitive therapy with other agents.

Although not approved by the FDA for use as a tocolytic, terbutaline has been studied in the United States and is used widely as a tocolytic agent. For tocolysis, it is administered via subcutaneous boluses. Given the potential for maternal cardiac toxicity, terbutaline should only be used for a maximum of 48–72 hours and should only be used in an inpatient setting.

2. Magnesium sulfate—Although its exact mechanism of action is unknown, magnesium sulfate appears to inhibit calcium uptake into smooth muscle cells, reducing uterine contractility. The efficacy of magnesium is debated, but several small studies have shown an effect comparable to that of beta-mimetics, and it may be better tolerated than beta-mimetics. Magnesium sulfate may appear less likely to cause serious side effects than the beta-mimetics, but its therapeutic range is close to the range at which it will cause respiratory and cardiac depression. Therefore, patients receiving magnesium sulfate should be monitored closely for signs of toxicity, with frequent checks of deep tendon reflexes, pulmonary examinations, and strict calculations of the patient’s fluid balance. These effects may be reversed by calcium gluconate (10 mL of a 10% solution given intravenously), and this antidote should be kept at the bedside when magnesium sulfate is used.

3. Calcium channel blockers—Calcium channel blockers such as nifedipine work as tocolytics by inhibiting calcium uptake into uterine smooth muscle cells via voltage-dependent channels, thereby reducing uterine contractility. Several studies have shown nifedipine to be equally or more efficacious than beta-mimetics in preterm labor. Other advantages are its low incidence of maternal side effects and ease of administration. Nifedipine can be given by mouth. A common regimen for tocolysis is nifedipine 20 mg by mouth, then 10–20 mg by mouth every 6 hours until contractions diminish sufficiently.

4. Prostaglandin synthase inhibitors—Prostaglandin synthase inhibitors such as indomethacin have been shown to be as effective as ritodrine for tocolysis, but their use has been limited by potentially serious fetal effects. Indomethacin works as a tocolytic by inhibiting prostaglandin synthesis, an important mediator in uterine smooth muscle contractility. The advantages of indomethacin are its ease of administration (it can be given by rectum or by mouth) and its potent tocolytic activity. However, it has been associated with oligohydramnios and premature closure of the ductus arteriosus. In preterm infants delivered before 30 weeks’ EGA, some studies have demonstrated an increased risk of intracranial hemorrhage, necrotizing enterocolitis, and patent ductus arteriosus after birth. A common regimen for tocolysis is indomethacin 100 mg per rectum loading dose (or 50 mg by mouth), then 25–50 mg by mouth or rectum every 4–6 hours. Ultrasound should be performed every 48–72 hours to check for oligohydramnios. Because of the potentially serious fetal effects, many centers limit its use to infants less than 32 weeks' EGA and its duration of use to less than 48 hours.

5. Treatment with multiple tocolytics—All tocolytics have significant failure rates; therefore, if 1 tocolytic appears to be failing, that agent should be stopped and another agent should be tried. The use of multiple tocolytics at the same time appears to have an additive tocolytic effect, but also appears to increase the risk of serious side effects. For example, magnesium sulfate used in combination with nifedipine theoretically can cause serious maternal hypotension. Likewise, magnesium sulfate supplemented by 1–2 doses of subcutaneous terbutaline may be safe and effective, but sustained treatment with the 2 can increase the patient's risk of pulmonary edema. It should be remembered that the patient who is difficult to tocolyze may have an unrecognized chorioamnionitis or placental abruption, conditions that may be contraindications to use of any tocolysis at all.

6. Results of tocolytic therapy—With all tocolytics, a point may be reached where further therapy is not indicated. This may be due to adverse maternal or fetal response to the progress of labor. Thus, if cervical dilatation reaches 5 cm, the treatment should be considered a failure and abandoned. Conversely, if labor resumes after a period of quiescence, treatment should be carefully considered because the recrudescence of contractions may be a sign of intrauterine infection. In some cases, therapy may be reinstituted using the same or a different drug.

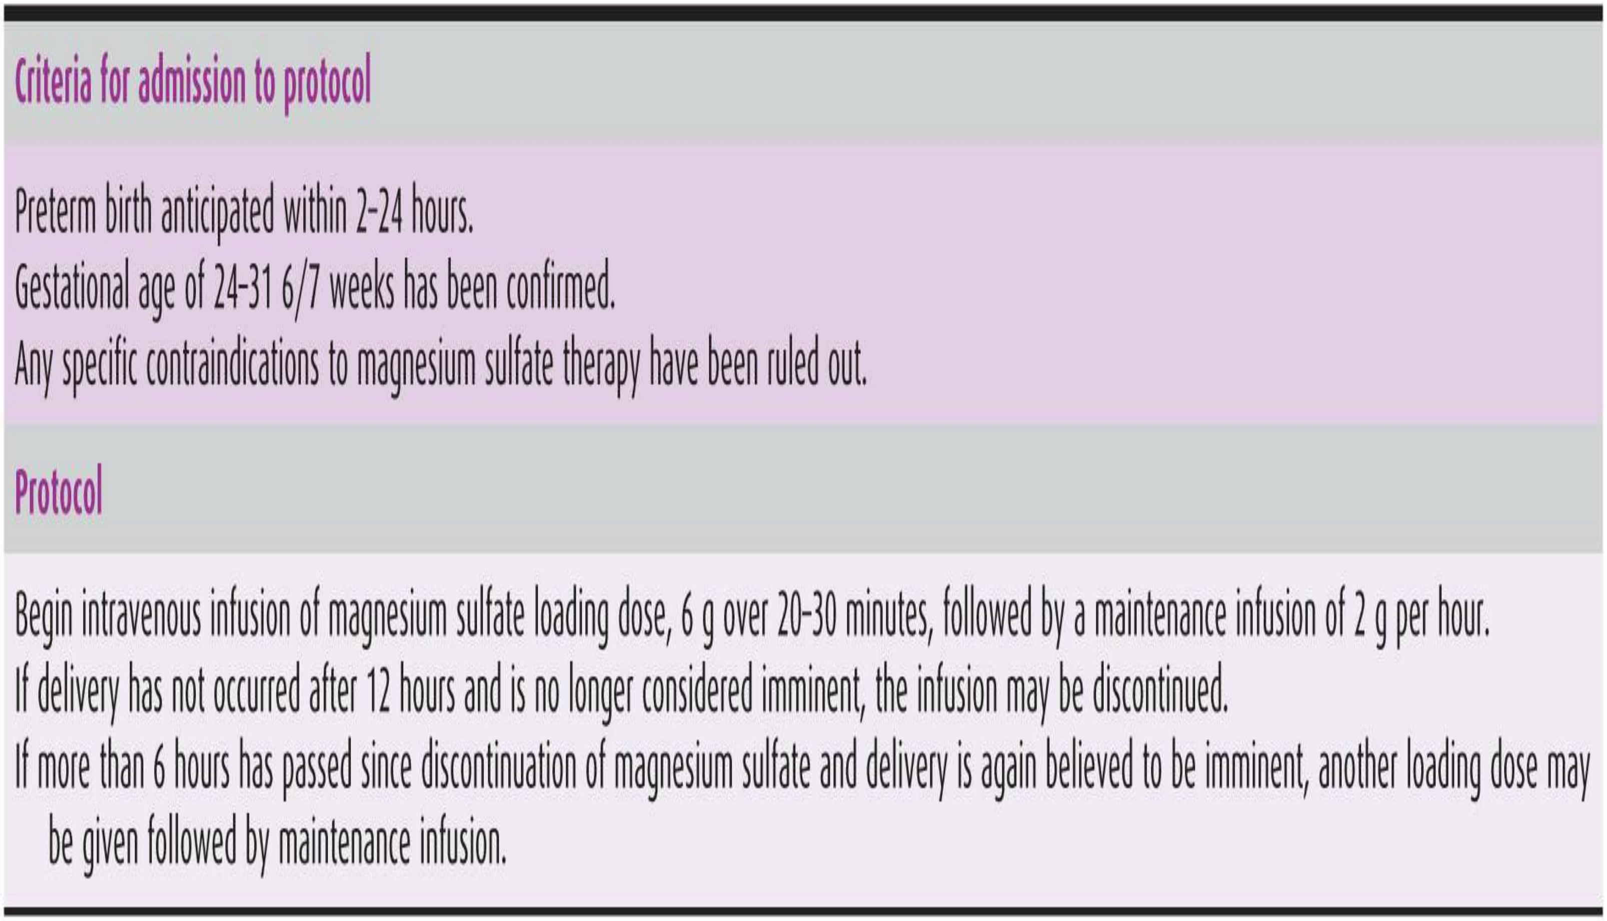
D. Antibiotics

Antibiotic therapy as a treatment of preterm labor and a means of prolonging pregnancy has been studied and has shown no benefit in delaying preterm birth in this population of patients. Patients with preterm labor should be started on antibiotics for prevention of neonatal GBS infection if the patient's GBS status is positive or unknown. Penicillin or ampicillin is used as first-line agents; cefazolin, clindamycin, erythromycin, or vancomycin can be used if the patient is allergic to penicillin. If the patient is successfully tocolyzed and there is no sign of imminent delivery or if the patient's most recent rectovaginal GBS culture (within 5 weeks) is negative, GBS prophylaxis can be discontinued.

E. Magnesium Sulfate for Fetal/Neonatal Neuroprotection

Several recent large trials have shown a reduced risk of cerebral palsy in fetuses exposed to magnesium sulfate in utero. The largest trial from the United States demonstrated a significant reduction in moderate to severe cerebral palsy in children at or beyond 2 years of age who received magnesium sulfate immediately before delivery. The optimal candidates for magnesium for this indication are not well defined, but it is reasonable to offer magnesium sulfate to any woman between 24 0/7 and 32 0/7 weeks of gestation immediately before delivery to reduce the risk of adverse neurologic outcomes (Table 14–4).

Table 14–4. Protocol for use of magnesium sulfate for fetal neuroprotection.



Criteria for admission to protocol
Preterm birth anticipated within 2-24 hours. Gestational age of 24-31 6/7 weeks has been confirmed. Any specific contraindications to magnesium sulfate therapy have been ruled out.
Protocol
Begin intravenous infusion of magnesium sulfate loading dose, 6 g over 20–30 minutes, followed by a maintenance infusion of 2 g per hour. If delivery has not occurred after 12 hours and is no longer considered imminent, the infusion may be discontinued. If more than 6 hours has passed since discontinuation of magnesium sulfate and delivery is again believed to be imminent, another loading dose may be given followed by maintenance infusion.

Data from Rouse DJ, Hirtz DG, Thom E, et al. A randomized controlled trial of magnesium sulfate for the prevention of cerebral palsy. *N Engl J Med* 2008:359:895–905.

F. Conduct of Labor and Delivery

Premature infants younger than 34 weeks should be delivered in a hospital equipped for neonatal intensive care whenever possible, because inter-hospital transfer after birth is more hazardous. Although the route of delivery for very-low-birth-weight infants has been hotly debated, there is no conclusive evidence of a benefit to routine caesarean delivery. Indications for caesarean are the usual obstetrical indications, including nonreassuring fetal status, malpresentation, and history of prior caesarean.

If caesarean delivery is indicated, the decision to operate is based on maturity of the fetus and prognosis for survival. In borderline cases (23–24 weeks’ gestation and 500–600 g EFW), the wishes of the parents with regard to intervention assume an important place. When performing a caesarean delivery, it is important to ascertain that the uterine incision is adequate for extraction of the fetus without delay or unnecessary trauma. This may require a vertical incision when the lower uterine segment is incompletely developed. Trauma to the newborn may be minimized by en caul delivery.

When birth follows the unsuccessful use of parenteral tocolytic agents, keep in mind the potential residual adverse effects of these drugs. β-Adrenergic agents may cause neonatal hypotension, hypoglycemia, hypocalcemia, and ileus. Magnesium sulfate may be responsible for respiratory and cardiac depression.

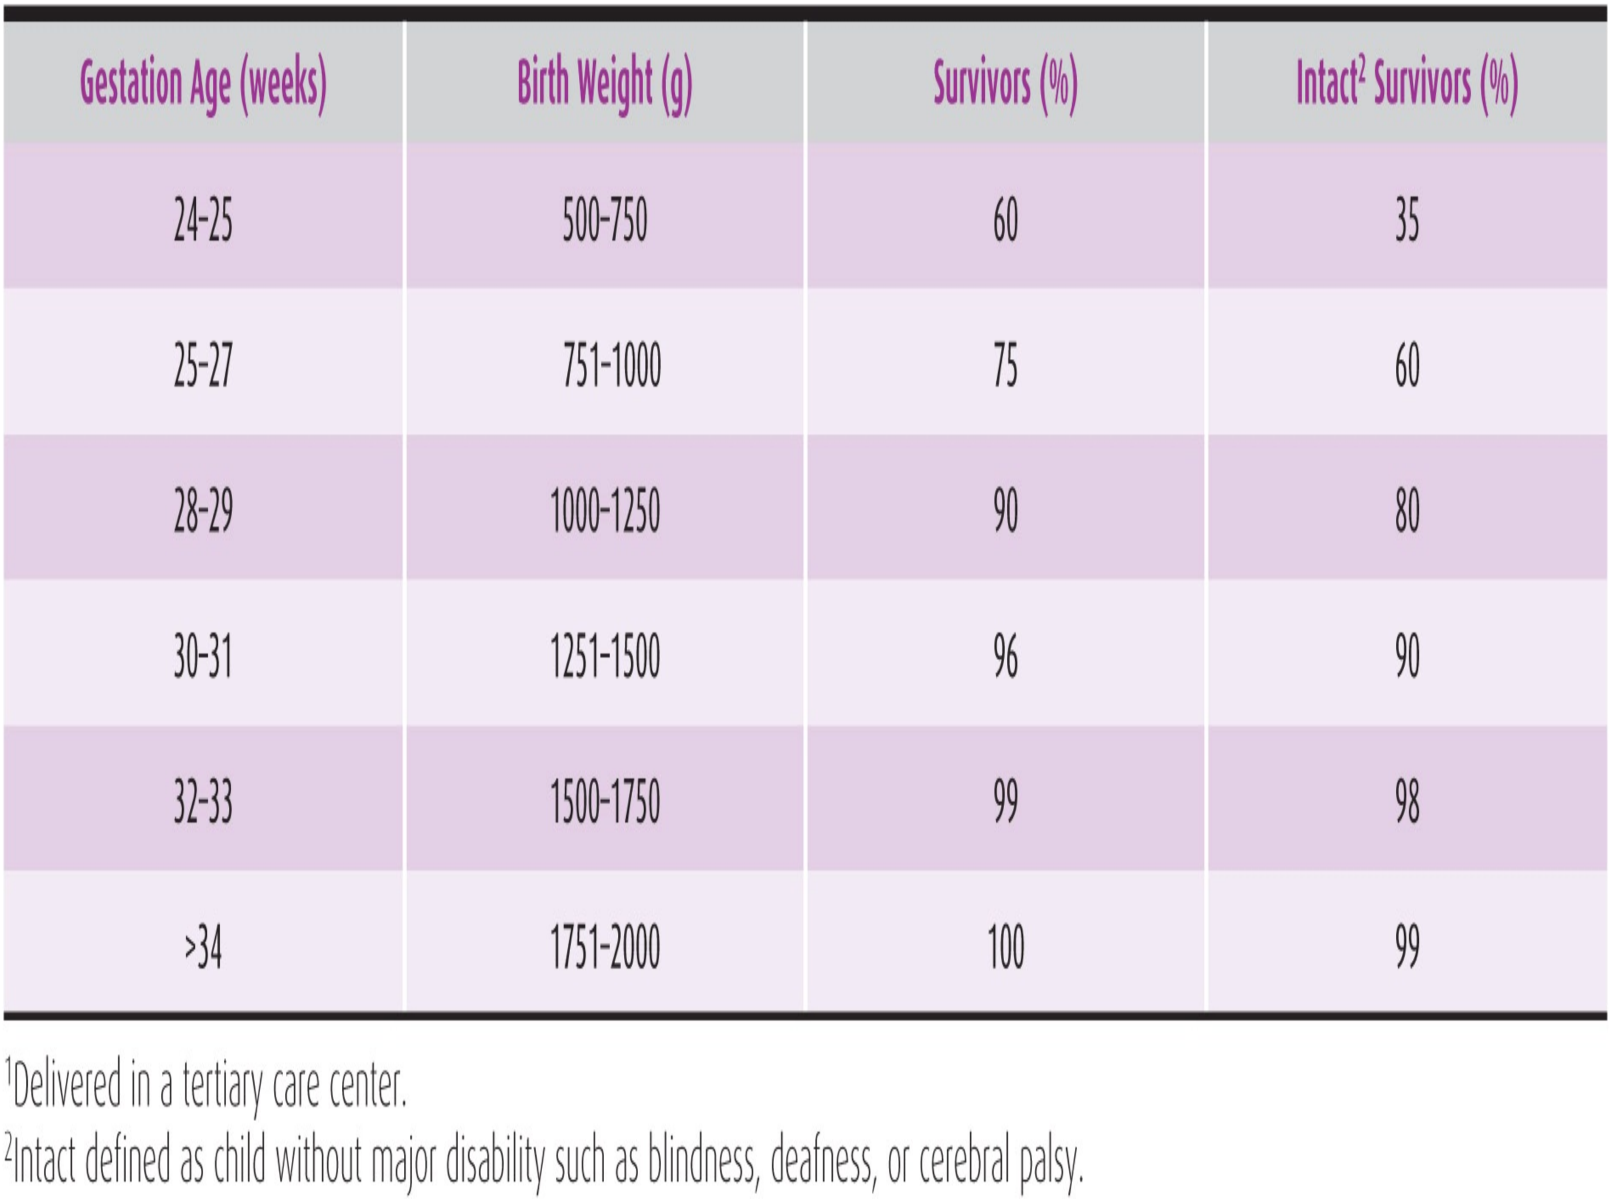
G. Cord pH & Blood Gases

Apgar scores are often low in low-birth-weight babies. This finding does not indicate asphyxia or compromised status but merely reflects the immaturity of the physiologic systems. Therefore, it is crucial to obtain cord pH and blood gas measurements for premature (and other high-risk) infants in order to document the status at birth. Cord pH and blood gas measurements may also be helpful in reconstructing intrapartum events, clarifying resuscitative measures, and determining the need for more intensive neonatal care.

Prognosis

Excellent neonatal care in the delivery room and nursery will do much to ensure a good prognosis for the preterm infant (see Chapter 22). Lower-birth-weight babies have a lesser chance of survival and a greater chance of permanent sequelae in direct relationship to size. Making generalizations regarding survival rates and sequelae is difficult because of the many causes of preterm delivery, the different levels of perinatal care, and the institutional differences in reported series. However, general figures for survival and morbidity have been reported and are helpful in counseling patients (Table 14–5).

Table 14–5. Approximate neonatal survival of preterm infants.[1]



Gestation Age (weeks)	Birth Weight (g)	Survivors (%)	Intact[2] Survivors (%)
24-25	500-750	60	35
25-27	751-1000	75	60
28-29	1000-1250	90	80
30-31	1251-1500	96	90
32-33	1500-1750	99	98
>34	1751-2000	100	99

PREMATURE RUPTURE OF MEMBRANES

ESSENTIALS OF DIAGNOSIS

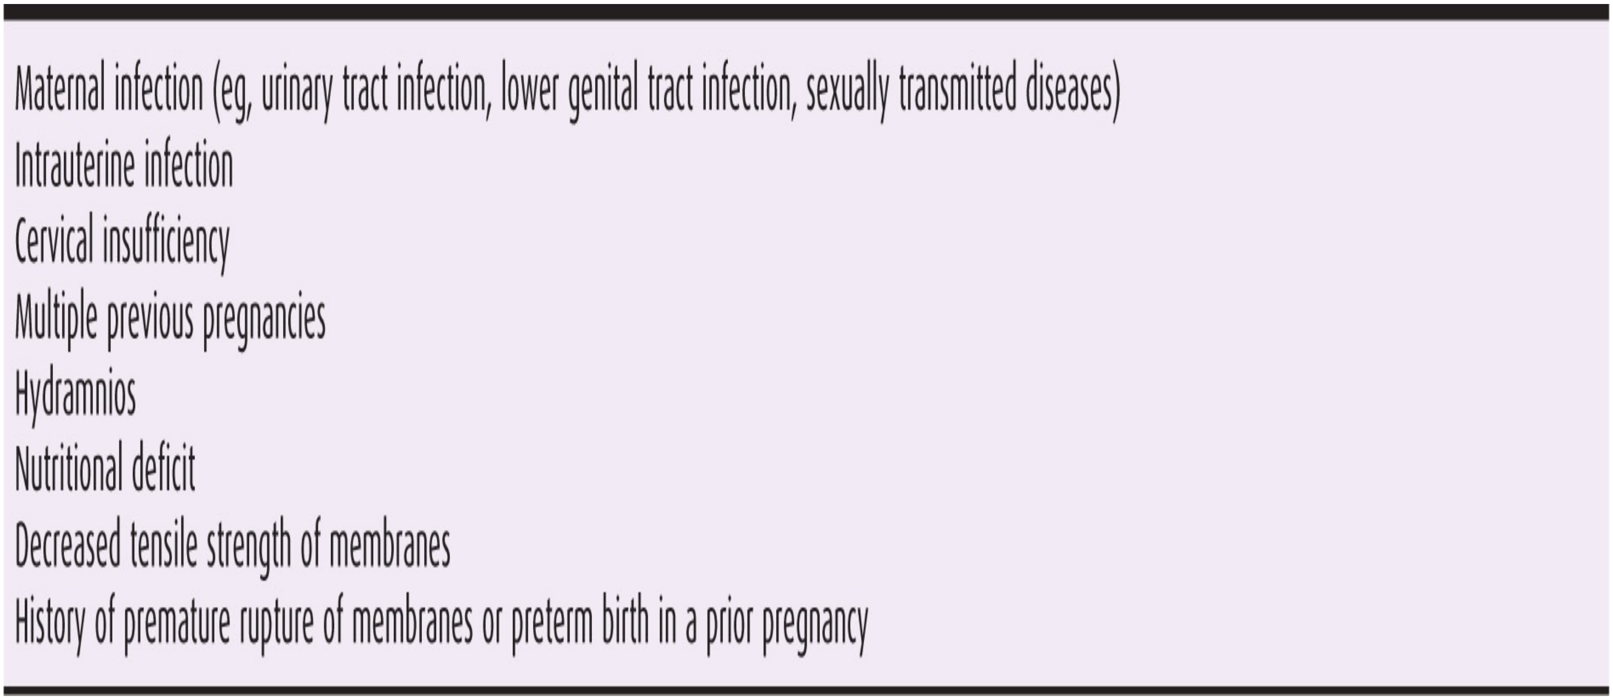
- History of a gush of fluid from the vagina or watery vaginal discharge
- Demonstration of amniotic fluid in the vagina on physical exam
- Absence of active labor

Pathogenesis

Rupture of the membranes may occur at any time during pregnancy. Premature rupture of the membranes (PROM) is defined as rupture of membranes before the onset of active labor. It becomes a particular problem if the fetus is preterm (preterm premature rupture of membranes [PPROM]) or, in the case of a term fetus, if the period of time between rupture of the membranes and the onset of labor is prolonged. If 24 hours elapse between rupture of the membranes and the onset of labor, the problem is one of prolonged PROM.

The exact cause of rupture is not known, although many conditions are associated with PROM (Table 14–6). PROM occurs in approximately 10.7% of all pregnancies. In approximately 94% of cases, this occurs at term or ≥37 weeks (approximately 20% of these are cases of prolonged rupture). Preterm fetuses (<37 weeks) account for approximately 5% of the total number of cases of PROM.

Table 14–6. Diseases and disorders associated with premature rupture of the membranes.



Maternal infection (eg, urinary tract infection, lower genital tract infection, sexually transmitted diseases)
Intrauterine infection
Cervical insufficiency
Multiple previous pregnancies
Hydramnios
Nutritional deficit
Decreased tensile strength of membranes
History of premature rupture of membranes or preterm birth in a prior pregnancy

The pathophysiology of PROM is poorly understood. Risk factors include decidual hemorrhage, a history of spontaneous preterm birth in a prior pregnancy, bacterial colonization of the membranes, and invasive procedures such as amniocentesis. PROM is an important cause of preterm labor, prolapse of the cord, placental abruption, and intrauterine infection. Chorioamnionitis is an important sequela of PROM and may precede endomyometritis or sepsis of the newborn.

In extremely prolonged rupture of the membranes, the fetus may have an appearance similar to that of Potter’s syndrome (ie, flattened facial features, wrinkling of the skin). If rupture of membranes with subsequent oligohydramnios occurs early in pregnancy at less than 26 weeks’ EGA, it can cause pulmonary hypoplasia and limb positioning defects in the newborn.

Prevention

As with preterm labor, there are few interventions known to prevent PPROM. For women with a history of a prior spontaneous preterm birth, there is evidence indicating that progestin administered via either vaginal suppositories of progesterone or weekly intramuscular injections of 17-α hydroxyprogesterone caproate from 16 weeks until approximately 36–37 weeks reduces the risk of recurrent preterm birth by approximately 30%. Furthermore, vaginal progesterone may also reduce the risk of preterm birth in women found to have a short cervix on transvaginal ultrasound in the midtrimester. But, aside from these specific interventions, there is little we can do to prevent PPROM.

Clinical Findings

A. Symptoms

The diagnostic evaluation must be efficient and impeccably conducted to minimize the number of vaginal examinations and the risk of chorioamnionitis. Symptoms are the key to diagnosis; the patient usually reports a sudden gush of fluid or continued leakage. Additional symptoms that may be useful include the color and consistency of the fluid and the presence of flecks of vernix or meconium, reduced size of the uterus, and increased prominence of the fetus to palpation.

B. Sterile Speculum Examination

A most important step in accurate diagnosis is examination with a sterile speculum. This examination is the key to differentiating PROM from hydrorrhea gravidarum, vaginitis, increased vaginal secretions, and urinary incontinence. The examiner should look for the 3 hallmark confirmatory findings associated with PROM:

1. Pooling—the collection of amniotic fluid in the posterior fornix.
2. Nitrazine test—a sterile cotton-tipped swab should be used to collect fluid from the posterior fornix and apply it to Nitrazine (phenaphthazine) paper. In the presence of amniotic fluid, the Nitrazine paper turns blue, demonstrating an alkaline pH (7.0–7.25).
3. Ferning—Fluid from the posterior fornix is placed on a slide and allowed to air-dry. Amniotic fluid will form a fernlike pattern of crystallization.

Together, these 3 findings confirm ruptured membranes, although several factors may produce false-positive results. Alkaline pH on Nitrazine test can also be caused by vaginal infections or the presence of blood or semen in the sample. Cervical mucus can cause ferning, but usually patchy and less extensive than with PROM. During the speculum examination, the patient’s cervix should be visually inspected to determine the degree of dilatation and effacement and the presence of cord prolapse. If vaginal pool is significant, the pool can be collected and sent for fetal lung maturity determination if the gestational age is greater than 32 weeks. Cervical secretions should also be sent for culture, and a wet mount should be performed.

If no free fluid is found, a dry pad should be placed under the patient’s perineum and observed for leakage. Other confirmatory tests for PROM include observed loss of fluid from the cervical os when the patient coughs or performs a Valsalva maneuver during speculum examination and oligohydramnios on ultrasound examination. If the examiner still cannot confirm rupture of membranes and the patient’s history is highly suspicious for PROM, it may be necessary to perform amniocentesis and inject a dilute solution of indigo carmine dye. This can be done after removal of amniotic fluid for pulmonary maturity testing, analysis for evidence of subacute intra-amniotic infection, and possible culture and sensitivity testing. After 15–30 minutes, examination of the patient’s perineal pad will reveal blue dye if the membranes are ruptured.

C. Physical Examination

Once PROM is confirmed, a careful physical examination is necessary to search for other signs of infection. Given the risk of infection, there is no indication for digital cervical examination if the patient is in early labor. The sterile speculum examination is sufficient to distinguish between early and advanced labor.

D. Laboratory Studies

Initial laboratory studies should include a complete blood count with differential. In preterm pregnancies, evaluation should also include urine collected by catheterization for urinalysis, culture, and sensitivity testing and ultrasound examination for fetal size and amniotic fluid index. For patients between 32 and 34 weeks, a specimen of amniotic fluid collected from the vaginal pool or via amniocentesis can be sent for fetal lung maturity studies. Furthermore, many centers perform amniocentesis in all women with PPROM before 34 weeks to test for evidence of intra-amniotic infection.

E. Chorioamnionitis

In all cases of chorioamnionitis, it is safer for the fetus to be delivered than to be retained in utero.

The most common organisms causing chorioamnionitis are those that ascend from the vagina (eg, *Escherichia coli*, *Bacteroides*, GBS, group D streptococcus, and other anaerobes). The most reliable signs of infection include the following: (1) Fever—the temperature should be checked every 4 hours. (2) Maternal leukocytosis—a daily leukocyte count and differential can be obtained. An increase in the white blood cell count or neutrophil count may indicate the presence of intra-amniotic infection. (3) Uterine tenderness—check every 4 hours. (4) Tachycardia—either maternal pulse >100 beats/min or fetal heart rate >160 beats/min—is suspicious. (5) Foul-smelling amniotic fluid.

A number of confounding factors may complicate the diagnosis of chorioamnionitis. For example, corticosteroid administration may cause mild leukocytosis (increase of 20–25%), and labor is associated with leukocytosis. If the diagnosis of chorioamnionitis is equivocal, amniocentesis can be performed to evaluate for evidence of infection, as described earlier in this chapter.

Differential Diagnosis

The differential diagnosis includes the increased physiologic vaginal discharge associated with pregnancy, vaginal infections such as bacterial vaginosis, and passage of a woman’s mucus plug. Physical examination with testing of any vaginal discharge or pool can distinguish among these entities.

Complications

Complications associated with PROM are primarily associated with duration of membrane rupture and the development of chorioamnionitis. Treatment outlined below is directed toward expediting delivery and preventing chorioamnionitis and fetal/neonatal infection. Complications with PPROM are primarily related to prematurity and the risk of fetal/neonatal infection. As in patients with preterm labor, treatment is directed toward reducing the likelihood of pre-term birth and reducing the risk of prematurity-related complications in the infant such as RDS and neurologic injury.

Treatment

The management of PROM depends on several factors, including gestational age and the presence or absence of chorioamnionitis.

A. Chorioamnionitis

If chorioamnionitis is present in the patient with PROM, the patient should be actively delivered *regardless of gestational age*. Broad-spectrum antibiotics should be started to treat the chorioamnionitis. If the patient is not in labor, labor should be induced to expedite delivery. Caesarean delivery should be reserved for the usual obstetric indications (eg, fetal malpresentation, nonreassuring fetal status).

B. Term Pregnancy Without Chorioamnionitis

The term pregnancy (EGA ≥37 weeks) with PROM in the absence of infection can be managed expectantly or actively. One large study found that starting induction of labor at presentation as opposed to expectant management reduced the time interval between PROM and delivery and the frequency of chorioamnionitis and postpartum febrile morbidity and neonatal antibiotic treatment. Therefore, active management with induction of labor at time of presentation for the woman with PROM at term is the preferred management strategy.

C. Preterm Pregnancy Without Chorioamnionitis

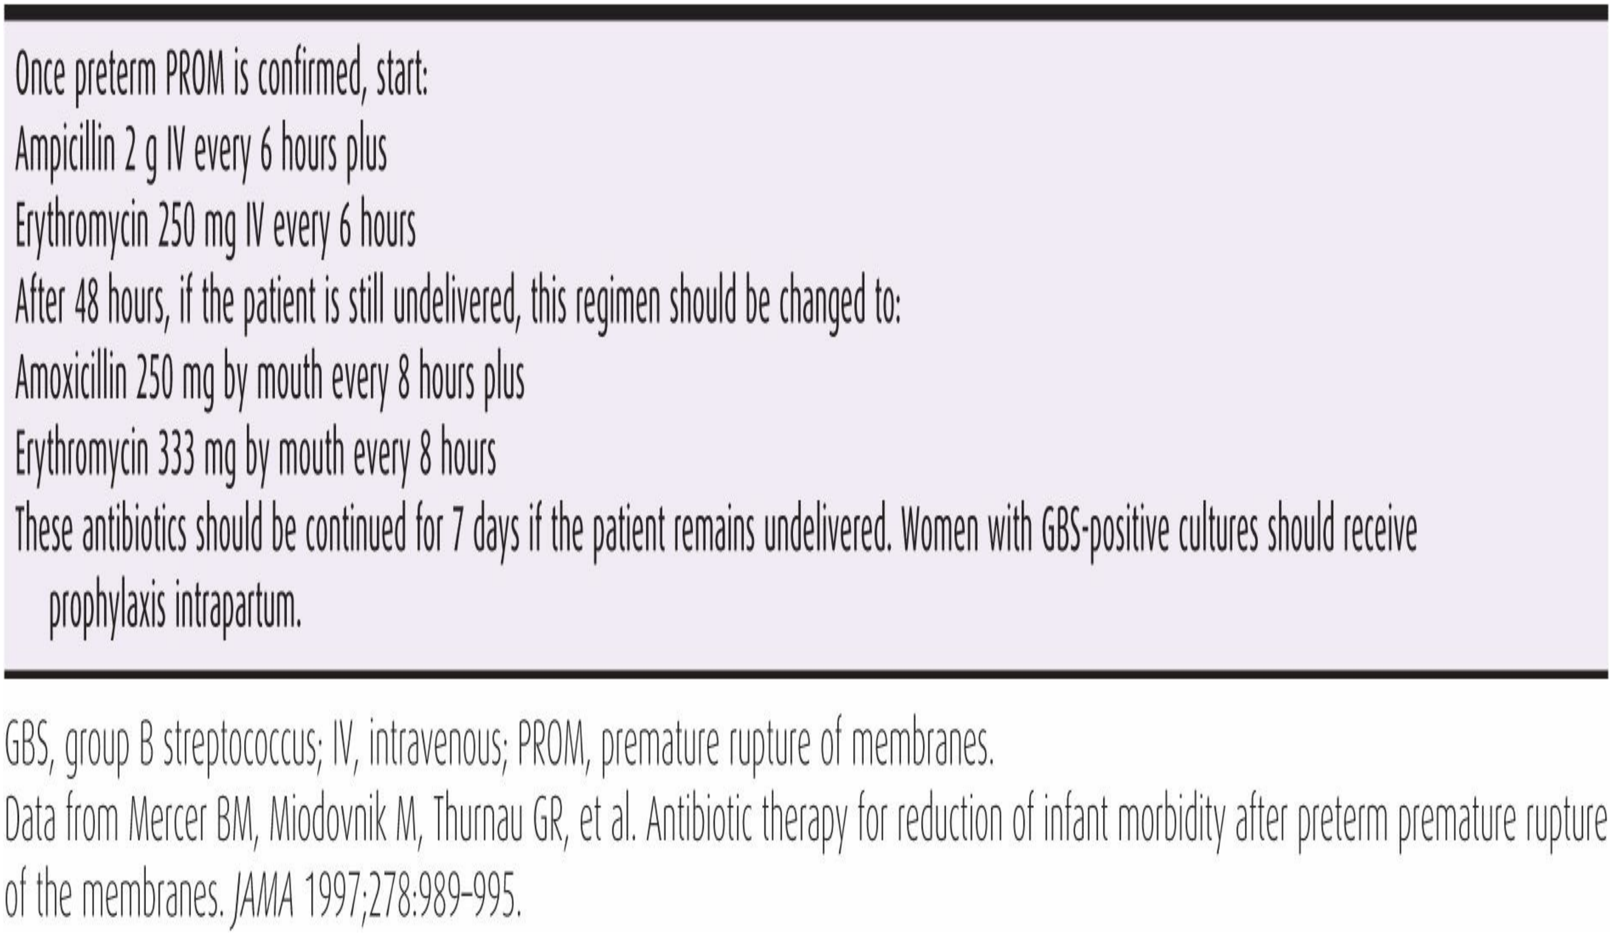
The principles of managing the preterm PROM patient are similar to those for managing the preterm labor patient. The key difference is the much increased risk of developing chorioamnionitis associated with preterm PROM. Pregnancies beyond 34 weeks' EGA can be managed as a term pregnancy with induction of labor or delivery via caesarean delivery (if indicated) because there is no evidence that antibiotics, corticosteroids, or tocolytics improve outcome in these patients.

Rupture of membranes before viability (ie, before 22–24 weeks of gestation) can be managed in one of several ways. One option is termination of pregnancy, given the high risk of adverse pregnancy outcome and prematurity. However, in the patient without evidence of chorioamnionitis, expectant management may be considered. Several case series have documented substantial survival rates (15–50%) with PPROM at 18–22 weeks. Although many patients may be unwilling to accept the risk of chorioamnionitis (30%) and even sepsis, they should be informed of the option of expectant management with antibiotic therapy.

For pregnancies with PROM between 24 and 34 weeks' EGA, several interventions have been shown to prolong pregnancy and improve outcome. After chorioamnionitis has been ruled out and a specimen of amniotic fluid from vaginal pool collection or amniocentesis sent for determination of fetal lung maturity, management should consist of the following interventions.

1. Antibiotics—Antibiotics have emerged as an important treatment for preterm PROM. In contrast to preterm labor, where antibiotics have shown no benefit in prolonging pregnancy, antibiotics appear to be effective in prolonging the latency period from rupture of membranes to delivery in patients with preterm PROM. They have also been shown to decrease the infection rate in these patients. A number of well-designed studies have shown improved neonatal outcomes with antibiotics alone and with antibiotics combined with corticosteroid therapy. Table 14–7 provides 1 recommended protocol for antibiotic use in preterm PROM.

Table 14–7. Antibiotic therapy for preterm premature rupture of membranes.



Once preterm PROM is confirmed, start:
Ampicillin 2 g IV every 6 hours plus
Erythromycin 250 mg IV every 6 hours
After 48 hours, if the patient is still undelivered, this regimen should be changed to:
Amoxicillin 250 mg by mouth every 8 hours plus
Erythromycin 333 mg by mouth every 8 hours
These antibiotics should be continued for 7 days if the patient remains undelivered. Women with GBS-positive cultures should receive prophylaxis intrapartum.

GBS, group B streptococcus; IV, intravenous; PROM, premature rupture of membranes.
Data from Mercer BM, Miodovnik M, Thurnau GR, et al. Antibiotic therapy for reduction of infant morbidity after preterm premature rupture of the membranes. *JAMA* 1997;278:989–995.

2. Corticosteroids—The National Institutes of Health (NIH) consensus development panel recommends the use of steroids in PROM patients before 32 weeks' EGA in the absence of intra-amniotic infection. In this patient population, corticosteroids have been shown to decrease the rate of RDS, necrotizing enterocolitis, and intraventricular hemorrhage. The benefit of steroids at 32–33 weeks in women with PPROM is unclear. However, steroids may also be considered in patients with PPROM between 32 and 33 6/7 weeks, especially if pulmonary immaturity has been documented via testing of amniotic fluid.

3. Tocolytics—No study has shown that tocolytics alone improve fetal outcome in women with PPROM. In general, the use of tocolytics in the PPROM patient should be either avoided entirely or limited to 48 hours' duration to permit administration of corticosteroids and antibiotics.

4. Magnesium sulfate for fetal neuroprotection—As with the management of preterm labor, consideration should be given to administering magnesium sulfate for fetal neuroprotection if delivery is felt to be imminent in the PPROM patient between 24 and 32 weeks of gestation. See Table 14–4 for a suggested protocol.

If after starting these interventions the fetal lung profile from testing of amniotic fluid returns as mature, the fetus should be delivered. Again, if at any time the patient shows signs of chorioamnionitis, the fetus should be delivered.

D. Role of Outpatient Management

In rare selected cases, patients who remain undelivered may be candidates for outpatient management. If leakage of fluid stops, the amniotic fluid volume normalizes, and the patient remains afebrile without evidence of increasing uterine irritability, she can be discharged home. These patients should be monitored very closely on an outpatient basis. They must be reliable and compliant with follow-up appointments. They also must take their temperature 4 times per day and be counseled on the warning signs of chorioamnionitis. These patients should also be monitored with frequent biophysical profiles; some sources recommend daily testing.

PROLONGED OR POSTTERM PREGNANCY

ESSENTIALS OF DIAGNOSIS

- Confirmation of gestational age greater than 42 completed weeks

---

Pathogenesis

The prolonged or postterm pregnancy is defined as pregnancy that has reached 42 weeks of gestation from the first day of the LMP or 40 weeks' gestation from the time of conception. Most fetuses will show effects of impaired nutritional supply (weight loss, reduced subcutaneous tissue, scaling, parchment-like skin). This condition is referred to as dysmaturity. The most common cause of prolonged pregnancy is incorrect dating due to variable length of the menstrual cycle. This has been reduced in recent years with widespread use of first-trimester ultrasound for dating. The cause of most cases of true prolonged pregnancy remains unknown. Experiments of nature, such as anencephalic fetuses and those with placental sulfatase deficiency, suggest that changes in placental steroid metabolism due to fetal hormonal signaling play a central role in the timing of delivery. At least 3% of infants are born after 42 completed weeks' gestation (in some series, as many as 12%). Because of the potential risks of dysmaturity, these infants deserve particular attention.

The maternal risks usually relate to large fetal size (ie, dysfunctional labor, arrested progress of labor, fetopelvic disproportion). Large fetal size may result in birth injury (eg, shoulder dystocia). Placental insufficiency is thought to be associated with aging of the placenta and is the basis for another group of fetal problems. Oligohydramnios, which is more common in postterm gestation, may lead to cord compromise.

Complications resulting from prolonged pregnancy result in a sharp rise in perinatal mortality and morbidity rates (2–3 times those of infants born at 37–42 weeks). Complications in the survivors increase the chance of neurologic sequelae.

Prevention

The most common cause of an apparent postterm pregnancy is an error in pregnancy dating. First-trimester ultrasound is an accurate way to confirm a patient's estimated date of delivery and has been shown to reduce the incidence of pregnancies diagnosed as postterm.

Clinical Findings

The diagnosis of prolonged pregnancy is made by confirmation of the gestational age by referring to records of early pregnancy tests and ultrasound examinations, the exact time of conception (if known), and clinical parameters (eg, LMP, quickening, detection of fetal heart tones).

Differential Diagnosis

The most likely differential diagnosis of the suspected post-term pregnancy is incorrect pregnancy dating, which may be determined via a careful review of the patient's dating criteria. However, it may be difficult to ascertain the correct due date in a patient who presents for prenatal care late in pregnancy or has not had any early ultrasounds in pregnancy.

Treatment

The principal risk of labor induction has been thought to be an increased rate of caesarean birth. It has now been conclusively demonstrated, however, that induction of labor at 41 weeks does not increase the caesarean rate compared with expectant management with antepartum testing. Therefore, many authorities offer induction of labor at 41 completed weeks, reserving expectant management for those patients who refuse induction.

To adequately assess the risk of fetal compromise, the following is a useful protocol for pregnancies beyond 41 weeks' gestation:

1. Some form of fetal surveillance is advised, either with nonstress testing and measurement of amniotic fluid volume twice per week or with biophysical profiles twice per week.
2. Perform ultrasonic monitoring at least twice weekly to assess amniotic fluid volume (biophysical profiles may be obtained at the same time).
3. Have the mother count fetal movements each day.

The following additional precautions should be taken:

1. Decreased fetal movement warrants an immediate biophysical profile evaluation.
2. Abnormalities in the nonstress test mandate induction or a backup test such as the full biophysical profile.

3. An abnormal contraction stress test, decreased amniotic fluid volume, abnormal biophysical profile, or other signs of fetal distress require delivery.
4. A large or compromised fetus may require caesarean delivery (see discussion of macrosomia in Chapter 16).
5. In the absence of fetopelvic disproportion or fetal distress, labor can be induced. Fetal monitoring should be continuous.

RH ALLOIMMUNIZATION & OTHER BLOOD GROUP INCOMPATIBILITIES

ESSENTIALS OF DIAGNOSIS

- Maternal Rh-negativity and presence of antibody on indirect Coombs' test
- Rh or other antibody titer posing fetal risk
- May have a previous infant with hemolytic disease of the newborn
- Postnatal fetal cord blood findings of Rh-positivity and anemia (hemoglobin <10 g)

Pathogenesis

A fetus receives half of its genetic components from its mother and half from its father; therefore, the fetus may have red blood cell (RBC) antigens different from those of its mother. Some blood groups may act as antigens in individuals not possessing those blood groups. The antigens reside on red blood cells. If enough fetal cells cross into the maternal blood, a maternal antibody response may be provoked. If these maternal antibodies cross the placenta, they then can enter the fetal circulation and destroy the fetal erythrocytes, causing hemolytic anemia. This leads to fetal responses to meet the challenge of enhanced blood cell breakdown. These changes in the fetus and newborn are called erythroblastosis fetalis or fetal hydrops. Several blood groups are capable of producing fetal risk, but those in the Rh group have caused the overwhelming majority of cases of erythroblastosis fetalis, so the Rh group is used as the example.

The Rh blood group is the most complex human blood group. Rh antigens are lipoproteins that are confined to the red cell membrane. The Rh antigens are D, C, c, E, e, and G. The major antigen in this group, Rh (D), or Rh factor, is of particular concern. A woman who is lacking Rh(D) (otherwise known as Rh-negative) may carry an Rh-positive fetus if the fetus inherited the D antigen from the father. If fetal red blood cells pass into the mother's circulation in sufficient numbers, maternal IgG antibodies to the D antigen may develop and cross the placenta, causing hemolysis of fetal blood cells (Fig. 14–1). Hemolytic disease of the newborn may occur, and severe disease may cause fetal death.

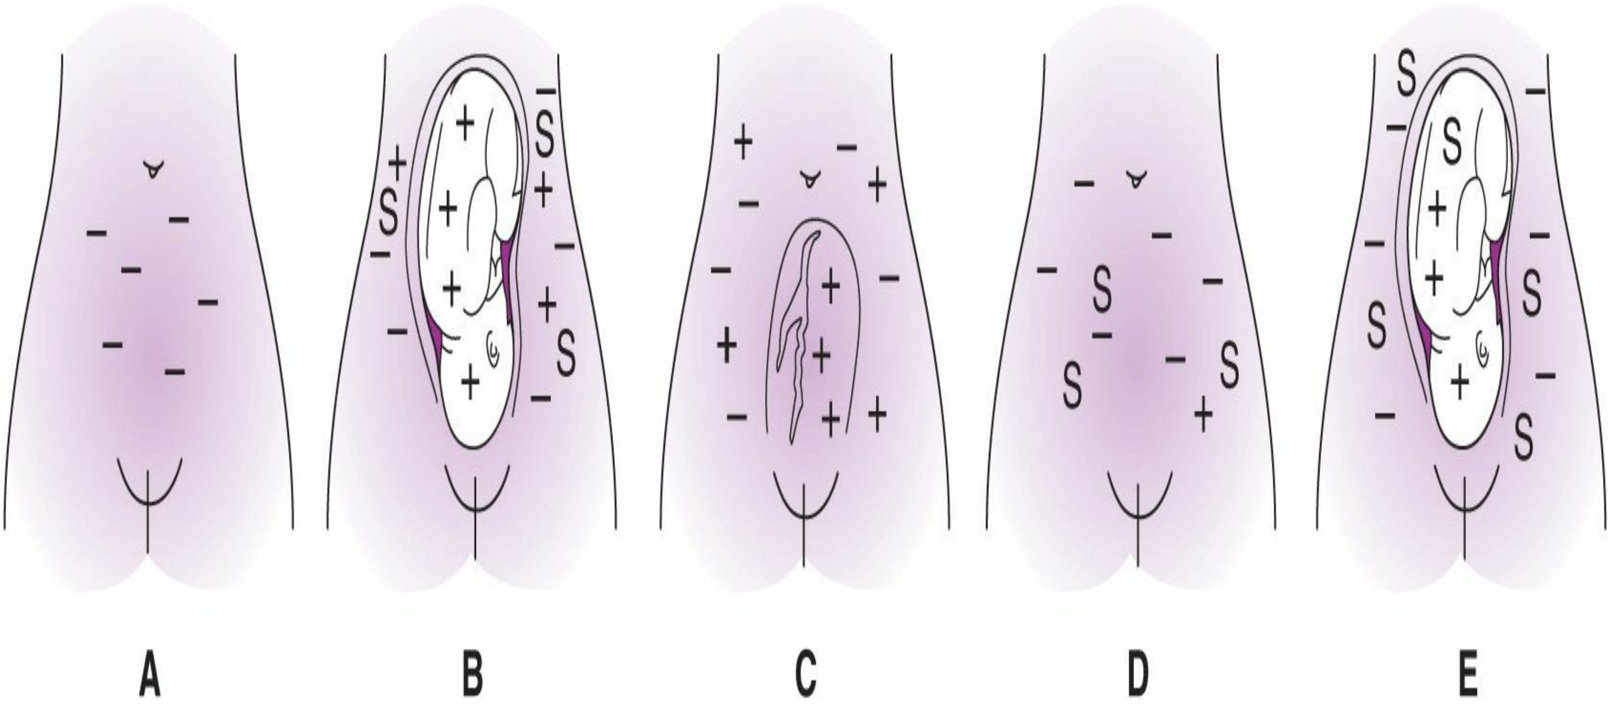

Figure 14–1. A: Rh-negative woman before pregnancy. **B:** Pregnancy occurs. The fetus is Rh-positive. **C:** Separation of the placenta. **D:** After delivery, Rh alloimmunization occurs in the mother, and she develops antibodies (S) to the Rh-positive antigen. **E:** The next pregnancy with an Rh-positive fetus. Maternal antibodies cross the placenta, enter the fetal bloodstream, and attach to Rh-positive red cells, causing hemolysis.

In standard testing when the father is Rh-positive, 2 possibilities exist: he is either homozygous or heterozygous. Forty-five percent of Rh-positive persons are homozygous for D and 55% are heterozygous. If the father is homozygous, all of his children will be Rh-positive; if he is heterozygous, his children will have a 50% chance of being Rh-positive. By way of contrast, the Rh-negative individual is always homozygous.

Basque populations have the highest incidence of Rh negativity (30–35%). White populations in general have a higher incidence than other ethnic groups (15–16%). African Americans have a rate of 8%, African blacks 4%, Indoeurasians 2%, and North American Indians 1%.

In mothers who do not receive prophylaxis with anti-D immunoglobulin, the overall risk of alloimmunization for an Rh-positive ABO-compatible infant with an Rh-negative mother is approximately 16% after 2 deliveries of Rh-positive infants. Of these, 1.5–2% of reactions will occur antepartum and 7% within 6 months of delivery; the remainder (7%) manifest early in the second pregnancy, most likely as the result of an amnestic response. ABO incompatibility between an Rh-positive fetus and an Rh-negative mother provides some protection against Rh alloimmunization; in these cases the overall incidence is 1.5–2%. In mothers who receive prophylaxis with anti-D immunoglobulin administered both antepartum and postpartum, the risk of alloimmunization is reduced to 0.1%.

A. Maternal Rh Alloimmunization

Rh alloimmunization generally occurs by 1 of 2 mechanisms: (1) after incompatible blood transfusion or (2) after fetomaternal hemorrhage between a mother and an incompatible fetus. Fetomaternal hemorrhage may occur during pregnancy or at delivery. With no apparent predisposing factors, fetal red cells have been detected in maternal blood in 6.7% of women during the first trimester, 15.9% during the second trimester, and 28.9% during the third trimester. Predispositions to fetomaternal hemorrhage include spontaneous or induced abortion, amniocentesis, chorionic villus sampling, abdominal trauma (eg, due to motor vehicle accidents or external version), placenta previa, abruptio placentae, fetal death, multiple pregnancy, manual removal of the placenta, and caesarean section.

Although the exact number of Rh-positive cells necessary to cause alloimmunization of the Rh-negative pregnant woman is unknown, as little as 0.1 mL of Rh-positive cells can cause sensitization. Even with delivery, this amount occurs in less than half of cases.

Fortunately, there are other mitigating factors to Rh alloimmunization. A very important factor is that approximately 30% of Rh-negative persons never become sensitized (non-responders) when given Rh-positive blood. ABO incompatibility also confers a protective effect (see Incidence).

The initial maternal immune response to Rh sensitization is low levels of immunoglobulin (Ig) M. Within 6 weeks to 6 months, IgG antibodies become detectable. In contrast to IgM, IgG is capable of crossing the placenta and destroying fetal Rh-positive cells.

B. Other Blood Group Alloimmunization

Of the other blood groups that may evoke an immunoglobulin capable of crossing the placenta (often called atypical or irregular immunizing antibodies), those that may cause severe fetal hemolysis (listed in descending order of occurrence) are Kell, Duffy, Kidd, MNSs, and Diego. P, Lutheran, and Xg groups may also cause fetal hemolysis, but it usually is less severe.

Prevention

Prevention of Rh (D) alloimmunization is possible by identifying women known to be negative for the Rh (D) antigen and administering anti-D immunoglobulin to prevent sensitization.

A. Prepregnancy or First Prenatal Visit

On the first prenatal visit, all pregnant women should be screened for the ABO blood group and the Rh(D) antigen. They should also undergo antibody screening (indirect Coombs' test). All Rh-negative mothers should receive prophylaxis according to the following protocol.

B. Visit at 28 Weeks

Antibody screening is performed. If negative, 300 μg of anti-D immunoglobulin (RhIgG) is given. If positive, the patient should be managed as Rh-sensitized.

C. Visit at 40 Weeks

If more than 12 weeks have elapsed since anti-D immunoglobulin administration, consideration should be given to administering 300 μg of anti-D immunoglobulin at 40 weeks of gestation.

D. Postpartum

If the infant is Rh(D)-positive, 300 µg of RhIgG is administered to the mother (provided maternal antibody screening is negative). Although RhIgG should generally be given within 72 hours after delivery, it has been shown to be effective in preventing alloimmunization if given up to 28 days after delivery. If the antibody screen is positive, the patient is managed as if she will be Rh-sensitized during the next pregnancy.

E. Special Fetomaternal Risk States

Several circumstances may occur during pregnancy that mandate administration of RhIgG to the unsensitized patient outside the management protocol described.

1. Abortion—Sensitization will occur in 2% of spontaneous abortions and 4–5% of induced abortions. In the first trimester, because of the small amount of fetal blood, 50 µg of RhIgG apparently is sufficient to prevent sensitization. However, because the cost of RhIgG has dropped, a full 300-µg dose is usually given. The same dose is recommended for exposure after the first trimester. The risk of Rh alloimmunization after threatened abortion is less well understood, but many experts agree that RhIgG should also be given to these patients.

2. Amniocentesis, Chorionic Villus Sampling, and Cord Blood Sampling—If the placenta is traversed by the needle, there is up to an 11% chance of sensitization. Therefore, administration of 300 µg of RhIgG is recommended when these procedures are performed in the unsensitized patient.

3. Antepartum Bleeding—In cases of antepartum vaginal bleeding or when there is evidence of a subchorionic hematoma or placenta abruption on ultrasound, administration of 300 µg of RhIgG is recommended. If the pregnancy is carried more than 12 weeks from the time of RhIgG administration, a repeat prophylactic dose is recommended.

4. External cephalic version—Fetomaternal hemorrhage occurs in 2–6% of patients who undergo external cephalic version, whether failed or successful; therefore, these patients should receive 300 µg of RhIgG.

F. Delivery With Fetomaternal Hemorrhage

Fetomaternal hemorrhage so extensive that it cannot be managed with 300 µg of RhIgG occurs in only approximately 0.4% of patients. The amount of hemorrhage can be quantified by the Kleihauer-Bethke test and additional doses of RhIgG given according to the amount of fetomaternal hemorrhage.

Clinical Findings

Hemolytic disease of the newborn occurs when the maternal antibodies cross the placenta and destroy the Rh-positive fetal red blood cells. Fetal anemia results, stimulating extramedullary erythropoietic sites to produce high levels of nucleated red cell elements. Immature erythrocytes are present in the fetal blood because of poor maturation control. Hemolysis produces heme, which is converted to bilirubin; both of these substances are neurotoxic. However, although the fetus is in utero, heme and bilirubin are effectively removed by the placenta and metabolized by the mother.

When fetal red blood cell destruction far exceeds production and severe anemia occurs, erythroblastosis fetalis may result. This is characterized by extramedullary hematopoiesis, heart failure, edema, ascites, and pericardial effusion. Tissue hypoxia and acidosis may result. Normal hepatic architecture and function may be disturbed by extensive liver erythropoiesis, which may lead to decreased protein production, portal hypertension, and ascites. On ultrasound, fetal hydrops may be visualized, which is defined as the presence of any 2 of the following: pleural effusion, ascites, pericardial effusion, increased skin thickness, polyhydramnios, or increased placental thickness.

In the immediate neonatal interval, the primary problem may relate to anemia and the sequelae mentioned previously. However, hyperbilirubinemia may also pose an immediate risk and certainly poses a risk as further red cell breakdown occurs. The immature (and often compromised) liver, with its low levels of glucuronyl transferase, is unable to conjugate the large amounts of bilirubin. This results in a high serum bilirubin level, with resultant kernicterus (bilirubin deposition in the basal ganglia).

Treatment

A. Management of the Unsensitized Rh-Negative Patient

Management of the pregnancy complicated by alloimmunization is guided by 2 factors: whether the patient has a history of an affected fetus in a previous pregnancy (ie, fetus with severe anemia or hydrops) and maternal antibody titers.

1. No history of previous fetus affected by rh alloimmunization—Once the antibody screen is positive for alloimmunization, these patients should be followed up with antibody titers at intake, 20 weeks' EGA, and then every 2–4 weeks. As long as antibody titers remain below the critical titer (<1:32 in our laboratory, but each laboratory must establish its own norms), there is no indication for further intervention. Once antibody titers reach 1:32, additional surveillance should be performed because a titer of 1:32 places the fetus at significant risk of hydrops and demise before 37 weeks. Ultrasound assessment of blood flow in the fetal middle cerebral artery (MCA) by Doppler has been shown to be a reliable and noninvasive screening tool for detecting moderate to severe fetal anemia. It is based on the concept that the fetus preserves oxygen delivery to the brain in the setting of anemia by increasing flow to the brain of the low viscosity blood. Ultrasound is performed to identify the circle of Willis, and blood flow in the proximal third of the MCA can be estimated using Doppler. High peak velocity blood flow in this area (>1.5 multiples of the median) correlates well with severe fetal anemia. This test can be performed at 2-week intervals in these patients, so more invasive diagnostic interventions can be avoided until evidence of severe anemia is observed.

In the past, amniocentesis has been used to determine amniotic fluid bilirubin levels and identify fetuses at risk of severe anemia; however, given the invasive nature of repeated amniocenteses, ultrasound for MCA Dopplers has widely replaced amniocentesis for this indication.

2. History of a prior fetus affected by rh alloimmunization—Antibody titers need not be followed in these pregnancies because amniocentesis is indicated by the history of prior affected fetus. Amniocentesis may be performed to determine the fetal genotype if the father of the fetus is determined to be heterozygous for D. If the fetus is determined to have the D antigen, that fetus is considered to be at risk of hemolytic disease and severe anemia regardless of maternal antibody titers. In general, after a first affected pregnancy, future pregnancies tend to manifest with more severe disease and at an earlier gestational age. For this reason, MCA Doppler surveillance should be initiated at 18 weeks and repeated every 1–2 weeks. Treatment of these patients is dictated by MCA Doppler.

3. Results of MCA Dopplers—Once it is determined that a patient should be followed with MCA Dopplers, the results of the MCA Dopplers will place the fetus into one of three categories:

A. Unaffected or mildly affected fetus—The fetus that has normal MCA Doppler studies is considered to be unaffected or mildly affected. Testing should be repeated every 2–3 weeks, and delivery should be entertained at term or near term and after the fetus has achieved pulmonary maturity.

B. Moderately affected fetus—The fetus that has MCA Doppler studies nearing 1.5 multiples of the median should be tested more frequently, every 1–2 weeks. Delivery may be required before term, and the fetus is delivered as soon as pulmonary maturity is reached. In some cases, enhancement of pulmonary maturity by use of corticosteroids may be necessary.

C. Severely affected fetus—The severely affected fetus has MCA Doppler studies >1.55 multiples of the median or has frank evidence of hydrops (eg, ascites, pleural or pericardial effusion, subcutaneous edema). Intervention usually is needed to allow the fetus to reach a gestational age at which delivery and neonatal risks are fewer than the risks of in utero therapy.

If the fetus is preterm, cordocentesis or percutaneous umbilical cord blood sampling is recommended at this stage to directly assess the fetal hematocrit. Intrauterine transfusions are generally performed between 18 and 35 weeks of gestation. Before 18 weeks, access to the umbilical vein is limited due to the small caliber of the vessel. After 35 weeks, the risk/benefit ratio favors delivery of a fetus with evidence of severe anemia. Once severe anemia is confirmed, intrauterine transfusion can be performed directly into the umbilical vein. The transfusion is performed using O-negative, cytomegalovirus-negative, washed, leukocyte-depleted, irradiated packed red cells. The intraperitoneal technique was used in years past but has largely been replaced by intravascular fetal transfusion secondary to its more predictable absorption.

After transfusion, repeat transfusions or delivery usually will be necessary, as production of fetal blood markedly decreases or ceases. Timing of these transfusions may be assisted by ultrasonic determination of MCA Doppler studies. Delivery should take place when the fetus has documented pulmonary maturity.

STILLBIRTH

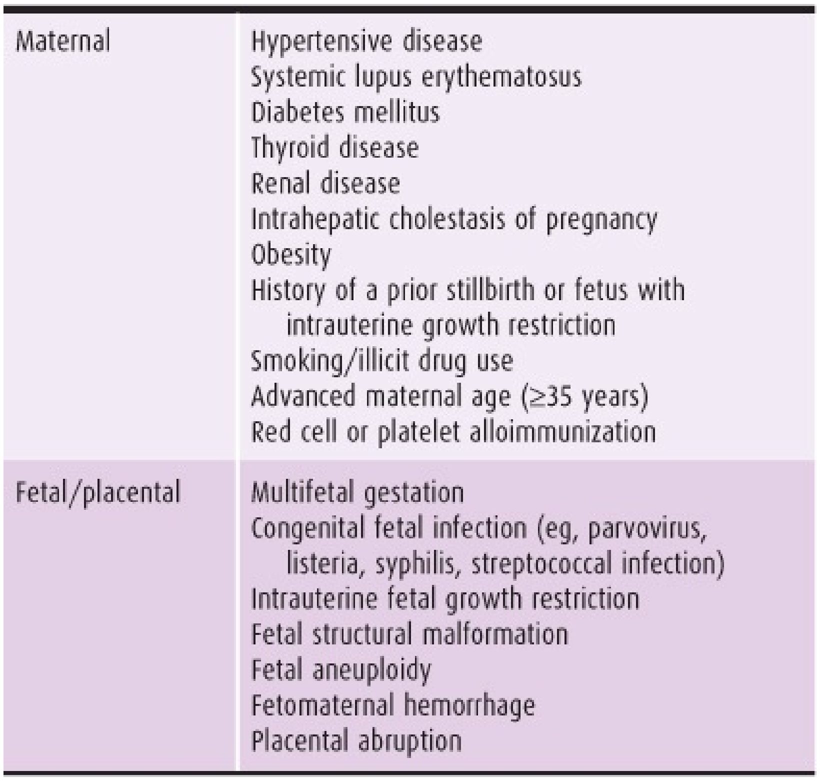
ESSENTIALS OF DIAGNOSIS

- Intrauterine fetal death at or beyond 20 weeks' gestation

Pathogenesis

Stillbirth affects <1% of pregnancies, with an incidence of approximately 6 per 1000 pregnancies in the United States. There are a number of known risk factors for stillbirth, which are presented in Table 14–8.

Table 14–8. Risk factors and etiologies for stillbirth.



Maternal	Hypertensive disease Systemic lupus erythematosus Diabetes mellitus Thyroid disease Renal disease Intrahepatic cholestasis of pregnancy Obesity History of a prior stillbirth or fetus with intrauterine growth restriction Smoking/illicit drug use Advanced maternal age (≥35 years) Red cell or platelet alloimmunization
Fetal/placental	Multifetal gestation Congenital fetal infection (eg, parvovirus, listeria, syphilis, streptococcal infection) Intrauterine fetal growth restriction Fetal structural malformation Fetal aneuploidy Fetomaternal hemorrhage Placental abruption

In the past, cord accident was thought to be the cause of many stillbirths. However, more recent data suggest that a nuchal cord is found in approximately 30% of normal births and is most likely an incidental finding when a stillbirth is diagnosed. In order for a stillbirth to be attributed to cord accident, evidence of cord obstruction or compromise (ie, thrombosis) should be seen on pathologic examination, and other causes of stillbirth should be excluded.

In many cases, up to 50% of stillbirths, it is difficult to elucidate a cause of the stillbirth. In some cases, this may be attributable to incomplete workup. However, in many cases, the stillbirth may be unexplained despite a thorough evaluation.

Prevention

Compliance with prenatal care is an important strategy that may prevent stillbirth. The early diagnosis of fetal abnormalities and obstetrical complications such as preeclampsia may allow for the initiation of an appropriate surveillance strategy or timely delivery in order to avoid stillbirth.

Clinical Findings

Stillbirth is diagnosed with the absence of cardiac activity in a fetus at or beyond 20 weeks of gestational age on ultrasound or at birth. Some women with stillbirth may report decreased or absent fetal movement, vaginal bleeding, or abdominal pain.

However, in many cases, the patient may be asymptomatic for the stillbirth and may even report what she thought was normal fetal movement.

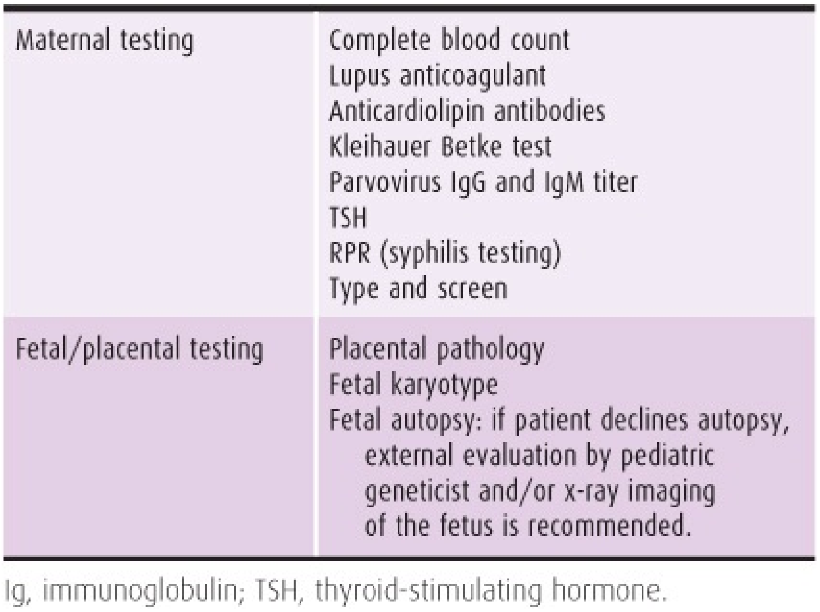
Treatment

Once a stillbirth is diagnosed, it is important to initiate an evaluation to determine the cause. A complete history and physical is the first step to look for findings suggestive of a possible cause. For instance, vaginal bleeding may be suggestive of placental abruption, and maternal fever and abdominal pain may indicate congenital fetal infection.

A. Evaluation

Ultrasound examination should be performed to confirm the fetal demise and the gestational age and to evaluate for any signs of fetal abnormality. Further testing can be divided into maternal and fetal testing (Table 14–9). The role of investigation for maternal inherited thrombophilia is controversial. Testing for maternal inherited thrombophilia should be considered if the fetus is severely growth restricted, if there is evidence of thrombosis on placental pathology, or if there is a personal or family history of deepvenous thrombosis. Maternal toxicology screen should be considered if there is a suspicion for maternal drug abuse. Testing for diabetes should be performed if the patient was not screened during the pregnancy or if the fetus is large for gestational age. Placental pathology will test for evidence of abruption, thrombosis, or infarction. Additionally, placental pathology can evaluate for signs of viral or bacterial infection. Fetal autopsy is recommended for all stillbirths. However, the patient may decline, in which case external fetal evaluation and x-rays are recommended. Fetal karyotype may be obtained by testing amniotic fluid obtained via amniocentesis before delivery of the fetus or evaluation of fetal or placental tissue. One limitation to testing karyotype from any of these tissues is culture failure. Amniocentesis appears to have the highest yield in terms of success in determining fetal karyotype.

Table 14–9. Evaluation of stillbirth.



Maternal testing	Complete blood count Lupus anticoagulant Anticardiolipin antibodies Kleihauer Betke test Parvovirus IgG and IgM titer TSH RPR (syphilis testing) Type and screen
Fetal/placental testing	Placental pathology Fetal karyotype Fetal autopsy: if patient declines autopsy, external evaluation by pediatric geneticist and/or x-ray imaging of the fetus is recommended.

Ig, immunoglobulin; TSH, thyroid-stimulating hormone.

B. Delivery

Depending on the gestational age of the pregnancy, the pregnancy can be delivered by either induction of labor or dilation and evacuation. Some centers with expertise in late second-trimester dilation and evacuation may offer the procedure up to 26–28 weeks. With adequate cervical preparation before the procedure, an intact specimen can be obtained in many cases to allow for autopsy. Alternatively, labor induction can be performed regardless of gestational age. Hysterotomy or caesarean delivery is generally reserved for patients who fail induction of labor.

Prognosis

The prognosis for future pregnancies depends on the underlying cause of the stillbirth. For women in whom no etiology for stillbirth is found despite a thorough evaluation, the risk of recurrent stillbirth after 20 weeks is approximately 1–2%.

Congenital Fetal Infections

Unzila Nayeri, MD
Stephen Thung, MD

PARVOVIRUS

ESSENTIALS OF DIAGNOSIS

- Caused by parvovirus B19, a single-stranded DNA virus
- Clinical manifestations: commonly asymptomatic, erythema infectiosum, systemic symptoms (fever, arthropathy, malaise), or aplastic crises
- Complications in pregnancy: fetal demise, fetal anemia, hydrops fetalis
- Diagnosis: serologic tests (immunoglobulin [Ig] G and IgM antibodies); serum viral DNA polymerase chain reaction
- Antenatal sonographic findings: fetal anemia, hydrops, elevated middle cerebral artery peak systolic velocity
- Fetal diagnosis: cordocentesis
- Fetal treatment: intrauterine blood transfusion

Pathogenesis

Parvovirus B19 infection, a common childhood infection, tends to be more frequent in late winter or early spring. The infection is caused by a single-stranded DNA virus, the B19 parvovirus, which is transmitted through respiratory secretions and hand-to-mouth contact. The virus has a predilection for rapidly dividing cells such as erythroid progenitor cells.

Prevalence of seropositivity increases with age, and about 50–60% of reproductive-aged women have documented antibodies to parvovirus B19 consistent with prior infection. Immunity is considered lifelong, although reinfection has been documented. The incidence of acute parvovirus infection during pregnancy is 3.3–3.8%. Schoolteachers, day care workers, and homemakers are most susceptible. Nonimmune individuals exposed in a classroom have a 20–30% risk of infection. The secondary attack rate for household members is up to 50%.

During pregnancy, the virus can cross the placenta and infect red cell progenitors in the fetal bone marrow. The virus suppresses erythropoiesis by attaching to the “P” antigen on red cell stem cells. This results in severe anemia and high-output congestive heart failure. In addition to the reduced survival of fetal red blood cells, anemia is further complicated by the increased demands of an expanding intravascular volume and the inability of the immature immune system to control the infection. Additionally, the virus can attack fetal myocardiocytes via the same “P” antigen and cause a cardiomyopathy, further exacerbating the congestive heart failure.

Prevention

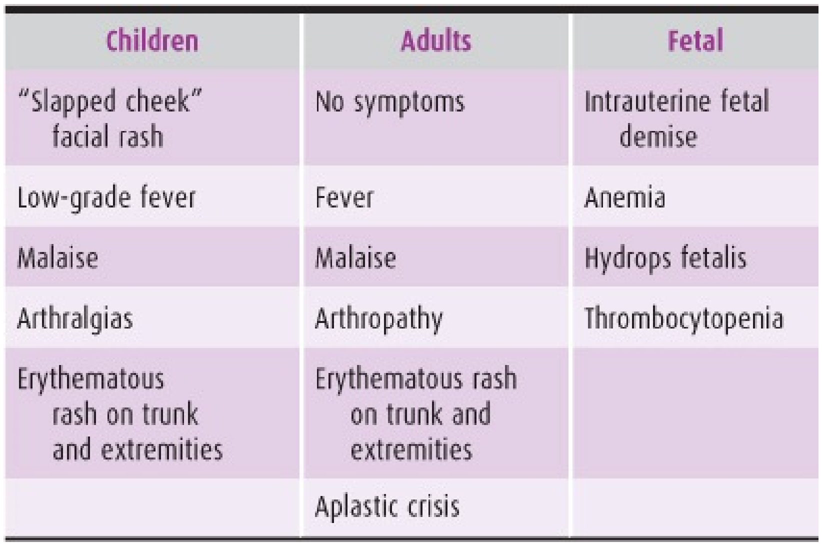
Pregnant women who are susceptible to parvovirus B19 should avoid contact with known infected individuals. However, since 20% of infections are subclinical, exposure cannot be eliminated by identifying and excluding individuals with acute parvovirus B19 infection. Additionally, those with infection are infectious prior to the onset of symptoms. Therefore, a policy to routinely remove women from occupations considered high risk, such as day care attendants, is not recommended. On the other hand, patients should be counseled on careful hand washing and avoidance of sharing food and drink.

Clinical Findings

A. Symptoms & Signs (Table 15–1)

Parvovirus B19 causes the common childhood illness erythema infectiosum (also known as “fifth disease”). Erythema infectiosum is characterized by a low-grade fever, malaise, arthralgias, and a “slapped cheek” facial rash. Patients may also present with a “lace-like” erythematous rash on the trunk and extremities. The incubation period for parvovirus is 10–20 days. Although the typical rashes are more common in children, adults may also present with dermatologic manifestations.

Table 15–1. Clinical manifestations of parvovirus.



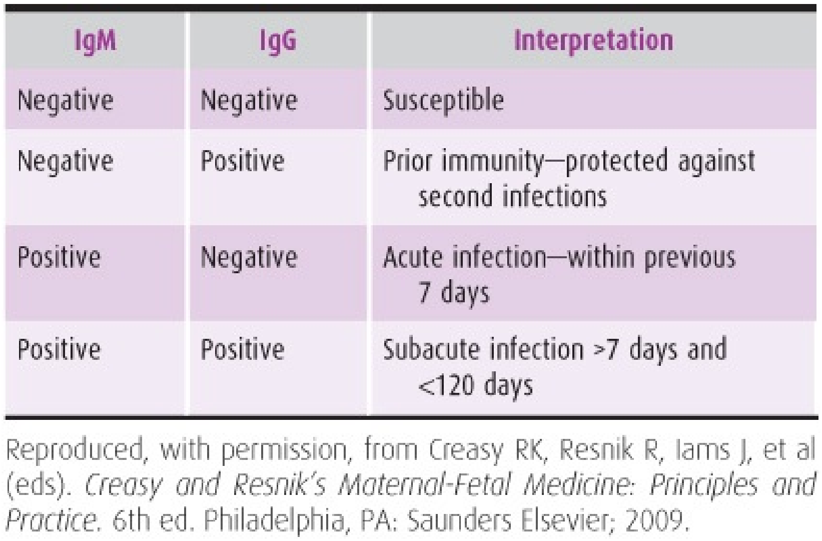
Children	Adults	Fetal
“Slapped cheek” facial rash	No symptoms	Intrauterine fetal demise
Low-grade fever	Fever	Anemia
Malaise	Malaise	Hydrops fetalis
Arthralgias	Arthropathy	Thrombocytopenia
Erythematous rash on trunk and extremities	Erythematous rash on trunk and extremities	
	Aplastic crisis	

Systemic symptoms are noted 1–4 days prior to the onset of the rash. These symptoms include fever, malaise, and arthropathy, which is more common in adults. Patients with hemoglobinopathies such as sickle cell anemia are at risk for aplastic crises, which are usually self-limited. Patients infected with this virus are considered infectious 5–10 days following exposure up to the onset of symptoms. Once the rash presents, individuals are no longer infectious.

B. Laboratory Findings

Serologic testing is used to diagnose maternal parvovirus infection. Immunoglobulin (Ig) M antibody capture radioimmunoassay and enzyme-linked immunosorbent assay (ELISA) are commonly used, with sensitivities ranging from 80–90%. There are various possible combinations of serologic test results that indicate varying disease states (Table 15–2). IgM antibodies are detected 7–10 days after exposure, peak at 10–14 days, and remain positive for several months. Indicating prior infection, IgG antibodies present several days after IgM, plateau at 4 weeks, and persist for many years. When both IgM and IgG are positive, establishing the exact timing of infection is difficult.

Table 15–2. Possible serologic test results for parvovirus.



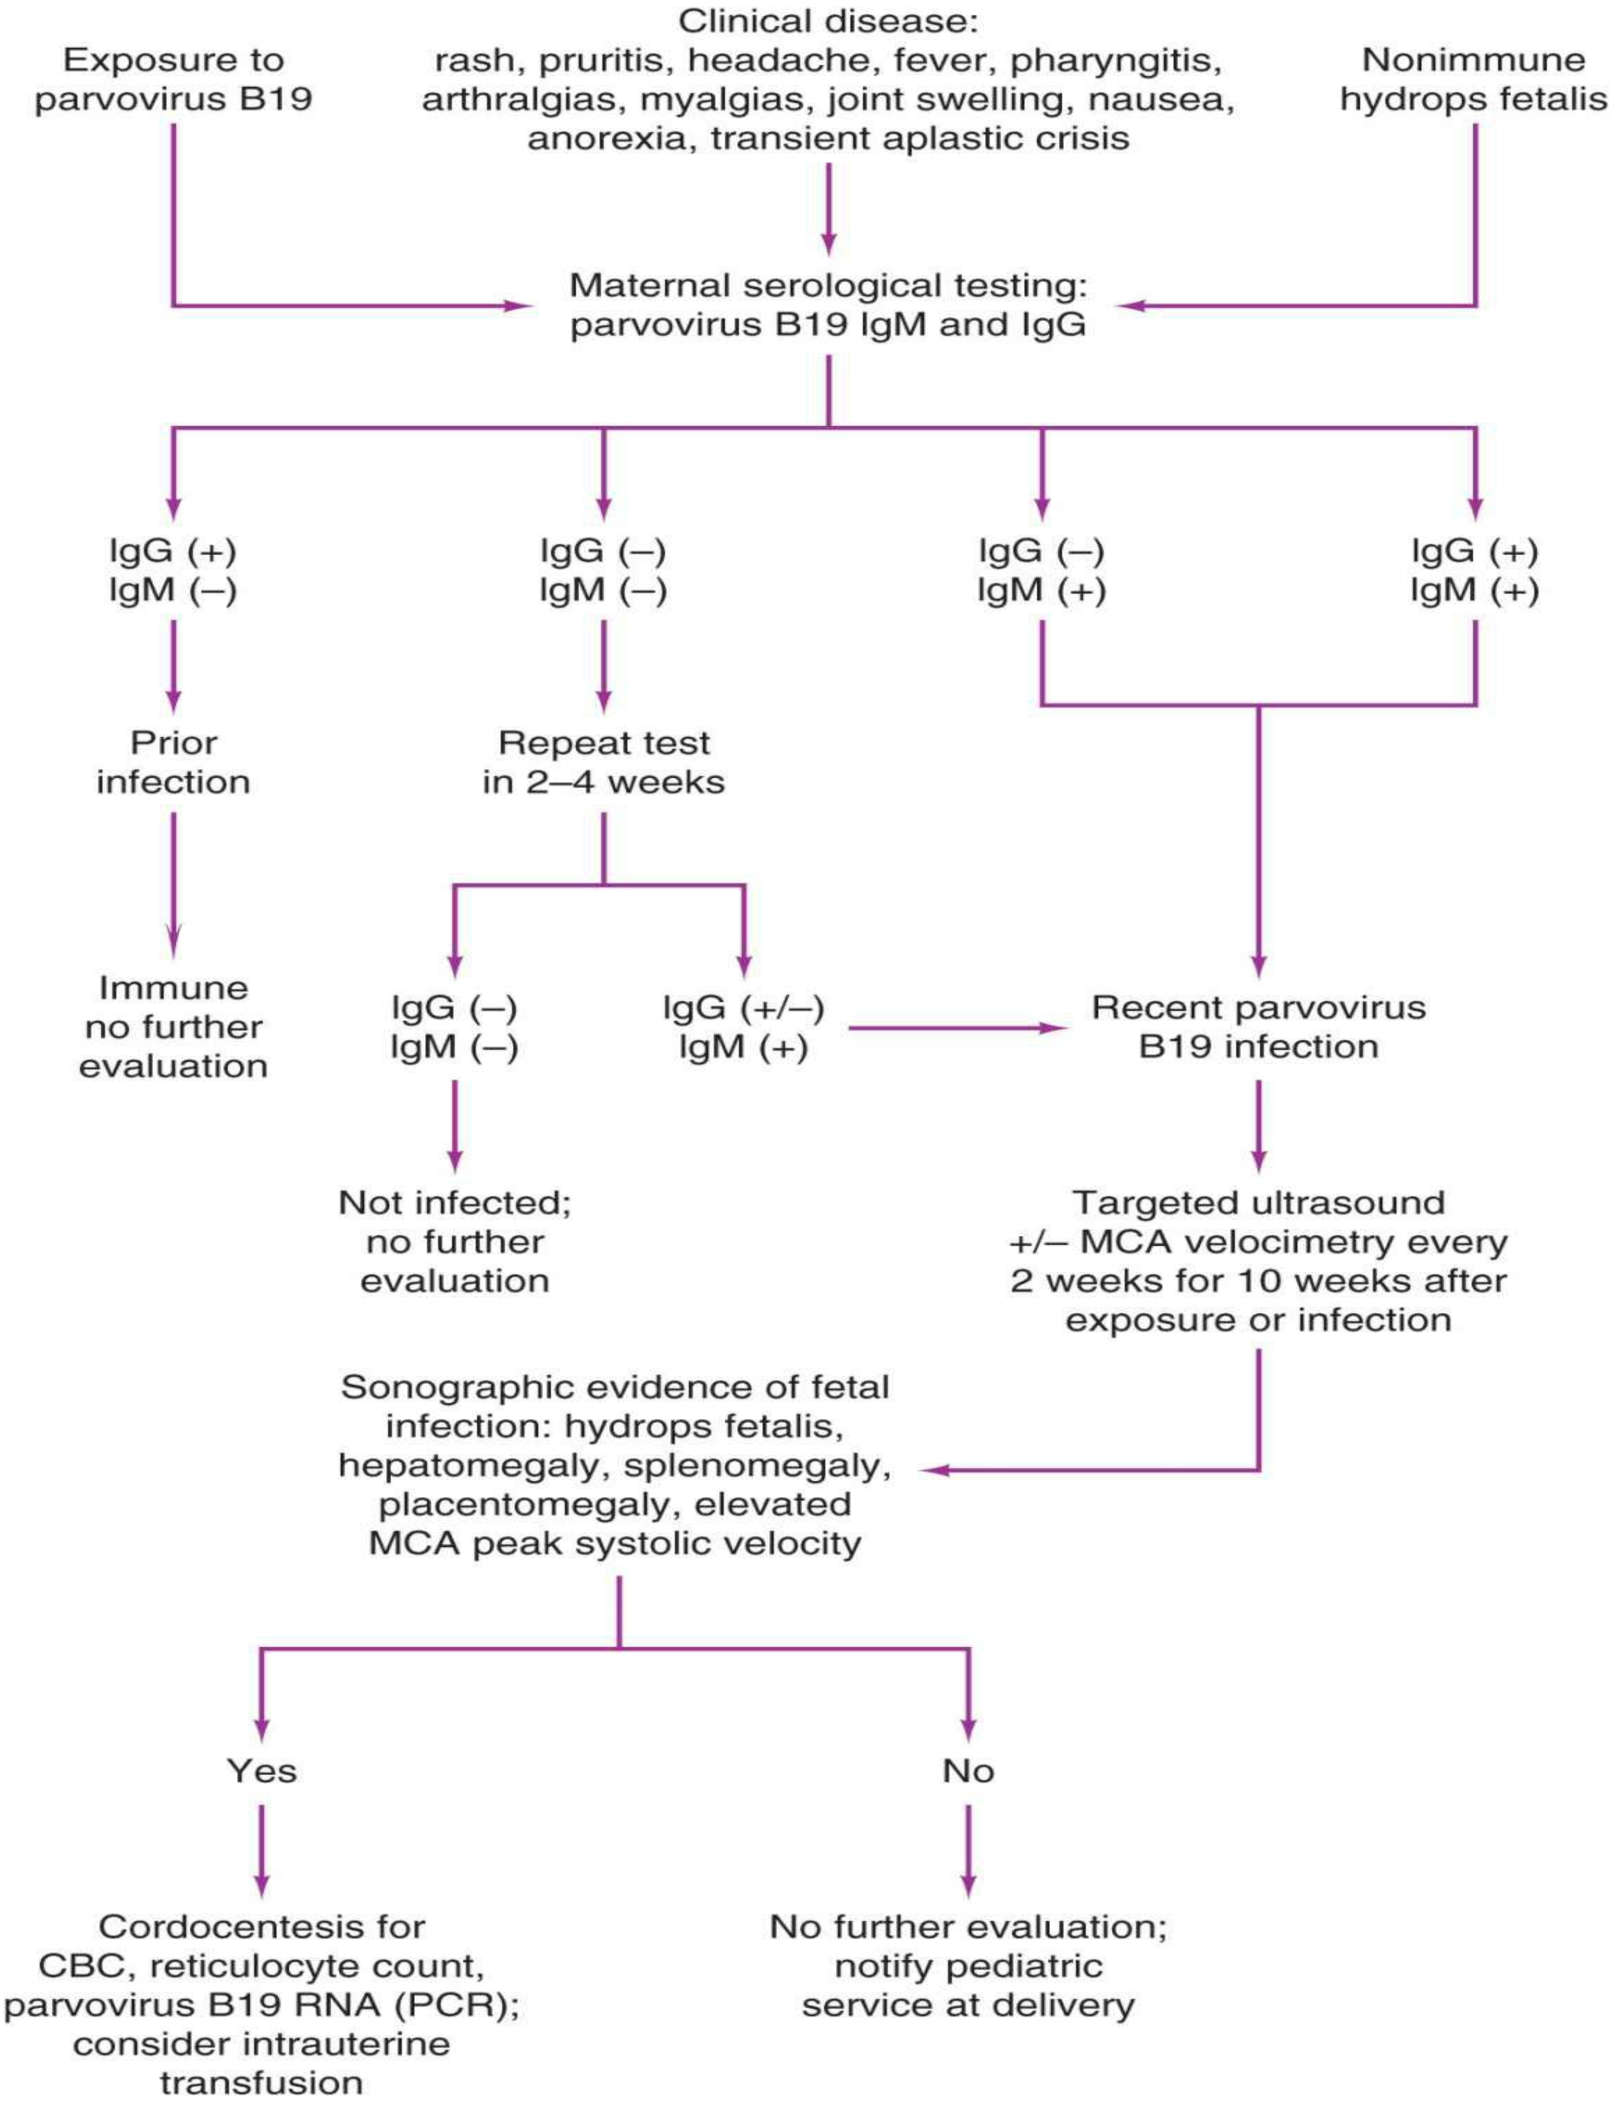
IgM	IgG	Interpretation
Negative	Negative	Susceptible
Negative	Positive	Prior immunity—protected against second infections
Positive	Negative	Acute infection—within previous 7 days
Positive	Positive	Subacute infection >7 days and <120 days

Reproduced, with permission, from Creasy RK, Resnik R, Iams J, et al (eds). *Creasy and Resnik's Maternal-Fetal Medicine: Principles and Practice*. 6th ed. Philadelphia, PA: Saunders Elsevier; 2009.

Polymerase chain reaction (PCR) assays may also be used to detect viral B19 DNA. In patients with a history of significant exposure and negative IgM serologies, PCR may be used to clarify the diagnosis because it is a sensitive method of detecting small amounts of viral DNA.

Fetal parvovirus infection is diagnosed using PCR analysis of viral B19 DNA in amniotic fluid obtained via amniocentesis. The more invasive method of percutaneous fetal blood sampling can also be used to directly test fetal blood for B19 IgM. This approach is rarely used because it is associated with a fetal loss rate of 1%.

Pregnant patients who have been exposed to parvovirus infection should undergo serologic testing for IgG and IgM antibodies. A woman with a positive IgG and a negative IgM antibody has had a prior infection and is therefore immunized. A positive IgM antibody indicates an acute or subacute parvovirus infection, depending on the IgG status. An infection that occurs during pregnancy and prior to 20 weeks increases the risk for fetal loss. On the other hand, infection after 20 weeks has a lower risk of fetal loss, yet infection remains associated with fetal anemia and hydrops. Patients should undergo serial ultrasound every 2 weeks for at least 10 weeks after the initial exposure to evaluate for evolving fetal hydrops from high-output cardiac failure. The ultrasound should also evaluate the fetus for severe fetal anemia by measuring the middle cerebral artery peak systolic flow (Fig. 15–1).



Exposure to parvovirus B19
Clinical disease: rash, pruritis, headache, fever, pharyngitis, arthralgias, myalgias, joint swelling, nausea, anorexia, transient aplastic crisis
Nonimmune hydrops fetalis
Maternal serological testing: parvovirus B19 IgM and IgG
IgG (+) IgM (–)
IgG (–) IgM (–)
IgG (–) IgM (+)
IgG (+) IgM (+)
Prior infection
Repeat test in 2–4 weeks
Immune no further evaluation
IgG (–) IgM (–)
IgG (+/–) IgM (+)
Recent parvovirus B19 infection
Not infected; no further evaluation
Targeted ultrasound +/– MCA velocimetry every 2 weeks for 10 weeks after exposure or infection
Sonographic evidence of fetal infection: hydrops fetalis, hepatomegaly, splenomegaly, placentomegaly, elevated MCA peak systolic velocity
Yes
No
Cordocentesis for CBC, reticulocyte count, parvovirus B19 RNA (PCR); consider intrauterine transfusion
No further evaluation; notify pediatric service at delivery]

Figure 15–1. Algorithm for evaluation and management of human parvovirus B19 infection in pregnancy. A pregnant woman who is negative for IgG and IgM is susceptible to infection. Therefore, in the case of a recent parvovirus exposure, additional testing with PCR of maternal blood for B19 DNA should be pursued given the possibility of false-negative serologies. The patient should also undergo repeat serologic testing in 3 weeks since IgM antibodies should eventually present in a true infection.

C. Imaging Studies

Ultrasound is a useful tool to screen for fetal anemia and hydrops. Sonographic signs of hydrops include fetal skin edema, ascites, or pleural or pericardial effusions. Doppler velocimetry of the fetal middle cerebral artery is considered an accurate tool to screen for severe fetal anemia (Fig. 15–2). Increases in the peak systolic velocity correlate with worsening fetal anemia. Suspected severe fetal anemia should be confirmed via cordocentesis, at which time therapeutic fetal blood transfusion may be performed.

Differential Diagnosis

Rubella

Enteroviruses

Arboviruses

Streptococcal infection

Allergy

Drug reactions

In the setting of fetal hydrops:

Immune hydrops (Rh isoimmunization)

Nonimmune hydrops

Structural defects (cardiac tumors, neck masses, intracranial hemorrhage, etc)

Anemia (due to glucose-6-phosphate dehydrogenase deficiency, fetomaternal hemorrhage etc)

Infection (cytomegalovirus, syphilis, *Toxoplasma*, etc) Genetic disorders

Placental disorders (chorangioma, chronic vein thrombosis)

Complications

Parvovirus infection in pregnancy has been linked to intrauterine fetal demise in the late second and third trimester. The risk of fetal loss in pregnancies infected prior to 20 weeks of gestation is 11%. The risk dramatically decreases to less than 1% if infection occurs after 20 weeks' gestation. Experts recommend that a workup for parvovirus be included in the evaluation of these intrauterine fetal demises.

In addition to causing fetal loss, the virus may lead to anemia and subsequent hydrops fetalis. The median interval between diagnosis of maternal infection and hydrops is 3 weeks. Fifty percent of cases occur within 2–5 weeks of maternal infection, and 93% of fetal manifestations occur within 8 weeks. The risk of anemia with hydrops depends on the gestational age at which maternal infection occurs. If infection occurs during the first 12 weeks of pregnancy, the risk of hydrops is 5–10%. This risk decreases to less than 5% if infection develops during weeks 13–20. After week 20 of gestation, the risk of hydrops is less than 1%. Hydropic fetuses with parvovirus are also at risk for severe thrombocytopenia. Despite studies linking parvovirus to teratogenicity in fetal animals and case reports of human infection and subsequent fetal malformations, most data suggest that parvovirus B19 is not a teratogen.

Treatment

Mild to moderate anemia is generally well tolerated by the fetus and resolves without sequelae. However, severe anemia can lead to hydrops fetalis and death. If severe anemia is suspected based on elevated Doppler middle cerebral artery peak systolic velocity or signs of hydrops, the fetal hematocrit should be assessed by percutaneous umbilical vein sampling (cordocentesis). Confirmed fetal anemia should be treated with intrauterine blood transfusion. The fetal platelet count should also be determined because the fetus is at risk for thrombocytopenia. Platelets should be available at the time of transfusion. Although there is a risk of fetal death after periumbilical blood sampling, multiple retrospective studies have demonstrated the benefit of such a procedure in hydropic fetuses with parvovirus infection. Usually, only 1 intrauterine transfusion is required because hematopoiesis recovers as the parvovirus infection is cleared.

The delivery of a neonate with hydrops should occur in a tertiary care setting to maximize pregnancy outcome. These infants generally require respiratory assistance with mechanical ventilation and may also require abdominal paracentesis and thoracocentesis of fetal ascites and pleural effusions to aid in resuscitation. Postnatal outcomes depend on gestational age, illness severity, and associated conditions.

Prognosis

Although parvovirus B19 infection during pregnancy is associated with fetal loss and hydrops fetalis, most intrauterine parvovirus infections have an excellent long-term prognosis. Historically, the mortality rate of fetal hydrops was close to 30%. With intrauterine transfusion therapy, over 90% of fetuses who require and survive these transfusions recover within 6–12 weeks with an overall mortality rate of less than 10%. Long-term neurologic and psychomotor outcomes of infants following intrauterine blood transfusion for hydrops have been reported. Most studies are reassuring and suggest no neurodevelopmental abnormalities, although the data are limited.

VARICELLA-ZOSTER VIRUS

ESSENTIALS OF DIAGNOSIS

- Caused by varicella-zoster virus (VZV), a single-stranded DNA virus
- Clinical manifestations: nonspecific prodromal symptoms and vesicular lesions
- Prevention: varicella vaccine; immunity following prior infection
- Diagnosis: usually clinical but can be confirmed by serologic tests for anti-VZV IgM
- Complications of maternal VZV in pregnancy: pneumonia, respiratory failure
- Congenital varicella infection: dermatomal scarring, chorioretinitis, limb hypoplasia, microcephaly, low birth weight
- Treatment of pregnant women: oral antivirals and, in the case of maternal complications such as pneumonia, intravenous antiviral therapy

---

Pathogenesis

The varicella-zoster virus (VZV) is a DNA virus that belongs to the herpesvirus family and causes varicella (chickenpox) and herpes zoster (shingles). Although a majority of infections occur in children, 2% of cases occur in adults. In children, the infection is often benign and self-limited, whereas in adults, it can be devastating. Adults over the age of 20 contribute to over half of varicella-related deaths.

The virus is transmitted by respiratory droplets and direct contact with vesicular lesions. Once droplets enter conjunctiva or nasal/oral mucosa, the virus replicates in regional lymph nodes and spreads to internal organs. Secondary viremia occurs as the virus is released into the bloodstream and attacks cutaneous tissue leading to VZV exanthem. Infectivity is present from 1–2 days prior to the onset of the rash up until the lesions crust over. VZV is highly infectious, with secondary attack rates approximating 90% in susceptible household contacts.

Following a primary VZV infection, the virus remains dormant in dorsal root ganglia. In the setting of impaired immunity, the virus may be reactivated to cause herpes zoster, a vesicular erythematous skin rash that presents along dermatomes. Although there are isolated case reports of reinfection, primary VZV is associated with lifelong immunity.

Prevention

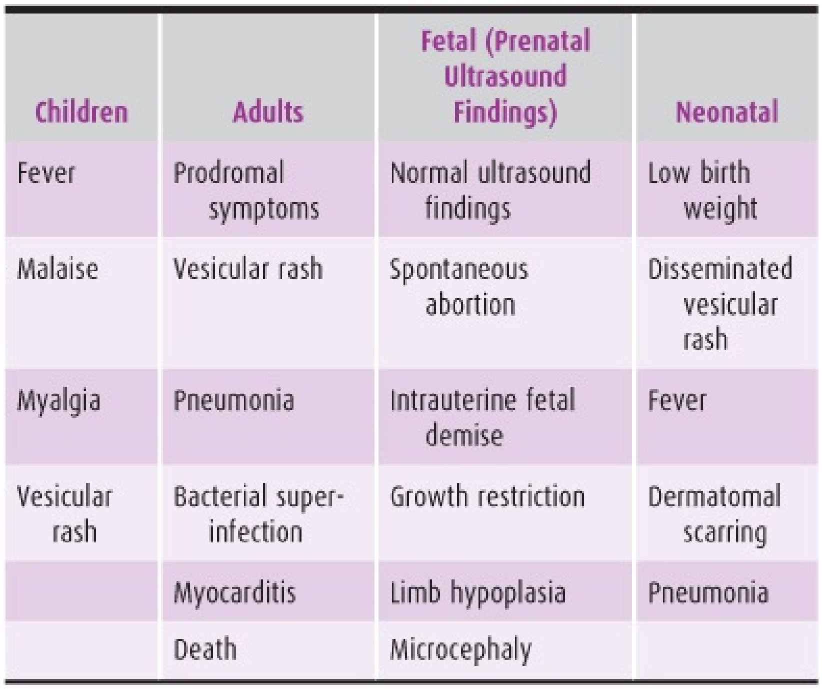
To prevent the complications of VZV in pregnancy, all reproductive-aged women should be vaccinated for varicella if naturally acquired immunity is not present. Varivax, the varicella vaccine, is a live attenuated virus vaccine. The vaccine is contraindicated in pregnancy, immunocompromised states, systemic illnesses, and patients with allergies to neomycin (a component of the vaccine). One dose of the vaccine is sufficient in individuals ages 1–12, and 2 doses, administered 4–6 weeks apart, are required in those over the age of 12. Conception should be delayed until at least 1 month after the second dose. Pregnant patients known to be nonimmune to VZV should be counseled to avoid contact with individuals with varicella.

Clinical Findings

A. Symptoms & Signs (Table 15–3)

The incubation period is 10–21 days after the initial infection. The period of infectivity begins 48 hours prior to the onset of the rash and lasts until the vesicular lesions are crusted over. During this time period, patients experience prodromal symptoms such as fever, malaise, and myalgia. This is followed by a 6- to 10-day vesicular rash on the trunk, face, and scalp. The lesions usually occur in crops and evolve from vesicle to pustule to eventually a crusted over dry scab.

Table 15–3. Clinical manifestations of varicella infection.



Children	Adults	Fetal (Prenatal Ultrasound Findings)	Neonatal
Fever	Prodromal symptoms	Normal ultrasound findings	Low birth weight
Malaise	Vesicular rash	Spontaneous abortion	Disseminated vesicular rash
Myalgia	Pneumonia	Intrauterine fetal demise	Fever
Vesicular rash	Bacterial superinfection	Growth restriction	Dermatomal scarring
	Myocarditis	Limb hypoplasia	Pneumonia
	Death	Microcephaly	

B. Laboratory Findings

Although the diagnosis of varicella is clinical, serologic tests can be performed to confirm the diagnosis in unclear cases. Using ELISA, anti-VZV IgM can be detected 3 days after the onset of symptoms and IgG can be detected 7 days after symptomatology. Immunofluorescence of vesicular lesions and viral cultures or viral DNA PCR of vesicular fluid can also establish the diagnosis.

Prenatal diagnosis of fetal varicella is possible by percutaneous umbilical vein blood sampling (cordocentesis) for identification of viral-specific antibody or DNA. The virus can also be identified by culture, antibody detection or viral DNA PCR in chorionic villi, or amniotic fluid. Although testing may be reassuring if test results are negative, positive test results do not correlate with severity of fetal infection. Invasive testing to make a fetal diagnosis is not routinely recommended.

C. Imaging Studies

Women with VZV who present with respiratory complaints should undergo imaging by chest x-ray. A diffuse or military infiltrative pattern usually distributed in the peribronchial region is suggestive of VZV pneumonia.

Although prenatal ultrasound can be used to look for markers of congenital VZV, the ultrasound is usually unremarkable. Ultrasound findings include hydrops, echogenic foci in liver and bowel, limb deformities, cardiac malformations, microcephaly, ventriculomegaly, and growth restriction.

Differential Diagnosis

Drug eruptions

Viral exanthems

Herpes simplex

Bullous pemphigoid

Dermatitis herpetiformis

Syphilis

Insect bites

Impetigo

Rickettsial disease

Complications

VZV infection occurs in 1–5 cases per 10,000 pregnancies. Pregnancies complicated by VZV infection are associated with maternal, fetal, and neonatal health risks.

Complications of primary VZV infection are more common in adults and include bacterial superinfection of vesicles, pneumonia, glomerulonephritis, myocarditis, adrenal insufficiency, and death. Patients may also experience benign cerebellar ataxia and Guillain-Barré syndrome.

VZV pneumonia occurs in up to 20% of adult cases of VZV and may be more severe in pregnant women. Symptoms include cough, shortness of breath, fever, and tachypnea and typically present within 1 week of the rash. VZV pneumonia is considered a medical emergency because pregnant patients are at risk for respiratory failure.

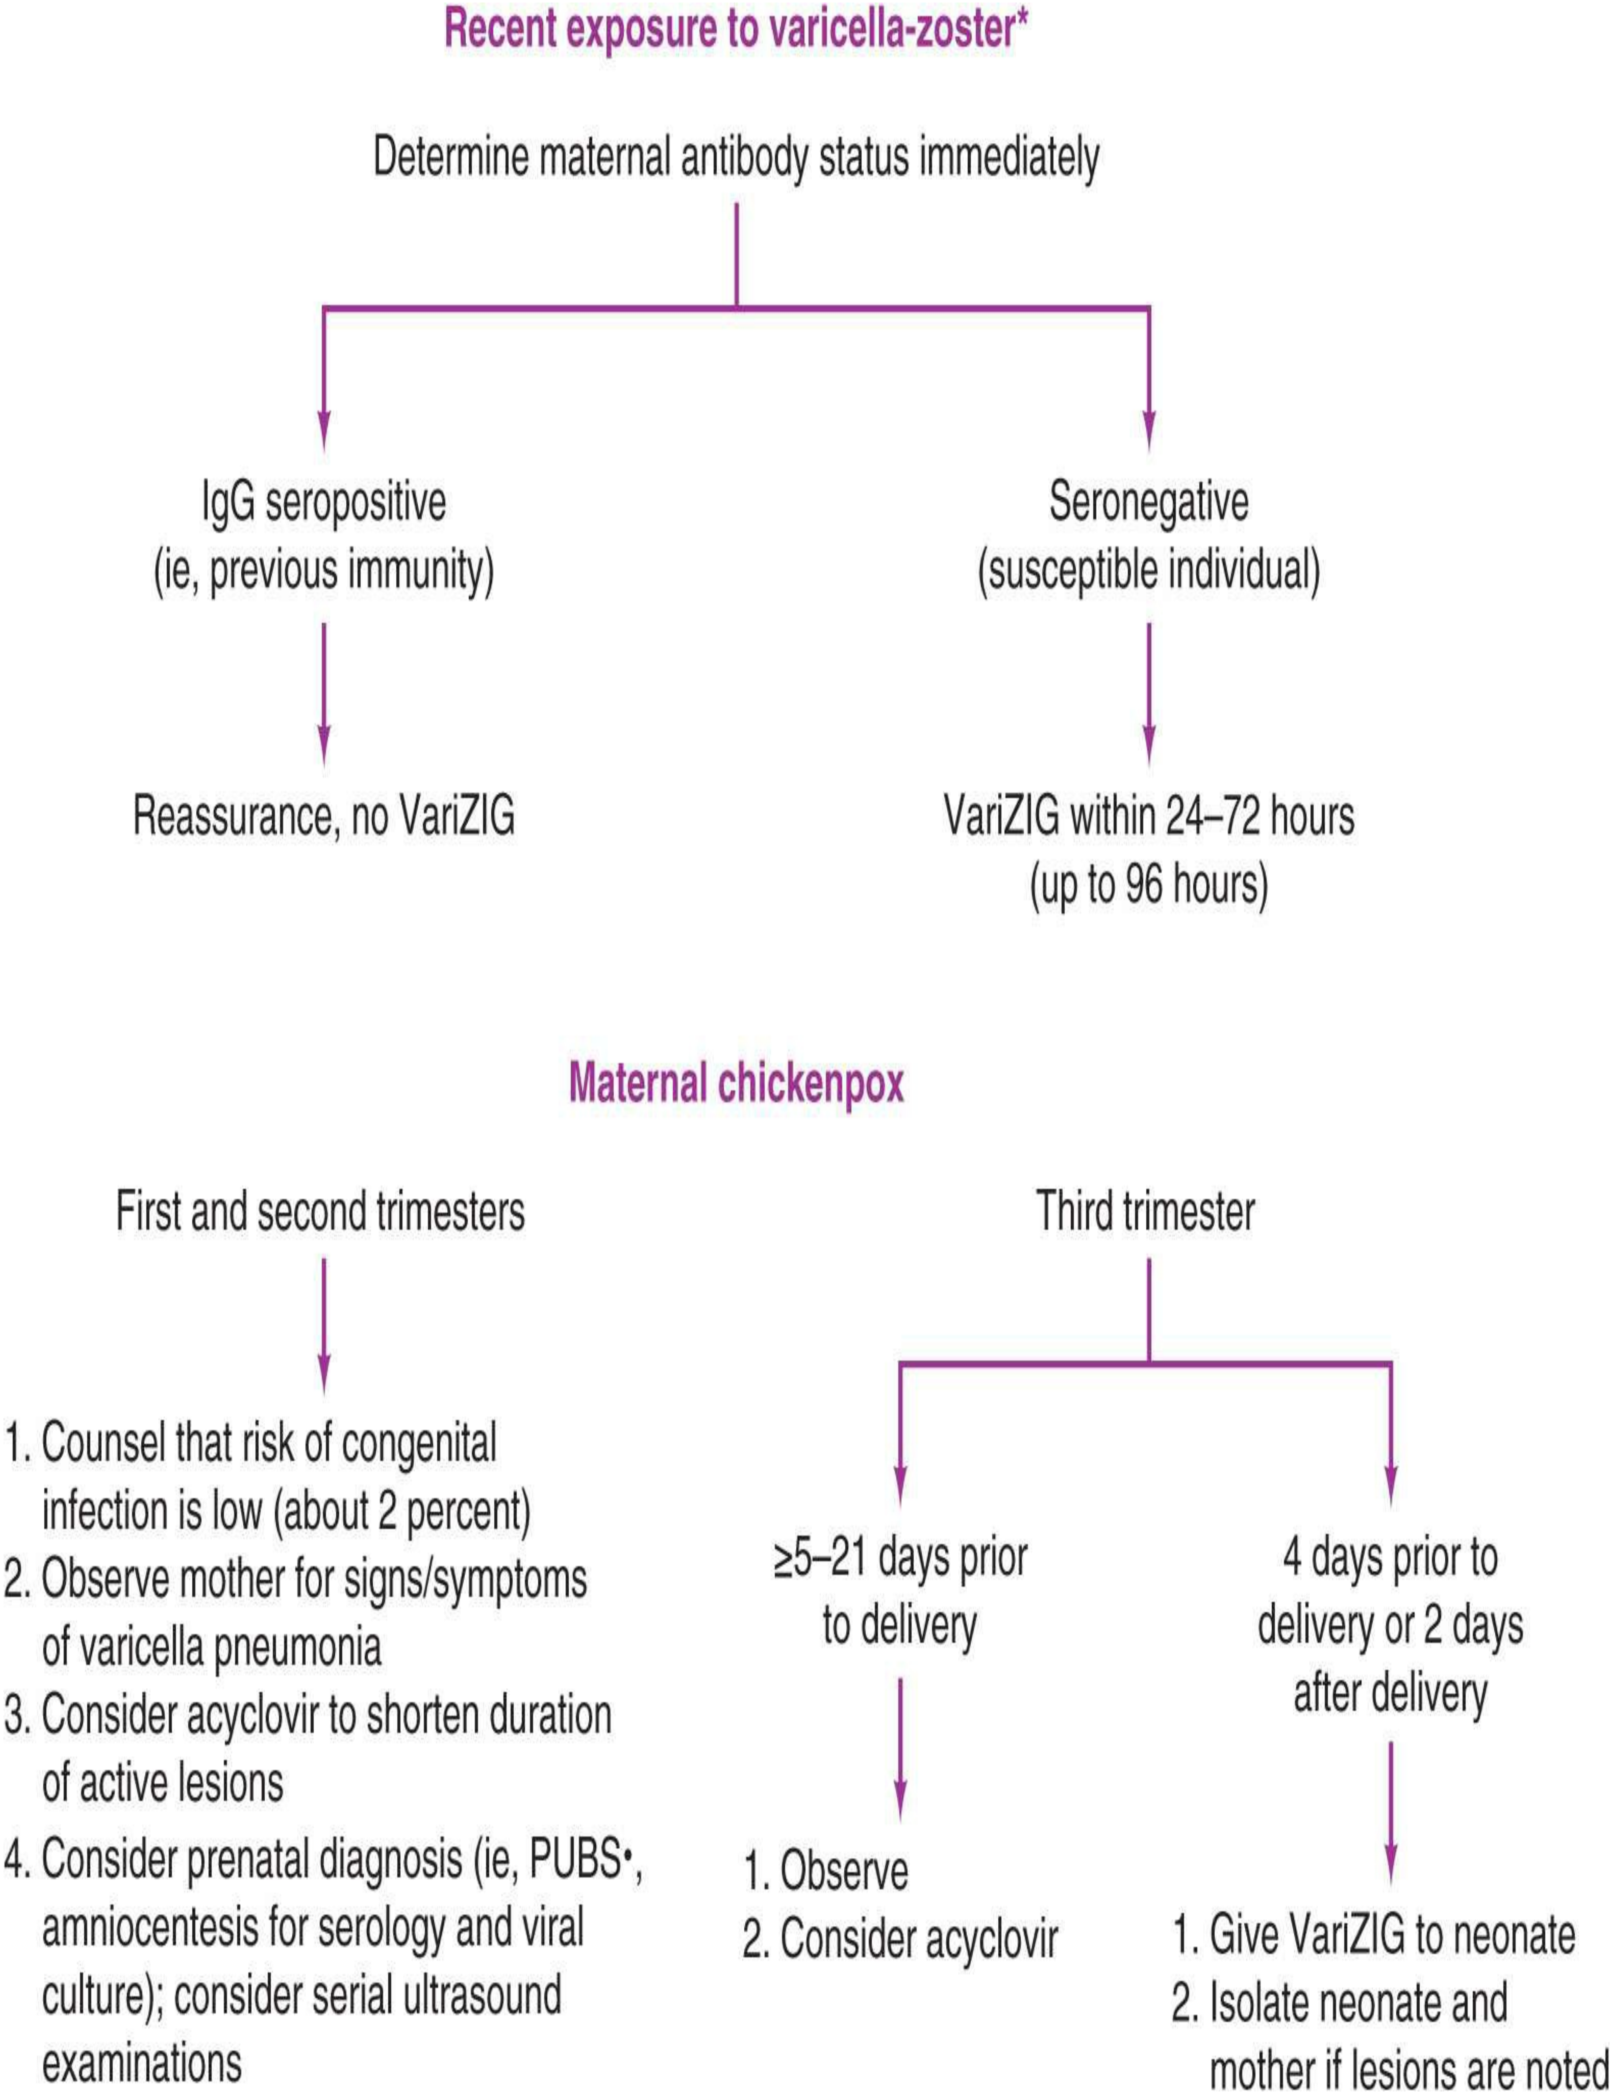
In terms of adverse effects on the pregnancy, acute VZV infection has been associated with spontaneous abortion, intrauterine fetal death, and congenital VZV syndrome. The risk of congenital VZV syndrome is low, close to 2%, and is limited to VZV exposure during the first 20 weeks of gestation.

Neonatal VZV is associated with up to a 25% mortality rate. Infants born to women who develop acute VZV from 5 days before delivery to 48 hours postpartum are at risk for serious consequences due to immaturity of the neonatal immune system and lack of maternal protective antibodies. Clinical manifestations of neonatal VZV include fever, disseminated vesicular rash, pneumonia, and encephalitis. Complications include dermatomal scarring, ocular abnormalities, chorioretinitis, limb hypoplasia, microcephaly, and low birth weight.

Treatment

At the first prenatal visit, all pregnant women should be questioned about prior VZV infection. About 70–90% of women who are uncertain about their prior history will actually have detectable antibodies and be immune. Patients with a well-defined history of infection should be reassured that second infections are extremely unlikely and that, in these cases, risks to the fetus are insignificant. It is unclear whether antenatal VZV screening of all pregnant women with negative or indeterminate VZV histories is cost effective.

If a susceptible pregnant patient is exposed to VZV, she should be treated within 72–96 hours (Fig. 15–3). Prophylactic intervention with varicella-zoster immune globulin (VZIG) in the incubation period can prevent or attenuate the manifestations of VZV, but it does not prevent fetal infection. Pregnant women who develop VZV despite immunoprophylaxis should be treated with oral acyclovir or valacyclovir for 1 week. Patients with pneumonia, encephalitis, or disseminated infection should have supportive care and be treated with intravenous acyclovir for 10 days.



Recent exposure to varicella-zoster*
Determine maternal antibody status immediately
IgG seropositive (ie, previous immunity)
Seronegative (susceptible individual)
Reassurance, no VariZIG
VariZIG within 24–72 hours (up to 96 hours)
Maternal chickenpox
First and second trimesters
Third trimester
≥5–21 days prior to delivery
4 days prior to delivery or 2 days after delivery

1. Counsel that risk of congenital infection is low (about 2 percent)
2. Observe mother for signs/symptoms of varicella pneumonia
3. Consider acyclovir to shorten duration of active lesions
4. Consider prenatal diagnosis (ie, PUBS•, amniocentesis for serology and viral culture); consider serial ultrasound examinations

1. Observe
2. Consider acyclovir

1. Give VariZIG to neonate
2. Isolate neonate and mother if lesions are noted

Figure 15–3. Management of varicella-zoster infection in pregnancy. (*) If period of exposure is uncertain or diagnostic evaluation is delayed, consider immunoglobulin M (IgM) and serial immunoglobulin G (IgG) testing. Empiric use of VariZIG may be appropriate if susceptibility is suspected. (•) Percutaneous umbilical blood sampling. (Reproduced, with permission, from Riley LE. Varicella-zoster virus infection in pregnancy. In Hirsch MS, Lockwood CJ (eds). *UpToDate*. Waltham, MA: UpToDate; 2010. http://www.utdol.com.)

Prognosis

Maternal VZV infection is associated with high maternal morbidity and mortality rates. Prognosis is improved with prompt medical attention, supportive care, and treatment of serious conditions such as pneumonia and encephalitis.

The risk of congenital VZV syndrome depends on the gestational age at which exposure occurs. Maternal infection after 20 weeks is not associated with congenital anomalies, and prognosis is favorable, as long as maternal health is optimized. Infection prior to 20 weeks is associated with a low risk of congenital VZV. Prenatal ultrasound diagnosis of fetal anomalies suggestive of congenital VZV syndrome carries a poorer prognosis.

RUBELLA

ESSENTIALS OF DIAGNOSIS

- Caused by an RNA virus transmitted via respiratory droplets
- Prevention: rubella vaccine
- Clinical manifestations: subclinical infection or mild, self-limited disease
- Diagnosis: serologic testing—rubella IgM and IgG antibodies
- Congenital rubella syndrome: deafness, ocular defects, central nervous system defects, and cardiac malformations

---

Pathogenesis

The rubella virus is part of the RNA togavirus family. Commonly referred to as the German measles, the virus is transmitted via respiratory droplets. From the respiratory tract, the virus replicates in lymph nodes and hematogenously disseminates throughout the body. Hematogenous spread of the virus across the placenta leads to fetal infection or congenital rubella syndrome (CRS). The virus causes cytopathic damage to vessels and ischemia in affected organs, leading to the various congenital defects.

Prevention

Primary prevention of rubella is possible through preconceptional vaccination. Since the introduction of the vaccine in 1969, the incidence of rubella in the United States has declined dramatically—from 0.45 per 100,000 in 1990 to 0.1 per 100,000 in 1999. The rubella vaccine consists of a live attenuated virus. Currently, the vaccine is recommended for all children from age 12–15 months and 4–6 years in conjunction with measles and mumps (MMR vaccine). Although it is recommended that women receiving the rubella vaccine delay conception for at least 1 month, there are no data to suggest an increase in complications if inadvertently given during pregnancy.

Reproductive-age women should be tested for immunity to rubella prior to pregnancy. If results indicate susceptibility, these patients should be vaccinated prior to conception. If patients are not seen before conception and instead present at the time of pregnancy, obstetricians should test for rubella at the first prenatal appointment. Susceptible women are counseled to avoid exposure to individuals with viral exanthems.

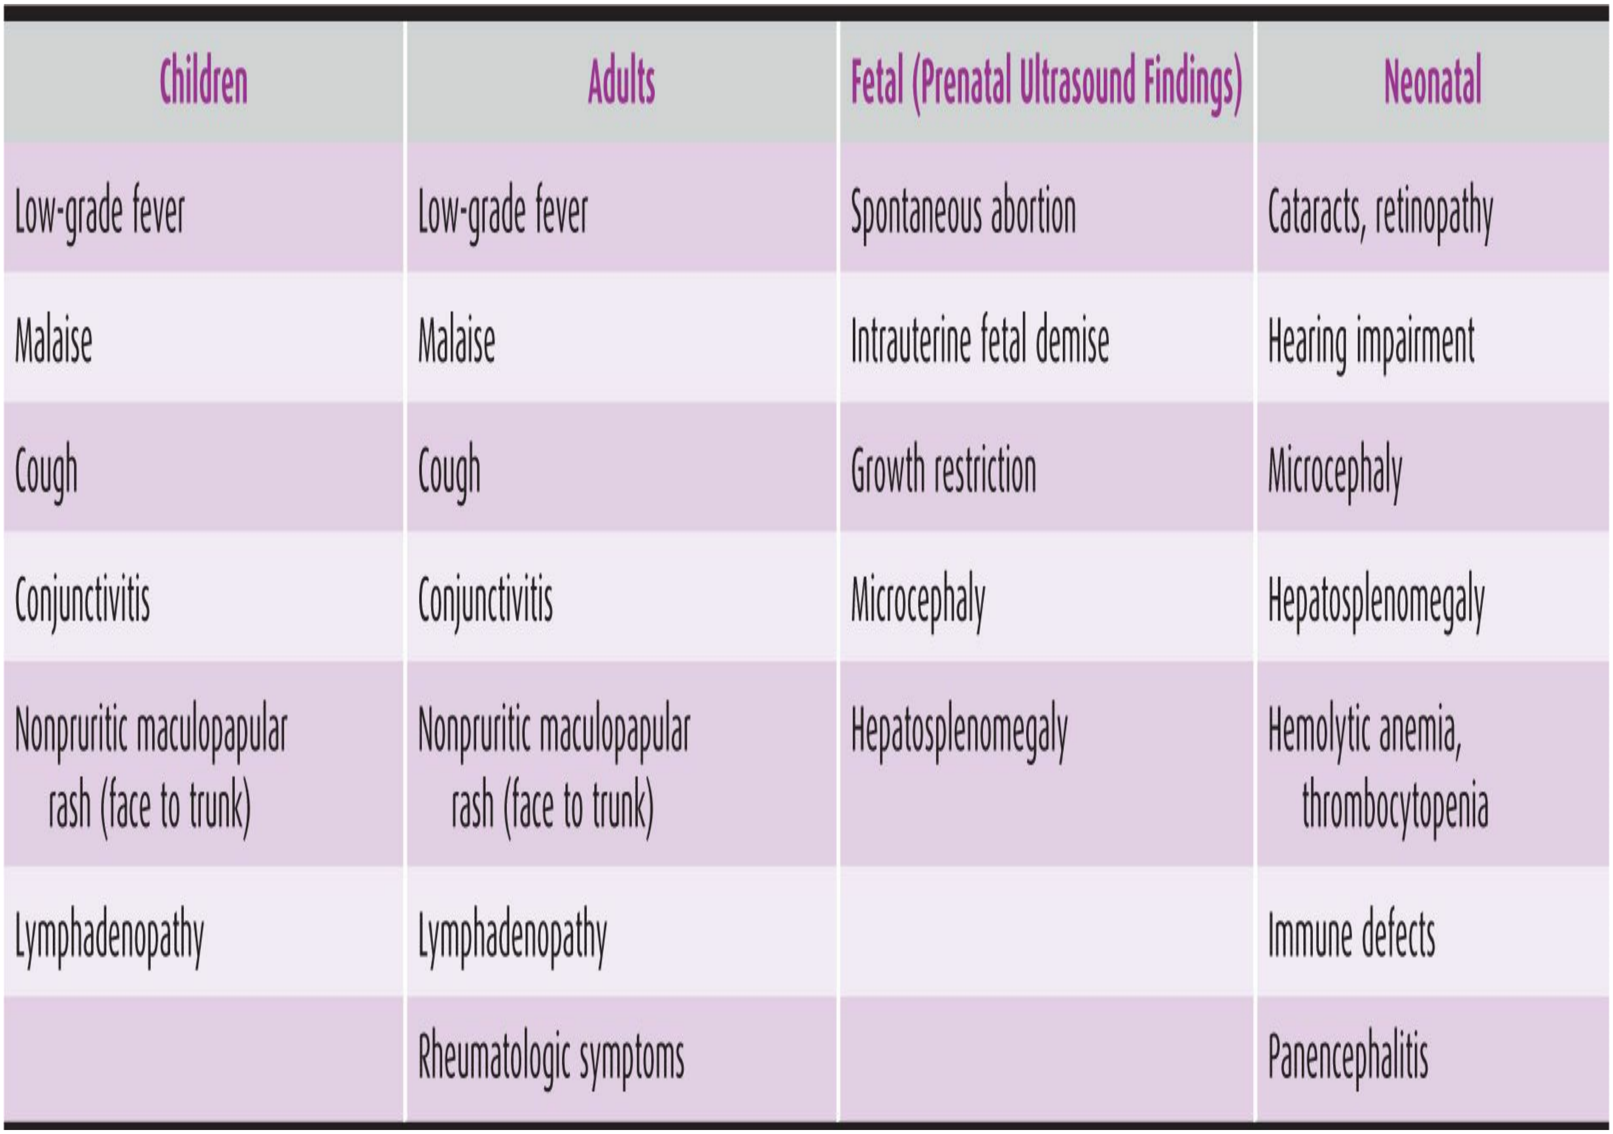
Pregnant women who are rubella nonimmune should be vaccinated immediately after delivery. Ninety-five percent of individuals receiving the vaccine will seroconvert. Vaccinated women can continue breastfeeding and will not transmit the virus to susceptible contacts. Postpartum vaccination programs have been shown to reduce rubella susceptibility in pregnant nonimmune women. A study in 2004 revealed that one-third of pregnant women are also susceptible to mumps. Therefore, the Centers for Disease Control and Prevention (CDC) recommends that rubella-susceptible women receive the MMR vaccine postpartum.

Clinical Findings

A. Symptoms & Signs (Table 15–4)

Acquired rubella may be subclinical or present as a mild, self-limited disease associated with an exanthem. Although 25–50% of individuals are asymptomatic, symptoms include low-grade fevers, conjunctivitis, cough, and malaise. The incubation period is 2–3 weeks. Symptoms usually last 1–5 days followed by the onset of the rash. The characteristic exanthem of rubella is a nonpruritic, erythematous, maculopapular rash. The rash typically starts on the face and then disseminates to the trunk and extremities lasting 1–3 days. Resolution of the rash follows the same pattern as dissemination. Patients may be contagious for 7–10 days as the virus is present in blood and nasopharyngeal secretions both prior to and following the onset of symptoms. Generalized tender lymphadenopathy, particularly postauricular adenopathy, may also be present. Female adolescents may present with rheumatologic sequelae, including morning stiffness and symmetric joint pain. Rare complications of rubella include thrombocytopenia, hemolytic anemia, and hepatitis.

Table 15–4. Clinical manifestations of rubella.



Children	Adults	Fetal (Prenatal Ultrasound Findings)	Neonatal
Low-grade fever	Low-grade fever	Spontaneous abortion	Cataracts, retinopathy
Malaise	Malaise	Intrauterine fetal demise	Hearing impairment
Cough	Cough	Growth restriction	Microcephaly
Conjunctivitis	Conjunctivitis	Microcephaly	Hepatosplenomegaly
Nonpruritic maculopapular rash (face to trunk)	Nonpruritic maculopapular rash (face to trunk)	Hepatosplenomegaly	Hemolytic anemia, thrombocytopenia
Lymphadenopathy	Lymphadenopathy		Immune defects
	Rheumatologic symptoms		Panencephalitis

B. Laboratory Findings

The diagnosis of rubella is usually established [CD1] by serologic testing of rubella-specific IgG and IgM, via enzyme-linked immunoassays and other serologic tests. IgM antibody concentration reaches a peak 7–10 days after the onset of the infection and decreases over the next 4 weeks. The serum concentration of IgG rises slowly but remains positive over the lifetime of an individual. A rubella

PCR or positive culture may also facilitate the diagnosis. The virus may be isolated from blood, nasal cavity, pharynx, or urine.

If rubella exposure occurs in a susceptible woman, serologic tests should be performed. If acute infection is documented with the presence of an IgM antibody, the patient should be counseled regarding the option for prenatal diagnosis. There are various methods to establish the prenatal diagnosis of rubella. Fetal blood via cordocentesis can be tested for rubella-specific IgM concentrations. This is limited in use because fetal immunoglobulins are unlikely to be present prior to 22–24 weeks. PCR can be performed on chorionic villi, fetal blood, and amniotic fluid. Although these tests can determine the presence of rubella in the fetal compartment, the results do not correlate with the level of fetal injury.

Differential Diagnosis

Rubeola

Roseola

Other viral exanthems

Drug reaction

Complications

Although the virus is usually self-limited in adults, rare complications of adult rubella have been reported. These serious complications include encephalitis, thrombocytopenia with hemorrhagic manifestations, neuritis, and conjunctivitis.

The virus can also adversely impact the developing fetus. Pregnant women infected with rubella are at higher risk for spontaneous abortion, fetal infection, growth restriction, and fetal demise. Due to the established rubella vaccination programs in the United States, the incidence of CRS has dramatically decreased, and there are now fewer than 50 cases of CRS each year. However, about 10–20% of reproductiveage women in the United States are not immune, and their fetuses are at risk for CRS. In developing countries without national guidelines for rubella vaccination, the burden of disease is higher, and CRS affects from 10–90 per 100,000 live births.

Rubella is considered one of the most teratogenic viruses during pregnancy. Congenital infection depends on the time of exposure to the virus. About 50–80% of neonates exposed to the virus prior to 12 weeks' gestation will manifest signs of congenital infection. The risk of CRS decreases with advancing gestational age. CRS is rare if infection occurs beyond 18 weeks' gestation.

Common anomalies associated with CRS include deafness (60–75%), eye defects such as cataracts or retinopathy (10–30%), central nervous system anomalies (10–25%), and cardiac malformations (10–20%). Other findings include microcephaly, growth retardation, hepatosplenomegaly, hemolytic anemia, and thrombocytopenia. Fetal infection is chronic and persistent after birth. Although most infants with CRS are asymptomatic at birth, they develop signs and symptoms over time. Because of the lack of clinical manifestations at birth and the risk for progression, timely diagnosis is important. Late manifestations of CRS include hearing loss, endocrine disorders, immune defects, and panencephalitis.

Treatment

Treatment for acute rubella infection in children and adults is supportive therapy. Glucocorticoids and platelet transfusion are considered in patients with complications such as thrombocytopenia or encephalopathy. Administration of immune globulin to susceptible women exposed to rubella during pregnancy is controversial. The clinical benefit of immunoglobulins for postexposure prophylaxis of rubella and prevention of fetal infection has yet to be demonstrated.

Prognosis

Pregnant women with rubella have a favorable prognosis when it comes to their health. Unfortunately, the prognosis of CRS is potentially devastating because affected neonates commonly suffer serious sequelae and permanent damage.

SYPHILIS

ESSENTIALS OF DIAGNOSIS

- Caused by the spirochete *Treponema pallidum*
- Stages:
  - Primary stage: defined by chancre
  - Secondary stage: systemic process involving a maculopapular rash, lymphadenopathy, flu-like symptoms, and condyloma lata
  - Latent stage: subclinical infection with positive serologic tests
    - Early latent syphilis: within 1 year of the initial infection
    - Late latent syphilis: infection 1 year after the primary infection
  - Tertiary stage: systemic disease with cardiovascular, neurologic, and cutaneous manifestations
- Diagnosis: direct visualization by dark field microscopy, serologic titers (VDRL and rapid plasma reagin, nonspecific treponemal tests; fluorescent treponemal antibody absorption test, treponemal-specific tests)
- Complications in pregnancy: spontaneous abortion, growth restriction, stillbirth, congenital anomalies, preterm delivery, fetal/neonatal infection, and neonatal death
- Treatment: penicillin

Pathogenesis

Syphilis is a chronic systemic infection caused by the motile spirochete *Treponema pallidum*. It is most commonly acquired through direct sexual contact. During pregnancy, infection can also occur via transplacental transmission. Exposure to open lesions containing the organisms facilitates transmission of the spirochete across mucous membranes or skin abrasions. The infection is acquired in 50–60% of partners after a single sexual exposure to an infected lesion. The tissue destruction observed in syphilis infections is a result of the immune response rather than a direct insult from the spirochete itself.

Although the incidence of syphilis steadily declined in the 1990s to early 2000s, there was a notable increase from 2003 to 2005. During this period, there was a parallel rise in the number of diagnosed cases of congenital syphilis (Fig. 15–4).

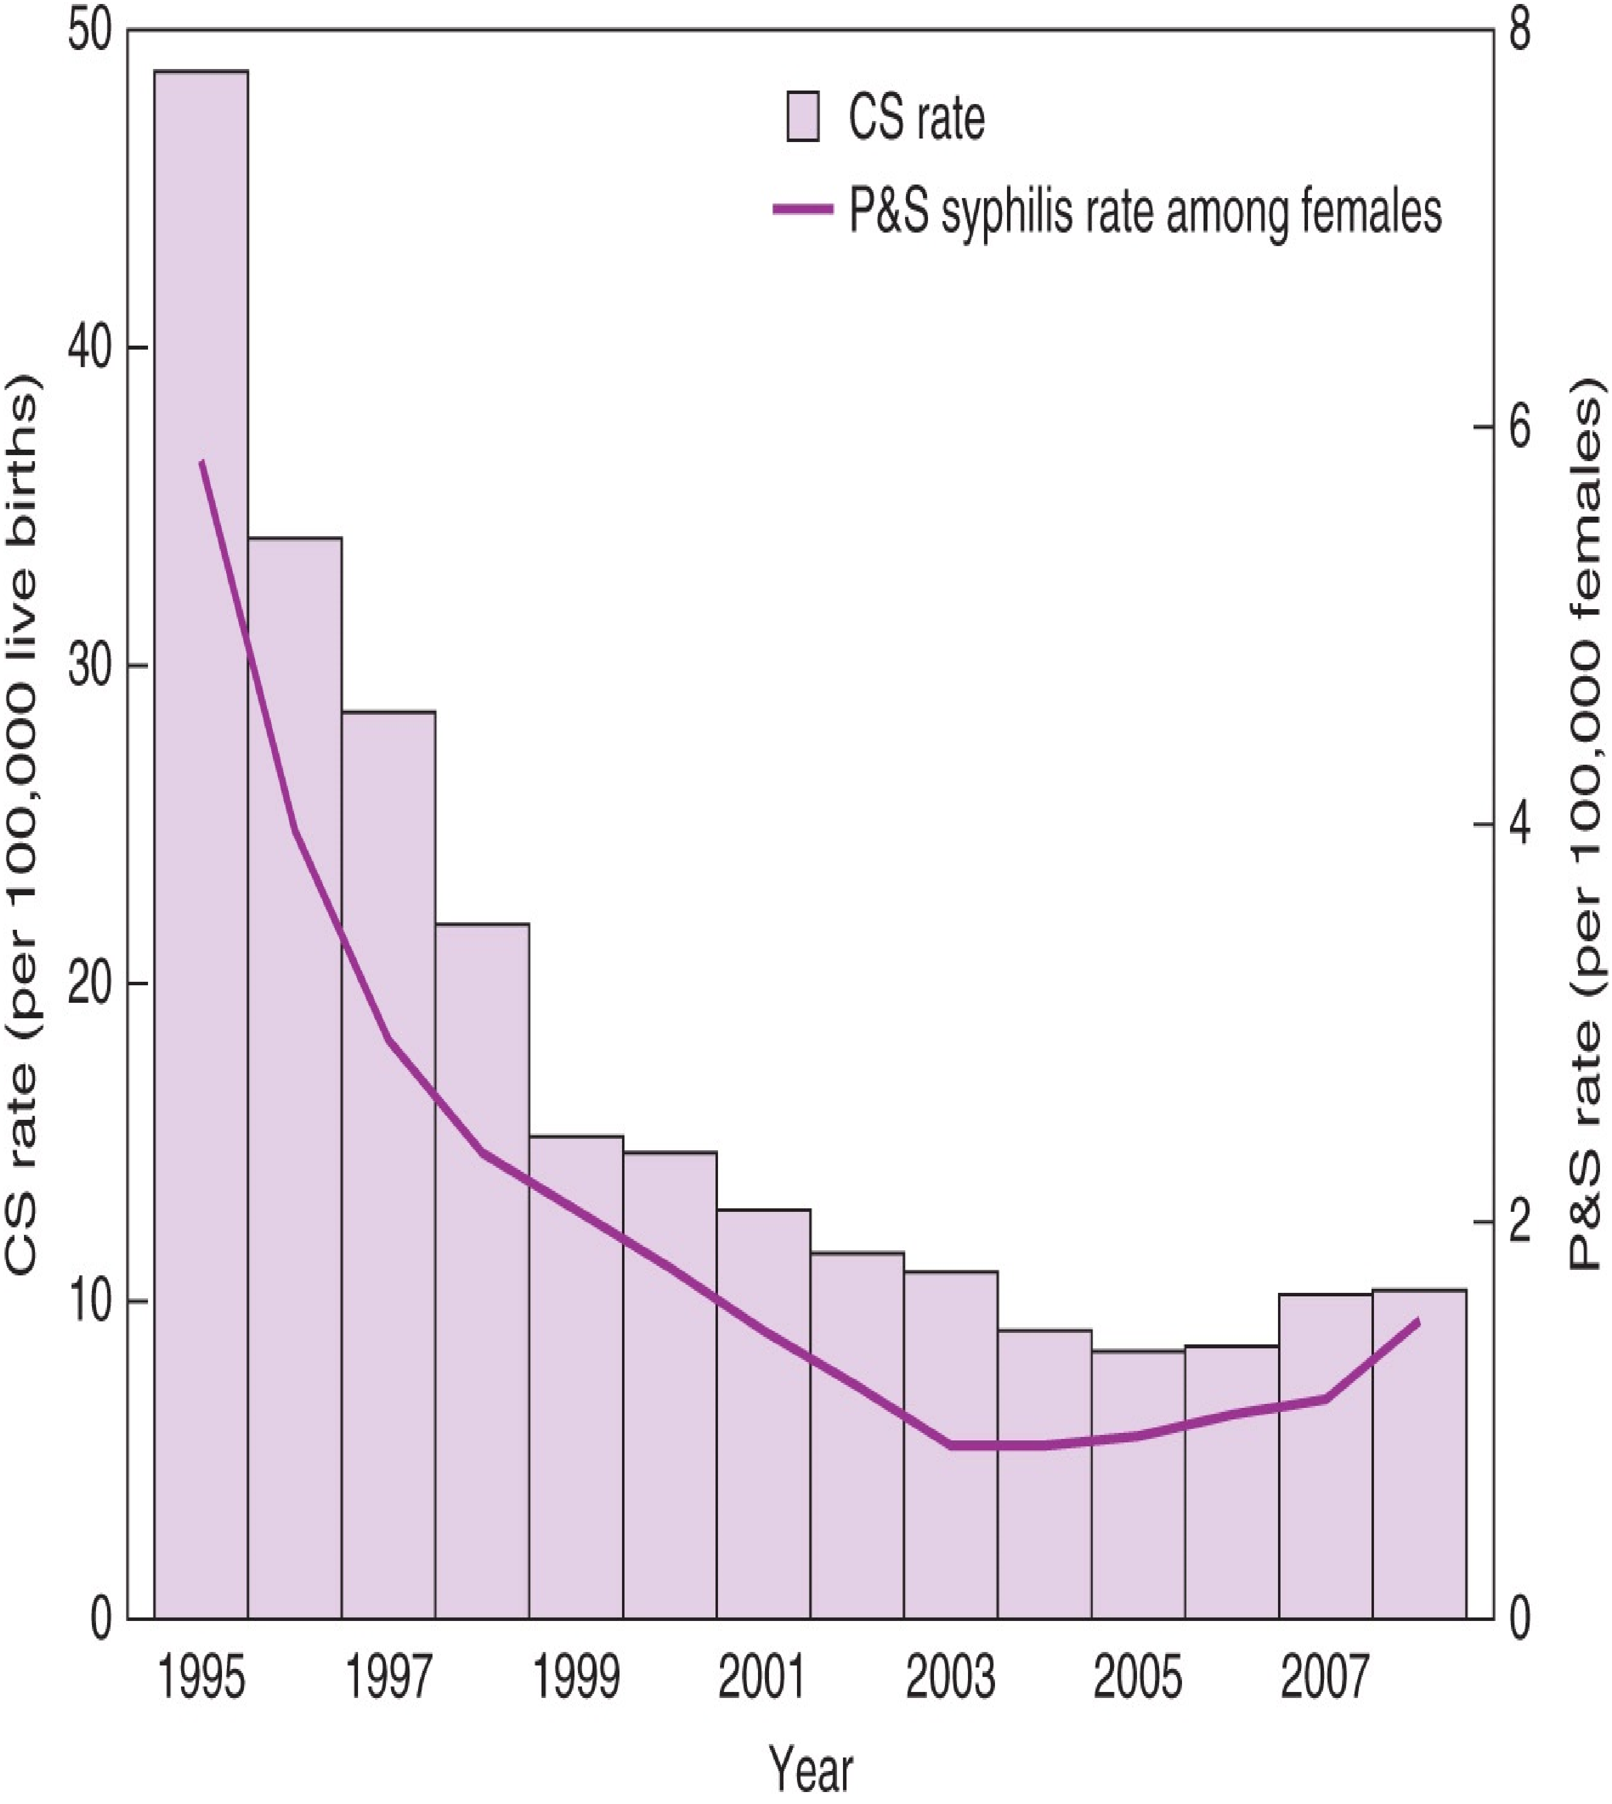

Figure 15–4. Congenital syphilis (CS) rate among infants age <1 year and rate of primary and secondary (P&S) syphilis among females age ≥10 years. (Reproduced from Centers for Disease Control and Prevention. National Electronic Telecommunication System for Surveillance, United States, 1995–2008. http://www.cdc.gov/mmwr/preview/mmwrhtml/mm5914a1.htm.)

Prevention

Public health strategies, counseling, and education of patients on sexually transmitted infections can help reduce the risk of these infections. Although correct and consistent use of latex condoms may decrease the risk of syphilis transmission, sexual abstinence is the only guaranteed method to avoid transmission. Other risk factors associated with syphilis in pregnancy include poverty, sexual promiscuity, and illicit drug use. Avoiding activities leading to risky behavior, such as alcohol and drug use, may also help prevent transmission. The risk of syphilis can be further modified by early identification of infected patients, screening of high-risk populations, adequate treatment of patients and exposed individuals, and improved access to health care.

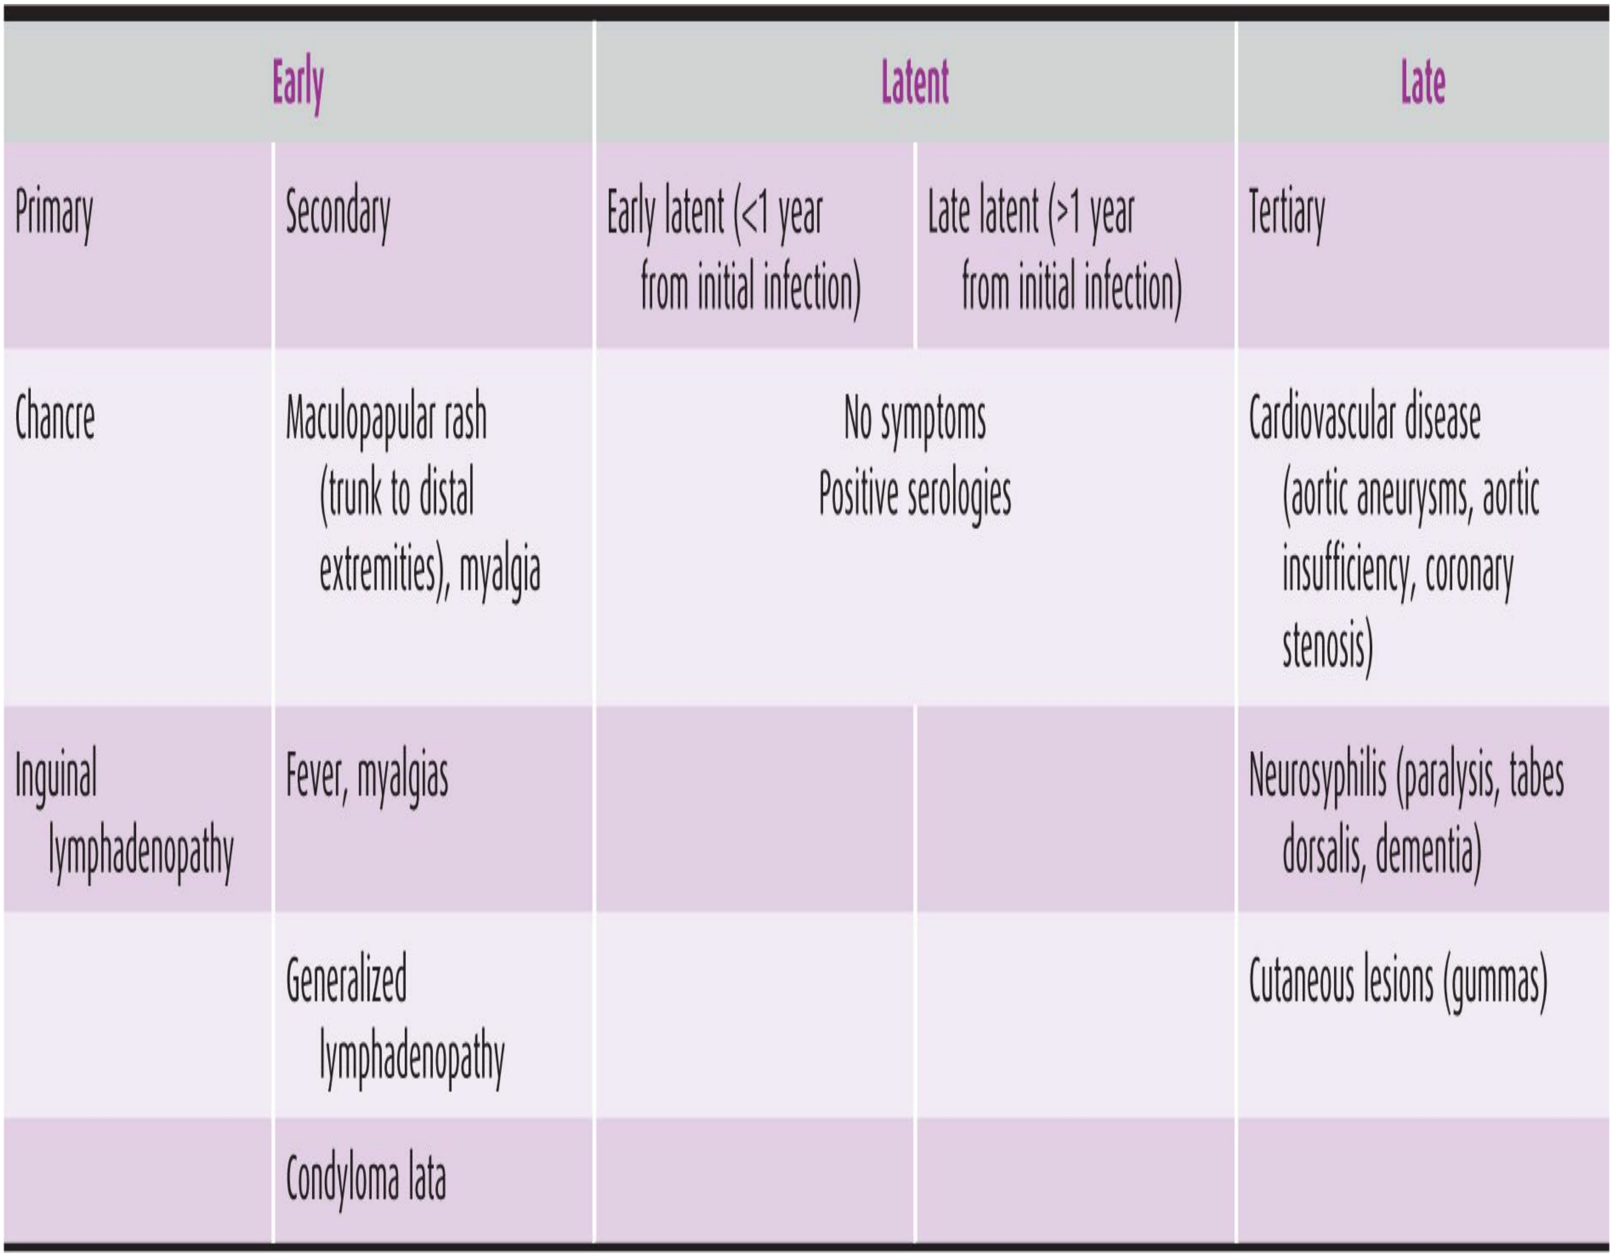
Congenital syphilis can be prevented by screening all pregnant women and treating those with evidence of infection. Patients should be encouraged to seek early prenatal care, and all pregnant women should undergo screening at the initial prenatal visit. High-risk patients should be rescreened in the third trimester, around 28 weeks of gestation, and in areas with high rates of congenital syphilis, rescreening upon admission in labor should be considered. Women with an intrauterine fetal demise after 20 weeks of gestation should also be evaluated for syphilis.

Clinical Findings

A. Symptoms & Signs

Syphilis is an infection that presents in different stages over a period of time if untreated. Early syphilis, which occurs within the first year after acquisition of the infection, includes primary and secondary syphilis. Latent syphilis refers to the absence of symptoms in the setting of positive serologies and often follows secondary syphilis. Tertiary or late syphilis, which involves the central nervous and cardiovascular systems, manifests years to decades after the initial infection. Table 15–5 summarizes the clinical manifestations of the various stages of syphilis.

Table 15–5. Clinical manifestations of the various stages of syphilis.



Early		Latent		Late
Primary	Secondary	Early latent (<1 year from initial infection)	Late latent (>1 year from initial infection)	Tertiary
Chancre	Maculopapular rash (trunk to distal extremities), myalgia	No symptoms Positive serologies		Cardiovascular disease (aortic aneurysms, aortic insufficiency, coronary stenosis)
Inguinal lymphadenopathy	Fever, myalgias			Neurosyphilis (paralysis, tabes dorsalis, dementia)
	Generalized lymphadenopathy			Cutaneous lesions (gummas)
	Condyloma lata			

The chancre, the characteristic lesion of primary syphilis, is a painless, nontender ulcer with an indurated base and raised border. The lesion is found at the site of inoculation. In women, it is most often found on the external genitalia, on the cervix, or in the vagina. Primary syphilis may also manifest with painless inguinal lymphadenopathy. The incubation period varies from 10–90 days, with a mean incubation time of 3 weeks. The primary chancre heals spontaneously in 3–6 weeks in the absence of treatment.

Secondary syphilis is a systemic process characterized by disseminated spread of the infection. This stage typically presents 6 weeks to 6 months after the onset of the primary chancre. Patients present with skin and mucous membrane lesions, along with flu-like symptoms (fever and myalgia) and generalized lymphadenopathy. The generalized maculopapular rash begins on the trunk and proximal extremities and spreads to the entire body, including the palms, soles, and scalp. Condyloma lata are wart-like lesions found in the genital area. The rash usually resolves spontaneously within 2–6 weeks. Patients then enter the latent stage of syphilis.

Patients with latent syphilis are usually asymptomatic with no findings on physical examination. Serologic tests continue to be positive during this time. Latent syphilis is further divided into early and late latent syphilis. If latent infection occurs within 1 year of the initial infection, it is defined as early latent syphilis. Late latent syphilis refers to infection that occurs 1 year after the time of initial infection. A patient can remain in the latent stage for many years.

About one-third of individuals with untreated syphilis will progress to the tertiary stage. Widespread tissue destruction in the tertiary stage results in cardiovascular disease, neurosyphilis, and cutaneous and osseous lesions. Obliterative endarteritis occurs as the spirochete develops a predilection for arterioles. Cardiovascular syphilis manifests with aortic aneurysms, aortic insufficiency, and coronary stenosis. Neurosyphilis is characterized by paralysis, paresthesias, tabes dorsalis, blindness, gait abnormalities, confusion, and dementia.

The Argyll-Robertson pupil (pupil that does not react to light but is able to accommodate) is pathognomonic for tertiary syphilis. Gummas are classic dermatologic manifestations. These gummas consist of necrosis surrounded by an inflammatory infiltrate encapsulated by proliferating connective tissue and form reddish-brown nodular lesions in the skin.

B. Laboratory Findings

Testing for syphilis can be performed either with direct visualization of the organism or by direct serologic testing. Using dark field microscopy, spirochetes can be identified in bodily fluid or lesions. More recently, direct fluorescent antibody stains have replaced dark field microscopy, but technicians still require a fluorescent microscope to visualize the organism. Serologic tests may initially return negative in the early stages of chancre formation. Therefore, these lesions should be sampled for detection of spirochetes and undergo dark field examination.

Serologic testing consists of a nonspecific screening test followed by a confirmatory treponemal antibody test. The nontreponemal screening tests include the Venereal Disease Research Laboratories (VDRL) test, rapid plasma reagin (RPR) test, or automated reagin test. Reported as a titer, these tests use cardiolipin antigens to detect circulating antibodies and can be used to follow response to treatment. In certain patients, however, a low titer may persist for a long period of time. Due to the nonspecific nature of these tests, false-positive results are not uncommon (0.2–3.2%) and may occur in a multitude of settings including various infections, malignancies, connective tissue diseases, and chronic liver disease.

The fluorescent treponemal antibody absorption test (FTA-ABS) is the most commonly used confirmatory test that detects antibodies specifically directed to treponemal cellular components. Because these tests remain positive even after treatment, they are not used to follow response to treatment. In pregnancy, seropositive women should be considered infected unless a treatment history is well documented and subsequent serologic antibody titers have declined.

Less than 10% of patients with untreated syphilis progress to symptomatic late neurosyphilis. In the absence of clinical signs or symptoms of neurologic involvement, the CDC does not recommend routine lumbar puncture in primary and secondary syphilis. However, in patients with latent syphilis, lumbar puncture should be performed if there are signs of neurologic involvement, evidence of active tertiary syphilis, treatment failure, or HIV infection. The diagnosis of neurosyphilis depends on a combination of tests including reactive serologies, abnormal cerebrospinal fluid (CSF) cell count, elevated protein, and/or reactive CSF VDRL.

Serial quantitative VDRL titers facilitate the diagnosis of reinfection or persistence of active syphilis. With adequate treatment, VDRL titers decrease and become negative within 6–12 months in early syphilis and within 12–24 months in late syphilis. Further diagnostic tests (such as lumbar puncture) and appropriate treatment are needed if titers continue to rise.

Congenital syphilis is diagnosed easily in the setting of a fetus with clinical manifestations of syphilis, placentomegaly, and positive laboratory studies confirming the infection. However, many neonates do not manifest signs and symptoms of congenital infection. Although cord blood may return positive for nonspecific tests for syphilis, the diagnosis is difficult due to the transplacental transfer of maternal nontreponemal and treponemal IgG antibodies to the fetus. In these complicated situations, treatment must be based on the diagnosis of syphilis in the mother, treatment status of the mother, comparison of maternal and infant nontreponemal serologic titers at the time of delivery, and presence of clinical findings of syphilis in the infant. Infants with positive VDRL tests results with no clinical evidence of syphilis should have monthly VDRL titers for at least 9 months; rising titers indicate the need for therapy.

Differential Diagnosis

Primary Syphilis

Granuloma inguinale

Lymphogranuloma venereum

Herpes simplex

Chancroid

Carcinoma

Trauma

Lichen planus

Psoriasis

Mycotic infections

Bowen’s disease

Secondary Syphilis

Drug eruptions

Psoriasis

Lichen planus

Pityriasis rosea

Tinea versicolor

Parasitic infections

Viral exanthems

Rocky Mountain spotted fever

Complications

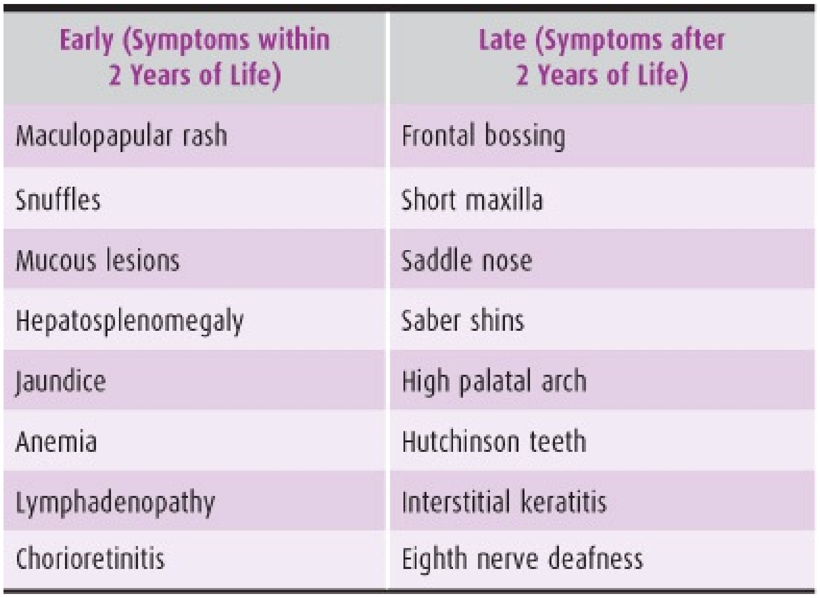
In addition to the aforementioned manifestations of the various stages of syphilis, complications of congenital syphilis result in significant neonatal morbidity. Although vertical transmission can occur at any time during pregnancy and at any stage of syphilis, the risk of congenital infection is greater in the earlier stages of the disease. Women with primary or secondary syphilis are more likely to transmit the disease to their fetuses than are women with latent disease. Maternal primary syphilis and secondary syphilis are associated with a 50% risk of congenital syphilis, whereas early latent syphilis carries a 40% risk of congenital syphilis. The risk of congenital syphilis is even lower, close to 10%, among patients with late latent syphilis. Although serious adverse outcomes are more likely to occur with transmission in the earlier stages, most pregnant women are in the latent stage of syphilis at the time of diagnosis and have had the infection for more than 1 year.

Although the spirochete can cross the placenta and infect the fetus as early as the sixth week of gestation, clinical manifestations do not appear until after the 16th week. By this time, the fetal immune system has matured and can respond to the spirochete. It is the immune reaction to the infection that is responsible for tissue destruction rather than direct injury by the spirochete. The risk of congenital syphilis is increased with infection late in pregnancy, treatment less than 30 days before delivery, inappropriate treatment of the mother, and the lack of prenatal serologic testing.

Untreated syphilis is associated with significant adverse effects on the pregnancy including spontaneous abortion, intrauterine growth restriction, fetal demise, congenital anomalies, preterm delivery, and neonatal death. Stillbirth rates range from 10–35%. Fetuses with congenital infections exhibit hepatosplenomegaly, ascites, polyhydramnios, placental thickening, and hydrops.

Congenital syphilis is divided into 2 clinical syndromes: early and late congenital syphilis (Table 15–6). Early congenital syphilis refers to the manifestations of syphilis within the first 2 years of life. These infants can present with a maculopapular rash, snuffles (flu-like syndrome associated with nasal discharge), mucous lesions, hepatosplenomegaly, jaundice, anemia, lymphadenopathy, chorioretinitis, and iritis. Late congenital syphilis presents after 2 years of age. Findings consistent with late congenital syphilis include frontal bossing, short maxilla, saddle nose, saber shins, high palatal arch, Hutchinson teeth, interstitial keratitis, and eighth nerve deafness. Infants may also have other neurologic manifestations such as mental retardation, hydrocephalus, and optic nerve atrophy.

Table 15–6. Signs and symptoms of congenital syphilis.

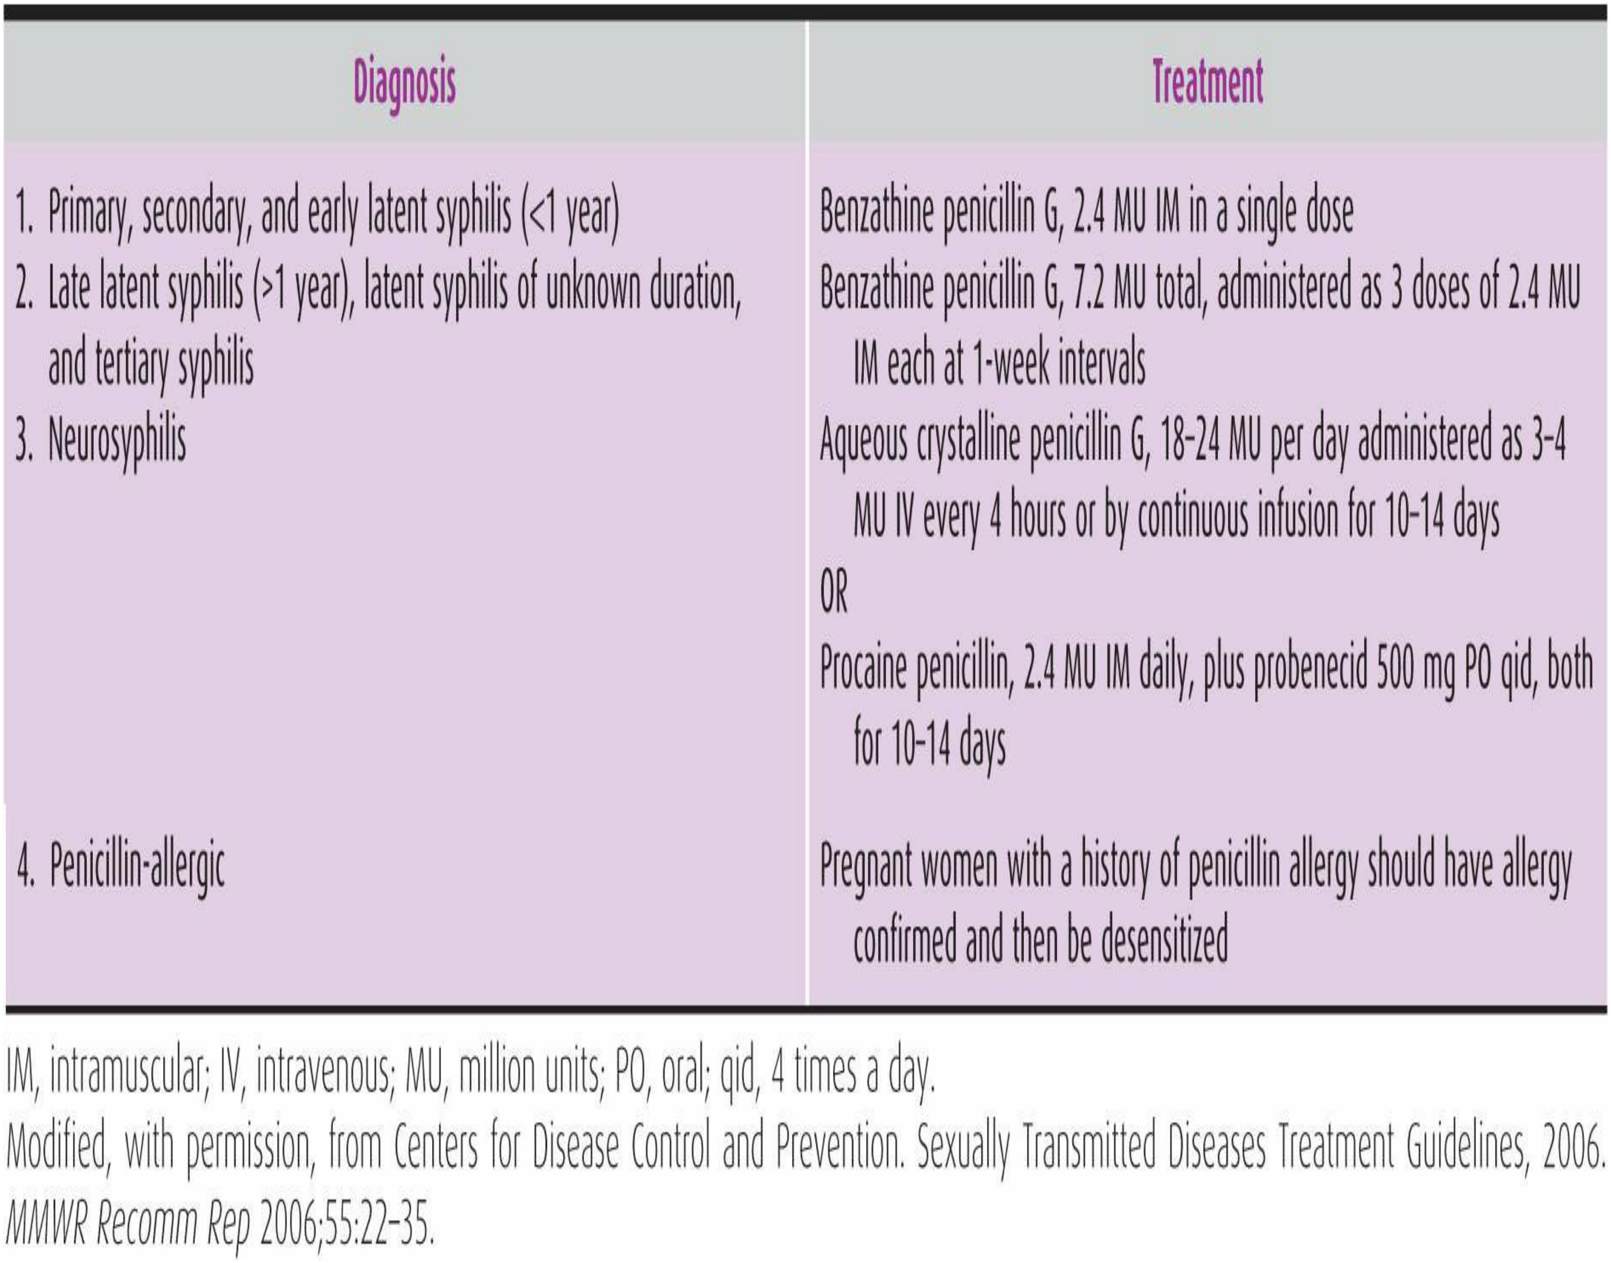


Early (Symptoms within 2 Years of Life)	Late (Symptoms after 2 Years of Life)
Maculopapular rash	Frontal bossing
Snuffles	Short maxilla
Mucous lesions	Saddle nose
Hepatosplenomegaly	Saber shins
Jaundice	High palatal arch
Anemia	Hutchinson teeth
Lymphadenopathy	Interstitial keratitis
Chorioretinitis	Eighth nerve deafness

Treatment

Pregnant women with a history of sexual contact with a person with documented syphilis, positive dark field microscopic visualization of spirochetes, positive serologies via a specific treponemal test, or evidence of reinfection should be treated. Penicillin G is the treatment of choice for all stages of syphilis and is effective in treating maternal disease, preventing fetal transmission, and treating fetal disease (Table 15–7). Although alternatives to penicillin are available to treat nonpregnant penicillin-allergic patients, parenteral penicillin G is the only therapy with documented efficacy for syphilis during pregnancy because it crosses the placenta in adequate amounts, effectively treating the fetus. Therefore, it is recommended that patients with known penicillin allergy undergo desensitization followed by subsequent treatment with penicillin. Although erythromycin was previously used for treatment of syphilis in pregnancy, its efficacy for treatment of the fetus and prevention of transmission is inadequate. Doxycycline and tetracycline may be used to treat nonpregnant patients. The efficacy of antibiotics such as ceftriaxone and azithromycin is currently under investigation.

Table 15–7. CDC-recommended treatment of syphilis during pregnancy.



Diagnosis	Treatment
1. Primary, secondary, and early latent syphilis (<1 year)	Benzathine penicillin G, 2.4 MU IM in a single dose
2. Late latent syphilis (>1 year), latent syphilis of unknown duration, and tertiary syphilis	Benzathine penicillin G, 7.2 MU total, administered as 3 doses of 2.4 MU IM each at 1-week intervals
3. Neurosyphilis	Aqueous crystalline penicillin G, 18-24 MU per day administered as 3-4 MU IV every 4 hours or by continuous infusion for 10-14 days OR Procaine penicillin, 2.4 MU IM daily, plus probenecid 500 mg PO qid, both for 10-14 days
4. Penicillin-allergic	Pregnant women with a history of penicillin allergy should have allergy confirmed and then be desensitized

IM, intramuscular; IV, intravenous; MU, million units; PO, oral; qid, 4 times a day.

Modified, with permission, from Centers for Disease Control and Prevention. Sexually Transmitted Diseases Treatment Guidelines, 2006. *MMWR Recomm Rep* 2006;55:22-35.

Desensitization can occur in an oral or intravenous manner. Regardless of the route, patients should undergo desensitization in a hospital setting due to potential serious IgE-mediated allergic reactions.

Early disease, with documentation that the initial infection occurred within the past year, is treated with a single dose of benzathine penicillin. Because of treatment failures even after adherence to recommended guidelines, some experts recommend additional therapy with a second dose of penicillin G 1 week after the initial dose. Despite adequate therapy, risk factors for treatment failure include high VDRL titers at the time of diagnosis, unknown duration of infection, treatment within 4 weeks of delivery, and ultrasound signs of fetal syphilis.

Late latent syphilis, latent syphilis of unknown duration, and tertiary syphilis should be treated with 3 doses of benzathine penicillin at weekly intervals. Neurosyphilis requires more intensive treatment with high doses of intravenous aqueous crystalline penicillin or intramuscular procaine penicillin for 10–14 days.

Patients may develop the Jarisch-Herxheimer reaction within several hours after treatment. Symptoms last for 12–24 hours and include fever, chills, myalgias, vasodilation, mild hypotension, and tachycardia. In addition to the symptoms present in nonpregnant individuals, women undergoing treatment in the second trimester are at risk for preterm contractions, preterm labor (highest risk 48 hours after treatment), decreased fetal movement, fetal distress, and fetal death. Patients improve with supportive therapy because the Jarisch-Herxheimer reaction is usually self-limited and resolves by 24–36 hours.

Response to therapy should be monitored with clinical and serologic examination at 1, 3, 6, 12, and 24 months after treatment. Titers usually decline at least 4-fold within 12–24 months of treatment. Patients with persistent clinical symptoms or with sustained 4-fold increases in the nontreponemal test titer have either failed therapy or become reinfected. These patients need retreatment, CSF analysis, and HIV testing. Pregnant women treated for syphilis need repeat serologic titers at 28–32 weeks of gestation and at delivery. Women at high risk for reinfection may have serologies checked monthly.

After adequate treatment, nontreponemal serologic tests often become negative. The treponemal test results usually remain positive for life. Certain patients may have positive nontreponemal tests despite treatment. In these cases, titers are usually not higher than 1:8.

Prognosis

The number of cases of early syphilis has recently been rising, particularly among intravenous drug users and the HIV population. The syphilis rate among women increased from 1.1 cases per 100,000 females in 2007 to 1.5 cases per 100,000 females in 2008. Women of reproductive age make up 80% of the female population with syphilis. Therefore, syphilis is an important health concern. Serious sequelae for the fetus and neonate are due to the failure to diagnose or adequately treat maternal disease.

The efficacy of penicillin for treatment of syphilis in pregnancy ranges from 95–100%. Prognosis is usually favorable once the patient is adequately treated. However, pregnant patients require close follow-up because treatment failure may result in a congenitally infected fetus and neonate.

CYTOMEGALOVIRUS

ESSENTIALS OF DIAGNOSIS

- Caused by double-stranded DNA herpes virus
- Prevention: strict personal hygiene
- Diagnosis: serologic testing in adults; amniotic fluid PCR for prenatal diagnosis
- Antenatal sonographic findings: microcephaly, ventriculomegaly, intracranial calcifications,

hydrops, growth restriction, placentomegaly, and echogenic bowel

---

Pathogenesis

Cytomegalovirus (CMV) is a double-stranded DNA virus that belongs to the herpesvirus family. It has the ability to establish lifelong latency in the host after primary infection and can periodically reactivate with shedding of virus. CMV is the most common congenital infection. Birth prevalence estimates range from 0.2–2.5%.

Horizontal transmission of CMV results from transplantation of infected organs, blood transfusions, sexual contact, or contact with contaminated saliva or urine. Vertical transmission is due to transplacental infection, ingestion of genital tract secretions during delivery, or breastfeeding. Because the virus has the potential to remain latent in host cells after resolution of initial infection, CMV infections in pregnant women are either primary or recurrent. If the initial infection occurs during pregnancy, it is considered a primary infection. A recurrent infection refers to an infection in which maternal CMV antibodies are present prior to conception.

CMV seropositivity increases with age. In the United States, approximately 50–80% of adult women have serologic evidence of prior CMV infection. Although maternal pre-existing immunity decreases the risk of intrauterine transmission, the presence of antibodies is not absolutely protective against either reinfection or vertical transmission. The rate of seroconversion in pregnancy is about 1–4%.

Hematogenous spread of the virus across the placenta is responsible for congenital infection. Dissemination is more likely during primary infection. In the case of primary infection in pregnancy, there is a 50% risk of fetal infection. The rate of transmission increases as the pregnancy progresses, with the highest risk of transmission in the third trimester. However, the severity of fetal injury is greatest if maternal primary infection occurs in the first trimester. In the setting of recurrent infection, the risk of fetal transmission is overall lower, with a 5–10% risk.

Prevention

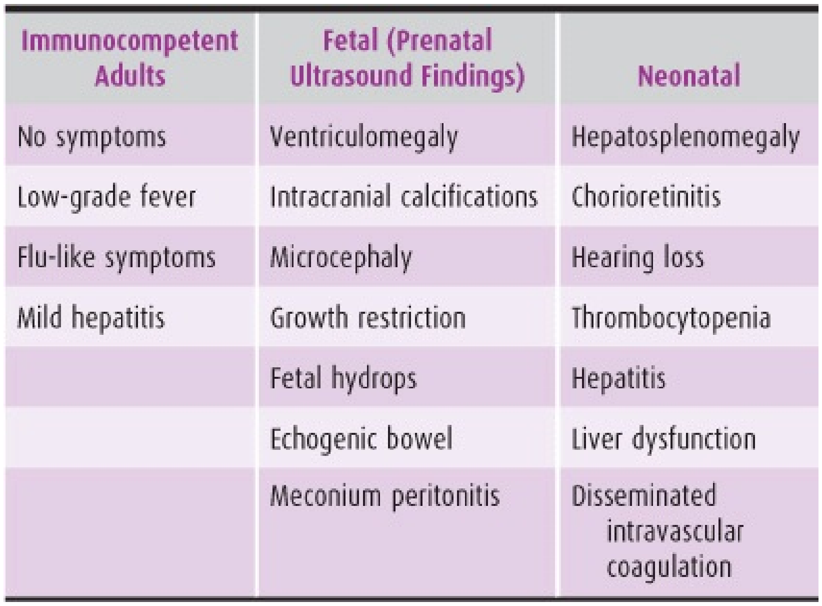
There is no vaccine to prevent CMV infection, and there is a lack of data to suggest that treatment of maternal infection prevents the risk of congenital CMV infection. For these reasons, routine prenatal screening for CMV is not recommended. Preventive measures, such as careful handwashing techniques, should be employed to decrease the risk of CMV infection during pregnancy. Susceptible individuals should avoid sharing food or drinks with young children. Seronegative pregnant women should also be transfused with CMV-negative blood products and counseled regarding safe sexual practices if not in a monogamous relationship.

Clinical Findings

A. Symptoms & Signs (Table 15–8)

Clinical manifestations of CMV depend on the integrity of the host immune system. Immunocompromised individuals are at risk for severe infection and may present with complications such as myocarditis, hepatitis, pneumonitis, retinitis, and/or meningoencephalitis. In pregnant women, CMV infections are either subclinical or consist of mild nonspecific symptoms. Fever, flu-like symptoms, or mild hepatitis are more likely to occur in individuals with primary infections rather than reinfection or reactivation. The incubation period for CMV is 1–2 months.

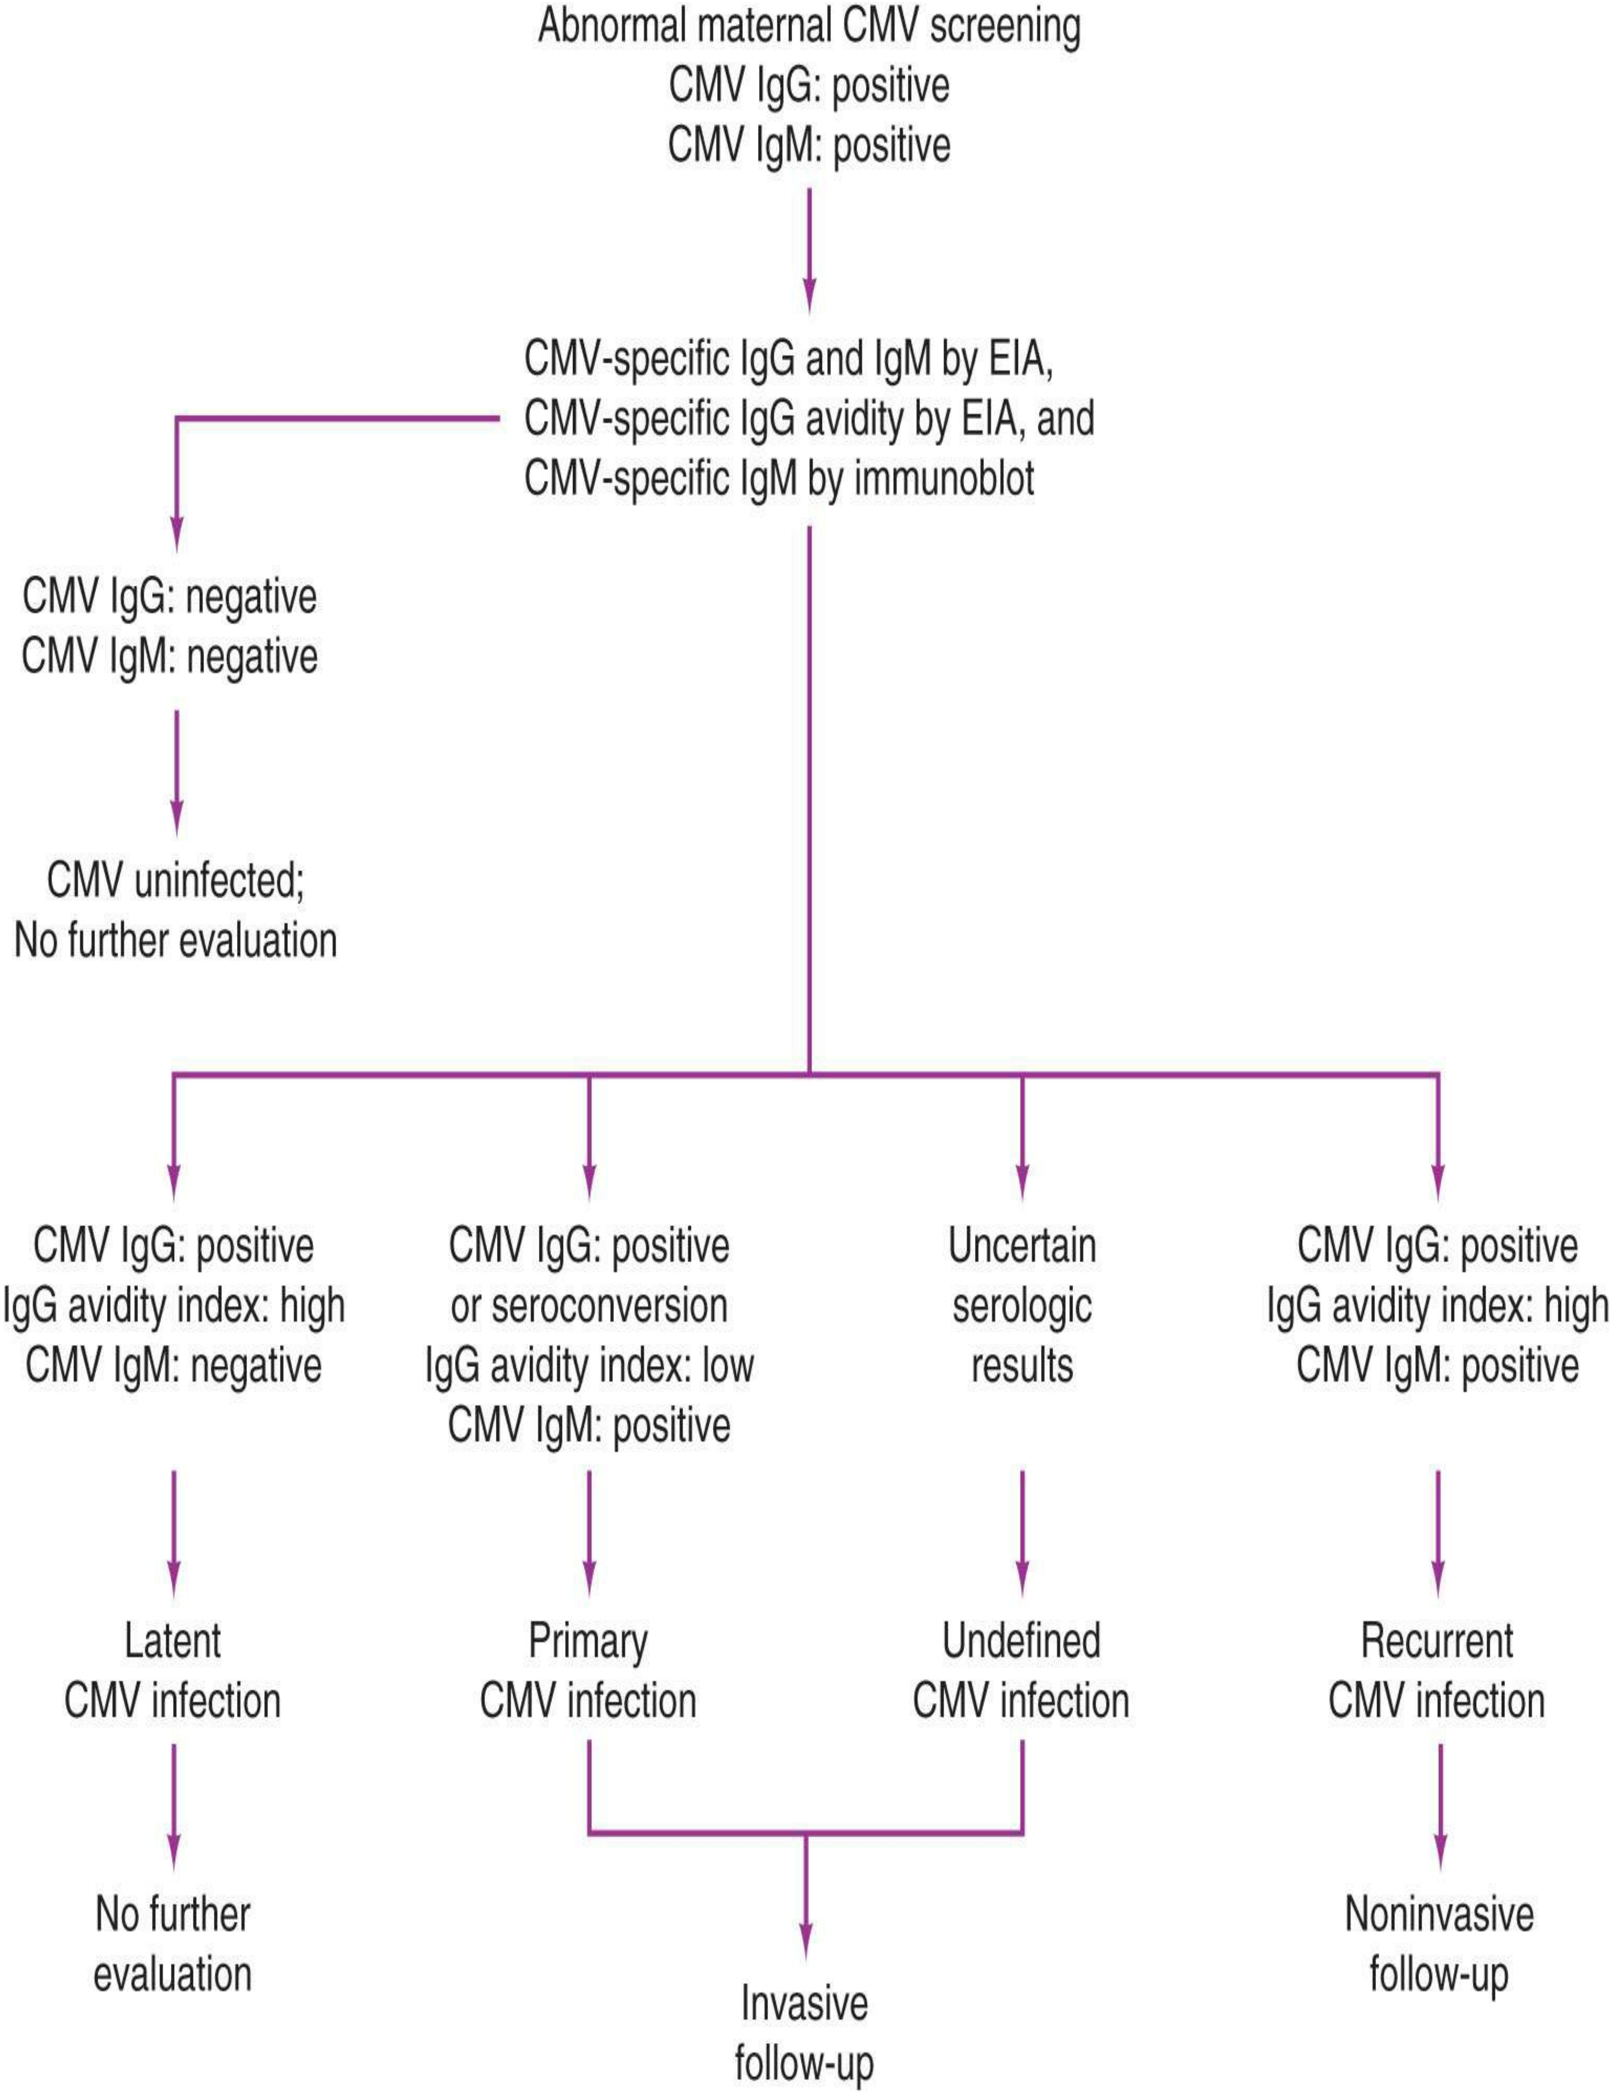
Table 15–8. Clinical manifestations of cytomegalovirus.



Immunocompetent Adults	Fetal (Prenatal Ultrasound Findings)	Neonatal
No symptoms	Ventriculomegaly	Hepatosplenomegaly
Low-grade fever	Intracranial calcifications	Chorioretinitis
Flu-like symptoms	Microcephaly	Hearing loss
Mild hepatitis	Growth restriction	Thrombocytopenia
	Fetal hydrops	Hepatitis
	Echogenic bowel	Liver dysfunction
	Meconium peritonitis	Disseminated intravascular coagulation

B. Laboratory Findings

Maternal infection during pregnancy is diagnosed by serologic testing. Primary infection is confirmed in the setting of seroconversion of CMV-specific IgG in paired acute and convalescent sera. Serum samples are collected 3–4 weeks apart and tested in parallel for anti-CMV IgG. Seroconversion from negative to positive or a significant increase in anti-CMV IgG titers is consistent with infection. IgM titers are not reliable in diagnosing CMV because the sensitivity of CMV IgM assays ranges from 50–90%. Additionally, IgM titers can remain positive for more than a year and revert from negative to positive in women with reactivation or reinfection with a different strain. Positive IgM titers decline over a period of 30–60 days. When CMV-specific IgG and IgM are both positive, CMV IgG avidity testing can be performed to confirm primary CMV infection. A low-avidity CMV IgG test is suggestive of CMV infection occurring in the preceding 6 months. Alternatively, a high-avidity test virtually excludes the possibility of a primary CMV infection occurring within the previous 4 months. Avidity testing is performed in the United States by Focus Diagnostics, a reference laboratory in California. Figure 15–5 depicts a management strategy for suspected maternal CMV infection.



Abnormal maternal CMV screening
CMV IgG: positive
CMV IgM: positive
CMV-specific IgG and IgM by EIA,
CMV-specific IgG avidity by EIA, and

Figure 15–5. Algorithm for evaluation of suspected maternal primary cytomegalovirus (CMV) infection in pregnancy. EIA, enzyme immunoassay; IgG, immunoglobulin G; IgM, immunoglobulin M. (Reproduced, with permission, from Cunningham FG, Leveno KJ, Bloom SL, Hauth JC, Rouse DJ, Spong CY. *Williams Obstetrics*, 23rd ed. http://www.accessmedicine.com. Copyright © The McGraw-Hill Companies, Inc. All rights reserved.)

The diagnosis of CMV can also be made by PCR antigen identification and viral culture. The highest concentrations of virus are found in urine, seminal fluid, saliva, and breast milk. Although viral cultures can be positive within 72–96 hours, a minimum of 21 days is required before the culture is reported as negative.

The preferred method for diagnosing congenital CMV is via PCR identification of CMV in amniotic fluid. Sensitivities of PCR range from 70–100%. Data suggest that sensitivities are higher if the testing is performed after 21 weeks' gestation and after a 6-week lag time between maternal infection and the procedure. This period allows sufficient time for the virus to infect the placenta and fetus with subsequent replication of the virus in the fetal kidney followed by excretion into the amniotic fluid. Therefore, if an amniocentesis is performed soon after infection and returns negative, the procedure should be repeated later in pregnancy. Identification of the virus or the viral load in the amniotic fluid does not correlate with the severity of fetal injury.

C. Imaging Studies

Prenatal ultrasound may help diagnose congenital CMV. Sonographic findings concerning for severe injury include microcephaly, ventriculomegaly, intracranial calcifications, hydrops, growth restriction, and oligohydramnios. Other ultrasound markers suggestive of infection include placentomegaly, echogenic bowel, meconium peritonitis, ascites, and pleural effusions. A normal ultrasound does not exclude the possibility of infection and sequelae.

Differential Diagnosis

Epstein-Barr virus

Acute hepatitis

Acute HIV

Human herpesvirus-6

Herpes simplex virus

Rubella

Enteroviral infections

Lymphocytic choriomeningitis virus

Toxoplasmosis

Complications

Congenital CMV is more likely in the setting of primary infection acquired earlier in the pregnancy.

Approximately 5–15% of infants who develop congenital CMV are symptomatic at birth. Severe clinical manifestations include hepatosplenomegaly, intracranial calcifications, jaundice, growth restriction, microcephaly, chorioretinitis, hearing loss, thrombocytopenia, and hepatitis (Table 15–8). The most severely affected infants have a mortality rate of about 30%. Deaths are usually secondary to liver dysfunction, bleeding, disseminated intravascular coagulation, or secondary bacterial infections. Eighty percent of survivors have serious morbidity. Of the 85–90% of neonates who are asymptomatic at birth, 10–15% will develop hearing loss, chorioretinitis, or dental defects by the age of 2.

Treatment

Supportive therapy and symptomatic relief are recommended in infected immunocompetent pregnant women. Antiviral drugs, such as ganciclovir, should be used in immunocompromised patients with CMV because these medications decrease mortality and morbidity associated with serious CMV infections. Antiviral drugs have not been shown to decrease the risk of congenital CMV. Until recently, there has been no promising effective treatment for congenital CMV. More recent data suggest improved outcomes when using hyperimmune globulin as treatment and prophylaxis for congenital CMV infection. However, the study was limited in that it was neither randomized nor controlled, and therefore, its findings must be interpreted with caution.

Prognosis

Immunocompetent pregnant women with CMV have a favorable prognosis. However, congenital CMV poses a threat to infants and children and is, in fact, the most common congenital infection. It can be potentially devastating and is a major cause of permanent auditory, cognitive, and neurologic impairment.

TOXOPLASMOSIS

ESSENTIALS OF DIAGNOSIS

- Caused by an intracellular parasite
- Transmitted following consumption of undercooked meat or contact with oocysts from infected cat feces
- Clinical manifestations vary depending on the integrity of the immune system
- Diagnosis
  - Serologic testing in adults
  - DNA PCR of amniotic fluid for prenatal diagnosis
- Congenital toxoplasmosis: chorioretinitis, hydrocephalus, ventriculomegaly, and periventricular calcifications
- Treatment during pregnancy
  - Spiramycin therapy in women with documented acute toxoplasmosis
  - Therapy with pyrimethamine, sulfadiazine, and leucovorin if fetal diagnosis is confirmed

---

Pathogenesis

Toxoplasma gondii is an obligate intracellular parasite with 3 distinct life forms: trophozoite, cyst, and oocyst. Wild and domestic cats are the only known host for the oocyst. The oocyst is formed in the intestine and then shed in cat feces. The oocysts become infective 1–5 days later and may remain infectious for over a year. Other animals, such as cows, ingest the oocyst. The oocyst then becomes the invasive trophozoite, which then spreads throughout the body forming cysts in brain and muscle.

In developed countries, the prevalence of infection has declined over the last 30 years. Higher rates of infection are present in less developed countries and those with tropical climates where undercooked meats and unfiltered water are more prevalent. Ten to 50% of adults have evidence of previous infection. Maternal infection results from consumption of uncooked or undercooked meat or contact with oocysts from the feces of an infected cat. Following primary maternal infection, fetal infection occurs after transmission of parasites across the placenta. The trophozoite forms tissue cysts in the brain and muscle and can remain dormant for years.

About 50% of adults in the United States have developed immunity to *Toxoplasma*, and this immunity is generally lifelong, mediated by T lymphocytes, except in the case of immunocompromised patients. In the setting of primary infection, the overall rate of fetal infection is one-third. Although the risk of fetal infection increases with gestational age at seroconversion, severe infection is more likely with infection in the first trimester. The rate of vertical transmission increases from 10–15% in the first trimester, to 25% in the second trimester, and to more than 60% in the third trimester. Reinfection leading to congenital toxoplasmosis is exceedingly uncommon.

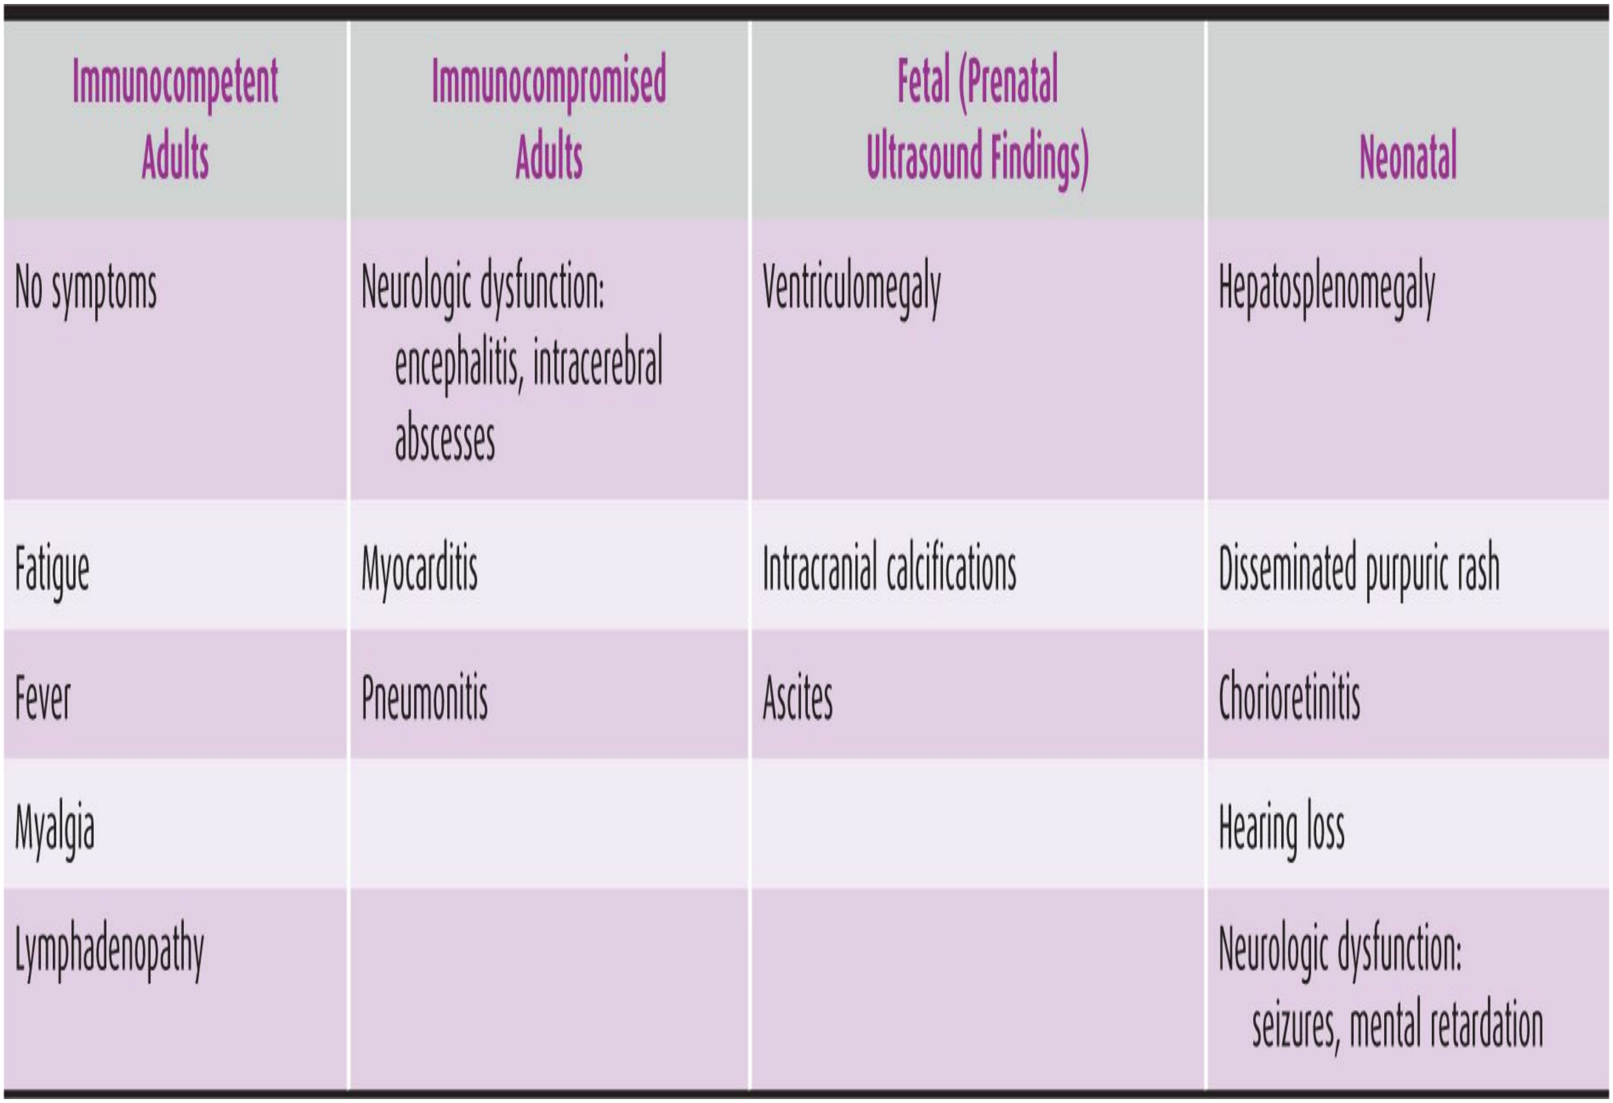
Prevention

Prevention of toxoplasmosis is extremely important in pregnancy. Pregnant women should avoid contact with cat litter. If cat litter is handled, gloves should be worn and hands should be thoroughly washed. Conscientious hand hygiene is also important following the preparation of meat. Fruits should be washed, and meat should be cooked thoroughly (to 152°F/66°C). Women should also avoid drinking unfiltered water and ingesting soil by observing strict hand hygiene after contact with soil.

Clinical Findings

A. Symptoms & Signs (Table 15–9)

Table 15–9. Clinical manifestations of toxoplasmosis.



Immunocompetent Adults	Immunocompromised Adults	Fetal (Prenatal Ultrasound Findings)	Neonatal
No symptoms	Neurologic dysfunction: encephalitis, intracerebral abscesses	Ventriculomegaly	Hepatosplenomegaly
Fatigue	Myocarditis	Intracranial calcifications	Disseminated purpuric rash
Fever	Pneumonitis	Ascites	Chorioretinitis
Myalgia			Hearing loss
Lymphadenopathy			Neurologic dysfunction: seizures, mental retardation

Immunocompetent individuals with an acute infection may be either asymptomatic or present with vague nonspecific symptoms such as fatigue, fever, and myalgias. These patients may also present with lymphadenopathy. Immunocompromised patients, on the other hand, can have devastating consequences following infection. Neurologic dysfunction is not uncommon and includes encephalitis, meningoencephalitis, and intracerebral abscesses. Other manifestations include myocarditis and pneumonitis.

B. Laboratory Findings

Maternal diagnosis of toxoplasmosis is confirmed by serologic testing. Anti-*Toxoplasma* antibody can be detected using indirect fluorescent antibodies, indirect hemagglutination and agglutination tests, and ELISA. IgM-specific antibodies suggest acute infection. Diagnosis of an infection during pregnancy is most precise when 2 blood samples, greater than 2 weeks apart, document seroconversion from negative to positive *Toxoplasma*-specific IgM or IgG. In certain parts of Europe, women undergo serial testing with the goal of detecting early infection. However, the benefit of routine testing is controversial given the lack of data suggesting that treatment improves clinical outcomes. In the United States, diagnosis of a recent *Toxoplasma* infection is challenging in the setting of a single sample. IgM can remain positive for 10–13 months, and there is substantial variation among individuals. Twenty-five percent of women will have persistently positive IgM lasting years, and in certain patients, low IgG avidity will also remain positive for years. Rising IgG titers are also not useful due to the variation among laboratories. In the setting of a positive IgM and a negative IgG result with both tests positive 2 weeks later, recent infection is likely.

To confirm primary *Toxoplasma* infection, an avidity test for *Toxoplasma* IgG antibody is performed. In the setting of high-avidity IgG testing, infection within the previous 3–5 months is excluded. The functional avidity of IgG is low in the case of primary infection. In the United States, serologic diagnosis of an acute infection should be confirmed by the Palo Alto Medical Foundation Research Institute, a reference laboratory. The laboratory runs a panel of tests known as the Toxoplasma Serologic Profile, which includes the Sabin Feldman dye test, double-sandwich IgM ELISA, IgA and IgG ELISA, and a differential agglutination test.

The diagnosis of congenital toxoplasmosis is confirmed by identification of PCR toxoplasmic DNA in amniotic fluid. The sensitivity and specificity of real-time PCR are 92.2% and 100%, respectively. However, false-positive and false-negative tests do occur. Although the presence of *Toxoplasma*-specific IgM in fetal blood is extremely sensitive for diagnosis, due to the risk of fetal loss, cordocentesis is not widely used.

C. Imaging Studies

Ultrasonography is helpful in providing prognostic information. The most commonly noted abnormalities include intracranial calcifications and ventriculomegaly. These findings are usually seen after 21 weeks' gestation.

Differential Diagnosis

CMV

Disseminated tuberculosis

Acute HIV

Epstein-Barr virus (mononucleosis)

Brain abscess

Leukemia

Lymphoma

Pneumocystis pneumonia

Progressive multifocal leukoencephalopathy

Sarcoidosis

Syphilis

Cryptococcus neoformans

Aspergillus

Complications

Although *Toxoplasma* infection is usually benign in immunocompetent pregnant women, infection in pregnancy can have serious consequences for the neonate. Approximately 3 per 1000 infants demonstrate evidence of congenital toxoplasmosis, with clinically significant infection present in 1 per 1000 pregnancies. Approximately 20% of neonates born to mothers with acute toxoplasmosis have clinical manifestations in infancy. These infants can present with hepatosplenomegaly, disseminated purpuric rash, ascites, and chorioretinitis. Central nervous system (CNS) manifestations include periventricular calcifications, ventriculomegaly, seizures, and mental retardation. The classic triad of congenital toxoplasmosis includes chorioretinitis, hydrocephalus, and periventricular calcifications.

Untreated asymptomatic infants at birth are at high risk for subsequently developing abnormalities. The most common delayed complication is chorioretinitis, which can result in vision loss. Additional sequelae that may manifest later in life include mental retardation, deafness, and seizures. Recent data do not suggest an association between congenital toxoplasmosis and reduced birth weight or small for gestational age infants.

Treatment

Toxoplasmosis infection in the immunocompetent adult is usually asymptomatic or self-limited and does not require treatment. Immunocompromised patients, on the other hand, should be treated with oral sulfadiazine and pyrimethamine.

Although there is no strong evidence demonstrating the efficacy of prenatal treatment, certain data suggest that prenatal therapy may reduce, but not eliminate, the risk of congenital infection. Therefore, therapy is usually offered to pregnant women diagnosed with acute infection. Treatment usually consists of spiramycin, a macrolide antibiotic that has the potential to concentrate in the placenta and, therefore, prevent fetal transmission. Because it does not cross the placenta, it is not used to treat fetal infection. Spiramycin is used commonly in Europe with favorable outcomes and is available in the United States through the CDC.

Pyrimethamine and sulfadiazine are folic acid antagonists that can be used to treat documented fetal infection. Pyrimethamine is teratogenic in animals, and both medications can cause bone marrow suppression. Due to the adverse effects of these medications, these drugs should only be used if fetal infection is confirmed. As of yet, there are no clinical trials to clearly demonstrate that the regimen is more effective than spiramycin. Leucovorin calcium (folinic acid) is added to the regimen to prevent bone marrow suppression. The efficacy and safety of other drugs such as azithromycin and clarithromycin in treating toxoplasmosis is currently under investigation.

Aggressive early treatment of neonates with congenital infection is recommended and includes therapy with pyrimethamine, sulfadiazine, and leucovorin for 1 year. Early therapy decreases the risk of late complications of toxoplasmosis.

Prognosis

Infection in immunocompetent women has a favorable prognosis. The prognosis of congenital toxoplasmosis is variable and depends on the clinical sequelae, which range from an asymptomatic state to severe neurologic morbidity.

LISTERIA

ESSENTIALS OF DIAGNOSIS

- Caused by gram-positive motile *Bacillus*
- Preventive measures: thoroughly cooking raw meets, washing raw vegetables, avoiding unpasteurized foods
- Clinical manifestations in healthy pregnant women: asymptomatic, vague, flu-like symptoms including fever, chills, malaise, and myalgias
- Complications in pregnancy: fetal death, premature delivery, neonatal infection
- Diagnosis: cultures on blood, amniotic fluid, placenta
- Treatment: penicillin/ampicillin with or without gentamicin for synergistic effect

---

Pathogenesis

Listeria monocytogenes is a food-borne gram-positive motile **Bacillus** capable of causing life-threatening infections in humans. It is a facultative intracellular parasite that primarily inhabits soil and decaying vegetative matter. Animals carrying the organism contaminate foods of animal origin such as meat and dairy products. Although there are multiple species of *Listeria*, *L monocytogenes* is the only species that is considered pathogenic in humans. The organism’s virulence is attributed to listeriolysin O, a pore-forming toxin, that enables the pathogen to suppress antigen-induced T-cell activation. Most *Listeria* infections in adults are due to oral ingestion followed by intestinal mucosal penetration and subsequent systemic infection.

Annually, there are approximately 1600 cases of listeriosis in the United States, with a 16% mortality rate. About 1 in 6 cases of listeriosis occurs during pregnancy. Recent data show that the overall incidence of listeriosis is decreasing, with a 26% decrease noted by the CDC from 1998 to 2009. Human listeriosis can occur as either a sporadic illness or an epidemic. The sporadic form occurs more commonly than the epidemic form (responsible for >95% of cases). The epidemic form is due to widespread contamination of food products. High-risk foods include unpasteurized soft cheeses, processed/delicatessen meats, hot dogs, smoked seafood, and pâtés. Several outbreaks of listeriosis in the United States have been associated with Mexican-style soft cheeses made from unpasteurized milk.

Although *L monocytogenes* can be isolated from the feces of 1–5% of healthy adults, systemic infections usually occur in individuals with predisposing conditions such as pregnancy, old age, and immunocompromised states. Decreased cell-mediated immunity in pregnancy is believed to be the cause of increased susceptibility of pregnant women to listeriosis. Subsequent fetal and/or neonatal infection most likely occurs from hematogenous dissemination of the organism through the placenta, although ascending infection from cervical colonization with *L monocytogenes* may also play a role.

Prevention

Prevention of *Listeria* infections is important on a legislative as well as individual level. Government agencies such as the US Department of Agriculture (USDA) have instituted policy changes to reduce *L monocytogenes* contamination. Large-scale producers of ready-to-eat meat have been required to develop *L monocytogenes* control programs and institute various measures such as postpackaging pasteurization.

Individuals can prevent infection with *Listeria* by following certain recommendations. Recommendations include thoroughly cooking raw meats; carefully washing raw vegetables; avoiding unpasteurized milk or products made from unpasteurized milk; keeping uncooked meats and poultry separate from vegetables and from cooked foods and ready-to-eat foods; washing hands, knives, countertops, and cutting boards after handling and preparing uncooked foods; and consuming perishable and ready-to-eat foods as soon as possible. Pregnant women should also avoid soft cheeses such as feta, brie, and queso fresco and delicatessen meats.

Clinical Findings

A. Symptoms & Signs

In immunocompromised, elderly, and pregnant patients, *Listeria* can lead to invasive disease, such as meningitis and sepsis. In healthy adults, if ingested in high numbers, the organism can cause febrile gastroenteritis. The incubation period for *Listeria* is generally 6–90 days, but may be only 24 hours during widespread epidemics of gastroenteritis.

Listeriosis in pregnancy is most common in the third trimester. Although many pregnant infected women are asymptomatic, about two-thirds manifest nonspecific flulike symptoms characterized by fever, chills, myalgias, malaise, and upper respiratory complaints. Infection is usually mild and self-limited, but pregnant women may present with signs and symptoms of sepsis. Listerial CNS infection in pregnancy is generally rare. Maternal listeriosis can lead to serious consequences such as fetal death, premature delivery, and neonatal infection.

B. Laboratory Findings

There are no specific clinical manifestations that help distinguish listeriosis from other infections that manifest with fever and nonspecific flu-like symptoms. Therefore, blood cultures are necessary in establishing the diagnosis. Routine cerebrospinal fluid analysis is limited because pregnant women do not usually present with CNS infections. Although routine stool cultures are not helpful in diagnosing systemic listeriosis, stool cultures using selective media may be valuable in patients with *Listeria* gastroenteritis. Amniocentesis may be performed to help diagnose fetal listerial infection. Additionally, cultures obtained from the uterus or placenta may also establish the diagnosis.

C. Imaging Studies

Magnetic resonance imaging (MRI) is superior to computed tomography scan for detecting *Listeria* lesions in the CNS. It is recommended that patients with *Listeria* meningitis or systemic listeriosis with CNS signs and symptoms undergo an MRI.

Differential Diagnosis

Maternal

Influenza

Urinary tract infection

Pyelonephritis

Meningitis

Fetal

Group B *Streptococcus*

Escherichia coli

Klebsiella pneumoniae

Complications

Maternal listeriosis is associated with fetal loss, premature delivery, neonatal infection, and neonatal death. In a review of 222 cases of maternal infection, the pregnancy was complicated by abortion or stillbirth in 20% of cases, while neonatal sepsis resulted in 68% of surviving neonates. Neonatal listeriosis has been divided into 2 distinct clinical and serologic entities: early-onset and late-onset disease. Early-onset disease occurs in infants infected in utero with signs of infection presenting soon after birth; it presents as diffuse sepsis with multiorgan involvement including liver, lungs, and CNS. Early-onset disease is associated with a high rate of fetal demise and neonatal mortality. Granulomatosis infantiseptica refers to a severe in utero infection in which disseminated abscesses and/or granulomas are present in multiple internal organs. Late-onset neonatal disease presents in term infants who present with signs and symptoms of infection days to weeks after delivery. These neonates usually present with meningitis and long-term neurologic sequelae such as mental retardation. Intrapartum transmission or nosocomial infection after delivery is usually responsible for late-onset disease. Both types of neonatal listeriosis are associated with a high neonatal mortality rate.

Treatment

Parenteral ampicillin or penicillin G is the recommended antibiotic regimen for treatment of listeriosis. Listerial microbial resistance to penicillins or derivatives of penicillins has not been described under natural conditions. Dose and duration of therapy depend on age and type of infection. Pregnant women are usually treated with ampicillin 2 g intravenously every 4–6 hours; this dose provides adequate transplacental penetration. Optimal duration of therapy in pregnancy has not been established and varies between 2 and 4 weeks. When complicated listerial infections are present—involving the CNS, endocarditis, or infections in neonates and immunocompromised adults—gentamicin may be added to ampicillin for a synergistic effect. Trimethoprim-sulfamethoxazole is effective in patients allergic to penicillins.

Prognosis

Although maternal prognosis after listerial infection is generally favorable, fetal and neonatal infection can be severe with perinatal case fatality rates ranging from 22–45%. Listeriosis carries a poorer prognosis for fetuses affected at earlier gestations. Prompt diagnosis and proper antibiotic therapy can significantly reduce the fetal and neonatal complications associated with maternal listeriosis.

16

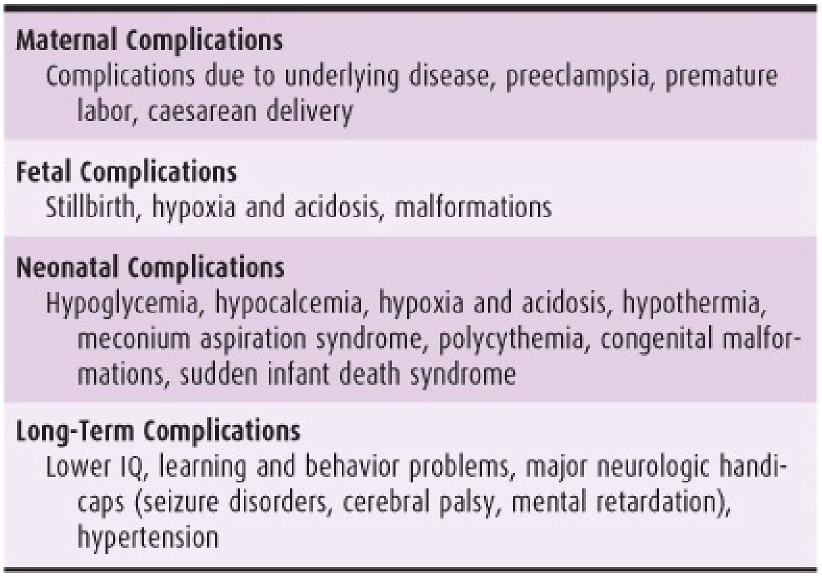
Disproportionate Fetal Growth

Jeannine Rahimian, MD, MBA

Weight at delivery once was considered evidence of prematurity (birthweight <2500 g) or postmaturity (macrosomia; birthweight >4500 g). These criteria later were revised upon the realization that birthweight can be reflective of other pathologic processes aside from prematurity. Abnormalities in fetal growth at each end of the spectrum—both large for gestational age fetuses and fetuses with suspected intrauterine growth restriction—are associated with an increased risk of adverse perinatal outcome. Normative standards applying to such ultrasound parameters as estimated fetal weight, abdominal circumference, and head circumference (HC) were developed.

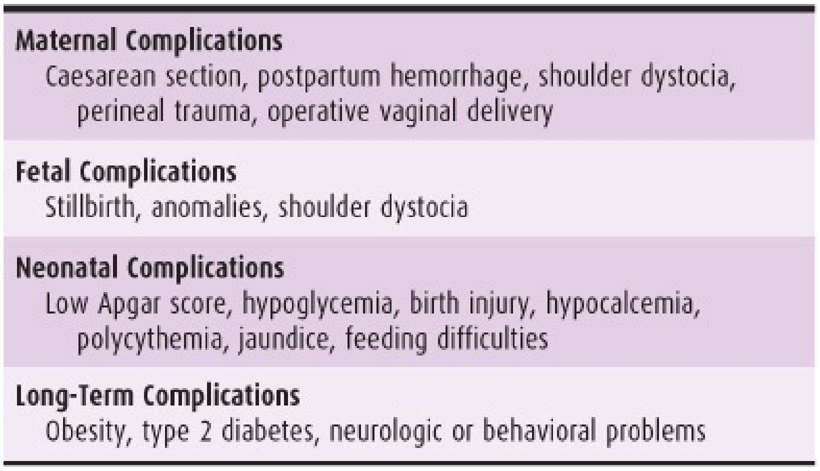
Abnormal fetal growth or fetal size is most commonly defined on the basis of estimated fetal weight. Fetuses with an estimated fetal weight ≤ the 10th percentile are classified as having intrauterine growth restriction (IUGR), and those with a weight ≥ the 90th percentile are classified as large for gestational age (LGA). Both IUGR and LGA fetuses have increased risk for perinatal morbidity and mortality (Tables 16–1 and 16–2). The pathogenesis, differential diagnosis, and treatment are different for the 2 extremes of growth.

Table 16–1. Some complications associated with intrauterine growth restriction pregnancy.



Maternal Complications
Complications due to underlying disease, preeclampsia, premature labor, caesarean delivery
Fetal Complications
Stillbirth, hypoxia and acidosis, malformations
Neonatal Complications
Hypoglycemia, hypocalcemia, hypoxia and acidosis, hypothermia, meconium aspiration syndrome, polycythemia, congenital malformations, sudden infant death syndrome
Long-Term Complications
Lower IQ, learning and behavior problems, major neurologic handicaps (seizure disorders, cerebral palsy, mental retardation), hypertension

Table 16–2. Some complications of large for gestational age pregnancy.



Maternal Complications
Caesarean section, postpartum hemorrhage, shoulder dystocia, perineal trauma, operative vaginal delivery

Fetal Complications
Stillbirth, anomalies, shoulder dystocia

Neonatal Complications
Low Apgar score, hypoglycemia, birth injury, hypocalcemia, polycythemia, jaundice, feeding difficulties

Long-Term Complications
Obesity, type 2 diabetes, neurologic or behavioral problems

INTRAUTERINE GROWTH RESTRICTION

ESSENTIALS OF DIAGNOSIS

- Estimated fetal weight less than the 10th percentile for gestational age on ultrasound

---

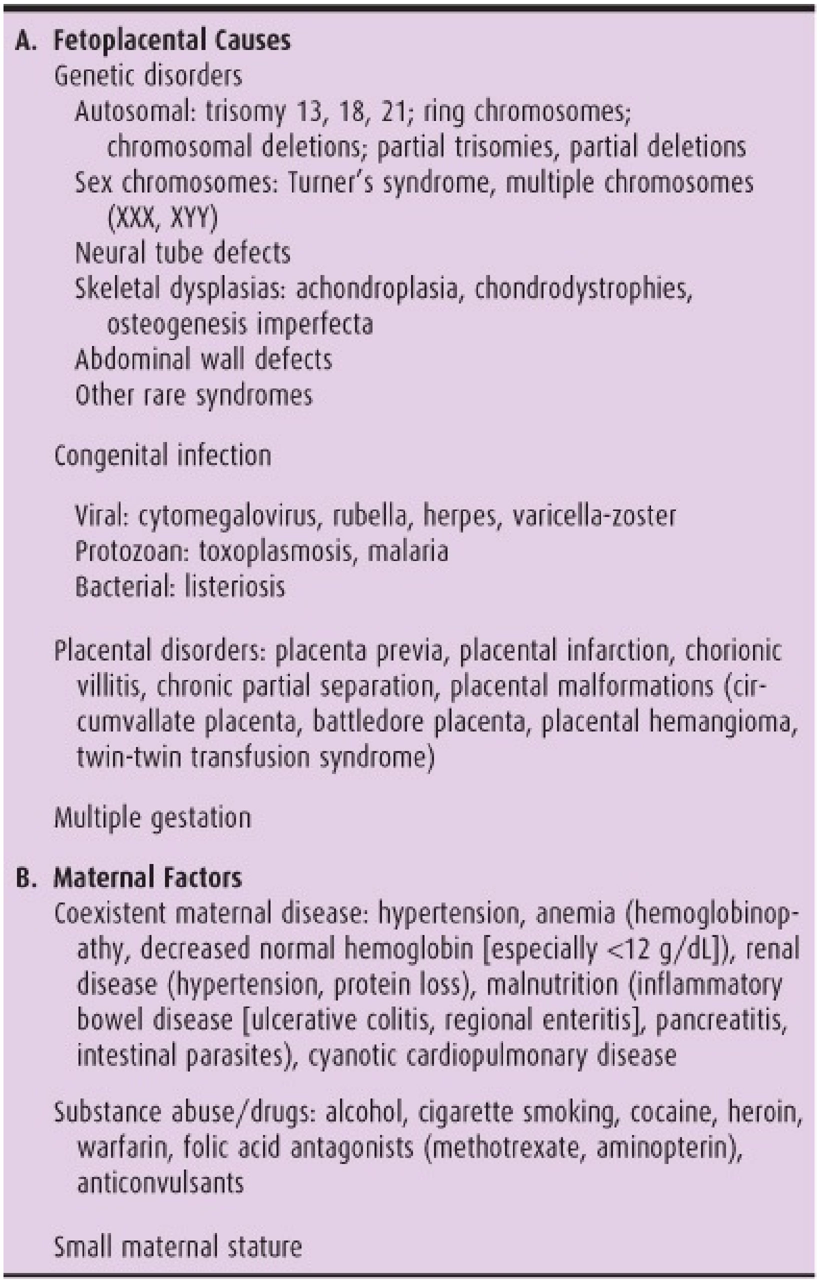
Many terms have been used to describe fetuses with disproportionately small growth. **Intrauterine growth restriction** (IUGR) is used to designate a *fetus* that has not met its growth potential and is defined as estimated fetal weight (EFW) at or below the 10th percentile for gestational age. **Small for gestational age** (SGA) is a term that applies to the *infant* that is less than the 10th percentile at birth.

Pathogenesis

Approximately 70% of fetuses with EFW below the 10th percentile are simply constitutionally small; thus, the term IUGR is inaccurate for many fetuses. Distinguishing between normal and pathologic growth can be difficult, but a fetus with normal anatomy, normal amniotic fluid volume, and normal growth pattern over time will generally be constitutionally small rather than IUGR. Some nonpathologic factors that affect fetal birthweight are maternal height, paternal height, parity, ethnicity, and fetal sex.

A classification of IUGR pregnancy delineated by cause is given in Table 16–3. Any inference of suboptimal growth requires, by definition, serial observations. It cannot be emphasized too strongly that a pregnancy cannot be described as IUGR unless the gestational age is known with certainty.

Table 16–3. Pathogenic classification of intrauterine growth restriction pregnancy.



A. Fetoplacental Causes

- Genetic disorders
  - Autosomal: trisomy 13, 18, 21; ring chromosomes; chromosomal deletions; partial trisomies, partial deletions
  - Sex chromosomes: Turner's syndrome, multiple chromosomes (XXX, XYY)
  - Neural tube defects
  - Skeletal dysplasias: achondroplasia, chondrodystrophies, osteogenesis imperfecta
  - Abdominal wall defects
  - Other rare syndromes

- Congenital infection
  - Viral: cytomegalovirus, rubella, herpes, varicella-zoster
  - Protozoan: toxoplasmosis, malaria
  - Bacterial: listeriosis

- Placental disorders: placenta previa, placental infarction, chorionic villitis, chronic partial separation, placental malformations (circumvallate placenta, battledore placenta, placental hemangioma, twin-twin transfusion syndrome)

- Multiple gestation

B. Maternal Factors

- Coexistent maternal disease: hypertension, anemia (hemoglobinopathy, decreased normal hemoglobin [especially <12 g/dL]), renal disease (hypertension, protein loss), malnutrition (inflammatory bowel disease [ulcerative colitis, regional enteritis], pancreatitis, intestinal parasites), cyanotic cardiopulmonary disease

- Substance abuse/drugs: alcohol, cigarette smoking, cocaine, heroin, warfarin, folic acid antagonists (methotrexate, aminopterin), anticonvulsants

- Small maternal stature

Compared with an appropriate for gestational age (AGA) fetus, the IUGR fetus has altered body composition (including decreased body fat, total protein, whole body DNA and RNA, glycogen, and free fatty acids), altered distribution of weight among organs, and altered body proportions. Approximately 20% of IUGR infants are symmetrically small, with a relatively proportionate decrease in many organ weights. Eighty percent are asymmetrically small, with relative sparing of brain weight, especially when compared with that of the liver or thymus.

Numerous authors have differentiated between symmetric and asymmetric IUGR pregnancy in terms of cause and prognosis. *Symmetric IUGR* refers to infants in which all organs are decreased proportionally. Symmetric IUGR infants are more likely to have an endogenous defect that results in impairment of early fetal cellular hyperplasia. Symmetric IUGR infants have proportionately small brains, usually because of a decreased number of brain cells. Although this may be the result of early, severe nutritional deprivation, the cause is more often a genetic disorder, infection, or other problem. Usually the thymus is small, with an average decrease of 25%. This decrease may explain in part the decreased cellular immunity seen in IUGR infants.

Asymmetric IUGR refers to infants in which organs are decreased disproportionately (abdominal circumference is affected to a greater degree than is HC). Asymmetric IUGR more likely is caused by intrauterine deprivation that results in redistribution of flow to the brain and heart at the expense of less important organs, such as the liver and kidneys. In asymmetric IUGR infants, brain weight is decreased only slightly compared with that of AGA controls, primarily as a result of decreased brain cell size and not because of decreased brain cell numbers. Cerebral abnormalities include decreased myelination, decreased utilization of metabolic substrates other than glucose, and altered protein synthesis. In experimental animals, these changes are more likely to produce adverse effects in the brain stem and cerebellum. This differential sparing is particularly prominent when deprivation occurs in the latter half of pregnancy. Deprivation early in pregnancy is associated with less cerebral sparing and diffusely slowed brain growth.

Although this classification is helpful in establishing a differential diagnosis and framework for discussion, it is not sufficiently precise to serve as a basis for decisions regarding intervention or viability.

A number of etiologies have been shown to have an association with IUGR, either symmetric or asymmetric.

A. Fetoplacental Causes

1. Congenital abnormalities—Genetic disorders account for approximately one-third of IUGR infants. The frequency of IUGR in chromosomally abnormal infants ranges from 20 to 60%, and the risk of an IUGR infant having a major congenital anomaly is 10%. An infant with an autosomal trisomy is more likely to be IUGR. The most common trisomy is **trisomy 21 (Down syndrome**), with an incidence of 1.6 per 1000 live births. At term, such infants weigh an average of 350 g less than comparable normal infants and are 4 times more likely to be IUGR. This decrease is most apparent in the last 6 weeks of pregnancy. A similar decrease in birth-weight occurs in translocation Down syndrome, whereas mosaic Down syndrome is associated with an intermediate decrease in birthweight.

The second most common autosomal trisomy is **trisomy 18 (Edwards' syndrome**), which occurs in 1 in 6000–8000 live births. Eighty-four percent of these infants are IUGR. Ultrasound evaluation may reveal associated anomalies. The condition is associated with an increased likelihood of breech presentation, polyhydramnios, fetal neural tube defects, and visceral anomalies. The average birthweight of infants with trisomy 18 is almost 1000 g less than that of controls. In contrast to the placental weight in infants with trisomies 13 and 21, the placental weight in infants with trisomy 18 also is markedly reduced.

Trisomy 13 occurs in 1 in 5000–10,000 live births. More than 50% of affected infants have IUGR. Birthweights average 700–800 g less than those of controls.

Other more rare autosomal chromosome abnormalities, such as ring chromosomes, deletions, and partial trisomies, are associated with an increased likelihood of IUGR. Sex chromosome abnormalities may be associated with lower birthweight. Extra X chromosomes (>2) are associated with a 200-g to 300-g decrease in birthweight for each extra X. **Turner's syndrome** is associated with an average birthweight of approximately 400 g below average. Fetuses with mosaic Turner's syndrome are intermediately affected.

Growth impairment as a result of fetal chromosome abnormalities usually occurs earlier than impairment caused by placental abnormalities. However, there is considerable clinical overlap, so gestational age at the time of diagnosis is not always of clinical value.

Fetuses with neural tube defects frequently are IUGR, weighing approximately 250 g less than controls. Anencephalic fetuses are IUGR, even considering the absent brain and skull, with average third-trimester birth-weights of approximately 1000 g less than matched controls. Certain dysmorphic syndromes are associated with an increased incidence of IUGR fetuses. **Achondroplasia** may be associated with low birthweight if either parent is affected but usually is associated with normal birthweight if a spontaneous mutation is the cause. **Osteogenesis imperfecta** consists of a spectrum of diseases, all of which result in IUGR fetuses.

Infants born with abdominal wall defects are characteristically IUGR, particularly those with **gastroschisis**.

Other autosomal recessive syndromes associated with IUGR include **Smith-Lemli-Opitz syndrome, Meckel's syndrome, Robert's syndrome, Donohue's syndrome**, and **Seckel's syndrome**. These conditions are rare and are most likely to be diagnosed antepartum in families with a previously affected child. Infants with renal anomalies such as renal agenesis (**Potter's syndrome**) or complete urinary tract outflow obstruction often have IUGR.

Other congenital anomalies associated with an increased incidence of IUGR outcome are **duodenal atresia** and **pancreatic agenesis**.

2. Congenital infections—(See also Chapter 15, Congenital Fetal Infections, for more discussion.) Chronic intrauterine infection is responsible for 5–10% of IUGR pregnancies (Table 16–3). The most commonly identified pathogen is cytomegalovirus (CMV). Although CMV can be isolated from 0.5 to 2% of all newborns in the United States, clinically obvious infection at the time of birth affects only 0.2–2 in 1000 live births. Active fetoplacental infection is characterized by cytolysis, followed by secondary inflammation, fibrosis, and calcification. Only infants with clinically apparent infection at birth are likely to be IUGR. Signs of congenital infection are nonspecific but include central nervous system involvement (eg, microcephaly), chorioretinitis, intracranial (periventricular) calcifications, pneumonitis, hepatosplenomegaly, and thrombocytopenia.

Congenital rubella infection increases the risk of IUGR. Infection in the first trimester results in the most severely affected fetuses, primarily as a result of microvascular endothelial damage. Such infants are likely to have structural cardiovascular and central nervous system defects such as microcephaly, deafness, glaucoma, and cataracts.

Other viruses implicated in causing IUGR are herpesvirus, varicella-zoster virus, influenza virus, and poliovirus, but the number of such cases is small. As expected by virtue of their chronic, indolent nature, protozoan infections are associated with IUGR. The most common protozoan, *Toxoplasma gondii*, usually is acquired by ingestion of raw meat. Only women with a primary infection are at risk for having an affected infant. The average incidence is 1 in 1000 live births in the United States, but the incidence varies widely among locations and social populations. Approximately 20% of newborns with congenital toxoplasmosis will have IUGR. Malaria is another protozoan infection associated with IUGR.

Although bacterial infections occur commonly in pregnancy and frequently are implicated in premature delivery, they are not commonly associated with IUGR. Chronic infection from *Listeria monocytogenes* is an exception. Infants usually are critically ill at the time of delivery and often have encephalitis, pneumonitis, myocarditis, hepatosplenomegaly, jaundice, and petechiae.

3. Placental factors—The placenta plays an important role in normal fetal growth. Placental weight has shown to be less with IUGR fetuses than with AGA fetuses, suggesting that appropriate fetal growth may depend on the size or weight of the placenta. Several placental abnormalities are associated with an increased likelihood of an IUGR fetus. **Placenta previa** is associated with an increased incidence of IUGR, probably because of the unfavorable site of placental implantation. Complete placenta previa is associated with a higher incidence of IUGR than is partial placenta previa. Decreased functional exchange area as a result of **placental infarction** also is associated with an increased incidence of IUGR fetuses. **Premature placental separation** or varying degrees of placental abruption may occur at any time during pregnancy, with variable effects. When not associated with fetal death or premature labor, premature placental separation may increase the risk of IUGR. Malformations of the placenta or umbilical cord, such as **single umbilical artery (UA), velamentous umbilical cord insertion, circumvallate placenta, placental hemangioma, battledore placenta**, and **twin-twin transfusion syndrome**, also are associated with an increased risk of IUGR. **Chronic villitis**, chronic inflammation of placental villi, is seen with increased frequency when the placentas of IUGR pregnancies are examined histologically. Finally, **uterine anomalies** may be associated with impaired fetal growth, primarily because of suboptimal uterine blood flow.

4. Multiple gestation—Multiple gestation has long been associated with premature delivery. However, it also is associated with a 20–30% increased incidence of IUGR fetuses, most often as a result of placental insufficiency, twin-twin transfusion syndrome, preeclampsia, or anomalies. Fetal growth has a direct relationship to the number of fetuses present and the type of placentation (monochorionic vs. dichorionic). Serial ultrasound estimates of fetal weights should be considered in a multiple gestation pregnancy.

B. Maternal Factors

Numerous maternal diseases are associated with suboptimal fetal growth. Any woman who has borne 1 IUGR fetus is at increased risk for recurrence, with a 2-fold and 4-fold increased risk for IUGR birth after 1 or 2 IUGR births, respectively.

1. Hypertension—Hypertension is the most common maternal complication causing IUGR. Systemic hypertension results in decreased blood flow through the spiral arterioles and decreased delivery of oxygen and nutrients to the placenta and fetus. Hypertension may be associated with placental infarction.

2. Drugs—Both social drugs and prescribed medications can affect fetal growth. **Alcohol** use has long been known to be associated with impaired fetal growth. Virtually all infants with fetal alcohol syndrome exhibit signs of growth restriction.

Cigarette smoking is much more common among women of childbearing age in the United States than is alcoholism. Smoking causes one-third of IUGR cases and is the single most preventable cause of IUGR pregnancy in the United States today. Women who smoke have a 3-fold to 4-fold increase in IUGR infants. Birthweight is reduced by approximately 200 g, with the amount of growth restriction proportional to the number of cigarettes smoked per day. Women who quit smoking at 7 months' gestation have newborns with higher mean birthweights than do women who smoke throughout the entire pregnancy. Women who stop smoking before 16 weeks' gestation are not at increased risk for having an IUGR fetus.

Heroin and cocaine are also associated with an increased risk of IUGR, but confounding variables make determination of a direct cause-and-effect relationship difficult. Methadone use has not been shown to be associated with an increased incidence of IUGR.

Pharmacologic agents have been associated with an increased incidence of IUGR, primarily as a result of teratogenic effects. Warfarin has been associated with an increased incidence of IUGR, primarily as a result of the sequelae of intrauterine hemorrhage. Folic acid antagonists are associated with an increased risk of spontaneous abortion stillbirth, severe malformations, and IUGR.

IUGR fetuses are more common with maternally administered immunosuppressive drugs (eg, cyclosporine, azathioprine, corticosteroids), but when controlled for the underlying maternal disease, the medications per se probably have little effect on fetal growth. Furthermore, β-blockers are also associated with an increased risk of IUGR.

3. Malnutrition and malabsorption—Maternal weight at birth, prepregnancy weight, and weight gain during pregnancy account for 10% of the variance in fetal weight and increase the risk of delivering an infant <2500 g. Studies of infants borne by women who were pregnant during the Siege of Leningrad during World War II showed that daily intake must be reduced to <1500 kcal/d before a measurable effect on birthweight becomes evident. Maternal **malabsorption** may predispose to IUGR pregnancy. The most common clinical situations are inflammatory bowel disease (ulcerative colitis or regional enteritis), pancreatitis, and intestinal parasites. **Maternal eating disorders** such as bulimia and anorexia are also associated with IUGR.

4. Vascular disease and hypoxemia—Diseases that affect maternal microvascular perfusion can be associated with IUGR. These include collagen vascular disease, insulin-dependent diabetes mellitus associated with microvasculopathy, and preeclampsia. Also, chronic maternal hypoxemia due to pulmonary disease or cyanotic heart disease is associated with growth restriction.

5. Maternal features—A small woman may have a smaller-than-normal infant because of reduced growth potential. These mothers and infants are completely normal and healthy, but they are constitutionally small because of genetic variation. The ponderal index (PI) can be used to evaluate whether an infant is simply constitutionally small or is affected by IUGR. The PI is calculated using the following formula:

$$\text{PI} = [\text{Weight (in g)} \times 100]/[\text{length (in cm)}]^3$$

Infants affected by asymmetric IUGR will have a low PI (ie, they will be long, lightweight infants with a PI below the 10th percentile), whereas small normal infants will have a normal PI.

Women who were SGA at birth have a 2-fold increase in risk of IUGR in their offspring.

Maternal parity exerts a modest effect on birthweight. First-born infants tend to be smaller and more often categorized as IUGR. This effect decreases with successive deliveries and is not seen beyond the third birth.

6. Sex of fetus—At term, female fetuses are an average 5% (150 g) smaller and 2% (1 cm) shorter than male fetuses. Referring to separate norms for male and female fetuses may increase the power of biometry in assessing IUGR.

Prevention

Because many causes of IUGR are not preventable, few interventions have proved effective for prevention. Interventions that have shown benefit include smoking cessation, antimalarial chemoprophylaxis, and balanced protein and energy supplementation. Smoking is the single most common preventable cause of IUGR in infants born in the United States. As discussed in Maternal Factors, women who quit smoking at 7 months' gestation have newborns with higher mean birthweights than do women who smoke throughout the pregnancy. Women who quit smoking before 16 weeks' gestation are not at any increased risk for an IUGR infant. Limited data suggest that **balanced nutritional supplementation** improves mean birthweight. As expected, such supplementation more likely will benefit those with poor nutrition or adolescent pregnancies. Pregnant women should avoid close contact with individuals known to be infected or colonized with rubella virus or CMV. Nonpregnant women of reproductive age should be tested for immunity to rubella virus and, if susceptible, should be immunized prior to conception. Currently no vaccine exists for CMV.

Women of childbearing age should be tested for immunity to *T gondii* if this protozoan infection is clinically suspected. If the woman is immune, her risk of having an affected infant is remote. However, if she is susceptible, she should be cautioned to avoid cat feces and uncooked meat. If the screening immunoglobulin M (IgM) for *Toxoplasma* is positive, no action should be taken based on this result without confirmation by a regional reference laboratory with expertise in *Toxoplasma* testing.

Therapeutic medications are not a major cause of IUGR pregnancy, but benefits and risks should be weighed whenever medications are prescribed. Any woman of childbearing age should be questioned about the possibility of pregnancy before receiving therapeutic or diagnostic radiation to the pelvis.

Placental factors causing IUGR pregnancies are not generally preventable. It has been postulated that low-dose aspirin and dipyridamole may increase prostacyclin production in certain patients and thus prevent idiopathic uteroplacental insufficiency. The role of these agents in preventing IUGR resulting from placental insufficiency in at-risk populations is unclear at this time.

Preventive measures for the maternal diseases listed in Table 16–3 are beyond the scope of this chapter. Treatment of many of these conditions may decrease the likelihood of IUGR pregnancy. Treatment of hypertension has a positive effect on birthweight, at least in the third trimester. However, strict bed rest and hospitalization do not seem to have any beneficial effects for patients with a history of hypertension. Although a complex issue, protein supplements for patients with significant proteinuria may increase the amount of protein available for placental transfer. Correction of maternal anemia (of whatever cause) improves oxygen delivery to the fetus, thus improving fetal growth. However, routine supplements, such as with iron, have not been shown to be associated with any altered clinical outcomes.

Treatment of malabsorption syndrome (of whatever cause) can be expected to improve nutrient absorption and subsequent nutrient transfer to the fetus. Inflammatory bowel disease should be treated if required, but if possible, pregnancy should be deferred until the disease has been quiescent for approximately 6 months. Intestinal parasites should be appropriately treated and negative cultures confirmed prior to pregnancy.

Clinical Findings

A. Ultrasound Evaluation of Estimated Fetal Weight

The diagnosis of IUGR is made when biometric parameters on ultrasound indicate that the EFW is less than the 10th percentile for gestational age. In any pregnancy at risk for IUGR, baseline ultrasound studies should be obtained early in gestation. Careful attention should always be given to gestational dating (menstrual history, serial examinations, biochemical pregnancy testing, quickening, ultrasound). An IUGR outcome, however, may develop in pregnancies without identified risk factors. For some pregnancies, the first sign of IUGR may be a lagging fundal height on clinical examination. If the fundal height varies from the assigned gestational age by more than 2 cm, ultrasound is indicated to assess the EFW and amniotic fluid volume. Careful attention to fundal height measurement is associated with 46–86% sensitivity for detecting IUGR.

Ultrasound examination early in pregnancy is accurate in establishing the estimated date of confinement (EDC) and may sometimes identify genetic or congenital causes of IUGR pregnancy. Serial ultrasound examinations are important in documenting growth and excluding anomalies. An antenatal diagnosis of IUGR is not precise given that EFW cannot be measured directly and must be calculated from a combination of directly measured parameters. Overall prediction of weight via birthweight formulas can have a 10–20% error rate. Selection of the most useful biometric parameter depends on the timing of measurements. The crown–rump length is the best parameter for dating of pregnancy in the first trimester. The biparietal diameter (BPD) and HC are most accurate in the second trimester, with a margin of error of 7–11 days for BPD and 3–5 days for HC. HC is more useful in establishing gestational age in the third trimester because BPD loses its accuracy secondary to variations in shape. Abdominal circumference measurement is the single most sensitive measurement for evaluating fetal growth restriction. The fetal abdominal circumference reflects the volume of fetal subcutaneous fat and the size of the liver, which in turn correlates with the degree of fetal nutrition. Acidemia and hypoxemia are more common when the abdominal circumference is below the 5th percentile for gestational age.

The femur length is not helpful for identifying IUGR but can identify skeletal dysplasia. Because the definition of IUGR ultimately depends on birthweight and gestational age criteria, formulas that optimally predict birthweight in a given population will be the most important contributor to ultrasonographic criteria.

Fetuses from different populations show different growth patterns. The growth curves developed by Battaglia and Lubchenco in the 1960s do not reflect the variation in birthweight for various ethnic populations. The growth curves used today also do not reflect the median birthweight increase over the last 3 decades. Racial and ethnic anthropometric variations may suggest a need for specific charts for different communities.

Differential Diagnosis

If the fundal height on clinical examination is small, other diagnoses that should be entertained are oligohydramnios or a healthy pregnancy with the wrong due date (ie, the true gestational age is earlier than assigned). Ultrasound can help to differentiate among these diagnoses.

Complications

Numerous maternal and perinatal complications have been associated with IUGR pregnancies (Table 16–1). Underlying maternal disease is more likely to be present (Table 16–3), and these women require more intensive prenatal care. Premature labor or preeclampsia is more common. IUGR fetuses at any gestational age are less likely to tolerate labor well, and the need for operative delivery is increased.

Perinatal morbidity and mortality are significantly increased in low-birthweight infants, with an inverse relationship between neonatal weight and perinatal mortality. At any given gestational age, IUGR neonates have a higher mortality than do AGA neonates. However, at any given birthweight, outcomes are similar for IUGR and AGA neonates. Perinatal morbidity and mortality are especially increased in infants born at term with birthweights at or below the 3rd percentile. Increased risk of mortality is affected by the primary etiology of growth restriction and may be modified by the severity and progression of maternal factors (eg, hypertension control). With the advent of fetal surveillance, the perinatal mortality rate associated with IUGR has decreased to 2–3 times that of the AGA population. The past decade has witnessed increased attention to minimizing the perinatal complications of surviving IUGR neonates. With continued improvements in antenatal surveillance and neonatal care, the perinatal mortality rate for IUGR pregnancies in most centers now is 1.5–2 times that of the AGA population. Unfortunately, this rate likely will not reach that of the AGA population in the near future because of the persistent occurrence of lethal anomalies and severe congenital infections.

IUGR fetuses are at risk for in utero complications, including hypoxia and metabolic acidosis, which may occur at any time but are more likely to occur during labor. Up to 50% of growth-restricted fetuses exhibit abnormal fetal heart rate patterns, most often variable decelerations. Hypoxia is the result of increasing fetal oxygen requirements during pregnancy, with a rapid increase during the third trimester. If the fetus receives inadequate oxygen, hypoxia and subsequent metabolic acidosis will ensue. If undetected or untreated, this condition will lead to decreased glycogen and fat stores, ischemic end-organ damage, meconium-stained amniotic fluid, and oligohydramnios, eventually resulting in vital organ damage and intrauterine death.

IUGR infants are at increased risk for neonatal complications, including meconium aspiration syndrome, low Apgar scores, UA pH <7.0, need for intubation in the delivery room, seizures, sepsis, polycythemia, hypoglycemia, hypocalcemia, temperature instability, apneic episodes, and neonatal death. All IUGR infants require a thorough postnatal evaluation for congenital anomalies.

Treatment

The initial evaluation of the fetus suspected to be growth restricted involves:

- Evaluation for other evidence of fetal compromise. Depending on the gestational age, this may involve performing a biophysical profile and Doppler studies of umbilical and fetal vessels (see below for more details).
- Detailed fetal anatomic survey by ultrasound.
- Detailed maternal history for any evidence of recent infection, medication or drug exposure, any maternal medical disorders that are associated with IUGR such as hypertension, or any history of IUGR in a prior pregnancy.
- Physical examination and laboratory testing for any evidence of preeclampsia.
- Maternal serum testing for viral and parasitic infections if there is a history suggestive of recent infection.

The role of maternal evaluation for inherited and acquired thrombophilia is controversial in these patients. Studies have not demonstrated a consistent link between maternal thrombophilia and IUGR. If an association exists, it is likely a weak one.

Depending on the findings, consideration may be given to fetal karyotyping via genetic amniocentesis if IUGR presents prior to the third trimester and severe growth restriction is suspected (ie, EFW <3rd percentile). Amniocentesis should also be considered for karyotyping if any structural malformations are found or if there is polyhydramnios. Amniocentesis may also be performed to assess for pulmonary maturity for selected fetuses.

Treatment of IUGR pregnancy presupposes an accurate diagnosis. Even with the history, physical examination, and ultrasound examination, an accurate diagnosis remains difficult, and some IUGR pregnancies will not be detected. Conversely, some fetuses suspected to be growth restricted may have a normal birth weight or may be found to be constitutionally small.

All pregnant women who are smoking should be advised to discontinue cigarette smoking as well as use of alcohol and all recreational drugs. Although bed rest often is recommended, no evidence shows that bed rest results in improved outcome or increased fetal birthweight for fetuses with suspected IUGR. The increased uterine blood flow that occurs when the patient is in the lateral recumbent position theoretically may result in some benefit for fetuses with asymmetric IUGR.

However, data do not support this theory.

Because IUGR fetuses are at risk for antepartum or intrapartum compromise, they should be followed carefully. The goal of fetal surveillance is to identify those fetuses at greatest risk of stillbirth and neonatal morbidity related to acidosis who may benefit from preterm delivery. The best method for monitoring a fetus with suspected IUGR is not well established; however, it typically involves ultrasound for biophysical profile and Doppler studies of umbilical and fetal vessels.

- **The biophysical profile (BPP)** is useful for assessing fetal well-being. With a normal BPP score, the risk of fetal asphyxia in the following week is low (approximately 1 in 1000). As part of the BPP, the amniotic fluid volume is assessed. Decreased amniotic fluid volume is clinically associated with IUGR. This finding is thought to result from decreased perfusion of the fetal kidneys, which leads to decreased urine production. **Oligohydramnios**, defined as a maximum vertical pocket of fluid <2 cm or amniotic fluid index of <5 cm, may be seen with IUGR infants, but the presence of a normal amniotic fluid index should not preclude the diagnosis of IUGR.
- **Umbilical artery (UA) Doppler velocimetry** can be used to estimate the likelihood of adverse perinatal outcome and is useful in determining the intensity of fetal surveillance. Placental circulatory insufficiency is associated with increased placental resistance, which is associated with decreased maternofetal oxygen transfer. This increase in placental resistance is manifested by a fall in forward blood flow through the UA due to increased downstream impedance. During the compensated stage, diastolic flow in the UA is reduced or absent. Reversal of diastolic flow in the UA is a sign of severe hypoxemia and acidemia. Although the use of UA Doppler studies for general population screening remains unproven, it is recommended as the primary method of surveillance for already identified IUGR fetuses. Doppler flow studies, in particular the systolic-to-diastolic ratio (S/D ratio), helps reduce unnecessary interventions and improve overall fetal outcome (including reducing the risk of perinatal death) in IUGR pregnancies. A recent study showed that of fetuses with suspected IUGR evaluated by Doppler studies, none of those with normal UA Doppler flow measurements were delivered with metabolic acidemia. This finding suggests that intense antenatal surveillance may be unnecessary in a fetus with a normal UA S/D ratio and normal amniotic fluid index. Abnormal UA flow is associated with an increased risk of caesarean or operative delivery.
- In fetuses with suspected IUGR, abnormal **middle cerebral artery (MCA) Doppler studies** and UA S/D ratios are strongly associated with low gestational age at delivery, low birthweight, and low UA pH. Also, mean birth-weight, interval to delivery, need for emergent delivery, and occurrence of fetal distress all are related to the severity of abnormal Doppler findings after correction for gestational age. Abnormal Doppler cerebroplacental ratio (MCA pulsatile index divided by UA pulsatile index) also has been associated with a statistically significant increase in perinatal morbidity and mortality. Respiratory distress syndrome and intracranial hemorrhage are not associated with abnormal Doppler studies.
- Doppler studies of other fetal vessels such as the descending aorta, inferior vena cava, and ductus venosus have also been shown to correlate with fetal acidosis and risk of demise.

In addition to fetal kick counts, antepartum testing with BPP and UA Doppler are recommended once or twice per week for the fetus with suspected IUGR. The significance of abnormal UA Doppler results can be clarified by investigations of MCA circulation and Doppler studies of venous structures, including the ductus venosus.

Ultrasound examinations to assess adequacy of fetal growth should be performed at least every 3–4 weeks. Measurements should include BPD, HC, abdominal circumference, and femur length, especially in patients in whom an asymmetric IUGR fetus is suspected. Probably the most sensitive index of an asymmetric IUGR fetus is the abdominal circumference. The femur length/abdominal circumference ratio is a gestational age–independent ratio (normal 0.20–0.24). Asymmetric IUGR fetuses generally have a ratio >0.24.

Every IUGR pregnancy must be individually assessed for the optimal time of delivery (ie, the point at which the baby will do as well or better outside the uterus than inside). This would be whenever surveillance indicates fetal maturity, fetal compromise, or gestational age of 37–38 weeks (beyond which time there is no advantage to an IUGR fetus remaining in utero). Data are conflicting as to whether IUGR accelerates pulmonary maturity. Therefore, the current recommendation is to administer glucocorticoids to women likely to deliver before 34 weeks, as would be done with any other pregnancy.

IUGR pregnancies are at increased risk for intrapartum problems, so whenever possible, delivery should take place in a center where appropriate obstetric care, anesthesia, and neonatal care are readily available. Caesarean delivery may be necessary, and the presence of meconium-stained amniotic fluid or a compromised infant should be anticipated.

The mode of delivery must be individualized. Caesarean delivery is often indicated, especially when fetal monitoring reveals evidence of fetal compromise, malpresentation, or situations where traumatic vaginal delivery might be expected.

Continuous electronic fetal heart rate monitoring should be performed during labor in all cases, even if recent ante-partum testing has been reassuring. Arteriovenous cord blood gas determinations also are useful; as many as 50% of IUGR infants have some degree of metabolic acidosis. Minimization of anesthesia is generally preferable, but controlled epidural anesthesia usually is safe. Maternal hypotension or hypovolemia must be avoided.

Prognosis

An IUGR pregnancy per se is not considered life-threatening for the mother. However, increased maternal morbidity and mortality may result from an underlying condition (eg, hypertension or renal disease). Most women who deliver IUGR infants can be expected to have long-term prognoses equivalent to those of women delivering AGA infants.

Infants with a low birthweight have a relatively high morbidity and mortality. Short-term morbidity includes impaired thermoregulation, hypoglycemia, polycythemia, and impaired immune function. Studies have shown that the rate of neonatal death, Apgar score at 5 minutes <3, UA pH <7.0, seizures during the first day of life, and incidence of intubation are significantly increased when the fetus is at or below the 3rd percentile for birthweight.

As for long-term prognosis for the infant, reports of national survey data show that IUGR infants appear to catch up in weight in the first 6 months of life. However, IUGR infants tend to remain physically small and are shorter, lighter, and have smaller HCs than do AGA infants.

Taken as a group, IUGR infants have more neurologic and intellectual deficits than do their AGA peers. IUGR infants have lower IQs as well as a higher incidence of learning and behavioral problems. Major neurologic handicaps, such as severe mental retardation, cerebral palsy, and seizures, are more common in IUGR infants. The incidence of sudden infant death syndrome (SIDS) is increased in IUGR infants, who account for 30% of all SIDS cases. Adults who were IUGR at birth are at higher risk for developing ischemic heart disease and related disorders, including hypertension, stroke, diabetes, and hypercholesterolemia.

LARGE FOR GESTATIONAL AGE PREGNANCY

ESSENTIALS OF DIAGNOSIS

- EFW greater than the 90th percentile for gestational age on ultrasound.
- Macrosomia represents a subset of LGA fetuses weighing >4500 g.

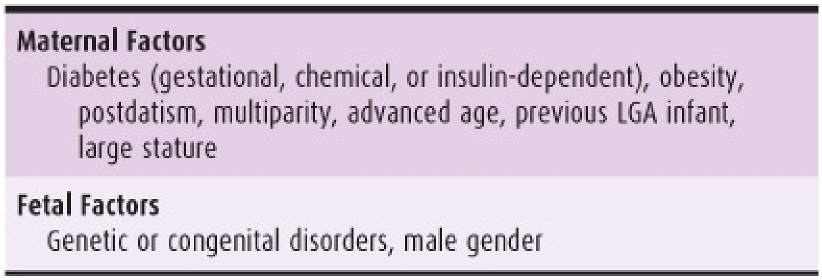
Although the **large for gestational age (LGA)** fetus is defined according to the same concept as the IUGR fetus (LGA = heaviest 10% of newborns), LGA pregnancy has received substantially less attention since it is generally associated with fewer maternal and fetal complications than IUGR. *Large for gestational age* is defined as EFW above the 90th percentile for any specific gestational age. **Macrosomia** generally refers to fetuses with an EFW of at least 4500 g regardless of the gestational age; fetuses that are >4500 g are >95th percentile at any gestational age and therefore represent an extreme subset of LGA fetuses. The risk of morbidity is greater for infants born weighing between 4000 and 4500 g compared to the average population. However, the risk of infant morbidity is substantially increased at birthweights greater than 4500 g. Although there are numerous reports and studies regarding macrosomia, few data regarding LGA as defined here are available. Therefore, this section concentrates on fetal macrosomia, with additional comments regarding LGA pregnancies.

Pathogenesis

Numerous endocrinologic changes occur during pregnancy to ensure an adequate fetal glucose supply. In the second half of pregnancy, increased concentrations of human placental lactogen, free and total cortisol, and prolactin combine to produce modest maternal insulin resistance, which is countered by postprandial hyperinsulinemia. In those who are unable to mount this hyperinsulinemic response, relative hyperglycemia may develop (ie, gestational diabetes). Because glucose crosses the placenta by facilitated diffusion, fetal hyperglycemia ensues. This in turn produces fetal hyperinsulinemia with resultant intracellular transfer of glucose, leading to fetal macrosomia.

Factors that predispose to LGA pregnancy are listed in Table 16–4. As with IUGR pregnancy, diagnosis of LGA pregnancy depends on knowing with certainty the gestational age of the fetus.

Table 16–4. Factors that may predispose to fetal macrosomia or large for gestational age (LGA) pregnancy.



Maternal Factors
Diabetes (gestational, chemical, or insulin-dependent), obesity, postdatism, multiparity, advanced age, previous LGA infant, large stature
Fetal Factors
Genetic or congenital disorders, male gender

A. Maternal Diabetes

Maternal diabetes, whether gestational, chemical, or insulin dependent, is the condition classically associated with fetal macrosomia. The "Pedersen hypothesis" was long assumed to account for fetal macrosomia, that is, the condition was the result of inadequate management of diabetes during pregnancy. Initial reports suggested that careful control of blood glucose level in insulin-dependent diabetic women would prevent fetal macrosomia, but recent studies have suggested that the problem is not so simple and that the incidence may correlate better with cord blood concentrations of maternally acquired anti-insulin immunoglobulin G (IgG) antibodies and/or increased serum levels of free fatty acids, triglycerides, and the amino acids alanine, serine, and isoleucine. Cord serum epidermal growth factor concentrations also have been found to be higher than normal in pregnancies complicated by prepregnancy diabetes and gestational diabetes.

A significant correlation exists between plasma leptin levels and neonatal birthweight, which suggests that leptin levels are directly related to the quantity of body fat tissue in fetal macrosomia.

B. Maternal Obesity

Maternal obesity is associated with a 3- to 4-fold increased likelihood of fetal macrosomia. The increased risk of macrosomia associated with maternal obesity appears to be independent of comorbidities such as gestational or pregestational diabetes.

C. Postdatism

Prolonged pregnancy is more likely to result in a macro-somic fetus, presumably because of continued delivery of nutrients and oxygen to the fetus.

D. Genetic and Congenital Disorders

Several genetic and congenital syndromes are associated with an increased incidence of macrosomia. **Beckwith-Wiedemann syndrome** is frequently associated with fetal macrosomia, usually because of pancreatic islet cell hyperplasia (nesidioblastosis). Affected infants usually have hypoglycemia, macroglossia, and omphalocele. They also may have intestinal malrotation or visceromegaly. Although usually a sporadic event, other inheritance patterns have been suggested in a few families. Other rare syndromes include **Weaver's syndrome, Sotos' syndrome, Nevo's syndrome, Ruvalcaba-Myhre syndrome**, and **Marshall's syndrome. Carpenter's syndrome** and **fragile X syndrome** may be associated with an increased incidence of LGA infants.

E. Constitutionally Large Fetus

Fetuses who are suspected of being LGA may simply be large secondary to constitutional factors. **Large maternal stature** should be considered as contributing to macrosomia because birthweight tends to correlate more closely with maternal height than maternal weight. **Male fetuses** are more likely to be considered LGA because male fetuses are an average of 150 g heavier than appropriately matched female fetuses at each gestational week during late pregnancy. Series addressing fetal macrosomia generally report an increased incidence of male fetuses, usually approximately 60–65%. One recent study showed that male fetuses were twice as likely to be diagnosed with macrosomia as compared with female fetuses.

F. Maternal Weight Gain

Excessive maternal weight gain in pregnancy is associated with macrosomia. A weight gain of more than 40 lb significantly increased the incidence of macrosomia by an odds ratio of 3.3.

Prevention

Prevention of macrosomia and ensuing complications requires early detection of risk factors. Risk factors for having a macrosomic infant include multiparity, advanced maternal age, and previous delivery of a macrosomic infant. When controlled for gestational age and fetal gender, the average birthweight with successive pregnancies increases by 80–120 g up to the fifth pregnancy. Multiparity is also associated with other risk factors (eg, obesity, diabetes) and therefore may be a confounding variable. Advanced maternal age also contributes to increased birthweight. However, as with multiparity, it is also associated with obesity and diabetes.

Consideration should be given to evaluating patients with the risk factors noted in Table 16–4 for possible fetal macrosomia with an ultrasound estimate of fetal size and weight.

For patients with gestational or pregestational diabetes, adequate control of maternal glucose levels is thought to prevent the development of macrosomia, although neonatal complications despite excellent metabolic control have been reported. Prepregnancy weight and degree of weight gain are strong indicators for macrosomia regardless of glycemic control. However, the rates of macrosomia and complications are reduced overall when postprandial levels are monitored. Studies have shown that the risk of macrosomia is reduced to near normal in diabetic women who monitor 1-hour postprandial glucose levels and that 1-hour postprandial glucose levels are directly related to fetal abdominal circumference values. One study showed that when postprandial glucose levels were kept below 104 mg/dL, macrosomia rates of diabetic women were similar to those of nondiabetics. Chapter 31 reviews diabetes and pregnancy in more detail.

Infants of women who participate in regular aerobic exercise programs have lower average birthweights compared with infants in the general population but no demonstrable adverse effects. To date, no studies have evaluated the potential efficacy of exercise programs as a means of decreasing birthweight in women at risk for LGA pregnancy.

Clinical Findings

The first sign of macrosomia may be detected when the fundal height measurement on clinical examination exceeds the margin of error (>3 cm) for that gestational age. A diagnosis of macrosomia is made when the EFW on ultrasound (as determined by measurements of the HC, BPD, abdominal circumference, and femur length) exceeds 4500 g. Nonetheless, EFW by ultrasound is not very accurate. More than 30 different formulas for EFW calculation have been proposed, attesting to the inadequacy of each individual method. No single formula has been consistently better than the others. Even in skillful hands, the error of fetal weight estimates by ultrasound is 10–20%. One review of ultrasonographic diagnosis of macrosomia shows sensitivity ranging from 24 to 88% and specificity from 60 to 98%. The margin of error in estimating fetal weight means that the EFW by ultrasound must be at least 4750 g in order to predict a birthweight of 4000 g with a confidence interval of 90%. The best single measurement in evaluating macrosomia in diabetic mothers is abdominal circumference. An initial abdominal circumference above the 70th percentile is significantly associated with subsequent delivery of an LGA infant. Fetal body composition and fetal shoulder width cannot be accurately assessed by ultrasound.

Differential Diagnosis

If the fundal height on clinical examination is increased, the differential diagnosis includes polyhydramnios, fetal structural abnormality (such as sacrococcygeal teratoma), and undiagnosed multiple gestation in addition to macrosomia or LGA fetus. Ultrasound can differentiate among these diagnoses.

Complications

Macrosomic pregnancies are at increased risk for many fetal and maternal complications (Table 16–2). Macrosomic pregnancies are more likely to require **caesarean delivery**, usually because of failure to progress. In particular, primigravidas delivering a macrosomic infant are at increased risk for complications such **as prolonged labor, postpartum hemorrhage, operative vaginal delivery, and emergency caesarean section** as compared to delivering a normal weight infant. Primigravidas also have a higher risk of these complications compared with multiparous women delivering a macrosomic infant. Fetal distress, as determined by electronic fetal monitoring, is not more common in macrosomic pregnancies.

Shoulder dystocia occurs in 5–24% of vaginally delivered macrosomic fetuses. The incidence of shoulder dystocia correlates not only with increasing fetal weight but also with increasing chest circumference to HC. Shoulder dystocia of macrosomic infants also is related to maternal stature, but the association is not as clear. Approximately 10–15% of infants with shoulder dystocia experience brachial plexus injury; facial nerve injury and fractures of the humerus or clavicle also may be seen.

The risk of fetal **brachial plexus injury** in macrosomic infants delivered vaginally is 0.3–4%. Brachial plexus injury with shoulder dystocia is approximately 7% in infants whose birthweights exceed 4000 g but is 14% for mothers with gestational diabetes. The doubled risk may be secondary to increased fetal abdominal obesity in diabetic mothers. In diabetic patients, a correlation exists between the level of fetal truncal asymmetry (abdominal circumference/BPD ratio) as measured by ultrasound and the incidence and severity of shoulder dystocia. In addition to macrosomia, risk factors for shoulder dystocia include previous shoulder dystocia and maternal diabetes (3- to 4-fold increase compared to nondiabetic mothers). Lesser risk factors that are mediated through fetal size include previous delivery of a large fetus and excessive maternal weight gain during pregnancy. The risk of shoulder dystocia is similar in primigravidas and multigravidas delivering macrosomic infants.

Perineal trauma is more likely with a macrosomic pregnancy and is related to an increased incidence of shoulder dystocia and operative vaginal delivery. Vaginal delivery of a macrosomic infant increases by 5-fold the risk of third- or fourth-degree laceration.

Although gestational diabetes and postdatism predispose to fetal macrosomia, no evidence indicates that fetal macrosomia or an LGA fetus predisposes to gestational diabetes or postdatism.

The incidence of **stillbirth** remains higher in macrosomic fetuses than in controls of average weight. This problem has persisted even with the availability of fetal monitoring and presumably reflects the increased incidence of maternal diabetes and postdatism. Stillbirths are known to be increased in nonanomalous diabetic mothers, but the cause is not understood. Additionally, excessive prepregnancy weight is an independent risk factor for unexplained death. In fact, large fetal macrosomia is significantly associated with unexplained fetal death even after controlling for maternal age, diabetes, and hypertension.

Many of the neonatal complications of fetal macrosomia are the result of underlying maternal diabetes or birth trauma and include low Apgar scores, hypoglycemia, hypocalcemia, polycythemia, jaundice, and feeding difficulties. LGA infants have significantly higher absolute nucleated red blood cell counts, lymphocyte counts, and packed cell volumes. These hematologic abnormalities are the same for all LGA infants regardless of whether they are infants of nondiabetic mothers, insulin-dependent diabetic mothers, or non–insulin-dependent gestational diabetics. This situation is believed to reflect a compensatory increase in erythropoiesis as a result of chronic intrauterine hypoxia resulting from increased placental oxygen consumption and decreased fetal oxygen delivery.

LGA infants of diabetic mothers have an increased incidence of cardiac septal hypertrophy.

Treatment

Labor induction for suspected macrosomia has not been shown to reduce the risk of shoulder dystocia, and caesarean delivery reducing the incidence of fetal macrosomia and intrapartum complications remains an unproven hypothesis.

Several published reviews of fetal macrosomia suggest routine caesarean delivery for fetuses with estimated weights of 5000 g or more (or estimated weights ≥4500 g in diabetic pregnancies). This suggestion is based in part on the data given in Table 16–2 and in part on anthropometric studies suggesting that very macrosomic fetuses have bisacromial circumferences in excess of HCs. Because of current limitations in the sensitivity and specificity of ultrasound-derived fetal weight calculations, decisions regarding scheduled abdominal delivery must be partially based on clinical grounds. Such considerations are particularly warranted in women who are obese or are diabetic or in postdate pregnancies. Maternal age and maternal preference also should be considered when deciding on delivery method.

Intrapartum management considerations center on close observation of the patient’s labor curve and avoidance of interventions that may be associated with an increased likelihood of traumatic vaginal delivery. Although data are conflicting, some studies have shown that patients with a protracted active phase of labor are more likely to experience shoulder dystocia. Close attention to a patient’s progress during labor may help detect this risk factor for shoulder dystocia. Furthermore, vacuum-assisted vaginal delivery increases the risk of shoulder dystocia. If the estimate of fetal weight is greater than 4000 g, the vacuum should be avoided if the second stage is prolonged, and in general, the vacuum should be used with caution. Because of these factors, women at risk for macrosomic or LGA babies should deliver in facilities where adequate obstetric care, pediatric care, and anesthesia are available. Large-bore intravenous access must be established, and blood must be available. Delivery should occur in a setting where immediate operation can be accomplished.

Prognosis

Any woman who delivers an LGA baby should be informed that the risk of her having another LGA baby is increased by 2.5- to 4-fold. Such women should be screened for previously undiagnosed chemical or insulin-dependent diabetes and, even if screening is negative, should be followed carefully in any subsequent pregnancy to rule out gestational diabetes.

Obese women should be strongly encouraged to lose weight prior to becoming pregnant. Any woman who has delivered an LGA infant should be encouraged to seek early care for any subsequent pregnancy, if for no other reason than early confirmation of the EDC, which can minimize the likelihood of subsequent postdatism. Women who deliver an LGA infant with an underlying genetic or congenital disorder should receive genetic counseling regarding recurrence risks and the feasibility of antepartum diagnosis.

In addition to the many neonatal complications previously noted, infants of mothers with gestational or pregestational diabetes are at increased risk for subsequent obesity, type 2 diabetes, or both. Infants who suffer from neonatal complications are at increased risk for subsequent neurologic or behavioral problems.

Multiple Gestation

Melissa C. Bush, MD
Martin L. Pernoll, MD

ESSENTIALS OF DIAGNOSIS

- The incidence of multiple gestations has risen significantly over several decades, primarily due to increased use of fertility drugs for ovulation induction, superovulation, and assisted reproductive technologies (ART), such as in vitro fertilization (IVF).
- Compared with singleton pregnancies, twin pregnancies are more likely to be complicated by hypertensive disorders, gestational diabetes mellitus, anemia, preterm birth, ante- and postpartum hemorrhage, and maternal death.
- The perinatal mortality rate of twins is 3–4 times higher—and for triplets much higher still—than in singleton pregnancies as a result of chromosomal abnormalities, prematurity, structural anomalies, hypoxia, and trauma.
- This is particularly true of monozygotic twins, which are also uniquely susceptible to twin–twin transfusion syndrome.

Pathogenesis

In the United States, between 1980 and 2004, the twin rate climbed 101% with 68,339 twins born in 1980 and 137,085 twins born in 2006. Multiple gestations now comprise 3% of all pregnancies, and twins comprise 25–30% of deliveries resulting from assisted reproductive technologies (ART). Significant maternal and neonatal effects are felt from this increase in multiple births. The financial costs are also staggering, with combined costs of ART plus pregnancy care, delivery, and neonatal care reaching hundreds of thousands of dollars in some cases. Maternal morbidity and mortality rates are much higher in multiple pregnancy than in singleton pregnancy. Compared with singleton pregnancies, twin pregnancies are more likely to be complicated by hypertensive disorders, gestational diabetes mellitus, anemia, preterm birth, ante- and postpartum hemorrhage, and maternal death. Earlier and more precise sonography has revealed the incidence of multiple gestation to be 3.29–5.39% before 12 weeks. However, in over 20% of such cases, one or more of the pregnancies spontaneously disappears (“vanishing twin”). Although this event may be associated with vaginal bleeding, the prognosis remains good for the remaining twin.

Approximately two-thirds of twin pregnancies end in a singleton birth; the other embryo is lost from bleeding, is absorbed within the first 10 weeks of pregnancy, or is retained and becomes mummified (fetus papyraceous). Fetus papyraceous is a small, blighted, mummified fetus usually discovered at the delivery of a well-developed newborn. This occurs once in 17,000–20,000 pregnancies spontaneously and is also the result of multifetal reduction. The cause is thought to be death of one twin, amniotic fluid loss, or reabsorption and compression of the dead fetus by the surviving twin.

Twins can be monozygotic or dizygotic. Higher order multiples can result from either or both processes.

A. Monozygotic Multiple Gestation

Monozygotic twins ("identical twins") are the result of the division of a single fertilized ovum that subsequently divides into 2 separate individuals. Monozygotic twinning occurs in about 4–5 of 1000 pregnancies in all races. The rate is remarkably constant in all populations and is not influenced by heredity, age of the mother, or other factors. Monozygotic twins are always of the same sex. However, the twins may develop differently depending on the time of preimplantation division. Normally, monozygotic twins share the same physical characteristics (skin, hair and eye color, body build) and the same genetic features (blood characteristics: ABO, M, N, haptoglobin, serum group; histocompatible genes), and they are often mirror images of one another (one left-handed, the other right-handed, etc). However, their fingerprints differ.

The paradox of "identical" twins is that they may be the antithesis of identical. The very earliest splits are sometimes accompanied by a simultaneous chromosomal error, resulting in heterokaryotypic monozygotes, one with Down syndrome and the other normal. Furthermore, monozygotic twins may be discordant for fetal structural malformations.

Monozygotic triplets result from repeated twinning (also called supertwinning) of a single ovum. Conversely, trizygotic triplets develop by individual fertilization of 3 simultaneously expelled ova. Triplets may also be produced by the twinning of 2 ova and the elimination of 1 of the 4 resulting embryos. Similarly, quadruplets may be monozygotic, paired dizygotic, or quadrizygotic (ie, they may arise from 1 to 4 ova).

Monoamniotic twins are the rarest form of monozygotic twins, with an incidence of about 1:10,000 pregnancies (1–5% of monozygotic gestations). The perinatal mortality is much higher than that of other monozygotic twins (23%) mostly due to cord entanglement as a result of the absence of a dividing membrane.

1. Placenta & cord—The placenta and membranes of monozygotic twins vary (Fig. 17–1), depending on the time of initial division of the embryonic disk. Variations are noted below.

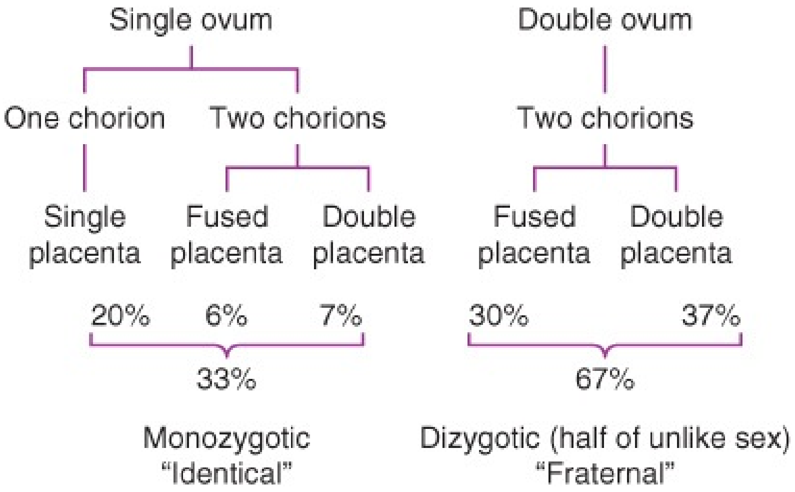

Figure 17–1. Placental variations in twinning. (Reproduced, with permission, from Benson RC. *Handbook of Obstetrics & Gynecology*. 8th ed. Los Altos, CA: Lange; 1983.)

1. Division prior to the morula stage and differentiation of the trophoblast (day 3) results in separate or fused placentas, 2 chorions, and 2 amnions (dichorionic/diamniotic). (This process grossly

resembles dizygotic twinning and accounts for almost one-third of monozygotic twinning.) This is clinically relevant since dichorionic twins have a much lower rate of complications.

2. Division after differentiation of the trophoblast but before the formation of the amnion (days 4–8) yields a single placenta, a common chorion, and 2 amnions (monochorionic/diamniotic). (This accounts for about two-thirds of monozygotic twinning.)
3. Division after differentiation of the amnion (days 8–13) results in a single placenta, 1 (common) chorion, and 1 (common) amnion (monochorionic/monoamniotic). This is rare.
4. Division later than day 15 may result in incomplete twinning. Just prior to that time (days 13–15), division may result in conjoined twins.

At delivery, the membranous T-shaped septum or dividing membrane of the placenta between the twins must be inspected and sectioned for evidence of the probable type of twinning (Fig. 17–2). Monochorionic, diamniotic twins most commonly have a transparent (<2 mm) septum made up of 2 amniotic membranes only (no chorion and no decidua). Dichorionic, diamniotic twins almost always have an opaque (thick) septum made up of 2 chorions, 2 amnions, and intervening decidua.

Figure 17–2. Chorionic and amniotic membranes of twins. (Reproduced, with permission, from Benson RC. *Handbook of Obstetrics & Gynecology*. 8th ed. Los Altos, CA: Lange; 1983.)

A monochorionic placenta can be identified by stripping away the amnion or amnions to reveal a single chorion over a common placenta. In virtually every case of monochorionic placenta, vascular communications between the 2 parts of the placenta can be identified by careful dissection or injection. In contrast, dichorionic placentas (of dizygotic twinning) only rarely have an anastomosis between the fetal blood vessels. All twin placentas are sent for pathologic examination to confirm chorionicity.

Placental and membrane examination is a certain indicator of zygosity in twins with monochorionic placentas because these are always monozygotic. Overall, approximately 1% of twins are monoamniotic, and these too are monozygotic. Determination of zygosity is clinically significant in case intertwin organ transplantation is needed later in life, as well as for assessing obstetrical risks. Monozygotic twins can rarely be discordant for phenotypic sex when one twin is phenotypically female due to Turner’s syndrome (45,XO) and its sibling is male (46,XY).

Monochorionic placentation is associated with more disease processes as a result of placental vascular problems. Inequities of the placental circulation in one area (marginal insertion, partial infarction, or thinning) may lead to growth discordance between the twins. Due to vascular anastomoses in monochorionic placentation, standard multifetal reduction using intrathoracic potassium chloride can only be performed with dichorionic placentation.

The most serious problem with monochorionic placentas is local shunting of blood—also called **twin–twin transfusion syndrome**. This problem affects approximately 15% of monochorionic twin pregnancies and occurs because of vascular anastomoses to each twin that are established early in embryonic life. The possible communications are artery to artery, vein to vein, and combinations of these. Artery-to-vein communication is by far the most serious; it is most likely to cause twin–twin transfusion. In uncompensated cases, the twins, although genetically identical, differ greatly in size and appearance. The recipient twin is plethoric, edematous, and hypertensive. Ascites and kernicterus are likely. The heart, liver, and kidneys are enlarged (glomerulotubal hypertrophy). Hydramnios follows fetal polyuria. Although ruddy and apparently healthy, the recipient twin with hypervolemia may die of heart failure during the first 24 hours after birth. The donor twin is small, pallid, and dehydrated (from growth restriction, malnutrition, and hypovolemia). Oligohydramnios may be present. Severe anemia, due to chronic blood loss to the other twin, may lead to hydrops and heart failure.

Velamentous insertion of the cord occurs in about 7% of twins but in only 1% of singletons. There is a corresponding increase in the potentially catastrophic vasa previa. The incidence of 2-vessel cord (single umbilical artery) is 4–5 times higher in monozygotic twins than in singletons.

Monochorionic, monoamniotic twins (1:100 sets of twins) have < a 90% likelihood of both surviving because of cord entanglement that compromises fetal-placental blood flow. Other common complications are congenital anomalies in 26% of monoamniotic twins and discordant birth weights, primarily due to twin–twin transfusion syndrome. Some authors advocate planned caesarean delivery at 32–34 weeks in an attempt to prevent in utero demise due to cord accidents, as well as continuous external fetal monitoring from about 27 weeks until delivery.

2. The fetus—There are several unusual fetal findings that may be seen in the setting of monozygotic twinning. Conjoined twins result from incomplete segmentation of a single fertilized ovum between the 13th and 14th days; if cleavage is further postponed, incomplete twinning (ie, 2 heads, 1 body) may occur. Lesser abnormalities are also noted, but these occur without regard to specific organ systems. Conjoined twins are described by site of union: pyopagus (at the sacrum); thoracopagus (at the chest); craniopagus (at the heads); and omphalopagus (at the abdominal wall). Curiously, conjoined twins usually are female. Numerous conjoined twins have survived separation.

An acardiac twin is a parasitic monozygotic fetus without a heart. It is thought to develop from reversed circulation, perfused by 1 arterial–arterial and 1 venous–venous anastomosis. This represents the twin reversed arterial perfusion (TRAP) syndrome. The otherwise normal donor twin is at risk for cardiac hypertrophy and failure and has a 35% mortality rate. Various methods of cord occlusion are being studied as in utero therapy.

B. Dizygotic Multiple Gestation

Dizygotic twins (“fraternal twins”) are produced from separately fertilized ova. They bear only the resemblance of brothers or sisters and may or may not have the same blood type. Significant differences usually can be identified over time. Slightly more than 30% of twins are monozygotic; nearly 70% are dizygotic. Twins of different sexes are always dizygotic (fraternal). Twins of the same sex may be monozygotic or dizygotic. Although monozygotism is random—ie, it does not fit any discernible genetic pattern—dizygotism has hereditary determinants.

In North America, dizygotic twinning occurs about once in 83 conceptions and triplets occur about once in 8000 conceptions. A traditional approximation of the incidence of spontaneous multiple pregnancies is as follows:

Twins	1:80
Triplets	$1:80^2 = 1:6400$
Quadruplets (etc)	$1:80^3 = 1:512{,}000$

About 75% of dizygotic twins are the same sex. Many factors influence dizygotic twinning including age and ethnicity. Race is a factor, with multiple gestations most common in blacks, least common in Asians, and of intermediate occurrence in whites. The incidence of spontaneous dizygotic twinning varies from 1.3 in 1000 in Japan to 49 in 1000 in western Nigeria. The rate in the United States is about 12 in 1000. Spontaneous twinning increases with advancing maternal age. The widespread use of ART has increased the frequency of dizygotic twins with a minimal effect on the incidence of monozygotic twins.

Dizygotic twinning is more common among women who become pregnant soon after cessation of long-term oral contraception. This may be a reflection of high “rebound” gonadotropin secretion. Induction of ovulation in previously infertile patients has resulted in many multiple pregnancies—even the gestation of septuplets and octuplets. The estrogen analog clomiphene citrate increases the incidence of dizygotic pregnancy to about 5–10%.

Clinically, zygosity cannot be ascertained prenatally, so chorionicity seen on ultrasound is a useful surrogate marker for stratification of perinatal risk, with increased risks associated with monochorionicity.

Prevention

A. Multiple Gestations

Although ovulation induction agents result in fewer multiple pregnancies when used by experts, even in the best of hands, it is inevitable that some multiple pregnancies will occur. For example, clomiphene citrate induction of multiple ovulation increases the rate of dizygotic pregnancy above 5–10%.

With many forms of ART (eg, ovulation induction, in vitro fertilization), iatrogenic multiple pregnancies regularly occur in which the number of fetuses is so great that they may preclude any being carried to the point of viability. When this occurs, many authorities recommend multifetal pregnancy reduction by transabdominal intracardiac potassium chloride injection. Efforts are under way to recommend limiting the number of embryos transferred; legislation to this effect has been enacted in the United Kingdom. The American Society for Reproductive Medicine is now recommending single-embryo transfers in good-prognosis candidates.

Clinical Findings

With the ready availability of ultrasound, it is rare that multiple gestations go undiagnosed during pregnancy. Early diagnosis facilitates appropriate prenatal care.

A. Symptoms & Signs

All of the common annoyances of pregnancy are more troublesome in multiple gestations. The effects of multiple gestation on the patient include earlier and more severe pressure in the pelvis, nausea, backache, varicosities, constipation, hemorrhoids, abdominal distention, and difficulty in breathing. A “large pregnancy” may be indicative of twinning (distended uterus). Fetal activity is greater and more persistent in twinning than in singleton pregnancy.

Considering the possibility of multiple gestation is essential to early diagnosis. If one assumes that all pregnancies are multiple until proved otherwise, physical examination alone will identify most cases of twinning before the second trimester. Indeed, diagnosis of twinning is possible in over 75% of cases by physical examination. The following signs should alert the physician to the possibility or definite presence of multiple pregnancy:

1. Uterus larger than expected (>4 cm) for dates.
2. Excessive maternal weight gain that is not explained by edema or obesity.
3. Polyhydramnios, manifested by uterine size out of proportion to the calculated duration of gestation, is almost 10 times more common in multiple pregnancy.
4. History of assisted reproduction.
5. Elevated maternal serum α fetoprotein (MSAFP) values (see following section, Laboratory Findings).
6. Outline or ballottement of more than 1 fetus.
7. Multiplicity of small parts.
8. Simultaneous recording of different fetal heart rates, each asynchronous with the mother’s pulse and with each other and varying by at least 8 beats/min. (The fetal heart rate may be accelerated by pressure or displacement.)
9. Palpation of 1 or more fetuses in the fundus after delivery of 1 infant.

Some of the common complications in early pregnancy may also occur as a result of multiple gestation. For example, maternal bleeding in the first trimester can indicate threatened or spontaneous abortion; however, the dead fetus may be 1 of twins, as demonstrated by realtime ultrasonography (1 anechoic or hypoechoic amniotic sac and 1 normal sac). In the second and third trimester, the demise of 1 fetus in a multiple gestation may rarely trigger disseminated intravascular coagulation (DIC), just as a singleton intrauterine demise might. This theoretical complication is so rare that DIC screening is no longer performed.

B. Laboratory Findings

The majority of multiple gestations are currently identified by using MSAFP screening or routine ultrasound. Indeed, identification of multiple gestation is so important for the institution of appropriate care that many authorities recommend routine ultrasonic scanning for early confirmation of gestational age and then again at 18–20 weeks. First-trimester ultrasonography is even more helpful for determining chorionicity and is becoming standard of care, especially since many patients undergo first-trimester ultrasound for nuchal translucency (NT) screening. Interestingly, NT measurements are similar for a given crown-rump length regardless if it is a singleton, twin, or higher order multiple gestation.

The maternal hematocrit and hemoglobin values and the red cell count usually are considerably reduced, in direct relationship to the increased blood volume. Indeed, maternal hypochromic normocytic anemia is almost universal because fetal demand for iron increases beyond the mother's ability to assimilate iron in the second trimester.

C. Ultrasound Findings

Ultrasonography is the preferred imaging modality for the diagnosis of multiple gestation and is potentially able to differentiate multiple gestation as early as 4–5 weeks (by endovaginal probe). Dichorionicity is suggested by fetuses of different genders, separate placentas, a thick (>2 mm) dividing membrane, or a "twin peak sign" in which the membrane inserts into 2 fused placentas. In the absence of these findings, monochorionicity is likely, particularly if the twins are spontaneously conceived. A first-trimester scan is highly recommended since definitive diagnosis of chorionicity may not be possible with second- and third-trimester scans. See the chapter on imaging in pregnancy (Chapter 11) for more details.

Differential Diagnosis

Multiple pregnancy must be distinguished from the following conditions.

A. Singleton Pregnancy

Inaccurate dates may give a false impression of the duration of the pregnancy, and the fetus may be larger than expected.

B. Polyhydramnios

Either single or multiple pregnancy may be associated with excessive accumulation of fluid.

C. Hydatidiform Mole

Although usually easily distinguished from multiple gestation, this complication must be considered in diagnosis early in pregnancy.

D. Abdominal Tumors Complicating Pregnancy

Fibroid tumors of the uterus, when present in great numbers, are readily identified. Ovarian tumors are generally single, discrete, and harder to diagnose. A distended bladder or full rectum may elevate the pregnant uterus.

E. Complicated Twin Pregnancy

If 1 dizygotic twin dies early in pregnancy and the other lives, the dead fetus may become flattened and mummified (fetus papyraceous; see earlier section on fetal pathologic factors). Its portion of a fused placenta will be pale and atrophic, but remnants of 2 sacs and 2 cords may be found. If 1 twin dies in late pregnancy, considerable enlargement of the uterus persists, although the findings on palpation may be unusual and only 1 fetal heartbeat will be heard. Ultrasonography can confirm the diagnosis.

Complications

A. Maternal

A gravida with a multiple pregnancy has about 5 times the likelihood of having a morbid (febrile, complicated) course as an average patient of the same parity with a single fetus.

Multiple gestations are associated with an increased incidence of maternal anemia, urinary tract infection, preeclampsia-eclampsia, hemorrhage (before, during, and after delivery), and uterine atony. Although blood volume is increased in multiple gestations, maternal anemia often develops because of greater demand for iron by the fetuses. However, prior anemia, poor diet, and malabsorption may precede or compound iron deficiency during multiple gestation. Hypochromic normocytic anemia is 2–3 times more common in multiple pregnancy than in singleton pregnancy. Urinary tract infection is at least twice as frequent in multiple pregnancy as in singleton pregnancy due to increased ureteral dilatation secondary to higher serum progesterone and uterine pressure on the ureters. Preeclampsia–eclampsia occurs about 3 times more often in multiple pregnancy than in a singleton pregnancy.

Additionally, respiratory tidal volume is increased, but the woman pregnant with twins often is “breathless” (possibly due to increased levels of progesterone). Marked uterine distention and increased pressure on the adjacent viscera and pelvic vasculature are typical of multiple gestation. Theca lutein cysts and even ascites may be seen as a result of abnormally high levels of chorionic gonadotropin in occasional multiple pregnancies. The maternal cardiovascular, respiratory, gastrointestinal, renal, and musculoskeletal systems are especially subject to stress in multiple pregnancy, combined with greater maternal–fetal nutritional requirements.

Placenta previa develops more frequently because of the large size of the placenta or placentas. Placenta previa may be responsible for antepartum bleeding, malpresentation, or unengagement of the first fetus. A large placenta (or placentas) and possibly fundal scarring or tumor may lead to low implantation of the placenta. Premature separation of the placenta may occur antepartum, perhaps in association with preeclampsia–eclampsia or with rupture of membranes of twin A and the initiation of strong uterine contractions, or after the delivery of the first twin. Careless traction on the first cord may encourage early partial separation of the placenta.

A thinned uterine wall, secondary to unusually large uterine contents, is associated with hypotonic uterine contractions and a longer latent stage of labor. However, prolonged labor is uncommon in multiple pregnancy because rupture of the membranes generally is followed by improvements in the uterine contraction pattern. Hemorrhage is about 5 times as frequent in multiple as in single pregnancies. Uterine atony often is accompanied by excessive loss of blood postpartum due to inability of the overdistended uterus to contract well and remain contracted after delivery.

Operative intervention is more likely in multiple pregnancy because of increased risk of obstetric problems such as malpresentation, prolapsed cord, and fetal distress.

Glucose tolerance tests demonstrate that rates of both gestational diabetes mellitus and gestational hypoglycemia are much higher in multiple gestation compared with findings in singleton pregnancy. This is not surprising given the placental origin of human placental lactogen, which causes insulin resistance.

B. Fetal

Perinatal mortality and morbidity rates are increased in multiple pregnancy, mainly because of preterm delivery and its complications (ie, trauma or asphyxia). The incidence of spontaneous abortion of at least 1 of several fetuses is increased in multiple pregnancy. Stillbirth occurs twice as often among twins as among singleton pregnancies. Common causes of fetal death are developmental anomalies, fetal growth restriction, cord compression, or placental disorders. In general, the higher the number of fetuses, the greater is the risk of fetal growth restriction.

Monochorionic twin pregnancies have a substantially increased risk of death as compared with their dichorionic counterparts because of the almost ever-present vascular anastomoses that may cause the twin–twin transfusion syndrome or acute feto-fetal hemorrhage after intrauterine demise of 1 twin. The greatest hazard from cord compression is cord entanglement of monozygotic twins with only 1 amniotic sac. Almost twice as many monozygotic as dizygotic twins die in the perinatal period. Attrition is even greater for triplets, quadruplets, and higher order pregnancies. Even so, preterm delivery and intrapartum complications are the most common causes of fetal loss and morbidity in multiple pregnancy.

Preterm premature rupture of the membranes and pre-term labor and delivery, often with a long prodromal phase, are common occurrences in multiple pregnancy. The average gestational age at delivery is 36–37 weeks for twins, 33 weeks for triplets, and 31 weeks for quadruplets. Efforts to reduce the incidence of prematurity have thus far been largely unsuccessful. All too frequently, preterm delivery is occasioned by premature rupture of the membranes, which occurs in about 25% of twin, 50% of triplet, and 75% of quadruplet pregnancies. Delivery before the 36th week is twice as frequent in twin pregnancies as in singleton pregnancies. Intracranial injury is more common in premature infants, even those delivered spontaneously. An increased risk of cerebral palsy is found in twins, especially very low-birthweight babies, and also in liveborn co-twins of fetuses who died in utero.

Prolapse of the cord occurs 5 times more often in multiple than in singleton pregnancy. Premature separation of the placenta before delivery of the second twin may cause death of the second twin by hypoxia. When there are 2 separate placentas, 1 of them may deliver immediately after the first twin. Although the second twin may not be compromised, it is best to proceed with its delivery, both for its protection and to conserve maternal blood.

Major fetal structural malformations are present in approximately 2% of twin infants, compared with 1% of singletons, whereas minor malformations are found in 4% of twins compared with about 2.5% of singletons. Monozygotic twins are at higher risk than dizygotic twins.

Fetal malpresentation is more common in multiple gestations. Both twins present in cephalic presentation in almost 50% of cases. Twin A will be cephalic and twin B a breech in slightly more than 33% of cases (Fig. 17–3). Both fetuses will be breech presentations in 10% of cases, and almost that many will be single (or double) transverse presentations. Approximately 70% of first twins present by the vertex. Breech presentation occurs in slightly more than 25%. Overall, noncephalic presentation occurs 10 times more often in multiple pregnancy than in singleton pregnancy.

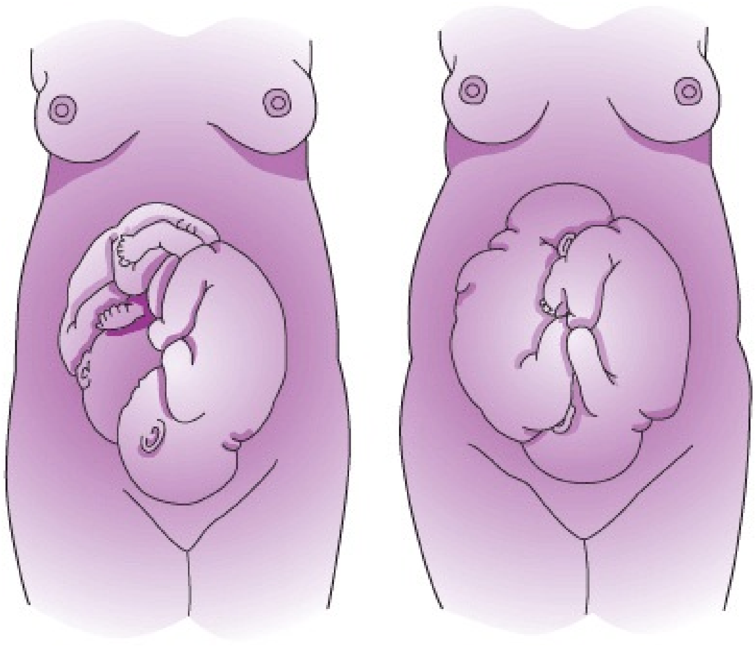

Figure 17–3. Left: Both twins presenting by the vertex. **Right:** One cephalic and one breech presentation. (Reproduced, with permission, from Benson RC. *Handbook of Obstetrics & Gynecology*. 8th ed. Los Altos, CA: Lange; 1983.)

Treatment

A. Prenatal Diagnosis

The usual indications for prenatal diagnosis and counseling in a singleton pregnancy also apply to twin and higher order gestations. Because the incidence of twin gestation increases with maternal age, women with multiple gestations are often candidates for prenatal genetic diagnosis. Because the risk of aneuploidy is increased, some centers offer invasive testing to all patients carrying multiple gestations who will be over age 33 at delivery. Now that most patients have prenatal screening with ultrasound and/or maternal serum testing, the role of age is becoming less important for stratification of risk for aneuploidy. Genetic counseling should make clear to the patient the need to obtain a sample from each fetus, the risk of a chromosomal abnormality, potential complications of the procedure, the possibility of discordant results, and the ethical and technical concerns when 1 fetus is found to be abnormal.

In twin pregnancies not accompanied by neural tube defects, the median MSAFP level will be 2.5-fold that of the median level for singleton pregnancies at 14–20 weeks’ gestation. The levels in triplets and quadruplets are 3 and 4 times as high, respectively. A value greater than 4.5 times the median is considered abnormal for twin gestations and requires a targeted ultrasound and possible amniocentesis for the determination of amniotic fluid α fetoprotein and acetylcholinesterase. Serum screening is less effective in multiple gestations, with serum screening detecting only 47% of Down syndrome pregnancies. NT screening with first-trimester serum markers can detect about 70% of Down syndrome fetuses in twin pregnancies, with some added benefit to incorporating second-trimester markers.

Both amniocentesis and chorionic villus sampling can safely be performed in multiple gestations in experienced centers. Careful documentation of the location of the fetuses and the membrane separating the sacs is important in case there is discordance for aneuploidy. Selective termination of an aneuploid fetus can be performed via ultrasound-guided intracardiac injection of potassium chloride. The pregnancy can then continue carrying the normal twin only. Multifetal reduction may be performed to decrease the risk of serious perinatal morbidity and mortality associated with preterm delivery by reducing the number of fetuses from 3 or more to twins or even a singleton.

B. Antepartum Management

To prevent the complications of multiple gestation, it is imperative to make the diagnosis as early in pregnancy as possible. Later in pregnancy, ultrasonography is useful to monitor the growth of the fetuses and to detect structural anomalies. It is recommended to perform routine growth scans on twins every 4 weeks in the third trimester, or more frequently if growth restriction is detected. Antepartum testing is routinely performed in twins with suspected intrauterine growth restriction or growth discordance but is not universally performed in normally grown uncomplicated twins.

Enhanced antenatal care assists in improving outcome. The most commonly used techniques are iron and calcium supplementation, vitamin and folic acid administration (in an attempt to avoid anemia), a high-protein diet, and more weight gain than usual (ideal weight for height plus 35–45 lb). Supplementation with magnesium, zinc, and essential fatty acids has also been recommended.

There is not enough evidence to suggest a policy of routine hospitalization for bed rest in multiple pregnancy because no reduction in the risk of preterm birth or perinatal death is evident. There is also no evidence that prophylactic cerclage improves outcome. More frequent antenatal visits are scheduled, and several authorities recommend closely following cervical length by ultrasound. Early and prompt therapy for any complications (eg, vaginal infections, pre-eclampsia–eclampsia) should be instituted, bearing in mind that preeclampsia–eclampsia is a common complication of multiple pregnancy.

Tocolytic drugs may be used to suppress premature labor and extend gestation 48 hours so that the effects of steroids may be realized. There is no evidence that long-term oral or intravenous tocolysis improves outcome; however, this is still commonly practiced to a degree. Most authorities recommend starting with intravenous magnesium sulfate. If terbutaline is used, very close monitoring for pulmonary edema must be maintained, because this complication is much more likely with administration of β-mimetic agents in multiple gestation. Also, indomethacin is a very effective tocolytic in the second and early third trimesters, but it may influence fetal ductal constriction and decreased amniotic fluid volume, complications that appear to be gestational age dependent, so it should not be used after 32 weeks’ gestation. Fetal fibronectin can be helpful, particularly when negative, to determine how aggressively to tocolyze.

Neonatal outcome is very much dependent on gestational age at delivery. In general, morbidity and mortality rates are similar for twins and singletons of equivalent gestational ages. Advances in neonatal intensive care have made survival possible even at 23 weeks’ gestation, although usually with considerable morbidity, including but not limited to intra-ventricular hemorrhage, chronic lung disease, and necrotizing enterocolitis. Because intact survival is much more likely after 32–34 weeks, it is desirable to prolong gestation at least to this point when possible. The adage “1 day in utero saves 2 days in intensive care” applies to the economic as well as the emotional costs of caring for premature infants. For the dichorionic diamniotic twin pregnancy that is otherwise uncomplicated, recent studies have found that neonatal morbidity is reduced when delivery is at about 38 weeks, so routine delivery at that time is recommended, by either induction of labor or caesarean if indicated.

Optimal treatment of twin–twin transfusion syndrome in utero remains controversial. Laser therapy for ablation of anastomotic placental vessels is available in several centers around the United States and shows improved short-term survival as compared to expectant management and serial amnioreduction. Two-year neurodevelopmental outcomes are also improved in patients treated with laser. After delivery, therapy for twin–twin transfusion syndrome includes replacing blood in the donor twin to correct fluid and electrolyte imbalance. In the recipient twin, phlebotomy may be necessary until normal venous pressure is restored. Often, other therapy for cardiac failure (eg, digitalis) is necessary.

C. Labor & Delivery

All patients carrying a multiple gestation should be delivered in a well-equipped hospital by an experienced physician who has adequate assistance. It is desirable to have a pediatrician (or neonatologist) in attendance. Delivery must be done in the operating room in case an emergent caesarean section is needed for twin B. An early epidural is recommended; in case of emergent caesarean section, anesthesia is already established and general anesthesia can usually be avoided. Prematurity, trauma of manipulative delivery, and associated asphyxia are the major preventable causes of morbidity and mortality in twins, especially the second twin.

Admit the patient to the hospital at the first sign of suspected labor or preterm labor, if there is leakage of amniotic fluid, or if significant bleeding occurs. We instruct patients to come in for >4 contractions per hour at <34 weeks' gestation. An ultrasound evaluation should be performed to ascertain the presentation of each fetus and its estimated fetal weight. Routine, continuous electronic fetal heart rate monitoring is recommended. Labor should be conducted so that immediate caesarean section can be performed if required. A pediatric nurse team for each infant plus obstetric and anesthesiologic attendants should be present. Insert an intravenous line and send a specimen of blood for typing, antibody screening, and complete blood count.

If either twin shows signs of persistent compromise, proceed promptly to caesarean section delivery. Other indications for primary caesarean section include (but are not limited to) malpresentation, monoamniotic twins, gross disparity in fetal size, and placenta previa. In the United States, all higher order multiple gestations are delivered by caesarean delivery.

In a woman with a previous lower segment caesarean scar, limited literature suggests that delivery of twins does not mandate a repeat caesarean section in the absence of other complications. Concomitant with increasing rates of elective and nonelective caesarean section, caesarean by patient request is becoming more common. In addition, less resident training in vaginal breech delivery can decrease a clinician's comfort with breech extraction of a second twin.

Management of twins that are candidates for vaginal delivery may proceed as outlined below. Intrapartum twin presentations may be classified as follows: (1) twin A and twin B cephalic (slightly >40% of all twins); (2) twin A vertex and twin B noncephalic (almost 40%); and (3) twin A noncephalic and twin B cephalic, breech, or transverse (about 20%).

The current intrapartum management of twins is as follows. For cephalic–cephalic presentations in labor (category 1 above), vaginal delivery of both twins may be chosen in the absence of standard indications for caesarean section delivery. Of course, if either twin develops fetal distress, caesarean section delivery should be performed. Category 2 twins, each >32 weeks and weighing more than 1500–2000 g, can usually be managed successfully by vaginal delivery of both. This is generally accomplished by total breech extraction of twin B immediately after the delivery of twin A if the patient has been consented for this procedure. External cephalic version of twin B has also been described. While external version was previously recommended for conversion of twin B from breech to cephalic, now most operators deliver vaginal second twins by complete breech extraction. When either twin A or both twins are noncephalic (category 3), primary caesarean section should be performed. This is also sometimes recommended in cases of noncephalic twin B where the estimated fetal weight is much greater than that of twin A. The ultrasound machine should be in the operating room to confirm the presentation of twin B after the delivery of twin A. The amount of time between delivery of twin A and B is still a matter of controversy. If electronic fetal monitoring suggests fetal well-being, it is not necessary to deliver twin B within a prescribed amount of time such as 30 or 60 minutes. Difficult forceps operation or rapid extraction should be avoided, but forceps to protect the aftercoming premature head may be useful. The umbilical cord should be clamped promptly to prevent the second twin of a monozygotic twin pregnancy from exsanguinating into the first born.

Perform a vaginal examination immediately after delivery of twin A to note the presentation and station of the second twin, the presence of a second sac, an occult cord prolapse, or cord entanglement.

Cut the cord as far outside the vagina as possible so that it can hang loosely to permit vaginal examination or manipulation. This eliminates inadvertent cord traction on the placenta. Tag and label the cords (twin A and B) so that they may be associated with the proper placenta or placentas.

One twin may obstruct the delivery of both fetuses in locked twins. In this circumstance, twin A is always breech and twin B cephalic presentation, and the heads become impacted in the pelvis. Locked twins can be avoided by caesarean delivery in all cases in which it is known that twin A is not cephalic. However, if the obstetrician is presented with an emergent case of locked twins (Fig. 17–4), having an assistant support the twin already partially delivered as a breech while pushing both heads upward out of the pelvis with rotation of both fetuses may accomplish delivery of the first. This may require deep anesthesia. If this cannot be done, caesarean with abdominal delivery of both fetuses may be the safest route. An alternative while caesarean preparations are under way is to elevate the partially delivered twin, establish an airway, and protect the cord.

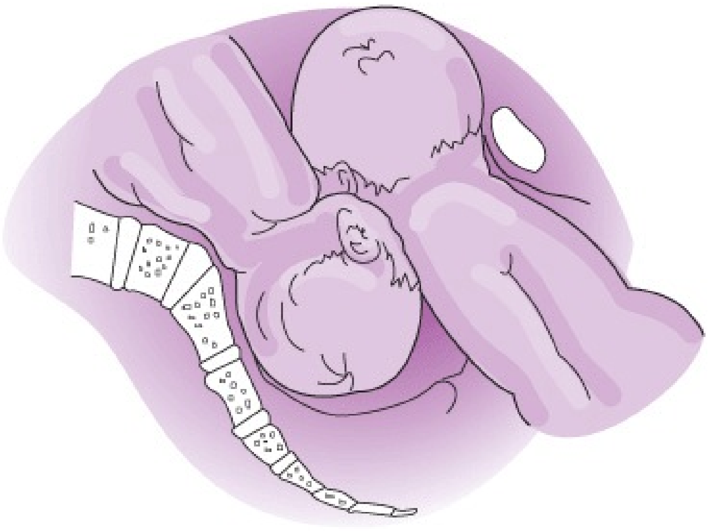

Figure 17–4. Locked twins. (Reproduced, with permission, from Benson RC. *Handbook of Obstetrics & Gynecology*. 4th ed. Los Altos, CA: Lange; 1971.)

Postpartum hemorrhage is common in multiple pregnancy. Increased intravenous oxytocin, elevation, and massage of the fundus and an intravenous ergot or prostaglandin product (only after the last fetus is delivered) may be required. After delivery, if separation of the placenta is delayed or bleeding is brisk, manual extraction of the placenta may be necessary. Currently, we recommend prophylactic rectal misoprostol in the operating room followed by oral misoprostol every 6 hours for 24 hours after delivery for all multiple gestations.

Preeclampsia–eclampsia and premature labor and delivery are managed as outlined elsewhere in this book.

If it is desired to determine zygosity after delivery, concordance of placental examination, clinical comparisons, and hematologic and serologic tests provides presumptive evidence of monozygotic twinning. The total probability of diagnosis of zygosity is >95% using ABO, MNSs, Rh, Kell, Kidd, Duffy, and Lewis A and B antigens and approaches 100% using chromosomal analysis.

Prognosis

The US maternal mortality rate for women carrying a multiple gestation is only slightly higher than for singletons. With diligent care, many mothers and babies will do well. A history of previous dizygotic twins increases the likelihood of multiple gestation in a future pregnancy 10-fold.

Third-Trimester Vaginal Bleeding

Sarah A. Wagner, MD

Vaginal bleeding in the third trimester can be very worrisome to a patient and clinician. When evaluating a patient with this problem, it is important to consider all the possible diagnoses in order to arrive at the appropriate conclusion and treatment. The most common causes of third-trimester vaginal bleeding are:

- Cervical bleeding associated with cervical change
- Abruptio placentae
- Placenta previa
- Vasa previa

Cervical bleeding associated with cervical change will be discussed in the section on the evaluation of preterm labor and labor at term.

ABRUPTIO PLACENTAE

Abruptio placentae (placental abruption) is defined as the premature separation of the normally implanted placenta from the uterine wall after 20 weeks of gestation but prior to the delivery of the infant. It is diagnosed retrospectively, evident only when the inspection of the placenta reveals a clot over the placental bed with disruption of the underlying placental tissue. The placental tissue may not show overt evidence of disruption if the abruption-to-delivery interval is short. One-third of all antepartum bleeding in the third trimester is due to placental abruption, and it will occur in 1 in 75–225 deliveries. About 1 in 830 abruptions end in fetal demise.

ESSENTIALS OF DIAGNOSIS

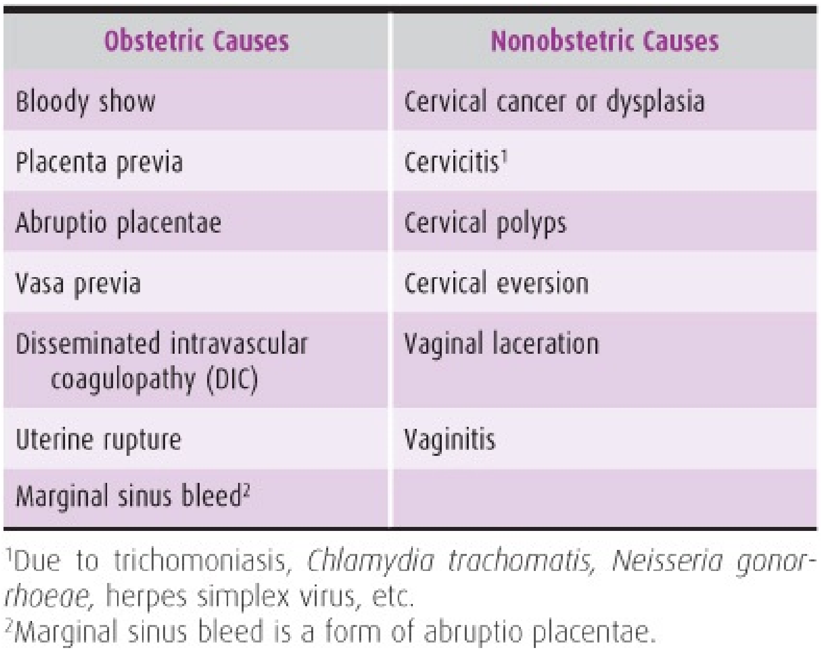
- ▸ Bleeding from the vagina
- ▸ Uterine activity
- ▸ Fetal heart rate abnormalities
- ▸ Changes in maternal hemodynamic status

Pathogenesis

Placental abruption may be the end of a chronic vascular pathologic process or may be due to a single inciting event. Bleeding due to vascular disruption accumulates and tracks along the decidua, separating the placenta from the remaining decidual layer. This may result in a partial abruption, referring to a self-limited hematoma that does not dissect the placental attachment further, or it may proceed to a complete abruption, leaving no decidual interface intact.

Abruption can be classified into 3 broad categories that allow for a description of the clinical and laboratory findings (Table 18–1).

Table 18–1. Common causes of third-trimester bleeding.



Obstetric Causes	Nonobstetric Causes
Bloody show	Cervical cancer or dysplasia
Placenta previa	Cervicitis[1]
Abruptio placentae	Cervical polyps
Vasa previa	Cervical eversion
Disseminated intravascular coagulopathy (DIC)	Vaginal laceration
Uterine rupture	Vaginitis
Marginal sinus bleed[2]	

[1] Due to trichomoniasis, *Chlamydia trachomatis, Neisseria gonorrhoeae,* herpes simplex virus, etc.

[2] Marginal sinus bleed is a form of abruptio placentae.

- Grade 1: A small amount of vaginal bleeding and abnormal uterine activity or irritability are usually noted. The fetal heart rate tracing is within normal limits. Maternal hemodynamic status is normal, and all coagulation studies and laboratory values are within normal limits.
- Grade 2: A mild to moderate amount of vaginal bleeding is noted. Uterine activity may be tetanic or with frequent palpable and painful contractions. The fetal heart rate tracing may show decreased variability or late decelerations. Maternal hemodynamic status shows signs of compensation, including orthostatic hypotension and tachycardia, while maintaining overall blood pressure. Maternal fibrinogen may be decreased.
- Grade 3: External uterine bleeding may range from mild (likely concealed) to severe. The uterus is typically painful and tetanic. Fetal death has occurred. Maternal hemodynamic status is unstable, showing signs of severe volume depletion with hypotension and tachycardia. Thrombocytopenia and coagulation panel value abnormalities are present. Fibrinogen concentration level is typically <150 mg/dL.

The primary cause of placental abruption is unknown in most cases; however, it has been linked to several risk factors. Mechanical force or trauma is sometimes implicated, usually as a result of domestic violence or a motor vehicle accident. The clinical picture following a traumatic event can be severe in nature, and symptoms typically present within 24 hours. Blunt abdominal trauma can compress the placental interface, allowing for a shearing effect when decompression occurs. Rapid deceleration is the typical inciting event during a motor vehicle accident. Prolonged continuous fetal monitoring is critical in assuring the safety of the pregnancy. The mechanical force of rapid decompression of the uterus is an uncommon etiology. This can occur after the delivery of the first infant during the vaginal delivery of a twin gestation or after rupture of membranes in a patient with polyhydramnios.

Several factors can put a patient at risk for this disease. Maternal hypertension (>140/90 mm Hg) has been strongly associated with the occurrence of placental abruption. In fact, all hypertensive disorders of pregnancy have been implicated as risk factors. Forty to fifty percent of patients with grade 3 abruptions are found to have hypertensive disease of pregnancy.

Smoking is associated with a significant increase in the incidence of placental abruption, with a 2.5 relative risk of abruption severe enough to cause fetal death. Hypertension with concomitant cigarette smoking during pregnancy further increases the risk of abruption.

The relationship between age and the risk of placental abruption is not clear when other confounding factors, such as hypertension and multiparity, are corrected. Most authors feel that there is no direct correlation; however, a Norwegian study done over 15 years showed a strong relationship between placental abruption and maternal age among all levels of parity.

Increasing parity is a risk factor for placental abruption. The incidence in primigravidas is 1%, and this incidence increases to 2.5% in grand multiparas, correcting for confounding factors. This may be due to impaired decidualization after the implantation of multiple past placentas on the uterine wall.

Acquired or inherited thrombophilias may be associated with an increased risk of abruption. Factor V Leiden and prothrombin gene mutations have been implicated in multiple studies. Less common inherited thrombophilias, including protein C, protein S, and antithrombin deficiencies, may also be associated.

Approximately 2–5% of pregnancies that are complicated by preterm premature rupture of membranes will also be complicated by placental abruption. There is an even more substantial risk in patients who subsequently develop chorioamnionitis after rupturing membranes. It is difficult to ascertain whether the abruption is the cause or an effect of the ruptured membranes.

There is a well-known association between cocaine abuse and placental abruption, and up to 10% of women who use cocaine during pregnancy will incur this complications. It is likely due to acute vasoconstriction and disruption of vascular integrity directly as a result of cocaine use.

A history of placental abruption significantly predisposes a patient to another placental abruption. Five to 17% of all pregnancies complicated by abruption will recur in subsequent pregnancies. After 2 abruptions, the risk of recurrence increases to 25%. The reason for this association is unknown.

Clinical Findings

A. Symptoms & Signs

Most placental abruptions will present with the clinical triad, although many will not fill all 3 of the following categories:

- Fetal distress or fetal death: Fetal distress is typically the first clinical sign among patients who have continuous fetal monitoring during the abruption. A nonreassuring fetal heart rate tracing or poor biophysical profile score may indicate fetal compromise from a decrease in the placental exchange surface area or from severe maternal hypotension due to a large blood loss.
- Tetanic uterine activity (ie, contractions).
- Uterine bleeding, external or concealed.

Prompt evaluation is critical in caring for the patient with third-trimester uterine bleeding and possible placental abruption. All other common and potentially life-threatening causes of bleeding should be ruled out, including placenta previa, vasa previa, vaginal trauma, and vaginal or cervical malignancy. Once all other causes have been ruled out, placental abruption becomes the most likely diagnosis. Nearly 80% of patients with placental abruption will present with the complaint of vaginal bleeding. The 20% who do not exhibit this hallmark will commonly be diagnosed with labor or preterm labor. Patients occasionally complain of symptoms consistent with uterine tenderness and will be found to have increased uterine tone upon physical exam. Patients with these symptoms upon presentation will have a more severe abruption.

B. Laboratory Findings

Blood type and Rh status, hemoglobin, hematocrit, platelet count, coagulation studies, and fibrinogen level should be sent. A Kleihauer-Betke test should be sent for all women who are Rh negative.

C. Imaging Studies

Ultrasound has become important in the diagnosis and characterization of placental abruption. More than 50% of patients with confirmed abruption will have evidence of hemorrhage on ultrasound. Echogenicity, size, and location of the hemorrhage can be described, allowing the clinician to better understand the timing and severity of the abruption. If the ultrasound is performed during the early phases of the abruption, the area of hemorrhage will appear isoechoic or hyperechoic compared with the echogenicity of the placenta. The hematoma becomes hypoechoic within 1 week and sonolucent within 2 weeks of the initial hemorrhage.

The size and location of the hematoma are important in evaluating the severity of the abruption. A larger hematoma is associated with a worse prognosis than a smaller hematoma. A retroplacental hemorrhage has a worse prognosis than a subchorionic hemorrhage, which is defined as a collection of blood between the chorion and the decidua. A retroplacental hemorrhage that is >60 mL in volume has at least a 50% morality rate associated with it.

Prevention

Although no intervention has been shown to prevent placental abruption, known risk factors for placental abruption include poorly controlled maternal hypertension, smoking, and cocaine use. Counseling patients against smoking and cocaine use and helping them find appropriate cessation programs may reduce the risk of abruption, as may anti-hypertensive medication for women with poorly controlled hypertension.

Treatment

The hemodynamic status of the mother should be immediately evaluated and stabilization performed if necessary. Two large-bore intravenous lines should be placed, and the fetal heart rate should be monitored continuously. Crystalloid infusion should be started to rapidly correct the volume deficit, and packed red blood cells should be given if severe anemia is evident or if there is continued uterine bleeding. Urine output should be maintained above 30 mL/h. If no transfusion is required immediately, 4 units of packed red blood cells should be crossed and held nearby. Fresh frozen plasma should be administered for a fibrinogen level <100 mg/dL, and platelets should be given if the platelet count is <20,000 or <50,000 for a patient with severe continued hemorrhage or a requirement for emergent caesarean delivery. The clinician should not be falsely reassured by normal blood pressure and pulse, as the patient may have had hypertension previously and has had too rapid a volume loss to produce tachycardia.

Mode and timing of delivery depend greatly on the severity of the placental abruption and the gestational age of the pregnancy. If a grade 1 abruption has occurred and the gestational age is >37 weeks, the most appropriate course of action is induction or augmentation of labor with very close monitoring of the maternal and fetal status at all times. In the case of a preterm fetus with a grade 1 abruption, conservative management is indicated. Expectant management with short-term hospitalization has been shown to prolong the length of the pregnancy and has not been shown to increase morbidity or mortality of the fetus or the mother. If conservative management is pursued, administration of corticosteroids to promote fetal lung maturity is indicated if the gestational age is <34 weeks.

If the decision has been made to deliver the infant, close monitoring throughout labor and delivery is imperative. The hemodynamic status of the mother needs to be known at all times, and the fetal heart rate should be evaluated continuously. Serial coagulation studies and complete blood count should be obtained. If possible, an intrauterine pressure catheter should be use to evaluate uterine tone. If it appears that the patient's labor curve is progressing normally, a vaginal delivery is the preferable method of delivery.

An emergent caesarean section may be necessary at any point during labor. An increase in the resting tone of the myometrium may indicate a worsening of the abruption, and the possible compromise of blood flow to the fetus is an indication for emergent delivery. Other indications include a nonreassuring fetal heart rate tracing, severe hemorrhage, and disseminated intravascular coagulation. If an indication for emergent delivery has been identified, the maternal hemodynamic status should be quickly stabilized and correction of coagulopathy should be performed before proceeding. If the fetal status is reassuring and the caesarean is for maternal reasons, the correction of hypovolemia and coagulopathy can be done in a more controlled manner to avoid fluid overload prior to the surgery.

Prognosis

Outcome depends significantly on the gestational age of the fetus and the severity of the abruption. Prematurity, intrauterine growth restriction, caesarean delivery, and perinatal mortality are all increased in pregnancies that are complicated by placental abruption. In 1999, a review found that a pregnancy complicated by abruption, of any level of severity, had a 9-fold increase in the incidence of perinatal death, a 2-fold increase in the incidence of intrauterine growth restriction, and a 4-fold increase in the incidence of preterm birth.

Placental abruption is also associated with a substantial recurrence risk in future pregnancies of approximately 5–17%. After a history of 2 pregnancies affected by placental abruption, the risk of recurrence is approximately 25%. Unfortunately, there is no intervention that has been demonstrated to reduce the risk of recurrence. Preconception counseling should be targeted toward eliminating known risk factors such as smoking or cocaine use.

Anenth CV, Oyelese Y, Srinivas N, et al. Preterm premature rupture of membranes, intrauterine infection, and oligohydramnios: Risk factors for placental abruption. *Obstet Gynecol* 2004;104:71. PMID: 15229003.

PLACENTA PREVIA

When the placenta implants such that the placental tissue is located adjacent to or overlying the internal cervical os, it is called **placenta previa**. Placenta previa is the leading cause of third-trimester bleeding, complicating 4 in 1000 pregnancies over 20 weeks. The incidence is higher in early pregnancy prior to the development of the lower uterine segment, and most of these previas resolve as the pregnancy progresses.

There are 3 types of placenta previa (Fig. 18–1):

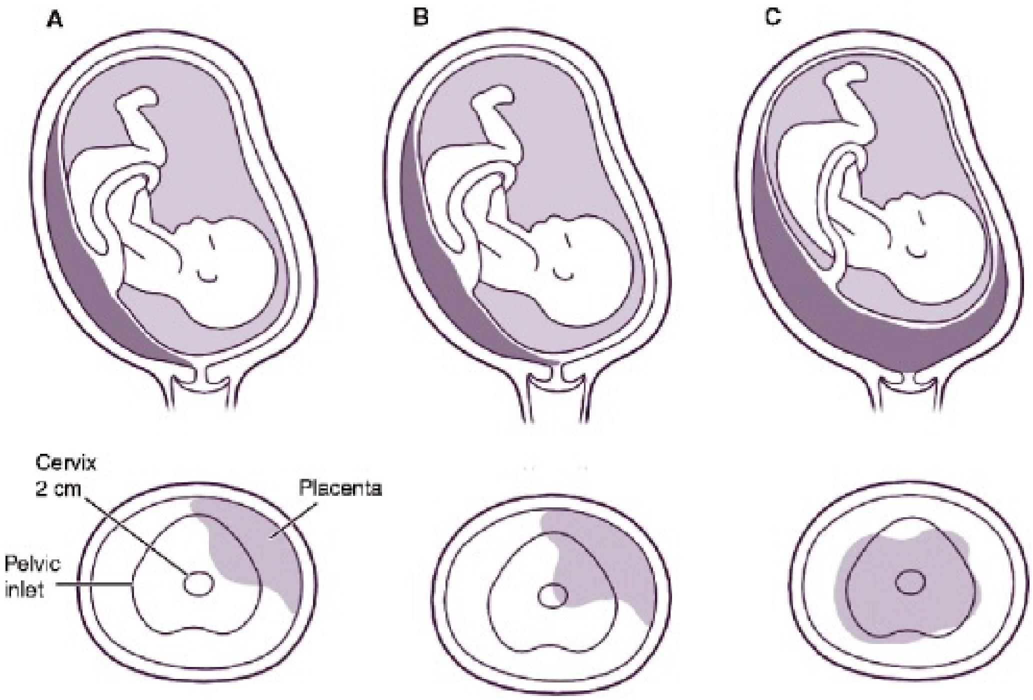


Figure 18–1. A: Marginal placenta previa. **B:** Partial placenta previa. **C:** Complete placenta previa.

- Marginal placental previa: Characterized by the placenta being proximate to the margin of the internal os. It does not cover the os.
- Partial placenta previa: The placenta partially occludes the os, but does not completely cover it.
- Complete placenta previa: The internal os is fully covered by the placenta. This type is associated with the greatest risk of morbidity and mortality because it can cause the greatest amount of blood loss.

ESSENTIALS OF DIAGNOSIS

- Painless vaginal bleeding
- Ultrasonographic findings consistent with placenta previa

Pathogenesis

When a placenta implants in the lower part of the uterus, the pregnancy is at risk for placenta previa. There are several risk factors, including multiparity, increasing maternal age, history of prior caesarean section or uterine surgery, and multiple gestation.

Multiparas are at higher risk for placenta previa compared to nulliparas. The incidence of previa in nulliparas is 0.2%, whereas grand multiparas have an incidence of 5%. The theory behind this phenomenon is that once a placenta has implanted into a certain part of the uterine wall, it has permanently altered its constitution, making implantation at a different site more likely in subsequent pregnancies. Increasing maternal age has been a risk factor, and the cause of this association is unclear. The increased risk may be due to higher parity in older mothers, but it may also be an independent risk factor.

The risk of placenta previa increases directly with the number of uterine surgeries a patient has had in the past. This is mostly seen with increasing numbers of caesarean sections. The risk of placenta previa in second pregnancies after a first pregnancy delivered by caesarean section is 1–4%. The risk increases to nearly 10% in patients with 4 or more previous caesarean deliveries. Furthermore, it has been suggested that previas identified in the second trimester in patients with a previous caesarean delivery have a lower likelihood of resolving as the pregnancy progresses. Risk increases with previous curettage for spontaneous or induced abortion, thought to be due to a scarred active segment of the uterus.

Other risk factors for placenta previa include multiple gestation and smoking. This is due to the greater surface area of the placenta in these situations.

Placenta previa can be associated with several other conditions, including malpresentation, preterm premature rupture of membranes, and intrauterine growth restriction. There may also be an increased risk of congenital anomalies; however, there is no association with any specific anomaly.

Patients with placenta previa are at higher risk for developing placenta accreta, increta, or percreta.

- Placenta accreta: There is no decidua basalis, and the fibrinoid layer is incompletely developed.
- Placenta increta: The placenta invades the myometrium.
- Placenta percreta: The placenta penetrates the myometrium and may invade nearby viscera.

Previous uterine surgery is the risk factor most associated with placenta accreta. Patients with no prior uterine surgery and placenta previa will have accreta 4% of the time. Patients with 1 prior uterine surgery and placenta previa will have accreta 10–35% of the time. Multiple prior caesarean deliveries and placenta previa incurs a 60–65% risk of accreta. Two-thirds of patients with placenta accreta will require a caesarean-hysterectomy.

Clinical Findings

A. Symptoms & Signs

Placenta previa typically presents with painless vaginal bleeding, usually in the third trimester. Lack of pain with the presence of bleeding is what distinguishes placenta previa from placental abruption. The bleeding occurs in conjunction with the development of the lower uterine segment. As the myometrium becomes thinner, the placenta–decidua interface is disrupted, causing bleeding. The thinness of the lower uterine segment prevents it from contracting to minimize the bleeding from the uterine surface of the implantation site; however, sometimes the bleeding itself can irritate the myometrium and precipitate contractions.

The clinician should have a high index of suspicion for placenta previa in all patients who present with bleeding after 24 weeks. One-third of patients with placenta previa will present with bleeding before 30 weeks, one-third will present between 30 and 36 weeks, and one-third will present after 36 weeks. Ten percent of all women with previa will reach full term without an episode of bleeding. On average, a patient’s first episode of bleeding will occur at 34 weeks, with delivery at 36 weeks. Risk of perinatal mortality and morbidity decreases linearly as gestational age increases.

B. Laboratory Findings

Baseline admission labs including blood type and Rh status, hemoglobin, hematocrit, and platelet count should be sent. Coagulation studies and fibrinogen concentration are not as important in patients with previa as in patients with abruption; however, if there is any doubt of the diagnosis, these should also be sent. A Kleihauer-Betke test should be sent for all women who are Rh negative.

C. Imaging Studies

Prior to the advent of routine second-trimester ultrasound, patients with placenta previa were diagnosed at the onset of bleeding. Currently, most cases are diagnosed by ultrasound in the second trimester, although most of these will resolve. Five to fifteen percent of all patients will have placenta previa at 17 weeks. Ninety percent of these will resolve by 37 weeks. This occurs because as the lower uterine segment develops, more distance is created between the placenta and the cervix. Complete previa and marginal or partial previa diagnosed in the second trimester will persist in 26% and 2.5% of patients, respectively. All patients who have placenta previa diagnosed before 24 weeks should have a sonogram between 28 and 32 weeks to reassess the position of the placenta.

Treatment

The initial management of a patient with a bleeding placenta previa is very similar to the initial management of a patient with placental abruption. Hemodynamic status of the mother should be immediately evaluated and stabilization performed if necessary. Large-bore intravenous lines should be placed, and the fetal heart rate should be monitored continuously.

Hemodynamic stabilization should be performed immediately. Crystalloid infusion should be started in order to rapidly correct a volume deficit, and packed red blood cells should be given if severe anemia is evident or if there is continued uterine bleeding. The goal hematocrit is at least 30% if the patient is bleeding. If no transfusion is required immediately, 4 units of packed red blood cells should be crossed and held nearby. The urine output should be maintained above 30 mL/h.

Subsequent management depends on gestational age, stability of the mother and fetus, the amount of bleeding, and presentation of the fetus. Delivery is always indicated if there is a nonreassuring fetal heart rate pattern despite resuscitation efforts, including maternal supplemental oxygen, left-side positioning, or intravascular volume replacement; if there is life-threatening maternal hemorrhage; or if the gestational age is >34 weeks and there is known fetal lung maturity. If the fetus is ≥37 weeks of gestational age and there is persistent bleeding or persistent uterine activity, delivery is also indicated. Digital cervical exams should be avoided.

Between 24 and 36 weeks, if maternal and fetal stability and well-being are assured, conservative expectant management may be indicated. About 75% of patients with symptomatic placenta previa are candidates for conservative management, and 50% of these patients can prolong their pregnancy by at least 4 weeks. Thirty percent of patients treated this way will progress to term without bleeding again. Seventy percent will have at least 1 more episode of bleeding, and 10% of these patients will have a third episode.

Conservative management, after stabilization has occurred and little or no uterine bleeding is noted, consists of several steps. Hydration and blood transfusion are given if necessary. Continuous fetal heart rate monitoring is required in cases where there is continued uterine bleeding, contractile activity, or intrauterine growth restriction. Tocolytic agents, if there is no suspicion for placental abruption, may be given if membranes have not been ruptured and there is contractile uterine activity. The patient should be restricted to bed rest with bathroom privileges. She should be given stool softeners, iron supplementation, and vitamin C. Steroids to promote fetal lung maturity should be administered if the gestational age is <34 weeks.

After steroids have been administered, if there is little or no uterine activity or bleeding, the patient may be a candidate for home therapy. To be considered for home therapy, the patient must be very reliable, have 24-hour contact via telephone, and have the ability to return quickly to the hospital at any time. She should remain on bed rest with bathroom privileges and should continue to take stool softeners and vitamin therapy. Strict instructions should be given regarding returning to the hospital if she experiences contractions or another episode of bleeding.

Fetal growth, amniotic fluid index, and placental location should be assessed by ultrasound every 3 weeks. Most experts agree that for the patient with complete placenta previa that is otherwise uncomplicated, delivery is recommended at 36–37 weeks.

If uterine bleeding is not excessive, patients with marginal previa may be delivered vaginally. Upon descent, the fetal head should tamponade bleeding. Abdominal delivery is indicated in most cases of placenta previa and in all cases of complete previa. If a caesarean section is performed, care should be taken not to disrupt the placenta upon fetal delivery. If possible, a uterine incision away from the placental bed should be used. For example, if there is an anterolateral placenta, a vertical incision in the lower uterine segment opposite the site of placental implantation should be used. A high transverse incision may be necessary for a low anterior placenta. In all cases, the operating room should be prepared for the possibility of the necessity to perform a hysterectomy.

As noted earlier, 66% of patients with placenta accreta will require a caesarean-hysterectomy. There are several surgical options if uterine preservation is important. The placenta can be removed and the uterine defect can be oversewn to abate the active focus of bleeding. The area of accreta can be resected and the uterus repaired. The last option includes leaving the placenta in situ. This is only acceptable in patients who are not actively bleeding. The cord should be ligated and cut close to its base. The patient should be treated with antibiotics and possibly methotrexate postpartum. In the rare case where bladder invasion is evident, the placenta should not be removed. These patients will likely require hysterectomy and partial cystectomy. (See Chapter 21.)

Prognosis

Neonatal outcomes have much improved in the last 20 years, secondary to conservative management, the liberal use of caesarean section, improved neonatal care, and earlier diagnosis. The perinatal mortality rate has fallen from 60% to 10% over the past several decades due to the ability to resuscitate and support infants who are increasingly more premature. Most mortality is due to prematurity. An earlier of episode of bleeding brings with it a higher risk of prematurity and thus a higher risk of mortality. The maternal mortality rate has decreased from 25% to <1% in patients with access to health care. Maternal mortality remains high in developing countries.

VASA PREVIA

Vasa previa is a condition in which fetal vessels traverse the membranes in the lower uterine segment, crossing over the cervical os on front of the fetal head. This can occur with a velamentous insertion of the umbilical cord, where Wharton's jelly is not present to protect the fetal vessels, or in the case where a succenturiate lobe of the placenta has a vascular communication traversing the os. Rupture of these vessels can occur with or without rupturing membranes, and the result is fetal exsanguination. Vasa previa complicates approximately 1 in 1000 to 1 in 5000 pregnancies.

ESSENTIALS OF DIAGNOSIS

- Ultrasonographic evidence of vasa previa
- Painless vaginal bleeding upon rupture of membranes
- Fetal heart rate abnormalities
- Positive Apt, Ogita, or Loendersloot tests

Clinical Findings

A. Symptoms & Signs

The typical presentation of vasa previa is vaginal bleeding that occurs upon rupture of membranes with concomitant specific changes in the fetal heart rate tracing. With the onset of bleeding, the fetal heart responds to loss of intravascular volume with reflex tachycardia. Reflex tachycardia is usually followed by bradycardia accompanied by occasional accelerations. With severe fetal anemia, a sinusoidal fetal heart rate pattern may be seen. The clinician must have a high index of suspicion in order to make the correct diagnosis in enough time to prevent fetal death.

B. Laboratory Findings

Very rarely, the fetal heart rate does not show signs of acute volume loss, and the blood can be analyzed to determine its origin. The Apt, Ogita, and Loendersloot tests take between 5 and 10 minutes to perform and are available to identify fetal hemoglobin. They have varying sensitivities depending on the amount of dilution of the blood with amniotic fluid. However, these tests are primarily of historical interest. If a patient is bleeding from a diagnosed or strongly suspected vasa previa, caesarean delivery should be expedited.

C. Imaging Studies

With improvement in ultrasound technology and an increased awareness among providers about this disorder, many cases are now being diagnosed in the antepartum period via ultrasound. The ultrasound finding of either velamentous cord insertion or succenturiate lobe of the placenta should prompt providers to evaluate for vasa previa. The use of color Doppler during transvaginal ultrasound can clearly identify fetal vessels coursing through the fetal membranes and can establish the diagnosis. If the vessel is a fetal artery, pulsed Doppler can help confirm and measurement of the pulse rate can help to ascertain the diagnosis. Vasa previa can be distinguished from funic presentation (free loops of umbilical cord resting adjacent to the cervix) by mapping the fetal vessels from the placenta or cord insertion. Additionally, changes in maternal position may allow for free cord as in funic presentation to move, whereas vessels in a vasa previa will remain in place.

Treatment

If a patient presents with the previously mentioned classic findings, the appropriate course of action is to deliver immediately via caesarean section to prevent impending fetal demise. If the patient has been identified antenatally, it is recommended that the patient be monitored very closely for any evidence of vaginal bleeding and to administer corticosteroids to promote fetal lung maturity. Several experts recommend inpatient observation starting at 32 weeks. Inpatient observation allows for emergent caesarean in event of nonreassuring fetal testing, preterm labor, or pre-term premature ruptured membranes. Empiric delivery at approximately 35 weeks of gestation without confirmation of lung maturity via amniocentesis is also recommended by several experts. Oyelese et al report that the mean gestational age at delivery in patients who are diagnosed antenatally is approximately 35 weeks, and almost 30% of these patients still require emergent delivery after membranes are ruptured. Because the rates of morbidity and mortality are so high after ruptured membranes in these patients, they recommend delivery at 35 weeks in order to avoid a catastrophic event and feel that it is justified even in the light of possible complications due to prematurity.

Prognosis

Fetal mortality has been reported as >50% in pregnancies complicated by vasa previa. Antenatal diagnosis increases the chance of fetal survival significantly. In one study, the rates of survival for fetuses and neonates with and without antenatal diagnosis were 97% and 44%, respectively.

Malpresentation & Cord Prolapse

Karen Kish, MD

BREECH PRESENTATION

ESSENTIALS OF DIAGNOSIS

- Breech presentation occurs when the fetal pelvis or lower extremities engage the maternal pelvic inlet.
- Breech presentation may be suspected based on clinical examination, either by palpating fetal parts over the maternal abdomen or by pelvic examination.
- The diagnosis can be confirmed via ultrasound.

Breech presentation, which complicates 3–4% of all pregnancies, occurs when the fetal pelvis or lower extremities engage the maternal pelvic inlet. Three types of breech are distinguished, according to fetal **attitude** (Fig. 19–1). In **frank breech**, the hips are flexed with extended knees bilaterally. In **complete breech**, both hips and knees are flexed. In **footling breech**, 1 (single footling breech) or both (double footling breech) legs are extended below the level of the buttocks.

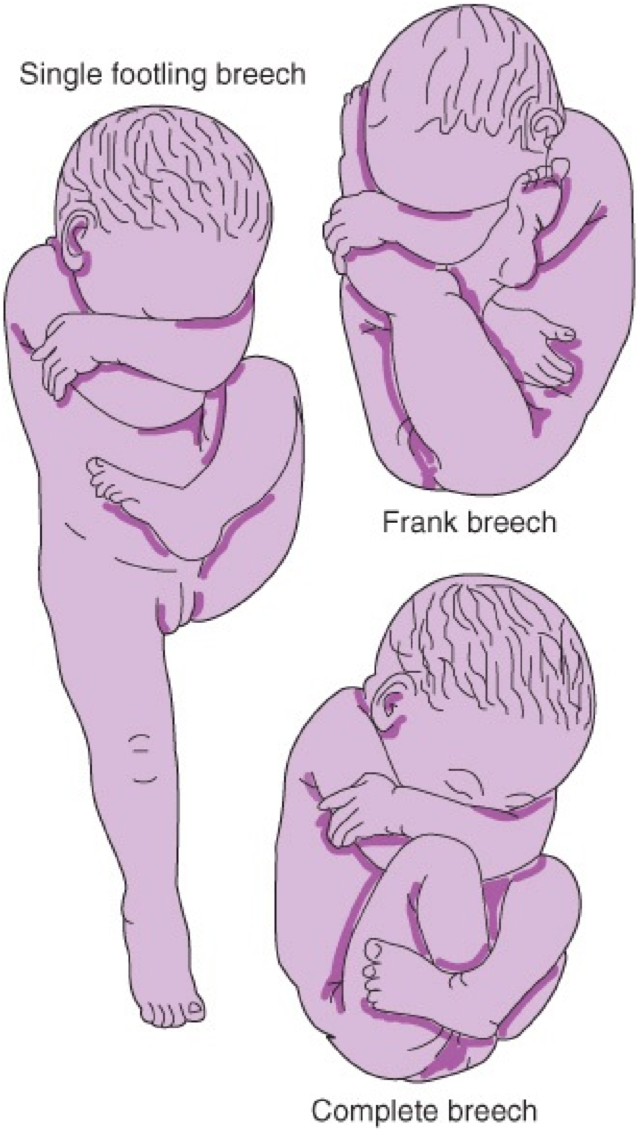

Figure 19–1. Types of breech presentations. (Reproduced, with permission, from Pernoll ML. *Benson and Pernoll's Handbook of Obstetrics and Gynecology*. 10th ed. New York, NY: McGraw-Hill; 2001.)

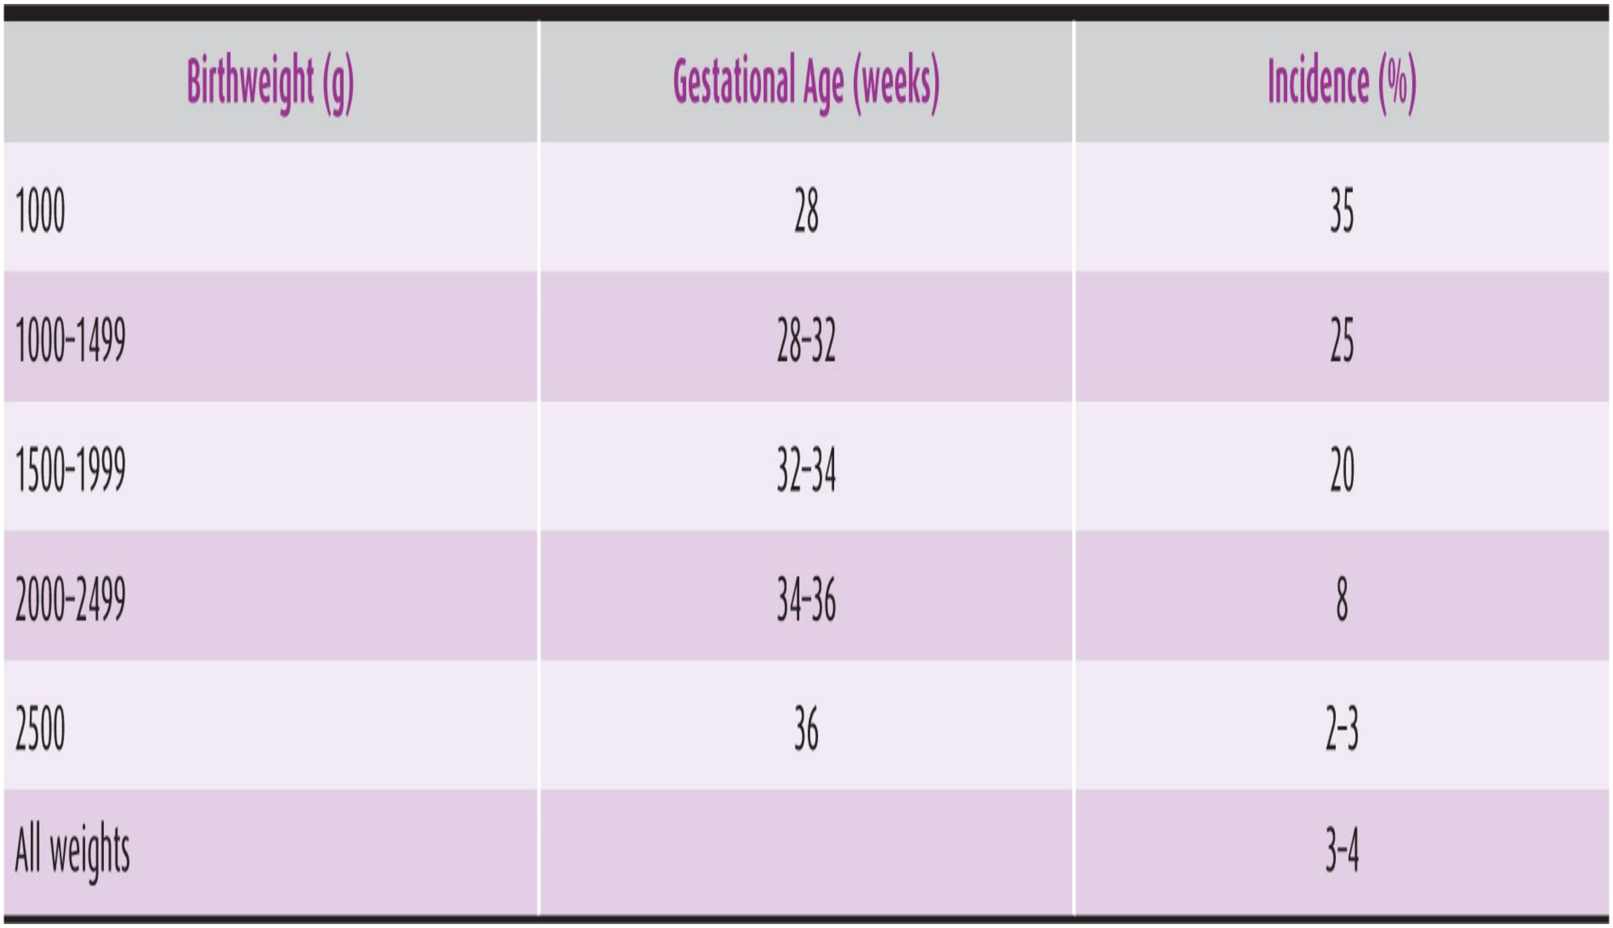
In singleton breech presentations in which the infant weighs less than 2500 g, 40% are frank breech, 10% complete breech, and 50% footling breech. With birth weights of more than 2500 g, 65% are frank breech, 10% complete breech, and 25% footling breech. The incidences of singleton breech presentations by birth weight and gestational age are listed in Table 19–1.

Table 19–1. Incidence of singleton breech presentations by birthweight and gestational age.



Birthweight (g)	Gestational Age (weeks)	Incidence (%)
1000	28	35
1000-1499	28-32	25
1500-1999	32-34	20
2000-2499	34-36	8
2500	36	2-3
All weights		3-4

Fetal **position** in breech presentation is determined by using the fetal sacrum as the point of reference to the maternal pelvis. This is true for frank, complete, and footling breeches. Eight possible positions are recognized: sacrum anterior (SA), sacrum posterior (SP), left sacrum transverse (LST), right sacrum transverse (RST), left sacrum anterior (LSA), left sacrum posterior (LSP), right sacrum anterior (RSA), and right sacrum posterior (RSP). The **station** of the breech presenting part is the location of the fetal sacrum with regard to the maternal ischial spines.

Pathogenesis

Before 28 weeks, the fetus is small enough in relation to intrauterine volume to rotate from cephalic to breech presentation and back again with relative ease. As gestational age and fetal weight increase, the relative decrease in intrauterine volume makes such changes more difficult. In most cases, the fetus spontaneously assumes the cephalic presentation to better accommodate the bulkier breech pole in the roomier fundal portion of the uterus.

Breech presentation occurs when spontaneous version to cephalic presentation is prevented as term approaches or if labor and delivery occur prematurely before cephalic version has taken place. Some causes include oligohydramnios, polyhydramnios, uterine anomalies such as bicornuate or septate uterus, pelvic tumors obstructing the birth canal, abnormal placentation, advanced multiparity, and a contracted maternal pelvis.

In multiple gestations, each fetus may prevent the other from turning, with a 25% incidence of breech in the first twin, nearly 50% for the second twin, and higher percentages with additional fetuses. Additionally, 6% of breech presentations are found to have congenital malformations, which include congenital hip dislocation, hydrocephalus, anencephalus, familial dysautonomia, spina bifida, meningomyelocele, and chromosomal trisomies 13, 18, and 21. Thus, those conditions that alter fetal muscular tone and mobility increase the likelihood of breech presentation.

Clinical Findings

A. Palpation & Ballottement

Performance of Leopold's maneuvers and manual ballottement of the uterus through the maternal abdominal wall may confirm breech presentation. The softer, more ill-defined breech may be felt in the lower uterine segment above the pelvic inlet. Diagnostic error is common, however, if these maneuvers alone are used to determine presentation.

B. Pelvic Examination

During vaginal examination, the round, firm, smooth head in cephalic presentation can easily be distinguished from the soft, irregular breech presentation if the presenting part is palpable. However, if no presenting part is discernible, further studies are necessary (ie, ultrasound).

C. Radiographic Studies

X-ray studies will differentiate breech from cephalic presentations and help determine the type of breech by locating the position of the lower extremities. X-ray studies can reveal multiple gestation and skeletal defects. Fetal attitude may be seen, but fetal size cannot readily be determined by x-ray film. Because of the risks of radiation exposure to the fetus with this technique, ultrasonography is now used instead of radiography to determine fetal presentation or malformations.

D. Ultrasound

Ultrasonographic scanning by an experienced examiner will document fetal presentation, attitude, and size; multiple gestation; location of the placenta; and amniotic fluid volume. Ultrasound also will reveal skeletal and soft tissue malformations of the fetus.

Complications

A. Birth Anoxia

Umbilical cord compression and prolapse may be associated with breech delivery, particularly in complete (5%) and footling (15%) presentations. This is due to the inability of the presenting part to fill the maternal pelvis, either because of prematurity or poor application of the presenting part to the cervix so that the umbilical cord is allowed to prolapse below the level of the breech (see below). Frank breech presentation offers a contoured presenting part, which is better accommodated to the maternal pelvis and is usually well applied to the cervix. The incidence of cord prolapse in frank breech is only 0.5% (the same as for cephalic presentations). Compression of the prolapsed cord may occur during uterine contractions, causing moderate to severe variable decelerations in the fetal heart rate and leading to fetal anoxia or death. If breech vaginal delivery is attempted, continuous electronic monitoring is mandatory during labor in these cases to detect ominous decelerations. If they occur, immediate caesarean delivery must be performed.

B. Birth Injury

The incidence of birth trauma during vaginal breech delivery is 6.7%, 13 times that of cephalic presentations (0.51%). Only high forceps and internal version and extraction procedures have higher rates of birth injury than do vaginal breech deliveries. The types of perinatal injuries reported in breech delivery include tears in the tentorium cerebellum, cephalohematomas, disruption of the spinal cord, brachial palsy, fracture of long bones, and rupture of the sternocleidomastoid muscles. Vaginal breech delivery is the main cause of injuries to the fetal adrenal glands, liver, anus, genitalia, spine, hip joint, sciatic nerve, and musculature of the arms, legs, and back.

Factors contributing to difficult vaginal breech delivery include a partially dilated cervix, unilateral or bilateral nuchal arms, and deflexion of the head. The type of procedure used may affect the neonatal outcome.

1. Partially dilated cervix—Delivery of a breech fetus may progress even though the cervix is only partially dilated because the bitrochanteric and bisacromial diameters are smaller than the biparietal diameter. This is true especially in prematurity. The hips and shoulders may negotiate the cervix, but the aftercoming head becomes entrapped, resulting in difficult delivery and birth injury.

2. Nuchal arms—During partial breech extraction and more often in total breech extraction, excessive downward traction on the body results in a single or double nuchal arm. This occurs because of the rapid descent of the body, leading to extension of 1 or both arms, which become lodged behind the neck. When delivery of the shoulder is difficult to accomplish, a nuchal arm should be suspected. To dislodge the arm, the operator rotates the body 180 degrees to bring the elbow toward the face. The humerus can then be identified and delivered by gentle downward traction. In cases of double nuchal arm, the fetus is rotated counterclockwise to dislodge and deliver the right arm and rotated clockwise to deliver the left arm. If this action is unsuccessful, the operator must insert a finger into the pelvis, identify the humerus, and possibly extract the arm, resulting in fracture of the humerus or clavicle. Nuchal arms cause a delay in delivery and increase the incidence of birth asphyxia.

3. Deflexion of the head—*Hyperextension of the head* is defined as deflexion or extension of the head posteriorly beyond the longitudinal axis of the fetus (5% of all breech deliveries). Causes of hyperextension include neck cysts, spasm of the neck musculature, and uterine anomalies, but over 75% have no known cause. Although deflexion may be documented by ultrasonographic or x-ray studies weeks before delivery, there is little apparent risk to the fetus until vaginal delivery is attempted. At that time, deflexion causes impaction of the occipital portion of the head behind the pubic symphysis, which may lead to fractures of the cervical vertebrae, lacerations of the spinal cord, epidural and medullary hemorrhages, and perinatal death. If head deflexion is diagnosed prior to delivery, caesarean section should be performed to avert injury. Caesarean section cannot prevent injuries such as minor meningeal hemorrhage or dislocation of the cervical vertebrae, which may develop in utero secondary to longstanding head deflexion.

4. Type of delivery—More complex delivery procedures have a higher rate of birth trauma. Whereas few infants are injured during spontaneous breech births, as many as 6% are injured during partial breech extraction and 20% during total breech extraction of singleton infants. Injuries associated with total breech extraction of singleton infants usually are extensive and severe, and this procedure should never be attempted unless fetal survival is in jeopardy and caesarean section cannot be immediately performed.

An additional important factor in breech injury and perinatal outcome is the experience of the operator. Inexperience may lead to hasty performance of obstetric maneuvers. Delay in delivery may result in birth asphyxia due to umbilical cord compression, but haste in the management of breech delivery results in application of excessive pressure on the fetal body, causing soft tissue damage and fracture of long bones. Too-rapid extraction of the body from the birth canal causes the arms to extend above the head, resulting in unilateral or bilateral nuchal arms and difficult delivery of the aftercoming head. All breech deliveries should be performed slowly and methodically by experienced obstetricians who execute the maneuvers with gentleness and skill—not speed.

Treatment

A. Antepartum Management

Following confirmation of breech presentation, the mother must be closely followed to evaluate for spontaneous version to cephalic presentation. If breech presentation persists beyond 36 weeks, external cephalic version should be considered (see below). Version is a procedure used to turn the fetal presenting part from breech to cephalic presentation (cephalic version) or from cephalic to breech presentation (podalic version). Because cephalic version is performed by manipulating the fetus through the abdominal wall, the maneuver is known as **external cephalic version**. Podalic version is performed by means of internal maneuvers and is known as **internal podalic version** (see below). External cephalic version is regaining popularity, whereas internal podalic version is rarely used.

In women considering a vaginal breech delivery of a singleton infant, radiographic pelvimetry using x-ray, computed tomography, or magnetic resonance imaging should be performed to rule out women with a borderline or contracted pelvis. Attempts at vaginal delivery with an inadequate pelvis are associated with a high rate of difficulty and significant trauma to mother and fetus. Difficult vaginal delivery may still occur in women with adequate pelvic measurements.

External cephalic version is used in the management of singleton breech presentations or in a nonvertex second twin. In carefully selected patients, it is safe for both mother and fetus. The goal is to increase the proportion of vertex presentations near term, thus increasing the chance for a vaginal delivery. In the past, external cephalic version was performed earlier in gestation but was accompanied by high reversion rates, making additional procedures necessary. Now it is performed in patients who have completed 36 weeks of gestation so that the risk of spontaneous reversion is decreased, and, if complications arise, delivery of a term infant can be accomplished. Current success rates for external cephalic version range from 35 to 85% (mean 60%).

Patients with unengaged singleton breech presentations of at least 36 weeks' gestation are candidates for external cephalic version. The procedure is more successful in multigravidas, those with a transverse or oblique lie, and those with a posterior placenta. Use of fetal heart rate monitoring and real-time ultrasonography is essential to document fetal well-being during the procedure. The use of tocolytics in external cephalic version is controversial. Recent evidence indicates that tocolytics offer an advantage in nulliparous women, but reports on which type of tocolytic confers the highest success rate are conflicting. Thus, these agents should be used at the discretion of the physician. Additionally, evidence regarding the use of regional anesthesia is inconsistent. Recent randomized controlled trials have shown an increased success rate in those with epidural anesthesia. However, the ultimate decision should be based on physician experience.

Contraindications to external cephalic version include engagement of the presenting part in the pelvis, marked oligohydramnios, placenta previa, uterine anomalies, presence of nuchal cord, multiple gestation, premature rupture of membranes, previous uterine surgery (including myomectomy or metroplasty), and suspected or documented congenital malformations or abnormalities (including intrauterine growth retardation).

Complications are rare, occurring in only 1–2% of all external cephalic versions. Complications include placental abruption, uterine rupture, rupture of membranes with resultant umbilical cord prolapse, amniotic fluid embolism, preterm labor, fetal distress, fetomaternal hemorrhage, and fetal demise. Thus, given the potential for catastrophic outcome, this procedure should be performed in a facility where immediate access to caesarean delivery is available. Patients require extensive counseling regarding the version procedure, with disclosure of all risks, benefits, and alternatives so that an informed medicolegal decision can be made.

1. Fetal heart rate abnormalities—These can be readily documented during external cephalic version by intermittent electronic fetal monitoring (EFM) or ultrasonographic surveillance. Fetal bradycardia occurs in 20% of cases, but normal cardiac activity usually will return if the procedure is stopped for a short time. If significant unremitting fetal cardiac alterations occur, the attempt at version should be discontinued and preparation for caesarean delivery undertaken immediately.

2. Fetomaternal transplacental hemorrhage (FMH)—This may occur during version and has been reported to occur in 6–28% of patients undergoing external cephalic version, although the amount of hemorrhage rarely results in clinically significant anemia. The **Kleihauer-Betke acid elution test** should be performed if this condition is suspected. In cases of an Rh-negative–unsensitized woman, Rh immune globulin (RhoGAM) should be administered after external cephalic version to cover the calculated amount of FMH.

3. Technique—External cephalic version is performed by first obtaining informed consent from the patient. An ultrasound examination is performed to verify presentation and to rule out fetal or uterine abnormalities. A nonstress test is done, and results must be reactive. If desired, a tocolytic is administered to prevent contractions or irritability. Anesthesia is also administered if desired. To perform the external cephalic version, both of the operator’s hands are placed on the patient’s abdomen, and a forward roll is attempted by lifting the breech upward while placing pressure on the head downward toward the pelvis. If this maneuver is unsuccessful, a backward roll can be attempted. Fetal well-being should be monitored intermittently with Doppler or real-time ultrasound scanning. The procedure should be abandoned in case of any significant fetal distress or patient discomfort or if multiple attempts are unsuccessful. Following the procedure, external fetal heart rate monitoring should be continued for 1 hour to ensure stability. If the patient is Rh negative, administer anti-D immune globulin. If the patient is stable, she can be sent home to await the onset of spontaneous labor if the version is successful. If unsuccessful, the patient can be scheduled for an elective caesarean section or a trial of labor with a breech vaginal delivery planned if the mother is a good candidate.

Recent studies have evaluated acupuncture and moxibustion (burning herbs to stimulate acupuncture points) to determine their role in facilitating spontaneous version of the breech fetus. To date, these trials have not found a consistent benefit to either mode.

B. Management during Labor

1. Examination—Patients with singleton breech presentations are admitted to the hospital with the onset of labor or when spontaneous rupture of membranes occurs because of the increased risk of umbilical cord complications. Upon admission, a repeat ultrasound is obtained to confirm the type of breech presentation and to ascertain head flexion. The fetus is again screened for lethal congenital malformations, such as anencephaly, which would preclude caesarean delivery for fetal indications. A thorough history is taken, and a physical examination is performed to evaluate the status of mother and fetus. Based on these findings, a decision must be made regarding the route of delivery (see below).

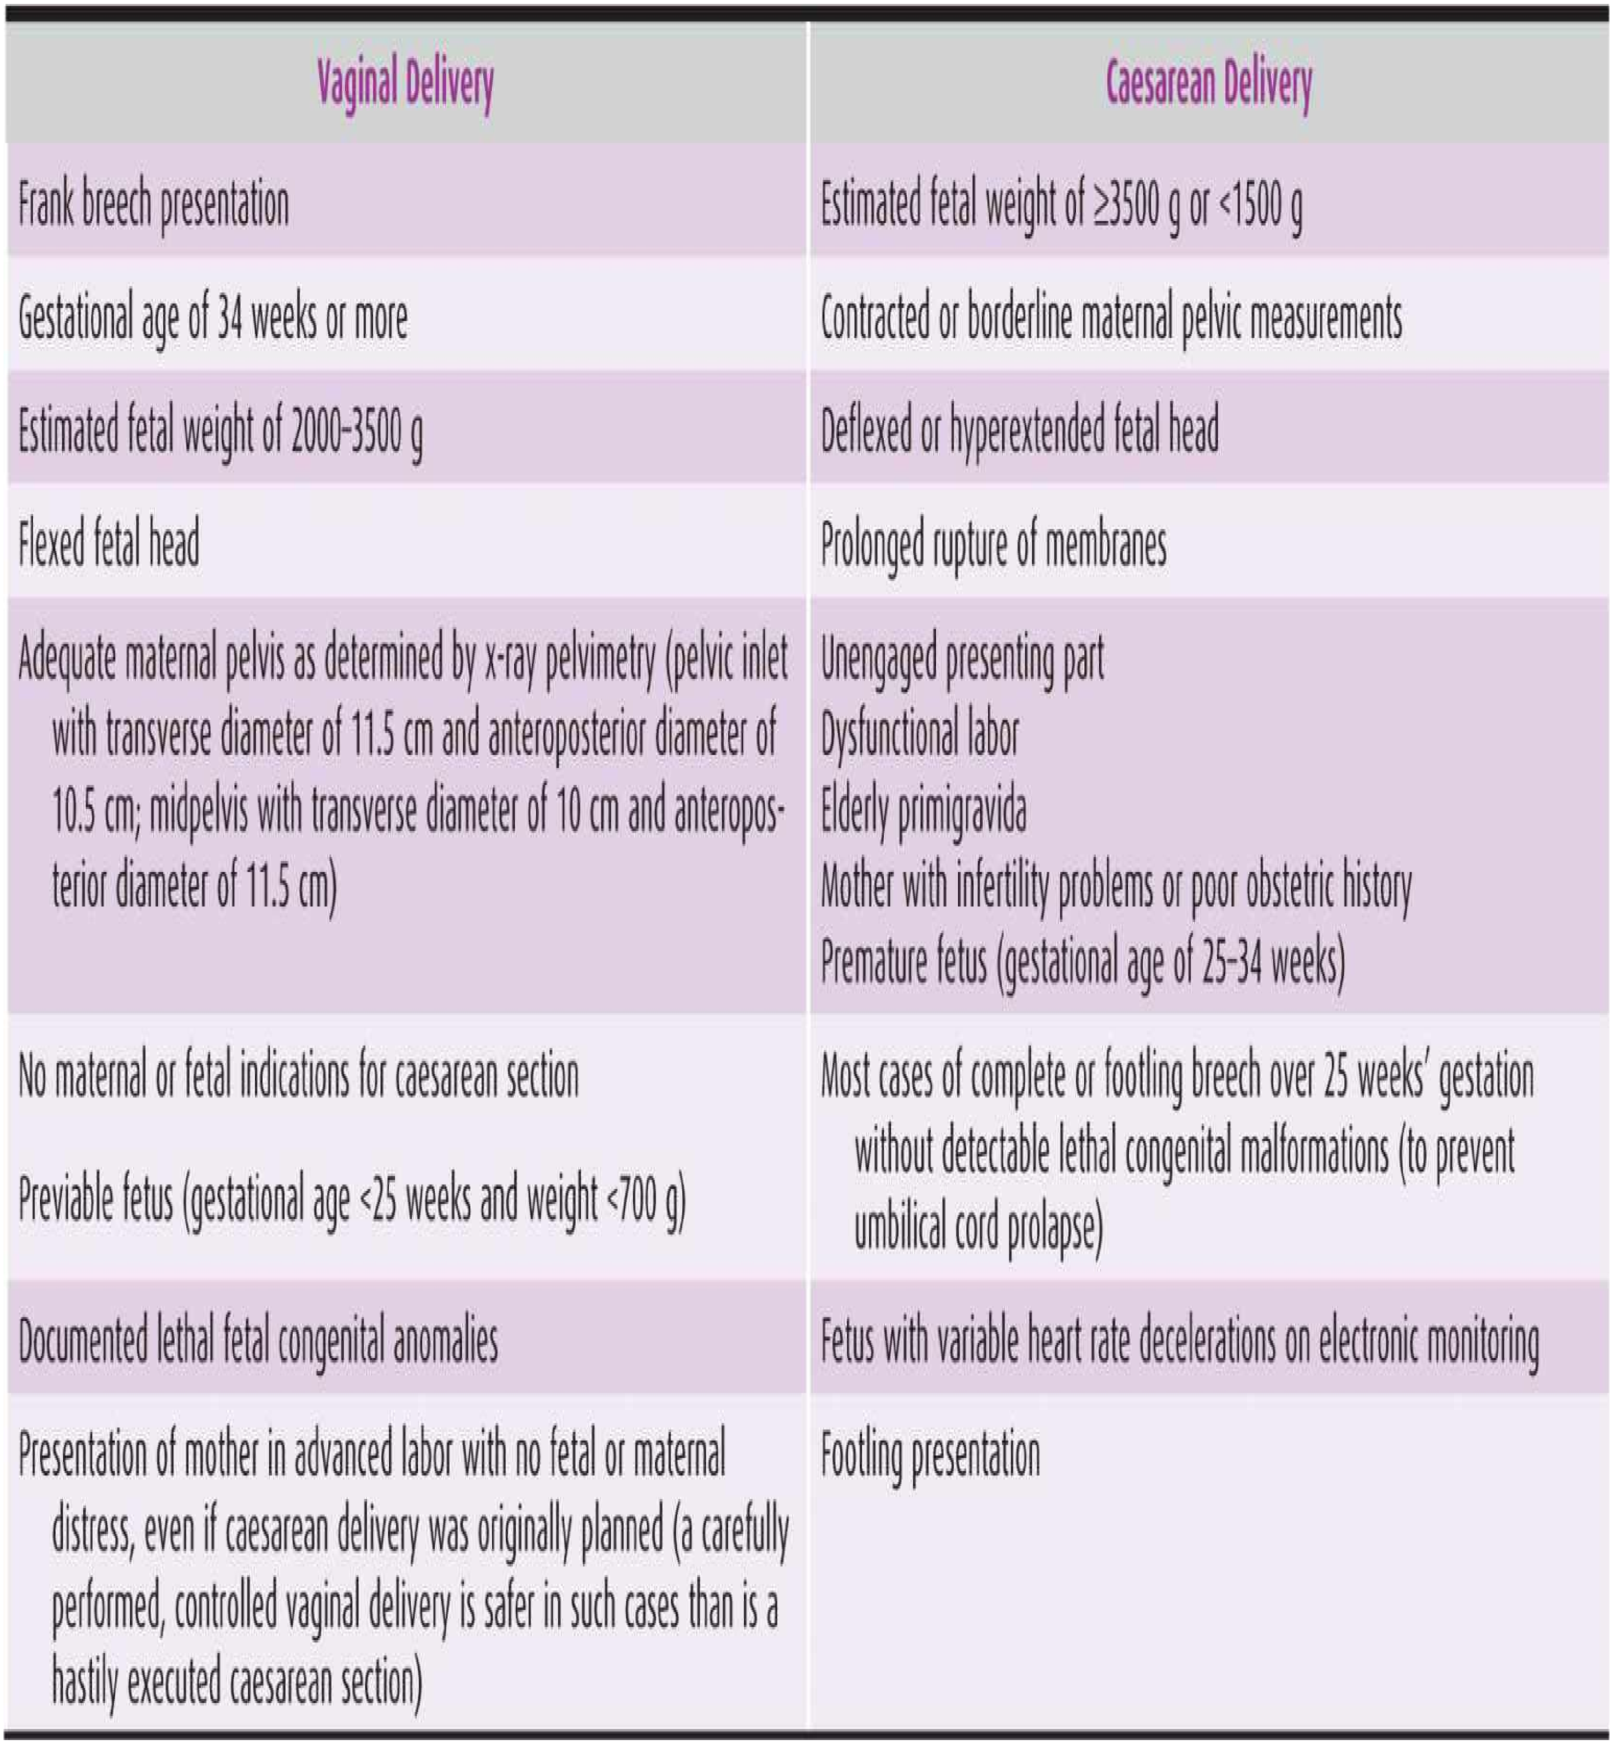
2. Electronic fetal monitoring—Continuous electronic fetal heart rate monitoring is essential during labor. If a fetal electrocardiographic electrode is needed, care should be taken to avoid injury to the fetal anus, perineum, and genitalia when attaching the electrode to the breech presenting part. An intrauterine pressure catheter can be used to assess the frequency, strength, and duration of uterine contractions. With the catheter in place, fetal distress or dysfunctional labor can easily be identified and the decision to proceed with a caesarean section made expeditiously to optimize fetal outcome.

3. Oxytocin—The use of oxytocin in the management of breech labor is controversial. Although some obstetricians condemn its use, others use oxytocin with benefit and without complications. Generally, oxytocin should be administered only if uterine contractions are insufficient to sustain normal progress in labor. Continuous fetal and uterine monitoring should be used whenever oxytocin is administered.

C. Delivery

The decision regarding route of delivery must be made carefully on an individual basis. Criteria for vaginal or caesarean delivery are outlined in Table 19–2.

Table 19–2. Criteria for vaginal or caesarean delivery in breech presentation.



Vaginal Delivery	Caesarean Delivery
Frank breech presentation	Estimated fetal weight of ≥3500 g or <1500 g
Gestational age of 34 weeks or more	Contracted or borderline maternal pelvic measurements
Estimated fetal weight of 2000–3500 g	Deflexed or hyperextended fetal head
Flexed fetal head	Prolonged rupture of membranes
Adequate maternal pelvis as determined by x-ray pelvimetry (pelvic inlet with transverse diameter of 11.5 cm and anteroposterior diameter of 10.5 cm; midpelvis with transverse diameter of 10 cm and anteroposterior diameter of 11.5 cm)	Unengaged presenting part Dysfunctional labor Elderly primigravida Mother with infertility problems or poor obstetric history Premature fetus (gestational age of 25–34 weeks)
No maternal or fetal indications for caesarean section Previable fetus (gestational age <25 weeks and weight <700 g)	Most cases of complete or footling breech over 25 weeks' gestation without detectable lethal congenital malformations (to prevent umbilical cord prolapse)
Documented lethal fetal congenital anomalies	Fetus with variable heart rate decelerations on electronic monitoring
Presentation of mother in advanced labor with no fetal or maternal distress, even if caesarean delivery was originally planned (a carefully performed, controlled vaginal delivery is safer in such cases than is a hastily executed caesarean section)	Footling presentation

Prior to 1975, virtually all viable singleton breech presentations were delivered vaginally. Caesarean section was reserved for specific fetal indications, such as unremitting distress or prolapsed umbilical cord, or maternal indications, such as placenta previa, abruptio placentae, or failure of progress in labor. However, breech infants delivered vaginally had a 5-fold higher mortality rate in comparison to cephalic presentations.

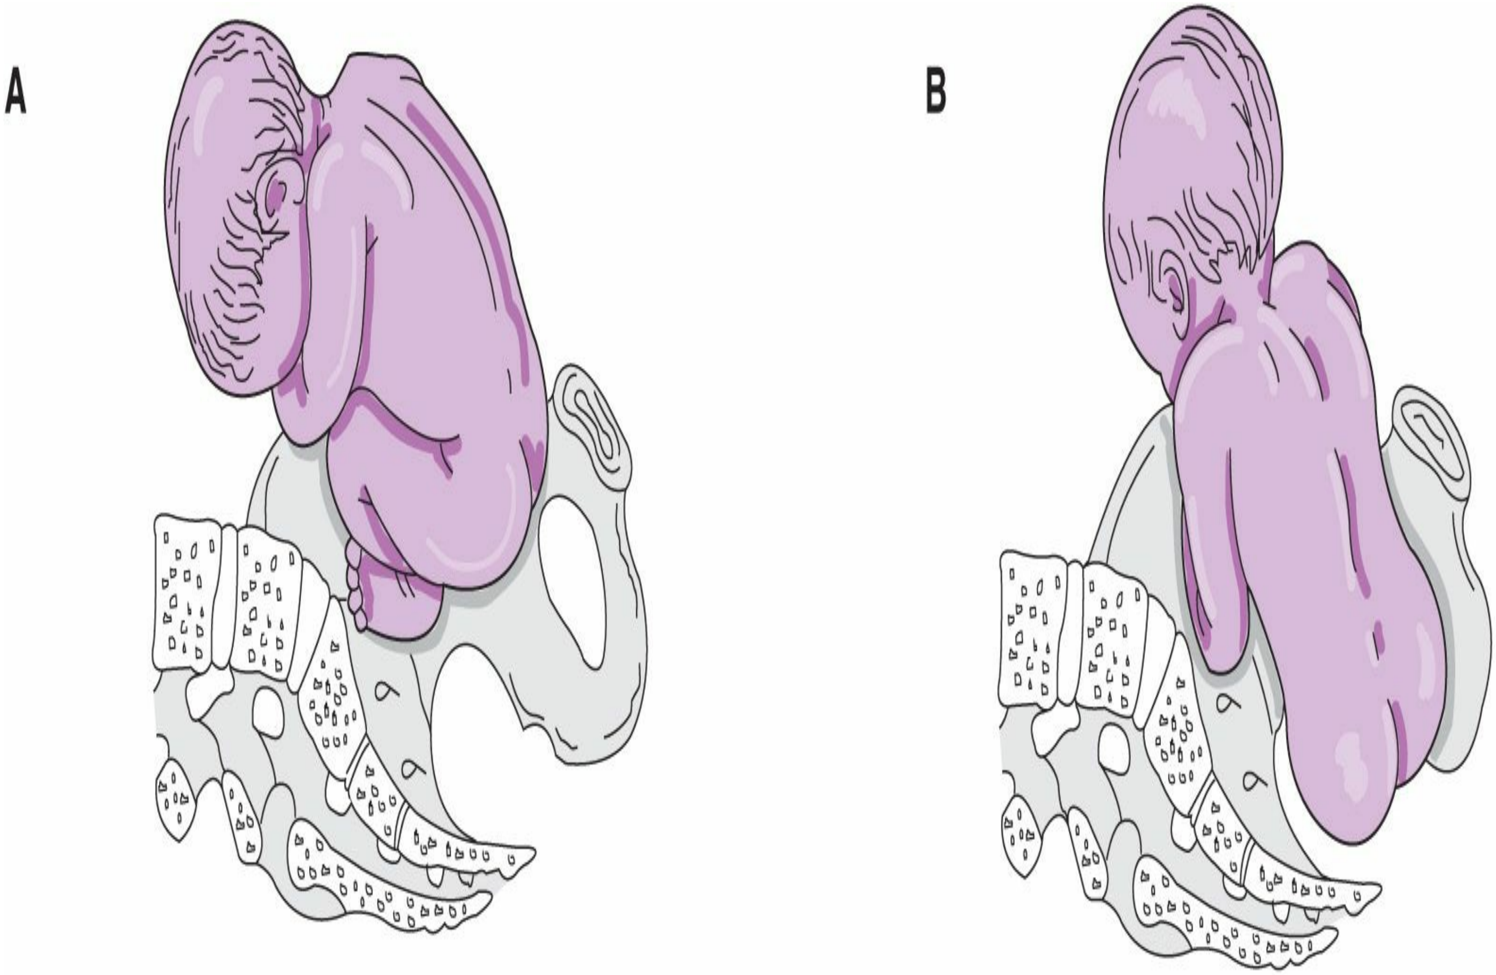
Recent studies have shown that planned caesarean delivery decreases perinatal and neonatal morbidity and mortality, with no difference in maternal morbidity and mortality versus planned vaginal breech delivery. Thus, caesarean delivery has now become much more common in breech presentation. Only obstetricians skilled in breech techniques should attempt any breech delivery, whether vaginal or caesarean. Nevertheless, broader familiarity with the technique is needed because unanticipated vaginal breech delivery is still encountered.

1. Caesarean delivery—The type of incision chosen is extremely important. If the lower uterine segment is well developed, as is usually the case in women at term in labor, a transverse “lower segment” incision is adequate for easy delivery. In premature gestations, in an unlabored uterus, or in many cases of malpresentation, the lower uterine segment may be quite narrow, and a low vertical incision is almost always required for atraumatic delivery.

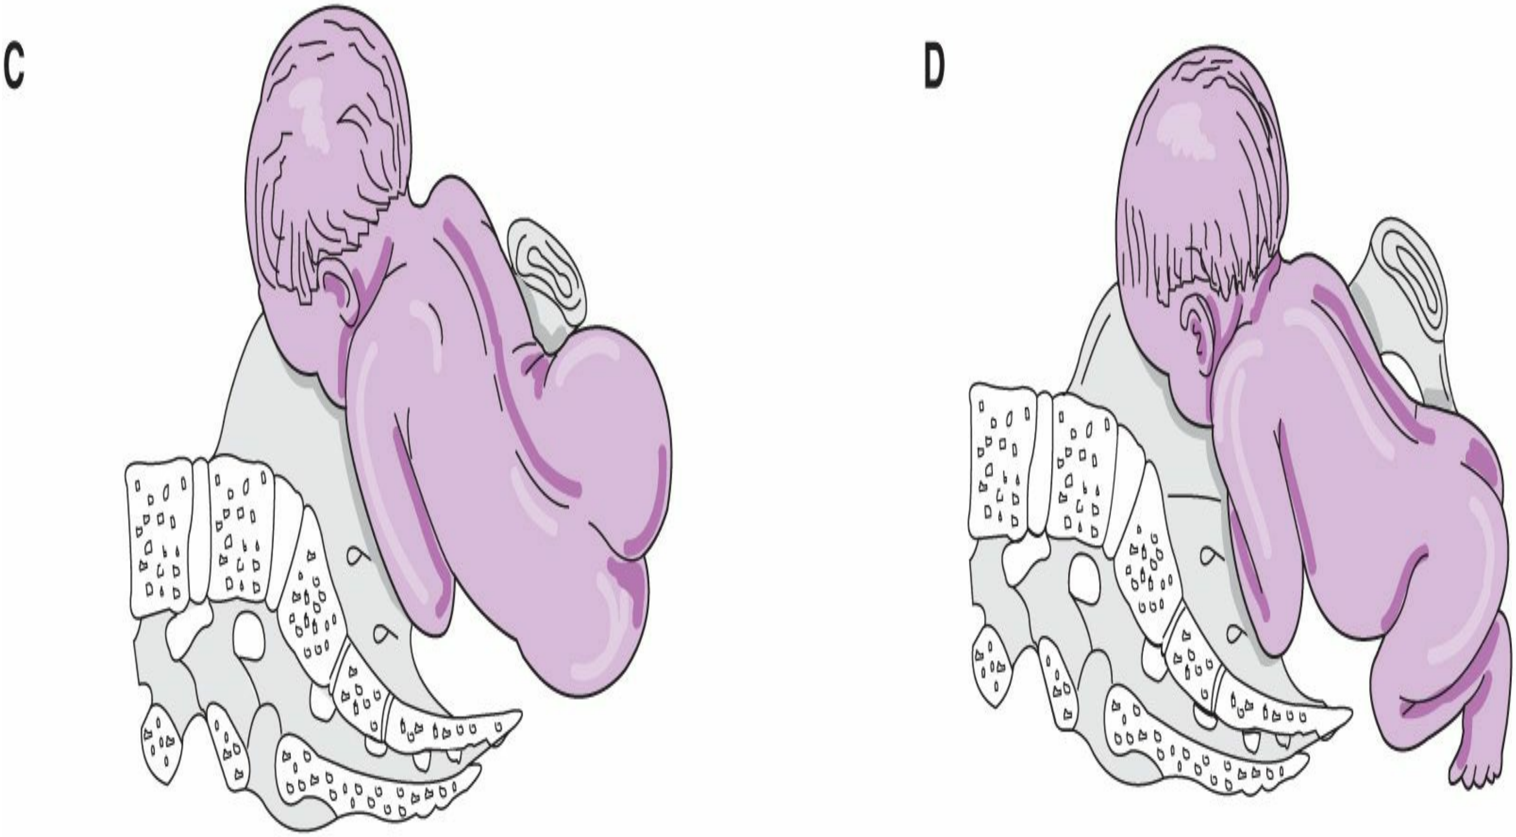
2. Vaginal delivery—Obstetricians who contemplate performing a vaginal breech delivery should be experienced in the maneuver and should be assisted by 3 physicians: (1) an experienced obstetrician who will assist with delivery; (2) a pediatrician capable of providing total resuscitation of the newborn; and (3) an anesthesiologist, to ensure that the mother is comfortable and cooperative during labor and delivery. The type of anesthesia required depends on the type of breech delivery. Multiparous women undergoing spontaneous breech delivery may require no anesthesia or only intravenous analgesia for pain relief during labor and a pudendal anesthetic during delivery. Epidural anesthesia may also be administered during labor or in anticipation of partial breech extraction, including application of Piper forceps to the aftercoming head. In emergency circumstances, complete relaxation of the perineum and uterus is essential for a successful outcome. This is accomplished by immediate induction of inhalation anesthesia or by administration of intravenous nitroglycerin.

A. SPONTANEOUS VAGINAL DELIVERY—During spontaneous delivery of an infant in the frank breech position, delivery occurs without assistance, and no obstetric maneuvers are applied to the body. The fetus negotiates the maternal pelvis as outlined below, while the operator simply supports the body as it delivers.

Engagement occurs when the bitrochanteric diameter of the fetus has passed the plane of the pelvic inlet. As the fetus descends into the pelvis (Fig. 19–2), the buttocks reach the levator ani muscles of the maternal pelvis. At this point, internal rotation occurs, whereby the anterior hip rotates beneath the pubic symphysis, resulting in a sacrum transverse position. The bitrochanteric diameter of the fetal pelvis is now in an anteroposterior position within the maternal pelvis. The breech then presents at the pelvic outlet and, upon emerging, rotates from sacrum transverse to sacrum anterior. Crowning occurs when the bitrochanteric diameter passes under the pubic symphysis. As this occurs, the shoulders enter the pelvic inlet with the bisacromial diameter in the transverse position. As descent occurs, the bisacromial diameter rotates to an oblique or anteroposterior diameter, until the anterior shoulder rests beneath the pubic symphysis. Delivery of the anterior shoulder occurs as it slips beneath the pubic symphysis. Upward flexion of the body allows for easy delivery of the posterior shoulder over the perineum.



A
B



C
D

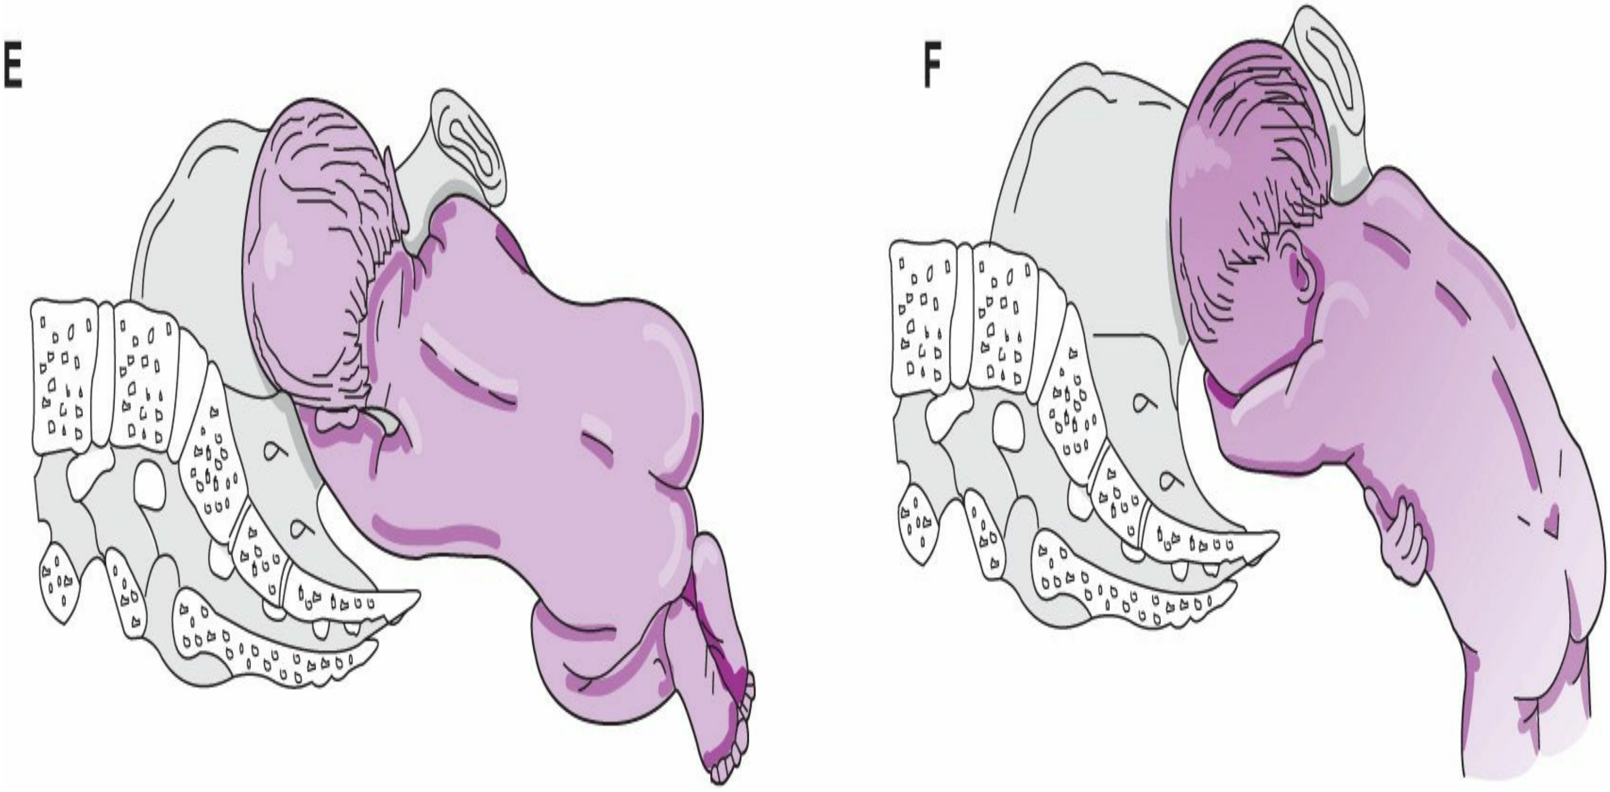


Figure 19–2. Mechanism of labor in breech delivery. **A:** Mechanism of breech delivery. Right sacrum transverse at the onset of labor; engagement of the buttocks usually occurs in the oblique or transverse diameter of the pelvic brim. **B:** Early second stage. The buttocks have reached the pelvic floor, and internal rotation has occurred so that the bitrochanteric diameter lies in the anteroposterior diameter of the pelvic outlet. **C:** Late second stage. The anterior buttock appears at the vulva by lateral flexion of the trunk around the pubic symphysis. The shoulders have not yet engaged in the pelvis. **D:** The buttocks have been delivered, and the shoulders are adjusting to engage in the transverse diameter of the brim. This movement causes external rotation of the delivered buttocks so that the fetal back becomes uppermost. **E:** The shoulders have reached the pelvic floor and have undergone internal rotation so that the bisacromial diameter lies in the AP diameter of the pelvic outlet. Simultaneously, the buttocks rotate anteriorly through 90 degrees. This is called **restitution**. The head is engaging in the pelvic brim, and the sagittal suture is lying in the transverse diameter of the brim. **F:** The anterior shoulder is born from behind the pubic symphysis by lateral flexion of the delivered trunk.

As the shoulders descend, the head engages the pelvic inlet in a transverse or oblique position. Rotation of the head to the occiput anterior position occurs as it enters the midpelvis. The occiput then slips beneath the pubic symphysis, and the remainder of the head is delivered by flexion as the chin, mouth, nose, and forehead slip over the maternal perineum.

As delivery of the breech occurs, increasingly larger diameters (bitrochanteric, bisacromial, biparietal) of the body enter the pelvis, whereas in cephalic presentation, the largest diameter (biparietal diameter) enters the pelvis first. Particularly in preterm labors, the head is considerably larger than the body and provides a better “dilating wedge” as it passes through the cervix and into the pelvis. The smaller bitrochanteric and bisacromial diameters may descend into the pelvis through a partially dilated cervix, but the larger biparietal diameter may be trapped. Delivery in these cases is described in the following.

B. PARTIAL BREECH EXTRACTION—Partial breech extraction (assisted breech extraction) is used when the operator discerns that spontaneous delivery will not occur or that expeditious delivery is indicated for fetal or maternal reasons. The body is allowed to deliver spontaneously up to the level of the umbilicus. The operator then assists in delivery of the legs, shoulders, arms, and head.

As the umbilicus appears at the maternal perineum, the operator places a finger medial to one thigh and then the other thigh, pressing laterally as the fetal pelvis is rotated away from that side by an assistant. Thus, the thigh is externally rotated at the hip and results in flexion of the knee and delivery of one, then the other, leg. The fetal trunk is then wrapped in a towel to support the body. When both scapulae are visible, the body is rotated counterclockwise. The operator locates the right humerus and laterally sweeps the arm across the chest and out the perineum (Fig. 19–3). In a similar fashion, the body is rotated clockwise to deliver the left arm. The head then spontaneously delivers by gently lifting the body upward and applying fundal pressure to maintain flexion of the fetal head (Fig. 19–4). During partial breech extraction, the anterior shoulder may be difficult to deliver if it is impacted behind the pubic symphysis. In this event, the body is gently lifted upward toward the pubic symphysis, and the operator inserts 1 hand along the hollow of the maternal pelvis and identifies the posterior humerus of the fetus. By gentle downward traction on the humerus, the posterior arm can be easily delivered, thus allowing for easier delivery of the anterior shoulder and arm.

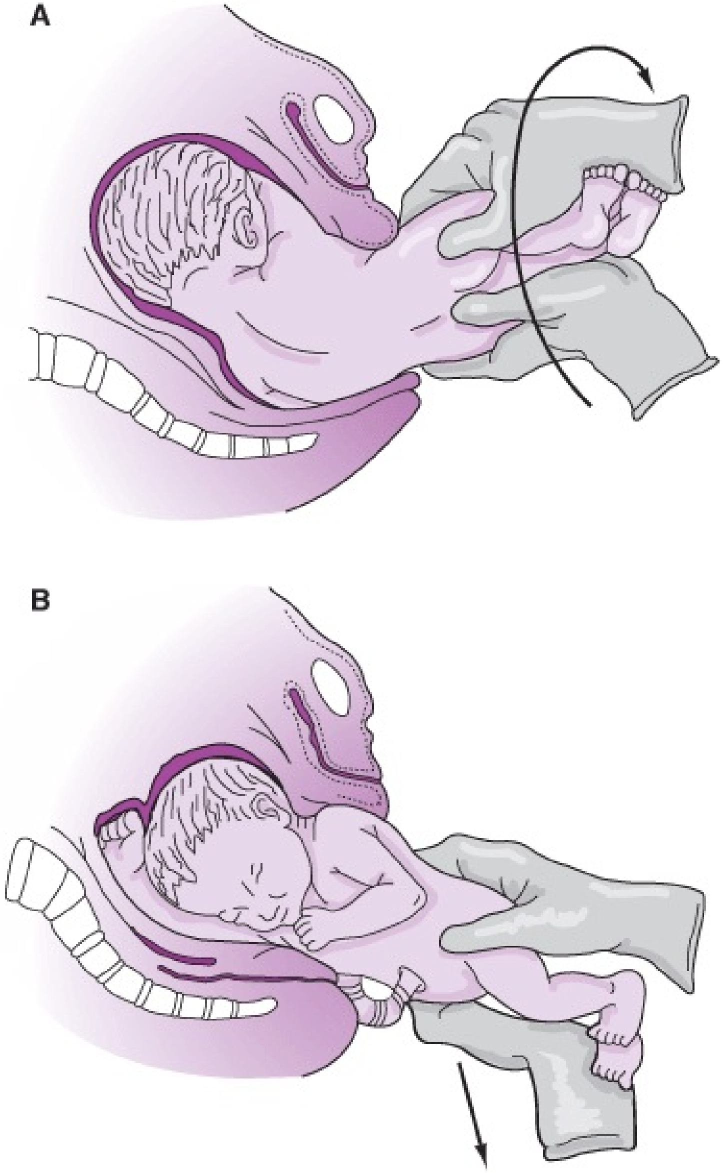

Figure 19–3. Assisted delivery of the shoulders. **A:** Shoulders engaged, posterior (left) shoulder at

lower level in pelvis than anterior shoulder. **B:** Rotation of trunk causing posterior shoulder to rotate to anterior and slip beneath the pubic symphysis.

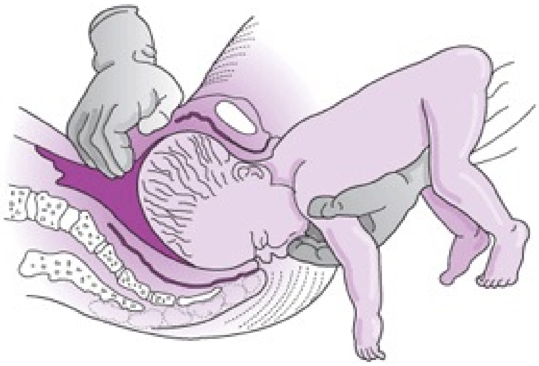

Figure 19–4. Maneuver for delivery of the head. The fingers of the left hand are inserted into the infant's mouth or over the infant's mandible; the right hand exerts pressure on the head from above. (Modified and reproduced, with permission, from Pernoll ML. *Benson and Pernoll's Handbook of Obstetrics and Gynecology*. 10th ed. New York, NY: McGraw-Hill; 2001.)

The operator may elect to manually assist in delivery of the head by performing the **Mauriceau-Smellie-Veit maneuver** (Fig. 19–5). In this procedure, the index and middle fingers of 1 of the operator's hands are applied over the maxilla as the body rests on the palm and forearm of the operator. Two fingers of the operator's other hand are applied on either side of the neck with gentle downward traction. At the same time, the body is elevated toward the pubic symphysis, allowing for controlled delivery of the mouth, nose, and brow over the perineum. Likewise, Piper forceps may be used electively or when the Mauriceau-Smellie-Veit maneuver fails to deliver the aftercoming head. Piper forceps may only be used when the cervix is completely dilated and the head is engaged in the pelvis. Ideally, the head is in a direct occiput anterior position, but a left or right occiput anterior position is acceptable. Piper forceps should not be attempted in the occiput transverse positions because this may result in significant fetal and maternal injury. An assistant supports and slightly elevates the fetal trunk while the operator places each forceps blade alongside the fetal parietal bones (Fig. 19–6). After proper placement is confirmed, the forceps are locked, and gentle traction is applied to flex and deliver the head over the perineum. A midline episiotomy is often indicated to allow for easier application of the forceps and for delivery.

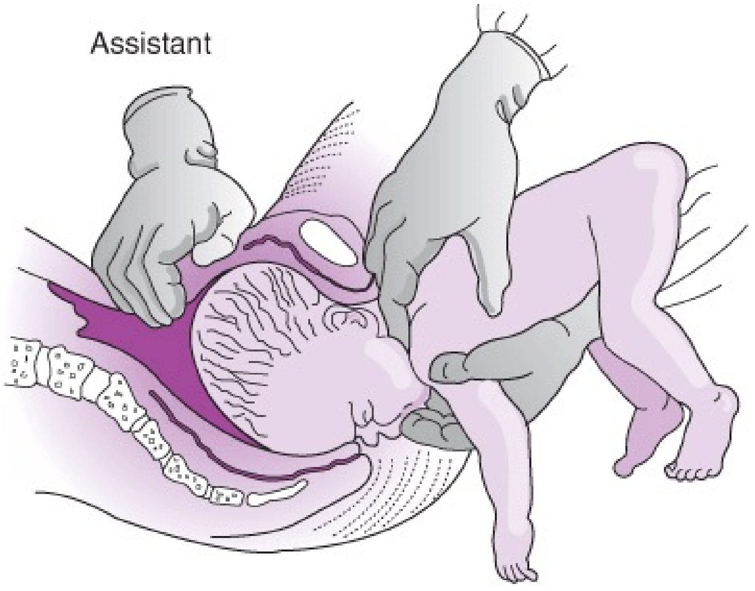

Figure 19–5. Mauriceau-Smellie-Veit maneuver for delivery of the head. The fingers of the left hand are inserted into the infant's mouth or over the infant's mandible; the fingers of the right hand curve over the shoulders. An assistant exerts suprapubic pressure on the head. (Reproduced, with permission, from Pernoll ML. *Benson and Pernoll's Handbook of Obstetrics and Gynecology*. 10th ed. New York, NY: McGraw-Hill; 2001.)

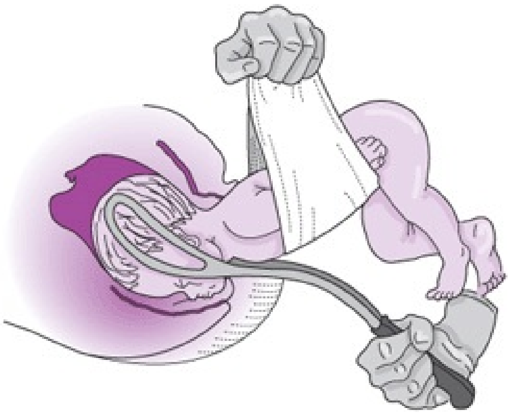

Figure 19–6. Application of Piper forceps, using towel sling support. The forceps are introduced from below, left blade first, aiming directly at intended positions on sides of the head. (Reproduced, with permission, from Pernoll ML. *Benson and Pernoll's Handbook of Obstetrics and Gynecology*. 10th ed. New York, NY: McGraw-Hill; 2001.)

If, after delivery of the body, the spine remains in the posterior position and rotation is unsuccessful, extraction of the head in a persistent occiput posterior position may be accomplished by the **modified Prague maneuver**. One hand of the operator supports the shoulders from below, while the other hand gently elevates the body upward toward the maternal abdomen. This action flexes the head within the birth canal and results in delivery of the occiput over the perineum.

In premature breech presentations, the incompletely dilated cervix may allow delivery to the smaller body, but the relatively larger aftercoming head may be entrapped. Prompt delivery is mandatory because severe asphyxia leading to death may rapidly ensue. Gentle downward traction on the shoulders combined with fundal pressure applied by an assistant may effect delivery. If this fails, the anesthesiologist should administer nitroglycerin or inhalation anesthesia to obtain complete relaxation of the lower uterine segment and pelvic floor with reattempt at delivery.

If delivery is still not accomplished, **Dührssen's incisions** must be considered to preserve fetal life. Incisions are made in the posterior cervix at the 6 o'clock position to loosen the entrapped head. Occasionally, additional incisions are necessary at the 2 and 10 o'clock positions. Dührssen's incisions invariably release the fetal head, but the maternal consequences may be severe with resultant hemorrhage. Thus, this procedure should be performed only in an emergent situation. Prevention of head entrapment can be accomplished by delivering viable premature breech gestations by caesarean section.

C. TOTAL BREECH EXTRACTION—In total breech extraction (Fig. 19–7), the entire body is manually delivered. This procedure is used only occasionally when fetal distress is encountered and an expeditious delivery is indicated, and under certain conditions in the setting of delivery of a second twin in a nonvertex position following successful vaginal delivery of a first twin. Total breech extraction has been virtually replaced by caesarean delivery in modern obstetrics.

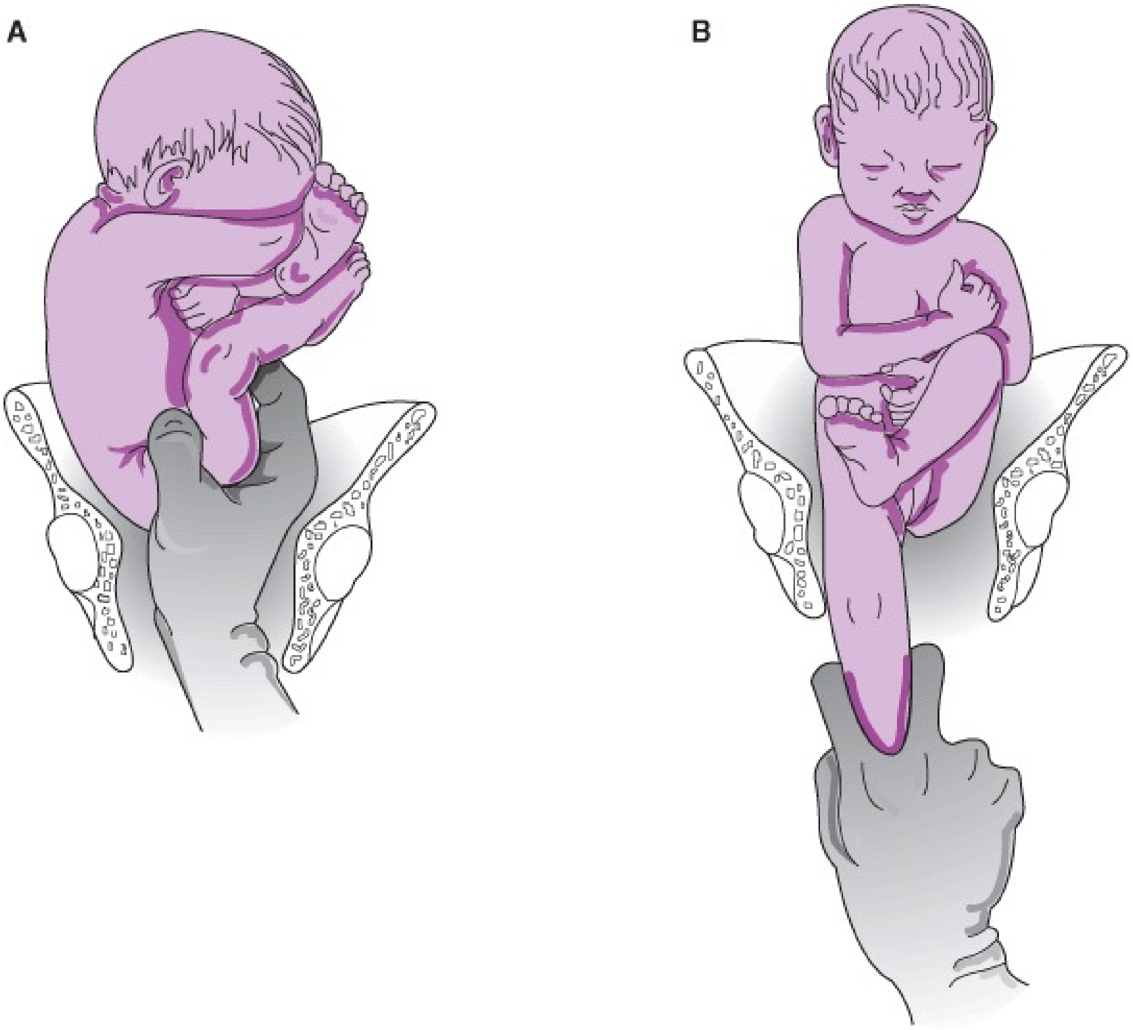

Figure 19–7. Extraction of breech. **A:** Abduction of thigh and pressure in popliteal fossa cause the knee to flex and become accessible. **B:** Delivery of leg by traction on the foot.

For complete or footling presentation, total breech extraction is accomplished by initially grasping both feet and applying gentle downward pressure until the buttocks are delivered (Fig. 19–8). A generous midline or mediolateral episiotomy is then performed. The operator gently grasps the fetal pelvis, with both thumbs placed directly on either side of the sacrum. The spine is rotated, if necessary, until it rests under the pubic symphysis. Gentle, firm downward pressure is applied to the body until both scapulas are visible. The shoulders, arms, and head are delivered as in partial breech extraction.

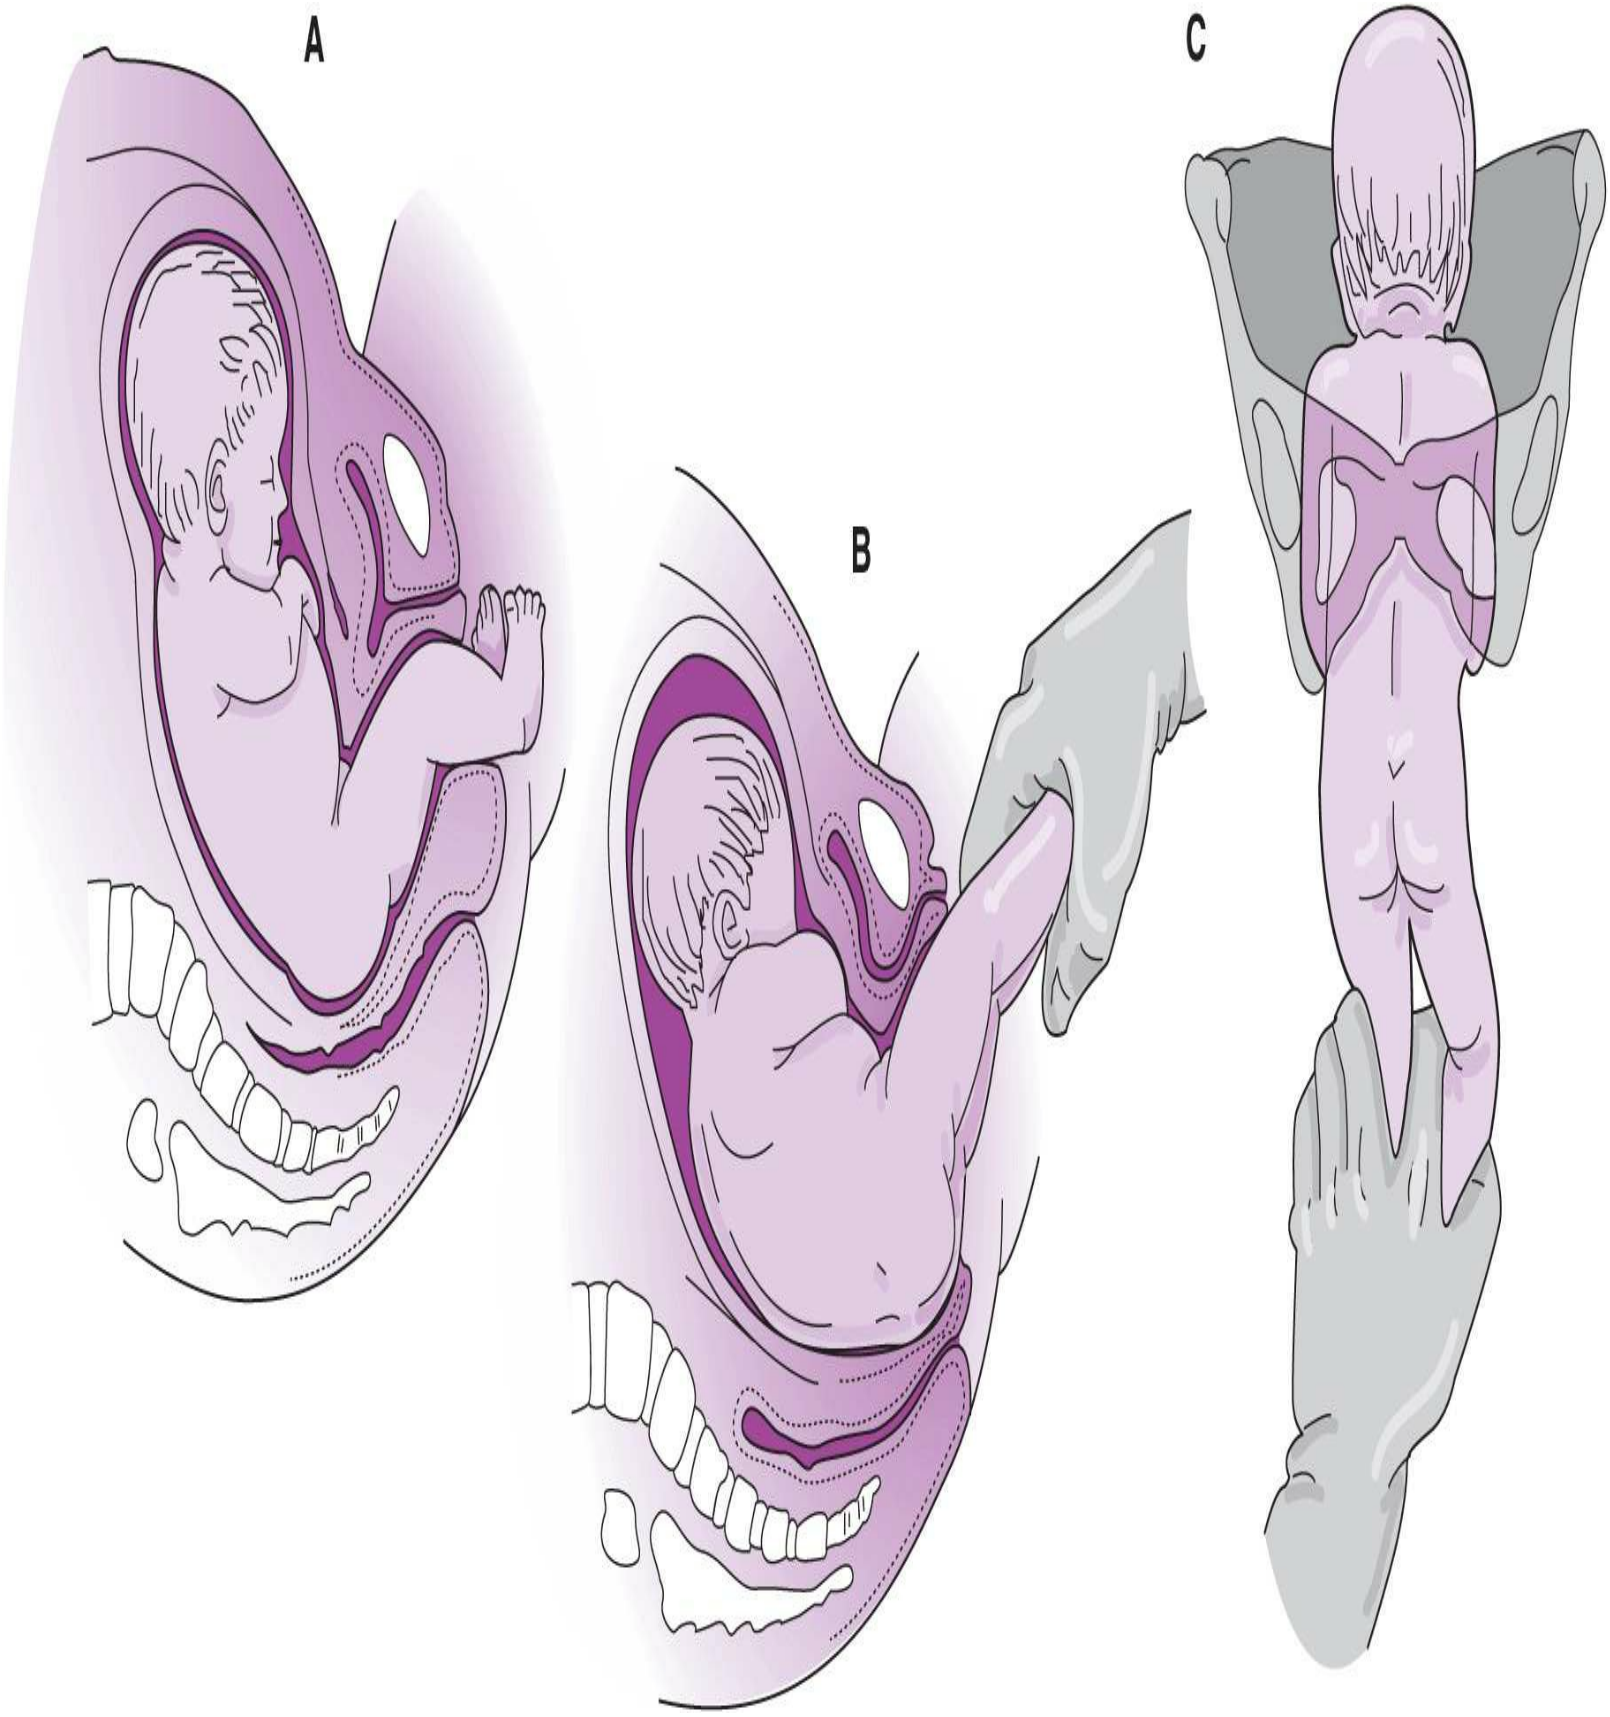

Figure 19–8. Extraction of breech. **A:** Buttocks brought to hollow of sacrum. **B:** Traction on anterior leg causes buttocks to advance and rotate into direct anteroposterior diameter of pelvis. Continued downward traction causes the back to rotate anteriorly. **C:** Further downward traction causes the shoulders to engage in the transverse diameter of the inlet.

If the fetus is in frank breech presentation, the index finger of the right hand must initially be placed into the anterior groin of the fetus and gentle downward pressure applied (Fig. 19–9). As the fetus descends further into the birth canal, the left index finger is inserted into the posterior groin, and additional gentle downward traction is applied, until the buttocks are delivered through the vaginal introitus (Fig. 19–10). The fetus is gently rotated until the spine rests directly under the pubic symphysis. To deliver the extended legs from the birth canal, the operator places the index finger in the popliteal fossa of 1 leg and applies pressure upward and outward, causing the knee to flex. As the knee flexes, the foot is often seen or easily palpated. The lower leg is grasped firmly and gently delivered, and the opposite leg is then delivered. The rest of the body is extracted as previously described for footling presentation.

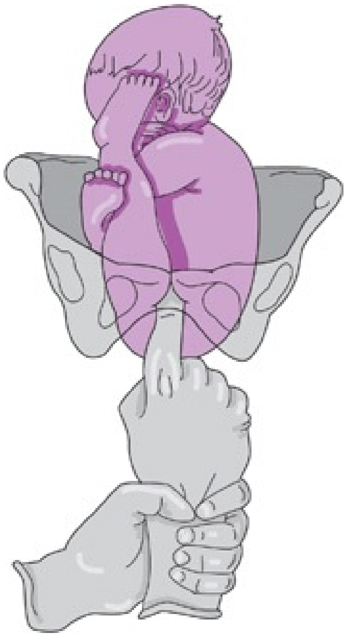

Figure 19–9. Delivery of breech with 1 finger in the groin. The wrist is supported with the other hand. When the posterior groin is accessible, the index finger of the other hand is placed in the groin to complete delivery of the breech.

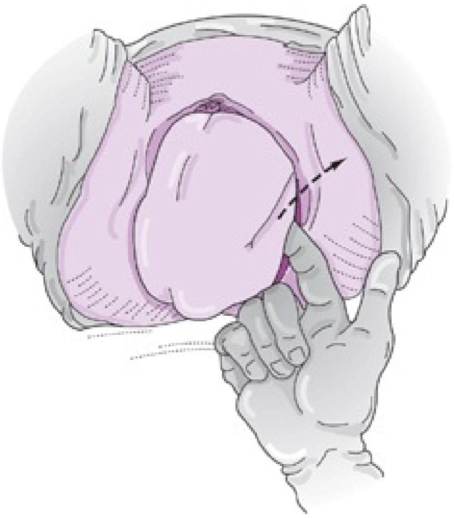

Figure 19–10. Flexion and abduction of the thigh to deliver extended leg.

D. Internal podalic version—Internal podalic version is now rarely used because of the high fetal and maternal morbidity and mortality associated with the procedure. It is occasionally performed as a life-saving procedure or in cases of a noncephalic second twin (see Chapter 17 for delivery of a second twin). Internal podalic version is the only alternative to caesarean section for rapid delivery of the second twin in a noncephalic presentation if external cephalic version fails. Thus, when caesarean section is unavailable or when a life-threatening condition arises (maternal hemorrhage due to premature placental separation, fetal distress, prolapsed umbilical cord), internal version may be required.

A life-threatening condition is the only indication for internal podalic version. The cervix must be completely dilated, and the membranes must be intact. A skilled operator is crucial for safe performance of this procedure. In several French studies, internal podalic version was found to be a reliable and effective technique with excellent long-term maternal and fetal prognoses.

Internal podalic version is contraindicated in cases in which the membranes are ruptured or oligohydramnios is present, precluding easy version. This procedure should not be performed through a partially dilated cervix or if the uterus is firmly contracted down on the fetal body. However, recent studies have indicated that intravenous nitroglycerin can be used to provide transient uterine relaxation without affecting maternal or fetal outcome.

Internal podalic version is associated with considerable risk of traumatic injury to both fetus and mother. Prior to 1950, when this procedure was performed much more frequently than it is today, associated uterine rupture and hemorrhage caused 5% of all maternal deaths. Perinatal mortality rates were 5–25% (primarily due to traumatic intracerebral hemorrhage and birth asphyxia). Considerable birth trauma, including long bone fractures, dislocations, epiphyseal separations, and central nervous system deficits, was also linked to this procedure. For these reasons, internal podalic version has been abandoned with rare exceptions in favor of caesarean section.

Internal podalic version is performed by first establishing an intravenous line for administration of parenteral fluids, including blood. Cross-matched blood should be available in the hospital blood bank. Anesthesia is then administered to relax the uterus. The patient is then placed in the dorsolithotomy position. The operator’s hand is inserted through the fully dilated cervix along the fetal body until both feet are identified, and traction is applied to bring the feet into the pelvis and out the introitus. Then, both feet are firmly grasped. An amniotomy is then performed, and dorsal traction is applied on both lower extremities until both feet are delivered through the vagina. A total breech extraction for delivery of the body is then performed (Fig. 19–11).

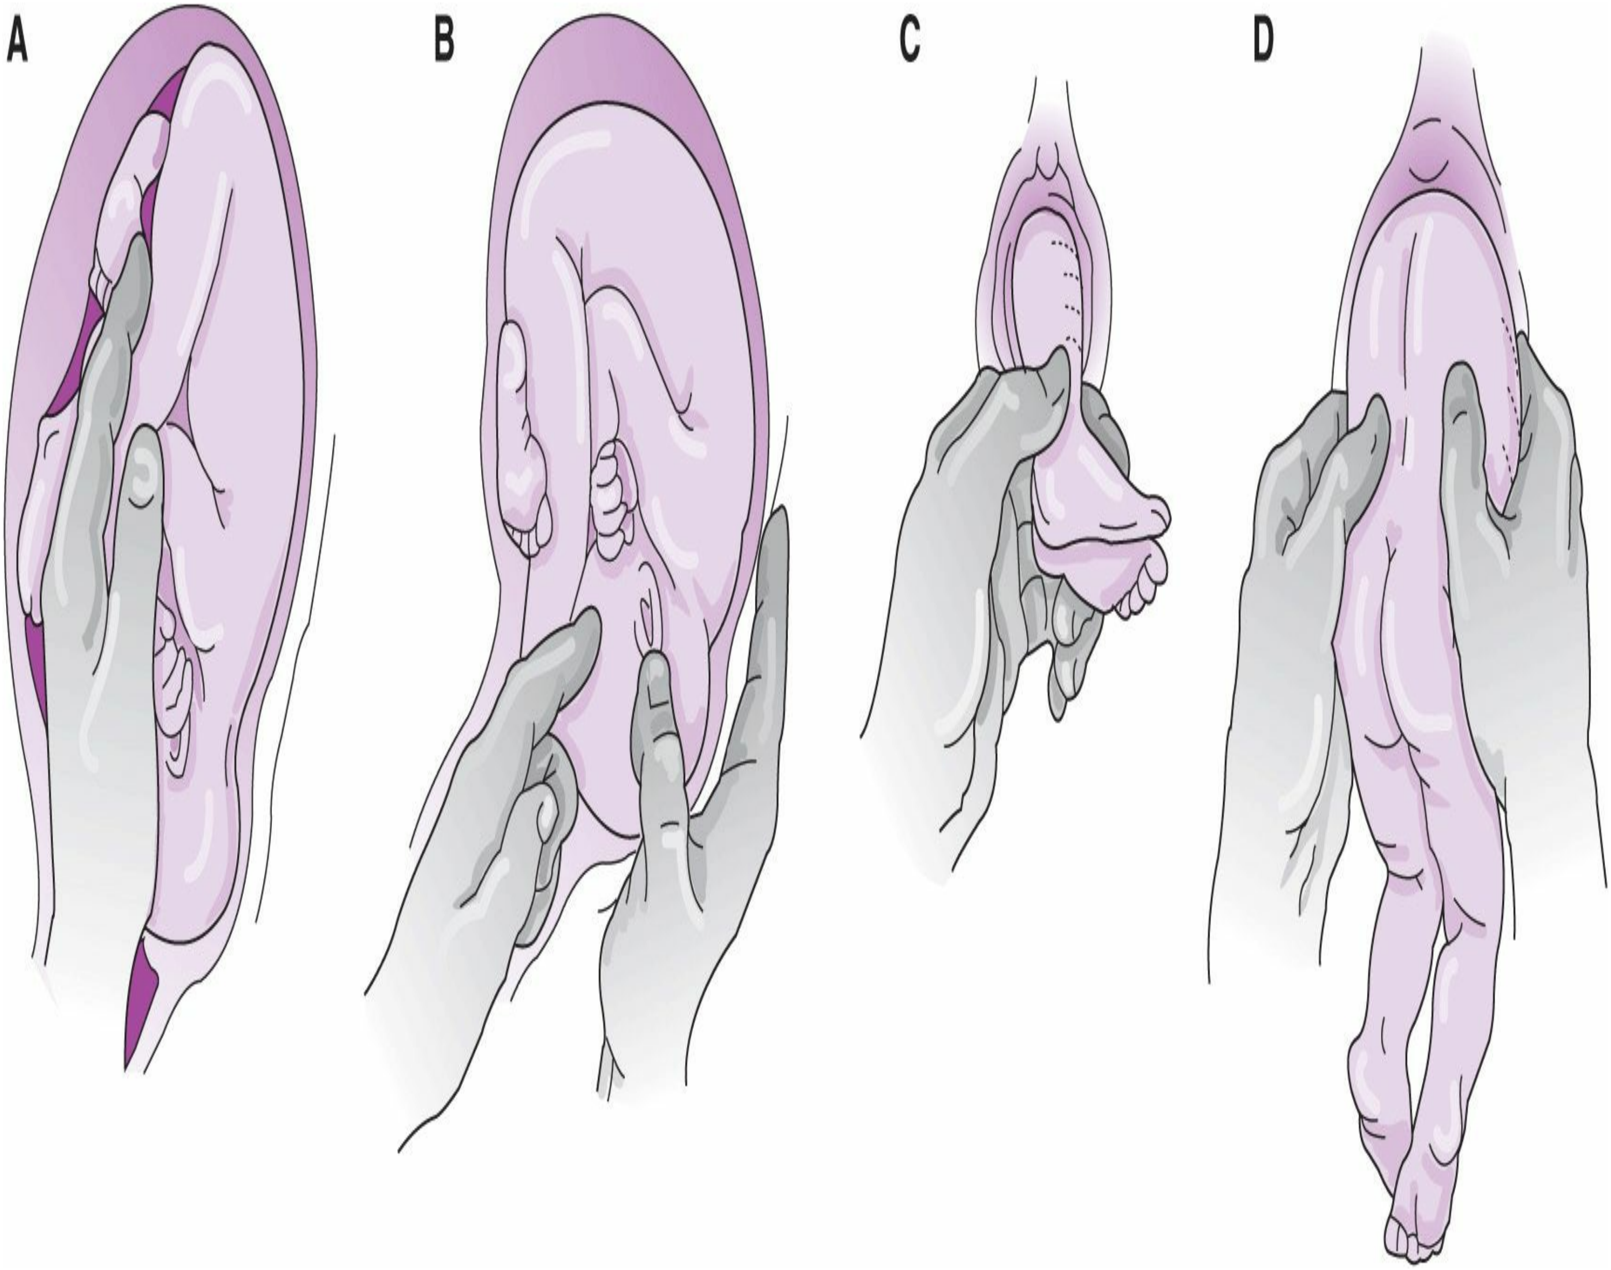

Figure 19–11. Internal podalic version and extraction. **A:** Feet are grasped. **B:** Baby is turned; hand on abdomen pushes head toward uterine fundus. **C:** Feet are extracted. **D:** Torso is delivered. From this point onward, procedure is the same as for uncomplicated breech delivery.

Prognosis

The incidence of caesarean section for breech delivery has been steadily increasing, from approximately 30% in 1970 to 85% in 1999. A recent review of breech deliveries in California revealed an 88% caesarean section rate, with more vaginal deliveries performed in public teaching hospitals and far fewer in private facilities. A decreased number of practitioners currently are skilled in vaginal breech delivery, and although academic faculty support its teaching, there are insufficient numbers of vaginal breech deliveries to properly teach this procedure at most institutions. It should be noted that caesarean section for the immature or malformed fetus does not improve chances for perinatal survival; vaginal delivery should be performed in these cases.

The Term Breech Trial Collaborative Group recently conducted a randomized controlled trial to compare planned caesarean section with vaginal birth for selected breech presentation pregnancies. They found that fetuses of women who underwent planned caesarean sections were less likely to die or to experience poor outcomes in the immediate neonatal period than were fetuses of women who underwent vaginal birth. There was no difference in the 2 groups in terms of maternal mortality or serious morbidity. They concluded that a policy of planned caesarean section will result in 7 caesarean births to avoid 1 infant death or serious morbidity. Because of the results of this trial, the American College of Obstetricians and Gynecologists recommends planned caesarean delivery for persistent breech presentations at term.

COMPOUND PRESENTATION

ESSENTIALS OF DIAGNOSIS

- *Compound presentation* is prolapse of a fetal extremity alongside the presenting part.
- Prolapse of the hand in cephalic presentation is most common, followed by prolapse of an upper extremity in breech presentation. Prolapse of a lower extremity in cephalic presentation is relatively rare.
- Compound presentations are uncommon, occurring in only 1 in 1000 pregnancies.

Pathogenesis

Obstetric factors that prevent descent of the presenting part into the pelvic inlet predispose to prolapse of an extremity alongside the presenting part (ie, prematurity, cephalopelvic disproportion, multiple gestation, grand multiparity, and hydramnios). Prematurity occurs in over 50% of compound presentations. In twin gestations, over 90% of compound presentations are associated with the second twin.

Because of poor application of the presenting part to the cervix found in compound presentations, umbilical cord prolapse is common (occurring in 11–20% of cases) and is a major contributor to fetal loss during labor.

Clinical Findings

The diagnosis of compound presentation is made by palpation of a fetal extremity adjacent to the presenting part on vaginal examination. The diagnosis is usually made during labor; as the cervix dilates, the prolapsed extremity is more easily palpated alongside the vertex or breech. Compound presentation may be suspected if poor progress in labor is noted, particularly when the presenting part fails to engage during the active phase. If the diagnosis of compound presentation is suspected but uncertain, ultrasound can be used to locate the position of the extremities and search for malformations.

Complications

Umbilical cord prolapse is a risk in all cases of compound presentation, and continuous fetal heart rate monitoring should be performed to detect fetal distress or changes in the fetal heart rate. Umbilical cord complications should be managed by immediate caesarean delivery (see below).

Treatment

Management of compound presentation depends on gestational age and type of presentation. Given that 50% of compound presentations are associated with prematurity, viability of the fetus should be documented prior to delivery. If the fetus is considered nonviable, labor should be permitted and vaginal delivery anticipated. The small size of the fetus makes dystocia or difficult vaginal delivery uncommon.

Labor can be allowed and vaginal delivery anticipated in viable cephalic presentations with a prolapsed hand. These cases generally pose no difficulty in labor or delivery because the hand moves upward into the lower uterine segment as the vertex descends into the birth canal. Therefore, expectant management (as opposed to manual reduction of the fetal hand into the uterus) is generally advised.

Prognosis

Compound presentations have been associated historically with perinatal mortality rates ranging from 9 to 19%. Contributing factors are prematurity, prolapsed umbilical cord, and traumatic vaginal delivery.

SHOULDER DYSTOCIA

ESSENTIALS OF DIAGNOSIS

- *Shoulder dystocia* is defined as an inability to deliver the shoulders after the head has delivered.
- Characteristically, after the head is delivered, the chin presses tightly against the perineum as the anterior shoulder becomes impacted behind the pubic symphysis.
- This condition is an acute obstetric emergency requiring prompt, skillful management in order to prevent significant fetal damage or death.
- The incidence of shoulder dystocia ranges from 0.15 to 1.7% of all vaginal deliveries.

Pathogenesis

Primary risk factors that can influence clinical management are fetal macrosomia, gestational or overt diabetes mellitus, a history of shoulder dystocia in a prior birth, a prolonged second stage of labor, and instrumental delivery, particularly a midpelvic delivery. Other risk factors, such as a history of a macrosomic infant, maternal obesity, multiparity, and postterm pregnancy, are mediated through the primary risk factors. However, most women who experience shoulder dystocia have no combination of risk factors that allows clinically useful identification.

Prevention

Efforts at prevention focus on patients with the clinically important risk factors: history of shoulder dystocia, macrosomia by estimated fetal weight (EFW), diabetes, prolonged second stage of labor, and instrumental delivery. Although no study has shown conclusively that offering caesarean delivery in the presence of various combinations of these risk factors is advisable from a risk–benefit analysis, most practitioners apply some or all of these in an attempt to reduce the risk of shoulder dystocia. An example of one approach follows.

1. Prior shoulder dystocia: Offer caesarean.
2. Prior brachial plexus injury: Strongly suggest caesarean.
3. Nondiabetic with macrosomia by EFW (varying thresholds applied between 4500 and 5000 g): Offer caesarean.

4. Diabetic with macrosomia (varying thresholds applied between 4000 and 4500 g): Offer caesarean.
5. Macrosomia by EFW: Avoid instrumental delivery.

It should be noted that labor induction in a nondiabetic woman due to suspected fetal macrosomia does not decrease the occurrence of shoulder dystocia nor does it decrease the rate of caesarean section.

Clinical Findings

Shoulder dystocia should be anticipated given any indications of macrosomia. The diagnosis is confirmed when gentle downward pressure on the head fails to deliver the anterior shoulder from behind the pubic symphysis. At this point, the fetus is at risk for asphyxiation as the fetus cannot expand its chest to breathe, and umbilical cord circulation is compressed within the birth canal. Confronted with this terrifying dilemma, the inexperienced operator often continues to apply downward pressure on the head in a vain attempt to deliver the anterior shoulder. Such action should be avoided, not only because it is ineffective but also because it can potentially damage the brachial plexus and result in permanent Erb’s palsy. A number of maneuvers designed to alleviate shoulder dystocia without increasing traction have been described. No specific sequence of these maneuvers has be shown to be superior to any other, but a commonsense approach based on ease of performance and limitations of risk can be described. Initially, the operator places a hand in the birth canal to assess the posterior outlet. If inadequate, an episiotomy or a proctoepisiotomy is performed. At the same time, assistants including a pediatrician and an anesthesiologist are summoned to aid in the delivery.

Complications

Birth injuries related to shoulder dystocia include fracture of the humerus or clavicle and injury to the brachial plexus (**Erb’s palsy**). Fractures of the humerus and clavicle generally heal without incident, and most injuries to the brachial plexus resolve with minimal or no neurologic deficit detectable during the neonatal period. However, approximately 10% of cases of Erb’s palsies do not resolve. Studies attempting to distinguish the clinical course of patients with permanent injuries from those with transient injuries have found no clinically distinct characteristics. Some severe cases of shoulder dystocia may lead to hypoxic-ischemic encephalopathy and possible death. Maternal complications of shoulder dystocia include postpartum hemorrhage and lacerations involving the cervix, vagina, and perineum

Treatment

The **McRoberts’ maneuver** should be used initially because it is simple and resolves shoulder dystocia in 42% of cases. The maternal legs are hyperflexed onto the maternal abdomen, resulting in flattening of the sacrum and cephalad rotation of the symphysis pubis. If the shoulders remain undelivered, suprapubic pressure is applied by an assistant to dislodge the anterior shoulder while gentle downward pressure on the head is applied. Suprapubic pressure and/or proctoepisiotomy increases success rates to between 54% and 58%. If these attempts are unsuccessful, the examiner can attempt to rotate the fetal shoulders into the oblique position by placing 2 fingers against the posterior shoulder and pushing it around toward the fetal chest (**Rubin maneuver**) or pushing the posterior shoulder around toward the fetal back (**Wood’s maneuver**) in a corkscrew fashion.

If the maneuvers to this point fail, delivery of the posterior arm (Barnum maneuver) is indicated.

The obstetrician's hand is inserted posteriorly into the hollow of the maternal sacrum, and the posterior arm of the fetus is identified. Gentle pressure by the examiner's forefinger on the fetal antecubital fossa will cause flexion of the arm. As the arm flexes across the chest, the forearm is gently grasped, and the hand and forearm are gently delivered from the birth canal. If not, the trunk can be rotated to bring the free arm anteriorly, resulting in delivery. Deliberate fracture of the clavicle also can be performed, preferably in a direction away from the fetal lungs. This action diminishes the size of the shoulder girdle and should facilitate delivery.

Finally, if all previous techniques fail, a **Zavanelli maneuver** can be performed in which the fetal head is replaced in anticipation of a caesarean delivery. A subcutaneous symphysiotomy also can be performed to allow disimpaction of the fetal shoulders. Both of these procedures can be very difficult, are associated with high maternal and fetal morbidity, and should be performed only when other conventional maneuvers have failed.

Prognosis

Women with a history of shoulder dystocia in a prior pregnancy are at increased risk of shoulder dystocia in future pregnancies. Retrospective data put this recurrence risk at 1–25%. It is reasonable to offer women with a history of shoulder dystocia caesarean delivery in future pregnancies.

UMBILICAL CORD PROLAPSE

ESSENTIALS OF DIAGNOSIS

- *Umbilical cord prolapse* is defined as descent of the umbilical cord into the lower uterine segment, where it may lie adjacent to the presenting part (occult cord prolapse) or below the presenting part (overt cord prolapse) (Fig. 19–12).

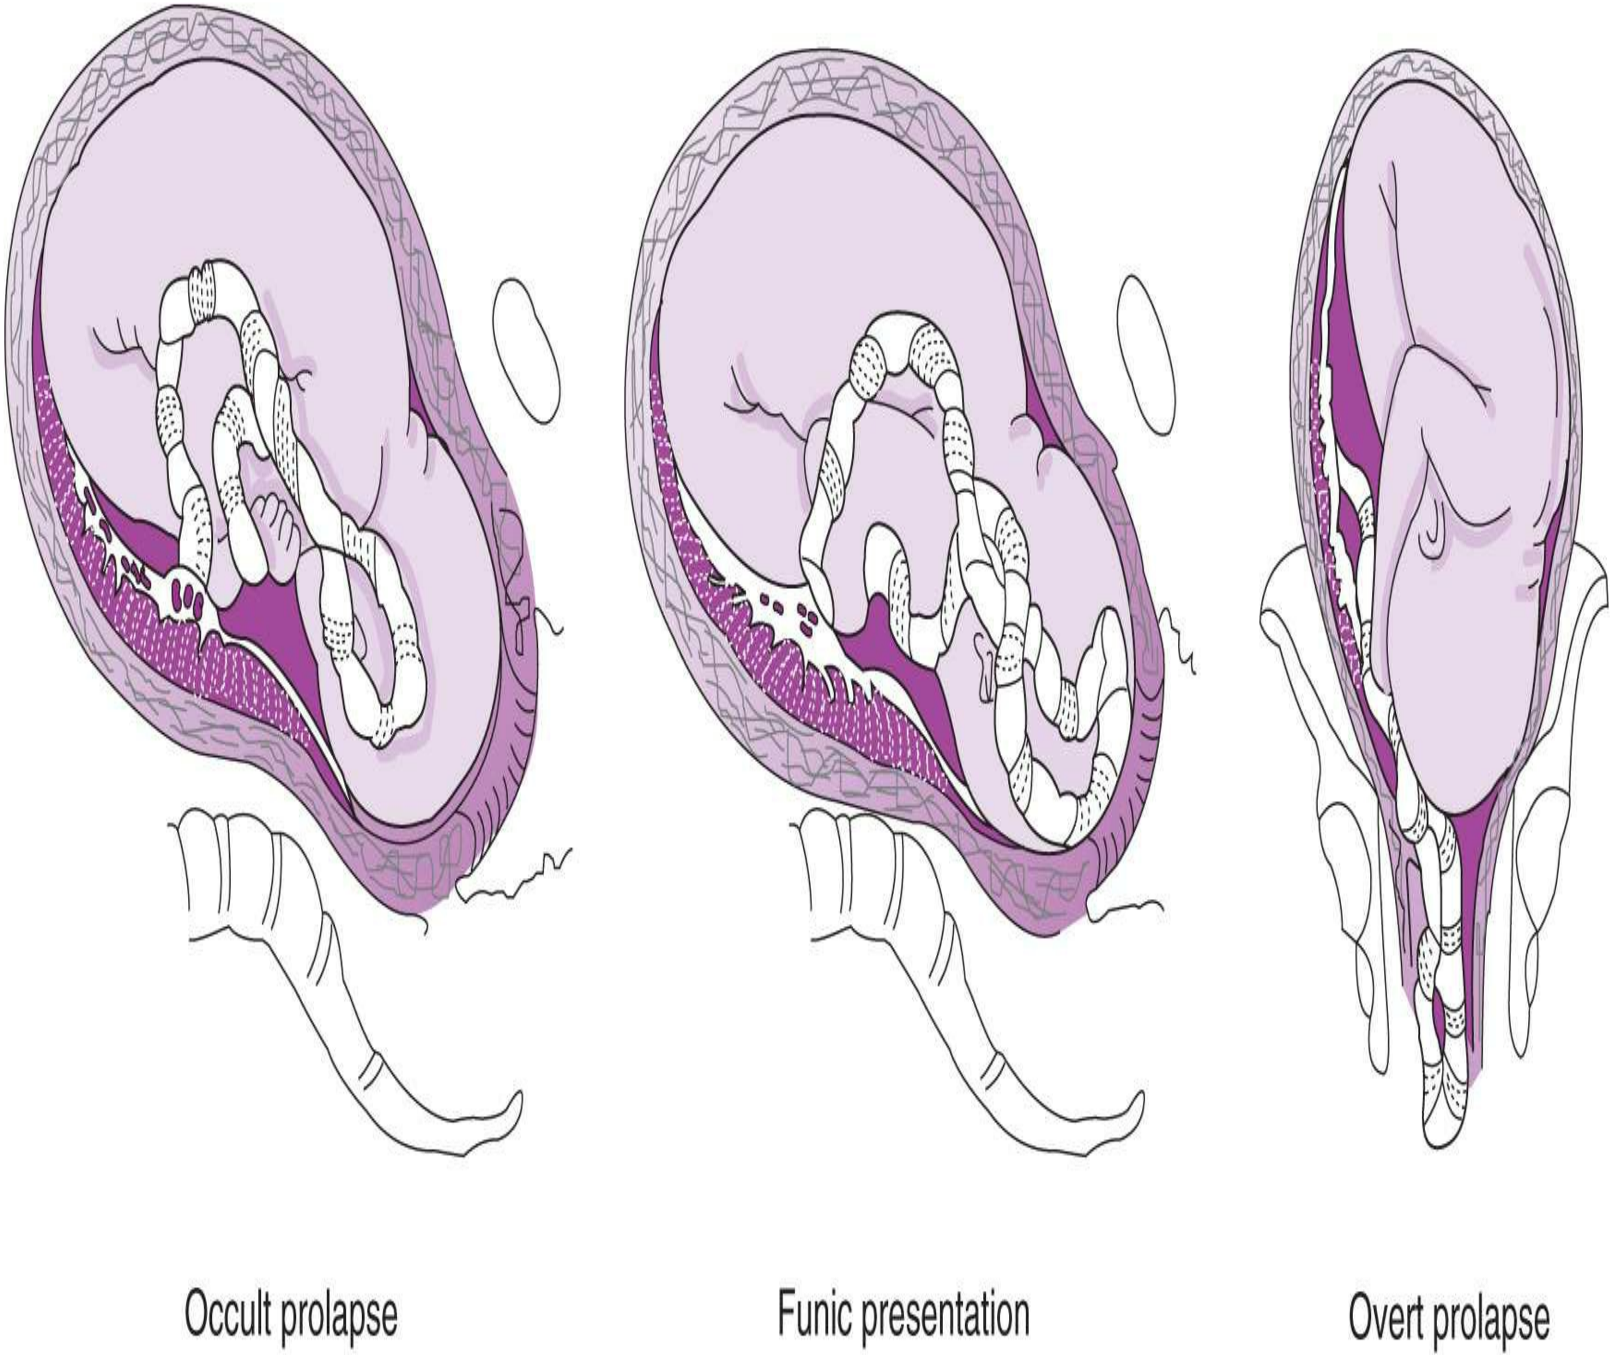

Figure 19–12. Types of prolapsed cords.

- In occult prolapse, the umbilical cord cannot be palpated during pelvic examination, whereas in funic presentation, which is characterized by prolapse of the umbilical cord below the level of the presenting part before the rupture of membranes occurs, the cord often can be easily palpated through the membranes.
- Overt cord prolapse is associated with rupture of the membranes and displacement of the umbilical cord into the vagina, often through the introitus.

Prolapse of the umbilical cord to a level at or below the presenting part exposes the cord to intermittent compression between the presenting part and the pelvic inlet, cervix, or vaginal canal. Compression of the umbilical cord compromises fetal circulation and, depending on the duration and intensity of compression, may lead to fetal hypoxia, brain damage, and death. In overt cord prolapse, exposure of the umbilical cord to air causes irritation and cooling of the cord, resulting in further vasospasm of the cord vessels. For these reasons, cord prolapse is considered to be an obstetric emergency.

The incidence of overt umbilical cord prolapse in cephalic presentations is 0.5%, frank breech 0.5%, complete breech 5%, footling breech 15%, and transverse lie 20%. The incidence of occult prolapse is unknown because it can be detected only by fetal heart rate changes characteristic of umbilical cord compression. However, some degree of occult prolapse appears to be common, given that as many as 50% of monitored labors demonstrate fetal heart rate changes compatible with umbilical cord compression. In most cases, the compression is transient and can be rectified simply by changing the patient's position.

Whether occult or overt, umbilical cord prolapse is associated with significant rates of perinatal morbidity and mortality because of intermittent compression of blood flow and resultant fetal hypoxia. The perinatal mortality rate associated with all cases of overt umbilical cord prolapse approaches 20%. Prematurity, itself a contributor to the incidence of umbilical cord prolapse, accounts for a considerable portion of this perinatal loss.

Pathogenesis

Any obstetric condition that predisposes to poor application of the fetal presenting part to the cervix can result in prolapse of the umbilical cord. Cord prolapse is associated with prematurity (<34 weeks' gestation), abnormal presentations (breech, brow, compound, face, transverse), occiput posterior positions of the head, pelvic tumors, multiparity, placenta previa, low-lying placenta, and cephalopelvic disproportion. In addition, cord prolapse is possible with polyhydramnios, multiple gestation, or premature rupture of the membranes occurring before engagement of the presenting part. A recent study revealed that obstetric intervention contributes to nearly half of cases of umbilical cord prolapse. Examples cited include amniotomy, scalp electrode application, intrauterine pressure catheter insertion, attempted external cephalic version, and expectant management of preterm premature rupture of membranes.

Prevention

Patients at risk for umbilical cord prolapse should be treated as high-risk patients. Patients with fetal malpresentation or poorly applied cephalic presentations should be considered for ultrasonographic examination at the onset of labor to determine fetal lie and cord position within the uterine cavity. Because most prolapses occur during labor as the cervix dilates, patients at risk for cord prolapse should be continuously monitored to detect abnormalities of the fetal heart rate. Artificial rupture of membranes should be avoided until the presenting part is well applied to the cervix. At the time of spontaneous membrane rupture, a prompt, careful pelvic examination should be performed to rule out cord prolapse. Should amniotomy be required and the presenting part remains unengaged, careful needling of the membranes and slow release of the amniotic fluid can be performed until the presenting part settles against the cervix.

Clinical Findings

A. Overt Cord Prolapse

Overt cord prolapse can be diagnosed simply by visualizing the cord protruding from the introitus or by palpating loops of cord in the vaginal canal.

B. Funic Presentation

The diagnosis of funic presentation is made by pelvic examination if loops of cord are palpated through the membranes. Antepartum detection of funic presentation is discussed below.

C. Occult Prolapse

Occult prolapse is rarely palpated during pelvic examination. This condition can be inferred only if fetal heart rate changes (variable decelerations, bradycardia, or both) associated with intermittent compression of the umbilical cord are detected during monitoring.

Complications

A. Fetus

The fetus in good condition whose well-being is jeopardized by umbilical cord compression may exhibit violent activity readily apparent to the patient and the obstetrician. Variable fetal heart rate decelerations will occur during uterine contractions, with prompt return of the heart rate to normal as each contraction subsides. If cord compression is complete and prolonged, fetal bradycardia occurs. Persistent, severe, variable decelerations and bradycardia lead to development of hypoxia, metabolic acidosis, and eventual damage or death. As the fetal status deteriorates, activity lessens and eventually ceases. Meconium staining of the amniotic fluid may be noted at the time of membrane rupture.

B. Maternal

Caesarean section is a major operative procedure with known anesthetic, hemorrhagic, and operative complications. These risks must be weighed against the real risk to the fetus of continued hypoxia if labor were to continue.

Maternal risks encountered at vaginal delivery include laceration of the cervix, vagina, or perineum resulting from a hastily performed delivery.

C. Neonatal

The neonate at delivery may be hypoxic, acidotic, or moribund. A pediatric team should be present to effect immediate resuscitation of the newborn.

Treatment

A. Overt Cord Prolapse

The diagnosis of overt cord prolapse demands immediate action to preserve the life of the fetus. An immediate pelvic examination should be performed to determine cervical effacement and dilatation, station of the presenting part, and strength and frequency of pulsations within the cord vessels. If the fetus is viable, the patient should be placed in the knee–chest position, and the examiner should apply continuous upward pressure against the presenting part to lift and maintain the fetus away from the prolapsed cord until preparations for caesarean delivery are complete. Alternatively, 400–700 mL of saline can be instilled into the bladder in order to elevate the presenting part. Oxygen should be given to the mother until the anesthesiologist is prepared to administer a rapid-acting inhalation anesthetic for delivery. Successful reduction of the prolapsed umbilical cord has been described, but such an attempt may worsen fetal heart rate changes and should not delay preparation for caesarean delivery. Abdominal delivery should be accomplished as rapidly as possible through a generous midline abdominal incision, and a pediatric team should be on standby in the event immediate resuscitation of the newborn is necessary.

B. Occult Cord Prolapse

If cord compression patterns (variable decelerations) of the fetal heart rate are recognized during labor, an immediate pelvic examination should be performed to rule out overt cord prolapse. If occult cord prolapse is suspected, the patient should be placed in the lateral Sims or Trendelenburg position in an attempt to alleviate cord compression. If the fetal heart rate returns to normal, labor can be allowed to continue, provided no further fetal insult occurs. Oxygen should be administered to the mother, and the fetal heart rate should be continuously monitored electronically. Amnioinfusion can be performed via an intrauterine pressure catheter in order to instill fluid within the uterine cavity and possibly decrease the incidence of variable decelerations. If the cord compression pattern persists or recurs to the point of fetal jeopardy (moderate to severe variable decelerations or bradycardia), a rapid caesarean section should be accomplished.

C. Funic Presentation

The patient at term with funic presentation should be delivered by caesarean section prior to membrane rupture. However, there is no consensus on management if the fetus is premature. The most conservative approach is to hospitalize the patient on bed rest in the Sims or Trendelenburg position in an attempt to reposition the cord within the uterine cavity. Serial ultrasonographic examinations should be performed to ascertain cord position, presentation, and gestational age.

D. Route of Delivery

Vaginal delivery can be successfully accomplished in cases of overt or occult cord prolapse if, at the time of prolapse, the cervix is fully dilated, cephalopelvic disproportion is not anticipated, and an experienced physician determines that delivery is imminent. Internal podalic version, midforceps rotation, or any other operative technique is generally more hazardous to mother and fetus in this situation than is a judiciously performed caesarean delivery. Caesarean delivery is the preferred route of delivery in most cases. Vaginal delivery is the route of choice for the previable or dead fetus.

Prognosis

A. Maternal

Maternal complications include those related to anesthesia, blood loss, and infection following caesarean section or operative vaginal delivery. Maternal recovery is generally complete.

B. Neonatal

Although the prognosis for intrapartum cord prolapse is greatly improved, fetal mortality and morbidity rates still can be high, depending on the degree and duration of umbilical cord compression occurring before the diagnosis is made and neonatal resuscitation is started. If the diagnosis is made early and the duration of complete cord occlusion is < 5 minutes, the prognosis is good. Gestational age and trauma at delivery also affect the final neonatal outcome. If complete cord occlusion has occurred for longer than 5 minutes or if intermittent partial cord occlusion has occurred over a prolonged period of time, fetal damage or death may occur.

Operative Delivery

Marc H. Incerpi, MD

An operative delivery refers to an obstetric procedure in which active measures are taken to accomplish delivery. Operative delivery can be divided into operative vaginal delivery and caesarean delivery. The last several years have seen a steady decline in the operative delivery with an increase in the caesarean section rate. In addition, vacuum-assisted vaginal delivery has become more common than forceps. Most recent data from births in the United States during 2005 indicate that the vacuum-to-forceps ratio is approximately 4:1. The success and safety of these procedures are based on operator skill, proper timing, and ensuring that proper indications are met while contraindications are avoided. This chapter explains how each procedure is performed, the indications and contraindications to the procedure, the potential complications, and how to minimize complications.

FORCEPS OPERATIONS

The obstetric forceps is an instrument designed to assist with delivery of the baby's head. The invention of the precursor to modern forceps is credited to Peter Chamberlin in the 1600s. It is used either to expedite delivery or to assist with certain abnormalities in the cephalopelvic relationship that interfere with advancement of the head during labor. The primary functions of the forceps are to assist with traction of the fetal head and/or to assist with rotation of the fetal head to a more desirable position.

Although forceps-assisted vaginal deliveries were once extremely popular, the most recent data demonstrate that only one-quarter of all operative vaginal deliveries are performed using forceps. The reverse was true approximately 10 years ago. In fact, many investigators are concerned that the use of forceps is becoming a lost art. The reasons often cited in contributing to the decline in the use of forceps are (1) medicolegal implications and fear of litigation, (2) reliance on caesarean section as a remedy for abnormal labor and suspected fetal jeopardy, (3) perception that the vacuum is easier to use and less risky to fetus and mother, and (4) decreased number of residency programs that actively train residents in the use of forceps. These factors have led to a cycle in which less teaching has led to a decrement in technical skills, an increased fear of litigation, and a resultant further decrease in the use of forceps.

THE OBSTETRIC FORCEPS

The obstetric forceps (Fig. 20–1) consists of 2 matched parts that articulate or "lock." Each part is composed of a blade, shank, lock, and handle. Each blade is designed so that it possesses 2 curves: the cephalic curve, which permits the instrument to be applied accurately to the sides of the baby's head, and the pelvic curve, which conforms to the curved axis of the maternal pelvis. The tip of each blade is called the toe. The front of the forceps is the concave side of the pelvic curve. The blades are referred to the left and right according to the side of the mother's pelvis on which they lie after application. During application, the handle of the left blade is held in the left hand, and the blade is applied to the left side of the mother's pelvis. Conversely, the handle of the right blade is held in the right hand and inserted so as to lie on the right side of the mother's pelvis. When the blades are inserted in this order, the right shank comes to lie atop the left so that the forceps articulate, or lock, as the handles are closed.

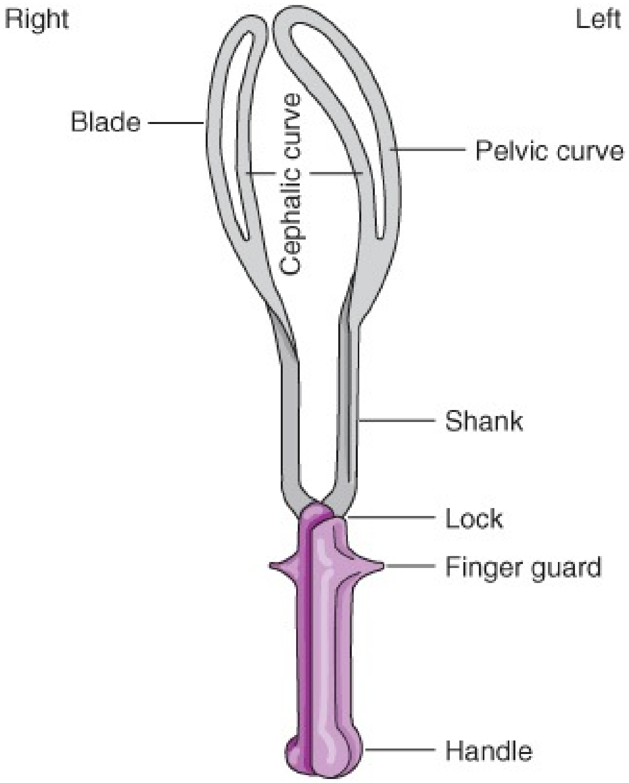

Figure 20–1. DeLee modification of Simpson forceps. (Reproduced, with permission, from Benson RC. *Handbook of Obstetrics & Gynecology*. 8th ed. Los Altos, CA: Lange; 1983.)

Physicians have been modifying 1 or more of the 4 basic parts since forceps were first invented. Although more than 600 kinds of forceps have been described, only a few are currently in use (Fig. 20–2). Although it is beyond the scope of this chapter to discuss all the different varieties of forceps and their indications, a brief comment on the more common types of forceps is appropriate. Simpson or Elliot forceps are most often used for outlet vaginal deliveries, whereas Kielland or Tucker-McLane forceps are used for rotational deliveries. Piper forceps are used in the United States for delivery of the aftercoming head in vaginal breech deliveries. The pelvic and cephalic curve, shank, blade, lock, and handle are different for each type of forceps. These features determine the type of forceps that is best suited for the appropriate indication. For example, Piper forceps, which are specifically designed for breech deliveries, have a reverse pelvic curve compared to other forceps. Simpson forceps are suited for application to the molded fetal head, whereas Tucker-McLane forceps or Kielland forceps are more appropriate to the fetal head with little or no molding.

INDICATIONS & CONDITIONS FOR FORCEPS DELIVERY

In each of the following indications for forceps delivery, it must be emphasized that caesarean section is an alternative procedure that should be considered depending on the prevailing circumstances. Recognizing the inherent risks of both procedures, the obstetrician must decide which operation (vaginal delivery or caesarean section) will be safer for the mother and baby.

The indications for forceps delivery are as follows: (1) nonreassuring fetal heart rate pattern, (2) shortening of the second stage of labor for maternal reasons, (3) prolonged second stage of labor not due to dystocia, and (4) delivery of the aftercoming head in a breech presentation. A prolonged second stage of labor has been defined according to parity. In a nulliparous patient, a prolonged second stage is defined as more than 3 hours with a regional anesthetic or more than 2 hours without a regional anesthetic. In a multiparous patient, more than 2 hours with a regional anesthetic or more than 1 hour without a regional anesthetic constitutes a prolonged second stage of labor.

In order for the patient to be considered a candidate for forceps-assisted vaginal delivery with a cephalic presentation, *all* of the following prerequisites must be met: (1) complete cervical dilatation, (2) ruptured membranes, (3) fetal head engaged with the fetal head position known, (4) empty bladder, (5) no evidence of cephalopelvic disproportion, (6) adequate analgesia, (7) caesarean section capability, and (8) an experienced operator.

CLASSIFICATION OF FORCEPS DELIVERIES

In 1988 the American College of Obstetricians and Gynecologists redefined the classification of forceps. As discussed later, the same classification should be applied to vacuum delivery. This classification uses the leading bony point of the fetal skull and its relationship to the maternal ischial spines in centimeters as the point of reference. Each station of the fetal head refers to the relationship of the leading bony part of the fetal skull with respect to the ischial spines. The fetal head is said to be at 0 station when the head is at the level of the spines. When the head is above this level, the station is described as –1 through –5, corresponding to the number of centimeters above the level of the ischial spines. When the head is below this level, the station is described as +1 through +5, corresponding to the number of centimeters below the level of the ischial spines.

The classification of forceps is defined as follows:

1. **Outlet forceps** is the application of forceps when (a) the fetal scalp is visible at the introitus without separating the labia, (b) the fetal skull has reached the pelvic floor, (c) the sagittal suture is in the anteroposterior diameter or in the right or left occiput anterior or posterior position, and (d) the fetal head is at or on the perineum. According to this definition, rotation of the fetal head must be ≤45 degrees.
2. **Low forceps** is the application of forceps when the leading point of the fetal skull is at station +2 or greater and not on the pelvic floor. Low forceps have 2 subdivisions: (a) rotation ≤45 degrees and (b) rotation >45 degrees.
3. **Midforceps** is the application of forceps when the head is engaged but the leading point of the fetal skull is above station +2.

Only rarely should an attempt be made at forceps delivery above station +2. Under unusual circumstances, such as sudden onset of severe fetal or maternal compromise or transverse arrest, application of forceps above station +2 can be attempted while simultaneously initiating preparation for a caesarean delivery in case the forceps maneuver is unsuccessful. *Under no circumstances should forceps be applied to an unengaged head*.

PREPARATION OF THE PATIENT FOR FORCEPS DELIVERY

The patient must be placed in the dorsal lithotomy position and the bladder should be emptied. The legs should be comfortably placed in stirrups with the hips flexed and abducted. The abdomen and legs should be adequately draped, and the vagina and the perineum should be prepped in usual fashion. If conduction (spinal/epidural) anesthesia is to be used, it must be administered prior to the foregoing steps in delivery. If pudendal block or local infiltration is to be used, it should be administered after the preliminary examination has been performed and all is in readiness for delivery. An appropriate and effective anesthetic is essential to the performance of a forceps delivery.

The Preliminary Examination

Before the application of forceps, a careful examination if necessary to determine the following:

1. **The position of the fetal head**, which usually is easily determined by first locating the lambdoid sutures and then determining the direction of the sagittal suture. The posterior fontanelle is readily evident after the 3 sutures running into it are identified. If the most accessible fontanelle is found to have 4 sutures running into it, it is the anterior fontanelle and the position usually is occiput posterior. In the presence of marked edema of the scalp or caput succedaneum, both sutures and fontanelles may be masked, and the position can only be determined by feeling an ear and noting the direction of the pinna. It must be emphasized that if the position of the fetal head cannot be adequately determined, then forceps should not be applied.
2. **The station of the fetal head**, which is the relationship of the presenting part to the ischial spines, must be determined. In labor that proceeds swiftly without complications, such a determination usually is simple and accurate. However, when the first or especially the second stage of labor is prolonged and is further complicated by marked molding and a heavy caput, this relationship may suggest a false level of the head in the pelvis. If the head can be felt above the symphysis pubis, forceps should not be used.
3. **The adequacy of the pelvic diameters** of the midpelvis and outlet is determined by noting the following: (a) the prominence of the ischial spines, the degree to which they shorten the transverse diameter of the midpelvis, and the amount of space between the spine and the side of the fetal head; (b) the contour of the accessible portion of the sacrum and the amount of space posterior to the head usually based on the length of the sacrospinous ligament; and (c) the width of the subpubic arch. This kind of appraisal is neither needed nor feasible for outlet forceps, but is essential for indicated low forceps or midforceps.

APPLICATION OF FORCEPS

A major concept to bear in mind is that the application of forceps should use finesse rather than force. Before the forceps are applied to the fetal head, a “phantom application” should be performed first. It is vital to inspect the forceps to ensure that they consist of a complete and matched set and that they articulate (lock) easily. Forceps should be applied in a delicate fashion in order to avoid potential injury to the vagina and perineum. The goal is for the blades to fit the fetal head as evenly and symmetrically as possible. The blades should lie evenly against the side of the head, covering the space between the orbits and ears (Fig. 20–3). It is important to emphasize that correct application prevents soft tissue and nerve injury, as well as bony injuries to the fetal head. After the forceps have been applied, they should articulate easily. If the forceps cannot be easily articulated, the forceps should be removed and a second attempt made. Once the forceps articulate, the following checks should be performed for delivery of an occiput anterior position before any traction is placed on the fetal head. (1) The sagittal suture should be perpendicular to the plane of the shanks. (2) The posterior fontanelle should be 1 finger-breadth away from the shanks equidistant from the sides of the blades, and directly in front of the articulated forceps. (3) If fenestrated (open) blades are used, the amount of fenestration in front of the fetal head should admit no more than the tip of 1 finger. After these checks have been performed, then traction can safely be applied to the fetal head. Traction forces should be applied in the plane of least resistance and should follow the pelvic curve. This can best be accomplished by applying downward pressure on the shanks with outward pressure exerted upon the handle of the forceps. Once the fetal head begins to emerge out of the vagina, the forceps are disarticulated, and the head is delivered via a modified Ritgen maneuver. After delivery, it is important to ensure that no vaginal or perineal lacerations go unrecognized, paying particular attention to deep lateral vaginal sidewall (sulcal) lacerations. Lacerations, if present, should be repaired in customary fashion.

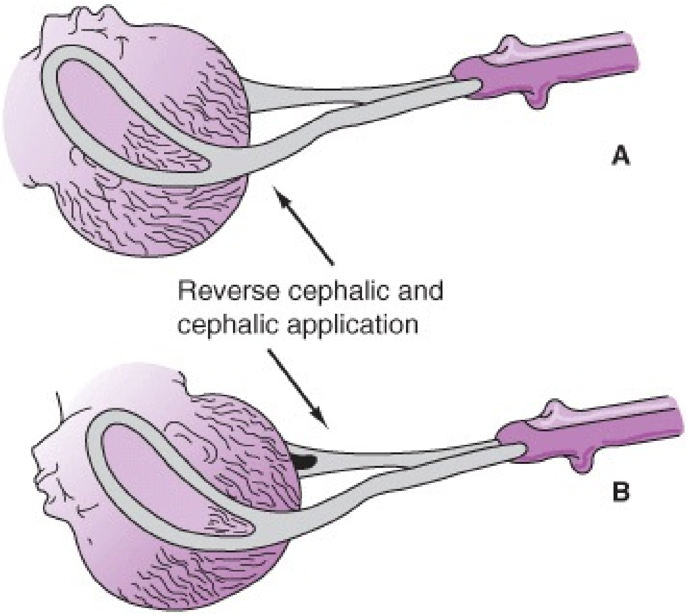

Figure 20–3. Forceps correctly applied along occipitomental diameter of head in various positions of the occiput. **A:** Occiput posterior. **B:** Occiput anterior. (Reproduced, with permission, from Benson RC. *Handbook of Obstetrics & Gynecology*. 8th ed. Los Altos, CA: Lange; 1983.)

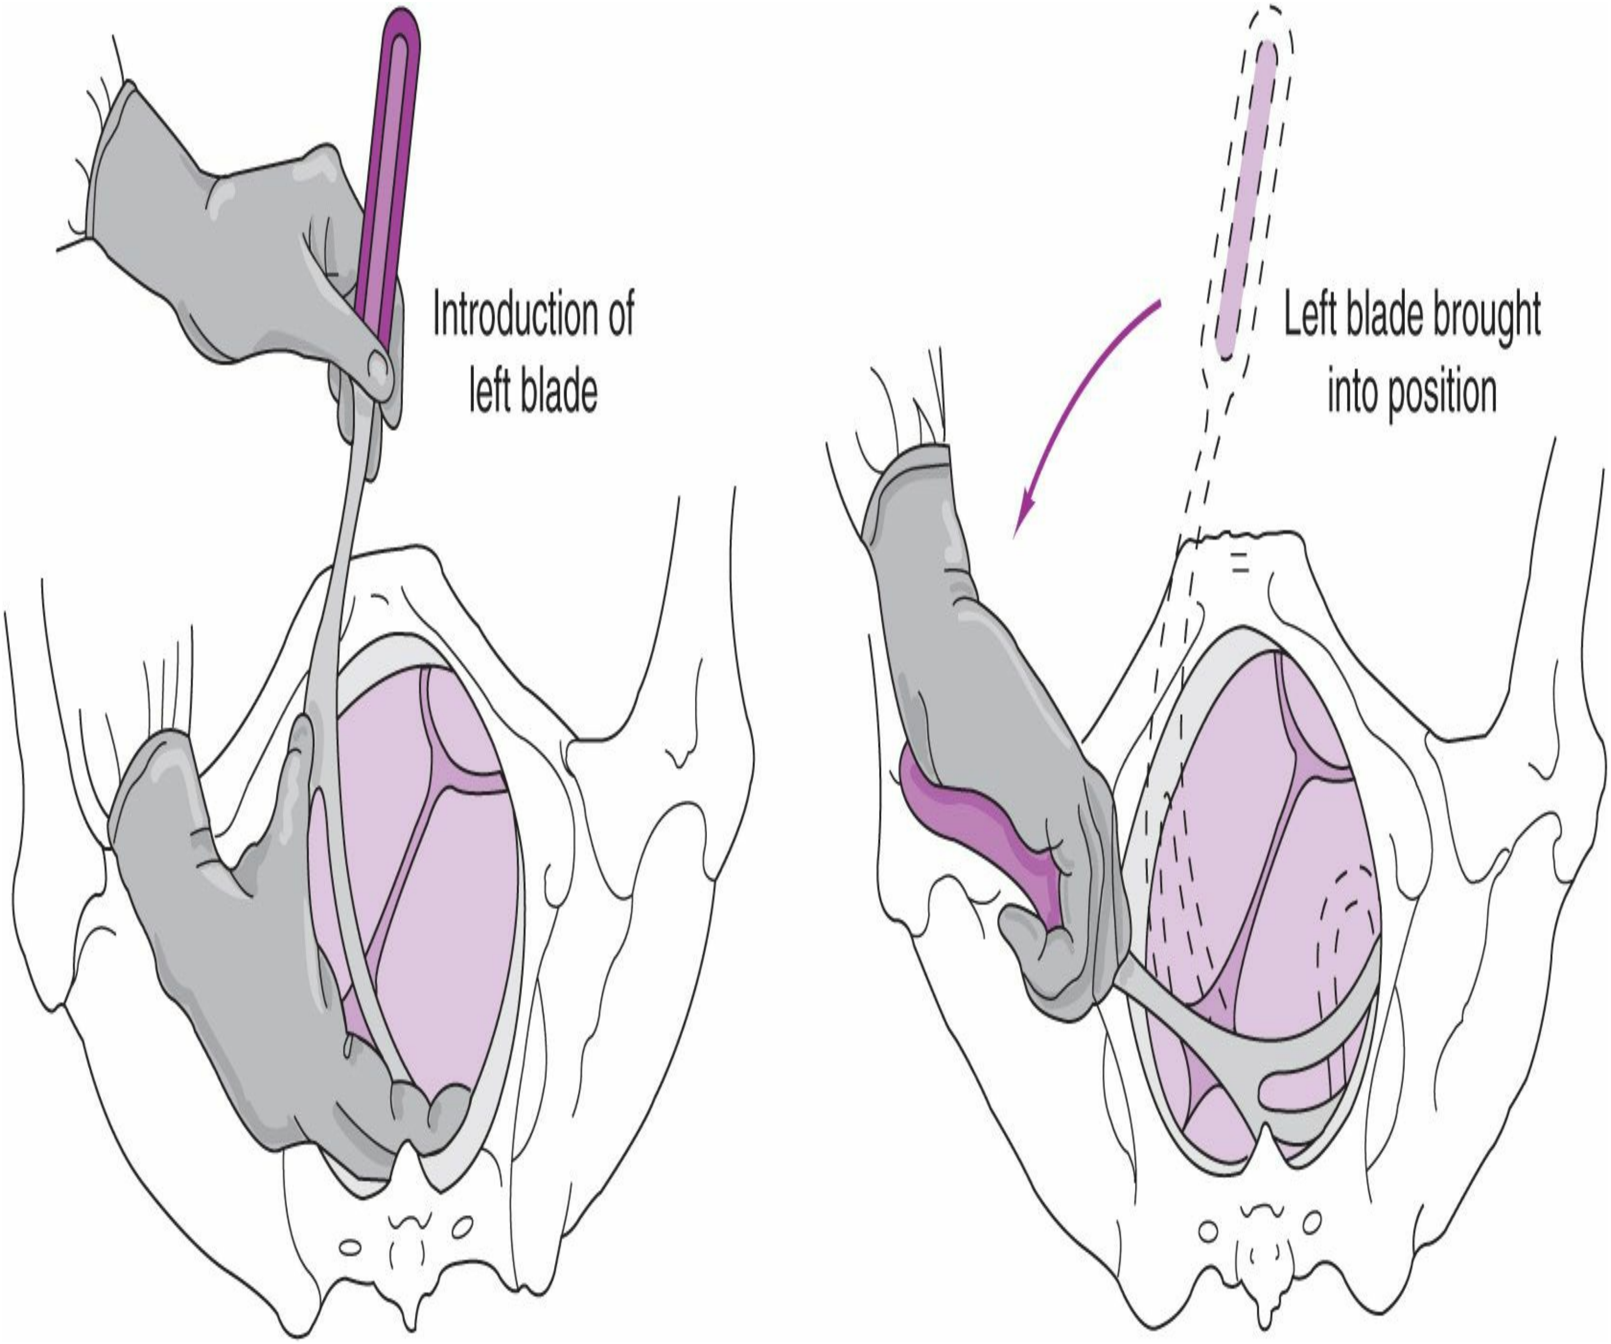
A more detailed step-by-step description of a forceps-assisted vaginal delivery in the occiput anterior position is as follows (Figs. 20–4 through 20–6). The left handle is held between the thumb and fingers of the left hand. Using 2 or 3 fingers of the right hand placed into the vagina, the blade is guided to its correct position on the left side of the fetal head (Fig. 20–4). This maneuver is repeated with the right hand and the right blade, using the fingers of the left hand placed into the vagina to guide the blade (Fig. 20–5). The handles are depressed slightly before locking, in order to place the blades properly along the optimal diameter of the fetal head (Fig. 20–6).



Introduction of left blade
Left blade brought into position

Figure 20–4. Introduction of left blade (left blade, left hand, left side of pelvis). The handle is held with the fingers and thumb, not clenched in the hand. The handle is held vertically. The blade is guided with the fingers of the right hand. Placement of blade is completed by swinging the handle down to the horizontal plane.

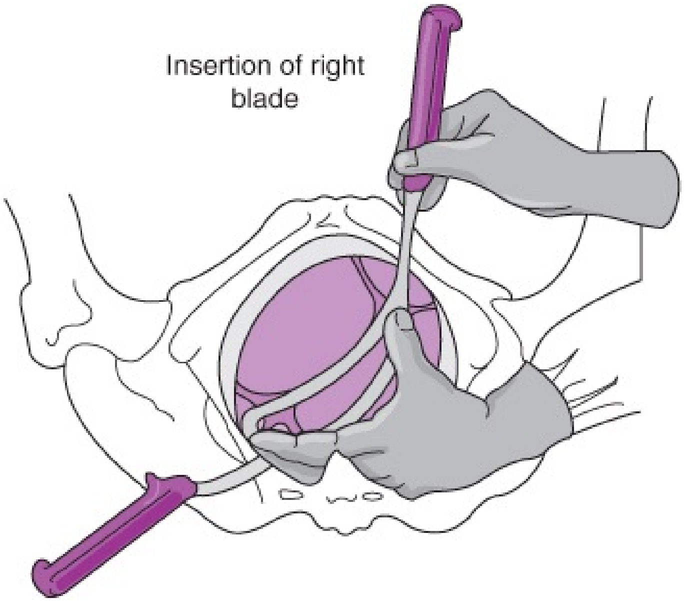


Figure 20–5. Introduction of right blade (right blade, right hand, right side of pelvis). The left blade is already in place. The handle is grasped with the fingers and thumb, not gripped in the whole hand. The handle is held vertically. (Reproduced, with permission, from Benson RC. *Handbook of Obstetrics & Gynecology*. 8th ed. Los Altos, CA: Lange; 1983.)

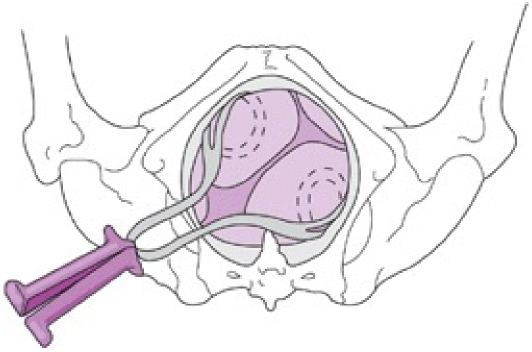

Figure 20–6. Both blades introduced. The 2 handles are brought together and locked. If application is correct, the handles lock precisely, without the need for force. (Reproduced, with permission, from Benson RC. *Handbook of Obstetrics & Gynecology*. 8th ed. Los Altos, CA: Lange; 1983.)

The forceps are designed such that they lock easily as the handles are closed if the application is accurate. If the handles are askew or if any force is needed to achieve precise articulation, the application is faulty and the position must be rechecked. If simple manipulation of the blades does not permit easy articulation, the forceps should be removed, the position verified (by feeling an ear, if necessary), and the blades reapplied correctly. After the 3 checks have been adequately performed, traction can be applied.

Obstetricians hold forceps for traction in different ways. One method is to grab the crossbar of the handle between the index and middle fingers of the left hand from underneath and to insert the middle and index fingers of the right hand in the crotch of the instrument from above. Another method is to grasp the handles with the fingers on the top of the handles or shanks and the thumbs on the bottom. Traction is made only in the axis of the pelvis along the curve of the birth canal. No more force is applied than can be exerted by the flexed forearms; the muscles of the back must be used, and the feet must not be braced. If a greater degree of traction is needed, the cause may be cephalopelvic disproportion, asynclitism of the fetal head, or an error in the evaluation of the pelvic diameters. The obstetrician then should reassess the possibility of successful vaginal delivery.

As the head begins to distend the perineum, both the amount and direction of traction must be altered. The farther the head advances, the less the resistance offered by both the pelvis and soft parts; hence, only minimal traction should be applied as the head is about to be delivered. The head negotiates the final position of the pelvic curve by extension, and the physician should simulate this movement by elevating the handles of the forceps more and more as the head crowns (Fig. 20–7). If the forceps are allowed to remain in place throughout delivery of the fetal head, the handles will have passed the vertical plane as delivery of the head is completed. It is preferable to remove the forceps as the head crowns in the reverse order of their application by first disarticulating the forceps and raising the right handle until the blade is delivered. The left blade is then removed in similar fashion. Early removal of the forceps reduces the size of the mass that must pass through the introitus and thus reduces the likelihood of lacerations or extensions of episiotomies. After removal of the forceps, the head may recede; however, if the forceps have not been removed too soon, the head can be delivered by the use of the modified Ritgen maneuver during the next contraction. Because rotations with forceps and vaginal breech deliveries are now rarely, if ever performed, it is beyond the scope of this chapter to discuss these techniques.

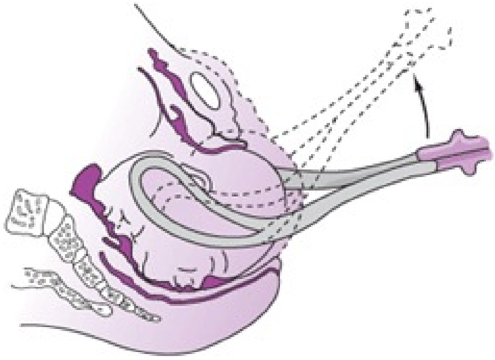

Figure 20–7. Upward traction with low forceps. As the head extends, the handles are raised until they pass the vertical. Little force is needed. One hand suffices; the other hand may support the perineum. (Reproduced, with permission, from Benson RC. *Handbook of Obstetrics & Gynecology*. 8th ed. Los Altos, CA: Lange; 1983.)

DANGER & SAFETY OF FORCEPS

Although the use of forceps has fallen into disfavor over the last few years, few studies have prospectively evaluated the safety of forceps. A number of injuries to both mother and baby can result from the use of forceps, some serious and even fatal. Maternal complications include lacerations of the vagina and cervix, episiotomy extensions involving third- and fourth-degree lacerations, pelvic hematomas, urethral and bladder injuries, and uterine rupture. In addition, blood loss and the need for blood transfusion are increased in forceps deliveries. The baby may sustain minor facial lacerations, forceps marks, facial and brachial plexus palsies, cephalohematomas, skull fractures, intracranial hemorrhage, and seizures.

Many of these serious injuries and many of the minor ones inflicted by obstetric forceps result from errors in judgment rather than lack of technical skill. Such errors include failure to recognize the essential conditions for forceps delivery and lack of an appropriate indication for the operation as outlined earlier. The potential for injury increases in the following settings: (1) intervention occurs too early, before maximal molding and descent have been achieved by the patient’s voluntary efforts, (2) continued traction is used in the presence of unrecognized cephalopelvic disproportion, (3) errors in diagnosis of the position of the fetal head, and (4) unwillingness to abandon the procedure and perform caesarean section. Most reports clearly demonstrate that maternal and/or fetal complications are more common with midforceps than with low or outlet forceps. The perception of increased fetal and maternal risk has served as one of the major driving forces contributing to the widespread decline in the use of forceps.

THE VACUUM EXTRACTOR

The idea of using a suction device applied to the fetal scalp to help facilitate deliver of the fetal head originated in the 1700s. The first vacuum cup was not designed until 1890. As one could well imagine, the first types of vacuum devices were crude, resembling a toilet plunger. In fact, the vacuum device did not gain much popularity until Malmström introduced a metal vacuum cup in 1954. The most common type of vacuum in use today is a pliable, Silastic cup with a handheld pump and gauge that allow delivery of the proper amount of suction pressure to the fetal head to effect delivery. Two models are shown in Figures 20–8 and 20–9. The vacuum extractor works by allowing the external traction forces applied to the fetal scalp to be transmitted to the fetal head. The traction on the vacuum apparatus increases the forces of delivery and facilitates passage of the fetus through the pelvis. In order for delivery to be accomplished, both traction on the fetal scalp and compression of the fetal head occur.

INDICATIONS & CONTRAINDICATIONS FOR VACUUM DELIVERY

With the exception of delivery of the aftercoming head in a breech presentation, the indications for vacuum use are similar to those of forceps: (1) nonreassuring fetal heart rate pattern, (2) shortening of the second stage of labor for maternal reasons, and (3) prolonged second stage of labor. In addition, as mentioned earlier, the classification of forceps deliveries is the same classification used for vacuum deliveries, and the prerequisites are similar. Contraindications for vacuum delivery include the following: face presentation, breech presentation, true cephalopelvic disproportion, congenital anomalies of the fetal head (eg, hydrocephalus), gestational age <34 weeks, an unengaged fetal head, fetal demineralization disorder (eg, osteogenesis imperfecta), and known or suspected fetal bleeding diatheses (eg, hemophilia). In addition, caution must be exercised when the estimated fetal weight is >4000 g.

VACUUM APPLICATION

Before the vacuum is applied to the fetal head, the patient is prepared and the initial patient examination is performed as discussed earlier with regard to forceps deliveries. Application of the vacuum is perceived by many to be simpler than the use of the forceps. Before application occurs, the vacuum system should be assembled to ensure that no leaks are present. The cup should then be inserted into the vagina by directing pressure toward the posterior aspect of the vagina. The objective is to place the center of the cup directly over the sagittal suture at the *median flexion point* located approximately 3 cm anterior to the posterior fontanelle. This cup placement should allow for adequate maintenance of flexion of the fetal head during the entire procedure. The following checks should be performed prior to application of traction to the fetal head. (1) No maternal tissue should be included under the cup margin. (2) The cup should be placed in the midline over the sagittal suture and not off to the side of the head.

After the cup has been appropriately placed on the fetal scalp, an initial suction is applied, and the cup edges are reexamined to ensure that no maternal tissue is trapped underneath the vacuum cup. While the cup is held firmly against the fetal head, the pressure is increased to approximately 100–150 mm Hg to maintain the cup’s position. The cup edges should be reexamined. If no maternal tissue is found under the cup edges, the pressure is increased to 500–600 mm Hg at the beginning of the uterine contraction. As the mother pushes, traction is applied downward along the pelvic axis. If more than 1 contraction is necessary, the vacuum pressure can be decreased to low levels between contractions. The axis of traction is then extended upward to a 45-degree angle to the floor as the head emerges. Once the head has completely delivered through the vagina, the suction is withdrawn and the cup removed.

EFFECTIVENESS & SAFETY OF VACUUM

Most reports demonstrate that the vacuum is effective, with a failure rate of approximately 10%. The following factors have been implicated in determining the effectiveness of vacuum delivery: cup design, shape, size, and traction site attachment, consistency and strength of vacuum, strength of maternal expulsive efforts and coordination with traction, fetal size and extent of cephalopelvic disproportion, station and deflection of the fetal head, and angle and technique of traction.

The safety of the vacuum has been called into question. In May 1998, the US Food and Drug Administration issued a Public Advisory Statement regarding fetal complications associated with vacuum delivery. The purpose of this statement was to advise practitioners that vacuum devices might cause serious or fetal complications when improperly used. As a result, the following recommendations were made. (1) The vacuum should be used only when a specific obstetric indication is present. (2) Persons using the vacuum should be experienced and aware of the indications, contraindications, and precautions. (3) Those who use the vacuum should read and understand the instructions for the particular instrument being used. (4) The neonatal care staff should be educated about the potential complications of vacuum. (5) Individuals responsible for the care of the neonate should be alerted that vacuum has been used. (6) All adverse reactions should be reported to the Food and Drug Administration.

Use of the vacuum has been associated with a variety of neonatal injuries ranging from benign superficial scalp markings to serious and potentially life-threatening intracranial hemorrhages. The most common neonatal complication is retinal hemorrhage, which may occur in as many as 50% of deliveries. Fortunately, the complication rarely has any clinical significance. Cephalohematoma involves bleeding beneath the periosteum and complicates approximately 6% of all vacuum deliveries. Because the bleeding is located under the periosteum, significant bleeding rarely results because of the inability of the blood to cross the sutures. Subgaleal hematoma, a more serious complication, occurs in 50 per 10,000 vacuum deliveries. The condition arises when bleeding occurs in the loose subaponeurotic tissues of the scalp. Because bleeding occurs above the periosteum, it is not contained by the sutures. Consequently, there is the potential for life-threatening hemorrhage. The subgaleal space actually extends from the orbits of the eyes to the nape of the neck. This potential space can accommodate over half of a newborn’s blood volume. Intracranial hemorrhage occurs in approximately 0.35% of vacuum deliveries. It can be a catastrophic complication that includes subdural, subarachnoid, intraventricular, and/or intraparenchymal hemorrhage. These complications can be quite severe but fortunately are rare.

Most authorities agree that injury can be significantly decreased or eliminated if the following protocol is used. (1) Traction is applied only when the patient is actively pushing. (2) Applying torsion or twisting the cup in an attempt to rotate the head is prohibited. (3) The duration of time during which the cup is applied to the fetal head should not exceed 20 minutes. (4) The procedure should be abandoned after the cup has dislodged or “popped off” from the fetal head twice. It should not be applied a third time. (5) The procedure should be abandoned if there is no fetal descent after a single pull. (6) Neonatal staff should be present at the time of the vacuum delivery. (Note: This also applies to forceps deliveries.) (7) Under no circumstances should the operator switch from vacuum to forceps or vice versa. An excellent study examining neonatal injury associated with operative vaginal delivery clearly demonstrated that the greatest incidence of neonatal injury occurred in babies in whom both vacuum and forceps were used. The practitioner must be cognizant of the risk of shoulder dystocia, which is increased with instrumental delivery. Shoulder dystocia occurs more commonly with vacuum deliveries than with forceps deliveries. A simple ABC mnemonic for vacuum extraction is as follows:

A: **A**sk for help, **a**ddress the patient (obtain informed consent), **a**nesthesia
B: **B**ladder empty
C: **C**ervix fully dilated
D: **D**ownward traction, shoulder **d**ystocia
E: **E**xamine fetal head position
F: **F**lexion point

A detailed and complete delivery note should accompany each operative delivery. The medical record must document the indication for the procedure, the fetal station and head position at the time of the application(s) of forceps or vacuum, the type of device used, the total application time, the number of applications and “pop-offs” if vacuum was used, and if unsuccessful, the subsequent mode of delivery. It would also be prudent to include a comment in the medical record that the patient was informed of the potential complications of operative vaginal delivery.

Somewhat surprisingly, relatively few randomized, prospective studies have compared vacuum with forceps. In surveying the medical literature, the following conclusions can be drawn. On the whole, the vacuum extractor is less likely to achieve a successful vaginal delivery than is the forceps. The vacuum is significantly less likely to cause serious maternal injury than is the forceps. Although the vacuum is associated with a greater incidence of cephalohematoma, other facial/cranial injuries are more common with forceps. In comparing Apgar scores, the trend is toward more low 5-minute Apgar scores in the vacuum group than in the forceps group. Thus, an overall reduction in severe maternal injuries appears to be the most immediate benefit associated with the use of the vacuum. However, at this time, which instrument results in fewer major adverse neonatal effects remains to be determined.

Although both forceps and vacuum have proved to be useful in assisting with vaginal delivery, the vacuum is quickly becoming the preferred instrument of choice. Both forceps and vacuum extractors are acceptable and safe instruments for operative vaginal delivery. While candidates should be selected on an individualized basis and counseled accordingly, the skill of the operator should also influence the decision to attempt an operative delivery as well as the choice of instrument. Each instrument, however, has inherent risks. While the vacuum has been primarily associated with immediate neonatal morbidity, long-term data do not suggest any increased risk of neurodevelopmental delay in children delivered by either vacuum or forceps. In order to minimize both maternal and fetal risks, the operator must be familiar with the indications, contraindications, application, and use of the particular instrument. Guidelines similar to those discussed in this chapter should exist in order to facilitate a safe and effective delivery. While maternal morbidity may be slightly higher with forceps delivery, it is overall low in comparison with the morbidity that may be associated with delivery by caesarean section. In an era in which caesarean section rates are climbing, one must consider all of the available delivery modes and individualize them accordingly for each patient in order to ensure the most efficacious and safest delivery experience.

CAESAREAN SECTION

Caesarean section or caesarean delivery refers to the delivery of a fetus, placenta, and membranes through an abdominal and uterine incision. The first documented caesarean section on a living person was performed in 1610. The patient died 25 days later. Since that time, numerous advances have made caesarean section a safe procedure. In the past 35 years, the rate of caesarean section has steadily increased from 5% to approximately 30%. Over this time, the maternal mortality ratio (maternal deaths per 100,000 births) has decreased from almost 300 to <10. The following factors are often cited as contributing to the increasing caesarean section rate: (1) lower operative vaginal delivery rates, (2) lower rates of vaginal births after caesarean section (VBAC), and (3) fewer vaginal breech deliveries. In order for the practitioner to perform this common operation safely, he or she must be aware of the indications, risks, operative technique, and potential complications of this procedure.

INDICATIONS

Caesarean section is used in cases where vaginal delivery either is not feasible or would impose undue risks to the mother or baby. Some of the indications for caesarean section are clear and straightforward, whereas others are relative. In some cases, fine judgment is necessary to determine whether caesarean section or vaginal delivery would be better. It is not practical to list all possible indications; however, hardly any obstetric complication has not been dealt with by caesarean section. The following indications are currently the most common.

Repeat Caesarean Section

A prior uterine incision from a myomectomy or previous caesarean section may weaken the uterine wall or predispose to rupture if labor is permitted. The initial dictum of “once a caesarean, always a caesarean” was held for many years. However, as multiple publications documenting the safety of VBAC began appearing in the literature, many physicians moved away from this long-held belief. In 2000, a national goal was set to lower the rate of repeat caesarean sections to 3% while increasing the VBAC rate to 35%. The major incentives that led to this change in philosophy were fewer delivery risks with vaginal delivery, less need for anesthesia, less postpartum morbidity, shorter hospital stay, lower costs, and the encouragement of earlier and often smoother interaction and bonding between mother and infant. As more and more VBACs were performed in less than ideal settings, more complications arose. There may be no greater obstetric catastrophe than a uterine rupture resulting in maternal and/or fetal death. In fact, there appears to be a trend back toward the belief of “once a caesarean, always a caesarean.” Suffice it to say, “once a caesarean, always a controversy.”

In general, patients who are the most suitable candidates for trial of labor after caesarean section (TOLAC) are those (1) with 1 prior low-transverse caesarean section, (2) who present in labor, (3) with nonrecurring conditions (eg, breech, abnormal fetal heart rate patterns, placenta previa in prior pregnancy), and (4) with a prior vaginal delivery. Patients who are not candidates for a TOLAC include women with a prior classical (vertical) uterine incision or prior myomectomy. If a trial of labor is to be conducted, the patient must be placed on continuous fetal heart rate and uterine activity monitoring, and a dedicated obstetrician and anesthesiologist must be immediately available to intervene in case uterine rupture is suspected. Prostaglandins for cervical ripening must be avoided, and oxytocin must be used in a judicious and conservative fashion, if at all. Current studies cite a maternal mortality rate of close to 1% in cases of uterine rupture and a perinatal mortality rate of approximately 50% in association with uterine rupture. Therefore, it is of utmost importance that equipment for both maternal and electronic fetal monitoring and appropriate obstetric and neonatal facilities are available. A large-bore intravenous catheter must be used, and blood for possible maternal transfusion must be available. Appropriate anesthesia, a fully equipped operating room, and obstetric and neonatal staff experienced in emergency care must all be immediately available.

Cephalopelvic Disproportion/Dystocia

Cases in which the fetal head is too large to traverse the pelvis should be managed by caesarean section. As discussed earlier, if the head does not engage during labor, operative vaginal delivery should not be attempted. Rather, caesarean section must be performed. Inlet disproportion should be suspected in the primigravida if the patient begins labor with the fetal head unengaged. In a significant number of these patients, the fetal head fails to engage, and caesarean section is indicated. Midpelvic disproportion may be suspected if the anteroposterior diameter is short, the ischial spines are prominent, the sacrospinous ligament is short, and the fetus is large. Outlet disproportion usually requires a trial of forceps or vacuum before a safe vaginal delivery is determined to be impossible.

Dystocia literally means “difficult labor.” This occurs when a patient’s labor progresses and then either stops completely (arrests) or becomes prolonged (protracted). When either of these situations occurs during labor, the patient warrants careful reassessment, including evaluation of the labor pattern, contraction pattern, estimated fetal weight and fetal presentation, and evaluation of the pelvis. In other words, the 3 P’s (power, passenger, and pelvis) must be adequate in order for a vaginal delivery to occur.

Abnormal Fetal Lie & Malpresentation

Transverse lie and breech presentations are common indications for caesarean section. The trend toward caesarean delivery for breech deliveries has been hastened by a large randomized trial comparing breech infants born vaginally versus those born by caesarean section; better outcomes were achieved after caesarean section. Although some still consider vaginal breech delivery to be an acceptable option, experience with the technique is largely disappearing from practice. External cephalic version is a reasonable alternative for some patients and can be attempted to convert the fetus to cephalic presentation. However, this procedure is successful in allowing vaginal birth in only 50% of cases.

Fetal Heart Rate Tracing Abnormalities

Fetal monitoring before and during labor may disclose fetal problems that otherwise would not be evident. As a result of continuous fetal monitoring, the number of caesarean sections performed for a “nonreassuring fetal status” has increased. Best estimates demonstrate that approximately 10% of caesarean sections are performed for this indication.

Other Indications

In addition to the indications discussed earlier, other conditions that may lead to caesarean section are placenta previa, preeclampsia–eclampsia if remote from term, placental abruption, multiple gestations, fetal abnormalities (eg, hydrocephalus), cervical cancer, and active genital herpes infection. One other indication that is becoming more prevalent is patient choice. The idea of primary elective caesarean section continues to increase in popularity and generate controversy.

PREOPERATIVE PREPARATION FOR CAESAREAN SECTION

The following steps are generally taken before caesarean section is performed. The patient is made aware of the indications for the caesarean section, the alternatives, and the potential risks, benefits, and complications. She then signs a form indicating that she has received the appropriate information and consents to the procedure (“informed consent”). An intravenous 18-gauge needle should be in place with an appropriate intravenous solution running before the operation begins. The patient is given an antacid to minimize the likelihood of aspiration during anesthesia. A Foley catheter is placed to allow for continuous bladder drainage before, during, and after surgery. Anesthesia is administered, and the abdomen is prepped. The patient is covered with sterile drapes. Tilting the patient slightly to the left moves the uterus to the left of the midline and minimizes pressure on the inferior vena cava.

OPERATIVE PROCEDURE

Abdominal Incision

Opinions differ regarding the type of abdominal incision that should be performed. Most obstetricians use the transverse (Pfannenstiel) incision with or without transection of the rectus muscles because wound dehiscence is rare and because the cosmetic result is usually better. In cases in which the caesarean section must be performed urgently or emergently, especially in patients with prior abdominal surgery or marked obesity, the midline vertical suprapubic incision is preferred because it is much quicker and the exposure for expeditious delivery and resolving uterine bleeding (by hysterectomy, if needed) usually is better. In the presence of a prior lower abdominal scar, it is important to enter the peritoneal cavity at the upper end of the incision to avoid entering the bladder, which may have been pulled upward on the abdominal wall at the time of closure of the previous incision.

Uterine Incision

Before the uterine incision is made, laparotomy pads that have been soaked in warm saline and wrung out can be placed on either side of the uterus to catch the spill of amniotic fluid. The degree of dextrorotation should also be determined by noting the position of the round ligaments so that the uterine incision will be centered. Torsion should not be corrected; instead, access to the midline should be obtained by retracting the abdominal wall to the patient’s right. The different types of uterine incisions will be discussed later.

Encountering the Placenta

If the placenta is encountered beneath the uterine incision, the operator should avoid cutting through it; otherwise serious fetal bleeding may result. If the placenta cannot be avoided, an incision can be made through it. However, the baby must be delivered as quickly as possible and the cord clamped immediately to prevent significant blood loss.

Delivery

The operator delivers the baby, and then the placenta delivers. Recent evidence has demonstrated that blood loss can be minimized by massaging the uterus to allow for spontaneous placental expulsion rather than by manually separating and extracting the placenta. After delivery of the placenta, the uterus should be massaged and oxytocin administered in a dilute intravenous solution at a rate sufficient to maintain a firm contraction. The uterine cavity is wiped clean with a sponge so as to remove any retained membranes. The uterus is exteriorized, and active bleeding sinuses are clamped with either Pennington clamps or ring forceps.

Closure of the Uterine Incision

The closure of the uterine incision is dependent on the type of incision that is made. In general, the entire thickness of the myometrium should be closed. In order to potentially decrease the likelihood of uterine rupture during a subsequent pregnancy, the uterine incision should be closed in 2 layers. The 2 types of uterine incisions used most often and discussed here are the classical uterine incision and the low-transverse uterine incision.

CLASSICAL CAESAREAN SECTION

This is the simplest to perform. However, it is associated with the greatest loss of blood and with a greater risk of uterine rupture with subsequent pregnancies when compared with low-transverse incisions. The currently accepted indications for classical caesarean section are placenta previa, transverse lie (especially back down), and preterm delivery in which the lower uterine segment is poorly developed. A classical caesarean section may be preferred if extremely rapid delivery is needed, because this type of incision may offer the fastest means of delivering the baby. Nonetheless, the hazards of this procedure must be weighed against the additional minute or so needed to dissect the bladder away from the lower uterine segment and make the transverse semilunar low-transverse uterine incision.

In performing a classical procedure, a vertical incision is made in the body of the uterus. A scalpel is used to enter the uterine activity, and the incision is enlarged with bandage scissors. The fetus is delivered through the incision. After the placenta and membranes are removed, the uterine defect is repaired with 3 layers of running, interlocking absorbable suture. Number 0 suture is recommended for the 2 deeper layers, and 2-0 suture is used for the superficial layer to reap-proximate the serosal edges.

LOW-TRANSVERSE CAESAREAN SECTION

Because the low-transverse uterine incision (Figs. 20–10 through 20–17) is associated with less blood loss and the risk of subsequent uterine rupture is less than with a classical caesarean section, this type of caesarean delivery is performed more frequently. After the peritoneal cavity is opened and the uterus identified, the bladder fold of peritoneum is picked up with tissue forceps and incised transversely. The bladder is bluntly separated from the anterior aspect of the uterus inferiorly for a distance of 3–4 cm. The bladder is held away from this area by a specially designed bladder retractor. A transverse incision is made through the anterior uterine wall with the scalpel. Using either bandage scissors or fingers, the transverse incision is extended in a semilunar fashion and extended superiorly at the lateral edges in order to avoid the uterine vessels.

The head is lifted carefully anteriorly and, as necessary, superiorly to bring it from beneath the symphysis forward through the uterine and abdominal incisions. **B:** As the fetal head is lifted through the incision, pressure usually is applied to the uterine fundus through the abdominal wall to help expel the fetus. (Reproduced, with permission, from Cunningham FG, Leveno KJ, Bloom SL, et al. *Williams Obstetrics*. 22nd ed. New York, NY: McGraw-Hill; 2005, p 596.)

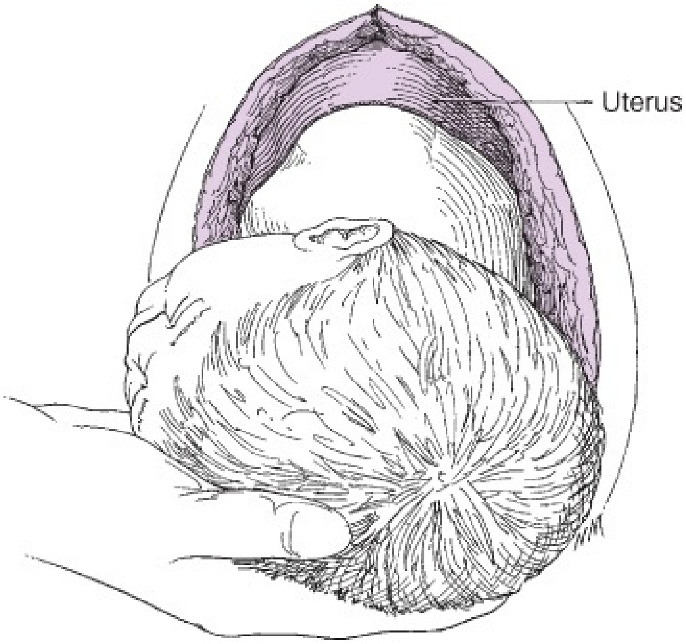

Figure 20–15. The shoulders are delivered, and the oxytocin infusion is begun.

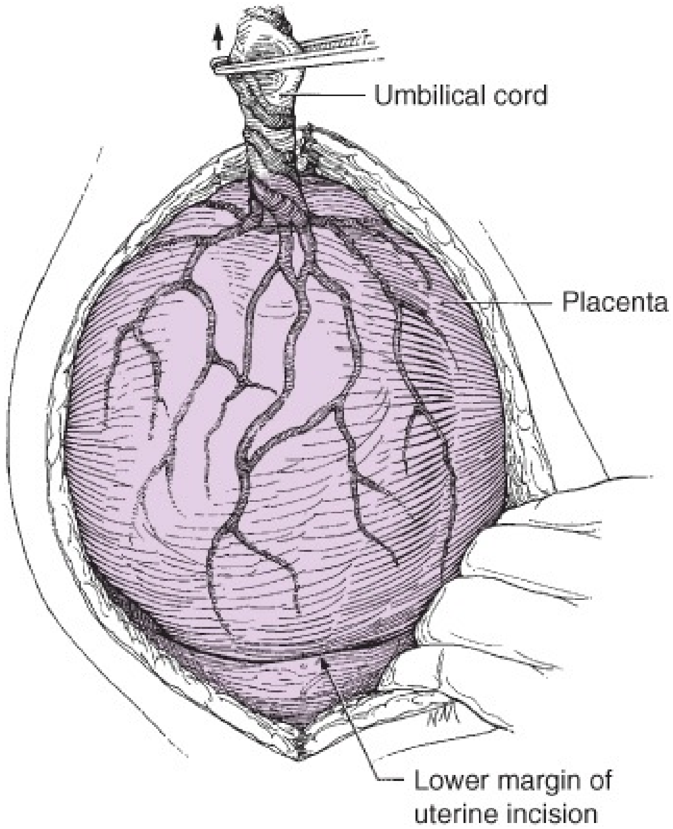

Figure 20–16. Placenta bulging through the uterine incision as the uterus contracts.

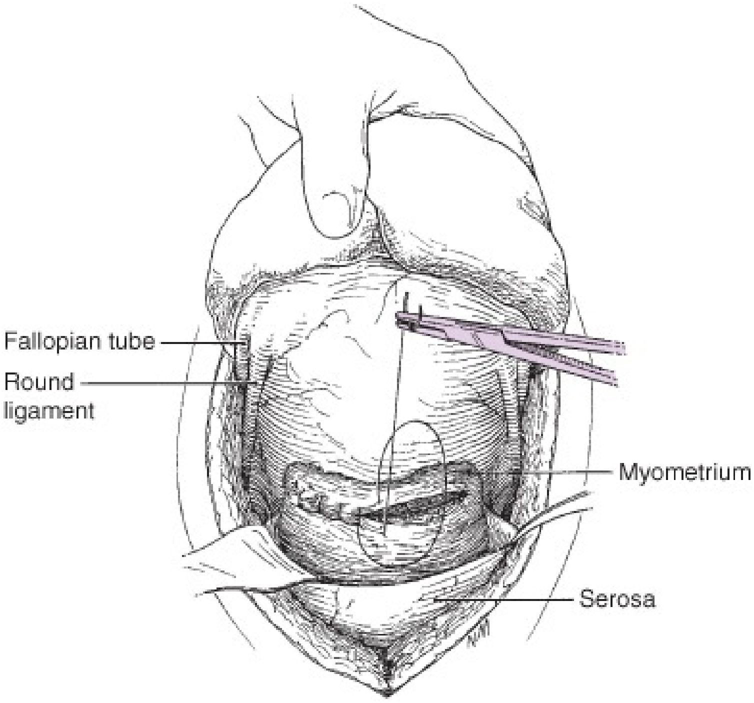

Figure 20–17. The cut edges of the uterine incision are approximated with a running-lock suture.

If the maneuver can be easily done, the fetal presenting part is elevated with the hand, making sure not to flex the wrist, thereby increasing the possibility of extension of the incision inferiorly toward the cervix. If the head is located deep in the pelvis, the head can safely be pushed up by an assistant inserting a hand into the vagina to elevate the fetal head for ease of delivery. After the baby and placenta are delivered, the uterus is exteriorized and clamps are placed on the cut edges of the uterus in areas of significant bleeding from the uterine sinuses. The uterine incision is generally closed in 2 layers using number 0 chromic catgut or other absorbable suture. After adequate hemostasis has been achieved, the bladder peritoneum either is reapproximated with suture or is left in place. Before the uterus is returned to the peritoneal cavity, the adnexa should be inspected for the presence of any pathology, such as ovarian cysts. Some practitioners prefer to close the anterior peritoneum with absorbable suture, whereas others prefer to leave it alone. The fascia, subcutaneous tissue, and skin are reapproximated in standard fashion.

COMPLICATIONS

The most common complications that result from caesarean section are postpartum hemorrhage, endometritis, and wound infection. Administering prophylactic antibiotics and ensuring hemostasis prior to closure of the abdomen have helped decrease the incidence of these complications. New data are emerging that demonstrate a lower risk of endometritis when antibiotics are given prior to the skin incision when compared to after clamping of the umbilical cord. The major factors affecting healing of the uterine incision are hemostasis, accuracy of apposition, quality and amount of suture material, and avoidance of infection and tissue strangulation. It can generally be stated that the longer the operative procedure, the greater is the likelihood of postoperative complications. Disasters following caesarean section are rare. Some clearly are not preventable. Others are the direct result of faulty surgical technique, especially lack of attention to hemostasis, inept or ill-chosen anesthesia, inadequate blood product replacement or transfusion of mismatched blood, and delayed diagnosis or mismanagement of infection.

Unfortunately, little information about the integrity of a particular scar in a subsequent pregnancy is gained by inquiry into the presence or absence of postoperative infection and location of the incision. In a later pregnancy, pain in the area of the scar may suggest dehiscence. Approximately 50% of all ruptures of classical uterine scars occur before the onset of labor. The incidence of uterine rupture is approximately 4–9% of classical scars and 0.7–1.5% of low-transverse scars. Rupture of a classical scar usually is catastrophic, occurring suddenly, totally, and with partial or total extrusion of the fetus into the abdominal cavity. Shock due to internal hemorrhage is a prominent sign. Rupture of the low-transverse scar usually is more subtle and almost always occurs during active labor. The most common presenting sign (present in more than 80% of cases) is a change in the fetal heart rate pattern. A newly recognized finding of variable or late decelerations should alert the obstetrician. Additional findings that might signal uterine rupture include vaginal bleeding, abdominal pain (especially over the prior incision site), and loss of fetal station. A scalp electrode to ensure a continuous fetal heart rate tracing should be utilized as soon as possible in patients who are undergoing TOLAC. If uterine rupture is suspected, the patient must undergo surgery as soon as possible.

PERINATAL MORBIDITY & MORTALITY

Although it may appear on the surface that caesarean delivery is the safest for the baby, this may not be entirely true. Although usually benign, transient tachypnea of the newborn is more common with caesarean section than with vaginal delivery. The risk of fetal hemorrhage and hypoxia is present when the placenta is encountered below the uterine incision and is inadvertently or purposely transected. There is also the potential risk for laceration of the baby at the time that the uterine incision is made. Fetal laceration is reported to occur on an infrequent basis at a rate of approximately 0.2–0.4% of all caesarean sections. The usual site is on the face, in the area of the cheek, but it may also occur on the buttock, ear, head, or any other body site under the incision. Therefore, it is of great importance that care is taken when incising the layers of the uterus. This is especially true in a prolonged labor, in which the uterus may be very thin. Because of the potential complications to the baby inherent with each caesarean section, each infant should be examined by a trained professional as soon as possible after delivery.

CAESAREAN HYSTERECTOMY

A major indication for caesarean hysterectomy is the inability to stop bleeding. The most common reason for performing caesarean hysterectomy is abnormal placental implantation, such as placenta accreta, increta, and percreta. As the caesarean section rate continues to escalate, these complications are becoming more common. Other indications for caesarean hysterectomy include intractable uterine atony, inability to repair a ruptured uterus, and large uterine myomas. Caesarean hysterectomy is a potentially morbid procedure because of increased blood loss and potential for injury to the bladder, ureter, or bowel.

The technical aspects of hysterectomy at the time of caesarean section are similar to those of hysterectomy in the nonpregnant patient except that all structures, cleavage planes, and pedicles are highly vascular. Therefore, there is significant risk for excessive blood loss and the need for the transfusion of blood products. In cases in which there is a suspicion that caesarean hysterectomy may need to be performed, the anesthesiologist and blood bank personnel should be informed. It is recommended that blood products (packed red blood cells and fresh frozen plasma) are available. Lastly, a vascular surgeon or gynecologic oncologist should be available to assist if needed. Studies have demonstrated that caesarean hysterectomy performed on a non-emergent basis is much safer than hysterectomy performed on an emergent basis. Specifically, injury to the bladder and ureter and the need for blood transfusions are more common when caesarean hysterectomy is performed emergently.

Postpartum Hemorrhage & the Abnormal Puerperium

Sarah B.H. Poggi, MD

POSTPARTUM HEMORRHAGE

ESSENTIALS OF DIAGNOSIS

- Postpartum hemorrhage denotes excessive bleeding (>500 mL in vaginal delivery) following delivery. Hemorrhage may occur before, during, or after delivery of the placenta. Actual measured blood loss during uncomplicated vaginal deliveries averages 700 mL, and blood loss often may be underestimated. Nevertheless, the criterion of a 500-mL loss is acceptable on historical grounds.
- Blood lost during the first 24 hours after delivery is *early postpartum hemorrhage*; blood lost between 24 hours and 6 weeks after delivery is *late postpartum hemorrhage*.

Pathogenesis

The incidence of excessive blood loss following vaginal delivery is 5–8%. Postpartum hemorrhage is the most common cause of excessive blood loss in pregnancy, and most transfusions in pregnant women are performed to replace blood lost after delivery. Hemorrhage is the third leading cause of maternal mortality in the United States and is directly responsible for approximately one-sixth of maternal deaths. In less developed countries, hemorrhage is among the leading obstetric causes of maternal death.

Causes of postpartum hemorrhage include uterine atony, obstetric lacerations, retained placental tissue, and coagulation defects.

A. Uterine Atony

Postpartum bleeding is physiologically controlled by constriction of interlacing myometrial fibers that surround the blood vessels supplying the placental implantation site. Uterine atony exists when the myometrium cannot contract.

Atony is the most common cause of postpartum hemorrhage (50% of cases). Predisposing causes include excessive manipulation of the uterus, general anesthesia (particularly with halogenated compounds), uterine overdistention (twins or polyhydramnios), prolonged labor, grand multi-parity, uterine leiomyomas, operative delivery and intrauterine manipulation, oxytocin induction or augmentation of labor, previous hemorrhage in the third stage, uterine infection, extravasation of blood into the myometrium (Couvelaire uterus), and intrinsic myometrial dysfunction.

B. Obstetric Lacerations

Excessive bleeding from an episiotomy, lacerations, or both causes approximately 20% of postpartum hemorrhages. Lacerations can involve the uterus, cervix, vagina, or vulva. They usually result from precipitous or uncontrolled delivery or operative delivery of a large infant; however, they may occur after any delivery. Laceration of blood vessels underneath the vaginal or vulvar epithelium results in hematomas. Bleeding is concealed and can be particularly dangerous because it may go unrecognized for several hours and become apparent only when shock occurs.

Episiotomies may cause excessive bleeding if they involve arteries or large varicosities, if the episiotomy is large, or if a delay occurred between episiotomy and delivery or between delivery and repair of the episiotomy.

Persistent bleeding (especially bright red) and a well-contracted, firm uterus suggest bleeding from a laceration or from the episiotomy. When cervical or vaginal lacerations are identified as the source of postpartum hemorrhage, repair is best performed with adequate anesthesia.

Spontaneous rupture of the uterus is rare. Risk factors for this complication include grand multiparity, malpresentation, previous uterine surgery, and oxytocin induction of labor. Rupture of a previous caesarean section scar after vaginal delivery may be an increasingly important cause of postpartum hemorrhage.

C. Retained Placental Tissue

Retained placental tissue and membranes cause 5–10% of postpartum hemorrhages. Retention of placental tissue in the uterine cavity occurs in placenta accreta, which is an increasingly frequent diagnosis in this era of multiple caesarean deliveries. Retained placental tissue may also develop in cases managed by manual removal of the placenta, in mismanagement of the third stage of labor, and in unrecognized succenturiate placenta.

Ultrasonographic findings of an echogenic uterine mass strongly support a diagnosis of retained placental products. The technique probably is better used in cases of hemorrhage occurring a few hours after delivery or in late postpartum hemorrhage. Transvaginal duplex Doppler imaging also is effective in evaluating these patients. Some evidence indicates that sonohysterography may aid in the diagnosis of residual trophoblastic tissue. If the endometrial cavity appears empty, unnecessary dilatation and curettage may be avoided.

D. Coagulation Defects

Coagulopathies in pregnancy may be acquired coagulation defects seen in association with several obstetric disorders, including abruptio placentae, excess thromboplastin from a retained dead fetus, amniotic fluid embolism, severe preeclampsia, eclampsia, and sepsis. These coagulopathies may present as hypofibrinogenemia, thrombocytopenia, and disseminated intravascular coagulation. Transfusion of more than 8 U of blood in itself may induce a dilutional coagulopathy.

Von Willebrand’s disease, autoimmune thrombocytopenia, and leukemia may occur in pregnant women.

Prevention

Prevention of hemorrhage is preferable to even the best treatment. All patients in labor should be evaluated for risk of postpartum hemorrhage. Risk factors include coagulopathy, hemorrhage, or blood transfusion during a previous pregnancy; anemia during labor; grand multiparity; multiple gestation; large infant; polyhydramnios; dysfunctional labor; oxytocin induction or augmentation of labor; rapid or tumultuous labor; severe preeclampsia or eclampsia; vaginal delivery after previous caesarean birth; general anesthesia for delivery; forceps delivery; and delay in placental delivery after vaginal delivery of the infant.

Complications

Although any woman may suffer excessive blood loss during delivery, women already compromised by anemia or intercurrent illness are more likely to demonstrate serious deterioration of condition, and anemia and excessive blood loss may predispose to subsequent puerperal infection. Major morbidity associated with transfusion therapy (eg, viral infection, transfusion reactions) is infrequent but is not insignificant. Moreover, other types of treatment for anemia may involve some risk.

Postpartum hypotension may lead to partial or total necrosis of the anterior pituitary gland and cause postpartum panhypopituitarism, or Sheehan's syndrome, which is characterized by failure to lactate, amenorrhea, decreased breast size, loss of pubic and axillary hair, hypothyroidism, and adrenal insufficiency. The condition is rare (<1 in 10,000 deliveries). A woman who has been hypotensive postpartum and who is actively lactating probably does not have Sheehan's syndrome. Hypotension also can lead to acute renal failure and other organ system injury. In extreme hemorrhage, sterility will result from hysterectomy performed to control intractable postpartum hemorrhage.

Treatment

A. Predelivery Preparation

All obstetric patients should have blood typed and screened on admission. Patients identified as being at risk for postpartum hemorrhage should have their blood typed and cross-matched immediately. The blood should be reserved in the blood bank for 24 hours after delivery. A large-bore intravenous catheter should be securely taped into place after insertion. Delivery room personnel should be alerted to the risk of hemorrhage. Severely anemic patients should be transfused as soon as cross-matched blood is ready.

With concerns associated with blood transfusion, autologous blood donation in obstetric patients at risk for postpartum hemorrhage has been advocated. Despite careful evaluation for risk factors, with the exception of cases of placenta previa, our ability to predict which patients will have hemorrhage and require blood transfusion remains poor; therefore, the cost of such an approach may not be justified.

B. Delivery

Following delivery of the infant, the uterus is massaged in a circular or back-and-forth motion until the myometrium becomes firm and well contracted. Excessive and vigorous massage of the uterus before, during, or after delivery of the placenta may interfere with normal contraction of the myometrium and, instead of hastening contraction, may lead to excessive postpartum blood loss.

C. Third Stage of Normal Labor; Placental Separation

The placenta typically separates from the uterus and is delivered within 5 minutes of delivery of the infant in 50% of cases and within 15 minutes in 90% of cases. Attempts to speed separation are of no benefit and may cause harm. Spontaneous placental separation is impending if the uterus becomes round and firm, a sudden gush of blood comes from the vagina, the uterus seems to rise in the abdomen, and the umbilical cord moves down out of the vagina.

The placenta then can be removed from the vagina by gentle traction on the umbilical cord. Prior to placental separation, gentle steady traction on the cord combined with upward pressure on the lower uterine segment (Brandt-Andrews maneuver) ensures that the placenta can be removed as soon as separation occurs and provides a means of monitoring the consistency of the uterus. Adherent membranes can be removed by gentle traction with ring forceps. The placenta is inspected for completeness immediately after delivery.

Manual Removal of the Placenta

Opinion is divided about the timing of manual removal of the placenta. In the presence of hemorrhage, it is unreasonable to wait for spontaneous separation, and manual removal of the placenta should be undertaken without delay. Traditionally, in the absence of bleeding, many have advocated removal of the placenta 30 minutes after delivery of the infant. Newer evidence suggests that to prevent postpartum hemorrhage, a placenta that has not been delivered by 18 minutes should be removed.

Efforts to promote routine manual removal of the placenta were often made in the past. The rationale includes shortening the third stage of labor, decreasing blood loss, developing experience in manual removal as practice for dealing with placenta accreta, and providing a way to simultaneously explore the uterus. Evidence now indicates that manual removal of the placenta may be a risk factor for postpartum endometritis. These real or potential benefits must be weighed against the discomfort caused to the patient, the risk of infection, and the risk of causing more bleeding by interfering with normal mechanisms of placental separation.

Technique: The uterus is stabilized by grasping the fundus with a hand placed over the abdomen. The other hand traces the course of the umbilical cord through the vagina and cervix into the uterus to palpate the edge of the placenta. The membranes at the placental margin are perforated, and the hand is inserted between the placenta and the uterine wall, palmar side toward the placenta. The hand is then gently swept from side to side and up and down to peel the placenta from its attachments to the uterus. When the placenta has been completely separated from the uterus, it is grasped and pulled from the uterus.

The fetal and maternal sides of the placenta should be inspected to ensure that it has been removed in its entirety. On the fetal surface, incomplete placental removal is manifested as interruption of the vessels on the chorionic plate, usually shown by hemorrhage. On the maternal surface, it is possible to see where cotyledons have been detached. If evidence of incomplete removal is observed, the uterus must be re-explored and any small pieces of adherent placenta removed. The uterus should be massaged until a firm myometrial tone is achieved. Depending on the patient’s other risk factors for postpartum endometritis, prophylactic antibiotics can be given at the time of manual removal of the placenta.

Immediate Postpartum Period

Uterotonic agents can be administered as soon as the infant’s anterior shoulder is delivered. There is a significantly lowered incidence of postpartum hemorrhage in patients receiving oxytocin (either low-dose intravenous [IV] or intramuscular [IM]) at the time of delivery of the anterior shoulder and controlled cord traction compared to patients receiving IV oxytocin after placental delivery. There was no greater incidence of placental retention. However, populations without ultrasound screening for twins have a potential risk for entrapment of an undiagnosed second twin, and oxytocin should only be given after placental delivery. Routine administration of oxytocics during the third stage reduces the blood loss of delivery and decreases the chances of postpartum hemorrhage by 40%. Oxytocin, 10–20 U/L of isotonic saline, or other IV solution by slow IV infusion or 10 U IM can be used. Bolus administration should not be used because large doses (>5 U) can cause hypotension. Recently, sublingual misoprostol (800 μg) has been found to be clinically as effective as oxytocin (40 U/L) for treatment of postpartum hemorrhage. This information is particularly useful for low-resource areas because misoprostol does not have to be refrigerated or require specialized equipment for administration, but regardless of setting, misoprostol is a useful adjunct to treatment of postpartum hemorrhage. Ergot alkaloids (eg, methylergonovine maleate 0.2 mg IM) also can be routinely used, but they are not more effective than oxytocin and pose more risk because they rarely cause marked hypertension. This occurs most commonly with IV administration or when regional anesthesia is used. Ergot alkaloids should not be used in hypertensive women or in women with cardiac disease.

Repair of Lacerations

If bleeding is excessive before placental separation, manual removal of the placenta is indicated. Otherwise, excessive manipulation of the uterus should be avoided.

The vagina and cervix should be carefully inspected immediately after delivery of the placenta, with adequate lighting and assistants available. The episiotomy is quickly repaired after massage has produced a firm, tightly contracted uterus. A pack placed in the vagina above the episiotomy helps to keep the field dry; attaching the free end of the pack to the adjacent drapes reminds the operator to remove it after the repair is completed.

The tendency of bleeding vessels to retract from the laceration site is the reason for one of the cardinal principles of repair. Begin the repair above the highest extent of the laceration. The highest suture is also used to provide gentle traction to bring the laceration site closer to the introitus. Hemostatic ligatures are then placed in the usual manner, and the entire birth canal is carefully inspected to ensure that no additional bleeding sites are present. Extensive inspection also provides time to confirm that prior hemostatic efforts have been effective.

A cervical or vaginal laceration extending into the broad ligament should not be repaired vaginally. Laparotomy with evacuation of the resultant hematoma and hemostatic repair or hysterectomy are required.

Large or expanding hematomas of the vaginal walls require operative management for proper control. The vaginal wall is first exposed by an assistant. If a laceration accompanies the hematoma, the laceration is extended so that the hematoma can be completely evacuated and explored. When the bleeding site is identified, a large hemostatic ligature can be placed well above the site. This ensures hemostasis in the vessel, which is likely to retract when lacerated. The hematoma cavity should be left open to allow drainage of blood and ensure that bleeding will not be concealed if hemostasis cannot be achieved.

If no laceration is present on the vaginal side wall when a hematoma is identified, then an incision must be made over the hematoma to allow treatment to proceed as outlined.

Following delivery, recovery room attendants should frequently massage the uterus and check for vaginal bleeding.

Evaluation of Persistent Bleeding

If vaginal bleeding persists after delivery of the placenta, aggressive treatment should be initiated. It is not sufficient to perform perfunctory uterine massage, for instance, without searching for the cause of the bleeding and initiating definitive treatment. The following steps should be undertaken without delay:

1. Manually compress the uterus.
2. Obtain assistance.
3. If not already done, obtain blood for typing and cross-matching.
4. Observe blood for clotting to rule out coagulopathy.

5. Begin fluid or blood replacement.
6. Carefully explore the uterine cavity.
7. Completely inspect the cervix and vagina.
8. Insert a second IV catheter for administration of blood or fluids.

A. Measures to Control Bleeding

1. Manual exploration of the uterus—The uterus should be explored immediately in women with postpartum hemorrhage. Manual exploration also should be considered after delivery of the placenta in the following circumstances: (1) when vaginal delivery follows previous caesarean section; (2) when intrauterine manipulation, such as version and extraction, has been performed; (3) when malpresentation has occurred during labor and delivery; (4) when a premature infant has been delivered; (5) when an abnormal uterine contour has been noted prior to delivery; and (6) when there is a possibility of undiagnosed multiple pregnancy—to rule out twins.

Ensure that all placental parts have been delivered and that the uterus is intact. This should be done even in the case of a well-contracted uterus. Exploration performed for reasons other than evaluation of hemorrhage also should confirm that the uterine wall is intact and should attempt to identify any possible intrauterine structural abnormalities. Manual exploration of the uterus does not increase febrile morbidity or blood loss.

Technique: Place a fresh glove over the glove on the exploring hand. Form the hand into a cone and gently introduce it by firm pressure through the cervix while stabilizing the fundus with the other hand. Sweep the backs of the first and second fingers across the entire surface of the uterus, beginning at the fundus. In the lower uterine segment, palpate the walls with the palmar surface of 1 finger. Uterine lacerations will be felt as an obvious anatomic defect. All exploration should be gentle because the postpartum uterus is easily perforated.

Uterine rupture detected by manual exploration in the presence of postpartum hemorrhage requires immediate laparotomy. A decision to repair the defect or proceed with hysterectomy is made on the basis of the extent of the rupture, the patient’s desire for future childbearing, and the degree of the patient’s clinical deterioration.

2. Bimanual compression & massage—The most important step in controlling atonic postpartum hemorrhage is immediate bimanual uterine compression, which may have to be continued for 20–30 minutes or more. Fluid replacement should begin as soon as a secure IV line is in place. Typed and cross-matched blood is given when it is available. Manual compression of the uterus will control most cases of hemorrhage due to uterine atony, retained products of conception (once the products are removed), and coagulopathies.

Technique: Place a hand on the patient’s abdomen and grasp the uterine fundus; bring it down over the symphysis pubis. Insert the other hand into the vagina, and place the first and second fingers on either side of the cervix and push it cephalad and anteriorly. The pulsating uterine arteries should be felt by the fingertips. Massage the uterus with both hands while maintaining compression. Prolonged compression (20–30 minutes) may be required but almost always is successful in controlling bleeding.

Insert a Foley catheter into the bladder during compression and massage because vigorous fluid and blood replacement will cause diuresis. A distended bladder will interfere with compression and massage, will contribute to the patient’s discomfort, and may itself be a major contributor to uterine atony.

3. Curettage—Curettage of a large, soft postpartum uterus can be a formidable undertaking because the risk of perforation is high and the procedure commonly results in increased rather than decreased bleeding. The suction curette, even with a large cannula, covers only a small area of the postpartum uterus, and its size and shape increase the likelihood of perforation. A large blunt curette, the “banjo” curette, probably is the safest instrument for curettage of the postpartum uterus. It can be used when manual exploration fails to remove fragments of adherent placenta.

Curettage should be delayed unless bleeding cannot be controlled by compression and massage alone. Overly vigorous puerperal curettage can result in focal complete removal of the endometrium, particularly if the uterus is infected, with subsequent healing characterized by formation of adhesions and **Asherman’s syndrome** (amenorrhea and secondary sterility due to intrauterine adhesions and uterine synechiae). If circumstances permit, ultrasonic evaluation of the postpartum uterus may distinguish those patients who will benefit from curettage from those who should be managed without it.

4. Uterine packing—Although once widely used for control of obstetric hemorrhage, uterine packing is no longer favored. The uterus may expand to considerable size after delivery of the placenta, thus accommodating both a large volume of packing material and a large volume of blood. The technique also demands considerable technical expertise because the uterus must be packed uniformly with 5 yards of 4-inch gauze, sometimes with the aid of special instrumentation (Torpin packer). However, this method has been used successfully, avoiding conversion to laparotomy in 9 reported cases. As a last resort, uterine packing may be particularly appropriate in centers where an interventional radiologist is not immediately available.

An alternative for uterine packing that relies on the same principle of uterine tamponade is the Bakri balloon. This device is an inflatable balloon that inflates up to 800 mL. Due to a double lumen port, drainage of blood can still occur so that concealed hemorrhage does not occur. The balloon can easily be moved after deflation vaginally. An advantage of the device is that it can be inserted at time of hemorrhage from a vaginal approach or at time of laparotomy; in either case, it can be removed vaginally. The success of the device has been described in case series.

5. Uterotonic agents—Oxytocin 20–40 U/L of crystalloid should be infused, if not already running, at a rate of 10–15 mL/min. Methylergonovine 0.2 mg can be given IM but is contraindicated if the patient is hypertensive. Intramyometrial injection of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) to control bleeding was initially described in 1976. Intravaginal or rectal prostaglandin suppositories, intrauterine irrigation with prostaglandins, and intramyome-trial injection of prostaglandins also have been reported to control hemorrhage from uterine atony. IM administration of 15-methylprostaglandin analogue was successful in treating 85% of patients with postpartum hemorrhage due to atony. Failures in these series occurred in women who had uterine infections or unrecognized placenta accreta. Side effects usually are minimal but may include transient oxygen desaturation, bronchospasm, and, rarely, significant hypertension. Transient fever and diarrhea may occur. Rectal misoprostol (800 μg), a prostaglandin E_1 analogue, has been found to be effective in the treatment of primary postpartum hemorrhage secondary to atony. As mentioned earlier, sublingual misoprostol (800 μg) has been found to be clinically as effective as oxytocin (40 U/L) for treatment of postpartum hemorrhage due to atony. This information is particularly useful for low-resource areas because misoprostol does not have to be refrigerated or require specialized equipment for administration.

6. Radiographic embolization of pelvic vessels—Embolization of pelvic and uterine vessels by angiographic techniques is increasingly common and has success rates that range from 85–95% in experienced hands. In institutions with trained interventional radiologists, the technique is worth considering in women of low parity as an alternative to hysterectomy. With the patient under local anesthesia, a catheter is placed in the aorta and fluoroscopy is used to identify the bleeding vessel. Pieces of absorbable gelatin sponge (Gelfoam) or coil are injected into the damaged vessel (most typically the uterine artery) or into the internal iliac vessels if no specific site of bleeding can be identified. If bleeding continues, further embolization can be performed. This technique has the advantage of being effective even when the cause of hemorrhage is extrauterine and in the presence or absence of uterine atony. Many authors recommend embolization before internal iliac ligation, because ligation obstructs the access route for angiography. Adequate recanalization can occur to maintain fertility, although at this point, there are only limited case series demonstrating maintenance of fertility with pelvic artery embolization in this setting (as opposed to use for uterine fibroids). Although pelvic artery embolization is clearly preferable to hysterectomy in a patient desiring fertility, it is important to remember that the procedure does have an inherent complication rate, about 3–5%, with reports in the medical literature of loss of circulation to the lower extremities, labial and buttock necrosis, and vesicovaginal fistula.

7. Operative management—The patient’s wishes regarding further childbearing should be made clear as soon as laparotomy is contemplated for the management of postpartum hemorrhage. If the patient’s wishes cannot be ascertained, the operator should assume that the childbearing function is to be retained. Whenever possible, the spouse or family members should also be consulted prior to laparotomy.

A. PRESSURE OCCLUSION OF THE AORTA—Immediate temporary control of pelvic bleeding may be obtained at laparotomy by pressure occlusion of the aorta, which will provide valuable time to treat hypotension, obtain experienced assistants, identify the source of bleeding, and plan the operative procedure. In the young and otherwise healthy patient, pressure occlusion can be maintained for several minutes without permanent sequelae.

B. UTERINE ARTERY LIGATION—During pregnancy, 90% of the blood flow to the uterus is supplied by the uterine arteries. Direct ligation of these easily accessible vessels can successfully control hemorrhage in 75–90% of cases, particularly when the bleeding is uterine in origin. Recanalization can occur, and subsequent pregnancies have been reported.

Technique: The uterus is lifted upward and away from the side to be ligated. Absorbable suture on a large needle is placed around the ascending uterine artery and vein on 1 side of the uterus, passing through the myometrium 2–4 cm medial to the vessels and through the avascular area of the broad ligament. The suture includes the myometrium to fix the suture and to avoid tearing the vessels. The same procedure is then performed on the opposite side. If the ligation is performed during caesarean section, the sutures can be placed just below the uterine incision under the bladder flap. It is not necessary to mobilize the bladder otherwise. Bilateral utero-ovarian artery ligation can also be performed in an attempt to reduce blood flow to the uterus. This technique should be performed with absorbable suture near the point of anastomoses between the ovarian artery and the ascending uterine artery at the utero-ovarian ligament.

C. B-LYNCH BRACE SUTURE—An alternative to the vessel ligation techniques is placement of a brace suture to compress the uterus in cases of diffuse bleeding from atony or percreta (Fig. 21–1). This technique, initially described in 1997, and in multiple small cases series since, has become increasing popular due to the simplicity of the procedure.

Figure 21–1. B-Lynch brace suture

Technique: Laparotomy is made in the standard way for caesarean section, and a low-transverse uterine incision is made after the bladder is taken down. The uterus is exteriorized. To test the effectiveness of the method, the uterus is compressed manually, and another operator checks the vagina for decreased bleeding. Using no. 2 catgut, the uterus is punctured 3 cm from the right lower incision and 3 cm from the right lateral border. The suture is threaded to emerge 3 cm above the upper incision margin and 4 cm from the lateral border. The catgut is now visible anteriorly as it is passed over to compress the uterine fundus approximately 34 cm from the right cornual border. The suture is fed posteriorly and vertically to enter the posterior wall of the uterine cavity at the same level as the previous entry point. After manual compression, the suture is tightened and then passed posteriorly on the left side and passed around the uterine fundus again, this time on the left. The suture is brought anteriorly to puncture the uterus at the upper part of the left uterine incision and then reemerge below the lower incision in a symmetric fashion. With 1 operator providing compression, the other throws the knot. The hysterotomy is closed in the standard fashion for a caesarean section.

D. INTERNAL ILIAC ARTERY LIGATION—Bilateral internal iliac (hypogastric) artery ligation is the surgical method most often used to control severe postpartum bleeding (Fig. 21–2). Exposure can be difficult, particularly in the presence of a large boggy uterus or hematoma. Failure rates of this technique can be as high as 57% but may be related to the skill of the operator, the cause of the hemorrhage, and the patient’s condition before ligation is attempted.

(b) Posterior view

(a) Anterior view

(c) Anterior view

Figure 21–2. Location of ligatures for right internal iliac (hypogastric) artery ligation.

Technique: The peritoneum lateral to the infundibulopelvic ligament is incised parallel with the ligament, or the round ligament is transected. In either case, the peritoneum to which the ureter will adhere is dissected medially, which removes the ureter from the operative field. The pararectal space is then enlarged by blunt dissection. The internal iliac artery on the lateral side of the space is isolated and doubly ligated (but not cut) with silk ligatures at its origin from the common iliac artery. The operator must be careful not to tear the adjacent thin veins. Blood flow distally to the uterus, cervix, and upper vagina is not occluded, but the pulse pressure is sufficiently diminished to allow hemostasis to occur by in situ thrombosis. Fertility is preserved, and subsequent pregnancies are not compromised.

E. HYSTERECTOMY—Hysterectomy is the definitive method of controlling postpartum hemorrhage. Simple hemostatic repair of a ruptured uterus with or without tubal ligation in a woman of high parity or in poor condition for more extensive surgery may be preferred unless she has intercurrent uterine disease. The procedure is undoubtedly lifesaving.

8. Blood replacement—Blood and fluid replacement are required for successful management of postpartum hemorrhage. Massive transfusions may be necessary in patients with severe hemorrhage. Component therapy is advocated, with transfusion of packed cells, platelets, fresh-frozen plasma, and cryoprecipitate when indicated. Blood products should be obtained and given without delay when needed, because postponing transfusion may only contribute to the development of disseminated intravascular coagulation. In specialized settings, there may be a role for off-label use of recombinant activated factor VII, which was originally developed for hemophilia patients, but has been used successfully in several cases of fulminant postpartum hemorrhage.

B. Management of Delayed Postpartum Hemorrhage

Delayed postpartum hemorrhage (bleeding ≥2 weeks after delivery) is almost always due to subinvolution of the placental bed or retained placental fragments. Involution of the placental site is normally delayed when compared with that of the rest of the endometrium. However, for unknown reasons, in subinvolution the adjacent endometrium and the decidua basalis have not regenerated to cover the placental implantation site. The involutional processes of thrombosis and hyalinization have failed to occur in the underlying blood vessels, so bleeding may occur with only minimal trauma or other (unknown) stimuli. Although the cause of subinvolution is unknown, faulty placental implantation, implantation in the poorly vascularized lower uterine segment, and persistent infection at the implantation site have been suggested as possible factors. Uterine compression and bimanual massage, as previously described, control this type of bleeding, but it may be necessary to continue compression and massage for 30–45 minutes or longer. As previously mentioned, transvaginal ultrasound may aid in diagnosis of retained placental products. If imaging studies suggest intracavitary tissue, curettage is warranted.

Broad-spectrum antibiotics should be started when resuscitation allows. Oxytocin 10 U IM every 4 hours or 10–20 U/L IV solution by slow continuous infusion, 15-methyl $PGF_{2\alpha}$ (Prostin 15M) 0.25 mg IM every 2 hours, or ergot alkaloids, such as methylergonovine maleate 0.2 mg orally every 6 hours, should be administered for at least 48 hours.

Prognosis

Postpartum hemorrhage has a recurrence rate of approximately 10% in future pregnancies. There are limited data on outcomes of pregnancies after uterine artery embolization or B-Lynch suture. It is unknown if these procedures put future pregnancies at increased risk of complications, although there are case reports and series of uneventful pregnancy outcomes after these procedures.

PLACENTA ACCRETA

ESSENTIALS OF DIAGNOSIS

- A layer of decidua normally separates the placental villi and the myometrium at the site of placental implantation. A placenta that directly adheres to the myometrium without an intervening decidual layer is termed *placenta accreta*.
- Classification

A. By Degree of Adherence

1. Placenta accreta vera—Villi adhere to the superficial myometrium.
2. Placenta increta—Villi invade the myometrium.
3. Placenta percreta—Villi penetrate the full thickness of the myometrium.

B. By Amount of Placental Involvement

1. Focal adherence—A single cotyledon is involved.
2. Partial adherence—One or several cotyledons are involved.
3. Total adherence—The entire placenta is involved.

Pathogenesis

Estimates of the incidence of placenta accreta (all forms) vary from 1 in 2000 to 1 in 7000 deliveries. Placenta accreta vera accounts for approximately 80% of abnormally adherent placentas, placenta increta accounts for 15%, and placenta percreta accounts for 5%. The rate has risen over the last 2 decades, paralleling the increasing caesarean section rate. The condition has emerged as the major cause of peripartum hysterectomy in high-resource countries.

Both excessive penetrability of the trophoblast and defective or missing decidua basalis have been suggested as causes of placenta accreta. Histologic examination of the placental implantation site usually demonstrates the absence of the decidua and Nitabuch’s layer. Cases of placenta accreta have been seen in the first trimester, suggesting that the process may occur at the time of implantation and not later in gestation.

Although the exact cause is unknown, several clinical situations are associated with placenta accreta, such as previous caesarean section, placenta previa, grand multiparity, previous uterine curettage, and previously treated Asherman’s syndrome.

These conditions share a common possible defect in formation of the decidua basalis. The incidence of placenta accreta in the presence of placenta previa after 1 prior uterine incision is between 14% and 24%, after 2 is 23–48%, and after 3 is 35–50%. The incidence of placenta accreta after successful treatment of Asherman’s syndrome may be as high as 15%.

Clinical Findings

Adverse effects from placenta accreta in pregnancy or during the course of labor and delivery are uncommon. Rarely, intraabdominal hemorrhage or placental invasion of adjacent organs prior to labor has occurred, with the diagnosis made at laparotomy.

The diagnosis of placenta increta prior to delivery based on the lack of the sonolucent area normally seen beneath the implantation site during ultrasonographic examination is a finding confirmed in several reports. Sonographic antenatal diagnosis of the less invasive placental accreta also has been reported. Color Doppler imaging appears to be particularly helpful in diagnosis. Magnetic resonance imaging has also aided in the diagnosis of placenta accreta. The diagnosis is more often established when no plane of cleavage is found between the placenta or parts of the placenta and the myometrium in the presence of postpartum hemorrhage. Retained placental parts prevent the myometrium from contracting and thereby achieving hemostasis. Bleeding can be brisk. Inspection of the already separated placenta shows that portions are missing, and manual exploration may produce additional placental fragments.

Delayed spontaneous separation of the placenta is also an indication of an unusually adherent placenta. Focal or partial involvement may be manifested as difficulty in establishing a cleavage plane during manual removal of the placenta. Removal of a totally adherent placenta is difficult. Persistent efforts to manually remove a totally adherent placenta are futile and waste time, and they result in even more blood loss. Preparation for hysterectomy should begin as soon as the diagnosis is suspected.

Complications

The immediate morbidity associated with an abnormally adherent placenta is that associated with any type of postpartum hemorrhage. Massive blood loss and hypotension can occur. Intrauterine manipulation necessary to diagnose and treat placenta accreta may result in uterine perforation and infection. Sterility may occur as a result of hysterectomy performed to control bleeding. Perhaps due to diagnosis prior to delivery and preparation of the obstetric team, the condition is not a leading cause of mortality in the United States.

Recurrence may be common with lesser degrees of adherence.

Treatment

Fluid and blood replacement should begin as soon as excessive blood loss is diagnosed. Insertion of a second large-bore IV catheter may be necessary. Evaluation of puerperal hemorrhage should be performed as outlined earlier in Evaluation of Persistent Bleeding.

Conservative treatment of placenta accreta in women of low parity is increasingly attempted. A recent series described success in 131 of 167 women managed with serial IM methotrexate injections after pelvic artery embolization. The placenta (or portions of it) is left in situ if bleeding is minimal and will later slough off. Successful subsequent pregnancies have been reported, although the risk of recurrence of placenta accreta may be high.

Successful conservative treatment of placenta percreta is rare, but the conservative approach may be a reasonable option if only focal defects are present, blood loss is not excessive, and the patient wishes to preserve fertility. In anticipated cases of severe placenta accreta, preoperative balloon occlusion and embolization of the internal iliac arteries may minimize intraoperative blood losses. Successful embolization in unpredicted cases of placenta accreta has been reported. However, additional resection of adjacent organs, such as partial cystectomy, may be necessary in placenta percreta.

Prognosis

For women who were successfully treated with conservative management and uterine preservation, subsequent pregnancies have been reported, although the risk of recurrence of placenta accreta may be high.

UTERINE INVERSION

ESSENTIALS OF DIAGNOSIS

- Uterine inversion is prolapse of the fundus to or through the cervix so that the uterus is in effect turned inside out.
- Almost all cases of uterine inversion occur after delivery and may be worsened by excess traction on the cord before placental separation.
- Nonpuerperal uterine inversion is rare and usually is associated with tumors (eg, polypoid leiomyomas).

Pathogenesis

In series reported within the past 30 years, the incidence of uterine inversion has varied from 1 in

4000 to 1 in 100,000 deliveries; an incidence of 1 in 20,000 is frequently cited. One worker reported no inversions in more than 10,000 personally conducted deliveries. More recent reviews indicate a greater incidence of uterine inversion, approximately 1 in 2000 to 1 in 2500 deliveries.

The exact cause of uterine inversion is unknown, and the condition is not always preventable. The cervix must be dilated, and the uterine fundus must be relaxed for inversion to occur. Rapid uterine emptying may contribute to uterine relaxation.

Conditions that may predispose women to uterine inversion include fundal implantation of the placenta, abnormal adherence of the placenta (partial placenta accreta), congenital or acquired weakness of the myometrium, uterine anomalies, protracted labor, previous uterine inversion, intrapartum therapy with magnesium sulfate, strong traction exerted on the umbilical cord, and fundal pressure.

Prevention

Many cases of uterine inversion result from mismanagement of the third stage of labor in women who already are at risk for developing uterine inversion. The following maneuvers are to be avoided: excessive traction on the umbilical cord, excessive fundal pressure, excessive intraabdominal pressure, and excessively vigorous manual removal of the placenta.

Clinical Findings

The diagnosis of uterine inversion usually is obvious. Shock and hemorrhage are prominent, as is considerable pain. A dark red–blue bleeding mass is palpable and often visible at the cervix, in the vagina, or outside the vagina. A depression in the uterine fundus or even an absent fundus is noted on abdominal examination. Partial inversion in which the fundus stays within the vagina can escape immediate notice if the attendant is not aware of this complication.

If the uterus is inverted but does not protrude through the cervix, the inversion is *incomplete*. In *complete* inversion, the fundus has prolapsed through the cervix. Occasionally, the entire uterus may prolapse out of the vagina.

Puerperal inversion has also been classified on the basis of its duration. Acute inversion occurs immediately after delivery and before the cervix constricts. Once the cervix constricts, the inversion is termed *subacute*. Chronic inversion is noted more than 4 weeks after delivery. Today, nearly all cases of uterine inversion are of the acute variety and are recognized and treated immediately after delivery.

Differential Diagnosis

In some cases, a prolapsed fibroid may have clinical findings similar to uterine inversion; however, with a prolapsed fibroid, the uterine fundus should be palpable on abdominal examination.

Complications

The morbidity and mortality associated with uterine inversion correlate with the degree of hemorrhage, the rapidity of diagnosis, and the effectiveness of treatment.

The immediate morbidity is that associated with any postpartum hemorrhage; however, endomyometritis frequently follows uterine inversion. The intestines and uterine appendages may be injured if they are entrapped by the prolapsed uterine fundus. Death has occurred from uterine inversion, although with prompt recognition, definitive treatment, and vigorous resuscitation, the mortality rate in this condition should be quite low.

Treatment

Successful management of patients with uterine inversion depends on prompt recognition and treatment. If initial measures fail to relieve the condition, it may progress to the point at which operative treatment or even hysterectomy is necessary. Shock associated with uterine inversion typically is profound. Hemorrhage can be massive, and hypovolemia should be vigorously treated with fluid and blood replacement.

A. Manual Repositioning of the Uterus

Treatment should begin as soon as the diagnosis of uterine inversion is made. Assistance is vital. An initial attempt should be made to reposition the fundus. The inverted fundus, along with the placenta if it is still attached, is slowly and steadily pushed upward in the axis of the uterus (Fig. 21–3). If the placenta has not separated, do not remove it until an adequate IV infusion has been established.

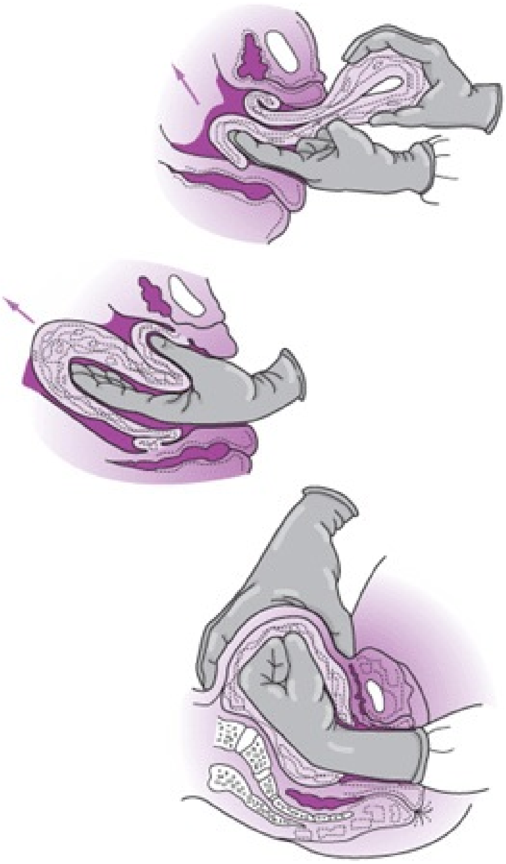

Figure 21–3. Replacement of an inverted uterus.

If the initial attempt fails, induce general anesthesia, preferably with a halogenated agent (eg, halothane) to provide uterine relaxation. Alternatively, 50 µg of IV nitroglycerin can be given as a bolus to relax the uterus and avoid intubation. The dose can be repeated at least once. While awaiting anesthesiology assistance, easily available tocolytics may be used effectively. Either IV magnesium sulfate or terbutaline 0.25 mg given as a bolus dose IV has been used successfully to achieve uterine relaxation in subacute inversion, and neither has been associated with bleeding.

Technique: The operator's fist is placed on the uterine fundus, and the fundus is gradually pushed back into the pelvis through the dilated cervix. The general anesthetic or uterine relaxant is discontinued. Infusion of oxytocin or ergot alkaloids is started and fluid and blood replacement continued. Alternatively, prostaglandins can be used to effect uterine contraction after repositioning. Bimanual uterine compression and massage are maintained until the uterus is well contracted and hemorrhage has ceased. The placenta can then be removed.

Antibiotics should be started as soon as is practical. Oxytocics or ergot alkaloids are continued for at least 24 hours. Frequent determinations of the hematocrit level should be made to ascertain the need for further blood replacement. Iron supplements should begin with resumption of oral intake.

B. Surgical Repositioning of the Uterus

Surgical repositioning of the uterus is rarely necessary in contemporary medical practice in the United States. However, when all other efforts have failed to reposition the everted uterus, operative intervention may be lifesaving. This is generally accomplished by a vertical incision through the lower uterine segment directly posterior. The uterus is repositioned by either pulling from above or, very rarely, pushing from below (using a sterile glove). The incision is then repaired as would be any uterine incision. Blood replacement, antibiotics, and careful monitoring are necessary for successful perioperative management.

Prognosis

It is not clear whether uterine inversion is at increased risk of recurrence in future pregnancies. The prognosis for women with uterine inversion in whom the uterus was successfully restored to its normal anatomic position is generally considered to be excellent.

POSTPARTUM & PUERPERAL INFECTIONS

General Considerations

Infections are among the most prominent puerperal complications. An improved understanding of the natural history of female genital infections and the availability of powerful antibiotics may have produced a complacent attitude toward puerperal infections that is unrealistic. Postpartum infections still are costly to both patients and society, and they are associated with an admittedly small but not negligible threat of serious disability and death.

Puerperal morbidity due to infection has occurred if the patient’s temperature is higher than 38°C (100.4°F) on 2 separate occasions at least 24 hours apart following the first 24 hours after delivery. Overt infections can and do occur in the absence of these criteria, but fever of some degree remains the hallmark of puerperal infection, and the patient with fever can be assumed to have a genital infection until proved otherwise.

Incidence

Puerperal infectious morbidity affects 2–8% of pregnant women and is more common in those of low socioeconomic status, who have undergone operative delivery, with premature rupture of the membranes, with long labors, or who have multiple pelvic examinations.

Morbidity & Mortality

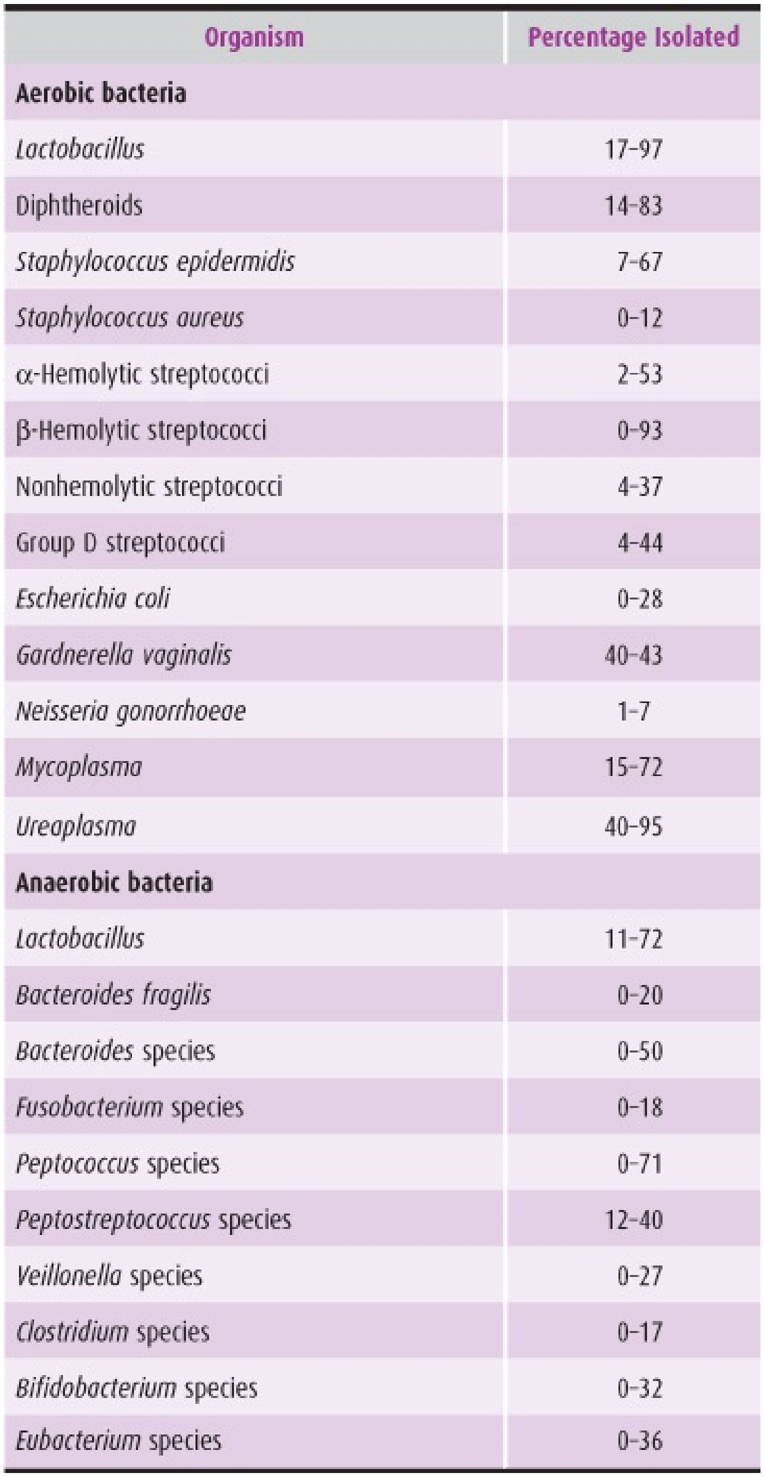
Postpartum infections are responsible for much of the morbidity associated with childbirth, and they either are directly responsible for or contribute to the death of approximately 7% of all pregnant women who die each year in the United States. The costs are considerable, not only in additional days of hospitalization and medications but also in time lost from work.

Sterility may result from the sequelae of postpartum infections, such as periadnexal adhesions. Hysterectomy occasionally is required in patients with serious postpartum or postoperative infection.

Pathogenesis

The flora of the birth canal of pregnant women is essentially the same as that of nonpregnant women, although variations in culture techniques and in the study populations have produced markedly different results. The vaginal flora typically includes aerobic and anaerobic organisms that are commonly considered pathogenic (Table 21–1). Several mechanisms appear to prevent overt infection in the genital tract, such as the acidity of the normal vagina; thick, tenacious cervical mucus; and maternal antibodies to most vaginal flora.

Table 21–1. Percentage of organisms isolated from the vagina or cervix in normal pregnant and nonpregnant women.



Organism	Percentage Isolated
Aerobic bacteria	
Lactobacillus	17–97
Diphtheroids	14–83
Staphylococcus epidermidis	7–67
Staphylococcus aureus	0–12
α-Hemolytic streptococci	2–53
β-Hemolytic streptococci	0–93
Nonhemolytic streptococci	4–37
Group D streptococci	4–44
Escherichia coli	0–28
Gardnerella vaginalis	40–43
Neisseria gonorrhoeae	1–7
Mycoplasma	15–72
Ureaplasma	40–95
Anaerobic bacteria	
Lactobacillus	11–72
Bacteroides fragilis	0–20
Bacteroides species	0–50
Fusobacterium species	0–18
Peptococcus species	0–71
Peptostreptococcus species	12–40
Veillonella species	0–27
Clostridium species	0–17
Bifidobacterium species	0–32
Eubacterium species	0–36

During labor and particularly after rupture of the membranes, some of the protective mechanisms are no longer present. Examinations and invasive monitoring apparatus probably facilitate the introduction of vaginal bacteria into the uterine cavity. Bacteria can be cultured from the amniotic fluid of most women undergoing intrauterine pressure monitoring, but overt postpartum infection is seen in fewer than 10% of these cases. Contractions during labor may spread bacteria present in the amniotic cavity to the adjacent uterine lymphatics and even into the bloodstream.

The postpartum uterus initially is devoid of mechanisms that keep it sterile, and bacteria may be recovered from the uterus in nearly all women in the postpartum period. Whether or not disease is clinically expressed depends on the presence of predisposing factors, the duration of uterine contamination, and the type and amount of microorganisms involved. The necrosis of decidua and other intrauterine contents (lochia) promotes an increase in the number of anaerobic bacteria, heretofore limited by lack of suitable nutrients and other factors necessary for growth.

Sterility of the endometrial cavity returns by the third or fourth postpartum week. Granulocytes that penetrate the endometrial cavity and the open drainage of lochia are effective in preventing infection in most patients.

Etiology

Almost all postpartum infections are caused by bacteria normally present in the genitalia of pregnant women. The lochia is an excellent culture medium for organisms ascending from the vagina. In women who have undergone caesarean section, more devitalized tissue and foreign bodies (sutures) are present, providing additional fertile ground for possible contamination and subsequent infection. Approximately 70% of puerperal soft tissue infections are mixed infections consisting of both aerobic and anaerobic organisms; infections occurring in women undergoing caesarean section are more likely to be serious.

General Evaluation

The source of infection should be identified, the likely cause determined, and the severity assessed. Most women with fever in the postpartum period have endometritis. Urinary tract infection is the next most common infection. Neglected or virulent endomyometritis may progress to more serious infection. Generalized sepsis, septic pelvic thrombophlebitis, or pelvic abscess may be the end result of an initial infection of the endometrial cavity.

1. Endometritis

ESSENTIALS OF DIAGNOSIS

- Infection of the endometrium
- Fever and a soft, tender uterus on physical examination

Pathogenesis

All of the following circumstances have led to higher than normal postpartum infection rates: prolonged rupture of the membranes (>24 hours), chorioamnionitis, an excessive number of digital vaginal examinations, prolonged labor (>12 hours), toxemia, intrauterine pressure catheters (>8 hours), fetal scalp electrode monitoring, preexisting vaginitis or cervicitis, operative vaginal deliveries, caesarean section, intrapartum and postpartum anemia, poor nutrition, obesity, low socioeconomic status, and coitus near term.

Caesarean section and low socioeconomic class are consistently associated with higher rates of postpartum infection, and caesarean section is easily the most common identifiable risk factor for development of puerperal infection. Some series report an infection rate of 40–80% following caesarean section delivery. Postpartum infection is more likely to be serious after caesarean section than after vaginal delivery. A history of bacterial vaginosis is associated with a higher risk of postcaesarean endometritis.

Clinical Findings

A. Symptoms & Signs

Fever and a soft, tender uterus are the most prominent signs of endometritis. The lochia may or may not have a foul odor. Leukocytosis is seen. In more severe disease, high fever, malaise, abdominal tenderness, ileus, hypotension, and generalized sepsis may be seen. Movement of the uterus causes increased pain.

1. Fever—Although the puerperium is a period of high metabolic activity, this factor should not raise the temperature above 37.2°C (99°F) and then only briefly in the first 24 hours postpartum. Modest temperature elevations may occur with dehydration. Any woman with a fever over 38°C (100.4°F) at any time in the puerperium should be evaluated.

Endometritis results in temperatures ranging from 38°C to over 40°C (100.4°F to >104°F), depending on the patient, the causative microorganism, and the extent of infection. The lower range of temperatures is more common. Endometritis usually develops on the second or third postpartum day. Early fever (within hours of delivery) and hypotension are almost pathognomonic for infection with β-hemolytic streptococci.

2. Uterine tenderness—The uterus is soft and exquisitely tender. Motion of the cervix and uterus may cause increased pain.

Abdominal tenderness is generally limited to the lower abdomen and does not lateralize. A carefully performed baseline examination should include an adnexal evaluation. Adnexal masses palpable on abdominal or pelvic examination are not seen in uncomplicated endometritis, but tubo-ovarian abscess may be a later complication of an infection originally confined to the uterus. Bowel sounds may be decreased and the abdomen distended and tympanitic.

Pelvic examination confirms the findings disclosed by abdominal examination.

B. Laboratory Findings

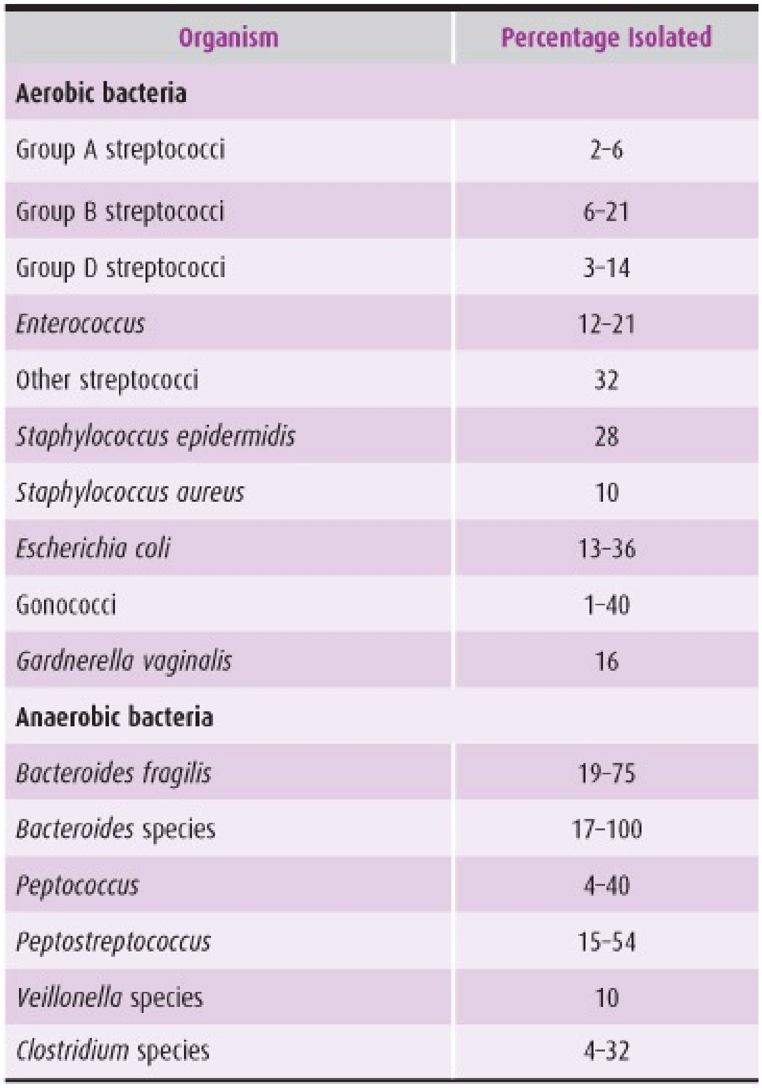
1. Hematologic findings—Leukocytosis is a normal finding during labor and the immediate puerperal period. White blood cell counts may be as high as 20,000/μL in the absence of infection, so higher counts can be anticipated in infection. Bacteremia is present in 5–10% of women with uncomplicated endometritis. *Mycoplasma* is frequently recovered from the blood of patients with postpartum fever. Infections with *Bacteroides* as the predominant organism are frequently associated with positive blood cultures.

2. Urinalysis—Urinalysis should be routinely performed in patients thought to have endometritis because urinary tract infections are often associated with a clinical picture similar to that of mild endometritis. If pyuria and bacteria are noted in a properly collected specimen, appropriate antibiotic therapy for urinary tract infections should be started and a portion of the specimen sent for culture.

3. Lochia cultures—Bacteria colonizing the cervical canal and ectocervix almost always can be recovered from lochia cultures, but they may not be the same organisms causing endometritis. Accurate cultures can be achieved only if specimens obtained transcervically are free from vaginal contamination. Material should be obtained using a speculum to allow direct visualization of the cervix and a gloved culture device (a swab that is covered while it is passed through a contaminated area, then uncovered to obtain a culture from the desired area). Transabdominal aspiration of uterine contents does secure an uncontaminated specimen, but routine use of this technique probably is not justified, and confirmation of placement within the uterine cavity may be difficult. Unless special means are taken to prevent cervical contamination and to ensure the recovery of anaerobic species, results of lochia cultures must be interpreted with great care.

4. Bacteriologic findings—Although the organisms responsible for puerperal infections vary considerably among hospitals, most puerperal infections are due to anaerobic streptococci, gramnegative coliforms, *Bacteroides* spp., and aerobic streptococci. *Chlamydia* and *Mycoplasma* are also implicated in many postpartum infections, but clinical isolates are rare because of the difficulty in culturing these organisms. Gonococci are recovered in varying degrees. The percentage of representative microorganisms recovered from women with endometritis is given in Table 21–2.

Table 21–2. Percentage of organisms recovered from women with postpartum endomyometritis.



Organism	Percentage Isolated
Aerobic bacteria	
Group A streptococci	2-6
Group B streptococci	6-21
Group D streptococci	3-14
Enterococcus	12-21
Other streptococci	32
Staphylococcus epidermidis	28
Staphylococcus aureus	10
Escherichia coli	13-36
Gonococci	1-40
Gardnerella vaginalis	16
Anaerobic bacteria	
Bacteroides fragilis	19-75
Bacteroides species	17-100
Peptococcus	4-40
Peptostreptococcus	15-54
Veillonella species	10
Clostridium species	4-32

Patterns of bacterial isolates in puerperal infections in the patient’s hospital are more important in guiding selection of appropriate antibiotics than are studies from the literature.

A. Aerobic Bacteria—Group A streptococci are no longer a major cause of postpartum infection, but infection with these organisms still occurs occasionally, often associated with rapid progression of toxic shock syndrome. If more than an isolated instance of infection due to these streptococci occurs, immediate measures should be taken to halt a potential epidemic. Penicillin is highly effective.

In as many as 30% of women with clinically recognized endometritis, group B streptococci are partly or wholly responsible for the infection. Classic presenting signs are high fever and hypotension shortly after delivery. However, group B streptococci are commonly recovered from the vaginas of pregnant women whether or not they have endometritis. Why some women with positive cultures develop serious illness whereas others do not undoubtedly depends on the presence of predisposing factors as well as other, as yet unknown, elements. It is interesting that positive cultures in women do not correlate well with the incidence of streptococcal infection in their newborns. Penicillin is the treatment of choice for patients with endometritis.

Group D streptococci, which include *Streptococcus faecalis*, are common isolates in endometritis. Ampicillin in high doses is the treatment of choice. Aminoglycosides are also effective against this group.

Staphylococcus aureus is not commonly seen in cultures from women with postpartum infections of the uterus. *Staphylococcus epidermidis* is frequently recovered from women with postpartum infections. These organisms are typically not seen in pure culture. When established staphylococcal infections require treatment, nafcillin, cloxacillin, or cephalosporins should be used.

Among the gramnegative aerobic organisms likely to be recovered in postpartum uterine infections, *Escherichia coli* is the most common. In postpartum uterine infections, *E coli* is more likely to be isolated from seriously ill patients, whereas in urinary tract infections, it is the most commonly isolated organism but is not necessarily found in the sickest patients. Hospital-acquired *E coli* is most susceptible to aminoglycosides and cephalosporins.

The incidence of *Neisseria gonorrhoeae* is 2–8% in pregnant women antepartum. Unless repeat screening examinations and treatment of patients with positive cultures are undertaken in women near term, the incidence of asymptomatic endocervical gonorrhea at delivery probably is only slightly less, and it is reasonable to believe that some cases of puerperal endometritis are gonococcal in origin.

Gardnerella vaginalis, a cause of vaginitis, is seen in isolates from women with postpartum infections, usually in those with a polymicrobial cause, although pure isolates have been reported.

Other gramnegative bacilli that are commonly encountered on medical and surgical wards (eg, *Klebsiella pneumoniae, Enterobacter, Proteus*, and *Pseudomonas* spp.) are uncommon causes of endometritis.

b. Anaerobic bacteria—Anaerobic bacteria are involved in puerperal infections of the uterus in at least 50% and perhaps as many as 95% of cases. They are much less commonly seen in urinary tract infections. Anaerobic peptostreptococci and peptococci are commonly recovered in specimens from women with postpartum infection, particularly with other anaerobic species. Clindamycin, chloramphenicol, and the newer cephalosporins are active against these organisms.

Bacteroides spp., particularly *Bacteroides fragilis*, are commonly found in mixed puerperal infections. These are likely to be the more serious infections (eg, puerperal pelvic abscess, caesarean section wound infections, and septic pelvic thrombophlebitis). When infection with this organism is suspected or confirmed, clindamycin, chloramphenicol, or third-generation cephalosporins should be used.

Gram-positive anaerobic organisms are represented only by *Clostridium perfringens*, which is not infrequently isolated from an infected uterus but which is a rare cause of puerperal infection.

C. OTHER ORGANISMS—*Mycoplasma* and *Ureaplasma* spp. are common genital pathogens that have been isolated from the genital tract and blood of postpartum women both with and without overt infection. These pathogens are frequently found in the presence of other bacteria. The role of these organisms in puerperal infections is unknown.

Chlamydia trachomatis is now thought to be the leading cause of pelvic inflammatory disease in some populations. Because the population most at risk for pelvic inflammatory disease is the same as that most likely to become pregnant, it is not surprising that *Chlamydia* is in some way involved in puerperal infections, but it is infrequently isolated as a cause of early postpartum endometritis. *Chlamydia* is more frequently associated with mild late-onset endometritis, so cultures for this organism should be obtained from patients with endometritis diagnosed several days after delivery. *Chlamydia* is difficult to culture, and it is possible that as more effective culture techniques become available, the place of this organism in the morbidity associated with postpartum infections will be clarified.

Differential Diagnosis

In the immediate postpartum period, involuntary chills are common and are not necessarily an indication of overt infection. Lower abdominal pain is common as the uterus undergoes involution with continuing contractions.

Extragenital infections are much less common than endometritis and urinary tract infections. Most of these infections can be effectively ruled out by history and examination alone. Patients should be asked, at a minimum, about coughing, chest pain, pain at the insertion site of IV catheters, breast tenderness, and leg pain. Examination of the breasts, chest, IV catheter insertion site, and leg veins should determine whether these areas might be the source of the postpartum fever. Chest x-ray films are rarely of benefit unless signs and symptoms point to a possible pulmonary cause of the fever.

Treatment

The choice of antibiotics for treatment of endometritis depends on the suspected causative organisms and the severity of the disease. If the illness is serious enough to require antibiotics, initial therapy should consist of IV antibiotics in high doses. Factors reinforcing the need for this approach include the large volume of the uterus, the expanded maternal blood volume, the brisk diuresis associated with the puerperium, and the difficulty in achieving adequate tissue concentrations of the antibiotic distal to the thrombosed myometrial blood vessels. Clindamycin plus an aminoglycoside is a standard first-line regimen. Good evidence now indicates that once-a-day dosing of gentamicin is as effective as the traditional thrice-daily regimen. Single-agent therapy with second- or third-generation cephalosporins is an acceptable alternative.

The response to therapy should be carefully monitored for 24–48 hours. Deterioration or failure to respond determined both clinically and by laboratory test results requires a complete reevaluation. Ampicillin is added when the patient has a less than adequate response to the usual regimen, particularly if *Enterococcus* spp. are suspected.

IV antibiotics are continued until the patient has been afebrile for 24–48 hours. Randomized and prospective trials have shown that additional treatment with oral antibiotics after IV therapy is unnecessary. Patients with documented concurrent bacteremia can be treated similarly, unless they have persistently positive blood cultures or a staphylococcal species cultured. If the patient remains febrile despite the standard antibiotic regimens, further evaluation should be initiated to look for abscess formation, hematomas, wound infection, and septic pelvic thrombophlebitis.

For patients known to be infected or at extremely high risk for infection at the time of delivery, initial therapy with 2- or 3-drug regimens in which 1 of the agents is clindamycin is prudent. Single-agent IV infusion of broad-spectrum agents such as piperacillin or cefoxitin appears to be equally effective.

2. Urinary Tract Infection

ESSENTIALS OF DIAGNOSIS

- Urine culture demonstrating the presence of bacteria in the urine in a patient symptomatic for urinary tract infection
- Pyelonephritis typically presents with symptoms of flank pain and/or systemic signs of fever, chills, and nausea/vomiting

---

Pathogenesis

Approximately 2–4% of women develop a urinary tract infection postpartum. After delivery, the bladder and lower urinary tract remain somewhat hypotonic, and residual urine and reflux result. This altered physiologic state, in conjunction with catheterization, birth trauma, conduction anesthesia, frequent pelvic examinations, and nearly continuous contamination of the perineum, is sufficient to explain the high incidence of lower urinary tract infections postpartum. In many women, preexisting asymptomatic bacteria, chronic urinary tract infections, and anatomic disorders of the bladder, urethra, and kidneys contribute to urinary tract infection postpartum.

Clinical Findings

A. Symptoms & Signs

Urinary tract infection usually presents with dysuria, frequency, urgency, and low-grade fever; however, an elevated temperature is occasionally the only symptom. White blood cells and bacteria are seen in a centrifuged sample of catheterized urine. A urine culture should be obtained. The history should be reviewed for evidence of chronic antepartum infections. If a woman had an antepartum urinary tract infection, then her postpartum infection likely is caused by the same organism. Repeated urinary tract infections call for careful postpartum evaluation. Urethral diverticulum, kidney stones, and upper urinary tract anomalies should be ruled out.

Urinary retention postpartum in the absence of regional anesthesia or well after its effects have worn off almost always indicates urinary tract infection.

Pyelonephritis may be accompanied by fever, chills, malaise, and nausea and vomiting. Characteristic signs of kidney involvement associated with pyelonephritis include costovertebral angle tenderness, dysuria, pyuria, and, in the case of hemorrhagic cystitis, hematuria.

B. Laboratory Findings

E coli is easily the most common organism isolated from infected urine in postpartum women (approximately 75% of cases). Other gramnegative bacilli are much less likely to be recovered. *E coli* is less likely to be the causative organism in women who had repeated urinary tract infections in the recent past.

Treatment

Antibiotics with specific activity against the causative organism are the cornerstone of therapy in uncomplicated cystitis. These drugs include sulfonamides, nitrofurantoin, trimethoprim-sulfamethoxazole, oral cephalosporins (cephalexin, cephradine), and ampicillin. Some hospitals report a high incidence of microbial resistance to ampicillin. The oral combination of amoxicillin-clavulanic acid provides a better spectrum of bacterial sensitivity. Sulfa antibiotics can be used safely in women who are breastfeeding if the infants are term without hyperbilirubinemia or suspected glucose-6-phosphate dehydrogenase deficiency. High fluid intake should be encouraged.

Pyelonephritis requires initial therapy with high doses of IV antibiotics, such as ampicillin 8–12 g/d or first-generation cephalosporins (cefazolin 3–6 g/d, cephalothin 4–8 g/d). An aminoglycoside can be added when resistant organisms are suspected or when the patient has clinical signs of sepsis. A long-acting third-generation cephalosporin, such as ceftriaxone 1–2 g every 12 hours, also can be used. The response to therapy may be rapid, but some women respond with gradual defervescence over 48 hours or longer. Urine cultures should be obtained to guide any necessary modifications in drug therapy if the patient's response is not prompt. Even with prompt resolution of fever, antibiotic therapy should be continued IV or orally for a total of 10 days. Urine for culture should be obtained at a postpartum visit after therapy has been completed.

3. Pneumonia

ESSENTIALS OF DIAGNOSIS

- Pneumonia typically presents with fever, chills, and productive cough.
- Women with obstructive lung disease, smokers, and those undergoing general anesthesia have an increased risk for developing pneumonia postpartum.

Clinical Findings

A. Symptoms & Signs

Symptoms and signs are the same as those of pneumonia in nonpregnant patients: productive cough, chest pain, fever, chills, rales, and infiltrates on chest x-ray film. In some cases, careful differentiation from pulmonary embolus is required.

B. X-Ray & Laboratory Findings

Chest x-ray film confirms the diagnosis of pneumonia. Gram-stained smears of sputum and material for culture should be obtained.

Streptococcus pneumoniae and *Mycoplasma pneumoniae* are the 2 most likely causative organisms. *S pneumoniae* can easily be identified on gram-stained smears. Infection with *M pneumoniae* can be suspected on clinical grounds.

Treatment

Appropriate antibiotics, oxygen (if the patient is hypoxic), IV hydration, and pulmonary toilet are the mainstays of therapy.

4. Caesarean Section Wound Infection

ESSENTIALS OF DIAGNOSIS

- Wound erythema and tenderness +/− drainage from the wound
- The patient may also demonstrate systemic signs of infection such as fever or malaise

---

Pathogenesis

Wound infection occurs in 4–12% of patients after caesarean section. The following risk factors predispose to subsequent wound infection in women undergoing caesarean section: obesity, diabetes, prolonged hospitalization before caesarean section, prolonged rupture of the membranes, chorioamnionitis, endomyometritis, prolonged labor, emergency rather than elective indications for caesarean section, and anemia.

Prevention

The high rate of infection (averaging 35–40%) after caesarean section is sufficient reason to consider prophylactic perioperative antibiotic administration. A major difference in practice in terms of prophylactic antibiotic administration prior to caesarean delivery has recently been advocated. While historically antimicrobial prophylaxis has been given after umbilical cord clamping, due to concerns regarding the masking of a neonatal infection, reductions in postcaesarean wound infection as great as 50% can be attributed to a single dose of cefazolin (1 g) given IV prior to skin incision.

Clinical Findings

A. Symptoms & Signs

Fever with no apparent cause that persists to the fourth or fifth postoperative day strongly suggests a wound infection. Wound erythema and tenderness may not be evident until several days after surgery. Occasionally, wound infections are manifested by spontaneous drainage, often accompanied by resolution of fever and relief of local tenderness. Rarely, a deep-seated wound infection becomes apparent when the skin overtly separates, usually after some strenuous activity by the patient.

B. Laboratory Findings

Gram-stained smears and culture of material from the wound may be helpful in guiding selection of the initial antibiotic. Blood cultures may be positive in the patient with systemic sepsis due to wound infection. The organisms responsible for most wound infections originate on the patient's skin. *S aureus* is the organism most commonly isolated. *Streptococcus* species, *E coli*, and other gramnegative organisms that may originally have colonized the amniotic cavity are also seen. Occasionally, *Bacteroides*, which comes only from the genital tract, is isolated from material taken from serious wound infections. In addition, methicillin-resistant *S aureus* (MRSA) is an emerging isolate from caesarean delivery wound infections. At this point, prophylactic antibiotic regimens have not addressed this particular organism.

Rarely, necrotizing fasciitis and the closely related synergistic bacterial gangrene can involve caesarean section incisions. They are recognized by their intense tissue destruction, lack of sensation in the involved tissues, and rapid extension. Radical debridement of necrotic and infected tissue is the cornerstone of treatment.

Treatment

A. Initial Evaluation

The incision should be opened along its entire length and the deeper portion of the wound gently explored to determine whether fascial separation has occurred. If the fascia is not intact, the wound is dissected to the fascial level, debrided, and repaired. Wound dehiscence has a high mortality rate and should be treated aggressively. Dehiscence is uncommon in healthy patients and with Pfannenstiel incisions. The skin can be left open to undergo delayed closure or to heal by primary intention.

If the fascia is intact, the wound infection can be treated by local measures.

B. Definitive Measures

Mechanical cleansing of the wound is the mainstay of therapy for caesarean wound infection. Opening the wound encourages drainage of infected material. The wound can be packed with saline-soaked gauze 2–3 times per day, which will remove necrotic debris each time the wound is unpacked. The wound can be left open to heal, or it can be closed secondarily when granulation tissue has begun to form.

Costantine MM, Rahman M, Ghulmiyah L, et al. Timing of perioperative antibiotics for cesarean delivery: A meta-analysis. *Am J Obstet Gynecol* 2008;301.e1–301.e6. PMID: 18771991.

Thurman AR. Post-cesarean delivery infectious morbidity: Focus on preoperative antibiotics and methicillin-resistant Staphylococcus aureus. *Am J Infect Control* 2010;38:612–616. PMID: 20627452.

5. Episiotomy Infection

ESSENTIALS OF DIAGNOSIS

- Pain at the episiotomy site

- Physical examination demonstrates disruption of the episiotomy wound

---

Pathogenesis

It is surprising that infected episiotomies do not occur more often than they do, because contamination at the time of delivery is universal. Subsequent contamination during the healing phase also should be common, yet infection and disruption of the wound are infrequent (0.5–3%). The excellent local blood supply is suggested as an explanation for this phenomenon.

In general, the more extensive the laceration or episiotomy, the greater are the chances for infection and breakdown of the wound. More tissue is devitalized in a large episiotomy, thereby providing greater opportunity for contamination. Women with infections elsewhere in the genital area probably are at greater risk for infection of the episiotomy.

Clinical Findings

A. Symptoms & Signs

Pain at the episiotomy site is the most common symptom. Spontaneous drainage is frequent, so a mass rarely forms. Incontinence of flatus and stool may be the presenting symptom of an episiotomy that breaks down and heals spontaneously.

Inspection of the episiotomy site shows disruption of the wound and gaping of the incision. A necrotic membrane may cover the wound and should be debrided if possible. A careful rectovaginal examination should be performed to determine whether a rectovaginal fistula has formed. The integrity of the anal sphincter should be evaluated.

B. Laboratory Findings

Infection with mixed aerobic and anaerobic organisms is common. *Staphylococcus* may be recovered from cultures of material from these infections. Culture results frequently are misleading because the area of the episiotomy typically is contaminated with a wide variety of pathogenic bacteria.

Treatment

Initial treatment should be directed toward opening and cleaning the wound and promoting the formation of granulation tissue. Warm sitz baths or Hubbard tank treatments help the debridement process. Attempts to close an infected, disrupted episiotomy are likely to fail and may make ultimate closure more difficult. Surgical closure by perineorrhaphy should be undertaken only after granulation tissue has thoroughly covered the wound site. There is an increasing trend toward early repair of episiotomy wound dehiscence, in contrast to conventional wisdom, which suggests a 3- to 4-month delay. Several large case series show excellent results once initial infection is treated.

6. Mastitis

ESSENTIALS OF DIAGNOSIS

- One or both breasts are tender, erythematous, and engorged on physical examination.
- With infectious mastitis or breast abscess, the patient commonly demonstrates fever and malaise.

Pathogenesis

Congestive mastitis, or breast engorgement, is more common in primigravidas than in multiparas. Infectious mastitis and breast abscesses also are more common in women pregnant for the first time and are seen almost exclusively in nursing mothers.

Infectious mastitis and breast abscesses are uncommon complications of breastfeeding. They almost certainly occur as a result of trauma to the nipple and the subsequent introduction of organisms from the infant's nostrils to the mother's breast. *S aureus* contracted by the infant while in the hospital nursery is the usual causative agent.

Clinical Findings

A. Symptoms & Signs

Breast engorgement usually occurs on the second or third postpartum day. The breasts are swollen, tender, tense, and warm. The patient's temperature may be mildly elevated. Axillary adenopathy can be seen.

Mastitis presents 1 week or more after delivery. Usually only 1 breast is affected and often only 1 quadrant or lobule. It is tender, reddened, swollen, and hot. There may be purulent drainage, and aspiration may produce pus. The patient is febrile and appears ill.

B. Laboratory Findings

The organism responsible for infectious mastitis and breast abscess almost always is *S aureus*. *Streptococcus* spp. and *E coli* are occasionally isolated. Leukocytosis is evident.

Treatment

A. Congestive Mastitis

The form of treatment depends on whether or not the patient plans to breastfeed. If she does not, tight breast binding, ice packs, restriction of breast stimulation, and analgesics help to relieve pain and suppress lactation. Medical suppression of lactation probably does not hasten involution of congested breasts unless the drug is taken very early after delivery. Bromocriptine 2.5 mg twice daily orally for 10 days is an effective regimen, although concerns about its side effect profile have curtailed its use. For the woman who is breastfeeding, manually emptying the breasts following infant feeding is all that is necessary to relieve discomfort.

B. Infectious Mastitis

Infectious mastitis is treated in the same way as congestive mastitis. Local heat and support of the breasts help to reduce pain. Cloxacillin, dicloxacillin, nafcillin, or a cephalosporin—antibiotic with activity against the commonly encountered causative organisms—should be administered. Infants tolerate the small amount of antibiotics in breast milk without difficulty. It may be prudent to check the infant for possible colonization with the same bacteria present in the mother's breast.

If an abscess is present, incision and drainage are necessary. The cavity should be packed open with gauze, which is then advanced toward the surface in stages daily. Most authorities recommend cessation of breastfeeding when an abscess develops. Antistaphylococcal antibiotics should be prescribed. Inhibition of lactation is also recommended.

POSTPARTUM DEPRESSION

ESSENTIALS OF DIAGNOSIS

- Depression that begins in the 12 months after delivery
- Criteria for diagnosis are the same as nonpregnancy-related depression
- Symptoms must be present nearly every day for at least 2 weeks

Pathogenesis

Considering the excitement, anticipation, and tension associated with imminent delivery, the marked hormonal alterations after delivery, and the substantial new burdens and responsibilities that result from childbirth, it is not surprising that some women experience depression after delivery. The incidence of postpartum depression is difficult to estimate, but the disorder is common. The pathogenesis is not well understood; genetic susceptibility combined with a major life event and hormonal changes in the puerperium appears to underlie many cases of postpartum depression. The greatest risk factor for depression is a history of depression prior to pregnancy. In women who suffered from depression before they became pregnant and in those without effective support mechanisms, the severity of depression may be more profound and the consequences far more serious. An openly psychotic state may develop within a few days after delivery and render the woman incapable of caring for herself or her newborn. In some cases, she may harm her infant and herself.

Clinical Findings

A. Symptoms & Signs

Symptoms of postpartum depression include derangements in sleep patterns, energy level, appetite, weight, and libido. Women often complain of depressed mood and/or anxiety. Other symptoms include irritability, anger, feelings of guilt, a sense of feeling overwhelmed, feelings of inadequacy, and inability to bond emotionally with the baby. To meet a diagnosis of postpartum depression, the symptoms must be present nearly every day for at least 2 weeks.

B. Laboratory Tests

Several screening tools are available for evaluating postpartum women for depression. The Edinburgh Postnatal Depression Scale is one such questionnaire that is able to identify most women with postpartum depression. Hypothyroidism is emerging as a cause of some cases of postpartum depression, and screening for this disorder should be considered if suggested by clinical presentation.

Differential Diagnosis

The main differential diagnosis of postpartum depression is postpartum blues. Postpartum blues, however, is characterized by transient symptoms of depression, whereas postpartum depression requires that the characteristic symptoms be present nearly every day for at least 2 weeks.

Complications

Complications of postpartum depression include poor bonding with the infant, which can impact child development. Additionally, women with postpartum depression are at increased risk of suicide and infanticide.

Treatment

The first step in managing women with postpartum depression is an evaluation to determine the severity of her depression and whether she is a threat to herself or others. Psychiatric consultation should be obtained for the postpartum woman who shows symptoms of severe depression or overt psychosis. Initial treatment options include psychosocial therapy and pharmacotherapy. Some antidepressant medications are compatible with breastfeeding, although all antidepressants are transferred through the breast milk in some amount. For women unresponsive to pharmacotherapy, electroconvulsive therapy has been used with success.

22
Neonatal Resuscitation

Elisabeth L. Raab, MD, MPH
Lisa K. Kelly MD

Delivery of a high-risk fetus requires multidisciplinary prenatal decision making to ensure the best outcome for the newborn and mother. Obstetricians, neonatologists, and, in appropriate cases, pediatric medical and/or surgical sub-specialists must work together to determine an appropriate plan of care for the fetus and delivery of the newborn and provide counseling for the family. Discovery of a significant complication during pregnancy often warrants referral of the mother to a perinatologist for further evaluation and possible treatment. When circumstances allow, the mother of a high-risk fetus should be transferred to a tertiary care center with experience in high-risk obstetric and neonatal care prior to delivery. Numerous studies have shown improved outcomes for low-birth-weight (LBW) infants (<2500 g) who are delivered at a center with a higher level of neonatal care.

Successful transition from fetal to ex utero life involves a complex series of hormonal and physiologic changes, many of which occur or begin before birth. Events such as cord compression, placental abruption, meconium aspiration, and premature delivery or the presence of infection or major congenital malformations may alter or prevent the essential postnatal transition. Any process that prevents or hinders the newborn from inflating the lungs with air and establishing effective ventilation, oxygenation, and/or circulation will result in a depressed newborn in need of resuscitation for survival.

RESUSCITATION OF THE HIGH-RISK INFANT

The American Academy of Pediatrics (AAP) guidelines mandate that at least 1 skilled person capable of carrying out resuscitation of a newborn be present at every delivery. When a delivery is identified as high risk, 2 or more skilled people may be required to provide adequate care. Often it is useful to assign roles to the resuscitation staff to ensure that the resuscitation flows as smoothly as possible. The equipment required for resuscitation, such as the bag and mask used for ventilation, the blender for oxygen and air delivery, the suction equipment, the radiant warmer, and the monitors, should be checked prior to the delivery. Communication between the obstetric and neonatal staff about the maternal medical and obstetric history as well as the prenatal history of the fetus is essential to ensure that the neonatal team can anticipate and interpret the problems the newborn may have in the delivery room.

Delivery Room Management

Although the expectations may be different and the need for resuscitation more common, the same principles apply to a high-risk delivery as to a routine delivery: The newborn should be kept warm and rapidly assessed to determine the need for intervention.

The initial evaluation and resuscitation may take place in the delivery room or, in centers with a high-risk delivery service, preferentially in an adjacent room specifically designed for high-risk resuscitations. Typically the newborn is brought immediately to a radiant warmer, although some institutions weigh extremely premature infants prior to transfer to the warmer bed in order to determine the birth weight if viability is in question. The infant is dried with prewarmed towels to prevent heat loss. At some centers, LBW newborns are put into polyurethane bags or wrapped with polyethylene occlusive wrap after delivery; these measures have been shown to significantly improve temperature stability during stabilization and transport to the neonatal intensive care unit (NICU). In addition, a knit hat is used to prevent heat loss from the head. Preterm infants are at increased risk for thermal instability given their greater body surface area to weight ratio, thinner skin, and relative paucity of subcutaneous fat compared to term infants. Hypothermia (body temperature <36°C) can occur rapidly in the preterm infant and may cause complications such as hypoglycemia and acidosis.

After rapidly drying the infant and removing the wet towels, the resuscitation team should position and clear the airway. The team then assesses the newborn's respiratory effort, heart rate, color, and activity to determine the need for intervention. Drying the patient and suctioning the airway usually provide adequate stimulation for the newborn to breathe. Rubbing the back or flicking the soles of the feet may be done to provide additional stimulus if initial respirations are irregular.

Positive-pressure ventilation (PPV) should be started if the newborn is apneic or has a heart rate less than 100 bpm. Figure 22–1 shows the correct positioning of the neck and placement of the mask. PPV will not be effective if the airway is not extended slightly and the mask is not applied to the face in the correct manner, with a tight seal around the nose and mouth. In addition, sufficient pressure must be given to produce adequate chest wall movement. A pressure manometer should be attached to the bag to monitor the amount of pressure that is being delivered. Overdistention of the lung causes significant trauma to the lung parenchyma and may cause complications such as a pneumothorax or lead to development of pulmonary interstitial emphysema (PIE), especially in the very-low-birth-weight (VLBW) neonate (birth weight <1500 g). Inability to move the chest wall with high pressures may indicate the lack of a good seal between the mask and the face, an airway obstruction, or significant pulmonary or extrapulmonary pathology compromising ventilation, such as pleural effusions, a congenital chest or abdominal mass, or a congenital diaphragmatic hernia (CDH). If the infant's respiration is markedly depressed, endotracheal intubation should be considered.

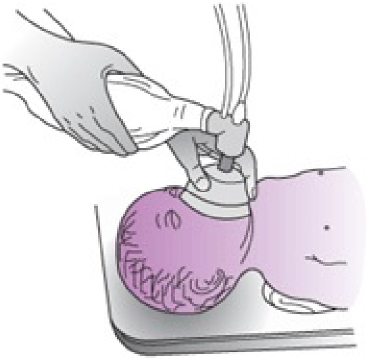

Figure 22–1. Technique of bag and mask ventilation of the newborn. The neck should be slightly extended. An anesthesia bag should have a manometer attached; a self-inflating bag should have an oxygen reservoir attached.

Chest compressions should be initiated if the heart rate is less than 60 bpm after 30 seconds of effective PPV. Figure 22–2 shows the acceptable methods for administering compressions to a neonate. Pressure should be applied to the sternum to depress it one-third of the anteroposterior diameter of the chest. Compressions should be coordinated with breaths: A single cycle should consist of 3 compressions followed by a single breath, and each cycle should last for 2 seconds. Compressions should be continued until the heart rate rises above 60 bpm. PPV should be continued until the heart rate is >100 bpm and the patient is showing adequate respiratory effort. If the heart rate remains <60 bpm after 30 seconds of compressions, administration of epinephrine is indicated. Failure to respond to PPV and chest compressions is a clear indication for endotracheal intubation; intubation should be attempted at this time if it has not already been performed. Figure 22–3 shows the landmarks used to guide placement of the endotracheal tube (ETT) between the vocal cords.

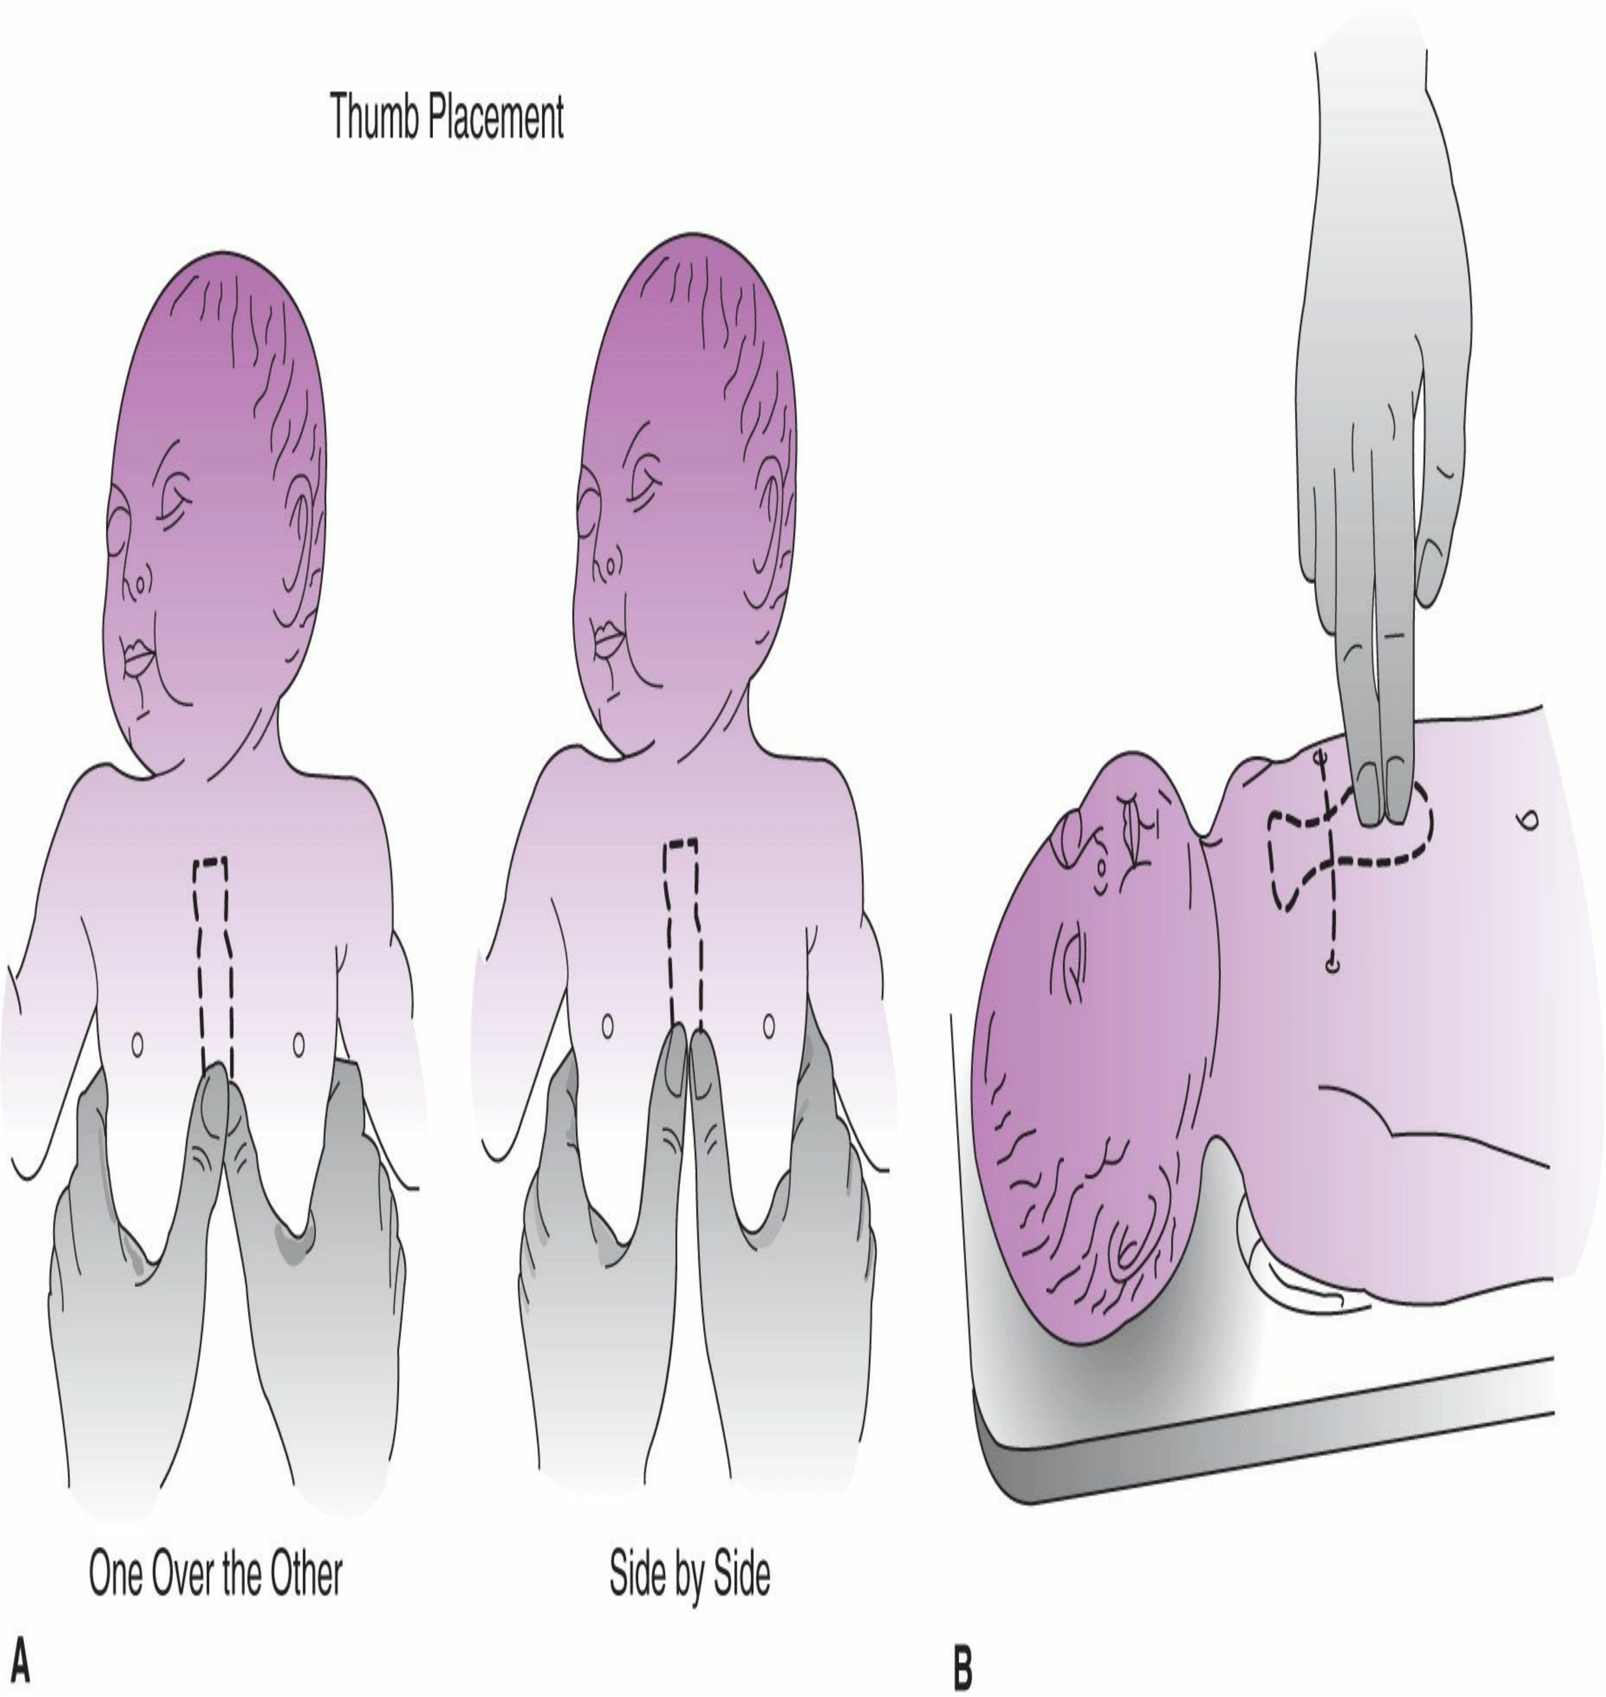

Figure 22–2. A: Thumb technique for performing chest compressions on an infant. The two thumbs, placed either side by side or overlapping one another, are used to depress the lower third of the

sternum, with the hands encircling the torso and the fingers supporting the back. **B**: Two-finger method for performing chest compressions on an infant. The tips of the middle finger and either the index finger or ring finger of one hand are used to compress the lower third of the sternum.

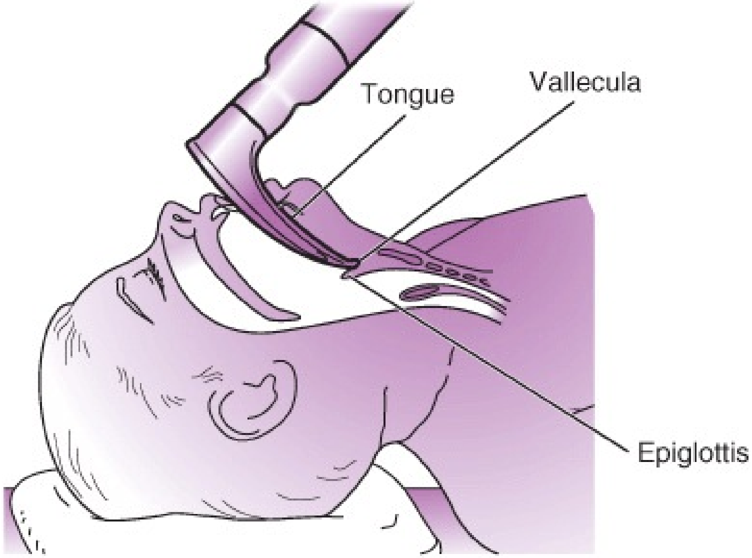

Figure 22–3. Landmarks for placement of the laryngoscope.

Epinephrine can be given via an ETT or an umbilical venous catheter. The standard dose of epinephrine in neonates is 0.01–0.03 mg/kg. The 2010 AAP guideline recommends giving epinephrine via the intravenous (IV) route and only giving endotracheal epinephrine if IV access cannot be obtained. If using the ETT, a dose of 0.05–0.1 mg/kg of the 1:10,000 concentration solution is recommended. The dose can be repeated every 3–5 minutes until the heart rate rises above 60 bpm.

When the infant's response to resuscitation is poor, other factors that may be complicating successful resuscitation of a newborn should be considered. Previous recommendations from the AAP have stated that the use of naloxone (Narcan) may be considered in cases of recent (<4 hours prior to delivery) administration of narcotics to the nonsubstance-using mother. However, the 2010 AAP recommendations do not recommend the use of naloxone under any circumstances and recommend only appropriate support of respiratory depression and oxygenation. Hypovolemia should be suspected if there is a perinatal history consistent with blood loss (eg, placental abruption, placenta previa) or sepsis and the baby is hypotensive and pale, with weak pulses and cool extremities. A 10 cc/kg IV infusion of normal saline, lactated Ringer's solution, or O-negative blood, if available and anemia is suspected, can be given to treat the suspected hypovolemia. The dose can be repeated if there is minimal improvement with the initial bolus. Metabolic acidosis may be present at birth if the baby was significantly distressed in utero or may develop after birth if oxygenation and/or perfusion are compromised. Although use of bicarbonate in resuscitation is not included in the AAP recommendations, significant acidosis will cause pulmonary vasoconstriction and poor myocardial contractility and should be treated. The umbilical artery can be catheterized to provide ongoing access to blood samples for determination of the extent of acidosis and the response to treatment during resuscitation. If bicarbonate is used, the dose is 2 mEq/kg IV of a 0.5 mEq/mL (4.2%) solution. Bicarbonate should be given slowly via an IV line and should be used only after ventilation is established so that the carbon dioxide (CO_2) produced with bicarbonate administration can be removed. Otherwise, bicarbonate administration may result in a significant increase in intracellular acidosis.

Apgar scores are assigned at 1 and 5 minutes of life and continued at 5-minute intervals for up to

20 minutes as long as the score remains below 7. The Apgar score is a means of communicating the newborn's status during resuscitation; it should not be used to determine the need for resuscitation. The initial assessment of the newborn and assignment of the Apgar score are discussed in further detail in Chapter 9.

In the past, 100% oxygen has been the standard for neonatal resuscitation; however, 2 recent meta-analyses have demonstrated increased survival when resuscitation is initiated with air as compared to 100% oxygen. Therefore, the 2010 AAP recommendations now recommend beginning resuscitation with room air. There have been few studies looking at the use of blended oxygen and target oxygen saturations in either preterm or term infants. However, given the known toxicities of oxygen, the recent recommendations are to use blended oxygen when available and to target arterial saturations in the interquartile range for each gestational age (Fig. 22–4). If blended oxygen is not available and the baby remains bradycardic after 90 seconds of resuscitation, it is recommended to increase the oxygen to 100% until recovery of a normal heart rate.

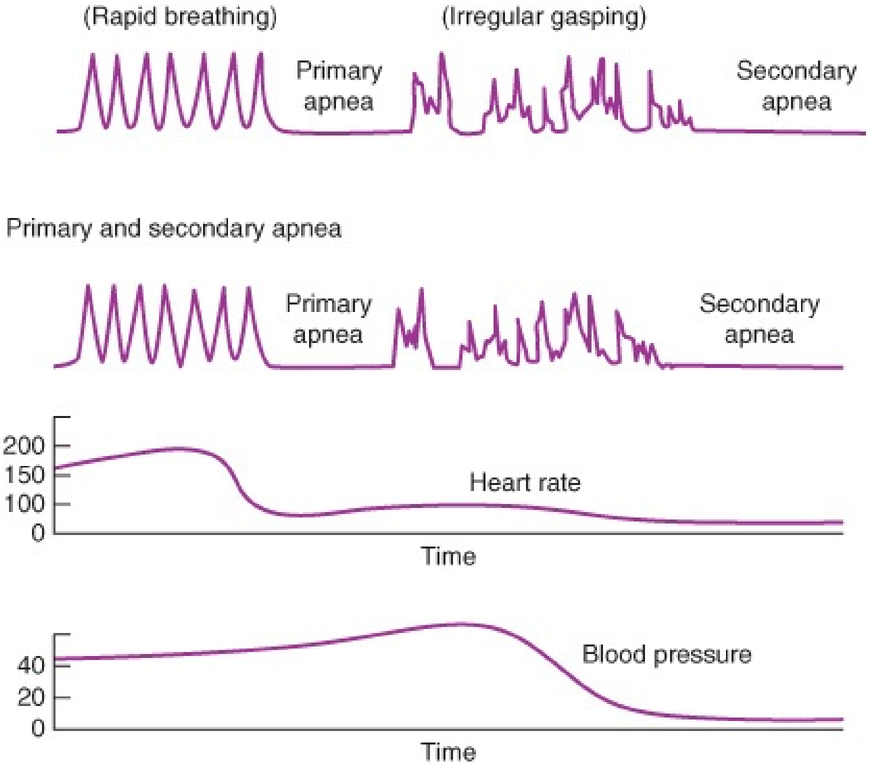

Figure 22–4. Heart rate and blood pressure changes during apnea.

Specific Considerations in the Delivery Room

A. Meconium

Meconium-stained fluid is present in 10–20% of deliveries. It is extremely rare if delivery takes place prior to 34 weeks' gestation. Passage of meconium in utero usually indicates fetal distress, and those personnel present at the delivery should be alerted by the presence of meconium to the possibility that the newborn may be depressed at birth.

It is no longer recommended by the AAP that all meconium-stained babies receive intrapartum suctioning. An active, crying, well-appearing infant does not require endotracheal intubation regardless of the presence of meconium staining or the thickness of the meconium. If the newborn is in distress or has depressed respiratory effort, the appropriate intervention is to intubate and suction the trachea before stimulating the baby in any way. If no meconium is suctioned from the airway, resuscitation should proceed according to the standard algorithm. If meconium is suctioned from the trachea, another attempt should be made to intubate the patient and suction the trachea again. However, if the patient has significant bradycardia, it may be appropriate to defer repeated suctioning and provide PPV.

The majority (94–97%) of infants born through meconium-stained fluid will not develop meconium aspiration syndrome, but when it does occur, infants are often critically ill. Meconium can block the airway and prevent the newborn's lungs from filling with air, a vital step in normal transitioning. Meconium aspiration into the lungs can cause obstruction of the small airways and consequently areas of atelectasis, gas trapping, and overdistention in addition to a chemical pneumonitis. The infant born through meconium may have pulmonary hypertension and inadequate oxygenation and requires close observation and early initiation of treatment when appropriate.

B. Asphyxia

Despite optimal prenatal care, some infants sustain injury prior to or during delivery that results in asphyxia. Perinatal asphyxia is characterized by the presence of hypoxemia, hypercapnia, and metabolic acidemia. It is the result of compromised oxygen delivery and blood flow to the fetus, either chronically or acutely, that stems from processes such as placental insufficiency, cord compression, trauma, and placental abruption.

If significant prepartum or peripartum hypoxic–ischemic injury has occurred, the infant likely will be depressed at birth and may not respond to initial interventions to establish respiration. The initial response in the newborn to hypoxemia is rapid breathing, followed shortly thereafter by a period of apnea, termed *primary apnea*. Drying the infant and rubbing the back or flicking the soles of the feet is sufficient to stimulate respiration during primary apnea. However, without intervention at this point, continued oxygen deprivation will lead to a series of gasps followed by a period of secondary apnea. It is important to recognize that an infant who does not respond to stimulation is likely exhibiting secondary apnea and requires further intervention. Respiration will not resume with stimulation if secondary apnea has begun, and positive pressure is necessary to reverse the process. Heart rate changes typically begin toward the end of primary apnea, whereas blood pressure typically is maintained until the period of secondary apnea.

Effective resuscitation of an asphyxiated newborn usually requires treatment of acidosis. Perinatal asphyxia may also be complicated by hypoglycemia and hypocalcemia. Myocardial dysfunction may be present, and fluid boluses and continuous infusion of inotrope may be required for adequate blood pressure support. However, in the presence of significant myocardial dysfunction, repeated volume boluses will worsen the cardiovascular status. In these cases, early administration of an inotrope (eg, dobutamine) with or without low to moderate doses of a vasopressor (eg, dopamine) is appropriate. In addition, seizures may occur in the newborn with perinatal asphyxia. Seizures usually are the result of hypoxic–ischemic injury to the cerebral cortex, but hypoglycemia and hypocalcemia also may cause seizure activity in the depressed neonate. In the newborn, phenobarbital (15–20 mg/kg IV) typically is given as the first-line treatment of seizures not caused by hypoglycemia or hypocalcemia. An additional 5–10 mg/kg bolus can be given to control status epilepticus. Asphyxiated infants are at increased risk for persistent pulmonary hypertension (discussed in detail later in the section Pathology & Care of the High-Risk Term Neonate).

The severity of the insult sustained by the newborn can be difficult to assess in the neonatal period. The presence of abnormal findings on the neurologic examination and the severity and persistence of those abnormalities are the most useful measures for assessing the degree of brain injury. Laboratory (umbilical cord and baby blood gases, serum creatinine level, liver function tests, blood lactate level, and cardiac enzyme levels) studies, radiographic (brain magnetic resonance imaging [MRI]) studies, and electroencephalographic (EEG) findings provide additional information to help predict the likelihood and anticipated extent of an adverse neurodevelopmental outcome. Early onset of seizure activity has been shown to increase the likelihood of a poor outcome. Infants with severe hypoxic–ischemic encephalopathy, which is characterized by absent reflexes, flaccid muscle tone, seizures, and a markedly altered level of consciousness, either die within several days of birth or have significant neurologic sequelae. It is a misconception that perinatal asphyxia is the cause of cerebral palsy. A minority of cases of cerebral palsy are actually attributable to intrapartum complications.

Several randomized, controlled studies have shown that induced hypothermia is protective in babies with mild-moderate asphyxia. Both selective hypothermia (ie, head cooling) and total body cooling have been shown to be effective. Devices are now available to regulate and safely cool neonates to a core temperature of 33.5–34.5°C. Therefore, it is now recommended that infants with moderate asphyxia should be cooled. Ideally the therapy should be initiated within 6 hours of the event (ie, birth). Timely transfer to a center that provides therapeutic hypothermia is of the utmost importance.

C. Shock

The newborn who fails to respond to initial attempts at resuscitation may be in circulatory shock. A number of different pathophysiologic processes can result in shock in the delivery room. Circulatory collapse can result from absolute (hemorrhage, capillary leak) or relative (vasodilatation) hypovolemia, cardiac dysfunction (asphyxia, congenital heart disease [CHD]), abnormal peripheral vasoregulation (prematurity, asphyxia, sepsis), or a combination of these factors. The peripartum history often helps elucidate the etiology. The presence of risk factors for sepsis (prolonged rupture of membranes, maternal fever, chorioamnionitis), hemorrhage (placenta previa, placental abruption, trauma), or perinatal asphyxia may be informative. Pallor or peripheral hyperemia, weak pulses with tachycardia, and cool or warm extremities are present on examination. Hypotension in the newborn immediately following delivery is commonly defined as a mean arterial pressure that is equal to or less than the gestational age. It is worth noting that blood pressure is normal in the early (compensated) phase of shock; hypotension may only develop as the process progresses.

As mentioned earlier in Delivery Room Management, a 10 cc/kg normal saline bolus typically is given to the newborn with hypotension. An additional 10–20 cc/kg is often given if the improvement in circulation is inadequate. Unmatched O-negative blood can be transfused in 10–15 cc/kg aliquots if severe anemia from blood loss is suspected. Volume should be administered slowly and judiciously to preterm infants who lack the mechanisms to autoregulate cerebral blood flow and protect the brain against reperfusion injury. Excessive volume may worsen the patient’s status if cardiac dysfunction is the cause of hypotension. As discussed earlier, administration of sodium bicarbonate or THAM (tromethamine) may be indicated to treat metabolic acidosis in the newborn in shock. Vasopressor/inotrope infusions should be initiated in neonates who do not respond to volume resuscitation.

D. Cyanosis

Although acrocyanosis (cyanosis of the hands and feet) is often normal in the newborn, central cyanosis is not. Cyanosis is due to inadequate oxygen delivery to the tissue, either as a result of poor blood flow (peripheral vasoconstriction in acrocyanosis or low cardiac output in cardiogenic shock) or insufficiently oxygenated blood (pulmonary hypertension or severe parenchymal lung disease). Free-flow oxygen can be administered if a newborn has central cyanosis despite regular respirations. Free-flow oxygen can be delivered by holding a mask or oxygen tubing that is connected to a flowing source of 100% oxygen close to the baby’s nose and mouth. Oxygen can be gradually withdrawn when the newborn turns pink. PPV is often indicated if the baby remains cyanotic despite free-flow oxygen. Lack of improvement of central cyanosis with administration of free-flow oxygen necessitates an evaluation of the cause of cyanosis. As discussed earlier, provision of 100% oxygen may have significant side effects if it is used for newborn resuscitation.

E. Prematurity

The delivery of a preterm infant requires a skilled multidisciplinary resuscitation team that has an understanding of the myriad problems associated with preterm delivery and has experience handling VLBW newborns. The presence at delivery of physicians, nurses, and a respiratory therapist trained in newborn resuscitation will optimize the early care of the newborn. Details of the delivery room care of the preterm infant are discussed in the section Delivery Room Management earlier in this chapter.

The neonatal team should meet with the family prior to delivery whenever possible. The parents should be informed about the prognosis for the fetus and need for intensive care admission if appropriate. It is critical that the family understand the plan for resuscitation in the delivery room and the anticipated short- and long-term problems the newborn may face. Often it is helpful to families to discuss the emotional impact of the admission and the possibility of a prolonged stay of their newborn in the intensive care unit. If the fetus is at the limits of viability, currently considered 23–24 weeks’ gestation and/or weight <500 g, it is essential that the parents understand the considerable risk of death and the serious cognitive, motor, and pulmonary complications that may occur if the newborn does survive. The neonatal team must have a clear conversation with the parents about the possible options for postnatal management. Unfortunately, it often is difficult to make definitive plans given that the margin of error for prenatal determination of birth weight and gestational age is wide enough to have a significant impact on the viability of the fetus. Although many physicians have strong feelings of their own, it is vital that the course of resuscitation of a newborn at the limits of viability incorporates the family’s wishes. Nevertheless, parents should understand that the fetus’s viability will be reassessed after delivery, and that the maturity of the newborn, the newborn’s condition at delivery, and the response to the resuscitative efforts made, in combination with available outcomes data, ultimately will determine the management in the delivery room.

F. Abdominal Wall Defects

Gastroschisis is the herniation of abdominal contents through an abdominal wall defect. The defect in gastroschisis usually is small and to the right of the umbilicus, and the intestines are unprotected by the peritoneal sac. *Omphalocele* also involves the herniation of abdominal contents through the abdominal wall, but the defect is in the umbilical portion of the abdominal wall, and the herniated viscera are covered by the peritoneal sac. Both defects require emergent care in the delivery room. Current delivery room recommendations suggest positioning the baby right side down to avoid kinking the mesenteric blood vessels and compromising blood flow to the intestines. The baby’s lower body, including the defect and externalized organs, should be placed in a “bowel bag,” which is then secured at the mid-thorax. This allows for direct visualization of the intestines while also limiting fluid losses. A nasogastric tube (at least 10 French) should be placed to allow for adequate decompression of the stomach and intestines.

Despite these measures, patients will still have increased heat and insensible fluid losses, and IV fluid should be started promptly at 1.5 times normal maintenance requirements to prevent dehydration and hypernatremia. Electrolytes and fluid status must be monitored closely. A surgical consultation should occur prenatally if the defect is diagnosed in utero. An urgent surgical evaluation should be obtained upon admission of the newborn to the NICU.

PATHOLOGY & CARE OF THE PRETERM INFANT

In 2008, 12.3% of all births in the United States were preterm, a slight decrease from 12.8% in 2006. Advances in obstetric and neonatal care have markedly increased the survival of premature infants and improved outcomes. However, prematurity continues to account for a significant percentage of neonatal and infant mortality in the United States. As tinier and less mature infants survive, we face new ethical and medical challenges to continue improving the long-term and societal impact of the care provided in the NICU.

Respiratory Distress Syndrome

In 1959, Mary Ellen Avery and Jere Mead reported data showing that the severe respiratory disease seen in preterm infants, then known as hyaline membrane disease, was due in part to a deficiency of surfactant. Surfactant, a complex of phospholipids and protein secreted by type II pneumocytes, reduces surface tension in the alveoli of the lung. Its absence, or deficiency, results in diffuse microatelectasis and decreased functional residual capacity leading to the presentation of a “ground-glass” pattern and poor expansion of the lungs on chest radiograph (CXR). The lung disease of the preterm infant, now known as respiratory distress syndrome (RDS), also is a consequence of the immature architecture of the lung at the time of birth.

RDS presents as tachypnea and increased work of breathing that develops shortly after birth. Both oxygenation and ventilation are impaired, and blood gas analysis typically reveals hypoxia and a respiratory acidosis. Although most commonly seen in premature infants, RDS is associated with other conditions as well. Infants of diabetic mothers are at risk, even at term, because high levels of insulin in the fetus suppress lung maturation, including surfactant production. Without intervention, RDS typically worsens over the first few days of postnatal life. Historically, improvement was often heralded by a marked increase in urine output (“diuretic phase” of RDS).

The likelihood of RDS is inversely proportional to gestational age. It now is standard to give corticosteroids to mothers at risk of delivery before 32–34 weeks’ gestation to hasten maturation of fetal organs, including the lungs, and to decrease the incidence and severity of RDS. Some larger preterm infants may require supplemental oxygen by nasal cannula or no respiratory assistance whatsoever. Babies with significant RDS typically require assisted ventilation. Ventilatory support can be given with continuous positive airway pressure (CPAP), a pressure- or volume-limited ventilator, or a high-frequency ventilator. A recent analysis concluded the data are not sufficient to recommend any mode of mechanical ventilation over the other as standard therapy for RDS. Provision of positive end-expiratory pressure (PEEP) (either as CPAP or PEEP) quickly after delivery is vital in order to prevent collapse of the lungs. If the lungs are allowed to collapse, oxygenation and ventilation will be compromised further and higher pressures will be required to reinflate the lungs, causing avoidable barotrauma and volutrauma to the lungs.

Exogenous surfactant administration has significantly reduced morbidity and mortality from RDS since its routine use began in the early 1990s. Prophylactic administration of surfactant to the preterm infant (ie, before 15 minutes of age) has been shown to reduce neonatal morbidity (pneumothorax and pulmonary interstitial edema) and mortality compared to rescue therapy (ie, waiting until after the diagnosis of RDS is made). Proposed explanations of this finding include a more homogeneous distribution of surfactant in the fluid-filled lung and the delivery of surfactant after a minimal period of PPV minimizing barotrauma and volutrauma to the lung. However, it is very important to ensure correct placement of the ETT prior to surfactant administration in the delivery room. If the ETT position cannot be determined, it may be better to delay surfactant until CXR has confirmed placement. If the degree of RDS is significant, an additional 2–4 doses of surfactant can be given every 6–12 hours depending on the surfactant preparation used. The newborn should be monitored closely after receiving surfactant because rapid changes in respiratory status usually occur, necessitating aggressive weaning of the ventilator settings. If the ventilator support is not weaned appropriately, the improving lung compliance will result in high tidal volume ventilation leading to volu-trauma and hypocapnia. Complications such as obstruction of the ETT, pneumothorax, or pulmonary hemorrhagic edema may occur with surfactant. Pulmonary hemorrhagic edema likely is due to the surfactant administration-associated rapid decrease in pulmonary vascular resistance and the resulting pulmonary overcirculation through the ductus arteriosus. Blood gases should be checked frequently to prevent hypocapnia, which is associated with an increased incidence of periventricular leukomalacia (PVL) in the preterm neonate.

Despite the advances attributable to prenatal steroids, surfactant, and newer modes of ventilation, RDS continues to carry significant morbidity, including the risk of chronic lung disease, which is defined as the need for supplemental oxygen or ventilatory support at 36 weeks' postmenstrual age. New strategies have evolved over recent years to improve outcomes of newborns with RDS. Given the toxicities of oxygen, as discussed earlier, efforts are being made to limit exposure of preterm infants to hyper-oxia. Many centers now aim to keep the oxygen saturation percent in the 80s or low 90s for preterm babies to prevent periods of hyperoxygenation and free-radical production. Although the data are scant and not well controlled, no current evidence suggests adverse neurologic effects of the lower saturations. However, it is recommended that saturations be kept in the high 90s once an infant's corrected gestational age reaches near-term. Future studies must be designed to investigate the potential side effects of lower saturations, including the development of pulmonary hypertension and subsequent cor pulmonale during infancy or early childhood.

Another recent change in neonatal practice has been the adoption of permissive hypercapnia. Permissive hypercapnia involves allowing CO_2 levels in the blood to rise above the normal value of 40 mm Hg in order to minimize the pressures required for ventilation and thereby reduce the lung injury caused by ventilator-induced barotrauma and volu-trauma. This practice allows for infants to remain extubated who might have been reintubated in the past because of CO_2 retention. Although the procedure differs, CO_2 levels of 45–55 mm Hg are generally accepted, with some centers allowing higher CO_2 levels without a change in ventilatory management. The side effects of this approach are unknown, but hypercapnia may decrease the autoregulatory capacity of cerebral vessels, resulting in a more or less pressure-passive cerebral circulation. Therefore, the potential long-term neurodevelopmental effects of hypercapnia-associated pressure-passive cerebral circulation require investigation.

Encouraged by data from nonrandomized studies at Columbia University, many neonatologists are now trying to avoid intubation and/or mechanical ventilation, even in the tiniest babies. Using CPAP with nasal prongs for newborns with respiratory distress soon after birth (regardless of gestational age or birth weight) and a strategy of permissive hypercapnia, physicians at Columbia University reported a low incidence of bronchopulmonary dysplasia (BPD) compared to other tertiary care centers, without any significant increase in mortality. Because these findings require confirmation in appropriately designed randomized clinical trials, some centers have chosen an intermediate approach: VLBW infants are intubated for surfactant administration, but the ETT is removed shortly after and the period of mechanical ventilation is brief. Although approaches differ, early extubation is now a widely shared goal among neonatologists.

Dexamethasone was a key part of efforts to prevent and/or treat BPD for many years. However, a number of studies have shown a worse neurodevelopmental outcome in preterm infants who received dexamethasone treatment compared to controls with a similar degree of illness in the neonatal period. Many studies are still in progress, and data on long-term outcomes are not yet available, but the routine use of dexamethasone is no longer recommended. Dexamethasone is now reserved for those patients with the most severe lung disease, although, in general, no data support a better pulmonary outcome with its use. The available data suggest that there may be a window for dexamethasone use at 7–14 postnatal days, categorized as “moderately early” treatment, which has not been seen to cause any adverse outcomes. However, as mentioned earlier, a significant direct benefit associated with the use of dexamethasone is not available. Steroids also are now usually given in lower doses and shorter courses than in the past. The AAP currently recommends that neonatologists counsel parents about the risks and benefits of dexamethasone prior to initiating treatment. Future studies are needed to evaluate the effect, if any, of the newer treatment regimens on neurodevelopment outcome.

Nutrition

Providing optimal nutrition is an essential and challenging part of the care of the premature baby. Preterm infants are born with minimal nutrient stores and high metabolic demands, and growth failure is a frequent complication of prematurity. Supplying adequate nutrition for growth and development is complicated by the fact that many preterm newborns are too unstable to receive enteral nutrition in the first few days of postnatal life. There may be clear contraindications to enteral feeding, such as hypotension and vasopressor requirements, or factors can arise that can raise concerns about early initiation of enteral feeds, such as cocaine exposure in utero, indomethacin administration, the presence of a patent ductus arteriosus (PDA), or respiratory instability. Parenteral hyperalimentation is used to meet the newborn’s initial fluid and nutritional requirements, but the ultimate goal is to meet those needs with enteral feedings given as early as safely possible.

An IV infusion of 10% glucose typically is started soon after birth to maintain glucose homeostasis. Extremely low-birth-weight (ELBW) babies (birth weight <1000 g) may require lower concentrations of dextrose because of higher total fluid requirements. Calcium supplementation in the dextrose infusion is standard for VLBW babies because transfer of calcium from mother to fetus primarily occurs during the third trimester, so VLBW babies are born with inadequate stores. The infusion rate of fluids typically is begun at 80–120 cc/kg/d depending on the immaturity and severity of illness of the neonate. Excessive fluids should be avoided because they have been associated with an increased risk for RDS, PDA, intraventricular hemorrhage (IVH), and necrotizing enterocolitis (NEC). Electrolytes and fluid status must be closely monitored over the first few days of life to determine appropriate fluid management. Depending on the level of immaturity, prenatal steroid exposure, and ambient humidity, ELBW infants may have enormous insensible losses and may develop hypernatremia if fluid needs are not met.

Protein breakdown can begin within the first postnatal days in preterm infants receiving only dextrose-containing fluids as nutrition. As a result, protein supplementation should be started as soon as possible to prevent a catabolic state. Parenteral hyperalimentation containing amino acids can be safely initiated immediately after delivery without development of acidosis, hyperammonemia, or uremia. The amino acid infusion should be started at 1.5–2.5 g/kg/d and advanced over several days to a goal of 3–4 g/kg/d.

Preterm newborns typically require a glucose infusion rate (GIR) of 6–8 mg/kg/min. The GIR is advanced in small increments to provide additional calories. Carbohydrate should account for approximately 40% of the 90–120 kcal/kg/d provided to the neonatal patient receiving parenteral nutrition. (Caloric requirements are higher with enteral feeding, typically 120–150 kcal/kg/d.) The need for GIR in excess of 15–18 mg/kg/min for adequate caloric support is rare. Glucose levels should be monitored and the dextrose infusion adjusted to maintain normoglycemia (ie, plasma glucose concentration 60–160 mg/dL). An insulin infusion can be started in the unusual event that hyperglycemia persists despite restricting the GIR to 4–6 mg/kg/min to continue to provide adequate calories for growth.

Intralipids provide the essential fatty acids required for multiple physiologic processes. Ideally, 40–50% of the daily caloric intake for a preterm infant receiving parenteral nutrition should come from fat. Usually a continuous 20% infusion at 0.5–1 g/kg/d is started on the first or second day of life, with the ultimate goal of providing 3 g/kg/d. Triglyceride and cholesterol levels must be monitored closely; elevated levels may require lower levels of lipid supplementation. Lipid infusion of 0.5–1 g/kg/d is required to prevent essential fatty acid deficiency.

In addition to providing protein, glucose, and fats, parenteral hyperalimentation provides electrolytes, vitamins, and minerals for the preterm infant unable to tolerate enteral feeds. Electrolyte levels must be monitored periodically to ensure appropriate levels. Particular attention must be paid to providing maximal amounts of calcium and phosphorous to VLBW infants who are at risk for developing osteopenia of prematurity.

It is important to begin enteral feeds as soon as possible in preterm infants. Delayed enteral feeding has adverse effects on the gut, such as mucosal atrophy, decreased digestive enzyme activity, and altered intestinal motility. In addition, long-term parenteral nutrition can cause cholestasis and presents an increased risk of infection because of the prolonged need for central venous access. Regimens for initiation of enteral feeding in VLBW infants vary but usually involve starting volumes of 10–20 mL/kg/d. Feeds are given via an orogastric or nasogastric tube for all but the most mature infants. The infant is monitored carefully for signs of feeding intolerance, such as abdominal distention, emesis, or large-volume gastric residuals while the feed volume is increased daily by 10–20 mL/kg. Some centers continue small-volume feeds for 5–10 days before advancing the volume toward the ultimate goal of 140–160 mL/kg/d.

Mothers of preterm infants should be encouraged to provide breast milk for their babies. Although infants are not typically developmentally ready to coordinate oral feeding until they reach 34 weeks' gestation and thus are unable to breastfeed initially, preterm infants can receive expressed breast milk via a gavage tube. The advantages of breastfeeding on everything from the appropriate function of the immune system to developmental outcomes and IQ are well documented. The caloric value of human milk clearly has proven to be superior to formula. Many NICUs now use pasteurized human breast milk banks to provide these benefits to infants whose mothers are unable to breastfeed. Human milk fortifiers are used to increase the protein, calories, calcium, phosphorous, vitamins, and minerals of mature human milk in order to meet the needs of the growing premature infant. Breast-fed infants should receive iron supplements once they reach the goal volume of enteral feeds.

Special formulas have been designed to better meet the nutritional needs of preterm infants receiving formula. Premature infant formulas contain 24 kcal/oz and provide higher amounts of protein, medium-chain triglycerides, vitamins, and minerals (eg, calcium and phosphorous) than standard formulas. If needed for adequate growth, the caloric content of preterm formula can be increased with any of a number of commercially available supplements, the majority of which provide additional calories as carbohydrate or fat. Although term infants gain an average of 30 g/d, 15–20 g/d is considered sufficient growth in the preterm infant.

Necrotizing Enterocolitis

NEC is a significant cause of morbidity and mortality in neonates. Although gastrointestinal in origin, NEC may lead to septic shock, respiratory failure, and death. Only 10% of cases occur in term newborns. The most premature and smallest infants are disproportionately affected; NEC occurs in 5–10% of all VLBW infants.

The presentation of NEC is highly variable. Signs and symptoms often are specific to the gastrointestinal tract, such as abdominal distention and/or erythema, emesis, bilious gastric residuals, and bloody stools; however, they may be nonspecific, such as apnea, temperature instability, and lethargy. Findings may be subtle initially, or the onset may be fulminant. Acidosis and thrombocytopenia are worrisome findings that may indicate necrotic bowel. Hyponatremia, due to upregulated sodium transport into the gut, and edema, due to increased capillary leak, often develop. Respiratory distress develops from abdominal competition due to inflammation and distention. The pathognomonic feature of NEC is the presence of intestinal pneumatosis on abdominal x-ray. Pneumatosis results from the production of hydrogen from bacteria in the bowel wall. Serial x-rays are obtained to follow disease progression. Air in the portal venous system or free air in the abdominal cavity indicates intestinal perforation, warranting surgical intervention for either an exploratory laparotomy to resect the necrotic bowel or placement of a right lower quadrant drain to decompress the abdomen if the patient is very small or unstable. Whether or not perforation has occurred, treatment of NEC typically includes 10–14 days of broad-spectrum antibiotics and discontinuation of enteral feeds. Many infants require fluid resuscitation and vasopressor/inotrope support. Seventy-five percent of infants with NEC survive, but half sustain long-term complications such as intestinal strictures and short gut syndrome.

Prematurity and enteral feeds have been clearly linked to NEC, but the pathogenesis of NEC is not well defined and is widely considered to be multifactorial. An infectious component is suggested by the association of certain organisms with outbreaks of NEC and the immature immune function of the preterm gastrointestinal tract. Mucosal injury as a result of altered intestinal and/or mucosal blood flow, either during periods of ischemia from hypotension or vascular spasm or during reperfusion and free-radical production, is believed to make the infant vulnerable. The presence of bacteria, ischemia and reperfusion, formula, and other unknown factors may all work together to trigger the inflammatory cascade responsible for the pathologic findings of NEC.

Risk factors for NEC include ELBW, polycythemia, umbilical catheters, enteral feeding, formula feeding, low Apgar scores, cyanotic heart disease, in utero cocaine exposure, and the presence of a

PDA. Data on whether or not the rate of advancement of enteral feeds contributes to the development of NEC are conflicting. However, a recent study showed a decreased incidence of NEC in VLBW neonates who received small-volume feeds for 10 days before advancement compared to those who received daily 20 cc/kg advancement of feeds. The incidence of NEC has also been shown to decrease when standardized feeding regimens are instituted within a unit. The effect may be due to heightened awareness of signs and symptoms of feeding intolerance rather than to the actual specific regimen, but the effect has been reproduced and is dramatic.

NEC occurs less frequently in infants who receive breast milk. The protective effect of breast milk is speculated to result from the transfer of components of breast milk such as cytokines, immunoglobulins, growth factors, and probiotics to the infant. The protective effects of breast milk appear to occur even in those infants who are fed pasteurized donor breast milk. Other studies have shown a decreased incidence and severity of NEC in VLBW neonates who received supplementation with probiotic bacteria such as *Lactobacillus acidophilus*, *Bifidobacterium* spp., and *Streptococcus thermophilus*. However, further studies are needed to examine the safety of probiotics given recent reports of sepsis due to supplemented probiotic organisms. Antenatal steroids also have a protective effect against NEC, likely due to a demonstrated effect on gastrointestinal maturation and PDA closure.

Patent Ductus Arteriosus

During fetal life, close to 90% of the blood that leaves the right ventricle flows from the pulmonary artery to the aorta through the ductus arteriosus. After birth the pulmonary pressure falls, blood flow to the lungs increases, and the ductus arteriosus, primarily as a response to the increased oxygen tension in the blood and decreased circulating levels of prostaglandin E_2 (PGE_2), begins to close. Functional closure of the ductus arteriosus occurs within the first 1–2 days of postnatal life in the vast majority of term neonates, and definitive anatomic closure of the ductus usually is complete by the end of the first postnatal week. However, in neonates born prematurely, this process takes longer and may not always occur. In preterm neonates, failure of the ductus arteriosus to close is the result of several factors, including persistent hypoxia as a result of RDS and the continued presence of PGE_2. A PDA may be asymptomatic initially, but as the pulmonary pressure continues to fall, the left-to-right shunt of blood through the ductus arteriosus increases. Increasing left-to-right shunt produces pulmonary overcirculation (often with >50% of the left ventricular output shunting back into the lungs), worsening respiratory distress and gas exchange, an increasing oxygen requirement, and systemic hypotension. The presence of a PDA is suggested on physical examination by a hyperdynamic precordium (left ventricular overload), bounding palmar and brachial pulses, and a holosystolic precordial murmur. The pulse pressure usually is wide, and CXR typically demonstrates cardiomegaly and pulmonary congestion. Unless contraindications such as renal insufficiency, active bleeding, or thrombocytopenia are present, indomethacin, a nonselective inhibitor of the cyclooxygenase enzyme, is the first-line treatment of PDA because indomethacin effectively decreases prostaglandin synthesis. Indomethacin also has certain actions not directly related to inhibition of prostaglandin synthesis, such as a drug-induced decrease in global cerebral blood flow. This action may contribute to the indomethacin-induced decrease in severe IVH observed in ELBW neonates given indomethacin shortly after birth. However, there appears to be no significant long-term neurodevelopmental benefit of prophylactic indomethacin administration. In neonates with a PDA, fluids should be restricted to prevent worsening of pulmonary edema. Indomethacin may fail to achieve closure of the ductus, particularly in those who were born most prematurely or who received therapy later in postnatal life (beyond 10–14 days). Persistent patency of the ductus typically requires a repeat course of indomethacin followed by surgical ligation of the ductus, depending on the patient's age and clinical status. It should also be noted that the combination of indomethacin and postnatal steroid use has been shown to increase the likelihood of a spontaneous intestinal perforation. Therefore, care should be used when considering the use of those 2 drugs in combination.

Intraventricular Hemorrhage

IVH is one of the most feared complications of prematurity; severe IVH is a major risk for adverse long-term neurodevelopmental outcome. The incidence of IVH (approximately 20% in VLBW infants) is inversely proportional to gestational age. A number of factors combine to put the preterm neonate at risk. The blood vessels in the periventricular germinal matrix are abundant, immature, and fragile. These vessels may bleed when exposed to changes in blood flow. Sick newborns often experience periods of hypotension and hypertension, and they lack effective autoregulatory mechanisms to protect the brain during these variations in perfusion pressure. Changes in carbon dioxide levels in the blood also play an important role in regulating cerebral blood flow, and VLBW newborns may swing from hypocarbia to hypercarbia and back, particularly during the first few hours of life. In addition, bleeding may be aggravated by abnormal coagulation, particularly in the septic newborn.

Most IVH occurs during the first postnatal day; few cases occur after 5 days of life. Recent findings suggest that, at least in the VLBW neonate, IVH during the transitional period is caused by an ischemia–reperfusion cycle. Although IVH usually occurs without any clear outward signs that the process is occurring, a large bleed may cause a sudden change in mental status, a drop in hematocrit (Hct) level, and/or a full fontanelle. IVH is characterized as grade I when hemorrhage is confined to the region of the germinal matrix. Grade II IVH involves both the germinal matrix and the ventricles but does not fill or distend the ventricles. IVH grades I and II typically resolve and are not associated with a worse neurologic outcome than that expected for babies of the same gestational age without hemorrhages. Grade III IVH fills greater than 50% of the ventricles with blood and causes distention of the ventricles. Grade III IVH carries a significantly increased risk of mortality and adverse neurologic outcome because it more frequently evolves into ex vacuo or obstructive (fibrosis obstructs the ventricular system) hydrocephalus. IVH is classified as grade IV when the hemorrhage involves the brain parenchyma. This hemorrhage historically was considered to be an extension of IVH into the parenchyma but may more accurately represent a distinct process of venous infarction or severe ischemia followed by reperfusion in the periventricular white matter. Irrespective of the etiology, intraparenchymal hemorrhage results in tissue destruction and is associated with neurodevelopmental deficits in a marked majority of affected patients.

Although numerous preventative therapies have been evaluated (indomethacin, phenobarbital, vitamin E, morphine), none is currently recommended for routine prophylactic use. Every effort is made to keep blood pressure and carbon dioxide levels stable and within the normal range and to avoid unnecessary interventions, such as suctioning, which elevate intracranial pressure. Current guidelines recommend routine cranial ultrasound screening for infants less than 30 weeks' gestation between postnatal days 7 and 14 days and again when the infant reaches a corrected gestational age between 36 and 40 weeks. However, once IVH is detected, serial studies should be done to follow the bleed for progression and the ventricles for further dilation.

Performing an ultrasound study earlier than postnatal day 7 for newborns who are particularly unstable often is useful; the presence of a significant intraparenchymal bleed may help with decisions about direction of care for those whose viability is in question. Many centers advocate brain MRI prior to discharge to evaluate for white matter injury that may go undetected on cranial ultrasound and has been shown to be predictive of significant neurologic sequelae.

Retinopathy of Prematurity

Retinopathy of prematurity (ROP) is a disorder of retinal vascular proliferation that primarily affects premature infants. It is the second most common cause of blindness in children in the United States. Under normal conditions, the retina is completely vascularized by 36–40 weeks of gestation. The earlier in gestation delivery occurs, the larger the avascular region of the retina at birth and the greater the risk for ROP. The pathogenesis of ROP is not completely clear but seems to involve a period of vessel damage (from acidosis, hyperoxia, infection, etc) and cessation of vessel development followed by a period of abnormal proliferation. Hyperoxia and/or fluctuations in PaO_2 have been clearly shown to have an adverse effect on retinal development.

VLBW neonates, especially those who are critically ill and were born before 28 weeks' completed gestation, are at the highest risk for ROP. ROP tends to develop at 33 to 36 weeks' corrected gestation irrespective of the gestational age at birth. It may resolve spontaneously, as occurs in over 80–90% of cases, or, in rare cases, may progress to complete retinal detachment. Screening ophthalmologic examinations are recommended to monitor the progression of retinal vascularization in infants born at less than 31 weeks' gestation or weighing less than 1500 g. Screening should also be considered for infants weighing 1500–2000 g or born at 31 weeks' gestation or greater who have had an unstable course. The initial examination should be performed at 4 weeks of life or 30–31 weeks' corrected gestational age, whichever comes later. The frequency of repeat examinations is dictated by the findings, with the goal being early detection of ROP that meets criteria for surgical intervention.

PATHOLOGY & CARE OF THE HIGH-RISK TERM NEONATE

Persistent Pulmonary Hypertension

During fetal life, oxygenated blood is delivered to the fetus from the placenta. Pulmonary vascular resistance is elevated in utero; consequently minimal blood flow goes to the lungs. Instead, as noted in PDA, close to 90% of the output from the right ventricle passes from the pulmonary artery to the aorta through the ductus arteriosus. However, successful transition from fetal to extrauterine life requires a drop in pulmonary vascular resistance. The fall in pulmonary pressures results from a series of events that begins before birth but accelerates when a baby is born, the baby cries (filling the lungs with air), and the umbilical cord is cut (increasing the systemic resistance). A number of processes can interrupt this process, either by mechanically blocking the airways, thus preventing essential lung expansion and increase in the partial pressure of oxygen, or by preventing relaxation of the pulmonary vascular bed. Meconium aspiration syndrome, asphyxia, sepsis, pneumonia, and CDH are among the most common causes of persistently elevated pulmonary vascular resistance, termed *persistent pulmonary hypertension of the newborn* (PPHN).

PPHN results in severe hypoxia in the newborn. Blood continues to shunt away from the pulmonary circulation through the foramen ovale, ductus arteriosus, or both, bringing poorly saturated blood to the body. Treatment consists of interventions aimed at lowering the pulmonary vascular resistance. Acidosis and hypoxemia are potent pulmonary vasoconstrictors and are to be avoided. When possible, PaO_2 is maintained in the normal range (80–100 mm Hg). Supplemental oxygen is weaned cautiously because even relatively small changes can cause an acute decompensation. Every effort should be made to maintain left ventricular output and blood pressure (thus systemic perfusion) in the normal range and to keep the blood pH in the 7.3–7.4 range. Acidosis is a vasoconstrictor, but aggressive use of bicarbonate or THAM may not be beneficial. Although hyperventilation was used in the past to maintain an alkaline pH, concerns about ventilator-induced lung damage and the effect of hypocarbia on cerebral blood flow have altered this practice. In addition, studies have shown that it is the normalized pH, not the decreased CO_2, that improves pulmonary vasoconstriction. Most physicians adjust the ventilator support to target a $PaCO_2$ of 40–50. High-frequency ventilators are often used, allowing for higher mean airway pressures without increasing barotrauma and volutrauma to the lungs. Vasopressors, typically dopamine, are used to maintain systemic blood pressure. If there is evidence of myocardial dysfunction, an inotrope such as dobutamine typically is used, and vasopressor support is adjusted to prevent undesirable increases in systemic vascular resistance. Patients with PPHN are extremely sensitive to noise and tactile stimulation, so infusions of sedatives and analgesia are routinely used to minimize agitation. However, use of neuromuscular blockade is to be avoided because it does not appear to improve clinical outcome and is associated with significant side effects, including sensorineural hearing loss.

Nitric oxide is a selective pulmonary vasodilator. Inhaled nitric oxide (iNO) has been proven to improve oxygenation and decrease the need for extracorporeal membrane oxygenation (ECMO) in term infants with PPHN. iNO is routinely started at 20 ppm, although lower doses may be as effective. iNO is weaned as the patient stabilizes and the supplemental oxygen requirement falls. Despite the dramatic improvement in outcomes since the availability of iNO, a number of patients with PPHN will still require ECMO. Historically the criterion for ECMO has been a greater than 80% estimated risk of mortality with continued conventional medical management. General guidelines for the criteria for ECMO include an oxygenation index greater than 35–60 for between 0.5 and 6 hours, an alveolar–arterial oxygen difference greater than 605–620 (at sea level) for 4–12 hours, or a preductal PaO_2 less than 40 for more than 2 hours. ECMO is contraindicated in neonates less than 34 weeks' gestational age because of technical issues regarding catheter placement as well as the increased risk of intracranial bleeding in the preterm neonate. A preexisting grade II or higher IVH, signs of severe irreversible brain damage, lethal congenital anomalies, and nonreversible pulmonary disease are other contraindications to ECMO. Survival of patients with PPHN treated with ECMO varies depending on the underlying cause of PPHN. The survival rate of patients with meconium aspiration syndrome is greater than 90%, but the survival rate of patients with CDH is only 50%.

Congenital Diaphragmatic Hernia

CDH is a defect that results from incomplete development and closure of the diaphragm, usually at the foramen of Bochdalek at 8–10 weeks' gestation. The defect in the diaphragm allows the contents of the abdominal cavity to migrate into the chest, resulting in compression of the lungs and, in more severe cases, the heart. The compression leads to pulmonary hypoplasia, abnormal lung development, and potentially underdevelopment of 1 or both ventricles. Ninety percent of CDH involves the left hemidiaphragm. CDH is now generally prenatally diagnosed, but a number of cases still go undiagnosed, even with routine prenatal care.

A number of features should raise suspicion about the possibility of CDH in the newborn with cyanosis and respiratory distress. Breath sounds may be absent on the left side of the chest and the heart sounds shifted to the right. The abdomen tends to be scaphoid, as some of the abdominal organs typically have shifted into the thorax. It may be difficult to effectively ventilate and resuscitate the patient. If a CDH is suspected, mask and bag ventilation must be avoided. The patient should be intubated and a sump/replogle tube placed as soon as possible to prevent air from filling the stomach and bowel and thus compromising ventilation further. Many centers use sedation and sometimes paralysis to minimize activity and prevent competition from swallowed air. CXR observation of bowel loops in the chest confirms the diagnosis.

Surgical repair of the defect usually is delayed until the patient's condition stabilizes and the reactive component of the pulmonary hypertension has improved. Efforts are made to use the lowest ventilator settings tolerated to minimize ventilator-induced lung injury. Surfactant, iNO, high-frequency ventilation, and, if necessary, ECMO are often used to manage patients with CDH. However, surfactant administration has been shown to be of no benefit, and some studies suggest that it may be associated with an increased need for ECMO, so its routine use cannot be recommended. To date, the evidence also has not shown a clear benefit of iNO for patients with CDH. Additional studies are needed to evaluate the role of each of these interventions in the care of the patient with CDH.

Reported survival rates vary from approximately 35–80%, perhaps reflecting differences between centers and/or bias related to referral patterns. The prognosis depends on the severity of the underlying pulmonary hypoplasia and the degree of reactive pulmonary hypertension, as well as the presence of other anomalies or a chromosomal abnormality. Development of a pneumothorax has been shown to predict a poor outcome. Failure to achieve a preductal PaO_2 greater than 100 mm Hg or a $PaCO_2$ lower than 60 in the first 24 hours of life generally indicates a poor prognosis as well. Some physicians argue that infants in whom the $PaCO_2$ level never falls below 80 or who never achieve a preductal oxygen saturation of at least 85% for at least 1 hour have severe pulmonary hypoplasia and are not appropriate candidates for ECMO. However, the outcome of the individual patient is hard to predict, and every measure must be made to provide gentle ventilation and accept higher $PaCO_2$ and lower PaO_2 levels as long as systemic oxygen delivery is appropriate.

Transient Tachypnea of the Newborn

The differential diagnosis for the newborn with tachypnea in the first postnatal hours ranges from RDS to sepsis to CHD. One of the most common causes of tachypnea in the newborn is transient tachypnea of the newborn (TTN). TTN results when fetal lung fluid production fails to cease with the onset of labor. The incidence of TTN is significantly increased when the baby is delivered via caesarean section without labor especially if performed before 39 weeks of gestation.

The newborn presents with tachypnea, increased work of breathing, and cyanosis. Infants with TTN may require moderate supplemental oxygen; some may be sick enough to require intubation. CXR reveals interstitial and alveolar edema; fluid is characteristically seen in the right middle lobe fissure. Symptoms of TTN typically resolve over the first 24–48 hours (fetal lung fluid production ceases in response to stress), and CXR clears by the second or third day of life. However, TTN is a diagnosis of exclusion, and other causes of tachypnea and respiratory distress must be ruled out. An evaluation for sepsis (including initiation of antibiotic therapy pending culture results) as well as other causes of tachypnea is generally warranted.

Congenital Heart Disease

CHD occurs in approximately 1 in 100 live births, and approximately 3 in 1000 have CHD that requires surgical repair or results in death within the first year of life. CHD rarely presents in the delivery room. In fact, the majority of infants with prenatally diagnosed CHD initially appear well. Nevertheless, the newborn with cyanosis who fails to respond to 100% oxygen (hyperoxia test; see below) should be evaluated for structural heart disease. Complex CHD typically presents as cyanosis or congestive heart failure and circulatory shock and only rarely as an asymptomatic murmur in a newborn. Signs such as tachypnea, weak peripheral pulses, or cool extremities may develop quickly with closure of the ductus arteriosus if the lesion has ductal-dependent pulmonary or systemic flow. Right-sided obstructive lesions (eg, pulmonic atresia or stenosis), which are dependent on the ductus for pulmonary blood flow, tend to present with cyanosis due to diminished or absent pulmonary blood flow. Left-sided obstructive lesions (eg, coarctation of the aorta and hypoplastic left heart syndrome) typically present as shock and often are initially misdiagnosed as sepsis. However, statistically the term neonate who develops signs of shock after the first 24–48 hours of life is approximately 5 times more likely to have ductal-dependent CHD than bacterial sepsis.

The initial steps in evaluating a stable patient for suspected CHD include 4-extremity blood pressure measurements, measurement of preductal and postductal saturations, electrocardiogram, CXR, and hyperoxia test. If the PaO_2 level fails to increase above 100 after exposure to 100% fraction of inspired oxygen (FiO_2) for 15 minutes, cyanotic CHD is likely; if the PaO_2 level increases above 250, CHD is unlikely. CXR may reveal black lungs that signify diminished pulmonary blood flow (as occurs in right-sided obstructive lesions) or congestion (as occurs with obstructed pulmonary venous return). The diagnosis of CHD usually is established by echocardiogram, although cardiac catheterization is sometimes necessary to clarify the specifics of the abnormal anatomy in complex cases. Low-dose PGE infusion should be started when critical CHD is suspected in order to maintain or reestablish ductal patency. Once the diagnosis of cyanotic heart disease has been made, supplemental oxygen should be used sparingly but as necessary to keep oxygen saturations around 75–

85% until surgical repair occurs. This supplementation should provide adequate oxygen delivery to prevent the development of metabolic acidosis without decreasing pulmonary vascular resistance and causing pulmonary overcirculation.

Esophageal Atresia/Tracheoesophageal Fistula

Esophageal atresia occurs when there is an interruption in the separation of the foregut into the trachea and esophagus during the fourth week of gestation. In its most common form, there is a proximal esophageal pouch and a fistula between the trachea and the distal segment of the esophagus. The newborn with esophageal atresia typically presents in the first few hours after birth with copious secretions and coughing or gagging with the first feed. Respiratory distress may develop if secretions or feeds are aspirated. The prenatal istory often is remarkable for polyhydramnios due to the inability of the fetus to regulate amniotic fluid levels by swallowing. The diagnosis usually is apparent when a CXR reveals a nasogastric tube coiled in the proximal esophageal pouch. Absence of a gastric bubble on x-ray usually suggests that a distal fistula is not present. Emergent gastrostomy may be necessary to decompress the stomach. The feasibility of primary repair depends on the distance between the proximal and distal portions of the esophagus. If primary repair is not possible, initial surgery involves ligation of the fistula. Patients typically then undergo serial dilations of the proximal pouch and delayed anastomosis or may require colonic interposition if the gap remains too wide to close. Postoperative complications include leaking or stenosis at the anastomosis site, poor esophageal motility, and gastroesophageal reflux.

Polycythemia

Polycythemia, defined as a central venous Hct greater than 65%, results from either increased in utero erythropoiesis or from maternofetal or twin–twin transfusion. Increased in utero erythropoiesis occurs most often as a response to fetal hypoxia, usually from placental insufficiency. Erythropoiesis in the fetus is also increased with maternal diabetes, chromosomal abnormalities, and endocrine disorders such as congenital adrenal hyperplasia, thyroid disease, and Beckwith-Wiedemann syndrome. Maternofetal hemorrhage most commonly results from delayed cord clamping.

Polycythemia may cause congestive heart failure from volume overload, as in the case of the recipient twin in twin–twin transfusion syndrome. More commonly, the complications attributed to polycythemia arise from hyper-viscosity rather than increased blood volume. Blood viscosity increases as the Hct level rises, placing the polycythemic infant at risk for complications from impaired blood flow and oxygen delivery. Polycythemia may present as hypoglycemia, poor feeding, respiratory distress, pulmonary hypertension, lethargy, jitteriness, or seizures. Infants are at increased risk for NEC, and thrombotic strokes may occur.

Although IV hydration may be useful, a symptomatic neonate with Hct level greater than 65% or an asymptomatic neonate with Hct level greater than 70% should undergo a partial exchange transfusion performed to decrease blood viscosity and ameliorate any symptoms. The volume of blood that should be removed and then replaced with isotonic saline (to lower the viscosity without causing hypovolemia) is determined by the following formula:

$$\text{Volume to be exchanged} = [\text{Blood volume} \times (\text{Observed hematocrit} - \text{Desired hematocrit})]/\text{Observed hematocrit}$$

Blood volume usually is estimated at 80–90 mL/kg in a term infant and 90–100 mL/kg in a preterm infant. The goal Hct usually is 55%. The hope is that partial exchange will prevent symptoms from worsening and further complications from developing, but long-term follow-up studies have failed to show any benefit.

Hyperbilirubinemia

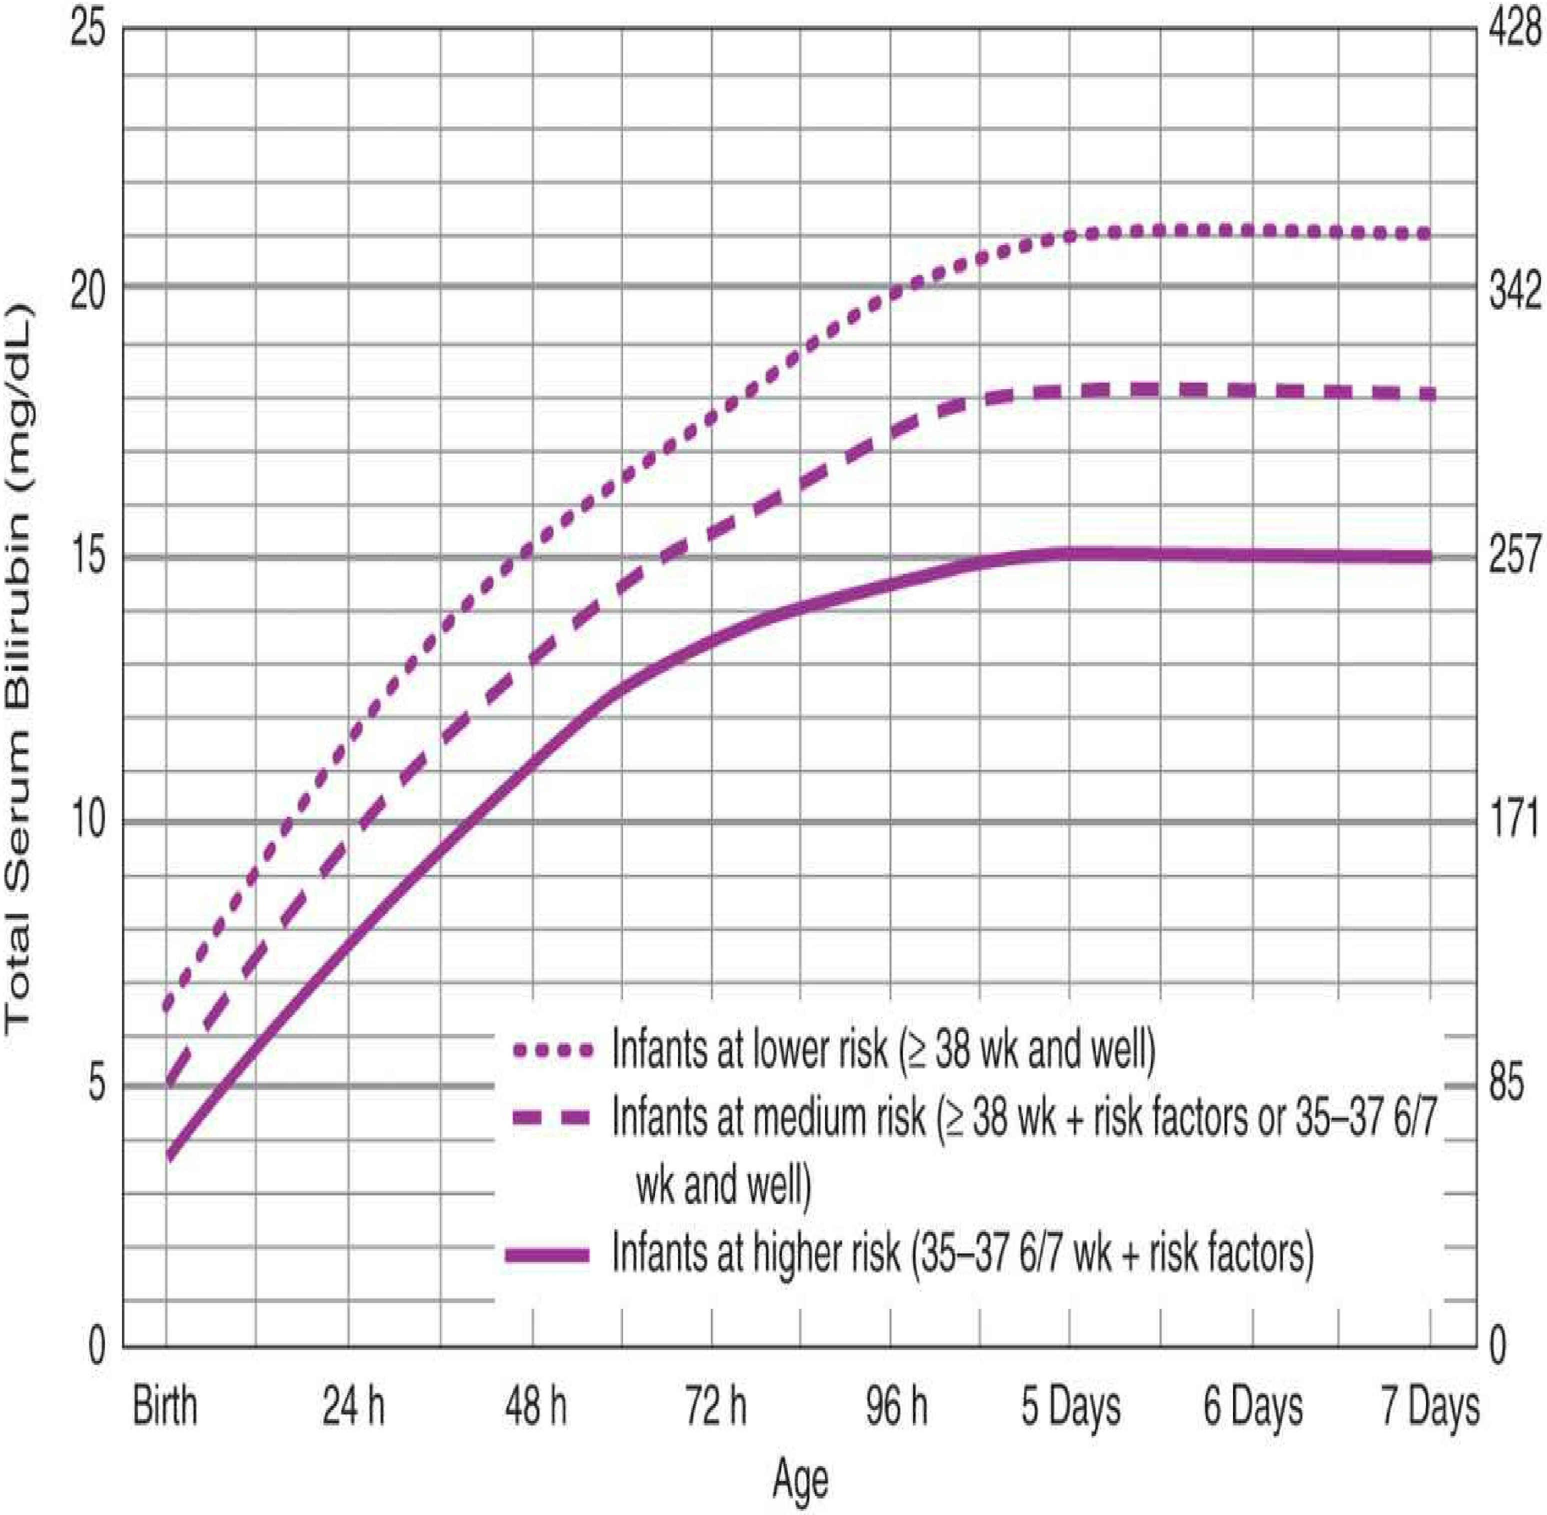
Hyperbilirubinemia is a common problem in the neonatal period, affecting 60–70% of all infants born in the United States to some degree. In most instances, the level of the unconjugated form of bilirubin is elevated. Although the course usually is benign and an increase in serum bilirubin level occurs in all newborns during the first postnatal days, severe unconjugated hyperbilirubinemia can cause kernicterus and long-term neurologic damage.

Bilirubin is produced when heme-containing compounds such as hemoglobin are broken down. The initial unconjugated product is fat soluble but water insoluble, a form that can cross the blood–brain barrier and cause central nervous system toxicity but cannot be excreted. The blood carries bilirubin to the liver, where it is conjugated to a water-soluble and excretable form by the enzyme glucuronyl transferase. The immature hepatic enzyme function in the newborn impairs bilirubin conjugation and thus excretion. The shorter life span of red blood cells and increased red cell mass in neonates further predispose the newborn to elevated plasma concentrations of bilirubin, as does the increased reabsorption of bilirubin that occurs in the sterile newborn intestinal tract.

Hyperbilirubinemia may be severe when other coexisting factors increase hemolysis, decrease the rate of bilirubin conjugation, or impede excretion. Hemolysis is increased by abnormal red cell enzyme function (glucose-6-phosphate dehydrogenase [G6PD] deficiency, less frequently pyruvate kinase deficiency) or morphology (spherocytosis, elliptocytosis) and isoimmunization due to ABO, minor antigen, or Rh incompatibility. Sepsis can increase hemolysis. A number of inborn errors of metabolism and enzyme defects can impair conjugation. Conjugation is impaired when there is delayed maturation of the conjugating enzymes, as is thought to occur in cases of congenital hypothyroidism. Obstructed biliary flow, as in biliary atresia, and gastrointestinal obstruction cause decreased excretion. Many disease states are associated with hyperbilirubinemia.

Hyperbilirubinemia presents clinically as jaundice, a yellow–green discoloration of the skin and mucous membranes. A serum bilirubin level should be checked in all jaundiced newborns. It is standard policy in some nurseries to check a total serum bilirubin (TSB) level in all newborns prior to discharge. Most centers check a level within 24–48 hours of life in all VLBW infants as risk for sequelae from hyperbilirubinemia is believed to exist at lower serum bili-rubin concentrations in preterm neonates. The etiology of the pathologic hyperbilirubinemia must be sought. A blood type, Coombs' test, Hct level, and reticulocyte count will provide important information, as will the parent's ethnicity, maternal blood type, and history of jaundice in siblings. It is important to determine whether it is the level of conjugated or unconjugated fraction of bilirubin that is elevated. The differential diagnosis, evaluation, and treatment are markedly different depending on whether or not the elevated portion is conjugated. A conjugated bilirubin level greater than 10% of the total value should prompt an investigation for biliary obstruction or causes of hepatocellular damage such as TORCH (toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex) infection, galactosemia, and α_1-antitrypsin deficiency. A complete sepsis workup is indicated in the ill-appearing patient.

The AAP has established practice parameters to help direct the use of phototherapy and exchange transfusion for hyperbilirubinemia in infants of greater than 35 weeks' gestation. Phototherapy causes the photoisomerization of unconjugated bilirubin to a water-soluble form that can be excreted by the kidneys and gastrointestinal tract. Phototherapy is contraindicated for conjugated hyperbilirubinemia; it is ineffective and can cause a bronze staining of the skin. Figure 22–5 shows the current AAP recommendations for initiation of phototherapy. A patient should receive phototherapy if the TSB level lies above the line for the appropriate risk group for the patient. A newborn is considered to have risk factors if any of the following are present: isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis, or albumin level less than 3.0 g/dL.

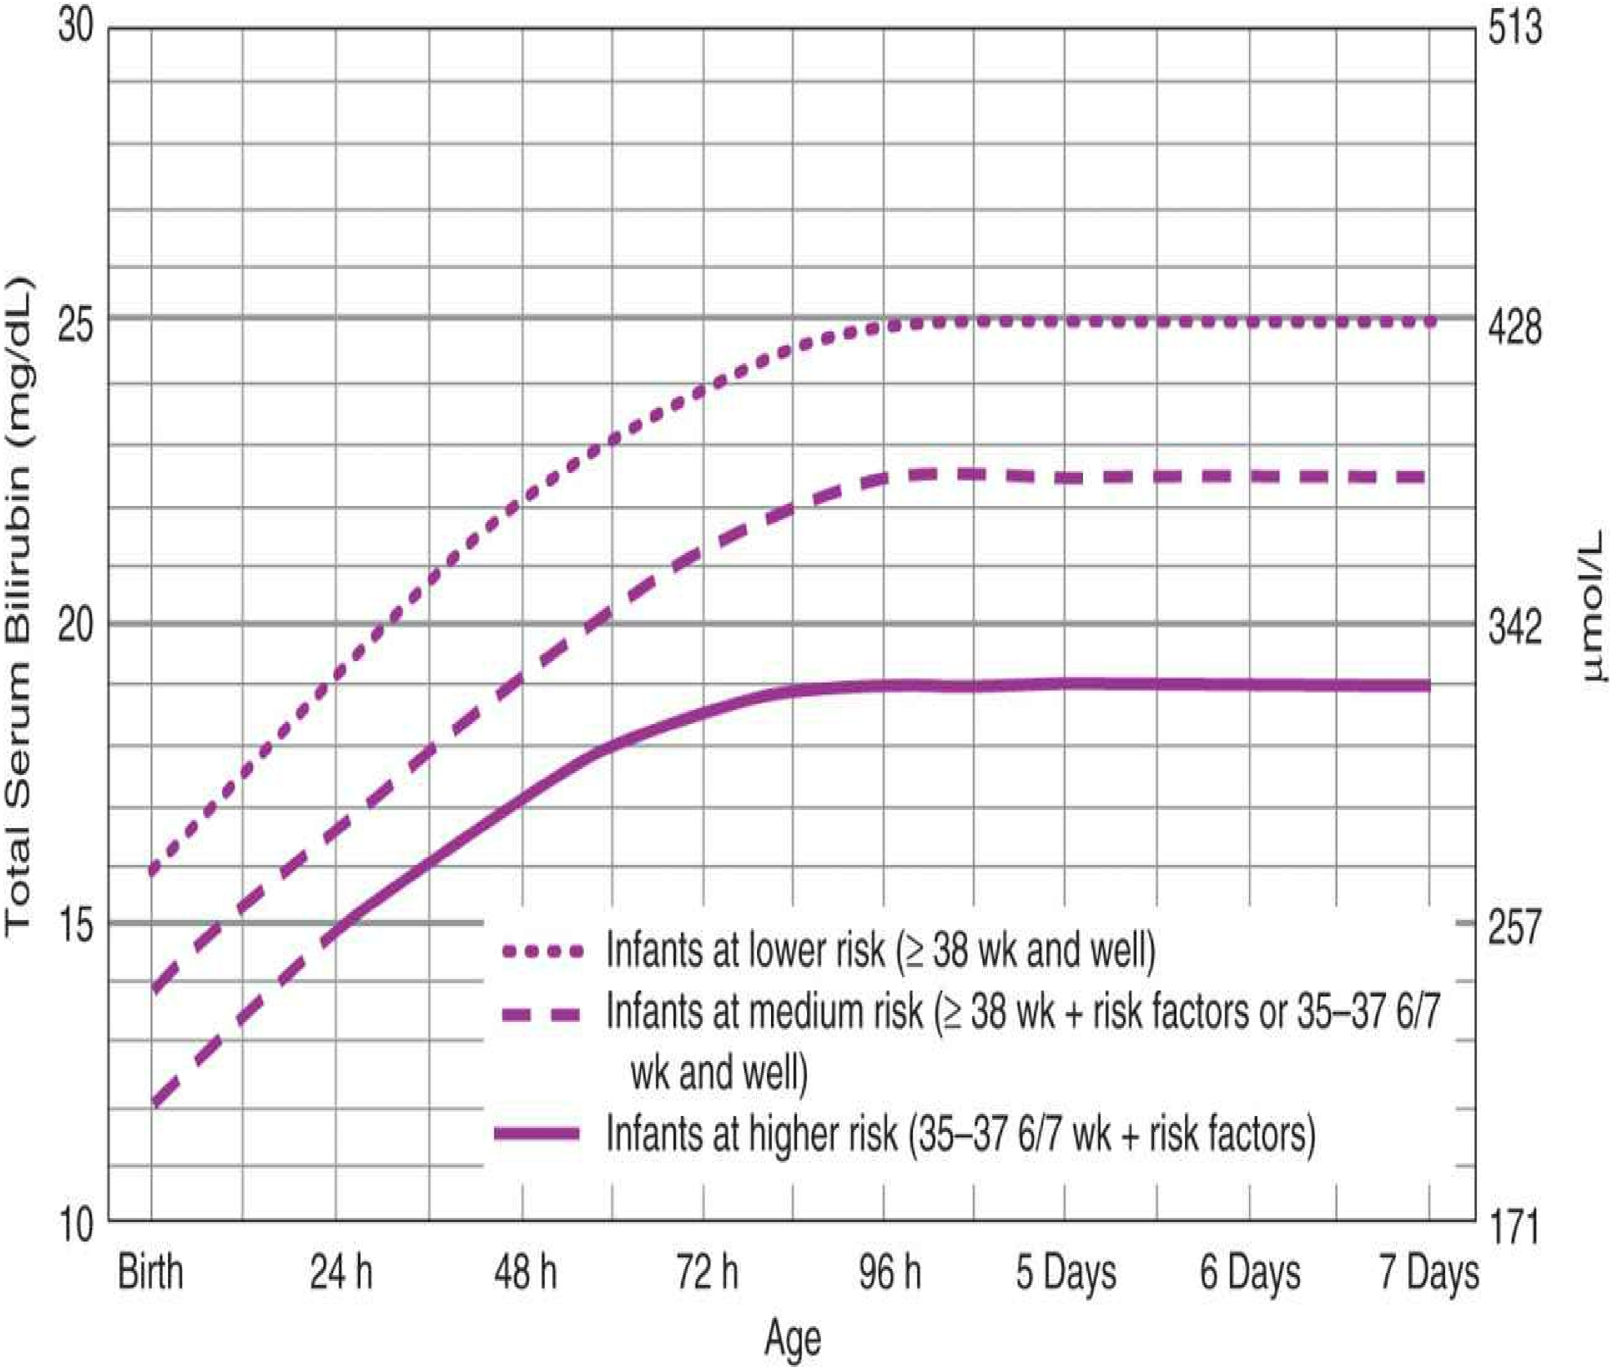


- Use total bilirubin. Do not subtract direct reacting or conjugated bilirubin.
- Risk factors = isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis, or albumin < 3.0g/dL (if measured).
- For well infants 35–37 6/7 wk can adjust TSB levels for intervention around the medium risk line. It is an option to intervene at lower TSB levels for infants closer to 35 wks and at higher TSB levels for those closer to 37 6/7 wk.
- It is an option to provide conventional phototherapy in hospital or at home at TSB levels 2–3 mg/dL (35–50 mmol/L) below those shown but home phototherapy should not be used in any infant with risk factors.

Figure 22–5. Guidelines for phototherapy in hospitalized infants of 35 or more weeks' gestation. G6PD, glucose-6-phosphate dehydrogenase; TSB, total serum bilirubin. (Data from the American Academy of Pediatrics, Subcommitte on hyperbilirubinemia: Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics* 2004; 114:297–316.)

Insensible losses increase under phototherapy, and liberal IV fluids should be given in anticipation of increased daily fluid needs. Infants who appear well, are tolerating enteral feeds, and are not likely to require an exchange transfusion should continue feeding. Enteral nutrition will increase stooling and facilitate bilirubin excretion. IV fluid should be given in addition if oral intake is insufficient or if needed for adequate hydration.

Figure 22–6 shows the AAP guidelines for exchange transfusion. Exchange transfusion effectively removes anti-red blood cell antibodies circulating in the blood and may have an effect on removing circulating bilirubin. Twice the blood volume (estimated at 80–100 cc/kg) is slowly removed from the patient in aliquots of 5–10 cc, with each aliquot followed by transfusion of an equal volume of fresh type O-negative blood, reconstituted with plasma to a hematocrit of 45–50%. The guidelines shown in Figure 22–6 are intended to apply to the newborn who has a continuous rise in TSB level despite intensive phototherapy or to a neonate readmitted to the hospital after discharge who continues to have a TSB above the exchange level for 6 hours after initiation of phototherapy. Immediate exchange is recommended if the TSB is more than 5 mg/dL greater than the exchange threshold or if the patient has abnormal findings on neurologic examination that suggest acute bilirubin encephalopathy. Complications of exchange transfusion include hypocalcemia, hypoglycemia, hypothermia, coagulation abnormalities, apnea, and bradycardia. Many centers delay resuming oral feeds until 24–48 hours after exchange because of the increased risk of NEC after exchange.



- The dashed lines for the first 24 hours indicate uncertainty due to a wide range of clinical circumstances and a range of responses to phototherapy.
- Immediate exchange transfusion is recommended if infant shows signs of acute bilirubin encephalopathy (hypertonia, arching, retrocolitis, opisthotonos, fever, high pitched cry) or if TSB is ≥5 mg/dL (85 µmol/L) above these lines.
- Risk factors—isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis.
- Measure serum albumin and calculate B/A ratio.
- Use total bilirubin. Do not subtract direct reacting or conjugated bilirubin.
- If infant is well and 35–37 6/7 wk (median risk) can individualize TSB levels for exchange based on actual gestational age.

Figure 22–6. Guidelines for exchange transfusion in infants of 35 or more weeks' gestation. G6PD, glucose-6-phosphate dehydrogenase; TSB, total serum bilirubin. (Data from the American Academy of Pediatrics, Subcommitte on hyperbilirubinemia: Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics* 2004;114:297–316.)

Indications for phototherapy and exchange transfusion in preterm infants are not well established. A reasonable guideline is to begin phototherapy when the bilirubin concentration is equal to 0.5% of the birth weight (in grams) and to consider an exchange transfusion when the concentration reaches 1% of the birth weight. These numbers represent a very general guideline, however, and it is important that treatment decisions take into account the etiology of the jaundice and the patient's overall clinical status. The presence of significant bruising, hemolysis, sepsis, or acidosis should lower the physician's threshold for initiating treatment.

Infection

Infection is a significant cause of morbidity and mortality in the newborn. The immature newborn immune system places the neonate at increased risk for infection. The preterm infant, whose immune system is markedly immature and who has diminished levels of immunoglobulin compared to the term newborn, is at particularly high risk. Typically infection is acquired when organisms ascend into the uterine cavity and come into contact with the fetus, but infection can be acquired hematogenously, from the mother's blood, or at the time of delivery when the newborn passes through the vaginal canal.

A. Sepsis

Neonatal sepsis occurs in 1 in 1000 term infants and 1 in 4 preterm infants. Risk factors for neonatal sepsis include premature delivery, multiple pregnancy, prolonged rupture of amniotic membranes (>18 hours), maternal fever, maternal group B *Streptococcus* (GBS) colonization, and chorioamnionitis. The most common causes of early-onset (within the first week of life) sepsis are GBS and *Escherichia coli*. *Listeria monocytogenes*, enterococci, and several different gramnegative rod species are other identified causes of early-onset neonatal sepsis. Late-onset infection in hospitalized infants is more often due to *Staphylococcus* spp.

Signs and symptoms of sepsis in the newborn can be very subtle and nonspecific, such as temperature instability, hypoglycemia or hyperglycemia, apnea, poor feeding, or tachypnea. In contrast, some neonates present in fulminant shock. A complete blood count and blood culture should be sent if sepsis is suspected and antibiotics should be started. A decreased or elevated white blood cell count, a predominance of immature white blood cell forms, and thrombocytopenia are suggestive of infection. Although nonspecific, an elevated C-reactive protein (CRP) level indicates the presence of an inflammatory or infectious process, and data support the negative predictive value of a CRP level in the evaluation for sepsis in the neonate. In addition, CXR is indicated to evaluate for pneumonia. Often differentiating an infiltrate from atelectasis, RDS, or retained lung fluid is difficult, but serial films may be useful in differentiating the various processes. There is debate about whether a culture of cerebrospinal fluid (CSF) is necessary in the newborn evaluated for early-onset sepsis. (A CSF culture is clearly warranted in suspected late-onset sepsis because the incidence of coexisting meningitis with late-onset bacteremia is very high.) Unless signs of meningitis (eg, seizure activity or altered mental status) or a documented positive blood culture is present, meningitis is unlikely in the immediate newborn period. However, studies have reported positive CSF cultures with concurrent negative blood cultures in asymptomatic neonates. The issue has been further complicated by the current widespread use of maternal intrapartum antibiotics. Consequently, given the ramifications of failure to diagnose or only partially treat a case of meningitis, CSF culture is a routine part of the newborn sepsis evaluation in many institutions, and if the infant is unable to have a lumbar puncture, meningitic doses of antibiotic should be used. Urine culture, a routine part of the sepsis evaluation for late-onset disease, is rarely useful in the first few days of life.

Antibiotics that provide broad-spectrum coverage, typically ampicillin and gentamicin in the first few days of life, should be continued for 48–72 hours pending the results of all cultures that were sent for analysis. Vancomycin and gentamicin are often used for nosocomial infections. If bacteremia is documented by a positive blood culture or highly suspected based on clinical status or laboratory findings, antibiotics should be continued for 7–10 days. IV antibiotics usually are continued for a minimum of 2 weeks for gram-positive meningitis and 3 weeks for gramnegative meningitis.

The Centers for Disease Control and Prevention (CDC) developed guidelines in 1996 that recommended screening for GBS colonization at 35–37 weeks' gestation. It was recommended that colonized women and those with other risk factors receive intrapartum antibiotic therapy beginning at least 4 hours prior to delivery. The incidence of early-onset GBS sepsis has been reduced by 65% in communities that have adopted the CDC GBS prevention guidelines. Currently, no evidence suggests an increased incidence of non-GBS early-onset sepsis with adoption of the guidelines, as had been feared.

B. Conjunctivitis

Infection of the conjunctiva may occur within the first few weeks of life. Prophylaxis with erythromycin 0.5% ophthalmic ointment immediately after delivery is now a standard part of newborn care. Conjunctivitis usually presents with injection of the conjunctiva and discharge from the eye, usually bilaterally, in the first week of life. Erythema of the conjunctiva helps differentiate conjunctivitis from lacrimal duct obstruction, a common cause of eye discharge in the neonate.

Chlamydia trachomatis and *Neisseria gonorrhoeae* are the most notable causes of neonatal conjunctivitis. Maternal treatment of either infection during pregnancy reduces the risk of infection in the neonate. Gonococcal conjunctivitis produces a purulent discharge and may cause serious complications, including blindness. A Gram stain and culture of the discharge should be performed if there is any suspicion of infection to determine appropriate therapy. It is important to recognize that the infant with *Chlamydia* conjunctivitis may have or may develop *Chlamydia* pneumonia. *Chlamydia* pneumonia commonly presents in the first 6 weeks of life with tachypnea and cough. The infant with gonococcal conjunctivitis should receive 7 days of IV or intramuscular treatment with a third-generation cephalosporin such as ceftriaxone. *Chlamydia* conjunctivitis is treated with oral erythromycin for 14 days.

C. Viral Infection

A number of viral infections can cause disease in the newborn. The infection may be acquired in utero or at the time of delivery. Antibody titers and cultures should be sent when congenital viral infection is suspected. A number of viruses (including cytomegalovirus [CMV], varicella, and parvovirus) and parasites such as *Toxoplasma gondii* are associated with congenital infection, and the presentation at birth varies significantly depending on the cause. Herpesvirus and enterovirus infections can present acutely with respiratory failure and/or shock. Hepatitis and coagulopathy are often seen in neonates with viral sepsis, even early in the disease process before end-organ damage is even suspected, and should raise suspicion about the possibility of a viral process. There is no maternal history of herpes simplex virus (HSV) in the majority of neonates diagnosed with HSV sepsis or encephalitis. Acyclovir is used to treat herpes viruses such as HSV and varicella.

Transmission from mother to infant at birth is one of the most efficient modes of hepatitis B virus (HBV). Between 80% and 90% of children born to mothers who are both hepatitis B surface antigen (HBsAg) and hepatitis B e antigen (HBeAg) positive will become infected, and 90% of those infants will become chronic HBV carriers. Transmission falls to less than 25% if HBeAg is negative and to 12% if anti-HBe is present. Babies born to HBsAg-positive mothers should receive hepatitis B immune globulin (HBIg) and the hepatitis B vaccine within 12 hours of delivery. If the mother's status is unknown at the time of delivery, the newborn should receive the vaccine within 12 hours of life. If the newborn weighs more than 2 kg, HBIg can be deferred for up to 7 days to allow determination of the mother's status according to the AAP *Red Book* guidelines. However, given the less reliable immune response to vaccine in the preterm host, HBIg should not be deferred in patients weighing less than 2 kg. Appropriate postexposure prophylaxis in the newborn has been shown to prevent transmission in 95% of exposures.

Perinatal infection with human immunodeficiency virus (HIV) now accounts for almost all new infections in preadolescents in the United States. The risk of perinatal transmission if an HIV-positive mother does not receive antiretroviral therapy during pregnancy is 13–39%. A trial of zidovudine during pregnancy and delivery, with continued treatment for the newborn for 6 weeks after delivery, showed a greater than 60% reduction in transmission. It is currently recommended that HIV-positive women receive zidovudine prophylaxis in addition to the standard current recommendations for antiretroviral therapy for all HIV-positive patients. Zidovudine prophylaxis/treatment of the newborn should be started and analysis for HIV DNA polymerase chain reaction sent when in utero exposure to HIV is recognized before 7 days of life.

Infant of the Diabetic Mother

From 50,000–100,000 infants are born to diabetic mothers every year in the United States. The infant of a diabetic mother (IDM) is at increased risk for congenital malformations, macrosomia, birth injury, and a number of postnatal complications, such as RDS, polycythemia, and hypoglycemia. With improved obstetric monitoring and neonatal care, perinatal mortality has decreased significantly over the past few decades. With decreased losses from stillbirths, perinatal asphyxia, and RDS, congenital malformations now represent the single most important cause of perinatal mortality and severe morbidity in IDMs.

Studies have shown that IDMs have a 2- to 8-fold higher risk of a structural malformation compared to infants born to nondiabetic mothers. The most common malformations in IDMs are neural tube defects, CHD, renal anomalies, and abnormalities of the genitourinary tract. The exact pathogenesis of the malformations is unclear, but various mechanisms, including altered levels of arachidonic acid and/or myoinositol, free-radical damage, and altered gene expression have been proposed. The risk of structural malformations has been clearly shown to correlate with poor glycemic control in the first trimester. Consequently, tight control of glucose levels must begin prior to conception in order to decrease the risk of structural malformations.

Metabolic alterations seen in IDMs are more closely associated with glycemic control later in pregnancy. Elevated maternal glucose levels result in elevated fetal glucose levels that produce hyperinsulinism in the fetus. Insulin is a growth factor, and abnormal exposure to insulin results in fetal macrosomia. After delivery, the hyperinsulinemic state persists, but there is no longer an ongoing supply of glucose coming across the placenta; the newborn is thus at risk for hypoglycemia. IDMs should be closely monitored after birth to ensure that glucose requirements are met. Severe and/or prolonged hypoglycemia can cause significant injury to the developing brain. Poor glucose control during the second and third trimesters is associated with an increased risk for macrosomia and neonatal hypoglycemia. Other metabolic derangements frequently seen in IDMs are hypocalcemia and hypomagnesemia.

IDMs are at increased risk for RDS. Surfactant production occurs later than normal in diabetic pregnancies. Polycythemia also occurs at a higher rate. The greater red cell volume, in turn, increases the risk of hyperbilirubinemia. Hyperglycemia and the resulting hyperinsulinemia in the fetus generate a catabolic state, causing oxygen consumption. Erythropoiesis is believed to occur as a response to fetal hypoxia.

Asymmetric hypertrophic cardiomyopathy is a frequent finding in IDMs. The cardiomyopathy may be asymptomatic, apparent only as cardiomegaly on CXR, or it may be clinically significant, usually as a result of left ventricular outflow tract obstruction and/or poor ventricular filling and cardiac output related to hypertrophy of the ventricular septum. The hypertrophy of the cardiac muscle resolves over time, and the only indicated treatment is supportive care.

Intrauterine Growth Restriction

Intrauterine growth restriction (IUGR) describes a pattern of aberrant and reduced fetal growth that is identified by prenatal ultrasound examinations. The growth restriction is classified as asymmetric if the head circumference, used as a marker for brain growth, is spared. IUGR refers to growth in utero, and IUGR newborns may or may not be small for gestational age (SGA). (The definition of SGA varies, but historically it has been defined as less than the 10th percentile for gestational age at birth.) IUGR can result from a range of processes that may originate with the fetus (chromosomal abnormalities, fetal gender, genetic inheritance, TORCH infection), the placenta (abnormal implantation or insertion of the cord, preeclampsia, placental insufficiency), or the mother (chronic disease such as diabetes, systemic lupus erythematosus, or cyanotic heart disease; smoking; abnormal uterine anatomy; low pregnancy weight gain). The etiology of IUGR in approximately 40% of patients is never determined. CMV and toxoplasmosis studies are sometimes sent for affected newborns to determine an infectious cause. However, given the number of idiopathic cases of IUGR, some have questioned the utility of sending these cultures for infants with no physical examination or imaging study findings suggestive of congenital infection. Prenatal management of the IUGR fetus is impacted by the increased risk of intrauterine demise and perinatal asphyxia with IUGR, but also requires consideration of the fact that gestational age at birth is still a major determinant of outcome in the premature growth-restricted infant. There is currently great interest in the connection between low birth weight and the development of type 2 diabetes, hypertension, and coronary artery disease in adulthood.

The Dysmorphic Infant

It is estimated that 2% of all newborns have a serious congenital malformation. Advances in prenatal care now allow for early diagnosis of many congenital birth defects or diseases, but many are still difficult or impossible to detect in utero. Dysmorphic features and structural abnormalities may be immediately apparent, or they may be subtle and identified only upon close inspection. Every newborn should undergo a thorough examination to identify features suggestive of underlying pathology, genetic abnormalities, or specific syndromes or disorders.

Transfer of the newborn to a referral center where an evaluation by a clinical geneticist or dysmorphologist can be conducted may be warranted if significant abnormalities are present. The remarkable progress in our understanding of human genetics over the past decade has dramatically increased our ability to identify the genetic defects responsible for countless diseases and syndromes.

In addition, each year, more is understood about numerous multifactorial disorders, improving the odds that affected patients will be correctly diagnosed. A geneticist can help identify pertinent elements of the family, exposure, and prenatal history and direct a thorough but targeted radiologic and cytogenetic workup for the newborn. It is preferable to avoid making conclusions about the diagnosis (ie, a particular syndrome or sequence) until a complete evaluation has been performed. The emotional impact of an unsuspected defect or syndrome on the new parents should not be ignored, and misinformation can only hinder the process of acceptance (Table 22–1).

Critical Care Obstetrics

Nathan S. Fox, MD
Johanna Weiss Goldberg, MD
Ramada S. Smith, MD

Critical care medicine has increasingly become an area of interest to the obstetrician–gynecologist. Pregnancy complications such as shock, thromboembolism, acute respiratory distress syndrome (ARDS), and coagulation disorders can lead to significant morbidity. Furthermore, the approach to these patients can be influenced by a variety of physiologic changes that are unique to pregnancy. This chapter provides a basic approach to some of the common clinical problems that often require complex multidisciplinary care and knowledge of invasive hemodynamic monitoring.

PULMONARY ARTERY CATHETERIZATION

The flow-directed pulmonary artery catheter has been a major addition to the clinician's armamentarium because of its applicability to a wide range of cardiorespiratory disorders. The catheter allows simultaneous measurement of central venous pressure (CVP), pulmonary artery pressure (PAP), pulmonary capillary wedge pressure (PCWP), cardiac output, and mixed venous oxygen saturation. The pulmonary artery catheter is a 7F triple-lumen polyvinyl chloride catheter with a balloon and thermodilution cardiac output sensor at the tip. The distal port is used to measure PAP when the balloon is deflated and PCWP when inflated. A proximal lumen is present 30 cm from the balloon tip; this can be used to monitor the CVP and to administer fluids and drugs. Both ports can be used to withdraw blood. Oximetric catheters also have 2 optical fibers that permit continuous measurement of mixed venous oxygen saturation by reflection spectrophotometry.

Insertion Technique

A 16-gauge catheter is used to gain access to the internal jugular or subclavian vein (Fig. 23–1). Pertinent anatomic landmarks for the internal jugular vein approach are shown in Figure 23–2. A guidewire is then introduced into the vein through the catheter, and the 16-gauge catheter sheath is removed. A pulmonary artery catheter is inserted over the guidewire, and the guidewire is removed. The central venous and pulmonary artery ports are connected to a pressure transducer, so that the characteristic waveforms of the various heart chambers can be identified as the catheter is advanced (Fig. 23–3). When the catheter is in the superior vena cava, the balloon is inflated with 1–1.5 mL of air, and the catheter is advanced forward into the main pulmonary artery. Table 23–1 shows the average distance in centimeters the catheter must be advanced from various insertion sites. From the main pulmonary artery, the flow of blood moves the catheter into a branch of the pulmonary artery, where it wedges and records the PCWP.

Clavicular head
Internal jugular vein

Figure 23–2. Important anatomic landmarks associated with the internal jugular vein approach for right heart catheterization.

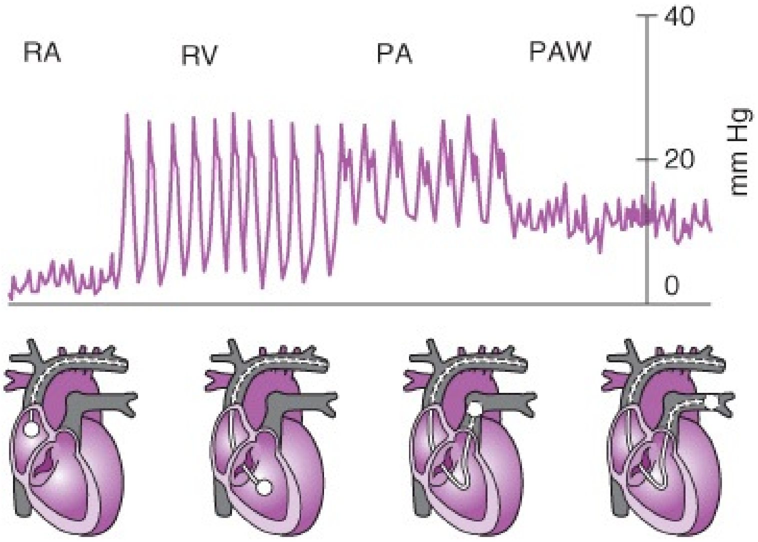

Figure 23–3. Changes in waveforms observed during placement of a pulmonary artery catheter. RA, right atrium; RV, right ventricle; PA pulmonary artery; PAW, pulmonary artery wedge. (Reproduced, with permission, from Rosenthal MH. Intrapartum intensive care management of the cardiac patient. *Clin Obstet Gynecol* 1981;24:796.)

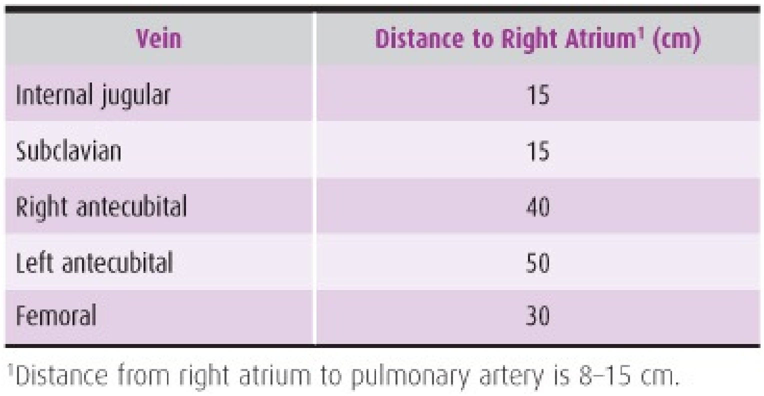
Table 23–1. Distance to right atrium from various sites of insertion in pulmonary artery catheterization.



Vein	Distance to Right Atrium[1] (cm)
Internal jugular	15
Subclavian	15
Right antecubital	40
Left antecubital	50
Femoral	30

[1] Distance from right atrium to pulmonary artery is 8–15 cm.

Criteria for verification of the true PCWP include (1) x-ray confirmation of catheter placement, (2) characteristic left atrial waveform configuration, (3) mean PCWP lower than mean PAP, (4) respiratory variation demonstrated by fluctuation of the PCWP waveform baseline with inspiration and expiration, and (5) blood samples showing higher oxygen tension and lower CO_2 tension than in arterial blood.

After deflation of the balloon, the pulmonary artery waveform should again be visualized. Fiberoptic catheters allow verification of PCWP by showing a sudden increase in mixed venous saturation to 95% or greater.

Indications for Invasive Monitoring

According to the American College of Obstetricians and Gynecologists, invasive hemodynamic monitoring may provide useful information for critical conditions during pregnancy such as:

- Shock (septic, hemorrhagic, cardiogenic, unexplained)
- Pulmonary edema (eg, severe pregnancy-induced hypertension [PIH], congestive heart failure [CHF], unexplained or refractory)
- Severe PIH with persistent oliguria unresponsive to fluid challenge
- ARDS
- Severe cardiac disease

Hemodynamic Parameters Available With Pulmonary Artery Catheterization

During the diastolic period of the cardiac cycle, the left ventricle, left atrium, and pulmonary vascular bed essentially become a common chamber (Fig. 23–4). In a normal cardiovascular system, the left ventricular end-diastolic pressure (LVEDP), left atrial pressure, and PCWP are essentially interchangeable. A disparity may develop between PCWP and LVEDP when LVEDP is greater than 15 mm Hg; however, for clinical purposes, the PCWP provides a fairly accurate index of LVEDP, especially if the “a” wave (caused by retrograde transmission of the left atrial contraction) can be identified in the wedge tracing. The relationships described earlier can be substantially altered by mitral or aortic valvular disease.

Figure 23–4. Pulmonary capillary wedge pressure in diastole (ventricles relaxed).

A. Cardiac Output

The thermal sensing device in the tip of a pulmonary artery catheter allows for rapid determination of cardiac output by the thermodilution method. Five milliliters of 5% dextrose in water is injected through the central venous port at a constant distance from the thermistor tip. The use of this solution at room temperature can minimize sources of potential error associated with inaccurate temperature measurements and catheter warming. The change in pulmonary artery temperature is detected by the thermistor. The cardiac output is inversely proportional to the fall in temperature and is computed by planimetric or computerized methods. The average of 3 values within 10% of each other is typically utilized to calculate cardiac output.

B. Systemic Vascular Resistance

Systemic vascular resistance (SVR) represents the total resistance to forward flow of blood through the body's vascular tree. SVR is calculated as follows:

$$\text{SVR} = \frac{[(\text{MAP} - \text{CVP})] \times 80}{\text{CO}}$$

During pregnancy, this parameter is usually in the range of 800–1200 dynes · s · cm^{-5}. Depending on the clinical condition, a reduction or increase in SVR may be desirable in the presence of normal blood pressure (eg, septic shock), in which a very low SVR may be seen despite normal or low blood pressure. In order to maintain vital organ perfusion, vasopressor therapy may be indicated to increase SVR.

C. Pulmonary Capillary Wedge Pressure

The PCWP provides important information on 2 basic parameters of cardiopulmonary function: (1) pulmonary venous pressure, which is a major determinant of pulmonary congestion; and (2) the left atrial and left ventricular filling pressures, from which ventricular function curves can be constructed.

Pulmonary capillary wedge pressure can be reliably assessed by CVP monitoring only in the absence of significant myocardial dysfunction. The measurement of PCWP has certain advantages over measurement of CVP alone. A disparity between right and left ventricular function may be seen in conditions such as myocardial infarction, valvular disease, sepsis, and severe PIH. Under these circumstances, the management of fluid therapy based on CVP alone could have adverse results. Additionally, cardiac output and mixed venous oxygen tension cannot be determined with a simple CVP catheter.

D. Ventricular Function Curves

Myocardial performance is best interpreted in terms of left ventricular function curves (ie, the Frank-Starling relationship). The cardiac output and PCWP are used to construct the ventricular function curve by plotting the ventricular stroke work index against the mean atrial pressure or ventricular end-diastolic pressure (usually the PCWP). The left ventricular stroke work index is calculated by the following formula:

$$\text{LVSWI} = \text{SVI} \times (\text{MAP} - \text{PCWP}) \times 0.0136$$

(LVSWI = left ventricular stroke work index [g-m/m^2]; SVI = stroke volume index [mL/beat/m^2]; MAP = mean arterial pressure [mm Hg]; PCWP = pulmonary capillary wedge pressure [mm Hg]).

Ventricular function curves provide a useful index of cardiovascular status to guide inotropic and vasoactive drug therapy. Evaluation of myocardial contractility by ventricular function curves allows one to obtain optimal filling pressures and stroke volume index in critically ill patients. The effects of therapy (eg, diuretics, antihypertensive agents, or volume expanders) can be evaluated on the basis of performance. Under normal conditions, a small rise in filling pressure is accompanied by a rapid rise in stroke work. Unfavorable conditions such as hypoxia or myocardial depression produce a shift in the curve to the right and downward such that lower stroke work indices are seen at higher filling pressures.

E. Mixed Venous Oxygen Saturation

The mixed venous oxygen saturation (SvO_2) reflects the body's capacity to provide adequate tissue oxygenation. This parameter is affected by cardiac output, hemoglobin concentration, arterial oxygen saturation, and tissue oxygen consumption. An SvO_2 of 60–80% usually indicates normal oxygen delivery and demand with adequate tissue perfusion. An SvO_2 greater than 80% reflects increased oxygen delivery and decreased oxygen utilization. This situation may be seen in patients with hypothermia or sepsis who are receiving supplemental oxygen. A high SvO_2 may also provide confirmatory evidence that the pulmonary artery catheter is in the wedge position. Finally, a low SvO_2 (<60%) indicates increased oxygen demands with decreased oxygen delivery due to anemia, low cardiac output, or decreased arterial oxygen saturation.

Measurement of SvO_2 allows for continuous monitoring of cardiorespiratory reserve by providing an index of tissue oxygen delivery and utilization. Changes in SvO_2 will be apparent with infusion of vasoactive drugs, volume loading, or afterload reduction. Although many intensive care units rely on direct measurement of cardiac output alone, this parameter does not always accurately reflect tissue oxygenation. For instance, normal cardiac output might not be adequate to meet increased oxygen requirements in malignant hyperthermia or thyroid storm.

F. Maternal Oxygen Consumption

Mixed venous oxygen saturation results can be used with arterial blood gas analysis to provide useful information about the metabolic status of the critically ill obstetric patient. Resting maternal oxygen consumption progressively increases during pregnancy. Occasionally, one needs to pay particular attention to the metabolic status of critically ill women or those with ARDS. Factors such as tachycardia or fever that are associated with increased oxygen consumption should be minimized under these circumstances.

The Fick relationship:

$$\mathrm{CO} = \frac{\mathrm{VO_2}}{\mathrm{AvO_2diff.}} \times 100$$

provides a method for calculating oxygen consumption (VO_2), if the cardiac output (CO) and systemic arteriovenous oxygen (AvO_2) concentration difference is known. The AvO_2 difference can be calculated by subtracting the oxygen content of desaturated mixed venous blood from that of arterial blood that passes through the pulmonary artery catheter. For example, a patient with a cardiac output minus AvO_2 difference of 5 mL would have an oxygen consumption (VO_2) of 300 mL.

$$\begin{gathered} 6000\ \mathrm{mL\ min^{-1}} \times 5\ \mathrm{mL\ per\ 100\ mL\ blood} \\ \mathrm{VO_2}\ 100 = 300\ \mathrm{mL\ min^{-1}} \end{gathered}$$

An understanding of these relationships will allow the clinician to better understand how to use physiologic variables for interpreting the hemodynamic and pulmonary condition of critically ill patients.

G. Colloid Osmotic Pressure

The plasma colloid oncotic pressure (COP) is another measurement that can be useful in critical care (Table 23–2). Plasma COP is the pressure exerted by certain plasma proteins that hold fluid in the intravascular space. Albumin accounts for 75% of the oncotic pressure of plasma, with the rest coming from globulin and fibrinogen. It has been demonstrated in dogs that iatrogenic reduction in plasma proteins resulted in pulmonary edema with only minimal increases in left atrial pressure. Subsequent studies in humans identified cases of pulmonary edema in which normal or slightly elevated PCWP was present. From these studies, the important concept of a COP-PCWP gradient evolved. It appears that when the COP-PCWP gradient is less than 4 mm Hg, the likelihood of pulmonary edema is increased, although not all patients with a decreased gradient will develop pulmonary edema. The determination of COP and its relationship to the PCWP can play a crucial role in the detection of patients likely to develop pulmonary edema in the face of normal left-sided filling pressures.

Table 23–2. Serum colloid oncotic pressure during pregnancy.

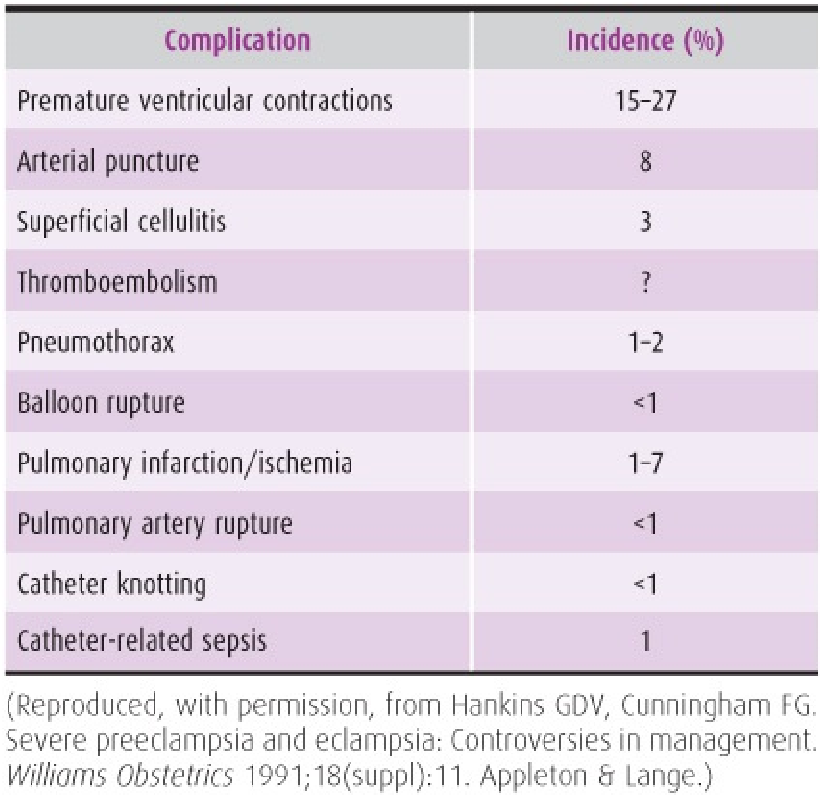
	Normotensive (mm Hg)	Hypertensive (mm Hg)
Antepartum (term)	22.4 ± 0.5	17.9 ± 0.7
Postpartum (first 24 hours)	15.4 ± 2.1	13.7 ± 0.5

Studies of pregnant women have demonstrated that patients with certain conditions in which the risk of pulmonary edema is markedly increased tend to have lowered COP (eg, hypovolemic shock, severe PIH, prolonged tocolytic therapy, and frank pulmonary edema).

Complications

The most common complication associated with pulmonary artery catheter placement is dysrhythmia. More serious complications also include pulmonary infarction, thromboembolism, balloon rupture with air embolism, pulmonary artery or valve rupture, catheter knotting, infection, arterial puncture, thromboembolism, pneumothorax, and pulmonary hemorrhage. Table 23–3 summarizes the complication rates for pulmonary artery catheterization.

Table 23–3. Complications of pulmonary artery catheterization.



Complication	Incidence (%)
Premature ventricular contractions	15–27
Arterial puncture	8
Superficial cellulitis	3
Thromboembolism	?
Pneumothorax	1–2
Balloon rupture	<1
Pulmonary infarction/ischemia	1–7
Pulmonary artery rupture	<1
Catheter knotting	<1
Catheter-related sepsis	1

(Reproduced, with permission, from Hankins GDV, Cunningham FG. Severe preeclampsia and eclampsia: Controversies in management. *Williams Obstetrics* 1991;18(suppl):11. Appleton & Lange.)

A. Dysrhythmia

Premature ventricular contractions may transiently occur as the catheter tip enters the right ventricle. However, they usually resolve after advancement of the catheter into the pulmonary artery. If the dysrhythmia is refractory to lido-caine, 50–100 mg given intravenously, the catheter should be withdrawn from the cardiac chambers.

B. Pulmonary Infarction

Pulmonary infarction may occur when the catheter migrates distally and wedges spontaneously for a prolonged period. This complication, as well as thromboembolism, may be avoided by monitoring the PCWP at regular intervals and by using a continuous heparinized flow system.

C. Balloon Rupture

Balloon rupture can be avoided by limiting the number of balloon inflations and by inflating only to the smallest necessary volume. Inflation of the balloon beyond 2 mL of air is unnecessary and may be harmful. To avoid rupture of a pulmonary artery branch, inflation of the balloon should be stopped immediately when the wedge tracing is seen.

D. Catheter Knotting

Catheter knotting is usually the result of advancing the catheter 10–15 cm farther than is necessary to reach the right ventricle or pulmonary artery. Withdrawing the catheter while the balloon is still inflated may cause tricuspid rupture or chordae tendineae tears.

E. Infection and Phlebitis

Infection and phlebitis can be minimized by using aseptic technique. The risk of associated sepsis is related to excessive catheter manipulation and the duration of catheterization.

NONINVASIVE MONITORING FOR CRITICALLY ILL PATIENTS

Pulse oximetry is a simple tool that can be used with invasive monitoring for patients with cardiovascular or respiratory compromise. The correlation between pulse oximetry and direct blood oxygen saturation is excellent when oxygen saturation is greater than 60%. Factors adversely affecting the accuracy of pulse oximetry include movement, peripheral vasoconstriction, hypotension, anemia, hypothermia, intravascular dye, and possibly nail polish.

OBSTETRIC SHOCK

Shock may be defined as an imbalance between oxygen supply and demand. The basic underlying defect is a significant reduction in the supply of oxygenated blood to various tissues due to inadequate perfusion. In obstetrics, this reduction often results from hemorrhage, sepsis, or pump failure. The physiologic compensation common to all shock states involves tachycardia and peripheral vasoconstriction to maximize cerebral and cardiac perfusion by way of the sympathetic nervous system. Failure of these compensatory mechanisms will lead to a predominance of anaerobic metabolism and lactic acidosis, which can be potentially devastating to the patient and fetus. Cardiogenic shock may be seen in pregnant women with cardiac dysrhythmias, congenital heart disease, peripartum cardiomyopathy, and congestive heart failure. The following discussion will focus on 2 of the more common shock syndromes complicating pregnancy—those related to hemorrhage and sepsis.

HYPOVOLEMIC SHOCK

ESSENTIALS OF DIAGNOSIS

- Recent history of acute blood loss or excessive diuresis
- Hypotension, tachycardia, tachypnea, and oliguria with progression to altered mental status
- Precipitous drop in hematocrit (if from hemorrhage)

Pathogenesis

Hypovolemic shock is a leading cause of maternal mortality in the United States and is most commonly associated with obstetric hemorrhage. Bleeding severe enough to cause hemorrhagic shock may result from a wide variety of conditions, including ruptured ectopic pregnancy; abruptio placentae; placenta previa; placenta accreta; rupture, atony, or inversion of the uterus; surgical procedures; obstetric lacerations; or retained products of conception.

During normal pregnancy, the blood volume expands by approximately 1500 mL. This hypervolemia results from hormonal alterations and may be considered protective against peripartum bleeding. During acute hemorrhage, the body responds to volume loss by hemodynamic, volume-altering, and hormonal mechanisms.

Hemodynamic adjustments result from activation of the sympathetic nervous system. These changes include vasoconstriction of arteriolar resistance vessels, constriction of venous capacitance vessels, and redistribution of blood flow away from peripheral organs to preserve adequate cerebral and cardiac blood flow.

Volume adjustments occur from extravascular fluid shifts into the intravascular compartment. The rate of plasma refill depends on the magnitude of volume depletion.

If these mechanisms are insufficient to restore circulatory function, other compensatory effects, such as secretion of antidiuretic hormone (ADH), cortisol, aldosterone, and catecholamines will occur. Epinephrine, in addition to causing peripheral vasoconstriction, will have inotropic and chronotropic effects on the heart. ADH, cortisol, and aldosterone will help conserve water and salt, which may then result in reduced blood flow to the kidneys and decreased urine output.

These homeostatic mechanisms serve to maintain adequate tissue perfusion until approximately 25–30% of the circulating blood volume is lost. Inadequate tissue perfusion and oxygenation will then lead to anaerobic metabolism and lactic acidosis. Over a prolonged period of vasoconstriction, there may be decompensation of the peripheral vasculature leading to damaged or leaky capillaries. Observations of blood flow regulation during pregnancy suggest that uterine arteries have limited capacity to autoregulate fetoplacental perfusion. Thus uteroplacental blood flow is critically dependent on systemic maternal cardiac output.

Clinical Findings

The clinical manifestations of hemorrhagic shock depend on the quantity and rate of volume depletion. Orthostatic signs and symptoms may be masked by the hypervolemia of pregnancy, especially if a source of bleeding is not evident. Additionally, because pregnant women usually are young and healthy, their ability to tolerate significant blood loss is greater than a typical medical patient. Therefore, they may experience significant blood loss before showing some of the signs or symptoms of shock. Obvious hypotension and tachycardia in the presence of external bleeding should alert the clinician to the possibility of shock. A careful physical examination will identify decreased tissue perfusion in several different organ systems, including the heart, brain, kidneys, lungs, and skin. Altered mental status, dizziness, diaphoresis, and cold, clammy extremities, as well as a fast, “thready” pulse are common findings in significant hemorrhagic shock. Oliguria (<30 mL/h), CVP of less than 5 cm H_2O, and PCWP of less than 5 mm Hg are all consistent with significant volume depletion. Fetal heart monitoring may reveal bradycardia or late decelerations.

Differential Diagnosis

Hypovolemic shock should be differentiated from other shock syndromes resulting from sepsis or heart failure. Usually, there is a history of profound bleeding. Because shock may affect several organ systems, it is essential that its underlying cause be identified. Patients with septic shock will tend to be febrile, with associated abnormal white blood cell counts and clinical evidence of infection. Cardiogenic shock may be associated with clinical and radiographic evidence of pulmonary congestion or a previous history of heart disease.

Complications

Electrolyte imbalance, acidosis, acute tubular necrosis, stress-induced gastric ulceration, pulmonary edema, and ARDS are common complications associated with hemorrhagic shock. Myocardial infarction is a rare complication in the obstetric population.

Treatment

The treatment of hemorrhagic shock should be directed toward replacing blood volume and optimizing cardiac performance. The source of bleeding should be controlled. Uterine atony that is unresponsive to massage and oxytocin may benefit from methylergonovine (0.2 mg intramuscularly), 15-methyl prostaglandin $F_{2\alpha}$ (0.25 mg intramuscularly), or misoprostol (1000 mcg rectally). Persistent bleeding may require uterine artery ligation, hypogastric artery ligation, or even caesarean hysterectomy. Decisions regarding blood and fluid replacement should be guided by central pressures and urine output, although pulmonary artery catheterization is rarely necessary. A military antishock trousers suit will mobilize blood pooled in the lower body and return it to the central circulation, improving systemic cardiac output and organ perfusion. Supplemental oxygen will minimize tissue hypoxia and fetal acidosis.

Initial rapid volume replacement with crystalloid solution given through a large-bore intravenous site is a temporizing measure until blood replacement is possible. Typically, 1–2 L of lactated Ringer’s solution can be administered as rapidly as possible. Compared with normal saline, the electrolyte composition of lactated Ringer’s solution more closely approximates plasma, and the metabolism of lactate to bicarbonate provides some buffering capacity for acidosis.

Guidelines for perioperative transfusion of red blood cells have been defined by the National Institutes of Health. Initial treatment of hemorrhagic shock should involve volume replacement by crystalloid or colloid solutions that do not carry risks for disease transmission or transfusion reaction. The use of perioperative red blood cell transfusion should not rely solely on the dogma of “transfusing to a hematocrit above 30%” as the sole criterion because there is poor evidence supporting its usefulness. The decision of whether to transfuse red cells should also take into account other factors such as patient age, hemodynamic status, anticipated bleeding, and medical or obstetrical complications. If it is necessary to transfuse large amounts of blood, it is important to note and correct the presence of electrolyte imbalances, acid–base abnormalities, hypothermia, and the dilution of platelets and coagulation factors, which may require the transfusion of other blood products.

The risk of posttransfusion hepatitis has been dramatically decreased by testing blood products with a commercially available hepatitis C assay. The test is a qualitative, enzyme-linked immunosorbent assay (ELISA) for the detection of antibody to hepatitis C virus (anti-HCV) in human serum or plasma. The ELISA test has a specificity of 99.84% in a low prevalence population. A supplemental assay, the recombinant immunoblot assay, can be performed on blood that has a repeat reactive anti-HCV.

Fluid balance from intravenous infusions or urine output should be meticulously recorded with daily weights. Oliguria refractory to volume loading may be improved by the addition of intravenous dopamine in low doses (2–5 μg/kg/min) to improve renal perfusion. A diuretic such as bumetanide 0.5–1 mg administered intravenously (IV), not to exceed 10 mg/day, should be considered for patients with prolonged oliguria despite normal or elevated pulmonary capillary wedge pressures.

Blood tests should include complete blood count, serum electrolytes, creatinine, arterial blood gas analysis, and coagulation profile. Urinalysis is also important. A baseline chest radiograph and electrocardiogram are desirable. Typed and cross-matched transfusion products should be available from the blood bank. One to 2 ampules of sodium bicarbonate (50–100 mEq) can be administered intravenously to correct acidosis (pH <7.20). Frequent serial hematocrits may provide an index of acute blood loss. A baseline hematologic profile (prothrombin time [PT], partial thromboplastin time [PTT], fibrinogen, platelets) is necessary to evaluate the possibility of coagulopathy.

Prognosis

Maternal and fetal survival rates are directly related to the magnitude of volume depletion and length of time the patient remains in shock. If the hemorrhage is controlled and intravascular volume is restored within a reasonable interval, the prognosis is generally good in the absence of associated complications. However, the return of fetal blood flow may lag behind correction of maternal flow.

SEPTIC SHOCK

ESSENTIALS OF DIAGNOSIS

- History of recent hospitalization or surgery
- Pelvic or abdominal infection with positive confirmatory cultures
- Temperature instability, confusion, hypotension, oliguria, cardiopulmonary failure

---

Pathogenesis

Septic shock is a life-threatening disorder secondary to bacteremia. The American College of Obstetricians and Gynecologists defines septic shock as sepsis with hypotension despite adequate fluid resuscitation, with the presence of perfusion abnormalities including (but not limited to) lactic acidosis and oliguria. The incidence of bacteremia in obstetric patients has been estimated to be between 0.7% and 10%. Although gramnegative bacteria are usually responsible for most of these infections, septic shock may also result from infection with other bacteria, fungi, protozoa, or viruses. The most common cause of obstetric septic shock is postoperative endometritis (85%). Other commonly associated conditions include antepartum pyelonephritis, septic abortion, and chorioamnionitis.

Sepsis may lead to a systemic inflammatory response that can be triggered not only by infections, but also by noninfectious disorders, such as trauma and pancreatitis. However, there is strong evidence to support the concept that endotoxin is responsible for the pathogenesis of gramnegative septic shock. *Escherichia coli* has been implicated in 25–50% of cases of septic hypotension, but a variety of other organisms may be causative, including *Klebsiella, Enterobacter, Serratia, Proteus, Pseudomonas, Streptococcus, Peptostreptococcus, Staphylococcus, Fusobacterium, Clostridium,* and *Bacteroides*. The gramnegative endotoxin theory does not explain gram-positive shock, although an understanding of the proposed mechanisms will serve to exemplify the multisystemic effects of this disorder.

Endotoxin is a complex lipopolysaccharide present in the cell walls of gramnegative bacteria. The active component of endotoxin, lipid A, is responsible for initiating activation of the coagulation, fibrinolysis, complement, prostaglandin, and kinin systems. Activation of the coagulation and fibrinolysis systems may lead to consumptive coagulopathy. Complement activation leads to the release by leukocytes of mediators that are responsible for damage to vascular endothelium, platelet aggregation, intensification of the coagulation cascade, and degranulation of mast cells with histamine release. Histamine will cause increased capillary permeability, decreased plasma volume, vasodilatation, and hypotension. Release of bradykinin and β-endorphins also contributes to systemic hypotension. Early stages of septic shock involve low SVR and high cardiac output with a relative decrease in intravascular volume. Late or cold shock subsequently involves an endogenous myocardial depressant factor that has not been isolated. This factor is associated with decreased cardiac output and continued low SVR in the absence of pressor agents. Recent studies suggest that tumor necrosis factor (TNF) may lead to depressed myocardial function during septic shock. Monocytes and macrophages incubated with endotoxin produce this 17-kDa polypeptide within 40 minutes. Direct injection of TNF into animals leads to many of the changes seen in endotoxic shock. Other possible factors include interleukin (IL)-1, IL-6, IL-8, interferon gamma, and granulocyte stimulating factor.

Clinical Findings

A. Symptoms and Signs

Septic shock can be divided into 3 stages: preshock, early shock (warm shock), and late (or cold) shock. In preshock, patients present with tachypnea and respiratory alkalosis (above the mild respiratory alkalosis seen in normal pregnancy). Their condition is best described as a moderate hyperdynamic state, with elevated cardiac output, decreasing SVR, and normal blood pressures. Response to therapy will be greatest at this stage. Early shock is a more hyperdynamic state. Blood pressure drops (systolic blood pressure < 60 mm Hg), and SVR decreases dramatically (< 400 dynes · s · cm^{-5}). Altered mental status, temperature instability, and sinusoidal fluctuations in arterial blood pressure may be seen at this stage. As this condition progresses into late shock, activation of the sympathetic nervous system with release of catecholamines will lead to intense vasoconstriction, which serves to shunt blood from the peripheral tissues to the heart and brain (cold shock). The compensatory vasoconstriction results in increased cardiac work. Lactic acidosis, poor coronary perfusion, and the influence of myocardial depressant factor may also contribute to poor cardiac performance (Fig. 23–5). The fetus is more resistant to the effects of endotoxin than the mother; however, alterations in uteroplacental flow can lead to hypoxia, acidosis, placental abruption, intracranial hemorrhage, and fetal demise.

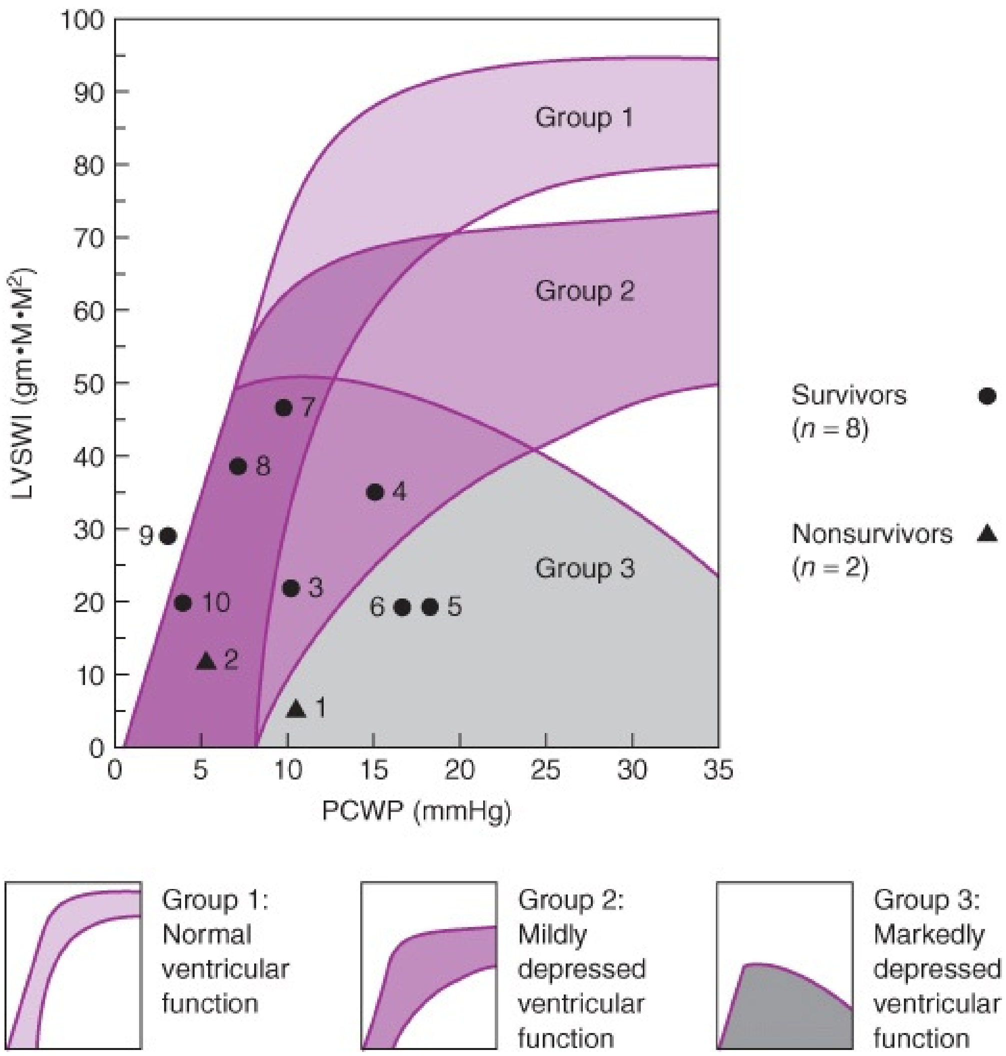

Figure 23–5. Presenting left ventricular function of 10 pregnant women with septic hypotension. LVSWI, left ventricular stroke work index; PCWP, pulmonary capillary wedge pressure. (Reproduced, with permission, from Lee W, Clark SL, Cotton DB, et al. Septic shock during pregnancy. *Am J Obstet*

Gynecol 1988;159:410.)

The clinical manifestations of septic shock depend on the target organs affected. The most common cause of death in patients with this condition is respiratory insufficiency secondary to ARDS.

B. Laboratory Findings

Complete blood cell count, serum electrolytes, urinalysis, baseline arterial blood gases, chest radiograph, and a coagulation profile are laboratory studies important in the management of these patients. Hematologic findings may include significant anemia, thrombocytopenia, and leukocytosis. Serum electrolytes are often abnormal because of acidosis, fluid shifts, or decreased renal perfusion. Urinalysis permits evaluation of renal involvement. In addition to urine cultures, aerobic and anaerobic blood cultures may be helpful to confirm the diagnosis and guide antibiotic therapy.

Arterial blood gas measurements and a chest radiograph will facilitate clinical assessment of the ventilatory and oxygenation status. Early stages of septic shock will be associated with respiratory alkalosis, which later progresses to metabolic acidosis.

A baseline electrocardiogram (ECG) should be performed to rule out myocardial infarction or cardiac dysrhythmia. Abdominal radiographic studies may be useful to rule out other intrapelvic or intraabdominal sources of obstetric sepsis (eg, bowel perforation, uterine perforation, tubo-ovarian abscess). Significant disseminated intravascular coagulation (DIC) will be identified by abnormal PT, PTT, or fibrinogen levels.

Differential Diagnosis

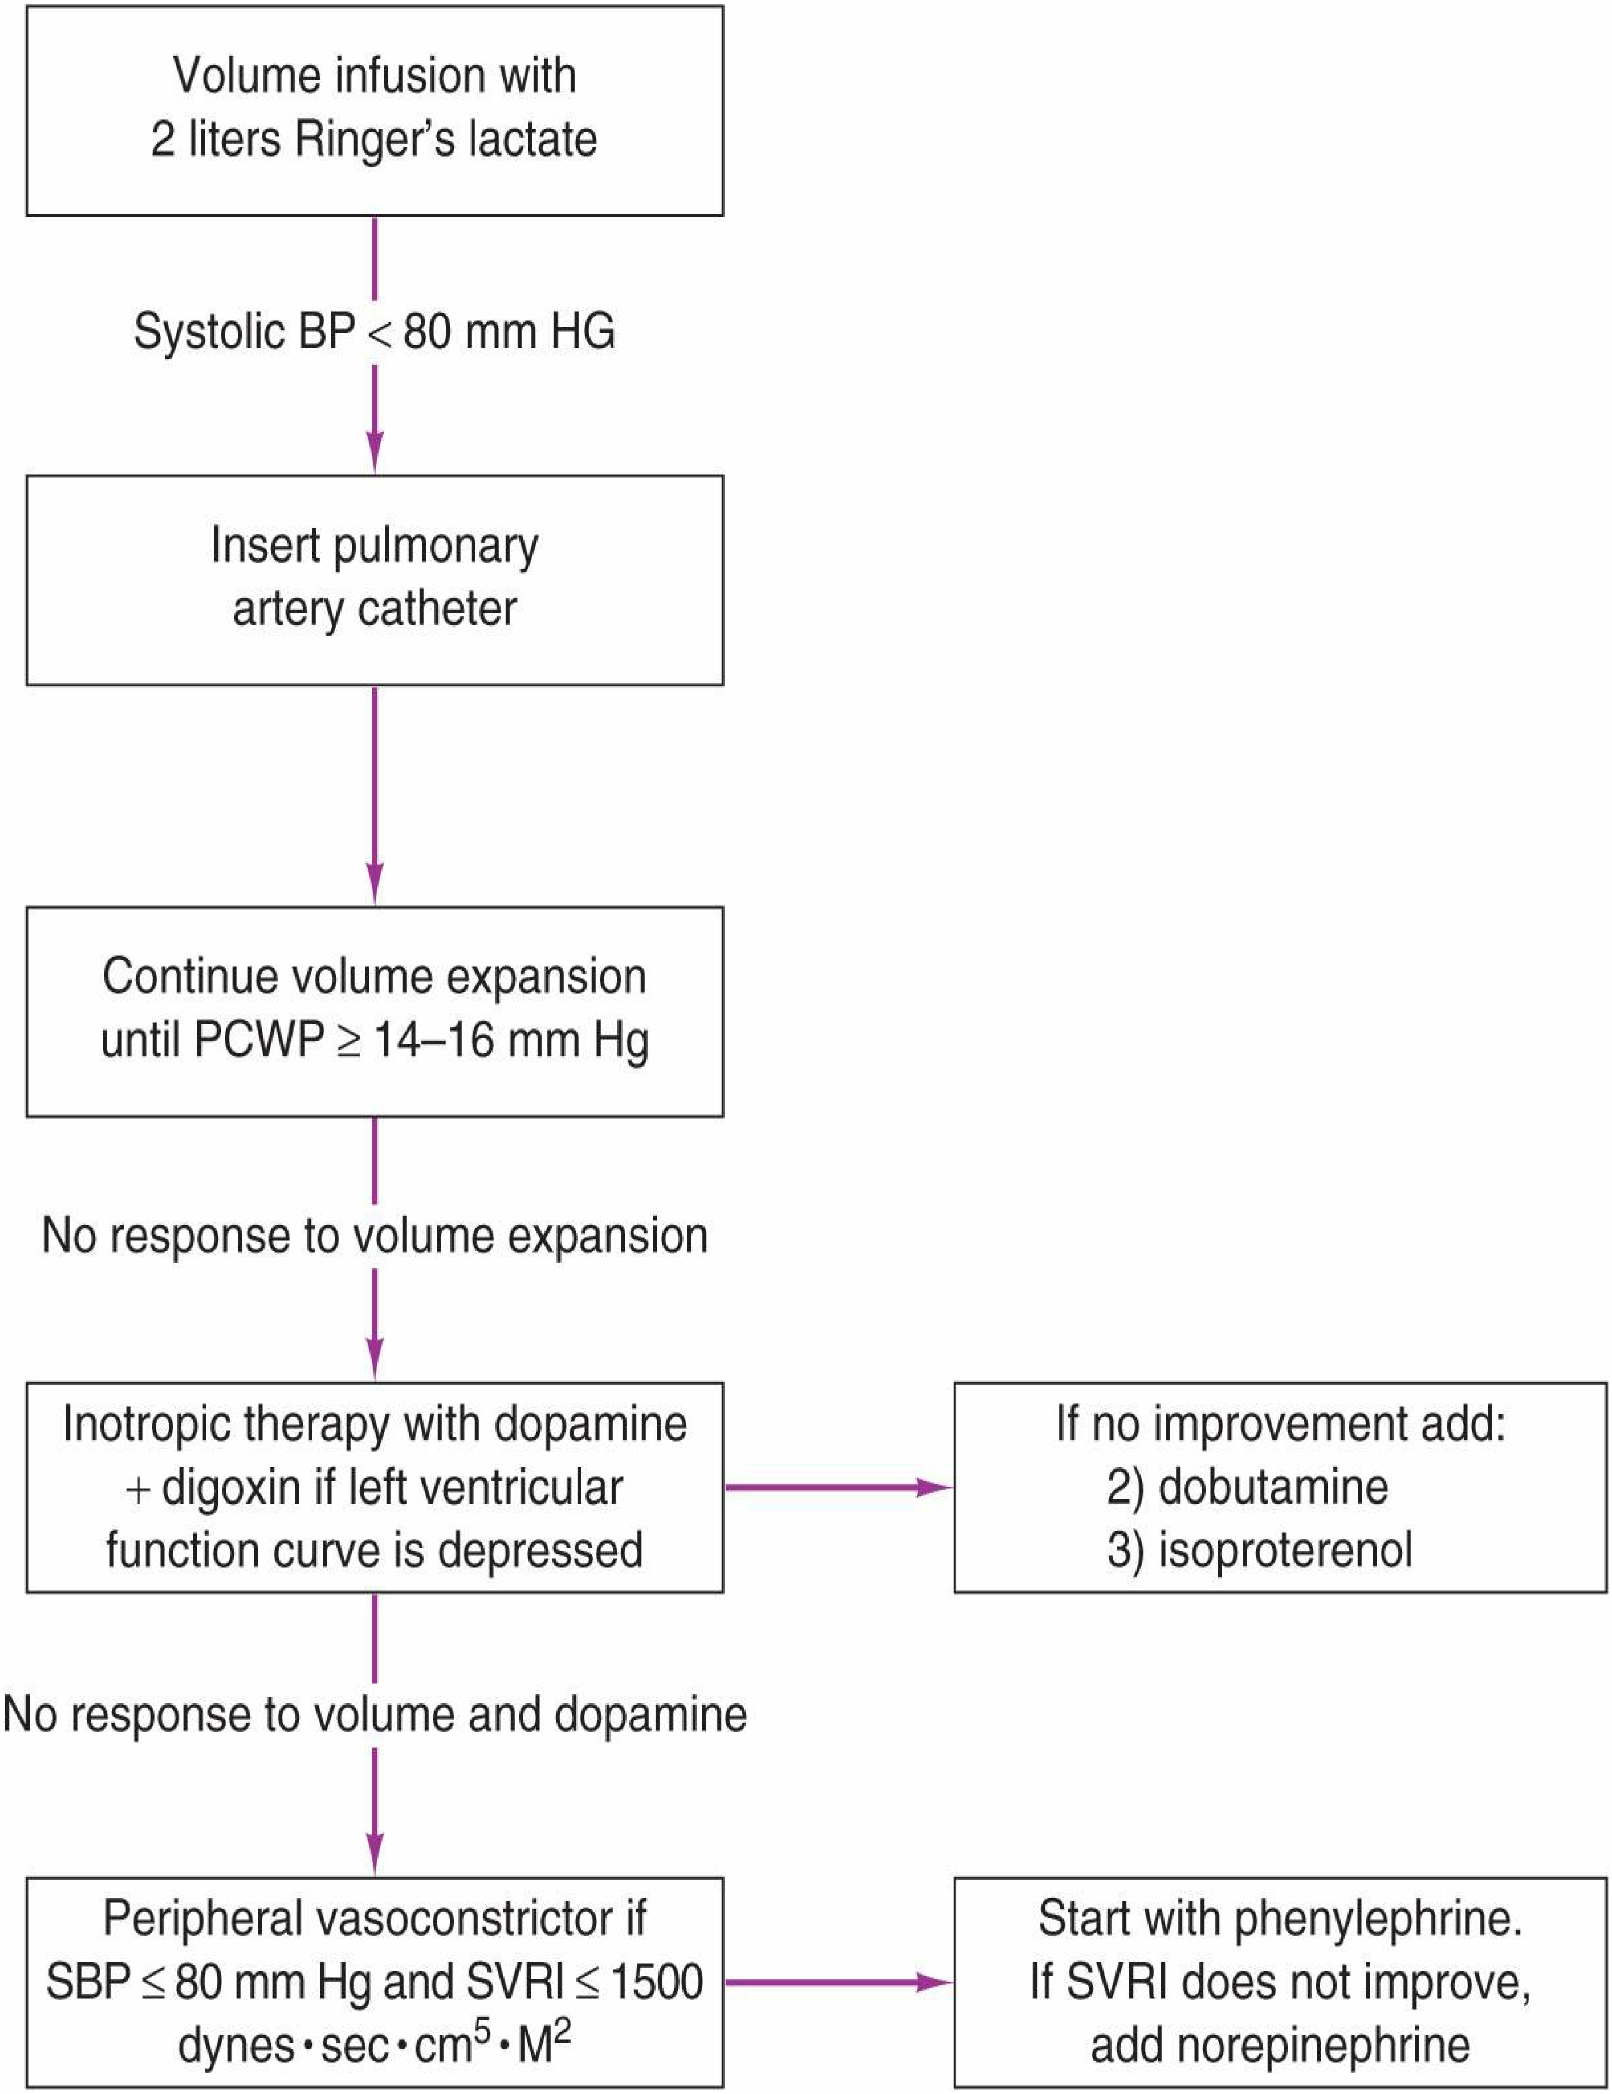
The differential diagnosis should include other hypovolemic and cardiogenic shock syndromes. Additional causes of acute cardiopulmonary compromise include amniotic fluid embolism, pulmonary thromboembolism, cardiac tamponade, aortic dissection, and diabetic ketoacidosis. The history, physical examination, and laboratory studies will usually be sufficient to distinguish between these diagnoses.

Complications

Numerous complications may occur with septic shock, depending on the target organs involved. Aside from ARDS, some of the more serious complications include congestive heart failure and cardiac dysrhythmias. Systemic hypotension and ischemic end-organ damage can lead to hepatic failure or renal insufficiency. Fetal or maternal demise are the most dire outcomes.

Treatment

Successful management of obstetric septic shock depends on early identification and aggressive treatment focused on stabilization of the patient, removal of underlying causes of sepsis, broad-spectrum antibiotic coverage, and treatment of associated complications. Febrile patients with mild hypotension who respond rapidly to volume infusion alone do not require invasive monitoring. In other cases, the pulmonary artery catheter should be used to guide specific therapeutic maneuvers for optimizing myocardial performance and maintaining systemic cardiac output and blood pressure. A hemodynamic approach for stabilizing pregnant women with septic shock should include (1) volume repletion and hemostasis, (2) inotropic therapy with dopamine on the basis of left ventricular function curves, and (3) addition of peripheral vasoconstrictors (phenylephrine first, then norepinephrine) to maintain afterload (Fig. 23–6).



Volume infusion with 2 liters Ringer's lactate
Systolic BP < 80 mm HG
Insert pulmonary artery catheter
Continue volume expansion until PCWP ≥ 14–16 mm Hg
No response to volume expansion
Inotropic therapy with dopamine + digoxin if left ventricular function curve is depressed
If no improvement add:
2) dobutamine
3) isoproterenol
No response to volume and dopamine
Peripheral vasoconstrictor if SBP ≤ 80 mm Hg and SVRI ≤ 1500 dynes • sec • cm⁵ • M²
Start with phenylephrine. If SVRI does not improve, add norepinephrine

Figure 23–6. Hemodynamic algorithm for treatment of obstetric septic shock. SVRI, systemic vascular resistance index; PCWP, pulmonary capillary wedge pressure; SBP, systolic blood pressure. (Reproduced, with permission, from Lee W, Clark SL, Cotton DB, et al. Septic shock during pregnancy. *Am J Obstet Gynecol* 1988;159:410.)

A. General Measures

Septic shock during pregnancy should be treated with a broad-spectrum antibiotic regimen such as ampicillin, gentamicin, and clindamycin. Aminoglycoside maintenance doses should be titrated in relation to serum peak and trough levels, or a 24-hour dosing regimen may be used. Newer antibiotics such as imipenem, cilastatin, vancomycin, and the extended spectrum penicillins (eg, ticarcillin) are also proving to be effective therapies. There must be a careful search for infected or necrotic foci that can result in persistent bacteremia, and surgical intervention may be necessary. In one study, 40% of septic obstetric patients required surgical removal of infected products of conception, and all survived. If chorioamnionitis is present in the septic obstetric patient, prompt delivery is necessary. However, if the pregnancy is not the cause of infection, immediate delivery is usually not required. Supportive care should also include control of fever with antipyretics, hypothermic cooling blankets, or both. Correction of maternal acidosis, hypoxemia, and systemic hypotension will usually improve any abnormalities in the fetal heart tracing.

B. Cardiovascular Support

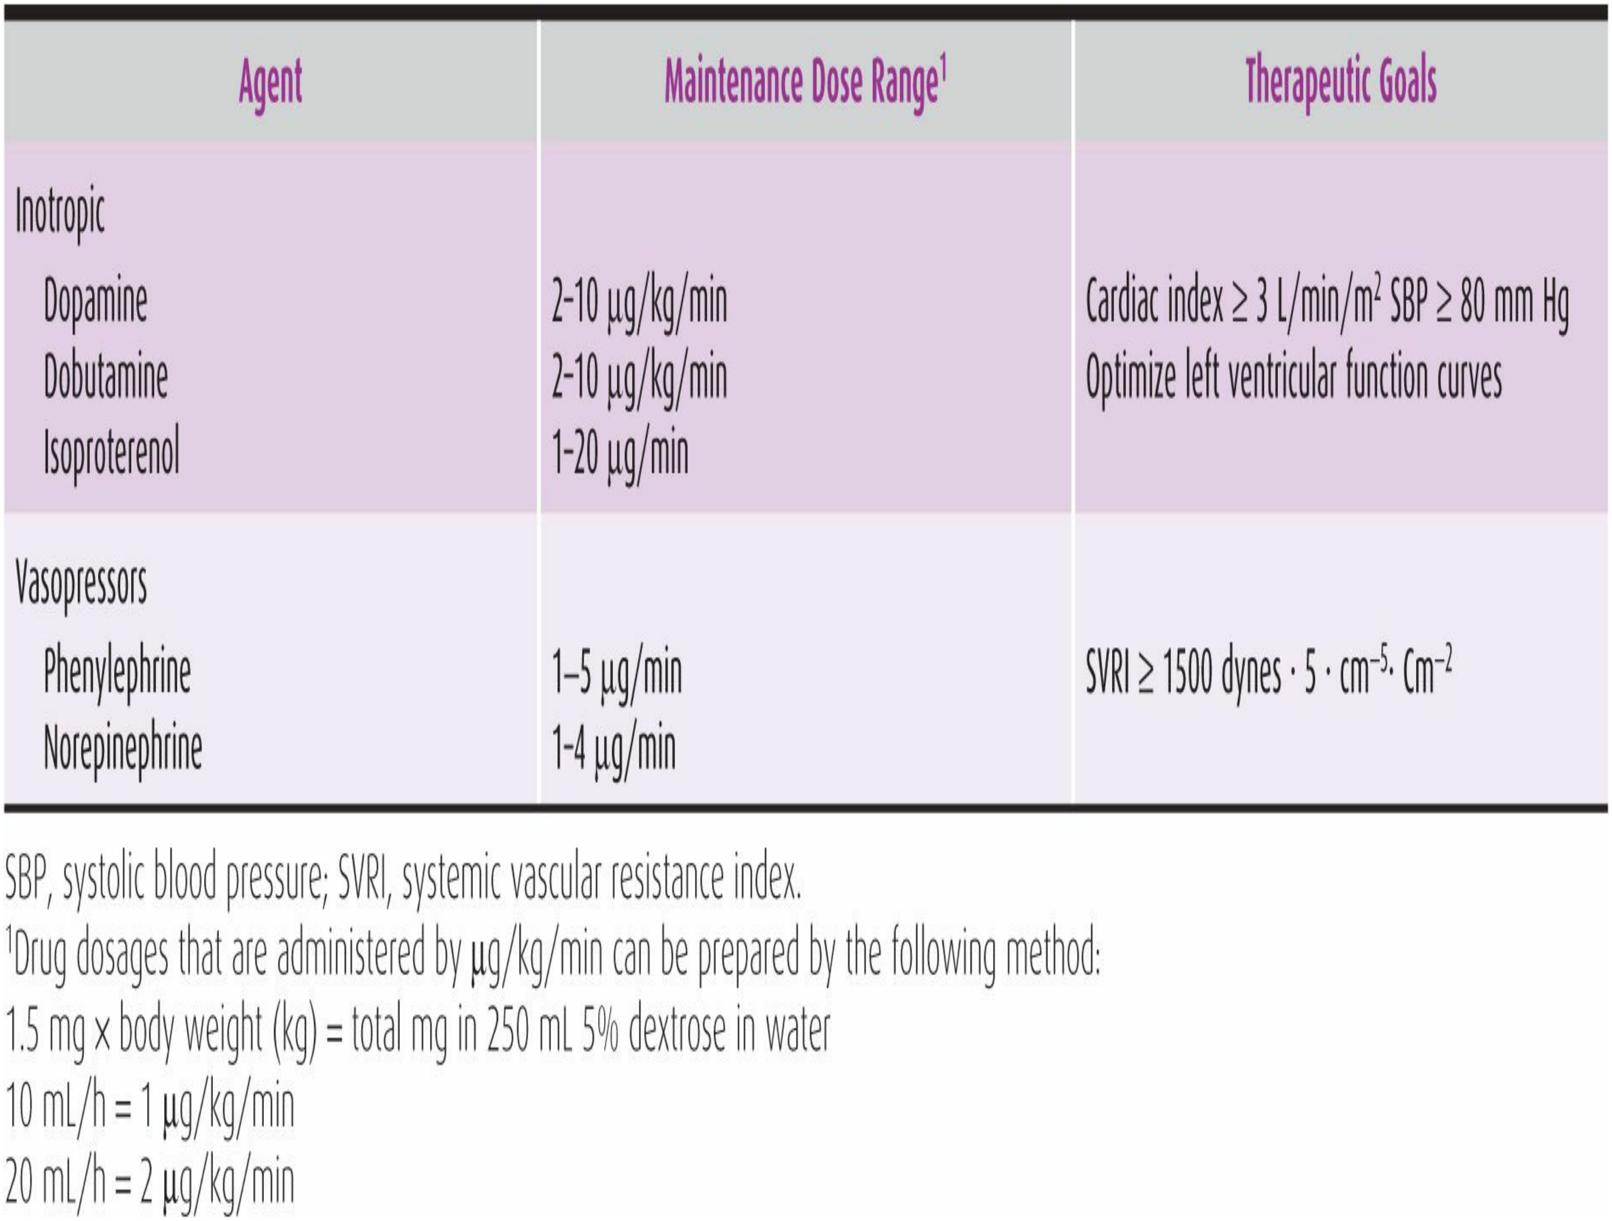
Aggressive treatment of obstetric septic shock must rapidly and effectively reverse organ hypoperfusion, improve oxygen delivery, and correct acidosis. Priority should be given to cardiopulmonary support with the additional understanding that other major organ systems can also be severely affected.

A sequential hemodynamic approach for stabilizing obstetric septic shock with volume repletion, inotropic therapy, and peripheral vasoconstrictors is recommended. Volume therapy initially begins with 1–2 L of lactated Ringer’s solution infused over approximately 15 minutes. However, it is important that volume infusion not be withheld in a hypotensive patient pending placement of a pulmonary artery catheter. The total amount of crystalloid administered should be guided by the presence or absence of maternal hypoxemia secondary to pulmonary edema and left ventricular filling pressures, as estimated by PCWP.

In general, myocardial performance will be optimized according to the Starling mechanism at a PCWP of 14–16 mm Hg. Such preload optimization is mandatory before the initiation of inotropic therapy. Blood component therapy can also be an important adjunctive measure if the patient has experienced significant hemorrhage and has developed an associated coagulopathy.

If the shock state persists despite volume replacement and adequate hemostasis, efforts should be directed toward improving myocardial performance and vascular tone. Inotropic agents such as dopamine, dobutamine, or isoproterenol are excellent choices for improving myocardial contractility in an obstetric patient with a failing heart (Table 23–4). We recommend dopamine as the first-line drug of choice for treating septic hypotension when inotropic therapy is indicated. This substance is a chemical precursor of norepinephrine that has alpha-adrenergic, beta-adrenergic, and dopaminergic receptor stimulating actions. The dopamine infusion is initiated at 2–5 μg/kg/min and titrated against its effect on improving cardiac output and blood pressure in patients with obstetric septic shock. At low doses (0.5–5.0 μg/kg/min), this sympathomimetic amine acts primarily on the dopaminergic receptors, leading to vasodilation and improved perfusion of the renal and mesenteric vascular beds. Higher dopamine doses (5.0–15.0 μg/kg/min) are associated with predominant effects on the β receptors of the heart. The beta-adrenergic effects are responsible for improved myocardial contractility, stroke volume, and cardiac output. Much higher dopamine dosages (15–20 μg/kg/min) will elicit an alpha-adrenergic effect, similar to a norepinephrine infusion, and result in generalized vasoconstriction. Vasoconstrictive action associated with high doses of infused dopamine can actually be detrimental to organ perfusion and will rarely be useful under these clinical circumstances. Although myocardial performance after dopamine therapy is best evaluated by ventricular function curves, it is reasonable to maintain a systemic cardiac index above 3 L/min/m^2.

Table 23–4. Sympathomimetic and vasopressor drugs useful for therapy of obstetric septic shock.



Agent	Maintenance Dose Range[1]	Therapeutic Goals
Inotropic		
Dopamine	2-10 μg/kg/min	Cardiac index ≥ 3 L/min/m^2 SBP ≥ 80 mm Hg
Dobutamine	2-10 μg/kg/min	Optimize left ventricular function curves
Isoproterenol	1-20 μg/min	
Vasopressors		
Phenylephrine	1–5 μg/min	SVRI ≥ 1500 dynes · 5 · cm^{-5}· Cm^{-2}
Norepinephrine	1-4 μg/min	

SBP, systolic blood pressure; SVRI, systemic vascular resistance index.

[1] Drug dosages that are administered by μg/kg/min can be prepared by the following method:
1.5 mg x body weight (kg) = total mg in 250 mL 5% dextrose in water
10 mL/h = 1 μg/kg/min
20 mL/h = 2 μg/kg/min

If satisfactory ventricular function is not achieved with dopamine, a second inotropic agent such as dobutamine (2–20 μg/kg) should be added to the dopamine regimen. Dobutamine is a direct myocardial β_1 stimulant that increases cardiac output with only minimal tachycardia. Isoproterenol should be considered a third-line agent, which can be titrated at 1–20 μg/min. This drug acts primarily on beta-adrenergic receptors to increase contractility and heart rate. However, potential side effects may include ventricular ectopy, excessive tachycardia, and undesired vasodilatation. Digoxin is commonly added to the previously described regimen to improve the force and velocity of myocardial contraction. This agent is given in a loading dose of 0.5 mg IV, followed by 0.25 mg every 4 hours for a total dose of 1.0 mg. IV digoxin should be given under continuous ECG monitoring with special attention to serum potassium levels. The usual maintenance dosage during pregnancy is 0.25–0.37 mg/dL depending on plasma drug levels.

A peripheral vasoconstrictor may be initiated if there is a reduced systemic vascular resistance index (SVRI; less than 1500 dynes · s · cm^{-5}) accompanied by a systolic blood pressure of less than 80 mm Hg despite inotropic therapy. It should be emphasized that maintenance of afterload appears to be a major hemodynamic determinant associated with maternal survival. Because of its pure alpha-adrenergic activity (which increases SVR), phenylephrine (1–5 μg/kg/min) is the initial drug of choice. Norepinephrine is only indicated for septic shock patients with decreased afterload who do not respond to volume loading, inotropic therapy, and phenylephrine. This drug is a mixed adrenergic agonist with a primary effect on the alpha receptors, which leads to generalized vasoconstriction and increased SVR. Although the therapy of septic shock should focus primarily on stabilization of maternal factors, vasopressor agents should be administered cautiously during pregnancy because they have been reported to decrease uterine blood flow in animals with experimentally induced spinal hypotension.

Some investigators have advocated large doses of corticosteroids for the acute management of septic shock, but human clinical trials have failed to demonstrate any conclusive benefit.

Newer investigational agents include corticosteroids and antiendotoxin therapy. Multicenter trials of endotoxin antibodies have suggested a possible improvement in mortality rate and organ failure in some subgroups of nonpregnant septic patients.

Prognosis

Despite all medical and surgical therapeutic options, the overall maternal mortality rate in septic shock is approximately 50%. The prognosis is worsened by the presence of ARDS or preexisting medical problems.

AMNIOTIC FLUID EMBOLISM

ESSENTIALS OF DIAGNOSIS

- Sudden, unexplained peripartum respiratory distress, cardiovascular collapse, and coagulopathy
- Bleeding secondary to coagulopathy or uterine atony (common)
- Amniotic fluid debris in right side of the heart on autopsy

---

Pathogenesis

Amniotic fluid embolism is a rare but potentially devastating complication of pregnancy that often results in poor obstetric outcome. Most of the information about amniotic fluid embolism has been derived from clinical reports, because the rarity of the disorder does not allow for clinical trials, and no suitable animal model exists. The first major review of the literature regarding this condition was by Morgan in 1979. This evaluated 272 cases. Since that time, a national registry was initiated by Clark. The incidence of amniotic fluid embolism is difficult to estimate and may be anywhere from 1 in 8000 to 1 in 30,000.

The basic mechanism of disease is related to the effects of amniotic fluid on the respiratory, cardiovascular, and coagulation systems. One of the classic theories hypothesized that the following 3 primary acute events occur: (1) pulmonary vascular obstruction, leading to sudden decreases in left ventricular filling pressures and cardiac output; (2) pulmonary hypertension with acute cor pulmonale; and (3) ventilationperfusion inequality of lung tissue, leading to arterial hypoxemia and its metabolic consequences.

Only a small volume of amniotic fluid (1–2 mL) is transferred to the maternal circulation during normal labor. Thus enhanced communication between the amniotic fluid sac and the maternal venous system is necessary for amniotic fluid embolism to occur. Sites of entry may include endocervical veins lacerated during normal labor, a disrupted placental implantation site, and traumatized uterine veins. Squamous cells and trophoblastic tissue are often found in the maternal pulmonary vasculature of patients who underwent pulmonary artery catheterization. However, one must see more specific material such as mucin, fetal debris, vernix, lanugo, and squamous cells coated with white blood cells and granular debris to confirm the diagnosis. If meconium is present, a more dramatic response is seen. Fetal demise has also been shown to worsen this condition. Once amniotic debris enters the venous system, it travels rapidly to the cardiopulmonary circulation, leading to shock and arterial hypoxemia. Myocardial dysfunction may result from ischemic injury or right ventricular dilatation. Some experimental evidence suggests that amniotic fluid may have a direct myocardial depressant effect. Endothelin, a vasoconstrictive peptide found in vascular endothelial cells, has been implicated. Other factors that may play a role include proteolytic enzymes, histamine, prostaglandins, complement, and biogenic amines (eg, serotonin). These mediators are seen in other shock states such as sepsis and anaphylaxis, leading Clark to suggest that amniotic fluid embolism be termed “anaphylactoid syndrome of pregnancy.” The effects of systemic hypotension and hypoxemia may lead to cardiopulmonary collapse, renal insufficiency, hepatic failure, seizures, and coma.

Amniotic fluid embolism is almost always associated with some form of DIC. The etiology of coagulopathy associated with amniotic fluid embolism is incompletely understood, but it is known that amniotic fluid has potent total thromboplastin and antifibrinolytic activity, both of which increase with advancing gestational age. Once clotting is triggered in the pulmonary vasculature, local thrombin generation can cause vasoconstriction and microvascular thrombosis.

Limited hemodynamic observations with pulmonary artery catheterization suggest that in humans with amniotic fluid embolism, left ventricular dysfunction is the only significant hemodynamic alteration that is consistently documented. The response to amniotic fluid embolus in humans may be biphasic, initially resulting in intense vasospasm, severe pulmonary hypertension, and hypoxia. The transient period of right heart failure with hypoxia is later followed by a secondary phase of left heart failure, as reflected by elevated pulmonary artery pressure with subsequent return of right heart function. This biphasic theory may account for the extremely high maternal mortality rate within the first hour (25–34%) and explains why pulmonary hypertension can be difficult to document in patients with this disorder.

Clinical Findings

A. Symptoms and Signs

In his classic review of 272 patients with amniotic fluid embolus, Morgan characterized the main presenting clinical features: 51% presented with respiratory distress and cyanosis, 27% with hypotension, and only 10% with seizures. The Clark national registry noted 30% of patients presented with seizures or seizure-like activity, 27% with dyspnea, 17% with fetal bradycardia, and 13% with hypotension. Between 37% and 54% of patients exhibited an associated bleeding diathesis. Risk factors identified in the Morgan study included multiparity, tumultuous labor, or tetanic uterine contractions. Other studies have noted risk factors including advanced maternal age, use of uterine stimulants, caesarean section, uterine rupture, high cervical lacerations, premature separation of the placenta, and intrauterine fetal demise. Clark, however, was unable to identify any notable risk factors. Other presenting signs that have been described include tachypnea, peripheral cyanosis, bronchospasm, and chest pain.

B. Laboratory Findings

Arterial blood oxygen tension typically indicates severe maternal hypoxemia. This hypoxemia may result from ventilationperfusion inequality with atelectasis and associated pulmonary edema. The diagnosis of significant coagulopathy is manifested by the presence of microangiopathic hemolysis, hypofibrinogenemia, prolonged clotting times, prolonged bleeding time, and elevated fibrin split products. The chest radiograph is nonspecific, although pulmonary edema is often noted. The ECG typically reveals unexplained tachycardia, nonspecific ST- and T-wave changes, and a right ventricular strain pattern. Lung scans occasionally identify perfusion defects resulting from amniotic fluid embolism even though chest radiographic findings are normal.

Differential Diagnosis

Many conditions may mimic the effects of amniotic fluid embolism on the respiratory, cardiovascular, and coagulation systems. Pulmonary thromboembolism can result in severe hypoxemia with pulmonary edema. In contrast to amniotic fluid embolism, chest pain is a relatively common finding. Congestive heart failure due to fluid overload or preexisting heart disease may mimic the cardiorespiratory compromise observed during amniotic fluid embolism. Hypotension may result from several disorders, including septic chorioamnionitis or postpartum hemorrhage. Pulmonary aspiration (Mendelson’s syndrome) is associated with tachycardia, shock, respiratory distress, and production of a frothy pink sputum, but is usually also associated with bronchospasm and wheezing. Other conditions in the differential diagnosis include air embolism, myocardial infarction, anaphylaxis, placental abruption, eclampsia, uterine rupture, transfusion reaction, and local anesthesia toxicity.

Treatment

Amniotic fluid embolism remains one of the most devastating and unpreventable conditions complicating pregnancy. Therapeutic measures are supportive and should be directed toward minimizing hypoxemia with supplemental oxygen, maintaining blood pressure, and managing associated coagulopathies. Patients with poor oxygenation often require intubation and positive end-expiratory pressure. Adequate oxygenation will minimize related cerebral and myocardial ischemia and acidosis-induced pulmonary artery vasospasm. Pulmonary artery catheterization should be considered in the absence of coagulopathy to guide inotropic therapy with dopamine. If invasive hemodynamic monitoring is not available, rapid digitalization should be considered. Finally, the development of consumptive coagulopathy may require replacement of depleted hemostatic components in cases with significant uncontrollable bleeding or abnormal clotting parameters.

Prognosis

Maternal mortality rates range from 60–80%; however, a recent study quoted a 26.4% mortality rate. Of those patients who do not survive, 25% die within the first hour, and 80% within the first 9 hours. Correspondingly high perinatal morbidity and mortality rates would be expected.

PULMONARY THROMBOEMBOLISM

ESSENTIALS OF DIAGNOSIS

- Unexplained chest pain and dyspnea (most frequent presenting symptoms)
- History of pulmonary embolism, deepvenous thrombosis, prolonged immobilization, or recent surgery
- Physical examination: usually nonspecific, depending on extent of cardiopulmonary involvement, but may include tachycardia, wheezing, pleural friction rub, and pulmonary rales
- Laboratory evaluation: decreased arterial blood oxygen tension to less than 90 mm Hg in the sitting position
- Diagnostic studies: pulmonary radionuclide ventilationperfusion scanning, spiral computed tomography, and angiography

---

Pathogenesis

Pulmonary thromboembolism is a rare complication of pregnancy (0.09%) but is a significant cause of maternal morbidity and mortality. Mortality has been documented as 12.8% if untreated and 0.7% if therapy is instituted. The diagnosis of deepvenous thrombosis (DVT) occurs in the antepartum period approximately half the time and is evenly distributed throughout each trimester. Pulmonary embolism has a higher incidence in the postpartum period. Predisposing factors commonly include advanced maternal age, obesity, traumatic delivery, abdominal delivery, thrombophlebitis, and endometritis. Patients with underlying thrombophilias or previous thrombotic events are at greater risk for this condition.

More than 100 years ago, Virchow postulated that the basic mechanism of thrombus formation is related to a combination of vessel injury, vascular stasis, and alterations in blood coagulability. Venous thrombi consist of fibrin deposits and red blood cells with varying amounts of platelet and white blood cell components. In most cases, lower extremity and pelvic thrombi are responsible for the pathologic sequelae.

Ordinarily, the vascular endothelium does not react with either platelets or the blood coagulation system unless it is disrupted by vessel injury. Such injury exposes subendothelial cells to blood elements responsible for activation of the extrinsic coagulation cascade. Disruption of the vascular endothelium may occur during traumatic vaginal delivery or caesarean section.

Pregnancy is associated with venous stasis, especially in the lower extremities, because the enlarging uterus reduces blood return to the inferior vena cava by direct mechanical effects. Hormonal factors may also contribute to vasodilatation and stasis during pregnancy. Stasis prevents the hepatic clearance of activated coagulation factors and minimizes mixing of these factors with their serum inhibitors. In this manner, venous stasis becomes another predisposing factor for the formation of thrombi. Stasis secondary to prolonged bedrest for medical or obstetric complications will predispose a pregnant woman to increased venous stasis and formation of vascular thrombi. The period of greatest risk for thrombosis and embolism appears to be the immediate postpartum, especially after caesarean delivery.

The maternal circulation becomes hypercoagulable from alterations in the coagulation and fibrinolytic systems. Serum concentrations of most coagulation proteins, such as fibrinogen and factors II, VII, VIII, IX, and X, increase during pregnancy. These changes are also associated with decreased fibrinolytic activity, which is responsible for the conversion of plasminogen to the active proteolytic enzyme plasmin.

Women with congenital or acquired thrombophilias are at increased risk for thrombosis; in fact, up to half of women who have these events in pregnancy may have an underlying disorder. The most commonly recognized thrombophilia in the white population is factor V Leiden mutation (5%). Other less common but significant disorders include prothrombin gene mutation G20210A (2–4%), antithrombin III deficiency (0.02–0.2%), protein C deficiency (0.2–0.5%), protein S deficiency (0.08%), and hyperhomocysteinemia (1%). The antiphospholipid antibody syndrome also significantly increases maternal risk of thromboembolism and other pregnancy complications.

Once a venous thrombus is formed, it may dislodge from its peripheral vascular origin and enter the central maternal circulation. Propagation of the original venous clot or recurrent pulmonary emboli are possible. DVTs limited to the calf rarely embolize, but approximately 20% extend to the proximal lower extremity.

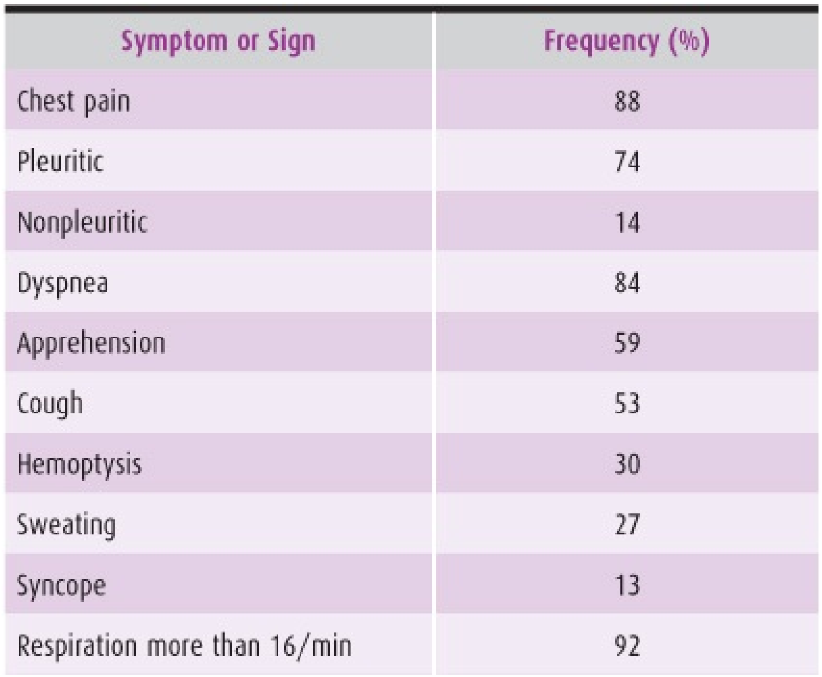
Clinical Findings

A. Symptoms and Signs

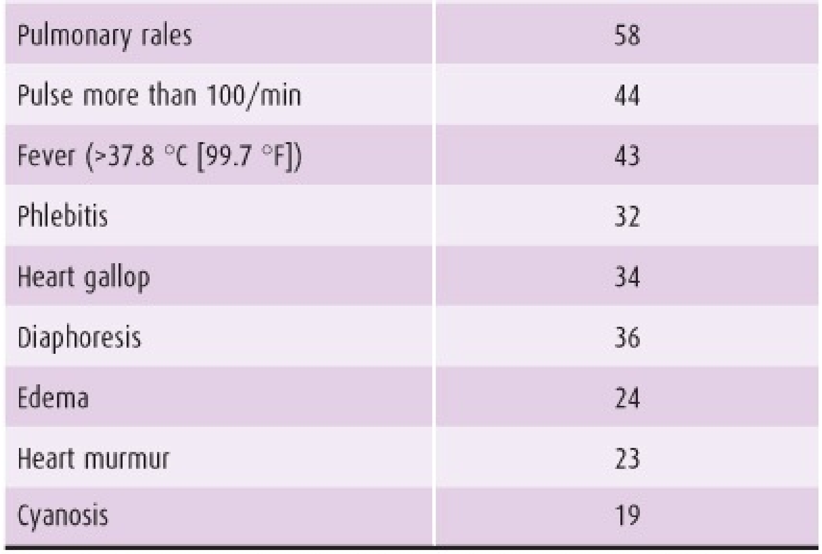
The subsequent cardiopulmonary effects of pulmonary embolus will depend on the location and size of thrombi in the lung. A patient with a large embolus affecting the central pulmonary circulation may present with acute syncope, respiratory distress, and shock. Smaller emboli may not have significant clinical sequelae.

No single symptom or combination of symptoms is sensitive or specific for the diagnosis of pulmonary embolus. Classic triads (hemoptysis, chest pain, and dyspnea; or dyspnea, chest pain, and apprehension) are rarely seen (Table 23–5). Chest pain and dyspnea were the most common symptoms in patients with angiographically documented pulmonary emboli (more than 80%). Physical findings include tachycardia, tachypnea (rate >16/min), pulmonary rales, wheezing, and pleural friction rub.

Table 23–5. Symptoms and signs in 327 patients with pulmonary embolus confirmed by angiography.



Symptom or Sign	Frequency (%)
Chest pain	88
Pleuritic	74
Nonpleuritic	14
Dyspnea	84
Apprehension	59
Cough	53
Hemoptysis	30
Sweating	27
Syncope	13
Respiration more than 16/min	92



Pulmonary rales	58
Pulse more than 100/min	44
Fever (>37.8 °C [99.7 °F])	43
Phlebitis	32
Heart gallop	34
Diaphoresis	36
Edema	24
Heart murmur	23
Cyanosis	19

B. Laboratory Findings

There are no specific routine laboratory findings associated with the diagnosis of pulmonary embolus, although arterial blood gas measurements will often reveal significant hypoxemia. In the upright position, almost all healthy young pregnant women will have an arterial blood oxygen tension greater than 90 mm Hg. An alveolar-atrial (A-a) gradient of greater than 20 is suspicious for pulmonary embolus. The ECG may reveal unexplained tachycardia associated with cor pulmonale (right axis deviation, S wave in lead I, Q wave plus T wave inversion in lead III). A chest roentgenogram may be normal or may show infiltrates, atelectasis, or effusions. Thirty percent of patients with a pulmonary embolus will have a normal chest x-ray.

It is generally accepted that a normal radionuclide perfusion study can effectively rule out pulmonary embolus. Perfusion studies are occasionally equivocal, and ventilation scanning may be required to clarify the diagnosis. Ventilation scanning will improve the specificity of the perfusion study, because this will rule out airway disorders that may be responsible for reduced pulmonary perfusion. The radiation exposure is minimal (<0.1 rad). Unfortunately, a V/Q scan can only confirm a diagnosis if it is normal or indicates high probability of embolus. Therefore, 40–60% of patients will require further testing.

Spiral computed tomography (CT) is a newer form of imaging that has a sensitivity and specificity of 94% in the nonpregnant patient. Spiral CT may also be helpful in detecting other abnormalities causing pulmonary symptoms (eg, pleural effusions, consolidation, emphysema, pulmonary masses). However, this study may miss emboli below the segmental level. Magnetic resonance imaging has limited value in diagnosing pulmonary embolism in pregnancy because it has not been well studied.

If the previously mentioned studies are equivocal, pulmonary angiography should be considered. Subsequent exposure of the fetus to the relatively low levels of ionizing radiation from angiography can be minimized with appropriate pelvic shielding and selective angiography on the basis of prior radionuclide scanning.

Noninvasive Doppler should be considered as an initial diagnostic test for suspected DVT involving the lower extremities. Compression ultrasound uses firm compression with the transducer probe to detect intraluminal filling defects. Imaging is most useful for the distal iliac, femoral, and popliteal veins. Doppler is also useful for the proximal iliac veins. Sensitivity is 95%, with a 96% specificity. Impedance plethysmography measures impedance flow with pneumatic cuff inflation.

Sensitivity and specificity are 83% and 92%, respectively. Compression of the inferior vena cava by the gravid second- or third-trimester uterus may cause false-positive results.

If the above noninvasive tests are inconclusive, it may be helpful to confirm the extent of the original thrombotic event by venography with pelvic shielding. The soleal calf sinuses and the valves involving the popliteal and femoral veins are the sources of most deep venous thrombi. Venography is associated with induced phlebitis in approximately 3–5% of procedures performed. Radiofibrinogen methods to detect thrombus formation will result in placental transfer of radioactive iodine and are contraindicated in pregnant or nursing women.

Differential Diagnosis

Any condition potentially related to cardiopulmonary compromise during pregnancy should be included in the differential diagnosis. This includes amniotic fluid and air emboli, spontaneous pneumothorax, septic shock, and preexisting heart disease.

Treatment

A. Preventive Treatment

Once predisposing risk factors to pulmonary embolus are identified, it is important to minimize the possibility of further complications. In patients at higher risk for DVT, prophylactic measures should be directed toward preventing venous stasis that leads to clot formation. Mechanical maneuvers such as raising the lower extremities 15 degrees above the horizontal, keeping the legs straight rather than bent at the knees when sitting, or performing calf flexion exercises may be useful, as may external pneumatic compression. One method used to prevent perioperative thrombophlebitis includes minidose heparin prophylaxis, 5000 U subcutaneously 2 hours before surgery and every 12 hours until routine ambulation is achieved. Minidose heparin prophylaxis significantly decreases not only the incidence of DVT but also the incidence of fatal pulmonary emboli. Subcutaneous minidose heparin may be reinstituted approximately 6 hours after delivery. Postpartum or postoperative ambulation is important in minimizing thromboembolic complications during this high-risk period. Some women may require therapeutic anticoagulation during pregnancy to prevent a thromboembolic event. Included in this category are women with artificial heart valves, antithrombin III deficiency, antiphospholipid antibody syndrome, history of rheumatic heart disease and atrial fibrillation, homozygosity for factor V Leiden or prothrombin gene mutation, and recurrent thromboembolic disease. Therapeutic anticoagulation can be achieved by using subcutaneous heparin 2–3 times a day, adjusting for a PTT of 2.0–3.0 times normal. Low molecular weight heparin (LMWH) can also be used. LMWH does not cross the placenta, and it has been shown to be relatively safe in pregnancy. In addition, complications of heparin therapy (osteoporosis, thrombocytopenia) are less common with this medication, and dosing in pregnancy usually may require fewer adjustments. The PTT does not need to be followed; instead, peak antifactor Xa levels can be checked every 4–6 weeks. It is controversial whether other disorders, such as protein C or S deficiency, or a family history of thrombophilias, require anticoagulation therapy. These patients may benefit from minidose heparin prophylaxis. LMWH can also be used for prophylaxis. The typical dose is either weight-based or empiric.

B. Treatment of Documented Pulmonary Embolism

Once pulmonary embolism is documented, therapeutic intervention should be directed to correction of arterial hypoxemia and any associated hypotension. Other measures should prevent clot propagation or recurrent emboli. Supplemental oxygen should be given to achieve an arterial oxygen tension of at least 70 mm Hg. A loading dose of 5000–10,000 U of heparin should be given intravenously by continuous infusion, followed by a maintenance dose of approximately 1000 U/h. The PTT should be maintained at 1.5–2.5 times control values. Other investigators recommend the use of heparin levels for monitoring anticoagulation therapy. Heparin levels may be measured on the third or fourth day and should be approximately 0.2 μg/mL, not to exceed 0.4 μg/mL. Alternatively, LMWH can also be used for therapeutic anticoagulation. Leg elevation, bedrest, and local heat will be beneficial to patients who have associated DVT. Intravenous morphine may be helpful in alleviating anxiety and ameliorating chest pain.

Intrapartum care of pulmonary embolus is complicated, and individual treatment approaches may vary. Selected patients with recent pulmonary thromboembolism, ileo-femoral DVT, or heart valve prosthesis should probably continue full anticoagulation with high-dose heparin during labor or surgical procedures. Under these circumstances, the risk for potential bleeding complications from anticoagulant needs to be balanced against the risk of thromboembolism. Although there is a higher incidence of wound hematomas associated with peripartum anticoagulation, there is no clear evidence that this regimen is associated with excessive postpartum hemorrhage after normal vaginal delivery.

Postpartum patients receiving heparin may be switched over to warfarin once oral intake is tolerated. Warfarin is considered safe during breastfeeding. Heparin should be continued for the first 5–7 days of warfarin therapy. By the time heparin is discontinued, the international normalized ratio should be 2.0–3.0 times the normal value. Alternatively, it may be desirable to continue moderate doses of subcutaneous heparin (10,000 U twice daily) or LMWH. Postpartum anticoagulation should be continued for at least 3 months if the patient developed pulmonary embolus in the third trimester.

C. Complications of Treatment

The major complication of anticoagulant therapy is maternal or fetal hemorrhage. Heparin does not cross the placenta due to its large molecular weight, but it has been associated with maternal thrombocytopenia and osteoporosis. These effects can be reduced with LMWH. Warfarin is known to cross the placental barrier, and its use in the first trimester has been associated with embryopathy (nasal hypoplasia and stippled epiphyses) in approximately 5–8% of fetuses. Fetal nervous system abnormalities (eg, hydrocephalus) have also been noted with the use of warfarin during pregnancy.

A small percentage of patients will experience recurrent pulmonary emboli despite full anticoagulation. These patients may be candidates for vena caval ligation by a transabdominal approach under general or regional anesthesia. If the pelvis is suspected as the source of embolus, the right ovarian vein should also be ligated. It has been estimated that approximately 95% of patients with pulmonary embolism massive enough to cause hypotension eventually die. In this context, pulmonary artery embolectomy may be life-saving.

Placement of a vena caval umbrella via the internal jugular vein is an option for unstable patients with recurrent emboli who would not be prime surgical candidates. Although abdominal radiography is required for this procedure, placement of the umbrella filter does not require general anesthesia. This strategy will prevent larger emboli from reaching the pulmonary circulation.

Prognosis

Pulmonary embolus, with a mortality rate of 12–15% if left untreated, will develop in approximately one-fourth of untreated patients with antenatal DVT. In a review of pregnancies complicated by DVT treated with anticoagulant therapy, the incidence of pulmonary embolus was 4.5% of patients, with a maternal mortality rate of less than 1%.

DISSEMINATED INTRAVASCULAR COAGULATION

ESSENTIALS OF DIAGNOSIS

- History of recent bleeding diathesis, especially concurrent with placental abruption, amniotic fluid embolism, fetal demise, sepsis, preeclampsia–eclampsia, or saline abortion.
- Clinical evidence of multiple bleeding points associated with purpura and petechiae on physical examination.
- Laboratory findings classically include thrombocytopenia, hypofibrinogenemia, and elevated PT, elevated D-dimer, and fibrin split products that do not easily correct with replacement.

Pathogenesis

DIC is a pathologic condition associated with inappropriate activation of coagulation and fibrinolytic systems. It should be considered a secondary phenomenon resulting from an underlying disease state. The most common obstetric conditions associated with DIC are intrauterine fetal death, amniotic fluid embolism, pre-eclampsia-eclampsia, HELLP (hemolysis, elevated liver enzymes, and low platelet count syndrome), placenta previa, and placental abruption. Saline-induced abortion is also a cause. It is a separate condition from dilutional coagulopathy, which often follows hemorrhage and volume replacement with crystalloid and red blood cells. Dilutional coagulopathy represents a diminished amount of factors and can be easily corrected b replacing these factors. DIC, however, represents a cascade of events leading to the activation of the coagulation cascade and continued consumption of the clotting factors.

The most widely accepted theory of blood coagulation entails a “cascade theory” (Fig. 23–7). Basically, the coagulation system is divided into intrinsic and extrinsic systems. The intrinsic system contains all the intravascular components required to activate thrombin by sequential activation of factors XII, XI, IX, X, V, and II (prothrombin). The extrinsic system is initially activated by tissue thromboplastin, leading to sequential activation of factors VII, X, V, and prothrombin. Both the intrinsic and extrinsic pathways converge to activate factor X, which subsequently reacts with activated factor V in the presence of calcium and phospho-lipid to convert prothrombin to thrombin.

Figure 23–7. Coagulation cascade mechanism.

Thrombin is a proteolytic enzyme responsible for splitting fibrinogen chains into fibrinopeptides, leading to the formation of fibrin monomer. This central enzyme is capable of activating factor XIII to stabilize the newly formed fibrin clot and will enhance the activity of factors V and VIII.

Activation of the coagulation system also stimulates the conversion of plasminogen to plasmin as a protective mechanism against intravascular thrombosis. Plasmin is an enzyme that inactivates factors V and VIII and is capable of lysing fibrin and fibrinogen to form degradation products. Thus the normal physiologic hemostatic mechanism represents a delicate and complex balance between the coagulation and fibrinolytic systems.

Pregnancy is considered to represent a hypercoagulable state. With the exception of factors XI and XIII, there is an overall increase in the activity of coagulation factors. Fibrinogen rises as early as 12 weeks' gestation and reaches a peak level of 400–650 mg/dL in late pregnancy. The fibrinolytic system is depressed during pregnancy and labor but returns to normal levels within 1 hour of placental delivery. The early puerperium is accompanied by a secondary rise in fibrinogen, factors VIII, IX, X, and anti-thrombin III; a return to nonpregnant levels occurs by 3–4 weeks postpartum.

The complex pathophysiology of DIC is characterized by (1) procoagulant system activation, (2) fibrinolytic system activation, (3) inhibitor consumption, (4) cytokine release, (5) cellular activation, and (6) resultant end-organ damage. DIC occurs as a secondary event in a wide variety of illnesses associated with excess production of circulating thrombin. The pathophysiologic factors responsible for inappropriate activation of the clotting mechanism include endothelial cell injury, liberation of thromboplastin from injured tissue, and release of phospholipid from red cell or platelet injury. All these mechanisms may contribute to development of a bleeding diathesis resulting from increased thrombin activity. Additionally, widespread DIC will cause increased platelet aggregation, consumption of coagulation factors, secondary activation of the fibrinolytic system, and deposition of fibrin into multiple organ sites, which can result in ischemic tissue damage. The associated thrombocytopenia and presence of fibrin split products will impair hemostasis.

Specific obstetric conditions associated with DIC include the following.

A. Placental Abruption

DIC may occur in placental abruption involving liberation of tissue thromboplastin or possible intrauterine consumption of fibrinogen and coagulation factors during the formation of retroplacental clot. This leads to activation of the extrinsic coagulation mechanism. Placental abruption is one of the most common obstetric causes of DIC.

B. Retained Dead Fetus Syndrome

Another cause of DIC is retained dead fetus syndrome involving liberation of tissue thromboplastin from nonviable tissue. This cause is less common in recent years due to advanced ultrasound technology and the earlier detection of this condition.

C. Amniotic Fluid Embolism

This involves not only the release of tissue thromboplastin, but also the intrinsic procoagulant properties of amniotic fluid itself. It is likely that the associated hypotension, hypoxemia, and tissue acidosis will encourage the activation of coagulation factors.

D. Preeclampsia-Eclampsia

This condition is associated with chronic coagulation abnormalities that may lead to thrombocytopenia and elevation of fibrin degradation products. It is uncertain whether endothelial damage activates procoagulant proteins and platelets or the reverse, although the former is more likely. Eclampsia is associated with DIC 11% of the time; with HELLP syndrome this increases to 15%. Preeclampsia together with placental abruption also significantly increases this association.

E. Saline or Septic Abortion

Saline-induced abortion has been associated with subclinical DIC. Severe cases of DIC have occurred in 1 in 400 to 1 in 1000 cases. Disease may be related to the release of tissue thromboplastin from the placenta. Septic abortion may also cause release of tissue thromboplastin or release of bacterial endotoxin (phospholipids).

F. Other

Other triggers of DIC include septicemia, viremias (eg, HIV, varicella, cytomegalovirus, hepatitis), drugs, and acidosis.

Clinical Findings

A. Symptoms and Signs

Acute clinical manifestations of DIC are variable and include generalized bleeding, localized hemorrhage, purpura, petechiae, and thromboembolic phenomena. Also, fever, hypotension, proteinuria, hypoxia, hemorrhagic bullae, acral cyanosis, and frank gangrene have been described. Widespread fibrin deposits may affect any organ system, including the lungs, kidneys, brain, and liver. Chronic DIC (eg, fetal demise) is associated with slower production of thrombin and may be associated with minimal or absent clinical signs and symptoms.

B. Laboratory Findings

Although histologic diagnosis of fibrin deposits is the only definitive manner by which DIC may be confirmed, there are a host of indirect tests suitable for the clinical evaluation of coagulopathy.

1. Platelets—Platelets are decreased (<100,000/μL) in more than 90% of cases. In the absence of other causes, spontaneous purpura usually does not occur when platelet counts are greater than 30,000/μL.

2. Prothrombin time—PT measures the time required for clotting by the extrinsic pathway and is dependent on the ultimate conversion of fibrinogen to fibrin. It is prolonged in only 50–75% of patients with DIC. The explanations for the normal PTs are, first, the presence of circulating activated clotting factors such as thrombin or factor Xa, that accelerate the formation of fibrin; and second, the presence of early degradation products, which are rapidly clottable by thrombin; these may cause the test to register a normal or fast PT.

3. Partial thromboplastin time—PTT is frequently normal in DIC (40–50% of the time) and is not as helpful for establishing the diagnosis. This test measures the function of the intrinsic and final common pathways of the coagulation cascade.

4. Thrombin time (TT)—TT is elevated in 80% of patients with DIC. It is affected only by the amount of circulating fibrinogen or the presence of thrombin inhibitors such as fibrin degradation products and heparin. This test specifically measures the time necessary for conversion of fibrinogen to fibrin.

5. Fibrinogen—Fibrinogen is often decreased, with approximately 70% of patients with DIC having a serum level less than 150 mg/dL. The normal physiologic increase of serum fibrinogen levels during pregnancy may mask a pathologic decrease in this parameter.

6. Fibrin split products—Values greater than 40 μg/mL are suggestive of DIC. These are elevated in 85–100% of patients with DIC. These degradation products are diagnostic of the plasmin biodegradation of fibrinogen or fibrin, so indicate only the presence of plasmin.

7. Clotting time and clot retraction—Observation of clotting time and ability of the clot to retract can be performed by using 2 mL of blood in a 5-mL glass test tube. These are relatively simple bedside tests that can provide qualitative evidence of hypofibrinogenemia. When the clot forms, it is usually soft but not reduced in volume (adding celite will hasten this reaction). Over the next half hour, the clot should retract, with the volume of serum exceeding that of the formed clot. If this phenomenon does not occur, low serum fibrinogen levels can be suspected.

8. Peripheral blood smear—A peripheral blood smear reveals schistocytes in approximately 40% of patients with DIC.

9. Bleeding time—The time required for hemostasis after skin puncture will become progressively prolonged as the platelet count falls below 100,000/μL. Spontaneous continuous bleeding from puncture sites may develop if the platelet count falls below 30,000/μL.

10. Newer tests—Several of these laboratory findings are more reliable than the classic studies.

A. D-DIMER—This is a neoantigen formed as a result of plasmin digestion of cross-linked fibrin when thrombin initiates the transition of fibrinogen to fibrin and activates factor XIII to cross-link the fibrin formed. The test is specific for fibrin (not fibrinogen) degradation products and is abnormal in 90% of cases.

B. ANTITHROMBIN III LEVEL—This is abnormal in 89% of cases.

C. FIBRINOPEPTIDE A—This is abnormal 75% of the time.

Differential Diagnosis

Most acute episodes of generalized bleeding in obstetric patients will be related to pregnancy, but other rare causes of congenital or acquired coagulopathies need to be considered. These include idiopathic thrombocytopenic purpura, hemophilia, and von Willebrand’s disease. Placental abruption is often associated with uterine tenderness, fetal bradycardia, and uterine bleeding. DIC associated with fetal demise usually does not become apparent until at least 5 weeks after the absence of heart tones has been documented. Amniotic fluid embolus is typically associated with acute onset of respiratory distress and shock. Preeclampsia is characterized by hypertension and proteinuria, which may lead to eclamptic seizures.

Complications

In addition to the potential complications of uncontrolled hemorrhage previously discussed, widespread fibrin deposition may affect any major organ system. This may include the liver (hepatic failure), kidneys (tubular necrosis), and lungs (hypoxemia).

Treatment

Although individual measures will be dictated by the specific obstetric condition, the primary, most important treatment of pregnancy-related DIC is correction of the underlying cause. In most cases, prompt termination of the pregnancy is required. Moderate or low-grade DIC may not be associated with clinical evidence of excessive bleeding and often will require close observation but no further therapy.

Supportive therapy should be directed to the correction of shock, acidosis, and tissue ischemia. Cardiopulmonary support, including inotropic therapy, blood replacement, and assisted ventilation, should be implemented with the patient in close proximity to a delivery suite. Fetal monitoring, careful recording of maternal fluid balance, and serial evaluation of coagulation parameters are extremely important. If sepsis is suspected, antibiotics should be employed. Central monitoring with a pulmonary artery catheter is relatively contraindicated due to potential bleeding complications. Vaginal delivery, without episiotomy if possible, is preferable to caesarean section. Failure of improvement in the coagulopathy within several hours after delivery suggests sepsis, liver disease, retained products of conception, or a congenital coagulation defect.

Blood component therapy should be initiated on the basis of transfusion guidelines reported by the National Institutes of Health. Criteria for red cell transfusions were discussed earlier (see Hypovolemic Shock). Fresh-frozen plasma has only limited and specific indications, which include massive hemorrhage, isolated factor deficiencies, reversal of warfarin, antithrombin II deficiency, immunodeficiencies, and thrombocytopenic purpura. Although most cases of severe obstetric hemorrhage will lead to laboratory evidence of coagulation abnormalities, transfusion of fresh-frozen plasma may not always benefit these patients; the amount transfused is usually insufficient for replacing coagulation factors lost by dilution or clot formation. Even with massive obstetric hemorrhage, most procoagulant levels are above 30% of normal values, which is sufficient for maintaining clinical hemostasis in most patients. Specific replacement of fibrinogen should be accomplished by cryoprecipitate. Each unit of cryoprecipitate carries approximately 250 mg of fibrinogen. Platelets should only be administered in the face of active bleeding with a platelet count < 50,000/µL or prophylactically with platelet count 20–30,000/µL or less or after massive transfusion (>2 times blood volume). Platelets should be transfused on the basis of 1 U/10 kg body weight to raise the cell count above 50,000/µL. However, it should be noted that clotting factors containing fibrinogen may be associated with enhanced hemorrhage and also with thrombosis when given to patients with DIC. For this reason, they should be administered with extreme caution. Obstetricians should remember that Rh immune globulin should be given to Rh-negative recipients of platelets from Rh-positive donors.

Subcutaneous low-dose heparin or LMWH may be effective in treating the intravascular clotting process of DIC. Heparin acts as an anticoagulant by activating anti-thrombin III but has little effect on activated coagulation factors. Anticoagulation is contraindicated in patients with fulminant DIC and central nervous system insults, fulminant liver failure, or obstetric accidents. The one instance, however, in which heparin has been demonstrated to benefit pregnancy-related DIC is in the case of the retained dead fetus with an intact vascular system, in which case heparin may be administered to interrupt the coagulation process and thrombocytopenia for several days until safe delivery may be implemented.

Prognosis

Most cases of obstetric DIC will improve with delivery of the fetus or evacuation of the uterus. The maternal and fetal prognosis will be more closely related to the associated obstetric condition than to the coagulopathy.

ACUTE RESPIRATORY DISTRESS SYNDROME (ARDS)

ESSENTIALS OF DIAGNOSIS

- History of gastric aspiration, infection/sepsis, preeclampsia-eclampsia, seizures, hemorrhage, coagulopathy, or amniotic fluid embolism
- Progressive respiratory distress with decreased lung compliance
- Severe hypoxemia refractory to oxygen therapy
- Diffuse infiltrates on chest roentgenogram
- Normal PCWP, with absence of radiographic evidence of congestive heart failure

Pathogenesis

ARDS is a severe form of lung disease with acute onset, characterized by bilateral infiltrates on chest x-ray, no evidence of intravascular volume overload (PCWP no greater than 18 mm Hg), and severely impaired oxygenation, demonstrated by a ratio of arterial oxygen tension (PaO_2) to the fraction of inspired oxygen (FIO_2) of less than 200 mm Hg. ARDS appears to occur more commonly in obstetric patients than in the general population. Its incidence in the nonpregnant population is 1.5 per 100,000, but it has been estimated to occur in between 1 in 3000 and 1 in 10,000 pregnant patients. ARDS has many causes, including gastric aspiration, amniotic fluid embolism, sepsis, coagulopathy, massive blood transfusion, and shock. It can be easily confused with cardiogenic pulmonary edema secondary to alterations in preload, myocardial contractility, or afterload. A basic understanding of the differences between cardiogenic and noncardiogenic pulmonary edema is essential before rational therapeutic intervention may be implemented.

The basic underlying pathologic change responsible for ARDS is lung injury that results in damage to the pulmonary epithelium and endothelial tissue. This, in turn, leads to enhanced vascular permeability. Factors determining the net flux of lung fluid between the capillary lumen and interstitial space are quantitatively related by the Starling equation:

$$\text{Net fluid flux} = \kappa[(\text{Pcap} - \text{Pis}) - (\pi\text{cap} - \pi\text{is})]$$

(k = filtration coefficient, Pcap = pulmonary capillary hydrostatic pressure, Pis = interstitial space hydrostatic pressure, πcap = pulmonary capillary serum colloid osmotic pressure, πis = interstitial space fluid colloid osmotic pressure)

Normally, fluid flows from the capillary system to the interstitial space and is returned to the systemic circulation by the pulmonary lymphatic system. An increase in left atrial pressure is observed when the left ventricle is unable to pump all the returning blood into the left atrium. Accordingly, the pulmonary capillary hydrostatic pressure increases, facilitating net movement of lung fluid into the interstitial space. When capillary fluid efflux into the interstitial space exceeds lymphatic resorption, the clinical presentation of pulmonary edema will occur. Although colloid osmotic pressure in the interstitial space and serum also plays a role in pulmonary edema, the most common factor is increased capillary hydrostatic pressure secondary to increased preload (fluid overload), afterload (severe hypertension), and decreased myocardial contractility (postpartum cardiomyopathy).

Capillary membrane permeability plays a much larger role in the genesis of noncardiogenic pulmonary edema (ARDS). Such injury due to hypoxic ischemia, vasoactive substances, chemical irritation, or microthrombi facilitates further efflux of capillary fluid and plasma proteins into the interstitium. This increase in permeability acutely produces atelectasis and diminished compliance of the lung, and damage is usually nonuniform. As the functional capability of atelectatic bronchioles diminishes, shunting and hypoxemia develop.

Maternal physiologic changes can contribute to the severity of ARDS. It has been suggested that decreased extra-thoracic compliance, decreased functional residual capacity, higher oxygen deficit, limited cardiac output increases, and anemia may adversely affect the clinical presentation and course of ARDS during pregnancy.

Clinical Findings

A. Symptoms and Signs

Classic signs of respiratory distress are tachypnea, intercostal retractions, and even cyanosis, depending on the degree of hypoxemia. Fetal tachycardia or late decelerations may reflect maternal hypoxemia and uteroplacental insufficiency. Pulmonary rales in noncardiogenic pulmonary edema will be indistinguishable from those of cardiogenic pulmonary edema, but physical findings consistent with the cardiogenic disorder (ventricular gallop, jugular venous distention, and peripheral edema) are not typical features of ARDS. Unfortunately, the physiologic changes of pregnancy may mask the significance of these physical findings during the more subtle stages of respiratory distress.

B. Laboratory Findings

Arterial blood gas determinations will reveal a progressive moderate to severe hypoxemia despite oxygen therapy. Depending on the obstetric cause of ARDS, other laboratory findings will be variable or nonspecific. The initial chest roentgenogram will often be normal, even in the presence of clinically significant respiratory distress. Within the next 24–48 hours, patchy or diffuse infiltrates will progress to prominent alveolar infiltrates (Fig. 23–8). Unlike in cardiogenic pulmonary edema, the heart will most likely be of normal size in a patient with ARDS. PCWP measured by right heart catheterization is the procedure most helpful in differentiating ARDS and pulmonary edema. The PCWP is elevated (>20 mm Hg) in cardiogenic pulmonary edema but is often normal in ARDS.

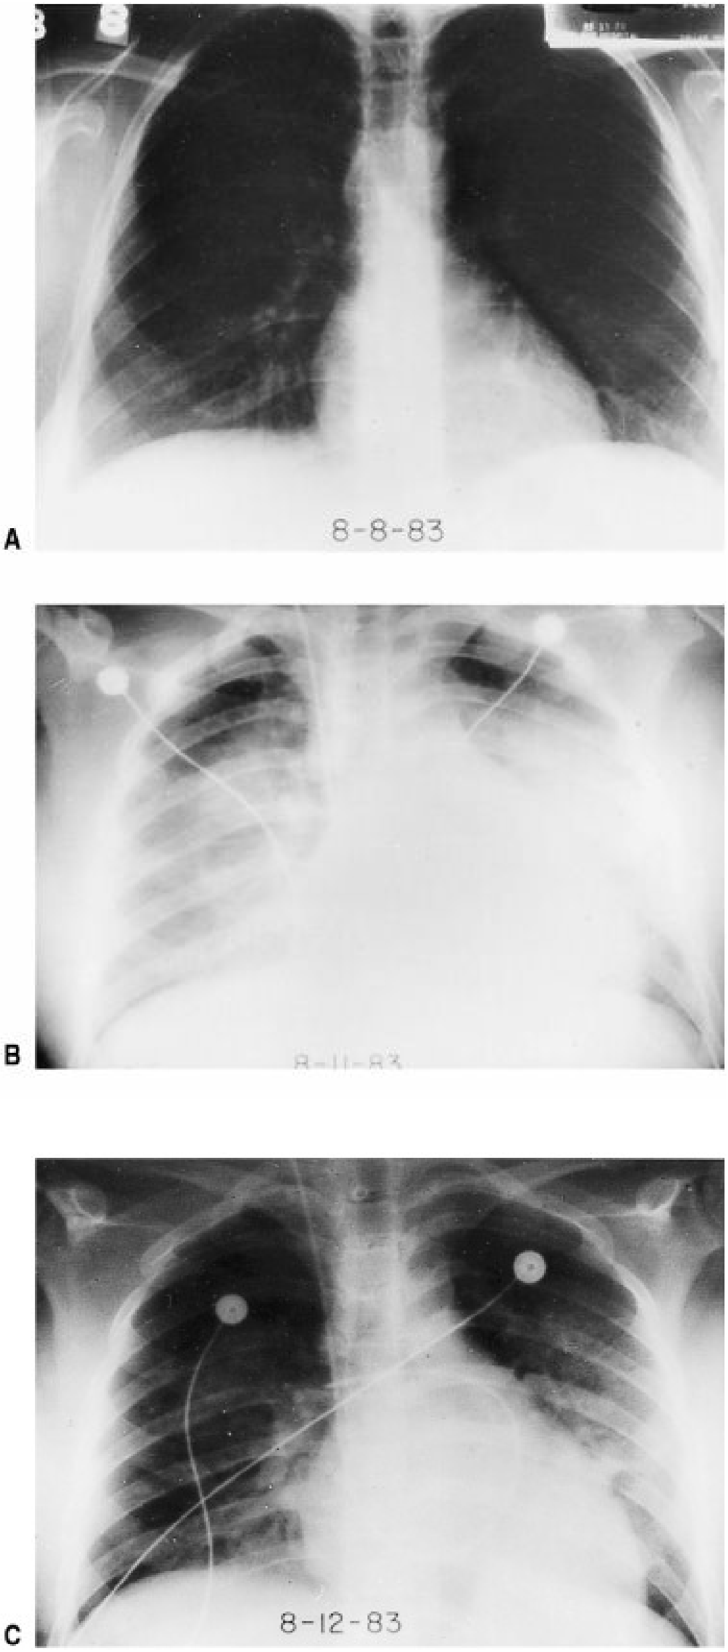

Figure 23–8. Sequence of chest radiographs from a 21-year-old woman during her first pregnancy with antepartum pyelonephritis and acute respiratory distress syndrome (ARDS). **A:** Normal chest film. **B:** Bilateral patchy pulmonary densities have developed, consistent with the diagnosis of ARDS. Much of the apparent increase in heart size is related to shallow inspiration and supine technique. **C:** ARDS has improved dramatically, with only minimal residual pulmonary densities.

Measurement of endobronchial fluid COP has also been used to differentiate capillary permeability-induced pulmonary edema from hydrostatic or cardiogenic pulmonary edema. In pulmonary edema secondary to capillary permeability, the COP of endobronchial fluid obtained from endotracheal tube suctioning is usually greater than 75% of the simultaneously obtained plasma COP. In cardiogenic pulmonary edema, the COP of the endobronchial fluid is usually less than 60% that of plasma.

Histopathologically, idiopathic pulmonary fibrosis and ARDS are remarkably similar. Both show evidence of acute alveolar injury, which is characterized by interstitial inflammation, hemorrhage, and edema. This is followed by a hypercellular phase, loss of alveolar structure, and pulmonary fibrosis.

Differential Diagnosis

ARDS should be differentiated from infectious pneumonitis and cardiogenic causes of pulmonary edema. Cardiogenic pulmonary edema will usually respond more rapidly to diuretic therapy than will ARDS, in which abnormalities in capillary membrane permeability are not quickly resolved by such intervention.

Treatment

Therapy should be directed toward the prevention of hypoxemia, correcting acid–base abnormalities, removal of inciting factors, and hemodynamic support appropriate for the specific cause (eg, amniotic fluid embolus, DIC). Cardiogenic pulmonary edema is usually treated with a combination of diuretics, inotropic therapy, and afterload reduction. If a hemodynamic profile is not immediately available by pulmonary artery catheter, the clinician may elect to begin oxygen and furosemide (20 mg IV) for the presumptive diagnosis of cardiogenic pulmonary edema. By contrast, it should be apparent that the basic therapy for ARDS is supportive. Endotracheal intubation with mechanical ventilation is almost always required. The pulmonary artery catheter will be helpful in guiding fluid management and optimizing cardiac performance. Additionally, mixed venous oxygen saturation from the distal port of the pulmonary artery catheter will provide an index of oxygen utilization.

In obstetric patients, reasonable therapeutic goals for cardiorespiratory support include a mechanical ventilator tidal volume of less than 10 mL/kg, PCWP 8–12 mm Hg, arterial blood oxygen tension greater than 60 mm Hg, and mixed venous oxygen tension greater than 30 mm Hg. If unable to maintain PaO_2 of at least 60 mm Hg on 50% or less inspired oxygen, positive end-expiratory pressure (PEEP) in amounts of up to 15 cm H_2O may be helpful. However, it is important to avoid barotrauma to the remaining functional alveolar units, so high tidal volumes and pressures should be avoided. If the mixed venous tension is low, transfusion of red blood cells or inotropic therapy may improve oxygen transport and delivery.

Since the presence of capillary membrane abnormalities in ARDS is associated with rapid equilibration of proteinaceous material between the capillaries and interstitial spaces, intravenous colloid replacement should be discouraged in lieu of crystalloid resuscitation. A policy of relative fluid restriction should be followed, but only if the following criteria are met: stable fetus, no evidence of metabolic acidosis, normal renal function, and no need for vasopressor therapy or PEEP. Sedation and pain relief should be used liberally and may help to decrease oxygen consumption. Nutritional support for patients on prolonged mechanical ventilation must be considered; enteral feeding is preferred, as it may reduce the translocation of gut bacteria into the body. Prospective controlled studies have not demonstrated the benefit of steroid therapy for ARDS. Once therapy for cardiopulmonary support has been implemented, a thorough search for predisposing factors to ARDS must be identified for specific intervention.

Potential future therapies for ARDS include high-frequency ventilation, extracorporeal membrane oxygenation, intravenous oxygen, inhaled nitric oxide, surfactant replacement, oxygen-free radical scavengers, arachidonic acid metabolite inhibitors, antiprotease agents, antiendotoxin antibodies, anti-tumor necrosis factor antibodies, and other immunologic therapies for sepsis.

The timing of delivery in these patients is unclear from the literature. Based on the high rates of fetal death, preterm labor, fetal heart rate abnormalities, and perinatal asphyxia, most authorities recommend delivery after a gestational age of 28 weeks. In one review, only 10 of 39 patients with antepartum ARDS were discharged undelivered, and all had pylelonephritis or *Varicella*. Caesarean section should be reserved for standard obstetrical indications.

Prognosis

Older series suggested a mortality rate as high as 50–60% for patients with ARDS. More recent reviews show rates of 39–44%. One study of 41 patients demonstrated a 24.4% mortality rate; this has been attributed to possible differences in patient population as well as improvements in critical care. Many affected patients developed pulmonary complications that included barotrauma and pneumothorax. Fortunately, survivors of ARDS usually do not demonstrate permanent long-term pulmonary dysfunction.

Catanzarite V, Willms D, Wong D, et al. Acute respiratory distress syndrome in pregnancy and the puerperium: Causes, courses, and outcome. *Obstet Gynecol* 2001;97:760. PMID: 11339930.

CARDIOPULMONARY ARREST

ESSENTIALS OF DIAGNOSIS

- Cardiopulmonary arrest can be caused by a number of conditions during pregnancy.
- Without treatment, mortality is high for both the patient and the fetus.
- Treatment should follow standard basic and advanced cardiac life support algorithms, with some minor modifications due to pregnancy.
- Perimortem caesarean delivery may assist resuscitation by relieving aortocaval compression and increasing venous return to the heart. If necessary, it should be performed within 5 minutes of arrest for maximal effect.

Pathogenesis

Many of the critical conditions discussed in this chapter can lead to cardiopulmonary arrest. Cardiopulmonary arrest during pregnancy poses a unique challenge in that both the patient and the fetus are acutely at risk of severe morbidity and mortality. The prevalence ranges from 1 in 20,000 to 1 in 50,000 pregnancies, but this prevalence is likely increasing due to the increased prevalence of advanced maternal age and obesity in pregnancy, as well as women with other chronic medical problems becoming pregnant with the assistance of assisted reproductive technologies.

Clinical Findings

Cardiopulmonary arrest in pregnancy presents similar to nonpregnant women, beginning with symptoms such as chest pain, weakness, shortness of breath, and diaphoresis, and eventually leading to cardiac arrest. However, due to the vague nature of some of the early symptoms and overlap with typical symptoms of pregnancy, early warning signs may be missed more frequently in pregnant women.

Differential Diagnosis

The differential diagnosis of cardiopulmonary arrest includes conditions specific to pregnancy, and those present in the general population. The most common causes of cardiopulmonary arrest in pregnant women are:

1. Pulmonary embolism
2. Hemorrhage
3. Sepsis
4. Peripartum cardiomyopathy
5. Stroke
6. Preeclampsia–eclampsia
7. Anesthesia-related complications
8. Amniotic fluid embolism
9. Myocardial infarction
10. Preexisting cardiac disease
11. Trauma

Complications

Mortality is very high for pregnant women with cardiopulmonary arrest. Fetal demise is also very common. Due to this, treatment should be initiated immediately with the goal to maximize maternal cardiac output and ventilation.

Treatment

Due to the high mortality associated with cardiopulmonary arrest during pregnancy, resuscitation should follow standard algorithms of basic and advanced cardiac life support, with some modifications for the pregnancy. It is not proper to defer potential life-saving treatment for the patient due to a fear of exposing the fetus to medications and therapies. The most effective interventions for saving the fetus are those that save the mother’s life. Therefore, medications used in resuscitation protocols should be used without hesitation.

It may be difficult to perform cardiac compressions due to a large uterus and engorged breasts. Compressions should not be performed in the supine position, as the gravid uterus may cause aortocaval compression, diminished venous return, and subsequent decreased cardiac output. Patients should be positioned with a left lateral tilt before compressions are applied. This can be accomplished using a moving table or a wedge or with manual displacement of the uterus. Defibrillation and cardioversion have been successfully used during pregnancy without disturbance of the fetal cardiac conduction system. It is important, however, to remove fetal monitors to prevent arcing.

The decision to perform a perimortem caesarean section should be made rapidly, within 4–5 minutes of cardiac arrest, to optimize both maternal and neonatal survival. This extreme measure can maximize maternal survival by relieving aortocaval compression and increasing blood flow back to the heart. Although the minimum gestational age for perimortem caesarean delivery is controversial, aortocaval compression begins as early as 20 weeks; therefore, hysterotomy should be considered as part of resuscitative measures in pregnancies of at least 20–22 weeks or greater.

Prognosis

Unfortunately, prognosis is poor, but it depends on the etiology of the cardiopulmonary arrest, coexisting morbidities, and the ability to begin resuscitation expeditiously and effectively.

Obstetric Analgesia & Anesthesia

John S. McDonald, MD
Biing-Jaw Chen, MD
Wing-Fai Kwan, MD

Analgesia is the loss or modulation of pain perception. It can be (1) local and affect only a small area of the body, (2) regional and affect a larger portion of the body, or (3) systemic. Analgesia is achieved by the use of hypnosis (suggestion), systemic medication, regional agents, or inhalational agents.

Anesthesia is the total loss of sensory perception and may include loss of consciousness. It is induced by various agents and techniques. In obstetrics, **regional anesthesia** is accomplished with local anesthetic techniques (epidural, spinal) and **general anesthesia** with systemic medication and endotracheal intubation.

The terms *analgesia* and *anesthesia* are sometimes confused in common usage. Analgesia denotes those states in which only modulation of pain perception is involved. Anesthesia denotes those states in which mental awareness and perception of other sensations are lost. Attempts have been made to divide anesthesia into various components, including analgesia, amnesia, relaxation, and loss of reflex response to pain. Analgesia can be regarded as a component of anesthesia if viewed in this way.

The use of techniques and medications to provide pain relief in obstetrics requires an expert understanding of their effects to ensure the safety of both mother and fetus.

ANATOMY OF PAIN

It may be academic to argue that pain should be defined as the parturient’s response to the stimuli of labor, because agreement on a definition of pain has eluded scholars for centuries.

Nevertheless, it should be appreciated that the “pain response” is a response of the total personality and cannot be dissected systematically and scientifically. Physicians are obligated to provide a comfortable or at least a tolerable labor and delivery. Many patients are tense and apprehensive at the onset of labor, although they may have little or no discomfort. The physician must be knowledgeable of the options for pain relief and respond to the patient’s needs and wishes.

The evolution of pain in the first stage of labor originally was described as involving spinal segments T11 and T12. Subsequent research has determined that segments T10–L1 are involved. Discomfort is associated with ischemia of the uterus during contraction as well as dilatation and effacement of the cervix. Sensory pathways that convey nociceptive impulses of the first stage of labor include the uterine plexus, the inferior hypogastric plexus, the middle hypogastric plexus, the superior hypogastric plexus, the lumbar and lower thoracic sympathetic chain, and the T10–L1 spinal segments.

Pain in the second stage of labor also is produced by distention of the vagina and perineum. Sensory pathways from these areas are conveyed by branches of the pudendal nerve via the dorsal nerve of the clitoris, the labial nerves, and the inferior hemorrhoidal nerves. These are the major sensory branches to the perineum and are conveyed along nerve roots S2, S3, and S4. Nevertheless, other nerves, such as the ilioinguinal nerves, the genital branches of the genitofemoral nerves, and the perineal branches of the posterior femoral cutaneous nerves, may play a role in perineal innervation.

Although the major portion of the perineum is innervated by the 3 major branches of the pudendal nerve, innervation by the other nerves mentioned may be important in some patients. The type of pain reported may be an ache in the back or loins (referred pain, perhaps from the cervix), a cramp in the uterus (due to fundal contraction), or a “bursting” or “splitting” sensation in the lower vaginal canal or pudendum (due to dilatation of the cervix and vagina).

Dystocia, which usually is painful, may be due to feto-pelvic disproportion; tetanic, prolonged, or dysrhythmic uterine contractions; intrapartum infection; or many other causes.

SAFETY OF OBSTETRIC ANESTHESIA

Substantial advances in the quality and safety of obstetric anesthesia have been made in the past 3 decades. Outdated techniques, such as “twilight sleep” and mask anesthesia, have been recognized as ineffective or unsafe and have been replaced by epidural infusion of narcotic/local anesthesia mixtures and patient-controlled analgesia during labor and postoperatively. When required, general anesthesia is provided using short-acting drugs with well-known fetal effects, and careful attention is focused on airway management.

Maternal mortality relating to anesthesia has been reduced 10-fold since the 1950s, largely because of an enhanced appreciation of special maternal risks associated with anesthesia. The overall anesthesia-related death rate in the United States now is as low as 1.0 per million live births, a 5-fold decline in the last decade. Regional anesthesia now is more commonly performed for caesarean delivery, fewer births occur in hospitals performing fewer than 500 deliveries per year, and having both in-house anesthesia and obstetric physician coverage is more common. Historically, women have a higher chance of dying under general anesthesia than regional anesthesia during caesarean deliveries. During the 1970s and 1980s, the case fatality rate for general anesthesia during caesarean delivery was 32.3 per million and the rate for regional anesthesia was 1.9 per million. Thus 17 women died under general anesthesia for every 1 who died from regional anesthesia. By the 1990s, that ratio dropped to 6 to 1. In the 2000s, the case fatality rate for general anesthesia during caesarean delivery has decreased to 6.5 per million and case fatality rate for regional anesthesia has slightly increased to 3.8. The relative risk of general compared with regional anesthesia fell to 1.7. General anesthesia now seems just as safe as a spinal or epidural for caesarean delivery. The decline in deaths under general anesthesia could be attributed to better anesthetic monitoring, better management of difficult airway-failed intubation, and expertise with laryngeal airway mask and other airways devices. Difficulty with intubation, aspiration, and hypoxemia leading to cardiopulmonary arrest are the leading causes of anesthesia-related maternal death under general anesthesia. And the leading causes of anesthesia-related maternal death from regional anesthesia are high spinal or epidural block, respiratory failure, and drug reaction.

Another point of concern is that the overall maternal mortality (not related specifically to anesthesia) has increased in the United States since 1985. This increase in maternal mortality is most pronounced in older parturients (older than 35 years), particularly in black parturients. Cardiomyopathy, hypertension, obesity, and hemorrhage are the principal etiologies associated with these rising mortality rates and are important factors for the anesthesiologist to consider.

TECHNIQUES OF ANALGESIA WITHOUT THE USE OF DRUGS

Psychophysical Methods

Three distinct psychologic techniques have been developed as a means of facilitating the birth process and making it a positive emotional experience: “natural childbirth,” psycho-prophylaxis, and hypnosis. So-called *natural childbirth* was developed by Grantly Dick-Read in the early 1930s and popularized in his book *Childbirth Without Fear*. Dick-Read’s approach emphasized the reduction of tension to induce relaxation. The psychoprophylactic technique was developed by Velvovski, who published the results of his work from Russia in 1950. In Russia in the mid-1950s, it became evident that obstetric psychoprophylaxis was a useful substitute for poorly administered or dangerously conducted anesthesia for labor and delivery. This method was later introduced in France by Lamaze. Hypnosis for pain relief has achieved periodic spurts of popularity since the early 1800s and depends on the power of suggestion.

Many obstetricians argue that psychoprophylaxis can largely eliminate the pain of childbirth by diminishing cortical appreciation of pain impulses rather than by depressing cortical function, as occurs with drug-induced analgesia. Relaxation, suggestion, concentration, and motivation are factors that overlap other methods of preparation for childbirth. Some of them are closely related to hypnosis.

These techniques can significantly reduce anxiety, tension, and fear. They provide the parturient with a valuable understanding of the physiologic changes that occur during labor and delivery. In addition, they provide an opportunity for closer understanding and communication between the patient and her mate, who may be an important source of comfort to her during the stressful process of childbirth. If psychophysical techniques do no more than this, they deserve the obstetrician’s support.

Studies undertaken to assess the effectiveness of psychophysical techniques have reported widely divergent results, with effectiveness ranging from as low as 10–20% to as high as 70–80%. The overall benefit is best judged by the parturient herself, with validation by the observations of attendants. As is no doubt true in other aspects of medical practice in which emotional overlay and subjective reporting play a role in the evaluation of specific types of therapy, the personality and level of enthusiasm of the doctor can strongly influence the patient’s reactions to a given therapy. Practitioners who are skeptical of psychophysical techniques cannot expect to accomplish very much using them.

None of these psychophysical techniques should be forced on a patient, even by a skillful provider. The patient must not be made to feel that she will fail if she does not choose to complete her labor and delivery without analgesic medication. It must be made clear to the patient from the outset that she is expected to ask for help if she feels she wants or needs it. All things considered, psychophysical techniques should be viewed as adjuncts to other analgesic methods rather than substitutes for them.

The effectiveness of hypnosis is partially due to the well-known, although incompletely understood, mechanisms by which emotional and other central processes can influence a person’s overall responses to the pain experience. Verbal suggestion and somatosensory stimulation may help to alleviate discomfort associated with the first stage of labor. In addition, hypnotic states may provide apparent analgesia and amnesia for distressing, anxiety-provoking experiences. Finally, hypnotic techniques may substantially improve the parturient’s outlook and behavior by reducing fear and apprehension. However, certain practical points with regard to hypnosis must be considered because the time needed to establish a suitable relationship between physician and patient often is more than can be made available in the course of a busy medical practice.

ANALGESIC, AMNESTIC, & ANESTHETIC AGENTS

General Comments & Precautions

1. If the patient is prepared psychologically for her experience, she will require less medication. Anticipate and dispel her fears during the antenatal period and in early labor. Never promise a painless labor.
2. Individualize the treatment of every patient, because each one reacts differently. Unfavorable reactions to any drug can occur.
3. Know the drug you intend to administer. Be familiar with its limitations, dangers, and contraindications as well as its advantages.
4. All analgesics given to the mother will cross the placenta. Systemic medications produce higher maternal and fetal blood levels than regionally administered drugs. Many drugs have central nervous system depressant effects. Although they may have the desired effect on the mother, they also may exert a mild to severe depressant effect on the fetus or newborn.

The ideal drug will have an optimal beneficial effect on the mother and a minimal depressant effect on the offspring. None of the presently available narcotic and sedative medications used in obstetrics has selective maternal effects. The regional administration of local anesthetics accomplished this goal to a large extent because the low maternal serum levels that are produced expose the fetus to insignificant quantities of drugs.

Pharmacologic Aspects

A. Route of Administration

Systemic techniques of analgesia and anesthesia include both oral and parenteral routes of administration. Parenteral administration includes subcutaneous, intramuscular, and intravenous injection. Sedatives, tranquilizers, and analgesics usually are given by intramuscular injection. In some cases, the intravenous route is preferred.

The advantages of intravenous administration are (1) avoidance of variable rates of uptake due to poor vascular supply in fat or muscle; (2) prompt onset of effect; (3) titration of effect, avoiding the "peak effect" of an intramuscular bolus; and (4) smaller effective doses because of earlier onset of action.

The disadvantages of intravenous injection are inadvertent arterial injection and the depressant effect of over-dosage, but the advantage of smaller dosage outweighs the disadvantages.

Always administer the lowest concentration and the smallest dose to obtain the desired effect.

B. Physical and Chemical Factors

Anesthetics penetrate body cells by passing through the lipid membrane boundary. This membrane is not permeable to charged (ionized) drugs but is permeable to unionized forms of drugs. Much of the total drug transfer is dependent on the degree of lipid solubility, so local anesthetics are characterized by aromatic rings that are lipophilic, and all are lipid-soluble. The intermediate amine radical of a local anesthetic is a weak base that in aqueous solutions exists partly as undissociated free base and partly as dissociated cation. Figure 24–1 shows the equilibrium for such an existence and the Henderson-Hasselbalch equation, with which the proportion of the anesthetic in the charged and uncharged forms can be determined. The ratio of the cation to the base form of the drug is important, because the base form is responsible for penetration and tissue diffusion of the local anesthetic, whereas the cation form is responsible for local analgesia when the drug contacts the site of action within the sodium channel on the axolemma.

$$\underset{\text{Cation}}{R{:}NH^+ + OH^-} \rightleftharpoons \underset{\text{Base}}{R{:}N + HOH}$$

$$pH = pK_a + \log \frac{\text{Base}}{\text{Cation}}$$

Figure 24–1. Local anesthetics are weak bases coexisting as undissociated free base and dissociated cation. Their proportion can be calculated by means of the Henderson-Hasselbalch equation.

The pK_a of a drug is the pH at which equal proportions of the free base and cation form occur. Most local anesthetics used in obstetric analgesia have pK_a values ranging from 7.7–9.1 (Table 24–1). Because the pH of maternal blood is equal to or greater than 7.4, the pK_a of local anesthetics is so close that significant changes in maternal and fetal acid–base balance may result in fluxes in the base versus the cation forms of the drug. For example, a rising pH shifts a given amount of local anesthetic cation to the base form; conversely, a fall in pH generates more of the cationic form.

Table 24–1. pKa values of the more commonly used local anesthetics.

Drug	Brand Name	pKa
Bupivacaine	Marcaine	8.1
Chloroprocaine	Nesacaine	8.7
Etidocaine	Duranest	7.7
Lidocaine	Xylocaine	7.9
Ropivacaine	Naropin	8.0
Tetracaine	Pontocaine	8.5

Physical factors are important in drug transfer. Drugs with a molecular weight (MW) under 600 cross the placenta without difficulty, whereas those with MW over 1000 do not. A molecule such as digoxin (MW 780.95) crosses the ovine placenta very poorly. Molecular weights of most local anesthetics are in the 200–300 range. From the physical aspect, most local anesthetics cross the maternal–fetal barrier by simple diffusion according to the principles of Fick's law (Fig. 24–2), which states that the rate of diffusion of a drug depends on the concentration gradient of the drug between the maternal and fetal compartments and the relationship of the thickness and total surface available for transfer.

$$Q/T = K\left[\frac{A(C_M - C_F)}{D}\right]$$

Figure 24–2. Fick's law. A, surface area available for drug transfer; C_M, maternal drug concentration; C_F, fetal drug concentration; D, membrane thickness; K, diffusion constant of the drug; Q/T, rate of diffusion.

C. Placental Transfer

Factors other than the physical or chemical properties of a drug may affect its transfer across the placenta. These factors include the rate and route of drug administration and the distribution, metabolism, and excretion of the drug by the mother and fetus. Fick's law may appear to be a simple method of determining drug transfer, but other complexities exist: differential blood flow on either side of the placenta, volume of maternal and fetal blood, and various shunts in the intervillous space that are important determinants of the final amount of drug a fetus may receive. Certain maternal disorders, such as hypertensive cardiovascular disease, diabetes, and preeclampsia-eclampsia, may alter placental blood flow and in some way affect the extent of drug distribution.

As the placenta matures, the thickness of the epithelial trophoblastic layer progressively decreases. This reduction may cause the thickness of the tissue layers between the maternal and fetal compartments to decrease 10-fold (from as much as 25 μm in early gestation to 2 μm at term in some species). As gestation progresses, the surface area of the placenta also increases. At term, these changes in physical structure tend to favor improved transfer of drugs across the placenta.

Placental transfer is affected by the pH of the blood on both sides of the placenta. The pH of the blood on the fetal side of the placenta normally is 0.1–0.2 U lower than that on the maternal side. Therefore, passage of drug to the fetal unit results in a tendency for more of the drug to exist in the ionized state. Because the maternal–fetal equilibrium is established only between the unionized fraction of the drug on either side of the barrier, this physiologic differential will expedite maternal–fetal transfer of drug. With more drug in the ionized form in the fetal unit, the new equilibrium that arises results in a greater total (ionized plus unionized) drug load in the fetus. Because the pK_a values of commonly used local anesthetics are closer to the maternal blood pH, these agents tend to accumulate on the fetal side of the placenta. This also is true of other basic drugs such as morphine, meperidine, and propranolol. Further decreases in the fetal pH lead to additional drug entrapment in the fetus. For acidic drugs (eg, thiopental) the shift in total drug concentration is in the opposite direction, that is, toward the maternal side of the placenta.

In summary, the rate of transfer of a drug is governed mainly by (1) lipid solubility, (2) degree of drug ionization, (3) placental blood flow, (4) molecular weight, (5) placental metabolism, and (6) protein binding.

D. Fetal Distribution

After a drug deposited in the maternal compartment passes through the maternal–fetal barrier, the drug must reach the fetus and undergo distribution (Fig. 24–3). The response of the fetus and newborn depends on drug concentration in vessel-rich organs, such as the brain, heart, and liver. Drugs transferred from the maternal to the fetal compartment of the placenta are then diluted before distribution to the various fetal vital organs. Approximately 85% of the blood in the umbilical vein, which passes from the placenta to the fetus, passes through the fetal liver and then into the inferior vena cava. The remainder bypasses the liver and enters the vena cava primarily via the ductus venosus. An admixture of blood coming from the lower extremities, the abdominal viscera, the upper extremities, and the thorax further reduces the drug concentration. Blood from the right atrium shunts from right to left through the foramen ovale into the left atrium, resulting in a final concentration on the left side of the heart that is only slightly lower than that in the vena cava.

Figure 24–3. Relationship between maternal and fetal compartments and distribution of drugs between them. Drug is passed from the maternal compartment, via the placenta (a partial barrier), to the fetal compartment, where the principles of drug dynamics (ie, distribution, biotransformation, and excretion) determine the eventual specific organ tissue levels. One purely mechanical barrier exists between the maternal and fetal compartments, which attains importance in the late first and second stages of labor—the umbilical cord, which is susceptible to partial and total occlusion.

The amount of drug ultimately reaching a vital organ is related to that organ's blood supply. Because the central nervous system is the most highly vascularized fetal organ, it receives the greatest amount of drug. Once the drug reaches the fetal liver, it may either be bound to protein or metabolized.

The uptake of drug by fetal tissues can be very rapid after either intravenous or epidural administration. Measurable concentrations of local anesthetics have been found in fetal tissues as early as 1–2 minutes after injection. Lipid solubility of a drug is important in developing concentrations in certain organs with high lipid content, such as the adrenal, ovary, liver, and brain.

Drug metabolism and excretion are the final features of the fetal distribution picture. The fetal liver is able to metabolize drugs and numerous substrates as early as the second trimester, an ability that improves to term. Narcotics and sedatives are metabolized much more slowly by the fetal liver, producing a prolonged effect of these drugs in the newborn who is exposed in utero. Finally, the ability of the fetus to excrete drugs is also reduced by reduced renal function.

Systemic Analgesics & Anesthetics

A. Sedatives (Hypnotics)

The principal use of sedative–hypnotic drugs is to produce drowsiness. For many years, these drugs were the only ones available to reduce anxiety and induce drowsiness. The latent phase of the first stage of labor can be managed by either psychologic support alone or utilization of sedative–hypnotic compounds. Psychologic support may be complemented by the use of sedatives. When properly used, these drugs induce tranquility and an enhanced feeling of well-being. They are poor analgesics and do not raise the pain threshold appreciably in conscious subjects. Amnesia does not occur. Labor may be slowed by large doses of sedatives, especially when given too early in the first stage.

The use of barbiturates alone for obstetric analgesia is not common practice and should be discouraged. The required dosage is dangerous to the fetus, which is extremely sensitive to central nervous system depression by these drugs. Periodic apnea and even abolition of all movements outlast the effects of the barbiturates on the mother.

B. Tranquilizers & Amnestics

These drugs are used principally to relieve apprehension and anxiety and to produce a calm state. Additionally, they may potentiate the effects of other sedatives. An analgesic-potentiating effect is often claimed for this group of agents but has not been definitely demonstrated. Hydroxyzine and diazepam are popular tranquilizer–amnestics. Scopolamine, which was widely popular in obstetrics in the past, produces no analgesia but has a mild sedative and marked amnestic effect. Scopolamine is no longer used because the amnesia produced is excessive and prolonged. Diazepam should be avoided during labor because it has a long chemical half-life, which is even more prolonged in the neonate. Diazepam readily crosses the placenta and is found in significant concentrations in fetal plasma. At present, diazepam is not recommended if the neonate is premature because of the threat of kernicterus.

Other potential side effects related to the use of diazepam are fetal hypotonia, hypothermia, and a loss of beat-to-beat variability in the fetal heart rate.

One of the controversies over diazepam concerns the content of sodium benzoate and benzoic acid buffers. Both compounds are potent uncouplers of the bilirubin–albumin complex, and some investigators have suggested that the neonate may be more susceptible to kernicterus because of an increase level of free circulating bilirubin. However, because injectable diazepam is effective in the treatment of human newborn seizure disorders, opiate withdrawal, and tetanus and because it is regarded as a useful adjunct in obstetric analgesia, a study was undertaken in animals in which comparable quantities of sodium benzoate were injected to determine whether significant amounts of bilirubin would be made available to the circulation. Midazolam, a short-acting water-soluble benzodiazepine, appears to be devoid of the neonatal effects seen with diazepam and is more rapidly cleared. In small doses it could conceivably become a useful anxiolytic for the laboring patient. Midazolam is 3–4 times more potent than diazepam, and there is a brief delay in the onset of its sedative effect after intravenous injection. Doses should be kept below 0.075 mg/kg to avoid excessive anterograde amnesia.

C. Narcotic Analgesics

Systemic analgesic drugs (including narcotics) are commonly used in the first stage of labor because they produce both a state of analgesia and mood elevation. The favored drugs are codeine 60 mg intramuscularly or meperidine 50–100 mg intramuscularly or 25–50 mg (titrated) intravenously. The combination of morphine and scopolamine was once popular for its “twilight sleep” effect but is rarely used now. Common undesirable effects of this combination of drugs are nausea and vomiting, cough suppression, intestinal stasis, and diminution in frequency, intensity, and duration of uterine contractions in the early first stage of labor. Also, amnesia is excessive for these patients.

Morphine is not used in active laboring patients because of the excessive respiratory depression seen in the neonate compared with equipotent doses of other narcotics. Fetuses who are of young gestational age, are small for dates, or have undergone trauma or long labor are more susceptible to narcosis.

Fentanyl is a popular synthetic narcotic that has been used in obstetrics in both the systemic and epidural compartments. Its use in the epidural compartment has met with good success when combined with small quantities and low concentrations of bupivacaine. Data supporting its use come from both Europe and the United States.

Sufentanil is a derivative of fentanyl with increased potency and lipophilicity. It is widely used for intrathecal and epidural analgesia during labor. Potential adverse effects of sufentanil include possible placental deposition and neonatal respiratory depression. Adding intrathecal or epidural sufentanil to bupivacaine improves labor analgesia with faster onset and longer duration compared with bupivacaine alone. The usual dose is 3–5 μg intrathecally and 10–15 μg epidurally.

Remifentanil is a newer ultra short-acting synthetic opioid with rapid onset (approximately 1 minute) after intravenous administration. It is rapidly metabolized by nonspecific blood and tissue esterases, not depending on renal or hepatic function, and hence it does not accumulate in the fetus. This rapid onset and elimination facilitate its effective and safe use during labor. Remifentanil has been administered as intravenous analgesia for labor using a variety of methods, including baseline infusion, PCA boluses (with or without baseline infusion), and target-controlled infusions.

Butorphanol (Stadol) is a synthetic parenteral analgesic that has agonist and antagonist of opioid properties. It is 5 times as potent as morphine and 40 times as potent as meperidine. The typical doses are 1–2 mg intravenously or intramuscularly every 3–4 hours. Onset of analgesia is within a few minutes after intravenous injection. There is less respiratory depression compared with an equivalent dose of morphine due to ceiling effect from its agonist-antagonist properties. This property makes butorphanol particularly useful for labor analgesia, when respiratory depression of the fetus/neonate is a concern.

Nalbuphine (Nubain) is a mixed agonist/antagonist opioid similar to butorphanol commonly used for parenteral labor analgesia. Its potency is equivalent to that of morphine on a milligram basis. The onset of action after intravenous injection is 2–3 minutes with duration of 5–6 hours. The usual dose is 10–20 mg intravenously every 4–6 hours. It is metabolized predominantly by the liver and excreted by the kidney.

D. Thiobarbiturate

Intravenous anesthetics such as thiopental and thiamylal are widely used in general surgery. However, less than 4 minutes after a thiobarbiturate is injected into the mother’s vein, the concentrations of the drug in the fetal and maternal blood will be equal. The mother will lose consciousness and airway protective reflexes with a thiopental dose of 1.5–2 mg/kg; therefore, it should be used only in association with general endotracheal anesthesia. Thiopental doses of 3–4 mg/kg are used for induction of general anesthesia.

E. Propofol

Propofol is a newer induction agent that was introduced into practice in the United States in the early 1990s. As an induction agent, it is similar to the barbiturates in mild cardiac depression and loss of peripheral vasomotor tone. It offers the advantages of rapid clearance, short duration of action, antiemetic properties, and reduced risk of airway reactivity. It is an ideal agent for induction of general anesthesia at a dose of 2 mg/kg in parturients. It also can be used in 10- to 20-mg increments during surgery under regional block to treat nausea and vomiting. Neonatal Apgar scores and umbilical gases are similar after induction with propofol or barbiturates.

F. Etomidate

Etomidate is an intravenous induction agent that has been used in obstetric anesthesia since 1979. It produces a rapid onset of anesthesia with minimal cardiorespiratory effects. This property makes it ideal for parturients who are hemodynamically unstable or who would not tolerate hemodynamic aberrations well. With an induction dose of 0.2–0.3 mg/kg, etomidate undergoes a rapid hydrolysis that leads to quick recovery. Etomidate crosses the placenta rapidly; however, large variations in the UV/MV (umbilical vein: maternal vein) ratio (0.04–0.5) have been reported. Etomidate may cause pain at the injection site and involuntary muscle movements in some patients.

G. Ketamine

The phencyclidine derivative ketamine produces anesthesia by a dissociative interruption of afferent pathways from cortical perception. It has become a useful and widely used adjunctive agent in obstetrics because maternal cardiovascular status and uterine blood flow are well maintained. Effective maternal analgesia results from low doses of 0.25–0.5 mg/kg but without loss of consciousness or protective reflexes. The margin of safety is narrow, however, so it should be used only by physicians able to easily secure and protect the airway if loss of consciousness occurs. For caesarean delivery, general anesthetic induction can be produced with 1–2 mg/kg intravenously. Ketamine stimulates the cardiovascular system to maintain heart rate, blood pressure, and cardiac output. It is useful in the setting of major blood loss, when rapid induction of general anesthesia is required. However, it has significant hallucinogenic effects that limit its utility in obstetrics.

H. Inhalation Anesthetics

Inhaled anesthetics are administered as a component of general anesthesia. In the past, inhaled anesthetics were given during labor in subanesthetic concentrations to treat contraction pain, but they are no longer used for this indication. The mask administration of these gases to the conscious laboring patient can result in airway obstruction, aspiration, and hypoxia. Also, the vaporized gases would unacceptably contaminate the labor room environment because effectively scavenging of exhaust gases from the room is not possible. Finally, of all the presently used volatile anesthetics, only nitrous oxide has analgesic properties at subanesthetic concentrations.

The most commonly used inhaled anesthetics in pregnancy are nitrous oxide, sevoflurane, desflurane, and isoflurane. These drugs all readily cross the placenta and produce significant blood concentrations in the fetus. During the brief exposure to maternally administered anesthetic gases, the fetus is not adversely affected. Fetal cardiac output is slightly reduced by these drugs, but critical organ blood flow is unaffected, and fetal acid–base status is unchanged. Exposure to minimum alveolar concentrations of anesthetic gases for more than 15 minutes is associated with reduced Apgar scores, but other parameters of fetal and newborn well-being are unimpaired.

The term parturient is more sensitive to the anesthetic effects of all inhaled anesthetics, presumably as a result of elevated progesterone levels. This increased sensitivity of 20–30% compared with nonpregnant subjects places the patient at increased risk for obtundation and aspiration; therefore, these drugs should not be administered without preparation for endotracheal intubation. Volatile agents except N_2O produce uterine relaxation, and high concentrations should be avoided during delivery to prevent uterine atony and postpartum hemorrhage. At low concentrations (<1%), they produce amnesia, and their tocolytic effects are easily counteracted by standard infusions of oxytocin (Pitocin).

REGIONAL ANESTHESIA

Regional anesthesia is achieved by injection of a local anesthetic (Table 24–2) around the nerves that pass from spinal segments to the peripheral nerves responsible for sensory innervation of a portion of the body. More recently, narcotics have been added to local anesthetics to improve analgesia and reduce some side effects of local anesthetics. Regional nerve blocks used in obstetrics include the following: (1) lumbar epidural and caudal epidural block, (2) subarachnoid (spinal) block, (3) combined spinal epidural block, and (4) pudendal block.

*Compared with procaine

Infiltration of a local anesthetic drug and pudendal block analgesia carry minimal risks. The hazards increase with the amount of drug used. The safety and suitability of regional anesthesia depend on proper selection of the drug and the patient and the obstetrician–gynecologist's knowledge, experience, and expertise in the diagnosis and treatment of possible complications. Major conductive anesthesia and general anesthesia in obstetrics require specialized knowledge and expertise in conjunction with close maternal and fetal monitoring. This field of expertise has developed as a subspecialty within anesthesia, reflecting the need for specialized understanding of the obstetric patient and her response and of the fetal responses to anesthesia.

Patient Selection

Regional anesthesia is appropriate for labor analgesia, caesarean delivery, and other obstetric operative procedures (eg, postpartum tubal ligation, cervical cerclage). Most patients prefer to remain awake; however, occasionally a choice is made to provide general anesthesia.

The anesthesiologist will assess the patient to determine the relative risks of general versus regional anesthesia. For example, some forms of valvular heart disease may contraindicate regional block, and general anesthesia may be considered more appropriate. Other contraindications to regional anesthesia include infection, coagulopathy, hypovolemia, progressive neurologic disease, and patient refusal.

Patient Preparation

The woman who is well informed and has a good rapport with her physician generally is a calm and cooperative candidate for regional or general anesthesia. The patient and her partner should be well informed early in her pregnancy of the options for labor anesthesia as well as for caesarean section if that circumstance arises. The anesthesiologist can be involved early in pregnancy if the patient has special concerns about anesthesia (family history of anesthetic risk, previous back surgery, coagulation problems). Some hospitals have obstetric anesthesia preassessment clinics that deal with these patient concerns.

Local Anesthetic Agents

A local anesthetic drug blocks the action potential of nerves when their axons are exposed to the medication. Local anesthetic agents act by modifying the ionic permeability of the cell membrane to stabilize its resting potential. The smaller the nerve fiber, the more sensitive it is to local anesthetics because the susceptibility of individual nerve fibers is inversely proportional to the cross-sectional diameter of the fibers. Hence, with regional anesthesia, the patient's perception of light touch, pain, and temperature and her capacity for vasomotor control are obtunded sooner and with a smaller concentration of the drug than is the perception of pressure or the function of motor nerves to striated muscles. The exception to this rule is the sensitivity of autonomic nerve fibers that are blocked by the lowest concentration of local anesthetic despite their being larger than some sensory nerves.

Only anesthetic drugs that are completely reversible and nonirritating and cause minimal toxicity are clinically acceptable. Other desirable properties of regional anesthetic agents include rapidity of onset, predictability of duration, and ease of sterilization. Table 24–2 summarizes the local anesthetics commonly used in obstetrics and gynecology together with their uses and doses.

All local anesthetics have certain undesirable dose-related side effects when absorbed systemically. All these drugs are capable of stimulating the central nervous system and may cause bradycardia, hypertension, or respiratory stimulation at the medullary level. Moreover, they may produce anxiety, excitement, or convulsions at the cortical or subcortical level. This response stimulates grand mal seizures because it is followed by depression, loss of vasomotor control, hypotension, respiratory depression, and coma. Such an episode of indirect cardiovascular depression often is accentuated by a direct vasodilatory and myocardial depressant effect. The latter is comparable to the action of quinidine. This effect explains why lidocaine is useful for treatment of certain cardiac arrhythmias.

Chloroprocaine is an ester derivative that was popular in 1970s primarily because of its rapid onset and short duration of action and its low toxicity to the fetus. It is metabolized by plasma cholinesterase and therefore does not demand liver enzyme degradation, as do the more complex and longer acting amide derivatives. Chloroprocaine has a half-life of 21 seconds in adult blood and 43 seconds in neonatal blood. Direct toxic effects on the fetus are minimized because fewer drugs are available for transfer in the maternal compartment.

The potency of chloroprocaine is comparable to that of lidocaine and mepivacaine, and the drug is 3 times more potent than procaine. Its average onset of action ranges from 6–12 minutes and persists for 30–60 minutes, depending on the amount used. Chloroprocaine is often used for urgent caesarean delivery when epidural catheter is already placed to avoid general anesthesia.

Bupivacaine, the amide local anesthetic, is related to lido-caine and mepivacaine but has some very different physico-chemical properties. It has a much higher lipid solubility, a higher degree of binding to maternal plasma protein, and a much longer duration of action. More than with other local anesthetics, the concentration of bupivacaine can be reduced to produce sensory block with minimal motor block. Because injection of bupivacaine for labor pain relief now is mostly in the form of continuous small-volume and minimal concentration administration via a pump mechanism, the complications previously of concern, such as hypotension and convulsions, are now rare.

A word of caution is needed regarding the administration of bupivacaine for caesarean delivery. This drug has been implicated in certain cardiovascular catastrophes associated with initial drug injection, such as cardiac arrests that were refractory to full and appropriate resuscitative attempts. Although these catastrophes are rare, the practitioner is well advised to inject no more than 5 mL of the drug at any one time, to wait 4–5 minutes, then to repeat the procedure until the desired volume has been delivered. The maximum concentration of bupivacaine now allowed by the Food and Drug Administration (FDA) for obstetric epidural anesthesia is 0.5%. The dose of more than 3 mg/kg is considered a toxic dose now. The safety of bupivacaine can be enhanced by giving it in fractional doses (eg, 5 mL every 5 minutes).

Ropivacaine is a newer amide local anesthetic introduced into the United States in the mid-1990s. It is less lipid-soluble than bupivacaine, and initial studies suggested that it produced less motor blockade and was less cardiotoxic than its homologue bupivacaine. Later studies have been less convincing in documenting improved efficacy and safety, but ropivacaine has replaced bupivacaine in some institutions. There is ongoing study of the safety and efficacy of levobupivacaine, the levorotatory isomer of bupivacaine, which may also prove less cardiotoxic than its racemic parent molecule. Both of these newer amide local anesthetics are used in doses and concentrations similar to those of bupivacaine.

Local Infiltration Analgesia

Local tissue infiltration of dilute solutions of anesthetic drugs generally yields satisfactory results because the target is the fine nerve fibers. Nevertheless, one must keep in mind the dangers of systemic toxicity when large areas are anesthetized or when reinjection is required. It is good practice, therefore, to calculate in advance the milligrams of drug and volume of solution that may be required to keep the total dosage below the accepted toxic dose.

Infiltration in or near an area of inflammation is contra-indicated. Injections into these zones may be followed by rapid systemic absorption of the drug as a result of increased vascularity of the inflamed tissues. Moreover, the injection may introduce or aggravate infection.

Regional Analgesia Techniques

A. Lumbar Epidural Block

This analgesic technique is well suited to obstetric anesthesia. Either bolus injections or continuous infusion of local anesthetics is used for labor, vaginal delivery, or caesarean surgery. Narcotics are added to supplement the quality of the block.

After the patient is evaluated, an epidural block can be placed once labor is established. Drug dosages can be adjusted as circumstances change. The catheter can be used for surgery and postoperative analgesia if necessary. The second stage of labor is prolonged by epidural anesthesia; however, the duration of the first stage is unaffected. The use of outlet forceps is increased, but fetal outcome is not adversely affected by epidural block.

The epidural block technique must be exact, and inadvertent massive (high) spinal anesthesia occasionally occurs. Other undesirable reactions include the rapid absorption syndrome (hypotension, bradycardia, hallucinations, and convulsions), postpartum backache, and paresthesias. Epidural block should eradicate pain between T10 and L1 for the first stage of labor and between T10 and S5 for the second stage of labor.

The procedure is as follows. Inject 3 mL of a 1.5% aqueous solution of lidocaine or similar agent into the catheter as a test dose. If spinal anesthesia does not result after 5–10 minutes, inject an additional 5 mL. Inject 10 mL of the anesthetic solution in total to slowly accomplish an adequate degree and suitable level of anesthesia. Once the block is established, a continuous infusion of 10–12 mL/h will maintain the block for labor. Bupivacaine 0.125–0.25% is most often used for an epidural block, with fentanyl 2–5 μg/mL in the epidural mixture.

The mother is nursed in a wedged or lateral position to prevent aortocaval compression. The sympathectomy produced by the block predisposes the patient to venous pooling and reduced venous return. Maternal blood pressure must be measured frequently when the epidural is in effect.

B. Caudal Block

Caudal anesthesia (Fig. 24–4) is an epidural block approached through the caudal space. It can provide selective sacral block for the second stage of labor; however, it is rarely used now because of complications specific to the obstetric patient. The descent of the fetal head against the perineum, in addition to the sacral edema at term, obscures the landmarks of the sacral hiatus. This makes the caudal procedure technically challenging, and reports of transfixing the rectum and fetal skull puncture with the epidural needle have led many anesthesiologists to avoid this technique. Lumbar epidural anesthesia is considered a safer alternative.

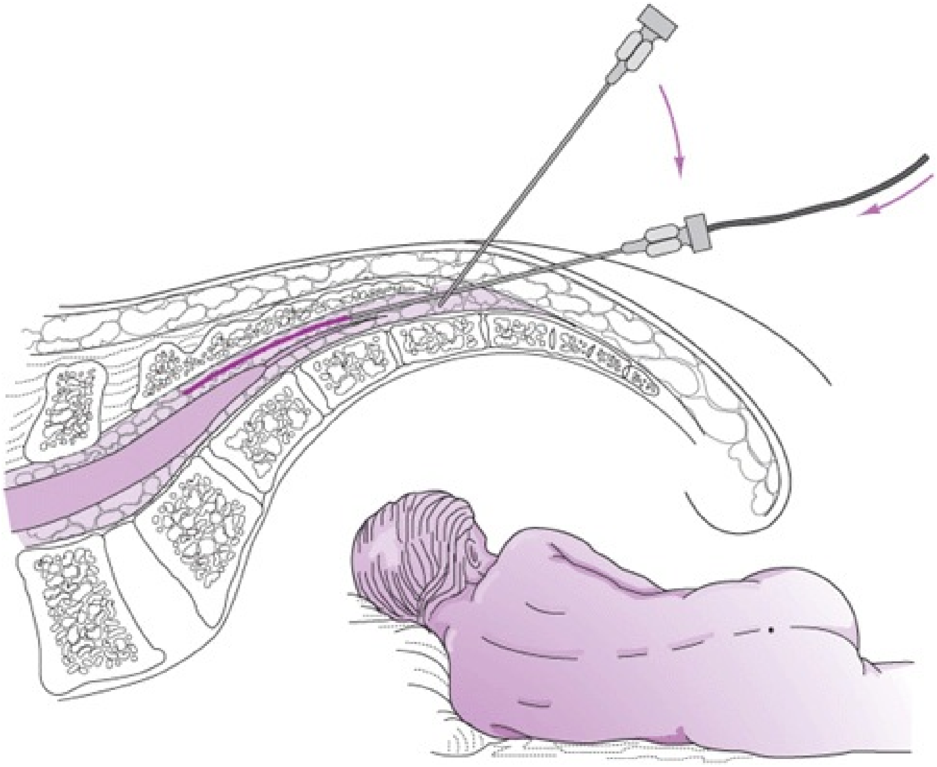

Figure 24–4. Caudal catheter in place for continuous caudal anesthesia.

C. Spinal Anesthesia

Spinal anesthesia currently is the anesthetic of choice for caesarean delivery. Spinal anesthesia can be performed more quickly than epidural anesthesia and provides ideal operating conditions, including dense sensory and motor block. The onset of sympathectomy is more abrupt than with epidural block, so care must be taken to ensure that the patient is adequately preloaded with 1.5–2 L of saline solution before performing the technique. Spinal anesthesia is used less commonly these days to alleviate the pain of delivery and the third stage of labor. The advantages of spinal anesthesia are that the mother remains conscious to witness delivery, no inhalation anesthetics or analgesic drugs are required, the technique is not difficult, and good relaxation of the pelvic floor and lower birth canal is achieved. Prompt anesthesia is achieved within 5–10 minutes. The dosage of spinal anesthetic is small. Complications are rare and easy to treat. However, spinal headache occurs in 1–2% of patients.

D. Combined Spinal–Epidural Analgesia

The use of combined spinal–epidural anesthesia (CSE) became popular in the mid 1990s as an alternative to epidural anesthesia for labor. A small dose of local anesthetic and narcotic (2.5 mg bupivacaine and 25 μg fentanyl) is injected through a spinal needle, which is introduced through the epidural needle and advanced into the intrathecal space. The spinal needle is withdrawn and the epidural catheter placed for later use. The spinal medication produces immediate pain relief and minimal motor block and may allow ambulation. Later in labor, the epidural catheter is used for continuous infusion of epidural solution, similar to that described for standard epidural anesthesia in labor.

Detractors of CSE argue that the technique may increase the incidence of post–lumbar puncture headache and that ambulation even after low-dose spinal injection is unsafe for both mother and baby. Finally, because the technique is technically cumbersome, it may be associated with higher complication rates, although the studies did not support this statement.

The most serious consequence of spinal or epidural anesthesia is maternal mortality. Maternal deaths associated with use of 0.75% bupivacaine for caesarean delivery and labor were reported in the late 1980s, prompting the FDA to outlaw the use of this drug in obstetrics. These deaths were attributed to venous uptake of the drug and immediate and lasting myocardial depression from the local anesthetic, which did not respond to appropriate cardiac resuscitative efforts. Today maternal mortality associated with regional anesthesia is lower, primarily because bolus dosing of high concentrations of local anesthesia is no longer performed.

Most side effects of spinal or epidural anesthesia are secondary to block of the sympathetic nerve fibers that accompany the anterior roots of the spinal thoracic and upper lumbar nerves (thoracolumbar outflow). Thus many physiologic regulating mechanisms are disturbed. The blood pressure falls as a result of loss of arterial resistance and venous pooling—assuming no compensation is made by change of the patient’s position (eg, Trendelenburg position). If high thoracic dermatomes (T1–T5) are blocked, alteration of the cardiac sympathetic innervation slows the heart rate and reduces cardiac contractility. Epinephrine secretion by the adrenal medulla is depressed. Concomitantly, the unopposed parasympathetic effect of cardiac slowing alters vagal stimulations. As a result of these and related changes, shock follows promptly, especially in hypotensive or hypovolemic patients. Moreover, a precipitous fall in the blood pressure of the arteriosclerotic hypertensive patient is inevitable.

Fluids, oxygen therapy for adequate tissue perfusion, shock position to encourage venous return, and pressor drugs given intravenously are recommended.

In the past, postdural puncture headache (PDPH) due to leakage of cerebrospinal fluid through the needle hole in the dura was an early postoperative complication in up to 15% of patients. Small-caliber needles (25F) decrease the incidence of headache to 8–10%. With the introduction of pencil-point Whitaker and Sprotte spinal needles, the incidence of PDPH has been reduced to 1–2%. Therapy for PDPH includes recumbent position, hydration, sedation, and, in severe cases, epidural injection of 10–20 mL of the patient’s fresh blood to “seal” the defect.

Rarely, spinal or epidural anesthesia caused nerve injury and transient or permanent hypesthesia or paresthesia. Excessive drug concentration, sensitivity, or infection may have been responsible for some of these complications. The incidence of serious complications of spinal or epidural anesthesia is considerably lower than that of cardiac arrest during general anesthesia.

E. Paracervical Block

Paracervical block is no longer considered a safe technique for the obstetric patient. In the past, paracervical anesthesia was used to relieve the pain of the first stage of labor. Pudendal block was required for pain during the second stage of labor. Sensory nerve fibers from the uterus fuse bilaterally at the 4–6 o’clock and 6–8 o’clock positions around the cervix in the region of the cervical–vaginal junction. Ordinarily, when 5–10 mL of 1% lidocaine or its equivalent is injected into these areas, interruption of the sensory input from the cervix and uterus promptly follows.

Many now consider paracervical block to be contraindicated in obstetrics because of the potential adverse fetal effects. Many reports in the literature place the incidence of fetal bradycardia at 8–18%. However, recent work with accurate fetal heart rate monitoring associated with continuous uterine contraction patterns suggests that the incidence is closer to 20–25%. Some researchers have attempted to investigate the significance of the bradycardia. One explanation is that an acid–base disturbance in the fetus does not occur unless the bradycardia lasts longer than 10 minutes and that neonatal depression is rare unless associated with delivery during the period of bradycardia. There seems to be little difference in the incidence and severity of fetal bradycardia by paracervical block between complicated and uncomplicated patients. Other disadvantages of paracervical block include maternal trauma and bleeding, fetal trauma and direct injection, inadvertent intravascular injection with convulsions, and short duration of the block.

F. Pudendal Nerve Block

Pudendal block has been one of the most popular of all nerve block techniques in obstetrics. The infant is not depressed, and blood loss is minimal. The technique is simplified by the fact that the pudendal nerve approaches the spine of the ischium on its course to innervate the perineum. Injection of 10 mL of 1% lidocaine on each side will achieve analgesia for 30–45 minutes approximately 50% of the time.

Both the transvaginal and transcutaneous methods are useful for administering a pudendal block. The transvaginal technique has important practical advantages over the trans-cutaneous technique. The "Iowa trumpet" needle guide can be used, and the operator's finger should be placed at the end of the needle guide to palpate the sacrospinous ligament, which runs in the same direction and is just anterior to the pudendal nerve and artery. Appreciating the sensation of the needle puncturing the ligament usually is difficult. This facet of the technique (no definite end point) may make it difficult for the inexperienced clinician to perform. Aspiration of the syringe for possible inadvertent entry into the pudendal artery should be accomplished, and, if no blood is returned, 10 mL of local anesthetic solution should be injected in a fanlike fashion on the right and left sides. The successful performance of the pudendal block requires injection of the drug at least 10–12 minutes before episiotomy. Often in clinical practice, pudendal block is performed within 4–5 minutes of episiotomy, so the local anesthetic may not have adequate time to take effect.

1. Advantages and disadvantages—Advantages of pudendal nerve block are its safety, ease of administration, and rapidity of onset of effect. Disadvantages include maternal trauma, bleeding, and infection; rare maternal convulsions due to drug sensitivity; occasional complete or partial failure; and regional discomfort during administration.

The pudendal perineal block, like any other nerve block, demands some technical experience and knowledge of the innervation of the lower birth canal. Nevertheless, in spite of a well-placed bilateral block, skip areas of perineal analgesia may be noted. The possible reason is that although the pudendal nerve of S2–S4 derivation does contribute to the majority of fibers for sensory innervation to the perineum, other sensory fibers also are involved. For example, the inferior hemorrhoidal nerve may have an origin independent from that of the sacral nerve and therefore will not be a component branch of the pudendal nerve. In this case, it must be infiltrated separately. In addition, the posterior femoral cutaneous nerve (S1–S3) origin may contribute an important perineal branch to the anterior fourchette bilaterally. In instances in which this nerve plays a major role in innervation, it must be blocked separately by local skin infiltration.

Two other nerves contribute to the sensory innervation of the perineum: the ilioinguinal nerve, of L1 origin, and the genital branch of the genitofemoral nerve, of L1 and L2 origin. Both of these nerves sweep superficially over the mons pubis to innervate the skin over the symphysis of the mons pubis and the labium majus. Occasionally, these nerves must also be separately infiltrated to provide optimal perineal analgesic effect. Thus it should be apparent that a simple bilateral pudendal nerve block may not be effective in many cases. For maximum analgesic effectiveness, in addition to a bilateral pudendal block, superficial infiltration of the skin from the symphysis medially to a point halfway between the ischial spines may be necessary. Thus a true perineal block may be regarded as a regional technique.

Either lumbar epidural or caudal epidural block should eradicate pain between the T10 and S5 levels for the second stage. All of these nerves are denervated because they all are derived from L1–S5 segments.

2. Procedure (Fig. 24–5)

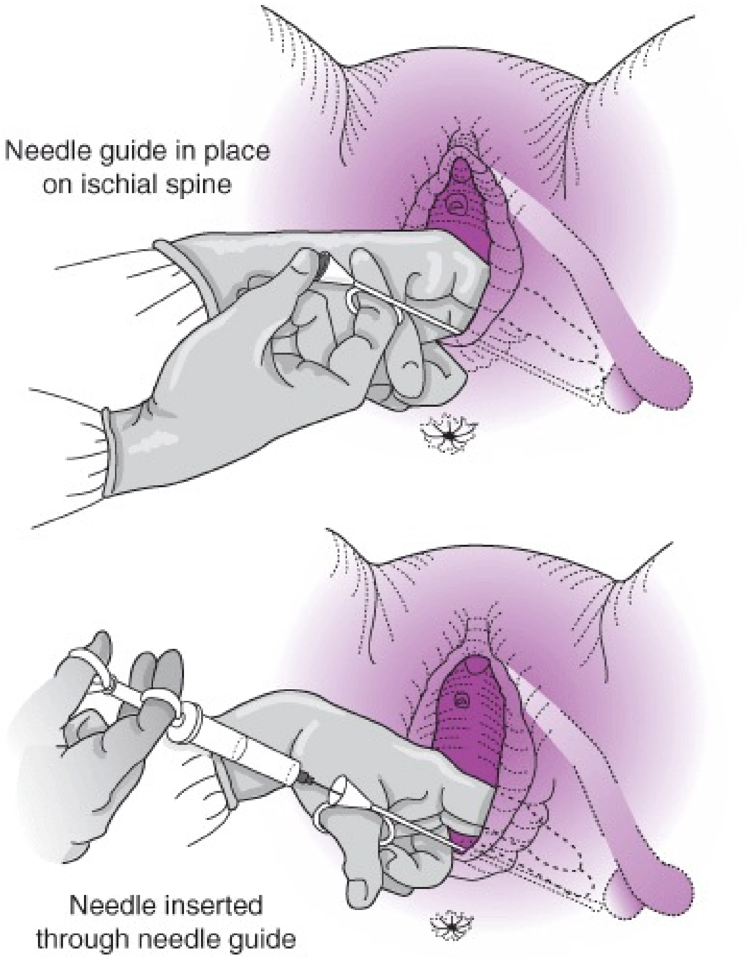

Figure 24–5. Use of needle guide ("Iowa trumpet") in pudendal anesthetic block. (Reproduced, with permission, from Benson RC. *Handbook of Obstetrics & Gynecology*. 8th ed. Los Altos, CA: Lange; 1983.)

1. Palpate the ischial spines vaginally. Slowly advance the needle guide toward each spine. After placement is achieved, the needle is advanced through the guide to penetrate approximately 0.5 cm. Aspirate, and if the needle is not in a vessel, deposit 5 mL below each spine. This blocks the right and left pudendal nerves. Refill the syringe when necessary, and proceed in a similar manner to anesthetize the other areas specified. Keep the needle moving while injecting and avoid the sensitive vaginal mucosa and periosteum.
2. Withdraw the needle and guide approximately 2 cm and redirect toward an ischial tuberosity. Inject 3 mL near the center of each tuberosity to anesthetize the inferior hemorrhoidal and lateral femoral cutaneous nerves.
3. Withdraw the needle and guide almost entirely and then slowly advance toward the symphysis pubica almost to the clitoris, keeping approximately 2 cm lateral to the labial fold and approximately 1–2 cm beneath the skin. Injection of 5 mL of lidocaine on each side beneath the symphysis will block the ilioinguinal and genitocrural nerves.

If the procedure explained is carefully and skillfully done, only slight discomfort will be felt during the injections. Prompt flaccid relaxation and good anesthesia for 30–60 minutes can be expected. A summary of anesthetic approaches in labor is shown in Figure 24–6.

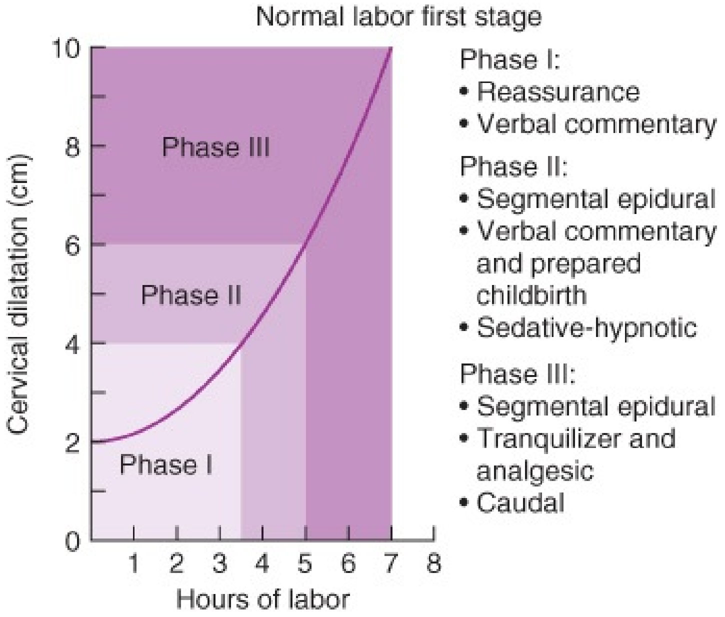

Figure 24–6. First-stage management in a primipara can be divided into 3 phases. Phase I (early labor) should be managed by simple reassurance and verbal commentary if the patient has received adequate antepartum education. An epidural may be performed once labor is well established. Phase II can be handled by a segmental epidural block, continued reassurance, a sedative–hypnotic drug, a narcotic, or a tranquilizer. Phase III, the accentuated phase of labor, can be handled by segmental epidural block, a combination tranquilizer and analgesic, or a caudal epidural block. However, use of reassurance and verbal commentary in conjunction with prepared childbirth methods may be adequate for some patients to tolerate the discomfort of phase III labor.

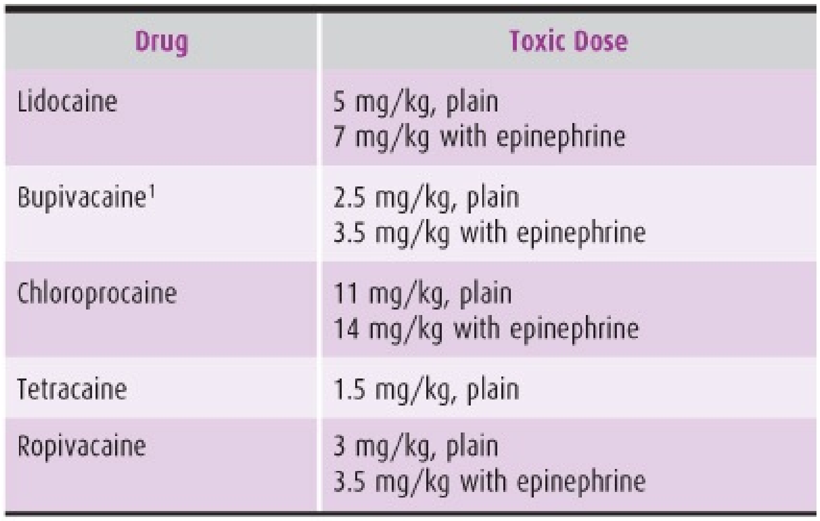
Prevention & Treatment of Local Anesthetic Overdosage

The correct dose of any local anesthetic is the smallest quantity of drug in the greatest dilution that will provide adequate analgesia. The pregnant patient is more likely to have an intravascular drug injection because of venous distention in the epidural space and may be more susceptible to the toxic effects of local anesthetics (Table 24–3). Injection of the drug into a highly vascularized area will result in more rapid systemic absorption than, for example, injection into the skin. To prevent too-rapid absorption, the operator can add epinephrine to produce local vasoconstriction and prolong the anesthetic. A final concentration of 1:200,000 is desirable, especially when a toxic amount is approached. Epinephrine is contraindicated in patients with increased cardiac irritability of medical or drug origin.

Table 24–3. Toxic doses of local anesthetics commonly used in obstetrics.



Drug	Toxic Dose
Lidocaine	5 mg/kg, plain 7 mg/kg with epinephrine
Bupivacaine[1]	2.5 mg/kg, plain 3.5 mg/kg with epinephrine
Chloroprocaine	11 mg/kg, plain 14 mg/kg with epinephrine
Tetracaine	1.5 mg/kg, plain
Ropivacaine	3 mg/kg, plain 3.5 mg/kg with epinephrine

[1] Dose as low as 90 mg have produced cardiac arrest.
All epinephrine concentrations 1:200,000.

Treatment of local anesthetic overdosage manifested by central nervous system toxicity (a convulsion) is generally achieved effectively and without incident. However, the clinician must be aware of certain basic principles. These include the recognition of prodromal signs of a central nervous system toxic reaction and immediate treatment as required. A toxic central nervous system reaction to local anesthetics consists of ringing in the ears, diplopia, perioral numbness, and deep, slurred speech. An adequate airway must be maintained, and the patient should receive 100% oxygen, with respiratory assistance if necessary. Protection of the patient’s airway and immediate injection of thiopental 50 mg or midazolam 1–2 mg usually stop the convulsion immediately. Succinylcholine was recommended in the past, but it is a potent neuromuscular relaxant that requires placement of an endotracheal tube with positive-pressure ventilation. Studies have indicated that cellular metabolism is greatly increased during convulsive episodes so that a definite increase in cellular oxygenation occurs—hence the use of a depressant selective for the hypothalamus and thalamus because these sites are the foci of irritation.

Local anesthetics-induced cardiotoxicity, especially by bupivacaine, is serious consequence when local anesthetic overdosage happens. The treatment of this complication is usually difficult, and the patient may suffer from arrhythmias (ventricular tachycardia) to even cardiac arrest. Intralipid intravenous infusion is recommended for bupivacaine-induced cardiotoxicity. Current guidelines suggest that 20% lipid emulsion initially be administered as a bolus of 1.5 mL/kg over 1 minute. After completion of the bolus, a continuous infusion of 0.25 mL/kg/min should be started. If the patient does not respond to the initial bolus, 1 to 2 additional boluses may be administered. The rate of the infusion may be increased to 0.5 mL/kg if there is persistent hypotension. The infusion should be continued until 10 min after the patient regains hemodynamic stability. An upper limit of 10 mL/kg is the recommended upper limit for administration in 30 minutes. Any patient that has had local anesthetic toxicity should be monitored for 12 hours after the event, as recurrence of cardiovascular instability has been shown to occur even after lipid administration.

ANESTHESIA FOR CAESAREAN DELIVERY

With few exceptions, all caesarean deliveries in the United States are performed with spinal, epidural, or general anesthesia. Maternal and neonatal outcomes are good when these techniques are performed effectively. In 1982, more than half of the caesarean births in the United States were performed under general anesthesia. By 1998, the rate had dropped to less than 10% of all caesarean births. Spinal anesthesia has become more common than epidural anesthesia for caesarean delivery in the past few years, primarily as a result of the introduction of newer spinal needles that prevent post–lumbar puncture headaches. Although the majority of anesthesia-related maternal mortality is associated with caesarean birth, the rate has continued to decline dramatically over the last few decades and now is less than 1.5 anesthesia-related deaths per million live births in the United States.

Regional Analgesia

A. Lumbar Epidural Block

Lumbar epidural blockade can be used for caesarean analgesia and adequate analgesia for operative delivery. As mentioned in the discussion of regional anesthesia, the major hazard of the regional analgesic technique is blockade of sympathetic fibers and a decrease in vascular resistance, along with venous pooling and hypotension. However, this can be greatly alleviated by elevating the patient's right hip to prevent compression of the vena cava by the gravid uterus when the patient is lying on the operating table. In addition, the anesthesiologist can rotate the operating table 15–20 degrees to the left to rotate the uterus away from the vena cava.

An epidural catheter can be placed immediately before surgery, or a catheter used to provide pain relief for labor can be reinjected for the surgery. After the catheter is suitably placed and taped in position, the patient should be rotated slightly out of the supine position to remove the hazard of vena cava occlusion when local anesthetic is injected as a test dose. Lidocaine 2% with epinephrine 1:200,000 can be used, or lidocaine 2% without epinephrine can be used if cardiovascular instability is present. Bupivacaine 0.5% or mepivacaine 1.5% with or without epinephrine (as described for lidocaine) also can be used. The total dosage for the therapeutic test is approximately 3 mL, which is an adequate amount to ascertain whether or not inadvertent subarachnoid injection of the drug has occurred. Incremental injections of 5 mL are then titrated to produce a T4–T6 sensory level. Usually a total volume of 18–20 mL of local anesthetic is required.

The blood pressure is monitored every 5 minutes and the dermatome levels examined every 5 minutes for the first 20 minutes to ascertain the height and density of the analgesic block. Usually a waiting period of only 15–20 minutes is needed for adequate analgesic block for incision. During this time, the patient's abdomen is surgically scrubbed and prepared and the patient draped for caesarean delivery. If a brief episode of hypotension occurs, the patient is given a rapid infusion of lactated Ringer's solution. In addition, the uterus must be shifted away from the vena cava. If these measures are not sufficient to relieve a brief episode of hypotension, 5–10 mg of ephedrine or 50–100 μg of phenylephrine can be administered intravenously for a mild vasopressor effect.

B. Subarachnoid Block

Spinal block is now the most common anesthesia used for elective caesarean delivery in the United States. The advantages are immediate onset of analgesia, so no waiting period is needed for the block to become effective, and the absence of drug transmission from the maternal to the fetal compartment because the anesthetic is deposited in the subarachnoid space in such small quantities. In addition, subarachnoid block may be a simpler technique to perform because the end point is definite—the identification of fluid from the subarachnoid space. The disadvantages are a more profound and rapid onset of hypotension and more frequent nausea and vomiting due either to unopposed parasympathetic stimulation of the gastrointestinal tract or to hypotension. Subarachnoid block usually is achieved via the paramedian or midline technique, details of which are beyond the scope of this text. The agents most commonly used for subarachnoid analgesia are lidocaine 5% (50–75 mg) and bupivacaine 10–12.5 mg. As with the lumbar epidural technique, the patient is prehydrated with 500–1000 mL of lactated Ringer’s solution.

After the technical aspects of the procedure have been completed, the patient is placed in the supine position with the uterus displaced to the left as described. If hypotension occurs, the uterus should be pushed farther to the left to improve return of blood from the lower extremities into the circulation and increase right atrial pressure and thus cardiac output, and a bolus of Ringer’s lactate should be given. If these measures are not successful, the patient should receive ephedrine 5–10 mg or phenylephrine 50–100 μg intravenously to sustain a mild vasopressor effect. During a period of hypotension, the mother should receive oxygen by mask to increase oxygen delivery to the uteroplacental bed. Newer spinal needles are associated with a low incidence (1–2%) of spinal headache (PDPH). As a result, spinal anesthesia is becoming more popular for elective caesarean surgery.

C. Combined Spinal-Epidural Anesthesia

The combination of spinal and epidural technique (CSE) has increased in popularity and may provide rapid and effective anesthesia for caesarean delivery. Advantages of CSE include the rapid onset of surgical anesthesia with a smaller spinal dose and ability to extend the duration by activation of epidural anesthesia. The use of smaller local anesthetic dose may decrease the incidence of maternal hypotension, which can be significantly detrimental both to the mother and the fetus.

General Anesthesia

General anesthesia is indicated for caesarean delivery when regional techniques cannot be used because of coagulopathy, infection, hypovolemia, or urgency. Some patients prefer to be “put to sleep” and refuse regional techniques.

Ideally, general anesthesia for caesarean delivery should cause the mother to be unconscious, feel no pain, and have no unpleasant memories of the procedure; the fetus should not be jeopardized, with minimal depression and intact reflex irritability.

General anesthesia for caesarean delivery is substantially modified from the typical nonobstetric technique. A rapid sequence technique is used with cricoid pressure to prevent aspiration, with recognition that the risks for the term obstetric patient include (1) full stomach (and aspiration), (2) difficulty with laryngoscopy and intubation, and (3) rapid desaturation if intubation is unsuccessful.

A. Patient Preparation

Preoperative medication usually is not required when the patient is brought to the caesarean section room. Alert the patient preoperatively that she may have a lucid “window” during the operative procedure when she experiences pain or hears voices. Explain that the condition results from the need to maintain a light analgesic state in order to protect the fetus from large doses of drugs. The patient should be prepared with 30 mL of nonparticulate antacid to offset gastric acidity. The patient is given 100% oxygen with a close-fitting mask for 3 minutes before induction.

B. Procedure

When the surgeon is ready to make the incision, thiopental 2.5 mg/kg should be injected intravenously and cricoid pressure exerted by an assistant. Immediately, succinylcholine 120–140 mg intravenously should be administered, and intubation and inflation of the cuff performed. Intubation is confirmed by auscultation and monitoring end-tidal CO_2 before the cricoid pressure is released and the incision made. After 6–8 breaths of 100% oxygen, the patient should be given nitrous oxide 50% with oxygen 50% until delivery of the fetus. Low concentrations of halothane or isoflurane (0.5%) will reduce the incidence of awareness. Intermediate-acting muscle relaxants maintain paralysis. An attempt must be made to keep the induction-to-delivery time under 10 minutes. Five minutes is required for redistribution of barbiturate back across the placenta into the maternal compartment. After delivery of the fetus, the nitrous oxide concentration can be increased to 70% if oxygen saturation is more than 98% and intravenous narcotics and benzodiazepines injected for supplemental anesthesia.

The patient should be fully awakened and on her side before extubation. Postoperative analgesia can be provided by patient-controlled administration of morphine or meperidine.

With this approach, good neonatal outcomes are anticipated if induction-to-delivery times and uterine entry-to-delivery times are kept to a minimum.

Local Anesthesia

Local infiltration anesthesia as a primary technique for caesarean delivery is very rarely used. When used, local anesthesia is performed to provide supplemental anesthesia in patients with inadequate epidural or spinal blockade. However, there may be situations when regional or general anesthesia is not immediately available, and caesarean delivery under local anesthesia may be necessary for fetal indications (eg, prolonged fetal bradycardia during the first stage of labor). The general nerve supply of the abdominal wall is composed of 6 of the lowest thoracic nerves, the ilioinguinal and the iliohypogastric nerves bilaterally. The 3 primary nerves that make up the sensory input from the abdomen all end as anterior cutaneous nerves in the abdominal wall. For emergent caesarean delivery, one can use 1% lidocaine in a 10-mL syringe with a 3.5-inch 25-gauge spinal needle injected just under the skin from the umbilicus to near symphysis pubis. If the knife follows this line during incision, the patient will not feel pain. Then, the subcutaneous, muscle and rectal sheath layers are injected as the abdomen is opened. This is the most rapid method for analgesia and delivery by caesarean section and may be a choice in cases in which anesthesia is not available or possible for a period of time. The major disadvantages of local infiltration are the potential for systemic toxicity and technical difficulties in providing adequate anesthesia for surgery, but it can be life-saving for the fetus when immediate delivery is needed for fetal indications.

ANESTHESIA FOR SPECIAL OBSTETRICAL CIRCUMSTANCES

Multiple Gestations

A. Psychoanalgesia

The psychoprophylactic technique helps to prepare the patient for the intrapartum experience. When the labor progresses normally, psychoanalgesia can effectively reduce apprehension and enhance the pleasurable aspects of childbirth. It also may prepare the patient for an understanding of some of the complications of multiple gestations (uterine inertia in the first stage of labor, uterine atony in the third stage, and possible need for caesarean delivery) and reduce the total amount of drugs required for analgesia.

B. Pudendal Nerve Block

Pudendal nerve block usually is reserved for cases in which epidural block is not available. Analgesia is more limited and does not provide as effective analgesia should version or breech extractions of the second twin be required.

C. Epidural Block

This technique is useful as a first-stage analgesic method, but only a segmental type should be used (T10–L2) to prevent the increased hazard of hypotension secondary to a combined large-segment sympathetic block and vena cava occlusion. Ideal management entails the use of lumbar epidural block for the first stage of labor and low caudal block for the late second stage of labor. Epidural anesthesia does not affect fetal outcome with twin delivery but has the advantage of enabling the obstetrician to intervene more easily if the second twin presents abnormally. The need for a general anesthetic can be avoided if an epidural is in place and a caesarean section is required urgently for delivery of the second twin.

D. Spinal Block

The low subarachnoid block is rarely used at the end of the second stage for crowning, delivery, and episiotomy. A low spinal block does not provide a sufficiently high block for caesarean section should it be required urgently (eg, in malpresentation or cord prolapse of the second twin). Therefore, an epidural anesthetic is always preferable for the labor and delivery of multiple births.

E. Inhalation Analgesics

Nitrous oxide is the only inhalation anesthetic that is analgesic at low concentrations. Experience is needed to use nitrous oxide safely because the pregnant patient is sensitive to the drug’s anesthetic effects and she can easily become obtunded. Loss of airway reflexes and aspiration are causes of maternal mortality.

General endotracheal anesthesia can be used for caesarean delivery of twins. Neonatal depression is more likely if the induction-to-delivery time is long (>8 minutes), especially if the uterine incision-to-delivery time also is prolonged (>3 minutes).

Midforceps Delivery

Midforceps delivery is rarely used in current practice given the limited number of practitioners skilled in the technique. Midforceps delivery generally involves both rotation and traction. Therefore, the anesthetic regimen must provide relaxation as well as analgesia for the perineum, lower vagina, and upper birth canal. In order for the obstetrician to perform the procedures necessary for delivery, optimal conditions must be provided so that maternal and fetal trauma can be minimized. Regional analgesia with a lumbar, caudal, epidural, or subarachnoid block is preferred because these blocks provide analgesia and optimal relaxation.

The Trapped Head

On the rare occasion when breech delivery is complicated by a trapped head, the application of forceps or other manipulations may be required urgently. If an epidural block is in place, no further analgesia will be required; however, if one is not in place, immediate anesthesia and pelvic relaxation will be required to facilitate rapid delivery and minimize trauma. The best technique for this purpose is general anesthesia with halothane after suitable protection of the patient from the hazards of aspiration. Protection should include use of antacid 30 mL orally and adequate oxygenation, followed by thiopental 200 mg intravenously, succinylcholine 80–100 mg intravenously, and rapid intubation with cricoid pressure. Another approach described in the literature is administration of 50–100 μg intravenous nitroglycerin to relax the lower uterine segment.

Preeclampsia–Eclampsia

This syndrome is classically described as the proteinuric hypertension. However, it can affect multiple organ systems and be associated with other variants, the most notable being HELLP syndrome, the constellation of hemolysis, elevated liver enzymes and low platelet count. Preeclampsia–eclampsia accounts for approximately 20% of maternal deaths per year in the United States. The primary pathologic characteristic of this disease process is generalized arterial spasm and endothelial dysfunction. As gestation lengthens, there is a tendency toward a fluid shift from the vascular to the extravascular compartment with resultant hypovolemia—in spite of an expanded extracellular fluid space.

It is estimated that nearly 50% of eclamptic patients who die have myocardial hemorrhages or areas of focal necrosis. Major disorders of central nervous system function probably are caused by cerebral vasospasm. Optimal anesthetic management of these patients during the intrapartum period must include a careful preanesthetic evaluation of the cardiovascular and central nervous systems.

The physiologic changes of severe preeclampsia–eclampsia are exaggerated by regional block as a result of restricted intravascular volume, which may lead to considerable depression of blood pressure. Small subgroups of these patients suffer from reduced cardiac output (compared with normal pregnancy), decreased intravascular fluid space, and marked increases in SVR. Patients with severe hemodynamic changes may require direct monitoring of pulmonary artery and wedge pressures to manage labor and the effects of epidural anesthesia. Uterine blood flow is increased with epidural block because of the favorable reduction of SVR, as long as central filling pressures and mean arterial pressure are well maintained.

Regional and general anesthesia is used in the management of preeclamptic patients. Contraindications to regional anesthesia include coagulopathy and urgency for delivery in the setting of nonreassuring fetal testing. The latter may mitigate against taking excessive time for placing a spinal or epidural if the baby requires immediate delivery.

Epidural anesthesia may be preferred to spinal anesthesia in cases of severe hypertension. The more graduated onset of sympathetic block with this technique is thought to produce less hypotension than would occur with spinal block. However, recent evidence suggests that adequate volume preloading of these patients, who by definition are depleted intravascularly, results in similar hemodynamic responses to both regional techniques. More study is required to confirm these findings. However, spinal and epidural anesthesia now usually is encouraged for the management of preeclamptic patients. Obstetricians have become aware that epidural anesthesia is a valuable adjunct in the management of hypertension as a result of the pain relief as well as the vasodilation produced by epidural block. In the past, epidural anesthesia was avoided because of an exaggerated concern over hypotension; now epidural anesthesia is encouraged if the patient’s volume status is well managed and if coagulopathy does not complicate the clinical picture.

Hemorrhage and Shock

Intrapartum obstetric emergencies demand immediate diagnosis and therapy for a favorable outcome for the mother and fetus. Placenta previa and abruptio placentae can be accompanied by serious maternal hemorrhage. Aggressive obstetric management may be indicated, but superior anesthetic management will play a major role in reducing maternal and fetal morbidity and mortality rates. The primary threat to the mother is blood loss, which reduces her effective circulating blood volume and her oxygenation potential. Similarly, the chief hazard to the fetus is diminished uteroplacental perfusion secondary to maternal hypovolemia and hypotension. The perinatal mortality rate associated with placenta previa and abruptio placentae ranges from 15–20% in some studies and up to 50–100% in other studies. The overall morbidity and mortality rates for both the fetus and the mother depend on the gestational age and health of the fetus, the extent of the hemorrhage, and the therapy given.

Good anesthetic management demands early consultation. Reliable intravenous lines should be established early. In addition, recommendations for treatment and control of shock must be formulated. Prompt caesarean delivery often is indicated. Ketamine can support blood pressure for induction. A modified nitrous oxide–oxygen relaxant method of general anesthesia will provide improved oxygenation for both the mother and the fetus and will have a minimal effect on maternal blood pressure. As surgery progresses, it may be necessary to administer large volumes of warm blood, intravenous fluids, or even vasopressors when imperative. Regional block is contraindicated in the presence of hypovolemia.

Umbilical Cord Prolapse

Umbilical cord prolapse is an acute obstetric emergency that is a critical threat to the fetus. Often, because of confusion, irrational behavior by the medical staff may threaten the mother’s life. For example, a haphazard rapid induction of anesthesia without attention to many of the essential safety details may be attempted. Naturally, prolapse of the umbilical cord is incompatible with fetal survival unless the fetal presenting part is elevated at once and maintained in that position to avoid compression of the cord. There then should be adequate time for methodical, safe induction of anesthesia. General anesthesia is induced as soon as the abdomen is prepped and draped. In the rush of the emergency situation, the anesthesiologist must remain meticulous in his or her assessment and management of the mother’s airway. A failed intubation and its consequent cardiorespiratory arrest constitute the leading cause of anesthetic maternal mortality.

Breech Delivery

Epidural anesthesia can be used for the labor patient with a breech presentation. The need for breech extraction is not increased by the use of epidural anesthesia, and a functioning epidural may prevent the need for general anesthesia should an emergency arise at delivery.

If an epidural block is not in place at the time of delivery, the anesthesiologist must be prepared to proceed with an immediate endotracheal general anesthesia if the after-coming fetal head becomes trapped. Drugs, monitors, and anesthetic equipment must be prepared in anticipation of such an event.

Because vaginal breech delivery is associated with an increased risk of perinatal mortality in singleton pregnancies, excellent communication and cooperation between the obstetrician and the anesthesiologist is greatly needed to succeed in an atraumatic delivery. Instead of vaginal delivery, most obstetricians perform caesarean delivery for singleton fetuses in breech presentation now.

Emergency Caesarean Section

General anesthesia is the technique most suitable for the urgent cesarean delivery. It entails placement of an endotracheal tube with an inflated cuff to protect the patient from aspiration of gastric contents into the lung after administration of adequate barbiturate and a muscle relaxant to facilitate endotracheal intubation. Several safety measures must be taken. (1) Give 30 mL of a nonparticulate antacid (sodium citrate) within 15 minutes of induction. (2) Accomplish denitrogenation with 100% oxygen by tight-fitting mask. (3) Inject thiopental 2.5 mg/kg intravenously. (4) Apply cricoid pressure. (5) Give succinylcholine 100–120 mg intravenously. (6) Intubate the trachea and inflate the cuff. (7) Give 6–8 deep breaths of 100% oxygen. (8) Continue to administer nitrous oxide 50% with oxygen 50%, half minimum alveolar concentration (MAC) of volatile agents, and maintain relaxation with muscle relaxants. (9) Supplement with short-acting narcotics and midazolam after the baby is delivered.

These steps should be instituted rapidly and with effective communication between the anesthesiologist and the obstetrician, who should be scrubbed and prepared to make the incision. With this technique, anesthesia can be induced and the fetus delivered within 30 minutes from the time caesarean section is ordered. To prevent vena cava occlusion from the gravid uterus, a wedge should be placed under the patient’s right hip or the operating table rotated slightly to the left.

ANESTHESIA FOR NONOBSTETRIC COMPLICATIONS

Anesthesiologists use the following classification system developed by the American Society of Anesthesiologists (ASA). It is used in both emergency and nonemergent situations to record physical status and to ascertain that proper materials are available for the anticipated procedure.

Class 1: No organic, physiologic, biochemical, or psychiatric disturbance

Class 2: Mild to moderate systemic disturbance that may or may not be related to the reason for surgery, eg, heart disease that only slightly limits physical activity, essential hypertension, anemia, extremes of age, obesity, chronic bronchitis)

Class 3: Severe systemic disturbance that may or may not be related to the reason for surgery (eg, heart disease that limits activity, poorly controlled hypertension, diabetes mellitus with vascular complications, chronic pulmonary disease that limits activity)

Class 4: Severe systemic disturbance that is life-threatening with or without surgery (eg, congestive heart failure, crescendo angina pectoris, advanced pulmonary, renal, and hepatic dysfunction)

Class 5: Moribund patient who has little chance of survival but is submitted to surgery as a last resort (resuscitative effort) (eg, uncontrolled hemorrhage as from a ruptured abdominal aneurysm, cerebral trauma, pulmonary embolus)

Emergency operation (E): Any patient in whom an emergency operation is required (eg, otherwise healthy 30-year-old woman who requires dilatation and curettage for moderate but persistent hemorrhage [ASA class 1E])

Hypertension

Pre-existing hypertensive cardiovascular disease in a pregnant woman should be differentiated from preeclampsia–eclampsia. Unlike the latter, the manifestations of hypertensive disease usually are present before week 20 of pregnancy and persist after delivery. The untreated disease by itself presents a serious challenge to the obstetrician and increases maternal and fetal risk. Chronic hypertension does not specifically contraindicate any of the anesthetic options, but the anesthesiologist must assess and manage abnormalities of volume and vascular resistance to prevent hypotension. Systemic analgesia with sedatives and tranquilizers may be selected for first-stage pain relief, but a hazard still remains.

Heart Disease

Pregnancy superimposed on heart disease presents serious problems in anesthetic management. Patients with functional class I or II rheumatic or congenital heart disease usually fare well throughout pregnancy. Except for patients with fixed cardiac output (moderate to severe aortic stenosis or mitral stenosis), regional analgesia epidural block provides ideal management of first- and second-stage pain relief. This avoids undesirable intrapartum problems such as anxiety, tachycardia, increased cardiac output, and the Valsalva maneuver. The lumbar epidural catheter can be activated for first-stage analgesia with sensory levels of T10 through L2 segments. With the restricted epidural technique, wide variations in blood pressure usually will be avoided and adequate analgesia provided.

Patients with valvular heart disease must be thoroughly assessed before onset of labor so that the anesthesiologist can determine the risks of regional block, tolerance to volume loading, and sympathectomy and determine the need for invasive monitoring. These patients require thorough physical examination, electrocardiography, echocardiography, and Doppler assessment of valve areas and left ventricular function.

Patients with stenotic lesions may not tolerate fluid loading or sympathetic block. Epidural narcotic anesthesia does not provide complete analgesia for labor but may be an appropriate choice if the patient does not tolerate the autonomic effects of local anesthetics. Patients with regurgitant valve lesions generally do well with this afterload reduction of epidural local anesthesia. Central monitoring of preload is indicated with severe lesions.

Marfan's syndrome and ischemic heart disease require early and aggressive management of labor pain to prevent hypertension and tachycardia. Early lumbar epidural anesthesia with narcotic/local anesthetic mixtures is recommended.

Diabetes Mellitus

Diabetes presents unique problems in anesthetic management because of the hazard to the fetus. The patient with diabetes requires a detailed regimen of antepartum care that extends through the intrapartum and the neonatal period. Moreover, hypotension presents an anesthetic hazard in situations of reduced fetal reserve common to diabetes. The latent phase of labor is best managed with psychological support, mild sedatives, or tranquilizers. The latter part of the first stage can be managed with small intravenous doses of narcotics or epidural block. If labor continues without signs of fetal distress and analgesia for the second stage is desired, either local or pudendal block or epidural or saddle block is appropriate. If a patient is allowed to undergo the stress of labor but fetal decompensation is evident, operative delivery must be performed at once, with emphasis on preventing hypotension. Careful regional block can be used if time permits. If time does not permit placement of a regional block, emergency general endotracheal anesthesia is indicated. Blood glucose levels should be measured intraoperatively because the unconscious patient cannot report hypoglycemia.

Gastrointestinal Difficulties

Gastrointestinal nonstriated muscle has diminished tone and motility during pregnancy. Some medical gastrointestinal difficulties present special problems in management during the intrapartum period. Peptic ulcer often improves during pregnancy, but in some cases the disease worsens in the last trimester and causes serious problems during labor and the immediate postpartum period. Ulcer perforation and hematemesis are rare in labor. Nonetheless, good management of analgesia during delivery is necessary to decrease anxiety and apprehension.

Ulcerative colitis may worsen during pregnancy. Perinatal and maternal mortality rates are not increased because symptomatic management usually is adequate. Regional ileitis may become more severe during pregnancy.

Chronic pancreatitis may be reactivated during pregnancy. Acute pancreatitis occasionally occurs in the third trimester. The significant laboratory values are elevated serum amylase and reduced serum calcium levels, along with typical symptoms of epigastric pain and nausea and vomiting.

Sympathetic blocking techniques are not contraindicated for anesthetic management of the first and second stages of labor in these gastrointestinal disorders that may coincide with pregnancy. It is clinically desirable to alleviate anxiety and apprehension in the first stage of labor because tension may exacerbate the disease process. Therefore, a tranquilizer–narcotic combination early in the first stage of labor should be considered and then lumbar epidural block for first- and second-stage management. Subarachnoid block can be administered to manage the second stage of labor successfully, with use of a true saddle block obtunding chiefly the sacral fibers.

Psychiatric Disorders

Most patients approaching delivery look on the experience as one of the happiest times of their lives. However, some patients undergo severe emotional stress during the third trimester and as delivery nears.

The obstetrician and the anesthesiologist should talk openly with a psychiatric patient about the problems of labor and delivery management and offer suggestions for management of discomfort so that she will have minimal emotional stress. The ideal technique is the combined use of lumbar epidural block for the first stage and lumbar or caudal epidural block for the second stage. It is best to carefully point out to the patient the reasons for choosing the technique and to review the technical points of the procedure so that she will not be alarmed when the block is attempted. These techniques are preferred because they afford early and continuous analgesia during labor and delivery.

TREATMENT OF COMPLICATIONS OF ANESTHETICS

Resuscitation of the Mother

Anesthesia is responsible for 10% of maternal mortality. The most common cause of maternal death is failure to intubate the trachea at induction of general anesthesia. Less frequently, maternal death results from inadvertent intravascular injection of local anesthetic (toxic reaction) or inadvertent intrathecal injection of anesthetic (total spinal).

When faced with maternal cardiovascular collapse, full cardiopulmonary resuscitation (CPR) is indicated:

1. Establish a patent airway.
2. Aspirate mucus, blood, and vomitus with a tracheal suction apparatus. Use a laryngoscope for direct visualization of air passages and intubate the trachea.
3. Administer oxygen by artificial respiration if respirations are absent or weak. If high spinal anesthesia has occurred, continue to ventilate the patient until paralysis of the diaphragm has dissipated.
4. Give vasopressors intravenously (ephedrine 10–20 mg). Place the patient in the wedged supine position with the feet elevated and give transfusions of plasma, plasma expanders, and blood for traumatic or hemorrhagic shock.
5. Specifically treat cardiac arrhythmias in accordance with advanced cardiac life support (ACLS) recommendations.
6. Provide external cardiac massage in the absence of adequate rhythm and blood pressure.
7. Consider immediate caesarean delivery to salvage fetus and improve venous return if the patient does not immediately respond to efforts.

Full cardiopulmonary arrest can be averted if the prodromal symptoms are recognized and treated immediately. A total spinal block is recognized by excessive and dense sensory and motor block to a test injection of local anesthesia through the epidural catheter. Further injections are avoided, and the patient's blood pressure is supported with fluid, positioning, and vasopressors.

An intravascular injection of local anesthetic is recognized early by symptoms of drowsiness, agitation, tinnitus, perioral tingling, bradycardia, and mild hypotension. The patient should be immediately given 100% oxygen and a small dose of diazepam (5 mg), midazolam (1 mg), or thiopental (50 mg). Further treatment may not be needed. The patient must be watched closely and the epidural catheter removed.

Section IV. Surgical & Medical Complications of Pregnancy

25
Surgical Disorders in Pregnancy

Ella Speichinger, MD
Christine H. Holschneider, MD

The incidence of surgical disease is the same in pregnant and nonpregnant patients. A total of 1.5–2% of all pregnancies undergo nonobstetric surgical intervention. Presenting symptoms of surgical diseases are often similar in pregnant and nonpregnant patients. The most common surgical disorders in pregnancy are appendicitis, cholecystitis, intestinal obstruction, adnexal torsion, trauma, and cervical and breast disease. Limited imaging can be performed during pregnancy if results would significantly alter management. The second trimester is the preferred time for nonurgent surgery. Surgery should not be delayed in any trimester if systemic infection or severe disease is suspected, as this is associated with higher risk to mother and fetus. Whenever possible, regional anesthesia should be performed. Pregnancy does not change prognosis, which depends largely on the extent of disease at diagnosis. A multidisciplinary approach with maternal–fetal medicine, surgery, anesthesia, and neonatology during treatment planning is invaluable to ensure optimal outcomes for both the mother and fetus.

Surgical interventions other than caesarean section are performed in 1.5–2.0% of all pregnancies. Altered anatomy and physiology and potential risks to the mother and fetus make diagnosis and management of surgical disorders more difficult during pregnancy. The interests of mother and fetus are best served by the obstetrician’s active participation with the anesthesiologist, neonatologist, and general surgeon throughout the mother’s diagnosis and management of a nonobstetric surgical disorder. It is imperative that the obstetrician be well informed about the ways in which surgical disorders influence pregnancy and vice versa, the risks of diagnostic and therapeutic procedures to the fetus, and appropriate management of preterm labor in the immediate postoperative period.

Surgical disorders can be either incidental to or directly related to the pregnancy. Diagnostic evaluation requires gentle, sensitive elicitation of physical signs, at times without sophisticated diagnostic aids that involve risk to the developing fetus. Good judgment regarding the timing, methods, and extent of treatment is important. In the absence of peritonitis, visceral perforation, or hemorrhage, surgical disorders during gestation generally have little effect on placental function and fetal development.

MATERNAL CONSIDERATIONS

Pregnancy is accompanied by physiologic and anatomic changes that alter the evaluation and management of the surgical patient. The 30–50% increase in plasma volume during pregnancy affects cardiac output and may alter drug distribution and laboratory test results. Red cell mass increases but not as much as the plasma volume, resulting in a slight physiologic anemia. Colloid osmotic pressure is decreased during pregnancy. Increased interstitial fluid is seen as mild edema, particularly in the lower extremities. Systemic vascular resistance decreases during pregnancy. Systolic and diastolic blood pressures characteristically drop during the early second trimester, with a gradual return to baseline by term. Functional pulmonary residual capacity decreases due to limitation of diaphragmatic excursion. Minute ventilation increases due to increased tidal volume and respiratory rate. A compensated mild respiratory alkalosis exists. Increased renal blood flow is evidenced by increased glomerular filtration rate and decreased serum creatinine and blood urea nitrogen values. Gastrointestinal motility is diminished, resulting in delayed gastric emptying and constipation. The enlarging uterus may alter the anatomic relation among the different organs. When the patient is in the supine position, the enlarged uterus may compress the inferior vena cava and result in the hypotensive vena cava compression syndrome.

FETAL CONSIDERATIONS

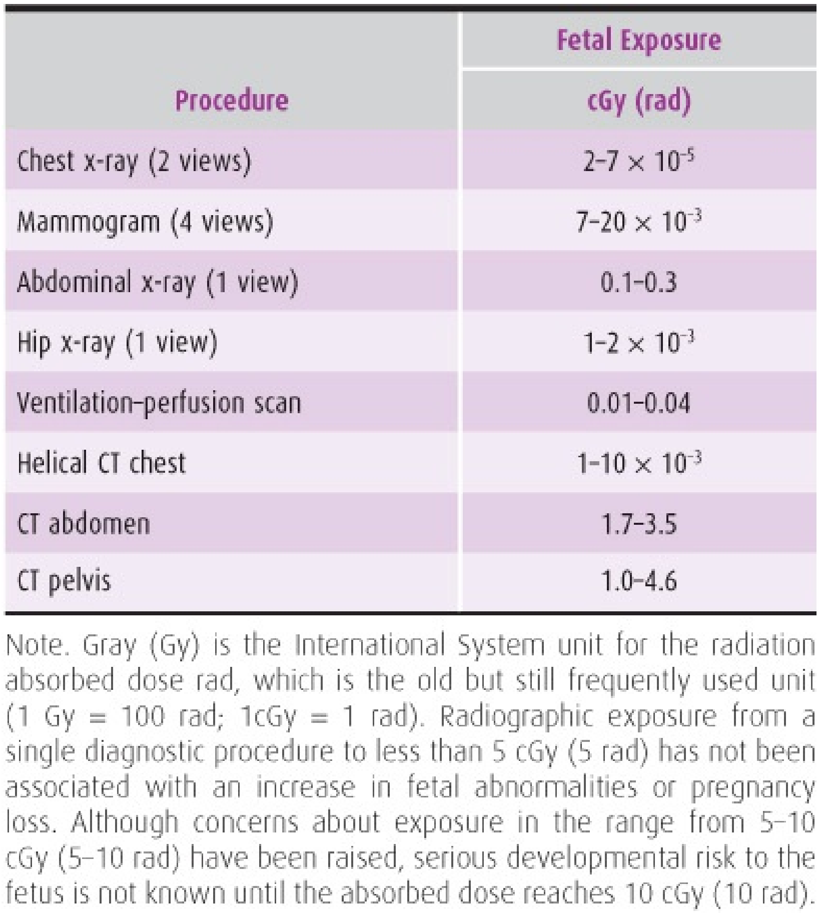
Optimal care of the pregnant surgical patient requires that potential hazards to the fetus be minimized. This includes risks associated with the maternal disease, diagnostic radiologic procedures, therapeutic drugs, anesthesia, and surgery. Assessment of the risks and benefits to the mother is relatively easy but less so for the fetus because of its relative inaccessibility.

A number of imaging modalities are available for diagnosis during pregnancy, including ultrasound (US), magnetic resonance imaging (MRI), computed tomography (CT), and x-ray.

Radiation Exposure

Although no definite harmful effects from the diagnostic use of US and MRI during pregnancy are reported, exposure to radiation is associated with fetal risks. Limited diagnostic CT or x-ray procedures can be undertaken with care in the pregnant patient. The fetus should be shielded whenever possible. The risk of adverse fetal effects associated with radiation exposure changes with gestational age and is related to the radiation dose to the fetus. These risks fall principally into 2 categories: teratogenicity and carcinogenicity. For example, within 2 weeks of fertilization, the embryo is most susceptible to implantation failure. If implantation was not affected, teratogenicity is extremely unlikely. Before 8 weeks, the fetus is at risk for radiation-induced growth restriction. At 8–15 weeks, the embryo is the most susceptible to mental retardation, with an approximately 4% risk on exposure at 10 cGy and 60% at 150 cGy. Teratogenic effects are unlikely in embryos older than 20 weeks. The most common fetal defects seen with direct fetal irradiation of 10 cGy or more are microcephaly, mental retardation, intrauterine growth restriction, and eye abnormalities. Current evidence suggests no increased structural or developmental fetal risk with radiation doses less than 5 cGy. The second set of concerns exists regarding in utero radiation exposure and its association with an increase in childhood neoplasms. The risk appears to be dose-related. Natural background fetal radiation exposure is estimated at 0.1 cGy. Fetal exposure to 2–5 cGy is estimated to translate into a relative risk of 1.5–2.0 for fatal childhood cancer, recognizing that the absolute risk is still very low (2 in 2000). Table 25–1 outlines estimates of fetal radiation exposure with various diagnostic procedures.

Table 25–1. Estimated fetal radiation exposure from common diagnostic radiologic procedures.



Procedure	Fetal Exposure
	cGy (rad)
Chest x-ray (2 views)	$2–7 \times 10^{-5}$
Mammogram (4 views)	$7–20 \times 10^{-3}$
Abdominal x-ray (1 view)	0.1–0.3
Hip x-ray (1 view)	$1–2 \times 10^{-3}$
Ventilation–perfusion scan	0.01–0.04
Helical CT chest	$1–10 \times 10^{-3}$
CT abdomen	1.7–3.5
CT pelvis	1.0–4.6

Note. Gray (Gy) is the International System unit for the radiation absorbed dose rad, which is the old but still frequently used unit (1 Gy = 100 rad; 1cGy = 1 rad). Radiographic exposure from a single diagnostic procedure to less than 5 cGy (5 rad) has not been associated with an increase in fetal abnormalities or pregnancy loss. Although concerns about exposure in the range from 5–10 cGy (5–10 rad) have been raised, serious developmental risk to the fetus is not known until the absorbed dose reaches 10 cGy (10 rad).

Exposure to Contrast

Traditionally, it has been recommended that use of iodine contrast be avoided during pregnancy. Although in vivo animal studies have not documented teratogenesis, ionic contrast when instilled directly into the amniotic sac during amniofetography has provoked neonatal hypothyroidism. Intravenous use of nonionic contrast media has been reported to have no effect on neonatal thyroid function. Given the existing data, the American College of Radiology states that definitive conclusions regarding the safety of intravascular iodinated contrast use cannot be made and recommends its use in pregnancy only if necessary. Before administration, it is important to weigh information that will be obtained by the addition of iodine contrast and to obtain informed consent. It is essential that infants whose mothers have received iodine contrast have thyroid function tested postnatally.

Gadolinium crosses the placenta and is thought to be excreted by the fetal kidneys into the amniotic fluid. There is a theoretical concern for toxicity related to persistence of free gadolinium. The American College of Radiology discourages its use in pregnancy, stating it should be used only if absolutely essential and following informed consent. However, the US Food and Drug Administration classifies gadolinium as a class C drug, and the European Society of Radiology states that based on available evidence, the use of gadolinium in pregnancy appears to be safe.

In summary, routine preoperative radiologic procedures are not justified. However, if clinical management of the pregnant patient would be significantly altered based on the findings of a judiciously performed radiologic procedure, the limited fetal exposure risk is generally warranted. Gadolinium should be considered only if the diagnostic information gained from the study is essential for the health of the mother. When multiple diagnostic images are required, consultation with a dosimetry expert may be helpful in calculating estimated fetal dose.

Surgical and Anesthesia Risks

Fortunately, most women who require surgery during pregnancy are otherwise relatively healthy and undergo an uneventful postoperative course. Generally, the safety of nonobstetric surgery in pregnancy and general anesthesia has been well established. Nevertheless, some increased risks are associated with surgery and anesthesia during pregnancy, and purely elective surgical procedures should be postponed until after pregnancy. Individual studies have suggested a possible increase in neural tube defects; other registries have documented adverse effects including low birth weight, prematurity, intrauterine growth restriction, and early neonatal death, but they are thought to correlate with the underlying condition that necessitates the surgical procedure. A review of 54 articles documenting pregnancy outcomes of nonobstetric surgical procedures between 1966 and 2002 found a low rate of miscarriage, congenital abnormalities, and preterm birth, but firm conclusions cannot be made, as no suitable control group existed. Thus, despite the general safety of anesthetic agents in pregnancy, some concern remains regarding teratogenicity in early gestation, and all but truly emergent surgery should be postponed until the second trimester. The second trimester is the preferred surgery time over the third trimester, as the risk of preterm labor and spontaneous abortion is lowest at that time. Whenever possible, regional anesthesia should be performed. No known reproductive toxicity is associated with currently used local anesthetic agents at recommended dose ranges. Short-term postoperative use of narcotic analgesic agents, frequently in combination with acetaminophen or nonsteroidal anti-inflammatory drugs before 32 weeks, generally appears to produce no adverse fetal effects.

Because intrauterine asphyxia is a major risk to the fetus consequent to maternal surgery, monitoring and maintaining maternal oxygen-carrying capacity, oxygen affinity, arterial PO_2, and placental blood flow throughout the preoperative, operative, and postoperative periods are important. For gestations greater than 18 weeks, attention should be given to providing uterine displacement to prevent venocaval compression when the patient is in the supine position. Supplemental oxygen administration and maintenance of circulating volume also assist fetal oxygenation. A reduction in maternal blood pressure can lead directly to fetal hypoxia. Greater reductions in uteroplacental perfusion by direct vascular constriction and an increase in uterine tonus are noted in association with the use of vasopressors, especially those with predominantly α-adrenergic activity. Ephedrine, with its peripheral beta-adrenergic effect, produces much less vasospasm and has traditionally been the vasopressor of choice in the pregnant patient, especially for treating hypotensive complications of regional anesthesia. More recent data find phenylephrine a good alternative with no untoward fetal effects.

To ensure fetal well-being, continuous electronic fetal heart rate monitoring should be used when maternal surgery is performed after 24 weeks as long as the monitoring device can function outside the sterile surgical field. In some cases, intraoperative electronic fetal monitoring may be considered in previable pregnancies to facilitate maternal positioning and oxygenation. At minimum, if the fetus is considered to be viable, electronic fetal and contraction monitoring is advised both before and after the procedure to assess fetal well-being and to evaluate for signs of preterm labor.

The severity of the inflammatory response associated with the disease requiring surgery appears to be more important in determining pregnancy outcome than is the use of anesthesia or the surgical procedure itself. Premature labor does not appear to be a common result of procedures such as exploratory laparotomy unless visceral perforation and peritonitis are encountered or a low pelvic procedure is performed with significant uterine manipulation. Prophylactic use of tocolytics in this setting is controversial. Often, a single dose of a beta-adrenergic agent such as terbutaline is sufficient to arrest contractions. Use of indomethacin may be preferred if significant inflammation is present;

however, patency of fetal ductus arteriosus and amniotic fluid index should be monitored if used for more than 48 hours. If possible, uterine activity should be monitored after surgery to detect preterm labor and allow for early intervention. There are no studies to guide the decision to administer prophylactic glucocorticoids at the time of nonobstetric surgery. In the absence of systemic maternal infection, glucocorticoids should be considered if the gestation is between 24 and 34 weeks to reduce perinatal morbidity and mortality if preterm delivery occurs. Additionally, there is no literature to support progesterone supplementation perioperatively unless the corpus luteum is removed before 12 weeks of gestation.

DIAGNOSTIC CONSIDERATIONS

History

Clues to the cause of surgical disorders in pregnancy are often found in a careful review of the medical history. The stage and status of pregnancy are also relevant.

Pain

Pain is the most prominent symptom encountered with acute abdominal conditions complicating pregnancy. Generalized abdominal pain, guarding, and rebound strongly suggest peritonitis secondary to bleeding, exudation, or leakage of intestinal contents. Peritoneal signs can be less obvious in pregnancy as the uterus may displace the infected organ from contact with the parietal peritoneum. Cramping with lower central abdominal pain suggests a uterine disorder. Lower abdominal pain on either side suggests torsion, rupture, or hemorrhage of an ovarian cyst or tumor. Right lower or midabdominal pain suggests appendicitis. Disorders of the descending and sigmoid colon with left lower quadrant pain are infrequently encountered because of the relatively young age of obstetric patients. Midabdominal pain early in gestation suggests an intestinal origin. Upper abdominal pain is often related to the liver, spleen, gallbladder, stomach, duodenum, or pancreas. Constipation is a common problem but is rarely associated with other symptoms.

Other Symptoms

Abdominal pain associated with nausea and vomiting after the first trimester usually suggests a gastrointestinal disorder. Nausea and vomiting associated with the inability to pass gas or stool points to an intestinal obstruction. Diarrhea is seldom encountered in association with acute surgical problems except as a symptom of recurrent ulcerative colitis.

Syncope associated with pain and signs of peritoneal irritation usually indicate an acute abdominal emergency with rupture of a viscus, ischemia, or hemorrhage. A temperature of 38 °C (100.4 °F) or greater suggests infection, which may be localized by other clinical findings. Fever can also be associated with later stages of visceral necrosis in the cases of torsion or intestinal ischemia. Vaginal bleeding usually points to an intrauterine or cervical problem. Urinary tract infection is often accompanied by urinary frequency and urgency.

Physical Examination

The patient with an acute abdomen should undergo careful assessment of the reproductive organs, and her vital signs and general condition should be noted as well as the presence or absence of bowel sounds, abdominal rigidity or rebound tenderness, and the presence or absence of a mass. The fewest possible number of abdominal examinations should be gently performed without haste and with adequate explanation, using the flat part of the hand and starting in an asymptomatic area.

Laboratory Studies

Several laboratory studies routinely used in the evaluation of surgical disease have altered normal values during pregnancy; they are discussed where appropriate for the specific disease entity. The white blood cell count is considered elevated if the value is above 16,000/μL in any trimester. An interval of several hours usually passes between onset of hemorrhage and detection of lowered hematocrit values.

ANESTHESIA

The type of anesthesia is determined primarily by the planned surgical procedure. All general anesthetic agents cross the placenta but are not thought to be teratogenic. Regional anesthesia minimizes fetal exposure but may either not be appropriate for the surgical procedure or the maternal condition. If general anesthesia is anticipated, it is important to consider the physiologic changes in pregnancy, such as increased oropharyngeal swelling and decreased glottic opening, which can complicate intubation and ventilation. Obesity and preeclampsia can exacerbate these difficulties, leading to aspiration, failed intubation, and subsequent maternal and fetal hypoxia. Despite this, successful general anesthesia optimizes maternal and fetal oxygenation and reduces intraoperative uterine irritability. During either regional or general anesthesia, liberal oxygen supplementation should be employed to avoid maternal and fetal hypoxia.
