Delay in diagnosis and performance of surgery is the factor primarily responsible for increased maternal morbidity rates and perinatal loss, especially with maternal abdominal trauma. Immediate surgical exploration is generally indicated in the presence of unmistakable signs of peritoneal irritation, evidence of strangulating intestinal obstruction with possible gangrene, or intraabdominal hemorrhage. In subacute conditions, care should be used in deciding to proceed with surgery. Surgery that is not urgent and can be delayed is best deferred until the second trimester or puerperium. Surgical techniques usually are not altered because of the pregnancy. Essentials of good preoperative care include adequate hydration, availability of blood for transfusion, and appropriate preoperative medication that will not decrease oxygenation for mother and fetus. Gestational age, uterine size, the specific surgical disorder, and the anticipated type of surgery to be performed are important factors in the selection of the abdominal incision. At operation, the least extensive procedure necessary should be performed with as little manipulation of the uterus as possible. Unless an obstetric indication is present or the uterus interferes with performance of a procedure, it usually is best not to perform a caesarean delivery during an abdominal operation.

Postoperative care depends on the gestational age and the operation performed. For patients whose gestation has reached viability, electronic monitoring of fetal heart rate and uterine activity should be continued in the immediate postoperative period, with staff capable of performing an emergent caesarean section readily available. Oversedation and fluid or electrolyte imbalance are to be avoided. Encouragement of early maternal activity and resumption of normal food intake are generally recommended.

THROMBOPROPHYLAXIS

Both pregnancy and surgery increase the risk of venous thromboembolism (VTE). Beginning in early pregnancy, vitamin K coagulation factors and type-1 plasminogen activator inhibitor increase, whereas protein S levels decrease. Surgery increases venous stasis and causes endothelial damage. Both mechanical and pharmacologic thromboprophylaxis reduce the incidence of symptomatic VTE. Pneumatic compression devices have few contraindications and should be considered for all pregnant women undergoing surgery. Pharmacologic thromboprophylaxis should be weighed against the patient’s risk of thrombosis versus perioperative bleeding. Pregnant women who have an inherited or acquired thrombophilia, prolonged immobilization, past history of VTE, malignancy, age older than 35 years, multiple gestation, systemic illness, or obesity are at increased risk for VTE.

Dargaud Y, Rugeri L, Vergnes MC, et al. A risk score for the management of pregnant women with increased risk of venous thromboembolism: A multicentre prospective study. *Br J Haematol* 2009;145:825–835. PMID: 19388925.

LAPAROSCOPY IN PREGNANCY

Over the past 2 decades, laparoscopy has been increasingly used during pregnancy in the management of a variety of surgical disorders, most commonly for the exploration and treatment of adnexal masses, for appendectomy, and for cholecystectomy, but also for more technical surgical procedures such as nephrectomy, splenectomy, or retroperitoneal lymphadenectomy. The major advantages are decreased postoperative morbidity, less pain, shorter hospital stay, and postoperative recovery time. There may also be benefits specific to pregnancy, such as less uterine manipulation and better visualization around the enlarged uterus. Possible drawbacks are the risk of injury to the pregnant uterus, technical difficulty with exposure because of the enlarged uterus, increased carbon dioxide absorption, and decreased uterine blood flow secondary to excessive intraabdominal pressure. Knowledge of the short- and long-term effects of laparoscopy on the human fetus is limited. Laparoscopy has been performed during all trimesters. During the first half of pregnancy, the risks inherent to the laparoscopic procedure do not appear to be substantially increased compared with the risks in nonpregnant patients. The largest population-based study of 2181 laparoscopies and 1522 laparotomies before 20 weeks' gestation did not find any differential impact of laparoscopy versus laparotomy on perinatal outcome. Fetal loss appears to be associated with maternal disease severity rather than with operative technique. Risks of uterine injury can be mitigated by placing a supraumbilical port 6 cm above the fundus using the open (Hasson's) technique; others recommend inserting the Veres needle in the left upper quadrant. Trocar placement under ultrasound guidance has also been described. Because there is uncertainty regarding the possible adverse effects of pneumoperitoneum and potential for fetal acidosis, attempts should be made to keep intraabdominal pressure between 8 and 12 mm Hg and not to exceed 15 mm Hg. Intraoperative CO_2 monitoring should be used to maintain end-tidal CO_2 between 32 and 34 mm Hg.

GASTROINTESTINGAL DISEASES & DISORDERS

Early accurate diagnosis of serious abdominal surgical disease during pregnancy is more difficult for the following reasons: (1) altered anatomic relationships, (2) impaired palpation and detection of nonuterine masses, (3) depressed symptoms, (4) symptoms that mimic the normal discomforts of pregnancy, and (5) difficulty in differentiating surgical and obstetric disorders. In general, elective surgery should be avoided during pregnancy, but operation should be performed promptly for definite or probable acute disorders. The approach to surgical problems in pregnant or puerperal patients should be the same as in nonpregnant patients, with prompt surgical intervention when indicated. The risk of inducing labor with diagnostic laparoscopy or laparotomy is low, provided unnecessary manipulation of the uterus and adnexa is avoided. Spontaneous abortion is most likely to occur if surgery is performed before 14 weeks' gestation or when peritonitis is present.

APPENDICITIS

ESSENTIALS OF DIAGNOSIS

- Symptoms include abdominal pain, usually localized to right lower or mid quadrant, with nausea, vomiting, and/or anorexia.
- Patients may have an elevated white blood cell count with a left shift.
- Ultrasound or CT scan demonstrates enlargement or inflammation of the appendix.

Clinical Findings

Acute appendicitis is the most common extrauterine complication of pregnancy for which surgery is performed. Suspected appendicitis accounts for nearly two-thirds of all nonobstetric exploratory celiotomies performed during pregnancy; most cases occur in the second and third trimesters.

Appendicitis occurs in 0.1–1.4 per 1000 pregnancies. Although the incidence of disease is not increased during gestation, rupture of the appendix occurs 2–3 times more often during pregnancy secondary to delays in diagnosis and operation. Maternal and perinatal morbidity and mortality rates are greatly increased when appendicitis is complicated by peritonitis.

A. Symptoms & Signs

The diagnosis of appendicitis in pregnancy is challenging. Signs and symptoms often are atypical and not dramatic. Right lower quadrant or middle quadrant pain almost always is present when acute appendicitis occurs in pregnancy but may be ascribed to so-called round ligament pain or urinary tract infection. In nonpregnant women, the appendix is located in the right lower quadrant (65%), in the pelvis (30%), or retrocecally (5%). Traditionally it was taught that pregnancy displaces the appendix upwardly. However, some retrospective studies suggest that there is only minimal appendiceal migration throughout pregnancy.

The most consistent clinical symptom encountered in pregnant women with appendicitis is vague pain on the right side of the abdomen, although atypical pain patterns abound. Muscle guarding and rebound tenderness are much less demonstrable as gestation progresses. If pain changes from localized tenderness to a more diffuse nature, appendiceal perforation should be suspected. Rectal and vaginal tenderness are present in 80% of patients, particularly in early pregnancy. Nausea, vomiting, and anorexia usually are present, as in the nonpregnant patient. During early appendicitis, the temperature and pulse rate are relatively normal. High fever is not characteristic of the disease, and 25% of pregnant women with appendicitis are afebrile.

B. Laboratory Findings

The relative leukocytosis of pregnancy (normal 6000–16,000/μL) clouds interpretation of infection. Although not all patients with appendicitis have white blood cell counts above 16,000/μL, at least 75% show a left shift in the differential. Urinalysis may reveal significant pyuria (20%) as well as microscopic hematuria. This is particularly true in the latter half of pregnancy, when the appendix migrates closer to the retroperitoneal ureter.

C. Imaging

In the nonpregnant patient, CT of the abdomen with and without contrast has become an important tool aiding in the diagnosis of appendicitis. To avoid the risk of radiation to the fetus, US has a distinct role as the first-line imaging modality in pregnancy (Fig. 25–1). Graded compression ultrasonography has been found to have a high positive predictive value but average sensitivity in diagnosing appendicitis. MRI is helpful in further aiding the diagnosis in patients for whom sonographic findings are nondiagnostic. If US is nondiagnostic and MRI is not available, CT may be appropriate. A noncompressible appendix on ultrasound is abnormal, whereas MRI or CT may demonstrate an enlarged, fluid-filled appendix with or without a fecalith. An appendix measuring > 6 mm should be considered abnormal.

Figure 25–1. Acute appendicitis diagnosed by graded compression ultrasonography. **A**: Longitudinal image of the right lower quadrant demonstrates the appendix as a blind-ending, thick-walled tubular structure. **B**: Transverse images with and without compression demonstrate this structure remains at least 6 mm thick with compression. (Images used, with permission, from Dr. Maitraya Patel, Olive View-UCLA Medical Center, Sylmar, CA.)

Differential Diagnosis

Pyelonephritis is the most common misdiagnosis in patients with acute appendicitis in pregnancy. The differential diagnosis of appendicitis includes gastrointestinal disorders such as gastroenteritis, small bowel obstruction, diverticulitis, pancreatitis, mesenteric adenitis, diverticulitis, and neoplasm; also possible are gynecologic and obstetric disorders such as ruptured corpus luteum cyst, adnexal torsion, ectopic pregnancy, placental abruption, early labor, round ligament syndrome, chorioamnionitis, degenerating myoma, or salpingitis.

Complications

Postoperative preterm labor has been reported to occur in 25% of second-trimester and as high as 50%

of third-trimester patients. Most preterm deliveries occur within the first postoperative week. Perinatal loss may occur in association with preterm labor and delivery or with generalized peritonitis and sepsis, occurring in 0–1.5% of uncomplicated appendicitis cases. Twenty-five percent of pregnant women with appendicitis will progress to perforation; this risk is greatest when surgery is delayed more than 24 hours. With appendiceal rupture, fetal loss rates are reportedly as high as 30%, and maternal mortality rates as high as 4% are reported. This is of particular concern because appendiceal rupture occurs most frequently in the third trimester.

Treatment

Immediate surgical intervention is indicated once the diagnosis of appendicitis is made. In the setting of active labor, the surgery should be performed immediately postpartum. Delaying treatment increases the risk of perforation, which in turn increases the risk of fetal loss. Under appropriate conditions, laparoscopic appendectomy may be as safe as open appendectomy. A systematic review of 637 cases of laparoscopic appendectomy showed a significantly higher rate of fetal loss (6% vs. 3.1%), though equal or lesser rates of preterm delivery compared with open appendectomy. Large series report a negative surgical exploration rate between 13% and as high as 55%, likely due to the many processes that may mimic appendicitis in pregnancy. When the appendix appears normal at laparotomy, careful exploration for other nonobstetric and obstetric conditions is important.

Treatment of nonperforated acute appendicitis complicating pregnancy is appendectomy. A single dose of preoperative prophylactic antibiotics should be routinely given. In the setting of perforation, peritonitis, or abscess formation, broad-spectrum intravenous antibiotics should be continued until culture and sensitivities can narrow antibiotic choice. If drainage is necessary for generalized peritonitis, drains should be placed transabdominally and not transvaginally. During the first trimester, a transverse incision at McBurney’s point or over the area of maximal tenderness is generally considered appropriate. If the diagnosis is not certain, a vertical midline incision can be made. Laparoscopy is an alternate surgical approach used with increasing frequency, especially in the first half of pregnancy. In the late second or third trimester, a muscle-splitting incision centered over the point of maximal tenderness usually provides optimal appendiceal exposure. As a rule, appendiceal disease is managed and the pregnancy is left alone. A Smead-Jones combined mass and fascial closure with secondary wound closure 72 hours later may be advisable when the appendix is gangrenous or perforated or in the presence of peritonitis or abscess formation.

Induced abortion is rarely indicated. Depending on the gestational age and expert neonatal care available, abdominal delivery occasionally is performed when peritonitis, sepsis, or a large appendiceal or cul-de-sac abscess occurs. Data are limited, so making definitive recommendations regarding the use of prophylactic tocolytics is difficult. It appears unnecessary in uncomplicated appendicitis but may be appropriate with advanced disease. Caution is indicated because of reports that tocolytics are associated with an increased risk of pulmonary edema in women with sepsis. Labor that follows shortly after surgery in the late third trimester should be allowed to progress because it is not associated with a significant risk of wound dehiscence. At times, the large uterus may help wall off an infection, which after delivery may become disrupted, leading to an acute abdomen within hours postpartum.

Prognosis

Better fluid and nutritional support, use of antibiotics, safer anesthesia, prompt surgical intervention, and improved surgical technique have been important elements in the significant reduction of maternal mortality from appendicitis during pregnancy. Similarly, the fetal mortality rate has significantly improved over the past 50 years. Perinatal loss is low and maternal mortality negligible in cases of uncomplicated appendicitis, but increase significantly in the setting of peritonitis or appendiceal rupture. Thus it is imperative to avoid surgical delay. A higher negative laparotomy or laparoscopy rate may be an acceptable trade-off for a lower fetal mortality rate.

CHOLECYSTITIS & CHOLELITHIASIS

ESSENTIALS OF DIAGNOSIS

- ▸ Patients usually present with abdominal pain in the right upper quadrant or epigastric region.
- ▸ Serum laboratories may demonstrate an elevation in the white blood cell count and/or elevated liver enzymes.
- ▸ Ultrasound of the right upper quadrant of the abdomen is usually diagnostic in these cases.

Clinical Findings

Gallbladder disease is one of the most common medical conditions and the second most common surgical disorder during pregnancy. Gallstones are responsible for 90% of cholecystitis in Western countries; parasitic infections are a less common cause. Acute cholecystitis occurs in 1 in 1600 to 1 in 10,000 pregnancies. Well-described risk factors for cholelithiasis are age, female sex, fertility, obesity, and family history. It has been estimated that at least 3.5% of pregnant women harbor gallstones. Multiparas are at increased risk of gallbladder disease. Both progesterone and estrogen increase bile lithogenicity; progesterone decreases gallbladder contractility. These changes are seen by the end of the first trimester of pregnancy.

A. Symptoms and Signs

Signs and symptoms are similar to those seen in the non-pregnant state and include anorexia, nausea, vomiting, dyspepsia, and intolerance of fatty foods. Biliary tract disease may cause right upper quadrant, epigastric, right scapular, shoulder, and even left upper quadrant or left lower quadrant pain that tends to be episodic. Biliary colic attacks often are of acute onset, seemingly are triggered by meals, and may last from a few minutes to several hours. Fever, right upper quadrant pain, and tenderness under the liver with deep inspiration (Murphy’s sign) are often present in patients with acute cholecystitis. In severe cases the patient may have mild jaundice or appear septic.

B. Laboratory Findings

An elevated white blood cell count with an increase in immature forms is seen with acute cholecystitis. Aspartate transaminase (AST) and alanine transaminase (ALT) levels are often increased. Modest increases in the alkaline phosphatase and bilirubin levels are anticipated very early in cholecystitis or common duct obstruction. However, a more characteristic pattern of relatively normal AST and ALT levels with elevated alkaline phosphatase and bilirubin levels is generally found after the first day of the attack. These changes are not diagnostic and do not signify common bile duct stone or obstruction alone, but when present they serve to support the diagnosis. Elevated lipase and amylase support the diagnosis of an associated pancreatitis.

C. Imaging

US findings of gallbladder stones, a thickened gallbladder wall, fluid collection around the gallbladder, a dilated common bile duct, or even swelling in the pancreas are suggestive of cholelithiasis and cholecystitis. The diagnostic accuracy of US for detecting gallstones in pregnancy is 95%, making it the diagnostic test of choice.

Differential Diagnosis

The major diagnostic difficulty imposed by pregnancy is differentiating between cholecystitis and appendicitis. In addition to its association with gallstones, cholecystitis can be infectious secondary to *Salmonella typhi* or parasites. A number of other lesions of the biliary tract occur rarely during gestation, including choledochal cysts, which are seen as a spherical dilatation of the common bile duct with a very narrow or obstructed distal end. Associated pancreatitis may be present. Severe preeclampsia with associated right upper quadrant abdominal pain and abnormal liver function tests; hemolysis, elevated liver enzymes, and low platelet count (HELLP) syndrome; acute fatty liver of pregnancy; and acute viral hepatitis are in the differential diagnosis. The presence of proteinuria, nondependent edema, hypertension, and sustained increases in AST and ALT levels compared with alkaline phosphatase level are clinical and laboratory features usually associated with preeclampsia. Peptic ulcer disease, myocardial infarction, and herpes zoster also have overlapping symptoms.

Complications

Secondary infection with enteric flora such as *Escherichia coli*, *Klebsiella*, or *Streptococcus faecalis* complicates one-fifth of cases. Pancreatitis may frequently accompany cholecystitis during pregnancy. Removal of the gallbladder and gallstones may be preferred over conservative medical therapy when pancreatitis is concurrent, as it is associated with fetal loss in 3–20% of pregnant patients. Other uncommon complications of cholecystitis during gestation are retained intraductal stones, gangrenous cholecystitis, galbladder perforation with biliary peritonitis, cholecystoenteric fistulas, and ascending cholangitis.

Treatment

The initial management of symptomatic cholelithiasis and cholecystitis in pregnancy is nonoperative with bowel rest, intravenous hydration, correction of electrolyte imbalances, and analgesics. If antibiotics are not routinely given, they should be administered if no improvement is seen in 12–24 hours or if systemic symptoms are noted. This therapy results in resolution of acute symptoms in most patients. Surgical intervention is indicated if symptoms fail to improve with medical management, for recurrent episodes of biliary colic, and for complications such as recurrent cholecystitis, choledocholithiasis, and gallstone pancreatitis. Because recurrence rates for symptomatic biliary disease during pregnancy may be as high as 60–92%, active surgical management, especially in the second trimester, has been advocated in recent years. Recent literature has demonstrated the safety of open and laparoscopic cholecystectomy during pregnancy. Endoscopic retrograde cholangiopancreatography (ERCP) with endoscopic sphincterotomy may be an alternative for selected patients with common bile duct stones. Operative therapy for uncomplicated cholecystitis performed during the second and third trimesters does not appear to be associated with an appreciable increase in morbidity and mortality rates or fetal loss.

Prognosis

The outcomes for mother and fetus after uncomplicated gallbladder surgery are excellent. Morbidity and mortality rates increase with maternal age and extent of disease.

ACUTE PANCREATITIS

ESSENTIALS OF DIAGNOSIS

- Patients usually present with epigastric pain that may radiate to the back.
- Serum amylase and lipase levels are elevated, findings diagnostic of pancreatitis.
- Ultrasound may demonstrate an enlarged pancreas and fluid within the peritoneal cavity.

Clinical Findings

The incidence of acute pancreatitis in pregnancy reportedly ranges from 1 in 1000 to 1 in 5000 deliveries. Pancreatitis occurs most frequently in the third trimester and puerperium. The mortality rate associated with acute pancreatitis may be higher during pregnancy because of delayed diagnosis. The ultimate cause of pancreatitis is the presence of activated digestive enzymes within the pancreas. Many cases of pancreatitis are idiopathic. As in the nonpregnant state, cholelithiasis is the most commonly identified cause, followed by alcoholism, lipidemia, viral and drug-induced pancreatitis, familial pancreatitis, structural abnormalities of the pancreas or duodenum, severe abdominal trauma, vascular disease, and preeclampsia-associated pancreatitis.

A. Symptoms & Signs

Gravidas with pancreatitis usually present with severe, steady epigastric pain that often radiates to the back in general approximation of the retroperitoneal location of the pancreas. Often exacerbated by food intake, its onset may be gradual or acute and is frequently accompanied by nausea and vomiting. During gestation, patients may present primarily with vomiting with little or no abdominal pain. Although physical examination is rarely diagnostic, several findings of note may be present, including a low-grade fever, tachycardia, and orthostatic hypotension. The latter finding may be present with hemorrhagic pancreatitis in addition to Cullen's sign (periumbilical ecchymosis) and Turner's sign (flank ecchymosis). Epigastric tenderness and ileus also may be present.

B. Laboratory Findings

The cornerstone of diagnosis is the determination of serum amylase and lipase levels. Interpretation of serum amylase levels in pregnancy is difficult at times because of the physiologic, up to 2-fold rise in serum amylase level during pregnancy. A laboratory serum amylase level that is more than 2 times above the upper limit of normal suggests pancreatitis. However, an elevated serum amylase level is not specific for pancreatitis because cholecystitis, bowel obstruction, hepatic trauma, or a perforated duodenal ulcer can cause similar serum amylase level elevations. Serum amylase levels usually return to normal within a few days of an attack of uncomplicated acute pancreatitis. Serum lipase level is a pancreas-specific enzyme and lipase elevation can guide the differential diagnosis toward pancreatitis. In severe pancreatitis, hypocalcemia develops as calcium is complexed by fatty acids liberated by lipase.

C. Imaging

Sonographic examination may demonstrate an enlarged pancreas with a blunted contour, peritoneal or peripancreatic fluid, and abscess or pseudocyst formation. Ultrasonography allows for the diagnosis of cholelithiasis, which may be etiologic for pancreatitis. The mere presence of gallstones, however, does not demonstrate etiologic relevance. US is also helpful for evaluating other differential diagnostic considerations.

Differential Diagnosis

Especially pertinent in the differential diagnosis of pancreatitis in pregnancy are hyperemesis gravidarum, preeclampsia, ruptured ectopic pregnancy (often with elevated serum amylase levels), perforated peptic ulcer, intestinal obstruction or ischemia, acute cholecystitis, ruptured spleen, liver abscess, and perinephric abscess.

Complications

Although all of the usual complications of pancreatitis can occur in parturients, there is no special predisposition to complications during pregnancy. Acute complications include hemorrhagic pancreatitis with severe hypotension and hypocalcemia, acute respiratory distress syndrome, pleural effusions, pancreatic ascites, abscess formation, and liponecrosis.

Treatment

Treatment of acute pancreatitis is aimed at correcting any underlying predisposing factors and treating the pancreatic inflammation. In pregnancy, acute pancreatitis is managed as it is in the nonpregnant state, except that nutritional supplementation is considered at an earlier point in treatment to protect the fetus, either via nasojejunal tube feeding of an elemental formula or total parenteral nutrition. Treatment is primarily medical and supportive, including bowel rest with or without nasogastric suction, intravenous fluid and electrolyte replacement, and parenteral analgesics. Antibiotics are reserved for cases with evidence of an acute infection. In patients with gallstone pancreatitis, consideration is given to early cholecystectomy or ERCP after the acute inflammation subsides. In pancreatitis not caused by gallstones, surgical exploration is reserved for patients with pancreatic abscess, ruptured pseudocyst, severe hemorrhagic pancreatitis, or pancreatitis secondary to a lesion that is amenable to surgery. Pregnancy does not influence the course of pancreatitis.

Prognosis

Maternal mortality rates as high as 37% were reported before the era of modern medical and surgical management. Respiratory failure, shock, need for massive fluid replacement, and severe hypocalcemia are predictive of disease severity. Most recent single-institution series reflect a reduced maternal mortality rate of less than 1%; perinatal death ranges from 3–20%, depending on severity of disease. Preterm labor appears to occur in a high proportion of patients with acute pancreatitis in later gestation.

PEPTIC ULCER DISEASE

ESSENTIALS OF DIAGNOSIS

- ▸ Patients typically present with epigastric discomfort.
- ▸ Endoscopy is diagnostic of peptic ulcer disease.
- ▸ Pathogenesis

Pathogenesis

Pregnancy appears to be somewhat protective against the development of gastrointestinal ulcers, as gastric secretion and motility are reduced and mucus secretion is increased. Close to 90% of women with known peptic ulcer disease experience significant improvement during pregnancy, but more than half will have recurrence of symptoms within 3 months postpartum. Thus peptic ulcer disease occurring as a complication of pregnancy or diagnosed during gestation is encountered infrequently, although the exact incidence is unknown. Infection with *Helicobacter pylori* is associated with the development of peptic ulcer disease.

Clinical Findings

Signs and symptoms of peptic ulcer disease in pregnancy can be mistakenly dismissed as being a normal part of the gravid state. Dyspepsia is the major symptom of ulcers during gestation, although reflux symptoms and nausea are also common. Epigastric discomfort that is temporally unrelated to meals is often reported. Abdominal pain might suggest a perforated ulcer, especially in the presence of peritoneal signs and systemic shock. Endoscopy is the diagnostic method of choice for these patients if empiric clinical therapy, including lifestyle and diet modifications, antacids, antisecretory agents, and treatment for *H pylori* when positive, fail to improve symptoms.

Differential Diagnosis

Gastroesophageal reflux disease and functional or nonulcer dyspepsia are common occurrences in pregnancy and may result in symptoms very similar to those of peptic ulcer disease. Biliary colic, chronic pancreatitis, Mallory-Weiss tears, and irritable bowel syndrome must also be considered. In recent years the diagnosis of persistent hyperemesis gravidarum has been linked to *H pylori* infection. Women with jaundice, persistent symptoms of dysphagia or odynophagia, weight loss, occult gastrointestinal bleeding, a family history of gastrointestinal cancers or unexplained anemia postpartum should be assessed for malignancy. A history of prior gastric surgery should prompt an evaluation for surgical complications. Ulcer perforation should be suspected in the setting of sudden, severe, diffuse abdominal pain followed by tachycardia and peritoneal signs.

Complications

Fewer than 100 parturients with complications of peptic ulcer disease, such as perforation, bleeding, and obstruction, have been reported. Most of these cases have occurred in the third trimester of pregnancy. Gastric perforation during pregnancy has an exceedingly high mortality rate, partly because of the difficulty in establishing the proper diagnosis. Other causes of upper gastrointestinal bleeding in pregnancy are reflux esophagitis and Mallory-Weiss tears. Surgical intervention is indicated for significant bleeding ulcerations. In patients requiring surgery for complicated peptic ulcers late in the third trimester, concurrent caesarean delivery may be indicated to enhance operative exposure of the upper abdomen and to prevent potential fetal death or damage from maternal hypotension and hypoxemia.

Treatment

Dyspepsia during pregnancy first should be treated with dietary and lifestyle changes, supplemented with antacids or sucralfate. When symptoms persist, H_2-receptor antagonists or, in severe cases, proton pump inhibitors can be used. Administration of triple-drug therapy for *H pylori* during pregnancy is controversial; because complications from peptic ulcer disease during pregnancy are low and there are theoretical concerns of teratogenicity from treatment, it is often deferred until postpartum. Empiric treatment of *H pylori* without testing is not recommended.

ACUTE INTESTINAL OBSTRUCTION

ESSENTIALS OF DIAGNOSIS

- Patients typically present with the classic triad of abdominal pain, vomiting, and obstipation.
- The diagnosis is confirmed with abdominal x-ray series.

Pathogenesis

Intestinal obstruction is an infrequently encountered complication of pregnancy that is estimated to occur in approximately 1–3 of every 10,000 pregnancies. However, it is the third most common nonobstetric reason for laparotomy during pregnancy (following appendicitis and biliary tract disease). It occurs most commonly in the third trimester. The most common causes of mechanical obstruction are adhesions (60%) and volvulus (25%), followed by intussusception, hernia, and neoplasm. Volvulus is much more prevalent during pregnancy; the risk is greatest when uterine size rapidly changes (eg, second trimester and immediately postpartum).

Clinical Findings

The same classic triad of abdominal pain, vomiting, and obstipation is observed in pregnant and nonpregnant women with intestinal obstruction. Pain may be diffuse, constant, or periodic, occurring every 4–5 minutes with small-bowel obstruction or every 10–15 minutes with large-bowel obstruction. Bowel sounds are of little value in making an early diagnosis of obstruction, and tenderness to palpation typically is absent with early obstruction. Vomiting occurs early with small-bowel obstruction. Guarding and rebound tenderness are observed in association with strangulation or perforation. Late in the course of disease, fever, oliguria, and shock occur as manifestations of massive fluid loss into the bowel, acidosis, and infection. The classic findings of bowel ischemia include fever, tachycardia, localized abdominal pain, marked leukocytosis, and metabolic acidosis. Unfortunately, most laboratory abnormalities arise once bowel ischemia has progressed to bowel necrosis.

The diagnosis usually is confirmed by radiologic studies, which should be obtained when intestinal obstruction is suspected. A single abdominal series (upright and supine abdominal film) is nondiagnostic in up to 50% of early cases, but serial films usually reveal progressive changes that confirm the diagnosis. Volvulus should be suspected when a single, grossly dilated loop of bowel is seen. A volvulus primarily occurs at the cecum but may also be seen at the sigmoid colon. Occasionally, more extensive radiologic imaging is indicated, given the high risk of fetal death with delayed treatment.

Differential Diagnosis

The diagnosis of hyperemesis gravidarum in the second and third trimesters should be viewed with caution and made only after gastrointestinal causes of the symptoms including pancreatitis have been excluded. Mesenteric ischemia, adynamic ileus of the colon, and acute colonic pseudo-obstruction (Ogilvie’s syndrome) are included in the differential diagnosis but are rarely seen during pregnancy.

Prognosis

Intestinal obstruction in pregnancy is associated with a maternal mortality rate of 6%, often secondary to infection and irreversible shock. Early diagnosis and treatment are essential for an improved outcome. Perinatal mortality is approximately 20% and usually results from maternal hypotension and resultant fetal hypoxia and acidosis.

Treatment

The management of bowel obstruction in pregnancy is essentially no different from treatment of nonpregnant patients. The cornerstones of therapy are bowel decompression, intravenous hydration, correction of electrolyte imbalances, and timely surgery when indicated. The patient's condition must be rapidly stabilized. The amount of fluid loss often is underestimated and may be 1–6 L by the time obstruction is identified on a scout film. Aggressive hydration is needed to support both the mother and the fetus. A nasogastric tube should be placed. Colonoscopy has been used successfully in the reduction of volvulus averting laparotomy. Ogilvie's syndrome can be managed with bowel rest, rehydration, and a rectal tube for large bowel decompression. Surgery is mandatory if perforation or gangrenous bowel is suspected or when the patient's symptoms do not resolve with medical management. A vertical midline incision on the abdomen provides the best operative exposure and can be extended as needed. Surgical principles for intraoperative management apply similarly to pregnant and nonpregnant patients. Caesarean delivery is performed first if the large uterus prevents adequate exposure of the bowel in term pregnancies or if indicated obstetrically. The entire bowel should be examined carefully because there may be more than 1 area of obstruction or limited bowel viability.

INFLAMMATORY BOWEL DISEASE

(See Chapter 29, Gastrointestinal Disorders in Pregnancy, for more details.)

ESSENTIALS OF DIAGNOSIS

- Crohn's disease is one subcategory, characterized by insidious onset; episodes of low-grade fever, diarrhea, and right lower quadrant pain; and perianal disease with abscess and fistulas formed. Radiographic evidence of ulceration, structuring, or fistulas of the small intestine or colon. May involve any segment of the gastrointestinal tract from the mouth to the anus.
- Ulcerative colitis is the other subcategory of inflammatory bowel disease, manifesting with bloody diarrhea, lower abdominal cramps, fecal urgency, anemia, and low serum albumin. It is diagnosed with sigmoidoscopy and only involves the colon.

Clinical Findings

Inflammatory bowel disease (IBD) (Crohn's disease and ulcerative colitis) often affects women in their childbearing years; however, initial presentation of IBD during pregnancy is rare. IBD presents with crampy abdominal pain and diarrhea stained with blood or mucus. More rarely the patient has weight loss and fevers.

Differential Diagnosis

Because some of the early IBD symptoms are found in normal pregnancies, diagnosis can be delayed, leading to poorer outcome. Initial evaluation should begin with ultrasound, which can also evaluate gallbladder, pancreas, and adnexa. Bowel wall thickening or abscess formations may be seen. Gold standard for diagnosis is endoscopy with biopsy, which can be safely performed during pregnancy.

Treatment

Initial management includes dietary modifications or bulking agents. Other medications that have been safely used in pregnancy are sulfasalazine, prednisone, and occasionally antibiotics. Patients receiving sulfasalazine should be given folate supplementation because sulfasalazine inhibits its absorption. Patients taking corticosteroids should receive stress-dose steroids during delivery or in surgery. Safety data of immunosuppressant use such as cyclosporine and anti–tumor necrosis factor-α in pregnancy are limited, but these agents have been used for persistent flares. Surgery during pregnancy is indicated for intestinal obstruction, megacolon, perforation, hemorrhage, abscess formation, and failed medical management. Delivery route should be based on obstetric indications except for patients who have active perianal disease; those with an ileal pouch and anastomosis may consider caesarean section to prevent injury to the anal sphincter.

Prognosis

The impact of IBD on pregnancy outcomes is controversial, though in general maternal and fetal outcomes are improved if IBD is in remission before conception. Postpartum flare is more common in Crohn's disease than ulcerative colitis.

HEMORRHOIDS

ESSENTIALS OF DIAGNOSIS

- Patients with hemorrhoids typically present with complaints of painless bleeding, prolapse, pain, pruritus, and/or fecal soilage.
- Hemorrhoids are visible on physical examination or anoscopy.

Pathogenesis

Pregnancy is the most common cause of symptomatic hemorrhoids. Approximately 9–35% of pregnant and postpartum women suffer from hemorrhoids. Higher incidences of constipation, increased blood volume, and venous congestion secondary to the enlarging uterus contribute to hemorrhoid formation.

Clinical Findings

Patients with hemorrhoids typically present with complaints of painless bleeding, prolapse, pain, pruritus, and/or fecal soilage. On physical examination, hemorrhoids are visualized as a protrusion into or out of the anal canal. Internal hemorrhoids may require anoscopy for visualization.

Treatment

The current management approach to hemorrhoid disease is conservative, with simple outpatient treatment preferred, particularly during pregnancy and the puerperium. Medical therapy with dietary changes, avoidance of excessive straining, fiber supplementation, stool softeners, and hemorrhoidal analgesics often is the only requirement for nonthrombosed hemorrhoids. Often 6 weeks or longer are needed to perceive improvement. If conservative treatments fail, rubber-band ligation, infrared coagulation, or sclerotherapy appear to be safe during pregnancy. Hemorrhoidectomy is the best means of definitive therapy for hemorrhoidal disease but is rarely necessary during pregnancy. It should be considered postpartum if the patient continues to fail to respond to conservative measures, if hemorrhoids are severely prolapsed and require manual reduction, or if associated pathology such as ulceration, severe bleeding, fissure, or fistula is present. Thrombosis or clots in the vein lead to severe symptoms. If thrombosed external hemorrhoids remain tender and persist despite conservative treatment, surgical excision under local anesthesia is preferred over clot extraction, as this results in a high rate of clot recurrence.

Longo SA, Moore RC, Canzoneri BJ, Robichaux A. Gastrointestinal conditions during pregnancy. *Clin Colon Rectal Surg* 2010;23:80–89. PMID: 21629625.

SPONTANEOUS HEPATIC & SPLENIC RUPTURE

ESSENTIALS OF DIAGNOSIS

- Patients with spontaneous hepatic or splenic rupture typically present with severe abdominal pain and the rapid onset of shock.

Pathogenesis

intraabdominal hemorrhage during pregnancy has diverse causes, including trauma, preexisting splenic disease, and preeclampsia–eclampsia. Often, the exact cause cannot be determined preoperatively. Spontaneous hepatic rupture may be associated with severe preeclampsia–eclampsia. (See Chapter 26, Hypertension in Pregnancy, for more details on preeclampsia–eclampsia.)

Clinical Findings

Spontaneous hepatic or splenic rupture is usually manifested by severe abdominal pain and shock, with thrombocytopenia and low fibrinogen levels.

Treatment

Exploratory celiotomy in conjunction with aggressive transfusion of blood products including packed red blood cells, fresh-frozen plasma, and platelets should be undertaken immediately, as this has been associated with improved survival rates.

Bleeding from a lacerated or ruptured spleen does not cease spontaneously and requires immediate surgical attention. Evidence of a hemoperitoneum on imaging studies or a hemorrhagic peritoneal lavage in association with a falling hematocrit level and abdominal pain establish the presence of a hemoperitoneum.

RUPTURED SPLENIC ARTERY ANEURYSM

ESSENTIALS OF DIAGNOSIS

- Women with ruptured splenic artery aneurysm typically present with epigastric, left upper quadrant, or left shoulder pain.
- The diagnosis is usually confirmed by abdominal radiography or ultrasound.

Pathogenesis

Autopsy data suggest that splenic artery aneurysm occurs in 0.1% of adults and appear to be more common in women. It is estimated that 6–10% of lesions will rupture, with portal hypertension and pregnancy being the main risk factors. Twenty-five to 40% of ruptures occur during gestation, especially in the last trimester, and are a major cause of intraperitoneal hemorrhage. Pregnant women who develop ruptured splenic artery aneurysm have a 75% mortality rate, with an even higher fetal mortality rate of up to 95%. Most patients with this condition are thought preoperatively to have placental abruption or uterine rupture.

Clinical Findings

Before rupture, the presenting symptoms may be completely absent or vague. The most common symptom is vague epigastric, left upper quadrant, or left shoulder pain. In approximately 25% of patients a 2-stage rupture is seen, with a smaller primary hemorrhage into the lesser sac, which may allow for temporary tamponade of the bleeding until complete rupture into the peritoneal cavity occurs, causing hemorrhagic shock. A bruit may be audible. A highly diagnostic finding on flat x-ray film of the abdomen is demonstration in the upper left quadrant of an oval calcification with a central lucent area. In stable clinical situations, angiography can provide positive confirmation and is the gold standard for diagnosis. In pregnancy, however, ultrasonography and pulsed-wave Doppler studies are preferred in order to minimize fetal radiation exposure.

Treatment

A splenic artery aneurysm in a woman of childbearing age should be treated in a timely manner, even during pregnancy, because of the increased risk of rupture and associated mortality. The elective operative mortality rate reportedly ranges between 0.5% and 1.3%.

PELVIC DISEASES & DISORDERS

OVARIAN MASSES

ESSENTIALS OF DIAGNOSIS

- Most ovarian masses during pregnancy present as an incidental finding on routine obstetrical ultrasound to evaluate the fetus.
- Some women may experience pelvic pain or discomfort due to the mass.

Pathogenesis

The incidental finding of an adnexal mass in pregnancy has become more common with the routine use of ultrasonography. As many as 1–4% of pregnant women are diagnosed with an adnexal mass. The majority of the masses are functional or corpus luteum cysts and spontaneously resolve by 16 weeks' gestation. More than 90% of unilateral, non-complex masses less than 5 cm in diameter that are noticed in the first trimester are functional and resolve spontaneously. Patients who undergo assisted reproduction present a special subgroup, as their ovaries frequently have ovarian cysts in the first trimester due to ovarian hyperstimulation. Pathologic ovarian neoplasms tend not to resolve. The most common pathologic ovarian neoplasms during pregnancy are benign cystic teratoma, serous or mucinous cystadenoma, and cystic corpus luteum. Of the adnexal masses that persist, 1–10% will be malignant.

Clinical Findings

Most adnexal masses discovered during pregnancy are found as incidental findings at time of ultrasound performed for evaluation of the fetus. Thus most women are asymptomatic for the ovarian mass. However, some women may experience pelvic pain or discomfort related to the mass.

Differential Diagnosis

Ovarian masses must be differentiated from lesions of the colon, pedunculated leiomyomas, pelvic kidneys, and congenital abnormalities of the uterus. If ultrasound cannot distinguish between leiomyoma and ovarian neoplasm, MRI can improve diagnostic precision.

Treatment

The 3 main reasons for advising surgery for an adnexal mass in pregnancy are the risks of rupture, torsion, and malignancy. Determination of the actual risk of rupture or torsion of a benign-appearing adnexal mass in pregnancy remains an unsettled issue. It is estimated that only approximately 2% of such masses will rupture during gestation, and the incidence of torsion in recent published series ranges from 0–15%. The challenge to the clinician is to weigh for each individual patient these risks against the risks of abdominal surgery during pregnancy, including miscarriage, rupture of membranes, and preterm labor. If adnexal masses diagnosed in the first trimester require surgery in pregnancy, it is generally advisable to perform the operation via laparotomy or laparoscopy in the second trimester unless signs or symptoms suggestive of torsion or highly aggressive malignancy indicate the need for more immediate intervention. Similarly, asymptomatic ovarian masses that are initially noted in the third trimester of pregnancy can be followed until the time of delivery or postpartum because the size of the uterus may present access problems and because preterm labor may be inadvertently induced.

The risk of malignancy can be largely gauged by the ultrasonographic characteristics of the mass. Ultrasonography usually facilitates delineation of the size and morphology of adnexal masses. If the mass is unilateral, mobile, and cystic, anaplastic elements are less likely and operation can be deferred.

Any adnexal lesion that is present after 14 weeks' gestation, is growing in size on serial ultrasonographic evaluations, contains solid and complex components or internal papillae, is fixed, is surrounded by abdominal ascites, or is symptomatic warrants surgical exploration and pathologic diagnosis.

TORSION OF THE ADNEXA

ESSENTIALS OF DIAGNOSIS

- Adnexal torsion may be suspected in the woman with an adnexal mass who experiences the sudden onset of pelvic pain, usually severe in nature.
- Ultrasound is useful in confirming the presence of an adnexal mass.
- Laparoscopy or laparotomy is diagnostic for confirming the presence of torsion.

Pathogenesis

Torsion of the adnexa can involve the ovary, tube, and ancillary structures, either separately or together. The most common time for occurrence of adnexal torsion is between 6 and 14 weeks and in the immediate puerperium. Although torsion of normal adnexa has been described, it commonly is associated with a cystic neoplasm.

Clinical Findings

Symptoms include abdominal pain and tenderness that usually are sudden in onset and result from occlusion of the vascular supply to the twisted organ. Shock and peritonitis may ensue. Ultrasonography frequently demonstrates an adnexal mass and altered blood flow on Doppler studies. The diagnosis of torsion is ultimately made at surgery.

Treatment

Prompt operation is necessary to prevent tissue necrosis, pre-term labor, and potential perinatal death. Laparoscopy appears to be as safe as laparotomy for mother and fetus. The right ovary is involved more frequently than is the left ovary. Benign cystic teratomas and cystadenomas are the most common histologic findings in ovaries that have undergone torsion. Traditional thinking has been that ovarian cysts that have undergone torsion must not be untwisted before pedicle clamping because of the concern for potential fatal thromboembolic complications. However, recent series on both nonpregnant and pregnant patients demonstrate that adnexa that had undergone torsion can safely be untwisted, followed by the appropriate removal of the mass (eg, cystectomy). Oophoropexy may be performed to prevent future re-occurrence of the torsion. These adnexa are capable of recovering and being functional. Salpingo-oophorectomy can be reserved for the management of active bleeding or suspicious neoplasms. If cystectomy includes corpus luteum before 12 weeks' gestation, progesterone supplementation should be initiated.

CARCINOMA OF THE OVARY

(See also Chapter 50, Premalignant and Malignant Disorders of the Ovaries and Oviducts.)

ESSENTIALS OF DIAGNOSIS

- Symptoms of ovarian cancer are often vague and mimic some of the common symptoms associated with pregnancy.
- Certain ultrasound findings, although not diagnostic of malignancy, can be suggestive of malignancy.
- The diagnosis is confirmed on pathologic examination of surgically excised tissue.

Pathogenesis

Carcinoma of the ovary occurs in less than 0.1% of all gestations and has been encountered in all trimesters. Between 1% and 10% of all ovarian tumors complicating pregnancy are malignant. Consistent with the young age of the pregnant population, most malignant neoplasms are germ cell tumors (dysgerminoma, endodermal sinus tumor, malignant teratoma, embryonal carcinoma, and choriocarcinoma) and tumors of low malignant potential, but cystadenocarcinomas do occur. The majority of ovarian malignancies diagnosed in pregnancy are early-stage disease.

Clinical Findings

Symptoms of ovarian cancer are often vague and include bloating, increasing abdominal girth, and urinary frequency, findings that are common during pregnancy. Most cases of ovarian cancer diagnosed during pregnancy are found when an adnexal mass is seen during routine ultrasound to evaluate the fetus. Ultrasound findings suggestive of ovarian malignancy are a mass with a solid component or thick septations, evidence of flow within the solid component on color Doppler interrogation, and the presence of other masses in the pelvis suggestive of enlarged nodes.

Treatment

Solid and complex ovarian tumors with significant solid components discovered during pregnancy generally should be treated surgically because of the low but significant incidence of cancer (1–10%). The treatment of gestational ovarian cancer follows the same principles as that for the nonpregnant patient. If the adnexal mass is complex, laparoscopy may be considered if intact removal in an endoscopic bag is feasible. If an open approach is taken, the incision needs to be of sufficient size not only to remove the tumor intact, but also to properly explore the abdomen and to reduce uterine manipulation until the definitive surgical course of management is determined. Upon abdominal entry, peritoneal washings should be obtained and the contralateral ovary examined. If abnormal in appearance, biopsy should be performed; otherwise, routine biopsy is unnecessary. Adequate tissue should be obtained for histologic diagnosis on frozen section. If the tumor is benign, residual ovarian tissue should be conserved if possible.

If malignant, staging is performed. Conservative surgery is appropriate for an encapsulated tumor if no evidence of uterine or contralateral ovarian involvement is seen. In more advanced stages, the extent of surgery, including tumor debulking, will depend on gestational age and the patient's wishes with regard to the pregnancy. Early termination of pregnancy does not improve outcome of ovarian cancer. In some cases, optimal surgical cytoreduction of the tumor to <1cm residual disease can be accomplished with the uterus and pregnancy left in situ. Neoadjuvant chemotherapy may offer an interim treatment for selected patients diagnosed at midgestation to allow for fetal maturity before extensive surgical cyto-reduction. Elevated tumor markers, such as α-fetoprotein, lactate dehydrogenase, β-human chorionic gonadotropin, and cancer antigen-125, during the preoperative workup of an adnexal mass must be interpreted with caution because pregnancy itself may cause an increase in these values.

LEIOMYOMAS

ESSENTIALS OF DIAGNOSIS

- The diagnosis of leiomyomas in pregnancy is made based on ultrasound

---

Clinical Findings

Uterine leiomyomas are found in 0.1–3.9% of pregnancies. Most women with fibroids during pregnancy are asymptomatic. A degenerating leiomyoma or one undergoing torsion is characterized by acute abdominal pain with point tenderness over the site of the leiomyoma. Ultrasonography is of great value to document the location, size, and consistency of leiomyomas in a pregnant uterus. Cystic changes in leiomyomas are often visualized when clinical signs of degeneration are present.

Complications

A large cohort study of obstetric outcomes of women diagnosed ultrasonographically with uterine leiomyomas in pregnancy found an increased risk of caesarean delivery (mostly before labor onset), breech presentation, malposition, preterm delivery, placenta previa, and severe postpartum hemorrhage. Uterine leiomyomas may further complicate pregnancy by undergoing degeneration or torsion, or by causing mechanical obstruction of labor.

Treatment

Conservative treatment with analgesia, reassurance, and supportive therapy almost always is adequate. Occasionally, surgery during pregnancy is indicated for torsion of an isolated, pedunculated leiomyoma. With the exception of a pedunculated leiomyoma on a narrow stalk, myomectomy should not be performed during pregnancy because of the risk of uncontrollable hemorrhage.

Qidwai GI, Caughey AB, Jacoby AF. Obstetric outcomes in women with sonographically identified uterine leiomyomata. *Obstet Gynecol* 2006;107:376–382. PMID: 16449127.

Vergani P, Locatelli A, Ghidini A, et al. Large uterine leiomyomata and risk of cesarean delivery. *Obstet Gynecol* 2007;109:410–414. PMID: 17267843.

CANCER IN PREGNANCY

The incidence of cancer in pregnancy is approximately 1 in 1000. The most common malignancies diagnosed during pregnancy are cervical cancer (26%; see also Chapter 48, Premalignant and Malignant Disorders of the Uterine Cervix), breast cancer (26%), leukemias (15%), lymphomas (10%; see also Chapter 34, Hematologic Disorders in Pregnancy), and malignant melanomas (8%). Once cancer is diagnosed during pregnancy, a multidisciplinary team of maternal–fetal medicine specialists, oncologists, surgeons, and radiation oncologists can assist the patient in making difficult decisions regarding treatment timing and continued pregnancy.

CERVICAL CANCER

(See also Chapter 48, Premalignant and Malignant Disorders of the Uterine Cervix.)

ESSENTIALS OF DIAGNOSIS

- The diagnosis of cervical cancer during pregnancy is usually made on the basis of cervical biopsy after abnormal pap smear or detection of cervical mass.
- Pregnancy should not limit evaluation of abnormal cervical cytology or evaluation of a cervical mass.

Pathogenesis

Invasive cervical cancer complicates approximately 0.05% of pregnancies. Diagnosis during pregnancy occurs more frequently in areas in which routine prenatal cytologic examination is done. Significantly abnormal cervical cytology in pregnancy calls for colposcopic evaluation.

Clinical Findings

As is the case with nonpregnant patients, cervical cancer in pregnancy primarily presents with bleeding, but the diagnosis is frequently missed because the bleeding is assumed to be pregnancy-related rather than due to cancer. The possibility of cancer must be kept in mind, and if a cervical lesion or mass is seen during prenatal care, it must be biopsied.

Treatment

The diagnosis and management of invasive cervical cancer during pregnancy presents the patient and the physician with many challenges. Management is determined by the stage of the cancer, the gestational age, and the patient's desires regarding the pregnancy. Pregnancy does not appear to affect the prognosis for women with cervical cancer and the fetus is not affected by the maternal disease, but may suffer morbidity from its treatment (eg, preterm delivery).

If the pregnancy is early and the disease is stage I–IIA, radical hysterectomy and therapeutic lymphadenectomy can be performed with the fetus left in situ, unless the patient is unwilling to terminate the pregnancy. Women at a gestational age closer to fetal viability or who decline termination may decide to continue the pregnancy after careful discussion regarding the maternal risks. Delivery in patients with cervical dysplasia and carcinoma in situ may be via the vaginal route. Patients with invasive cervical cancer should be delivered by caesarean section to avoid potential cervical hemorrhage and dissemination of tumor cells during vaginal delivery. A caesarean radical hysterectomy with therapeutic lymphadenectomy is the procedure of choice for patients with stage IA2–IIA2 disease once fetal maturity is established. As in the nonpregnant patient, radiation with concomitant chemotherapy is used for the treatment of more advanced disease. In the first trimester, irradiation may be carried out with the expectation of spontaneous abortion. In the second trimester, interruption of the pregnancy by hysterotomy before radiation therapy should be considered, although some experts advocate proceeding with immediate radiation treatment, again awaiting spontaneous evacuation of the uterus. In selected cases with locally advanced disease in which the patient declines pregnancy termination, consideration may be given to neoadjuvant chemotherapy in an effort to prevent disease progression during the time needed to achieve fetal maturity. Delivery should be by caesarean section. A lymphadenectomy can be performed at the same time. Postpartum the patient should receive chemoradiation following guidelines established for the nonpregnant patient.

BREAST CANCER

ESSENTIALS OF DIAGNOSIS

- ▸ Women with breast cancer during pregnancy usually present with a breast mass or thickening.
- ▸ The diagnosis is confirmed with biopsy.
- ▸ Pregnancy should not limit a thorough evaluation of a breast mass.

Breast cancer is the most common cancer diagnosed in women in the United States. One of every 5 cases occurs in women younger than 45 years, and 2–5% of women with breast cancer are pregnant when the diagnosis is made. In the United States, the incidence of breast cancer in pregnancy is 3 per 10,000 live births. For this reason, careful breast examination should be performed during prenatal and postnatal care, and a family history should be obtained.

Clinical Findings

Pregnancy- and lactation-related changes in the breast increase the frequency and range of breast problems and make the diagnosis of breast cancer more difficult. A painless lump is the most common presentation of gestational breast cancer. Bloody nipple discharge may be a presenting symptom and requires workup. Any mass found by the patient or by the obstetrician should be fully evaluated without undue delay.

Differential Diagnosis

The differential diagnosis is broad and includes lactating adenoma, galactocele, milk-filled cyst, fibroadenoma, abscess, and cancer.

Complications

Management of the pregnant woman with breast carcinoma is difficult because it requires careful consideration of both mother and fetus. The general approach to treatment of breast cancer in pregnancy should be similar to that in nonpregnant patients and should not be delayed because of pregnancy.

Treatment

Initial management of the pregnant patient with a breast mass does not differ significantly from that for nonpregnant women. When a localized lesion is present, breast ultrasonography is the preferred first imaging modality during pregnancy. It is safe and helpful in distinguishing between cystic and solid masses. Although the sensitivity of mammography is diminished by the breast changes in pregnancy, the study still may be helpful for selected patients with inconclusive ultrasound examinations. With low-dose mammography and appropriate shielding, fetal radiation exposure is minimal. Nonetheless, it is generally recommended that the procedure be avoided during the first trimester. Gadolinium-enhanced breast MRI is an imaging technique that may be indicated in selected patients, although there is a paucity of data on MRI features of pregnancy-associated breast cancer. Cystic lesions should be aspirated and the fluid, if bloody, examined cytologically. Malignant cells are rarely found in nonbloody fluid. Fine-needle aspiration, core biopsy, or incisional biopsy can be used in some cases, but surgical excisional biopsy may be most appropriate for clinically suspicious or cytologically equivocal lesions. The increased vascularity of the breasts is associated with a higher rate of bleeding, and the lactating breast is prone to infectious complications, but neither pregnancy nor lactation appears to interfere with excisional biopsy in an outpatient setting.

Breast cancer is classified according to the tumor-node metastasis (TNM) staging system. If a pregnant woman has clinically positive nodes or suspicious symptoms, she should undergo radiographic staging of lung, liver, and bone; asymptomatic women with clinically node-negative early-stage breast cancer do not. This can be done with plain films with abdominal shielding, abdominal ultrasound, MRI, and radionuclide bone scans, which are thought to be safe in pregnancy.

Termination of pregnancy has not been shown to improve survival rates. Modified radical mastectomy is the preferred local management of pregnant patients with breast cancer, with the goal of avoiding the need for adjuvant radiation therapy. Radical mastectomy is well tolerated during pregnancy. Breast-conserving surgery, which must be combined with adjuvant radiation, is limited primarily to patients presenting in the late second and third trimester, for whom surgery is performed during pregnancy and radiation treatment postponed until after delivery. For a patient who desires breast-conserving surgery outside the third trimester, a detailed discussion is imperative. For management of the lymph nodes, axillary dissection has been the traditional treatment of choice. Sentinel lymph node biopsy can be safely performed during pregnancy using colloid, but outcomes data are limited.

Adjuvant chemotherapy is frequently recommended for premenopausal women with breast cancer. The recommendation of chemotherapy for a pregnant woman with breast cancer is a complex decision, but the indications for adjuvant chemotherapy for gestational breast cancer are generally the same as for the nonpregnant patient. Chemotherapy during the first trimester is contraindicated as it is associated with miscarriage and major malformations. The chemotherapeutic agents used in gestational breast cancer are generally the same as those used in nonpregnant patients; cyclophosphamide, doxorubicin, and fluorouracil have been given successfully during the second and third trimesters, with no measurable increase in congenital malformations but an increased incidence of prematurity and intrauterine growth restriction. Neoadjuvant chemotherapy may be a treatment option in select patients with locally advanced or metastatic gestational breast cancer. Chemotherapy should be stopped after 35 weeks to decrease the risk of neonatal neutropenia. Use of radiation and endocrine therapy should be avoided during pregnancy. Breastfeeding should be avoided during chemotherapy, hormone therapy, or radiation. There is no contraindication to breastfeeding after completion of therapy for breast cancer.

The results of treatment are much the same stage for stage as they are in nonpregnant patients, but pregnancy-associated breast cancers tend to be more advanced at diagnosis (larger tumor size, more frequently involved lymph nodes), resulting in an overall worse prognosis for this group of patients as a whole. Diagnostic delay is blamed for more advanced disease at diagnosis.

Prognosis

Subsequent pregnancies need not necessarily be discouraged after a suitable period of recuperation and observation, as subsequent pregnancy does not increase the risk of recurrence or death from breast cancer. For women who are breast cancer antigen (BRCA)-1 or BRCA-2 mutation carriers, there is no evidence that pregnancy decreases their breast cancer risk. With respect to fetal outcomes, there appears to be an increase in preterm birth among women receiving chemotherapy during pregnancy. There are no reported cases of metastatic disease to the fetus.

LYMPHOMAS AND LEUKEMIAS

(See also Chapter 34, Hematologic Disorders in Pregnancy.)

ESSENTIALS OF DIAGNOSIS

- Most women diagnosed with Hodgkin's lymphoma during pregnancy present with painless lymphadenopathy.
- Biopsy is necessary to make a diagnosis of Hodgkin's lymphoma.
- Patients with leukemia may experience symptoms related to pancytopenia.
- Leukemia may be suspected on the basis of circulating blasts on peripheral blood smear.
- The diagnosis of leukemia is made on the basis of bone marrow biopsy.

Clinical Findings

The incidence of Hodgkin's lymphoma in pregnancy is estimated to be 1 in 1000 to 1 in 6000 pregnancies, with non-Hodgkin's lymphomas being significantly less frequent.

The typical presentation is painless adenopathy, and adequate biopsy is essential for diagnosis. Hodgkin's lymphoma is curable even in advanced stages, and prognosis and stage distribution in pregnancy is comparable to those in the nonpregnant patient.

The incidence of leukemia in pregnancy is estimated at 1 in 100,000. The acute leukemias are more frequent. The diagnosis is made by examination of bone marrow samples, which can be safely performed during pregnancy. Acute leukemia places pregnant patients at very high risk for bleeding and infection complications.

Treatment

Approximately 70% of patients present with early-stage disease and can be treated with either single-agent chemotherapy or, in selected cases, modified supradiaphragmatic radiation.

Patients in early pregnancy presenting with extensive infradiaphragmatic disease, for which radiation therapy would be a significant component of curative therapy, should consider termination of pregnancy because of the associated significant teratogenic risks. Standard chemotherapy regimens appear moderately safe to use in the second and third trimester.

Treatment of acute leukemia should be started immediately after diagnosis for an attempt at cure. Depending on the gestational age, the management during pregnancy poses many challenges to the patient, her family, and the treating physicians. Chronic myelogenous leukemia can be treated with interferon throughout pregnancy. There are rare reports of lymphoma and leukemia metastases to the fetus.

MALIGNANT MELANOMA

ESSENTIALS OF DIAGNOSIS

- Patients with melanoma usually present with a suspicious skin lesion.
- The diagnosis is made by biopsy or excision of the lesion.

Approximately 30–35% of women diagnosed with melanoma are of childbearing age, and approximately 0.1–1% of female melanoma patients are pregnant.

Clinical Findings

Most present with stage I disease. Clinical signs of melanoma are the same in pregnant and nonpregnant women. Suspicious lesions are those that have changed in size, color, or shape; bleed; or are ulcerated. The diagnosis is made by excision, allowing for microstaging. Tumor thickness, tumor site, and presence of metastases are the most important prognostic factors.

Treatment/Prognosis

There has been long-standing controversy regarding the prognosis of pregnancy-associated melanoma, but more recent evidence suggests that patients with early primary lesions and wide surgical excision with appropriate margins have a prognosis comparable to that of their nonpregnant counterparts. Moreover, pregnancy termination has not been shown to improve survival. Data on higher stage melanoma diagnosed in pregnancy are limited. Malignant melanoma is the tumor that most frequently metastasizes to the placenta or fetus, accounting for more than half of all tumors with fetal involvement. Postpartum the placenta should be sent for pathologic evaluation.

CARDIAC DISEASE

ESSENTIALS OF DIAGNOSIS

- Cardiac disease complicates 1–4% of all pregnancies in the United States.
- Rheumatic and congenital heart disease constitute the majority of cases.

Treatment

Patients requiring cardiac surgery should undergo the procedure before becoming pregnant. Nevertheless, the rare patient will require cardiac surgery during pregnancy. Most available reports on cardiac surgery during pregnancy involve closed and open mitral valvuloplasties and mitral or aortic valve replacement.

Cardiac surgery can be performed with good results in pregnancy, although there is maternal and fetal risk. Operations should generally be performed early in the second trimester when organogenesis is complete and there is comparatively less hemodynamic burden and less risk of preterm labor than later in gestation.

Prognosis

Maternal mortality rates average 1–9%, related to the specific procedure performed and the patient’s preoperative cardiovascular status. Percutaneous balloon valvuloplasty should be considered the preferred technique to treat valvular disease during pregnancy. Perinatal mortality is expected in 2–10% of percutaneous balloon valvuloplasties. Perinatal loss is thought to be greater after open valvular or bypass surgery due largely to the nonpulsatile blood flow and hypotension associated with cardiopulmonary bypass. Close fetal surveillance by electronic heart rate and uterine contraction monitoring is essential during any cardiac surgical procedure, whether or not cardiopulmonary bypass is used. During bypass, blood flow to the uterus can be assessed indirectly by changes in the fetal heart rate, and alterations in flow can be made accordingly.

Weiss BM. Managing severe mitral valve stenosis in pregnant patients—Percutaneous balloon valvuloplasty, not surgery, is the treatment of choice. *J Cardiothorac Vasc Anesth* 2005;19:277–278. PMID: 15868549.

NEUROLOGIC DISEASE

(See also Chapter 33, Nervous System and Autoimmune Disorders in Pregnancy.)

ESSENTIALS OF DIAGNOSIS

- The most common neurosurgical emergency to complicate pregnancy is intracranial hemorrhage.
- Symptoms and signs of subarachnoid hemorrhage include headache, nausea and vomiting, stiff neck, photophobia, seizures, and a decreasing level of consciousness.

Pathogenesis

Intracranial hemorrhage during pregnancy is rare (1–5 per 10,000 pregnancies) but is associated with significant maternal and fetal mortality and serious neurologic morbidity in survivors. Cerebral aneurysm rupture is responsible for approximately 70% of intracranial hemorrhage; arteriovenous malformations (AVM) cause 25%, and the remaining cases are due to eclampsia, coagulopathy, trauma, and intracranial tumors. During pregnancy the risk of bleeding from an AVM that had not bled previously is 3.5%, which is close to the annual bleeding rate in the nonpregnant patient. However, mortality due to a bleeding AVM in pregnancy is higher (30%) than in the nonpregnant state (10%). The risk of rebleeding from an AVM in the same pregnancy is 27%. Intracranial hemorrhage with associated neurologic damage during pregnancy (limited capacity for decision making, persistent vegetative state, brain death) poses significant medical and ethical challenges in caring for the mother and fetus.

Most commonly, bleeding from an aneurysm occurs in the subarachnoid space, whereas bleeding from an AVM is located within the brain parenchyma.

Clinical Findings

Symptoms and signs of subarachnoid hemorrhage include headache, nausea and vomiting, stiff neck, photophobia, seizures, and a decreasing level of consciousness. The headache usually is very sudden in onset, whereas the headache associated with intraparenchymal bleeding usually is somewhat less severe and is slower in onset. Focal neurologic deficits may be absent in up to 40% of patients. CT or MRI confirm the diagnosis of an intracranial bleed. Cerebral angiography may be needed to identify and characterize an aneurysm or AVM.

Treatment

Early surgical or endovascular intervention after aneurysmal hemorrhage during pregnancy is associated with reduced maternal and fetal mortality. Neurosurgical centers with significant experience in cerebral aneurysm procedures have better outcomes than lower volume centers. For patients with AVM, the decision to treat the lesion during pregnancy is less clear but should follow the same guidelines that apply to nonpregnant patients.

Prognosis

Once the intracranial hemorrhage has been effectively treated, vaginal delivery can proceed according to obstetric indications. For women who have not received definitive treatment, delivery route is controversial. Maternal and fetal mortality appear the same with elective caesarean delivery or instrumental vaginal delivery under regional anesthesia. Aneurysm rupture has been reported during elective caesarean delivery, which is not considered protective. Regardless of delivery route, blood pressure control is imperative.

Qaiser R, Black P. Neurosurgery in pregnancy. *Semin Neurol* 2007; 27:476–481. PMID: 17940927.

TRAUMA

ESSENTIALS OF DIAGNOSIS

- Automobile accidents are the most common nonobstetric cause of death during pregnancy.
- The most common cause of fetal death is death of the mother.
- Initial treatment focuses on immediate stabilization of the mother followed by evaluation of the fetus.

Pathogenesis

Approximately 7% of pregnancies are complicated by trauma, such as motor vehicle accidents (40%), falls (30%), direct assaults to the maternal abdomen (20%), and other causes (10%). Automobile accidents are the most common nonobstetric cause of death during pregnancy. The most common cause of fetal death is death of the mother. The second most common cause of fetal death is placental abruption. Pregnant women with traumatic injuries may be victims of physical abuse. Suicide also contributes to injury-related death. A pregnancy may increase family stress; therefore, the practitioner should be alert for signs of abuse and/or depression.

Treatment

The primary initial goal in treating a pregnant trauma victim is to stabilize the mother’s condition. Rapid hemorrhage can occur because approximately 600 mL of blood flow is directed to the uterus each minute. To optimize maternal and fetal outcome, an organized team approach to the pregnant trauma patient is essential. Maternal assessment and management are similar to those for the nonpregnant patient, keeping in mind the goal of protecting the fetus from unnecessary drug and radiation exposure. The fetus should be evaluated early during trauma assessment, and after fetal viability is reached, continuous fetal heart rate and uterine activity monitoring should be instituted, as long as it does not interfere with maternal resuscitative efforts. This information becomes critical when making management decisions for mother and fetus. Emergent caesarean section should be initiated if cardiopulmonary resuscitation has been unsuccessful after 4 minutes; this may provide the fetus with a greater chance for intact survival and allow for a successful maternal resuscitation. Caesarean delivery is also indicated if there is a nonreassuring fetal heart rate tracing in the setting of a stable mother, or if the enlarged uterus does not allow for repair of maternal injuries.

After immediate stabilization, the fetal heart rate and uterine contractions should be monitored for posttraumatic placental abruption. This usually occurs quite soon after the injury but rarely manifests as late as 5 days after trauma. Monitoring should continue for at least 4 hours after the trauma unless suspicious findings, including uterine contractions, vaginal bleeding, abdominal or uterine tenderness, postural hypotension, and fetal heart rate abnormalities, are noted. If any of these signs occur or if the trauma was severe, monitoring should be extended to 24–48 hours. Nonreassuring fetal heart rate patterns and fetal death can occur despite mild maternal trauma or pain. Ultrasound is helpful if abruption is visualized, but many are not. There is little evidence that the Kleihauer-Betke test reliably predicts significant fetomaternal hemorrhage, but it is recommended to determine if additional doses of Rh_o (D) immunoglobulin are needed for Rh-negative patients. Routine coagulation profiles are not clinically helpful in the setting of a stable mother.

26
Hypertension in Pregnancy

David A. Miller, MD

Hypertension is a common medical disorder that affects 20–30% of adults in the United States and complicates as many as 5–8% of all pregnancies. Hypertensive disorders of pregnancy rank among the leading causes of maternal morbidity and mortality. Approximately 15% of maternal deaths are attributable to hypertension, making it the second leading cause of maternal mortality in the United States. Severe hypertension increases the mother's risk of heart attack, cardiac failure, cerebral vascular accidents, and renal failure. The fetus and neonate also are at increased risk from complications such as poor placental transfer of oxygen, fetal growth restriction, preterm birth, placental abruption, stillbirth, and neonatal death.

Hypertension is defined as a sustained blood pressure higher than 140/90 mm Hg. In the nonpregnant patient, essential hypertension accounts for more than 90% of cases; however, many other conditions must be considered (Table 26–1). In the pregnant patient, hypertension may be attributable to any of the conditions summarized in Table 26–1. In addition, unique forms of hypertension, gestational hypertension and preeclampsia, occur only during pregnancy. Gestational hypertension is characterized by elevated blood pressure diagnosed for the first time during pregnancy in patients without evidence of proteinuria. Preeclampsia is characterized by the onset of hypertension and proteinuria, usually during the third trimester of pregnancy. The National High Blood Pressure Education Program Working Group stated that edema occurs too frequently in normal pregnant women to be a useful marker in the diagnosis of preeclampsia. Therefore, edema is no longer recommended as a diagnostic criterion for preeclampsia. Management of preeclampsia differs from the management of other forms of hypertension during pregnancy. Therefore, it is important to distinguish preeclampsia from other forms of hypertension that may complicate pregnancy.

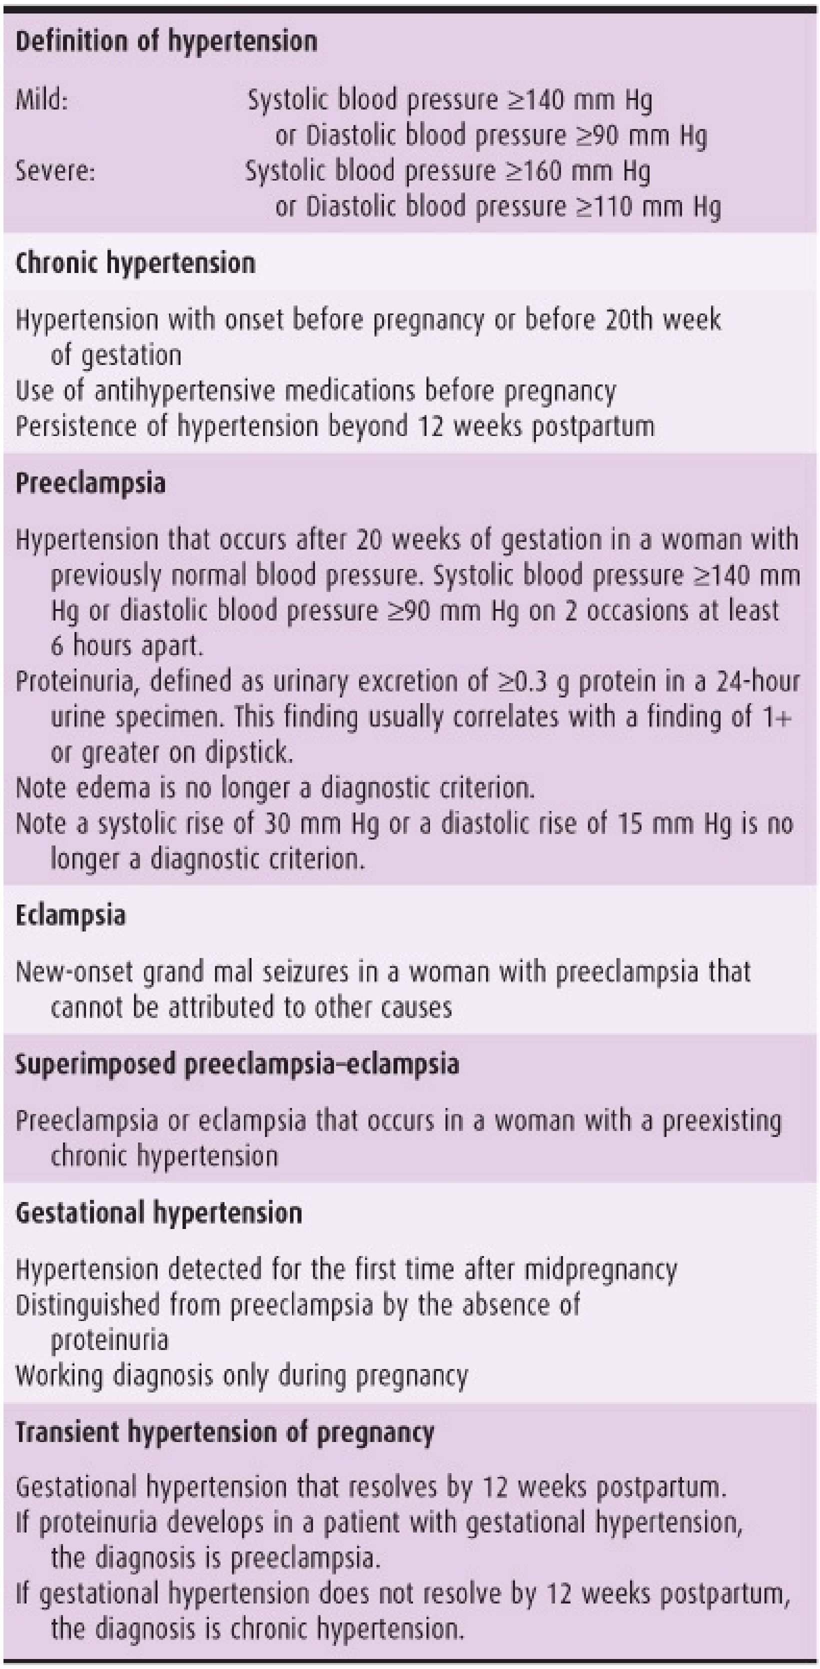
Classification of hypertension during pregnancy can be viewed as a continuum. On one end of the spectrum is the patient with hypertension that was present before pregnancy (or was recognized during the first half of pregnancy), does not worsen appreciably during pregnancy, and persists after delivery. This condition would be classified as chronic hypertension. On the other end of the spectrum is the patient with no evidence of chronic hypertension who experiences the abrupt onset of hypertension and proteinuria late in pregnancy followed by complete resolution postpartum. In this case, the hypertension observed during pregnancy may be the result of factors related entirely to pregnancy and not to an underlying medical cause. This condition would be classified as preeclampsia. Between these 2 extremes are gestational hypertension and cases in which varying degrees of preeclampsia are superimposed upon varying degrees of chronic hypertension. These broad categories have some value in estimating risk. Isolated mild to moderate chronic hypertension may have little effect on pregnancy outcome. On the other hand, severe hypertension of any cause may increase the risk to mother and fetus. The highest risks are associated with preeclampsia or eclampsia. The classification system of hypertension in pregnancy proposed by the National High Blood Pressure Education Program Working Group is summarized in Table 26–2.

Table 26–2. Classification of hypertension in pregnancy.



Definition of hypertension

Mild:	Systolic blood pressure ≥140 mm Hg or Diastolic blood pressure ≥90 mm Hg
Severe:	Systolic blood pressure ≥160 mm Hg or Diastolic blood pressure ≥110 mm Hg

Chronic hypertension

Hypertension with onset before pregnancy or before 20th week of gestation
Use of antihypertensive medications before pregnancy
Persistence of hypertension beyond 12 weeks postpartum

Preeclampsia

Hypertension that occurs after 20 weeks of gestation in a woman with previously normal blood pressure. Systolic blood pressure ≥140 mm Hg or diastolic blood pressure ≥90 mm Hg on 2 occasions at least 6 hours apart.
Proteinuria, defined as urinary excretion of ≥0.3 g protein in a 24-hour urine specimen. This finding usually correlates with a finding of 1+ or greater on dipstick.
Note edema is no longer a diagnostic criterion.
Note a systolic rise of 30 mm Hg or a diastolic rise of 15 mm Hg is no longer a diagnostic criterion.

Eclampsia

New-onset grand mal seizures in a woman with preeclampsia that cannot be attributed to other causes

Superimposed preeclampsia–eclampsia

Preeclampsia or eclampsia that occurs in a woman with a preexisting chronic hypertension

Gestational hypertension

Hypertension detected for the first time after midpregnancy
Distinguished from preeclampsia by the absence of proteinuria
Working diagnosis only during pregnancy

Transient hypertension of pregnancy

Gestational hypertension that resolves by 12 weeks postpartum.
If proteinuria develops in a patient with gestational hypertension, the diagnosis is preeclampsia.
If gestational hypertension does not resolve by 12 weeks postpartum, the diagnosis is chronic hypertension.

CHRONIC HYPERTENSION

ESSENTIALS OF DIAGNOSIS

- Hypertension with onset before pregnancy or before 20th week of gestation
- Persistence of hypertension beyond 12 weeks postpartum
- Blood pressure ≥140 mm Hg systolic or ≥90 mm Hg diastolic

Pathogenesis

Chronic hypertension complicates as many as 5% of pregnancies. It is characterized by a history of high blood pressure before pregnancy, elevation of blood pressure during the first half of pregnancy, or high blood pressure that lasts for longer than 12 weeks after delivery. The pathogenesis of chronic hypertension or essential hypertension is poorly understood. Factors that may contribute to the development of chronic hypertension are derangements in sympathetic neural activity or angiotensin II activity. There appears to be a genetic component in that hypertension is more common in individuals with a family history of hypertension. Other risk factors that predispose one to develop chronic hypertension during a person's lifetime are African American race, obesity, dyslipidemia, and physical inactivity.

Clinical Findings

Chronic hypertension is defined as women who have a blood pressure of ≥140 mmHg systolic or ≥90 mmHg diastolic before pregnancy, during the first 20 weeks of pregnancy, or >12 weeks after pregnancy. During the first trimester of pregnancy, women with a history of chronic hypertension will likely manifest blood pressure elevations. However, during normal pregnancy, maternal blood volume increases by 40–60%. Cardiac output and renal blood flow increase significantly. Blood pressure normally decreases throughout the first half of pregnancy under the influence of progesterone, reaching a nadir in midpregnancy and returning to prepregnancy levels by the end of the third trimester. For this reason, blood pressure may normalize during the second trimester in women with underlying chronic hypertension.

Evaluation of the patient with chronic hypertension is directed at end organs and systems most likely to be affected by hypertension, including the eyes, heart, kidneys, uteroplacental circulation, and the fetus. Laboratory tests include a complete blood count, glucose screen, electrolyte panel, serum creatinine, urinalysis, and urine culture. In some cases, additional tests may be needed. In patients with possible renal disease (serum creatinine ≥0.8 mg/dL, urine protein >1+ on dipstick), a 24-hour urine collection for creatinine clearance and total protein will provide baseline information that may be helpful in diagnosing the onset of preeclampsia later in pregnancy. An electrocardiogram may reveal left ventricular hypertrophy in the patient with long-standing hypertension. Chest radiography with abdominal shielding or echocardiogram may reveal cardiomegaly.

Differential Diagnosis

In women with hypertension, underlying disorders must be excluded (Table 26–1). The search for an underlying cause should include a complete history and physical examination, taking into account the normal changes that accompany pregnancy. Blood pressure should be measured in both arms with the patient in a sitting position and the arm at the level of the heart, and multiple measurements should be obtained on different occasions. If possible, measurements should be obtained outside of the office setting. The fifth Korotkoff sound should be used to determine diastolic pressure. Auscultation of the flanks may reveal a renal artery bruit. Funduscopic examination may reveal typical findings associated with long-standing hypertension or possibly diabetes. An enlarged thyroid gland may indicate thyroid disease. Absent peripheral pulses suggest coarctation of the aorta. Heart, skin, and joints should be evaluated thoroughly. Antinuclear antibody may help suggest a diagnosis of collagen vascular disease. A suppressed thyroid-stimulating hormone level suggests hyperthyroidism. Rarely, elevated urinary catecholamine levels may point to pheochromocytoma.

Complications

Complications related to chronic hypertension include superimposed preeclampsia, fetal growth restriction, pre-term birth, and placental abruption. The risk of developing one of these complications correlates with the degree of maternal blood pressure elevation; the higher the blood pressure, the greater the risk of one of these complications. Unfortunately, the benefit of maternal blood pressure control appears to be limited to preventing maternal morbidities and does not appear to extend to reducing the risk of these obstetric complications.

Treatment

Management of the chronic hypertensive patient during pregnancy is targeted to 2 goals: (1) maternal blood pressure control to minimize the risk of maternal complications related to blood pressure elevations such as stroke and myocardial infarction, and (2) early detection of any obstetrical or fetal complications related to chronic hypertension.

A number of antihypertensives have been shown to be safe and effective during pregnancy in controlling maternal blood pressure. Treatment of elevated blood pressure with antihypertensives reduces the risk of maternal morbidities related to hypertension but does not reduce the risk of fetal complications such as intrauterine growth restriction, preeclampsia, and placental abruption.

A. Treatment of Mild Chronic Hypertension

In pregnant women with mild hypertension and no evidence of renal disease, serious medical complications are rare. Moreover, there is no consensus that antihypertensive medication can reduce the risk of fetal death, growth restriction, placental abruption, preeclampsia, or eclampsia in these women. Therefore, antihypertensive medication is not usually necessary. Avoidance of alcohol and tobacco is encouraged. Sodium restriction may be considered (2–3 g/d). Rigorous activity should be avoided, as should weight reduction. Despite the lack of evidence supporting the benefit of antihypertensive therapy in women with blood pressure <180/110 mm Hg, many clinicians are reluctant to withhold medication when the blood pressure remains ≥150/100 mm Hg despite lifestyle modifications. A practical management algorithm using a blood pressure of 150/100 mm Hg as the threshold for initiation of antihypertensive therapy in women without evidence of end-organ involvement and 140/90 mm Hg as the threshold in women with evidence of renal involvement is summarized in Figure 26–1. Prenatal visits are scheduled every 2–4 weeks until 34–36 weeks and weekly thereafter. At each visit, blood pressure, urine protein, and fundal height are evaluated. Patients are questioned regarding signs and symptoms of preeclampsia, including headache, abdominal pain, blurred vision, scotomata, rapid weight gain, or marked swelling of the hands and/or face. Antepartum fetal monitoring usually is started around 32–34 weeks, and, in most cases, delivery is accomplished by 39–40 weeks' gestation.

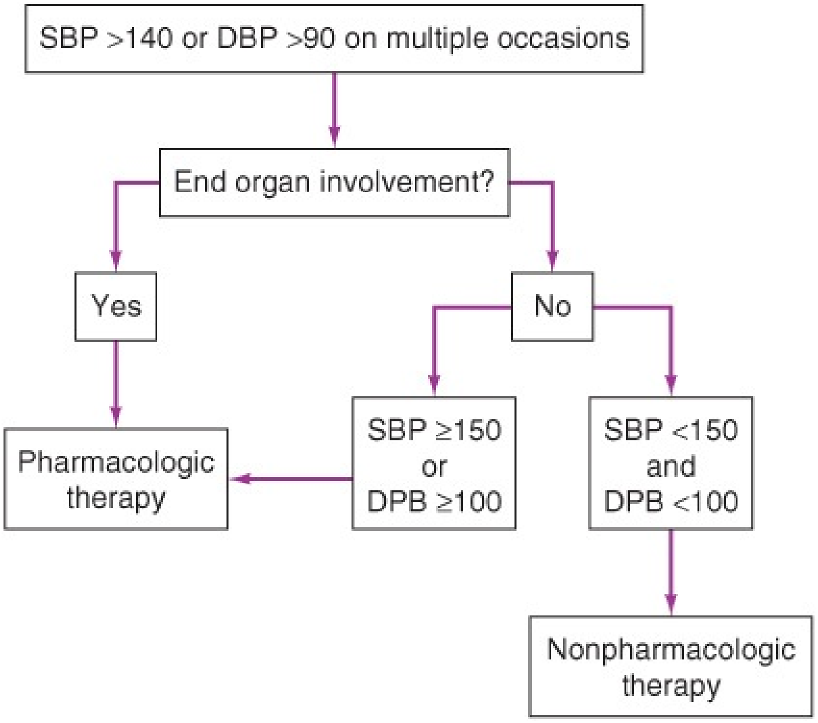


Figure 26–1. Management algorithm for chronic hypertension in pregnancy. DBP, diastolic blood pressure; SBP, systolic blood pressure.

B. Treatment of Severe Chronic Hypertension

Women with sustained blood pressure ≥180/110 mm Hg or those with evidence of renal disease may be at higher risk for serious complications, such as heart attack, stroke, or progression of renal disease, and are candidates for anti-hypertensive medication. As summarized in Figure 26–1, many clinicians would use a lower threshold of 150/100 mm Hg for instituting antihypertensive therapy during pregnancy.

Frequent prenatal visits may be needed to check the effectiveness of the medication. Fetal growth, blood pressure, and proteinuria are assessed at each visit, and evidence of superimposed preeclampsia is aggressively sought. Management of preeclampsia is described later in this chapter. In women with evidence of renal disease, some clinicians measure creatinine clearance and 24-hour urinary protein excretion each trimester. Sonographic assessment of fetal growth is performed every 2–4 weeks, antepartum testing is initiated by 32–34 weeks, and delivery is accomplished after 38 weeks or when fetal lung maturity is demonstrated. In some cases, hypertension worsens significantly during pregnancy without the development of overt preeclampsia. If exacerbation of chronic hypertension necessitates preterm delivery, corticosteroids should be considered in attempt to accelerate fetal maturity.

C. Antihypertensive Therapy in Chronic Hypertension

Several choices for initial antihypertensive therapy during pregnancy are available. Methyldopa has been studied extensively and is recommended by many as the first-line antihypertensive agent in pregnancy. It is a centrally acting alpha-adrenergic agonist that appears to inhibit vasoconstricting impulses from the medullary vasoregulatory center. The total daily dosage of 500 mg to 2 g is administered in 2–4 divided doses. Peak plasma levels occur 2–3 hours after administration, and the maximum effect occurs 4–6 hours after an oral dose. The agent is excreted primarily by the kidney. Sedation and postural hypotension are the most common side effects. A positive direct Coombs' test may be seen, usually after 6–12 months of therapy. Hemolytic anemia may occur in these patients and is an indication to stop the medication. Fever, liver function abnormalities, granulocytopenia, and thrombocytopenia are rare side effects.

Labetalol is an alpha$_1$-adrenergic blocker and a nonselective beta-adrenergic blocker. The beta-blockade/alpha-blockade ratio is 7:1. A large body of clinical evidence suggests that use of labetalol is safe during pregnancy. It appears to lack teratogenicity and crosses the placenta in small amounts. One randomized study showed no advantages of labetalol over methyldopa. Another study reported a higher incidence of small for gestational age newborns in patients treated with labetalol. The usual starting dose is 100 mg twice per day (BID), and the dose can be increased weekly to a maximum of 2400 mg daily. Titration increments should not exceed 200 mg BID.

Nifedipine is a calcium channel blocker that has been used during pregnancy for tocolysis and treatment of hypertension. Several reports suggest that nifedipine use is safe during pregnancy; however, the cumulative experience with this agent is not as extensive as with methyldopa and labetalol. When nifedipine is used for treatment of chronic hypertension during pregnancy, the long-acting formulation (Procardia XL, Adalat CC) may improve patient compliance. The principal benefit of this agent is once-daily dosing. The usual starting dose is 30 mg daily. If necessary, the dose may be increased to 60–90 mg daily. The neuro-muscular-blocking action of magnesium may be potentiated by simultaneous calcium channel blockade; therefore, nifedipine should be used with caution in patients receiving magnesium sulfate. The sublingual route of administration is associated with unpredictable blood levels and should be avoided.

Other antihypertensive medications used in pregnancy include atenolol, metoprolol, prazosin, minoxidil, hydralazine, thiazide diuretics, and clonidine. Published experience with these agents is limited, and they should not supplant methyldopa, labetalol, or nifedipine as first-line agents in pregnancy.

Use of angiotensin-converting enzyme inhibitors (enalapril, captopril) during pregnancy is associated with fetal hypocalvaria, renal defects, anuria, and fetal and neonatal death. These agents are contraindicated in pregnancy. With few exceptions, diuretics (furosemide, hydrochlorothiazide) should be avoided during pregnancy. Fetal bradycardia, growth retardation, and neonatal hypoglycemia have been reported in patients treated with blockers.

D. Fetal Assessment in Chronic Hypertension

Pregnancies complicated by chronic hypertension, regardless of the cause, are at increased risk for poor fetal growth. An initial ultrasound examination should be performed as early as possible to confirm the due date and to ensure that no obvious fetal anomalies are present. Thereafter, fetal growth may be assessed by ultrasound as needed, usually no more frequently than every 2–4 weeks. Antepartum fetal monitoring usually is started by 32–34 weeks. If the nonstress test is used as the method of surveillance, it should be accompanied by assessment of amniotic fluid volume. Doppler velocimetry of the umbilical, uterine, and middle cerebral arteries are helpful in optimizing the timing of delivery, particularly in cases of suspected fetal growth restriction.

Prognosis

Pregnancy outcome usually is good in patients with mild chronic hypertension and no other serious medical conditions. Fetal growth restriction, superimposed preeclampsia, placental abruption, and preterm delivery are the most common complications. The outlook is less favorable in women with severe hypertension early in pregnancy and in those with evidence of end-organ compromise, such as renal insufficiency and/or cardiovascular disease. By necessity, management is individualized. Close monitoring for development of fetal growth restriction and superimposed preeclampsia is indicated.

Report of the National High Blood Pressure Education Program Working Group on high blood pressure in pregnancy. *Am J Obstet Gynecol* 2000;183:S1. PMID 10920346.

GESTATIONAL HYPERTENSION

ESSENTIALS OF DIAGNOSIS

- Maternal blood pressure elevation of ≥140 mm Hg systolic or ≥90 mm Hg diastolic on 2 occasions 6 hours apart in a previously normotensive woman ≥20 weeks' gestation
- No evidence of proteinuria

Pathogenesis

Gestational hypertension appears to affect approximately 6% of pregnancies. The pathogenesis of gestational hypertension is unclear, and it is equally unclear whether gestational hypertension represents an early stage of preeclampsia or whether it is an entirely separate disease entity. Gestational hypertension is considered to be a provisional diagnosis as many women with gestational hypertension will go on to be diagnosed with either preeclampsia or chronic hypertension. If preeclampsia has not developed and the maternal blood pressure has returned to normal by 12 weeks postpartum, then a diagnosis of transient hypertension of pregnancy is made.

Clinical Findings

A diagnosis of gestational hypertension is made when (1) maternal blood pressure is elevated to ≥140 mm Hg systolic or ≥90 mm Hg diastolic on 2 occasions 6 hours apart in a previously normotensive woman ≥20 weeks' gestation, and (2) there is no evidence of proteinuria. Gestational hypertension is classified as mild or severe based on the degree of blood pressure elevation. It is considered to be severe when the systolic blood pressure is persistently ≥160 mm Hg or the diastolic blood pressure is persistently ≥110 mm Hg.

Complications

Approximately 15–25% of women diagnosed with gestational hypertension go on to develop preeclampsia. Women with mild gestational hypertension do not appear to be at increased risk of preterm birth, intrauterine growth restriction, abruption, or stillbirth. Women with severe gestational hypertension, however, are at increased risk of adverse outcomes, including preterm birth, intrauterine growth restriction, and placental abruption.

Treatment

Given the 15–25% risk of progression to preeclampsia, treatment includes close surveillance for signs and symptoms of preeclampsia. Patient education regarding symptoms of preeclampsia (headache, visual changes, epigastric or abdominal pain) is recommended. Initial evaluation includes 24-hour urine collection to confirm the absence of significant proteinuria and serum laboratory evaluation to evaluate hepatic transaminases, creatinine, hematocrit, platelets, and lactic acid dehydrogenase. Derangements in any of these serum laboratories would be indicative of a diagnosis of preeclampsia as opposed to gestational hypertension.

For the patient with mild gestational hypertension, fetal surveillance with ultrasound for fetal growth approximately once per month and weekly biophysical profiles can assess fetal well-being. Antihypertensives are not recommended in women with mild gestational hypertension, as they have not been shown to improve outcomes. Delivery is recommended at 39–40 weeks' gestation.

Because severe gestational hypertension is associated with an increased risk of adverse outcomes at a rate similar to that of severe preeclampsia, women with severe gestational hypertension are generally managed the same way as women with severe preeclampsia (see Treatment section under Preeclampsia, later).

Prognosis

Most women experience normalization of their blood pressure within 2 weeks after delivery. Approximately 15% of women diagnosed with gestational hypertension will have persistently elevated blood pressure >12 weeks after delivery and will meet a diagnosis of chronic hypertension. The recurrence rate of gestational hypertension in future pregnancies is approximately 25%.

PREECLAMPSIA

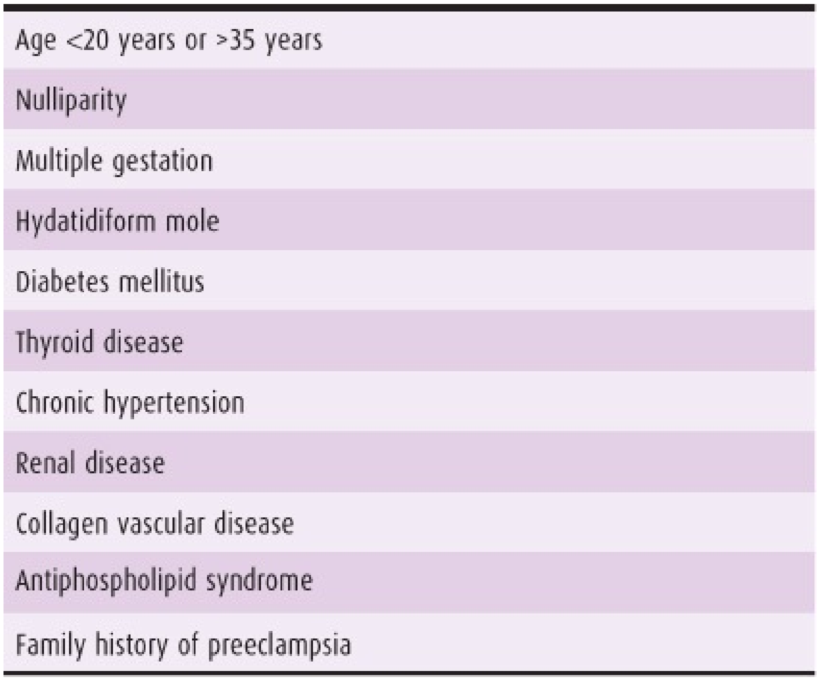
ESSENTIALS OF DIAGNOSIS

- Maternal blood pressure elevation of ≥140 mm Hg systolic or ≥90 mm Hg diastolic on 2 occasions 6 hours apart
- Proteinuria ≥300 mg in a 24-hour urine specimen

Pathogenesis

Preeclampsia complicates 5–7% of all pregnancies. Preeclampsia occurs with increased frequency among young, nulliparous women. However, the frequency distribution is bimodal, with a second peak occurring in multiparous women greater than 35 years of age. Among daughters of preeclamptic women, the risk of preeclampsia is significantly higher than the population risk. Other predisposing factors for preeclampsia are listed in Table 26–3.

Table 26–3. Risk factors for preeclampsia.



Age <20 years or >35 years
Nulliparity
Multiple gestation
Hydatidiform mole
Diabetes mellitus
Thyroid disease
Chronic hypertension
Renal disease
Collagen vascular disease
Antiphospholipid syndrome
Family history of preeclampsia

Normal pregnancy is associated with decreased maternal sensitivity to endogenous vasopressors. Apparent early in gestation, this effect leads to expansion of the maternal intravascular space and a decline in blood pressure throughout the first half of pregnancy, with a nadir at midgestation. Thereafter, continued expansion of intravascular volume leads to a gradual rise in the blood pressure to prepregnancy levels by term. Women destined to develop preeclampsia do not exhibit normal refractoriness to endogenous vasopressors. As a result, normal expansion of the intravascular space does not occur, and the normal decline in blood pressure during the first half of pregnancy may be absent or attenuated. Despite normal to elevated blood pressure, intravascular volume is reduced.

The etiology of preeclampsia is not known; however, a growing body of evidence suggests that maternal vascular endothelial injury plays a central role in the disorder. Some reports suggest that endothelial damage in preeclampsia results in decreased endothelial production of prostaglandin I_2 (prostacyclin), a potent vasodilator and inhibitor of platelet aggregation. Endothelial cell injury exposes subendothelial collagen and can trigger platelet aggregation, activation, and release of platelet-derived thromboxane A_2 (TXA_2), a potent vasoconstrictor and stimulator of platelet aggregation. Decreased prostacyclin production by dysfunctional endothelial cells and increased TXA_2 release by activated platelets and trophoblast may be responsible for reversal of the normal ratio of prostacyclin and TXA_2 observed in preeclampsia. The predominance of TXA_2 may contribute to the vasoconstriction and hypertension that are central features of the disorder. Elevated intravascular pressure combined with damaged vascular endothelium results in movement of fluid from the intravascular to the extravascular spaces, leading to edema in the brain, retinae, lungs, liver, and subcutaneous tissues. Hypertension and glomerular endothelial damage lead to proteinuria. The resultant decrease in intravascular colloid oncotic pressure contributes to further loss of intravascular fluid. Hemoconcentration is reflected in a rising hematocrit. Consumption of platelets and activation of the clotting cascade at the sites of endothelial damage may lead to thrombocytopenia and disseminated intravascular coagulation (DIC). Soluble fibrin monomers produced by the coagulation cascade may precipitate in the microvasculature, leading to microangiopathic hemolysis and elevation of the serum lactate dehydrogenase level. Cerebral edema, vasoconstriction, and capillary endothelial damage may lead to hyperreflexia, clonus, convulsions, or hemorrhage. Hepatic edema and/or ischemia may lead to hepatocellular injury and elevation of serum transaminases and lactate dehydrogenase levels. The right upper quadrant or epigastric pain observed in severe preeclampsia is thought to be caused by stretching of Glisson's capsule by hepatic edema or hemorrhage. Intravascular fluid loss across damaged capillary endothelium in the lungs may result in pulmonary edema. In the retinae, vasoconstriction and/or edema may lead to visual disturbances, retinal detachment, or blindness. Movement of fluid from the intravascular space into the subcutaneous tissues produces the characteristic nondependent edema of preeclampsia.

Endothelial damage appears to be capable of triggering a cascade of events culminating in the multiorgan system dysfunction observed in preeclampsia. However, the mechanism of endothelial injury remains speculative. In one theory, decreased placental oxygenation triggers the placenta to release an unknown factor into the maternal circulation. This circulating factor is capable of damaging or altering the function of maternal endothelial cells and triggering the cascade of events described. In support of this theory, cultured trophoblasts exposed to a hypoxic environment release a variety of potentially vaso-active factors, including thromboxane, interleukin-1, and tumor necrosis factor. Moreover, serum from preeclamptic women, when applied to human endothelial cell cultures, alters the release of a variety of procoagulant, vasoactive, and mitogenic factors, including endothelin, nitric oxide, and prostacyclin. Serum from the same woman 6 weeks after delivery does not produce this effect. Likewise, serum from a nonpreeclamptic woman at the same gestational age fails to trigger these endothelial changes. In many cases, reduced placental oxygenation may be explained by maternal vasculopathy (chronic hypertension, renal disease, collagen vascular disease) and in others by abnormal placental mass (multiple gestation, diabetes, hydatidiform mole). In another subset of patients, reduced placental oxygenation late in pregnancy may be the result of abnormal endovascular trophoblast invasion early in pregnancy. In the first trimester of a normal pregnancy, proliferating trophoblast invades the decidual segments of the maternal spiral arteries, replacing endothelium and destroying the medial elastic and muscular tissue of the arterial wall. The arterial wall is replaced by fibrinoid material. During the second trimester, a second wave of endovascular trophoblastic invasion extends down the lumen of the spiral arteries deeper in the myometrium. The endothelium and musculoelastic architecture of the spiral arteries are destroyed, resulting in dilated, thin-walled, funnel-shaped vessels that are passive conduits of the increased uteroplacental blood flow of pregnancy. In some women destined to develop preeclampsia, the first wave of endovascular trophoblastic invasion may be incomplete, and the second wave does not occur. As a result, the deeper segments of the spiral arteries are not remodeled but instead retain their musculoelastic architecture and their ability to respond to endogenous vasoconstrictors, reducing maternal perfusion of the placenta and predisposing to relative placental hypoxia later in pregnancy. In addition, myometrial portions of the spiral arteries exhibit a unique abnormality characterized by vessel wall damage, fibrinoid necrosis, lipid deposition, and macrophage and mononuclear cell infiltration of vessel walls and surrounding tissues. These changes, histologically similar to those observed in atherosclerosis, are referred to as acute atherosis and may lead to vascular lumen obliteration and placental infarction. Importantly, these changes are attributed to abnormal endovascular trophoblastic invasion during the second trimester of pregnancy, predisposing the fetus to suboptimal placental perfusion early in gestation. Interestingly, the clinical manifestations are observed most often in the third trimester, possibly due to increasing fetal and placental oxygen demands with advancing gestation.

The reason that endovascular trophoblastic invasion progresses normally in most pregnancies but abnormally in others is unclear. One theory maintains that maternal antibodies directed against paternal antigens on invading trophoblasts are necessary to shield those antigens from recognition by decidual natural killer cells, protecting the invading trophoblast from attack and rejection by the cellular arm of the maternal immune system. Supporting this theory is the observation that preeclampsia appears to be associated with primi-paternity and the presumed lack of previous maternal exposure and sensitization to paternal trophoblast antigens in a previous pregnancy.

Additional support for this theory is provided by the observation that preeclampsia is more common among women using barrier contraception than among those using nonbarrier forms of contraception before pregnancy. This suggests that maternal exposure (and presumably sensitization) to paternal antigens on sperm is protective against preeclampsia. The observed inverse relationship between duration of cohabitation before pregnancy and the incidence of preeclampsia provides further evidence that maternal sensitization to paternal antigens is protective against preeclampsia. The interplay between immunology and genetics is underscored by the observation that preeclampsia may be more common in pregnancies in which the father was the product of a preeclamptic pregnancy. Applied to the theory under discussion, this suggests that some genetically determined paternal antigens are less antigenic than others and therefore less likely to provoke an antibody response in an exposed mother, decreasing maternal production of “blocking” antibodies and increasing the likelihood of abnormal placental invasion and preeclampsia. Alternatively, paternally inherited genes may code for altered fetal production of insulin-like growth factor-2, an insulin homologue related to placental invasion. Other genes that may be inherited from the father and play a role in the development of preeclampsia include genes coding for angiotensinogen, methylenetetrahydrofolate reductase, and the factor V Leiden mutation.

Some studies have demonstrated that invading trophoblastic cells in normal pregnancy undergo an “antigenic shift” to resemble vascular endothelial antigens, masking them from recognition and rejection by decidual natural killer cells. Invading trophoblasts in preeclamptic pregnancies may fail to make this antigenic shift, exposing them to recognition by natural killer cells and halting normal invasion.

Recent work has demonstrated that soluble fms-like tyrosine kinase-1 (sFlt-1) is increased in the placenta and serum of women with preeclampsia. This protein adheres to placental growth factor and vascular endothelial growth factor (VEGF), preventing their interaction with endothelial receptors and causing endothelial dysfunction. Interrupted angiogenesis may contribute to faulty placental invasion early in pregnancy and subsequent risk for placental hypoxia–ischemia and preeclampsia. Unbound placental growth factor and VEGF have been found in decreased concentration during and even before the development of clinical preeclampsia.

Genetic, immunologic, and other factors govern the complex interaction between the maternal host and the invading trophoblast. Detailed discussion of these and other possible etiologies of the entity of preeclampsia are beyond the scope of this chapter. Regardless of the etiology, thorough familiarity with the clinical aspects of the disorder can help guide thoughtful and coherent management.

Preeclampsia exerts an effect on many different maternal organ systems:

A. Brain

Pathologic findings in preeclampsia-induced cerebral injury include fibrinoid necrosis, thrombosis, microinfarcts, and petechial hemorrhages, primarily in the cerebral cortex. Cerebral edema may be observed. Head computed tomographic findings include focal white matter hypodensities in the posterior cerebral hemispheres, temporal lobes, and brain stem, possibly reflecting petechial hemorrhage with resultant local edema. Magnetic resonance imaging may reveal occipital and parietal abnormalities in the watershed distribution of the major cerebral arteries, as well as lesions in the brain stem and basal ganglia. Subarachnoid or intraventricular hemorrhage may occur in severe cases.

B. Heart

Preeclampsia is characterized by the absence of normal intravascular volume expansion, a reduction in normal circulating blood volume, and a loss of normal refractoriness to endogenous vasopressors, including angiotensin II. Invasive hemodynamic monitoring in preeclamptic patients has yielded conflicting information. Depending on disease severity, effects of previous therapy, and other factors, preeclampsia has been described variously as a state of abnormally high cardiac output and low systemic vascular resistance, a state of abnormally low cardiac output and high systemic vascular resistance, or a state of high cardiac output and high systemic vascular resistance. These divergent observations underscore the complexity of the disorder.

C. Lungs

Alterations in colloid oncotic pressure, capillary endothelial integrity, and intravascular hydrostatic pressure in preeclampsia predispose to noncardiogenic pulmonary edema. In women with preeclampsia superimposed on chronic hypertension, preexisting hypertensive cardiac disease may exacerbate the situation, superimposing cardiogenic pulmonary edema on noncardiogenic, preeclampsia-related pulmonary edema. Excessive administration of intravenous (IV) fluid and postpartum mobilization of accumulated extravascular fluid also increase the risk of pulmonary edema. In eclampsia, pulmonary injury may result from aspiration of gastric contents, leading to pneumonia, pneumonitis, or adult respiratory distress syndrome.

D. Liver

Histologic lesions in the liver are characterized by sinusoidal fibrin deposition in the periportal areas with surrounding hemorrhage and portal capillary thrombi. Centrilobular necrosis may result from reduced perfusion. Inflammation is not characteristic. Subcapsular hematomas may develop. In severe cases involving hepatocellular necrosis and DIC, intrahepatic hematomas may progress to liver rupture. Right upper quadrant pain or epigastric pain are classic symptoms attributed to stretching of Glisson’s capsule. Elevation of serum transaminases is a hallmark of HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome.

E. Kidneys

Distinct histologic changes have been described in the kidneys of women with preeclampsia. The classic renal lesion of preeclampsia, glomeruloendotheliosis, is characterized by swelling and enlargement of glomerular capillary endothelial cells, leading to narrowing of the capillary lumen. There is an increased amount of cytoplasm containing lipid-filled vacuoles. Mesangial cells may be swollen as well. Immunoglobulins, complement, fibrin, and fibrin degradation products have been observed in the glomeruli, but their presence is variable.

F. Eyes

Retinal vasospasm, retinal edema, serous retinal detachment, and cortical blindness may occur in the setting of preeclampsia. Blindness is uncommon and usually transient, resolving within hours to days of delivery.

Prevention

The observed alteration in the ratio of vasoconstrictive and vasodilatory prostaglandins in preeclampsia led investigators to study the effectiveness of prostaglandin synthesis inhibitors in preventing the disorder. Several small trials of low-dose aspirin reported significant reductions in the incidence of preeclampsia in high-risk populations. However, in 1994 the Collaborative Low-Dose Aspirin Study in Pregnancy (CLASP) Collaborative Group reported a large randomized trial comparing low-dose aspirin with placebo in more than 9300 high-risk patients. Low-dose aspirin did not reduce the incidence of preeclampsia in this high-risk population. Because the risks of the regimen are few, some physicians may reasonably choose to use it.

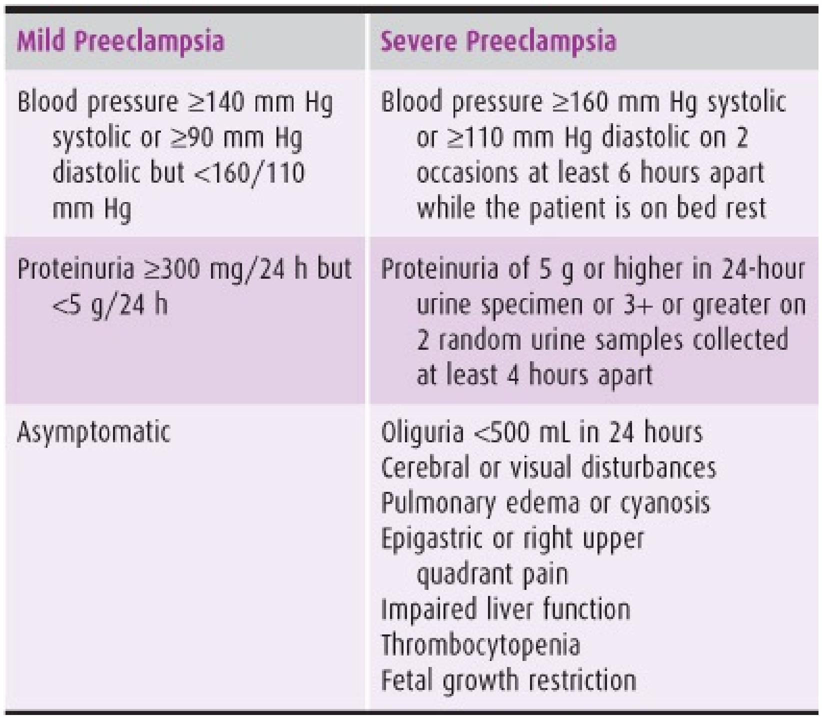
Calcium is essential in the synthesis of nitric oxide, a potent vasodilator believed to contribute to the maintenance of reduced vascular tone in pregnancy. Calcium supplementation during pregnancy has been proposed as a means to prevent preeclampsia. Although individual studies have demonstrated mixed results regarding the efficacy of calcium supplementation, a meta-analysis concluded that calcium supplementation of at least 1 gram daily during pregnancy appears to reduce the risk of preeclampsia by approximately 50%.

Clinical Findings

A diagnosis of preeclampsia is made based on 2 criteria: (1) elevated maternal blood pressure of ≥140 mm Hg systolic or ≥90 mm Hg diastolic on 2 occasions 6 hours apart, and (2) proteinuria ≥300 mg in a 24-hour urine specimen. In the past, the classic diagnostic triad included hypertension, proteinuria, and edema. Recently, the National High Blood Pressure Education Working Group recommended eliminating edema as a diagnostic criterion because it is too frequent an observation during normal pregnancy to be useful in diagnosing preeclampsia. In addition to the classic findings of hypertension and proteinuria, women with preeclampsia may complain of scotomata, blurred vision, or pain in the epigastrium or right upper quadrant. Examination often reveals brisk patellar reflexes and clonus. Laboratory abnormalities include elevated levels of hematocrit, lactate dehydrogenase, serum transaminases and uric acid, and thrombocytopenia. Although biochemical evidence of DIC may be detected with increased fibrin degradation products, hypofibrinogenemia and prolongation of the prothrombin time and activated partial thromboplastin time usually are seen only in cases complicated by abruption or multiple organ failure.

Preeclampsia is classified into mild or severe based on the degree of hypertension and proteinuria and the presence of other findings (Table 26–4). The HELLP syndrome is a variant of preeclampsia that is characterized by hemolysis, elevated liver enzymes, and low platelets. It complicates 10% of cases of severe preeclampsia and up to 50% of cases of eclampsia. Right upper quadrant pain, nausea, vomiting, and malaise are common. Hypertension and proteinuria are variable. The hallmark of the disorder is microangiopathic hemolysis leading to elevation of serum lactate dehydrogenase level and fragmented red blood cells on peripheral smear. Transaminase levels are elevated, thrombocytopenia is present, and DIC may be evident. Management is similar to that of severe preeclampsia. (See Chapter 29, Gastrointestinal Disorders in Pregnancy, for a more extensive review of HELLP syndrome.)

Table 26–4. Classification of preeclampsia.



Mild Preeclampsia	Severe Preeclampsia
Blood pressure ≥140 mm Hg systolic or ≥90 mm Hg diastolic but <160/110 mm Hg	Blood pressure ≥160 mm Hg systolic or ≥110 mm Hg diastolic on 2 occasions at least 6 hours apart while the patient is on bed rest
Proteinuria ≥300 mg/24 h but <5 g/24 h	Proteinuria of 5 g or higher in 24-hour urine specimen or 3+ or greater on 2 random urine samples collected at least 4 hours apart
Asymptomatic	Oliguria <500 mL in 24 hours Cerebral or visual disturbances Pulmonary edema or cyanosis Epigastric or right upper quadrant pain Impaired liver function Thrombocytopenia Fetal growth restriction

Complications

Complications related to preeclampsia include preterm birth, intrauterine fetal growth restriction, placental abruption, maternal pulmonary edema, and eclampsia. The estimated incidence of eclampsia is 1–3 per 1000 preeclamptic patients. Eclampsia is defined as one or more generalized convulsions in the setting of preeclampsia.

Treatment

In the management of preeclampsia, with few exceptions, maternal interests are best served by immediate delivery. However, this approach may not be in the best interest of the fetus. In the case of extreme prematurity, for example, the fetus may benefit from a period of expectant management during which corticosteroids are administered to accelerate fetal maturation. The decision to proceed with immediate delivery versus expectant management is based on several factors, including disease severity, fetal maturity, maternal and fetal condition, and cervical status.

A. Mild Preeclampsia

Women with mild preeclampsia are hospitalized for further evaluation and, if indicated, delivery. If mild preeclampsia is confirmed and the gestational age is 40 weeks or greater, delivery is indicated. At gestational ages of 37–40 weeks, cervical status is assessed and, if favorable, induction is initiated. If the cervical status is unfavorable, preinduction cervical ripening agents are used as needed. Occasionally, women with very unfavorable cervical examinations between 37 and 40 weeks may be managed expectantly for a limited time with bed rest, antepartum fetal surveillance, and close monitoring of maternal condition, including blood pressure measurement every 4–6 hours and daily assessment of patellar reflexes, weight gain, protein-uria, and symptoms. A complete blood count and levels of serum transaminases, lactate dehydrogenase, and uric acid should be checked weekly to twice weekly. Delivery is indicated if the cervical status becomes favorable, antepartum testing is abnormal, the gestational age reaches 40 weeks, or evidence of worsening preeclampsia is seen. If expectant management is undertaken after 37 weeks, the patient should understand that the only known benefit is a possible reduction in the rate of caesarean birth.

Women with mild preeclampsia before 37 weeks' gestation are managed expectantly with bed rest, twice-weekly antepartum testing, and maternal evaluation as described. Corticosteroids are administered if the gestational age is <34 weeks; amniocentesis is performed as needed to assess fetal pulmonary maturity. When extended expectant management is undertaken, fetal growth is assessed with ultrasound every 3–4 weeks. Occasionally, outpatient management is reasonable in carefully selected, reliable, asymptomatic patients with minimal proteinuria and normal laboratory test results. This approach includes bed rest at home, daily fetal movement counts, twice-weekly antepartum testing, serial evaluation of fetal growth, and frequent assessment, often by a visiting nurse, of blood pressure, proteinuria, weight gain, patellar reflexes, and symptoms. Any evidence of disease progression constitutes an indication for hospitalization and consideration of delivery. The benefit of prophylactic intrapartum magnesium sulfate in preventing convulsions in patients with mild preeclampsia has not been demonstrated conclusively in the literature.

B. Severe Preeclampsia

Severe preeclampsia mandates hospitalization. Delivery is indicated if the gestational age is 34 weeks or greater, fetal pulmonary maturity is confirmed, or evidence of deteriorating maternal or fetal status is seen. Acute blood pressure control may be achieved with hydralazine, labetalol, or nifedipine. The goal of antihypertensive therapy is to achieve a systolic blood pressure <160 mm Hg and a diastolic blood pressure <105 mm Hg. Overly aggressive control of the blood pressure may compromise maternal perfusion of the intervillous space and adversely affect fetal oxygenation. Hydralazine is a peripheral vasodilator that can be given in doses of 5–10 mg administered intravenously (IV). The onset of action is 10–20 minutes, and the dose can be repeated in 20–30 minutes if necessary. Labetalol can be administered in doses of 5–20 mg by slow IV push. The dose can be repeated in 10–20 minutes. Nifedipine is a calcium channel blocker that can be used in doses of 5–10 mg orally. The sublingual route of administration should not be used. The dose can be repeated in 20–30 minutes, as needed.

Management of severe preeclampsia before 34 weeks is controversial. In some institutions, delivery is accomplished regardless of fetal maturity. In others, delivery is delayed for a limited period of time to permit the administration of corticosteroids. Four large randomized controlled trials comparing magnesium sulfate with other methods of treatment to prevent convulsions in women with severe preeclampsia have demonstrated that magnesium sulfate is associated with a significantly lower rate of eclampsia than either no treatment or nimodipine. Lucas and colleagues reported no seizures among 1049 preeclamptic women receiving magnesium sulfate prophylaxis. Nonetheless, tonic–clonic convulsions may occur despite magnesium sulfate therapy. Magnesium sulfate is initiated, fetal status is monitored continuously, and antihypertensive agents are used as needed to maintain a systolic blood pressure <160 mm Hg and a diastolic blood pressure <105 mm Hg. Between 33 and 35 weeks, consideration should be given to amniocentesis for pulmonary maturity studies. If mature, immediate delivery is indicated. If immature, corticosteroids are administered and, if possible, delivery is delayed 24–48 hours. Between 24 and 32 weeks, antihypertensive therapy is instituted as indicated, corticosteroids are administered, and extensive maternal counseling is undertaken to clarify the risks and benefits of pregnancy prolongation. Neonatology consultation is helpful to delineate the neonatal risks specific to gestational age and estimated fetal weight. The duration of expectant management is determined on an individual basis, taking into account maternal wishes, estimated fetal weight, gestational age, and maternal and fetal status. Expectant management is contraindicated in the presence of fetal compromise, uncontrollable hypertension, eclampsia, DIC, HELLP syndrome, cerebral edema, pulmonary edema, or evidence of cerebral or hepatic hemorrhage. When severe preeclampsia is diagnosed before 24 weeks of gestation, the likelihood of a favorable outcome is low. Thorough counseling should address realistically the risks and anticipated benefits of expectant management and should include the option of pregnancy termination. If an appropriately informed patient declines the option of pregnancy termination, expectant management should proceed as outlined previously.

C. Intrapartum Management of Preeclampsia

In women with preeclampsia without contraindications to labor, vaginal delivery is the preferred approach. Cervical ripening agents and oxytocin are used as needed. If magnesium sulfate is used for seizure prophylaxis, it is administered as an IV loading dose of 4–6 g over 20–60 minutes, followed by a maintenance dose of 1–2 g/h. Urine output and serum creatinine level are monitored, and the magnesium dose is adjusted accordingly to prevent hypermagnesemia. Patellar reflexes and respiratory rate should be assessed frequently. In the presence of patellar reflexes, serum magnesium levels usually are unnecessary. Therapeutic magnesium levels range from 4–8 mg/dL. Loss of patellar reflexes is observed at magnesium levels of 10 mg/dL or higher, respiratory paralysis may occur at levels of 15 mg/dL or above, and cardiac arrest is possible with levels in excess of 25 mg/dL. Calcium gluconate (10 mL of 10% solution) should be available in the event of hypermagnesemia. To avoid pulmonary edema, total IV fluids should not exceed 100 mL/h. Pain control is achieved with regional anesthesia or with intramuscular or IV narcotic analgesics. Invasive hemodynamic monitoring is reserved for refractory pulmonary edema, adult respiratory distress syndrome, or oliguria unresponsive to fluid challenge. If caesarean section is required, platelets should be available for possible transfusion for patients with platelet counts <50,000/mm^3. Use of other blood products is guided by clinical and laboratory findings.

D. Management of Eclampsia

In most cases eclamptic seizures are self-limited, lasting 1–2 minutes. The first priorities are to ensure that the airway is clear and to prevent injury and aspiration of gastric contents. Diazepam or lorazepam should be used only if seizures are sustained. Nearly all tonic–clonic seizures are accompanied by a prolonged fetal heart rate deceleration that resolves after the seizure has ended. Once the patient has been stabilized, delivery is indicated. If possible, a 10- to 20-minute period of in utero resuscitation should be permitted before delivery. Convulsions alone do not constitute an indication for caesarean section. However, if vaginal birth is not possible within a reasonable period of time, caesarean delivery is performed in most cases. A number of studies suggest that magnesium sulfate is superior to phenytoin, diazepam, and a lytic cocktail at preventing recurrent seizures in women with eclampsia.

CONCLUSION

Hypertensive disorders of pregnancy remain among the most common causes of adverse maternal and perinatal outcome. These disorders can be regarded as a spectrum of disease, ranging from isolated chronic hypertension to pure preeclampsia–eclampsia. Isolated mild or moderate chronic hypertension appears to have little effect on pregnancy outcome. Morbidity and mortality are highest among patients with severe preeclampsia or eclampsia.

Appropriate management of newly diagnosed chronic hypertension entails a thorough search for an underlying cause. Close maternal and fetal surveillance is necessary, and a high index of suspicion must be maintained for the development of superimposed preeclampsia.

The management of preeclampsia is influenced by many factors, including disease severity, gestational age, and fetal condition. Optimal management requires an appreciation of the complexity of the disease process and familiarity with its manifestations in multiple organ systems. Maternal and fetal risks and benefits must be assessed thoroughly. Individualized treatment plans should be formulated and discussed with the patient, and she should be encouraged to participate in major decisions regarding her care. In atypical cases, alternative diagnoses must be considered.

Cardiac & Pulmonary Disorders in Pregnancy

Afshan B. Hameed, MD, FACC
Martin N. Montoro, MD

CARDIAC DISORDERS IN PREGNANCY

CARDIOVASCULAR CHANGES IN NORMAL PREGNANCY

Hemodynamic adaptations of pregnancy are geared to augment blood flow to the developing fetoplacental unit. These alterations may stress the maternal cardiovascular system, leading to signs and symptoms similar to those seen in heart disease. Women with preexisting cardiovascular disease are particularly at risk, as they may exhibit marked clinical deterioration during the course of pregnancy.

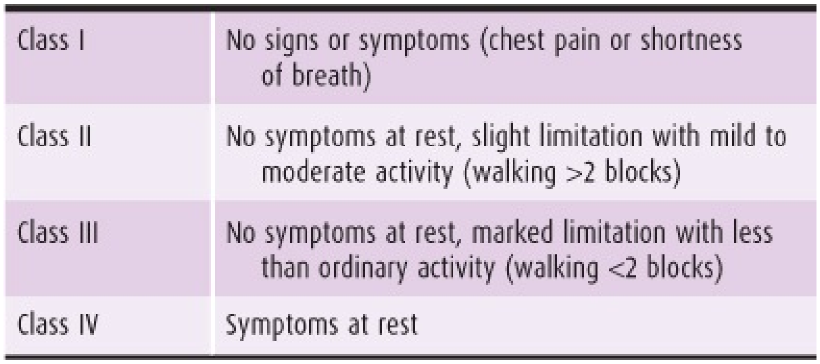
Blood volume begins to increase as early as 6 weeks of gestation and continues to rise until midpregnancy. The hormonally mediated increase in plasma volume is disproportionately higher than the red cell mass, resulting in the so-called physiologic anemia of pregnancy. Cardiac output (CO) is increased by 50% above the nonpregnant state as a product of increased stroke volume, along with an increased heart rate by 10–20 beats/min. CO peaks in the mid-second trimester and plateaus thereafter. Myocardial contractility improves, left atrial and left ventricular chamber sizes increase, and peripheral vascular resistance falls (effects of progesterone, circulating prostaglandins, atrial natriuretic peptides, endothelial nitric oxide, and the low-resistance vascular bed of the placenta). The systemic arterial pressure falls during the first trimester, remains stable during the second trimester, and returns to pregestational levels before term. The reduction in diastolic pressure is more pronounced than the reduction in systolic pressure, leading to a wide pulse pressure. Supine hypotensive or uterocaval syndrome may occur in 0.5–11% of pregnancies and is related to the acute occlusion of inferior vena cava by the gravid uterus in the supine position; it is characterized by significant decreases in blood pressure and heart rate. This contrasts with the tachycardia seen with hypotension in the nonpregnant state. Patients usually complain of lightheadedness, nausea, dizziness, and syncope in extreme cases. Symptoms are alleviated by changing to a left lateral recumbent position.

Hemodynamic changes during labor and delivery are in part related to the fear, anxiety, and pain experienced by the patient at that stage. Additionally, uterine contractions displace 300–500 mL of blood with each contraction, further augmenting CO. Oxygen consumption increases 3-fold. These changes in CO are less pronounced if the patient remains in the supine position with leftward tilt and receives adequate analgesia. Immediately after delivery, relief of caval compression coupled with autotransfusion from the contracting uterus produces a further increase in CO. This may lead to acute cardiac decompensation in the immediate postpartum period. Most of these physiologic changes revert to prepregnancy levels by 2 weeks postpartum.

HEART DISEASE

Heart disease is surpassing other causes of maternal mortality in recent years. Cardiac disease complicates approximately 1% of all pregnancies. Pregnant patients with significant symptoms on exertion, such as patients in New York Heart Association (NYHA) functional classes III and IV (Table 27–1), have high event rates and may succumb to complications of heart disease, such as heart failure, arrhythmias, and stroke. Patients with stenotic lesions (eg, mitral or aortic stenosis) and minimal baseline symptoms (NYHA class I or II) may deteriorate rapidly.

Table 27–1. New York Heart Association functional classification of heart disease.



Class I	No signs or symptoms (chest pain or shortness of breath)
Class II	No symptoms at rest, slight limitation with mild to moderate activity (walking >2 blocks)
Class III	No symptoms at rest, marked limitation with less than ordinary activity (walking <2 blocks)
Class IV	Symptoms at rest

As a greater proportion of the pediatric population is surviving surgical correction of congenital anomalies, many children are reaching adulthood and subsequently becoming pregnant. Pregnant women with congenital heart disease now outnumber those with rheumatic heart disease in most developing countries. Acquired conditions such as ischemic heart disease are also not uncommon today as women are delaying childbearing to the third and fourth decades of life. As the general population becomes more susceptible to diabetes mellitus, morbid obesity, and hypertension, more frequent encounters with ischemic heart disease in pregnant patients are expected.

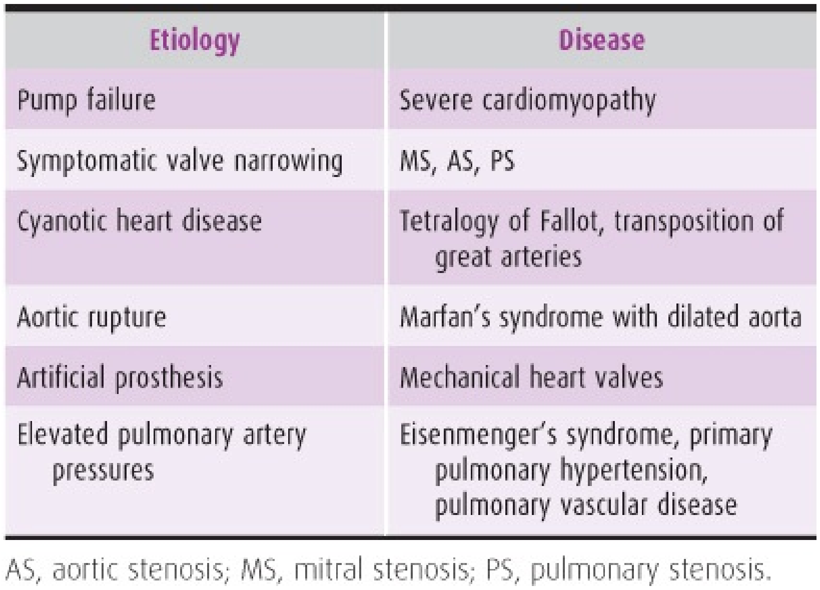
CARDIOVASCULAR EVALUATION DURING PREGNANCY

Most women with heart disease have successful pregnancies, but complacency in the diagnosis and management of pregnant patients can have direct consequences for both the mother and the fetus. Therefore, it is essential to evaluate every pregnant woman with heart disease for her risk of adverse outcomes during pregnancy, labor, delivery, and postpartum. In general, all such women should be referred to a tertiary care center for a multidisciplinary management by an obstetrician, cardiologist, clinical geneticist, and neonatologist.

Preconception Counseling

Care of women with cardiac disease should ideally begin with preconception counseling. Certain conditions may need treatment before attempting pregnancy. Cardiac conditions associated with high maternal mortality include pulmonary hypertension (primary and secondary), peripartum and other cardiomyopathies with reduced ejection fraction, Marfan's syndrome with aortic root enlargement, and complicated coarctation of aorta (Table 27–2). These patients should be advised against pregnancy and offered termination of pregnancy at an appropriate gestational age. In general, valve stenoses are problematic in pregnancy, and regurgitant lesions are relatively well tolerated. Management principles in pregnant women are similar to those in the nonpregnant state. Preconception counseling allows for optimal timing for conception, completion of all diagnostic procedures beforehand (especially those involving radiation exposure), discontinuation of teratogenic drugs, and scheduling of corrective/palliative surgery before pregnancy.

Table 27–2. High-risk pregnancy in women with heart disease.

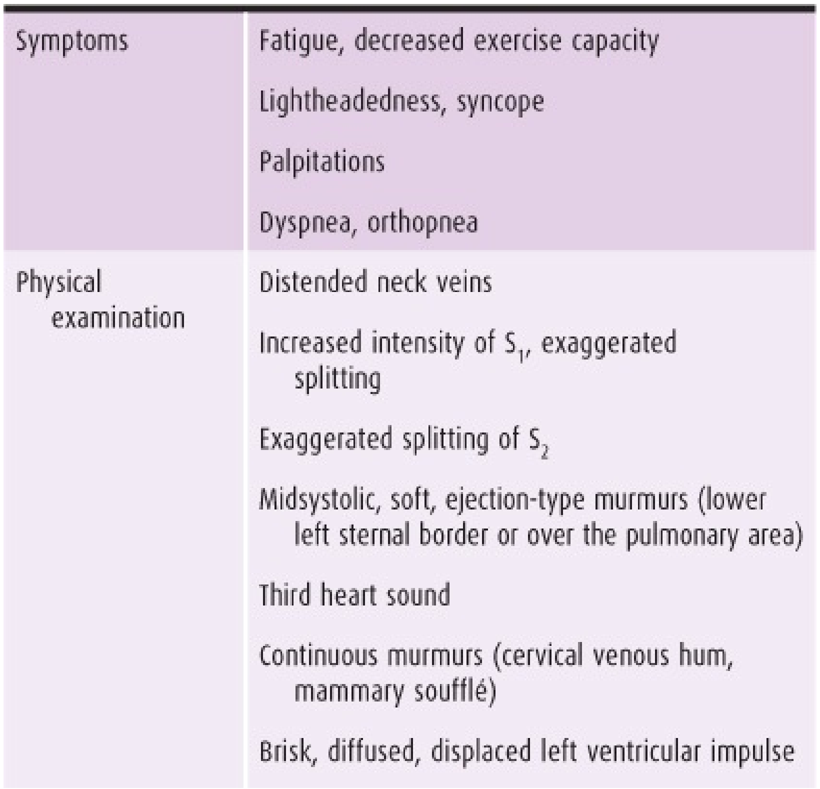


Etiology	Disease
Pump failure	Severe cardiomyopathy
Symptomatic valve narrowing	MS, AS, PS
Cyanotic heart disease	Tetralogy of Fallot, transposition of great arteries
Aortic rupture	Marfan's syndrome with dilated aorta
Artificial prosthesis	Mechanical heart valves
Elevated pulmonary artery pressures	Eisenmenger's syndrome, primary pulmonary hypertension, pulmonary vascular disease

AS, aortic stenosis; MS, mitral stenosis; PS, pulmonary stenosis.

The initial evaluation should include a careful medical history, comprehensive physical examination, and noninvasive diagnostic testing. Common findings in normal pregnancy are listed in Table 27–3. Siu et al identified the following prognostic indicators to predict cardiac events in pregnancy (ie, heart failure, arrhythmia, stroke, death):

Table 27–3. Common findings in normal pregnancy.



Symptoms	Fatigue, decreased exercise capacity Lightheadedness, syncope Palpitations Dyspnea, orthopnea
Physical examination	Distended neck veins Increased intensity of S_1, exaggerated splitting Exaggerated splitting of S_2 Midsystolic, soft, ejection-type murmurs (lower left sternal border or over the pulmonary area) Third heart sound Continuous murmurs (cervical venous hum, mammary soufflé) Brisk, diffused, displaced left ventricular impulse

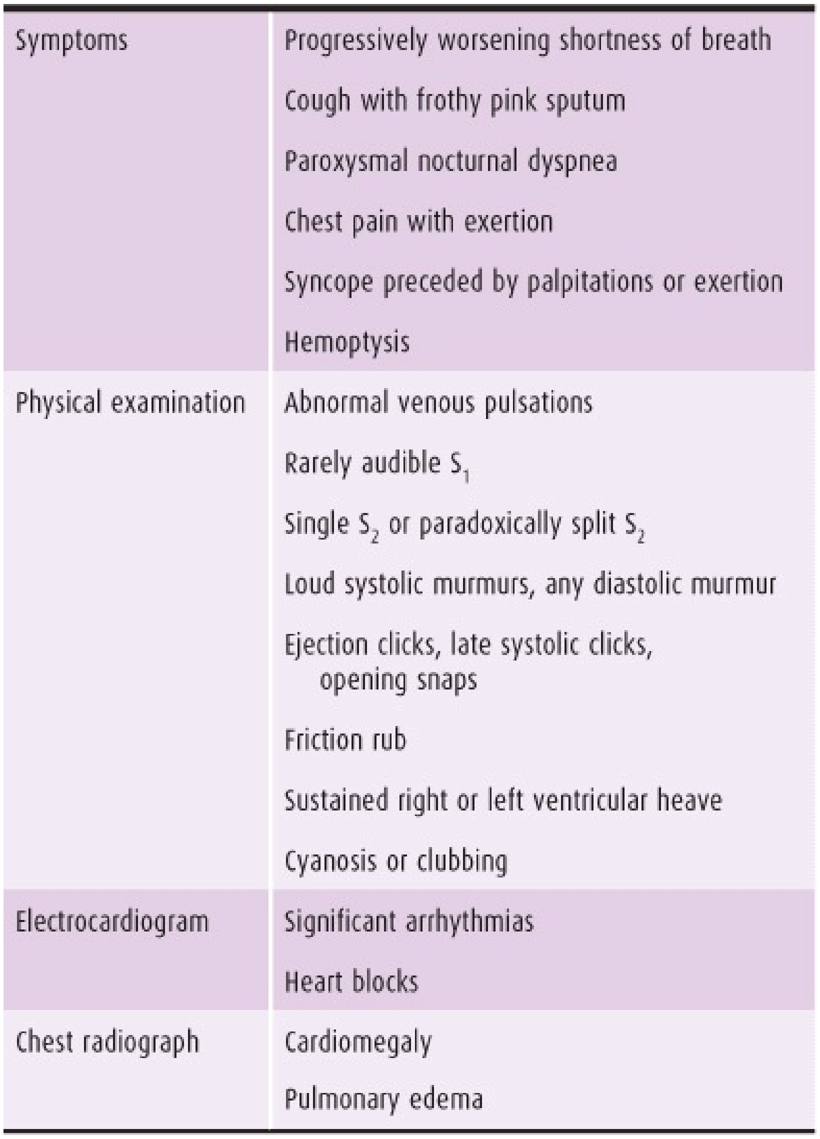
	Palpable right ventricular impulse
Electrocardiogram	QRS axis deviation Small Q and inverted P in lead III (abolished by inspiration) Sinus tachycardia, higher incidence of arrhythmias
Chest radiograph	Horizontal position of heart Increased lung markings
Echocardiography	Slightly increased systolic and diastolic left ventricular dimensions Moderate increase in size of right atrium, right ventricle, and left atrium Functional pulmonary, tricuspid, and mitral regurgitation

1. **N**ew York Heart Association (NYHA) functional class ≥II (or cyanosis)
2. **O**utlet obstruction of the left heart
3. **P**rior cardiac event (heart failure, arrhythmia, stroke)
4. **E**jection fraction <40%

The risk of a cardiac event with 0, 1, and >1 prognostic indicators were estimated to be 5%, 27%, and 75%, respectively.

Most pregnant patients experience reduced exercise tolerance and easy fatigability. This may be aggravated by the weight gained during gestation and physiologic anemia of pregnancy. Syncopal episodes or lightheadedness may occur due to mechanical compression of the inferior vena cava by the gravid uterus leading to poor venous return to the heart, especially in the third trimester. Other frequent complaints include hyperventilation and orthopnea (from mechanical pressure of the enlarged uterus on the diaphragm). Palpitations are common and probably are related to the hyperdynamic circulation of pregnancy rather than arrhythmias in most cases. Signs and symptoms of cardiovascular disease are listed in Table 27–4.

Table 27–4. Signs and symptoms indicative of significant cardiovascular disease.



Symptoms	Progressively worsening shortness of breath Cough with frothy pink sputum Paroxysmal nocturnal dyspnea Chest pain with exertion Syncope preceded by palpitations or exertion Hemoptysis
Physical examination	Abnormal venous pulsations Rarely audible S_1 Single S_2 or paradoxically split S_2 Loud systolic murmurs, any diastolic murmur Ejection clicks, late systolic clicks, opening snaps Friction rub Sustained right or left ventricular heave Cyanosis or clubbing
Electrocardiogram	Significant arrhythmias Heart blocks
Chest radiograph	Cardiomegaly Pulmonary edema

Hyperventilation is a common phenomenon in pregnancy and is likely related to the effect of progesterone on the respiratory center. It is important to differentiate hyperventilation from dyspnea, which is a common finding in congestive heart failure. Bibasilar crackles are commonly heard in normal pregnancy and result from atelectasis that develops from basal compression of the lungs due to uterine enlargement and the subsequent increase in intraabdominal pressure.

The physical examination should focus on facial, digital, or skeletal abnormalities that suggest the presence of congenital anomalies. One should observe for clubbing, cyanosis, or pallor. The first heart sound usually is widely split (which can be misinterpreted as a fourth heart sound). A loud first heart sound suggests mitral stenosis (MS), whereas a low-intensity first heart sound indicates first-degree heart block. A widely split second heart sound goes along with atrial septal defect (ASD), whereas a paradoxically split sound occurs in severe left ventricular hypertrophy or left bundle branch block. A third heart sound is normal in pregnancy. A fourth heart sound, ejection click, opening snap, or mid to late systolic click suggests heart disease. Functional systolic murmurs can be heard in most pregnant women and can result from the hyperkinetic circulation of pregnancy. These murmurs are midsystolic and are heard best at the lower left sternal border and over the pulmonic area. Continuous benign murmurs, such as the cervical venous hum and mammary soufflé, also result from increased flow secondary to the hemodynamic changes of pregnancy. The venous hum is best heard over the right supraclavicular fossa, and the mammary soufflé is best auscultated over the breast in late gestation. Diastolic murmurs heard during pregnancy require further investigation by echocardiography and Doppler ultrasound.

Diagnostic Tests

A. Electrocardiography

The QRS axis in normal pregnancy usually is within normal limits but can shift to the extreme right or left of that range. A small Q wave and an inverted P wave in lead III are abolished by deep inspiration. Greater R-wave amplitude can be seen in leads V_1 and V_2. The incidences of sinus tachycardia and premature atrial/ventricular beats, as well as the susceptibility to paroxysmal supraventricular and ventricular arrhythmias, are increased.

B. Chest Radiograph

The radiation exposure from a routine chest radiograph is minimal; however, chest x-ray films still should not be taken casually in pregnancy. Chest x-ray may be performed for appropriate indications with abdominopelvic protective lead shielding. The findings on chest films may mimic abnormal disease conditions. Straightening of the left heart border due to enlargement of the main pulmonary artery can be seen. The heart is more horizontal, and the lung markings are more prominent due to redistribution secondary to increased pulmonary venous pressure.

C. Echocardiography

Small pericardial effusions are common in normal pregnant women late in pregnancy. Dilation of mitral, tricuspid, and pulmonary annuli and enlargement of all the cardiac chambers are seen. Mild physiologic regurgitation of these valves is observed. Transthoracic echocardiography can be used safely on both the mother and the fetus to rule out congenital heart disease, ventricular dilatation, and aortic root disease. Doppler ultrasound can evaluate the significance of valvular lesions, estimate pulmonary pressures, and rule out intracardiac shunts. Transesophageal echocardiography can improve visualization of posteriorly situated cardiac structures, such as the left atrium and mitral valve.

D. Exercise Stress Testing

Stress testing usually is indicated for preconception workup for estimation of myocardial reserve to determine whether a woman can safely carry a pregnancy to term. Some low-level exercise protocols have been developed for implementation during pregnancy to evaluate for ischemic heart disease. These protocols allow the heart rate to go up to only 70% of age-predicted heart rate and are considered safe in the first half of pregnancy.

E. Cardiac Catheterization

Pulmonary artery catheterization without fluoroscopy, at the bedside, is a relatively safe procedure and allows for hemodynamic monitoring during labor and delivery in select patients. Left or right heart catheterization under fluoroscopy should be undertaken only when absolutely essential (eg, for percutaneous coronary intervention or balloon valvuloplasty). Every effort should be taken to shield the abdominal and pelvic areas and to avoid radiation exposure of the fetus.

VALVULAR HEART DISEASE

1. Mitral Stenosis

ESSENTIALS OF DIAGNOSIS

- Mitral stenosis (MS) is the most common valve lesion seen in pregnancy.
- It is characterized by narrowing of the opening within the mitral valve.

Pathogenesis

Mitral stenosis may be congenital or due to rheumatic heart disease, Libman-Sacks endocarditis in lupus, or Lutembacher's syndrome (MS in association with an atrial septal defect). Rheumatic heart disease develops after a group A β-hemolytic streptococcal infection of the upper airway. Even though its incidence in developing countries has declined as a result of the prevalent use of antibiotics, rheumatic valvular disease still afflicts a large majority of women of childbearing age in Asia, Central America, and South America.

Clinical Findings

The characteristic findings include a right ventricular lift, a loud first heart sound (S_1), an accentuated pulmonic component of the second heart sound (P_2), an opening snap, and a low-frequency diastolic rumble at the apex with presystolic accentuation (if the patient is in sinus rhythm). The murmur is best heard with the bell of the stethoscope in the left lateral decubitus position. The electrocardiogram often is normal but may indicate left atrial enlargement, right-axis deviation, or even right ventricular hypertrophy. Echocardiogram is diagnostic.

Complications

The increased left atrial pressure may predispose the patient to atrial arrhythmias (ie, atrial fibrillation). This new-onset atrial fibrillation can precipitate acute decompensation even in the setting of mild to moderate MS due to acceleration of ventricular rate that decreases the diastolic filling period and thus increases pulmonary venous pressure. The pregnant cardiac patient also is at risk for developing thromboembolic complications in a setting of existing hypercoagulable state as well as venous stasis in the legs.

Treatment

The goals are to prevent/treat tachycardia and atrial fibrillation, prevent fluid overload, and alleviate pain and anxiety. Beta blockers, diuretics, and occasionally digitalis and anticoagulants may be necessary to treat congestive failure and atrial arrhythmias. Patients with chronic atrial fibrillation should be anticoagulated with subcutaneous heparin. Anemia, infection, and thyrotoxicosis should be corrected. Large fluctuations in hemodynamics due to venous pooling in the legs should be prevented by the use of elastic support hose, especially late in pregnancy. Medical management remains the first-line therapy in patients with MS. In patients with severe MS, mitral valvotomy may be performed for symptom relief before pregnancy. Balloon valvuloplasty has become a preferred, less invasive procedure, especially for patients with a noncalcified, pliable valve with excellent results. Mitral valve placement is considered as a last resort due to high maternal morbidity and fetal loss rates and should be deferred until after the pregnancy if possible.

Patients with MS should be delivered vaginally at term unless caesarean section is indicated for obstetric reasons. Narcotic-epidural anesthesia is the preferred option for delivery. Other considerations include maintenance of meticulous fluid balance, oxygen administration, and left lateral decubitus position during labor. The second stage of labor may be shortened with use of outlet forceps. Careful hemodynamic monitoring during labor and delivery is indicated in patients with compromised circulation. Postpartum uterotonics should be given cautiously and blood loss carefully monitored. Redistribution of fluid from the interstitial to the intravascular space immediately postpartum may precipitate pulmonary edema in these patients.

Prognosis

The risk of developing heart failure increases progressively throughout pregnancy and in the peripartum period. Labor imposes an additional load, and congestive failure may develop for the first time during labor in a previously well-controlled patient with MS. The overall mortality rate in women with rheumatic mitral valve disease is 1% overall and reaches 3–4% in women with class III and IV severity.

2. Mitral Regurgitation

ESSENTIALS OF DIAGNOSIS

- Mitral regurgitation is characterized by a mitral valve that does not close properly during systole, leading to leakage of blood from the left ventricle into the left atrium.

Pathogenesis

Mitral regurgitation (MR) is one of the most common valvular lesions seen in adulthood. The most common cause of MR is mitral valve prolapse, which is seen in approximately 50% of cases of MR. With mitral valve prolapse, there is myxomatous degeneration of the valve, which causes stretching out of the valve and chordae tendineae. MR can also be caused by ischemic heart disease, rheumatic fever, and Marfan’s syndrome.

Clinical Findings

Mitral regurgitation is generally well tolerated in pregnancy. The characteristic finding on physical examination is a long systolic murmur that ends with the second heart sound and is best heard at the apex with radiation into the axilla. An associated third heart sound is often present, and an opening snap may be present with associated mitral valve stenosis.

Complications

Severe MR may lead to left atrial enlargement, atrial fibrillation, and/or congestive heart failure (CHF).

Treatment

No treatment is indicated in an asymptomatic patient. Symptoms are usually related to CHF and respond well to digitalis, diuretics, and vasodilators. Anticoagulation should be used for atrial fibrillation.

3. Mitral Valve Prolapse

ESSENTIALS OF DIAGNOSIS

- Prolapse of one or both mitral valve leaflets into the left atrium during systole

---

Pathogenesis

Mitral valve prolapse (MVP) is a common congenital cardiac lesion in the general population. However, only 2–4% of the affected individuals have significant MR. It can be inherited as an autosomal dominant disorder with incomplete penetrance. MVP may be an idiopathic finding; it may also be seen in conjunction with other disorders such as Marfan’s syndrome, autosomal dominant polycystic kidney disease, and Ehlers-Danlos syndrome.

Clinical Findings

On physical examination, patients with MVP may have a midsystolic click and/or a midsystolic or late systolic murmur at the apex of the left ventricle. Echocardiogram confirms the findings and can also evaluate for MR.

Treatment

All patients with a history of MVP should undergo comprehensive prepregnancy clinical evaluation and echocardiography.

Prognosis

MVP is generally well tolerated in pregnancy unless associated with severe MR, left atrial enlargement, left ventricular dysfunction, or atrial fibrillation. Severe MR can worsen during pregnancy, and patients may develop progressive atrial enlargement, atrial fibrillation, and clinical decline. Select patients should be referred for mitral valve repair before pregnancy.

4. Aortic Stenosis

ESSENTIALS OF DIAGNOSIS

- Narrowing of the area within the aortic valve

Pathogenesis

In reproductive years, the most common cause of aortic stenosis (AS) is bicuspid aortic valve followed by rheumatic heart disease. Bicuspid aortic valve may be associated with aortic root enlargement and is important in the preconception evaluation and counseling.

Clinical Findings

Common symptoms include chest pain due to decreased coronary perfusion, syncope due to decreased cerebral perfusion, and congestive heart failure due to increased left atrial pressure. Physical examination is significant for diminished and delayed carotid pulse. Left ventricular apical impulse is usually displaced and sustained with a harsh systolic ejection murmur that can be heard in the second right intercostal space. Electrocardiogram may demonstrate left ventricular hypertrophy and left atrial enlargement.

Complications

Pregnancy is contraindicated if the patient has severe AS without symptoms, history of symptomatic AS, or history of heart failure, syncope, or cardiac arrest. AS causes a fixed CO, decreased coronary and cerebral perfusion, and an increase in the left atrial pressure. Hemodynamic changes of pregnancy put these patients at an elevated risk.

Treatment

Patients with mild to moderate AS who are asymptomatic should be advised to restrict their physical activity and can be managed expectantly during pregnancy. Patients with severe AS should strongly be considered for mechanical relief of their obstruction. Aortic balloon valvuloplasty can be performed before pregnancy *or* after 20 weeks of gestation if the valve anatomy is favorable. Aortic valve replacement is considered a last resort and is associated with significant fetal loss and maternal morbidity.

OTHER CARDIAC VALVULAR LESIONS

1. Aortic Regurgitation

Patients with aortic insufficiency tolerate pregnancy well because the fall in peripheral resistances favors forward blood flow and decreases the regurgitant fraction.

2. Pulmonary Stenosis

Isolated pulmonary stenosis is well tolerated in pregnancy. Favorable maternal and fetal outcomes have been reported in the absence of right ventricular failure. Transvalvular pressure gradients of >60 mm Hg may warrant relief of obstruction. Right ventricular failure or arrhythmias may be seen.

CONGENITAL CARDIAC LESIONS

ESSENTIALS OF DIAGNOSIS

- Congenital cardiac lesions are structural malformations of the heart present at birth that developed during fetal life or perinatal transition.
- With improvements in cardiac care, more children who were born with cardiac malformations are reaching reproductive age.
- Congenital cardiac lesions are associated with an increased risk of fetal and maternal complications.

Pathogenesis

With advances in the care of children born with cardiac structural malformations during the 20th century, more women with congenital heart defects—repaired or unrepaired—are reaching reproductive age. Congenital cardiac defects may be classified as cyanotic or acyanotic. The most common acyanotic congenital cardiac lesion is bicuspid aortic valve. The presence of congenital cyanotic heart disease is not an absolute contraindication to pregnancy but does increase the risk of fetal loss. Heart failure occurs in 47% patients with cyanotic heart disease versus 13% with acyanotic lesions, and maternal mortality approaches 4–16% in uncorrected lesions.

Women with congenital heart defects in general are at increased risk of maternal and fetal complications during pregnancy. The absolute risk of each complication varies according to the underlying lesion. The maternal complications associated with congenital heart defects in pregnant women include heart failure, arrhythmias, thromboembolism, endocarditis, and pulmonary hypertension.

Fetal complications related to maternal cardiac disease are an increased risk of miscarriage, stillbirth, intrauterine growth restriction and prematurity, and in many cases iatrogenic preterm birth for maternal indications. Fetuses of women with congenital heart disease are also at increased risk of congenital heart defect. The recurrence risk depends on the specific type of defect, but in general, the risk is approximately 5–10%.

Clinical Findings, Treatment, and Prognosis

Clinical findings, treatment, and prognosis vary according to underlying heart lesion. General tenets of management of women with congenital heart disease during the antepartum period are close surveillance for maternal symptoms of decompensation during pregnancy, fetal surveillance for evidence of pregnancy loss or intrauterine growth restriction, and fetal echocardiogram (usually performed at 20 weeks) to assess for recurrent congenital heart defect.

In terms of labor management, women with repaired or unrepaired defects with normal cardiac function may be allowed to labor and deliver normally. In many cases, however, women may require a more controlled labor and delivery with planned induction of labor and assisted second stage with vacuum or forceps. Caesarean delivery is usually reserved for obstetrical indications due to the increased blood loss and increased risk of postdelivery infection when compared with vaginal birth. The management of pregnancies in women with specific cardiac defects is discussed next.

A. Coarctation of Aorta

The most common site of coarctation is distal to the left subclavian artery. Unoperated coarctation of aorta is rarely encountered in pregnancy. Postrepair coarctation patients require careful prepregnancy evaluation to exclude important cardiovascular residua or sequelae. It is a rare cause of secondary hypertension and may be associated with ASD and ventricular septal defect (VSD), bicuspid aortic valve, Berry aneurysm of the circle of Willis, and hypertension. A gradient of <20 mm Hg across the coarctation is associated with favorable maternal and fetal outcomes. Patients with coarctation are at risk for aortic aneurysm, dissection and rupture, CHF, cerebrovascular accident due to uncontrolled hypertension or rupture of intracranial aneurysm, and bacterial endocarditis. The key is to avoid hypotension and excessive blood loss at the time of delivery.

B. Atrial Septal Defect

Atrial septal defect (ASD) is one of the most common congenital heart defects seen in adults. Secundum ASD is the most commonly seen during pregnancy, and the majority of these patients have uncomplicated pregnancies. Primum ASDs may be associated with cleft mitral valve. Partial anomalous pulmonary venous connection is characteristically associated with sinus venosus ASD. There is an additional risk for pulmonary hypertension and arrhythmias. Physical examination includes systolic ejection murmur at the left sternal border and wide fixed split second heart sound. Electrocardiogram may reveal a partial right bundle branch block, right axis deviation, right ventricular hypertrophy, or left axis deviation in patients with ostium primum defects.

Patients with large defects are prone to CHF, atrial fibrillation, and paradoxical embolism. Consider prophylactic anticoagulation and meticulous leg care in the peripartum period (compression stockings, leg squeezers) in patients with large ASDs to prevent embolization. Systemic hypertension may lead to an increase in left to right shunt, which may lead to pulmonary volume overload. The key is to avoid volume overload.

C. Ventricular Septal Defect

Most ventricular septal defects (VSD) encountered during pregnancy have either been repaired or are clinically insignificant. VSD is generally well tolerated during pregnancy. Patients with large defects are at risk for CHF, arrhythmias, and pulmonary hypertension. Systemic hypertension may lead to an increase in left to right shunt, which may lead to pulmonary volume overload similar to an ASD.

D. Patent Ductus Arteriosus

Patent ductus arteriosus (PDA) is an uncommon lesion encountered in pregnancy. Most patients with small PDA tolerate pregnancy well. Symptoms are primarily fatigue and dyspnea. Physical examination findings include widened pulse pressure and a continuous murmur in the pulmonic area. Moderate-size PDA may cause left atrial and left ventricular enlargement with associated left ventricular volume overload and heart failure. These patients are at risk for pulmonary hypertension and reversal of shunt (right to left) secondary to elevated pulmonary pressures (Eisenmenger’s syndrome). Systemic hypertension may lead to an increase in left to right shunt, which may lead to pulmonary volume overload/CHF similar to that seen in ASD and VSD physiology.

E. Eisenmenger’s Syndrome

Eisenmenger’s syndrome is the reversal of a left to right shunt (ASD, VSD, PDA) due to progressive pulmonary hypertension. Right to left shunting leads to systemic arterial oxygen desaturation and central cyanosis. The degree of cyanosis is determined by the extent of pulmonary vascular obstructive disease. Maternal mortality approaches 30–50% and fetal loss may be as high as 75%. It is one of the few conditions in which pregnancy is contraindicated. If the patient is seen for the first time early in pregnancy, she should strongly be advised to terminate pregnancy. Various pulmonary vasodilators have been successfully used in pregnancy to lower the pulmonary pressures, but the overall prognosis remains grim. In these patients, the pulmonary pressures may reach systemic levels, and therefore, a minimal lowering of systemic blood pressure may cause massive right to left shunting. This may lead to worsening hypoxia, setting up a vicious cycle of further pulmonary vasoconstriction, and may result in rapid hemodynamic deterioration. Therefore, continuous pulse oximetry and oxygen administration to keep oxygen saturations above 90% is beneficial. Narcotic epidural or general endotracheal anesthesia should be used to avoid risk of systemic hypotension. Although these patients are at high risk for thromboembolism due to hypercoagulability of pregnancy and polycythemia, the benefit of anticoagulation has not been confirmed. Patients may undergo assisted vaginal delivery if they are stable, and caesarean section is reserved for obstetrical indications and/or for unstable patients. Patients with Eisenmenger’s syndrome may have serious complications in the postpartum period, and therefore, prolonged hospitalization is recommended.

F. Tetralogy of Fallot

Patients with conotruncal abnormalities, including tetralogy of Fallot (TOF), complex pulmonary atresia, or truncus arteriosus, have an increased prevalence of 22q11.2 microdeletion. All adult patients considering pregnancy or reproduction should be screened for 22q11.2 microdeletion, as this has an important impact on the chance of congenital heart disease in the offspring, and be offered prepregnancy genetic counseling. Most patients with TOF have had prior intracardiac repair, but they remain at increased risk of maternal and fetal complications. Poor prognostic indicators in patients with TOF are hematocrit >65%, history of syncope, CHF, cardiomegaly, right ventricular hypertrophy, and oxygen saturations <90%.

G. Marfan's Syndrome

Marfan's syndrome is an autosomal dominant condition that causes cystic medial necrosis of the aorta and may lead to dissecting aneurysm in pregnancy. There is an increased risk of rupture, dissection, and cardiovascular complications if aortic root diameter is more than 4 cm. Patients with aortic root dilatation ≥4 cm should be advised against pregnancy and offered termination if pregnant. Prophylactic beta-blockers should be considered to retard the progression of aortic root dilatation in pregnancy. In addition to the more ominous cardiovascular complications, obstetrical morbidities, including uterine inversion, postpartum hemorrhage, and rectovaginal perforation, have been reported.

PERIPARTUM CARDIOMYOPATHY

ESSENTIALS OF DIAGNOSIS

- Peripartum cardiomyopathy is a dilated cardiomyopathy of unknown cause.
- It usually is diagnosed during late pregnancy or in the 4–5 months after delivery.
- It is diagnosed with the finding of left ventricular systolic dysfunction in a woman with no history of cardiac disease.

Pathogenesis

At present, the etiology of peripartum cardiomyopathy is unclear. A number of pathophysiologic mechanisms have been proposed, including inflammation, myocarditis, an abnormal maternal immunologic response to fetal antigens, and other environmental factors. A single clear cause, however, has not been identified.

Clinical Findings

Patients usually present with dyspnea, cough, chest discomfort, or fatigue. The diagnosis is based on the following criteria:

- Presentation with heart failure during the last month of pregnancy or within 5 months postpartum
- Absence of an underlying cause for the heart failure
- No history of heart disease before presentation
- Evidence of left ventricular systolic dysfunction by an ejection fraction <45% or reduced shortening fraction

Echocardiogram typically reveals a reduction in cardiac contractility and dilation of the left ventricle without hypertrophy. Serial B-type natriuretic peptide levels may be a useful marker to follow through the pregnancy.

Complications

Patients with ejection fraction of <35% are at risk or thromboembolism; therefore, prophylactic anticoagulation during pregnancy and full anticoagulation for 7–10 days after delivery should be considered.

Treatment

Patients with a diagnosis of peripartum cardiomyopathy should be delivered after stabilization of the mother. Principles of therapy are similar to that in the nonpregnant state, including supportive care (consisting of bed rest and fluid and salt restriction) and medical therapy. Medical therapy includes diuretics, vasodilators, and digitalis with or without beta-blockers. The use of angiotensin-converting enzyme inhibitors is contraindicated during pregnancy.

Prognosis

Cardiac function normalizes within 6 months of delivery in approximately half of patients with peripartum cardiomyopathy. Long-term outcomes of patients with previous history of peripartum cardiomyopathy is related to recovery of left ventricular ejection fraction (LVEF). Patients with recovered LVEF have a 20% risk of developing heart failure during future pregnancy. On the other hand, patients with persistent left ventricular dysfunction have a 30% risk of congestive heart failure and 17% risk of maternal mortality in their subsequent pregnancy. There is considerable controversy regarding the safety of subsequent pregnancy in patients with a history of peripartum cardiomyopathy and normalization of left ventricular function. It is recognized that left ventricular systolic function may decline with the subsequent pregnancy, even in patients who had normalization after the prior pregnancy. Careful prepregnancy counseling and discussion about the risks, including the potential for life-threatening complications, should be outlined with the patient and partner before proceeding with a subsequent pregnancy.

PREGNANCY AFTER PROSTHETIC HEART VALVE REPLACEMENT

ESSENTIALS OF DIAGNOSIS

- Patients with prosthetic heart valve are particularly at risk during pregnancy due to difficulties in maintaining adequate and consistent levels of anticoagulation.

Pathogenesis

Many women with a history of valvular heart disease may have undergone prosthetic valve replacement before pregnancy, either with mechanical or bioprosthetic valves. The use of bioprosthetic/tissue valve obviates the need for anticoagulants, but the life span of bioprosthetic valves is only 8–10 years, and anticoagulation may still be required if the patient is in atrial fibrillation. Compared with mechanical valves, the high rate of bioprosthetic valve deterioration is primarily determined by the younger age group (ie, childbearing years ([29% vs. 82%]). Recent studies report no impact of pregnancy on the overall bioprosthetic valve longevity. The majority of pregnant women have mechanical prosthesis in place these days.

Complications

Women with prosthetic valves during pregnancy are at risk of a number of complications, including valve failure, heart failure, thromboembolism, bleeding related to anticoagulation, and infection.

Treatment

Management of women with mechanical valves involves careful therapeutic anticoagulation. The options include oral anticoagulation with warfarin, unfractionated heparin, and low-molecular-weight heparin. Use of warfarin in the first trimester of pregnancy carries the risk of teratogenicity, as it crosses the placental barrier and can affect fetal cartilage and bone development. Warfarin in doses <5 mg/day has significantly lower risk of fetal complications. As warfarin crosses the placental barrier, it may cause fetal anticoagulation with risk of intracranial bleeding at the time of delivery. Therefore, warfarin is not a preferred agent toward the end of pregnancy, and patients are generally switched to a heparin preparation at 36 weeks of gestation. Unfractionated heparin and low-molecular-weight heparin do not cross the placental barrier and have no teratogenic threat to the fetus. Three regimens for anticoagulation during pregnancy are heparin throughout the pregnancy, warfarin throughout the pregnancy, or a combination of both drugs using heparin during the first trimester to minimize the possible teratogenic effect of warfarin, switching to warfarin in the late first trimester, then switching back to heparin in the late third trimester in anticipation of delivery in order to minimize fetal anticoagulation. There is considerable controversy regarding the best approach to the patient who requires anticoagulation for a mechanical heart valve during pregnancy. The risk to the mother versus the risk to the fetus must be discussed and carefully reviewed. It should be emphasized that regardless of the anticoagulation regimen used, meticulous monitoring and follow-up are mandatory.

SUMMARY

Most pregnant patients with cardiac disease have successful outcomes with careful follow-up. Valvular stenotic lesions pose a high risk to the mother and the fetus, whereas regurgitant lesions are tolerated well by pregnant women. Extremely high-risk patients should be advised against pregnancy and be offered termination if they become pregnant. A team of high-risk obstetrician, cardiologist, and anesthesiologist is recommended to optimize maternal and fetal outcome.

PULMONARY DISORDERS IN PREGNANCY

ASPIRATION PNEUMONITIS

ESSENTIALS OF DIAGNOSIS

- Aspiration of gastric contents can occur during pregnancy, most commonly during labor or after delivery.
- Aspiration can lead to pneumonitis that may be life-threatening.

Pathogenesis

A number of factors in pregnancy contribute to an increased risk of aspiration and aspiration pneumonitis. The risk of aspiration of gastric contents is increased during pregnancy due to elevated intraabdominal pressure, decreased gastroesophageal sphincter tone, delayed gastric emptying, and diminished laryngeal reflexes. Aspiration may be the result of passive regurgitation or active vomiting. Aspiration was reported to account for 30–50% of maternal deaths related to anesthetic complications, and if bacterial infection after aspiration occurred, usually after 24–72 hours, the mortality rate could be even higher. Due to advances in obstetric—and particularly anesthetic—management, the incidence of aspiration pneumonitis and its complications has been considerably reduced. Aspiration pneumonitis has also been called Mendelson’s syndrome, named after the physician who described a large series of women with this complication in association with aspiration at time of operative intervention.

Prevention

Given the high risk associated with aspiration pneumonitis, including the possibility of maternal death, every effort should be made to prevent this potentially catastrophic condition. General anesthesia is the main risk factor related to aspiration, and expert airway management during induction and intubation is extremely important.

Oral intake during labor is not generally recommended. Women undergoing elective caesarean delivery should not be given anything by mouth for at least 6–8 hours before the procedure. All anesthetized obstetric patients should be intubated. Laryngeal reflexes will generally prevent aspiration while patients are awake, but the reflexes will be altered in patients who are given excessive sedation, in patients who are under anesthesia, or in patients with seizures. Pain, anxiety, narcotics, and labor itself may cause delayed gastric emptying and increased intragastric pressure. Lowering the volume of gastric contents to <25 mL and raising the gastric pH to >2.5 will reduce the risk of pulmonary injury if aspiration occurs. Clear, nonparticulate systemic alkalizers (eg, sodium citrate-Bacitra, or Alka-Seltzer) must be used instead of particulate oral antacids (eg, magnesium trisilicate, Maalox, Riopan). Thirty milliliters of a clear antacid should be routinely given to all women 30 minutes before induction of anesthesia.

Gastric acidity may also be reduced by histamine-2 (H_2) receptor blockers. Cimetidine and ranitidine have been reported to be safe for use during pregnancy. Metoclopramide may increase lower esophageal sphincter tone and enhance gastric emptying. However, antacids are preferred, particularly in emergency situations, because they are reliable and fast acting. H_2 blockers and metoclopramide are not recommended for routine use.

Clinical Findings

The pathologic mechanism, clinical manifestations, and outcome depend on the volume (≥25 mL), acidity (pH ≤2.5), and composition (presence or absence of solid particles) of the aspirate. Small volumes of a very acidic aspirate will be highly toxic, whereas relatively large volumes of a buffered aspirate can be relatively well tolerated. Aspiration of large, solid particulate matter may occlude portions of the larger bronchi, resulting in hypoxia, pulmonary hypertension, and even death. With smaller particles, bronchial obstruction occurs more distally, resulting in atelectasis, hypoxia, and inflammation of the bronchial mucosal and respiratory distress. Symptoms immediately after aspiration include dyspnea, bronchospasm, cyanosis, tachycardia, and even respiratory arrest. The patient will be hypoxic, hypercapnic, and acidotic. If infection supervenes, fever and leukocytosis will occur 48–72 hours later. The localization of the chest X Ray abnormalities will depend on the patient’s position when the aspiration occurred: a) at the lung bases if she was upright, b) in the upper lobes or in the superior segment of the lower lobes if she was supine. A picture of diffuse interstitial pulmonary edema (“white out”) may be seen after aspiration of large amounts of very acidic material.

Treatment

If aspiration occurs during anesthesia, immediate intubation and suction should be performed, followed by ventilation and adequate oxygenation. Positive end-expiratory pressure may help to better expand areas of fluid-filled collapsed lung. Bronchoscopic suction should be performed as soon as possible if the aspirate contains solid particles. A chest x-ray film should be taken and serial blood gas determinations made. These patients should be managed in the intensive care unit.

If the gastric fluid pH is >3.0 and the patient appears to be well oxygenated, she can be followed closely with periodic chest x-ray films and blood gas determinations. The picture usually resolves without antibiotics in 48–72 hours, except when infection occurs. Therefore, antibiotics should not be given routinely or empirically; they should be administered when clinical evidence and cultures indicate the presence of a superimposed bacterial infection. The bacterial flora is often polymicrobial but anaerobes from the mouth usually predominate, and therefore penicillin or clindamycin are the antibiotics more often recommended. The use of corticosteroids is not universally agreed upon.

ASTHMA DURING PREGNANCY

ESSENTIALS OF DIAGNOSIS

- Most patients are diagnosed with asthma before pregnancy and already are receiving treatment.
- Symptoms suggestive of asthma include cough, dyspnea, chest tightness, and wheezing, particularly when episodes occur episodically.
- Pulmonary function studies are useful to confirm the diagnosis and should be part of the initial investigations.

Pathogenesis

The general prevalence of asthma appears to be increasing. Recent studies report that asthma occurs in up to 9% of the general US population and in 3.7–8.4% of pregnant women. Therefore, asthma has become one of the most common medical illnesses complicating pregnancy. The increased prevalence is reported worldwide, particularly in urban areas, and is generally attributed to industrial pollution. However, marked geographic variations occur, and the extent to which genetic predisposition plays a role is still under active investigation.

Common triggers of asthma include upper respiratory infections (more commonly viral); administration of beta-blockers, aspirin, or nonsteroidal anti-inflammatory drugs; sulfites and other food preservatives; allergens such as pollen, animal dander, mites, or molds; smoking; gastric reflux; and exercise or other causes of hyperventilation. Both cigarette smoking and other major environmental pollutants are specifically associated with fetal damage.

Childhood-onset asthma affects males more often than females. In contrast, adult-onset asthma reportedly occurs more frequently in women. Overall, the prevalence and severity of asthma are consistently reported to be greater in women than in men. Women also are reported to require more frequent emergency room visits and more hospitalizations. Therefore, sex hormones are believed to play a role in the differences observed in the occurrence of asthma, although the exact mechanisms are not completely understood. Asthma shows variations during the menstrual cycle, with premenstrual exacerbation more often reported. Reports on asthma during the menopause are more conflicting, with some studies noting improvement but others reporting more episodes of bronchospasm after 6 months of hormone replacement therapy.

No consistent effect (either worsening or improvement) during pregnancy has been observed, although one-third of women with more severe disease reportedly became worse late in the second trimester or early in the third trimester. Possible factors contributing to improvement include the higher levels of cortisol (anti-inflammatory) and progesterone (smooth muscle relaxant) and for worsening the higher (5–6 times) rate of sinusitis and gastroesophageal reflux during pregnancy. Others speculate that pregnancy does not have an effect on asthma and that the variations observed are simply part of the natural history of the disease or due to variable medication compliance when women find out that they are pregnant. Some become more compliant and their asthma improves, and others stop their medication, fearing for the fetus, and their disease worsens. The responses in subsequent pregnancies are somewhat more consistent and in 60% of women tend to be similar to those that occurred during the first pregnancy.

Clinical Findings

A diagnosis of asthma is usually made on clinical grounds and without much difficulty if an adequate history and physical examination are obtained. Most patients are diagnosed with asthma before pregnancy and already are receiving treatment. Symptoms suggestive of asthma include cough, dyspnea, chest tightness, and wheezing, particularly when episodes occur episodically. Pulmonary function studies are useful to confirm the diagnosis and should be part of the initial investigation and surveillance of disease. The forced expiratory volume in 1 second (FEV_1)/forced vital capacity (FVC) ratio will be <70%, and the airway obstruction can be reversed by administration of a short-acting $beta_2$-agonist preparations.

Asthma currently is classified according to severity as (1) mild intermittent, (2) mild persistent, (3) moderate persistent, and (4) severe persistent. In mild intermittent asthma, symptoms do not occur more often than twice per week, and nocturnal symptoms do not occur more often than twice per month. The peak expiratory flow (PEF) or the FEV_1 is >80% of normal, with <20% variability. In mild persistent asthma, symptoms occur more often than twice per week but not daily, and nocturnal symptoms occur more often than twice per month. The PEF or FEV_1 still is at least 80% of normal, but with greater (20–30%) variability. In moderate persistent asthma, symptoms occur daily, and nocturnal symptoms occur more than once per week. The PEF or FEV_1 is <80% but >60% of normal, with >30% variability. In severe persistent asthma, daytime symptoms occur continually, and nocturnal attacks occur frequently. The PEF or FEV_1 is <60% of normal, with >30% variability.

Differential Diagnosis

Rarely, bronchospasm is caused by a condition other than asthma. These conditions include acute left ventricular heart failure (also called *cardiac asthma*), pulmonary embolism, exacerbation of chronic bronchitis, carcinoid tumors, upper airway obstruction (laryngeal edema, foreign body), gastroesophageal reflux, and cough caused by some medications.

Complications

Potential maternal complications include hyperemesis gravidarum, pneumonia (women with asthma account for >60% of pneumonia cases in pregnancy), preeclampsia, vaginal bleeding, more complicated labors, and more caesarean deliveries. Fetal complications can include intrauterine growth restriction, preterm birth, low birth weight, neonatal hypoxia, and increased overall perinatal mortality. Women with severe asthma are at the highest risk. However, patients are at little or no increased risk when the disease is effectively treated and controlled.

Treatment

A. General Measures

The main goal of therapy is to maintain normal or near normal maternal pulmonary function to allow adequate fetal oxygenation, prevent exacerbations, and allow the patient to maintain her usual activities. In general, pregnant women are receptive to educational interventions that will improve their asthma management, and the benefits are likely to continue after delivery. A good example is learning the proper use of portable peak flow meters to objectively evaluate asthma severity, because clinical symptoms and the patient's own perception of the severity of asthma often are inaccurate. The PEF rate correlates well with FEV_1 and allows the detection of worsening at an early stage before serious symptoms appear as well as the evaluation of response to treatment while the patient is still at home. Avoidance of potential asthma triggers also is extremely important. The general principles of management for pregnant asthmatic women are similar to those for nonpregnant patients and include removing pets if necessary, encasing mattresses and pillows in airtight covers, carefully washing the bedding, keeping ambient humidity <50%, avoid vacuuming (or at least wear a mask), using air conditioning and air filters, avoiding outdoor activities when allergens and air pollution levels are high, and avoiding nonallergen irritants, such as strong odors, food additives, aspirin, beta-blockers, and particularly tobacco smoke. Several recent studies have shown that these measures not only are beneficial, but are cost-effective as well. Every effort should be made to achieve smoking cessation during pregnancy, which is a very serious but modifiable factor associated with adverse outcome.

Patients undergoing immunotherapy may continue doing so during pregnancy but without any further dose increase. Starting immunotherapy de novo during pregnancy is not recommended because uterine contractions are likely to develop if anaphylaxis occurs.

Influenza vaccination is currently recommended for all pregnant women during the flu season. This recommendation is of the utmost importance for pregnant women with asthma. Asthma sufferers also should receive the pneumococcal vaccine but preferably before pregnancy.

Treating rhinitis and sinusitis, which often are associated with asthma and may trigger exacerbations, is important. Treatment of rhinitis includes reducing exposure to antigens (environmental control); intranasal cromolyn sodium, antihistamines (tripelennamine or chlorpheniramine), and intranasal steroids are very beneficial. For treatment of sinusitis, amoxicillin (erythromycin if allergic to penicillin), oxymetazoline (nasal spray or drops), and pseudoephedrine are more often used.

B. Pharmacologic Therapy

Many women have the impression that most, if not all, medications might be harmful to the fetus. However, they should be informed that the risk of uncontrolled asthma is far worse than any of the potential side effects of the most common medications used to treat asthma. Most women with asthma can be managed effectively during pregnancy, and complications are generally confined to patients with uncontrolled asthma.

1. Mild intermittent asthma—These patients do not need daily medications. When symptoms occur, 2 puffs of a short-acting beta$_2$ agonist can be used as needed. More data are available for use of albuterol than for any other beta$_2$ agonist during pregnancy, and no harm to the fetus has been observed to date. These women may still experience severe exacerbations, which may be separated by long asymptomatic periods, and a short course of systemic corticosteroids may be needed.

2. Mild persistent asthma—The preferred therapy for this group of patients is a low-dose inhaled corticosteroid. More experience is available for budesonide use in pregnancy, and the published data regarding its safety and lack of risk for congenital anomalies are reassuring. Less experience is reported with beclomethasone, but the published data also are reassuring. Inhaled corticosteroids suppress and may even prevent airway inflammation, which plays a critical role in the pathogenesis of asthma and may decrease airway responsiveness as well. Because they may decrease and sometimes even obviate the need for systemic steroids, their use is now recommended at earlier stages of asthma. However, the full benefits may not be seen for 2–4 weeks, so they are not recommended as part of the treatment of acute attacks. Use of a mouth spacer to minimize systemic absorption is strongly recommended. Inhaled corticosteroids are likewise beneficial for rhinitis (2 sprays in each nostril twice daily).

Alternative, but not preferred, therapies for this group include inhaled cromolyn sodium, leukotriene receptor antagonists, or sustained-release theophylline. Cromolyn sodium is also anti-inflammatory drug, but its efficacy is less predictable than that of the inhaled corticosteroids, and the benefits may not be seen for 4–6 weeks. Nevertheless, cromolyn sodium seems to be free of side effects for mother or fetus. Few data on the use of leukotriene receptor modifiers during pregnancy are available; they are reported to be safe in animals, but human data are limited. The extensive experience with theophylline during pregnancy indicates that it is safe for the fetus except when maternal levels exceed 12 μ/mL. In these cases, the fetus or newborn may develop jitteriness, tachycardia, and vomiting.

3. Moderate persistent asthma—The preferred treatment is a combination of a low-dose or medium-dose inhaled corticosteroid and a long-acting beta$_2$ agonist. Alternative therapies (but again not preferred) include a low-dose or medium-dose inhaled corticosteroid and either theophylline or a leukotriene receptor antagonist. However, given the limited data on human pregnancy, the use of leukotriene receptor modifiers is reserved for patients who showed a very good response before pregnancy but are not responding well to other medications while pregnant.

4. Severe persistent asthma—The preferred treatment is a high-dose inhaled corticosteroid and a long-acting inhaled beta$_2$ agonist as well as (if needed) a systemic corticosteroid, such as 2 mg/kg/d of prednisone or equivalent steroid not to exceed 60 mg/d, with an attempt to taper to the minimal effective dose. An alternative, but not preferred, treatment includes a high-dose inhaled corticosteroid and sustained-release theophylline (keeping maternal systemic levels at 5–12 μg/mL for the reasons explained previously).

The US Food and Drug Administration has recently issued warnings about the use of long-acting beta-agonists (LABAs). A paradoxical increase in exacerbations in some patients, particularly in children, has been reported mainly with LABA monotherapy. The specific recommendations include (1) not to use LABAs without other asthma-controller medications, (2) stop LABA use once asthma control is achieved and maintain it with other medications, (3) do not use LABAs if the asthma is controlled with inhaled steroids, and (4) use fixed-dose combinations with an inhaled steroid to minimize the likelihood of LABA use alone.

Systemic corticosteroids are used when any of the other drug combinations cannot control the asthma. They usually are given first as a short, rapidly tapering course (eg, 40–60 mg/d of prednisone or equivalent steroid for 1 week, tapering off during the second week). If these courses fail to effectively control symptoms for <2–3 weeks, long-term systemic corticosteroid treatment may be needed. In these cases, the lowest effective dose or alternate-day therapy, if possible, should be used. Potential maternal side effects include impaired glucose tolerance or frank diabetes mellitus, preeclampsia, intrauterine growth restriction, and premature delivery. With prolonged use (>1–2 months) of pharmacologic doses, maternal adrenal insufficiency may occur, and adequate coverage during periods of stress (including labor and delivery) is mandatory. Use during the first trimester is associated with a higher risk for facial clefts (lip and palate). Pregnant women with asthma who are steroid dependent should be managed by an internist/pulmonologist who is experienced in the treatment of asthma during pregnancy.

C. Other Asthma Medications

Nonselective beta agonists such as epinephrine and isoproterenol are sometimes given subcutaneously during acute asthma attacks. Epinephrine use during pregnancy should be avoided because epinephrine causes vasoconstriction and reduces fetal oxygenation. It is teratogenic in animals as well as in humans. Isoproterenol also is teratogenic in animals. Because many other alternative therapies are available, isoproterenol use in humans is best avoided. Iodine-containing medications should be avoided during pregnancy because the fetus may be at risk for developing a goiter, which may become very large and cause airway obstruction and even asphyxia. Nedocromil sodium is similar to cromolyn sodium. No reports on humans are available, but nedocromil sodium has not been observed to be teratogenic in animal experiments. Anticholinergic medications such as atropine (which block bronchoconstriction by inhaled irritants) may accelerate the fetal heart rate and inhibit breathing. Ipratropium has not been reported to be teratogenic in animals, but data on humans are lacking. Glycopyrrolate has been used safely in humans near term, and no defects have been reported in animal experiments.

1. Acute asthmatic attack—During acute exacerbations, dyspnea, cough, wheezing, and chest tightness increase and expiratory flow decreases. A few, well-educated patients with relatively mild attacks might be managed at home, taking advantage of the judicious use of peak flow measurements. However, any serious exacerbation most likely will require hospitalization. Great care should be exercised to maintain a maternal $PO_2 > 70\ \text{mm Hg}$ and O_2 saturation >95%. A maternal $PO_2 < 60\ \text{mm Hg}$ will result in marked fetal hypoxia.

General measures include reassuring the patient and avoiding sedatives, which may depress respiration. Oxygen can be administered by mask or nasal catheter with the goal of maintaining $PO_2 > 70\ \text{mm Hg}$ and O_2 saturation >90% to ensure adequate fetal oxygenation at all times. A few patients may require endotracheal intubation and mechanical ventilation to maintain an adequate oxygen supply. Blood gas determinations are necessary for this purpose. A chest x-ray film should be part of the initial evaluation. Antibiotics are given only if evidence of bacterial infection is present. Some pregnant women receiving large amounts of intravenous fluids, beta$_2$ agonists, and corticosteroids reportedly develop pulmonary edema, so this risk should be considered under these circumstances.

Initial pharmacologic treatment includes an inhaled beta$_2$ agonist administered by a metered-dose inhaler, 2–4 puffs every 20 minutes to a maximum of 3 doses or less if side effects appear. A subcutaneous beta$_2$ agonist (eg, terbutaline 0.25 mg) is also given and can be repeated once 20 minutes later. Systemic corticosteroids are recommended early in the course of treatment of acute exacerbations. The most frequently used corticosteroid is methylprednisolone administered intravenously at an initial dose of 1–2 mg/kg/d. At present, intravenous theophylline is used much less frequently for acute exacerbations because of the early use of corticosteroids. When necessary, the recommended initial loading dose is 5–6 mg/kg given intravenously over 20–30 minutes. The loading dose is not given if the patient was receiving adequate oral doses before the acute attack, or only half the loading dose is given if the patient was receiving theophylline but only intermittently. Maintenance doses are 0.7 mg/kg/h. Serum levels should be monitored to avoid maternal levels in excess of 12 μg/mL.

After admission to the hospital, administration of beta$_2$-agonists is continued by nebulized aerosol every 4–6 hours; administration of intravenous corticosteroids also is continued (eg, methylprednisolone 0.5–1 mg/kg twice daily). If theophylline was started, it is continued per the maintenance dose protocol, with careful monitoring of maternal serum levels to avoid fetal toxicity. As the patient improves, the beta$_2$-agonist aerosols are continued (2 puffs every 4–6 hours), and at this point the inhaled steroids (high dose, per the protocol for the severe persistent asthma) are resumed or the therapy initiated if the patient was not receiving them before the acute attack. If the clinical improvement continues, the systemic steroids can be switched to the oral route (eg, prednisone 0.5 mg/kg/d, with gradual tapering attempted while maximizing inhaled steroid treatment). If theophylline was being given, it also should be changed to the oral route (6 mg/kg), with close monitoring of maternal serum levels.

D. Management During Labor and Delivery

The medications that were being administered before the onset of labor should be continued. Adequate control should be maintained, because labor has been reported to trigger an acute attack in approximately 10% of women with asthma. Peak expiratory flow measurements should be obtained at regular intervals to monitor pulmonary status closely. Adequate hydration should be maintained and pain relief provided as necessary. Fentanyl is considered a good analgesic choice for these patients. Analgesics and/or narcotics, which can cause histamine release, should be avoided because of the possibility of respiratory depression and bronchospasm. Continuous O_2 monitoring is mandatory to ensure that O_2 saturation is >95% at all times.

Medications to avoid include prostaglandin F_2 because it may cause bronchospasm. Prostaglandin E_2, either gel or suppository, is safe for women with asthma and can be used if necessary from the obstetric standpoint. Oxytocin is safe and considered the medication of choice for induction.

Epidural anesthesia is preferred because it reduces O_2 consumption and minute ventilation. General anesthesia may trigger an attack, but the risk may be reduced by pretreatment with atropine (see earlier for potential fetal effects) and glycopyrrolate, which have a bronchodilatory effect. A low concentration of halogenated anesthetic may provide bronchodilation as well. For induction, ketamine is preferred. It is very important that an anesthesiologist experienced in the care of pregnant women be consulted ahead of time when anticipating anesthesia needs.

Ergot derivatives should be avoided because they may precipitate bronchospasm. If postpartum hemorrhage occurs, oxytocin is the best choice. If a prostaglandin is needed, then prostaglandin E_2 is preferred. Aspirin and nonsteroidal anti-inflammatory drugs (eg, indomethacin) may trigger severe bronchospasm as well as ocular, nasal, dermal, and gastrointestinal inflammation in 3–8% of asthmatic patients and are best avoided. Magnesium is safe for asthma but with careful monitoring to avoid respiratory depression.

E. Fetal Monitoring

An ultrasound examination in early pregnancy is useful to confirm dating and to provide a baseline to evaluate future growth assessment. Serial ultrasounds are recommended for women with moderate and severe asthma because they are the most at risk for fetal growth restriction. No specific guidelines have been issued for antepartum fetal surveillance other than very general recommendations such as “when needed in the third trimester to assure fetal well being” and “daily recording of fetal movements is encouraged.” Many institutions offer fetal surveillance starting at 32–34 weeks to patients with moderate and severe asthma and at any time during the third trimester when an exacerbation occurs. There is unanimous agreement that all patients with asthma should undergo continuous fetal monitoring during labor and delivery.

F. Breastfeeding

Inhaled beta_2 agonists, cromolyn sodium, steroids (inhaled), and ipratropium are safe while breastfeeding. Systemic (oral or parenterally administered) steroids may enter into breast milk but only in small amounts if the total daily dosage contains <40 mg of prednisone (or equivalent steroid).

PNEUMONIA

ESSENTIALS OF DIAGNOSIS

- ▶ Although the incidence of pneumonia in pregnancy is not increased over nonpregnant women, pneumonia is associated with an increased risk of maternal and fetal complications.
- ▶ Pneumonia typically presents with fever, chills, and productive cough.

Pathogenesis

Pneumonia is a rare complication of pregnancy, affecting fewer than 1% of all pregnancies. However, it is associated with significant fetal and maternal morbidity. In fact, before the advent of antibiotics, pneumonia in pregnancy was associated with maternal mortality rate of >20%.

A number of different organisms are implicated in causing pneumonia during pregnancy. The most common identifiable organisms are pneumococcus and *Haemophilus influenza*. Viral agents are also implicated in causing pneumonia, including influenza A, infectious mononucleosis, and, less frequently, varicella. Influenza A has been of particular concern in recent years due to well-publicized outbreaks with exceedingly virulent strains. Influenza A has a higher mortality rate in pregnancy than in nonpregnant patients. Pregnant women with viral pneumonia can develop superimposed bacterial infection.

Prevention

One important preventative measure is the injectable influenza vaccine. The intramuscular influenza vaccine consists of inactivated virus. This vaccine is safe when administered during any trimester of pregnancy. It is recommended that pregnant women receive this vaccine during the flu season.

Clinical Findings

Pneumonia usually presents with fever, chills, and productive cough. Patients may also experience pleuritic chest pain and shortness of breath. On physical examination, most women are febrile. Many women will be tachycardic or tachypneic. Chest auscultation reveals rales or decreased breath sounds over the affected fields. With bacterial pneumonia, chest radiograph demonstrates lobar consolidation or infiltrate. With viral pneumonia, chest radiograph may appear normal. Complete blood count reveals leukocytosis with a left shift in most cases.

Differential Diagnosis

Depending on the patient’s presenting signs and symptoms, the differential diagnosis includes pulmonary embolism, bronchitis, and uncomplicated influenza.

Complications

Pneumonia during pregnancy increases the risk of a number of fetal and maternal complications, including pulmonary edema and preterm labor.

Treatment

In general, inpatient management is advised for pregnant women with pneumonia. Treatment with antibiotics is the cornerstone of therapy. Community-acquired pneumonia should be treated with azithromycin or azithromycin plus ceftriaxone in severe cases. For patients with varicella pneumonia, acyclovir is recommended. Treatment of influenza and influenza pneumonia during pregnancy is recommended with oseltamivir. For cases of oseltamivir-resistant strains of influenza, zanamivir is recommended. Maternal oxygen saturation should be maintained ≥96% with oxygen nasal canula or face mask if needed.

TUBERCULOSIS

ESSENTIALS OF DIAGNOSIS

- Pregnancy is not associated with an increased risk of contracting tuberculosis or progression from latent tuberculosis to active tuberculosis.
- Pregnancy and prenatal care do provide a unique screening opportunity for women at risk of tuberculosis.
- Effective treatment of tuberculosis during pregnancy and/or in the postpartum period is important to prevent transmission to the neonate.

Pathogenesis

Tuberculosis (TB) was the leading causes of death in the United States for many years until the introduction of effective therapy in the early 1950s. Since then, the number of reported cases declined steadily, until recently, when higher numbers are being identified. This situation is attributed to increased immigration from countries with a high tuberculosis prevalence and particularly to the HIV/acquired immunodeficiency syndrome (AIDS) epidemic. Worldwide, TB is very prevalent, with 8 million new cases and 2 million deaths annually. Eighty percent of TB deaths in women occur during their childbearing years, and pregnant women are not spared from TB effects. Many of these at-risk women will seek health care only when pregnant, thus providing an opportunity for diagnosis and treatment.

Tuberculosis in adults is mainly (>95%) a disease of the pulmonary parenchyma caused by *Mycobacterium tuberculosis*, a nonmotile, acid-fast aerobic rod. Transmission usually occurs by inhalation of droplets produced by infected individuals when coughing. The droplets can remain suspended in the air for prolonged periods (several hours). The persons most at risk for becoming infected are family members and other close contacts, such as coworkers and roommates (elderly residents and employees in long-term care facilities, correctional institutions), homeless individuals, and intravenous drug users. After the initial inhalation, the bacilli multiply in the alveoli and subsequently spread to the regional lymph nodes and to other organs such as the upper lung regions, kidneys, bones, central nervous system, and, rarely, during pregnancy, to the placenta. In most people, the infection is contained by cell-mediated immunity, which develops 2–10 weeks after exposure, when the infected sites are walled off by granulomatous inflammation and the tuberculin tests then becomes reactive. At this stage, these persons are not infectious and are asymptomatic except for the positive tuberculin skin test. After the initial exposure, the risk of developing active disease during the following 2–5 years is generally given as 5–15%, but the risk later falls to very low levels <1–2%. However, active disease may ensue if a person is unable to contain the infection when first exposed or if the person subsequently becomes immunocompromised and the infection is reactivated at a time remote from the initial exposure.

Clinical Findings

Most cases of tuberculosis can be diagnosed on the basis of a history of cough, weight loss, positive tuberculin skin test, and chest x-ray film.

A. Symptoms and Signs

Primary TB infection is usually asymptomatic, except in the rare instances when dissemination occurs. Typical symptoms include cough, sometimes with hemoptysis, low-grade fever, weight loss, fatigue, night sweats, and anorexia, although some patients may have few symptoms. In extrapulmonary TB, the symptoms are related to the organ system involved.

B. Laboratory Findings

The definitive diagnosis is made after positive identification of the bacilli by Ziehl-Neelsen staining and a positive culture, usually from a sputum sample. At times, the sample for culture will be obtained from the urine, other body fluid, or a body tissue. Although acid-fast bacilli can be identified on stained slides, culture confirmation is required, which may take several weeks. Faster detection methods are currently under development.

C. Tuberculin Skin Test

The tuberculin skin test is the most important screening test for tuberculosis. It should be performed early in pregnancy, especially in high-risk populations. An induration of 5 mm or greater is considered positive in individuals with HIV infection; those in close contact of persons with active, infectious tuberculosis; in persons with typical x-ray findings who were never previously treated; and in intravenous drug users. An induration of 10 mm or more is considered positive in persons who have risk factors other than HIV, such as diabetes mellitus, silicosis, chronic use of corticosteroids or other immunosuppressive drugs, cancer (solid tumors as well as leukemias and lymphomas), chronic renal insufficiency, gastrectomy or intestinal bypass, or malabsorption and chronic malnutrition with body weight 10% or less below the ideal. Data are being accumulated on the effectiveness of other methods that could be used as an alternative to the skin test.

D. Chest X-Ray Film

With the abdomen shielded and preferably after the first trimester, a chest x-ray film should be taken in patients in whom skin testing is positive after an earlier negative test and in patients with a suggestive history or physical examination even though skin testing is negative. Findings suggestive of TB include upper lobes or superior lower lobe segments' nodular infiltrates that at times may become cavitary. A calcified hilar node and an also calcified peripheral nodule (Ghon's complex) constitute a healed primary lesion. A small number of patients may initially have a normal x-ray.

Complications

Congenital tuberculosis is rare, although cases of fetal infection have been reported. The infection may occur when the fetus swallows infected amniotic fluid or be bloodborne through the umbilical circulation. The criteria for diagnosis include positive bacteriologic studies occurring within the first few days of life with an exclusion of an extrauterine infection source, as more commonly contamination occurs after birth from an infected mother or a close relative. The most common signs are nonspecific and include fever, failure to thrive, lymphadenopathy, hepatomegaly, and splenomegaly. The disease usually is miliary or disseminated. An early diagnosis is necessary for effective treatment.

Treatment

A. Medical Therapy

Untreated tuberculosis is far riskier to the mother and fetus than any of the potential medications necessary to treat active disease. Treated TB does not seem to lead to adverse maternal or fetal outcomes, whereas untreated cases are associated with intrauterine growth restriction, low birth weight, and lower Apgar scores. A preventive course of isoniazid (isonicotinic acid hydrazide [INH]) is generally recommended for those with a positive skin test and no evidence of active disease. Unless there is high risk of developing TB (eg, close contact with a person with active disease), such preventive therapy is withheld in those older than 35 years and during pregnancy and early postpartum because of an increased risk for INH-related hepatitis, particularly in Latina and African American women. Some authors recommended antepartum INH prophylaxis if there is well-documented evidence of recent (<2 years) TB skin conversion to positive even if there are no other risk factors. The argument is that waiting until after delivery might not be as effective in preventing recurrences, perhaps because the high frequency of noncompliance with medication taking postpartum. When the duration of PPD positivity is unknown, but greater than 2 years, and no active disease, INH prophylaxis is postponed until after delivery. In those at high risk (particularly in cases of HIV/AIDS or close contacts with a person with active TB), preventive INH treatment is initiated as soon as evidence of tuberculosis infection (but no active disease) is documented. The recommended dose of INH is 300 mg/d for 6–9 months as well as pyridoxine (vitamin B_6) to prevent INH-related neuropathy. Periodic evaluation of liver function is recommended to detect hepatotoxicity early if it occurs. Most studies have shown no teratogenic effects of INH.

Active tuberculosis should be treated as soon as the diagnosis is made. Most treatment programs consist of a 3-drug regimen, usually INH 5 mg/kg/d (total 300 mg/d), ethambutol 15 mg/kg/d, and rifampin 10 mg/kg/d (maximum 600 mg/d) for 8 weeks, and the INH and rifampin to complete 9 months. Local public health departments should be consulted to obtain data about drug resistance. These 3 medications cross the placenta, but no adverse fetal side effects have been reported to date. Pyrazinamide has been used in addition to the 3 medications mentioned in areas of highly drug-resistant tuberculosis but is not routinely recommended during pregnancy because of limited safety data. Because of the risk for fetal (and maternal) ototoxicity, streptomycin, kanamycin, and capreomycin should not be used. Isoniazid has many therapeutic advantages (eg, high efficacy, patient acceptability, and low cost) and appears to be the safest drug for use during pregnancy. The major side effects of INH are hepatitis, hypersensitivity reactions, peripheral neuropathy, and gastrointestinal distress. A baseline liver function test should be obtained and then repeated periodically because of higher risk of hepatotoxicity during pregnancy and the first 6 months postpartum. Pyridoxine 50 mg/d should be administered to prevent INH-induced neuritis due to vitamin B_6 deficiency. Optic neuritis is a rare complication reported with ethambutol use. Rifampin may cause hepatitis, hypersensitivity reactions, occasional hematologic toxicity, flulike syndrome, abdominal pain, acute renal failure, and thrombocytopenia. Rifampin may increase the metabolic rate of oral contraceptives through activation of the hepatic P450 enzyme system, so an alternative form of contraception may be necessary after delivery in these patients while they are taking rifampin.

B. Obstetric Management

Routine antepartum obstetric management includes adequate rest and nutrition, family support, correction of anemia if present, and regular follow-up visits. Immediate neonatal contact is allowed if the mother has received treatment for inactive disease and no evidence of reactivation is present. In patients with inactive disease in whom prophylactic INH was not given or those with active disease in whom adequate treatment was given, early neonatal contact may be allowed, provided the mother is reliable in continuing therapy. A mother with active disease should receive at least 3 weeks of treatment before coming into contact with her baby, and the baby must also receive prophylactic INH.

There are no absolute contraindications to breastfeeding once the mother is noninfectious. Although antituberculosis drugs are found in breast milk, the concentrations are low, and the risk of toxicity in the infant is considered to be minimal. However, each case should be judged individually. In general, breastfeeding is not contraindicated while the mother is taking antituberculosis medications.

Immunization of the newborn with bacille Calmette-Guérin (BCG) vaccine remains controversial. If prompt use of INH as prophylaxis is unlikely or if the mother has INH-resistant disease, BCG vaccination of the infant should be considered.

Prognosis

If the pregnant patient is adequately treated with antituberculosis chemotherapy for active disease, tuberculosis generally has no deleterious effect, either during the course of pregnancy or the puerperium or on the fetus. Pregnant women have the same prognosis as nonpregnant women.

Tuberculosis is not a reason for recommending a therapeutic abortion, as it was sometimes the case before the advent of effective treatment.

Renal & Urinary Tract Disorders in Pregnancy

Nathan S. Fox, MD
Andrei Rebarber, MD

For a discussion of normal renal and urinary tract function in pregnancy, see Chapter 6, Normal Pregnancy.

URINARY TRACT INFECTION

Asymptomatic Bacteriuria

ESSENTIALS OF DIAGNOSIS

- Urine culture demonstrating the presence of bacteria in the urine in the absence of maternal symptoms of urinary tract infection

---

Pathogenesis

Asymptomatic bacteriuria is defined as the presence of actively multiplying bacteria in the urinary tract, excluding the distal urethra, in a patient without any obvious symptoms. The incidence is the same in nonpregnant and pregnant females and averages 2–10%; however, a number of physiologic changes that occur during pregnancy predispose a woman to bacteriuria, including increased glucose concentration in the urine and increased stasis due to the relaxant progesterone effect. Risk factors for developing asymptomatic bacteriuria include low socioeconomic status, parity, age, sexual practice, and medical conditions such as diabetes and sickle cell trait. *Escherichia coli* is the most common offending organism for asymptomatic bacteriuria (approximately 80% of cases). The *Klebsiella-Enterobacter-Serratia* group, *Staphylococcus aureus*, *Enterococcus*, group B *Streptococcus*, and *Proteus* are responsible for the remainder of cases.

The primary concern with asymptomatic bacteriuria in pregnancy is that it is associated with an increased risk of both maternal and fetal complications during pregnancy (see later).

Prevention

Certain underlying medical disorders may predispose a woman to asymptomatic bacteriuria during pregnancy. Asymptomatic bacteriuria is twice as common in pregnant women with sickle cell trait and 3 times as common in pregnant women with diabetes or with renal transplant as in normal pregnant women. Therefore, we advise that monthly routine urine cultures should be performed in these women when pregnant.

Clinical Findings

The diagnosis of asymptomatic bacteriuria is based on isolation of microorganisms with a colony count $>10^5$ organisms per milliliter of urine in a clean-catch specimen in a woman who is experiencing no symptoms of urinary tract infection. When obtaining a clean-catch specimen, the patient should be instructed to clean the vulvar area from front to back to avoid contamination of the urine sample.

Complications

The main risk of asymptomatic bacteriuria is the development of pyelonephritis. Due to anatomic dilation in the renal system during pregnancy, there is increased stasis of urine in the pregnant urinary tract and a much higher risk of developing an overt infection from the bacteruria. Due to this risk, many authorities advocate screening all pregnant women for bacteruria, and unlike nonpregnant women, a pregnant woman found to have bacteruria should be treated promptly. If asymptomatic bacteriuria is left untreated in pregnancy, up to 40% of patients will develop symptoms of urinary tract infection (UTI), a significant increase from the almost negligible risk in nonpregnant women. Approximately 25–30% of women will develop acute pyelonephritis. With treatment, the rate is less than 10%. Asymptomatic bacteriuria has been associated with preterm delivery, fetal loss, and preeclampsia. Treatment of asymptomatic bacteruria has been associated in large reviews with a reduction in the risk of preterm birth and low birth weight babies. On the other hand, approximately 2% percent of pregnant women with a negative urine culture will develop symptomatic cystitis and pyelonephritis.

Treatment

A midstream urine specimen should be collected for culture at the initial prenatal visit and repeated later in pregnancy. At each prenatal visit, dipstick testing should be performed. If proteinuria is present, urinalysis, culture, or both should be done. A pregnant woman with sickle cell trait should have urine culture and sensitivity testing every 4 weeks. The US Preventive Health Task Force states that single urine culture at 12–16 weeks' gestation has 80% sensitivity. Alternatively, regular dipstick testing for leukocyte esterase and nitrites has a negative predictive value >95% and sensitivity of 50–92%.

Pregnant women should be encouraged to maintain adequate fluid intake and to void frequently.

The initial antibiotic selection should be empiric. Based on the fact that the most common offending pathogen is *E coli*, a sulfonamide, nitrofurantoin, or a cephalosporin is a reasonable choice. These antibiotics should be safe for the mother and fetus, with minimal side effects. A 5- to 14-day course of one of these agents will effectively eradicate asymptomatic bacteriuria in approximately 65% of pregnant patients. A urine culture should be repeated 1–2 weeks after therapy is started. Recurrent infections occur in approximately 30% of patients treated once and in approximately 15% of patients who have been treated twice and/or have not responded to initial therapy.

Nitrofurantoin (US Food and Drug Administration [FDA] category B) should be avoided in mothers with glucose-6-phosphatase deficiency. Additionally, sulfa drugs (FDA category B) are often avoided late in pregnancy because of the theoretical increased likelihood of neonatal hyperbilirubinemia. Tetracyclines (FDA category D) are contraindicated during pregnancy because of dental staining in the exposed child. Trimethoprim (FDA category C) is a folic acid antagonist; therefore, trimethoprim-sulfamethoxazole is generally avoided during organogenesis; it may be used when alternatives are limited.

Suppressive therapy may be appropriate for women with bacteriuria that persists after 2 or more courses of therapy. Nitrofurantoin (50–100 mg orally at bedtime) for the duration of the pregnancy is a commonly used.

Smaill F, Vazquez JC. Antibiotics for asymptomatic bacteriuria in pregnancy. *Cochrane Database Syst Rev* 2007:CD000490. PMID: 17443502.

Acute Cystitis

ESSENTIALS OF DIAGNOSIS

- Urine culture demonstrating the presence of bacteria in the urine in a patient symptomatic for urinary tract infection

---

Pathogenesis

Acute Cystitis is uncommon in pregnancy (approximately 1%). The bacteria causing Acute Cystitis are similar to those in asymptomatic bacteriuria.

Clinical Findings

Clinically, the patient presents with symptoms of urinary frequency, urgency, dysuria, and suprapubic discomfort. The urine often is cloudy and malodorous and should be cultured to confirm the diagnosis and to identify antibiotic sensitivities. A colony count of $\geq 10^3$ confirms cystitis in a symptomatic patient.

Treatment

The treatment of cystitis is the same as for asymptomatic bacteriuria. A urine culture should be repeated 1–2 weeks after therapy is started. As with asymptomatic bacteriuria, suppressive therapy may be appropriate for women with UTI that persists after 2 or more courses of therapy. Nitrofurantoin (50–100 mg orally at bedtime) for the duration of the pregnancy is commonly used.

Acute Pyelonephritis

ESSENTIALS OF DIAGNOSIS

- The presence of bacteria in urine culture
- Maternal symptoms of flank pain and/or systemic signs of fever, chills, nausea/vomiting

---

Pathogenesis

Acute pyelonephritis occurs in 1–2% of all pregnant women (usually, although not invariably, in those with previous asymptomatic bacteriuria) and is associated with risk to the mother and fetus. It is one of the most common causes of hospitalization during pregnancy.

Certain anatomic changes that occur during pregnancy predispose pregnant women to pyelonephritis, including increased stasis of the urine in the urinary tract due to smooth muscle relaxation in the ureters.

Prevention

Acute pyelonephritis is best prevented by screening for and treating asymptomatic bacteruria.

Clinical Findings

Clinical manifestations of acute pyelonephritis include fever, shaking chills, costovertebral angle tenderness, flank pain, nausea and vomiting, headache, increased urinary frequency, and dysuria. Patients almost always have pyuria on urinalysis. Urine examination will reveal significant bacteriuria with pyuria and white blood cell casts in the urinary sediment. A count of 1–2 bacteria per high-power field in unspun urine or >20 bacteria in the sediment of a centrifuged specimen of urine collected by bladder catheterization helps in the bedside diagnosis. The absence of pyuria should raise suspicion for another disorder. Due to this, a urine specimen should be obtained and sent for culture before any antibiotics are given in order to properly identify the causative organism and antibiotic susceptibility. Blood cultures may also be sent, as they will be positive 10–20% of the time, although it is unclear whether management should be any different for women with positive blood cultures as outcomes tend to be the same.

Differential Diagnosis

For the patient presenting with back or flank pain, the differential diagnosis includes appendicitis, musculoskeletal pain, costochondritis, and chorioamnionitis. Urinalysis and urine culture can help to differentiate among these disorders.

Complications

Maternal complications include fever, bacterial endotoxemia, endotoxic shock, renal insufficiency, anemia, leukocytosis, thrombocytopenia, and elevated fibrin split product levels. Risk factors for recurrent or severe disease are a history of pyelonephritis, urinary tract malformation, or urinary calculi. The maternal anemia may be due to marrow suppression, increased erythrocyte destruction, or diminished red cell production. Pulmonary dysfunction has been described in association with acute pyelonephritis. Symptoms and signs may range from minimal (mild cough and slight pulmonary infiltrate) to severe (adult respiratory distress syndrome requiring intensive therapy).

Obstetrical complications include preterm labor and prematurity, fetal death, and intrauterine growth restriction.

Treatment

A pregnant woman with pyelonephritis initially should be evaluated in the hospital. Antibiotics should be given parenterally once a urine culture is sent, and hypovolemia should be corrected. Acetaminophen can be used as an antipyretic, if indicated. Vital signs, including respiratory rate, and input and output should be closely monitored. Pulse oximetry may be useful. A first-generation cephalosporin (FDA category B) such as cefazolin 1 g parenterally every 8 hours usually is effective. However, due to increasing antibiotic resistance, the local susceptibilities should be considered when selecting the initial antibiotic. Ceftriaxone 1 g parenterally every 24 hours often is effective for most *Enterobacteriaceae* in this setting. The urine culture and sensitivities guide therapy thereafter. When the patient is afebrile for 48 hours, parenteral therapy may be changed to an effective oral antibiotic.

A total course of 14 days of antibiotic is commonly administered. Note that drugs with very high protein binding, such as ceftriaxone, may be inappropriate the day before parturition because of the possibility of bilirubin displacement and subsequent kernicterus.

If no clinical response is seen in 48–72 hours, a resistant organism can be treated by adding an aminoglycoside such as gentamicin 3–5 mg/kg per 24 hours in 3 divided doses given every 8 hours. Failure to respond may be caused by urolithiasis or a structural urinary tract abnormality. Ultrasound imaging of the kidneys and urinary tract usually is the next diagnostic test if the patient does not defervesce after 48 hours of antibiotic therapy. Perinephric abscess causing persistent pain and fever can be identified by ultrasound. Perinephric abscess usually is due to obstruction complicated by infection. The perinephric abscess should have percutaneous drainage (preferably computed tomography or ultrasound-guided) for both diagnostic and therapeutic purposes, in addition to administration of antibiotic therapy. An intravenous pyelogram or computed tomography urogram is often useful if a lack of response continues. A preliminary “scout” film and a film taken 15 minutes after administration of intravenous contrast often are helpful. In selected cases of persistent infection or obstruction, cystos-copy and retrograde pyelography are needed.

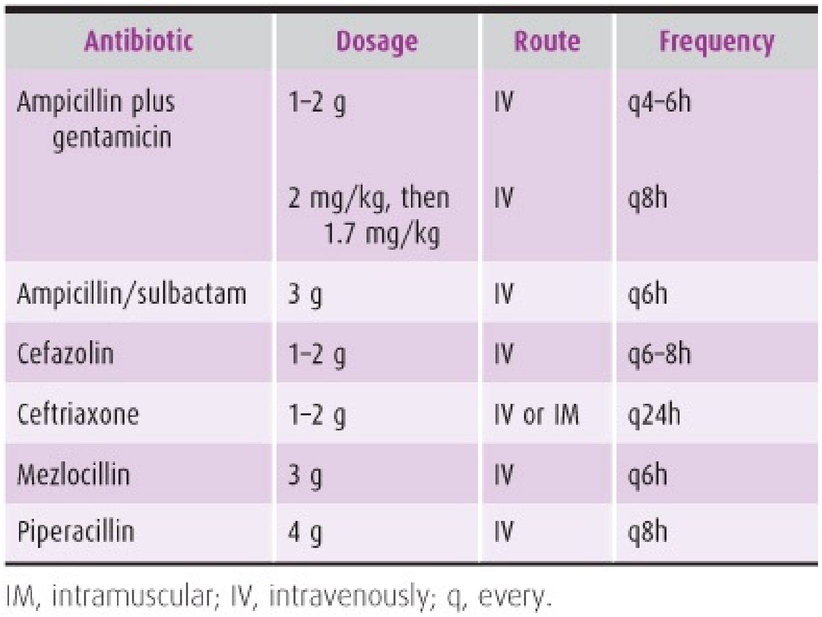
Although many women who present with pyelonephritis will have uterine contractions, they are almost always due to the fever and resultant hypovolemia. Tocolytics should be used with extreme caution, as they can greatly increase the risk of respiratory distress. Typically the contractions resolve with the administration of intravenous (IV) fluids and antibiotics.

Respiratory distress is a severe systemic complication of pyelonephritis. It is caused by bacterial endotoxins increasing alveolar permeability and a resultant pulmonary edema. It is more common in women with the following: tachycardia, tachypnea, blood transfusion, fever of 103° degrees, tocolytics, and excessive IV fluids. Patients presenting with respiratory symptoms should be managed aggressively and often require an intensive care setting, as shock can ensue.

Prognosis

Cunningham reported that after an episode of pyelonephritis, recurrent bacteriuria occurred in 28% of women, and pyelonephritis recurred in 10% during the same pregnancy. A more recent study by Wing et al identified that 5% of pregnant patients had urine culture positive for organisms only 2 weeks after completion of initial therapy for pyelonephritis. In the same study, 6.3% had culture positive for organisms later in their antepartum course, and 6.3% developed recurrent pyelonephritis. For this reason, antibiotic suppressive therapy with nitrofurantoin 100 mg orally at bedtime, or a similar regimen, is continued during the pregnancy and during the puerperium, often for 6 weeks (Table 28–1). Monthly urine cultures to identify a recurrent UTI may be similar in effectiveness to antibiotic suppression for patients who are allergic or who prefer not to take antibiotics.

Table 28–1. Antibiotic regimen for pyelonephritis.



Antibiotic	Dosage	Route	Frequency
Ampicillin plus gentamicin	1–2 g	IV	q4–6h
	2 mg/kg, then 1.7 mg/kg	IV	q8h
Ampicillin/sulbactam	3 g	IV	q6h
Cefazolin	1–2 g	IV	q6–8h
Ceftriaxone	1–2 g	IV or IM	q24h
Mezlocillin	3 g	IV	q6h
Piperacillin	4 g	IV	q8h

IM, intramuscular; IV, intravenously; q, every.

Periodic culture of the urine assists in detection of recurrence. **Relapse** is defined as recurrent infection from the same species and type-specific strain of organism present before treatment; this represents a treatment failure. Most relapses occur <2 weeks after completion of therapy. **Reinfection** is recurrent infection due to a different strain of bacteria after successful treatment of the initial infection, occurring >3 weeks after the completion of therapy.

Hill JB, Sheffield JS, McIntire DD, Wendel GD Jr. Acute pyelonephritis in pregnancy. *Obstet Gynecol* 2005;105:18–23. PMID: 15625136.

URINARY CALCULI

ESSENTIALS OF DIAGNOSIS

- Maternal symptoms of urinary tract obstruction that may include back or flank pain, hematuria, and/or dysuria
- Evidence of urinary tract calculi on imaging studies

Pathogenesis

The incidence of urinary calculi is not altered by pregnancy. The incidence is 0.03–0.35% of pregnancies, and the incidence increases as gestational age advances (only 20% present in the first trimester). Stones cause obstruction, infection, pain, and hematuria (present in 75–95% of patients, one-third of whom have gross hematuria). Recurrent hospitalization, preterm labor and delivery, and need for operative intervention are increased. The causes of urinary calculi are the same in pregnant and nonpregnant women: chronic UTI, hyperparathyroidism or other causes of hypercalciuria, gout (uric acid), and obstructive uropathy. Congenital or familial cystinuria and oxaluria are less common causes. Most stones are composed of calcium, usually calcium phosphate.

The physiologic hydroureter of pregnancy is more prominent on the right side; however, stones occur with equal frequency on either side. The physiologic hydroureter of pregnancy increase the likelihood that a pregnant patient will spontaneously pass her stone(s).

Clinical Findings

Patients may present with a variety of symptoms, including typical renal or ureteric colic, vague abdominal or back pain that may radiate into the groin, fever, nausea, and vomiting. The patient may have a history of recurrent UTI or hematuria. Fever, bacteriuria, and flank pain may suggest coexisting pyelonephritis from obstruction. The differential diagnosis includes other acute abdominal conditions unrelated to pregnancy (eg, appendicitis, biliary colic or tract disease, adnexal torsion) and conditions related to pregnancy (eg, abruption placentae, preterm labor, chorioamnionitis). When fever attributed to pyelonephritis persists beyond 48 hours of parenteral antibiotic treatment, then obstruction due to urolithiasis must be evaluated. Hematuria, ranging from microscopic to gross, is usually present, although it is not pathognomonic for urolithiasis. The index of suspicion should be high in the clinical situations described, in patients in whom urine culture is negative in the setting of suspected pyelonephritis, or in cases of persistent hematuria or recurrent UTI.

Clinical diagnosis is confirmed by ultrasound examination of the urinary tract. In a study by Butler et al in 57 pregnant women had 73 admissions for symptomatic nephrolithiasis over a 13-year period, they noted that calculi were visualized in 21 of 35 (60%) renal ultrasonographic examinations and 4 of 7 (57%) abdominal x-ray studies when these were performed as the initial test. In contrast, urolithiasis was discovered in 93% of cases $(n = 8)$ in which single-shot intravenous pyelography was performed as the initial diagnostic test. In selected cases, excretory urography includes a precontrast scout film and another image obtained 20 minutes after contrast injection. This examination exposes the fetus to 0.2 rad. The common indications for intravenous pyelography include microscopic hematuria and recurrent UTI. Sterile urine culture should be performed when pyelonephritis is suspected. Alternate means of assessing for urinary tract stones during pregnancy if ultrasound is inconclusive include magnetic resonance urography (which involves no radiation exposure to the fetus) and computed tomography urogram.

Differential Diagnosis

The differential diagnosis of urinary tract calculi includes pyelonephritis, appendicitis, chorioamnionitis, cholecystitis, and cholelithiasis. The combination of urinalysis, urine culture, and imaging studies of the abdomen and pelvis can distinguish among these diagnoses.

Complications

A recent retrospective cohort study by Swartz et al found that women admitted for nephrolithiasis during pregnancy had an increased risk of preterm delivery versus those without stones (adjusted odds $\text{ratio} = 1.8$; 95% confidence interval, 1.5–2.1). This finding has potential implications for counseling of pregnant women with kidney stones requiring hospital admission and possible use of biomarkers (eg, cervical length or fetal fibronectin testing) to better identify at-risk pregnancies. Additionally, it may prompt definitive treatment of small, asymptomatic stones in women during reproductive years.

Treatment

Treatment includes hospital admission, adequate hydration, urine culture and Gram stain, appropriate antibiotic therapy, correction of electrolyte imbalances, and systemic analgesia (eg, opioids). Epidural analgesia may be considered for patients with severe pain. Most (75–85%) stones pass spontaneously, due in part to the normally dilated urinary tract of pregnancy. The patient should strain her urine so that a stone can be analyzed. Surgical intervention, such as ureteral stenting, transurethral cystoscopic stone extraction, nephrostomy drainage, or open surgery, can be performed by a urologist if indicated for unremitting pain, sepsis, infection unresponsive to antibiotic therapy, or obstructive uropathy. Shock wave lithotripsy is contraindicated during pregnancy, although it has been performed in 6 pregnancies inadvertently. More recently, ureteroscopy and holmium:YAG laser lithotripsy has been performed successfully in 8 pregnant women with 10 symptomatic stones and 2 encrusted ureteral stents. This device delivers energy to a localized area, can be used with flexible ureteroscopes, and is effective with stones of all compositions. Procedural success was achieved in all but 1 case (91%), with no obstetric or urologic complications.

ACUTE RENAL FAILURE

ESSENTIALS OF DIAGNOSIS

- Acute renal failure is defined as sudden reduction in renal function and glomerular filtration rate.
- The most common causes of acute renal failure in pregnancy are severe preeclampsia and placental abruption.

Pathogenesis

Acute renal failure is defined as sudden impairment in kidney function that leads to retention of waste products (eg, urea) and abnormal fluid and electrolyte balance. It occurs infrequently in pregnancy but carries a high mortality rate; therefore, it must be prevented when possible and treated aggressively. Most cases in pregnancy result from acute hypovolemia associated with obstetric hemorrhage (placenta previa, placental abruption, or postpartum hemorrhage), preeclampsia, or sepsis.

Clinically, acute renal failure is a condition in which the kidneys are temporarily unable to perform their excretory and regulatory functions. Blood urea nitrogen and serum creatinine concentrations are increased. Without prompt intervention, the condition may result in abortion, low birthweight, premature labor, and stillbirth. Dialysis may be required. Although hypotension-induced preterm contractions may occur during dialysis, numerous successful pregnancy outcomes have been reported after dialysis during pregnancy. In these cases renal failure most often is the result of intrinsic renal disease.

Similar to nonpregnant patients, acute renal failure can be classified as prerenal, renal, or postrenal. A classic formula in determining the cause of renal failure is the fractional excretion of sodium

(FENa). It is defined as the (urine sodium/plasma sodium) divided by (urine creatinine/plasma creatinine). It can also be stated as (urine sodium × plasma creatinine) divided by (urine creatinine × the plasma sodium). Either way, it reflects the amount of sodium excreted as compared with the creatinine. If the renal tubules are working (eg, as in prerenal failure) the sodium excretion should be less than the creatinine, as the kidneys work extra hard to maintain sodium. If the tubules are not working (eg, renal cause, acute tubular necrosis), the kidneys will not be able to resorb sodium and the fractional sodium excreted will be elevated. This can also be measured with urinary sodium levels.

In the prerenal type, acute renal failure occurs due to renal hypoperfusion secondary to maternal hypovolemia (eg, hemorrhage, hyperemesis gravidarum, dehydration, abruptio placentae, septicemia), circulating nephrotoxins (eg, aminoglycosides), aortic or renal artery stenosis or a narrowed off renal arteriole (due to sepsis, nonsteroidal anti-inflammatory drugs [NSAIDs], and certain dyes), mismatched blood transfusion, preeclampsia–eclampsia, disseminated intravascular coagulation, and hypoxemia (eg, chronic lung disease and heart failure). In prerenal failure, the patient typically is clinically hypovolemic with an increased pulse and decreased blood pressure. Laboratory tests show a serum blood urea nitrogen (BUN) to creatinine ratio >20, an FENa <1, urinary sodium <20 mEq/L (often <10) and urinalysis with concentrated urine, few elements in sediment, and positive hyaline casts.

Renal causes can be divided into 4 groups: glomerular, tubular, interstitial and vascular. For all groups, the FENa is >1. Glomerular causes can be from systemic lupus erythematosus (SLE), postinfectious glomerulonephritis, or membranoproliferative glomerulonephritis. In the preceding causes, low complement levels are found. With normal complement levels, the glomerular causes can be immunoglobulin A nephropathy, Goodpasture’s syndrome, or rapidly progressive glomerulonephritis. In all glomerular causes, urinalysis shows red blood cell (RBC) casts, dysmorphic RBC’s and protein.

When the renal failure is from the tubules, it is called acute tubular necrosis. It can be caused by an ischemic insult, shock, and surgery. It can also be caused by toxins, either endogenous (magnesium, creatinine phosphokinase) or exogenous (drugs, dyes, aminoglycosides). These patients typically have a normal physical exam. Urinalysis may be normal or may have brown pigmented casts. Urinary sodium is >25 mEq/L (often >60). Again, FENa is >1.

Renal failure from the interstitium can be caused by NSAIDs and allergies (often to penicillins and cephalosporins). Eosinophils are found in the blood and urine. The patients typically have a fever and rash. If renal failure is caused by a vasculitis, “telescoped” urinary sediment may be seen, in which red cells, white cells, oval fat bodies, and all types of casts are noted in relatively equal amounts.

The postrenal type is caused by urinary obstruction from ureteric stone, retroperitoneal tumor, and other diseases. Bilateral ureteral obstruction due to polyhydramnios is rare. The BUN to creatinine ratio is usually approximately 10.

Prevention

In obstetric practice, prevention of acute renal failure should be the aim, with appropriate volume replacement to maintain adequate urine output. Proper management of high-risk obstetric conditions (eg, preeclampsia–eclampsia, abruptio placentae, chorioamnionitis), ready blood availability, and avoidance of nephrotoxic antibiotics are important.

Clinical Findings

Acute renal failure is defined as urine output <400 mL in 24 hours (or <0.5 mL/kg/h) or an increase in serum creatinine (at least 1.5 fold). BUN concentrations are also typically increased.

The clinical course has been divided into an oliguric phase, a diuretic phase, and a recovery phase. In the oliguric phase, urine output drops to <30 mL/h, with accumulation of BUN and potassium. The patient becomes acidotic with the increase in hydrogen ion and loss of bicarbonate. In the diuretic phase, large volumes of dilute urine are passed, with loss of electrolytes due to absence of function of the renal tubules. As tubular function returns to normal in the recovery phase, the volume and composition of urine normalize. Clinical manifestations and complications include anorexia, nausea and vomiting, lethargy, cardiac arrhythmia (secondary to electrolyte disturbance), anemia, renal or extrarenal infection, thrombocytopenia, metabolic acidosis, and electrolyte imbalance (hyperkalemia, hyponatremia, hypermagnesemia, hyperphosphatemia, hypocalcemia).

Complications

Without prompt intervention, obstetric complications include pregnancy loss, low birth weight, premature labor, and stillbirth.

Treatment

Specific treatments include the following.

A. Emergency Treatment

Underlying causes of acute renal failure (eg, hemorrhagic shock) may require emergency treatment for correction of the underlying disorder.

B. Surgical Measures

Surgical measures include determination and correction of any obstructive uropathy or sepsis due to infected products of conception. Such problems should be treated as surgically appropriate. If obstructive uropathy is determined to be the cause, the placement of a ureteral stent or nephrostomy is indicated. Infected products of conception can be removed via dilation and curettage. Hypovolemia due to internal bleeding or uterine bleeding may require laparotomy to ligate any bleeding blood vessels or hysterectomy for definitive treatment of uterine bleeding.

C. Routine Measures

Routine measures include achieving fluid and electrolyte balance. Fluid intake can be calculated from urinary output, loss of fluid from other sources (eg, diarrhea, vomiting), and insensible loss of approximately 500 mL/d (correcting for fever may be necessary). Intake and output must be recorded carefully. The patient should be weighed daily and should maintain a constant weight or lose weight slowly (250 g/d assuming a room temperature of 22–23 °C [71–73 °F]). Hyperkalemia is a significant problem that can be controlled by administering glucose and insulin. The diet should be high in calories and carbohydrates, and low in protein and electrolytes. Parenteral feeding may be given in cases of nausea and vomiting. Prophylactic antibiotics should not be used, but known infections can be treated with antibiotics without renal toxicity. Indwelling bladder catheters are to be avoided when possible.

D. Dialysis

Dialysis is indicated if serum potassium levels rise to 7 mEq/L or more, serum sodium levels are 130 mEq/L or less, the serum bicarbonate is 13 mEq/L or less, BUN levels are more than 120 mg/dL or there are daily increments of 30 mg/dL in patients with sepsis, and dialyzable poisons or toxins are present. Different criteria are applied for renal failure in the antepartum period with a continuing pregnancy. In these cases, dialysis is instituted earlier in the process in consideration of fetal well-being. Although specific criteria have not been firmly established, one commonly used figure is a BUN level of 60 mg/dL.

E. Special Circumstances: Thrombotic Thrombocytopenic Purpura–Hemolytic Uremic Syndrome

Thrombotic thrombocytopenic purpura–hemolytic uremic syndrome (TTP-HUS) is characterized by the otherwise unexplained combination of thrombocytopenia and micro-angiopathic anemia. Renal failure caused by thrombotic microangiopathy may occur. Patients have been traditionally considered to have TTP when neurologic abnormalities are dominant and acute renal failure is minimal or not present, and considered to have HUS when acute renal failure is dominant and neurologic abnormalities are minimal or absent. Renal insufficiency may occur in either pregnancy-associated TTP or HUS, although it is more prevalent among patients with HUS. The optimal therapy of TTP-HUS developing in association with pregnancy includes delivery because distinction from preeclampsia may not be possible but is otherwise the same as for patients who are not pregnant. Patients who were treated with plasma infusion with or without plasma exchange in a series resulted in improved survival.

CHRONIC RENAL DISEASE

ESSENTIALS IN DIAGNOSIS

- Chronic renal disease is defined as persistent kidney damage with impairment in renal function.
- The prognosis for pregnancy outcome depends on the degree of renal impairment.

Pathogenesis

Chronic renal disease, once an absolute contraindication to pregnancy, is now encountered much more often as the prognosis has become much better in the past 30 years. Currently, the best prognostic indicator is the degree of renal disease (mild moderate or severe) present before pregnancy.

For mild disease (creatinine <1.5 mg/dL), the majority of women do well and their pregnancies progress without difficulty. With moderate renal disease (creatinine 1.5–3 mg/dL), fetal outcome is usually good (>90%), but maternal status often deteriorates (up to 40% of these women). With severe disease (creatinine >3 mg/dL), women are usually infertile, and if pregnancy is achieved, the outcome for both the fetus and the patient are poor.

The normal physiologic changes seen in pregnancy are different in women with chronic renal disease. Glomerular filtration rate does increase, but often only in the patients with mild disease. Proteinuria usually more than doubles in women with underlying renal disease. Interestingly, though, even nephrotic range proteinuria is not considered by itself to be harmful to the patient or the fetus.

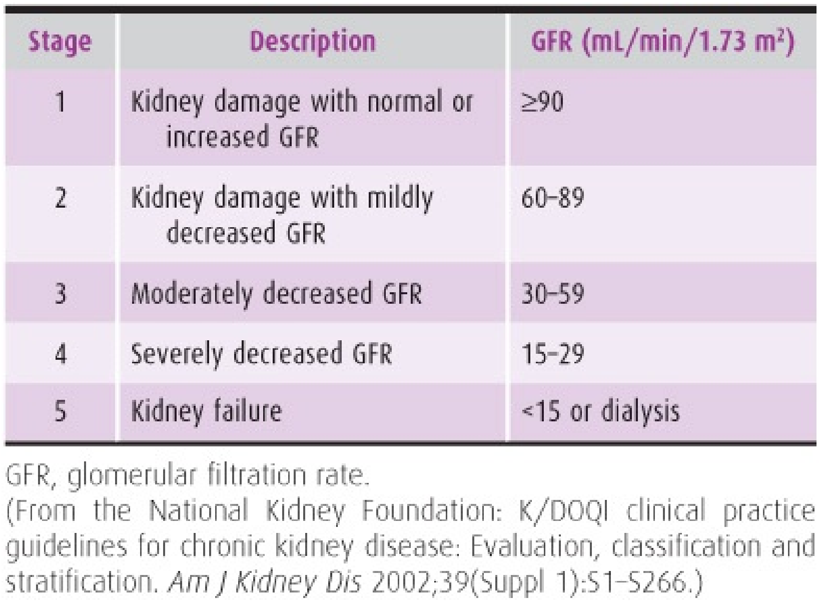
Despite all of the preceding generalizations, it is difficult to counsel women based on their serum creatinine alone. This is due to the fact that specific renal diseases tend to behave differently from one another. Therefore, it is important to know the patient's underlying condition before managing her during pregnancy. Also, the presence of hypertension before conception, regardless of the patient's renal function and serum creatinine, increases the risk to both mother and fetus. One generalization that can be made, though, is that women with chronic renal disease are at increased risk of developing gestational hypertension and preeclampsia. Therefore, all of these women should be watched closely for these diseases.

It should be stated that most of the data regarding chronic renal disease and pregnancy are based on retrospective and observational data only.

Clinical Findings

Chronic renal disease can be staged based on the patient's glomerular filtration rate (Table 28–2). Women with chronic renal disease may also demonstrate some degree of elevation in serum creatinine.

Table 28–2. Stages of chronic renal disease.



Stage	Description	GFR (mL/min/1.73 m^2)
1	Kidney damage with normal or increased GFR	≥90
2	Kidney damage with mildly decreased GFR	60–89
3	Moderately decreased GFR	30–59
4	Severely decreased GFR	15–29
5	Kidney failure	<15 or dialysis

GFR, glomerular filtration rate.
(From the National Kidney Foundation: K/DOQI clinical practice guidelines for chronic kidney disease: Evaluation, classification and stratification. *Am J Kidney Dis* 2002;39(Suppl 1):S1–S266.)

Complications

Chronic renal disease is associated with an increased risk of a number of obstetrical complications, including preeclampsia, prematurity, intrauterine growth restriction, and pregnancy loss. The risk of these complications increases with increasing maternal serum creatinine level.

Treatment

General guidelines for management of patients with chronic renal disease begins with preconceptual counseling, if possible. Pregnancy should be discouraged for patients with a serum creatinine above 1.5 (some would allow up to 2.0, especially if the patient is normotensive), or at least the patient should be made fully aware that the pregnancy may have a very poor outcome for her fetus and herself. In fact, approximately 40% of women with this level of chronic kidney disease may experience an irreversible decline in glomerular filtration rate that is greater than predicted based on the patient's previous course. Patients with more than minimal disease should be comanaged by a maternal–fetal medicine specialist and either a nephrologist or an internist familiar with the management of renal diseases. Blood pressure should be strictly controlled. Baseline laboratory values should include serum creatinine, electrolytes, albumin, and cholesterol/triglycerides (for nephritic patients), and some would add baseline liver function tests, uric acid, and lactate dehydrogenase levels to help aid in the subsequent diagnosis of superimposed preeclampsia. A 24-hour urine collection for protein and creatinine clearance should be obtained as well. Patients should have close follow-up and start noninvasive fetal monitoring at approximately 32 weeks. Baby acetylsalicylic acid and calcium therapy for the prevention of preeclampsia may be considered in these patients to start after 10 weeks' gestation.

A. Glomerulonephritis

Acute glomerulonephritis during pregnancy is rare, with an estimated incidence of 1 in 40,000 pregnancies. The condition is associated with increased perinatal loss. The clinical course is variable during pregnancy and may be easily mistaken for preeclampsia. In some patients, the condition resolves early in pregnancy, with return to normal renal function. Microscopic hematuria with RBC casts is a common finding in acute glomerulonephritis. Treatment is similar to that of the nonpregnant patient and consists of controlling blood pressure, preventing congestive heart failure, administering fluids and electrolytes, and close follow-up.

The outcome of pregnancy with chronic glomerulonephritis depends on the degree of functional impairment of the kidneys, blood pressure levels before conception, and the exact histology of the glomerulonephritis. For patients with active glomerulonephritis, the principal risk for pregnancy is superimposed preeclampsia. Conditions associated with poor fetal outcome include preexisting hypertension, severe proteinuria during the first trimester, primary focal and segmental hyalinosis, and sclerosis. Successful pregnancy should be anticipated, although renal function is expected to decrease. The incidence of fetal intrauterine growth restriction, premature labor, abruptio placentae, and intrauterine fetal demise is increased. Routine prenatal care should include periodic renal function tests, control of blood pressure, ultrasonic evaluation of fetal growth, and antepartum testing for fetal well-being. Hypertension at the time of conception correlates with worsening maternal renal function during pregnancy. Early delivery is indicated after evaluation of pulmonary maturity as appropriate.

B. Lupus Nephritis

It is unclear whether patients with SLE are more likely to have a flare during pregnancy. It is known that an exacerbation is more likely if the patient has active disease at conception. Therefore, many people recommend delaying pregnancy until the SLE has been in remission for 6–12 months. This can decrease the risk of flare from 66% to 33%. What seems to be true is that pregnancy itself does not cause the flare. In small controlled studies, the rate of flare is not different between SLE-similar pregnant and nonpregnant women. If a flare does occur, severe renal manifestations can occur. Prednisone and other immunosuppressive agents have been used with success during pregnancy.

SLE patients, like other renal patients, also have a worse prognosis if pregestational hypertension exists. Specific to SLE, however, is the poor prognosis associated with antiphospholipid antibodies and lupus anticoagulant.

C. Systemic Sclerosis and Periarteritis Nodosum

For patients with these diseases, the outcome for the patients and their pregnancies is quite poor. Most of the (scant) literature describes poor fetal outcome, accelerating maternal hypertension, and occasional maternal death. There are some new data showing a better prognosis with angiotensin-converting enzyme (ACE) inhibitor treatment, but at this time most authorities recommend against conception and for early termination, if possible.

D. Diabetic Nephropathy

Diabetic nephropathy refers to diabetic patients with proteinuria of 300 mg/d. It is most commonly seen in pregestational type 1 diabetic patients, but as the pregnant population ages, more women with type 2 diabetes will have diabetic nephropathy by the time they become pregnant.

Currently, perinatal survival in these patients is approximately 95%, compared with 99% in the general population. Pregnancy does not seem to worsen renal function in mildly affected patients at baseline (serum creatinine <1.5, creatinine clearance >80 mL/min), but for those patients with moderate or severe renal dysfunction at baseline, they typically worsen as pregnancy progresses. It is unclear whether pregnancy worsens these patients' *long-term* renal function. Some studies suggest that for women with severe renal dysfunction, those who become pregnant progress to renal failure sooner than those who do not become pregnant.

Some of the renal deterioration can be avoided by strict blood pressure control during pregnancy. Because ACE inhibitors are generally contraindicated in pregnancy, a calcium channel blocker can be used instead to control hypertension, as they also have renal protective properties.

E. Reflux Nephropathy

Reflex nephropathy is a disease of the urinary tract system that starts in childhood. It is a common and generally mild disease. The majority of women have preserved renal function and are normotensive; consequently, their pregnancies are uneventful. The only significant complication that does develop is bacteruria and urinary tract infections. Therefore, they should be frequently screened for bacteruria and treated accordingly. In addition to this, because the disease may be inherited, their children should be evaluated after birth for this condition.

F. Polycystic Kidney Disease

Although the recessive form is quite rare and extremely severe, autosomal dominant polycystic kidney disease is more common and has been studied in pregnancy. Like other renal diseases, these patients do well in pregnancy if they start without hypertension and severe renal dysfunction. Again, like with the other diseases, they are more likely to develop gestational hypertension and preeclampsia. These patients, however, are also more prone to develop urinary tract infections.

G. Solitary Kidney

A solitary kidney may be the result of developmental aberration or disease requiring removal of 1 kidney. A single kidney may be abnormally developed or it may be located low, perhaps even within the true pelvis. A second small, virtually functionless kidney may not be discovered by the usual diagnostic tests. Anatomic and functional hypertrophy of the kidney usually occurs and is augmented by pregnancy. These patients should be evaluated preconceptually for the presence of infection. If renal function is normal, pregnancy is not contraindicated, and good outcomes are expected.

During pregnancy, infection in a solitary kidney must be treated aggressively. An increased rate of preeclampsia with a solitary kidney has been reported.

H. Renal Transplantation

Approximately 0.5% of women who have undergone transplantation in the reproductive age range become pregnant. A number of large series document successful pregnancy outcomes after renal transplantation. Patients with adequate renal function before pregnancy will experience little if any deterioration in graft function during pregnancy. The likelihood of graft rejection during pregnancy remains the same as in nonpregnant graft recipients. For renal transplant patients considering pregnancy, a stable serum creatinine level <1.4 mg/dL identifies a group more likely to experience an uncomplicated obstetric outcome (97% vs. 75% for patients with a higher serum creatinine level). The spontaneous abortion rate is not increased.

Patients should wait 2 years from transplantation to attempt pregnancy. They may wait only 1 year if the kidney is from a living-related donor. This is done to avoid rejection. Despite this recommendation, women who do not wait this period are still likely to have a successful pregnancy. Patients should have a serum creatinine of <2 (and preferably <1.5) as well as no signs of rejection before conception. Patients should not be hypertensive or should be made normotensive with medication before conception.

Antirejection drugs should be reduced to maintenance levels (prednisone ≤15 mg/d and azathioprine ≤2mg/kg/d; a safe dosage for cyclosporine has not been established but should be maintained <5 mg/kg/d if possible). Immunosuppressive levels should be checked frequently, as levels tend to decrease in pregnancy. Patients on steroids should have early glucose intolerance screening. Electrolyte and liver function values should be checked every 6 weeks.

The risk of infection is considerably higher during pregnancy in renal transplant patients. Primary or reactivated herpesvirus or cytomegalovirus infection may be seen. A higher rate of hepatitis B surface antigenemia is seen in dialysis patients as well.

The route of delivery depends primarily on obstetric indications. In patients with aseptic necrosis of the hip joints or other bony dystrophy secondary to long-standing disease, caesarean delivery may be required. Vaginal delivery should be the aim for patients with renal transplant. A transplanted kidney in the false pelvis usually does not cause obstruction leading to dystocia. If a caesarean section becomes indicated, close attention should be made not to damage the transplanted kidney, as it is typically located in the pelvis.

Preterm delivery, both spontaneous and indicated, is common (45–60%). Intrauterine growth restriction and fetal abnormalities caused by immunosuppressive agents taken by the mother may occur.

I. Chronic Renal Disease Requiring Dialysis

As opposed to the horrendous pregnancy outcome noted in older literature, there are data that women on dialysis have approximately a 50% chance of delivering a live infant, albeit often growth restricted or premature. There are a number of pregnancy-related differences in dialysis management:

- Erythropoietin requirements are higher to maintain an appropriate hemoglobin concentration.
- Fetal heart and uterine contraction monitoring are required, as dialysis may induce hypotension or placental insufficiency.
- The placenta produces vitamin D, so the dose of calciferol may need to be reduced to avoid hypercalcemia.
- Since pregnancy is a hypercoagulable state, more heparin may be required during dialysis.

Prognosis

For mild disease (serum creatinine <1.5 mg/dL), the majority of women do well, and their pregnancies progress without difficulty. With moderate renal disease (creatinine 1.5–3 mg/dL), fetal outcome is usually good (>90%), but maternal status often deteriorates (up to 40% of these women). With severe disease (creatinine >3 mg/dL), women are usually infertile, and if pregnancy is achieved, the outcome for both the fetus and the patient are poor.

Gastrointestinal Disorders in Pregnancy

Chad K. Klauser, MD
Daniel H. Saltzman, MD

HYPEREMESIS GRAVIDARUM

ESSENTIALS OF DIAGNOSIS

- Hyperemesis gravidarum is defined as unexplained intractable nausea, retching, or vomiting beginning in the first trimester, resulting in dehydration, ketonuria, and typically a weight loss of more than 5% of prepregnancy weight.
- Symptoms typically start between 3 and 5 weeks of pregnancy and 80% resolve by 20 weeks.
- Treatment frequently includes avoidance of noxious stimuli, medications to relieve nausea and vomiting, hydration, and possibly hospitalization.

Pathogenesis

Hyperemesis gravidarum (HEG) affects 0.3–2% of pregnant women. The pathogenesis is largely unknown, with possible contributing factors being increased levels of human chorionic gonadotropin (hCG), estradiol, and possible progesterone. It is more common among younger mothers and those with a history of motion sickness, migraines, and nausea and vomiting associated with oral contraceptives. It is more commonly seen in women carrying multiple gestations, and patients with siblings or a mother with HEG are more likely to be affected.

Clinical Findings

A. Symptoms & Signs

HEG is associated with severe nausea and vomiting that may result in dehydration, weight loss, and frequently social isolation and negative impacts on relationships with family and friends. Patients with HEG, rather than nausea and vomiting of pregnancy, tend to have an earlier onset and longer duration. Excess salivation (ptyalism) may also be seen in a subset of women with HEG.

B. Laboratory Findings

Suppressed thyroid-stimulating hormone/elevated free thyroxine and elevated liver enzymes, bilirubin, amylase, and lipase may all be noted in patients with severe nausea and vomiting; these are transiently abnormal and resolve with improvement of HEG.

C. Imaging Studies

No imaging studies are needed for the diagnosis of hyperemesis; however, they can be used to exclude other conditions such as pancreatitis, cholecystitis, or intracranial lesions.

Differential Diagnosis

Other medical conditions should be suspected if the onset of severe nausea and vomiting is after 9 weeks of gestational age. The differential diagnosis for late HEG should include gastroenteritis, gastroparesis, biliary tract disease, hepatitis, peptic ulcer disease, pancreatitis, appendicitis, pyelonephritis, ovarian torsion, diabetic ketoacidosis, migraines, drug toxicity or withdrawal, psychological conditions, acute fatty liver of pregnancy, and preeclampsia.

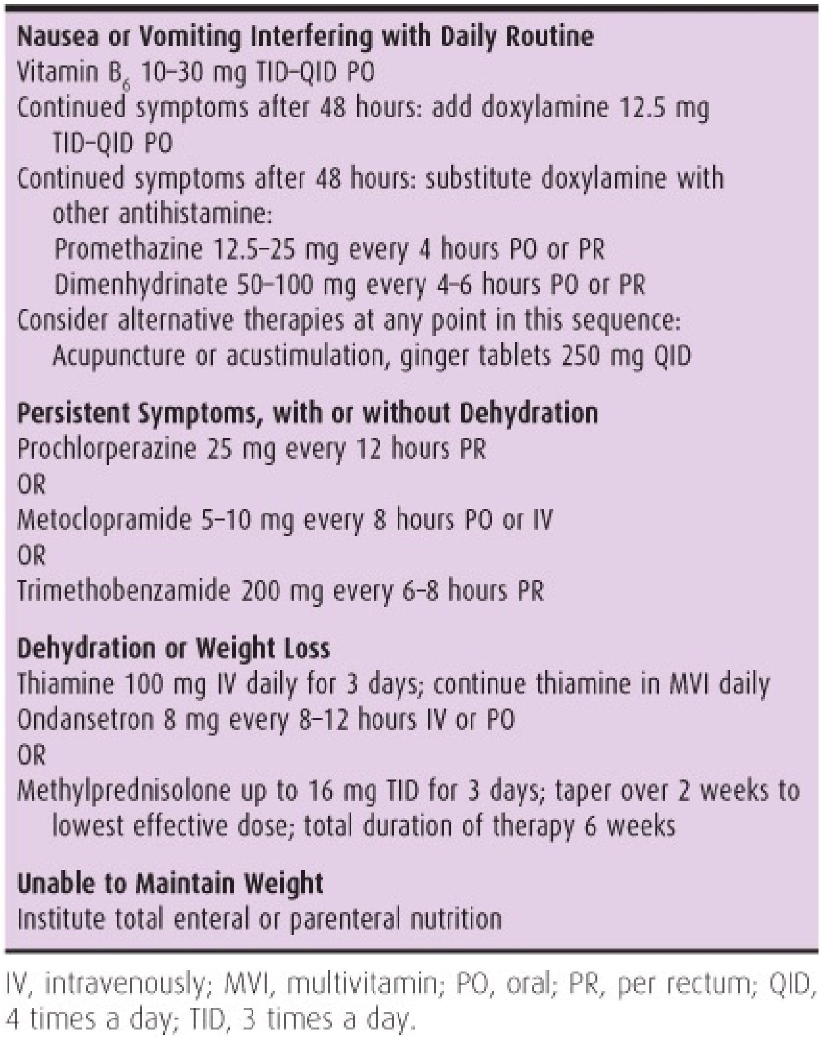
Complications

Maternal complications of HEG can include Wernicke's encephalopathy, acute tubular necrosis, central pontine myelinolysis, Mallory-Weiss tear of the esophagus, pneumomediastinum, and splenic avulsion. Additionally, significant psychological burden of the disease has been reported, with depression, anxiety, and lost work frequently seen among those with persistent or severe HEG. Fortunately, no clear fetal complications have been associated with HEG. One study did show that women with HEG who gain <7 kg during the entire pregnancy have a slightly higher risk of low birth weight and preterm birth. However, there are no congenital anomalies or increased risk of miscarriage or stillbirth noted.

Treatment

Treatment of HEG begins with supportive measures including hydration and vitamin supplementation (in particular thiamine to prevent Wernicke's encephalopathy). Nonpharmacologic measures such as acupuncture, hypnotherapy, avoidance of defined nausea triggers, herbal teas, vitamin B_6, and ginger may help alleviate nausea and vomiting in a subset of patients. Antihistamines as a class have been shown to be efficacious and have a long history of safety during pregnancy. Other antiemetics can be used in an algorithm that balances safety and efficacy (Table 29–1). Patients have also been shown to benefit from frequent contact with the health care provider or from an outpatient nursing services program. If weight loss persists despite therapy, nutritional supplementation by enteral tube feeding or parenteral feeding is necessary. If a patient requires hospitalization, it usually occurs prior to 8 weeks.

Table 29–1. Safe and effective use of antiemetics.



Nausea or Vomiting Interfering with Daily Routine

Vitamin B_6 10–30 mg TID–QID PO

Continued symptoms after 48 hours: add doxylamine 12.5 mg TID–QID PO

Continued symptoms after 48 hours: substitute doxylamine with other antihistamine:

- Promethazine 12.5–25 mg every 4 hours PO or PR
- Dimenhydrinate 50–100 mg every 4–6 hours PO or PR

Consider alternative therapies at any point in this sequence:

- Acupuncture or acustimulation, ginger tablets 250 mg QID

Persistent Symptoms, with or without Dehydration

Prochlorperazine 25 mg every 12 hours PR

OR

Metoclopramide 5–10 mg every 8 hours PO or IV

OR

Trimethobenzamide 200 mg every 6–8 hours PR

Dehydration or Weight Loss

Thiamine 100 mg IV daily for 3 days; continue thiamine in MVI daily

Ondansetron 8 mg every 8–12 hours IV or PO

OR

Methylprednisolone up to 16 mg TID for 3 days; taper over 2 weeks to lowest effective dose; total duration of therapy 6 weeks

Unable to Maintain Weight

Institute total enteral or parenteral nutrition

IV, intravenously; MVI, multivitamin; PO, oral; PR, per rectum; QID, 4 times a day; TID, 3 times a day.

Prognosis

More than 50% of women have resolution of symptoms by 16 weeks of gestational age and 80% by 20 weeks. However, approximately 10% will be affected to some degree with severe nausea and vomiting for the duration of the pregnancy. HEG has been shown to recur in up to 80% of subsequent pregnancies, although earlier aggressive medical therapy prior to significant symptoms has been demonstrated to reduce both the severity and recurrence rate overall in future pregnancies.

PEPTIC ULCER DISEASE

ESSENTIALS OF DIAGNOSIS

- Epigastric pain, anorexia, postprandial nausea and vomiting, or abdominal fullness.

- The incidence and severity of peptic ulcer disease (PUD) decrease during pregnancy, whereas symptoms of dyspepsia may be increased among this group.
- Esophagogastroduodenoscopy is generally considered as safe during pregnancy and is recommended for the evaluation of PUD when symptoms are severe and nonresponsive to medical therapy.

Pathogenesis

Peptic ulcers represent an erosion of the gastrointestinal mucosa, extending through the muscularis mucosae. The majority are caused by *Helicobacter pylori* infection or the use of nonsteroidal anti-inflammatory drugs (NSAIDs). These exposures affect the gastric mucosal function and repair through alterations in gastric acid secretion, gastric metaplasia, and immune responses. The incidence of PUD during pregnancy is approximately 1 in 4500 pregnancies, compared with approximately 1 per 1000 of the general population. This finding may be related to the fact that many of the risk factors/exacerbating factors for PUD are less common during pregnancy, including cigarette use, NSAID use, and alcohol intake. Ulcers are 5 times more common in the duodenum than in the stomach.

Prevention

Although PUD is multifactorial, in the absence of *H pylori*, abstaining from cigarette use and limiting the use of aspirin, NSAIDs, and alcoholic beverages may decrease both the incidence of primary occurrence and recurrence.

Clinical Findings

The classic signs of gastric or duodenal ulcer are related to a burning epigastric pain that is relieved by meals or antacids. PUD must be differentiated from reflex esophagitis or simple heartburn, which commonly occurs during pregnancy. Patients with a gastric or duodenal ulcer most often report discomfort rather than pain and describe the feeling as “acid,” burning, or indigestion. Pain from a duodenal ulcer occurs several hours postprandially during the day, occurs nocturnally, and is relieved by eating food. Pregnant patients tend to have milder symptoms than nonpregnant patients.

Most commonly, the diagnosis is confirmed by endoscopic visualization of the ulcer crater in the stomach or duodenum. Upper gastrointestinal x-ray films with barium studies usually are avoided during pregnancy because of radiation exposure and because endoscopy is a more direct diagnostic method. The presence of *H pylori* can be confirmed based on biopsy histology, culture, or urease test.

Differential Diagnosis

PUD should be distinguished from other common gastrointestinal problems during pregnancy such as gastroesophageal reflux disease (GERD), nausea and vomiting of pregnancy, HEG, pancreatitis, acute cholecystitis, viral hepatitis, appendicitis, acute fatty liver of pregnancy, and irritable bowel syndrome. GERD is extremely common in pregnancy and may be partially distinguished from PUD by the findings of pain radiating to the neck, pain exacerbated by drinking acidic drinks, and recumbency. Other symptoms more commonly seen with GERD include nocturnal asthma, hoarseness, laryngitis, or periodontal disease. Pancreatitis is marked with pain exacerbated with eating, pain radiating to the back, and presence of leukocytosis or pyrexia. Additionally, serum amylase and lipase levels are generally increased with pancreatitis. Acute cholecystitis is also associated with exacerbation after ingestion of fatty meals, right upper quadrant pain, fever, and leukocytosis. Acute hepatitis is diagnosed serologically, whereas appendicitis typically has an acute onset of abdominal pain, rebound tenderness, pyrexia, leukocytosis, and anorexia.

Complications

Complications of PUD occur in pregnancy much less frequently than in the general population. Case reports have documented complications such as hematemesis, perforation, and gastrointestinal obstruction during pregnancy. The fetus generally is not adversely affected unless significant maternal compromise occurs. One retrospective study proposed a small increased risk of low birthweight and preterm delivery in women diagnosed with PUD when compared to pregnant patients without PUD.

Treatment

Documented PUD is treated symptomatically during pregnancy by avoiding symptom-provoking foods and using antacids and sucralfate. Supportive advice can be given regarding cessation of smoking, bed rest, and avoidance of stress. For persistent symptoms, an H_2 antagonist such as cimetidine or ranitidine can be given. With continued symptoms, a proton pump inhibitor such as lansoprazole can be added to the drug regimen. Eradication of *H pylori* is 90% successful with an antibiotic such as amoxicillin or clarithromycin, a bismuth compound, and a proton pump inhibitor. Both the H_2 antagonists and proton pump inhibitors have been extensively studied for teratogenic effects, and no significant abnormal findings have been associated with their use during pregnancy.

INFLAMMATORY BOWEL DISEASE

ESSENTIALS OF DIAGNOSIS

- Crohn’s disease is one subcategory of inflammatory bowel disease (IBD), characterized by insidious onset, episodes of low-grade fever, diarrhea, right lower quadrant pain, and perianal disease with abscess and fistulas formed. Radiographic evidence includes ulceration, stricturing, or fistulas of the small intestine or colon. It may involve any segment of the gastrointestinal tract from the mouth to the anus.
- Ulcerative colitis is the other subcategory of IBD manifesting with bloody diarrhea, lower abdominal cramps, fecal urgency, anemia, and low serum albumin. It is diagnosed with sigmoidoscopy and only involves the colon.

Pathogenesis

Inflammatory bowel disease (IBD) affects approximately 500,000 individuals in the United States at present. There are 2 major categories of IBD: Crohn's disease and ulcerative colitis. Ulcerative colitis is characterized by recurrent episodes of inflammation affecting the mucosal layer of the colon. Lesions are seen to affect the colon in a continuous fashion. In contrast, Crohn's disease is characterized by inflammation affecting the full thickness of the bowel wall and is associated with "skip lesions" in the bowel, lesions separated by unaffected areas. Crohn's disease can affect any area of the gastrointestinal tract from the mouth to the anus, but the most commonly affected site is the distal ileum.

Although the cause of the inflammatory lesions is poorly understood, risk factors have been identified. Most cases of IBD initially present between the ages of 15 and 40 years. Both types of IBD are more common in individuals of Jewish descent. The disease may also have a hereditary component because a family history of IBD increases one's risk of developing IBD.

Clinical Findings

A. Symptoms & Signs

Both Crohn's disease and ulcerative colitis often affect women during their reproductive years and have similar risks in pregnancy as well as with similar treatments. In these conditions, cramping, lower abdominal pain, and diarrhea are the main complaints. Weight loss and anorexia may occur, as well as electrolyte imbalance with severe diarrhea.

B. Diagnostic Studies

Flexible sigmoidoscopy is considered safe during pregnancy and preferred to colonoscopy unless it is felt to be critical for making treatment decisions. The diagnosis is established by finding characteristic intestinal ulcerations and excluding alternative diagnoses.

Differential Diagnosis

The differential diagnosis for IBD includes enteric infection, bowel ischemia, diverticulitis, amyloidosis, diarrhea of acquired immunodeficiency syndrome, celiac sprue, and NSAID-induced changes.

Complications

Poor maternal weight gain, bowel perforation, toxic megacolon, and obstruction are rare complications of IBD during pregnancy. Fertility rates for both ulcerative colitis and Crohn's disease are similar to baseline. Additionally, women with IBD are as likely to flare during pregnancy (34% chance per year) as when not pregnant (32% chance per year).

Both ulcerative colitis and Crohn's disease are associated with an increased risk of first-trimester miscarriage, preterm birth, and small for gestational age infants, as well as an increased caesarean delivery rate. Women who experienced increased disease activity at conception have experienced the most significant increase in these poor obstetrical outcomes. Contradictory findings have been found in regard to congenital anomalies, with some showing an increased risk with ulcerative colitis but not Crohn's disease. These findings are not consistent and may be associated with medications used during the pregnancy.

Treatment

Treatment of IBD typically consists of both dietary changes and medications. Total parenteral nutrition may be required in extreme cases for a period of time during a pregnancy. Sulfasalazine is a frequently used first-line medication that does cross the placenta but has not been associated with an increased risk of birth defects or pregnancy loss. Supplemental folic acid should be given as an adjunct to sulfasalazine. Steroids are also frequently used for moderate to severe cases of IBD, with possible association with low-birth-weight infants and increased risk of oral clefts (when given <10 weeks and at high dose). Immunosuppressive medications such as azathioprine and 6-mercaptopurine can be used in refractory cases, although there are concerns for potential fetal myelotoxicity, as well as miscarriage and preterm birth. Cyclosporine should only be used in those women not responsive to steroids to avoid emergency colectomy; it may be associated with an increased risk of preterm birth and intrauterine growth restriction. Methotrexate is contraindicated in pregnancy secondary to its mutagenic and teratogenic effects. Select antibiotics may be used, especially with Crohn’s disease.

In terms of obstetrical management, serial growth ultrasounds and monitoring for preterm labor should be considered in women affected by IBD. Caesarean delivery is generally reserved for obstetrical indications, with the exception of active perianal disease or the presence of an ileoanal pouch.

Prognosis

Symptoms of active IBD during pregnancy are similar to those in the nonpregnant state: abdominal pain, cramping, and rectal bleeding. Pregnancy is not contraindicated with IBD, but when possible, the disorder should be controlled by surgery or medication prior to conception. Pregnancy does not exert an adverse effect on IBD. In most patients, pregnancy and delivery proceed smoothly.

ACUTE FATTY LIVER OF PREGNANCY

ESSENTIALS OF DIAGNOSIS

- Acute fatty liver of pregnancy (AFLP) is a rare complication of the third trimester of pregnancy involving acute hepatic failure (average gestational age at onset of 36 weeks).

- Symptoms of AFLP include malaise, anorexia, nausea, vomiting, epigastric pain, headache, or jaundice.
- Laboratory abnormalities include thrombocytopenia, elevated transaminases, hyperuricemia, and elevated creatinine. Additionally, hyperbilirubinemia, hypoglycemia, and hyperammonemia are found.
- Other findings may include hypertension, low-grade fever, bleeding from coagulopathy, agitation, or confusion of the patient.

Pathogenesis

Acute fatty liver of pregnancy (AFLP) occurs in approximately 1:10,000 pregnancies and is associated with microvesicular fatty infiltration of the liver and possibly kidney, leading to fatty liver and renal insufficiency. Although it has been diagnosed as early as 23 weeks' gestational age and as late as 1–2 weeks postpartum, it typically occurs in the third trimester, with an average age at diagnosis of 36 weeks. Approximately 50% of patients with AFLP have associated preeclampsia and/or HELLP (hemolysis, elevated liver enzymes, and low platelet count) syndrome. Additionally, it is more common in first pregnancies, multiple gestations, and a male fetus. AFLP has been associated with an inherited defect in mitochondrial beta-oxidation of fatty acids, long-chain 3-hydroxyacyl coenzyme A dehydrogenase deficiency (LCHAD). Both fetal possession and maternal possession of the defect have been linked to a significantly increased risk of developing AFLP, with many women having recurrences in subsequent pregnancies.

Clinical Findings

A. Symptoms & Signs

The patient typically reports malaise and fatigue for 1–2 weeks prior to presentation, with gradual onset of anorexia, worsening nausea and vomiting, headaches, and epigastric/right upper quadrant pain. On physical exam, jaundice may be noted, as well as a deep yellow-orange–colored urine.

B. Laboratory Findings

Laboratory studies typically reveal some degree of thrombocytopenia, as well as low serum glucose and elevated transaminases, bilirubin, creatinine, and ammonia levels. Additionally, varying degrees of coagulopathy can also be found.

C. Imaging Studies

Imaging studies are most useful to exclude other diagnoses such as intrahepatic hemorrhage or hepatic infarct, although changes consistent with nonspecific fatty infiltrations can be seen on computed tomography scan or hepatic ultrasound.

D. Special Tests

Liver biopsy is usually diagnostic, but frequently, coagulation abnormalities preclude this from being done. Moreover, the clinical presentation and laboratory values often lead to a certain diagnosis. Screening both the patient and the neonate after delivery for the LCHAD mutation can greatly assist in the diagnosis and counseling for future pregnancy.

Differential Diagnosis

AFLP is frequently confused with thrombotic thrombocytopenic purpura (TTP), hemolytic-uremic syndrome (HUS), sepsis, HELLP syndrome, or severe preeclampsia. TTP does not typically have significant elevation of liver transaminases, and there is usually a more severe thrombocytopenia present. HUS has an earlier and more severe renal involvement with less hepatic laboratory abnormalities. Hypertensive diseases (preeclampsia/HELLP) may overlap the diagnosis of AFLP frequently; however, increased ammonia levels and a more significant elevation in aspartate transaminase (AST)/alanine transaminase (ALT) and bilirubin are found in AFLP.

Treatment

Patients suspected to have AFLP should be hospitalized in either a labor and delivery unit or intensive care unit, based on maternal/fetal stability. Hypoglycemia should be corrected, and a patient should receive replacement of blood products or coagulation factors as needed. Once the mother is stabilized, delivery should be achieved; induction of labor can be attempted, based on the gestational age, maternal response to resuscitation, and fetal condition since caesarean section may be associated with an increased risk of complications due to maternal coagulopathy. Caesarean section should be performed under general anesthesia, a midline vertical incision should be considered (less dissection, more avascular planes), and placement of a subfascial and subcutaneous drain upon closing the abdomen may be beneficial to track bleeding and decrease hematoma formation. Supportive therapy should be continued in the postpartum period, with special attention to maintaining adequate perfusion to liver, kidneys, and other organs. Pancreatitis can be a lethal complication of AFLP, requiring close monitoring in the postpartum period. Initial improvement is generally is seen within 3–5 days after delivery, with hospitalization of up to 15–20 days not being unusual. Plasmapheresis has been proposed for patients that have worsening hepatic and renal function despite delivery, although the benefit of this is uncertain.

Prognosis

The maternal mortality rate from AFLP and associated complications (eg, infection, disseminated intravascular coagulation) is approximately 10%, which is significantly improved from a historical rate of 70%. Fetal/neonatal mortality is 23%, largely secondary to indicated preterm birth. Liver transplant is a rare but occasionally life-saving procedure for women progressing to fulminant liver failure. As mentioned earlier, the patient, father, and neonate should be screened for the LCHAD mutation. The risk of recurrence in future pregnancies is significant, especially among families with LCHAD deficiency, ranging from 15–70%.

HELLP SYNDROME

ESSENTIALS OF DIAGNOSIS

- HELLP syndrome is a disorder in the spectrum of preeclampsia/eclampsia characterized by hemolysis with a microangiopathic blood smear, elevated liver enzymes, and a low platelet count.
- Up to 20% of patients with HELLP syndrome will be normotensive and/or lack proteinuria.

Pathogenesis

HELLP syndrome complicates up to 1 in 200 pregnancies and is seen in 10–20% of women with preeclampsia. It generally occurs in the third trimester. HELLP syndrome is a disorder characterized by hemolysis, elevated liver enzymes, and low platelets (hence, the acronym HELLP). It is believed to fall within the spectrum of disorders related to preeclampsia, although the absolute cause is unknown.

Clinical Findings

A. Symptoms & Signs

Patients most commonly present with abdominal/epigastric pain, nausea, vomiting, and malaise. Frequently, this is associated with elevated blood pressure and proteinuria (80%). Jaundice, oliguria, and ascites may be seen less frequently.

B. Laboratory Findings

The diagnosis of HELLP syndrome is dependent on the presence of *all* of the following laboratory findings: evidence of hemolysis (demonstrated by the presence of schistocytes on peripheral smear, bilirubin ≥1.2 mg/dL, or serum lactate dehydrogenase ≥600 IU/L), platelet count <100,000, and serum AST ≥70 IU/L. Women who have some but not all of these laboratory abnormalities are given a diagnosis of partial HELLP syndrome. Additionally, mild elevation of prothrombin time (PT)/partial thromboplastin time (PTT) and decrease in fibrinogen may be seen in some women.

Differential Diagnosis

The differential diagnosis includes severe preeclampsia; a significant overlap in symptoms and findings may be seen, but HELLP is diagnosed when the previously mentioned laboratory findings are met. AFLP has abnormal PT/PTT more commonly and more significant liver failure. TTP and HUS do not affect hepatic function as frequently as HELLP syndrome.

Complications

Complications can include disseminated intravascular coagulation (21%), placental abruption (16%), acute renal failure (8%), pulmonary edema (6%), and subcapsular liver hematoma (1%). Hepatic rupture in patients with HELLP syndrome, especially with significant thrombocytopenia, has been associated with a 50% mortality rate. Risk factors for rupture include advanced maternal age, multiparity, and preeclampsia. Blood products may be required in up to 50% of affected pregnancies, and maternal mortality may approach 1%. Neonatal loss rate may range from 7 to 25%, based on gestational age at delivery and presence of growth restriction.

Treatment

Management of the patient diagnosed with HELLP syndrome includes stabilization of the patient/fetus, with replacement of blood and coagulation factors as needed; monitoring urine output/renal function; and treatment of hypertensive disease as necessary. Delivery is the primary treatment and is standard in all but special circumstances. Vaginal delivery is preferred unless there is evidence of fetal growth restriction, placental abruption, or early gestational age with rapidly worsening disease. Antenatal corticosteroids can be given for pregnancies <34 weeks, with some benefit conferred during the labor induction process. If caesarean section is required, a vertical midline incision is recommended secondary to fewer wound separations or infections. HELLP syndrome frequently resolves quickly after delivery, although the platelets and transaminases may nadir up to 36 hours after delivery before improving. Intravenous steroids have not been shown to affect long-term outcome, although one trial demonstrated more rapid recovery of the platelet count with steroids.

Prognosis

Complications of HELLP syndrome can be significant for both the mother and the fetus; however, with prompt recognition and delivery, the vast majority of patients rapidly improve. Recurrence rate for HELLP syndrome ranges from 3 to 25%, whereas the incidence of preeclampsia in subsequent pregnancies ranges from 25 to 75%. Additionally, these women may be at increased risk for cardiovascular disease later in life in the nonpregnant state. Low-dose aspirin prophylaxis has been demonstrated to reduce the recurrence rate in future pregnancies.

OTHER GASTROINTESTINAL DISORDERS IN PREGNANCY

VIRAL HEPATITIS

Hepatitis A

Hepatitis A may occur sporadically or in epidemics. A generalized viremia occurs with the infection that is predominantly hepatic. Symptoms include nausea, headaches, poor appetite, and weight loss. Additionally, diarrhea, fever, and jaundice can be seen. The primary mode of transmission is the fecal–oral route. Excretion of the virus in stool normally begins approximately 2 weeks prior to the onset of clinical symptoms and is complete within 3 weeks after the onset of clinical symptoms. No known carrier state exists for the virus. Both blood and stool are infectious during the 206-week incubation period. Illness during the third trimester may be associated with an increased risk of preterm labor. Vertical transmission of hepatitis A has not been reported, and breastfeeding is encouraged with attention to appropriate hand washing. The hepatitis A vaccine is safe to receive during pregnancy.

Hepatitis B

This virus is typically transmitted by inoculation of infected blood or blood products or through sexual intercourse. The virus is contained in most body secretions, and infection by parenteral and sexual contact has been documented. Groups at risk for hepatitis B infection are intravenous drug users, men who have sex with men, health care personnel, spouses of hepatitis carriers, those with multiple sexual partners, and Southeast Asian emigrants. Approximately 5–10% of people infected with hepatitis B virus become chronic carriers of the virus. The incubation period is 6 weeks to 6 months. The clinical features of hepatitis A and B are similar, although hepatitis B is more insidious. Fulminant hepatitis is rare with hepatitis A but occurs in approximately 1% of patients infected with hepatitis B.

The hepatitis B surface antigen (HBsAg) is the marker usually measured in blood to document prior exposure. This is the first manifestation of viral infection; it usually appears before clinical evidence of the disease and lasts throughout the infection. Persistence of HBsAg after the acute phase of hepatitis usually is associated with clinical and laboratory evidence of chronic hepatitis. The hepatitis B core antibody (HBcAb) is produced against the core of the viral particle and occurs with acute hepatitis B infection at the onset of clinical illness. Hepatitis B e antigen (HBeAg) is found only when HBsAg is present. Pregnant women who are HBeAg positive in the third trimester frequently transmit this infection to the offspring (80–90%), whereas those who are negative have a much lower transmission rate (10–20%).

Treatment of an acute infection during pregnancy is supportive, and there is no associated increased mortality or teratogenicity. Women with elevated hepatitis B viral loads ($>10^6$ copies/mL) or who are HBeAg positive during the third trimester are frequently treated with lamivudine, which has been demonstrated to significantly decrease the risk of vertical transmission. In addition, newborns born to HBsAg-positive mothers should receive hepatitis B immunoglobulin within 12 hours after birth concurrently with the first pediatric dose of the vaccine. Breastfeeding is not contraindicated in patients with hepatitis B (chronic or acute).

Hepatitis C

Up to 85% of infected individuals become chronic carriers. The incubation period usually is 7–8 weeks, but ranges from 3 to 21 weeks. The course of infection is similar to that of hepatitis B. Hepatitis C antibody is present in approximately 90% of patients. However, the antibody may not be detectable for weeks after infection. Acute or chronic hepatitis C does not adversely affect a pregnancy, with similar rates of miscarriage, growth restriction, preterm delivery, or hypertensive disorders among infected patients and controls. Vertical transmission occurs in 5–8% of infected pregnancies and is increased with concomitant HIV infection (36%). The risk of vertical transmission is increased with higher hepatitis C viral loads. The mode of delivery does not appear to influence transmission rate; however, fetal scalp blood sampling or placement of a fetal scalp electrode for fetal heart rate monitoring should be avoided if possible. Prolonged rupture of membranes increases transmission risk, but in the premature fetus, risks of the gestational age must be balanced against the risk of transmission. Breastfeeding is not contraindicated in women infected with hepatitis C.

CHOLECYSTITIS

Cholecystitis occurs rarely during pregnancy (0.3%) secondary to the relaxing effects of progesterone on the smooth muscle of the gallbladder and biliary duct. Acute inflammation during pregnancy is treated with intravenous fluids and limitation of oral intake. If acute cholecystitis does not resolve or if pancreatitis develops, cholecystectomy should be considered. If this operation can be performed in the second trimester, the fetal loss rate is likely not increased. The laparoscopic approach in pregnancy is widely accepted. After 20 weeks' gestation, it should be performed with special care to avoid injury to the uterus. In the third trimester, surgical intervention can contribute to preterm delivery, and monitoring of uterine contractions should be done after surgery. Additionally, it is generally recommended to have fetal monitoring during the surgical procedure, especially if the pregnancy is past viability. See Chapter 25 (Surgical Disorders in Pregnancy) for an extended review of this topic.

INTRAHEPATIC CHOLESTASIS OF PREGNANCY

Intrahepatic cholestasis of pregnancy is characterized by accumulation of bile acids in the liver with subsequent accumulation in the plasma, causing pruritus and jaundice. It is similar to cholestasis that occasionally occurs during combined oral contraceptive therapy. Estrogens are considered to play a role in its etiology, probably by slowing the enzymes involved in bile transport. Its incidence varies with geographical location and ethnicity (most common in Chile); there is an increased incidence with multiple pregnancies.

The most significant symptom is total-body itching, specifically involving the palms and soles. The differential diagnosis includes hepatitis and biliary tract disease, in addition to AFLP and the HELLP syndrome. Laboratory values show increased levels of alkaline phosphatase, bilirubin, and serum bile acids (chenodeoxycholic acid, deoxycholic acid, cholic acid). AST and ALT levels may be mildly elevated. Patients may be symptomatic weeks before the diagnostic laboratory abnormalities are noted.

Symptomatic treatment of pruritus with antihistamines such as diphenhydramine is useful as an initial therapy. Ursodeoxycholic acid (10–15 mg/kg/d in 2 divided doses) has been shown to inhibit absorption of bile acids and increase their biliary excretion. In doing so, the medication normalizes bile acids, improves liver function tests, and alleviates pruritus. Oral steroids also have been used to relieve symptoms. There is rapid resolution of both laboratory abnormalities and symptoms after delivery.

Intrahepatic cholestasis of pregnancy has been associated with fetal death, spontaneous preterm birth, meconium staining of the amniotic fluid and/or placenta, and postpartum hemorrhage. No specific method of antepartum testing has been demonstrated to prevent fetal demise, although twice-weekly modified biophysical profile testing is suggested by some. Poor obstetrical outcomes seem to be highest in women with total bile acid levels >40 nmol/L. There is no consensus on management of patients with regard to delivery; varying strategies include amniocentesis for fetal lung maturity between 36 and 37 weeks' gestational age, delivery at 37–38 weeks without fetal lung maturity studies, or allowing spontaneous labor to ensue if bile acids are <40 nmol/L and only intervening earlier if the bile acids are higher than this threshold.

Dermatologic Disorders in Pregnancy

Abigail Ford Winkel, MD

PHYSIOLOGIC SKIN CHANGES IN PREGNANCY

ESSENTIALS OF DIAGNOSIS

- Physiologic changes, especially endocrine processes, result in a variety of effects on the skin in pregnancy.
- Most common changes include hyperpigmentation, striae, vascular changes, and hair loss (postpartum).
- Many changes related to pregnancy resolve postpartum without treatment.

Pathogenesis

Immunologic, metabolic, vascular, and endocrine changes in pregnancy cause cutaneous changes in almost all pregnancies. Hyperpigmentation is related to increased levels of melanocyte-stimulating hormone, estrogen, and progesterone. Vascular changes are related to the effect of estrogen causing congestion, distention, and proliferation of blood vessels.

Prevention

Few interventions have been successful at preventing these changes, which occur as the result of physiologic processes. Judicious use of sunscreen may reduce the appearance of hyperpigmentation and melasma. Varicosities in the legs may be prevented by leg elevation, support hose, and avoiding prolonged sitting or standing.

Clinical Findings

A. Symptoms & Signs

Hyperpigmentation occurs in up to 90% of women, and it is more pronounced in women with darker skin tones. It is most frequently localized in the nipples, areolae, and axillae. The linea alba darkens to become the linea nigra, a dark linear streak on the midline of the abdomen.

Melasma, also known as chloasma or “the mask of pregnancy,” is a symmetric brown hyperpigmentation in malar, mandibular, or central facial areas. It is exacerbated by exposure to the sun and certain cosmetics.

Erythema begins in early gestation and appears either diffuse and mottled or focused in the palmar and thenar areas.

Venous congestion and vascular permeability during pregnancy can lead to **varicosities** in up to 40% of women. They result from increased venous pressures by the gravid uterus on femoral and pelvic vessels.

Dilation of arterioles leads to central erythematous spots with fine vessels radiating outward, called **capillary hemangiomas (spider angiomas**). They are most commonly seen around the gums, tongue, upper lip, and eyelids.

Striae, pinkish or purplish lines, may form on the abdomen, buttocks, and breasts. Striae form as a result of structural changes in the skin caused by weight gain and hormonal influence. Increased activity of the adrenal gland during pregnancy may increase their occurrence.

Nonpitting **edema** of the face, eyelids, and extremities is observed in many pregnant women, with changes most pronounced in the morning and improving throughout the day.

Changes in the distribution and amount of hair are common during pregnancy. Increased hair growth in facial areas and around the breasts occurs, particularly during the second and third trimesters. Importantly, there are no signs of virilization, and hirsutism regresses slightly or remains unchanged postpartum. Increased recruitment of hair follicles into the growing phase (anagen) may result in thickening of scalp hair in late gestation. Postpartum loss of hair is fairly common. During pregnancy, the number of hair follicles in the resting phase (telogen) is decreased by about half and then nearly doubles in the first few weeks postpartum.

Nails may become brittle with transverse grooving, distal onycholysis, and subungual hyperkeratosis. These changes are benign and do not require treatment.

Differential Diagnosis

It is important to distinguish physiologic changes in pregnancy from more worrisome conditions. Erythema, for instance, might be diagnostic of hyperthyroidism, cirrhosis, or systemic lupus erythematosus. Striae are normal findings in pregnancy but may be observed with adrenocortical hyperactivity. Edema, while common, is also an important symptom of preeclampsia, and this condition should be considered in affected women. When pronounced nail onychodystrophy is seen, psoriasis, lichen planus, and onychomycosis should be excluded.

Complications

In general, cutaneous changes of pregnancy are of cosmetic concern only. Some vascular changes result in discomfort that may respond to supportive therapy.

Treatment

Because most changes occurring in pregnancy improve postpartum, no therapy other than reassurance is required. Many remedies have been proposed for striae in pregnancy (vitamin E oil, lubricants, lotions), but none are effective. Laser technology is under investigation as a potential treatment and has shown some promise. If hyperpigmentation does not resolve postpartum, some patients respond to retinoic acid and corticosteroid preparations. Vascular changes are not likely to completely regress postpartum and may be treated with laser, electrodessication, or sclerotherapy.

Prognosis

Hyperpigmentation decreases or, in most cases, disappears postpartum. Vascular changes may become less pronounced but may not resolve completely. Striae usually become silvery-white and sunken, but they rarely disappear. Hair loss usually stops 2–6 months postpartum as the hair follicles enter the growing phase (anagen).

DERMATOSES & CUTANEOUS DISORDERS AFFECTED BY PREGNANCY

ATOPIC DERMATITIS

ESSENTIALS OF DIAGNOSIS

- ▸ Atopic dermatitis (eczema) is commonly exacerbated in pregnancy.
- ▸ Most patients have a history of atopy, but dermatitis may present for the first time in pregnancy.

Pathogenesis

Estrogen and progesterone modulate immune and inflammatory cell functions, including mast cell secretion. This leads to urticaria and exacerbation of cutaneous inflammatory conditions. For some women, atopic dermatitis may improve with pregnancy, but some women experience worsening of or no change in their disease status during pregnancy.

Prevention

Treatment to decrease pruritus can discourage itching, which may improve symptoms. Additionally, maintaining skin hydration with emollients with a low water content (ie, thick creams or petroleum jelly) can protect against the dry, itchy, scaly skin that is associated with atopic dermatitis.

Clinical Findings

A. Symptoms & Signs

In most cases, patients will have a history of atopic dermatitis prior to pregnancy. The diagnosis of atopic dermatitis is a clinical one. The hallmark finding is pruritus. Other clinical manifestations include grouped, crusted erythematous papules and plaques present with excoriations. The skin creases and flexural surfaces are commonly involved.

B. Laboratory Findings

Although there are no laboratory findings specific to the diagnosis of atopic dermatitis, serology, histopathology, and immunofluorescence may show increased levels of immunoglobulin E (IgE).

Differential Diagnosis

Other sources of dermatitis, including contact or allergic dermatitis, tinea infection, and scabies, may mimic these conditions. Additionally, other disorders unique to pregnancy may also manifest in pruritus, including cholestasis of pregnancy and polymorphic eruption of pregnancy. The distribution of any rash can help distinguish between these conditions.

Complications

Bacterial, viral, or fungal superinfections may arise. Patients can have allergic reactions to topical treatments.

Treatment

Symptomatic treatment involves topical corticosteroids, such as hydrocortisone, or systemic antihistamines. For patients who do not respond to topical interventions, oral prednisone may be required. Methotrexate may be used for treatment of severe atopic dermatitis in nonpregnant patients; however, its use is absolutely contraindicated during pregnancy.

Prognosis

Atopic dermatitis is not associated with any adverse effects on the fetus. The prognosis is not affected by pregnancy.

PSORIASIS

ESSENTIALS OF DIAGNOSIS

- ▸ Chronic plaque psoriasis is the most common type of psoriasis to develop or worsen in pregnancy.
- ▸ Forty percent to 60% of patients with psoriasis improve during pregnancy; only 14% worsen.

Pathogenesis

The pathophysiology is poorly understood. There is a genetic component as well an inciting injury to the skin. The Koebner phenomenon refers to the increased appearance of psoriatic lesions in area of skin trauma. Immune cells move from the dermis to the epidermis, where they stimulate keratinocytes to proliferate. High levels of interleukin-10 in pregnancy may explain the improved prognosis in some patients.

Prevention

No preventative measures have been identified.

Clinical Findings

A. Symptoms & Signs

In chronic plaque psoriasis, red and white scaly patches appear on the top first layer of the epidermis. Skin accumulates in these sites giving a silvery-white appearance, most commonly on elbows and knees, although any surface may be affected.

B. Laboratory Findings

Skin biopsy or scraping can confirm the diagnosis.

Differential Diagnosis

Drug reactions, pityriasis rosea, contact dermatitis, and tinea infections may mimic psoriasis.

Complications

Psoriatic arthritis develops in 10–15% of patients with psoriasis.

Treatment

Phototherapy and topical corticosteroids may be of use. Methotrexate, cyclosporine, and retinoids used in treatment of nonpregnant women are not recommended in pregnancy.

Prognosis

There is currently no cure for psoriasis, but various treatments can help to control the symptoms. Patients have an increased risk of nonmelanoma skin cancers and should be in the regular care of a dermatologist.

CUTANEOUS LUPUS ERYTHEMATOSUS

ESSENTIALS OF DIAGNOSIS

- Chronic cutaneous lupus is rarely affected by pregnancy. Women with systemic lupus erythematosus (SLE) in remission for 3 months or more and who do not have nephropathy or cardiopathy tolerate pregnancy well.
- Cutaneous flares are the most common manifestation of SLE in pregnancy.

Pathogenesis

Binding of autoantibodies to cell membranes in the cutaneous tissues initiates an immunologic cascade that leads to lesion formation.

Prevention

Ultraviolet light may precipitate exacerbations, and avoidance may be helpful in some cases.

Clinical Findings

A. Symptoms & Signs

Erythematous papules or small plaques with slight scaling form. Lesions may expand and merge into larger plaques.

B. Laboratory Findings

Most patients have positive antinuclear antibody screens. Anti-Ro (SS-A) and anti-La (SS-B) should be checked in pregnant patients, as well as complete blood count to screen for anemia, leukopenia, and thrombocytopenia. Decreased complement and elevated erythrocyte sedimentation rate may be observed but are nonspecific.

C. Special Tests

Biopsy of skin shows deposition of immunoglobulin and complement at the dermoepidermal junction. Biopsies of unaffected skin may be higher yield than those of skin lesions. Immunofluorescence may not be helpful with older lesions.

Differential Diagnosis

Drug eruptions and allergic reactions may mimic cutaneous lupus erythematosus.

Complications

If conception occurs during the active phase of systemic lupus erythematosus (SLE), 50% of patients will worsen during pregnancy. Patients with SLE have an increased risk of pregnancy loss, and premature birth is not uncommon. Patients are at increased risk of preeclampsia. Neonatal lupus and congenital heart block may be seen especially in patients with circulating SS-A (anti-Ro) and SS-B (anti-La) antibodies.

Treatment

Topical and intralesional therapy is with steroid treatment. Scarring from lesions may lead to alopecia. Antimalarial treatments such as hydroxychloroquine and systemic corticosteroids may also be used for cases unresponsive to local treatment.

Prognosis

Cutaneous lupus erythematosus without SLE has a good prognosis. Some patients may experience intermittent exacerbations, often in the warmer months of the year, and some patients may experience remission.

CUTANEOUS TUMORS

ESSENTIALS OF DIAGNOSIS

- Tumors may appear for the first time, enlarge, or increase in number during pregnancy.
- Granuloma gravidarum (pyogenic granuloma) is a vascular tumor that occurs in 2% of patients between the second and fifth months of pregnancy.
- Desmoid tumors, leiomyomas, and keloids may grow rapidly during pregnancy.
- Melanocytic nevi may develop, enlarge, or darken during pregnancy.

Pathogenesis

Proliferation of capillaries causes granuloma gravidarum to develop. Molluscum fibrosum gravidarum is also a result of the hormonal effects on vasculature. An increase in estrogen and progesterone receptors has been observed on melanocytes, which may explain changes in melanocytic nevi.

Prevention

No preventative measures have been identified.

Clinical Findings

A. Symptoms & Signs

Granuloma gravidarum is a red or purple nodule that most commonly occurs on gingival surfaces in the mouth but may also occur at other sites such as fingers. Molluscum fibrosum gravidarum are soft fibromas appearing later in pregnancy on the face, neck, and chest wall. Melanocytic nevi are dark, raised nodules of varying size that can occur anywhere on the body.

B. Laboratory Findings

If appearance is classic for a common benign lesion, biopsy is not necessary. Care should be taken in biopsying vascular lesions.

Differential Diagnosis

A wide variety of epidermal, melanocytic, fibroblastic, vascular, follicular, sebaceous, nervous, smooth muscle, and eccrine tumors may be considered. Metastatic tumors should be considered and biopsy performed if suspicion for malignancy exists.

Complications

Complications are limited to maternal cosmetic and physical effects. No fetal impact should be anticipated.

Treatment

In most cases, observation is all that is required. If symptoms exist, surgical resection may be considered.

Prognosis

Many lesions regress postpartum and do not require surgical resection.

SPECIFIC DERMATOSES OF PREGNANCY

PRURITIC URTICARIAL PAPULES AND PLAQUES OF PREGNANCY

ESSENTIALS OF DIAGNOSIS

- The most common pruritic dermatosis unique to pregnancy.
- Pruritic, erythematous papules that coalesce into plaques forming usually after the 34th week of

gestation.

- The lesions usually appear during the third trimester and disappear completely within 2 weeks after delivery.

Pathogenesis

Pruritic urticarial papules and plaques of pregnancy (PUPPP) are also known as polymorphic eruption of pregnancy. The pathogenesis of PUPPP is still unclear. However, it is likely that overdistension of abdominal connective tissue exposes antigens in collagen bundles that provoke an allergic-type reaction, leading to lesions within the striae gravidarum. It affects approximately 1 in 160 to 1 in 300 pregnancies.

Prevention

No preventative measures have been identified.

Clinical Findings

A. Symptoms & Signs

The diagnosis of PUPPP is based on clinical signs and symptoms. Generally red, unexcoriated papules and plaques are found principally on the abdomen. A marked halo may surround the plaques. Lesions are found on the striae, legs, and arms. Notably, the characteristic papules spare the periumbilical region, leaving what may appear to be a periumbilical “white halo.”

B. Laboratory Findings

No relevant laboratory studies yield specific findings for PUPPP. However, immunofluorescence can distinguish PUPPP from pemphigoid gestationis because no immunoglobulin component will be identified with PUPPP.

Differential Diagnosis

Lesions cluster on the striae and tend to spare the umbilical area, differentiating PUPPP from pemphigoid gestationis. The differential diagnosis also includes erythema multiforme, drug reactions, viral syndromes, and scabies.

Complications

This condition poses no real danger for mother or fetus. It is not associated with adverse fetal or maternal outcomes.

Treatment

Symptomatic treatment with antihistamines, topical steroids, and antipruritic medications usually is helpful. Occasionally, oral corticosteroid therapy is necessary for control of extreme pruritus unresponsive to initial treatment.

Prognosis

PUPPP is self-limited and resolves after pregnancy. It is unclear if women who experience PUPPP with one pregnancy are at increased risk of recurrence in future pregnancies.

INTRAHEPATIC CHOLESTASIS OF PREGNANCY

ESSENTIALS OF DIAGNOSIS

- Seen only in pregnancy; results in pruritus and exclusively secondary skin lesions.
- Usually arises after the 30th week of pregnancy.
- Cholestasis is more prominent in South American and Scandinavian populations.

Pathogenesis

Intrahepatic cholestasis of pregnancy (ICP) affects between 0.3 and 5.6% of pregnancies in the United States. The incidence of ICP appears to vary according to ethnicity, with higher incidence rates among Araucanos Indians in Chile and people of Bolivian descent. The cause of ICP is not well understood. Certain genetic mutations have been associated with an increased predisposition to ICP. Alterations in estrogen and progesterone metabolism have also been associated with ICP. Increased levels of both hormones have been associated with ICP. Intrahepatic dysfunction of biliary secretion leads to elevation of bile acids in serum and deposition of bile salts in the skin, causing pruritus. Hormonal factors are likely to contribute to the condition.

Prevention

No preventative measures have been identified.

Clinical Findings

A. Symptoms & Signs

Patients with ICP typically present with a generalized pruritus (often severe) without an identifiable rash focused on palms and soles and sometimes extending to legs and abdomen. Symptoms tend to be worse at night. On physical examination, patients may show signs of excoriations.

B. Laboratory Findings

Testing of serum bile acids and liver function tests should be performed for every pregnant woman with pruritus. Serum total bile acid concentrations are increased in women with ICP. Serum cholic acid is often increased more than chenodeoxycholic acid. Serum aminotransferases may also be elevated. The prothrombin time is usually normal in women with ICP.

Differential Diagnosis

The diagnosis of ICP is made on the basis of pruritus with elevated bile acids and/or abnormal liver enzymes. However, viral hepatitis, gallbladder disease, pemphigus gestationis, and the papular dermatoses of pregnancy should be considered. The absence of a rash helps to distinguish ICP from other dermatoses. The presence of pruritus distinguishes ICP from other causes of abnormal liver function tests.

Complications

ICP is associated with an increased risk of adverse perinatal outcomes, including preterm birth and stillbirth. The earlier in gestation the onset of pruritus, the greater is the risk of prematurity. Patients with higher levels of bile acids have been found to have higher rates of spontaneous preterm birth. Additionally, the incidence of fetal demise appears to be 1–3%. Stillbirths cluster around weeks 37–39 of pregnancy. Although the absolute cause of stillbirth is poorly understood, there is some evidence suggesting that the increased levels of circulating bile acids interfere with cardiac electrical conduction leading to fetal arrhythmia and sudden stillbirth. Because stillbirth in these women appears to be a sudden and unpredictable event, fetal surveillance with nonstress testing and/or biophysical profiles has not been shown to reduce the risk of adverse outcome. Nonetheless, most practitioners advise the initiation of fetal surveillance twice per week once a diagnosis of ICP has been made.

Treatment

Ursodeoxycholic acid (UDCA) may result in a sustained decrease in serum bile acids that improves maternal symptoms. UDCA has not been shown to reduce the risk of stillbirth, primarily because the studies evaluating the effect of UDCA on ICP were not powered to address the effect on fetal/neonatal outcomes. However, in theory, reducing circulating bile acids with UDCA may also reduce the risk of adverse fetal outcomes. Once a diagnosis of ICP is made, fetal surveillance twice per week with nonstress testing and/or biophysical profiles is recommended. The optimal timing of delivery is unclear, but many experts advise delivery at 37–38 weeks or delivery at 36 weeks after confirmation of fetal lung maturity with amniocentesis.

Prognosis

The pruritus typically resolves within days after delivery. ICP is associated with a substantial recurrence risk, which has been reported to be in the range of 40–70%. Women with a history of ICP may also experience recurrent pruritus and cholestasis with oral contraceptives. If a patient with ICP desires oral contraception, a pill with a low dose of estrogen should be prescribed.

PUSTULAR PSORIASIS OF PREGNANCY

ESSENTIALS OF DIAGNOSIS

- Also called impetigo herpetiformis.
- Characterized by a pustular eruption on an erythematous base with total-body distribution.
- This rare condition may represent an acute form of psoriasis that occurs during pregnancy.
- Most patients have personal or family history of psoriasis.

Pathogenesis

Impetigo herpetiformis, or pustular psoriasis of pregnancy, is a very rare skin disorder with few cases described in the medical literature. The pathogenesis is still unclear, although it may be associated with high levels of progesterone and low levels of calcium in the last trimester of pregnancy. Reduced levels of epidermal skin-derived antileukoproteinase (elafin) have been implicated in the formation of pustules.

Prevention

No preventative measures have been identified.

Clinical Findings

A. Symptoms & Signs

Generalized erythematous patches covered with sterile pustules occur. Lesions start on the intertriginous or flexor surfaces and extend centrifugally, including mucosal membranes. Fever, nausea, diarrhea, and malaise often accompany this presentation. Pruritus is not common. Patients may have associated hypocalcaemia.

B. Laboratory Findings

Biopsy confirms presence of spongiform pustules with neutrophils in the epidermis. Immunofluorescence is negative.

Differential Diagnosis

Biopsy and culture can distinguish between pustular psoriasis of pregnancy and other pustular dermatoses and infections such as candidiasis and impetigo. Lesions may become superinfected, causing difficulty with diagnosis.

Complications

Skin lesions that develop superimposed infections may lead to sepsis. Severe hypocalcemia can cause tetany, seizures, and delirium.

Treatment

Treatment generally starts with oral corticosteroids. The steroids are then slowly tapered. Hypocalcemia should be corrected with calcium supplementation.

Prognosis

Increased maternal and perinatal mortality has been reported, but these cases may be related to secondary infection and sepsis. These patients may be at increased risk of placental insufficiency with adverse pregnancy outcomes such as miscarriage, fetal growth restriction, and stillbirth. Consequently, fetal surveillance with biophysical profiles and ultrasound assessment of fetal growth are advised. The skin lesions typically resolve quickly in the postpartum period. Pustular psoriasis of pregnancy may recur with subsequent pregnancies with an earlier gestational age at onset.

PEMPHIGOID GESTATIONIS (HERPES GESTATIONIS)

ESSENTIALS OF DIAGNOSIS

- ▸ Rare condition; appears in second and third trimesters.
- ▸ Lesions present as erythematous plaques with vesicles that soon form bullae in the periphery of the lesion (herpetiform appearance).
- ▸ Lesions start on the trunk and tend to spare the face, palms, and soles.

Pathogenesis

Despite the name, the herpes virus is not the causative agent. An autoimmune reaction against a placental matrix antigen has been implicated. Autoantibodies form that lead to deposition of immune complexes in the skin and complement activation, resulting in tissue damage and blister formation.

Prevention

No preventative measures have been identified.

Clinical Findings

A. Symptoms & Signs

Urticarial papules and plaques usually begin on the trunk and spread to the entire body including the distal extremities. Bullous lesions develop as the disease progresses. Lesions on mucous membranes are uncommon; however, they may occur. The vesicles are not clustered and are more peripheral than herpes. Systemic signs include malaise, fevers, and chills.

B. Laboratory Findings

Biopsy is necessary for diagnosis. Most patients have circulating immunoglobulin G that will fix C3 complement. Immunofluorescence testing of bullous lesions demonstrates C3 in a homogeneous, linear band at the basement membrane zone.

Differential Diagnosis

Pemphigus vulgaris can be excluded by histologic examination. The pustules, fever, and hypocalcemia of impetigo herpetiformis are not present in herpes gestationis. Dermatitis herpetiformis is pruritic, but the clusters of vesicles do not form bullae, and no plaques are present. In herpes gestationis, a crust forms, and a hyperpigmented area, but little or no scarring, occurs after the lesion heals.

Complications

Pruritus can interfere with daily activities and sleep. Ruptured bullae may be painful and develop superficial ulcerations that interfere dramatically with quality of life. Newborns may be small for gestational age at birth, but usually do not have associated morbidity and mortality.

Treatment

Topical or oral corticosteroids are the treatment of choice, typically prednisone 20–60 mg daily. Oral antihistamines may also relieve symptoms. Cyclosporine and intravenous immunoglobulin have been used in refractory conditions.

Prognosis

Exacerbations and remissions occur during pregnancy. The condition usually abates by 6 weeks postpartum, although exacerbations may occur during the postpartum period. Pemphigoid gestationis is associated with placental insufficiency, which increases the risk of intrauterine growth restriction and prematurity. Fetal surveillance with biophysical profiles and ultrasound assessment of fetal growth is advised in these women. The disease tends to recur in subsequent pregnancies.

Diabetes Mellitus & Pregnancy

Aisling Murphy, MD
Carla Janzen, MD
Stacy L. Strehlow, MD
Jeffrey S. Greenspoon, MD
Sue M. Palmer, MD

According to the Centers for Disease Control and Prevention, diabetes mellitus was estimated to affect 24 million people in the United States in 2008, an increase of 3 million over the preceding 2 years. Prevalence of diabetes, primarily type 2 disease, is expected to rise even further by 2030, as a consequence of population aging, lifestyle changes, and increasing obesity rates. Approximately 25% of adults with the condition are currently undiagnosed.

Data suggest that this upward trend in prevalence is also affecting pregnant women. Preexisting diabetes affects 1% of all pregnancies, whereas approximately 7% of pregnant women are diagnosed with gestational diabetes mellitus (GDM), a condition traditionally defined as glucose intolerance with onset or first recognition during pregnancy. Even higher rates may be seen in certain minority groups, in particular African American and Hispanic gravidas.

Before the introduction of insulin in 1922, women with preexisting diabetes did not often conceive. When pregnancy did occur, it commonly resulted in the death of the mother. This fact prompted Joseph de Lee to recommend in his seminal 1913 textbook that all such pregnancies be terminated. He observed that “the attempt to carry the pregnancy up to term or even to viability of the child is too perilous.”

The introduction of insulin, as well as improvements in general obstetric care, rapidly decreased maternal mortality. However, the risk of stillbirth and neonatal death remained much higher in diabetics than in the general population until the 1960s. Since that time, there has been a dramatic decrease in perinatal mortality due to improved neonatal intensive care, fetal surveillance, and greatly improved diabetic control, the result of self-blood glucose monitoring and intensified insulin regimens. Today, if good glycemic control is achieved, the risk of perinatal mortality approaches that of the general obstetric population. Nevertheless, both preexisting diabetes and GDM continue to pose significant risks during pregnancy.

Currently, the priorities for diabetes care providers are first to identify and control diabetes prior to conception and second to appropriately screen and treat GDM during pregnancy in an effort to prevent maternal and fetal/neonatal complications. Evidence exists that treatment of even mild GDM results in improved outcomes in both mother and baby.

Metabolism in Normal & Diabetic Pregnancy

To accommodate the growth of a healthy fetus, profound metabolic changes occur in all pregnant women during gestation. In particular, it is well established that insulin sensitivity decreases in normal women as gestation advances. However, despite much research, the mechanism behind this phenomenon is unknown. Alterations in maternal cortisol levels, as well as in the placental hormones including estrogen, progesterone, placental growth factor, and human placental lactogen (hPL) (also known as human chorionic somatomammotropin), have all been implicated.

Although some degree of insulin resistance occurs in all women, only a relatively small number develop GDM. Affected women share the same risk factors as patients with type 2 diabetes, and like type 2 disease, GDM is characterized both by insulin resistance and by inadequate insulin secretion. It therefore appears that GDM may be considered as type 2 diabetes that is unmasked by the diabetogenic milieu of pregnancy.

Insulin is an anabolic hormone with essential roles in carbohydrate, fat, and protein metabolism. It promotes the uptake of glucose, storage of glucose as glycogen, lipogenesis, and uptake and utilization of amino acids. A lack of insulin or decreased peripheral responsiveness to insulin results in hyperglycemia and lipolysis. Elevation of free fatty acids leads to an increase in the formation of ketone bodies, acetoacetate, and β-hydroxybutyrate. When blood glucose levels exceed the renal threshold for absorption of filtered glucose, glycosuria occurs and causes an osmotic diuresis with dehydration and electrolyte losses.

In the first trimester of normal pregnancies, insulin sensitivity is unchanged or increased. This appears to be because both estrogen and progesterone levels rise at this time but their effects on insulin activity are antagonistic. Progesterone causes insulin resistance, whereas estrogen has the opposite effect. Because insulin secretion rises while insulin sensitivity is unchanged, the result is a decrease in fasting glucose levels, which reach a nadir by the 12th week. The decrease averages 15 mg/dL; thus, fasting values of 70–80 mg/dL are common by the 10th week of pregnancy.

However, in the second trimester, higher postprandial glucose levels occur, facilitating transfer of glucose across the placenta from mother to fetus. Glucose transfer occurs via a facilitated diffusion that becomes saturated at 250 mg/dL. Fetal glucose levels are 80% of maternal levels. In contrast, maternal amino acid levels are lowered due to active placental transport to the fetus. Lipid metabolism in the second trimester shows continued maternal storage until midgestation, then enhanced mobilization (lipolysis) as fetal fuel demands increase.

hPL, which increases up to 30-fold during pregnancy, is thought to be the hormone mainly responsible for insulin resistance and lipolysis. hPL also decreases the hunger sensation and diverts maternal carbohydrate metabolism to fat metabolism in the third trimester. hPL is similar in structure to growth hormone and acts by reducing the insulin affinity to insulin receptors. The net effect is to favor placental transfer of glucose to the fetus and to reduce the maternal use of glucose. The hPL levels rise steadily during the first and second trimesters, with a plateau in the late third trimester.

Maternal cortisol levels, which likewise rise during pregnancy, may also contribute to insulin resistance by stimulating endogenous glucose production and glycogen storage and decreasing glucose utilization.

Recently, researchers have challenged the view that the insulin resistance of pregnancy is mediated entirely by hormonal changes. Attention has turned to the role adipokines such as tumor necrosis factor-α (TNF-α), adiponectin, and leptin may play. In particular, the change in TNF-α level has been found to be a significant predictor of insulin resistance during pregnancy. TNF-α is produced by the placenta as well as by adipose tissue and may act in a paracrine fashion to impair insulin signaling mechanisms, resulting in decreased insulin sensitivity.

Fetal Effects of Hyperglycemia

Elevated glucose levels are toxic to the developing fetus, producing an increase in miscarriages and major malformations in direct proportion to the glucose level. The mechanism by which teratogenesis occurs has not been definitively established, but oxidative stress as a consequence of fetal hyperglycemia may play a role. These birth defects (Table 31–1), which may be fatal or seriously deleterious to quality of life, are largely preventable by improvement in preconception glucose control.

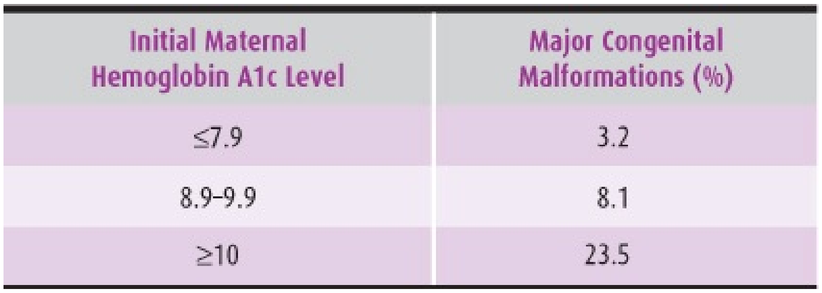
Because most malformations occur within the first 8 weeks of gestation, when most women are just beginning prenatal care, preconception care is essential for women with diabetes. Hemoglobin A1c (HbA1c), which reflects the blood glucose concentration over the previous 2 months, can predict the risk for malformations when measured in the first trimester (Table 31–2).

Table 31–2. Relationship between initial pregnancy value of glycosylated hemoglobin and rate of major fetal congenital malformations.



Initial Maternal Hemoglobin A1c Level	Major Congenital Malformations (%)
≤7.9	3.2
8.9–9.9	8.1
≥10	23.5

The fetus continues to experience the effects of hyperglycemia beyond the period of organogenesis. Whereas glucose crosses the placenta, insulin does not. This leads to increased fetal production of insulin to compensate for its hyperglycemic environment.

Insulin and insulin-like growth factors promote excessive fetal growth, which may result in macrosomia. Macrosomia, variously defined as a birth weight of more than 4000 g or more than 4500 g, is a risk factor for both maternal and fetal morbidity. Maternal risks include caesarean delivery, vaginal laceration, and postpartum hemorrhage. Shoulder dystocia with resultant birth injury, in particular Erb's palsy, is the most feared fetal complication.

There is a disproportionate increase in subcutaneous fat and visceromegaly in macrosomic infants of diabetic mothers, which results in a relatively large abdominal circumference with normal head and skeletal growth. This abnormal growth dynamic appears to predispose these infants to shoulder dystocia. In the presence of maternal diabetes, birth weights of greater than 4500 g have been associated with rates of shoulder dystocia of up to 50% in some studies.

In addition, fetal hyperinsulinemia leads to enlargement of internal organs such as the heart. Ventricular septal hypertrophy may, in rare cases, lead to cardiac failure as a result of left ventricular outflow obstruction.

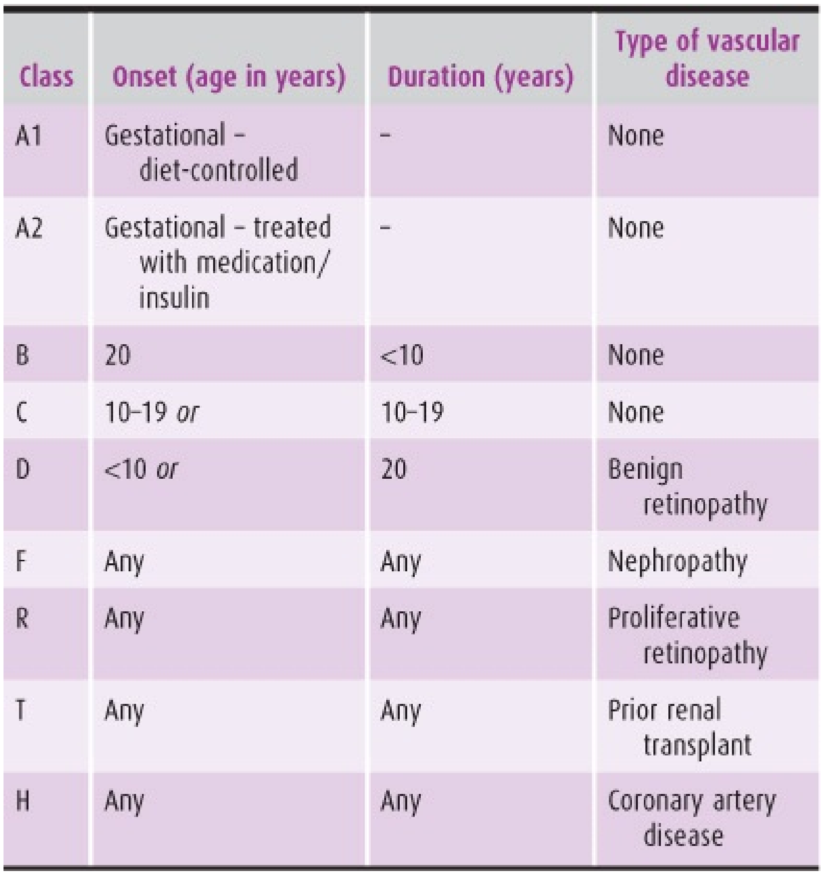
CLASSIFICATION OF DIABETES

The American Diabetes Association (ADA) classifies diabetes mellitus into 4 clinical types:

1. Type 1 diabetes, formerly referred to as insulin-dependent or juvenile-onset diabetes
2. Type 2 diabetes, formerly referred to as non–insulin-dependent or adult-onset diabetes
3. Other specific types of diabetes related to a variety of genetic-, drug-, or chemical-induced diabetes
4. Gestational diabetes

The first 3 categories typically refer to pregestational diabetes or diabetes that has been diagnosed prior to the onset of pregnancy. The severity of pregestational diabetes can be classified according to the White classification system (Table 31–3). This system categorizes diabetes by duration of disease and the presence of end-organ damage, which has prognostic implications for outcomes of women with diabetes mellitus during pregnancy.

Table 31–3. Modified White classification of diabetes complicating pregnancy.



Class	Onset (age in years)	Duration (years)	Type of vascular disease
A1	Gestational – diet-controlled	–	None
A2	Gestational – treated with medication/ insulin	–	None
B	20	<10	None
C	10–19 *or*	10–19	None
D	<10 *or*	20	Benign retinopathy
F	Any	Any	Nephropathy
R	Any	Any	Proliferative retinopathy
T	Any	Any	Prior renal transplant
H	Any	Any	Coronary artery disease

PREGESTATIONAL DIABETES

ESSENTIALS OF DIAGNOSIS

- Abnormal maternal glucose tolerance precedes pregnancy.
- Associated with increased risk of adverse maternal and fetal outcomes including fetal structural malformations.
- Risk of complications correlates with degree of glycemic control.

Pathogenesis

A. Type 1 Diabetes

Type 1 diabetes mellitus, formerly called insulin-dependent diabetes, results from autoimmune destruction of beta cells in the islets of the pancreas, usually leading to an absolute insulin deficiency. Type 1 diabetes accounts for approximately 5–10% of patients with preexisting disease. Although onset generally occurs in the young, type 1 disease can appear in older persons and may occasionally present for the first time during pregnancy.

Type 1 diabetes has multiple identified genetic predispositions. Susceptibility is increased by a gene or genes located near or within the human leukocyte antigen (HLA) locus on the short arm of chromosome 6 (6p). The risk to offspring of developing type 1 with an affected sibling is 5% if 1 haplotype is shared, 13% for 2 haplotypes, and 2% if no haplotypes are shared. If both parents are affected, the risk of the condition is 33%. It is believed that an environmental agent triggers the disease in genetically susceptible individuals. The exact nature of the trigger is, as yet, unknown.

In rare cases, type 1 diabetes is not associated with evidence of autoimmunity and is termed “idiopathic diabetes.” Patients with this form of the disorder suffer from episodic attacks of ketoacidosis. They may have an absolute insulin deficiency only during these attacks.

B. Type 2 Diabetes

Type 2 diabetes mellitus, formerly non–insulin-dependent diabetes, is characterized both by insulin resistance and by beta cell dysfunction. This form of the disorder accounts for 90–95% of all patients with diabetes.

Type 2 diabetes is a multifactorial illness that is influenced by heredity, environment, and lifestyle choices. It is typically gradual in onset and may go undiagnosed for many years. Ketoacidosis is rare in this setting. The majority of affected patients are obese.

Although several genes have been associated with the disorder, progression to frank disease can be modified by factors such as diet and exercise. With type 2 diabetes, the risk of diabetes in a first-degree relative is almost 15%, and approximately 30% more will have impaired glucose tolerance. If both parents are affected, the incidence of diabetes in the offspring is 60–75%, although lifestyle modification can decrease the risk.

Clinical Findings

Profound thirst, increased urination, and weight loss or even overt ketoacidosis are the usual symptoms prompting medical evaluation. According to the ADA, there are 4 ways of diagnosing diabetes in nonpregnant patients:

1. Symptoms of diabetes plus random plasma glucose concentration ≥200 mg/dL. The classic symptoms of diabetes include polyuria, polydipsia, and unexplained weight loss.
2. Fasting plasma glucose ≥126 mg/dL. Fasting is defined as no caloric intake for at least 8 hours.
3. Two-hour plasma glucose level ≥200 mg/dL during an oral glucose tolerance test (OGTT). The test uses a glucose load containing the equivalent of 75 g of anhydrous glucose dissolved in water.
4. HbA1c ≥6.5% using a standardized assay.

In the absence of unequivocal hyperglycemia, these criteria should be confirmed by repeat testing on a different day.

Complications

In the case of preexisting disease, poor periconceptional glucose control is associated with an increased risk of spontaneous abortion and fetal malformations. Later in gestation, poor glycemic control may result in intrauterine fetal demise.

Maternal hyperglycemia causes an overproduction of fetal insulin and insulin-like growth factors, which may lead to macrosomia and its attendant risks including operative delivery, shoulder dystocia, and birth injury. Conversely, in diabetic mothers with vascular disease, intrauterine growth restriction may occur.

Neonatal complications in infants of diabetic mothers may include respiratory distress syndrome

(RDS), hypoglycemia, hypocalcemia, and hyperbilirubinemia. Additionally, these children may be more likely to develop diabetes and obesity in the long term. The fetus responds to maternal hyperglycemia with pancreatic hyperplasia and increased basal insulin secretion, which are associated with a lifetime increased risk of diabetes. Mothers with diabetes during pregnancy have offspring with higher rates of diabetes at age 20–24 years than do women who develop diabetes after the pregnancy (45% vs. 8.6%). This observation suggests that the hyperglycemia during pregnancy had an effect beyond the mother’s genetic tendency.

Pregnant women with diabetes are also at increased risk of complications including preeclampsia, preterm delivery, and, in the case of type 1 disease, diabetic ketoacidosis.

Treatment

Prevention of hyperglycemia through rigorous control of blood glucose level is the mainstay of treatment in the pregnant woman with pregestational diabetes. This is best accomplished by careful preconceptional counseling and achievement of normal HbA1c levels before pregnancy in pregestational diabetics, frequent (usually 4–5 times per day) home glucose level monitoring, adjustment of diet, and regular exercise.

Non–weight-bearing or low-impact exercise can be initiated or continued. Even short episodes of exercise will sensitize the patient’s response to insulin for approximately 24 hours. All care providers should stress the importance of diet. Soluble fiber provides satiety and improves both the number of insulin receptors and their sensitivity. Carbohydrate restriction improves glycemic control and may enable a patient to achieve her glycemic goals using diet and activity. Calories are prescribed at 25–35 kcal/kg of actual body weight, generally 1800–2400 kcal/d. Diet should be approximately 40% carbohydrate, 40% fat, and 20% protein usually divided into 3 meals and 2 or 3 snacks per day. A bedtime snack is particularly important to prevent nocturnal hypoglycemia. When postprandial values exceed the targets, it is important to review all recent food intake and to adjust food choice, preparation, and portion size.

Self-monitoring of fasting, 1- or 2-hour postprandial, and nighttime blood glucose levels using a glucose meter provides instant feedback to assess the patient’s diet and behavior. When the glycemic goals are met, the feedback is a powerful motivator. Diet and/or activity errors are identified and corrected as needed. Optimal glucose levels during pregnancy are fasting levels of 70–95 mg/dL and 1-hour postprandial values <130–140 mg/dL or 2-hour postprandial values <120 mg/dL.

A minimum of 2 visits to a dietitian improves education and active participation regarding diet. Food records are useful. The dietitian reviews content and calories and suggests how to include favorite ethnic foods to improve compliance. Other family members should be encouraged to participate in the dietary education because their understanding and support increase the chance for a successful diet. Often, the other family members will benefit from the healthful diet changes. Additional follow-up visits between patient and dietitian are important when glycemic goals are not reached, weight change is too great or too small, or the patient is having difficulty maintaining the diet.

When normoglycemia cannot be achieved with diet and exercise alone, medication is added. Although not endorsed by either the American College of Obstetricians and Gynecologists or the ADA, oral hypoglycemic agents such as glyburide and metformin are commonly employed.

Glyburide, a sulfonylurea, is variously categorized as either pregnancy class B or C. It is believed to cross the placenta in only minimal amounts, and studies to date have demonstrated generally favorable results when compared to insulin. Glyburide is commenced at doses of 2.5–5 mg/d and titrated upward to a maximum of 20 mg/d to achieve optimal blood glucose control.

Metformin, a biguanide that suppresses hepatic glucose production and increases insulin sensitivity, has been used for many years as a first-line agent in nonpregnant patients with type 2 diabetes. It is pregnancy category B but is known to cross the placenta and is therefore usually avoided in the first trimester. Studies to date have shown metformin to be a safe and effective treatment for diabetes in pregnancy, although in a randomized controlled trial comparing treatment with metformin to treatment with glyburide, significantly more patients in the metformin group required the addition of insulin in order to achieve euglycemia.

Due to its extensive safety record, insulin remains the first-line treatment of diabetes in pregnancy for many obstetricians. Daily doses of 0.7 U/kg in the first trimester increasing progressively to 1 U/kg later in gestation are commonly employed, although obese women may require significantly higher amounts. Doses are usually divided into basal coverage with intermediate-acting agents such as NPH (neutral protamine Hagedorn) and prandial coverage with rapid-acting or regular insulin. Subcutaneous insulin pumps may also be considered in selected patients.

Preconception Care

Patients with preexisting diabetes should be encouraged to see a physician for care prior to conception. Preconceptional care has been shown to result in improved pregnancy outcomes. Evaluation at the preconceptional visit includes the following:

1. A complete history and physical examination. To provide a risk assessment, a comprehensive review of the patient’s history should be performed. Any teratogenic medications such as angiotensin-converting enzyme inhibitors should be discontinued, and prenatal vitamins containing a minimum of 0.4 mg of folic acid should be prescribed.
2. An assessment of glycemic control. Adjustments in medications, diet, and exercise can be made to optimize glycemic control. The goal is to achieve an HbA1c of <7% to minimize the risks of spontaneous abortion and congenital anomalies.
3. An eye examination for retinopathy. Patients with retinopathy should be followed carefully for evidence of progression. If needed, laser therapy can be performed during gestation.
4. An assessment of renal function. Renal function is assessed with a serum creatinine level and a 24-hour urine collection or urinary albumin/creatinine ratio to measure protein excretion. Patients with overt nephropathy should be advised of the risks of pregnancy complications, which include worsening renal function, preeclampsia, fetal growth restriction, and preterm delivery.
5. An assessment of thyroid function. Thyroid function should be assessed, particularly in type 1 diabetics, because of the association between autoimmune thyroid disease and diabetes. In addition patients with longstanding diabetes or hypertension may be screened for ischemic heart disease with an electrocardiogram.

Antenatal Care

After confirmation of pregnancy, patients should have regular antenatal care to assess glycemic control. Evaluation is by self-monitoring of blood glucose, and treatment is adjusted accordingly.

In the first trimester, an ultrasound may be obtained to document viability, particularly if glycemic control is suboptimal. Routine antenatal laboratory evaluations should be undertaken. A urine culture is particularly important because diabetic patients are at increased risk of asymptomatic bacteriuria.

In the second trimester, a fetal ultrasound for anatomy is recommended given the risk of fetal anomalies. Fetal echocardiography is indicated in patients with preexisting diabetes to screen for congenital heart disease.

In the third trimester, further ultrasounds are indicated to assess fetal growth. This also applies to patients who have received a diagnosis of gestational diabetes. In addition, in light of the increased risks of fetal demise, surveillance of fetal well-being is commenced, usually at 32–34 weeks of gestation. This consists of twice weekly nonstress testing or a modified biophysical profile twice weekly. Maternal fetal movement monitoring ("kick counts") using a count to 10 or similar method is recommended for all pregnant women, including those with diabetes, to reduce the stillbirth rate.

Timing of delivery involves balancing the risks of delivery, in particular prematurity and RDS, with the risks of expectant management, namely stillbirth. When fetal assessment is not reassuring, the mature fetus should be delivered. In such cases near term, amniocentesis to obtain amniotic fluid for pulmonary maturity may be helpful. If the fetus is mature, delivery may proceed. If the fetus is immature, then a decision must be made in which the risk of fetal jeopardy is balanced against the risks of preterm birth. Participation of the patient, her partner, and the neonatology and perinatology departments may facilitate a plan.

In the absence of a clear indication for delivery, such as the development of preeclampsia, assessment of fetal lung maturity is recommended for elective delivery prior to 39 weeks. In patients with GDM or preexisting diabetes who require insulin or oral medications to maintain euglycemia, expectant management beyond the due date is generally not recommended.

Preterm labor is more frequent among patients with diabetes. The main goal of tocolysis is to delay delivery so that glucocorticoid therapy to accelerate fetal lung maturation can be administered over 48 hours. Magnesium sulfate tocolysis is widely used. Nifedipine is a reasonable alternative. Beta-adrenergic mimetics such as terbutaline should be avoided if possible because these drugs may cause severe hyperglycemia and, rarely, ketoacidosis. Because glucocorticoids also cause hyperglycemia, a continuous intravenous infusion of insulin may be necessary to maintain normal glucose levels.

Maternal diabetes is not an indication for caesarean section in and of itself; however, if macrosomia coexists, the risk of shoulder dystocia is greatly increased. Therefore, the American College of Obstetricians and Gynecologists recommends that elective caesarean be considered in this setting, in particular if the estimated fetal weight is >4500 g.

SEVERE HYPERGLYCEMIA & KETOACIDOSIS

The metabolic changes that result in decreased insulin sensitivity during pregnancy also make severe hyperglycemia and ketoacidosis more common. Presenting symptoms of ketoacidosis are similar to the nonpregnant patient and include nausea, vomiting, dehydration, abdominal pain, and confusion. Abnormal laboratory findings include an anion gap metabolic acidosis (arterial pH <7.3), low serum bicarbonate (<15 mEq/L), hyperglycemia, and elevated serum ketones. Management is essentially the same in pregnant and nonpregnant patients and consists of insulin therapy, careful monitoring of potassium level, and fluid replacement. Attention should also be paid to fetal well-being, but diabetic ketoacidosis is not an indication for delivery, because although fetal heart rate monitoring often demonstrates nonreassuring patterns initially, these usually improve as maternal ketoacidosis is corrected.

Intrapartum Management

The goal of intrapartum management is to avoid maternal hyperglycemia and thus minimize the risk of neonatal hypoglycemia after delivery.

Glucose infusion is provided to all patients in labor as 5% dextrose in lactated Ringer's solution or a similar crystalloid. The rate usually is 125 mL/h (providing 6.25 g of glucose per hour) unless the patient requires more. Intravenous fluid bolus prior to conduction anesthesia should not contain glucose.

A bedside glucose monitor can be used to monitor glucose levels every 2–4 hours in early labor and every 1–2 hours in active labor. Patients requiring insulin may receive a continuous infusion of regular insulin, often prepared as 25 U in 250 mL of saline (0.1 U/mL) according to the institution's protocol for intravenous insulin. Most patients require approximately 0.5–2.0 U/h, although rates are adjusted based on the capillary glucose level.

Cervical ripening for induction of labor, if indicated, is conducted in the same manner as for nondiabetic parturients. Continuous electronic fetal monitoring is used. In diabetic pregnancies, the fetus's ability to tolerate the stress of labor may be limited. Fetal heart rate abnormalities should be evaluated with acoustic or scalp stimulation or fetal oxygen saturation monitoring. If fetal well-being cannot be demonstrated, expeditious delivery, often by caesarean section, is indicated. If fetal macrosomia is suspected, operative vaginal delivery should be considered with great caution, if at all. The infant of the diabetic is at increased risk for shoulder dystocia, and this should be anticipated with adequate personnel, obstetric anesthesia, and neonatal resuscitation available at delivery.

If a repeat caesarean delivery or other elective surgery is planned, it should be scheduled for early morning, if possible. The patient should take her evening insulin or oral hypoglycemic dose on the preceding night, but the morning dose should be held. The morning of surgery, the glucose level is monitored and basal insulin needs usually are treated with continuous intravenous insulin to maintain blood glucose between 70 and 120 mg/dL.

Postpartum Care

Postpartum, the patient should start back on an ADA diet as soon as clinically indicated. Insulin sensitivity increases markedly postpartum. In patients with GDM, blood glucose should normalize after delivery. In pregestational patients, as a rule of thumb, insulin doses can be reduced to approximately half the pregnancy dose. Close monitoring of blood glucose should be continued, particularly in the setting of type 1 disease. If the patient underwent surgery, a sliding scale may be implemented until oral intake can be established. The glucose levels should be kept below 140–150 mg/dL to assist the patient in healing. Breastfeeding is strongly encouraged and may be protective against development of childhood diabetes in the infant. Postfeed hypoglycemia can be avoided by increasing caloric intake in the form of snacks.

Contraception

Contraceptive options for diabetic women without vascular complications are the same as for nondiabetic women. In women with an increased risk for embolism, hormonal contraception containing estrogen is not recommended, but progesterone-only methods, including the levonorgestrel intrauterine system, can be offered. Permanent sterilization should be made available to women with diabetes who have completed childbearing.

Prognosis

The prognosis for women with pregestational diabetes is generally not altered by pregnancy. A small percentage of women with end-organ damage related to diabetes prior to pregnancy may experience worsening of their disease. Women with moderate to severe diabetic nephropathy prior to pregnancy (defined as serum creatinine of ≥1.9 mg/dL) are at increased risk of permanent decline in renal function with pregnancy. Approximately 10% of women meeting these criteria progressed to end-stage renal disease. Similarly, diabetic retinopathy worsens in some women during pregnancy. The strict glycemic control achieved during pregnancy is associated with worsening proliferative retinopathy. Laser therapy, however, is an effective treatment of retinopathy and is safe during pregnancy.

GESTATIONAL DIABETES MELLITUS

ESSENTIALS OF DIAGNOSIS

- GDM has been traditionally defined as any degree of glucose intolerance with onset or first recognition during pregnancy.
- The hallmark of GDM is insulin resistance.
- GDM is associated with an increased risk of maternal and fetal/neonatal complications.

Pathogenesis

Approximately 7% of pregnancies are affected by GDM, ranging from 1–14%, depending on the population studied and the diagnostic criteria employed. However, prevalence of the disease is expected to continue to rise as a result of the increasing prevalence of risk factors such as obesity in the gravid population.

The hallmark of GDM is insulin resistance, and as such, it is etiologically similar to type 2 diabetes. Indeed, many patients with a diagnosis of GDM that is made early in gestation may in fact have glucose intolerance that antecedes the pregnancy. Likewise, it is known that as many as 50% of patients with GDM will ultimately go on to develop type 2 diabetes later in life. In recognition of this, the International Association of Diabetes and Pregnancy Study Groups (IADPSG) recently recommended that high-risk women found to have diabetes by standard criteria early in pregnancy be classified as having “overt” rather than “gestational” diabetes.

GDM and type II diabetes are pathogenetically related. In fact, GDM can be considered to be type 2 disease that is unmasked by the metabolic changes of pregnancy. Therefore, it is not surprising that the risk factors for both conditions are similar and include obesity, family history, minority ethnicity, and older age.

The progressive insulin resistance that occurs in normal pregnancies is associated with an increase in insulin release by the beta cells of the pancreas in order to maintain glucose homeostasis. Women with GDM exhibit more insulin resistance than normal patients, which is a function of their prepregnancy metabolic state. GDM becomes manifest when the beta cells are unable to overcome the decreased insulin sensitivity and hyperglycemia results.

Women with GDM continue to demonstrate postpartum defects in insulin action. These defects include the regulations of glucose clearance, glucose production, and plasma-free fatty acid concentrations, together with defects in pancreatic beta cell function, which precede the development of type 2 diabetes.

Clinical Findings

Despite decades of research, the optimal approach to screening and diagnosis of GDM has remained the subject of much controversy. Risk assessment for GDM is performed at the first prenatal visit in all women who do not already have diagnosed diabetes. Women at high risk should undergo screening with plasma glucose as soon as feasible. High-risk characteristics include the following:

1. Age >35–40 years
2. Obesity (nonpregnant body mass index [BMI] >30)
3. Prior history of GDM
4. Heavy glycosuria (>2+ on dipstick)
5. History of unexplained stillbirth
6. Polycystic ovarian syndrome
7. Strong family history of diabetes

If results of testing do not demonstrate diabetes, these women should be retested between 24 and 28 weeks’ gestation.

In the past, universal plasma screening was recommended for all women. However, it is acceptable to forgo this in women deemed to be of low risk. A low-risk individual meets all of the following criteria:

1. Age <25 years
2. Not a member of an ethnic group at increased risk (ie, not Hispanic American, African American, Native American, Asian American, or Pacific Islander)
3. BMI ≤325
4. No previous history of abnormal glucose tolerance
5. No previous history of adverse obstetric outcome
6. No known diabetes in a first-degree relative

However, when these criteria are applied, only 10% of the population will be exempt from screening; therefore, many obstetricians believe it is more practical to administer a plasma glucose screen in all pregnant women.

Currently, both the American College of Obstetricians and Gynecologists and the ADA advocate a 2-step approach to screening. Step 1 consists of a 1-hour 50-g oral glucose challenge test (GCT), which is administered between 24 and 28 weeks of gestation. The GCT can be performed at any time of day and without regard to time of prior meal. If this screening test is positive, it is followed by the diagnostic test, a 3-hour 100-g OGTT.

The correct threshold for an abnormal result for the GCT has not been definitively defined. The original blood glucose value for an abnormal screen (>140 mg/dL) was chosen arbitrarily and later validated by its ability to predict future development of diabetes in the mother and not by any correlation with adverse pregnancy outcome. In fact, the blood glucose threshold above which adverse outcomes begin to increase has never been established. The recent Hyperglycemia and Adverse Pregnancy Outcome (HAPO) study addressed this issue and found that no discrete threshold exists. Instead, there is a continuous relationship between blood glucose levels and adverse outcome. This study confirmed that even in women who did not meet the criteria for a diagnosis of GDM, the risk of complications increased in proportion to an increase in blood glucose.

At the blood glucose threshold of 140 mg/dL, 80% of patients with GDM will be detected, but approximately 15% of all patients screened will require further definitive testing. Lowering the threshold from 140 to 130 mg/dL, as many experts advocate, would result in a detection rate of 90%, but would result in false-positive screens in many more women. In patients whose screening result is >200 mg/dL, a diagnosis of GDM can be made without further testing.

Diagnostic testing is usually accomplished by administration of a 3-hour 100-g OGTT after an overnight fast. Two different classification schemes of results are employed, which were adapted from the original O’Sullivan and Mahar whole blood values. There is no clear advantage to one scheme over the other. A diagnosis of GDM is made when 2 or more thresholds are met or exceeded. However, morbidity is increased with even a single abnormal value, and therefore, many physicians advocate initiation of dietary therapy in this scenario.

Outside of the United States, a 1-step approach to testing using a 2-hour 75-g oral glucose load is widely used. In 2010, following publication of the findings of the HAPO study, the IADPSG proposed that this 1 -step approach replace the current screening and diagnostic tests. Based on the recommendations of the IADPSG, the diagnosis of GDM can be made if there is 1 or more abnormal value on the 75-g OGTT. Thresholds for both the 100-g and 75-g OGTT are listed in Table 31–4.

Table 31–4. Diagnostic criteria for gestational diabetes mellitus.

	100-g GTT Plasma/Serum Level (mg/dL) (Carpenter/Coustan)	100-g GTT Plasma Level (mg/dL) (National Diabetes Data Group)	75-g GTT Plasma Level (mg/dL) (IADPSG)
Fasting	95	105	92
1-hour	180	190	180
2-hour	155	165	153
3-hour	140	145	–

GTT, glucose tolerance test; IADPSG, International Association of Diabetes and Pregnancy Study Groups.

Complications

Similar to pregestational diabetes, GDM is associated with an increased risk of maternal and fetal complications including preeclampsia, stillbirth, and macrosomia. Infants born to mothers with gestational diabetes are at increased risk of hypoglycemia, hyperbilirubinemia, hypocalcemia, and RDS.

GDM may also be associated with long-term health consequences for the fetus. Offspring of mothers with GDM appear to be at increased risk of obesity and impaired glucose tolerance later in life.

Unlike offspring of women with pregestational diabetes, fetuses of women with true GDM are not at increased risk of fetal structural malformation.

Treatment

Treatment of women with GDM focuses on achieving rigorous control of blood glucose level and thus minimizing the risk of maternal and fetal complications. At time of diagnosis, dietary counseling is provided, and patients are prescribed a 1800–2400 kcal/d diabetic diet. Diet should be approximately 40% carbohydrate, 40% fat, and 20% protein usually divided into 3 meals and 2 or 3 snacks per day.

Patients are advised to initiate home glucose monitoring of fasting, 1- or 2-hour postprandial, and nighttime blood glucose levels using a glucose meter. Optimal glucose levels during pregnancy are fasting levels of 70–95 mg/dL and 1-hour postprandial values <130–140 mg/dL or 2-hour postprandial values <120 mg/dL. When postprandial values exceed the targets, it is important to review all recent food intake and to adjust food choice, preparation, and portion size. When normoglycemia cannot be achieved with diet and exercise alone, medication is added.

As with pregestational diabetes, treatment of GDM that has failed treatment with dietary modification alone typically starts with insulin as first-line therapy. However, a number of studies have demonstrated that oral hypoglycemics such as glyburide and metformin are efficacious at achieving glycemic control with a favorable safety profile for the fetus. Glyburide, a sulfonylurea, is variously categorized as either pregnancy class B or C. It is believed to cross the placenta in only minimal amounts, and studies to date have demonstrated generally favorable results when compared to insulin. Glyburide is commenced at doses of 2.5–5 mg/d and titrated upward to a maximum of 20 mg/d to achieve optimal blood glucose control.

Antenatal Care

Women with GDM that is well controlled by diet alone usually do not require antenatal fetal testing. In the setting of excellent glycemic control achieved by diet alone, fetal surveillance with nonstress testing or biophysical profiles may be initiated at 40 weeks. However, for women who require medication for control of their blood sugars, who are noncompliant, or who have GDM that is not well controlled, earlier initiation of fetal surveillance and ultrasound assessment of fetal growth are advised.

Intrapartum Management

As with women with pregestational diabetes, the goal of intrapartum management of women with GDM is to avoid maternal hyperglycemia and thus minimize the risk of neonatal hypoglycemia after delivery.

Glucose infusion is provided to all patients in labor as 5% dextrose in lactated Ringer’s solution or a similar crystalloid. The rate usually is 125 mL/h (providing 6.25 g of glucose per hour) unless the patient requires more. Intravenous fluid bolus prior to conduction anesthesia should not contain glucose.

A bedside glucose monitor can be used to monitor glucose levels every 2–4 hours in early labor and every 1–2 hours in active labor. Patients requiring insulin may receive a continuous infusion of regular insulin, often prepared as 25 U in 250 mL saline (0.1 U/mL) according to the institution’s protocol for intravenous insulin. Most patients require approximately 0.5–2.0 U/h, although rates are adjusted based on the capillary glucose level.

Cervical ripening for induction of labor, if indicated, is conducted in the same manner as for nondiabetic parturients. Continuous electronic fetal monitoring is used. If fetal well-being cannot be demonstrated, expeditious delivery, often by caesarean section, is indicated. If fetal macrosomia is suspected, operative vaginal delivery should be considered with great caution, if at all. The infant of the diabetic is at increased risk for shoulder dystocia, and this should be anticipated with adequate personnel, obstetric anesthesia, and neonatal resuscitation available at delivery.

If a repeat caesarean delivery or other elective surgery is planned, it should be scheduled for early morning, if possible. The patient should take her evening insulin or oral hypoglycemic dose on the preceding night, but the morning dose should be held. The morning of surgery, glucose level is monitored and basal insulin needs usually are treated with continuous intravenous insulin to maintain blood glucose between 70 and 120 mg/dL.

Postpartum Care

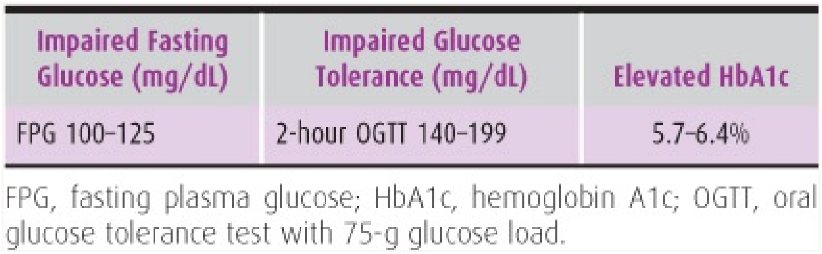
Because GDM resolves with delivery of the fetus and placenta, routine postpartum care in the immediate postpartum period is sufficient. For the patient with true GDM, all medications for blood sugar control are discontinued after delivery, as is blood glucose monitoring.

Prognosis

Women diagnosed with GDM are at increased risk to develop type 2 diabetes in the future. They have about a 50% risk of developing the disease within 10–15 years. Lifestyle modification may delay or entirely prevent the onset of diabetes in adults with impaired glucose tolerance, and therefore, counseling of a patient with GDM should include a discussion of the long-term prevention of progression to nongestational diabetes.

All patients with GDM should have a 2-hour, 75-g OGTT approximately 6 weeks postpartum. Those with normal glucose tolerance should be reassessed every 3 years. Those with impaired glucose tolerance or impaired fasting glucose should be reevaluated annually (Table 31–5).

Table 31–5. Categories of increased risk for diabetes.



Impaired Fasting Glucose (mg/dL)	Impaired Glucose Tolerance (mg/dL)	Elevated HbA1c
FPG 100–125	2-hour OGTT 140–199	5.7–6.4%

FPG, fasting plasma glucose; HbA1c, hemoglobin A1c; OGTT, oral glucose tolerance test with 75-g glucose load.

All women should be encouraged to eliminate or reduce any other risk factors (in addition to glucose intolerance) for cardiovascular disease. In practice, this means referral to programs, as needed, to cease smoking and to avoid environmental smoke; to engage in regular physical activity; to consume an appropriate diet; to achieve and maintain a normal weight; and to be treated for individual cardiovascular disease risk factors.

Thyroid & Other Endocrine Disorders During Pregnancy

Cynthia Gyamfi Bannerman, MD

THYROID DISORDERS

Thyroid diseases are among the most common endocrine disorders encountered during pregnancy. They are challenging both because of pregnancy-related changes in thyroid physiology that make diagnosis of thyroid disorders difficult and because of the limited number of medications used to treat mother and fetus. Screening for subclinical thyroid disorders remains a highly debated topic.

THYROID FUNCTION DURING NORMAL PREGNANCY

The thyroid, a gland that functions to provide thermal and metabolic regulation, develops from the third week in gestation from the primitive pharynx. The gland then migrates to the neck and starts to produce thyroid hormone by 10–12 weeks' gestation.

Maternal thyroid physiology is altered during normal pregnancy. There is glandular hyperplasia with thyroid enlargement. Thyroid volume is increased on ultrasound examination, but the echostructure is unchanged. The normal increase in the renal glomerular filtration rate causes an increase in urinary iodide clearance, necessitating increased intake of dietary iodine in order to make and maintain thyroid hormone concentrations. Both total thyroxine (T_4) and triiodothyronine (T_3) levels increase because the level of their carrier, thyroxine-binding globulin (TBG), becomes elevated. Estrogen causes increased TBG synthesis with decreased TBG clearance. Because of the similar subunits of chorionic gonadotropin and thyrotropin (thyroid-stimulating hormone [TSH]), crossover between these 2 peptides can lead to an increase in free thyroxine (fT_4) in the first trimester. The TSH level is lowest and fT_4 level highest when human chorionic gonadotropin (hCG) levels peak. Elevated fT_4 causes suppression of TSH, which, in turn, causes barely detectable levels of maternal thyrotropin-releasing hormone (TRH). Overall, the demand for T_4 increases by an estimated 1–3% above daily nonpregnant needs. The increased demand starts very early, reaching a plateau at 16–20 weeks. These normal physiologic changes make diagnosis of thyroid disease during pregnancy difficult.

Studies from animal models have helped to elucidate the role of maternal T_4 in the fetus. T_3 is made by conversion of maternal T_4. It has been demonstrated that if maternal T_4 is low, fetal T_3 levels in the brain will be low even in the presence of normal maternal and fetal serum T_3, suggesting that both T_3 and T_4 in the fetal brain are maternal T_4 dependent. Further evidence of a maternal source of T_3 in the fetal brain is that by midgestation, fetal concentration of T_3 is 34% of adult levels. This is much higher than would be expected considering the low circulating fetal serum levels. It is during midgestation that initial growth velocity of the fetal brain occurs, and animal data suggest that the thyroid hormone necessary for this development is primarily maternally derived. Toward the end of the first trimester, the fetal hypothalamic–pituitary–thyroid axis becomes active. By 14 weeks' gestation, fetal production of T_4 is detectable. Normal thyroid hormones levels in the fetus and newborn are crucial for subsequent brain maturation and intellectual development.

HYPERTHYROIDISM

ESSENTIALS OF DIAGNOSIS

- Elevated free T_4 and T_3 levels; suppressed TSH levels
- Signs and symptoms of hyperthyroidism include heat intolerance, fatigue, anxiety, diaphoresis, tachycardia, and a widened pulse pressure

---

Pathogenesis

The prevalence of hyperthyroidism (also known as thyrotoxicosis) during pregnancy ranges from 0.05 to 0.2%. The most common cause of hyperthyroidism during pregnancy is Graves' disease. Graves' disease is caused by thyroid-stimulating antibody (TSAb) belonging to the immunoglobulin (Ig) G class, which binds with high affinity to the TSH receptor. TSAb may cross the placenta, bind to fetal TSH receptors, and cause fetal or neonatal hyperthyroidism. However, the placenta acts as a partial barrier, so usually only those with high titers are likely to be affected. Other causes of hyperthyroidism include thyroiditis, thyroid adenoma, and multinodular goiter.

Clinical Findings

The signs and symptoms of hyperthyroidism—heat intolerance, fatigue, anxiety, diaphoresis, tachycardia, and a widened pulse pressure—can all be found during normal pregnancy. Signs specific to hyperthyroidism would be pulse >100 bpm, goiter, and exophthalmos, but these may not be present. Gastrointestinal symptoms such as severe nausea and vomiting may also be present, but these can be related to β-hCG elevations. Laboratory tests will confirm elevated T_4, fT_4, T_3, and free T_3 (fT_3) levels and a suppressed or undetectable TSH level. TSAb titers will be elevated in a significant number of patients. Other laboratory findings may include a normocytic, normochromic anemia, mild neutropenia, and elevated liver enzymes.

Subclinical hyperthyroidism, a condition resulting from suppressed levels of TSH and normal levels of T_4 and T_3, is also seen in pregnancy. It was determined that 1.7% of screened women had subclinical disease. There is no effect of subclinical hyperthyroidism in pregnancy, so screening and treatment for this entity are not warranted.

Complications

The most common complication of hyperthyroidism in pregnancy is preeclampsia. With large amounts of trans-placental transfer of thyroid-stimulating immunoglobulins, thyrotoxicosis could develop in the fetus or newborn. Fetal hypothyroidism may also result from overadministration of thioamides. Poorly controlled hyperthyroidism has also been associated with an increased risk of miscarriage, pre-term labor, and low-birth-weight infants.

Thyroid storm is a life-threatening complication of women with hyperthyroidism that may result in heart failure if untreated. This complication developed in 8% of women with thyrotoxicosis. Classic findings of thyroid storm include thermoregulatory dysfunction; central nervous system (CNS) effects including agitation, delirium, and coma; gastrointestinal dysfunction; and cardiovascular manifestations such as tachycardia or heart failure. This can be precipitated by labor and delivery, caesarean delivery, infection, or preeclampsia. T_4-induced cardiomyopathy, however, is reversible.

Treatment

Treatment during pregnancy almost always consists of antithyroid medications. Surgery is performed in exceptional situations, such as allergic reactions to all drugs available or lack of response to very large doses (“drug resistance”), which in most cases has been the result of noncompliance. The goals of treatment are to rapidly achieve and maintain euthyroidism with the minimum but effective amount of medication, provide symptomatic relief, and keep fT_4 levels in the upper third of normal.

Thionamides are the most commonly prescribed class of medication used for the treatment of hyperthyroidism. The medications available are propylthiouracil (PTU) and methimazole. Both drugs work by blocking thyroid hormone synthesis; however, PTU also blocks peripheral conversion of T_4 to T_3. Some physicians prefer PTU, but reports of large numbers of patients indicate that the 2 drugs are equally effective and have similar side effects. PTU is shorter acting, meaning more pills are required more often; therefore, methimazole may be preferable when compliance is a problem. The initial methimazole dose is 20–40 mg/d, and the initial PTU dose is 200–400 mg/d. The dose is gradually reduced as improvement occurs. Most women can be effectively treated on an outpatient basis; however, hospitalization may be considered in severe, uncontrolled cases in the third trimester because of increased risk for complications. Women who have remained euthyroid while taking small amounts of PTU (≤100 mg/d) or methimazole (≤10 mg/d) for 4 weeks or longer can stop taking the medication altogether by 32–34 weeks’ gestation under close surveillance. The purpose is to minimize the risk of fetal/neonatal hypothyroidism, which is otherwise uncommon with PTU doses ≤200 mg/d or methimazole ≤20 mg/d. The therapy is resumed if symptoms recur. Women with large goiters, long-standing hyperthyroidism, or significant eye involvement should remain on treatment throughout pregnancy. Other potential side effects of antithyroid medications are pruritus, skin rash, urticaria, fever, arthralgias, cholestatic jaundice, lupus-like syndrome, and migratory polyarthritis. Leukopenia may be a medication effect but is also seen in untreated Graves’ disease; therefore, a white blood cell (WBC) count should be obtained before treatment is started. Agranulocytosis is the most severe complication, but fortunately, it is uncommon and found in only 0.1% of patients. Treatment prior to pregnancy is preferred to treatment during pregnancy because outcomes tend to be better. Recently, methimazole has become the treatment of choice for hyperthyroidism in pregnancy. This is because PTU has been found to cause irreversible liver damage, leading potentially to liver failure.

β-Blockers (propranolol 20–40 mg every 6–8 hours) can be used for symptomatic relief in severe cases but only for short periods (few weeks) and before 34–36 weeks’ gestation. They inhibit conversion from T_4 to T_3 but may be related to intrauterine growth restriction and hypoglycemia if used for prolonged periods of time.

Treatment of thyroid storm is aimed at reducing synthesis of thyroid hormone, minimizing release of thyroid hormone from the thyroid gland, and blocking peripheral effects of thyroid hormone. Aggressive treatment for thyroid storm is critical to the patient’s survival. PTU or methimazole is started immediately and may be administered via nasogastric tube if the patient has altered mental status. Iodine solution such as potassium iodide (SSKI) or Lugol’s solution may also be given. Iodine solution works by inhibiting thyroid hormone release. If the patient has a history of iodine-induced anaphylaxis, then lithium carbonate is given instead. Fluid hydration and nutritional support are also important. β-Blockers are also given for relief of symptoms such as tachycardia and palpitations, and they may also inhibit peripheral conversion of T_4 to T_3. Glucocorticoids may also be used in severe cases to reduce peripheral conversion of T_4 to T_3. Aspirin should be avoided in these patients because it can increase concentrations of fT_4 and T_3.

Prognosis

The maternal and fetal prognosis with hyperthyroidism in pregnancy that is well controlled is generally excellent.

A. Effect of Hyperthyroidism on Pregnancy

Potential complications of hyperthyroidism in the mother include spontaneous abortion, pregnancy-induced hypertension, preterm delivery, anemia, higher susceptibility to infections, placental abruption, and, in severe, untreated cases, cardiac arrhythmias, congestive heart failure, and thyroid storm. In the fetus, possible complications include fetal and neonatal hyperthyroidism, intrauterine growth restriction, stillbirth, prematurity, and morbidity related to antithyroid medications. Most maternal and neonatal complications are seen in cases of uncontrolled or untreated hyperthyroidism.

Approximately 1–5% of infants born to women with Graves' disease have hyperthyroidism at birth due to trans-placental transfer of TSAbs. The fetal/neonatal risk correlates with maternal TSAb titer level. Signs of fetal hyperthyroidism include fetal tachycardia (heart rate >160 bpm), fetal goiter, and poor growth. High levels of fetal thyroid hormone detected by cordocentesis have been confirmed in a few cases. Tests of fetal well-being are recommended for poorly controlled cases and for patients with high TSAb titers, even if they are euthyroid. Serial ultrasounds are useful for dating and fetal growth evaluation.

Breastfeeding is allowed if the total daily dose of PTU is ≤150 mg or daily dose of methimazole is ≤10 mg. The medication should be given immediately after each feeding and the infant monitored periodically.

B. Effect of Pregnancy on Hyperthyroidism

Pregnancy is not thought to alter the course of hyperthyroidism.

TRANSIENT HYPERTHYROIDISM OF HYPEREMESIS GRAVIDARUM

ESSENTIALS OF DIAGNOSIS

- Severe nausea and vomiting accompanied by weight loss
- Low serum TSH with mildly elevated fT_4

Pathogenesis

Biochemical hyperthyroidism is seen in most women (66%) with hyperemesis gravidarum. The most likely etiology is thyrotropin receptor stimulation from high serum concentrations of hCG.

Clinical Findings

Laboratory abnormalities include low serum TSH and mildly elevated fT_4. Serum T_3 levels are not elevated in women with transient hyperthyroidism of hyperemesis gravidarum. The degree of thyroid function abnormalities correlates with the severity of vomiting.

Differential Diagnosis

Women in early pregnancy with weight loss, tachycardia, vomiting, and laboratory evidence of hyperthyroidism may be difficult to differentiate from early, true thyrotoxicosis. Women with transient hyperthyroidism of hyperemesis gravidarum have no previous history of thyroid disease, no palpable goiter, and, except for tachycardia, no other symptoms or signs of hyperthyroidism. Test results for thyroid antibodies are negative. With transient hyperthyroidism of hyperemesis gravidarum, TSH level may be suppressed and fT_4 level elevated, but the T_3 level is lower than in true hyperthyroidism. With true hyperthyroidism, both levels are usually elevated.

Treatment

Treatment is symptomatic, and antithyroid medication is not recommended.

Prognosis

The mild hyperthyroidism associated with transient hyperthyroidism of hyperemesis gravidarum usually resolves by 20 weeks' gestation. The time to resolution is widely variable (1–10 weeks).

HYPOTHYROIDISM

ESSENTIALS OF DIAGNOSIS

- Elevated TSH and low free T_4 levels
- Symptoms: modest weight gain, fatigue, sleepiness, lethargy, decreased exercise capacity, depression, and cold intolerance (very unusual in normal pregnancy)

Pathogenesis

Overt hypothyroidism (elevated TSH, low free T_4) has been reported in 1 in 1000 to 1 in 2000 deliveries. A study by Casey and colleagues found that the incidence of overt hypothyroidism in pregnant women was 1.8 per 1000. Subclinical hypothyroidism (elevated TSH, normal fT_4) is more common, with an incidence of 23 per 1000 in pregnancy. This makes the overall incidence of hypothyroidism 2.5%.

The most common cause of hypothyroidism is Hashimoto's thyroiditis, which is found in 8–10% of women of reproductive age. Less common causes are transient hypothyroidism in silent (painless) and subacute thyroiditis, drug induced, high-dose external neck radiation, congenital hypothyroidism, inherited metabolic disorders, and thyroid hormone resistance syndromes. Secondary hypothyroidism may occur in pituitary or hypothalamic disease. Drugs that may cause hypothyroidism by interfering with thyroid hormone synthesis and/or its release include antithyroid drugs (PTU, methimazole), iodine, and lithium. Increased T_4 clearance is caused by carbamazepine, phenytoin, and rifampin. Amiodarone decreases T_4 to T_3 conversion and inhibition of T_3 action. Interference with intestinal absorption is seen with aluminum hydroxide, cholestyramine, ferrous sulfate, calcium, vitamins, soy, and sucralfate. Many pregnant women take ferrous sulfate, and it is important to ensure that T_4 is taken at least 2 hours before (sometimes even 4 hours is recommended) because insoluble ferric–T_4 complexes may form, resulting in reduced T_4 absorption.

Clinical Findings

The clinical diagnosis is difficult and frequently unsuspected except in advanced cases. Symptoms are insidious and may be masked by the hypermetabolic state of pregnancy. Symptoms include modest weight gain, fatigue, sleepiness, lethargy, decreased exercise capacity, depression, and cold intolerance (very unusual in normal pregnancy). Signs include general slowing of speech and movements, dry and pale or yellowish skin, sparse thin hair, hoarseness, bradycardia (also unusual in pregnancy), myxedema, hyporeflexia, prolonged relaxation of reflexes, carpal tunnel syndrome, and a diffuse or a nodular goiter.

The best laboratory test is the TSH level; current sensitive assays allow very early diagnosis and accurate treatment monitoring. Other useful tests include fT_4 and antibody titers. A low fT_4 with an elevated TSH is diagnostic of hypothyroidism. A macrocytic or normochromic, normocytic anemia may be present as well. It usually results from decreased erythropoiesis, but it may result from vitamin B_{12}, folic acid, or iron deficiency. Levels of lipids and creatine phosphokinase (of muscle origin) may be elevated. Hypothyroidism may be seen more commonly in women with type 1 diabetes.

Complications

A. Effect of Hypothyroidism on Pregnancy

Some studies have reported a 2-fold increased rate of spontaneous abortion in women with elevated levels of thyroid antibodies, even if they are euthyroid, but this finding is not universally confirmed. These antibodies (antiperoxidase [TPO], antimicrosomal antibody [AMA], and antithyroglobulin [ATG]) may cross the placenta and cause neonatal hypothyroidism, which, if untreated, may lead to serious cognitive deficiencies. Lower IQs in infants of even very mildly hypothyroid women have been reported. There is an increased risk of preeclampsia, placental abruption, intrauterine growth restriction, prematurity, and intrauterine fetal demise. The severity of the hypertension and other perinatal complications is greater in the more severely hypothyroid woman. Early treatment and close monitoring to ensure euthyroidism will prevent or decrease perinatal complications.

B. Effect of Pregnancy on Hypothyroidism

Pregnancy is known to cause increasing requirement of thyroid hormone. That is the reason for evaluation of maternal TSH levels every trimester, with more frequent evaluation every 4 weeks if changes to dosing are deemed necessary. Requirements usually return to prepregnancy levels postpartum, and dosing can also be adjusted on a monthly schedule after that time.

Treatment

L-Thyroxine has long been the treatment drug of choice. The hormonal content of the synthetic drugs is more reliably standardized, and they have replaced desiccated thyroid as the mainstay of therapy. Administration of T_4 alone is recommended. In the normal physiologic process, T_4 is deiodinated to T_3 in the extrathyroidal tissues. In addition, during early pregnancy, the fetal brain is unable to use maternal T_3. The best time to take L-thyroxine is early in the morning, on an empty stomach. Women experiencing nausea and vomiting should be allowed to take it later in the day until they improve. Numerous reports indicate that T_4 requirements increase during pregnancy. TSH levels should be checked every 4 weeks, with adjustments made until the TSH is at the lower end of the normal range. The initial dose should be 2 μg/kg of actual body weight. Further adjustments are made according to the TSH level. If the TSH level is elevated but <10 μU/mL, add 25–50 μg/d; if the TSH level is >10 but <20, add 50–75 μg/d; and if the TSH level is >20, add 75–100 μg/d. Changes made at less than 4-week intervals may lead to overtreatment. Up to 85% of women receiving T_4 replacement before pregnancy will require higher doses while they are pregnant. The levels should be checked early in pregnancy and then every trimester to maintain euthyroidism. After delivery, the dosage is reduced to the prepregnancy amount, and the TSH level is measured 4–8 weeks postpartum. In women with pituitary disease, the TSH level cannot be used to guide therapy. In these cases, the fT_4 level should be kept in the upper third of normal.

SUBCLINICAL HYPOTHYROIDISM

ESSENTIALS OF DIAGNOSIS

- Elevated serum TSH with normal fT_4 levels

Pathogenesis

Subclinical hypothyroidism is a condition characterized by an elevated TSH with a normal fT_4. The incidence of this finding is approximately 2.5% in pregnant women and 5% in women of reproductive age. The causes of sub-clinical hypothyroidism are thought to be the same as overt hypothyroidism.

Clinical Findings

Subclinical hypothyroidism is diagnosed when woman are found to have elevations in TSH and normal fT_4 levels. Women are asymptomatic for thyroid disease.

Complications

The interest in subclinical hypothyroidism and intellectual development in offspring was reignited after several recent publications addressed a possible relationship between the two. Haddow and colleagues performed a study comparing pregnant women with hypothyroidism to pregnant controls with normal thyroid function. They found that children of women with hypothyroidism scored 4 points lower on a standard IQ test when compared to controls $(P = 0.06)$. In addition, 15% of cases had an IQ score of 85 or less compared to 5% of controls $(P = 0.08)$. Although neither of these values is statistically significant, when the results were sub-analyzed for those women with untreated hypothyroidism, as opposed to those on medication, they found that the IQ scores were 7 points lower in cases than controls $(P = 0.005)$, and 19% had IQ scores <85 compared with 5% of controls $(P = 0.007)$, suggesting that the greater effect on pediatric neurodevelopment is in the untreated mothers with hypothyroidism. Pop and colleagues had similar results when they studied pediatric neurodevelopment at 10, 12, and 24 months in children of mothers with abnormal thyroid function at 12 weeks' gestation. Note that neither of these studies evaluated infants of women with subclinical hypothyroidism. Haddow evaluated infants of mothers with overt hypothyroidism, whereas Pop evaluated infants of women with hypothyroxinemia, thought to be the more clinically relevant deficiency.

The discrepancy in findings from these 2 studies has led to conflicting position statements regarding the surveillance for hypothyroidism in pregnant women from the American Association of Clinical Endocrinologists, the American Thyroid Association, the Endocrine Society, and the American College of Obstetricians and Gynecologists (ACOG). Current obstetric practice does not involve screening for thyroid disease unless the patient has risk factors, such as pregestational diabetes, or is symptomatic. The most recent joint position statement of the 3 previously mentioned endocrine societies recommends routine TSH evaluation (with fT_4 if TSH is abnormal) both preconceptionally or as soon as pregnancy has been diagnosed. However, ACOG does not support the performance of thyroid function tests in asymptomatic pregnant women. ACOG advises that the current data are limited because of their observational nature. To date, there has not been a clinical trial that specifically addresses isolated subclinical hypothyroidism and neurodevelopmental outcomes, making recommendations regarding the management of this mild thyroid dysfunction difficult. Furthermore, the available clinical literature has not shown that the identification and treatment of women with subclinical hypothyroidism prevents the purported neurodevelopmental sequelae. The National Institute of Child Health and Human Development Maternal-Fetal Medicine Units network is currently conducting a clinical trial to help answer these questions.

Certain pregnant women are at high risk for hypothyroidism and should undergo screening, including those with previous therapy for hyperthyroidism, high-dose neck irradiation, previous postpartum thyroiditis, presence of a goiter, family history of thyroid disease, treatment with amiodarone, suspected hypopituitarism, and type 1 diabetes mellitus.

Treatment

ACOG does not advocate routine screening and treatment for subclinical hypothyroidism at this time.

CONGENITAL HYPOTHYROIDISM

ESSENTIALS OF DIAGNOSIS

- Elevated serum TSH and low T_3 and T_4 in the neonate

Pathogenesis

Congenital hypothyroidism is found in 1 in 4000 to 1 in 7000 infants after diagnosis from national screening programs. Congenital hypothyroidism is defined as hypothyroidism in the neonate. Most cases of congenital hypothyroidism are sporadic, resulting from thyroid dysgenesis. However, approximately 15% appear to be hereditary, mostly due to an inborn error in thyroid hormone synthesis. Early and aggressive treatment is critical to improve neonatal outcomes.

Transient congenital hypothyroidism has been described in a number of settings, including iodine deficiency and in utero exposure to antithyroid drugs.

Clinical Findings

Low serum T_4 and high serum TSH levels in the neonate confirm a diagnosis of congenital hypothyroidism. Most neonates are asymptomatic at birth, mainly because some maternal T_4 crosses the placenta. Signs that may present over time include lethargy, slow movement, hoarse cry, poor feeding, and constipation.

Complications

The first report of a possible correlation between thyroid disease and mental retardation in offspring came from iodine-deficient areas of Switzerland in 1915. Mothers of children with mental retardation were noted to have abnormal thyroid function. Choufoer and colleagues then described the effect of maternal thyroid levels on the newborn in 1965. They described pregnancy outcomes related to endemic goiter in iodine-deficient New Guinea. They found neurologic manifestations of cretinism, or physical stunting and mental retardation, in women who were not clinically hypothyroid, but who had a low concentration of thyroid hormone. In this same decade, Man and Jones evaluated a cohort of 1349 children of mothers with hypothyroxinemia, defined in that time as a low serum butanol-extractable with a normal thyroid-binding globulin. They found an association between low BEI and low infant Bayley scores on mental and motor development. The Bayley Scales of Infant Development were designed to test the cognitive, motor, and behavioral development of infants up to 42 months of age. The test has high validity and reliability. These and other observations of maternal thyroid disease led to the landmark double-blind study by Pharoah and colleagues in 1971. They gave alternate families in New Guinea either 4-mL injections of iodized oil or a saline placebo and then returned a year later to initiate periodic evaluation of any offspring delivered after treatment. They concluded that supplementation of iodine in pregnancy prevented subsequent cretinism.

Treatment

Oral thyroid supplementation, usually T_4, is the treatment for congenital hypothyroidism. Treatment is usually starting when screening tests for congenital hypothyroidism return as positive without waiting for result of confirmatory tests.

Prognosis

With early diagnosis and initiation of treatment, long-term outcomes are excellent, with normal growth and development.

POSTPARTUM THYROIDITIS

ESSENTIALS OF DIAGNOSIS

- Postpartum thyroiditis is diagnosed if the serum TSH is either elevated or depressed in the year after delivery.
- This phenomenon has been noted in 5–10% of women in their first postpartum year.
- Women with high thyroid autoantibodies are generally affected, and women with type 1 diabetes are at high risk to develop this complication.

Clinical Findings

The symptoms involve fatigue, palpitations, heat intolerance, and nervousness. There are 2 distinct clinical phases. The first phase lasts from 1–4 months after delivery and is characterized by destruction-induced thyrotoxicosis. Laboratory findings during this phase demonstrate an elevation in free T_4 and suppressed TSH. There is an abrupt onset, and a goiter may be palpable. Approximately two-thirds of these women will become euthyroid. Between 4 and 8 months, the other third will develop hypothyroidism.

Treatment

T_4 replacement is helpful, but about 30% of women will go on to develop permanent hypothyroidism. The clinical course may vary, with some patients experiencing only the hyperthyroid phase and others only the hypothyroid phase. Treatment in the immediate postpartum period is limited to symptomatic patients only (β-blockers for the hyperthyroid phase and low-dose levothyroxine or T_3 for the hypothyroid phase, which is enough to alleviate symptoms and allows recovery of thyroid function when discontinued). Additionally, there is a positive correlation between postpartum depression and postpartum thyroiditis, so these patients should be screened accordingly.

SOLITARY THYROID NODULE DURING PREGNANCY

ESSENTIALS OF DIAGNOSIS

- Thyroid nodule palpable on physical examination

Clinical Findings

Thyroid nodules are frequently first detected during pregnancy when many women see a doctor for the first time. The risk of malignancy for a solitary nodule varies between 5% and 43%, depending on various factors including previous radiation, rate of growth, and patient age.

Treatment

Women with a thyroid nodule diagnosed during pregnancy should undergo fine-needle aspiration of the nodule. Thyroid radionuclide scanning is contraindicated during pregnancy. Women with benign nodules may be followed; in most cases, surgery in these women is deferred until after delivery.

Women with thyroid cancer should undergo surgery. Surgery during pregnancy carries a higher risk if it is performed during the first and the third trimesters (miscarriage, premature delivery, and fetal death); surgery during the second trimester reportedly has a lower complication rate. Radioactive iodine should never be given during pregnancy. There is no evidence that thyroid cancer occurs more frequently during pregnancy. However, because of the indolent course of these carcinomas, many practitioners advocate postponing surgery until the postpartum period.

OTHER ENDOCRINE DISORDERS

HYPERPARATHYROIDISM

ESSENTIALS OF DIAGNOSIS

- Elevated serum parathyroid hormone (PTH) and calcium levels

---

Pathogenesis

Hyperparathyroidism is a frequently occurring disease but has been uncommonly reported to occur during pregnancy. Just over 120 cases have been reported since 1931, with the first successful surgery performed in 1947. Hyperparathyroidism peaks in incidence from the third to fifth decades; however, it is rare in pregnancy, with an incidence of 0.8%. The PTH level remains unchanged during the first half of pregnancy and then rises gradually until term, coinciding with the time of greatest fetal skeletal calcification. PTH promotes calcium (Ca) transport from mother to fetus. The most potent factor affecting PTH secretion is the free Ca level (inverse correlation), but calcitonin, vitamin D, and magnesium also play a role. Calcitonin is secreted by C cells inside the thyroid, but these cells actually are of neural crest origin and migrate to the thyroid. Calcitonin is a Ca-lowering hormone whose secretion is also mainly affected by free Ca levels, but in this case, the correlation is direct. Its action is antagonistic to that of PTH, and it plays a role in Ca homeostasis and bone remodeling. Vitamin D increases the efficiency of intestinal Ca absorption, plays a role in the maintenance of Ca and phosphorus levels, and has a role in the mineralization of bone matrix. In order to exert its action, vitamin D must be transformed into active metabolites [$1,25\text{-(OH)}_2D_3$] in the kidney, and PTH is needed for the process. Hyperparathyroidism is characterized by hypercalcemia, which is a result of elevated PTH. Most patients are asymptomatic, but those with symptoms generally will have nausea, vomiting, renal colic, muscular weakness, mental symptoms, and polyuria.

Whether Ca metabolism during pregnancy is influenced by other hormones, such as estrogen, progesterone, or hCG, is not known. The placenta plays a major role in transporting Ca against a gradient. PTH facilitates this transport, although neither PTH nor calcitonin crosses the placenta. The fetal Ca concentration (both total and free) increases gradually from 5.5 to 11.0 mg/dL from the second trimester to term. In the fetus, the PTH level is suppressed but detectable, and cord levels are 25% lower than in the mother. Calcitonin in cord is higher than in the mother, a combination favoring skeletal growth, which also causes Ca levels in the newborn to fall to normal. Given these findings, all the observed changes in normal pregnancy favor mineralization of the fetal skeleton.

During pregnancy, the etiology of hyperparathyroidism is an adenoma in 89–90% of cases, hyperplasia (of all the glands) in 9%, and carcinoma in 1–2%. The latter should be suspected in severe hyperparathyroidism, particularly if a palpable neck mass is present (palpable neck masses are reported in <5% of parathyroid adenomas). Rarely, it occurs in a familial pattern with or without other endocrine abnormalities (eg, multiple endocrine adenomatosis). Other causes of hypercalcemia during pregnancy are uncommon and include vitamin D toxicity, sarcoidosis, various malignancies, milk-alkali syndrome, thyrotoxicosis, adrenal insufficiency, and secondary hyperparathyroidism in those undergoing chronic hemodialysis or after renal transplantation.

Clinical Findings

The most common presentation of hyperparathyroidism is asymptomatic elevation in serum Ca level. If patients are symptomatic, it is usually related to the hypercalcemia, which may manifest with neuropsychiatric disturbances such as depression and anxiety, constipation, nausea, renal stones, and/or polyuria. Serum intact PTH levels are elevated in most patients with hyperparathyroidism. A diagnosis of hyperparathyroidism can be confirmed with elevated urinary Ca excretion levels.

Differential Diagnosis

Because hyperparathyroidism can be primary (from elevated PTH) or secondary (generally from a cancer-secreting PTH), the differential diagnosis includes a thorough search for malignancy.

Complications

Reported complications include 27.5% fetal mortality and 19% neonatal tetany. Neonatal hypocalcemia is often the initial clue to the presence of maternal hyperparathyroidism. The condition occurs because the high levels of maternal Ca inhibit the activity or the proper development of the infant’s parathyroid glands. It develops between days 2 and 14 after delivery, depending on the severity of the maternal hyper-calcemia, and usually resolves with appropriate therapy. One case of hypocalcemia persisting for 3 months and another case of hypocalcemia that became permanent have been reported.

Complications in the mother include 36% nephrolithiasis, 19% bone disease, 13% pancreatitis, 13% urinary tract infections and pyelonephritis, 10% hypertension (100% in all cases of carcinoma thus far reported), and 8% hypercalcemic crisis. Maternal deaths have occurred among those with complications of pancreatitis or hypercalcemic crisis. Women who developed hypercalcemic crisis had a 30% maternal death rate and 40% fetal demises. Pancreatitis is reported in only 1.5% of nonpregnant hyperparathyroid patients and in <1% of normal pregnancies. Most pregnant women with hyperparathyroidism (76%) are symptomatic, whereas 50–80% of nonpregnant hyperparathyroid patients are asymptomatic at the time of diagnosis.

Treatment

Treatment of these women involves diuresis with normal saline to increase urine output. Furosemide can be given to block tubular Ca reabsorption. Potassium and magnesium need to be replaced. Additionally, mithramycin can be given to inhibit bone resorption, calcitonin can be given to decrease skeletal release of Ca, and oral phosphorus will lower Ca levels. However, surgery is the treatment of choice for confirmed hyperparathyroidism. In pregnancy, the optimal time for surgery is the second trimester, when the complication risks (abortion or premature labor) are reduced. An experienced surgeon performing the neck exploration will be able to proceed appropriately in case of parathyroid hyperplasia (removal of all glands with parathyroid tissue transplantation); experience helps to lower the complication. Postoperatively, hypocalcemia may occur in patients with significant osteitis fibrosa or if injury occurs to the normal parathyroid glands during surgery. When surgery is not possible, maintaining adequate hydration and administering oral phosphates may be temporary measures until surgery can be safely performed. Preventing hypercalcemic crisis is of utmost importance; if it develops, aggressive treatment is recommended.

Prognosis

Because of Ca shunting to the fetus, pregnancy may improve hyperparathyroidism. Surgical treatment confers the best prognosis, but medical management is a good temporizing measure.

HYPOPARATHYROIDISM

ESSENTIALS OF DIAGNOSIS

- Low PTH, hypocalcemia, and hyperphosphatemia in the setting of normal renal function
- Clinical signs: dry, scaly skin; brittle nails; coarse hair; and positive Chvostek’s (present in 10% of normals) and Trousseau’s signs

---

Pathogenesis

The most common cause of hypoparathyroidism is surgical removal or damage to the parathyroid glands, or their vascular supply, during thyroid surgery. Idiopathic hypoparathyroidism s relatively rare and is seldom seen in pregnancy. It may be isolated or occur in association with agenesis of the thymus or as part of a familial disorder, which includes deficiencies of thyroid, adrenal, and ovarian function; pernicious anemia; and mucocutaneous candidiasis. Pseudohypoparathyroidism (deficient end-organ response to PTH in bone and kidney) is a rare hereditary disorder infrequently encountered during pregnancy. The severity of symptoms depends on the degree of hypocalcemia, and symptoms range from clumsiness (fingers), mental changes (mainly depression), muscle stiffness, parkinsonism, and acral and perioral paresthesias to laryngeal stridor, tetany, and convulsions.

Clinical Findings

Clinical signs include dry, scaly skin; brittle nails; coarse hair; and positive Chvostek's (present in 10% of normals) and Trousseau's signs. Ectopic soft tissue calcifications and a prolonged QT interval on the electrocardiogram may be observed. Pseudohypoparathyroidism is more likely if the patient has unusual skeletal or developmental defects and if other family members are affected. The diagnosis usually is evident from the history and confirmed by a "normal" or low PTH level in the presence of hypocalcemia, hyperphosphatemia, and normal renal function.

Complications

After delivery, hypoparathyroid women may develop hypercalcemia with the same dose of Ca and vitamin D that was effective during pregnancy. Hypersensitivity to vitamin D in lactating women may result from the effect of prolactin on 1α-hydroxylase vitamin D activity. Serum Ca levels should be monitored closely and the doses readjusted as necessary. Vitamin D travels into breast milk, even when low doses are taken, so many physicians discourage breastfeeding in these women.

Treatment

From 1–4 g/d of elemental Ca and 50,000–100,000 U/d of vitamin D usually are recommended. The synthetic vitamin D analogue $1\ \alpha,25\text{-(OH)}_2D_3$ at doses of 0.25–2 2μ/d is considered safer by some authors.

Prognosis

Before the availability of specific therapy, maternal morbidity and mortality rates were high, and termination of pregnancy was frequently recommended. Currently, the prognosis is much improved provided the mother is kept eucalcemic.

ADRENAL DISORDERS

Pregnancy is rarely associated with diseases of the adrenal glands, particularly in those with excessive cortisol secretion, because of the high prevalence of infertility in these women.

CUSHING'S SYNDROME

ESSENTIALS OF DIAGNOSIS

- Signs of glucocorticoid excess, including striae, obesity, hypertension, and glucose intolerance
- Elevated serum and urinary cortisol levels

Pathogenesis

Cushing's syndrome is an unusual diagnosis made during pregnancy because up to 75–80% of women with excess cortisol experience menstrual irregularities and infertility. Excess cortisol, either endogenous or exogenous, suppresses gonadotropin secretion. Cushing's syndrome is usually due to an adrenocorticotropic hormone (ACTH)–producing pituitary tumor (Cushing's disease), ectopic ACTH secretion by a nonpituitary tumor, or cortisol secretion by an adrenal adenoma or carcinoma, although the most common cause of Cushing's syndrome is exogenous corticosteroid treatment.

Cushing’s disease, bilateral adrenal hyperplasia, is precipitated by corticotropin-producing pituitary adenomas, most of which are microadenomas. About 25% of Cushing’s syndrome will be corticotropin independent and caused by an adrenal adenoma.

Clinical Findings

The clinical diagnosis is difficult because the changes occur insidiously. During pregnancy, the diagnosis is even more difficult because weight gain, skin striae (stretch marks), and fatigue are common during normal pregnancy, but all other symptoms and signs will be the same as outside of pregnancy and include hypertension, hirsutism, and glucose intolerance among many others. The laboratory diagnosis also is more difficult during pregnancy. Urinary free cortisol excretion may overlap with that seen in some cases of Cushing’s syndrome, and the suppression to exogenous corticosteroids may be incomplete. However, the diurnal variations of both ACTH and cortisol are preserved; therefore, measurement of morning and evening cortisol levels remains very useful. Therefore, the diagnosis may be confirmed by the loss of diurnal variation; elevated levels of urinary free cortisol, particularly if >250 mg per 24 hours; and lack of cortisol suppression to dexamethasone. Measurements of ACTH may be useful as well (“normal” or high in Cushing’s disease and suppressed in adrenal tumors). Magnetic resonance imaging (MRI) may confirm the presence of a pituitary or adrenal tumor. A few cases of “pregnancy-induced” Cushing’s syndrome with spontaneous resolution postpartum have been reported and attributed to a placental corticotropin-releasing factor. However, long-term follow-up revealed other causes of Cushing’s syndrome in most of the women.

Complications

The most common complication (64%) is preterm labor, resulting in considerable fetal morbidity and mortality. Intrauterine growth restriction occurs in 26–37% and fetal losses (spontaneous abortions and stillbirths) in 16%. Little information about the long-term quality of survival of those born premature but alive is available. Hypertension and diabetes mellitus complicate 70% and 32% of these pregnancies, respectively, and unfavorably influence the outcome of these pregnancies if untreated. Maternal mortality has occurred in 5% of cases.

Treatment

An attempt at some form of treatment is advocated given the poor outcome. Surgery in the second trimester can be attempted when a pituitary or adrenal tumor is found. Few reports of these procedures performed during pregnancy are documented. Medical therapy is limited, and the potential side effects of the medications are not well known. Metyrapone, cyproheptadine, aminoglutethimide, and ketoconazole (teratogenic in animals) have been used in a few patients. All efforts should be made to control the hypertension and hyperglycemia that are so commonly seen with excess cortisol. Early delivery in the third trimester as soon as the fetus is mature is recommended, with postponement of definitive treatment of the mother until after delivery.

ADRENAL INSUFFICIENCY (ADDISON’S DISEASE)

ESSENTIALS OF DIAGNOSIS

- Symptoms include weakness, fatigue, nausea and vomiting, and weight loss
- Low serum cortisol levels

Pathogenesis

Primary adrenocortical insufficiency (Addison's disease) often is the result of autoimmune destruction of the adrenal glands (in the era before antibiotics, tuberculosis was the most common cause). More than 90% of the gland has to be destroyed for symptoms to develop. Occasionally, it is associated with other autoimmune endocrine disorders (polyendocrine autoimmune deficiency) such as diabetes, Graves' disease, or Hashimoto's thyroiditis. Secondary adrenal failure results from reduced or absent ACTH secretion caused by various pituitary disorders or inhibition from chronic exogenous steroid use. Causes of partial or complete anterior pituitary insufficiency in women of reproductive age include tumors, pituitary surgery or radiation, and postpartum infarction (Sheehan's syndrome). Less common causes are acute pituitary hemorrhage, infiltration by granulomatous diseases, thalassemia, necrosis from increased intracranial pressure, and lymphocytic hypophysitis. A few cases of pituitary necrosis in pregnant type 1 diabetic women have been reported.

Clinical Findings

Symptoms include weakness, fatigue, nausea and vomiting, and weight loss. On laboratory testing, the patient is found to have low cortisol levels.

Treatment

Since the advent of steroid treatment, most pregnancies have been successfully managed. Even women with anterior pituitary insufficiency may conceive because of advances in infertility treatment and, with proper hormonal replacement, may carry their pregnancies to term. Infants of well-treated mothers with adrenal insufficiency appear to be normal. The daily steroid replacement dose is 20–25 mg/m^2 by mouth (ie, 30–37.5 mg/d of hydrocortisone or equivalent steroid). Two-thirds of the daily dose (20–25 mg) is given in the morning and one-third (10–12.5 mg) in the late afternoon. Usually the daily dosage does not need to be changed during pregnancy. However, compensation is required for periods of stress and during labor and delivery (up to 300 mg of hydrocortisone or equivalent steroid given intravenously in divided doses the first day and gradual tapering to the maintenance dose over the next several days). In secondary adrenal insufficiency, mineralocorticoid replacement is not necessary, but women with primary adrenal disease also should receive fludrocortisone 0.05–0.1 mg/d by mouth.

CONGENITAL ADRENAL HYPERPLASIA

ESSENTIALS OF DIAGNOSIS

- ▶ The most common cause is 21-hydroxylase deficiency.
- ▶ Elevated serum 17-hydroxyprogesterone is seen.
- ▶ Clinical signs include virilization, hirsutism, and menstrual irregularities. Neonates affected by congenital adrenal hyperplasia may present with ambiguous genitalia.

Pathogenesis

Congenital adrenal hyperplasia can be caused by a number of different genetic defects in enzymes involved in cortisol synthesis. These enzymatic deficiencies are inherited as autosomal recessive traits (25% risk of inheriting the condition and 50% of being a carrier). Of the several inherited enzymatic deficiencies of cortisol synthesis that may cause congenital adrenal hyperplasia, the 21-hydroxylase deficiency accounts for 90–95% of cases. In fact, 21-hydroxylase deficiency is one of the most common inherited genetic disorders.

Clinical Findings

Congenital adrenal hyperplasia is typically a diagnosis made in infancy via neonatal screening. Physical signs include virilization and ambiguous genitalia. Affected individuals may have salt wasting. Later in life, women may experience acne, accelerated bone age, hirsutism, and menstrual irregularity. The diagnosis of classic 21-hydroxylase deficiency is made based on high serum concentrations of 17-hydroxyprogesterone. Patients with nonclassic 21-hydroxylase deficiency may have only mild elevations in 17-hydroxyprogesterone yet will have very high values after ACTH stimulation test.

If both parents are known to carry a gene associated with autosomal recessive inheritance of congenital adrenal hyperplasia, prenatal diagnosis is available via chorionic villus sampling or amniocentesis to determine whether the fetus is affected.

Complications

Complications vary depending on whether the mother or the fetus (or both) carry a diagnosis of congenital adrenal hyperplasia. When the fetus is affected, the low cortisol level stimulates excessive ACTH secretion, which in turn causes adrenal enlargement, or hyperplasia. The excessive secretion of androgens leads to masculinization of the external genitalia (congenital sexual ambiguity) and the low cortisol level to adrenal insufficiency. Untreated, these conditions can be life threatening.

In many cases, the diagnosis is made and treatment initiated after birth when the newborn becomes ill. However, prenatal diagnosis (chorionic villous sampling and DNA testing) now is commonplace when both parents are known to be carriers of a mutation associated with congenital adrenal hyperplasia.

Treatment

If the fetus is found to have 21-hydroxylase deficiency and the fetus is female, treatment of the mother with dexamethasone may prevent the development of adrenal hyperplasia and virilization of the external genitalia. The sex of the fetus can be determined by chorionic villous sampling, so early treatment can be initiated. Those born with virilization of the external genitalia will require surgical reconstruction to allow vaginal intercourse.

In affected females, the earlier the treatment is initiated, the higher the likelihood that they will be ovulatory and fertile. During pregnancy, glucocorticoid therapy should be continued and adjusted to avoid excessive androgen levels. Otherwise the steroid management is the same as described for adrenal insufficiency. Genetic counseling should be mandatory for these women, before they consider pregnancy, given the high risk of transmission and the severity of the disease.

If the mother is known to be affected by congenital adrenal hyperplasia, her regimen of glucocorticoid will likely require an increase in dose during pregnancy to maintain levels within the normal range for pregnancy. Additionally, a glucocorticoid that is metabolized by the placenta such as hydrocortisone is suggested to minimize excessive glucocorticoid exposure to the fetus.

PHEOCHROMOCYTOMA

ESSENTIALS OF DIAGNOSIS

- Hypertension with headache and diaphoresis
- Elevated catecholamines and metanephrines on 24-hour urine tests

---

Pathogenesis

Pheochromocytomas are rare in the general population, but they are a potentially lethal cause of hypertension during pregnancy. They are catecholamine-secreting tumors of the adrenal medulla. However, given the severity of the complications (48% maternal mortality and 55% fetal mortality) if untreated, the possibility of its existence must always be considered in the differential diagnosis.

Clinical Findings

The symptoms are similar to those outside of pregnancy and are caused by excess catecholamines. They include sustained or labile hypertension, headaches, palpitations, diaphoresis, and anxiety. Blurred vision and convulsions are reported more commonly during pregnancy. Elevated levels of free catecholamines and their metabolites meta-nephrine and vanillylmandelic acid in a 24-hour urine collection confirm the diagnosis. Urinary metanephrine levels >1.2 mg/d are considered highly suggestive of pheochromocytoma. A plasma level of total catecholamines >2000 pg/mL, drawn after the patient has been in the supine position for >30 minutes, also is highly suggestive. For tumor localization, MRI is the test of choice during pregnancy. Most pheochromocytomas are benign and are located in the adrenal glands, but approximately 10% are located elsewhere and difficult to find, and approximately 12% are malignant. In a few patients, the pheochromocytoma may be part of a familial disorder and more likely to be bilateral.

Differential Diagnosis

Differentiation from preeclampsia may be difficult when proteinuria is also present.

Complications

Complications include spontaneous abortion, intrauterine growth restriction, placental abruption, and fetal and maternal death.

Treatment

Few of the reported cases were diagnosed during pregnancy. However, if the diagnosis is made, surgical removal during the second trimester is recommended. Blood pressure control is attempted first with adequate adrenergic blockade (usually phenoxybenzamine), followed by β-adrenergic blockade if necessary, until surgery can be performed in the second trimester or, if after 26–28 weeks, until the fetus is mature. Phenoxybenzamine is considered safe, but it does cross the placenta and has the potential to cause depression and transient hypotension in the newborn. The dose should be started at 10 mg twice daily and increased by 10–20 mg daily until hypertension is controlled. Vaginal delivery is not recommended because of precipitation of hypertensive crisis by mechanical pressure on the tumor from changes in posture, contractions, and fetal movements.

PITUITARY DISORDERS

PROLACTINOMAS

ESSENTIALS OF DIAGNOSIS

- Elevated serum prolactin concentration
- MRI of the head confirming a microadenoma (<10 mm) or macroadenoma (≥10 mm)

Pathogenesis

Prolactinomas are the most common pituitary tumors encountered during pregnancy, particularly since the availability of effective treatments for restoring fertility. They generally arise as lactotroph adenomas from monoclonal expansion of a single cell that has undergone a mutation. Most cases of prolactinomas are sporadic, but they have also been described as a clinical feature of multiple endocrine neoplasia type 1 (MEN1).

Clinical Findings

The most common symptoms include amenorrhea, galactorrhea, and hyperprolactinemia. Bromocriptine has been used successfully to prevent amenorrhea, and thus, many women have had successful pregnancies. The diagnosis usually is made when the prolactin level is high enough to cause galactorrhea, oligomenorrhea, or amenorrhea. MRI confirms the diagnosis. The tumors are divided into microadenomas (<10 mm) or macroadenomas (≥10 mm). The risk of growth during pregnancy is low (1–2%) for microadenomas, in contrast to the 15–25% risk of growth for untreated macroadenomas. Previously treated macroadenomas (bromocriptine, cabergoline, and/or surgery) have a lower risk (4%) of growth during pregnancy.

Differential Diagnosis

There are other tumors that can arise in the parasellar region. These include germ cells tumors, lymphoma, and sarcomas.

Complications

Complications of uncurbed tumor growth include visual disturbances, headache, and diabetes insipidus. Marked tumor growth can lead to blindness.

Treatment

If the tumor enlarges, medical therapy (bromocriptine or cabergoline) is started, and visual field examinations are performed daily. If no rapid response occurs, high-dose steroid therapy is added. If still no response occurs, surgery should be strongly considered. Few reports of surgery during pregnancy are documented, but medical therapy, continued until after delivery, generally has been safe and effective. Serial visual field examinations or MRI is not recommended for microadenomas unless symptoms appear. If severe headache occurs, MRI is recommended even if no visual field defects are detected. MRI should always be performed if visual field defects are detected. Visual field disturbances are more common with macroadenomas. With macroprolactinomas, monthly visual field examinations and MRI are recommended if tumor growth is suspected. In addition to headaches and visual changes, pituitary infarction and diabetes insipidus are rarely seen. Complications of tumor growth are more likely to appear during the first trimester.

Prognosis

Labor and delivery are generally uncomplicated, but shortening the duration of the second stage in women experiencing tumor growth during pregnancy is recommended in an effort to prevent intracranial pressure elevation during the most active pushing. Most women with prolactinomas are allowed to breastfeed. MRI usually is recommended approximately 3–4 months after delivery to reassess tumor size. These women do very well during pregnancy.

ACROMEGALY

ESSENTIALS OF DIAGNOSIS

- Elevated concentrations of growth hormone
- Failure of an oral glucose tolerance test to suppress growth hormone

---

Clinical Findings

The clinical diagnosis is infrequently made early in the disease because changes in shoe or glove size and coarsening of facial features develop slowly. In normal pregnancy, pituitary growth hormone concentrations will decrease as placental epitopes are secreted. Determination of growth hormone levels during pregnancy requires specific assays able to differentiate growth hormone from pituitary or placental origin. Diagnosis is confirmed if an oral glucose tolerance test fails to suppress pituitary growth hormone.

Complications

Untreated patients with acromegaly can develop hypertension, diabetes, visual loss, cardiomyopathy, and arthritis.

Treatment

In general, medical therapy is stopped when pregnancy is diagnosed. Octreotide has been used successfully. However, bromocriptine administration throughout gestation without untoward effects to mother or infant has been reported. The data for octreotide are limited, so until its safety is determined, octreotide should be stopped when pregnancy is diagnosed. Elective surgery during pregnancy is safer during the second trimester. Emergency surgery is reserved for women with pregnancy-associated tumor enlargement and visual loss.

Prognosis

Early diagnosis and treatment of acromegaly can lead to a good prognosis.

SHEEHAN’S SYNDROME

ESSENTIALS OF DIAGNOSIS

- ▸ Panhypopituitarism as defined by decreased levels of TSH, prolactin, follicle-stimulating hormone, luteinizing hormone, and estradiol

---

Pathogenesis

H.L. Sheehan described the syndrome bearing his name as partial or complete pituitary insufficiency due to postpartum necrosis of the anterior pituitary gland in women with severe blood loss and hypotension during delivery. Nevertheless, up to 10% of cases have no history of bleeding or hypotension. The clinical manifestations depend on the extent of pituitary destruction and hormonal deficiencies. With destruction of 90% or more, symptoms of acute adrenal insufficiency predominate (see Adrenal Insufficiency). Women may present with persistent hypotension, tachycardia, hypoglycemia, and failure to lactate. If the condition is not treated promptly, serious complications and even death may occur. In most cases, the full-blown picture may take longer, even years, to appear. The most common manifestation of this syndrome is in women who have recently delivered and suffered a postpartum hemorrhage. This leads to an infarct in the pituitary due to low blood flow in that region.

Clinical Findings

Failure to lactate, breast involution, and, if untreated, breast atrophy may occur. Fatigue, weight loss, and postural hypotension are common complaints. Hyponatremia and anemia (usually normocytic and normochromic) are frequent laboratory abnormalities. Hormonal deficiencies point to a secondary cause, with low T_4, TSH, estrogen, gonadotropin, cortisol, and ACTH levels. Provocative hormonal testing may be necessary to confirm the diagnosis. Once the diagnosis of secondary hormonal deficiency is established, MRI of the pituitary and hypothalamus is necessary to exclude a tumor or other pathology.

Differential Diagnosis

Other problems that can manifest as hypopituitarism include lymphocytic hypophysitis involving lymphocytic infiltration into the pituitary; hemochromatosis, where iron is deposited into the pituitary; and exogenous causes such as radiation or surgery in that area.

Complications

Untreated Sheehan’s syndrome can lead to persistent hypotension, tachycardia, failure to lactate, and hypoglycemia.

Treatment

All deficient hormones must be replaced. However, it is well known that some patients with clear panhypopituitarism may recover TSH and even gonadotropin function after cortisol replacement alone. The mechanism is unknown, but it is speculated that cortisol has a permissive effect on other hypothalamic and pituitary functions. Rare cases of spontaneous recovery have been reported.

Prognosis

The outcome of pregnancy in women with Sheehan's syndrome shows no increased perinatal morbidity or mortality if the mothers are treated properly. Women with persistent amenorrhea and anovulation will require fertility treatment to become pregnant in the future.

DIABETES INSIPIDUS

ESSENTIALS OF DIAGNOSIS

- Polyuria
- Elevated serum sodium
- Water restriction test (excludes primary polydipsia)

Pathogenesis

Diabetes insipidus (DI) is caused by a deficiency of antidiuretic hormone (ADH), called central DI, or by renal tubule resistance to ADH action, called nephrogenic DI. A transient form of DI during pregnancy has been observed with increasing frequency and has been attributed to excessive placental production of vasopressinase, perhaps decreased hepatic clearance, and, because most of the patients reported had abnormal liver function, preeclampsia, fatty liver, or hepatitis. It is possible that some of these cases represent mild preexisting DI unmasked by pregnancy. It usually resolves several weeks after delivery but may recur in subsequent pregnancies, so follow-up is recommended.

The incidence during pregnancy has been reported as 1 in 50,000 to 1 in 80,000 deliveries. Approximately 60% of women with previously known DI worsen, 20% improve, and 20% do not change during pregnancy. Worsening is attributed to excessive placental vasopressinase production. Some women with DI who also develop placental insufficiency show DI improvement, which is attributed to decreased vasopressinase production by the damaged placenta.

A variety of lesions may cause DI, such as pituitary surgery, radiation, trauma, tumors, granulomas, and infections. However, no etiology is found in as many as 50% of patients, and these cases are labeled as "idiopathic."

Clinical Findings

Clinical symptoms include polyuria of 4–15 L/d and intense thirst, particularly for ice-cold fluids. A high-normal plasma sodium concentration is suggestive of DI in the patient with polyuria. The diagnosis of DI is confirmed by the standard water deprivation test. The goal of the water restriction test is to raise plasma osmolality and to assess for the normal physiologic response to water restriction. However, this test may prove hazardous during pregnancy because 3–5% of body weight may be lost during the test. This degree of dehydration, which is required to produce sufficient stimulation for ADH secretion, may lead to uteroplacental insufficiency and fetal distress. Even before fetal distress occurs, uterine contractions and even frank labor may be precipitated, forcing termination of the test before it can be properly interpreted. Uterine contractions respond rapidly to intravenous fluid administration. If the decision is made to perform a water deprivation test, continuous fetal monitoring is recommended.

Differential Diagnosis

The differential includes primary psychogenic polydipsia or osmotic dieresis.

Complications

The primary complications associated with DI are electrolyte imbalance and dehydration.

Treatment

The treatment of choice is intranasal desmopressin (DDAVP). It also can be given subcutaneously when the intranasal route cannot be used. The usual dose is 10–25 μg once or twice daily (or 2–4 μg subcutaneously). The dosage is adjusted according to fluid intake, urinary output, osmolality, and plasma electrolytes. An increased metabolic clearance rate stimulated by vasopressinase may require higher doses of the drug. Close follow-up is necessary to prevent dehydration or the opposite, water intoxication. Many reports indicate that DDAVP is safe during pregnancy and postpartum, even while the mother is breastfeeding. Oxytocin secretion appears to be normal, and no labor difficulties have been reported. No difficulties with lactation have been reported even in women with central DI.

Prognosis

Treated DI has a good prognosis and is not thought to cause long-term complications or change life expectancy.

33
Nervous System & Autoimmune Disorders in Pregnancy

Laura Kalayjian, MD
T. Murphy Goodwin, MD
Richard H. Lee, MD

DISORDERS OF THE NERVOUS SYSTEM

CEREBROVASCULAR DISORDERS

ESSENTIALS OF DIAGNOSIS

- Headaches, visual disturbances, syncope, and hemiparesis are among the most common presenting findings.
- Computed tomography scan and magnetic resonance imaging can be used in pregnancy to increase the delineation of cerebrovascular involvement. Arteriography is considered definitive if surgical intervention is being considered because arteriography can more precisely localize the involved area.

Pathogenesis

The causes of cerebrovascular disease include insufficiency (*arteriosclerosis, cerebral embolism, vasospasm from hypertensive disease*) and disorders associated with bleeding into the cerebral cortex (*arteriovenous malformation, ruptured aneurysm*). The brain becomes infarcted from lack of blood flow, or intracranial bleeding results in a space-occupying lesion. The severity of such disorders can be affected by blood pressure, oxygen saturation (anemia or polycythemia), hypoglycemia, and adequacy of collateral circulation.

The overall incidence of ischemic cerebrovascular accidents in pregnancy is approximately 1 in 20,000 births, with most occurring in the last trimester or immediately postpartum. Etiologic factors for stroke include cardioembolic disorders, cerebral angiopathies, hematologic disorders, and cerebral vein thrombosis. Causes exclusive to pregnancy are eclampsia, choriocarcinoma, and amniotic fluid embolism. Although cerebral ischemic disease can occur in either the arterial or venous system, approximately 75% of occlusive cerebral disease occurs on the arterial side.

Cerebrovascular accidents involving subarachnoid hemorrhage or intraparenchymal hemorrhage similarly occur at a rate of 1 in 20,000 births. These events usually are the result of aneurysms or arteriovenous malformations. The most common aneurysm is the saccular (berry) variety, which protrudes from the major arteries in the circle of Willis, particularly at its bifurcations. Aneurysms have an increasing tendency to bleed as the pregnancy progresses, likely due to changes in hemodynamic factors. Rupture of arteriovenous malformations has been found to occur evenly throughout gestation. No consensus has been reached regarding the increased frequency of bleeding from either an aneurysm or arteriovenous malformation during pregnancy or the immediate postpartum period. Rupture of the malformation appears to be more frequent during pregnancy. Eclampsia can lead to cerebral hemorrhage when elevated blood pressures lead to vasospasm, loss of autoregulatory function, and rupture of the vessel wall.

Clinical Findings

Headaches, visual disturbances, syncope, and hemiparesis are among the most common presenting findings. The pattern of clinical signs and symptoms generally allows recognition of the area of the brain involved. Computed tomography (CT) scan and magnetic resonance imaging (MRI) can be used in pregnancy to increase the delineation of cerebrovascular involvement. Arteriography is considered definitive if surgical intervention is being considered because arteriography can more precisely localize the involved area. Because coagulopathies can also cause intracranial bleeding or may be secondary to the cerebrovascular lesion itself, a coagulation profile should be performed. Additionally, antinuclear antibody (ANA), lupus anticoagulant, factor V Leiden, homocysteine, anticardiolipin, proteins C and S, antithrombin III, and plasminogen levels should be considered with thrombotic cerebral events.

Treatment

The treatment of ischemic or hemorrhagic cerebrovascular disease is best managed supportively; however, surgery is indicated for treatment of some aneurysms and arteriovenous malformations. Anticoagulation with heparin may be required depending on the etiology of the infarction; tissue plasminogen activator is relatively contraindicated in pregnancy, but it has been used successfully according to several case reports. Normalization of blood pressure, adequate respiratory support, therapy for metabolic complications, and treatment of coagulopathies or cardiac abnormalities are crucial. Dexamethasone 10 mg intravenously initially, followed by 5 mg every 6 hours for 24 hours, may decrease cerebral edema and be of some assistance prior to surgery or in recovery. Additionally, hyperventilation, mannitol infusions, phenobarbital coma, and intracerebral pressure monitoring may be helpful with severe cerebral edema. Once the patient’s condition has been stabilized, physical therapy and rehabilitation should begin as soon as possible.

Appropriate surgery for aneurysms and arteriovenous malformations should be performed with the pregnancy undisturbed unless fetal maturity allows for caesarean birth just prior to the neurosurgical procedure. On the other hand, inoperable lesions during pregnancy are managed by pregnancy conservation until fetal maturity is sufficient to allow abdominal birth. Once a lesion has been surgically corrected, vaginal delivery can be attempted depending on the practitioner’s comfort level. However, the second stage of labor should be modified by regional anesthesia and forceps delivery to reduce cerebral pressures associated with the Valsalva maneuver.

Prognosis

The percentage of patients with venous occlusion who recover from the initial episode without neurologic sequelae during rehabilitation equals that of patients with arterial occlusion. Thrombosis of the superior sagittal sinus is a rare complication. Its incidence is increased in pregnancy, and it has a high mortality rate of approximately 55%.

If the cerebral hemorrhagic disorder is operable, the prognosis is favorable, with few long-term neurologic deficits. In inoperable lesions or when severe maternal cerebral hemorrhage has occurred, the prognosis—although unfavorable—is better for those with aneurysms than for those with arteriovenous fistulas. If a neurosurgical procedure is performed during pregnancy, the fetus usually is not adversely affected, despite the induced hypotension that is often necessary. The prognosis for the mother and fetus is the same as that in a normal gestation once the condition has been corrected.

CEREBRAL NEOPLASMS

ESSENTIALS OF DIAGNOSIS

- The clinical manifestations are generally characterized by a slow progression of neurologic signs with evidence of increased intracranial pressure and headache.
- CT or MRI of the brain reveals a mass lesion within the skull.

Pathogenesis

Cerebral neoplasms occur primarily at the extremes of life; thus, primary cancer or even metastatic tumors are uncommon during the childbearing years. Although brain tumors are not specifically related to gestation, meningiomas, angiomas, and neurofibromas are thought to grow more rapidly with pregnancy. Of the primary neoplasms (half of all brain tumors), gliomas are the most common (50%), with meningiomas and pituitary adenomas accounting for 35%. Of the metastatic cerebral tumors, lung and breast tumors account for 50%. *Choriocarcinoma* commonly metastasizes to the cerebrum.

Clinical Findings

A. Symptoms & Signs

The clinical manifestations, although dependent on the type and location of the tumor, are generally characterized by a slow progression of neurologic signs with evidence of increased intracranial pressure. One of the most frequent signs is headache, which must be differentiated from that occurring in tension and in vascular or inflammatory conditions. Pain that is not relieved by analgesics or muscle relaxants (as a tension headache would be), the absence of a history of migraine headaches, and the lack of signs of infection or meningeal inflammation all point to increased intracranial pressure as a possible cause of the headache. Tumors in the pituitary gland or occipital region may be associated with visual deficits. Other presenting signs and symptoms include nausea, vomiting, double vision, vertigo, seizures, and altered mental status.

B. Imaging Studies

CT scan and MRI are of greatest assistance in revealing space-occupying lesions. MRI is generally preferred during pregnancy, although fetal radiation exposure from CT of the brain is minimal.

C. Laboratory Findings

If the cerebrospinal fluid glucose and protein levels are normal, inflammation or infection of the central nervous system is unlikely. Similarly, an increase in the cerebrospinal fluid human chorionic gonadotropin (hCG) titer raises the suspicion of metastatic choriocarcinoma. Pleocytosis may be present with cerebral neoplasia, but usually it is lymphocytic or monocytic, without an increase in the number of polymorphonucleocytes. Finally, failure to find blood or xanthochromic fluid in the cerebrospinal fluid helps in differentiating a neoplasm from a hemorrhagic lesion, unless the tumor has undergone hemorrhagic necrosis.

Treatment

The treatment of cerebral neoplasms during pregnancy depends on the type of tumor, its location, and the stage of gestation. Anticonvulsants should be used only if seizures have occurred. Steroids can be used to decrease intracranial pressure causing focal neurologic signs or headaches. Deterioration of the patient's status in early pregnancy should prompt a discussion about the risks of continuing the pregnancy. Nevertheless, most such pregnancies can be carried through successfully. During the second trimester, treatment with surgery, chemotherapy, or directed radiation can be started and the pregnancy allowed to continue. Later in gestation, maternal treatment can be delayed until delivery. Pituitary adenomas can be treated with bromocriptine if visual problems or disabling headaches occur.

Prognosis

Brain tumors usually do not affect pregnancy or the fetus unless the neoplasm leads to early delivery or maternal death. When diagnosed in the second or third trimester, the outcome for the fetus is excellent, even though therapy may be initiated during the course of the pregnancy.

MIGRAINE HEADACHE

ESSENTIALS OF DIAGNOSIS

- Headache attacks that last 4–72 hours in duration.
- Headaches may be associated with nausea or vomiting, photophobia, or phonophobia.
- Headaches may also be accompanied by focal neurologic symptoms ("aura").

Chronic migraine headaches decrease during pregnancy in 50–80% of affected patients. Women with classic migraine (migraine with aura) may experience their initial onset during pregnancy.

Clinical Findings

Most often, the patient has a history of migraine headaches, which usually are described as "pounding" and may settle in the eyes, the temporal region, or occiput. The pain can be unilateral or bilateral. Frequently, migraines are associated with gastrointestinal complaints (eg, nausea, vomiting, and diarrhea) or with systemic symptoms (eg, vertigo or syncope). Light sensitivity (photophobia) and noise sensitivity (sonophobia) often accompany the pain. An aura may or may not precede the headache. Aura is characterized by focal neurologic symptoms, most commonly visual changes, that are fully reversible. Sleep often aborts the attack.

The diagnosis of migraine headaches usually is made clinically by the characteristics of the pain, associated symptoms, event triggers (see below), and absence of neurologic signs. Tension and caffeine withdrawal headaches typically are associated with bandlike pressure pain. If vertigo is associated with migraine headaches, it is important to rule out Ménière's disease (labyrinthitis). In the latter, vertigo is accompanied by tinnitus, a fluctuating sensorineural hearing loss, and nystagmus. If vertigo is associated with ataxia of gait, it is almost always central in origin, in which case head trauma, brain tumors, seizure disorders, and multiple sclerosis must be excluded. Syncope (fainting) may occur with migraine or vascular headaches and is common during pregnancy. However, when syncope occurs with migraine headache, it usually is associated with vertigo. Rarely, ocular nerve palsy develops in association with migraine headaches; the third cranial nerve is the most commonly involved, and the palsy usually disappears with abatement of the migraine. It is important to visualize the optic disk to ensure that cerebrospinal fluid pressure is not increased. In cases where the disk borders are not sharp, *pseudotumor cerebri* or an intracranial mass lesion should be considered first.

Treatment

Treatment of migraine headaches initially includes identification of any trigger that precipitates attacks, followed by avoidance of those triggers. Common triggers for some migraine patients include missing meals, stress, aged cheeses, sausage or other nitrates, chocolate, citrus fruit, wine and other sulfites, monosodium glutamate, strong odors, lights or glare, and inadequate sleep. When this environmental manipulation fails to control migraines, drug therapy is indicated. Migraine therapy is either abortive or prophylactic depending on the frequency and severity of attacks. Preferred abortive medications during pregnancy include acetaminophen, acetaminophen and codeine or other narcotics, and magnesium. The following are more effective migraine abortive medications but are not preferred during pregnancy: butalbital, isometheptene, caffeine, aspirin, naproxen, ibuprofen, and triptan drugs (eg, sumatriptan). The nonsteroidal anti-inflammatory drugs should not be used for prolonged periods and should be avoided in the third trimester because of possible oligohydramnios or premature closure of the ductus arteriosus. Prophylactic medications should be instituted if abortive therapy is only partially effective and if disabling migraines are occurring more than once per week. Options include beta mimetic blockers, low-dose tricyclic antidepressants, calcium channel blockers, magnesium, riboflavin, and topiramate. Valproic acid or divalproate should be avoided in pregnancy.

Prognosis

Migraine headaches usually have no deleterious long-term effect on mother or fetus, and treatment of acute exacerbation usually is successful.

EPILEPSY & SEIZURE DISORDERS

ESSENTIALS OF DIAGNOSIS

- Epilepsy is defined as 2 or more unprovoked seizures.
- Seizures associated with epilepsy can be generalized convulsive (tonic-clonic or grand mal), complex partial (loss of awareness or staring with mild motor movements), focal motor or sensory (jacksonian with no loss of awareness), absence or petit mal (brief eye blinking with no postictal confusion), myoclonic jerks, or auras of déjà vu, fear, or abnormal odors.

The onset of epilepsy is not increased during pregnancy. More than 95% of patients who have seizures during pregnancy have a history of epilepsy or have been receiving anti-convulsant therapy. Patients whose seizures are adequately controlled are not likely to experience a deterioration of their condition during pregnancy. On the other hand, patients who have experienced frequent and uncontrolled seizures before pregnancy likely will experience the same pattern, particularly during early pregnancy.

Clinical Findings

A detailed history from the patient and observers helps to distinguish true seizures from other forms of loss of consciousness, such as syncopal episodes, hysteric attacks, or hyperventilation. These problems do not commonly involve a postictal confusional state, nor do they usually involve loss of bladder or bowel control or tongue biting. Non–central nervous system causes, such as hypoxia, hypoglycemia, hypocalcemia, and hyponatremia, also must be excluded. Finally, seizures may result from drug withdrawal, medications, or exposure to toxic substances; thus, appropriate physical examination and screening for toxic substances are important in patients suffering an apparent first seizure during pregnancy.

Detailed neurologic workup is required in patients whose first seizure occurs during pregnancy. Electroencephalogram (EEG), CT scan with shielding or MRI, and lumbar puncture are useful for detailing the cause of the seizure and are not contraindicated during pregnancy. In established epilepsy, EEG is useful to confirm the type of epilepsy and therefore provide the appropriate drug therapy.

Treatment

Treatment of epilepsy should consist of the medication that has been most beneficial for the patient and at the lowest possible dose to maintain seizure control with some caveats. Some antiepileptic agents are more likely to cause birth defects than are others, and attempts to change medications should be made prior to conception.

During pregnancy, anticonvulsant levels change as a result of decreased protein binding, increased plasma volume, and alterations in the absorption and excretion of drugs. In addition, lamotrigine, phenytoin, phenobarbital, and carbamazepine have an increased plasma clearance that probably is related to high hepatic metabolism. These factors most often lead to low antiseizure plasma levels. Noncompliance, morning sickness, and hyperemesis gravidarum are other reasons for low drug levels. Therefore, blood level measurements of antiseizure medications are used to monitor and maintain a therapeutic range. Levels should be checked at least each trimester and prior to delivery. More frequent monitoring may be needed. Because of decreased protein binding, serum-free drug levels rather than routine serum levels will be more accurate. Breakthrough seizures can result from poor sleep in the third trimester because the patient cannot obtain a comfortable sleeping position. For patients with refractory seizures while taking medication, an attempt should be made to maximize the dosage and the level of 1 medication before switching or adding another agent.

In patients with status epilepticus, control of seizures is mandatory for the safety of the patient and fetus. Lorazepam 2 mg intravenous (IV) push followed by 2 mg IV every minute up to 0.1 mg/kg is first-line treatment. If seizures continue, phenytoin 20 mg/kg slow IV push at a rate of 50 mg/min or fosphenytoin 20 phenytoin equivalents/kg IV at 150 phenytoin equivalents/min can be given intravenously. General anesthesia can be considered if seizures persist. In these cases, cerebral edema almost invariably is present and may be reduced with dexamethasone, mannitol, or hyperventilation. Many cases of status epilepticus in pregnancy are the result of inadequate treatment with antiepileptic drugs, abrupt withdrawal of phenobarbital or benzodiazepines, noncompliance, or failure to monitor serum levels.

Antiepileptic drugs and seizures can negatively affect a fetus. Seizures can cause maternal and fetal injury, spontaneous abortion, premature labor, and fetal bradycardia. All antiepileptic drugs cross the placenta, equilibrate rapidly in cord blood, and may have teratogenic effects. The risk of anomalies among infants exposed to anticonvulsants is approximately 2-fold greater than in the general population. The previous thinking that women with seizure disorders had an increased risk of fetal malformations even without exposure to anticonvulsant medication has been disproved. The most common defects fall into 2 categories: major and minor malformations. Major malformations include orofacial clefts, neural tube defects, and congenital heart disease. Minor malformations consist of craniofacial anomalies (eg, low-set ears, widely spaced eyes), short neck, and hypoplastic fingernails. The *fetal hydantoin syndrome* (associated with phenytoin) was the first described association between antiepileptic drugs and birth defects. It affects 3–5% of exposed offspring. It is characterized by mental retardation, small for gestational age size, craniofacial anomalies, and limb defects. A milder phenytoin-associated syndrome may be present at a greater frequency (8–15%) but is detectable only by careful assessment during the first 3 years of life. Use of trimethadione in pregnancy has been abandoned given the high rate of anomalies (up to 30%) associated with intrauterine trimethadione exposure.

The teratogenic potential of specific antiepileptic agents has been the subject of much debate. Prospective pregnancy registries have been established around the world to clarify the risks. The older anticonvulsants—ethosuximide, carbamazepine, phenobarbital, valproic acid, primidone, and phenytoin—are all pregnancy category D because of known increased risk of birth defects in exposed fetuses. Neural tube defects are most common with carbamazepine (0.5–1%) and valproic acid (1–2%). The North American AED (antiepileptic drug) Pregnancy Registry has determined that the overall major malformation rate with exposure to valproic acid is 10.7%. Other pregnancy registries and studies have found the teratogenic potential of valproic acid increases with doses higher than 1000 mg/d or levels higher than 70 μg/mL. Besides neural tube defects, hypospadia, polydactyly, and kidney and heart malformation have been associated with valproic acid, so its use during pregnancy should be avoided if possible. Phenobarbital, previously believed to be safe during pregnancy, has a malformation rate of 6.5%, which is slightly higher than the approximately 3% rate of other antiepileptic drugs such as carbamazepine, phenytoin, and lamotrigine. Less human data on the newer antiepileptic drugs are available, with the exception of lamotrigine and oxcarbazepine. All newer antiepileptic drugs are category C, but more data are needed before they can be deemed safe.

Treatment with 2 or more antiseizure medications approximately doubles the risk for malformations.

Women with existing seizure disorders who are contemplating pregnancy should be tested to determine whether they still require anticonvulsant therapy—particularly if anticonvulsants were started during childhood or if the patient has been seizure-free for 2–5 years. If a pregnant woman requires seizure medication, she should be informed of the likelihood of fetal anomalies associated with each drug, and a discussion regarding the risks and benefits of attempting to switch to a different or safer drug, if available, should ensue. The patient should be counseled regarding folic acid supplementation (4 mg/d) starting at least 3 months preconceptionally to possibly reduce the chance of neural tube defects.

If the patient is taking an antiseizure medication metabolized by the P450 liver enzyme system, she should take vitamin K 10 mg/d from week 36 until delivery to prevent hemorrhage in her baby. This is in addition to the intramuscular vitamin K the infant will receive after delivery.

Antiepileptic drugs pass into the breast milk to varying degrees, depending on protein-binding characteristics. The benefits of breast milk usually outweigh the small risk from the medication to the infant. If a breastfed infant is too sedated and not feeding well, presumably from the medication in the breast milk, breastfeeding should be suspended and supplanted with formula.

Mothers with frequent seizures must be counseled on seizure and infant safety. Sponge baths instead of tub baths and use of a strap on the changing table will decrease potential injury to an infant in case of a maternal seizure.

MULTIPLE SCLEROSIS

ESSENTIALS OF DIAGNOSIS

- Multiple sclerosis is a clinical diagnosis made on the basis of 2 or more clinically distinct episodes of central nervous system dysfunction.
- The diagnosis may be supported by findings on laboratory or imaging studies such as MRI.

Pathogenesis

Multiple sclerosis is an autoimmune demyelinating process in the white matter of the central nervous system. It affects women twice as often as men and usually has its onset between the ages of 20 and 40 years. People in the Northern Hemisphere are more commonly affected. The cause is not known, but possible etiologies include environmental, viral, and genetic.

Clinical Findings

The 2 patterns of disease are relapsing remitting and primary progressive. Findings include weakness in the extremities, sensory loss, difficulty with coordination, and visual problems. Increased reflexes, spasticity, and bladder control problems develop over time. Myasthenia gravis should be ruled out with an anticholinesterase (neostigmine) challenge and acetylcholine receptor antibody testing. Guillain-Barré syndrome should be ruled out if the patient has a history of recent viral infection.

Laboratory tests and imaging should be performed to rule out other possible etiologies. Serum should be checked for vitamin B_{12}, Lyme and HTLV-1 (human T-cell lympho-tropic virus type 1) titers, erythrocyte sedimentation rate (ESR), ANA, and rheumatoid factor. An MRI would reveal lesions (plaques) in the white matter of the brain and spinal cord. Active plaques would enhance with contrast materials. An elevated level of immunoglobulin (Ig) G in the cerebro-spinal fluid is virtually diagnostic.

Treatment

Treatment options include interferon beta-1a, interferon beta-1b, and glatiramer. These medications decrease relapse rates, decrease disease activity as measured by serial MRI, and decrease disease progression. The interferon beta-1b and -1a multiple sclerosis trials showed an increased rate of spontaneous abortions of exposed fetuses. Although the increased rate did not reach statistical significance, there is good reason for caution. In patients planning to become pregnant, interferon treatment should be switched to glatiramer until conception and then discontinued once pregnancy is established. Symptomatic treatment of spasticity, pain, fatigue, and bowel and bladder dysfunction will be required as well. IV immunoglobulin (IVIG) has been used in the postpartum period to decrease the risk of exacerbation with some success. Short courses of corticosteroids may be helpful if the patient has optic neuritis or other disabling relapse.

Prognosis

The disease is characterized by exacerbations and remissions, with 70% of patients experiencing slow progression over a number of years. Pregnancy does not appear to exert any deleterious effect on multiple sclerosis and may improve the rate of exacerbation. The risk of exacerbations is increased in the first 3 months postpartum. Family planning should be discussed because of the progressive nature of the disease. If so desired, families should be completed or started as soon as possible.

MYASTHENIA GRAVIS

ESSENTIALS OF DIAGNOSIS

- Myasthenia gravis is an autoimmune disorder characterized by antibodies to acetylcholine receptors at the neuromuscular junction.
- It is characterized by muscle weakness, particularly with repetitive movement.

Myasthenia gravis is a chronic disorder of the neuromuscular junction of striate muscles as result of acetylcholine receptor dysfunction. Antibodies to acetylcholine receptors usually are present. It occurs more commonly in females than in males, and its peak occurrence is in the third decade of life. It is characterized by abnormal voluntary muscle function with muscle weakness after repeated effort. Although some cases of myasthenia gravis appear to be hereditary, most adult cases appear to be acquired.

Clinical Findings

The most common symptom is easily fatigued small muscles, most frequently the ocular muscles, which results in double vision. Weakness usually increases as the muscles are used repeatedly. Patients who may not have noticeable symptoms in the morning may be easily diagnosed in the afternoon. Difficulties with swallowing and speech are not uncommon, and the facial muscles are almost always affected.

The diagnosis can be confirmed by administering edrophonium (Tensilon; a total of 10 mg, consisting of 2 mg followed by 8 mg 45 seconds later) to assess improvement in muscular weakness. A radioimmunoassay for the acetylcholine receptor antibody can be performed. Repetitive nerve stimulation would show a decrement >15% in a person with the condition.

One-third of patients with myasthenia gravis experience exacerbation during pregnancy, one-third do not experience a change in disease, and one-third experience remission during pregnancy. The disease does not affect uterine activity because the uterus consists of smooth muscle. The length of labor is not affected. However, an assisted second stage might be considered because of maternal fatigue. Exacerbations are most common during the postpartum period. Placental transfer of acetylcholine receptor antibodies can occur, so the fetus should be monitored at frequent intervals during pregnancy with fetal kick counts and ultrasound. A rare finding in neonates is arthrogryposis multiplex congenita, congenital contractures secondary to lack of movement in utero. Antibodies may affect the fetal diaphragm and lead to pulmonary hypoplasia and polyhydramnios. From 12–15% of newborns will be affected with transient myasthenia gravis. The mean duration of neonatal symptoms is 3 weeks.

Treatment

Treatment with anticholinesterases (eg, neostigmine) is the same as in the nonpregnant state, although dosages must be administered more frequently during pregnancy. Other treatment options include thymectomy, steroids, plasma exchange, and IVIG. During labor, anticholinesterases should be administered parenterally rather than orally. Parenteral and regional anesthesia is not contraindicated in labor. Curare-like agents (eg, aminoglycoside antibiotics) and magnesium sulfate, as well as the older general anesthetics such as ether and chloroform, should be avoided. Women taking anticholinesterase drugs are advised not to breastfeed.

OTHER NEUROLOGIC DISORDERS AFFECTING PREGNANCY

SPINAL CORD DISORDERS

Spinal cord lesions that are caused by trauma, tumor, infection, or vascular disorders usually do not prevent conception. Diagnosis and therapy should be performed without regard to pregnancy. In general, pregnancy coexisting with trauma to the spinal cord from any cause, even paraplegia, proceeds unremarkably with the exception of an increased frequency of urinary tract infections and sepsis from pressure necrosis of the skin. Fetal growth usually is unimpeded even though initial maternal weight is frequently <100 lb because of muscular wasting. Generally labor proceeds without evidence of fetopelvic disproportion. Women whose paraplegia is related to anterior horn cell damage or to cord lesions below the tenth thoracic level have appropriate perception of labor contractions and may require analgesia or anesthesia. In most patients, rapid, painless labors are the rule, with the only abnormality being a prolonged second stage because of decreased muscular effort. Paraplegic patients may develop autonomic hyperreflexia during labor due to loss of central regulation of the sympathetic nervous system below the level of the lesion. This is best managed with an epidural, continuous monitoring of the cardiac rhythm and blood pressures, antihypertensives, and an assisted second stage.

DISORDERS OF CRANIAL NERVES

Palsies of the facial nerve due to inflammation are called *Bell’s palsy*. Although patients may complain of paresthesia over the area of paralysis, this is strictly a motor disorder involving paralysis of the muscles of facial expression on 1 side that are innervated by the facial nerve. Given that approximately one-fifth of cases of Bell’s palsy occur during pregnancy or shortly thereafter, it has been suggested that pregnancy increases the frequency of this disorder, although viral infections also have been causally related. Treatment with corticosteroids (prednisone 40–60 mg/d) and acyclovir is helpful if given within 1 week of onset. However, Bell’s palsy usually is self-limited. Because the patient is unable to blink or close her eye on the affected side, corneal damage will occur if frequent eye drops and nighttime closure of the eye with patches and lubrication are not instituted. Rarely is surgical decompression of the nerve indicated.

GUILLAIN-BARRÉ SYNDROME

Guillain-Barré syndrome is an acute inflammatory demyelinating polyneuropathy often related to an upper respiratory or gastrointestinal infection or recent immunization. Rapid onset of weakness occurs, most frequently in an ascending pattern involving the extremities first, then respiratory muscles and face. Hospitalization is required, and supportive treatment aimed at preventing respiratory failure is mandatory. If the vital respiratory capacity falls to 800 mL or below, tracheostomy should be performed. Plasmapheresis or IVIG is the treatment of choice to shorten the course of illness. Most patients progress normally through pregnancy and deliver at term, so abortion is not mandated. On the other hand, if respiratory paralysis occurs near term, caesarean delivery may be indicated to improve ventilation.

PERIPHERAL NEUROPATHIES

Carpal tunnel syndrome is a neuropathic disorder related to median nerve compression by swelling of the tissue in the synovial sheaths at the wrist. Symptoms usually are limited to paresthesia over the thumb, index, and middle fingers and the medial portion of the ring finger. Most commonly, symptoms are noted at night and usually are best treated conservatively with elevation of the affected wrist and splinting. The syndrome usually abates postpartum. Surgery and corticosteroids are rarely indicated.

Compression of the femoral or obturator nerve can occur from retraction at the time of caesarean delivery or hysterectomy, but it is most commonly related to pressure of the fetus just before and during vaginal delivery.

Femoral nerve palsy results in weakness of the iliopsoas and quadriceps muscles and sensory loss over the anterior thigh. Obturator nerve palsy is characterized by adduction weakness of the thigh and minimal sensory loss over the medial aspect of the affected limb. *Peroneal neuropathy* reveals footdrop and weakness on dorsiflexion of the foot, occasionally with paresthesia in the foot and second toes. This disorder usually appears 1–2 days postpartum and may be related to prolonged episiotomy repair and to pressure on the nerve from knee stirrups. Women at risk include small women with relatively large babies, those who have had midforceps rotations, and those who have had prolonged labor, especially with abnormally large infants (owing to compression of the L4–5 lumbosacral nerve trunk). The prognosis is excellent with conservative therapy, but occasionally a short leg brace is necessary.

Brachialgia or the *thoracic outlet syndrome* occurs when the brachial plexus and subclavian artery are compressed by the clavicle and first rib. Occurrence in pregnancy is increased because of the greater weight of the breasts and abdomen. The pain is referred to the lateral aspect of the hand and forearm, although motor symptoms are rare. Blanching of the fingers and exacerbation of symptoms when the hands are elevated are diagnostic. The syndrome usually is self-limited; posture instruction and strengthening of shoulder suspension muscles are helpful. Surgical removal of the rib is very occasionally necessary (as in the nonpregnant patient).

Herniation of intervertebral disks occurs more commonly in the lumbar than the cervical region. There are both motor and sensory findings along the distribution of the sciatic nerve. It is limited to 1 extremity and must be differentiated from more serious disorders such as spinal cord tumors and hemorrhage. Diagnosis usually can be made by physical examination and history. MRI of the spine is the best diagnostic modality if needed. Conservative management with bedrest and physical therapy is helpful. The process should cause no problems during pregnancy or vaginal delivery unless the patient has cervical disk disease. In that event, caesarean delivery is advised to prevent herniation and paralysis. Surgical correction should be avoided during pregnancy if possible.

AUTOIMMUNE DISORDERS

RHEUMATOID ARTHRITIS

ESSENTIALS OF DIAGNOSIS

- Inflammatory arthritis involving 3 or more joints
- The presence of certain biomarkers on serum testing such as rheumatoid factor, elevated C-reactive protein, or elevated ESR
- Most patients with rheumatoid arthritis in pregnancy diagnosed prior to pregnancy

---

Pathogenesis

Rheumatoid arthritis is a chronic autoimmune disease characterized by symmetric inflammatory synovitis. The prevalence in North America is 0.5–3.8%, and it occurs 3 times more frequently in women.

Clinical Findings

Symptoms of rheumatoid arthritis are insidious, with a prodrome of fatigue, weakness, generalized joint stiffness, and myalgias preceding the appearance of joint swelling. The diagnosis can be made when the patient is found to have inflammatory arthritis involving 3 or more joints; the patient has abnormal biomarkers such as rheumatoid factor, elevated C-reactive protein, or elevated ESR, the duration of symptoms is more than 6 weeks; and other diseases have been excluded. Laboratory findings are mild leukocytosis, elevated ESR (which may not always reflect the activity of the disease), and a positive rheumatoid factor (in the majority of patients).

Treatment

Treatment consists of rest, anti-inflammatory drugs, splints, physical therapy, a well-balanced diet, and adequate movement of all joints. Cyclooxygenase (COX)-1 and COX-2 inhibitors should be avoided in pregnancy. If they are used, therapy should be limited to short courses prior to 32 weeks' gestation to avoid premature closure of the ductus arteriosus, and the amniotic fluid index should be followed for oligohydramnios. Low-dose oral corticosteroid therapy, hydroxychloroquine, or sulfasalazine can be substituted safely for COX inhibitors. Tumor necrosis factor (TNF)-α inhibitors, penicillamine, gold, and methotrexate should be avoided. Methotrexate should be stopped 1–3 months prior to conception, and patients on leflunomide should wait to conceive until serum concentrations are undetectable. Symptoms improve during pregnancy in approximately 75% of women. However, many patients relapse within 6 months postpartum. The activity of the disease during pregnancy is best followed by assessment of duration of morning stiffness and the number of joints involved. Levels of Ro/SS-A and La/SS-B antibodies should be obtained to determine the fetal risk for complete heart block. In cases of severe postpartum exacerbation, early termination of breastfeeding may be necessary in order to allow the full range of pharmacologic therapy, including TNF-α inhibitors.

Prognosis

The course is variable and unpredictable, with spontaneous remissions and exacerbations.

SYSTEMIC LUPUS ERYTHEMATOSUS

ESSENTIALS OF DIAGNOSIS

- Systemic lupus erythematosus (SLE) is a multisystem autoimmune disorder with a wide spectrum of disease manifestations.
- The diagnosis can be made when 4 of the following criteria are present: malar rash, discoid rash, photosensitivity, oral ulcers, serositis, renal disorders, neurologic disorders, hematologic disorders (hemolytic anemia, leukopenia, thrombocytopenia), immunologic disorders (anti-DNA, anti-Sm, false-positive Venereal Disease Research Laboratory [VDRL] test), or an abnormal ANA titer.
- As with other autoimmune diseases in pregnancy, the diagnosis of SLE is usually made prior to pregnancy.

Pathogenesis

Systemic lupus erythematosus (SLE) is a chronic inflammatory disease that can affect many different organ systems. It is of interest to obstetricians because it affects women more commonly than men (10:1), and the women it affects tend to be of reproductive age. The cause of SLE is unknown, and the clinical course is variable. Common serologic markers of SLE are present 5 years before the diagnosis is made in up to 50% of women. Complications of pregnancy characteristic of SLE may precede the clinical diagnosis by many years as well.

Clinical Findings

The diagnosis can be made when 4 of the following criteria are present: malar rash, discoid rash, photosensitivity, oral ulcers, serositis, renal disorders, neurologic disorders, hematologic disorders (hemolytic anemia, leukopenia, thrombocytopenia), immunologic disorders (anti-DNA, anti-Sm, false-positive Venereal Disease Research Laboratory [VDRL] test), or an abnormal ANA titer.

Differential Diagnosis

The differential diagnosis includes rheumatoid arthritis, drug-induced SLE syndromes, polyarteritis, chronic active hepatitis, and, late in pregnancy, preeclampsia. Common symptoms at presentation in pregnancy are malaise, fever, myalgias, and weight loss.

Complications

Considerable controversy exists about the effects of pregnancy on SLE and vice versa. Most patients who become pregnant while their SLE is not active for at least 6 months seem to have few problems except for a 2- to 3-fold increased risk of superimposed preeclampsia and fetal growth restriction; the risk of a lupus flare is 20%. Women with active SLE are at very high risk for superimposed preeclampsia (60–80%), fetal growth restriction, preterm birth, and lupus flare (50–80%). Women with preexisting renal disease frequently have some deterioration in renal function, but it is irreversible in only 10% of cases.

Treatment

Management during pregnancy includes a careful history, physical examination, and laboratory evaluation. A history of prior spontaneous abortions or fetal losses should be elicited. The history should note the manifestations of SLE in the past; determination of the severity of disease activity is important in anticipating pregnancy complications. Although the fertility rate of patients with SLE is normal, patients have a higher percentage of total fetal losses. This may be associated with the presence of antiphospholipid antibodies. Physical examination should focus on signs of active disease. Laboratory evaluation should include a complete blood count, serum chemistries, and liver function tests. ANA (if the diagnosis is not previously confirmed), double-stranded DNA, urine protein, C3, C4, and CH_{50} tests should be obtained. Subsequent changes in these values may herald a flare of lupus nephritis. The results of the SS-A, lupus anticoagulant, anticardiolipin antibody, and anti-β_2 glycoprotein 1 tests should be known. The presence of SS-A is associated with neonatal lupus, manifested by cutaneous lesions or congenital heart block. Anticardiolipin antibody and lupus anticoagulant anti-β_2 glycoprotein 1 tests are associated with antiphospholipid antibody syndrome (APS), which predisposes patients to thromboembolic events, fetal death, fetal growth restriction, and preeclampsia. Prophylactic treatment with daily baby aspirin and heparin is recommended when APS is diagnosed. Diagnostic criteria require a clinical event (as listed earlier) plus a positive lupus anticoagulant result, moderate- to high-titer anticardiolipin antibody (>40 IgG phospholipid units or IgM phospholipid units or >99th percentile for the testing laboratory), or anti-β_2 glycoprotein 1 antibodies (IgG or IgM >99th percentile for the testing laboratory). These tests should be positive on 2 occasions 12 weeks apart. Most fetal loss in SLE appears to be due to concomitant APS, which occurs in approximately 30% of patients.

Distinguishing between superimposed preeclampsia in the third trimester and an SLE flare often is difficult. In fact, it is not possible to say with certainty that preeclampsia is not present, but careful consideration can suggest whether an SLE flare is a contributing factor. In a pregnancy remote from term, aggressive empiric therapy of presumed SLE may allow significant prolongation of pregnancy.

Serial ultrasounds for fetal growth and antenatal testing starting at 32–34 weeks should be instituted to ensure fetal well-being. Delivery is often recommended at 39 weeks' gestation. Uterine artery Doppler at midgestation can be used to predict early-onset preeclampsia and fetal growth restriction.

The mainstay of treatment of SLE in pregnancy consists of corticosteroids, hydroxychloroquine, and azathioprine. Corticosteroids appear to be weak teratogens, resulting in 1 extra facial cleft for every 1000 first-trimester exposures. Thereafter, there is a risk of premature rupture of membranes and preterm birth, but usually after 34 weeks' gestation. Corticosteroids also increase the risk for gestational diabetes and maternal hypertension. Medications used to treat SLE that should be avoided during conception and pregnancy include mycophenolate mofetil, cyclophosphamide, methotrexate, and warfarin. Little information on the use of newer agents (eg, rituximab, abatacept) is available. The chance of successful pregnancy outcome for women with SLE has improved dramatically over the years with better understanding of the natural history of the disease and medical therapy in pregnancy.

SCLERODERMA (SYSTEMIC SCLEROSIS)

ESSENTIALS OF DIAGNOSIS

- Scleroderma, or systemic sclerosis, is a rare condition that is uncommonly seen in pregnancy.
- It is a systemic disorder characterized by the presence of thickened, hardened skin, circulatory abnormalities, and often involvement of multiple organ systems.

Clinical Findings

Pregnancy in patients with scleroderma is rare because the disorder occurs most frequently in patients beyond reproductive age. Symptoms include malaise, fatigue, arthralgias, Raynaud’s phenomenon, and myalgias. The course of the disease appears to improve or remain unchanged during pregnancy. One study did show an increase in pre-term births. Pregnancy progresses normally in otherwise stable disease. When scleroderma-related renal disease and/or hypertension are present, pregnancy is at increased risk of being complicated by preeclampsia or malignant hypertension.

Treatment

Treatment options for women with systemic sclerosis in pregnancy include anti-inflammatory and immunosuppressive drugs such as prednisone, hydroxychloroquine, and nonsteroidal anti-inflammatory drugs.

Hematologic Disorders in Pregnancy

Christina Arnett, MD
Jeffrey S. Greenspoon, MD
Ashley S. Roman, MD, MPH

ANEMIA

Anemia is a significant maternal problem during pregnancy. The Centers for Disease Control and Prevention defines anemia as a hemoglobin concentration of <11 g/dL (hematocrit of <33%) in the first or third trimester or a hemoglobin concentration of <10.5 g/dL (hematocrit <32%) in the second trimester. A pregnant woman will lose blood during delivery and the puerperium, and an anemic woman is at increased jeopardy of blood transfusion and its related complications.

During pregnancy, the blood volume increases by approximately 50% and the red blood cell mass by approximately 33%. This relatively greater increase in plasma volume results in a lower hematocrit but does not truly represent anemia.

Anemia in pregnancy most commonly results from a nutritional deficiency in either iron or folate. Pernicious anemia due to vitamin B_{12} deficiency almost never occurs during pregnancy. Other anemias occurring during pregnancy include anemia of chronic disease; anemia due to hemoglobinopathy; immune, chronic (eg, hereditary spherocytosis or paroxysmal nocturnal hemoglobinuria), or drug-induced hemolytic anemia; and aplastic anemia.

1. Iron Deficiency Anemia

ESSENTIALS OF DIAGNOSIS

▸ Hypochromic and microcytic anemia with evidence of depleted iron stores

---

Pathogenesis

Iron deficiency is responsible for approximately 95% of the anemias during pregnancy, reflecting the increased demands for iron. The total body iron consists mostly of (1) iron in hemoglobin (approximately 70% of total iron; approximately 1700 mg in a 56-kg woman) and (2) iron stored as ferritin and hemosiderin in reticuloendothelial cells in bone marrow, the spleen, and parenchymal cells of the liver (approximately 300 mg). Small amounts of iron exist in myoglobin, plasma, and various enzymes. The absence of hemosiderin in the bone marrow indicates that iron stores are depleted. This finding is both diagnostic of anemia and an early sign of iron deficiency. Subsequent events are a decrease in serum iron, an increase in serum total iron-binding capacity, and anemia.

During the first half of pregnancy, iron requirements may not be increased significantly, and iron absorbed from food (approximately 1 mg/d) is sufficient to cover the basal loss of 1 mg/d. However, in the second half of pregnancy, iron requirements increase due to expansion of red blood cell mass and rapid growth of the fetus. Increased numbers of red blood cells and a greater hemoglobin mass require approximately 500 mg of iron. The iron needs of the fetus average 300 mg. Thus, the additional amount of iron needed due to the pregnancy is approximately 800 mg. Data published by the Food and Nutrition Board of the National Academy of Sciences show that pregnancy increases a woman's iron requirements to approximately 3.5 mg/d. This need outstrips the 1 mg/d of iron available from the normal diet.

Prevention

It is unclear whether the well-nourished, nonanemic woman benefits from routine iron supplementation during pregnancy. However, for women with a history of iron deficiency anemia, at least 60 mg/d of elemental iron should be prescribed to prevent anemia during the course of pregnancy and the puerperium.

Clinical Findings

A. Symptoms & Signs

The symptoms may be vague and nonspecific, including pallor, easy fatigability, headache, palpitations, tachycardia, and dyspnea. Angular stomatitis, glossitis, and koilonychia (spoon nails) may be present in longstanding severe anemia.

B. Laboratory Findings

The hematocrit is <33% in the first or third trimesters or <32% in the second trimester. The hemoglobin may fall as low as 3 g/dL, but the red cell count is rarely below $2.5 \times 10^6/\text{mm}^3$. The red cells usually are hypochromic and microcytic, with mean corpuscular volumes of <79 fL. Serum ferritin concentrations fall to <15 µg/dL and transferrin saturation to <16%. Serum iron levels usually are <60 µg/dL. The total iron-binding capacity is elevated in both normal pregnancies and pregnancies affected by iron deficiency anemia and, therefore, is of little diagnostic value by itself. The reticulocyte count is low for the degree of anemia. Platelet counts are frequently increased, but white cell counts are normal. Bone marrow biopsy demonstrates lack of stainable iron in marrow macrophages and erythroid precursors but usually is unnecessary in uncomplicated iron deficiency anemia.

Differential Diagnosis

Anemia due to chronic disease or an inflammatory process (eg, rheumatoid arthritis) may be hypochromic and microcytic. Anemia due to thalassemia trait can be differentiated from iron deficiency anemia by normal serum iron levels and ferritin levels, the presence of stainable iron in the marrow, and elevated levels of hemoglobin A_2. Other less common causes of microcytic, hypochromic anemia include sideroblastic anemia and anemia due to lead poisoning.

Complications

Iron deficiency anemia may be associated with intrauterine growth retardation and preterm birth. There also appears to be an association between iron deficiency anemia and an increased risk of postpartum depression.

Angina pectoris or congestive heart failure may develop as a result of marked iron deficiency anemia. **Sideropenic dysphagia (Paterson-Kelly syndrome, Plummer-Vinson syndrome**) is a rare condition characterized by dysphagia, esophageal web, and atrophic glossitis due to long-standing severe iron deficiency anemia.

Severe anemia with hemoglobin <6–7 g/dL has been associated with reduced fetal oxygenation, abnormal fetal heart tracing, low amniotic fluid volume, and intrauterine fetal demise.

Treatment

In an established case of anemia, prompt adequate treatment is necessary.

A. Oral Iron Therapy

Ferrous sulfate 300 mg (containing 60 mg of elemental iron, of which approximately 10% is absorbed) should be given 3 times per day. If this agent is not tolerated, ferrous fumarate or gluconate should be prescribed. Therapy should be continued for approximately 3 months after hemoglobin values return to normal in order to replenish iron stores. Hemoglobin levels should increase by at least 0.3 g/dL/wk if the patient is responding to therapy.

Iron is best absorbed in the ferrous or reduced form from an empty stomach. Administering ascorbic acid via supplement or citrus juice at the time of iron supplementation creates a mildly acidic environment that aids the absorption of iron.

B. Parenteral Iron Therapy

The indication for parenteral iron is intolerance of, or refractoriness to, oral iron. In most cases of moderate iron deficiency anemia, the total iron requirements equal the amount of iron needed to restore hemoglobin levels to normal or near normal plus 50% of that amount to replenish iron stores.

Iron dextran is the most widely available parenteral iron preparation in the United States. While it may be given intramuscularly, it is preferable to administer it intravenously (IV). Each 2-mL vial provides 100 mg of elemental iron. After a 0.5-mL test dose, iron dextran can be administered intramuscularly or IV at a rate not to exceed 100 mg/d of elemental iron. Intramuscular injection must always be given into the muscle mass of the upper outer quadrant of the buttock with a 2-in, 20-gauge needle, using the Z technique (ie, pulling the skin and superficial musculature to one side before inserting the needle to prevent leakage of the solution and subsequent tattooing of the skin). Intramuscular iron raises hemoglobin concentration only slightly faster than oral iron administration due to slow and occasionally incomplete mobilization of iron from the muscle. Risks of parenteral iron administration include anaphylactic reaction (approximately 1% risk), muscle necrosis, fever, and phlebitis.

Other forms of IV iron such as ferric gluconate complex may also be administered IV. Ferric gluconate complex is associated with a lower incidence of adverse reactions.

C. Erythropoietin

Few studies have evaluated the role of erythropoietin in pregnant women with iron deficiency anemia. Although the data are conflicting, erythropoietin administered in conjunction with IV iron may be associated with a shorter time to targeted hematologic indices than IV iron alone. The addition of erythropoietin to iron therapy may be considered in women for whom rapid correction of anemia is desired, particularly women in the third trimester of pregnancy.

D. Blood Transfusion

Blood transfusion is generally reserved for women with coexisting issues such as operative deliver or postpartum hemorrhage or women with evidence of active bleeding. It may also be considered for women with hemoglobin <6–7 g/dL due to the increased risk of obstetrical and fetal complications in women with anemia of this severity.

2. Megaloblastic Anemia of Pregnancy

ESSENTIALS OF DIAGNOSIS

- Macrocytic anemia with low serum levels of folate or vitamin B_{12}

Pathogenesis

Megaloblastic anemia of pregnancy is most commonly caused by folic acid deficiency and is common where nutrition is inadequate. In the United States, access to fresh vegetables and the fortification of grains makes folate deficiency much less common than in the developing world.

In the nonpregnant woman, the minimum daily intake of folate necessary for adequate hematopoiesis and to maintain stores is 50 mg. However, this requirement increases during pregnancy. In order to meet this need and to decrease the neural tube defects associated with folate deficiency, a dietary supplement of at least 400 mg/d of folic acid is recommended.

Additional folic acid may be required in states of heightened DNA synthesis, such as multifetal gestation. Similarly, patients with a chronic hemolytic anemia such as **sickle cell anemia** require additional folate supplementation in order to meet the demand imposed by increased hematopoiesis. Other hemolytic states are also commonly complicated by folic acid deficiency, including **hereditary spherocytosis** and **malaria**.

Folic acid absorption or metabolism may be impaired by the use of oral contraceptives, pyrimethamine, trimethoprim-sulfamethoxazole, primidone, phenytoin, or barbiturates. Alcohol consumption also interferes with folate metabolism. Jejunal bypass surgery for obesity or the malabsorption syndrome (sprue) may impair folic acid absorption.

Megaloblastic anemia may also be caused by vitamin B_{12} deficiency. Women with a history of partial or total gastrectomy or Crohn’s disease are at risk of vitamin B_{12} deficiency.

Clinical Findings

A. Symptoms & Signs

The symptoms are nonspecific (eg, lassitude, anorexia, nausea and vomiting, diarrhea, and depression). Pallor often is not marked. Rarely, a sore mouth or tongue is present. Occasionally, purpura may be a clinical manifestation. Megaloblastic anemia should be suspected if iron deficiency anemia fails to respond to iron therapy.

B. Laboratory Findings

Folic acid deficiency results in a hematologic picture similar to that of true pernicious anemia (autoimmune disease that leads to vitamin B_{12} deficiency), which is extremely rare in women of childbearing age.

The hemoglobin may be as low as 4–6 g/dL, and the red cell count may be <2 million/μL in severe cases. Extreme anemia often is associated with leukocytopenia and thrombocytopenia.

The red cells are macrocytic (mean corpuscular volume usually >100 fL) and appear as macro-ovalocytes on peripheral blood smear. However, in pregnancy, macrocytosis may be concealed by accompanying iron deficiency or thalassemia. Up to 70% of folate-deficient patients also lack iron stores.

Serum folate levels <4 ng/mL are suggestive of folic acid depletion in nonpregnant patients. However, in otherwise normal pregnant patients, folate tends to fall slowly to low levels (3–6 ng/mL) with advancing gestation. The red cell folate level in megaloblastic patients is lower, but in 30% of patients, the values overlap. The peripheral white blood cells are hypersegmented. Seventy-five percent of folate-deficient patients have more than 5% neutrophils with 5 or more lobes, but this also may be true for 25% of normal pregnant patients.

The urinary excretion of formiminoglutamic acid (FIGLU) has been used to diagnose folate deficiency, but levels are abnormal only in severe megaloblastic anemia. Bone marrow aspirate demonstrates megaloblastic erythropoiesis but usually is not necessary for diagnosis. Serum iron and vitamin B_{12} levels should be normal.

In women with vitamin B_{12} deficiency, low serum levels of vitamin B_{12} are seen.

Treatment

If the megaloblastic anemia is due to folate deficiency, folic acid 1–5 mg/d orally is initiated. This therapy produces the maximum hematologic response, replaces body stores, and provides the minimum daily requirements. The hematocrit should rise approximately 1% each day, beginning on day 5–6 of therapy. The reticulocyte count should become elevated after 3–4 days of therapy and is the earliest morphologic sign of response. Iron supplementation should be administered as indicated.

For women with vitamin B_{12} deficiency, 1000 μg of vitamin B_{12} should be administered intramuscularly or subcutaneously monthly.

Prognosis

Megaloblastic anemia due to folate deficiency during pregnancy carries a good prognosis if adequately treated.

The anemia usually is mild unless associated with multifetal pregnancy, systemic infection, or hemolytic disease (eg, sickle cell anemia). Low birthweight as well as fetal neural tube defects are known to be associated with maternal folic acid deficiency. The associations with placental abruption, spontaneous abortion, and preeclampsia–eclampsia are not universally accepted. Even without treatment, anemia due to folate deficiency usually resolves after delivery when folate demands normalize.

3. Aplastic Anemia

ESSENTIALS OF DIAGNOSIS

- Pancytopenia
- Empty bone marrow on biopsy

Pathogenesis

Aplastic anemia with primary bone marrow failure during pregnancy is rare. The anemia may be secondary to exposure to known marrow toxins, such as chloramphenicol, phenylbutazone, mephenytoin, alkylating chemotherapeutic agents, or insecticides. In approximately two-thirds of cases, no obvious cause is detected. Idiopathic aplastic anemia in pregnancy may have a spontaneous remission following delivery or pregnancy termination but may recur in subsequent pregnancies. The condition likely is immunologically mediated.

Clinical Findings

The rapidly developing anemia causes pallor, fatigue, tachycardia, painful ulceration of the throat, and fever. The diagnostic criteria are pancytopenia and empty bone marrow on biopsy examination.

Complications

Aplastic anemia in pregnancy may cause increased fetal wastage, prematurity, or intrauterine fetal demise. Increased maternal morbidity and death usually are due to infection and hemorrhage.

Treatment

The patient must avoid any toxic agents known to cause aplastic anemia. Blood product replacement with packed red blood cells and platelets should be used as needed. In some cases, delivery or termination of pregnancy may be necessary. Bone marrow transplantation is performed if remission does not occur following delivery or termination of pregnancy. Other possible treatments include antithymocyte antibody, corticosteroids, or immunosuppressive agents. Infection must be treated aggressively with appropriate antibiotics, but most authorities do not recommend giving prophylactic antibiotics.

Prognosis

Pregnancy generally does not affect the prognosis of aplastic anemia. Prognosis is dependent on degree of bone marrow cellularity and patient age.

4. Drug-Induced Hemolytic Anemia

ESSENTIALS OF DIAGNOSIS

- Anemia with evidence of hemolysis

Pathogenesis

Drug-induced hemolytic anemia usually occurs as a result of drug-mediated immunologic red cell injury. For example, a drug can act as a hapten with an erythrocyte protein to which an antidrug antibody attaches. Hemolysis occurs as a result of the subsequent immune response. Many drugs used in pregnancy can have such an effect, including cephalosporins, acetaminophen, and erythromycin.

In African-American women, drug-induced hemolytic anemia is more likely caused by drug-induced oxidative damage rather than a drug-mediated immune mechanism. The most common congenital erythrocyte enzymatic defect to cause this condition is **glucose-6-phosphate dehydrogenase (G6PD) deficiency**. This X-linked disorder causes a heterozygous state in 10–15% of

African-American females, but enzyme activity is variable due to random X-chromosome inactivation.

Decreased G6PD activity in one-third of patients in the third trimester causes an increased risk of hemolytic episodes. More than 40 substances toxic to susceptible people are recognized, including sulfonamides, nitrofurans, antipyretics, some analgesics, sulfones, vitamin K analogues, uncooked fava beans, some antimalarials, naphthalene, and nalidixic acid. Specific laboratory tests to identify susceptible individuals include a glutathione stability test and cresyl blue dye reduction test.

Clinical Findings

The red blood cell count and morphology are normal until hemolysis occurs. Levels of anemia are variable depending on the degree of hemolysis. Hemolysis can be diagnosed based on examination of peripheral smear, which may demonstrate spherocytes, elliptocytes, schistocytes, or helmet cells (fragmented red blood cells). Elevated lactate dehydrogenase (LDH) is also used to diagnose hemolysis. Patients with hemolytic anemia also demonstrate an increase in reticulocyte count.

Complications

Exposure of the G6PD-deficient fetus to maternally ingested oxidant drugs (eg, sulfonamides) may produce fetal hemolysis, hydrops fetalis, and fetal death.

Treatment

Management includes immediate discontinuation of any suspected medications, treatment of intercurrent illness, and blood transfusion where indicated.

SICKLE CELL DISEASE

ESSENTIALS OF DIAGNOSIS

- ▶ Abnormal hemoglobin (hemoglobin S) leads to sickling of erythrocytes in the setting of decreased oxygen tension.
- ▶ Hemoglobin electrophoresis demonstrates hemoglobin S.
- ▶ Pregnancy in women with sickle cell disease is associated with an increased risk of obstetrical complications.

Pathogenesis

Sickle cell hemoglobin (hemoglobin S) results from a genetic substitution of valine for glutamic acid at codon 6 of the β-globin chains. Decreased oxygen tension causes hemoglobin S to form insoluble polymers in curvilinear strands. These polymers deform the normal biconcave structure of the erythrocyte. The process is reversible but eventually leads to cell membrane damage and permanent sickling.

Patients homozygous for the hemoglobin S gene have **sickle cell anemia (SS disease**), and those who are heterozygous have **sickle cell trait**. Approximately 8–10% of African-Americans carry the sickle cell trait, whereas approximately 1 in 500 has sickle cell anemia.

Other sickling syndromes exist when the gene for hemoglobin S is inherited along with the gene for another abnormal hemoglobin, such as hemoglobin C or thalassemia. Hemoglobin C, also caused by β-globin chain mutation, is less soluble than normal hemoglobin A and has a propensity to form hexagonal crystals. Women who are heterozygous for both the S and C genes have **hemoglobin SC disease**. Maternal mortality rates are as high as 2–3%. Hemoglobin SC disease is peculiarly associated with embolization of necrotic fat and cellular bone marrow with resultant respiratory insufficiency. Neurologic symptoms from fat embolism have been reported with sickle cell disease.

In **hemoglobin S/beta-thalassemia disease**, the patient is heterozygous for both hemoglobin S and beta-thalassemia. The severity of complications during pregnancy is related to hemoglobin S concentrations in this particular disease.

Sickle cell disease is characterized by chronic hemolytic anemia and intermittent crises of variable frequency and severity. Although persons with sickle cell trait are not anemic and usually are asymptomatic, they are at increased risk of developing urinary tract infections during pregnancy and are at higher risk for preeclampsia. Additionally, their red blood cells tend to sickle when oxygen tension is significantly lowered.

Clinical Findings

A. Symptoms & Signs

1. Chronic anemia—Chronic anemia results from the shortened survival time of the homozygous S red blood cells due to circulation trauma and intravascular hemolysis or phagocytosis by reticuloendothelial cells in the spleen and liver.

2. Sickling of red blood cells—Intravascular sickling leads to vaso-occlusion and infarction. Small blood vessels supplying various organs and tissues can be partially or completely blocked by sickled erythrocytes, resulting in ischemia, pain, necrosis, and organ damage.

3. Crises—Crises of variable frequency and severity occur. **Pain crises** involve the bones and joints. They usually are precipitated by dehydration, acidosis, or infection. An **aplastic crisis** is characterized by rapidly developing anemia. The hemoglobin may be as low as 2–3 g/dL due to cessation of red blood cell production. An **acute splenic sequestration** crisis is associated with severe anemia and hypovolemic shock, resulting from sudden massive trapping of red blood cells within the splenic sinusoids.

4. Other manifestations—Other manifestations include increased susceptibility to bacterial infection; bacterial pneumonia and pulmonary infarction; myocardial damage and cardiomegaly; and functional and anatomic renal abnormalities in the form of sickle cell nephropathy or papillary renal necrosis, resulting in hematuria. Central nervous system manifestations include headache, convulsions, hemorrhage, or thrombosis (from vaso-occlusion). Ophthalmologic abnormalities include anoxic retinal damage, retinal detachments, vitreous hemorrhages, and proliferative retinopathy. Hepatosplenomegaly or cholelithiasis may occur.

B. Laboratory Findings

Screening for abnormal hemoglobin is imperative in the population at risk. Hemoglobin electrophoresis ascertains the diagnosis and can differentiate between homozygous and heterozygous states.

Complications

Sickle cell anemia is associated with serious risks for mother and fetus. Pregnant women with sickle cell disease face increased rates of maternal mortality and morbidity from hemolytic and folic acid deficiency anemias, frequent crises, pulmonary complications, congestive heart failure, infection, and preeclampsia–eclampsia. It is encouraging, however, that maternal mortality has decreased to 1% since 1972. There is an increased incidence of early fetal wastage, stillbirth, preterm delivery, and fetal growth restriction. The course of pregnancy is generally more benign in women with hemoglobin SC disease than women with sickle cell disease.

Treatment

Preconception counseling is essential in women with sickle cell disease to optimize the patient's health prior to conception. Many women with sickle cell disease are treated with hydroxyurea. Hydroxyurea use in pregnancy has been associated with fetal structural malformations in animals and is poorly studied in humans. Therefore, it should be discontinued prior to conception. Assessment of preconception health includes maternal echocardiogram to evaluate ejection fraction and to look for signs of pulmonary hypertension. Type and screen should also be tested for any sign of alloimmunization. Many women with sickle cell disease have a history of multiple blood transfusions, which puts them at risk of development of alloantibodies that could affect the fetus.

Additionally, preconception or prenatal genetic counseling is of great importance. If both partners have the gene for S hemoglobin, their offspring have a 1 in 4 chance of having sickle cell anemia. If it is determined that a fetus is at risk of hemoglobinopathy, chorionic villus sampling or amniocentesis can diagnose these disorders in the fetus. Preimplantation genetic diagnosis using single-blastomere DNA analysis prior to in vitro fertilization has allowed for the successful transfer of unaffected embryos.

Optimal prenatal care, including prevention or rapid treatment of complications, is necessary to increase the chance for a good outcome. Pneumococcal polyvalent vaccine has been shown to reduce the incidence of pneumococcal infection in adults with sickle disease and therefore is highly recommended. This vaccine is not contraindicated in pregnancy. Similarly, influenza vaccine should be administered annually. Folic acid 1 mg/d will prevent megaloblastic anemia, which can result from intense hematopoiesis. Serial ultrasonic evaluations are essential to assess fetal growth. Antepartum testing should begin at 32–34 weeks' gestation. Careful surveillance for asymptomatic bacteriuria and demonstration of cure is important for preventing pyelonephritis. Regional anesthesia can be safely administered to patients with sickle cell disease while they are in labor.

In the management of crises, the most common predisposing factors—infection, dehydration, and hypoxia—should be evaluated and treated. Symptomatic treatment of pain crisis consists of IV fluid, oxygen supplementation, and adequate analgesics (eg, morphine). Bacterial pneumonia or pyelonephritis must be treated vigorously with IV antibiotics. Streptococcal pneumonia is common and is a serious complication. In all cases, adequate oxygenation must be maintained by face mask as necessary.

The concentration of hemoglobin S should be <50% of the total hemoglobin to prevent crisis. Blood transfusion should be considered in cases of a fall in hematocrit to <25%, but this decision must be guided by the individual patient history and her status during pregnancy. Important considerations are repeated crisis; symptoms of tachycardia, palpitation, dyspnea, or fatigue; and evidence of inadequate or retarded intrauterine growth.

Randomized controlled trials have shown that administration of prophylactic hypertransfusion or exchange transfusion is not necessary to prevent maternal and fetal complications, except in well-defined circumstances. Transfusion carries the risks of allergic reaction, delayed hemolytic reaction, isoimmunization, and transmission of infection.

Bone marrow transplant has been limited by the complications of infection and graft-versus-host disease but shows promise as a potential long-term solution to sickle cell anemia. In utero stem cell therapy with normal hemoglobin stem cells is a potential future treatment for affected fetuses.

THALASSEMIA

ESSENTIALS OF DIAGNOSIS

- The thalassemias are genetically determined disorders of reduced synthesis of 1 or more of the structurally normal globin chains in hemoglobin.
- Thalassemia is associated with varying degrees of anemia, depending on the type and number of globin chains that are reduced or absent.

Pathogenesis

Thalassemia is found throughout the world but is concentrated in the Mediterranean coastal areas, central Africa, and parts of Asia. The high incidence in these regions may represent a balanced polymorphism due to heterozygous advantage.

All thalassemias are inherited as an autosomal recessive trait. The 2 major groups are the alpha- and beta-thalassemias, both of which affect the synthesis of hemoglobin A, which contains 2 α and 2 β chains. The severity of the anemia varies with the type of hemoglobin abnormality.

Alpha-thalassemia is due to defective production of α-globin chains, resulting in a relative excess of β-globin chains. In beta-thalassemia, hemoglobin β-chain synthesis is defective, but the α chains are produced normally. In both cases, the unbalanced synthesis results in a relative excess of the normally produced chain. The normal globin chains then form tetramers that precipitate within red blood cell precursors in the bone marrow, resulting in ineffective erythropoiesis, red cell sequestration and destruction, and hypochromic anemia. The most severe forms of this disorder may cause intrauterine or childhood death. A person who is heterozygous, or a carrier, for a thalassemia trait may be asymptomatic.

Clinical findings

A. Alpha-Thalassemia

Normally, a patient has 4 functional α-globin genes. Disease severity with alpha-thalassemia varies depending on how many genes are absent or mutated.

1. Alpha-thalassemia-2 trait is seen when 1 of the 4 genes is absent. These patients are not anemic, do not have microcytic red cells, and have a normal hemoglobin electrophoresis.
2. Alpha-thalassemia-1 trait, or alpha-thalassemia minor, is seen when 2 of the 4 genes are absent. These patients may have mild anemia with microcytic red cells, but their hemoglobin electrophoresis is normal.
3. Hemoglobin H (β_4) disease results from deletion of 3 of the 4 α-globin genes. In patients with this

disease, some normal hemoglobin A ($\alpha_2\beta_2$) is produced because one of the α-globin genes is present, but the excess of β-globin changes causes the formation of hemoglobin H (β_4) as well. Anemia of variable degree results that usually is worsened in pregnancy. Hemoglobin electrophoresis demonstrates 5–30% hemoglobin H.

4. Hemoglobin Barts is seen with loss of all 4 α-globin genes. This condition is not compatible with extrauterine life. It is associated with fetal hydrops and intrauterine fetal demise.

Maternal hemoglobin H is generally diagnosed prior to pregnancy. Alpha-thalassemia-2 trait and alpha-thalassemia minor may not be diagnosed prior to pregnancy and are relevant in that if the father is a carrier of thalassemia or another hemoglobinopathy, the fetus at risk for significant disease. If the fetus is at risk for thalassemia, prenatal diagnosis is available via DNA testing of fetal cells obtained from amniocentesis or chorionic villus sampling. Preimplantation genetic diagnosis is also available for couples at risk of having a fetus with severe alpha-thalassemia who are undergoing in vitro fertilization.

B. Beta-Thalassemia

Beta-thalassemia results from impaired β-globin chain production. **Beta-thalassemia major** is the homozygous state, in which there is little or no production of β-chains. At birth, the neonate usually is asymptomatic because fetal hemoglobin F ($\alpha_2\gamma_2$) contains no β-globin chain. However, this protection disappears at birth, when fetal hemoglobin production terminates. At approximately 1 year of age, a baby with defective β-globin production usually begins to show signs of thalassemia (anemia, hepatosplenomegaly) and requires frequent blood transfusions. Affected individuals often die in their late teens or early 20s because of congestive heart failure, often related to myocardial hemosiderosis and liver failure. However, improved treatment with transfusion and iron chelation has led to overall improved survival and even to successful pregnancies in women with beta-thalassemia major.

Beta-thalassemia minor, the heterozygous state, is frequently diagnosed only after the patient fails to respond to iron therapy or delivers a baby with homozygous disease. Such patients usually suffer from mild to moderate hypochromic microcytic anemia, with increased red blood cell count, elevated hemoglobin A_2 ($\alpha_2\delta_2$) concentrations, increased serum iron levels, and iron saturation >20%, although hemoglobin electrophoresis may miss a small percentage of patients with beta-thalassemia minor.

Suspected adult cases of thalassemia are diagnosed by hemoglobin electrophoresis. As with alpha-thalassemia, antenatal diagnosis of beta-thalassemia is possible. Molecular hybridization measures the number of intact α-globin structural genes in fetal cells obtained by amniocentesis. Preimplantation genetic diagnosis allows for the transfer of unaffected embryos after in vitro fertilization.

LYMPHOMA & LEUKEMIA

1. Hodgkin’s Lymphoma

Hodgkin’s lymphoma (previously known as Hodgkin’s disease) is the most common lymphoma to affect women of childbearing age. Even so, it is uncommon during pregnancy, affecting only approximately 1 in 6000 pregnancies.

Clinical Findings

Patients may be asymptomatic or have fever, weight loss, and pruritus. The most common finding is peripheral lymphadenopathy. Histologic evaluation of the affected nodes establishes the diagnosis.

Careful staging is essential prior to the initiation of treatment with radiotherapy or chemotherapy. Modifications of standard staging modalities, such as the use of magnetic resonance imaging (MRI), can allow for adequate staging during pregnancy. However, some procedures, such as staging laparotomy, after the first trimester impose risks to the pregnancy.

Complications

Complications associated with Hodgkin's lymphoma during pregnancy are related to treatment of the disease, not the disease itself. Chemotherapy during the first trimester is associated with an increased risk of fetal structural malformation. During the second and third trimesters, chemotherapy is associated with intrauterine growth restriction, preterm birth, stillbirth, and adverse fetal neurodevelopmental outcomes such as mental retardation and learning disabilities. Children exposed to chemotherapy in utero appear to be at increased risk of cancer themselves.

Treatment

Treatment is tailored to the individual based on the extent of disease and the gestational age. Radiotherapy is an effective treatment option if radiation scatter to the fetus can be minimized. Chemotherapy is relatively safe later in gestation but best avoided in the first trimester if the clinical situation allows. Pregnancy termination is an alternative if Hodgkin's lymphoma is diagnosed early in gestation. Although pregnancy itself does not appear to adversely affect the lymphoma, pregnancy termination permits the aggressive radiotherapy and chemotherapy often necessary. Conversely, if the diagnosis is made later in gestation and the patient is asymptomatic, delaying therapy until fetal lung maturity is established may be reasonable.

Women with Hodgkin's lymphoma are extremely susceptible to infection and sepsis. Sequelae of treatment include radiation pneumonitis causing restrictive lung disease, pericarditis leading to congestive heart failure, hypothyroidism, and ovarian failure. Given that 85% of relapses in Hodgkin's lymphoma occur within 2 years, it is generally accepted that pregnancy should be deferred for 2 years following remission. The risk of second malignancies, especially leukemia, is dramatically increased.

2. Non-Hodgkin's Lymphoma

Until recently, non-Hodgkin's lymphomas were encountered infrequently in pregnancy. However, because 5–10% of individuals infected with the human immunodeficiency virus (HIV) will develop a lymphoma, the incidence of non-Hodgkin's lymphomas is rising. Similar to Hodgkin's lymphoma, extensive staging is essential. Treatment with radiotherapy is indicated for localized disease, whereas chemotherapy is used for more extensive disease. Care of the pregnant patient with lymphoma requires a multidisciplinary approach by obstetrician-gynecologists, hematologic oncologists, perinatologists, and neonatologists. With careful treatment, the fetuses of affected women appear to tolerate treatment of lymphoma quite well.

3. Leukemia

Leukemias are malignant proliferations of cells of the hematopoietic system. Acute leukemias are derived from primitive progenitor cells of either the myeloid lineage (**acute myelogenous leukemia** [AML]) or the lymphocytic lineage (**acute lymphocytic leukemia** [ALL]). Chronic leukemias are also derived from either myeloid cells (**chronic myelogenous leukemia** [CML]) or lymphocytic cells (**chronic lymphocytic leukemia** [CLL]). All leukemias are rare before age 40 years with the exception of ALL, a childhood disease with a median age at diagnosis of 10 years.

Clinical Findings

Affected individuals often present with the symptoms of anemia (fatigue, weakness), thrombocytopenia (bleeding, bruising), or neutropenia (infection) caused by the replacement of normal hematopoietic cells with leukemia cells in the bone marrow. White blood cell count in the serum can be low, normal, or extremely elevated. Diagnosis is made by cytochemical, genetic, and immunochemical evaluations of the cells of a bone marrow biopsy or aspirate.

Treatment

Treatment of acute leukemia is based on immediate initiation of chemotherapy. For example, the median survival time of untreated patients with AML is 3 months or less. Exposure to chemotherapy during organogenesis frequently results in fetal death. However, most authorities consider chemotherapy safe in the second and third trimesters. A period of pancytopenia following chemotherapy can be complicated by infection and hemorrhage. Patients often require erythrocyte and platelet transfusions, as well as antibiotic medications.

Acute leukemia during pregnancy is associated with premature delivery, fetal growth restriction, and fetal loss, but these findings are more likely due to chemotherapy and its complications rather than the leukemia itself.

HEMORRHAGIC DISORDERS

Although hemorrhagic disorders (eg, immune thrombocytopenic purpura [ITP], disseminated intravascular coagulation, circulating anticoagulants) are not common during pregnancy, these conditions could cause significant risks for both mother and fetus.

1. Gestational Thrombocytopenia

Incidental thrombocytopenia of pregnancy, also termed *gestational thrombocytopenia*, affects 5% of pregnancies. It is characterized by mild, asymptomatic thrombocytopenia with platelet levels usually >70,000/μL. It usually occurs late in gestation and resolves spontaneously after delivery. Gestational thrombocytopenia has no association with fetal thrombocytopenia. Its etiology is unclear, although some authorities suspect that gestational thrombocytopenia represents a very mild form of ITP. Antiplatelet antibodies are isolated from patients in both groups and therefore do not aid in diagnosis. Routine obstetric management is appropriate.

2. Immune Thrombocytopenic Purpura

In ITP, also called **idiopathic thrombocytopenic purpura**, platelet destruction is secondary to a circulating immunoglobulin (Ig) G antiplatelet antibody that crosses the placenta and may affect fetal platelets.

Clinical Findings

The maternal clinical picture varies from asymptomatic to minor bruises or petechiae, bleeding from mucosal sites, or rarely fatal intracranial bleeding. Splenomegaly may be present. In the peripheral circulation, the platelet count often is between 80,000 and 160,000/μL, but it may be lower. The bone marrow aspirate demonstrates hyperplasia of megakaryocytes, although this test is rarely indicated.

The diagnosis can be made once laboratory evaluation demonstrates an isolated thrombocytopenia and other causes, such as drug-induced or HIV-related thrombocytopenia, have been excluded. Antiplatelet antibody testing is not diagnostic.

Complications

Because maternal IgG antiplatelet antibodies cross the placenta, the fetus is at risk for severe thrombocytopenia. Fortunately, only approximately 10% of infants born to women with ITP have platelet counts less than 50,000/μL at birth. Antepartum identification of severely affected fetuses has proved difficult. Maternal and fetal platelet counts do not correlate well, nor do levels of maternal antiplatelet antibody and fetal platelet levels. Given the low incidence of severe neonatal thrombocytopenia and morbidity, most authorities do not recommend direct fetal platelet determination by fetal scalp sampling or umbilical cord blood sampling.

Treatment

The standard management is to initiate treatment when the platelet count falls to <30,000–50,000/μL, although significant bleeding does not begin until platelet levels are <10,000/μL. Glucocorticoids suppress the phagocytic activity in the splenic monocyte-macrophage system, increasing platelet levels in approximately two-thirds of patients. Patients refractory to steroid therapy are candidates for immunoglobulin infusion, which has been a great benefit to most patients who fail glucocorticoid therapy. Splenectomy usually is reserved for patients refractory to prednisone and IV immunoglobulin. Immunosuppressive agents should be used with great caution and only in extraordinary cases of ITP in pregnancy. Transfusion of platelets and whole blood may be necessary to restore losses from acute hemorrhage or to normalize low perioperative platelet counts (<50,000/mL).

THROMBOEMBOLISM

Pathogenesis

Venous thromboembolism (VTE) affects approximately 1 in 1000 pregnancies. Pregnancy and the puerperium are periods of increased risk for these events because they are hypercoagulable states. Indeed, all the elements of **Virchow’s triad** (circulatory stasis, vascular damage, and hypercoagulability of blood) are present. Increased venous capacity during pregnancy coupled with compression of large veins by the gravid uterus causes venous stasis. Endothelial damage occurs at delivery and is more extensive after caesarean delivery, contributing to the increased risk of VTE after caesarean section. Coagulation is favored during pregnancy due to estrogen stimulation of coagulation factors and decreased activity of the fibrinolytic.

Inherited thrombophilias such as **activated protein C resistance** (most commonly due to the **factor V Leiden** mutation), prothrombin gene mutation, **antithrombin III deficiency**, and **protein C and protein S deficiency**, along with acquired thrombophilias such as the **antiphospholipid syndrome (APS**), have emerged as important risk factors for VTE. Other risk factors include prior VTE, older age, smoking, and immobilization.

1. Superficial Thrombophlebitis

Patients with thrombosis of the superficial veins of the saphenous system present with tenderness, pain, or erythema along a vein. A palpable cord is sometimes present. Because of the possibility of concurrent deep vein thrombosis (DVT), compression ultrasound is reasonable to confirm the diagnosis and exclude DVT. Treatment consists of compression stockings, ambulation, leg elevation, local heat, and analgesic medications. Of note, the superficial femoral vein belongs to the deep venous system despite its name. A thrombus in this vein requires treatment for DVT.

2. Deep Vein Thrombosis

Approximately half of DVT in pregnancy occurs antepartum and half occurs postpartum. Previous clinical practices that contributed to thrombosis, such as prolonged postpartum bed rest, likely falsely elevated the risk of DVT in the puerperium. Greater than 80% of DVT in pregnancy occurs in the left lower extremity rather than the right, a finding attributed to compression of the left iliac vein by the right iliac artery as it branches off the aorta.

Clinical Findings

The presentation of DVT is variable but frequently includes lower extremity tenderness, swelling, color changes, and a palpable cord. **Homan's sign**, pain elicited by passive dorsiflexion of the foot, may be present. Occasionally, the extremity is pale and cool with decreased pulses due to reflex arterial spasm.

Diagnosis

The modality of choice for diagnosis of DVT is real-time ultrasound, used with duplex and color Doppler ultrasound. Venography remains the standard but has been largely replaced by the less invasive diagnostic tests. MRI is used when there is a strong clinical suspicion of thrombus not detected by ultrasound or if the ultrasound results are equivocal. With MRI, anatomy above the inguinal ligament can be evaluated, as can pelvic blood flow.

Treatment

Anticoagulation, bed rest, and analgesia are the fundamental treatments of DVT. Ambulation with elastic stockings begins once all symptoms have abated, usually in 7–10 days. Patients are initially anticoagulated with unfractionated heparin or low-molecular-weight heparin. **Low-molecular-weight heparin** has a longer half-life and increased bioavailability, making administration easier and anticoagulant response more predictable. It is associated with fewer bleeding problems than unfractionated heparin and does not require laboratory monitoring. In the postpartum state, the patient can then transition to warfarin. Due to embryopathy and fetal hemorrhage, warfarin is contraindicated during pregnancy. Antepartum DVT is treated with anticoagulation for the rest of pregnancy and then for 6–12 weeks postpartum for at least a total of 3–6 months of therapy. DVT occurring postpartum should be treated with anticoagulation for 3–6 months.

3. Pulmonary Embolism

Pulmonary embolism accounts for approximately 20% of maternal deaths in the United States. Its antepartum and postpartum prevalence are approximately equal, although postpartum pulmonary embolism is associated with higher mortality rates. Clinical evidence of DVT often precedes pulmonary embolization. However, given the prevalence of thrombosis originating in the iliac veins during pregnancy, antecedent DVT is frequently not clinically apparent.

Prevention

Prophylactic anticoagulation should be considered for women at high risk for thromboembolism during pregnancy. Women with inherited thrombophilias that confer a high risk for thrombosis during pregnancy, such as antithrombin III deficiency, homozygosity for factor V Leiden mutation, or prothrombin gene mutation, or compound heterozygosity for factor V Leiden and prothrombin gene mutations, should be anticoagulated during pregnancy regardless of whether they have an antecedent history of thromboembolism. Women with lower risk thrombophilias, such as protein C or S deficiency and heterozygosity for prothrombin gene mutation (G20210A) or factor V Leiden mutation, *and* a history of thromboembolism should also receive anticoagulation during pregnancy. Women with a prior VTE that was related to a temporary risk factor (eg, prolonged immobilization after injury) do not require anticoagulation during pregnancy. However, for women with a prior thromboembolic event related to pregnancy or estrogen-containing birth control pills and no thrombophilia, consideration may be given to anticoagulation during pregnancy. For this subgroup of women, the American College of Obstetricians and Gynecologists indicates that surveillance without anticoagulation is also acceptable.

Clinical Findings

The most common presenting symptom of pulmonary embolus is dyspnea, followed by pleuritic chest pain, apprehension, cough, syncope, and hemoptysis. Associated signs include tachypnea and tachycardia.

Diagnosis

Initial evaluation of the symptoms associated with pulmonary embolism usually consists of arterial blood gas measurement, chest radiograph, and electrocardiogram. Ventilation–perfusion scintigraphy may be used to evaluate for perfusion defects and ventilation mismatches that suggest pulmonary embolus. The test has negligible fetal radiation exposure. High-probability scans are indicative of pulmonary embolism in 88% of cases. Conversely, in patients with normal or near-normal scans, pulmonary embolism was detected by angiography only 4% of the time. However, the usefulness of this modality is limited by that fact that the majority of results are reported as intermediate- or low-probability scans, categories without much diagnostic value. Because of these limitations, spiral computed tomographic (CT) pulmonary angiography has emerged as a useful, noninvasive modality for the detection of pulmonary embolism but is limited in the detection of small emboli. Pulmonary artery catheterization with angiography remains the gold standard but is used less frequently due to its invasive nature.

Treatment

Treatment of pulmonary embolism is anticoagulation. Guidelines such as those published by the American College of Chest Physicians (2004) should be followed. The factors influencing anticoagulant choice (heparin vs. warfarin [Coumadin]) are the same as those for DVT. First-line therapy during pregnancy is adjusted-dose unfractionated heparin or low-molecular-weight heparin. Therapeutic anticoagulation should be continued for at least 4–6 months to prevent recurrence. Vena caval filter use may be necessary should recurrent embolization occur despite anticoagulation.

SEPTIC PELVIC THROMBOPHLEBITIS

ESSENTIALS OF DIAGNOSIS

- Septic pelvic thrombophlebitis is thrombosis in the veins of the pelvis due to infection.

- It is associated with abdominal pain and high fever.
- CT or MRI can confirm the diagnosis.

Pathogenesis

Septic pelvic thrombophlebitis is thrombosis in the veins of the pelvis due to infection. The most important risk factor is caesarean section, especially if complicated by infection. In fact, almost 90% of cases occur after caesarean delivery. The overall incidence is low, affecting only approximately 1 in every 2000 pregnancies.

Pelvic infection leads to infection of the vein wall and intimal damage. Thrombogenesis occurs at the site of intimal damage. The clot is then invaded by microorganisms. Suppuration follows, with liquefaction, fragmentation, and, finally, septic embolization.

Both the uterine and ovarian veins may be involved, as well as the common iliac, hypogastric, and vaginal veins and the inferior vena cava. The ovarian vein is the most common site of septic thrombosis (40% of cases). The onset of symptoms may be as early as 2–3 days postpartum or as late as 6 weeks after delivery.

Clinical Findings

The condition is suspected when fever persists in the puerperium despite adequate antibiotic therapy for aerobic and anaerobic organisms and no other discernible cause of fever. Abdominal pain and back discomfort are common presenting symptoms. A picket-fence fever curve (“hectic” fevers) with wide swings from normal to as high as 41°C (105.8°F) is seen in 90% of cases. Tachycardia and tachypnea may be present. Leukocytosis usually is present. Blood cultures drawn during fever spikes yield positive results more than 35% of the time.

Pelvic examination often is consistent with a normal postpartum examination and therefore not helpful in diagnosing this condition. However, in approximately 30% of cases, hard, tender, wormlike thrombosed veins may be palpable in the vaginal fornices or in 1 or both parametrial areas. A temperature spike may be noted after examination because of disturbance of infected pelvic veins; this may be considered a diagnostic indication of septic pelvic thrombophlebitis. Chest radiograph often reveals evidence of multiple, small septic emboli. CT or MRI may assist in the diagnosis of pelvic vein thrombosis and eliminate other pelvic causes, such as abscess.

Differential Diagnosis

The differential diagnosis includes pyelonephritis, meningitis, systemic lupus erythematosus, tuberculosis, malaria, typhoid, sickle cell crisis, appendicitis, and torsion of the adnexa.

Complications

The serious complications associated with this condition are septic pulmonary emboli, extension of the venous clot in the pelvis, renal vein thrombosis, ureteral obstruction, and death.

Treatment

The mainstays are anticoagulation with heparin and broad-spectrum antibiotics (including coverage for anaerobes and common Enterobacteriaceae). Within 48–72 hours of initiation of heparin therapy, fever should resolve. Treatment usually is empirically continued for 7–10 days, although the optimal duration of therapy is not well defined.

Section V. General Gynecology

35

Gynecologic History, Examination, & Diagnostic Procedures

Charles Kawada, MD
Drorith Hochner-Celnikier, MD

The gynecologist needs to approach each patient not just as a person requiring medical intervention for a specific presenting problem, but also as one who may have a variety of factors possibly affecting her health. The initial approach to the gynecologic patient and the general diagnostic procedures available for the investigation of gynecologic complaints are presented here. Although other aspects of the general medical examination are left to other texts, concern for the patient's total health and well-being is mandatory.

THE PERIODIC HEALTH SCREENING EXAMINATION

It is now a generally accepted part of the physician's responsibility to advise patients to have periodic medical evaluations. The frequency of visits varies according to the patient's age and specific problem.

The periodic health screening examination helps detect the following ailments of women that are especially amenable to early diagnosis and treatment: diabetes mellitus; urinary tract infection or tumor; hypertension; malnutrition or obesity; thyroid dysfunction or tumor; and breast, abdominal, or pelvic tumor. These conditions can be detected by a review of systems, with specific questions regarding recent abnormalities or any variation in function. Determination of weight, blood pressure, and urinalysis may reveal variations from the previous examination. An examination of the thyroid gland, breasts, abdomen, and pelvis, including a Papanicolaou (Pap) smear, should then be performed. A rectal examination also is advisable, and a conveniently packaged test for occult blood (Hemoccult) is recommended for patients older than 40 years. Patients of an advanced age (>50 years) may undergo blood test for lipid profile, bone density scan, pelvic ultrasound examination, and mammogram.

The physician should be concerned about conditions other than purely somatic ones. Unless a patient's problems require the services of a psychiatrist or some other specialist, the doctor should be prepared to act as a counselor and work with the patient during a mutually agreeable time when it is possible to listen to her problems without being hurried and to give support, counsel, and other kinds of help as required.

HISTORY

To adequately evaluate the gynecologic patient, it is important to establish a rapport during the history taking. The patient needs to tell her story to an interested listener who does not allow body language or facial expressions to imply disinterest or boredom. One should avoid cutting off the patient's story, because doing so may obscure important clues or other problems that may have contributed to the reasons for the visit.

The following outline varies from the routine medical history because, in evaluating the gynecologic patient, the problem often can be clarified if the history is obtained in the following order.

Identifying Information

A. Age

Knowledge of the patient’s age sets the tone for the complaint and the approach to the patient. Obviously, the problems and the approach to them vary at different stages in a woman’s life (pubescence, adolescence, childbearing years, and premenopausal and postmenopausal years).

B. Last Normal Menstrual Period

The date of onset of the last normal menstrual period (LNMP) is important to define. A missed period, irregularity of periods, erratic bleeding, or other abnormalities may all imply certain events that are more easily diagnosed when the date of onset of the LNMP is established.

C. Gravidity & Parity

The process of taking the patient’s obstetric history is detailed in Chapter 6, but the reproductive history should be recorded as part of the gynecologic evaluation. A convenient symbol for recording the reproductive history is a 4-digit code denoting the number of term pregnancies, premature deliveries, abortions, and living children (TPAL) (eg, 2-1-1-3 means 2 term pregnancies, 1 premature delivery, 1 abortion, and 3 living children).

Chief Complaint

The chief complaint usually is best elicited by asking “What kind of problem are you having?” or “How can I help you?” It is important to listen carefully to the way the patient responds to this question and to allow her to fully explain her complaint. The patient should be interrupted only to clarify certain points that may be unclear.

Present Illness

Each of the problems the patient describes must be obtained in detail by questioning regarding what exactly the problem is, where exactly the problem is occurring, the date and time of onset, whether the symptoms are abating or getting worse, the duration of the symptoms when they do occur, and how these symptoms are related to or influence other events in her life. For example, the site, duration, and intensity of pain must be accurately described. Getting a sense of how the pain affects her life often is helpful in evaluating the intensity of pain: “Does the pain prevent you from standing or walking?”

It is important to maintain eye contact with the patient and to listen to every word. Do not rely on a patient’s sophistication as a measure of her knowledge of anatomy and medical terminology. It is important for the physician to judiciously adjust the level of terminology according to the patient’s knowledge and vocabulary. Communicating with the patient in this manner may help the physician obtain an accurate history and establish rapport.

In addition to physiologic events and the life cycle, symptoms described could be related to starting a new job, the beginning of a new relationship or difficulties in the current relationship, an exercise regimen, new medication, and any emotional changes in the patient’s life.

Past History

After the physician is satisfied that all possible information concerning the present illness and the important corollaries has been obtained, the past history should be elicited.

A. Contraception

Continuing with the history, it is important to elicit whether the patient is using or needs some form of contraception. If she is using contraception, her level of satisfaction with her chosen method should be determined. In patients taking oral contraceptives, the history should reflect the agent and dose, whether there is a great variation in the time of day she takes her pill, and any impact of the pill on other physiologic functions. Other forms of hormonal contraceptives, including vaginal rings, dermal patches, and injectable contraceptives, have become available and have their own unique issues. It is extremely important to ask questions during the remainder of the history and to key the physical examination to ascertain whether there are any contraindications to the patient's current form of contraception.

B. Medications & Habits

Any medications, prescribed or otherwise, that are being taken or that were being taken when symptoms first occurred should be described. Particular attention must be directed to use of hormones, steroids, and other compounds likely to influence the reproductive tract. Herbal preparations may not be viewed by the patient as medications, so this question should be specifically asked. In addition to medications, the patient should be questioned concerning her use of street drugs. It must be ascertained whether the patient smokes and, if so, how much and for how long. It is important to ascertain the amount of alcohol ingested, if any. This questioning provides an ideal time to indicate the health risks of various habits.

C. Medical

It is important to discover any history of serious medical and psychiatric illnesses and whether hospitalization was required. Particularly important are illnesses in the major organ systems. It is important to know whether there is a major endocrinopathy in the patient's history. Notable weight gain or loss prior to the onset of the patient's current symptoms should be detailed. Other important details include when she had her last physical examination, including pelvic examination and Pap smear.

D. Surgical

The surgical history includes all operations, the dates performed, and associated postoperative or anesthetic complications.

E. Allergies

Questioning should continue relating any possible allergic reactions to drugs or specific foods. The reaction produced (eg, rash, gastrointestinal upset) must be elicited and the approximate time when it occurred ascertained. Any testing to confirm or deny the observation must be noted. Latex allergy has become more common and severe and should be considered prior to most medical procedures, such as drawing blood samples, pelvic examination, and taking blood pressures.

F. Bleeding & Thrombotic Diatheses

Determining whether or not the patient bleeds excessively in relation to prior surgery or minor trauma is important. A history of easy bruising or of bleeding from the gums while brushing teeth may be useful in this judgment. The patient should be asked whether she or one of her close relatives experienced venous thromboembolism (VTE). A history of VTE may guide the physician as to which treatment to offer. Suspicion of a bleeding or clotting problem indicates the need for further laboratory evaluation.

G. Obstetrics

The obstetric history includes each of the patient's pregnancies listed in chronologic order. The date of birth; sex and weight of the offspring; duration of pregnancy; length of labor; type of delivery; type of anesthesia; and any complications should be included.

H. Gynecologic

The first item in the gynecologic past history is the menstrual history: age at menarche, interval between periods, duration of flow, amount and character of flow, degree of discomfort, and age at menopause. The menstrual history often is an important clue in the diagnosis.

A prior history of sexually transmitted disease (STD) needs to be detailed. Although in the past it was more common to note only gonorrhea and syphilis, it is important to also document exposure to human immunodeficiency virus (HIV), hepatitis, herpesvirus, chlamydia, and papillomavirus. Any treatment or admissions to the hospital for treatment of salpingitis, endometritis, or tubo-ovarian abscess must be carefully documented. Attempts to assess the impact of these processes in relation to ectopic pregnancy, infertility, and type of contraception must be elicited.

Although its significance is less than that of the prior stated diseases, the occurrence of episodes of vaginitis should not be dismissed. Their frequency and the medications used to treat them should be discussed. In the case of such infections, it is important to detail whether or not the episode was pathologic or merely a misinterpreted physiologic circumstance.

I. Sexual

The sexual history should be an integral part of any general gynecologic history. In taking a sexual history, the physician must be nonjudgmental and not embarrassed or critical.

Questions that may be covered include the following. Is she currently sexually active? Is the relationship satisfactory to her and, if not, why not? A question regarding whether the patient is heterosexual or lesbian is important but often difficult to ask because the question may be offensive to some patients. It is important, however, not to assume that a relationship is heterosexual because a lesbian woman will lose all rapport with the physician when the physician is insensitive to such issues.

J. Social

A social history can be an extension of earlier questions pertaining to the marital and sexual history. Knowing the type of work the patient does, the type of educational background, and her community activities may assist in ascertaining the patient's relationship to her entire environment.

The patient's involvement with her own health care should be carefully elicited, including her attention and knowledge concerning diet, health screening examinations, recreation, and the degree of regular physical exercise.

Family History

The patient's family history must include the state of health of immediate relatives (parents, siblings, grandparents, and offspring). In addition to listing these relatives, it is useful in cases where genetic illnesses may be apparent to record a 3-generation pedigree.

The incidence of familial heart disease, hypertensive renal or vascular disease, diabetes mellitus (insulin-dependent or non–insulin-dependent), vascular accidents, and hematologic abnormalities should be ascertained. If the patient has a problem with hirsutism or if she perceives excessive hair growth, it is important to elicit whether anyone in her family has the same distribution of hair growth. Familial history of breast, ovarian, and colon cancers is important to elicit because a close familial history may require additional testing and close follow-up. It is important to relate the time of menopause in the mother or grandmother and to ascertain a history of osteoporosis.

PHYSICAL EXAMINATION

The physical examination is most useful if it is conducted in an environment that is aesthetically pleasing to the patient. Adequate gowning and draping assist in preventing embarrassment. Often a physician’s assistant escorts the patient to the dressing area and gives explicit instructions about what to take off and how to put on her gown and then may assist in draping the patient.

A physician may have a female assistant remain in the examining room to assist when necessary, but whether or not she remains solely as a chaperone depends on local custom and the preference of the patient and the physician. A chaperone is not legally required, but the physician, male or female, must use good judgment, especially during the breast and pelvic examinations. If the patient wants her partner, relative, or a friend to be present, the request should be honored unless, in the physician’s judgment, such an arrangement would interfere with the examination or with obtaining an accurate history. It is highly recommended that the physician explain the steps and acts that will be taken, especially during the pelvic examination when the patient might lack a direct eye contact with the physician.

General Examination

If the gynecologist is the primary care physician for the patient, a general physical examination should be performed annually or whenever the situation warrants. A complete examination obviously provides more information, demonstrates the physician’s thoroughness, and establishes rapport with the patient.

General Evaluation

A. Vital Signs

As part of every examination—whether for a specific problem, routine annual examination, or a return visit for a previously diagnosed problem—the patient should be weighed and her blood pressure taken. Postmenopausal patients should have their height measured to document any loss of height from osteoporosis and vertebral fractures. Before the patient empties her bladder for the examination, determination should be made as to whether the urine will need to be sent for urinalysis, culture, or pregnancy testing.

The examination of the chest should include visual assessment for any skin lesions and symmetry of movement. Auscultation and percussion of the lungs are important for excluding primary pulmonary problems such as asthma and pneumonia. The examination of the heart includes percussion for size and auscultation for arrhythmias and significant murmurs.

Breast Examination

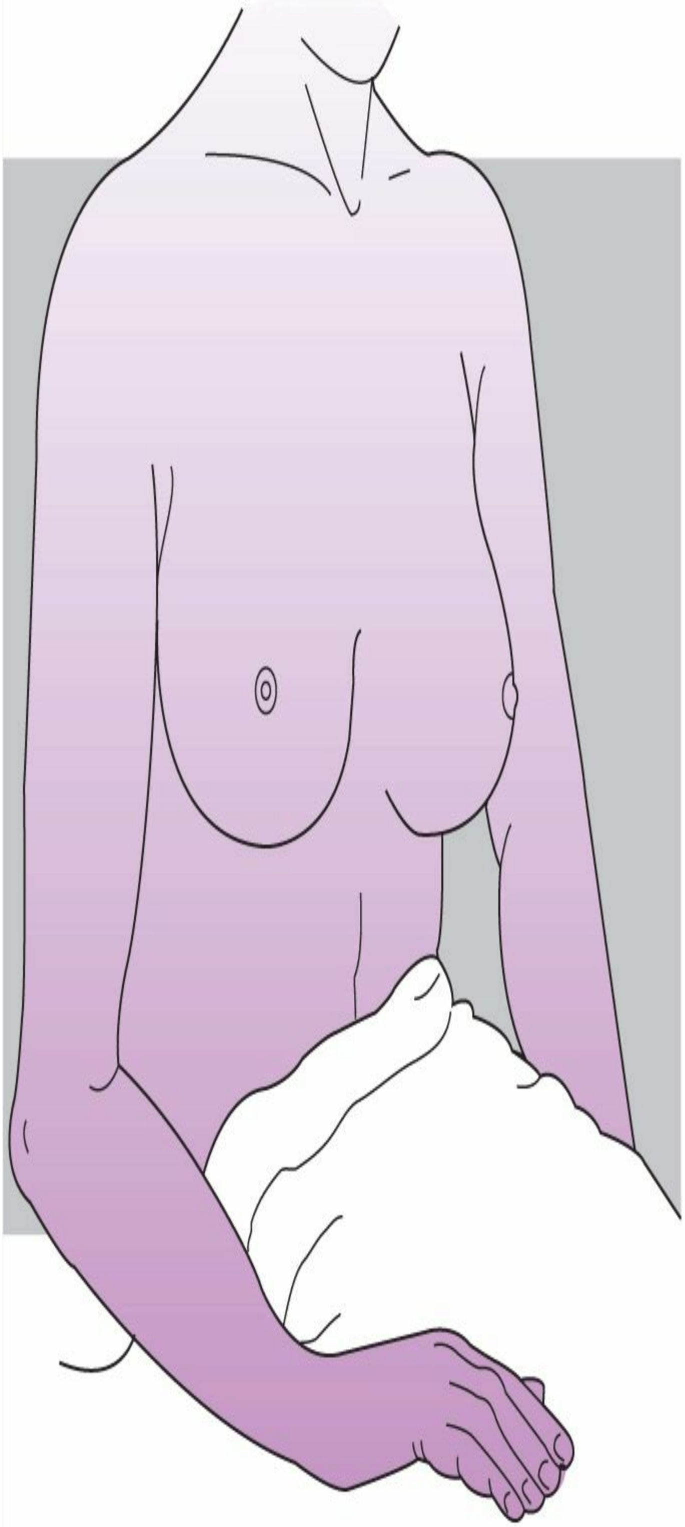
(See also Chapter 5.)

Breast examination should be a routine part of the physical examination. Breast cancer will occur in 1 in 8 women in the United States during her lifetime. Physicians who treat women should educate patients on the technique of self-examination, because the well-prepared patient is one of the most accurate screening methods for breast disease.

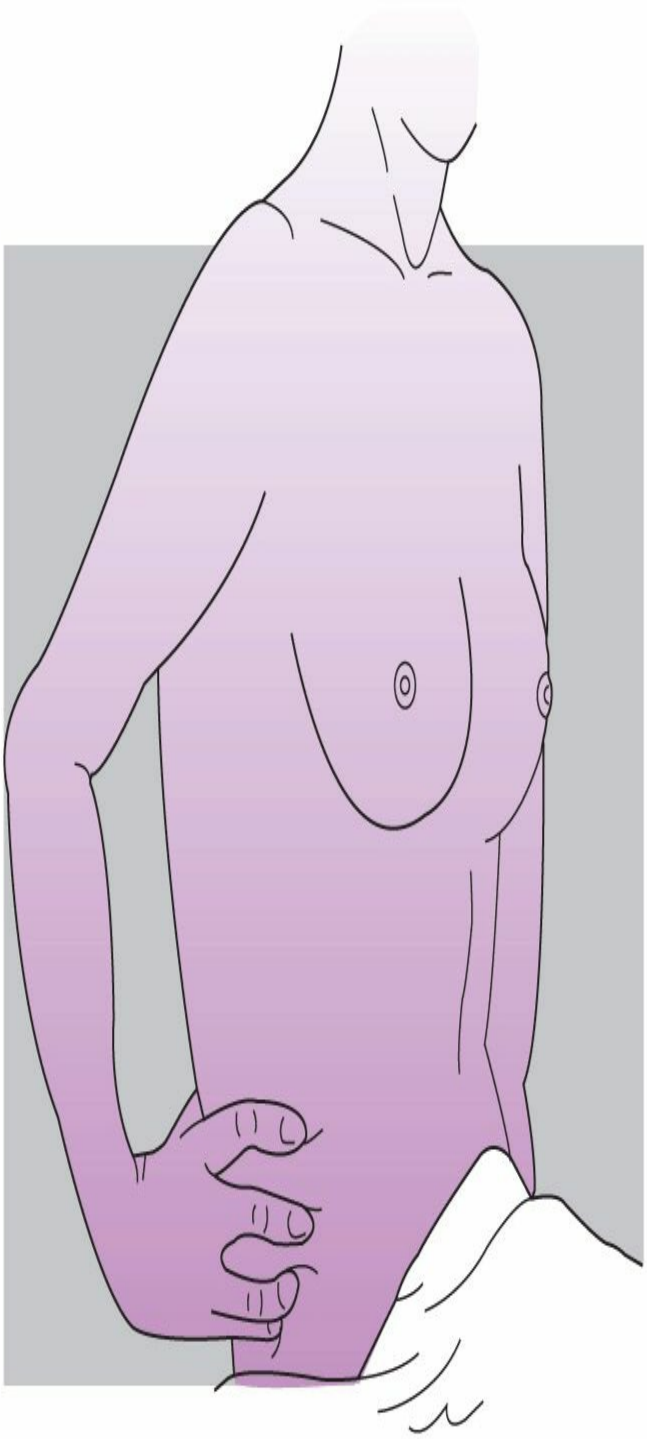
The physical examination provides an ideal time to ascertain the frequency and methodology of breast self-examination. It also is an ideal time to teach the patient how to perform breast self-examination. The patient should be advised to examine herself in the mirror, looking for skin changes or dimpling, and then carefully palpate all quadrants of the breast. Most women prefer to do this with soapy hands while showering or bathing. The examination should be repeated at the same time each month, preferably 1 week after the initiation of the menses, when the breasts are least nodular; postmenopausal women should perform self-examination on the same day each month.

The frequency of mammography or the earlier use of mammography depends on both the individual woman and her family history. Patients with a positive family history of breast cancer should have a mammogram at an earlier age, particularly those whose mother, aunt, or sister developed premenopausal breast cancer. In general, a mammogram should be obtained every 1–2 years from ages 40–50 years and annually thereafter. Ultrasonography now can reliably differentiate solid from cystic lesions; this technique complements but does not supplant mammography. Breast self-examination, physician examination, mammography, and ultrasonography are complementary, and all should be used for the early detection of breast cancer. Annual magnetic resonance imaging (MRI) examination of the breast is indicated only in patients carrying BRCA1/2 mutations or with very strong familial history of breast cancer. However, this examination is complementary to the other techniques for early detection of breast cancer and does not replace them.

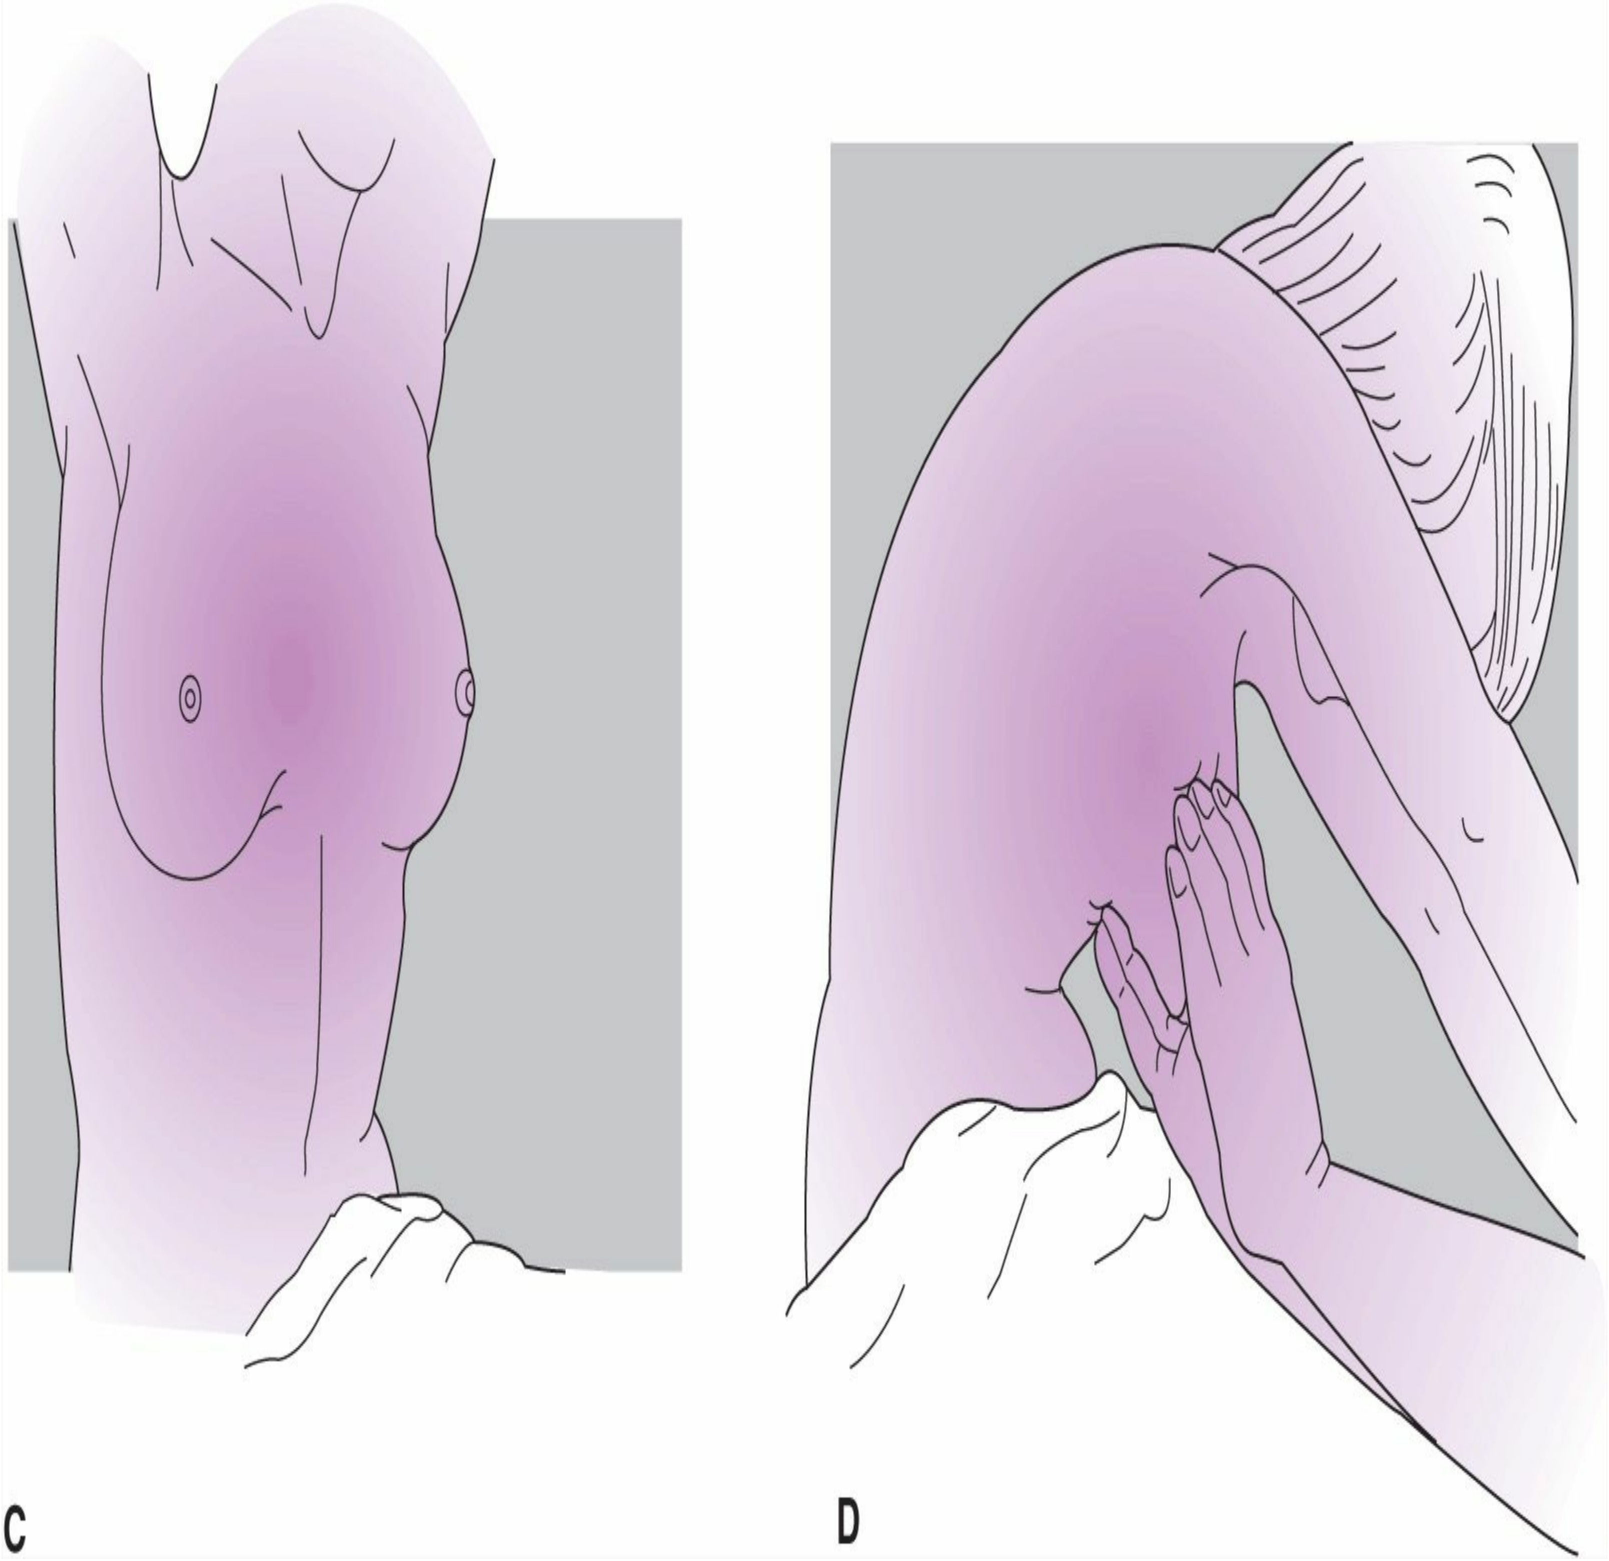
The correct technique for breast examination is shown in Figure 35–1. If abnormalities are encountered, a decision should be reached concerning the need for mammography (or other imaging methods) or direct referral to a breast surgeon unless the gynecologist is trained in performing breast biopsies. Skin lesions, particularly eczematous lesions in the area of the nipple, should be closely observed; if they are not easily cured by simple measures, they should be biopsied. An eczematous lesion on the nipple or areola may represent Paget’s carcinoma.



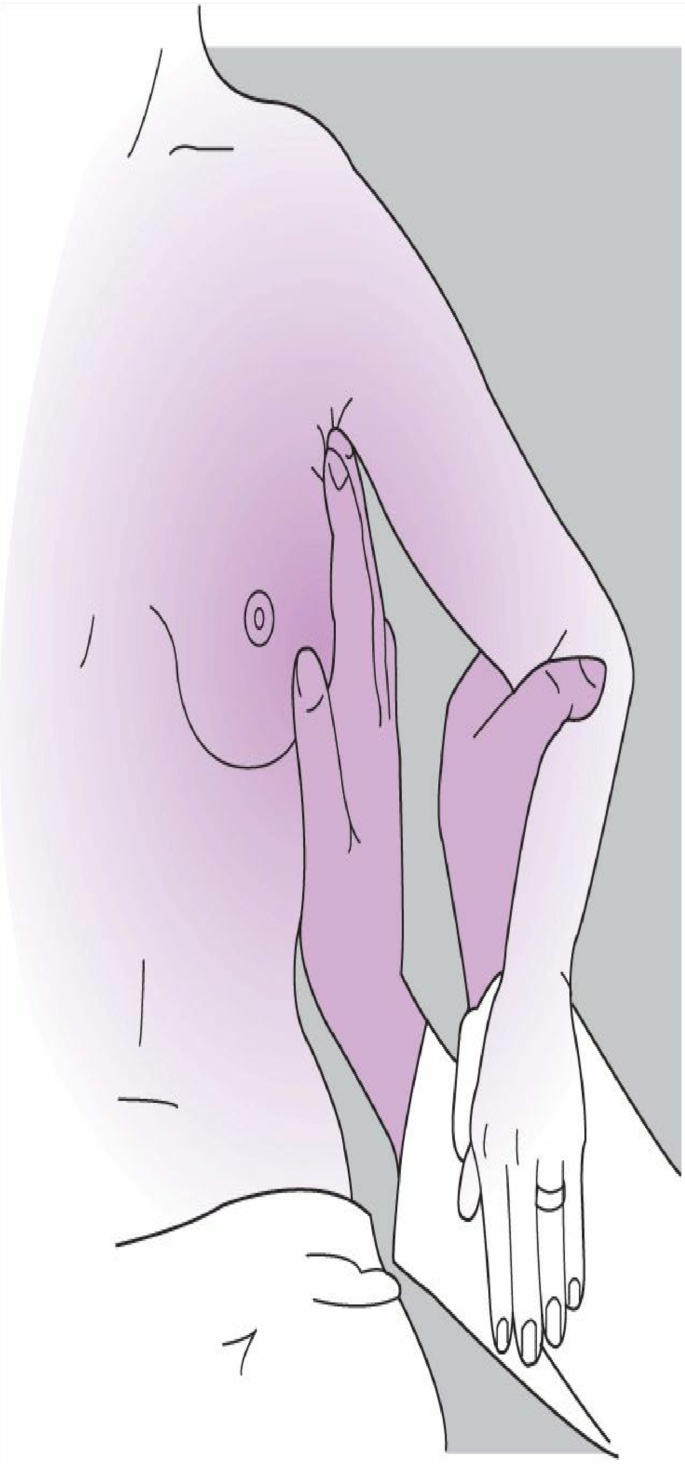
A



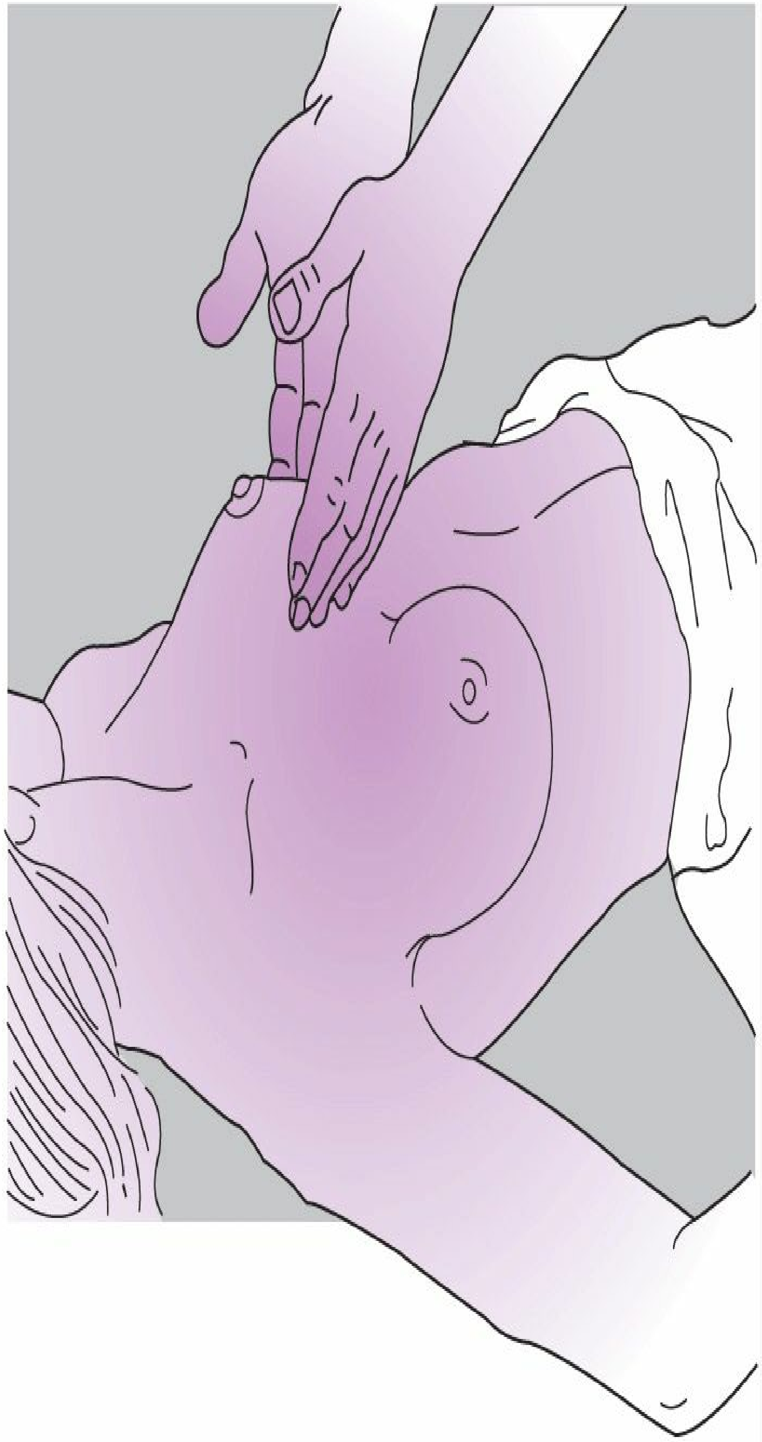
B



C
D



E



F

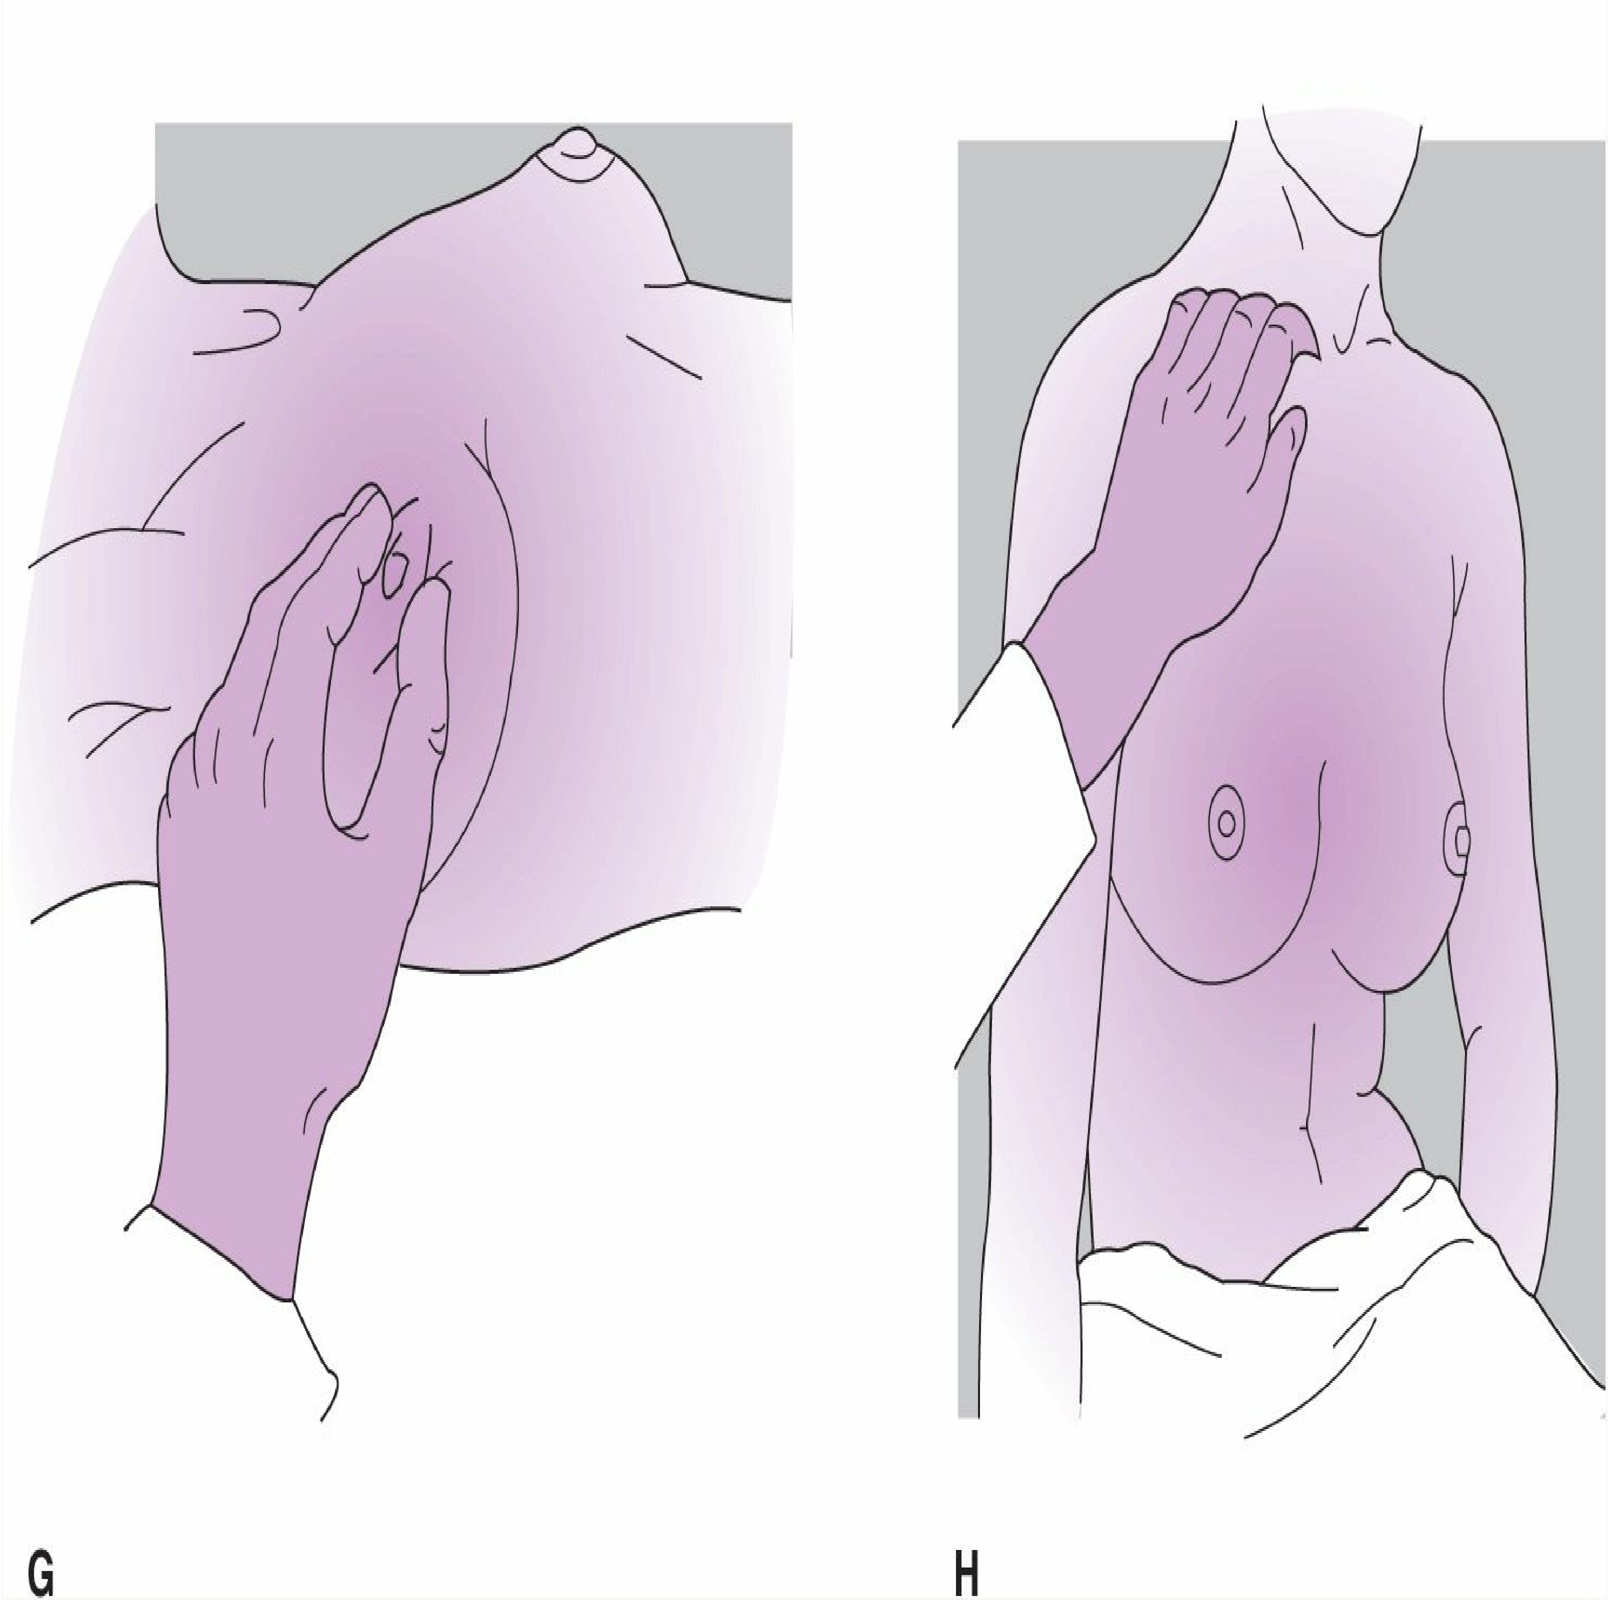


Figure 35–1. Breast examination by the physician. **A:** Patient is sitting, arms at sides. Perform visual inspection in good light, looking for lumps or for dimpling or wrinkling of skin. **B:** Patient is sitting, hands pressing on hips so that pectoralis muscles are tensed. Repeat visual inspection. **C:** Patient is sitting, arms above head. Repeat visual inspection of breasts and perform visual inspection of axillae. **D:** Patient is sitting and leaning forward, hands on examiner's shoulders, the stirrups, or her own knees. Perform bimanual palpation, paying particular attention to the base of the glandular portion of the breast. **E:** Patient is sitting, arms extended 60–90 degrees. Palpate axillae. **F:** Patient is supine, arms relaxed at sides. Perform bimanual palpation of each portion of breast (usually each quadrant, but smaller sections for unusually large breasts). Repeat examinations **C, E**, and **F** with patient supine, arms above head. **G:** Patient is supine, arms relaxed at sides. Palpate under the areola and nipple with

the thumb and forefinger to detect a mass or test for expression of fluid from the nipple. **H:** Patient is either sitting or supine. Palpate supraclavicular areas.

Abdominal Examination

The patient should be lying completely supine and relaxed; the knees may be slightly flexed and supported as an aid to relaxation of the abdominal muscles. Inspection should detect irregularity of contour or color. Auscultation should follow inspection but precede palpation because the latter may change the character of intestinal activity. Palpation of the entire abdomen—gently at first, then more firmly as indicated—should detect rigidity, voluntary guarding, masses, and tenderness. If the patient complains of abdominal pain or if unexpected tenderness is elicited, the examiner should ask her to indicate the point of maximal pain or tenderness with 1 finger. Suprapubic palpation is designed to detect uterine, ovarian, or urinary bladder enlargements. A painful area should be left until last for deep palpation; otherwise, the entire abdomen can be guarded voluntarily. As a final part of the abdominal examination, the physician should carefully check for any abnormality of the abdominal organs: liver, gallbladder, spleen, kidneys, and intestines. In some instances, the demonstration of an abnormality of the abdominal muscle reflexes may be diagnostically helpful. Percussion of the abdomen should be performed to identify organ enlargement, tumor, or ascites.

Pelvic Examination

The pelvic examination is a procedure feared by many women, so it must be conducted in such a way as to allay her anxieties. A patient's first pelvic examination may be especially disturbing, so it is important for the physician to attempt to allay fear and to inspire confidence and cooperation. The empathic physician usually finds that by the time the history has been obtained and a painless and nonembarrassing general examination performed, a satisfactory gynecologic examination is not a problem. Relaxing surroundings; a nurse or attendant chaperone if indicated; warm instruments; and a gentle, unhurried manner with continued explanation and reassurance are helpful in securing patient relaxation and cooperation. This is especially true with the woman who has never before undergone a pelvic examination. In these patients, a 1-finger examination and a narrow speculum often are necessary. In some cases, vaginal examination is not possible; palpation of the pelvic structures by rectal examination is then the only recourse. Occasionally an ultrasound examination may be helpful in ascertaining whether the pelvic organs are normal in size and configuration in patients who cannot adequately relax the abdominal muscles. If a more definitive pelvic examination is essential, it can be performed with the patient anesthetized.

A. External Genitalia (Fig. 35–2)

The pubic hair should be inspected for its pattern (masculine or feminine), for the nits of pubic lice, for infected hair follicles, and for any other abnormalities. The skin of the vulva, mons pubis, and perineal area should be examined for evidence of dermatitis or discoloration. The glans clitoridis can be exposed by gently retracting the surrounding skin folds. The clitoris is at the ventral confluence of the 2 labia; it should be no more than 2.5 cm in length, most of which is subcutaneous. The major and minor labia usually are the same size on both sides, but a moderate difference in size is not abnormal. Small protuberances or subcutaneous nodules may be either sebaceous cysts or tumors. External condylomata are often found in this area. The urethra, just below the clitoris, should be the same color as the surrounding tissue and without protuberances. Normally, vestibular (Bartholin's) glands can be neither seen nor felt, so enlargement may indicate an abnormality of this gland system. The area of vestibular glands should be palpated by placing the index finger in the vagina and the thumb outside and gently feeling for enlargement or tenderness (Fig. 35–3). The perineal skin may be reddened as a result of vulvar or vaginal infection. Scars may indicate obstetric lacerations or surgery. The anus should be inspected at this time for the presence of hemorrhoids, fissures, irritation, or perianal infections (eg, condylomata or herpesvirus lesions).

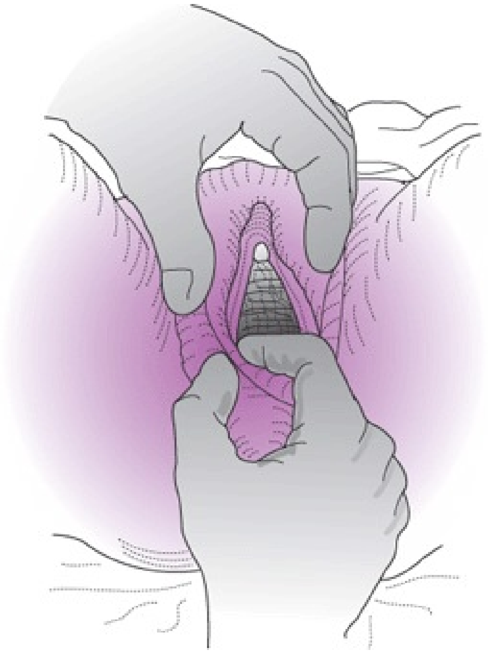

Figure 35–3. Palpation of vestibular glands.

B. Hymen

An unruptured hymen may present in many forms, but only a completely imperforate, cribriform, or septate hymen is pathologic. After rupture, the hymen may be seen in various forms (Fig. 35–4). After the birth of several children, the hymen may disappear almost completely.

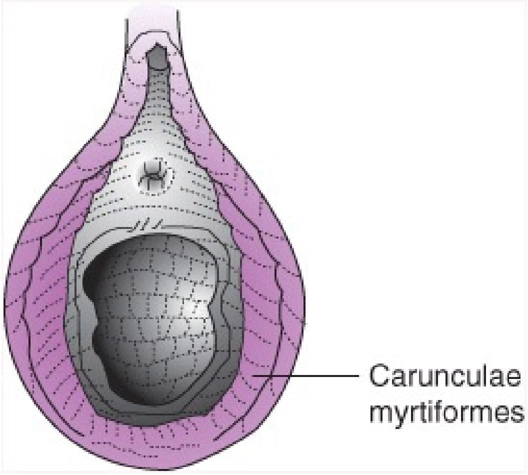

Figure 35–4. Ruptured hymen (parous introitus).

C. Perineal Support

To determine the presence of pelvic relaxation, the physician spreads the labia with 2 fingers and tells the patient to "bear down." This will demonstrate urethrocele, cystocele, rectocele, or uterine prolapse, although sometimes an upright position may be necessary to demonstrate significant prolapse.

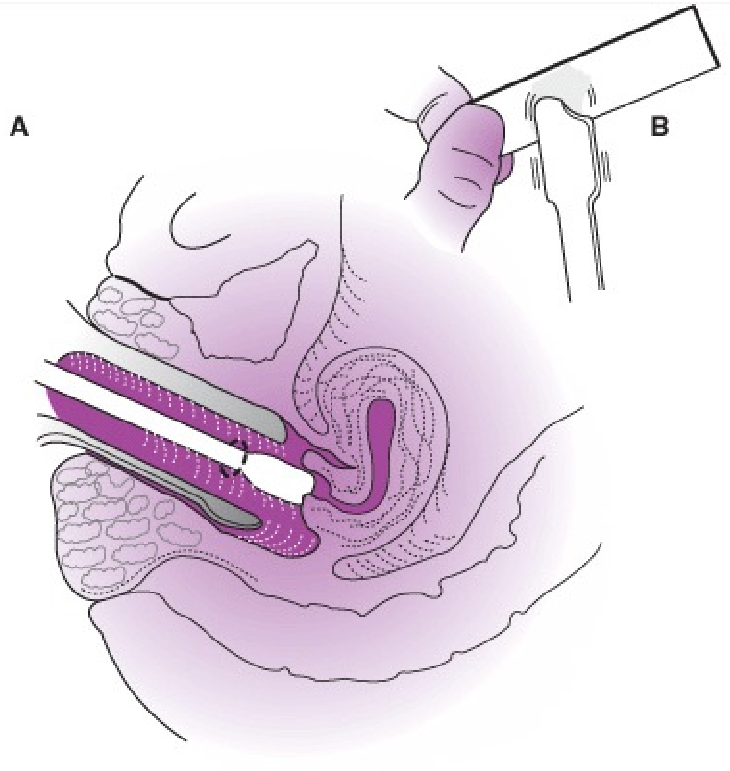
D. Urethra

Redness of the urethra may indicate infection or a urethral caruncle or carcinoma. The paraurethral glands are situated below the urethra and empty into the urethra just inside the meatus. With the labia spread adequately for better vision, the urethra may be "stripped" (ie, pressure exerted by the examining finger as it is moved from the proximal to the distal urethra) to express discharge from the urethra or paraurethral glands.

Vaginal Examination

The vagina should first be inspected with the speculum for abnormalities and to obtain a Pap smear before further examination. A speculum dampened with warm water but not lubricated is gently inserted into the vagina so that the cervix and fornices can be thoroughly visualized (Fig. 35–5). The cervix should be inspected for discharge, color, erosion, and other lesions. At that time, any discharge can be obtained for test of microbiology, virology, or microscopy and a Pap smear performed. After the Pap smear is prepared, the vaginal wall is again carefully inspected as the speculum is withdrawn (Fig. 35–6). The type of speculum used depends on the preference of the physician, but the most satisfactory instrument for the sexually active patient is the Pederson speculum, although the wider Graves speculum may be necessary to afford adequate visualization (Fig. 35–7). For the patient with a small introitus, the narrow-bladed Pederson speculum is preferable. When more than the usual exposure is necessary, an extra large Graves speculum is available. To visualize a child's vagina, a Huffman or nasal speculum, a large otoscope, or a Kelly air cystoscope is invaluable.

Next, the vagina is palpated; unless the patient's introitus is too small, the index and middle fingers of either hand are inserted gently and the tissues palpated. The vaginal walls should be smooth, elastic, and nontender.



Materials Needed

One cervical spatula, cut tongue depressor, cotton swab, or small brush made especially for obtaining endocervical cells.
One glass slide (one end frosted). Identify by writing the patient's name on the frosted end with a lead pencil.
One speculum (without lubricant).
One bottle of fixative (75% ethyl alcohol) or spray-on fixative, eg, Aqua-Net or Cyto-Spray.

Figure 35–6. Preparation of a Papanicolaou (Pap) smear. **A:** Obtain cervical scraping from complete squamocolumnar junction by rotating 360 degrees around the external os. **B:** Place the material 1 in from the end of the slide and smear along the slide to obtain a thin preparation. Place a saline-soaked cotton swab or small endocervical brush into the endocervical canal and rotate 360 degrees. Place this specimen onto the same slide and quickly fix with fixative. Bimanual Examination

The uterus and adnexal structures should be outlined between the 2 fingers of the hand in the vagina and the flat of the opposite hand, which is placed on the lower abdominal wall (Fig. 35–8). Gentle palpation and manipulation of the structures will delineate position, size, shape, mobility, consistency, and tenderness of the pelvic structures—except in the obese or uncooperative patient or in a patient whose abdominal muscles are taut as a result of fear or tenderness. Tenderness can be elicited either on direct palpation or on movement or stretching of the pelvic structures.

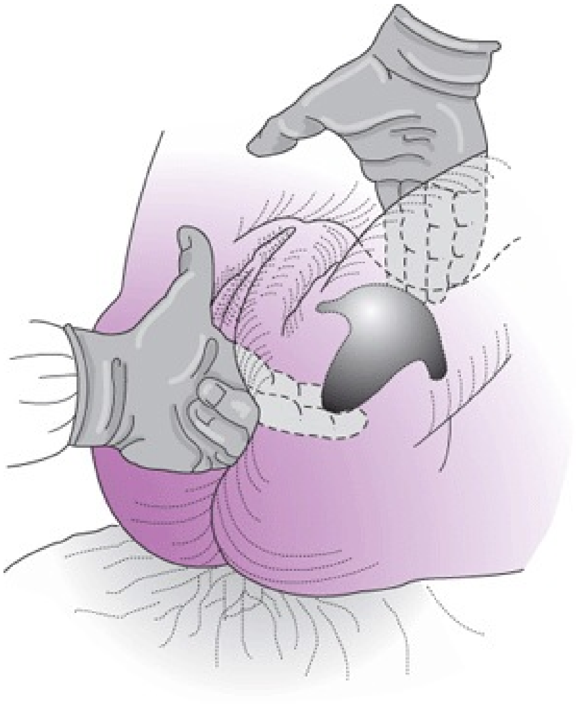

Figure 35–8. Bimanual pelvic examination.

A. Cervix

The cervix is a firm structure traditionally described as having the consistency of the tip of the nose. Normally it is round and approximately 3–4 cm in diameter. Various appearances of the cervix are shown in Figure 35–5. The external os is round and virtually closed. Multiparous women may have an os that has been lacerated. An irregularity in shape or nodularity may be due to 1 or more nabothian cysts. If the cervix is extremely firm, it may contain a tumor, even cancer. The cervix (along with the body of the uterus) normally is moderately mobile, so it can be moved 2–4 cm in any direction without causing undue discomfort. (When examining a patient, it is helpful to warn her that she will feel the movement of her uterus but that ordinarily this maneuver is not painful.) Restricted mobility of the cervix or corpus often follows inflammation, neoplasia, or surgery.

Cancer
Cysts

Figure 35–5. Uterine cervix: normal and pathologic appearance.

B. Corpus of the Uterus

The corpus of the uterus is approximately half the size of the patient's fist and weighs approximately 70–90 g. It is regular in outline and not tender to pressure or moderate motion. In most women, the uterus is anteverted; in approximately one-third of women, it is retroverted (see Chapter 42). A retroverted uterus usually is not a pathologic finding. In certain cases of endometriosis or previous salpingitis, the "tipped" uterus may be the result of adhesions caused by the disease process. The uterus usually is described in terms of its size, shape, position, consistency, and mobility.

C. Adnexa

Adnexal structures (fallopian tubes and ovaries) cannot be palpated in many overweight women because the normal tube is only approximately 7 mm in diameter and the ovary is no more than 3 cm in its greatest dimension. In very slender women, however, the ovaries nearly always are palpable and, in some instances, the oviducts are as well. Usually no adnexal structures can be palpated in the postmenopausal woman. Unusual tenderness or enlargement of any adnexal structure indicates the need for further diagnostic procedures; an adnexal mass in any woman is an indication for investigation.

Rectovaginal Examination

At the completion of the bimanual pelvic examination, a rectovaginal examination should always be performed especially after age 40 years. The well-lubricated middle finger of the examining hand should be inserted gently into the rectum to feel for tenderness, masses, or irregularities. When the examining finger has been inserted a short distance, the index finger can then be inserted into the vagina until the depth of the vagina is reached (Fig. 35–9). It is much easier to examine some aspects of the posterior portion of the pelvis by rectovaginal examination than by vaginal examination alone. The index finger can now raise the cervix toward the anterior abdominal wall, which stretches the uterosacral ligaments. Usually this process is not painful; if it causes pain—and especially if the finger in the rectum can palpate tender nodules along the uterosacral ligaments—endometriosis may be present.

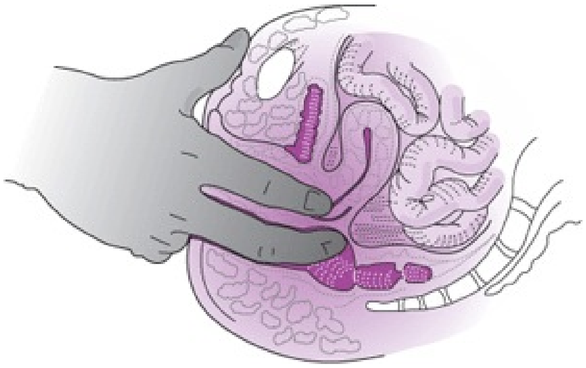

Figure 35–9. Rectovaginal examination.

Occult Bleeding Due to Colorectal Cancer

In the United States, colorectal cancer (CRC) is the third most common cancer diagnosed among men and women and the second leading cause of death from cancer. CRC largely can be prevented by the detection and removal of adenomatous polyps, and survival is significantly better when CRC is diagnosed while still localized. Recent evidence has revealed an unacceptably wide range of sensitivity among strategies aimed at checking the feces for occult blood, with some practices and tests performing so poorly that the large majority of prevalent cancers are missed at the time of screening. Therefore, a single stool sample for fecal occult blood testing obtained by digital rectal examination is not adequate for the detection of CRC and should not be used for CRC screening. Furthermore, it is the physician’s role to encourage patients above 50 years of age or those with familial CRC to undergo procedures aimed at prevention of CRC (such as colonoscopy, sigmoidoscopy, or computed tomography [CT] scan) and to not diagnose CRC using methods detecting occult blood in the stool.

DIAGNOSTIC OFFICE PROCEDURES

Certain diagnostic procedures can be performed in the office because complicated equipment and general anesthesia are not required. Other office diagnostic procedures useful in specific situations (eg, tests used in infertility evaluation) can be found in appropriate chapters elsewhere in this book.

Tests for Vaginal Infection

If abnormal vaginal discharge is present, a sample of vaginal discharge should be scrutinized. A culture is obtained by applying a sterile cotton-tipped applicator to the suspect area and then transferring the suspect material to an appropriate culture medium. Because this procedure is inconvenient to perform in the physician's office, most laboratories supply a prepackaged kit that allows the physician to put the cotton-tipped applicator into a sterile container, which is then sent to the laboratory. The vaginal discharge can also be tested for the vaginal pH. An acidic pH of 4–5 is consistent with fungal infection, whereas an alkaline pH of 5.5–7 suggests infections such as bacterial vaginosis and *Trichomonas*. Often an endocervical infection may be perceived as a vaginal infection. Obtaining a swab for gonorrhea and chlamydia testing from the endocervix is warranted.

A. Saline (Plain Slide)

To demonstrate *Trichomonas vaginalis* organisms, the physician mixes on a slide 1 drop of vaginal discharge with 1 drop of normal saline warmed to approximately body temperature. The slide should have a coverslip. If the smear is examined while it is still warm, actively motile trichomonads usually can be seen.

The saline slide can also be used to look for the mycelia of the fungus *Candida albicans*, which appear as segmented and branching filaments. The slide can be useful in looking for bacterial vaginosis by looking for "clue cells," epithelial cells covered from edge to edge by short coccobacilli-type bacteria.

B. Potassium Hydroxide

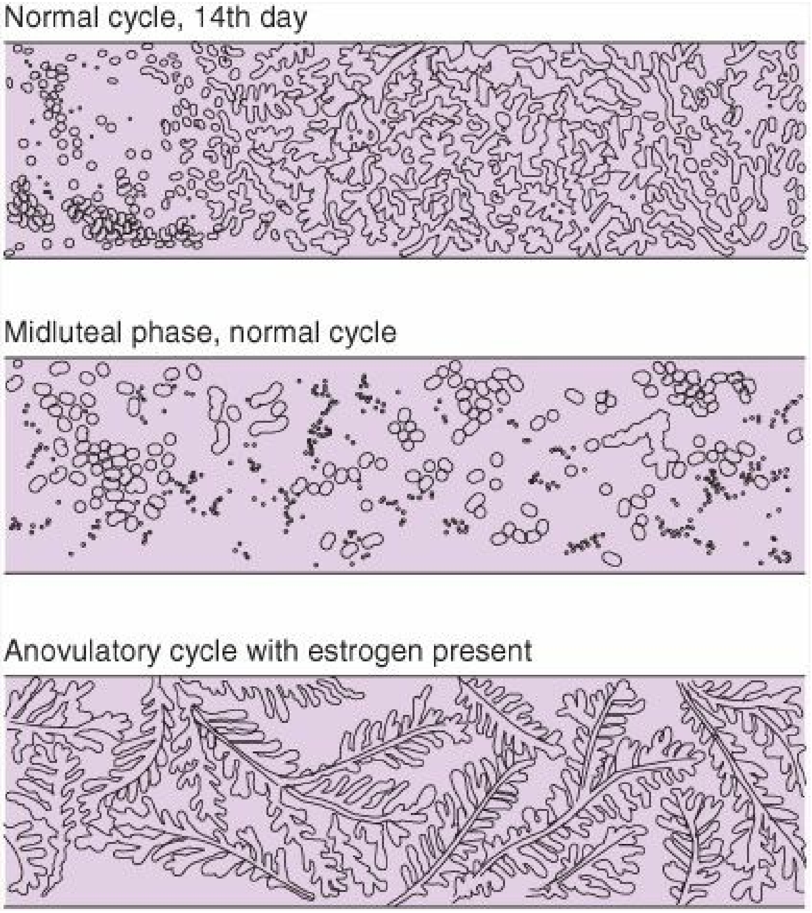
One drop of an aqueous 10% potassium hydroxide solution is mixed with 1 drop of vaginal discharge on a clean slide and a coverslip applied. The potassium hydroxide dissolves epithelial cells and debris and facilitates visualization of the mycelia of a fungus causing vaginal infection. The slide can be brought near the nose to determine if the discharge has a "fishy" odor. This odor is strongly suggestive of bacterial vaginosis, a common vaginal infection associated with a mixed anaerobic bacterial flora. In addition, this same slide with a coverslip can be magnified with a microscope to visualize mycelia that may have been hidden by debris with just the saline smear.

C. Bacterial Infection

Bacterial infection may be present, especially if there is an ischemic lesion such as occurs after radiation therapy for cervical carcinoma, or if a patient is suspected of having bacterial vaginosis, gonorrhea, or a *Chlamydia trachomatis* infection. Material from the cervix, urethra, or vaginal lesion can be smeared, stained, and examined microscopically, or the material can be cultured.

Fern Test for Ovulation

The fern test can determine the presence or absence of ovulation or the time of ovulation. When cervical mucus is spread on a clean, dry slide and allowed to dry in air, it may or may not assume a frondlike pattern when viewed under the microscope (sometimes it can be seen grossly). The fern frond pattern indicates an estrogenic effect on the mucus without the influence of progesterone; thus, a non-frondlike pattern can be interpreted as showing that ovulation has occurred (Fig. 35–10).



Normal cycle, 14th day
Midluteal phase, normal cycle
Anovulatory cycle with estrogen present

Figure 35–10. Patterns formed when cervical mucus is smeared on a slide, permitted to dry, and examined under a microscope. Progesterone makes the mucus thick and cellular. In the smear from a patient who failed to ovulate (**bottom**), there is no progesterone to inhibit the estrogen-induced fern pattern. (Reproduced, with permission, from Ganong WF. *Review of Medical Physiology*. 20th ed. New York, NY: McGraw-Hill; 2003.)

Schiller Test for Neoplasia

Although colposcopy is more accurate, the Schiller test can be performed when cancer or precancerous changes of the cervix or vaginal mucosa are suspected. The suspect area is painted with Lugol's (strong iodine) solution, which interacts and marks the glycogen-rich epithelial cells of the cervix. Any portion of the epithelium that does not accept the dye is abnormal because of the presence of scar tissue, neoplasia and precursors, and columnar epithelium. Biopsy of samples taken from this area should be performed if there is any suspicion of cancer.

Biopsy

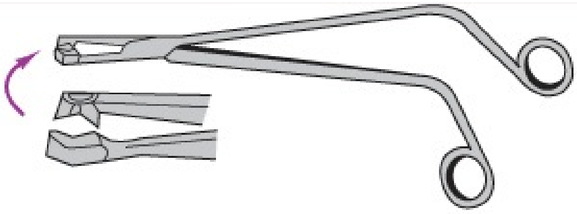
A. Vulva & Vagina

For biopsy of the vulva or vagina, a 1–2% aqueous solution of a standard local anesthetic solution can be injected around a small suspicious area and a sample obtained with a skin punch or sharp scalpel.

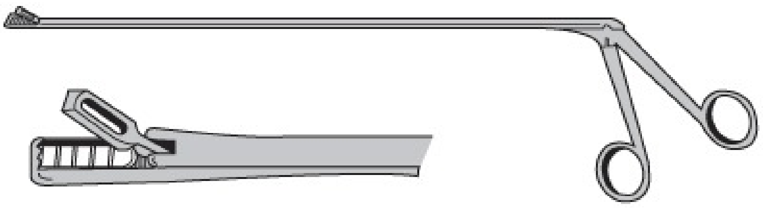
Bleeding usually can be controlled by pressure or by Monsel's solution, but occasionally suturing is necessary.

B. Cervix

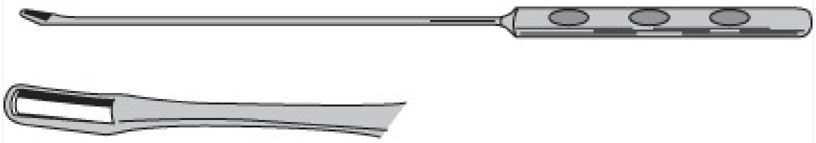
Colposcopically directed biopsy is the method of choice for the diagnosis of cervical lesions, either suspected on visualization or indicated after an abnormal Pap smear. Colposcopy should reveal the full columnar–squamous "transformation zone" (TZ) at the juncture of the exocervix and endocervix. In addition, it may be advisable to sample the endocervix by curettage. Specific instruments have been devised for cervical biopsy and endocervical curettage (Fig. 35–11). The cervix is less sensitive to cutting procedures than is the vagina, so 1 or more small biopsy samples of the cervix can be taken with no or little discomfort to the patient. Bleeding usually is minimal and controlled with light pressure for a few minutes or by use of Monsel's solution. A "4-quadrant" biopsy sample of the squamocolumnar junction can be taken at 12, 3, 6, and 9 o'clock positions if colposcopy is not available. A Schiller test often may more quickly direct the physician to the area that should be biopsied.



Tischler cervical biopsy forceps



Kevorkian-Younge cervical biopsy forceps



Duncan curette

Figure 35–11. Biopsy instruments.

C. Endometrium

Endometrial biopsy can be helpful in the diagnosis of ovarian dysfunction (eg, infertility) or irregular uterine bleeding and as a test for carcinoma of the uterine corpus. Endometrial biopsy can be performed with flexible disposable cannulas, such as the Pipelle, which have replaced most metal curettes previously used (Fig. 35–12). In fact, endometrial biopsies have dramatically reduced the need for formal dilatation and curettage (D&C) because the accuracy of biopsy is nearly the same. Because the procedure causes cramping, the patient should be warned and advised to take a pain medication such as ibuprofen 1 hour prior to the procedure.

DIAGNOSTIC LABORATORY PROCEDURES

Routine procedures that are not discussed here but should be considered with periodic primary care visits include a complete blood count (including differential white cell count), glucose screening, lipid profile, and thyroid function tests. The frequency with which these tests are performed should be at the discretion of the physician, based on risk factors and presenting complaints.

Urinalysis

Urinalysis should be obtained in symptomatic patients and should include both gross and microscopic examinations. A microscopic examination may reveal crystals or bacteria, but unless the specimen is collected in a manner that will exclude vaginal discharge, the presence of bacteria is meaningless (see below).

Urine Culture

Studies have demonstrated that a significant number of women (approximately 3% of nonpregnant women and 7% of pregnant women) have asymptomatic urinary tract infections. Culture and antibiotic sensitivity testing are required for the diagnosis and as a guide to treatment of urinary tract infections.

Reliable specimens of urine for culture often can be obtained by the "clean-catch" method: The patient is instructed to cleanse the urethral meatus carefully with soap and water, to urinate for a few seconds to dispose of urethral contaminants, and then to catch a "midstream" portion of the urine. It is essential that the urine not dribble over the labia, but this may be difficult for some patients to accomplish.

A more reliable method of collecting urine for culture is by sterile catheterization performed by the physician or nurse. However, care must be exercised in catheterization to minimize the risk of introducing an infection.

Other Cultures

A. Urethral

Urethral cultures are indicated if an STD is suspected.

B. Vaginal

A culture usually is unnecessary for the diagnosis of vaginal infections, because visual inspection or microscopic examination usually will enable the physician to make a diagnosis, eg, curdlike vaginal material that reveals mycelia (candidiasis). However, a culture should be obtained in questionable cases. In cases of vaginal candidiasis refractory to the common treatment, it is advisable to characterize the yeast and examine its specific sensitivity to various antimycotic drugs available, enabling elimination of the troublesome infection.

C. Cervical

As in the case of the urethra, the usual indication for a culture of cervical discharge is the suspected presence of an STD.

Specific Tests

A. Herpesvirus Hominis

Herpesvirus hominis (HSV) (herpes genitalis, both types 1 and 2) is a frequently seen vulvar lesion (see Chapter 43). It can be diagnosed by the cytopathologist, who finds typical cellular changes. Other methods that are more accurate and more often used for the detection of HSV infection include culturing and identifying the virus using polymerase chain reaction (PCR) technique.

B. Human Papillomavirus

Human papillomavirus (HPV) infection is associated with the development of genital warts and the occurrence of vaginal and cervical intraepithelial lesions. Some of these lesions are precancerous or cancerous in origin. Different HPV subtypes are linked to either benign or more aggressive epithelial changes. The different subtypes can be identified by the specific fingerprints obtained from the PCR products.

C. Chlamydia & Gonorrheal Infections

These sexually transmitted infections are the 2 most prevalent infections, with chlamydia being the most common. They are found more often in women who have multiple sexual partners and those who do not use barrier methods of contraception. Nucleic acid amplification testing is the most commonly used method of diagnosis, with a sensitivity >90%.

D. Human Immunodeficiency Virus

Acquired immunodeficiency syndrome (AIDS) has become one of the most difficult issues confronting all kinds of clinicians. The need to screen for HIV in the general population has become more pressing given that the largest increase in incidence is seen in young heterosexually active females with no other risk factors. An accurate blood test is available for diagnosis. Prior to drawing the blood, the physician must discuss with the patient the accuracy of the blood test for diagnosing the presence of HIV. The patient must be made aware that there are infrequent false-positive tests and a "window" during which the test may be falsely negative prior to the development of antibodies. At present, a written consent must be signed by the patient prior to drawing the blood.

Other Specific Tests

Specific diagnostic laboratory procedures may be indicated for some of the less common venereal diseases (eg, lymphogranuloma venereum and hepatitis B and C). A screening test for *Streptococcus* B carrier is advocated at 35–37 weeks' gestation. A 1-step culture swab from the lower vagina, followed by the anus, is recommended. These tests are discussed with the specific diseases in other chapters of this book.

Pregnancy Testing

Pregnancy testing is discussed in Chapter 6.

Papanicolaou Smear of Cervix

The Pap smear is an important part of the gynecologic examination. The frequency of the need for this test has been recently revised. Epidemiologic statistics have led the US Preventive Services Task Force to recommend that for the average woman who has had 3 normal Pap smears, a Pap test every 2 or 3 years is adequate. This recommendation is based on the observation that most cervical cancers are slow growing. The American College of Obstetricians and Gynecologists recommends annual Pap smear screenings from 3 years after the start of sexual intercourse but no later than age 21 years. For women aged 30–64 years, the frequency of screening may be reduced to every 2–3 years after 3 consecutive negative Pap smears. Patients at risk, including women with multiple sexual partners, a history of STD, genital condylomata, or prior abnormal Pap smears; women who are receiving immune suppression therapy; women who are infected with HIV; or women who were exposed to diethylstilbestrol (DES) in utero, should continue to be screened annually. Women who are HIV positive should have cervical cytology testing every 6 months after diagnosis, and then annually after 2 consecutive normal test results. HPV vaccination status does not change theses cervical cytology screening recommendations. The physician can consider discontinuing cervical cytology at 65–70 years of age if patient has had 3 or more normal results in a row, no abnormal test results in 10 years, no history of cervical cancer, and no history of DES exposure in utero, is HIV negative, is not immunodepressed, and does not have other risk factors for new acquisition of STDs; if cervical cytology has been discontinued, the physician should review risk factors annually to evaluate the need for re-initiation of screening.

Aside from premalignant and malignant changes, other local conditions often can be suspected by the cytologist. Viral infections, such as HSV, HPV, and condylomata acuminata, can be seen as mucosal changes. Actinomycosis and *Trichomonas* infections can be detected by a Pap smear.

The Pap smear is a screening test only. Positive tests are an indication for further diagnostic procedures, such as colposcopy, endocervical curettage, cervical biopsy or conization, endometrial biopsy, or D&C. The properly collected Pap smear can accurately lead to the diagnosis of carcinoma of the cervix in approximately 95% of cases. The Pap smear also is helpful in the detection of endometrial abnormalities such as endometrial polyps, hyperplasia, and cancers, but it detects fewer than 50% of cases.

The techniques of collection of a Pap smear may vary, but the following is a common procedure.

The patient should not have douched for at least 24 hours before the examination and should not be menstruating. The speculum is placed in the vagina after it has been lubricated with water only. With the cervix exposed, a specially designed plastic or wooden spatula is applied to the cervix and rotated 360 degrees to abrade the surface slightly and to pick up cells from the squamocolumnar area of the cervical os. Next, a cotton-tipped applicator or a small brush is inserted into the endocervix and rotated 360 degrees. These 2 specimens can be mixed or placed on the slide separately according to the preference of the examiner. A preservative is applied immediately to prevent air drying, which would compromise the interpretation. The slide is sent to the laboratory with an identification sheet containing pertinent history and findings (see Fig. 35–6). Another method called ThinPrep automates the preparation of the Pap smear slide so that the variability introduced by the clinician preparing the slide itself is no longer a factor. With this method, the specimen is placed in a liquid-based medium and sent to the laboratory. In addition, the ThinPrep technique decreases the rate of smears showing atypical squamous cells–undetermined significance (ASCUS), thereby decreasing the need for colposcopic evaluations. For these reasons, in many parts of the country, the ThinPrep technique has replaced the conventional Pap smear. However, any advantages of the liquid-based technique over the conventional method in terms of sensitivity and specificity are unclear

The liquid-based medium allows for testing for high-risk HPV, the most common being subtypes 16, 18, 31, 33, and 35. Testing for high-risk HPV has been proposed by the American Society for Colposcopy and Cervical Pathology as a method of evaluating and sorting out patients with ASCUS Pap smear results. If no high-risk HPV is present in the ASCUS Pap smear, then these individuals can be followed-up with a repeat Pap smear in 1 year, similar to those who have a negative Pap smear. Patients known to have a high-risk HPV subtype would undergo colposcopic evaluation.

The laboratory reports the Pap smear using the Bethesda System, which has advocated a standardized reporting system for cytologic reports. Chapter 48 discusses the recently updated nomenclature.

Alternatives to the traditional Pap smear are being evaluated in an attempt to decrease the false-negative and false-positive Pap smear results. Evidence indicates that computerized screening of Pap smears can decrease the likelihood of missing significant pathologies. Various methods of computerized screening have been developed to aid the human eye in picking up abnormalities, although no system has yet achieved widespread acceptance.

Colposcopy

The colposcope is a binocular microscope used for direct visualization of the cervix (Fig. 35–13). Magnification as high as 60 × is available, but the most popular instrument in clinical use has 13.5 × magnification, which effectively bridges the gap between what can be seen by the naked eye and by the microscope. Some colposcopes are equipped with a camera for single or serial photographic recording of pathologic conditions.

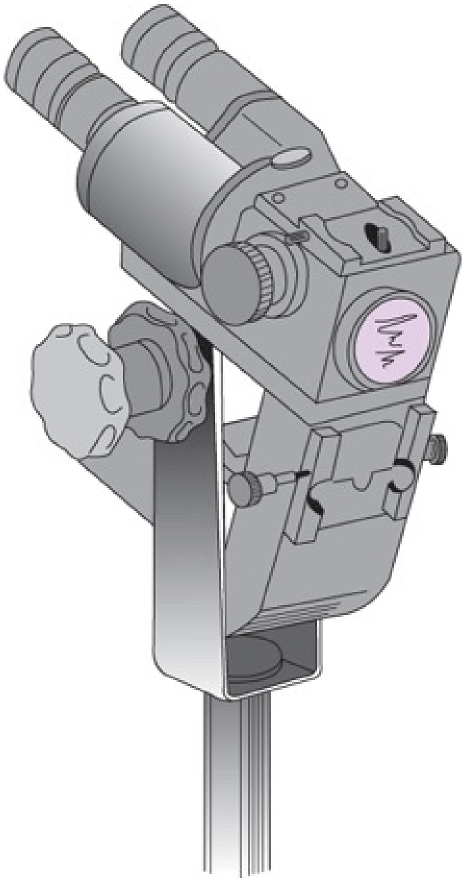

Figure 35–13. Zeiss colposcope.

Colposcopy does not replace other methods of diagnosing abnormalities of the cervix; rather, it is an additional and important tool. The 2 most important groups of patients who can benefit by its use are (1) patients with an abnormal Pap smear and (2) DES-exposed daughters, who may have dysplasia of the vagina or cervix (see Chapter 40).

The colposcopist is able to see areas of cellular dysplasia and vascular or tissue abnormalities not visible otherwise, which makes possible the selection of areas most propitious for biopsy. Stains and other chemical agents are also used to improve visualization. The colposcope has reduced the need to perform blind cervical biopsies for which the rate of finding abnormalities is low. In addition, the necessity for a cone biopsy, a procedure with a high morbidity rate, has been greatly reduced. Thus the experienced colposcopist is able to find focal cervical lesions, obtain directed biopsy at the most appropriate sites, and make decisions about the most appropriate therapy largely based on what is seen through the colposcope.

Hysteroscopy

Hysteroscopy enables the gynecologist to examine the uterine cavity through a fiberoptic instrument, called the hysteroscope. Moreover, surgical interventions such as polypectomy, myomectomy, septectomy, and resection of intrauterine adhesions can be performed via the hysteroscope. In order to inspect the interior of the uterus with the hysteroscope, the uterine cavity is inflated with a solution (usually saline, but other solutions such as glycine or dextran can be used) or by carbon dioxide insufflation. Diagnostic hysteroscopy is usually performed with no sedation; however, intravenous sedation, paracervical block, or general anesthesia is often adequate for operative hysteroscopies.

Hysteroscopic applications include evaluation for abnormal uterine bleeding, resection of uterine synechiae and septa, removal of polyps and intrauterine devices (IUDs), resection of submucous myomas, and endometrial ablation. Most of these therapeutic maneuvers require extensive manipulation, so regional or general anesthesia is required.

Hysteroscopy should be performed only by physicians with proper training. The tip of the instrument should be inserted just beyond the internal cervical os and then advanced slowly, with adequate distention under direct vision. Hysteroscopy is often used in conjunction with other operative procedures, such as curettage and laparoscopy.

Failure of hysteroscopy may be the result of cervical stenosis, inadequate distention of the uterine cavity, bleeding, or excessive mucus secretion. The most common complications include perforation, bleeding, and infection. Perforation of the uterus usually occurs at the fundus. Unless a viscus is damaged or internal bleeding develops, surgical repair may not be required. Bleeding generally subsides, but fulguration following attempts to remove polyps or myomas may be required to stop bleeding in some cases. Parametritis or salpingitis, rarely noted, usually necessitates antibiotic therapy. Intravascular extravasation of fluid or gas from hysteroscopy often does not become clinically significant but has been associated with severe consequences such as hyponatremia, air embolism, cerebral edema, and even death.

Culdocentesis

The passage of a needle into the cul-de-sac—culdocentesis—in order to obtain fluid from the pouch of Douglas is a diagnostic procedure that can be performed in the office or in a hospital treatment room (Fig. 35–14). The type of fluid obtained indicates the type of intraperitoneal lesion (eg, bloody with a ruptured ectopic pregnancy, pus with acute salpingitis, or ascitic fluid with malignant cells in cancer). With refinements in ultrasound technology enabling more definitive evaluation of pelvic pathology, culdocentesis is performed rarely today.

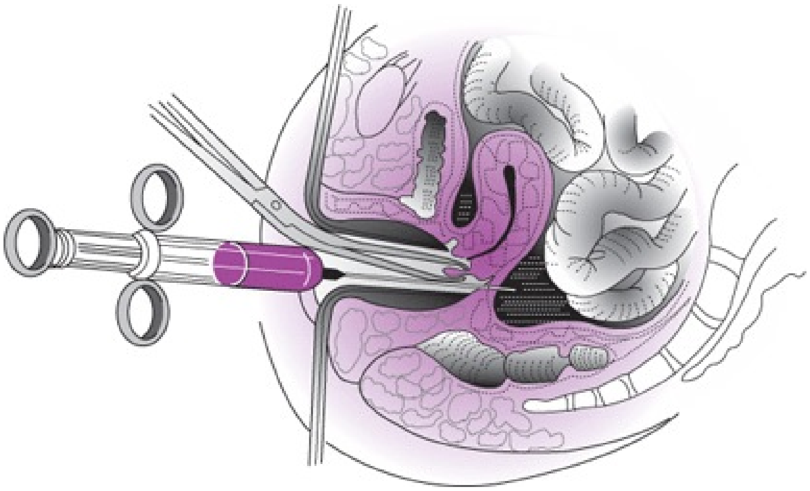

Figure 35–14. Culdocentesis.

Radiographic Diagnostic Procedures

Many common radiologic procedures may be helpful in the diagnosis of pelvic conditions. The “flat film” shows calcified lesions, teeth, or a ring of a dermoid cyst and indicates other pelvic masses by shadows or displaced intestinal loops. Use of contrast media frequently is indicated to help delineate pelvic masses or to rule out metastatic lesions. Barium enema, upper gastrointestinal series, intravenous urogram, and cystogram may be helpful. With the improvement of technologies such as ultrasound, CT scans, and MRI, the use of “flat films” for the diagnosis of gynecologic abnormalities has become less frequent.

Hysterography & Sonohysterography

The uterine cavity and the lumens of the oviducts can be outlined by instillation of contrast medium through the cervix, followed by fluoroscopic observations or film. The technique was first widely used for the diagnosis of tubal disease as part of the investigation of infertile women. Its use now is being extended to the investigation of uterine disease.

To diagnose tubal patency or occlusion, the medium is instilled through a cervical cannula. Filling of the uterine cavity and spreading of the medium through the tubes are watched via a fluoroscope, with the radiologist taking spot films at intervals for subsequent, more definitive, scrutiny. If no occlusion is present, the medium will reach the fimbriated end of the tube and spill into the pelvis—evidence of tubal patency. This procedure can reveal an abnormality of the uterus (eg, congenital malformation, submucous myomas, or endometrial polyps).

Another technique that is gaining acceptance is sonohysterography, in which the uterine cavity is filled with fluid while ultrasound is used to delineate the architecture of the endometrial cavity and detect a spillage through the fallopian tubes. Thus, it becomes easier to diagnose intrauterine abnormalities, such as polyps or fibroids, and tubal patency.

Angiography

Angiography is the use of radiographic contrast medium to visualize the blood vascular system. By demonstrating the vascular pattern of an area, tumors or other abnormalities can be delineated. Angiography also is used to delineate continued bleeding from pelvic vessels postoperatively, to visualize bleeding from infiltration by cancer in cancer patients, to embolize the uterine arteries in order to treat postpartum hemorrhage following vaginal or caesarean deliveries, to decrease acute bleeding in cases of cervical or cornual pregnancies, and/or to reduce the size of uterine myomas. These vessels then can be embolized with synthetic fabrics to stop the bleeding or indicate therapy that can prevent the need for a major abdominal operation in a highly compromised patient.

Computed Tomography

CT scan is a diagnostic imaging technique that provides high-resolution 2-dimensional images. The CT scan takes cross-sectional images through the body at very close intervals so that multiple “slices” of the body are obtained. The beam transmission is measured and calculated through an array of sensors that are approximately 100 times more sensitive than conventional x-rays. The computer is able to translate the densities of different types of tissues into gray-scale pictures that can be read on an x-ray film or a television monitor.

Contrast media can be given orally, intravenously, or rectally. They are used to outline the gastrointestinal and urinary systems, thus helping to differentiate these organ systems from the pelvic reproductive organs. In gynecology, the CT scan is most useful in accurately diagnosing retroperitoneal lymphadenopathy associated with malignancies. It also has been used to determine the depth of myometrial invasion in endometrial carcinoma as well as extrauterine spread. It is an accurate tool for locating pelvic abscesses that cannot be located by ultrasonography. Often a needle can be placed into an abscess pocket to both drain the abscess and determine what organism may be involved. Pelvic thrombophlebitis often can be diagnosed by CT scan as an adjunct to clinical suspicion. Common abnormalities such as ovarian cysts and myomas are easily diagnosed (Fig. 35–15).

Magnetic Resonance Imaging

MRI is a diagnostic imaging technique that creates a high-resolution, cross-sectional image of the body like a CT scan. The technique is based on the body absorbing radio waves from the machine. A small amount of this energy is absorbed by the nuclei in the various tissues. These nuclei act like small bar magnets and are influenced by the magnetic field created by the machine. These nuclei then emit some of the radio waves back out of the body. The waves are picked up by sensitive and sophisticated receivers, and these signals are translated into images by computer technology.

The advantages of MRI include the fact that it uses nonionized radiation that has no adverse or harmful effects on the body. MRI is superior to CT in its ability to differentiate among various types of tissue, including inflammatory masses, cancers, and abnormal tissue metabolism. Its disadvantages are mainly its high cost and its poor demonstration of calcifications. Its main use in gynecology appears to be staging and follow-up of pelvic cancers. MRI in obstetrics is used mainly as an adjunct to ultrasonic prenatal diagnosis of fetal anomalies. It allows for multiple image cuts that can help decipher complex anomalies. Other potential uses of MRI include evaluation of placental blood flow and accurate performance of pelvimetry.

Ultrasonography

Ultrasonography records high-frequency sound waves as they are reflected from anatomic structures. As the sounds waves pass through tissues, they encounter variable acoustic densities. Each of the tissues returns a different echo, depending on the amount of energy reflected. This echo signal can be measured and converted into a 2-dimensional image of the area under examination, with the relative densities shown as differing shades of gray.

Ultrasonography is a simple and painless procedure that has the added advantage of freedom from any radiation hazard. It is especially helpful in patients in whom an adequate pelvic examination may be difficult, such as in children, virginal women, and obese and uncooperative patients.

The pelvis and lower abdomen are scanned and recorded at regular intervals of distance, using a sector scanner that provides a better 2-dimensional picture than does the linear array scanner (Fig. 35–16). Generally, the abdominal scan is performed with the bladder full; this condition elevates the uterus out of the pelvis, displaces air-filled loops of bowel, and provides the operator with an index of density—a sonographic “window” differentiating the pelvic organs.

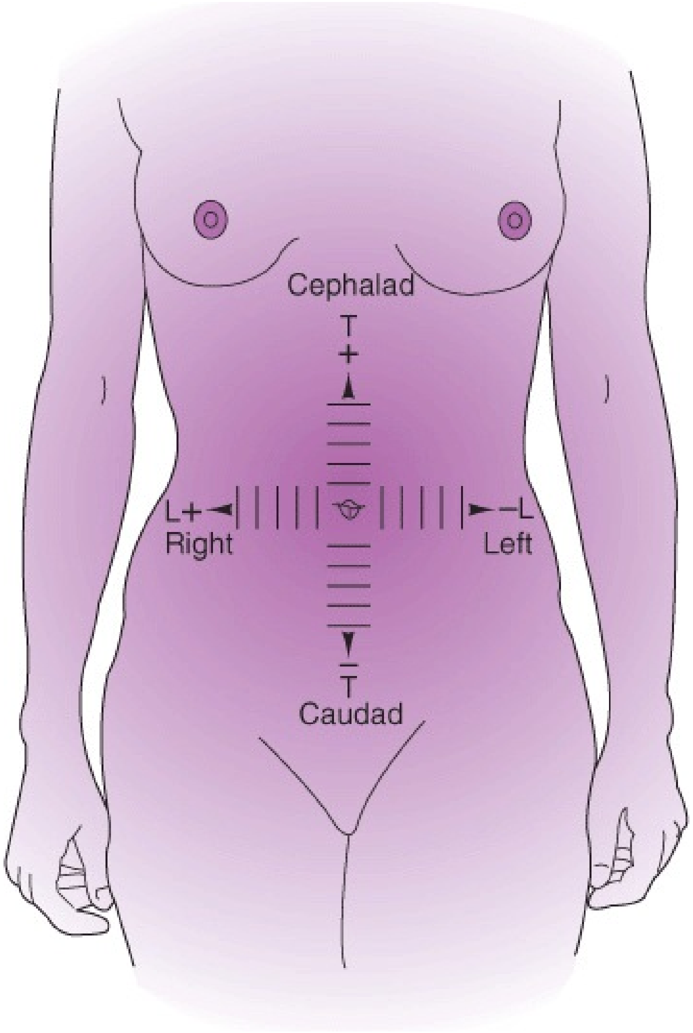

Figure 35–16. Planes of ultrasonograms.

Ultrasonography can be helpful in the diagnosis of almost any pelvic abnormality, as all structures, normal and abnormal, usually can be demonstrated. In most instances, a clinical picture has been developed—by history, physical examination, or both—before ultrasonograms are obtained. Thus, the scan often corroborates the clinical impression, but it also may uncover an unexpected condition of which the clinician should be aware.

There are many indications for ultrasonography. Normal early pregnancy can be diagnosed, as can pathologic pregnancies such as incomplete and missed abortions and hydatidiform moles. Ultrasonography can be extremely helpful in avoiding the placenta and fetus during midtrimester amniocentesis. The uses for ultrasound examination in obstetrics are discussed elsewhere in this book.

Ultrasonography may be used to locate a lost IUD or a foreign body in the vagina of a child. Congenital malformations such as a bicornuate uterus or vaginal agenesis are sometimes, but not always, detected. The development of 3-dimensional CT scan has introduced this technology to the more accurate diagnosis of congenital uterine abnormalities.

Ultrasound examination is useful in the placement of uterine tandems for radiation therapy for endometrial cancer and for guidance during second-trimester abortion procedures.

One of the more common uses for ultrasonography is the diagnosis of pelvic masses. Often because of their location, attachment, and density, myomas can be diagnosed without too much difficulty (Fig. 35–17A).

Adnexal masses can be found with relative ease by ultrasonography, although an accurate diagnosis is more difficult because of the various types of adnexal masses that can be found (Fig. 35–17B and C).

Ovarian cysts can be described as unilocular or multilocular, totally fluid-filled, or partially solid. A common adnexal mass, the dermoid cyst, can have characteristic ultrasound findings because of fat tissue and bone densities seen in these cysts (Fig. 35–17D). Pelvic abscesses can be diagnosed by ultrasonography, especially if a well-encapsulated large abscess pocket is present.

In addition to the traditional abdominal scan, the vaginal probe scan has become a useful modality. The vaginal probe is used for determining early gestations and can diagnose a pregnancy as early as 5 weeks from the LNMP. The vaginal ultrasonographic probe is capable of visualizing ectopic pregnancies quite accurately.

Ultrasonography is commonly used to diagnose ovarian cysts, especially in obese patients in whom abdominal scans are of limited use. The vaginal scan is used often to determine follicular size with in vitro fertilization and to predict the best time for ovum retrieval.

Innovations in ultrasound probes and computerizing processes of the obtained images enable the development of 3-dimensional ultrasound machines. The 3-dimensional images help to accurately evaluate normal and abnormal findings, such as uterine shape and cavity, pelvic masses, and fetal malformations.

Carbon Dioxide Laser

Controlled tissue vaporization by laser is a modality for treatment of cervical, vaginal, or perineal condylomata and dysplasia. It also can be used for conization of the cervix for diagnosis of dysplasia or carcinoma within the cervical canal.

The vaporization procedure is not difficult, but training is essential, especially in the physics of laser light and the potential risks of laser therapy not only to the patient but to the operator and others in the immediate vicinity. Antiseptic preparation of the vagina should be gentle to avoid trauma to the tissue that is to be examined histologically. Local anesthesia, with or without preliminary intravenous sedation, usually is adequate.

Advantages of the laser method of cervical conization include little or no pain; a low incidence of infection because the beam sterilizes the tissues; decreased blood loss, because the laser instrument—at a decreased energy level—is a hemostatic agent; less tissue necrosis than occurs with electrocautery (but probably the same as with excision by a sharp knife); and a decreased incidence of postoperative cervical stenosis.

Loop Electrosurgical Excision Procedure

Loop electrosurgical excision procedure (LEEP) is another modality of therapy for vulvar and cervical lesions. LEEP uses a low-voltage, high-frequency alternating current that limits thermal damage but at the same time has good hemostatic properties. It is most commonly used for excision of vulvar condylomata and cervical dysplasias and for cone biopsies of the cervix. It has displaced sharp knife and laser cone biopsies for treatment of most cervical dysplasias.

The technique requires the use of local anesthesia followed by the use of a wire loop cautery unit that cauterizes and cuts the desired tissue. Loops of various sizes are used for specimens of different size. The major advantages of LEEP are its usefulness in an office setting with lower equipment cost, minimal damage to the surrounding tissue, and low morbidity.

Imaging in Gynecology

Micah J. Hill, DO
Alan H. DeCherney, MD

CASE REPORT

C.O. is a 29-year-old white woman who presented with a history of infertility for several years, followed by a history of recurrent pregnancy losses.

Her past medical and surgical histories were negative. On gynecologic history, she was remarkable in that she reported severe dysmenorrhea for several years that was relieved by nonsteroidal anti-inflammatory drugs. Her gynecologist found a low luteal phase progesterone level and treated her with 50 mg of clomiphene citrate on days 5–9 of the cycle.

She responded well to the medication, with a subsequent conception. The pregnancy resulted in a spontaneous abortion 5 weeks later. No dilatation and curettage (D&C) was required, and the patient recovered well. She was still unable to conceive on her own and was again given clomiphene citrate therapy. Again, she conceived and had a spontaneous abortion—this time at 7 weeks' gestation. No D&C was performed.

The patient was evaluated for recurrent pregnancy losses. Karyotype was normal for both partners. Hormonal evaluation was normal with the exception of a low midluteal phase progesterone level. Immunologic and infectious screening failed to reveal a cause for the recurrent losses. The hysterosalpingogram (HSG) demonstrated a midline filling defect.

The patient was informed of the results and the potential for future miscarriages. The need for further evaluation and possible repair performed via a hysteroscopic or abdominal approach, together with its risks and benefits, was carefully explained to the patient. She elected to try clomiphene citrate therapy one more time and hoped to avoid surgery.

At 8 weeks' gestation, vaginal ultrasonography (US) revealed positive fetal cardiac activity in an ovulation induced by clomiphene citrate. While still taking micronized progesterone 100 mg 3 times daily, she was referred to her gynecologist for routine obstetric care. At 12 weeks' gestation, the patient had an incomplete abortion that required a D&C. She recovered uneventfully and later returned to the office for further evaluation and treatment.

Several months were allowed to lapse before a hysteroscopy/laparoscopy was performed, which revealed a broad-based intrauterine septum and stage I endometriosis. To evaluate the depth and width of the septum, a LaparoScan (EndoMedix, Irvine, CA) laparoscopic 7.5-Hz probe was used during the procedure. The septum was removed with a hysteroscopic resectoscope loop on a 40-W setting. After the resection, the ultrasonic probe was again used to measure the thickness of the myometrium and to verify the resection of the septum. A 30-mL 18-F Foley catheter with the distal tip resected was placed in the fundus and inflated. The patient was discharged and placed on therapy consisting of a broad-spectrum antibiotic and conjugated estrogen 2.5 mg daily.

DISCUSSION

The new millennium saw a proliferation of imaging techniques used in medical practice. Research into the development, refinement, and application of imaging in gynecology is apparent in the literature.

The HSG has been considered the gold standard for imaging the uterine corpus for benign disorders (submucous myomas, submucous polyps, localization of tubal occlusion, and evaluation of müllerian fusion defects) and malignant disease (endometrial carcinoma). In the case reported, the standard scout film was obtained, and the cervix was prepared after the following were assured: position of the uterus, absence of pelvic tenderness, and negative pregnancy test. The water-soluble contrast medium was injected into the uterine cavity, and oblique and anteroposterior films were obtained. These films showed a midline uterine filling defect of the type usually seen with septate or bicornuate uteri.

US performed on this patient during her pregnancies failed to show the filling defect. If suspected, the septum might have been encountered with more careful scanning. The scans of the last pregnancy revealed only an eccentrically placed pregnancy that might be seen on US even in normally structured uteri. Although not helpful at this point, US examination of the uterus between conceptions might have been helpful if used with a distending medium. This is especially useful in patients allergic to iodine contrast medium (Table 36–1). This technique of ultrasonic HSG is performed by occluding the cervix with a uterine injector and distending the uterus. The method can demonstrate the separate cavities as well as the possible difference between the septate and the bicornuate uterus while demonstrating tubal patency. The technique was adopted for this patient during her uterine septum resection, with the addition of ultrasonic contrast between the endometrial cavity and septum and the myometrium. Readers are referred to the many fine texts on diagnostic pelvic US for instruction and further discussion of these techniques. The development of “sonicated” contrast solutions may add greatly to the usefulness of US.

Abnormal uterine bleeding
Allergies to iodine dyes
Amenorrhea
Infertility

Using 2 video cameras (1 for the resectoscope and the other for the laparoscope and the LaparoScan laparoscopic US probe), all aspects of the surgery were evaluated. This setup allowed the operating surgeon adequate visualization of the uterine cavity during the resection and enabled other personnel in the operating room to follow the progress of the surgery. The laparoscopic video allowed for careful monitoring of the uterine surface and assured the surgeon that there would be less likelihood of a uterine perforation, a complication that could result in bowel injury. The laparoscopic US probe with a picture within a picture was useful because it allowed visualization of the 2 separate cavities and measurement of the length and width of the septum. It also enabled the operator to demonstrate the complete removal of the septum.

IMAGING OF THE UTERUS & CERVIX

Although plain film radiographs are one of the most common forms of imaging in radiology, they are rarely the test of choice for identifying gynecologic pathology. However, they can be used to detect calcified leiomyomas as well as an intrauterine device (IUD). Such films can help determine if an IUD has been expelled from the uterine cavity or has penetrated the uterine wall and migrated to an ectopic location.

Pelvic US, magnetic resonance imaging (MRI), and computed tomography (CT) imaging are more common modalities in assessment of the uterus and the cervix. Pelvic US is the most common initial imaging approach in diagnosis of uterine disease. Modalities for pelvic US include a transvaginal approach, transabdominal approach, and saline infusion sonohysterosalpingogram. Pelvic US plays a significant role in the diagnosis of uterine leiomyomas (submucosal, intramural, and subserosal) and polyps and in the monitoring of follicular development in assisted reproduction. In more recent years, 3-dimensional (3D) US has been investigated in comparison to 2-dimensional (2D) US and hysteroscopy. Salim and colleagues showed 3D US to be superior over 2D US in the measurement of intramural versus submucosal involvement of leiomyoma. Additionally, US is often the initial test to suggest other pathology such as müllerian anomalies and adenomyosis. Occasionally, the detection and localization of myomas, assessment of their size, and their differential diagnosis are difficult. In the circumstances of adenomyosis, müllerian anomalies, or additional information needed on myomas, it can be useful to perform MRI of the pelvis. MRI produces images with excellent soft tissue resolution and is useful for evaluation of congenital abnormalities of the uterus, leiomyomas, adenomyosis, gestational trophoblastic disease, and endometrial carcinoma diagnosis and staging. MRI can accurately measure the volume of the myoma, which aids in determining whether medical management of myomas has resulted in shrinkage or whether conservatively treated myomas are growing. Malignant degeneration of myomas visualized by MRI, as described by some authors, allows for early and appropriate intervention.

MRI can effectively discern between the septate and the bicornuate uterus, thus avoiding the more costly laparoscopy. MRI may provide a clear anatomic picture of complicated müllerian fusion defects (didelphys with transverse vaginal septum or noncommunicating uterine segment) and allow for proper planning of surgical repair. If pelvic MRI had been performed on the patient in the opening case report, the image probably would have appeared the same as the MRI shown in Figure 36–1. (See review of MRI findings of müllerian fusion defects in Table 36–2.)

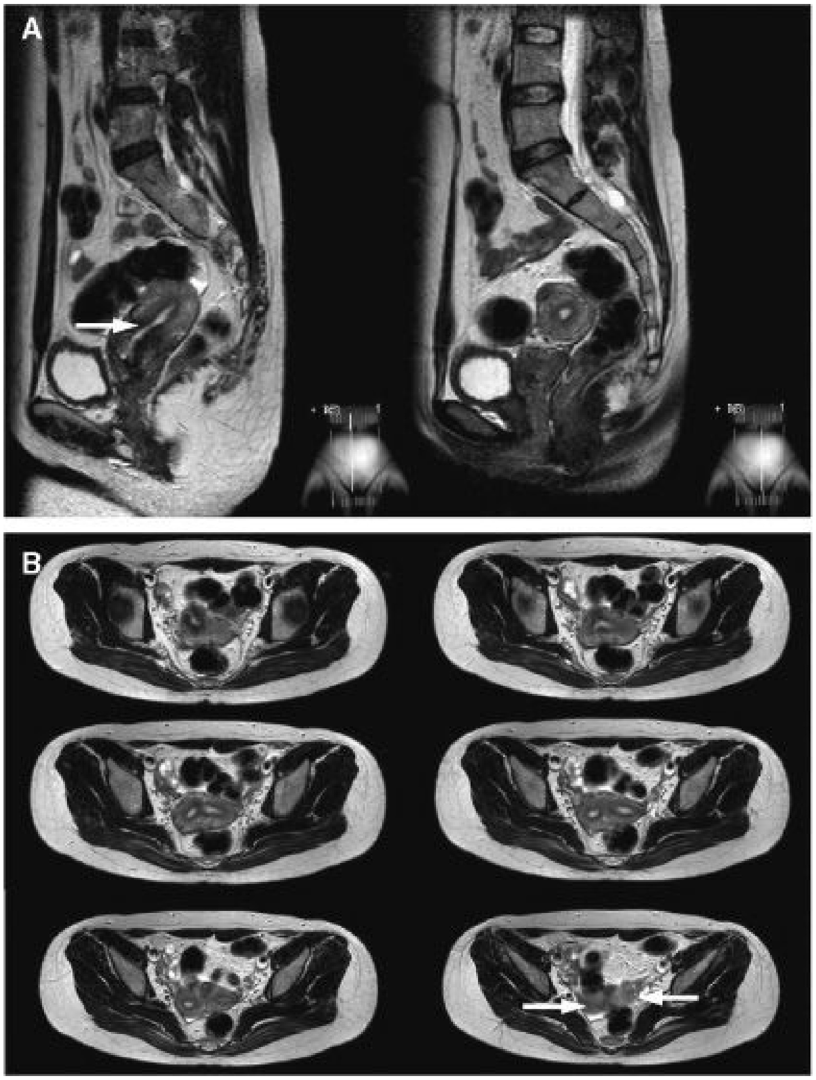

Figure 36–1. Magnetic resonance imaging of a bicornuate uterus. (Reproduced, with permission, from (Simons M. Hysteroscopic morcellator system can be used for removal of a uterine septum. *Fertil Steril* 2011;96(2):e118–121.)

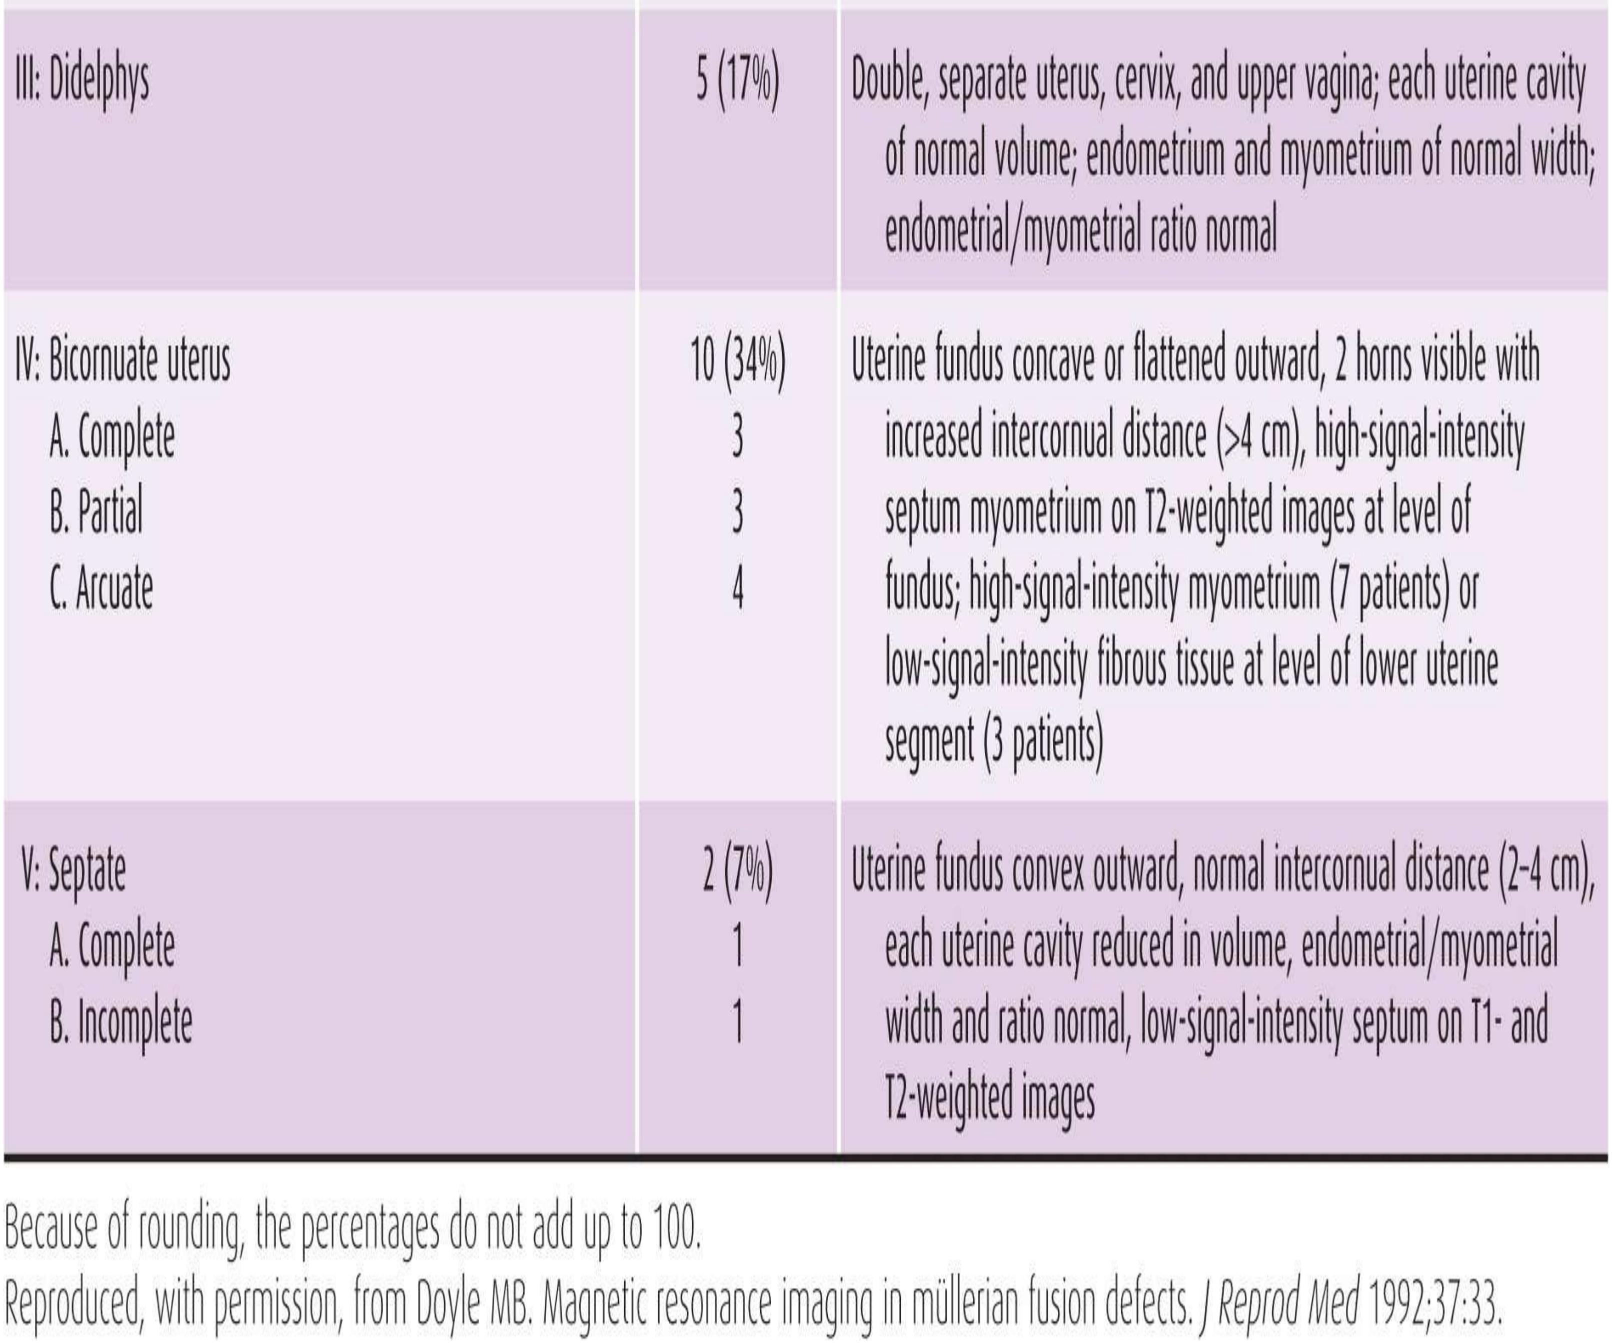
Table 36–2. Types of müllerian anomalies and associated MRI findings.

Class and Type	No.	Finding
I: Segmental agenesis/hypoplasia	7 (24%)	Agenesis: no identifiable organ or small amorphous tissue remnant. Hypoplasia: uterus small for patient's age, maintains adult body/cervix ratio of 2:1, reduced intercornual distance (<2 cm), low signal intensity on T2-weighted images with poor zonal differentiation, endometrial/myometrial width reduced
A. Vaginal	0	
B. Cervical	0	
C. Fundal	0	
D. Tubal	0	
E. Combined	7	
II: Unicornuate uterus	5 (17%)	Banana-shaped uterus, normal width of endometrium and myometrium, endometrial/myometrial ratio preserved
A1. Rudimentary horn with endometrium		
(A) Communicating with main uterine cavity	0	
(B) Not communicating with main uterine cavity	1	
A2. Rudimentary horn without endometrium	1	
B. No rudimentary horn	3	



III: Didelphys	5 (17%)	Double, separate uterus, cervix, and upper vagina; each uterine cavity of normal volume; endometrium and myometrium of normal width; endometrial/myometrial ratio normal
IV: Bicornuate uterus A. Complete B. Partial C. Arcuate	10 (34%) 3 3 4	Uterine fundus concave or flattened outward, 2 horns visible with increased intercornual distance (>4 cm), high-signal-intensity septum myometrium on T2-weighted images at level of fundus; high-signal-intensity myometrium (7 patients) or low-signal-intensity fibrous tissue at level of lower uterine segment (3 patients)
V: Septate A. Complete B. Incomplete	2 (7%) 1 1	Uterine fundus convex outward, normal intercornual distance (2–4 cm), each uterine cavity reduced in volume, endometrial/myometrial width and ratio normal, low-signal-intensity septum on T1- and T2-weighted images

Because of rounding, the percentages do not add up to 100.

Currently, histopathologic evaluation of colposcopic biopsies is required to diagnose cervical cancer and its precursor lesions. However, the technique is expensive and often requires a waiting period before histopathologic results are available and necessary treatment can be scheduled. Several new imaging techniques that evaluate the cervical epithelium are under investigation. Optical techniques, such as elastic backscattering and fluorescence and Raman spec-troscopies, have been used to noninvasively examine tissue morphology and the biochemical composition of the cervix. Optical coherence tomography (OCT) is a noninvasive imaging technique that uses coherent light to form images of subsurface tissue structures with 10- to 20-μm resolution and up to 1-mm depth. A study by Zuluaga and colleagues showed that simple quantitative analysis of images obtained with an OCT system can be used for noninvasive evaluation of normal and abnormal cervical tissue in vivo. OCT imaging could have broad applications for screening and detection of cervical malignancies and their precursors. It may also aid in surgical planning by allowing surgeons to identify margins in vivo without obtaining frozen sections.

IMAGING OF THE ENDOMETRIUM

Pelvic US has been used to evaluate the uterine cavity, and endometrial thickness has been used as a marker for endometrial pathology. The following guidelines should be used to obtain interobserver consistency in the evaluation of the endometrium. Obtain measurements from the midfundal region in the sagittal plane. Obtain the maximal double-thickness dimension, remembering to exclude the hypoechoic area between the myometrium and the endometrium. Any fluid between the anterior and posterior walls should be subtracted from the total measurement. Endometrial thickness ranges from 4–8 mm during the follicular phase and 7–14 mm during the luteal phase with a uniform echogenic appearance.

Premenopausal women should be evaluated during the early follicular phase, immediately following the menses when the endometrium has a uniform linear appearance. Menopausal women usually have an endometrial stripe <4 mm. Menopausal women on hormone replacement therapy (HRT) may have an endometrial thickness exceeding 8 mm and a small amount of fluid (<1 mm) (Table 36–2).

Approximately one-fifth of patients with abnormal uterine bleeding have submucous myomas or polyps. A study by Tur-Kaspa and colleagues found that 20% of infertile patients had some abnormality on SIS: arcuate uterus (15%), polyps (13%), submucosal fibroids (3%), and adhesions (<1%). These lesions may be detected by irregularities in the endometrial stripe or by saline infusion sonohysterography (SIS), a technique that involves saline infusion to distend the uterine cavity. Using SIS, a polyp appears as a smoothly marginated focal lesion that protrudes into the endometrial cavity. Kelekci and colleagues showed the sensitivities and specificities for detecting cavitary lesions with transvaginal US, SIS, and hysteroscopy to be 56.3% and 72%, 81.3% and 100%, and 87.5% and 100%, respectively. The sensitivity and specificity rates of US in detecting endometrial pathology reportedly increase when color flow and power Doppler imaging are used. However, tissue sampling is required to make a definitive diagnosis and to rule out malignancy in any patient not on HRT with a hyperechogenic endometrial stripe >4 mm.

3D US has been studied for evaluation of the endometrium. The ability of 3D US to produce coronal images of the cornua may increase slightly the sensitivity of SIS for detecting lesions in this location that otherwise might be difficult to evaluate. Endometrial abnormalities that can be seen in women with congenital malformations of the uterus may be imaged to greater advantage with 3D US techniques. 3D US has also been demonstrated to be a valid measurement technique for assessing volume. However, hysteroscopy likely will become the new gold standard for evaluating the endometrium because of the ability of hysteroscopy to directly visualize the endometrium and perform biopsies as indicated. The technique may become more cost effective as use of office hysteroscopy becomes more widespread. Evaluation of the endometrium using transvaginal sonography as the initial screening tool, followed by endometrial biopsy or possibly hysteroscopy, is likely to become the standard of care (Fig. 36–2).

Newer imaging modalities are under investigation to decrease the number of imaging tests often ordered in the evaluation of infertility. These tests seek to evaluate tubal patency, tubal architecture, the uterine cavity, and the myometrium in 1 study. Unterweger and colleagues showed that 3D dynamic magnetic resonance hysterosalpingography (3D dMR-HSG) can evaluate tubal patency in addition to MRI evaluation of the uterus and pelvic structures. Virtual hysterosalpingogram (VHSG) and multislice CT hysterosalpingography (MSCT-HSG) are similar tests but use CT technology in place of MRI for evaluation. Although these tests are more expensive than traditional procedures, they can provide the information previously gained from pelvic US, HSG, and MRI/CT in a single radiologic modality.

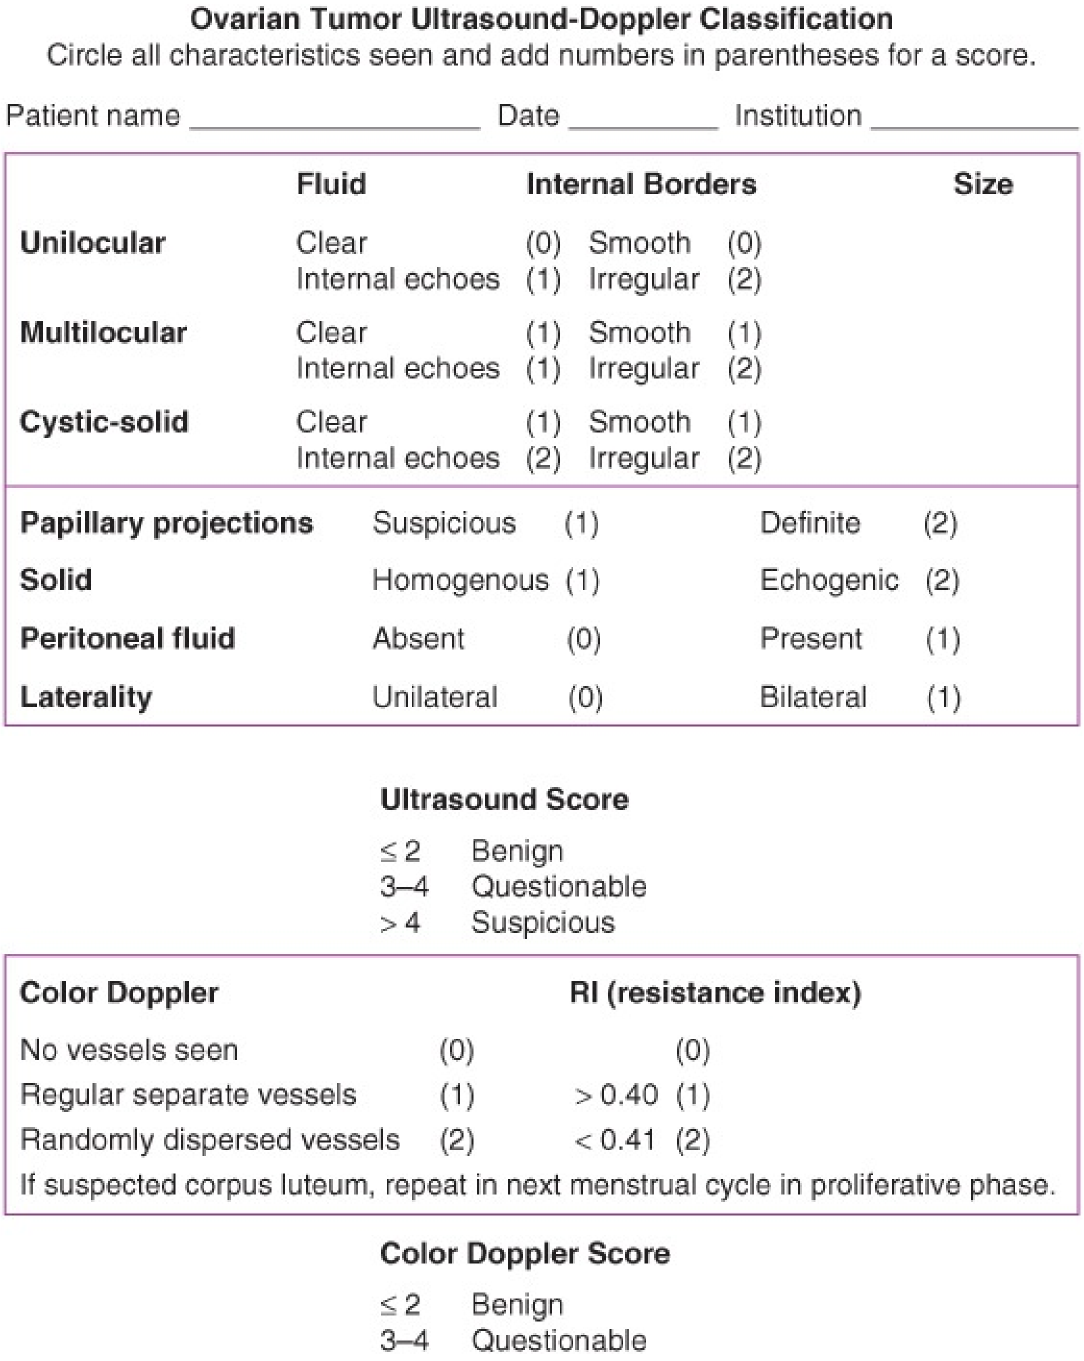
IMAGING OF THE OVARIES

The flat plate of the abdomen may still be useful in the diagnosis of dermoid cysts of the ovary, which are identified by the presence of calcified teeth. However, cystic and solid structures of the ovary now are better evaluated by transabdominal US, transvaginal US (TVUS), CT, and MRI.

Transvaginal assessment of the ovary is frequently used in assisted reproduction cycles, both in management and prediction of success. Antral follicles measure 2–10 mm in size and appear as small hypoechoic structures within the ovary and are typically measured in a basal state. Hendriks and colleagues have shown that the number of basal antral follicles is superior to follicle-stimulating hormone in predicting poor ovarian response. The ovarian follicles also change size in response to ovarian stimulation, whether exogenous or endogenous. These changes are monitored during assisted reproductive technology (ART) cycles to help in the timing of human chorionic gonadotropin (hCG) injections, oocyte retrieval, management of gonadotropin stimulation, and determining the need for cycle cancellation.

US is frequently used in the evaluation of ovarian pathology. TVUS combined with color flow and Doppler can be used for evaluation of blood flow to the adnexal structures and for diagnosis of ovarian torsion. Venous and lymphatic flow is occluded in early torsion, but arterial flow may be present. Arterial flow ceases completely later in the torsion. Torsion is diagnosed by Doppler study showing no venous or arterial flow, but a study showing arterial blood flow does not necessarily rule out the diagnosis.

Approximately 12,000 women in the United States die annually of ovarian cancer. Unfortunately, the ability of the pelvic examination to detect early ovarian malignancy is poor. CA-125 monoclonal marker for ovarian cancer also is a poor predictor of early cases. In an attempt to discriminate between malignant and benign adnexal masses, morphologic criteria have been assigned to increase suspicion concerning US findings when ovarian cancer is suspected. Cysts larger than 4 cm, solid and cystic components, septa, and papillary nodules have all been described (Fig. 36–3). In addition, Doppler flow studies have been used to distinguish between benign and malignant masses (Table 36–3).



Ovarian Tumor Ultrasound-Doppler Classification

Circle all characteristics seen and add numbers in parentheses for a score.

Patient name ___________________ Date __________ Institution ______________

	Fluid		Internal Borders		Size
Unilocular	Clear	(0)	Smooth	(0)	
	Internal echoes	(1)	Irregular	(2)

CT may be useful for preoperative staging of ovarian cancer or for planning second-look procedures. CT may also be useful for biopsy and drainage in patients with benign-appearing adnexal masses (ovarian cysts or tubo-ovarian abscesses). Contraindications to needle biopsy and drainage include lack of a safe unobstructed path for the needle, bleeding disorders, and lack of a motivated patient. 3D US can be useful in the evaluation of gynecologic diseases. It can reconstruct any plane of interest and is particularly valuable in visualizing abnormalities in the coronal plane. In addition, 3D

US is better able to measure volumes than is 2D US and, therefore, is helpful when evaluating patients with conditions ranging from fibroids to infertility. CT can be used in conjunction with pelvic US to diagnose and manage several conditions, such as pelvic inflammatory disease, adnexal torsion, ovarian vein thrombosis, and hemorrhagic ovarian cysts. In addition, MRI has been shown to be particularly useful in the evaluation of ovarian vein thrombosis.

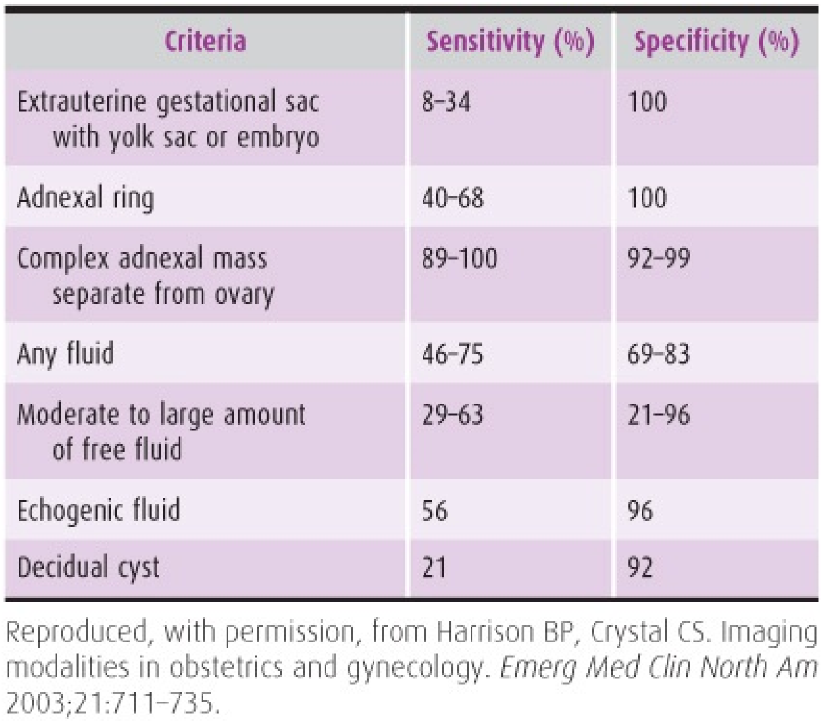
IMAGING OF THE FALLOPIAN TUBES

Endoscopic techniques provide the best direct evaluation of the patency and architecture of the fallopian tubes. HSG provides the best indirect evaluation of tubal function. HSG allows demonstration of tubal patency and visualization of tubal rugations while avoiding the more costly laparoscopic surgery. Some disadvantages of HSG are pelvic infection, dye allergies, failure to detect adnexal adhesions, and false-positive results for tubal occlusion. Salpingitis isthmica nodosa (SIN) is suggested when a honeycombing of the contrast material appears in the tubes during HSG. Hydrosalpinges are suggested when a hypoechoic “sausaging” of the tube is seen on US. Hysterosalpingo-contrast sonography, 3D dMR-HSG, VHSG, and MSCT-HSG are alternatives to laparoscopy, as women with normal findings probably have a normal pelvis.

IMAGING IN ECTOPIC PREGNANCY

Adnexal sonography is a valuable tool in assessing women with suspected ectopic pregnancy (Table 36–4). When hCG levels reach 6500 mIU/mL, most normal intrauterine pregnancies can be detected as a gestational sac by transabdominal US. However, the sonographic appearance of a pseudogestational sac should not be confused with the gestational sac. In the latter, a double ring sign resulting from the decidua parietalis is seen abutting the decidua capsularis.

Table 36–4. Criteria for diagnosis of ectopic pregnancy.



Criteria	Sensitivity (%)	Specificity (%)
Extrauterine gestational sac with yolk sac or embryo	8–34	100
Adnexal ring	40–68	100
Complex adnexal mass separate from ovary	89–100	92–99
Any fluid	46–75	69–83
Moderate to large amount of free fluid	29–63	21–96
Echogenic fluid	56	96
Decidual cyst	21	92

Reproduced, with permission, from Harrison BP, Crystal CS. Imaging modalities in obstetrics and gynecology. *Emerg Med Clin North Am* 2003;21:711–735.

TVUS, on the other hand, has the advantage of earlier and better localization of the pregnancy, with less pelvic discomfort because the bladder is not painfully distended. An hCG level of 1000–2000 mIU/mL is the discriminatory zone in which an intrauterine pregnancy can be detected by TVUS. The double-ring sign and the yolk sac must be identified to ensure that the pregnancy is intrauterine. When an intrauterine pregnancy is not visualized on TVUS and the hCG level exceeds 1000–2000 mIU/mL, suspicion for an ectopic pregnancy should be high. However, multiple gestations and heterotopic pregnancies may take several more days to be identified. Both of these conditions are more common in patients undergoing ART. Because it is not well established at what hCG levels multiple gestation or heterotopic pregnancies should be visualized on US, particular caution is needed in evaluating for ectopic pregnancies in ART patients.

IMAGING OF THE PERITONEUM

In recent years, newer imaging modalities have been evaluated for their ability to detect peritoneal pathology, primarily malignant processes and endometriosis. US has limited ability to detect peritoneal pathology, especially smaller processes. Shaw and colleagues concluded that, although MRI may have a role, CT imaging remains the test of choice for the diagnosis of pelvic malignancy. For deep and surface pelvic endometriosis, Bazot and colleagues showed that MRI has a high sensitivity and specificity for diagnosis. Despite these recent advances in peritoneal imaging, laparoscopy remains the gold standard for the diagnosis of peritoneal pathology.

IMAGING OF THE PITUITARY GLAND

Although the pituitary gland is located outside the pelvis, imaging of the gland is indicated in gynecologic patients with hyperprolactinemia. Patients with hyper-prolactinemia may present with infertility, galactorrhea, decreased libido, and oligomenorrhea. Imaging of the pituitary has been recommended with prolactin levels over 100 ng/mL or in any patient with persistently elevated prolactin levels. A recent study by Bayrak and colleagues showed that while the size of the pituitary prolactinoma does correlate with serum prolactin levels, patients with macroadenomas may present with only moderate prolactin elevations, and therefore, any patient with persistently elevated prolactin levels should undergo pituitary imaging.

Historically, pituitary imaging was performed with a coned-down x-ray film of the sella turcica. MRI has replaced this approach with a greater sensitivity for detecting microadenomas as compared to both x-ray and CT scans. On MRI examination, microadenomas are commonly identified as areas of low-intensity T1 signaling.

CONCLUSION

The imaging techniques prevalent today have proved to be valuable tools in the diagnosis and treatment of benign and malignant gynecologic disorders. To provide the patient with the highest level of medical care, the contemporary practicing gynecologist must constantly keep abreast of the new developments and applications of diagnostic imaging. No matter what technology is used today and in the future, the goal will always be the same: to provide quick, low-risk, accurate diagnosis of gynecologic conditions while keeping in mind the cost effectiveness of the care delivered.

Pediatric & Adolescent Gynecology

Dvora Bauman, MD

Pediatric and adolescent gynecology is a unique subspecialty of gynecology that encompasses reproductive health care of girls and young women under the age of 20 years, although some experts extend the age limit to 22 years.

This field has expanded greatly over the last decades, as increased attention has been directed to disorders of developmental physiology. The spectrum of gynecologic problems that a physician might encounter in young girls is age specific and involves different skills than those applied for adults. Currently, pediatric and adolescent gynecology includes a vast array of diagnoses and treatment modalities for these particular patients.

Pediatric and adolescent gynecology starts with an observation of abnormal external genitalia in a newborn. Later on in childhood, it involves early detection of infections, labial adhesions, congenital anomalies, and even genital tumors. With adolescents, normal pubertal development, evaluation of menstrual disorders, and treatment of genetic and hormonal ailments need to be addressed. Educational approach should be implemented for issues of budding sexuality in teenagers. Concomitantly counseling of proper use of contraceptives is imperative to lower the rates of teen pregnancies and sexually transmitted infections.

The American College of Obstetricians and Gynecologists recommends that adolescents should have their first visit to a gynecologist for health guidance, general physical screening, and the provision of preventive health care services at age 13–15 years. A pelvic examination of adolescents who are sexually active may be deferred until the age of 18 years, unless medically indicated. This first visit should provide an opportunity for the gynecologist to start the physician–patient relationship, recommend proper health behaviors, and dispel myths and fears.

The first gynecologic visit is of paramount importance in establishing a trustful relationship between the young woman and her health care provider for many years to come.

ANATOMIC & PHYSIOLOGIC CONSIDERATIONS

Newborn Infants

During the first few weeks after birth, follicle-stimulating hormone (FSH) rises in the newborn due to the abrupt withdrawal of placental and maternal sex steroid hormones, resulting in hyperestrogenic physiologic effect. Breast budding occurs in nearly all female infants born at term. In some cases, breast enlargement is marked, and there may be fluid discharge from the nipples. No treatment is indicated. The labia majora are bulbous, and the labia minora are thick and protruding (Fig. 37–1). The clitoris is relatively large, with a normal index of 0.6 cm^2 or less.* The hymen initially is turgid, covering the external urethral orifice. Vaginal discharge is common in some cases and can even be bloody for the first 2 weeks, and is composed mainly of cervical mucus and exfoliated vaginal cells. Endometrial cell shedding might occur.

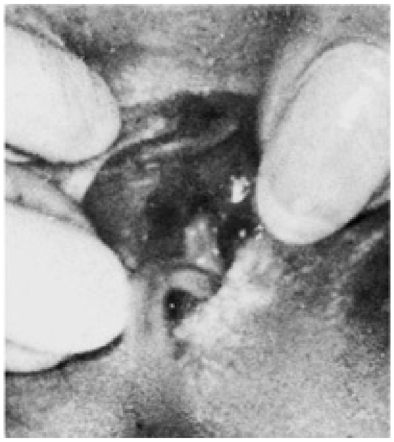

Figure 37–1. External genitalia of a newborn female. Note the hypertrophy and turgor of the vulvar tissues. A small catheter is inserted into the vagina to demonstrate patency. (Reproduced, with permission, from Huffman JW. *The Gynecology of Childhood and Adolescence*. New York, NY: WB Saunders; 1968.)

The vagina is approximately 4 cm long at birth. The uterus is enlarged (4 cm in length) and without axial flexion; the ratio between the cervix and the corpus is 3:1. Columnar epithelium protrudes through the external cervical os, creating a reddened zone of physiologic eversion. The ovaries remain abdominal organs in early childhood before descending into the pelvis.

Young Children

In early childhood, the female genital organs receive little estrogen stimulation. The labia majora flatten. The labia minora are thin structures running beside the upper part of vestibule and ending at the 3 and 9 o’clock positions. The hymen become thin (Fig. 37–2) and atrophic. The clitoris remains relatively small, although the clitoral index is unchanged. The vagina, lined with atrophic mucosa with relatively few rugae, offers very little resistance to trauma and infection. The vaginal barrel contains neutral or slightly alkaline secretions and mixed bacterial flora. Because vaginal fornices do not develop until puberty, the cervix in childhood is flush with the vaginal vault, and its opening appears as a small slit. The uterus regresses in size and does not regain the size present at birth until approximately age 6 years. At laparotomy, the uterus may appear as merely a strip of dense tissue in the anteromedial area of the broad ligaments. The ovaries at this age have the volume of 1–2.7 mL with small resting follicles (Table 37–1).

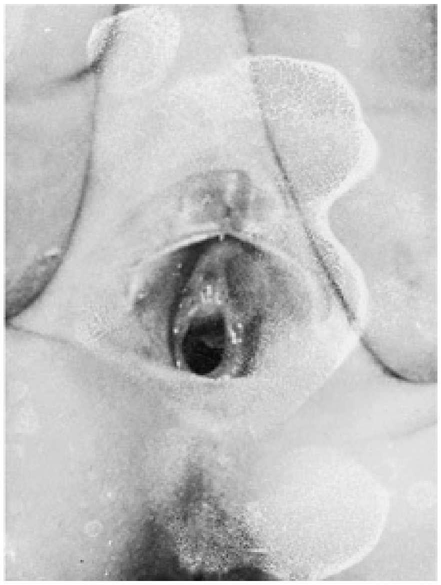

Figure 37–2. External genitalia of a child 3 years of age.

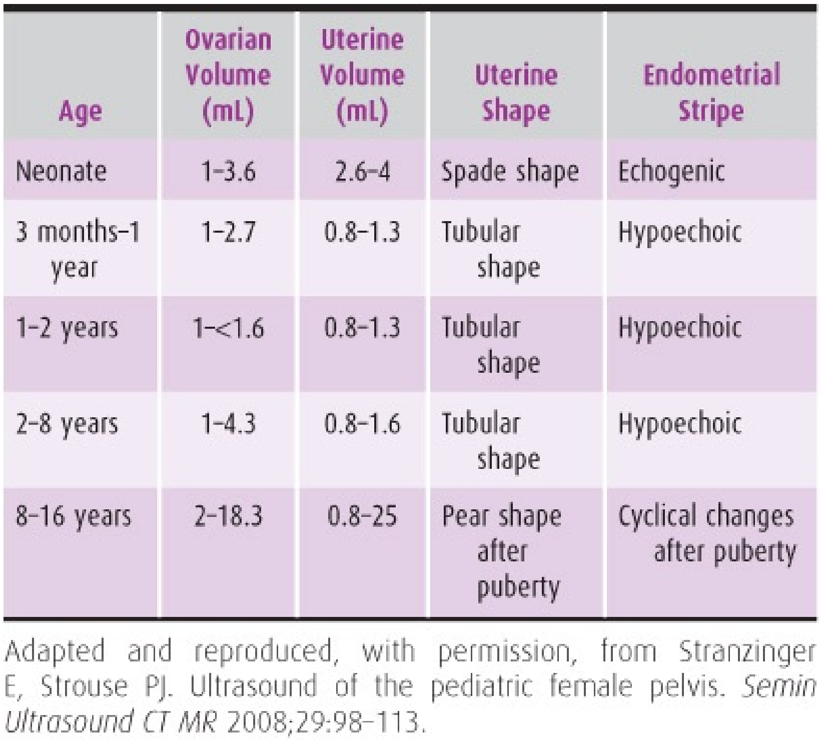
Table 37–1. Normal volume of the ovaries and the uterus.



Age	Ovarian Volume (mL)	Uterine Volume (mL)	Uterine Shape	Endometrial Stripe
Neonate	1–3.6	2.6–4	Spade shape	Echogenic
3 months–1 year	1–2.7	0.8–1.3	Tubular shape	Hypoechoic
1–2 years	1–<1.6	0.8–1.3	Tubular shape	Hypoechoic
2–8 years	1–4.3	0.8–1.6	Tubular shape	Hypoechoic
8–16 years	2–18.3	0.8–25	Pear shape after puberty	Cyclical changes after puberty

Adapted and reproduced, with permission, from Stranzinger E, Strouse PJ. Ultrasound of the pediatric female pelvis. *Semin Ultrasound CT MR* 2008;29:98–113.

Older Children

During late childhood (age 7–10 years), the external genitalia again show signs of estrogen stimulation: the mons pubis thickens, the labia majora fill out, and the labia minora become rounded. The hymen thickens, losing its thin, transparent character. The vagina elongates to 8 cm, the mucosa becomes thicker, the corpus uteri enlarge, and the ratio of cervix to corpus becomes 1:1. The cervix remains flush with the vault (Fig. 37–3).

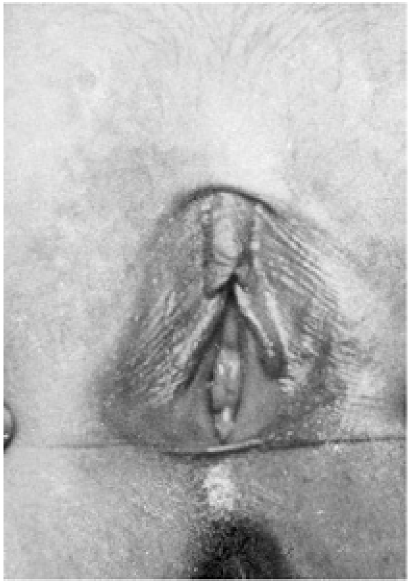


Figure 37–3. External genitalia of a child 11 years of age. Early estrogen response is evidenced by the fuller labia, wrinkling of the vulvar mucosa, and thickening of the hymen.

By the time a girl reaches age 9–10 years, uterine growth begins, with alteration in uterine shape resulting primarily from myometrial proliferation. Rapid endometrial proliferation occurs as menarche is imminent. Prior to this time, the endometrium gradually thickens, with modest increases in the depth and complexity of the endometrial glands. As the ovaries enlarge and descend into the pelvis, the number of ovarian follicles increases. Although these follicles are in various stages of development, ovulation generally does not occur.

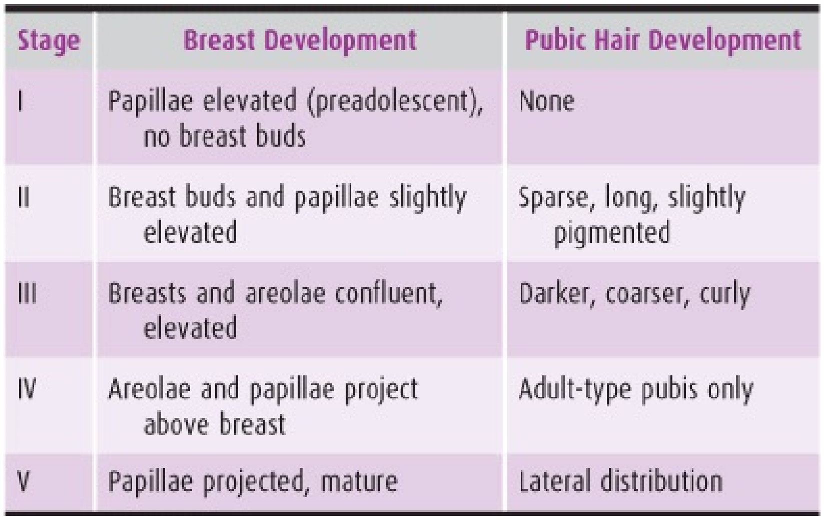
Young Adolescents

During early puberty (age 10–13 years), the external genitalia take on adult appearance. The major vestibular glands (Bartholin's glands) begin to produce mucus just prior to menarche. The vagina reaches adult length (10–12 cm) and becomes more distensible, the mucosa thickens, vaginal secretions grow more acidic, and lactobacilli reappear. With the development of vaginal fornices, the cervix becomes separated from the vaginal vault, and the differential growth of the corpus and cervix becomes more pronounced. The corpus grows twice as large as the cervix. The ovaries descend into the true pelvis.

Secondary sexual characteristics develop, often rapidly, during the late premenarchal period. Body habitus becomes more rounded, especially the shoulders and hips. Accelerated somatic growth velocity (the adolescent growth spurt) occurs. At the same time, estrogen increases adipose tissue deposition and initiates stromal and ductal growth in the breasts. Physiologic leukorrhea often is noted.

Pubic hair growth, or pubarche (adrenarche), appears to be under the control of adrenal androgens and is a process that is independent of although associated with gonadarche. Sparse, long, slightly curly, pigmented hair over the pubic area gives way to coarse, pigmented curly hair. The pubic hair pattern assumes the characteristic triangle with the base above the mons pubis. Hair growth in the axilla appears later, also as a result of adrenocorticosteroid stimulation. The development of secondary sexual features described by Marshall and Tanner is summarized in Table 37–2 (see Fig. 4–3).

Table 37–2. Tanner classification of female adolescent development.



Stage	Breast Development	Pubic Hair Development
I	Papillae elevated (preadolescent), no breast buds	None
II	Breast buds and papillae slightly elevated	Sparse, long, slightly pigmented
III	Breasts and areolae confluent, elevated	Darker, coarser, curly
IV	Areolae and papillae project above breast	Adult-type pubis only
V	Papillae projected, mature	Lateral distribution

GYNECOLOGIC EXAMINATION OF INFANTS, CHILDREN, & YOUNG ADOLESCENTS

Examination of the Newborn Infant

Newborns should be examined immediately upon delivery or in the nursery. When an infant is born with ambiguous genitalia, immediate actions should be to counsel the parents and to prevent dehydration, as congenital adrenal hyperplasia accounts for >90% of cases of ambiguous genitalia, and salt-wasting forms may lead to rapid dehydration and fluid imbalances. In most cases, an internal examination is unnecessary, as most gynecologic abnormalities that should be recognized at this stage are limited to the external genitalia.

A. General Examination

As in adults, the first step in a genital evaluation of the newborn is a careful general examination, which may reveal abnormalities suggesting genital anomaly (eg, webbed neck, abdominal mass, edema of the hands and legs, coarctation of the aorta).

B. Clitoris

Clitoral enlargement in the newborn almost always is associated with congenital adrenal hyperplasia. Other causes, such as hermaphroditism and neoplasms, also must be considered.

C. Vulva & Vagina

The vaginal orifice should be evident when the labia are separated or retracted. If the vaginal orifice cannot be located, the infant most likely has an imperforate hymen or vaginal agenesis. Inguinal hernias are uncommon in females, and the presence of bilateral inguinal masses suggests the possibility that the child is a genetic male and may require karyotype testing.

D. Rectoabdominal Examination

Usually, the uterus and adnexa in the newborn cannot be palpated on rectal examination; therefore, is occasionally needed. An ovary that is palpable on abdominal examination denotes enlargement, and the possibility of an ovarian tumor should be investigated, even though pelvic masses in newborns likely represent a Wilms’ tumor.

Examination of the Premenarchal Child

The examination of the premenarchal and peripubertal child should focus on the main symptoms identified in this population: pruritus, dysuria, skin color changes, and discharge.

Parents can be helpful during the examination of a young child because they provide a sense of security and they can distract the patient. Placing a child up to age 5 years on her parent’s lap affords a better opportunity to perform an adequate examination. Older children can be placed on the examination table so the examiner may have adequate exposure of the genitalia when the patient is asked to flex her knees and abduct her legs. Asking the young patient to assist in the examination may distract the child as well as provide her with a sense of control. In rare cases, the knee–chest position may be useful in visualizing the upper vagina and cervix.

In older girls, explaining procedures and providing health information during the examination may decrease apprehension and help establish a good patient–physician relationship.

A. Physical Examination

1. General inspection—The examination begins with an evaluation of the patient’s general appearance, nutritional status, body habitus, and any gross congenital anomalies.

2. Breasts—Breast budding does not normally begin before the age of 7.5–8 years. Prominence of the nipple and breast development at an earlier age may be early signs of sexual precocity. Appropriate monitoring may include assessment of bone age, as well following height and breast development at 3-month intervals.

3. Abdomen—Inspection and palpation of the abdomen should precede examination of the genitalia. If the child is ticklish, having her place one hand on or under the examiner’s hand usually will overcome the problem.

The ovary of a premenarchal child is situated high in the pelvis. This location and the small size of the pelvic cavity tend to force ovarian tumors above the true pelvic brim. Thus, large neoplasms of the ovary are likely to be mistaken for other abdominal masses (eg, polycystic kidney). Although inguinal hernias are less common in females than in males (approximately 1:10), they may occur, usually without discomfort. An excellent method of demonstrating an inguinal hernia is to have the child stand up and increase the intraabdominal pressure by blowing up a balloon.

4. Genitalia—The vulva and vestibule can be exposed by light lateral and downward pressure on each side of the perineum, a technique referred to as *labial separation*. When exposure of the vaginal walls is necessary, the labia can be grasped between the examiner’s thumb and forefinger and pulled forward, downward, and sideways, a technique called *labial traction* (Fig. 37–4). Particular attention should be paid to the adequacy of perineal hygiene, because poor hygiene may predispose a child to local inflammation. The examiner should look for skin lesions, perineal excoriations, ulcers, and tumors. Signs of hormonal stimulation in early childhood and absence of such signs later in adolescence are important signs of endocrine disorders associated with precocious or delayed puberty. Enlargement of the clitoris is of diagnostic significance, especially during early pubertal development, because it alerts the clinician to the presence of an endocrinopathy.

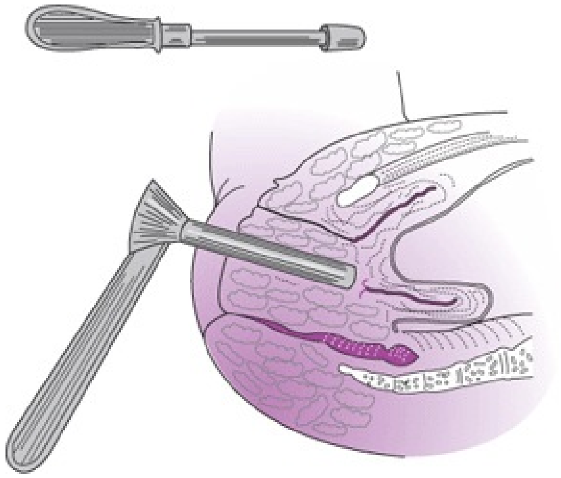


Figure 37–4. Huffman vaginoscope used for examination of a premenarchal child.

The normal hymen has multiple configurations including annular, crescentic, and fimbriated/redundant. Special attention to hymen appearance is given during forensic examination of sexual abuse victims, and the examiner should be familiar with vast variations of normal anatomy.

In some patients, the vestibule or the vaginal orifice may not be visible because of labial adhesions or congenital anomalies. The former condition is frequently mistaken for vaginal agenesis or imperforate hymen.

It is unnecessary to perform a digital vaginal examination in a child whose vagina is very narrow and in whom the hymeneal orifice is small and extremely sensitive. Gentle rectal digital examination can be accomplished, but accurate intrapelvic evaluation is better achieved by other diagnostic procedures such as sonography, computed tomography, vaginoscopy, or laparoscopy.

B. Vaginoscopy

Instrumentation is required when it is necessary to carefully visualize the upper third of the vagina for a source of abnormal vaginal bleeding, to detect and remove foreign bodies, or to exclude penetrating injuries. The water endoscope (hysteroscope, cystoscope) distends the vagina and permits visualization of the vaginal mucosa, while washing away secretions, blood, and debris (Fig. 37–5).

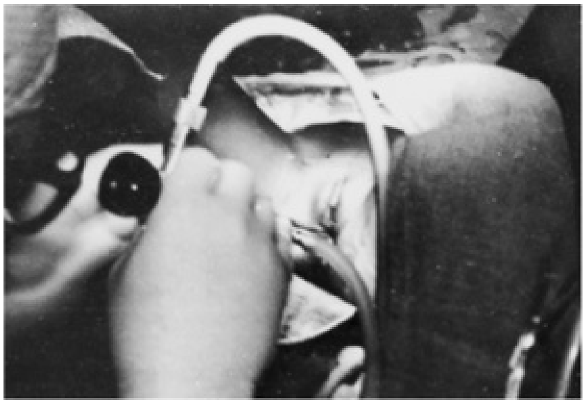

Figure 37–5. Performing vaginoscopy under anesthesia using a water cystoscope.

In infancy and childhood, the hymenal orifice normally is smaller than 1 cm. An instrument 0.3–0.4 cm in diameter can be used to examine those girls. Topical lidocaine gel can be used to anesthetize the vulva and provide lubrication in older premenarchal girls. In younger girls and in cases where the aperture is too small to allow instrument passage without patient discomfort, vaginoscopy should not be further attempted without general anesthesia.

Vaginoscopy is a safe and short procedure with few, if any, adverse effects; therefore, it should be used frequently as a diagnostic tool. A “see and treat” approach may be applied to both diagnose and take care of the problem with the same equipment.

Examination of the Adolescent

The adolescent’s first trip to the gynecologist is often laden with fear and apprehension. Time spent putting the patient at ease and winning her confidence will save time and frustration in the examining room. The communicative skills that permit establishment of a good physician–patient relationship with teenagers can be acquired by training. The physician should make it clear that the adolescent is the patient, rather than the accompanying adult, if present. Questions about high-risk behaviors, including sexual behavior and sexually transmitted diseases (STDs), should be asked privately without the presence of the accompanying adult.

The American College of Obstetricians and Gynecologists recommends that adolescents should have their first visit to a gynecologist for health guidance, general physical screening, and the provision of preventive health care services at age 13–15 years. It is reasonable to observe even those who are not sexually active in each stage of adolescence: early adolescence, ages 13–15; middle adolescence, ages 15–17; and late adolescence, ages 17–19.

Unfortunately, many adolescents do not seek health care until after first intercourse. In the United States, the median age of first sexual intercourse is 16.5 years, but as many as 7% of adolescents report their first vaginal intercourse before 13 years of age.

After the history is taken, the patient should be given a brief description of what the examination entails. Girls under the age of 18 years should be informed that pelvic examination is not necessary unless medically indicated, yet an external genital examination can provide an opportunity to familiarize adolescents with normal anatomy and allow the practitioner an opportunity to visualize the perineum for any anomalies. The girl should be assured that any examination will not be painful. While performing the physical examination, the health care provider should reassure the adolescent about her normal anatomy and proper development. Following the examination, the patient is given an opportunity to speak alone with the examiner. Confidentiality is essential to the physician–patient relationship, and problems can be discussed with the patient's guardians only with the patient's consent.

The examination should start with general inspection. A breast examination is an integral part of the physical examination of every female patient, followed by abdominal palpation.

The examination is also used to provide the patient with health maintenance instructions and explanations about her body and its various functions. Many adolescents are not familiar with the appearance of their own genitalia. Some physicians use mirrors during the examination to show normal anatomic details, to demonstrate abnormalities, and to provide explanations regarding health maintenance. Others use a colposcope attached to a video monitor; this provides an enlarged image seen simultaneously by the examiner and the patient and permits direct communication.

The introitus of most virginal adolescents is approximately 1 cm in diameter and will admit a narrow speculum when clinically indicated. The Huffman-Graves and Pedersen specula both are designed to allow for easy inspection of the cervix in adolescents, in whom the vagina is 10–12 cm long (Fig. 37–6). In a patient with a large hymenal opening, bimanual examination is performed by inserting a finger into the vagina. If the hymenal orifice is too small for digital examination, rectal examination can be performed.

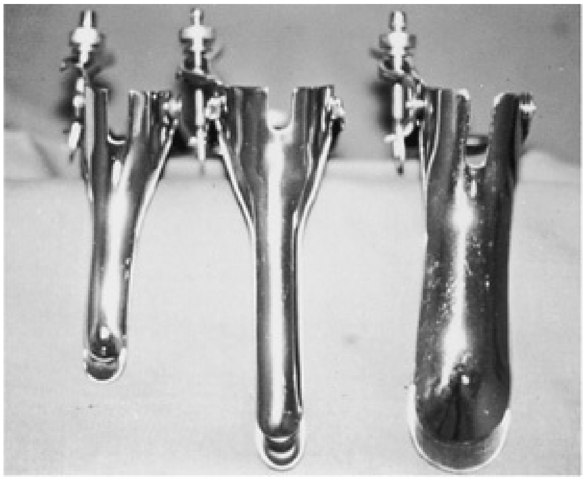

Figure 37–6. The Huffman-Graves speculum (middle) is as long as the adult Graves speculum **(right)** and as narrow as the short pediatric Graves speculum **(left)**.

All sexually active girls should be screened annually for chlamydia and gonorrhea. Urine-based sexually transmitted infection (STI) testing is an efficient means for accomplishing such screening without speculum examination.

The gynecologic visit serves as an excellent opportunity to review basic health care maintenance. For example, current recommendations advise universal vaccination for hepatitis B for all adolescents at ages 11–12 years, with immunization for older adolescents based on risk status and discussion regarding human papillomavirus vaccine. In addition, screening for eating disorders, depression, and behavioral risks including sexual activity and tobacco, alcohol, and substance abuse should be done routinely. To assist providers of adolescent health care, the American Medical Association has issued recommendations based on annual health guidance, screening, and immunization schedules. For more information regarding specific legal rights for adolescents, the Guttmacher Institute has established a Web site for practitioner assistance (www.guttmacher.org).

ACOG Committee on Gynecological Practice. ACOG committee opinion No. 431: Routine pelvic examination and cervical cytology screening. *Obstet Gynecol* 2009;113:1190–1193. PMID: 19384150.

Examination of the Young Victim of Sexual Abuse

Studies show that approximately 38% of girls are sexually victimized before age 18 years. Among adolescent girls in grades 9–12, 26% report experiencing physical or sexual abuse. Therefore, all adolescents should be asked about history of abuse. Many children who are possible victims of sexual abuse are brought to a hospital emergency room or to their physician’s office for a comprehensive medical evaluation. Statutes vary from state to state as to the need for legal consent from a parent or guardian to perform a genital examination and collect evidence in cases of suspected abuse.

A. History

In some facilities, a designated individual conducts an investigative interview to minimize repetitive questioning of the child. When asking young children about abuse, line drawings, dolls, or other aids are generally used only by professionals trained in interviewing young children. However, this does not preclude the physician from asking relevant questions to obtain a detailed history, a review of systems, and basic information about the assault. An account of the incident is extremely valuable, as it can later be used in court as evidence, or it may reveal an unusual area of injury and thus uncommon sites for collection of evidence. It is important to know how and from whom the patient sustained the injury and whether the child is in a safe environment.

It is imperative that the clinician use questions that are not leading, avoid showing strong emotions such as shock or disbelief, and maintain a “tell me more” or “and then what happened” approach. The courts have allowed physicians to testify regarding specific details of the child’s statements obtained in the course of taking a medical history to provide a diagnosis and treatment. The American Academy of Child and Adolescent Psychiatry and the American Professional Society on the Abuse of Children have published guidelines for interviewing sexually abused children.

The examiner should note the patient’s composure, behavior, and mental state, as well as how she interacts with her parents and other persons. Victims of physical or sexual abuse must be removed immediately from an unsafe environment.

The information should be recorded carefully, using the patient’s own words. Written notes in the medical record or audiotape or videotape should be used to document the questions asked and the child’s responses. Although a detailed history is desirable, the victim should not be made to repeatedly recount the incident. When obtaining a history from a very young child is not possible, the physician should obtain accounts of the incident from other sources.

B. Physical Examination

The physical examination has 2 purposes: to detect and treat injuries and to collect samples that later can be used as evidence.

1. Detection of injuries—Nonspecific findings are relatively common in young children. Vulvar irritation is often seen in small children as a result of poor local hygiene, maceration of the skin because of wetness from diapers, or excoriations caused by local infection. Such nonspecific findings should not be regarded as diagnostic of sexual abuse. It is important to remember that the examination is often normal in most children who were sexually abused. In one study of 2384 children who were seen in a tertiary referral center, <5% had genital findings suggesting abuse. The examination was deemed normal in 96.3% of children referred for the evaluation. Even so, interviews of the children indicated that 68% of the girls reported penetration of vagina or anus.

The physician should be familiar with normal genital anatomy, particularly that of the hymen, and should be able to distinguish hymenal trauma. A "clock system" approach is applied to describe hymen lacerations, which usually appear in the form of notches and clefts in the posterior rim between 3 and 9 o' clock. Studies showing that partial tears of the hymen, as well as abrasions and contusions, may heal to leave very little or no sign of previous injury emphasize the importance of urgent evaluations. Additional methods to demonstrate hymenal continuity involve saline irrigation on the posterior rim of the hymen or gentle pulling of Foley catheter balloon against the hymenal margins. In postpubertal girls, penetration and stretch trauma can result in hymeneal remnants.

2. Collection of evidence—During the general inspection, all foreign material (eg, sand and grass) should be removed and placed in clearly labeled envelopes. Scrapings from underneath the fingernails and loose hairs on the skin are collected. Semen can be detected on the skin many hours after the assault. A Wood's lamp can be used to detect the presence of seminal fluid on the patient's body, because the ultraviolet light causes semen to fluoresce. The stain can be lifted off the skin with moistened cotton swabs for further analysis.

If vaginal penetration is suspected, vaginal fluid is collected and sent for sexual disease evaluation, wet-mount preparation, cytology, acid phosphatase determination, and enzyme p30. To avoid additional psychological trauma in a prepubescent child, these specimens can be collected without the insertion of a pediatric speculum, via vaginal aspiration using a feeding tube or Angiocath. An immediate wet-mount preparation done by the examining physician may detect motile sperm.

Culture swabs are obtained from the rectum, vagina, urethra, and pharynx. Current data indicate that a prepubertal child with gonorrhea or trichomonas most likely had genital–genital contact. The mode of transmission of other STIs is controversial. Testing for STIs, including human immunodeficiency virus (HIV), should be offered. In pubertal girls, postcoital contraception should be recommended.

All specimens must be clearly labeled and the containers and envelopes sealed and signed by the examiner. All persons handling the materials must sign for them. Such a system is necessary to maintain the chain of evidence; otherwise, these specimens may not be admissible in court. Some hospitals provide preassembled "rape kits" that guide the examiner in documenting and collecting specimens in a manner suitable for legal uses.

If an STI or other signs of abuse are found, all states require that the findings be reported to child protective service agencies for investigation of sexual abuse. Furthermore, it is important to keep in mind that a normal physical examination does not exclude the possibility of sexual abuse.

CONGENITAL ANOMALIES OF THE FEMALE GENITAL TRACT

The reproductive organs in the female consist of external genitalia, internal duct system (the müllerian ducts), and the gonads. These 3 components originate embryologically from different primordia. External genitalia, including the lower part of vagina, are formed predominantly from the urogenital sinus. The müllerian (paramesonephric) duct system, after complex developmental changes, ends with a final configuration of fallopian tubes, the uterine corpus and cervix, and the upper portion of the vagina. The gonads are derived from the endoderm beneath the coelomic epithelium (detailed embryologic development is described in Chapter 2).

The etiology of these defects is not fully understood. Most forms are of isolated occurrence. Müllerian duct and urogenital sinus malformations are inherited in a polygenic/multifactorial fashion. Considering the influence of embryologic development on adjacent structures (gastrointestinal and urinary systems), one may encounter associated malformations in those systems as well.

ANOMALIES OF EXTERNAL GENITALIA

ANOMALIES OF THE VULVA & LABIA

Minor differences in the contour or size of vulvar structures are not unusual. Often there is considerable variation in the distance between the posterior fourchette and the anus or between the urethra and the clitoris. Rare anomalies of the vulva include bifid clitoris, a caudal appendage resembling a tail; congenital prolapse of the vagina; and variations in the insertion of the bulbocavernosus muscle, which may alter the appearance of the labia majora and at times obliterate the fossa navicularis. Duplication of the vulva is an extremely rare anomaly, which may be associated with duplication of the urinary or intestinal tracts.

There is considerable variation in the size and shape of the labia minora. One of the labia may be considerably larger than the other, or both labia may be unusually large. These variations usually require no treatment (Fig. 37–7). If asymmetry is significant or if large labia are pulled into the vagina during intercourse, the hypertrophied labia can be trimmed surgically to provide a more symmetric appearance or to relieve dyspareunia.

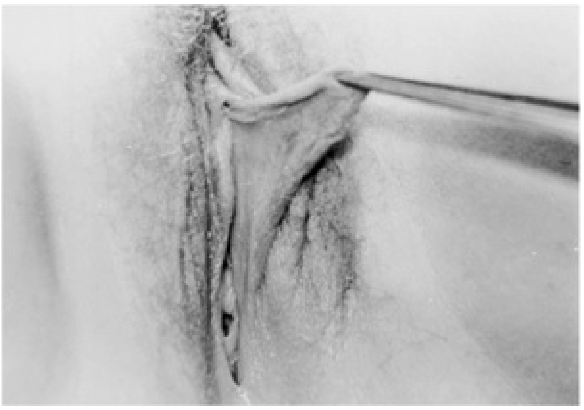

Figure 37–7. Labial asymmetry resulting from enlargement of the left labium minor.

ANOMALIES OF THE CLITORIS

Clitoral enlargement almost invariably suggests exposure to elevated levels of androgens. Such enlargement is often associated with fusion of the labioscrotal folds and could be part of the sexual ambiguity and disorders of sex development. Recklinghausen’s neurofibromatosis, lymphangiomas, and fibromas may also involve the clitoris and cause enlargement. When an isolated neoplasm causes enlargement of the clitoris, therapy consists of excision of the neoplasm with reduction of the clitoris to normal size.

In children with disorders of sex development, clitoral reduction is often performed as part of therapy once the diagnosis is made and a female gender is assigned. Many techniques have been described. Although the surgery is often performed in early childhood, the long-term effects on sexual function are unknown. A recent study of 39 adults who had intersex conditions with ambiguous genitalia and who were living as females showed that those who had undergone clitoral surgery had higher rates of nonsensuality and of inability to achieve orgasm. The authors concluded that sexual function of adult females could be compromised by clitoral surgery.

ANOMALIES OF THE HYMEN

Hymenal anomalies result from incomplete degeneration of the central portion of the membrane. Variations include imperforate, microperforate, septate, and cribriform hymens. Hymenal anomalies require surgical correction if they block vaginal secretions or menstrual fluid, interfere with intercourse, or preclude the use of tampons.

Providers should be aware that there have been reports of familial occurrence of hymenal abnormalities and thus alert young women that their daughters may have a similar abnormality.

Imperforate Hymen

Imperforate hymen has an incidence of 1 in 1000 and represents a persistent portion of the urogenital membrane. It occurs when the mesoderm of the primitive streak abnormally invades the urogenital portion of the cloacal membrane. The normal perforation occurs late in fetal life. When mucocolpos develops from accumulation of vaginal secretions behind the hymen, the membrane is seen as a shiny, thin bulge (Fig. 37–8). The distended vagina forms a large mass that may interfere with urination and at times may be mistaken for an abdominal tumor. The diagnosis is quite easy, and resection of the hymen is recommended in the symptomatic infant only. Topical anesthetic is used to prevent discomfort to the newborn, and the central portion of the obstructing membrane is excised. Aspiration should be avoided due to the risks of recurrence and ascending infection. Asymptomatic girls can be monitored throughout childhood, with the optimal time for surgery being just after the onset of puberty.

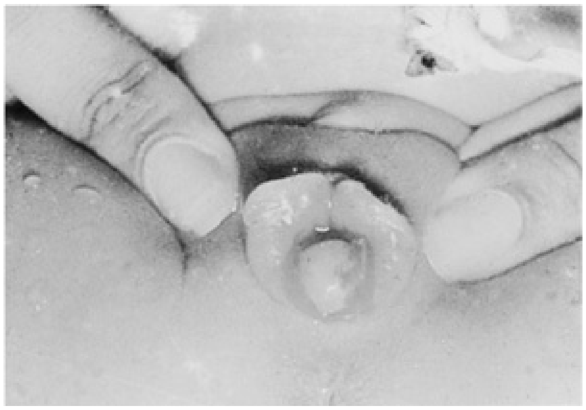

Figure 37–8. Mucocolpos in a newborn infant.

Imperforate hymen often is not diagnosed until an adolescent presents with complaints of primary amenorrhea and cyclic pelvic pain. It may present as back pain or difficulty with defecation or urination secondary to mass effect from vaginal distention. Inspection of the vulva may reveal a purplish-red hymenal membrane bulging outward as a result of accumulation of blood above it (hematocolpos) (Fig. 37–9). Blood may fill the uterus (hematometra) and spill through the fallopian tubes into the peritoneal cavity. Endometriosis and vaginal adenosis are known but not inevitable complications.

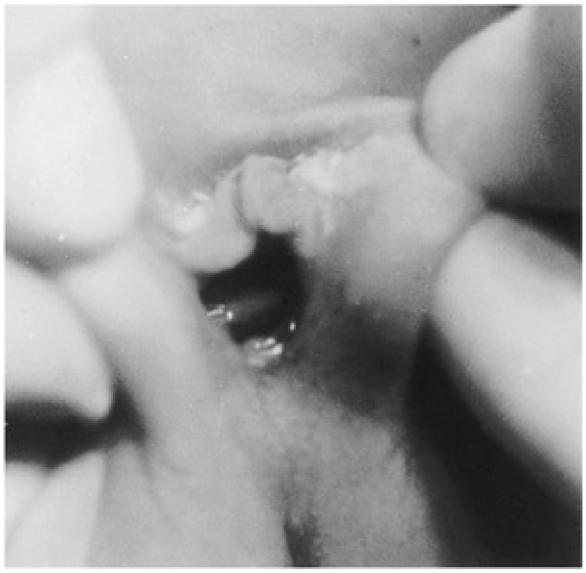

Figure 37–9. Newborn infant following excision of an imperforate hymen. Forward traction on the labia majora provides an unimpaired view of the hymenal ring. Note the large opening created. No bleeding was noted, and no sutures were required.

The procedure is usually done under general anesthesia with the patient in lithotomy position. A Foley catheter is used to drain the bladder and properly delineate the urethra. A primary small crescentic incision is done in the central part of hymenal bulging membrane; after evacuation of the old blood, the hymenal orifice should be enlarged to allow the egress of menstrual flow, tampon use, and eventually comfortable sexual intercourse. A small incision may coalesce, allowing the obstructing membrane to reform.

ANOMALIES OF INTERNAL DUCT SYSTEM

The actual incidence of müllerian anomalies is not definitively known. An incidence of 3.2% was identified in several studies on fertile women. Urinary tract abnormalities are the most common anomalies associated with müllerian defects, including ipsilateral renal agenesis, duplex collecting systems, renal duplication, and horseshoe kidneys. In female patients with renal anomalies, the incidence of genital defects is estimated to be between 25% and 89%.

ANOMALIES OF THE VAGINA

1. Transverse Vaginal Septum

Transverse vaginal septa result from faulty fusion or canalization of the urogenital sinus and müllerian ducts. The incidence is approximately 1 in 30,000 to 1 in 80,000 women. Approximately 46% occur in the upper vagina, 40% in the midportion, and 14% in the lower vagina. When the septum is located in the upper vagina, it is likely to be patent, whereas those located in the lower part of the vagina are more often complete. The septum is usually less than 1 cm thick and is rarely associated with uterine anomalies.

A complete septum results in signs and symptoms similar to those of an imperforate hymen. Diagnosis is often delayed until after menarche, when menstrual blood is trapped behind an obstructing membrane. An incomplete septum usually is asymptomatic at menarche, as the central aperture allows for vaginal secretions and menstrual flow to egress from the vagina. The first symptoms may appear at the beginning of sexual intercourse, resulting in dyspareunia.

Treatment

If the diagnosis of a complete septum is established prior to menarche, ultrasound or magnetic resonance imaging (MRI) may help define the septum and its thickness preoperatively. It is extremely important to identify a cervix, most reliably seen on MRI, to differentiate between a high septum and congenital absence of the cervix. The corrective surgery consists of septum incision, creating an aperture to allow drainage. Incision of a complete septum is most easily accomplished when the upper vagina is distended and the membrane is bulging, reducing the risk of injury to adjacent structures. Because of the technical difficulties in performing intravaginal surgery on immature structures, it is best to limit the procedure only to allow the establishment of vaginal drainage.

Surgical correction of vaginal narrowing should be performed only when the patient is contemplating initiation of sexual activity. Thin septum can be excised with its surrounding ring of subepithelial connective tissue at the level of partition followed by primary end-to-end anastomosis of the upper and lower vaginal mucosa; thicker septum may require undermining and mobilization of the upper and lower vaginal mucosa before anastomosis. To avoid scar contracture and vaginal stenosis, a circumferential Z-plasty can be helpful. Postoperatively, use of vaginal mold or dilators may further decrease the risk of vaginal stenosis.

2. Longitudinal Vaginal Septum

Longitudinal vaginal septum forms when the distal ends of the müllerian ducts fail to fuse properly. The uterus may be septate or bicornuate, with 1 or 2 cervices (Fig. 37–10). As many as 20% of patients with *longitudinal vaginal septum* may present with associated renal abnormalities and occasionally with anorectal malformations, including imper-forated anus with rectovestibular fistula and cloaca.

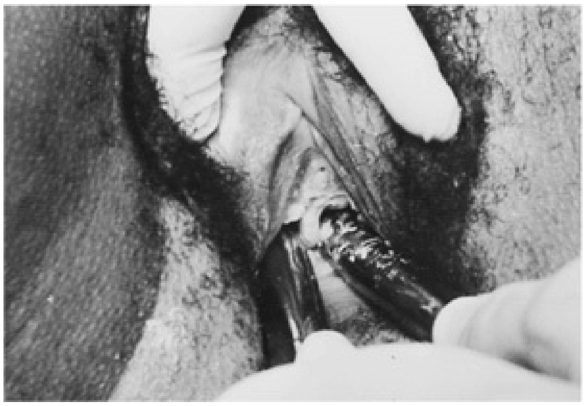

Figure 37–10. Longitudinal septum dividing the vagina.

Asymptomatic longitudinal septum requires no treatment. Division of the septum is indicated when dyspareunia is present, vaginal delivery dystocia is anticipated, or worsening of dysmenorrhea occurs. The menstrual pain derives from accumulation of blood in obstructed hemivagina, while normal blood exits from the nonobstructed portion. Care should be taken to avoid damage to the cervix while resecting the upper part of the septum.

3. Vaginal Agenesis (Müllerian Aplasia)

Vaginal agenesis includes the congenital absence of the vagina accompanied by variable müllerian duct development (**Mayer-Rokitansky-Kuster-Hauser [MRKH] syndrome**). The incidence of vaginal agenesis is approximately 1 in 5000. The external genitalia of patients with vaginal agenesis are normal or may reveal only a small dimple at the vaginal introitus (Fig. 37–11). Vaginal agenesis is usually accompanied by cervical and uterine agenesis; however, 7–10% of affected individuals may have a normal uterus or rudimentary uterus with functional endometrium.

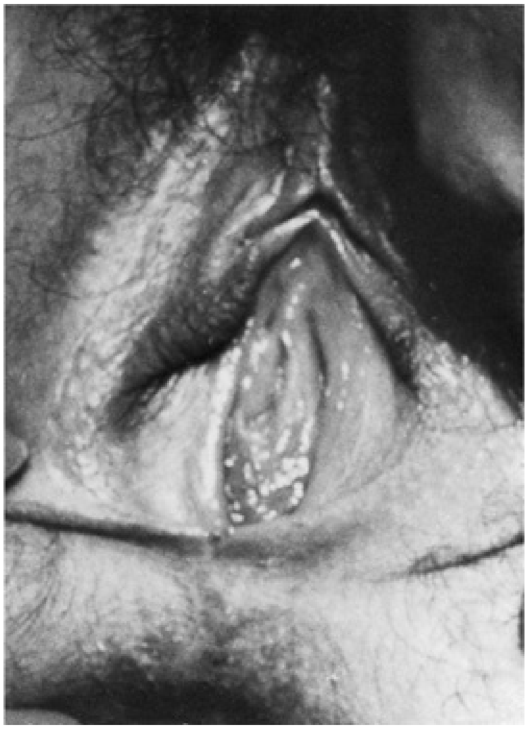

Figure 37–11. Vaginal agenesis in a girl 16 years of age.

Other developmental defects are often present, affecting the urinary tract (45–50%), the spine (10%), and, less frequently, the middle ear and other mesodermal structures. Evaluation of those systems should be performed soon after diagnosis.

Persons with vaginal agenesis typically have normal female karyotypes with normal ovaries and ovarian function; thus, they develop normal secondary sexual attributes. Patients often present with primary amenorrhea or, in women with functioning uteri, with cyclic pelvic pain. Serum testosterone level and karyotyping may identify the rare instances in which müllerian agenesis represents the effects of testicular activity, indicating male pseudohermaphroditism.

Treatment

The consultation of the adolescent with vaginal agenesis and her family involves a multidisciplinary approach. It should consist of confirmation of the ability to create a functional vagina and emphasize that she has normal ovarian function and thus preserved fertility with assisted reproductive technology and surrogacy.

Creation of a satisfactory vagina is the objective of treatment of vaginal agenesis. Treatment should be deferred until the patient is contemplating sexual activity. Nonoperative creation of a vagina using serial vaginal dilators, in a method described by Frank and later modified by Ingram, is relatively risk-free but requires patient motivation and cooperation. The procedure takes a few months to complete. Repetitive coitus can also be used to create a functioning vagina. Recent studies have shown that use of dilators resulted in 85–90% success for creation of functional vagina.

Surgical creation of neovagina is another option, and discussion should fully describe that many surgical techniques will require postoperative dilatation to maintain vaginal adequacy. Currently, there are multiple operative methods but no consensus on the best approach.

The modified Abbé–McIndoe vaginoplasty is most commonly performed. The procedure involves the creation of a cavity by surgical dissection between the urethra and bladder anteriorly and the perineal body and rectum posteriorly. The cavity is lined by a split-thickness skin graft overlying a plastic or soft silicone mold. The labia minora are secured around the mold for 7 days prior to removal. Postoperatively, the patient must continue to use dilators for several months to maintain vaginal patency. Patient satisfaction rates greater than 80% have been reported. Complications include graft failure, hematoma, fistula formation, and rectal perforation.

The laparoscopic Davydov technique uses the patient's own pelvic peritoneum to line the neovagina. It involves dissection of the perineum to create a neovaginal space while laparoscopically mobilizing the peritoneum. The peritoneum is then sutured to the introitus, and a purse-string suture closes the cranial end of the neovagina. A vaginal mold is left in situ for 6 weeks, and the patient then begins daily dilation until regularly sexually active. Complications related to laparoscopic injury and fistula formation have occurred; however, patients report similar sexual function to women with a native vagina.

The modified laparoscopic Vecchietti procedure creates a dilation-like neovagina in 7–9 days. It involves placement of an acrylic 2-cm olive-shaped bead onto the vaginal dimple that is gradually pulled superiorly by threads laparoscopically placed that are then connected to the traction device placed on the patient's abdomen. The threads are then gradually tightened approximately 1.0–1.5 cm per day for a week. Postoperatively, the patients must comply with daily vaginal dilation until regularly sexually active.

Bowel vaginoplasty is the preferred method of most pediatric general surgeons, given the immediate and long-term correction of the anomaly. Each bowel segment has advantages and disadvantages. Bowel vaginoplasty is performed by selecting an approximately 10-cm segment of bowel that can be mobilized but retain an adequate vascular pedicle to reach the perineum. Sigmoid vaginoplasty has been the most commonly used bowel segment, given its proximity to the perineum and therefore little difficulty performing a tension-free anastomosis to the introitus.

Postoperative sexual satisfaction has been assessed in a validated fashion in only a relatively small number of patients who underwent bowel vaginoplasty. Seventy-five percent of patients reported satisfaction.

4. Partial Vaginal Agenesis (Atresia)

Vaginal atresia occurs when the urogenital sinus fails to contribute to the lower portion of the vagina. The affected segment of the vagina is replaced by a soft mass of tissue. The cause of this uncommon anomaly is unknown. Absence of the distal vagina may be identified by sonographic visualization of the accumulated blood in the upper vagina, cervix, and uterus.

The symptoms are similar to those associated with imperforate hymen after the menarche. Vulvar inspection reveals findings identical with those of vaginal agenesis, but rectoabdominal palpation reveals a large, boggy pelvic mass. Diagnostic imaging using sonography, computed tomography (CT), or MRI will confirm the diagnosis.

Treatment

Surgery is indicated because obstruction to menstrual flow may occur. In some patients, drainage of the uterus can be achieved through a reconstructed vagina. In others, particularly when the uterus is rudimentary, consideration may be given to performing a hysterectomy.

ANOMALIES OF THE UTERUS

Uterine anomalies result from agenesis of the müllerian duct or a defect in fusion or canalization. The classification by the American Society for Reproductive Medicine (ASRM) is most accepted. These anomalies include bicornuate uterus (37%), arcuate uterus (15%), incomplete septum (13%), uterine didelphys (11%), complete septum (9%), and unicornuate uterus (4%).

Most uterine anomalies are asymptomatic and therefore are not detected during childhood or early adolescence. Symptoms during adolescence are primarily caused by retention of menstrual flow. MRI can be helpful in determining the anatomy in cases complicated by obstructive anomalies and is often considered as the “gold standard” for imaging of anomalies in reproductive tract (Fig. 37–12).

Figure 37–12. Classification system of müllerian duct anomalies developed by the American Fertility Society (1998). DES, diethylstilbestrol. (Reproduced, with permission, from the American Society for

Reproductive Medicine, copyright 2012.)

Asymptomatic abnormalities often escape detection until they interfere with reproduction; thus, they are described in more detail in other chapters of this text.

1. Unicornuate Uterus & Rudimentary Uterine Horn

A unicornuate uterus is a single-horned uterus with its corresponding fallopian tube and round ligament. It results from agenesis of 1 müllerian duct, with absence of structures on that side. When the other hemiuterus is present, it often creates a small rudimentary uterine horn. If this rudimentary horn does not communicate with the other uterine cavity or the vagina, menstrual blood cannot escape, resulting in severe dysmenorrhea, hematometra, or pyometra. A pregnancy that occurs in a rudimentary horn may result in rupture, a complication that is potentially fatal for both mother and fetus (Fig. 37–13).

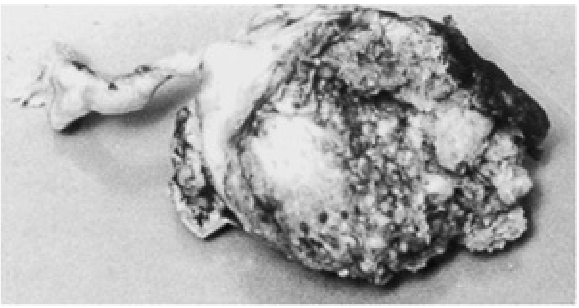

Figure 37–13. Pregnancy in a noncommunicating rudimentary uterine horn that has resulted in rupture.

Ideally, a rudimentary horn should be resected before conception. The tube and ovary on the affected side can be preserved, provided that the blood supply is not impaired. If the endometrial cavity of the remaining horn is entered during the operation, caesarean section is a reasonable mode of delivery for any subsequent pregnancies.

As suspected with unilateral impairment in müllerian development, associated renal anomalies are common. Patients with müllerian anomalies with a unicornuate uterus are at increased risk of premature labor and breech presentation. As in other obstructive anomalies, endometriosis and subsequent fertility issues may be significant in patients with an associated obstructed uterine horn or hemiuterus (Fig. 37–14).

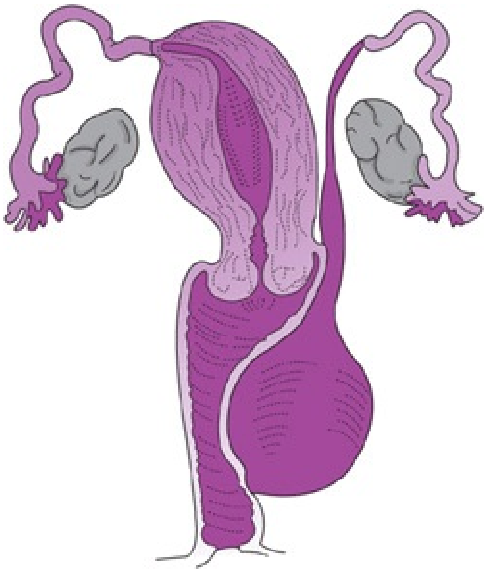

Figure 37–14. Unicornuate uterus with obstructed hemivagina. The endometrium lining the obstructed part bleeds at menarche, and the blood filling the lower part of the cyst forms a mass that protrudes into the vagina.

2. Bicornuate Uterus & Septate Uterus

The bicornuate uterus results from partial fusion of the müllerian ducts, leading to varying degrees of separation of the uterine horns. The fundus is deeply indented, often heart-shaped. Presently, no surgical intervention is recommended, and patients are followed closely for obstetric concerns, although reproductive function is good overall. In most cases, the vagina is normal.

The septate uterus has a smooth, normal external surface at the fundus, but the endometrial cavity is split into 2 by a midline septum. There are higher risks for miscarriage and other obstetrical complications. Hysteroscopic resection of septum is currently the technique of choice and almost totally replaces abdominal metroplasty. The surgical correction may improve reproductive performance. However, in young women, the decision to surgically intervene before attempts at pregnancy still remains unclear. The presence of a concomitant vaginal septum may influence the timing of intervention.

ANOMALIES OF THE OVARIES

During development, the ovaries, which are abdominally located in the neonate, descend to the pelvis at puberty. The ovaries may be drawn by the round ligament into the inguinal canal or the labium major. A firm inguinal mass should alert the examiner to the possible presence of an aberrant gonad, possibly containing testicular elements, even in the presence of female external genitalia. A karyotype should be obtained. At the time of hernia repair, the gonad should be biopsied. If it proves to be an ovary, it should be returned to the peritoneal cavity and the hernia repaired. If a testis is identified, the gonad should be removed. During childhood, the ovary is never at rest, and follicles grow and degenerate continuously.

Gonadal Dysgenesis (Turner’s Syndrome)

Turner’s syndrome is a disorder in females characterized by the absence of all or part of a normal second sex chromosome. Approximately half of patients have monosomy X (45,X). Most of the rest have mosaicism for 45,X, with 1 or more additional cell lineages, and others (5–10%) have a duplication (isochromosome) of the long arm of 1 X chromosome [46,X,i(Xq)]. Turner’s syndrome occurs in 1 in 2500 to 1 in 3000 live-born girls.

The genetic disorder leads to a constellation of physical findings that often includes congenital lymphedema, short stature, and gonadal dysgenesis. In addition, broad chest and small nipples, webbed neck, coarctation of the aorta, renal abnormalities, prominent epicanthal folds, nevi, and other somatic anomalies (eg, short fourth metacarpal) frequently occur. In most adults with gonadal dysgenesis, the normal gonad is replaced by a white fibrous streak, 2–3 cm long and approximately 0.5 cm wide, located in the gonadal ridge. Histologically, the streak gonad is characterized by interlacing waves of dense fibrous stroma, indistinguishable from normal ovarian stroma.

Increased atresia and failure of germ cell formation deplete oocyte supply, but when atresia is incomplete, pubertal changes, spontaneous menstruation, and even pregnancies have been reported.

One-fifth to one-third of affected girls receive a diagnosis as newborns because of puffy hands and feet or redundant nuchal skin. However, in many, the condition is not diagnosed until adolescence when they fail to enter puberty. Turner’s syndrome is the most common cause of short stature in otherwise healthy girls; therefore, karyotype testing should be considered in children and adolescents with height stature below the third percentile.

Girls with Turner’s syndrome need gonadal hormone therapy for sexual development, enhancement of growth, maintenance of reproductive tissue, and psychosocial health. In addition, prevention of chronic disease, specifically bone loss and possible early heart diseases, needs to be addressed in these girls.

The administration of very-low-dose estradiol (ethinyl estradiol 100 ng/kg/d) in combination with growth hormone at an early age has been shown to assist in enhancing and promoting optimal pubertal height and age-appropriate feminization.

ANOMALIES OF THE URETHRA & ANUS

Failure of a newborn infant to pass meconium or urine demands investigation. Passage of feces or urine through the vagina suggests a fistulous communication, and usually either the urethra or the anus is imperforate.

In general, anomalies are divided into 2 major groups: those that form complete obstruction of the intestinal tract and those that are associated with some type of abnormal opening or fistula.

Because findings are so diverse, only broad generalizations on the management of urogenital anomalies of this type can be offered. Most intestinal and urinary tract obstructions must be corrected soon after birth; however, some associated genital tract anomalies (eg, müllerian anomalies), although diagnosed at the same time, might benefit from postponing final correction until after the onset of puberty.

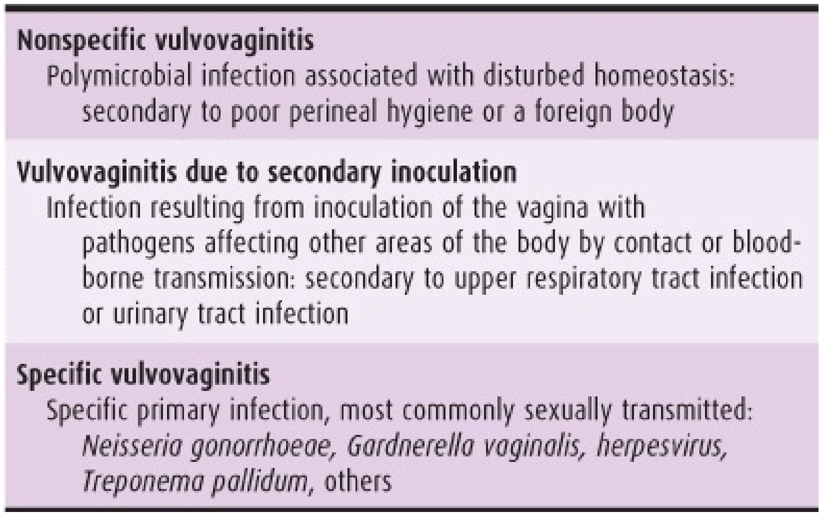
GYNECOLOGIC DISORDERS IN PREMENARCHAL CHILDREN

VULVOVAGINITIS

Pruritus vulvae and vulvovaginitis are common gynecologic disorders in children. Pruritus vulvae refers to itching of the external female genitalia. Vulvovaginitis, although inconsistently delineated in the literature, generally involves irritation of the skin or mucosal tissue and vaginal discharge. The child is susceptible to both these conditions for several reasons: The prepubertal vulva is thin without labial fat pads and pubic hair, as well as anatomically in close proximity to the anus and its contaminants; the unestrogenized vagina is atrophic with pH ranges excellent for bacterial growth;

and perineal hygiene often is suboptimal as supervision declines with age. Table 37–3 lists classification of vulvovaginitis according to cause.

Table 37–3. Classification of vulvovaginitis according to cause.



Nonspecific vulvovaginitis	Polymicrobial infection associated with disturbed homeostasis: secondary to poor perineal hygiene or a foreign body
Vulvovaginitis due to secondary inoculation	Infection resulting from inoculation of the vagina with pathogens affecting other areas of the body by contact or blood-borne transmission: secondary to upper respiratory tract infection or urinary tract infection
Specific vulvovaginitis	Specific primary infection, most commonly sexually transmitted: *Neisseria gonorrhoeae, Gardnerella vaginalis, herpesvirus, Treponema pallidum*, others

Clinical Findings

Acute vulvovaginitis may denude the thin vulvar or vaginal mucosa; however, bleeding usually is minimal. Vaginal discharge may vary from minimal to copious mucopurulent, and at times, it is blood-stained. Symptoms vary from minor discomfort to relatively intense perineal pruritus. The child often complains of a burning sensation, particularly when urine flows, accompanied by a foul-smelling discharge. Vulvovaginitis should be excluded in children prior to treatment for urinary tract infection. The irritating discharge inflames the vulva and often causes the child to scratch the area to the point of bleeding. Inspection of the vagina reveals an area of redness and soreness that may be minimal or may extend laterally to the thighs and backward to the anus.

Diagnosis is suspected by the typical appearance of the inflamed tissue. A wet-mount preparation reveals numerous leukocytes and occasional red blood cells. Culture of vaginal secretions sometimes identifies the offending organism.

Evaluation of the vaginal secretions may include smears for Gram stain, bacterial cultures, cultures for mycotic organisms, wet prep, *Trichomonas*, and parasitic ova.

Improvement of perineal hygiene is important to relieve the symptoms and to prevent recurrences. Most cases of nonspecific pruritus vulvae resolve with improvements in hygiene and avoidance of irritants, including soaps.

Any evidence of pathogens that are usually involved in STIs must be followed by evaluation of sexual abuse.

Amoxicillin (20–40 mg/kg/d in 3 divided doses) is effective against a variety of potentially pathogenic organisms in nonspecific vulvovaginitis. A concomitant tonsillitis should raise the suspicion of genital inoculation by *Streptococcus* group A pathogens and should be treated the same way as the throat infection. In cases with intense perianal pruritus that is especially bothersome during the night, antiparasitic treatment could alleviate the symptoms. Infection with *Candida* species is quite rare in healthy children after diaper weaning until the onset of puberty. When the infection is severe and extensive mucosal damage is seen, a short course of topical estrogen cream is given to promote healing of vulvar and vaginal tissues. When irritation is intense, hydrocortisone cream may be necessary to alleviate the itch. In recurrent infections refractory to treatment or associated with a foul-smelling, bloody discharge, vaginoscopy is necessary to exclude a foreign body or tumor.

FOREIGN BODIES

Vaginal foreign bodies induce an intense inflammatory reaction and result in blood-stained, foul-smelling discharge. Usually, the child does not recall inserting the foreign object or will not admit to it. Radiographs are not reliable for revealing a foreign body because many objects are not radiopaque, the most common being a small piece of reincarnated toilet paper. Foreign bodies in the lower third of the vagina can be flushed out with warm saline irrigation. If the vagina cannot be adequately inspected in the office even after removal of the foreign body, vaginoscopy is indicated to confirm that no other foreign bodies are present in the upper vagina. General anesthesia is applied in some cases, based on the age and psychosocial development of the patient.

URETHRAL PROLAPSE

Occasionally, vulvar bleeding is the result of urethral prolapse. The urethral mucosa protrudes through the meatus and forms a hemorrhagic, sensitive vulvar mass that is separated from the vagina. Treatment consists of warm soaks and a short course of therapy using estrogen cream, when the lesion is small and urination is unimpaired. Resection of the prolapsed tissue should be reserved for a symptomatic child with indwelling catheter inserted for 24 hours after surgery.

LICHEN SCLEROSUS

Lichen sclerosus of the vulva is a hypotrophic dystrophy with prevalence of 1 in 900 girls. It has bimodal age distribution in postmenopausal period and in prepubertal age. Histologically, the findings in both age groups are similar, with flattening of the rete pegs, hyalinization of the subdermal tissues, and keratinization.

The clinical presentation includes a whitish ivory colored lesion that does not extend beyond the middle of the labia majora laterally or into the vagina medially (Fig. 37–15). The clitoris, posterior fourchette, and anorectal areas are frequently involved, forming a figure of 8. Although most lesions are predominantly white, some have pronounced vascular markings. They tend to bruise easily, forming bloody blisters, and they are susceptible to secondary infections. Symptoms consist of intense pruritus, vulvar irritation, and dysuria. Scratching is common and occasionally provokes bleeding or leads to secondary infection and introital distortion.

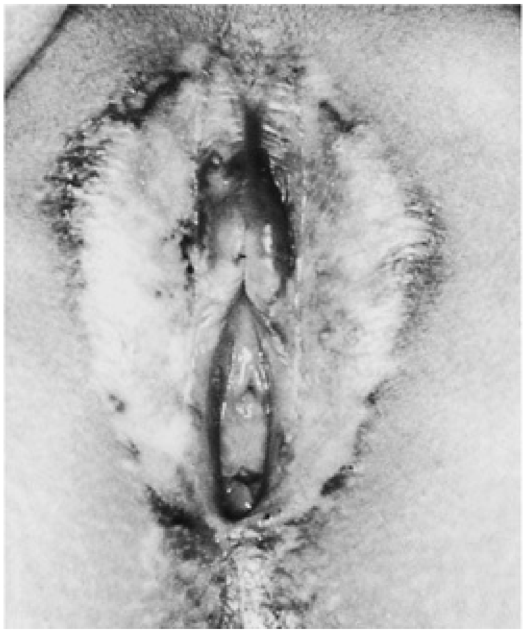


Figure 37–15. Lichen sclerosus of the vulva in a 6-year-old child.

Histologic confirmation is not necessary in children as opposed to postmenopausal women because of no known malignant potential in this age group. Treatment usually consists of improved local hygiene and reduction of trauma. Currently, the use of ultrapotent topical corticosteroids (clobetasol propionate 0.05%) once or twice daily for 4–8 weeks is accepted as first-line therapy. Occasionally, symptom relief does not occur before 12 weeks of treatment. New treatments with topical calcineurin inhibitors seem to be effective; however, their long-term safety has not been determined. Over half of children improve significantly or recover during puberty.

LABIAL ADHESION

Labial adhesion is common in prepubertal children with an estimated occurrence of 0.6–3.0% and a peak incidence at 13–23 months. The cause is not known but probably is related to low estrogen levels. The skin covering the labia is extremely thin, and local irritation may induce scratching, which may denude the labia. The labia then adhere in the midline, and re-epithelialization occurs on both sides (Fig. 37–16). It is important to differentiate this condition from congenital absence of the vagina.

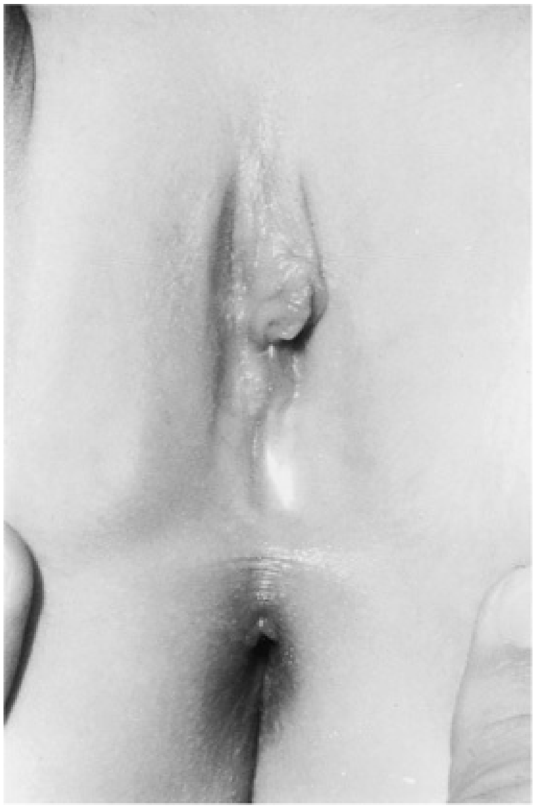

Figure 37–16. Labial adhesion in a young girl. Note the translucent vertical line in the center where the labia are fused together.

Most children with small areas of labial adhesions are asymptomatic. Dysuria and recurrent urinary infections are cardinal symptoms in those with complete or anterior adhesion, although infrequent.

Asymptomatic minimal to moderate labial fusion does not require treatment. Symptomatic fusion may be treated with a course of estrogen cream applied twice daily for 3–12 weeks resulting in successful separation in 50–88% of the cases. When approaching puberty in girls with medical treatment failure or if severe urinary symptoms exist, surgical separation of the labia is indicated. This can be performed in the operating room under anesthesia or as an in-office procedure using 1–2% topical lidocaine (Xylocaine) gel. Because of low estrogen levels, recurrences of labial adhesion are common until puberty. After puberty, the condition resolves spontaneously. Improved perineal hygiene and removal of vulvar irritants may help prevent recurrences.

GENITAL INJURIES

Most injuries to the genitalia during childhood are accidental. Many are of minor significance, but a few are life-threatening and require surgical intervention. The physician must determine how the child sustained the injury, bearing in mind that the child requires protection if she is the victim of physical or sexual abuse.

1. Vulvar Injuries

Contusion of the vulva mainly from straddle injury usually does not require treatment. A hematoma manifests as a round, tense, ecchymotic, tender mass (Fig. 37–17). A small vulvar hematoma usually can be controlled by pressure with an ice pack. The vulva should be kept clean and dry. A hematoma that is large or continues to increase in size may require incision, with removal of clotted blood and ligation of bleeding points. If the source of bleeding cannot be found, the cavity should be packed with gauze and a firm pressure dressing applied. The pack is removed in 24 hours. Prophylactic broad-spectrum antibiotics may be advisable.

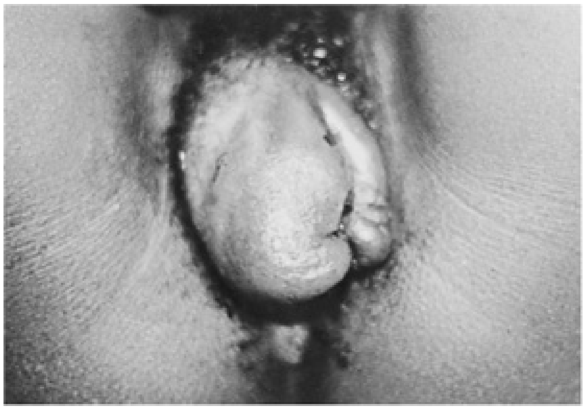

Figure 37–17. Large vulvar hematoma secondary to bicycle injury.

When a large hematoma obstructs the urethra, insertion of a catheter is necessary, usually by a suprapubic approach. Radiography of the pelvis may be necessary to rule out pelvic fracture.

2. Vaginal Injuries

Vaginal injuries occur when a girl falls on a sharp object and impales herself; additionally, there is an increasing rate of accidents involving insufflation injuries caused by a fall off jet skis or direct contact with pool or spa jets, allowing pressurized water to enter the vagina. Such injuries might produce no sign of external genital trauma, but careful examination (often under anesthesia) will reveal the extent of injury.

When the hymen is lacerated or other evidence indicates an object has entered the vagina or penetrated the perineum, a detailed examination of the whole vaginal canal is necessary to exclude injuries to the upper vagina or intrapelvic viscera (Fig. 37–18).

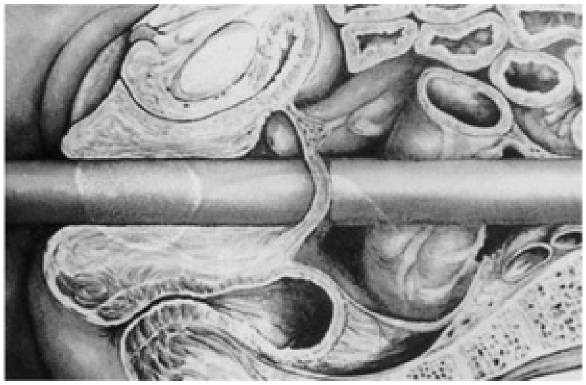

Figure 37–18. Transvaginal perforation of cul-de-sac and penetration of peritoneal cavity by a fall on a mop handle. Scanty bleeding from a hymenal tear was the only symptom on admission.

Most vaginal injuries involve the lateral walls. Generally, there is relatively little blood loss, and the child does not have much pain if only the mucosa is damaged. If the laceration extends beyond the vaginal vault, exploration of the pelvic cavity is necessary to rule out extension into the broad ligament or peritoneal cavity. Bladder and bowel integrity must be confirmed by catheterization and rectal palpation. Because of the small caliber of the organs involved, special instruments, as well as proper exposure and assistance, may be required for repair of vaginal injuries in young girls. Alternatively, the bleeding may be controlled by angiographic embolization of the bleeding vessel. Many vaginal lacerations are limited to the mucosal and submucosal tissues and are repaired with fine suture material after complete hemostasis is secured.

3. Anogenital Injuries Caused by Abuse

Sexual abuse is defined as coerced or forced vaginal, anal, intercrural, and oral–genital fondling or penetration. Many children who are victims of sexual abuse do not sustain physical injuries. The hymen is examined in a "clock"-defined method, being at the 12 o'clock position under the clitoris and 6 o'clock position above the anus, independent of child position during the evaluation. The diagnosis of sex abuse, which was once focused on genital measurements, mainly hymenal configuration, is currently based on descriptive statements made by a child.

The hymen is an elastic structure, and therefore, it does not always demonstrate signs of abuse on examination. In a published study of 2310 children referred for possible sexual abuse, 96.3% of all children had a normal examination. In another study, pregnant adolescents were found to have an intact hymen as well. Unfortunately, even when injured, many of these children may not be seen for weeks, months, or even years after the incident. The delay allows for semen and debris to wash away and for most, if not all, injuries to heal.

Injuries to the vulva may be caused by manipulation of the vulva or introitus, without vaginal penetration, or by friction of the penis against the child's vulva ("dry intercourse"). Erythema, swelling, skin bruising, and excoriations are found on the labia and vestibule. These injuries are superficial and often limited to the vulvar skin; they should resolve within a few days and require no special treatment.

Meticulous perineal hygiene is important in the prevention of secondary infections. Sitz baths should be used to remove secretions and contaminants. In some patients with extensive skin abrasions, broad-spectrum antibiotics should be given as prophylaxis. Large vulvar tears require suturing, which is best performed under general anesthesia. For infected wounds or bites, antitetanus immunization should be given if the child is not already immunized. Broad-spectrum antibiotics should be used for therapy rather than prophylaxis. Most vaginal injuries occur when an object penetrates the vagina through the hymenal opening. A detailed examination including vaginoscopy is necessary to exclude injuries to the upper vagina.

Examination of the anus and rectum is easier than is examination of the vagina, and most children tolerate it well. Because the anal sphincter and anal canal allow for some dilatation, a tear of the anal mucosa or sphincter rarely occurs following a digital assault. However, penetration by a larger object almost always results in some degree of injury, which varies from swelling of the anal verge to gross tearing of the sphincter. In the period immediately following penetration, the main findings are sphincter laxity resulting in anal dilatation, swelling, and small tears of the anal verge. If the sphincter is not severed, it may be in spasm and will not permit a digital examination. Within days, the swelling subsides and the mucosal tears heal, occasionally forming skin tags. If not severed, the anal sphincter regains function. Repeated anal penetration over a prolonged period may cause the anal sphincter to become loose, forming an enlarged opening. The anal mucosa thickens and loses its normal folds. Although some investigators suggest that many children who experience anal assault exhibit perianal scars and tags, longitudinal studies show that anal injuries heal completely in most children.

Occasionally, child victims of abuse contract an STI. The risk of a prepubertal child contracting an STI after sexual assault is relatively low, estimated to range from 2–5%. Treatment of gonorrhea, chlamydia, and syphilis may be deferred until the results of tests become available. A repeat VDRL (Venereal Disease Research Laboratory) test to detect seroconversion is required 6 weeks later. Prophylaxis for hepatitis B with hepatitis B vaccination is recommended following sexual assault. For nonimmune victims with a high-risk exposure, practitioners may also consider adding hepatitis B immune globulin to the regimen. The Sexually Transmitted Diseases Treatment Guidelines do not recommend the routine screening for HIV for all child victims of sexual abuse. Clinicians should try to identify children who are at high risk for HIV exposure and consider offering them counseling and prophylactic therapy. In pubertal girls, the need for postcoital contraception must be addressed. Guidelines for the care of the child and adolescent who has experienced sexual abuse are best found in the literature dedicated to the topic.

Female genital mutilation (female circumcision), which can be viewed as a form of child abuse, is still practiced in some parts of the world. It is estimated that 100–140 million girls and women have undergone some form of female genital mutilation. Victims may suffer from infections, bleeding injury to adjacent tissue, and scarring of the damaged tissue, resulting in urinary and menstrual retention, dyspareunia, and difficulties with childbirth. The World Health Organization and other health organization have openly condemned this practice.

Protective Services & Counseling

It is imperative to ensure that the child will be discharged to a safe environment. When the child is suspected of being a victim of sexual abuse, it is advisable to admit her to the hospital, followed by referral to child protective services for further evaluation.

In the period immediately following sexual assault or disclosure of sexual abuse, the child and her family often require intensive day-to-day emotional support, counseling, and guidance. Child victims often show signs of depression and have feelings of guilt, fear, and low self-esteem. Appropriate referral for counseling is imperative. The major emphasis of emotional support involves strengthening the child’s ego, improving her self-image, and helping her to learn to trust others and feel secure again. To begin the strengthening process, the child needs to realize that she was a victim. Often, the child has both positive and negative feelings toward the perpetrator and may need help in sorting out these feelings. The child’s relationships with her parents and other family members are critical and may need restructuring. Following this crisis intervention phase, a treatment program using individual and peer-group therapy is initiated.

GENITAL NEOPLASMS

Genital tumors are uncommon but must be considered when a girl is found to have a chronic genital ulcer, nontraumatic swelling of the external genitalia, tissue protruding from the vagina, a fetid or bloody discharge, abdominal pain or enlargement, or premature sexual maturation. Virtually every type of genital neoplasm reported in adults has also been found in girls younger than 14 years. Approximately 50% of the genital tumors in children are premalignant or malignant and account for 1% of all childhood malignancies.

1. Benign Tumors of the Vulva & Vagina

Teratomas, hemangiomas, simple cysts of the hymen, retention cysts of the paraurethral ducts, benign granulomas of the perineum, and condylomata acuminata are some of the benign vulvar neoplasms observed in children and adolescents.

Obstruction of a paraurethral duct may form a relatively large cyst that distorts the urethral orifice. The recommended treatment is surgical intervention.

Teratomas usually present as cystic masses arising from the midline of the perineum. Although a teratoma in this area may be benign, local recurrence is likely. To prevent recurrences, a generous margin of healthy tissue is excised about the periphery of the mass.

Capillary hemangiomas usually require no therapy except reassurance. However, because of their tendency to bleed, cavernous hemangiomas are best treated surgically.

Most benign tumors of the vagina in children are unilocular cystic remnants of the mesonephric duct (Fig. 37–19) and do not require surgery. Symptomatic cysts (eg, those that block the vagina) can be treated surgically. Removal of a large portion of the cyst wall and marsupialization of the edges, which prevents reaccumulation of fluid, usually are sufficient.

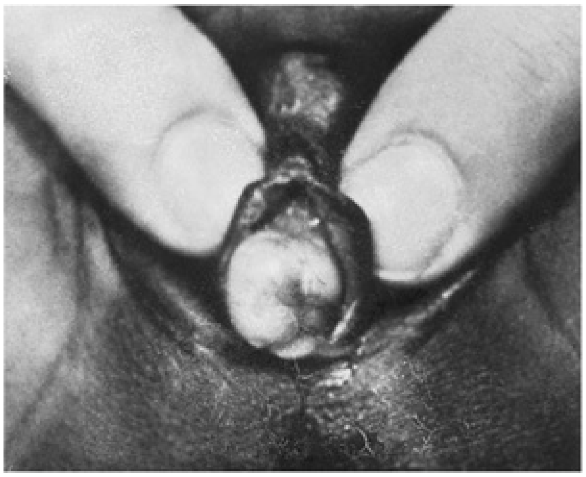

Figure 37–19. Simple vulvar or hymeneal cyst arising posterior to the urethra of a newborn infant.

2. Malignant Tumors of the Vagina & Cervix

Botryoid Sarcoma (Embryonal Rhabdomyosarcoma)

Embryonal rhabdomyosarcomas are most commonly seen in very young girls (<3 years old). The tumor usually involves the vagina, but the cervix may be affected as well, particularly in the teenager group, and these tumors have a better prognosis. The clinical presentation is characterized by vaginal bleeding in a child and irregular bleeding in the pubertal girl. Tumors arise in the submucosal tissues and spread rapidly beneath an intact vaginal epithelium. In the early stages, the tumor can be seen by vaginoscopy as 1 or more polypoid projections into the vaginal cavity; later on, it bulges into a series of grapelike growths out of the vestibule (thus the term botryoid sarcoma; Fig. 37–20). The diagnosis is made on the basis of histologic evaluation. Occasionally, electron microscopy may be required to confirm the final diagnosis.

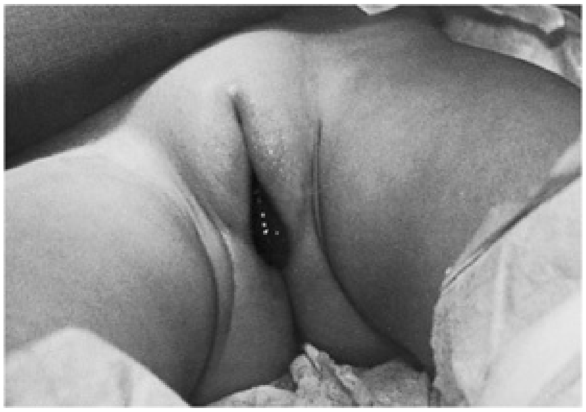

Figure 37–20. Botryoid sarcoma presenting as a hemorrhagic growth extruding from the vagina.

Over the years, there has been a shift in the treatment of this condition from radical surgery to a multimodal approach involving conservative surgery with chemotherapy and radiotherapy. This approach has been associated with improved survival and preservation of normal anatomy and function.

The operative intervention frequently consists just of cervical conization or simple hysterectomy with preservation of the ovaries. It is then followed by combination chemotherapy (vincristine, dactinomycin, and cyclophosphamide).

Early detection and the combination of surgery, chemotherapy, and occasionally radiation for residual tumor have improved the prognosis of patients, with 2- and 5-year survival rates for early disease reaching >96% and 83%, respectively.

Other Malignant Tumors of the Vagina

Three types of vaginal carcinoma may appear during childhood and the early teens. Endodermal carcinoma occurs most often in young children. Carcinoma arising in a remnant of a mesonephric duct (mesonephric carcinoma) occurs more often in girls 3 years of age or older. Clear cell adenocarcinoma of müllerian origin, often associated with a history of antenatal exposure to diethylstilbestrol (DES), is encountered most frequently in postmenarchal teenage girls. The clinical features and treatment of malignant lesions of the vagina and cervix are similar to those in adult women.

3. Ovarian Tumors

With the increasing use of imaging modalities, greater numbers of ovarian cysts are being diagnosed. The majority of these cysts are asymptomatic and regress spontaneously with time; therefore, many clinicians prefer to observe only. The decision to intervene is based on cyst size, ultrasound characteristics, and clinical symptoms.

Ovarian Torsion

Based on the abdominal location of the ovary and the long utero-ovarian ligament, the adnexa of prepubertal girls are at increased risk of torsion, with a reported prevalence of 3%. The diagnosis is complicated by its vague clinical presentation. The only consistent symptoms are abdominal pain and ovarian enlargement on the same side as demonstrated by sonography. Doppler flow studies may further contribute to the diagnosis; however, even presence of flow in the ovarian vessels should not preclude the clinical impression. When ovarian torsion is suspected, a prompt surgical procedure should be carried out for diagnosis and appropriate management, usually accomplished by operative laparoscopy. During surgery, a conservative approach is advocated because of the enormous revitalization ability of ovarian tissue in these patients and the low rate of true neoplasms; 25% of patients have normal ovaries, and another almost 50% of patients have functional cysts involved. Oophoropexy should be considered in cases of recurrent torsion or single ovary involvement.

Although ovarian tumors are the most common genital neoplasm encountered in children and adolescents, they represent only 1% of all neoplasms in premenarchal children. Ovarian tumors of all varieties (except Brenner's tumors) have been reported in premenarchal children, but in this population, they are rarely malignant.

Benign Tumors

Benign cystic teratomas (dermoid cysts) account for at least 30% of all neoplasms in this age group, with an 18% incidence and bilaterality in 10% of cases. They are usually asymptomatic and diagnosed by abdominal sonography performed for other indications. Expectant management for cysts smaller than 6 cm might be reasonable, considering the low risk for torsion and malignant transformation (<0.17%) and the increased risk of jeopardizing reproductive function with surgical treatment.

Other tumors, such as functional teratoma and gonadoblastoma, are rare and managed by surgical removal.

Malignant Tumors

Seventy percent of ovarian cancers in youth are of germ cell origin, with dysgerminoma accounting for half of them. Although the most common symptoms of ovarian tumors are abdominal pain and an abdominal mass, acute severe pain, peritoneal irritation, or intraabdominal hemorrhage can be the presenting sign. Despite the advancement in imaging technology applied for exploration of ovarian masses, at least 25% of all childhood ovarian tumors elude diagnosis until exploratory laparotomy is performed. The use of serum markers, such as inhibin or α-fetoprotein, may be helpful in children with ovarian enlargement.

The management of ovarian neoplasms in premenarchal children varies from that in older patients, because continued ovarian function is necessary to complete sexual and somatic maturation in children. In postpubertal patients, surgical intervention should aim, whenever possible, to preserve reproductive potential. Unilateral salpingo-oophorectomy is usually undertaken in young women with stage IA tumors (<10 cm, removed unruptured without evidence of metastatic spread). Approximately 8–15% of dysgerminomas are bilateral, and thus, the contralateral ovary is inspected and any suspicious areas are biopsied. If there is bilateral involvement, then the uterus can be left in situ for future reproduction options with ovum donation. The survival rate for patients treated for dysgerminoma in earlier stage was found to be 96.9%. If a tumor has extended beyond the ovary, more radical surgery (bilateral salpingo-oophorectomy with hysterectomy) is indicated, regardless of age. Germ cell tumors are highly responsive to chemotherapy, with the exception of dysgerminomas, which respond well to radiation; however, multiagent chemotherapy is used in those tumors as well in order to preserve reproductive potential.

PUBERTY

Puberty is the process by which sexually immature persons become capable of reproduction. These changes occur largely as the result of maturation of the hypothalamic–pituitary–gonadal axis. Puberty is characterized by progressive incline in gonadotropin-releasing hormone (GnRH) production, leading to increasing levels of FSH and luteinizing hormone (LH). These changes are obtained by 2 mechanisms occurring in the hypothalamus: increasing resistance to circulating estrogen levels and a decrease in inhibitory activity of neurotransmitters upon GnRH-secreting neurons. Changes are determined by genetic and environmental factors, such as geographic location and body fat composition, and mediated by the leptin and kisspeptin proteins. As a rule, breast development, which initially may be unilateral, growth of genital hair, and a marked increase in growth rate (*adolescent growth spurt*) precede uterine bleeding by approximately 2 years. The normal sequence of events in sexual development is outlined in Figure 37–21. Pubic and axillary hair may appear before, at about the same time, or well after the appearance of breast tissue. The vaginal mucosa, which in prepubertal girls is a deep red color, takes on a moist pastel pink appearance as estrogen exposure increases. Menarche—the first menstrual shedding of thickened endometrial lining—indicates the process of development of secondary sexual features. Regular ovulatory cycles, which usually occur 20 months later, mark the end of pubertal maturation.

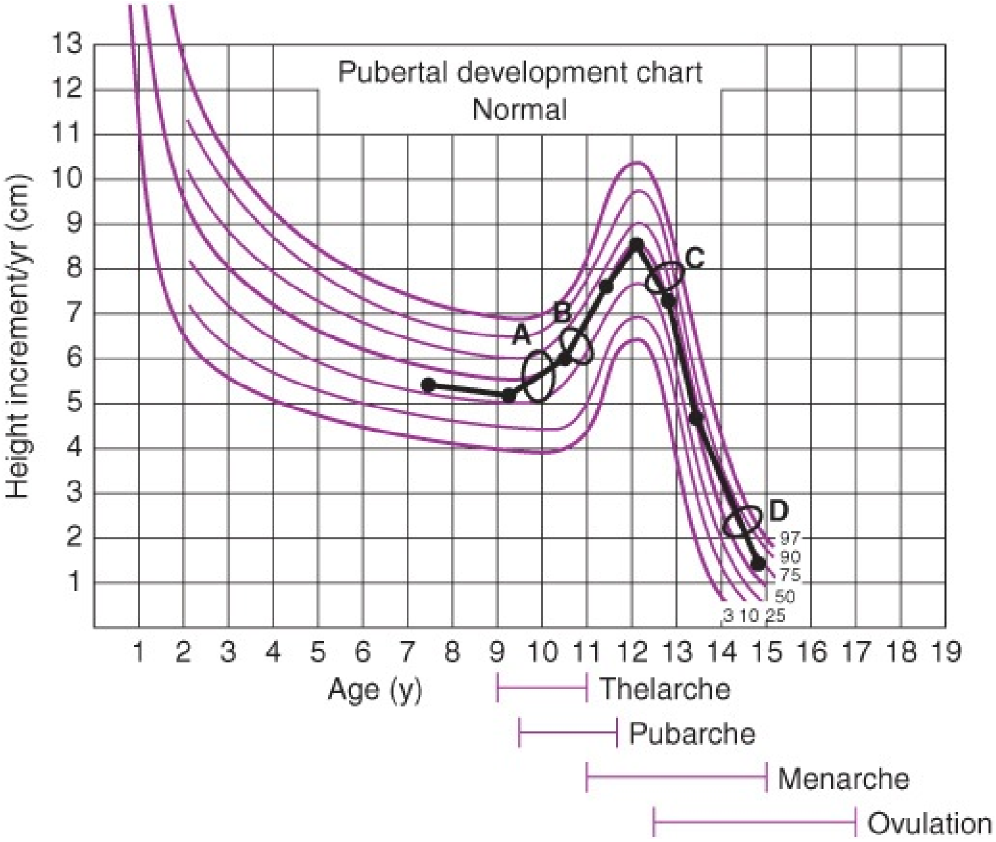

Figure 37–21. Pubertal development chart for a normally developing female adolescent. Growth data are converted to growth velocity and plotted. The growth velocity curve shows initial acceleration in growth, followed by the growth spurt and subsequent deceleration. Superimposed on this curve are the following pubertal events: **A,** thelarche; **B,** pubarche; **C,** menarche; **D,** onset of ovulation.

(Reproduced, with permission, from Reindollar RH, McDonough PG. Delayed sexual development: Common causes and basic clinical approach. *Pediatr Ann* 1981;10:178.)

The first menstrual period occurs at an average age of 12.43 years in girls in the United States. Although the age of menarche in African-American girls is quite similar, secondary sexual features often occur earlier.

Normal range of menarche is from age 10 to 14 years. In the presence of secondary sexual characteristics, medical intervention can be deferred until 16 years of age.

DISORDERS OF SEXUAL MATURATION

Precocious Puberty

Sexual precocity is the onset of sexual maturation at any age that is 2.5 standard deviations earlier than the normal age for that population, being usually before the age of 8 years. It may be classified as central, or GnRH-dependent, precocious puberty (true precocious puberty), or peripheral, or GnRH-independent, precocious puberty (pseudoprecocious puberty).

Central Precocious Puberty

Central precocious puberty (CPP), or GnRH-dependent precocious puberty, is normal pubertal development that occurs at an early age. Premature activation of the hypothalamic–pituitary axis is followed by gonadotropin secretion, which in turn stimulates the gonads to produce steroid hormones and, subsequently, pubertal changes. GnRH-dependent precocious puberty is seen more frequently in girls than in boys. The cause of such early development often remains unclear. Most girls suspected of having CPP are otherwise healthy children whose pubertal maturation begins at the early end of the normal distribution curve. In general, the older the child is, the less the chance of finding an organic etiology for CPP. Central nervous system (CNS) imaging studies of these otherwise healthy 6- to 8-year-old girls usually reveal no structural abnormalities.

Occasionally, precocious puberty is associated with CNS abnormalities, including hypothalamic hamartomas, optic gliomas, and neurofibromas, as well as other CNS neoplasms. Cranial irradiation and CNS injuries may also be associated with precocious puberty. Prolonged excessive therapy with exogenous sex steroids or endocrine disorders such as hypothyroidism may accelerate hypothalamic–pituitary axis maturation, resulting in precocious puberty.

The diagnosis is made with the help of a careful history and physical examination in conjunction with radiologic and laboratory evaluations.

Peripheral GnRH-Independent Precocious Puberty

Peripheral precocious puberty, or GnRH-independent precocious puberty, is the appearance of pubertal development, but the presence of sex steroids is independent of pituitary gonadotropin release. Causes of precocious puberty include congenital adrenal hyperplasia, tumors that secrete human chorionic gonadotropin, tumors of the adrenal gland or gonads, McCune-Albright syndrome (MAS), and exposure to exogenous sex steroid hormones.

A. Endogenous Estrogens

The ovary in the newborn female contains 1–2 million primordial follicles, most of which undergo atresia during childhood without producing significant quantities of estrogen. However, large follicular cysts capable of estrogen production occur occasionally and may cause early feminization. Benign tumors of the ovary (eg, teratoma, cystadenoma) may produce estrogen or may induce surrounding ovarian tissue to produce steroids. Circulating sex steroids (estrogen or testosterone) come from either the adrenal gland or the gonad, independent of the hypothalamic–pituitary portion of the pubertal axis. Granulosa cell tumors capable of estrogen production are a rare cause of prepubertal feminization. Other rare tumors of extragonadal origin, including adrenal adenomas and hepatomas, may produce estrogens as well.

B. Exogenous Estrogens

Ingestion of estrogens or prolonged use of creams containing estrogens is a possible, but uncommon, cause of early feminization. A phytoestrogen-enriched diet (mostly soybean extracts) could exert a similar effect. Prompt discontinuation is indicated. Xenoestrogens (endocrine disruptors) found in rivers and soil of industrial regions might stimulate the estrogen receptors as well.

C. McCune-Albright Syndrome

MAS in its classic form consists of at least 2 features of the triad of polyostotic fibrous dysplasia, café-au-lait skin pigmentation (Fig. 37–22), and autonomous endocrine hyperfunction, the most common form of which is GnRH secretion and subsequent precocious puberty. Other endocrine and nonendocrine tissues also may be affected, including the adrenal, thyroid, pituitary, liver, and heart.

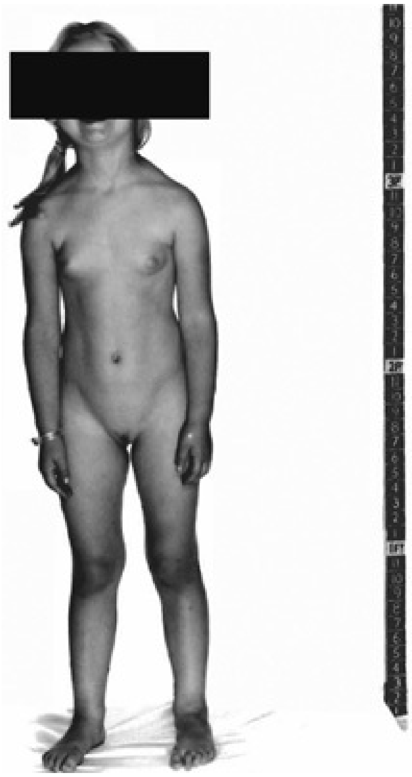

Figure 37–22. Four-year-old child with idiopathic precocious puberty.

MAS is caused by a postzygotic somatic mutation in the gene coding for the subunit of the stimulatory G protein, which is involved in transmitting hormone signals. In patients with MAS, the signaling cascades are activated in the absence of hormone stimulation.

Affected children usually present at a younger age than those with idiopathic precocious puberty. Vaginal bleeding occurs early and, in most, is the first sign of puberty. The diagnosis is made on the basis of skin pigmentation and demonstration of bone lesions or pathologic fractures.

The prognosis for children with MAS is unfavorable. Adult height is significantly reduced. Multiple endocrinopathies often exist as well. As in adults, most patients have menstrual abnormalities, and many are infertile.

D. Incomplete Forms of Pubertal Development

Occasionally, for reasons that remain unclear, only 1 sign of pubertal development is present. Premature thelarche and premature pubarche, which are more common conditions than true precocious puberty, are 2 benign normal variant conditions that can look like precocious puberty but are nonprogressive or very slowly progressive. It possibly results from transient elevations of the levels of circulating steroid hormones or from extreme sensitivity of the end organ (eg, breast tissue) to the low, prepubertal levels of sex hormones. Such isolated development, however, may represent the initial sign of precocious puberty, and these patients should be re-evaluated at regular intervals.

E. Premature Thelarche

Premature thelarche is the isolated development of breast tissue prior to age 8 years, most commonly occurring between 1 and 3 years of age. It may affect 1 or both breasts (Fig. 37–23). A thorough history, physical examination, and growth curve review can help distinguish this normal variant from true sexual precocity. On examination, the somatic growth pattern is not accelerated and bone age is not advanced. The diagnosis is made by exclusion of other disorders. Occasionally, premature thelarche occurs when the child is exposed to exogenous estrogens.

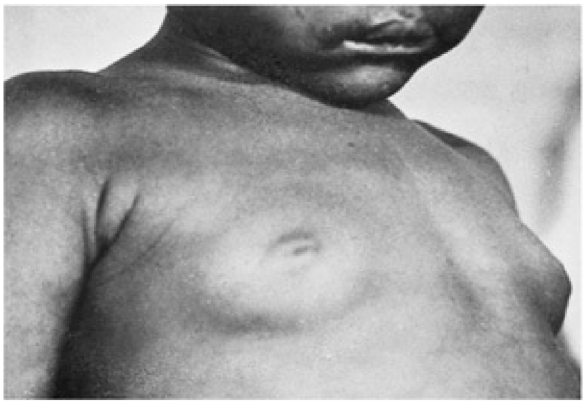

Figure 37–23. Premature thelarche in a child 5 years of age.

F. Premature Pubarche

Premature pubarche previously was defined as the appearance of pubic or axillary hair prior to age 8 years, without other signs of precocious puberty (Fig. 37–24). However, new guidelines suggest that this presentation should not be considered precocious unless noted before age 7 years in white girls and before age 6 years in black girls. Such hair growth may be idiopathic and of no clinical significance.

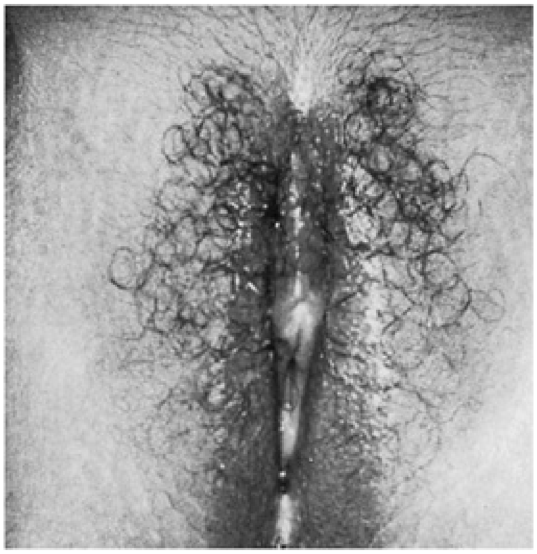

Figure 37–24. Premature pubarche in a child 4 years of age.

Premature pubarche probably results from an earlier-than-usual increase in the secretion of androgens by the adrenal glands. Regulation of adrenal androgen secretion is distinct from that of gonadal steroids. Early appearance of pubic hair may be a very early sign of developing polycystic ovary disorder and, therefore, should be followed up closely. The diagnosis of idiopathic premature pubarche is made only after thorough evaluation of adrenal and gonadal function that fails to detect an abnormality.

Signs of severe androgen excess (eg, clitoral enlargement, growth acceleration, acne) should prompt further investigation for a rare virilizing tumor (Leydig cell tumor) or a variant form of congenital adrenal hyperplasia.

G. Premature Menarche

Premature menarche denotes the appearance of cyclic vaginal bleeding in children in the absence of other signs of secondary sexual development. The cause is unknown but may be related to increased end-organ sensitivity of the endometrium to low prepubertal levels of estrogens. Alternatively, bleeding may be related to transient elevation of estrogens due to premature follicular development. These patients have estradiol levels in the prepubertal range, and when given GnRH, the response of the pituitary gland is similar to that seen in prepubertal children.

Thorough evaluation of the genital tract should be done to exclude other pathologies like tumors, which are seen in up to 20% of patients.

The diagnosis of premature menarche is formulated by exclusion and is confirmed when the cyclic nature of the bleeding becomes apparent. The prognosis is excellent. Adult height is uncompromised, the menstrual pattern is normal, and fertility potential remains unimpaired.

Evaluation of the Patient with Precocious Puberty

When evaluating the patient with sexual precocity, the age at onset, duration, and progression of signs and symptoms constitute important historical information. Family history and review of systems may add important facts.

A. General Changes

Enhancement of general growth and advanced skeletal maturation are coincident with the onset of estrogen-stimulated change acting directly on the growth plate of the bone.

B. Skin

Additional androgen-dependent findings include acne and adult-type body odor.

C. Breast Development

Breast development is at least at Tanner stage II, with the areolae having a broadened, darkened appearance.

D. Genitalia

Genital changes reflect estrogen-induced thickening of the genital tissues. Increased vaginal secretions may result in leukorrhea. Dark, coarse pubic hair may be present.

Diagnosis

The diagnosis of GnRH-dependent precocity requires demonstration of pubertal gonadotropin secretion. The diagnostic evaluation required to document early pubertal development and differentiate central from peripheral causes includes the determination of serum LH, FSH, and estradiol levels, and a GnRH stimulation test. In patients with GnRH-dependent precocious puberty, the results of these tests will be in the normal pubertal range.

With improvements in imaging technology, clinicians often order such studies to help establish the diagnosis. Sonography may aid in the evaluation of the ovaries and adrenal glands. Uterine size and endometrial thickness are estrogen dependent and serve as a good bioassay to determine the length of time and magnitude of estrogen exposure. Ovarian cysts and tumors are also visible. Sonography of the adrenal glands is less sensitive than abdominal CT and MRI. Skeletal imaging to document skeletal age and a bone scan may identify areas of fibrous dysplasia in patients with MAS. Brain MRI is indicated in patients with sexual precocity or with neurologic signs.

Treatment of GnRH-Dependent Precocious Puberty

The treatment of choice for GnRH-dependent precocious puberty is GnRH analogues. Analogues of GnRH are modifications of the native hormone, which have greater resistance to degradation and increased affinity for the pituitary GnRH receptors.

Treatment with GnRH analogues decreases gonadotro-pins and sex steroids to prepubertal levels, which is followed by regression of secondary sexual features. Treatment also causes a deceleration in the skeletal maturation rate, preserving or even improving predicted height, unless bone age is so advanced that further growth is precluded. The efficacy of GnRH analogs in increasing adult height is undisputed only in girls with early-onset (<6 years old) central precocious puberty. The decision of whether to treat with GnRH analogues is made based on the girl’s predicted final height and her emotional maturity. Treatment is continued until puberty is appropriate based on age. Resumption of puberty occurs promptly after discontinuation of GnRH analogue therapy.

DELAYED SEXUAL MATURATION

Delayed sexual development has been defined as the absence of normal pubertal events at an age 2.5 standard deviations later than the mean. The absence of thelarche by age 14 years or the absence of menarche by age 16 years is an indication for investigation. Classification can be based on the gonadotropic level: eugonadotropic, hypogonadotropic, or hypergonadotropic primary amenorrhea.

1. Delayed Menarche with Eugonadotropic Function Including Hyperprolactinemia

Patients with functioning gonads and delayed sexual maturation usually consult a physician while they are in their mid-teens because of amenorrhea. Most have well-formed female configuration with adequately developed breasts. Many of these patients suffer from an inappropriate hypothalamic–pituitary–ovarian feedback mechanism, leading to anovulation and in some cases androgen excess as well. Primary amenorrhea may persist until a progestin challenge is given. Patients should be monitored for continued menstrual shedding. Persistent amenorrhea is treated with progestins administered every other month to prevent endometrial hyperplasia. A sexually active girl should be given oral contraceptives rather than cyclic progestins. Further evaluation is required for diagnosis of adult-onset congenital adrenal hyperplasia and those with polycystic ovarian disease.

The possibility of pregnancy in an adolescent who has not begun to menstruate is highly unlikely but must be borne in mind when considering causes of delayed menarche in patients with normal pubertal development.

Congenital Anomalies

Patients with congenital anomalies of the paramesonephric (müllerian) structures may complain of primary amenorrhea. The most common defect is congenital absence of the uterus and vagina. Other causes are obstructive abnormalities, such as imperforate hymen, transverse vaginal septa, and agenesis of the cervix. Gynecologic examination supplemented by pelvic sonogram or MRI establishes the diagnosis of these congenital anomalies.

Androgen Insensitivity

The complete forms of androgen insensitivity are also associated with amenorrhea and normal breast development. Affected persons have normal testicular function but are not responsive to testosterone, and the development of breasts is secondary to the small amounts of unopposed estrogens produced by the testis. Pubic and axillary hair is scant or often absent. A short blind vaginal pouch is present. Once pubertal development has been completed, surgical extirpation of the gonads and reconstruction of the vagina are necessary. Recent data suggest that regardless of the technique used, sexual function may be impaired in some of these young women. A study of 66 women with complete forms of androgen insensitivity showed that 90% had sexual difficulties, most commonly sexual infrequency and vaginal penetration difficulty.

2. Delayed Puberty with Hypogonadotropic (Hypothalamic) Dysfunction

Hypothalamic–pituitary dysfunction is characterized by low to normal levels of gonadotropins (FSH, LH), similar to prepubertal state.

Constitutional Growth Delay

The onset of puberty depends on an ill-defined stage of maturity that is reflected in skeletal age. Maturation is partly genetically determined but also depends on multiple environmental factors; thus the chronologic age of puberty varies considerably. Statistical limits of normal variation in a defined population group indicate that, by definition, 2.5% of all normal adolescents will develop later than the age defined as “normal.” This group has been labeled “late bloomers” or as having a constitutional growth delay (CGD). These girls often have retarded linear growth within the first 3 years of life, and then their growth resumes at a normal rate. As a result, these girls grow either along the lower growth percentiles or beneath the curve but parallel to it for the remainder of the prepubertal years. At the expected time of puberty, the height of children with CGD begins to drift further from the growth curve because of delayed onset of the pubertal growth spurt. Catch-up growth, onset of puberty, and pubertal growth spurt occur later than average, resulting in normal adult stature and sexual development. Although CGD is a variant of normal growth rather than a disorder, absence of signs of puberty (including the growth spurt) often concerns the patient when her adolescent friends have developed secondary sexual features and gained the characteristic increase in height.

The diagnosis of hypothalamic–pituitary dysfunction is made by exclusion of other causes of delayed sexual maturation. Growth charts, bone age, and the GnRH challenge test differentiate constitutional delay from similar conditions associated with GnRH deficiency. Reassurance is the only treatment necessary, but the patient must be kept under observation until regular menstrual cycles are established. Occasionally, an adolescent requires hormonal replacement therapy because of emotional distress over her condition.

Kallmann's Syndrome

Kallmann's syndrome is a genetic condition characterized by hypogonadotropic hypogonadism and anosmia. It affects approximately 1 in 40,000 females, with most presentations of the "sporadic" type. Various forms of Kallmann's syndrome are inherited, and the gene responsible for the X-linked form has been identified.

The clinical features include deficiency of GnRH associated with anosmia. Because GnRH neurons originate extracranially within the olfactory system, both can be simultaneously affected, and the defects are believed to be secondary to abnormalities of neuronal migration during development. Patients with Kallmann's syndrome fail to develop secondary sexual features, and blood levels of gonadotropins are very low.

Patients with Kallmann's syndrome have a diminished gonadotropin response to the GnRH stimulation test. Pulsatile administration of GnRH for 1 week usually restores subsequent pituitary responsiveness to GnRH. All postpubertal-age patients with Kallmann's syndrome are candidates for gonadal steroid replacement therapy in the absence of specific contraindications. Estrogen replacement therapy is used to initiate and sustain sexual development. Induction of ovulation with human menopausal gonadotropins or GnRH is necessary when pregnancy is desired.

Brain Tumors

A pituitary or parasellar tumor, particularly craniopharyngioma or pituitary adenoma, must be considered in the evaluation of a patient with delayed sexual maturation. Craniopharyngiomas are rapidly growing tumors that often develop in late childhood. Pituitary adenomas are slow growing, may become symptomatic during puberty, and may interfere with sexual maturation.

Hyperprolactinemia

An occult pituitary prolactinoma in adolescents with unexplained delayed sexual maturation must be ruled out. Serum prolactin levels should be measured yearly in patients with unexplained delayed sexual maturation.

Eating Disorders

Weight loss due to extreme dieting causes marked decrease of fat tissue concentration, resulting in suppression of GnRH activity, even in cases of almost normal weight without notable loss of muscle (often seen in athletes). It should be emphasized that the very first sign of anorexia nervosa could be primary or secondary amenorrhea.

Heroin addiction may cause amenorrhea, but its effects on sexual maturation have not been documented.

3. Delayed Puberty with Hypergonadotropic Dysfunction

Gonadal Failure

Gonadal failure is characterized by high levels of gonadotropins (FSH, LH), similar to the menopausal state. The common pathway of all ovarian failure disorders is the prominent deficiency of estrogen and the essential need for estrogen-containing replacement therapy in order to achieve normal development and prevent late consequences of estrogen deprivation.

Most patients with gonadal dysgenesis present during adolescence with delayed puberty and primary amenorrhea. For young women with gonadal failure, the most common cause is Turner's syndrome, which occurs with an incidence of 1 in 2500 to 1 in 10,000 live births. The syndrome is sex chromosomal aberration of 45,X monosomy. If untreated, estrogen and androgen levels are decreased, and FSH and LH levels are increased. Estrogen-dependent organs show the predictable effects of hormonal deficiency. Breasts contain little parenchymal tissue, and the areolar tissue is only slightly darker than the surrounding skin. The well-differentiated external genitalia, vagina, and müllerian derivatives remain small. Pubic and axillary hairs fail to develop in normal quantity. These patients should be closely monitored for development of illness caused by affected systems, such as the cardiovascular, urinary, and endocrine systems.

However, normal pubertal development, menstruation, and even pregnancies have been reported in adults with gonadal dysgenesis. It is possible that a few of these persons maintain some germ cells into adulthood. Spontaneous development is more commonly observed in patients with mosaicism with a 46,XX line. The rare offspring of these women probably do not have an increased risk for chromosomal abnormalities. In order to achieve pregnancy in a majority of women with gonadal dysgenesis, ovum donation treatment by using assisted reproductive technology may be offered.

Some patients may have ovarian failure even though they have a normal chromosome complement and 2 intact sex chromosomes (46,XX). An autosomal recessive form of ovarian failure has been demonstrated in some families. A small percentage of ovarian failures may be reversible and may be predicted by detection of anti-müllerian hormone levels, although the assay has not yet demonstrated clinical yield. Other causes of follicular depletion include chemotherapy, irradiation, infections (eg, mumps), infiltrative disease processes of the ovary (eg, tuberculosis), autoimmune diseases, and unknown environmental agents.

A karyotype is necessary to rule out the presence of Y chromosome material. DNA probes and assays for the minor histocompatibility antigen H-Y have also been used to identify Y chromosome material. A high incidence of neoplastic changes in the gonadal ridge has been reported in the presence of a Y chromosome (Fig. 37–25), so prophylactic gonadectomy is recommended. Replacement hormonal therapy is then given in a cyclic manner.

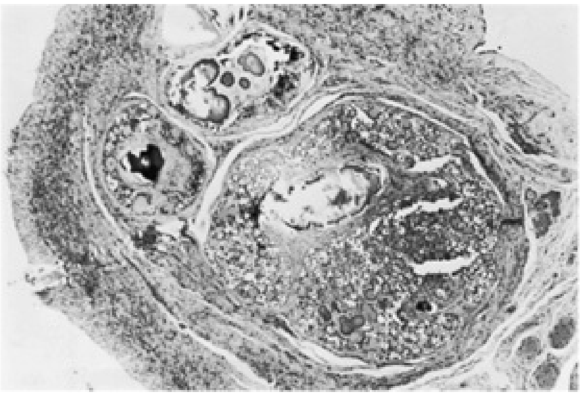

Figure 37–25. Gonadoblastoma developing in a gonadal ridge in a patient with gonadal dysgenesis and 45,XO/46,XY karyotype.

Some patients have similar features, yet follicles are present but unresponsive, a condition called the *resistant ovary syndrome*. It is characterized by delayed menarche or primary amenorrhea, a 46,XX chromosome complement, high FSH levels, and ovaries with apparently normal follicular apparatus that do not respond to endogenous gonadotropins. Absence of follicular receptors for gonadotropins is assumed to be responsible for ovarian dysfunction in these patients. These individuals may have normally developed secondary sexual characteristics. Estrogen replacement therapy is required to prevent long-term complications of estrogen deficiency (eg, vaginal dryness, osteoporosis). Pregnancies have been reported in some patients treated with menotropins or following discontinuation of estrogen therapy.

Evaluation of the Patient with Delayed Sexual Development

Determination of gonadal function can be accomplished by obtaining a medical history and performing a detailed physical examination, supplemented by selected laboratory studies. Historical information should center around previous growth and pubertal development. Linear and velocity growth charts as well as a pubertal development chart clarify previous growth patterns and are useful in subsequent follow-up. Knowledge of previous medical disorders may immediately identify the cause of aberrant puberty.

Physical examination must include height and weight assessments and a careful search for somatic anomalies. Staging of pubertal development by Tanner criteria is most important in the determination of gonadal function. Presence of breast development signifies prior gonadal function. Imaging studies such as pelvic sonogram and CT and MRI are required for confirmation of congenital absence of the vagina and uterus.

Absence of pubic hair is suggestive of the androgen insensitivity syndrome. Karyotype will identify the 46,XY cell line in patients with testicular feminization syndrome. Patients with complete pubertal development and well-formed female configuration (“pear shape”) display evidence of continued estrogen production, and normal müllerian systems probably have inappropriate positive feedback and thus chronic anovulation. Progesterone challenge in such patients is helpful. A withdrawal bleed signifies a normal müllerian system and acceptable estrogen production.

Serum gonadotropin assays are performed for further elucidation. Elevated FSH levels suggest gonadal failure. Karyotype determination is crucial in diagnosing the various etiologies of gonadal failure. The presence of a Y chromosome in either group dictates gonadal removal.

Low FSH levels suggest interference with hypothalamic–pituitary maturation and gonadotropin release. Skull films and prolactin assays must be obtained for all patients to rule out the presence of pituitary or hypothalamic tumors. Appropriate endocrine evaluation identifies the occasional patient with hypothyroidism or congenital adrenal hyperplasia and the rare patient with Cushing's syndrome. Diagnosis of Kallmann's syndrome is suspected in hypogonadotropic patients who have an associated anosmia, and the diagnosis is confirmed by GnRH challenge tests. The presumed diagnosis of constitutional delay is made by exclusion of all other causes and by the typical GnRH release patterns after GnRH challenge.

BLEEDING DISORDERS

Vaginal Bleeding in the Premenarchal Child

When vaginal bleeding occurs in children, 2 sources generally should be suspected: (1) the endometrium (bleeding usually is a manifestation of precocious puberty) and (2) a local vulvar or vaginal lesion (eg, vulvovaginitis, foreign bodies, urethral prolapse, trauma, botryoid sarcoma, adenocarcinoma of the cervix or vagina, and vulvar skin disorders).

Vaginal bleeding during childhood should always alert the physician to the possibility of a genital tumor, which could be present in up to 20% of girls with no signs of pubertal maturation. Vaginoscopy and examination under anesthesia are the mainstays of evaluation to exclude the presence of tumors, foreign bodies, and other local lesions. Suspicious lesions require biopsy for diagnosis. Sexual abuse should be always be kept in mind by the physician attending a prepubertal girl with vaginal bleeding.

Disorders of Menstrual Cycle in Adolescents

One of the most common gynecologic complaints of adolescents is a problem with the menstrual period. In most cases, there is no true medical disorder, especially in the first 2 years after menarche, when 50–80% of periods are anovulatory. Dysfunctional uterine bleeding accounts for 95% of abnormal vaginal bleeding in teenagers. Screening for inherited coagulation disorders, such as von Willebrand's disease, may be indicated, as 18% of adolescents hospitalized for menorrhagia have an underlying bleeding disorder.

Pubertal Menorrhagia

In the adolescent, the normal cycle length is 21–45 days, the length of the period is 7 days or less, and product use is no more than 3–6 pads or tampons per day. Menorrhagia is defined as heavy menstrual bleeding that lasts for more than 7 days or results in the loss of more than 80 mL of blood per menstrual cycle.

Heavy bleeding starting from the first menstrual period after menarche might be the first sign of a bleeding disorder, such as von Willebrand's disease (5–20%) or platelet dysfunction.

Pubertal menorrhagia is a result of dysfunctional uterine bleeding more often secondary to anovulation. This is reflection of the immaturity of the hypothalamic–pituitary–ovarian axis; in fact, in 55–82% of adolescents, it takes 24 months for onset of regular ovulatory cycles after menarche. This abnormality is even more common in girls with polycystic ovary syndrome (PCOS), and bleeding disorders such as abnormal platelet function or von Willebrand's disease are the most common inherited bleeding disorders. A positive bleeding history alone had a sensitivity for detecting any bleeding disorder of 82%. It should be followed by initial laboratory evaluation including a complete cell count, prothrombin time, activated partial thromboplastin time (aPTT), and fibrinogen or thrombin clot time, although all of these tests might be normal in patients with VWD. Further evaluation is better done in collaboration with hematologists with expertise in bleeding disorders.

Management of anovulatory bleeding is directed toward controlling symptoms and preventing blood loss based on degree of anemia. Hormonal contraception is the first-line treatment for menorrhagia, and the dosage is adjusted based on severity of the bleeding. Daily administration could reach several pills a day until control of bleeding is achieved, followed by tapering during the following days. Other preparations include medroxyprogesterone acetate and levonorgestrel-secreting intrauterine devices, which have been used by several experts. Consideration of the negative effect on final height caused by the estrogen component must be done based on clinical condition of the patient.

In severe cases, hospitalization and intravenous conjugated equine estrogen in doses of 25 mg every 4–6 hours until bleeding stops for 24 hours have been used successfully. If oral contraceptives are given for secondary amenorrhea, they should be continued for at least 9–12 months before attempting to stop. If menses do not resume within 8 weeks, oral contraceptive pills should be resumed for another 9–12 months.

Adolescents who fail hormonal management should be referred for consideration of hemostatic therapies including desmopressin (DDAVP), antifibrinolytic medications (aminocaproic acid, tranexamic acid), and clotting factor concentrates. In the management of acute severe menorrhagia, every effort is made to preserve future fertility. Invasive intervention should be reserved as a last resort treatment.

POLYCYSTIC OVARIAN SYNDROME IN ADOLESCENTS

The prevalence of PCOS in the general population has been estimated to be 5–10%. The classic presentation is characterized by features of anovulation, amenorrhea, oligomenorrhea, or irregular cycles in combination with signs of androgen excess, acne, hirsutism, or alopecia. It is associated frequently with insulin resistance.

PCOS usually presents at the late pubertal age but may also present before menarche in the form of androgen excess as premature pubarche/adrenarche.

Recent literature has identified a specific biochemical marker (adiponectin) that is significantly lower in concentration in the daughters of women who have PCOS before the onset of hyperandrogenism and may be an early marker of metabolic derangement in adolescent girls.

Primary amenorrhea as the initial feature occurs in 1.4–14% of adolescents with PCOS. As with adults, Rotterdam Criteria should be used to make the diagnosis of PCOS in adolescents; however, some researchers have challenged the consensus of Rotterdam Criteria in adolescents because they may lead to overestimation of the syndrome, because the physiologic process of early puberty is characterized by relative androgenemia, insulin resistance, cystic ovaries, and anovulatory cycles. They have proposed alternative diagnostic criteria in adolescents, which include 4 of the following 5 criteria: (1) oligo- or amenorrhea 2 years after menarche; (2) clinical hyperandrogenism; (3) hyperandrogenemia; (4) insulin resistance or hyperinsulinemia; and (5) polycystic ovaries. The finding of polycystic ovaries in adolescents as the only sign should be considered with caution because 25% of healthy adolescents may present with similar finding.

Adolescents who are obese and have a diagnosis of PCOS should undergo a 2-hour 75-g oral glucose tolerance test (OGTT). This is a more sensitive test than the fasting glucose test to detect diabetes and impaired glucose tolerance, which is a significant risk factor for diagnosis. A fasting glucose/insulin ratio has been proposed as a rapid and easy screening alternative; in adolescents, a ratio of <7 is suggestive as compared with a ratio of <4.5 in adults.

An early diagnosis should be made in order to avoid late health consequences such as diabetes, cardiovascular disease, endometrial hyperplasia, and infertility. Any adolescent with androgen excess should be monitored for evidence of hypertension and hypertriglyceridemia regardless of body weight because of the higher risk for metabolic syndrome.

Treatment

Treatment options for adolescents with PCOS include weight loss for obese girls and lifestyle modifications, including calorie restriction and an increase in formal exercise; symptom-directed therapy to address the main symptoms noted by the adolescent; and metabolic correction of the underlying insulin resistance using insulin-sensitizing medications.

Although weight loss of as little as 5–10% has been shown to result in reduction in testosterone increase in sex hormone-binding globulin and resumption of menses and ovulation, unfortunately, diet and behavioral therapies have been shown to fail in adolescents, with follow-up showing weight regain of 75–121% at 5 years. Obesity can exacerbate the PCOS phenotype in previously asymptomatic individuals. Weight reduction has been shown to improve free androgen levels, insulin sensitivity, and ovulatory function. When menstrual irregularity is accompanied by symptoms such as acne, hirsutism, and obesity, PCOS should be suspected, and treatment may need to address some of these symptoms as well.

Pregnancy should always be considered in a young woman with abnormal bleeding or amenorrhea until proven otherwise. Nonmenstrual causes of bleeding, such as hypothyroidism, cervicitis, condylomas, polyps, cervical cancer, estrogen-producing ovarian tumors, and vaginitis, also should be considered.

ADOLESCENT PREGNANCY AND CONTRACEPTION

Juvenile pregnancy is rare. The youngest known patient was a Peruvian girl aged 5 years 8 months, who in 1939 delivered at term by caesarean section a healthy male infant weighing 2950 g (6 lb 8 oz). Both mother and infant survived. In every reported instance, the underage mothers were sexually precocious, and most had menstruated for several years before becoming pregnant. Juvenile pregnancy per se does not increase the chance of congenital anomalies in the offspring. However, in many cases, the mother is a victim of sexual abuse, and if the pregnancy is the result of incest, there is a greater likelihood of genetic malformations carried by recessive genes.

Most precocious mothers and their babies have not done well, with increased incidences of spontaneous abortion, pregnancy-induced hypertension, and premature labor and delivery. In patients younger than 9 years, <50% have normal labor, with a 35% likelihood of neonatal loss.

The underage mother and her family may need psychiatric counseling, both during pregnancy and after delivery. Lessening the emotional, social, and medical trauma associated with such a gestation is an important task for all who assist in the care of the pregnant child.

For years it has been accepted that adolescent pregnancy is a high-risk pregnancy. Many pregnant adolescents come from low socioeconomic backgrounds and have poor education and perhaps poor general health due to inadequate nutrition, iron deficiency anemia, cigarette smoking, drug abuse, or STDs. Proper education and dietary counseling may improve nutritional status and prevent anemia.

Complications of labor and delivery are highly dependent on the quality of prenatal care. Preeclampsia–eclampsia, which is more common in a first pregnancy, occurs more frequently among adolescents than among adult women. Prematurity and small for gestational age infants are a major problem in adolescent pregnancies. Predisposing factors are high-risk factors such as low prepregnancy weight, poor weight gain, adverse socioeconomic conditions, cigarette smoking, anemia, first pregnancy, and deficient prenatal care, all of which occur more commonly in adolescents. To minimize prenatal complications and to improve maternal and fetal outcome, the young patient should be enrolled in an aggressive prenatal care program. That care should not only improve the pregnancy outcome of adolescents, but also enhance their social, educational, and emotional adjustment.

PREGNANCY TERMINATION

The rate of teenage abortion remains higher in the United States than in other Western countries for which data are available. In many countries, the legal authorities ruled in favor of a minor’s right to have an abortion. In others systems, the evacuation of uterine contents can be performed by medical (RU-486) or surgical (dilatation and currettage) technique, both of which are accepted in adolescents; the preferable method is still undetermined. For minors who do not want parental involvement social support is required to perform it on them.

CONTRACEPTION IN ADOLESCENTS

More than 95% of adolescent pregnancies are unintended. By age 18 years, 1 in 4 adolescents experiences a pregnancy. Half of adolescent pregnancies occur in the first 6 months after initiation of sexual activity. Despite a decline in teenage pregnancy rates during the 1990s, teenage pregnancy rates remain higher in the United States than in other Western countries. In addition, teenagers in the United States use contraceptives less frequently and use less effective methods of contraception than do their European counterparts. Although great inroads in adolescent access to health care have been made over the last decade, problems of cost and fears of lack of confidentiality still appear to inhibit young women from obtaining contraceptives, ultimately resulting in high teenage pregnancy rates.

These findings reinforce the importance of addressing contraception during an adolescent’s initial health care evaluation.

Postponing sexual activity is an appropriate option to suggest. If this is not realistic, counseling regarding various methods of contraception requires consideration not only of the side effects and efficacy of the various methods but also of the personal requirements of each teenager. Extended regimens such as available 84/7 day and no “placebo” regimens have shown similar efficacy; these may be new options for patient who desire lower frequency of menses such as athletes and military personnel, although studies in adolescents are lacking. Using “Quik Start” (same day of the visit) seems to improve compliance from 56 to 72%.

The common hormonal contraceptive methods are applicable in adolescents with the same success as in adult women; however, teenagers are more likely to forget taking a daily pill, thus resulting in a high failure rate of 9–18% and low long-term compliance of 44%. Long-lasting methods such as the patch, vaginal ring, and hormonal Depo system may be more efficient in preventing pregnancy in young girls. Inserting an IUD in girls before first pregnancy is reasonable under some conditions but still remains controversial. Screening patients for STIs before insertion should be encouraged.

Health benefits of adolescents taking hormonal contraceptive methods include decreased menstrual pain; increased menstrual regularity; decreased risk of pelvic inflammatory disease, anemia, and fibrocystic breast disease; improved long-term fertility; and treatment of acne and hirsutism. The importance of both contraception and STI prevention should be reviewed, and the use of barrier methods together with hormonal method should be encouraged.

Emergency contraception with progestin-only regimens is a highly effective means of preventing pregnancy if taken up to 72 hours after intercourse; despite decreasing efficacy, it should be provided up to 120 hours after unprotected coitus. Improving access through education or prescribing pills in advance or over the telephone may give a young woman a second chance at preventing unintended pregnancy.

SEXUALLY TRANSMITTED INFECTIONS

STIs are the most common infectious diseases in adolescents today. Approximately 25% of all sexually active adolescents aged 13–19 years become infected each year. By age 15 years, 1 in 4 girls in the United States has had sexual relations. The younger the age of first intercourse, the higher is the risk for STIs. Chlamydia is the most prevalent of the bacterial STIs, with almost 30% of inner-city female adolescents aged 12–19 showing positive cultures in a longitudinal 2-year study of family planning, school-based, and STI clinics. Sequelae of chlamydial infections include pelvic inflammatory disease (PID), ectopic pregnancy, and infertility. This age group accounts for 8% of cases of HIV in females, with the majority of these women asymptomatic at the time of positive testing. In the United States, 15- to 24-year-olds accounted for approximately 60% of gonorrhea cases, 25% of syphilis cases, and 17% of hepatitis B cases in 1996. By the time they reach college age, 43% of women are infected with human papillomavirus.

Nearly 70% of patients with PID are younger than 25 years. The estimated incidence of PID in sexually active females is approximately 1 in 8 for 15-year-olds and 1 in 10 for 16-year-olds. PID in adolescents should be treated with hospitalization and intravenous antibiotics. Tubo-ovarian abscess has been found in 2–4% of adolescents with adnexal masses. Treatment includes broad-spectrum antibiotics and possible surgical drainage. Patients who have had PID or tubo-ovarian abscess are at high risk for pelvic pain, pelvic adhesive disease, infertility, and ectopic pregnancy.

CERVICAL CANCER SCREENING & HUMAN PAPILLOMAVIRUS VACCINE IN ADOLESCENTS

Human papillomavirus (HPV) is the most common sexually acquired infection in the world, with a prevalence of 50% among young sexually active adolescents. Most of these infections are self-limiting and harmless, but persistent infection with oncogenic HPV types can cause cervical cancer in women. HPV also causes other anogenital cancers (eg, of the vagina, vulva, and penis), head and neck cancers, and genital warts in both men and women.

The availability of the new vaccine (2006) against carcinogenic types of HPV (mainly types 16 and 18) has led to major changes in the prevention and management of cervical disease. Two vaccines are currently approved for use in humans, and both have shown more than 95% efficacy in preventing cervical dysplasia associated with vaccine type and a high safety profile.

Several organizations, including the American College of Obstetricians and Gynecologists (ACOG), have recommended vaccination for young women aged 9–26 years. Because current HPV vaccines are prophylactic, the greatest impact will be seen by vaccinating girls before they are exposed to HPV and thus before sexual debut.

Some countries introduced the vaccine as a part of scholar vaccination program, which severed the administration of the vaccine from the sexual permissiveness context. The duration of protection seems to be longer than 6 years, but the exact duration of protection and other details on the future of the vaccine are still not clear and need more clinical trials.

Health care providers should encourage vaccinated adolescents to continue with the use of protective methods against other STDs and emphasize the importance of cervical cancer screening with a Papanicolaou (Pap) test. Screening in low-risk adolescent should be initiated 3 years after the onset of sexual activity and not later than age 21 years.

Considering the rarity of cervical cancer among adolescents, the management of abnormal cervical cytology differs from that of the adult population. The American Society for Colposcopy and Cervical Pathology (ASCCP) advises against HPV testing and against treatment of low-grade squamous intraepithelial lesions or cervical intraepithelial neoplasia I. In adherent adolescents, treatment of cervical intraepithelial neoplasia II should also be deferred. In patients with high-grade lesions or incompliant adolescents with lower grade lesions, ablative or excisional procedures are indicated. Cryotherapy offers a 92–95% cure rate for cervical intraepithelial neoplasia 2–3 in young women. Loop electrosurgical excisional procedure offers similar cure rates and does not appear to impact cervical competence in future pregnancies with depths of excision of 1.5 cm or less.

Complications of Menstruation & Abnormal Uterine Bleeding

Asher Shushan, MD

PREMENSTRUAL SYNDROME

ESSENTIALS OF DIAGNOSIS

- Symptoms include mood symptoms (irritability, mood swings, depression, anxiety), physical symptoms (bloating, breast tenderness, insomnia, fatigue, hot flushes, appetite changes), and cognitive changes (confusion and poor concentration).
- Symptoms must occur in the second half of the menstrual cycle (luteal phase).
- There must be a symptom-free period of at least 7 days in the first half of the cycle.
- Symptoms must occur in at least 2 consecutive cycles.
- Symptoms must be severe enough to require medical advice or treatment.

General Considerations

Premenstrual syndrome (PMS) has been defined as “the cyclic occurrence of symptoms that are of sufficient severity to interfere with some aspects of life and that appear with consistent and predictable relationship to the menses.” Although the symptoms themselves are not unique, the restriction of the symptoms to the luteal phase of the menstrual cycle is pathognomonic of PMS. It is a psycho-neuroendocrine disorder with biologic, psychological, and social parameters that is both difficult to define adequately and quite controversial. One major difficulty in detailing whether PMS is a disease or a description of physiologic changes is its extraordinary prevalence. Up to 75% of women experience some recurrent PMS symptoms; 20–40% are mentally or physically incapacitated to some degree, and 5% experience severe distress. The highest incidence occurs in women in their late 20s to early 30s. PMS is rarely encountered in adolescents and resolves after menopause. Evidence suggests that women who have suffered with PMS and premenstrual dysphoric disorder are more likely to suffer from perimenopausal symptoms.

The symptoms of PMS may include headache, breast tenderness, pelvic pain, bloating, and premenstrual tension. More severe symptoms include irritability, dysphoria, and mood lability. When these symptoms disrupt daily functioning, they are clustered under the name *premenstrual dysphoric disorder* (PMDD).

Other symptoms commonly included in PMS are abdominal discomfort, clumsiness, lack of energy, sleep changes, and mood swings. Behavioral changes include social withdrawal, altered daily activities, marked change in appetite, increased crying, and changes in sexual desire. In all, more than 150 symptoms have been related to PMS. Thus the symptom complex of PMS has not been clearly defined.

Pathogenesis

The etiology of the symptom complex of PMS is not known, although several theories have been proposed, including estrogen–progesterone imbalance, excess aldosterone, hypoglycemia, hyperprolactinemia, and psychogenic factors. A hormonal imbalance previously was thought to be related to the clinical manifestations of PMS/PMDD, but in the most recent consensus, physiologic ovarian function is believed to be the trigger. This is supported by the efficacy of ovarian cyclicity suppression, either medically or surgically, in eliminating premenstrual complaints.

Further research has shown that serotonin (5-hydroxytryptamine [5-HT]), a neurotransmitter, is important in the pathogenesis of PMS/PMDD. Both estrogen and progesterone have been shown to influence the activity of serotonin and gamma-aminobutyric acid (GABA) centrally. Many of the symptoms of other mood disorders resembling the features of PMS/PMDD have been associated with serotonergic dysfunction. Disturbances in cortical GABA neuronal function and modulation by neuroactive steroids have been implicated as potentially important contributors to the pathogenesis of PMS/PMDD. GABA levels are decreased in women with PMS/PMDD during the late luteal phase compared with normal women.

Diagnosis

No objective screening or diagnostic tests for PMS and PMDD are available; thus special attention must be paid to the patient's medical history. Certain medical conditions (eg, thyroid disease and anemia) with symptoms that can mimic those of PMS/PMDD must be ruled out.

The patient is instructed to chart her symptoms during the month. According to the American College of Obstetricians and Gynecologists criteria, PMS can be diagnosed if the patient reports at least 1 affective symptom (depression, angry outbursts, irritability, anxiety, confusion, or social withdrawal) and somatic symptom (breast tenderness, abdominal bloating, headache, or swelling of extremities) during the 5 days before menses in each of the 3 prior menstrual cycles. These symptoms should be relieved within 4 days of the onset of menses, without recurrence until at least cycle day 13, and should be reproducible during 2 cycles of prospective recording.

Clinical Findings

A careful history and physical examination are most important to exclude organic causes of PMS localized to the reproductive, urinary, or gastrointestinal tracts. Most patients readily describe their symptoms, but careful questioning may be needed with some patients who may be reluctant to do so. Although it is important not to lead a patient to exaggerate her concerns, it is equally important not to minimize them.

Symptoms of PMS may be specific, well localized, and recurrent. They may be exacerbated by emotional stress. Migraine-like headaches may occur, often preceded by visual scotomas and vomiting. Symptomatology varies among patients but often is consistent in the same patient.

One of the most common symptoms of PMS is *mastodynia*, or mastalgia (pain, and usually swelling, of the breasts caused by edema and engorgement of the vascular and ductal systems). A positive correlation between degree of ductal dilatation and degree of breast pain has been documented. Mastodynia specifically refers to a cyclical occurrence of severe breast pain, usually in the luteal phase of the menstrual cycle, and it may be the primary symptom of this syndrome in some. It has been shown to be related to high gonadotropin levels. Estrogen stimulates the ductal elements, whereas progesterone stimulates the stroma. An augmented response to prolactin has also been suggested. Examination is always necessary to rule out neoplasm, although most malignant tumors are painless. The presence of solitary or multiple cystic areas suggests fibrocystic change. The diagnosis usually can be confirmed by aspiration, but excisional biopsy occasionally is necessary. Serial mammograms or ultrasound examinations can be used to help monitor these patients (see Chapter 5).

A psychiatric history should be obtained, with special attention paid to a personal history of psychiatric problems or a family history of affective disorders. A mental status evaluation of affect, thinking, and behavior should be performed and recorded. A prospective diary correlating symptoms, daily activities, and menstrual flow can be useful to document changes and to encourage patient participation in her care.

If underlying psychiatric illness is suspected, a psychiatric evaluation is indicated. The most common associated psychiatric illness is depression, which generally responds to antidepressant drugs and psychotherapy. Recall that psychiatric illnesses have premenstrual exacerbations, so medications should be altered accordingly.

Treatment

Treatment of PMS/PMDD depends on the severity of the symptoms. For some women, changes in eating habits—limiting caffeine, alcohol, tobacco, and chocolate intake, and eating small, frequent meals high in complex carbohydrates—may be sufficient. Decreasing sodium intake may alleviate edema. Stress management, cognitive behavioral therapy, and aerobic exercise have all been shown to improve symptoms.

Low-risk pharmacologic interventions that may be effective include calcium carbonate (1000–1200 mg/d) for bloating, food cravings, and pain; magnesium (200–360 mg/d) for water retention; vitamin B_6 (note that prolonged use of 200 mg/d may cause peripheral neurotoxicity) and vitamin E; nonsteroidal anti-inflammatory drugs (NSAIDs); spironolactone for cyclic edema; and bromocriptine for mastalgia. Traditional Chinese herbal medicines are frequently used to treat PMS in China. A recent well-designed study has reported on the effectiveness of Jingqianping in the treatment of PMS. However, currently there is insufficient evidence to support the use of Chinese herbal medicine for PMS.

For symptoms of severe PMS and PMDD, further pharmacologic intervention may be necessary. Large, well-designed, randomized, placebo-controlled trials of fluoxetine and sertraline and smaller trials of several other serotonin reup-take inhibitors have shown clear benefit compared with placebo for women diagnosed with PMDD, with at least moderately beneficial response rates in 50–60% of women taking active drug. This is not a generic antidepressant effect, because agents with different mechanisms are not effective. Treatment should be given 14 days prior to the onset of menstruation and continued through the end of the cycle. Anxiolytics such as alprazolam and buspirone also have been shown to be efficacious, but their side effects and potential for dependence must be seriously considered.

Hormonal interventions have been shown to be effective. Use of selected oral contraceptives and transdermal estradiol patch has been suggested because they suppress ovulation. Recently, the US Food and Drug Administration approved the use of a pill containing drospirenone, which is a progestin derived from spironolactone rather than 19-nortestosterone, for treating PMDD. This approval permits the manufacturer to make claims about the drug’s effectiveness in treating PMDD. However, the product label notes that effectiveness after 3 cycles is unknown.

Use of gonadotropin-releasing hormone (GnRH) agonists leads to a temporary “medical menopause” and an improvement in symptoms. Their limitations lie in a hypoestrogenic state and a risk for osteoporosis, although “add-back” therapy with estrogen and progesterone may obviate these problems. There is no conclusive evidence that progesterone can help women with PMS. Danazol may improve mastalgia. Finally, bilateral oophorectomy is a definitive surgical treatment option; again, estrogen replacement would be recommended.

DYSMENORRHEA

Dysmenorrhea, or painful menstruation, is one of the most common complaints of gynecologic patients. Many women experience mild discomfort during menstruation, but the term *dysmenorrhea* is reserved for women whose pain prevents normal activity and requires medication, whether an over-the-counter or a prescription drug.

There are 3 types of dysmenorrhea: (1) primary (no organic cause), (2) secondary (pathologic cause), and (3) membranous (cast of endometrial cavity shed as a single entity). This discussion focuses mainly on primary dysmenorrhea. Secondary dysmenorrhea is discussed elsewhere in this book in association with specific diseases and disorders (eg, endometriosis, adenomyosis, pelvic inflammatory disease, cervical stenosis, fibroids, and endometrial polyps). Membranous dysmenorrhea is rare; it causes intense cramping pain due to passage of a cast of the endometrium through an undilated cervix. Another cause of dysmenorrhea that should be considered is cramping due to the presence of an intrauterine device (IUD).

Pathogenesis

Pain during menstruation has long been known to be associated with ovulatory cycles. The mechanism of pain has been attributed to prostaglandin activity. Advances in the last 3 decades and current understanding suggest that in primary dysmenorrheal there is abnormal and increased prostanoid and possibly eicosanoid secretion, which in turn induces abnormal uterine contractions. The contractions reduce uterine blood flow, leading to uterine hypoxia.

Other studies have confirmed increased leukotriene levels as a contributing factor. Vasopressin was thought to be an aggravating agent, but atosiban, a vasopressin antagonist, has shown no effect on menstrual pain.

Psychological factors may be involved, including attitudes passed from mother to daughter. Girls should receive accurate information about menstruation before menarche; this can be provided by parents, teachers, physicians, or counselors. Emotional anxiety due to academic or social demands may be a cofactor.

Clinical Findings

Reactions to pain are subjective, and questioning by the physician should not lead the patient to exaggerate or minimize her discomfort. History taking is most important and should include the following questions: When does the pain occur? What does the patient do about the pain? Are there other symptoms? Do oral contraceptives relieve or intensify the pain? Does the pain become more severe over time?

Because dysmenorrhea almost always is associated with ovulatory cycles, it does not usually occur at menarche but rather later in adolescence. As many as 14–26% of adolescents miss school or work as a result of pain. Typically, pain occurs on the first day of the menses, usually about the time the flow begins, but it may not be present until the second day. Nausea and vomiting, diarrhea, and headache may occur. The specific symptoms associated with endometriosis are not present.

The physical examination does not reveal any significant pelvic disease. When the patient is symptomatic, she has generalized pelvic tenderness, perhaps more so in the area of the uterus than in the adnexa. Occasionally, ultrasonography or laparoscopy is necessary to rule out pelvic abnormalities such as endometriosis, pelvic inflammatory disease, or an accident in an ovarian cyst.

Differential Diagnosis

The most common misdiagnosis of primary dysmenorrhea is secondary dysmenorrhea due to endometriosis. With endometriosis, the pain usually begins 1–2 weeks before the menses, reaches a peak 1–2 days before, and is relieved at the onset of flow or shortly thereafter. Severe pain during sexual intercourse or findings of adnexal tenderness or mass or cul-de-sac nodularity, particularly in the premenstrual interval, help to confirm the diagnosis (see Chapter 56). A similar pain pattern occurs with adenomyosis, although in an older age group and in the absence of extrauterine clinical findings.

Treatment

NSAIDs or acetaminophen may relieve mild discomfort. Addition of continuous heat to the abdomen in addition to NSAIDs decreases pain significantly. For severe pain, codeine or other stronger analgesics may be needed, and bed rest may be desirable. Occasionally, emergency treatment with parenteral medication is necessary. Analgesics may cause drowsiness at the dosages required.

A. Antiprostaglandins

Antiprostaglandins are now used for treatment of dysmenorrhea. The newer, stronger, faster-acting drugs appear to be more useful than aspirin. Ibuprofen and naproxen, NSAIDs that are available over the counter, have been extremely effective in reducing menstrual prostaglandin and relieving dysmenorrhea. More specific cyclooxygenase-2 (COX-2) inhibitors are now available, but concerns about their adverse effects have recently attracted attention. Rofecoxib, valdecoxib, and lumiracoxib are effective for treating primary dysmenorrhea. Thus far, COX-2 inhibitors are equally effective but not better than naproxen. Given the above considerations, concerns about safety of COX-2 inhibitors, the short duration of therapy for relieving primary dysmenorrhea, and the low costs of NSAIDs, it is prudent to recommend established NSAIDs with track records of long-term safety as the preferred pharmacologic agent. The drug must be used at the earliest onset of symptoms, usually at the onset of, and sometimes 1–2 days prior to, bleeding or cramping.

Antiprostaglandins work by blocking prostaglandin synthesis and metabolism. Once the pain has been established, antiprostaglandins are not nearly as effective as with early use.

B. Oral Contraceptives

Cyclic administration of oral contraceptives, usually in the lowest dosage but occasionally with increased estrogen, prevents pain in most patients who do not obtain relief from antiprostaglandins or cannot tolerate them. The mechanism of pain relief may be related to absence of ovulation or to altered endometrium resulting in decreased prostaglandin production. In women who do not require contraception, oral contraceptives are given for 6–12 months. Many women continue to be free of pain after treatment has been discontinued. NSAIDs act synergistically with oral contraceptive pills to improve dysmenorrhea.

C. Surgical Treatment

In a few women, no medication controls dysmenorrhea. Cervical dilatation is of little use. Laparoscopic uterosacral ligament division and presacral neurectomy are infrequently performed, although some physicians consider these procedures to be important adjuncts to conservative operation for endometriosis.

Adenomyosis, endometriosis, or residual pelvic infection unresponsive to medical therapy or conservative surgical therapy eventually may require hysterectomy with or without ovarian removal in extreme cases. Rarely, a patient with no organic source of pain eventually requires hysterectomy to relieve symptoms.

D. Adjuvant Treatments

Continuous low-level topical heat therapy has been shown to be as effective as ibuprofen in treating dysmenorrhea, although its practicality in daily life may be questionable. Many studies have indicated that exercise decreases the prevalence and/or improves the symptomatology of dysmenorrhea, although solid evidence is lacking.

A recent Cochrane review analyzed 7 randomized controlled trials of transcutaneous electrical nerve stimulation (TENS) compared with placebo or no treatment. Overall, high-frequency TENS is more effective for pain relief in primary dysmenorrhea than placebo TENS.

Currently, there is insufficient evidence to recommend the use of herbal and dietary therapies for dysmenorrhea.

ABNORMAL UTERINE BLEEDING

ESSENTIALS OF DIAGNOSIS

- Abnormal uterine bleeding includes abnormal menstrual bleeding and bleeding due to other causes such as pregnancy, systemic disease, or cancer.
- In childbearing women, a complication of pregnancy must always be considered.
- Exclusion of all possible pathologic causes of abnormal bleeding establishes the diagnosis of dysfunctional uterine bleeding (nearly 60% of cases).

General Considerations

Abnormal uterine bleeding includes abnormal menstrual bleeding and bleeding due to other causes such as pregnancy, systemic disease, or cancer. The diagnosis and management of abnormal uterine bleeding present some of the most difficult problems in gynecology. Patients may not be able to localize the source of the bleeding from the vagina, urethra, or rectum. In childbearing women, a complication of pregnancy must always be considered, and one must always remember that more than 1 entity may be present, such as uterine myomas and cervical cancer.

Patterns of Abnormal Uterine Bleeding

The standard classification for patterns of abnormal bleeding recognizes 7 different patterns.

1. **Menorrhagia (hypermenorrhea)** is heavy or prolonged menstrual flow. The presence of clots may not be abnormal but may signify excessive bleeding. “Gushing” or “open-faucet” bleeding is always abnormal. Submucous myomas, complications of pregnancy, adenomyosis, IUDs, endometrial hyperplasias, malignant tumors, and dysfunctional bleeding are causes of menorrhagia.
2. **Hypomenorrhea (cryptomenorrhea)** is unusually light menstrual flow, sometimes only spotting. An obstruction such as hymenal or cervical stenosis may be the cause. Uterine synechiae (Asherman’s syndrome) can be causative and are diagnosed by a hysterogram or hysteroscopy. Patients receiving oral contraceptives occasionally complain of light flow and can be reassured that this is not significant.
3. **Metrorrhagia (intermenstrual bleeding)** is bleeding that occurs at any time between menstrual periods. Ovulatory bleeding occurs midcycle as spotting and can be documented with basal body temperatures. Endometrial polyps and endometrial and cervical carcinomas are pathologic causes. In recent years, exogenous estrogen administration has become a common cause of this type of bleeding.
4. **Polymenorrhea** describes periods that occur too frequently. This usually is associated with anovulation and rarely with a shortened luteal phase in the menstrual cycle.
5. **Menometrorrhagia** is bleeding that occurs at irregular intervals. The amount and duration of bleeding also vary. Any condition that causes intermenstrual bleeding can eventually lead to menometrorrhagia. Sudden onset of irregular bleeding episodes may be an indication of malignant tumors or complications of pregnancy.
6. **Oligomenorrhea** describes menstrual periods that occur more than 35 days apart. Amenorrhea is diagnosed if no menstrual period occurs for more than 6 months. Bleeding usually is decreased in amount and associated with anovulation, either from endocrine causes (eg, pregnancy, pituitary-hypothalamic causes, menopause) or systemic causes (eg, excessive weight loss). Estrogen-secreting tumors produce oligomenorrhea prior to other patterns of abnormal bleeding.
7. **Contact bleeding (postcoital bleeding)** is self-explanatory but must be considered a sign of cervical cancer until proved otherwise. Other causes of contact bleeding are much more common, including cervical eversion, cervical polyps, cervical or vaginal infection (eg, *Trichomonas*), or atrophic vaginitis. A negative cytologic smear does not rule out invasive cervical cancer, and colposcopy, biopsy, or both may be necessary.

Evaluation of Abnormal Uterine Bleeding

Detailed history, physical examination, cytologic examination, pelvic ultrasound, and blood tests are the first steps in the evaluation of abnormal uterine bleeding. The main aim of the blood tests is to exclude a systemic disease, pregnancy, or a trophoblastic disease. The blood tests usually include complete blood count, assay of the β subunit of human chorionic gonadotropin (hCG), and thyroid-stimulating hormone (TSH).

A. History

Many causes of bleeding are strongly suggested by the history alone. Note the amount of menstrual flow, the length of the menstrual cycle and menstrual period, the length and amount of episodes of intermenstrual bleeding, and any episodes of contact bleeding. Note also the last menstrual period, the last normal menstrual period, age at menarche and menopause, and any changes in general health. The patient must keep a record of bleeding patterns to determine whether bleeding is abnormal or only a variation of normal. However, most women have an occasional menstrual cycle that is not in their usual pattern. Depending on the patient's age and the pattern of the bleeding, observation may be all that is necessary.

B. Physical Examination

Abdominal masses and an enlarged, irregular uterus suggest myoma. A symmetrically enlarged uterus is more typical of adenomyosis or endometrial carcinoma. Atrophic and inflammatory vulvar and vaginal lesions can be visualized, and cervical polyps and invasive lesions of cervical carcinoma can be seen. Rectovaginal examination is especially important to identify lateral and posterior spread or the presence of a barrel-shaped cervix. In pregnancy, a decidual reaction of the cervix may be the source of bleeding. The appearance is a velvety, friable erythematous lesion on the ectocervix.

C. Cytologic Examination

Although most useful in diagnosing asymptomatic intraepithelial lesions of the cervix, cytologic smears can help screen for invasive cervical (particularly endocervical) lesions. Although cytology is not reliable for the diagnosis of endometrial abnormalities, the presence of endometrial cells in a postmenopausal woman is abnormal unless she is receiving exogenous estrogens. Likewise, women in the secretory phase of the menstrual cycle should not shed endometrial cells. Of course, a cytologic examination that is positive or suspicious for endometrial cancer demands further evaluation.

Tubal or ovarian cancer can be suspected based on a cervical smear. The technique of obtaining a smear is important, because a tumor may be present only in the endocervical canal and may not shed cells to the ectocervix or vagina. Laboratories should report the presence or absence of endocervical cells. The current use of a spatula and endocervical brush has significantly increased the adequacy of cytologic smears from the cervix. Any abnormal smear requires further evaluation (see Chapter 48).

D. Pelvic Ultrasound Scan

Pelvic ultrasonography has become an integral part of the gynecologic pelvic examination. The scan can be performed either transvaginally or transabdominally. The transvaginal examination is performed with an empty bladder and enables a closer look with greater details at the pelvic organs. The transabdominal examination is performed with a full bladder and enables a wider, but less discriminative, examination of the pelvis. The ultrasound scan can add many details to the physical examination, such as a description of the uterine lining and its width and regularity (Fig. 38–1) and the presence of intramural or submucous fibroids (Fig. 38–1), intrauterine polyps, and adnexal masses. Persistent thick and irregular endometrium is one of the preoperative predictors of endometrial pathology and demands further evaluation and tissue biopsy.

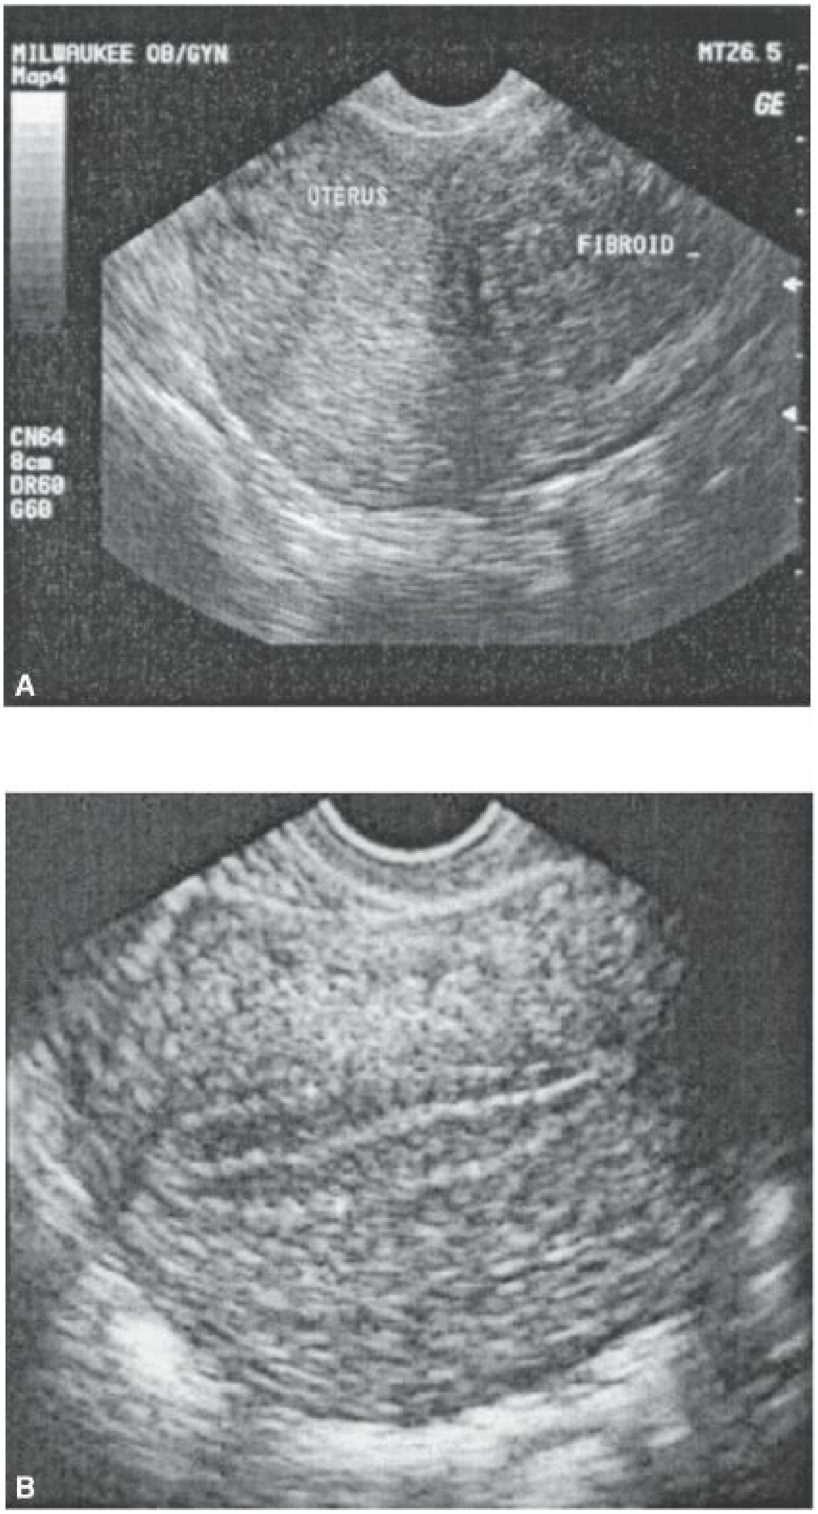

Figure 38–1. Typical ultrasound scan of a uterine fibroid (**A**) and normal endometrial lining (**B**).

Sonohysterography is a modification of the pelvic ultrasound scan. The ultrasound is performed following injection of saline by a thin catheter into the uterus. This technique increases significantly the sensitivity of transvaginal ultrasonography and has been used to evaluate the endometrial cavity for polyps, fibroids, and other abnormalities.

F. Endometrial Biopsy

Methods of endometrial biopsy include use of the Novak suction curette, the Duncan curette, the Kevorkian curette, or the Pipelle. Cervical dilatation is not necessary with these instruments. Small areas of the endometrial lining are sampled.

If bleeding persists and no cause of bleeding can be found or if the tissue obtained is inadequate for diagnosis, hysteroscopy and, in some cases, formal dilatation and curettage (D&C) must be performed.

E. Hysteroscopy

Placing an endoscopic camera through the cervix into the endometrial cavity allows direct visualization of the cavity (Fig. 38–2). Because of its higher diagnostic accuracy and suitability for outpatient investigation, hysteroscopy is increasingly replacing D&C for the evaluation of abnormal uterine bleeding. Hysteroscopy currently is regarded as the gold standard evaluation of pathology in the uterine cavity. Resection attachments allow immediate capability to remove or biopsy lesions.

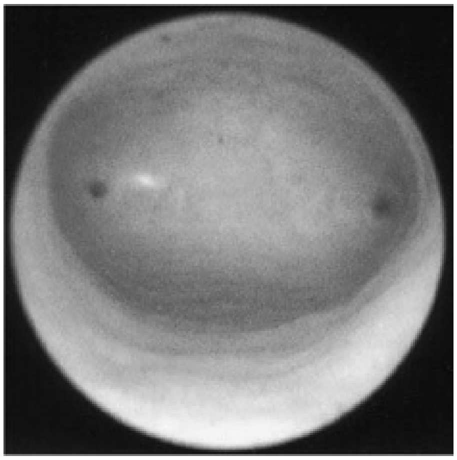

Figure 38–2. Hysteroscopic view of the uterine cavity.

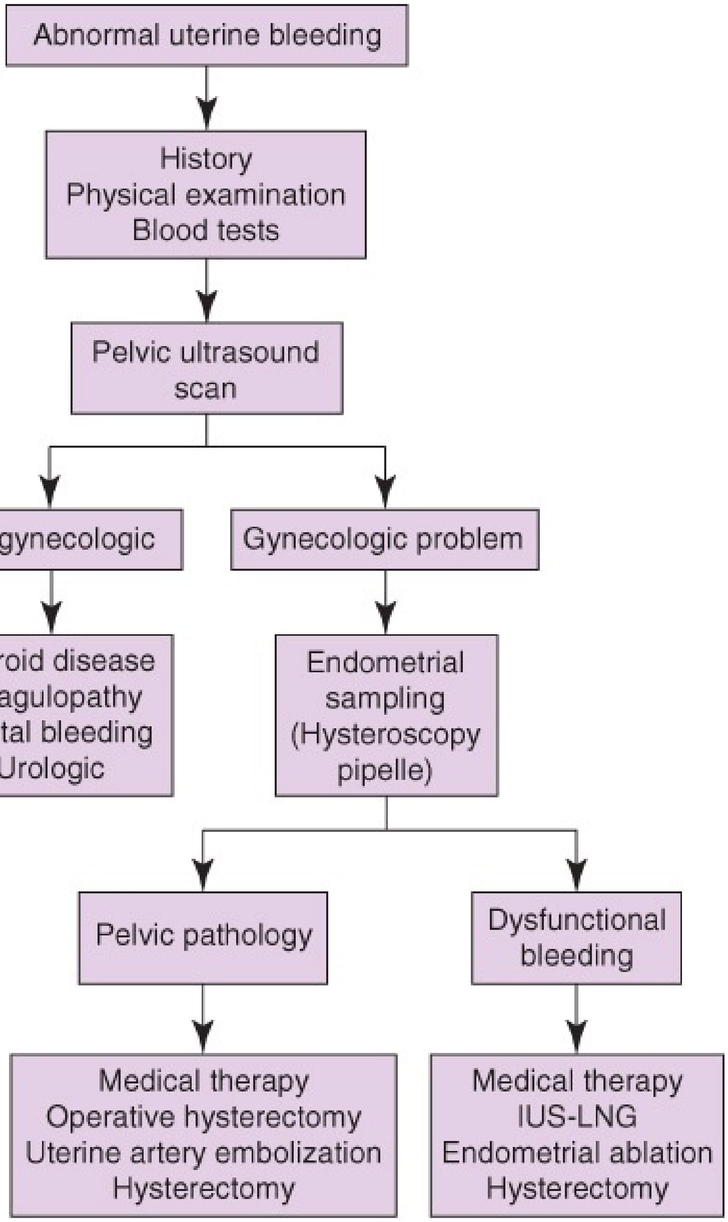
G. Dilatation & Curettage

For many years, D&C has been regarded as the gold standard for the diagnosis of abnormal uterine bleeding. It can be performed with the patient under local or general anesthesia, almost always in an outpatient or ambulatory setting. With general anesthesia, relaxation of the abdominal musculature is greater, allowing for a more thorough pelvic examination, more precise evaluation of pelvic masses, and more complete curettage. Nevertheless, D&C is a blind procedure, and its accuracy, particularly when the cause of the abnormal uterine bleeding is a focal lesion such as a polyp, is debatable.

General Principles of Management (Fig. 38–3)



Abnormal uterine bleeding
History
Physical examination
Blood tests
Pelvic ultrasound scan
Nongynecologic
Gynecologic problem
Thyroid disease
Coagulopathy
Rectal bleeding
Urologic
Endometrial sampling (Hysteroscopy pipelle)
Pelvic pathology
Dysfunctional bleeding
Medical therapy
Operative hysterectomy
Uterine artery embolization
Hysterectomy
Medical therapy
IUS-LNG
Endometrial ablation
Hysterectomy

Figure 38–3. General principles of management of abnormal uterine bleeding. IUS-LNG, intrauterine system-levonorgestrel releasing.

In making the diagnosis, it is important not to assume the obvious. A careful history and pelvic examination are vital. The possibility of pregnancy must be considered, as well as use of oral contraceptives, IUDs, and hormones.

Another important evaluation during the workup of abnormal uterine bleeding is to decide whether the bleeding is associated with ovulatory or anovulatory cycles. In ovulatory cycles, the bleeding might be due to a persistent corpus luteum cyst or short luteal phase. In anovulatory cycles, the endometrium outgrows its blood supply, partially breaks down, and is sloughed in an irregular manner. In these cases, an organic cause of anovulation must be excluded (eg, thyroid or adrenal abnormalities). Conversion from proliferative to secretory endometrium (by combined oral contraceptive pills or progesterone in the luteal phase) corrects most acute and chronic bleeding problems.

Improved diagnostic techniques and treatment have resulted in decreased use of hysterectomy to treat abnormal bleeding patterns. If pathologic causes (eg, submucous myomas, adenomyosis) can be excluded, if there is no significant risk for cancer development (as from atypical endometrial hyperplasia), and if there is no acute life-threatening hemorrhage, most patients can be treated with hormone preparations or minimally invasive procedures, which are considered as alternatives to hysterectomy. Myomectomy (hysteroscopic, laparoscopic, or conservative) can be suggested for treatment of myoma if the patient wishes to retain her childbearing potential. Endometrial ablation and endometrial resection may offer successful outpatient and in-office alternatives.

For menorrhagia, antifibrinolytic therapy has been shown to significantly decrease blood loss during menses, as have prostaglandin synthetase inhibitors. Long-acting intramuscular progestin administration (Depo-Provera) can be given but may result in erratic bleeding or even amenorrhea. Finally, levonorgestrel-releasing IUDs are as effective as endometrial resection in decreasing blood loss.

1. ABNORMAL UTERINE BLEEDING DURING PREGNANCY

See Chapter 18.

2. ABNORMAL BLEEDING DUE TO NONGYNECOLOGIC DISEASES & DISORDERS

In the differential diagnosis of abnormal bleeding, nongynecologic causes of bleeding (eg, rectal or urologic disorders) must be ruled out, because patients may have difficulty differentiating the source of bleeding. Gynecologic and nongynecologic causes of bleeding may coexist. Systemic disease may cause abnormal uterine bleeding. For example, myxedema usually causes amenorrhea, but less severe hypothyroidism is associated with increased uterine bleeding. Liver disease interferes with estrogen metabolism and may cause variable degrees of bleeding. Both of these conditions are usually clinically apparent before gynecologic symptoms appear. Blood dyscrasias and coagulation abnormalities can also produce gynecologic bleeding. Patients receiving anticoagulants or adrenal steroids may expect abnormalities. Extreme weight loss due to eating disorders, exercise, or dieting may be associated with anovulation and amenorrhea.

3. DYSFUNCTIONAL UTERINE BLEEDING

Exclusion of all possible pathologic causes of abnormal bleeding establishes the diagnosis of dysfunctional uterine bleeding (nearly 60% of cases). Dysfunctional bleeding occurs most commonly at the extremes of reproductive age (20% of cases occur in adolescents and 40% in patients over age 40 years). Management depends on the age of the patient (adolescent, young woman, or premenopausal woman).

Treatment

A. Adolescents

Because the first menstrual cycles frequently are anovulatory, the menses not unusually are irregular, and explanation of the reason is all the treatment that is necessary. Heavy bleeding—even hemorrhage—may occur. Invasive diagnostic procedures usually are not necessary in young patients, but physical (pelvic or rectal if possible) examination, pelvic ultrasonography, and basic blood tests must be performed to exclude pregnancy or pathologic conditions. Estrogens given orally should be adequate for all patients except extremely rare cases requiring curettage to control hemorrhage. Numerous regimens are available, including estrogens followed by progesterone, progesterone alone, or combination oral contraceptives. For acute hemorrhage, high-dose estrogen given intravenously (25 mg conjugated estrogen every 4 hours) gives rapid response. In hemodynamically stable patients, the oral dose of conjugated estrogens is 2.5 mg every 4–6 hours for 14–21 days. Once bleeding has stopped, medroxyprogesterone acetate 5 mg once or twice per day should be given for 7–10 days.

Oral contraceptives, 3–4 times the usual dose, are just as effective and may be simpler to use than sequential hormones. Again, the dose is lowered after a few days, and the lower dose is continued for the next few cycles, particularly to raise the hemoglobin levels in an anemic patient. Medroxyprogesterone acetate 10 mg/d for 10 days can be given to patients who have proliferative endometrium on biopsy. In patients receiving cyclic therapy, 3–6 monthly courses are usually administered, after which treatment is discontinued and further evaluation performed if necessary. In adolescents in whom the bleeding is not severe, oral contraceptives can be used as normally prescribed.

B. Young Women

In patients 20–30 years old, pathologic causes are similarly not very common, and the appropriate diagnostic procedures should be considered after the initial evaluation by history, physical and cytologic examination, and pelvic ultrasound. Hormonal management is the same as for adolescents.

C. Premenopausal Women

In the later reproductive years, even more care must be given to excluding pathologic causes because of the possibility of endometrial cancer. The initial evaluation should be complemented by hysteroscopy and endometrial biopsy and should clearly establish anovulatory or dyssynchronous cycles as the cause before hormonal therapy is started. Recurrences of abnormal bleeding demand further evaluation.

D. Surgical Measures

For patients whose bleeding cannot be controlled with hormones, who are symptomatically anemic, and whose lifestyle is compromised by persistence of irregular bleeding, D&C may temporarily stop bleeding. If bleeding persists, levonorgestrel-releasing IUDs or a minimally invasive procedure such as endometrial ablation may be offered. Studies have shown that approximately 80% of patients scheduled for hysterectomy changed their minds following endometrial ablation. However, if these minimally invasive procedures fail or if the patient prefers a definitive solution, hysterectomy may be necessary. Definitive surgery may also be needed for coexistent endometriosis, myoma, and disorders of pelvic relaxation.

4. POSTMENOPAUSAL BLEEDING

Postmenopausal bleeding may be defined as bleeding that occurs after 12 months of amenorrhea in a middle-aged woman. When amenorrhea occurs in a younger person for 1 year and premature ovarian failure or menopause has been diagnosed, episodes of bleeding may be classified as postmenopausal, although resumption of ovulatory cycles can occur. Follicle-stimulating hormone (FSH) levels are particularly helpful in the differential diagnosis of menopausal versus hypothalamic amenorrhea. An FSH level greater than 30 mIU/mL is highly suggestive of menopause.

Postmenopausal bleeding is more likely to be caused by pathologic disease than is bleeding in younger women and must always be investigated. Nongynecologic causes must be excluded; these causes are more likely to result from pathologic disease in older women, and patients may be unable to determine the site of bleeding. The source of bleeding should not be assumed to be nongynecologic unless there is good evidence or proper evaluation has excluded gynecologic causes.

Neither normal (“functional”) bleeding nor dysfunctional bleeding should occur after menopause.

Although pathologic disorders are more likely, other causes may also occur. Atrophic or proliferative endometrium is not unusual. Secretory patterns should not occur unless the patient has resumed ovulation or has received progesterone therapy. After nongynecologic causes of bleeding are excluded, gynecologic causes must be considered.

Exogenous Hormones

The most common cause of postmenopausal uterine bleeding is the use of exogenous hormones. In the past, face creams and cosmetics contained homeopathic amounts of estrogens, but today, this cause is highly unlikely. Careful history taking becomes vital, because patients may not follow specific instructions on the use of estrogen and progesterone therapy.

In light of the new caution placed on postmenopausal hormone replacement therapy (HRT) because of cardiovascular risks, long-term estrogen/progesterone administration for prevention of osteoporosis is no longer recommended. Women continue HRT for menopausal symptoms to improve their quality of life. Regular menstrual bleeding may resume if they take HRT agents cyclically. Not uncommonly, these patients present with vaginal bleeding as many as 6–12 months after initiation of HRT. If bleeding is still occurring by that time, further investigation is warranted to determine its etiology. If endometrial hyperplasia is found, specific attention must be paid to the presence of atypia and treatment started by increasing the progesterone component or by hysterectomy.

Vaginal Atrophy & Vaginal & Vulvar Lesions

Bleeding from the lower reproductive tract almost always is related to vaginal atrophy, with or without trauma. Examination reveals thin tissue with ecchymosis. Rarely, a tear at the introitus or deep in the vagina requires suturing. With vulvar dystrophies, a white area and cracking of the skin of the vulva may be present. Cytologic study of material obtained from the cervix and vagina will reveal immature epithelial cells with or without inflammation. After coexisting upper tract lesions are excluded, treatment can include local or systemic estrogen therapy for vaginal lesions. Vulvar lesions require further diagnostic evaluation to determine the proper treatment.

Tumors of the Reproductive Tract

The differential diagnosis of organic causes of postmenopausal uterine bleeding includes endometrial hyperplasias (simple, complex, and atypical), endometrial polyps, endometrial carcinoma or other more rare tumors such as cervical or endocervical carcinoma, uterine sarcomas (including mixed mesodermal and carcinosarcomas), and, even more rarely, uterine tube and ovarian cancer. Estrogen-secreting ovarian tumors also should be considered.

Uterine sampling must be done and tissue obtained. Endocervical curettage should be performed, along with any endometrial sampling technique. If a diagnosis cannot be established or is questionable with office procedures, D&C is necessary. Hysteroscopy performed in the office or operating room may prove helpful in locating endometrial polyps or fibroids that could be missed even by fractional curettage. Pelvic ultrasonography may be extremely helpful in the diagnosis of ovarian tumors and in evaluation of the thickness of the endometrium, as well as in discerning between uterine myomas and adnexal tumors. Recurring episodes of postmenopausal bleeding may rarely require hysterectomy, even when a diagnosis cannot be established by endometrial sampling.

Benign Disorders of the Vulva & Vagina

Jacob Bornstein MD, MPA

Disorders of the vulva and vagina are very common and cause considerable discomfort. Until recently, however, our understanding of vulvar conditions has been scant due to the lack of communication between gynecologists, dermatologists, pathologists, and sex therapists, each with his or her own ideas of the natural history, mode of diagnosis, and preferred therapy. An obvious consequence is the propagation of terms for the same disorders. The establishment in 1970 of the International Society for the Study of Vulvovaginal Disease (ISSVD) fostered exchange of ideas, collective discussion, and understanding of the natural history and modern treatment of vulvar diseases. Common terminology was established. The terminology of benign vulvar and vaginal disorders used in this chapter is based on the guidelines of the ISSVD. The morphologic and functional approach is accessible to the novice in vulvar and vaginal disease. At the same time it emphasizes breakthroughs in the understanding of the different vulvar pain syndromes, the influence of the vaccine against human papillomavirus (HPV) on vulvar diseases, and the modern treatment of the vulvar dermatoses. The premalignant and malignant vulvar and vaginal disorders are discussed in Chapter 47.

ANATOMY & PHYSIOLOGY

The anatomy of the vagina and vulva is described in Chapter 1. In recent years the vulvar vestibule, the site of origin of vestibulodynia, the “provoked” vulvar pain of dyspareunia, has been a focus of attention. Although the vulvar skin is devoid of estrogen receptors, the development of vaginal disorders is influenced by the presence or absence of endogenous or exogenous estrogen. Estrogen thickens the vaginal epithelium, which leads to the accumulation of glycogen in the epithelial cells. The intraepithelial glycogen metabolizes to lactic acid. The resultant vaginal pH of 3.5–4.0 promotes the growth of normal vaginal flora, chiefly lactobacilli and acidogenic corynebacteria. Asymptomatic *Candida* organisms may be present in small quantities.

ESSENTIALS OF DIAGNOSIS

Evaluation of a patient with vulvar and/or vaginal symptoms requires the following:

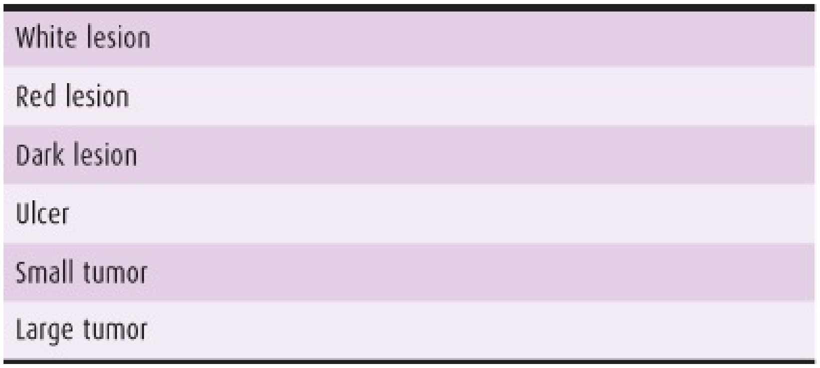
- ▸ A meticulous review of physiologic systems to reveal underlying medical conditions that may lead to vulvar symptoms.
  - Diabetes mellitus may be associated with vulvar pruritus or pain as a consequence of vulvovaginal candidiasis or, in advanced cases, as a result of neuropathic pain.
  - Elevated serum levels of biliary salts, such as in biliary stasis or primary biliary cirrhosis, may cause vulvar pruritus.
  - Hematologic disorders such as polycythemia or lymphoma may be associated with systemic symptoms, including vulvar pruritus.
  - A complete history of potential causes of vulvar irritation, including creams, powders, soaps, type

  of underwear, and cleansing techniques, should be reviewed.
  - Assessment of compliance to previous prescriptions may help determine whether failure of past treatments is attributable to incorrect diagnosis or to inadequate treatment.
  - Patients sometimes refrain from the use of common medications for vulvar disease due to their high potency or potential for side effects. Typical examples are systemic or potent topical steroids such as clobetasol propionate (Dermovate) and tricyclic antidepressants such as amitriptyline.
  - Information regarding previous infections should be elicited.
  - Sexual activity, although sensitive to both patient and healthcare provider, needs evaluation.
  - The use of feminine hygiene products (eg, douching, soaps, perfumes) and medications (eg, pessaries, diaphragms, oral contraceptive pills, antibiotics) can alter the normal vaginal flora.
  - Overlying garments made of synthetic fabrics that retain heat and moisture can exacerbate vulvovaginal symptoms.

- Active inquiry about vulvar pain, discharge, and pruritus, as patients may fail to disclose these intimate matters.
- A physical examination including inspection of all mucosal and skin surfaces, because many skin conditions, such as psoriasis, seborrheic dermatitis, pemphigus, and lichen planus, can affect the vulva.
- A vaginal examination including evaluation of the physical, chemical, and microbiologic properties of vaginal discharge. The perianal region should be inspected, as many vulvar disorders affect it. Specimens and cultures may include vaginal wet prep and culture for yeast and bacteria. HPV DNA determination may be required.
- Vulvar examination: although examination of the vulva and vagina may be completed using a magnifying glass, a colposcopic examination (ie, “vulvoscopy,” “vaginoscopy” is preferred, especially if a biopsy is to be taken. Two processes are important in the diagnosis of vulvar and vaginal lesions:

1. Try to assess to which of the 6 morphologic types (Table 39–1) the lesion belongs. Then mentally browse the list of possible causes for that lesion.

Table 39–1. Morphologic classification of vulvovaginal disease.



White lesion
Red lesion
Dark lesion
Ulcer
Small tumor
Large tumor

2. Biopsy liberally any suspicious lesion, because in most cases the final diagnosis is based on histopathologic findings. Thus the vulvar biopsy is almost a universal requirement.

PRINCIPLES OF OBTAINING A VULVAR BIOPSY

A satisfactory full-thickness sample of the skin and tumor can be obtained with a dermatologic punch biopsy under local anesthesia. Many vulva experts endeavor not to compress the sample tissue so as to preserve the original morphology of the lesion. Inclusion of the lesion margins helps identify abnormal features. This is also important in case of an ulcer, as its center may be necrotic and noninformative. Hospitalization is not required in most cases. Bleeding can be controlled by local pressure, argentum nitrate application, or, in rare cases, by applying a stitch.

VULVAR DISORDERS

The color of vulvar epithelium or lesions depends principally on the width of keratin layer, vascularity of the dermis, thickness of the overlying epidermis, and the amount of intervening pigment, either melanin or blood pigment.

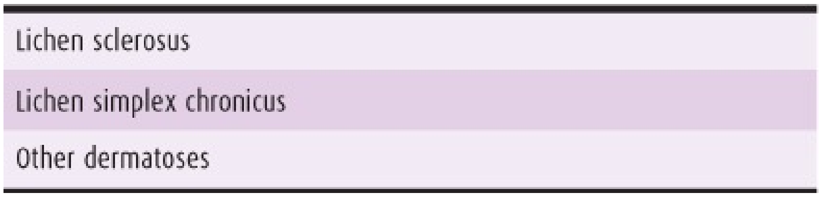
WHITE LESION

Pathogenesis

The white appearance of a lichenoid lesion of the vulva is primarily due to the maceration of a thickened keratin layer resulting from increased moisture in the vulvar area. The epidermal thickening of neoplasia obscures the underlying vasculature and, in conjunction with the macerating effects of the moist environment, usually produces a hyperplastic white lesion. A diffuse white lesion of the vulva may also occur with the loss or absence of melanin pigmentation as with vitiligo, a hereditary disorder. Leukoderma is a localized white lesion resulting from transient loss of pigment in a residual scar formed after healing of an ulcer.

Formerly, a white lichenoid lesion was termed **leukoplakia, kraurosis vulva**, and **senile vulvitis**. In 1976 Jeffcoate introduced the term **dystrophy**, but in 1987 the ISSVD changed the term to **nonneoplastic epithelial disorders of vulvar skin and mucosa** (Table 39–2). This term was coined to emphasize that excision procedures such as vulvectomy are not required, as this condition is not neoplastic. Implied by the term is the need of a biopsy for definitive diagnosis. The use of the term **dystrophy with atypia** has been abandoned, and lesions that contain atypia are now called **vulvar intraepithelial neoplasia** (VIN). They are described in Chapter 47.

Table 39–2. Classification of nonneoplastic epithelial disorders of vulvar skin and mucosa.



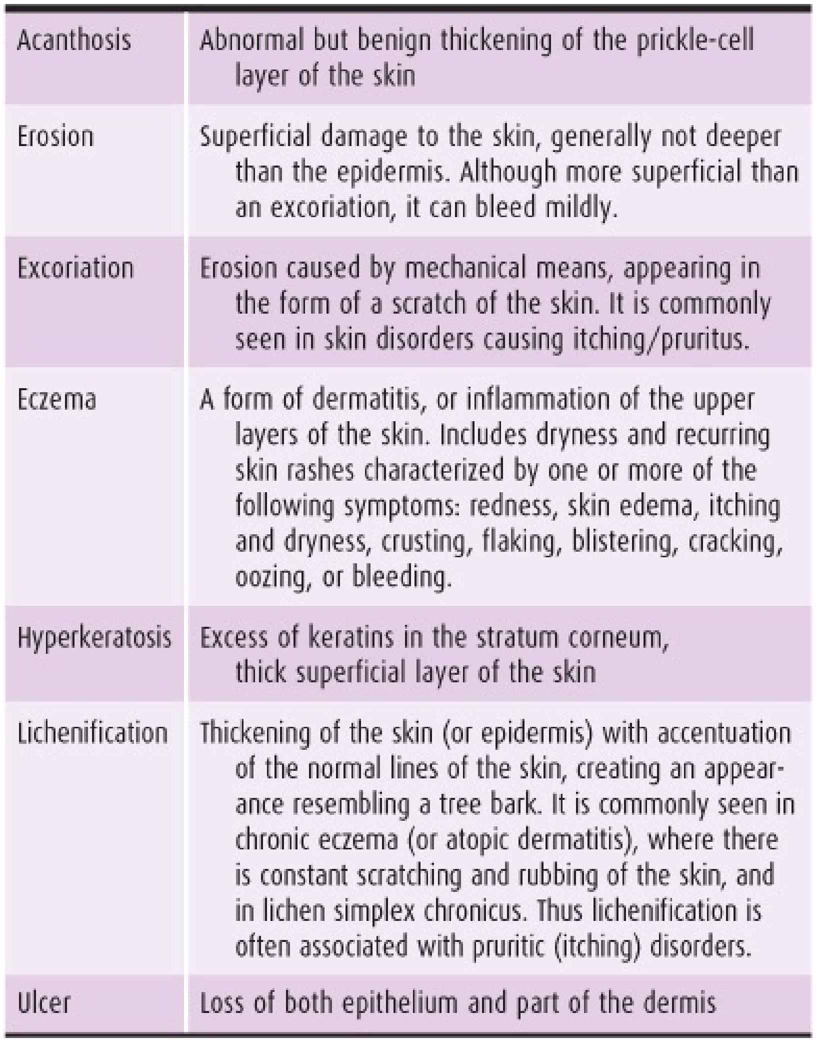
Lichen sclerosus
Lichen simplex chronicus
Other dermatoses

LICHEN SCLEROSUS

ESSENTIALS OF DIAGNOSIS

- Lichen sclerosus is the most common nonneoplastic epithelial vulvar disorder.
- Intense pruritus occurs, usually in women older than 60 years.
- The vulvar skin is thin, wrinkled, and white, with areas of lichenification and hyperkeratosis (see Table 39–3 for definitions).

Table 39–3. Dictionary of vulvar terms.



Acanthosis	Abnormal but benign thickening of the prickle-cell layer of the skin
Erosion	Superficial damage to the skin, generally not deeper than the epidermis. Although more superficial than an excoriation, it can bleed mildly.
Excoriation	Erosion caused by mechanical means, appearing in the form of a scratch of the skin. It is commonly seen in skin disorders causing itching/pruritus.
Eczema	A form of dermatitis, or inflammation of the upper layers of the skin. Includes dryness and recurring skin rashes characterized by one or more of the following symptoms: redness, skin edema, itching and dryness, crusting, flaking, blistering, cracking, oozing, or bleeding.
Hyperkeratosis	Excess of keratins in the stratum corneum, thick superficial layer of the skin
Lichenification	Thickening of the skin (or epidermis) with accentuation of the normal lines of the skin, creating an appearance resembling a tree bark. It is commonly seen in chronic eczema (or atopic dermatitis), where there is constant scratching and rubbing of the skin, and in lichen simplex chronicus. Thus lichenification is often associated with pruritic (itching) disorders.
Ulcer	Loss of both epithelium and part of the dermis

- The anterior parts of the labia minora of both sides agglutinate.
- Erosions, fissures, subepithelial hemorrhages, and ulcerations result from scratching.
- Biopsy is required.

Pathogenesis

Lichen sclerosus, a benign, chronic, inflammatory process, is the most common vulvar dermatologic disorder. Possible etiologic factors of this multifactorial condition include vitamin A deficiency, an autoimmune process, excess of the enzyme elastase, and decreased activity of 5-alpha reductase enzyme, which prevents the conversion of testosterone to dihydrotestosterone (the trophic hormone of the skin) and results in thinning of the skin. The effectiveness of treatment with topical testosterone cream supports the latter hypothesis.

Clinical Findings

A. Symptoms & Signs

This disease usually appears in women older than 60 years. Of the rare appearances in childhood, spontaneous resolution at adolescence occurs in approximately half. Most patients present with pruritus. Some complain of vulvar pain or dyspareunia and/or present with asymptomatic white lesions.

The progression and typical clinical characteristics of acute lichen sclerosus include the following:

1. Erythema and edema of vulvar skin
2. Development of white plaques representing lichenification and hyperkeratosis
3. Uniting of white plaques
4. Intense pruritus leading to scratch–itch cycle
5. Telangiectasias and subepithelial hemorrhages resulting from scratching
6. Erosions, fissures, and ulcerations

The progression and typical clinical characteristics of chronic lichen sclerosus include the following:

1. Thin, wrinkled, and white skin with a cigarette-paper appearance
2. Agglutination of the anterior parts of the labia minora of both sides to cover the clitoris and create phimosis (Fig. 39–1)

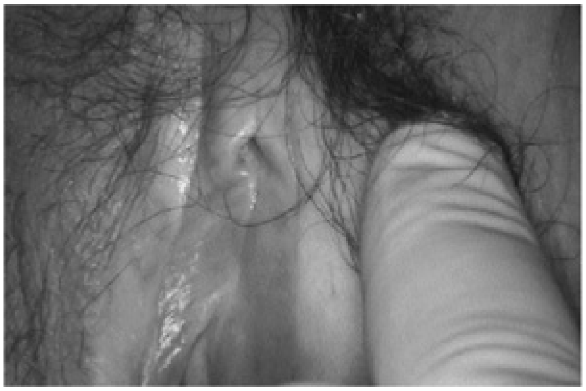


Figure 39–1. Advanced lesion of lichen sclerosus. The labia minora and prepuce of the clitoris have blended into the labial skin.

3. Contraction of the vulvar structures with resultant introital stenosis, previously termed **kraurosis**
4. Involvement of the perianal region in the form of 8: around the vulva and around the anus.
5. Development in some women of islands of hyperplastic epithelia within the atrophic lichen sclerosus epithelium

Histologic Findings

Definitive diagnosis depends on identification of the following 5 histologic features in the biopsy (Fig. 39–2):

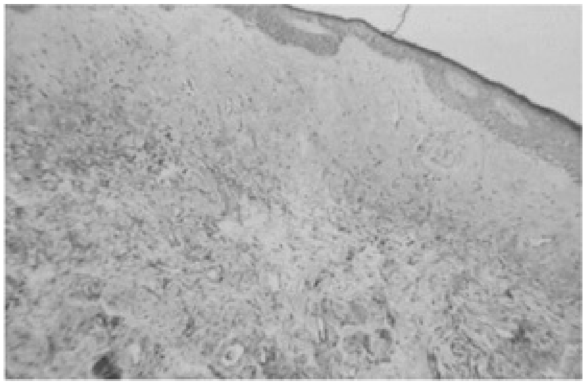

Figure 39–2. Microscopic appearance of lichen sclerosus, characterized by hyperkeratosis, flattened epidermis, and hyalinization of the dermis.

1. Thin hyperkeratotic layer
2. Thinning of the epithelial layer
3. Flattening of the papillae (Rete pegs)
4. Homogenization of the stroma
5. Deep lymphocytic infiltration

Differential Diagnosis

Other causes of a white lesion in the vulva are vitiligo, lichen simplex chronicus, and other dermatoses, such as psoriasis.

Complications

The high rate of squamous cell cancer in women with lichen sclerosus (3–5%) prompts biopsy of all new lesions. Cancer develops mainly in women who continue to suffer from vulvar itch or neglect treatment. It is expected that the introduction of clobetasole, an effective topical treatment for lichen sclerosus, may decrease the incidence of vulvar carcinoma developing from lichen sclerosus lesions.

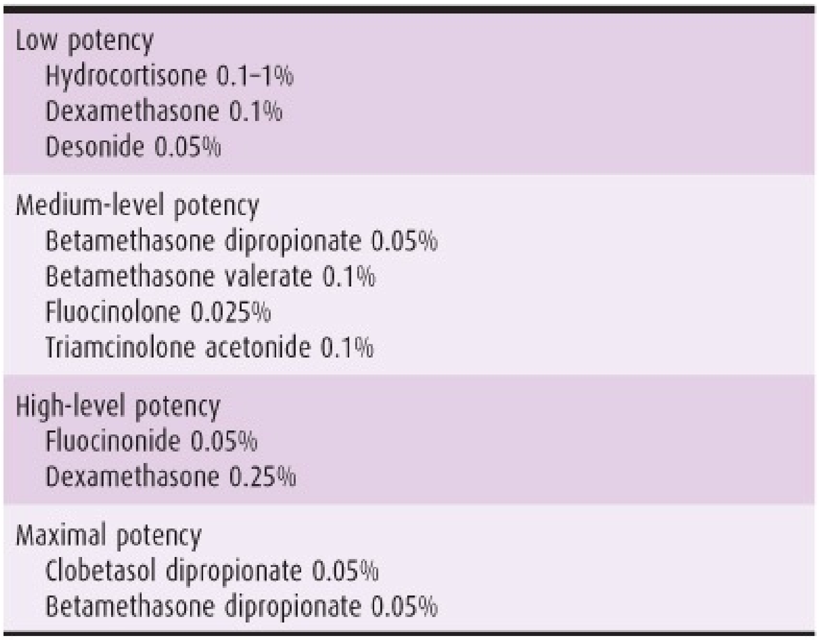
Treatment

The first step is to stop the itch–scratch cycle and minimize the dermal inflammation. General measures of vulvar hygiene should be applied: avoiding tight undergarments, cleansing daily with mild soap, and drying the vulvar skin with a hair dryer.

A. Medications

An oral antihistamine agent can be taken at bedtime. Although clobetasole dipropionate 0.05% (Dermovate) is a superpotent topical steroid (Table 39–4), it is recommended at the start to obtain immediate relief, stop the itch–scratch cycle, and reinstitute the patient’s belief in the health care provider. To prevent or minimize the side effects of this steroid, topical application should be in a small amount, similar to that of toothpaste on a toothbrush, twice daily for 2 weeks, then once daily for 2 weeks, then twice weekly for 2 weeks, and then as needed for the rest of the woman’s life. Some recommend tapering to a lower-potency topical steroid for treatment maintenance. Atrophic degeneration of the skin secondary to the steroid is rare.

Table 39–4. Potency of steroids.



Low potency Hydrocortisone 0.1–1% Dexamethasone 0.1% Desonide 0.05%
Medium-level potency Betamethasone dipropionate 0.05% Betamethasone valerate 0.1% Fluocinolone 0.025% Triamcinolone acetonide 0.1%
High-level potency Fluocinonide 0.05% Dexamethasone 0.25%
Maximal potency Clobetasol dipropionate 0.05% Betamethasone dipropionate 0.05%

Note: Only representative products are listed.

Some recommend tacrolimus cream, retinoid, antimalarial agents, or photodynamic therapy for these who do not respond to clobetasole. Surgical therapy should be limited to treatment of introital narrowing leading to dyspareunia or associated intraepithelial or invasive squamous cell neoplasia.

When nothing else relieves the itch, either of the following may be tried: intralesional injection of steroids or surgical undermining of the affected skin without excision, with the intention of undercutting the nerve fibers (Mering procedure).

The following 3 treatments, popular in the past, have been discontinued:

1. Topical application of 2% testosterone propionate ointment; less effective than clobetasole, it leads to virilization.
2. Intralesional injection of alcohol, a painful procedure that leads to sloughing of the vulvar tissues.
3. Vulvectomy; after this unnecessary mutilation, the disease tends to recur at the adjacent tissues.

Prognosis

The disease is chronic and usually recurs with cessation of treatment. The introduction of clobetasole dipropionate leads to resolution of symptoms in most patients and reversal of skin changes in approximately half of patients.

VULVAR LICHEN SIMPLEX CHRONICUS

Vulvar lichen simplex chronicus is the current term for the condition that includes the previously designated hyperplastic dystrophy, squamous cell hyperplasia, atopic dermatitis, atopic eczema, and neurodermatitis.

Clinical Findings

A. Symptoms & Signs

Vulvar lichen simplex chronicus is characterized by benign epithelial thickening and hyperkeratosis resulting from chronic irritation, such as from the use of perfumed pads or chronic vulvovaginal infections. The accompanying pruritus leads to rubbing and scratching, which becomes involuntary over time. As epithelial thickening develops, the humid environment of the vulva causes maceration, and a raised white lesion may become diffuse and even involve the adjacent thighs, perineum, or perianal skin.

Histopathologic Findings

Biopsy is necessary to exclude intraepithelial neoplasia and invasive tumor. Histologic examination demonstrates hyperkeratosis and acanthosis (see Table 39–3 for definitions), resulting in thickening of the epithelium and elongation of the rete pegs. In contrast to lichen sclerosus, there is no dermal inflammatory infiltrate.

Differential Diagnosis

Differential diagnosis includes the other nonneoplastic epithelial disorders such as lichen sclerosus, flat condyloma acuminatum, psoriasis, and vulvar intraepithelial neoplasia.

Treatment

Treatment of squamous cell hyperplasia starts with general measures of vulvar hygiene. Sitz baths and lubricants can help restore moisture to cells and reconstruct the epithelial barrier. Oral antihistamines may help relieve pruritus. In addition, topical application of medium-potency steroids twice daily can decrease the inflammation and pruritus. Vulvar epithelium takes at least 6 weeks to heal. For intractable cases, antidepressants or subcutaneous intralesional injection of steroids can be considered.

LICHEN PLANUS

Clinical Findings

Lichen planus rarely affects the vulva. It is a mucocutaneous dermatosis characterized by the presence of sharply marginated flat-topped papules on the skin and less sharply marginated white plaques on oral and genital mucous membranes. The pathogenesis is unknown. In the vulva 2 clinical aspects can be observed: classic leukoplastic lesions and erosive lesions. Vulvar erosive lichen planus seems to be more frequent but is often ignored. The clinical appearance of vaginal erosive lichen planus is similar to that of desquamative inflammatory vaginitis.

Treatment

Treatment of lichen planus is mainly topical, starting with hydrocortisone foam for the vagina (Colifoam). If unsuccessful, fluorinated corticosteroids, ultrapotent corticosteroids, or topical treatment with tacrolimus 0.1% can be tried. Careful and frequent examination of the vagina for formation of adhesions is important. In cases of severe pruritus and intensive mucocutaneous involvement, systemic steroids should be used. Introital stenosis and vaginal adhesions can be treated by use of vaginal dilators in graduated sizes or from surgical release of scars.

RED LESION

The red color of these lesions results from thinning epidermis, revealing capillary vasculature. Other causes are vasodilatation associated with inflammation and neovascularization of a neoplasia. Although they may manifest any acute dermatitis, red lesions are mainly associated with acute candidal vulvovaginitis. Vulvovaginitis is discussed later in this chapter, under Vaginal Disorders. Paget’s disease, a nonsquamous intraepithelial neoplasia characterized by an eczematous-like red lesion spreading over the vulvar skin, is discussed in Chapter 47. Other red lesions include seborrheic dermatitis, lupus erythematosus, and some cases of VIN. VIN also presents as a white or dark lesion and as an ulcer or tumor.

PSORIASIS

Psoriasis is a chronic relapsing dermatosis that affects the scalp, the extensor surfaces of the extremities, the trunk, and the vulva. Sometimes the vulvar skin is the only body surface affected. Primary lesions are raised and appear typically erythematous, resembling a candidal infection. Most lesions are sharply demarcated. The silver scaly crusts that characterize psoriasis on other parts of the body are usually absent; hence the lesion is red. Treatment includes topical corticosteroids.

DARK LESION

Dark lesions result from an increased quantity or concentration of melanin or hemosiderin pigments, sometimes subsequent to trauma. A persistent dark lesion on the vulva skin likely represents a nevus or a melanoma.

MELANOSIS OR LENTIGO

Melanosis or lentigo is a benign darkly pigmented flat lesion that may be mistaken for a melanoma. A nevus on the vulvar skin may be flat, slightly elevated, papillomatous, dome-shaped, or pedunculated. Melanomas of the vulva are uncommon neoplasms constituting only 1–3% of vulvar cancers. They are extremely aggressive malignant lesions and may arise from pigmented nevi of the vulva.

CAPILLARY HEMANGIOMA

Senile (cherry) hemangiomas are usually multiple, small, dark blue, asymptomatic papules that are discovered incidentally during examination of the older patient. Excision biopsy is needed only if the hemangiomas bleed repeatedly. A cryosurgical probe or carbon dioxide laser can also be used.

Childhood hemangiomas are usually diagnosed in the first few months of life. They may vary in size from small strawberry hemangiomas to large cavernous ones. They tend to be elevated and bright red or dark, depending on their size and the thickness of the overlying skin. Although tending to increase in size during the first few months of life, they often become static or regress without therapy after age 18 months. Although most of these hemangiomas only require observation, and not therapy, larger ones may require treatment with cryosurgery, argon laser therapy, or sclerosing solutions.

OTHER DARK LESIONS

In some VIN, melanin pigment that is not contained in atypical squamous cells concentrates in local macrophages, causing dark coloration of the tumor. Vulvar epithelium may darken after use of estrogen cream or oral contraceptive pills. Kaposi’s sarcoma, dermatofibroma, and seborrheic keratoses are examples of dark lesions. Biopsy of a dark lesion should include the whole lesion, as incomplete removal of melanoma has been suggested as a cause of accelerated spread.

ULCER

The most common cause of ulcerative lesion is a sexually transmitted disease (STD). The most common STD causing vulvar ulcer or erosion is herpes genitalis.

HERPES GENITALIS

ESSENTIALS OF DIAGNOSIS

- Frequently preceded by a prodrome: burning, itching and flu-like symptoms.
- Vesicles develop but erode rapidly, resulting in painful erosions or ulcer.
- Each erosion is surrounded by a red halo (Fig. 39–3).

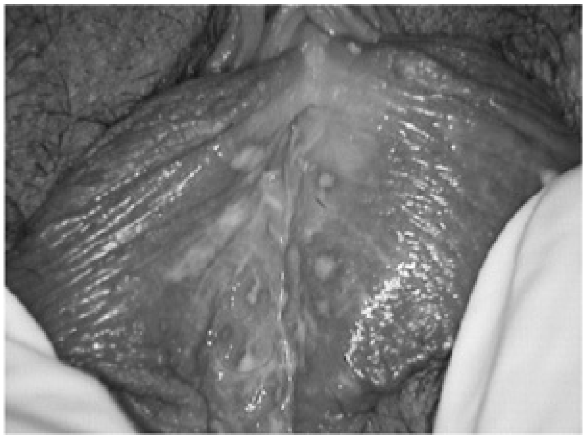


Figure 39–3. Ulcers of herpes genitalis. Each is surrounded by a red halo. The lesions are spread in a serpentine-like fashion.

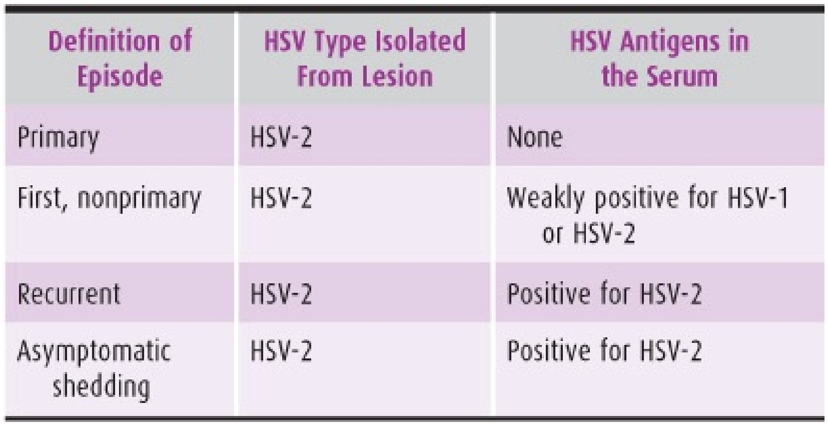
- Lesions are spread in a serpentine-like fashion.
- Recurrences are common.
- Only 20% of affected patients are diagnosed correctly.
- The gold-standard of diagnosis is viral culture. Other reliable tests are glycoprotein-G–based specific serology and polymerase chain reaction.

Herpesvirus hominis (herpes simplex virus [HSV], herpes genitalis) is responsible for recurrent and disabling symptomatic disease, venereal transmission, and infection to the neonate (ie, herpes encephalitis). HSV type 1 and type 2 are the variants that affect the vulva and vagina. Serologic prior exposure to HSV type 2 is evident in 20–25% of women. Approximately 83% of patients develop antibodies to HSV type 2 within 21 days of a primary infection. Approximately 60% of primary genital infections are by herpesvirus simplex type 2, and the remainder by type 1.

Pathogenesis

Infection occurs through intimate contact, mainly sexual intercourse. The virus contaminates secretions and mucosal surfaces, entering the skin and mucosa through cracks and other lesions. In turn, the erosions and ulcers of herpes simplex provide a port of entry to other sexually transmitted infections, such as HIV. The virus initially replicates in the dermis and epidermis and then stays latent in a nearby nerve ganglion. Incubation time is 2–7 days. Periods of viral shedding without any symptoms may occur (Table 39–5). This asymptomatic shedding is of particular concern. When unrecognized, the patient continues to have unprotected sexual intercourse, unknowingly transmitting the virus to her partner. This phenomenon is extremely common. For approximately half of the afflicted, asymptomatic viral shedding is identifiable within 1 year of the primary outbreak. Later, decreased viral shedding frequency, down to 2% at 10 years, makes detection difficult.

Table 39–5. Definition of episode of genital herpes infection.



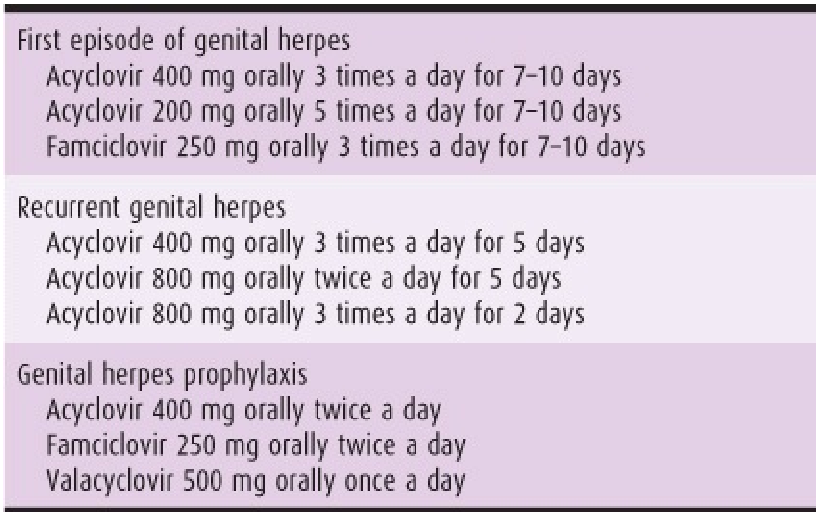
Definition of Episode	HSV Type Isolated From Lesion	HSV Antigens in the Serum
Primary	HSV-2	None
First, nonprimary	HSV-2	Weakly positive for HSV-1 or HSV-2
Recurrent	HSV-2	Positive for HSV-2
Asymptomatic shedding	HSV-2	Positive for HSV-2

Prevention

Avoidance of direct contact with active lesions prevents spread of the disease. Recommendations for prevention of dissemination are as follows:

- Precautions even in the absence of active lesions, due to asymptomatic shedding of the virus. The most frequent shedding occurs during the year after the first episode.
- Constant use of condoms. However, the condom does not prevent all infections, as lesions may develop in the area outside the tissue covered by the condom.
- The carrier in a serologically discordant couple should consider taking suppressive antiherpetic medication for prolonged periods.
- Administration of a prolonged suppressive therapy for individuals with 6 or more recurrences per year, patients who suffer from distressing prodromes or outbreaks, and men with lesions outside the area that can be protected by a condom (Table 39–6).

Table 39–6. Oral treatment of herpes genitalis.



First episode of genital herpes Acyclovir 400 mg orally 3 times a day for 7–10 days Acyclovir 200 mg orally 5 times a day for 7–10 days Famciclovir 250 mg orally 3 times a day for 7–10 days
Recurrent genital herpes Acyclovir 400 mg orally 3 times a day for 5 days Acyclovir 800 mg orally twice a day for 5 days Acyclovir 800 mg orally 3 times a day for 2 days
Genital herpes prophylaxis Acyclovir 400 mg orally twice a day Famciclovir 250 mg orally twice a day Valacyclovir 500 mg orally once a day

Clinical Findings

A. Symptoms & Signs

Prodromal symptoms of tingling, burning, or itching, as well as flu-like feeling with fever, malaise, headaches, and myalgia, may present shortly before the appearance of vesicular eruptions. The vesicles erode rapidly, resulting in painful erosions or ulcers (see Table 39–3 for definitions) distributed in small patches or involving most of the vulvar surfaces. Each lesion is surrounded by a red halo. The lesions appear in a serpentine-like fashion on the vulva, hence the name of the disease: herpes (from Latin, "serpentine, snake-like"). In contrast to the common myth, the typical herpes simplex skin lesion is not a vesicle but rather an erosion or ulcer. Bilateral inguinal adenopathy may be present. Urinary symptoms such as dysuria and urinary retention may develop, necessitating hospitalization and placement of a urinary catheter. In 20% of the cases, the primary infection is asymptomatic (Table 39–5). In 60% of the affected, herpesvirus infection is incorrectly diagnosed as a recurrent yeast infection. Lesions may persist for 2–6 weeks with no subsequent scarring.

Diagnosis

Due to the far-reaching implications on a woman and her relationship with her partner, genital herpes should be carefully diagnosed using the appropriate tests and after all other conditions in the differential diagnosis of vulvar ulcers are excluded.

The gold standard of diagnosis is viral culture on fibro-blasts. The virus can be cultured from vesicle fluid or a scraping from an erosion or an ulcer during the acute phase. However, organisms cannot usually be cultured after the primary lesions heal, which occurs within 2 weeks. Although polymerase chain reaction is a sensitive test to detect HSV DNA, its detection in a lesion may indicate a previous outbreak rather than a current event.

A smear scraped from the lesion and stained by Papanicolaou stain or Giemsa (Tzanck test) yields fast results, but is less sensitive and less specific than a culture. Cytologic characteristics of genital herpes include the following:

1. Giant cells
2. Multiple nuclei
3. Molding of the nuclei (compression of one into another)
4. Ground-glass appearance

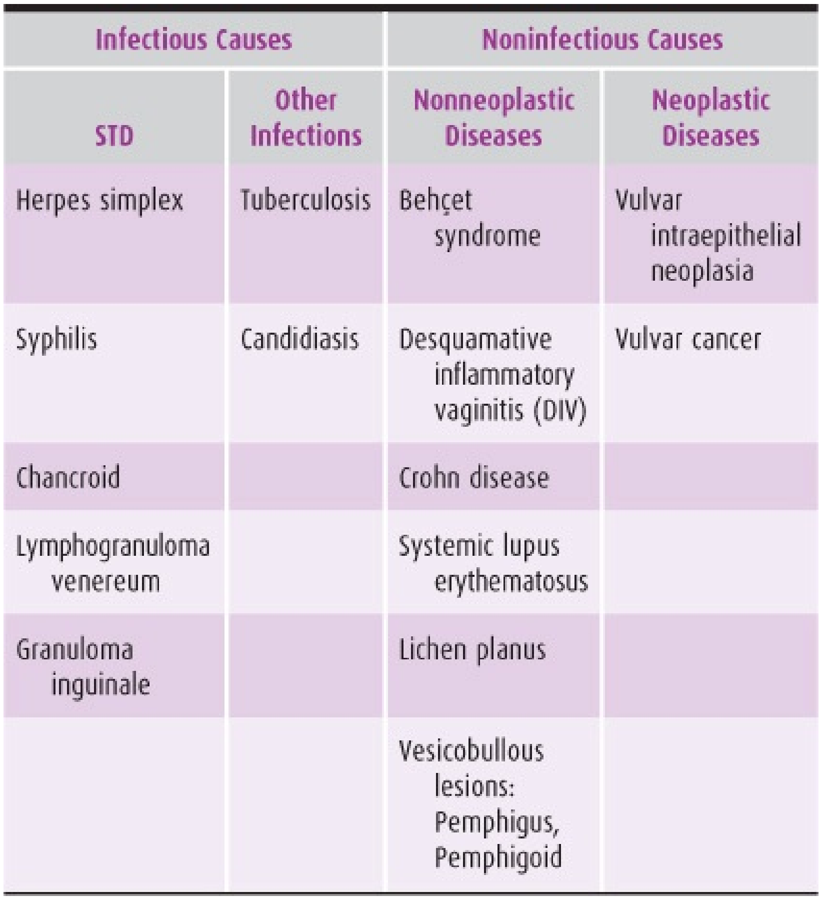
A. Serologic Tests

Approximately 85% of individuals develop immunoglobulin (Ig) M antibodies to HSV 2 virus within 21 days of exposure. In the past, serologic tests were unreliable because they could not differentiate between herpes virus types 1 and 2, which share approximately 80% of their antigens. New type-specific serologic tests for herpes simplex virus are now available. To distinguish between herpes simplex types 1 and 2, the IgG and IgM antibodies of the type-specific glycoprotein G–based assays should be specifically requested.

Differential Diagnosis

Sometimes the first referral is for a vulvar ulcer of unknown etiology. Although genital herpes is the most frequent cause of vulvar ulcer, other causes, mainly sexually transmitted infections such as syphilis, chancroid, and lymphogranuloma venereum, exist as well (Table 39–7). Noninfectious causes include Behçet's syndrome and desquamative inflammatory vaginitis (DIV), which are discussed later in this chapter. Of particular significance in the differential diagnosis is vulvovaginal candidiasis, recognized as the “great imitator” of genital herpes. Itching and considerable erythema usually present in vulvar and vaginal candidiasis. Persistent scratching can lead to small ulcers or excoriations (see Table 39–3 for definition) that resemble herpetic lesions. Many physicians diagnose any burning, itching, and erythematous lesion in the vulva as vulvar candidiasis and treat with antifungal medications. As a result, many cases of genital herpes are misdiagnosed. Suspicion for genital herpes should increase when a lesion is particularly painful; when there is a complaint about ulcer or erosions, burning vulvar pain, nonspecific influenza-like symptoms, or referred pain to the legs; or when presumed candidiasis does not heal after 1 course of therapy.

Table 39–7. The differential diagnosis of vulvar ulcers.



Infectious Causes		Noninfectious Causes	
STD	Other Infections	Nonneoplastic Diseases	Neoplastic Diseases
Herpes simplex	Tuberculosis	Behçet syndrome	Vulvar intraepithelial neoplasia
Syphilis	Candidiasis	Desquamative inflammatory vaginitis (DIV)	Vulvar cancer
Chancroid		Crohn disease	
Lymphogranuloma venereum		Systemic lupus erythematosus	
Granuloma inguinale		Lichen planus	
		Vesicobullous lesions: Pemphigus, Pemphigoid	

Complications

In addition to pain and discomfort, herpes genitalis entails social and psychologic implications, such as stigmatization and apprehension of recurrent outbreaks during which sexual activity should be abstained. Furthermore, there is a moral obligation to forewarn every partner, before sexual intercourse, of the possibility of infection. The embarassment of self-disclosure may lead to reluctance to start a new relationship. To ease the stress, the health care provider should inform the patient that administration of acyclovir or its valine analog valcyclovir in a continuous prophylactic manner, as suppressive treatment, prevents outbreaks and reduces viral transmission.

A. Neonatal Herpes

The incidence of neonatal herpes simplex virus infection ranges from 1 in 1800 live births in California to 1 in 60,000 in England. Infection of the newborn is associated with a 60% mortality rate, and at least half of the survivors have significant neurologic and/or ocular sequelae. The risk of infection to an infant born vaginally to a woman with active primary genital infection is 40–50% and to one with recurrent infection, 5%. However, most infants who develop herpetic infection are born to women who have no history or clinical evidence of infection during pregnancy. Therefore, identification of women whose infants may be in jeopardy is difficult. All pregnant women should be asked whether they or their partners have had genital herpetic lesions. Women with a history of herpes can deliver vaginally if no clinical signs or symptoms of infection are present. Obtaining routine weekly vaginal cultures to detect herpes is no longer standard procedure. However, some physicians initiate suppressive antiviral therapy at 36 weeks to decrease the need for caesarean section in women with frequent outbreaks.

Treatment

The lesions of herpesvirus infection are self-limiting and heal spontaneously unless they become infected secondarily. Symptomatic treatment includes good genital hygiene, loose-fitting undergarments, cool compresses or sitz baths, and oral analgesics. Indications for hospitalization for a severe primary infection include urinary retention, severe headache or other systemic symptoms, and body temperature exceeding 38.3 °C (101 °F). Immunosuppressed patients are more prone to systemic dissemination and should be carefully managed. Treatment includes intravenous acyclovir for hospitalized patients and oral and/or topical antivirals for ambulatory patients. Recurrent herpes should be treated at the onset of prodromal symptoms or vesicle formation. If initiated early, 1-day treatment may suffice. Once-daily continuous prophylactic (suppressive) dosing for many years may be considered for frequent recurrent outbreaks, with 40–70% of patients free of recurrence at 1 year (Table 39–6).

Prognosis

Despite measurable humoral and cell-mediated immunity, reactivation of the virus occurs. After replication in the skin, the viral particles are transported along the peripheral sensory nerve fibers to the dorsal root ganglion, where latent infection is established. Exogenous factors known to contribute to activation of herpesvirus include fever, emotional stress, and menstruation. Immunocompromised patients are prone to develop extensive local disease and systemic dissemination. Whether frequent coitus promotes recurrent disease is unknown. Type 2 virus is more likely than type 1 to recur. Approximately 50% of patients have a recurrence within 6 months of the primary infection. The recurrent ulcers tend to be smaller, fewer in number, and confined to a constant area in the vulva, cervix, or vagina. Healing is generally complete in 1–3 weeks. The virus is not recoverable within 7 days of healing of recurrent lesions. Inguinal adenopathy and systemic symptoms generally do not occur with recurrent outbreaks. Primary infections can generally be distinguished from secondary infections based on clinical findings. Extragenital sites, such as the fingers (herpetic whitlow), buttocks, and trunk (eczema herpeticum, see Table 39–3), have been described.

BEHÇET’S SYNDROME

Behçet’s syndrome is a rare inflammatory disorder characterized by a classic symptom triad: (1) recurrent oral aphthae or ulcers, (2) recurrent genital aphtae or ulcerations, and (3) uveitis. The painful genital ulcers are preceded by small vesicles or papules and last for variable periods. Their borders are irregular. After healing, deep ulcerations may result in scarring or fenestration of the labia. Ocular lesions begin as superficial inflammation and may proceed to iridocyclitis and even blindness. In addition to the classic symptoms, the disease may cause thrombophlebitis or involve the joints in a form of monoarticular arthritis. Central nervous system symptoms manifest in severe disease. Susceptibility to Behçet’s disease is strongly associated with the HLA-B51 allele. Prevalence is highest in Eastern Europe and the Mediterranean. Although the exact etiology is unknown, the disease likely represents an underlying autoimmune process.

Behçet's syndrome, together with disseminated lupus erythematosus and pemphigus, should be included in the differential diagnosis of recurrent aphthous ulcers of the oral and vaginal mucosa. Ophthalmic examination and human leukocyte antigen typing can aid in diagnosis. Treatment starts with colchicine tablets. Topical and systemic corticosteroids provide immediate relief.

INVESTIGATION OF A VULVAR ULCER

Patient History

A thorough patient history should be taken, including the general health condition, because debilitating or chronic diseases such as AIDS can lead to chronic infections that generate ulcers. The patient should be asked about outbreaks of vulvar ulcers, as well as previous evaluations and their results. Recurrent lesions are typical of both genital herpes and Behçet's syndrome. Finally, the patient should be asked about any medications she takes. Severe allergic reactions, such as manifested by Stevens-Johnson syndrome, may also cause large ulcers in the vulva and vagina.

Physical Examination

A general physical checkup should include assessment of dermatologic diseases, such as lichen planus, which, in addition to the characteristic dark plaques in the back and limb areas, may appear as extensively desquamated skin and ulcers in the vulva. Pemphigus vulgaris, an autoimmune dermatologic disease with antibodies directed against intercellular sites of stratified squamous epithelium, may present as vesicobullous lesions in the vulva. The oral mucosae should be checked for aphthae or ulcers. Behçet's syndrome, Crohn's disease, lichen planus, and pemphigus vulgaris present as ulcerative lesions in both oral and genital skin and mucosa.

Specific Tests

Using dark-field microscopy, a sample from the base of the ulcer should be investigated for the presence of *Treponema pallidum*, the causative agent of syphilis. Cultures for HSV and serologic tests to exclude chlamydia, systemic lupus erythematosus, HIV, and syphilis should be taken. The absence of a clear diagnosis prompts a biopsy to enable visualization of granulomas and vasculitis apparent in Crohn's disease and Behçet's syndrome and to exclude malignant and pre-malignant tumors.

SMALL TUMORS

CONDYLOMA ACUMINATUM

ESSENTIALS OF DIAGNOSIS

- Asymptomatic white papillary growths, small at first, tend to coalesce (Fig. 39–4).

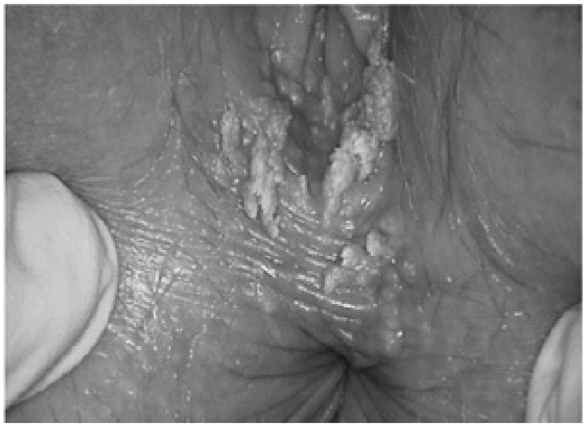


Figure 39–4. Vulvar and perineal condylomata acuminata.

- Affects the vulva, vagina, and cervix in women; the penis and scrotum in men; and the pubis, perineum, perianal, and oropharyngeal areas in both sexes.
- A colposcope is necessary to identify small and flat lesions.
- Biopsy may be needed to rule out neoplasia.
- Recurrent respiratory papillomatosis, characterized by laryngeal papillomas on the vocal cords, may develop in infants delivered through an infected vaginal canal.

Pathogenesis

The incubation period ranges from a few weeks to months, and sometimes years. Hence it is impossible to determine the day the viral infection was contracted. Condylomata acuminata (genital warts) are caused by the human papilloma virus (HPV), mainly types 6 and 11. Other types of HPV, particularly 16, 18, 45, 31, and 52, are responsible for intraepithelial and invasive neoplasia in the vagina, cervix, vulva, oropharynx, perineum, and perianal areas. The rate of HPV infection is high and rising. Worldwide, 30 million cases of genital warts (condylomata acuminata) are diagnosed annually. It is estimated that 30–60% of the population has been infected with HPV at some point in their lives. Clinical symptoms, however, present in fewer than 1%. The virus is small and contains all its genetic material on a single double-stranded molecule of DNA. Viral DNA probes have identified more than 35 types of HPV that infect the genital tract. Most HPV types cause asymptomatic infections. The viruses are sexually transmitted and infect both partners.

Prevention

Two vaccines against HPV are available: a bivalent vaccine against high-risk HPV types 16 and 18 and a quadrivalent vaccine against types 6, 11, 16, and 18. Administration is recommended before sexual debut. Both vaccines are intended to protect against cervical cancer and high-grade cervical intraepithelial neoplasia (CIN) caused by HPV 16 and HPV 18. Only the quadrivalent vaccine is designed to prevent condylomata acuminata and low-grade CIN caused by HPV 6 and HPV 11. The quadrivalent vaccine has been approved by the US Food and Drug Administration for women aged 9–45 years and men aged 9–26 years. Both prophylactic vaccines are aimed to prevent primary persistent infection and are targeted against the L1 gene product, which is the major protein of the HPV capsid. The vaccines are produced by inserting the HPV L1 gene into the DNA of the yeast *Saccharomyces cerevisiae* and creating a recombinant DNA. The yeast expresses the L1 capsid protein that spontaneously assembles into a virus-like particle (VLP). The VLP resembles the native HPV virus, but lacks the DNA core. Therefore, it does not carry any infectious or carcinogenic risk. The human immune system recognizes the VLP as if it were HPV itself, thus producing a neutralizing antibody response. The commercial vaccine contains the 97% purified VLP adsorbed onto an aluminum adjuvant, which varies between pharmaceutical companies. The adjuvant system 04 (AS04) of the bivalent vaccine more significantly accelerates an immune reaction.

Both vaccines demonstrate cross-protection, although against different HPV types. Both vaccines are safe and effective.

Clinical Findings

A. Symptoms & Signs

The typical condyloma is a white, exophytic, or papillomatous growth (Fig. 39–4). Papillary growths, small at first, tend to coalesce and form large cauliflower-like masses that may proliferate profusely. Condyloma acuminata may affect the vagina, cervix, vulva, oropharynx, perineum, and perianal areas.

The florid, papillomatous condyloma is a raised white lesion with fingerlike projections often containing capillaries. Although large lesions can be seen with the naked eye, the colposcope is necessary to identify smaller lesions. Colposcopic examination also permits identification of flat, spiked, and inverted condyloma. Flat condyloma appear as white lesions with somewhat granular surfaces. A mosaic pattern and punctation may also be present, suggesting VIN, which must be excluded by biopsy. Hyperkeratotic lesions present as spiked lesions, with surface projections and prominent capillary tips.

Differential Diagnosis

Other small tumors and cysts of the vulva, to be discussed later in this chapter, should be ruled out before diagnosing condylomata acuminata. In particular, molluscum contagiosum and epidermal and keratin cysts are look-alikes. Condyloma lata, a variation of secondary syphilis, should also be considered in differential diagnosis. Syphilis infection is discussed in Chapter 43.

Definitive diagnosis has medicolegal significance, because condylomata acuminata are sexually transmitted. In children they have been implicated as signs of sexual abuse.

Complications

Condylomatous warts may grow rapidly during pregnancy. Warts at the vaginal introitus may bleed during delivery and predispose the newborn to genital warts or recurrent respiratory papillomatosis (RRP). RRPs are laryngeal papilloma on the vocal cords that may, in rare cases, descend to the pulmonary parenchyma, present as recurrent pneumonia, and become fatal. However, unlike herpetic lesions, vulvar, vaginal, and cervical HPV lesions are not contraindications to a vaginal delivery, but rather require treatment during pregnancy. Condylomata that are recognized early in pregnancy should be treated at 30–32 gestational weeks to allow healing before delivery. When treatment is not successful, or the condylomata cover considerable vulvar area or tend to bleed, delivery by caesarean section should be considered.

Treatment

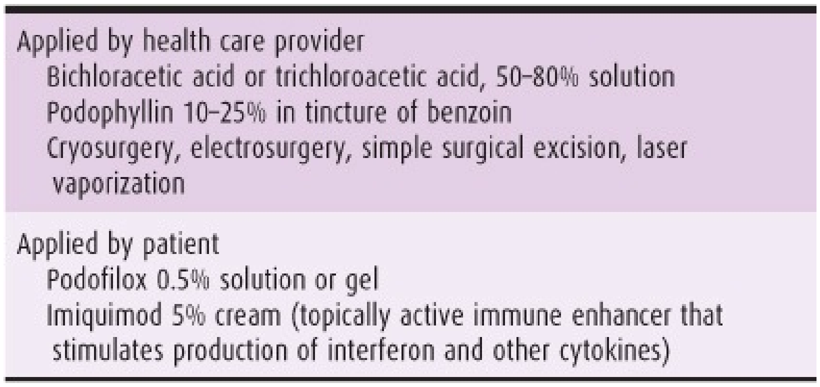
Before treatment is initiated, the entire lower genital tract should be examined with the colposcope and a cytologic smear taken from the cervix. Lesions may extend to the anal canal or urethral meatus. Treating condylomata only in the vulva, while disregarding others in the vagina or cervix, may result in frequent recurrences. Some recommend testing for syphilis, hepatitis B and C, chlamydia, and HIV due to comorbidity of sexually transmitted diseases. A biopsy may be indicated to rule out intraepithelial or invasive neoplasia. Natural infection after an outbreak produces a low-level, ineffective immune response. Recurrences after treatment may represent reinfection or clinical manifestation of latent disease. The virus presents in normal cells as well as in those with condylomatous changes; therefore, recurrence is common. Biopsy should be considered, especially if the cervix is involved, the condyloma does not respond to standard treatment, or the lesion is pigmented, indurated, fixed, and/or ulcerated. Normal micropapillae of the inner labia minora (vestibular micropapillomatosis) are often confused with papillary HPV and lead to unnecessary therapy. True HPV disease is patchy, with koilocytes, and with more intense acetowhite changes.

During treatment, the patient should keep the area as clean as possible and abstain from sexual intercourse or have her partner use a condom. If clinical disease recurs, then the sexual partner should be examined and treated as necessary. Penile, urethral, and perianal warts in the male may be overlooked.

Whether treatment actually affects the natural progression or eradicates HPV infection is unclear. Concomitant vulvovaginitis should be treated initially. Treatment should be based on patient preference and convenience. Table 39–8 details treatments of condylomata acuminata. If treatment fails with an initial regimen, a different agent can be used. Patients should be informed that, though rare, complications of treatment can result in adhesions, scarring, and loss of pigmentation.

Treatment may be self-administered by the patient or applied by the health care provider (Table 39–8). Clinical disease may appear on only a small area of the infected surface. Hence some specialists recommend CO_2 laser ablation of all visible lesions, plus a low-dose treatment (brushing), under colposcopic guidance, of a 1-cm margin of normal adjacent skin in all areas where subclinical HPV infection may coexist. Intralesional or systemic interferon has demonstrated effectiveness in refractory cases. Chemotherapeutic agents such as fluorouracil ointment or bleomycin in the form of intralesional injections can also be used as second-line therapies.

Table 39–8. Treatment of condyloma acuminata.



Applied by health care provider
Bichloracetic acid or trichloroacetic acid, 50–80% solution
Podophyllin 10–25% in tincture of benzoin
Cryosurgery, electrosurgery, simple surgical excision, laser vaporization
Applied by patient
Podofilox 0.5% solution or gel
Imiquimod 5% cream (topically active immune enhancer that stimulates production of interferon and other cytokines)

During pregnancy, electrocoagulation, cryotherapy, or CO_2 laser therapy should be administered at approximately 32 weeks to avoid, on one hand, post-treatment necrosis, which may last as long as 4–6 weeks, and to prevent, on the other hand, recurrence if treated too early. Podophyllin, podofilox, and imiquimod should not be used during pregnancy.

Prognosis

Recurrences are frequent with all treatment modalities. Prevention of recurrence is particularly difficult in patients who are immunosuppressed or currently receiving long-term corticosteroid therapy. Examination of sexual partners is not necessary because most partners are likely to have subclinical infection. The use of condoms for a few months after treatment may help in reducing “ping-pong” transmission to and from partners who may be infected.

MOLLUSCUM CONTAGIOSUM

These benign epithelial poxvirus-induced tumors are dome-shaped, with a typical umbilicus. Size varies, up to 1 cm. Lesions are often multiple and are mildly contagious. As mentioned above, they are look-alikes of condylomata acuminata. Under the microscope they appear as numerous inclusion bodies (molluscum bodies) in the cytoplasm of cells. Each lesion can be treated by desiccation, freezing, or curettage and chemical cauterization of the base. Topical imiquimod is an alternative therapy. Scarring is frequent.

EPIDERMAL CYSTS

Previously named keratin cysts, these cysts are of epidermal origin. They are lined with squamous epithelium and filled with oily material and desquamated epithelial cells. Epidermal inclusion cysts may result from suturing of skin fragments during closure of the vulvar mucosa and skin after trauma or episiotomy. However, most epidermal cysts arise from occlusion of pilosebaceous ducts. These cysts are usually small, solitary, and asymptomatic, but rarely become irritated or infected.

SEBACEOUS CYSTS

Sebaceous cysts develop when sebaceous gland ducts become occluded and sebaceous material accumulates. These cysts are frequently multiple and almost always involve the labia majora. Although generally asymptomatic, acutely infected cysts may require incision and drainage.

APOCRINE SWEAT GLAND CYSTS

Apocrine sweat glands, abundant in the skin of the labia majora and the mons pubis, become active after puberty. Occlusion of the ducts with keratin results in the extremely pruritic, microcystic Fox-Fordyce disease. This disease should be suspected in patients with consistent vulvar pruritus.

ACROCHORDON

An acrochordon is a flesh-colored, soft polypoid tumor of the vulvar skin, also called a *fibroepithelial polyp* or simply a *skin tag*. The tumor does not become malignant and is of no clinical importance, unless it becomes traumatized, causing bleeding. Simple excisional biopsy in the office is ordinarily adequate therapy.

LARGE TUMORS

BARTHOLIN’S DUCT CYST AND ABSCESS

Clinical Findings

Obstruction of the main duct of Bartholin’s gland results in retention of secretions and cystic dilatation. Infection is an important cause of obstruction; however, other causes include inspissated mucus and congenital narrowing of the duct. Secondary infection may result in recurrent abscess formation.

The gland and duct are located deep in the posterior third of each labium major, with the duct opening into the vestibule. Enlargement in the postmenopausal patient may reflect a malignant process (although the incidence is <1%), and biopsy should be considered.

Acute symptoms generally result from infection, which leads to pain, tenderness, dyspareunia, and even difficulty in walking with adducted thighs. The surrounding tissues become edematous and inflamed. A fluctuant, tender mass is usually palpable. Unless an extensive inflammatory process is present, systemic symptoms or signs of infection are unlikely.

Treatment

Primary treatment consists of drainage of the infected cyst or abscess, preferably by marsupialization or by insertion of a Word catheter (an inflatable bulb-tipped catheter). The incision should be made in the vestibule, close to the original orifice of the Bartholin's gland duct. Simple needle aspiration, or incision and drainage, may provide only temporary relief, as recurrent cystic dilatation may recur. Appropriate antibiotics should be administered if considerable inflammation develops. Excision of the cyst may be required in recurrent cases or in the postmenopausal patient.

LEIOMYOMA, FIBROMA, & LIPOMA

Tumors of mesodermal origin present infrequently on the vulva. However, they can become extremely large. Leiomyomas, arising from muscle in the round ligament, appear as firm, symmetric, freely mobile tumors deep in the substance of the labium majus. Fibromas, arising from proliferation of fibroblasts, vary in size from small subcutaneous nodules revealed incidentally to large polypoid tumors. Large tumors often undergo myxomatous degeneration and are very soft and cystic to palpation. Lipomas consist of a combination of mature fat cells and connective tissue. They can be differentiated from degenerated fibromas only by histopathologic examination. Small tumors can be removed under local anesthesia in the office. Large tumors require general anesthesia and operating room facilities. The diagnosis of sarcoma is based on histologic assessment.

NEUROFIBROMA

Neurofibromas are fleshy polypoid lesions that may manifest as solitary, solid tumors of the vulva or be associated with generalized neurofibromatosis (Recklinghausen's disease). Arising from the neural sheath, they are usually small lesions of no consequence. Multiple disfiguring tumors of the vulva may interfere with sexual function and require excision or vulvectomy.

GRANULAR CELL MYOBLASTOMA (SCHWANNOMA)

Granular cell myoblastoma is usually a solitary, painless, slow-growing, infiltrating but benign tumor of neural sheath origin, most commonly found in the tongue or integument. Approximately 7% involve the vulva. The infected area consists of small subcutaneous nodules 1–4 cm in diameter. With increasing size, they erode through the surface and result in ulcerations that may be confused with cancer. The margins of the tumor are indistinct, and wide local excision is necessary to completely excise the cells extending into contiguous tissues. The area of resection must be periodically re-examined and secondary excision performed promptly if recurrence is suspected.

VARICOSITIES

Clinical Findings

Varicosities of the vulva involve 1 or more veins. Severe varicosities of the legs and vulva may be aggravated during pregnancy. Symptomatic vulvar varices in a woman who is not pregnant are uncommon and may signify an underlying vascular disease, either primary or secondary to a tumor in the pelvis. Rupture of a vulvar varicosity during pregnancy may cause profuse hemorrhage. Pain and tenderness may be caused by acute phlebitis or thrombosis.

Treatment

Treatment of vulvar and vaginal varicosities is seldom necessary. Surgical intervention is generally required only in rare cases of rupture and hemorrhage. Persistent postpartum cases may be alleviated by injection of a sclerosing agent.

HEMATOMA

The vulva has a rich blood supply arising predominately from the pudendal vessels. A ruptured vessel, especially in a pregnant woman, can cause significant bleeding and hematoma formation due to the distensible nature of the vulvar tissue. In rare cases, intercourse leads to laceration with external bleeding or to hematoma that may dissect the tissues in the labia majora or the rectovaginal septum. After trauma, an ice pack should be applied. If the hematoma continues to expand, embolization of the vessel, which is usually a branch of the pudendal artery, is a new, noninvasive approach to control the bleeding. Alternatively, the area should be incised and any bleeders (which may be multiple) ligated. The wound can be packed and left open or closed with a drain in place, if appropriate. Antibiotics should be administered on an individual basis, depending on the initiating event and contamination in the area.

EDEMA

Clinical Findings

The loose integument of the vulva predisposes to the development of edema. Causes of vulvar edema include vascular or lymphatic obstruction resulting from an underlying neoplasm or infection such as lymphogranuloma venereum (LGV), vaginal delivery accompanied by frequent vaginal examinations, trauma from a bicycle accident (saddle injury) in a young girl, and a kick to the pudendum. Severe generalized vulvar edema may represent an underlying systemic illness such as congestive heart failure, nephrotic syndrome, preeclampsia, or eclampsia. Acute edema may result from a systemic or local allergic reaction, immobilization, or ovarian hyperstimulation syndrome.

Treatment

An ice pack applied to the perineum after an acute trauma tends to retard the development of severe edema. Ice application should be restricted to 15 minutes every hour to prevent cold burns. Warm packs or warm sitz baths may then be applied after 1–2 days to help resolve the associated inflammation and/or hematoma.

LYMPHANGIOMA

Lymphangiomas are tumors of the lymphatic vessels. They may be difficult to differentiate from hemangiomas microscopically unless blood cells are present within the blood vessels. Lymphangioma cavernosum may cause a diffuse enlargement of 1 side of the vulva and extend over the remainder of the vulva and perineum. A tumor that is sufficiently enlarged should be surgically excised. Lymphangioma simplex tumors (circumscription tumors) are usually small, soft, white, or purple nodules or small wartlike lesions most commonly seen on the labia majora. Usually asymptomatic, they do not require excision unless intense pruritus and excoriation present. Lymphangioma simplex tumors are not alleviated with topical measures.

OTHER VULVAR TUMORS

A number of other uncommon cystic vulvar tumors must be considered in the differential diagnosis of vulvar tumors. Anteriorly Skene’s duct cyst should be differentiated from urethral diverticulum, as careless incision of the latter may damage the urethra and result in urinary incontinence. An inguinal hernia may extend into the labium majus, causing a large cystic dilatation. Suspicion of an inguinal hernia is indication for ultrasound examination of the contents of the labial tumor. The appearance of peristaltic waves is evident that a hernia is in fact present. Occlusion of a persistent processus vaginalis (canal of Nuck) may cause a cystic tumor or hydrocele. Gartner’s duct cyst is a dilatation of the mesonephric duct vestiges, always at the lateral vaginal wall. Supernumerary mammary tissue that persists in the labia majora may form a cystic or solid tumor, or even an adenocarcinoma. Engorgement of such tissue in the pregnant patient can be symptomatic.

VULVAR MANIFESTATION OF SYSTEMIC DISEASES

LEUKEMIA

Rarely, nodular infiltration and ulceration of the vulva and rectovaginal septum occur with acute leukemia.

DERMATOLOGIC DISORDERS

Recurrent ulcerations of the mucous membranes of the mouth and vagina may be manifestations of disseminated lupus erythematosus. Bullous eruptions of apparently normal skin and mucous membrane surfaces of the vulva may be early signs of pemphigus vulgaris (a rare, chronic vesicobullous disease, associated with the autoimmune disease, keratinolysis). Contact dermatitis is an inflammatory response of the vulvar tissue to agents that may be either locally irritating or inductive of sensitivity on contact. The local reaction to a systemically administered drug is called dermatitis medicamentosa.

OBESITY

Acanthosis nigricans is a hyperpigmented lesion associated with obesity and is characterized by papillomatous hypertrophy. Although generally benign, it may be associated with an underlying adenocarcinoma. Pseudoacanthosis nigricans is a benign process that may appear on the skin of the vulva and inner thighs in obese and darkly pigmented women. Glucose intolerance, insulin resistance, chronic anovulation, and androgen disorders may be associated.

Intertrigo is an inflammatory reaction involving the genitocrural folds or the skin under the abdominal panniculus. Common in obese individuals, it results from persistent moistness of the skin surfaces. A superficial fungal or bacterial infection may be concomitant. The area may be either erythematous or white from maceration. Maintaining dryness by wearing absorbent cotton undergarments and dusting with cornstarch powder may be helpful.

DIABETES MELLITUS

Diabetes mellitus is the systemic disease most commonly associated with chronic pruritus vulvae. Diabetic vulvitis is caused by chronic vulvovaginal candidiasis. The diagnosis of diabetes should be considered in any patient who responds poorly to antifungal treatment or who has recurrent fungal infections. Such patients should undergo glucose tolerance testing. In rare cases of long-term diabetes mellitus, the associated neuropathy may present as vulvar pruritus or burning. In uncontrolled diabetes, the vulvar epithelium often undergoes lichenification and secondary bacterial infection. Occasionally, vulvar abscesses, chronic subcutaneous abscesses, and draining sinuses develop from a bacterial infection. Treatment should include controlling the underlying diabetes and specific therapy for the bacterial or fungal infection. Suppressive antifungal therapy using fluconazole should be initiated in diabetic patients with recurrent vulvovaginal candidiasis.

Necrotizing fasciitis presents most commonly in diabetics. It is an uncommon, acute, rapidly spreading, sometimes fatal polymicrobial infection of the superficial fascia and subcutaneous fascia. It may appear after a surgical procedure or after minor trauma. It presents as an extremely painful, tender, edematous, and indurated region with central necrosis and peripheral purplish erythema. Treatment requires incision and debridement of involved tissue and broad-spectrum antibiotics.

INFESTATIONS OF THE VULVA

PEDICULOSIS PUBIS

Pathogenesis

The crab louse (*Phthirus pubis*) is transmitted through sexual contact or from shared infected bedding or clothing. The louse eggs are laid at the base of a hair shaft near the skin. The eggs hatch in 7–9 days, and the louse must attach to the skin of the host to survive. The result is intense pubic and anogenital itching.

Clinical Findings

Minute pale-brown insects and their ova may be seen attached to terminal hair shafts.

Treatment

Treatment consists of permethrin 1% cream, lindane 1% shampoo, or pyrethrins with piperonyl butoxide. Lindane is not recommended for pregnant or lactating women or for children younger than 2 years. It is important to treat all contacts and sterilize clothing that was in contact with the infested area.

SCABIES

Pathogenesis

Sarcoptes scabiei causes intractable itching and excoriation (see Table 39–3 for definition) of skin surfaces in the vicinity of minute skin burrows where parasites deposited ova. The scabies mite is transmitted, often directly, from infected persons.

Treatment

The patient should take a hot soapy bath, scrubbing the burrows and encrusted areas thoroughly. Treatment consists of application of permethrin cream (5%) to the entire body from the neck down, with particular attention to the hands, wrists, axillae, breasts, and anogenital region. It should be washed off after 8–14 hours. Alternatively, lindane (1%) in lotion or cream form can be applied in a thin layer to all areas of the body and washed off after 8 hours. All potentially infected clothing or bedding should be washed or dry-cleaned. All people who were in contact must be treated as described to prevent reinfection. Therapy should be repeated in 10–14 days if new lesions develop.

ENTEROBIASIS (PINWORM, SEATWORM)

Clinical Findings

Enterobius vermicularis infection is common in children. Symptoms are nocturnal perineal itching and perianal excoriation. To diagnose, apply adhesive cellulose tape to the anal region, stick the tape to a glass slide, and examine under the microscope for ova.

Treatment

Patients should wash their hands and scrub their nails after defecation. Underclothes must be boiled. Application of ammoniated mercury ointment to the perianal region twice daily relieves itching. Pinworms succumb to systemic treatment with pyrantel pamoate, mebendazole, or pyrvinium pamoate.

MYCOTIC INFECTIONS OF THE VULVA

FUNGAL DERMATITIS (DERMATOPHYTOSES)

Clinical Findings

Tinea cruris is a superficial fungal infection of the genitocrural area that is more common in men than in women. The most common carriers are *Trichophyton mentagrophytes* and *Trichophyton rubrum*. The initial lesions are usually located on the upper inner thighs and are well circumscribed, erythematous, dry, scaly areas that coalesce. Scratching causes lichenification and a gross appearance similar to neurodermatitis. Diagnosis depends on microscopic examination (as for *Candida*) (Fig. 39–5). Culture on Sabouraud's medium confirms diagnosis.

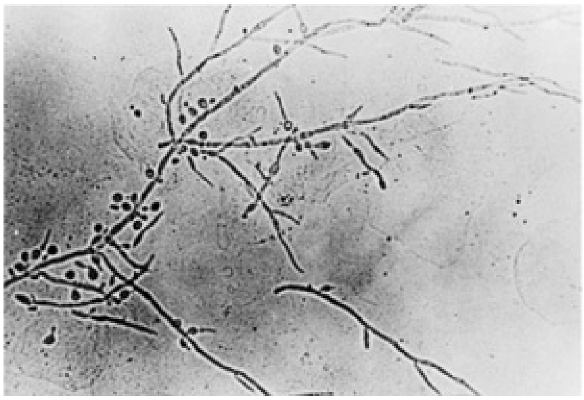


Figure 39–5. Potassium hydroxide preparation showing branched and budding *Candida albicans*.

Treatment

Treatment with 1% haloprogin, tolnaftate, or a similar agent is effective. Twice-daily application of topical imidazole preparation for 2–3 weeks is also highly effective.

Tinea versicolor generally involves the skin of the trunk, although vulvar skin is occasionally involved. The lesions are usually multiple and may have a red, brown, or yellowish appearance. Diagnosis is the same as for other fungal infections. Treatment with selenium sulfide suspension daily for 5–7 days is usually effective, as are topical imidazole preparations applied for 4 weeks. Ketoconazole has been used in recalcitrant cases.

DEEP CELLULITIS CAUSED BY FUNGI

Blastomycosis and actinomycosis are examples of deep mycoses that usually affect internal organs but may also involve the skin. Involvement of the vulvar epithelium in these diseases is rare in the United States. Diagnosis is usually by laboratory exclusion of the granulomatous sexually transmitted diseases, tuberculosis, and other causes of chronic infection. Treatment of blastomycosis with amphotericin B or hydroxystilbamidine is not very effective. Penicillin successfully treats actinomycosis in most cases.

OTHER INFECTIONS OF THE VULVA

IMPETIGO

Impetigo is caused by the hemolytic *Staphylococcus aureus* or by streptococci. This autoinoculable disease spreads quickly throughout the body, also to the vulva. The thin-walled vesicles and bullae that develop display reddened edges and crusted surfaces after rupture. The disease is common in children, particularly on the face, hands, and vulva.

The patient must be isolated and the blebs incised or crusts removed aseptically. Neomycin or bacitracin should be applied topically twice daily for 1 week. Bathing with an antibacterial soap is recommended.

FURUNCULOSIS

Vulvar folliculitis is caused by a staphylococcal infection of hair follicles. Furunculosis occurs if the infection spreads into the perifollicular tissues, producing localized cellulitis. Some follicular lesions are palpable as tender subcutaneous nodules that resolve without suppuration. A furuncle begins as a hard, tender subcutaneous nodule that ruptures through the skin, discharging blood and purulent material. After expulsion of a core of necrotic tissue, the lesion heals. New furuncles may appear sporadically over time.

Applications of topical antibiotic lotions effectively treat minor infections. Deeper infections can be treated with hot soaks, followed by incision and drainage of the pustules. Appropriate systemic antibiotics are warranted when extensive furunculosis is present.

ERYSIPELAS

Erysipelas is a rapidly spreading erythematous lesion of the skin caused by invasion of the superficial lymphatics by β-hemolytic streptococci. Erysipelas of the vulva is exceedingly rare and is most commonly seen after trauma to the vulva or a surgical procedure. Systemic symptoms of chills, fever, and malaise associated with an erythematous vulvitis should raise suspicion of this infection. Vesicles and bullae may appear, and erythematous streaks leading to the regional lymph nodes are typical.

Treatment consists of systemic (preferably parenteral) penicillin or large doses of orally administered tetracycline.

HIDRADENITIS SUPPURATIVA

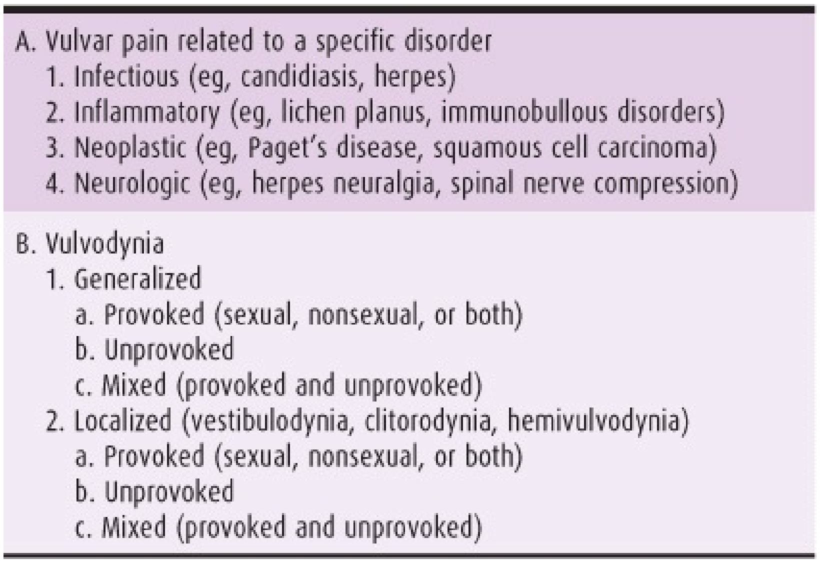
Hidradenitis suppurativa is a refractory process of the apocrine sweat glands, usually associated with staphylococci or streptococci. Inspissation of secretory material and secondary infection occlude ducts of these glands. Multiple pruritic subcutaneous nodules appear and eventually develop into abscesses and then rupture. The process generally involves the skin of the entire vulva, resulting in multiple abscesses and subsequent chronic draining of sinuses and scars. Treatment at an early stage consists of drainage and administration of antibiotics based on organism-sensitivity testing. Long-term therapy with isotretinoin may be considered. Antiandrogen therapy with cyproterone acetate or ethinyl estradiol is an effective alternative treatment. When severe chronic infections do not respond to medical therapy, the involved skin and subcutaneous tissues, down to the deep fascia, must be removed. The area will generally not heal after a primary closure. The wound may therefore be left open and allowed to heal by secondary intention or a split-thickness graft may be placed. Squamous cell carcinoma is rarely associated with hidradenitis suppurativa.

VESTIBULAR DISEASE

VULVAR PAIN SYNDROME

Vulvar pain in the absence of relevant visible physical findings is termed **vulvodynia** (Table 39–9). Women suffering from vulvodynia describe their symptoms as burning, rawness, irritation, dryness, and hyperpathia (pain provoked by very light touch). Approximately 16% of the female population has experienced vulvodynia at some time. The ISSVD has classified vulvodynia by localized vulvodynia (provoked or unprovoked) and generalized vulvodynia (provoked or unprovoked) (Table 39–9).

Table 39–9. Terminology of vulvar pain (ISSVD 2003).



A. Vulvar pain related to a specific disorder
  1. Infectious (eg, candidiasis, herpes)
  2. Inflammatory (eg, lichen planus, immunobullous disorders)
  3. Neoplastic (eg, Paget's disease, squamous cell carcinoma)
  4. Neurologic (eg, herpes neuralgia, spinal nerve compression)

B. Vulvodynia
  1. Generalized
    a. Provoked (sexual, nonsexual, or both)
    b. Unprovoked
    c. Mixed (provoked and unprovoked)
  2. Localized (vestibulodynia, clitorodynia, hemivulvodynia)
    a. Provoked (sexual, nonsexual, or both)
    b. Unprovoked
    c. Mixed (provoked and unprovoked)

LOCALIZED PROVOKED VULVODYNIA, OR VESTIBULODYNIA

ESSENTIALS OF DIAGNOSIS

- Affects mostly young women: 20–30 years old.
- Introital pain on vestibular or vaginal entry (entry dyspareunia).
- Vestibular tenderness—pressure from a cotton-tipped applicator at the vestibule reproduces the pain.
- Erythema is seldom seen. No other lesions are present.

Pathogenesis

Localized provoked vulvodynia, or provoked vestibulodynia (PVD), was formerly known as vulvar vestibulitis and clitorodynia. The vestibule is the nonkeratinized squamous epithelium of the vulva between the labia minora. The “Hart” line is the external perimeter including the hymen (Fig. 39–6). In the vulvar vestibule of PVD, mast cell proliferation and degranulation, hyperinnervation (Fig. 39–7), decreased natural killer cell activity, and enhanced heparanase activity have been detected. Inflammation of the vestibule is related to both mast cell proliferation and hyperinnervation, which act reciprocally, and ultimately increase local inflammation. Mast cells secrete mediators, such as nerve growth factor (NGF), histamine, and serotonin, which have been found to sensitize and induce the proliferation of C-afferent nerve fibers. These nerve fibers release neuropeptides, including NGF, which increase the proliferation and degranulation of mast cells, cause hyperesthesia, and enhance the inflammatory response. Although mast cells are activated by inflammation, they themselves increase inflammation. This, in turn, increases the density of nerve fibers, leading to further activation of mast cells, and contributing to inflammation. In this way, both inflammatory hyperinnervation and neurogenic inflammation play significant roles in the cycle, resulting in chronic vulvar pain.

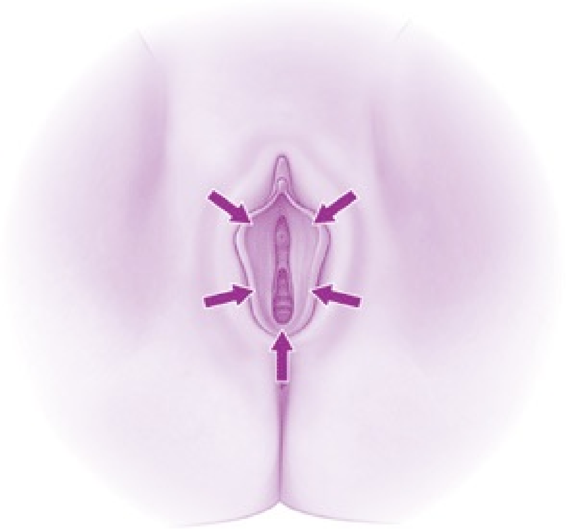


Figure 39–6. Hart line is the outer perimeter of the vestibule.

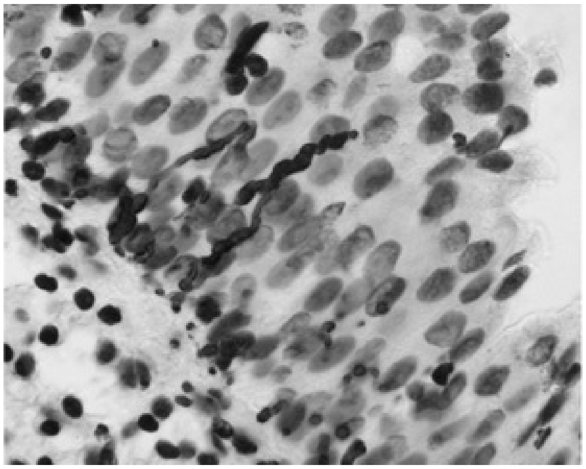

Figure 39–7. Hyperinnervation of the vestibular epithelium. Stain by PGP 9,13.

Prevention

There are currently no prophylactic measures.

Clinical Findings

A. Signs & Symptoms

Two clinical criteria only are needed for diagnosis: (1) introital pain on vestibular or vaginal entry (entry dyspareunia), (2) vestibular tenderness—pressure from a cotton-tipped applicator at the vestibule, which reproduces the pain. Originally, a third criterion, vestibular erythema, was used by Friedrich. However, erythema is rarely seen in LPV. Biopsy is not required for diagnosing LPV.

This condition may affect women of all ages, but mainly those between 20 and 30 years of age, who complain of introital dyspareunia (severe pain or burning on vaginal penetration by their partner). However, some women, due to shyness or despair, complain of persistent vaginal discharge. The clue to diagnosis in these cases may be extreme sensitivity at bimanual pelvic examination and expression of fear from speculum insertion. The woman should be questioned in regard to several factors that may be associated with vestibulodynia: prior surgery to the vestibule (ie, episiotomy, vaginal surgery, CO_2 laser treatment), prior infections (eg, HPV, herpes, *Candida*), and associated urologic disorders, mainly interstitial cystitis. Interstitial cystitis and vestibulodynia have similar pathogeneses, including increased mast cell count in the subepithelial tissue.

B. Different Clinical Presentations of Vestibulodynia

- Primary (pain since first attempt at sexual intercourse) or secondary (pain is experienced after an initial period of pain-free intercourse)
- Pure (without concomitant vulvovaginitis) or complicated (with recurrent vulvovaginitis)
- With or without continuous vulvar pain

Differential Diagnosis

Vaginismus is an involuntary contraction of the muscles at the introitus. It is usually secondary to vestibulodynia, but in many cases is erroneously the only diagnosis received by a patient with dyspareunia. Vulvovaginitis should be excluded. Vaginal pH and microscopic examination of vaginal secretions with KOH and normal saline are effective for evaluating vaginitis. Acetowhite changes with application of 5% acetic acid, as well as any distinct lesions, should be biopsied to evaluate for an underlying dermatosis, infection, or neoplastic process. Other causes of vestibular sensitivity should be assessed (Table 39–9).

Complications

Intractable dyspareunia may have a detrimental affect on intimate relationships. Secondary depression is common.

Treatment

Some women, often after consultation with a number of physicians, administer antifungal or antibacterial medications for long periods, to no avail. Frustrated, they become apprehensive of additional treatment failure. Implementation of the following 3-level treatment plan is therefore suggested. Starting with simple measures, this plan should be reevaluated every 3 months.

1. The initial 3 months should focus on pelvic floor physical therapy with biofeedback. The patient should maintain vulvar hygiene, including the use of cotton underwear, drying of the skin, and avoidance of constrictive garments and irritating agents. Topical application of 5% lidocaine cream once daily, and of soothing oils, such as nut oil and tea-tree oil, twice daily, are recommended. In women with a poorly estrogenized vagina due to menopause or to consumption of birth control pills, a daily application of topical estrogenic preparation may be effective. A low-oxalate diet with supplementation of daily calcium citrate may relieve symptoms by decreasing the urinary oxalate crystal concentration that irritates the vulvar vestibule.
2. If, after 3 months, the condition does not improve, oral treatment with the tricyclic antidepressant amitriptyline (Elatrolet) 10–75 mg daily, pregabalin, or gabapentin may be initiated for 3 months.
3. For women who continue to complain of severe dyspareunia after these 2 periods, surgical therapy by vulvar vestibulectomy (Fig. 39–8) with vaginal advancement is the most effective treatment. Vaginal advancement covers the tissue defect and places the mucous-skin junction, which may be sensitive, outside the introitus. The combined sum of complete and partial responses to surgery from 38 studies of surgical treatment is 89%. A high proportion, 93%, of women who underwent vestibulectomy expressed satisfaction with the surgery, stating they would recommend it to another woman experiencing similar symptoms.

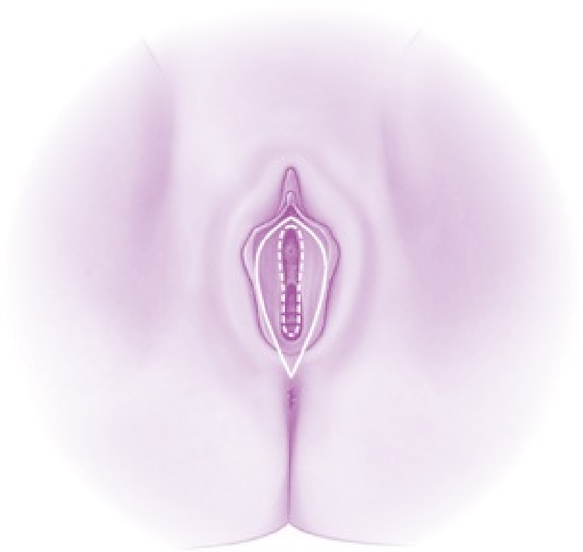

Figure 39–8. The outline of vestibulectomy for localized provoked vulvodynia.

Treatments that were proposed in the past but abandoned due to lack of efficacy include intralesional or systemic interferon injection to treat possible HPV, trigger point injections with long-acting injectable anesthetics or steroids, and CO_2 laser vaporization.

New therapies that are currently being evaluated include injections of botulism toxin, topical application of nitroglycerine or nifedipine to treat vaginal muscle spasm as the source of vulvodynia, and topical application of tricyclic antidepressant amitriptyline.

Prognosis

Available treatments cure as many as two-thirds of those affected. In recalcitrant cases, women continue to suffer from dyspareunia, even subsequent to surgery. For them, referral to a pain treatment center may be an option.

GENERALIZED UNPROVOKED VULVODYNIA

The etiology of this condition is unknown. The pain involves a larger surface area than does that of localized provoked vulvodynia. The average patient is in her 60s and suffers from hypertension, sometimes receiving various treatments. The pain or burning is usually constant, sometimes with periods of relief and flares. For definitive diagnosis, the following conditions must be excluded: localized provoked vulvodynia, infections and dermatoses, pudendal nerve entrapment, pudendal nerve injury due to childbirth, referred pain from ruptured disk, neuropathic viruses such as herpes simplex or varicella-zoster, and neurologic disease such as multiple sclerosis. A test for allodynia and hyperalgesia using a cotton-tipped swab is usually negative. Therefore, diagnosis of this neuropathic pain is by exclusion.

The most effective treatment for generalized unprovoked vulvodynia is tricyclic antidepressants, mainly amitriptyline (Elatrolet) 10–75 mg daily. Initial relief is expected after a few weeks. In the meantime, topical local anesthetics may be applied. The patient should be counseled on elimination of irritants. If symptoms are not relieved after 3 months, initiation of anticonvulsants such as gabapentin should be considered. If the patient is refractory to such treatment, the next step is referral to a pain clinic, where epidural, other regional blocks, or narcotics may be used.

VAGINAL DISORDERS

VAGINITIS

CANDIDIASIS

ESSENTIALS OF DIAGNOSIS

- Intense vulvar pruritus
- A white vaginal discharge
- Vulvar erythema
- Filaments and spores in vaginal discharge can be seen in saline (“wet prep”) and KOH preparations
- The gold standard for diagnosis is a vaginal culture

Pathogenesis

Approximately 75% of women experience an episode of vulvovaginal candidiasis during their lifetime. *Candida albicans*, the most common *Candida* species, causes symptomatic vulvovaginitis in approximately 90% of the cases. *C albicans* frequently inhabits the mouth, throat, large intestine, and vagina. Clinical infection is dependent on considerable growth and colonization and may be associated with a systemic disorder (diabetes mellitus, HIV, obesity), pregnancy, medication (antibiotics, corticosteroids, oral contraceptives), and chronic debilitation.

Prevention

Nonabsorbent undergarments should be avoided. The vulva and vaginal area should be kept dry. Controlling any underlying metabolic illnesses, especially diabetes, can prevent candidal growth. Even when diabetes is not present, a low-sugar diet is recommended, as the glucose in a vaginal discharge may promote the growth of the yeast. Complicating medications, especially antibiotics, estrogen, or oral contraceptive, should be discontinued if possible. Some experts recommend administering a prophylactic dose of an antifungal medication simultaneous to every antibiotic administration.

Clinical Findings

A. Symptoms & Signs

Vulvovaginal candidiasis presents with intense vulvar pruritus; a white, cheesy vaginal discharge; and vulvar erythema. A burning sensation may follow urination, particularly if there is excoriation of the skin from scratching. Widespread involvement of the skin adjacent to the labia may suggest an underlying systemic illness. The labia minora may be erythematous and edematous.

B. Wet Prep Evaluation

Diagnosis is based on a normal vaginal pH ≤4.5 and microscopic evaluation of vaginal secretions both in a saline preparation (wet prep) and mixed with 10% KOH solution. Identification of *C albicans* requires detections of filamentous forms (pseudohyphae) of the organism (Fig. 39–5). Spores may be present as well, but the presence of spores alone may indicate a *Candida glabrata* infection. The gold standard for diagnosis is a vaginal culture.

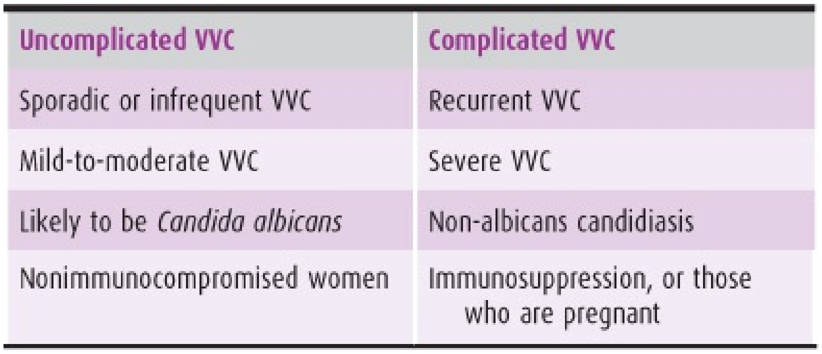
Differential Diagnosis

Genital herpes and localized provoked vulvodynia should be included in the differential diagnosis. Other causes of vaginal discharge are discussed later in this chapter.

Complications

Complications include an entity called complicated vulvovaginal candidiasis, described in Table 39–10.

Table 39–10. Classification of vulvovaginal candidiasis (VVC).

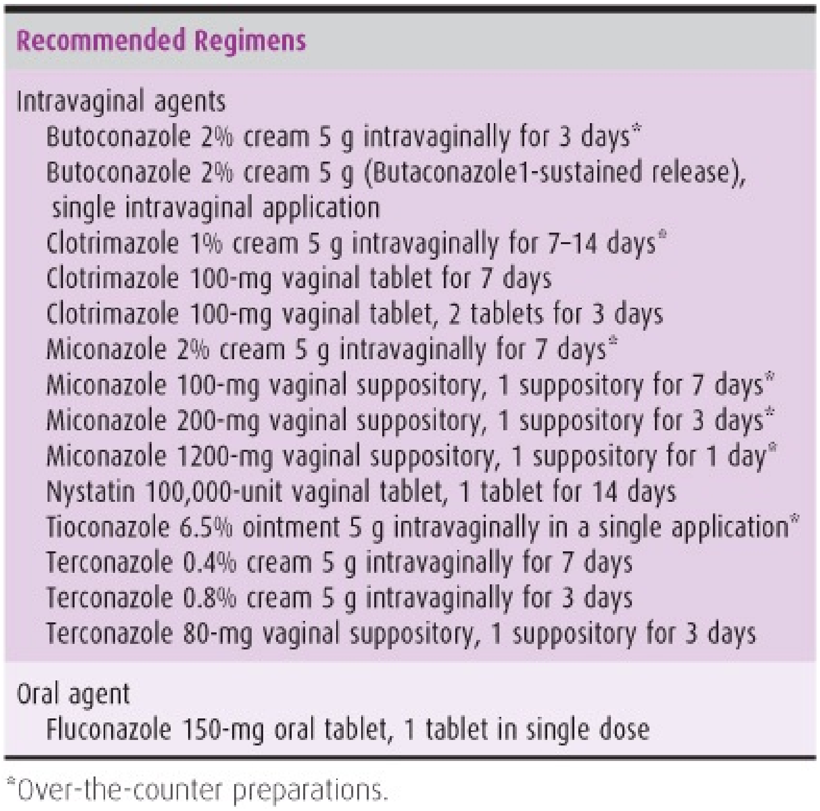


Uncomplicated VVC	Complicated VVC
Sporadic or infrequent VVC	Recurrent VVC
Mild-to-moderate VVC	Severe VVC
Likely to be *Candida albicans*	Non-albicans candidiasis
Nonimmunocompromised women	Immunosuppression, or those who are pregnant

Treatment

The current medical treatment of candidal infection is by imidazoles, fungistatic agents that interfere with the production of the sterol of the cell wall (Table 39–11). These are available as topical creams, vaginal suppositories, and oral agents. Application of a topical steroid may be beneficial to the patient with severe vulvar itch or edema. In evaluating the patient with complicated candidal vulvovaginitis, underlying predisposing disease processes should be addressed. Additionally, cultures of the vagina should be taken to identify resistant strains. *C glabrata* and *Candida tropicalis*, which are detected with increasing frequency, require prolonged periods of treatment.

Table 39–11. Imidazole medications used in the treatment of noncomplicated vulvovaginal candidiasis.



Recommended Regimens

Intravaginal agents
- Butoconazole 2% cream 5 g intravaginally for 3 days*
- Butoconazole 2% cream 5 g (Butaconazole1-sustained release), single intravaginal application
- Clotrimazole 1% cream 5 g intravaginally for 7–14 days*
- Clotrimazole 100-mg vaginal tablet for 7 days
- Clotrimazole 100-mg vaginal tablet, 2 tablets for 3 days
- Miconazole 2% cream 5 g intravaginally for 7 days*
- Miconazole 100-mg vaginal suppository, 1 suppository for 7 days*
- Miconazole 200-mg vaginal suppository, 1 suppository for 3 days*
- Miconazole 1200-mg vaginal suppository, 1 suppository for 1 day*
- Nystatin 100,000-unit vaginal tablet, 1 tablet for 14 days
- Tioconazole 6.5% ointment 5 g intravaginally in a single application*
- Terconazole 0.4% cream 5 g intravaginally for 7 days
- Terconazole 0.8% cream 5 g intravaginally for 3 days
- Terconazole 80-mg vaginal suppository, 1 suppository for 3 days

Oral agent
- Fluconazole 150-mg oral tablet, 1 tablet in single dose

*Over-the-counter preparations.

Treatment regimens for complicated candidal vulvovaginitis include prolonging antifungal therapy for at least 2 weeks, consistent with the life cycle of yeast; self-medication for 3–5 days upon first evidence of symptoms; and prophylactic treatment for several days before menstruation or during antibiotic therapy. Oral administration of fluconazole 150 mg weekly for 6 months or itraconazole 100 mg daily for 6 months may reduce the frequency of recurrence to 10% during maintenance therapy. Liver function should be monitored during prolonged oral therapy. Treatment of the partner may be considered in cases of symptomatic balanitis. Gentian violet 1%, an aniline dye, has demonstrated effectiveness against *C albicans* and *C glabrata* when painted over vaginal surfaces once weekly. Boric acid compounded in a 600-mg suppository form, administered daily for 6 weeks, is also effective treatment for candidiasis and yeast infestation. Polyenes, such as nystatin, which is not absorbed in the gastrointestinal tract, may be taken orally to reduce intestinal colonization. Flucytosine may be administered in resistant cases.

Prognosis

Recurrent disease may result from insufficient duration of therapy, recontamination, or resistant strains. Unfortunately, in 57% of patients, recurrences present within 6 months of discontinuation of prophylactic treatment.

BACTERIAL VAGINOSIS

ESSENTIALS OF DIAGNOSIS

- Homogeneous vaginal discharge
- Amine (fishy) odor when potassium hydroxide solution is added to vaginal secretions (commonly called the “whiff test”)
- Presence of clue cells (more than 20% of epithelial cells) on microscopy (Fig. 39–9)

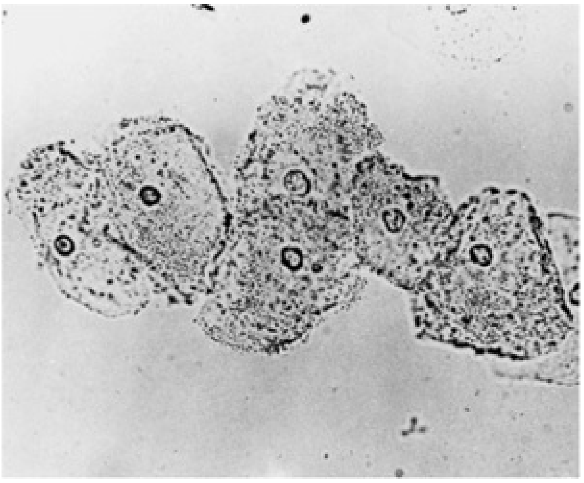


Figure 39–9. Bacterial vaginosis. Saline wet mount of clue cells. Note the absence of inflammatory cells.

- Vaginal pH >4.5
- Decrease in lactobacillus, small gram-variable rods, or curved gram-variable rods in gram-stained smear

---

Pathogenesis

Bacterial vaginosis (BV), previously referred to as *Gardnerella* vaginitis, *Haemophilus* vaginitis, or nonspecific vaginitis, is the most common cause of symptomatic bacterial infection in reproductive-aged women in many countries. This condition is characterized by an alteration in the normal vaginal flora. The concentration of the hydrogen peroxide–producing lactobacillus decreases, and there is overgrowth of *Gardnerella vaginalis*, *Mobiluncus* spp., anaerobic gramnegative rods (*Prevotella* spp., *Porphyromonas* spp., *Bacteroides* spp.), and *Peptostreptococcus* spp. Whether bacterial vaginosis is a true sexually transmitted disease is controversial, although women who are not sexually active are rarely affected.

Prevention

Maintaining vaginal pH at a normal range may prevent recurrences. The potential benefit of lactobacillus intravaginal suppositories in restoring normal flora, and of acidifying vaginal douching, is being studied.

Clinical Findings

A. Symptoms & signs

Bacterial vaginosis presents as a “fishy” vaginal discharge, which is more noticeable after unprotected intercourse, due to the increased pH caused by the ejaculate. The patient complains of a milky, homogenous, malodorous, usually nonirritating discharge. The term **vaginosis**, rather than **vaginitis**, is used due to the absence of vaginal mucosal inflammation, such as presents in candidal infections.

B. Diagnostic Scales

Two diagnostic scales are often used to diagnose bacterial vaginosis: Amsel’s criteria and Nugent’s score. According to Amsel’s criteria, which establishes accurate diagnosis of bacterial vaginosis in

90% of affected women, 3 of the following 4 criteria must be met:

1. Homogeneous vaginal discharge (color and amount may vary).
2. Amine (fishy) odor when potassium hydroxide solution is added to vaginal secretions (whiff test).
3. Presence of clue cells (>20% of epithelial cells) on microscopy. Clue cells are identified as numerous stippled or granulated epithelial cells (Fig. 39–9). This appearance is caused by the adherence of *G vaginalis* organisms to the edges of the vaginal epithelial cells.
4. Vaginal pH >4.5.

Nugent's score is a Gram stain scoring system that provides a more sensitive (93%) and specific (70%) diagnosis than does the wet mount. The score is calculated by assessing for the presence of the following:

1. Large gram-positive rods (lactobacillus morphotypes; decrease in lactobacillus, scored 0–4)
2. Small gram-variable rods (*G vaginalis* morphotypes, scored 0–4)
3. Curved gram-variable rods (*Mobiluncus* spp. morphotypes, scored 0–2)

The total score ranges from 0 to 10. A score of 7–10 is consistent with bacterial vaginosis.

C. Other Diagnostic Tests

A culture of *G vaginalis* is not recommended as a diagnostic tool due to low specificity. Cervical Papanicolaou tests have low sensitivity. However, a DNA probe-based test may be clinically useful. Other commercially available tests for the diagnosis of BV include a card test for the detection of elevated pH and trimethylamine and proline aminopeptidase. The home-use of the VI-Sense panty liner has recently demonstrated effectiveness in the early detection of BV and of its recurrences after medical treatment.

Differential Diagnosis

Cervicitis and cervical neoplasia should be considered in the differential diagnosis of bacterial vaginosis.

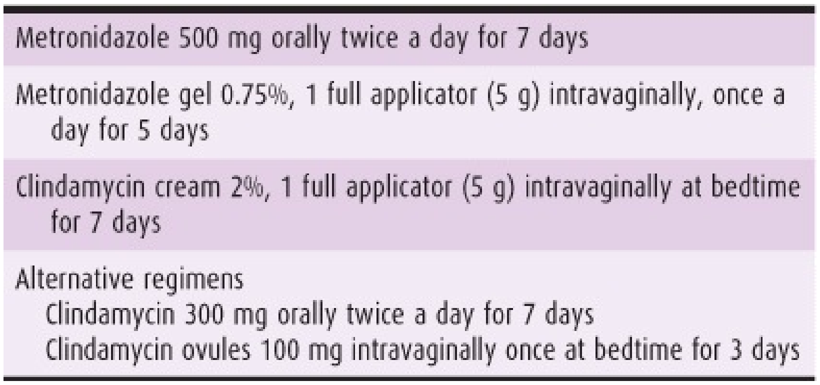
Complications

BV is reported to increase the risk of preterm delivery. It is unclear whether metronidazole treatment of asymptomatic pregnant women reduces the rates of preterm delivery and adverse pregnancy outcomes. In nonpregnant women, BV is associated with posthysterectomy vaginal cuff cellulitis, postabortion infection, and pelvic inflammatory disease.

Treatment

Treatment should be administered to symptomatic patients and considered in asymptomatic patients. Several treatment regimens exist (Table 39–12). Of importance, intravaginal administration of oil-based clindamycin reduces the effectiveness of condoms and diaphragms. For pregnant women, metronidazole 250 mg orally 3 times daily is recommended for 7 days or, alternatively, clindamycin 300 mg orally twice daily for 7 days. There is no evidence supporting the use of topical agents during pregnancy. Management strategies for recurrent vaginosis include use of condoms, longer treatment periods, prophylactic maintenance therapy, oral or vaginal application of yogurt containing lactobacillus acidophilus, intravaginal planting of other exogenous lacto-bacilli, and acidification of the vagina. Treatment of the male rarely helps in preventing recurrence in the female.

Table 39–12. Treatment of bacterial vaginosis.



Metronidazole 500 mg orally twice a day for 7 days
Metronidazole gel 0.75%, 1 full applicator (5 g) intravaginally, once a day for 5 days
Clindamycin cream 2%, 1 full applicator (5 g) intravaginally at bedtime for 7 days
Alternative regimens Clindamycin 300 mg orally twice a day for 7 days Clindamycin ovules 100 mg intravaginally once at bedtime for 3 days

Prognosis

Recurrence is frequent. Overgrowth of candida albicans after antibiotic treatment of bacterial vaginosis may be misinterpreted as recurrent bacterial vaginosis. A “universal” treatment of vulvovaginitis using a combination of clotrimazole and metronidazole in a single vaginal suppository has demonstrated effectiveness. Its use may prevent candida overgrowth.

TRICHOMONAS VAGINITIS

ESSENTIALS OF DIAGNOSIS

- Profuse, frothy, greenish, and foul-smelling discharge
- pH of the vagina usually exceeding 5.0
- Vaginal erythema with multiple small petechiae (strawberry spots)
- Wet mount reveals an increase in polymorphonuclear cells and motile flagellates in 50–70% of zculture-confirmed cases

---

Pathogenesis

Trichomonas vaginalis is a unicellular flagellate protozoan (Fig. 39–10) that is larger than polymorphonuclear leukocytes but smaller than mature epithelial cells. *T vaginalis* infects the lower urinary tract in both women and men. It is the most prevalent nonviral sexually transmitted disease in the United States. Nonsexual transmission is infrequent because large numbers of organisms are required to produce symptoms.

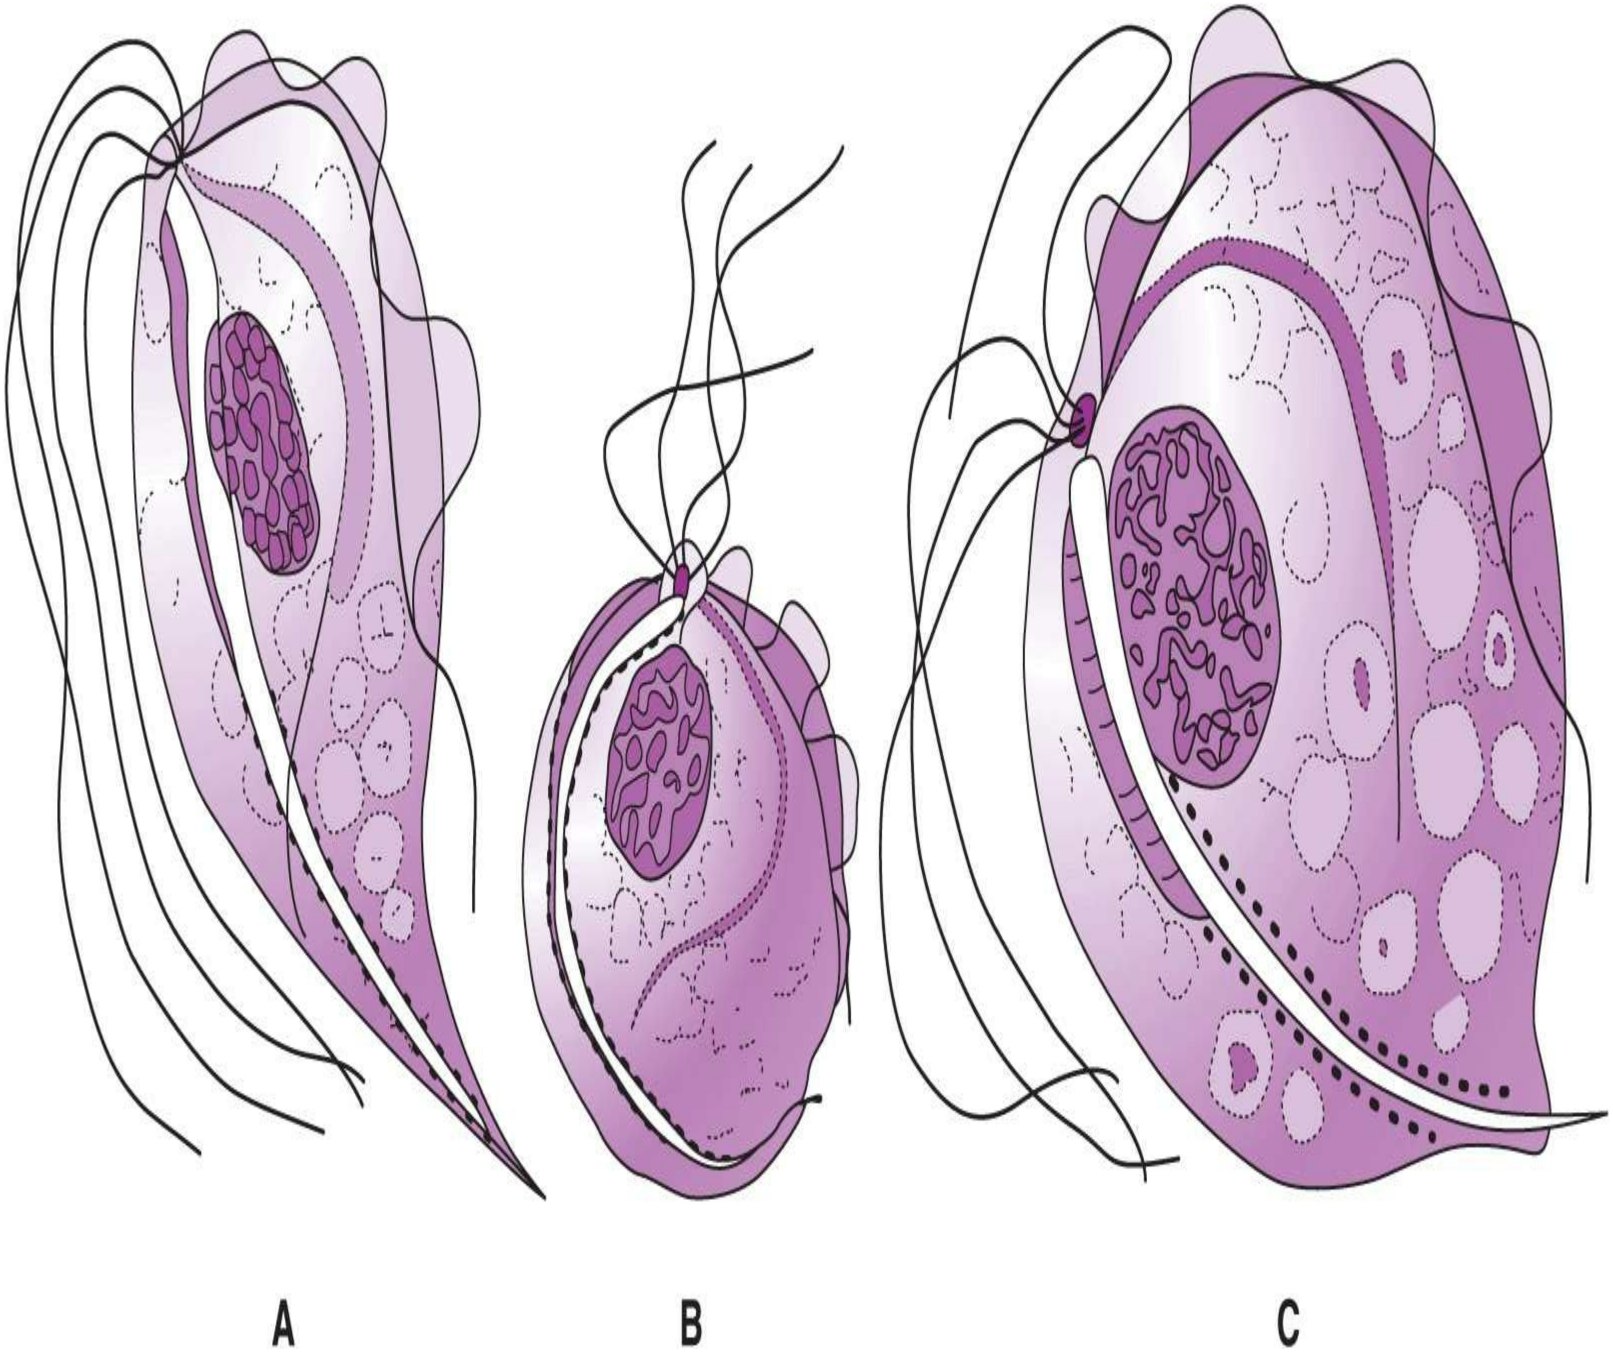


Figure 39–10. Trichomonas vaginalis as found in vaginal and prostatic secretions. **A:** Normal trophozoite. **B:** Round form after division. **C:** Common form seen in stained preparation. Cysts not found. (Reproduced, with permission, from Brooks GF, Butel JS, Ornston LN. *Jawetz, Melinick, & Adelberg's Medical Microbiology*. 19th ed. Appleton & Lange; 1991.)

Clinical Findings

A. Symptoms & Signs

A persistent vaginal discharge is the principal symptom with or without secondary vulvar pruritus. The discharge is profuse, extremely frothy, greenish, and at times foul-smelling. The pH of the vagina usually exceeds 5.0. Involvement of the vulva may be limited to the vestibule and labia minora. The labia minora may become edematous and tender. Urinary symptoms may occur; however, burning with urination is most often associated with severe vulvitis. Examination of the vaginal epithelium and cervix shows generalized vaginal erythema with multiple small petechiae, the so-called strawberry spots, which may be confused with epithelial punctation. Wet mount with normal saline reveals an increase in polymorphonuclear cells and characteristic motile flagellates in 50–70% of culture-confirmed cases.

B. Wet Mount Diagnosis

Vaginal trichomoniasis is usually diagnosed by microscopy of a wet mount preparation of vaginal secretions. Sensitivity is only 60–70%. Immediate evaluation is required, as the heat generated by the microscope light source causes the *T vaginalis* to discontinue its typical movements.

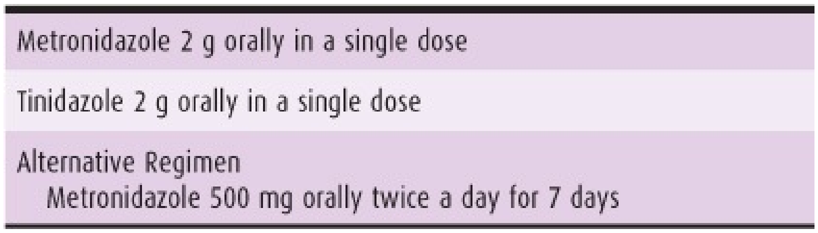
C. Other Diagnostic Tests

Other tests for trichomoniasis include immunochromato-graphic capillary flow dipstick technology and nucleic acid probing. Sensitivity exceeds 83%, and specificity is 97%. Results of the immunochromatographic Trichomonas Rapid Test are available in 10 minutes, and those of the nucleic acid probe test within 45. False-positive results do occur. Papanicolaou smears have a sensitivity of approximately 60% and also yield false-positive results. Culture is the most sensitive and specific method of diagnosis. In women in whom trichomoniasis is suspected but not confirmed by microscopy, vaginal secretions should be cultured for *T vaginalis*.

Treatment

Systemic therapy with metronidazole is the treatment of choice, because trichomonads sometimes present in the urinary tract system. Partners should be treated simultaneously, with intercourse avoided or a condom used until treatment is completed. US Centers for Disease Control and Prevention recommendations are presented in Table 39–13. If such treatments are not effective, sensitivity of a culture of *T vaginalis* to metronidazole and tinidazole should be determined. Side effects of metronidazole include nausea or emesis with alcohol consumption. Contraindications include certain blood dyscrasias (neutropenia) and central nervous system diseases. An oncogenic effect has been demonstrated in animals but not in humans. Resistance to metronidazole therapy is rare but is rising and can be confirmed in vitro.

Table 39–13. Treatment of *Trichomonas vaginitis*.



Metronidazole 2 g orally in a single dose
Tinidazole 2 g orally in a single dose
Alternative Regimen Metronidazole 500 mg orally twice a day for 7 days

Trichomoniasis is associated with a number of perinatal complications and increased incidence in the transmission of HIV. Women with trichomoniasis should be evaluated for other sexually transmitted diseases, including *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, syphilis, and HIV.

NEISSERIA GONORRHOEAE

Of women infected by *N gonorrhoeae*, 85% are asymptomatic. The glandular structures of the cervix, urethra, vulva, perineum, and anus are most commonly infected. In acute disease, patients present with a copious mucopurulent discharge and gramnegative diplococci within leukocytes. However, diagnosis should be confirmed with nucleic acid amplification or a culture from the endocervix, urethra, rectum, or mouth. An estimated 15–20% of women with lower tract disease develop upper genital tract disease with salpingitis, tubo-ovarian abscess, and peritonitis. Ectopic pregnancy and infertility are classic long-term consequences. If active infection is present during vaginal delivery, the newborn may develop conjunctivitis by contamination. Uncomplicated gonococcal infections of the cervix are treated with ceftriaxone 125 mg administered intramuscularly (IM) in a single dose. Single oral doses of cefixime 400 mg, ciprofloxacin 500 mg, ofloxacin 400 mg, or levofloxacin 250 mg are other recommended regimens. Quinolones are no longer recommended because some strains of *N gonorrhoeae* are quinolone-resistant. Spectinomycin 2 g IM in a single dose is an option for patients sensitive to cephalosporins. Empirical Treatment of *C trachomatis* should be considered, as this infection often coexists.

CHLAMYDIA TRACHOMATIS

The screening of sexually active young women for *C trachomatis* is important because some infections are asymptomatic, and some present with a mucopurulent cervicitis, dysuria, and/or postcoital bleeding. *C trachomatis* can be identified by culture (50–90% sensitivity), a direct fluorescent antibody (50–80% sensitivity), enzyme immunoassay (40–60% sensitivity), or, most recently, by using nucleic acid amplification tests (polymerase chain reaction or ligase chain reaction, 60–100% sensitivity). All tests have a specificity >99%. *C trachomatis* causes atypical cytologic findings on Papanicolaou smear and an ascending infection, salpingitis, in 20–40% of untreated patients. More than 50% of upper tract infections may be caused by *C trachomatis*, leading to tubal occlusion, ectopic pregnancy, or infertility. Untreated *C trachomatis* can also cause neonatal conjunctivitis. *C trachomatis* may present as LGV, which most commonly affects the vulvar tissues. Retroperitoneal lymphadenopathy may present. The initial lesion in LGV presents as a transient, painless vesicular lesion or shallow ulcer at the inoculation site. More advanced disease is characterized by anal or genital fistulas, stricture, or rectal stenosis. The disease is uncommon in the United States, but endemic in Southeast Asia and Africa.

If *C trachomatis* is suspected or diagnosed, both the patient and partner should be treated. They should also be evaluated for concurrent gonococcal infections. Recommended therapy includes azithromycin 1 g orally in a single dose or doxycycline 100 mg orally twice daily for 7 days. Erythromycin base 500 mg orally 4 times daily for 7 days, ofloxacin 300 mg orally twice daily, and levofloxacin 50 mg once daily for 7 days are alternative regimens. Doxycycline, levofloxacin, and ofloxacin should be avoided in pregnancy and during lactation. Patients should abstain from intercourse for 7 days. Test of cure is required in cases of possible reinfection or persistent symptoms and during pregnancy. Repeat testing should be considered 3 weeks after treatment with erythromycin. Rescreening is recommended 3–4 months after treatment. For LGV, the recommended regimen is doxycycline 100 mg twice daily for 21 days.

OTHER INFECTIONS

Mycoplasma hominis and *Ureaplasma urealyticum* also cause genital disease. Polymerase chain reaction is more sensitive than culture. Mycoplasma infections can cause infertility, spontaneous abortion, postpartum fever, salpingitis, and pelvic abscess, as well as nongonococcal urethritis in men. The most effective treatment is doxycycline 100 mg orally twice daily for 10 days.

CONDITIONS MIMICKING VAGINITIS

Cervicitis due to chlamydial infection, cervical polyps, or cervical or vaginal cancer can cause a mucopurulent discharge and bleeding. Adenocarcinoma of the cervix may be missed by cytologic cervical screening and by colposcopy, becasue it generally develops in the endocervical canal rather than at the squamocolumnar junction. Excessive cervical ectropion may cause excessive discharge of cervical mucus from normal endocervical cells. Vaginal adenosis may cause the same type of clear, mucoid-type discharge without associated symptoms. Excessive desquamation of the vaginal epithelium may produce a diffuse gray-white pasty vaginal discharge, which may be confused with candidiasis. Vaginal pH is normal. Microscopic evaluation shows normal bacterial flora, mature vaginal squamae, and no increase in the number of leukocytes. Excessive but normal vaginal discharge should be treated with reassurance and, if required, with cryosurgery, carbon dioxide treatment, or loop conization of the cervix. Continuous use of a tampon should be avoided.

DESQUAMATIVE INFLAMMATORY VAGINITIS

This rare condition of vaginitis should be considered in a patient with hard-to-treat vaginitis. The cause is unknown. Patients complain of a profuse purulent vaginal discharge, burning and pain upon urinating (dysuria) or intercourse (dyspareunia), and occasional spotting. Adherence of both vaginal walls, with gradual stenosis, is a common complication. The disease is a variant of the dermatologic disease lichen planus. In many cases, typical lichen planus layers are found on the skin, oral mucosa, and gums. Upon inspection, the vagina is found to be erythematous, inflamed, and desquamated. A thick discharge and a white membrane cover the vagina. The purulent discharge contains many immature epithelial and pus cells without any identifiable cause. Vaginal erythema is present, and synechiae may develop in the upper vagina, causing partial occlusion. Vaginal pH may be elevated. Wet mount and Gram’s stain demonstrate an increased number of parabasal cells, an absence of gram-positive bacilli, and the presence of gram-positive cocci.

The recommended therapy is intravaginal administration of 2% clindamycin cream 5 g daily for 7 days or clindamycin pessaries followed by a foam containing hydrocortisone and pramoxine into the vaginal mucosa to create a protective layer. A second line of therapy is vaginal insertion of corticosteroids in the form of suppository or cream. Recently, application of tacrolimus cream, as an immunosuppressor agent, has also been suggested.

CHEMICAL VAGINITIS

Chemical vaginitis secondary to multiple irritating offenders, including topical irritants (sanitary supplies, spermicides, feminine hygiene supplies, soaps, perfumes); allergens (latex, antimycotic creams), and possibly excessive sexual activity, can cause pruritus, irritation, burning, and vaginal discharge. The etiology may be confused with vulvovaginal candidiasis. Treatment consists of removal of the offending agent. A short course of corticosteroid treatment may be used along with sodium bicarbonate sitz baths and topical vegetable oils.

ATROPHIC VAGINITIS

Clinical Findings

Prepubertal, lactating, and postmenopausal women lack the vaginal effects of estrogen production. The pH of the vagina is abnormally high, and the normally acidogenic flora of the vagina may be replaced by mixed flora. The vaginal epithelium is thinned and more susceptible to infection and trauma. Although most patients are asymptomatic, many postmenopausal women report vaginal dryness, spotting, presence of a serosanguineous or watery discharge, and/or dyspareunia. Some of the symptoms of irritation are caused by a secondary infection. On examination, the vaginal mucosa is thin, with few or absent vaginal folds. The pH is 5.0–7.0. The wet mount shows small, rounded parabasal epithelial cells and an increased number of polymorphonuclear cells.

Treatment

Treatment includes intravaginal application of estrogen cream. Because approximately one-third of the vaginal estrogen is systemically absorbed, this treatment may be contraindicated in women with a history of breast or endometrial cancer. The estradiol vaginal ring, which is changed every 90 days, may provide a preferable route of administration for some women. Estradiol hemihydrate (Vagifem) 1 tablet intravaginally daily for 2 weeks and then twice a week for at least 3–6 months may be more convenient. Systemic estrogen therapy should be considered if there are no contraindications.

FOREIGN BODIES

Pathogenesis

Foreign bodies commonly cause vaginal discharge and infection in preadolescent girls. Paper, cotton, or other materials may be placed in the vagina and cause secondary infection. Children may require vaginoscopy using a small-caliber hysteroscope or vaginal examination under anesthesia to identify or rule out a foreign body or tumor high in the vaginal vault. The vaginal canal can be flushed in the office using a small catheter in an attempt to remove a foreign body. In adults, a forgotten menstrual tampon, a contraceptive device, or a pessary may cause a malodorous discharge. The diagnosis can usually be made by pelvic examination.

Clinical Findings

Clinical symptoms associated with foreign bodies include abnormal malodorous vaginal discharge and intermenstrual spotting. Symptoms are generally secondary to drying of the vaginal epithelium and micro-ulcerations, which can be detected by colposcopy. Ulcerative lesions, particularly associated with tampon use, are typically located in the vaginal fornices and have rolled, irregular edges with a red granulation tissue base (Fig. 39–3). Regenerating epithelium at the ulcer edge may shed cells that may be interpreted as atypical, suggesting dysplasia. The lesions heal spontaneously once tampon use is discontinued. A foreign body retained in the vagina for a prolonged period may erode into the bladder or rectum.

Treatment

Treatment involves removal of the foreign body. Rarely, antibiotics are required for ulcerations or cellulitis of the vulva or vagina. Dryness or ulceration of the vagina secondary to use of menstrual tampons is transient and heals spontaneously.

Toxic shock syndrome is the most serious complication associated with the use of vaginal tampons. It may develop also without tampon use. The syndrome has been linked to staphylococcal vaginal infection in healthy young women who use high-absorbency tampons continuously throughout the menstrual period. Some of the clinical manifestations are secondary to the release of staphylococcal exotoxins. Symptoms consist of a high fever (≥38.9 °C [102 °F]), possibly accompanied by severe headache, sore throat, myalgia, vomiting, and diarrhea. The disease may resemble meningitis or viremia. Palmar erythema and a diffuse sunburn-like rash have been described. The skin rash usually disappears within 24–48 hours, but occasionally a patient has a recurrent maculopapular, morbilliform eruption between days 6 and 10. Superficial desquamation of the palms and soles often follows within

2–3 weeks. Progressive hypotension may occur and proceed to shock levels within 48 hours. Multisystem organ failure may occur, including renal and cardiac dysfunction. The incidence of toxic shock syndrome was 1 in 100,000 among females 15–44 years of age in 1986. Any menstruating woman who presents with sudden onset of a febrile illness should be evaluated and treated for toxic shock syndrome. The tampon should be removed, cultures sent, and the vagina cleansed to decrease the organism inoculum. Appropriate supportive measures should be provided and β-lactamase–resistant penicillin or vancomycin (if the patient is allergic to penicillin) administered. Women who have been treated for toxic shock syndrome are at considerable risk for recurrence. Therefore, these women should avoid tampon use.

VIRAL INFECTIONS

The viruses that affect the vagina are the herpesvirus (herpes simplex, varicella-zoster, and cytomegalovirus), poxvirus (molluscum contagiosum), and papillomavirus types. The main features of these infections have been discussed under Vulvar Diseases.

HERPESVIRUS

The herpesvirus (HSV) may cause erosions, ulcerations, or an exophytic necrotic mass involving the vagina or cervix and causing a profuse vaginal discharge. The cervix may be tender to manipulation and bleed easily. The primary lesion lasts approximately 2 weeks and heals without scarring. Recurrent infections may cause cervical lesions. The virus may be cultured from ulcers or ruptured vesicles. Cervical cytologic examination may reveal multinucleated giant cells with intranuclear inclusions.

HUMAN PAPILLOMAVIRUS INFECTION

As discussed in the section on Vulvar Diseases, condylomata may affect the vagina and cervix as well. Condylomatous vaginitis causes a rough vaginal surface, manifesting white projections from the pink vaginal mucosa. Vaginal discharge resulting from a secondary yeast or bacterial infection is the most common symptom of florid condylomas. Postcoital bleeding may occur. No specific symptoms are related to the other types of condylomas. States of immunosuppression (pregnancy, HIV infection, diabetes, renal transplant) are associated with massive proliferation of condyloma and are often difficult to treat.

PARASITIC INFECTION

Less common causes of vaginitis are parasitic infections with pinworms (*Enterobius vermicularis*) and *Entamoeba histolytica*. Pinworm infection is generally seen in children. Fecal contamination at the introitus is the source of infection. The perineal area is extremely pruritic. The parasite is generally detected by pressing a strip of adhesive cellulose tape to the perineum. The tape is then adhered to a slide, allowing the double-walled ova to be identified under the microscope. *E histolytica* infection of the vagina and cervix is rare in the United States but is quite common in developing countries. Severe infection may resemble cervical cancer, but symptoms are generally due to vulvar involvement. Trophozoites of *E histolytica* may be demonstrated on wet-mount preparations or occasionally on a Papanicolaou smear.

Benign Disorders of the Uterine Cervix

Izabella Khachikyan, MD
Pamela Stratton, MD

CONGENITAL ANOMALIES OF THE CERVIX

The cervix develops from the paramesonephric (müllerian) ducts in the sixth week of embryologic development. The midline fusion and subsequent canalization of the 2 müllerian ducts give rise to the uterine corpus, cervix, and upper vagina (Fig. 40–1). Müllerian duct anomalies result from nondevelopment, defective lateral or vertical fusion, or resorption failure. The most common type of müllerian fusion defect is a lateral fusion defect in which the resulting defective organs can be either symmetrical or asymmetrical and can be obstructed or unobstructed. These fusion defects result from failure of fusion of the müllerian ducts, failure of formation of 1 müllerian duct, or absorption of the intervening septum. Defective resorption of the tissue between the fused müllerian ducts results in a uterine septum that can be partial or extend to the full length to the cervix. The most common lateral fusion defect is a septum. **Vertical fusion** refers to the fusion of the müllerian ducts with the urogenital sinus. The absence of müllerian development results in agenesis of the cervix and uterus. A double cervix is frequently associated with a longitudinal vaginal septum and is an example of lack of fusion. A single hemicervix or septate cervix composed of single muscular septum that can be an extension of a lower uterine segment or vaginal septum is seen with resorption failure. Approximately 20–30% of women with müllerian duct anomalies also have urinary tract abnormalities, a finding that warrants urinary tract imaging. Women with müllerian duct anomalies have normal ovaries and develop normal secondary sex characteristics.

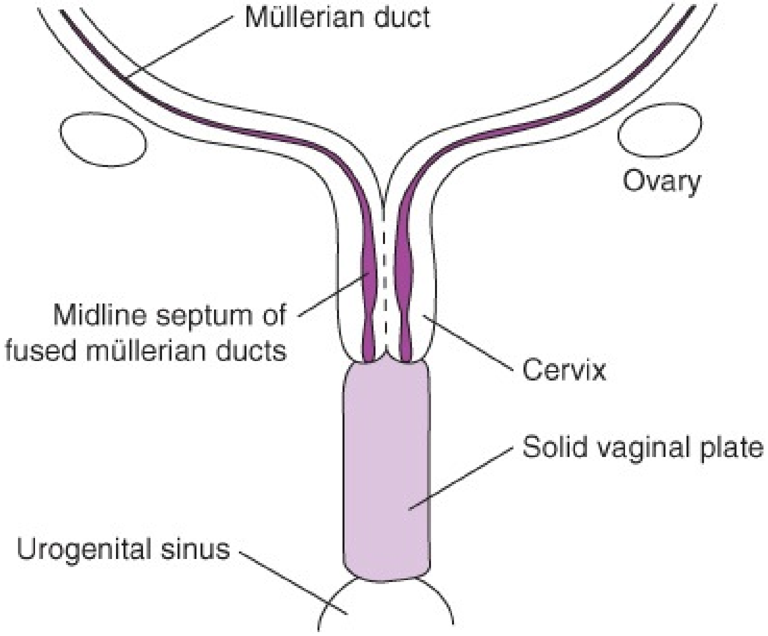

Figure 40–1. Fusion of müllerian ducts to form cervix and corpus uteri.

Cervical Agenesis

Isolated cervical agenesis is rare, but cases of an absent uterine cervix with a normal uterine corpus and normal vagina have been reported. These cases presumably result from either failure of müllerian duct canalization or abnormal epithelial proliferation after canalization. More common is absence of the cervix combined with absence of the uterine corpus and upper vagina, known as müllerian agenesis or Mayer-Rokitansky-Kuster-Hauser syndrome, which occurs in approximately 1 in 4000 female births. Because most of the vagina is derived from müllerian ducts, the vagina may be shortened in müllerian agenesis. Female offspring of women with müllerian agenesis have been studied to identify a possible genetic contribution to this disorder. Because no offspring with müllerian agenesis have been reported, this disorder is assumed to result from a polygenic multifactorial inheritance pattern.

Cervical agenesis with a normal functioning uterine corpus must be differentiated from müllerian agenesis (Figs. 40–2 and 40–3). In the former, menstrual blood may accumulate within the uterus or result in retrograde flow and development of endometriosis. Thus cervical agenesis is usually diagnosed at menarche when patients present with primary amenorrhea and cyclic abdominopelvic pain. Suppression of menstruation with continuous combined estrogen/progesterone pills may improve the pain-related complaints. Ultrasonography, magnetic resonance imaging (MRI), and laparoscopy can help with the diagnosis by defining the anatomy.

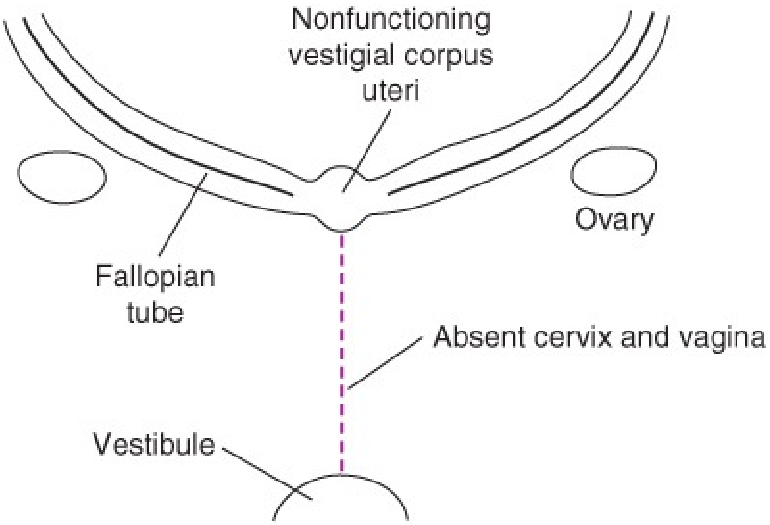

Figure 40–2. Congenital absence of vagina.

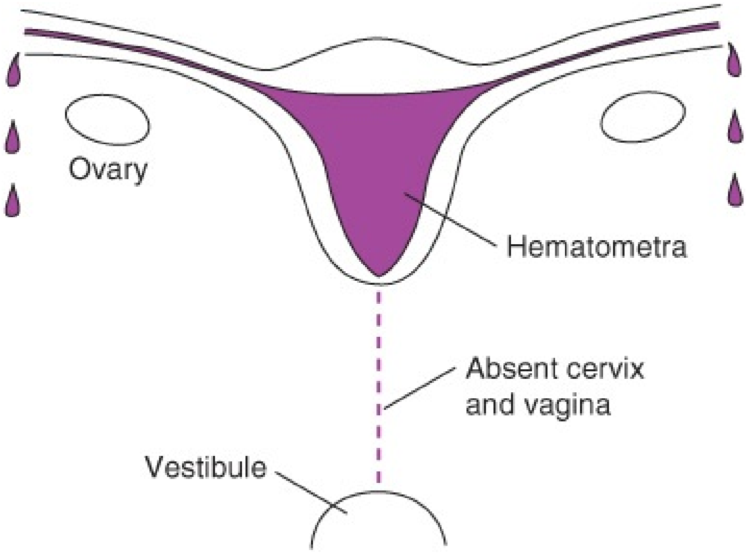

Figure 40–3. Cervical agenesis with hematometra and retrograde menstruation.

Women without a cervix or without a cervix and uterus cannot carry a pregnancy. Because women have normally functioning ovaries, they can undergo in vitro fertilization with their partner's sperm. Pregnancy is achieved with use of a surrogate woman who carries the pregnancy.

Women with müllerian or cervical agenesis may have a shortened or absent vagina. Nonsurgical treatment to lengthen or create a vagina involves the use of vaginal dilators that are under constant perineal pressure. One example is using a bicycle stool designed by Ingram that facilitates dilator use under constant perineal pressure. The most common surgical approach to correct vagina agenesis is the McIndoe technique to create a neovagina. The Vecchietti operation combines a surgical and nonsurgical approach to creating a neovagina and is performed by laparoscopy. Other surgical options include colonovaginoplasty using a segment of colon and vaginoplasty using skin flaps.

Incomplete Müllerian Fusion

Congenital uterine anomalies are asymptomatic and thus often are undiagnosed. As with müllerian anomalies in general, these defects arise from agenesis, lateral or vertical fusion defects, or lack of canalization. Complete failure of fusion of the müllerian ducts results in duplication of reproductive structures. One example is uterus didelphys (2 uteri). Uterus bicornuate bicollis (2 cervices) has 2 separate uterine horns, each with a distinct cervix and vagina. The 2 vaginas are separated by a midline, longitudinal septum. If incomplete fusion results in a uterine horn ending blindly, a hematocolpos can develop (Fig. 40–4). Bicornuate uterus and arcuate uterus occur when there is partial or incomplete fusion of the müllerian ducts. In a bicornuate uterus, 2 discrete uterine cavities lead to the same cervix. The arcuate uterus may demonstrate minimal depression of the uterine fundus and is often clinically insignificant.

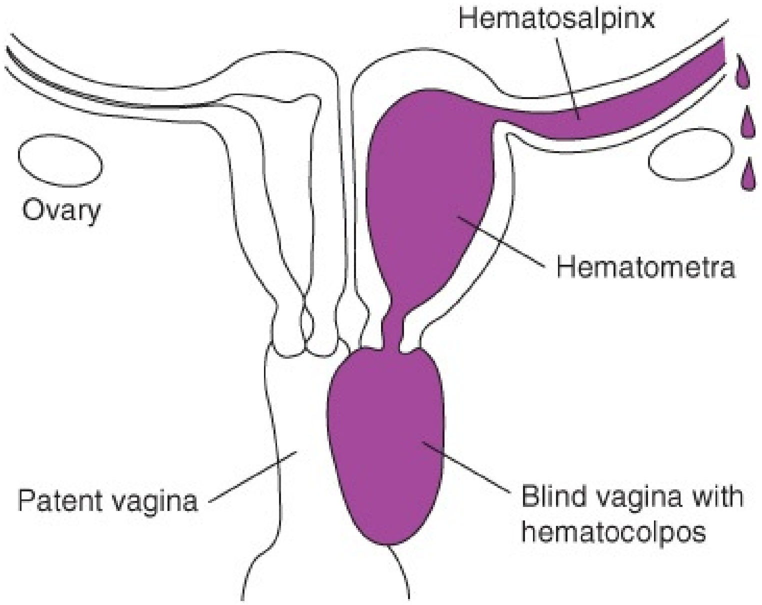

Figure 40–4. Uterus didelphys with blind vagina hematocolpos, hematometra, hematosalpinx, and retrograde menstruation.

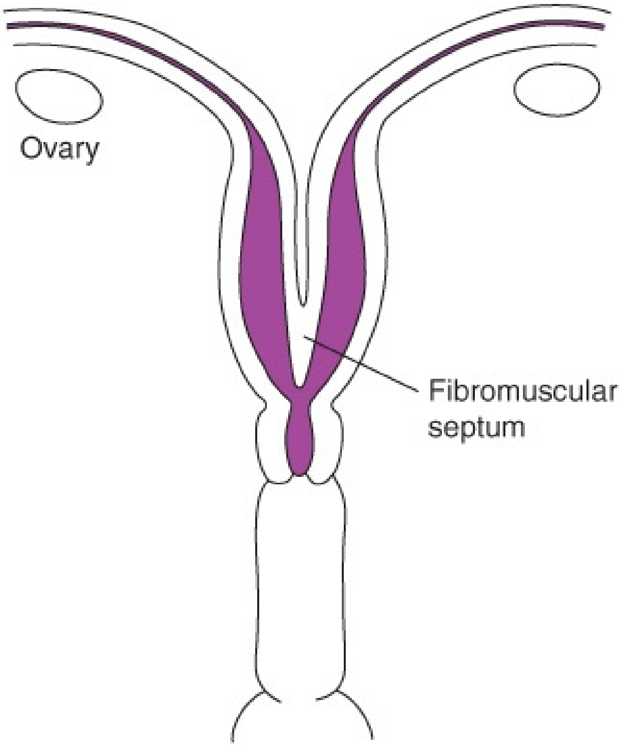
Women with müllerian fusion defects resulting in uterine anomalies have a higher rate of adverse pregnancy outcome. Premature birth may occur in 15–25%, miscarriage is observed in 25–50%, and malpresentation is similarly common (Fig. 40–5).

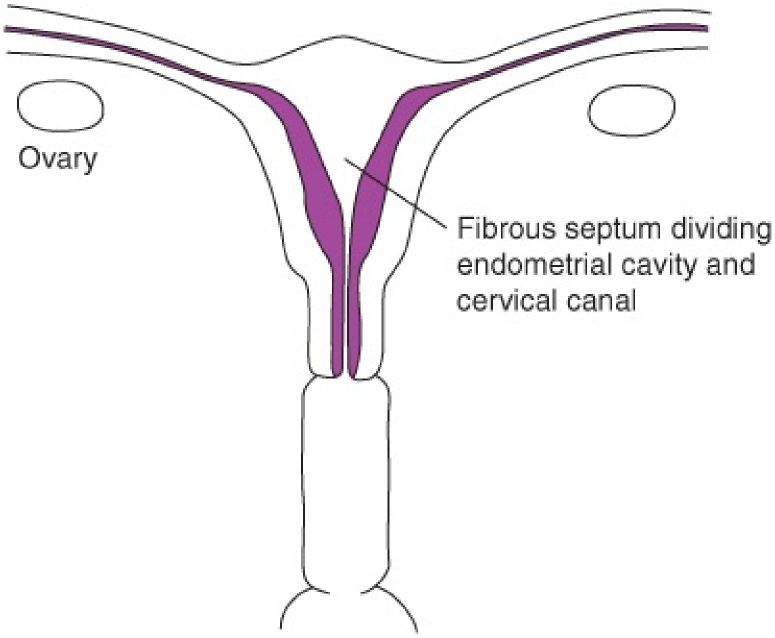


Ovary
Fibromuscular septum

Figure 40–5. Complete bicornuate uterus with fibromuscular septum at the level of internal cervical os.

Failure of Resorption

Defective resorption of the tissue between the fused müllerian ducts will result in uterine septum formation. The septum consists of fibromuscular tissue and can be either partial or full, extending the length of the uterus (Fig. 40–6). Failure or incomplete resorption of this septum is associated with reproductive and obstetric complications. First- and second-trimester spontaneous miscarriages are common and usually occur between 8 and 16 weeks' gestation. Obstetric complications include premature labor, preterm delivery, malpresentation, intrauterine growth restriction, and lower term birth rate. Approximately 15–25% of spontaneous miscarriages are due to müllerian abnormalities.



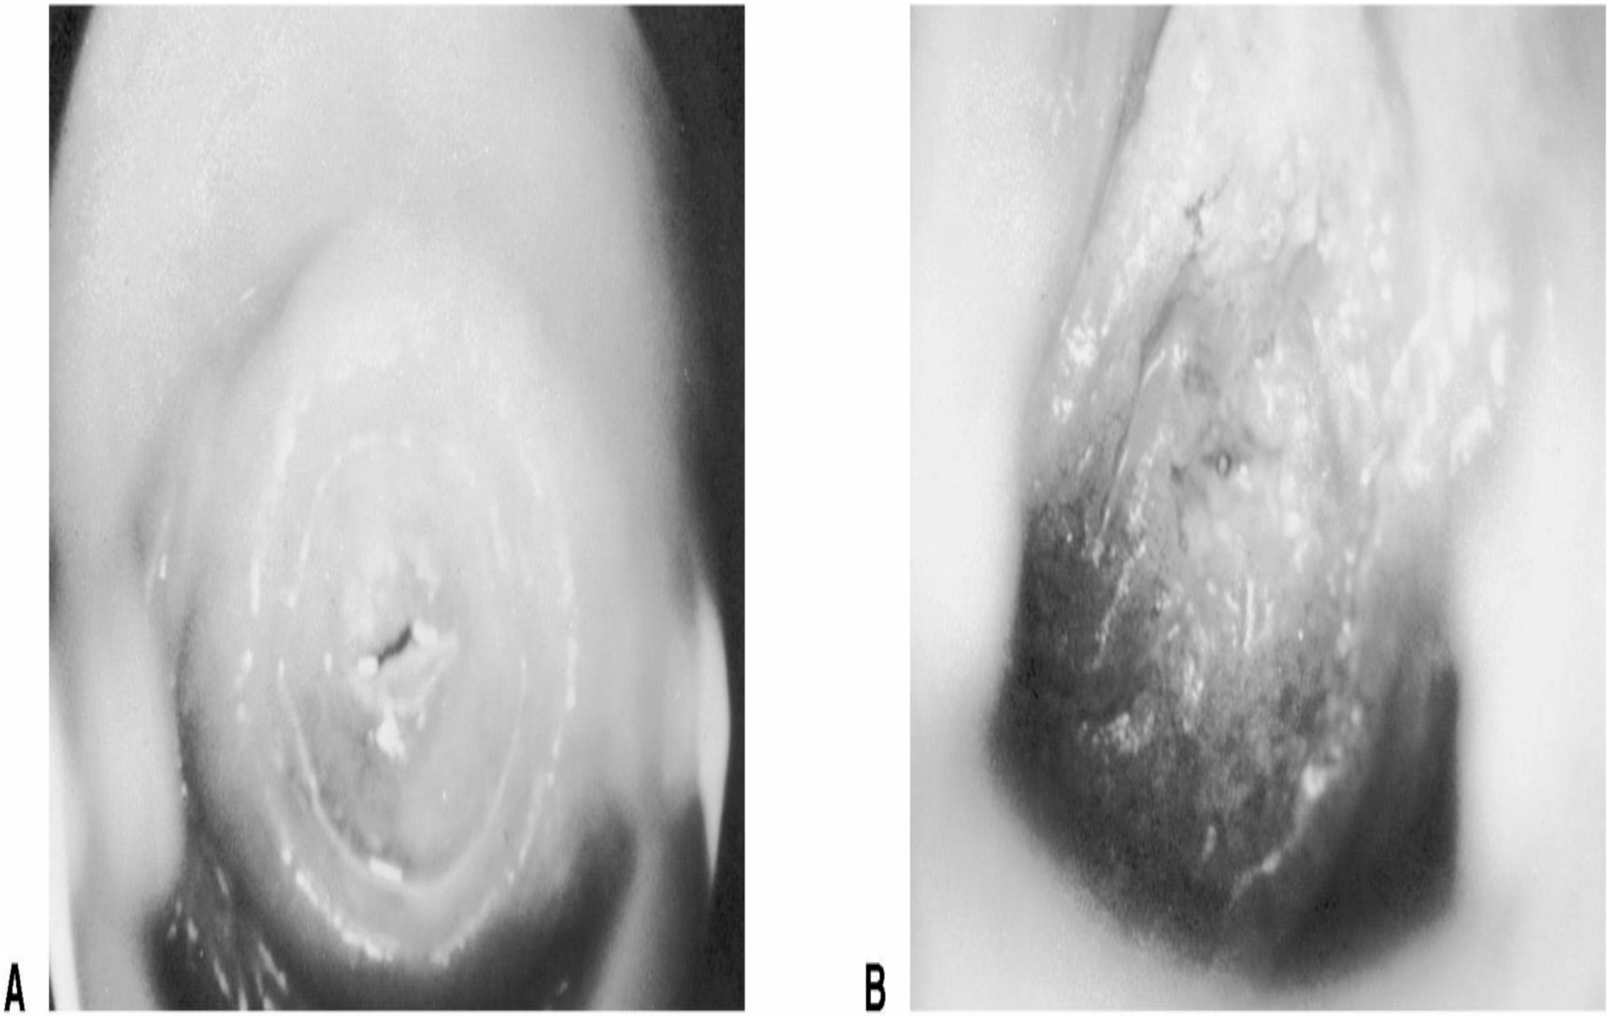
Ovary
Fibrous septum dividing endometrial cavity and cervical canal

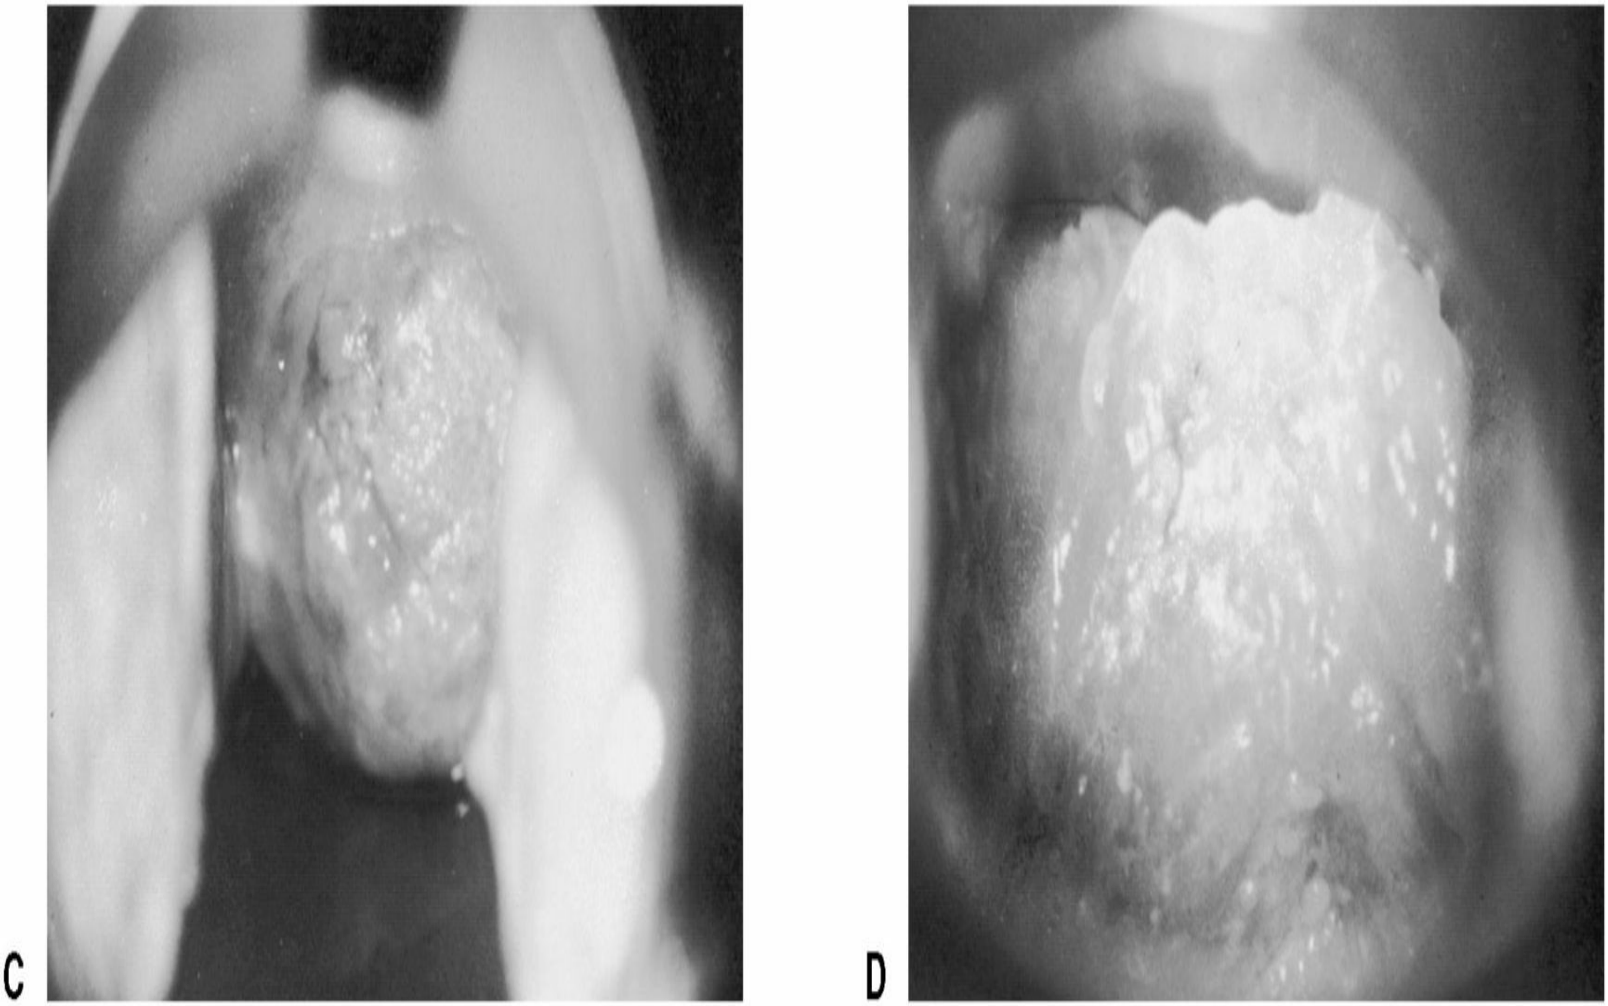
Figure 40–6. Complete septate uterus.

If a septate uterus is identified in association with reproductive or obstetric complications, surgical therapy is recommended because it is hypothesized that the septum interferes with placentation. Hysteroscopic resection of the uterine septum improves reproductive outcome in women with recurrent spontaneous miscarriages. Ultrasound, MRI, sonohysterography, and hysterosalpingogram provide information to differentiate a septate uterus from other uterine abnormalities. Combined laparoscopy and hysteroscopy is the most reliable method to accurately differentiate a septate uterus from a bicornuate uterus.

CERVICAL ABNORMALITIES DUE TO DIETHYLSTILBESTROL EXPOSURE IN UTERO

Diethylstilbestrol (DES), a synthetic nonsteroidal estrogen, was used between the 1940s and 1971 to prevent premature birth, miscarriages, and other obstetric complications. Although the number of pregnant women treated with DES is unknown, estimates range from 2–10 million. DES crosses placenta and affects reproductive tract cell differentiation. In utero exposure to DES is also associated with vaginal clear cell carcinoma in female offspring, necessitating cytologic and colposcopic screening. Common structural changes of the cervix include collars, hoods, cockscombs, and pseudopolyps, cervical hypoplasia, and transverse septa (Fig. 40–7). Anomalies of the uterus include a T-shaped uterine cavity, hypoplastic uterus, adhesions, and constrictions of uterine cavity.





C
D

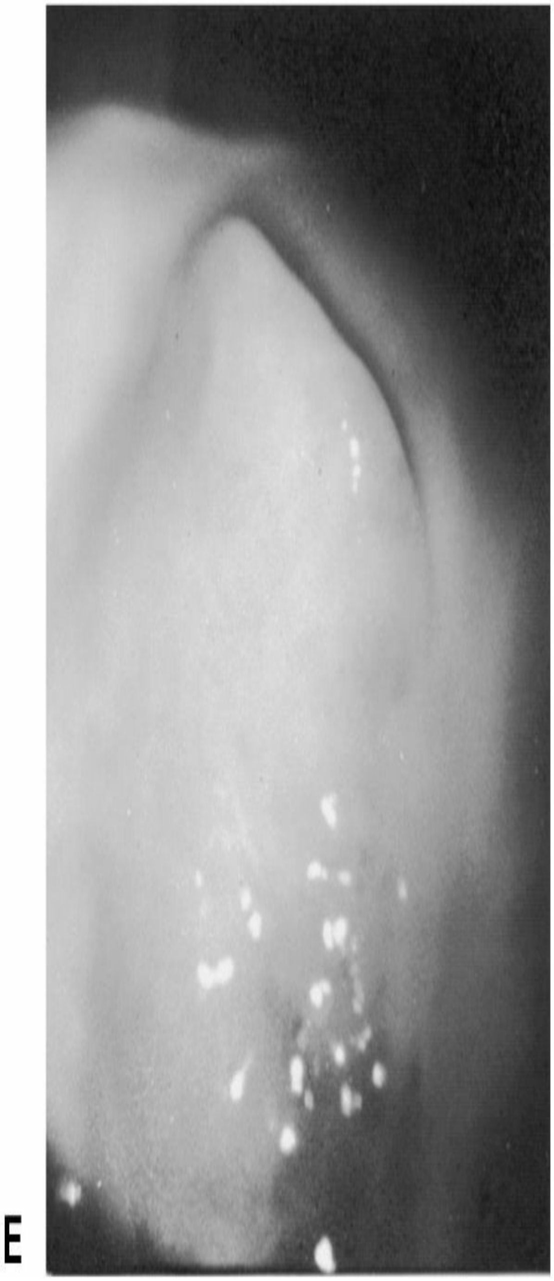


Figure 40–7. Cervical changes in women exposed to diethylstilbestrol in utero. **A:** Circular sulcus. **B:** Central depression and ectopy. **C:** Portio vaginalis covered by columnar epithelium (ectopy). **D:** Anterior cervical protuberance (rough). **E:** Anterior cervical protuberance (smooth).

Women who are exposed to DES in utero and have cervical abnormalities are at increased risk for infertility. These women are also at increased risk for adverse outcomes in pregnancy, including miscarriage, ectopic pregnancy, and premature delivery. The use of prophylactic cervical cerclage for cervical incompetence related to DES exposure in utero is considered based on standard recommendations for cerclage placement.

CERVICAL INJURIES

Lacerations

Cervical lacerations are frequent complications of a vaginal delivery. With vaginal deliveries, the most common site of cervical lacerations is the lateral aspect of the cervix. Clinically significant lacerations that are associated with vaginal bleeding or that require suturing complicate less than 5% of vaginal deliveries. Cervical cerclage, precipitous labor, vacuum extraction, nulliparity, and episiotomy are associated with increased risk for clinically significant lacerations. Cervical lacerations that cause abnormal vaginal bleeding or that extend to the lower uterine segment or vaginal wall warrant repair. Careful inspection of the entire cervix after delivery enables identification and repair of these clinically significant lacerations. Asymptomatic lacerations that are small may not need repair. Cervical lacerations do not appear to affect the outcome of subsequent pregnancies.

Performance of dilatation and curettage (D&C), particularly on the postmenopausal patient, can result in cervical laceration, most commonly during dilatation. When a tenaculum tears through the cervix with dilatation, it can easily be repaired by suturing, if needed. Use of cervical laminaria preoperatively may decrease the risk of laceration. Preoperative use of misoprostol to soften the cervix and reduce the force required to dilate it has been reported as an additional strategy.

Cervical lacerations are also reported with operative hysteroscopy, with use of the resecting loop, the roller-ball, and other instruments used to ablate the endometrium.

Perforations

Perforation of the cervix may occur inadvertently during sounding of the uterus, cervical dilatation, insertion of radioactive sources, or conization of the cervix or during self-induced abortion with sharp objects (eg, wires or darning or knitting needles). The urinary bladder and the rectum are at risk for injury because of their close proximity to the cervix. Perforations may involve the entire thickness and result in hemorrhage or hematoma if the uterine vessels are involved.

Ulcerations

Ulceration of the cervix may result from pressure necrosis related to vaginal pessary use. Cervical ulceration may also develop in women with complete uterine prolapse whose cervix protrudes through the vaginal introitus.

Cervical Stenosis

Cervical stenosis may lead to significant symptoms. In premenopausal women, cervical stenosis may obstruct menstrual flow, leading to amenorrhea, pelvic pain, and endometriosis. Additionally, cervical stenosis may impede the movement of semen into the uterus and thus be associated with an increased risk of infertility. Pyometra, although uncommon in women with cervical stenosis, is more common in postmenopausal women. Evacuation of pyometra and biopsy of intrauterine contents to rule out endometrial carcinoma is advised.

Although cervical stenosis may be present from birth, it may be caused by other factors. Cervical surgery such as cone biopsy, loop excision, or cryotherapy for treatment of dysplasia may lead to cervical stenosis. Excision by loop diathermy is less likely to cause cervical stenosis than a cold knife cone biopsy, perhaps because less stroma is removed or because suturing performed with cold knife cone may heal occluding the cervical os. Other causes of stenosis are trauma to the cervix, radiation therapy, and cervical cancer. Cervical atrophy with menopause may result in cervical stenosis.

The diagnosis of cervical stenosis is made clinically, by the inability to pass a small cervical dilator. The obstruction of the cervical canal may be suggested by visualizing intrauterine contents on ultrasonography of the uterus. Treatment of cervical stenosis involves opening or widening the cervical canal. The gentle passage of graduated sounds through the cervical canal at weekly intervals during the intermenstrual phase for 2–3 months after treatment will prevent or correct stenosis. In some circumstances, passing dilators under ultrasound guidance may be helpful. If the stenosis is associated with scar tissue, techniques to vaporize the scar tissue with laser treatment or enlarge the canal with loop diathermy and the resecting loop of the hysteroscope may be performed.

Annular Detachment

Annular detachment of the cervix is an extremely rare obstetric complication in which the cervix is devitalized and torn during labor. Proposed mechanisms include previous cervical damage, failure of the external os to dilate, and compromised blood supply by pressure of the fetal head. The diagnosis may be unrecognized or may be made when the detached ring or portion of cervix is expelled during delivery.

Complications of Cervical Injuries

Cervical injuries can result in immediate and delayed complications. Hemorrhage, although uncommon, is the most immediate and serious complication of cervical laceration. When the cervical tear extends into the lower uterine segment, vaginal bleeding may be present, but occult hemorrhage may occur and result in hypovolemic shock out of proportion to visible blood loss.

Cervical stenosis, cervical incompetence, and failure of the cervical dilation during labor are all sequelae of cone biopsy, and less commonly, unrecognized or improperly repaired lacerations. Repeated or habitual abortion, often occurring during the second trimester of pregnancy, may be due to cervical incompetence.

NORMAL CERVIX

General Considerations

The squamocolumnar junction of the cervix undergoes change over reproductive life. In younger women, the squamocolumnar junction is on the ectocervix. When it extends to replace a large part of the ectocervix, the term **cervical ectopy** is used, and the cervix appears red, granular and inflamed-appearing. Over time, the squamocolumnar junction moves toward the external os through the process of squamous metaplasia, in which the columnar epithelium on the ectocervix is gradually converted to stratified squamous epithelium. Initially, the metaplastic epithelium is thin and immature, but it becomes thicker and more mature, eventually becoming stratified squamous epithelium. Microscopically, the squamocolumnar junction rarely demonstrates an abrupt transition from squamous to columnar epithelium, but instead has a zone of immature squamous metaplasia (Figs. 40–8 and 40–9). On colposcopy, cervical ectopy has a fine villiform pattern (Figs. 40–10 and 40–11). This change from a mucous membrane of a single layer of columnar epithelium to one of the stratified squamous epithelium may be accelerated during 3 periods of a woman’s life: fetal existence, adolescence, and during the first pregnancy.

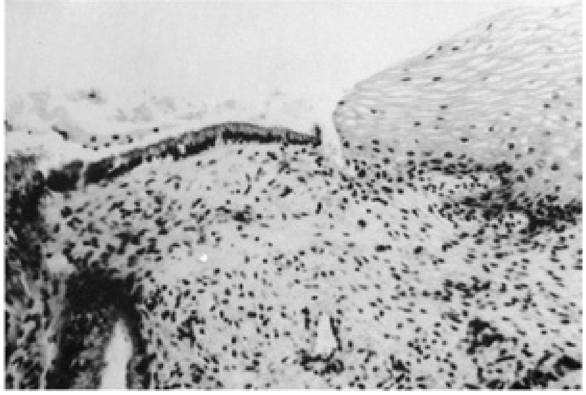

Figure 40–8. Abrupt transition, squamocolumnar junction.

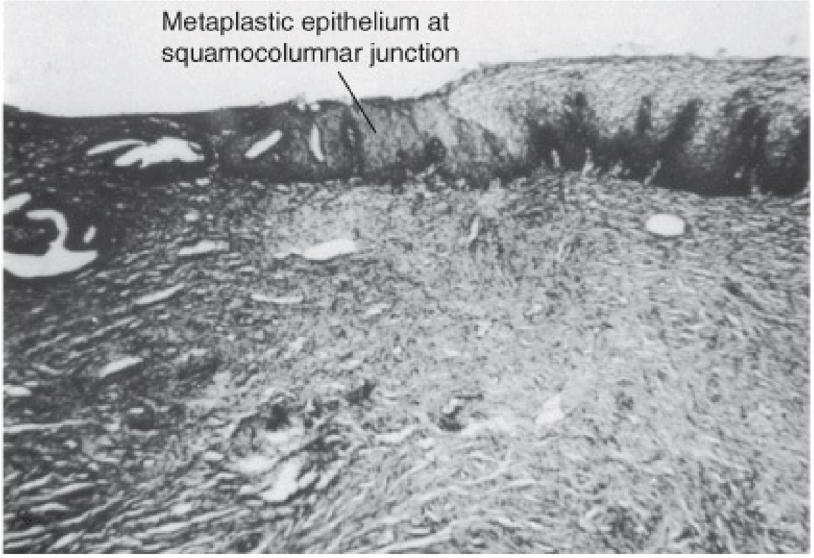

Figure 40–9. Metaplastic epithelium at the squamocolumnar junction.

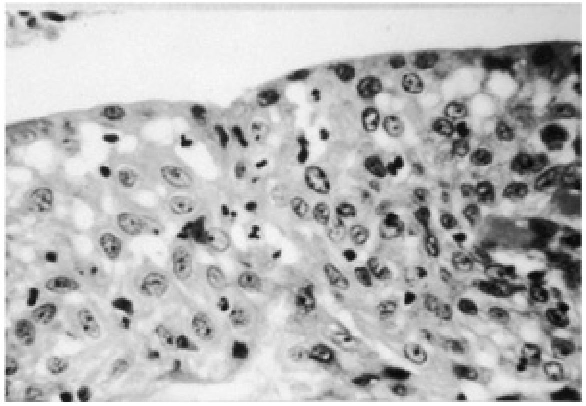

Figure 40–10. Squamous epithelium showing histologic changes of human papillomavirus infection.

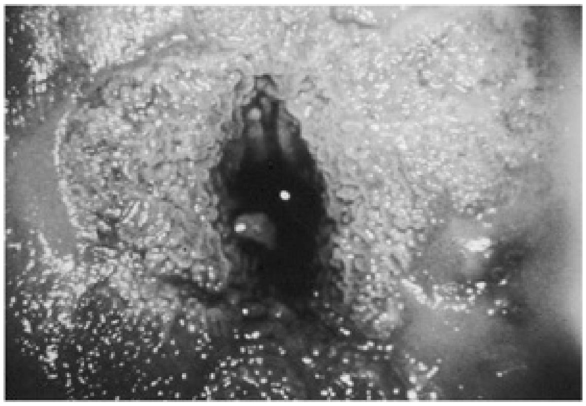

Figure 40–11. Colposcopic view of villiform pattern of cervical ectopy.

By the time a woman reaches her fifth decade, the squamocolumnar junction has receded into the endocervical canal, and the ectocervix is completely covered by squamous epithelium. In the process, the crypts and clefts of columnar epithelium are bridged over and may be occluded, obstructing the egress of mucus, producing the common, typical nabothian cysts of the cervix.

CERVICAL INFECTIONS

General Considerations

Annually 3 million women are diagnosed with cervicitis. Most common causes of infectious cervicitis are *Neisseria gonorrhoeae, Chlamydia trachomatis,* herpes simplex virus (HSV), human papillomavirus (HPV), and trichomoniasis, *Mycoplasma genitalium,* cytomegalovirus, and bacterial vaginosis (covered in Chapter 43). Cervicitis often is asymptomatic and may be undiagnosed for some time. If untreated, cervicitis can result in pelvic inflammatory disease and ultimately lead to a higher risk of infertility, ectopic pregnancy, and chronic pelvic pain. Advances in colposcopy and sensitive testing for infectious diseases have allowed better assessment of the causes of acute and chronic cervicitis. Methods for testing gonorrhea include urethral Gram stain, culture on Thayer-Martin media, DNA probes, and DNA amplification techniques. Testing for chlamydia can be performed using nucleic acid amplification techniques on cervical or urine specimens. For HPV infection, cervical cytology (Pap test) and HPV testing are used with colposcopy and biopsy for detection of HPV disease. The signs of cervicitis are caused by edema and increased vascularity, making the cervix appear swollen and reddened. The presence of hypervascularity, erythema, and ectopy may be found with either squamous metaplasia or inflammatory changes requiring therapy. Cervicitis can be diagnosed histologically when polymorphonuclear leukocytes, lymphocytes, or histiocytes are noted. The cervix is in direct contact with the vagina and is exposed to viral, bacterial, fungal, and parasitic agents. Cervical infections occur in the absence of vaginal disease. Through sexual contact, the cervix may be infected with *N gonorrhoeae, C trachomatis*, HSV, HPV, and *Mycoplasma* spp. Because many women are asymptomatic, screening women in high-risk populations such as those with multiple partners and those with inconsistent use of condoms is important. Patients diagnosed with gonorrhea or chlamydia are at risk for infection with other sexually transmitted diseases (STDs). Counseling and testing should be offered for syphilis, hepatitis B, and HIV, as well as testing for HPV.

Pathogenesis

C trachomatis and *N gonorrhoeae* are sexually transmitted infections (STIs) commonly causing endocervicitis as well as upper reproductive tract infections. More than 1.1 million cases of *C trachomatis* and 350,000 cases of *N gonorrhoeae* were reported in United States in 2007. As *C trachomatis* is often "silent," an undiagnosed, ongoing infection may ascend into the endometrial cavity to the fallopian tubes, causing salpingitis as well as pelvic peritonitis. With the cervix as a reservoir, the organism may infect the fetus during its passage through the birth canal. *C trachomatis* transmitted to the eyes causes trachoma and inclusion conjunctivitis or pneumonia of the newborn.

As with *Chlamydia* infections, *N gonorrhoeae* first causes a cervical infection, which may ascend infecting the endometrium and fallopian tubes. The ascending infection for either agent may occur at the end of menses when there is no protective mucus plug. As with *C trachomatis, N gonorrhea* can be transmitted to newborns during vaginal delivery, causing neonatal ophthalmia.

Fitz-Hugh-Curtis syndrome or perihepatitis is a rare complication usually caused by *C trachomatis* and *N gonorrhoeae* and is characterized by adhesions between the liver and the parietal peritoneum.

There are 2 types of HSV, herpes simplex virus type 1 (HSV-1) and herpes simplex virus type 2 (HSV-2). Although HSV-2 causes most of the genital herpes infections, HSV-1, the etiology of the common cold sore or fever blister, causes some through oral–genital or genital–genital contact. HSV infection produces cervical lesions similar to those found on the vulva. First the lesion is vesicular and then becomes an ulcer. Primary infections may be extensive and severe, producing constitutional symptoms of low-grade fever, myalgia, and malaise lasting approximately 2 weeks. The ulcers heal without scarring. Once infection has occurred, even after healing, the virus continues to reside in the nerve cells of the affected area for life. HSV recurrences are less severe in both symptoms and duration. HSV is found in the lesions caused by HSV infection, but viral shedding can also occur in asymptomatic patients without obvious lesions. Women with either active infection or asymptomatic HSV shedding from normal-appearing skin can infect their infants during vaginal delivery. Those with a positive HSV test near term are advised to undergo caesarean section.

HPV is spread by skin-to-skin contact. Women with vulvar HPV lesions should be assessed for cervical HPV lesions and infection. The cervical lesions are flatter than typical genital warts (condylomata acuminata) seen on the vulva and perianal skin. In fact, they often are invisible to the naked eye, becoming visible only after application of a dilute solution of acetic acid (acetowhite epithelium) or by colposcopic examination (white epithelium, mosaicism, and coarse punctation). There are more than 120 HPV types. Low-risk types 6, 11, 42, 43, 44, 54, and 55 are associated with benign lesions of the cervix, whereas types 16, 18, 31, 33, 35, 39, 45, and 56 are considered high risk and found in association with cervical intraepithelial neoplasia and invasive cancers. Seventy percent of infections resolve in 1 year and 90% by 2 years. Persistent HPV infection may progress to precancerous lesions and, over time, progress to cervical cancer.

Prevention

Abstinence and the use of condoms and barrier methods for protection during coitus are the most important strategies for prevention of cervicitis. Although avoiding sexual contact with infected persons is a sound recommendation, most women do not know whether their partner(s) have an STI, and many of these partners, if infected, are asymptomatic. Because chlamydia and gonorrhea are most prevalent in young adults aged 19 to 25 and have significant long-term complications, annual screening for these 2 infections is advised in high-risk populations, regardless of whether they have symptoms. Other "at risk" populations include those having multiple sexual partners, inconsistently using condoms, with a previous history of STIs, and individuals who engage in other high-risk behaviors (eg, current or prior drug abusers); however, these different risk factors may be difficult to assess.

Because asymptomatic patients are at similar risk of developing complications as symptomatic women, detecting infection in asymptomatic patients is also important.

Treating affected partners at the same time the woman is treated is important to prevent reinfection. Counseling patients and her sexual partner(s) may also be useful.

Detection and treatment of cervicitis in pregnancy has important health benefits for the fetus and newborn. For example, pregnant women should be screened for syphilis and HIV at the first prenatal visit (see Chapter 43). Women with a history of HSV should be screened near term (see Chapter 43). Women at high risk of premature delivery should be screened for bacterial vaginosis (see Chapter 43).

The prompt recognition and proper repair of cervical lacerations lessen the risk of cervical stenosis and cervical incompetence in future pregnancies.

When hysterectomy is performed, if possible, the cervix should be removed to minimize the risk of cervical diseases. Although some recommend retaining the cervix at the time of hysterectomy to maintain sexual function or vaginal support, clinical studies do not provide evidence to support this recommendation.

Clinical Findings

A. Symptoms & Signs

1. Acute Cervicitis—Purulent vaginal discharge is the primary sign and symptom of acute cervicitis. Some women have vaginal bleeding, most frequently after sexual intercourse, although intermenstrual bleeding and bleeding during examination can also occur. The appearance of the discharge varies depending on the pathogen—often thick and creamy discharge is noted in gonorrheal infection, foamy and greenish-white in trichomonal infection, white and curd-like in candidiasis, and thin and gray in bacterial vaginosis. In bacterial vaginosis, an amine or fishy odor is released when the discharge is combined with potassium hydroxide. Vulvar burning and itching may be prominent symptoms of cervicitis.

Chlamydia infections may produce a purulent discharge from a reddened, congested cervix or may be relatively asymptomatic, without visible signs. The muculopurulent discharge of chlamydia infection is often indistinguishable from that of gonorrheal infection. On inspection, the cervix infected by *N gonorrhoeae* reveals an acutely inflamed and edematous cervix with a purulent discharge from the external os. In trichomonal infection, a strawberry-like appearance covers the ectocervix and may extend to the adjacent vaginal mucosa. In candidiasis, a white cheesy exudate may be difficult to wipe away and once wiped off usually leaves punctate hemorrhagic areas.

Gonorrheal or chlamydial cervicitis may be accompanied by urethritis with frequency, urgency, and dysuria. If any infection is associated with acute salpingitis, the symptoms and signs will include pelvic peritonitis. Postcoital bleeding or intermenstrual spotting may occur because of hyperemia of the infected cervix associated with freely bleeding areas. Cervical friability with bleeding occurs when endocervical smears are obtained.

Colposcopic findings of acute cervicitis reveal an altered microangioarchitecture with marked increase in the surface capillaries, which when viewed end-on may show a pattern of diffuse “punctation.” Trichomoniasis is typified by characteristic double-hairpin capillaries. In an inflammatory process, the colposcopic picture is diffuse with ill-defined margins in contrast with the localized and sharply demarcated vascular changes associated with intraepithelial neoplasia (Chapter 48). Invasive cancers may be secondarily infected, so in addition to the colposcopic changes associated with malignancy, those related to inflammation are also present.

2. Chronic Cervicitis—In chronic cervicitis, leukorrhea may be the chief symptom. Although not as profuse as in acute cervicitis, the discharge may cause vulvar irritation. The discharge may be frankly purulent and variable in color, or may simply be thick, tenacious, turbid mucus. Intermenstrual or postcoital bleeding may occur. Associated symptoms may be lower abdominal pain, lumbosacral backache, dysmenorrhea, dyspareunia, urinary frequency, urgency, and dysuria.

Inspection of the chronically infected cervix often reveals only abnormal discharge, with the upper vagina appearing normal.

B. Laboratory Findings

1. Stains and Smears—Mucopurulent cervicitis is defined as evidence of purulent material on inspection of an inflamed cervix along with 10 or more polymorphonuclear leukocytes per high-powered microscopic field seen on Gram’s stain of the discharge. In acute cervicitis with *N gonorrhoeae*, the sensitivity of Gram’s stain for detection of diplococci is only 50%. Thus use of Gram’s stain for diagnosis is not recommended in women because of its low sensitivity in detecting infection. Identification of motile flagellated organisms on saline wet smear preparations suggests *Trichomonas vaginalis*. In symptomatic patients, with signs suggesting *Trichomonas*, further testing of nucleic acid amplification, culture testing may be necessary. Bacterial vaginosis can be seen on saline wet mount by the coating of epithelial cells with bacteria called “clue cells.” Bacterial vaginosis is diagnosed by using Amsel criteria: thin homogeneous white, yellow discharge, presence of the “clue cells” on microscopy, vaginal pH >4.5, and fishy odor on adding alkaline 10% potassium hydroxide solution. Presence of 3 of these criteria will confirm the diagnosis of bacterial vaginosis. Candidal infections can be seen on potassium hydroxide preparations, with the distinctive presence of hyphae.

2. Detection of Specific Agents Causing Cervical Infections—Previously, culture was the preferred method to detect infection. *N gonorrhoeae* culture is performed on Thayer-Martin or blood agar medium. Although culture has excellent specificity, the sensitivity is no higher than 70% in females. Culture can be influenced by how the specimen was collected, transport conditions, culture procedures, and identification of a positive culture.

More recently, infection is detected more reliably with nucleic acid amplification methods such as polymerase chain reaction (PCR), transcription-mediated amplification, and strand displacement amplification. The benefit of using nucleic acid amplification is its high sensitivity and specificity (82–100%). The specimen can be obtained noninvasively from either a vulvar swab or urine, with non–clean catch urine specimens having greater sensitivity than cervical testing. These tests also allow for simultaneous detection of both *N gonorrhoeae* and *C trachomatis* from the same specimen. Sensitivity with urine and cervical samples is similar for *C trachomatis*, but sensitivity for *N gonorrhoeae* is higher with cervical swab. Enzyme immunoassay and direct fluorescent antibody rely on antigen detection and have a sensitivity ranging from 70–80%, but the specimen still requires invasive testing using a swab from the cervix or urethra.

HSV infection can be detected by viral culture, PCR, and direct fluorescence antibody. Most laboratories are moving toward nonculture assays such as PCR, which offer high sensitivity and specificity.

Syphilis is detected by using nontreponemal rapid plasma reagin (RPR) or Venereal Disease Research Laboratory (VDRL) tests and subsequent confirmation with micro-hemagglutination assay for *Treponema pallidum* (MHA-TP), fluorescent treponemal antibody-absorption (FTA-ABS) tests.

Combining HPV testing with cervical cytology appears to be the most effective strategy for detecting abnormal cervical pathology. Cervical cytology with HPV testing is first performed in women at 21 years of age regardless of the age of onset of sexual activity because of the low risk of cancer in women under age 21. If cytology is normal and HPV testing is negative, follow-up screening is done in 3 years. If cytology is abnormal, colposcopy with directed biopsy is advised.

3. Blood Studies—In uncomplicated cervicitis not accompanied by salpingitis, the white count may be normal. With salpingitis, a leukocytosis is common with an elevated white count. The erythrocyte sedimentation rate may be slightly elevated.

Cytopathology

Until recently, the Papanicolaou (Pap) smear has been the primary tool to examine the pathologic changes related to cervical neoplasia. Cellular changes of mild dysplasia (low-grade squamous intraepithelial lesion [SIL]), moderate or severe dysplasia (carcinoma in situ [CIS], high-grade SIL), and invasive cancer may be delineated on cytology testing.

Epithelial cell changes associated with cervical inflammation may be difficult to distinguish from those related to neoplastic disease. Nuclear enlargement, clumping of chromatin, hyperchromatism, and nucleoli, as well as cytoplasmic eosinophilia and poorly defined cell membranes, are nonspecific findings of “cytologic atypia.” A few inflammatory cells can be seen on the cytology slide, particularly immediately before, during, and immediately after menses. However, large numbers of polymorphonuclear leukocytes or histiocytes indicate an acute cervicitis. When the inflammatory cells are so dense that the epithelial cells are obscured, the smear should be repeated after the inflammatory process has been treated.

Cervical cytology evaluation can also aid in the diagnosis of specific cervical infections. At times, a specific diagnosis can be made either by identifying the infectious organism(s) or by noting changes in the epithelial cells characteristic of a specific type of infection. For example, trichomonads and yeast forms can be identified directly on cytology slides. HPV infection is characterized by squamous epithelial cell enlargement, multinucleation, and the perinuclear “halo” effect of koilocytosis. Enlarged, multinucleated cells with ground-glass cytoplasm and nuclei containing inclusion bodies are indicative of HSV infection.

Histopathology of Cervical Infections

Both *N gonorrhoeae* and *C trachomatis* infections produce a nonspecific acute inflammatory reaction of edema and increased vascularity, and the cervix becomes swollen and reddened. Gross appearance of acute cervicitis must be distinguished clinically and histologically from cervical ectopy. Infection causes the glandular epithelium to hyperfunction, producing a copious purulent or mucopurulent exudate and mucus mixed with inflammatory cells. Microscopically, stromal edema and infiltration by polymorphonuclear leukocytes are seen, and some mucous membrane may be denuded. As the acute infection subsides, swelling and redness disappear, and polymorphonuclear leukocytes are replaced by lymphocytes, plasma cells, and macrophages—the histologic picture of chronic cervicitis. Almost all parous women may have findings characteristic of chronic cervicitis on biopsy that are not significant unless they also have clinical signs and symptoms of cervicitis.

Differential Diagnosis

Noninfectious cervicitis may result from the effects of endogenous or exogenous hormones on the cervicovaginal mucosa. When cervical discharge is noted, bimanual examination may aid in diagnosis of pelvic infection with the clinical signs of cervical motion tenderness and induration.

Infectious cervicitis must be distinguished from cervical intraepithelial neoplasia. This may be hampered because inflammatory conditions may also result in epithelial atypia on cytologic examination. Colposcopy is a useful adjunct (see Chapter 48). Cervical cytology and histologic examination by endocervical curettage and biopsy may help distinguish chronic cervicitis from cervical neoplasia.

Complications

N gonorrhoeae or *C trachomatis* cervicitis is often complicated by salpingitis and pelvic inflammatory disease, which are associated with an increased risk of infertility, ectopic pregnancy, and chronic pelvic pain. The occurrence of gonorrheal or chlamydial cervicitis in HIV-infected women has been reported to be associated with increased shedding of HIV-1 that, in turn, increases the infectiveness of these women. Although a history of genital infections is more common among women with carcinoma of the cervix, these agents do not increase the risk of developing cancer.

Treatment

Selecting the treatment for cervicitis depends on the nature of the infection, whether the patient is pregnant or breastfeeding, her plans for future pregnancy, the severity of the cervical infection as indicated by the presence or absence of complicating factors such as salpingitis, and previous treatment. Instrumentation should be avoided during the acute cervicitis to minimize the risk of ascending infection.

A. Acute Cervicitis

Treatment of acute cervicitis is directed at diagnosing a specific organism; treatment is then directed accordingly.

1. Trichomoniasis—Metronidazole is used to treat *T vaginalis* infection. Metronidazole can be administered as 2 g orally in a single dose or tinidazole 2 g orally in a single dose, or alternatively as metronidazole 500 mg twice daily for 7 days. Any of these regimens have cure rates of approximately 90–95%. Patients should be advised not to use alcohol during treatment. Abstinence from alcohol should continue for 24 hours after treatment with metronidazole and for 72 hours after using tinidazole. Pregnant women should be given 2 g orally as a single dose; those who are breastfeeding should stop breastfeeding for 12–24 hours. Sex partners should be treated and intercourse should be avoided until women and their sex partners are cured. Topical forms of metronidazole are less efficacious (<50%) than the oral preparations.

2. Candidiasis—Candidiasis is most effectively treated with topically applied azole drugs. This will result in relief of symptoms. Treatment course may be 1, 3, or 7 days, depending on the severity of infection. Effective treatments include butoconazole 2% cream 5 g intravaginally for 3 days, clotrimazole 1% cream 5 g intravaginally for 7–14 days, clotrimazole 100 mg vaginal tab for 7 days, miconazole 25 cream 5 g intravaginally for 7 days, miconazole 200-mg vaginal suppository for 3 days or 100 mg for 7 days. A single dose of 150 mg fluconazole by mouth is an effective treatment.

3. Bacterial Vaginosis—See Chapter 43, Sexually Transmitted Diseases and Pelvic Infections.

4. *C trachomatis*—*C trachomatis* can be treated with azithromycin 1 g orally in a single dose or alternatively with doxycycline 100 mg twice daily for 7 days. Alternative treatments with erythromycin base 500 mg orally 4 times a day for 7 days, erythromycin ethylsuccinate 800 mg orally 4 times a day for 7 days or ofloxacin 300 mg orally twice a day for 7 days, or levofloxacin 500 mg orally once a day for 7 days are suggested. In pregnancy, azithromycin 1 g orally in a single dose or amoxicillin 500 mg orally 3 times a day for 7 days can be given; alternatively erythromycin could be used as well. Doxycycline, ofloxacin, and levofloxacin are contraindicated in pregnancy. Because of the high rate of coinfection with *N gonorrhoeae* and *C trachomatis* (up to 42%), when *N gonorrhoeae* infection is found, it is recommended that patients also receive treatment for *C trachomatis*.

5. *N gonorrhoeae*—Cervicitis due to *N gonorrhoeae* can be treated with ceftriaxone 125 mg administered intramuscularly in a single dose, cefixime 400 mg orally in a single dose, ciprofloxacin 500 mg orally in a single dose, or ofloxacin 400 mg or levofloxacin 250 mg orally in a single dose. In pregnancy, fluoroquinolones should be avoided. Fluoroquinolones also should not be used in patients residing in or who may have acquired infections in Europe, Middle East, Asia, the Pacific (including Hawaii), or California because of increasing quinolone-resistant *N gonorrhoeae* (QRNG) in these areas (see Chapters 43 and 44 and the 2006 Centers for Disease Control and Prevention guidelines for treatment of STDs for full recommendations).

B. Chronic Cervicitis

Several studies have demonstrated that microscopic findings of 10 or more polymorphonuclear leukocytes per high-power field do not correlate with specific infection using more sensitive testing for *N gonorrhoeae* and *C trachomatis*. Therefore, an asymptomatic patient with chronic cervicitis who does not test positive for an STD does not need to be treated.

Surgical procedures may be useful for treatment of symptomatic chronic cervicitis, especially in the absence of an infectious pathogen or evidence of dysplasia. Cryosurgery, electrocauterization, and laser therapy have been used, although there is a high risk for recurrence and risk for cervical injury.

Treatment of Complications

A. Cervical Hemorrhage

Cervical hemorrhage after surgical procedures such as cone biopsy, electrocauterization, loop excision, cryosurgery, or laser vaporization requires suture ligation of bleeding vessels. For less severe bleeding, directed topical coagulation of bleeding areas with Monsel’s solution or silver nitrate is successful. Electrocauterization may also be beneficial.

B. Salpingitis

Inflammation of the fallopian tubes usually necessitates the administration of a broad-spectrum antibiotic. Intravenous administration may be advised to obtain adequate antibiotic levels.

C. Leukorrhea

Persistent cervical discharge after treatment may indicate either persistent infection or reinfection. Testing should be performed and selective antibiotic treatment administered.

D. Cervical Stenosis

Cervical surgery is a common cause of cervical stenosis and secondary amenorrhea after the surgical procedure suggests cervical stenosis. Inability to insert a 2.5-mm diameter dilator is consistent with cervical stenosis. Cervical stenosis is treated by dilating the cervical canal.

E. Infertility

Normally, midcycle cervical mucus enhances transportation of sperm through the cervical canal. Factors that influence production of normal cervical mucus could have an impact on fertility. They include surgical factors (cauterization, freezing, or vaporization) or removal (conization or loop excision) of the endocervical glandular cells and cervical infections. Treatment includes low-dose estrogen for 1 week before ovulation or intrauterine insemination with washed and incubated sperm.

GRANULOMATOUS INFECTIONS OF THE CERVIX

Tuberculosis, tertiary syphilis, and granuloma inguinale rarely present as chronic cervical lesions. When present, cervical nodules, ulcerations, or granulation tissue may produce a chronic inflammatory exudate characterized histologically by lymphocytes, giant cells, and histiocytes. The gross appearance of the cervix may be difficult to distinguish from carcinoma of the cervix.

Tuberculosis

Since 1986, the incidence of tuberculosis in the United States has increased, particularly among African Americans, Hispanics, and Asians. Some of the increase has been attributed to the HIV epidemic. In the past, genital tuberculosis has accounted for only 1% of patients with pelvic inflammatory disease; however, in European and Asian countries, the occurrence ranges from 5–13%. With increasing numbers of immigrants to the United States and with the rise in incidence of AIDS in American women, an increase in the incidence of pelvic tuberculosis may occur. Genitourinary tuberculosis is commonly secondary to infection elsewhere in the body, usually pulmonary, but active pulmonary disease can be documented in only one-third of patients. Vascular dissemination is responsible for infection of the fallopian tubes in almost all patients with genital tuberculosis, and involvement of the endometrium follows in 90%. Cervical disease can occur by direct extension or lymphatic spread but is rare, occurring in only 1% of cases. The chief clinical manifestations of pelvic and cervical involvement are abdominal pain, irregular bleeding, and constitutional symptoms. The cervix may be hypertrophied and nodular, without any visible lesion. Speculum examination may demonstrate either an ulcerative or a papillary lesion, thus resembling neoplastic disease.

The diagnosis of tuberculosis of the cervix must be made by biopsy. Histologically, the disease is characterized by tubercles undergoing central caseation. Because such lesions may be caused by other entities such as amoebiasis, schistosomiasis, brucellosis, tularemia, sarcoidosis, and foreign body reaction, the tubercle bacillus must be demonstrated by acid-fast stains or culture.

The reader is referred to other texts for the details of medical therapy of genital tuberculosis. Most patients are cured by medical management alone. Patients who respond poorly or who have other problems (eg, tumors, fistulas) may require total hysterectomy and bilateral salpingo-oophorectomy after a trial of chemotherapy.

RARE INFECTIOUS DISEASES OF THE CERVIX

Lymphogranuloma venereum, a chlamydial infection, and chancroid, caused by *Haemophilus ducreyi*, may attack the cervix along with other areas of the reproductive tract.

Cervical actinomycosis may occur as a result of contamination by instruments and by intrauterine devices. The cervical lesion may be a nodular tumor, ulcer, or fistula. Prolonged penicillin or sulfonamide therapy is recommended.

Schistosomiasis of the cervix is secondary to involvement of the pelvic and uterine veins by the blood fluke *Schistosoma haematobium*. Cervical schistosomiasis may produce a large papillary growth that ulcerates and bleeds on contact, resembling cervical cancer. In other instances, Schistosomiasis may be found in endocervical polyps and be associated with intermenstrual and postcoital bleeding. An ovum occasionally can be identified in a biopsy specimen taken from the granulomatous cervical lesion. However, the diagnosis usually is made by recovering the parasite from the urine or feces. Chemical, serologic, and intradermal tests for schistosomiasis are available.

Echinococcal cysts may involve the cervix. Treatment consists of surgical excision.

CYSTIC ABNORMALITIES OF THE CERVIX

Nabothian Cysts

Nabothian cysts develop when a cleft or tunnel of columnar endocervical epithelium becomes covered by squamous metaplasia. They appear grossly as translucent or yellow and may vary in diameter from a few millimeters to 3 cm.

Mesonephric Cysts

Microscopic remnants of the mesonephric (wolffian) duct are often seen deep in the lateral vaginal fornices externally in the normal cervix. Occasionally they become cystic, forming structures up to 2.5 mm in diameter, lined by cuboid epithelium. They may be confused with deeply situated nabothian cysts, but their location and the wolffian-type cells lining the cysts serve as useful distinguishing features.

BENIGN NEOPLASMS OF THE CERVIX

1. CERVICAL POLYPS

ESSENTIALS OF DIAGNOSIS

- Intermenstrual or postcoital bleeding
- A soft, red pedunculated protrusion from the cervical canal at the external os
- Microscopic examination confirms the diagnosis of benign polyp

---

General Considerations

Cervical polyps are small, pedunculated, often sessile neoplasms of the cervix. Most originate from the endocervix; a few arise from the portio (Fig. 40–12). They are composed of a vascular connective tissue stroma and are covered by columnar, squamocolumnar, or squamous epithelium. Polyps are relatively common, especially in multigravidas over 20 years of age. They are rare before menarche, but an occasional polyp may develop after menopause. Asymptomatic polyps often are discovered on routine pelvic examination. Most are benign, but all should be removed and submitted for pathologic examination because malignant change may occur. Moreover, some cervical cancers present as a polypoid mass.

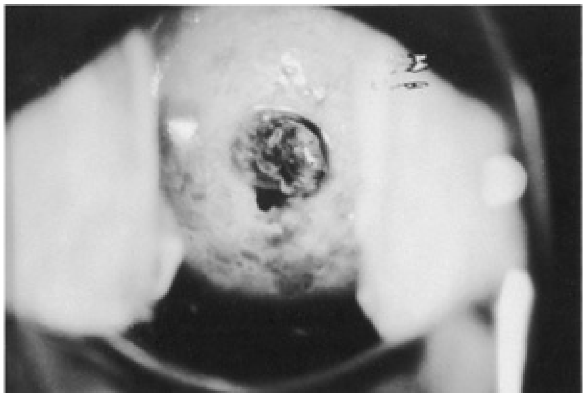

Figure 40–12. Cervical polyp.

Polyps arise as a result of focal hyperplasia of the endocervix. Whether this is due to chronic inflammation, an abnormal local responsiveness to hormonal stimulation, or a localized vascular congestion of cervical blood vessels is not known. They are often found in association with endometrial hyperplasia, suggesting that hyperestrogenism plays a significant etiologic role. Most polypoid structures are vascular, often are infected, and are subject to displacement or torsion. Increased discharge and postcoital bleeding are common symptoms.

Endocervical polyps usually are red, flame-shaped, fragile growths. The polyps vary from a few millimeters in length and diameter to larger tumors 2–3 cm in diameter and several centimeters long. These polyps usually are attached to the endocervical mucosa near the external os by a narrow pedicle, but occasionally the base is broad. On microscopic examination, the stroma of a polyp is composed of fibrous connective tissue containing numerous small vessels in the center. There is often extravasation of blood and marked infiltration of the stroma by inflammatory cells (polymorphonuclear neutrophils, lymphocytes, and plasma cells). The surface epithelium resembles that of the endocervix, varying from typical picket-fence columnar cells to areas that show squamous metaplasia and mature stratified squamous epithelium. The surface often has many folds, as is much of the normal endocervical mucosa.

Ectocervical polyps are pale, flesh-colored, smooth, and rounded or elongated, often with a broad pedicle. They arise from the outer cells of the cervix and are less likely to bleed than endocervical polyps. Microscopically, ectocervical polyps are more fibrous than endocervical polyps, with few or no mucus glands, and are covered by stratified squamous epithelium.

Metaplastic alteration of both types of polyp is common. Inflammation, often with necrosis at the tip (or more extensively), is typical of both polyp types.

The incidence of malignant change in a cervical polyp is estimated to be <1%. Squamous cell carcinoma is the most common type of malignancy, although adenocarcinomas have been reported. Endometrial cancer may involve the polyp secondarily. Sarcoma rarely develops within a polyp.

Botryoid sarcoma, an embryonal rhabdomyosarcoma tumor of the cervix (or vaginal wall) resembling small pink or yellow grapes, contains striated muscle and other mesenchymal elements. It is extremely malignant.

Because polyps are a potential focus of cancer, they must be examined routinely for malignant characteristics upon removal.

Clinical Findings

A. Symptoms & Signs

Intermenstrual or postcoital bleeding is the most common symptom of cervical polyps. Leukorrhea (white or yellow mucous secretion) and menorrhagia have also been associated with cervical polyps.

Abnormal vaginal bleeding is often reported. Post-menopausal bleeding is frequently described by older women. In the setting of infertility, it is reasonable to remove them as a potential contributing factor.

Cervical polyps appear as smooth, red, fingerlike projections from the cervical canal. They usually are approximately 1–2 cm in length and 0.5–1 cm in diameter. Generally they are too soft to be felt by the examiner’s finger.

B. X-Ray Findings

Polyps high in the endocervical canal may be demonstrated by hysterosalpingogram or saline infusion sonohysterography.

C. Laboratory Findings

Vaginal cytology will reveal signs of infection and often mildly atypical cells. Blood and urine studies are not helpful.

D. Special Examination

A polyp high in the endocervical canal may be seen with the aid of a special endocervical speculum or by hysteroscopy. Some polyps are found only at the time of diagnostic D&C in the investigation of abnormal bleeding.

Differential Diagnosis

Masses projecting from the cervix may be polypoid but are not necessarily polyps. Adenocarcinoma of the endometrium or endometrial sarcoma may present as a mass at the external os or extending beyond. Discharge and bleeding usually occur.

Typical polyps are easy to diagnose by gross inspection, but ulcerated and atypical-appearing growths must be distinguished from other small submucous pedunculated myomas or endometrial polyps arising low in the uterus. Any of these growths may result in dilatation of the cervix, presenting just within the os and resembling cervical polyps. Products of conception, usually decidua, may push through the cervix and resemble a polypoid tissue mass, without other signs and symptoms of pregnancy. Condylomata, submucous myomas, and polypoid carcinomas are diagnosed by microscopic examination.

Complications

Cervical polyps may be infected, some by virulent staphylococci, streptococci, or other pathogens. Serious infections occasionally follow instrumentation for the identification or removal of polyps. A broad-spectrum antibiotic should be administered at the first sign or symptom of spreading infection.

Acute salpingitis may be initiated or exacerbated by polypectomy.

It is unwise to remove a large polyp and then perform a hysterectomy several days later. Pelvic peritonitis may complicate the latter procedure. A delay of several weeks or 1 month between polypectomy and hysterectomy is recommended.

Treatment

A. Medical Measures

Appropriate testing for cervical discharge should be performed as indicated and treatment administered if infection is identified.

B. Specific Measures

Most polyps can be removed in the physician’s office. The base of the polyp is grasped with forceps and twisted until the growth is avulsed, usually causing little bleeding. When performing polypectomy it is important to cauterize its base to reduce the chances of the bleeding and to decrease the recurrence rate. Large polyps and those with sessile attachments may require excision in an operating room to allow for administration of anesthesia, use of a hysteroscope, and control of any bleeding.

If the cervix is soft, patulous, or definitely dilated and the polyp is large, hysteroscopy should be performed, especially if the pedicle is not readily visible. Exploration of the cervical and uterine cavities with the hysteroscope allows for further identification of other polyps. All tissue must be sent to a pathologist to be examined for possible underlying malignant or premalignant conditions.

Prognosis

Removal of simple, solitary cervical polyps is usually curative.

2. PAPILLOMAS OF THE CERVIX

ESSENTIALS OF DIAGNOSIS

- Asymptomatic
- Papillary projection from the exocervix
- The presence of koilocytes with or without cytologic atypia
- Colposcopic identification

General Considerations

Cervical papillomas are benign neoplasms found on the ectocervix. The neoplasms consist of 2 types: (1) The typical solitary papillary projection from the exocervix composed of a central core of fibrous connective tissue covered by stratified squamous epithelium. This is a true benign neoplasm, and the cause is unknown. (2) Condylomata of the cervix, which may be present in various forms ranging from a slightly raised area on the exocervix that appears white after acetic acid application (on colposcopy) to the typical condyloma acuminatum. These usually are multiple and are caused by HPV infection, an STD. Similar lesions of the vagina and vulva are often, but not always, present. Evidence of HPV infection can be found in 1–2% of cytologically screened women. The incidence is much higher in women attending STD clinics.

Prevention

Contraception with condoms and other barrier methods may prevent primary infection and reinfection.

Clinical Findings

A. Symptoms & Signs

There are no characteristic symptoms of cervical papillomas; they are often discovered on routine pelvic examination or colposcopic examination for dysplasia revealed by Pap smear.

B. Laboratory Findings

Cytologic findings of koilocytes—squamous cells with perinuclear clear halos—are strongly suggestive of HPV infection. Dysplastic squamous cells are frequently found in association with koilocytes. HPV type testing of cervical or vaginal secretions may be used to determine whether there are oncogenic risk types. Biopsy of involved epithelium reveals papillomatosis and acanthosis. Mitoses may be frequent, but in the absence of neoplastic change, the cells are orderly with regular nuclear features. Koilocytes predominate in the superficial cells.

Complications

Intraepithelial neoplasia is associated with certain types of HPV infection (see Cervical Intraepithelial Neoplasia, Chapter 48). Infection with HPV anywhere in the genital tract, vulva, vagina, or cervix increases the risk of developing squamous cell carcinoma of the cervix.

Treatment

Solitary papillomas should be surgically excised and submitted for pathologic examination. Likewise, colposcopically directed biopsies of flat condylomata should be submitted for histopathologic examination. Flat condylomata may be completely removed with a biopsy instrument if they are small. More extensive lesions may require cryotherapy, loop excision, or laser vaporization. Dysplasia associated with HPV infection should be managed according to the severity and extent of the dysplastic process (see Cervical Intraepithelial Neoplasia, Chapter 48).

Prognosis

Because the entire lower genital tract is a target area for HPV infection, long-term follow-up with attention to the cervix, vagina, and vulva is necessary.

3. LEIOMYOMAS OF THE CERVIX

The paucity of smooth muscle elements in the cervical stroma makes leiomyomas that arise in the cervix uncommon. The corpus leiomyoma/cervical leiomyoma ratio is in the range of 12:1.

Although myomas usually are multiple in the corpus, cervical myomas are most often solitary and may be large enough to fill the entire pelvic cavity, compressing the bladder, rectum, and ureters (Fig. 40–13). Grossly and microscopically they are identical to leiomyomas that arise elsewhere in the uterus.

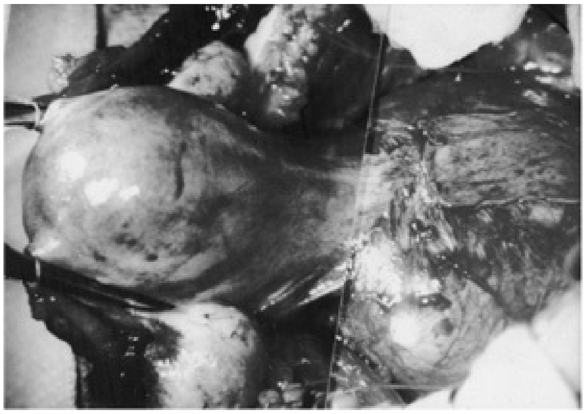

Figure 40–13. Large cervical leiomyoma filling true pelvis.

Clinical Findings

A. Symptoms & Signs

Cervical leiomyomas are often silent, producing no symptoms unless they become very large. Symptoms result from pressure on surrounding organs such as the bladder, rectum, or soft tissues of the parametrium, or obstruction of the cervical canal. Frequency and urgency of urination are the result of bladder compression. Urinary retention occasionally occurs as a result of pressure against the urethra. Heavy vaginal bleeding may occur. Hematometra may develop with obstruction of the cervix.

If the direction of growth is lateral, there may be ureteral obstruction with hydronephrosis. Rectal encroachment causes constipation. Dyspareunia may occur if the tumor occupies the vagina. Large cervical leiomyomas in pregnancy, because of their location, unlike those involving the corpus, may cause soft-tissue dystocia, preventing descent of the presenting part in the pelvis. Cervical leiomyomas of significant size can be readily palpated on bimanual examination.

B. Imaging

A plain film may demonstrate the typical mottled calcific pattern associated with cervical leiomyomas. Hysterography may define distortion of the endocervical canal. Intravenous urography may demonstrate ureteral displacement or obstruction. Transvaginal ultrasound or MRI can be helpful in determining the size and location.

Treatment

Small, asymptomatic cervical leiomyomas do not require treatment. If the leiomyomas become symptomatic, removal may be possible via hysteroscopic resection. If additional multiple leiomyomas are present that cannot be resected with the hysteroscope, uterine artery embolization, abdominal myomectomy, or hysterectomy may be indicated, depending on the patient’s desire for preservation of fertility.

Because of the proximity of the pelvic ureter to the cervix, the ureter is at risk of damage in operation involving a cervical leiomyoma. Dissecting the ureters or placement of stent may prevent its injury.

Prognosis

Recurrence of cervical myomas after surgical removal is rare.

Benign Disorders of the Ovaries & Oviducts

Ofer Lavie, MD

ESSENTIALS OF DIAGNOSIS

- Benign adnexal mass refers not only to ovarian abnormalities but also to masses originating in the fallopian tube (ectopic pregnancy, pyosalpinx), ovaries (ovarian cyst, tuboovarian abscesses, adnexal torsion), uterine ligaments, lateral uterine masses (myomas), and gastrointestinal tract (diverticulitis, appendicitis) and even the urinary system (pelvic kidney).
- Benign adnexal masses originating from the genital system are common in women in the reproductive age group and are caused by physiologic cysts or benign neoplasms.
- Most adnexal masses are discovered incidentally, and the management of these benign masses is dictated by their presentation.
- The evaluation of these masses should be assessed according to the algorithm shown in Figure 41–1, including a thorough patient history, physical examination, laboratory tests, and imaging modalities.

Clinical Findings

Patient history should include review of patient age and family history in particular for the occurrence of ovarian familial cancers. A full physical examination should be performed, including a node survey and breast, abdominal, and pelvic examination. In many cases the radiologic studies, including ultrasonography of the pelvis and sometimes computed tomography (CT), would be of most importance in the assessment of the patient with an adnexal mass (Fig. 41–1). One way to approach the adnexal mass is to think of it in regard to the patient's age. For the young woman, the majority of ovarian cysts are benign: hemorrhagic corpus luteum follicular cysts and dermoid cysts are common in this age group; however, tubal abnormalities, including ectopic pregnancies, and sequela from tubal infection should be strongly considered (Table 41–1). On the other hand, the majority of ovarian or tubal cancers occur postmenopausally.

Less common conditions that must be excluded
Pelvic kidney
Carcinoma of the colon, rectum, appendix
Carcinoma of the fallopian tube
Retroperitoneal tumors (anterior sacral meningocele)
Uterine sarcoma or other malignant tumors

Differential Diagnosis

The clinical challenge in assessing an adnexal mass is to distinguish between a benign and malignant mass (Table 41–1) or findings that indicate a need for intervention or treatment versus masses that can be followed up conservatively (Fig. 41–2). Generally, when malignancy is *not* suspected, and if clinically the patient is stable, then expectant management is indicated, as many of these cysts are physiologic in nature and thus are expected to regress over time.

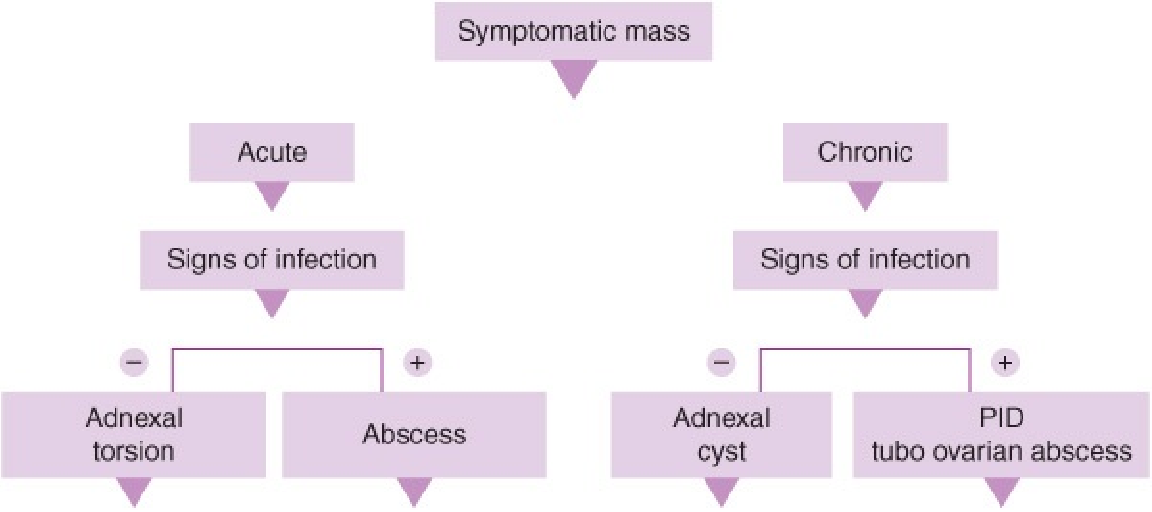

Figure 41–2. Triage for making the diagnosis of an adnexal mass

Patients should be re-evaluated 6 weeks after initial presentation, and persistent masses should be considered potentially benign or malignant neoplasms that warrant operative evaluation.

Treatment

Operative intervention is indicated when a patient is symptomatic because of hemorrhage of a ruptured cyst, ovarian torsion, or failure of previous treatments, for example, failure to treat an adnexal abscess. The risk of malignancy must always be assessed and excluded (see Chapter 50 to be checked for proper evaluation). The exclusion of a neoplastic process should be performed mainly through use of imaging modalities. For instance, sonographic indices as suggested in Table 41–2 should indicate whether the adnexal mass is at high risk for involving a neoplastic process.

Table 41–2. Ultrasonographic characteristic for discrimination between benign and malignant adnexal mass.

	Benign	Malignant
Solid components	−	+
Irregularities of outline	−	+
Unilocular	+	−
Septated	−	+
Papillary projections separations	−	+
Doppler Index (Resistance)	High	Low

Pathologic diagnosis by frozen section during surgery can aid in determining what type of treatment is indicated; however, in a young patient, final diagnosis and treatment of an adnexal malignancy should be based on analysis of permanent, rather than frozen sections because pathologic examination of frozen specimens can sometimes lead to incorrect surgical decisions. For most benign ovarian cysts, laparoscopy is the preferred method because of its shorter recovery time, as well as less pain, blood loss, and overall cost compared with laparotomy. Even extremely large ovarian cysts (reaching the umbilicus and higher) currently are being managed laparoscopically. A laparoscopic approach is recommended if the cyst appears benign by preoperative evaluation (Table 41–2). For most young patients, ovarian cystectomy is favored over oophorectomy in order to retain fertility.

PHYSIOLOGIC ENLARGEMENT: FUNCTIONAL CYSTS

FOLLICULAR CYSTS

ESSENTIALS OF DIAGNOSIS

- The most common functional cyst is the follicular cyst.
- Follicular cysts (Fig. 41–3) vary in diameter from 3 to 8 cm.

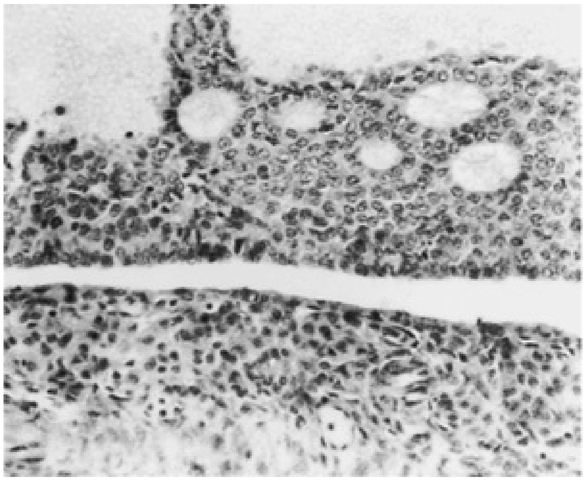

Figure 41–3. Wall of a follicular cyst showing the proliferating granulosa cells with tiny cystic Call-Exner bodies in the upper portion of the figure. They have artifactually pulled away from the underlying theca cells.

- Histologically, they are seen to be lined by an inner layer of granulosa cells and an outer layer of theca interna cells that may or may not be luteinized.

Pathogenesis

These cysts result from a failure in ovulation, most likely secondary to disturbances in the release of the pituitary gonadotropins. The fluid of the incompletely developed follicle is not reabsorbed, producing an enlarged follicular cyst.

Clinical Findings

Typically follicular cysts are asymptomatic, although bleeding and torsion can occur. Large cysts may cause aching pelvic pain, dyspareunia, and occasionally abnormal uterine bleeding associated with a disturbance of the ovulatory pattern.

Treatment

Most follicular cysts disappear spontaneously within 60 days without treatment. Use of oral contraceptive pills (OCPs) has often been recommended to help establish a normal rhythm; however, recent data show that this practice may not produce more rapid resolution than expectant management.

Aspiration of follicular cysts was performed in the past; however, recent data suggest that the diagnostic value of this procedure is relatively low and cysts greater than 8 cm in maximal diameter have a 95% tendency to recur after an aspiration procedure.

CORPUS LUTEUM (GRANULOSA LUTEIN) CYSTS

Clinical Findings

These are thin-walled unilocular cysts ranging from 3–11 cm in size. After normal ovulation, the granulosa cells lining the follicle become luteinized. In the stage of vascularization, blood accumulates in the central cavity, producing the corpus hemorrhagicum. Resorption of the blood then results in a corpus luteum, which is defined as a cyst when it grows larger than 3 cm. A persistent corpus luteum cyst may cause local pain or tenderness. It can also be associated with either amenorrhea or delayed menstruation, thus simulating the clinical picture of an ectopic pregnancy. A corpus luteum cyst may be associated with torsion of the ovary, causing severe pain, or it may rupture and bleed, in which case the patient presents with peritoneal signs and acute abdomen.

Treatment

Laparoscopy or laparotomy is usually required to control hemorrhage into the peritoneal cavity and/or to perform detorsion of the adnexa. Unless acute complications develop, symptomatic therapy is indicated. As with follicular cysts, corpus luteum cysts usually regress after 1 or 2 months in menstruating patients, and OCPs have been recommended but may be of questionable benefit.

THECA LUTEIN CYSTS

Clinical Findings

Elevated levels of chorionic gonadotropin can produce theca lutein cysts and thus are seen in patients with hydatidiform mole or choriocarcinoma and in patients undergoing chorionic gonadotropin or clomiphene therapy. Rarely, they are seen in normal pregnancy. The cysts are lined by theca cells that may or may not be luteinized, and they may or may not have granulosa cells. They are usually bilateral and are filled with clear, straw-colored fluid. Abdominal symptoms are minimal, although a sense of pelvic heaviness or aching may be described. Rupture of the cyst may result in intraperitoneal bleeding. Continued signs and symptoms of pregnancy, especially hyperemesis and breast paresthesias, are reported.

Treatment

The cysts disappear spontaneously after termination of the molar pregnancy, treatment of the choriocarcinoma, or discontinuation of fertility therapy; however, such resolution may take months to occur. Surgery is reserved for complications such as torsion and hemorrhage.

ENDOMETRIOMAS

Clinical Findings

In women with endometriosis, endometriotic foci on the ovarian surface may develop a fibrous enclosure and manifest cyst formation as a result of accumulation of fluid and blood. These endometrial cysts vary from several millimeters to even 10 cm in size. Endometriomas are also referred to as "chocolate cysts" because they contain thick, brown blood debris inside. Filmy or fibroid adhesions from these cysts to the pelvic sidewall, cul-de-sac and fallopian tubes are common and may obscure visualization of the cyst.

Endometriomas are usually associated with chronic pelvic pains, dyspareunia, dysmenorrhea, and infertility.

Differential Diagnosis

The tumor marker CA-125 is commonly elevated in these forms of cysts, which creates a serious clinical problem in distinguishing these cysts from malignant epithelial tumors.

De Ziegler D, Borghese B, Chapron C. Endometriosis and infertility: Pathophysiology and management. *Lancet* 2010:376:730–738. PMID: 20801404.

HYPERTHECOSIS

Clinical Findings

Hyperthecosis, or thecomatosis, commonly produces no gross enlargement of the ovary (Fig. 41–4). Thus the lesions are demonstrable only by histologic examination of the excised gonad. They are characterized by nests of stromal cells demonstrating increased cytoplasm, simulating the changes seen in the normal theca after stimulation by pituitary gonadotropin. In the premenopausal woman, hyperthecosis is associated with virilization and clinical findings similar to those seen in polycystic ovarian disease (see following text). These alterations may also be associated with postmenopausal bleeding and endometrial hyperplasia.

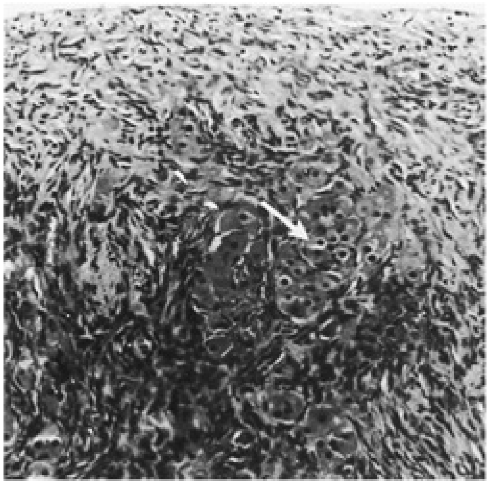

Figure 41–4. In hyperthecosis, nests of rounded eosinophilic luteinized stroma cells are found in the ovarian cortex.

POLYCYSTIC OVARIAN SYNDROME (STEIN-LEVENTHAL SYNDROME)

Clinical Findings

Polycystic ovarian syndrome (PCOS) is characterized by persistent anovulation that can lead to clinical manifestations, including enlarged polycystic ovaries, secondary amenorrhea or oligomenorrhea, obesity, hirsutism, and infertility. The syndrome has a prevalence of 5–10%, with variance among races and ethnicities. Approximately 50% of patients are hirsute, and 30–75% are obese. A presumptive diagnosis of PCOS often can be made based on the history and initial examination. According to an international consensus group, the syndrome can be diagnosed if at least 2 of the following conditions are present: oligomenorrhea or amenorrhea, hyperandrogenism, and polycystic ovaries on ultrasound. Polycystic ovaries have been called “oyster ovaries” because they are enlarged and “sclerocystic” with smooth, pearl-white surfaces without indentations. Many small, fluid-filled follicle cysts lie beneath the thickened fibrous surface cortex (Fig. 41–5). Luteinization of the theca interna is usually observed, and occasionally focal stromal luteinization is seen. Laboratory testing often reveals mildly elevated serum androgen levels, an increased ratio of luteinizing hormone to follicle-stimulating hormone (LH/FSH), lipid abnormalities, and insulin resistance. Anovulation is identified in women with persistently high concentrations of LH and low concentrations of FSH, a low day-21 progesterone level, or on sonographic follicular monitoring. PCOS is presumably related to hypothalamic pituitary dysfunction and insulin resistance. A primary ovarian contribution to the problem has not been clearly defined.

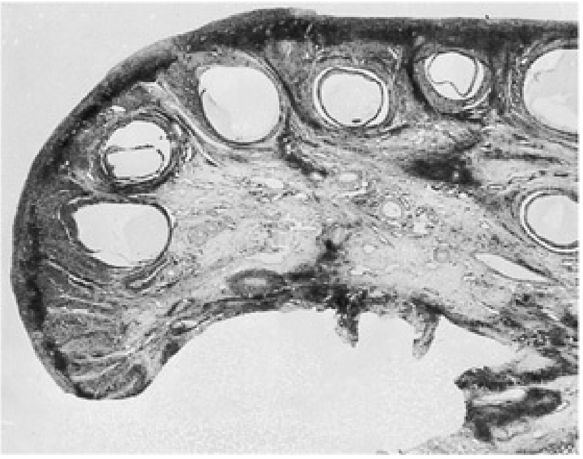

Figure 41–5. Polycystic ovary with a thickened capsule and prominent subcapsular cysts. Note lack of corpora lutea or corpora albicantia due to anovulation.

Treatment

Most patients with PCOS seek treatment for either hirsutism or infertility. The hirsutism can be treated with any agent that lowers androgen levels, and OCPs are typically the first choice in patients not desiring pregnancy. Infertility in PCOS patients is often responsive to clomiphene citrate. In the recalcitrant case, the experienced clinician can add human menopausal gonadotropin to produce the desired ovulation. Recent studies indicate that therapy with metformin improves fertility rates both when given alone and, even more so, when given in conjunction with clomiphene. Studies show that a small reduction in body weight, as little as 2–7%, is associated with improved ovulatory function in women with PCOS. As patients with PCOS are chronically anovulatory, the endometrium is stimulated by estrogen alone. Thus endometrial hyperplasia, both typical and atypical, and endometrial carcinoma are more frequent in patients with PCOS and long-term anovulation. Many of these markedly atypical endometrial features can be reversed by large doses of progestational agents, such as megestrol acetate 40–60 mg/d for 3–4 months. Follow-up endometrial biopsy is mandatory to determine endometrial response and subsequent recurrence.

Lewis V. Polycystic ovary syndrome. A diagnostic challenge. *Obstet Gynecol Clin North Am* 2001;28:1–20. PMID: 11292997.

LUTEOMA OF PREGNANCY

Clinical Findings

Tumorlike nodules of lutein cells may form in the ovaries during pregnancy and are often both multifocal and bilateral. The nodules range up to 20 cm in diameter, but most often they range from 5–10 cm. On section they reveal well-delineated, soft, brown masses with focal hemorrhage. Microscopically, they are formed of sheets of large luteinized cells with abundant cytoplasm and relatively uniform nuclei with occasional mitoses. Clinically, they appear ominous to the obstetrician, who becomes aware of them only when the abdomen is open at the time of caesarean delivery. Unilateral salpingo-oophorectomy can be performed for frozen section in the belief that the large masses are malignant. A confirmatory biopsy is adequate, and follow-up will reveal total regression a few months later.

OVARIAN NEOPLASMS

Evaluation

Ovarian neoplasms may arise from any histologic element of the ovary and are most often benign, especially in premenopausal women. The characteristics of the mass and the age of the patient are important factors guiding diagnosis and treatment. The overall risk of malignancy of an ovarian cyst is 13% in a premenopausal woman versus 45% in a postmenopausal woman. Therefore, vigilant workup of these masses with the aid of ultrasound and close follow-up is essential. Use of cancer antigen-125 (CA-125) for diagnostic purposes is controversial. New tumor markers are being pursued fervently such that soon we may be able to more accurately distinguish malignant from benign adnexal masses. With the increased use of imaging studies has come discovery of incidental, asymptomatic, small ovarian cysts. These cysts should be evaluated by ultrasound. If they do not contain septa or solid components, they can be closely followed. However, any mass that enlarges or changes in character, especially in postmenopausal women, should be explored surgically.

Treatment

The preferred treatment of all ovarian tumors is surgical excision with careful exploration of the abdominal contents. If the risk of malignant neoplasia is confidently low, laparoscopy is preferred. In patients requesting future fertility, cystectomy is performed if possible; otherwise a unilateral oophorectomy is performed. Frozen section is helpful in identifying the type and neoplastic potential of the tumor. However, because adequate sampling of a large ovarian neoplasm often is impossible, final opinion and prognosis *must* be based on analysis of permanent, rather than frozen, sections. Therefore, in a patient desirous of retaining fertility, the surgeon must act on the side of retention of the uterus and contralateral ovary if the pathologist has the slightest doubt as to tumor malignancy.

EPITHELIAL TUMORS

Clinical Findings

Epithelial tumors account for approximately 60–80% of all true ovarian neoplasms and include the common serous, mucinous, endometrioid, clear cell, and transitional cell (Brenner) tumors, as well as the stromal tumors with an epithelial element. The epithelium of these tumors arises from a common anlage (ie, the mesothelium lining the coelomic cavity and ovarian surfaces). This basic thesis explains the similarity of the epithelia of the upper genital canal—endocervix, endometrium, and endosalpinx—to those found in the ovarian tumors. Most tumors presumably arise from invaginated surface epithelium and proliferation or malignant degeneration in the epithelial lining of the resulting surface inclusion cyst (Fig. 41–6). The epithelial tumors are classified on the basis of their histologic appearance.

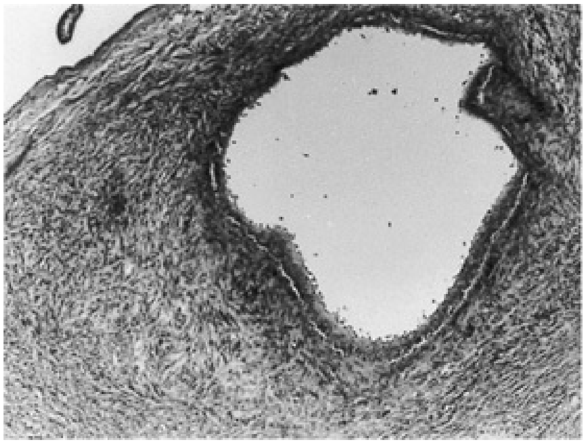

Figure 41–6. Most surface (germinal) inclusion cysts, such as the one shown here, undergo a serous (tubal) metaplasia. By definition, cysts larger than 1 cm in diameter are termed cystadenomas.

SEROUS TUMORS

Clinical Findings

Serous tumors have been reported in all age groups and are responsible for approximately 50% of all epithelial ovarian neoplasms. Low-grade neoplasms generally are found in patients in their 20s and 30s, whereas their anaplastic counterparts occur more commonly in perimenopausal and postmenopausal women. Serous cystadenomas are benign lesions, commonly unilocular, with a smooth surface, and containing thin, clear yellow fluid. The cells lining the cyst are a mixed population of ciliated and secretory cells similar to those of the endosalpinx. They may grow large enough to fill the abdominal cavity, but usually they are smaller than their mucinous counterparts.

Benign serous tumors are bilateral in approximately 15–20% of cases. Focal proliferation of the underlying stroma may produce firm papillary projections into the cyst, forming a serous cystadenofibroma (Fig. 41–7). These tumors appear to be simple on ultrasonographic evaluation, and although there may be some small internal aches, these are purely cystic in appearance (Table 41–1). It is important to study these papillary projections thoroughly to rule out atypical proliferation. Some serous tumors consist of benign stromal proliferation interspersed with tiny serous cysts; these are known as *serous adenofibromas*.

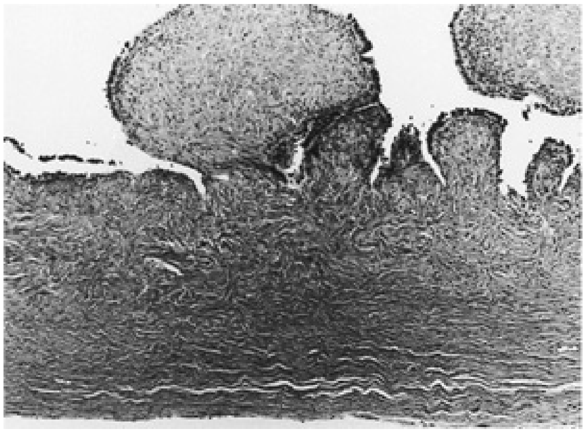

Figure 41–7. Serous cystadenofibromas usually form unilocular cysts with firm white papillations protruding into the cyst, seen here microscopically.

MUCINOUS TUMORS

Clinical Findings

Mucinous tumors account for approximately 10–20% of all epithelial ovarian neoplasms, of which approximately 75%–85% are benign. The benign tumors are typically found in women in their 30s through 50s. Bilateral tumor development occurs in 8–10% of all cases, whether the tumors are benign or malignant. They are the largest tumors found in the human body; 15 reported tumors have weighed more than 70 kg (154 lb). Consequently, the more massive the tumor, the greater the possibility that it is mucinous. They generally are asymptomatic, and patients present with either an abdominal mass or nonspecific abdominal discomfort. In postmenopausal patients, luteinization of the stroma rarely may result in hormone production (usually estrogen) leading to associated endometrial hyperplasia with vaginal bleeding. During pregnancy, hormonal stimulation may result in virilization.

Histologically, they are usually smooth-walled; true papillae are rare (compared with the serous variety). The tumors generally are multilocular, and the mucus-containing locules appear blue through the tense capsule (Fig. 41–8). The internal surface is lined by tall columnar cells with dark, basally situated nuclei and mucinous cytoplasm (Fig. 41–9).

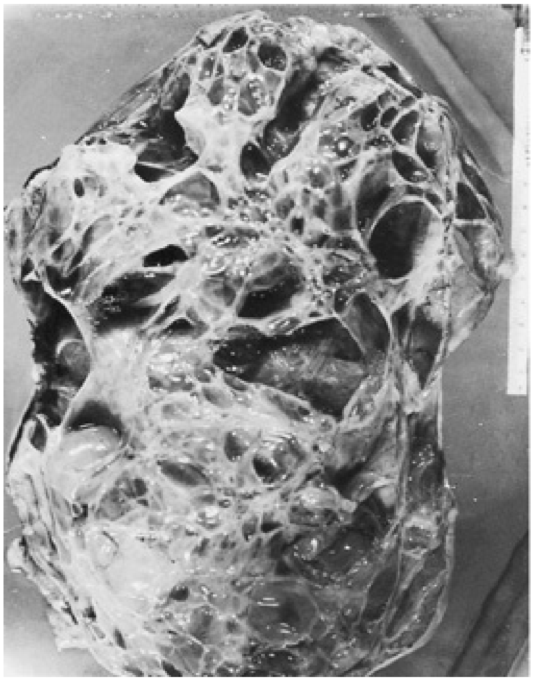

Figure 41–8. Multilocular mucinous cystadenoma of the ovary.

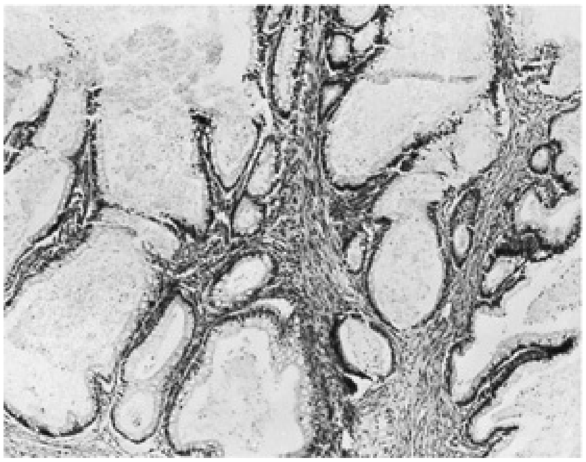

Figure 41–9. Mucinous cystadenoma. The lining cells are tall and columnar with basally situated nuclei. Generous sampling of these tumors is necessary to rule out a higher-grade lesion.

The epithelium of mucinous cysts resembles that of the endocervix in approximately 50% of cases; in the other 50%, mucin-containing goblet cells resembling intestinal epithelial cells are present. Careful study of mucinous neoplasms has shown that the histologic appearance may vary greatly from area to area; some areas appear benign, whereas others are of low malignant potential or are frankly malignant. Hence sampling must be more extensive than in the typical serous tumor. Metastases from appendiceal and other primary tumors may simulate closely a mucinous cystadenoma.

ENDOMETRIOID LESIONS

Clinical Findings

Endometrioid tumors are characterized by proliferation of benign nonspecific stroma in which bland endometrial-type glands may be found. The only clearly recognizable benign endometrioid tumors are the uncommon endometrioid adenofibroma and the proliferative endometrioid adenofibroma. If the epithelial growth is exuberant but cytologically benign, it is termed a *proliferative* rather than a low malignant potential tumor, as the prognosis appears to be invariably excellent (Fig. 41–10).

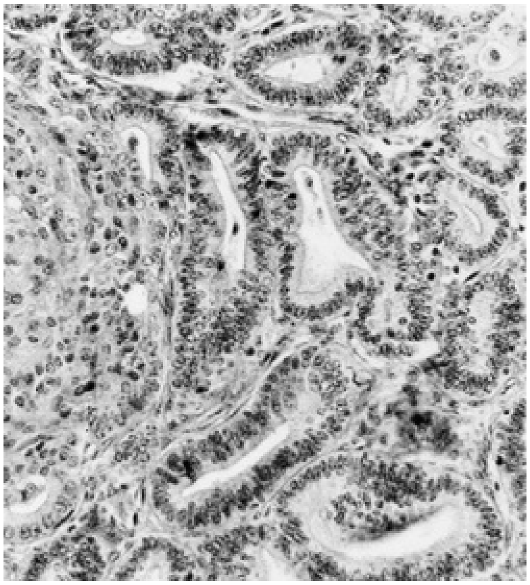

Figure 41–10. Endometrioid cystadenomas contain a proliferation of bland endometrial-like glands without the stroma of endometriosis.

Endometriosis of the ovary (see Chapter 56) represents a benign “tumorlike” condition rather than a true neoplasm. Because pelvic endometriosis may be found in association with endometrioid lesions, one hypothesis is that these lesions arise from preexisting endometriosis.

CLEAR CELL (MESONEPHROID) TUMORS

Clinical Findings

Like the endometrioid tumors, clear cell tumors in their benign form are rare and are virtually limited to clear cell adenofibromas in which a solid proliferation of nonspecific stroma contains small cytologically bland glands formed by columnar cells with clear cytoplasm. The clear cell component usually coexists with another epithelial type. The clear cell histology also is associated with endogenous endometriosis in the pelvic in up to 25% of cases. Clinically, they appear like any other benign ovarian mass and are diagnosed only on histologic examination. The prognosis is excellent.

TRANSITIONAL CELL (BRENNER) TUMORS

Clinical Findings

Transitional cell tumors are adenofibromas in which the proliferating epithelial element has a transitional cell appearance, which represents metaplasia. Brenner tumors account for 1–2% of primary ovarian tumors; more than 98% are benign, and nearly 95% of cases are unilateral. They frequently are so small that they are incidental operative findings. However, the tumor may reach 5–8 cm in diameter and present as an adnexal mass on pelvic examination. On section they are firm and pale yellow or white (Fig. 41–11). The epithelium is composed of nests of cells with ovoid nuclei having a prominent longitudinal groove (“coffee-bean nuclei”; Fig. 41–12). Occasionally there is a mucinous metaplasia of the cells in the center of one or more of these nests, which may account for the 10% incidence of mucinous cystadenomas found associated with Brenner tumors.

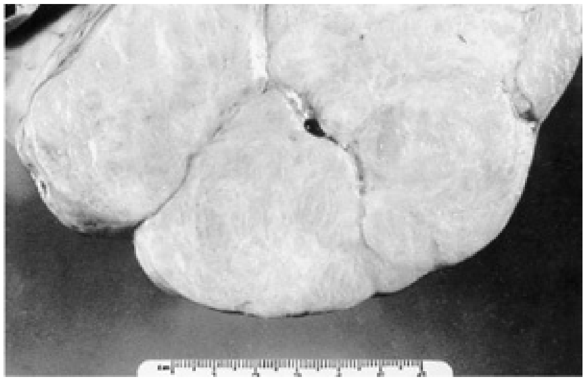

Figure 41–11. Cut surface of a Brenner tumor is firm, solid, and yellowish-white and resembles a fibrothecoma.

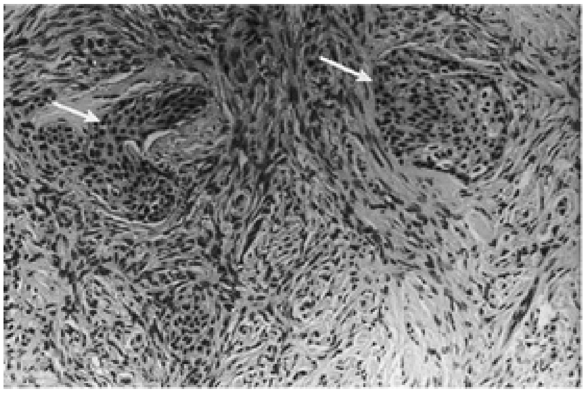

Figure 41–12. In a transitional cell (Brenner) tumor, islands of bland transitional cells (arrows) proliferate, accompanied by prominent proliferation of benign spindly fibroblast-like cells.

Brenner tumors are considered benign, although a malignant variant has been identified.

SEX CORD-STROMAL TUMORS

THECOMA

Clinical Findings

This type of tumor can occur at any age, although they are most commonly found in postmenopausal women. They account for only 2% of all ovarian tumors and may not be a true neoplasm but instead a condition of hyperplasia of the cortical stroma. Histologically, the mass is filled with lipid-containing cells that are similar to theca cells, and the tumor is known to produce estrogen. As such, these tumors often present with dysfunctional uterine bleeding or postmenopausal bleeding. Occasionally they have presented with adenocarcinoma of the endometrium given the unopposed estrogen production by the tumor. The tumors range from nonpalpable to more than 20 cm in size. They are rarely bilateral and rarely malignant.

Treatment

Treatment of thecoma is tailored to patient age and ranges from a total hysterectomy and bilateral salpingo-oophorectomy for menopausal or postmenopausal women to a salpingo-oophorectomy or ovarian cystectomy if possible in patients who desire to retain fertility.

FIBROMA

Clinical Findings

Unlike thecomas, fibromas produce no hormones. They can occur at any age but most often occur in the years before menopause. They range in size from incidental findings to greater than 20 cm. They are multinodular and whorled, and they are formed from bundles of collagen-producing spindle cells. They can be found as part of Meigs' syndrome, in which a patient is found to have a pelvic mass (fibroma or thecoma or granulose cell tumor) in concert with ascites and hydrothorax. Fibromas are also part of a hereditary basal cell nevus syndrome in which basal cell carcinoma is found with mesenteric cysts, calcification of the dura, and keratocysts of the jaw.

HILUS CELL TUMOR

Clinical Findings

These tumors are a subset of Leydig cell tumors, which originate from the ovarian hilum or less frequently from the ovarian stroma. The typical presentation includes hirsutism, virilization, and menstrual irregularities. Hilus cell tumors rarely attain a palpable size. Histologically, groups of steroid cells containing eosinophilic cytoplasm and lipochrome pigment are found. For the tumor to be defined as a Leydig cell neoplasm, elongated eosinophilic crystalloids of Reinke must be found.

GERM CELL TUMORS

MATURE TERATOMAS

Clinical Findings

Mature cystic teratomas, commonly referred to as *dermoid cysts*, compose some 40–50% of all benign ovarian neoplasms. They contain well-differentiated tissue derived from any of the 3 germ cell layers, including hair and teeth as ectodermal derivatives. They account for the majority of benign ovarian neoplasms in reproductive-age women and usually are asymptomatic unless complications such as torsion or rupture occur. Transvaginal ultrasound is known to be very accurate in the diagnosis of dermoid cysts, with the hair and sebum, rather than calcium, creating highly reflective irregular solid components within fluid-containing masses. Up to 15% of cases are bilateral, and these tumors can grow to a large size, weighing several kilograms.

Differential Diagnosis

Although most mature teratomas contain cells from all germ cell layers, a subset of monodermal teratomas exists. Those tumors composed mostly or entirely of thyroid tissue are called *struma ovarii*. These tumors account for only 3% of all teratomas, and only 5% of these will produce symptoms of thyrotoxicosis.

Cases in which immature neuroepithelial tissue is present should always be suspected as immature cystic teratoma, which have some malignant potential.

Treatment

Studies have detailed several advantages to the laparoscopic approach to removal of dermoids, including less postoperative pain and blood loss, shorter hospital stay, and lower overall cost. Recent studies have shown that dermoid cysts can usually be removed laparoscopically without intraperitoneal spillage. If intraoperative spillage does occur, the potential for chemical peritonitis or excess adhesion formation has led to the recommendation of copious saline irrigation until the lavage is clear. The risk of peritonitis, however, is quite low (<0.2%) with laparoscopic removal of dermoid cysts.

BENIGN TUMORS OF THE OVIDUCT

Benign lesions of the uterine tube are routinely asymptomatic and rarely large enough to be palpable —with the exception of the paratubal or parovarian cyst—so the diagnosis is made incidentally during a routine ultrasonographic examination or at the operating table or in the pathology laboratory.

CYSTIC TUMORS

Clinical Findings

Hydatid cysts of Morgagni are cystic tumors of the uterine tube located at or near the fimbriated end. They are lined by tubal-type epithelium, filled with clear fluid, and are usually approximately 1 cm in diameter. They are most often found inadvertently during a pelvic operative procedure. On rare occasions, torsion produces an acute surgical emergency.

Occasionally, larger paratubal or parovarian cysts develop, especially in the broad ligament (Fig. 41–13). These cysts are almost always serous tumors of low malignant potential with a benign clinical outcome.

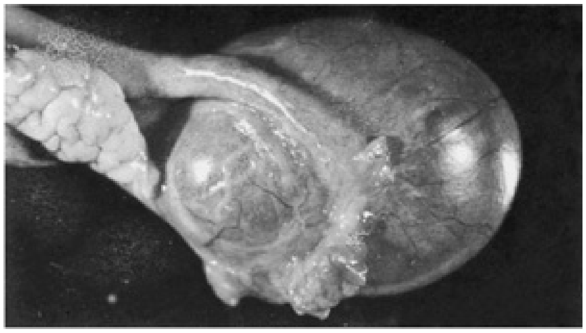

Figure 41–13. Parovarian cyst. Note the orientation of the cyst to the fimbriated end of the oviduct.

A third type of cyst associated with the fallopian tubes is the *Walthard cell rest*. This type is found as a 1-mm cyst beneath the serosa of the fallopian tube. It appears to represent an inclusion cyst in which the mesothelium has undergone metaplasia similar to transitional cell (Brenner) tumors.

EPITHELIAL TUMORS

Benign epithelial tumors of the uterine tube are extremely rare. The polyps that occur in the cornual portion appear to be of endometrial rather than tubal origin.

ADENOMATOID TUMORS

The adenomatoid tumor probably is the most common benign tumor found in the uterine tube. It actually represents a benign mesothelioma, but the compact nature of the adenomatous pattern may be mistaken for malignancy. Adenomatoid lesions rarely measure more than 1–1.5 cm. They are always incidental findings when the adnexa are removed for other purposes. Similar lesions, usually cystic, may involve the myometrium or ovary.

OTHER BENIGN TUBAL AND PARATUBAL TUMORS

Other benign tubal tumors, such as leiomyomas and teratomas, are rare, as are benign adnexal tumors of probable wolffian origin. Adrenal cortical nests, however, are common incidental embryologic rests found in the broad ligament, seen as yellowish ovoid nodules 3–4 mm in diameter.

Urinary Incontinence & Pelvic Floor Disorders

Christopher M. Tarnay, MD

PELVIC FLOOR DISORDERS

Pelvic floor disorders (PFDs) include urinary incontinence, pelvic organ prolapse, fecal incontinence, and other sensory and emptying abnormalities of the lower urinary and gastrointestinal tracts. Nearly one-quarter of all women and more than one-third of older women reported symptoms of at least 1 pelvic floor disorder. The prevalence of PFDs increase as women age. Advances in modern medicine during the last 80 years have increased the life expectancy of women well into the eighth and ninth decades. We are caring for patients longer and better than ever, effectively managing chronic medical problems such as hypertension, cardiovascular disease, and diabetes, enabling women to enjoy longer and more productive lives. Using US Census data projections, by 2030, more than one-fifth of women will be 65 years of age or older. This will result in a large population of women living up to one-third of their life after menopause, thereby introducing a whole host of medical issues and health concerns.

A prime example of this is the problem of urinary incontinence, which has become more prevalent as the population of aging women grows. Urinary incontinence affects millions adult women in the United States. It is estimated to affect 50% of American women during their lifetime and results in substantial medical, social, and economic burdens. Despite its prevalence and estimated costs in excess of $19.5 billion annually, up to two-thirds of women do not seek help for incontinence, primarily because of social embarrassment or because they are unaware that help is available. Because of increasing awareness by both patients and physicians, the societal concept that incontinence is part of the “normal” aging process is no longer acceptable.

ESSENTIALS OF DIAGNOSIS

- The symptoms of urinary incontinence involve involuntary leakage of urine.
- History and clinical examination can often effectively diagnose the correct condition.
- Two most common types are **stress incontinence** (loss of urine with physical exertion) and **urinary urge incontinence** (sudden urge to urinate and losing urine before toileting).
- The term **overactive bladder** (OAB) is often used to describe the most common symptoms of urinary urgency, usually accompanied by frequency and nocturia, with or without urgency urinary incontinence.
- The use of pads to protect soiling undergarments is the most common coping mechanism for women.
- Behavioral methods such as fluid restriction, avoidance of dietary triggers, and pelvic floor muscle strengthening can be helpful to reduce symptoms.
- Surgery, such as a midurethral sling, can be effective to cure stress urinary incontinence.
- Medications or neuromodulation can be helpful for women with urinary urge incontinence who do not respond to behavioral methods.

ANATOMY

The urinary and reproductive tracts are intimately associated during embryologic development. The lower urinary tract can be divided into 3 parts: the bladder, the vesical neck, and the urethra (Fig. 42–1). The bladder is a hollow muscular organ lined with transitional epithelium designed for urine storage. The bladder musculature consists of layers of smooth muscle, which are densely intertwined and constitute the detrusor muscle. The bladder stays relaxed to facilitate urine storage and contracts periodically to completely evacuate its contents when appropriate and acceptable. At the bladder base is the trigone, which is embryologically distinct from the bladder.

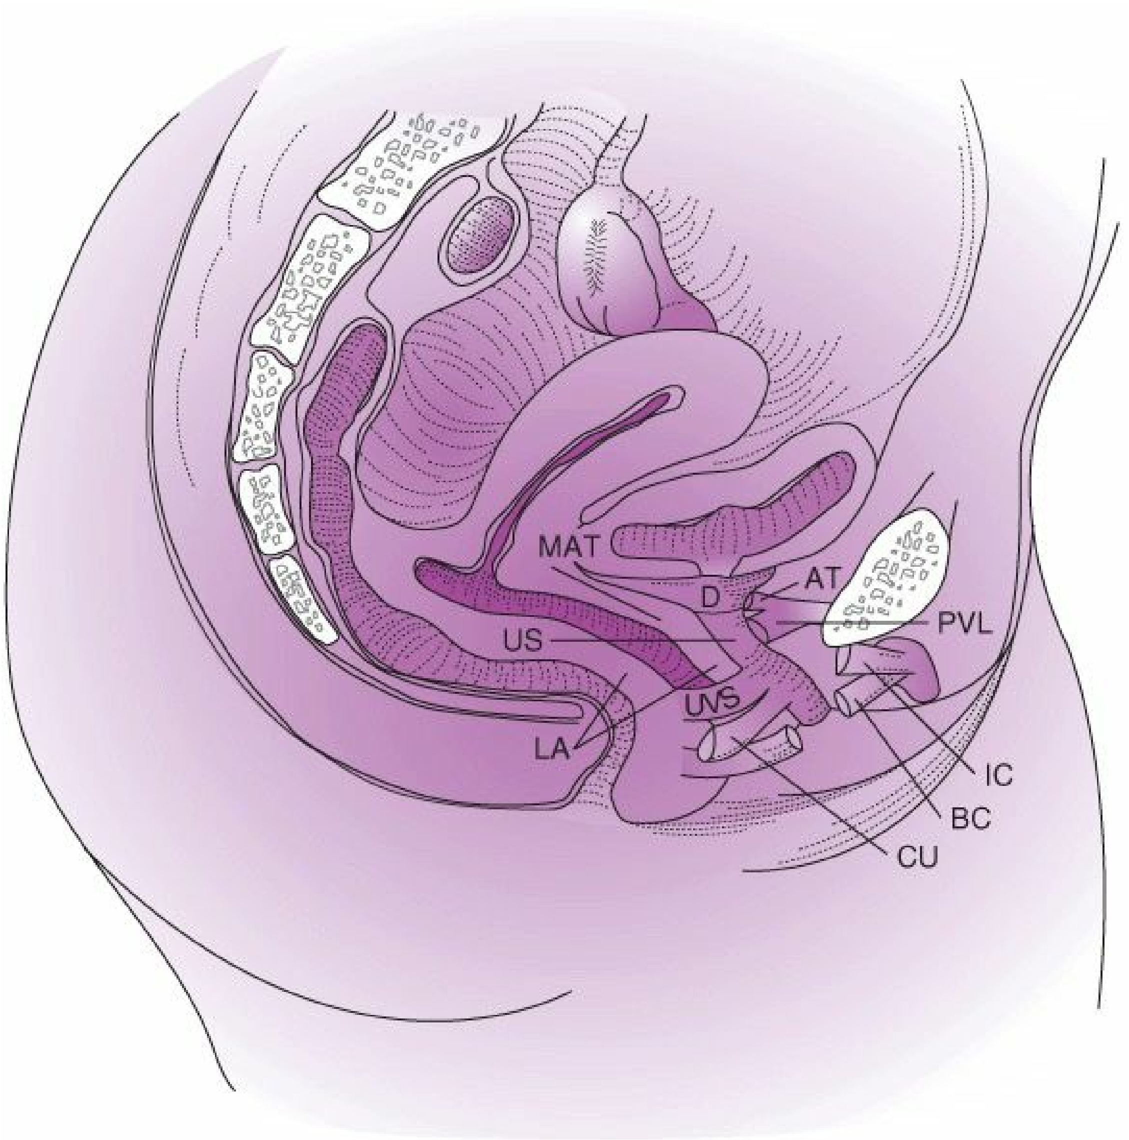

Figure 42–1. Interrelationships and approximate location of paraurethral structures. Levator ani muscles are shown as light lines running deep to the pelvic viscera. AT, arcus tendineus fasciae pelvis; BC, bulbocavernosus muscle; CU, compressor urethrae; D, detrusor loop; IC, ischiocavernosus muscle; LA, levator ani muscles; MAT, muscular attachment of the urethral supports; PVL, pubovesical ligament (muscle); US, urethral sphincter; UVS, urethrovaginal sphincter.

The 2 ureteral orifices and the internal urethral meatus form the boundaries of the trigone. The trigone has 2 distinct muscular layers: superficial and deep. The deep layer shares a similar cholinergic autonomic innervation as the detrusor muscle, whereas the superficial layer is densely innervated by noradrenergic nerves. This distinct difference in receptor distribution is important, as it provides opportunities to target more specific sites for pharmacotherapeutic intervention. The superficial detrusor layer extends muscular fibers that contribute to the distal urethra and posterior to the proximal urethra. The urethral "sphincter" itself is not a well-delineated structure; rather, it is a complex and intricate meshwork of intertwining smooth and striated muscle fibers that functionally responds neurophysiologically to variable degrees of vesicle pressures and facilitates urine storage and voiding.

The female urethra is approximately 3–4 cm long. The composition and support of the urethra and bladder neck play key roles in the function and maintenance of urinary continence. Together the striated urethral and periurethral muscles compose the extrinsic urethral sphincter mechanism. The urethral sphincter, along with the levator ani, function in the reflex contraction. The urethra is surrounded by dense vasculature that contributes to the urethral mucosal seal and urethral closure pressure. An abundance of submucosal glands are found along the dorsal surface. Most of the urethral diverticula arise from this area. The uroepithelium is stratified squamous (Fig. 42–2).

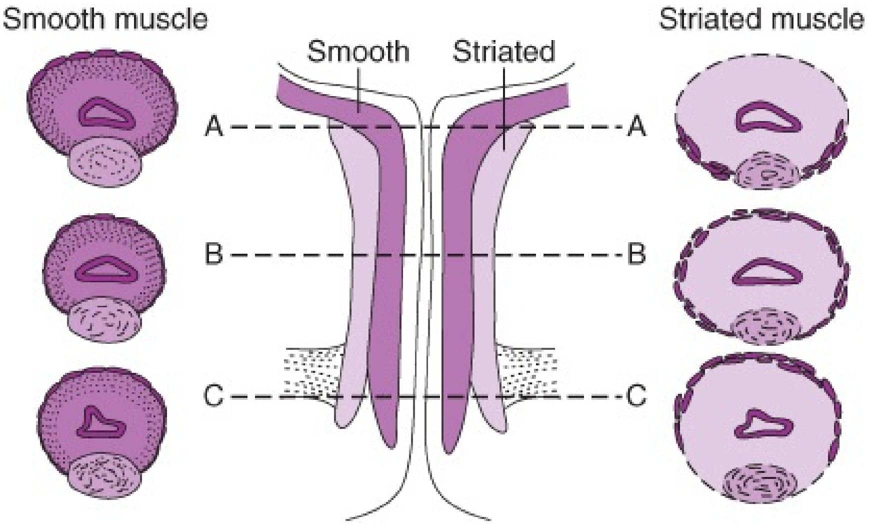

Figure 42–2. Urethral anatomy. The submucosal vascular plexus matures after puberty but undergoes great changes after menopause. The amount of smooth and especially striated muscles decreases with age, and the striated components become almost rudimentary. (Reproduced, with permission, from Rud T, Asmussen M. Neurophysiology of the lower urinary tract as measured by simultaneous urethral cystometry. In Ostergard DR, Bent AE (eds): *Urogynecology and Urodynamics: Theory and Practice*. 4th ed. Baltimore, MD: Williams & Wilkins; 1996, p. 55.)

Support of the urethra and distal vaginal wall are closely linked. For much of its length, the urethra is fused with the vaginal wall, and the structures that determine urethral position and distal anterior vaginal wall position are the same. The anterior vaginal wall and urethral support system provide a supportive layer on which the proximal urethra and mid urethra rest. The major components of this supportive structure are the vaginal wall, the endopelvic fascia, the arcus tendineus fasciae pelvis, and the levator ani muscles (Fig. 42–3). The endopelvic fascia is a dense, fibrous connective tissue layer that surrounds the vagina and attaches it to each arcus tendineus fascia pelvis laterally. Each arcus tendineus fascia pelvis in turn is attached to the pubic bone ventrally and to the ischial spine dorsally. They act like the cable of a suspension bridge that is supported at each end to the pelvis and provides attachment points along the vaginal length, providing the support of the anterior vaginal wall. Although it is well defined as a fibrous band near its origin at the pubic bone, the arcus tendineus fascia pelvis appears as a sheet of fascia as it fuses with the endopelvic fascia, where it merges with the levator ani muscles.

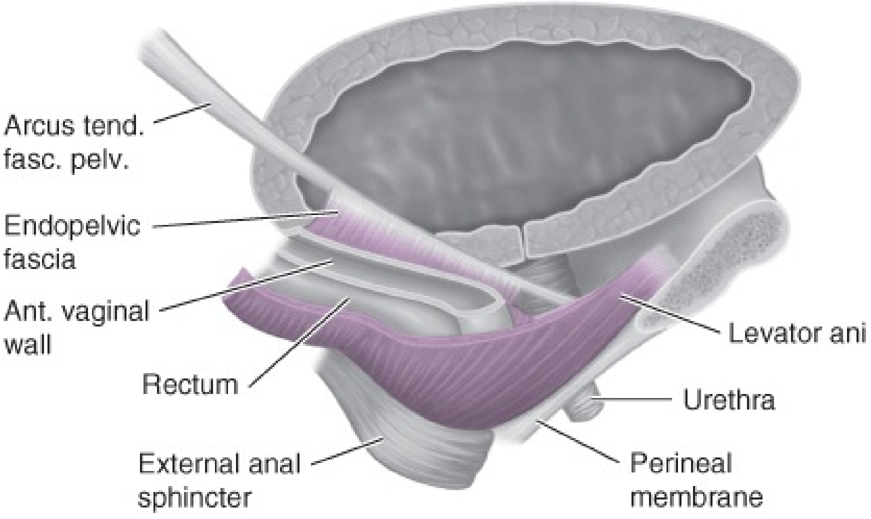

Figure 42–3. Lateral view of the components of the urethral support system. Note how the levator ani muscles support the rectum, vagina, and urethrovesical neck. Also note how the endopelvic fascia beside the urethra attaches to the levator ani muscle; contraction of the levator muscle leads to elevation of the urethrovesical neck. Puborectalis muscle is removed for clarity. (Reproduced, with permission, from Ashton-Miller J, DeLancey JOL. Functional anatomy of the female pelvic floor. *Ann NY Acad Sci* 2007;1101:266–296.)

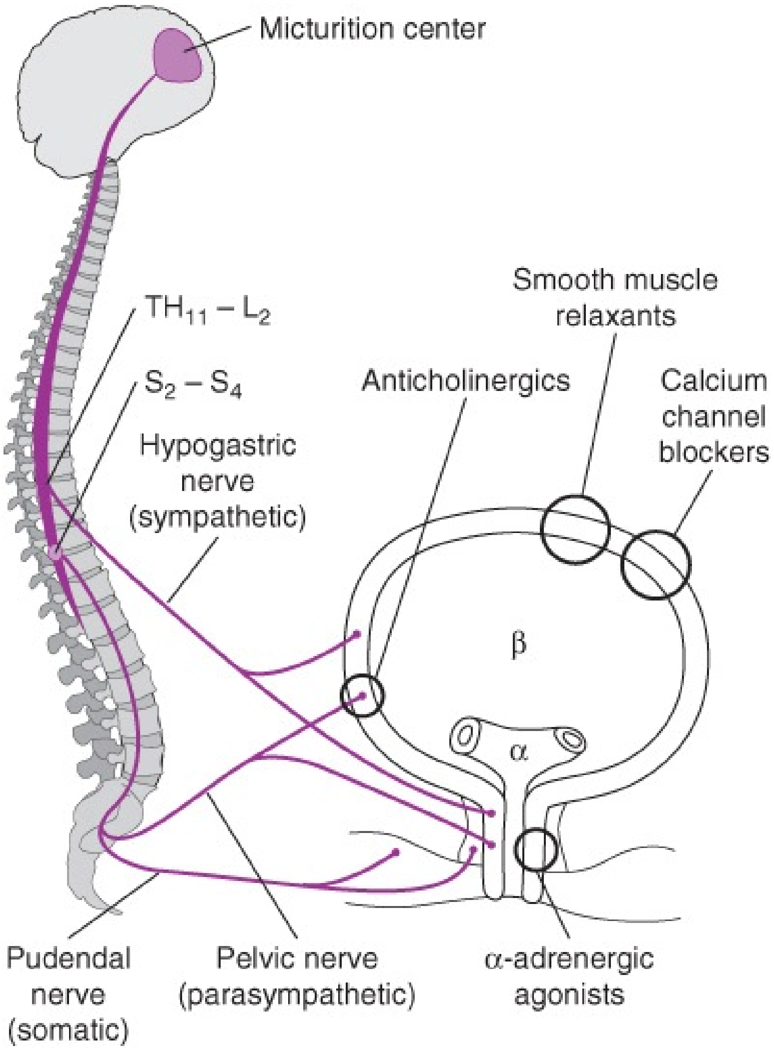
The principal components of the basin-like pelvic floor are the pelvic bones (including the coccyx), the endopelvic fascia, and the levator and perineal muscles. These structures normally support and maintain the position of the pelvic viscera despite great increments in intraabdominal pressure that occur with straining, coughing, and heavy lifting when the patient is in the erect position. The urogenital hiatus (“anterior levator muscle gap”), which permits the urethra, vagina, and anus to emerge from the pelvis, is a site of potential weakness. Attenuation of the pubococcygeal and puborectal portions of the levator muscles, whether as the result of a traumatic delivery or of involutional changes, widens the levator gap and converts this potential weakness to an actual defect. If there has been a concomitant injury or attenuation of the endopelvic fascia (uterosacral and cardinal ligaments, rectovaginal and pubocervical fascia), heightened intraabdominal pressure gradually leads to uterine prolapse, along with anterior vaginal prolapse, rectocele, and enterocele. If the integrity of the endopelvic fascia and its condensations has been maintained, the incompetency of the genital hiatus and levator muscles may be associated only with elongation of the cervix.

Neuroanatomy

Neuronal innervation of the lower urinary tract is considered part of the autonomic and somatic nervous systems. The autonomic system (ie, the para-sympathetic and sympathetic components) receives visceral sensation and regulates smooth muscle actively during conscious and involuntary lower urinary tract functions. The autonomic nervous system constitutes the bulk of neural control of the lower urinary tract. Sympathetic contributions from T1–L2 and parasympathetic contributions from S2–4 compose the neuronal control system (Fig. 42–4). Voluntary control of micturition is controlled by the central nervous system. Cortical control of the detrusor muscle rests in the supramedial portion of the frontal lobes and in the genu of the corpus callosum. Receiving both sensory afferent and modulating motor efferent nerves, the net effect is that the brain provides tonic inhibition of detrusor contraction. Lesions in the frontal lobe chiefly cause loss of voluntary control of micturition and thus loss of suppression of the detrusor reflex, resulting in uncontrolled voiding or urge urinary incontinence. The pons and mesencephalic reticular formation in the brainstem constitute the micturition center. A reflex activation in the central brainstem and peripheral spinal cord mediate a coordinated series of events, consisting of relaxation of the striated urethral musculature and detrusor contraction that result in opening of the bladder neck and urethra. Lesions that interrupt these pathways have various effects depending on the level of interruption, essentially resulting abnormal detrusor function.



Micturition center

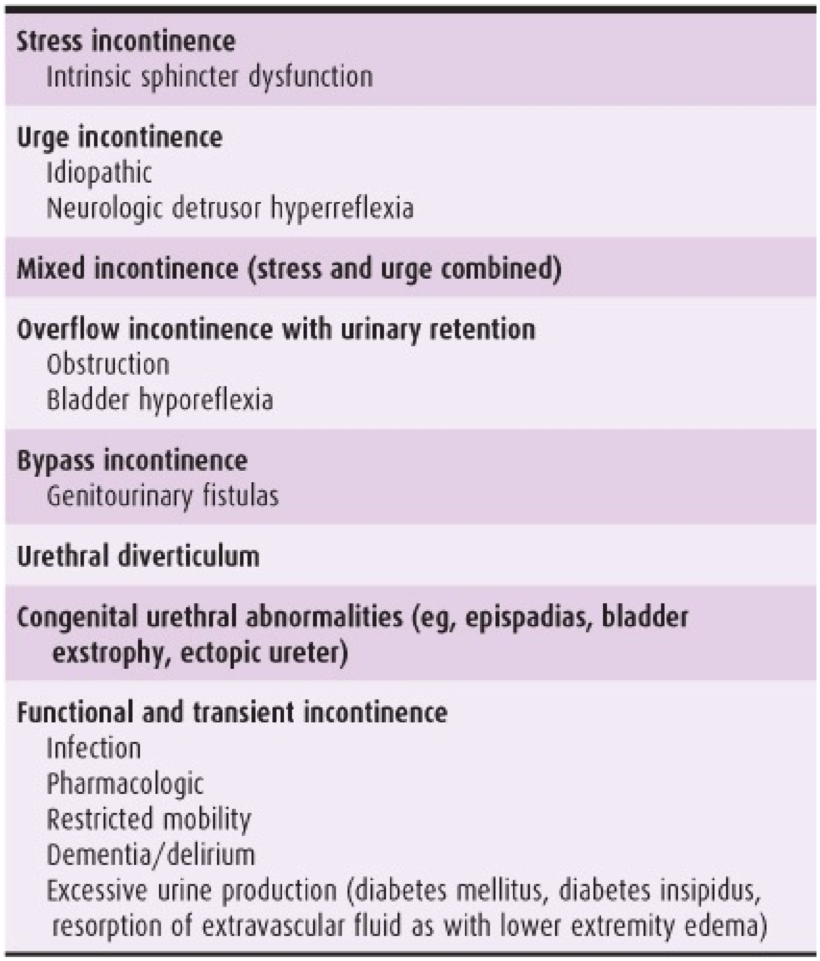
URINARY INCONTINENCE

Definition

Urinary incontinence as defined by the Consensus Committee on Pelvic Floor Disorders is the complaint of any involuntary leakage of urine. Incontinence can be a sign, a symptom (patient complaint), or a condition diagnosed by an examiner. There are many types and causes of urinary incontinence (Table 42–1). The reported incidence of urinary incontinence varies widely, ranging from 10–70% of women living in a community setting to more than 50% of women living in a nursing home. Incontinence becomes more common as women age, particularly after menopause.

Table 42–1. Differential diagnosis.



Stress incontinence Intrinsic sphincter dysfunction
Urge incontinence Idiopathic Neurologic detrusor hyperreflexia
Mixed incontinence (stress and urge combined)
Overflow incontinence with urinary retention Obstruction Bladder hyporeflexia
Bypass incontinence Genitourinary fistulas
Urethral diverticulum
Congenital urethral abnormalities (eg, epispadias, bladder exstrophy, ectopic ureter)
Functional and transient incontinence Infection Pharmacologic Restricted mobility Dementia/delirium Excessive urine production (diabetes mellitus, diabetes insipidus, resorption of extravascular fluid as with lower extremity edema)

Pathogenesis

PFDs are most assuredly caused by multiple factors. The multifactorial model is the clearest one to explain the incidence of PFD and variety of anatomic findings despite shared risk factors.

For urinary incontinence, numerous factors play a role in maintaining urinary continence; therefore, the development of incontinence is frequently not attributable to any single cause. Sex, age, hormonal status, birthing trauma, and genetic differences in connective tissue all contribute to the development of incontinence. Urinary incontinence is 2–3 times more common in women than in men because of women’s shorter urethral length and the risk of connective tissue, muscle, and nerve injury associated with childbirth. Observational studies have consistently noted a high incidence of incontinence in the elderly population, with 1 study finding a 30% higher prevalence for each 5-year increase in age. The association of childbirth with urinary incontinence has long been suspected and has generated new interest in identifying the causes. In 1 study of more than 15,000 women, the risk of developing urinary incontinence was 2.3 times higher in women who had a vaginal delivery compared with nulliparous women. Damage to the pelvic floor neuromusculature during vaginal delivery may lead to loss of pelvic muscle strength and nerve function, resulting in both stress urinary incontinence (SUI) and pelvic floor support defects. Although muscle strength may be regained over time or with the help of pelvic floor muscle exercises, dysfunction may be permanent.

Aging and incontinence are closely associated. The prevalence of incontinence increases as women age, but the specific cause is unclear. Global decrease in the storage capacity, reduced receptor response, general loss in muscle tone, or latent manifestation from denervation during parturition may all be important factors. The state of hypoestrogenism as a woman transitions to menopause may also contribute to urinary incontinence. Although estrogen reduces urinary urgency, results from studies specifically examining menopausal status have been equivocal, with some studies showing a positive association and others showing no association. Abnormalities in the muscular components and innervation of the pelvic floor and the connective tissue to this region likely contribute to the multifactorial etiology of incontinence. Initial observations that the prevalence of abdominal hernias, lower leg varices, and uterine prolapse was higher in women with SUI suggested that connective tissue weakness might identify women at risk for developing incontinence. Subsequent studies have supported a connection between relative collagen deficiencies in the connective tissues of incontinent patients versus continent controls.

Incontinence affects a woman's quality of life, and it is an uncomfortable and embarrassing problem. The psychosocial impact on the patient as well as her family is enormous. Women with urinary incontinence are reported to be more depressed, to have lower self-esteem, and to be ashamed about their appearance and the odor. Urinary incontinence affects sexual desire and reduces sexual activity. This can curb social interactions to the point where individuals become isolated and even entirely homebound.

Prevention

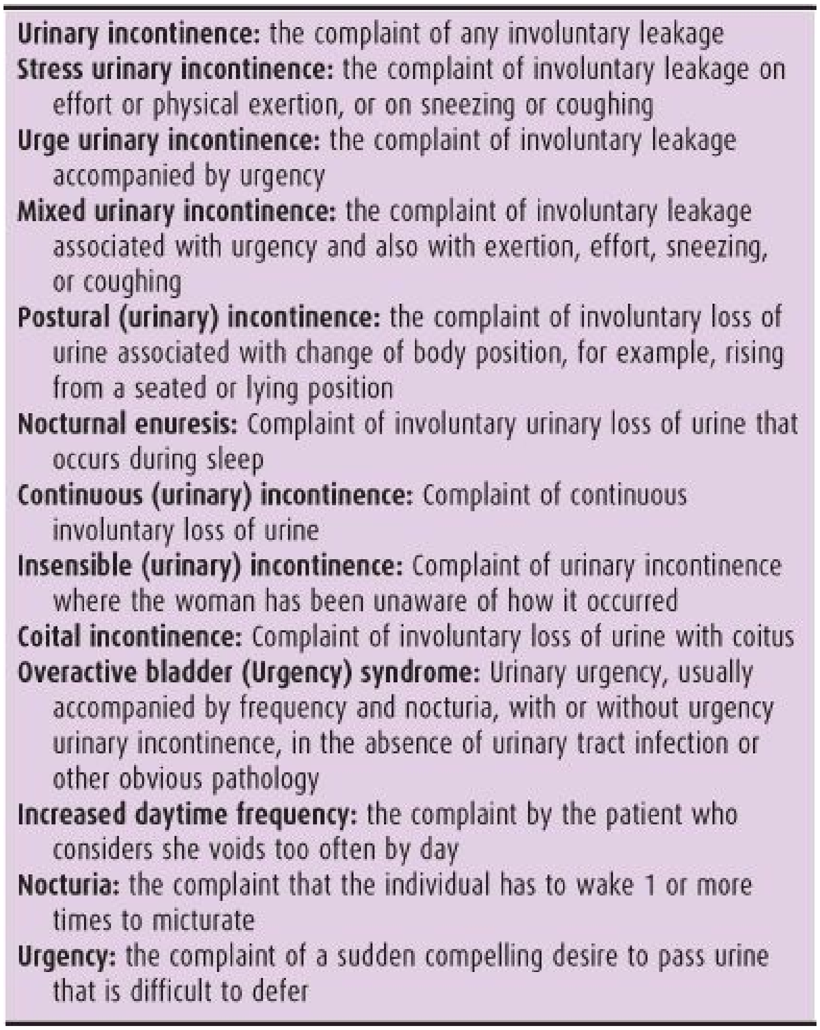
One of the first attempts at the prevention of urinary incontinence was described by Dr. Arnold Kegel in the 1950s. To reduce the risk of postpartum urinary loss, women were taught to contract and thereby strengthen the levator ani muscles in what is now commonly known as a "Kegel" exercise. Other attempts at mitigating the potential detrimental impact of pregnancy and vaginal delivery on the subsequent development of urinary incontinence have led to the increasing prevalence of maternal choice caesarean delivery as a method of perineal preservation. To date there are no high-quality data supporting either empiric pelvic floor strengthening or the avoidance of vaginal delivery as a protective measure against future urinary incontinence.

For urge-related urinary loss, the avoidance of caffeinated beverages, alcoholic drinks, or other potentially irritative foods or beverages can be suggested as a measure to reduce urgency and frequency.

Clinical Findings

The first step in evaluating an incontinent patient is a thorough history. The nature and extent of the patient's lower urinary tract symptoms (LUTS) should be elucidated. Knowledge of the duration, frequency, and severity of the urinary incontinence is essential to understanding the social implications and its impact on the patient's life and aids the clinician in determining the direction and extent of diagnostic and therapeutic measures (Table 42–2). A multitude of diagnostic and imaging studies are available, but taking a thorough but focused urogynecologic history can isolate many of the easily reversible causes of incontinence (Table 42–3). Knowledge of the use of protective items, such as sanitary napkins, panty liners, absorbent pads, or adult diapers, is useful in quantitating urinary loss. Including questions about menopausal status and use of hormone treatment, history of urinary tract infections, previous surgery to remedy incontinence, and the patient's mental and functional status are essential.

Table 42–2. Lower urinary tract symptoms.



Urinary incontinence: the complaint of any involuntary leakage

Stress urinary incontinence: the complaint of involuntary leakage on effort or physical exertion, or on sneezing or coughing

Urge urinary incontinence: the complaint of involuntary leakage accompanied by urgency

Mixed urinary incontinence: the complaint of involuntary leakage associated with urgency and also with exertion, effort, sneezing, or coughing

Postural (urinary) incontinence: the complaint of involuntary loss of urine associated with change of body position, for example, rising from a seated or lying position

Nocturnal enuresis: Complaint of involuntary urinary loss of urine that occurs during sleep

Continuous (urinary) incontinence: Complaint of continuous involuntary loss of urine

Insensible (urinary) incontinence: Complaint of urinary incontinence where the woman has been unaware of how it occurred

Coital incontinence: Complaint of involuntary loss of urine with coitus

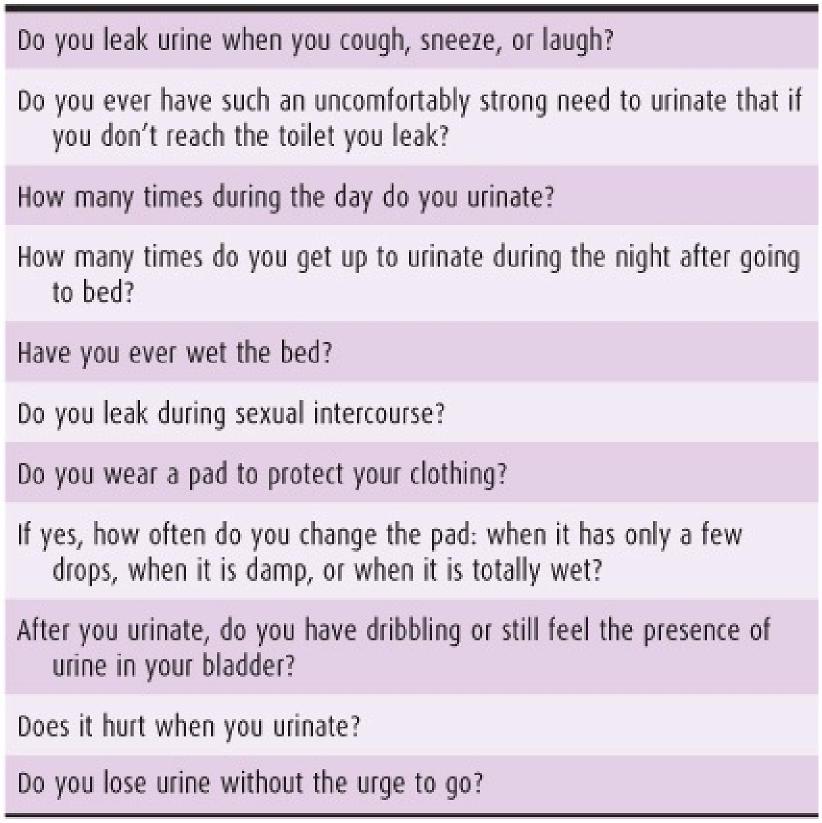
Overactive bladder (Urgency) syndrome: Urinary urgency, usually accompanied by frequency and nocturia, with or without urgency urinary incontinence, in the absence of urinary tract infection or other obvious pathology

Increased daytime frequency: the complaint by the patient who considers she voids too often by day

Nocturia: the complaint that the individual has to wake 1 or more times to micturate

Urgency: the complaint of a sudden compelling desire to pass urine that is difficult to defer

Table 42–3. Helpful questions when taking history of incontinence.



Do you leak urine when you cough, sneeze, or laugh?
Do you ever have such an uncomfortably strong need to urinate that if you don't reach the toilet you leak?
How many times during the day do you urinate?
How many times do you get up to urinate during the night after going to bed?
Have you ever wet the bed?
Do you leak during sexual intercourse?
Do you wear a pad to protect your clothing?
If yes, how often do you change the pad: when it has only a few drops, when it is damp, or when it is totally wet?
After you urinate, do you have dribbling or still feel the presence of urine in your bladder?
Does it hurt when you urinate?
Do you lose urine without the urge to go?

A. Patient Questionnaires

Survey instruments can be valuable in helping to identify and determine the severity of patient symptoms. Although initially designed for clinical research, short forms of longer questionnaires exist and can be used for clinical care. Surveys such as the Urinary Distress Inventory (UDI-6) and Incontinence Impact Questionnaire (IIQ-7) can be easily filled out by a patient to facilitate diagnosis and to follow treatment interventions.

B. Voiding Diary

A voiding diary, or urolog, that quantitates frequency and volume is a helpful tool. For a 24- to 48-hour period, the patient records all fluid intake and measures and records all urine output, including frequency and episodes of leakage (Fig. 42–5). Numerous studies have validated the voiding diary as a reliable tool in the diagnosis and management of urinary urgency or urge incontinence. These data are beneficial to the physician because they clarify home voiding patterns, particularly in the elderly. They are often useful to patients as well because they provide a focus on the problem and can serve as a baseline for treatment interventions such as behavioral training, bladder drills, and pharmacologic management.

Urolog

Date	Time	Fluids (type and how much) ounces	Urine (how much) ounces or mL	Accidents/ Leaks
example 9/1/00	8:00	Water 8 oz		
9/1/00	8:30		150 mL	

Figure 42–5. Urinary diary (urolog).

C. Urinalysis

Examination of the urine is an essential part of the workup of urinary incontinence for any patient with LUTS. Infection is a common cause of urinary complaints, including frequency, urgency, and incontinence. A clean-catch voided specimen is suitable for routine urinalysis; however, a sterile "in and out" catheterized specimen is appropriate for patients unable to correctly perform collection or if urine culture has been previously equivocal because of skin flora contamination.

Urinary protein, glucose, ketones, hemoglobin, casts, and nitrates can indicate primary renal disease or injury. Microscopic evaluation of the urinary sediment may indicate renal tubular damage with the presence of casts or indicate infection by the presence of leukocytes and red blood cells. More than 6–8 white blood cells per high-power field along with the presence of bacteria are very suggestive of urinary tract infection.

D. Physical Examination

A general gynecologic and neurologic examination should be performed on all patients, with a focus on the vaginal walls and pelvic floor. The patient should come to the clinic with a comfortably full bladder for spontaneous uroflowmetry and postvoid residual assessment. An examination should be performed with the patient in the lithotomy position. The examination should begin with an assessment of the vulvar area. In postmenopausal patients, atrophy and change in labial architecture may be due to estrogen deficiency. Vulvar dermatoses may be coexistent with vulvar complaints ascribed to incontinence. The presence of inflammation or irritation from chronic moisture or pad usage should be noted. The presence of discharge should be noted because this may mimic urinary incontinence. Examination of the urethra with palpation of the anterior vaginal wall under the urethra for fluctuance, masses, or discharge may reveal signs of urethral diverticulum, infection of the urethra, or rarely carcinoma. Tenderness may point to urethral pain syndrome, a condition marked by episodic urethral pain usually with voiding, and by daytime frequency and nocturia.

Vaginal wall integrity must be assessed. Vaginal rugae, or the folds in the epithelium, are normal and tend to be absent if the underlying supportive endopelvic fascia is detached. The presence of anterior wall defects (cystoceles), posterior vaginal wall defects (rectoceles), and apical defects (uterine prolapse or enteroceles) can be quantified. The uterocervical position, or, if the woman has had a hysterectomy, the cuff position and its descent should be recorded. The position of the vaginal walls should be noted in the lithotomy position at rest and with Valsalva's/straining maneuver. A Sims' speculum or the lower blade of a Graves' speculum allows easy visualization of either the anterior or posterior vaginal wall. The severity of vaginal laxity, which may be masked in the supine position, can often best be elicited by repeating the examination in the standing position while the patient places 1 foot on the step of the examination table or on a small portable step.

Mobility at the level of the bladder neck is often seen in women with urinary incontinence. Urethral hypermobility must be interpreted with caution because it may be present in women without incontinence. In the absence of mobility, the physician must question the diagnosis of stress incontinence and entertain the possibility of a fixed and damaged urethral sphincter (**intrinsic sphincteric deficiency**) to explain stress-related urinary loss.

E. Urinary Cough Stress Test

Having the patient perform Valsalva's maneuver or to cough forcefully multiple times to reproduce urine loss at the beginning of the examination may reveal the presence of incontinence. Observation of urine lost immediately with the cough or Valsalva's maneuver may obviate the need for more complex urodynamic testing if the complaint is minor. If no urine loss is exhibited, the patient is asked to stand with legs shoulder width apart and asked to cough. Immediate loss of urine suggests a diagnosis of SUI.

Bimanual examination to evaluate the uterine size, position, and descent within the vaginal canal and palpation of the ovaries should be performed. A rectovaginal examination permits adequate assessment of the posterior vaginal wall. Anal sphincter tone can be assessed at rest and with anal tightening. The presence of fecal impaction must be ruled out because this condition has been shown to be a contributing factor to urinary incontinence, particularly in the elderly population.

F. Neurologic Examination

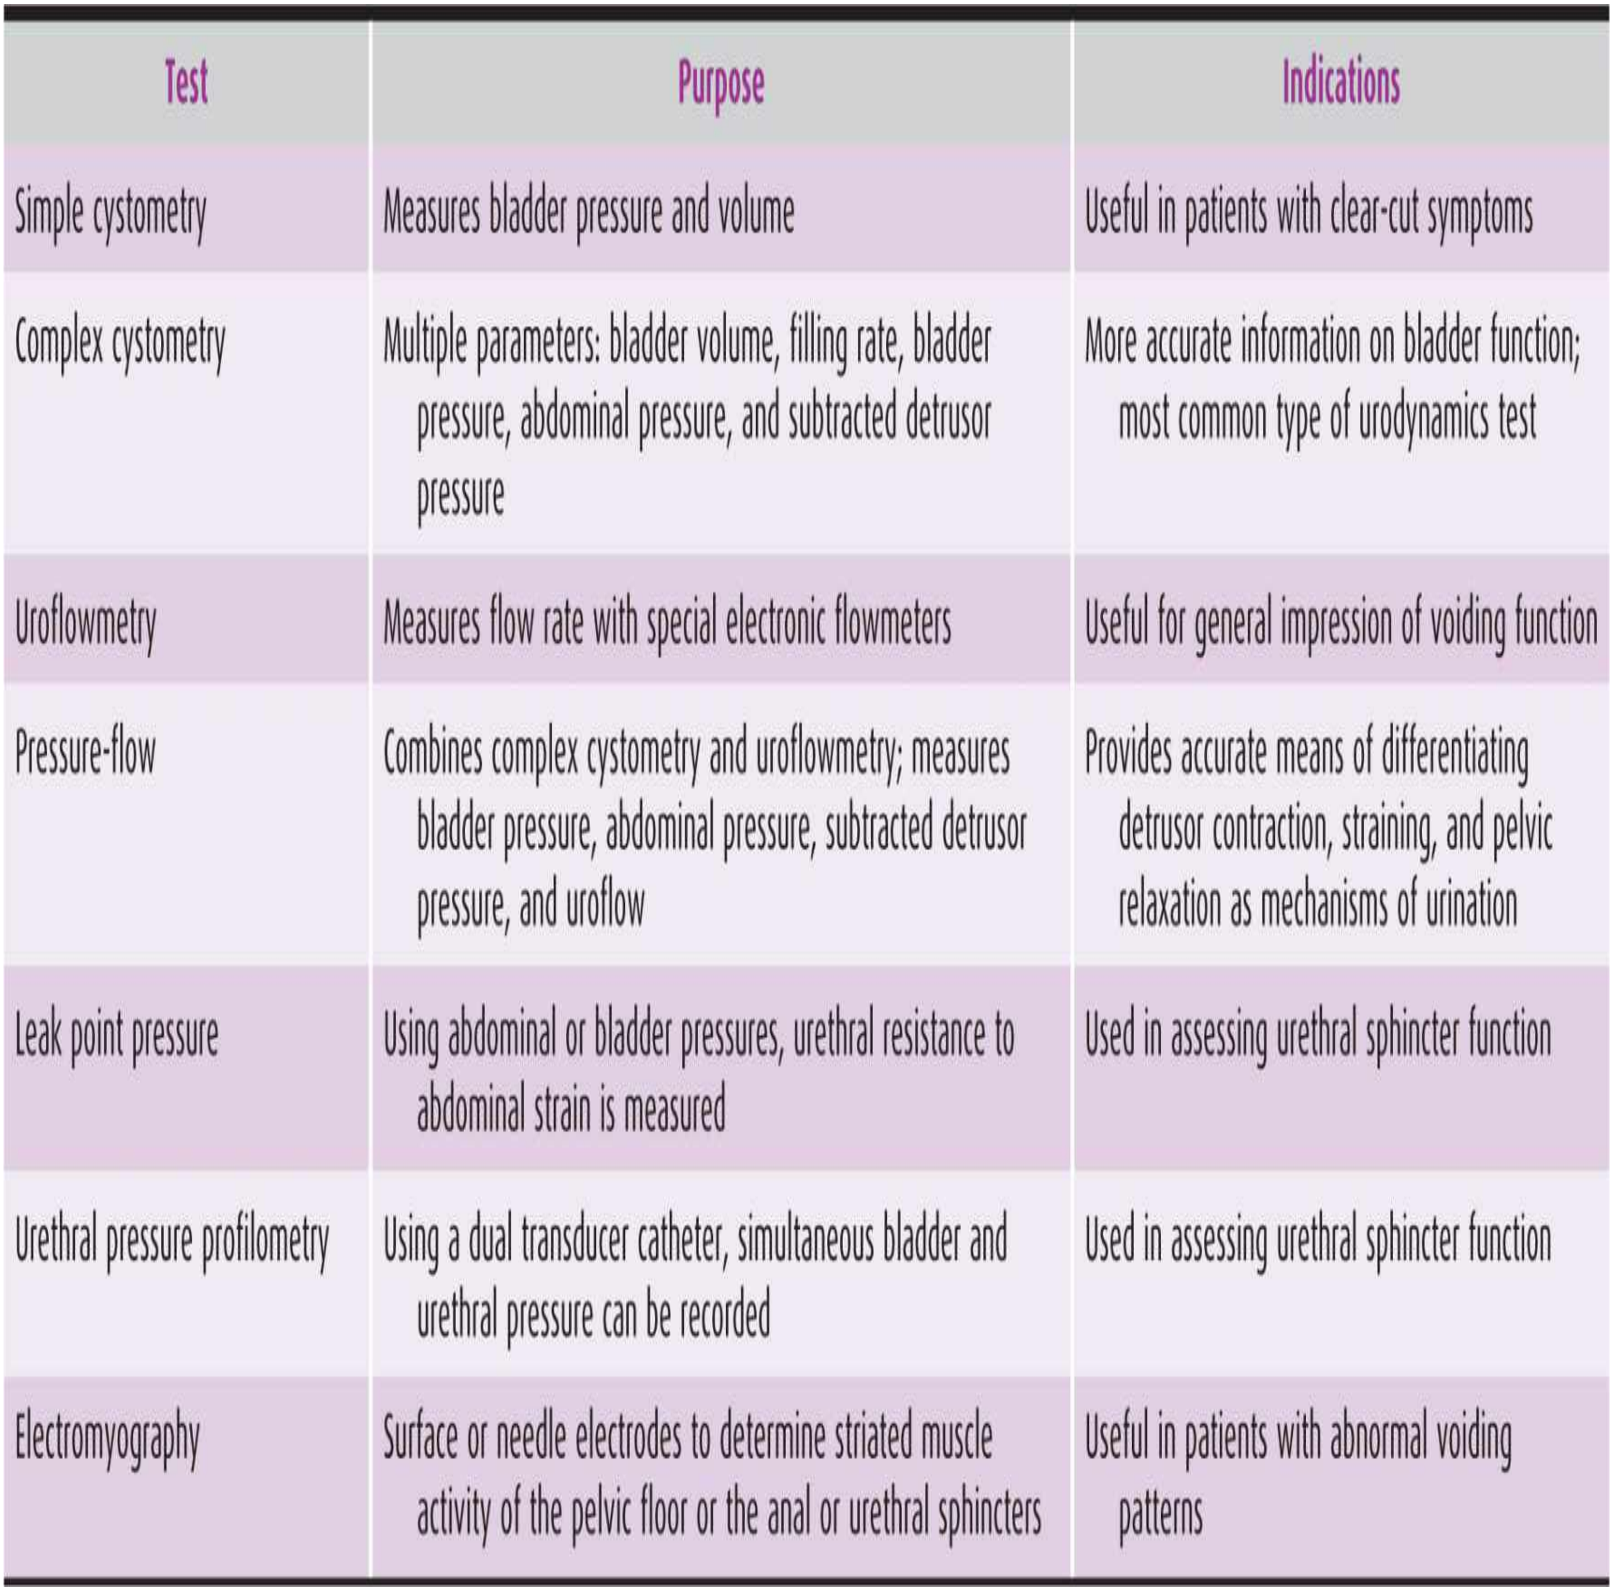
The control of micturition is complex and multitiered, with both autonomic and voluntary control. In addition to a complete history and screening for neurologic symptoms, a thorough physical examination is important because many neurologic diseases may present with voiding dysfunction in the absence of overt neurologic findings.

Mental status, motor strength, sensory function, deep tendon reflexes, and sacral spinal cord integrity should all be assessed. Testing the patient's orientation to place and time and assessing speech and comprehension skills will help to ascertain her mental status. Motor control may be diminished in focal brain or cord lesions, most commonly Parkinson's disease, multiple sclerosis, and cerebrovascular accident. Motor strength is tested in the lower extremities by assessing hip, knee, and ankle flexion, as well as ankle eversion and inversion. Deep tendon reflexes are tested at the patella, ankle, and foot planus. Sensation can be tested at the dermatomes using light touch and pin-prick over the perineum and thigh area. Deficits should be noted, but it should be kept in mind that there is considerable overlap in sensory innervation in the sensory nerve roots. The sacral spinal cord nerve roots 2–4 contain vital neurons controlling micturition. The anal wink reflex and the bulbocavernosus reflex can confirm integrity of neurovisceral and urethral reflex functions. These reflexes can be evoked by stroking the perianal area and looking for an external anal sphincter contraction, and by tapping or gently squeezing the clitoris and watching for contraction of the bulbocavernosus muscle, respectively. These reflexes are often easier to elicit at the beginning of the examination, but their absence is not always indicative of neurologic deficit. Clinically observed neurologic deficits should lead to a neurologic consultation.

G. Urodynamics

A urodynamic study is any test that provides objective dynamic information about lower urinary tract function. Many methods and tests are available (Table 42–4). Some methods are simple, such as diaries that track frequency and volume of urination, and some methods are more complex, requiring special equipment and training. A cystometrogram can aid in the discovery of an unstable bladder, overflow incontinence, reduced bladder capacity, or abnormalities of bladder sensation. A cystometrogram can be performed using water manometry or more advanced methods. Complex urodynamic testing increases the diagnostic accuracy and may often identify the reason for failure of previous therapy. Uroflowmetry can be performed to measure detrusor pressure and flow rate to evaluate for voiding dysfunction. If a poorly functioning urethra, such as in intrinsic sphincter deficiency (ISD), is suspected, urethral pressure profile (UPP) or abdominal leak point pressure (ALPP) can be measured to evaluate urethral closure pressures. Such testing is particularly helpful in difficult or complex cases.

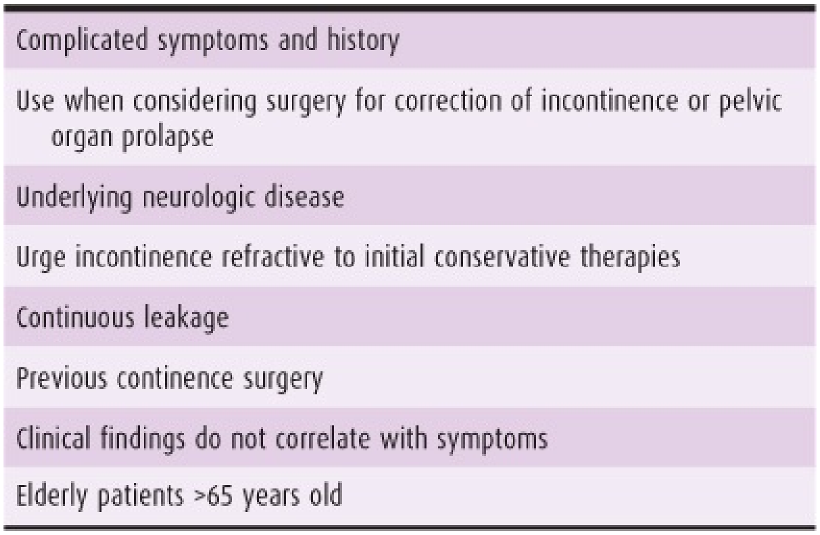
Table 42–4. Urodynamic testing methods.



Test	Purpose	Indications
Simple cystometry	Measures bladder pressure and volume	Useful in patients with clear-cut symptoms
Complex cystometry	Multiple parameters: bladder volume, filling rate, bladder pressure, abdominal pressure, and subtracted detrusor pressure	More accurate information on bladder function; most common type of urodynamics test
Uroflowmetry	Measures flow rate with special electronic flowmeters	Useful for general impression of voiding function
Pressure-flow	Combines complex cystometry and uroflowmetry; measures bladder pressure, abdominal pressure, subtracted detrusor pressure, and uroflow	Provides accurate means of differentiating detrusor contraction, straining, and pelvic relaxation as mechanisms of urination
Leak point pressure	Using abdominal or bladder pressures, urethral resistance to abdominal strain is measured	Used in assessing urethral sphincter function
Urethral pressure profilometry	Using a dual transducer catheter, simultaneous bladder and urethral pressure can be recorded	Used in assessing urethral sphincter function
Electromyography	Surface or needle electrodes to determine striated muscle activity of the pelvic floor or the anal or urethral sphincters	Useful in patients with abnormal voiding patterns

The indications for more complex testing in the form of multichannel urodynamics are not standardized, and each patient must be assessed individually (Table 42–5). However, some basic criteria, if met, indicate a need for urodynamic evaluation, which can aid in more accurate diagnosis and thus appropriate medical or surgical management.

Table 42–5. Indications for multichannel urodynamic testing.



Complicated symptoms and history
Use when considering surgery for correction of incontinence or pelvic organ prolapse
Underlying neurologic disease
Urge incontinence refractive to initial conservative therapies
Continuous leakage
Previous continence surgery
Clinical findings do not correlate with symptoms
Elderly patients >65 years old

H. Cystourethroscopy

Endoscopic evaluation is an invaluable adjunct for the diagnosis and management of the urogynecologic patient. It is a simple office procedure that can yield important data when performed by experienced operators. Cystourethroscopy is indicated for hematuria and irritative voiding symptoms, particularly in the presence of previous continence surgery, obstructive voiding, suspicion of diverticula or fistula, or persistent incontinence and as a preoperative evaluation before reconstructive pelvic surgery.

I. Imaging Tests

Radiologic studies can be an integral component of the evaluation of lower urinary tract dysfunction and abnormalities. However, these modalities are of limited use in the evaluation of all but the most complex of incontinent patients. Ultrasound has become an increasingly frequent adjunct investigation for pelvic floor disorders both in the office and in the urodynamic laboratory. Magnetic resonance imaging (MRI) has become more extensively used in patients with PFDs and prolapse. As the technique becomes less costly, applications for the uses of MRI to aid in the urogynecologic workup will expand.

Differential Diagnosis

See Table 42–1.

STRESS URINARY INCONTINENCE

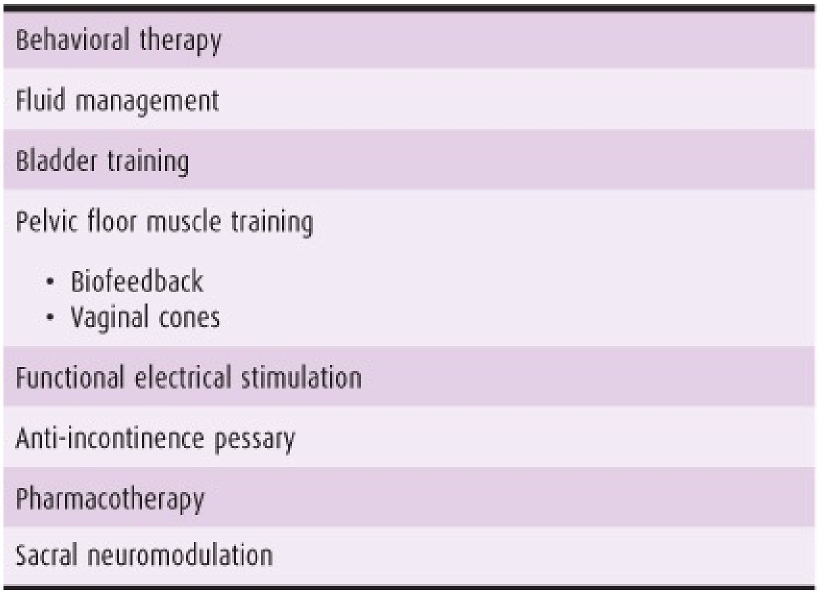
Stress urinary incontinence (SUI) is defined as the complaint of involuntary leakage on effort or physical exertion or on coughing or sneezing. Normally, at rest the intraurethral pressure is greater than the intravesical pressure. The pressure difference between the bladder and the urethra is known as the **urethral closure pressure**. If intraabdominal pressure increases, as it does with a cough, sneeze, or strain, and if this pressure is not equally transmitted to the urethra, then continence is not maintained and leakage of urine occurs. What is thought to cause this inequity of pressure transmission is not universally accepted; however, surgical therapy directed at stabilization of the suburethral support appears to be the mechanism for long-term correction.

Treatment

A. Nonsurgical Measures

For most patients with SUI, consideration of the simplest, least invasive, and least costly interventions is appropriate (Table 42–6). Dietary measures can be instituted, with identification of items that can be modified. Reduction in consumption of caffeinated beverages and alcoholic drinks should be encouraged. Fluid restriction in patients without chronic medical problems, such as cardiovascular, renal, or endocrinologic disease, can be attempted. Timed voiding to prevent filling the bladder to a capacity that causes urine loss should be undertaken with the use of a urine diary. The diary can also facilitate discussion between patient and clinician as therapy progresses.

Table 42–6. Nonsurgical management of urinary incontinence.



Behavioral therapy
Fluid management
Bladder training
Pelvic floor muscle training • Biofeedback • Vaginal cones
Functional electrical stimulation
Anti-incontinence pessary
Pharmacotherapy
Sacral neuromodulation

Pelvic floor muscle exercises or Kegel exercises have been found to be extremely helpful in patients with mild to moderate forms of incontinence. Focused repetitive voluntary contractions of the levator ani muscles (pubococcygeus, coccygeus, and iliococcygeus) created by having the patient contract or “squeeze” the muscle as if to prevent the passage of rectal gas is an effective therapy. The contractions exert a closing force on the urethra and increase muscle support to the pelvic organs. The patient should be provided written and verbal instructions on performing the exercises. Repetitions, with each contraction held for 3–5 seconds alternated with periods of relaxation, should be begun at 45–100 repetitions daily. In settings in which the patient is motivated and has individual instruction and thorough follow-up and support, results for cure or improvement of bladder control (reduction in urine loss) can be up to 75%.

1. Biofeedback—Biofeedback is an adjunct to pelvic floor exercises that is used to facilitate the patient’s comprehension of the proper muscles to contract. By using a pressure catheter and myographic monitoring, a visual or auditory signal of the physiologic response can be provided to the patient to help refine exercise skills. Using surface electro-myography on the perineum to measure levator contraction and a pressure monitor in the vagina or rectum to indicate abdominal pressure, the patient can be instructed to preferentially contract the pelvic floor without concomitant abdominal contraction. Studies using a variety of techniques demonstrate a 54–95% cure rate or improvement in SUI. The efficacy of this modality is highly dependent on patient motivation and compliance. Pelvic floor muscle exercises with or without biofeedback require continued implementation and practice or effectiveness will wane.

2. Electrical stimulation—As an alternative to active patient contraction of the levator muscles, electrical stimulation of the muscles via small electrical currents can be used to help both SUI and mixed incontinence. Using intravaginal or transrectal electrodes with stimulators, the pelvic muscles automatically contract and are thereby artificially “trained.” When used long term, weakened muscles are strengthened and innervation re-established during activation. Experiences with the devices are variable, but they generally show a positive impact on incontinence and acceptable patient tolerance.

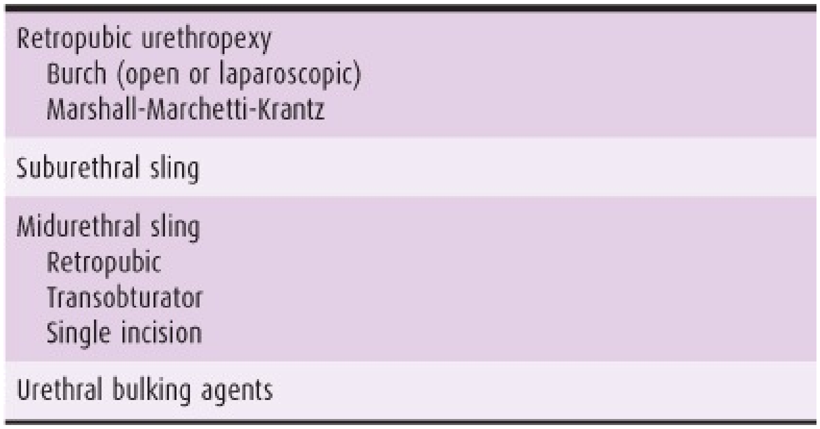
3. Pessaries—Intravaginal devices or pessaries to correct the anatomic deficits associated with stress incontinence have long been used to address this vexing problem. Many devices have been proffered, but long-term solutions to incontinence have yet to be proven in the general population. Pessaries, traditionally used for treatment of genital prolapse, have also been shown to have a potential role in supporting the bladder neck and urethra and preventing stress incontinence. Many pessary devices designed to fit within the vagina and elevate the bladder neck are available. Continence can often be achieved because many devices adequately obstruct the bladder neck and urethra. As with all intravaginal devices, maintenance is essential to avoid urinary obstruction and vaginal erosion if the pessary is too compressive.

B. Surgical Management

Surgical treatment may be offered for moderate to severe incontinence. Urinary incontinence is not a life-threatening condition, and the decision to operate must be based on the patient’s symptoms and the impact on daily life. Many patients are able to tolerate slight urine loss, and what often provokes a desire for treatment is an increase in loss above a tolerable threshold. If medical management to improve bladder control is possible and symptoms are reduced to below this threshold, then medical management is most desirable. If not, surgery should be considered.

At least 130 operative procedures have been described for treatment of female urinary stress incontinence. It is therefore not surprising that many of these procedures have not resulted in long-term success. For patients who desire surgical correction, the options can be categorized by method of surgical approach (Table 42–7). Common to most surgical procedures is restoration of bladder neck support by elevation of the urethrovesical junction. Some procedures reconstruct bladder neck supports and provide a stable suburethral layer.

Table 42–7. Surgical treatment of stress urinary incontinence.



Retropubic urethropexy Burch (open or laparoscopic) Marshall-Marchetti-Krantz
Suburethral sling
Midurethral sling Retropubic Transobturator Single incision
Urethral bulking agents

Assessment of the cure rate of any surgical treatment for genuine stress incontinence must take into account the selection of patients, accuracy of the preoperative diagnosis, length of postoperative follow-up, and criteria for cure. Reported cure rates for procedures range from 60–100%, with 75–90% being the generally accepted rate. Most failures appear to result from incorrect preoperative diagnosis, poor surgical technique, and healing failures.

1. Abdominal Retropubic Colpopexy—The Marshall-Marchetti-Krantz (MMK) and Burch's colposuspension are the 2 classic retropubic surgeries for incontinence. They share the same mechanism of correction. First, both suspend the periurethral and paravaginal tissue at the level of the urethrovesical junction, and second, both use a firm point of attachment for fixation of these suspension sutures. In the MMK procedure, the sutures are fixed to the periosteum of the pubic bone, and in Burch's procedure, the iliopectineal ligament (Cooper's ligament) (Fig. 42–6). Burch's colposuspension has been a longstanding treatment of patients with hypermobility of the bladder neck and genuine SUI. In both longitudinal studies and randomized comparative trials against other procedures, Burch's procedure maintains high objective and subjective cure rates of 80% after 5 years and 68% after 10 years of follow-up.

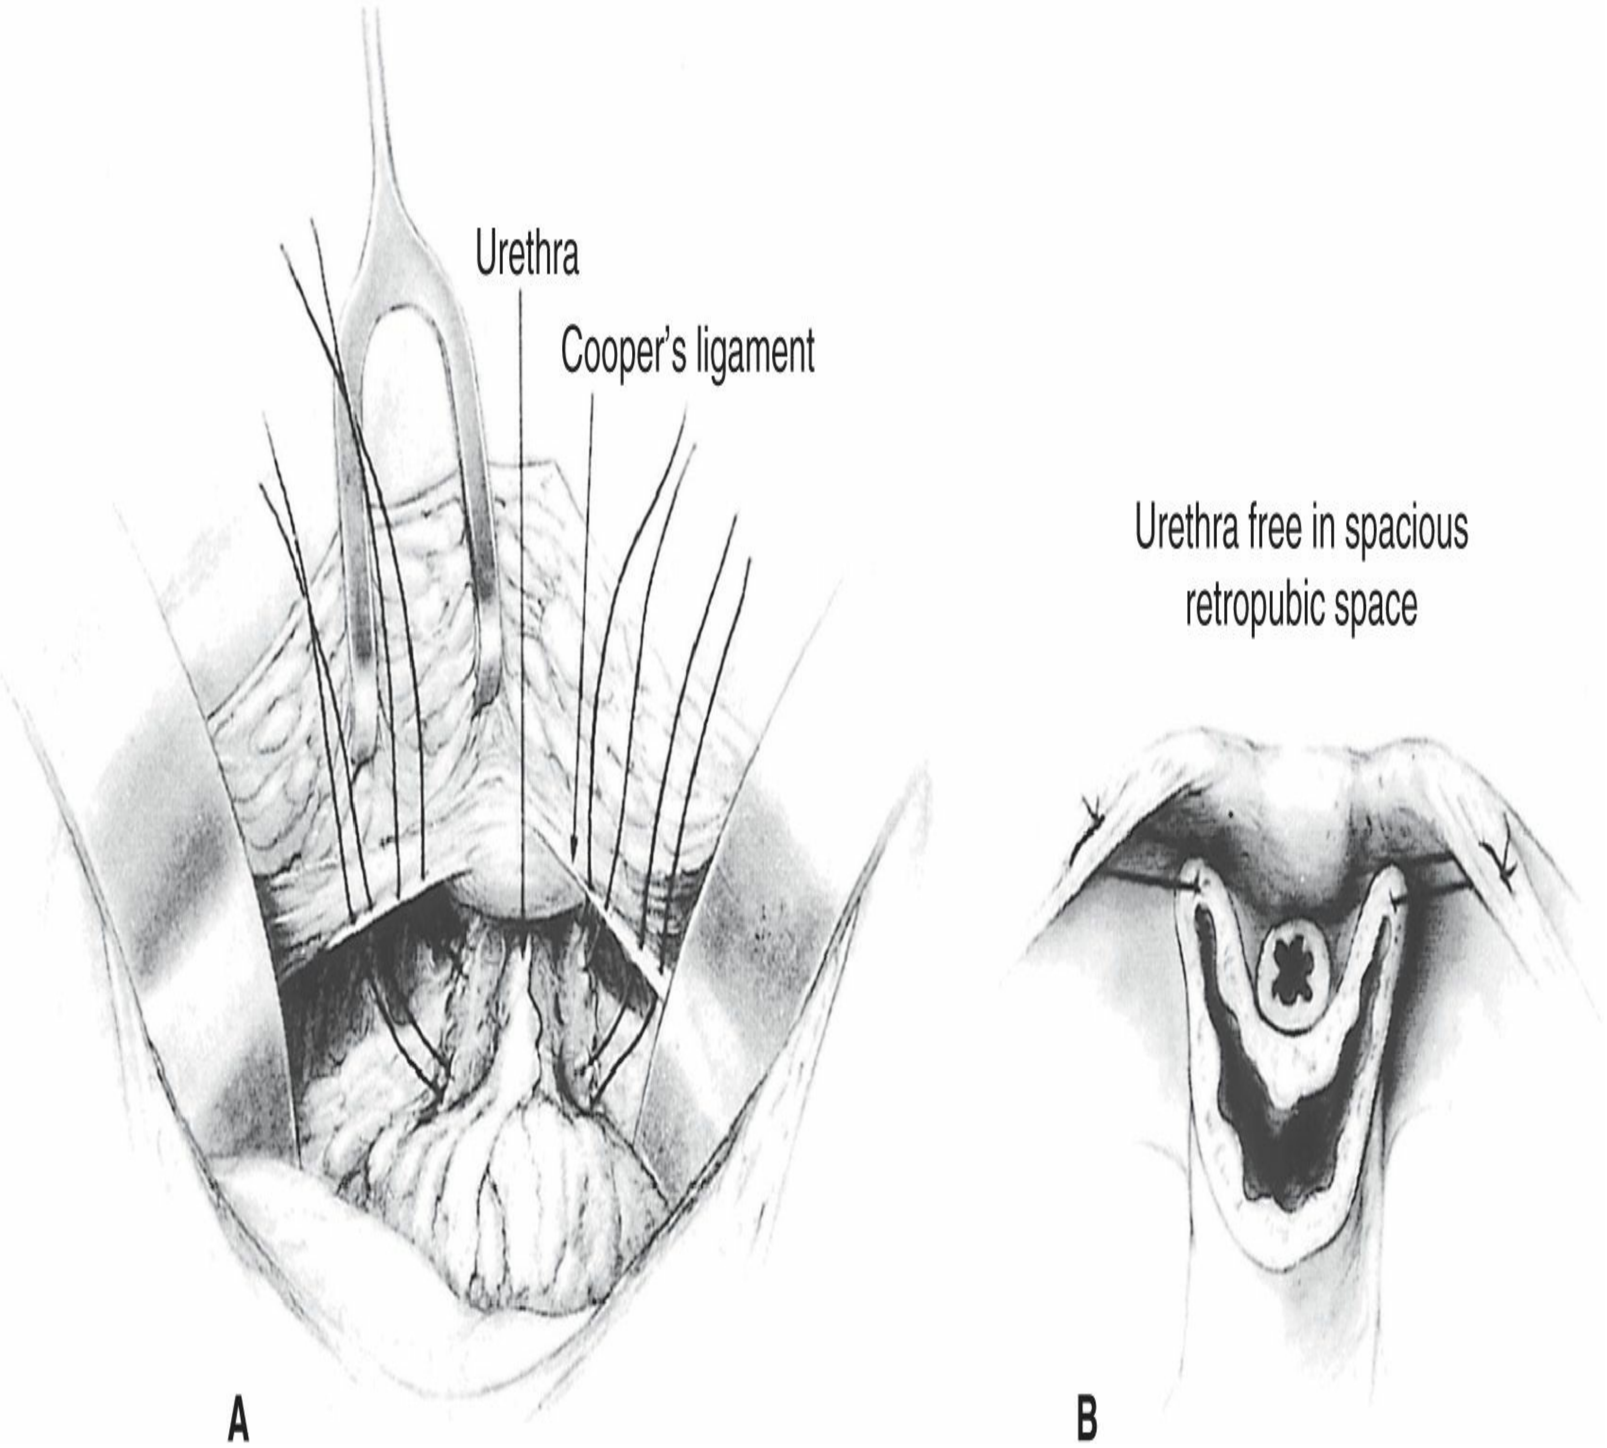


Figure 42–6. Abdominal surgical procedure to correct stress incontinence. **A:** Anterior vaginal wall has been mobilized. Two sutures have been placed on either side and far lateral from the midline.

Distal sutures are opposite the midurethra. Proximal sutures are at the end of the vesicourethral junction. Sutures are attached to Cooper's ligament. **B:** Cross-section shows urethra free in the retropubic space, with anterior vaginal wall lifting and supporting it. (Reproduced, with permission, from Tanagho EA. Colpocystourethropexy. *J Urol* 1876;116:751. Copyright 1976 by Williams & Wilkins.)

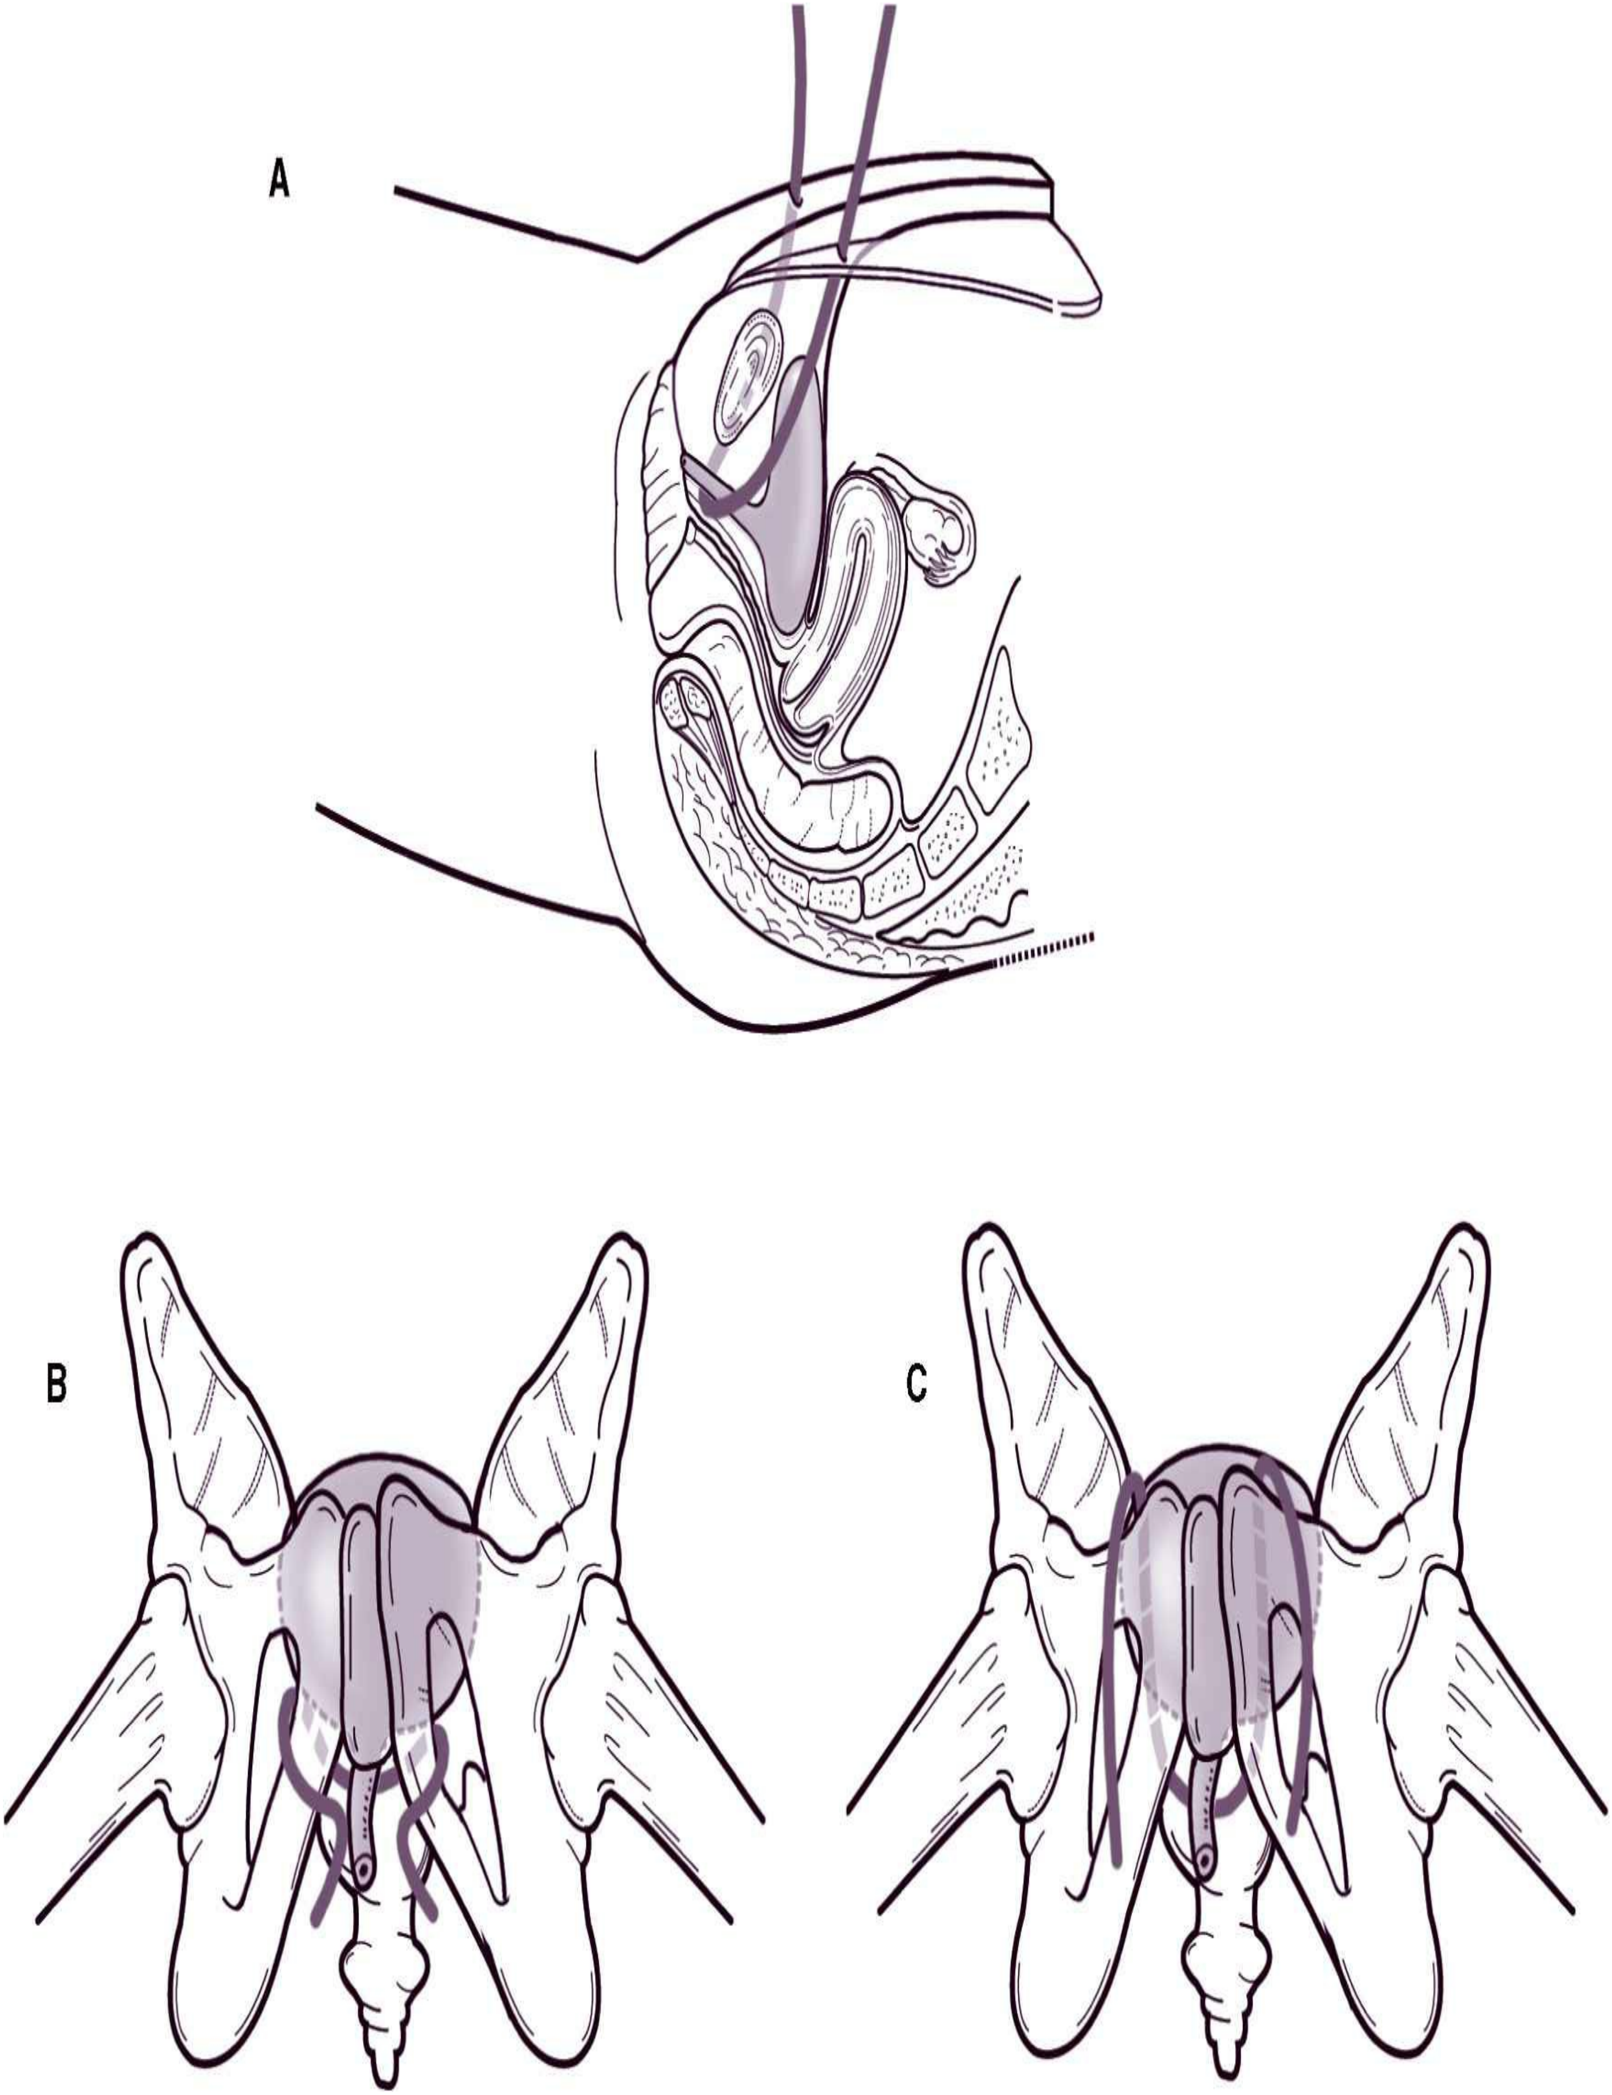
A laparoscopic approach to Burch's colposuspension offers the benefit of minimally invasive surgery with the same level of efficacy.

2. Suburethral Slings—The suburethral sling was one of the original surgical procedures developed for correction of SUI. The concept of restoring continence by encircling the urethra with supportive tissue, either from the patient or foreign material, was introduced at the beginning of the 20th century. Contemporary techniques have used a patient's own fascia harvested from the leg or rectus fascia, or donor fascia in the form of cadaveric fascia lata. Cure rates of suburethral sling procedures for genuine stress incontinence vary from 70–95%. Reported rates vary because of the heterogeneity of patients, and many are previous surgical failures. Variations in sling material and technique have made cure rates among sling techniques difficult to interpret. Furthermore, most studies vary in the definition of cure and may not distinguish between cure and improvement.

In a large prospective trial comparing suburethral fascial slings versus Burch's procedure, at 24 months, success rates were higher for women who underwent the sling procedure than for those who underwent Burch's procedure (66% vs. 49%, respectively). These efficacy results are notable; in a review study summarizing cure rates of surgical treatments for SUI, 16 studies comparing sling procedures with colpo-suspension were reviewed. Of the 4 that were randomized controlled trials comprising 150 patients, none reported a difference in cure.

3. Midurethral Slings—This recent modification of the sling is the use of tension-free vaginal mesh made of polypropylene placed at the level of the midurethra. This technique, developed in Sweden, was introduced to the United States in the late 1990s. Use of tension-free vaginal tape (TVT) (Fig. 42–7) was developed as a minimally invasive technique for surgical correction of genuine SUI. The initial study had an 84% cure rate in 75 women with 2-year follow-up. The success rates of this procedure that have been reported in trials range from 86% to 99%, with up to 10-year follow-up. Because these results have been reproduced, most clinicians consider the midurethral sling as the gold standard for continence surgery.

Because of the success of TVT midurethral sling, numerous other devices using the same principles and technique are available. All use a polypropylene mesh but have different designs of delivery needle/trocar, mesh construction, and sheath type. Comparative data between devices are scanty.



A
B
C

Figure 42–7. A: Placement of midurethral sling in the sagittal view. **B:** Retropubic passage of midurethral sling. **C:** Transobturator passage of midurethral sling.

Because of the success of TVT midurethral sling, numerous other devices using the same principles and technique are available. All use a polypropylene mesh but have different designs of delivery needle/trocar, mesh construction, and sheath type. Comparative data between devices are scanty.

An alternate to retropubic passage is the transobturator route, in which the sling is passed through the obturator foramen laterally. This creates a more lateral point of fixation. The purported advantage is reduction in bladder, bowel, or major vascular injury because this method avoids the space of Retzius and does not traverse the peritoneal space. Studies suggest 2-year cure rates comparable to those of retropubic passage (94%). There are reservations regarding the transobturator approach as it relates to correcting SUI due to a poorly functioning urethra and in complications related to groin pain, particularly in thin patients (Fig. 42–7).

A more recent introduction is the **single-incision slings**, in which instead of passing externally through the obturator foramen, the mesh sling is anchored internally into the fascia/muscle of the obturator.

C. Periurethral and Transurethral Injection

Periurethral or transurethral injection of a bulking agent into the submucosal space of the bladder neck causes narrowing or coaptation of the proximal urethra and bladder neck opening. This increases urethral resistance to involuntary urine loss without changing resting urethral closure pressure. Currently glutaraldehyde cross-linked bovine collagen and calcium hydroxyl apatite are the most commonly used materials. This procedure is generally reserved for genuine SUI caused by intrinsic sphincteric deficiency. The injections can be performed with the patient under sedation with local anesthetic in an outpatient or office setting. These materials are biologic and resorb over time. Improvement and cure rates are 53–66% in the short term, and complications are minimal.

D. Artificial Sphincters

The artificial urethral sphincter is an effective option for patients with incontinence not amenable to standard surgical treatment because of urethral scarring or atony. The artificial urinary sphincter is best used in patients with incontinence due to poor urethral sphincter function. The sphincter obstructs the urethra by compressing the bladder neck via a pressure-regulated balloon and releases the compression when the patient desires to void. Reported success rates are up to 91%, but complication rates are high, with 21% of patients requiring surgical replacement of parts or the entire sphincter.

URGE URINARY INCONTINENCE

Urge urinary incontinence is the complaint of involuntary leakage accompanied by urgency. Urge urinary incontinence may be associated with involuntary contractions of the bladder or detrusor contractions; however, most often it is attributable to increased sensation with strong urge. The term **overactive bladder** (OAB) is often used to describe the most common symptoms of urinary urgency, usually accompanied by frequency and nocturia, with or without urgency urinary incontinence, in the absence of urinary tract infection or other obvious pathology. Not all patients with OAB have detrusor overactivity, and neither will all patients with detrusor overactivity have OAB. OAB is a term that lends itself to encompassing all conditions related to bladder urgency and frequency with and without incontinence. OAB has become a preferred clinical term because it comprises the spectrum of related symptoms.

Pathogenesis

The incidence of OAB varies depending on the population studied and the definition applied. Consequently, the reported prevalence varies widely from 8–50% in the general population, and in women older than 65 years, it is estimated to be at least 38%. An important concept is that involuntary detrusor contractions for bladder emptying are normally overridden by cortical inhibition of reflex bladder activity. In the majority of cases the cause of OAB symptoms is unknown. Patients with underlying neurologic disease may manifest with urinary incontinence. Although neurologic disease is not a common cause of OAB, multiple sclerosis, cerebrovascular disease, Parkinson’s disease, and Alzheimer’s disease are most often associated with involuntary bladder contractions.

Clinical Findings

OAB is suggested by urinary frequency often associated with a strong urge or a sense of impending urine loss. Incontinence often occurs before reaching the toilet. Physical or environmental stimuli, such as running water, cold weather, or hand washing, may elicit an urge. Patients often describe “key in lock” syndrome. This is typically characterized by an uncontrollable urge to void when unlocking the door after returning from a trip out of the house. The first thing done upon return is to immediately rush to the toilet or risk losing urine.

Treatment

Adequate therapy depends greatly on accuracy of diagnosis of OAB. History is most often suggestive, and the diagnosis can be supported by urinary diary or confirmed with office cystometry or more precisely with multichannel urodynamics.

Patients with OAB first should be offered simple treatments. Behavioral modifications and medical treatment are the standard first-line therapy for urge urinary incontinence.

A. Behavioral Therapy

Behavioral therapy includes bladder training, timed voiding, and pelvic floor muscle exercises. Bladder training is an educational program that combines written and verbal instruction to educate patients about the mechanisms of normal bladder control with the teaching of relaxation and distraction skills to resist premature signals to urinate. Creating a voiding schedule for which the patient urinates at preset intervals while attempting to ignore the urge to urinate may progressively lead to re-establishment of cortical voluntary control over the micturition reflex.

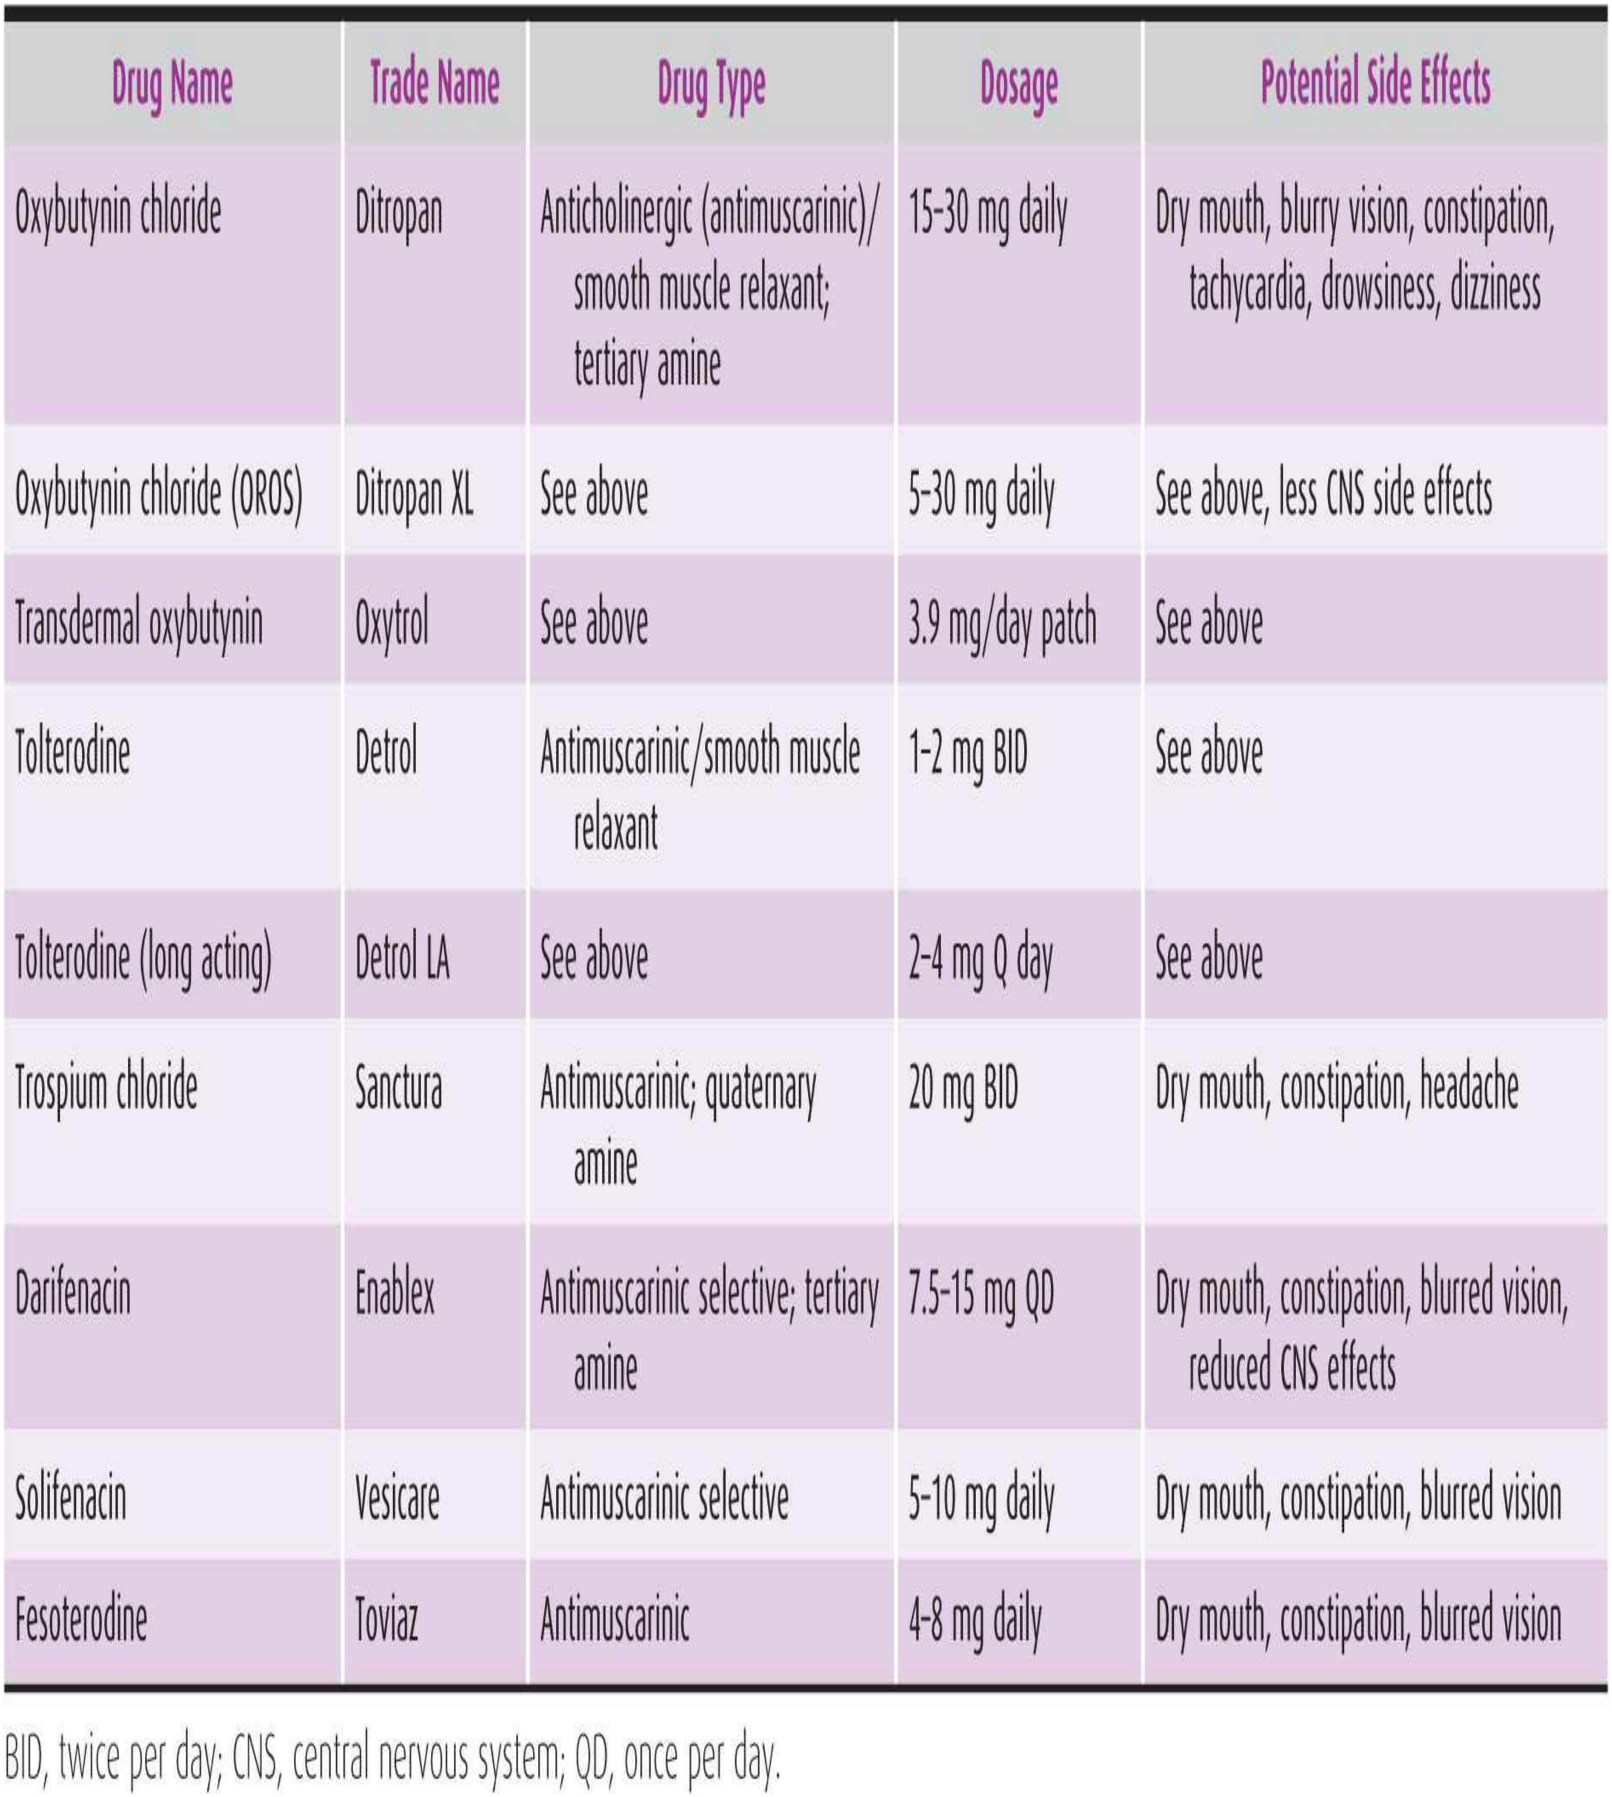
Timed voiding is a form of bladder retraining that again mandates regularly scheduled voiding and attempts to match the person’s natural voiding schedule. No effort is made to motivate the patient to delay voiding by resisting the urge. This method is geared more toward elderly patients with more challenging problems who have skilled help available.

Pelvic floor exercises may aid in the treatment of OAB. Evidence supports the utility of this modality in all types of incontinence. Particularly when augmented with biofeedback, pelvic floor exercises can greatly reduce symptoms of urinary frequency and urge incontinence, by up to 54–85%.

B. Pharmacologic Therapy

One of the most effective and popular treatments for urge urinary incontinence and OAB is drug therapy. Numerous agents for the treatment of these patients have been tried over the years, but only a few have demonstrated substantial impact on reduction of symptoms in controlled trials. One of the main difficulties in treating OAB is that the cause of OAB is still under investigation. The drugs available can be divided into classes by mechanism of action (Table 42–8).

Table 42–8. Pharmacologic treatment of urge incontinence.



Drug Name	Trade Name	Drug Type	Dosage	Potential Side Effects
Oxybutynin chloride	Ditropan	Anticholinergic (antimuscarinic)/ smooth muscle relaxant; tertiary amine	15-30 mg daily	Dry mouth, blurry vision, constipation, tachycardia, drowsiness, dizziness
Oxybutynin chloride (OROS)	Ditropan XL	See above	5-30 mg daily	See above, less CNS side effects
Transdermal oxybutynin	Oxytrol	See above	3.9 mg/day patch	See above
Tolterodine	Detrol	Antimuscarinic/smooth muscle relaxant	1-2 mg BID	See above
Tolterodine (long acting)	Detrol LA	See above	2-4 mg Q day	See above
Trospium chloride	Sanctura	Antimuscarinic; quaternary amine	20 mg BID	Dry mouth, constipation, headache
Darifenacin	Enablex	Antimuscarinic selective; tertiary amine	7.5-15 mg QD	Dry mouth, constipation, blurred vision, reduced CNS effects
Solifenacin	Vesicare	Antimuscarinic selective	5-10 mg daily	Dry mouth, constipation, blurred vision
Fesoterodine	Toviaz	Antimuscarinic	4-8 mg daily	Dry mouth, constipation, blurred vision

BID, twice per day; CNS, central nervous system; QD, once per day.

Antimuscarinics, or anticholinergics, have become the mainstay of drug treatment of OAB. Acetylcholine is the primary neurotransmitter involved with bladder contraction. The detrusor muscle of the bladder is heavily populated with cholinergic receptors. Anticholinergic activity, therefore, is a property of most drugs used to treat OAB. The mainstays of drug therapy for OAB include oxybutynin chloride and tolterodine. Oxybutynin chloride has been shown in randomized placebo-controlled trials to be effective in increasing bladder capacity, decreasing the frequency of detrusor contractions, and improving symptoms of urinary urgency in approximately 70% of patients. It is effective for both idiopathic and neuropathic etiologies of detrusor instability.

Tolterodine is a medication designed specifically for OAB. It also has anticholinergic activity with specificity for the bladder, and it acts through muscarinic receptors as well as smooth muscle relaxation. In a multicenter randomized controlled trial, the medication compared favorably with oxybutynin in terms of reducing the number of micturitions in 24 hours and the number of incontinent episodes. Because of its bladder specificity, tolterodine has a more favorable side effect profile than oxybutynin. It is also dosed less frequently and improves patient compliance. Both are available in immediate-release and long-acting formulations. Oxybutynin is also available for delivery in a transdermal patch.

A large randomized comparative trial evaluating the performance of the long-acting formulations of oxybutynin and tolterodine demonstrated similar efficacy. Adverse events were similar, but the occurrence of dry mouth was higher in the oxybutynin group.

Other antimuscarinics are available. All significantly improve OAB symptoms compared with placebo. Evidence suggests that medications such as darifenacin, solifenacin, trospium chloride, and fesoterodine have side effects similar to or lower than those of traditional antimuscarinics. Comparative trials exist essentially demonstrating comparable efficacy and adverse event profiles. Most of the clinical effectiveness of antimuscarinics, however, is limited by side effects. Long-term compliance of these medications appears to be imperfect at best.

C. Sacral Neuromodulation

Electrical stimulation to the nerves that control the bladder have been used in people with OAB. An electrode is placed via the sacral foramen alongside a sacral nerve (usually S3). In a second procedure, the electrode is connected by cables under the skin to an implanted programmable pulse generator that provides stimulation within set stimulation parameters. Implantation of the pulse generator is usually carried out only after a successful trial. The technology has been used for patients with OAB, urgency incontinence, and voiding (retention of urine) difficulties, and for some patients with defecation problems. It has also been used in the management of chronic pelvic pain, and it is approved for fecal incontinence, but this indication is not included in this review.

In patients with urge urinary incontinence caused by detrusor overactivity, sacral neuromodulation seems to act primarily by activation of nonmuscular afferent sacral nerve fibers that inhibit parasympathetic motor neurones in the cord through interneurons. It appears that any change induced by implanted electrodes persists only while the stimulator is turned on, returning to baseline when the stimulation is stopped. A longer lasting benefit has, however, been reported for stimulation via vaginal or anal plug electrodes, persisting after active treatment stops. These devices are expensive, the surgery is invasive, and many people need another operation.

It is not clear how best to use these devices. However, implantable stimulators that provide continuous electrical stimulation to the nerves or nerve roots supplying the bladder and pelvis, or to the peripheral nerves that share the same nerve roots, can benefit selected patients with difficult-to-control urinary problems.

MIXED INCONTINENCE

Mixed incontinence occurs when both stress incontinence and urge incontinence occur simultaneously. Patients may present with symptoms of both types of incontinence. These patients present both a diagnostic and therapeutic dilemma. The prevalence of mixed incontinence is more common than most practitioners realize. A detailed history will reveal symptoms of SUI with urine loss associated with cough, sneeze, or other increase in Valsalva’s pressure, as well as urinary urgency, frequency, and concomitant incontinence. The coexistence of these 2 conditions may be brought about by many causes. Patients with SUI often preemptively urinate to avoid a full bladder and subsequent urine loss, thereby conditioning the bladder to habituate to a low functional capacity. This may promote premature signaling of bladder fullness and result in frequent urge symptoms.

Treatment

For mixed incontinence, treatment should be based on the patient’s worst symptoms. Often patients can prioritize their symptoms, stating that one component impacts their life more than the other. By having the patient separate the symptoms, a practical management plan with realistic expectations can be devised. A great disservice can be done by operating on a patient to restore bladder neck support and remove stress symptoms when the patient’s main concern is daily urge incontinence while she is at work. Conservative measures should be tried first, and if symptoms do not improve, surgical measures can be entertained to target alleviation of the stress component; however, there is a 50–60% chance that urge symptoms may resolve after a midurethral sling is performed.

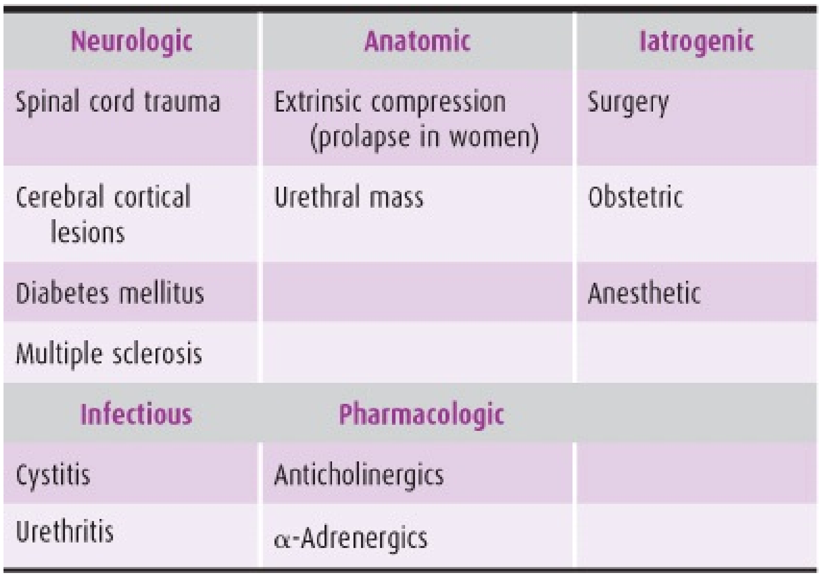
OVERFLOW INCONTINENCE

Overflow incontinence is the involuntary loss of urine associated with bladder overdistention in the absence of detrusor contraction.

Pathogenesis

This condition classically occurs in men who have outlet obstruction secondary to prostatic enlargement that progresses to urinary retention. In women this is a relatively uncommon cause of urinary incontinence. When it does occur, it can be from increased outlet resistance from advanced vaginal prolapse causing a “kink” in the urethra or after an anti-incontinence procedure that has overcorrected the problem. Additionally, it can result from bladder hyporeflexia from a variety of neurologic causes (Table 42–9).

Table 42–9. Causes of overflow incontinence.



Neurologic	Anatomic	Iatrogenic
Spinal cord trauma	Extrinsic compression (prolapse in women)	Surgery
Cerebral cortical lesions	Urethral mass	Obstetric
Diabetes mellitus		Anesthetic
Multiple sclerosis		
Infectious	**Pharmacologic**	
Cystitis	Anticholinergics	
Urethritis	α-Adrenergics	

Overflow incontinence most often occurs due to postoperative obstruction if the bladder neck is overcorrected or with a hyporeflexic bladder due to neurologic disease or spinal cord injury. The normal act of voiding is controlled centrally by sacral and pontine micturition centers. Impaired emptying can be the result of disruption of either central or peripheral neurons mediating detrusor function. Failure to identify the cause early may lead to permanent dysfunction and may lead to injury to the detrusor muscle or compromise in the parasympathetic ganglia in the bladder wall.

Clinical Findings

Usually symptoms are loss of urine without awareness or intermittent dribbling and constant wetness. Suprapubic pressure or pain may be associated. Patients will often note a sensation of a full bladder and the need to strain in order to empty or apply suprapubic pressure to void. Patients are at risk for urinary tract infection secondary to persistent residual urine in the bladder, which acts as a medium for bacterial growth. It is commonly seen after a bladder neck suspension. Complaints of poor urinary stream and sense of incomplete emptying combined with having to strain or apply hand pressure to void are likely.

Evaluation should always include a postvoid residual and, if the diagnosis is questionable, voiding pressure flow studies. An imaging study of the upper urinary tract to evaluate the ureters and kidney should follow, because persistent high-volume retention can lead to reflux and hydroureter or hydronephrosis and renal injury if left unchecked.

Treatment

Bladder drainage to relieve retention is the first priority. Self-intermittent or prolonged catheterization may be necessary, depending on resolution of the inciting cause. In cases of postoperative urinary retention, bladder function can be evaluated by serial postvoid residual urine determinations. Although no normal volume for residual urine is universally accepted, less than 100 mL is generally considered to be within normal limits and greater than 150 mL is considered abnormal. More than 1 value is needed because persistently high residual volumes will require prolonged catheterization.

When urinary retention occurs in the setting of neurologic disease, diabetes, or stroke, correction of the underlying cause is often impossible; therefore, the goal is to prevent injury or damage to the upper urinary tract. Intermittent self-catheterization is preferable to an indwelling catheter, which may predispose to infection, bladder spasms, or erosion.

Medical therapy may assist in the care of these patients. Acetylcholine agonists can stimulate detrusor contractions in patients who have vesical areflexia. α-Adrenergic blockers can facilitate bladder emptying by relaxing tone at the bladder neck.

Behavior modification in the form of timed voiding on a preset schedule to empty regardless of urge will prevent accumulation of excess urine. Usually a voiding pattern of every 2–3 hours is preferable. In bladder areflexia, manual pressure or abdominal splinting may facilitate emptying.

BYPASS INCONTINENCE

Urinary loss due to abnormal anatomic variations is uncommon but extremely important to consider in the evaluation of the incontinent woman. Bypass incontinence may often mimic other forms of urinary incontinence but usually presents as constant dribbling or dampness. Patients may complain of positional loss of urine without urge or forewarning. Diagnosing this type of incontinence requires a high level of suspicion and an understanding of the underlying anatomic deviation in the lower urinary tract. Genitourinary fistulas (vesicovaginal or ureterovaginal) can be a debilitating cause of incontinence and are formed because of poor wound healing after a traumatic insult (eg, obstetric laceration, pelvic surgery, perineal trauma, or radiation exposure). Leakage due to fistulas is generally continuous, although it may be elicited by position change or stress-inducing activities. Evaluation should include a careful examination of the vaginal walls for fistulas. This can be facilitated by filling the bladder with milk or dilute indigo carmine dye and looking for pooling in the vaginal canal. Pad testing can be performed by having the patient ingest 200 mg of oral phenazopyridine hydro-chloride (Pyridium) several hours before a subsequent examination. By placing a tampon in the vagina and on the perineum, the diagnosis may be confirmed by inspection of the pads after a period of time. Further imaging (intravenous urography) and cystoscopy can identify the exact location of the aberrant communication. If diagnosis is made early, the fistulous tract may heal with prolonged catheterization. However, if this procedure is unsuccessful or if diagnosis is made late, surgical correction is generally the only hope for cure.

Urethral Diverticula

Another important but uncommon cause of involuntary urine loss is urethral diverticula. Diverticula are essentially weaknesses or “hernias” in the supportive fascial layer of the bladder or urethra. Urethral diverticulum is most likely to cause symptoms of urinary loss. It has an incidence of 0.3–3% in women and is thought to be largely an acquired condition resulting from obstruction and expansion of the paraurethral Skene’s glands. The symptoms of constant small amounts of leakage or urethral discharge are often described. A suburethral mass is visible and palpable on physical examination. Urine or discharge may often be “milked” by palpation of the suburethral mass. Treatment is usually surgical excision of the diverticulum.

FUNCTIONAL AND TRANSIENT INCONTINENCE

Incontinence may be caused by factors outside the lower urinary tract and is particularly significant in the geriatric population, because often a multitude of special circumstances affect the health of the elderly. Physical impairment, cognitive function, medication, systemic illness, and bowel function are all factors that may contribute to incontinence. Many immobile patients are incontinent because of the inability to toilet. Cognitive disturbances limit a patient’s ability to respond normally to the sensation to void. Numerous medications have effects on the bladder that may reduce capacity, inhibit bladder function, increase diuresis and bladder load, or relax the urinary sphincter. Additionally, stool impaction and constipation both have been associated with increased prevalence of urinary incontinence. Treatments should first identify the etiologic factors of the incontinence and then reduce or remove the cause.

PROGNOSIS

Urinary incontinence is fundamentally a condition that affects quality of life. The natural history of incontinence is generally that of stability or progression. Excluding transient causes, spontaneous resolution is not a feature of this condition. Most women learn coping skills (pad use, frequent toileting, timed voiding) and adaptive measures (fluid restriction or toilet mapping) to handle the detriment in quality of life. Although bothersome and even socially debilitating, the extent of treatment is dependent on patient direction. One example of true health risk with incontinence is in the instance of outlet obstruction and urinary retention with resultant overflow incontinence. Chronic urinary retention may lead to upper urinary tract dilation and ultimately lead to reduction in urinary function, therefore intervention in this setting is warranted.

PELVIC ORGAN PROLAPSE

Pelvic organ prolapse (POP), including anterior vaginal and posterior vaginal prolapse, uterine prolapse, and enteroceles, is a common group of clinical conditions affecting women. The prevalence rates increase with age, and POP currently affects millions of women. In the United States, POP is responsible for more than 200,000 surgeries per year. The lifetime risk that a woman will undergo surgery for prolapse or urinary incontinence is 11%, with a third of surgeries representing repeat procedures. The risk of requiring a repeat procedure for POP may be as high as 29%. As our population ages, quality-of-life–altering conditions such as POP will demand more attention from our health care services. Prolapse can be asymptomatic or manifest with severe debility and associated bladder, bowel, or sexual dysfunction. The ability to screen, diagnose, and treat these entities will become increasingly important for clinicians.

Defects in the pelvic supporting structures result in a variety of clinically evident pelvic relaxation abnormalities. Pelvic support defects can be classified by their anatomic location.

Anterior Vaginal Wall Defects

ESSENTIALS OF DIAGNOSIS

- **Anterior vaginal prolapse** describes an anterior vaginal wall defect in which the bladder is associated with the prolapse. It is also known as a cystocele (Fig. 42–8).

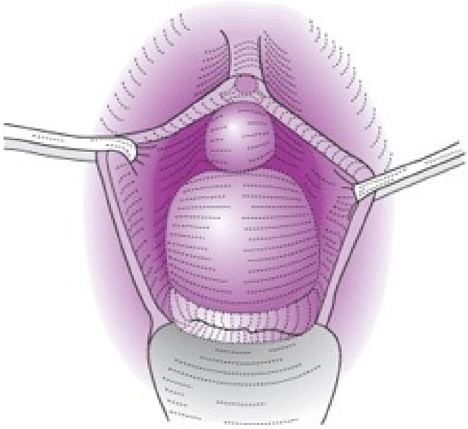

Figure 42–8. Anterior vaginal prolapse, known as a cystocele.

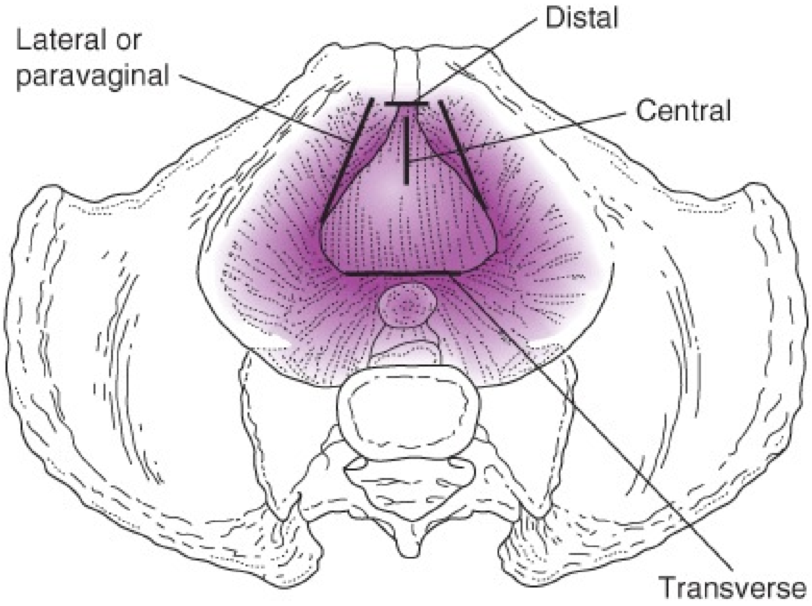
- **Paravaginal/midline/transverse prolapse** are terms used to indicate the location of anterior vaginal wall defects (Fig. 42–9).



Distal
Lateral or paravaginal
Central
Transverse

Figure 42–9. Four areas in which pubocervical fascia can break or separate—4 defects.

Apical Prolapse

ESSENTIALS OF DIAGNOSIS

- **Uterine prolapse** is shown in Figure 42–10.

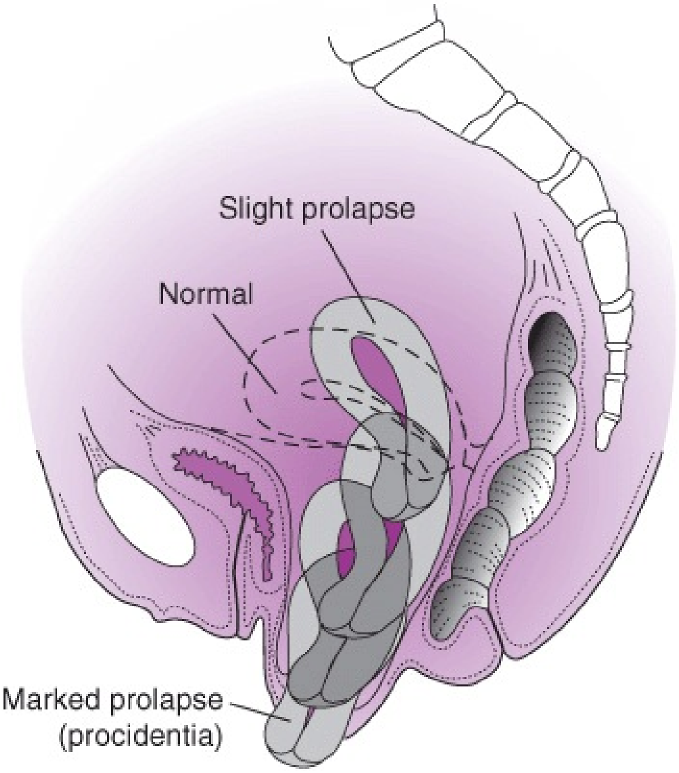


Figure 42–10. Prolapse of the uterus.

- **Vaginal vault prolapse** (posthysterectomy)
- **Enterocele** describes an apical vaginal wall defect in which bowel is contained within the prolapsed segment (Fig. 42–11). Generally occurs in posthysterectomy women, but can occur with the uterus in situ.

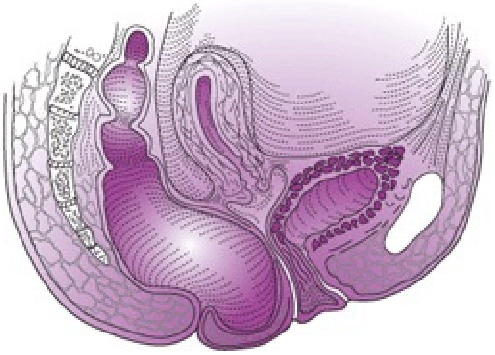

Figure 42–11. Enterocele and prolapsed uterus.

Posterior Vaginal Wall Prolapse

ESSENTIALS OF DIAGNOSIS

- **Posterior vaginal wall prolapse** describes a posterior vaginal wall defect. It is also known as a rectocele (Figs. 42–12 and 42–13).

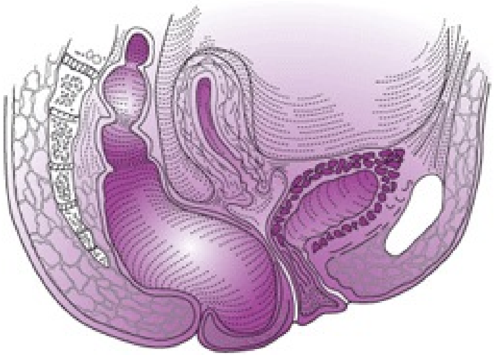

Figure 42–12. Posterior vaginal prolapse.

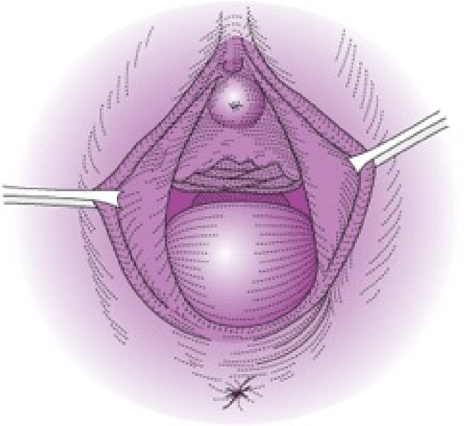

Figure 42–13. Posterior vaginal prolapse, known as rectocele.

Description and Staging of Pelvic Organ Prolapse

Two general classifications are used to describe and document the severity of pelvic organ prolapse. The most current system employs objective measurements from fixed anatomic points. The Pelvic Organ Prolapse Quantification (POP-Q) system standardizes terminology of female pelvic organ prolapse. This is accepted as the most objective method for quantifying prolapse as it provides a more precise description of the anatomy. This descriptive system contains a series of site-specific measurements of vaginal and perineal anatomy. Prolapse in each segment is evaluated and measured relative to the hymen, which is a fixed anatomic landmark that can be consistently identified. The anatomic position of the 6 defined points for measurement should be in centimeters above the hymen (negative number) or centimeters beyond the hymen (positive number). The plane at the level of the hymen is defined as 0 (Fig. 42–14 and Table 42–10). Stages are assigned according to the most severe portion of the prolapse when the full extent of the protrusion has been demonstrated. An ordinal system is used for measurements of different points along the vaginal canal that facilitates communication among clinicians and enables objective tracking of surgical results. The POP-Q system has generally replaced the “1/2 way” system designed by Baden and Walker.

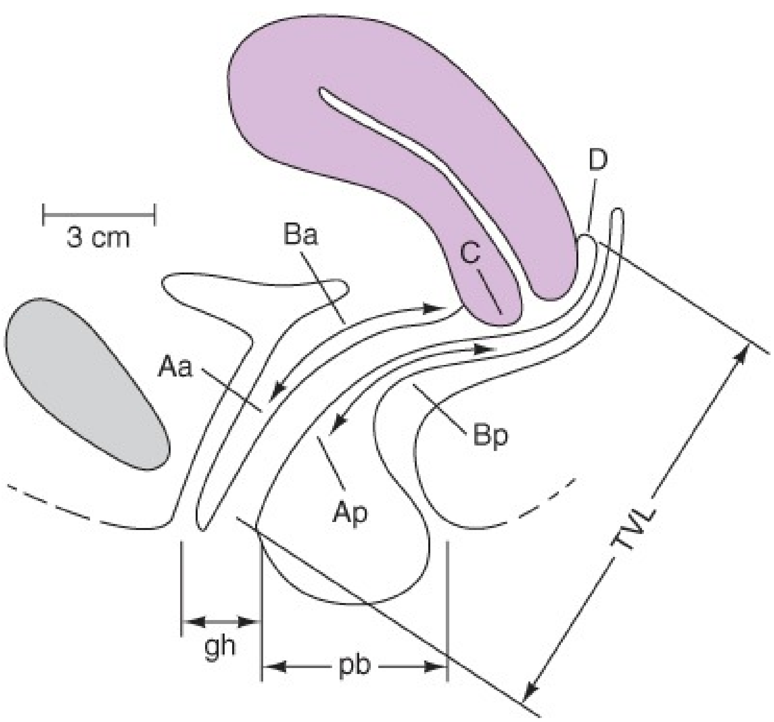

Figure 42–14. Six sites (points *Aa, Ba, C, D, Bp,* and *Ap*), genital hiatus (*gh*), perineal body (*pb*), and total vaginal length (*TVL*) used for pelvic organ quantitation. (Reproduced with permission from Bump RC, Mattiasson A, Bø K, et al. The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. *Am J Obstet Gynecol* 1996;175:10–17.)

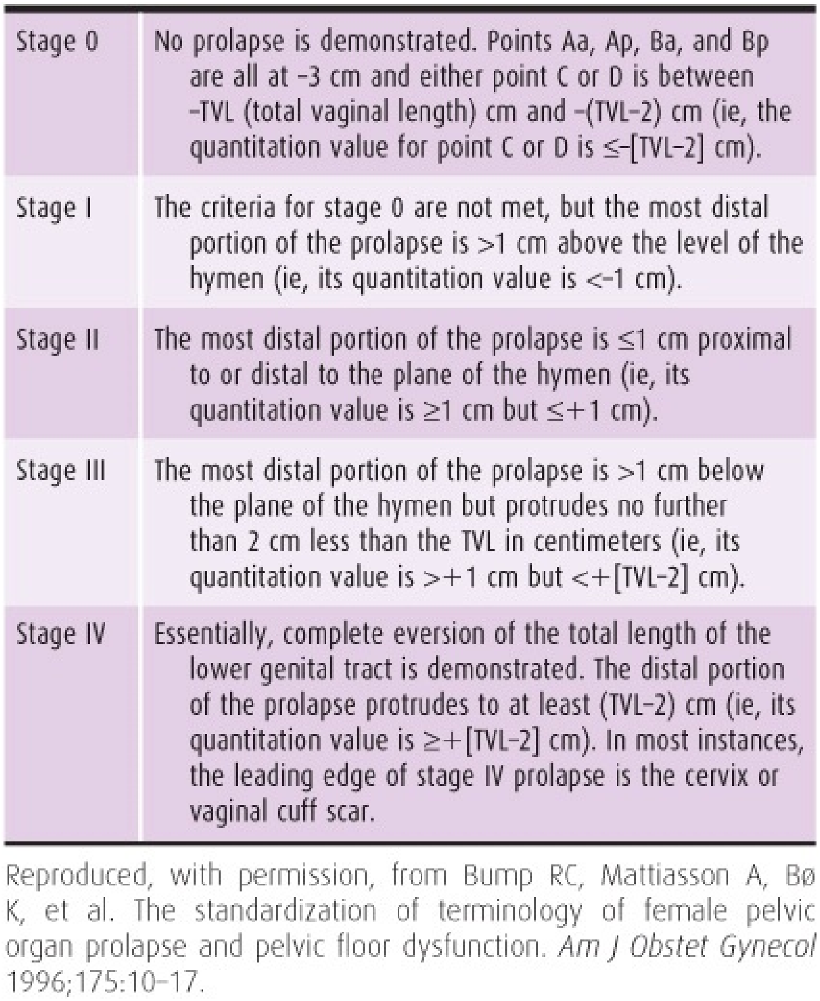
Table 42–10. Staging of pelvic organ prolapse.



Stage 0	No prolapse is demonstrated. Points Aa, Ap, Ba, and Bp are all at -3 cm and either point C or D is between -TVL (total vaginal length) cm and -(TVL-2) cm (ie, the quantitation value for point C or D is ≤-[TVL-2] cm).
Stage I	The criteria for stage 0 are not met, but the most distal portion of the prolapse is >1 cm above the level of the hymen (ie, its quantitation value is <-1 cm).
Stage II	The most distal portion of the prolapse is ≤1 cm proximal to or distal to the plane of the hymen (ie, its quantitation value is ≥1 cm but ≤+1 cm).
Stage III	The most distal portion of the prolapse is >1 cm below the plane of the hymen but protrudes no further than 2 cm less than the TVL in centimeters (ie, its quantitation value is >+1 cm but <+[TVL-2] cm).
Stage IV	Essentially, complete eversion of the total length of the lower genital tract is demonstrated. The distal portion of the prolapse protrudes to at least (TVL-2) cm (ie, its quantitation value is ≥+[TVL-2] cm). In most instances, the leading edge of stage IV prolapse is the cervix or vaginal cuff scar.

Reproduced, with permission, from Bump RC, Mattiasson A, Bø K, et al. The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. *Am J Obstet Gynecol* 1996;175:10–17.

A better understanding of the pathophysiology of the pelvic supportive defects, their causes, and clinical presentations allows the individualization of the therapy most likely to successfully affect long-term outcome for each patient. Because POP is a disease impacting the quality of life, obtaining a detailed symptom history is an essential starting point.

General Considerations

Anterior and posterior vaginal relaxation, as well as incompetence of the perineum, often accompanies prolapse of the uterus. Large anterior vaginal prolapse is more common than posterior vaginal prolapse because the bladder is more easily carried downward than is the rectum. Before menopause, the prolapsed uterus hypertrophies and is engorged and flaccid. After the menopause, the uterus atrophies. In procidentia, the vaginal mucosa thickens and cornifies, coming to resemble skin.

ESSENTIALS OF DIAGNOSIS

The symptoms of POP are in general not unique to any particular vaginal defect. Often the symptoms are a reflection of only the most prominent point of prolapse. Most women become symptomatic only when the prolapse nears the vaginal opening. A critical concept is that the functional complaints may not always relate to the anatomic findings.

Symptoms of POP include:

- ▸ Sensation of vaginal fullness, pressure, heaviness, “something falling out”
- ▸ Sensation of “sitting on a ball”
- ▸ Discomfort in the vaginal area
- ▸ Presence of a soft, reducible mass bulging into the vagina and distending through vaginal introitus
- ▸ With straining or coughing, there is increased bulging and descent of the vaginal wall.
- ▸ Back pain and pelvic pain are often also associated with POP. It is important in women with these complaints to investigate other causes, as a direct link in mild to moderate prolapse is unproven.
- ▸ Urinary symptoms are also common:
    - Feeling of incomplete emptying of the bladder
    - Stress incontinence
    - Urinary frequency
    - Urinary hesitancy
    - Perhaps a need to push the bladder up in order to void (splinting)
    - Patients with advanced prolapse may have “potential” stress urinary incontinence. A condition in which underlying urinary incontinence is masked by kinking of the urethra and causing functional continence.

Defecatory symptoms may also occur, more commonly in posterior vaginal prolapse. The sense is one of incomplete emptying, need to strain, or manually splint in the vagina or on the perineal body (space between vagina and anus) in order to defecate. The history may include prolonged, excessive use of laxatives or frequent enemas. Other nonspecific symptoms such as low back pain, dyspareunia, or even fecal and gas incontinence may be reported.

Symptoms of sexual function may also be elicited. Coital laxity or a sense of feeling “loose” may be reported. Avoiding intercourse as a consequence of embarrassment may occur. Attention to this aspect of a woman’s symptoms is especially critical if any surgical intervention is considered.

Pathogenesis

For pelvic organ prolapse, proven risk factors include age, increasing parity, obesity, and history of pelvic surgery, specifically hysterectomy. Additionally, certain lifestyle or disease conditions can promote the development of POP. Chronic coughing from lung disease and straining from chronic constipation, for example, may increase the pressures on the pelvic floor. Acting as a constant piston, driving forces exerted onto the pelvic support tissues can cause herniation of the vaginal walls. In a similar manner, occupational activity requiring repetitive heavy lifting (eg, environmental service workers or care providers of the elderly) may promote the development of POP with this daily insult of frequent pelvic pressure.

Furthermore, menopausal status, physical debilitation, and even neurologic decline can contribute to the development of POP. Yet even with a multitude of risk factors, certain women are predisposed to developing POP. As prolapse has been demonstrated in women with no identifiable risk factors, the inherent quality of a woman’s connective tissue plays a large role in the susceptibility to the development of prolapse and related conditions. Investigating the genotype, consistency, and composition of the endopelvic “fascial” tissues and the interplay of enzymatic remodeling is an area of intense interest and current research.

Parity has long been recognized as a prime risk factor for the development of POP. Not surprisingly, it is also strongly associated with anal and urinary incontinence as well. Parity is clearly associated with POP, as case-controlled studies show vaginal parity as an independent risk factor with a 3-fold increased risk for POP among parous women compared with nullipara controls. This risk increases up to 4.5-fold with more than 2 vaginal deliveries. The question of whether it is the pregnancy, the size of the baby, or the mode of delivery that plays the largest role in the development of POP is still not clear. During labor, as the vertex descends through the vagina, the physical forces on the pelvic tissues can be severe. The muscles, viscera, connective tissue, and nerves are all potentially susceptible to injury. Forces of compression and stretching combine to injure pelvic-floor nerves, leading to ischemia and neurapraxia. Myofascial fibers can be disrupted or torn because of distention of the fetal head and body. When tissues are injured, the body will repair them. Factors impairing adequate tissue repair and wound healing may also play an as yet undetermined role in the development of POP.

Clinical Findings

A. Physical Examination

Examination for pelvic organ prolapse should begin in the dorsal lithotomy position. Inspection of the vulva and perineum should focus on evaluation of vulvar architecture and the presence of pressure ulceration or erosions or other skin lesions. Epithelial skin lesions, particularly in the elderly, should be biopsied.

At first, with the patient at rest, the labia should be separated and any prolapse noted (Figs. 42–8 and 42–13). Examination of the patient with vaginal prolapse reveals a relaxed and open genital hiatus with a thin-walled, rather smooth, bulging mass. Vaginal rugae are normally present. A loss of rugation denotes disruption of the connective tissue attachment below the epithelium.

During evaluation for urinary incontinence, a stress test is performed at this initial portion of the examination. The patient should be asked to cough forcefully, and any loss of urine is noted.

For prolapse assessment, when using the POP-Q system, the genital hiatus, perineal body, and vaginal length can be recorded. (Use of a wooden PAP spatula and tape measure can be helpful.) Vaginal support can then be assessed with strain (cough or Valsalva's maneuver), and the point of maximal protrusion should be noted in centimeters relative to the hymen and recorded. A speculum can also be used to "usher" the prolapse out during straining. This is also the most effective way to evaluate uterocervical support. In posthysterectomy patients, the cuff can often be visualized by the presence of "dimples" in the vaginal epithelium at the apex. Discriminate examination of the vaginal walls using the posterior blade of a Graves' speculum or Sims' retractor should then be used to evaluate the anterior and posterior walls separately, again noting the point of maximal prolapse during strain. For evaluation of the anterior wall, compress the posterior wall and have the patient strain. For evaluation of the posterior wall, elevate the anterior wall and have the patient strain. Complete examination should also include a rectovaginal palpation. In this way, one can evaluate for the presence of concurrent enterocele in addition to a rectocele. The septal defect may involve only the lower third of the posterior vaginal wall, but it often happens that the entire length of the rectovaginal septum is thinned out. The finger in the rectum confirms sacculation into the vagina. A deep pocket into the perineal body may be noted, so that on apposition of the finger in the rectum and the thumb on the outside, the perineal body seems to consist of nothing but skin and rectal wall.

Assessment of anal sphincter tone should also be performed both at rest and with squeeze contraction. The presence of perianal lesions or hemorrhoids should be noted.

If during examination the prolapse is not able to be reproduced based on symptoms, examination with the woman in the standing position should be performed. With the patient facing the seated examiner, knees slightly bent, and with strain, prolapse not demonstrable in the supine position because of poor Valsalva's maneuver can often be confirmed in the upright position.

Assessment of the pelvic floor strength is accomplished by vaginal or rectovaginal palpation of the levator ani musculature. Within 2 to 3 cm from the hymen, the bulk of the pubococcygeus component of the levator ani muscle can be palpated. The patient should be asked to contract the muscle, and the tone, symmetry, and duration of contraction should be recorded. This portion of the examination is often a valuable time to provide feedback to the patient about the volitional ability to contract the pelvic floor muscles. If the patient's ability to identify and contract the muscles is inadequate, the examiner may facilitate isolation of the proper muscles using verbal cues and manual feedback.

Evaluation of urinary function is also important in patients with POP. This is most germane in patients with large anterior vaginal defects. With prolapse of the anterior vagina, the bladder and urethra may herniate into the vagina. The urethra can bend and kink as it is fixed distally at the level of the pubourethral ligament. This "kinking" can alter normal voiding function in 2 fundamental ways. First, it will increase outflow resistance and impair normal emptying. After voiding, simple catheterization or ultrasonographic measure should be performed and the residual volume measured. Although not standardized, postvoid residual volumes greater than 100 mL are considered elevated and may indicate abnormal voiding and require referral for more sophisticated testing.

The second way urethral kinking can impact voiding is by masking underlying stress urinary incontinence. With increased outflow resistance, functional continence is created. Reduction of the prolapse during examination can be performed (elevation of anterior segment with a pessary, ring forceps, or speculum). The patient strains/coughs and the presence of urinary loss confirms the condition of SUI. This is termed **stress incontinence on prolapse reduction** and may be addressed with an anti-incontinence procedure at the same time if surgery is offered for POP.

B. Imaging Studies

In general, a complete discriminative gynecologic examination is all that is necessary to accurately assess pelvic organ prolapse. In certain cases, further diagnostic studies can be used.

Recent advances in radiologic medicine have allowed assessment of the pelvic floor with sonography and MRI. Despite newer techniques, intravenous pyelogram or computed tomography urogram still hold great value, as they are simple and safe methods to visualize the urinary tract. They can be used to evaluate the bladder and ureters. The course of the ureters can be identified preoperatively if obstruction caused by pelvic mass or scarring is suspected. These imaging tests can be used to evaluate for fistulae, congenital anomalies, or suspected damage as a result of operative injury. However, they lack sensitivity in imaging the pelvic floor and its associated defects, do not yield much information regarding vaginal support and pelvic floor musculature, and lack dynamic capabilities.

Ultrasound techniques can be an important tool to the urogynecologist. Compared with other radiologic techniques, ultrasound is noninvasive and inexpensive and does not require contrast media. Its main disadvantage is that the quality of the study depends heavily on the skill of the operator. When performed transabdominally, transvaginally, or transperineally and combined with Doppler or endoluminal transducers, the bladder, urethra, and surrounding structures can be visualized with detail.

1. Videocystourethrography (VCUG)—VCUG combines a fluoroscopic voiding cystourethrogram with simultaneous recording of intravesical, intraurethral, and intraabdominal pressure and urine flow rate. The contrast in the bladder allows dynamic evaluation of the bladder and bladder support.

2. Magnetic Resonance Imaging—MRI has evolved into an important tool for the evaluation of the pelvic floor. It is an ideal modality because its resolution of soft tissues is superior to that of other radiologic techniques. The capability to image in multiple planes is also an advantage, particularly when visualizing the complex 3-dimensional relationships of the pelvic floor. Dynamic straining can be used to demonstrate prolapse under pressure and is often useful in surgical planning. As this modality becomes less costly and techniques evolve to allow evaluation of patients in the upright position, the information provided by MRI will be invaluable in increasing our knowledge and understanding of functional pelvic support.

Differential Diagnosis

Prolapse of the vagina is generally a straightforward diagnosis. However, less common disease entities may present as bulges in the vagina. Tumors of the urethra and bladder are often more indurated and fixed than is anterior vaginal prolapse.

A large urethral diverticulum may look and feel like an anterior vaginal prolapse but usually is more focal and may be painful. With urethral diverticulum, compression may express some purulent material from the urethral meatus. Anterolateral defects can represent embryologic remnants such as a Gartner’s duct cyst.

Skene’s and Bartholin’s glands can become obstructed and enlarge to form cysts or abscesses. Rarely, hemangiomas will present as vaginal bulging, although they will often have characteristic purple discoloration on the overlying epithelium.

Soft tumors (lipoma, leiomyoma, sarcoma, myofibroblastoma) of the vagina are more fixed and are nonreducible.

Cervical tumors—as well as endometrial tumors (pedunculated myoma or endometrial polyps)—if prolapsed through a dilated cervix and presenting in the lower third of the vagina, may be confused with mild or moderate uterine prolapse. Myomas or polyps may coexist with prolapse of the uterus and cause unusual symptoms.

Despite the variety of possibilities, the history and physical findings in vaginal or uterine prolapse are so characteristic that diagnosis is usually not a challenge.

Prevention

Prevention of genital prolapse is the focus of much debate. Antepartum, intrapartum, and postpartum exercises, especially those designed to strengthen the levator and perineal muscle groups (Kegel), often help improve or maintain pelvic support. Obesity, chronic cough, straining, and traumatic deliveries must be corrected or avoided. Estrogen therapy after menopause may help to maintain the tone and vitality of pelvic musculofascial tissues; however, evidence is lacking to support its benefit to prevent or postpone the appearance of anterior vaginal prolapse and other forms of relaxation.

Treatment

Pelvic organ prolapse, except in rare situations, is a condition that impacts only the quality of life. Consequently, the extent and type of treatment should reflect and be commensurate with the degree of impact on the quality of life the patient experiences. Patient perception is also a critical component, and self-image and conceptual discomfort are relevant to any discussion of therapy. Common reasons to intervene are when function is impaired because of the prolapse. Anterior prolapse can contribute to urinary incontinence or, when severe, urinary obstruction. Bulging vaginal epithelium can come into contact with undergarments and clothing and over time develop pressure sores and erosions. A posterior vaginal defect can become so large that fecal evacuation is difficult, or the patient finds it necessary to manually reduce the posterior vaginal wall into the vagina to expedite expulsion of feces. Mobility can be impaired by a large prolapse. All of the preceding complaints are reasons to discuss surgical repair.

Chronic decubitus ulceration of the vaginal epithelium may develop in procidentia. Urinary tract infection may occur with prolapse because of anterior vaginal prolapse, and partial ureteral obstruction with hydronephrosis may occur in procidentia. Hemorrhoids result from straining to overcome constipation. Small-bowel obstruction from a deep enterocele is rare.

A. Conservative Measures

The patient with a small or moderate-sized POP requires reassurance that the pressure symptoms are not the result of a serious condition and that, in the absence of urinary retention or severe skin pressure ulceration, no serious illness will result. The natural history of POP is such that it either will stay the same or progress. There is some evidence that a small subset of patients may experience regression of the prolapse after menopause or postpartum if the prolapse is noted shortly after delivery. Reassurance and observation of prolapse should be encouraged in the absence of symptoms.

If prolapse presents in the reproductive years, surgical correction of POP is rarely indicated in women who are not family complete. If the young woman does present with significant symptoms related to POP or with a disturbing degree of urinary incontinence, then temporary medical measures may provide adequate relief until she has completed childbearing, whereupon a definitive operative procedure can be accomplished.

1. Pessary—Pessary use in selected patients may provide adequate relief of symptoms. There are a variety of available pessary types and sizes that allow for individualization of therapy (Fig. 42–15). For the most common type of POP of the anterior or apical segment, a ring pessary is usually a sensible starting point for treatment. For the patient with complicating medical factors who is a poor operative risk, the temporary use of a vaginal pessary may provide relief of symptoms until her general condition has improved.

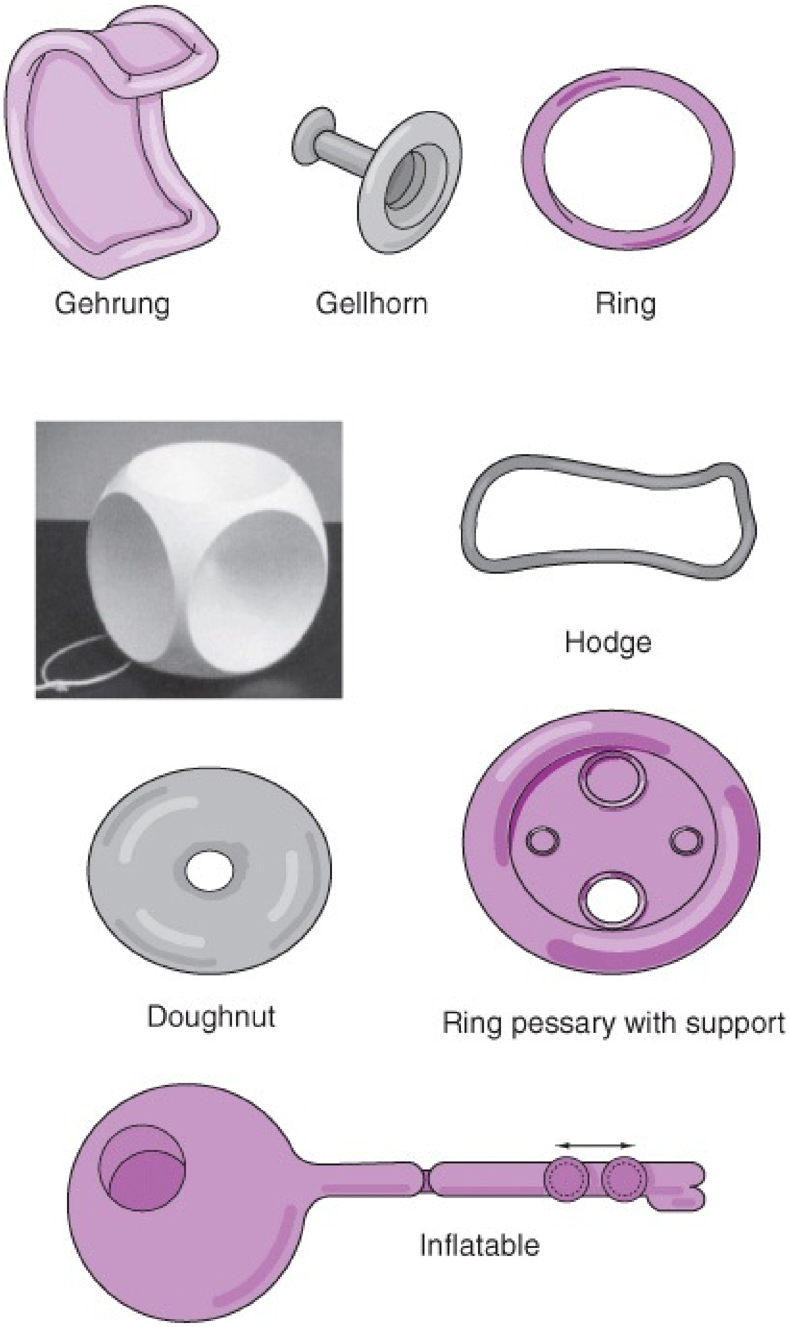


Figure 42–15. Types of pessaries.

Prolonged use of pessaries, if improperly managed, may lead to pressure necrosis and vaginal ulceration. The vaginal pessary is a prosthesis of ancient lineage, now made of rubber, plastics, and silicone-based material, often with a metal band or spring frame. Many types have been devised, but fewer than a dozen are basically unique and specifically helpful.

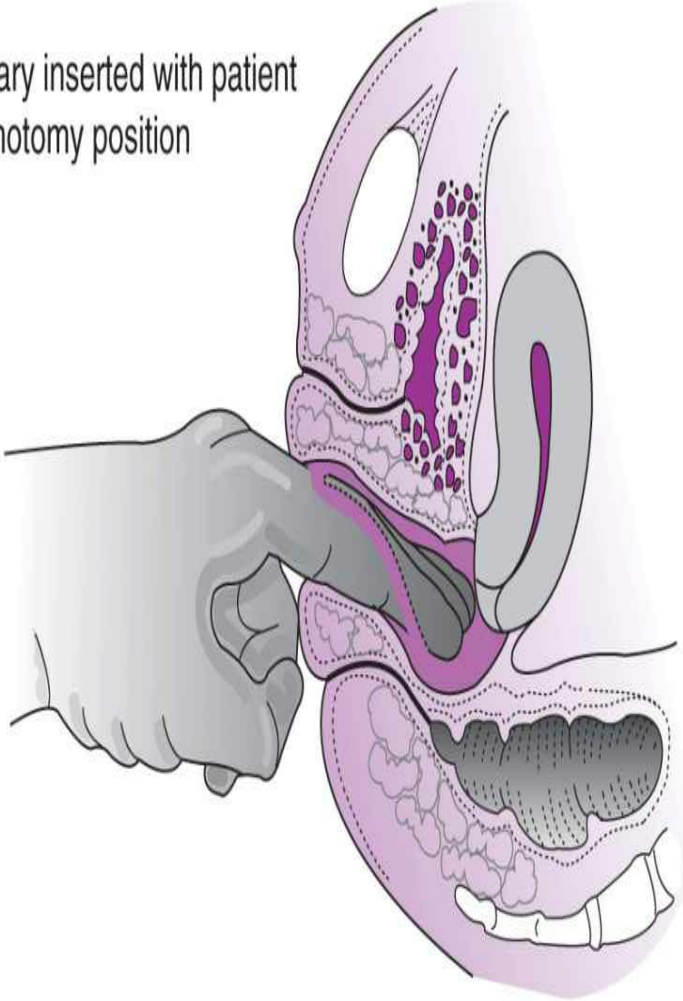
Pessaries are principally used to support the uterus and vaginal walls. They are effective because they reduce vaginal prolapse and increase the tautness of the pelvic floor structures. Little or no leverage is involved. Either by placement behind the pubic bone and perineal body or by filling the vaginal vault, pessaries remain in place to hold up the prolapsing vaginal walls or uterus. In most cases, adequate support anteriorly and a reasonably good perineal body are required; otherwise, the pessary may slip from behind the symphysis and extrude from the vagina.

Pessaries are contraindicated in acute genital tract infections and in adherent retroposition of the uterus.

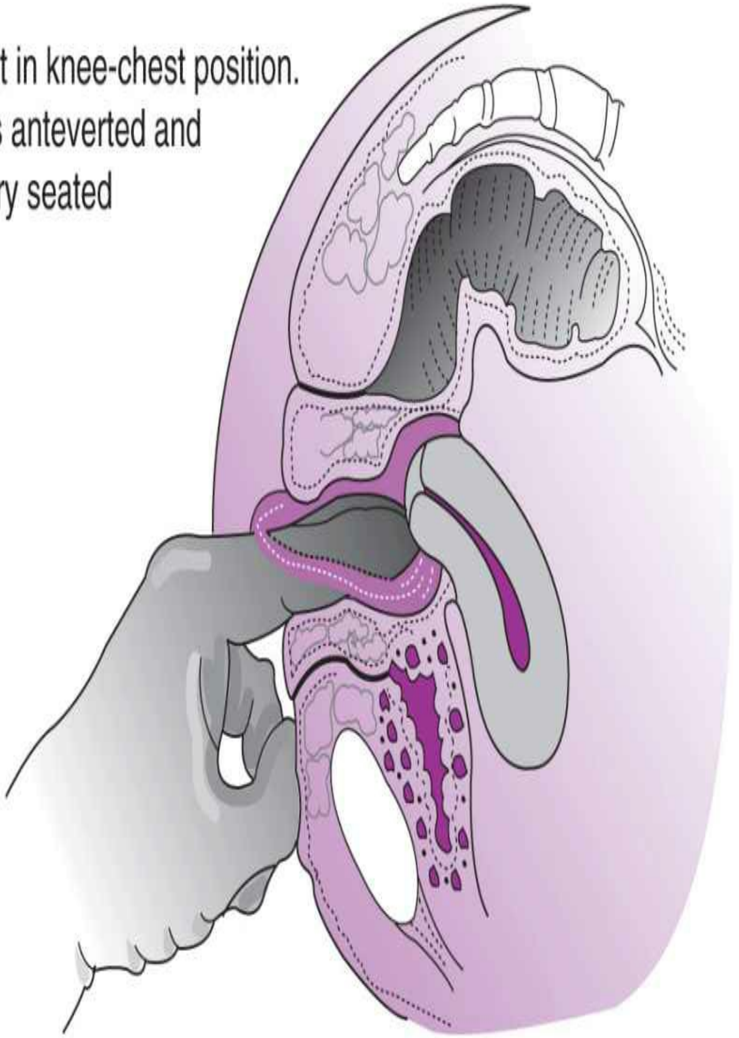
Several pessary types are available:

- A **ring pessary** with or without support provides relief of uterine prolapse or anterior vaginal prolapse.
- **Gellhorn pessaries** are uniquely shaped like a collar button and provide a ringlike platform for the cervix or apex. The pessary is stabilized by a stem that rests on the perineum. These pessaries are used to correct marked prolapse when the perineal body is reasonably adequate.
- The **doughnut** is made of soft rubber or silicone, and this type of pessary provides support for severe uterine prolapse or vault prolapse.
- The **Gehrung pessary** resembles 2 firm letter *U*s attached by crossbars. It rests in the vagina with the cervix cradled between the long arms; this arches the anterior or posterior vaginal wall and helps reduce the vaginal prolapse.
- The **Hodge pessary (Smith-Hodge, or Smith and other variations)** is an elongated, curved ovoid. One end is placed behind the symphysis and the other in the posterior vaginal fornix. The anterior bow is curved to avoid the urethra; the cervix rests within the larger, posterior bow. This type of pessary is used to hold the uterus in place after it has been repositioned.
- The **inflatable pessary** functions much like a doughnut pessary. The ball valve is moved up and down; when the ball is in the down position, air inflates the pessary; when in the up position, the air is sealed in and inflation is maintained.
- The **cube** is a flexible rubber cube with suction cups on each of its 6 sides that adhere to the vaginal walls. This is useful in women with severe prolapse. However, vaginal erosions are common and can be severe. Frequent monitoring initially to identify pressure ulcers is critical.

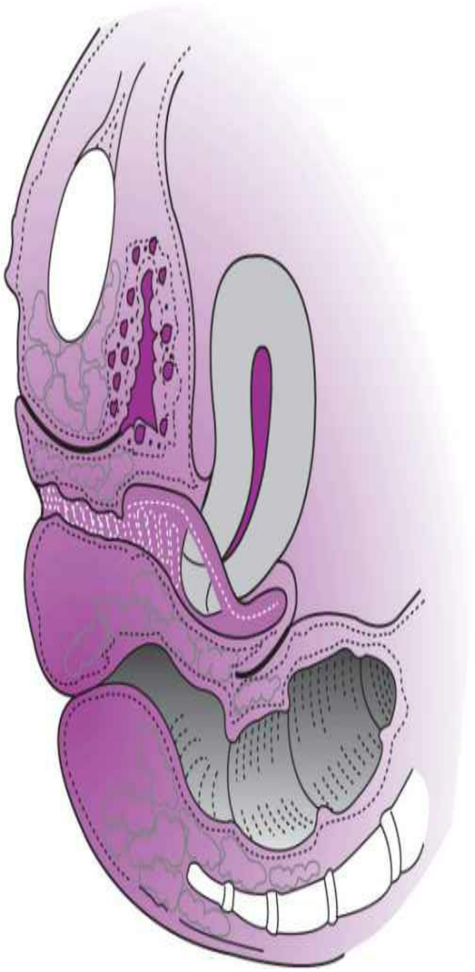
A. FITTING OF PESSARIES—Medicine is known as both an art and a science. Pessary fitting (Fig. 42–16) falls into the art category. Pessaries that are too large cause irritation and ulceration; those that are too small may not stay in place and may protrude.



Pessary inserted with patient in lithotomy position



Patient in knee-chest position. Uterus anteverted and pessary seated



Final seating of pessary and support of uterus

Figure 42–16. Insertion of Hodge-type pessary.

In general, fitting a pessary is very much a trial-and-error endeavor. Once a type is selected based on the defects in the vaginal anatomy and on symptoms, sizing is best done with an office sizing set. This task is somewhat complicated as each pessary has its own measurement system, but familiarity with each pessary over time simplifies this task. The pessary should be lubricated and inserted with its widest dimension in the oblique diameter of the vagina to avoid painful distention at the introitus. With a finger of the opposite hand, depress the perineum to widen the introitus. Each pessary type has an optimal method for insertion.

Once a pessary is in place, the forefinger should pass easily between the sides of the frame and the vaginal wall at any point; if it cannot, the pessary is too large. After the pessary has been fitted, the patient should be asked to stand, walk, and squat to determine whether pain occurs or whether the pessary becomes displaced. The patient should be shown how to withdraw the pessary if it becomes displaced or is uncomfortable and cautioned that a contraceptive vaginal diaphragm cannot be used while a vaginal pessary is in place.

During the initial period of pessary wear, any discomfort, bleeding, or disturbance in defecation or urinary function should be reported immediately. The patient should be examined 1–2 weeks after insertion to inspect for the presence of pressure and inflammatory or allergic reactions. A repeat exam in 4 weeks can be done; then visits should be done at 3- to 6-month intervals to assess for continued proper fit and to evaluate for vaginal erosion and inflammation as a result of pessary use. For women who are unable to remove and clean the pessary themselves, the pessary should be changed approximately every 2–3 months.

The pessary should be maintained with an acidic pH gel such as Trimo-San (Milex Products, Chicago, IL). In post-menopausal patients, topical estrogen can vitalize the vaginal mucosa and reduce ulceration. An estrogen-containing ring can also be used in conjunction by “piggybacking” the ring with the pessary and then changing it every 3 months.

Vaginal pessaries are not curative of prolapse, but they may be used for months or years for palliation with proper supervision.

A neglected pessary may cause fistulas or promote genital infections, but there is no clear evidence that cancer occurs as a result of wearing a modern pessary.

2. Pelvic Floor Muscle Exercises—In some patients, improvement of pressure symptoms and of urinary control may be obtained by using pelvic floor muscle exercises, also referred to as Kegel exercises. These exercises are aimed to tighten and strengthen the pubococcygeus muscles. Evidence strongly supports use of Kegel exercises as first-line management in the treatment of urinary and fecal incontinence; however, they may also have some benefit in the relief of POP symptoms. Kegel exercises work best after specific instruction on how to perform them as most women do not perform them either correctly or in optimal fashion without supervised instruction and feedback.

3. Estrogens—In postmenopausal women, local estrogen therapy for a number of months may improve the tone, quality, and vascularity of the musculofascial supports. It is available in cream, parvule, and ring insert forms. With counseling, local estrogen can be offered to all post-menopausal women to reduce urogenital atrophy. For postmenopausal patients with exposed prolapse, who are awaiting surgery, or using a pessary, local therapy should be recommended to promote healthy epithelium particularly in preparation for surgery.

B. Surgical Measures

1. Anterior Vaginal Prolapse

A. Anterior vaginal colporrhaphy—Anterior vaginal colporrhaphy is the most common surgical treatment for anterior vaginal prolapse (Fig. 42–17). Traditional anterior colporrhaphy (anterior repair) is a vaginal approach that involves dissecting the vaginal epithelium from the underlying fibro-muscular connective tissue and bladder, and then plicating the vaginal muscularis across the midline. Excess vaginal epithelium may be excised and the wound closed. Recurrence of anterior prolapse as high as 52% has been reported and has always been a limitation of all reparative procedures. Modifications involving permanent suture material and graft materials have been introduced in the hope of increasing durability.

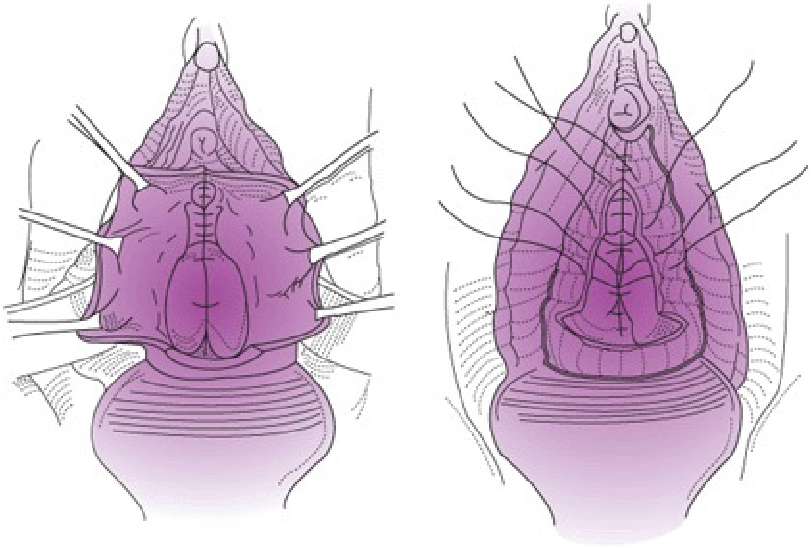


Figure 42–17. Repair of anterior vaginal prolapse.

B. Paravaginal repair—The etiology of the anterior vaginal prolapse has been much debated, beginning with White in 1912. The repair of defects in the anterior vaginal segment has traditionally been done by midline plication. An alternative method based on the anatomic observations by Richardson and colleagues advocates identification of the specific defect in the pubocervical fascia underlying the anterior vaginal epithelium and repairing the discrete breaks (Fig. 42–9). This relationship and a lack of correction of apical defects may help explain why no single operative repair should be universally applied to patients with anterior vaginal wall defects and why traditional repair has resulted in high recurrence rates.

Paravaginal repair is performed for anterior vaginal prolapse that is confirmed to be a result of detachment of the pubocervical fascia from its lateral attachment at the arcus tendineus fascia pelvis (white line). This defect can be unilateral or bilateral. It can be confirmed preoperatively by noting loss of the lateral sulci and lack of rugation over the epithelium along the base of the bladder and elongation to the anterior vaginal wall. Clinically, vaginal examination using a speculum reveals a preponderance of the prolapse lateralized to 1 side as the speculum is withdrawn. In addition, a ring forceps can be used by gently exerting anterior traction along the vaginal sulci. If the defect is reduced, then the defect is consistent with a paravaginal defect and can be approached with a paravaginal repair technique.

The surgery can be performed either abdominally or vaginally. Both require identification of the white line and placement of serial sutures from the medial portion of the pubocervical fascia to the lateral side-wall at the level of the white line as it runs from the ischial spine over the obturator internus muscle to the posterior and inferior aspect of the pubic bone on the ipsilateral side. Reapproximation of the detached pubocervical fascia should reduce the anterior vaginal prolapse. This procedure can be done with other reconstructive procedures in the vagina as well as surgery to alleviate incontinence. Short-term surgical studies have shown good results, but no long-term or comparative data exist for this repair.

A transabdominal approach to the paravaginal repair may be elected to correct the anterior vaginal prolapse when an abdominal approach is necessary for other pelvic conditions such as abdominal hysterectomy, adnexal surgery, or, most commonly, with sacral colpopexy for apical prolapse repair.

2. Posterior Vaginal Prolapse—The traditional repair (Fig. 42–18) involves posterior midline incision, often high, to the level of the posterior fornix. The vaginal epithelium is separated off the underlying fibromuscular layer and endopelvic fascia. This fibromuscular layer is then serially plicated across the midline. Some describe adding levator muscle plication as well. No attempt at identifying specific fascial defects is made.

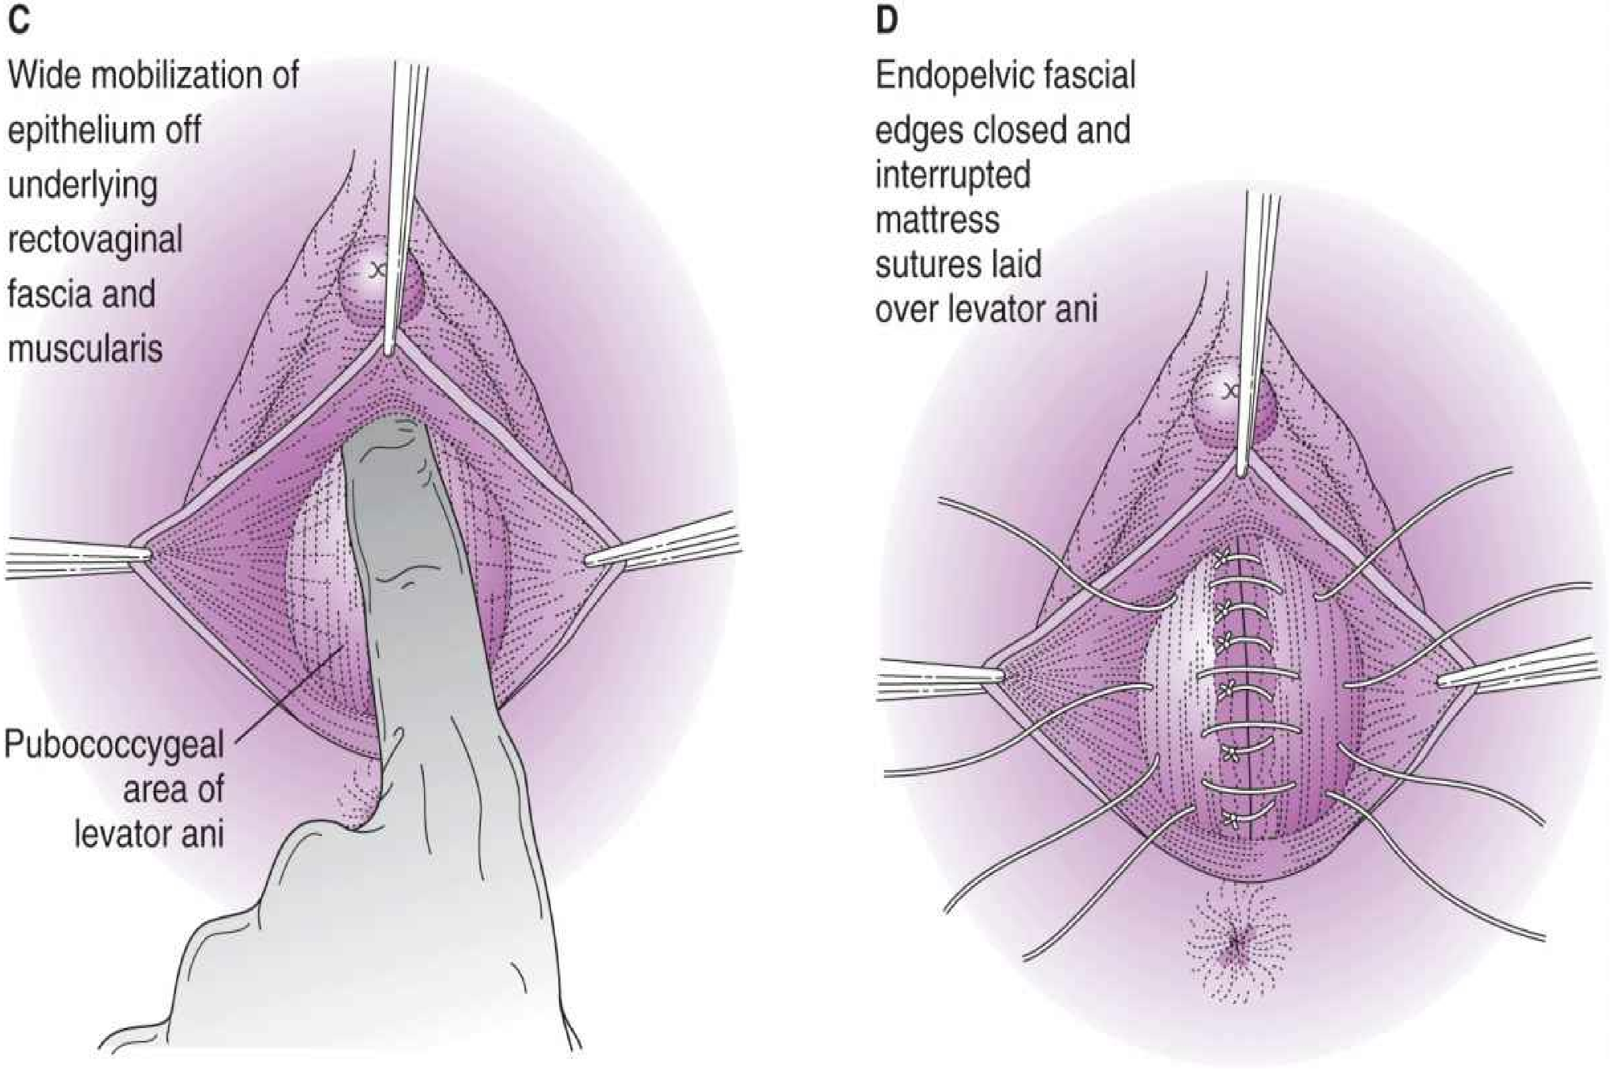
Incision at level of perineual border of posterior vaginal epithelium

B
Posterior epithelium reflected and rectocele exposed



C
Wide mobilization of epithelium off underlying rectovaginal fascia and muscularis

Pubococcygeal area of levator ani

D
Endopelvic fascial edges closed and interrupted mattress sutures laid over levator ani

Figure 42–18. Repair of rectocele.

An alternate method of posterior vaginal defect (rectocele) repair relies on the identification of discrete defects in the rectovaginal fascia (Fig. 42–19). The surgeon inserts a finger of the nondominant hand into the rectum to inspect the rectovaginal fascia for defects. The rectal wall is brought forward to distinguish the uncovered muscularis (fascial defect) from the muscularis that was covered by the smooth semitransparent rectal vaginal septum. The defects are then repaired with interrupted sutures to plicate over the rectal wall. In this manner, the isolated defects are repaired, and the functional anatomy is optimally restored. Notably absent is any effort to plicate the levator ani musculature, as this often results in a bandlike stricture over the posterior wall—a likely cause of dyspareunia. Randomized trials do not support improved outcomes using this technique.

Perineorrhaphy is generally combined with posterior vaginal repairs. This procedure is principally aimed at restoring the perineal body and reducing the vaginal outlet (genital hiatus) to more normal caliber. Reapproximation of the superficial transverse perinei muscle and the bulbocavernosus muscle rebuilds the perineum and lengthens the distance between vaginal opening and anal verge.

A. POSTOPERATIVE FACTORS—The prognosis after vaginal repair is excellent in the absence of a subsequent pregnancy or comparable factors (eg, constipation, obesity, large pelvic tumors, bronchitis, bronchiectasis, heavy manual labor) that increase intraabdominal pressure. The recurrence of the POP is probable when a specific defect of pelvic supports has been overlooked or ignored; in such cases, subsequent progression of the overlooked site may itself lead to new symptoms or even to disruption of the previously repaired segment.

Postoperative avoidance of straining, coughing, and strenuous activity is advisable. Careful instruction about diet to avoid constipation, about intake of fluids, and about the use of stool-softening laxatives and lubricating suppositories is necessary to ensure durable integrity of the rectocele repair.

B. MESH AUGMENTATION IN VAGINAL SURGERY—Efforts to reduce prolapse recurrence rates have ushered in a dramatic increase in the use of mesh for vaginal repairs. Current evidence would only support the use of synthetic mesh to augment anterior vaginal repairs but at the expense of increased rates of complications. Clinically significant rates of vaginal erosions, painful intercourse, and pelvic pain have all been reported with the use of permanent mesh materials.

3. Apical vaginal repair—Prolapse of the vaginal apex includes:

- Uterine prolapse
- Posthysterectomy vaginal cuff prolapse
- Enterocele

All of the preceding clinical conditions indicate a failure of apical support. The procedures used to address surgical repair require knowledge of the specific support structures available to reestablish normal anatomy.

Uterine prolapse is almost always accompanied by some degree of enterocele, and, as the degree of uterine descent progresses, the size of the hernial sac increases. Similarly, posthysterectomy prolapse of the vaginal vault may be the result of poor repair and identification of cuff support structure at the time of hysterectomy or may develop as a result of an enterocele that was overlooked (not repaired). Consequently, it is critical to always address apical cuff support at the time of surgery if a hysterectomy is being performed. Less common, after hysterectomy, the enterocele is located anterior to the vaginal vault, where it may be easily confused with typical anterior vaginal prolapse.

Apical vaginal repair may be accomplished transabdominally or transvaginally. A review of vaginal operations includes, among others, sacrospinous ligament suspension, iliococcygeal fixation, and high uterosacral ligament suspension (high McCall culdoplasty).

Because the normal vaginal axis is directed some distance posteriorly (almost horizontally when the patient is in an erect position) over the levator plate, operative correction by any means, whether by the vaginal or the abdominal route, should restore a normal vaginal axis. This is accomplished by suspension of the vaginal apex far back on the uterosacral ligaments, the presacral fascia, or the sacrospinous ligaments.

A. SACROSPINOUS LIGAMENT FIXATION—A popular method of vaginal vault suspension is that of unilateral or bilateral fixation to the sacrospinous ligament. In this technique, the vaginal epithelium is separated from the rectovaginal tissues. Perforation through the rectal pillar is accomplished by directing blunt dissection toward the ischial spine through the loose areolar tissue. After an appropriate location on the sacrospinous ligament is identified (usually 2–3 cm medial to the ischial spine), one of several techniques may be used to safely pass 2 or more permanent (or delayed absorbable) ligatures through the ligament to the submucosal apex of the vagina. Tying the sutures brings the vaginal apex to that sacrospinous ligament, and a posterior colporrhaphy is then performed (as noted previously). Closing the dead space by intermittently suturing the vaginal mucosa to the underlying reconstituted rectovaginal septum may be useful.

Vaginal vault suspension to 1 or both sacrospinous ligaments has the potential of injury to the pudendal nerve or pudendal vessels and is often technically difficult. Because gluteal and posterior leg pain is a potential complication of this procedure, particularly if the branches of the sacral plexus are disturbed by suturing deep to the ligament, the procedure requires a skilled vaginal surgeon and should be undertaken only by those familiar with the technique.

B. ILIOCOCCYGEAL VAGINAL SUSPENSION—First described in 1962, this procedure uses the fascia overlying the iliococcygeal muscle. Although not nearly as commonly used as other procedures, this point of attachment allows reliable apical fixation without the need to gain peritoneal access. It is generally a safe procedure requiring a posterior vaginal incision in the midline with wide dissection of the overlying epithelium. Bilateral placement of permanent or delayed absorbable suture can be used.

C. BILATERAL UTEROSACRAL LIGAMENT SUSPENSION—The use of the uterosacral ligaments to attach the vaginal cuff has become a re-appreciated technique in apical repairs. Several modifications of the procedure have been described since its introduction in 1938. This technique, as with the other vaginal procedures, can be done at the time of vaginal hysterectomy or to correct posthysterectomy apical cuff prolapse. After entrance into the peritoneum is complete, traction on the ipsilateral posterior vaginal wall with rectal digital examination will facilitate transperitoneal identification of the uterosacral ligament. Placement of a pair of permanent sutures in a lateral-to-medial fashion, 1 at the level of the ischial spine and another placed more cephalad, can be performed bilaterally. These sutures are then brought to the ipsilateral vaginal apices. Fixation of the cuff at this level reproduces cuff placement to the normal position of the cervicovaginal junction. Anterior vaginal repair should be performed before tying down the vaginal cuff.

A risk of this procedure is medial displacement and kinking of the ureters, which has been reported to occur in up to 11% of patients undergoing this procedure. Cystoscopic assessment of ureteral function without and with tension on the fixation sutures, before tying down the vaginal apices, is critical to identify any potential compromise intraoperatively. If ureteral flow reduction is identified, then removal of the sutures on the affected side will often restore normal function.

D. ABDOMINAL SACROCOLPOPEXY—Vaginal vault suspension can also be performed abdominally by attaching the vaginal cuff to the sacral promontory. Abdominal sacrocolpopexy is an excellent primary procedure for apical vaginal prolapse and enterocele and is the procedure of choice for those who are already having an abdominal approach for hysterectomy or for another indication. In this procedure, a laparotomy is performed, and the cul-de-sac and peritoneum overlying the sacrum are visualized. A window in the peritoneum over the sacral promontory is created, and 2 permanent sutures are placed through the anterior longitudinal ligament, approximately at the level of S1. The vaginal cuff is then exposed by dissecting off the overlying peritoneum. Fixation of a graft over the anterior and posterior vagina is then performed fashioning a Y-shape or 2 individual strips of graft. This Y graft is then brought posteriorly along the hollow of the sacrum and affixed to the anterior longitudinal ligament sutures overriding the sacral promontory. Avoidance of undue tension is critical to prevent postoperative dyspareunia.

Dissection and suture placement over the sacrum may introduce risk of operative hemorrhage. During placement of the sacral sutures, the nearby fragile sacral veins may be lacerated. Bleeding from these veins is difficult to control if the veins retract into the bone. Use of sterile thumbtacks to occlude these veins has been an operative technique used to stem potentially life-threatening hemorrhage.

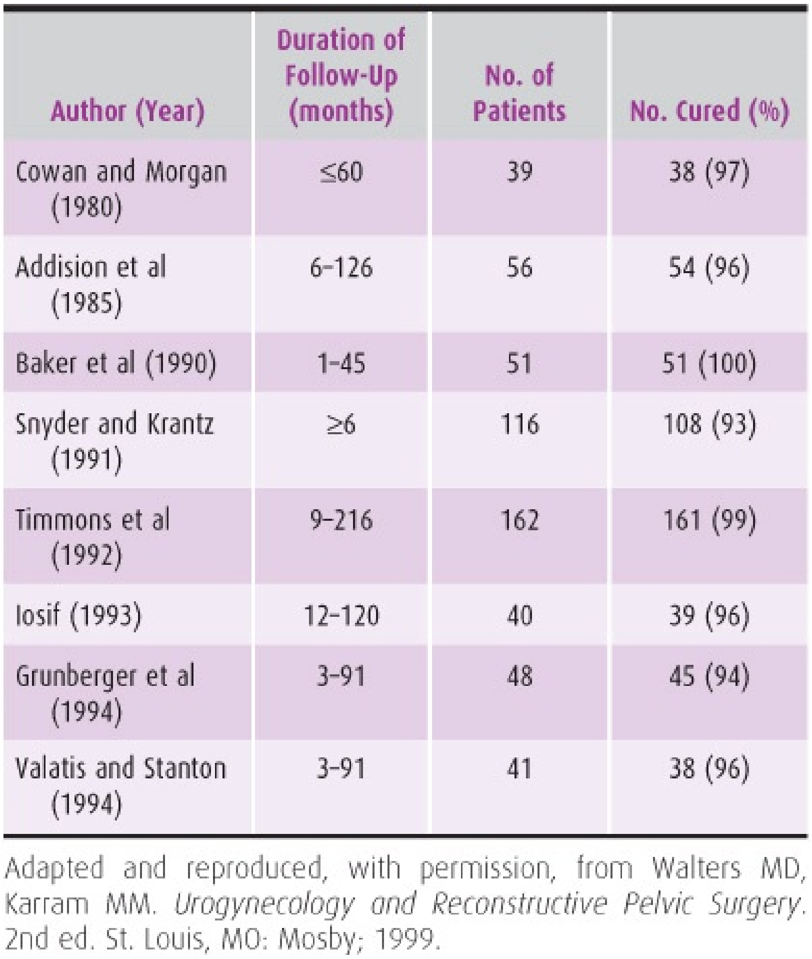
Many different graft types have been described, as well as different methods of attaching these grafts to the vagina. Biologic grafts, however, have high failure rates when placed at the apex. Synthetic grafts are effective; however, they have erosion complication rates between 5% and 10%. As graft technologies continue to evolve, identification of the optimal graft material that maximizes durability and compatibility may materialize.

Numerous studies demonstrate this colpopexy to be highly curative of apical/uterine prolapse. Most surgeons consider the sacrocolpopexy to be the gold standard for apical repair. In the largest prospective evaluation of sacrocolpopexy outcome, the success rates are more than 95%. The procedure can also be performed laparoscopically. A prospective study evaluating outcomes of this approach in more than 100 women describe no apical recurrences and no mesh complication. Another retrospective study of 188 cases resulted in a 10% erosion rate; however, 13 of the 19 erosions occurred with concomitant hysterectomy.

The addition of robotic assistance has been introduced to facilitate the technical aspects of laparoscopic repair. To date no prospective trial exists on efficacy.

E. OBLITERATIVE VAGINAL OPERATIONS (COLPOCLEISIS AND LE FORT'S OPERATION)—These are used primarily for severe uterovaginal prolapse in elderly patients and chronically ill patients who no longer desire coital function. It has the advantage of being done with either regional or local anesthesia. These procedures are highly effective and generally well tolerated. Traction produced by the obliterating scar tissue under the bladder neck and the urethra that may actually cause or aggravate stress incontinence is associated with these operations. Closing the genital hiatus may reduce the chance of recurrence and can be achieved by performing an "extended" perineorrhaphy concomitantly (Table 42–11).

Table 42–11. Follow-up and cure rate after abdominal sacral colpopexy.



Author (Year)	Duration of Follow-Up (months)	No. of Patients	No. Cured (%)

Sexually Transmitted Diseases & Pelvic Infections

Gillian Mackay, MD

SEXUALLY TRANSMITTED DISEASES

The term **sexually transmitted diseases** (STDs) is used to describe disorders spread by intimate contact. Although this usually means sexual intercourse, it also includes close body contact, kissing, cunnilingus, anilingus, fellatio, mouth–breast contact, and anal intercourse. Many STDs can also be transmitted to the fetus in utero by transplacental spread or passage through the birth canal and via lactation during the neonatal period. The organisms involved are adapted to growth in the genital tract and are present in body secretions or blood. Having one STD increases the risk of coinfection with other STDs; therefore, full screening should be offered to all patients with a new STD diagnosis.

Physicians have a critical role in the prevention and treatment of STDs. The clinician's role is to understand the microbiology of STDs in order to appropriately diagnose and treat patients. Treatment is aimed at alleviating symptoms and preventing future sequelae, as well as the prevention of transmission to others and providing appropriate patient education and counseling, as the mainstay of prevention is through lifestyle and behavioral modification. Multiple cohort studies have demonstrated the protective effects of both male and female condoms in the prevention of most STDs.

Most treatment regimens detailed below are based on guidelines issued by the US Center for Disease Control and Prevention (CDC).

VULVAR LESIONS & GENITAL ULCERS

Genital herpes, syphilis, and, less commonly, chancroid are the most prevalent genital ulcerative lesions in the United States. The diagnosis is difficult to make by physical examination alone. Thus the workup for all genital ulcers should include serologic screening for syphilis, culture/antigen testing for herpes simplex virus (HSV)-1 and HSV-2, and culture for *Haemophilus ducreyi* in areas where chancroid is prevalent. More than 1 infectious etiology may be present in a single lesion.

HERPES SIMPLEX

ESSENTIALS OF DIAGNOSIS

- Most commonly caused by HSV-2 but increasingly also caused by HSV-1
- Painful genital ulcers
- Chronic, lifelong, relapsing condition
- Transmissible even in the absence of lesions
- Antivirals improve symptoms, speed healing of lesions, and may decrease asymptomatic viral shedding

---

Pathogenesis

Genital herpes simplex virus (HSV) is a chronic viral infection cause by 2 types of virus: HSV-1 and HSV-2. Most cases of recurrent genital herpes are caused by HSV-2, and at least 50 million persons in the United States are infected with this type of genital herpes. However, an increasing proportion of genital herpes infections in some populations (eg, young women and men who have sex with men) have been attributed to infection by HSV-1.

Most patients infected with HSV-2 have not been diagnosed with genital herpes. Many of these patients have mild or unrecognized infections but shed virus intermittently in the genital tract. As a result, the majority of genital herpes infections are transmitted by persons unaware that they have the infection or who are asymptomatic when transmission occurs.

Prevention

Counseling at the time of diagnosis is essential in order to educate the patient regarding the high probability of recurrence and the prevention of transmission to sexual partners. Sex partners of patients with genital herpes should be evaluated and counseled. Patients should be counseled that viral shedding can occur during asymptomatic periods and that this can lead to transmission. Consistent condom use is associated with a decline in transmission of genital HSV infection. For patients with symptomatic genital HSV-2 infection and an uninfected partner, chronic suppressive therapy to reduce clinical recurrences and viral transmission should be considered. Valacyclovir (500 mg daily) is the best-studied regimen for this specific indication and offers the convenience of once-daily dosing; however, acyclovir may be a reasonable alternative.

For prevention of neonatal herpes, see Genital Herpes in Pregnancy.

Clinical Findings

A. Symptoms & Signs

The clinical diagnosis of genital herpes is often difficult or inaccurate. Classically, patients present with multiple painful vesicular or ulcerative lesions on the genitals. However, these are absent in many cases, particularly in infections caused by HSV-1. After initial infection, the virus remains dormant, but can be reactivated at a future time, which manifests as a recurrent, symptomatic episode with painful ulceration. Recurrences and subclinical shedding are much less frequent for genital HSV-1 infection than for genital HSV-2 infection.

Patients with a primary HSV infection may, in addition to painful ulceration, have multiple constitutional symptoms such as fever, headaches, and malaise.

B. Laboratory Findings

Cell culture and polymerase chain reaction (PCR) are the preferred tests for HSV in symptomatic patients. The sensitivity of viral culture is low, especially for recurrent lesions, and declines rapidly as lesions begin to heal. PCR assays for HSV DNA are more sensitive and are increasingly used. PCR is the test of choice for detecting HSV in spinal fluid for diagnosis of HSV infection of the central nervous system (CNS). Viral culture isolates should be typed to determine which type of HSV is causing the infection. Failure to detect HSV by culture or PCR does not indicate an absence of HSV infection, because viral shedding is intermittent.

Both type-specific and non–type-specific antibodies to HSV develop during the first several weeks after infection, persist indefinitely, and can be tested for serologically. Immunoglobulin (Ig)M testing for HSV is not useful, because the IgM tests are not type-specific and might also be positive during recurrent episodes of herpes.

Because nearly all HSV-2 infections are sexually acquired, the presence of type-specific HSV-2 antibody implies anogenital infection and should prompt appropriate counseling. The presence of HSV-1 antibody alone is more difficult to interpret. In most cases, the presence of HSV-1 antibody indicates oral HSV infection acquired during childhood, which might be asymptomatic. However, acquisition of genital HSV-1 is increasing and can be asymptomatic. Lack of symptoms in an HSV-1 seropositive person does not distinguish anogenital from orolabial or cutaneous infection, and regardless of site of infection, these persons remain at risk for acquiring HSV-2.

Type-specific HSV serologic assays may be useful in the evaluation of the following situations: patients with recurrent genital symptoms or atypical symptoms with negative HSV cultures, patients with a clinical diagnosis of genital herpes without laboratory confirmation, and patients who have a partner with genital herpes.

Differential Diagnosis

Differential diagnosis includes other causes of genital ulceration such as syphilis and chancroid among infectious causes and drug eruptions and Behçet’s disease among noninfectious causes.

Complications

Urinary retention can occur due to severe dysuria associated with extensive genital lesions. Rarely patients can develop severe herpes infection manifesting as disseminated infection, pneumonitis, hepatitis, or CNS complications such as meningoencephalitis. These patients should be hospitalized for close monitoring and intravenous antiviral administration.

Treatment

Systemic antiviral drugs can help to control the symptoms of herpes episodes and may also be used as daily suppressive therapy. However, these drugs neither eradicate latent virus nor affect the risk, frequency, or severity of recurrences after the drug is discontinued.

A. First Clinical Episode of Genital Herpes

1. Recommended regimens—Choose one of the following:

1. Acyclovir 400 mg orally 3 times a day for 7–10 days
2. Acyclovir 200 mg orally 5 times a day for 7–10 days
3. Famciclovir 250 mg orally 3 times a day for 7–10 days
4. Valacyclovir 1 g orally twice a day for 7–10 days

Treatment can be continued for longer than 10 days if lesions are not resolved.

B. Suppressive Therapy for Recurrent Genital Herpes

Suppressive therapy reduces the frequency of genital herpes recurrences by 70–80% in patients who have frequent recurrences. Treatment also is effective in patients with less frequent recurrences. Treatment with valacyclovir 500 mg daily decreases the rate of HSV-2 transmission in discordant, heterosexual couples in which the source partner has a history of genital HSV-2 infection. Suppressive antiviral therapy also is likely to reduce transmission when used by persons who have multiple partners and by those who are HSV-2 seropositive without a history of genital herpes.

1. Recommended Regimens—Choose one of the following:

1. Acyclovir 200 mg orally twice a day
2. Famciclovir 250 mg orally twice a day
3. Valacyclovir 500 mg orally once a day (may be less effective than the other regimens in patients with >10 episodes per year)
4. Valacyclovir 1g orally once a day

C. Episodic Therapy for Recurrent Genital Herpes

Effective treatment of recurrences requires initiation of therapy within 1 day of lesion onset or during the prodrome that precedes some outbreaks; therefore, patients should be provided with a supply of drug or a prescription in order to be able to start therapy in a timely fashion should a recurrence occur.

1. Recommended regimens—Choose one of the following:

1. Acyclovir 400 mg orally 3 times a day for 5 days
2. Acyclovir 800 mg orally twice a day for 5 days
3. Acyclovir 800 mg orally 3 times a day for 2 days
4. Famciclovir 125 mg orally twice a day for 5 days
5. Famciclovir 1 g orally twice a day for 1 day
6. Famciclovir 500 mg once, followed by 250 mg twice daily for 2 days
7. Valacyclovir 500 mg orally twice a day for 3 days
8. Valacyclovir 1 g orally once a day for 5 days

D. Genital Herpes in Pregnancy

Most mothers of infants who acquire neonatal herpes do not have a history of clinically evident genital herpes. The risk for transmission to the neonate from an infected mother is dependent on when in pregnancy they acquire the infection. In women who acquire genital herpes near the time of delivery, transmission is high (30–50%); conversely, in women with a history of recurrent herpes at term or who acquire genital HSV during the first half of pregnancy, the risk of transmission is low (<1%). However, because recurrent genital herpes is much more common than initial HSV infection during pregnancy, the proportion of neonatal HSV infections acquired from mothers with recurrent herpes is significant.

Prevention of neonatal herpes depends both on preventing acquisition of genital HSV infection during late pregnancy and avoiding exposure of the infant to herpetic lesions during delivery. Women without known genital herpes should be counseled to abstain from intercourse during the third trimester with partners known or suspected of having genital herpes. In addition, pregnant women without known orolabial herpes should be advised to abstain from receptive oral sex during the third trimester with partners known or suspected to have orolabial herpes. Type-specific serologic tests may be offered to uninfected women whose sex partner has HSV infection.

All pregnant women should be asked whether they have a history of genital herpes. At the onset of labor, all women should be questioned carefully about symptoms of genital herpes, including prodromal symptoms, and all women should be examined carefully for herpetic lesions. Women without symptoms or signs of genital herpes or its prodrome can deliver vaginally. Although caesarean section does not completely eliminate the risk for HSV transmission to the infant, women with recurrent genital herpetic lesions at the onset of labor should deliver by caesarean section to prevent neonatal HSV infection.

Acyclovir can be administered orally to pregnant women with first-episode genital herpes or severe recurrent herpes. Acyclovir treatment late in pregnancy reduces the frequency of caesarean sections among women who have recurrent genital herpes by diminishing the frequency of recurrences at term and should be offered to patients for suppression from approximately 36 weeks of gestation.

E. Genital Herpes and HIV

HIV-positive patients can have prolonged or severe episodes of genital, perianal, or oral herpes. HSV shedding is also increased in HIV-infected persons. Suppressive or episodic therapy with oral antiviral agents is effective in decreasing the clinical manifestations of HSV in this population.

1. Recommended regimens—Choose one of the following:

A. SUPPRESSION

1. Acyclovir 400–800 mg orally 2–3 times a day
2. Famciclovir 500 mg orally twice a day
3. Valacyclovir 500 mg orally twice a day

B. EPISODIC INFECTION

1. Acyclovir 400 mg orally 3 times a day for 5–10 days
2. Famciclovir 500 mg orally twice a day for 5–10 days
3. Valacyclovir 1 g orally twice a day for 5–10 days

Prognosis

HSV is a chronic, relapsing condition. Suppressive therapies are effective at reducing the number of outbreaks in patients with recurrent episodes.

CONDYLOMATA ACUMINATA

See Chapter 39.

CHANCROID

ESSENTIALS OF DIAGNOSIS

- Caused by gramnegative rod *Haemophilus ducreyi*
- Painful, tender genital ulcer
- Suppurative inguinal adenopathy

Pathogenesis

Chancroid prevalence has declined in the United States in recent years. Worldwide prevalence has also declined, but it may still be found in areas of Africa and the Caribbean. The causative organism is the highly infectious gramnegative rod *Haemophilus ducreyi*. Exposure is usually through coitus, but accidentally acquired lesions of the hands have been reported. The incubation period is typically 4–10 days. Chancroid is a reportable disease.

Prevention

Sexual partners should be treated, regardless of symptoms, if they have had sexual contact in the 10 days preceding the patient's onset of symptoms.

Clinical Findings

A. Symptoms & Signs

The chancroid lesion begins as an erythematous papule that evolves into a pustule and ultimately degenerates into a saucer-shaped ragged ulcer circumscribed by an inflammatory wheal. Typically, the lesion is very tender and produces a heavy, foul discharge that is contagious. Patients typically have more than 1 ulcer, and these are almost exclusively confined to the genital region.

Painful inguinal adenitis is noted in approximately 50% of cases, although this may occur less often in women. The nodes may undergo liquefaction, producing fluctuant buboes that may become necrotic and drain spontaneously.

B. Laboratory Findings

Definitive diagnosis is by identification of *H ducreyi* on specialized culture media that is not widely available from commercial sources and has sensitivity of less than 80%. There is no PCR test available in the United States that has been approved by the US Food and Drug Administration (FDA), although many labs have developed their own PCR test. However, this test may not be available at many centers due to cost. Therefore, in many cases the diagnosis is presumptive, based on symptoms of multiple painful ulcers with inguinal adenopathy and negative testing for other ulcerative diseases such as HSV and syphilis.

Differential Diagnosis

Syphilis, herpes simplex, granuloma inguinale, lymphogranuloma venereum, and Behçet's disease.

Complications

Inguinal scarring or fistula formation may occur from draining buboes.

Treatment

A. Local Treatment

Good personal hygiene is important. The early lesions should be cleansed with mild soap solution. Sitz baths are beneficial. Fluctuant lymph nodes should be needle aspirated or incised and drained through normal adjacent skin to prevent fistula formation or secondary ulcers from spontaneous rupture.

B. Antibiotic Treatment

The susceptibility of *H ducreyi* to antimicrobial agents varies regionally.

1. Recommended regimens—Choose one of the following. The course may have to be repeated.

1. Azithromycin 1 g orally in a single dose
2. Ceftriaxone 250 mg intramuscularly (IM) in a single dose
3. Ciprofloxacin 500 mg orally twice daily for 3 days (in nonpregnant patients over age 17 years who are not lactating)
4. Erythromycin base 500 mg orally 3 times daily for 7 days

Prognosis

Chancroid usually responds quickly to antibiotic therapy, with symptom improvement in 3 days and clinical improvement in 7 days. If there has been no improvement after 7 days, the patient should be re-evaluated. Given the difficulty in isolating *H ducreyi*, consideration should be given to the following possibilities: whether the original diagnosis was correct, existence of STD coinfection, poor compliance to treatment if a multidose regimen was selected, or antibiotic resistance. HIV-positive patients with chancroid may experience a higher rate of treatment failure, slower healing, and the need for prolonged antibiotic therapy. If the ulcers are not adequately treated, deep scarring may occur.

GRANULOMA INGUINALE (DONOVANOSIS)

ESSENTIALS OF DIAGNOSIS

- Painless, ulcerative vulvitis, chronic or recurrent
- Donovan bodies revealed by Wright’s or Giemsa’s stain

Pathogenesis

Granuloma inguinale is a chronic ulcerative granulomatous disease that usually develops in the vulva, perineum, and inguinal regions (Fig. 43–1). The disease is rare in the United States, being most common in India, Papua New Guinea, the Caribbean, central Australia, and southern Africa. The causative organism is *Klebsiella granulomatis* (formerly known as *Calymmatobacterium granulomatis*). The incubation period is 8–12 weeks. Granuloma inguinale is a reportable disease.

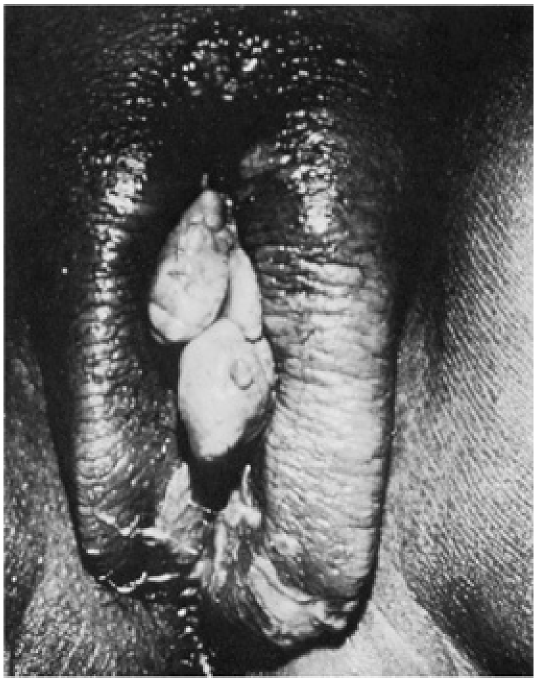

Figure 43–1. Granuloma inguinale.

Prevention

Personal hygiene is the best method of prevention. Therapy immediately after exposure may abort the infection. Sex partners must be considered for treatment. Partners who had sexual contact during the 60 days preceding the onset of symptoms or are clinically symptomatic should be examined and offered treatment.

Clinical Findings

A. Symptoms & Signs

Clinically, the disease is characterized as painless, slowly progressive ulcerative lesions on the genitals or perineum without regional lymphadenopathy. Although granuloma inguinale most often involves the skin and subcutaneous tissues of the vulva and inguinal regions, cervical, uterine, orolabial, and ovarian sites have been reported. A malodorous discharge is characteristic. The disorder often begins as a papule, which then ulcerates, with the development of a beefy-red granular zone with clean, sharp edges. The lesions are highly vascular and bleed easily, with poor healing, and are susceptible to secondary bacterial infection. Rarely, granuloma inguinale present as chronic cervical lesions. These lesions usually take the form of redness or ulceration, or they form granulation tissue. They produce a chronic inflammatory exudate characterized histologically by lymphocytes, giant cells, and histiocytes. They may mimic carcinoma of the cervix and must be distinguished from this as well as other neoplastic diseases.

B. Laboratory Findings

The causative organism is difficult to culture, and diagnosis requires visualization of dark-staining Donovan bodies on tissue crush preparation or biopsy. Donovan bodies are bacteria encapsulated in mononuclear leukocytes and are best seen in Wright-stained smears as small round or rod-shaped particles that stain purple in traditional hematoxylin and eosin preparations. Initial testing may be done with direct smear from beneath the surface of an ulcer, but if these are negative, a biopsy specimen should be taken. Biopsy of the lesion generally shows granulation tissue infiltrated by plasma cells and scattered large macrophages with rod-shaped cytoplasmic inclusion bodies. Pseudoepitheliomatous hyperplasia often is seen at the margin of the ulcer. No FDA-cleared molecular tests for the detection of *K granulomatis* DNA exist at this time.

Differential Diagnosis

Syphilis, herpes simplex, chancroid, lymphogranuloma venereum, and Behçet's disease.

Complications

Scarring may cause introital contraction, which may make coitus difficult or impossible; walking or sitting may also become painful.

Treatment

Several antimicrobial regimens have been effective. Treatment has been shown to slow progression of lesions, and healing typically proceeds inward from the ulcer margins. Prolonged therapy is sometimes necessary to permit adequate granulation and re-epithelialization.

1. Recommended regimen—Doxycycline 100 mg twice daily for at least 3 weeks and until all ulcers are completely healed.

2. Alternative regimens—Choose one of the following. All regimens are for 3 weeks or until all lesions are healed.

1. Azithromycin 1 g orally once per week
2. Ciprofloxacin 750 mg orally twice daily
3. Erythromycin base 500 mg orally 4 times a day
4. Trimethoprim-sulfamethoxazole 1 double strength (160 mg/800 mg) tablet orally twice daily

Sulfonamides, doxycycline, and ciprofloxacin are contraindicated in pregnant women. The addition of an aminoglycoside (eg, gentamicin 1 mg/kg intravenously [IV] every 8 hours) to these regimens can be considered if improvement is not evident within the first few days of therapy or for known HIV-positive patients.

Prognosis

Prognosis is good. Prolonged therapy is often required, but in most cases it is ultimately effective.

LYMPHOGRANULOMA VENEREUM

ESSENTIALS OF DIAGNOSIS

- ▸ Tender inguinal lymphadenopathy
- ▸ Genital ulcer is often not evident
- ▸ Diagnosis suggested by positive complement fixation test

Pathogenesis

The causative agent of lymphogranuloma venereum (LGV) is one of the aggressive L serotypes (L1, L2, or L3) of *Chlamydia trachomatis*. It is encountered more frequently in the tropical and subtropical nations of Africa and Asia but is also seen in the southeastern United States. Transmission is via sexual contact; men are affected more frequently than women (6:1). The incubation period is 7–21 days. Presence of this infection is strongly associated with HIV-positive status in men who have sex with men, with positive HIV found in up to 75% of this population with a diagnosis of LGV. LGV is a reportable disease.

Prevention

Avoiding infectious contact with a carrier is achieved by use of a condom or by refraining from coitus. Sexual contacts of a patient who has LGV within the 60 days before onset of the patient's symptoms should be examined, tested for urethral or cervical chlamydial infection, and treated with a chlamydia regimen.

Clinical Findings

A. Symptoms & Signs

In heterosexuals the most common presentation is tender, usually unilateral inguinal and/or femoral lymphadenopathy. A genital ulcer sometimes occurs at the site of inoculation (Fig. 43–2), although this has often disappeared by the time patient seeks care. Rectal exposure can result in proctocolitis, including mucoid and/or hemorrhagic rectal discharge, pain, constipation, fever, or tenesmus. In the late phase, systemic symptoms such as fever, headache, arthralgia, chills, and abdominal cramps may develop.

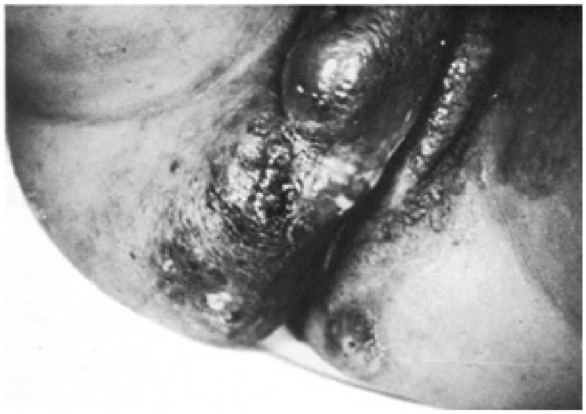

Figure 43–2. Lymphogranuloma venereum. Note involvement of perineum and spread over buttocks.

B. Laboratory Findings

Diagnosis is based on clinical suspicion, epidemiologic information, and the exclusion of other etiologies for proctocolitis, inguinal lymphadenopathy, or genital or rectal ulcers.

The diagnosis can be proved only by isolating *C trachomatis* from genital or lymph node specimens and confirming the immunotype. These procedures are seldom available, so less specific tests are used.

A complement fixation test using a heat-stable antigen that is group-specific for all *Chlamydia* species is available. A titer of >1:64 is considered positive, whereas a titer of <1:32 is considered negative. If acute or convalescent sera are available, a rise in titer is particularly helpful in making the diagnosis. Application of a microimmunofluorescent test may also be useful.

Differential Diagnosis

As with any disseminated disease, the systemic symptoms of LGV may resemble meningitis, arthritis, pleurisy, or peritonitis. The cutaneous lesions must be differentiated from those of granuloma inguinale, tuberculosis, early syphilis, and chancroid. In the case of colonic lesions, proctoscopic examination and mucosal biopsy are needed to rule out carcinoma, schistosomiasis, and granuloma inguinale.

Complications

LGV is an invasive, systemic infection, and if it is not treated early, LGV proctocolitis can lead to chronic, colorectal fistulas and strictures, which can involve the entire sigmoid. Vulvar elephantiasis can cause marked distortion of the external genitalia. Vaginal narrowing and distortion may result in severe dyspareunia.

Treatment

A. Chemotherapy

1. Recommended regimen—Doxycycline 100 mg twice daily orally for 21 days. If disease persists, the course should be repeated.

2. Alternative regimen—Erythromycin 500 mg orally 4 times daily for 21 days.

B. Local & Surgical Treatment

Anal strictures should be dilated manually at weekly intervals. Severe stricture may require diversionary colostomy. If the disease is arrested, complete vulvectomy may be done for cosmetic reasons. Abscesses should be aspirated.

Prognosis

Treatment cures infection and prevents ongoing tissue damage, although tissue reaction to the infection can result in scarring.

SYPHILIS

ESSENTIALS OF DIAGNOSIS

Primary Syphilis

- Painless genital sore (chancre) on labia, vulva, vagina, cervix, anus, lips, or nipples
- Painless, rubbery, regional lymphadenopathy followed by generalized lymphadenopathy in the third to sixth weeks
- Dark-field microscopic findings
- Positive serologic test in 70% of cases

Secondary Syphilis

- Bilaterally symmetric extragenital papulosquamous eruption
- Condyloma latum, mucous patches
- Dark-field findings positive in moist lesions
- Positive serologic test for syphilis
- Lymphadenopathy

Tertiary Syphilis

- Cardiac, neurologic, ophthalmic, and auditory lesions
- Gummas

Latent Syphilis

- History or serologic evidence of previous infection
- Absence of lesions
- Serologic test usually reactive; titer may be low

Pathogenesis

Syphilis is a chronic, systemic disease caused by the spirochete *Treponema pallidum*, which is transmitted by direct contact with an infectious moist lesion. In the majority of cases it is sexually acquired, although it can also be vertically transmitted from mother to fetus. The disease has been divided into several stages based on clinical presentation in order to guide best treatment. It is transmissible in the primary or secondary stages. Treponemes pass through intact mucous membranes or abraded skin, and 10–90 days later, a primary lesion, or chancre, develops (median incubation period is 21 days). Two weeks to 6 months (average of 6 weeks) after the primary lesion appears, the generalized cutaneous eruption of secondary syphilis may appear. Latent syphilis may follow the secondary stage and may last a lifetime, or tertiary syphilis may develop. The latter usually becomes manifest 4–20 or more years after disappearance of the primary lesion. Syphilis is a reportable disease.

Prevention

If a patient is known to have been exposed to syphilis, preventative treatment should not be delayed by waiting for symptoms to develop, although every effort should be made to reach a diagnosis, including a complete physical examination. Any patient who has been exposed and becomes symptomatic within 90 days of sexual contact should be treated regardless of negative serologies, and similarly, if it has been >90 days since exposure with positive titers, treatment should be initiated. If the duration since exposure is unknown and the treponemal antibody titer is greater than 1:32, treatment is indicated.

All pregnant women should undergo routine serologic testing for syphilis at the first prenatal visit, and this should be repeated at 28–32 weeks' gestation in high-risk regions. If the test result is positive, attention must be given to the patient's prior serologic test and therapy (if any) for syphilis. If doubt exists regarding whether the patient has active syphilis, repeat therapy is far better than the risk of congenital syphilis.

Syphilis is still a serious public health problem, and education is still the best method of control. Use of a condom, together with soap and water decontamination after coitus, would prevent most cases. Screening people at high risk for acquiring syphilis (men who have sex with men, who engage in high-risk behaviors, commercial sex workers, persons who exchange sex for drugs, and those in adult correctional facilities) is a recommended strategy.

Clinical Findings

A. Symptoms & Signs

1. Primary syphilis—The chancre (Fig. 43–3) is an indurated, firm, painless papule or ulcer with raised borders. Groin lymph nodes may be enlarged, firm, and painless. Genital lesions are not usually seen in women unless they occur on the external genitalia; however, careful examination may reveal a cervical or vaginal lesion. Primary lesions may occur on any mucous membrane or skin area of the body (nose, breast, perineum), and dark-field examination is required for all suspect lesions. Serologic tests should be done every week for 6 weeks or until positive.

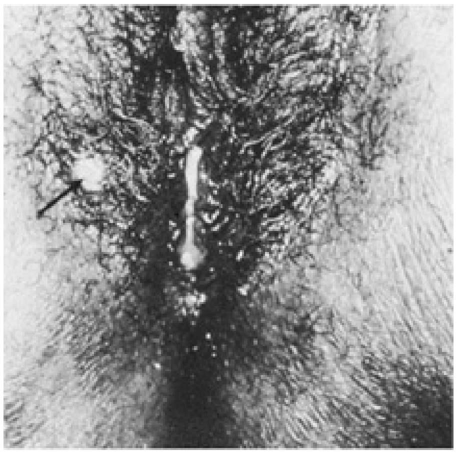

Figure 43–3. Chancre of primary syphilis (arrow).

2. Secondary syphilis—Signs of diffuse systemic infection become evident as the spirochetes spread hematogenously. A “viral syndrome” presentation, often with diffuse lymphadenopathy, is not uncommon. The characteristic dermatitis appears as diffuse, bilateral, symmetric, papulosquamous lesions that often involve the palms and soles. Lesions may also cover the trunk and be macular, maculopapular, papular, or pustular. Other systemic manifestations include patchy alopecia, hepatitis, and nephritis. Moist papules can be seen in the perineal area (condyloma lata). Mucous patches may also be seen; like condyloma lata, they are dark-field–positive, infectious lesions. Serologic tests for syphilis are invariably reactive in this stage.

3. Latent syphilis—With resolution of the lesions of primary and secondary infection or the finding of a reactive serologic test without a history of therapy, a patient passes into latency. Persons are infectious in the first 1–2 years of latency, with clinical relapses resembling the secondary stage occurring in approximately 25% of cases in the first year. Latent syphilis acquired within the preceding year is referred to as early latent syphilis. All other cases of latent syphilis are referred to as either late latent syphilis or latent syphilis of unknown duration.

4. Neurosyphilis—Although the CNS is always vulnerable to *T pallidum*, it is most commonly infected during latent syphilis. Neurologic involvement of ophthalmic and auditory systems can be detected. Cranial nerve palsy and meningeal signs should be evaluated on physical examination.

5. Syphilis during pregnancy—The course of syphilis is unaltered by pregnancy, but misdiagnoses are common. The chancre is often unnoticed or internal and not brought to medical attention. Chancres, mucous patches, and condyloma lata are often thought to be herpes genitalis.

The effect of syphilis on pregnancy outcome can be profound. The risk of fetal infection depends on the degree of maternal spirochetemia (greater in the secondary stage than in the primary or latent stages) and the gestational age of the fetus. Treponemes may cross the placenta at all stages of pregnancy, but fetal involvement is rare before 18 weeks. After 18 weeks, the fetus is able to mount an immunologic response, and tissue damage may result. The earlier in pregnancy the fetus is exposed, the more severe the fetal infection and the greater the risk of premature delivery or stillbirth. Antepartum infection in late pregnancy does not necessarily result in congenital infection; only 40–50% of such infants will have congenital infection. Placental infection can occur, with resultant endarteritis, stromal hyperplasia, and immature villi. Grossly, the placenta looks hydropic (pale yellow, waxy, and enlarged). Because polyhydramnios is frequently associated with symptomatic congenital infection, fetuses are ultrasonographically followed throughout pregnancy.

6. Congenital syphilis—Most infants with congenital syphilis are born to women of low socioeconomic status with inadequate or no prenatal care. Either these neonates may be affected at birth from intrauterine infection (hepatosplenomegaly, osteochondritis, jaundice, anemia, skin lesions, rhinitis, lymphadenopathy, nervous system involvement), or symptoms may develop weeks or months later. The clinical spectrum of congenital infection is analogous to adult secondary disease, as the disease is systemic from onset due to transplacental hematogenous inoculation. The specifics of congenital syphilis are beyond the scope of this text.

B. Laboratory findings

1. Identification of the organism—Definitive diagnosis of *T pallidum* is by identification of spirochetes by dark-field examination of specimens from cutaneous lesions. When this specimen is not available, diagnosis depends on the history and serologic tests. An immunofluorescent technique is now available for dried smears. Silver staining for *T pallidum* of biopsy specimens, placental sections, or autopsy material may confirm the diagnosis in difficult cases. Motile spirochetes can be identified in amniotic fluid obtained transabdominally in women with syphilis and fetal death. PCR is extremely specific for detection of *T pallidum* in amniotic fluid and neonatal serum and spinal fluid. Newer techniques involving molecular methods are now being used to diagnosis early syphilis.

2. Serologic tests—Diagnostic tests after the primary or secondary moist lesion has disappeared are confined largely to serologic testing. Serologic tests become positive several weeks after the primary lesion appears.

A. NONTREPONEMAL TESTS—These tests measure reaginic antibody detected by highly purified cardiolipin-lecithin antigen. They can be performed rapidly, easily, and inexpensively. Nontreponemal tests are used principally for syphilis screening, but due to their nonspecific nature, false positives can occur. Nontreponemal tests currently in use are the Venereal Disease Research Laboratory (VDRL), the Rapid Plasma Reagin test (RPR) and the Toluidine Red Unheated Serum Test (TRUST).

These antibody titers may correlate with disease activity, and results should be reported quantitatively. A 4-fold change in titer (equivalent to a change of 2 dilutions: eg, from 1:16 to 1:4 or from 1:8 to 1:32) is considered necessary to demonstrate a clinically significant difference between 2 nontreponemal test results that were obtained using the same serologic test. Sequential serologic tests in individual patients should be performed using the same testing method (eg, VDRL or RPR), preferably by the same laboratory. Nontreponemal test titers usually decline after treatment and might become nonreactive with time; however, in some persons, nontreponemal antibodies can persist for a long period of time.

The VDRL test generally becomes positive 3–6 weeks after infection, or 2–3 weeks after the appearance of the primary lesion, and is invariably positive in the secondary stage. False-positive serologic reactions are frequently encountered in a wide variety of situations, including collagen diseases, infectious mononucleosis, malaria, many febrile diseases, leprosy, drug addiction, old age, and possibly pregnancy. False-positive reactions are usually of low titer and transient and may be distinguished from true-positive results by specific treponemal antibody tests.

B. Treponemal antibody tests—The fluorescent treponemal antibody absorbed test (FTA-ABS) and microhemagglutination assay for *Treponema pallidum* (MHA-TP) detect antibody against *Treponema spirochetes*. Both tests are generally more sensitive and specific than nontreponemal tests. These tests remain positive despite therapy, so they are not given in titers or used to follow serologic response to treatment (Table 43–1).

Table 43–1. Percent sensitivity of serologic tests in untreated syphilis.

	Stage of Disease			
Type of Test	Primary	Secondary	Latent	Late
VDRL	59-87	100	73-91	37-94
FTA-ABS	86-100	99-100	96-99	96-100
MHA-TP	64-87	96-100	96-100	94-100

Reproduced, with permission, from Holmes KK, et al (eds). *Sexually Transmitted Diseases*. New York, NY: McGraw-Hill; 1984.

Differential Diagnosis

Syphilis has often been called “the great imitator” because so many of the signs and symptoms are indistinguishable from those of other diseases. Amongst others, primary syphilis must be differentiated from chancroid, granuloma inguinale, lymphogranuloma venereum, herpes genitalis, carcinoma, scabies, trauma, lichen planus, psoriasis, drug eruption, aphthosis, mycotic infections, Reiter’s syndrome, and Bowen’s disease. Secondary syphilis must be differentiated from pityriasis rosea, psoriasis, lichen planus, tinea versicolor, drug eruption, perlèche, parasitic infections, iritis, neuroretinitis, condyloma acuminatum, acute exanthems, infectious mononucleosis, alopecia, and sarcoidosis.

Complications

In one-third of untreated cases, the destructive lesions of tertiary syphilis develop. These may involve skin or bone (gummas), the cardiovascular system (aortic aneurysm or insufficiency), and the nervous system (meningitis, tabes dorsalis, paresis). The complications of tertiary syphilis are fatal in almost one-fourth of cases. However, another one-fourth never show any ill effects.

Treatment

Penicillin G, administered parenterally, is the preferred drug for treating all stages of syphilis. The preparation, dosage, and length of treatment depend on the stage and clinical manifestations of the disease. Selection of the appropriate penicillin preparation is important, because *T pallidum* can reside in sequestered sites that are poorly accessed by some forms of penicillin.

A. Early Syphilis & Contacts

Includes primary, secondary, and early latent syphilis (<1 year’s duration):

1. Recommended regimen—Benzathine penicillin G 2.4 million units IM in a single dose.

B. Late Syphilis

Includes latent syphilis of indeterminate duration or more than 1 year’s duration, gumma, and cardiovascular syphilis, but not neurosyphilis.

1. Recommended regimen—Benzathine penicillin G 2.4 million units IM weekly for 3 successive weeks (7.2 million units total).

C. Neurosyphilis

1. Recommended regimen—Aqueous crystalline penicillin G 18–24 million units per day, administered as 3–4 million units IV every 4 hours or continuous infusion, for 10–14 days.

2. Alternative regimen—Procaine penicillin 2.4 million units IM once daily plus probenecid 500 mg orally 4 times a day, both for 10–14 days.

D. Penicillin Allergy

Data to support the use of alternatives to penicillin in the treatment of early syphilis are limited. However, several therapies might be effective in nonpregnant, penicillin-allergic patients who have primary or secondary syphilis:

1. Recommended regimens—Choose one of the following:

1. Doxycycline 100 mg orally twice daily for 14 days
2. Tetracycline 500 mg orally 4 times daily for 14 days

Some limited studies suggest that ceftriaxone 1 g daily either IM or IV for 10–14 days is effective for treating early syphilis. However, the optimal dose and duration of ceftriaxone therapy have not been defined.

Azithromycin as a single 2-g oral dose is effective for treating early syphilis; however, azithromycin resistance and treatment failures have been documented in several geographical areas in the United States. Therefore, the use of azithromycin should be used with caution only when treatment with penicillin or doxycycline is not feasible. Close follow-up of persons receiving any alternative therapies is essential. Patients with a penicillin allergy whose compliance with therapy or follow-up cannot be ensured should be desensitized and treated with benzathine penicillin.

E. Syphilis in Pregnancy

Parenteral penicillin G is the only therapy with documented efficacy for syphilis during pregnancy. Pregnant women with syphilis in any stage who report penicillin allergy should be desensitized and treated with penicillin. If serologic tests are equivocal (eg, possible biologic false-positive result), it is better to err on the side of early treatment. Because of an increased risk for treatment failure, a second dose of 2.4 million units of penicillin IM is often recommended in pregnancy.

F. Congenital Syphilis

Adequate maternal treatment before 16–18 weeks' gestation prevents congenital syphilis. Treatment thereafter may arrest fetal syphilitic infection, but some stigmata may remain. Penicillin treatment with varying regimens and preparations is recommended for most cases depending on clinical presentation of the infant and results of serologic, laboratory, and radiologic testing. The details of the management of congenital syphilis are beyond the scope of this text.

G. Jarisch-Herxheimer Reaction

The Jarisch-Herxheimer reaction occurs in 50–75% of patients with early syphilis treated with penicillin. It is a febrile reaction accompanied by myalgias and headaches that occurs 4–12 hours after injection and is completed by 24 hours. The cause is uncertain but likely involves a release of treponemal toxic products upon organism lysis. The reaction is generally benign but may trigger labor or fetal distress in pregnancy. Prophylaxis with antipyretics or corticosteroids is of unknown value.

H. Coexisting Infection With HIV

Syphilis and HIV coinfection is alarmingly common; therefore, all patients with syphilis should be tested for HIV and vice versa. No specific changes in management for HIV-positive patients is recommended, but closer follow-up is necessary to ensure adequate treatment.

Prognosis

Untreated syphilis may progress to tertiary or neurosyphilis with resultant sequelae. Treatment with penicillin is highly effective at curing this infection.

VAGINITIS

BACTERIAL VAGINOSIS

ESSENTIALS OF DIAGNOSIS

- ▸ White homogenous vaginal discharge with fishy odor
- ▸ Presence of clue cells on wet preparation microscopy
- ▸ Vaginal pH >4.5

Pathogenesis

Bacterial vaginosis is the most prevalent vaginal infection, although almost 50% of affected women are asymptomatic. The term **bacterial vaginosis** refers to the changes of vaginal bacterial flora with a loss of lactobacilli, an increase in vaginal pH, and an increase in multiple anaerobic and aerobic bacteria. It is a polymicrobial infection, and commonly involved organisms include *Gardnerella vaginalis*, *Ureaplasma*, *Mycoplasma*, *Prevotella* spp., and *Mobiluncus* spp. *G vaginalis*, the predominant organism involved, is a small, nonmotile, nonencapsulated, pleomorphic rod. The characteristic fishy odor of bacterial vaginosis is due to anaerobic bacteria.

Bacterial vaginosis is associated with multiple sex partners, new sex partner, douching, lack of condom use, and lack of vaginal lactobacilli.

Prevention

Condom use and avoidance of douching will help to prevent bacterial vaginosis. It is not necessary to treat male sexual partners of affected women. Women with bacterial vaginosis who have sex with women should have their partners screened and, if positive, treated.

Clinical Findings

Patients usually complain of a vaginal discharge with an odor. Clinical criteria for diagnoses include (1) homogeneous white, noninflammatory discharge, (2) microscopic presence of clue cells, (3) vaginal discharge with pH >4.5, and (4) fishy odor with or without addition of 10% potassium hydroxide. Three of these 4 criteria are required to make a clinical diagnosis of bacterial vaginosis. Clue cells are the unstained vaginal cells in a wet preparation that appear to be dusted with many small dark particles, which are the *G vaginalis* organisms.

Gram stain is the gold standard for diagnosis, which shows a relative lack of lactobacilli and presence of gramnegative and gram variable rods and cocci.

Differential Diagnosis

Trichomoniasis, atrophic vaginitis, and desquamative inflammatory vaginitis should be considered in the differential diagnosis of bacterial vaginosis.

Complications

Observational studies have consistently shown an association between bacterial vaginosis and adverse pregnancy outcomes, including preterm delivery, preterm premature rupture of membranes, spontaneous abortion, and preterm labor. However, 2 large randomized, placebo-controlled trials demonstrated that treatment of bacterial vaginosis in asymptomatic pregnant women with metronidazole does not prevent preterm deliveries. Nevertheless, the CDC recommends that pregnant women with a history of preterm delivery and asymptomatic bacterial vaginosis be evaluated for treatment.

Treatment

Therapy should be initiated for symptomatic relief. Pregnant women who are at high risk for preterm labor may benefit from treatment. Treatment is recommended for low-risk groups during pregnancy if patients are infected and symptomatic. Lastly, patients who may also benefit from therapy are asymptomatic carriers before scheduled pelvic/abdominal surgery.

1. Recommended regimens—Choose 1 of the following:

1. Metronidazole 500 mg orally twice daily for 7 days
2. Metronidazole gel 0.75%, 1 full applicator (5 g) intravaginally once daily for 5 days
3. Clindamycin cream 2%, 1 full applicator (5 g) intravaginally at night for 7 days

2. Alternative regimens—Choose 1 of the following:

1. Tinidazole 2 g orally once a day for 2 days
2. Tinidazole 1 g orally once a day for 5 days
3. Clindamycin 300 mg orally twice daily for 7 days
4. Clindamycin ovules 100 mg intravaginally once at night for 3 days

During pregnancy, oral treatment is preferred to local agents due to the possibility of subclinical upper genital tract infection.

3. Recommended regimens in pregnancy—Choose 1 of the following:

1. Metronidazole 500 mg orally twice daily for 7 days
2. Metronidazole 250 mg orally 3 times a day for 7 days
3. Clindamycin 300 mg orally twice daily for 7 days

Prognosis

Thirty percent of patients with an initial response to therapy will have recurrent symptoms within 3 months, and greater than 50% will have recurrence within 12 months. If a patient has had multiple recurrences, suppressive therapy may be beneficial.

TRICHOMONIASIS

ESSENTIALS OF DIAGNOSIS

- Common infection caused by the flagellated protozoan *Trichomonas vaginalis*
- Purulent, malodorous, thin vaginal discharge
- Diagnosis by wet-prep, point-of-care tests or culture
- High rate of reinfection

Pathogenesis

Trichomoniasis is caused by the flagellated protozoan *Trichomonas vaginalis*. It is common, accounting for up to 35% of vaginitis in symptomatic patients, and should be considered in all women presenting with vaginal discharge. It is virtually always sexually transmitted, although it is usually transient and self-limited in male partners. The incubation period is thought to be 4–28 days.

Prevention

Use of condoms, limiting the number of sexual partners, and possibly good vulvar hygiene reduce the risk of acquiring trichomoniasis. Sex partners of patients with *T vaginalis* should be treated, and patients should abstain from sexual intercourse until both partners are treated and asymptomatic.

Clinical Findings

A. Symptoms & Signs

Symptoms include a purulent, malodorous, thin discharge (70%) with associated burning, pruritus, dysuria, frequency, and dyspareunia. Postcoital bleeding can occur. The urethra is also infected in the majority of women. The classically described green, frothy, foul-smelling discharge is found in fewer than 10% of symptomatic women. Many women, however, will be asymptomatic.

Physical examination often reveals erythema of the vulva and vaginal mucosa with observation of yellow-green discharge. Punctate hemorrhages may be visible on the cervix (“strawberry cervix”) in 2% of cases.

B. Laboratory Findings

Diagnosis of vaginal trichomoniasis is usually performed by immediate wet preparation microscopy of vaginal secretions. However, this has a sensitivity of only 60–70%.

FDA-cleared point-of-care tests for trichomoniasis exist and include OSOM Trichomonas Rapid Test, an immunochromatographic capillary flow dipstick technology, and the Affirm VP III, a nucleic acid probe test that evaluates for *T vaginalis, G vaginalis,* and *Candida albicans*.

Culture on Diamond’s medium is another sensitive and highly specific method of diagnosis. Among women in whom trichomoniasis is suspected but not confirmed by microscopy, vaginal secretions can be cultured for *T vaginalis*.

Differential Diagnosis

Bacterial vaginosis, atrophic vaginitis, and desquamative inflammatory vaginitis should be considered in the differential diagnosis of trichomoniasis.

Complications

Trichomoniasis is a risk factor for development of posthysterectomy cellulitis, tubal infertility, and cervical neoplasia. In pregnancy it is associated with preterm premature rupture of membranes and preterm delivery.

Treatment

1. Recommended regimens—Choose 1 of the following:

1. Metronidazole 2 g orally in a single dose
2. Tinidazole 2 g orally in a single dose

2. Alternative regimen—Metronidazole 500 mg orally twice a day for 7 days.

Prognosis

The recommended metronidazole regimens result in cure in 90–95% of cases. However, there is a high reinfection rate (approximately 17% in the first 3 months); therefore, rescreening of patients 3 months after treatment may be considered.

URETHRITIS & CERVICITIS

GONORRHEA

ESSENTIALS OF DIAGNOSIS

- May be asymptomatic
- Purulent vaginal discharge
- Urinary frequency and dysuria
- Diagnosis by Gram's stain, culture on selective media, or nucleic acid amplification tests
- May progress to pelvic infection or disseminated infection

Pathogenesis

Neisseria gonorrhoeae is a gramnegative diplococcus that may be recovered from the urethra, cervix, anal canal, or pharynx. The columnar and transitional epithelium of the genitourinary tract is the principal site of invasion. The organism may enter the upper reproductive tract (Fig. 43–4), causing salpingitis with its associated complications. Approximately 700,000 new infections occur each year. After exposure to an infected partner, 20–50% of men and 60–90% of women become infected. Without therapy, 10–17% of women with gonorrhea develop pelvic infection. The incubation period is 3–5 days. Gonorrhea is a reportable disease.

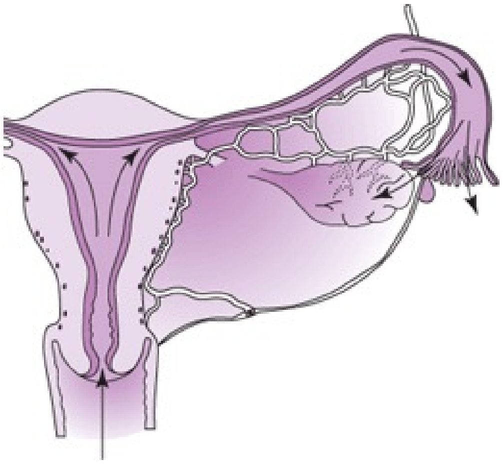

Figure 43–4. intraabdominal spread of gonorrhea and other pathogenic bacteria.

Prevention

Gonorrhea is a reportable disease that can be controlled only by the detection and treatment of asymptomatic carriers and their sexual partners. All high-risk populations should be screened by routine cultures, including all sexually active women age 25 years or less. Use of condoms will protect against gonorrhea. Sex partners of patients with *N gonorrhoeae* infection whose last sexual contact with the patient was within 60 days of the onset of symptoms or of diagnosis of the infection should be evaluated and treated for *N gonorrhoeae* and *C trachomatis* infections. If a patient's last sexual intercourse was >60 days before onset of symptoms or diagnosis, the patient’s most recent sexual partner should be treated. Patients should be instructed to abstain from sexual intercourse until therapy is completed and until they and their sex partners no longer have symptoms.

For prevention of ophthalmia neonatorum, all newborns should receive erythromycin ophthalmic ointment 0.5% to each eye in a single application shortly after delivery.

Clinical Findings

A. Symptoms & Signs

Many women with gonorrhea are asymptomatic. When symptoms occur, they are generally localized to the lower genitourinary tract and include vaginal discharge, urinary frequency or dysuria, and rectal discomfort. The vulva, vagina, cervix, and urethra may be inflamed and may itch or burn. Unilateral swelling in the inferior lateral portion of the introitus suggests involvement of Bartholin’s duct and gland. Anal itching, pain, discharge, or bleeding occurs rarely. Acute pharyngitis and tonsillitis rarely occur. Conjunctivitis can occur; in adults this is usually due to autoinoculation. Ophthalmia neonatorum may result from delivery through an infected birth canal.

Some asymptomatic carriers can develop systemic infection. A triad of polyarthralgia, tenosynovitis, and dermatitis may be present, or purulent arthritis without dermatitis. Septicemia can occur in the former clinical setting and *N gonorrhoeae* cultured from joint aspirates in the latter. Endocarditis and meningitis have been described.

Gonococcal invasion of nonkeratinized membranes in prepubertal girls produces severe vulvovaginitis. The typical sign is a purulent vaginal discharge with dysuria. The genital mucous membranes are red and swollen. Infection is commonly introduced by adults, and in such cases the physician must consider the possibility of sexual abuse.

B. Laboratory Findings

A presumptive diagnosis of gonorrhea can be made based on examination of the stained smear; however, confirmation requires positive identification on selective media. Secretions are examined under oil immersion for presumptive identification. gramnegative diplococci that are oxidase-positive and obtained from selective media (Thayer-Martin) usually signify *N gonorrhoeae*. However, this test is not completely sensitive so cannot completely rule out infection if negative. Specific diagnosis of infection with *N gonorrhoeae* can be performed by testing endocervical, vaginal, or urine specimens. Culture, nucleic acid hybridization tests, and nucleic acid amplification testing (NAATs) are also available for the detection of genitourinary infection with *N gonorrhoeae*.

Because nonculture tests cannot provide antimicrobial susceptibility results, in cases of suspected or documented treatment failure, clinicians should perform both culture and antimicrobial susceptibility testing.

Differential Diagnosis

Chlamydia, urinary tract infection, and pelvic inflammatory disease should be considered in the differential diagnosis.

Complications

The major complication is salpingitis, which may result in tubal scarring, infertility, and increased risk for ectopic gestations. *N gonorrhoeae* can be recovered from the cervix in approximately 50% of women with salpingitis. Asymptomatic carriers can also develop these complications. Resistant strains of *N gonorrhoeae* have emerged in some geographic areas; therefore, follow-up cultures are essential in these settings.

Treatment

Patients diagnosed with uncomplicated gonorrhea who are treated with any of the recommended or alternative regimens do not need a test-of-cure. It is crucial to instruct patients to abstain from sexual relations for the 7 days after therapy is initiated.

Dual therapy to cover for chlamydia infection has contributed greatly to the declining prevalence of chlamydial infections. Therefore, if chlamydial infection is not ruled out, the following regimens should be given with doxycycline (for nonpregnant patients) or azithromycin.

Quinolone-resistant gonorrhea is now widespread in the United States as well as many other regions. For this reason, quinolones are no longer recommended for treatment of gonorrhea.

A. Uncomplicated Infections

1. Recommended Regimens

- Ceftriaxone 250 mg IM in a single dose, **or**
- Cefixime 400 mg orally in a single dose, **plus**
- Azithromycin 1 g orally in a single dose, **or**
- Doxycycline 100 mg orally twice daily for 7 days (for *C trachomatis* coverage)

B. Pelvic Inflammatory Disease

See Pelvic Inflammatory Disease.

C. Disseminated Infections

Patients with disseminated gonococcal infection should be hospitalized. Evidence of endocarditis or meningitis should be sought, and the patient should be closely monitored.

1. Recommended regimen—Ceftriaxone 1 g IM or IV every 24 hours.

2. Alternative regimens—Choose 1 of the following:

1. Cefotaxime 1 g IV every 8 hours
2. Ceftizoxime 1 g IV every 8 hours

All of these regimens should be continued for 24–48 hours after improvement begins, at which time therapy can be switched to cefixime 400 mg orally twice daily to complete at least 1 week of antimicrobial therapy. No treatment failures have been reported with these recommended regimens.

D. β-Lactamase Allergy

Reactions to first-generation cephalosporins occur in only 5–10% of patients with a history of penicillin allergy and occur less frequently with third-generation cephalosporins. In patients with a history of penicillin allergy, the use of cephalosporins is contraindicated only in those with a history of a severe reaction to penicillin (eg, anaphylaxis, Stevens-Johnson syndrome, or toxic epidermal necrolysis).

Because data are limited regarding alternative regimens for treating gonorrhea among persons who have severe cephalosporin allergy, treatment of these individuals should be undertaken in consultation with an infectious disease specialists. Azithromycin 2 g orally is effective against uncomplicated gonococcal infection, but due to emerging antimicrobial resistance to macrolides, its use should be limited. Cephalosporin desensitization is possible but impractical in most clinical settings.

Prognosis

The prognosis is excellent for patients with gonorrhea who receive prompt treatment, although infertility may result from even a single episode.

CHLAMYDIA

ESSENTIALS OF DIAGNOSIS

- Mucopurulent cervicitis
- Salpingitis
- Urethral syndrome
- May progress to pelvic inflammatory disease
- May cause infection in neonates born to infected mothers

Pathogenesis

Chlamydia trachomatis is the most commonly reported infectious disease in the United States, with highest prevalence found in people age ≤25 years. Higher number of sexual partners and lower socioeconomic status are also associated with increased rates of chlamydial infection rates.

Chlamydiae are obligate intracellular organisms that have a cell wall similar to that of gramnegative bacteria. They are classified as bacteria and contain both DNA and RNA. They divide by binary fission, but like viruses they grow intracellularly. With the exception of the L serotypes, chlamydiae attach only to columnar epithelial cells without deep tissue invasion. *C trachomatis* infections are associated with many adverse sequelae due to chronic inflammatory changes as well as fibrosis. Chlamydia is a reportable disease.

Prevention

Many patients who have *C trachomatis* infection are asymptomatic. Therefore, screening with subsequent treatment of infection is the mainstay of prevention, as well as condom use. The CDC recommends annual screening of sexually active women age ≤25 years and older women with risk factors (eg, new or multiple sex partners).

Patients who test positive for chlamydia should be instructed to refer their sex partners for evaluation, testing, and treatment if they had sexual contact with the patient during the 60 days preceding onset of the patient’s symptoms or chlamydia diagnosis. In addition, the most recent sex partner should be evaluated and treated, even if the time of the last sexual contact was >60 days before symptom onset or diagnosis.

Clinical Findings

A. Symptoms & Signs

Women with chlamydial infection are often asymptomatic. Women with cervical infection may have a mucopurulent discharge with hypertrophic cervical inflammation. Salpingitis may cause pelvic pain or be asymptomatic.

B. Laboratory Findings

C trachomatis infection can be diagnosed either by testing urine or by collecting specimens from the endocervix or vagina. Rectal and oral *C trachomatis* infections in persons that engage in receptive anal or oral intercourse can be diagnosed by swabbing those areas. NAATs, cell culture, direct immunofluorescence, enzyme immunoassay, and nucleic acid hybridization tests are available for the detection of *C trachomatis*. NAATs are the most sensitive test for endocervical specimens and are also FDA approved for use on urine. Some NAATs are FDA approved for vaginal swabs. Most tests are not FDA approved for use on oropharyngeal or rectal specimens, although NAATs have been shown to have improved sensitivity and specificity compared with culture.

Differential Diagnosis

Mucopurulent cervicitis is frequently caused by *N gonorrhoea*, and selective cultures for this organism should be performed.

Complications

Adverse sequelae of chlamydia result from upper genital tract involvement. Salpingitis and pelvic inflammatory disease may lead to infertility due to tubal obstruction and ectopic pregnancy. Occasionally, patients with chlamydia infection develop perihepatitis (also known as Fitz-Hugh Curtis syndrome), an inflammation of the liver capsule and adjacent peritoneal surfaces. Adhesions may be seen in this area, which resemble “violin strings.” Perihepatitis is more commonly seen in pelvic inflammatory disease. The pathogenesis of this entity is not fully understood but may involve either direct extension of infected material from the cul-de-sac through the peritoneum and/or lymphatics or an immunologically mediated mechanism.

Perihepatitis should be suspected in persons with right-upper quadrant pain or pleuritic pain, in the clinical context of a lower genital tract infection. There are typically no associated liver enzyme abnormalities. Treatment is supportive, usually with nonsteroidal anti-inflammatory agents.

Pregnant women with cervical chlamydial infection can transmit infections to their newborns, and up to 50% of infants born to such mothers will have conjunctivitis. In 10% of infants, an indolent chlamydial pneumonitis develops at 2–3 months of age. This pathogen may also cause otitis media in the neonate.

Chlamydial infection in pregnancy is a risk factor for premature delivery and postpartum infections, particularly when it is acute. It is hypothesized that asymptomatic cervicitis predisposes to mild amnionitis. This event activates phospholipase A_2 to release prostaglandins, which cause uterine contractions that may lead to premature labor. Chlamydial infection is associated with higher rates of early postpartum endometritis as well as delayed infection from *Chlamydia* that may present several weeks postpartum.

Treatment

Dual therapy to cover for *N gonorrhea* is appropriate due to high rates of coinfection.

A. Recommended Regimens

- Azithromycin 1 g orally in a single dose, **or**
- Doxycycline 100 mg orally twice daily for 7 days, **plus**
- Ceftriaxone 250 mg IM in a single dose, **or**
- Cefixime 400 mg orally in a single dose (for *N gonorrhea* coverage)

B. Alternative regimens

Choose 1 of the following:

1. Erythromycin base 500 mg orally 4 times a day for 7 days
2. Erythromycin ethylsuccinate 800 mg orally 4 times a day for 7 days
3. Levofloxacin 500 mg orally once daily for 7 days
4. Ofloxacin 300 mg orally twice daily for 7 days

In pregnancy, amoxicillin 500 mg orally 3 times a day for 7 days is the recommended alternative regimen to azithromycin. Levofloxacin and ofloxacin should not be used in pregnant patients.

Except in pregnancy, test-of-cure (repeat testing 3–4 weeks after completing therapy) is not advised for persons treated with the recommended or alterative regimens, unless therapeutic compliance is in question, symptoms persist, or reinfection is suspected. However, patients should be rescreened approximately 3 months after treatment or, if this is not possible, whenever persons next present for medical care in the 12 months after initial treatment.

Prognosis

Treatment of chlamydial infection is usually effective, although reinfection can occur, particularly if sexual partners are inadequately treated. Long-term sequelae are discussed under Complications and are related to postinflammatory scar tissue formation.

BLOODBORNE INfECTIONS

HEPATITIS B

ESSENTIALS OF DIAGNOSIS

- ▸ Caused by hepatitis B virus (HBV)
- ▸ Acute illness is often asymptomatic
- ▸ Can lead to chronic carrier state—more likely if acquired earlier in life
- ▸ Treatment of acute illness is supportive
- ▸ Vaccination available
- ▸ Hepatitis B immunoglobulin indicated for postexposure prophylaxis along with vaccination

---

Pathogenesis

Hepatitis B is caused by infection with hepatitis B virus (HBV), an hepadnavirus. The incubation period is 6 weeks to 6 months. Concentration of HBV is highest in blood, with lower concentrations found in other body fluids such as wound exudates, semen, vaginal secretions, and saliva. HBV is more infectious and relatively more stable in the environment than other bloodborne pathogens such as hepatitis C virus (HCV) and HIV.

HBV is transmitted by percutaneous or mucous membrane exposure to blood or body fluids that contain blood. The primary risk factors associated with infection among adolescents and adults are unprotected sex with an infected partner, history of other STDs, and illegal injected-drug use. HBV is a reportable disease.

Prevention

Two products are available for hepatitis B prevention: hepatitis B immune globulin (HBIG) and hepatitis B vaccine. HBIG provides temporary (3–6 months) protection from HBV infection and is typically used as postexposure prophylaxis, either as an adjunct to hepatitis B vaccination in previously unvaccinated persons or alone in persons who have not responded to vaccination. HBIG is prepared from plasma known to contain high concentrations of anti-HBs. The recommended dose of HBIG is 0.06 mL/kg.

Hepatitis B vaccine contains hepatitis B surface antigen (HBsAg) produced by recombinant DNA technology and provides protection from HBV infection when used for both pre- and postexposure vaccination. There are multiple vaccines available, which have different schedules depending on the specific product. All products require a series of multiple doses over varying time frames, and which regimen is selected depends on local availability and the age of the patient. The vaccine should be administered IM in the deltoid muscle and can be administered simultaneously with other vaccines.

Prevention of perinatal infection can be achieved through routine screening of all pregnant women for HBsAg and immunoprophylaxis (both HBIG and hepatitis B vaccine) of infants born to HBsAg-positive mothers or mothers whose HBsAg status is unknown. Prevention in infancy and childhood can be achieved by routine infant vaccination, and vaccination of previously unvaccinated children and adolescents through age 18 years. Adults who are previously unvaccinated but at increased risk for HBV, such as health care workers, sex workers, men who have sex with men, persons in correctional facilities, intravenous drug users, or household contacts of persons known to carry HBV, should also be vaccinated. Hepatitis B vaccination is recommended for all unvaccinated adolescents, all unvaccinated adults at risk for HBV infection, and all adults seeking protection from HBV infection. Hepatitis B vaccine should be offered to all unvaccinated persons attending STD clinics or seeking treatment for STDs in other settings. This vaccine may be administered in pregnancy if necessary.

Unvaccinated persons or those known not to have responded to a complete hepatitis B vaccine series should receive both HBIG and hepatitis vaccine as soon as possible (preferably ≤24 hours) after a discrete, identifiable exposure to blood or body fluids that contain blood from an HBsAg-positive source. Hepatitis B vaccine should be administered simultaneously with HBIG at a separate injection site, and the vaccine series should be completed by using the age-appropriate vaccine dose and schedule. Exposed persons who are in the process of being vaccinated but who have not completed the vaccine series should receive HBIG and complete the vaccine series. Exposed persons who are known to have responded to vaccination are considered protected.

Patients known to be chronic carriers of HBV should be counseled to have their household contacts and sex partners immunized, use condoms for sexual intercourse, and cover cuts and skin lesions to prevent transmission to others.

Clinical Findings

A. Symptoms & Signs

Approximately 70% of patients with acute hepatitis B are asymptomatic, with the remainder having jaundice. Rarely patients will present with fulminant hepatic failure.

A serum sickness-like syndrome may develop during the prodromal period, followed by constitutional symptoms, anorexia, nausea, jaundice, and right upper quadrant discomfort. The symptoms and jaundice generally disappear after 1 to 3 months, but some patients have prolonged fatigue even after normalization of serum aminotransferase concentrations.

Patients with chronic hepatitis B are generally asymptomatic, unless they develop significant cirrhosis or have extra hepatic manifestations. Patients may report nonspecific symptoms such as fatigue. Physical examination may be normal, or there may be stigmata of chronic liver disease, or decompensated cirrhosis.

B. Laboratory Findings

Diagnosis of acute or chronic HBV infection is by serology. Because HBsAg is present in both acute and chronic infection, the presence of IgM antibody to hepatitis B core antigen (IgM anti-HBc) is diagnostic of acute or recently acquired HBV infection. Antibody to HBsAg (anti-HBs) is produced after a resolved infection and is the only HBV antibody marker present after vaccination. The presence of HBsAg and total anti-HBc, with a negative test for IgM anti-HBc, indicates chronic HBV infection. The presence of anti-HBc alone might indicate a false-positive result or acute, resolved, or chronic infection.

Differential Diagnosis

The differential diagnosis of hepatitis B is broad and includes any other cause for hepatitis such as other infectious causes, genetic causes of liver disease, alcoholic hepatitis, autoimmune hepatitis, and medications.

Complications

The most serious, yet rare complication is acute liver failure and death, which occurs in 1% of reported cases. Becoming a chronic carrier of HBV is also a potential complication of acute infection. Risk for chronic infection is inversely related to age at acquisition; approximately 90% of infected infants and 30% of infected children aged <5 years become chronically infected, compared with 2–6% of persons who become infected as adults. Among persons with chronic HBV infection, the risk for premature death from cirrhosis or hepatocellular carcinoma is 15–25%.

Treatment

The treatment of acute HBV is supportive care. There are no specific effective antiviral drugs available at this time.

Patients who have chronic HBV infection should be managed by physicians with specific expertise of chronic liver disease. The agents interferon, lamivudine, adefovir, dipivoxil, telbivudine, and entecavir may be used to treat chronic HBV infection.

Prognosis

Acute hepatitis B is usually a self-limited condition, and if the affected patient does not become a chronic carrier, complete recovery is expected in the majority of cases. Chronic carrier status is associated with the potential complications previously described.

HEPATITIS C

ESSENTIALS OF DIAGNOSIS

- ▸ Caused by hepatitis C virus (HCV), an RNA virus
- ▸ Primarily transmitted by parenteral route; rarely sexually transmitted
- ▸ Up to 85% of affected patients become chronic carriers; of these, up to 70% will develop chronic liver disease
- ▸ No effective vaccine
- ▸ No effective treatment for acute disease
- ▸ Chronic HCV can be treated with combination therapy of pegylated interferon and ribavirin

---

Pathogenesis

Hepatitis C is caused by hepatitis C virus (HCV), a small single-stranded RNA virus. HCV RNA can be detected in blood 1–3 weeks after exposure, and antibodies to HCV (anti-HCV) may be detected in the blood as early as 8–9 weeks postexposure. As with hepatitis B, hepatitis C may manifest as an acute or chronic illness and is the most common chronic bloodborne infection in the United States, with approximately 3.2 million people affected.

HCV is transmitted through parenteral exposures to contaminated blood, usually through use of injected drugs and, to a lesser extent, through exposures in health care settings as a consequence of inadequate infection-control practices. Transmission rarely follows receipt of blood, tissues, and organs from HCV-infected donors who were not identified during routine screening activities, which have been mandated in the United States since 1992. Occupational and perinatal exposures can also result in transmission of HCV.

Sexual transmission of HCV had been considered to occur rarely, although it is observed, especially among HIV-infected persons. Ten percent of patients with acute HCV infection report contact with a known HCV-infected sex partner as their only risk for infection. HCV is a reportable disease.

Prevention

No vaccine for hepatitis C is available, and prophylaxis with immune globulin is not effective in preventing HCV infection after exposure. Therefore, prevention is focused on reducing transmission and reducing chronic liver disease in HCV-infected persons by identifying them and providing medical management and antiviral therapy, as indicated.

Although sexual transmission occurs rarely, condom use is still advisable. Screening of patients who are at risk of HCV is the key to reducing transmission. Patients presenting to STD clinics or in correctional facilities should be offered screening for HCV. All patients with HIV infection should also be screened. Other risk factors for which HCV testing is recommended include prior blood transfusion or solid organ transplant before July 1992, prior transfusion of clotting factor concentrates produced before 1987, long-term dialysis, and signs and symptoms of liver disease.

To reduce the risk for transmission to others, HCV-positive persons should be advised not to donate blood, body organs, or semen; not share any personal items that might have blood on them (eg, toothbrushes and razors); and cover cuts and sores.

HCV-positive women do not need to avoid pregnancy or breastfeeding. However, they should be advised that approximately 6 of every 100 infants born to HCV-infected woman become infected. This infection occurs predominantly during or near delivery, and no treatment or delivery method has been demonstrated to decrease this risk. The risk is increased by the presence of maternal HCV viremia at delivery and also is greater if the woman is coinfected with HIV. HCV has not been shown to be transmitted through breast milk, although HCV-positive mothers should consider abstaining from breastfeeding if their nipples are cracked or bleeding. Infants born to HCV-positive mothers should be tested for HCV infection and, if positive, evaluated for the presence of chronic liver disease.

Clinical Findings

A. Symptoms & Signs

Patients newly infected with HCV typically are either asymptomatic or have a mild clinical illness. As a result, most infected persons remain unaware of their infection because they feel well and therefore serve as a source of transmission to others as well as being at risk for chronic liver disease and other HCV-related chronic diseases for decades to come.

B. Laboratory Findings

Testing for antibodies to HCV (anti-HCV) is recommended for screening of asymptomatic persons based on risk factors or a recognized exposure. Multiple FDA-approved tests are commercially available. Nucleic acid PCR testing to detect HCV RNA is necessary to confirm the diagnosis of current HCV infection in a patient with a positive anti-HCV. Elevated ALT levels are suggestive of chronic liver disease.

Differential Diagnosis

The differential diagnosis of hepatitis C is broad and includes any other cause for hepatitis such as other infectious causes, genetic causes of liver disease, alcoholic hepatitis, autoimmune hepatitis, and medications.

Complications

Chronic HCV infection develops in up to 85% of HCV-infected persons, and of these, up to 70% will develop evidence of active liver disease.

Treatment

Patients who have been determined to be anti-HCV positive should be evaluated for the presence of active infection, presence or development of chronic liver disease, and possible treatment.

Combination therapy with pegylated interferon and ribavirin is the treatment of choice for patients with chronic hepatitis C. Providers should consult with gastroenterology or infectious disease specialists who are familiar with the most current management options for HCV.

Prognosis

Cirrhosis occurs in up to 50% of chronically infected patients. In patients with cirrhosis, there is a risk of subsequent hepatic decompensation and also of hepatocellular carcinoma, the latter risk being up to 3% per year. Death may occur as a consequence of these complications.

HIV INFECTION AND ACQUIRED IMMUNE DEFICIENCY SYNDROME

ESSENTIALS OF DIAGNOSIS

Asymptomatic Infection

- HIV antibody, antigen, or ribonucleic acid or culture
- Mononucleosis-like syndrome with weight loss, fever, night sweats
- Lymphadenopathy
- Pharyngitis
- Erythematous maculopapular rash
- Extragenital lymphadenopathy.

Acquired Immunodeficiency Syndrome (AIDS)

- Opportunistic infections
- Cognitive difficulties or depression
- Kaposi’s sarcoma
- CD4 counts below 200
- Cervical neoplasia

Pathogenesis

HIV infection represents a spectrum of disease that begins with a brief acute viral syndrome that typically transitions to a chronic and clinically latent illness. Without treatment, this illness eventually progresses to a symptomatic, life-threatening immunodeficiency disease known as AIDS. In untreated patients, the time between initial HIV infection and the development of AIDS varies significantly from a few months to many years, with an estimated median time of approximately 11 years.

HIV is a single-stranded RNA retrovirus that attaches to the CD4 receptor of the target cell and integrates into the host genome. Its replication is present during all stages of the infection. This progressively depletes CD4 lymphocytes, which are essential for maintenance of effective immune function. When the CD4 cell count falls below 200 cells/μL, patients are at high risk for life-threatening AIDS-defining opportunistic infections. In the absence of treatment, virtually all HIV-infected persons will die of AIDS.

HIV infection can be acquired by sexual contact, parenteral exposure to blood or body fluids, or transmission from an infected woman to her fetus or infant. Sexual transmission risk is greatest for the female sexual partners of men with AIDS. Other factors that increase the risk for heterosexual acquisition of HIV infection are the number of exposures to high-risk sexual partners, anal-receptive intercourse, and infection with other STDs such as syphilis, genital herpes, chancroid, and condylomata acuminata. The reason for these findings is due to the high concentration of HIV in semen and the fact that coitus causes more breaks in the introital mucosa than in the penile skin. These breaks in the mucosa, similar to those that occur with anal-receptive intercourse, increase the chances for acquiring HIV through sexual contact. The presence of a genital ulcerative disease also increases the risk of infection in a similar fashion.

More than 80% of the female AIDS cases occur in women of reproductive age, making heterosexual and perinatal transmission important concerns. Minorities are disproportionately represented in the reported AIDS cases. In the United States most cases are due to HIV-1, with HIV-2 prevalence being very low. HIV-2 is endemic in parts of West Africa and has been reported increasingly in Angola, Mozambique, Portugal, and France. AIDS is a reportable disease.

Prevention

Primary prevention is based on condom use for sexual intercourse, avoiding the sharing of needles in persons who use IV drugs, universal precautions in occupations where blood of body fluid exposure is possible (ie, health care workers), and good prenatal care of HIV-infected pregnant women. In the latter group, antiretroviral therapy in pregnancy, in addition to peripartum intravenous antiretroviral therapy, caesarean section in selected cases, and avoidance of breastfeeding, can significantly decrease the risk of vertical transmission. In the third world, breastfeeding is still recommended for these women due to the risks associated with contaminated water for formula.

Secondary prevention guidelines for seropositive patients include refraining from donating blood, plasma, organs, or tissue and maintaining a mutually monogamous sexual relationship with condom use for all sexual activity. Circumcision decreases the transmission of HIV and is recommended in areas with high prevalence of HIV infection such as Africa.

Screening high-risk populations is essential in order to properly practice these prevention strategies. HIV serologic testing should include preand post-test counseling about interpretation of test results. HIV testing should be offered to persons that use or have used IV drugs, engaged in prostitution, have sex partners who are HIV-infected or are at risk for HIV infection, have other STDs, have lived in communities or were born in countries where the prevalence of HIV infection is high, have received blood transfusions between 1978 and 1985, have been inmates in correctional systems, or who are pregnant.

Clinical Findings

A. Symptoms & Signs

As many as 45–90% of patients develop an acute HIV-induced retroviral infection in the first few months after infection. This is similar to mononucleosis, with symptoms of weight loss, fever, night sweats, pharyngitis, lymphadenopathy, erythematous maculopapular rash, and extragenital lymphadenopathy. Critical awareness of this acute syndrome is important because of improved prognoses associated with early antiretroviral treatment. This syndrome usually resolves within several weeks, and the patient becomes asymptomatic. HIV-infected individuals ultimately show evidence of progressive immune dysfunction and the condition progresses to AIDS as immunosuppression continues and systemic involvement becomes more severe and diffuse. Characteristic opportunistic infections may occur, such as *Pneumocystis carinii* pneumonia, esophageal candidiasis, Kaposi’s sarcoma, disseminated *Mycobacterium avium* infection, tuberculosis, cytomegalovirus, recurrent bacterial pneumonia, toxoplasmosis, chronic cryptosporidiosis, disseminated histoplasmosis, invasive cervical cancer, and chronic HSV.

The CDC definition of AIDS is an HIV-infected person with a specific opportunistic infection (eg, *P carinii* pneumonia, CNS toxoplasmosis), neoplasia (eg, Kaposi's sarcoma), dementia, encephalopathy, wasting syndrome, rapid progression of cervical dysplasia to cancer, or CD4 lymphocyte count less than 200/μL.

B. Laboratory Findings

The diagnosis of HIV infection is usually by HIV-1 antibody tests. Routine testing for HIV-2, other than at blood banks, is currently not recommended unless a patient is at risk for HIV-2 infection or has clinical findings of HIV disease and has had a negative HIV-1 antibody test. In general, the enzyme-linked immunosorbent assay (ELISA) functions as a screening test for exposure to HIV. Most patients exposed to HIV develop detectable levels of antibody against the virus by 12 weeks after exposure. The presence of antibody indicates current infection, although the patient may be asymptomatic for years. The sensitivity and specificity of the ELISA test is 99% when it is repeatedly reactive.

The probability of a false-negative test in an uninfected woman is remote unless she is in the "window" before antibody is produced. Individuals in high-risk groups should be retested in 3 months.

Rapid HIV testing can be used to identify HIV infection in women who arrive at labor and delivery with undocumented HIV status and to provide an opportunity to begin prophylaxis of previously undiagnosed infection before delivery. Test results are available within a few hours. Most rapid assays have a sensitivity and specificity comparable to that of ELISA.

Viral load (evaluated by PCR) is useful in determining the activity level of the disease. In the acute infective period the viral load is usually extremely high. The CD4 count will also determine disease activity, as it decreases as the disease progresses.

Differential Diagnosis

The differential diagnosis of acute HIV infection includes mononucleosis due to Epstein-Barr virus or cytomegalovirus, toxoplasmosis, rubella, syphilis, viral hepatitis, disseminated gonococcal infection, and other viral infections. Opportunistic infections seen in HIV-infected patients may also present in patients with immunodeficiency of other etiologies.

Complications

Complications relate to the opportunistic infections that can occur in patients with HIV infection as well as development of cancers such as Kaposi's sarcoma, lymphoma, and cervical carcinoma.

Treatment

A. General Considerations

The specifics of treatment of HIV-infected patients is beyond the scope of this text, and these patients should be managed by specialists in infectious disease medicine. However, the general approach is to use combination highly active antiretroviral therapy (HAART) in order to increase disease-free survival through suppression of HIV replication and improvement in immunologic function. The CD4 count is the main indicator of immune function in HIV-infected patients, and this value is used to determine when to initiate HAART and chemoprophylaxis for opportunistic infections, as well as being a valuable prognostic indicator. Patients with a CD4 count of less than 200/μL should be initiated on HAART. Patients with CD4 counts of 200–500/μL may also benefit from HAART, although the benefit is less pronounced than with more immunosuppressed patients. Patients with a history of an AIDS-defining illness or patients who are pregnant should also be treated with HAART.

For selected patients with a CD4 cell count greater than 500/μL, HAART may be considered. Appropriate patients include those who are motivated to start lifelong therapy, and these patients should be advised that there is less evidence for the potential benefits of treatment at earlier stages of HIV infection. The decision to treat should be balanced against potential toxicities of long-term therapy.

The specifics of the HARRT regimens are outside the scope of this text, but in general, 2 nucleoside reverse transcriptase inhibitors and 1 non-nucleoside reverse transcriptase inhibitor or a protease inhibitor are used in combination.

Antibiotic prophylaxis against various opportunistic infections should be initiated in patients who have CD4 counts of less than 200/μL. The specific coverage depends on how low the CD4 count is, and these decisions should be made by specialists in infectious disease medicine.

B. HIV and Pregnancy

Maternal transmission of HIV can occur transplacentally before birth, peripartum by exposure to blood and bodily fluids at delivery, or postpartum through breastfeeding. Therefore, all pregnant women should be offered HIV testing. In the absence of any intervention, an estimated 15–30% of mothers with HIV infection will transmit the infection during pregnancy and delivery, and 10–20% will transmit the infection through breast milk. Vertical transmission of HIV-1 occurs mostly during the intrapartum period (50–70%) but also can occur in the antepartum period (15–30%), especially in untreated women who seroconvert during pregnancy. The mode of delivery may play a role in increasing or decreasing the risks of developing pediatric AIDS. It is recommended that membranes not be ruptured longer than 4 hours. Fetal scalp electrodes and scalp sampling are contraindicated.

Prenatal care must be individualized, with referral to support systems ideally occurring during the pregnancy rather than postpartum. Screening for other STDs is important. HIV-infected patients should undergo shielded chest radiography, a tuberculin skin test with controls, and cytomegalovirus and toxoplasmosis baseline serologic tests. Susceptible patients should receive hepatitis B virus, pneumococcal, and influenza vaccines. CD4 cell counts should be monitored each trimester, as should plasma viral load (HIV-1 RNA).

Zidovudine (ZDV) administered during the second and third trimesters, during labor, and for 6 weeks to the newborn has been shown to decrease vertical transmission from 25–30% to 5–8%. Combination HAART has been shown to reduce the overall transmission to approximately 1.2%.

Caesarean section before onset of labor and rupture of membranes further decreases the risk of vertical transmission; however, the risk of vertical transmission is related to the viral load. When the viral load is less than 1000 copies per milliliter, the perinatal transmission rate approaches zero. Therefore, it is reasonable to offer scheduled caesarean section before onset of labor and rupture of membranes to HIV-infected women with viral loads greater than 1000 copies per milliliter. The American College of Obstetricians and Gynecologists (ACOG) recommends that a scheduled caesarean section be performed at 38 weeks' gestation in order to prevent HIV transmission. ZDV infusion should be started 3 hours preoperatively. The increased maternal morbidity associated with caesarean section must be taken into account, however, when making decisions regarding mode of delivery. Whether caesarean section is beneficial when the mother has received HAART and/or has low to undetectable viral loads is unclear. Also unclear is whether caesarean section after rupture of membranes or onset of labor confers a decrease in HIV transmission.

In resource-rich settings, patients should be counseled against breastfeeding in order to further decrease the risk of transmission.

Prognosis

Although early mortality was nearly certain for most HIV-infected patients in the beginning of the epidemic in the 1980s, the introduction of potent combination therapy has resulted in profound reductions in morbidity and mortality.

PELVIC INfECTIONS

Because of their common occurrence and often serious consequences, infections are amongst the most important problems encountered in the practice of gynecology. A wide variety of pelvic infections, ranging from uncomplicated gonococcal salpingo-oophoritis to septic shock after rupture of a pelvic abscess, confront the general physician as well as the gynecologist. Pelvic infection can be due to processes in the following categories and will be discussed in the following section.

- Pelvic inflammatory disease, including tubo-ovarian abscess (TOA)
- Puerperal infections
- Postoperative pelvic infection after gynecologic surgery
- Abortion-associated infections
- Secondary to other infections

PELVIC INFLAMMATORY DISEASE

ESSENTIALS OF DIAGNOSIS

- Inflammation of upper female genital tract
- Usually polymicrobial
- Often diagnosed clinically based on the presence of cervical motion tenderness or uterine or adnexal tenderness
- Criteria exist to determine whether to manage patient as an inpatient or outpatient
- May result in pelvic scarring and infertility

Pathogenesis

Pelvic inflammatory disease (PID) comprises a spectrum of inflammatory disorders of the upper female genital tract, including any combination of endometritis, salpingitis, tubo-ovarian abscess, and pelvic peritonitis. Sexually transmitted organisms, particularly *N gonorrhoeae* and *C trachomatis*, are implicated in many cases. However, microorganisms that comprise the vaginal flora (eg, anaerobes, *G vaginalis*, *Haemophilus influenzae*, enteric gramnegative rods, and *Streptococcus agalactiae*) are also associated with PID, which is often polymicrobial. More uncommonly, cytomegalovirus, *Mycoplasma hominis*, *Ureaplasma urealyticum*, and *Mycoplasma genitalium* can cause PID. All women who have acute PID should be tested for *N gonorrhoeae* and *C trachomatis* and should be screened for other STDs.

Prevention

Screening and treating sexually active women and their sex partners for chlamydia and gonorrhea reduces their risk for PID. Early diagnosis and eradication of minimally symptomatic disease can also prevent salpingitis. Sex partners of women with PID should be examined and treated if they had sexual contact with the patient during the 60 days preceding the patient’s onset of symptoms. If a patient’s last sexual intercourse was >60 days before onset of symptoms or diagnosis, the patient’s most recent sex partner should be treated. Patients should be instructed to abstain from sexual intercourse until therapy is completed and until they and their sex partners no longer have symptoms.

Clinical Findings

A. Symptoms & Signs

Acute PID is difficult to diagnose due to a wide variation in symptoms and signs. Many women with PID have subtle or mild symptoms. Delay in diagnosis and treatment contributes to inflammatory sequelae in the upper reproductive tract. Consequently, a diagnosis of PID usually is based on clinical findings, although clinical diagnosis is imprecise, and many cases of PID go unrecognized.

Patients may complain of insidious or acute onset of lower abdominal and pelvic pain, which is usually bilateral. There may be a sensation of pelvic pressure or back pain. There is often an associated purulent vaginal discharge.

Nausea may occur, with or without vomiting. Headache and general lassitude are common complaints. Fever is not necessary for the diagnosis of acute salpingitis, although its absence may indicate other disorders. In one study, only 30% of women with laparoscopically confirmed acute salpingitis had fever.

Abdominal tenderness is often encountered, usually in both lower quadrants. The abdomen may be somewhat distended, and bowel sounds may be hypoactive or absent. Pelvic examination may demonstrate inflammation of the periurethral (Skene) or Bartholin’s glands as well as a purulent cervical discharge. Bimanual examination typically elicits extreme tenderness on movement of the cervix and uterus and palpation of the parametria.

Based on the CDC guidelines, the diagnosis of PID should be made and empiric treatment initiated in sexually active young women and other women at risk for STDs if they are experiencing pelvic or lower abdominal pain, if no cause for the illness other than PID can be identified, and if 1 or more of the following minimum criteria are present on pelvic examination: cervical motion tenderness, uterine tenderness, or adnexal tenderness.

B. Laboratory Findings

Saline microscopy of vaginal fluid may reveal abundant white blood cells. Complete blood count may reveal a leukocytosis with a shift to the left. Erythrocyte sedimentation rate and C-reactive protein may be elevated. Endocervical swabs may be positive for infection with *N gonorrhoeae* or *C trachomatis*. However, all these tests may be normal in a patient with PID; therefore, should be used as supportive evidence only, not as definitive diagnostic tools. Endometrial biopsy is more specific and usually shows histopathologic evidence of endometritis. In practice, however, this is often not done, although it may be particularly useful in women who have undergone laparoscopy with no visual evidence of salpingitis, as endometritis may be the only sign of PID in some cases.

C. Imaging

Transvaginal sonography or magnetic resonance imaging techniques showing thickened, fluid-filled tubes with or without free pelvic fluid or tubo-ovarian complex or Doppler studies suggesting pelvic infection (eg, tubal hyperemia) are quite specific for PID, although in less complicated cases, imaging may be normal.

D. Laparoscopy

Diagnostic laparoscopy can be used to obtain a more accurate diagnosis of salpingitis and a more complete bacteriologic diagnosis. However, this tool may not be available at some sites, and it may not be appropriate when symptoms are mild or vague. Laparoscopy will not detect endometritis and may not detect subtle inflammation of the fallopian tubes. It remains, however, a useful adjunct when the diagnosis is in question.

Differential Diagnosis

PID must be differentiated from other acute abdominal processes such as acute appendicitis, ectopic pregnancy, ruptured corpus luteum cyst with hemorrhage, diverticulitis, infected septic abortion, torsion of an adnexal mass, degeneration of a leiomyoma, endometriosis, acute urinary tract infection, regional enteritis, and ulcerative colitis.

Complications

Complications of acute salpingitis include pelvic peritonitis or generalized peritonitis, prolonged ileus, septic pelvic thrombophlebitis, abscess formation with adnexal destruction and subsequent infertility, and intestinal adhesions and obstruction. Rarely, dermatitis, gonococcal arthritis, or bacteremia with septic shock occurs.

Treatment

PID treatment regimens provide empiric, broad spectrum coverage of likely pathogens and should be given as soon as a presumptive diagnosis is made. Several antimicrobial regimens have been effective in achieving clinical and microbiologic cure in randomized clinical trials with short-term follow-up. However, the data on long-term outcomes and frequency of complications such as tubal infertility and ectopic pregnancy are limited.

All regimens used to treat PID should also be effective against *N gonorrhoeae* and *C trachomatis* because negative endocervical screening for these organisms does not rule out upper reproductive tract infection.

The majority of women with a clinical diagnosis of PID have symptoms of mild to moderate severity that usually respond well to outpatient antibiotic therapy. Hospitalization usually is warranted for women who are more severely ill, as well as the following cases:

- Patient in whom surgical emergencies (eg, appendicitis) cannot be excluded
- Patient who are pregnant
- Patients who have not responded well to outpatient oral therapy
- Patients who are unable to tolerate or comply with outpatient therapy
- Patients who have severe illness, nausea and vomiting, or high fever
- Patients with tubo-ovarian abscess

A. Outpatient Therapy

1. Recommended regimens

- Ceftriaxone 250 mg IM in a single dose (or other parenteral third-generation cephalosporin), **plus**
- Doxycycline 100 mg orally twice a day for 14 days, **with** or **without**
- Metronidazole 500 mg orally twice a day for 14 days **or**
- Cefoxitin 2 g IM in a single dose and probenecid 1 g orally in a single dose administered concurrently, **plus**
- Doxycycline 100 mg orally twice a day for 14 days, **with** or **without**
- Metronidazole 500 mg orally twice a day for 14 days

Data on alternative regimens are limited. Amoxicillin/clavulanic acid and doxycycline may be used, as well as ceftriaxone 250 mg IM single dose and azithromycin 1 g orally once a week for 2 weeks. When considering alternative regimens, the addition of metronidazole should be considered. As a result of the emergence of quinolone-resistant *N gonorrhoeae*, regimens that include a quinolone agent are no longer recommended for the treatment of PID. If parenteral cephalosporin therapy is not feasible, use of fluoroquinolones (levofloxacin 500 mg orally once daily or ofloxacin 400 mg twice daily for 14 days) with or without metronidazole (500 mg orally twice daily for 14 days) can be considered if the community prevalence and individual risk for gonorrhea are low.

If a response to therapy is not observed after 72 hours, the patient should be re-evaluated to confirm the diagnosis and consideration made to admitting the patient for inpatient therapy.

B. Inpatient Therapy

1. Recommended regimen A

- Cefotetan 2 g IV every 12 hours, **or** cefoxitin 2 g IV every 6 hours, **plus**
- Doxycycline 100 mg orally or IV every 12 hours

2. Recommended regimen B

- Clindamycin 900 mg IV every 8 hours, **plus**
- Gentamicin loading dose IV or IM (2 mg/kg body weight) followed by a maintenance dose (1.5 mg/kg) every 8 hours. Single daily dosing (3–5 mg/kg) can be substituted.

3. Alternative regimens

- Ampicillin/sulbactam 3 g IV every 6 hours, **plus**
- Doxycycline 100 mg orally or IV every 12 hours

Oral doxycycline is preferable due to pain associated with IV infusion and similar bioavailability of oral and parenteral preparations.

Parenteral agents can be discontinued 24 hours after clinical improvement is observed, but oral therapy with doxycycline should be continued to complete a course of 14 days of treatment. When tubo-ovarian abscess is present, metronidazole or clindamycin should be added to the inpatient or outpatient regimen to provide adequate anaerobic coverage.

C. Special Circumstances

All pregnant women with suspected PID should be hospitalized and treated with parenteral antibiotics. Doxycycline should not be used in pregnancy.

Patients with intrauterine devices (IUDs) with suspected PID do not necessarily need to have the IUD removed, particularly if the patient is at high risk of unintended pregnancy. However, caution should be exercised if the IUD remains in place, and close clinical follow-up is required. Re-evaluation for IUD removal should be considered if the patient is not clinically improving. Of note, the risk of PID is not increased in IUD users other than in the first 21 days after insertion, after which it is uncommon. The levonorgestrel-releasing IUD may have a protective effect against PID due to thickening of cervical mucus. If an IUD is removed due to PID, a new one may be reinserted 3 months after resolution of the infection if the patient is not at ongoing risk of PID.

Actinomyces israelii is a normal anaerobic commensal of the gastrointestinal tract but can be associated with pelvic infection and abscess. It is present on the Papanicolaou test of approximately 7% of IUD users. Most patients are asymptomatically colonized. If actinomyces is present, the patient should be examined, and if asymptomatic, there is no indication to administer antibiotics or remove the IUD. If the patient demonstrates symptoms of PID or tubo-ovarian abscess, antibiotics should be commenced and the IUD removed, as actinomyces preferentially grow on foreign bodies.

Actinomyces is sensitive to penicillin; a 14-day course of penicillin G (500 mg 4 times per day), or doxycycline (100 mg twice per day) in patients with penicillin allergy, may be adequate treatment for a very early, local infection, but prolonged IV therapy (weeks to months) is indicated for tubo-ovarian abscess or disseminated infection. Surgical drainage is usually required for actinomycotic abscesses, which are often the result of intestinal infections such as appendicitis but may be associated with IUD use.

Prognosis

A favorable outcome is directly related to the promptness with which adequate therapy is begun. A single episode of salpingitis has been shown to cause infertility in 12–18% of women. Follow-up care and education are necessary to prevent reinfection and complications. In some cases patients may experience recurrent or chronic pelvic infection resulting in chronic pelvic pain.

TUBO-OVARIAN ABSCESS

ESSENTIALS OF DIAGNOSIS

- ▸ Usually preceded by PID

- Lower abdominal and pelvic pain of varying degrees
- Nausea and vomiting
- Complex multiloculated adnexal mass on imaging
- Requires inpatient IV antibiotic therapy
- Ruptured tubo-ovarian abscess is a surgical emergency

Pathogenesis

Tubo-ovarian abscess (TOA) is part of the spectrum of PID and can be acute or more chronic in nature. TOA formation may occur after an initial episode of acute salpingitis, but it is usually seen with recurrent infection superimposed on chronically damaged adnexal tissue. Fallopian tube necrosis and epithelial damage by bacterial pathogens create an environment conducive to anaerobic invasion and growth. The adjacent ovary may become involved with an ovulation site serving as the portal of entry for infection and subsequent abscess formation. Pressure of the purulent exudate may cause rupture of the abscess with resultant fulminating peritonitis, necessitating emergency laparotomy.

Slow leakage of the abscess may cause formation of a cul-de-sac abscess. TOAs may occur in association with diverticulitis or in the presence of granulomatous infection. Disease can be bilateral, although unilateral disease is more common. Abscesses are usually polymicrobial.

Clinical Findings

A. Symptoms & Signs

The clinical spectrum varies greatly and may range from total absence of symptoms in a woman who, on routine pelvic examination, is found to have an adnexal mass to a moribund patient presenting with acute abdomen and septicemic shock.

Patients with TOA are often young, of low parity, with a history of previous pelvic infection, although it can occur in women of any age. Patients typically report pelvic and abdominal pain, fever, and nausea and vomiting developing over a week or so. Physical examination may reveal abdominal tenderness and guarding. Adequate pelvic examination is often difficult due to tenderness, but an adnexal mass may be palpated. If the patient has a ruptured TOA, she will likely present with symptoms and signs of an acute surgical abdomen and may develop signs of septic shock.

B. Laboratory Findings

Laboratory findings are generally of little value. The white count may vary from leukopenia to marked leukocytosis. Urinalysis may demonstrate pyuria without bacteriuria. An elevated erythrocyte sedimentation rate or C-reactive protein is suggestive of a diagnosis of TOA in the presence of an adnexal mass.

C. Imaging

Ultrasonography is the radiologic modality of choice and will typically demonstrate complex multiloculated adnexal masses that obscure normal adnexal structures. These masses may contain internal echoes consistent with inflammatory debris.

Computed tomography (CT) may be preferable in a patient in whom other abdominal pathology cannot be excluded, such as diverticulitis or appendicitis. CT findings consistent with TOAs include multilocular, thick walled, rim-enhancing adnexal masses containing increased fluid density.

Differential Diagnosis

An unruptured TOA must be differentiated from an ovarian cyst or tumor with or without torsion, unruptured ectopic pregnancy, periappendiceal abscess, uterine leiomyoma, hydrosalpinx, perforation of a diverticulum or diverticular abscess, perforation of peptic ulcer, urinary tract infection or calculi, and any systemic disease that causes acute abdominal distress.

Complications

Unruptured TOA may be complicated by rupture in 15% of cases. Other complications include sepsis (10–20%), reinfection at a later date, and subsequent bowel obstruction, infertility, and ectopic pregnancy due to pelvic adhesions.

Ruptured TOA is a surgical emergency and may be complicated by septic shock, intraabdominal abscess, and septic emboli with renal, lung, or brain abscess.

Treatment

A. Unruptured TOA

Treatment is similar to that of inpatient management of PID (see prior section), although total duration of therapy may be longer, depending on the size of the abscess and clinical response (up to 4–6 weeks, although an optimal duration of therapy has not been established). Patients should be monitored on an inpatient basis for 48–72 hours. Minimally invasive radiologic-guided drainage of abscesses is appropriate for large abscesses or for patients who are not worsening, but not improving on medical treatment alone. The drained fluid should be sent for culture so that ongoing antimicrobial therapy can be pathogen directed. If a patient is not improving despite these measures, or is worsening, surgical management should be considered, which generally involves exploratory laparotomy by an experienced gynecologic surgeon, as these cases are usually technically extremely challenging due to the inflammatory process, which destroys normal tissue planes. The extent of resection depends on the extent of disease, the patient’s age, and the patient’s desire for future fertility. A total abdominal hysterectomy and bilateral salpingo-oophorectomy is the optimal surgery in order to remove all areas of infected tissue. Surgical drains are often left in place.

Close follow-up is essential after initial hospitalization, with repeat imaging as indicated.

B. Ruptured TOA

This is an acute life-threatening emergency requiring immediate surgery in conjunction with antibiotic therapy. Total abdominal hysterectomy and bilateral salpingo-oophorectomy via a vertical midline incision is the procedure of choice, in association with aggressive fluid resuscitation. Careful surgical technique is necessary to avoid perforation of the bowel or transection of the ureters. Surgical drains should be left in place. Postoperatively, consideration should be made to placing the patient in the intensive care unit, where vital signs and urine output can be closely monitored and antibiotic treatment should be continued.

C. Special Considerations

Patients with a TOA and an IUD should have the IUD removed.

The majority of TOAs are found in premenopausal women, but when a postmenopausal women is found to have a TOA, there is a high risk of concurrent malignancy. Therefore, these patients should be counseled regarding this potential and consented for full staging.

TOA in pregnancy is rare, but is managed no differently from outside of pregnancy, with the exception of the avoidance of antibiotics with teratogenic potential.

Prognosis

Generally the patient with an unruptured abscess has an excellent prognosis. Medical therapy, followed by judicious surgical treatment, yields good results in most cases. Fertility may be greatly reduced, with an increased risk for ectopic pregnancy. The risk of reinfection must be considered if definitive surgical treatment has not been performed.

Before effective means of treating overwhelming septicemia became available and the need for immediate surgical intervention was recognized, the mortality rate from ruptured TOA was 80–90%. However, with modern therapeutic resources, both medical and surgical, the mortality rate is less than 2%.

POSTPARTUM ENDOMYOMETRITIS

ESSENTIALS OF DIAGNOSIS

- Common cause of fever in the postpartum patient
- Diagnosis is clinical
- Fever and uterine tenderness
- Laboratory tests are of limited use
- IV broad-spectrum antibiotics are mainstay of therapy and are continued until the patient has been afebrile for 24–48 hours

---

Pathogenesis

Puerperal infections refer primarily to postpartum infections of the uterus, which may involve the deciduas (endometritis), myometrium (endomyometritis), or parametria (parametritis). It is a common cause of postpartum fever and is usually a polymicrobial process involving a mixture of organisms from the genital tract. It can occur after either vaginal delivery or caesarean section.

Prevention

There are a number of strategies that can be used to decrease the rate of postpartum endomyometritis, including the use of prophylactic antibiotics at the time of caesarean section (both elective and nonelective) and avoidance of manual delivery of the placenta at caesarean section. Intrapartum chorioamnionitis increases the risk of postpartum endomyometritis; therefore, factors that decrease the risk of chorioamnionitis (eg, decreased number of internal vaginal examinations, shorter labor length) should also decrease the risk of postpartum endometritis.

Clinical Findings

A. Symptoms & Signs

Diagnosis is clinical and is suspected when a postpartum patient presents with fever and uterine tenderness.

B. Laboratory Findings

Laboratory tests are of limited value. Leucocytosis may be present, although this can be a normal finding in a postpartum patient. Endometrial cultures are not usually performed, as it is nearly impossible to obtain an uncontaminated specimen. Bacteremia can occur in 10–20% of cases, so consideration of blood cultures should be made.

Differential Diagnosis

The differential diagnosis of fever in a postpartum patient includes mastitis, surgical site infection, urinary tract infection, pneumonia, and deep vein thrombosis.

Complications

Peritoneal infection and pelvic abscess can occur as a result of endomyometritis, which may lead to pelvic adhesions and tubal occlusion.

Treatment

Administration of broad-spectrum antibiotics is the mainstay of therapy. Common practice is to use clindamycin 900 mg IV every 8 hours with gentamicin 1.5 mg/kg IV every 8 hours. This regimen is generally continued until the patient has been afebrile for 24–48 hours. For patients known to be colonized with group B streptococcus from universal screening, the addition of ampicillin 2 g IV every 6 hours is recommended. Subsequent oral antibiotic therapy is not required. Alternative regimens include cefotetan, cefoxitin, ceftriaxone, cefotaxime, and piperacillin, although data are limited.

Prognosis

The majority of patients will respond to therapy within 48–72 hours. A minority will have persistent fevers and require further evaluation.

POSTOPERATIVE PELVIC INFECTIONS

ESSENTIALS OF DIAGNOSIS

- Recent pelvic surgery
- Pelvic or low abdominal pain or pressure
- Fever and tachycardia
- Purulent, foul discharge
- Constitutional symptoms often present
- Vaginal cuff tenderness with cellulitis or abscess

Pathogenesis

Patients who have undergone gynecologic surgery, particularly hysterectomy, may develop postoperative infections of the remaining pelvic structures. These infections include vaginal cuff cellulitis, infected vaginal cuff hematoma, salpingitis, pelvic cellulitis, septic pelvic thrombophlebitis, and TOA with or without rupture. The incidence of such infections has been significantly reduced by the use of single-dose, perioperative antibiotic prophylaxis for hysterectomy.

The pathogenesis of posthysterectomy infection is simple. The apex of the vaginal vault consists of crushed, devitalized tissue, and the loose areolar tissue in the parametrial areas usually oozes postoperatively. These conditions provide an ideal medium for the myriad of pathogens that normally inhabit the vagina and are inoculated into the operative site during surgery. The term **pelvic cellulitis** implies that the soft tissue of the vaginal apex and adjacent parametrial tissues have been invaded by bacteria. Serum and blood at the cuff apex may become infected, resulting in an infected hematoma or cuff abscess. Infection may extend via lymphatic channels to the adnexa, resulting in salpingitis. Pelvic veins may become involved in the infectious process, particularly if *Bacteroides* or anaerobic streptococci are predominant pathogens.

Prevention

Many attempts have been made to decrease infectious morbidity after gynecologic surgical procedures. None have been uniformly successful, but the following measures may be helpful:

- Preoperative treatment of cervicitis, bacterial vaginosis, or vulvovaginitis if present
- Preparation of the vagina with hexachlorophene or povidone-iodine solution immediately before surgery
- Meticulous attention to hemostasis and gentle handling of tissues intraoperatively
- If hemostasis is less than desirable but is maximal under given circumstances, suction drains to that area should be placed
- Antimicrobial prophylaxis beginning preoperatively. For hysterectomy the antibiotic of choice is cefazolin 1–2 g IV administered not more than 60 minutes before surgical start time.
- Severe, more advanced infections may be prevented by early diagnosis, drainage, and prompt treatment of mild infections.

Clinical Findings

A. Symptoms & Signs

Fever due to postoperative pelvic infection usually does not occur before the third or fourth postoperative day. The vaginal cuff may appear hyperemic and edematous, and there is often a purulent exudate. When palpated, this site is usually indurated and tender. If infection involves the tubes and ovaries or intraabdominal abscess forms, the patient may complain of lower abdominal, pelvic, or back pain. Abdominal distention due to ileus may develop, as may urinary symptoms due to perivesical irritation.

The diagnosis of septic pelvic thrombophlebitis is rare and usually is not apparent until after the sixth postoperative day, at which time the patient usually has high spiking fevers with a diurnal variation. The pelvic findings are usually unrevealing except for mild pelvic tenderness.

An infected pelvic hematoma may only be evident by recurrent fevers. Rarely do these patients have symptoms, and their examination is may be unremarkable.

B. Laboratory Findings

Due to the polymicrobial nature of these infections, it is usually not possible to isolate a specific organism in a reasonable time. For this reason, broad-spectrum empirical antimicrobial administration is necessary. However, blood cultures or culture of any drained purulent material should be sent in order to assist with directing therapy in the case of poor clinical improvement.

Serial complete blood counts usually demonstrate leukocytosis but occasionally enable the physician to detect concealed hemorrhage, which may harbor a large pelvic abscess. Urinalysis is rarely helpful.

C. Imaging

Pelvic ultrasound is helpful in detecting hematomas or abscesses that develop as a complication of cuff infection. CT scan is the imaging modality of choice for septic pelvic thrombophlebitis, although a negative study does not necessarily exclude the diagnosis.

Differential Diagnosis

The differential diagnosis of postoperative fever includes pulmonary atelectasis, aspiration pneumonitis, deep vein thrombophlebitis, superficial phlebitis due to an indwelling venous catheter, urinary tract infection, wound infection, and drug fever.

Complications

Complications of postoperative pelvic infection include pelvic or intraabdominal abscesses, TOA with or without rupture, intestinal adhesions and obstruction, septic pelvic thrombophlebitis, and septicemia.

Treatment

If an infected cuff hematoma or abscess is found, adequate drainage can be established by separating the opposed vaginal edges with ring forceps or some other suitable instrument. The usual supportive measures are instituted, and broad-spectrum antibiotic therapy commenced. Pelvic abscesses in other locations may be drained with CT or ultrasound guidance and a drain left in place.

Septic pelvic thrombophlebitis is generally a diagnosis of exclusion when a patient has persistent fevers after 7–10 days of broad-spectrum antibiotics. The recommended treatment is systemic anticoagulation with either IV unfractionated heparin or subcutaneous low-molecular-weight heparin. In the absence of documented thromboses or underlying hypercoagulable state, anticoagulation is generally discontinued after resolution of fever for at least 48 hours. If pelvic branch vein thromboses are documented radiographically, anticoagulation with low-molecular-weight heparin is usually continued for at least 2 weeks. If septic emboli or extensive pelvic thromboses (eg, thrombosis involving the ovarian vein, iliac veins or vena cava) are documented radiographically, anticoagulation with low-molecular-weight heparin or warfarin for at least 6 weeks is recommended. Follow-up imaging to evaluate for persistence or resolution of thromboses should be obtained to guide subsequent management.

Prognosis

With prompt diagnosis and treatment, postoperative infections usually resolve completely without long-term sequelae.

ABORTION-ASSOCIATED INFECTIONS

ESSENTIALS OF DIAGNOSIS

- Incidence of postabortion infection is decreased with preprocedure antibiotic prophylaxis.
- Septic abortion is rare.
- There is a rare association with *Clostridium sordellii*.

Pathogenesis

Postabortal endometritis occurs in 5–20% of patients undergoing elective termination of pregnancy who do not receive prophylactic antibiotics; this rate is halved if antibiotics are used. It may occur in the presence or absence of retained products of conception. It is usually polymicrobial.

Septic abortion usually refers to intrauterine infection that leads to spontaneous abortion and is uncommon. Patients are usually extremely unwell compared with patients with postabortal endometritis. Infection is usually due to *Staphylococcus aureus*, gramnegative bacilli, or some gram-positive cocci. The infection may spread, leading to salpingitis, generalized peritonitis, and septicemia. Rarely septic abortion be associated with a foreign body, such as an IUD; invasive procedures, such as amniocentesis; or maternal bacteremia.

A small number of septic deaths related to *Clostridium sordellii* have been reported with medical abortion. Overall, infection rates after medical abortion are much lower than with surgical abortion. However, in 2005, 4 septic deaths were reported. They all occurred in California within 1 week of medical abortion. *C sordellii* infection was diagnosed in all 4 cases. Subsequently, 5 more deaths from clostridial sepsis after medical abortion in the United States and Canada have been reported, 2 from *Clostridium perfringens* and 3 from *C sordellii*. Interestingly, no abortion-related deaths from *Clostridial* infection have been reported in Europe, where mifepristone is widely used.

Reports are rare of fulminant lethal clostridial sepsis in women of childbearing age, but there is generally an association with childbirth, abortion, or cervical or uterine procedures. Sepsis related to *C sordellii* is unusual because of its subtle clinical manifestations and rapid progression to death. A causal relationship between mifepristone/misoprostol and *Clostridium* sepsis has not been established.

Prevention

Prophylactic antibiotics are the cornerstone of prevention. The agent recommended by ACOG for prophylaxis for induced abortion is doxycycline 100 mg orally 1 hour before the procedure and 200 mg orally after the procedure. An alternative regimen is metronidazole 500 mg orally twice a day for 5 days.

Clinical Findings

A. Symptoms & Signs

Signs and symptoms of postabortal endometritis include fever, enlarged and tender uterus, lower abdominal tenderness, and vaginal bleeding greater than expected. Common clinical features of septic abortion include fever, chills, malaise, abdominal pain, vaginal bleeding, and discharge, which is often sanguinopurulent. Physical examination may reveal tachycardia, tachypnea, lower abdominal tenderness, and a boggy, tender uterus with dilated cervix.

Patients with *C sordellii* sepsis after medical abortion generally present without fever, bacteremia, rash, or significant findings on pelvic examination, but have dramatic leukocytosis with a marked left shift, hemoconcentration, tachycardia, hypotension crampy abdominal pain, pleural/peritoneal effusion, and general malaise (weakness, nausea, vomiting, diarrhea).

B. Imaging

Pelvic ultrasound may reveal retained products of conception or may be unremarkable.

Differential Diagnosis

Other causes of infection such as PID, vaginitis, cervicitis, appendicitis, and urinary tract infection, should be excluded.

Complications

Postabortion infection can lead to intrauterine or intraabdominal scarring and in severe cases can lead to sepsis and rarely death.

Treatment

If retained products are demonstrated, suction dilatation and curettage should be performed to evaluate this infected material. In the absence of retained products, or after uterine evacuation, broad-spectrum antibiotics should be commenced, such as cefotetan 2 g IV every 12 hours plus doxycycline 100 mg orally twice a day. This course can be completed as an outpatient with doxycycline 100 mg orally twice a day with or without metronidazole 500 mg orally twice a day for a total of 14 days.

Patients who are demonstrating signs and symptoms of sepsis should be aggressively managed with fluid resuscitation, broad-spectrum antibiotics, uterine evacuation, assessment for uterine perforation, and supportive care in an intensive care unit.

Optimal therapy for *C sordellii* is unknown, but probably includes surgical debridement, removal of infected organs (eg, hysterectomy), and antibiotics with good anaerobic activity.

Prognosis

With prompt diagnosis and treatment, most abortion-associated infections are effectively cured. *C sordellii* is extremely rare, but its onset is insidious with subsequent rapid progression to severe illness and death; therefore, the index of suspicion should remain high, particularly in cases of recent medical abortion.

PELVIC TUBERCULOSIS

ESSENTIALS OF DIAGNOSIS

- Often results in infertility
- Associated with active or healed pulmonary tuberculosis
- Diagnosis by hysterosalpingogram or laparoscopy
- Recovery of *Mycobacterium tuberculosis* from either menstrual fluid or biopsy specimen

---

Pathogenesis

In the United States, pelvic tuberculosis is a rare entity. When it does occur, it usually represents secondary invasion from a primary lung infection via lymphatic or hematogenous spread. The overall incidence of pelvic tuberculosis in patients with pulmonary tuberculosis is approximately 5%. Prepubertal tuberculosis rarely results in genital tract infection.

After the pelvic organs become affected (Fig. 43–5), direct extension to adjacent organs may occur. The endometrium is involved in more than 90% of cases, with fallopian tube involvement in only 5%.

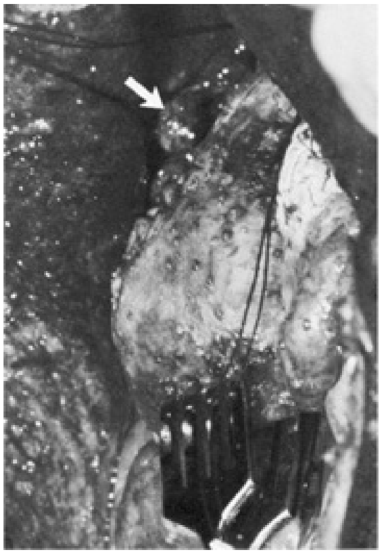

Figure 43–5. Miliary tuberculosis involving the uterus and peritoneum.

Prevention

Prevention is largely based on screening populations at risk of tuberculosis for active or latent disease in order to treat pulmonary tuberculosis early to prevent systemic spread and transmission to others. Populations at risk include foreign-born persons from areas with high tuberculosis prevalence, homeless populations, residents of correctional or long-term care facilities, health care workers who work with high-risk populations, low-income and medically underserved populations, and patients with immunocompromise.

Clinical Findings

A. Symptoms & Signs

The only complaint may be infertility, although dysmenorrhea, pelvic pain, and evidence of tuberculous peritonitis may also be present. Endometrial involvement may result in amenorrhea or other disturbance of the menstrual cycle. Abdominal or pelvic pain may be associated with low-grade fever, fatigue, and weight loss. Gross ascites may be present in tuberculous peritonitis.

Pelvic tuberculosis may be encountered in the course of a gynecologic surgery performed for other reasons. Although pelvic tuberculosis may be mistaken for chronic pelvic inflammation, some distinguishing features usually can be found: extremely dense adhesions without planes of cleavage, segmental dilatation of the tubes, and lack of occlusion of the tubes at the ostia.

B. Laboratory Findings

Diagnosis can be established on the basis of a complete history and physical examination, chest x-ray, and appropriate tests such as a tuberculin (Mantoux) test, sputum smears, and cultures. The best direct method of diagnosis in suspected genital tuberculosis is detection of acid-fast bacteria by Ziehl-Neelsen stain followed by culture on Lowenstein-Jensen medium. The specimen may be from menstrual discharge, from curettage or biopsy, or from peritoneum.

C. X-Ray Findings

A chest x-ray film should be obtained in any patient with proven or suspected tuberculosis of other organs or tissues. Upper lobe infiltrates and hilar adenopathy may be seen. A hysterosalpingogram may demonstrate irregular tubal lining and areas of dilatation. Saccular diverticula extending from the ampulla and giving the impression of a cluster of currants are characteristic of granulomatous salpingitis.

Differential Diagnosis

Pelvic tuberculosis should be differentiated from schistosomiasis, enterobiasis, lipoid salpingitis, carcinoma, chronic pelvic inflammation, and mycotic infections.

Complications

Sterility and tuberculous peritonitis are possible sequelae of pelvic tuberculosis.

Treatment

A. Medical Measures

To prevent the emergence of drug-resistant strains, the initial therapy of tuberculous infection should include 4 drugs. The drug regimen for the first 2 months of treatment should include isoniazid, rifampin, pyrazinamide, and streptomycin or ethambutol. Once drug susceptibility results are available, the drug regimen can be adjusted. The specifics and duration of treatment should be determined in conjunction with an infectious disease specialist.

B. Surgical Measures

The primary mode of treatment for pelvic tuberculosis is medical therapy; however, surgical intervention may be necessary. Medical therapy should be attempted for 12–18 months before evaluation for surgery. The ultimate indications for surgery include (1) masses not resolving with medical therapy, (2) resistant or reactivated disease, (3) persistent menstrual irregularities, and (4) fistula formation.

Prognosis

The prognosis for life and health is excellent if chemotherapy is instituted promptly, although the prognosis for fertility is poor.

TOXIC SHOCK SYNDROME

ESSENTIALS OF DIAGNOSIS

- High fever
- Diffuse macular rash
- Desquamation 1–2 weeks after onset of illness; particularly affects palms and soles
- Hypotension or orthostatic syncope
- Involvement of 3 or more of the following organ systems: gastrointestinal, muscular, mucous membrane, renal, hepatic, hematologic, CNS

Pathogenesis

Toxic shock syndrome (TSS) is a rare entity caused by exotoxins produced by the ubiquitous aerobic gram-positive coccus, *Staphylococcus aureus*. It was first described in 1978 in children, but was quickly identified as an illness occurring primarily in menstruating women. Cases can be menstrual or nonmenstrual. For the purposes of this chapter, menstrual cases will be discussed.

TSS is associated with the use of highly absorbent tampons, and since these types of tampons have been withdrawn from the market, the incidence has decreased. Since 1986 the incidence of menstrual TSS is 1 in 100,000 women (declined from 9 in 100,000 in 1980). However, tampon use is still a risk factor. Women who develop TSS are more likely to have used tampons with higher absorbencies, used tampons continuously for more days of their menstrual cycle, and kept a single tampon in place for a longer period of time. Nonmenstrual TSS has been reported with diaphragm use and after delivery.

The cause of toxic shock syndrome is preformed toxins produced by *S aureus* after colonization or infection by this microorganism. A pyrogenic toxin induces high fever and may enhance susceptibility to endotoxins that cause shock as well as liver, kidney, and myocardial damage. Other unrecognized toxins may play a role. How toxins gain access to the circulatory system is unknown. Tampon use has been associated with this syndrome, but evidence for the mechanism of toxin entry remains obscure. Insertion could cause mucosal damage. Vaginal ulcerations due to pressure changes usually are not observed, although vaginal erythema commonly is present. Superabsorbent tampons may obstruct the vagina, resulting in retrograde menstruation and peritoneal absorption of bacteria or toxin. Tampons may be associated with increased numbers of aerobic bacteria due to oxygen trapped in interfibrous spaces. The longer a tampon is left in place, the greater the risk for development of this syndrome.

Clinical Findings

A. Symptoms & Signs

The clinical manifestations of TSS are diverse based on the action of the *S aureus* toxin. The symptoms and signs typically develop rapidly, often in otherwise healthy individuals. Commonly affected patients have fever, hypotension, and skin manifestations. Additional symptoms and signs include chills, malaise, headache, sore throat, myalgias, fatigue, vomiting, diarrhea, abdominal pain, and orthostatic dizziness or syncope.

During the initial 48 hours of hospitalization, patients may develop diffuse erythroderma, severe watery diarrhea, decreased urine output, cyanosis, and edema of the extremities. Neurologic symptoms such as somnolence, confusion, irritability, agitation, and hallucinations may occur secondary to cerebral ischemia and edema.

A vaginal examination should be performed; if a tampon is present, it must be removed. Mucosal lesions should be sought, and a culture for *S aureus* performed. During convalescence, desquamation can be striking.

B. Laboratory Findings

Clinical laboratory test abnormalities usually reflect shock and organ failure. Leukocytosis may not be present, but the total number of mature and immature neutrophils usually exceeds 90%. Thrombocytopenia and anemia are present during the first few days, and abnormal coagulation studies may be observed. Disseminated intravascular coagulation can develop.

Other laboratory abnormalities may reflect multiorgan failure with elevated blood urea nitrogen and creatinine, elevated liver function tests, and an elevated creatine phosphokinase. Most laboratory tests will return to normal within 7–10 days of disease onset.

Although the majority of patient with TSS will have *S aureus* isolated from mucosal or wound sites, this finding is not required to make the diagnosis, which is largely clinical. *S aureus* is rarely isolated from blood cultures. Cultures from mucosal and wound sites should be obtained in order to try to isolate toxins production from *S aureus*. These tests are usually only available in specialized laboratories.

Differential Diagnosis

Other systemic diseases characterized by rash, fever, and systemic complications should be considered. Most patients will not have an obvious source of infection, such as a recent incision, soft-tissue abscess, or osteomyelitis, but these should be sought. Kawasaki’s disease of young children is similar but not as severe. Scarlet fever must be excluded. Rocky Mountain spotted fever, leptospirosis, and measles can be excluded by appropriate serologic tests.

Complications

Recurrences of TSS can occur. Often these cases are in patients who have not been treated with appropriate courses of antistaphylococcal antimicrobials or who fail to develop an appropriate antibody response to staphylococcal toxins. Recurrent episodes are generally milder than the initial disease. Recurrence may occur days to months after the initial episode.

Treatment

Aggressive supportive therapy is the mainstay of successful treatment, and patients should be managed in an intensive care setting. Aggressive fluid resuscitation is required and may be up to 10–20 L per day. Vasopressors, packed red blood cells, and coagulation factors may be necessary. Any foreign body in the vagina such as tampon or contraceptive device should be removed. Mechanical ventilation or hemodialysis may be necessary if acute respiratory syndrome or renal failure develop.

Although it is unclear whether antimicrobials alter the course of TSS, antistaphylococcal antibiotics are important in eradicating the infection and preventing recurrences. Antibiotics such as clindamycin that suppress protein synthesis and, therefore, toxin synthesis are more efficacious than cell wall active agents such as β-lactams. Current recommendations based on animal studies and clinical case series are as follows. Treatment is usually for 10–14 days.

1. Empiric therapy for all patients with suspected TSS—Clindamycin 600 mg IV every 8 hours **plus** vancomycin 30 mg/kg per day IV in 2 divided doses.

2. Patient With TSS and Culture/Sensitivity Results Available

A. METHICILLIN-SUSCEPTIBLE *S AUREUS*—Clindamycin 600 mg IV every 8 hours **plus** oxacillin **or** nafcillin 2 g IV every 4 hours.

B. METHICILLIN-RESISTANT *S AUREUS*—Clindamycin 600 mg IV every 8 hours **plus either** vancomycin 30 mg/kg per day IV in 2 divided doses **or** linezolid 600 mg oral or IV every 12 hours.

Prognosis

Death associated with TSS usually occurs within the first few days of hospitalization but may occur as late as 15 days after admission. Fatalities have been attributed to refractory cardiac arrhythmias, cardiomyopathy, irreversible respiratory failure, and rarely bleeding caused by coagulation defects, demonstrating the importance of good supportive care. The TSS-related mortality rate in menstrual cases has decreased since the syndrome was first recognized in 1980, from 5.5% in 1987 to 1.8% in 1996.

Workowski KA, Berman S. Centers for Disease Control and Prevention (CDC). Sexually transmitted diseases, treatment guidelines, 2010. *MMWR Recomm Rep* 2010;59:1–110. PMID: 21160459.

Antimicrobial Chemotherapy

Shmuel Benenson, MD
Lisa Green, MD, MPH
Alan H. DeCherney, MD

Microbial infection has always been a grave threat to obstetric and gynecologic patients. Developments in antimicrobial therapy, however, have led to decreases in puerperal and postoperative morbidity and perinatal mortality. Indeed antibiotic development is one of the most important advances in medicine in the 20th century. Empiric antibiotics for bacterial infections improve clinical symptoms and outcome. As a consequence, clinicians prescribe antibiotics very frequently and sometimes even when it is not necessary. This approach has led to huge overuse of antibiotics, which in turn has led to the appearance of multidrug-resistant bacteria. Clinicians need to adopt an approach where effective antibiotic treatment is given to those who have bacterial infections, while at the same time antibiotic use is limited when not indicated.

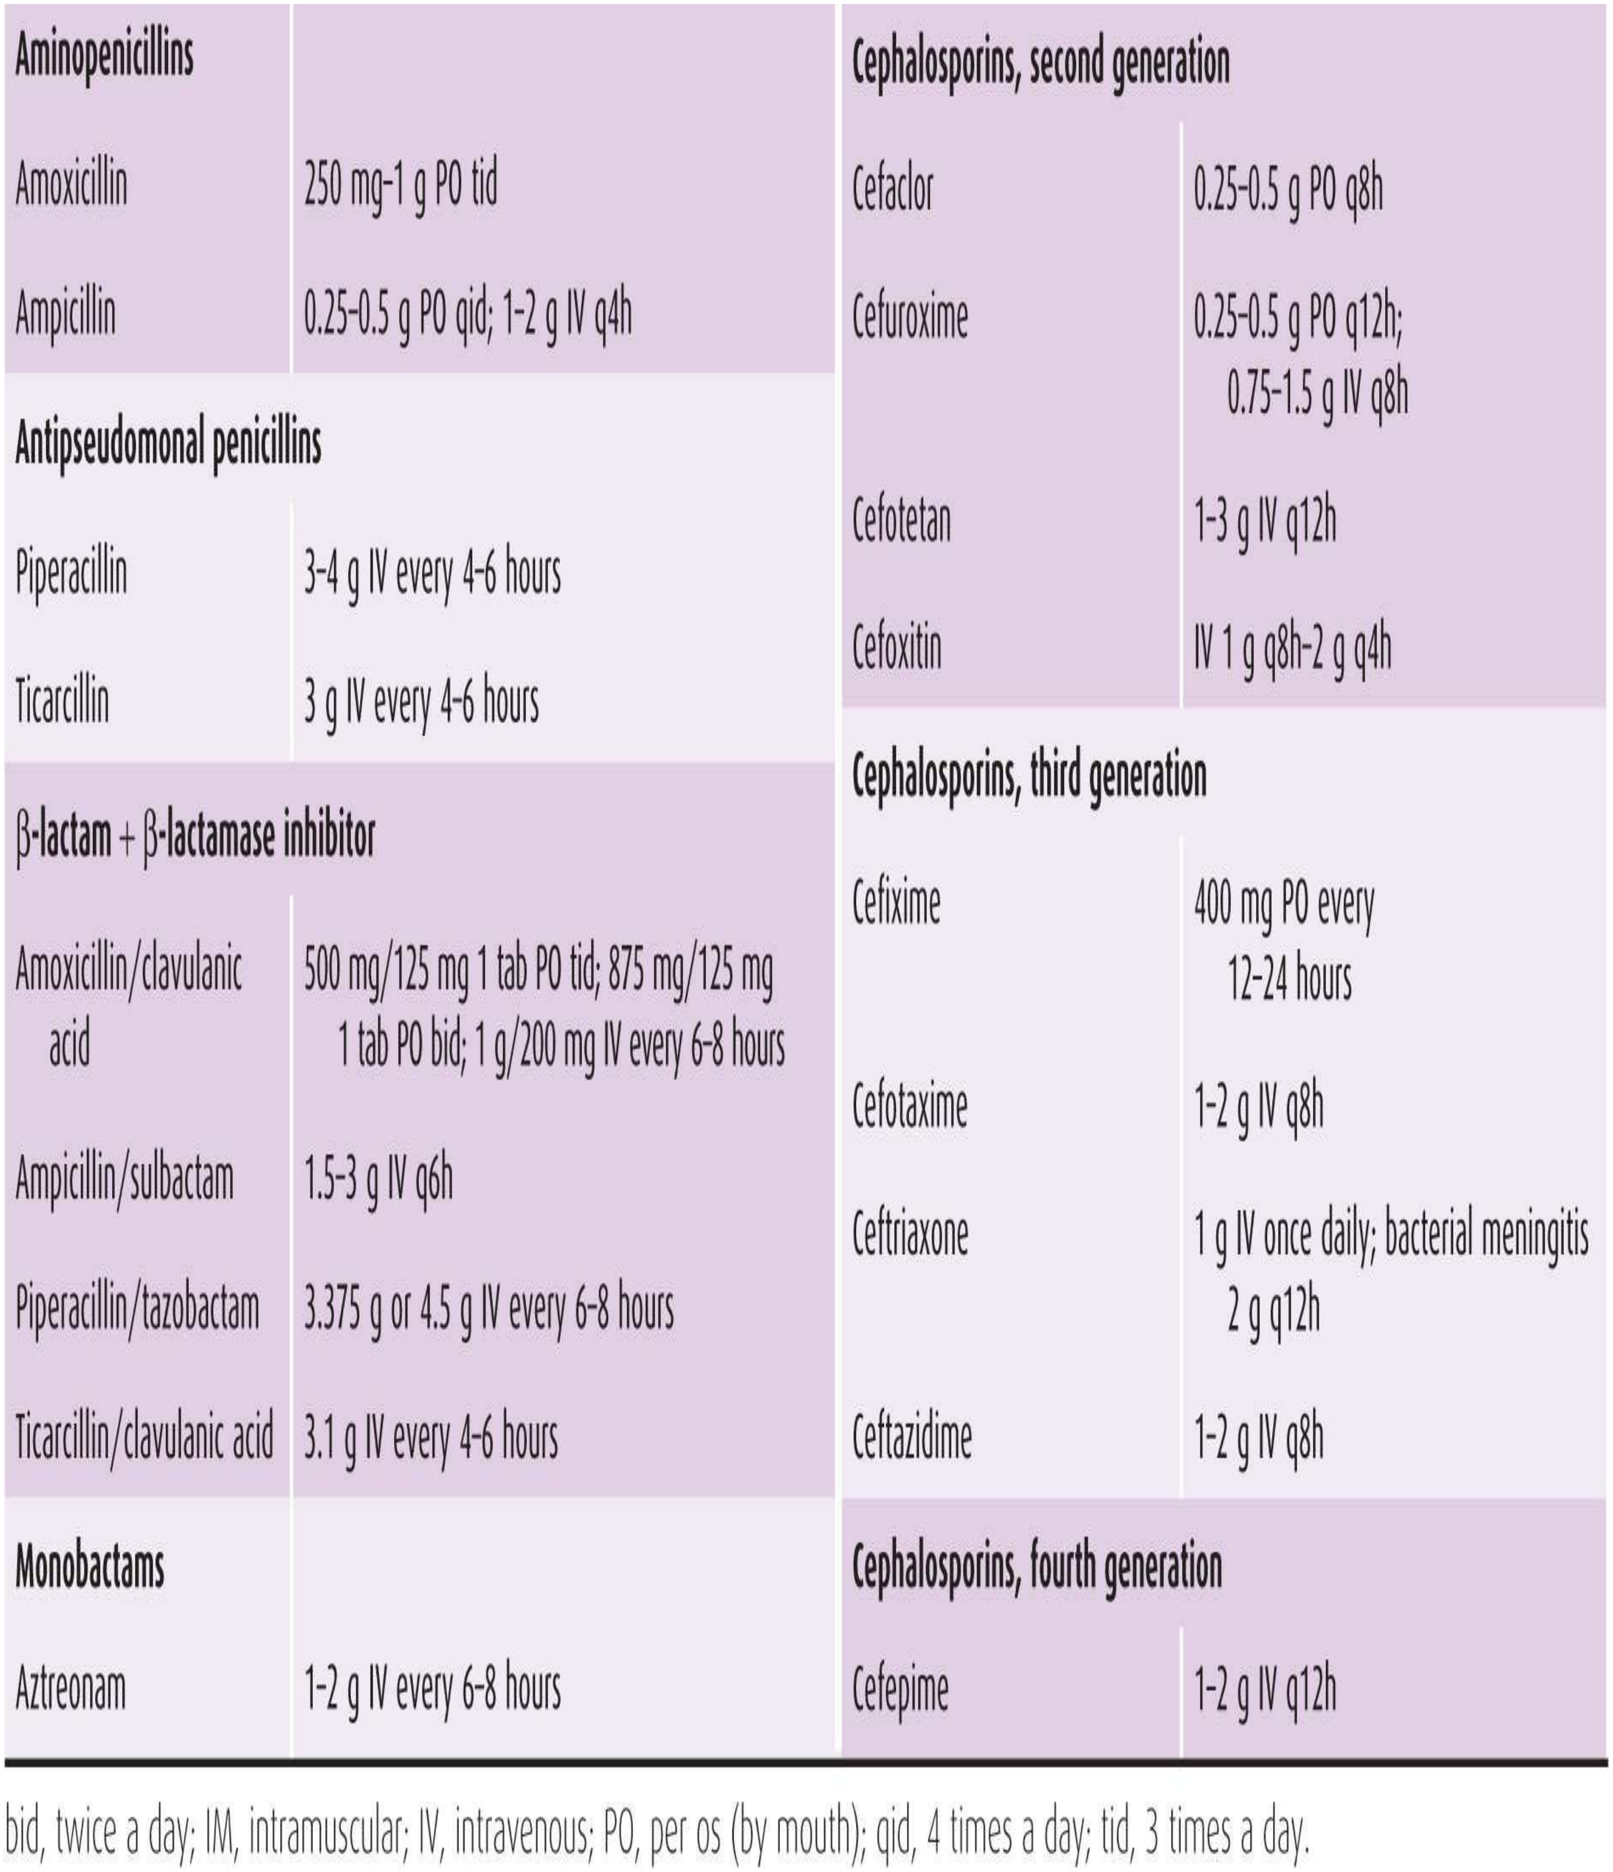
SELECTION OF ANTIMICROBIAL DRUGS

Several considerations are pertinent to most infections encountered in obstetric and gynecologic practice. First, the majority of patients are generally healthy and free of debilitating illness, with the exception of some elderly and oncology patients. Second, the lower genital tract (vagina and cervix) contains a complex flora (eg, anaerobes, gram-positive and gramnegative aerobes, and *Candida*), whereas the upper genital tract (uterus, fallopian tubes, and ovaries) is sterile. Infections in the upper genital tract usually result from spread of the lower genital tract flora when the upper tract is anatomically disrupted (eg, by sexually transmitted disease, by surgery, or during delivery). For this reason, most infections, such as postpartum or postoperative infection and pelvic inflammatory disease, are polymicrobial. Third, cultures must be obtained when infection is suspected (eg, pelvic abscess, chorioamnionitis), and empiric antibiotic therapy targeted at the potential organisms is usually indicated before culture results are available. However, in some gynecologic infections, because of laboratory limitations, culture results may not be available in a timely fashion, or tests may not even be performed at all. In some cases, surgical intervention (“source control”) rather than antibiotic treatment (“antibiotic control”) is the main component of treatment. Fourth, when selecting antibiotic agents in a pregnant woman, the potential risk for the fetus should be taken into account.

To serve as a guide to antibiotic selection, 5 tables are provided. Tables 44–1 and 44–2 provide the classification and dosages of selected β-lactam antibiotics and antibiotics from other classes. Table 44–3 presents the main or serious adverse events of antibiotics commonly used in obstetric-gynecologic practice and risk categories of antimicrobials in pregnancy. Table 44–4 shows recommended drugs and alternatives against selected bacteria encountered in obstetric-gynecologic practice. Finally, Table 44–5 shows suggested regimens for main clinical diagnoses.

Table 44–1. Antibiotic dosage of selected β-lactam agents.

Class, Agent	Usual Adult Dosage in Normal Renal Function
Natural penicillins	
Benzathine penicillin G	600,000–1.2 million units IM
Penicillin G	2–4 million units IV q4h
Penicillin V	0.25–0.5 g PO bid-qid
Antistaphylococcal penicillins	
Cloxacillin	0.25–0.5 g PO q6h; 1–2 g IV q4h
Dicloxacillin	0.125–0.5 g PO q6h
Nafcillin	1–2 g IV q4h
Oxacillin	1–2 g IV q4h
Carbapenems	
Ertapenem	1 g IV q24h
Imipenem	0.5 g IV q6h; for *Pseudomonas aeruginosa* 1 g IV every 6–8 hours
Meropenem	0.5–1 g IV q8h
Cephalosporins, first generation	
Cefadroxil	0.5–1 g PO q12h
Cephalexin	0.25–0.5 g PO q6h
Cefazolin	1–2 g IV q8h



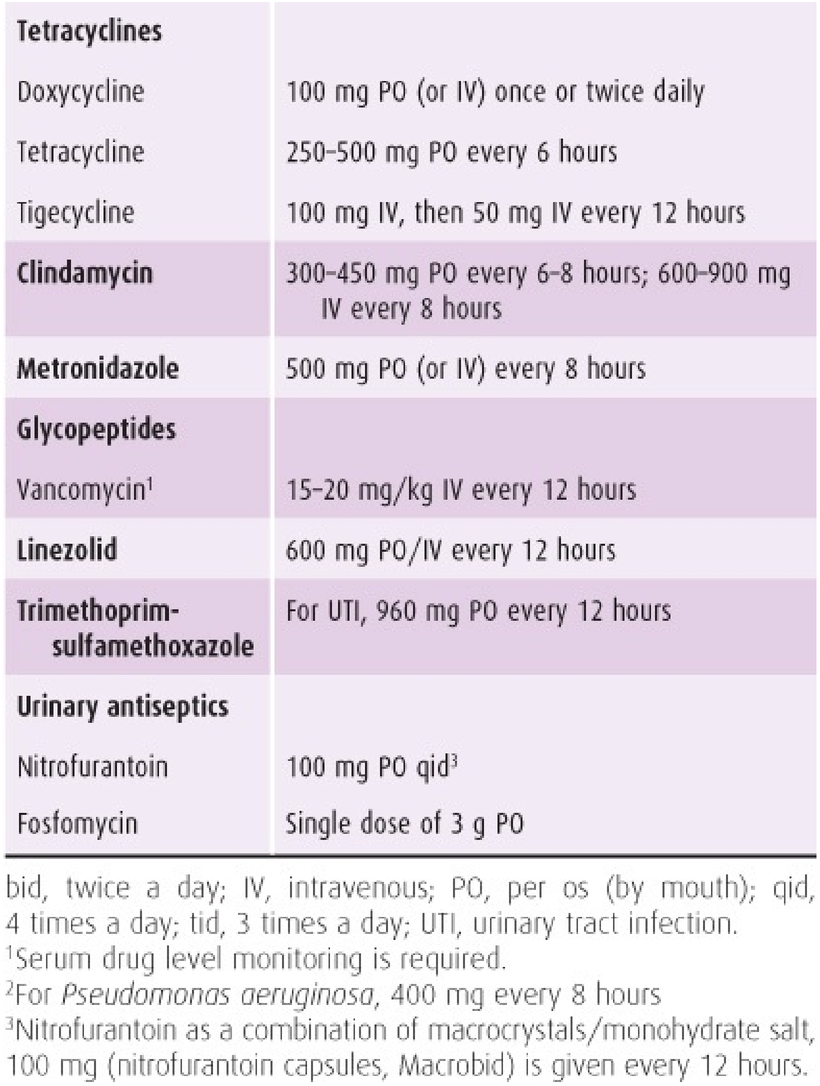
Aminopenicillins	
Amoxicillin	250 mg-1 g PO tid
Ampicillin	0.25–0.5 g PO qid; 1-2 g IV q4h
Antipseudomonal penicillins	
Piperacillin	3-4 g IV every 4-6 hours
Ticarcillin	3 g IV every 4-6 hours
β-lactam + β-lactamase inhibitor	
Amoxicillin/clavulanic acid	500 mg/125 mg 1 tab PO tid; 875 mg/125 mg 1 tab PO bid; 1 g/200 mg IV every 6-8 hours
Ampicillin/sulbactam	1.5–3 g IV q6h
Piperacillin/tazobactam	3.375 g or 4.5 g IV every 6–8 hours
Ticarcillin/clavulanic acid	3.1 g IV every 4-6 hours
Monobactams	
Aztreonam	1-2 g IV every 6–8 hours

Cephalosporins, second generation	
Cefaclor	0.25–0.5 g PO q8h
Cefuroxime	0.25–0.5 g PO q12h; 0.75–1.5 g IV q8h
Cefotetan	1-3 g IV q12h
Cefoxitin	IV 1 g q8h-2 g q4h
Cephalosporins, third generation	
Cefixime	400 mg PO every 12–24 hours
Cefotaxime	1-2 g IV q8h
Ceftriaxone	1 g IV once daily; bacterial meningitis 2 g q12h
Ceftazidime	1-2 g IV q8h
Cephalosporins, fourth generation	
Cefepime	1-2 g IV q12h

bid, twice a day; IM, intramuscular; IV, intravenous; PO, per os (by mouth); qid, 4 times a day; tid, 3 times a day.

Table 44–2. Antibiotic dosage of selected antimicrobial agents other than β-lactams.

Class, Agent	Usual Adult Dosage in Normal Renal Function
Aminoglycosides[1]	
Gentamicin, tobramycin	5 mg/kg once daily; 1.7 mg/kg every 8 hours
Amikacin	15 mg/kg once daily; 7.5 mg/kg every 12 hours
Fluoroquinolones	
Ciprofloxacin	250–500 mg PO bid; 400 mg IV bid[2]
Ofloxacin	200–400 mg PO/IV bid
Gatifloxacin	200–400 mg PO/IV every 24 hours
Levofloxacin	250–750 mg PO/IV every 24 hours
Moxifloxacin	400 mg PO/IV every 24 hours
Macrolides	
Erythromycin	0.25–0.5 g PO every 6 hours; 0.25–1.0 g IV every 6 hours
Roxithromycin	150 mg PO every 12 hours
Clarithromycin	0.25–0.5 g PO every 12 hours
Azithromycin	PO or IV. Tabs of 250 mg. Dose varies with indication. See text.



Tetracyclines	
Doxycycline	100 mg PO (or IV) once or twice daily
Tetracycline	250–500 mg PO every 6 hours
Tigecycline	100 mg IV, then 50 mg IV every 12 hours
Clindamycin	300–450 mg PO every 6–8 hours; 600–900 mg IV every 8 hours
Metronidazole	500 mg PO (or IV) every 8 hours
Glycopeptides	
Vancomycin[1]	15–20 mg/kg IV every 12 hours
Linezolid	600 mg PO/IV every 12 hours
Trimethoprim-sulfamethoxazole	For UTI, 960 mg PO every 12 hours
Urinary antiseptics	
Nitrofurantoin	100 mg PO qid[3]
Fosfomycin	Single dose of 3 g PO

bid, twice a day; IV, intravenous; PO, per os (by mouth); qid, 4 times a day; tid, 3 times a day; UTI, urinary tract infection.

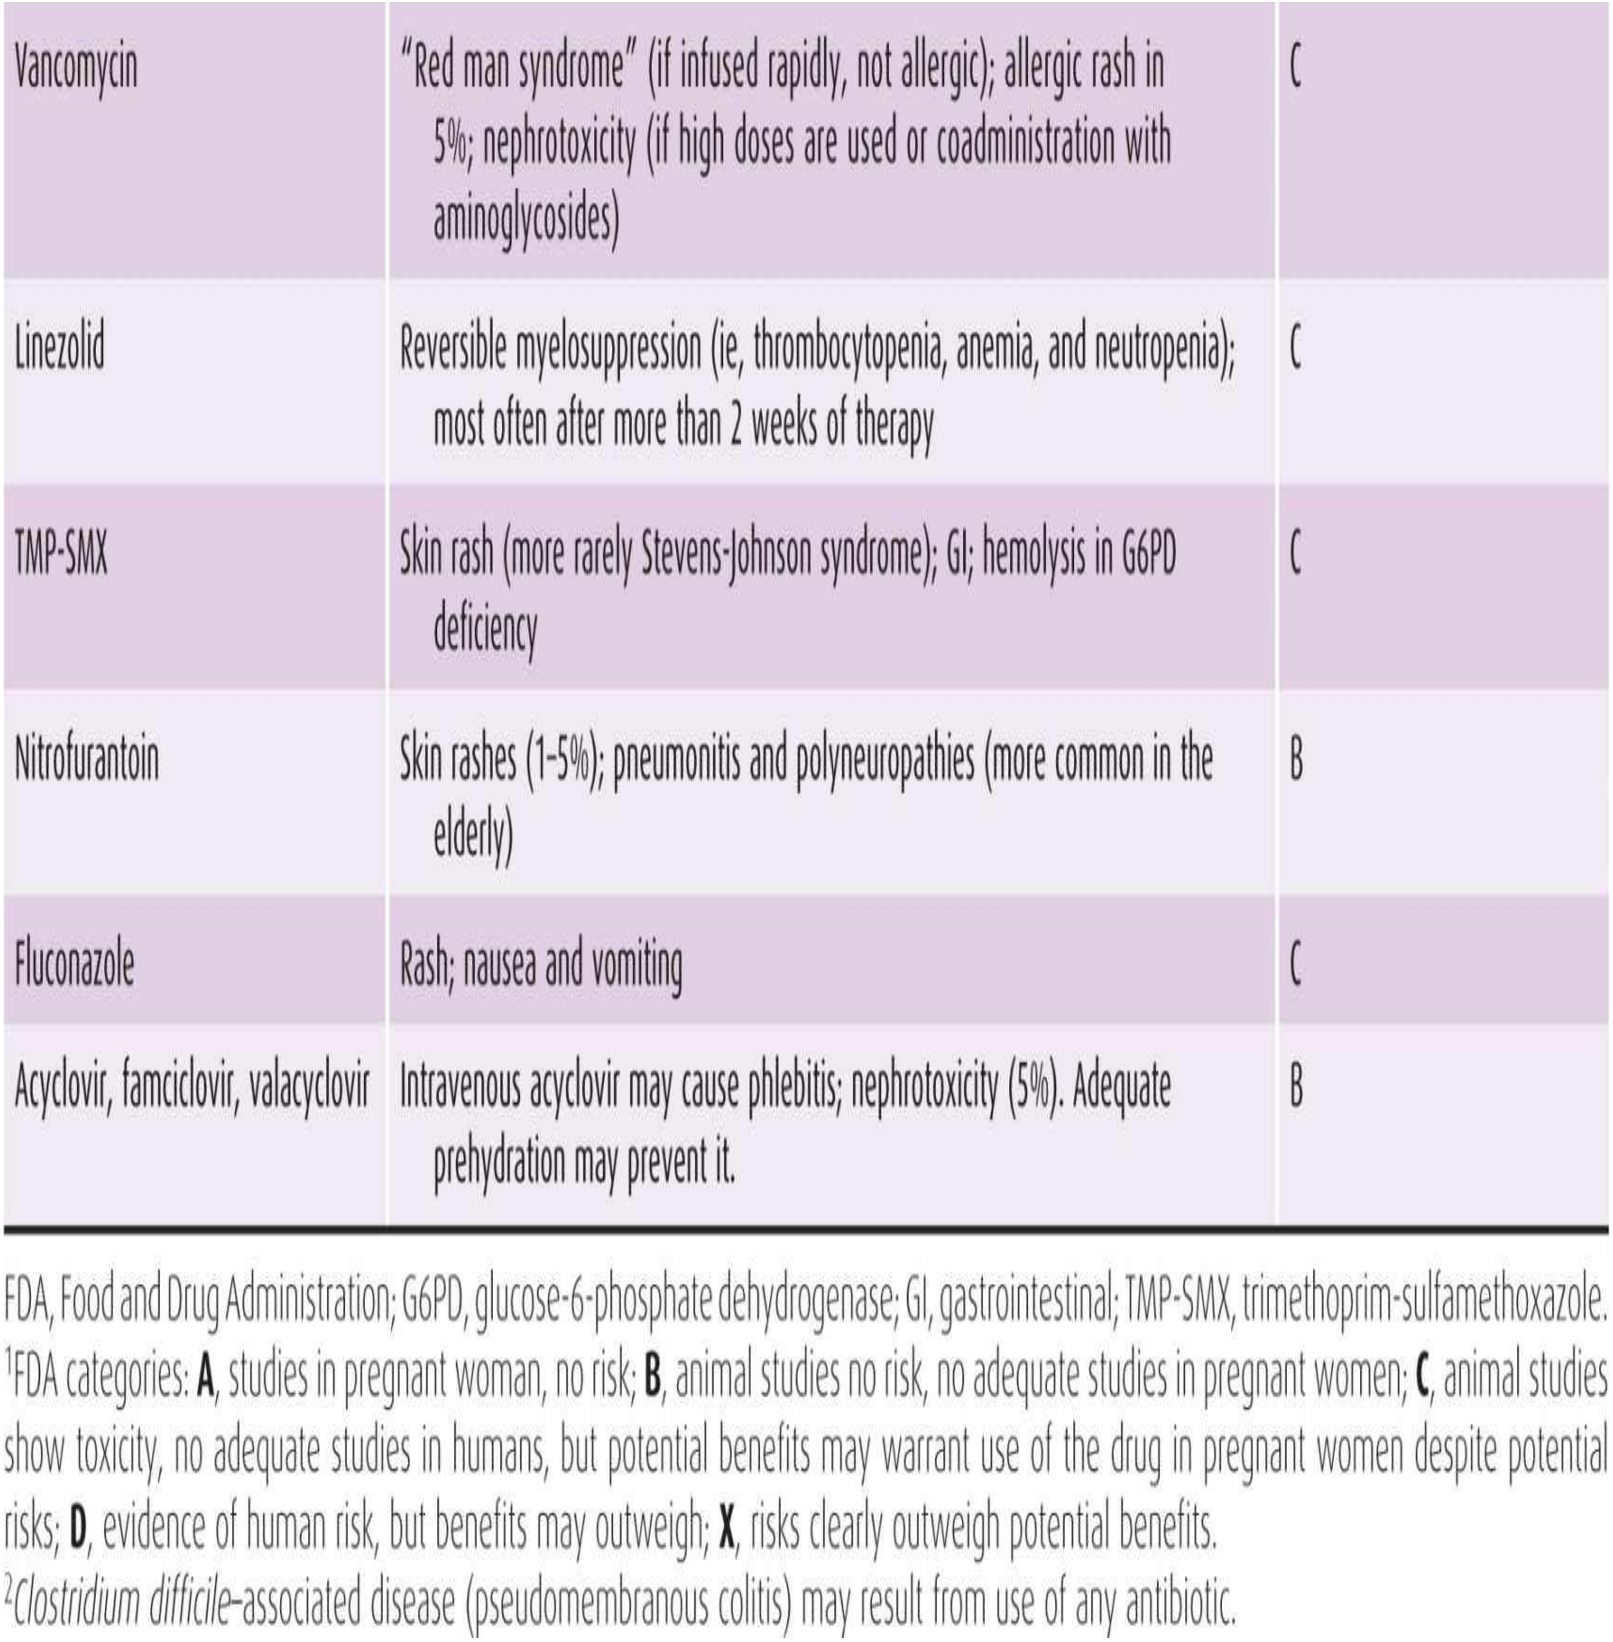
[1] Serum drug level monitoring is required.

[2] For *Pseudomonas aeruginosa*, 400 mg every 8 hours

[3] Nitrofurantoin as a combination of macrocrystals/monohydrate salt, 100 mg (nitrofurantoin capsules, Macrobid) is given every 12 hours.

Table 44–3. Main or serious adverse events of antibiotics commonly used in obstetric-gynecologic practice and pregnancy risk categories.

Antibiotic	Main or Serious Adverse Events	FDA Pregnancy Categories[1]
β-Lactams (penicillins, cephalosporins, carbapenems)	Late-type hypersensitivity (rash, fever); immediate-type (anaphylaxis); seizures in high concentrations	B (imipenem, C)
Aminoglycosides	Nephrotoxicity, ototoxicity	D
Fluoroquinolones	GI; QT prolongation	C
Macrolides	GI; drug–drug interactions (major concern – prolonged QT)	Erythromycin/azithromycin, B Clarithromycin, C
Tetracyclines	GI; esophagitis (take drug while sitting and with adequate amount of fluids); phototoxicity (avoid intense sun exposure)	D
Clindamycin	GI; *Clostridium difficile*–associated disease[2]	B
Metronidazole	Alcohol intolerance; metallic unpleasant taste; rarely, peripheral neuropathy with prolonged use	B



Vancomycin	"Red man syndrome" (if infused rapidly, not allergic); allergic rash in 5%; nephrotoxicity (if high doses are used or coadministration with aminoglycosides)	C
Linezolid	Reversible myelosuppression (ie, thrombocytopenia, anemia, and neutropenia); most often after more than 2 weeks of therapy	C
TMP-SMX	Skin rash (more rarely Stevens-Johnson syndrome); GI; hemolysis in G6PD deficiency	C
Nitrofurantoin	Skin rashes (1–5%); pneumonitis and polyneuropathies (more common in the elderly)	B
Fluconazole	Rash; nausea and vomiting	C
Acyclovir, famciclovir, valacyclovir	Intravenous acyclovir may cause phlebitis; nephrotoxicity (5%). Adequate prehydration may prevent it.	B

FDA, Food and Drug Administration; G6PD, glucose-6-phosphate dehydrogenase; GI, gastrointestinal; TMP-SMX, trimethoprim-sulfamethoxazole.

[1] FDA categories: **A**, studies in pregnant woman, no risk; **B**, animal studies no risk, no adequate studies in pregnant women; **C**, animal studies show toxicity, no adequate studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks; **D**, evidence of human risk, but benefits may outweigh; **X**, risks clearly outweigh potential benefits.

[2] *Clostridium difficile*–associated disease (pseudomembranous colitis) may result from use of any antibiotic.

Table 44–4. Recommended and alternative antimicrobial drugs against selected bacteria encountered in obstetric-gynecologic practice.

Suspected or Proved Etiologic Agent	Recommended Drug(s)	Alternative Drug(s)
Gram-negative cocci		
Neisseria gonorrhoeae	Cefixime, ceftriaxone	Spectinomycin, azithromycin. High prevalence of quinolone resistance in Asia and United States. Treat also *Chlamydia trachomatis*
Gram-positive cocci		
Streptococcus pneumoniae	Penicillin[1]	First/second-generation cephalosporins, macrolide, clindamycin, vancomycin
β-Hemolytic *Streptococcus* (eg, groups A, B, C, G)	Penicillin (some add clindamycin in severe groups A or B infections)	All β-lactams, macrolide
Enterococcus faecalis	Ampicillin + gentamicin (or streptomycin)	Vancomycin + gentamicin (or streptomycin)
Staphylococcus aureus, methicillin susceptible	Oxacillin, nafcillin	First-generation cephalosporin, vancomycin, clindamycin
Staphylococcus aureus, methicillin resistant	Vancomycin	TMP-SMX, linezolid, daptomycin, tigecycline
Gram-negative rods		
Acinetobacter baumannii	Imipenem (resistance increasing)	Ampicillin/sulbactam; colistin
Enterobacteriaceae (eg, *Escherichia coli*, *Klebsiella pneumoniae*, *Enterobacter* species etc.)	Agents vary with clinical setting. See text.	
Pseudomonas aeruginosa	Antipseudomonal β-lactam (eg, piperacillin, ceftazidime); ciprofloxacin; imipenem; meropenem	For serious infection, use a combination of antipseudomonal β-lactam + aminoglycoside (eg, gentamicin, amikacin)

Gram-positive rods		
Listeria monocytogenes	Ampicillin ± gentamicin	TMP-SMX
Anaerobes		
Actinomyces israelii	Ampicillin or penicillin	Doxycycline, ceftriaxone
Oropharyngeal anaerobes	Penicillin	Metronidazole, clindamycin cephalosporin
Bacteroides fragilis	Metronidazole	Cefoxitin, cefotetan, β-lactam + β-lactamase inhibitors, carbapenem (Resistance to clindamycin ~20%)
Clostridium difficile	Metronidazole	PO vancomycin (in severe cases)
Clostridium perfringens	Penicillin G ± clindamycin	Doxycycline
Miscellaneous		
Chlamydia trachomatis	Doxycycline/azithromycin	IV clindamycin
Chlamydia pneumoniae	Doxycycline	Macrolide, quinolone
Haemophilus ducreyi	Ceftriaxone, azithromycin	Ciprofloxacin
Mycoplasma species	Macrolide, quinolone	Doxycycline

[1] For penicillin intermediate-susceptible strains, use high-dose penicillin (except for meningitis). For penicillin-resistant strains, use vancomycin.

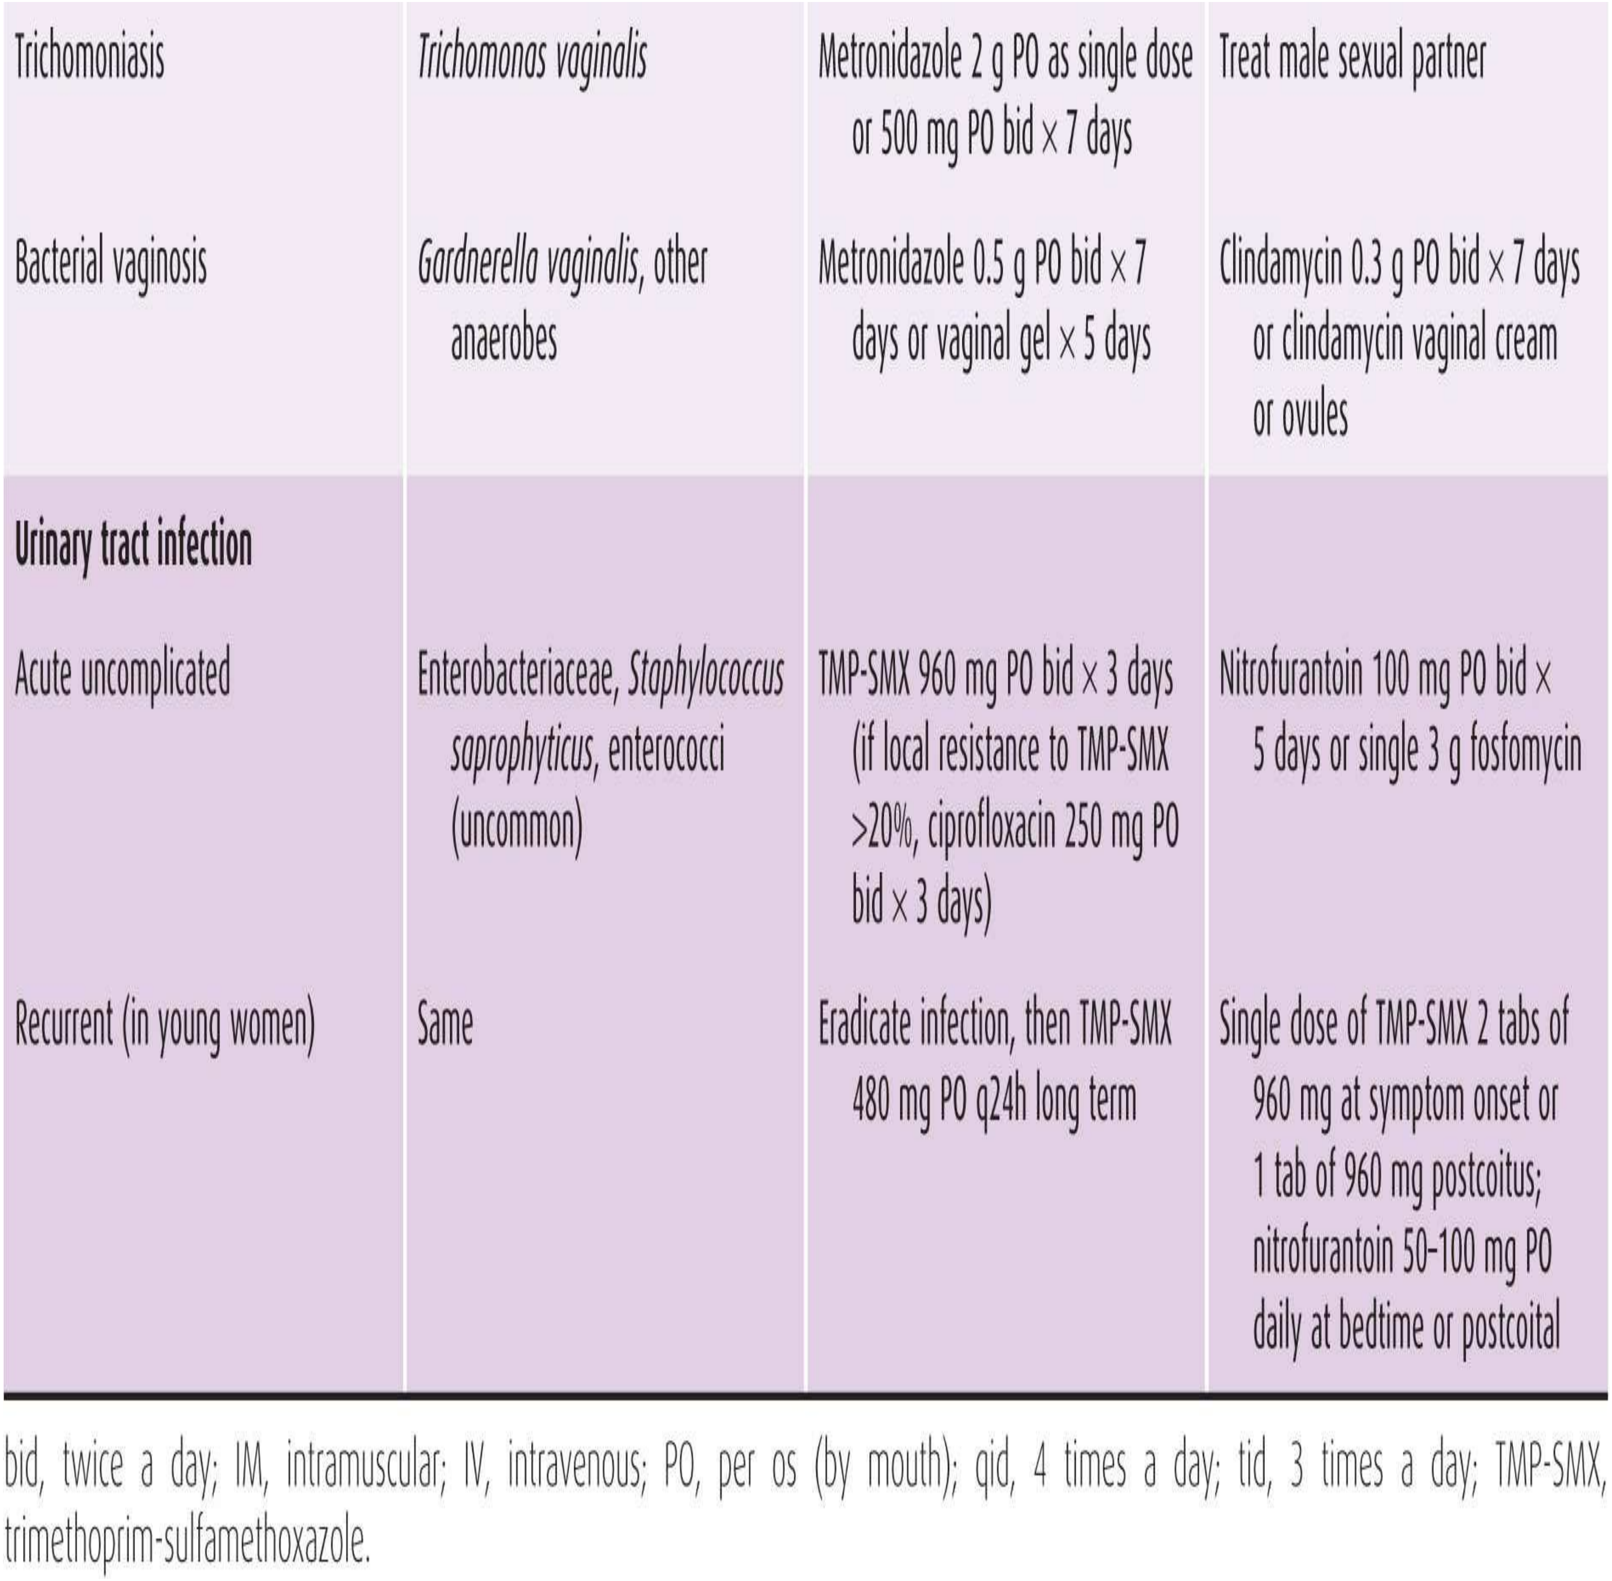
IV, intravenous; PO, per os (by mouth); TMP-SMX, trimethoprim-sulfamethoxazole.

Table 44–5. Treatment regimens for selected infections in obstetric-gynecologic practice.

Clinical Diagnosis	Etiologies	Recommended Regimen	Alternative Regimen/Comments
Chancroid	*Haemophilus ducreyi*	Ceftriaxone 250 mg IM single dose or azithromycin 1 g PO single dose	Ciprofloxacin 500 PO bid × 3 days
Non gonococcal urethritis	Common: chlamydia, *Mycoplasma hominis*. Other: *Trichomonas*, herpes simplex virus (HSV), *Mycoplasma genitalium*	Doxycycline 100 mg PO bid × 7 days or azithromycin 1 g PO single dose Evaluate and treat sex partner	Ofloxacin 300 mg PO bid × 7 days or levofloxacin 500 mg PO once daily × 7 days
Gonorrhea urethritis/cervicitis	*Neisseria gonorrhoeae* (50% have concomitant *Chlamydia trachomatis*; treat for both)	(Ceftriaxone 125 mg IM single dose or cefixime 400 mg PO single dose) PLUS (Azithromycin 2 g PO single dose or doxycycline 100 mg PO every 24 hours × 7 days)	Spectinomycin 2 g IM × 1 for *Neisseria gonorrhoeae*
Genital herpes			
Initial episode	Herpes simplex virus	Acyclovir 400 mg PO tid × 7-10 days or valacyclovir 1 g PO bid × 7-10 days or famciclovir 250 mg PO tid × 7-10 days	IV acyclovir (5 mg/kg q8h × 5-7 days) can be used in hospitalized patients with severe primary HSV infection

Periodic recurrences	Episodic therapy. Initiate therapy within 1 day of lesion onset or during the prodrome.	Acyclovir 800 mg PO tid × 2 days or valacyclovir 500 mg PO bid × 3 days or famciclovir 1 g PO bid × 1 day	Activity and side effects of valacyclovir and famcyclovir are similar to acyclovir
Frequent recurrences	Chronic suppressive therapy	Acyclovir 400 mg PO bid or famciclovir 250 mg PO bid or valacyclovir 1 g PO q24h	
Lymphogranuloma venereum	*Chlamydia trachomatis* (serovars L1–3)	Doxycycline 100 mg PO bid × 21 days	Erythromycin 500 mg PO qid × 21 days
Syphilis			
Early: less than 1 year	*Treponema pallidum*	Benzathine penicillin G, 2.4 million units IM × 1. In pregnancy, it is the only option. Desensitize if there is penicillin allergy.	Doxycycline 100 mg PO bid × 14 days or ceftriaxone 1 g IM/IV q24h × 10 days
Late: more than 1 year		Benzathine penicillin G 2.4 million units IM every week × 3	Doxycycline 100 mg PO bid × 28 days. Consider neurosyphilis.
Amnionitis, septic abortion, early postpartum endometritis	Bacteroides, streptococci (groups A, B), *Chlamydia Trachomatis*, Enterobacteriaceae	Lots of options: [Cefoxitin or (cefuroxime + metronidazole) or β-lactam + β-lactamase inhibitor] + doxycycline	Clindamycin + gentamicin
Actinomycosis (tubo-ovarian abscess)	*Actinomyces israelii*	Penicillin G 10–20 million units/d IV × 4–6 weeks, then penicillin V 2–4 g/d PO × 3–6 months	Doxycycline or ceftriaxone or clindamycin Remove intrauterine device

Pelvic inflammatory disease			
Outpatient	*Neisseria gonorrhoeae*, chlamydia, *Bacteroides*, streptococci, Enterobacteriaceae	(Ceftriaxone 250 mg IM/IV × 1 dose) then (doxycycline 100 mg PO bid ± metronidazole 500 mg PO bid × 14 days)	(Amoxicillin-clavulanate 875 mg PO bid + doxycycline 100 mg PO bid) × 14 days
Inpatient		(Cefoxitin 2 g IV every 6 hours + doxycycline 100 mg PO bid) × 14 days	(Clindamycin 900 mg IV q8h + gentamicin 5 mg/kg once daily + doxycycline 100 mg PO bid) × 14 days
Vaginitis			
Candidiasis	*Candida albicans* most common (other, *Candida glabrata*, *Candida tropicalis*)	Fluconazole 150 mg PO single dose (For recurrent episodes, fluconazole 150 mg PO every week)	Intravaginal azoles (variety of preparations) For azole-resistant, boric acid



Trichomoniasis	*Trichomonas vaginalis*	Metronidazole 2 g PO as single dose or 500 mg PO bid × 7 days	Treat male sexual partner
Bacterial vaginosis	*Gardnerella vaginalis*, other anaerobes	Metronidazole 0.5 g PO bid × 7 days or vaginal gel × 5 days	Clindamycin 0.3 g PO bid × 7 days or clindamycin vaginal cream or ovules
Urinary tract infection			
Acute uncomplicated	Enterobacteriaceae, *Staphylococcus saprophyticus*, enterococci (uncommon)	TMP-SMX 960 mg PO bid × 3 days (if local resistance to TMP-SMX >20%, ciprofloxacin 250 mg PO bid × 3 days)	Nitrofurantoin 100 mg PO bid × 5 days or single 3 g fosfomycin
Recurrent (in young women)	Same	Eradicate infection, then TMP-SMX 480 mg PO q24h long term	Single dose of TMP-SMX 2 tabs of 960 mg at symptom onset or 1 tab of 960 mg postcoitus; nitrofurantoin 50-100 mg PO daily at bedtime or postcoital

bid, twice a day; IM, intramuscular; IV, intravenous; PO, per os (by mouth); qid, 4 times a day; tid, 3 times a day; TMP-SMX, trimethoprim-sulfamethoxazole.

The following steps merit consideration in each patient.

A. Infectious Diagnosis?

The physician must attempt to decide on clinical grounds whether the patient has an infection or whether the symptoms and signs are caused by a noninfectious cause.

B. Diagnostic Microbiology

Before beginning antimicrobial drug treatment for a suspected infection, always attempt to obtain appropriate clinical specimens for culture in order to identify the causative infectious organism and its susceptibility to antimicrobial drugs. Gram stains of sterile body fluids or abscess fluid are one of the most useful tools available to direct an empiric antibiotic treatment. Cultures should be obtained from the suspected site of infection, and if infection is severe, blood cultures should be taken.

C. The Pathogen

The most likely pathogen (or pathogens) causing infection should be defined. This assessment is based on clinical information and epidemiology (eg, age, organ involved, community-acquired vs. hospital-acquired infection; Table 44–5).

D. Pathogen-Oriented Empiric Antibiotic Treatment

Selecting appropriate initial antimicrobial therapy is of high priority. Based on the probable pathogen causing the infection and the local susceptibility patterns, the physician should choose a drug (or drug combination) that is likely to be effective against the suspected microorganism.

E. Other Factors Influencing the Antibiotic Choice

1. Are there antibiotic allergies?
2. Pregnancy: Choose antibiotics in a pregnant woman in accordance with the US Food and Drug Administration's (FDA) use-in-pregnancy drug rating system (Table 44–3).
3. Renal failure may affect not only the choice of antibiotic but also its dosages.
   a. Dosages of antibiotics primarily excreted by the kidneys (eg, β-lactams, aminoglycosides, and fluoroquinolones) should be modified based on the creatinine clearance.
   b. Renal function should be monitored in patients treated with antibiotics that are potentially nephrotoxic (eg, aminoglycosides).
   c. Serum antibiotic levels should be monitored every 2 to 4 days when an aminoglycoside or vancomycin is used.
4. Severity of illness: In those who are seriously ill, the spectrum of the empiric antibiotic regimen needs to include coverage of potentially resistant pathogens.

F. Route of Administration

Intravenous (IV) antibiotics are preferred in serious infections. Oral therapy is effective for mild to moderately severe infections and for completion of therapy initially treated with IV antibiotics. For some antibiotics, absorption after oral administration depends on the proximity to other food intake (eg, amoxicillin-clavulanate and doxycycline should be taken immediately after eating food, whereas trimethoprim-sulfamethoxazole should be taken between meals).

G. Laboratory Results and Clinical Response

Based on the laboratory results (eg, culture and susceptibility) and on the patient clinical response, the desirability of changing the antimicrobial drug regimen should be considered. Conversion from a broad-spectrum to a narrow-spectrum drug should be carried out if possible. It is important to assess the clinical response of the patient before making changes based on culture results. Laboratory results should not automatically overrule clinical judgment.

H. Duration of Antimicrobial Therapy

In general, effective antimicrobial treatment results in marked clinical improvement within a few days. However, continued treatment for varying periods may be necessary to effect cure. The duration of therapy depends on clinical judgment. For most infections, the duration ranges from 5–7 to 10–14 days. For most postoperative and postpartum infections, IV antibiotics can be discontinued after the patient has been afebrile for 24–48 hours. Transfer from IV to oral can be made if the patient can eat and the absorption is not interrupted.

I. Adverse Reactions

The administration of antimicrobial drugs is occasionally associated with untoward reactions (Table 44–3). These reactions can be divided into 3 main groups.

1. Hypersensitivity—The most common reactions are fever and skin rashes. Hematologic or hepatic disorders and anaphylaxis are rare.

2. Direct toxicity—Most common are nausea, vomiting, and diarrhea. More serious toxic reactions are impairment of renal, hepatic, or hematopoietic function.

3. Suppression—Suppression of normal microbial flora and "superinfection" by drug-resistant microorganisms (such as *Clostridium difficile*).

J. Failure to Improve

When the patient is not improving despite adequate antibiotic treatment as determined by culture results, the following possibilities should be considered:

1. Presence of an undrained abscess, hematoma, or foreign body
2. Inappropriate antibiotic dose or route of administration
3. Low antibiotic concentration at the site of infection (eg, central nervous system [CNS])
4. Emergence of drug-resistant or -tolerant organism
5. Involvement of 2 or more microorganisms in the infectious process, of which only 1 was originally detected and used for drug selection

ANTIMICROBIAL DRUGS

1. Penicillins

The penicillins are among the most widely used antimicrobial drugs. The term penicillin is the generic term for a large group of antimicrobial substances, all of which share a common chemical nucleus consisting of a thiadolizine ring, the β-lactam ring, and a side chain; hence the synonym "β-lactams" for the whole group (ie, penicillins, cephalosporins, and carbapenems). The ring is essential for antibacterial activity, whereas the side chain determines the antibacterial spectrum and pharmacologic properties of a particular penicillin (Table 44–1). As a result of the common ring, the potential for allergic cross-sensitivity among penicillins is high. All β-lactam antibiotics inhibit formation of microbial cell wall. By binding to proteins in the cell wall (penicillin-binding proteins), they block the final transpeptidation reaction in the synthesis of cell wall peptidoglycan. This reaction results in bacterial cell death; thus, penicillin is bactericidal.

The most common mechanism of bacterial resistance against penicillin is the production of a β-lactamase enzyme, which destructs the β-lactam ring. This is the principal mechanism of penicillin resistance in *Staphylococcus aureus*, *Bacteroides fragilis*, and Enterobacteriaceae. When penicillin is combined with a β-lactamase inhibitor, the penicillin may escape breakdown.

Pharmacokinetics (Absorption, Distribution, & Excretion)

Acid-labile compounds are poorly absorbed and hence administered only parenterally (penicillin G, antipseudomonal penicillins). Acid-stable compounds vary in the proportion of absorption after oral administration (50% for cloxacillin, 60% for penicillin V, and 75% for amoxicillin). To minimize binding to foods, most oral penicillins should not be preceded or followed by food for at least 1 hour.

After absorption, penicillins are widely distributed in body fluids and tissues (lung, liver, kidney, muscle, bone, and placenta). The levels of penicillins in abscesses and peritoneal fluids are sufficient in the presence of inflammation. In many tissues, penicillin concentrations are equal to those in serum. Lower levels are found in the CNS; however, with active inflammation of the meninges, as in bacterial meningitis, penicillin levels in the cerebrospinal fluid exceed 1–10% of serum concentrations.

Most penicillins are rapidly excreted by the kidneys into the urine—90% by tubular secretion, which results in very high levels in the urine. Significant reduction in renal function must be taken into account in the administration of most penicillins.

Indications, Dosages, & Routes of Administration

A. Penicillin G, Penicillin V

In obstetric-gynecologic practice, penicillin is the drug of choice for treatment of infections caused by groups A and B streptococci, *Treponema pallidum* (causing syphilis), clostridia, and actinomycosis. Severe infections caused by enterococci should be treated by a synergistic combination of ampicillin (or penicillin G) and gentamicin. Penicillin is *not* recommended to treat *Neisseria gonorrhoeae* because of widespread resistance.

1. **Aqueous penicillin G** is given intravenously and produces high blood levels but is excreted rapidly. Therefore, for serious infections, it should be given every 4 hours (6 times daily). In adults with normal renal function, a dose of 18–24 million units a day is used in severe infections and 9–12 million units in other infections.
2. **Benzathine penicillin G** is an insoluble salt that is injected intramuscularly to establish a depot that yields very low drug levels for prolonged periods of time (ie, 3–4 weeks). An injection of 2.4 million units intramuscularly once per week for 1 or 3 weeks is the recommended treatment for early and late syphilis, respectively.
3. **Penicillin V** is made by a mild modification of the side chain of penicillin G, which allows it to resist gastric acid breakdown and thus can be given orally. Penicillin V is indicated in minor infections (eg, group A *Streptococcus* pharyngitis) in daily doses of 1–2 g (500 mg of penicillin V equals 800,000 units).

B. Amoxicillin, Ampicillin, Ticarcillin, Piperacillin

Several side-chain modifications of penicillin have been made to provide enhanced activity of these "broad-spectrum" penicillins.

1. **Amoxicillin** and **ampicillin**, in addition to being active against penicillin-susceptible organisms, are more active than penicillin against enterococci and *Listeria monocytogenes*. Due to widespread bacterial resistance among Enterobacteriaceae, these drugs can be given against Enterobacteriaceae (eg, to treat urinary tract infections) only after susceptibility studies are available. They are ineffective against *Pseudomonas aeruginosa*.

   Amoxicillin is available only for oral use in daily doses of 1.0 g every 8 hours. Amoxicillin has replaced oral ampicillin. IV ampicillin is given in a dose of 1–2 g every 4 hours (ie, 6–12 g daily) depending on the organism involved and the severity and site of infection.

2. **Ticarcillin and piperacillin** were introduced for gramnegative bacteria. They are active against many Enterobacteriaceae and also *P aeruginosa*. Because resistance emerges rapidly, susceptibility testing is required. Their anti–gram-positive spectrum mimics that of ampicillin. For severe *P aeruginosa* infection, piperacillin is preferred (it is 4 times more active against *P aeruginosa*), and addition of an aminoglycoside is required in order to decrease the likelihood of emergence of resistance.

   These drugs are administered IV only: piperacillin 4 g every 6 hours and ticarcillin 3 g every 4 hours.

C. β-Lactamase–Resistant Penicillins

These agents, which are resistant to destruction by β-lactamase, are used primarily to treat infections caused by βlactamase–producing *S aureus*. They are also active against other gram-positive aerobes (eg, group A *Streptococcus*, *Streptococcus pneumoniae*) but are inferior to penicillin for them. They are not active against the Enterobacteriaceae or enterococci.

1. Oral—Cloxacillin or dicloxacillin can be given in doses of 0.25–1.0 g every 6 hours in mild or localized staphylococcal infections. Food markedly interferes with absorption, and hence, they should not be preceded or followed by food for at least 1 hour.

2. IV—Nafcillin, oxacillin, and **cloxacillin** are the drugs of choice for the treatment of serious systemic methicillin-sensitive *S aureus* (MSSA) infections. The usual dose is 6–12 g/d (1–2 g every 4 hours), depending on the severity of the infection. Because these drugs are excreted primarily by hepatic mechanisms, dose reduction is not needed in renal failure (mild reduction of cloxacillin is needed in severe renal failure), but in hepatic failure, dose reduction is required.

D. Combinations of Penicillins plus β-Lactamase Inhibitors

Because the primary bacterial resistance mechanism against penicillin is through β-lactamase production, a β-lactamase inhibitor was combined with several penicillins. This inhibitor binds irreversibly to the β-lactamase, and thus allows the free penicillin to exert its antibacterial activity.

In addition to being active against the penicillin component–susceptible organisms (eg, streptococci, enterococci), these combinations are effective also against MSSA, *B fragilis* and many Enterobacteriaceae (some species of Enterobacteriaceae produce β-lactamases that are resistant to these inhibitors). They are not active against methicillin-resistant *S aureus* (MRSA) or vancomycin-resistant enterococci (VRE) because their mechanism of resistance is different.

Because of their wide spectrum of activity against bacteria involved in pelvic infections (eg, anaerobes, Enterobacteriaceae, enterococci), these combinations have been successful in many circumstances.

1. Oral—Amoxicillin-clavulanate is the only oral combination agent available. It should be administered at the start of the meal to decrease gastrointestinal side effects. The dose is 500 mg amoxicillin and 125 mg clavulanate given 3 times a day or 875 mg amoxicillin and 125 mg clavulanate given every 12 hours.

2. IV—Four parenteral combinations are available that are different in their anti–gramnegative spectrum of activity. **Amoxicillin-clavulanate** (amoxicillin 1.0 g, clavulanate 200 mg) and **ampicillin-sulbactam** (ampicillin 2.0 g, sulbactam 1.0 g) are administered 3 times daily and are active against many gramnegative organisms but not *P aeruginosa*. Ampicillin-sulbactam is sometimes active against resistant *Acinetobacter baumannii*. **Ticarcillin-clavulanate** (ticarcillin 3.0 g, clavulanate 0.1 g) given 4 to 6 times daily and **piperacillin-tazobactam** (piperacillin 4.0 g, tazobactam 0.5 g) given 3 to 4 times daily are active also against *P aeruginosa*. Piperacillin-tazobactam is the widest spectrum anti–gramnegative agent among these 4 agents.

Adverse Effects of Penicillins

Most of the serious side effects of the penicillins are due to hypersensitivity.

A. Allergy

Allergic reactions to penicillin occur in 1–10% of patients.

1. The most frequent (80–90%) are late reactions, which occur days after initiation of therapy. The common clinical signs are morbilliform rash and fever but also eosinophilia and interstitial nephritis (gastrointestinal symptoms are not a sign of allergy).
2. Immediate reactions (within 1 hour) occur as a result of histamine release from immunoglobulin (Ig) E–sensitized mast cells. These are the most dangerous reactions but fortunately are rare (0.05%). Immediate reactions may be associated with urticaria, angioedema, laryngeal edema, bronchospasm, and anaphylaxis.
3. Accelerated reactions occur in the first 1–72 hours and, except for laryngeal edema, are not life threatening.

The penicillin-allergic patient (any agent of the penicillin group; consider both trade and generic names) should be presumed to be allergic to other penicillins (unless skin tests prove otherwise). The risk of cross-allergy to a cephalosporin is estimated to be 10% and to a carbapenem 1%. In a patient with a history of delayed mild reaction to penicillin, cephalosporins can be used. When there is a history of immediate penicillin allergy, cephalosporins should not be administered (unless a cephalosporin skin test has been performed).

In circumstances where penicillin is the clear drug of choice and where alternatives are likely to be less effective, an oral desensitization protocol may be used safely. One such indication is the treatment of a pregnant woman with syphilis.

B. Toxicity

High penicillin blood levels may lead to high spinal fluid levels. This may occur when high doses are given in the presence of renal failure and may lead to seizures. Large doses of penicillins given orally may lead to gastrointestinal upset, particularly nausea and diarrhea. These symptoms are most marked with oral amoxicillin or amoxicillin-clavulanate. Penicillins can cause pseudomembranous colitis.

2. Cephalosporins

The cephalosporins are bactericidal agents that inhibit bacterial cell wall synthesis, similar to the penicillins, and are part of the β-lactam family. They consist of a β-lactam ring attached to a dihydrothiazoline ring. Substitutions of chemical groups at various positions on the basic structure have resulted in a proliferation of drugs with varying pharmacologic properties and antimicrobial activities. In patients with impaired renal function, dosage adjustment is required for most cephalosporins (not including ceftriaxone).

Cephalosporins have been divided into 3 (or 4) major groups or "generations" based mainly on their antibacterial activity (Table 44–1):

1. First-generation cephalosporins have good activity against aerobic gram-positive organisms (streptococci, MSSA; excluding enterococci) and many community-acquired gramnegative organisms.
2. Second-generation drugs have a slightly extended spectrum against gramnegative bacteria (eg, cefuroxime) and some also against anaerobes (eg, cefoxitin).
3. Third- and fourth-generation cephalosporins can be divided into 2 subsets: one type (ie, ceftriaxone, cefotaxime) has significant anti–gram-positive activity and also anti–community-acquired gramnegative activity (not *P aeruginosa*); the other type (ie, ceftazidime) is less active against gram-positive organisms but has broad-spectrum anti–gramnegative bacteria activity, including *P aeruginosa*. The fourth-generation agent cefepime is active against both gram-positive and gramnegative organisms, including *P aeruginosa*.

Not all cephalosporins fit neatly into this grouping, and there are exceptions to the general characterization of the drugs in the individual generations. However, the generational classification of cephalosporins is useful for discussion purposes. In this part, only a limited number of agents that are particularly useful will be discussed.

The most common mechanisms for resistance are production of β-lactamases, alteration of the penicillin-binding proteins (PBPs), and changes in the outer membrane. Some of the β-lactamases are plasmid mediated, and others are inducible and chromosomal mediated (*Enterobacter* species, *Citrobacter* species, *P aeruginosa*), which lead to treatment failure and emergence of resistance in isolates initially susceptible. The resistance of *S aureus* to methicillin and cephalosporins is mediated by change of the PBP. Extended-spectrum β-lactamases (ESBLs) have been recognized in the early 1980s. They confer resistance to almost all cephalosporins and penicillins (even to those that seemed sensitive in vitro) but not to carbapenems. The clue for the presence of ESBL is resistance of an Enterobacteriaceae to 1 or all third-generation cephalosporins. Today, most laboratories are performing a specific test (double disc diffusion) in order to identify an ESBL producer.

Indications, Dosages, & Routes of Administration

A. First-Generation Cephalosporins

These drugs are active against gram-positive cocci, including *S pneumoniae*, viridans streptococci, groups A and B streptococci, and MSSA. They are also active against many community-acquired gramnegative bacteria. They are inactive against enterococci and MRSA (like all other cephalosporins) and *P aeruginosa*. Oral anaerobic bacteria are usually sensitive, but most bowel anaerobes (ie, *B fragilis*) are not.

1. Oral—In general, these agents are rapidly and thoroughly absorbed. They are useful for mild to moderate MSSA and group A streptococcal infections of the skin and soft tissue (eg, cellulitis).

1. **Cephalexin** and **cephradine** are given orally in doses of 0.25–0.5 g 4 times daily. When treating a significant *S aureus* infection, a dose of 1.0 g 4 times daily should be used initially.
2. **Cefadroxil** can be given in doses of 0.5–1 g twice daily.

2. IV—Cefazolin is the most commonly used agent.

1. It is among the drugs of choice for surgical prophylaxis in gynecologic operations and caesarean section.
2. It serves as an alternative to β-lactamase–resistant penicillins (eg, nafcillin, oxacillin) for known or suspected MSSA infections (eg, cellulitis).
3. Cefazolin is an alternative to penicillin for group B streptococcal prophylaxis in patients with a delayed mild allergic reaction to penicillin.

Cefazolin can be given in doses of 0.5–2 g every 8 hours (depends on the severity of the infection).

B. Second-Generation Cephalosporins

These drugs are active against organisms also covered by first-generation drugs, but they have an extended anti– gramnegative activity (community acquired). In addition, cefoxitin and cefotetan are active against bowel anaerobes, especially *B fragilis*. They have no activity against enterococci, MRSA, and *P aeruginosa*.

1. Oral—They are useful for respiratory tract infections and for simple cystitis. **Cefuroxime axetil** or **cefprozil** is given orally in doses of 0.25–0.5 g twice daily.

2. IV—Due to the spectrum of activity, these drugs can be used to treat obstetric and gynecologic infections. They have no advantage over first-generation cephalosporins for perioperative prophylaxis.

1. **Cefuroxime** is given in doses of 750 mg to 1.5 g 3 times daily. For intraabdominal polymicrobial infections, an antianaerobic drug (ie, metronidazole) should be added to cefuroxime.
2. **Cefoxitin** and **cefotetan** have enhanced anaerobic activity and hence can generally be used alone for intraabdominal infections. These drugs should not be relied on as monotherapy in patients with bacteremia due to *B fragilis* because they may not be active against 5–30% of these isolates. Cefoxitin is given in doses of 2 g every 6–8 hours, and cefotetan is given in a dose of 1–2 g twice daily.

C. Third-/Fourth-Generation Cephalosporins

Third-/fourth-generation cephalosporins have the broadest anti–gramnegative spectrum of all cephalosporins. In addition to anti–gramnegative activity, ceftriaxone, cefotaxime, and cefixime have significant anti– gram-positive activity (less than that of first and second generations), whereas ceftazidime (which is less active against gram-positives) is active also against *P aeruginosa*. The fourth-generation agent cefepime is active against both gram-positive and gramnegative organisms, including *P aeruginosa*. None of these agents has good activity against the bowel anaerobe *B fragilis*. Most of these drugs are active against *N gonorrhoeae*.

Ceftriaxone is eliminated primarily by biliary excretion, and no dosage adjustment is required in renal insufficiency. The other drugs in this generation are eliminated by the kidneys and thus require dosage adjustments in renal insufficiency.

1. Oral—Cefixime is used in a very limited fashion. In obstetric-gynecologic practice, this agent can be used to treat uncomplicated gonococcal infection by 400 mg given once (combined with doxycycline or azithromycin for cotreatment of chlamydia).

2. IV

1. **Ceftriaxone** is a widely used agent due to its broad spectrum of activity against community-acquired infections and its long half-life, allowing a once-daily regimen (except for CNS infections). One dose of ceftriaxone 250 mg intramuscularly is used for treating uncomplicated gonorrhea (combined with doxycycline or azithromycin for cotreatment of chlamydia). For non-CNS infections (eg, community-acquired pneumonia, abdominal/gynecologic infections, and urinary tract infections), a once-daily dose of 1 g is given.
2. **Ceftazidime** is, for practical purposes, exclusively an antiaerobic gramnegative agent. It has an excellent anti–*P aeruginosa* activity and is used to treat hospital-acquired infections where *P aeruginosa* is an option. Ceftazidime is given in doses of 1–2 g every 8 hours.
3. **Cefepime** is an extended-spectrum cephalosporin that has activity against gram-positive organisms comparable with ceftriaxone and anti–gramnegative activity comparable to ceftazidime, including an excellent activity against *P aeruginosa*. It is used to treat hospital-acquired infections where gram-positive and gramnegative organisms are a possibility. In many centers, it has replaced ceftazidime due to its wider spectrum. As with all cephalosporins, it is not active against MRSA, *B fragilis*, and enterococci. Cefepime is given in doses of 1–2 g every 12 hours.

Adverse Effects of Cephalosporins

A. Allergy

Cephalosporins, both oral and IV formulations, are very well tolerated. There is approximately a 1–3% rate of primary allergic reactions to cephalosporins (rashes, fever, and eosinophilia). Anaphylaxis is rare, occurring in less than 0.02% of recipients. The incidence of cross-allergy between cephalosporins and penicillins is estimated to be approximately 10%. In a patient with a history of delayed mild reaction to penicillin, cephalosporins are commonly used. With a history of an immediate reaction to penicillin (eg, bronchospasm, hypotension), cephalosporins should be avoided. The risk with third-generation cephalosporins in this setting is as low as 1%, similar to those without that history.

B. Toxicity

Positive Coombs reaction occurs in 3%. Other uncommon adverse effects include nephrotoxicity and hematologic effects (granulocytopenia and thrombocytopenia).

C. Superinfection

Pseudomembranous colitis caused by *C difficile* may occur more frequently in recipients of second- and third-generation cephalosporins.

3. Unique β-Lactam Antibiotics

Monobactams (Aztreonam)

Aztreonam is active against most gramnegative aerobes (including *P aeruginosa*) but not against gram-positive organisms or anaerobes. Aztreonam resembles aminoglycosides in activity without their nephrotoxicity. Because it is active against gramnegative aerobes only, combination therapy is necessary for suspected mixed infections with gram-positive organisms and/or anaerobes. The usual dose is 1–2 g IV every 6–8 hours. Although aztreonam has potentially less toxicity than gentamicin, gentamicin is much less expensive, and the majority of obstetric-gynecologic patients are at low risk for gentamicin toxicity. It is an alternative anti–gramnegative agent in patients with allergy to penicillins or cephalosporins because there is little risk of cross-sensitivity.

Carbapenems

Carbapenems have the broadest antibacterial spectrum of the β-lactam class, largely because they are so β-lactamase stable. Four carbapenems—**ertapenem, doripenem, imipenem**, and **meropenem**—are in clinical use. All have excellent activity against gram-positive cocci, excluding MRSA. Imipenem is active against *Enterococcus faecalis* but not the other carbapenems. The carbapenems have the broadest anti–gramnegative spectrum, including *P aeruginosa* (except for ertapenem), and are the drugs of choice for ESBL gramnegative producers. Carbapenems are highly active against most anaerobic species including the bowel anaerobes (eg, *B fragilis*). Generally speaking, doripenem, imipenem, and meropenem are therapeutically equivalent and interchangeable in most clinical situations; ertapenem is different in its lack of activity against *P aeruginosa* and *A baumannii*. During the past decade, carbapenem resistance in Enterobacteriaceae and *A baumannii* has emerged, mostly mediated by a β-lactamase that hydrolyses carbapenems.

All the carbapenems must be administered parenterally. They are well distributed to various body compartments and penetrate well into most tissues. The usual doses are ertapenem 1 g once daily; doripenem 500 mg every 8 hours; imipenem 500 mg every 6 hours; and meropenem 0.5–1 g every 8 hours. Dosage adjustment is required in renal insufficiency.

Because carbapenems have an unusual spectrum, they should be reserved for serious nosocomial infections for the treatment of highly resistant organisms. They should not be used as a first-line treatment for pelvic infections.

Carbapenems generally are well tolerated. The most common adverse effects of imipenem are nausea, vomiting, diarrhea, and skin rashes. All carbapenems, particularly imipenem, have been associated with seizures. The cross-allergy between carbapenems and penicillins is probably low (ie, ~1%).

4. Aminoglycosides

These agents are in most instances bactericidal. They penetrate the cell wall and membrane and inhibit protein synthesis by binding irreversibly to the 30S subunit of the bacterial ribosome. The most commonly used aminoglycosides are **gentamicin, tobramycin**, and **amikacin**.

Aminoglycosides are active against almost all gramnegative rods including *P aeruginosa*. Among resistant gramnegative bacilli, amikacin is the most frequently active, tobramycin is the next frequently active, and gentamicin is the least frequently active. Aminoglycosides have some activity against some gram-positive aerobes (eg, staphylococci, enterococci) but are never given alone for these bacteria but are administered together with a β-lactam agent. Gentamicin, together with penicillin or ampicillin, usually is bactericidal against enterococci, but the incidence of high-level resistance of enterococci to gentamicin is increasing. Anaerobes are not susceptible to aminoglycosides.

General Properties of Aminoglycosides

A. Pharmacokinetics

Aminoglycosides are not absorbed from the gut. The IV route is preferred, although the intramuscular route can be used if thrombocytopenia is absent. They are distributed widely in tissues and achieve reasonable concentrations in bone, synovial fluid, and peritoneal fluid. Urinary concentrations are high and exceed serum concentrations by 100 times. They have limited penetration into the CNS and probably intraabdominal abscesses. There is a variation in the volume of distribution and rate of excretion of amino-glycosides in individual patients with normal renal function. Thus, it is important to monitor serum levels in all patients every 3–4 days. Aminoglycoside excretion is entirely renal, mandating dose adjustment for renal failure. The serum half-life is 2–3 hours.

B. Dosing & Serum Level Monitoring

Aminoglycosides demonstrate a postantibiotic effect (ie, persistent suppression of bacterial growth after short antibiotic exposure) against aerobic gramnegative bacilli. Hence aminoglycosides can be administered as a single daily dose (SDD) or with the conventional multiple daily dosing regimen. The SDD approach appears to be comparable in efficacy to the traditional multiple daily dosing, is simpler to administer, and is less toxic. Some clinicians prefer to continue to use multiple daily dosing in the pregnant patient.

Creatinine clearance should be calculated before aminoglycoside administration, and doses should be corrected accordingly. In normal renal function, once-daily dose of gentamicin or tobramycin is 5 mg/kg and amikacin 15 mg/kg, given over 60 minutes. In conventional dosing, 1.7 mg/kg of gentamicin or tobramycin is given every 8 hours, and 7.5 mg/kg of amikacin is given every 12 hours.

In patients treated by SDD, trough level should be obtained before the next dose every 3–4 days. In patients treated by multiple daily dosing, peak levels (30 minutes after completion of the infusion, to ensure that enough quantity of drug was administered) and trough levels (before the next dose) should be monitored. If trough levels are elevated, the next dose needs to be reduced or the interval prolonged.

C. Clinical Use in Obstetrics & Gynecology

1. Aminoglycosides are used to treat complicated **urinary tract infections** (ie, pyelonephritis). Gentamicin is a primary agent unless the patient has recently received gentamicin and is possibly infected with a relatively resistant gramnegative bacterium; in this situation, amikacin should be used while awaiting culture results.
2. Aminoglycosides are used to treat **intraabdominal infections** (combined with antianaerobic agent).
3. Gentamicin can be used to treat ***P aeruginosa*** **infections** in combination with piperacillin.
4. Amikacin is used empirically to treat gramnegative bacteria in **hospital-acquired infections** especially in specialized areas (eg, intensive care units).
5. Aminoglycoside effectiveness is not optimal for sterilization of abscesses and in lower respiratory tract infections because of poor activity in the presence of low pH.

D. Adverse Effects

1. Hypersensitivity reactions are uncommon.
2. All aminoglycosides can cause varying degrees of **nephrotoxicity**, expressed by a rising blood urea nitrogen and creatinine. Changes are usually reversible with discontinuation, and rational use can prevent it. Risk factors for nephrotoxicity (and ototoxicity) include concomitant liver disease,

concomitant use of other potentially nephrotoxic drugs (eg, vancomycin, nonsteroidal anti-inflammatory drugs), and prior renal disease. Prevention includes the following: use aminoglycosides for the shortest appropriate course, correct hypovolemia, avoid in the presence of risk factors, use SDD regimen, and monitor levels and serum creatinine. Serum creatinine levels should be obtained every 2–4 days.

3. **Ototoxicity** (eg, hearing loss, vertigo and loss of balance, or nystagmus) is frequently irreversible. Older patients are at greater risk.

5. Fluoroquinolones

All fluoroquinolones (FQs) inhibit bacterial DNA gyrase, a bacterial enzyme essential for DNA replication. They promote gyrase-mediated DNA breakage at specific sites, which leads to cell death. Quinolones are categorized based on spectrum of antimicrobial activity:

1. First-generation FQs (eg, nalidixic acid) are no longer used.
2. The second-generation agents, **ciprofloxacin** and **ofloxacin**, are very active against gramnegative organisms. Ciprofloxacin is the most potent FQ against *P aeruginosa*. They lack consistent activity against gram-positive cocci and anaerobes. There is increasing resistance of *N gonorrhoeae* against ciprofloxacin, once considered the drug of choice, and thus, FQs are no longer recommended in the United States for this indication.
3. Third- and fourth-generation FQs (**gatifloxacin, levofloxacin**, and **moxifloxacin**) have, in addition to anti–gramnegative activity (modest activity against *P aeruginosa*), enhanced anti–gram-positive activity, but limited activity against anaerobes. All FQs lack activity against MRSA and multidrug nosocomial gramnegative organisms.

All FQs are active against atypical respiratory pathogens (ie, *Chlamydia pneumoniae*, *Mycoplasma pneumoniae*, and *Legionella pneumophila*).

Their wide spectrums of activity, along with their excellent bioavailability, good tissue penetration, and safety, have made the FQs very attractive. The challenge is to limit their use to the appropriate setting where their enhanced spectrum is required, in order to reduce the risk of resistance selection and to lengthen their useful life.

Pharmacokinetics

Most FQs can be administered both orally and IV. Due to their excellent bioavailability, oral regimens provide similar serum levels as IV formulations, and thus, the oral route should be used preferentially whenever possible (ie, the patient is allowed to eat and does not have active nausea or vomiting). FQs have good tissue penetration. They are excreted mainly by the kidneys and require dose reduction in renal dysfunction (except moxifloxacin).

Clinical Use

1. **Urinary tract infections (UTIs):** Use of quinolones for uncomplicated community-acquired UTI should be reserved for infection due to organisms resistant to first-line treatment with trimethoprim-sulfamethoxazole (TMP-SMX). Ciprofloxacin is preferred when *P aeruginosa* is suspected. FQs are very useful in complicated UTI (eg, pyelonephritis).
2. **Pelvic inflammatory disease** as part of the antibiotic regimen. When *N gonorrhoeae* is a

possibility, ceftriaxone is preferred over FQs due to increased resistance. In this setting, azithromycin or doxycycline should be added to treat the possibility of chlamydia.

3. **intraabdominal infections:** Ciprofloxacin plus metronidazole is a reasonable option (although usually, anti–*P aeruginosa* treatment is unnecessary) because this combination provides good anti–gramnegative and anaerobic activity.
4. **Community-acquired pneumonia (CAP):** The advanced-generation FQs (eg, gatifloxacin, levofloxacin, and moxifloxacin) are active against the common pathogens causing CAP (ie, *S pneumoniae, Haemophilus influenzae, Moraxella catarrhalis, Mycoplasma* and *Chlamydia* species, and *L pneumophila*). Consequently, they are included as a therapeutic option ("respiratory quinolones") in the guidelines of CAP. However, in order to avoid the development of bacterial resistance, macrolides are preferred.

Dosing in Normal Renal Function

See Table 44–2.

Adverse Effects

FQs are well tolerated. The most common adverse effects are gastrointestinal symptoms, primarily nausea (5%), and CNS symptoms (1–4%) mainly in the elderly (eg, headache, dizziness, sleep disturbance, alteration of mood). The third-and fourth-generation FQs can cause QT prolongation and arrhythmia. Quinolone use may be associated with tendon rupture (eg, Achilles, shoulder, or hand) and hence should be discontinued with the first sign of tendon pain.

Quinolones should be avoided in pregnancy and nursing mothers because of the potential effect on developing cartilage.

Resistance

With widespread use of the FQs (partially due to their oral administration), the emergence of quinolone-resistant bacteria resulted (eg, *P aeruginosa*, nosocomial Enterobacteriaceae, *N gonorrhoeae, Salmonella* species).

6. Macrolides

The macrolides inhibit protein synthesis by reversibly binding to the 50S ribosomal subunit. Although generally bacteriostatic, they may be bactericidal under certain conditions or against certain microorganisms. Because their structure is different from that of β-lactams, macrolides are useful for β-lactam–allergic patients. Dose reduction is not necessary in mild to moderate renal failure (for azithromycin, no dose adjustment is needed even in severe renal failure). Resistance to one macrolide implies cross-resistance to other macrolides.

1. **Erythromycin**, the first macrolide, is active against many gram-positive bacteria (streptococci, MSSA, but *not* enterococci). *Campylobacter jejuni, Bordetella pertussis, Haemophilus ducreyi, Mycoplasma*, *Chlamydia*, and *Legionella* are also susceptible. It is not active against Enterobacteriaceae. It can be administered orally (250–500 mg every 6 hours) or IV (250 mg–1 g every 6 hours). Because of its common gastrointestinal side effects, the newer macrolides are often preferred.
2. **Roxithromycin** has a similar spectrum of activity as erythromycin. It is given solely by the oral route (150 mg twice daily) with fewer gastrointestinal side effects. It is not available in the United

States.

3. The spectrum of activity of **clarithromycin** is similar to that of erythromycin except for enhanced activity against respiratory gramnegative bacteria (eg, *H influenzae*) and atypical mycobacteria. Only oral preparations are available (250–500 mg twice daily). Clarithromycin is relatively nontoxic.
4. **Azithromycin** is a macrolide compound with unique properties—high and sustained tissue antibiotic levels (which are much greater than the serum antibiotic levels) and prolonged tissue half-life (between 2 and 4 days), which decrease the duration of therapy needed. Its spectrum of activity is similar to that of clarithromycin. Both oral (250-mg tablet commonly distributed in a pack containing 6 tablets) and IV formulations are available. The dose and duration of treatment vary with the indication (eg, CAP: 500 mg on first day, then 250 mg once daily; chlamydia cervicitis: 1 g orally as a single dose).

Clinical Use

1. Community acquired pneumonia (CAP)
2. Sexually transmitted diseases:
   a. Azithromycin (1 g orally once) is as effective as doxycycline (100 mg twice daily for 7 days) in treating chlamydia urethritis and cervicitis; cotreatment with single-dose ceftriaxone (250 mg intramuscularly) is necessary.
   b. *H ducreyi* (chancroid) genital ulcer disease has been treated with a single dose of azithromycin 1 g orally.
   c. Azithromycin may be used to treat *Chlamydia trachomatis* in pelvic inflammatory disease.
3. Macrolides are an alternative, in β-lactam–allergic patients, for the treatment of infections caused by groups A and B streptococci and MSSA.
4. Clarithromycin is active against *Helicobacter pylori* in duodenal/gastric ulcer as part of a combination therapy.

Adverse Effects

Gastrointestinal side effects (eg, nausea, vomiting, diarrhea) may occur; mostly with erythromycin. Allergic reactions are uncommon and are generally mild. Drug interactions are important (eg, elevation of warfarin blood levels) and have been reviewed elsewhere. Azithromycin has the least drug interactions of all the macrolides.

7. Tetracycline Group

The tetracyclines are bacteriostatic and act by interfering with protein synthesis at the ribosomal level (ie, 30S subunit). All have common basic chemical structures and antimicrobial activity. **Doxycycline** is the tetracycline of choice due to its superior pharmacokinetic properties, enhanced compliance, and lesser toxicity. Recently, a new generation (ie, glycylcyclines) that is also active against resistant bacteria has been developed. The clinical candidate of this class is **tigecycline**.

Antimicrobial Activity

Tetracyclines are active against a wide variety of organisms including the following:

1. Community-acquired respiratory tract pathogens (ie, *S pneumoniae, H influenzae, M catarrhalis*, and *Mycoplasma*, *Legionella*, and *Chlamydia* species)
2. *C trachomatis*
3. *Treponema pallidum* (syphilis)
4. The drug of choice for the treatment of *Rickettsia* and *Brucella* (with gentamicin)
5. They are *not* reliably active against *N gonorrhoeae*. 6. Tigecycline is also active against a variety of gram-positive and gramnegative organisms (including VRE, MRSA, and *N gonorrhoeae*, but not *P aeruginosa*).

Pharmacokinetics

The oral route is most commonly used, except for treatment of severe pelvic inflammatory disease (PID). Absorption is improved if the antibiotic is taken 1 hour before or 2 hours after meals. Doxycycline's long half-life permits dosing every 12 to 24 hours, thus improving compliance. Tetracyclines are excreted via the urine, except for doxycycline, which is excreted in the feces (therefore, there is no need for doxycycline dose adjustment in renal failure). Oral contraceptive efficacy may be decreased with simultaneous use of tetracyclines.

Clinical Use in Obstetrics & Gynecology

Doxycycline is the drug of choice for genital infections caused by *C trachomatis* (eg, PID, cervicitis, lymphogranuloma venereum) in nonpregnant women.

1. In mucopurulent cervicitis, doxycycline 100 mg twice daily orally is given for 7 days (or single-dose azithromycin 1 g) in addition to a single dose of intramuscular ceftriaxone 250 mg (to treat *N gonorrhoeae*).
2. For PID, doxycycline 100 mg twice daily orally is given for 14 days (in combination with ceftriaxone and metronidazole). It can be administered IV with the same dosing regimen, but the oral route is preferred whenever possible.
3. Doxycycline is an alternative to penicillin for the treatment of syphilis (*not* in pregnant woman or in neurosyphilis).

The equivalent dose of **tetracycline** is 250–500 mg (orally only) every 6 hours.

Adverse Effects & Contraindications

1. Hypersensitivity reactions with fever or skin rashes are uncommon.
2. Toxic photosensitivity reactions consisting of a red rash on areas exposed to sunlight can occur. Patients should avoid intense sun exposure during doxycycline treatment.
3. Esophageal ulceration can occur with doxycycline. Patients should be told to take the drug while sitting and with adequate amount of fluids.
4. Thrombophlebitis can occur with IV doxycycline use.
5. Superinfection with Candida of the anogenital region can occur.
6. Tetracyclines should be avoided by pregnant women due to a possible hepatotoxicity to the mother and dental deformities in the child (also during lactation).

8. Clindamycin

Clindamycin inhibits protein synthesis at the ribosomal level (ie, 50S subunit) and is generally bacteriostatic. Its spectrum of activity includes gram-positive cocci (groups A and B streptococci, MSSA) and anaerobes, although there is increasing resistance of *Bacteroides* species to clindamycin. It is *not* active against gramnegative aerobes (eg, Enterobacteriaceae) or enterococci.

Pharmacokinetics

Clindamycin is well absorbed from the gastrointestinal tract, and food does not decrease its absorption. Therapeutic blood levels can be achieved by the oral or parenteral routes of administration. It penetrates most body tissues well, but not the cerebrospinal fluid. It is metabolized primarily by the liver; therefore, doses of clindamycin should be reduced in severe hepatic insufficiency. Dose adjustment is *not* required in renal failure. The oral dose is 300–450 mg every 6–8 hours. The IV dose is 600–900 mg every 8 hours.

Clinical Use in Obstetrics & Gynecology

1. In intraabdominal/pelvic infections (eg, tubo-ovarian abscess), clindamycin (which is active against gram-positive cocci and anaerobes) must be combined with an agent active against gramnegative organisms (eg, gentamicin, ciprofloxacin). Because *B fragilis* plays an important role in these infections and there is increasing resistance of *B fragilis* to clindamycin, many experts turned to metronidazole.
2. Clindamycin is an option for mixed aerobic and anaerobic perineal infection (ie, soft tissue infection) in combination with an agent active against gramnegative organisms.
3. Clindamycin is an alternative drug for the treatment of groups A and B streptococci and MSSA in patients allergic to both penicillin and cephalosporins.
4. Clindamycin is the drug of choice (in combination with high-dose penicillin) for the treatment of necrotizing fasciitis caused by group A Streptococcus.
5. Clindamycin 300 mg orally twice a day or 2% vaginal cream 5 g intravaginally at bedtime (both for 7 days) or clindamycin ovules 100 mg intravaginally at bed time for 3 days is an alternative to metronidazole for treatment of bacterial vaginosis.

Adverse Effects

1. Diarrhea is the most significant side effect of clindamycin: Antibiotic-associated diarrhea occurs in up to 20% of patients; *C difficile*–associated diarrhea (CDAD) occurs less frequently. When CDAD occurs, clindamycin should be discontinued if possible and oral (or IV) metronidazole or (in severe cases) oral vancomycin started.
2. Allergic reactions (eg, rash and fever) can occur.
3. Minor reversible elevations of hepatocellular enzymes are frequent.

9. Metronidazole

Metronidazole is mainly an agent for the treatment of anaerobic infections including *B fragilis* and *Gardnerella vaginalis*. It also has antiparasitic activity, including *Entamoeba histolytica, Giardia lamblia*, and *Trichomonas vaginalis*. Metronidazole inhibits DNA synthesis and is rapidly bactericidal.

Pharmacokinetics

The drug is absorbed very well and can be taken with food. Serum levels are similar after equivalent oral and IV doses. It has excellent penetration into almost all tissues. The drug is metabolized in the liver and excreted in the kidney. The usual daily dose is 500 mg orally or IV every 8 hours. Dose reduction is required in severe renal failure and significant hepatic impairment.

Clinical Use in Obstetrics & Gynecology

1. Metronidazole is the drug of choice for *Bacteroides* species, *C difficile*-associated disease, *G vaginalis*, *E histolytica*, and *G lamblia*.
2. It is indicated (in combination) for mixed aerobic/anaerobic infections (eg, intraabdominal and pelvic infections).
3. For Trichomonas vaginitis, the recommended dose is 2 g orally as a single dose or 500 mg twice daily for 7 days. Both sexual partners should be treated.
4. For bacterial vaginosis, the recommended regimens are 500 mg orally twice daily for 7 days or vaginal gel (1 applicator intravaginally) for 5 days. Treatment of sexual partners is not recommended unless balanitis is present. Topical treatment of bacterial vaginosis is not recommended in pregnancy.

Adverse Effects

In general, metronidazole is well tolerated.

1. Alcoholic beverages should not be consumed while taking metronidazole because of a disulfiram-like effect (ie, nausea, vomiting, and headaches).
2. Patients complain of a metallic unpleasant taste while on oral therapy.
3. With prolonged use, peripheral neuropathy may develop.

10. Vancomycin

Vancomycin is the first glycopeptides antibiotic. The primary effect of glycopeptides is inhibition of cell wall synthesis. Vancomycin is active *only* against gram-positive organisms. Except for enterococci, vancomycin is bactericidal; however, the addition of gentamicin increases the bactericidal activity against enterococci. The excessive use of vancomycin has contributed to the emergence of VRE and also *S aureus* with intermediate resistance or complete resistance to vancomycin. Prudent use of vancomycin is essential to preserve the effectiveness of this important antibiotic.

Pharmacokinetics & Dosage

Vancomycin is poorly absorbed. Very high stool concentrations after oral administration make it active against *C difficile*-associated disease (CDAD). The route of administration is mostly IV with diverse tissue penetration. Initial doses are based on actual weight, 15–20 mg/kg IV every 12 hours (over 1–2 hours to avoid the “red man syndrome”). Subsequent doses are based on measured trough serum levels. Target trough level in serious infections should be 15–20 μg/mL. Because vancomycin is excreted primarily by the kidneys, in renal failure, the dose must be reduced or the interval between doses increased.

Clinical Use in Obstetrics & Gynecology

Vancomycin is less active than β-lactam antibiotics (eg, nafcillin, oxacillin) for MSSA, and thus, β-lactam antibiotics should be preferred in this setting.

1. Vancomycin is the treatment of choice for MRSA infections.
2. It is an alternative for the treatment of MSSA and groups A and B Streptococcus in patients with a history of anaphylaxis to β-lactam antibiotics.
3. For severe cases of *C difficile* diarrhea, vancomycin 125 mg every 6 hours for 10–14 days is indicated instead of metronidazole. Discontinue other antibiotic agents if possible.

Adverse Effects

1. If vancomycin is infused too rapidly, it may cause flushing of the face, neck, or torso ("red man syndrome"), pruritus, and hypotension. To avoid this, vancomycin should be infused no more rapidly than 500 mg/h. Because this reaction is not immunologically mediated, it does not preclude further use.
2. Allergy (rashes other than red man syndrome) occurs in 5% of patients.
3. Nephrotoxicity and ototoxicity are very uncommon (occur mostly when vancomycin is used in combination with another nephrotoxic or ototoxic drug such as an aminoglycoside).

11. Linezolid

Linezolid belongs to the oxazolidinones; it interferes with bacterial protein synthesis by binding at the 50S ribosomal subunit. It is bacteriostatic and active only against gram-positive bacteria including MRSA and VRE, which are the main indications for use (although MRSA and VRE resistance to linezolid was described). Oral drug is 100% bio-available. The oral and IV doses are 600 mg every 12 hours; no dose modification is required for renal or hepatic failure. Reversible myelosuppression (ie, thrombocytopenia, anemia, and neutropenia) has been reported, most often after more than 2 weeks of therapy. Its use in obstetric and gynecologic practice currently is limited.

12. Spectinomycin

Spectinomycin structure is similar (but not identical) to the aminoglycosides. It inhibits ribosomal protein synthesis and is bactericidal. Spectinomycin is used *only* as an alternative agent for the treatment of *N gonorrhoeae* when the drugs of choice (eg, cephalosporin or azithromycin) cannot be used or in resistant strains. One injection of 2 g intramuscularly is given. No dose adjustment is required in renal failure. There are no known serious adverse reactions.

13. Trimethoprim-Sulfamethoxazole

The combination of trimethoprim and sulfamethoxazole (TMP-SMX) inhibits 2 sequential steps in the synthesis of folic acid by bacteria. Alone, each agent is bacteriostatic, but together, they are synergistic and bactericidal. The combination is available in oral and IV forms of 80 mg trimethoprim and 400 mg sulfamethoxazole. There are also double-strength (DS) tablets (160 mg trimethoprim and 800 mg sulfamethoxazole).

Antimicrobial Activity

1. TMP-SMX has a wide spectrum of activity against gram-positive cocci (including some strains of MRSA) and gramnegative bacteria.
2. It is *not* active against enterococci, *P aeruginosa*, or anaerobes.
3. It is active against *L monocytogenes, Nocardia* species, and *Pneumocystis* (*carinii*) *jiroveci*.

Pharmacokinetics

Because oral TMP-SMX is well absorbed, the oral route is usually preferred. Each component is distributed widely to most tissues. It is excreted mainly by the kidneys; therefore, dose reduction is required in renal failure. The long half-life allows twice-daily dosing.

Clinical Use in Obstetrics and Gynecology

1. TMP-SMX is used to treat acute uncomplicated UTI (cystitis) in females (in the presence of <20% resistance of local *Escherichia coli*). The dose is 960 mg twice a day for 3 days.
2. It is useful for susceptible pathogens in the treatment of pyelonephritis.
3. In a young woman with recurrent episodes of uncomplicated UTI (3 or more episodes per year), TMP-SMX 1 single-strength tablet orally every 24 hours long term, after eradication of infection, is a possibility. An alternative is self-administered single-dose treatment (TMP-SMX DS, 2 tablets, 320/1600 mg) at symptom onset or 1 DS tablet after coitus.
4. TMP-SMX is an alternative in *L monocytogenes* infection (eg, meningitis or amnionitis) in a penicillin-allergic patient.
5. It is considered the drug of choice for the treatment and prevention of *P jiroveci* (*carinii*) pneumonia.

Toxicity & Side Effects

Although skin rashes are common, this combination usually is well tolerated.

1. Mild gastrointestinal symptoms occur in 3%.
2. Skin rashes occur in 3–5%; most are benign; however, severe skin rashes (eg, exfoliative dermatitis, Stevens-Johnson syndrome) may occur. Rashes are more common in HIV patients.
3. Thrombocytopenia and neutropenia can occur. Complete blood count should be performed weekly.
4. It should be avoided in patients with glucose-6-phosphate dehydrogenase deficiency because hemolysis can be precipitated.
5. If TMP-SMX is used in patients receiving warfarin, it enhances the response to warfarin; thus, the risk of bleeding is increased.

14. Urinary Antiseptics (Nitrofurantoin, Fosfomycin)

Urinary antiseptics are agents that concentrate in the urine but do not produce therapeutic levels in the serum. Therefore, they are useful only for the treatment of lower UTIs. This feature has advantages, including reduced suppression of normal flora.

Nitrofurantoin

Nitrofurantoin is active for both gramnegative (eg, Enterobacteriaceae) and gram-positive (eg, enterococci, coagulase-negative staphylococci) bacteria causing UTI. *Pseudomonas* species are resistant. It is well absorbed (preferably taken with food) but reaches therapeutic concentrations only in urine. The drug is contraindicated in creatinine clearance of <40 mL/min (because the excretion to urine is reduced and the drug accumulates in the serum) and in hepatic insufficiency. The urine should *not* be alkalinized because the drug effect is reduced in alkaline urine.

For uncomplicated UTI, nitrofurantoin is taken for 3–7 days at 100 mg twice daily. For the prophylaxis of recurrent uncomplicated UTI, it can be given daily at bedtime or postcoital as a single 50- or 100-mg dose, but pulmonary toxicity is a risk with long-term use. Nitrofurantoin may be administered as a combination of macrocrystals/monohydrate salt (nitrofurantoin capsules, Macrobid). The usual dose of this combination is 100 mg every 12 hours.

Skin rashes occur in 1–5% of patients and are reversible. Major adverse effects include pneumonitis and polyneuropathies. Because these are more common in the elderly, Macrodantin should be administered with caution to people 60 years of age or older.

Fosfomycin

Fosfomycin is used as a single oral dose of 3 g for treatment of uncomplicated UTI in women. The drug acts on the bacterial cell wall. It is active against the common pathogens of community-acquired UTI (eg, Enterobacteriaceae, *Staphylococcus saprophyticus*, and enterococci). *P aeruginosa* are usually resistant.

It is absorbed rapidly and excreted unchanged in the urine. Bactericidal concentrations persist for 24–48 hours in the urine. It is generally well tolerated, with diarrhea occurring in 9%. It may play a useful role in settings were compliance is a problem. Its high cost compared to the 3-day effective course of TMP-SMX is a limitation.

15. Antifungal Drugs

There are 3 main groups of antifungal agents: polyenes (eg, amphotericin B), azoles (eg, fluconazole), and echinocandins (eg, caspofungin). The major agents will be discussed briefly.

Amphotericin B

Amphotericin B is active and bactericidal against most invasive fungal pathogens (eg, *Candida* species and molds). It is poorly absorbed; hence, systemic infections must be treated IV. The dose for seriously ill patients is 0.7–1.0 mg/kg/d, typically infused over 4 hours. Thrice-weekly regimens may be used to minimize side effects. Elimination occurs via the biliary tract. Although amphotericin B is nephrotoxic, it does not accumulate in renal failure, and dose adjustments are made to minimize toxicity.

Fever and chills during infusion are common and usually diminish after the first week of treatment. Pretreatment by acetaminophen or ibuprofen is often used to reduce these symptoms. Nephrotoxicity is the main serious drug effect that limits its use. The incidence of renal failure may be reduced by saline infusion before each dose. Renal failure is usually reversible. The FDA pregnancy risk category is B.

To overcome the adverse effect–related dosage limitation, a liposomal delivery system was developed (eg, liposomal amphotericin [AmBisome]), allowing treatment with higher doses without increased systemic toxicity.

Triazoles (Fluconazole, Voriconazole)

These fungistatic agents are effective and less toxic alternatives to amphotericin B for the treatment of many systemic fungal infections. There are also some topical preparations and vaginal suppositories (eg, clotrimazole). They act by inhibition of the biosynthesis of ergosterol in the fungal cell membrane and, as a result, inhibition of cell growth.

Fluconazole

Fluconazole is available in both IV and oral preparations. Because absorption is excellent, the daily doses for oral and IV therapy are the same. It is excreted mainly in the kidneys; hence, dose adjustment is required in renal failure. It is active against yeasts (eg, *Candida species, Cryptococcus species*) but *not* against molds. The usual daily dose is 200–400 mg orally or IV once daily. In gynecology, it is often used to treat *Candida* vaginitis with a single oral dose of 150 mg. Alternatively, for this indication, there are many preparations of intravaginal azoles (eg, clotrimazole, miconazole) that are administered from one dose to 7–14 days. Fluconazole is well tolerated; side effects include rash (in <5%) and nausea and vomiting.

Voriconazole

Voriconazole is active against yeasts but also against molds. It is the drug of choice for the treatment of invasive aspergillosis. Voriconazole is available in both IV and oral preparations with excellent bioavailability. A loading dose of 6 mg/kg IV every 12 hours is followed by a maintenance dose of 4 mg/kg every 12 hours. With creatinine clearance of less than 50 mL/min, switch to oral therapy (due to accumulation of IV vehicle). The oral dose is 200 mg twice daily for patients who weigh more than 40 kg. Dose adjustment is necessary in hepatic insufficiency. The most frequent side effects include reversible visual disturbances and rash, both in 20%.

Echinocandins

Caspofungin is the first echinocandin. Its mechanism of action is inhibition of glucan (ie, an integral component of the fungal cell wall) synthesis. It is used to treat invasive candidiasis and invasive aspergillosis (an alternative to voriconazole). It is only available as IV formulation. Dose adjustment is necessary for patients with liver failure but *not* in renal failure. Caspofungin 70 mg IV on day 1 is followed by 50 mg IV once daily for maintenance. It is remarkably *not* toxic. There are also new agents in this class like **anidulafungin**. The FDA pregnancy risk category of the echinocandins is C.

16. Antiviral Drugs (Acyclovir, Valacyclovir, Famciclovir)

Only antiherpesvirus drugs will be discussed and *not* antiretrovirals or anticytomegalovirus agents.

Acyclovir acts by inhibition of viral DNA polymerase and thus blocks viral DNA synthesis. It is activated by the viral thymidine kinase. The antiviral spectrum of acyclovir is limited to herpesviruses (eg, herpes simplex virus [HSV] and varicella-zoster virus [VZV]). **Valacyclovir** is a prodrug of acyclovir. **Famciclovir** is a prodrug of penciclovir with similar spectrum of activity as acyclovir. The bioavailability of oral acyclovir is low (15–20%). Valacyclovir and famciclovir are readily absorbed after oral administration (bioavailability of 54–70% and 77%, respectively) and rapidly converted to their active form (acyclovir and penciclovir, respectively). Dose adjustment is required for these drugs in renal failure.

Clinical Use in Obstetrics & Gynecology

Acyclovir is the agent of choice for HSV and VZV and can be administered both orally and IV. Valacyclovir and famciclovir are comparably effective as oral alternatives and offer more convenient dosing regimen.

1. Acyclovir is effective in primary genital HSV infections. In outpatients, oral acyclovir (400 mg every 8 hours for 7–10 days) is used. Alternatively, oral valacyclovir or famciclovir (1,000 mg twice a day and 250 mg 3 times a day, respectively, both for 7–10 days) may be used. Topical acyclovir is less effective, and its use is discouraged. IV acyclovir (5 mg/kg every 8 hours for 5–7 days) can be used in hospitalized patients with severe primary HSV infections.
2. In recurrent genital HSV infections, patient-initiated treatment during the prodrome or at the first lesion appearance is associated with 2-day reduction in duration of symptoms. The options are acyclovir 800 mg 3 times a day for 2 days; valacyclovir 500 mg twice a day for 3 days; and famciclovir 1000 mg twice a day for 1 day.
3. Suppressive therapy reduces the frequency of genital HSV recurrences by 70–80% among patients who suffer frequent recurrences (ie, >6 per year). Effective regimens include acyclovir 400 mg twice a day, famciclovir 250 mg twice a day, and valacyclovir 1 g once daily.
4. Acyclovir treatment late in pregnancy reduces the frequency of caesarean sections among women who have recurrent genital herpes by diminishing the frequency of recurrences at term; the effect of antiviral therapy late in pregnancy on the incidence of neonatal herpes is not known. No data support the use of antiviral therapy among HSV-seropositive women without a history of genital herpes.
5. High-dose acyclovir is effective treatment for chickenpox and VZV in older adults.
6. For cytomegalovirus (CMV) infections, these agents are ineffective.

Toxicity & Side Effects

Oral agents (ie, acyclovir, valacyclovir, and famciclovir) are generally well tolerated. IV acyclovir may cause phlebitis and, in 5%, nephrotoxicity. Adequate prehydration may prevent it.

Available data do not indicate an increased risk for major birth defects in women treated with acyclovir during the first trimester, compared with the general population. However, data regarding prenatal exposure to valacyclovir and famciclovir are too limited to provide useful information on pregnancy outcomes.

ANTIMICROBIAL PROPHYLAXIS IN SURGERY

Indications

Antimicrobial prophylaxis reduces the incidence of wound infection after certain operations. It should be used only for procedures with high infection rates such as clean contaminated procedures (ie, involving mucosal surfaces such as the vagina), operations involving implantation of prosthetic material (eg, general surgeries where meshes are used, artificial joints), and procedures where the consequences of infection are serious.

Organisms Involved

For most gynecologic surgical site infections, the source of pathogens is the endogenous flora of the patient’s skin or vagina. Gynecologic surgical procedures, such as laparotomies or laparoscopies, do not breach surfaces colonized with bacteria from the vagina, and infections after these procedures more commonly result from skin bacteria only. The major pathogen in these clean surgeries is *S aureus*. Procedures breaching the endocervix, such as hysterosalpingogram, intrauterine device (IUD) insertion, endometrial biopsy, chromotubation, and dilation and curettage, may seed the endometrium and the fallopian tubes with microorganisms found in the upper vagina and endocervix (eg, Enterobacteriaceae, group B *Streptococcus*).

Timing

To be optimally effective, antibiotics must be given so that good tissue levels are present at the time of incision and for the duration of the operation. To achieve that goal, antibiotics should be started preferably less than 1 hour before incision for most agents (except for vancomycin and quinolones because they are infused over an hour). A convenient time to administer antibiotic prophylaxis is just before induction of anesthesia.

However, timing of antibiotic prophylaxis has historically been different with regard to caesarean delivery; the prophylactic antibiotic was given only after clamping of the umbilical cord. The rationale for this was to avoid exposure of the neonate to the antibiotics and to prevent any masking of newborn culture results in cases of a suspected newborn infection. In 2007, Sullivan and colleagues reported results from a randomized, prospective, double-blind trial comparing the administration of cefazolin an hour prior to skin incision with administration after cord clamping. The group receiving the earlier antibiotics had less overall infectious morbidity and less endometritis, with no associated increase in neonatal adverse effects. Other similar studies have found comparable results. In September 2010, this evidence prompted the American College of Obstetricians and Gynecologists (ACOG) to issue a Committee Opinion advocating that all patients undergoing caesarean delivery be given appropriate prophylactic antibiotics *prior* to skin incision.

Duration

In most instances, a single dose is sufficient. For procedures lasting more than 2 half-lives of prophylactic agent, intraoperative supplementary dose(s) may be required. In most cases, prophylaxis is not extended beyond 24 hours.

Antibiotic Prophylaxis Choices in Selected Procedures

1. Hysterectomy, either vaginal or abdominal: IV cefazolin 1–2 g 30 minutes before incision.
2. Cesarean section: IV cefazolin 1–2 g 30 minutes *before* incision.
3. Surgical abortion: first trimester, doxycycline 100 mg before procedure and 200 mg after; second trimester, IV cefazolin 1–2 g before procedure.
4. *No* antibiotic prophylaxis is indicated during IUD insertion, hysteroscopy, and endometrial biopsy.

An alternative in patients with immediate hypersensitivity to penicillins is clindamycin plus gentamicin. MRSA should be considered when it is prevalent in the community or in institutions where the rate of postoperative MRSA infection is high; in these circumstances, vancomycin should be considered.

Perioperative, Intraoperative, & Postoperative Complications in Gynecologic Surgery

Cecilia K. Wieslander, MD
Danielle D. Marshall, MD

PREOPERATIVE COMPLICATIONS

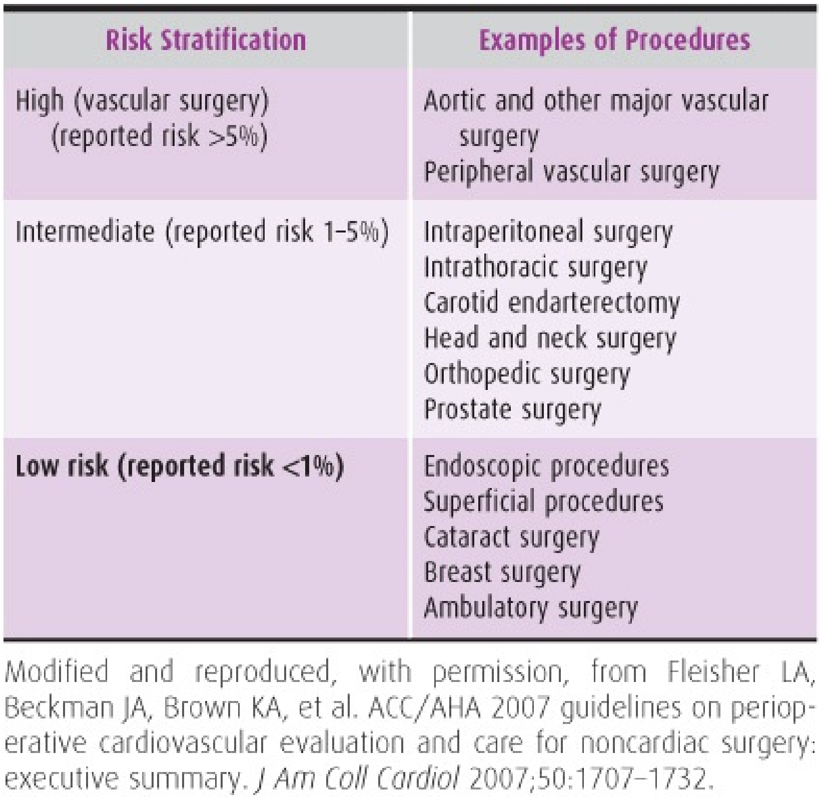
One of the main purposes of the preoperative history and physical exam is to identify any preoperative medical comorbidity that may lead to an increased perioperative morbidity or mortality. If comorbidities are identified, the surgeon should obtain medical consultation to ensure that the patient’s medical conditions are optimized and stable enough to proceed with surgery at an acceptable risk.

CARDIOVASCULAR DISEASE

Clinical Findings

Most gynecologic surgeries fall in the low (<1%) or intermediate (1–5%) risk of cardiac death or nonfatal myocardial infarction (Table 45–1). It is crucial to obtain a careful preoperative history to discover cardiac and/or comorbid diseases that would place the patient in a high surgical risk category. If the patient is found to have active cardiac conditions, such as unstable coronary syndrome, decompensated heart failure, significant arrhythmias, or severe valvular disease, the surgery should be delayed or cancelled (unless emergent), and the patient should be evaluated and treated (Table 45–2). One should also determine if the patient has a prior history of a pacemaker, implantable cardioverter-defibrillator, orthostatic intolerance, or other clinical risk factors that are associated with increased perioperative cardiovascular risk (Table 45–2). If the patient has a history of cardiac disease, any recent change in symptoms must be elicited. In addition, one should record current medications including doses and any use of alcohol, tobacco, and over-the-counter and illicit drugs. The history should also include the patient’s functional capacity (Table 45–3). Assessing a person’s capacity to perform common daily tasks correlates well with maximum oxygen uptake by treadmill testing.

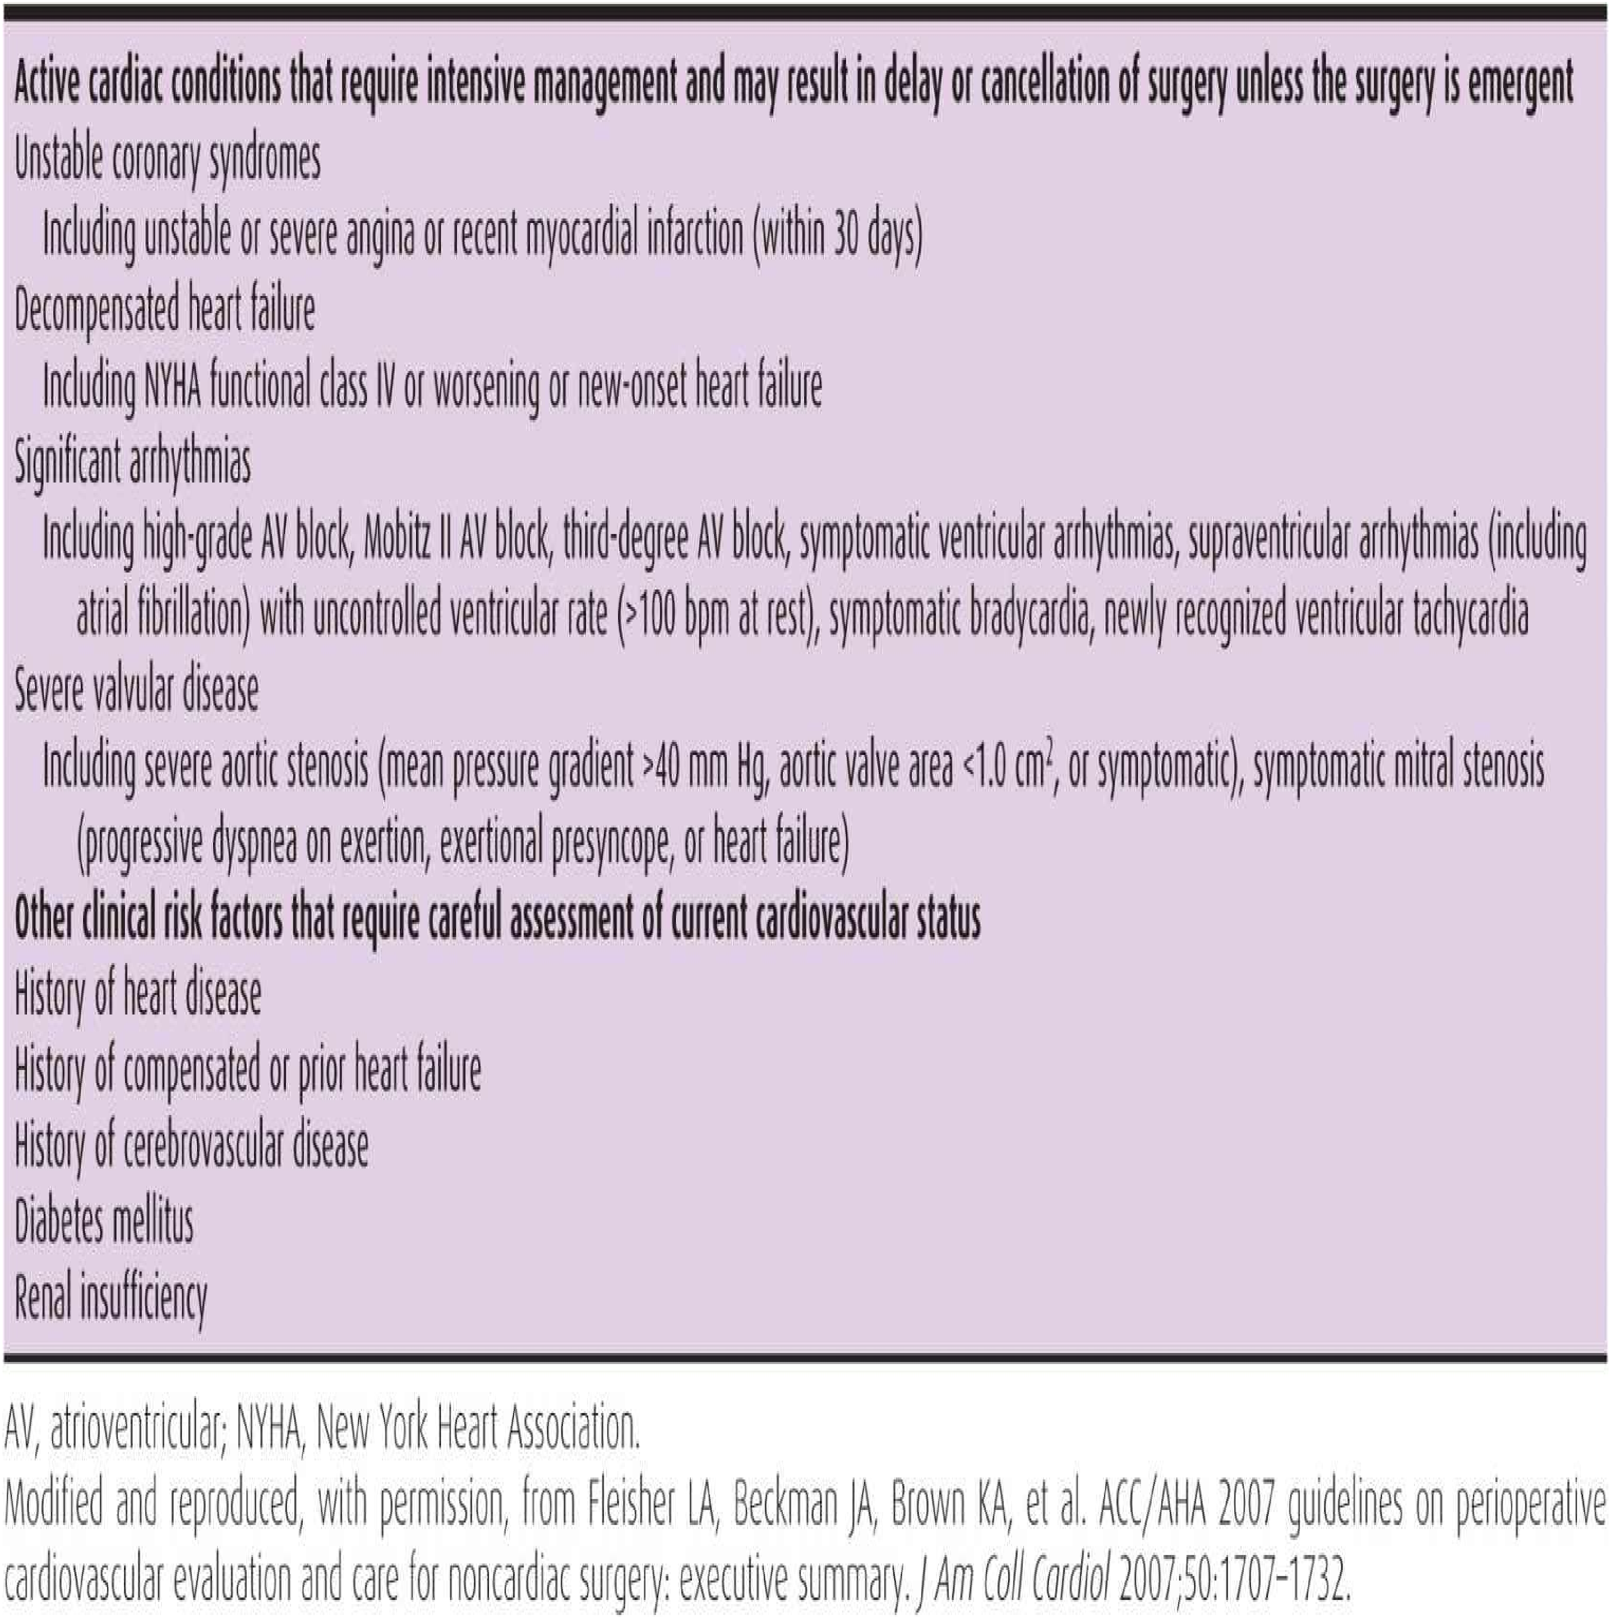
Table 45–1. Cardiac risk (cardiac death and nonfatal myocardial infarction) for noncardiac procedures.



Risk Stratification	Examples of Procedures
High (vascular surgery) (reported risk >5%)	Aortic and other major vascular surgery Peripheral vascular surgery
Intermediate (reported risk 1–5%)	Intraperitoneal surgery Intrathoracic surgery Carotid endarterectomy Head and neck surgery Orthopedic surgery Prostate surgery
Low risk (reported risk <1%)	Endoscopic procedures Superficial procedures Cataract surgery Breast surgery Ambulatory surgery

Modified and reproduced, with permission, from Fleisher LA, Beckman JA, Brown KA, et al. ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: executive summary. *J Am Coll Cardiol* 2007;50:1707–1732.

Table 45–2. Clinical risk factors for increased perioperative cardiovascular complications (myocardial infarction, heart failure, death).



Active cardiac conditions that require intensive management and may result in delay or cancellation of surgery unless the surgery is emergent

- Unstable coronary syndromes
  - Including unstable or severe angina or recent myocardial infarction (within 30 days)
- Decompensated heart failure
  - Including NYHA functional class IV or worsening or new-onset heart failure
- Significant arrhythmias
  - Including high-grade AV block, Mobitz II AV block, third-degree AV block, symptomatic ventricular arrhythmias, supraventricular arrhythmias (including atrial fibrillation) with uncontrolled ventricular rate (>100 bpm at rest), symptomatic bradycardia, newly recognized ventricular tachycardia
- Severe valvular disease
  - Including severe aortic stenosis (mean pressure gradient >40 mm Hg, aortic valve area <1.0 cm^2, or symptomatic), symptomatic mitral stenosis (progressive dyspnea on exertion, exertional presyncope, or heart failure)

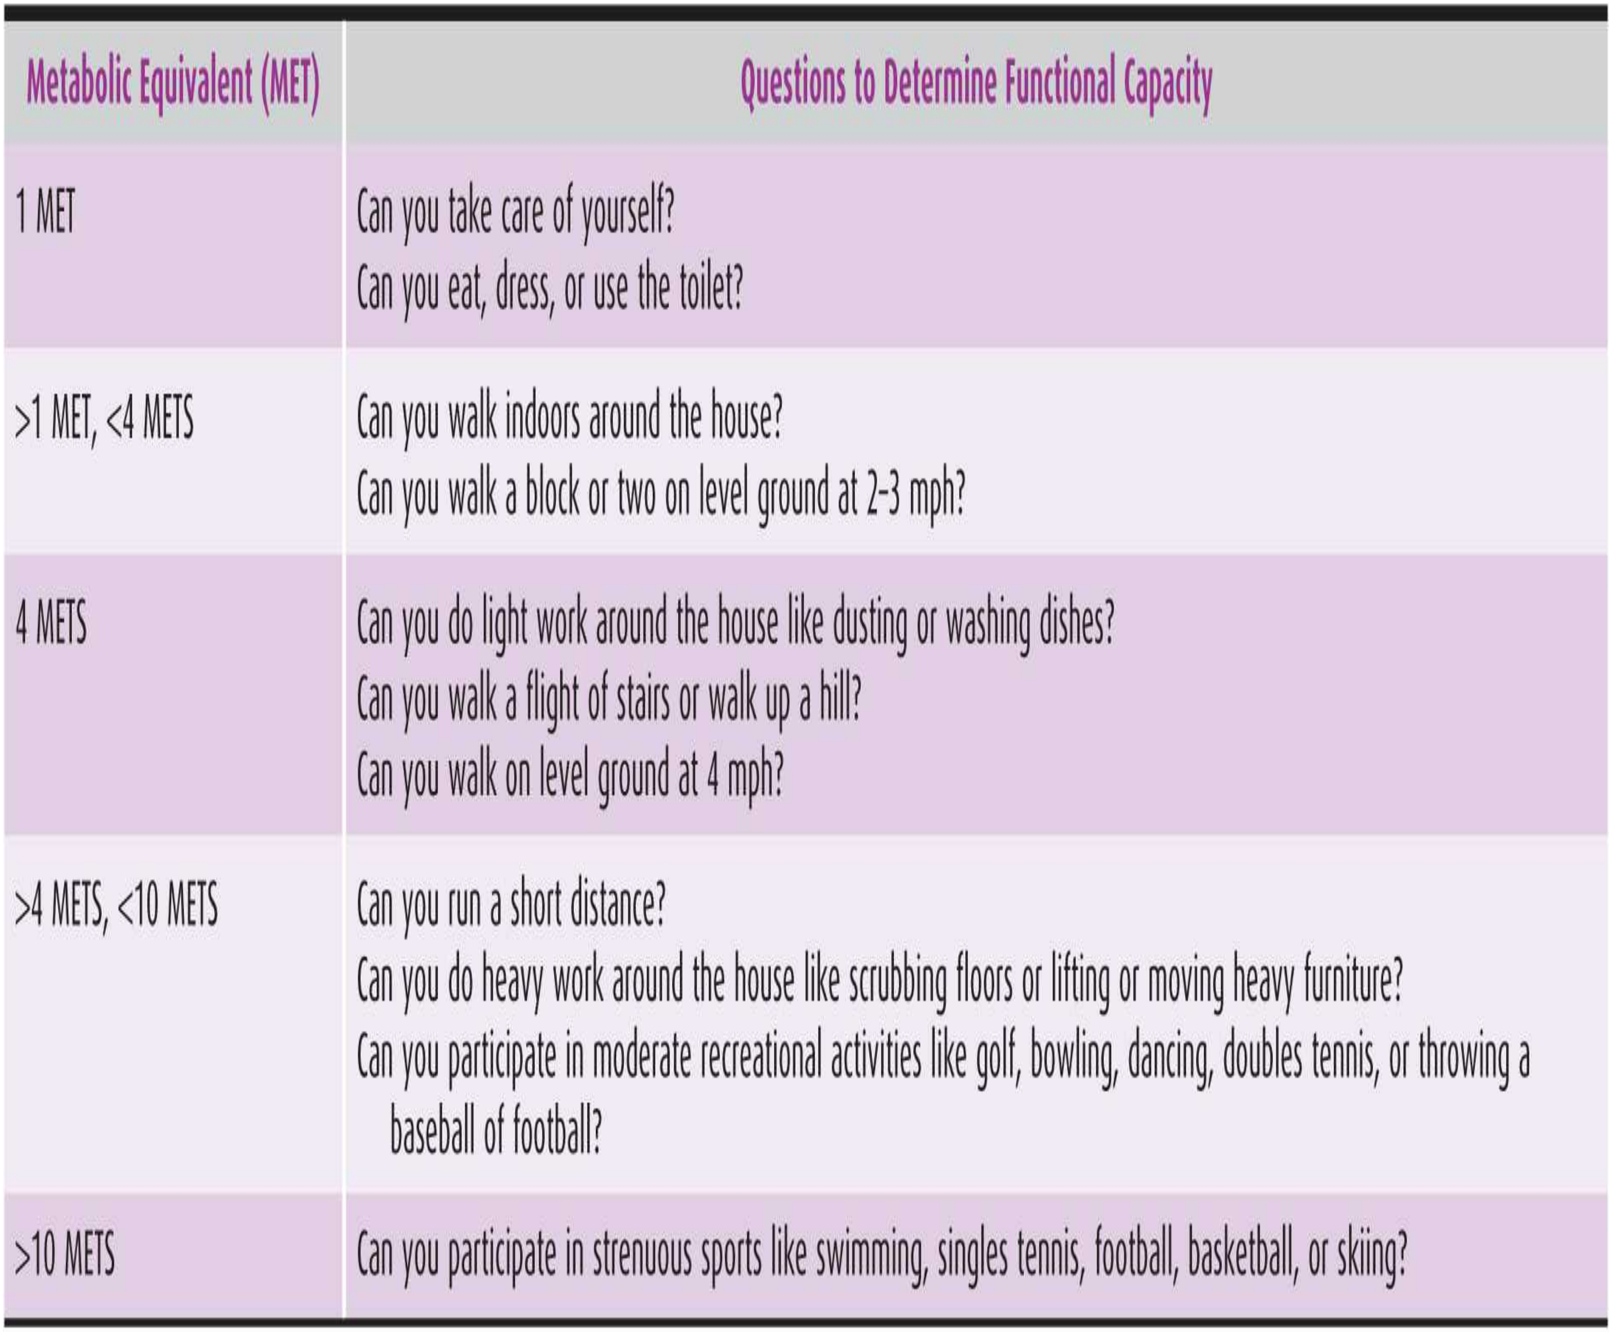
Other clinical risk factors that require careful assessment of current cardiovascular status

- History of heart disease
- History of compensated or prior heart failure
- History of cerebrovascular disease
- Diabetes mellitus
- Renal insufficiency

AV, atrioventricular; NYHA, New York Heart Association.

Modified and reproduced, with permission, from Fleisher LA, Beckman JA, Brown KA, et al. ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: executive summary. *J Am Coll Cardiol* 2007;50:1707–1732.

Table 45–3. Estimated energy requirements for various activities.



Metabolic Equivalent (MET)	Questions to Determine Functional Capacity
1 MET	Can you take care of yourself? Can you eat, dress, or use the toilet?
>1 MET, <4 METS	Can you walk indoors around the house? Can you walk a block or two on level ground at 2-3 mph?
4 METS	Can you do light work around the house like dusting or washing dishes? Can you walk a flight of stairs or walk up a hill? Can you walk on level ground at 4 mph?
>4 METS, <10 METS	Can you run a short distance? Can you do heavy work around the house like scrubbing floors or lifting or moving heavy furniture? Can you participate in moderate recreational activities like golf, bowling, dancing, doubles tennis, or throwing a baseball of football?
>10 METS	Can you participate in strenuous sports like swimming, singles tennis, football, basketball, or skiing?

Modified and reproduced, with permission, from Fleisher LA, Beckman JA, Brown KA, et al. ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: executive summary. *J Am Coll Cardiol* 2007;50:1707–1732.

The American College of Cardiology/American Heart Association 2007 Guidelines on Perioperative Cardiovascular Evaluation and Care for Noncardiac Surgery recommend a stepwise approach to perioperative cardiac assessment.

Step 1: Does the patient need emergency noncardiac surgery? If yes, one should proceed with surgery and perioperative surveillance and postoperative stratification and risk factor management. If no, one should proceed with step 2.

Step 2: Does the patient have active cardiac conditions (see Table 45–2)? If yes, the surgery should be postponed and the conditions evaluated and treated. If no, proceed with step 3.

Step 3: Is the planned procedure a low-risk surgery (see Table 45–1)? If yes, proceed with the planned surgery. If no, proceed with step 4.

Step 4: Does the patient have good functional capacity (≥4 metabolic equivalents [MET]; see Table

45–3) without symptoms? If yes, proceed with planned surgery. If no, proceed with step 5.

Step 5: If the patient has poor functional capacity, is symptomatic, or has unknown functional capacity, then the presence of active clinical risk factors determines the need for further evaluation. Clinical risk factors include a history of heart disease, compensated or prior heart failure, cerebrovascular disease, diabetes mellitus, and renal insufficiency.

- ≥3 clinical risk factors + high-risk surgery: testing should be considered if it will change management.
- ≥3 clinical risk factors + intermediate surgery: proceed with planned surgery with heart rate control with beta-blocker or consider noninvasive testing if it will change management.
- 1 or 2 clinical risk factors + high-risk surgery: proceed with planned surgery with heart rate control with beta-blocker or consider noninvasive testing if it will change management.
- 1 or 2 clinical risk factors + intermediate surgery: proceed with planned surgery with heart rate control with beta-blocker or consider noninvasive testing if it will change management.
- No clinical risk factors: proceed with planned surgery.

Treatment

A. Coronary Artery Disease

In patients with known or previous occult coronary artery disease, one has to determine the amount of myocardium in jeopardy, the ischemic threshold, the ventricular function, and whether the patient’s condition is optimized. Selective noninvasive testing can be used to determine the patient risk of ischemia during surgery.

B. Hypertension

Induction of anesthesia causes an increase in blood pressure and heart rate due to sympathetic activation. These changes are more pronounced in patients with untreated hypertension than in patients with well-controlled hypertension. Elective surgery should be delayed for stage 3 hypertension (systolic blood pressure ≥180 mm Hg and diastolic blood pressure ≥100 mm Hg). If emergent surgery is needed, rapid-acting intravenous agents should be used to control the blood pressure perioperatively.

Patients should continue taking their antihypertensive medications with a sip of water the morning of surgery, and medications should be resumed postoperatively. Some physicians recommend withholding angiotensin-converting enzyme inhibitors and angiotensin receptor antagonists the morning of surgery. These medications can be restarted postoperatively after the patient is euvolemic to decrease the risk of perioperative renal dysfunction.

Postoperatively, reversible causes of hypertension, such as pain, anxiety, hypervolemia, hypercarbia, hypoxia, and bladder distension should be treated. Patients on chronic antihypertensive medications should restart their usual medications as needed. Patients with sustained systolic blood pressure greater than 180 mm Hg or diastolic blood pressure greater than 110 mm Hg should be treated once reversible causes have been addressed.

C. Valvular Heart Disease

In patients with symptomatic aortic stenosis, elective non-cardiac surgery should be postponed or cancelled because the mortality risk is approximately 10%. Such patients require aortic valve replacement before elective but necessary noncardiac surgery. If the aortic stenosis is severe but asymptomatic, the surgery should be postponed or cancelled if the valve has not been evaluated within the year.

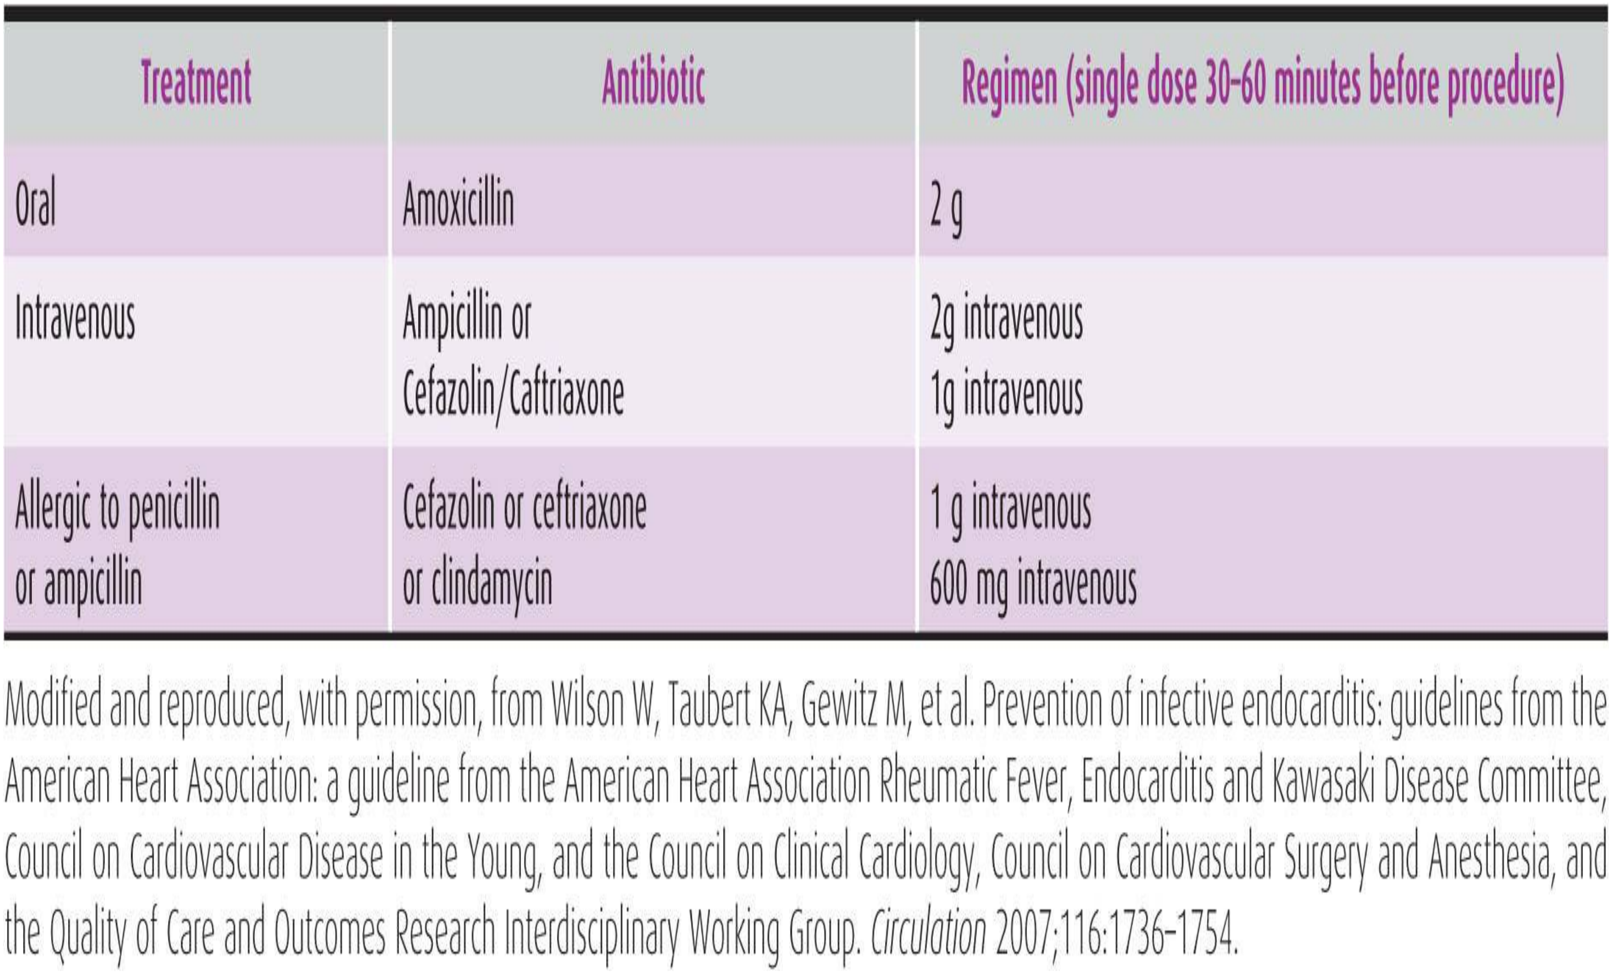
Significant mitral stenosis increases the risk of heart failure. When the stenosis is severe, the patient may benefit from balloon mitral valvuloplasty or open surgical repair before high-risk surgery. However, in general, preoperative surgical correction is not indicated, unless the valvular condition should be corrected to prolong survival.

Patients with atrial fibrillation who are at risk for thromboembolism should be given preoperative and postoperative intravenous heparin or low-molecular-weight heparin to cover periods of subtherapeutic anticoagulation.

Patients with mechanical prosthetic valves need careful anticoagulation management when they undergo surgery. Perioperative heparin is recommended for patients in whom the risk of bleeding with oral anticoagulation is high and the risk of thromboembolism without anticoagulation is also high. These patients include patients with mechanical heart valve in the mitral position, Bjork-Shiley valve, recent (<1 year) thrombosis or embolus, or 3 or more of the following risk factors: atrial fibrillation, previous embolus at any time, hypercoagulable condition, mechanical prosthesis, and left ventricular ejection fraction less than 30%.

Recommendations regarding endocarditis prophylaxis in patients with mechanical heart valves have recently been changed. The American Heart Association no longer recommends endocarditis prophylaxis in patients undergoing genitourinary or gastrointestinal surgery, including gynecologic surgery, or vaginal delivery or caesarean section. The only exception is in a patient with an infection that could cause bacteremia, such as chorioamnionitis or pyelonephritis. In these cases, the underlying infection should be treated in the usual fashion, and the treatment should include a regimen effective for infective endocarditis prophylaxis (Table 45–4). In addition to prosthetic heart valves, the American Heart Association only recommends endocarditis prophylaxis for previous infective endocarditis and congenital heart disease (Table 45–5).

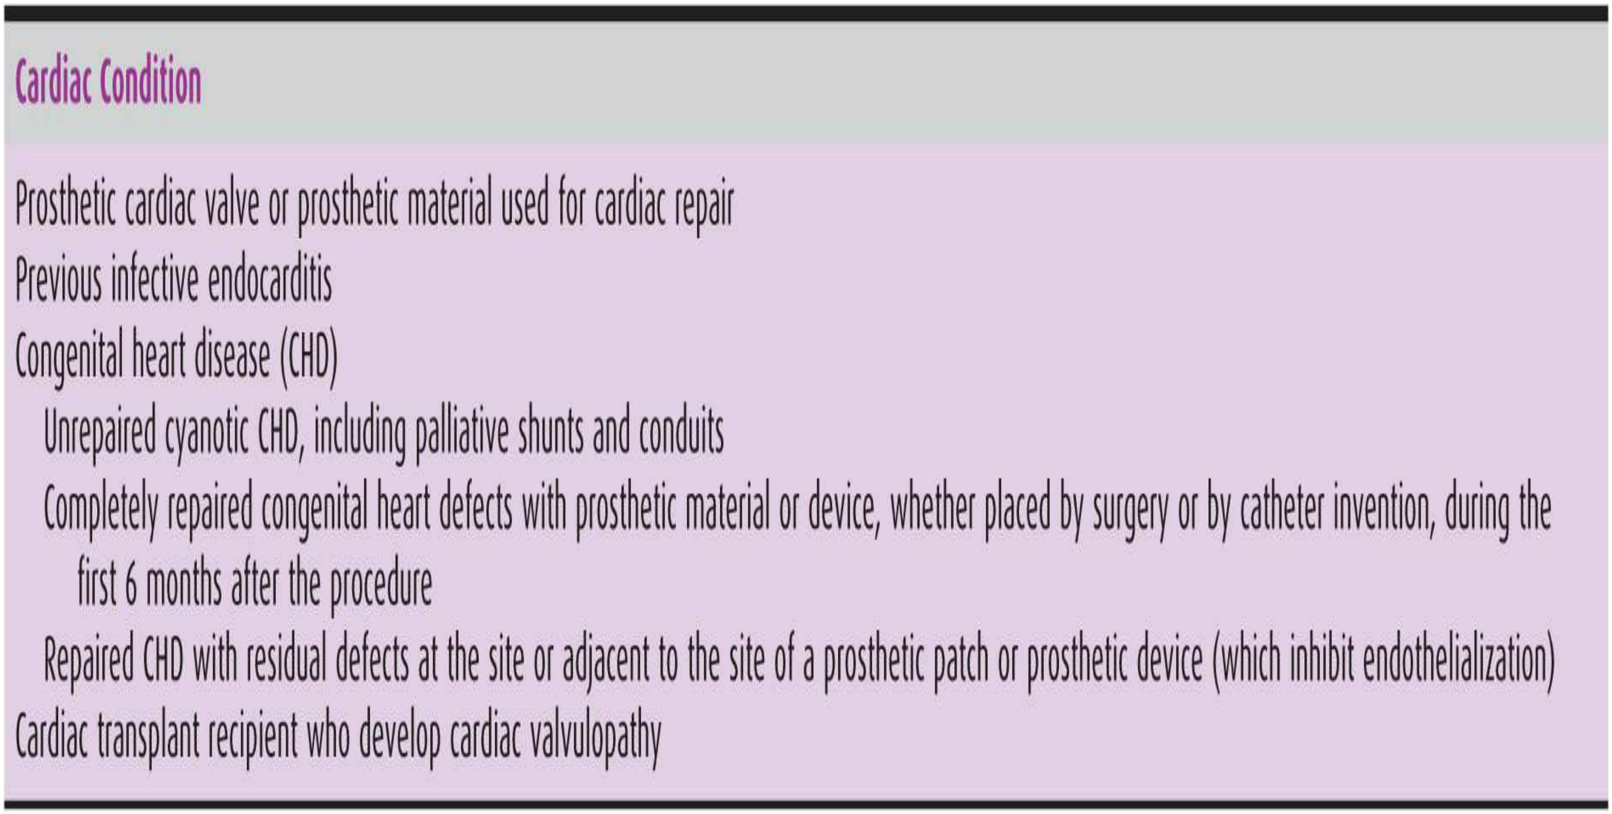
Table 45–4. Antibiotic prophylaxis for infective endocarditis.



Treatment	Antibiotic	Regimen (single dose 30–60 minutes before procedure)
Oral	Amoxicillin	2 g
Intravenous	Ampicillin or Cefazolin/Caftriaxone	2g intravenous 1g intravenous
Allergic to penicillin or ampicillin	Cefazolin or ceftriaxone or clindamycin	1 g intravenous 600 mg intravenous

Modified and reproduced, with permission, from Wilson W, Taubert KA, Gewitz M, et al. Prevention of infective endocarditis: guidelines from the American Heart Association: a guideline from the American Heart Association Rheumatic Fever, Endocarditis and Kawasaki Disease Committee, Council on Cardiovascular Disease in the Young, and the Council on Clinical Cardiology, Council on Cardiovascular Surgery and Anesthesia, and the Quality of Care and Outcomes Research Interdisciplinary Working Group. *Circulation* 2007;116:1736–1754.

Table 45–5. Cardiac conditions for which prophylaxis for obstetric-gynecologic procedures associated with infection or dental procedures is reasonable.



Cardiac Condition
Prosthetic cardiac valve or prosthetic material used for cardiac repair
Previous infective endocarditis
Congenital heart disease (CHD)
Unrepaired cyanotic CHD, including palliative shunts and conduits
Completely repaired congenital heart defects with prosthetic material or device, whether placed by surgery or by catheter invention, during the first 6 months after the procedure
Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)
Cardiac transplant recipient who develop cardiac valvulopathy

VENOUS THROMBOEMBOLISM

In patients with a prior history of venous thromboembolism (VTE; pulmonary embolism or deep vein thrombosis [DVT]), it is important to weigh the risk of a thromboembolic event during interruption of anticoagulation against the risk of bleeding when antithrombotic therapy is administered in close proximity to surgery. Patients can be divided into risk strata according to their suggested risk for perioperative thromboembolism:

High risk:

- Recent (within 3 months) VTE
- Severe thrombophilia (eg, deficiency of protein C, protein S or antithrombin, antiphospholipid antibodies, or multiple abnormalities)

Moderate risk:

- VTE within the past 3–12 months
- Nonsevere thrombophilic conditions (eg, heterozygous factor V Leiden mutation, heterozygous factor II mutation)
- Recurrent VTE
- Active cancer (treated within 6 months or palliative)

Low risk:

- Single VTE occurred >12 months ago and no other risk factors

For patients undergoing a major surgical procedure, vitamin K antagonists (warfarin) should be stopped 5 days and antiplatelet drugs (aspirin, clopidogrel) 7–10 days before the procedure. Nonsteroidal anti-inflammatory drugs (NSAIDs) cause reversible inhibition of platelet-mediated cyclooxygenase activity. NSAIDs with a short half-life (eg, ibuprofen, indomethacin) should be stopped on the day before surgery, whereas NSAIDs with an intermediate half-life (eg, naproxen, celecoxib) should be stopped 2–3 days before surgery. NSAIDs with a long half-life (>20 hours) should be stopped 10 days before surgery. If the international normalized ratio (INR) is still elevated (ie, ≥1.5) 1–2 days before surgery, low-dose (ie, 1–2 mg) oral vitamin K can be administered to normalize the INR. Vitamin K antagonists should be restarted approximately 12–24 hours after surgery and when there is adequate hemostasis. Similarly, anti-platelet drugs should be resumed approximately 24 hours (or the next morning) after surgery when there is adequate hemostasis.

Patients at high or moderate risk (see risk strata) for perioperative thromboembolism need bridging anticoagulation with therapeutic-dose subcutaneous low-molecular-weight heparin (LMWH) or intravenous unfractionated heparin (UFH). Patients at low risk for perioperative thromboembolism can use low-dose subcutaneous LMWH or no bridging. Bridging with LMWH can be easily administrated outside the hospital and does not require laboratory monitoring. A common regimen is enoxaparin 1 mg/kg twice a day. The last dose of therapeutic LMWH should be given the morning prior to the day of surgery, thus holding the evening dose. Therapeutic LMWH can be restarted in 24 hours for patients undergoing minor surgical or other invasive procedures but should be held for 48–72 hours in patients undergoing major surgery. Bridging using therapeutic-dose intravenous UFH is performed by achieving a target activated partial thromboplastin time (aPTT) of 1.5–2.0 times the control aPTT value. The infusion is stopped approximately 4 hours before the surgery and is restarted during the initial 24 hours postoperatively. Bridging with LMWH is preferred to intravenous UFH in an outpatient setting.

In patients who are receiving vitamin K antagonists and require an urgent surgical procedure, the anticoagulant effect can be reversed with low-dose (2.5–5 mg) intravenous or oral vitamin K. If an immediate reversal effect is needed, the patient can be given fresh-frozen plasma or other prothrombin concentrate in addition to vitamin K. Because there is no pharmacologic agent that can reverse the antithrombotic effect of aspirin, clopidogrel, or ticlopidine, transfusion of platelets or the administration of other prohemostatic agents can be given to patients who are undergoing surgery and have excessive or life-threatening bleeding.

Douketis JD, Berger PB, Dunn AS, et al. The perioperative management of antithrombotic therapy: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines (8th Edition). *Chest* 2008;133(6 Suppl):299S–339S. PMID: 18574269.

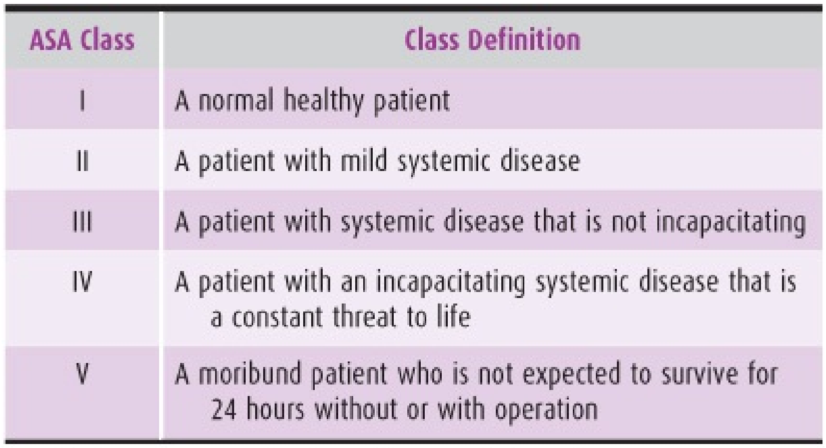
PULMONARY DISEASE

Complications

Postoperative pulmonary complications, such as atelectasis, pneumonia, respiratory failure, and exacerbation of underlying chronic lung disease, occur at similar rates to cardiac complications. In a study of 2964 patients undergoing elective noncardiac surgery, postoperative pulmonary and cardiac complications occurred in 2.0% and 2.2%, respectively.

All patients undergoing noncardiothoracic surgery should be evaluated for the presence of significant risk factors for postoperative pulmonary complications in order to receive pre- and postoperative interventions to reduce pulmonary risk. These risk factors include (1) chronic obstructive pulmonary disease, (2) age older than 60 years, (3) American Society of Anesthesiologists (ASA) class II or greater, (4) functionally dependent, (5) and congestive heart failure. Chronic obstructive pulmonary disease is the most commonly identified risk factor for postoperative pulmonary complications, with an odds ratio of 1.79. Advancing age is an important predictor of postoperative pulmonary complications, even after adjusting for comorbid conditions. The risk for pulmonary complications increases 2-fold for patients age 60–69 and 3-fold for patients age 70–79. The ASA classification (Table 45–6) has been proven to predict both postoperative pulmonary and cardiac complications. An ASA class of II or higher has a 4.9 times higher risk of pulmonary complications compared to ASA class I. Similarly, an ASA class of II or greater has a 2.3 times higher risk of pulmonary complications than ASA class of I or II combined. Functional dependence also increases the risk of postoperative pulmonary complications. Total dependence (inability to perform any activities of daily living) increases the risk by 2.5 times, whereas partial dependence (need for equipment or devices and assistance from another person for some activities of daily living) increases the risk by 1.7 times. Finally, congestive heart failure increases the risk of postoperative pulmonary complications by almost 3 times. Cigarette smoking has only a modest increased risk of pulmonary complications, with an odds ratio of 1.26. Contrary to previous beliefs, obesity and mild to moderate asthma are not significant risk factors for postoperative pulmonary complications.

Table 45–6. American Association of Anesthesiologists (ASA) classification.



ASA Class	Class Definition
I	A normal healthy patient
II	A patient with mild systemic disease
III	A patient with systemic disease that is not incapacitating
IV	A patient with an incapacitating systemic disease that is a constant threat to life
V	A moribund patient who is not expected to survive for 24 hours without or with operation

Modified and reproduced, with permission, from Smetana GW, Lawrence VA, Cornell JE. Preoperative pulmonary risk stratification for noncardiothoracic surgery: systematic review for the American College of Physicians. *Ann Intern Med* 2006;144:581–595.

Procedure-related risk factors are another important consideration when trying to reduce postoperative pulmonary complications. Certain procedures carry a higher risk of complications. These procedures include aortic aneurysm repair, thoracic surgery, abdominal surgery (especially upper abdominal surgery), neurosurgery, prolonged surgery, head and neck surgery, emergency surgery, and vascular surgery. The duration of surgery also affects postoperative pulmonary complications. A prolonged surgery lasting over 3–4 hours doubles the rate of postoperative pulmonary complications. Finally, general anesthesia and emergency surgery increase the risk of postoperative pulmonary complications by an odds ratio of 1.83 and 2.21, respectively.

Laboratory testing to estimate surgical risk has not been shown to be better than a careful history and physical exam. Therefore, the American College of Physicians does not recommend preoperative spirometry or chest radiography to predict risk for postoperative pulmonary complications. Spirometry is recommended for thoracic surgery only, and studies of preoperative chest radiographs have shown that 10–23% of chest radiographs are abnormal but only 1.3–3% were clinically significant. Interestingly, a low serum albumin of <3.5 mg/dL is a powerful marker of increased risk for postoperative pulmonary complications and should be measured in all patients who are suspected of having hypoalbuminemia. Measurements should be considered in patients with 1 or more risk factors for pulmonary complications.

Treatment

All patients who are found to be at higher risk for postoperative pulmonary complications after perioperative evaluation should receive treatment to reduce postoperative complications. These treatments include (1) deep breathing exercises or incentive spirometry and (2) selective use of a nasogastric tube in patients for postoperative nausea and vomiting, inability to tolerate oral intake, or symptomatic abdominal distension.

ENDOCRINE DISEASE

Endocrine disorders are common in patients presenting for elective surgery. This section will discuss the perioperative management of diabetes, hyper- and hypothyroidism, and corticosteroid-induced adrenal insufficiency.

1. Diabetes Mellitus

Clinical Findings

Diabetes is the most common endocrine disorder affecting almost 20 million Americans. Fifty percent of these patients are estimated to require surgery during their lifetime. All patients with diabetes should have a careful preoperative assessment. The physician should ask about existing diabetic complications, such as neuropathies (peripheral sensory, bladder dysfunction, gastroparesis, and hypoglycemic unawareness), retinopathy, nephropathy, hyperlipidemia, and hypertension. Preoperative glucose control should be evaluated, since elevated blood sugar >150 mg/dL leads to macrophage dysfunction. This increases the risk of infection and delayed wound healing. Glycosylated hemoglobin (HbA1c) value is an indicator of glycemic level over 120 days but is strongly related to the level over the last 2–3 months. A normal value is up to 6%, and the goal of the American Diabetes Association is an HbA1c level less than 7% (considered adequate control). HbA1c values over 8% correspond to average blood glucose levels greater than 180 mg/dL and are an indication of poor glycemic control. Because diabetes is the leading cause of renal failure, it is important to measure the renal function preoperatively. Impaired renal function increases the risk of perioperative hypoglycemia because it prolongs the half-life of insulin and sulfonylureas. The major goal of perioperative management in patients with diabetes is to minimize hyperglycemia and avoid hypoglycemia, hypovolemia, and hypo- or hyperkalemia. Surgery and anesthesia invoke a stress response that leads to a hypersecretion of counterregulatory hormones culminating in hyperglycemia. This may lead to diabetic ketoacidosis (DKA) in patients with type 1 diabetes and hyperosmolar hyperglycemia nonketosis (HHNK) in patients with type 2 diabetes. There are no current guidelines on perioperative glycemic control, but a reasonable approach is to maintain blood glucose levels at less than 200 mg/dL intraoperatively and less than 150 mg/dL postoperatively, but avoid levels less than 80 mg/dL.

Treatment

Perioperative management of antihyperglycemic medications can be challenging, especially if the patient is required to be NPO (nothing by mouth) perioperatively. Thiazolidinedione (rosiglitazone, pioglitazone, and troglitazone) can be held the morning of surgery and sulfonylureas (glipizide and glyburide) must be held preoperatively. The biguanide metformin, which has been associated with the development of lactic acidosis, should be withheld 24 hours preoperatively and restarted 48–72 hours postoperatively once normal renal function has been documented. Thiazolidinedione and sulfonylureas can be restarted once enteral intake is permitted.

Patients who routinely use insulin should preferably be scheduled as the first case of the day to minimize hyper-or hypoglycemia. Patients with type 1 diabetes need basal insulin at all times to avoid DKA. The night before the procedure, the patient should take usual oral intake and continue the usual dose of evening glargine/NPH or a mixture. Patients using insulin pumps should continue the usual overnight basal rate. During the morning of the procedure, short-acting hypoglycemics should not be given unless the blood sugar is greater than 200 mg/dL and greater than 3 hours preoperatively. If the patient takes glargine insulin (long-acting), the usual dose of glargine can be given or the patient can be placed on an insulin drip. Patients using an insulin pump should continue the usual basal rate and infuse D5 throughout the operation. If the patient takes NPH (intermediate-acting) or other insulin mixture, the following steps should be taken. No short-acting insulin should be given within 3–4 hours of the procedure (ie, no mixture preoperatively). Half the usual dose of intermediate-acting insulin, with D5 at a controlled rate, should be given throughout the procedure. If performing an operation without continuous D5, insulin should not be given preoperatively. During emergency surgery, bolus of short-acting insulin should not be given preoperatively. Instead, frequent (every 30–60 minutes) monitoring of blood sugars should be performed throughout the operation. An insulin drip should be started for blood sugars greater than 200 mg/dL.

2. Hyperthyroidism

Clinical Findings

Untreated hyperthyroidism causes an increase in blood pressure, heart rate, and circulating blood volume, which leads to an increased cardiac output of 50–300%. These changes may limit the patient’s ability to respond to the stress of surgery and can lead to thyroid storm and cardiovascular collapse. Therefore, thyroid function tests should be evaluated in all patients with hyperthyroidism preoperatively.

Treatment

Patients with uncontrolled hyperthyroidisms who present for elective surgery should have their surgery postponed until they have been stabilized medically. If a patient needs urgent or emergent surgery, the anesthesiologist should have drugs available that block the systemic effects of excess thyroid hormones, such as beta-blockers, antithyroid medications (propylthiouracil and methimazole), and iodine. The patient should take their antithyroid medications on the morning of surgery and resume the medications postoperatively when they tolerate enteral intake.

Complications

The most serious perioperative complication is thyroid storm, which usually arises from undiagnosed or under-treated hyperthyroidism. It can occur at any time in the perioperative period but usually occur intraoperatively or in the first 48 hours. Symptoms of thyroid storm are nonspecific and include fever (up to 41.1°C), tachycardia, and delirium. The mortality rate is 10–75%, and the patient must be treated in a critical care environment. Treatment includes thionamides, beta-blockers, antipyretics, and external cooling measures.

3. Hypothyroidism

Clinical Findings

Hypothyroidism is a common endocrine disorder that affects 1% of all patients. Patients with well-controlled hypothyroidism and patients with mild to moderately controlled hypothyroidism can usually undergo elective surgery without an increase in their perioperative risk. The physician should monitor closely for symptoms of worsening hypothyroidisms including delirium, prolonged ileus, infections without fever, and myxedema coma. Due to the long half-life of levothyroxine (1 week), it is not necessary for the patient to take their dose the morning of surgery. Levothyroxine can be restarted postoperatively once the patient tolerates enteral intake.

Treatment

Patients with severe hypothyroidism (myxedema coma) should be stabilized medically before any elective surgery. Myxedema coma is rare and usually presents postoperatively. It has a reported mortality rate of 80% and is precipitated by insults such as infection, cold exposure, and medications (sedatives and analgesics). Myxedema coma is characterized by severely depressed mental status (sometimes coma or seizures), hypothermia, bradycardia, hyponatremia, heart failure, and hypopnea. Myxedema coma is a medical emergency requiring intensive care admission and urgent administration of intravenous levothyroxine. Dehydration is often present, and aggressive fluid resuscitation with dextrose and normal saline should be performed. Intravenous glucocorticoids should be given because concomitant adrenal insufficiency is often present. Resolution of symptoms should be seen within 24 hours.

4. Adrenal Insufficiency

Adrenal insufficiency (AI) limits a patient’s ability to respond to stress during surgery.

Pathogenesis

Primary AI is caused by autoimmune adrenalitis, infection, adrenalectomy, and sepsis, whereas secondary AI is due to pituitary depression, damage, and tumors. Tertiary AI is caused by exogenous glucocorticoid administration, which suppresses hypothalamic corticotropin-releasing hormone and pituitary adrenocorticotropic hormone (ACTH). These patients may need perioperative steroid supplementation (stress dose steroids).

Treatment

There is a wide variability in individual response to a particular dose and length of treatment. However, in general, patients who have received the equivalent of 20 mg/d of prednisone for greater than 5 days may be at risk for AI. If the patient has been on therapy for 1 month or longer, they may have AI for up to 6–12 months after stopping therapy. Patients who have been on an equivalent dose of prednisone 5 mg (or less) for any period of time will usually not have AI and will not need to receive stress dose steroids. The treatment of patients taking more than 5 mg/d of prednisone or equivalent is controversial. Some experts recommend performing a short ACTH stimulation test preoperatively in patients receiving steroid equivalents of 20 mg/d. Only patients who do not respond appropriately would receive stress dose steroids perioperatively. Others perform the ACTH stimulation test for patients receiving 6–19 mg/d of prednisone while giving patients taking 20 mg/d or higher stress dose steroids. Finally, some authors recommend giving all patients taking more than 5 mg/d of prednisone equivalent-dose stress dose steroids. In our practice, we treat all patients taking more than 5 mg/d of prednisone with stress dose steroids perioperatively. Patients taking 5 mg/d or less of prednisone should continue their usual maintenance dose orally or intravenously as the clinical situation mandates.

Kohl BA, Schwartz S. Surgery in the patient with endocrine dysfunction. *Med Clin N Am* 2009;93:1031–1047. PMID: 19665618.

RENAL DISEASE

Clinical Findings

Preoperative laboratory studies should include a measure of the glomerular filtration rate (GFR) to ensure that the correct dosage of medications excreted by the kidney is given. A complete blood count and a type and screen should be performed because many patients with chronic renal disease have anemia and some patients may require a preoperative blood transfusion. Electrolytes should be checked because electrolyte disturbances are common. Up to 50% of patients have hyperkalemia, and some studies suggest that acute intervention should be reserved for potassium levels greater than 6.5 mmol/L.

Complications

Patients with chronic renal disease have a 2- to 5-fold higher risk of postoperative death and cardiovascular events than those with normal kidney function. Patients receiving dialysis are at the highest risk of such events.

During the preoperative assessment, the physician should establish the type and severity of kidney disease, any comorbid conditions, any complications related to the level of kidney function, risk for loss of kidney function, and risk for cardiovascular disease. Modifiable risk factors should be optimized prior to surgery. A mean arterial blood pressure of 110 mm Hg is associated with increased rates of cardiovascular and renal complications. Therefore, the preoperative blood pressure goal should be 130/80 mm Hg. To minimize the risk of volume overload, electrolyte imbalances, and uremic bleeding, patients requiring dialysis should receive it within 24 hour of surgery. Angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin II antagonists (ARAs) are associated with intraoperative hypotension, especially with induction of general anesthesia. It is recommended to discontinue ACEIs and ARAs for at least 10 hours before general anesthesia.

Treatment

If a patient needs contrast media intraoperatively or during a radiologic study, a nonionic contrast agent is recommended to reduce the risk of contrast-induced nephropathy. In addition, the patients should be well hydrated, other nephrotoxic drugs and hypotension should be avoided, and medications such as *N*-acetylcysteine (Mucomyst 600 mg orally twice daily on the day before and/or on the day of the procedure) can be given. Laparoscopy reduces renal blood flow and can cause hypotension (which can further aggravate reduced renal blood flow). To mitigate these changes, abdominal insufflation pressures should not exceed 15 mm Hg, and adequate fluid replacement is recommended.

Mathew A, Devereaux PJ, O’Hare A, et al. Chronic kidney disease and postoperative mortality: a systematic review and meta-analysis. *Kidney Int* 2008;73:1069–1081. PMID: 19665621.

HEPATIC DISEASE

Clinical Findings

Management of the surgical patient with liver disease should begin with a careful history and physical exam. This also serves as a screening test for patients with asymptomatic disease. One should ask about a history of prior surgeries, jaundice or blood transfusions, use of alcohol and other recreational drugs, sexual history, and a review of systems. The review of systems should include pruritus, easy fatigability, excessive bleeding after minor trauma, abdominal distension, and weight gain. The physical exam should include signs of liver disease, such as icterus, pallor, ascites, hepatomegaly, splenomegaly, palmar erythema, and spider nevi. If there is any suspicion of liver disease, blood testing for hepatic function should be performed including coagulation studies, electrolytes, and liver enzymes. However, routine preoperative testing of liver function is not recommended due to its low yield of abnormal results (<1%).

Complications

Older studies have reported high mortality rates in patients with acute hepatitis. It is therefore recommended to postpone elective surgery in these patients until the liver function tests have normalized. Surgery is generally considered safe in patients with chronic hepatitis. In general, patients with fatty liver tolerate surgery well, while patients with alcoholic hepatitis and cirrhosis have increased postoperative morbidity and mortality. Patients with a history of alcohol abuse have an increased risk of postoperative complications, such as poor wound healing, infections, bleeding, and delirium. Patients should refrain from using alcohol to improve liver function and should be monitored closely for signs of alcohol withdrawal.

Patients with cirrhosis have a high postoperative mortality of 10–80%. These patients may have nutritional disorders, ascites, abnormal coagulation profile, renal dysfunction, and encephalopathy. Five factors that significantly affect mortality in patients with cirrhosis include ascites, albumin, bilirubin, encephalopathy, and nutritional status. Cirrhotic patients benefit from aggressive preoperative treatment of coagulopathy, ascites, and encephalopathy. Coagulopathy can be managed preoperatively with vitamin K (10 mg subcutaneous); however, vitamin K does not correct the prothrombin time if there is decreased hepatic synthesis. In these cases, fresh-frozen plasma (FFP) infusion usually brings the prothrombin time to normal limits. If vitamin K and FFP fail to reduce the prothrombin time to within 3 seconds of normal, cryoprecipitate should be given. Cirrhotic patients are at high risk of developing encephalopathy postoperatively. Constipation, infection, upper gastrointestinal bleeding, uremia, alkalosis, and overuse of sedatives are known precipitating factors of encephalopathy. Ascites can cause respiratory compromise and wound dehiscence. It should be treated aggressively preoperatively with diuretics and paracentesis. Increasing evidence suggests that laparoscopic procedures have decreased operative morbidity and mortality compared with open procedures in patients with cirrhosis.

Rizvon MK, Chou CL. Surgery in the patient with liver disease. *Med Clin North Am* 2003;87:211–227. PMID: 12575891.

RHEUMATOLOGIC DISEASE

Complications

Two common challenges in the perioperative management of patients with rheumatologic disease are surgical positioning and perioperative management of antirheumatic medications. Patients with rheumatologic disease often have restricted joint mobility and pain. To decrease the risk of postoperative pain exacerbation and intraoperative injury to joints, it is important to preoperatively access the mobility of the joint. In addition, it is helpful to position these patients awake (ie, in lithotomy position) to ensure that the joints are not hyperflexed or hyperextended.

Treatment

When deciding on whether or not to stop an antirheumatic medication, one must weigh the risk of impaired wound healing and postoperative complications with maintaining disease control. Methotrexate has been extensively studied and should be continued in otherwise healthy patients. Compared with patients who discontinued the drug, patients who continued methotrexate had fewer infections and less flares. There are only a limited number of studies on leflunomide, and the results are conflicting. However, due to the very long half-life of leflunomide, its discontinuation would be necessary for a long time and is probably not necessary. Data on hydroxychloroquine do not show an increased risk of infection, and the drug has a long half-life. Clinical data are lacking on the perioperative use of sulfasalazine. The drug has a short half-life and is eliminated primarily via the kidneys. Some authors suggest withholding sulfasalazine at least the day of surgery. Three studies on azathioprine did not show the drug to be associated with any postoperative complications, and it is considered safe. Although preliminary data on tumor necrosis factor (TNF)–blocking agents show that the risk of infections may be lower than initially expected, it is still recommended to discontinue the drugs before surgery for several weeks. TNF-blocking agent should not be restarted until wound healing is complete. There are no data available on the drugs anakinra, rituximab, or abatacept. NSAIDs and aspirin should be discontinued as previously described in this chapter, whereas glucocorticoids should not be discontinued preoperatively. Patient with a suspected suppression of the hypothalamic–pituitary–adrenal axis should receive stress dose steroid supplementation, as previously described.

Pieringer H, Stuby U, Biesenback G. Patients with rheumatoid arthritis undergoing surgery: how should we deal with anti-rheumatic treatment? *Semin Arthritis Rheum* 2007;36:278–286. PMID: 17204310.

INTRAOPERATIVE COMPLICATIONS

Intraoperative complications can occur even in the most experienced surgeon’s hands. Several factors, such as a surgeon’s experience, technique, and knowledge of the pelvic anatomy, may prevent some of these complications. However, a surgeon must always be prepared to recognize and treat injuries when they occur in an organized and timely fashion. The complications listed in the following sections comprise some of the most common and serious complications encountered in gynecologic surgery.

URINARY TRACT INJURIES

1. Bladder Injury

Bladder injuries most commonly occur while dissecting down the bladder during abdominal or laparoscopic hysterectomy. The bladder may also be injured when attempting to enter the anterior cul-de-sac during vaginal hysterectomy. Bladder laceration can be confirmed by filling the bladder with either sterile milk or methylene blue retrograde through a urethral catheter. The bladder defect is repaired with 2 layers of absorbable suture. The Foley catheter is left in place for several days (5–7 days if injury is at the dome and 7–10 days if injury is at the bladder base) to prevent bladder distention and to allow the repair to heal. Another procedure that may result in bladder injury is retropubic suburethral slings used to treat stress urinary incontinence. The risk is approximately 5%. Therefore, this procedure includes routine cystoscopy to detect these injuries. If a cystotomy is present, the surgeon must replace the trocar and then continue Foley catheter drainage for 2–3 days. Very small injuries to the bladder such as a veress needle injury generally does not require repair and may be treated conservatively with Foley catheter drainage.

2. Ureteral Injury

Clinical Findings

Ureteral injuries are rare but recognized complications in gynecologic surgery. The incidence associated with hysterectomies ranges from 0.03–1.5%. Many of these intraoperative injuries go unrecognized and cause significant morbidity, including pyelonephritis, urine peritonitis, ureterovaginal fistula, and loss of a functioning kidney. Rates of injury are increased with operations for pelvic organ prolapse and in women with adhesions from endometriosis or prior surgery, distorted pelvic anatomy from malignancy, and enlarged uteri.

Common sites of ureteral injuries are at the level of the infundibulopelvic ligament, as the ureter courses under the uterine artery, at the distal uterosacral ligaments, and at the lateral apex of the vagina before its insertion into the bladder. Mechanisms for ureteral damage include transecting, ligating, kinking, burning, devascularizing, or crushing the ureters. Some of these injuries can be detected during surgery; however, the majority of injuries are unsuspected and diagnosed postoperatively. Early recognition of an injury is crucial to preserve the function of that kidney, and repair is most likely to be successful if done during the initial surgery.

Intraoperative cystoscopy with intravenous indigo carmine offers confirmation of bilateral ureteral patency. If efflux of blue dye is sluggish or absent from a ureteral orifice, then a ureteral injury should be suspected. If injury is confirmed, a urology consultation is recommended. If an abdominal procedure is being performed and a cystoscope is unavailable, another method of evaluating the ureteral function is through a purposeful cystotomy using an endoscope. In that case, a purse-string suture is placed at the dome of the bladder, and a small purposeful cystotomy is made within it. The 0- or 30-degree endoscope is then placed through the cystotomy to evaluate the bladder and ureteral orifices. Once the endoscope is removed, the purse-string suture is tied and a second imbricating layer is placed. The bladder should be drained postoperatively for 5–7 days using a Foley catheter. If cystoscopy is not diagnostic or there is strong suspicion of an injury, then transurethral stenting may be required and the appropriate consultation service should be called intraoperatively.

Studies on universal cystoscopy during routine hysterectomies have not been shown to be cost effective given the low rates of ureteral injury. However, if the patient is at higher risk or there is suspicion, cystoscopy should be performed.

If a patient develops flank pain in the postoperative period, a ureteral injury should be suspected. Urinary tract injury can be detected by an intravenous pyelogram (IVP). A renal ultrasound may reveal hydronephrosis or hydroureter. If a fluid collection is noted in the abdomen, it may be a urinoma from a transected ureter. Clear fluid draining from the surgical wound or from the vagina may be from a fistula. If this fluid is sent for creatinine levels, fluid from a urine leak would demonstrate a much higher creatinine concentration than the patient’s serum creatinine levels.

GASTROINTESTINAL TRACT INJURY

Bowel is susceptible to injury during all types of gynecologic, abdominal, laparoscopic, and vaginal surgeries. Patients at highest risk include those with adhesions from previous surgery, endometriosis, tubo-ovarian abscess, or advanced malignancy.

Small Bowel

Patients with adhesions from previous surgery are particularly at risk, especially upon entry into the peritoneal cavity. Small bowel can be injured from electrocautery or via enterotomy. Small defects of the serosal or muscularis may be repaired using interrupted 3-0 silk or synthetic absorbable sutures in 1 or 2 layers. Suture repair lines should be perpendicular to the long axis of the bowel to prevent narrowing of the bowel lumen. Larger injuries and thermal injuries may require segmental resection with reanastomosis or with use of stapling devices.

Large Bowel

Large bowel injury is repaired in a similar fashion as the small bowel. Suture repair and resection with reanastomosis are techniques used in repair. However, if bowel reanastomosis is not possible due to extensive damage or pathology, a diverting colostomy may be needed. Injury to bowel results in spillage of bowel contents into the peritoneal cavity, which causes peritonitis. If unrecognized, the patient usually develops fever, abdominal distention, and pain from peritonitis in the immediate postoperative period. An unrecognized thermal bowel injury from electrocautery may have a delayed onset of symptoms. Any unrecognized bowel injury could potentially be lethal.

Stany MP, Farley JH. Complications of gynecologic surgery. *Surg Clin North Am* 2008;88:343–359. PMID: 18381117.

VASCULAR INJURY

Major Vessel Injury

Injury to a major blood vessel, such as the iliac vessels, aorta, or vena cava, is a rare but catastrophic complication of pelvic surgery. Compared to the muscular walls of the major arteries, the thin-walled veins, such as the external iliac vein, may be more prone to injury during a lymph node dissection. If injury occurs, direct pressure should be applied. This allows time to allow adequate exposure for repair, to call for blood products, and to call a consulting surgeon if needed. If a major catastrophic vascular injury occurs to the aorta or iliac vessels during laparoscopy with a trocar or veress needle, a vertical exploratory laparotomy should be performed. Pressure should be placed over the area with a laparotomy sponge to tamponade the hemorrhage until vascular surgeons are available.

Hemorrhage

Intraoperative hemorrhage is defined as blood loss exceeding 1000 mL or blood loss of more than 25% of the patient's blood volume. At the onset of heavy or uncontrolled bleeding, the first step is to apply pressure to the site either with a finger or a moist laparotomy sponge. Good communication with the surgical team, including the anesthesiologist and scrub and circulating nurses, is essential in responding to a hemorrhage and calling for blood products if needed.

Once pressure has been applied, the sponges should be removed slowly in attempt to visualize the bleeding vessels. Knowledge of the pelvic anatomy is crucial to avoid damage to the surrounding major vessels, nerves, and ureter. After identification of vital structures in the surrounding area, the bleeding vessels should be isolated and ligated. Specific areas prone to hemorrhage include the retroperitoneum during lymph node dissections, dissection close to the uterine artery during hysterectomy, and dissection in the presacral space, which can cause bleeding from presacral venous plexus during abdominal sacral colpopexy.

A technique that may control hemorrhage is hypogastric artery ligation or internal iliac artery ligation. This will decrease the pulse pressure at the distal bleeding site. Another technique that may be useful in controlling hemorrhage after caesarean section is bilateral uterine artery ligation by placing a large stitch through the uterine wall at the level of the cervical isthmus to ligate the uterine artery. During this technique, one must be careful of the ureter running inferior to the uterine artery. Topical hemostatic agents, cautery, clips, and sutures may also control the bleeding.

Stany MP, Farley JH. Complications of gynecologic surgery. *Surg Clin North Am* 2008;88:343–359. PMID: 18381117.

NEUROLOGIC INJURY

Incorrect positioning of a patient while under anesthesia can cause significant neurologic injury resulting in sensory and motor deficits. These complications are rare, usually transient, and usually resolve spontaneously with minimal intervention. However, long-term disability occasionally occurs. During pelvic surgery, injury can involve components of the lumbosacral nerve plexus, specifically the femoral nerve, the obturator nerve, the sciatic nerve, the iliohypogastric nerve, the ilioinguinal nerve, the genitofemoral nerve, the lateral femoral cutaneous nerve, and the pudendal nerve.

Gynecologic surgery is the most common cause of iatrogenic femoral nerve injury. Injury can occur with prolonged compression by retractor blades, when the hip is hyperflexed and hyperabducted in lithotomy position or due to direct injury associated with surgical dissection. Injury most commonly occurs when self-retaining retractors rest on the psoas muscle compressing the femoral or genitofemoral nerves. Symptoms from impaired motor function of the femoral nerve include weakness or inability to flex at the hip or extend at the knee. Sensory impairment includes paresthesia over the anterior and medial thigh and medial aspect of the calf. The obturator nerve may be injured during retroperitoneal dissection, such as lymph node dissection for gynecologic malignancies. This nerve injury will present with sensory loss in the upper medial thigh and motor weakness in hip adductors.

Other nerves compromised during incorrect positioning in lithotomy include the sciatic and peroneal nerves. Sciatic nerve compression and stretch occur with prolonged hyperflexion of the thigh. The common peroneal nerve courses across the lateral head of the fibula and therefore is susceptible to compression injury if the lateral aspect below the knee rests firmly against lithotomy stirrups. As for positioning of the upper extremities during gynecologic surgery, care should be taken to avoid hyperabduction to minimize risk for brachial plexus injury.

Two nerves at risk during a low transverse abdominal incision are the ilioinguinal and iliohypogastric nerves. They are susceptible to injury when a Pfannenstiel incision is extended beyond the border of the oblique muscle, and they also can be incorporated into the fascial repair resulting in nerve entrapment syndrome. This can cause a sharp burning pain or paresthesia over the nerve distribution. Therefore, careful positioning and placement of retractor blades are the best defenses against neurologic injuries.

Irvin W, Andersen W, Taylor P, et al. Minimizing the risk of neurologic injury in gynecologic surgery. *Obstet Gynecol* 2004;103:374–382. PMID: 14754710.

POSTOPERATIVE COMPLICATIONS

ACUTE HEMORRHAGE

Acute hemorrhage in the postoperative period can occur after many different procedures. This may occur as a result of an unrecognized trocar injury to the inferior epigastric vessels, a high cervical laceration from a dilatation and curettage, or a loose suture on a uterine artery pedicle after vaginal hysterectomy. In the recovery room, if a patient is persistently hypotensive despite fluid resuscitation, an internal hemorrhage should be suspected. One should respond by resuscitating the patient, checking blood count and coagulation studies, and ordering blood products for transfusion. If the patient does not respond, the patient may need to return to the operating room. Emergent uterine artery embolization has also shown to be a successful technique for postoperative bleeding.

THROMBOEMBOLIC COMPLICATIONS

1. Deep Vein Thrombosis

DVT is a serious and potentially preventable complication of major gynecologic surgery. Patients at increased risk include those with malignancy, obesity, immobility, previous VTE, thrombophilia, smoking, estrogen-containing hormone therapy use, and increasing age. Untreated DVT can lead to a fatal pulmonary embolus.

ESSENTIALS OF DIAGNOSIS

- Diagnosis can usually be made with compression ultrasonography.
- If ultrasonography is negative but there is still a high suspicion for DVT, contrast venography is the gold standard and should be performed.

Clinical Findings

A careful history and physical is important in the diagnosis of DVT. Patients usually present complaining of unilateral leg swelling and calf or leg pain. Physical exam may reveal ipsilateral leg edema, calf tenderness, warmth, or erythema. During the exam, a cord can be palpated indicating a thrombosed vein. Homan's sign is pain with dorsiflexion of the foot. However, this sign is unreliable. A discrepancy in the calf diameter can be of some value in raising the suspicion for DVT.

Treatment

Patients with DVT should be treated with anticoagulants immediately. This is done as soon as DVT is confirmed by objective testing. If there is a delay in diagnostic testing and the clinical suspicious is high, therapy should be started before such testing. Several options are available for the initial treatment of DVT according to the American College of Chest Physicians Guidelines: (1) LMWH, administered subcutaneous, without monitoring; (2) intravenous (IV) UFH, with monitoring; (3) subcutaneous UFH, with monitoring; (4) weight-based subcutaneous UFH, without monitoring; and (5) subcutaneous fondaparinux, without monitoring. For those treatments requiring monitoring, coagulation studies such as INR and partial thromboplastin time (PTT) should be measured at baseline. With UFH, the PTT should be kept 1.5–2.5 times the control value.

Anticoagulation therapy is continued for 3–6 months. Therefore, oral anticoagulants, particularly warfarin, are often started at the same time as initial treatment with the LMWH or UFH therapies above. Oral anticoagulants do not exert their full effect for 48–72 hours. Warfarin is generally started a dose of 5 mg daily, and subsequent doses are adjusted to maintain the INR value at 2.5 (range 2.0–3.0). Therefore, the LMWH or UFH therapy is continued for at least 5 days until the warfarin takes effect and the INR is ≥2.0 for 24 hours. For patients in whom bleeding is a particular risk or laboratory monitoring is problematic, LMWH can be used for long-term treatment instead of warfarin. Due to more predictable pharmacokinetics, LMWH, such as enoxaparin, can be administered subcutaneous once or twice daily without laboratory monitoring in the majority of patients. This treatment, as well as oral anticoagulation, allows initial treatment of DVT as an outpatient. Recommended long-term therapy for distal or calf vein thrombosis includes 3 months of anticoagulation. Long-term treatment for a proximal DVT is 3–6 months of anticoagulation.

Surgical treatment, such as thrombectomy, occasionally can be considered for persistent severe swelling in the extremity. An inferior vena cava filter can be placed for patients who develop DVT or pulmonary embolism that occurs despite adequate anticoagulation or in patients who have contraindications to anticoagulation therapy.

2. Pulmonary Embolism

Laboratory and radiologic imaging is helpful in evaluating a patient for a pulmonary embolus (PE). With arterial blood gas, a low arterial Po_2 should raise suspicion for a PE. D-dimer assays are usually elevated and have a high negative predictive value in ruling out a PE. However, recent surgery can elevate D-dimer levels and, therefore, may have little value in the workup.

Chest radiograph findings frequently show no abnormalities. However, a peripheral lung density, enlargement of the main pulmonary artery, or a small pleural effusion can be seen. Chest radiograph can rule out other diagnoses on the differential, such as pneumonia. Electrocardiogram is helpful in ruling out myocardial infarction. It can also show characteristic changes of PE, such as S1Q3T3 patterns, right bundle branch block, and T-wave inversions in leads V1 through V4.

Spiral chest computed tomography (CT) is now the diagnostic procedure of choice for PE. It can frequently visualize the emboli and has high sensitivity and specificity. Pulmonary angiography is the “gold standard” test but is used less frequently given it is an invasive procedure. It is reserved in patients with a high clinical suspicion for PE despite a negative or nondiagnostic spiral CT. Another imaging modality is the ventilationperfusion (V/Q) scan. It is not the tests of choice because the results are frequently equivocal. It is useful in diagnosis in patients who cannot receive IV contrast.

Clinical Findings

PE is a potentially fatal complication of gynecologic surgery and usually occurs suddenly as a complication of a pelvic or lower extremity DVT. Risk factors are the same as noted earlier for DVT. Symptoms usually occur abruptly and include pleuritic chest pain, dyspnea, tachypnea, and tachycardia. A large embolus may result in hypotension, shock, and even sudden death from cor pulmonale. The symptoms are not specific for PE, and the differential diagnosis includes atelectasis, pneumonia, myocardial infarction, and pneumothorax.

Prevention

There is ample evidence that primary thromboprophylaxis reduces DVT and PE and that fatal PE can be prevented. Recommendations based on guidelines from the American College of Chest Physicians include prophylaxis with low-dose UFH, LMWH, or intermittent pneumatic compression (IPC) devices for the extremities. For a low-risk patient undergoing a brief procedure <30 minutes, prophylaxis is not necessary. For brief procedures and laparoscopy, in patients who have risk factors for VTE, prophylaxis may be indicated. During any major gynecologic procedure, prophylaxis is recommended with low-dose heparin twice daily; LMWH, such as enoxaparin, once daily; or IPC. This prophylaxis is started just prior to surgery and is used continuously until discharge. For patients with malignancy, who are particularly at high risk, the recommendation is to continue prophylaxis with LMWH once daily or low-dose heparin 3 times daily for 2 to 4 weeks after discharge.

Treatment

Cardiopulmonary resuscitation should be instituted if necessary, and the patient should be closely monitored. Due to the risk of mortality, patients with strong clinical suspicion of PE should get immediate treatment with anticoagulation. Treatment regimens for DVT and PE are similar given they are manifestations of the same disease process and are described earlier.

According to the American College of Chest Physicians and their guidelines, in patients with acute nonmassive PE, recommendations include initial treatment with LMWH over IV UFH. In patients with massive PE, where there is concern for subcutaneous absorption, the guidelines suggest IV UFH over LMWH. For patients with a massive PE with evidence of hemodynamic compromise, thrombolytic therapy with urokinase, streptokinase, or recombinant tissue plasminogen activator is also recommended in addition to anticoagulation. Patients who are highly compromised and cannot receive thrombolytic therapy due to bleeding risks may be candidates for surgical pulmonary embolectomy.

GASTROINTESTINAL TRACT COMPLICATIONS

1. Ileus

Ileus is defined as a pattern of bowel dysmotility that results in accumulation of gas and fluid in the gastrointestinal tract. During abdominal or pelvic surgery, there usually is some degree of ileus for 3–6 days postoperatively. This is due to an increase in sympathetic tone, which causes inhibition in bowel motility. Bowel manipulation during surgery causes an inflammatory reaction resulting in an ileus. Opiate pain medications also have an inhibitory effect and can prolong an ileus.

Clinical Findings

The patient usually complains of abdominal pain and may have nausea or vomiting. Clinical findings include abdominal distention with decreased or absent bowel sounds. On plain abdominal radiographs, there is generalized dilatation and gaseous distention of both the small and large bowel.

Treatment

If nausea, vomiting, and abdominal distention are severe, the patient should be restricted of oral intake. A nasogastric (NG) tube should also be inserted into the stomach. IV fluids should be administered, and electrolytes should be monitored. Although an NG tube is sometimes used for treatment, routine use in all patients does not prevent ileus. Early feeding in the postoperative period does not cause ileus and shortens hospital stays. Thoracic epidural analgesia use postoperatively has shown to promote quicker return to bowel function. The use of NSAIDs and opioid receptor antagonists has not been proven to decrease ileus.

2. Small Bowel Obstruction

Small bowel obstruction can result as a complication of an intraperitoneal operation. This is usually due to the formation of adhesions, which can trap or kink a segment of small intestine. Other causes include herniation through a laparoscopic trocar site, internal herniation, or an inflammatory process such as an abscess. Obstruction can occur in the immediate postoperative period or several years later due to dense adhesions. This results in partial or complete bowel obstruction and can cause bowel strangulation and perforation.

Plain abdominal radiographs are very sensitive in the diagnosis of small bowel obstruction. They usually reveal air-fluid levels of differential height within the same loop of bowel. In patients with inconclusive radiograph films, a CT scan (with IV and oral contrast) is sensitive and specific and can give incremental information on the grade of obstruction. Signs of bowel obstruction or strangulation on CT include continuous dilation of proximal small bowel with a discrete transition zone, serrated beak sign, mesenteric fluid and ascites, and intraluminal fluid. The colon usually contains little or no gas. Enteroclysis or small bowel follow-through study with oral contrast, as well as CT enterography and magnetic resonance imaging (MRI) contrast studies, are also available as diagnostic tests.

Clinical Findings

Obstruction is characterized by abdominal pain, vomiting, abdominal distention, and obstipation. On examination, the abdomen is distended and tender with high-pitched bowel sounds. It can be difficult to differentiate from a postoperative ileus and may require diagnostic studies.

Treatment

Small bowel obstruction requires immediate intervention to prevent bowel ischemia and infarction. If the patient has no signs of bowel strangulation or peritonitis, conservative treatment can be used. This includes bowel rest, IV fluid hydration, electrolyte replacement, and bowel decompression with an NG tube. Patients with leukocytosis, fever, peritonitis, metabolic acidosis, and continuous pain suggest bowel strangulation and require operative intervention. In patients who received conservation management, if there is no improvement in symptoms within 48 hours, operative intervention is recommended with either exploratory laparotomy or laparoscopy.

3. Constipation

Constipation and a reduction in the number of bowel movements are expected in the early postoperative period given low food intake, ileus, and narcotic use. If a bowel obstruction is not suspected, stool softeners and mild laxatives can be prescribed. An enema can also be used. Fecal impaction can also be present and cause diarrhea in the postoperative patient. It is diagnosed by digital rectal examination, and treatment involves disimpaction of the firm fecal masses.

4. Diarrhea

Pathogenesis

Most postoperative diarrhea is caused by antibiotic administration or oral contrast for radiographic studies. This is usually mild and self-limiting. Antibiotics can alter the bacterial flora in the gastrointestinal tract. If overgrowth with *Clostridium difficile* occurs, a more serious infection can occur. *C difficile* may be a complication after treatment with antibiotics such as clindamycin, penicillins, cephalosporins, or fluoroquinolones. If untreated, *C difficile* infection can progress to fulminant colitis, ileus, obstruction, perforation, and toxic megacolon; therefore, prompt diagnosis and treatment are essential.

Clinical Findings

Clinical findings include diarrhea, fever, and leukocytosis. If *C difficile* infection is suspected, the stool should be sent for cytotoxin assay. If the infection is strongly suspected despite negative toxin stool toxin assays, colonoscopy can be performed to detect pseudomembranous changes in the colon. Toxic megacolon is a clinical diagnosis based on dilatation of the colon >7 cm on plain films, accompanied by severe systemic toxicity.

Treatment

C difficile is becoming increasingly pathogenic and contagious. Once diagnosed, the patient should be placed in isolation with infection precautions. Management includes first withdrawal of the implicated antibiotic, and then treatment with preferably oral metronidazole or vancomycin. However, oral metronidazole is preferred in order to reduce vancomycin resistance and to reduce cost. If the infection is unresponsive to antibiotics and progresses to toxic megacolon, surgical intervention with colectomy may be necessary.

URINARY TRACT COMPLICATIONS

1. Urinary Retention

Postoperative urinary retention is the inability to void in the presence of a full bladder. Risk factors for development of postoperative urinary retention include prolonged duration of surgery and the use of regional anesthesia or epidural analgesia. The patient may complain of suprapubic discomfort with the inability to void. The bladder may be palpable on abdominal exam if severely distended. Retention is likely if the patient is unable to void within 8 hours after surgery or 8 hours after bladder catheter removal. The diagnosis is confirmed if a bladder ultrasound displays 500 mL of urine or if a postvoid residual is 500 mL or greater. If retention is present, complications and bladder dysfunction may result. An overdistended bladder can cause pain and an autonomic response, resulting in vomiting, hypotension, bradycardia, and cardiac dysrhythmias. Infection can also be a direct complication or an indirect complication due to an indwelling bladder catheter. Severe overdistention for prolonged periods may cause ischemia and long-term bladder dysfunction.

Treatment

Standard treatment for retention is immediate bladder drainage with sterile catheterization. Although intermittent in-out catheters are an alternative, most patients have an indwelling bladder catheter placed while in the hospital. The catheter is placed for approximately 24 hours, and then a void trial is performed. With incontinence procedures, such as suburethral slings, there may be retention due to overcorrection of the bladder neck requiring outpatient treatment with a catheter for several days.

2. Urinary Tract Infection

In the immediate postoperative period, patients are at risk for urinary tract infection (UTI). They are at risk of UTI due to urinary retention that follows surgery and anesthesia, as well as due to instrumentation or catheterization during surgery. Catheter-associated UTI is one of the most common nosocomial infections.

Cystitis and UTI can cause increased frequency of urination, urgency, and dysuria. White blood cells, leukocyte esterase, and nitrites can be seen on urine analysis. When fever is present, pyelonephritis should be considered. If untreated, pyelonephritis can progress to urosepsis.

In patients suspected of having a UTI, a urine specimen should be sent for culture. Appropriate antibiotic therapy should be instituted and adjusted based on culture and sensitivity results. In patients with urinary retention, a bladder catheter is recommended. However, in patients without urinary retention, removal of the bladder catheter at the earliest possible time is important in treating and preventing UTIs.

3. Lower Urinary Tract Fistula

A lower urinary tract fistula is a rare complication of gynecologic surgery and obstetric trauma. These fistulas include vesicovaginal and ureterovaginal fistulas. Risk factors for fistula include malignancy, radiation therapy, intraoperative injury to bladder or the ureter, and obstructed labor. Most lower urinary tract fistulas in the Unites States occur after hysterectomies.

A lower urinary tract fistula can present perioperatively as gross hematuria or urinoma noted after surgery. In the postoperative period, patients with fistulas usually present 1 to 3 weeks after surgery complaining of urinary incontinence or persistent vaginal discharge. A speculum exam may reveal a fluid collection in the vagina and scarring at the apex. If a vesicovaginal fistula cannot be seen, a "tampon test" can be performed in the clinic. This test is performed by instilling methylene blue transurethrally into the bladder after placing vaginal sponges or a tampon in the vagina. The patient is then asked to walk around and perform the Valsalva maneuver. Intravenous indigo carmine or oral phenazopyridine can be given to exclude an ureterovaginal fistula. A voiding cystourethrogram can also be performed to diagnose and evaluate the size and location of a vesicovaginal fistula.

Cystoscopy is indicated in all cases to evaluate the size, location, and number of fistulas and the condition of the tissue. Radiologic imaging such an IVP or cystoscopic retrograde urogram is recommended to exclude a ureterovaginal fistula or hydronephrosis.

If a vesicovaginal fistula is diagnosed early, conservative management can be attempted. Although the timing, fistula size, and success rate remain unclear, limited data suggest that fistulas less than 1 cm in size diagnosed within 3 weeks of surgery can close spontaneously after bladder drainage. In 1 study, 39% of fistulas closed with bladder drainage if diagnosed within 3 weeks of surgery, while only 3% closed if diagnosed greater than 6 weeks after surgery. The duration of bladder drainage remains unclear, but some authors recommend 4 weeks of continuous drainage.

Ureteral fistulas are usually treated with ureteral stents for 6 to 8 weeks. An IVP is performed after 4 to 6 weeks to evaluate if the fistula has healed. If the fistula has healed, the stent is removed and IVP is performed at 3, 6, 12, and 24 months to rule out stricture formation. If the fistula has not healed, the stent is left in place for 8 weeks and the IVP repeated. If the fistula is not healed in 8 weeks, surgical repair is recommended.

The timing of vesicovaginal fistulas is controversial. Ideally, the fistula should be repaired within 72 hours of injury, before inflammation and induration take place. Some surgeons recommend waiting 3 to 6 months until the fistula has matured. Other surgeons have successfully closed fistulas earlier, after the initial inflammation has subsided. Timing of surgical repair should be individualized and based on cystoscopic evidence of healing, including the fistula site and adjacent tissue being pliable, noninflamed, epithelialized, and free of granulation tissue and necrosis. Vesicovaginal fistulas can be repaired vaginally or abdominally, but the surgical technique is beyond the scope of this chapter.

INFECTIOUS COMPLICATIONS

Bacterial contamination of the operative site is a common occurrence in major gynecologic surgery. Hysterectomies are classified as "clean contaminated" cases due to the entrance into the genital tract and contamination with endogenous vaginal flora. Although antibiotic prophylaxis decreases the risk of postoperative infection, it still remains one of the most common postoperative complications. The diagnosis of a postoperative infection is generally made when there is pain and tenderness in the area contiguous with the infection and an oral temperature of ≥38°C on 2 separate occasions at least 6 hours apart or of >38.5°C at any time.

Prevention

Antibiotic prophylaxis is usually only indicated for hysterectomy and urogynecology procedures. Cefazolin (1 g) is the most commonly used agent and is given within 30 minutes of the start of the procedure. A second dose of intraoperative antibiotic may be given if the duration of the surgery approaches 3 hours or in cases with increased blood loss (>1500 mL). Doxycycline is also used before and after surgical abortion. For procedures such as laparoscopy or exploratory laparotomy that do not directly enter the genital tract, antibiotic prophylaxis is not indicated.

1. Hematoma & Pelvic Abcess

Clinical Findings

An abscess should be considered in the postoperative patient with fever and no other source or in a patient who has failed initial antibiotic treatment. The patient usually presents with fever and abdominal pain. Clinical findings may include a mass palpated on pelvic examination. Pelvic hematomas that become infected can also present in a similar manner.

Treatment

If an abscess is suspected, imaging should be performed with ultrasound or a CT scan with contrast. If confirmed, treatment involves parenteral antibiotics. Some regimens include gentamicin and clindamycin; ampicillin, gentamicin, and metronidazole; imipenem/cilastatin; and levofloxacin and metronidazole. Parenteral antibiotics are continued until the patient has been afebrile for 24 to 48 hours, and then patients are switched to oral antibiotics. Many abscesses, especially large ones, require drainage for adequate treatment. Percutaneous drainage of the fluid collection is often possible with insertion of a large-caliber "pigtail" catheter under ultrasound or CT guidance. An infected cuff hematoma or abscess can sometimes be managed by reopening the cuff. If the abscess does not respond to the above treatment, the patient may need a laparotomy with opening of the abscess, irrigation, and drain placement.

2. Wound Infection

A wound infection is usually localized to the skin and fatty tissue above the fascia. The diagnosis of a postoperative wound infection is usually made several days after surgery, on postoperative day 4 or 5.

Clinical Findings

With wound infections or cellulitis, skin erythema (redness and warmth), subcutaneous induration, and fever are usually present. If there is incisional drainage present, there may be an abscess or fluid collection beneath the incision.

Treatment

Cellulitis alone is usually treated with a single agent that is effective against streptococci, staphylococci, and most gramnegative organisms, such as a cephalosporin. If there is a fluid collection presenting with purulent drainage from the wound, it should be opened to allow drainage and debridement if necrotic tissue is present. The wound should be gently probed to check for fascial integrity. If the fascia is intact, the wound should be packed with moist gauze dressings 2 or 3 times daily.

3. Wound Dehiscence & Evisceration

Wound dehiscence is a postoperative wound separation that involves all layers of the abdominal wall. Risk factors include age, malnutrition, diabetes, smoking, malignancy, chronic steroid use, and obesity. Wound infection also predisposes the wound to disruption. Evisceration includes disruption of these layers with protrusion of intestines through the incision. The hallmark of this complication is profuse serosanguinous discharge from the abdominal incision. This is a surgical emergency that requires immediate closure in the operating room.

4. Necrotizing Fasciitis

ESSENTIALS OF DIAGNOSIS

- Diagnosis is based on physical findings of a rapidly progressing infection.
- Radiologic tests, such as CT, MRI, or plain films, will display gas in the subcutaneous tissue.
- Surgical exploration will confirm the diagnosis, which reveals necrotic subcutaneous tissue and fasciae.

Pathogenesis

Necrotizing fasciitis is a rare and often fatal infection that is characterized by extensive necrosis of the fascia and adjacent subcutaneous tissue. Predisposing factors include advanced age, obesity, hypertension, arteriosclerosis, diabetes, malnutrition, renal failure, immunosuppression, and trauma. The bacteria that cause these infections include group A *Streptococcus* and other anaerobes such as *Clostridium perfringens*.

Clinical Findings

The clinical triad includes sepsis, inordinate pain, and unilateral edema. On physical examination, patients may appear septic with a fever and leukocytosis. The skin around the incision site is usually cool, gray, and boggy, and may reveal crepitus. Usually, the wound will display a marked degree of subcutaneous edema and varying degrees of cutaneous discoloration. There also may be a sensory deficit over the area of infection.

Treatment

The most important treatment includes early and aggressive surgical debridement of the infection. This includes removal of all the necrotic tissue that is not bleeding and discolored. Healing is usually by secondary intention, with skin grafts often being necessary. Therefore, a gynecologic oncologist or plastic surgeon is usually involved. Treatment also includes broad-spectrum antibiotics, including a penicillin. Hyperbaric oxygen treatment can also lead to a decrease in the morbidity of these infections.

46
Therapeutic Gynecologic Procedures

Cecilia K. Wieslander, MD
Keri S. Wong, MD

The 4 most commonly performed gynecologic procedures in the United States are abdominal and vaginal hysterectomy, tubal sterilization, and dilation and curettage. This chapter will review these procedures, as well as other therapeutic operations. Indications, contraindications, technique, and complications will be discussed for each procedure.

Agency for Healthcare Research and Quality. HCUP Nationwide Inpatient Sample (NIS), Procedures. Healthcare Cost and Utilization Project (HCUP). 2006. Rockville, MD: Agency for Healthcare Research and Quality. http://www.hcupnet.ahrq.gov/HCUPnet.jsp.

DILATION & CURETTAGE

Indications

The procedure of cervical dilation and uterine curettage (D&C) is usually performed for 1 of the following indications: diagnosis and treatment of abnormal uterine bleeding, management of abortion (incomplete, missed, or induced), or diagnosis of cancer of the uterus. The diagnosis of abnormal bleeding is discussed in Chapter 38; D&C as a method of induced abortion is discussed in Chapter 58. This section will discuss the remaining therapeutic uses of D&C.

Technique

A. Cervical Dilation

Dilation of the cervix may be conducted under paracervical, epidural, spinal, or general anesthesia, depending largely on the indication for the procedure. Perioperative antibiotic prophylaxis is not recommended, but venous thromboembolism prophylaxis should be used in patients 40 years and older or with additional risk factors. Cervical dilation usually precedes uterine curettage but may be performed in a patient with cervical stenosis prior to insertion of an intrauterine contraceptive device (IUD) or radium device for treatment of cancer. Dilation may also precede hysterosalpingogram or hysteroscopy.

The patient is placed in the dorsal lithotomy position, with the back and shoulders supported and the extremities padded. The inner thighs, perineum, and vagina are prepared as for any vaginal operation; the surgeon and assistant should adhere to surgical principles of asepsis. A thorough pelvic examination under anesthesia is mandatory prior to performing cervical dilation, in order to determine the size and position of the cervix, uterus, and adnexa and the presence of any abnormalities. The patient voids normally before the operation if possible; urinary catheterization is used only if significant residual urine is suspected.

A right-angle retractor is placed anteriorly to gently retract the bladder. A weighted speculum is placed posteriorly to reveal the cervix. Under direct vision, the anterior lip of the cervix is grasped with a tenaculum, avoiding the vascular supply at 3 and 9 o'clock. The cervix is grasped firmly but with care taken not to compromise, or especially perforate, the endocervical canal. With gentle traction, the cervix can be brought down toward the introitus. Before proceeding further, a complete visual examination should be made of the cervix and the 4 vaginal fornices, because the latter areas (especially posteriorly) are otherwise difficult to examine. Areas that appear abnormal (even benign inclusion cysts) should be noted and followed as appropriate. Areas that are clearly abnormal should be biopsied. After the cervix and vagina are evaluated, the uterine cavity is examined. A uterine sound is gently inserted into the endocervix and then advanced into the uterine cavity in the plane of least resistance and most compatible with the position of the uterus as revealed by pelvic examination. The depth of the uterine cavity is recorded as well as any abnormalities such as leiomyomas or septa.

Perforation of the uterus during D&C is most likely to occur at the time of uterine sounding or cervical dilation. Recognized uterine perforations during D&C occur at a rate of 0.63–1.0% according to 2 large classical studies. The majority of perforations are thought to be due to misdirected or excessive force. Perforation is more likely to occur if the woman is postmenopausal (1 in 38), has cancer (1 in 48), or is post pregnancy (1 in 122). Other risk factors include having a retroverted or anteverted uterus or having cervical stenosis. Unless there is evidence of hemorrhage, injury to the bowel, or evulsion of the omentum, conservative treatment of uterine perforation is best.

If severe cervical stenosis is suspected from the preoperative office examination, cervical softening agents such as misoprostol or *Laminaria* tents may be used. Both oral and vaginal misoprostol and *Laminaria* tents have demonstrated a benefit over placebo in the ease of cervical dilation in pregnant and premenopausal women. In a systematic review of 10 randomized controlled trials involving premenopausal women undergoing hysteroscopy compared preprocedure misoprostol versus placebo to aid in cervical dilation, preprocedure misoprostol resulted in a reduced need for cervical dilation (relative risk [RR], 0.6; 95% confidence interval [CI], 0.5–0.7), a lower rate of cervical laceration (RR, 0.22; 95% CI, 0.1–0.6), and an increase in cervical dilatation (RR, 2.66; 95% CI, 1.7–3.5), but a higher rate of side effects (vaginal bleeding, cramping, and elevated temperature). For every 4 premenopausal women who received misoprostol prior to hysteroscopy, 1 avoided the need for further cervical dilation. For every 12 premenopausal women receiving misoprostol, 1 cervical laceration was avoided. The vaginal route of misoprostol may be more effective than oral misoprostol as shown by 1 study. In postmenopausal women and women who have been pretreated with gonadotropin-releasing hormone, randomized controlled trials have produced inconclusive results.

The most common dilators used are the Hegar, Pratt, and Hank dilators. Hegar dilators are relatively blunt, gently curved, and numbered sequentially according to width (ie, a No. 7 dilator is 7 mm wide). Pratt and Hank dilators differ from Hegar dilators in being more gradually tapered ("sharper"); they may have a solid core (Pratt) or a hollow center (Hank), allowing egress of trapped blood and air. Pratt or Hank dilators are measured in French sizes (a No. 20F Hank dilator is approximately the same diameter as a No. 9 Hegar dilator). The choice of dilator is largely based on surgical training; many prefer not to use the more pointed Hank dilators in a small postmenopausal uterus.

B. Endocervical Curettage

Fractional curettage should be used for abnormal uterine bleeding or if genital tract neoplasia is suspected. The cervical canal should be curetted prior to dilation of the cervix and curettage of the endometrial cavity, in order to preserve the histologic characteristics of the endocervix and prevent contamination of the endometrial sample with endocervical cells. If cervical conization is planned for diagnosis or treatment of cervical intraepithelial neoplasia, uterine sounding precedes conization, but cervical dilation and fractional curettage follow in order to minimize denuding of the endocervical epithelium. The Gusberg curette is a small, slightly curved instrument particularly well suited for endocervical curettage. The curette is placed in the endocervical canal to the level of the internal os; with a firm touch, each of the 4 walls is curetted with a single stroke, with the specimen delivered onto a coated cellulose sponge with a twirling motion of the curette. (The coated cellulose sponge is preferred over ordinary surgical sponges because tissue is less likely to adhere to it.) The cervix is then dilated as described earlier and curettage of the endometrium performed. The endocervical and endometrial specimens are immersed in fixative in separate containers and submitted to the pathologist.

Complications from endocervical curettage are rare in nongravid patients. Because of obvious risks to the fetus and membranes, endocervical curettage is contraindicated in pregnant women. Healing of the curetted endocervix may take 3 weeks or more; the cervical epithelium commonly takes 2 weeks to heal following a routine Papanicolaou (Pap) smear. Tissue should be allowed to heal before follow-up Pap smears are taken because regenerating cells are often mistaken for dysplastic cells.

C. Endometrial Polypectomy

The uterine cavity is explored with polyp forceps prior to diagnostic or therapeutic endometrial curettage. It is easier to remove polyps prior to curettage, preserving the histologic integrity necessary to differentiate benign uterine polyps from neoplasia. In a large series advocating routine exploration of the endometrial cavity preceding curettage, 64% of 130 diagnosed endometrial polyps were removed by ureteral stone forceps. Thirty-nine percent of the polyps were removed with exploring forceps after the curettage had been carried out. Pedunculated or submucous leiomyomas, intrauterine and intracervical synechias, and uterine anomalies may be first suspected at passage of the polyp forceps.

The technique of polypectomy includes gentle insertion of the forceps in the plane most compatible with the position of the uterus (as for uterine sounding). The forceps are opened slightly, rotated 90 degrees, and removed. Many clinicians repeat this procedure through 360 degrees, completely exploring the uterine cavity.

Skillful use of hysteroscopy for diagnosis and treatment of synechias, septa, leiomyomas, and polyps is preferred to blind polypectomy and curettage. With the new, narrow hysteroscope, the procedure is easily done as an office procedure similar to colposcopy for biopsy or laser conization.

D. Endometrial Curettage

Endometrial curettage is often both diagnostic and therapeutic. It is indicated for treatment of complications of pregnancy, including incomplete or missed abortion, postpartum retention of products of conception, and placental polyps. The procedure is also useful in women with menorrhagia who are hypovolemic and refractory to medical management to stop the acute bleeding. D&C should not be used to treat dysfunctional uterine bleeding in women without hypovolemia, because it has no effect on mean blood loss in subsequent periods (with the exception of the first period following the D&C) and is inferior to medical management. D&C is inferior to hysteroscopy in diagnosing and treating abnormal uterine bleeding due to uterine fibroids or endometrial polyps. It is contraindicated in infection, such as acute endometritis, salpingitis, and pyometra. If infected placental tissue must be removed, the D&C should follow a period of parenteral antibiotics. The technique of endometrial curettage is tailored to the individual patient. In determining the hormone responsiveness of the endometrium, a small but representative sample may be obtained from the anterior and posterior walls. When curettage is being performed therapeutically, a systematic, thorough approach is indicated. The largest sharp curette that can comfortably fit through the dilated cervix is chosen. A serrated curette may cause injury to the underlying basalis layer of the endometrium and myometrium. The anterior, lateral, and posterior walls are scraped with firm pressure in a clockwise or counterclockwise fashion from the top of the uterine fundus down to the internal os. The top of the cavity is curetted with a side-to-side motion. The curettings are retrieved onto the waiting gauze and immersed in fixative as soon as possible. If endometrial curettage is being used for diagnosis of infection (eg, tuberculous endometritis), a portion of the curettings should be placed in containers appropriate for culture (without fixative).

A single curettage will not remove the entire endometrium. Thorough curettage by an experienced gynecologist often removes 50–60% of the endometrium, as determined by immediate postcurettage hysterectomy. If risk factors for endometrial cancer are present and clinical suspicion for neoplasia persists despite a histologic diagnosis of benign endometrium, further evaluation with hysteroscopically guided biopsy or hysterectomy is indicated.

Perforation of the uterus occurred in 0.63% of a large series of D&Cs. Perforation is suspected when the sound or curette meets no resistance at the point expected by uterine size, consistency, and position determined by preoperative bimanual examination. Curettage may be continued if the area of suspected perforation is avoided. Should suction curettage be associated with perforation, laparoscopy must be used to continue the procedure to avoid aspiration of bowel into the uterine cavity. In the case of suspected perforation, the patient should be observed for at least 24 hours in the hospital for possible infection or hemorrhage. In a series of 70 uterine perforations, 55 were treated expectantly, and only 1 patient developed complications (pelvic abscess drained via colpotomy). In 7 patients, hysterectomy was elected but not indicated by operative findings. Today, laparoscopy is the method of choice for evaluating perforations in the hemodynamically stable patient.

E. Endometrial Biopsy

Outpatient curettage, or endometrial biopsy, should always be a diagnostic and not a therapeutic technique. The many techniques available, all compared to D&C under adequate anesthesia, are discussed in Chapter 35.

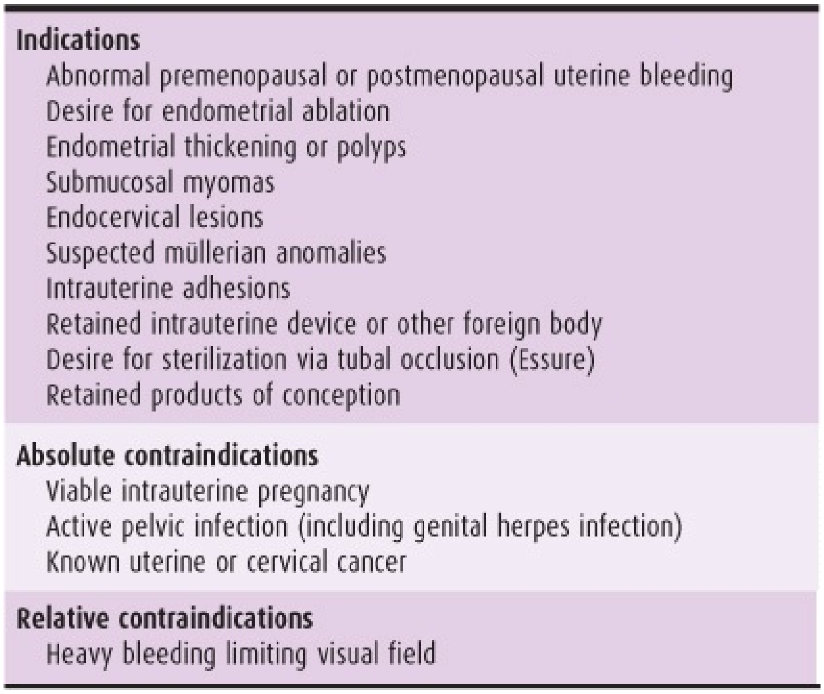
HYSTEROSCOPY

This section will discuss the therapeutic uses of hysteroscopy.

Indications & Contraindications

See Table 46–1.

Table 46–1. Indications and contraindications for hysteroscopy.



Indications
Abnormal premenopausal or postmenopausal uterine bleeding
Desire for endometrial ablation
Endometrial thickening or polyps
Submucosal myomas
Endocervical lesions
Suspected müllerian anomalies
Intrauterine adhesions
Retained intrauterine device or other foreign body
Desire for sterilization via tubal occlusion (Essure)
Retained products of conception
Absolute contraindications
Viable intrauterine pregnancy
Active pelvic infection (including genital herpes infection)
Known uterine or cervical cancer
Relative contraindications
Heavy bleeding limiting visual field

Technique

Hysteroscopes exist as both flexible and rigid models. Operative hysteroscopes are rigid and typically

8–10 mm in external diameter. The outer sleeve encloses a fiberoptic light source, a channel used to introduce a medium to distend the uterus, and a channel through which probes, forceps, and electrocautery or laser instruments may be visually directed in the uterine cavity. Viewing angles vary from 0 to 70 degrees.

The uterine cavity, which is normally collapsed, must be distended by a medium. Carbon dioxide is used in the outpatient setting for diagnostic purposes. Low-viscosity, electrolyte-poor fluids include glycine 1.5%, sorbitol 3%, and mannitol 5%. These fluids can be used with monopolar devices during electrosurgery because they do not conduct electricity. Glycine 1.5% and sorbitol 3% are hypo-osmolar solutions. The use of these fluids can cause hyponatremia and decreased serum osmolality, which can lead to cerebral edema and death. Mannitol 5% is iso-osmolar and acts as its own diuretic. It may cause hyponatremia but not decreased serum osmolality. Low-viscosity electrolyte fluids include normal saline and lactated Ringer’s solution. These fluids are isotonic, which decreases the risk of hyponatremia and decreased serum osmolality. Pulmonary edema can still occur, and therefore, careful attention should be paid to the fluid deficit. Two disadvantages to the use of electrolyte solutions are mixing of blood, which limits visualization, and the inability to use monopolar electrosurgery because these solutions are electroconductors. However, it is possible to conduct electrosurgery in electrolyte fluids using bipolar electrosurgical systems.

High-viscosity fluids include dextran-70, which is a colorless, viscous, polysaccharide solution. The advantage of using dextran is that it is immiscible with blood, which allows for clear visualization in the presence of bleeding. The disadvantage is that it is sticky, and when dry, can harden and crystallize into the equipment. Dextran can cause rare but serious complications including anaphylactic reactions, fluid overload, pulmonary edema, and coagulopathy. The manufacturer recommends that patients be followed closely for pulmonary edema in the following situations: the procedure lasts >45 minutes, absorption of more than 250 mL of dextran-70, resection of large areas of endometrium, or administration of intravenous fluids at more than maintenance rate. If pulmonary edema develops, the patient may need plasmapheresis, because dextran-70 contains mainly high-molecular-weight molecules that are excreted slowly or not at all from the kidneys. Beet sugar allergy is an absolute contraindication to using dextran-70. The volume of dextran-70 is usually limited to 300 mL but must not exceed 500 mL.

An abundance of instruments are available for use in hysteroscopic procedures, including blunt probes, micro-scissors, alligator clamps, rollerball electrode, wire loop for excision and coagulation (resectoscope), and devices for nonresectoscopic system endometrial ablation. Local or general anesthetics are chosen on the basis of expected hysteroscopic findings or procedures, concomitant operations planned, and the desires and cooperation of the patient. Most hysteroscopic examinations and virtually all therapeutic procedures are performed under general anesthesia. Following administration of anesthesia, the urinary bladder is drained, and the anterior lip of the cervix is grasped with a tenaculum. The cervix should then be gradually dilated to the same diameter as the external sleeve of the hysteroscope in order to provide a snug fit. An assistant must be constantly present during hysteroscopy to monitor uterine insufflation so that the pressure never exceeds 100 mm Hg and the flow rate of the distending medium never exceeds 100 mL/min. The chance of fluid overload is markedly increased when the mean infusion pressure exceeds the mean arterial pressure. The lowest infusion pressure needed to obtain good visualization should be used. The assistant and surgeon must monitor the fluid deficit closely to prevent volume overload. The surgeon should be sitting comfortably, with all instruments available to perform the hysteroscopic procedure safely and expeditiously. Following the procedure, intrauterine instruments should be inspected for their integrity. The microscissors in particular are delicate and could break within the uterus. If dextran is used, it must be immediately flushed from the hysteroscope before it is allowed to dry.

Complications

Hysteroscopic surgery is generally safe in experienced hands. The most common complications include cervical laceration (1–11%), hemorrhage (2.4%), and fluid overload (1.5%). Other complications include uterine perforation, visceral injury, carbon dioxide and air embolism, and rarely death. With laparoscopic observation, the serious complication of uterine perforation can almost always be prevented. If overt bleeding occurs during resection of a septum, polyp, or leiomyoma, the laparoscopic probe can be held against the uterine vessels to slow the blood flow. Alternatively, the bleeding area can be electrocoagulated, or a Foley catheter may be inserted into the uterine cavity and inflated to provide a tamponade. Infection is an unusual complication following hysteroscopy, and prophylactic antibiotics are not recommended. Air and carbon dioxide emboli are rare but serious complications that can result in circulatory collapse. Signs and symptoms of embolization include chest pain and dyspnea in the awake patient, sudden hypotension, decrease in oxygenation and/or in end-tidal carbon dioxide, or cardiac dysrhythmias in the anesthetized patient. Other findings include the presence of a "mill wheel" cardiac murmur, hypotension, tachycardia, or bradycardia. If gas embolization occurs, the patient should be placed in the left lateral decubitus position with the head tilted downward 5 degrees. This position favors movement of gas in the right ventricle toward the apex of the right ventricle. The gas may then be aspirated via cardiocentesis or by passing a catheter down the jugular vein into the right ventricle.

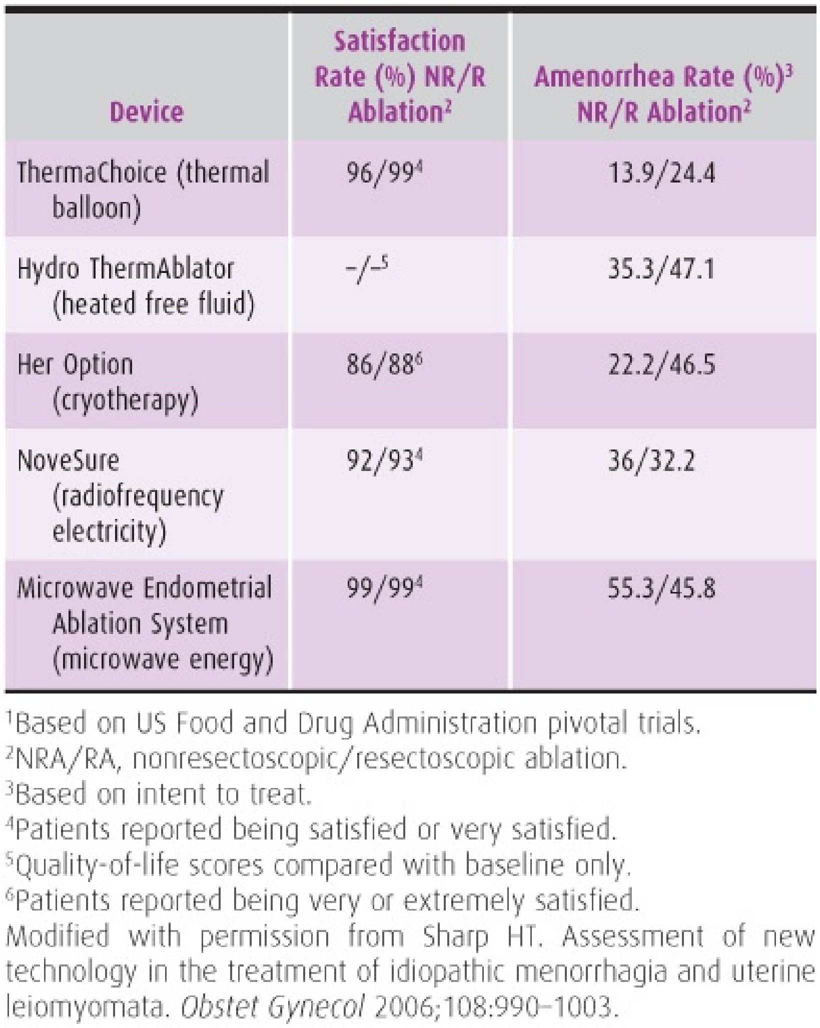
Complications of distending media include hyponatremia and pulmonary edema if an excessive amount results in vascular intervasation. The American College of Obstetricians and Gynecologists (ACOG) has adopted the following guidelines for fluid monitoring. (1) Hydration of patients should be monitored closely pre- and postoperatively. (2) If low-viscosity, electrolyte-poor fluids are used, the fluid deficit should be monitored at an extremely close interval when a deficit of 750 mL is reached. The procedure should be terminated in elderly patients, in patients with comorbid conditions, and in patients with cardiovascular compromise. (3) If fluid deficit reaches 1000–1500 mL of a nonelectrolyte solution or 2500 mL of an electrolyte solution, the procedure should be terminated. Electrolytes should be obtained, administration of diuretics should be considered, and further diagnostic and therapeutic interventions should begin as indicated. (4) In an outpatient setting with limited acute care and laboratory services, consideration should be given to terminate the procedure at a lower fluid deficit threshold. (5) An automated fluid monitoring system facilitates early recognition of excessive deficit in real-life totals. (6) In the absence of automated fluid monitoring, an individual should be designated to frequently measure intake and outflow and report the deficit to the operative team. Patients who need treatment for fluid overload from hypotonic agents may require transfer to an acute care facility and consultation. Seizure, permanent brain damage, and death have been reported with serum sodium levels of 112–118 mmol/L. If hyponatremia has existed for <24 hours, rapid correction can be made. However, if hyponatremia has existed for over 48 hours, rapid correction should not be undertaken due to the risk of neurologic compromise, seizures, and death. Consultation is strongly encouraged in these circumstances.

Prognosis

With proper selection of patients, hysteroscopic surgery has high success rates. Small pedunculated leiomyomas and polyps are usually retrieved by an experienced, patient surgeon. Submucous leiomyomas may be destroyed if they are not too vascular. In the treatment of intrauterine adhesions, the chance for success and restoration of a normal endometrial cavity depends on the density and extent of the adhesions and the area of normal endometrium remaining after dissection. Following hysteroscopic surgery for infertility in which the endometrium is denuded, postoperative estrogen therapy is prescribed by many physicians to promote rapid endometrial growth.

Both resectoscopic and nonresectoscopic endometrial ablation techniques exist and appear to be equivalent with respect to successful reduction in menstrual flow and patient satisfaction at 1 year (Table 46–2). Despite the high satisfaction rate, both resectoscopic and nonresectoscopic endometrial ablations are associated with hysterectomy rates of at least 24% within 4 years of the procedure.

Table 46–2. Patient satisfaction and amenorrhea rates associated with nonresectoscopic endometrial ablation compared with resectoscopic ablation at 12 months.[1]



Device	Satisfaction Rate (%) NR/R Ablation[2]	Amenorrhea Rate (%)[3] NR/R Ablation[2]
ThermaChoice (thermal balloon)	96/99[4]	13.9/24.4

LAPAROSCOPY

Laparoscopy is a transperitoneal endoscopic technique that provides excellent visualization of the pelvic structures and often permits the diagnosis of gynecologic disorders and pelvic surgery without laparotomy.

Laparoscopes range in diameter from 3–12 mm and have lenses with a viewing angle ranging from 0–135 degrees. The instrument has an effective length of over 25 cm and can be used with a fiberoptic light box. To facilitate visualization, carbon dioxide (CO_2) must be instilled into the peritoneal cavity to distend the abdominal wall.

Use of a pneumatic insufflator permits continuous monitoring of the rate, pressure, and volume of the gas used for inflation. In addition to the equipment used for observation, a variety of other instruments for resection, biopsy, coagulation, aspiration, and manipulation can be passed through separate ports or inserted through the same port as the laparoscope. Laparoscopic ports range in diameter from 3–20 mm in diameter. A laser (CO_2 or Nd:YAG) may be used with the laparoscope.

The laparoscope has become an invaluable tool in both diagnostic and operative gynecologic procedures. However, its use requires considerable expertise, and it should always be used by a surgeon familiar with the management of complications. Laparoscopic procedures are *major* intraabdominal operations performed through small incisions. This technique is rapidly performed and has a low morbidity rate and a short convalescence period. In many cases, laparoscopy may replace conventional laparotomy for diagnosis and treatment of gynecologic problems. It is a cost-effective outpatient procedure.

Indications

The indications will increase with the clinician’s experience and as technical innovations permit even more complicated procedures.

A. Diagnosis

1. Differentiation between ovarian, tubal, and uterine masses (eg, ectopic pregnancy, ovarian cyst, salpingitis, myomas, endometriosis, and tuberculosis)
2. Pelvic pain (eg, possible adhesions, endometriosis, ectopic pregnancy, ovarian torsion or hemorrhagic ovarian cyst, salpingitis, appendicitis, and nongynecologic pelvic pain)
3. Genital anomalies (eg, ovarian dysgenesis, müllerian anomalies)

4. Ascites (eg, ovarian diseases vs. cirrhosis)
5. Pelvic injuries after penetrating or nonpenetrating abdominal trauma
6. Diagnosis of occult cancer

B. Evaluation

1. Infertility (eg, tubal patency, ovarian biopsy)
2. “Second look” after tubal surgery or treatment of endometriosis
3. Peritoneal washings for cytology study
4. Peritoneal culture (eg, *Actinomyces* or tuberculosis)
5. Evaluation of uterine perforation
6. Evaluation of pelvic viscera to determine the feasibility of vaginal hysterectomy

C. Therapy

1. Tubal sterilization:
    a. Electrical: Unipolar or bipolar technique
    b. Mechanical: Silastic bands or rings, metal clips
2. Lysis of adhesions, with or without laser
3. Fulguration of endometriosis by laser or thermal cautery
4. Removal of extruded IUD
5. Uterosacral ligament division (denervation)
6. Treatment of ectopic pregnancy
7. Myomectomy
8. Salpingostomy for phimotic fimbria
9. Removal of tuboplastic hoods or splints
10. Ova collection for in vitro fertilization
11. GIFT (gamete intrafallopian transfer for fertilization)
12. Mini-wedge resection of ovary
13. Biopsy of tumor, liver, ovary, spleen, omentum, etc
14. Placement of intraperitoneal clips as markers for radiotherapy
15. Oophorectomy
16. Ovarian cystectomy
17. Laparoscopic-assisted vaginal hysterectomy, laparoscopic subtotal hysterectomy, and laparoscopic hysterectomy
18. Reconstructive surgery for pelvic organ prolapse and urinary incontinence

Contraindications

A. Absolute

Intestinal obstruction, generalized peritonitis, massive hemorrhage.

B. Relative

Severe cardiac or pulmonary disease, previous periumbilical surgery, shock, cancer involving anterior abdominal wall.

Additional factors weighing against performing laparoscopic surgery include extremes of weight, intrauterine pregnancy after the first or early second trimester, presence of a large mass, inflammatory bowel disease, and known severe intraperitoneal adhesions.

Preparation for Laparoscopy

Careful explanation of the risks and benefits of the planned procedure must be given to each patient prior to surgery. The risk of visceral and vascular injuries and the need to convert to laparotomy should be discussed with all patients. Patients with prior abdominal surgery, prior pelvic inflammation (appendicitis and pelvic inflammatory disease), or radiation therapy should be told that they are at increased risk of visceral or vascular injury or conversion to laparotomy. Preparation includes no solid food for at least 8 hours prior to surgery, no liquids for more than 6 hours preoperatively, a history and physical examination, and routine blood studies. Preoperative bowel cleansing can aid in visualization during surgery by decompressing the small bowel and sigmoid colon. Abdominal or perineal shaving is usually unnecessary, but skin preparation with an antiseptic is routine. Antibiotic prophylaxis is not recommended because the frequency of wound infection is low.

Anesthesia

Local anesthesia, local anesthesia with systemic analgesia, spinal or epidural block techniques, or general anesthesia with or without endotracheal intubation may be used. Special hazards of anesthesia exist (eg, reduced diaphragmatic excursion because of the pneumoperitoneum and because the patient may be operated on in the Trendelenburg position). Because of these factors, most procedures in the United States are performed with the patient under general anesthesia with endotracheal intubation. With adequate understanding of the physiology involved, effective anesthesia and laparoscopy can be accomplished safely.

An alternative to general anesthesia is local anesthesia with intravenous sedation. The patient may experience transient discomfort during manipulation of the uterine tubes, but in selected patients, this discomfort is easily tolerated.

Surgical Technique

The patient should be placed with her arms at her sides in the dorsal lithotomy position and draped after induction of anesthesia and preparation of the abdomen and pelvic area. The video monitor should be placed in a position that allows for easy viewing by the surgeon, usually at the patient’s feet or side. The bladder must be emptied by catheterization to decrease the risk of injury during subsequent introduction and use of other instruments. After careful bimanual examination, a tenaculum is attached to the cervix, and a uterine manipulator (Hasson, HUMI, Hulka, etc.) is placed into the cervical canal to elevate the uterus, which places tissue on tension. A 1-cm incision is made within or immediately below the umbilicus. The peritoneal cavity is entered blindly with a veress needle advanced at a 45-degree angle toward the hollow of the sacrum. Alternatively, the pelvis can be entered by using a trocar-cannula system or under direct visualization via a mini-laparotomy called “open laparoscopy.” Direct insertion of a cannula-trocar system can be accomplished safely if there have been no previous peritonitis or abdominopelvic surgeries. Open laparoscopy minimizes the risk of vascular injuries but does not eliminate intestinal injuries. Carbon dioxide should then be introduced and monitored by the pneumatic insufflator. The amount of gas insufflated will vary with the patient’s size, the laxity of the abdominal wall, and the planned procedure. In most patients, 2–3 L of gas will be needed to obtain adequate visualization. The maximum insufflation pressure should not exceed 15 mm Hg. If a veress needle is used, it is withdrawn and the laparoscopic trocar and cannula inserted. After proper abdominal entry, the trocar may be withdrawn and replaced with the fiberoptic laparoscope. The examiner manipulates the intrauterine cannula so that the pelvic organs can be observed. To test for tubal patency, methylene blue or indigo carmine solution can be injected through the intrauterine cannula. Direct observation of a lack of dye leakage attests to tubal patency. A second trocar with a cannula may be inserted under direct laparoscopic vision through a 5-mm transverse midline incision at the pubic hairline. Additional punctures are used as necessary for the placement of other instruments. A number of instruments are available including irrigators, the harmonic scalpel, forceps, scissors, staple applicators, and several vessel sealing and transection systems. Surgical knots may be tied and sutures placed using specially made equipment.

The operation is terminated by evacuating the insufflated gas through the cannula, followed by removal of all instruments and closure of the incisions. The skin can be closed with 3-0 subcuticular suture, skin glue, or steri-strips. Incisions >10 mm require fascial closure to avoid incisional hernias. A small dressing is applied to the wound.

A. Sterilization

Electrical cautery, Silastic rings or bands, and metal spring clips achieve sterilization by occluding the fallopian tubes. The advantages or disadvantages of the different techniques are of less significance than the skill with which a physician can perform any one technique; therefore, choice of method should depend on which technique is most comfortable for the physician. The failure rate of most sterilization methods is greater in women <28 years old.

1. Cautery—Laparoscopic sterilization with electrical cautery is one of the most common laparoscopic sterilization methods. Unipolar coagulation has a significantly lower pregnancy rate than bipolar coagulation (7.5/1000 vs. 24.8 over 10 years); however, bipolar coagulation is less likely to cause injury to adjacent structures (eg, bowel). At least 3 cm of the isthmic portion of the tube must be completely coagulated by using sufficient energy (25 W) delivered in a cutting waveform when using bipolar coagulation. The use of a current meter more accurately indicates complete coagulation than visual inspection. Generally, the tube is burned at 2 to 3 different locations, and division of the tube by cutting is not necessary.

2. Silastic Bands—Tubal occlusion with Silastic bands or rings results in a slightly higher pregnancy rate (17.7/1000 over 10 years) but fewer ectopic pregnancies. Mechanical problems in placement of the bands and bleeding from the tubes during the procedure are more common.

3. Clips—Tubal occlusion with clips (Hulka or Filshie clips) has a wide range of failure. Failure rates are higher for the Hulka clip (36.5/1000 over 10 years) than for the Filshie clip (0–4/1000 over 6–10 years). The advantages of using clips are that only a small portion of the tube is damaged (thus increasing the chance of successful sterilization reversal if the patient has regret) and that inadvertent burn injury to the bowel is avoided.

4. Interval Partial Salpingectomy—Compared to postpartum tubal ligation, interval partial salpingectomy has a higher failure rate of 20.1/1000 over 10 years.

B. Infertility

In procedures of sterilization reversal, laparoscopic visualization may be needed prior to reanastomosis, particularly if the ligation procedure involved electrocautery. Peritubal adhesions may be lysed with electric scissors, and salpingostomy may be accomplished. The minimal trauma of these procedures using laparoscopy and the saving of a major operative procedure are obvious benefits. Laparoscopy should be considered for women with complaints of abnormal bleeding and unexplained pelvic pain. More liberal use of the laparoscope has led to the diagnosis of many unsuspected cases of endometriosis.

Electrical fulguration of areas of endometriosis or laser destruction of these diseased areas by laparoscopy is a safe, effective, and rapid treatment. The use of laser obviously allows implants on structures such as bowel, bladder, and the fallopian tubes to be treated with a fairly wide margin of safety. Relief may be immediate and striking, whether the woman has complained of dysmenorrhea, dyspareunia, or generalized pelvic pain.

In infertility, the laparoscope has been important for ova collection for in vitro fertilization, GIFT, and other procedures. However, it is used less frequently now because most egg retrievals for in vitro fertilization are performed under ultrasound guidance.

C. Ectopic Pregnancy

In hemodynamically stable patients, laparoscopic linear salpingostomy is the preferred method for conservative management of tubal pregnancies. According to a recent Cochrane Database systematic review, the laparoscopic approach is less successful than the open approach in the elimination of tubal pregnancy due to the higher rate of persistent trophoblast tissue. However, it is feasible in virtually all patients, safe, and less costly compared to the open approach. Long-term follow-up shows a comparable intrauterine pregnancy rate and a lower repeat ectopic pregnancy rate. Persistent trophoblast tissue after laparoscopic salpingostomy can be significantly reduced after a prophylactic single dose of systemic methotrexate. An alternative conservative approach for those who meet the criteria is methotrexate administration.

D. Laparoscopic Hysterectomy

Laparoscopy can be used for total laparoscopic hysterectomy, laparoscopic-assisted vaginal hysterectomy, and laparoscopic subtotal hysterectomy (see section on hysterectomy). Other procedures that can be done via the laparoscope include vault suspension and pelvic reconstruction such as retropubic Burch colposuspension and abdominal sacral colpopexy.

E. Abdominal & Pelvic Pain

Laparoscopy has proved invaluable in differentiating various causes of acute and chronic pain. The technique may save the patient the necessity of a major exploratory operation. Fluid aspiration and tissue biopsy are possible through laparoscopy. Also, pelvic and intestinal disease can be differentiated. The appendix may be visualized and acute appendicitis may be diagnosed. Numerous cases of pain caused by intraabdominal adhesions also have been diagnosed by laparoscopy, and relief has been obtained following laparoscopic adhesion resection.

F. Trauma

In cases of intraabdominal trauma, laparoscopy can be used to exclude the need for a major abdominal operation.

G. Miscellaneous

“Missing” IUDs have been removed from the intraabdominal cavity. Mulligan plastic hoods from tuboplasty procedures, “lost” drains, and other foreign material have been removed from the abdomen by operative laparoscopy.

Postsurgical Care

Patients may be sent home following full recovery from anesthesia, usually in 1–2 hours. Recovery from more extensive procedures such as laparoscopic hysterectomy may require a longer hospital stay of 1–2 days. Postoperative pain is usually minimal, and patients are discharged with a prescription for a simple oral analgesic. The most common complaint is shoulder pain secondary to subdiaphragmatic accumulation of gas. Patients are encouraged to resume full activity, except for sexual relations, the day following surgery. Sexual relations may be resumed several days postoperatively after a simple procedure (eg, tubal ligation). Following extensive operative laparoscopy or other gynecologic procedures, coitus should be delayed for an appropriate interval (ie, until it is unlikely to cause discomfort or damage to the operative site). Patients should routinely be seen in the office 1–2 weeks postoperatively.

Complications

A review of the world experience of laparoscopic gynecologic operations, including 1,549,360 patients, showed an overall complication rate ranging from 0.2–10%. Higher complications rates were noted with prospective studies. The frequency of complications was less for nonoperative or minor procedures (0.06–7.0%) than for major operations (0.6–18%). Complications requiring conversion to laparotomy have been estimated to be 2.1% and are most commonly due to major vascular and intestinal injuries. The readmission rate to the hospital has been quoted to be 0.4–0.5%. The mortality rate for laparoscopy including 1,374,827 patients is 4.4 per 100,000 laparoscopies. The major causes of death are due to intestinal and vascular complications and anesthesia.

A. Vascular injuries

Major vascular injuries are infrequent (0.01–0.5%) and are almost 5 times more frequent during blind entry than during the laparoscopic operation itself. Catastrophic bleeding can occur if the aorta; inferior vena cava; or common, internal, or external iliac arteries and veins are injured. The mortality rate due to major vascular injuries is between 9 and 17%, and immediate conversion to laparotomy is almost always needed. Massive bleeding is often concealed in large retroperitoneal hematomas, and often only a small amount of intraperitoneal bleeding is seen. Open laparoscopic technique minimizes the risk of major vascular injury, but aortic injury has been reported in thin patients caused by the scalpel during the skin incision. The incidence of abdominal wall bleeding is 0.5%, and most injuries involve the inferior epigastric vessels (deep and superficial) and muscular vessels. Major bleeding requiring transfusion has been observed. The inferior epigastric vessels run in the lateral umbilical ligaments, and contrary to common belief, the inferior epigastric vessels cannot be seen via transillumination by the laparoscope. These are best avoided by placing the trocars lateral to the insertion of the round ligament into the anterior abdominal wall or 1–2 cm lateral to McBurney’s point (one-third the way between the anterior superior iliac spine and the umbilicus).

B. Intestinal Injury

Bowel injuries are uncommon (0.03–0.5%) but have a mortality rate of 2.5–5%. The colon and small bowel are injured at about the same rate, and they can be injured sharply or via thermal burns. About one-third are related to entry, and the rest are due to operative procedures. Unfortunately, most bowel injuries are not recognized intraoperatively (mean 4.4 postoperative days), likely due to the fact that most patients with laparoscopic intestinal injury do not present with the typical clinical signs of bowel perforation. Most patients present with low-grade fever, leukopenia, or normal leukocyte count. Pain at the trocar site near the injury, abdominal distention, and diarrhea with normal bowel sounds were commonly seen. Peritoneal signs, severe pain, nausea, vomiting, and ileus were uncommon, in a review of 266 cases of intestinal injury. Open laparoscopy has a similar rate of bowel injuries, but they are recognized more commonly intraoperatively.

C. Urinary Injuries

Urinary injuries during laparoscopy have a similar rate to open procedures (0.02–1.7%). Bladder injuries are more common than ureteral injuries and are recognized more frequently intraoperatively. About two-thirds of urinary injuries occur during laparoscopic-assisted vaginal hysterectomy.

D. Hernia at Site of Abdominal Wall Trocar

Ventral hernia formation is about 10 times lower with laparoscopy compared with laparotomy (0.06–1% vs. 11–13%). Five-millimeter trocar wounds do not require closure, whereas larger trocar wounds do. Most surgeons close incisions greater than 10 mm, due to the high rate of hernias. Richter’s hernias, where only a portion of the intestinal wall is entrapped in a defect of the peritoneum or posterior fascia, can be difficult to diagnose, since an externally visible bulge is often absent. The condition needs a high index of suspicion and can be diagnosed with an ultrasound or computed tomography scan.

E. Subcutaneous Emphysema & Gas Embolisms

Localized or generalized subcutaneous emphysema occurs in 0.3–2% of cases and generally has no clinical consequences. However, subcutaneous emphysema of the neck, face, and chest may be a manifestation of a pneumothorax or pneumomediastinum.

F. Postoperative Shoulder Pain

Pain from diaphragmatic irritation can be referred to the shoulder causing discomfort. Irritation of the diaphragm by the formation of carbonic acid (due to use of CO_2), stretching of the phrenic nerve by pneumoperitoneum, or pressure from the abdominal organs during Trendelenburg position are possible etiologies. It can be treated with mild analgesics and reassurance.

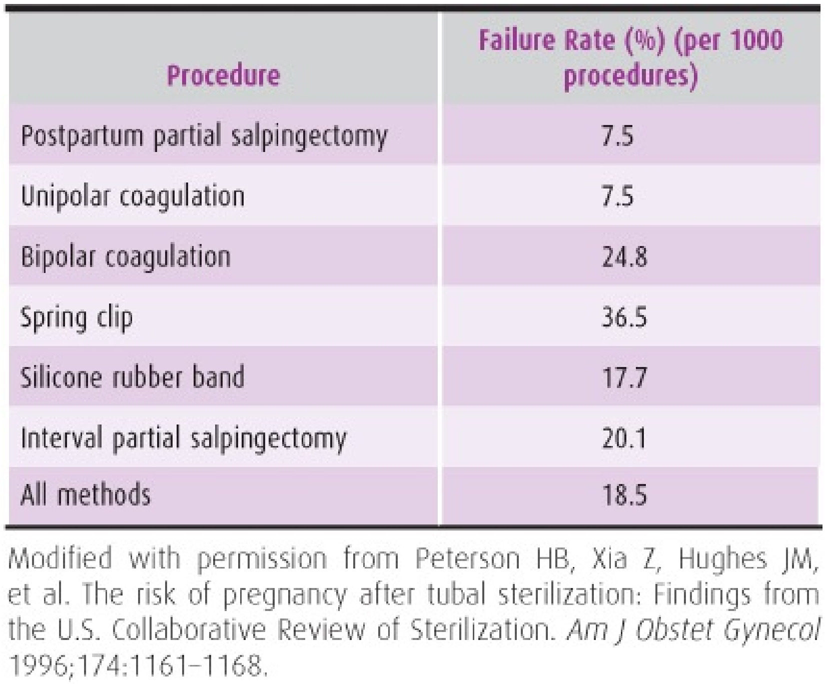
OPERATIONS FOR STERILIZATION OF WOMEN & MEN

Sterilization is a permanent method of contraception and is the most commonly used contraceptive method used in the United States. Approximately 700,000 tubal sterilizations and 500,000 vasectomies are performed in the United States annually.

TUBAL STERILIZATION

Thirty-three percent of US women use sterilization as their contraceptive method, and of those, 27% had tubal sterilization and 9% had partners who had a vasectomy. Table 46–3 lists the most common methods of tubal sterilization and their failure rates.

Table 46–3. Overall failure rates with tubal sterilization over 10 years.



Procedure	Failure Rate (%) (per 1000 procedures)
Postpartum partial salpingectomy	7.5
Unipolar coagulation	7.5
Bipolar coagulation	24.8
Spring clip	36.5
Silicone rubber band	17.7
Interval partial salpingectomy	20.1
All methods	18.5

Modified with permission from Peterson HB, Xia Z, Hughes JM, et al. The risk of pregnancy after tubal sterilization: Findings from the U.S. Collaborative Review of Sterilization. *Am J Obstet Gynecol* 1996;174:1161–1168.

Preoperative Counseling

Clear, comprehensive counseling is essential for women who are considering tubal sterilization. Possible medical and psychological complications must be carefully outlined (see Complications, later); women are more likely to regret having had the operation if they do not know what to expect. The physician should be alert to signs that the patient is undecided about having the operation or is being pressured by her partner or others. Regret or dissatisfaction is more common if the procedure is done postpartum than at another time, and these women are more than twice as likely to feel that preoperative counseling was inadequate. Temporary stress associated with the pregnancy may have influenced a premature decision for sterilization in these women.

Patients should be told that tubal sterilization is usually not reversible. Some methods are sometimes reversible (see Chapter 58). Most studies estimate that about 1–2% of women who undergo tubal sterilization request reversal. The major risk factor for subsequent regret of sterilization is young maternal age (younger than age 30 years) at the time of sterilization. Collaborative Review of Sterilization (CREST) study data showed that women who were younger than 30 years at the time of sterilization were twice as likely to seek information about reversal as women between age 30 and 34. Another major risk factor for regret is marital disharmony at the time of sterilization. In addition, women who have postpartum sterilization are more prone to regret than are women who have interval sterilization. Parity has not been found to be a significant risk factor for regret when controlling for maternal age. Pregnancy rates after tubal ligation reversals range from 55–90% by laparotomy and 31–78% via laparoscopy. Success of tubal ligation reversal depends on the woman's age at the timer of reversal (<35 years old) and length of remaining fallopian tube segment (>4 cm). Some studies have found improved pregnancy results when the initial sterilization procedure was performed using mechanical techniques rather than electrocautery.

Complications

Pain and menstrual disturbances (postbilateral tubal ligation syndrome) have been reported following tubal sterilization. The theory holds that destruction of the mesosalpinx might alter the blood supply and subsequent gonadotropin delivery to the ovary. Ovarian function and hormone production may then be altered. However, prospective controlled studies show that these problems are no more common than in women who have not undergone sterilization. Menstrual changes seem to be related to use of contraceptives—before sterilization. Oral contraceptives are associated with decreased menstrual flow and relief of dysmenorrhea. Once they are discontinued, heavier flow and pain may recur. Complaints of menstrual changes are much less frequent in the second half of the first postoperative year. Patients should be told that pelvic pain or menstrual disturbances may develop after tubal sterilization but are no more common than in other women of similar age and parity.

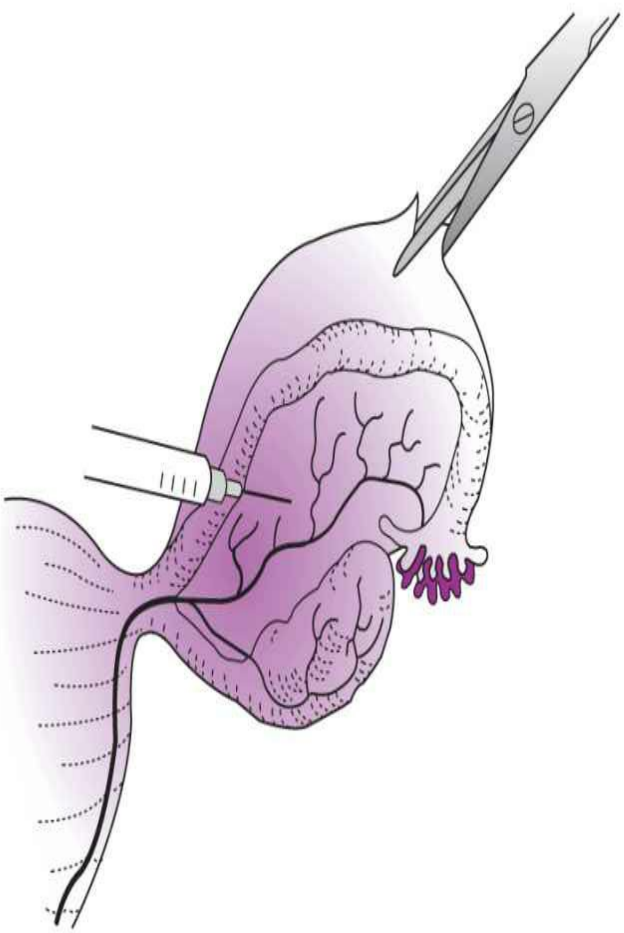
Patients who have undergone tubal sterilization require hysterectomy more frequently than patients who have not undergone this procedure. This is probably because most women who have tubal sterilizations have had children and are therefore more likely to have disorders typically treated with hysterectomy (eg, symptomatic pelvic relaxation, adenomyosis). Patients may have been sterilized secondary to medical reasons and gynecologic disorders that might eventually require further surgery. Some studies suggest that women are more likely to accept a surgical treatment if they have been sterilized.

Failure of sterilization is most often secondary to poor technique, for example, improper application of a clip or ring. Fistula formation may occur. A complication of failure is ectopic pregnancy (7.3 per 1000).

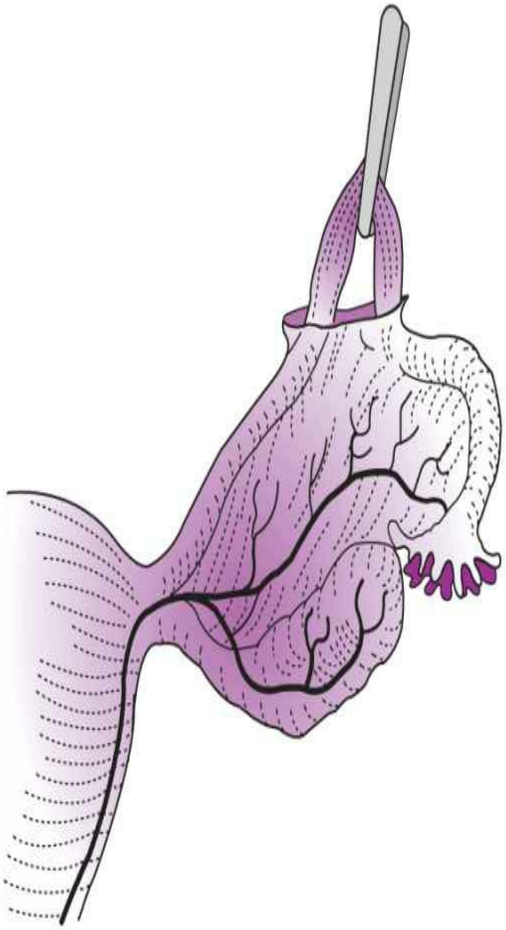
An association between decreased risk of ovarian cancer and tubal sterilization has been shown in several studies.

Technique (See Figs. 46–1 through 46–4).

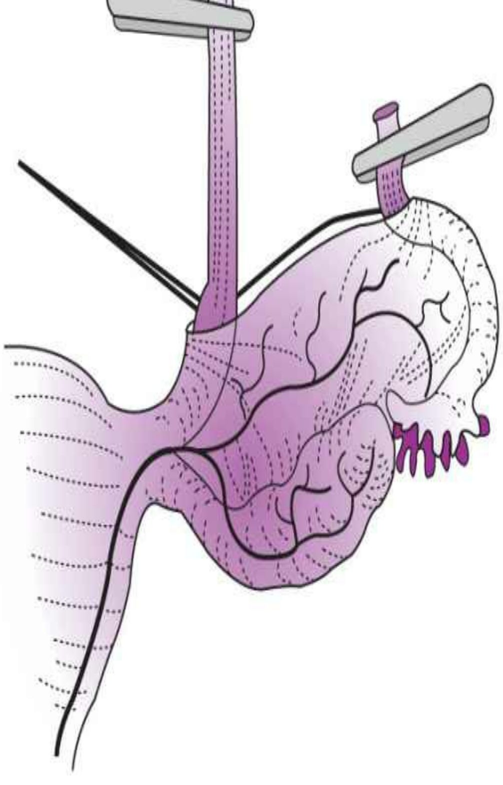
Postpartum tubal ligation uses a small infraumbilical incision to access the tubes. Mini-laparotomy involves a 2- to 3-cm incision made above the symphysis pubis. The incision is closed in 2 layers.

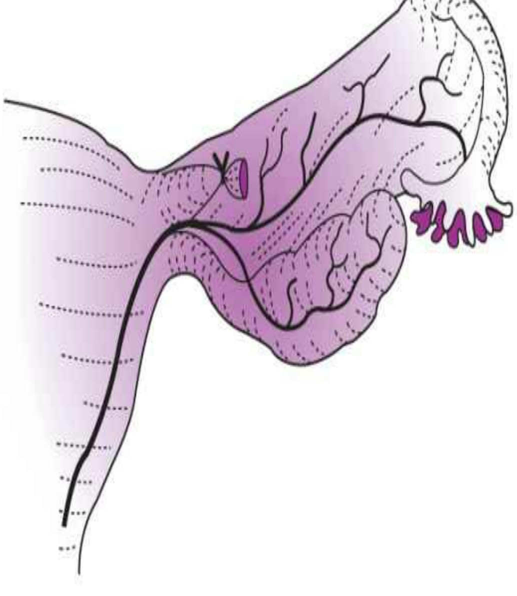


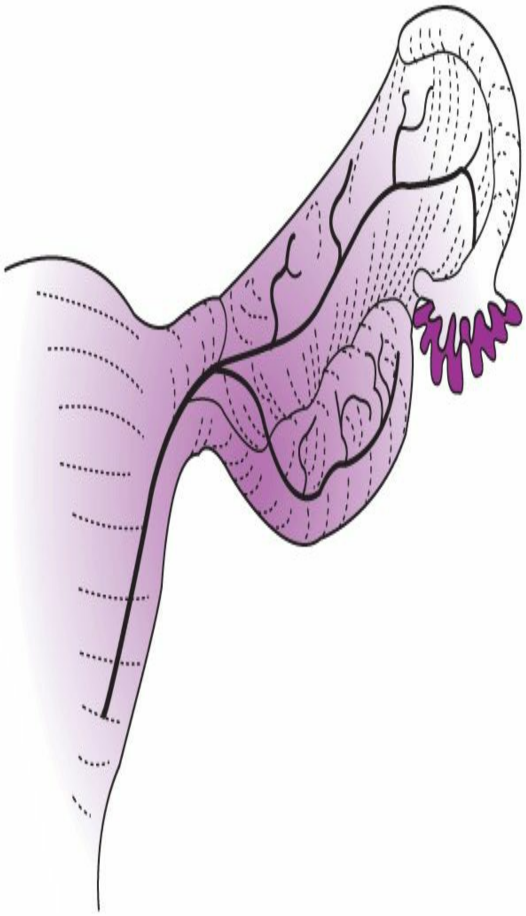
Saline with epinephrine injected below serosa, which becomes inflated locally. Muscular tube, and even blood vessels, can be separated from serosa, which is then cut open.



Muscular tube emerges through opening or is pulled out to form a U shape.







Fimbriated end is untouched, while the end leading to the uterus is stripped of serosa. This can usually be done without damaging blood vessels.

About 5 cm of muscular tube is cut away; the end is buried automatically in serosa. Fimbriated end and serosa opening are closed and tied together.

Blood supply continues normally between ovary and uterus. Hydrosalpinx or adhesion has not been noticed.

HYSTEROSCOPIC MICROINSERT PLACEMENT

A hysteroscopic tubal sterilization technique (Essure) was approved by the US Food and Drug Administration in 2002 (Fig. 46–5). It consists of a fallopian tube implant and a delivery catheter. The implant is a spring-like device 40 mm in length and 0.8 mm in diameter. It is made of titanium, stainless steel, and nickel that contain Dacron fibers that induce an inflammatory response and final fibrosis of the intramural tubal lumen. The implant is placed into the fallopian tube using a standard hysteroscope (<5 mm) with a 5-French working channel with continuous flow of normal saline. When released, the outer coil expands, which anchors the implant into the fallopian tube. Three to 8 coils should remain in the uterus for optimal placement. The procedure can be performed in the outpatient setting using oral analgesics alone or under local anesthesia with or without intravenous sedation. Hysterosalpingogram should be performed 3 months after the procedure to confirm closure of the fallopian tubes. The patient needs to use an alternative form of contraception until tubal occlusion is documented.

Polyethylene fibres
Right placement 3-8 coils in uterine cavity
Metal coils
Uterine cavity

Figure 46–5. Hysteroscopic microinsert placement. (Reproduced, with permission, from Hurskainen R, Hovi SL, Gissler M, et al. Hysteroscopic tubal sterilization: Systematic review of the Essure system. *Fertil Steril* 2010;94:16–19.)

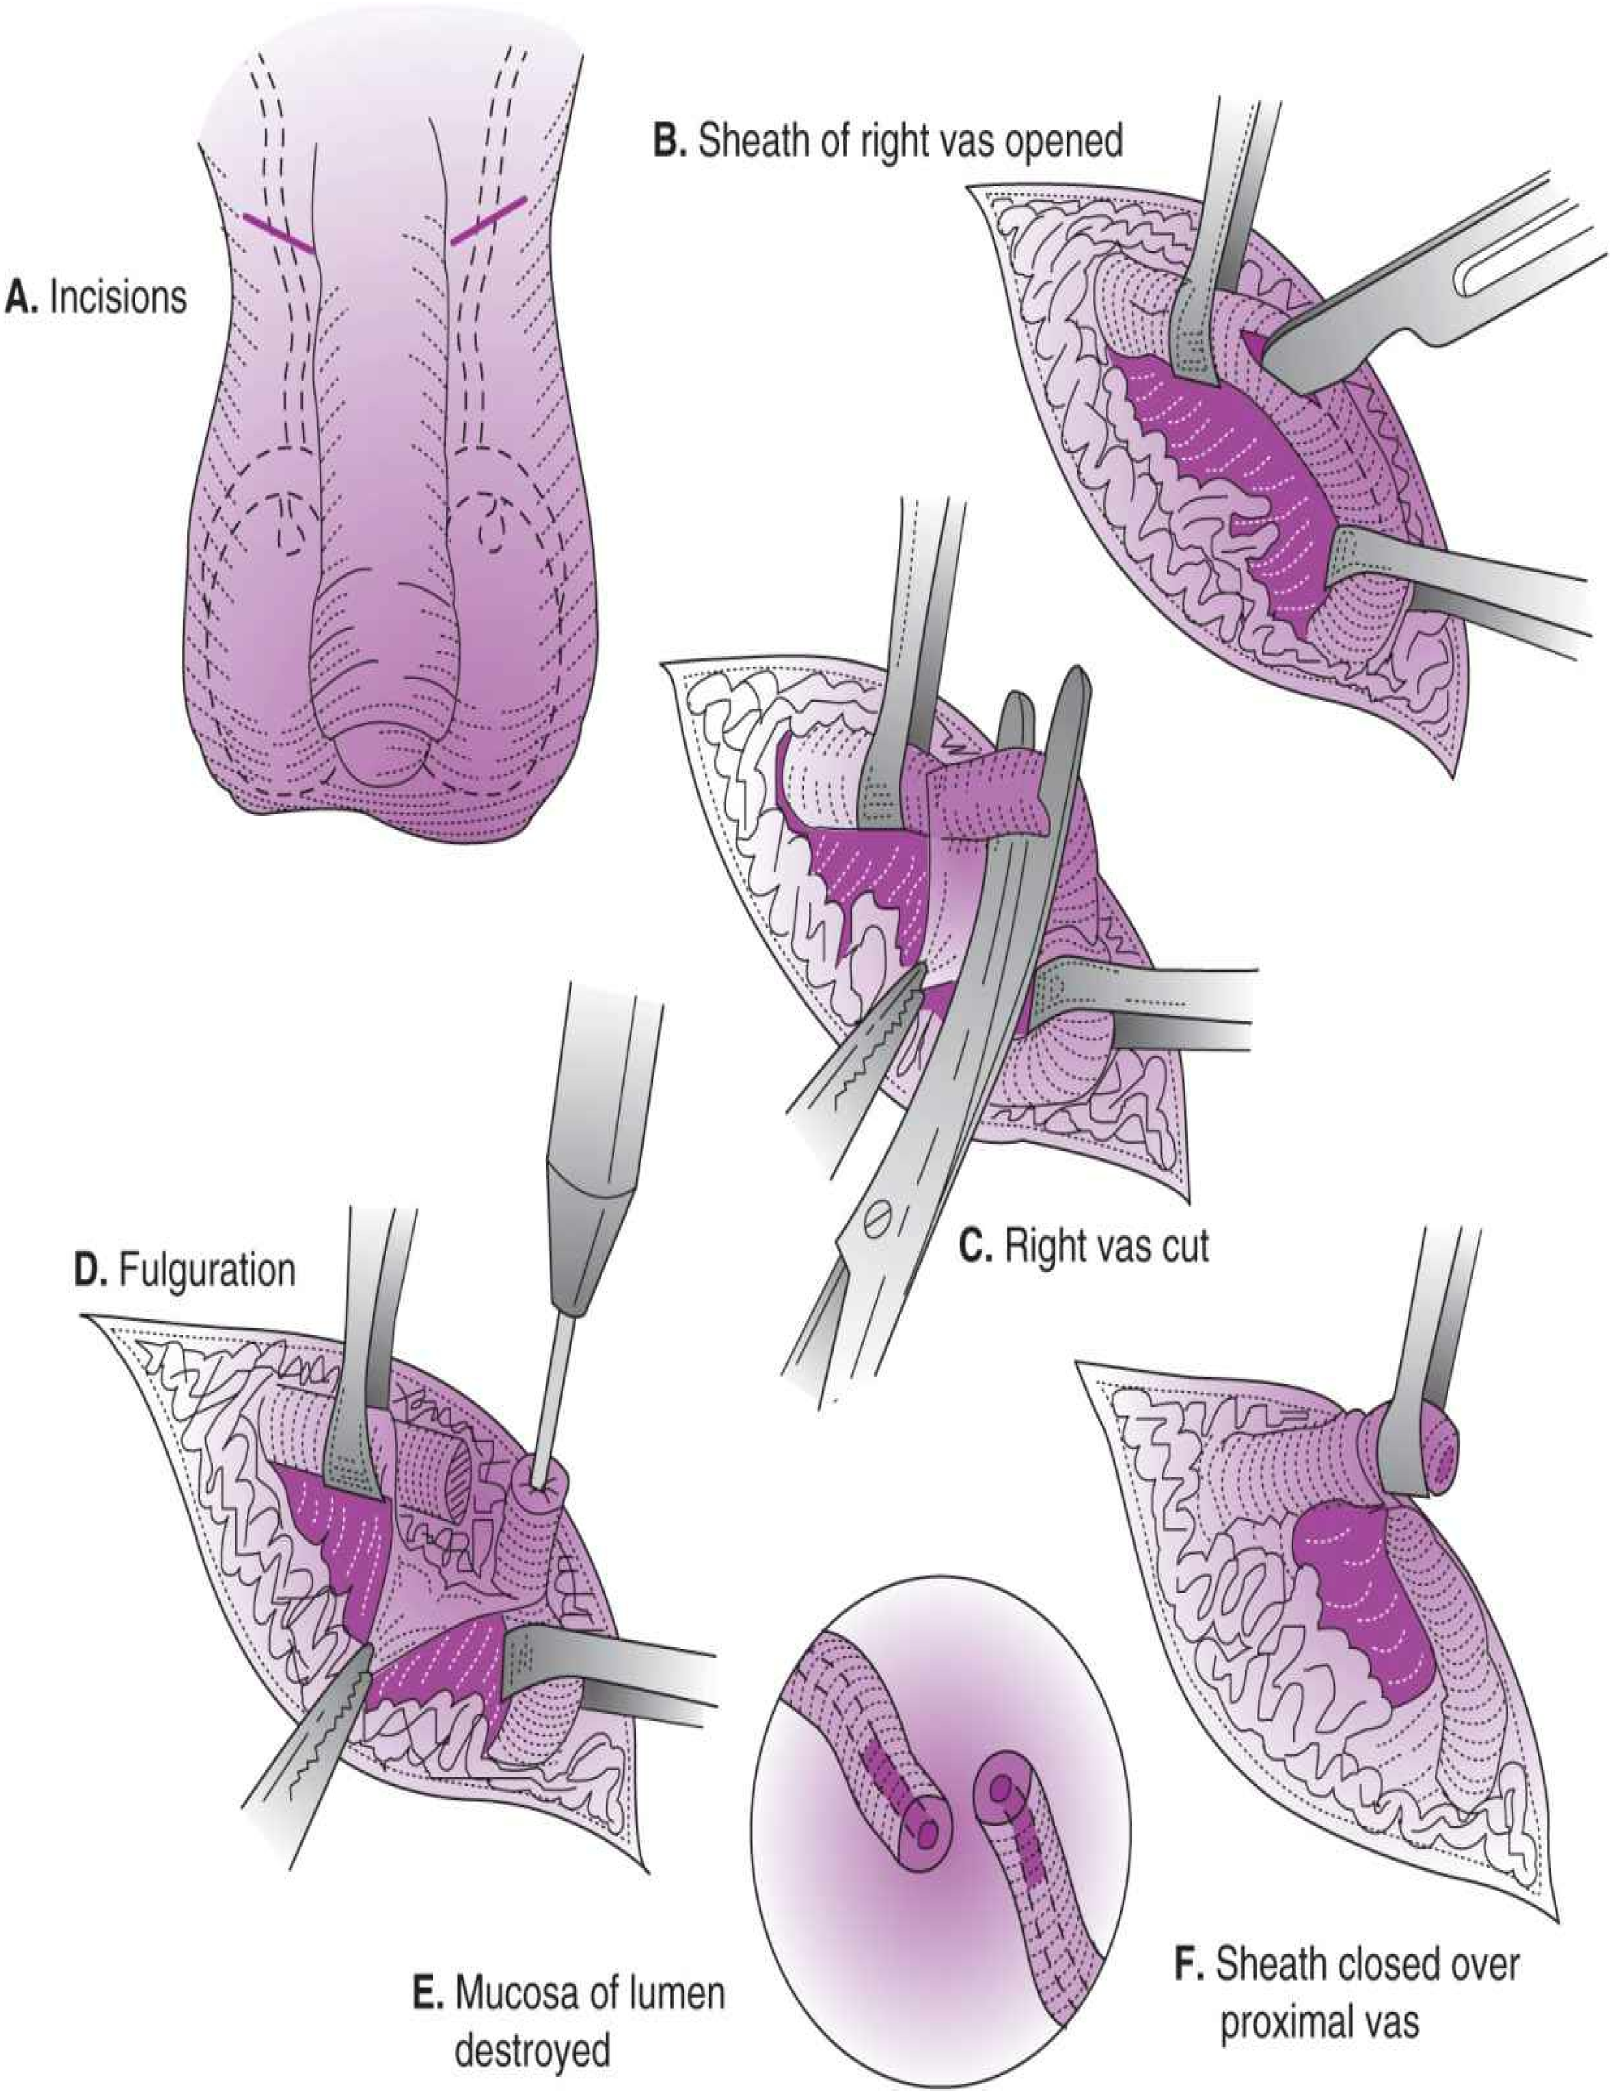
A recent systematic review showed that the bilateral placement success rate was 81–90% with up to 2 attempts. At 3 months postprocedure, 3.5% of patients did not show tubal occlusion, but after 6 months, all women with successful placement showed total occlusion. The Essure system has been shown to be safe, but unintended pregnancies have been reported (64 in 50,000 procedures). The majority of unintended pregnancies occurred in patients with inappropriate follow-up. However, misinterpreted hysterosalpingograms, undetected preprocedure pregnancies, and failure to follow product-labeling guidelines have also led to unintended pregnancies.

OTHER METHODS OF FEMALE STERILIZATION

Because of relatively high morbidity and mortality rates in comparison with tubal occlusion procedures, hysterectomy is justified for sterilization only if there is another unequivocal indication for hysterectomy. Transvaginal tubal ligation via culdotomy or culdoscopy is technically more difficult than transabdominal sterilization and has a higher infection rate. However, there may be less discomfort postoperatively.

VASECTOMY

Vasectomy, or vas occlusion, accounts for 9% of sterilizations in the United States. Partial vasectomy is usually done under local anesthesia via a small incision in the upper outer aspect of the scrotum (Fig. 46–6). Sutures or clips are placed tightly around the vas, demarcating a 1- to 1.5-cm segment, which is then excised. The ligated and fulgurated ends are tucked back into the scrotal sac, and the incision is closed. The same procedure is performed on the opposite side. The no-scalpel technique requires no incision because a sharpened dissection forceps is used to pierce the skin and dissect the vas. Microscopic examination confirms excision of vasal tissue.



A. Incisions
B. Sheath of right vas opened
C. Right vas cut
D. Fulguration
E. Mucosa of lumen destroyed
F. Sheath closed over proximal vas

Figure 46–6. Steps in vasectomy. (Modified with permission from a drawing by S. Taft. Reproduced, with permission, from Schmidt S. Vasectomy should not fail. *Contemp Surg* 1974;4:13)

Vasectomy is as effective as tubal sterilization with a reported failure rate of <1%. Half of the vasectomy failures in the CREST study occurred within 3 months of the procedure. Thus, sterility is assumed only after ejaculates are completely free of sperm after 3 months and after periodic microscopic analysis.

Complications are infrequent, usually involving slight bleeding, hematoma formation, skin infection, and reactions to sutures or local anesthetics.

HYSTERECTOMY

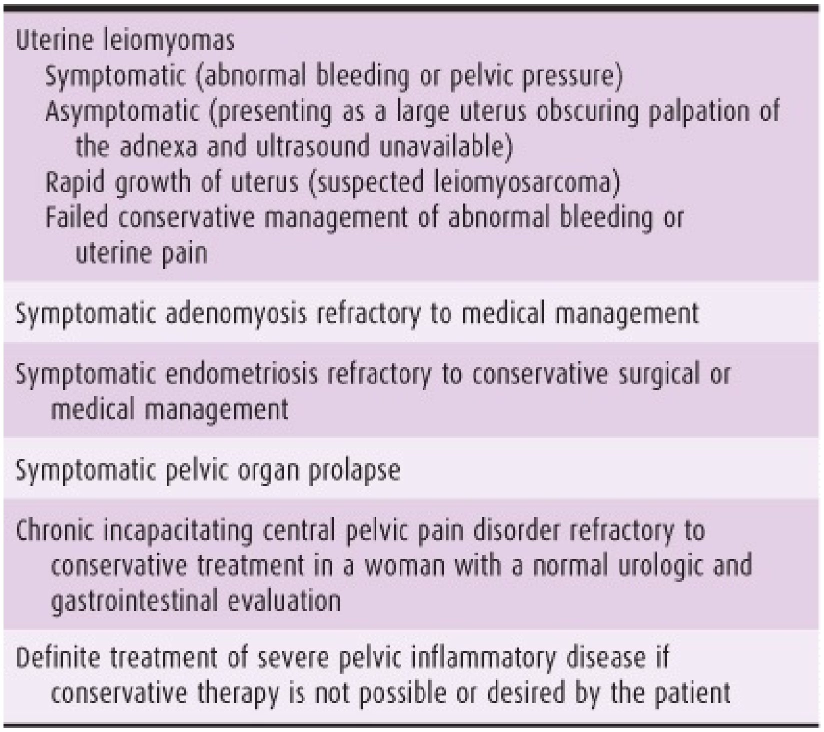
Hysterectomy is complete surgical removal of the uterus. It is the most common gynecologic surgery and second most common major operation performed in the United States with over 600,000 hysterectomies performed between 2003 and 2004. With advancements in medical and conservative surgical therapy of gynecologic conditions, the need for hysterectomy has declined, with small decreases in rates between 1997 and 2004. More women now wish to avoid major surgery if equally efficacious alternatives exist. Regulatory boards of gynecologists now support the use of hysterectomy as treatment for conditions refractory to more conservative management.

Indications

The indications for hysterectomy can be practically divided into those for the treatment of gynecologic cancer, benign gynecologic conditions, and obstetric complications. Hysterectomy for cancer of the uterus, ovary, and cervix is discussed in Chapters 47–50. Hysterectomy for obstetric complications, including excessive bleeding and molar pregnancy, is becoming less common (see Chapter 21).

The most common benign diseases and disorders (the indication for >90% of surgeries) that warrant hysterectomy are shown in Table 46–4.

Table 46–4. Benign diseases and disorders for which hysterectomy may be performed.



Uterine leiomyomas Symptomatic (abnormal bleeding or pelvic pressure) Asymptomatic (presenting as a large uterus obscuring palpation of the adnexa and ultrasound unavailable) Rapid growth of uterus (suspected leiomyosarcoma) Failed conservative management of abnormal bleeding or uterine pain
Symptomatic adenomyosis refractory to medical management
Symptomatic endometriosis refractory to conservative surgical or medical management
Symptomatic pelvic organ prolapse
Chronic incapacitating central pelvic pain disorder refractory to conservative treatment in a woman with a normal urologic and gastrointestinal evaluation
Definite treatment of severe pelvic inflammatory disease if conservative therapy is not possible or desired by the patient

Preoperative Evaluation

A. Diagnostic Tests to Detect Occult Cancer

Prior to hysterectomy, all patients should have a baseline evaluation to detect occult cancer. A Pap smear should be performed within 3 months before operation, and abnormalities should be followed with colposcopic examination with biopsy and endocervical curettage before surgery. Cervical conization is indicated prior to hysterectomy if (1) colposcopy fails to demonstrate the entire squamocolumnar junction, where cervical cancers typically arise; (2) colposcopically guided biopsies reveal cervical intraepithelial neoplasia I or less after a preceding high-grade squamous intraepithelial lesion Pap smear; (3) endocervical curettage demonstrates atypical endocervical cells; and (4) biopsy reveals microinvasive squamous cell carcinoma or squamous adenocarcinoma in situ. Cervical conization for the last scenario is performed to ensure that occult invasive cancer is not present. Frozen-section analysis of cervical conization tissue correlates well enough with “permanent” (hematoxylin and eosin) slide analysis that if intraepithelial neoplasia with clear margins is found, the surgeon may, with reasonable certainty, perform a hysterectomy that will totally include the tumor.

Biopsy for endometrial neoplasia must also be considered in certain clinical scenarios. Generally any woman over age 35 who presents with abnormal uterine bleeding should undergo endometrial evaluation (endometrial biopsy with pipelle, D&C, or hysteroscopy with directed biopsies) before hysterectomy. However, certain clinical situations that produce an unopposed estrogen effect on the endometrium warrant preoperative endometrial evaluation at any age: chronic anovulation and secondary oligomenorrhea, unopposed estrogen therapy for menopause, and known ovarian disorders associated with endometrial neoplasia (eg, polycystic ovarian syndrome, granulosa cell tumors). Unfortunately, frozen-section analysis of endometrial curettings is neither practical nor accurate, so hysterectomy usually must wait for permanent section.

Occult cancer may also be present outside the genital tract. All patients should have their stool checked for occult blood preoperatively. In women 40 years of age or older, mammography is standard.

B. Preoperative Evaluation of the Pelvis

In the woman with a small, mobile uterus with mobile adnexa, little diagnostic evaluation beyond bimanual examination is indicated. However, pelvic disease may have caused disturbance of normal tissue planes that endanger the urologic and gastrointestinal tracts. The following conditions may indicate the need for more extensive evaluation of the pelvis prior to hysterectomy: (1) pelvic inflammatory disease, especially if repeated, chronic, or associated with a tubo-ovarian complex; (2) endometriosis; (3) pelvic adhesions due to other causes of pelvic inflammation (eg, appendicitis, cholecystitis, previous pelvic surgery); (4) chronic pelvic pain; (5) questionable origin of a palpable pelvic mass; and (6) clinical suspicion of cancer (eg, palpable adnexa in a postmenopausal woman).

The most commonly used preoperative adjunctive diagnostic evaluation is pelvic ultrasound, which has advantages over computed tomography (CT) scan. Ultrasound is helpful in detecting masses in the difficult-to-examine patient (eg, obese) and in confirming a pelvic mass detected on bimanual examination.

Intravenous pyelography (IVP) or CT urogram is helpful in delineating the course of the ureters through the pelvis especially in the setting of inflammatory conditions that could distort or obstruct the ureters. Also, patients with known genital developmental anomalies should have preoperative imaging to look for concomitant urologic anomalies.

Prehysterectomy evaluation of the colon (beyond screening for occult blood in the stool) is indicated in any patient with symptoms for rectal disease. In most cases, proctoscopy or flexible proctosigmoidoscopy is sufficient. In cases of severe pelvic inflammation, chronic pelvic pain, or suspected cancer, complete colonoscopy or barium enema is indicated. Preoperative diagnosis of bowel disease will aid in the selection of the incision. If necessary, a consultant gastrointestinal surgeon can be present during the operation.

C. Preoperative Bowel Preparation

Preoperative bowel preparation is not required prior to hysterectomy. It has been a common practice in the past to use a mechanical bowel preparation prior to hysterectomy in patients where the likelihood of bowel injury is high. However, recent data in the colorectal literature have refuted these practices. Preoperative mechanical bowel preparation is associated with increased spillage of bowel contents during elective colon resection and leads to a higher rate of anastomotic leaks and wound infections compared to no mechanical bowel preparation.

D. Prophylactic Antibiotics

The incidence of febrile morbidity is approximately 14% in patients undergoing hysterectomy. Certain risk factors are associated with a higher likelihood of operative site infection. These factors include an abdominal surgical approach, blood loss greater than 750 mL, and no preoperative antibiotics. ACOG also recommends giving additional doses of intraoperative antibiotics during lengthy operations, given at intervals of 1 or 2 half-lives of the drug. A second dose of the prophylactic antibiotic may also be given in surgical cases with a blood loss >1500 mL. Patients diagnosed with a vaginal infection during preoperative evaluation should be treated prior to surgery.

A broad-spectrum antibiotic should be chosen that is effective against common (but not necessarily *all*) pathogens causing pelvic infection. The agent should have a low incidence of toxicity and side effects and should be easily administered and cost-effective. The proper dosage should be administered 30 minutes prior to incision to achieve therapeutic levels in tissue at the surgical site. It should *not* be an antibiotic reserved for serious infection. ACOG recommends intravenous (IV) cefazolin (1–2 g IV), clindamycin (600 mg IV), plus either gentamicin 1.5 mg/kg IV) or quinolone (400 mg IV) or aztreonam (1 g IV), or metronidazole (500 mg IV) plus gentamicin (1.5 mg/kg IV) or quinolone (400 mg IV) prior to vaginal or abdominal hysterectomy.

E. Thromboembolism Prophylaxis

Hysterectomy is a major surgical procedure, carrying at least a moderate risk of thromboembolism. The risk of calf vein thrombosis, proximal vein thrombosis, and pulmonary embolism can be minimized with the use of graduated compression stockings perioperatively and early ambulation postoperatively. Sequential compression devices will help prevent stasis as well. Compression stockings and devices should be in use prior to administration of anesthesia for optimal effect. For patients at high risk for thromboembolic disease, a dose of 5000 U subcutaneous heparin is given preoperatively and then every 8–12 hours postoperatively while in the hospital. Risk factors include malignancy, obesity, previous radiation therapy, immobilization, estrogen use, prolonged anesthesia, radical surgery, history of thromboembolism, nephrotic syndrome, HIV, and personal or family history of hypercoagulability (inherited thrombophilia). Low-molecular-weight heparin may also be used postoperatively.

F. Blood Products

It is not necessary to preoperatively cross-match all patients undergoing hysterectomy. Women who are not at particular risk of needing a transfusion during hysterectomy should at least have blood typing and antibody screening prior to surgery. Patients undergoing peripartum hysterectomy or hysterectomy for gynecologic cancer are more likely to need blood transfusion. Patients undergoing elective hysterectomy are more likely to need a transfusion if the starting hematocrit is low (30%), if they have pelvic inflammatory disease or pelvic abscess or adhesions, or if colporrhaphy is performed at the time of vaginal hysterectomy.

G. Informed Consent

Many women desire, and most insurance companies require, a second opinion prior to scheduling an elective hysterectomy. The patient must understand the diagnosis and be aware of alternative therapies (medical or conservative surgical options) and the risks and benefits of the operation. Common risks of surgery such as wound infection, cuff cellulitis, and blood loss are usually explained during preoperative counseling. The current medicolegal climate mandates the discussion of unusual complications, including the possibility of completing a vaginal or laparoscopic operation via an abdominal route and the risks of viral illness following transfusion, severe postoperative infection (including adnexal abscess), and vaginal vault prolapse.

Technique

A. Vaginal Versus Abdominal Hysterectomy

The route of hysterectomy is chosen according to the following guidelines.

1. Pelvic anatomy—The ideal candidate for vaginal hysterectomy has a gynecoid pelvis with a wide pubic arch and a vaginal apex >2 fingerbreadths at the apex. Some descent of the uterus is helpful but not mandatory; procidentia makes for a more complicated vaginal hysterectomy because of the greater vulnerability of the prolapsed ureters.

2. Uterine size—Most gynecologists will perform vaginal hysterectomy on a uterus equivalent in size to a uterus at 12 weeks’ gestation or smaller or a uterine weight of <280 g. More experienced surgeons have successfully removed uteri of up to 1200 g vaginally using bivalve and morcellation techniques.

3. Adnexa—In patients with symptoms or pelvic findings suggesting adnexal disease that may indicate adnexectomy, the abdominal route for hysterectomy is preferred. In addition, most surgeons offer patients the option of prophylactic removal of the ovaries after age 45 years old to decrease the risk of ovarian cancer, in spite of the lack of supporting evidence. Such patients may still undergo vaginal removal or laparoscopic-assisted vaginal hysterectomy if otherwise a good candidate for these routes.

4. Gastrointestinal tract—Especially in older patients or those with significant history of gastrointestinal complaints, the abdominal approach offers an opportunity for complete examination of the bowel.

5. Urologic disorders—Symptomatic or potential stress urinary incontinence can be treated vaginally (suburethral sling) or abdominally (retropubic urethropexy; see Chapter 42). The route of the hysterectomy should depend on the size of the uterus and not on the planned surgical procedure for the incontinence.

6. Pelvic organ prolapse—Pelvic organ prolapse can be treated via a vaginal, laparoscopic, robotic, or abdominal approach, and the choice of route is often surgeon dependent (see Chapter 42)

7. Medical disorders—In patients with significant heart or lung disease, the vaginal or laparoscopic approach is preferable when possible because of a lower incidence of postoperative pulmonary complications and earlier ambulation.

8. Previous surgery—Most surgeons are willing to perform a vaginal hysterectomy in patients with previous tubal ligation or caesarean section. The surgery would be more problematic in patients with a history of multiple caesarean births or complications (eg, postpartum endomyometritis) or with probable abdominal adhesions from previous laparotomy. Laparoscopic-assisted vaginal hysterectomy may be used in these situations.

The preceding guidelines may certainly be adjusted to the individual patient based on the surgeon’s experience and abilities. An examination performed under anesthesia when the physician first sees the patient may help to decide on the approach. Uterine size can be assessed with transvaginal ultrasound. Laparoscopic evaluation of the adnexa will further aid in the decision. All patients anticipating vaginal hysterectomy, laparoscopic hysterectomy, or laparoscopic-assisted vaginal hysterectomy should be told that the operation may have to be completed abdominally if difficulties arise.

B. Abdominal Hysterectomy

The technique of abdominal hysterectomy varies according to the indication for the operation, the size and placement of vital structures including the ureters (which may be distorted), and the pelvic anatomy. A standard, well-organized approach to abdominal hysterectomy is essential to avoid incidental injury. Modifications are made as necessary, always within an organized plan of operation.

The anesthetic of choice typically includes general endotracheal intubation, an inhalation agent, and an analgesic. Hysterectomies are of such duration and risk that using a mask alone is unwise. In patients with pulmonary compromise, spinal or epidural anesthesia may be used.

A sterile scrub of the abdomen and vagina is done, and a urinary catheter is placed so that the anesthesiologist can monitor urine output intraoperatively. The choice of incision is based on the suspected disease, prior surgeries/incisions, patient preference, and uterine size; in general, a midline incision extending from 2 fingerbreadths above the pubic symphysis to the umbilicus offers the greatest exposure. One modification of the low transverse incision to improve exposure is the Maylard muscle-splitting procedure or the Cherney detachment of the rectus muscles from their insertion on the pubic symphysis. For an uncomplicated hysterectomy with a small uterus, a Pfannenstiel incision is usually sufficient.

The surgeon and assistants should rinse excessive talcum powder from their gloves before making the incision to prevent granulomatous tissue reaction in the wound. Once the incision is complete, peritoneal fluid may be aspirated if the possibility of gynecologic cancer exists. The pelvic organs are then inspected and the upper abdomen palpated in a systematic fashion: right gutter, right hemidiaphragm, liver, gallbladder, pancreas, stomach (assessing the position of the indwelling gastric decompression tube if present), and spleen and right hemidiaphragm (gently, because of the risk of trauma to the spleen), left gutter, para-aortic lymph nodes, and omentum. Excessive bowel manipulation should be avoided to decrease the severity of postoperative adynamic ileus; at the least, the appendix and cecum should be inspected as well as the terminal meter of ileum. Older patients and those with gastrointestinal complaints would benefit from careful palpation and inspection of the bowel from rectum to ligament of Treitz. If desired, the wound may be protected with moist towels, a self-retaining retractor placed, and the bowel packed into the upper abdomen.

The classic extrafascial hysterectomy performed by Richardson remains the mainstay of surgical technique in abdominal hysterectomy. Choice of suture and needle is made according to surgeon experience and preference; 2-0, 0, or 1 absorbable sutures on half-curved taper needles are standard choices. The uterus is grasped either by the fundus with a Massachusetts double-toothed clamp or at the cornua with Ochsner or Kocher clamps. The round ligament is grasped proximal to the uterus; at its midportion, it is ligated by suture, and the suture is tagged with a small hemostat. The round ligament is divided about 0.5 cm proximal to the suture, thus opening the broad ligament at its apex. The anterior uterine peritoneum may be incised at the vesicouterine junction in preparation for advancement of the bladder. The peritoneum only should be incised; the potentially vascular areolar tissue should be avoided. When this procedure is repeated on the contralateral side, the anterior leaves of the broad ligament are opened; the uterine vessels first become apparent. Attention is then directed to the posterior leaf of the broad ligament.

The posterior leaf of the broad ligament is incised beginning at the ligated round ligament. The extent of the incision is determined by the decision to preserve or remove the adnexa. If the adnexa are to be removed, the peritoneum is incised parallel to the infundibulopelvic ligament to the pelvic sidewall; the loose areolar tissue is dissected medial to the internal iliac (hypogastric) artery, which is typically 0.5 cm thick with a visually appreciable (and certainly palpable) pulse. The dissection will reveal a clear area of peritoneum under the infundibulopelvic ligament; below this area at a variable distance lays the ureter on this medial leaf of peritoneum.

The intimate proximity of the ureters to the uterus makes ureteral identification important. Whereas the ureter is usually 4–6 cm deep to the infundibulopelvic ligament at the lateral margin of the uterus, it is only 0.5–2 cm below this vascular bundle at the level of the pelvic brim. Observing the ureter through the peritoneum or palpating the characteristic “snap” of the ureter should serve only to guide dissection and should not be a substitute for identification of the entire ureter through its pelvic course. The ureter tolerates careful dissection well as long as its blood-carrying adventitia is not stripped away. The ureter can always be found and dissection begun at the pelvic brim, where the ureter passes over the bifurcation of the iliac artery. The most serious ureteral injury is the unrecognized insult. The most common ureteral injuries during hysterectomy occur during ligation of the infundibulopelvic ligament, clamping and suture ligation of the uterosacral–cardinal ligament complex, placement of vaginal angle sutures, ligation of the vesicouterine ligament, ligation of the hypogastric artery as an adjunctive measure to lessen operative blood loss, and reperitonealization of the pelvic floor.

Once the course of the ureters is well established, the adnexal component of the operation is completed. If the adnexa are to be removed, the infundibulopelvic ligament is clamped, divided, and double ligated. The ligament may then be ligated again adjacent to the uterus to avoid back bleeding; the infundibulopelvic ligament is divided and the peritoneum incised to the back of the uterine fundus, always cognizant of the proximity of the ureter. If the adnexa are to be preserved, a hole is made in the avascular portion of the posterior leaf of the broad ligament superior to the ureter. The utero-ovarian ligament and fallopian tube are doubly clamped, divided, and ligated, with care taken to avoid incorporation of ovarian tissue into the ligature.

The peritoneal incision can be extended posteriorly around the uterus between the medial portions of the uterosacral ligaments. If the incision of the posterior leaf of the broad ligament is extended over the uterosacral ligaments, there is typically significant bleeding just lateral to the insertion of the ligament at the uterus. The advantages of making an incision between the uterosacral ligaments include clear identification of the rectum and its separation from the uterus, ease of suturing the vaginal cuff, and improved mobility of the peritoneum to allow reperitonealization under less tension.

The bladder is advanced down off of the lower uterine segment prior to clamping the uterine vessels. Surgeons-in-training have more difficulty with advancement of the bladder than with other aspects of abdominal hysterectomy. The principal difficulty in mobilization of the bladder is failure to identify the proper cleavage plane between the bladder and the uterus. At the attachment of the bladder to the lower uterine segment, a median raphe is variably present; it is typically a 1-cm long longitudinal band of thick connective tissue. The raphe is attenuated in pregnant or postmenopausal patients. The raphe is divided at midportion, and loose avascular fibroareolar tissue is seen immediately between the cervix and bladder. The uterus is retracted posteriorly and superiorly, roughly at an angle of 30 degrees to the long axis of the vagina. The midpoint of the peritoneal incision of the bladder flap is gently lifted with forceps; the avascular plane of the vesicovaginal and vesicocervical areolar spaces is continuous once the median raphe is divided. Metzenbaum scissors are pointed to the uterus, and sharp dissection reveals the shiny white pubocervical fascia overlying the cervix. Properly done, the dissection is bloodless, and the plane is recognized by the ease with which the bladder falls away from the cervix. The vesicouterine space is developed 2 cm beyond the anterior vaginal fornix. Care must be exercised in any dissection laterally, because the vesicouterine ligaments (“bladder pillars”) may bleed because of the paracervical and paravaginal veins present laterally.

The uterine vessels may be skeletonized by separating the loose avascular areolar connective tissue from the vessels. The intraligamentous course of the ureter is again checked; it is typically 2–3 cm inferolateral to the insertion of the uterine vessels into the uterus. The uterine vessels are clamped with a curved crushing clamp (eg, Heaney, Zeppelin, or curved Ballantine clamp). Double clamping may be used for larger vessels. It is not necessary to place another clamp on the uterine side of the pedicle to prevent back bleeding if the uterine arteries on both sides of the uterus are clamped before either pedicle is incised. The clamp is applied at the level of the internal os, with the tip of the clamp at a right angle to the long axis of the cervix; the temptation to clamp the entire cervix and “slide off” dragging paracervical tissue into the pedicle should be avoided in order to minimize the risk of the pedicle slipping out of the clamp. The uterine vessels are then ligated by suture at the tip of the clamp. Occasionally, a second application of the curved clamp is necessary to complete ligation of the uterine vessels.

Next, the cardinal ligament is assessed. On occasion, a single application of a straight clamp

(Ochsner, Kocher, or Ballantine clamp) will include the cardinal ligament to the level of its attachment at the lateral edge of the cervix and upper vagina. However, with an elongated cervix, multiple pedicles need to be taken before the upper vagina is encountered. A deep knife is often useful in dividing the cardinal ligament adjacent to the uterus, leaving a larger pedicle, which is less likely to slip out of the suture than one remaining after cutting with scissors flush to the clamp. The uterosacral ligaments are clamped at their insertion into the lower cervix, divided at their insertion, and ligated. Alternatively, they may be transected with large Mayo scissors while the vagina is entered posterolaterally. If division and suture ligation of either pedicle of the cardinal–uterosacral ligament complex fails to enter the vagina, the safest approach is to enter the vagina with the knife in the midline, either anteriorly or posteriorly, at the confluence of the vagina with cervix. Once entered, the cervix is circumferentially incised, with long Ochsner clamps used to control point bleeders and elevate the vaginal cuff. The vaginal cuff can also be cross-clamped with a curved clamp (Heaney or Zeppelins) from either side just below the cervix and amputated with Jorgenson’s scissors. The cervix is inspected to ensure complete excision. If the cervix is amputated without cross-clamping the vagina, sutures are placed at each lateral vaginal angle to ligate small paravaginal vessels coursing upward through the paravaginal tissues and to provide vaginal vault support. The suture is begun inside the vagina 1 cm from the upper border, then incorporates the cardinal and uterosacral ligaments, and finally transverses the vagina again to end up within the vagina. This suture is tagged, and the procedure is repeated on the contralateral side.

Surgical management of the cuff is individualized. In the case of marked pelvic inflammation and persistent oozing, the cuff may be left open to afford retroperitoneal drainage or allow egress of a closed drain system. In most cases, closing the cuff may reduce granulation tissue and possibly minimize ascension of bacteria from the vagina. The cuff may be closed with either interrupted figure-of-eight sutures or a double running suture; the key points with either closure are inversion of the cut edges into the vagina and hemostasis. If the vagina apex is cross-clamped prior to amputating the cervix, the cuff is closed with either a Heaney suture placed at the tip of each clamp, or with a running suture over each clamp. If a defect remains at the middle of the cuff, this can be closed with interrupted or figure-of-eight sutures.

The pelvis is irrigated and hemostasis checked in a systematic fashion from one lateral pedicle to the ipsilateral round ligament pedicle to the cuff and on to the other side. Small bleeding vessels must be ligated to minimize the risk of retroperitoneal hematoma formation, which may expand or become infected. For diffuse oozing, hemostatic agents such as thrombin powder or thrombostatic absorbable sponges may be useful. There is no advantage to closing the parietal peritoneum. Retained ovaries may be suspended to minimize the risk of torsion and adherence to the vaginal cuff. The utero-ovarian ligament can be conveniently attached to the round ligament stump to suspend the ovaries above the pelvis without placing the infundibulopelvic ligament under tension.

The abnormal appendix should be removed. In cases of hysterectomy for endometriosis, appendectomy will reveal microscopic endometriotic foci in some 3% of cases.

C. Supracervical Hysterectomy

Supracervical/subtotal hysterectomy, or removal of the uterine corpus without the cervix, made up 95% of hysterectomies prior to the 1940s. Despite Papanicolaou’s introduction of his cervical smear, concern over neoplastic changes occurring in the retained cervix made total abdominal hysterectomy (TAH) the leading approach to surgery from the 1950s and on. Several studies have addressed the debate about which approach leads to decreased morbidity. Proponents of supracervical hysterectomy believe that there is less damage to sympathetic and parasympathetic innervation that might occur with paracervical dissection. Thus, bladder function and orgasm are less likely to be affected with supracervical hysterectomy. However, 2 randomized controlled trials assessing psychosocial outcome and resultant sexual function found no difference between the 2 groups. A meta-analysis failed to detect a significant difference in stress or urge incontinence after supracervical versus total hysterectomy. Another randomized, double-blind, controlled trial showed no statistically significant difference in bladder, bowel, and sexual function between women who had undergone total versus supracervical hysterectomy. It has also been proposed that by leaving the cervix, vault prolapse and vaginal shortening might be avoided. Yet, a recent study performed on cadavers found equal resistance to forces applied to the vaginal apex after supracervical and total hysterectomy.

Those in favor of TAH suggest that it decreases the risk of cervical cancer, especially in women who might not follow up for routine Pap smears. In fact, a malignant or premalignant condition of the cervix or uterine corpus is an absolute contraindication to a supracervical hysterectomy. It also eliminates the small risk of cyclical bleeding (6.8%) that can occur after supracervical hysterectomy if residual endometrium is left behind.

Supracervical hysterectomy does decrease length of surgery, blood loss, and febrile morbidity. Current indications for supracervical hysterectomy include difficulty dissecting the cervix, distorted anatomy secondary to pelvic inflammatory disease or endometriosis, and compromised medical condition.

Following ligation of the uterine vessels, the uterine fundus may be amputated from the cervix; the level of amputation should be below the internal cervical os to avoid postoperative uterine bleeding from endometrial remnants. The endocervical canal can be resected or ablated to further avoid cyclical bleeding. The cervical stump is closed with figure-of-eight sutures.

D. Vaginal Hysterectomy

Vaginal hysterectomies are performed under general or regional anesthesia. Following administration of the anesthetic, a bimanual examination is mandatory before beginning surgery. The perineum is shaved or trimmed as necessary and a sterile wash performed. The patient is placed in a low lithotomy position and draped; the surgeon should participate in proper positioning of the patient, because excessive flexion of the hips can stretch the sciatic nerve and compress the femoral nerve and excessive extension of the knee can jeopardize the peroneal nerves. All bony prominences and soft tissues in contact with the leg stirrups should be carefully padded.

The urinary bladder may be drained by catheter, but this step is optional. The cervix is grasped with a tenaculum. As the surgeon exerts gentle traction downward on the cervix, 2 assistants maintain exposure with lateral vaginal retractors and protect the bladder with an anterior Heaney retractor. If desired, the junction of the vagina and cervix can be injected with a 1% 1:1000 epinephrine solution to minimize blood loss during incision of the cervix. Beginning posteriorly to minimize obscuring the field with blood, the surgeon circumferentially incises the cervix down to the level of the pubovesicocervical fascia. Gentle traction with the bladder retractor and downward traction of the cervix will allow exposure of the fibers of fascia between bladder and cervix, which are incised. When the bladder has been advanced up off of the cervix, attention is given to the posterior attachment of the cervix. While the assistant pulls the uterus upward, the posterior vaginal mucosa is tented away from the cervix. With the patient in the Trendelenburg position to allow as much emptying of the posterior cul-de-sac as possible, the posterior cul-de-sac is incised with a single stroke of the scissors. A retractor is placed within the opening, exposing the uterosacral ligaments. The uterosacral ligaments are grasped with Heaney clamps, making certain that the peritoneum posterior to the ligament is within the clamp. The ligament is cut and ligated with 2-0 or 0 absorbable suture and tagged with a hemostat for later manipulation of the cuff.

The cardinal ligament may next be clamped if the bladder is safely advanced; likewise, the uterine vessels are included in the next application of the Heaney clamps. The anterior cul-de-sac is entered by blunt and sharp dissection to the anterior vesicouterine fold of peritoneum. The anterior retractor is placed within this opening, and the bladder is gently lifted upward. The surgeon now clamps, incises, and ligates in pedicles the remaining portions of the broad ligaments bilaterally, incorporating the tissue between the anterior and posterior leaves of the broad ligament. The round ligament, utero-ovarian ligament, and fallopian tube are excised from the uterus and incorporated into these pedicles, and the uterus is removed from the field. A larger uterus may require special manipulation for delivery through the vaginal introitus (eg, bivalving the uterus in the midline, morcellation of the uterus into multiple extractable segments, or myomectomy). Rarely, in the event of a narrow introitus, an episiotomy may be performed to facilitate in the delivery of the uterus. The final suture on the utero-ovarian ligament is tagged to allow careful inspection of the tubes and ovaries. If ovarian disease is suspected or if prophylactic oophorectomy is planned, a clamp is placed above the ovary and uterine tube on the infundibulopelvic ligament for suture ligature, while traction is placed on the last stay suture. The entire ovary must be removed, because an ovarian remnant may become cystic and produce pain many years after the hysterectomy.

Once all pedicles are inspected and found to be hemostatic, some surgeons advocate closing the peritoneum with a running 2-0 absorbable suture, incorporating the cardinal and uterosacral ligament pedicles for support of the vaginal vault. Lateral vaginal angle sutures are placed from the vaginal mucosa at 2 o’clock, inside the cuff and including the uterosacral pedicle, then out through the cuff to the 4 o’clock position. If anterior or posterior colporrhaphy is planned, that operation is completed prior to complete closure of the cuff. The cuff may be closed in either a horizontal or vertical manner, grasping full vaginal thickness, by an interrupted absorbable 0 suture or a running simple suture. One small randomized controlled trial showed improved preservation of vaginal length with vertical closure. The goals of closure are obliteration of the cuff’s dead space back to the peritoneum and approximation of the cut edges of the vagina to afford healing and minimize postoperative granulation tissue. Modifications of the just-described technique are made by virtually every gynecologic surgeon based on operative findings and experience. Some surgeons will close the posterior cul-de-sac to prevent development of an enterocele or will shorten the uterosacral ligaments to suspend the vaginal vault. As in abdominal hysterectomy, the cuff can be left open to promote drainage with a running locked absorbable 0 suture. Another technique to drain the closure is insertion of a T-tube above the cuff, which is associated with a demonstrable reduction in postoperative febrile morbidity.

After the operation is completed, the vagina and perineum are gently cleansed. An indwelling bladder catheter is inserted and a vaginal pack may be placed. The patient is returned slowly to the dorsal supine position.

E. Laparoscopic Hysterectomy

The laparoscope can be used to aid vaginal hysterectomy by freeing abdominal adhesions (laparoscopic-assisted vaginal hysterectomy; LAVH) or to free the uterus in its entirety with removal via the vagina with the assistance of uterine manipulators (ie, V-care). Supracervical hysterectomy can also be done laparoscopically with morcellation and removal by culdotomy or through extended trocar sites. Advantages to laparoscopic hysterectomy (LH) include decreased length of hospital stay, decreased postoperative analgesia, and decreased convalescence period. There may be a lower complication rate compared to TAH, but there is no difference versus vaginal hysterectomy. Advantages of LH include the ability to inspect the peritoneal cavity and ovaries. Studies present conflicting data on whether there is a benefit of LH compared to vaginal hysterectomy in respect to hospital stay and blood loss. However, the laparoscopic approach requires significantly more operating time and a well-trained, experienced surgeon. Because of the costs for the endoscopic equipment, LH has been found to be more expensive despite the shorter hospital stay.

Complications with LH include hemorrhage and bowel or urinary tract damage. Conversion to abdominal hysterectomy may occur, especially in cases with large leiomyomas obstructing access to upper pedicles.

Postoperative Care of the Hysterectomy Patient

The details of postoperative care are dictated by the indications for surgery and the individual patient’s overall medical condition. General guidelines include the following:

1. A Foley catheter is left indwelling for 24 hours, but ideally not longer to decrease the risk of urinary tract infections.
2. Prophylactic postoperative antibiotics are not necessary unless there is concern for an underlying infection diagnosed at time of surgery.
3. Hydration, 2–3 L/d of balanced electrolyte solution, is given intravenously, depending on blood loss and intra-operative replacement.
4. Sips of water may be given the first night, followed by clear liquids or regular diet on the next postoperative day depending on the patient’s appetite. The absence of bowel sounds and flatus should not delay the advancement of diet.
5. Prophylactic heparin therapy, sequential compression device, or antiembolic stockings are used in patients according to risk for thromboembolic complications.
6. Ambulation is begun on the first postoperative day.
7. Adequate analgesia is given parenterally. Once the patient can tolerate a regular diet, she can be switched to oral analgesics.

Complications

Perioperative deaths may be due to cardiac arrest, coronary occlusion, or respiratory paralysis. Postoperative deaths are usually the result of hemorrhage, infection, pulmonary embolus, or intercurrent disease. A recent study of the morbidity of more than 10,000 hysterectomies found the mortality rate to be <0.1% with equal rates in the abdominal, laparoscopic, and vaginal groups. Mortality rates increase with age and medical complications for both vaginal and abdominal hysterectomies.

The bladder may be injured in 1–2% of all hysterectomies. Consequences are slight if the injury is to the dome of the bladder—which is usually the case away from the trigone. Ureteral injury occurs in 0.7–1.7% of abdominal hysterectomies and 0–0.1% of vaginal hysterectomies. The essential point is to recognize urologic injuries and correct them intraoperatively, avoiding the serious postoperative complications that occur from urinary extravasation.

Damage to the bowel occurs in 0.2–0.5% of all hysterectomies. A preoperative mechanical bowel preparation has not been shown to decreased morbidity after bowel resections; however, bowel preparation is preferred for laparoscopic hysterectomy to assist with bowel decompression. Small bowel injuries, assuming no obstruction, can be closed in a single layer or multiple layers depending on surgeon preference. The injury should be closed perpendicular to the long axis of the bowel. If multiple-layer closure is used, an interrupted or running layer of 3-0 silk or absorbable sutures is used to reapproximate the mucosa followed by interrupted 2-0 absorbable or silk sutures in the serosa. Bowel resection and anastomosis may be required for larger injuries. Large bowel injuries are repaired in the same fashion as small bowel injuries. Lack of a mechanical bowel preparation is not an indication for a colostomy. Large injuries may require bowel resection and reanastomosis. After the repair, the pelvis is copiously irrigated and a drain is used by some surgeons.

The most serious postoperative complication is hemorrhage (0.2–2% of patients). Bleeding usually originates at the lateral vaginal angles and is amenable to vaginal resuturing in most cases. Blood products are replaced as needed.

Infection remains the most common complication following hysterectomy. Even with immaculate technique and careful patient selection, the gynecologic surgeon can still expect a 10% rate of postoperative febrile morbidity. A postoperative temperature of 38°C (100.4°F) or higher on 2 consecutive determinations 6 hours apart must be investigated by (1) careful interview of the patient for localizing symptoms (eg, productive cough, intravenous line pain), (2) thorough physical examination (including pelvic examination for inspection and palpation of the cuff), and (3) appropriate laboratory studies (eg, urinalysis, chest x-ray, gram-stained smear of sputum, or complete blood count). Antibiotics are begun only if a focus of infection is identified or highly suspected. Broad-spectrum antibiotics covering anticipated pathogens are prescribed; single-agent semisynthetic penicillins (eg, piperacillin) and cephalosporins (eg, cefoxitin) offer sufficient coverage. In the presence of sepsis, multiagent comprehensive coverage (eg, penicillin, an aminoglycoside, and an anaerobic agent such as clindamycin or metronidazole) must be prescribed.

Granulation of the vaginal vault is part of the normal healing process and is evident on speculum examination in over half of cases. The granulation is rarely troublesome; light cauterization with silver nitrate sticks or electrocautery eliminates the granulation tissue promptly in most cases. Many suggestions have been made on ways to minimize granulation, including management of the cuff (open vs. closed), choice of suture (plain gut vs. chromic vs. newer synthetics), and drainage techniques. The most important common denominator is close apposition of the cut vaginal edges, which can be accomplished with any of the techniques.

Premalignant & Malignant Disorders of the Vulva & Vagina

Amer Karam, MD

PREINVASIVE DISEASE OF THE VULVA

ESSENTIALS OF DIAGNOSIS

- Possibly 1–2% of young women with cervical dysplasia have multifocal disease that tends to involve the upper third of the vagina and the vulva, perineum, and perianal areas—these surfaces arising from a common cloacogenic origin.
- A spectrum of disease may be found ranging from mild dysplasia to carcinoma in situ. Involvement may not be appreciated without careful inspection with and without the green colposcopy filter. Clinically, the appearance of vulvar intraepithelial neoplasia can be quite variable.
- Lesions are typically white and hyperkeratotic, but may also appear gray, pink, or brown.
- Colposcopy and biopsy of any suspicious lesion should be performed and is considered the gold standard for diagnosis.
- An abnormal vascular pattern is most frequently associated with a severe degree of dysplasia, carcinoma in situ, or early invasive disease.

General Considerations

The vulvar skin is 1 component of the anogenital epithelium, extending from the distal vagina to the perineum and perianal skin. The lower genital tract epithelium is of common cloacogenic origin. Neoplasia of the vulvar skin is often associated with multiple foci of dysplasia in the lower genital tract. A strong association exists between sexually transmitted diseases and vulvar intraepithelial neoplasia (VIN), primarily human papillomavirus (HPV), but also human immunodeficiency virus (HIV). Approximately 90% of VIN lesions are positive for HPV; multicentric VIN is primarily associated with high oncogenic risk HPV subtypes such as types 16, 18, and 31, whereas vulvar condylomata and low-grade VIN are frequently associated with low-risk HPV sub-types 6 and 11. Other risk factors include smoking and other genital precancers or cancers. VIN can also be classified into viral and nonviral etiologies. Younger women are more commonly affected by viral VIN than older women and are also more likely to exhibit multifocal disease. The incidence of VIN has increased over the past decade due to the increased incidence of HPV infections in young women. The incidence of vulvar carcinoma has increased as well but at a relatively slower rate. The long-term risk of malignant transformation of treated VIN III has been estimated at 3.4–7%, and the risk for progression of untreated VIN is thought to be higher.

Premalignant lesions of the vulva occur in both premenopausal and postmenopausal women, with the median age being approximately 40 years. The average age is shifting toward younger women, with 75% of lesions occurring during the premenopausal period. There is no racial predisposition to VIN, and the disease process is often asymptomatic. The most common presenting symptom is pruritus, which is seen in more than 60% of patients with VIN. The diagnosis is made by careful inspection of the vulvar area followed by biopsy of suspicious lesions.

Pathogenesis

Previously, the standard for reporting of vulvar dysplastic lesions was to classify VIN according to the degree of epithelial cellular maturation, with VIN I defined as immature cells occurring in the lower one-third of the epithelium and VIN III as complete loss of cellular maturation in the full thickness of epithelium, which is synonymous with carcinoma in situ of the vulva or Bowen's disease. VIN II was designated as intermediate between VIN I and VIN III. In 2004, the International Congress of the International Society for the Study of Vulvar Disease (ISSVD) recommended that the designation of VIN be reserved for high-grade lesions such as VIN II and III, which are at higher risk of progression to invasive disease.

In contrast to intraepithelial carcinoma of the cervix, which seems to arise from a single point of origin, dysplasia of the vulva is often multicentric. These lesions may be discrete or diffuse, single or multiple, and flat or raised. They even form papules and vary in color from the white appearance of hyperkeratotic tumors to a velvety red or black.

The microscopic appearance of dysplastic vulvar lesions is characterized by cellular disorganization and loss of stratification that involves essentially the full thickness of the epithelium. Cellular density is increased, and individual cells vary greatly in size, with giant and multinucleated cells, numerous mitotic figures, and hyperchromatism (Fig. 47–1). HPV cytopathic changes, such as perinuclear halos with displacement of nuclei, are also common.

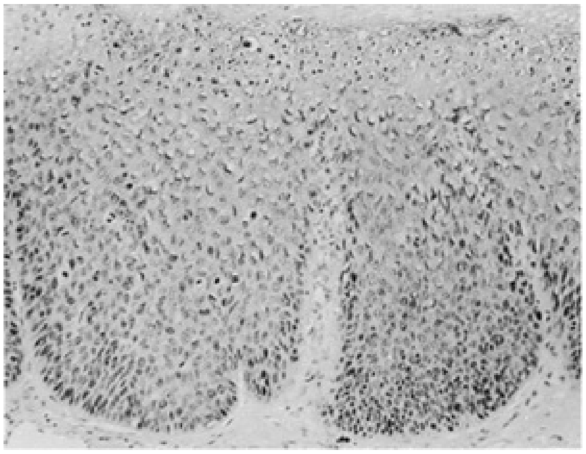

Figure 47–1. Carcinoma in situ demonstrating hyperkeratosis, acanthosis, and parakeratosis. The rete ridges are elongated and thickened, and individual cells are atypical.

Treatment

Treatment options for VIN are individualized based on biopsy results and include wide local excision, laser ablation, topical application of 5-fluorouracil (5-FU) or imiquimod, or superficial vulvectomy with or without split-thickness skin grafting. Untreated VIN has the potential for progression to invasive carcinoma. This risk may be high for women older than age 40 years. In younger patients, spontaneous regression may occur.

Treatment modality depends on the extent of involvement of the vulva, perineum, and perianal skin, which is defined by colposcopy. Wide local excision of small foci of VIN is preferred. For unifocal lesions, a 1-cm margin of uninvolved skin is usually curative. Carbon dioxide laser may be used for multifocal disease. Disadvantages of the laser include painful recovery and lack of pathology specimens. The incidence of foci of microinvasion in VIN III has been reported to range from 10 to 22% in different series. Extensive disease may be best treated by superficial vulvectomy. The surgical goal is to preserve as much of the normal anatomy as possible. In the superficial "skinning" vulvectomy procedure, the excised vulvar skin can be closed with fine suture or may need to be replaced with a split-thickness skin graft (Figs. 47–2 and 47–3) if the defect is too large.

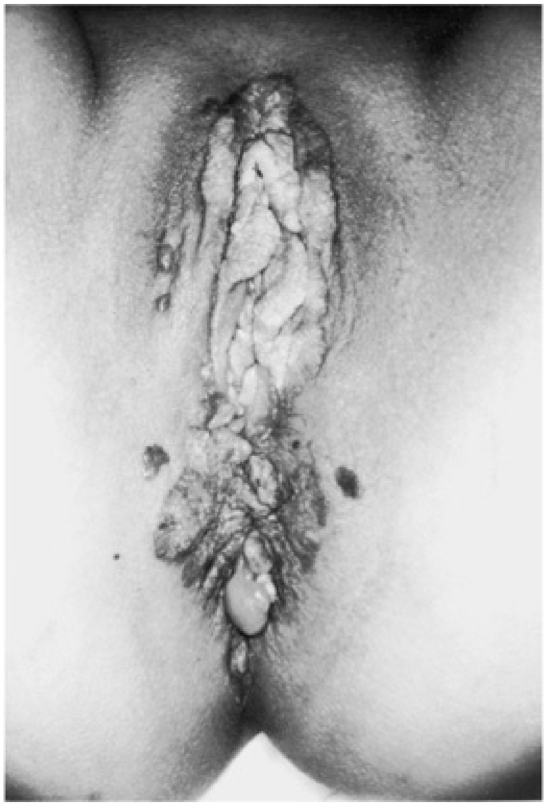

Figure 47–2. Diffuse, hypertrophic carcinoma in situ of the vulva and perianal skin. A skinning vulvectomy was performed.

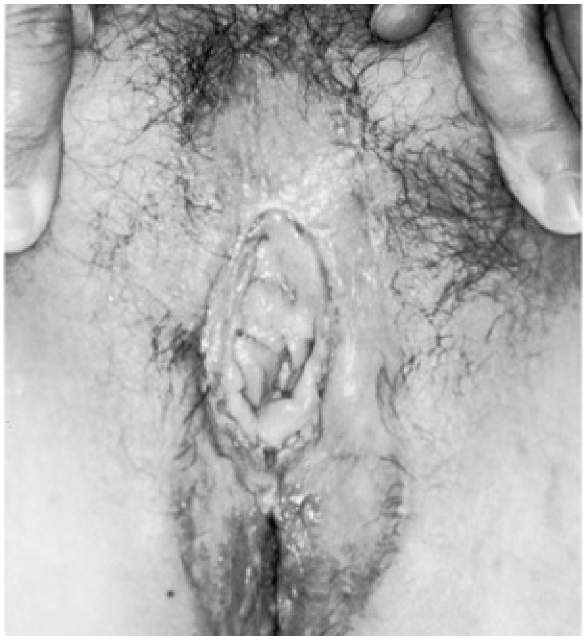

Figure 47–3. Appearance after skinning vulvectomy and split-thickness skin grafting of the lesion shown in Figure 47–2.

Topical application of imiquimod cream, which stimulates local cytokine release and enhances cell-mediated immunity, can be attempted in order to preserve vulvar anatomy, particularly in younger patients or around sensitive areas such as the clitoris. A recent review of published trials looking at topical imiquimod therapy for high-grade VIN reported a complete response rate of 51% with an additional 25% partial response rate. The use of 5-FU has fallen out of favor due to poor tolerance, with a significant proportion of patients reporting significant burning, pain, and ulcerations. Cryotherapy, photodynamic therapy, and ultrasonic surgical aspiration have each historically been proven useful in the treatment of some lesions, but remain investigational.

Follow-Up

Intraepithelial carcinoma of the vulva is often one manifestation of multifocal disease. For this reason, affected patients must be examined periodically for a number of years. Recommended follow-up includes thorough pelvic examinations with colposcopy every 3–4 months until the patient is disease free for 2 years. If the patient is disease free for a 2-year period, examinations can be done every 6 months.

EXTRAMAMMARY PAGET DISEASE

ESSENTIALS OF DIAGNOSIS

- Pruritus and vulvar soreness are the most frequent symptoms.
- These symptoms may persist for years before the patient seeks medical attention.
- The lesion may be localized to 1 labium or involve the entire vulvar area.
- The lesion usually has an eczematoid appearance macroscopically and usually begins on the hair-bearing portions of the vulva.
- It is not unusual for the disease process to extend beyond the vulva to involve the perirectal area, buttocks, thighs, inguinal area, and mons.
- Intraepithelial extramammary Paget’s disease presents as a lesion with hyperemic areas associated with a superficial white coating to give the impression of “cake icing.”
- Although these lesions can be very extensive, most are confined to the epithelial layer.
- The diagnosis is made by vulvar biopsy. It is important to palpate the lesion in its entirety.
- A generous biopsy should be taken of any area that appears to be thickened to rule out an underlying adenocarcinoma.

General Considerations

Paget’s disease of the skin is an intraepithelial neoplasia, or adenocarcinoma in situ, and accounts for <1% of all vulvar malignancies occurring mostly in Caucasian patients in their 60s and 70s. Reports of long-term survival suggest that the in situ stage of the disease persists for a long time or that invasive disease is a different clinicopathologic entity. At present, most experts posit that extramammary Paget’s disease (EMPD) arises as either an intraepithelial neoplasia that may progress to a dermally invasive carcinoma (primary EMPD) or epidermal infiltration of malignant cells from an underlying or distant carcinoma (secondary EMPD) such as primary adenocarcinoma of an underlying apocrine gland, Bartholin’s gland, or anorectum. Unlike mammary Paget’s disease, <20% of vulvar Paget’s disease is associated with an underlying adenocarcinoma. Paget’s disease with an underlying adenocarcinoma metastasizes frequently to regional lymph nodes and distally. Paget’s disease without an underlying adenocarcinoma behaves like an intraepithelial neoplasia and can be treated as such. However, patients with Paget’s disease should be carefully examined for the presence of synchronous primaries elsewhere; 20–30% of these patients will be found to have carcinomas at other sites, including the breast, rectum, bladder, cervix, ovary, and urethra.

Pathogenesis

The initial lesion may be confused with a number of benign forms of chronic vulvar pruritus. It is a pruritic, slowly spreading, velvety-red discoloration of the skin that eventually becomes eczematoid in appearance with secondary maceration and development of white plaques; it may spread to involve the skin of the perineum, the perianal area, and the adjacent skin of the thigh. Grossly, the lesion gives the impression of “cake icing.” Because of the serpiginous growth pattern of Paget cells in the basal layer of the epidermis, the true extent of disease is difficult to assess.

Paget’s disease of the vulvar skin is an intraepithelial disease. The typical Paget cell, pathognomonic of the disease process, apparently arises from abnormal differentiation of the cells of the basal layer of the epithelium (Fig. 47–4). The appearance of malignant cells varies from that of the clear cell of the apocrine gland epithelium to a totally undifferentiated basal cell. It has been suggested that there may be both an intraepithelial and an invasive variety of the disease. The intraepithelial stage of the disease persists for years without evidence of an underlying adenocarcinoma.

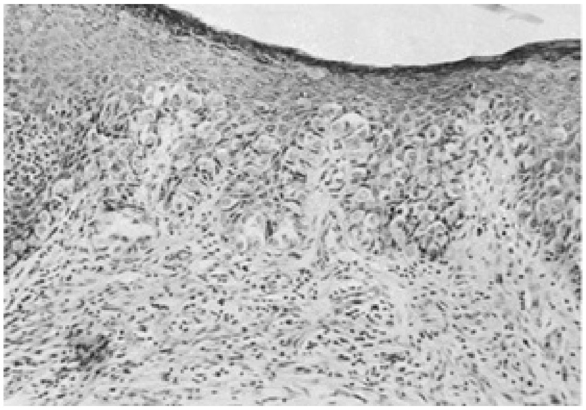

Figure 47–4. Paget’s disease with typical cells in the basal layer of the epidermis.

Treatment

Wide local excision is the primary treatment modality for this disease process. The lesion needs to be excised in its entirety; however, wide margins need to be removed around the primary lesion as disease often extends beyond the clinically visible erythematous area. The underlying dermis should be removed for adequate histologic evaluation. Often such a resection involves a complete vulvectomy. Careful histologic examination of the entire operative specimen is necessary to delineate the true extent of disease, ensure free surgical margins, and detect the remote possibility of underlying adenocarcinoma. For this reason, laser therapy is unsatisfactory. Patients who have Paget’s disease with underlying adenocarcinoma should be treated with radical local excision of the vulva and bilateral inguinal lymph node dissection as they would for any other invasive tumor involving the vulvar area.

Prognosis

Paget’s disease of the vulva has a great propensity for local recurrence even with negative resection margins, which may represent persistence of the disease or development of new disease in the remaining vulvar skin. EMPD characteristically requires repeated local excisions of recurrent disease after treatment of the primary disease by total vulvectomy. Invasive disease without evidence of lymph node metastases has a favorable prognosis; however, with nodal metastases, the disease is almost invariably fatal.

CANCER OF THE VULVA

ESSENTIALS OF DIAGNOSIS

- Typically occurs in postmenopausal women
- Long history of vulvar irritation with pruritus, local discomfort, and bloody discharge
- Appearance of early lesions like that of chronic vulvar dermatitis
- Appearance of late lesions like that of a large cauliflower or a hard ulcerated area in the vulva
- Biopsy necessary for diagnosis

General Considerations

Cancer of the vulva may arise from the skin, subcutaneous tissues, or glandular elements of the vulva. Approximately 90% of these tumors are squamous cell carcinomas. Less common tumors are EMPD with underlying adenocarcinoma, carcinoma of Bartholin’s gland, basal cell carcinoma, melanoma, sarcoma, and metastatic cancers from other sites.

Cancer of the vulva is uncommon, accounting for approximately 4% of gynecologic cancers. Vulvar cancer is more common in the poor and elderly in most parts of the world, and no race or culture is spared. Vulvar cancer is primarily a disease of postmenopausal women, with a peak incidence in women ages 60–70 years. The average age at the time of diagnosis is 65 years, and 75%

of patients are older than age 50 years. In general, the mean age of patients with carcinoma in situ is approximately 10 years less than that for patients with invasive cancer. Intraepithelial cancer of the vulva in women ages 20–40 years has increased remarkably in recent years. Two independent pathways for the development of vulvar carcinoma are thought to exist. HPV infection is strongly associated in younger women with vulvar cancer, whereas in older women, vulvar dystrophy and chronic inflammation are thought to be the prevailing carcinogenic pathways. Older women are more likely to have squamous hyperplasia in the tissue adjacent to the tumor.

Considering that cancer of the vulva is a disease of a body surface readily accessible to diagnostic procedures, early diagnosis should be the rule. This is not the case, however, and a 6- to 12-month delay in reporting symptoms of discovery of a tumor is common. Despite the advanced age of many of these patients and the frequent finding of a moderately large tumor, the disease is usually amenable to surgical therapy. In stage I and II disease, the corrected 5-year survival rate is >90%. A 75% corrected 5-year survival rate for all stages of vulvar cancer is reported by most institutions.

Risk factor most frequently associated with carcinoma of the vulva are cigarette smoking, immunodeficiency syndromes, a history of cervical carcinoma or dysplasia, HPV infection, and chronic vulvar irritation secondary to diabetes mellitus, granulomatous venereal disease, or vulvar dystrophy.

Pathogenesis

The gross appearance of vulvar cancer depends on the origin and histologic type. These tumors spread by local extension and, with few exceptions, by lymphatic embolization. The primary route of lymphatic spread is by way of the superficial inguinal, deep femoral, and external iliac lymph nodes (Fig. 47–5). Contralateral spread may occur as a result of the rich intercommunicating lymphatic system of the vulvar skin. Direct extension to the deep pelvic lymph nodes, primarily the obturator nodes, occurs in approximately 3% of patients and seems to be related to midline involvement around the clitoris, urethra, or rectum, or to cancer of a vestibular (Bartholin's) gland. Extension of the tumor to the lower and middle thirds of the vagina may also allow access of tumor cells to lymph channels leading to the deep pelvic lymph nodes.

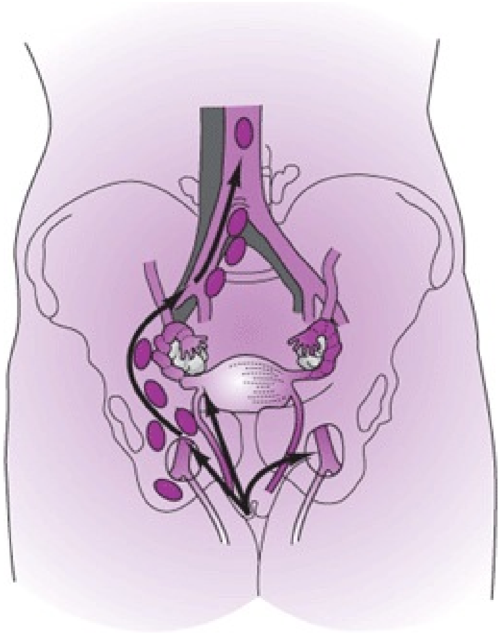

Figure 47–5. Lymphatic spread of cancer of the vulva.

The following sections describe the gross and histologic appearance of the various types of vulvar cancers.

A. Squamous Cell Carcinoma

Squamous cell carcinoma is by far the most common type of tumor and most frequently involves the anterior half of the vulva. In approximately 65% of patients, the tumor arises in the labia majora and minora, and in 25%, the clitoris or perineum is involved. More than one-third of tumors involve the vulva bilaterally or are midline tumors. These tumors are most frequently associated with nodal spread, particularly bilateral nodal metastases. Midline tumors that involve the perineum do not worsen the outlook unless they extend into the vagina or to the anus and rectum.

Squamous cell carcinoma of the vulva varies in appearance from a large, exophytic, cauliflowerlike lesion to a small ulcer crater superimposed on a dystrophic lesion of the vulvar skin (Figs. 47–6 and 47–7). Ulcerative lesions may begin as a raised, flat, white area of hypertrophic skin that subsequently undergoes ulceration. Exophytic lesions may become extremely large, undergo necrosis, and become secondarily infected and malodorous. A third variety arises as a slightly elevated, red, velvety tumor that gradually spreads over the vulvar skin. There does not appear to be a positive correlation between the gross appearance of the tumor and either histologic grade or frequency of nodal metastases. The primary determinant of nodal metastases is tumor size.

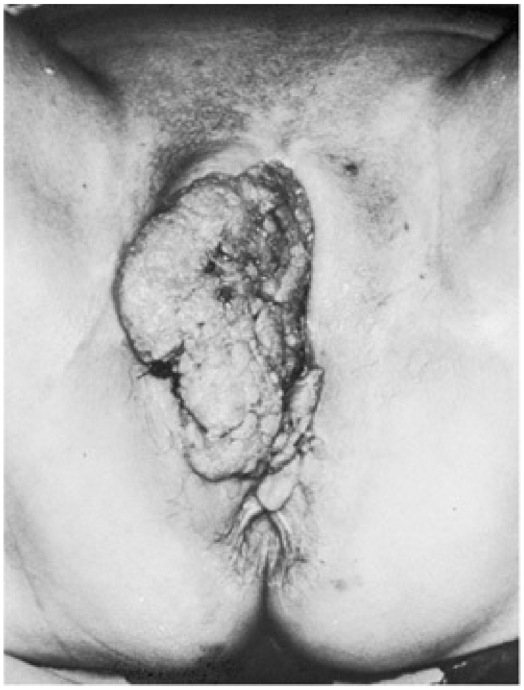

Figure 47–6. Large, exophytic, squamous cell carcinoma of the vulva, which was treated by radical vulvectomy and regional lymphadenectomy.

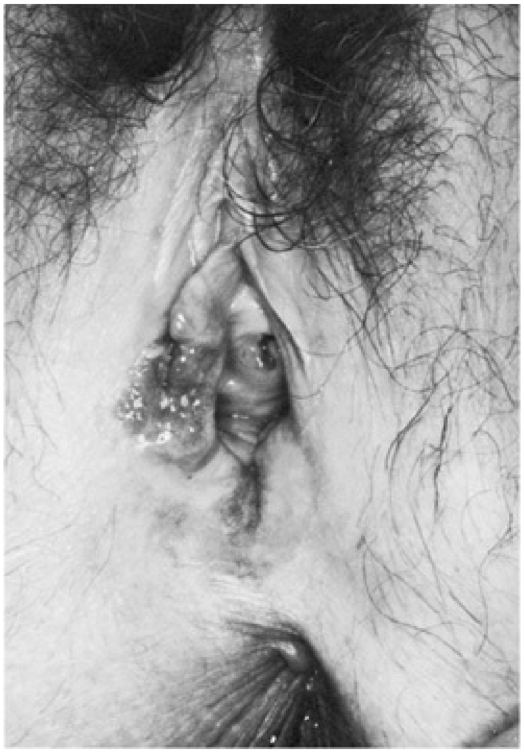

Figure 47–7. Ulcerative squamous cell carcinoma of the vulva.

Squamous cell cancers may be graded histologically from I to III. Grade I tumors are well differentiated, often forming keratin pearls; grade II tumors are moderately well differentiated; grade III tumors are composed of poorly differentiated cells. The extent of underlying inflammatory cell infiltration into the stroma surrounding the invasive tumor is variable. The histologic grade of the tumor may be of some significance in tumors <2 cm in diameter.

A variant of squamous cell carcinoma, **verrucous carcinoma**, is a locally invasive tumor that seldom metastasizes to regional lymph nodes. Grossly, the tumor looks like a mature condylomatous growth. It is distinguished from squamous cell cancer by histopathology of the tumor base, which reveals papillary fronds without a central core. Local recurrence is common if a wide vulvectomy is not performed; lymphadenectomy is usually not recommended unless suspicious nodes are encountered. Radiation therapy is usually contraindicated as it can induce an anaplastic transformation increasing the risk of metastases.

Depth of stromal penetration has proved to be the key factor in determining invasive potential of the tumor. The ISSVD, International Federation of Gynecology and Obstetrics (FIGO), and Tumor, Node, Metastasis (TNM) staging defined stage IA carcinoma of the vulva as a single lesion measuring 2 cm or less in diameter and exhibiting 1 focus of invasion to a depth of 1 mm or less. The depth of invasion was measured from the epidermal–stromal junction of the most superficial dermal papilla to the deepest point of tumor invasion.

B. Carcinoma of Bartholin's Gland

Carcinoma of Bartholin's gland accounts for approximately 1% of vulvar cancers and, although rare, is the most common site for vulvar adenocarcinoma. Approximately 50% of Bartholin's gland tumors are squamous cell carcinomas. Other types of tumors arising in the Bartholin's glands are adenocarcinoma, adenoid cystic, adenosquamous, and transitional cell carcinomas.

Because inflammatory disease of the Bartholin's gland is uncommon after age 40, older women with a mass in this location undergo biopsy to rule out cancer. Because of its location deep in the substance of the labium, a tumor may impinge on the rectum and directly spread into the ischiorectal fossa. Consequently, these tumors have access to lymphatic channels draining directly to the deep pelvic lymph nodes as well as to the superficial channels draining to the inguinal lymph nodes.

C. Basal Cell Carcinoma

Basal cell carcinomas account for 1–2% of vulvar cancers. Most tumors are small elevated lesions with an ulcerated center and rolled edges, so-called “rodent” ulcers. Some are described as pigmented tumors, moles, or simply pruritic maculopapular eruptions. These tumors arise almost exclusively in the skin of the labia majora, although occasionally a tumor can be found elsewhere in the vulva. The tumor is derived from primordial basal cells in the epidermis or hair follicles and is characterized by slow growth, local infiltration, and a tendency to recur if not totally excised.

On microscopic examination, the typical tumor consists of nodular masses and lobules of closely packed, uniform-appearing basaloid cells with scant cytoplasm and spherical or oval dark nuclei. Peripheral margination by columnar cells is usually prominent. In larger tumor nodules, there may be areas of central degeneration and necrosis.

If a sufficiently wide local excision is not performed, there is a tendency for local recurrence, estimated to be approximately 20%. A lymphadenectomy is rarely indicated as these tumors, although sometimes locally aggressive, rarely metastasize.

D. Malignant Melanoma

Approximately 5% of vulvar cancers are malignant melanomas, the second most common vulvar cancer. Because only 0.1% of all nevi in women are on vulvar skin, the disproportionate frequency of occurrence of melanoma in this area may be a result of the fact that nearly all vulvar nevi are of the junctional variety. Malignant melanoma most commonly arises in the region of the labia minora and clitoris, and there is a tendency for superficial spread toward the urethra and vagina. A nonpigmented melanoma may closely resemble squamous cell carcinoma on clinical examination. A darkly pigmented, raised lesion at the mucocutaneous junction is a characteristic finding; however, the degree of melanin pigmentation is variable, and amelanotic lesions do occur. The lesion spreads primarily through lymphatic channels and tends to metastasize early in the course of the disease; local or remote cutaneous satellite lesions may be found. In contrast to squamous cell cancers, melanoma is staged according to depth of invasion. All small pigmented lesions of the vulva are suspect and should be removed by excision biopsy with a 0.5-to 1-cm margin of normal skin. In the case of large tumors, the diagnosis should be confirmed by a generous biopsy.

Clinical Findings

The patient with vulvar cancer characteristically has had infrequent medical examinations. Approximately 10% are diabetic, and 30–50% are obese or hypertensive or demonstrate other evidence of cardiovascular disease. The incidence of complicating medical illness exceeds that expected in the age group under consideration.

Invasive squamous cell cancer is a disease mainly of the seventh and eighth decades of life, although approximately 15% of patients are age 40 years or younger. Approximately 20% of patients have a second primary cancer that was diagnosed prior to, at the time of, or subsequent to the diagnosis of vulvar cancer; 75% of these second primary cancers are in the cervix.

A. Symptoms & Signs

Vulvar pruritus and/or a vulvar mass are frequent complaints and are present in more than 50% of patients with vulvar cancer. Other patients complain of bleeding or vulvar pain, whereas approximately 20% of patients have no complaints, and the tumor is found incidentally during routine pelvic examination. Approximately 25% of patients have seen a physician and received various medical treatments without benefit of a biopsy of the tumor. The importance of performing a biopsy of any vulvar lesion cannot be overemphasized. A biopsy should be taken from the area that appears to be the most abnormal, and multiple biopsies may be necessary in the event of multifocal disease.

B. Differential Diagnosis

The differential diagnosis includes epidermal inclusion cysts, acrochordons, seborrheic dermatoses, lichen sclerosus and other vulvar dystrophies, condyloma acuminate, granulomatous venereal diseases (eg, syphilis, herpes, or granuloma inguinale), pyogenic infections, or benign tumor, such as a granular cell myoblastoma.

C. Unusual Vulvar Malignancies

Sarcomas of the vulva constitute a variety of malignant neoplasms that account for 1–2% of vulvar cancers. The most common is leiomyosarcoma, followed in frequency of occurrence by the fibrous histiocytoma group and an array of other sarcomas. Clinically, sarcoma may present as a subcutaneous nodule or may be exophytic and fleshy. Prognosis is usually poor and depends on histologic type, extent of local invasion, and treatment. In general, radical vulvectomy and regional lymphadenectomy are indicated, with the exception of tumors such as dermatofibrosarcoma protuberans, which is a locally aggressive tumor that tends to recur locally but does not metastasize.

Adenocarcinoma of the vulva is exceptionally rare unless it arises from the Bartholin’s gland or the urethra. Primary cancer of the breast from ectopic breast tissue has been reported. Rarely, a malignant tumor will arise from a vulvar sweat gland.

Metastatic cancers of the vulva constitute 8% of all vulvar tumors. They usually originate from a genital tract tumor, and 18% arise from the kidney or urethra. Advanced cervical cancer is the most common primary tumor. Other primary tumors have been reported, including malignant melanoma, choriocarcinoma, and adenocarcinoma of the rectum or breast. Cloacogenic carcinoma is primarily an anorectal neoplasm, occurring twice as often in women than in men; it may arise in anal ducts and present as a submucosal mass.

Metastatic epidermoid cancer tends to form nests of cells within the dermis. Adenocarcinoma, regardless of the primary site, invades the surface squamous epithelium. Because these tumors are a manifestation of advanced disease, the prognosis is uniformly grave.

Complications

A. Operative Morbidity & Mortality

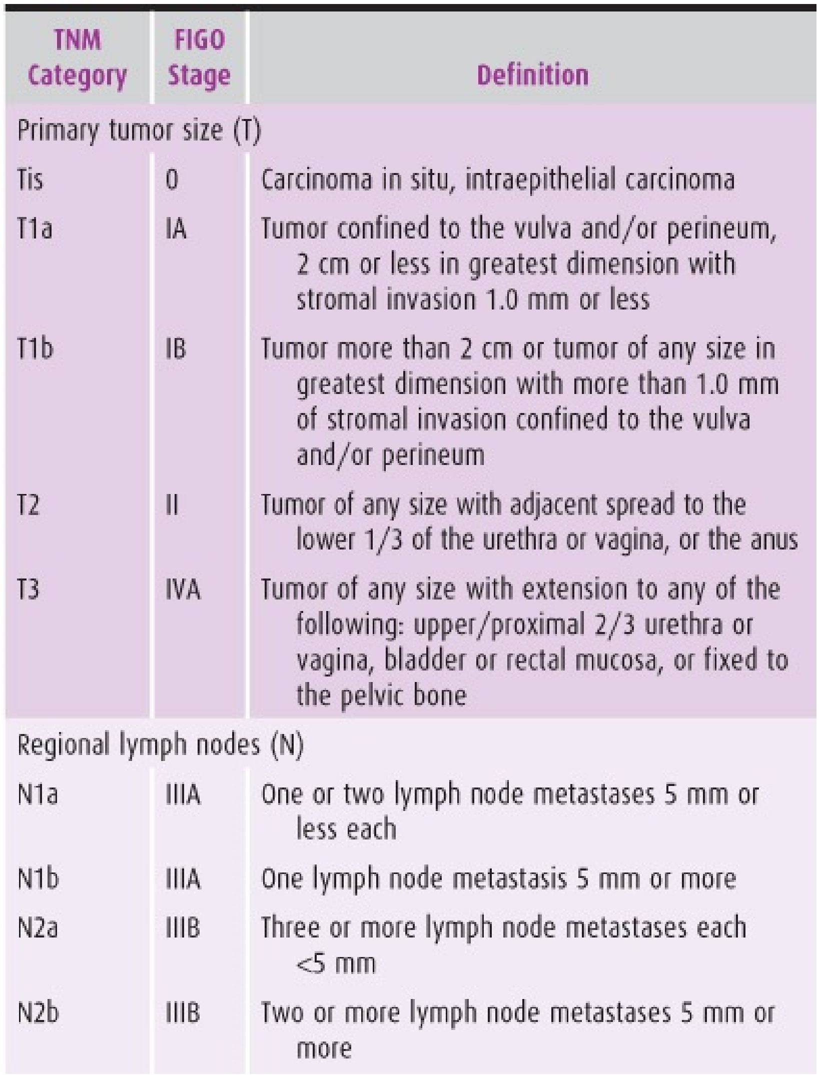
The most frequently encountered complication is wound breakdown, which occurs in well over 50% of patients undergoing radical vulvectomy and bilateral inguinal dissection. This complication is related to the amount of skin removed during the procedure, particularly at the groin areas. Separate groin incisions and careful handling of skin flaps have reduced the incidence of wound breakdown. Vigorous wound care with debridement almost always results in adequate healing.

Lymphedema occurs in up to 65% of patients who have had inguinofemoral lymph node dissection. Hemorrhage, lymphocyst formation, thromboembolic disease, urinary tract infections, and sexual dysfunction are other commonly associated morbidities.

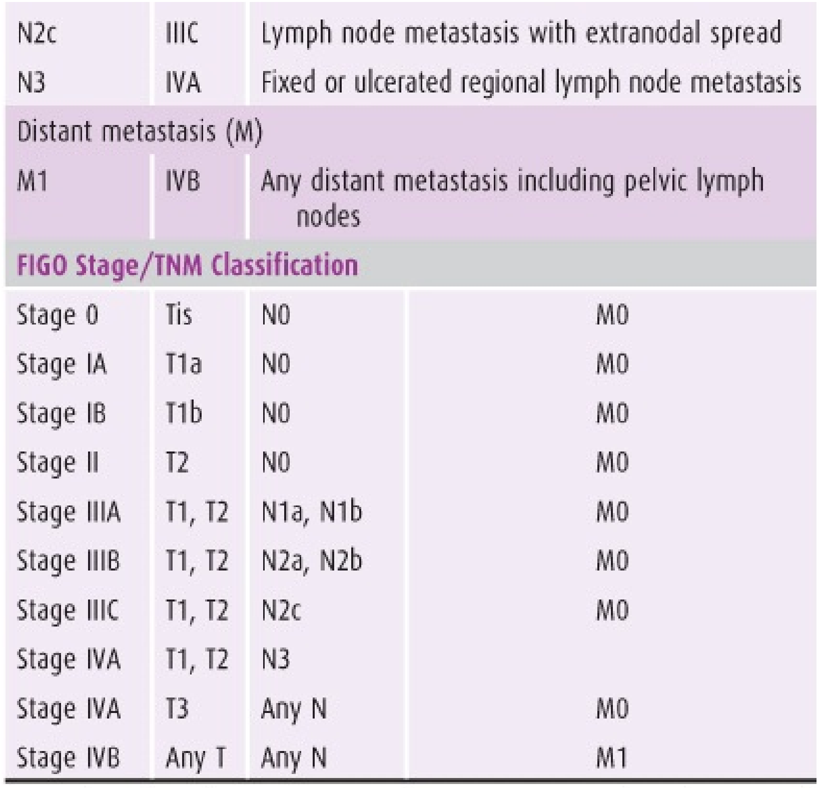
Treatment

Staging and treatment for vulvar cancer are surgical (Table 47–1). The primary treatment for invasive vulvar cancer is complete surgical removal of all tumor whenever possible. The recent trend is toward a more conservative surgical approach, departing from traditional en bloc resections.

Table 47–1. International Federation of Gynecology and Obstetrics (FIGO) staging of vulvar cancer.



TNM Category	FIGO Stage	Definition
Primary tumor size (T)		
Tis	0	Carcinoma in situ, intraepithelial carcinoma
T1a	IA	Tumor confined to the vulva and/or perineum, 2 cm or less in greatest dimension with stromal invasion 1.0 mm or less
T1b	IB	Tumor more than 2 cm or tumor of any size in greatest dimension with more than 1.0 mm of stromal invasion confined to the vulva and/or perineum
T2	II	Tumor of any size with adjacent spread to the lower 1/3 of the urethra or vagina, or the anus
T3	IVA	Tumor of any size with extension to any of the following: upper/proximal 2/3 urethra or vagina, bladder or rectal mucosa, or fixed to the pelvic bone
Regional lymph nodes (N)		
N1a	IIIA	One or two lymph node metastases 5 mm or less each
N1b	IIIA	One lymph node metastasis 5 mm or more
N2a	IIIB	Three or more lymph node metastases each <5 mm
N2b	IIIB	Two or more lymph node metastases 5 mm or more



N2c	IIIC	Lymph node metastasis with extranodal spread	
N3	IVA	Fixed or ulcerated regional lymph node metastasis	
Distant metastasis (M)			
M1	IVB	Any distant metastasis including pelvic lymph nodes	
FIGO Stage/TNM Classification			
Stage 0	Tis	N0	M0
Stage IA	T1a	N0	M0
Stage IB	T1b	N0	M0
Stage II	T2	N0	M0

Reproduced, with permission, from International Federation of Gynecology and Obstetrics. Annual Report on the results of treatment in gynecologic cancer. *Int J Gynecol Obstet,* 1991;36(Suppl):132. Copyright 1991, with permission from the International Federation of Gynecology & Obstetrics.

The number of preoperative studies ordered prior to surgery depends on the extent of disease and the general condition of the patient. A complete history and a thorough physical examination that includes cytologic study of the cervix and vulvoscopy should be performed. A large tumor may interfere with adequate pelvic examination. Bleeding may be caused by a lesion higher in the genital tract rather than the obvious vulvar tumor. In that case, the pelvic examination may be performed under anesthesia, and endometrial biopsy or dilatation and curettage (D&C) may be considered.

Chest radiography and other studies such as proctoscopy, pyelography, barium enema, and computed tomography (CT) scans are ordered on an individual basis, especially in the event of locally advanced disease or suspected metastases. Enlarged lymph nodes do not require biopsy; they will be excised by lymphadenectomy or thoroughly sampled at the time of operation.

Historically, the basic operation was radical vulvectomy and regional lymphadenectomy. The trend, however, is shifting away from standard en bloc radical vulvectomy and bilateral lymph node dissection toward wide radical local excision of the primary tumor with inguinal lymph node dissection. For a unifocal stage I lesion with <1 mm stromal invasion, wide radical local excision with surgical margins of at least 1–2 cm should be performed. Patients with unilateral lesions with a depth of invasion ≥1 mm should undergo ipsilateral groin dissection in addition to the above to determine nodal status. For patients with bilateral lesions, lesions impinging on or crossing the midline, or stage II or greater disease or if lymph node metastases are discovered at the time of unilateral lymphadenectomy, bilateral inguinal femoral lymphadenectomy can be performed. When disease has spread to lymph nodes, adjuvant radiation therapy is generally recommended; pelvic lymph node dissection is not required for staging or therapy. In general, lymphatic spread occurs in a sequential manner from the superficial to the deep inguinal lymph nodes. Consequently, if the superficial nodes harbor no metastatic disease, there is reasonable assurance that the deeper nodes are not involved. The role of sentinel node mapping is also being evaluated for patients with squamous vulvar carcinoma and melanomas and should be reserved for investigational use.

Postoperative radiation therapy is usually reserved for patients with more than 1 microscopically involved lymph node or if 1 of more lymph nodes are macroscopically involved. Radiation therapy can also be considered for patients with negative lymph nodes who are at high risk of local recurrence (tumors measuring >4 cm, positive or close margins, lymphovascular invasion).

When the disease involves the anus, rectum, rectovaginal septum, proximal urethra, or bladder, an adequate surgical resection is only possible with pelvic exenteration combined with radical vulvectomy. Operative mortality is high for these procedures, and the postoperative psychological impact is significant. In addition, with advanced-stage disease where ulcerated or fixed lymph nodes are palpated, attempts at lymphadenectomy have yielded very poor results. Based on data from the Gynecologic Oncology Group, this group of patients may benefit from preoperative chemoradiation, resulting in higher rates of successful resection and reduced need for more radical surgery. Chemotherapeutic agents such as cisplatin and 5-FU have been combined with radiation therapy. These chemotherapeutic agents are used as radiation sensitizers in large necrotic tumor beds, enhancing the radiation effects.

There is controversy concerning the extent of surgery required for treatment of malignant melanoma of the vulva. For some years, standard treatment consisted of vulvectomy with superficial and deep inguinal and pelvic lymphadenectomy. It is also generally treated with a more conservative surgical approach. If depth of the vulvar lesion is <1 mm, vulvar melanoma may be adequately treated with local incision using a 1-cm margin. However, if the depth of invasion is between 1 and 4 mm, excision requires a 2-cm margin in addition to a bilateral groin node dissection. Advanced or recurrent melanoma may be best treated with chemotherapy, radiation, or immunotherapy.

Radical wide local resection with wide surgical margins is the standard treatment for most vulvar sarcomas. Inguinofemoral lymphadenectomy should be performed for suspected metastases because the risk of lymphatic spread is low. The primary determinant of cure appears to be adequate wide removal of the primary lesion.

Follow-Up

After the immediate postoperative period, patients should be examined every 3 months for 2 years and every 6 months thereafter to detect recurrent disease or a second primary cancer. Nearly 80% of recurrent vulvar cancer occurs in the first 2 years. Treatment modalities depend on the location of recurrence. Malignant melanomas and sarcomas may recur locally or metastasize to the liver or lungs.

Prognosis

The principal prognostic factors in cancer of the vulva are the presence or absence of regional lymph node metastases, size and location of the lesion, and the histologic type. A 5-year survival rate of 75% and a 10-year survival rate of approximately 58% should be expected after complete surgical treatment of primary invasive squamous vulvar cancer. Lymph node status is the most important prognostic variable. Overall, the survival rate for patients with vulvar cancer and negative inguinal femoral nodes is 90%, whereas rates drop to almost 40% with nodal metastasis. Several authors have reported no deaths from cancer among patients who were found to have negative lymph nodes. With tumors <2 cm in diameter, the incidence of nodal metastases is 10–15%. In general, approximately 30% of patients undergoing surgery will have positive lymph nodes. With nodal metastases, the approximate 5-year cure rates are as follows: 1 node, 94%; 2 nodes, 80%; and 3 nodes or more, <15%. Patients who have 3 or more positive lymph nodes in the groin usually demonstrate palpably suspicious nodes preoperatively. These patients have a high incidence of metastases to the pelvic lymph nodes; however, pelvic lymphadenectomy does not improve survival rates. Involvement of contiguous organs such as the bladder or rectum increases the incidence of nodal metastases and worsens the prognosis accordingly.

The cure rate for adequately treated cancer of Bartholin's gland has not been established. There is a propensity for unresectable local recurrences under the pubic ramus despite a thorough primary operation.

Wide local excision of basal cell carcinoma should be curative. Some authors have reported an approximately 20% recurrence rate after local excision that may represent cases of incomplete excision.

Results of treatment of malignant melanoma are related to the level of penetration of the tumor into the dermis of the vulvar skin or the lamina propria of the vaginal mucosa and to the presence or absence of nodal metastases. The 5-year survival rate ranges from 24 to 70%. The prognosis of patients with metastases to groin lymph nodes is generally poor. Amelanotic cutaneous melanomas are particularly virulent tumors. The survival rate for patients with superficial spreading melanomas is much better than for those with the nodular variety, which tend to have a smaller diameter and exhibit aggressive vertical invasion, increased incidence of nodal metastases, treatment failures, and distant recurrences. The most common site of recurrence is at the site of resection or the groin lymph nodes (if not previously resected).

Sarcomas of the vulva tend to recur locally, particularly if the initial resection is not extensive, and metastasize to the liver and lungs.

PREINVASIVE DISEASE OF THE VAGINA

ESSENTIALS OF DIAGNOSIS

- Almost all lesions of vaginal intraepithelial neoplasia are asymptomatic.

- Lesions often accompany HPV infection, so patients may complain of vulvar warts. An abnormal Papanicolaou (Pap) smear is usually the first sign of disease.
- The diagnosis is made by colposcopic examination of the vagina with a directed biopsy.
- Colposcopic examination of the vagina can be difficult to perform, particularly if a hysterectomy has already been done, because lesions can lay hidden within the recesses of the vaginal cuff.
- Techniques similar to those used for colposcopic examination of the cervix are used for examination of the vagina.
- After application of 3–5% acetic acid to the vagina, a lesion under the colposcope may appear as white epithelium and may have mosaicism or punctuation.
- Lugol’s iodine may also help to identify the borders of a lesion.
- Lesions are often located along the vaginal ridges; they may appear to be raised or have spicules.
- Because the disease process tends to be multifocal, a thorough examination of the vagina from the introitus to the apex must be conducted.

General Considerations

Vaginal intraepithelial neoplasia (VAIN) can occur as an isolated lesion, but multifocal disease is more common. Although little is known regarding the natural history of VAIN, it is thought to be similar to that of cervical intraepithelial neoplasia (CIN). Many patients may have similar intraepithelial neoplastic lesions involving the cervix or vulva. At least one-half to two-thirds of patients with VAIN have been treated for similar disease in either the cervix or the vulva. In addition, VAIN can reappear several years later, necessitating long-term follow-up in these patients. Several investigators have recognized a “field effect” involving the squamous epithelium of the lower genital tract including the cervix, vagina, and vulva to be affected simultaneously by the same carcinogenic agent. The vagina lacks a transformation zone, whereas in the cervix, immature epithelial cells are infected with HPV. The upper third of the vagina is where the majority of these lesions are diagnosed. As in cervical and vulvar intraepithelial neoplasia, several investigators have found that smoking is associated with an increased risk of high-grade VAIN. Controversy still exists regarding the role of prior irradiation in the pathogenesis of vaginal neoplasia.

Condylomatous lesions of the lower genital tract often demonstrate associated dysplasias. For this reason, a biopsy should be made of condylomatous growth of the vagina prior to treatment.

Pathogenesis

As with other intraepithelial neoplasias occurring in the lower genital tract, VAIN is characterized by a loss of epithelial cell maturation. This is associated with nuclear hyper-chromatosis and pleomorphism with cellular crowding. The thickness of the epithelial abnormality designates the various lesions as VAIN I, II, or III. VAIN III is synonymous with carcinoma in situ of the vagina.

Treatment

The primary treatment modality for VAIN is surgical excision or carbon dioxide laser ablation. VAIN I lesions usually do not require treatment, as lesions typically regress, and usually close clinical observation is sufficient. VAIN II and III can be treated by laser ablation or excision. VAIN III lesions are more often associated with an early invasive lesion; therefore, adequate sampling should be performed before any ablative procedure is employed. If the lesion is focal, it is best removed in its entirety with local excision. When carcinoma in situ of the cervix extends to the upper vagina, the upper third of the vagina can be removed at the time of hysterectomy. If multifocal disease is present, a total vaginectomy may be performed with a split-thickness skin graft vaginal reconstruction. Topical 5-FU may also be used in treating multifocal VAIN. Approximately 80% of patients can expect to have evidence of regression of disease after 1 to 2 courses of treatment. Several small series have also reported success in using topical application of imiquimod for the treatment of high-grade VAIN, although the treatment remains investigational.

Follow-Up

VAIN tends to be multifocal, with involvement of the cervix and vulva in many cases. These lesions can be difficult to eradicate with only 1 treatment modality or treatment session. This group of patients must be monitored closely every 4–6 months with cytologic smears and HPV testing and close examination of not only the vagina but also the entire lower genital tract.

CANCER OF THE VAGINA

ESSENTIALS OF DIAGNOSIS

- Asymptomatic: abnormal vaginal cytology
- Early: painless bleeding from ulcerated tumor
- Late: bleeding, pain, weight loss, swelling

General Considerations

Primary cancers of the vagina are rare, representing approximately 0.3% of gynecologic cancers. Approximately 85% are squamous cell cancers, and the remainder, in decreasing order of frequency, are adenocarcinomas, sarcomas, and melanomas. A tumor should not be considered a primary vaginal cancer unless the cervix is uninvolved or only minimally involved by a tumor obviously arising in the vagina. By convention, any malignancy involving both cervix and vagina that is histologically compatible with an origin in either organ is classified as cervical cancer. Secondary carcinoma of the vagina is seen more frequently than primary vaginal cancers. Secondary, or metastatic, tumors may arise from cervical, endometrial, or ovarian cancer, breast cancer, gestational trophoblastic disease, colorectal cancer, or urogenital or vulvar cancer. Extension of cervical cancer to the vagina is probably the most common malignancy involving the vagina. In general, invasive vaginal carcinoma shares the same risk factors as cervical neoplasia such as smoking, HPV infection, multiple sexual partners, and a history of lower genital tract neoplasia. In addition, in utero diethylstilbestrol (DES) exposure is associated with an increased risk of primary vaginal adenocarcinoma, namely the clear cell variant.

Pathogenesis

Squamous cell carcinoma may be ulcerative or exophytic. It usually involves the posterior wall of the upper third of the vagina, but may be multicentric. Direct invasion of the bladder or rectum may occur. The incidence of lymph node metastases is directly related to the size of the tumor. The route of nodal metastases depends on the location of the tumor in the vagina. Tumors in the lower third metastasize like cancer of the vulva, primarily to the inguinal lymph nodes (Fig. 47–8). Cancers of the upper vagina, which is the most common site, metastasize in a manner similar to cancer of the cervix.

The lymphatic drainage of the vagina consists of a fine capillary meshwork in the mucosa and submucosa with multiple anastomoses. As a consequence, lesions in the middle third of the vagina may metastasize to the inguinal lymph nodes or directly to the deep pelvic lymph nodes.

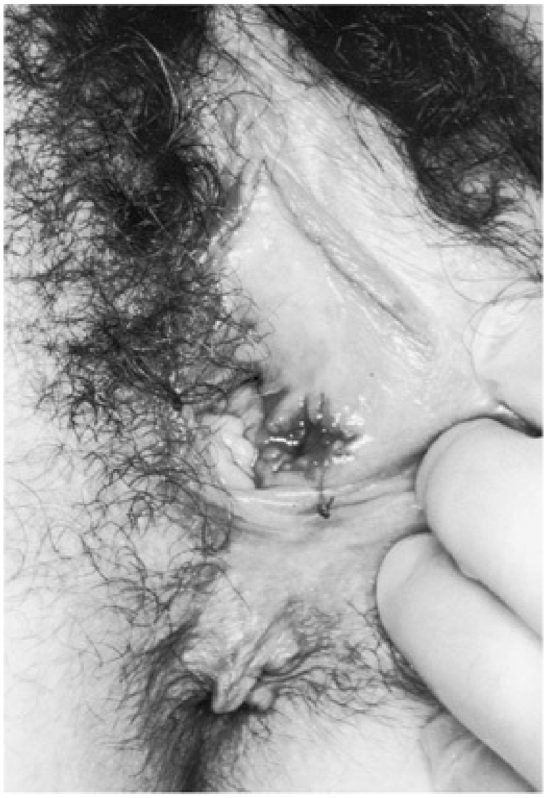

Figure 47–8. An ulcerated epidermoid cancer of the lower third of the vagina.

Adenocarcinomas account for the great majority of primary vaginal malignancies in young patients and may arise in areas of vaginal adenosis, endometriosis, wolffian duct remnants, or periurethral glands. In addition, the clear cell variant has been associated with a history of exposure to DES in utero (Fig. 47–9) with a mean age at diagnosis of 19 years. The risk of developing clear cell adenocarcinoma by age 24 years has been calculated to be 0.14–1.4 per 1000 exposed female fetuses.

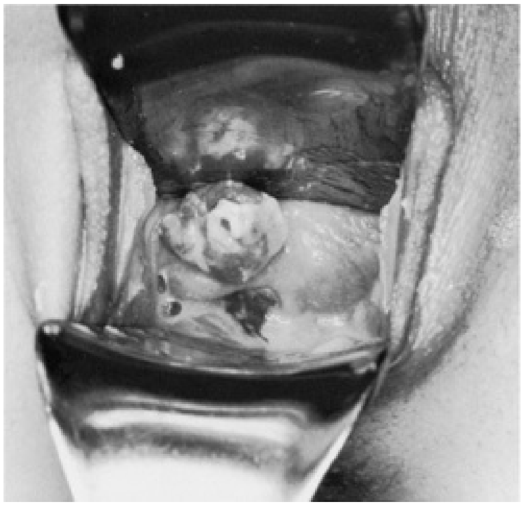

Figure 47–9. A clear cell adenocarcinoma of the vagina in a 19-year-old patient. The lesion is on the posterior wall of the upper third of the vagina.

Melanomas of the vagina are rare and most frequently arise from the anterior surface and lower half of the vagina and almost always occur in Caucasian patients. Nevi rarely occur in the vagina;

therefore, any pigmented lesion of the vagina should be excised or biopsied. Primary vaginal melanomas behave aggressively and tend to recur locally with distant spread and generally poor long-term survival.

The most common primary vaginal sarcoma is embryonal rhabdomyosarcomas or sarcoma botryoides, a highly aggressive tumor that occurs in infancy or early childhood replacing the vaginal mucosa with polypoid, edematous, “grapelike” masses that may protrude from the vaginal introitus. The outcome of these patients has improved with advent of multimodality treatment with chemotherapy, surgery, and radiation therapy. Leiomyosarcomas, endometrial stromal sarcomas, and carcinosarcomas occur in older women. The upper anterior vaginal wall is the most common site of origin. The appearance of these tumors depends on the size and the extent of disease at the time of diagnosis. In general, melanomas and sarcomas spread like squamous cell cancer, although hematogenous spread with liver and pulmonary metastases is more common.

Metastatic adenocarcinoma to the vagina may arise from the urethra, Bartholin’s gland, the rectum or bladder, the endometrial cavity, the endocervix, or an ovary, or it may be metastatic from a distant site. Hypernephroma of the kidney characteristically metastasizes to the lower third of the anterior wall of the vagina.

Clinical Findings

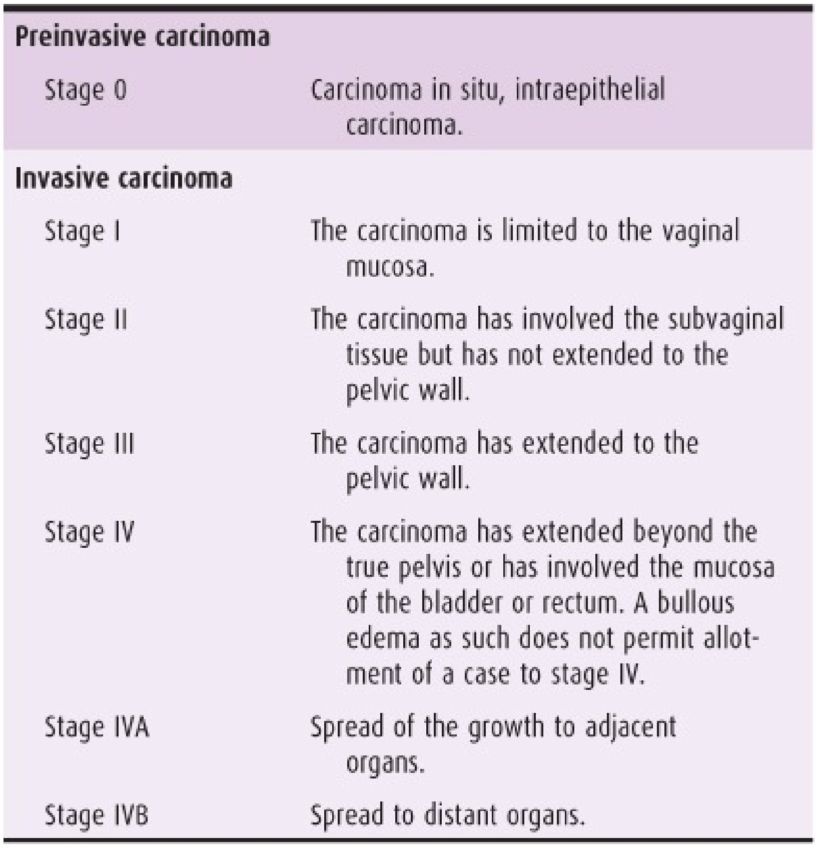
Vaginal cancer is often asymptomatic, discovered by routine vaginal cytologic examination, and confirmed by biopsy after delineation of the location and extent of the tumor by colposcopy.

Postmenopausal vaginal and/or postcoital bleeding are the most common presenting symptoms. Other common symptoms include vaginal discharge, a vaginal mass, or urinary symptoms. Approximately 50% of patients with invasive vaginal cancer report for examination within 6 months after symptoms are noted. Less commonly, advanced tumors may impinge upon the rectum or bladder or extend to the pelvic wall, causing pain or leg edema.

A diagnosis of primary cancer of the vagina cannot be established unless metastasis from another source is eliminated. A complete history and physical examination should be performed, including a thorough pelvic examination, cervical cytologic examination, endometrial biopsy when indicated, complete inspection of the vagina, including colposcopy, and biopsy of the vaginal tumor. Careful bimanual examination with palpation of the entire length of the vagina can detect small submucosal nodules not visualized during the examination. Biopsy should be performed to establish a histologic diagnosis.

The staging system for cancer of the vagina is clinical and not surgical (Table 47–2).

Table 47–2. International Federation of Gynecology and Obstetrics (FIGO) staging of carcinoma of the vagina.



Preinvasive carcinoma	
Stage 0	Carcinoma in situ, intraepithelial carcinoma.
Invasive carcinoma	
Stage I	The carcinoma is limited to the vaginal mucosa.
Stage II	The carcinoma has involved the subvaginal tissue but has not extended to the pelvic wall.
Stage III	The carcinoma has extended to the pelvic wall.
Stage IV	The carcinoma has extended beyond the true pelvis or has involved the mucosa of the bladder or rectum. A bullous edema as such does not permit allotment of a case to stage IV.
Stage IVA	Spread of the growth to adjacent organs.
Stage IVB	Spread to distant organs.

Differential Diagnosis

Benign tumors of the vagina are uncommon, are usually cystic, arise from the mesonephric (wolffian) or paramesonephric ducts, and are usually an incidental finding on examination of the anterolateral wall of the vagina (Gartner’s duct cyst).

An ulcerative lesion may occur at the site of direct trauma, following an inflammatory reaction caused by prolonged retention of a pessary or other foreign body, or, occasionally, following a chemical burn. Granulomatous venereal diseases seldom affect the vagina but may be diagnosed with appropriate laboratory studies and a biopsy.

Endometriosis that penetrates the cul-de-sac of Douglas into the upper vagina cannot be differentiated from cancer except by biopsy.

Treatment

Following biopsy confirmation of disease, all patients should undergo a thorough physical examination and evaluation of the extent of local and metastatic disease. Pretreatment evaluation may include the following studies: chest radiography, intravenous pyelogram, cystoscopy, proctosigmoidoscopy, and CT scan of the abdomen and pelvis. The optimal treatment of patients with invasive vaginal cancer is still controversial and should take into account the proximity of adjacent structures that preclude a proper surgical margin and the desire to preserve a functional vagina. In general, surgery is reserved for those patients with stage I lesions affecting the upper vagina incorporating a radical hysterectomy with an upper vaginectomy and a bilateral pelvic lymphadenectomy if a hysterectomy had not been previously performed. Otherwise the treatment consists of primary radiotherapy with brachytherapy for small superficial lesions and external beam radiotherapy with or without intracavitary radiotherapy for larger lesions. Interstitial therapy is commonly used unless there exists a small vault lesion, which may be adequately managed by a tandem and ovoid implant.

For locally advanced cancers, because of the poor outcomes associated with radiation therapy alone, concurrent chemotherapy sensitization has been proposed, although the data are still lacking. An exenterative procedure with removal of the vagina, uterus, tubes, ovaries, rectum, pelvis, and/or bladder and urethra with or without vaginal reconstruction may be considered for patients with a central recurrence after radiation therapy or select patients with stage IVA tumors, especially if a rectovaginal or vesicovaginal fistula is present.

The principles of treatment of primary adenocarcinoma of the vagina are the same as those for squamous cell cancer. However, preferred therapy for clear cell carcinoma of the vagina and cervix in young women has not been established. Approximately 60% of tumors occur in the upper half of the vagina, and the remainder occur in the cervix. The incidence of nodal metastases is approximately 18% in stage I and 30% or more in stage II disease. If the disease is found sufficiently early and is confined to the upper vagina and cervix, radical abdominal hysterectomy, upper vaginectomy, and pelvic lymphadenectomy with ovarian preservation can be performed. More advanced lesions are treated with irradiation.

For sarcoma botryoides, primary radiation therapy and local excision have historically yielded poor results. Primary chemotherapy with vincristine, dactinomycin, and cyclophosphamide plus radiation has led to excellent results in treating patients with this disease. Melanoma of the vagina may be treated with radiation, conservative excision, and/or radical surgery.

Prognosis

The size and stage of the disease at the time of diagnosis are the most important prognostic indicators in squamous cell cancers. The 5-year survival rate is approximately 77% in patients with stage I disease, 45% in patients with stage II disease, 31% in patients with stage III disease, and 18% in patients with stage IV disease.

Melanomas—even small ones—are very malignant, and few respond to therapy. The tumor recurs locally and metastasizes to the liver and lungs. Chemotherapy and immuno therapy have been used as adjunctive treatment.

Too few sarcomas of the vagina have been reported to generate survival data. Except for sarcoma botryoides, these tumors have a propensity for local recurrence and distant metastases, and the prognosis is usually poor.

Premalignant & Malignant Disorders of the Uterine Cervix

Christine H. Holschneider, MD

CERVICAL INTRAEPITHELIAL NEOPLASIA

ESSENTIALS OF DIAGNOSIS

- The cervix often appears grossly normal.
- Infection with the human papillomavirus is present.
- Dysplastic or carcinoma in situ cells are noted in a cytologic smear preparation (traditional Pap smear or liquid-based cytology).
- Colposcopic examination reveals an atypical transformation zone with thickened epithelium, coarse punctate, or mosaic patterns of surface capillaries.
- Iodine-nonstaining (Schiller-positive) area of squamous epithelium is typical.
- Biopsy diagnosis of cervical intraepithelial neoplasia (dysplasia or carcinoma in situ).

General Considerations

Lower genital tract squamous intraepithelial neoplasia is often multicentric (ie, affecting multiple anatomic sites that embryologically are derived from the same anogenital epithelium): cervical intraepithelial neoplasia (CIN), vaginal intraepithelial neoplasia (VAIN, see Chapter 47), vulvar intraepithelial neoplasia (VIN, see Chapter 47), and perianal intraepithelial neoplasia (PAIN). Approximately 10% of women with CIN have concomitant preinvasive neoplasia of the vulva, vagina, or anus. Conversely, 40–60% of patients with VIN or VAIN have synchronous or meta-chronous CIN.

CIN, formerly called dysplasia, means disordered growth and development of the epithelial lining of the cervix. There are various degrees of CIN. Mild dysplasia, or CIN I, is defined as disordered growth of the lower third of the epithelial lining. Abnormal maturation of the lower two-thirds of the lining is called moderate dysplasia, or CIN II. Severe dysplasia, CIN III, encompasses more than two-thirds of the epithelial thickness with carcinoma in situ (CIS) representing full-thickness dysmaturity. While histologically evaluated lesions are characterized using the CIN nomenclature, cytologic smears are classified according to the Bethesda system, which was most recently revised in 2001. Briefly, atypical squamous cells are divided into those of undetermined significance (ASC-US) and those in which a high-grade lesion cannot be excluded (ASC-H). Low-grade squamous intraepithelial lesion (LSIL) encompasses cytologic changes consistent with koilocytic atypia or CIN I. High-grade squamous intraepithelial lesion (HSIL) denotes the cytologic findings corresponding to CIN II and CIN III. CIN may be suspected because of an abnormal cytologic smear, but the diagnosis is established by cervical biopsy. Spontaneous regression, especially of CIN I, occurs in a significant number of patients, allowing for expectant management with serial cytologic smears in the reliable patient. A certain percentage of high-grade lesions will progress to an invasive cancer if left untreated. Because it is not presently possible to predict which lesions will progress, it is recommended that all patients with CIN II and CIN III be treated when diagnosed. The only 2 exceptions to this recommendation concern adolescents, in whom CIN II may be followed, as spontaneous regression is substantial and the risk of cancer almost nil, as well as pregnant women, in whom treatment should be deferred to the postpartum period.

Pathogenesis

Prevalence figures for CIN vary according to the socioeconomic characteristics and geographic area of the population studied, from as low as 1.05% in some family planning clinics to as high as 13.7% in women attending sexually transmitted disease (STD) clinics. CIN is most commonly detected in women in their 20s; the peak incidence of CIS is in women ages 25–35 years, whereas the incidence of cervical cancer rises most significantly after the age of 40 years.

The epidemiologic risk factors for CIN are similar to those for cervical cancer and include multiple sexual partners, early onset of sexual activity, a high-risk sexual partner (history of multiple sexual partners, human papillomavirus [HPV] infection, lower genital tract neoplasia, or prior sexual exposure to someone with cervical neoplasia), a history of sexually transmitted infections (STIs), cigarette smoking, human immunodeficiency virus (HIV) infection, acquired immunodeficiency syndrome (AIDS), other forms of immunosuppression, multiparity, and long-term oral contraceptive pill use.

HPVs are a prime etiologic factor in the development of CIN and cervical cancer. In fact, most of the above behavioral and sexual risk factors for cervical neoplasia become statistically insignificant as independent variables after adjusting for HPV infection. Analyses of cervical neoplasia lesions show the presence of HPV in more than 80% of all CIN lesions and in 99.7% of all invasive cervical cancers. The 2 most common high-risk HPV types are HPV-16, found in 50–70% of cervical cancers, and HPV-18, found in 7–20% of cases.

Infection with HPV is extremely common and varies with the patient’s age. In the United States, the prevalence of detectable HPV infection rises from 1% in newborns, to 20% in teenagers, to 40% in women 20–29 years of age, with a slow decline thereafter to a plateau of 5% in women age 50 years and older. A women’s lifetime risk for infection with HPV is approximately 50–80%. Condoms are not as protective against HPV as they are against other STDs because transmission can occur from labial-scrotal contact. Regular and consistent condom use is necessary to achieve a 60% protection against infection.

There are about 130 HPV types, about 30–40 of which infect the anogenital epithelium. Based on their malignant potential, HPV subtypes are categorized into low-risk and high-risk types. Low-risk HPV types (eg, types 6, 11, 42, 43, and 44) are associated with condylomata and low-grade lesions (CIN I), whereas high-risk HPV types (eg, types 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, and 68) are associated with invasive cancer in addition to high-grade lesions (CIN II and CIN III),

More than 90% of immunocompetent women will have a spontaneous resolution of their HPV infection over a 2-year period, and only approximately 5% will have cytologically detectable CIN. About 10% of women will have a persistent high-risk HPV infection, which places them at increased risk for developing CIN II/III and cervical cancer.

The vast majority of women infected with HPV do not develop CIN or cervical cancer. This suggests that infection with HPV alone is insufficient for the development of CIN or cervical cancer and underscores the importance of other cofactors, such as cigarette smoking or immunosuppression.

Cigarette smoking and HPV infection have synergistic effects on the development of CIN, and cigarette smoking is associated with a 2- to 4-fold increase in the relative risk for developing cervical cancer. Cigarette smoke carcinogens have been found to accumulate locally in the cervical mucus, and the cumulative exposure as measured by pack-years smoked is related to the risk of developing CIN or CIS. However, the mechanisms by which cigarette smoking contributes to cervical carcinogenesis are poorly understood.

The incidence of cervical neoplasia is increased in HIV-infected women, who, in some studies, have a 20–30% incidence of colposcopically confirmed CIN. With increasing immunosuppression, there is an increased risk of de novo HPV infection, persistent HPV infection, and progressive cervical neoplasia. Since 1993, invasive cervical cancer has been included as an AIDS-defining illness.

Prevention

A. HPV Vaccination

Two HPV vaccines are currently approved by the Food and Drug Administration (FDA), a quadrivalent vaccine (Gardasil) against HPV-16, -18, -6, and -11 and a bivalent vaccine (Cervarix) against HPV-16 and -18. In clinical trials, the efficacy of these vaccines for preventing CIN II or worse due to HPV types included in the vaccine was 93–100% in the HPV-naïve study population. In the entire study cohorts (those with or without prior HPV infection), the efficacy of either vaccine for preventing CIN II or worse was only 30–44%. Among HPV-naive populations, these vaccines also provided approximately 20–50% protection against CIN II or worse due to nonvaccine HPV types. The Centers for Disease Control and Prevention (CDC) Advisory Committee on Immunization Practices (ACIP) recommends that all girls 11–12 years of age should be routinely offered HPV vaccination, as well as girls and women age 13–26 who have not yet been vaccinated (catch-up population) and girls as young as 9 years, if indicated. In 2009, the FDA approved the use of the quadrivalent vaccine in males, and ACIP states that the quadrivalent vaccine may be given to males age 9–26 years to reduce their likelihood of acquiring genital warts and prevent the development of anal intraepithelial neoplasia and anal cancer.

These HPV vaccines are prophylactic and not therapeutic. Thus, immunization with HPV vaccine is most effective in female or male individuals who have not been infected with HPV (eg, before sexual debut). These recommendations are not altered if a girl or woman in the qualifying age group is found to have an abnormal Pap or a positive HPV test for the following reason: By their mid-20s, approximately 25% of women test positive for 1 of the 4 HPV types in the quadrivalent vaccine, but only 1% test positive for HPV-16 and -18, and only 0.1% test positive for all 4 HPV types. Thus, the bivalent or quadrivalent HPV vaccine should offer benefit to almost all individuals in the indicated age range. There is no evidence that HPV vaccine is harmful during pregnancy. However, HPV vaccination is not recommended during pregnancy due to limited safety data. Women who have started the vaccination series but became pregnant before completion or women who received the vaccination before knowing they were pregnant should be reassured and advised to resume the vaccination series postpartum. It is safe to offer HPV vaccination during lactation.

B. Screening for CIN & Cervical Cancer

Following the implementation of population-based screening programs and treatment of preinvasive and early invasive disease, there has been a 75% reduction in the incidence and mortality of cervical cancer in developed countries. In the United States, more than half of women who develop cervical cancer either have never had cervical cytology, have been screened only sporadically, or have not been screened within the previous 5 years. It is critical that women, whether vaccinated or not, follow current cervical cancer screening guidelines.

1. Cervical cytology screening—In 2012 new and generally consistent cervical cancer screening recommendations for the general population, HPV vaccinated and unvaccinated, were released by two separate groups: the U.S. Preventive Services Task Force (USPSTF) and the multidisciplinary partnership of the American Cancer Society, American Society for Colposcopy and Cervical Pathology, and American Society for Clinical Pathology (ACS/ASCCP/ASCP).

A. ONSET OF SCREENING—Cervical cytology screening should not begin before age 21 regardless of the age at onset of sexual intercourse. This recommendation is based on the fact that invasive cervical cancer is very rare in women younger than 21 years of age; yet there is significant potential for adverse effects associated with the follow-up of abnormal cervical cytology including anxiety, cost, morbidity and long-term consequences of overuse of follow-up procedures. In young women, there is a high prevalence of HPV infection shortly after the onset of intercourse, commonly associated with abnormal cervical cytology and followed by a very high subsequent spontaneous clearance rate of both HPV infection and dysplasia.

B. FREQUENCY OF SCREENING—Cervical cytology screening is recommended every 3 years for women 21–29 years of age. HPV testing should not be performed in this age group. Women age 30 or older should be screened with cytology and HPV co-testing every 5 years or cytology alone every 3 years.

C. DISCONTINUATION OF SCREENING—Screening should be discontinued in women older than 65 years with negative consecutive screening in the preceding 10 years. Screening should not be resumed for any reason. However, women who have completed their post-treatment surveillance for CIN 2/3 or worse, should continue routine screening for at least 20 years, even if that extends screening past age 65. Cytology testing should be discontinued in women who have had a total hysterectomy and do not have a prior history of CIN 2/3 or worse. Evidence of adequate negative prior screening is not required.

D. SPECIAL POPULATIONS—Based on 2009 ACOG guidelines, women who are HIV positive should be screened twice in the first year after diagnosis and annually thereafter. Women who are immunosuppressed for other reasons or had in utero DES exposure should be screened annually.

As previously discussed, the Pap test results are reported using the 2001 Bethesda nomenclature.

2. HPV testing—Currently, there are 2 US FDA-approved HPV tests in clinical practice. They test for the presence of 1 or more of 13 or 14 high-risk HPV types. High-risk HPV testing is currently being used in the United States for cervical cancer screening in the following scenarios:

- As a triage test for ASC-US cervical cytology in women 21 years of age or older with reflex-HPV testing on the residual preservative of the liquid-based cytology.
- As a triage test for LSIL in postmenopausal women.
- As a follow-up test after CIN I or negative colposcopy in women with ASC-US, ASC-H, LSIL, or atypical glandular cells (AGCs).
- In follow-up after treatment for CIN II/III.
- As an adjunct to cytology for the primary screening in women older than 30 years. HPV testing combined with a cervical cytology smear has been approved as a primary screening approach in the patient age 30 years and older, who still has her uterus and has no immunosuppression. If both results are negative, combined screening should not be repeated for 5 years. If cytology and HPV testing are positive, triaging to colposcopy is as outlined earlier. If cytology is normal, but HPV test is positive,

repeat cytology and HPV testing in 6–12 months is recommended, with colposcopy at that point if either test is abnormal. Type-specific testing for HPV-16 and HPV-18 has recently been FDA approved and can be used as an adjunct for women with negative cytology results but positive high-risk HPV test.

3. Visual screening in low-resource settings—Visual inspection of the cervix is being used as a screening tool in low-resource settings with no access to HPV testing or cytology screening. It has limited specificity but is economical and provides immediate results. Visual inspection can be performed by direct visual inspection or by performing cervicoscopy using acetic acid, toluidine blue, or Lugol's iodine as an adjunct.

Clinical Findings

A. Symptoms & Signs

There are usually no symptoms or signs of CIN, and the diagnosis is most often based on biopsy findings following an abnormal routine cervical cytology smear. Because high-grade dysplasia is a transitional phase in the pathogenesis of many cervical cancers, early detection by following the previously described screening guidelines is extremely important. If during pelvic examination, a cervical lesion is visualized, it should be promptly biopsied.

B. Pathology

On cytologic examination, the dysplastic cell is characterized by anaplasia, an increased nuclear-to-cytoplasmic ratio (ie, the nucleus is larger), hyperchromatism with changes in the nuclear chromatin, multinucleation, and abnormalities in differentiation.

Histologically, involvement of varying degrees of thickness of the stratified squamous epithelium is typical of dysplasia. The cells are anaplastic and hyperchromatic and show a loss of polarity in the deeper layers as well as abnormal mitotic figures in increased numbers. Benign epithelial alterations, particularly those of an inflammatory nature, the cytopathic effects of HPV, and technical artifacts may be mistaken for CIN I and CIN II.

The columnar epithelium of the mucus-secreting endocervical glands can also undergo neoplastic transformation. Adenocarcinoma in situ (ACIS) is defined as the presence of endocervical glands lined by atypical columnar epithelium that cytologically resembles the cells of endocervical adenocarcinoma, but that occur in the absence of stromal invasion. The diagnosis of ACIS can be made only by cone biopsy.

C. Special Examinations

All abnormal cervical cytology tests require further evaluation, such as visual inspection of the cervix, repeat cytology, HPV testing, staining with Lugol's solution (Schiller test) or toluidine blue, colposcopy, directed biopsy, endocervical sampling, or diagnostic conization (see Treatment section) (Fig. 48–1). The objective is to exclude the presence of invasive carcinoma and to determine the degree and extent of any CIN.

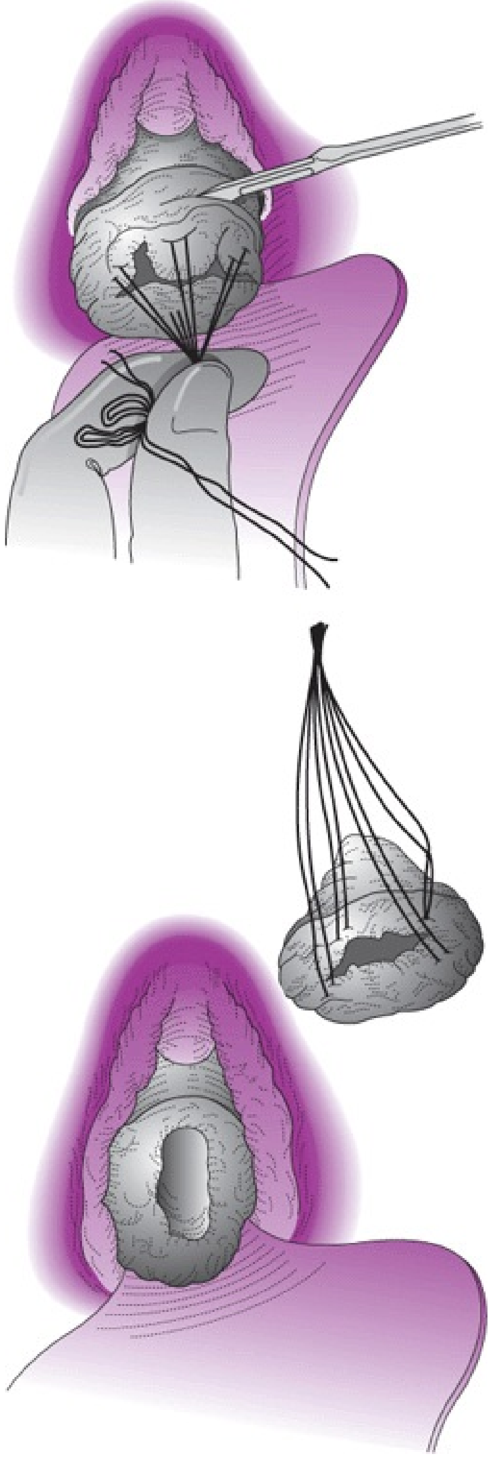

Figure 48–1. Conization of the cervix.

1. Repeat cervical cytology—There are 3 acceptable initial evaluation steps for patients with minimally abnormal cervical cytology smears (eg, ASC-US, postmenopausal LSIL): accelerated serial cytology smears, triage to colposcopy based on a positive HPV testing result, or immediate referral to colposcopy. All patients with ASC-H, premenopausal LSILs, HSILs, AGCs, or smears suspicious for cancer should be referred for immediate colposcopy.

Prior to performing a repeat smear for a patient with ASC-US, she should be evaluated and treated for potential underlying conditions that might contribute to an atypical smear, such as antimicrobials for infections or hormones for atrophic vaginitis. The cervical cytology smear should be repeated every 6 months until there are 2 consecutive normal smears. The use of serial cytologic smears is important, as the false-negative rate of a single repeat smear following an ASC-US diagnosis is as high as 33% for biopsy-proven HSILs (CIN II/III). A second abnormal smear (atypical squamous cell

[ASC] or worse) should be evaluated by colposcopy.

2. HPV testing—Testing for low-risk HPV types has no role in cervical cancer prevention. Testing for high-risk HPV types has become an integral part of the management of some abnormal cervical cytology smears (ie, ASC-US, post-menopausal LSIL). For patients with ASC-US, reflex HPV testing is the preferred approach, with triage of women who test positive for high-risk HPV to colposcopy. Reflex HPV testing refers to the concurrent collection of a specimen for cervical cytology and HPV testing, with the HPV testing being performed only in case of an abnormal cytologic screen. For ASC-US, this approach is the most cost-effective and has an equal or higher sensitivity for CIN II/III at the lowest referral rate to colposcopy compared to the 2 alternate approaches (accelerated serial cytology or immediate colpos-copy). Women with an ASC-US smear and a negative HPV test are followed with a cervical cytology smear at 1 year. The value of HPV testing for the triage of premenopausal patients with LSIL is limited because nearly 85% of the lesions are HPV positive.

3. Schiller test—The Schiller test is based on the principle that normal mature squamous epithelium of the cervix contains glycogen, which combines with iodine to produce a deep mahogany-brown color. Nonstaining, therefore, indicates abnormal squamous (or columnar) epithelium, scarring, cyst formation, or immature metaplastic epithelium, and constitutes a positive Schiller test. Lugol’s solution is an aqueous iodine preparation and is commonly used for the Schiller test.

4. Colposcopic examination—Colposcopy is the primary technique for the evaluation of an abnormal cervical cytology smear. The colposcope is an instrument that uses illuminated low-power magnification (5–15×) to inspect the cervix, vagina, vulva, or anal epithelium. Abnormalities in the appearance of the epithelium and its capillary blood supply often are invisible to the naked eye but can be identified by colposcopy, particularly after the application of 3–5% aqueous acetic acid solution. CIN produces recognizable abnormalities of the cervical epithelium in the majority of patients.

Indications for colposcopy are:

1. Abnormal cervical cytology smear or HPV testing;
2. Clinically abnormal or suspicious-looking cervix;
3. Unexplained intermenstrual or postcoital bleeding;
4. Vulvar or vaginal neoplasia; or
5. History of in utero DES exposure.

Details of the colposcopy technique are described in Chapter 40.

Normal colposcopic findings are those of:

1. The original squamous epithelium, which extends from the mucocutaneous vulvovaginal junction to the original squamocolumnar junction.
2. The transformation zone, which is the metaplastic squamous epithelium between the original squamocolumnar junction and the active squamocolumnar junction. The original squamocolumnar junction is the junction between the stratified squamous epithelium of the vagina and ectocervix and the columnar epithelium of the endocervical canal. In two-thirds of female infants, this original squamocolumnar junction is located on the ectocervix, in close to a third in the endocervical canal, and in a very small subset out in the vaginal fornices. During a woman’s life cycle, the squamocolumnar junction “migrates” as a consequence of various hormonal and

environmental influences that alter the cervical volume and cause squamous metaplasia of everted endocervical columnar cells. Following menarche, the squamocolumnar junction is generally found on the ectocervix, with further eversion during pregnancy. In the postmenopausal patient, the squamocolumnar junction is frequently within the endocervical canal. This squamous metaplasia is a dynamic process, and cervical neoplasia almost invariably originates within the transformation zone. If the new squamocolumnar junction is visualized in its entirety, the colposcopic examination is called satisfactory; if it cannot be fully visualized, the examination is called unsatisfactory.

3. The columnar epithelium of the endocervical canal.

Abnormal findings indicative of dysplasia and CIS are those of:

1. Leukoplakia or hyperkeratosis, which is an area of white, thickened epithelium that is appreciated prior to the application of acetic acid and may indicate underlying neoplasia.
2. Acetowhite epithelium, which is epithelium that stains white after the application of acetic acid.
3. Mosaicism or punctation reflecting abnormal vascular patterns of the surface capillaries. As a general rule, capillary thickness and intercapillary distances correlate with the severity of the lesion and thus tend to be larger and coarser in higher grade lesions.
4. Atypical vessels with bizarre capillaries with so-called corkscrew, comma-shaped, or spaghetti-like configurations suggest early stromal invasion (Figs. 48–2 through 48–4).

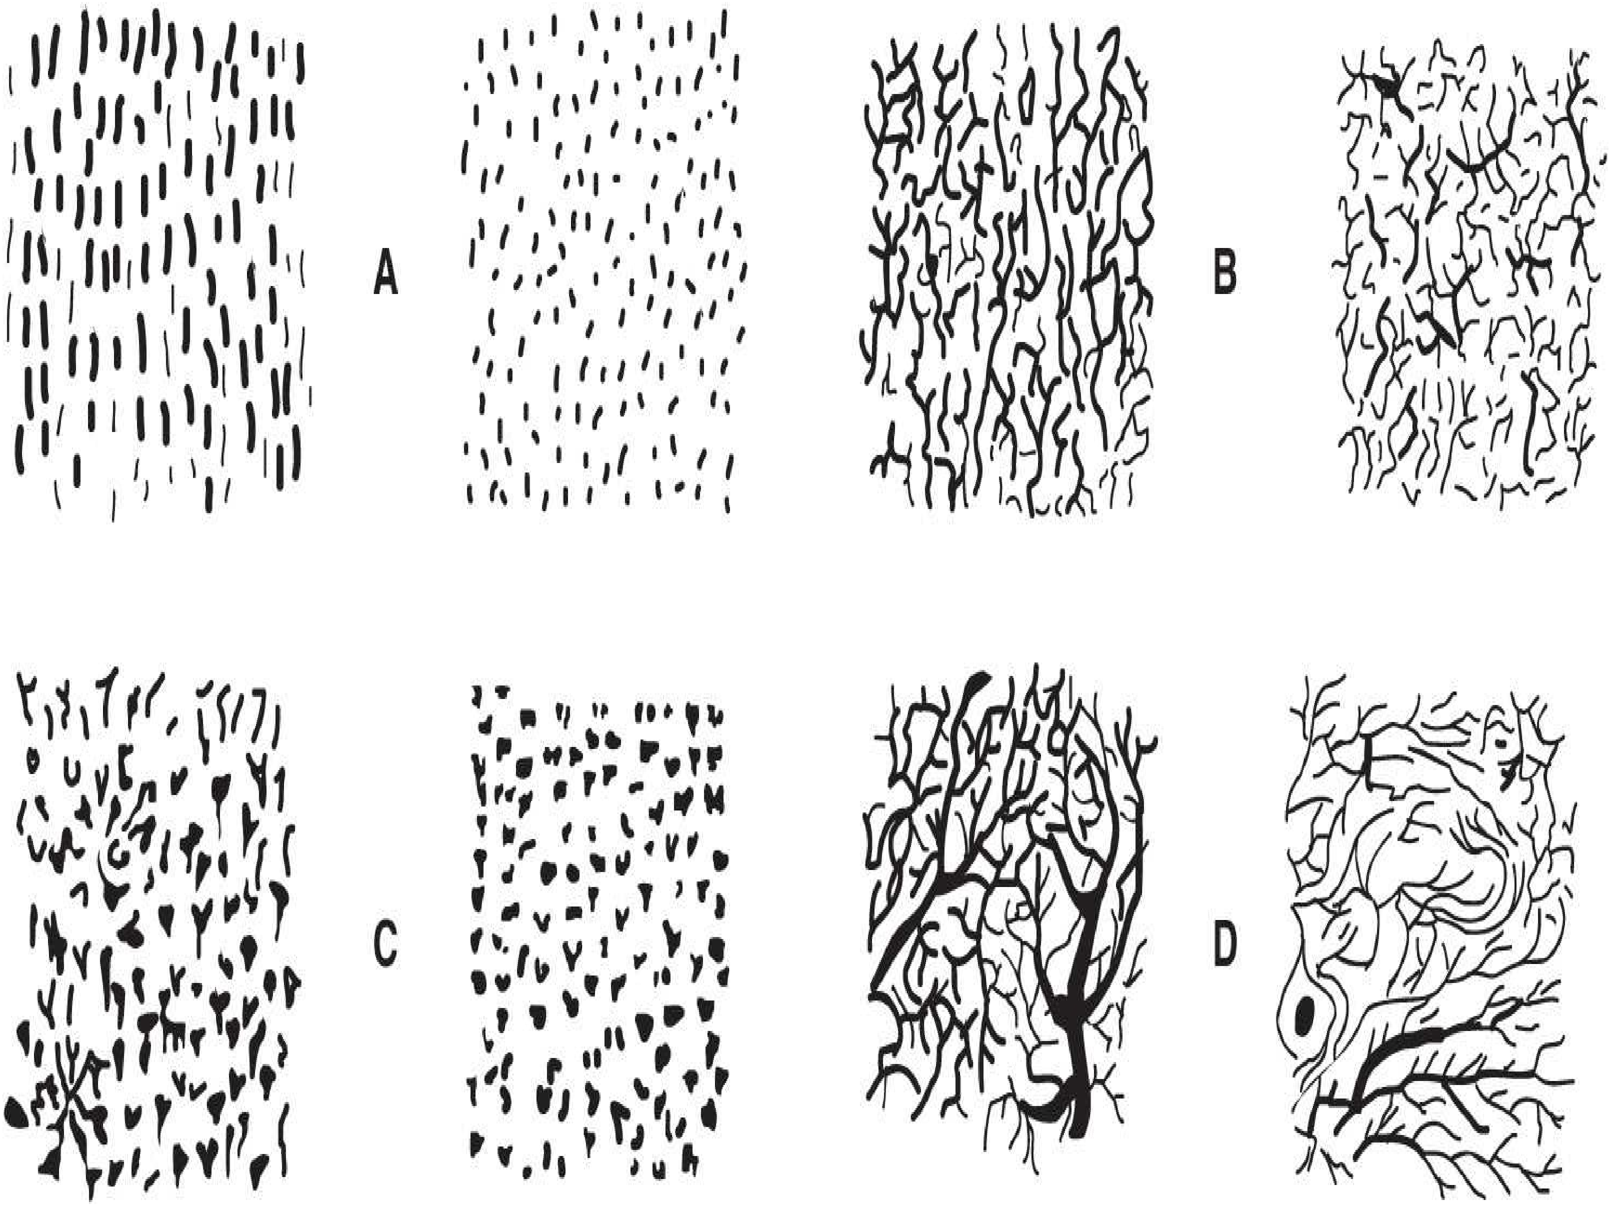

Figure 48–2. Schematic of different types of terminal vessels as observed in the normal squamous epithelium: hairpin capillaries (**A**), network capillaries (**B**) both found in normal states, double capillaries (**C**) seen in *Trichomonas* inflammation, and branching vessels (**D**) seen in the transformation zone. (Reproduced, with permission, from Johannisson E, Kolstat P, Soderberg G. Cytologic, vascular, and histologic patterns of dysplasia, carcinoma in situ and early invasive carcinoma of the cervix. *Acta Radiol Suppl* [Stockh] 1966;258:1.)

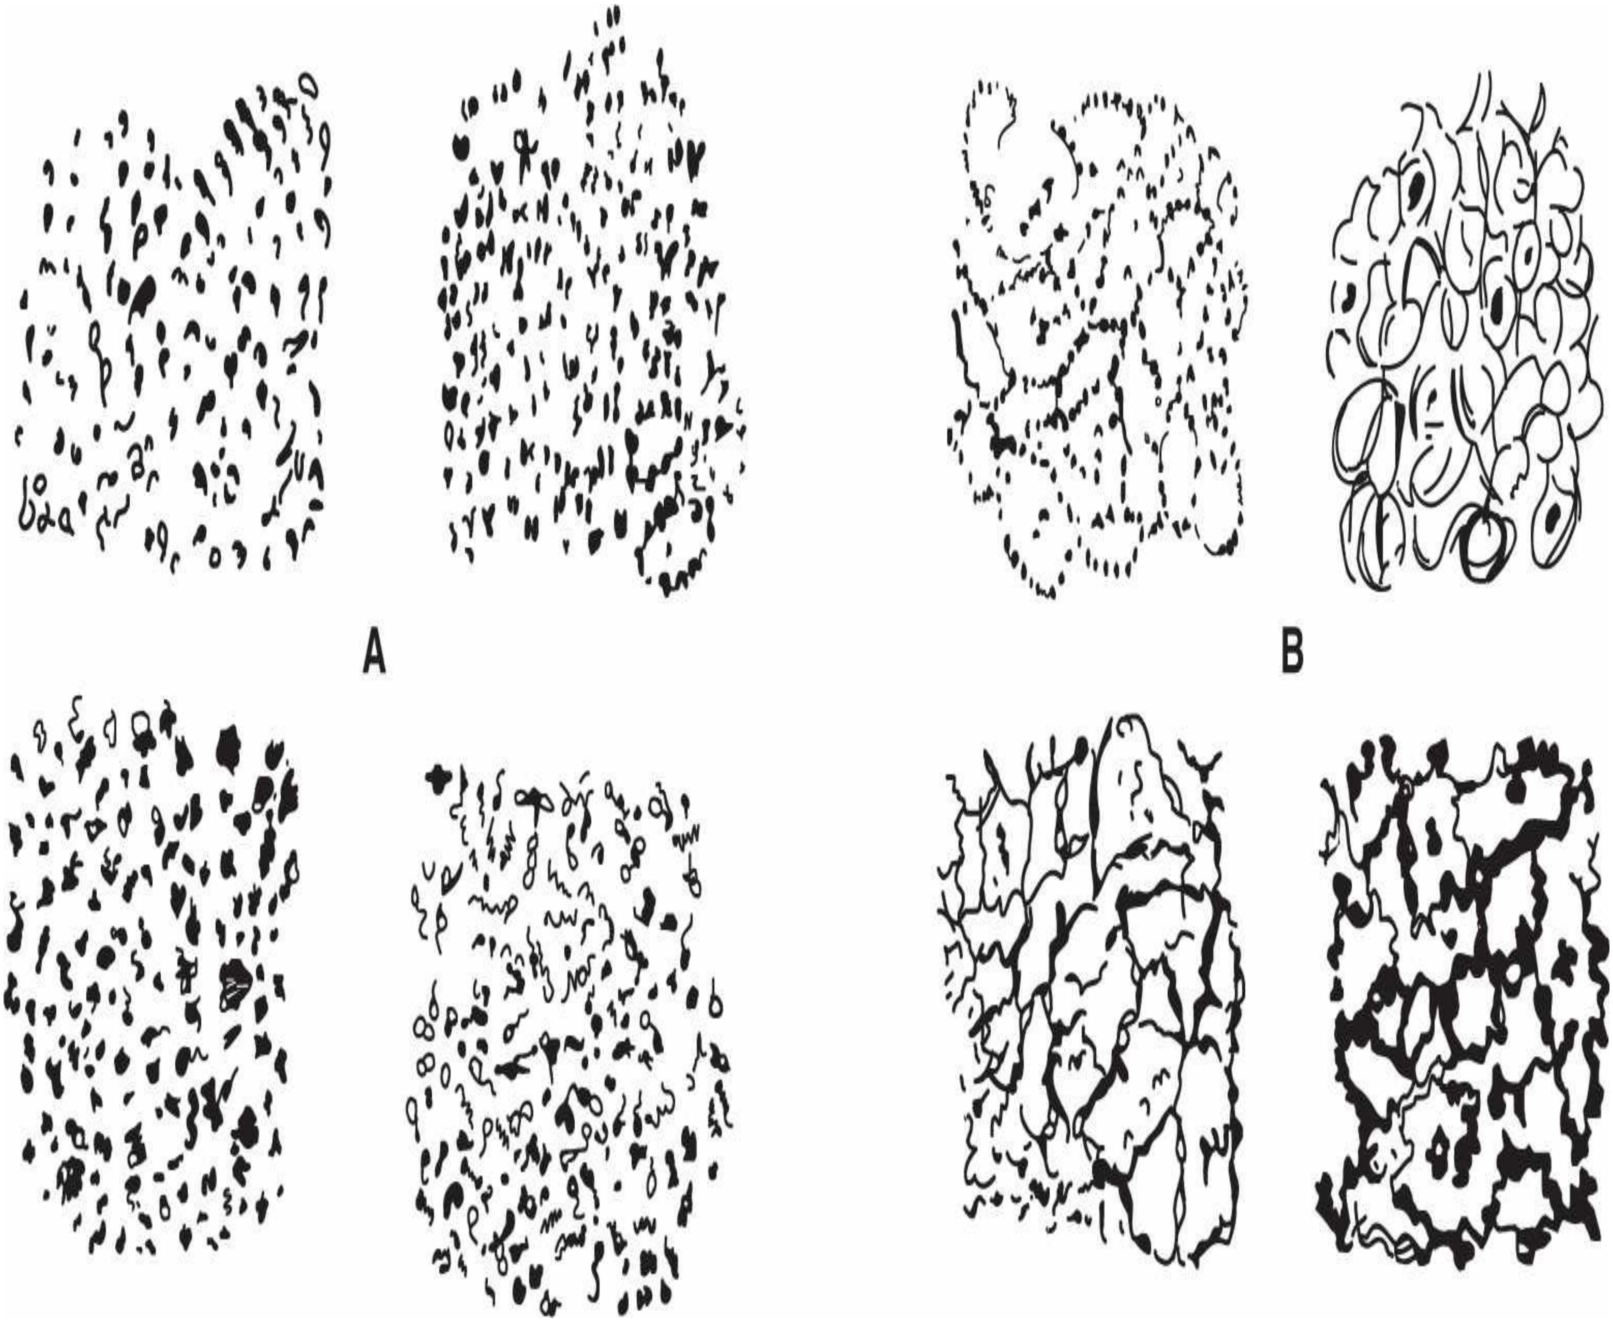

Figure 48–3. Schematic of punctation terminal vessels (**A**) and mosaic terminal vessels (**B**). (Reproduced, with permission, from Johannisson E, Kolstat P, Soderberg G. Cytologic, vascular, and histologic patterns of dysplasia, carcinoma in situ and early invasive carcinoma of the cervix. *Acta Radiol Suppl* [Stockh] 1966;258:1.)

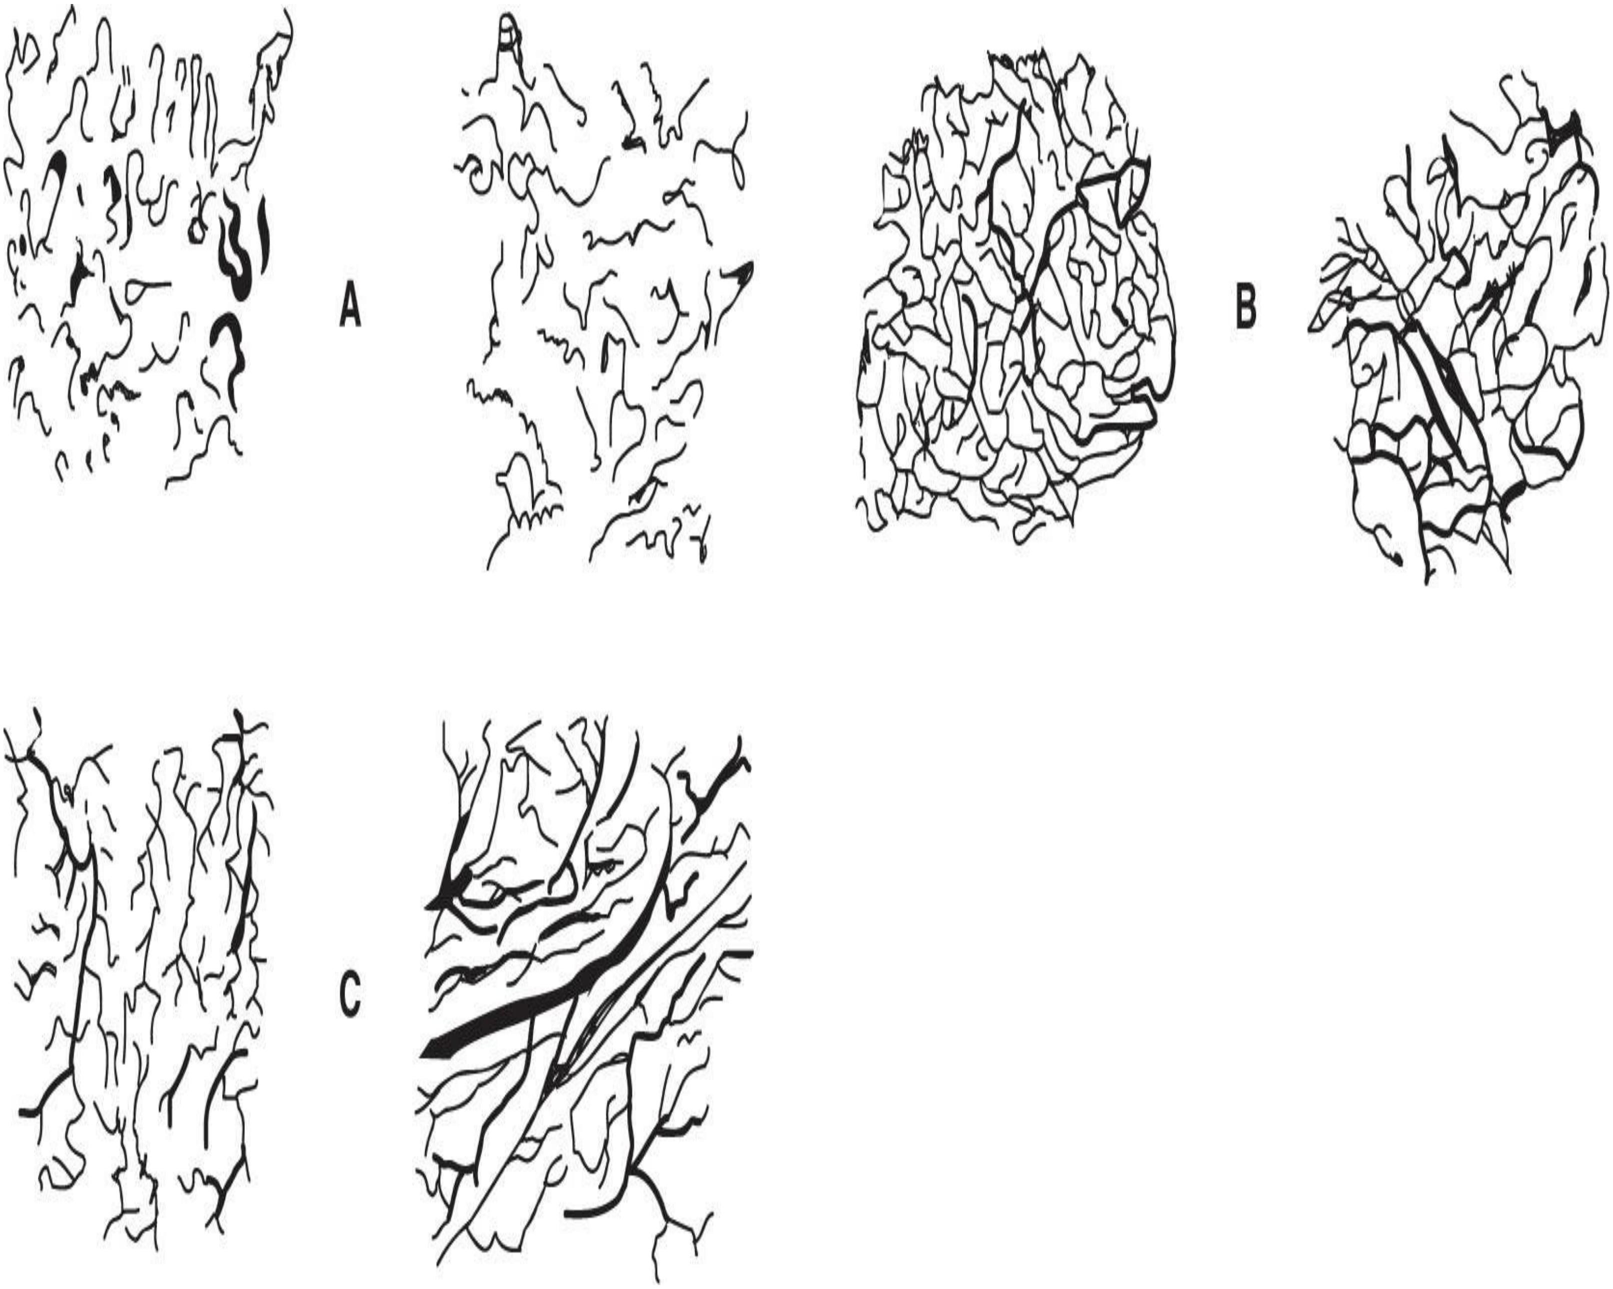

Figure 48–4. Schematic of atypical vessels: hairpinlike (**A**); networklike (**B**); and branching type (**C**). (Reproduced, with permission, from Johannisson E, Kolstat P, Soderberg G. Cytologic, vascular, and histologic patterns of dysplasia, carcinoma in situ and early invasive carcinoma of the cervix. *Acta Radiol Suppl* [Stockh] 1966;258:1.)

Colposcopically directed punch biopsy of the abnormal areas should be done. The transformation zone extends into the endocervical canal beyond the field of vision in 12–15% of premenopausal women and in a significantly higher percentage of postmenopausal women. Evaluation of the nonvisualized portion of the endocervical canal by endocervical sampling should be performed using a brush or curette, at a minimum, in every case in which colposcopy is unsatisfactory, where the lesion is extending into the endocervical canal, where the colposcopic impression does not explain the cervical cytology findings, or where ablative therapy is contemplated. Endocervical sampling is not indicated in pregnancy. In up to 20% of patients with CIN, the endocervical sampling is positive for dysplasia.

5. Diagnostic conization—Following expert colposcopic evaluation, diagnostic conization of the cervix (Fig. 48–1) is indicated if colposcopy is unsatisfactory, if the lesion extends into the cervical canal beyond the view afforded by the colposcope, if there is dysplasia on the endocervical sampling, if there is a significant discrepancy between the histologic diagnosis of the directed biopsy specimen and the cytologic examination, if ACIS is suspected, or if microinvasive carcinoma is suspected.

Differential Diagnosis

As CIN is generally asymptomatic, it is suspected based on an abnormal cervical cytology test, and diagnosis is confirmed by colposcopy-directed cervical biopsy or endocervical sampling. Abnormal cells on a cervical cytology smear may at times arise from locations other than the uterine cervix, including the vulva, vagina, and, especially in case of abnormal glandular cells, the endometrium and adnexae.

Complications

Understanding the natural history of the various degrees of CIN is central to the appropriate clinical management of these patients. In addition to the degree of dysplasia, it is likely that the course of a specific lesion is also influenced by a number of other factors, such as the patient's age, the inciting HPV type, the patient's immune competence, and smoking habits. For individuals who do not clear an HPV infection, longitudinal natural history studies suggest that the time from detection of an infection with high-risk HPV to development of CIN II/III is about 3–5 years and that another 10–20 years pass before the progression to cancer. It is estimated that 30–40% of CIN III actually progresses to cancer.

As summarized in Table 48–1, the majority of CIN I lesions will spontaneously regress without treatment. However, 9–16% of patients with untreated CIN I are diagnosed with CIN II/III over a 2-year follow-up. Spontaneous regression rates of CIN I overall are 60%; in young women, the rates are as high as 91%. Therefore, it is generally reasonable to expectantly follow the compliant patient with CIN I using enhanced surveillance to allow for spontaneous resolution (see following Treatment section). The majority of high-grade lesions will persist or progress (Table 48–1), so immediate treatment is generally warranted.

Table 48–1. Approximate rates of spontaneous regression, persistence, and progression of CIN.

	CIN I	CIN II	CIN III
Regression to normal	60%	40%	30%
Persistence	30%	35%	48%
Progression to CIN III	10%	20%	–
Progression to cancer	<1%	5%	30–40%

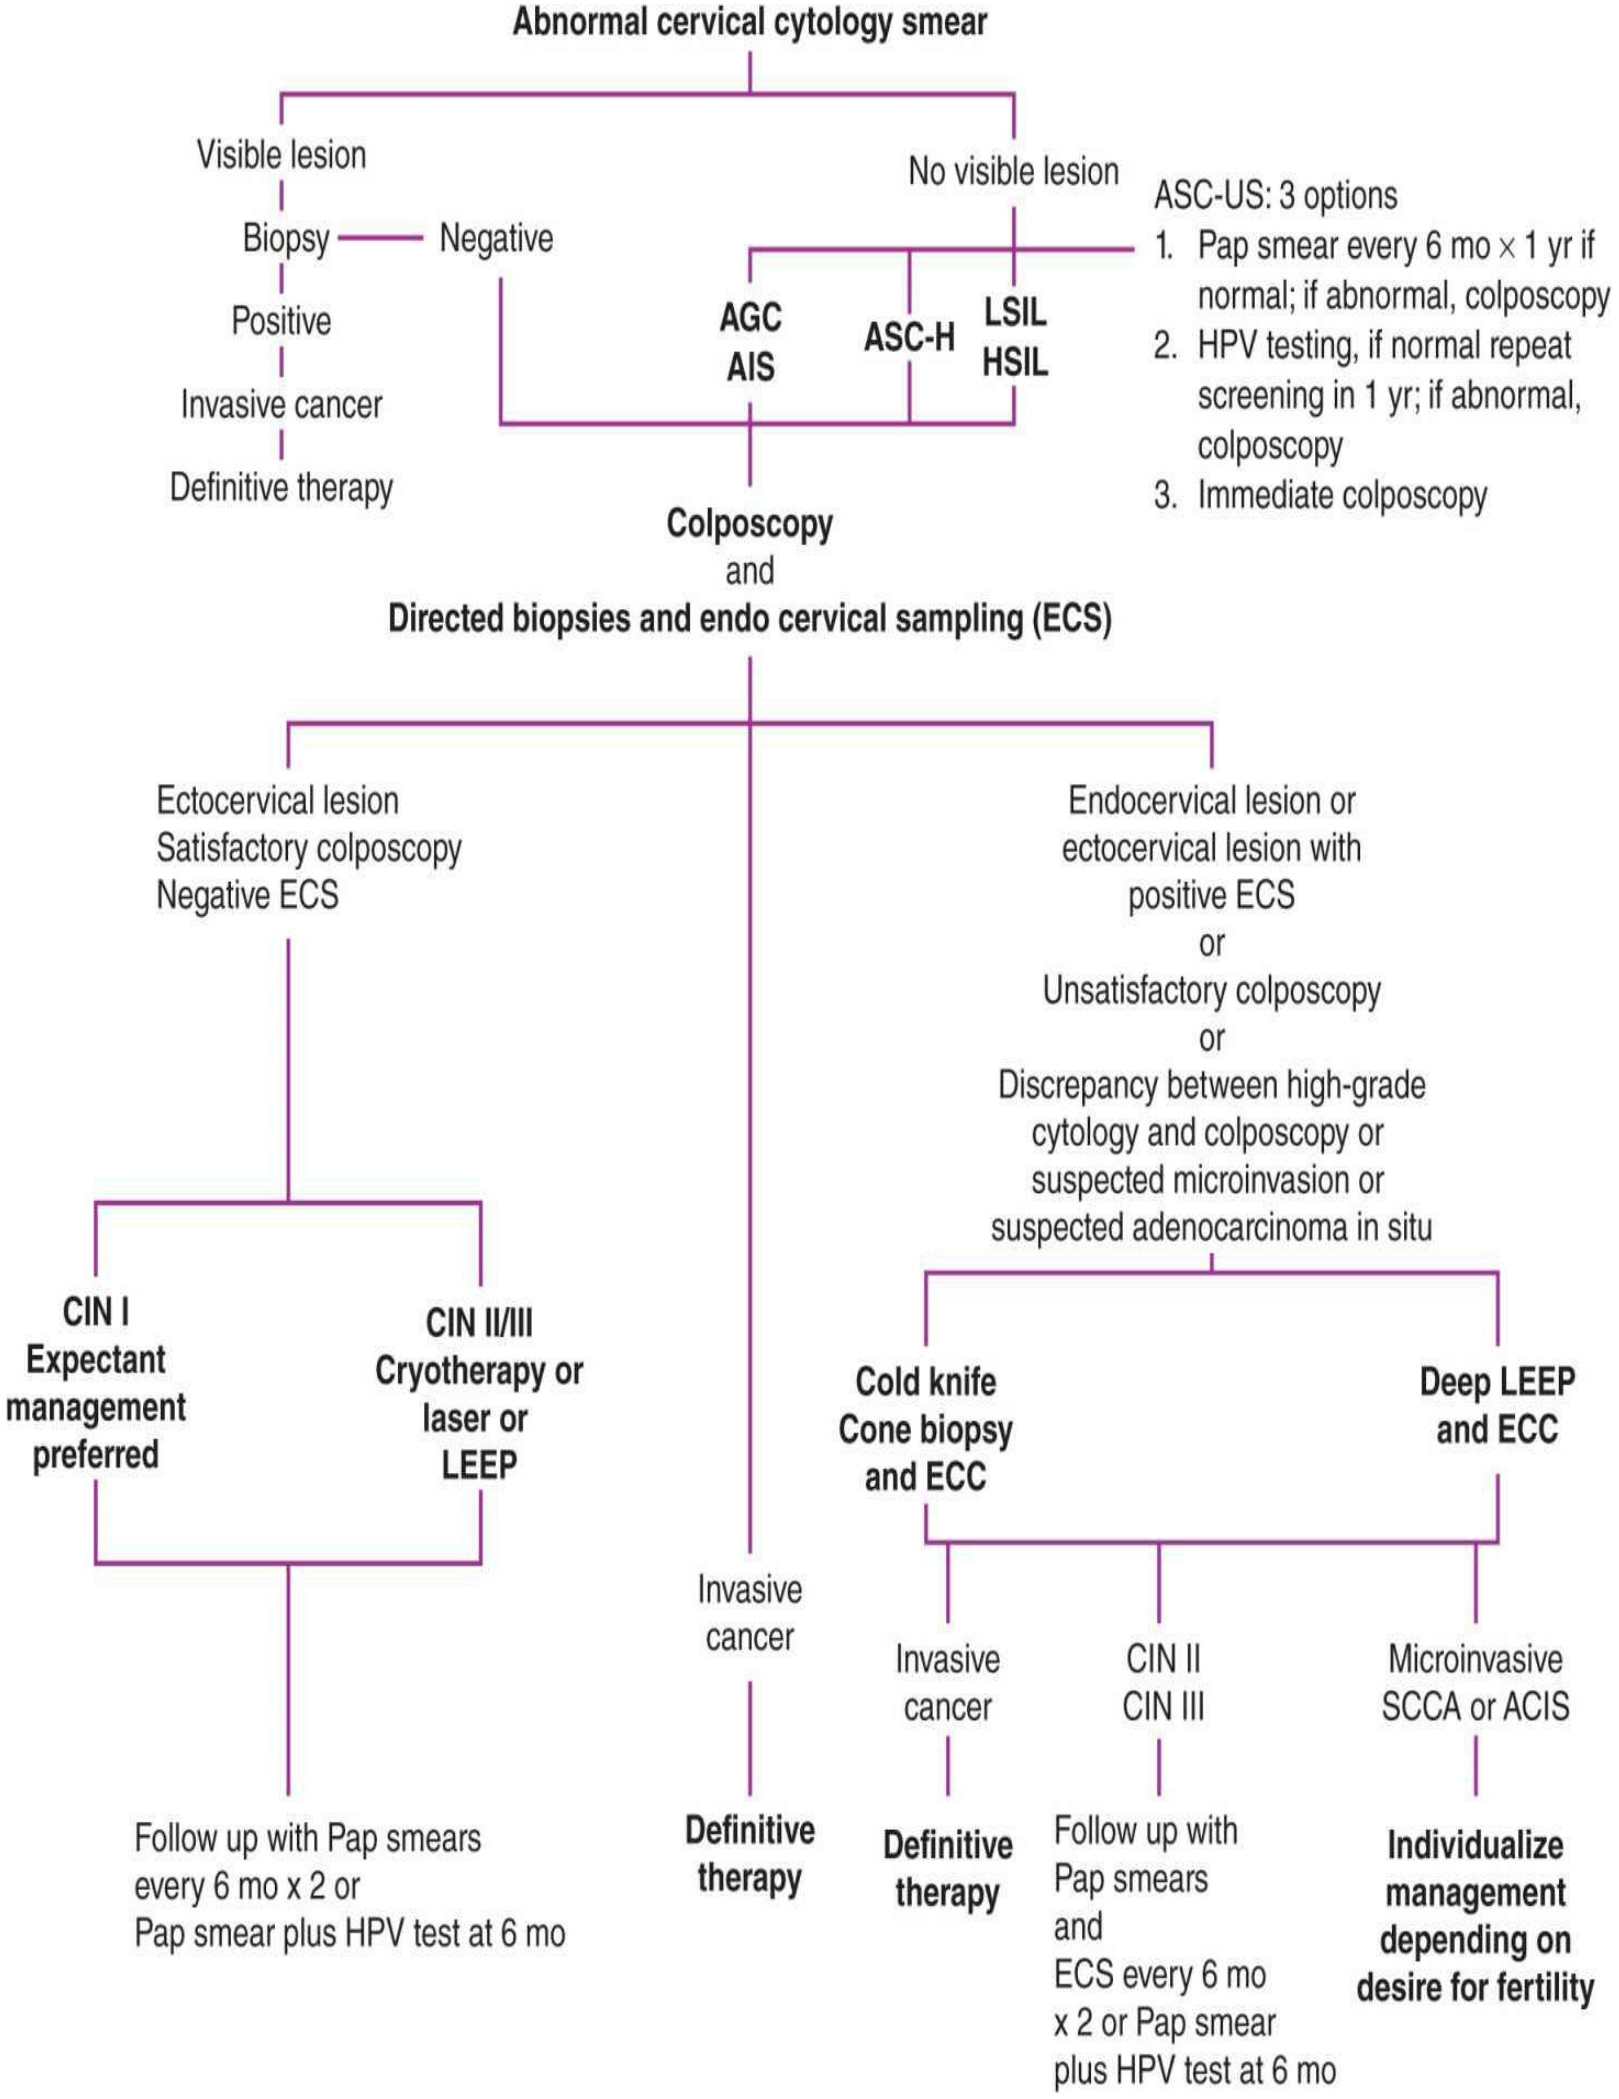
CIN, cervical intraepithelial neoplasia.

Treatment

Patient management is based on the results of the cervical cytology smear, findings at colposcopy, biopsy and endocervical sampling results, and individual patient characteristics, such as age, wishes regarding future pregnancies, HIV infection, and the likelihood of compliance with management recommendations. Consensus guidelines for the management of women with CIN have been developed and can be found online at the American Society for Colposcopy and Cervical Pathology Web site (www.asccp.org). Management options fall into 2 general categories: expectant management or treatment. Expectant management is appropriate for CIN I when preceded by a cervical cytology smear suggestive of a low-grade lesion (ASC-US, LSIL, or ASC-H). These women have a high chance of spontaneous regression. About 12–13% will be diagnosed with CIN II/III or worse in the subsequent 2 years. Thus, expectant management of these patients entails enhanced surveillance with either 2 cervical cytology specimens every 6 months or 1 HPV test at 12 months and a referral to repeat colposcopy if cytology reveals ASC or worse or the HPV test is positive. If the 2 cervical cytology specimens are normal and/or the HPV test is negative, routine screening may be resumed. Follow-up of women with CIN I beyond 24 months has shown that spontaneous regression or progression continues to occur. There are no data to suggest that it is unsafe to continue close clinical follow-up of a compliant patient with persistent CIN I.

Because we currently lack the means to identify individuals at risk for progressive disease, immediate treatment might be appropriate for high-risk patients likely to be lost to follow-up. On the other hand, CIN I preceded by HSIL or AGC–not otherwise specified has a high prevalence of underlying CIN II/III or worse and is thus managed more aggressively. Acceptable options include a diagnostic excisional procedure, review of all findings, or for patients who desire future childbearing, observation with cytology and colposcopy at 6-month intervals for 1 year. If colposcopy is unsatisfactory or endocervical sampling is positive, a diagnostic excisional procedure should be performed. In this setting, immediate excisional procedure is also the preferred approach for any patients who are beyond childbearing. CIN II and III are high-grade lesions, and prompt treatment is generally recommended except in adolescent and pregnant patients (see later Special Situations section).

Treatment options fall into 1 of 2 main categories: procedures that ablate the abnormal tissue and do not produce a tissue specimen for additional histologic evaluation and procedures that excise the area of abnormality, allowing for further histologic study. Prior to any therapeutic intervention, an assessment has to be made as to whether a patient qualifies for ablative therapy (eg, satisfactory diagnostic evaluation has excluded invasive disease) or if she requires an excisional procedure (conization) for further diagnostic workup. In most cases, conization is also the appropriate therapeutic intervention. If the intraepithelial lesion is confined to the ectocervix, treatment with cryotherapy, laser ablation, or a superficial excision by the loop electro-surgical excision procedure (LEEP) is appropriate. If the lesion extends into the endocervical canal, the endocervical curettage contains dysplastic epithelium, or the colposcopic examination is otherwise unsatisfactory, the endocervical canal must be included in the treatment by a deeper LEEP or cone biopsy (Fig. 48–5). A conization procedure is also indicated in cases of a significant discrepancy between cervical cytology and colposcopy/biopsy results, in cases of suspected microinvasive carcinoma or adenocarcinoma in situ.



Abnormal cervical cytology smear
Visible lesion
Biopsy
Negative
Positive
Invasive cancer
Definitive therapy
No visible lesion
ASC-US: 3 options
1. Pap smear every 6 mo × 1 yr if normal; if abnormal, colposcopy
2. HPV testing, if normal repeat screening in 1 yr; if abnormal, colposcopy
3. Immediate colposcopy
AGC
AIS
ASC-H
LSIL
HSIL
Colposcopy
and
Directed biopsies and endo cervical sampling (ECS)
Ectocervical lesion
Satisfactory colposcopy
Negative ECS
Endocervical lesion or ectocervical lesion with positive ECS
or
Unsatisfactory colposcopy
or
Discrepancy between high-grade cytology and colposcopy or suspected microinvasion or suspected adenocarcinoma in situ
CIN I
Expectant management preferred
CIN II/III
Cryotherapy or laser or LEEP
Cold knife
Cone biopsy and ECC
Deep LEEP and ECC
Invasive cancer
Invasive cancer
CIN II
CIN III
Microinvasive SCCA or ACIS
Follow up with Pap smears every 6 mo x 2 or Pap smear plus HPV test at 6 mo
Definitive therapy
Definitive therapy
Follow up with Pap smears and ECS every 6 mo x 2 or Pap smear plus HPV test at 6 mo
Individualize management depending on desire for fertility

Figure 48–5. Plan for management of the abnormal cytologic smear with visible or no visible cervical lesion. SCCA, squamous cell carcinoma.

The 5 most common techniques for the treatment of CIN include 2 ablative techniques—cryotherapy and laser ablation—and 3 excisional procedures—cold knife conization, laser cone excision, and LEEP. Evidence from controlled trials shows that these techniques are of equal efficacy, averaging 80–90% success rates in the treatment of CIN. Cure depends on the size of the lesion, endocervical gland involvement, margin status of any excisional specimen, and endocervical curettage results.

A. Cryotherapy

In cryotherapy, an office procedure not requiring anesthesia, nitrous oxide or carbon dioxide is used as the refrigerant for a supercooled probe. The cryoprobe is positioned on the ectocervix where it must cover the entire lesion, which at times is not easily achieved. It is then activated until blanching of the cervix extends at least 7 mm beyond the probe in all directions in order to assure that freezing extends beyond the depth of the crypts of the glands into which the dysplasia might be extending. Introduction of a 2-cycle freeze–thaw–freeze technique has improved efficacy. The advantages of cryotherapy include ease of use, low cost, widespread availability, and a low complication rate. Side effects include mild uterine cramping and a copious watery vaginal discharge for several weeks. Infection and cervical stenosis are rare. Follow-up colposcopic examinations can be unsatisfactory because of the inability to visualize the squamocolumnar junction.

B. Carbon Dioxide Laser

Carbon dioxide (CO_2) laser can be used either to ablate the transformation zone or as a tool for cone biopsies. The laser destroys tissue with a very narrow zone of injury around the treated tissue and is therefore both precise and flexible. The tissue is vaporized to a depth of at least 7 mm to assure that the bases of the deepest glands are destroyed. Posttreatment vaginal discharge may last 1–2 weeks, and bleeding that requires reexamination can occur in a small percentage of patients. The technique is expensive and requires significant training and attention to safety, as well as local or general anesthesia.

C. Loop Electrosurgical Excision Procedure

LEEP is frequently used for treating CIN II and CIN III because of its ease of use, low cost, and provision of additional tissue for histologic evaluation. LEEP uses a small, fine, wire loop attached to an electrosurgical generator to excise the tissue of interest. Various sizes of wire loop are available. Following LEEP excision of the transformation zone, frequently an additional narrow endocervical specimen (“top hat”) is removed to allow for histologic evaluation while avoiding excessive damage to the cervical stroma. Fulguration with a roller ball electrode is then used to achieve complete hemostasis in the excision bed. LEEP can be performed as an office procedure under local anesthesia. An insulated speculum to prevent conduction of electricity, a grounding pad, and a vacuum to remove the smoke are necessary. Complications are less frequent than with cold knife conization and include bleeding, infection, and cervical stenosis.

D. Cold Knife Conization

Cold knife conization of the cervix refers to the excision of a cone-shaped portion of the cervix using a scalpel. This technique can be individualized to accommodate the cervical anatomy and the size and shape of the lesion. For example, a wide, shallow cone specimen can be obtained from a young patient whose squamocolumnar junction is on the ectocervix. In an older patient, in whom the squamocolumnar junction tends to move more cephalad into the endocervical canal, a narrower, deeper cone is preferable. An endocervical sampling is performed after the conization to assess the remaining endocervical canal. Cervical cone biopsy is generally done in the operating room under local or general anesthesia. Complications include bleeding, infection, cervical stenosis, and cervical insufficiency. The need to perform the procedure in the operating room and a higher complication rate are distinct disadvantages of cold knife conization. However, it results in a specimen devoid of any thermal artifact that may complicate the histologic diagnosis and margin assessment seen with LEEP and laser conization. This becomes particularly important with suspected micro-invasive carcinoma and adenocarcinoma in situ.

Prognosis

Controlled trials show 80–90% success rates in the treatment of CIN, regardless of treatment modality used. Patients with larger lesions, endocervical gland involvement, positive margins, or positive endocervical curettage after an excisional procedure are at higher risk for persistent/recurrent disease than are women with negative margins. Most treatment failures are diagnosed within the first 1–2 years after therapy. A number of follow-up protocols have been advocated including HPV testing, serial cytology, endocervical sampling, colposcopy, or various combinations thereof. HPV testing at 6–12 months posttreatment is highly sensitive at detecting persistent/recurrent CIN and is more sensitive than cytology alone. A recent long-term multicohort study of 435 women treated for CIN II/III demonstrated the value of combined cervical cytology and high-risk HPV testing at 6 and 24 months postprocedure at a referral threshold for further evaluation and treatment if either the cytology test showed ASC or worse or the HPV test was positive: If both tests were negative at 6 months, the risk of persistent or recurrent CIN II/III was 4.6%; if both tests were negative at 6 and 24 months, the risk was 1.8%. In contrast, if either test was positive at 6 months, the risk of persistent CIN II/III or worse was 45–60%, indicating the need for immediate evaluation and treatment for these patients.

Outpatient therapy for CIN can reduce the risk of cervical cancer by 95%. However, the risk of invasive cancer among these patients remains increased for at least 20–25 years, necessitating long-term annual surveillance.

Management of recurrent dysplasia follows the same guidelines outlined in Figure 48–5. If a woman has completed childbearing, recurrent dysplasia can be treated by a simple hysterectomy after invasion has been ruled out. Women with a history of cervical dysplasia have a higher incidence of vaginal dysplasia. These women continue to need Pap tests after hysterectomy.

Impact of Treatment of CIN on Subsequent Fertility & Pregnancy

For women with CIN who desire future childbearing, management priorities are to diagnose and treat preinvasive disease and prevent cervical cancer while minimizing the impact on future fertility and pregnancy. Potential treatment-associated effects on future reproductive outcome include cervical stenosis, alteration of the cervical mucus, and removal or destruction of the collagen matrix of the cervical stroma. It appears that the cervix is better preserved following ablation compared with excision.

One of the main concerns for future pregnancy is the potential for treatment-associated preterm delivery with its associated neonatal morbidity and mortality from prematurity. These risks appear to vary by the type of treatment procedure, and many experts believe the risks are largely related to the amount and depth of tissue removed. Cold knife conization increases the risk of second-trimester pregnancy loss, preterm delivery, and perinatal mortality approximately 3-fold. The risk of preterm delivery increases further with the number of procedures performed. The data on LEEP are more conflicting. While in some studies, LEEP did not increase the risk of preterm delivery and perinatal mortality, others found that LEEP nearly doubles the risk of preterm premature rupture of membranes and preterm delivery. Cryotherapy does not appear to have such strong association with preterm delivery. Thus, strong consideration should be given to offer cryotherapy treatment to women who desire future pregnancy and are candidates for ablative therapy (as discussed earlier).

Special Situations

A. Adolescents & Young Women

Adherence to the ACOG/USPSTF/ACS/ASCCP cervical cancer screening guidelines, which recommend initiation of screening at 21 years of age, should largely obviate the need for the special management algorithms for adolescents and young women found at the American Society for Colposcopy and Cervical Pathology Web site (www.asccp.org), which rest on the guiding principle that expectant management is preferred in females age 20 years old or younger.

B. Pregnancy

Pregnant women routinely undergo cervical cytology screening at their first prenatal visit. As a result, it is not uncommon that an abnormal cervical cytology smear is first discovered during pregnancy. Colposcopy is generally performed for the same indications as in the nonpregnant patient. However, biopsies are limited unless there are colposcopic signs suggestive of high-grade dysplasia, CIS, or invasive disease. Endocervical curettage is not performed in pregnancy because of the potential risk of abortion and infection. The physiologic changes of pregnancy render the transformation zone easily accessible for satisfactory colposcopy by 20 weeks’ gestation in almost all women. Colposcopy during pregnancy can be challenging because pregnancy may produce changes in the cervical epithelium that mimic those of cervical dysplasia. Although the gravid cervix is more vascular, directed ectocervical biopsies can be performed safely with minimal increase in the risk of significant bleeding. After the diagnosis of CIN II/III has been established, the patient can be carefully followed with colposcopic examinations and cervical cytology smears each trimester. Repeat biopsies are only performed for progressive lesions. Treatment is deferred into the postpartum period. Even high-grade lesions discovered during pregnancy have a high rate of regression in the postpartum period. Conization during pregnancy is indicated only if early invasive disease is suspected and the timing and extent of the procedure during pregnancy are individualized. Complications of a cone biopsy in pregnancy include abortion, hemorrhage, infection, and incompetent cervix.

C. HIV Infection

HIV-infected women are more likely to have persistent HPV infection, and CIN is common in HIV-infected women. Based on ACOG guidelines, women who are infected with HIV should undergo cervical cytology screening twice in the first year after diagnosis of HIV infection and then annually. Women with advanced HIV appear to be more likely to have persistent HPV and CIN than those with early HIV infections. Use of highly active antiretroviral therapy (HAART) has been suggested to reduce the risk of CIN and cervical cancer. However, data are conflicting.

Cytologic abnormalities in HIV-infected women should be evaluated in the same manner as in uninfected women. Management of CIN in the HIV-infected patient presents a great challenge. Primary treatment of CIN in HIV-infected women is generally similar to the approach used in HIV-negative women. Generally, expectant management of CIN I is acceptable in HIV-infected women.

LEEP excision of the cervix appears to be most appropriate for patients with CIN II/III, and topical 5-fluorouracil cream is recommended by some experts as adjunctive therapy in this setting. Following treatment, the risk of recurrent CIN is high, especially in the immunocompromised patient with low CD4 counts and high viral loads. Recurrence rates may reach 80% within 3 years in markedly immunocompromised women. Thus, surveillance with cervical cytology and colposcopy is recommended by some experts as frequently as every 3 months.

D. Atypical Glandular Cells on Cervical Cytology Smear

Patients with AGCs on a cervical cytology smear have up to a 50% risk of having significant underlying pathology. Nine to 38% of women with AGC have significant neoplasia (CIN II/III, ACIS), and 3–17% have invasive cancer.

The 2001 Bethesda System divides glandular cell abnormalities into AGCs, AGC–favor neoplasia, endocervical ACIS, and adenocarcinoma. Given the high risk for significant pathology, any patient with glandular cell abnormalities on a cervical cytology smear requires immediate evaluation, which includes, at a minimum, colposcopy with careful endocervical sampling. Assessment of the endometrium is recommended in all patients older than age 35 years, in patients at any age with conditions associated with chronic anovulation, in those at increased risk for endometrial cancer, in any women with abnormal bleeding, in women with AGC–endometrial cells, and in women with AGC–nonspecified cell type. Diagnostic conization is indicated in all cases of AGC–favor neoplasia, ACIS, or suspected adenocarcinoma as well as persistent AGC–not otherwise specified, unless a definitive diagnosis has been made on the colposcopy-directed biopsy or endometrial sampling.

E. Adenocarcinoma In Situ

ACIS of the cervix is a precursor of adenocarcinoma of the cervix, which comprises about 25% of cervical cancers in the United States. The incidence of both in situ and invasive disease is rising, especially in young women, with up to 30% of cases occurring in women younger than 35 years of age. As with squamous intraepithelial neoplasia, HPV infection is almost universally found. ACIS has no pathognomonic clinical, cytologic, or colposcopic features. The lesion is not grossly visible on examination. Management is difficult. The lesion is usually at the transformation zone but may be located high in the endocervical canal, involve the deeper portions of the endocervical clefts, or be multifocal with skip lesions. Ten to 13% of ACIS is multifocal, defined as foci of ACIS separated by at least 2 mm of normal mucosa. Nearly half of women with ACIS have concomitant squamous CIN or cancer. Conization with negative margins is required to make the diagnosis of ACIS.

Follow-up surveillance after conization is difficult, as cervical cytology, endocervical curettage, or endocervical cyto-brush sampling each have a sensitivity of only approximately 50%. This is of particular concern because the incidence of residual ACIS or invasive adenocarcinoma following conization for ACIS is as high as 45% with positive conization margins and 27% with negative conization margins. Therefore, conservative management should be undertaken only in the young patient with a negative conization margin and negative endocervical sampling who is fully counseled and desires to maintain her fertility. After completion of childbearing, hysterectomy is generally recommended. In all other patients, hysterectomy should be performed as a definitive therapeutic intervention. Approximately 7% of patients with positive and 2% of patients with negative conization margins will have invasive disease on the hysterectomy specimen. Thus, extra-fascial hysterectomy can be recommended for those patients with negative conization margins. If conization margins are positive, prehysterectomy repeat conization is recommended or consideration can be given to the performance of a modified radical hysterectomy, especially if there is significantly altered anatomy following prior conization procedures or extensive disease and positive margins were found on the preceding conization specimen.

CANCER OF THE CERVIX

ESSENTIALS OF DIAGNOSIS

- Early disease is frequently asymptomatic, underscoring the importance of cervical cytology screening.
- Abnormal uterine bleeding and vaginal discharge are the most common symptoms.
- A cervical lesion may be visible on inspection as a tumor or ulceration; cancer within the cervical canal may be occult.

- Diagnosis must be confirmed by biopsy.

General Considerations

In the United States, an estimated 12,710 new cases of invasive cervical cancer are diagnosed annually, and there are 4290 deaths from the disease. In contrast, with more than 529,000 new cases diagnosed annually and a >50% mortality rate, cervical cancer is the second most common cause of cancer-related morbidity and mortality among women in developing countries. This dichotomy is largely the result of a 75% decrease in the incidence of cervical cancer in developed countries following the implementation of population-based screening programs and treatment of preinvasive disease. The average age at diagnosis of patients with cervical cancer is 51 years. However, the disease can occur in the second decade of life and during pregnancy, and nearly 20% of cervical cancers are diagnosed in women age 65 or older. More than 95% of patients with early cancer of the cervix can be cured.

Pathogenesis

The major epidemiologic risk factors for cervical cancer are the same as those for CIN and were discussed earlier. HPV is central to the development of cervical neoplasia. HPV DNA is found in 99.7% of all cervical carcinomas. HPV-16 is the most prevalent HPV type in squamous cell carcinoma and adenocarcinoma, followed by HPV-18 and HPV-45. Other associated risk factors are tobacco use, immunosuppression, infection with HIV or a history of other STIs, high parity, and oral contraceptive use.

HPV is epitheliotropic. Once the epithelium is acutely infected with HPV, 1 of 3 clinical scenarios ensues:

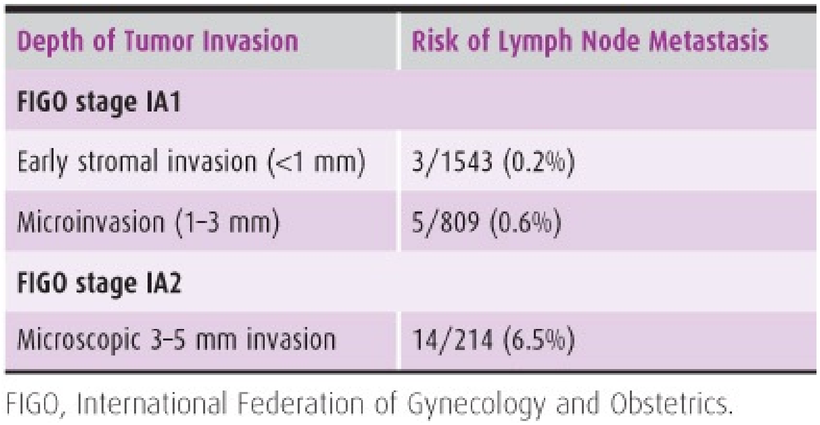
1. Asymptomatic latent infection;
2. Active infection in which HPV undergoes vegetative replication but not integration into the genome (eg, leading to condyloma or CIN I); or
3. Neoplastic transformation following integration of oncogenic HPV DNA into the human genome.

The virus infects a subset of primitive basal cells in the epithelium where it will undergo replication. The infected cell then enters the proliferating epithelial component. Active infection, in which HPV undergoes replication but remains episomal, is characterized by minimal viral oncogene expression. However, integration of HPV into the human genome is associated with cell immortalization, allowing for malignant transformation. This involves an upregulation of the viral oncogenes E6 and E7. These oncoproteins interfere with cell-cycle control in the human host cell. E6 and E7 have the ability to complex with the tumor suppressor genes p53 and Rb, respectively. The disabling of these 2 major tumor suppressor genes is thought to be central to host cell immortalization and transformation induced by HPV and the observed increased genetic instability.

Incipient cancer of the cervix is generally a slowly developing process. Most cervical cancers probably begin as a high-grade dysplastic change (see previous section) or CIS with gradual progression over a period of several years. At least 90% of carcinomas of the cervix develop from the intraepithelial layers, almost always within 1 cm of the squamocolumnar junction of the cervix either on the portio vaginalis of the cervix or slightly higher in the endocervical canal.

Early stromal invasion (stage IA1) up to a depth of 3 mm below the basement membrane is a localized process, provided there is no pathologic evidence of lymphovascular space involvement. Penetration of the stroma beyond this point carries an increased risk of lymphatic metastasis (Table 48–2). When the lymphatics are involved, tumor cells are carried to the regional pelvic lymph nodes (parametrial, hypogastric, obturator, external iliac, and sacral) (Fig. 48–6). The more pleomorphic or extensive the local disease, the greater is the likelihood of lymph node involvement. As the tumor grows, it also spreads by direct extension to the parametria.

Table 48–2. Risk of any lymph node metastasis for patients with microscopic squamous cell carcinoma of the cervix.



Depth of Tumor Invasion	Risk of Lymph Node Metastasis
FIGO stage IA1	
Early stromal invasion (<1 mm)	3/1543 (0.2%)
Microinvasion (1–3 mm)	5/809 (0.6%)
FIGO stage IA2	
Microscopic 3–5 mm invasion	14/214 (6.5%)

FIGO, International Federation of Gynecology and Obstetrics.

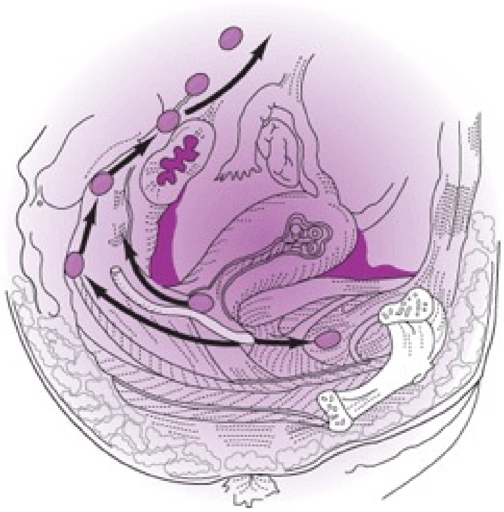


Figure 48–6. Lymphatic spread of carcinoma of the cervix.

Squamous cell carcinoma clinically confined to the cervix involves the regional pelvic lymph nodes in 15–20% of cases. When the cancer involves the parametrium (stage IIB), tumor cells can be found in the pelvic lymph nodes in 30–40% of cases and in the para-aortic nodes in approximately 15–30% of cases. The more advanced the local disease, the greater is the likelihood of distant metastases. The para-aortic nodes are involved in approximately 45% of patients with stage IVA disease.

Ovarian involvement is rare, occurring in approximately 0.5% of squamous cell carcinomas and 1.7% of adenocarcinomas. The liver and lungs are the most common sites of blood-borne metastasis, but the tumor may involve the brain, bones, bowels, adrenal glands, spleen, or pancreas.

When cancer of the cervix is untreated or fails to respond to treatment, death occurs in 95% of patients within 2 years after the onset of symptoms. Death can occur from uremia, pulmonary embolism, or hemorrhage from direct extension of tumor into blood vessels. Life-threatening sepsis from complications of pyelonephritis or vesicovaginal and rectovaginal fistulas is possible. Large bowel obstruction from direct extension of tumor into the rectosigmoid can be the terminal event. Pain from perineural extension is a significant management problem of advanced disease.

Pathology

Approximately 70–75% of cervical carcinomas are squamous cell; the remainder are composed of various types of adenocarcinomas (20–25%), adenosquamous carcinomas (3–5%), and undifferentiated carcinomas.

A. Squamous Cell Carcinomas

Cervical squamous cell carcinomas have been classified according to the predominant cell type: large cell nonkeratinizing, large cell keratinizing, and small cell carcinomas. The large cell nonkeratinizing variety accounts for the majority of tumors.

B. Verrucous Squamous Carcinoma

Verrucous squamous carcinoma, which has been associated with HPV-6, is a rare subtype of well-differentiated squamous carcinoma. It is a slow-growing, locally invasive neoplasm. Histologically, this tumor is composed of well-differentiated squamous cells with frondlike papillae and little apparent stromal invasion, but it is potentially lethal. Radical resection is the mainstay of therapy.

C. Papillary Squamous Carcinoma

Papillary squamous carcinoma of the cervix is characterized by highly dysplastic squamous cells forming papillary fronds with thin fibrovascular cores. The gross appearance of this lesion may be warty or fungating.

D. Adenocarcinoma

Adenocarcinoma of the cervix is derived from the glandular elements of the cervix. The incidence of adenocarcinomas, including the mucinous, endometrioid, clear cell, and serous types, has been rising over the last several decades, especially in women younger than 35 years of age. Part of this increase may be a result of an increasing prevalence of HPV infection, and part may be a result of improvements in screening and prevention of squamous preinvasive disease, thus leading to a histologic shift toward adenocarcinoma. When the initial growth of adenocarcinoma of the cervix is within the endocervical canal and the ectocervix appears normal, this lesion might not be diagnosed until it is advanced and ulcerative. Cervical adenocarcinoma is subdivided into endocervical type (usual type; minimal deviation adenocarcinoma [adenoma malignum] and well-differentiated villoglandular adenocarcinoma), endometrioid type, clear cell type, papillary serous type, intestinal type, mesonephric type, and mixed type. The clear cell type may be related to in utero exposure to DES. It has a prognosis comparable to that of other adenocarcinomas of the cervix.

E. Minimal Deviation Adenocarcinoma (Adenoma Malignum)

Adenoma malignum, or minimal deviation adenocarcinoma, is an extremely well-differentiated adenocarcinoma that may be difficult to recognize as a malignant process. It represents approximately 1% of adenocarcinomas of the cervix and has been associated with Peutz-Jeghers syndrome. It occurs mainly in the fifth and sixth decades of life. Diagnosis is often delayed because of frequently normal cervical cytology smears. Punch biopsies are often nondiagnostic, requiring conization for further evaluation.

F. Adenoid Cystic Carcinoma

Another uncommon variant of adenocarcinoma is adenoid cystic carcinoma. This lesion is considered more aggressive than most cervical adenocarcinomas and occurs more commonly in black women of high parity in their sixth and seventh decades of life. It should not be confused with adenoid basal carcinomas, which have an indolent growth pattern.

G. Adenosquamous Carcinoma

Adenosquamous carcinomas contain an admixture of malignant squamous and glandular cells; subtypes include the mature type, signetring type (mucoepidermoid carcinoma), and glassy cell type. Glassy cell carcinoma is a poorly differentiated form of adenosquamous carcinoma and is considered to have an extremely aggressive course. It accounts for approximately 1–2% of cervical cancers. Synchronous adenocarcinomas and squamous cell carcinomas that invade each other are called collision tumors.

H. Neuroendocrine Carcinomas

Approximately one-third of small cell carcinomas of the cervix stain positive for neuroendocrine markers (neuron-specific enolase, chromogranin, synaptophysin). These tumors need to be distinguished from small cell type of squamous tumors. They have a high frequency of lymphovascular space invasion, lymph node metastases, recurrence, and poor survival. Neuroendocrine carcinomas are not limited to the small-sized tumor cells. Poorly differentiated large cell carcinomas may express neuroendocrine differentiation by immunohistochemistry. Carcinoid tumors, arising from the argyrophil cells of the endocervical epithelium, are malignant but have rarely been associated with the carcinoid syndrome. Because of their propensity for early systemic spread, systemic chemotherapy is an integral part of the treatment of neuroendocrine tumors of the cervix.

I. Other Malignant Tumors

Direct extension of metastatic tumors to the cervix includes those originating from the endometrium, rectum, and bladder. Lymphatic or vascular metastases occur less often but are associated with endometrial, ovarian, gastric, breast, colon, kidney, and pancreas carcinomas. Sarcomas, lymphomas, choriocarcinomas, and melanomas are encountered rarely in the cervix.

Prevention

Until now, prevention of morbidity and death from cervical cancer largely involved recognition and treatment of preinvasive and early invasive disease. Over 60% of women who develop cervical cancer in developed countries either never have been screened or have not been screened in the preceding 5 years. Risk factors must be recognized, and screening, treatment intervention, and patient education must be modified.

Universal cytologic screening of all women age 21 years or older must be continued on a regular basis until better, more sensitive and specific means of screening are found and outreach into underserved areas is improved. Women with preinvasive cervical neoplasia should be treated and followed up closely (Fig. 48–5). It is important to remember that cervical cytology smears are of limited value in detecting frankly invasive disease, with some studies finding false-negative rates up to 50%. Sexual abstinence is an effective but impractical prophylactic measure. Education of young women and men about risk factors and the necessity for regular screening, as well as information about the association of HIV infection and smoking with the development of cervical cancers, is crucial.

The role of HPV vaccination has been discussed earlier.

Clinical Findings

A. Symptoms & Signs

Abnormal vaginal bleeding is the most common symptom of invasive cancer and may take the form of a blood-stained leukorrheal discharge, scant spotting, or frank bleeding. Leukorrhea, usually sanguineous or purulent, odorous, and nonpruritic, is frequently present. A history of postcoital bleeding may be elicited on specific questioning.

Pelvic pain, often unilateral and radiating to the hip or thigh, is a manifestation of advanced disease, as is the involuntary loss of urine or feces through the vagina, a sign of fistula formation. Weakness, weight loss, and anemia are characteristic of the late stages of the disease, although acute blood loss and anemia may occur in a bulky or ulcerating stage I lesion.

Physical examination findings include a grossly normal-appearing cervix with preclinical disease. As the local disease progresses, physical signs appear. Infiltrative cancer produces enlargement, irregularity, and a firm consistency of the cervix and eventually of the adjacent parametria. The growth pattern can be endophytic, leading to a barrel-shaped enlargement of the cervix, or exophytic, where the lesion generally appears as a friable, bleeding, cauliflowerlike lesion of the portio vaginalis. Ulceration may be the primary manifestation of invasive carcinoma; in the early stages, the change often is superficial, so that it may resemble an ectropion or chronic cervicitis. With further progression of the disease, the ulcer becomes deeper and necrotic, with indurated edges and a friable, bleeding surface. The adjacent vaginal fornices may become involved next. Eventually, extensive parametrial involvement by the infiltrative process may produce a nodular thickening of the uterosacral and cardinal ligaments with resultant loss of mobility and fixation of the cervix.

B. Biopsy

Because of the failure of malignant cells to desquamate and the obscuring effect of inflammatory cells, it is not uncommon for an invasive carcinoma of the cervix to exist despite a negative cytologic smear. Any suspicious lesion of the cervix should be sampled by adequate biopsy, regardless of cytologic examination result. Biopsy of any Schiller-positive areas or of any ulcerative, granular, nodular, or papillary lesion provides the diagnosis in most cases. Colposcopically directed biopsies with endocervical sampling or conization of the cervix may be required when reports of suspicious or probable exfoliated carcinoma cells are made by the pathologist and a visible or palpable lesion of the cervix is not evident. Colposcopic warning signs of early invasive cancer in a field of CIN include capillaries that are markedly irregular, appearing as commas, corkscrews, and spaghetti-shaped vessels with great variation in caliber and abrupt changes in direction, often causing acute angles. Ulcerations or a markedly irregular appearance of the cervix with a waxy, yellowish surface and numerous bizarre, atypical blood vessels are common. Bleeding may occur also after slight irritation.

C. Conization

In the setting of a biopsy revealing CIS, where invasion cannot be ruled out, or in the setting of a negative colposcopy in the face of a significantly abnormal cervical cytology smear, conization of the cervix should be performed to determine the presence or absence of invasion. If a cervical biopsy shows microinvasive cancer (<3 mm of invasion), a cone biopsy is necessary to rule out deeper invasion. The conization specimen should be properly marked for the pathologist (eg, with a pin or small suture), so that the area of involvement can be specifically localized in relation to the circumference and margins of the cervix. Conization for a lesion grossly suggestive of invasive cancer is not indicated, as it only delays the initiation of appropriate therapy and predisposes the patient to serious pelvic infections and bleeding. The diagnosis of such a lesion can almost always be confirmed by simple cervical biopsy.

D. Radiologic Findings

Chest radiographs are indicated in all patients with cervical cancer and an intravenous pyelogram (IVP) or computed tomography (CT) urogram should be performed to determine if there is any ureteral obstruction producing hydroureter and hydronephrosis. Magnetic resonance imaging (MRI), CT scan, lymphangiography, or positron emission tomography (PET) scanning may demonstrate involvement of the pelvic or periaortic lymph nodes or other sites of metastases. The sensitivities of CT, MRI, and PET for lymph node metastases in cervical cancer are approximately 45%, 60%, and 80%, respectively. Integrated PET CT appears to have a slightly higher sensitivity for detecting nodal metastases than PET alone. Although the latter imaging studies are not used to assign disease stage in the International Federation of Gynecology and Obstetrics (FIGO) classification, they may be of value for planning treatment, particularly the extent of the radiation therapy field or scope of surgery.

Clinical Staging

It is important to estimate the extent of the disease not only for prognostic purposes, but also for treatment planning. Clinical staging also affords a means of comparing methods of therapy for various stages of the disease worldwide. The classification adopted by FIGO is the most widely used staging system (Table 48–3). Cervical cancer is staged by clinical examination and evaluation of the bladder, ureters, and rectum. If the lesion is clearly confined to the cervix by office examination, only chest radiography and evaluation of the ureters by IVP or CT scan with intravenous contrast are necessary to assign the stage. If it is not possible to evaluate the extent of local disease in the office, examination under anesthesia with cystoscopy and proctoscopy may be necessary. Although CT scan, MRI, lymphangiography, and PET scan may offer information helpful for treatment planning, these findings do not change the FIGO stage of disease. The FIGO stage of disease is also not changed by surgicopathologic findings of metastatic disease at the time of radical hysterectomy or lymphadenectomy.

Table 48–3. 2009 International Federation of Gynecology and Obstetrics (FIGO) staging of cervical cancer.

FIGO Stage	Definition
Stage 0	Carcinoma in situ
Stage I	Cervical carcinoma confined to the cervix (extension to the corpus should be disregarded)
Stage IA[1]	Invasive cervical cancer diagnosed by microscopy only
Stage IA1	Stromal invasion no deeper than 3 mm, no wider than 7 mm in horizontal spread
Stage IA2	Stromal invasion >3, but no more than 5 mm and no wider than 7 mm in horizontal spread
Stage IB	Clinically visible lesion confined to the cervix or microscopic disease greater than stage IA
Stage IB1	Clinically visible lesion not >4 cm
Stage IB2	Clinically visible lesion >4 cm
Stage II	Tumor extends beyond uterus but not to pelvic sidewall or lower third of vagina
Stage IIA	Vaginal involvement without parametrial involvement
Stage IIA1	Clinically visible lesion not >4 cm
Stage IIA2	Clinically visible lesion >4 cm
Stage IIB	Parametrial involvement
Stage III	Tumor extends to pelvic sidewall and/or causes hydronephrosis and/or extends to lower third of vagina
Stage IIIA	Involvement of lower third of vagina with no extension to sidewall
Stage IIIB	Extension to pelvic sidewall and/or hydronephrosis
Stage IV	Extension beyond the true pelvis or into mucosa of rectum or bladder
Stage IVA[2]	Extension into adjacent organs
Stage IVB	Distant metastases

[1] The depth of invasion should be no more than 5 mm from the epithelial basement membrane of the adjacent most superficial epithelial papilla to the deepest point of invasion where the cancer originates. Vascular space invasion, venous or lymphatic, does not affect staging, but should be noted because it may affect future therapy. All macroscopically visible lesions (even with superficial invasion only) are allotted to stage IB.

[2] The presence of bullous edema is not sufficient to classify a tumor as stage IVA. The finding of malignant cells in cytologic bladder washings requires further histologic confirmation in order to be considered stage IVA.

Reproduced, with permission, from Sergio Pecorelli, Lucia Zigliani, Franco Odicino. Revised FIGO staging for carcinoma of the cervix. *Int J Gynecol Obste*. 2009;105:107-108.

Differential Diagnosis

A variety of lesions of the cervix can be confused with cancer. Entities that must sometimes be ruled out include cervical ectropion, acute or chronic cervicitis, condyloma acuminata, cervical tuberculosis, ulceration secondary to STD (syphilis, granuloma inguinale, lymphogranuloma venereum, chancroid), abortion of a cervical pregnancy, metastatic choriocarcinoma or other cancers, and rare lesions such as those of actinomycosis or schistosomiasis. Histopathologic examination is usually definitive.

Complications

The complications of cervical cancer, for the most part, are those related to tumor size or invasion, necrosis of the tumor, infection, and metastatic disease. The natural history of the disease was outlined earlier. There are also problems pertaining to treatment of the disease (eg, radical surgery or radiation therapy; see next section, Treatment).

Treatment

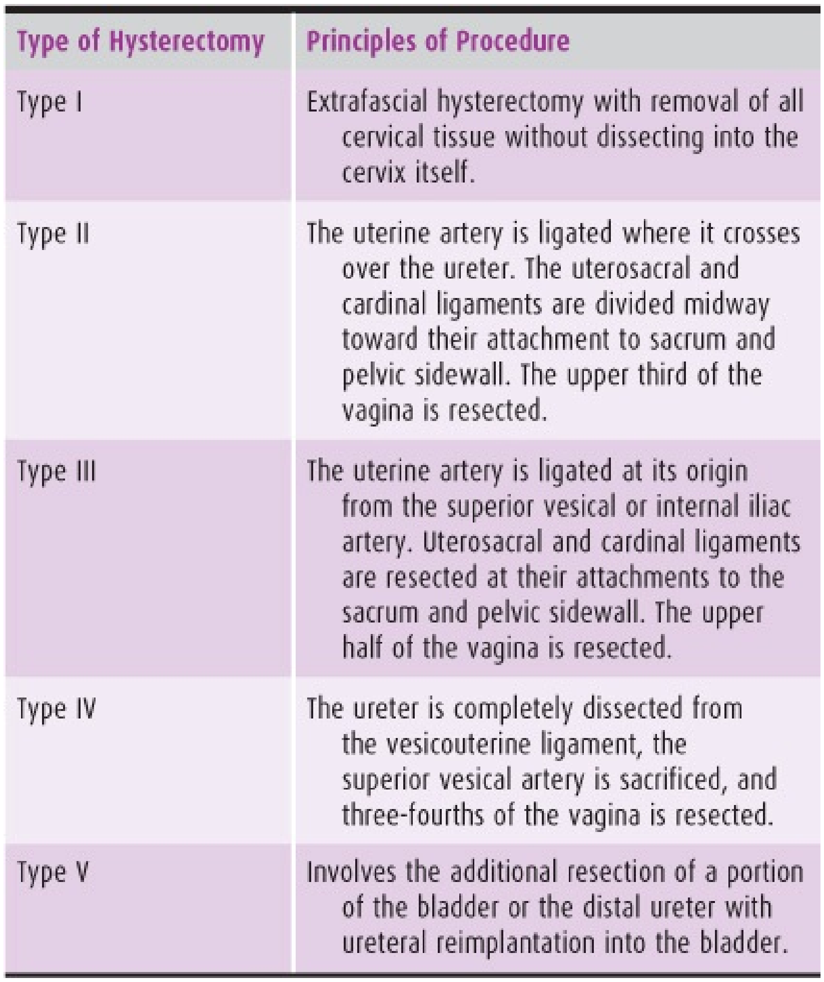
Invasive carcinoma of the cervix spreads primarily by direct extension and lymphatic dissemination. The therapy of patients with cervical cancer needs to address not only the primary tumor site, but also the adjacent tissues and lymph nodes. This is generally accomplished by either radical hysterectomy and pelvic lymphadenectomy, radiation with concomitant chemotherapy, or a combination thereof.

A. Treatment of Early-Stage Disease (Stage IA2 to IIA2)

Patients with early-stage cervical cancer may be treated either with radical hysterectomy and pelvic lymphadenectomy or with primary radiation with concomitant chemotherapy. The overall 5-year cure rates for surgery and for radiation therapy in operable patients are approximately equal. The advantages of surgery are that the ovaries may be left intact and be transposed out of the radiation field if adjuvant postoperative therapy appears necessary, that the extent of disease can be determined surgicopathologically, and that grossly metastatic lymph nodes can be resected. Furthermore, surgery may be more appropriate in sexually active women with early-stage disease as radiation causes vaginal stenosis and atrophy. Adjuvant radiation with or without concomitant chemotherapy is administered to selected patients at increased risk for recurrence following radical hysterectomy.

1. Radical hysterectomy & therapeutic lymphadenectomy—Radical hysterectomy (techniques initially described by Wertheim, Meigs, and Okabayashi) with pelvic lymphadenectomy is the surgical procedure for invasive cancer limited to the cervix and upper vagina (stages I and II). The operation is technically difficult and should be performed only by those experienced in radical pelvic surgery. Surgery involves dissection of the ureters from the paracervical structures so that the ligaments supporting the uterus and upper vagina can be removed. When the operation is done vaginally, a deep Schuchardt (paravaginal) incision is required for exposure. Five different types of hysterectomy have been described based on the extent of parametrial dissection and vaginal tissue removed (Table 48–4). Typically, a type I hysterectomy is indicated for patients with stage IA1 disease. An alternative treatment is cervical conization in the young patient wishing to preserve fertility. Stage IA2 to IIA2 can be treated with a type II (modified radical) or type III (radical) hysterectomy. It is rarely necessary to remove as much vaginal tissue as was initially recommended. As long as complete tumor clearance can be provided, a modified radical hysterectomy appears to provide therapeutic outcomes comparable to a radical hysterectomy for stage IB and IIA disease, but with shorter operating time and lower urologic morbidity. Full pelvic lymphadenectomy is indicated at the time of radical hysterectomy, followed by para-aortic lymphadenectomy for tumors larger than 2 cm or those with suspicious pelvic lymph nodes. Resection of all grossly involved lymph nodes provides a distinct survival advantage. Microscopic evaluation of the lymph nodes allows for tailoring of the postoperative radiation field, if indicated.

Table 48–4. Types of hysterectomy based on radicality.



Type of Hysterectomy	Principles of Procedure
Type I	Extrafascial hysterectomy with removal of all cervical tissue without dissecting into the cervix itself.
Type II	The uterine artery is ligated where it crosses over the ureter. The uterosacral and cardinal ligaments are divided midway toward their attachment to sacrum and pelvic sidewall. The upper third of the vagina is resected.
Type III	The uterine artery is ligated at its origin from the superior vesical or internal iliac artery. Uterosacral and cardinal ligaments are resected at their attachments to the sacrum and pelvic sidewall. The upper half of the vagina is resected.
Type IV	The ureter is completely dissected from the vesicouterine ligament, the superior vesical artery is sacrificed, and three-fourths of the vagina is resected.
Type V	Involves the additional resection of a portion of the bladder or the distal ureter with ureteral reimplantation into the bladder.

2. Adjuvant postoperative radiation with or without concomitant chemotherapy—Postoperative adjuvant radiation therapy with concomitant chemotherapy is indicated in women with localized cervical cancer at high risk for recurrent disease, such as positive lymph nodes, positive or close resection margins, or microscopic parametrial involvement. In this setting, adjuvant radiation with platinum-based chemotherapy is superior to adjuvant radiation alone, with an improvement in the 4-year progression-free interval from 63% to 80%. Women with intermediate-risk factors for recurrent disease, such as large tumor size, deep cervical stromal invasion, and lymphovascular space invasion, also benefit from postoperative adjuvant radiation. These patients have an improved 2-year recurrence-free survival of 88% with adjuvant radiation versus 79% without adjuvant therapy. Whether the addition of chemotherapy to the adjuvant radiation further improves outcomes for women with intermediate-risk factors is currently under investigation.

3. Primary radiation with concomitant chemotherapy—For the treatment of early cervical cancer (stages IA to IIA), primary therapy with definitive radiation or radical surgery followed by tailored radiation if indicated by the surgical findings produces comparable outcomes. The choice of treatment depends on the tumor size, the general condition of the patient, and patient preferences. Surgery is often preferred for young patients in the hope of preserving ovarian function. If it is likely that the patient will need postoperative radiation therapy, transposition of the ovaries to a location outside the radiation field can be performed. The main argument for primary chemoradiation exists in patients with larger tumors, due to the added morbidity of triple-modality therapy (see later section Special Situations; bulky stage IB2 and IIA2 cervical cancer). For primary radiation of cervical cancer, external-beam radiation is used in combination with intracavitary irradiation (see Chapter 52). At least 5 controlled trials have demonstrated the superiority of radiation with concomitant platinum-based chemotherapy over radiation alone. This has led to the adoption of radiation plus concomitant chemotherapy as the standard of care whenever radiation therapy is given for the treatment of cervical cancer over a broad spectrum of disease stages.

B. Treatment of Locally Advanced Disease (Stage IIB to IVA)

Patients with locally advanced cervical cancer are best treated with primary radiation (external beam plus brachy-therapy; see Chapter 52) with concomitant chemotherapy. Extended-field radiation should be considered in the presence of para-aortic lymph node metastases documented at surgical staging or by imaging, especially when biopsy confirmed and in the absence of other systemic metastases. The benefit of cisplatin-based combined-modality therapy over radiation alone for advanced disease has been demonstrated in at least 3 randomized controlled trials, which found a 30–50% reduction in the risk of death from cervical cancer for patients treated with chemoradiation compared to those treated with radiation alone. This difference is most significant for patients with stage II disease (and bulky IB disease) in whom, in 1 study, chemoradiation, compared to radiation alone, improved 5-year survival rates from 58% to 77%. For patients with more advanced disease, there is still significant benefit, but it appears to be less pronounced. The optimal drug regimen is not known. Many experts recommend weekly cisplatin concomitantly with radiation. A recent study suggested the superiority of weekly combination cisplatin/gemcitabine during chemoradiation. However, the experimental group also received 2 additional cycles of adjuvant cisplatin/gemcitabine after brachytherapy and toxicity was significant. It is unclear what proportion of the improvement in outcome can be attributed to the multiagent chemoradiotherapy versus the adjuvant chemotherapy. This question is currently being investigated by the Gynecologic Cancer Intergroup.

C. Treatment of Disseminated Primary (Stage IVB) & Persistent or Recurrent Disease

The use of chemotherapeutic agents in the treatment of cervical carcinoma has been discouraging. This is partly because most patients who may be candidates for this type of treatment either present with disseminated disease or have cancer that has already failed to respond to radical surgery or radiation therapy. In this setting, chemotherapy is generally palliative and not curative. Modest activity in recurrent or disseminated cervical cancer has been observed with single-agent cisplatin, ifosfamide, paclitaxel, and vinorelbine. If the patient can tolerate it, multiagent chemotherapy is preferred as it is associated with significantly higher response rates and longer progression-free survival. There is also a small overall survival advantage to multiagent chemotherapy with cisplatin and topotecan. Combination therapy using paclitaxel and platinum offers very similar outcomes, with response rate and median survival time of 36% and 9.7 months, compared to 27% and 9.6 months, respectively, for cisplatin and topotecan. Other acceptable combination regimens include cisplatin/vinorelbine and cisplatin/gemcitabine. Surgical resection of lung metastases is an alternative to palliative chemotherapy for highly selected patients with isolated, potentially resectable pulmonary metastases. Palliative radiation therapy may be indicated, especially for the control of symptoms, such as pain or hemorrhage. If a patient develops a palpable mass in the left supraclavicular region, it can be palliated with radiation therapy with concomitant chemotherapy, with or without resection.

D. Total Pelvic Exenteration for Isolated Central Pelvic Recurrence of Disease

Patients who develop a central recurrence of cervical cancer after primary therapy with radiation or after surgery followed by radiation may be candidates for this extensive, potentially curative surgical procedure if a complete evaluation fails to reveal evidence of metastatic disease. In a small proportion of patients with cancer of the cervix treated initially with radiation, a small recurrence of the cancer may be noted centrally within the cervix. A radical hysterectomy may be an alternative to total pelvic exenteration in this selected subgroup of patients. Surgery is the only potentially curative method of treating cancers that persist or recur centrally following adequate radiation therapy. In such instances, pelvic exenteration is often necessary to make certain that all of the cancer has been removed.

Pelvic exenteration is one of the most formidable of all gynecologic operations and requires removal of the bladder, rectum, and vagina, along with the uterus if hysterectomy has not yet been performed. This is followed by the reconstructive phase of the procedure. Urinary diversion needs to be provided, necessitating the creation of either a continent ileocolonic pouch or a noncontinent ileal conduit. In either case, a stoma is created in the anterior abdominal wall. If extensive rectal resection was required, a sigmoid colostomy serves for the passage of feces. If a low rectal anastomosis could be accomplished, a temporary diverting colostomy is recommended for all patients who have received prior radiation. The vagina can be reconstructed using various myocutaneous flaps, such as vertical rectus abdominis or gracilis myocutaneous flaps. Depending on the location of the lesion, an anterior (preservation of the rectosigmoid) or posterior (preservation of the bladder) exenteration is at times an alternative.

Because of the high surgical morbidity and mortality rates, stringent criteria are necessary to justify these procedures. Pelvic exenteration should be reserved primarily for problems that cannot be effectively managed in any other manner. In essence, this means (1) a biopsy-proven persistence or recurrence of cervical cancer following an adequate course of radiation therapy or radical surgery in which the recurrent or persistent tumor occupies the central portion of the pelvis (without metastases) and is completely removable; and (2) a patient who is able to cope with the urinary and fecal stomas in the abdomen created by the operation. Both psychological and physical preparation of the patient for this operation and its aftermath are of vital importance. Because of the extreme difficulties encountered in making an accurate assessment preoperatively, only about half of the patients explored for a total pelvic exenteration will intraoperatively be confirmed to have resectable, nonmetastatic disease. Favorable prognostic factors in addition to an isolated central pelvic recurrence with no side wall fixation are a long disease-free interval and size of the recurrence < 3 cm in diameter. The 5-year survival rate following pelvic exenteration for recurrent cervical cancer averages 30–40%.

E. Palliative Care

Comprehensive care of a patient with cancer involves, in addition to antitumor therapy, good symptom relief and personal and family support. The palliative care for patients with progressive cervical cancer poses many challenges. The emphasis should be to facilitate comfort, dignity, autonomy, and personal rehabilitation and development, especially in the face of an incurable disease.

Most patients with progressive cervical cancer eventually develop symptoms related principally to the site and extent of the malignant disease. Ulceration of the cervix and adjacent vagina produces a foul-smelling discharge. Tissue necrosis and slough may initiate life-threatening hemorrhage. If the bladder or rectum is involved in the tissue breakdown, fistulas result in incontinence of urine and feces. Pain caused by involvement of the lumbosacral plexus, soft tissues of the pelvis, or bone is frequently encountered in advanced disease. Ureteral compression leading to hydronephrosis and, if bilateral, to renal failure and uremia is a common terminal event. The comfort and well-being of the patient can be considerably enhanced even though cure cannot be effected. A foul, purulent discharge may be ameliorated by astringent douches and antimicrobial vaginal creams or suppositories. Hemorrhage from the vagina often can be controlled by packing the area with gauze impregnated with a hemostatic agent; occasionally, emergent radiation or hypogastric artery embolization is indicated.

Current management of severe pain combines the use of a long-acting narcotic such as morphine or a transdermal fentanyl patch with short-acting narcotics for breakthrough pain and nonsteroidal anti-inflammatory agents. Anxiolytics and antidepressants may be of considerable value. For patients with significant pain who are no longer responding to oral medications, a subcutaneous or intravenous morphine drip can be started. In patients with lower back or extremity pain, a peridural catheter can be placed and connected to a subcutaneous pump with a reservoir for continuous morphine instillation. This method gives pain relief without the sedating effects of oral and parenteral narcotics.

Radiation therapy may be very helpful in the relief of pain caused by bony metastases and in the treatment of lesions that recur following primary surgical treatment of cervical cancer. In general, if initial therapy was accomplished by adequate radiation therapy, retreatment is contraindicated because it does little good and carries the potential of massive radiation necrosis.

Special Situations

A. Stage IA1 Disease

The definitive diagnosis of microinvasive carcinoma of the cervix can only be made by conization. These patients may be treated by simple abdominal or vaginal hysterectomy. For a young woman desiring to maintain fertility, conization only is an acceptable treatment modality for microinvasive carcinoma with a depth of invasion of 3 mm or less, if the conization margins are negative, and if there is no evidence of lymphovascular space invasion. If conization margin and endocervical sampling are positive, the risk of residual disease is as high as 33%. In this case, repeat conization should be performed if uterine preservation is the goal. FIGO staging is not influenced by the presence of lymphovascular space invasion, which occurs in close to 10% of patients with stage IA1 disease. These patients have a small but significant risk for lymph node metastases to parametrial and pelvic lymph nodes. This subgroup of patients should therefore be treated like patients with stage IA2 disease.

B. Radical Trachelectomy

Over the past 2 decades, radical trachelectomy has evolved as an alternative to radical hysterectomy in carefully selected young women with early-stage (IA2 or small IB1) cervical cancer and no evidence of lymph node metastases who wish to preserve fertility. A preoperative MRI is critical for treatment planning as it allows for measurement of the distance between the upper margin of the lesion and the isthmus. The radical trachelectomy can be performed transvaginally or abdominally via open or robotic approach; ideally the cervix is amputated 1 cm above the tumor to optimize oncologic outcome and 1 cm below the isthmus to maintain some cervical function for future pregnancies. An open or minimally invasive therapeutic lymphadenectomy is performed, and following radical resection of the cervix, a cerclage is placed. Experience with this technique is growing, and the oncologic outcome, with recurrence rates <5% and mortality rates of 2–3%, is comparable in carefully selected patients to radical hysterectomy. A review of pregnancy outcomes in women who underwent radical trachelectomy revealed that 40% of women conceived following radical trachelectomy. Of those women who do conceive, 16–20% have a first-trimester abortion, close to 10% have a second-trimester pregnancy loss, 25% have a preterm delivery, and 42% deliver a live born infant at term.

The majority of successful pregnancy outcomes have occurred with a cerclage in place.

C. Bulky Cervical Cancer

The management of patients with stage IB2 and bulky IIA2 disease is a matter of considerable debate. Proposed management strategies include the following.

1. Primary radiation therapy with concomitant chemotherapy & the option of a subsequent adjuvant extrafascial hysterectomy—Radiation therapy is usually recommended for patients with bulky cervical cancers with the addition of concomitant chemotherapy. Many of these tumors, however, contain hypoxic central areas that do not respond well to radiation, as is reflected in a 15–35% pelvic failure rate. This provides the rationale for the performance of an adjuvant hysterectomy following radiation, which is associated with a significant reduction in pelvic recurrences to 2–5%. However, the impact of adjuvant hysterectomy on extrapelvic recurrences and survival is less well established.

2. Primary radical hysterectomy & therapeutic lymphadenectomy, followed by tailored radiation with concomitant chemotherapy when indicated by pathologic findings—The potential benefits of this approach include the removal of the large primary tumor, complete surgical staging with the opportunity to resect any grossly involved lymph nodes, and the preservation of ovarian function as ovarian transposition can be performed if adjuvant radiation therapy is likely. If postoperative radiation becomes necessary, the radiation field can be tailored to the surgicopathologic findings. The resection of macroscopically involved lymph nodes has a therapeutic benefit because it improves survival to that of patients with microscopic lymph node metastases only. A primary surgical approach should be taken in patients with acute or chronic pelvic inflammatory disease, an undiagnosed coexistent adnexal mass, or anatomic alterations that make radiation therapy difficult.

3. Neoadjuvant chemotherapy followed by radical hysterectomy and lymphadenectomy & subsequent chemoradiation when indicated by pathologic findings—Neoadjuvant chemotherapy, frequently 3 cycles of platinum-based combination therapy followed by radical hysterectomy and lymphadenectomy, has been proposed as a treatment strategy for these patients. Neoadjuvant chemotherapy is reported to improve the resectability of bulky lesions, pelvic disease control, and possibly long-term survival. Although this is a provocative treatment strategy, in most studies, patients ultimately received multimodality treatment with chemotherapy, radical surgery, and radiation, and it remains unclear whether the use of neoadjuvant chemotherapy followed by surgery gives superior long-term results in the era of modern chemoradiotherapy. This question is currently being studied in phase III trials by the European Organization for the Research and Treatment of Cancer.

D. Carcinoma of the Cervix during Pregnancy

Invasive carcinoma of the cervix in pregnancy is found more frequently in areas where routine prenatal cytologic examination is done. Abnormal cervical cytology in pregnancy calls for immediate colposcopic evaluation and any other diagnostic modalities necessary to exclude invasive cancer (see section on preinvasive disease).

Invasive cervical cancer complicates approximately 0.05% of pregnancies. As is the case with nonpregnant patients, the principal symptom is bleeding, but the diagnosis is frequently missed because the bleeding is assumed to be related to the pregnancy rather than to cancer. The possibility of cancer must be kept in mind. The diagnosis and management of invasive cervical cancer during pregnancy present the patient and the physician with many challenges. Pregnancy does not appear to affect the prognosis for women with cervical cancer, and the fetus is not affected by the maternal disease, but may suffer morbidity from its treatment (eg, preterm delivery).

If the pregnancy is early and the disease is stage I to IIA, radical hysterectomy and therapeutic lymphadenectomy can be performed with the fetus left in situ, unless the patient is unwilling to terminate the pregnancy. Women at a gestational age closer to fetal viability or who are unwilling to lose the baby may decide to continue the pregnancy after careful discussion regarding the maternal risks. With early-stage disease (≤stage IB1/IIA1), the literature supports expectant management with careful serial examinations to exclude disease progression as a reasonable choice. With more advanced disease (≥ stage IB2/IIA2), neoadjuvant chemotherapy may offer an opportunity to delay definitive therapy until fetal maturity while reducing maternal risks potentially associated with treatment delay. Delivery in patients with cervical dysplasia and CIS may be via the vaginal route. Patients with invasive cervical cancer should be delivered by caesarean section to avoid potential cervical hemorrhage and dissemination of tumor cells during vaginal delivery. A caesarean radical hysterectomy with therapeutic lymphadenectomy is the procedure of choice for patients with stages IA2–IIA disease as soon as fetal maturity is established.

As in the nonpregnant patient, radiation with concomitant chemotherapy is used for the treatment of more advanced disease. Irradiation may be carried out with the expectation of spontaneous abortion. In selected cases with locally advanced disease in which the patient declines pregnancy termination, consideration may be given to neoadjuvant chemotherapy in an effort to prevent disease progression during the time needed to achieve fetal maturity. Delivery should be by caesarean section. A lymphadenectomy can be performed at the same time. Postpartum the patient should receive chemoradiation following guidelines established for the nonpregnant patient.

E. Carcinoma of the Cervical Stump

About 2% of all cervical cancers occur in the cervical stump. Early-stage cervical cancer noted on a cervical stump (left in situ following supracervical hysterectomy for an unrelated indication) should be treated with radical trachelectomy and therapeutic lymphadenectomy in the medically fit patient. Surgery is preferred over chemoradiation in this setting as the delivery of an adequate radiation dose may be difficult in a patient with a short cervical stump. However, radiation with concomitant chemotherapy is the preferred treatment modality for patients with more advanced disease.

F. Cervical Cancer Incidentally Diagnosed after Simple Hysterectomy

Women who are found to have microinvasive disease after a simple hysterectomy do not require any additional therapy. Patients with invasive disease who do not have gross parametrial disease are candidates for a radical parametrectomy, upper vaginectomy, and lymphadenectomy. This approach may be particularly desirable for young women in whom ovarian function can be preserved or for any surgically fit women with enlarged lymph nodes that should be resected prior to chemoradiation. Indications for chemoradiation follow the same guidelines as outlined earlier. Chemoradiation may be associated with less morbidity and comparable onco-logic outcomes.

Complications of Therapy

A. Radical Surgery

The operative mortality rate in radical hysterectomy with lymphadenectomy has been reduced to <1%. The most common complication is prolonged bladder dysfunction. Approximately 75% of patients have adequate recovery of bladder function within 1–2 weeks after radical hysterectomy, and most patients will have satisfactory voiding function by 3 weeks. Serious complications include fistula formation; ureterovaginal fistula is the most common type (1–2%), followed by vesicovaginal and rectovaginal fistulas. Modified radical hysterectomy, as compared to radical hysterectomy, is associated with a shorter operating time, a more rapid return of bladder function, and fewer fistulas. Other complications are urinary tract infections, lympho-cysts and lymphedema, wound sepsis, dehiscence, thromboembolic disease, ileus, postoperative hemorrhage, and intestinal obstruction.

The surgical mortality rate from pelvic exenteration has been reduced from approximately 25% to <5%, but as many as 50% of patients experience major morbidity. Complications include intraoperative and postoperative hemorrhage, infectious morbidity, urinary fistulas or obstruction, urinary pouch dysfunction, pyelonephritis, bowel obstruction or intestinal leaks and fistulas, stomal retraction, electrolyte disturbances, and other less common occurrences.

B. Radiation Therapy with Concomitant Chemotherapy

See Chapter 52.

Posttreatment Follow-Up

Approximately 35% of patients with invasive cervical cancer will have recurrent or persistent disease following therapy. Approximately 50% of deaths from cervical cancer occur in the first year after treatment, another 25% in the second year, and 15% in the third year. This explains the generally accepted schedule of posttreatment surveillance in asymptomatic patients with more frequent visits initially. Symptomatic patients should be evaluated with appropriate examinations immediately when symptoms occur. The most common signs and symptoms of recurrent malignant disease are a palpable tumor in the pelvis or abdomen, ulceration of the cervix or vagina, pain in the pelvis, back, groin, and lower extremity, unilateral lower extremity edema, vaginal bleeding or discharge, supraclavicular lymphadenopathy, ascites, unexplained weight loss, progressive ureteral obstruction, and cough (especially with hemoptysis or chest pain).

The Society of Gynecologic Oncologists has recently developed risk-stratified recommendations for the posttreatment follow-up of patients with cervical cancer. These are summarized in Table 48–5.

Table 48–5. Cervical cancer surveillance recommendations.

	0–12 Months	12–24 Months	24–36 Months	3–5 Years	>5 Years
Review of symptoms and physical exam					
Low risk (early stage, treated with surgery alone, no adjuvant therapy)	Every 6 mo	Every 6 mo	Every 6 mo*	Every 6 mo*	Every 6 mo*
High risk (advanced stage, treated with primary chemo/RT or surgery plus adjuvant therapy)	Every 3 mo	Every 3 mo	Every 3 mo	Every 3 mo	Every 3 mo*
Pap test/cytology	Yearly†	Yearly†	Yearly†	Yearly†	Yearly†
Routine radiographic imaging (CXR, PET/CT, MRI)	Insufficient data to support routine use	Insufficient data to support routine use	Insufficient data to support routine use	Insufficient data to support routine use	Insufficient data to support routine use
Recurrence suspected	CT and/or PET scan	CT and/or PET scan	CT and/or PET scan	CT and/or PET scan	CT and/or PET scan

chemo, chemotherapy; CT, computed tomography; CXR, chest x-ray; MRI, magnetic resonance imaging; PET, positron emission tomography; RT, radiotherapy.

*May be followed by generalist or gynecologic oncologist.

†Insufficient evidence for cancer recurrence but may have value in detection of other lower genital tract neoplasia.

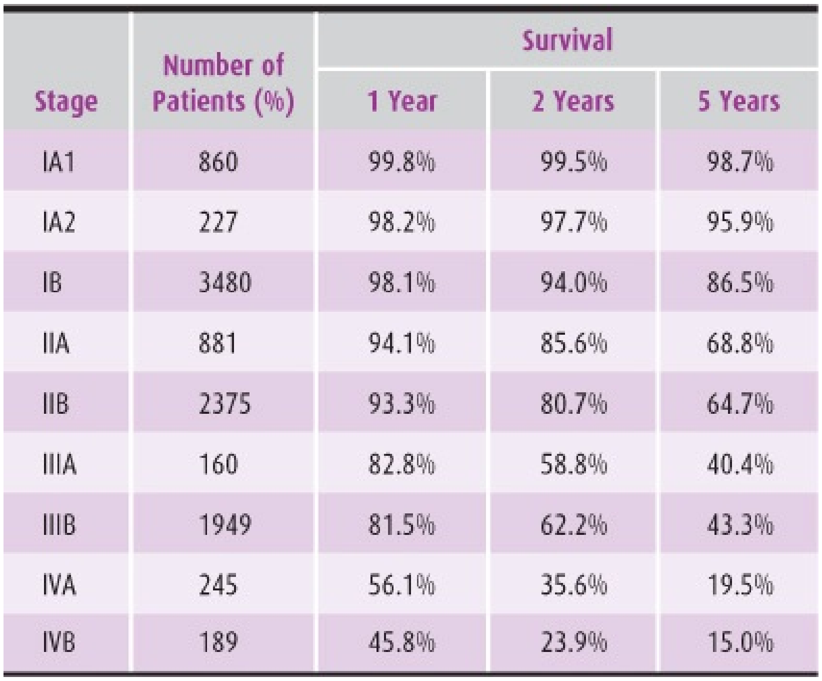
Reproduced, with permission, from Salani R, Backes FJ, Fung MF, et al. Posttreatment surveillance and diagnosis of recurrence in women with gynecologic malignancies: Society of Gynecologic Oncologists recommendations. *Am J Obstet Gynecol* 2011;204:466–478.

Prognosis

The major prognostic factors affecting survival are stage, lymph node status, tumor volume, depth of cervical stromal invasion, lymphovascular space invasion, and to a lesser extent, histologic type and grade. After stage of disease, lymph node status is the most important prognostic factor. For example, following radical surgery, patients with stage IB or IIA disease have a 5-year survival of 88–96% with negative lymph nodes, compared to 64–73% in the presence of lymph node metastases.

Table 48–6 summarizes survival rates by stage of disease. These are based on the FIGO Annual Report on the Results of Treatment in Gynecological Cancer, in which results of treatment for each stage of cervical cancer are reported by more than 100 participating institutions worldwide. The results are equated in terms of 5-year cure rates, or those patients who are living and show no evidence of cervical cancer 5 years after beginning therapy. Recurrences following radiation therapy are not often centrally located and thus amenable to exenteration procedures. Only approximately 25% of recurrences are localized to the central portion of the pelvis. The most common site of recurrence is the pelvic side wall.

Table 48–6. Survival of patients with cervical cancer based on International Federation of Gynecology and Obstetrics (FIGO) stage.



Stage	Number of Patients (%)	Survival		
		1 Year	2 Years	5 Years
IA1	860	99.8%	99.5%	98.7%
IA2	227	98.2%	97.7%	95.9%
IB	3480	98.1%	94.0%	86.5%
IIA	881	94.1%	85.6%	68.8%
IIB	2375	93.3%	80.7%	64.7%
IIIA	160	82.8%	58.8%	40.4%
IIIB	1949	81.5%	62.2%	43.3%
IVA	245	56.1%	35.6%	19.5%
IVB	189	45.8%	23.9%	15.0%

Premalignant & Malignant Disorders of the Uterine Corpus

Nicole D. Fleming, MD
Oliver Dorigo, MD, PhD

ENDOMETRIAL HYPERPLASIA & CARCINOMA

ESSENTIALS OF DIAGNOSIS

- Abnormal uterine bleeding: menorrhagia, metrorrhagia, or postmenopausal bleeding
- Risk factors: hyperestrogenism—long-term exposure to unopposed estrogens (polycystic ovarian syndrome, chronic anovulation, late menopause, and exogenous estrogens); metabolic syndrome including diabetes, hypertension, and obesity; nulliparity; increasing age; history of breast cancer; genetic predisposition (hereditary nonpolyposis colon cancer syndrome)
- Diagnosis: endometrial sampling, ultrasonography

Pathogenesis

Endometrial cancer is the most common gynecologic malignancy. The American Cancer Society estimates that over 43,000 new cases will be diagnosed in 2010, and over 7900 women will die from endometrial cancer. In the United States, white women have a lifetime risk of endometrial carcinoma of 2.4% compared with 1.3% for black women; however, survival for white women is about 8% greater at each stage of diagnosis compared to black women. The peak incidence of onset is in the seventh decade, but 25% of cancers occur in premenopausal women, and the disease has even been reported in women ages 20–30 years.

Most endometrial carcinomas arise on the background of endometrial hyperplasia and are well-differentiated tumors. There are 2 major types of endometrial cancer. Type I tumors are more common (85%) and tend to occur in younger women. These are associated with either endogenous or exogenous unopposed estrogen exposure and usually consist of a low-grade or well-differentiated tumor with a favorable prognosis. Type II tumors grow independent of estrogen, are associated with endometrial atrophy, and occur in an older population. Poorly differentiated endometrioid or nonendometrioid, such as papillary serous and clear cell, histologies are included in type II tumors and confer a high risk of relapse with poor prognosis. Gene expression profiles have also been shown to be different between type I and II tumors, with PTEN mutations more common in type I and p53 overexpression more common in type II tumors.

Estrogens and progesterone are the 2 main hormones that influence the metabolic and proliferative state of the endometrium. In general, estrogens stimulate the endometrium, unlike progesterone, which has an antiproliferative effect. Long-term exposure to estrogens can lead to endometrial hyperplasia and, subsequently, to hormone-driven atypical endometrial hyperplasia and endometrial cancer. Clinical circumstances with chronically high levels of estrogenic stimulation include obesity, metabolic syndrome, polycystic ovary syndrome, exogenous and unopposed estrogen replacement therapy, and chronic anovulation in the premenopausal women. Granulosa cell tumors of the ovary can produce high levels of estrogens and can be associated with endometrial hyperplasia or cancer. The selective estrogen receptor modulator (SERM) tamoxifen used for adjuvant therapy in breast cancer has a weak estrogenic effect on the endometrium and increases the incidence of endometrial cancer by about 2- to 3-fold. However, the benefit of tamoxifen therapy for breast cancer outweighed the potential increase in endometrial cancer reported with a 38% reduction in the 5-year cumulative hazard rate in the tamoxifen-treated group.

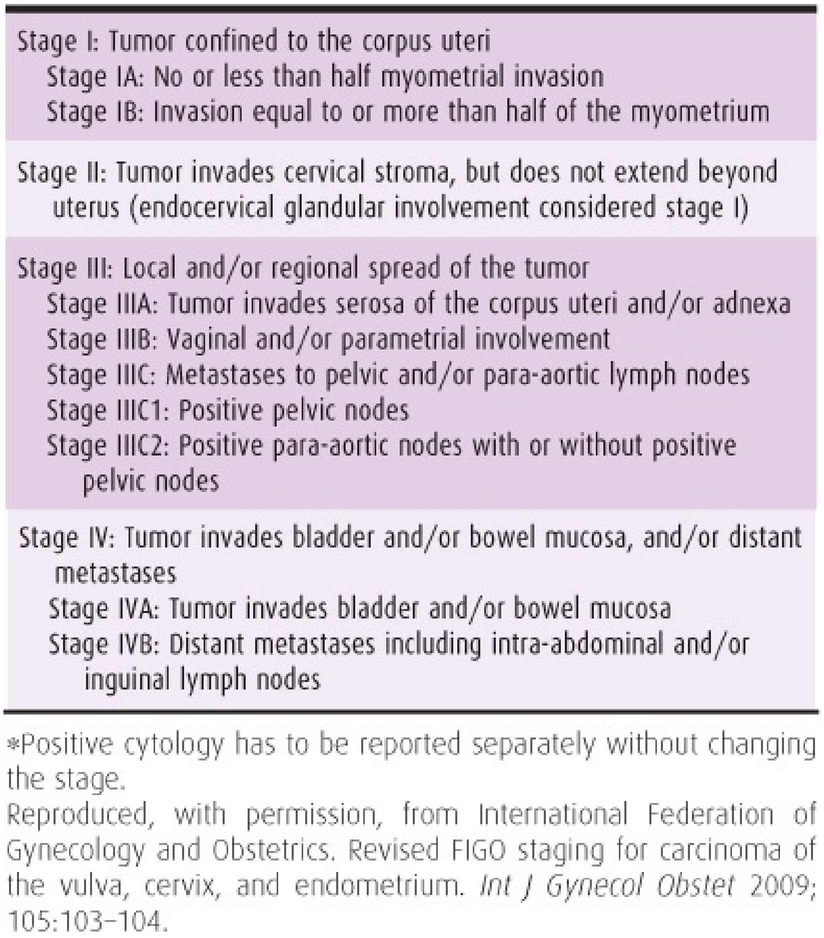
More than a dozen case-control studies indicate an association between estrogen administration and endometrial carcinoma. These studies report a 2- to 10-fold increase in the incidence of endometrial carcinoma in women receiving exogenous unopposed estrogens. The risk of cancer is related to both the dose and the duration of exposure and diminishes with cessation of estrogen use. The risk seems to be neutralized by the addition of cyclic progestin for 10 days at least every 1–3 months. In women without a hysterectomy, progestin should be added to the treatment to oppose the effect of estrogens on the endometrium. Endometrial biopsies to rule out endometrial hyperplasia or pelvic ultrasonography to evaluate the thickness of the endometrial stripe should be obtained if abnormal bleeding occurs.

About 5–6% of endometrial cancer cases develop on a genetic background. Women with a personal history of ovarian, colon, or breast cancer as well as those with a family history of endometrial cancer may be at higher risk. In hereditary nonpolyposis colorectal cancer (HNPCC) or Lynch syndrome, there is an autosomal dominant pattern of inheritance for colon and endometrial cancers most commonly, and rectal, ovarian, small bowel, and renal cancers less frequently. Patients with Lynch syndrome have an up to 70% lifetime risk of developing endometrial cancer, and a 10–12% risk of developing ovarian cancer. Most cases of HNPCC are a result of alterations in mismatch repair genes MSH2, MLH1, or MSH6.

Surgical Staging

In 1988, the Cancer Committee of the International Federation of Gynecology and Obstetrics (FIGO) introduced a surgical staging system for endometrial carcinoma based on abdominal exploration, pelvic washings, total hysterectomy with salpingo-oophorectomy, and selective pelvic and periaortic lymph node biopsies. This was revised by the FIGO Committee on Gynecologic Oncology in 2009 (Table 49–1). The grade of the tumors refers to the architecture and nuclear atypia on histology. The architecture of the tumor is judged by the percentage of differentiated (glandular) versus nondifferentiated (solid) elements within the tumor specimen. Grade 1 tumors consist of at least 95% glandular tissue and have <5% of a nonsquamous solid growth pattern. Areas of squamous differentiation are not considered to be solid tumor growth. Grade 2 tumors contain 6–50% of a nonsquamous solid growth pattern. Tumors with more than 50% of a solid pattern are classified as grade 3. The nuclear grade depends on the appearance of the nucleus (size of nucleus, chromatin pattern) and is more subjective. An architectural grade of 1 or 2 is raised by 1 point in the presence of significant nuclear atypia (nuclear grade 3).

Table 49–1. International Federation of Gynecology and Obstetrics (FIGO) surgical staging of carcinoma of the corpus uteri (2009).



Stage I: Tumor confined to the corpus uteri
- Stage IA: No or less than half myometrial invasion
- Stage IB: Invasion equal to or more than half of the myometrium

Stage II: Tumor invades cervical stroma, but does not extend beyond uterus (endocervical glandular involvement considered stage I)

Stage III: Local and/or regional spread of the tumor
- Stage IIIA: Tumor invades serosa of the corpus uteri and/or adnexa
- Stage IIIB: Vaginal and/or parametrial involvement
- Stage IIIC: Metastases to pelvic and/or para-aortic lymph nodes
- Stage IIIC1: Positive pelvic nodes
- Stage IIIC2: Positive para-aortic nodes with or without positive pelvic nodes

Stage IV: Tumor invades bladder and/or bowel mucosa, and/or distant metastases
- Stage IVA: Tumor invades bladder and/or bowel mucosa
- Stage IVB: Distant metastases including intra-abdominal and/or inguinal lymph nodes

*Positive cytology has to be reported separately without changing the stage.

Reproduced, with permission, from International Federation of Gynecology and Obstetrics. Revised FIGO staging for carcinoma of the vulva, cervix, and endometrium. *Int J Gynecol Obstet* 2009; 105:103–104.

Surgical stage I tumors account for 75% of all endometrial carcinomas, which explains the relatively good overall prognosis. Eleven percent of cancers are surgical stage II, and the remaining 11% and 3% are surgical stages III and IV, respectively.

A. Endometrial Hyperplasia

The glandular hyperplasias of the endometrium are benign conditions that can be classified as simple or complex and either with or without atypia. Because of their association with hyperestrogenic states, the atypical hyperplasias are considered premalignant lesions. Because endometrial hyperplasia and endometrial carcinoma present clinically as abnormal bleeding, thorough endometrial sampling or fractional curettage is always necessary when hyperplasia is present to rule out coexisting carcinoma.

1. Hyperplasia without atypia—Microscopically, this type of hyperplasia shows crowding of glands in the stroma without nuclear atypia. This type of hyperplasia is frequently asymptomatic and found incidentally in hysterectomy specimens. When followed without treatment over a 15-year period, approximately 1% progressed to endometrial cancer, whereas 80% spontaneously regressed.

Simple hyperplasia without atypia describes enlarged glands with an irregular outline. Long-term follow-up reveals a 1% risk of progression to carcinoma if untreated. Complex hyperplasia without atypia (previously designated “adenomatous hyperplasia”) describes a complex, crowded back-to-back glandular appearance with intraluminal papillae. Complex hyperplasia regresses under progestin therapy in approximately 85% of cases but progresses to cancer in 3–5% if untreated.

2. Hyperplasia with atypia—The histology of hyperplasia with atypia is characterized by endometrial glands that are lined with enlarged cells. An increased nuclear-to-cytoplasmic ratio is a sign of increased nuclear activity (eg, transcription). The nuclei may be irregular with coarse chromatin clumping and prominent nucleoli. These hyperplasias are generally considered premalignant. Progression to carcinoma occurs in 10% of simple atypical and in 30% of complex atypical hyperplasias. The majority of lesions regress with progestin therapy but have a higher rate of relapse when therapy is stopped compared to lesions without atypia. In peri- and postmenopausal patients with atypical hyperplasias who relapse after progestin therapy or who cannot tolerate the associated side effects, vaginal or abdominal hysterectomy is recommended.

A recent prospective cohort study by the Gynecologic Oncology Group (GOG) demonstrated that in patients with untreated atypical endometrial hyperplasia on preoperative biopsy, 42.6% had a concurrent endometrial carcinoma at hysterectomy. In the subset of women who had biopsies interpreted as less than atypical endometrial hyperplasia who underwent hysterectomy, 18.9% had cancer.

The term **atypical endometrial hyperplasia** should be applied to endometrial neoplasia without invasion. Severe atypical endometrial hyperplasia and adenocarcinoma in situ describe preinvasive histologies that are frequently difficult to distinguish from early invasive endometrial cancer. It is still a matter of debate whether the term **adenocarcinoma in situ** should be used for endometrial pathology. In contrast, the precursor lesion for serous carcinomas in endometrial intraepithelial carcinoma shows pleomorphic tumor cells in the epithelium of the endometrial surface and the underlying glands without stromal invasion.

In recent years, the term **endometrial intraepithelial neoplasia (EIN)** has been used to describe premalignant lesion of the uterine lining that predisposes to endometrioid endometrial adenocarcinoma. EIN lesions have been discovered by molecular, histologic, and clinical outcome studies and comprise a subset of endometrial hyperplasia lesions. EIN should not be confused with intraepithelial carcinoma (EIC), which is an early stage of papillary serous adenocarcinomas originating from the glandular endometrium.

B. Endometrial Carcinoma

Endometrial cancer is characterized by obvious hyperplasia and anaplasia of the glandular elements, with invasion of underlying stroma, myometrium, and vascular spaces. Although atypical complex hyperplasia is thought to be a precursor lesion, only approximately 25% of patients with endometrial carcinoma have a history of hyperplasia.

Important prognostic factors include stage, histologic grade and cell type, depth of myometrial invasion, presence of lymphovascular space involvement (LVSI), lymph node status, involvement of the lower uterine segment, and size of tumor.

Endometrial cancers of endometrioid histology of any grade with no myometrial invasion are almost never associated with lymph node metastases. The depth of myometrial invasion and histologic grade are correlated with the incidence of pelvic and aortic lymph node metastases. In the surgical pathology study GOG-33, nodal disease was more frequent with increasing grade (3% grade 1, 9% grade 2, 18% grade 3), depth of invasion (1% endometrium only, 5% inner one-third, 6% middle one-third, 25% outer one-third myometrial invasion), and LVSI (27% with LVSI, 7% without LVSI). Patients with poorly differentiated deeply invasive cancers have about a 35% incidence of involved pelvic nodes and a 10–20% incidence of aortic node metastases. Because patients with lymph node metastases are at very high risk for recurrence, these pathologic features have serious implications for treatment planning.

Endometrial cancer can spread by 4 possible routes: direct extension, lymphatic metastases, peritoneal implants after transtubal spread, and hematogenous spread. Undifferentiated lesions (grade 3) may spread to the pelvic and aortic nodes while still confined to the superficial myometrium. In serous and clear cell subtypes, the spread pattern is similar to that of ovarian cancer, and upper abdominal metastases are common. Hematogenous metastases to the lungs are uncommon with primary tumors limited to the uterus but do occur with recurrent or disseminated disease. Endometrial cancer spreads via a dual pathway to the pelvic and aortic lymph nodes (Fig. 49–1). The aortic nodes are rarely involved when the pelvic nodes are free of metastases. The lymph nodes most commonly involved in endometrial cancer are found in the obturator space.

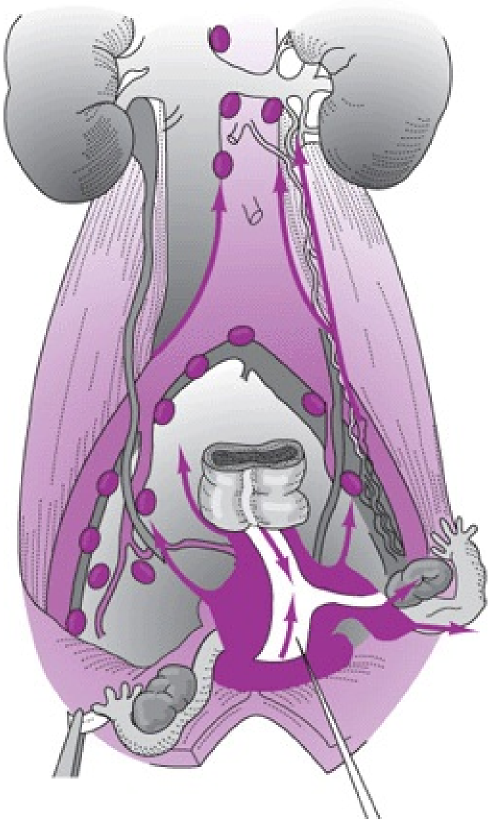


Figure 49–1. Dual lymphatic spread pattern of endometrial carcinoma.

Vaginal metastases occur by submucosal lymphatic or vascular metastases in approximately 3–8% of patients with clinical stage I disease. The concept that these metastases occur by spillage of tumor through the cervix at the time of surgery lacks convincing support. However, vaginal metastases are more common with higher histologic grade and with lower uterine segment or cervical involvement.

Pathologists recognize various histologic types of endometrial carcinoma. Approximately 80% of all endometrial cancers are of the endometrioid type with several variants: villoglandular, secretory, with squamous differentiation, and with ciliated cells. These types have similar presenting symptoms and signs, patterns of spread, and general clinical behavior. For this reason, they can be considered collectively for purposes of clinical workup, differential diagnosis, and treatment. Endometrial adenocarcinomas of the nonendometrioid phenotype show mucinous, serous, clear cell, squamous, small cell, mixed, or transitional cell differentiation.

1. Adenocarcinoma—The most common type of endometrial carcinoma is adenocarcinoma, composed of malignant glands that range from well-differentiated (grade 1) to anaplastic carcinoma (grade 3). To determine stage and prognosis, the tumor is usually graded by the most undifferentiated area visible under the microscope (Fig. 49–2). In the United States, adenocarcinoma comprises 80% of endometrial carcinomas.

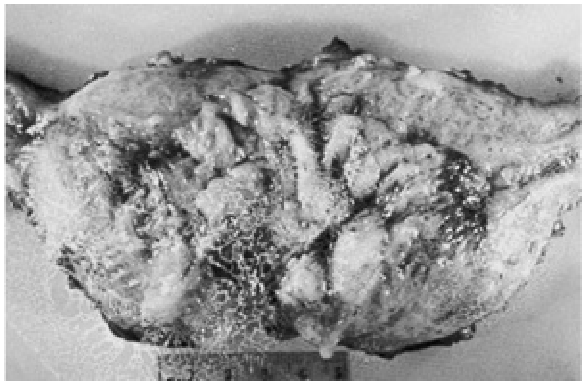

Figure 49–2. Adenocarcinoma of the endometrium. Note the sharp demarcation of the tumor at the isthmus.

2. Adenocarcinoma with squamous differentiation—Approximately 25% of endometrioid carcinomas contain focal to extensive squamous elements, ranging from bland squamous cells to foci that could be viewed as squamous carcinoma. The behavior of the tumors with squamous differentiation is dependent on the grade of the glandular component.

3. Serous carcinoma—Histologically, this cancer is identical to the complex papillary architecture seen in serous carcinomas of the ovary. Serous carcinoma represents approximately 10% of endometrial carcinomas. Women with serous carcinoma are more likely to be older and less likely to have hyperestrogenic states. These tumors account for 50% of all relapses in stage I tumors. Serous tumors spread early and involve peritoneal surfaces of the pelvis and abdomen. The tumors also have a propensity for myometrial and lymphatic invasion. The prognosis is unfavorable, and patients with serous tumors should be treated in a manner similar to that of patients with ovarian tumors.

4. Clear cell carcinoma—This subtype is not associated with clear cell carcinomas of the cervix and vagina that are seen in young women with diethylstilbestrol exposure. Clear cell carcinomas encompass approximately 1–4% of all endometrial carcinomas. Its microscopic appearance is significant for clear cells or hobnail cells. Solid, papillary, tubular, and cystic patterns are possible. Clear cell carcinoma is commonly high grade and aggressive with deep invasion and is seen at an advanced stage. The mean age at diagnosis is approximately 67 years, which is similar to the serous subtype, and it is not associated with a hyperestrogenic state.

5. Miscellaneous subtypes—Mucinous carcinomas make up 1–9% of endometrial adenocarcinomas. The cytoplasm is positive for mucin, carcinoembryonic antigen, and periodic acid-Schiff stain. Secretory carcinoma, present in 1–2% of cases, exhibits subnuclear or supranuclear vacuoles resembling early secretory endometrium. These rare cancers behave in a manner similar to that of typical endometrial carcinomas. Pure squamous cell carcinomas are extremely rare (<1%) and are associated with cervical stenosis, pyometra, and chronic inflammation.

Prevention

A doubling of the incidence of endometrial cancer in the 1970s correlated with unopposed estrogen use in hormone replacement and sequential oral contraceptives over the previous 10 years. The declining incidence in the 1980s paralleled progesterone use in hormone replacement regimens and low-dose estrogen combination birth control pills.

Estrogens are implicated as a causative factor in endometrial carcinoma based mainly on the high incidence of this disease in patients with presumed alterations in estrogen metabolism and in those who take exogenous estrogens. Furthermore, patients with anovulatory cycles are at higher risk of developing endometrial cancer because of prolonged periods of estrogenic stimulation of the endometrium without the opposing effects of progesterone. Progesterone has an antiproliferative effect on the endometrium and can induce apoptosis of endometrial cells.

Classically, endometrial carcinoma affects the obese, nulliparous, infertile, hypertensive, and diabetic white woman, but it can occur in the absence of all these factors. Unlike cervical cancer, it is not related to sexual history.

Prophylactic hysterectomy and bilateral salpingo-oophorectomy have been shown to be effective strategies for preventing endometrial and ovarian cancer in these high-risk patients.

Several modifiable risk factors for endometrial carcinoma have been described, including obesity, diabetes, hypertension, and nulliparity. Prevention of endometrial cancer is primarily based on weight control, physical exercise, adequate control of diabetes and hypertension, and increased surveillance of women at high risk. In addition, a careful family history of each patient will help identify patients with a genetic predisposition for endometrial cancer, for example, as part of the HNPCC syndrome. If appropriate, these patients should undergo genetic counseling and genetic testing. A hysterectomy after the completion of childbearing is appropriate for patients with HNPCC syndrome given the lifetime risk for endometrial cancer of up to 70%. Hormone therapy in postmenopausal patients without hysterectomy should always include a progestational agent to oppose the action of estrogens on the endometrium. Estrogens should be administered either continuously or cyclically using the lowest dose that controls symptoms. Progesterone (10 mg of medroxyprogesterone acetate or 200 mg of micronized progesterone) should be added for the last 10–14 days of the cycle to neutralize the risk of endometrial carcinoma. Alternatively, if estrogen and progesterone are administered continuously, 2.5 mg of medroxyprogesterone acetate is given daily.

Clinical Findings

The onset of endometrial bleeding facilitates detection in the earlier stages of disease. The most common presenting symptom is abnormal vaginal bleeding, particularly post-menopausal bleeding. Less frequently, severe cramps from hematometra or pyometra caused by an obliterated endocervical canal in elderly patients may be the presenting symptom.

A. Symptoms & Signs

Abnormal bleeding occurs in approximately 80% of patients and is the most important and early symptom of endometrial carcinoma. An abnormal vaginal discharge, especially after menopause or intermittent spotting, is reported by some patients. During the premenopausal years, the bleeding is usually described as excessive flow at the time of menstruation. However, bleeding may occur as intermenstrual spotting or premenstrual and postmenstrual bleeding. Approximately 5–10% of patients with postmenopausal bleeding have underlying cancer, but the probability increases with age and depends on underlying risk factors. Approximately 10% of patients complain of lower abdominal cramps and pain secondary to uterine contractions caused by detritus and blood trapped behind a stenotic cervical os (hematometra). If the uterine contents become infected, an abscess develops and sepsis may occur.

Physical examination is usually unremarkable but may reveal medical problems associated with advanced age. Speculum examination may confirm the presence of bleeding, but because it may be minimal and intermittent, blood might not be present. Atrophic vaginitis is frequently identified in these elderly women, but postmenopausal bleeding should never be ascribed to atrophy without a histologic sampling of the endometrium to rule out endometrial carcinoma. Bimanual and rectovaginal examination of the uterus in the early stages of the disease will be normal unless hematometra or pyometra is present. If the cancer is extensive at the time of presentation, the uterus may be enlarged and may be misdiagnosed as a benign condition such as leiomyomata. In advanced cases, the uterus may be fixed and immobile from parametrial extension.

Vaginal, vulvar, or inguinal–femoral lymph node metastases are rarely identified in early disease but are not uncommon in advanced cases or with recurrence following treatment. Ovarian metastases may cause marked enlargement of these organs.

B. Laboratory Findings

Routine laboratory findings are normal in most patients with endometrial carcinoma. If bleeding has been prolonged or profuse, anemia may be present. Cytologic study of specimens taken from the endocervix and posterior vaginal fornix can reveal adenocarcinoma in symptomatic patients. More important, endometrial carcinoma will be missed in 40% of symptomatic patients by routine cytologic examination. Accuracy has been greatly increased by aspiration cytologic study or biopsy (discussed under Special Examinations). Nevertheless, the Papanicolaou (Pap) smear is an integral part of the examination of all patients, because it identifies a small but definite percentage of patients with asymptomatic disease. Furthermore, the presence of benign endometrial cells in the cervical or vaginal smear of a menopausal or postmenopausal woman is associated with occult endometrial carcinoma in 2–6% of cases and in up to 25% with postmenopausal bleeding. Thus, any postmenopausal woman who shows endometrial cells on a routine cervical Pap smear requires evaluation for endometrial cancer, including endometrial sampling.

Routine blood counts, urinalysis, endocervical and vaginal pool cytology, chest radiography, stool guaiac, and sigmoidoscopy are useful ancillary diagnostic tests in patients with endometrial carcinoma. Liver function tests, blood urea nitrogen, serum creatinine, and a blood glucose test (because of the known relationship to diabetes) are considered routine. Serum CA-125 (cancer antigen-125), a well-established tumor marker for epithelial ovarian cancer, might be useful for endometrial cancer. Approximately 20% of patients with clinical stage I disease (preoperatively, the tumor appears to be confined to the uterus) have an elevated CA-125. In cases with extensive intraperitoneal spread or enlarged uterus, the tumor marker CA-125 may be markedly elevated. However, in contrast to patients with ovarian cancer, the value of CA-125 in the management of patients with endometrial cancer is limited.

C. Imaging Studies

Chest radiography might reveal metastases in patients with advanced disease but is rarely positive in the early stages. Colonoscopy is usually unnecessary in a patient with a negative stool guaiac test and normal sigmoidoscopic examination but should always be performed in the patient with gross or occult gastrointestinal bleeding or symptoms. In patients from families with HNPCC, a colonoscopy should be performed preoperatively, particularly if the patient screens positive for the HNPCC-associated DNA mismatch repair gene mutations.

Hysteroscopy can increase the diagnostic accuracy over office endometrial biopsy or dilatation and curettage. Hysteroscopy promotes the transtubal spread of tumor cells into the peritoneal cavity. However, the presence of a positive peritoneal cytology after hysteroscopy does not seem to alter the prognosis. Computed tomography is useful in assessing pelvic anatomy, visualizing enlarged lymph nodes in the pelvis and periaortic areas and diagnosing distant metastasis in the liver and lungs. Magnetic resonance imaging (MRI) is particularly helpful in identifying myometrial invasion and lower uterine segment or cervical involvement.

D. Special Examinations

1. Fractional curettage—Dilatation and fractional curettage (D&C) is the definitive procedure for diagnosis of endometrial carcinoma. It should be performed with the patient under anesthesia to provide an opportunity for a thorough and more accurate pelvic examination. It is carried out by careful and complete curettage of the endocervical canal followed by dilatation of the canal and circumferential curettage of the endometrial cavity. When obvious cancer is present with the first passes of the curette, the procedure should be terminated as long as sufficient tissue for analysis has been obtained from the endocervix and endometrium. Perforation of the uterus followed by intraperitoneal contamination with malignant cells, blood, and bacteria is a common complication in patients with endometrial carcinoma and can usually be avoided by gentle surgical technique and limitation of the procedure to the extent necessary for accurate diagnosis and staging. D&C is never considered curative in these circumstances and should not be performed with the same vigor as therapeutic curettage.

2. Endometrial biopsy—This procedure is attractive because it can be performed in an outpatient setting, resulting in a substantial savings in cost. It can usually be done without anesthesia, although paracervical block is effective when necessary. Results of endometrial biopsies (EMB) correlate well with endometrial curettings with the accuracy to detect cancer between 91% and 95%. The accuracy of identifying cancers with EMB is higher in postmenopausal patients than in premenopausal patients. There is a false-negative rate of approximately 10%, and all symptomatic patients with a negative EMB need to undergo a formal D&C. There are many types of office biopsy techniques including a Pipelle, Novak curet (Fig. 49–3), and Vabra aspirator (Fig. 49–4). All types of EMB are notoriously inaccurate for diagnosing polyps and will miss a significant number of cases of endometrial hyperplasia as well.

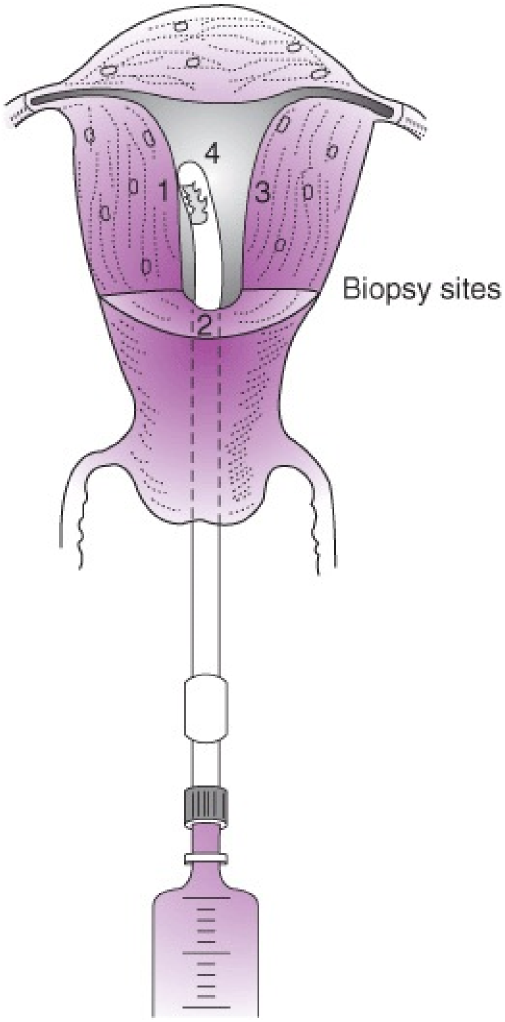

Figure 49–3. Technique of endometrial biopsy with Novak curet.

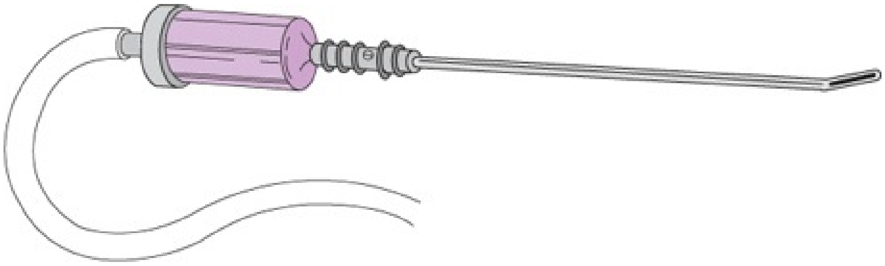

Figure 49–4. Vabra aspirator.

3. Pelvic ultrasonography—Ultrasonography can be helpful in the surveillance of asymptomatic, high-risk patients (eg, breast cancer patients on tamoxifen and women with strong family histories of endometrial cancer). Pelvic and transvaginal ultrasonography yield information about the size and shape of the uterus, as well as the thickness and surface contour of the endometrium. Transvaginal ultrasound measuring the lining thickness of the endometrium has an excellent negative predictive value for ruling out endometrial cancer or hyperplasia when the thickness is <5 mm, but provides less information when >5 mm. In postmenopausal women, an endometrial thickness of more than 5 mm is considered to be suspicious for hyperplasia or malignancy and should be further evaluated with an EMB. Transvaginal ultrasound, however, can yield a high false-positive rate in women who have been on tamoxifen for more than 2 years. The subendometrial edema that develops from tamoxifen use is indistinguishable from a thickened endometrial stripe. A sonohysterogram, which involves instilling sterile saline into the endometrial cavity prior to transvaginal ultrasound, can reduce false-positive results and better delineate the endometrial cavity.

4. Estrogen and Progesterone Receptor Assays—Estrogen and progesterone receptor assays should be obtained from the neoplastic tissue. This information helps in planning adjuvant or subsequent hormone therapy. Estrogen and progesterone receptor content are inversely proportional to histologic grade. In general, patients with tumors positive for 1 or 2 receptors have longer survival than patients with receptor-negative tumors. Furthermore, patients with receptor-positive tumors might be candidates for hormone-based therapy of recurrent tumor disease.

Differential Diagnosis

In the asymptomatic patient, a diagnosis may be made incidentally from an abnormal Pap smear, but cytologic discovery of endometrial cancer is not consistent and should not be relied on for early diagnosis. Screening for endometrial cancer in the general population is not recommended but should be performed for patients with a Lynch or HNPCC syndrome.

Clinically, the differential diagnosis of endometrial carcinoma includes all the various causes of abnormal uterine bleeding. In the premenopausal patient, complications of early pregnancy, such as threatened or incomplete abortion, must be considered initially. Other causes of bleeding in premenopausal patients are leiomyomata, endometrial hyperplasia and polyps, cervical polyps, an intrauterine device, and various genital or metastatic cancers. Cervical, endometrial, tubal, and ovarian neoplasms all can cause abnormal uterine bleeding. Although rare, metastatic cancers from the bowel, bladder, and breast have also been reported to cause abnormal uterine bleeding. After exclusion of anatomic causes for vaginal bleeding, a workup for hemophilias should be performed. In the postmenopausal age group, the differential diagnosis includes atrophic vaginitis, exogenous estrogens, endometrial hyperplasia and polyps, and various genital neoplasms. The likelihood of cancer increases with age. In the patient with a normal pelvic examination and recurrent postmenopausal bleeding following a recent negative D&C, tubal and ovarian cancer must be strongly considered. Patients with recurrent unexplained episodes of postmenopausal uterine bleeding should be considered for total hysterectomy and bilateral salpingo-oophorectomy.

Complications

Patients with advanced disease and deep myometrial invasion may present with severe anemia secondary to chronic blood loss or acute hemorrhage. If bleeding is significant and continuous, a short-term boost of radiation therapy is usually effective in slowing the hemorrhage.

The presence of a hematometra can be confirmed by sounding the uterus under anesthesia, followed by dilatation of the cervix to allow adequate drainage. When a pyometra is present, the patient may present with peritonitis or generalized sepsis, with all the consequent complications.

Perforation of the uterus at the time of D&C or EMB is not an uncommon problem. If the perforating instrument is large, loops of small bowel may be inadvertently retrieved through the cervical canal. A large perforation warrants laparoscopy or laparotomy to evaluate and repair the damage. If significant contamination of the peritoneal cavity with blood or necrotic tumor has occurred, the patient should be treated with broad-spectrum antibiotics to prevent peritonitis. Perforation in the patient with endometrial cancer should be viewed as a serious complication, as spillage of tumor into the peritoneal cavity may alter her prognosis.

Treatment

The mainstay of treatment is surgery, including a total hysterectomy with bilateral salpingo-oophorectomy and staging with pelvic and periaortic lymphadenectomy. Further postoperative therapy depends on the particular histologic characteristics and the extent of the tumor.

The majority of endometrial cancer cases are diagnosed at an early stage and can be treated with high cure rates. The most important treatment modality is surgery with total hysterectomy, bilateral salpingo-oophorectomy, and staging, including pelvic and periaortic lymphadenectomy. Primary radiation therapy is used only in patients with medical contraindications for surgery or advanced pelvic disease. It has been repeatedly demonstrated that radiation therapy can cure endometrial carcinoma in some patients. However, radiation therapy averages about a 20% lower cure rate compared to surgery in stage I disease. Primary chemotherapy is used infrequently and mostly in patients with metastatic disease. High-dose progesterone therapy, commonly with medroxyprogesterone acetate or megestrol acetate, may be used for patients who are inoperable or in younger patients who elect for fertility preservation. The overall response to high-dose progesterone therapy is up to 75% in grade 1 endometrial cancer cases limited to the endometrium. To verify that the patient is responding to therapy, regular endometrial sampling needs to be performed.

Adjuvant treatment is dependent on the results of surgical staging and histology. For example, adjuvant radiation therapy is frequently used in high-risk endometrial cancers of endometrioid histology to prevent pelvic recurrences. Advanced pelvic disease may be treated with radiation followed by systemic chemotherapy. Serous cancers of the endometrium behave biologically similar to ovarian cancer and are treated with adjuvant platinum-based chemotherapy possibly in conjunction with radiation.

A. Emergency Measures

Patients with endometrial adenocarcinoma may present with severe anemia after prolonged periods of vaginal bleeding. Acute and massive blood loss may lead to hypovolemic shock. The management of these patients includes stabilization of vital signs with volume substitution and blood transfusion. A tamponade of the uterus using vaginal packing might be useful, particularly in the presence of a bleeding cervical or vaginal tumor. Monsel’s solution or silver nitrate can further aid in obtaining hemostasis. An emergency D&C might help to control the bleeding but has to be performed with great caution to avoid perforation. If bleeding does not subside, a high-dose radiation boost to the whole pelvis is usually the treatment of choice to acutely control uterine bleeding in this situation. Rarely, in the face of very advanced lesions, embolization of the hypogastric arteries via percutaneous selective angiography may be required to control hemorrhage before treatment can be initiated. Hysterectomy should always be considered if it can be accomplished safely without jeopardizing curative therapy.

Elderly patients may present with severe lower abdominal pain and cramping secondary to hematometra or pyometra; these complications result from endometrial carcinoma in more than 50% of cases. When adequate blood levels of broad-spectrum antibiotics are established, the cervix should be dilated and the endometrial cavity adequately drained. In this setting, vigorous D&C is contraindicated because of the high risk of uterine perforation. If the cervix is well dilated, an indwelling drain is usually unnecessary, but if sepsis is not controlled within 24–48 hours, the patient should be re-examined to ascertain cervical patency. Once the infection has completely subsided and the patient has been afebrile for 7–10 days, gentle fractional curettage should be performed if the diagnosis was not confirmed at the initial procedure.

B. Radiation Therapy

Radiation therapy is used as primary therapy in patients considered too medically unstable for laparotomy. Adjuvant preoperative radiation is no longer used unless the patient presents with gross cervical involvement. In this situation, after preoperative whole-pelvic radiation and an intracavitary implant, an extrafascial hysterectomy is performed. Relative contraindications to preoperative radiation therapy include the presence of a pelvic mass, a pelvic kidney, pyometra, history of a pelvic abscess, prior pelvic radiation, and previous multiple laparotomies (see Chapter 52).

Adjuvant radiation therapy has been shown to significantly improve locoregional control in early-stage, high-risk endometrial cancer. Two randomized controlled clinical trials, one conducted in the United States by the GOG (GOG-99) and the other one conducted in Europe (PORTEC trial), demonstrated that the addition of postoperative external-beam radiation therapy (EBRT) in early-stage, high-risk endometrial cancers decreased the rate of vaginal and pelvic recurrences versus surgery alone. However, local radiation alone did not result in improvement of overall survival.

Accordingly, in the presence of extrauterine extension, lower uterine segment or cervical involvement, poor histologic differentiation, papillary serous or clear cell histology, or myometrial invasion greater than one-third of the full thickness, adjuvant radiation therapy is recommended. In the absence of these findings, it is difficult to justify the risk and morbidity of any additional treatment beyond simple total abdominal hysterectomy and bilateral salpingo-oophorectomy. In stage III and IV disease, the optimal adjuvant therapy has also been of much debate. Management options in advanced-stage disease can include systemic chemotherapy alone or in addition to radiation therapy to improve locoregional control. Overall, adjuvant therapy in patients with early-stage, high-risk endometrioid endometrial cancers should be individualized based on stage and grade, on whether surgical lymph node staging was performed, and on the risk of nodal versus vaginal recurrence.

C. Surgical Treatment

Because bleeding is usually an early sign of endometrial carcinoma, most patients present with early disease and can be adequately and completely treated by simple hysterectomy. Staging includes a bilateral salpingo-oophorectomy, peritoneal washings for cytology, and removal of pelvic and periaortic lymph nodes. Recently, minimally invasive methods, including laparoscopic-assisted and robotic-assisted endometrial cancer staging procedures, have been successfully performed. Laparoscopic surgery is currently the preferred management for patients with endometrial cancer, because patient outcome is equivalent to open surgery. In addition, length of hospital stay and recovery time are both shorter.

Pelvic and para-aortic lymphadenectomy play an important role in the surgical staging of endometrial cancer. A gross pathologic assessment of the uterus should be performed during surgery to determine the need for surgical staging in patients with grade 1 or 2 endometrioid adenocarcinomas. Patients who require surgical staging are patients with stage I disease with grade 3 lesions, tumors >2 cm in maximum dimension, tumors with >50% myometrial invasion, cervical extension, and evidence of extrauterine spread. Furthermore, staging should be performed in clear cell and papillary serous carcinomas in all cases because of a high incidence of lymphatic spread. However, the criteria for lymphadenectomy are not universally accepted and are under constant investigation. The therapeutic role of lymphadenectomy is still under investigation. Several studies have suggested that EBRT may be omitted or the radiation field reduced to the central pelvis if the lymph nodes are negative. Bulky, positive nodes, which are unlikely to respond to EBRT, should be removed during surgery.

Radical hysterectomy for stage II tumors is an accepted procedure that has the potential to omit adjuvant radiation therapy. A radical hysterectomy can also be an effective treatment for patients with recurrence following treatment with radiation therapy alone or for those who have previously received therapeutic doses of pelvic radiation therapy for other pelvic cancers. The increased risk of bowel or urinary tract injury in this setting must be understood and accepted by both patient and physician.

Patients who present with significant cervical involvement or vaginal and parametrial involvement should receive initial pelvic radiation. Exploratory laparotomy should then be considered in patients whose disease seems resectable. Hormonal therapy or chemotherapy is most appropriate for patients with clinical evidence of extrapelvic metastases. Palliative radiation to bone or brain metastases is beneficial for symptomatic relief. Pelvic radiation can be helpful for local tumor control and alleviation of bleeding.

D. Hormone Therapy

Progesterone has shown some efficacy in the treatment of recurrent endometrial carcinoma not amenable to irradiation or surgery. This type of therapy can be administered orally or parenterally. Oral megestrol, parenteral medroxyprogesterone acetate suspension, and parenteral hydroxyprogesterone caproate appear to have similar effectiveness with response rates of approximately 25%. Overall, approximately 13% of patients with recurrent disease appear to achieve long-term remission with progesterone therapy. The average duration of response is 20 months, and up to 30% of responders survive for 5 years. In general, the clinical response is better in patients with localized recurrence, well-differentiated tumors, long disease-free intervals, and positive estrogen or progesterone receptor status. Because some patients do not achieve remission until after 10–12 weeks of therapy, the minimum duration of treatment should be longer than 3 months. Although progesterones have a somewhat encouraging record in the treatment of recurrent endometrial adenocarcinoma, they are disappointing as prophylactic agents. They have not improved survival or decreased recurrence when used following definitive treatment of early-stage disease.

Tamoxifen, either alone or in combination with progesterone, has been used in advanced or recurrent endometrial cancer. Patients with well-differentiated, estrogen receptor– positive tumors and long disease-free intervals tend to have a better response to tamoxifen. Tamoxifen is administered orally at 10–20 mg twice daily. For single-agent tamoxifen, the overall response rate is approximately 15–20%. Studies using combination tamoxifen–progestin therapy suggest a possibly better clinical response of up to 40%.

E. Chemotherapy

Doxorubicin and cisplatin are the 2 most active agents in the treatment of advanced or recurrent endometrial cancer. Doxorubicin used as a single agent has an overall response rate of 38%, with 26% of the patients achieving a complete response. The combination of cisplatin and doxorubicin shows slightly longer survival than either agent alone. The addition of paclitaxel to cisplatin and doxorubicin shows an overall response rate of 57% with improved long-term survival compared to the same regimen without paclitaxel. More recently, the combination of paclitaxel and carboplatin has shown comparable response rates and less side effects. Other agents with antitumor activity against endometrial cancer include cyclophosphamide, hexamethylmelamine, and 5-fluorouracil.

Prognosis

The overall prognosis is considerably better than for the other major gynecologic cancers with 5-year survival rates of 96%, 67%, and 17% for local, regional, and distant disease at diagnosis, respectively.

The most important prognostic factors for endometrial cancer are stage, histologic type, grade, myometrial invasion, and the presence of lymphovascular space invasion. Identification of these risk factors is crucial for treatment decisions, surveillance, and counseling of the patient. The prognosis is worse with increasing age, higher pathologic grade, advanced-stage disease, increasing depth of myome-trial invasion, and presence of lymphovascular space invasion. Because the prognosis for each patient is dependent on a variety of factors, overall 5-year survival stratified by stage is indicated as a range of percentages. The overall 5-year survival rates are 81–95% for surgical stage I, 67–77% for stage II, 31–60% for stage III, and 5–20% for stage IV.

These figures underline the increasing risk for treatment failure and recurrence with increasing bulk and extension of tumor. In the absence of risk factors, a simple total abdominal hysterectomy and bilateral salpingo-oophorectomy should result in survival >95% at 5 years. However, in the presence of risk factors, a more aggressive surgical approach and using adjuvant radiation and chemotherapy may be warranted.

SARCOMA OF THE UTERUS (LEIOMYOSARCOMA, ENDOMETRIAL SARCOMAS)

ESSENTIALS OF DIAGNOSIS

- Bleeding: metrorrhagia, menorrhagia, postmenopausal or preadolescent bleeding
- Mass: rapid enlargement of the uterus or a leiomyoma

- Pain: pelvic discomfort as a result of mass effect from the enlarged uterus
- Malignant tissue: histology confirmed by D&C or in hysterectomy specimen

Pathogenesis

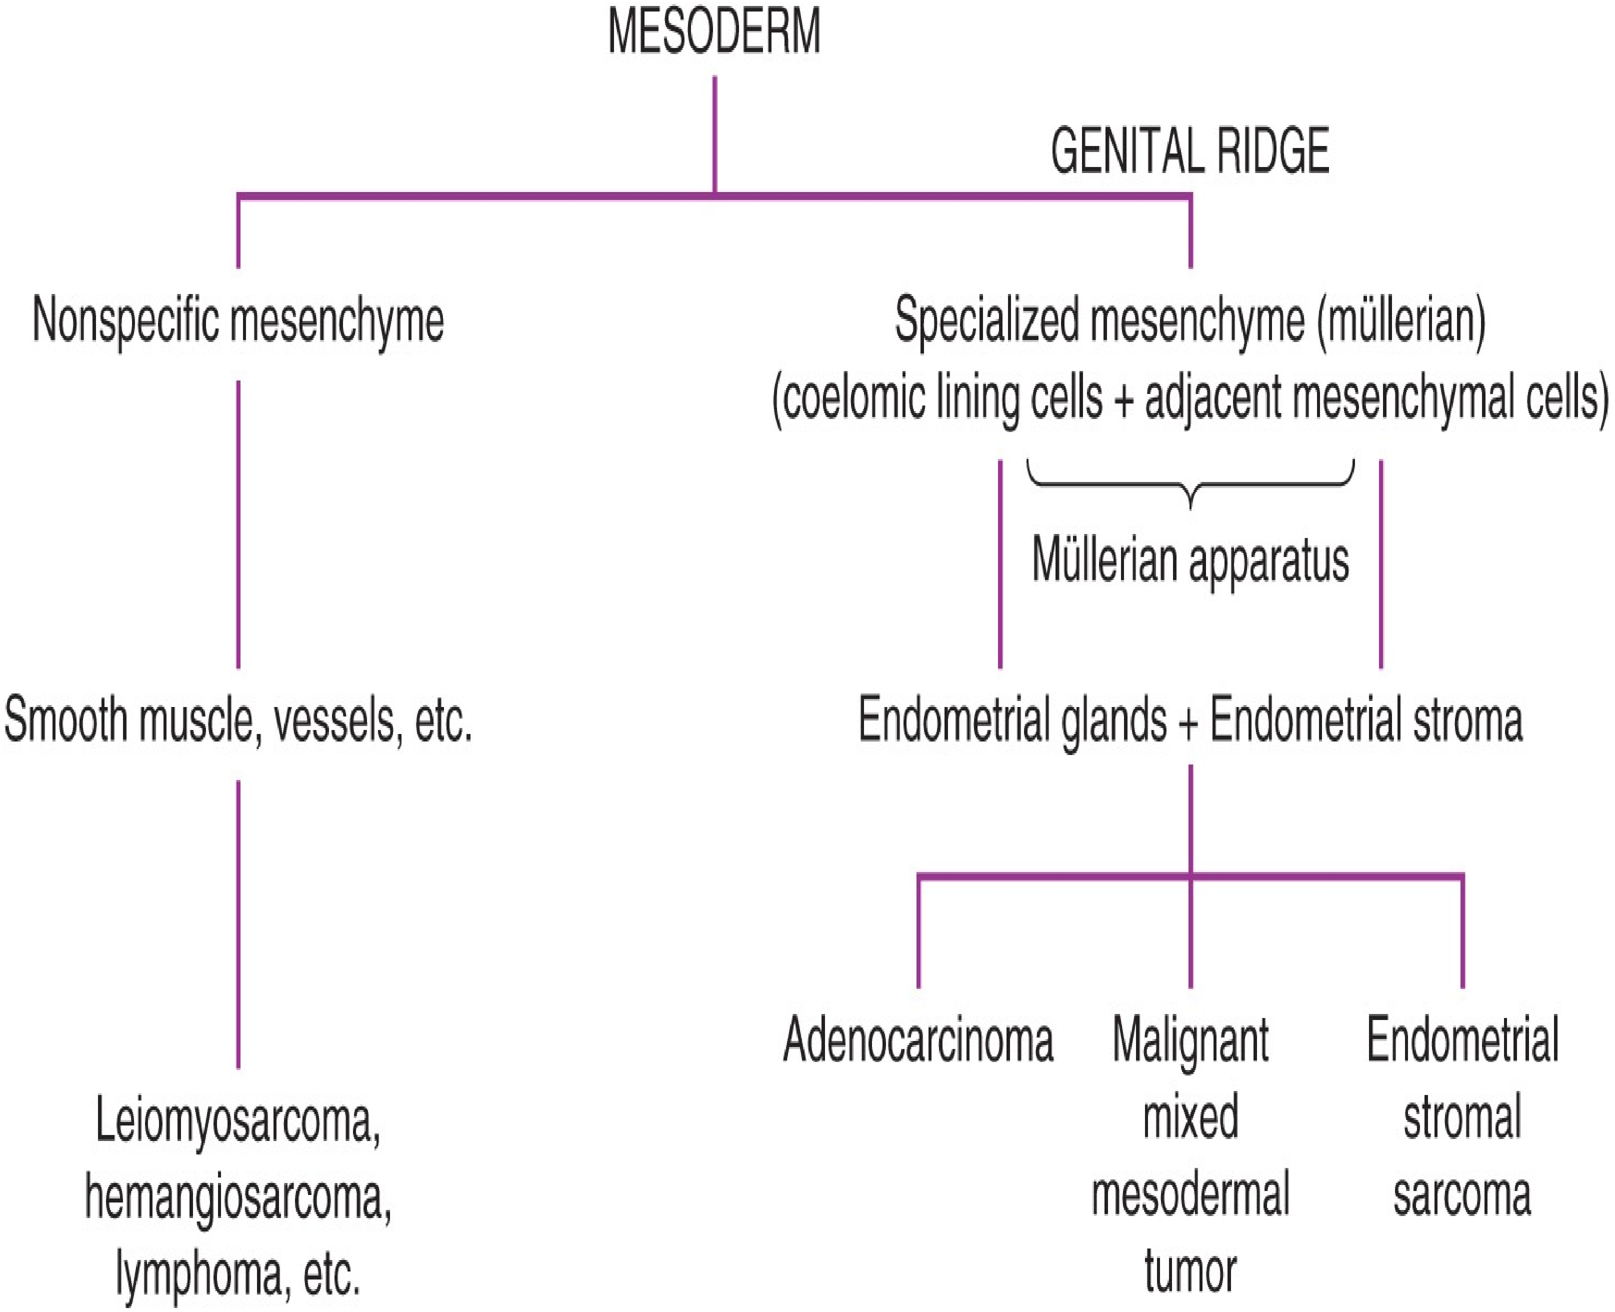
The uterine sarcomas are mesodermally derived highly malignant tumors and account for approximately 3–4% of all uterine malignancies. No common etiology has been identified in uterine sarcomas, but prior pelvic radiation therapy is associated with the mixed forms of uterine sarcoma.

Sarcomas can occur at any age but are most prevalent after age 40. A bimodal age distribution has been seen with uterine sarcomas, with a premenopausal or perimenopausal peak for patients with leiomyosarcoma and a postmenopausal peak for patients with carcinosarcoma. Sarcomas are well known as a source of hematogenous metastases, but with the exception of leiomyosarcomas, lymphatic permeation and contiguous spread are probably the most common methods of extension. Endometrial sarcomas can usually be diagnosed by EMB or D&C, but the sarcomas derived from the myometrium (leiomyosarcoma) frequently require hysterectomy to obtain adequate tissue for analysis.

In general, uterine sarcomas follow a very aggressive growth pattern with early metastasis to the abdomen, liver, and lung. There is no universal agreement on the histologic features that determine outcome, but most authorities agree that the number of mitotic figures per high-power field, vascular and lymphatic invasion, serosal extension, and degree of anaplasia are all helpful. Surgery is the most common primary treatment approach, followed by radiation and chemotherapy. Chemotherapeutic agents reported to be active against sarcomas include doxorubicin, cisplatin, ifosfamide, gemcitabine, and the taxanes. Clinical response rates for combination chemotherapy in recurrent and advanced disease are reported to be as high as 54%. However, most responses are partial and only temporary.

Histogenesis, Classification, & Staging

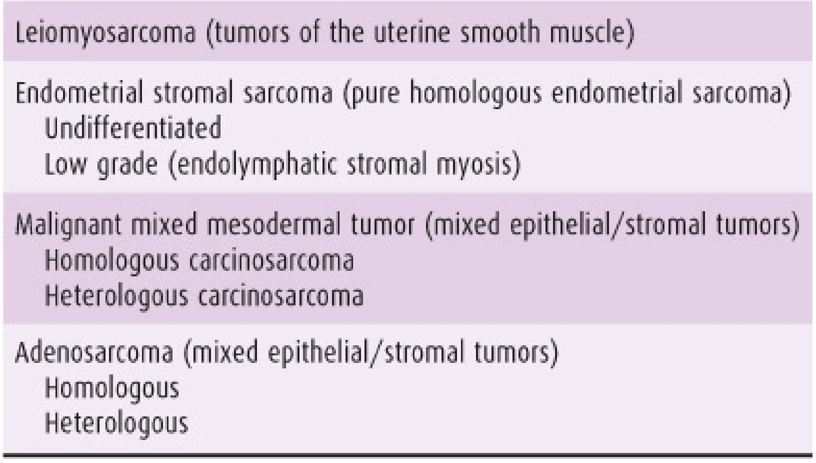
Although several classification systems exist for uterine sarcomas, they can be separated into 4 major categories: leiomyosarcomas (LMSs), endometrial stromal sarcomas (ESSs), malignant mixed mesodermal tumors (MMMTs), and adenosarcomas. LMSs are thought to arise from the myometrial smooth muscle cell or a similar cell lining blood vessels within the myometrium. ESS and MMMT arise from undifferentiated endometrial stromal cells, which retain the potential to differentiate into malignant cell lines that histologically appear native (homologous) or foreign (heterologous) to the human uterus. Because the undifferentiated stromal cells of the endometrium arise from specialized mesenchymal cells of the müllerian apparatus in the genital ridge, and ultimately from the mesoderm during embryogenesis, endometrial sarcomas have been variously termed “mesodermal,” “müllerian,” or “mesenchymal” sarcomas. The prognoses of patients with homologous and heterologous tumors are similar stage for stage, and this terminology has limited clinical usefulness. ESSs have been categorized in the older literature as “pure” and homologous endometrial sarcomas because they are composed of a single cell line. MMMTs, previously designated as “mixed” because they contain 2 or more cell lines, arise from an undifferentiated malignant stem cell. MMMTs contain both a carcinomatous or epithelium-derived element and a sarcomatous or mesenchymal element and have also been called “carcinosarcomas.” The carcinomatous element is usually an undifferentiated adenocarcinoma. The concept of this terminology is better understood by study of Figure 49–5, which graphically represents the histogenesis of uterine sarcomas. Table 49–2 combines the prevailing histogenetic terminology for endometrial sarcomas and depicts the various possibilities in each category.



MESODERM
GENITAL RIDGE
Nonspecific mesenchyme
Specialized mesenchyme (müllerian)
(coelomic lining cells + adjacent mesenchymal cells)
Müllerian apparatus
Smooth muscle, vessels, etc.
Endometrial glands + Endometrial stroma
Adenocarcinoma
Malignant mixed mesodermal tumor
Endometrial stromal sarcoma
Leiomyosarcoma, hemangiosarcoma, lymphoma, etc.

Figure 49–5. Histogenesis of uterine sarcomas.

Table 49–2. Classification of uterine sarcomas.

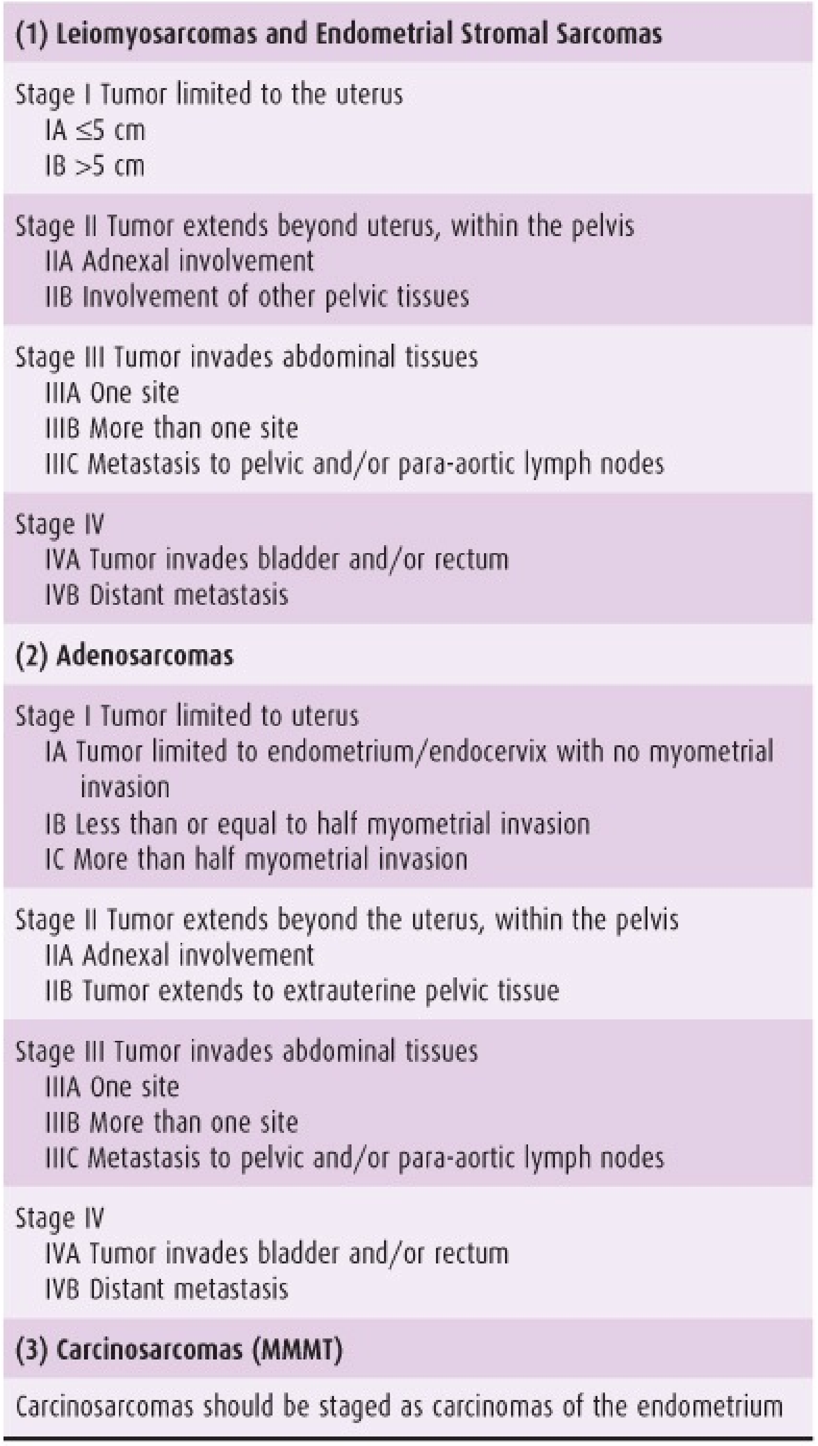


Leiomyosarcoma (tumors of the uterine smooth muscle)
Endometrial stromal sarcoma (pure homologous endometrial sarcoma) Undifferentiated Low grade (endolymphatic stromal myosis)
Malignant mixed mesodermal tumor (mixed epithelial/stromal tumors) Homologous carcinosarcoma Heterologous carcinosarcoma
Adenosarcoma (mixed epithelial/stromal tumors) Homologous Heterologous

Pure heterologous sarcomas, such as rhabdomyosarcoma, chondrosarcoma, osteosarcoma, and liposarcoma, are extremely rare. Other uterine sarcomas, like hemangiosarcomas, fibrosarcomas, reticulum cell sarcomas, and lymphosarcomas, are indistinguishable from identical sarcomas elsewhere in the body and are therefore not considered specialized tumors of the uterus.

Recently, a new FIGO classification and staging system has been specifically designed for uterine sarcomas in an attempt to reflect their different biologic behavior (Table 49–3). Carcinosarcomas should continue to be staged as carcinomas of the endometrium.

Table 49–3. International Federation of Gynecology and Obstetrics (FIGO) staging of uterine sarcomas (2009).



(1) Leiomyosarcomas and Endometrial Stromal Sarcomas	
Stage I	Tumor limited to the uterus
IA	≤5 cm
IB	>5 cm
Stage II	Tumor extends beyond uterus, within the pelvis
IIA	Adnexal involvement
IIB	Involvement of other pelvic tissues
Stage III	Tumor invades abdominal tissues
IIIA	One site
IIIB	More than one site
IIIC	Metastasis to pelvic and/or para-aortic lymph nodes
Stage IV	
IVA	Tumor invades bladder and/or rectum
IVB	Distant metastasis
(2) Adenosarcomas	
Stage I	Tumor limited to uterus
IA	Tumor limited to endometrium/endocervix with no myometrial invasion
IB	Less than or equal to half myometrial invasion
IC	More than half myometrial invasion
Stage II	Tumor extends beyond the uterus, within the pelvis
IIA	Adnexal involvement
IIB	Tumor extends to extrauterine pelvic tissue
Stage III	Tumor invades abdominal tissues
IIIA	One site
IIIB	More than one site
IIIC	Metastasis to pelvic and/or para-aortic lymph nodes
Stage IV	
IVA	Tumor invades bladder and/or rectum
IVB	Distant metastasis
(3) Carcinosarcomas (MMMT)	
Carcinosarcomas should be staged as carcinomas of the endometrium	

MMMT, malignant mixed mesodermal tumor.

Major Types of Sarcomas of the Uterus

A. Leiomyosarcomas

LMSs make up 35–40% of all uterine sarcomas and 1–2% of all uterine cancers. LMS usually occurs between ages 25 and 75 years, with a mean incidence at about age 50 years. Younger patients with this disease seem to have a more favorable outcome than postmenopausal women. Like the benign leiomyomas, LMSs are 1.5 times more common in African American patients than in the white population. Leiomyomas are commonly identified in uteri containing LMSs, but the incidence of malignant transformation of a leiomyoma is only 0.1–0.5%. Only approximately 5–10% of LMSs are reported to originate in a leiomyoma.

Abnormal uterine bleeding is the most common symptom of LMS, occurring in approximately 60% of patients; pelvic or abdominal pain and discomfort are reported by approximately 50% of all patients. Only approximately 10% of patients are aware of an abdominal mass. The deeply situated intramural position of most tumors impedes diagnosis by D&C, which is accurate in only 25% of cases. Abnormal cells might be identified on Pap smear. The diagnosis is more commonly made after pathologic analysis of a hysterectomy specimen.

LMSs spread by contiguous growth, invading the myometrium, cervix, and surrounding supporting tissues. Lymphatic dissemination is common in the late stages. Pelvic recurrence and peritoneal dissemination following resection are also common. In the more malignant types, hematogenous metastasis to the lungs, liver, kidney, brain, and bones probably occurs early but is clinically evident only in the lungs until the advanced stages.

The clinical behavior of the tumor is generally aggressive, with some correlation with the number of mitotic figures identified on microscopic examination. Low-grade LMSs are those with <5 mitoses per 10 high-power fields, with pushing rather than infiltrating margins. LMSs with 5–10 mitoses per 10 high-power fields are considered to be of intermediate grade, and tumors with mitotic counts >10 per 10 high-power fields are highly malignant and usually lethal; <20% of these patients are alive at 5 years. Tumor size and mitotic index are useful prognostic indicators, but other factors have to be taken into account. An invasive pattern, particularly into the blood and lymphatic vessels and the surrounding smooth muscle, is important. By contrast, cellular characteristics, such as atypia, anaplasia, and giant cells, are not accurate prognosticators of aggressive behavior. Clinically, the most reliable prognostic feature of LMS is stage. The prognosis of patients with extrauterine disease is much worse compared to patients with disease confined to the uterus. Patients with LMS mostly present at stage I. A pelvic MRI can help delineate the extent of uterine involvement and can help in the preoperative determination of a benign versus a malignant smooth muscle tumor by evidence of scattered foci of hemorrhage and necrosis and absence of calcifications. Benign leiomyomata have sharp boundaries, whereas sarcomas have infiltrating borders on MRI imaging.

Other unusual smooth muscle tumors of the uterus such as benign metastasizing leiomyoma and intravenous leiomyomatosis should be considered low-grade LMS or smooth muscle tumors of uncertain malignant potential (STUMP). Although they are histologically benign, they are notorious for local recurrence and can cause death by compression of contiguous or distant vital structures. Intravenous leiomyomatosis has been known to grow up the vena cava into the right atrium, impeding venous return and precipitating congestive heart failure. Because of their slow growth, they can frequently be controlled by repeated local excision. The metastatic lung lesions of benign metastasizing leiomyoma have disappeared following resection of the primary lesion in some cases, perhaps indicating hormone dependency.

B. Endometrial Sarcomas

1. Endometrial stromal sarcomas—ESSs make up 8% of all sarcomas. They occur predominantly in postmenopausal women. Patients with these tumors most commonly present with bleeding or lower abdominal discomfort and pain. The diagnosis can be made accurately by D&C in approximately 75% of cases. Although no etiologic relationship to hormones has been established, a small number of metastatic lesions have responded to progesterone therapy.

ESSs can be divided into 3 distinct subtypes: low-grade ESS, endometrial stromal nodules, and undifferentiated endometrial sarcomas previously known as high-grade ESS. The indolent low-grade ESSs—also called endolymphatic stromal myosis—have fewer than 10 mitoses per 10 high-power fields, with infiltrating margins and myometrial invasion. A benign form, the stromal nodule, contains pushing rather than infiltrating margins and fewer than 3 mitoses per 10 high-power fields, with no vascular or myometrial invasion.

The mean age at onset for low-grade ESS is 5–10 years earlier than for undifferentiated endometrial sarcomas. This tumor infiltrates surrounding structures and is characterized by indolent growth and a propensity to vascular invasion. Patients frequently present with yellowish wormlike extensions into the periuterine vascular spaces. Under such circumstances, it may be confused grossly with intravenous leiomyomatosis, as previously described. It tends to recur late, sometimes after 5–10 years, and can often be controlled by repeated local excisions. Low-grade ESSs frequently express estrogen and progesterone receptors. Adjuvant targeted hormonal treatment can be considered to reduce recurrence.

The undifferentiated endometrial sarcoma displays infiltrating margins and vascular and myometrial invasion and contains more than 10 mitoses per 10 high-power fields. These tumors are highly malignant and are associated with a poor prognosis, particularly when they extend beyond the uterus at the time of diagnosis. They spread by contiguous growth via the serosal uterine surface and lymphatic metastasis. Distant hematogenous metastases to the lungs and liver are usually a late event.

2. Carcinosarcoma (malignant mixed mesodermal tumors)—MMMTs account for 50% of all uterine sarcomas and 3–6% of all uterine tumors. They characteristically occur in postmenopausal women, with the exception of embryonal rhabdomyosarcoma of the cervix or vagina (sarcoma botryoides), which occurs also in infants and children. The incidence is about 3 times greater in black than in white women. Radiation therapy may be a predisposing cause, but the etiology of MMMTs is unknown. Many published series are available containing a significant number of patients with a history of pelvic radiation for benign or malignant conditions (Fig. 49–6).

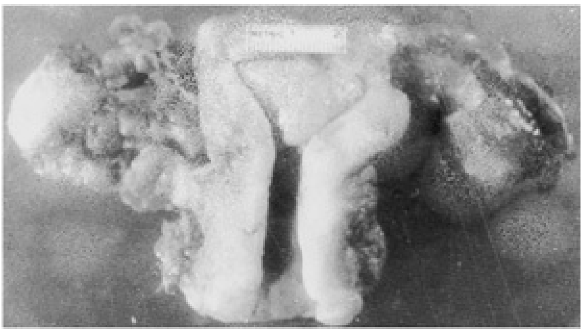

Figure 49–6. Mixed sarcoma of the uterine fundus. Prior full-pelvic radiation therapy had little effect on the tumor.

As with the other types, the presenting symptom of MMMT is usually bleeding. Abdominal discomfort and pain or a large, bulky polypoid mass filling the uterine cavity and prolapsing through the cervical os also occurs. Because the tumors are endometrial in origin, approximately 75% can be diagnosed accurately by D&C. Histologically, MMMTs are usually highly anaplastic, with many bizarre nuclei and mitotic figures. They contain a carcinomatous or epithelial component and a sarcomatous component, hence the term *malignant mixed mesodermal tumor*, or carcinosarcoma. The carcinomatous component is usually serous (two-thirds) or endometrioid (one-third), and rarely clear cell, mucinous, or squamous cell carcinoma. If the sarcomatous component is derived from the smooth muscle tissue of the uterus, they are called homologous MMMTs. If the sarcomatous component contains bone, striated muscle, cartilage, or fat, the term heterologous MMMT is applied. The most common heterologous elements are malignant skeletal muscle or cartilage resembling either pleomorphic rhabdomyosarcoma or embryonal rhabdomyosarcoma. Presence of the heterologous elements is a poor prognostic factor in stage I patients.

MMMTs spread by contiguous infiltration of the surrounding tissues and by early hematogenous and lymphatic dissemination. The metastatic deposits are usually composed of the epithelial malignant glands, but sarcomatous elements have been identified in some cases. The prognosis depends mainly on the extent of the tumor at the time of primary surgery; there are virtually no long-term survivors among those whose tumor has extended beyond the confines of the uterus at the time of diagnosis. Treatment includes total abdominal hysterectomy with bilateral salpingo-oophorectomy, lymphadenectomy, and tumor debulking if necessary and technically feasible. Active chemotherapeutic agents include cisplatin, ifosfamide, doxorubicin, epirubicin, carboplatin, paclitaxel, and gemcitabine.

C. Adenosarcomas

Adenosarcoma is a distinctive mixed müllerian tumor of low malignant potential that accounts for 1–2% of uterine sarcomas. It arises from the endometrium and is composed of a combination of benign-appearing glands and a stromal sarcoma or fibrosarcoma. Adenosarcomas usually occur in the postmenopausal age group but have been reported in adolescents and women of reproductive age. Bleeding is the most common symptom and has been associated with prior tamoxifen or radiation therapy. Recurrence occurs in 25% of patients and is usually late. The primary treatment is total abdominal hysterectomy and bilateral salpingo-oophorectomy. Postoperative radiation therapy is recommended for those tumors with deep myometrial invasion.

D. Other Uterine Sarcomas

Embryonal rhabdomyosarcoma of the cervix (sarcoma botryoides), which occurs in infants and children, was previously lethal. However, combination therapy using surgery, radiation, and chemotherapy has considerably improved the outlook for these patients.

Fibrosarcoma, hemangiosarcoma, reticulum cell sarcoma, hemangiopericytoma, and other esoteric and bizarre uterine sarcomas are rare. In general, these sarcomas behave like the other intermediate-grade uterine sarcomas, but treatment must be individualized according to age, histologic type, and the patient’s state of health.

Prevention

Indiscriminate use of radiation therapy for benign conditions in the pelvis should be avoided, as several clinical studies have suggested an etiologic role of pelvic radiation in the development of MMMT.

Clinical Findings

A. Symptoms & Signs

Abnormal uterine bleeding is the most common manifestation of uterine sarcoma. Other recurring complaints include pelvic discomfort or pain, constipation, urinary frequency and urgency, and the presence of a mass low in the abdomen. Uterine sarcoma should be suspected in any nonpregnant woman with a rapidly enlarging uterus. Severe uterine cramps may exist if the tumor has prolapsed into the endometrial cavity or through the cervix. Pelvic examination may reveal the characteristic grapelike structures of sarcoma botryoides protruding from the cervix or the presence of velvety fronds of ESS in the cervical canal. A necrotic fungating mass at the vaginal apex should suggest an infarcted myoma, LMS, or MMMT. The uterus is usually enlarged and often soft and globular. If the cancer has involved the cervix, cul-de-sac, or cardinal ligaments, fixation or asymmetry of the parametria may be found. In advanced cases, inguinal or supraclavicular node metastases may be evident. Patients with advanced uterine sarcomas may present with a large omental mass or ascites secondary to abdominal carcinomatosis.

B. Laboratory Findings

Standard laboratory evaluation of patients with uterine sarcoma should include a complete blood count and urinalysis, liver function studies (especially serum alkaline phosphatase, prothrombin time, and serum lactic dehydrogenase), blood urea nitrogen, and serum creatinine. CA-125 may be elevated. Estrogen and progesterone receptor analysis may indicate which patients are likely to respond to hormone therapy. Office EMB or punch biopsy of a prolapsed vaginal mass is helpful only if positive.

C. Radiograph Findings

The chest radiography may contain metastatic coin lesions characteristic of uterine sarcomas. Because uterine sarcomas commonly metastasize to the lung, a chest computed tomography (CT) scan should be considered when the routine films are negative, particularly before any radical extirpative surgery in the pelvis is performed. CT scan of the abdomen and pelvis is helpful in assessing the extent of abdominal disease, evaluating the kidneys for hydronephrosis, identifying enlarged retroperitoneal nodes, and identifying liver metastases. MRI scans are not routinely performed but may provide an accurate preoperative assessment of uterine size and degree of involvement.

D. Special Examinations

Pelvic ultrasonography may confirm the presence of a pelvic mass or help to differentiate an adnexal from a uterine mass in the obese patient. Sigmoidoscopy should always be performed in older women, and in young women if gastrointestinal bleeding or masses suspected of being malignant are present. Cystoscopy is indicated in locally advanced disease or in the presence of gross or microscopic hematuria.

Differential Diagnosis

The clinical diagnosis of uterine sarcoma is frequently overlooked. Diagnostic accuracy can be increased if the physician keeps these tumors in mind while investigating any pelvic mass. The tumor frequently does not present the classic picture of abnormal bleeding accompanied by a symmetrically enlarged soft globular uterus. It can masquerade as any condition causing uterine enlargement or a pelvic mass; of these, pregnancy, leiomyoma, adenomyosis, and adherent ovarian neoplasms or pelvic inflammatory disease are most likely to cause misinterpretation. When cytologic studies, EMB, or

D&C fail to provide the diagnosis—a situation not uncommon with LMS—laparotomy is necessary. At laparotomy, thorough evaluation is critical to the future management of the patient with uterine sarcoma and must include inspection (where possible) and palpation of all abdominal viscera, peritoneal and mesenteric surfaces, liver, both diaphragms, and retroperitoneal structures, especially the pelvic and aortic lymph nodes. Cytologic examination of peritoneal exudate is indispensable for treatment planning; if no free fluid is present, samples may be obtained by instilling 50–100 mL of normal saline into the abdominal cavity (pelvic washings). If a sarcoma is identified on frozen section of the hysterectomy specimen, suspicious lymph nodes should be removed. This information, gathered at the time of the initial exploration and carefully documented in the operative records, is critical for identification and staging of the neoplasm and for predicting outcome.

The pathologic diagnosis of uterine sarcoma is often extremely difficult and may require consultation with a gynecologic pathologist familiar with these tumors. As each cancer becomes more anaplastic, the parent cell or tissue becomes more difficult to identify histologically. Because proper treatment is predicated on accurate histologic diagnosis, every effort should be expended to identify the cell of origin.

Complications

Severe anemia from chronic blood loss or acute hemorrhage may be present. The severity and extent of other complications caused by uterine sarcomas are directly related to the size and virulence of the primary tumor. A pedunculated mass may protrude into the uterine cavity or prolapse through the cervix, causing bleeding or uterine cramps as the uterus attempts to expel the tumor. Infarction with subsequent infection and sepsis may ensue. Rupture of the uterus as a consequence of rapidly growing uterine sarcomas has been reported. Obstructed labor and postpartum uterine inversion secondary to endometrial sarcomas have also been noted. Extensive pulmonary metastases can produce hemoptysis and respiratory failure. Ascites is common in advanced disease with peritoneal metastases.

A wide variety of complications has been reported secondary to pressure or compression of a neighboring viscus or resulting from extension or metastases to other vital structures. Urethral elongation caused by stretching of the bladder over a rapidly growing mass can simultaneously produce obstruction and loss of sphincter control, with subsequent overflow incontinence. Colon compression may result in ribbon stools and, eventually, complete bowel obstruction. Ureteral obstruction is common, especially with recurrent pelvic sarcomas. Urinary diversion or colostomy may be required prior to treatment if life-threatening viscus obstruction is present in an untreated patient, but urinary diversion should not be performed unless there is some hope for cure or meaningful palliation, because it precludes a painless death from uremia.

Treatment

A. Emergency Measures

Hemorrhage from uterine sarcomas can be severe and requires prompt attention. In acute hemorrhage, blood volume should be replaced rapidly, using packed red blood cells, crystalloid solutions, volume expanders, and fresh-frozen plasma.

Emergency D&C should be used only to obtain tissue for analysis. Vigorous curettage is likely to aggravate or provoke bleeding. High-dose bolus radiation is a more reliable and safe method of controlling bleeding. A dose of 400–500 cGy administered daily to the whole pelvis over 2–3 days usually controls acute hemorrhage; this does not appreciably interfere with future management. If these measures are not successful, emergency embolization or ligation of the hypogastric arteries sometimes controls hemorrhage when hysterectomy is not indicated or technically feasible.

B. Surgical Measures

Extirpative surgery provides the best chance for long-term palliation or cure for patients with uterine sarcomas. Surgery is the cornerstone of the treatment plan and should be the central focus of attack against these cancers.

Because low-grade uterine sarcomas (some LMSs, endolymphatic stromal myosis, intravenous leiomyomatosis) have a propensity for isolated local spread and central pelvic recurrence, such patients should be considered for radical hysterectomy and bilateral salpingo-oophorectomy. The benefits of this type of therapy have not been conclusively shown, but, theoretically, the problem of local recurrence should be improved by more radical excision of the primary tumor. Lymph node metastases in these low-grade tumors are negligible; consequently, pelvic lymphadenectomy can be reserved for patients with enlarged or suspicious nodes. Pelvic recurrences of low-grade uterine sarcomas have been successfully treated by repeated excisions of all resectable tumor. Patients have been known to survive for many years following this type of conservative treatment. Partial or complete pelvic exenteration may occasionally be useful for recurrence of indolent tumors.

The high-grade uterine sarcomas (some LMSs, ESSs, all MMMTs) display early lymphatic, local, and hematogenous metastases, even when apparently confined to the uterus. For this reason, radical surgery has been abandoned in favor of simple total abdominal hysterectomy and bilateral salpingo-oophorectomy preceded or followed by adjunctive radiation therapy. At the time of surgical exploration, a thorough examination and evaluation of the abdominal contents must be performed and documented. Cytologic specimens and omental tissue should be obtained, and suspicious papillations, excrescences, and adhesions should be excised for pathologic analysis. A thorough staging procedure is important for prognosis and a postoperative treatment plan.

When uterine sarcomas recur in the lung and the metastatic survey is negative, unilateral isolated metastases can be excised after a chest CT scan has ruled out other lesions not apparent on the routine chest radiograph. Considering all sources, resection of isolated sarcoma metastases to the lung carries about a 25% 5-year cure rate.

C. Chemotherapy

Adjuvant single-agent doxorubicin has been shown to have a 25% response rate for LMS. Recent data suggest that use of combination gemcitabine and docetaxel in LMS improves progression-free survival and reduces risk of recurrence.

Because of the high hormone receptor content in ESS, adjuvant progestin or aromatase inhibitors are recommended. For receptor-negative tumors, doxorubicin- or ifosfamide-based chemotherapy is used. Tamoxifen and estrogen replacement therapy should be avoided in patients with ESS.

Doxorubicin, cisplatin, carboplatin, paclitaxel, gemcitabine, and ifosfamide display significant activity against MMMTs. Cyclophosphamide and vincristine also show activity. Some data suggest that combination chemotherapy is more effective than single-agent therapy. In advanced or metastatic disease, adjuvant combination chemotherapy is recommended. Trabectedin, a new agent, has been actively evaluated in sarcomas and appears to show some modest promise. Treatment with tyrosine kinase inhibitors like imatinib or sorafenib has shown response in some patients.

D. Radiation Therapy

When used as the only modality of treatment for uterine sarcomas, radiation has produced dismal results—very few survivors are reported in the literature following treatment with radiation therapy alone for any of the uterine sarcomas. Radiation therapy does provide local tumor control and reduces local recurrences when used in combination with surgery for the treatment of some endometrial sarcomas. However, it is unclear whether a combined surgical and radiation approach changes overall survival. Collected data indicate that adjuvant radiation therapy improves the 2-year survival rate in patients with ESS by approximately 20% and may also improve survival for those with MMMTs, although less convincingly. Although an occasional 5-year survivor with LMS has been reported following radiation therapy alone, analysis of large numbers of patients from different institutions does not support its use for these tumors. Nevertheless, in advanced forms of LMS, radiation may prove useful for palliation and control of pelvic symptoms such as massive bleeding or pain.

Prognosis

In determining the prognosis for patients with uterine sarcomas, a constellation of factors must be examined simultaneously. Such considerations as the patient’s age, state of health, and ability to withstand major surgery or radiation therapy (or both) must be evaluated. The most important clinical characteristic—and probably the overriding prognostic feature affecting the prognosis of these patients—is the stage of the disease at the time of diagnosis. In the high-grade sarcomas (LMS and mixed endometrial sarcoma), the presence of tumor outside the uterus at the time of diagnosis is a clear prognostic omen: Fewer than 10% of patients survive 2 years. Even when the disease is apparently limited to the uterus, the prognosis is poor: 10–50% survive 5 years. In intermediate-grade LMS and undifferentiated endometrial sarcoma, the outcome is improved, with up to 80–90% of patients surviving 5 years if the disease is clinically limited to the uterus at the time of surgery. Low-grade ESS and low-grade LMS have a generally favorable outcome: 80–100% of patients survive 5 years following complete excision of the uterus. Low-grade stromal tumors have been known to recur locally after 10–20 years; this confuses the survival statistics. Undoubtedly, these patients must be followed closely for life.

Karen Purcell, MD, PhD

OVARIAN CANCER

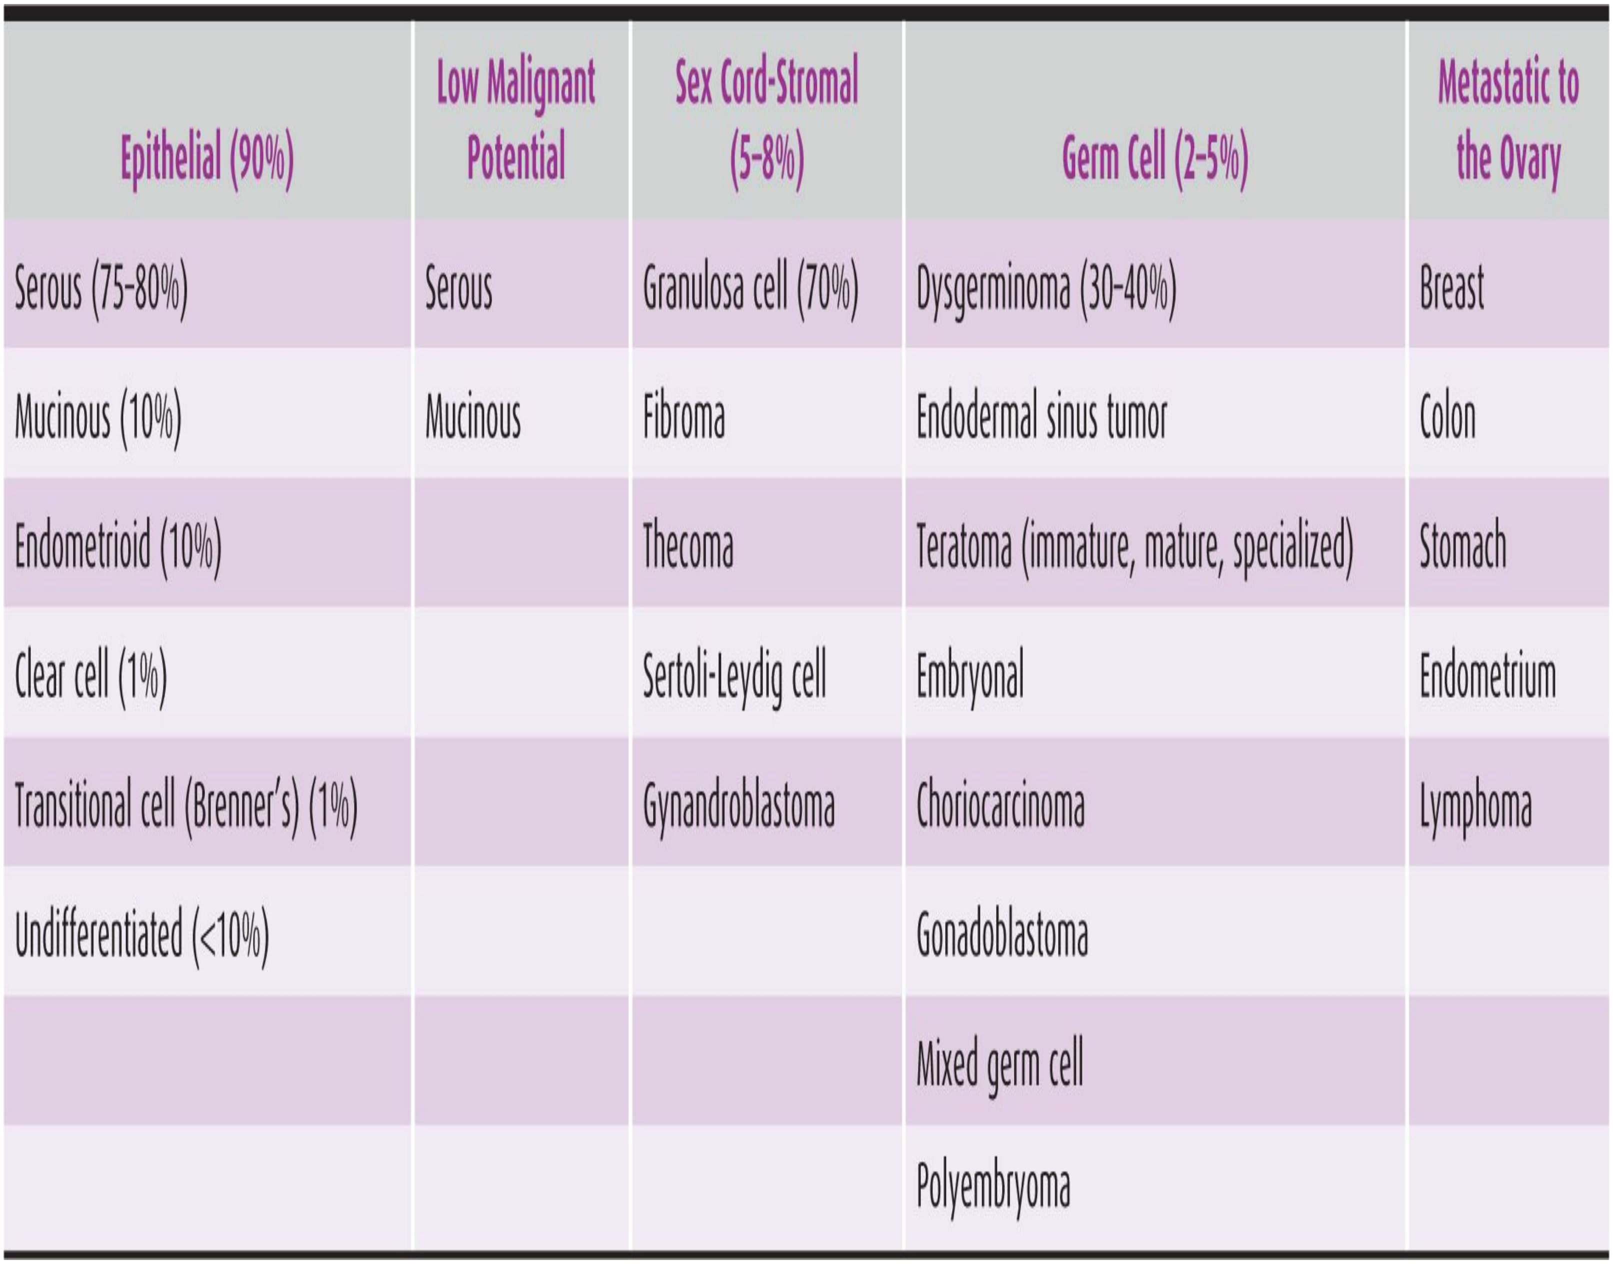
ESSENTIALS OF DIAGNOSIS

- Early-stage ovarian cancer often presents with vague and ill-defined symptoms.
- Late-stage disease presents with abdominal pain or bloating, early satiety, and/or urinary urgency or frequency.
- The majority of women present with late-stage disease.
- Pelvic ultrasound findings show complex adnexal mass(es).
- The mean age of diagnosis for epithelial ovarian cancer is in the mid-50s, with the majority diagnosed between ages 40 and 65.
- Hereditary causes of ovarian cancer diagnosed at earlier age by almost a decade.
- Nonepithelial ovarian tumors are more common in girls and younger women.

Pathogenesis

Although there are many different cell types present in the normal adnexa, the majority of adnexal cancers arise from the surface epithelial cells of the ovary (epithelial ovarian cancer [EOC]). Fewer ovarian cancers develop from the remaining cell types (sex cord-stromal, germ cell, or mixed cell type tumors) (Table 50–1), and even fewer adnexal cancers arise from the fallopian tubes, although recent evidence has shown that they account for a greater percentage than previously thought. The specific events leading to the transition of normal tissue to malignancy have not been established, nor has a definitive precursor lesion been identified. For sporadic tumors, molecular events leading to the inactivation of tumor suppressor genes (PTEN, p16, p53) or the activation of oncogenes (HER-2, c-myc, K-ras, Akt) have been described. For the small proportion of genetically heritable cancers, germline mutations in BRCA1, BRCA2, and other genes have been described, but the molecular pathway leading to tumorigenesis has not been elucidated. It is likely that epigenetic events also contribute to the transformation to cancer.

Table 50–1. Categories of ovarian cancer.



Epithelial (90%)	Low Malignant Potential	Sex Cord-Stromal (5–8%)	Germ Cell (2–5%)	Metastatic to the Ovary
Serous (75–80%)	Serous	Granulosa cell (70%)	Dysgerminoma (30–40%)	Breast
Mucinous (10%)	Mucinous	Fibroma	Endodermal sinus tumor	Colon
Endometrioid (10%)		Thecoma	Teratoma (immature, mature, specialized)	Stomach
Clear cell (1%)		Sertoli-Leydig cell	Embryonal	Endometrium
Transitional cell (Brenner's) (1%)		Gynandroblastoma	Choriocarcinoma	Lymphoma
Undifferentiated (<10%)			Gonadoblastoma	
			Mixed germ cell	
			Polyembryoma	

A. Epithelial Ovarian Cancer

The most prominent theory for the development of EOC associates the repeated trauma and repair to the ovarian epithelium during normal ovulation with subsequent genetic alterations and further progression to malignant transformation. This is supported by evidence that suppression of ovulation leads to a decreased incidence of EOC. A second theory invokes high serum concentrations of gonadotropins, estrogen, androgen, or inflammatory agents, leading to epithelial proliferation and subsequent transformation.

EOCs account for more than 90% of all malignant ovarian tumors and include serous, mucinous, endometrioid, clear cell, transitional cell types, and undifferentiated neoplasms. **Serous cystadenocarcinomas** represent 75–80% of EOCs. They present with extraovarian spread 85% of the time and are bilateral in half the cases. The tumors are typically large at the time of diagnosis, most being larger than 15 cm in diameter, with the unilocular or multilocular cystic structures containing papillae projecting into the lumen. Histologic sections resemble the endosalpinx with nuclear atypia in the stratified squamous epithelium. Psammoma bodies with irregular lamellar calcifications are frequently seen in these tumors. The grade of differentiation is based on the degree of preservation of the papillary architecture, the majority of which is poorly differentiated at the time of diagnosis.

Mucinous cystadenocarcinomas represent 10% of all EOCs, are typically unilateral, and are notable for the ability to attain very large sizes. Histologic sections resemble endocervical epithelium with large hyperchromatic nuclei and prominent nucleoli. The variability within the tumor requires extensive sampling to determine the most malignant focus. Given the similar cell architecture, they are often difficult to distinguish from metastatic tumors from the colon, appendix, endocervix, and pancreas. Thus after diagnosis of a mucinous tumor, an evaluation of the gastrointestinal (GI) tract is recommended.

Mucinous tumors, whether from ovarian origin or appendix, can be associated with a condition called pseudomyxoma peritonei where progressive accumulation of mucin within the abdominal cavity occurs and often leads to significant protracted morbidity secondary to bowel obstruction.

Endometrioid neoplasms of the ovary occur bilaterally in 30–50% of cases and account for 10% of EOCs. Histologic sections reveal an adenomatoid pattern with the degree of differentiation determined by the extent to which the glandular architecture is preserved. Rarely, this tumor arises within a focus of endometriosis, but not uncommonly, patients with endometrioid tumors of the ovary will have a synchronous endometrial carcinoma.

Clear cell carcinoma of the ovary, or mesonephroid carcinoma, accounts for <1% of EOCs. They typically present at a smaller size than the serous or mucinous cyst-adenocarcinomas. These tumors are aggressive and may be associated with hypercalcemia or hyperpyrexia. Histologic sections show features of “clear cells,” similar to renal cell carcinomas; occasionally, they are difficult to differentiate from mucinous neoplasms, although a weak staining pattern with the periodic acid-Schiff reaction is useful.

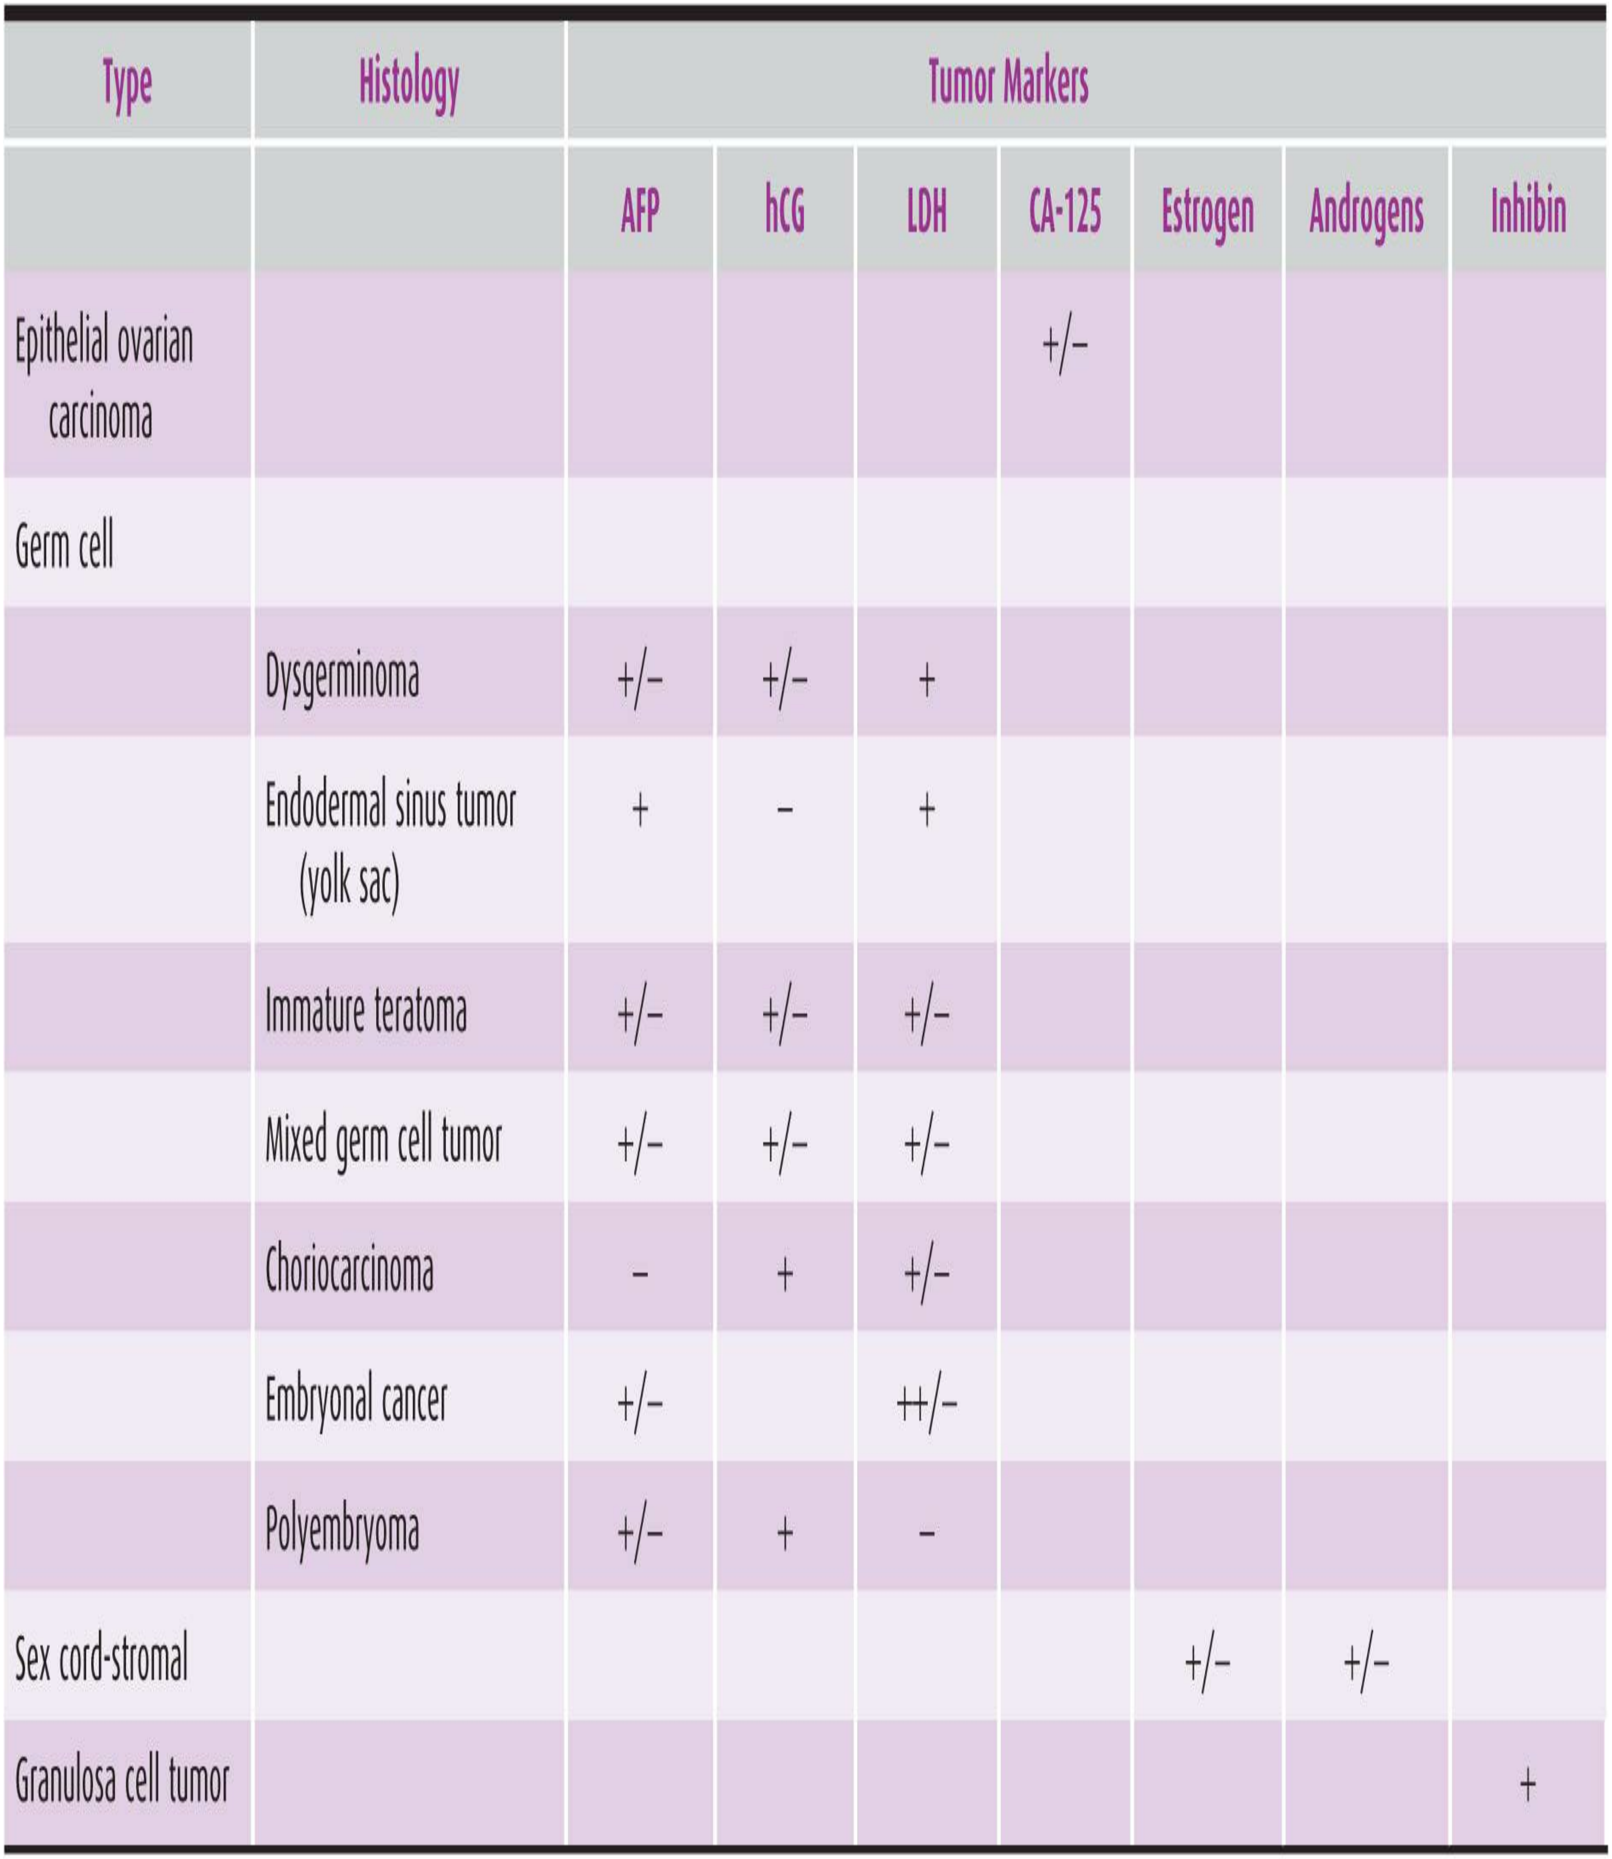
Transitional cell carcinoma, or Brenner’s tumor, accounts for <1% of EOCs. Histologic sections resemble low-grade transitional cell carcinoma of the urinary bladder. Compared to other types of EOCs, these patients have a poorer prognosis.

Undifferentiated carcinomas account for <10% of EOCs and are characterized by the absence of any microscopic features to define them as another type.

B. Germ Cell Tumors of the Ovary

Although EOCs typically occur in women near or in menopause, germ cell tumors tend to present in the second and third decades of life. Also different from EOCs, these tumors often have a good prognosis. Because they arise from the germ cell elements of the ovary, they often secrete hormones or proteins that can be used to monitor response to therapy (Table 50–2).

Table 50–2. Biologic markers associated with ovarian tumors.



Type	Histology	Tumor Markers						
		AFP	hCG	LDH	CA-125	Estrogen	Androgens	Inhibin
Epithelial ovarian carcinoma					+/−			
Germ cell								
	Dysgerminoma	+/−	+/−	+				
	Endodermal sinus tumor (yolk sac)	+	−	+				
	Immature teratoma	+/−	+/−	+/−				
	Mixed germ cell tumor	+/−	+/−	+/−				
	Choriocarcinoma	−	+	+/−				
	Embryonal cancer	+/−		++/−				
	Polyembryoma	+/−	+	−				
Sex cord-stromal						+/−	+/−	
Granulosa cell tumor								+

AFP, α fetoprotein; hCG, human chorionic gonadotropin; LDH, lactate dehydrogenase.

Dysgerminomas account for 30–40% of the germ cell tumors. They occur in young females and most often are unilateral at presentation. Although they are solid tumors, they may have areas of softening due to degeneration. At the time of surgery, they appear smooth and thinly encapsulated, with a brown or grayish-brown color. On histologic sections, nests of germ cells, which appear as large, rounded cells with central nuclei, are surrounded by undifferentiated stroma. If lymphocytic infiltration is present, it is considered a favorable prognostic indicator.

Immature teratomas are the malignant counterpart of mature cystic teratomas, or dermoids, and are the second most common germ cell malignancy. Histologic sections show a disordered collection of tissues derived from all 3 germ layers, with some components having an immature, embryonic appearance. The grade of the tumor is determined by the amount of immature neural tissue present, which correlated with prognosis and guidelines for chemotherapy. Typical presentation occurs in females <20 years old. They are usually unilateral, although the contralateral ovary may contain a mature teratoma. These tumors often secrete α fetoprotein (AFP).

Endodermal sinus tumors, or yolk sac tumors, are the third most common germ cell tumor. This is the most rapidly growing neoplasm that occurs at any site, and patients may present with an acute abdomen given they are friable, necrotic, and often hemorrhagic. These tumors are almost always bilateral and, on histologic section, resemble the primitive gut and liver; Schiller-Duval bodies, which show a single papilla lined by tumor cells with a central blood vessel, and the production of AFP are characteristic.

Embryonal carcinoma presents at a mean age of 15 years old and has a highly aggressive growth pattern. Histologic sections show solid sheets of large polygonal cells with pale, eosinophilic cytoplasm that give the appearance of a syncytium. Biologic markers of AFP, human chorionic gonadotropin (hCG), and estrogens are often secreted.

Choriocarcinoma of the ovary is a rare germ cell tumor. Unlike gestational choriocarcinoma, this primary ovarian tumor produces lower levels of hCG and may cause precocious puberty, uterine bleeding, or amenorrhea. Histologic sections show cytotrophoblasts, intermediate trophoblasts, and syncytiotrophoblasts.

Gonadoblastoma is a rare germ cell tumor that presents in the second decade of life and is located more commonly in the right ovary over the left. Patients have abnormal gonadal development with the presence of a Y chromosome. Histologic sections show nests of germ cells and sex cord derivatives surrounded by connective tissue stroma.

Mixed germ cell tumors account for 10% of germ cell neoplasms and contain 2 or more germ cell elements. The most frequent composition includes dysgerminoma and endodermal sinus tumor. Careful sectioning by the pathologist is necessary to determine all different components in order to correctly determine the chemotherapeutic regimens.

Polyembryoma is extremely rare and is seen in premenarchal girls with signs of pseudopuberty. It secretes AFP and hCG and histologically will contain the 3 somatic layers of early embryonic differentiation.

C. Sex Cord-Stromal Tumors of the Ovary

Sex cord-stromal tumors of the ovary account for 5–8% of all ovarian malignancies. **Granulosa cell tumors** account for 70% of this class of tumors. Because they secrete high levels of estrogen, they may cause precocious puberty in young girls or adenomatous hyperplasia and vaginal bleeding in postmenopausal women. Microscopically, the granulosa cells exhibit characteristic grooved or coffee bean nuclei; Call-Exner bodies represent multiple small cavities that contain eosinophilic fluid. Theca cells are present in varying amounts. Granulosa cell tumors are characterized by inhibin secretion, and this tumor marker can be used for monitoring tumor progression and response to therapy.

Like granulosa cell tumors, ovarian **thecomas** are associated with hyperestrogenism. This mostly benign ovarian tumor consists of lipid-laden stromal cells, which confer a yellow appearance on cut section.

Sertoli-stromal cell tumors are rare, consisting of testicular structures at different stages of development and therefore are usually virilizing. The average age at diagnosis is 25, and they are rarely bilateral. Microscopically, both Sertoli and Leydig cells are present. A variety of architectural patterns have been described.

D. Borderline Tumors of the Ovary

For 10% of women with malignant ovarian neoplasms, the histologic pattern shows atypical epithelial proliferation without stromal invasion. These tumors are termed serous tumors of low malignant potential (LMP) or noninvasive borderline tumors. They tend to have similar genetic alterations and molecular pathways to low-grade carcinomas, which are different from those seen with high-grade serous carcinomas. Although this has led some to hypothesize that the borderline tumors and low-grade carcinomas are a part of a progression to high-grade carcinomas, most believe they are 2 separate entities rather than a continuum of tumor progression often seen with other gynecologic malignancies. There is no evidence that low-grade serous carcinomas arise from serous tumors of LMP.

E. Metastatic Disease to the Ovary

Approximately 5% of ovarian tumors are due to metastases, with the primary tumor being located in the female genital tract, breast, or gastrointestinal tract. Traditionally, Krukenberg tumors signaled metastases from the stomach, although now the term is used more loosely to define ovarian tumors from any location in the gastrointestinal tract.

F. Hereditary Ovarian Cancer Syndromes

Although the majority of ovarian cancers are defined as sporadic, approximately 10–15% of cases are attributed to genetic causes. Breast–ovarian cancer syndrome is one such cause, with the majority of patients having mutations in BRCA1 or BRCA2. Germline mutations in BRCA1 confer a 35–45% lifetime risk of ovarian cancer, whereas BRCA2 mutations confer a 15–24% risk of ovarian cancer. Within the United States, approximately 1 in 800 women are carriers, and this rate is increased for women of Ashkenazi Jewish, French Canadian, or Icelandic descent.

A second syndrome is Lynch II syndrome, or hereditary nonpolyposis colorectal cancer (HNPCC). These women have a 12% risk of developing ovarian cancer and are also at increased risk of developing cancers of the colon, breast, and endometrium. Several gene mutations have been detected in families with Lynch II, including PMS1, PMS2, MSH2, MSH3, MSH6, and MLH1. Each of these is known to be involved in DNA mismatch repair.

G. Cancer of the Fallopian Tubes

Primary carcinoma of the fallopian tube is the least common cancer arising in the female genital tract, accounting for approximately 0.3% of all such cancers. Fallopian tube cancers are similar to EOC with regard to clinical presentation and biologic behavior. At least 95% of all primary carcinomas of the fallopian tube are papillary carcinomas. Bilaterality is found in 40–50% of cases, and this is believed to represent synchronous neoplasms rather than metastatic disease from one tube to the other. Grossly, the affected tube is fusiform or sausage-shaped. On initial inspection, these neoplasms resemble pyosalpinx or tubo-ovarian inflammatory disease. However, there is usually little associated serosal reaction with adhesion formation, as is noted with an inflammatory process.

Classically, the neoplastic fallopian tube contains solid or necrotic cancer tissue and a dark-brown or serosanguinous fluid. The fimbriated end of the fallopian tube is patent in as many as 50% of cases, and often tumor extrudes from the ostium to adhere to adjacent structures. Histologically, papillary carcinomas may exhibit papillary, papillary–alveolar, and alveolar growth patterns. There is no prognostic significance attached to these differences. Of note, women with BRCA1 and BRCA2 mutations are at substantially higher risk of fallopian tube cancer; consequently, women who have prophylactic oophorectomies should also have complete resection of the oviducts.

Prevention

The lifetime risk of ovarian cancer in the general population is 1.7%, and the majority of known risks factors are not amenable to change, with age, early menarche (prior to age 12), and late menopause (after age 50) being the most prominent. Ethnic differences confer variable risk. Caucasians have the highest age-adjusted annual incidence per 100,000 women in the United States with a rate of 14.3. Hispanics are less, at 11.5, then African-Americans at 10.1 and Asians at 9.7. Infertility is also a risk factor, whereas fertility treatment is unlikely to be a risk factor. Endometriosis is an independent risk factor of EOC; malignant transformation occurs in approximately 2.5% of patients, who are typically younger. The prognosis is typically better because the tumors are more often well-differentiated, low-stage carcinomas. Nulligravidity is a major risk factor for EOC.

Certain protective factors have been identified. The use of oral contraceptive pills (OCPs) decreased the risk of ovarian cancer, with increasing protection conferred by longer duration of use. The risk is reduced to half by 15 years of use, and the protection persists after discontinuing medication, although the effects become attenuated over time. Low-dose OCPs, with ≤ 35 μg of ethinyl estradiol are as effective as the higher dose OCPs. Women who have undergone tubal ligation were found to have a decreased risk by about a third to a half, with the effect being synergistic with a history of OCP use. However, caution must be taken when suggesting this as a preventive measure, especially in patients with hereditary syndromes because occult malignancies within the fallopian tubes are often present in women carrying a genetic mutation. Breastfeeding and progesterone use have also been shown to have a protective effect.

One environmental factor, current or past cigarette smoking, is known to increase the risk of mucinous ovarian cancer but not other types of EOC. The contribution of diet is uncertain, as most published studies have potential biases. The effects of exercise are also without a clear relationship to the risk of ovarian cancer. Obesity may lead to an increased risk of ovarian cancer. Previous studies had implicated talc use as leading to a small increased risk of ovarian cancer, although recent studies have not substantiated this.

Prevention by screening methods is currently not possible. The lack of sensitivity or specificity of available testing negates their use to identify women at risk of developing ovarian cancer, and therefore, screening by any modality is not recommended.

Risk Reduction in Women with Familial Ovarian Cancer Syndromes

One of the strongest known risk factors for ovarian cancer is a family history of the disease. A family pedigree of at least 3 generations should be evaluated by a geneticist to provide counseling and consent for potential genetic testing. Although a woman with a family history of ovarian cancer has an increased personal lifetime risk of 2–6%, women with a familial ovarian cancer syndrome are at significantly greater lifetime risk of 25–50%.

Efforts to find effective screening, through use of ultrasound or multimodal techniques encompassing humoral markers, have been disappointing. Thus prophylactic bilateral salpingo-oophorectomy (BSO) has been advocated to reduce the risk for patients with a familial ovarian cancer syndrome. This procedure leads to a significant reduction in the risk of ovarian cancer (80–90% for BRCA carriers) as well as decreased overall mortality; however, the gains in life expectancy are dependent on the age at the time of the procedure, with little gain for women undergoing the procedure after the age of 60. The decision to proceed with prophylactic BSO requires a careful discussion of consequences of infertility and premature menopause. Most suggest performing the procedure as soon as childbearing is complete or by age 35.

An alternative preventive measure may be the use of OCPs containing a high-potency progestin. Although results have been mixed, the majority show an appropriate reduction in risk of ovarian cancer in these women.

Clinical Findings

A. Symptoms & Signs

Early-stage EOC is associated with poorly defined or vague symptoms, which often are not severe enough to prompt a woman to seek medical attention. For later stage disease, which accounts for more than 70% of all diagnoses, the most common symptoms include an increased abdominal girth, pelvic or abdominal pain, bloating, urinary symptoms of frequency or urgency, or early satiety. Occasionally patients will have nausea or anorexia secondary to ascites or bowel metastases. Patients may also present with dyspnea due to pleural effusions. Rarely do patients present with paraneoplastic phenomena such as subacute cerebellar degeneration, seborrheic keratoses (sign of Leser-Trelat), Trousseau’s syndrome (migratory thrombophlebitis), or hypercalcemia of malignancy.

Approximately 15% of reproductive-age patients will present with menstrual abnormalities. Abnormal vaginal bleeding may occur in the presence of a synchronous endometrial carcinoma or as a consequence of metastatic disease to the lower genital tract. Excess androgens or estrogens may be present due to stimulation of normal theca, granulosa, or hilar cells that surround the neoplasm or due to secretion by a germ cell tumor or sex cord-stromal tumor. Ovarian stromal hyperplasia or hyperthecosis may also be associated with excess androgen production.

A pelvic exam will often reveal a solid, fixed, irregular adnexal mass. Unilateral, cystic masses in reproductive-age women are benign in up to 95% of cases. These masses, particularly when <6–8 cm in size, are observed through a menstrual cycle because many represent functional cysts that spontaneously resolve. An enlarging mass or one that is associated with pain merits prompt intervention. A cystic, somewhat immobile adnexal mass may represent a hydrosalpinx or tubo-ovarian abscess. Fixed, bilateral masses and firm masses with nodularity are suggestive of, but not diagnostic of, an ovarian malignancy (Table 50–3).

Table 50–3. Characteristics to be noted on physical exam of a pelvic mass.

	Benign	Malignant
Location	Unilateral	Bilateral
Mobility	Mobile	Fixed
Consistency	Cystic	Solid or firm
Cul-de-sac	Smooth	Nodular

Although several benign lesions may also present with similar findings, the presence of ascites or an upper abdominal mass are very suggestive of ovarian cancer. Abdominal distention is one of the more common findings. The presence of flank fullness and shifting dullness implies the presence of ascites or a large pelvic-abdominal mass. Together with these signs, tympanitic percussion noted over the lateral abdomen is consistent with a large mass that displaces the bowel to the periphery. In contrast, a central tympanitic percussion note is suggestive of ascites. Recent eversion of the umbilicus in a patient with abdominal distention may result from an increase in intraabdominal pressure secondary to ascites.

A rectal exam evaluating the presence of occult blood in the stool should also be performed given the possibility of a primary gastrointestinal malignancy with metastases to the ovary. Similarly, a breast exam should be performed, and the presence of a breast mass warrants a mammogram, given the possibility of a primary breast cancer with ovarian metastases. Particular attention should be paid to the lymph node–bearing areas, particularly the supraclavicular and inguinal areas. Metastatic disease to the skin rarely occurs in the presence of ovarian cancer. Sister Mary Joseph’s nodule refers to a metastatic implant in the umbilicus.

For patients with carcinoma of the fallopian tube, presentation typically occurs in the fifth or sixth decade of life, and the signs and symptoms are often similar to those noted in patients with ovarian cancer. In fact, it is difficult to differentiate tubal from ovarian carcinomas preoperatively. Fewer than 15% of patients are noted to have the classic triad of symptoms and signs associated with fallopian tube cancer including **hydrops tubae profluens** (a watery vaginal discharge), pelvic pain, and a palpable adnexal mass. Positive vaginal cytology in the absence of endometrial or cervical neoplasia suggests the possibility of a tubal cancer, but this is rarely diagnostic.

B. Laboratory Findings

The best characterized tumor marker in EOC is cancer antigen-125 (CA-125). CA-125 is a secreted glycoprotein present in fetal amniotic and coelomic epithelium, and its level can be detected in serum using immunoassay. The accepted upper limit of normal is 35 IU/mL, but this is a rather arbitrary cutoff. CA-125 is elevated in many patients with ovarian cancer, especially with serous histology, but is also elevated in other malignancies such as pancreatic, colon, breast, stomach, fallopian, or endometrial cancer. In addition, it is also elevated in certain benign conditions such as endometriosis, leiomyoma, or pelvic inflammatory disease, although rarely above 200 IU/mL. Therefore, it can be a useful adjunct in postmenopausal women, but not very useful in premenopausal women given the low incidence of EOC and greater incidence of benign lesions. Additionally, a normal CA-125 does not exclude the diagnosis of cancer and does not represent a reason to delay surgery.

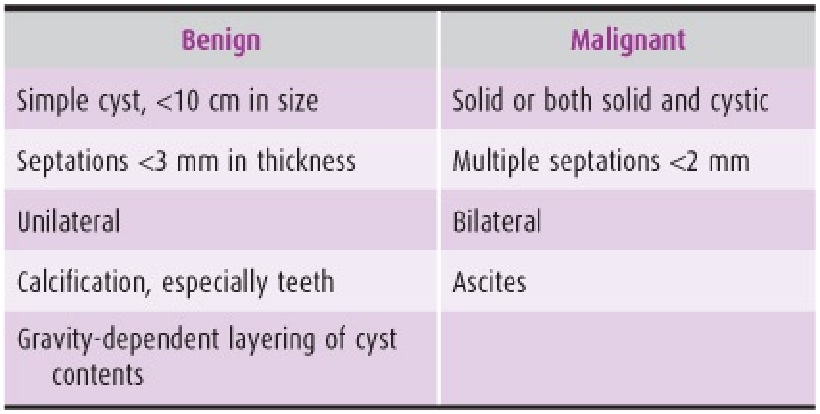
In young girls and adolescents presenting with an adnexal mass, serum AFP, lactate dehydrogenase (LDH), and hCG should be measured as potential biomarkers given the greater likelihood of a malignant germ cell tumor.

In all patients, a complete blood count (CBC), serum electrolyte test, and hCG level should be drawn. For patients with apparent ascites, a paracentesis is not advocated as a routine procedure once renal, cardiac, and hepatic failure have been excluded. False-negative results may occur in as many as 40% of patients with widespread intraabdominal disease. In contrast to paracentesis, diagnostic thoracentesis for cytology is recommended for staging purposes; the presence of a malignant pleural effusion confirms stage IV disease.

C. Imaging Studies

Pelvic ultrasound helps delineate the presence of a benign or malignant adnexal mass (Table 50–4), and a number of different scoring systems have been used, although there is no standardized system for evaluation of ovarian masses. Typical characteristics of ovarian cancer include a solid component, which is often nodular or papillary, septations, and ascites. Angiogenesis accompanying malignancy results in vascular abnormalities and increased blood flow compared with the vascular architecture and patterns of blood flow in nonmalignant lesions. The addition of color flow Doppler studies that evaluate the vascular patterns of adnexal masses improves the sensitivity and specificity of the radiographic diagnosis of benign and malignant lesions. However, even when combined with laboratory or physical findings, ultrasound is limited in making a definitive diagnosis, and surgery is required to document malignancy histologically.

Table 50–4. Ultrasonographic features to aid diagnosis of benign and malignant adnexal masses.



Benign	Malignant
Simple cyst, <10 cm in size	Solid or both solid and cystic
Septations <3 mm in thickness	Multiple septations <2 mm
Unilateral	Bilateral
Calcification, especially teeth	Ascites
Gravity-dependent layering of cyst contents	

Characterization of adnexal masses by computed tomography (CT) or magnetic resonance imaging (MRI) may provide clinically useful information in select instances. CT scanning provides information about the retroperitoneal structures in addition to the pelvic organs. MRI scans can add more information regarding the nature of the ovarian neoplasm. Because of the high cost and questionable benefit, this diagnostic procedure is infrequently used for ovarian tumors. However, it may be of particular benefit in the evaluation of pregnant patients because it avoids radiation exposure of the fetus.

A patient with suspected ovarian malignancy should undergo a radiograph of the chest to exclude metastatic parenchymal disease and to detect a pleural effusion. If the patient notes a change in bowel habits or if guaiac-positive stools are detected, a barium enema should be obtained. Patients who appear to have advanced ovarian cancer, evidenced by a nodular pelvic mass with or without ascites, may actually have colon cancer. Because of the genetic links among ovarian cancer, colon cancer, and breast cancer, a patient with a suspected ovarian malignancy should also undergo a screening mammogram study.

Twickler DM, Moschos E. Ultrasound and assessment of ovarian cancer risk. *AJR Am J Roentgenol* 2010;194:322. PMID: 20093591.

Differential Diagnosis

The differential diagnosis of a pelvic mass is influenced by the age of the patient, the characteristics of the mass on pelvic examination, and the radiographic appearance of the mass. In general, the prepubescent child and the postmenopausal woman are at greatest risk for a malignant ovarian neoplasm. The reproductive-age woman is more likely to have a functional ovarian cyst or endometrioma. Although functional cysts are typically mobile, both endometriomas and tubo-ovarian abscesses can present as an adnexal mass that is fixed, solid, and irregular.

Mature teratomas or dermoids are common ovarian neoplasms, occurring primarily in women ages 20–30 years. They represent the most common neoplasm diagnosed during pregnancy. Less than 1% of all teratomas are malignant.

An ovarian fibroma is another benign tumor that is noteworthy because of its association with Meigs’ syndrome. Meigs’ syndrome refers to the occurrence of an ovarian fibroma, ascites, and pleural effusion, which collectively mimic the presentation of ovarian cancer.

For masses diagnosed by ultrasound, pathologies such as pedunculated fibroids, hydrosalpinx, peritoneal inclusion cyst, and paraovarian cysts also need to be considered. Persistence of ultrasonic findings on a repeat scan after 4–6 weeks may help reduce the false-positive rate associated with ovarian masses.

Givens V, Mitchell GE, Harraway-Smith C, Reddy A, Maness DL. Diagnosis and management of adnexal masses. *Am Fam Physician* 2009;80:815. PMID: 19835343.

Complications

The majority of complications from ovarian cancer arise secondary to metastases. Metastases often arise from exfoliation into the peritoneal cavity and then migrate along the circulatory pattern of peritoneal fluid from the right paracolic gutter toward the upper abdomen. Additionally, hematogenous dissemination may occur. The bulk of the tumor, especially within the omentum, may lead to bowel obstruction or nutritional deficits. Removal of the mass may produce significant fluid shifts in women with advanced ovarian cancer.

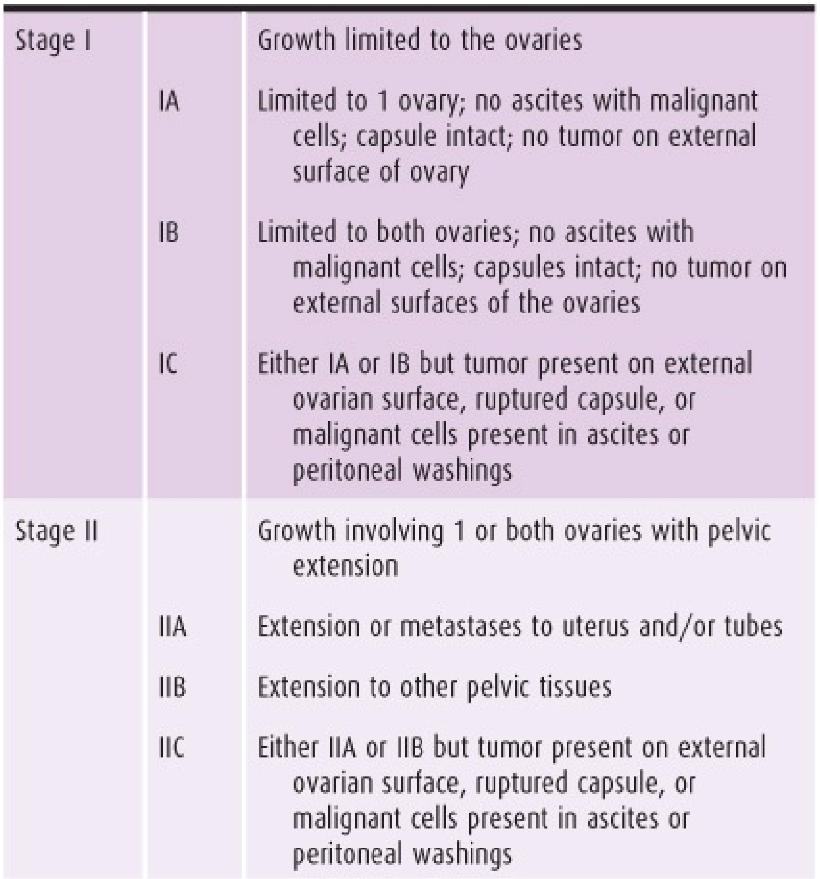
Patients are at an increased risk of venous thromboembolism (VTE) if metastatic disease, medical comorbidities, or clear cell histology exist. Additionally, the first 3 months after diagnosis give rise to an increased risk of VTE. For patients undergoing surgical intervention, VTE prophylaxis is given.

Treatment

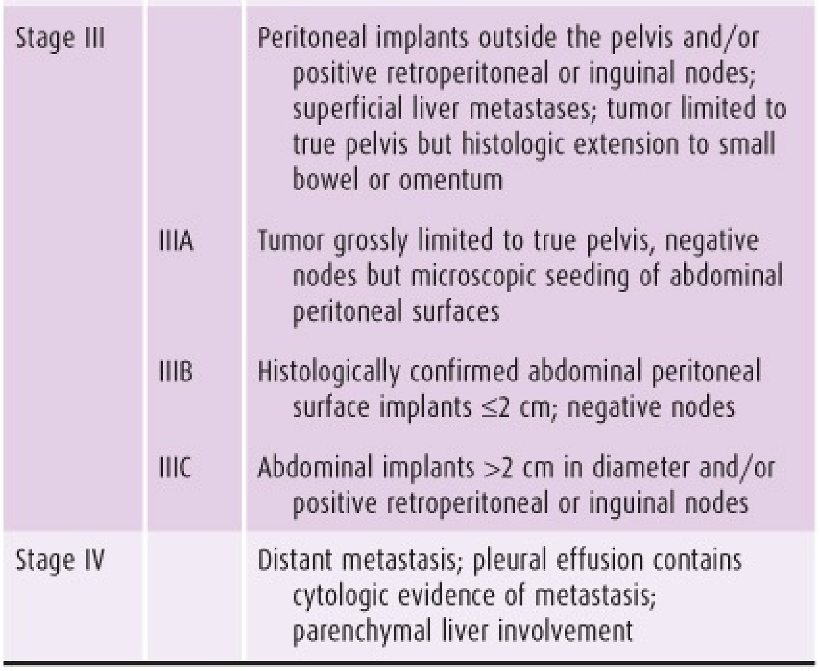
A. Surgical Intervention for Epithelial Ovarian Cancers

Surgical staging and tumor removal are required for all patients, unless the performance status of the patient limits surgical intervention. Initial surgical staging provides the definitive histologic diagnosis as well as the extent of disease. Obtaining the true stage of disease allows appropriate treatment and subsequent prognosis. Table 50–5 lists the current staging of ovarian cancer approved by the International Federation of Gynecology and Obstetrics (FIGO).

Table 50–5. International Federation of Gynecology and Obstetrics (FIGO) staging.



Stage I		Growth limited to the ovaries
	IA	Limited to 1 ovary; no ascites with malignant cells; capsule intact; no tumor on external surface of ovary
	IB	Limited to both ovaries; no ascites with malignant cells; capsules intact; no tumor on external surfaces of the ovaries
	IC	Either IA or IB but tumor present on external ovarian surface, ruptured capsule, or malignant cells present in ascites or peritoneal washings
Stage II		Growth involving 1 or both ovaries with pelvic extension
	IIA	Extension or metastases to uterus and/or tubes
	IIB	Extension to other pelvic tissues
	IIC	Either IIA or IIB but tumor present on external ovarian surface, ruptured capsule, or malignant cells present in ascites or peritoneal washings

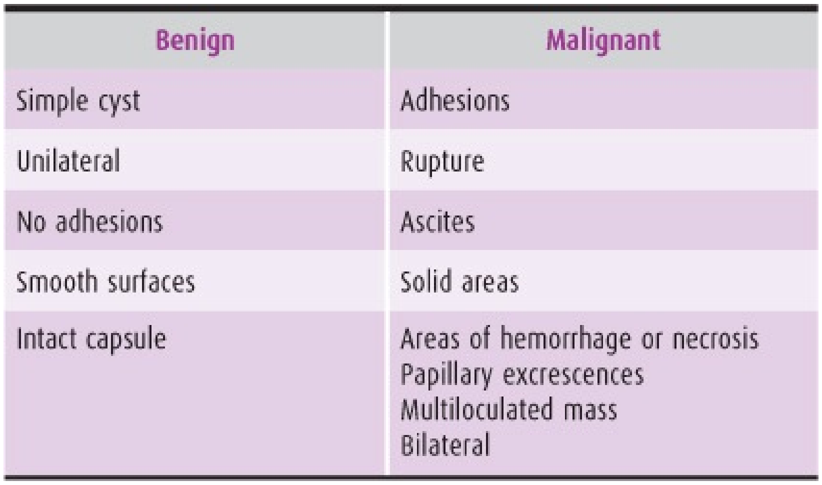


Stage III		Peritoneal implants outside the pelvis and/or positive retroperitoneal or inguinal nodes; superficial liver metastases; tumor limited to true pelvis but histologic extension to small bowel or omentum
	IIIA	Tumor grossly limited to true pelvis, negative nodes but microscopic seeding of abdominal peritoneal surfaces
	IIIB	Histologically confirmed abdominal peritoneal surface implants ≤2 cm; negative nodes
	IIIC	Abdominal implants >2 cm in diameter and/or positive retroperitoneal or inguinal nodes
Stage IV		Distant metastasis; pleural effusion contains cytologic evidence of metastasis; parenchymal liver involvement

Reproduced, with permission, from International Federation of Gynecology and Obstetrics. Reprinted from *Int J Gynecol Obstet* 2000;70:207–312.

Intraoperatively, several features have been described that assist in the differentiation of malignant from benign adnexal masses (Table 50–6). However, gross examination of a mass is never a substitute for histologic examination. Whenever the pathology of a pelvic or adnexal mass is in question, a frozen-section pathologic study should be requested. In the hands of experienced pathologists, false-positive and false-negative diagnoses occur in <5% of cases. Patients diagnosed with ovarian cancer have to undergo surgical staging to reduce the amount of disease and evaluate the extent of spread. Removal of the primary tumor, as well as the associated metastatic disease, is referred to as tumor debulking or cytoreductive surgery. In early stages and when fertility is desired, removal of the involved adnexa alone may be considered.

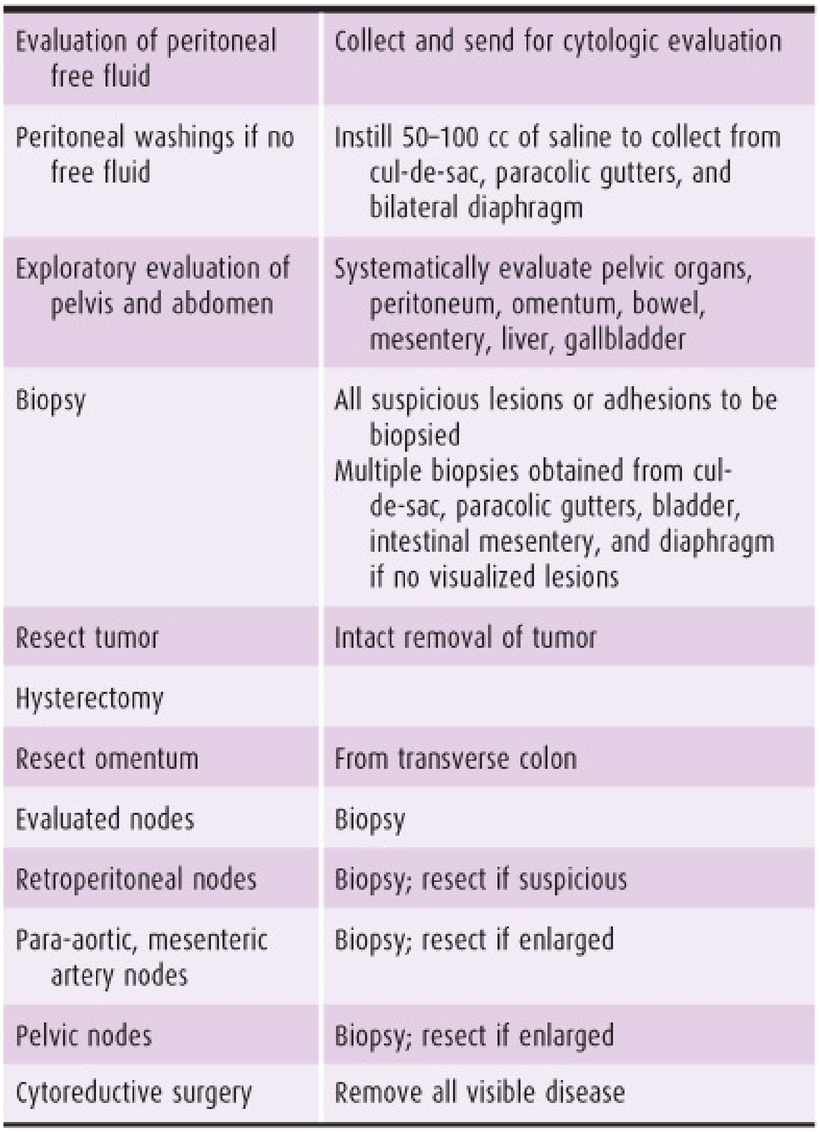
Table 50–6. Intraoperative features of benign and malignant masses.



Benign	Malignant
Simple cyst	Adhesions
Unilateral	Rupture
No adhesions	Ascites
Smooth surfaces	Solid areas
Intact capsule	Areas of hemorrhage or necrosis Papillary excrescences Multiloculated mass Bilateral

Surgical staging for ovarian cancer is performed by laparotomy. Initial recovery of ascites or pelvic free fluid is sent for cytologic evaluation. If no free fluid is present, “peritoneal washings” are obtained by instilling 50–100 cc of saline in the cul-de-sac, paracolic gutters, and underneath each hemidiaphragm. An exploratory laparotomy is then performed in a systematic and thorough manner, evaluating the pelvic organs, omentum, intestines, mesentery, gallbladder, liver, diaphragm, spleen, and entire peritoneum. The kidneys, pancreas, and lymph nodes are also evaluated in the retroperitoneum. Complete surgical staging of ovarian cancer requires the biopsy of pelvic and para-aortic lymph nodes. It is emphasized that the palpation of the retroperitoneal node-bearing areas is inaccurate and is not a substitute for biopsy and histologic examination. Table 50–7 lists the procedures included in surgical staging of ovarian cancer.

Table 50–7. Procedure to stage and remove ovarian cancer.



Evaluation of peritoneal free fluid	Collect and send for cytologic evaluation
Peritoneal washings if no free fluid	Instill 50–100 cc of saline to collect from cul-de-sac, paracolic gutters, and bilateral diaphragm
Exploratory evaluation of pelvis and abdomen	Systematically evaluate pelvic organs, peritoneum, omentum, bowel, mesentery, liver, gallbladder
Biopsy	All suspicious lesions or adhesions to be biopsied Multiple biopsies obtained from cul-de-sac, paracolic gutters, bladder, intestinal mesentery, and diaphragm if no visualized lesions
Resect tumor	Intact removal of tumor
Hysterectomy	
Resect omentum	From transverse colon
Evaluated nodes	Biopsy
Retroperitoneal nodes	Biopsy; resect if suspicious
Para-aortic, mesenteric artery nodes	Biopsy; resect if enlarged
Pelvic nodes	Biopsy; resect if enlarged
Cytoreductive surgery	Remove all visible disease

Removal of the tumor burden is also therapeutic. The extent of surgical resection is dependent on the stage of the disease as well as the age of the patient. If possible, complete removal of the tumor burden should be attempted as optimal cytoreduction or debulking improves subsequent systemic chemotherapy; large bulky tumors are often poorly vascularized and thus more resistant to chemotherapy and radiation therapy. Large tumor masses also consist of a higher proportion of cells in the resting phase of the cell cycle. However, even if complete resection is not possible, decreasing the tumor burden provides other benefits such as an improvement in symptoms (abdominal pain, bloating, satiety, or dyspnea) as well as a potential improvement in immune competence because ovarian tumors often produce immunosuppressive cytokines.

In general, the contralateral adnexa should be removed even when they are grossly normal. They are often the site of occult metastatic disease, and there is a significant risk of subsequent cancer. Exceptions to this generalization are made for young women with an apparent stage I epithelial ovarian neoplasm. If future fertility is desired and the patient is informed about a higher risk of recurrent disease, a more conservative surgical approach may be chosen. The histology and grade of the neoplasm, as well as the findings at the time of surgery, guide these decisions. Well-differentiated stage I lesions are associated with a much better 5-year survival rate than are moderately and poorly differentiated lesions. Mucinous and endometrioid neoplasms are associated with a better prognosis than serous and clear cell carcinomas of the ovary. If the frozen section during surgery does not reveal a reliable diagnosis of malignancy, the surgical procedure should be limited until the pathology results are finalized.

An infracolic omentectomy is recommended, even in the absence of gross tumor involvement, because it is a common site of microscopic metastatic disease. Removal of the omentum facilitates the distribution of intraperitoneal agents, may decrease the rate of accumulation of ascites postoperatively, and provides palliation to patients with omental metastases.

A hysterectomy is generally performed because the uterus is a common site for metastatic disease. There is also a risk of synchronous endometrial cancer in patients with endometrioid carcinoma of the ovary. In addition, removal of the uterus facilitates subsequent follow-up examinations and obviates potential problems secondary to uterine bleeding.

B. Surgical Intervention for Germ Cell Neoplasms

In contrast to epithelial ovarian neoplasms, most germ cell neoplasms are early stage at the time of diagnosis. This observation, in conjunction with the low incidence of bilaterality and the young age of most patients, for whom future fertility is desired, influences the surgical management of this group of neoplasms. For young women with a germ cell neoplasm of the ovary, removal of the involved adnexa with preservation of the normal-appearing contralateral adnexa and uterus is generally advocated. In view of the low incidence of bilaterality, biopsy or bivalving the contralateral ovary is not recommended because of the risk of peritubal and periovarian adhesions. Complete surgical staging of germ cell neoplasms is the same as for epithelial ovarian neoplasms and should be performed in all cases.

Certain characteristics unique to germ cell neoplasms make an impact on their surgical management. Dysgerminoma of the ovary has a propensity to metastasize to the pelvic and para-aortic lymph nodes in the absence of other evidence of metastatic disease. Performing a biopsy of these structures is particularly important. Endodermal sinus tumor of the ovary is the most rapidly growing neoplasm known to occur at any site. This diagnosis must be considered in a young woman with a rapidly enlarging pelvic or abdominal mass. Immature teratoma of the ovary may present with numerous peritoneal implants consistent with metastatic disease. It is important to adequately sample these lesions to determine whether or not they contain malignant elements.

C. Medical Intervention for Epithelial Ovarian Cancer

After the initial surgical intervention and definitive staging, subsequent treatment can be established. Almost all patients with EOC will receive chemotherapy. The 1 exception is for stage IA disease and grade 1 tumors, where a discussion of the risks and benefits of chemotherapy should be undertaken because chemotherapy after the initial surgical treatment may have no influence on survival. For all other stages, chemotherapy is indicated. Agents shown to be active against EOC include cisplatin, carboplatin, cyclophosphamide, and paclitaxel. Combination therapies have been demonstrated to be superior to single-agent treatment. Typically, chemotherapy is started 4–6 weeks after surgical intervention. Earlier administration has not been shown to provide a benefit.

Currently the most effective regimen uses a combination of paclitaxel and carboplatin. This combination has replaced the former treatment with cyclophosphamide and cisplatin because it was shown to be more efficacious in a number of clinical trials. A typical regimen includes systemic administration of carboplatin and paclitaxel for 6 cycles at 3-week intervals. Potential toxicities of this treatment include nausea, vomiting, diarrhea, alopecia, nephrotoxicity, and myelo-suppression (see Chapter 52).

Carboplatin is a second-generation platinum analogue that shows clinical efficacies and survival rates similar to cisplatin when used in combination with paclitaxel. However, the frequency of gastrointestinal side effects and neurotoxicity associated with carboplatin was found to be lower compared to cisplatin.

The route of administration may vary depending on the stage. Patients with optimally cytoreduced stage III EOC are offered intraperitoneal (IP) or systemic intravenous (IV) administration of the chemotherapeutic agents. The IP route has been shown to increase survival, although an increase in side effects is also noted. For patients with suboptimally cytoreduced disease or stage IV disease, systemic IV administration is the preferred route.

Occasionally, chemotherapy will be offered in patients with stage IV disease prior to surgical staging. This is termed neoadjuvant chemotherapy and may be useful to lessen the tumor burden, thereby decreasing the morbidities associated with surgical resection of advanced disease. It may also increase the chance of optimal debulking.

Assessment of response to combination chemotherapy is based on physical examination, changes in size of palpable or radiographically measurable lesions, and changes in the CA-125 level. Although the preoperative CA-125 level does not correlate with tumor burden, changes in response to chemotherapy appear to be of some prognostic benefit. An elevated CA-125 (>35 IU/mL) predicts persistent disease at second look in more than 97% of patients. However, a normal CA-125 level does not completely exclude the possibility of residual, subclinical disease.

Most patients develop resistance to platinum-based regimens during the course of treatment. Salvage therapy for ovarian cancer is rarely curative, although significant prolongation of survival may be achieved in some instances. The response to re-treatment with platinum-based chemotherapy is influenced by the time interval between completion of the initial regimen and subsequent disease recurrence: The greater the interval, the greater is the likelihood of a beneficial response, with platinum resistance defined as recurrence <6 months after completion of combination chemotherapy or progression on treatment.

D. Medical Intervention for Germ Cell Neoplasms

Significant advances have been made in the treatment of germ cell neoplasms of the ovary. Once associated with 5-year survival rates of <20–30%, these neoplasms are now considered curable in a majority of cases following the introduction and refinement of combination chemotherapy.

Dysgerminoma is the most radiation-sensitive neoplasm identified. Historically, it has been treated with whole abdominal radiation therapy with excellent results. More recently, chemotherapy with cisplatin-containing regimens has been administered with excellent results. A significant advantage of chemotherapy is the potential to preserve future reproductive potential compared with radiation therapy.

The other germ cell neoplasms are rare, and the optimal chemotherapy and duration of therapy have not been established. Regimens such as vinblastine/bleomycin/cisplatin, vincristine/dactinomycin/cyclophosphamide, and bleomycin/etoposide/cisplatin have been used with encouraging results. Response to chemotherapy is based on physical examination and the decrease in serum tumor markers, if initially elevated.

E. Radiation Therapy

With respect to germ cell neoplasms, radiation therapy has been used successfully in the treatment of patients with dysgerminoma. For patients with EOC, radiation therapy plays a limited role mainly because of radiation damage to the small bowel, liver, and kidneys. Radioisotopes such as intraperitoneal phosphorus-32 may be of benefit in patients with stage IC disease and those with microscopically positive second-look operations.

F. Intervention for Fallopian Tube Cancers

The surgical therapy of fallopian tube carcinoma is the same as that recommended for EOC. In addition, the same type of surgical staging should be performed if for no other reason than it is often not clear at the time of surgery whether the primary cancer is of ovarian or fallopian tube origin. The staging system for ovarian cancer is often applied to neoplasms of the fallopian tube, although this is by custom rather than FIGO recommendations.

Chemotherapy for fallopian tube cancer has evolved along the same lines as that for EOC. The currently used chemotherapeutic regimen is similar to that of EOC and includes platinum combination chemotherapy. Radiation may also be used in select cases with no residual disease after surgery. Because there are little data on well-staged tubal lesions, it is unclear if patients with early-stage disease benefit from adjuvant therapy.

G. Alternative Therapies

A number of alternative therapies have been applied for the treatment of EOC. Cytokines like interleukin-2 and interferon-γ, either alone or in combination with chemotherapy, have shown some promising effects. Monoclonal antibodies directed against ovarian cancer–associated antigens, including CA-125, HMFG (human milk-fat globulin), and HER-2/*neu*, have been used with variable clinical responses. Recently, antibodies against vascular endothelial growth factor (VEGF) have shown efficacy in patients with ovarian cancer. Anti-VEGF antibodies are currently being tested in combination with carboplatin and paclitaxel in first-line chemotherapy for ovarian cancer patients. Gene therapy trials have used different antitumor approaches, including the delivery of tumor suppressor gene p53 via recombinant adenovirus into the peritoneal cavities. The early trials have not shown significant clinical response, mainly as a result of the inefficiency of intraperitoneal and intratumoral gene transfer.

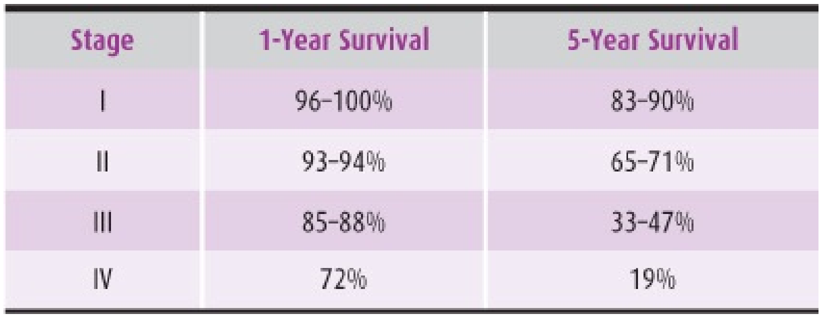
Prognosis

Ovarian cancer is the second most common gynecologic malignancy, yet the most common cause of death in women with such a malignancy. The prognosis for patients with ovarian cancer is primarily related to the stage of disease (Table 50–8). Within each stage of disease, other factors such as cell type and response to chemotherapy are also important in determining disease-free survival and overall survival. In general, patients with well-differentiated, diploid neoplasms with an S-phase fraction of <8–10% do better than patients who have poorly differentiated, aneuploid, rapidly proliferating (eg, high S-phase fraction) neoplasms.

Table 50–8. Overall survival rates for patients with epithelial ovarian cancer.



Stage	1-Year Survival	5-Year Survival
I	96–100%	83–90%
II	93–94%	65–71%
III	85–88%	33–47%
IV	72%	19%

In general, germ cell tumors are associated with better 5-year survival rates than epithelial ovarian neoplasms. Patients with dysgerminoma have a 5-year survival rate of 95%. Immature teratomas are associated with 5-year survival rates of 70–80%. An endodermal sinus tumor is associated with a 5-year survival rate of 60–70%. Embryonal carcinoma, choriocarcinoma, and polyembryoma are very rare lesions, and it is difficult to assess 5-year survival estimates. Epithelial ovarian neoplasms of low malignancy potential are characterized by 5-year survival rates of 95%, reflecting their protracted and indolent biologic behavior.

The prognosis for patients with fallopian tube carcinoma is based on the stage of disease. The overall 5-year survival rate is approximately 56%. The prognosis for early-stage disease is much better than for advanced disease, as 5-year survival is 84% with stage I disease, 52% with stage II, and 36% with stage III.

51
Gestational Trophoblastic Diseases

Paola Aghajanian, MD

ESSENTIALS OF DIAGNOSIS

- Uterine bleeding in first trimester
- Absence of fetal heart tones and fetal structures
- Rapid enlargement of the uterus or uterine size greater than anticipated by dates
- Human chorionic gonadotropin titers greater than expected for gestational age
- Vaginal expulsion of vesicles
- Hyperemesis gravidarum
- Theca lutein cysts
- Onset of preeclampsia in the first trimester

Pathogenesis

The spectrum of gestational trophoblastic disease includes hydatidiform moles (complete and partial) and gestational trophoblastic neoplasia comprising invasive moles, choriocarcinomas, and placental-site trophoblastic tumors (PSTT). These tumors are unique in that they develop from an aberrant fertilization event and hence arise from fetal tissue within the maternal host. They are composed of both syncytiotrophoblastic and cytotrophoblastic cells, with the exception of PSTT, which is derived from intermediate trophoblastic cells. In addition to being the first and only disseminated solid tumors that have proved to be highly curable by chemotherapy, they elaborate a unique and characteristic tumor marker, human chorionic gonadotropin (hCG).

A. Hydatidiform Mole

Hydatidiform mole is the most common form of gestational trophoblastic disease and is benign in nature. Its incidence varies worldwide from 1 in 125 deliveries in Mexico and Taiwan to 1 in 1500 deliveries in the United States. The incidence is higher in women younger than 20 and older than 40 years of age, in nulliparous women, in patients of low socioeconomic status, and in women whose diets are deficient in protein, folic acid, and carotene. Blood group A women impregnated by group O men have an almost 10-fold greater risk of subsequently developing gestational trophoblastic neoplasia than group A women impregnated by group A partners. Furthermore, women with blood group AB tend to have a relatively worse prognosis.

Two distinct forms of hydatidiform mole exist: complete and partial moles. Table 51–1 outlines the clinical, pathologic, and genetic characteristics of both. Cytogenetic studies demonstrate that complete moles are usually euploid, paternal in origin, and sex chromatin-positive—46 XX or 46 XY. They arise when an empty ovum (with an absent or inactivated nucleus) is fertilized by a haploid sperm that duplicates its chromosomes or by two haploid sperm. A partial mole, on the other hand, is triploid—69 XXY (70%), 69 XXX (27%), or 69 XYY (3%)—arising when an ovum with an active nucleus is fertilized by a duplicated sperm or two haploid sperm. Both of these processes result in a homozygous conceptus with a propensity for altered growth.

Table 51–1. Comparison of complete and partial hydatidiform moles.

	Complete	Partial
Karyotype	Diploid (46,XX or 46,XY)	Triploid (69,XXX or 69,XXY)
Fetus	Absent	Often present
Villi	Diffusely hydropic	Focally hydropic
Trophoblasts	Diffuse hyperplasia	Mild focal hyperplasia
Implantation-site trophoblast	Diffuse atypia	Focal atypia
P57, PHLDA2 immunostaining[1]	Negative	Positive
Fetal RBCs	Absent	Present
β-hCG (mIU per milliliter)	High (>50,000)	Slight elevation (<50,000)
Frequency of classic clinical symptoms[2]	Common	Rare
Risk for persistent GTT	20-30%	<5%

GTT, gestational trophoblastic tumor.

[1] PHLDA2 is the product of a paternally imprinted, maternally expressed gene stained by p57 immunohistochemistry. Complete moles stain negative, as their genome is exclusively paternally derived and cannot express PHLDA2.

[2] Hyperemesis, hyperthyroidism, excessive uterine enlargement, anemia, and preeclampsia. The frequency of these symptoms has decreased as a consequence of earlier diagnosis of molar pregnancies through evaluating hCG levels and ultrasonography.

Hydatidiform mole is thought to arise from extraembryonic trophoblasts. Histologic similarities between molar vesicles and chorionic villi support the view that one is derived from the other. Detailed morphologic studies of hysterectomy specimens containing intact molar pregnancies suggest that transformation of the embryonic inner cell mass at a stage just prior to the laying down of endoderm gives rise to hydatidiform moles. At this stage in embryogenesis, the inner cell mass has the potential to develop into trophoblasts, ectoderm, or endoderm. If normal development is interrupted, such that the inner cell mass loses its capacity to differentiate into embryonic ectoderm and endoderm, a divergent development pathway is created. This pathway may then result in production of extraembryonic mesoderm and molar vesicles with loose primitive mesoderm in their villous core.

Grossly, a hydatidiform mole is characterized by multiple grapelike vesicles filling and distending the uterus, usually in the absence of an intact fetus (Fig. 51–1). Most hydatidiform moles are recognizable on gross examination, but some are small and may seem to be ordinary abortuses. Microscopically, moles may be identified by three classic findings: edema of the villous stroma, avascular villi, and nests of proliferating trophoblastic elements surrounding villi (Figs. 51–2 and 51–3). The likelihood of malignant sequelae is higher in patients whose trophoblastic cells show increased proliferation and anaplasia. Although histologic studies of the trophoblast provide some basis for predicting a benign or malignant course for the mole, the correlation is not absolute.

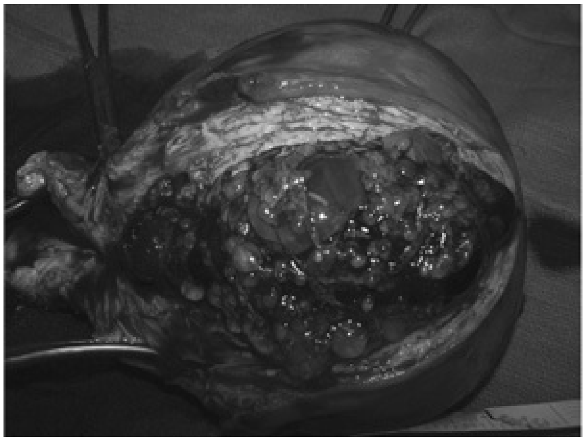


Figure 51–1. Hysterectomy specimen of a complete mole with anterior wall incised, displaying typical clear, “grapelike” vesicles filling the uterine cavity. Hysterectomy was performed as primary treatment for molar gestation. (Reproduced, with permission, from *Emiliano Chavira, MD.*)

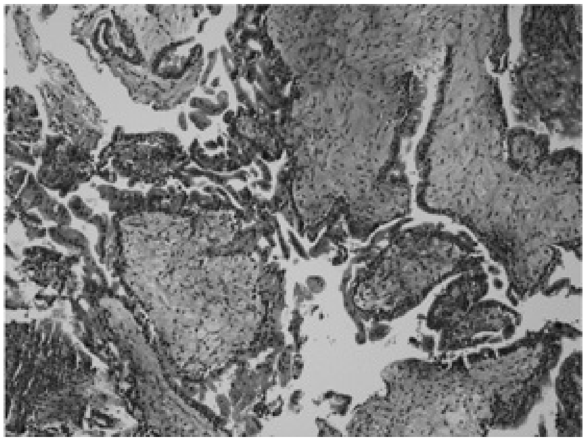

Figure 51–2. A complete mole characterized by enlarged, avascular chorionic villi with exuberant cytotrophoblastic and syncytiotrophoblastic proliferation. Magnified 100x. (Reproduced, with permission, from *Wenxue Xing, MD.*)

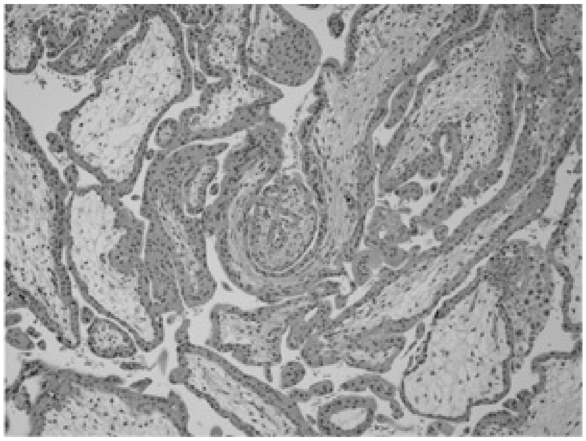

Figure 51–3. A partial mole showing a biphasic population of small, normal appearing, and enlarged villi with irregular contours. The large villi exhibit mild to moderate syncytiotrophoblastic proliferation. Fetal red blood cells can be appreciated in the villous capillaries. Magnified 100x. (Reproduced, with permission, from *Wenxue Xing*, *MD*.)

Today, with earlier detection, the classic pathologic presentation of molar pregnancies is less common. Therefore, it can be more difficult to differentiate histologically between a complete mole, a partial mole, and a nonmolar hydropic abortion. Use of flow cytometry can determine ploidy (eg, diploid versus triploid). Additionally, p57 immunohistochemistry staining can be used to stain for PHLDA2, a paternally imprinted, maternally expressed gene product that is absent in complete moles but present in partial moles and hydropic abortuses.

B. Invasive Mole

Invasive mole is reported in 10–15% of patients who have had a hydatidiform mole. Although considered a benign neoplasm, invasive mole, as its name implies, is locally invasive and invades the myometrium and adjacent structures. Additionally, it has the potential to completely penetrate the myometrium and cause subsequent uterine rupture and hemoperitoneum. However, it also has the ability to spontaneously regress. The microscopic findings are similar to that of a hydatidiform mole. Because adequate myometrium is rarely obtained at curettage and fewer hysterectomies are being performed in patients with trophoblastic disease, the diagnosis is less often made by histologic analysis.

C. Choriocarcinoma

Choriocarcinoma is reported in 2–5% of all cases of gestational trophoblastic neoplasia. The incidence in the United States is 1 in 40,000 pregnancies, but it is higher in Asia. It may accompany or follow any type of pregnancy. In about half of choriocarcinoma cases, the antecedent gestational event is a hydatidiform mole. Another 25% follow a term pregnancy, and the remaining 25% occur after an abortion.

Choriocarcinoma is a pure epithelial tumor composed of syncytiotrophoblastic and cytotrophoblastic cells. It usually presents as late vaginal bleeding in the postpartum period. An enlarged uterus, enlarged ovaries, and vaginal lesions may be noted during the physical examination.

Histologic evaluation of the tumor discloses sheets or foci of trophoblasts on a background of hemorrhage and necrosis, but no villi (Fig. 51–4). Assessment of trophoblastic tissue following or accompanying pregnancy may prove difficult because of the histologic similarities of the trophoblastic patterns in very early pregnancy and chorio-carcinoma. Consequently, the curettage specimen must be processed in its entirety, as the specimen may contain only small, isolated areas of choriocarcinoma. A histopathologic diagnosis of choriocarcinoma in any site is an indication for prompt treatment after confirmation by gonadotropin excretion measurements.

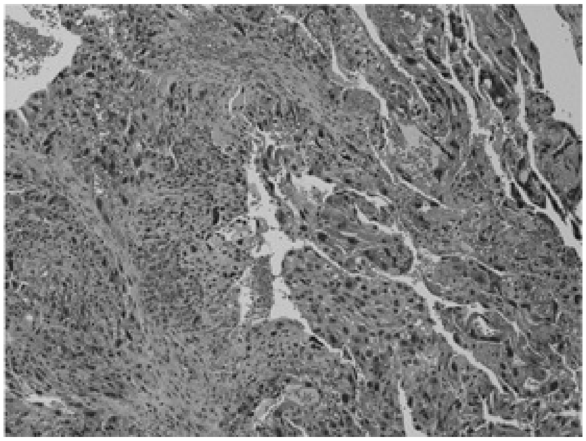

Figure 51–4. This choriocarcinoma demonstrates the typical avillous trophoblastic proliferation that characterizes this neoplasm. Masses of markedly atypical cytotrophoblasts are intimately associated with multinucleated syncytiotrophoblasts. Mitotic figures are readily identified. Magnified 100x. (*Reproduced, with permission, from Wenxue Xing, MD.*)

D. Placental-Site Trophoblastic Tumor

PSTT is a rare variant of gestational trophoblastic tumor. It may arise months to years after a hydatidiform mole or, less commonly, following a normal term pregnancy. The tumor is generally confined to the uterus, but local invasion may occur into the myometrium, lymphatics, or vasculature. It metastasizes late in its course. PSTT is derived from the intermediate trophoblasts of the placental bed, with minimal or absent syncytiotrophoblastic tissue. As syncytiotrophoblastic cells are generally absent from this tumor, minimal amounts of hCG are released in relation to the tumor burden. However, human placental lactogen is secreted, and its levels can be monitored to follow response to therapy.

Prevention

The only way to prevent the occurrence of gestational trophoblastic diseases is abstinence from sexual intercourse.

Clinical Findings

A. Symptoms & Signs

Abnormal uterine bleeding, usually during the first trimester, is the most common presenting symptom, occurring in more than 90% of patients with molar pregnancies. Three-fourths of these patients present before the end of the first trimester. Nausea and vomiting have been reported in 14–32% of patients with hydatidiform mole and may be confused with nausea and vomiting of pregnancy or hyperemesis gravidarum. Ten percent of these patients may have nausea and vomiting severe enough to require hospitalization.

About half of patients will have a uterine size that is greater than expected for their gestational age. However, in one-third of patients, the uterus may be smaller than expected. Multiple theca lutein cysts causing enlargement of one or both ovaries are seen in 15–30% of women with molar pregnancies. In about half of these cases, both ovaries are enlarged and may be a source of pain. Involution of the cysts proceeds over several weeks and usually parallels the decline of hCG values. In studies, patients with theca lutein cysts appear to have a greater likelihood of developing malignant sequelae of gestational trophoblastic neoplasia.

Preeclampsia in the first trimester or early second trimester—an unusual finding in normal pregnancies—has been said to be pathognomonic for a molar pregnancy. Hyperthyroidism from stimulation of thyrotropin receptors by hCG can also occur in 10% of patients, although the disease is usually subclinical, and most patients remain asymptomatic. Treatment involves evacuation of the mole. An occasional patient may require brief antithyroid therapy.

Because of the earlier diagnosis of molar pregnancies, the classic presenting symptoms and signs of gestational trophoblastic disease are now less prevalent. For instance, at the New England Trophoblastic Disease Center, the incidence of excessive uterine enlargement, hyperemesis, and preeclampsia was 28%, 8%, and 1%, respectively. The incidence of hyperthyroidism and respiratory insufficiency was negligible. Although the number of cases presenting with these classic signs and symptoms has decreased, the incidence of persistent postmolar gestational trophoblastic disease has remained static.

This highlights the importance of vigilant postmolar hCG surveillance. Any woman with a recent history of molar pregnancy, abortion, or normal pregnancy who presents with vaginal bleeding or a tumor in any organ should have a thorough physical examination and at least one hCG assay to ensure that gestational trophoblastic neoplasia is not the cause. This is of utmost importance given that the cure rate of properly treated gestational trophoblastic neoplasia approaches 90%.

B. Laboratory Findings

The principal characteristic of gestational trophoblastic neoplasms is their capacity to produce hCG. This hormone may be detected in the serum or urine of virtually all patients with hydatidiform mole or malignant trophoblastic disease, and its levels correlate closely with the presence of viable tumor cells. Consequently, monitoring of hCG levels is a necessary tool for the diagnosis, treatment, and surveillance of the disease process.

The usefulness of a serum gonadotropin assay depends on the hCG titer and the sensitivity of the test. Today, sensitive and specific immunoassays are available to differentiate hCG from luteinizing hormone by measuring the β chain of hCG. Serial β-hCG levels are best monitored in the same laboratory using the same immunoassay technique.

The rate of decline in hCG titers is also important. Normal postmolar pregnancy hCG regression curves highlighting the weekly hCG levels in patients undergoing spontaneous remission have been constructed, hence providing a reference for the comparison of random or serial values. In most instances, the hCG values exhibit a progressive decline to nondetectable levels within 14 weeks after evacuation of a molar pregnancy. If the hCG titer rises or plateaus, it must be concluded that viable tumor continues to persist. If the levels of hCG are very low and not responsive to treatment, a false-positive hCG result or “phantom hCG,” caused by cross-reaction of heterophilic antibodies with the hCG test, should be considered.

C. Ultrasonographic Findings

The simplicity, safety, and reliability of ultrasonography define it as the diagnostic method of choice for patients with suspected molar pregnancy. In a complete molar pregnancy, the characteristic ultrasound pattern consists of multiple hypoechoic areas corresponding to hydropic villi, at times described as a “snowstorm” pattern (Fig. 51–5). A normal gestational sac or fetus is not present. Theca lutein cysts may be visualized. In a partial mole, focal areas of trophoblastic changes and fetal tissue may be noted. Focal cystic changes in the placenta are also a hallmark finding. On the other hand, an ultrasonogram of a choriocarcinoma may reveal an enlarged uterus with a necrotic and hemorrhagic pattern, whereas that of PSTT may show an intrauterine mass.

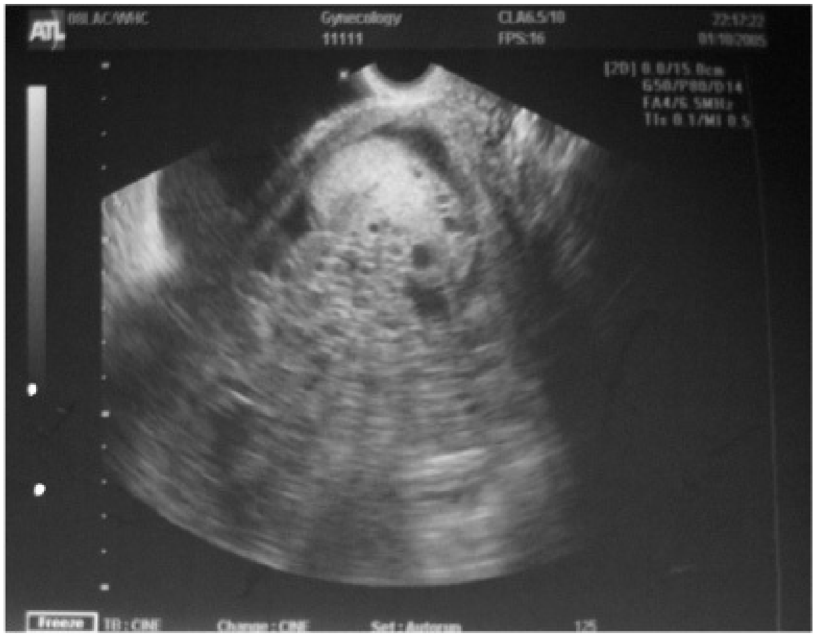

Figure 51–5. Vaginal ultrasound of patient in Figure 51–1 demonstrating the characteristic intrauterine hypoechoic areas corresponding to hydropic villi, at times described as a “snowstorm” pattern. (Reproduced, with permission, from *Emiliano Chavira, MD.*)

A pelvic ultrasound should be obtained in any patient who presents with bleeding in the first half of pregnancy and/or has a uterus greater than the gestational size. Even when the uterus is appropriate for gestational age, ultrasonography can be key in differentiating between a normal pregnancy and a hydatidiform mole.

Differential Diagnosis

Gestational trophoblastic disease must be distinguished from a normal pregnancy, an aborting pregnancy, and an ectopic pregnancy. Ultrasonography is a useful tool in this respect. Quantitative hCG levels improve the accuracy of the diagnosis. Analysis of tissue obtained from a dilatation and evacuation for histology and DNA content will prove invaluable.

Complications

The maternal–fetal barrier contains leaks large enough to permit passage of cellular and tissue elements. As a result, deportations of trophoblastic tissue to the lungs are frequent. Spontaneous regression of these ectopic trophoblastic tissues can occur. Less commonly, this results in a syndrome of acute pulmonary insufficiency. Symptoms of dyspnea and cyanosis, due to massive deportation of trophoblasts to the pulmonary vasculature and subsequent formation of pulmonary emboli, can present within 4–6 hours after evacuation of a molar pregnancy. Pulmonary edema leading to high-output congestive heart failure may complicate excessive fluid administration, preeclampsia, anemia, or hyperthyroidism.

Treatment

A. Hydatidiform Mole

1. Evacuation—After the diagnosis has been confirmed, blood type, hematocrit, and thyroid, liver, and renal function tests should be obtained. A chest radiograph can rule out metastasis to the lungs. Subsequently, the molar pregnancy should be terminated. Suction curettage under general anesthesia is the method of choice once the patient is deemed stable. This can be safely accomplished even when the uterus is the size of a 28-week gestation. Local or regional anesthesia may be an option for the stable, cooperative patient with a small uterus. Intravenous oxytocin should be administered after dilation of the cervix but before the start of evacuation and may be continued, if necessary, for 24 hours post-evacuation. Tissue should be submitted for pathologic study. Blood loss usually is moderate, but precautions should be taken for the possibility of hemorrhage requiring a transfusion. When a large hydatidiform mole (>12 weeks in size) is evacuated by suction curettage, a laparotomy setup should be readily available, as hysterotomy, hysterectomy, or bilateral hypogastric artery ligation may be necessary if perforation or hemorrhage occurs. After the completion of the evacuation, all Rh-negative patients should receive Rh immune globulin.

Hysterectomy continues to remain an option for good surgical candidates not desirous of future pregnancy and for older women (who are more likely to develop malignant sequelae). If theca lutein cysts are encountered at laparotomy, the ovaries should remain intact, as regression to normal size will occur with diminishing hCG titers. Surgical treatment of these cysts is indicated only if rupture, torsion, or hemorrhage occurs or if the enlarged ovaries become infected.

It is important to note that hysterectomy does not eliminate the need for careful postsurgical surveillance with hCG testing, although the likelihood of metastatic disease following hysterectomy for gestational trophoblastic disease decreases from 20 to 3.5%. Current recommendations restrict hysterotomy to cases complicated by hemorrhage. Medical induction of labor with prostaglandins, oxytocin, or intra-amniotic instillation of prostaglandin or hypertonic solutions is no longer an acceptable method for evacuation of a molar pregnancy.

2. Prophylactic chemotherapy—Controversy surrounds the use of prophylactic chemotherapy (with methotrexate or dactinomycin) after a complete molar pregnancy. Several studies indicate that the incidence of postmolar gestational trophoblastic neoplasia may be decreased with prophylactic chemotherapy. However, further studies are required to determine whether the potential side effects warrant such treatment in noncompliant patients and in those at high risk for persistent gestational trophoblastic disease (age >35 years, history of prior molar pregnancy, trophoblastic hyperplasia).

3. Surveillance—Despite earlier diagnosis of molar pregnancies, the incidence of persistent gestational trophoblastic disease has not decreased. Three-fourths of patients with malignant nonmetastatic trophoblastic disease and half of patients with malignant metastatic disease develop these tumors following a hydatidiform mole. In the remainder, disease arises subsequent to a term pregnancy, abortion, or ectopic pregnancy. Several clinical features of hydatidiform moles are recognized as having a high association with malignant trophoblastic neoplasia. In general, at diagnosis, the larger the uterus and the higher the hCG titer, the greater the risk for malignant gestational trophoblastic disease. The combination of theca lutein cysts and uterine size excessive for gestational age is associated with an extremely high risk of malignant sequelae. Pathologic specimens with marked nuclear atypia, necrosis, hemorrhage, or trophoblastic proliferation may also increase the risk of persistent disease.

Regardless of the method of termination (suction curettage or hysterectomy) or presence of high-risk features, close monitoring with serial hCG titers is essential for every patient, as the incidence of malignant sequelae approaches 20–30%. After evacuation of the molar pregnancy, the patient should undergo serial hCG determinations, beginning within 48 hours after evacuation and then at weekly intervals until hCG values decline to undetectable levels (<5 mIU per milliliter) on three successive assays. If titer remission occurs spontaneously within 14 weeks and without a titer plateau, the hCG titer should then be repeated monthly for at least 6 months to 1 year before the patient is released from close medical supervision. Thereafter, the patient may enter into a routine gynecologic care program.

A gynecologic examination should be done 1 week after evacuation, at which time blood may be taken for the hCG titer. Estimates of uterine size, presence of adnexal masses (theca lutein cysts) and presence of vulvar, vaginal, or cervical lesions should be noted. Unless symptoms develop, the examination may be repeated at 4-week intervals throughout the observation period. If pre-evacuation chest radiography has revealed pulmonary metastases, chest radiographs should be repeated at 4-week intervals until spontaneous remission is confirmed, then at 3-month intervals during the remainder of the surveillance period.

Effective contraceptive measures should be implemented and maintained throughout the period of surveillance. Studies have not shown an increased risk of persistent gestational trophoblastic neoplasia after a molar pregnancy with the use of oral contraceptives. Therefore, they remain the most widely used method of birth control. A patient who has entered into spontaneous remission with negative titers, examinations, and chest radiographs for 6 months to 1 year and who is desirous of becoming pregnant may terminate contraceptive practices. Successful pregnancy is the norm, and complications are similar to those of the general population.

Therapy for persistent gestational trophoblastic neoplasia after evacuation of a hydatidiform mole is usually instituted because of an abnormal hCG regression curve. The most critical period of observation is the first 4 to 6 weeks post-evacuation. Although the hCG titer usually returns to normal by 1–2 weeks after evacuation of a hydatidiform mole, it should normalize in most women by the eighth week.

Approximately 70% of patients achieve a normal hCG level within 8 weeks of evacuation. Very few patients whose hCG titers normalize during this interval will require future treatment. In the past, therapy for persistent disease was initiated for the 30% of women whose hCG titer remained elevated at or beyond 8 weeks post-termination. However, current data suggest that half of these patients will demonstrate a continuous decline in titers and ultimately achieve normal hCG levels without further treatment. The remaining half will experience a rising or plateauing titer with histologic evidence of an invasive mole or choriocarcinoma.

Delayed postevacuation bleeding is uncommon after a molar pregnancy and signifies the presence of an invasive mole or choriocarcinoma. It is invariably attended by an enlarging uterus and an abnormal hCG regression pattern. In some cases, curettage is effective in stopping the bleeding, although little intracavitary tissue will be present in most of these cases. The mainstay of treatment is chemotherapy.

B. Malignant Gestational Trophoblastic Neoplasia

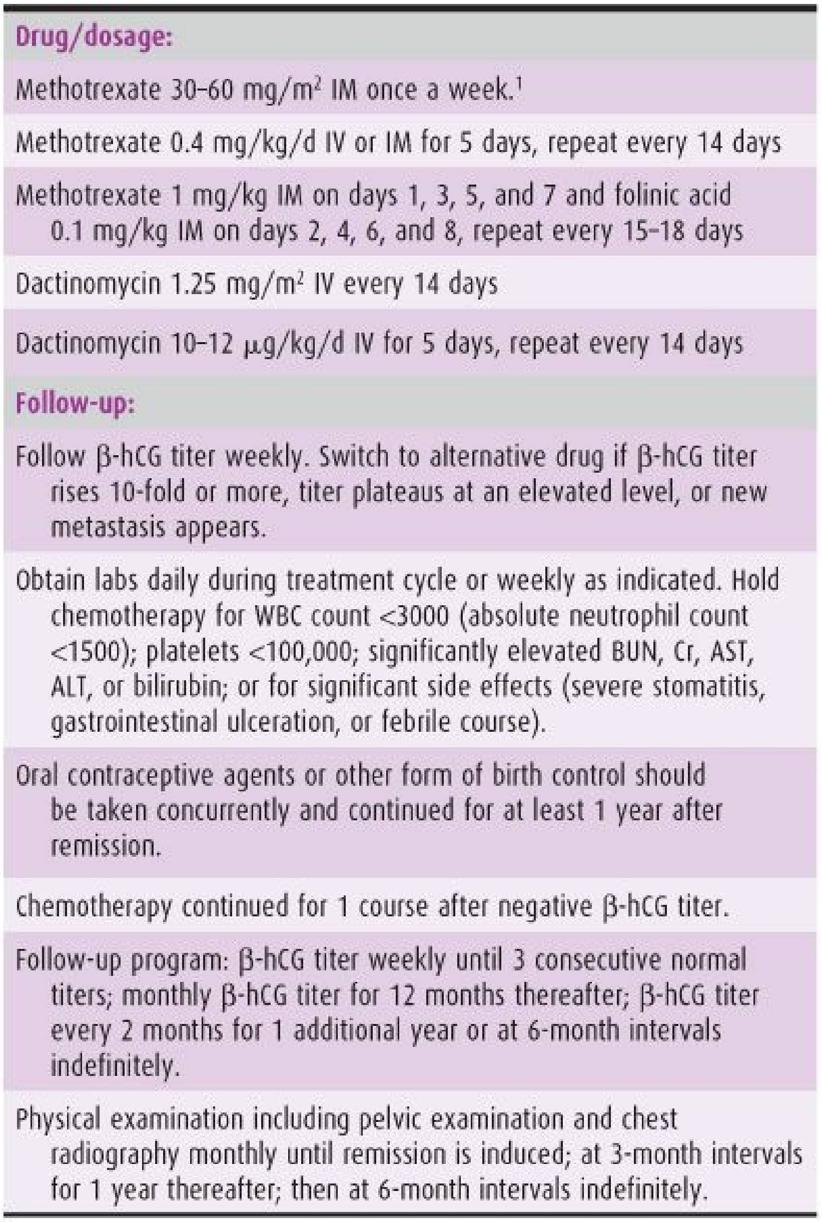
According to the 2002 criteria established by the International Federation of Gynecology and Obstetrics (FIGO), malignant gestational trophoblastic neoplasia may be diagnosed in the setting of (1) a rise in hCG levels of 10% or greater for ≥3 values over 2 weeks; (2) a plateau in ≥4 hCG values over 3 successive weeks; (3) hCG levels elevated at 6 months postevacuation; or (4) a tissue diagnosis of choriocarcinoma.

Once the diagnosis of malignant trophoblastic disease is suspected or established, an accurate history and physical examination are crucial. Most patients will have an enlarged uterus as well as ovarian enlargement caused by theca lutein cysts. Sites of metastasis must be sought, especially in the lower genital tract. A chest radiograph can diagnose lung metastases, although a chest computerized tomography (CT) will miss fewer pulmonary metastatic lesions. Liver metastases may be diagnosed with ultrasonography or CT scan. Brain metastases are best evaluated with a CT scan or magnetic resonance imaging (MRI). The ratio of serum hCG values to the concentration of hCG in cerebrospinal fluid (normal >60:1) may also prove helpful. Baseline hematologic counts, coagulation studies, and hepatic and renal function tests are critical in later assessing the risk of drug toxicity. After all sites of metastases have been identified and the patient's desires for preservation of reproductive function are determined, specific therapy should be initiated.

1. Nonmetastatic malignant gestational trophoblastic disease—Trophoblastic disease confined to the uterus is the most common malignant lesion seen in gestational trophoblastic neoplasia. The diagnosis is usually made during the postmolar surveillance period. Therapy for patients with nonmetastatic malignant trophoblastic disease includes (1) single-agent chemotherapy or (2) combination chemotherapy and hysterectomy, with surgery performed on the third day of drug therapy for patients who do not wish to preserve reproductive function.

Table 51–2 summarizes the recommended chemotherapeutic regimens available for nonmetastatic gestational trophoblastic neoplasia. Single-agent chemotherapy using methotrexate or dactinomycin has demonstrated clear-cut superiority over other protocols. A randomized trial conducted by the Gynecologic Oncology Group concluded that biweekly IV dactinomycin 1.25 mg/m^2 achieved a higher complete response rate as compared to weekly IM methotrexate 30 mg/m^2. The methotrexate dose used in this trial, however, was lower than the weekly dose of 50 mg/m^2 given typically to most low-risk patients and may have accounted for the superiority of the dactinomycin. Therefore, the regimen of choice in this group of patients has yet to be determined.

Table 51–2. Chemotherapy regimens for nonmetastatic or low-risk metastatic gestational trophoblastic disease.



Drug/dosage:
Methotrexate 30–60 mg/m^2 IM once a week.[1]
Methotrexate 0.4 mg/kg/d IV or IM for 5 days, repeat every 14 days
Methotrexate 1 mg/kg IM on days 1, 3, 5, and 7 and folinic acid 0.1 mg/kg IM on days 2, 4, 6, and 8, repeat every 15–18 days
Dactinomycin 1.25 mg/m^2 IV every 14 days
Dactinomycin 10–12 μg/kg/d IV for 5 days, repeat every 14 days
Follow-up:
Follow β-hCG titer weekly. Switch to alternative drug if β-hCG titer rises 10-fold or more, titer plateaus at an elevated level, or new metastasis appears.
Obtain labs daily during treatment cycle or weekly as indicated. Hold chemotherapy for WBC count <3000 (absolute neutrophil count <1500); platelets <100,000; significantly elevated BUN, Cr, AST, ALT, or bilirubin; or for significant side effects (severe stomatitis, gastrointestinal ulceration, or febrile course).
Oral contraceptive agents or other form of birth control should be taken concurrently and continued for at least 1 year after remission.
Chemotherapy continued for 1 course after negative β-hCG titer.
Follow-up program: β-hCG titer weekly until 3 consecutive normal titers; monthly β-hCG titer for 12 months thereafter; β-hCG titer every 2 months for 1 additional year or at 6-month intervals indefinitely.
Physical examination including pelvic examination and chest radiography monthly until remission is induced; at 3-month intervals for 1 year thereafter; then at 6-month intervals indefinitely.

ALT, alanine transaminase; AST, aspartate transaminase; Cr, creatinine; BUN, blood urea nitrogen; IM, intramuscular; IV, intravenous.

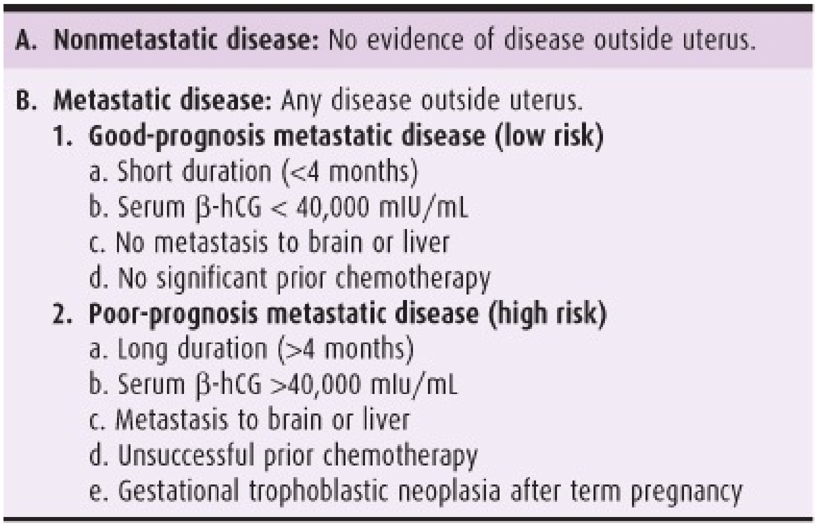
[1] For nonmetastatic disease only.

Treatment failure or intolerable side effects should result in administration of the alternative agent or regimen. Each treatment cycle should be repeated as soon as normal tissues (bone marrow and gastrointestinal mucosa) have recovered, with a minimum 7-day window between the last day of one course and the first day of the next course. Overall, the complete response rate to single-agent therapy ranges from 60 to 98%, with salvage rates approaching 100%. Methotrexate is contraindicated in the presence of hepatocellular disease or when renal function is impaired.

During treatment, weekly quantitative hCG titers and complete blood counts should be obtained. Before each course of therapy, liver and renal function assessments should be assessed. At least 1 additional course of drug therapy should be given after attainment of the first normal hCG value. The number of treatment cycles necessary to induce remission is proportionate to the magnitude of the hCG concentration at the start of therapy. An average of 3 or 4 courses of single-agent therapy is usually required. After remission has been induced and treatment is completed, hCG assays should be obtained monthly for 1 year.

2. Metastatic gestational trophoblastic disease—Treatment in metastatic disease uses either single-agent chemotherapy (Table 51–2) or multiagent chemotherapy in cases in which resistance to a single agent is anticipated. Several systems have been developed to determine at onset which patients will require more aggressive therapy. The National Cancer Institute system is used in the United States to determine whether the patient will have a good or poor prognosis in response to single-agent chemotherapy (Table 51–3).

Table 51–3. Categorization of gestational trophoblastic neoplasia.



A. **Nonmetastatic disease:** No evidence of disease outside uterus.

B. **Metastatic disease:** Any disease outside uterus.
  1. **Good-prognosis metastatic disease (low risk)**
    a. Short duration (<4 months)
    b. Serum β-hCG < 40,000 mIU/mL
    c. No metastasis to brain or liver
    d. No significant prior chemotherapy
  2. **Poor-prognosis metastatic disease (high risk)**
    a. Long duration (>4 months)
    b. Serum β-hCG >40,000 mIu/mL
    c. Metastasis to brain or liver
    d. Unsuccessful prior chemotherapy
    e. Gestational trophoblastic neoplasia after term pregnancy

Table 51–4 highlights the World Health Organization (WHO) scoring system in which patients are categorized into low- or high-risk groups based on risk factors such as age, type of antecedent pregnancy, interval from antecedent pregnancy to initiation of chemotherapy, pretreatment hCG level, size of largest tumor, site of metastases, number of metastases, and prior chemotherapy. A total score of 0–6 is considered low risk and a total score ≥7 is categorized as high risk.

Table 51–4. Modified WHO prognostic scoring system as adapted by FIGO.

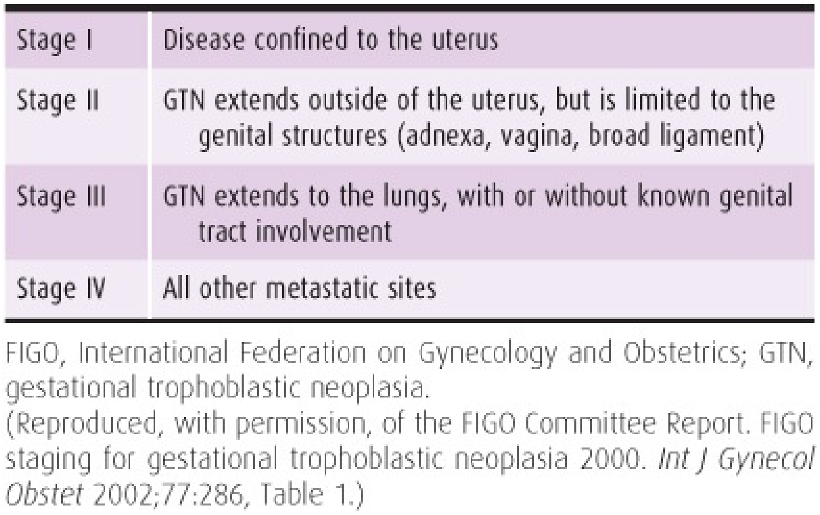
	0	1	2	4
Age, years	<40	≥40	–	–
Antecedent pregnancy	Mole	Abortion	Term	–
Interval months from index pregnancy	<4	4-<7	7-<13	≥13
Pretreatment serum hCG (IU/mL)	$<10^3$	10^3-$<10^4$	10^4-$<10^5$	$\geq 10^5$
Largest tumor size (including uterus)	–	3-<5 cm	≥5 cm	–
Site of metastases	Lung	Spleen, kidney	Gastrointestinal	Liver, brain
Number of metastases	–	1-4	5-8	>8
Previous failed chemotherapy	–	–	Single drug	2 or more drugs

FIGO, International Federation on Gynecology and Obstetrics, WHO, World Health Organization.

(Reproduced, with permission, of the FIGO Committee Report. FIGO staging for gestational trophoblastic neoplasia 2000. *Int J Gynecol Obstet* 2002;77:286, Table 4.)

The revised 2002 FIGO staging system combines the use of both anatomic and nonanatomic factors (Table 51–5). A patient is assigned a stage based on the anatomic location of disease and given a risk factor score based on the WHO prognostic scoring system. The goal of the revised FIGO staging is to improve the assessment and clinical management of patients and to unify staging to allow for international comparisons in treatment success.

Table 51–5. FIGO anatomic staging.



Stage I	Disease confined to the uterus
Stage II	GTN extends outside of the uterus, but is limited to the genital structures (adnexa, vagina, broad ligament)
Stage III	GTN extends to the lungs, with or without known genital tract involvement
Stage IV	All other metastatic sites

FIGO, International Federation on Gynecology and Obstetrics; GTN, gestational trophoblastic neoplasia.
(Reproduced, with permission, of the FIGO Committee Report. FIGO staging for gestational trophoblastic neoplasia 2000. *Int J Gynecol Obstet* 2002;77:286, Table 1.)

A. GOOD-PROGNOSIS PATIENTS—Based on the clinical classification of malignant disease, patients can be expected to respond satisfactorily to single-agent chemotherapy if (1) metastases are confined to the lungs or pelvis, (2) serum hCG levels are below 40,000 mIU/mL at the onset of treatment, and (3) therapy is started within 4 months of apparent onset of disease. The most common site of metastasis in gestational trophoblastic disease is the lungs. When a patient develops pulmonary metastasis with elevation of the hCG titer, choriocarcinoma is a more likely cause than metastatic invasive mole, although the latter can also metastasize to the lungs.

The advantage of single-agent chemotherapy over multiagent therapy lies in its more favorable toxicity profile, with fewer total side effects, and a lower likelihood that these effects would be irreversible. It is important to keep in mind that despite the “good-prognosis” designation of low-risk disease, failure of drug therapy does occur in 10% of cases. Therefore, meticulous care by a knowledgeable physician such as a gynecologic oncologist is necessary for optimal outcomes.

In good-prognosis patients, single-agent chemotherapy (Table 51–2) with methotrexate is considered the drug of choice. Ideally, the 5-day treatment course is given every other week, as the possibility of tumor regrowth increases with treatment gaps >2 weeks. Once negative titers have been achieved, an additional course is administered before beginning the period of surveillance. In cases in which resistance to methotrexate occurs, as manifested by rising or plateauing titers or by the development of new metastases, or cases in which negative titers are not achieved by the fifth course of methotrexate, the patient should be given dactinomycin. Dactinomycin should also be the agent of choice for patients who experience severe side effects with methotrexate.

B. POOR-PROGNOSIS PATIENTS—Poor-prognosis patients, based on the Clinical Classification of Malignant Disease, are those with any of the following risk factors: (1) serum hCG titers >40,000 mIU/mL at the onset of treatment, (2) diagnosis of disease more than 4 months after molar pregnancy, (3) brain or liver metastases, (4) prior unsuccessful chemotherapy, or (5) onset after term gestation. These patients respond poorly (<40% response rate) to single-agent therapy. A poor response is also seen in patients with advanced revised FIGO stages and WHO scores ≥7. These patients present a serious challenge to the clinician, as many have been previously treated with chemotherapy, have developed resistance to key agents, and/or have accumulated considerable toxicity with depleted bone marrow reserves. In fact, prior unsuccessful chemotherapy is considered to be one of the worst prognostic factors.

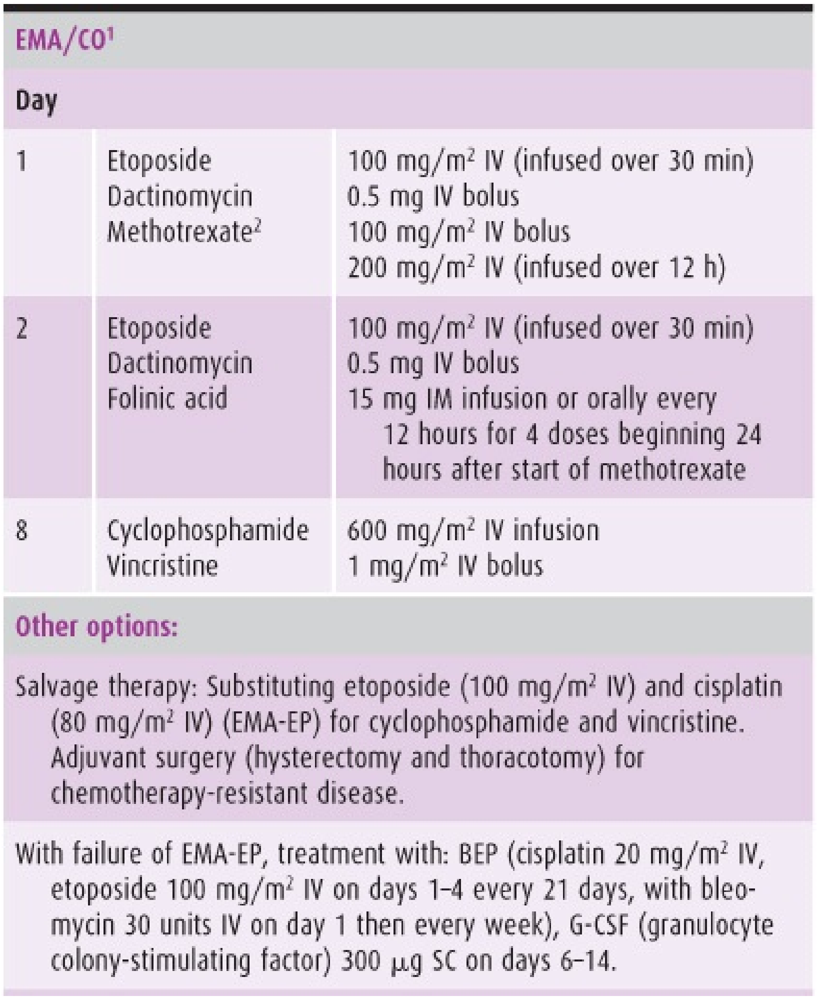
Generally, poor-prognosis patients are managed by a gynecologic oncologist and may require prolonged hospitalization and multiple courses of chemotherapy. They often need multispeciality care and other life-support measures, including hyperalimentation, antibiotics, and transfusions to correct the effects of marrow depression.

Central nervous system involvement, particularly brain metastases with focal neurologic signs, commonly occurs with choriocarcinoma. Because patients with brain or liver metastases are at high risk of sudden death from hemorrhagic lesions, it is standard practice to institute whole-brain or whole-liver irradiation concomitantly with combination chemotherapy. Uncertainty remains regarding whether radiation therapy exerts its beneficial effects by destroying tumor in combination with drug therapy or by preventing fatal hemorrhage and thus keeping the patient alive until remission with chemotherapy has been achieved. For acute bleeding episodes, surgical intervention or angiographic embolization should be considered.

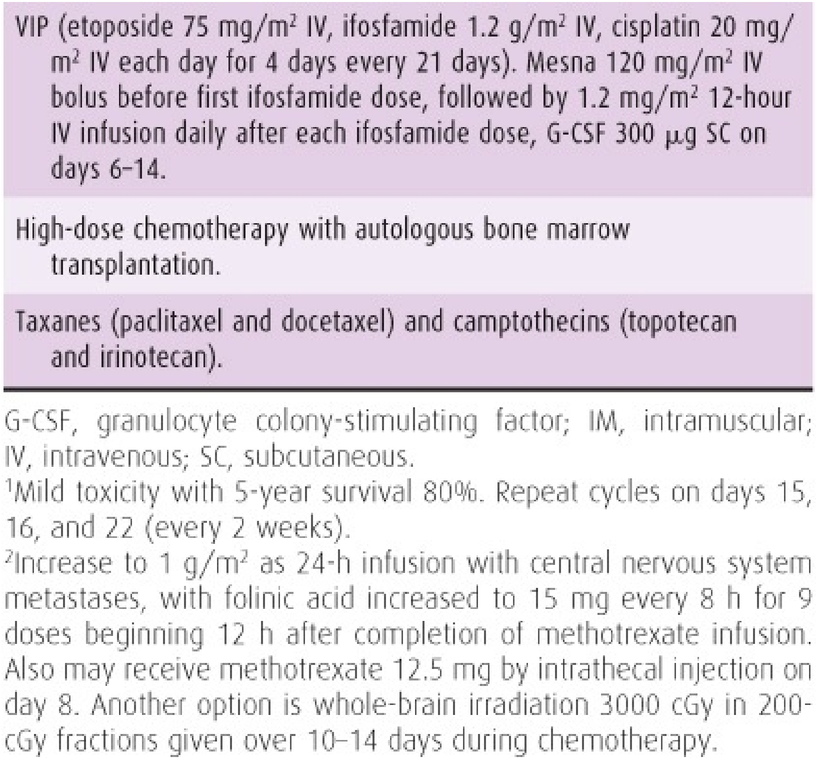
Cerebral metastases are treated over a 2-week period with radiation given at a dosage of 3 Gy daily, 5 days a week, to a total organ dose of 30 Gy. Whole-liver irradiation is usually accomplished over 10 days to attain a 20-Gy whole-organ dose given at a rate of 2 Gy daily, 5 days a week. Other treatment options include selective hepatic artery chemotherapy infusion.

Previously, patients with poor prognosis or high-risk gestational trophoblastic neoplasia were treated with methotrexate, dactinomycin, and chlorambucil or cyclophosphamide and the modified Bagshawe protocol (cyclophosphamide, hydroxyurea, methotrexate, vincristine, cyclophosphamide, and dactinomycin). Currently, etoposide, methotrexate, dactinomycin, cyclophosphamide, and vincristine (EMACO) chemotherapy (Table 51–6) repeated every 2 weeks provides the best response rate (approximately 80%) with the lowest side-effect profile. Monitoring for drug toxicity is the same as that in single-agent therapy but with higher vigilance due to the possibility of combined toxicity.

Table 51–6. Current treatment regimens for high-risk metastatic gestational trophoblastic disease.



EMA/CO[1]		
Day		
1	Etoposide Dactinomycin Methotrexate[2]	100 mg/m^2 IV (infused over 30 min) 0.5 mg IV bolus 100 mg/m^2 IV bolus 200 mg/m^2 IV (infused over 12 h)
2	Etoposide Dactinomycin Folinic acid	100 mg/m^2 IV (infused over 30 min) 0.5 mg IV bolus 15 mg IM infusion or orally every 12 hours for 4 doses beginning 24 hours after start of methotrexate
8	Cyclophosphamide Vincristine	600 mg/m^2 IV infusion 1 mg/m^2 IV bolus
Other options:		
Salvage therapy: Substituting etoposide (100 mg/m^2 IV) and cisplatin (80 mg/m^2 IV) (EMA-EP) for cyclophosphamide and vincristine. Adjuvant surgery (hysterectomy and thoracotomy) for chemotherapy-resistant disease.		
With failure of EMA-EP, treatment with: BEP (cisplatin 20 mg/m^2 IV, etoposide 100 mg/m^2 IV on days 1–4 every 21 days, with bleomycin 30 units IV on day 1 then every week), G-CSF (granulocyte colony-stimulating factor) 300 µg SC on days 6–14.		



VIP (etoposide 75 mg/m^2 IV, ifosfamide 1.2 g/m^2 IV, cisplatin 20 mg/m^2 IV each day for 4 days every 21 days). Mesna 120 mg/m^2 IV bolus before first ifosfamide dose, followed by 1.2 mg/m^2 12-hour IV infusion daily after each ifosfamide dose, G-CSF 300 μg SC on days 6–14.
High-dose chemotherapy with autologous bone marrow transplantation.
Taxanes (paclitaxel and docetaxel) and camptothecins (topotecan and irinotecan).

G-CSF, granulocyte colony-stimulating factor; IM, intramuscular; IV, intravenous; SC, subcutaneous.

[1] Mild toxicity with 5-year survival 80%. Repeat cycles on days 15, 16, and 22 (every 2 weeks).

[2] Increase to 1 g/m^2 as 24-h infusion with central nervous system metastases, with folinic acid increased to 15 mg every 8 h for 9 doses beginning 12 h after completion of methotrexate infusion. Also may receive methotrexate 12.5 mg by intrathecal injection on day 8. Another option is whole-brain irradiation 3000 cGy in 200-cGy fractions given over 10–14 days during chemotherapy.

Treatment of malignant trophoblastic disease must be continued with repeated courses of combination chemotherapy until hCG titers return to undetectable levels (<5 mIU/mL). Complete remission is documented only after 3 consecutive weekly normal hCG titers have been achieved. It is recommended that all high-risk patients receive at least 3 courses of multiagent chemotherapy after hCG titers have returned to normal. After remission is achieved, follow-up is the same as for hydatidiform moles and metastatic good-prognosis disease.

Salvage therapy for disease not responsive to EMACO substitutes cisplatin and etoposide for cyclophosphamide and vincristine (EP-EMA) (Table 51–6). Close monitoring of renal function is required because of nephrotoxicity secondary to cisplatin and renally excreted methotrexate. Other treatment options include paclitaxel, topotecan, and high-dose chemotherapy with autologous bone marrow transplantation. As stated previously, chemotherapy should be continued for at least 3 cycles after a negative hCG is achieved. In resistant cases, adjunctive measures along with chemotherapy may include hysterectomy, resection of metastatic tumors, or irradiation of unresectable lesions.

During and after treatment, a thorough discussion about birth control and reproductive options is of utmost importance. Oral contraceptive pills should be used if not contra-indicated. Contraceptive efforts should be continued for at least 1 year after remission.

3. Placental-Site Trophoblastic Tumor—As treatment of PSTT is generally resistant to chemotherapy, hysterectomy is the recommended route of treatment. Partial uterine resection involving the tumor is possible if the patient desires future fertility. Chemotherapy is indicated in cases of metastatic disease. EP-EMA is the preferred regimen over EMACO, with paclitaxel and topotecan used when resistance develops. The greatest adverse outcomes are associated with an interval of >2 years from the antecedent pregnancy to diagnosis.

Prognosis

The prognosis for molar pregnancies treated with evacuation is uniformly excellent, although close surveillance is needed, as outlined previously. After spontaneous normalization of hCG values after evacuation, recurrence rates are <0.5%. The prognosis for malignant nonmetastatic disease with appropriate therapy is also quite good, as almost all patients are cured. More than 90% of these patients can preserve reproductive function, but first-line therapy fails in 6.5%.

Additionally, more than 90% of patients with good-prognosis or low-risk metastatic disease respond to single-agent chemotherapy. Virtually all patients with this type of disease can be cured without the need for hysterectomy. In poor-prognosis or high-risk metastatic disease, the best results are achieved with the EMACO chemotherapy regimen and concurrent radiation. Approximately 75–85% of patients achieve remission with a 69% salvage rate. This is a similar response rate to agents used previously but with fewer side effects. Women with nonpulmonary metastases have the worst prognosis, with reports of survival ranging from 0 to 60% for hepatic involvement and 50–80% for central nervous system involvement. Survival decreases to <20% when prior chemotherapeutic agents have been administered or if brain metastasis develops while undergoing treatment. In metastatic disease that is in remission, relapse can occur in 8% of patients, usually in the first several months after termination of therapy but even as late as 3 years.

Over the years, deaths from chemotherapeutic drug toxicity have decreased considerably. However, multiagent chemotherapy, specifically a regimen containing etoposide, is associated with a 50% increased risk for secondary tumors. One retrospective study found that the relative risk for developing myeloid leukemia and colon cancer was 16.6 and 4.6, respectively. When survival exceeded 25 years, the relative risk for developing breast cancer was 5.8.

Subsequent pregnancies are not at increased risk for complications such as preterm labor, congenital anomalies, or stillbirth. These pregnancies should, however, be monitored early with ultrasonography and hCG levels as there is a 1% risk of recurrent gestational trophoblastic disease after 1 molar pregnancy and a 15% risk of recurrence after 2 molar pregnancies. After delivery, the placenta should be sent to pathology and an hCG level checked at the 6-week postpartum visit.

In cases in which pregnancy occurs before completion of standard postmolar surveillance, the pregnancy may be continued with close observation, and the risks discussed with the patient. Most of these pregnancies have a favorable outcome, but a small risk exists for delayed diagnosis of recurrent gestational trophoblastic disease.

Radiation and Chemotherapy for Gynecologic Cancers

Wafic M. ElMasri, MD
Oliver Dorigo, MD, PhD

Two European discoveries in the late 1800s led to future radiation treatment of human malignancies. While studying the penetrating power of cathode ray emission in Germany, Wilhelm Roentgen discovered x-rays on November 8, 1895. In France, the Curies isolated radium from uranium ore in 1898. Soon thereafter, Robert Abbe of New York City introduced radium for medical therapy, and Howard Kelly of Baltimore pioneered radium treatment of cervical cancer. Since then, radiation therapy has evolved to become a major modality in the treatment of many cancers, particularly those of the female reproductive tract.

RADIATION PRINCIPLES

Radiation therapy is used for definitive or palliative treatment of cancer and may be defined as therapeutic delivery of radiation to a target tissue, which results in tissue damage. Radiation causes breaks in DNA and generates free radicals from cell water that may damage cell membranes, proteins, and organelles. Such radiation may be electromagnetic or particulate, both of which transfer energy to the electrons or nuclei of the target atoms.

Electromagnetic radiation is energy that is transmitted at the speed of light through oscillating electric and magnetic fields. The energy contained in these fields can be described as discrete units known as photons. The energy of each photon is proportional to the frequency of the wave associated with that photon. Because radiation with a shorter wavelength has greater frequency, it carries greater energy per photon, allowing deeper tissue penetration. The most clinically relevant forms of electromagnetic radiation are x-rays and gamma rays. For therapeutic applications, x-rays are mechanically produced by linear accelerators that accelerate electrons to very high energies. These electrons then strike a target within the accelerator, usually tungsten, to produce a beam of x-rays that is targeted at the patient. Gamma rays are produced by the decay of radioactive substances. Currently, the most commonly used radioisotopes for gynecologic cancer treatments are cesium-137 and iridium-192.

Particulate radiation uses subatomic particles (electrons, neutrons, protons), instead of photons, to deliver the dose of radiation. Compared with electromagnetic radiation, particle-beam therapy enables more precise dose localization and better depth-dose distribution.

Interaction of Photons with Matter

The first step in the absorption of an incident photon with matter is the conversion of the energy of that photon into the kinetic energy of an electron, or electron–positron pair. Depending on the energy of the photon, this conversion takes place either through the photoelectric effect, the Compton effect, or pair production. In the lower range of energy transfer, the photoelectric effect predominates, whereas in the transfer of higher levels of energy, the Compton effect and pair production are more prevalent.

Photoelectric effect: an incident low-energy photon (0.5–100 kV) interacts with a tightly bound inner shell electron of the target tissue. The energy is completely absorbed by this electron, which is ejected from the atomic orbit with kinetic energy equal to the photon energy. The product electron then ionizes the surrounding tissue. The lower the energy of the incoming photon and the higher the atomic number of the tissue, the more likely photoelectric effect will occur. Absorption is directly proportional to the atomic number of the target. Tissues bearing elements of higher atomic numbers (eg, calcium in bone) absorb proportionately higher levels of radiation, which may lead to toxicity.

Compton effect: an incident mid-energy photon (100 kV–20 MV) transfers energy to an outer-shell electron in the target tissue, causing ejection of this electron. The photon's energy is incompletely absorbed; instead, the photon is scattered at an angle to its original path. Both the product electron and the scattered incoming photon (which now has lower energy) continue with ionizing interactions (Fig. 52–1). The Compton effect is inversely proportional to the energy of the incoming photon and is independent of atomic number (ie, all tissue absorbs the same amount of energy). The Compton effect accounts for the biologic effects on tissues seen in radiation therapy.

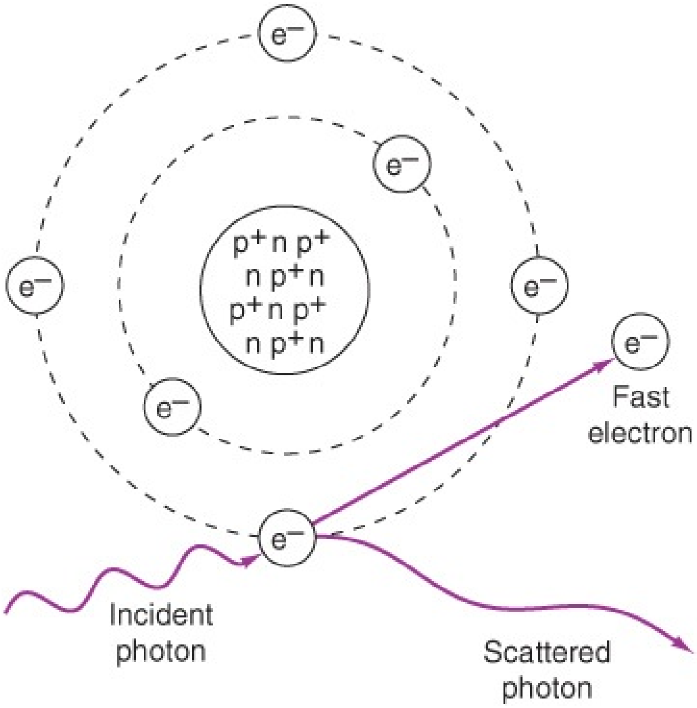

Figure 52–1. Absorption of an x-ray photon by the Compton process. The photon interacts with a loosely bound planetary electron of an atom of the absorbing material. Part of the photon energy is given to the electron as kinetic energy. The photon, deflected from its original direction, proceeds with reduced energy. e^-, electron; p^+, proton; n, neutron. (Reproduced, with permission, from Hall EJ. *Radiobiology for the Radiologist*. 4th ed. Philadelphia, PA: JB Lippincott; 1994, p. 7.)

Pair production: refers to a complex interaction between an incident high-energy photon (>1.02 MV) with the nucleus of a target atom resulting in formation of a pair of electron–positron (e+) and negatively charged electron (e–) that scatters in the opposite direction. Because the pair production interaction typically predominates at energy levels above the range that is usually used in therapy, it plays a small role in most clinical settings.

Interaction of Photons with Tissue

As a radiation beam travels through a patient, it deposits energy in the tissue through interactions such as the Compton effect. The depth of tissue penetration is dependent on the energy. At 100% depth dose, 250 KeV will be reached at the skin level, 1.25 MeV at 5 mm, 6 MeV at 1.2 cm, and 20 MeV at 10 cm.

These interactions set secondary electrons in motion, which result in further ionizations. These ionizations lead to the breakage of chemical bonds and subsequent damage to DNA and cellular structures. The result is reproductive cell death and apoptosis in case of excessive damage.

The most critical target for damage within the cell is DNA. Direct damage occurs when a photon becomes absorbed by an atom in the DNA resulting in DNA breaks that are beyond the cell's repair machinery. More commonly, however, DNA breaks are indirect. The water surrounding the DNA is ionized by the radiation, creating oxygen radicals, hydroxyl radicals, peroxide, and hydrated electrons. These highly reactive species then interact with the DNA to cause damage.

Dosage Theory

Normal tissues as well as malignant cells are susceptible to toxicity induced by radiation therapy, the extent of which depends on total dose, fractionization, and tumor volume.

After exposure to radiation, tissue survival follows a predictable curve that essentially constitutes the number of viable clone cells (Fig. 52–2). The shoulder represents the cell's enzymatic ability to reverse radiation-induced damage. As radiation increases, cells become incapable of self-repair, and a logarithmic pattern of cell destruction occurs. Importantly, for every increase in dosage that occurs beyond the shoulder, a constant fraction of cells is eliminated (**log-kill hypothesis**).

The implications of these observations provide some of the rationale for dividing (fractionating) the total dose of radiation therapy administered in the clinical setting. It is helpful to consider the so-called 4 Rs of radiobiology to understand the effects of fractionated doses at the cellular level:

A. Repair

Fractionation into small doses allows for sublethal injury repair (shoulder repetition) and results in the higher total dose necessary to achieve the same biologic effect. When a specified radiation dose is divided into ≥2 doses given at separate times, the number of cells surviving is higher than that seen when the same total dose is given at 1 time. However, fractionation allows the administration of a divided radiation dose that would not be tolerated by surrounding normal tissue if the specified dose were to be given in only 1 treatment.

B. Repopulation

The reactivation of stem cells that occurs when radiation is stopped is necessary for further tissue growth. Repopulation is cellular proliferation during delivery of a radiation therapy course. If the cancer repopulates slower than acutely responding normal tissue, fractionated radiation will be successful in eliminating tumor cells. The shorter the doubling time of tumor cells, the higher total dose of radiation will have to be delivered. Prolonged and unnecessary delays between radiation fractions decrease the effectiveness of the total radiation dose delivered.

C. Reoxygenation

Hypoxic cells are known to be relatively resistant to radiation. Oxygenated cells are 3 times more sensitive than cells irradiated under anoxic conditions (Fig. 52–2). Malignant cells located farther than 100 mm from capillary flow are at risk for hypoxia and may not be killed by radiation therapy. For this reason, it is important to correct anemia in patients undergoing radiation treatment so that tissue oxygen perfusion will be enhanced and tissues will become more radiosensitive. Fractionated radiation results in better oxygenation of initially hypoxic tumor cells. As tumor shrinks with radiation treatments, the percentage of hypoxic cells decrease and the percentage of radiation sensitive cells is increased.

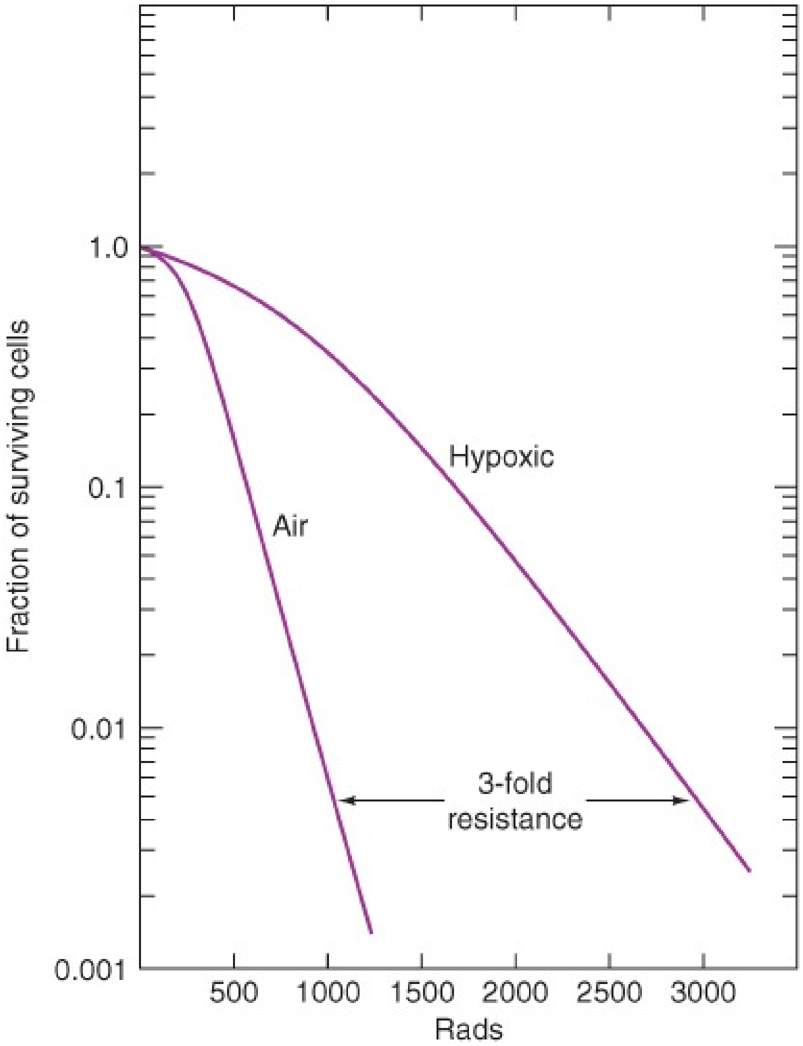

Figure 52–2. Typical radiation survival curve for mammalian cells. These cells have been irradiated and then plated out in culture, and the number of survivors has been determined by measuring the colonies (clones) of cells that survive. The curve is characterized by an initial shoulder followed by a log-linear region. Cells irradiated in air are considerably more sensitive than those irradiated in nitrogen (hypoxic), and the difference between the levels of killing is frequently about 3-fold. It is believed that most clinically demonstrable tumors have areas of hypoxia that lead to radioresistance. (Reproduced, with permission, from Morrow CP, Curtin JP, Townsend DE (eds). *Synopsis of Gynecologic Oncology*. 4th ed. New York: Churchill Livingstone; 1993, p. 449.)

D. Redistribution

Radiation-induced synchrony allows for cellular progression into a more radiosensitive part of the cell cycle during interfraction intervals. Within an asynchronous tumor cell population, fractionated radiation kills radiosensitive cells (late G_2 and M phase), leaving radioresistant cells (early G_1 and mid-late S phase) with little damage. Interfraction intervals allow for cell-cycle synchronization (progression to G_2 and M phase) and leads to higher overall cell death with each subsequent fraction. Cell killing is more effective with shorter cell-cycles.

Dosimetry

Dosimetry is the measurement of the amount of radiation absorbed by target tissue. The unit of absorbed dose is the Gray (Gy), which is defined as the joules of energy absorbed in a kilogram of tissue (J/kg). One Gy is equal to 100 rads. External pelvic irradiation is expressed in those terms, whereas internal irradiation (intracavitary) is also described in milligram-radium-equivalent hours (mgRaEq-hr). This latter unit is calculated by multiplying the mgRaEq of cesium or radium in the system by the number of hours the radioactive sources are left in place during treatment.

The amount of radiation used in radiation therapy varies depending on the type and stage of cancer. The typical dose for the primary treatment of solid epithelial tumors including advanced cervical cancer ranges from 60 to 85 Gy, whereas the lower doses between 20 and 40 Gy are used for lymphomas.

Adjuvant radiation therapy is used in selected cases after surgery for cervical and endometrial cancer. The radiation doses are typically lower compared with primary treatment, ranging between 45 and 60 Gy in 1.8- to 2-Gy fractions. Factors to be considered when planning radiation and selection of a dose include concurrent chemotherapy and patient comorbidities.

Planning of radiation treatment involves specialized treatment planning software that incorporates the radiation delivery method and several angles or sources to optimize the dose to the tumor and minimize the radiation effect on the surrounding healthy tissues. Computer-directed dosimetry permits the calculation of isodose curves, points of equal dose surrounding a radioactive source that permit critical considerations in avoiding overdose to the bladder and rectum. Unfortunately, the radiation tolerance of the bladder and rectum is close to the dosage levels required for curative radiation therapy of common pelvic cancers.

Fractionation

Fractionation is an important principle of radiation biology and treatment. The total radiation dose is given over a period of time at approximately 1.8–2 Gy per day over 5 days a week. Fractionation allows time for normal cells to recover and repair radiation-induced DNA damage. Tumor cells usually have dysfunctional repair mechanisms and are therefore preferentially effected by the radiation. In addition, fractionation allows tumor cells that were relatively radiation resistant during one treatment to enter a radiation sensitive phase of the cell cycle before the next fraction is given. Another tumor cell selective killing mechanism relates to hypoxia-induced radiation resistance. Hypoxic tumor cells might reoxygenate between fractions, therefore improving the effect of radiation during the next treatment.

TREATMENT METHODS

For gynecologic cancers, therapeutic radiation is delivered as external radiation (teletherapy), internal radiation (brachytherapy), or a combination of both.

External Irradiation (Teletherapy)

Early radiation therapists used electric x-ray sources that were basically modifications of Roentgen’s experimental apparatus. Electrons were accelerated across a vacuum tube to strike a tungsten target with the subsequent liberation of photons. These orthovoltage (140–400 keV) units were limited in their power to penetrate tissue effectively because of their relatively low energy output. Consequently, pronounced fibrotic skin changes and high absorbed bone radiation levels limited their usefulness in some patients.

As units generating higher levels of energy were developed, the penetrating power of the x-rays produced was enhanced, and less scattering of radiation was seen at the margins of the treatment area.

The surface skin dose was also diminished, of particular importance in the treatment of obese patients, and less toxic bone radiation was achieved (Fig. 52–3).

Figure 52–3. Typical isodose curves for orthovoltage (250 keV), cobalt 60, and a 6-MeV linear accelerator (LINAC). The most important difference between the megavoltage (cobalt 60 and LINAC) beams in comparison with the 250-keV beam is the movement of the 100% isodose line several millimeters beneath the surface. This results in elimination of the severe skin reactions characteristic of earlier radiation sources. In addition, the higher energy leads to deeper penetration as the energy of the beam increases.

The goal of external radiation treatment is to ensure that radiation is delivered to the target tissue without affecting uninvolved tissues and that the amount of radiation received is as uniform as possible. Traditionally, the planning of radiation treatment has been done in 2 dimensions (height and width). Today, this is achieved by optimized 3-dimensional conformal planning to more precisely target a tumor with radiation beams (height, width, and depth). Patients undergo computed tomography (CT) scanning in the treatment position, and the volume of abnormal tissue, that is, the gross tumor volume (GTV), is delineated. Given the possibility of microscopic extension along tissue planes, a margin of tissue is added to the GTV. This larger volume, the clinical tumor volume, is the volume of tissue to be irradiated. Using information from these images, special computer programs design radiation beams that "conform" to the shape of the tumor.

Internal Irradiation (Brachytherapy)

Brachytherapy is radiation therapy in which the source of therapeutic ionizing radiation is placed close to the treatment area. The chief advantage of local irradiation is that a relatively high dose of radiation can be applied to a limited anatomic region. The **inverse square law** has critical implications in clinical applications. The principle of the inverse square law states that the intensity of radiation is inversely proportional to the square of the distance from the source. An important implication is that the rapid falloff of radiant energy supplied by a central source precludes the achievement of cancerocidal doses at the margins of the pelvis. Consequently, external therapy must be used to provide adequate radiation to eliminate tumor at the periphery of large lesions and at the pelvic side walls, where metastatic disease may be present.

Brachytherapy can be delivered using an intracavitary approach with a variety of applicators, or via an interstitial approach using needles or catheters. Most applicators for intracavitary brachytherapy consist of an intrauterine tandem and paired colpostats or ovoids, which are placed in the lateral vaginal fornices. Interstitial applicators consist of multiple needles that are inserted into the tissue at or near the target site. Radioactive isotopes are then loaded into the applicators at the beginning of the treatment.

Several isotopes are available for brachytherapy. The most commonly used in the United States is a low-dose rate (LDR) approach employing cesium-137. However, acceptance of a high-dose rate (HDR) therapy, usually with iridium-192, is quickly gaining acceptance. HDR brachy-therapy offers some significant advantages over LDR, as it can be used on an outpatient basis, eliminates radiation exposure to medical personnel, and has shorter treatment times.

TREATMENT OF GYNECOLOGIC CANCER

Cervical Cancer

Treatment of cervical cancer is considered a prime example of the successful application of radiation therapy. The relative accessibility of a central cervical lesion, a predictable metastatic and local spread pattern, and the radiation tolerance of the cervix and surrounding tissues often permit the administration of curative therapy in cases of cervical carcinoma.

Radiation therapy with curative intent uses both external-beam and intracavitary radiation. Palliative radiation for advanced or recurrent cervical cancer may use either modality for control of bleeding, management of disease in the pelvis, and relief of pain.

The size of the radiation field used to treat a patient with carcinoma of the cervix must be carefully designed to encompass those structures at risk for regional spread of the cancer. The goal of external irradiation in is to sterilize metastatic disease to pelvic lymph nodes and the parametria and/or to decrease the size of the cervical lesion to allow optimal placement of intracavitary radioactive sources. A standard radiation field for external-beam radiation therapy extends inferiorly to the midpubis or 3–4 cm below the most distal disease, superiorly to the interface between the fourth and fifth interlumbar vertebrae, and lateral at least 1cm lateral to the bony pelvic markings. The dose for external-beam radiation therapy is approximately 40–45 Gy.

The rationale for external-beam radiation therapy is the treatment of the lymphatic lymph node chain along the pelvic side walls, but it also induces shrinkage of the primary cervical tumor. However, in order to deliver a curative dose to the tumor, brachytherapy needs to follow external-beam radiation therapy. This is done mainly by HDR radiation therapy applied directly to the tumor via a vaginal applicator. The doses of radiation are commonly calculated based on 2 reference points. Point A defines a point 2 cm lateral and 2 cm superior to the external cervical os in the plane of the implant. Point B is located 3 cm lateral to point A. The total dose for the primary treatment of cervical cancer ranges between 75 and 90 Gy when external and brachytherapy doses are combined.

Definitive radiation therapy is an acceptable alternative to radical surgery for women with early-stage disease (stages IA, IB1, and nonbulky IIA) and is the treatment of choice in more advanced stages. Concurrent cisplatin-based chemotherapy is synergistic and leads to better tumor control and clinical response. Numerous studies show that concomitant radiation therapy and chemotherapy (chemoradiation) improves overall and progression-free survival in patients with cervical cancer.

Concurrent chemotherapy does not generally lead to treatment delays, and it sensitizes cervical cancer cells to the effects of radiation therapy. Its proposed mechanisms of action include interference with and modification of sublethal injury repair, cell phase distribution, tumor vascularity, hypoxic cells, repopulation, cell survival curve, and apoptosis all culminating in maximal cellular lethal damage.

The treatment volume for women undergoing external-beam radiation therapy after radical surgery usually involves the whole pelvis. Patients with known or suspected metastatic disease to periaortic lymph nodes may be considered for extended-field irradiation that includes a para-aortic radiation field.

Endometrial Cancer

The decision to use radiation treatment for endometrial cancer is often made after comprehensive surgical staging has been performed and is dependent on the estimated risk of recurrent disease. Patients have been traditionally divided into different risk groups for adjuvant treatment decisions based on the likelihood of recurrence.

In general, low-risk patients have disease confined to the endometrium. Adjuvant radiation should be considered in patients over 60 years of age and patients with poorly differentiated tumors (grade 3), lower uterine segment involvement, or large tumor size. However, these criteria are controversial, and the decision to administer adjuvant radiation in early-stage disease is made at the physician’s discretion.

Intermediate-risk patients have cancers that are confined to the uterus but invade the myometrium or demonstrate occult cervical involvement. Other adverse prognostic factors that increase the risk for recurrence include invasion of the outer one-third of the myometrium, poor histologic differentiation, and the presence of lymphovascular invasion. The presence of these risk factors might prompt the administration of adjuvant pelvic radiation to reduce the rates of local recurrence.

Patients with **high risk of recurrence** have tumors with stromal cervical involvement (stage II), extrauterine disease (stage III and IV), or high-risk histologies (papillary serous or clear cell tumors). High-risk histologies have a propensity for lymphovascular and upper abdominal spread and are associated with a worse outcome than the hormone-dependent, more frequent endometrioid adenocarcinomas. When high-risk disease is present and confined to the pelvis, whole-pelvis radiation with or without vaginal brachytherapy should be considered. In the presence of distant disease, a combination of radiation and chemotherapy will be necessary to achieve tumor control.

Primary radiation therapy may be used in women who are considered to be at high surgical risk, such as the elderly and those with significant comorbidities. Patients with well-differentiated adenocarcinoma may be managed with tandem and ovoids or intrauterine Simon capsules. Patients with moderately or poorly differentiated cancers or those with involvement of the cervix are at risk for parametrial and pelvic lymph node spread and should receive whole-pelvic irradiation before brachytherapy.

Ovarian Cancer

The role of radiation therapy in the management of ovarian cancer is minor. There are no well-structured trials that demonstrate the benefit of external-beam radiation in the treatment of ovarian cancer. Several studies have compared the use of intraperitoneal chromic phosphate (^{32}P) with platinum-based chemotherapy in early-stage ovarian cancer. None of these trials showed a difference in 5-year survival rates, but the gastrointestinal complication rate was significant in the radiation group. Local radiation therapy is occasionally used for the treatment of isolated recurrences in ovarian cancer.

Vaginal Cancer

Radiotherapy remains the primary treatment for vaginal cancer, which is one of the rarest human malignancies and historically one of the gravest. A 1954 review of a published series of 992 patients reported an overall 5-year survival rate of 18%. More recent studies, however, have shown overall 5-year cure rates of 40–50%. Such improvement in survival rates is attributed to megavoltage external-beam therapy along with physical and technical advances in local irradiation. Despite radiation therapy being the primary treatment modality for vaginal cancers, there are no standardized treatment protocols. With squamous cell carcinoma comprising the most common form of vaginal cancer, most of these patients undergo whole-pelvic radiation therapy followed by intracavitary or interstitial brachytherapy. Patients with lesions involving the lower third of the vagina should have the inguinal and femoral lymph nodes included in the external-beam treatment field. Extended-field radiation to include periaortic lymph nodes may be needed if imaging studies reveal bulky pelvic or periaortic disease.

Vulvar Cancer

Slightly more common than vaginal cancer (5% vs. 2% of female malignancies), vulvar cancer is usually squamous cell in origin. The mainstay of treatment of stages I and II vulvar cancer is surgical, often consisting of radical vulvectomy plus inguinofemoral lymphadenectomy. Adjuvant pelvic radiation therapy benefits patients with close or positive surgical margins, as well as patients with positive inguinofemoral lymph nodes. In patients with more advanced vulvar squamous cancer (stage III or IV), chemoradiation may reduce the need for more radical surgery, including primary pelvic exenteration.

Complications of Radiation Therapy

Radiation therapy regimens are formulated to maximize the chances for cure while incurring the smallest amount of damage to normal tissues. The effects of radiation on normal tissue are what limit the doses of therapeutic radiation that can be administered. In gynecologic cancers, the most serious complications are those involving the gastrointestinal or genitourinary systems.

Planning of radiation dosimetry takes in account the sensitivity of the pelvic organs, which varies greatly between the different tissues. The vaginal mucosa tolerates 20,000–25,000 cGy in the area of the vaginal vault, whereas the bladder mucosa only tolerates 7000 cGy of total radiation. The rectum mucosa is even more sensitive, with 5000–6000 cGy as the maximum-tolerated dose. The most sensitive pelvic organs are the ovaries, which will cease all hormone production when a dose of 2000 cGy is reached. However, approximately 50% of all ovaries stop hormone production when about half of this dose is delivered.

Complications of radiation therapy are classified as early or delayed. **Early** radiation reactions result from direct damage of parenchymal cells in organs that are sensitive to radiation. These include enteritis, proctosigmoiditis, cystitis, vulvitis, and, occasionally, depression of bone marrow elements. Bowel side effects usually comprise cramping and diarrhea that require dietary adjustments and the judicious use of antidiarrheal agents. Such problems usually respond to appropriate medication, but occasionally radiation therapy must be interrupted or curtailed because of fulminant acute reactions.

Delayed radiation reactions are believed to be caused by slow vascular damage along with direct damage of parenchymal cells. Such injury may be manifested by chronic proctosigmoiditis, hemorrhagic cystitis, small- and large-bowel strictures, and the formation of rectovaginal and vesicovaginal fistulas. Pelvic fibrosis and loss of ovarian function may affect sexual activity in younger patients.

In order to protect the pelvic organs from radiation injury, isodose curves have to be calculated very carefully to minimize the radiation to the bladder and rectum. In young, fertile patients who require radiation therapy to the pelvis, the ovaries can surgically be moved from their location within the radiation field and area along the paracolic gutters (oophoropexy). In many cases, this will preserve ovarian function after radiation. When brachytherapy is administered using a vaginal applicator, the vagina is packed with gauze around the applicator, therefore creating a greater distance between the radiation source and the bladder and rectum.

NEW DIRECTIONS IN RADIATION THERAPY

Novel, improved radiation treatment strategies are under development. These include more effective radiation sensitizers, neutron beam therapy, and altered fractionation schemes. Intensity-modulated radiotherapy (IMRT) has emerged as a new teletherapy technique. IMRT improves the ability to conform the treatment volume to the 3-dimensional tumor shapes. The radiation beam’s intensity varies according to the shape of the tumor. The radiation dose intensity is increased in areas of gross tumor volume, whereas radiation to the surrounding tissue is significantly decreased. This tumor tailored radiation dose is intended to maximize tumor dose while protecting the surrounding normal tissue. As newer computer-imaging technologies continue to improve, further advances in anatomic contouring for planning and treatment are expected to translate into better local control rates, as well as improved survival with a wider margin of safety.

Section VII. Reproductive Endocrinology & Infertility

53
Infertility

Shahin Ghadir, MD
Gayane Ambartsumyan, MD, PhD
Alan H. DeCherney, MD

ESSENTIALS OF DIAGNOSIS

- ▶ Both male and female evaluation are needed to reach diagnosis.
- ▶ Male partner:
  - History
  - Semen analysis
  - If semen analysis abnormal, referral to urology, endocrine evaluation, and karyotyping in severe cases
  - State-mandated infectious disease panel if treatment includes intrauterine insemination or in vitro fertilization
- ▶ Female partner:
  - History, confirm ovulation
  - Physical exam to assess cervix, uterus, and adnexa for pathology
  - Cycle day 3 blood work and ultrasound to assess ovarian reserve
  - Hysterosalpingogram to evaluate uterine cavity and fallopian tubes
  - Possible saline sonogram to evaluate uterine cavity
  - Laparoscopy to assess endometriosis when indicated
  - State-mandated infectious disease panel if undergoing in vitro fertilization

---

The number of infertility visits has increased over the past decades. In some cases, couples have voluntarily delayed childbearing in favor of establishing careers and may experience an age-related decline in fertility. There have been significant advances in assisted reproductive technologies (ART), from improved embryo culture media to intracytoplasmic sperm injection (ICSI) and preimplantation genetic diagnosis (PGD), which have resulted in remarkable increases in in vitro fertilization–embryo transfer (IVF-ET) pregnancy rates. These advances coupled with increasing public awareness and acceptance of ART have spurred women or couples with infertility to seek medical care.

Definition

Infertility is defined as the inability of a couple to conceive within 1 year. **Sterility** implies an intrinsic inability to achieve pregnancy, whereas infertility implies a decrease in the ability to conceive and is synonymous with **subfertility. Primary infertility** applies to those who have never conceived, whereas **secondary infertility** designates those who have conceived at some time in the past.

Fecundity is the probability of achieving a live birth in 1 menstrual cycle. **Fecundability** is expressed as the likelihood of conception per month of exposure. Fertility, as well as infertility, of a woman or couple is best perceived as fecundability, as few infertile patients are sterile. It also allows for a direct comparison of treatment options over a more functional time frame.

The prevalence of women diagnosed with infertility is approximately 13%, with a range from 7 to 28%, depending on the age of the woman. It has remained stable over the past 40 years; ethnicity or race appears to have little effect on prevalence. However, the incidence of primary infertility has increased, with a concurrent decrease in secondary infertility, most likely as a result of social changes such as delayed childbearing.

In normal fertile couples having frequent intercourse, the fecundability is estimated to be approximately 20–25%. Approximately 85–90% of couples with unprotected intercourse will conceive within 1 year. Sterility affects 1–2% of couples.

PATHOGENESIS

Infertility can be due to either partner or both. Overall, an etiology for infertility can be found in 80% of cases with an even distribution of male and female factors, including couples with multiple factors. A primary diagnosis of male factor is made in approximately 25% of cases. Ovulatory dysfunction and tubal/peritoneal factors comprise the majority of female factor infertility. In 15–20% of infertile couples, the etiology cannot be found, and a diagnosis of unexplained infertility is made.

PREVENTION

Prevention of infertility is difficult to achieve and thus discuss, as a couple isn’t really aware of the diagnosis until they try to achieve pregnancy. Although difficult to do, there are a few steps one can take to possibly decrease risk of infertility.

Although infertility is defined as the failure to achieve pregnancy after 12 months or more, earlier evaluation may be justified depending on one’s history and is warranted for women over the age of 35. Because fertility is related to aging in women and perhaps in men after the age of 50, one should be aware of these risks when considering delaying childbearing. Therefore, it is the responsibility of the primary care provider or gynecologist to openly discuss fertility and aging during a well-woman visit. The new techniques of oocyte cryopreservations hold a great promise for women who would like to delay childbearing and should be addressed with women to increase awareness.

Weight extremes have also been associated with infertility in women, mainly due to anovulation. Thus a healthy lifestyle may improve fertility for women with ovulatory dysfunction. However, beyond what has been mentioned previously, there is little evidence that dietary variations enhance fertility. Women should also be advised to take folic acid supplement (at least 400 μg daily) when trying to conceive.

Smoking has a substantial adverse effect on female fertility demonstrated by a recent meta-analysis and also causes abnormalities in male semen parameters. Thus couples who smoke and are trying to conceive should be advised accordingly. Moderate alcohol and caffeine consumption has no adverse effect on fertility; however. higher levels of alcohol and recreational drugs should be discouraged for couples trying to conceive.

Lastly, couples trying to conceive should be advised to avoid using vaginal lubricants as these can be toxic to sperm based on their effect demonstrated in vitro. If needed, it may be better to recommend mineral oil, canola oil, or hydroxyethylcellulose-based lubricants.

Practice Committee of the American Society for Reproductive Medicine. Smoking and infertility. *Fertil Steril* 2006;86:S172–S177. PMID: 17055816.

DIFFERENTIAL DIAGNOSIS & CLINICAL FINDINGS

The armamentarium of diagnostic tests available for the evaluation of an infertile couple is large. Therefore, a clinician should be judicious in his/her use of tests. The history and physical exam shape the endocrinologic and radiologic testing algorithm specific to each patient. Other factors to consider include patient age, risks associated with the test, invasiveness, expense, and probabilities of significant findings (Table 53–1). The patient(s) should be included in the decision-making process.

Table 53–1. Causes of infertility.

Male Factor	**Ovulatory Factor (cont.)**
Endocrine disorders	Peripheral defects
Hypothalamic dysfunction (Kallmann's syndrome)	Gonadal dysgenesis
Pituitary failure (tumor, radiation, surgery)	Premature ovarian failure
Hyperprolactinemia (drug, tumor)	Ovarian tumor
Exogenous androgens	Ovarian resistance
Thyroid disorders	Metabolic disease
Adrenal hyperplasia	Thyroid disease
Anatomic disorders	Liver disease
Congenital absence of vas deferens	Renal disease
Obstruction of vas deferens	Obesity
Congenital abnormalities of ejaculatory system	Androgen excess, adrenal or neoplastic
Abnormal spermatogenesis	**Pelvic Factor**
Chromosomal abnormalities	Infection
Mumps orchitis	Appendicitis
Cryptorchidism	Pelvic inflammatory disease
Chemical or radiation exposure	Uterine adhesions (Asherman's syndrome)

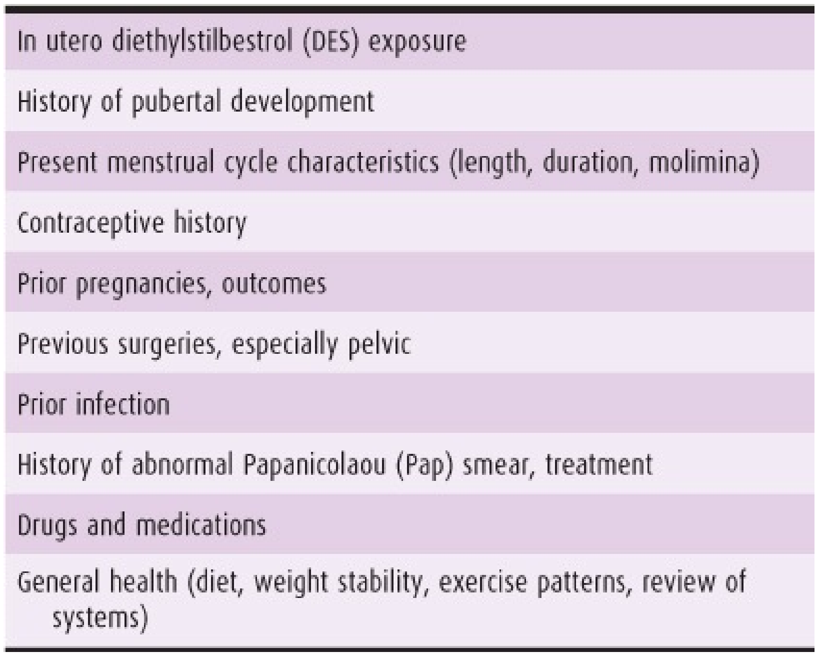
Abnormal motility	Endometriosis
Absent cilia (Kartagener's syndrome)	Structural abnormalities
Varicocele	Diethylstilbestrol (DES) exposure
Antibody formation	Failure of normal fusion of the reproductive tract
Sexual dysfunction	Myoma
Retrograde ejaculation	**Cervical Factor**
Impotence	Congenital
Decreased libido	DES exposure
Ovulatory Factor	Müllerian duct abnormality
Central defects	Acquired
Chronic hyperandrogenemic anovulation	Surgical treatment
Hyperprolactinemia (drug, tumor, empty selia)	Infection
Hypothalamic insufficiency	
Pituitary insufficiency (trauma, tumor, congenital)	

New Patient Assessment

The initial aspect of the interview includes discussion of the factors (ie, ovulation, sperm concentration, ovarian reserve, etc.) that affect fertility so that the patient(s) is aware of the potential etiologies. In this light, the physician can present an algorithm for the diagnostic evaluation that the patient will understand. This will help the patient grasp the peculiarities of the specific tests, such as timing the hysterosalpingogram to the day of the menstrual cycle, and provide an opportunity for the patient(s) to ask fertility-related questions and to address any information learned from friends, family, or the Internet.

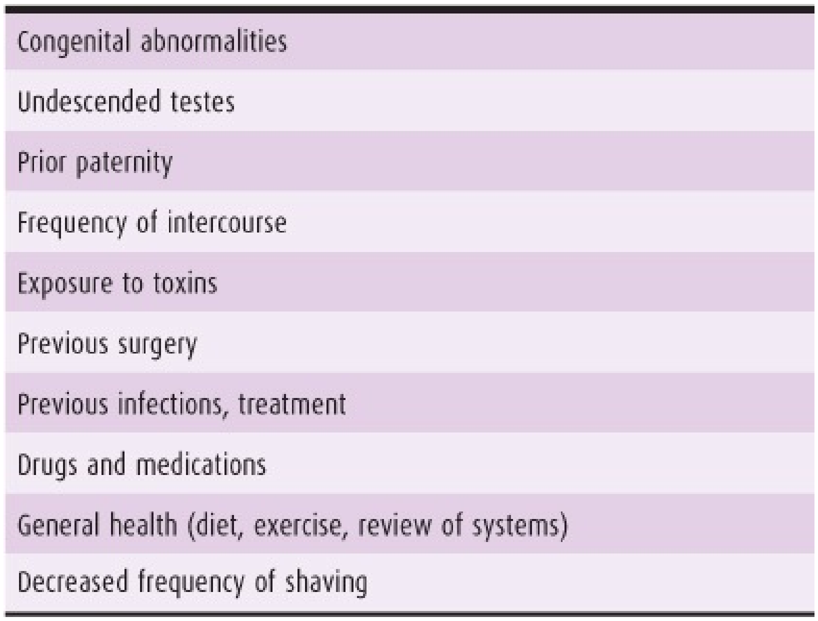
The initial clinical assessment should begin with a thorough history of both partners. Factors to consider while obtaining the medical history are outlined in Table 53–2 for the female and in Table 53–3 for the male. The history should guide the physical examination beyond the general evaluation; for example, a rectovaginal exam to detect uterosacral ligament nodularity associated with endometriosis is indicated if a woman presents with a history of severe dysmenorrhea. However, a thorough physical exam may divulge key information such as acanthosis nigricans and its association with insulin resistance.

Table 53–2. Medical history for female factor infertility.



In utero diethylstilbestrol (DES) exposure
History of pubertal development
Present menstrual cycle characteristics (length, duration, molimina)
Contraceptive history
Prior pregnancies, outcomes
Previous surgeries, especially pelvic
Prior infection
History of abnormal Papanicolaou (Pap) smear, treatment
Drugs and medications
General health (diet, weight stability, exercise patterns, review of systems)

Table 53–3. Medical history for male factor infertility.



Congenital abnormalities
Undescended testes
Prior paternity
Frequency of intercourse
Exposure to toxins
Previous surgery
Previous infections, treatment
Drugs and medications
General health (diet, exercise, review of systems)
Decreased frequency of shaving

The laboratory and radiologic tests assess 4 key aspects for fertility in a couple: the sperm (male factor), the oocyte (ovulatory factor and ovarian reserve), transport (pelvic factor including fallopian tubes), and implantation of ova (uterus). In many cases, the couple will be attempting to absorb significant amounts of information, some of which may be highly technical, at a time of heightened emotion. It is therefore helpful to offer literature or a written summary of the discussion. Frequently, the initial history will indicate a probable diagnosis or a contributing cause of infertility, but it is important to complete a basic evaluation of all of the major factors so a secondary diagnosis is not ignored.

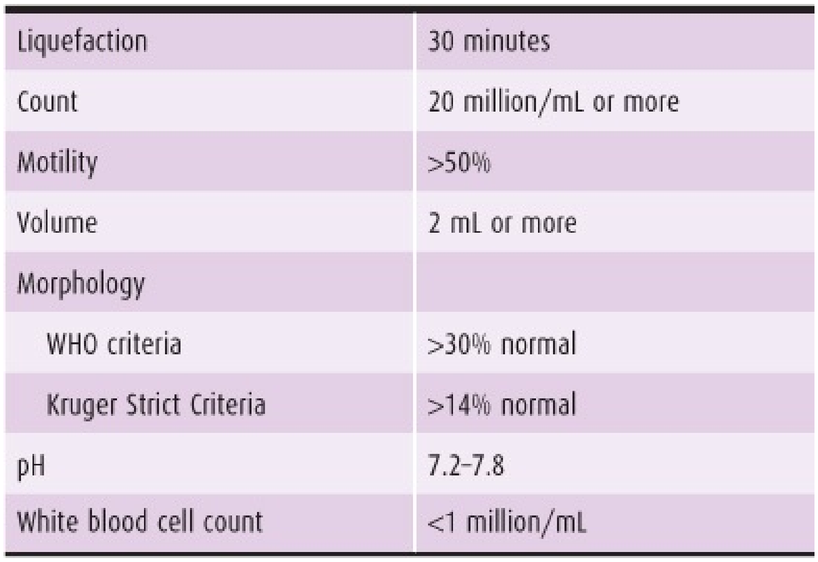
Evaluation of Male Partner

Male factor is diagnosed in 25–40% of infertile couples. The majority of the diagnoses involve testicular pathology such as varicocele. Although validation is incomplete, there is a trend toward increasing use of molecular techniques to quantify the fertility potential of semen as our knowledge of fundamental molecular genetics expands. Experience and investigation have relegated several tests previously used to assess fertilization to historical interest. Beyond the history and physical exam, the initial evaluation of male factor is through semen analysis. If abnormal, the semen analysis should be repeated in 4 weeks or more to confirm findings. Normal semen analysis excludes any important male factor, whereas abnormal semen analysis suggests the need for further evaluation (endocrine, urological, or genetic).

A. Semen Analysis

The male partner should abstain from coitus for 2–5 days before collecting the sample, and the specimen should be received in the lab within 1 hour of collection. Table 53–4 lists normal sperm values. If fundamental parameters of count and motility are normal, the assessment of the morphology of the sperm becomes more critical. Specialized expertise in determining sperm morphology and strict application of criteria should be used before declaring the semen normal.

Table 53–4. Normal semen parameters.



Liquefaction	30 minutes
Count	20 million/mL or more
Motility	>50%
Volume	2 mL or more
Morphology	
WHO criteria	>30% normal
Kruger Strict Criteria	>14% normal
pH	7.2–7.8
White blood cell count	<1 million/mL

The semen parameters in normal fertile males may vary significantly over time, and the first response to any abnormal result should be to wait an interval of several weeks and repeat the test. A normal semen analysis will usually exclude significant male factor. Although low counts, decreased motility, and increased numbers of abnormal forms are most frequently associated with infertility, unfavorable semen parameters may still be found in 20% of males undergoing vasectomy after having completed their families. If the semen analysis reveals abnormal or borderline parameters, the history should be reviewed for any proximate cause of an abnormality, keeping in mind that the cycle of spermatogenesis takes approximately 74 days. A male with <5 million sperm per milliliter warrants an endocrinologic evaluation including follicle-stimulating hormone (FSH), luteinizing hormone (LH), and testosterone, or a karyotype in selected cases. The patient should be referred to a urologist with a special interest and expertise in infertility as indicated.

B. DNA Assays

Several tests, including sperm chromatin structure assay (SCSA), comet, and terminal deoxyuridine triphosphate (dUTP) nick-end labeling (TUNEL), have been developed to quantify the damage to DNA or chromatin (packaged DNA). There is some evidence associating increased DNA damage as determined by these tests with poor fertility outcome. The SCSA determines the percent of chromatin that is fragmented by exposing sperm DNA to acid denaturation (fragmented DNA is more vulnerable). Clinical experience has not matched initial expectations, although the test may be useful for couples with unexplained infertility with repeated in vitro fertilization (IVF) failures. The comet assay consists of placing the sperm DNA on gel electrophoresis; DNA with increased strand breaks will be smaller and therefore travel further on the slide. The TUNEL assay identifies DNA strand breaks by their incorporation of labeled dUTP. The comet and TUNEL assay are not in wide clinical use.

C. Other Tests

More detailed assessment of sperm function may include postcoital test, antibody studies, a sperm penetration assay (hamster egg penetration assay). Such assessments are designed to investigate more subtle problems or abnormalities of function not revealed by the assessment of sperm number and motility. Although helpful in some cases, the sensitivity of these assays in detecting fertility is still uncertain and varies with the particular laboratory where the test is performed. Because no universal methodology has yet been accepted, the interpretation of these tests requires close communication with the laboratory selected.

Cervical mucus is a heterogeneous secretion containing more than 90% water. It has intrinsic properties including consistency, spinnbarkeit (stretchability), and ferning. When mucus is obtained from the cervical canal in the preovulatory phase, it normally exhibits a response to the high estrogen environment. The mucus is thin, watery, and acellular; it dries in a crystalline pattern (ferning), and acts as a facilitative reservoir for the sperm.

The functional sperm must interact normally with the egg and surrounding cells in the uterine tube. The normal migration of sperm is affected by attrition and filtering, and it is estimated that fewer than 1000 sperm will be found in the environment of the oocyte. The initial interaction of sperm and female genital tract can be determined by postcoital examination of the cervical mucus (Sims-Huhner test).

The purpose of the postcoital test is to determine the number of active spermatozoa in the cervical mucus and the length of sperm survival (in hours) after coitus. The test should be performed as close to ovulation as possible, but not after. The test involves aspirating cervical mucus with a syringe 6–8 hours after coitus and checking under a microscope for the number and the motility of the sperm; fewer than 10 motile sperm per high-power field is considered abnormal. The postcoital test is controversial and has limited use in the infertility workup. Its value in assessing cervical hostility to sperm has never been proven.

Tests developed to predict the fertilizing ability of sperm include the zona-free hamster egg penetration test (the sperm penetration assay) and the hemizona test. These assays compare the ability of sperm to penetrate the zona-free hamster egg (a hamster egg in which the zona pellucida has been enzymatically digested) or to bind to human zona with sperm from a known fertile donor. The value of these tests remains controversial, and they are not in general clinical use.

Sperm possess antigens and semen may contain antibodies including sperm-agglutinating, sperm-immobilizing, or cytotoxic antibodies. The antibodies can be measured in semen or in serum. The immunobead test is the antibody assay used in most labs and is considered positive when only 20% or more of motile spermatozoa have immunobead binding. However, the test is considered to be clinically significant when 50% of sperm are coated with immunobeads.

Evaluation of Female Partner

A. Ovulatory Factor

An ovulatory dysfunction is responsible for approximately 20–25% of infertility cases (~40% of female factor infertility). The problem should be investigated first by review of historical factors, including the onset of menarche, present cycle length (intermenstrual interval), and presence or absence of premenstrual symptoms (molimina), such as breast tenderness, bloating, or dysmenorrhea. Signs and symptoms of systemic disease, particularly of hyperthyroidism or hypothyroidism, and physical signs of endocrine disease (ie, hirsutism, galactorrhea, and obesity) should be noted. The degree and intensity of exercise, a history of weight loss, and complaints of hot flushes all are clinical clues to possible endocrine or ovulatory dysfunction.

1. Follicular pool—Early in gestation, the germ cells undergo mitosis to produce oogonia. The oogonia undergo meiosis in their transformation to oocytes but arrest at prophase of meiosis I until the time of ovulation. A layer of granulosa cells encircles the oocytes, creating the follicle. A female will have the highest number of germ cells, approximately 6 million, in her ovaries at 20 weeks' gestational age. Henceforth, atresia depletes the follicular pool at a brisk pace, with only 1–2 million oocytes remaining at the time of birth. The ovaries contain approximately 500,000 oocytes at the time of first ovulation. Menopause signals the complete depletion of germ cells, with a woman having ovulated approximately 500 oocytes during her reproductive years.

2. Ovarian reserve—An inverse relationship exists between fecundity and the age of the woman. The decline in fecundity is a result of progressive follicular atresia through apoptosis, which accelerates in the early thirties and progresses rapidly in the late thirties and early forties. Concomitantly, there is a decrease in follicular quality as a result of an increase in oocytes with chromosomal anomalies and progressive deletions in mitochondrial DNA. The concept of ovarian reserve represents the remaining follicular pool of the ovaries. As ovarian reserve decreases, the ovaries' responsiveness to gonadotropins decreases, necessitating higher amounts of FSH to achieve follicular growth and maturation.

Ovarian reserve should be evaluated in women older than 35 years of age who are seeking fertility. Evaluation of the level of FSH and estradiol in the early follicular phase (cycle days 2–4) may provide helpful guidance in terms of the likelihood of achieving success, as mild elevations in either FSH or estradiol may precede overt ovulatory dysfunction but still indicate a poor prognosis for successful pregnancy. Use of the clomiphene challenge test has gone out of favor, whereas newer tests such as inhibin-B and anti-müllerian hormone (AMH) remain to be validated in large studies. The specific cause of oligo-ovulation or anovulation is determined by the history, the physical examination, and appropriate laboratory studies.

3. Confirmation of ovulation—If the patient reports a history of mittelschmerz and/or regular menses with molimina (headaches, bloating, cramping, and emotional lability) and mild dysmenorrhea occurring at intervals of 28–32 days, the likelihood of the patient having regular ovulatory cycles is very high. Otherwise, ovulation can be confirmed with a serum progesterone assay performed in the mid-luteal phase or the third week of the cycle. Progesterone levels of 3 ng/mL or greater are consistent with ovulation.

Pelvic **ultrasonography** can provide evidence for ovulation. In the follicular phase, the developing follicle can be monitored to maturation and subsequent rupture. The disappearance of, or change in, the follicle and free fluid in the cul-de-sac can document ovulation.

To detect the LH surge, the patient can use commercially available urinary LH kits or serum LH assay. Ovulation occurs 24–36 hours after the onset of the LH surge and 10–12 hours after the peak of the LH surge. The kits can be used to time intercourse or intrauterine insemination.

The **basal body temperature** (BBT) is the temperature obtained in the resting state and should be taken shortly after awakening in the morning after at least 6 hours of sleep and before ambulating. Progesterone has a central thermogenic effect; it elevates the BBT by an average of 0.8 °F during the luteal phase. The luteal phase is thus characterized by a temperature elevation lasting about 10 days. When a biphasic monthly temperature pattern is recorded, it is confirmatory evidence of luteinization, but the absence of a biphasic pattern may be seen in ovulatory cycles.

The finding of secretory endometrium confirms ovulation. The use of an **endometrial biopsy** (EMB) near the end of the luteal phase can provide reassurance of an adequate maturational effect on the endometrial lining. Within 48 hours of ovulation, the **cervical mucus** changes under the influence of progesterone to become thick, tacky, and cellular, with loss of the crystalline fernlike pattern on drying.

The only absolute documentation of release of an oocyte is pregnancy. In the case of oligomenorrhea, amenorrhea, short or very irregular menstrual cycles, or when ovulation is not confirmed, evaluation of the hypothalamic–pituitary– ovarian axis is warranted. A usual initial assessment includes the serum concentrations of FSH, estradiol, prolactin, and thyroid-stimulating hormone.

4. Luteal phase defect—The subject of the inadequate luteal phase remains an area of controversy. There is disagreement on how to make the diagnosis, when the diagnosis is significant, and how best to treat the problem if diagnosed. Luteal phase defect is a histologic diagnosis made when the endometrium lags 3 days or more behind the expected pattern at the time of EMB. EMB to assess luteal phase defect is rarely performed nowadays due to high levels of variability in histologic diagnosis.

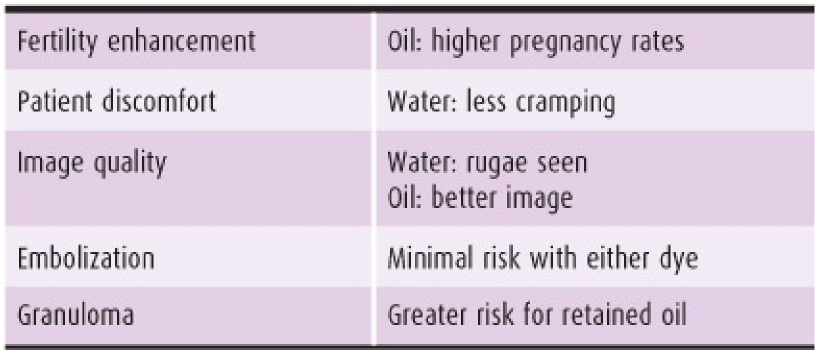
B. The Pelvic Factor

The pelvic factor includes abnormalities of the uterus, fallopian tubes, ovaries, and adjacent pelvic structures. Factors in the **history** that are suggestive of a pelvic factor include any history of pelvic infection, such as pelvic inflammatory disease or appendicitis, use of intrauterine devices, endometritis, and septic abortion. Endometriosis is included as a pelvic factor in infertility and may be suggested by worsening dysmenorrhea, dyspareunia, or previous surgical reports. Any history of ectopic pregnancy, adnexal surgery, leiomyomas, or exposure to diethylstilbestrol (DES) in utero should be noted as possibly contributory to the diagnosis of a pelvic factor. A **pelvic examination** can be informative, yielding information such as a fixed uterus suggestive of adhesions, leiomyomas, or adnexal masses.

A transvaginal **ultrasound** examination can be an efficient means of supplementing information gained from the standard bimanual examination. Hydrosalpinges, leiomyoma, and ovarian cysts, including endometriomas, can often be observed, and the appropriate focused evaluations initiated.

A **hysterosalpingogram** (HSG) is a fluoroscopic study performed by instilling radiopaque dye into the uterine cavity through a catheter to determine the contour of the endometrial cavity and patency of the fallopian tubes. Sensitivity and specificity of an HSG are approximately 65% and 85%, respectively. Abnormal findings include congenital malformations of the uterus, submucous leiomyomas, intrauterine synechiae (Asherman's syndrome), intrauterine polyps, salpingitis isthmica nodosa, and proximal or distal tubal occlusion. The hysterosalpingogram can be obtained in an outpatient setting with minimal analgesia consisting of premedication with a nonsteroidal anti-inflammatory drug. The test is usually scheduled for the interval after menstrual bleeding and before ovulation. Either water- or oil-based dye may be selected; Table 53–5 summarizes the advantages and disadvantages of each. There is evidence for a fertility-enhancing effect of HSG using the oil-based dye.

Table 53–5. Comparison of oil-based versus water-based dye used in the hysterosalpingogram.



Fertility enhancement	Oil: higher pregnancy rates
Patient discomfort	Water: less cramping
Image quality	Water: rugae seen Oil: better image
Embolization	Minimal risk with either dye
Granuloma	Greater risk for retained oil

Peritonitis is a risk of the procedure observed in up to 1–3% of patients; many clinicians use a short-course doxycycline during the immediate period before and after the procedure to minimize risk. An HSG is contraindicated in the presence of an adnexal mass or an allergy to iodine or radiocontrast dye.

A sonohysterogram, a transvaginal ultrasound of the uterus with instillation of saline into the uterine cavity, is a sensitive and specific test for the detection of intrauterine lesions, specifically space-occupying lesions. Hysterosalpingo contrast sonography, transcervical injection of sonopaque material during ultrasonography, is used to determine tubal patency as well as detect intrauterine defects; more commonly used in Europe, the procedure's sensitivity is comparable to that of HSG.

Laparoscopy with chromotubation (dye instillation) is the gold standard for the evaluation of tubal factor, and when performed in conjunction with hysteroscopy, information on uterine contour can be obtained simultaneously. Tubal abnormalities such as agglutinated fimbria or adhesions (which restrict motion of the tubes) or peritubal cysts may suggest tubal disease that would not necessarily be detected on hysterosalpingogram. The diagnosis of endometriosis is usually based on laparoscopic findings.

The necessity of laparoscopy in an infertility workup is controversial. There is significant evidence that pelvic pathology may exist in almost one-third of patients with normal HSG and ultrasound; consequently, some believe that with laparoscopy one can treat the pathology (such as adhesions) found at the time of procedure or can spare a patient needless cycles of ovulation induction that are unlikely to succeed by providing knowledge of severe pelvic disease. Others believe that although pelvic disease may be present, a stepwise empiric approach is more cost-effective.

C. The Cervical Factor

A cervical factor may be indicated by a history of abnormal Papanicolaou (Pap) smears, postcoital bleeding, cryotherapy, conization, or DES exposure in utero. The major evaluation of the cervical factor is by speculum examination, which may reveal evidence of cervicitis that may require further evaluation and treatment, or cervical stenosis, especially in a patient with prior history of cervical conization. If none of these findings are present, it is unlikely that cervical mucous presents a major obstacle. The postcoital test has been part of the assessment of cervical factor for many years in the past; however, the current consensus is that it is no longer required due to high variability in its methodology and interpretation. Moreover, treatment for otherwise unexplained infertility generally is a combination of ovarian stimulation and intrauterine insemination (IUI), which therefore bypasses the cervical factor. Therefore, postcoital test may only be reserved for patients in whom results will actually influence the treatment strategy.

Combined Factors & Unexplained Infertility

After the completion of the diagnostic workup, the findings should be reviewed with the patients and a treatment plan finalized based on guidance from the physician and input from the patient(s). In approximately 20% of couples, a combination of factors found may be suboptimal, and multiple therapies may need to be instigated, either sequentially or simultaneously.

Diagnosis of unexplained infertility, on the other hand, generally implies normal uterine cavity, bilateral patent tubes, normal semen analysis, and evidence of ovulation. Postcoital tests and endometrial biopsy are no longer necessary in order to diagnose unexplained infertility. For the couple with unexplained infertility, an empiric stepwise approach is an excellent option. However, depending on the history, workup, and individual situation, additional test(s) including surgery to rule out endometriosis should be discussed.

TREATMENT

Male Factor Infertility

Treatment options progress from least to most invasive or use of donor sperm. Mild to moderate disease can be treated with **intrauterine insemination** (IUI). Before the insemination, the semen is prepared to select for highly motile sperm, concentrate sperm, and remove seminal fluid (with prostaglandins). The prepared sperm is transcervically injected into the uterus.

ICSI is used in conjunction with IVF for treatment of severe disease (<2 million motile sperm or <4% normal sperm). In this procedure, a sperm is individually injected into each oocyte. The sperm can be retrieved from the testes by microsurgical epididymal sperm aspiration (MESA) or testicular sperm aspiration (TESA); a minimum number of sperm is necessary.

Indications for ICSI include poor semen analysis parameters (low number of motile sperm, poor morphology), fertilization failure with standard IVF, and spermatozoal defects leading to poor fertilization. A decade of experience with the procedure has proven its overall safety. However, offspring conceived using ICSI may be at increased risk of imprinting disorders (eg, Angelman's syndrome), and male children are at risk for inheriting the genetic disorder (eg, Y chromosome microdeletions) that rendered their father infertile.

The initial evaluation of FSH, LH, testosterone, and prolactin helps to differentiate between obstructive defects, primary hypogonadism (testicular defect), and secondary hypogonadism (hypothalamic or pituitary). **Obstructive defects** may be addressed through surgical reanastomosis or through retrieval of sperm via MESA or TESA for use with ICSI. **Retrograde ejaculation** can be treated with alpha sympathomimetics or urine can be centrifuged to collect sperm for IUI. Patients with **primary hypogonadism** should have a karyotype, as Klinefelter's syndrome (47,XXY) is the most common etiology.

Secondary hypogonadism, or hypogonadotropic hypogonadism, may be a result of a pituitary lesion such as prolactinoma or a hypothalamic etiology such as Kallmann's syndrome. Most prolactinomas respond to medical management. Pulsatile gonadotropin-releasing hormone (GnRH) administration with a pump or FSH replacement restores testosterone and sperm production in disorders leading to hypogonadotropic hypogonadism.

A **varicocele** is a dilatation of scrotal veins in the pampiniform plexus and is postulated to impair fertility through elevation of scrotal temperature. A clinical varicocele is one that is detected by examination and is present in 15% of men. Subclinical varicoceles can be detected by ultrasound or venography. There is contradicting evidence regarding whether ligation of clinical varicoceles leads to improved pregnancy rates; infertility is a questionable indication for the correction of subclinical varicoceles.

When male infertility is not amenable to therapy, **donor sperm** for insemination or IVF offers an opportunity for pregnancy. The use of donor sperm is common in clinical practice, and experience has lessened some of the medical, emotional, ethical, and legal issues. The American Society for Reproductive Medicine (ASRM) advocates use of frozen semen to reduce risk of transmission of infectious disease.

Female Factor Infertility

A. The Ovulatory Factor

The treatment and success of specific ovulatory disorders is determined by the age of the patient and the etiology of the anovulation. A stepwise approach, from least to most invasive (and expensive), usually starts with clomiphene citrate and progresses to ovulation induction with gonadotropins and, ultimately, IVF. The risk to the patient, cost of therapy, and fecundability increase with each step closer to IVF. If premature ovarian failure or early menopause is the etiology, the options include oocyte or embryo donation.

Induction of ovulation can be accomplished in 90–95% of patients with chronic anovulation, normal ovarian reserve, and absence of other endocrine abnormalities (eg, hyperprolactinemia or hypothyroidism). Clomiphene citrate is the agent of choice for women younger than 36 years of age with oligomenorrhea or amenorrhea and normal FSH, including women with polycystic ovary syndrome (PCOS). Clomiphene citrate blocks the feedback inhibition of estradiol on the hypothalamus and pituitary, leading to an increase in endogenous FSH. It is administered orally for 5 days starting on day 3–5 of the cycle; approximately half of the patients will ovulate at 50 mg/d and another 25% at 100 mg/d. Ultrasonographic and hormonal monitoring of follicular development is an option, which provides more information and allows greater control of the cycle. After a regimen has achieved ovulation, 3 cycles with either timed intercourse or IUI should be attempted. Side effects with clomiphene are common, including hot flushes, emotional lability or depression, bloating, and visual changes; most are mild and all disappear with discontinuation of the drug. The incidence of twin gestation is 8% and triplets or higher-order multiple pregnancy is <1%.

Aromatase inhibitor letrozole is an alternative option for patients who do not respond to clomiphene citrate or instead of clomiphene citrate. It was first used to induce ovulation in 2001. Letrozole works by inhibiting estrogen biosynthesis, thus releasing the hypothalamus/pituitary from negative feedback and increasing endogenous FSH secretion by the pituitary. It is also administered orally for 5 days starting on day 3–5. The starting dose is 2.5 mg, but studies have revealed improved response and higher pregnancy rates with 5 mg. The dose can be increased to up to 7.5 mg daily. As in the case of clomiphene citrate, ultrasound and hormonal monitoring is an option and may provide more information on individual response and how to proceed with future cycles. Letrozole has fewer side effects than clomiphene, and studies reveal at least similar if not better success rates than clomiphene. Lastly, letrozole has less thinning effect on the endometrium than clomiphene.

A patient in whom there is no response to clomiphene or letrozole, response but no pregnancy, pituitary insufficiency, or hypothalamic insufficiency should undergo ovulation induction with gonadotropins, often used in conjunction with IUI. Human menopausal gonadotropin (hMG) consists of FSH and LH isolated from the urine of postmenopausal women to various levels of purification (and LH content); recombinant FSH (rFSH) contains purely FSH. Gonadotropins are administered by subcutaneous (rFSH) or intramuscular injection (hMG), and the overall evidence indicates that the 2 preparations have similar efficacy.

Because of an increased risk of side effects such as multiple gestation and ovarian hyperstimulation syndrome (OHSS), the use of gonadotropins requires close monitoring with ultrasonography and estradiol levels. Consequently, it is more time-consuming and expensive than clomiphene or letrozole. The monitoring reveals both the number of developing follicles and their level of maturity. Mimicking the effects of the LH surge, human chorionic gonadotropins (hCG) is used to trigger ovulation. With perseverance, cumulative pregnancy rates of 45–90% can be achieved over 3–4 cycles with gonadotropin treatment; but even with careful monitoring there is a 25% risk of a multiple gestation. OHSS is a rare complication that occurs in <2% of cycles.

If pregnancy is not achieved with ovulation induction, IVF/embryo transfer (ET) is the next modality in the treatment algorithm. Development of the follicular cohort is induced with higher doses of FSH (hMG or rFSH). Follicular growth is monitored by ultrasonography and estradiol levels. When the leading follicles are mature, ovulation is triggered with hCG. The oocytes are retrieved from the follicles before ovulation by ultrasound-guided transvaginal aspiration of the follicular fluid. The oocytes are incubated with sperm for fertilization. Alternatively, ICSI is performed if male factor is also a concern. On average, several (from 1 to >3) embryos are transferred into the uterine cavity on day 3–5 after retrieval of the oocytes. OHSS is minimized by withholding hCG if there is a high number of follicles or elevated estradiol levels. Another option to limit the extent of OHSS is to cryopreserve the embryos for transfer at a later time, as pregnancy can prolong the course of OHSS.

When modification of lifestyle or body habitus does not successfully restore ovulation in the patient diagnosed with hypothalamic insufficiency, pulsatile GnRH is another viable option with high likelihood of restoring normal ovulation. Normal fertility is then restored during cycles of treatment, and most pregnancies occur within 3–6 cycles.

Hypothyroidism and hyperprolactinemia can lead to ovulatory dysfunction. Primary hypothyroidism leads to elevated thyroid-stimulating hormone levels, which is a secretogogue of prolactin. Elevated prolactin levels inhibit GnRH secretion, causing oligomenorrhea or amenorrhea. If elevated prolactin levels are detected in a woman with normal thyroid function, a full workup including thorough history (to rule out drugs such as psychotropics), physical exam (galactorrhea), and imaging (magnetic resonance imaging to rule out a prolactinoma or other central nervous system tumors) is likely to reveal the etiology. The elevated prolactin can be medically managed with dopamine agonist, leading to normalization of the cycle.

B. The Pelvic Factor

Adhesions resulting from **endometriosis** or **tubal occlusion** after salpingitis are 2 of the most common problems confronting infertile couples. With increasing pregnancy rates, IVF represents improved fecundability and lower risk over surgical repair except in unique circumstances. The role of surgical treatment is mostly limited to what can be accomplished at the time of diagnostic laparoscopy. There is some evidence to suggest that resection of mild endometriosis results in improved pregnancy rates. Laparoscopic resection or ablation of moderate or advanced endometriosis enhances fecundity in infertile women for the period immediately after surgery. Reversal of tubal sterilization is indicated in young women with adequate residual tubal length. Tubal interruption or resection increases IVF pregnancy rates in women with hydrosalpinx.

The role of **fibroids** in infertility is unclear, and most surgeons reserve myomectomy for treatment of recurrent abortion, repeated implantation failure, or with distortion of the endometrial cavity by a submucosal leiomyoma. The fibroids that distort the endometrial cavity are considered to be significant. These may be diagnosed by hysterosalpingogram, sonohysterogram, hysteroscopy, or magnetic resonance imaging.

C. The Cervical Factor

The absence of nurturing mucus at midcycle can be treated by bypassing the mucus with IUI. When the cervical mucus appears to be affected by cervicitis and inflammatory changes, some physicians advocate empiric treatment of patient and partner with doxycycline. When the cervix is altered by congenital malformation or past surgical treatment that has rendered endocervical glands absent or nonfunctional, IUI with washed sperm can be anticipated to result in pregnancy in 20–30% of patients per cycle in each of the first 3 cycles of treatment. Cervical factor patients who do not respond to these therapies can be offered IVF, gamete intrafallopian transfer (GIFT), or zygote intrafallopian transfer (ZIFT), although GIFT and ZIFT are now rarely used.

Unexplained Infertility

A diagnosis of unexplained infertility is assigned to couples with normal results of a standard infertility workup. The main treatment options include expectant observation with timed intercourse, ovarian stimulation with or without IUI, and IVF. Studies support the use of clomiphene with IUI for up to 4 cycles. The next step is usually hMG with intrauterine insemination for 3 cycles; if unsuccessful, IVF should be considered. The rationale for treatment with superovulation in women with documented ovulation is that by increasing the number of oocytes available, the likelihood of pregnancy is increased. In instances in which unexplained infertility may be the result of a fundamental defect in fertilization or in embryo transfer to the uterus, IVF may play a role in treatment. Donor oocytes or donor sperm may be considered in couples with continued difficulties in achieving pregnancy. For many, the hardest course to contemplate is no therapy at all.

COMPLICATIONS

The major complication associated with ovarian stimulation is OHSS. It has a broad spectrum of disease, ranging from mild to extremely severe cases. The pathophysiology of the disease is due to increased capillary permeability resulting in fluid shift from the intravascular to extravascular spaces. Risk factors for OHSS include young age, PCOS, higher doses of gonadotropins, and high serum estradiol levels. Severe cases of hyperstimulation warrant very careful monitoring and hospitalization, as it can lead to electrolyte abnormalities, abnormal liver function tests, respiratory distress, and hyponatremia. There are several methods used nowadays in order to prevent OHSS, including gentler stimulation protocols, coasting until lower estradiol levels are achieved, and most recently, GnRH agonist instead of hCG trigger.

There is also a concern about a possible association between ovulation induction agents, specifically >12 cycles of clomiphene citrate, and **ovarian cancer**. The possibility that ovulation induction increases the risk of ovarian cancer remains unproven. Primary infertility and endometriosis are independent risk factors for ovarian cancer. Although additional investigation is necessary, the low incidence of ovarian cancer makes it difficult to design an adequate study to detect an association of infertility drugs with ovarian cancer.

PROGNOSIS

The success rates of treatment for infertility depends on a variety of factors, including cause of infertility, woman's age, duration of infertility, and treatment modality. Health insurance plans vary a great deal in the amount and type of infertility treatments that are covered. For those couples without infertility coverage, treatment choices are dictated by medical and financial considerations. Not uncommonly, infertility treatment does not actually make the difference between conceiving and not conceiving, but allows for conception in the more immediate future rather than at a delayed point of time (increasing fecundability).

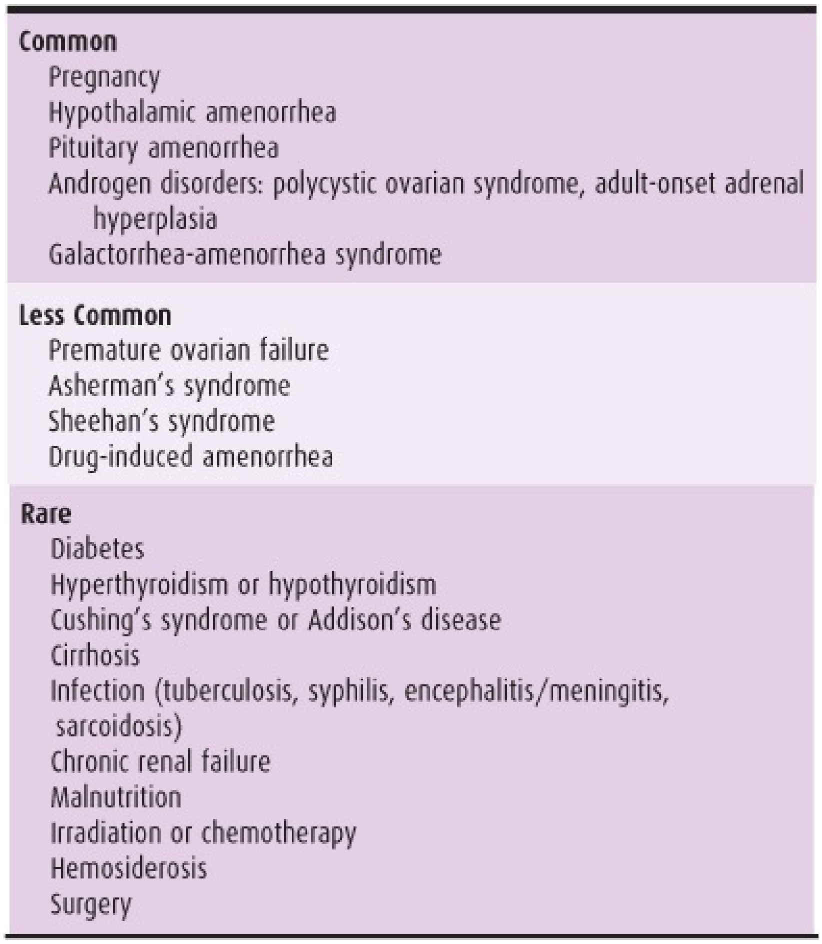
54
Amenorrhea

Alex Simon, MD
Wendy Y. Chang, MD
Alan H. DeCherney, MD

ESSENTIALS OF DIAGNOSIS

- Amenorrhea is literally defined as the absence of menses.
- **Primary amenorrhea** (seen in approximately 2.5% of the population) is clinically defined as the absence of menses by age 13 years in the absence of normal growth or secondary sexual development, or the absence of menses by age 15 years in the setting of normal growth and secondary sexual development.
  - Traditionally, evaluation was usually initiated by age 16 years if normal growth and secondary sexual characteristics were present, and at age 14 years if absent.
  - Because of secular trends toward earlier menarche over the past half century, the evaluation should begin at age 15 years, the age when more than 97% of girls should have experienced menarche.
  - The decision to evaluate should be made with a full understanding of the patient’s clinical presentation.
  - Evaluation should not be delayed in the setting of neurologic symptoms (suggestive of hypothalamic–pituitary lesion) or pelvic pain (suggestive of outflow obstruction).
- **Secondary amenorrhea** is clinically defined as the absence of menses for more than 3 cycle intervals, or 6 consecutive months, in a previously menstruating woman.
  - The incidence of secondary amenorrhea can be quite variable, from 3% in the general population to 100% under conditions of extreme physical or emotional stress.
  - Table 54–1 lists the most common causes of secondary amenorrhea.

Table 54–1. Causes of secondary amenorrhea.



Common

- Pregnancy
- Hypothalamic amenorrhea
- Pituitary amenorrhea
- Androgen disorders: polycystic ovarian syndrome, adult-onset adrenal hyperplasia
- Galactorrhea-amenorrhea syndrome

Less Common

- Premature ovarian failure
- Asherman's syndrome
- Sheehan's syndrome
- Drug-induced amenorrhea

Rare

- Diabetes
- Hyperthyroidism or hypothyroidism
- Cushing's syndrome or Addison's disease
- Cirrhosis
- Infection (tuberculosis, syphilis, encephalitis/meningitis, sarcoidosis)
- Chronic renal failure
- Malnutrition
- Irradiation or chemotherapy
- Hemosiderosis
- Surgery

Pathogenesis

Menstruation has long been an important societal marker of female sexual development, as well as one of the most tangible signs of female endocrine and reproductive tract maturation. Regular and spontaneous menstruation requires (1) functional hypothalamic–pituitary–ovarian endocrine axis, (2) an endometrium competent to respond to steroid hormone stimulation, and (3) an intact outflow tract from internal to external genitalia.

The human menstrual cycle is susceptible to environmental influences and stressors. Thus missing a single or occasional menstruation rarely reflects a significant pathology. However, prolonged or persistent absence of menses may be one of the earliest signs of neuroendocrine or anatomic abnormality.

Diagnosing and treating amenorrhea is important because of the implications for future fertility; risks of unopposed estrogen, including endometrial hyperplasia and neoplasia; risks of hypoestrogenism, including osteoporosis and urogenital atrophy; and impact on psychosocial development. Because of their significant overlap in etiology and treatment, primary and secondary amenorrhea are discussed collectively in this chapter.

Pregnancy is the most common cause of amenorrhea and must be considered in every patient presenting for evaluation of amenorrhea. Amenorrhea caused by aberrations of the normal menstrual cycle is discussed in Chapter 4. Chapters 37 and 55 discuss developmental anomalies of the reproductive organs and masculinization, respectively. This chapter discusses amenorrhea associated with 46, XX and 46, XY karyotypes, anatomic defects, and dysfunction of the hypothalamic–pituitary–ovarian axis, as well as systemic disorders that affect menstruation.

Both primary and secondary amenorrhea can result from abnormalities in the compartments linked with the occurrence of menses. This includes the hypothalamic–pituitary axis, the ovaries, and the outflow tract, namely the uterus, cervix, and vagina.

Clinical Findings

A. Hypothalamic–Pituitary Dysfunction

Gonadotropin-releasing hormone (GnRH)–secreting neurons of the hypothalamus originate in the olfactory bulb and migrate along the olfactory tract into the mediobasal hypothalamus and the arcuate nucleus. Under normal physiologic circumstances, the arcuate nucleus releases pulses of GnRH into the hypophyseal portal system approximately every hour. Discharge of GnRH releases luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the pituitary; LH and FSH, in turn, stimulate ovarian follicular growth and ovulation. The ovarian hormones estradiol and progesterone stimulate the development and shedding of the endometrium, culminating in the withdrawal bleeding of menses. Anovulation and amenorrhea occur as a result of interference with GnRH transport, GnRH pulse discharge, or congenital absence of GnRH (Kallmann's syndrome). Any of these situations leads to hypogonadotropic hypogonadism, resulting in amenorrhea.

1. Defects of GnRH transport—Interference with the transport of GnRH from the hypothalamus to the pituitary may occur with pituitary stalk compression or destruction of the arcuate nucleus. Pituitary stalk transsection from trauma, compression, radiation, tumors (craniopharyngioma, germinoma, glioma, teratomas), and infiltrative disorders (sarcoidosis, tuberculosis) may either destroy areas of the hypothalamus or prevent transport of hypothalamic hormones to the pituitary.

2. Defects of GnRH pulse production—The metabolic consequence of any significant reduction in the normal GnRH pulse frequency or amplitude is that little or no LH or FSH can be released, with the result that no ovarian follicles develop, virtually no estradiol is secreted, and the patient is amenorrheic. This is the biochemical status in normal prepubertal girls and those with constitutional delayed puberty, such as in anorexia nervosa, severe stress, extreme weight loss, or prolonged vigorous athletic exertion, and in hyperprolactinemia. Amenorrhea on this basis may also be an idiopathic phenomenon.

Less severe reductions in GnRH pulse amplitude and frequency result in diminished LH and FSH secretion with some follicular stimulation. The stimulation is insufficient to result in full follicular development and ovulation, but estradiol is secreted. This may occur with stress, hyperprolactinemia, as a result of vigorous athletic activity, or in the early stages of eating disorders. It may also be idiopathic.

Functional or hypothalamic amenorrhea results from abnormal hypothalamic GnRH secretion in the absence of pathologic processes. As a result, patients demonstrate decreased gonadotropin pulsations, absent follicular development and ovulation, and low estradiol secretion. Serum FSH levels are usually in the normal range; the setting of high FSH:LH ratio is consistent with prepubertal patterns. A number of environmental stressors are associated, including eating disorders and physical or psychologic stress. Weight loss, especially to a level of at least 10% below ideal body weight, and excessive exercise are also associated with hypothalamic amenorrhea. The female athlete triad syndrome is defined by amenorrhea, eating disorder, and osteopenia or osteoporosis.

Congenital GnRH deficiency is called idiopathic hypogonadotropic hypogonadism when it occurs as an isolated phenomenon and **Kallmann's syndrome** when it is associated with anosmia. These patients lack GnRH secretion and express low, prepubertal levels of serum gonadotropins. Follicular recruitment and ovulation do not occur. Although more than 60% of cases are sporadic, congenital GnRH deficiency can also be inherited in an autosomal dominant trait or X-linked recessive pattern.

Autosomal recessive mutations of the GnRH receptor gene have also been reported. This defect appears to produce a wider spectrum of physical symptoms than with the other gene defects, and the defect lies in the ability of the pituitary gland to recognize GnRH, rather than the ability of the hypothalamus to produce GnRH. It is debatable whether this is in fact Kallmann's syndrome, as the GnRH receptor development is not related to anosmia. More common in boys with delayed puberty, **constitutional delay** of puberty is an uncommon etiology of primary amenorrhea in girls. Patients demonstrate delayed adrenarche and gonadarche, but ultimately go on to have normal, albeit delayed, pubertal development.

B. Pituitary Defects

Pituitary causes of amenorrhea are rare; most are secondary to hypothalamic dysfunction. However, acquired pituitary dysfunction can ensue from previous local radiation or surgery. Excess iron deposition due to hemochromatosis or hemosiderosis may destroy gonadotropes.

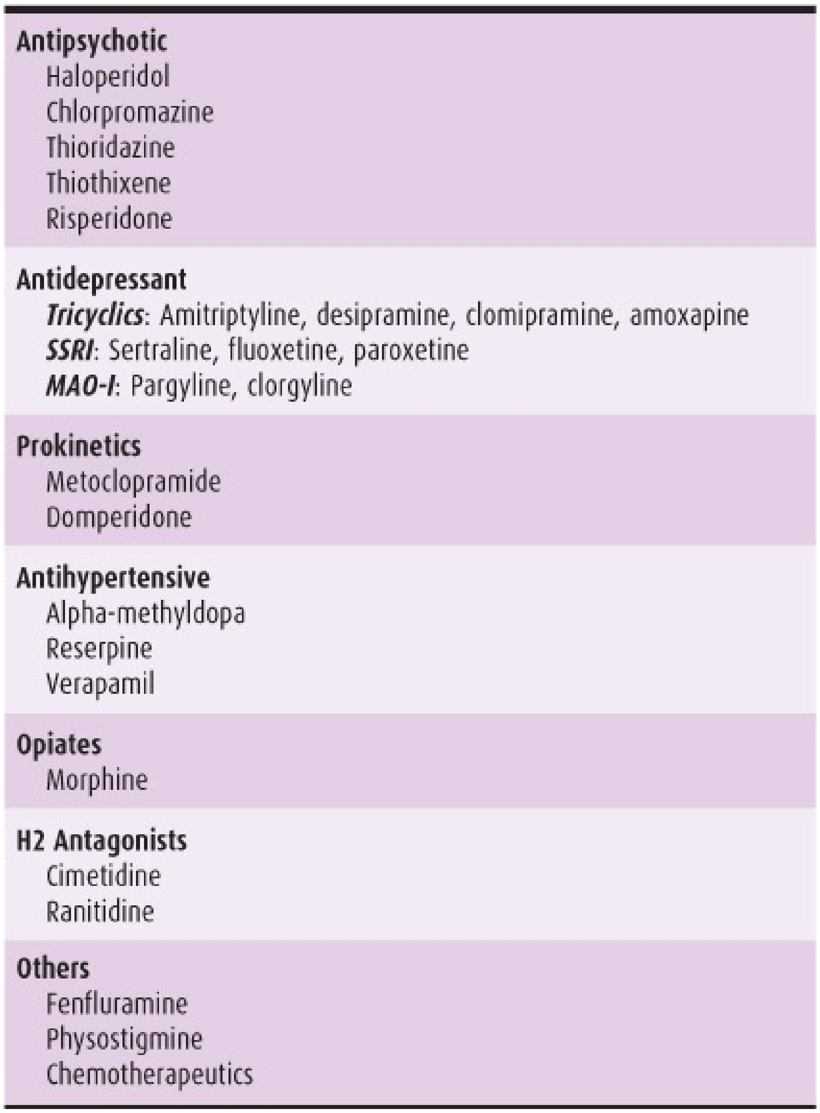
1. Congenital pituitary dysfunction—Congenital absence of the pituitary is a rare and lethal condition. Isolated defects of LH or FSH production do occur (rarely), resulting in anovulation and amenorrhea.

2. Acquired pituitary dysfunction—Sheehan's syndrome, characterized by postpartum amenorrhea, results from postpartum pituitary necrosis secondary to severe hemorrhage and hypotension and is a rare cause of amenorrhea. Surgical ablation and irradiation of the pituitary as management of pituitary tumors also can cause amenorrhea.

Iron deposition in the pituitary may result in destruction of the cells that produce LH and FSH. This occurs only in patients with markedly elevated serum iron levels (ie, hemosiderosis), usually resulting from extensive red cell destruction. Thalassemia major is an example of a disease that causes hemosiderosis.

Pituitary microadenomas and macroadenomas also lead to amenorrhea because of elevated prolactin levels, but the mechanism(s) underlying this cause of amenorrhea are unclear. Isolated hyperprolactinemia in the absence of adenoma is an uncommon cause of primary amenorrhea. However, the diagnosis is strongly suggested by a history of galactorrhea. Diagnosis is readily made by evaluating a serum prolactin level. Drugs given to treat medical conditions may induce hyperprolactinemia to result in amenorrhea. Discontinuation of the medication if possible or adequate treatment to reduce prolactin level may solve the problem. Table 54–2 lists the most common drugs associated with hyperprolactinemia.

Table 54–2. Drug-induced hyperprolactinemia.



Antipsychotic
Haloperidol
Chlorpromazine
Thioridazine
Thiothixene
Risperidone
Antidepressant
Tricyclics: Amitriptyline, desipramine, clomipramine, amoxapine
SSRI: Sertraline, fluoxetine, paroxetine
MAO-I: Pargyline, clorgyline
Prokinetics
Metoclopramide
Domperidone
Antihypertensive
Alpha-methyldopa
Reserpine
Verapamil
Opiates
Morphine
H2 Antagonists
Cimetidine
Ranitidine
Others
Fenfluramine
Physostigmine
Chemotherapeutics

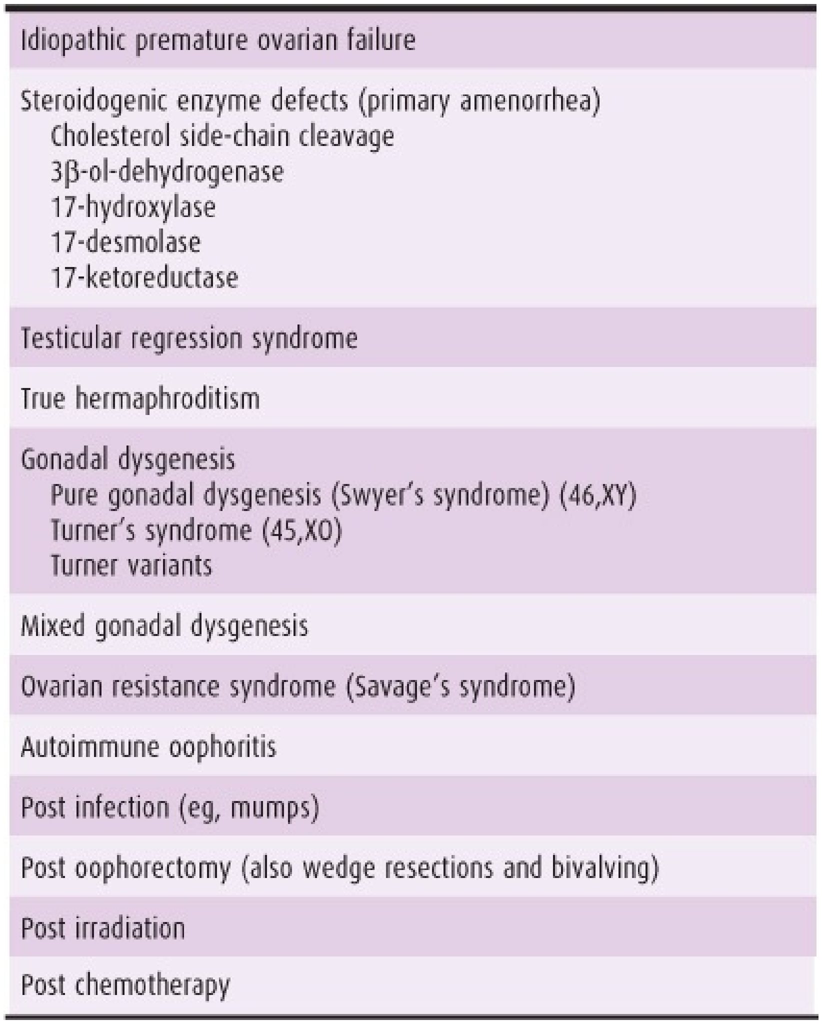
Hypothyroidism may also lead to elevated prolactin levels and thereby lead to amenorrhea.

C. Ovarian and Ovulatory Dysfunction

A variety of gonadal disorders can result in amenorrhea. The most common cause of primary amenorrhea is gonadal dysgenesis. This group of disorders is usually associated with sex chromosomal abnormalities, resulting in streak gonad development, premature depletion of ovarian follicles and oocytes, and absence of estradiol secretion. Patients usually present with hypergonadotropic amenorrhea regardless of degree of pubertal development. Primary ovarian failure is characterized by elevated gonadotropins and low estradiol (**hypergonadotropic hypogonadism**). Secondary ovarian failure is almost always caused by hypothalamic dysfunction and is characterized by normal or low gonadotropins and low estradiol (**hypogonadotropic hypogonadism**).

Table 54–3 lists the causes of primary ovarian failure.

Table 54–3. Causes of primary ovarian failure (hypergonadotrophic hypogonadism).



Idiopathic premature ovarian failure
Steroidogenic enzyme defects (primary amenorrhea) Cholesterol side-chain cleavage 3β-ol-dehydrogenase 17-hydroxylase 17-desmolase 17-ketoreductase
Testicular regression syndrome
True hermaphroditism
Gonadal dysgenesis Pure gonadal dysgenesis (Swyer's syndrome) (46,XY) Turner's syndrome (45,XO) Turner variants
Mixed gonadal dysgenesis
Ovarian resistance syndrome (Savage's syndrome)
Autoimmune oophoritis
Post infection (eg, mumps)
Post oophorectomy (also wedge resections and bivalving)
Post irradiation
Post chemotherapy

1. Ovarian dysgenesis—If the primitive oogonia do not migrate to the genital ridge, the ovaries fail to develop. Streak gonads, which do not secrete hormones, develop instead, and the result is primary amenorrhea. Cytogenetic abnormalities of the X chromosome account for the majority of abnormal ovarian development and function, and studies show that 2 intact X chromosomes are required to maintain normal oocytes. Fetuses with 45,X karyotype demonstrate normal oocyte number at 20–24 weeks' gestation, but there is rapid atresia resulting in absence of oocytes at birth. Similarly, women with deletions in either the long or short arm of one X chromosome also develop either primary or secondary amenorrhea.

A. GONADAL DYSGENESIS WITH NO Y CHROMATIN—- Turner's syndrome (45,XO or 45,XO,XX mosaics) and 46,XX gonadal dysgenesis are the most common karyotypes. Patients with Turner's syndrome usually present with primary amenorrhea. However, some patients with mosaic abnormalities may menstruate briefly, and a few have conceived.

B. GONADAL DYSGENESIS WITH Y CHROMATIN—Normal female sexual differentiation depends on testicular secretion of antimüllerian hormone (AMH) by Sertoli cells and testosterone by Leydig cells. AMH causes regression of müllerian structures, whereas testosterone and its metabolite dihydrotestosterone (DHT) promote differentiation of male internal and external genitalia, respectively. A variety of disorders can result in the presentation of amenorrhea in phenotypic females possessing Y chromatin material.

The vanishing testes syndrome occurs in 46,XY males with failed gonadal development. Although anorchia commonly occurs at approximately 7 weeks' gestational age, the patient's presentation depends on the timing of gonadal regression. Failure occurring later in development might result in male genitalia at birth, but absence of puberty as a consequence of gonadal failure. On the other hand, typical early gonadal failure before testicular development would result in absent secretion of testis-determining factor (TDF) and AMH. These patients would demonstrate feminization of internal and external genitalia and primary amenorrhea.

Swyer's syndrome, which presents as a form of early-onset vanishing testes syndrome, results from a deletion mutation in the TDF region of Y chromosome. These patients possess the 46,XY genotype but do not secrete testosterone or AMH, resulting in feminization of internal and external genitalia. Patients present with primary amenorrhea and gonadal failure. The syndrome is diagnosed by DNA hybridization studies showing abnormality in the short arm of the Y chromosome.

2. Premature Ovarian Failure—Menopause occurs when the ovaries fail secondary to depletion of ova. If this occurs before age 40 years, it is considered premature and affects 1–5% of women. It is marked by amenorrhea, increased gonadotropin levels, and estrogen deficiency. Woman presented with premature ovarian failure (POF) should be tested for karyotype to rule out sex chromosome translocations, short arm deletions, or the presence of an occult Y chromosome fragment, which is associated with an increased risk of gonadal tumors. Approximately 16% of women having fragile X permutation experience POF. Thus this permutation as well as other genetic trait reported to be associated with POF should be tested in some patients. Surgery affecting the ovaries, chemotherapy, and pelvic irradiation are iatrogenic causes of POF and should be discussed with the patient in order to use modalities aimed at preserving fertility.

3. Steroid Enzyme Defects—Figure 54–1 depicts normal steroidogenesis in the ovary. Genetic females with defects in enzymes 1–4 have normal internal female genitalia and 46,XX karyotype. However, they cannot produce estradiol, and thus they fail to menstruate or have breast development.

5 = Aromatase
6 = 17-Hydroxysteroid dehydrogenase

Figure 54–1. Steroidogenesis in the ovary.

Congenital lipoid adrenal hyperplasia describes 1 of 15 known defects in the steroidogenic acute regulatory protein, which facilitates cholesterol transport from the outer to the inner mitochondrial membrane. This enzyme catalyzes an early, rate-limiting step in tropic hormone-stimulated steroidogenesis. Patients thus present with hyponatremia, hyperkalemia, and acidosis in infancy. Both XX and XY individuals are phenotypically female. These patients can survive into adulthood given appropriate glucocorticoid and mineralocorticoid supplementation. XX patients may exhibit some secondary sexual characteristics at puberty, but present with amenorrhea and premature ovarian failure due to intraovarian accumulation of cholesterol.

4. Ovarian resistance (Savage's Syndrome)—Patients with this syndrome have elevated LH and FSH levels, and the ovaries contain primordial germ cells. A defect in the cell receptor mechanism is the presumed cause.

5. Polycystic ovary syndrome—One of the most common causes of secondary amenorrhea is **polycystic ovary syndrome** (**PCOS**). PCOS is the most common cause of ovulatory dysfunction in reproductive-age women. After exclusion of other etiologies (congenital adrenal hyperplasia, androgen-secreting tumors, Cushing's syndrome), the diagnosis is based on the presence of at least 2 of the following characteristics: (a) oligo- or anovulation, (2) clinical and/or biochemical signs of hyperandrogenism, (3) polycystic ovaries. Although the exact mechanism is unknown, it appears that insulin resistance and hyperinsulinemia play a permissive role. Abnormally elevated baseline insulin leads to increased androgens via decreased sex hormone-binding globulin and stimulation of ovarian insulin and insulinlike growth factor-I receptors. Insulin-sensitizing agents such as metformin and rosiglitazone are used as a sole or adjuvant agent for ovulation induction in PCOS.

D. Anatomic Abnormalities Associated With Amenorrhea (see Chapter 37)

1. Müllerian dysgenesis—Müllerian dysgenesis is characterized by congenital absence of the uterus and the upper two-thirds of the vagina. Affected individuals may ovulate regularly, have normal development of the secondary sex characteristic, and have a 46, XX karyotype.

2. Vaginal agenesis—Vaginal agenesis is characterized by failure of the vagina to develop.

3. Transverse vaginal septum—This anomaly results from failure of fusion of the müllerian and urogenital sinus-derived portions of the vagina.

4. Imperforate hymen—If the hymen is complete, menstrual efflux cannot occur.

5. Asherman's syndrome—In Asherman's syndrome, amenorrhea is caused by intrauterine synechiae. The usual cause is a complicated dilatation and curettage (D&C) (eg, infected products of conception, vigorous elimination of the endometrium), but the syndrome can occur after myomectomy, caesarean section, and tuberculous endometritis.

E. Amenorrhea in Women With 46, XY Karyotype

The details of embryonic sexual differentiation are discussed in Chapter 2. Briefly, the sexually undifferentiated male fetal testis secretes müllerian-inhibiting factor (MIF) and testosterone. MIF promotes regression of all müllerian structures: the uterine tubes, the uterus, and the upper two-thirds of the vagina. Testosterone and its active metabolite DHT are responsible for embryonic differentiation of the male internal and external genitalia.

1. Testicular feminization—In testicular feminization, a condition also addressed as complete androgen insensitivity syndrome, all müllerian-derived structures are absent because MIF is present. The external genital and mesonephric ducts cannot respond to androgens, because androgen receptors are either absent or defective. Affected individuals are therefore phenotypic females lacking a uterus and a complete vagina. They produce some estrogen, develop breasts, and are reared as girls and therefore present with primary amenorrhea. The syndrome is inherited in an X-linked recessive trait. In contrast to other dysgenetic gonads with a Y chromosome, the occurrence of gonadal malignancy is late (rarely before the age of 25) and the incidence is less, approximately 5–10%. Therefore, the removal of the nonfunctioning testes can be postponed until the age of 16–18 years to allow completion of puberty.

2. Pure gonadal dysgenesis (Swyer Syndrome)—If the primitive germ cells do not migrate to the genital ridge or the SRY gene is not functioning harboring a mutation, a testis will not develop, and a streak gonad will be present. Affected individuals have normal female internal and external genitalia, as neither MIF nor androgens are secreted by the streaks. Because these individuals produce no estrogen, they will not develop breasts. They are reared as girls and present clinically with either delayed puberty or primary amenorrhea. Removal of the streak gonads should be done as soon as the diagnosis is made to prevent the possible development of tumor in such gonads.

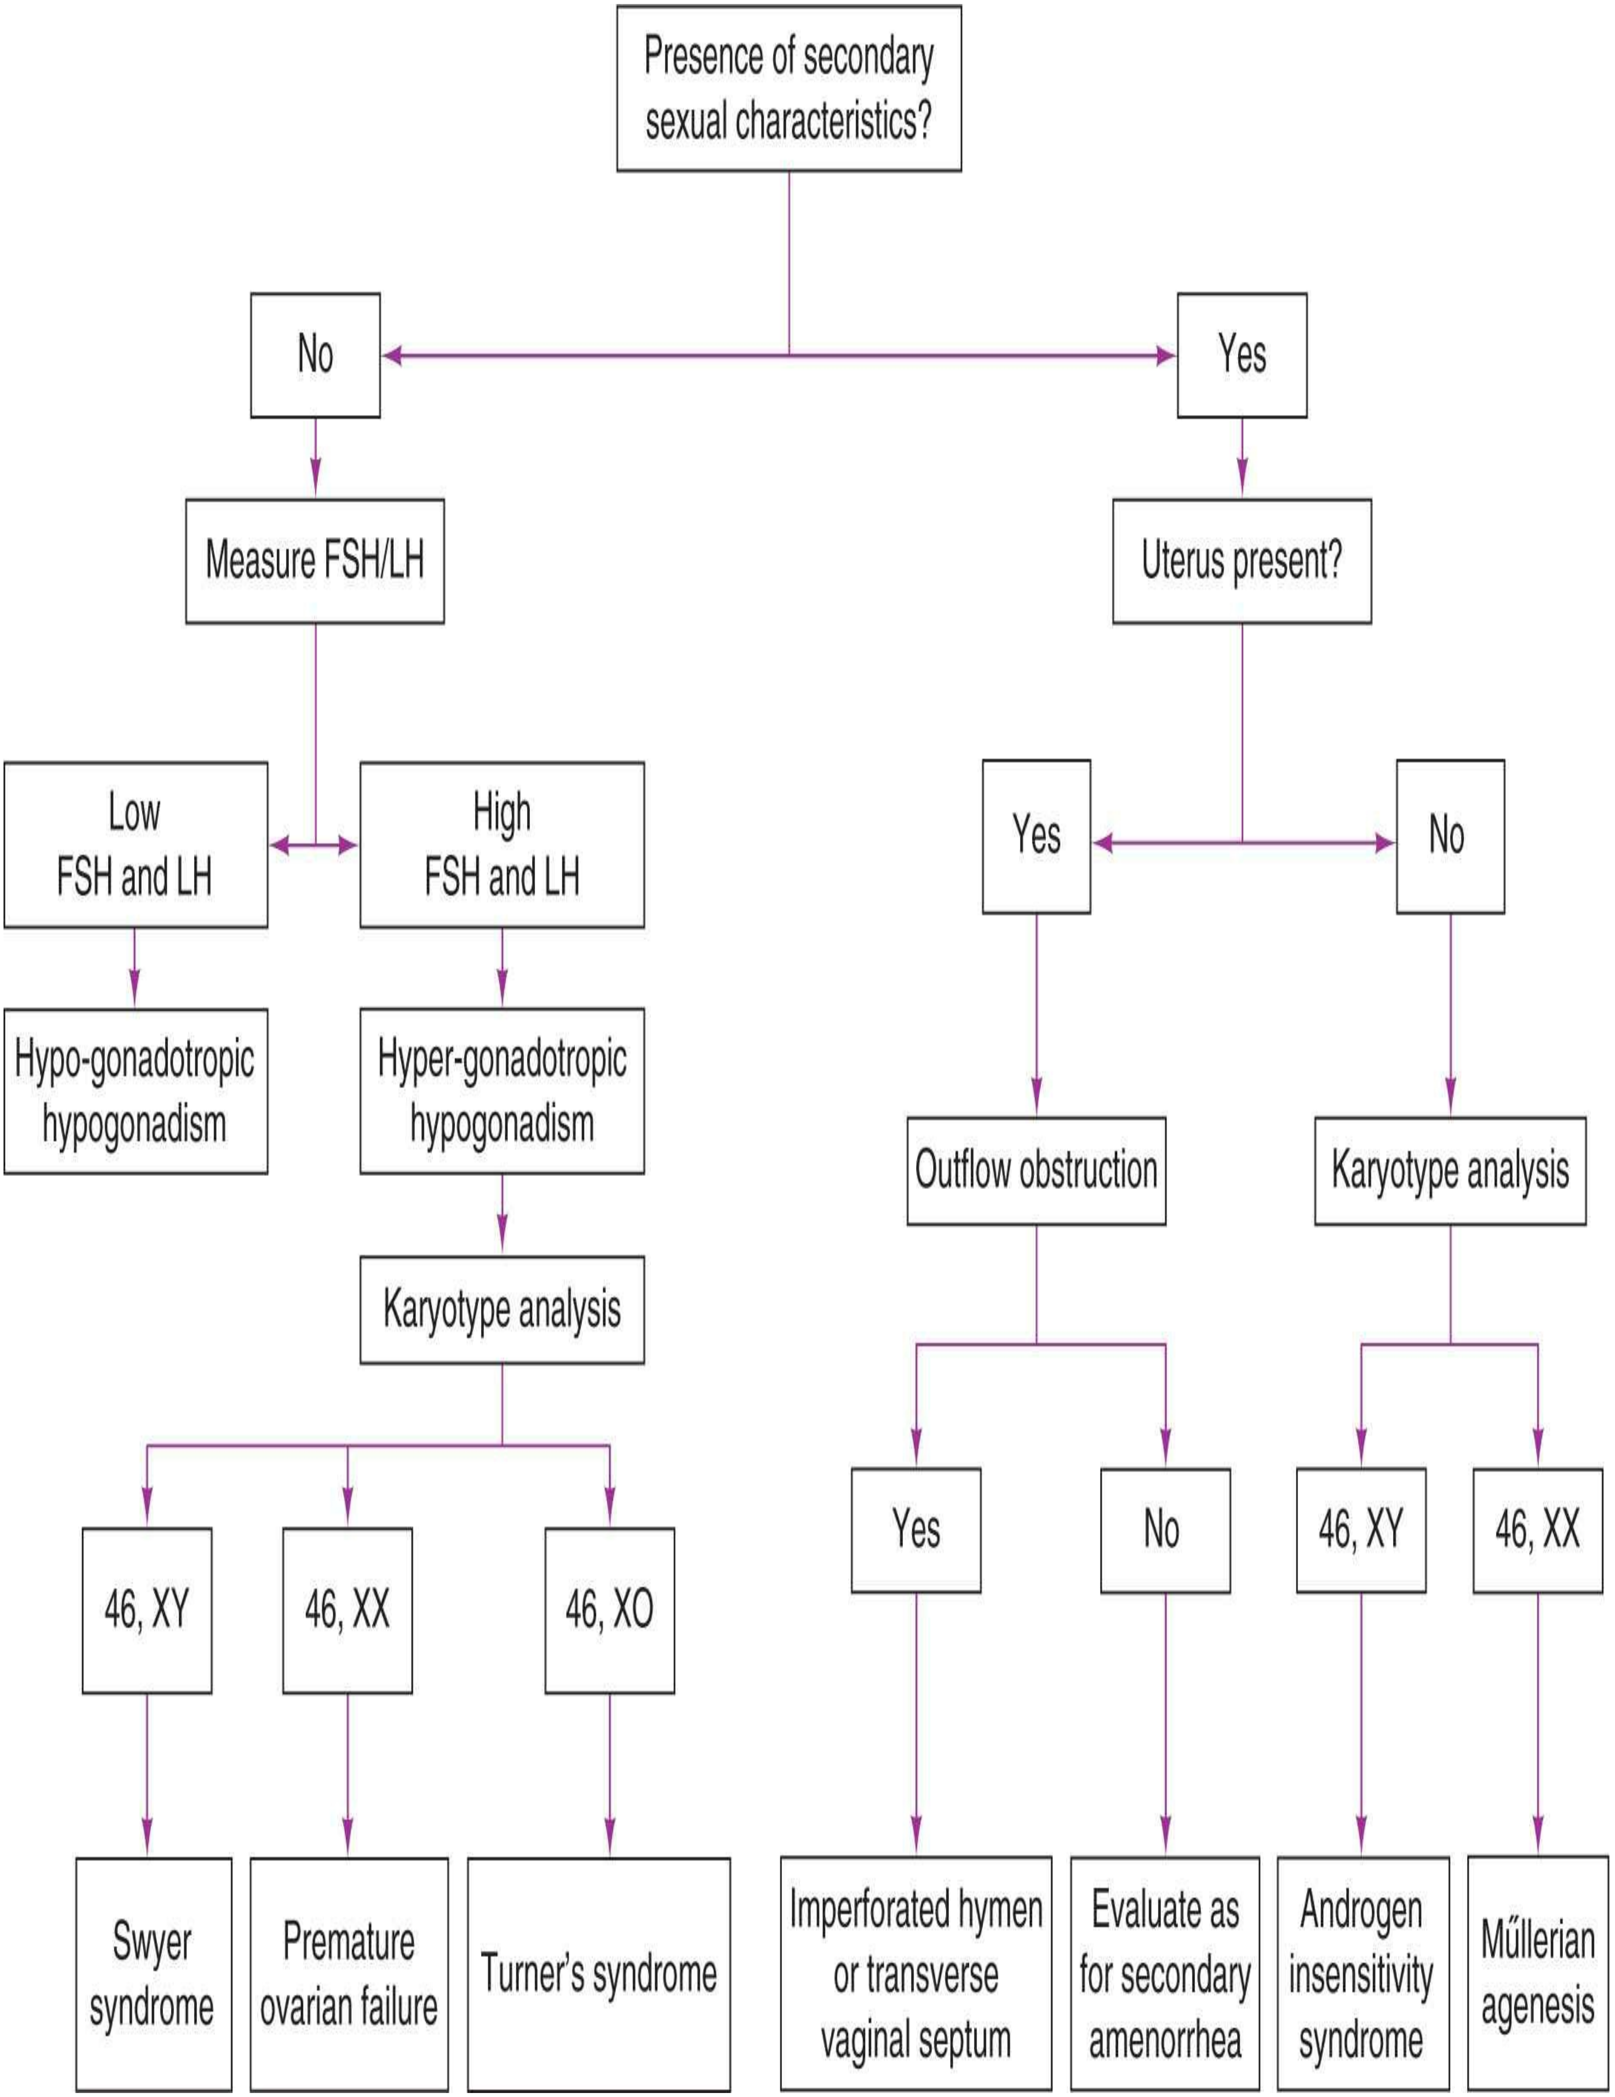
3. Anorchia—If the fetal testes regress before 7 weeks' gestation, neither MIF nor testosterone is secreted, and affected individuals will present with a clinical picture identical to that of pure gonadal dysgenesis. Individuals whose testes regress between 7 and 13 weeks' gestation present with ambiguous genitalia.

4. Testicular steroid enzyme defects—A testis with defective enzymes 1–4 will produce MIF but not testosterone (Fig. 54–1). Affected individuals have female external genitalia and no müllerian structures. They will be reared as girls and present clinically with either delayed puberty or primary amenorrhea.

A defect in enzyme 6 (17-hydroxysteroid dehydrogenase) results in ambiguous genitalia and virilization at puberty.

Differential Diagnosis

Figures 54–2 and 54–3 summarize the diagnostic workup for primary and secondary amenorrhea, respectively. It is important at the outset to determine which organ is dysfunctional and then to identify the exact cause. Medical history, patient symptoms and complaints, and physical examination will lead to the correct diagnosis. Applying other assisting tests will substantiate the diagnosis. Once this has been done, specific therapy can be planned.



Presence of secondary sexual characteristics?
No
Yes
Measure FSH/LH
Uterus present?
Low FSH and LH
High FSH and LH
Yes
No
Hypo-gonadotropic hypogonadism
Hyper-gonadotropic hypogonadism
Outflow obstruction

Thyroid disease
Prolactine <100 ng/mL
Prolactine >100 ng/mL
Withdrawal bleed-positive
Withdrawal bleed-negative
Microadenoma or other cause most likely
MRI, CT, cone view to evaluate for prolactinoma
Anovulation
Estrogen + progesterone challenge test
Consider other cause if test is negative
Bleed present
No bleed
Check FSH + LH
Outflow problem
FSH and LH are high
FSH and LH are low
Ovarian failure
Hypogonadotropic hypogonadism

Figure 54–3. Workup for patients with secondary amenorrhea.

Any patient with amenorrhea who has a uterus should be tested for pregnancy and for serum levels of thyroid-stimulating hormone (TSH) and prolactin. Galactorrhea should be identified or ruled out by physical examination.

A. Diagnosis of Primary Amenorrhea

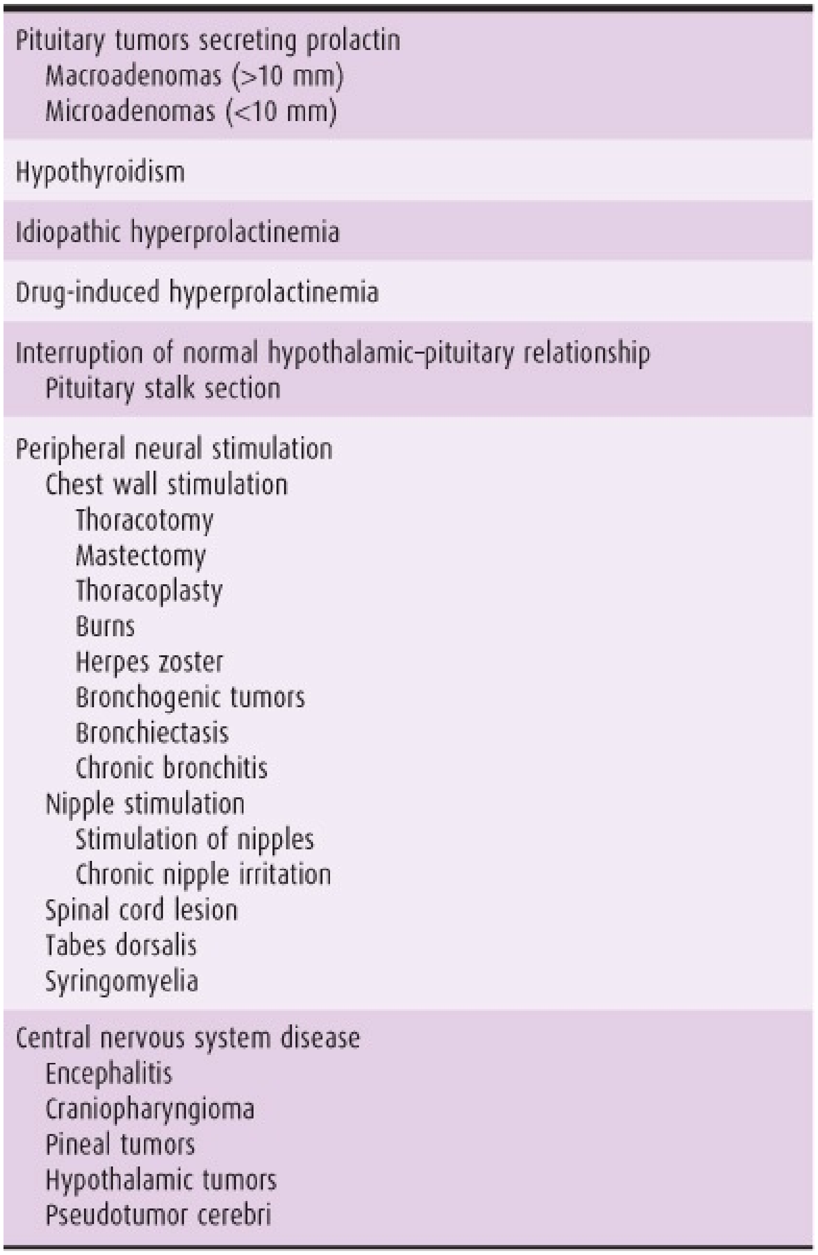
Figure 54–2 outlines the diagnostic scheme for primary amenorrhea. Pelvic examination should be done to establish the presence of a vagina and uterus and no vaginal septum or imperforate hymen that might account for the failure of appearance of menses. Because pelvic examination of an adolescent girl may be difficult, pelvic ultrasound or examination under anesthesia may be required to establish the presence of a uterus. Other diagnostic tools, namely pelvic computed tomography (CT) scan and magnetic resonance imaging (MRI), may be helpful.

If no uterus is present, serum testosterone levels should be measured and karyotyping done to differentiate between müllerian agenesis and testicular feminization.

B. Diagnosis of Amenorrhea Associated With Galactorrhea-Hyperprolactinemia

Figure 54–3 outlines the diagnostic workup of patients with galactorrhea or hyperprolactinemia. Table 54–4 summarizes the differential diagnosis of galactorrhea-amenorrhea.

Table 54–4. Differential diagnosis of galactorrheahyperprolactinemia.



- Pituitary tumors secreting prolactin
  - Macroadenomas (>10 mm)
  - Microadenomas (<10 mm)
- Hypothyroidism
- Idiopathic hyperprolactinemia
- Drug-induced hyperprolactinemia
- Interruption of normal hypothalamic-pituitary relationship
  - Pituitary stalk section
- Peripheral neural stimulation
  - Chest wall stimulation
    - Thoracotomy
    - Mastectomy
    - Thoracoplasty
    - Burns
    - Herpes zoster
    - Bronchogenic tumors
    - Bronchiectasis
    - Chronic bronchitis
  - Nipple stimulation
    - Stimulation of nipples
    - Chronic nipple irritation
  - Spinal cord lesion
  - Tabes dorsalis
  - Syringomyelia
- Central nervous system disease
  - Encephalitis
  - Craniopharyngioma
  - Pineal tumors
  - Hypothalamic tumors
  - Pseudotumor cerebri

Patients with primary hypothyroidism have elevated thyroid-releasing hormone (TRH) levels. TRH acts to stimulate the release of prolactin and may thereby lead to galactorrhea-amenorrhea syndrome. TSH is also elevated and easier to measure and thus is the screening test for hypothyroidism.

Once hypothyroidism is adequately treated, serum prolactin must be measured again after thyroid function has become normal. If prolactin remains elevated or is initially higher than 50–200 ng/mL, the patient should be further studied via cone view of the sella or CT or MRI scan of the sella to rule out pituitary micro- or macroadenoma.

A meticulous history must be taken to ascertain whether the hyperprolactinemia is caused by ingestion of drugs. Prolactin secretion is inhibited by dopamine and stimulated by serotonin and TRH. Any drug that blocks the synthesis or binding of dopamine will increase the prolactin level. Prolactin is increased by serotonin agonists and decreased by serotonin antagonists. Pituitary macroadenoma should be ruled out if prolactin levels are higher than 50–100 ng/mL, even if the patient is taking drugs that lead to raised prolactin levels.

C. Diagnosis of Amenorrhea Caused by Primary Ovarian Failure

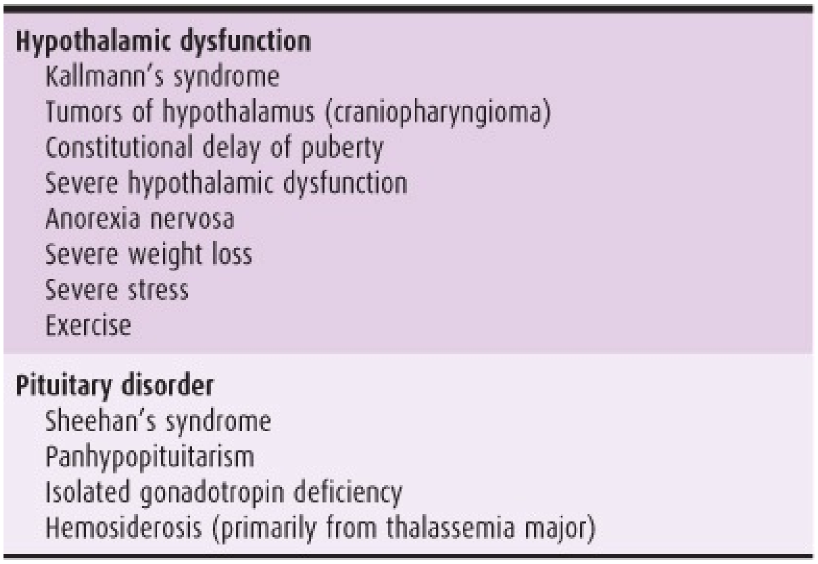
Table 54–3 lists the causes of primary ovarian failure.

Karyotyping is indicated for all women who present with premature menopause, particularly if their amenorrhea is primary. Patients with primary amenorrhea may have a steroid enzyme defect. Autoimmune oophoritis is a reversible cause of ovarian failure that must be investigated.

D. Diagnosis of Amenorrhea Associated with Hypothalamic–Pituitary Dysfunction

Table 54–5 summarizes the differential diagnosis of hypoestrogenic amenorrhea. The category includes amenorrhea associated with athletic activity, weight loss, or stress. Differentiation of hypothalamic from pituitary dysfunction can be achieved by giving GnRH, but is generally not a worthwhile effort, as pituitary causes are rare and can often be diagnosed on the basis of the history. Moreover, in Kallmann's syndrome, a single bolus dose of GnRH may not elicit a normal response. Up to 40 doses of GnRH have been required to prime the pituitary so that it will respond normally. A GnRH pump also has been used.

Table 54–5. Differential diagnosis of hypoestrogenic amenorrhea (hypogonadotropic hypogonadism).



Hypothalamic dysfunction
Kallmann's syndrome
Tumors of hypothalamus (craniopharyngioma)
Constitutional delay of puberty
Severe hypothalamic dysfunction
Anorexia nervosa
Severe weight loss
Severe stress
Exercise
Pituitary disorder
Sheehan's syndrome
Panhypopituitarism
Isolated gonadotropin deficiency
Hemosiderosis (primarily from thalassemia major)

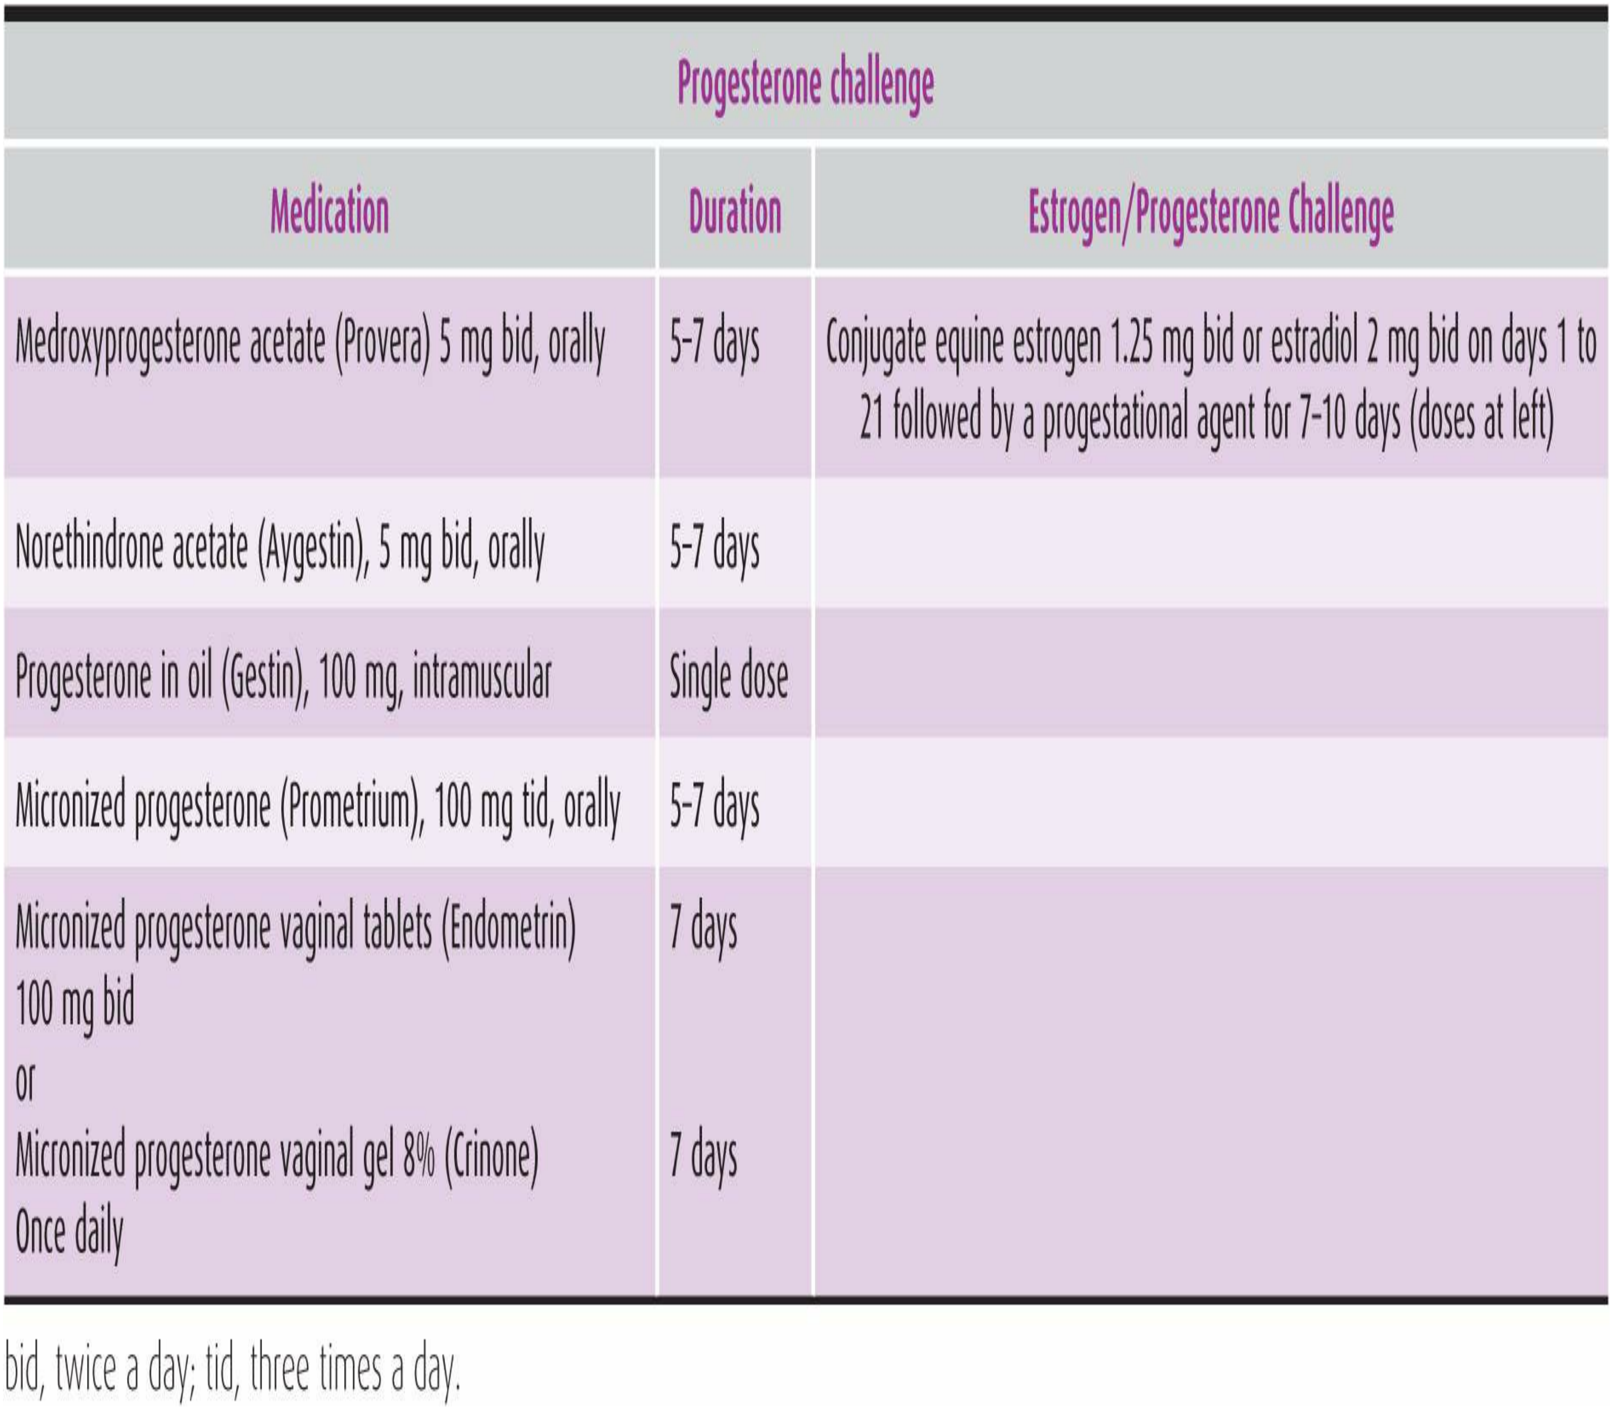
If there is a significant history consistent with Sheehan's syndrome, pituitary function testing is indicated in order to determine the functional capacity of the gland—particularly the integrity of the pituitary–adrenal axis.

In girls with primary amenorrhea, observing the pattern of LH and FSH release after administration of GnRH will help to determine whether the patient is undergoing late pubertal changes.

E. Diagnosis of Secondary Amenorrhea

These patients are studied according to the scheme outlined in Figure 54–3. The first step is the progestin challenge, which indirectly determines whether the ovary is producing estrogen. If the endometrium has been primed with estrogen, exogenous progestin will produce menses. Give either medroxyprogesterone acetate 10 mg orally daily for 5–7 days, or progesterone 100 mg intramuscularly as a single dose. Other progestative preparations can be used as well (Table 54–6). If vaginal bleeding follows, the ovaries are secreting estrogen. If it does not, it can be concluded that there is no estrogen or that the patient has Asherman's syndrome.

Table 54–6. Progesterone and estrogen/progesterone challenge test methods.



Progesterone challenge

Medication	Duration	Estrogen/Progesterone Challenge
Medroxyprogesterone acetate (Provera) 5 mg bid, orally	5-7 days	Conjugate equine estrogen 1.25 mg bid or estradiol 2 mg bid on days 1 to 21 followed by a progestational agent for 7-10 days (doses at left)
Norethindrone acetate (Aygestin), 5 mg bid, orally	5-7 days	
Progesterone in oil (Gestin), 100 mg, intramuscular	Single dose	
Micronized progesterone (Prometrium), 100 mg tid, orally	5-7 days	
Micronized progesterone vaginal tablets (Endometrin) 100 mg bid or Micronized progesterone vaginal gel 8% (Crinone) Once daily	7 days 7 days	

bid, twice a day; tid, three times a day.

From a practical standpoint, if a patient has not had a D&C, it is virtually impossible for her to have Asherman's syndrome, so the diagnostic steps summarized in the following paragraphs can be disregarded.

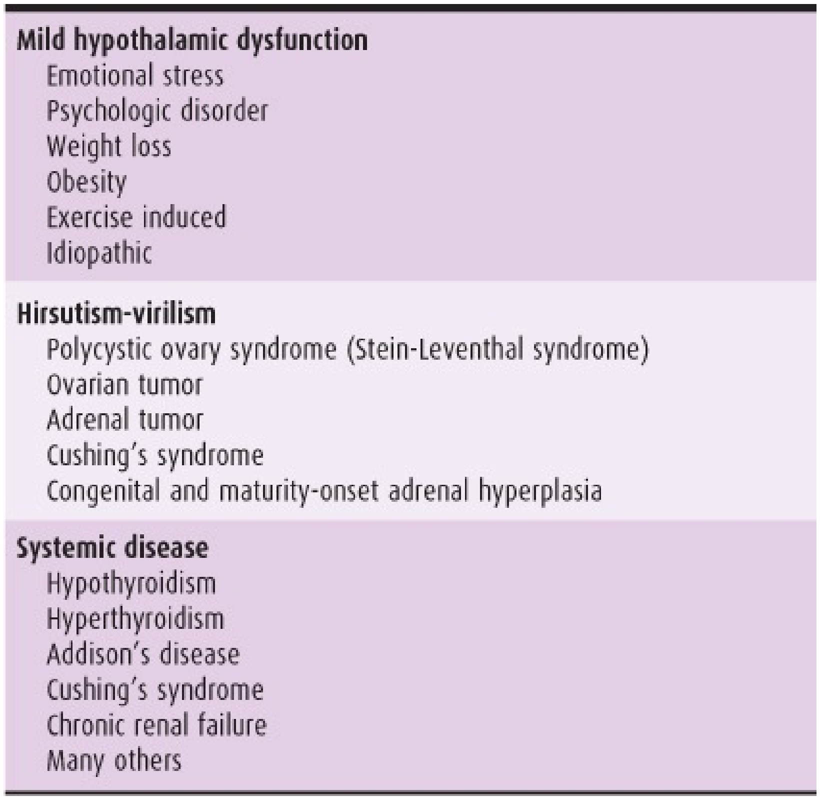
Asherman's syndrome can be ruled out by administration of conjugated estrogen 2.5 mg orally daily or estradiol 4 mg daily for 21 days, followed by a progestational agent for 7–10 days (Table 54–6). Patients with Asherman's syndrome do not bleed after this regimen.

Asherman's syndrome can also be diagnosed by weekly serum progesterone tests. Any value in the ovulatory range (>3 ng/mL) not associated with menses is indicative of Asherman's syndrome. Hysterosalpingography, sonohysterography, and hysteroscopy can also lead to a diagnosis of Asherman's syndrome. Three dimensional ultrasound (3D US) is a non invasive tool and may also help in diagnosis. In a patient who does not have Asherman's syndrome and who does not respond to the progestin challenge, ovarian dysfunction may be of hypothalamic or ovarian origin. The distinction is based on the FSH level. Primary ovarian dysfunction resulting in low estradiol secretion is associated with high serum FSH. Values vary in different laboratories, but in general an FSH level higher than 40 mIU/mL indicates primary ovarian failure. POF resulting in secondary amenorrhea can be due to genetic cause such as XO/XX mosaicism and 47XXX. Carriers of fragile X permutation are at an increased risk to develop POF, with a reported prevalence of 10–20%. Therefore, patients with secondary amenorrhea and high gonadotropin levels should have karyotype analysis and screened for the fragile X mutation. In addition, POF can be due to an autoimmune process, ovarian infectious disease such as mumps oophoritis, or a physical insult such as surgery, irradiation, or chemotherapy.

Patients who bleed in response to the progestin challenge (ie, whose ovaries are secreting estrogen) fit into one of 4 categories: (1) virilized, with or without ambiguous genitalia; (2) hirsute, with polycystic ovaries, hyperthecosis, or mild maturity-onset adrenal hyperplasia; (3) nonhirsute, with hypothalamic dysfunction; or (4) amenorrheic secondary to systemic disease.

Table 54–7 sets forth the differential diagnosis for patients with amenorrhea who respond to progestin challenge test and are considered to have anovulation. Clinical examination, transvaginal ultrasound, and hormonal profile (FSH, LH, androgens, insulin) may be helpful in establishing the diagnosis of PCOS.

Table 54–7. Differential diagnosis of eugonadotropic eugonadism (progestin-challenge positive).



- **Mild hypothalamic dysfunction**
  - Emotional stress
  - Psychologic disorder
  - Weight loss
  - Obesity
  - Exercise induced
  - Idiopathic
- **Hirsutism-virilism**
  - Polycystic ovary syndrome (Stein-Leventhal syndrome)
  - Ovarian tumor
  - Adrenal tumor
  - Cushing's syndrome
  - Congenital and maturity-onset adrenal hyperplasia
- **Systemic disease**
  - Hypothyroidism
  - Hyperthyroidism
  - Addison's disease
  - Cushing's syndrome
  - Chronic renal failure
  - Many others

Complications

The complications of amenorrhea can be numerous, including infertility and psychosocial developmental delays with lack of normal physical sexual development. Hypoestrogenic patients can develop severe osteoporosis and fractures, the most hazardous to life being femoral neck fracture (see Chapter 59). The complications associated with amenorrhea in patients who respond to progestin challenge are endometrial hyperplasia and carcinoma (see Chapter 59) resulting from unopposed estrogen stimulation.

Treatment

A. Management of Patients Desiring Pregnancy—Ovulation Induction

1. Ovulation induction in patients with amenorrhea-galactorrhea with pituitary macroadenoma—Dopamine agonist drugs such as cabergoline and bromocriptine remain the first-line treatment of hyperprolactinemia of any cause, including macroadenomas. These drugs can decrease prolactin secretion and tumor size. Surgical therapy—transsphenoidal or frontal removal of the pituitary adenoma or the entire gland—may be required if tumor size or secretion are resistant to dopamine agonists, the lesion is rapidly enlarging or causing symptoms such as visual changes or headaches, or in women with giant adenomas (>3 cm) who wish to discontinue agonist treatment for conception and the duration of pregnancy. Approximately half of surgically treated patients will menstruate normally after this procedure.

2. Ovulation induction in patients with amenorrhea-galactorrhea without macroadenoma (including patients with microadenomas)—These patients ovulate readily in response to dopamine agonist treatment, with dose titrated until serum prolactin is normal. Patients are maintained on the lowest dose necessary to maintain normal prolactin levels. Once pregnancy has been achieved, the agent can be discontinued. Patients with macroadenomas may need to continue therapy throughout pregnancy to avoid further growth of the lesion.

Patients taking drugs that raise the prolactin level should discontinue them if possible, but continued use of such drugs is not a contraindication to therapy.

3. Ovulation induction in patients with hypothyroidism—Amenorrheic patients with hypothyroidism frequently respond to thyroid replacement therapy.

4. Ovulation induction in patients with primary ovarian failure—According to Rebar and associates, patients with primary ovarian failure can be made to ovulate only under very rare circumstances. Patients with reversible ovarian failure include those with autoimmune oophoritis, who can be successfully treated with corticosteroids. Otherwise, almost all patients with primary ovarian failure fall into the category of idiopathic premature ovarian failure and cannot be made to ovulate. In vitro fertilization (IVF) with donor oocytes is the only way they can have children.

Any patient with a Y chromosome should undergo oophorectomy to prevent tumor development.

5. Ovulation induction in patients with hypoestrogenic hypothalamic amenorrhea (progestin-challenge negative)—In these patients with low estrogen levels, the pituitary does not release high quantities of LH and FSH (as would be expected with an intact, normally functioning, negative feedback mechanism). Therefore, even though clomiphene citrate (an antiestrogen) is unlikely to stimulate gonadotropin release, many reproductive endocrinologists treat such patients successfully with a single course of clomiphene citrate, 150 or 250 mg daily for 5 days, on the chance that ovulation will occur.

Injections of exogenous gonadotropins (human recombinant follicle-stimulating hormone combined with human recombinant luteinizing hormone or human menopausal gonadotropin [hMG]) is usually first-line therapy. Patients showing some ovarian stimulation by clomiphene can be treated with a combination of clomiphene and hMG—the advantage being a reduction in the amount of hMG required and thus a substantial cost savings. Ovulation induction with gonadotropins must be carefully monitored with serial ultrasound and estradiol determinations to avoid hyperstimulation. Hyperstimulation is the stimulation of too many follicles, with associated ovarian enlargement and ascites, as well as other systemic abnormalities.

If a specific and potentially reversible cause of amenorrhea can be identified (eg, marked weight loss), it should be corrected.

6. Ovulation induction in patients who bleed in response to progestin challenge—Virtually all of these patients respond to clomiphene citrate. The starting dose is 50 mg orally daily for 5 days. This can be increased to a maximum of 250 mg orally daily in 50-mg increments until ovulation is induced. Efficacy of clomiphene, however, plateaus at 100 mg/d. This medication is approved by the US Food and Drug Administration for use up to 150 mg/d. Ovulation occurs 5–10 days after the last dose. Patients with elevated androgens who do not respond to clomiphene citrate may respond to combined treatment with an oral hypoglycemic agent and clomiphene. If clomiphene therapy with or without oral hypoglycemic agents is ineffective, gonadotropin therapy may be attempted. Care must be taken in using FSH in these patients, as they are likely to become hyperstimulated.

Laparoscopic ovarian drilling (LOD) is a surgical method of ovulation induction in PCOS patients. LOD involves electrocautery or laser drilling of the ovarian cortex, with the goal of creating foci of laser or thermal damage in the cortex and ovarian stroma. In general, at least 6 puncture sites 2–4 mm in depth are made in the ovary away from the hilum. The mechanism of action is unknown, but may involve destruction of androgen-producing stromal cells, a sudden drop in ovarian androgen levels, improved follicular microenvironment, or increased gonadotropin secretion. This procedure may cause postoperative pelvic adhesions, resulting in tubal compromise.

B. Management of Patients Not Desiring Pregnancy

Patients who are hypoestrogenic must be treated with a combination of estrogen and progesterone to maintain bone density and prevent genital atrophy. The dose of estrogen varies with the age of the patient. Oral contraceptives are good replacement therapy for most women. Combinations of 0.625–1.25 mg of conjugated estrogens orally daily on days 1 through 25 of the cycle with 5–10 mg of medroxyprogesterone acetate on days 16 through 25 are a suitable alternative. Calcium intake should be adjusted to 1–1.5 g of elemental calcium daily.

Patients who respond to the progestin challenge require occasional progestin administration to prevent the development of endometrial hyperplasia and carcinoma. Oral contraceptive pills may be used to regulate the menstrual cycle. Oral contraceptives also help with management of hirsutism. Alternatively, progestational medication in a dose detailed in Table 54–6 for 10–13 days every month or every other month is sufficient to induce withdrawal bleeding and to prevent the development of endometrial hyperplasia. Patients with hyper-prolactinemia need periodic prolactin measurements and radiographic cone views of the sella turcica to rule out the development of macroadenoma.

Prognosis

The prognosis for amenorrhea is good. It is not usually a life-threatening clinical event, as with proper evaluation, tumors can be recognized and treated. Many patients with hypothalamic amenorrhea will spontaneously recover normal menstrual cycles.

Virtually all amenorrheic women who do not have premature ovarian failure can be made to ovulate with a dopamine agonist, clomiphene citrate, insulin-sensitizing agents, and gonadotropins.

55
Hirsutism

Ariel Revel, MD

ESSENTIALS OF DIAGNOSIS

- Excess coarse body hair in sex hormone–dependent areas
- Only in women and children
- Ferriman–Gallwey score ≥8 (Fig. 55–1)

Figure 55–1. Ferriman–Gallwey hirsutism scoring system. Each of the 9 body areas most sensitive to androgen is assigned a score from 0 (no hair) to 4 (frankly virile), and these separate scores are summed to provide a hormonal hirsutism score. (Reproduced, with permission, from Hatch R, et al. *Am J Obstet Gynecol* 1981; 140:850–830. [Fig. 5]. © Elsevier.)

- Adult male distribution pattern
- Testing for elevated androgens is not recommended in mild cases.
- Main causes are polycystic ovary syndrome, idiopathic, congenital adrenal hyperplasia, androgen-secreting tumors, Cushing syndrome, acromegaly, drugs.
- Topical and/or systemic treatments control hirsutism in most cases.
- Allow 4–6 months for any treatment to be effective.

Hirsutism, unwanted hair growth, is a common and distressing condition that, although often thought to be a cosmetic problem, significantly affects psychologic well-being. In Western society, excessive facial or body hair in women is unacceptable. Women who do not conform to a prevailing feminine ideal of physical appearance because of hirsutism may feel unattractive and suffer from low self-esteem, and such women may find social interactions difficult. Hirsutism is however, more than a cosmetic problem because it usually represents a hormonal imbalance, resulting from a subtle excess of androgens that may be of ovarian origin, adrenal origin, or both. The underlying cause of hirsutism is usually polycystic ovary syndrome (PCOS). It is important to differentiate idiopathic hirsutism from other causes. Physicians should be familiar with therapies for these conditions.

Pathogenesis

A. Hair Growth Cycle

The hair growth cycle comprises 3 phases: anagen (growth phase), catagen (involution phase), and telogen (rest phase). Hormonal regulation plays an important role in the hair growth cycle in a site-specific pattern. Androgens increase hair follicle size, hair fiber diameter, and the proportion of time terminal hairs spent in the anagen phase. Androgen excess in women leads to increased hair growth in most androgen sensitive sites, but will manifest with loss of hair in the scalp region, in part by reducing the time scalp hairs spends in the anagen phase.

B. The Sebaceous Glands

The sebaceous glands are microscopic glands in the skin that secrete an oily/waxy matter, called sebum, to lubricate the skin and hair. They are found in greatest abundance on the face and scalp, though they are distributed throughout all skin sites except the palms and soles.

C. Types of Hair

Hair can be categorized as either vellus (fine, soft, and not pigmented) or terminal (long, coarse, and pigmented). Follicle size and type of hair can change in response to numerous factors, particularly androgens. Nonetheless, the number of hair follicles does not change over an individual’s lifetime.

D. The Role of Androgens

Androgens are necessary for terminal hair and sebaceous gland development and mediate differentiation of pilosebaceous units into either a terminal hair follicle or a sebaceous gland. In the former case, androgens transform the vellus hair into a terminal hair; in the latter, the sebaceous component proliferates and the hair remains vellus.

D. Male-Pattern Hair Growth

Male-pattern hair growth occurs in sites where relatively high levels of androgen are necessary for pilosebaceous unit differentiation. Although androgen underlies most cases of hirsutism, there is only a modest correlation between the quantity of hair growth and androgen levels. This is thought to result from the fact that stimulation of hair growth from the follicle does not depend solely on circulating androgen concentrations, but also depends on local factors and variability in end-organ sensitivity to circulating androgens

E. Physiology of Androgens

Androgens are steroids that stimulate the development of male secondary sex characteristics and consequently promote the growth of sexual hair. The major androgens are testosterone, dihydrotestosterone, androstenedione, dehydroepiandrosterone (DHEA), and dehydroepiandrosterone sulfate adrenocorticotropic hormone (DHEAS). In order to comprehend the role played by elevated levels of androgens in the development of hirsutism, one must understand the sources of androgens, their metabolic pathways and sites of action, and their interrelationship with other steroid hormones such as estrogens and corticosteroids.

1. Production—All steroid hormone production begins with the 2-stage rate-limiting step of cholesterol conversion to pregnenolone, which is regulated by trophic hormones. In the nonpregnant woman, androgens are produced by both the ovaries and the adrenals, as well as by peripheral conversion. The rate-limiting step in androgen formation is the regulation of P450c17 gene expression, which is dependent on the concentrations of luteinizing hormone (LH) in the ovary and adrenocorticotropic hormone (ACTH) in the adrenal cortex.

2. Ovarian production of androgens—Androgens are produced by the normal ovary as precursors in the synthesis of estrogens. When gonadotropin-releasing hormone (GnRH) is secreted in a pulsatile fashion, thecal cells are stimulated to secrete and bind LH. In response to ligand binding, the theca cells of the preantral follicle produce androstenedione, DHEA, and testosterone. In the normal female, follicle-stimulating hormone (FSH) secreted from granulosa cells stimulates the granulosa cells to aromatize these androgens to the estrogens, estrone and estradiol. This relationship produces a system of androgen anabolism and catabolism balanced and coordinated to meet the needs of the follicular cycle.

3. Adrenal production of androgens—Stimulation of the adrenal gland by ACTH results in androgen production in the zona reticularis and zona fasciculata of the adrenal cortex. The main androgen manufactured is DHEAS, with smaller amounts of DHEA and androstenedione. A phenomenon called adrenarche occurs and is usually chronologically timed before menarche in females. During this period, the adrenal cortex has a significant increase in adrenal hormone production, as a result of increased responsiveness of androgens and their precursors to the circulating levels of ACTH. This results in adrenocortical secretion of DHEAS at a level similar to that of cortisol secretion. Controversy remains regarding the causative factors.

4. Circulation

A. TESTOSTERONE—Testosterone, by virtue of its plasma concentration and its potency, is one of the major androgens. It is the second most potent androgen after dihydrotestosterone, and circulating levels are 20–80 ng/dL in adult women. The ovary and the adrenals contribute equally to testosterone production, with each supplying approximately 25% of the total circulating level. The other 50% of circulating testosterone is derived from peripheral conversion of androstenedione, although the ovarian contribution to testosterone levels may increase during the periovulatory portion of the menstrual cycle. Peripheral levels of testosterone display a slight diurnal variation that parallels that of cortisol. In normal women, 99% of testosterone is protein-bound, of which 80% is bound to sex hormone-binding globulin (SHBG) and 19% is loosely bound to albumin. The remaining 1% is free and unbound. The free and albumin-bound testosterone are the biologically active forms of circulating testosterone.

B. DIHYDROTESTOSTERONE—Circulating levels of dihydrotestosterone, the most potent androgen, are 2–8 ng/dL or one-tenth those of testosterone. Although both the ovary and the adrenal gland secrete it, most dihydrotestosterone is produced by peripheral conversion of testosterone by 5α-reductase.

C. ANDROSTENEDIONE—Androstenedione, one of the 17-ketosteroids, is not very potent, with only 20% of the effectiveness of testosterone. Synthesis and secretion occur mostly in the ovaries and adrenals in equal amounts, with the remaining 10% being produced peripherally. Androstenedione levels display a diurnal variation paralleling that of cortisol and may simultaneously increase by as much as 50% when cortisol levels rise. Moreover, periovulatory increases in androstenedione levels can also be observed. In contrast to testosterone, androstenedione is bound mainly to albumin and secondarily to SHBG.

D. DHEA AND DHEAS—DHEA and DHEAS, both weak androgens, have approximately 3% of the effectiveness of testosterone and are the other major precursors of 17-ketosteroids. DHEA is primarily produced by the adrenals (60–70%), with ovarian production and hydrolysis of DHEAS accounting for the remainder. DHEA has a large diurnal variation similar to that of cortisol. Conversely, DHEAS is derived almost entirely from the adrenal, has only slight diurnal variation, and circulates in high concentrations. The DHEAS level may provide a good clinical assessment of adrenal function.

5. Action—The skin and hair follicles are androgen-responsive and thus have the capacity to metabolize androgens. DHEA, androstenedione, and testosterone enter the target cell and are reduced to dihydrotestosterone by 5α-reductase. Dihydrotestosterone is then bound to a cytoplasmic receptor protein that transports the androgen into the cell nucleus, where it is bound to chromatin and initiates transcription of stored genetic information. In the hair follicle, this promotes hair growth, leading to increased hair growth and initiating the conversion of vellus to terminal hair.

In females a certain amount of androgenic stimulation is expected, with the greatest levels noted at puberty, when these increased levels result in the clinical appearance of pubic hair and axillary hair. Similarly, androgens stimulate the facial pilosebaceous glands, resulting in the pubertal development of acne.

Metabolic conversion of androgens to dihydrotestosterone may be accelerated. This results in irreversible conversion of vellus hair to terminal hair in areas of androgen-sensitive skin. Thus, in excess androgens are pathologic, and the clinical signs and symptoms of hirsutism and virilization result.

Hirsutism results from an interaction between the plasma androgens and the apparent sensitivity of the hair follicle to androgen. The sensitivity of the hair follicle is determined in part by the local metabolism of androgens, particularly by conversion of testosterone to dihydrotestosterone by 5α-reductase, and subsequent binding of these molecules to the androgen receptor. Some women have hirsutism without hyperandrogenemia (idiopathic hirsutism). Most women with a 2-fold or greater elevation of androgen levels have some degree of hirsutism or an alternative pilosebaceous response, such as acne vulgaris, seborrhea, or pattern alopecia.

F. Definition of Hirsutism & Hypertrichosis

Hirsutism is defined as the development of androgen-dependent terminal body hair in a woman in places in which terminal hair is normally not found.

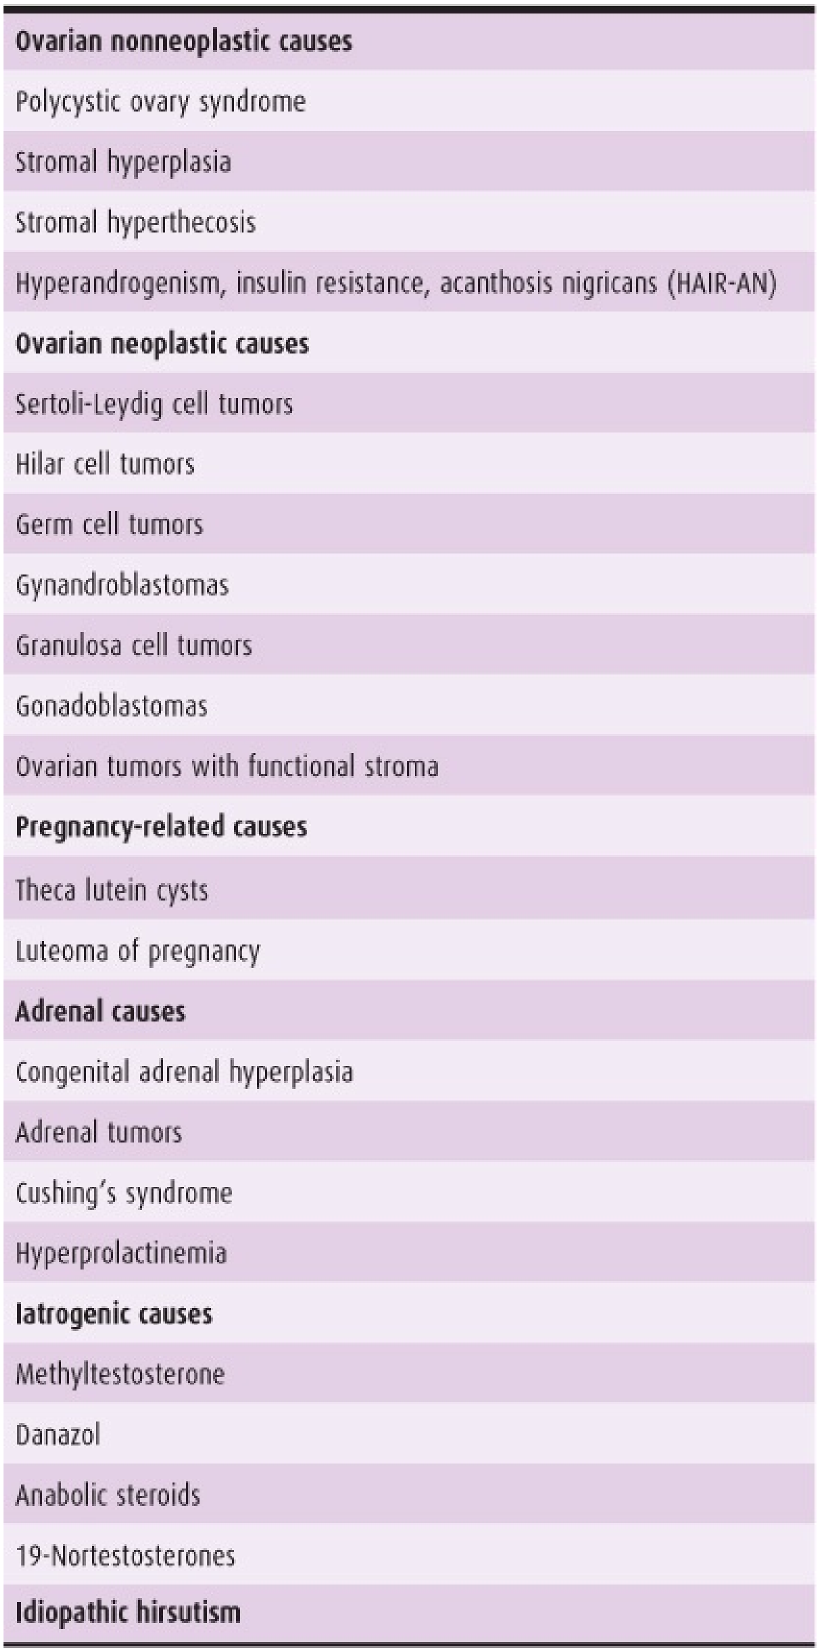
Hirsutism usually represents androgen overproduction or enhanced androgen metabolism in the skin. This is most often manifested as increased “midline hair” on the upper lip, chin, ears, cheeks, lower abdomen, back, chest, and proximal limbs. Most women with a two-fold or greater elevation of androgen levels have some degree of hirsutism or an alternative pilosebaceous response, such as acne vulgaris, seborrhea, or pattern alopecia. Nevertheless, some women have hirsutism without hyperandrogenemia (“idiopathic hirsutism”).

Hypertrichosis is a generalized excessive hair overgrowth occurring on the trunk and hands and *not* localized to the androgen-dependent areas of the skin. Although the mechanisms of hypertrichosis are poorly defined, it is not thought to be an androgen-dependent process. There are 2 distinct types of hypertrichosis: generalized hypertrichosis, which occurs over the entire body, and localized hypertrichosis, which is restricted to a certain locations, such as on the extremities, the head, and the back. Hypertrichosis may also be either congenital or, more commonly, acquired later in life. Congenital forms of hypertrichosis are X-linked dominant traits. Causes of acquired hypertrichosis include cancer metabolic disorders, anorexia, thyroid disorders, and most commonly drugs or chemicals such as oral phenytoin, diazoxide, minoxidil, and cyclosporine. Acquired generalized hypertrichosis can be obtained through cancer. The hair that grows due to this condition is known as malignant down.

G. Etiology

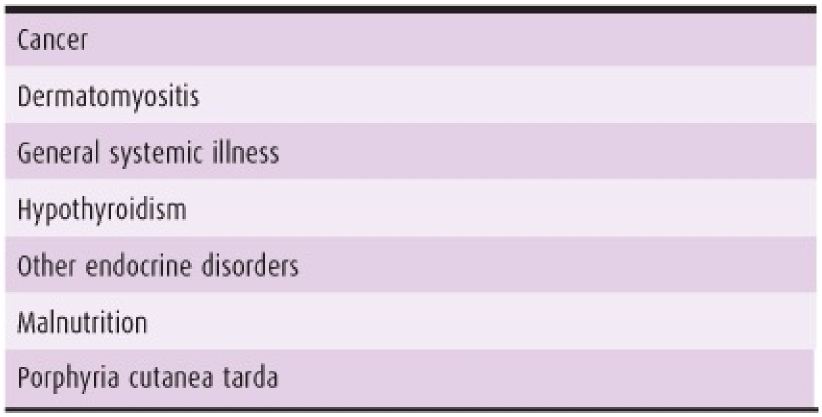
The goal of working up selected hirsute women is to attempt to determine the specific etiology and to provide a baseline in case it becomes necessary to reassess the patient because of progression of the disorder. Table 55–1 details the ovarian, adrenal, and iatrogenic causes of hirsutism, whereas Table 55–2 details the etiology of hypertrichosis.

Table 55–1. Differential diagnosis of hirsutism.



Ovarian nonneoplastic causes
Polycystic ovary syndrome
Stromal hyperplasia
Stromal hyperthecosis
Hyperandrogenism, insulin resistance, acanthosis nigricans (HAIR-AN)
Ovarian neoplastic causes
Sertoli-Leydig cell tumors
Hilar cell tumors
Germ cell tumors
Gynandroblastomas
Granulosa cell tumors
Gonadoblastomas
Ovarian tumors with functional stroma
Pregnancy-related causes
Theca lutein cysts
Luteoma of pregnancy
Adrenal causes
Congenital adrenal hyperplasia
Adrenal tumors
Cushing's syndrome
Hyperprolactinemia
Iatrogenic causes
Methyltestosterone
Danazol
Anabolic steroids
19-Nortestosterones
Idiopathic hirsutism

Table 55–2. Etiology of hypertrichosis.



Cancer
Dermatomyositis
General systemic illness
Hypothyroidism
Other endocrine disorders
Malnutrition
Porphyria cutanea tarda

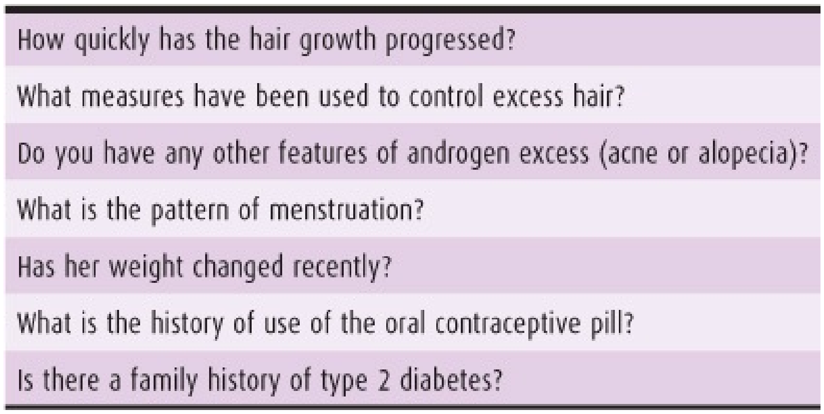
Prevention

Hirsutism is generally not a preventable condition; thus most causes of hirsutism are beyond a woman’s control. Patients should be advised to avoid unnecessary medicines known to cause hirsutism, control obesity, and prevent insulin resistance.

Clinical Findings & Diagnosis

It is important to define the age of onset and to correlate it to puberty. Important aspects of history of hirsute patients are detailed in Table 55–3.

Table 55–3. Important aspects of the patient history.



How quickly has the hair growth progressed?
What measures have been used to control excess hair?
Do you have any other features of androgen excess (acne or alopecia)?
What is the pattern of menstruation?
Has her weight changed recently?
What is the history of use of the oral contraceptive pill?
Is there a family history of type 2 diabetes?

A. Symptoms & Signs

Examination should assess the distribution of excess hair. Weight and height are measured to calculate body mass index (BMI). Physical examination should search for acanthosis nigricans, representing insulin resistance. Signs of virilization, such as clitoromegaly, male pattern balding, deepening voice, or decreased breast size, should be assessed. The Ferriman–Gallwey grading system (Fig. 55–1) system provides a subjective determination of severity of hirsutism. It is especially useful to determine treatment effectiveness and for research purposes. Hair growth is rated from 0 (no growth of terminal hair) to 4 (complete and heavy cover) in 9 locations, giving a maximum score of 36. The 9 locations measured are the upper lip, chin, chest, upper back, lower back, upper abdomen, lower abdomen, the upper arms, and the thighs. In white women, a score of 8 or higher is regarded as indicative of androgen excess. With other ethnic groups, the amount of hair expected for that race should be considered.

This rating scale has since been modified by the American Association of Clinical Endocrinologists to include a total of 19 locations, with the 10 extra locations being sideburns, neck, buttocks, inguinal area, perianal area, forearm, leg, foot, toes, and fingers. Each area has its own specified definition of the 4-point scale.

B. Psychologic Dysfunction

Cystic acne, hirsutism, and alopecia can have a devastating psychosocial effect in young girls and women of reproductive age. These manifestations may be associated with severe anxiety and depression. The occurrence of obesity in conjunction with hyperandrogenism can have a further negative effect on self-esteem and self-image. The fear of social rejection can make some women reclusive and may retard development of their social skills and confidence. Correction of the underlying pathophysiologic condition can help ameliorate the psychologic dysfunction.

C. Laboratory Findings

Measurement of serum testosterone concentrations helps identify the occasional case of severe androgen excess that needs further investigation, but it is not essential in women with a clearly benign presentation, especially as testosterone assays perform poorly in the female range. According to current guidelines, testosterone measurement is needed only for women with moderate to severe hirsutism, when other symptoms of polycystic ovary syndrome (PCOS) are present, or when there is rapid progression of hirsutism or other signs of virilization. Obese women with PCOS, particularly those with a family history of type 2 diabetes, should be assessed for metabolic syndrome with an oral glucose tolerance test and cholesterol profile. The value of laboratory tests for mild to moderate hirsutism is not proven. The investigation of severe cases should include free and total testosterone levels, prolactin, LH, and FSH. Obese patients with PCOS could benefit from glucose tolerance tests and cholesterol levels.

D. Imaging Studies

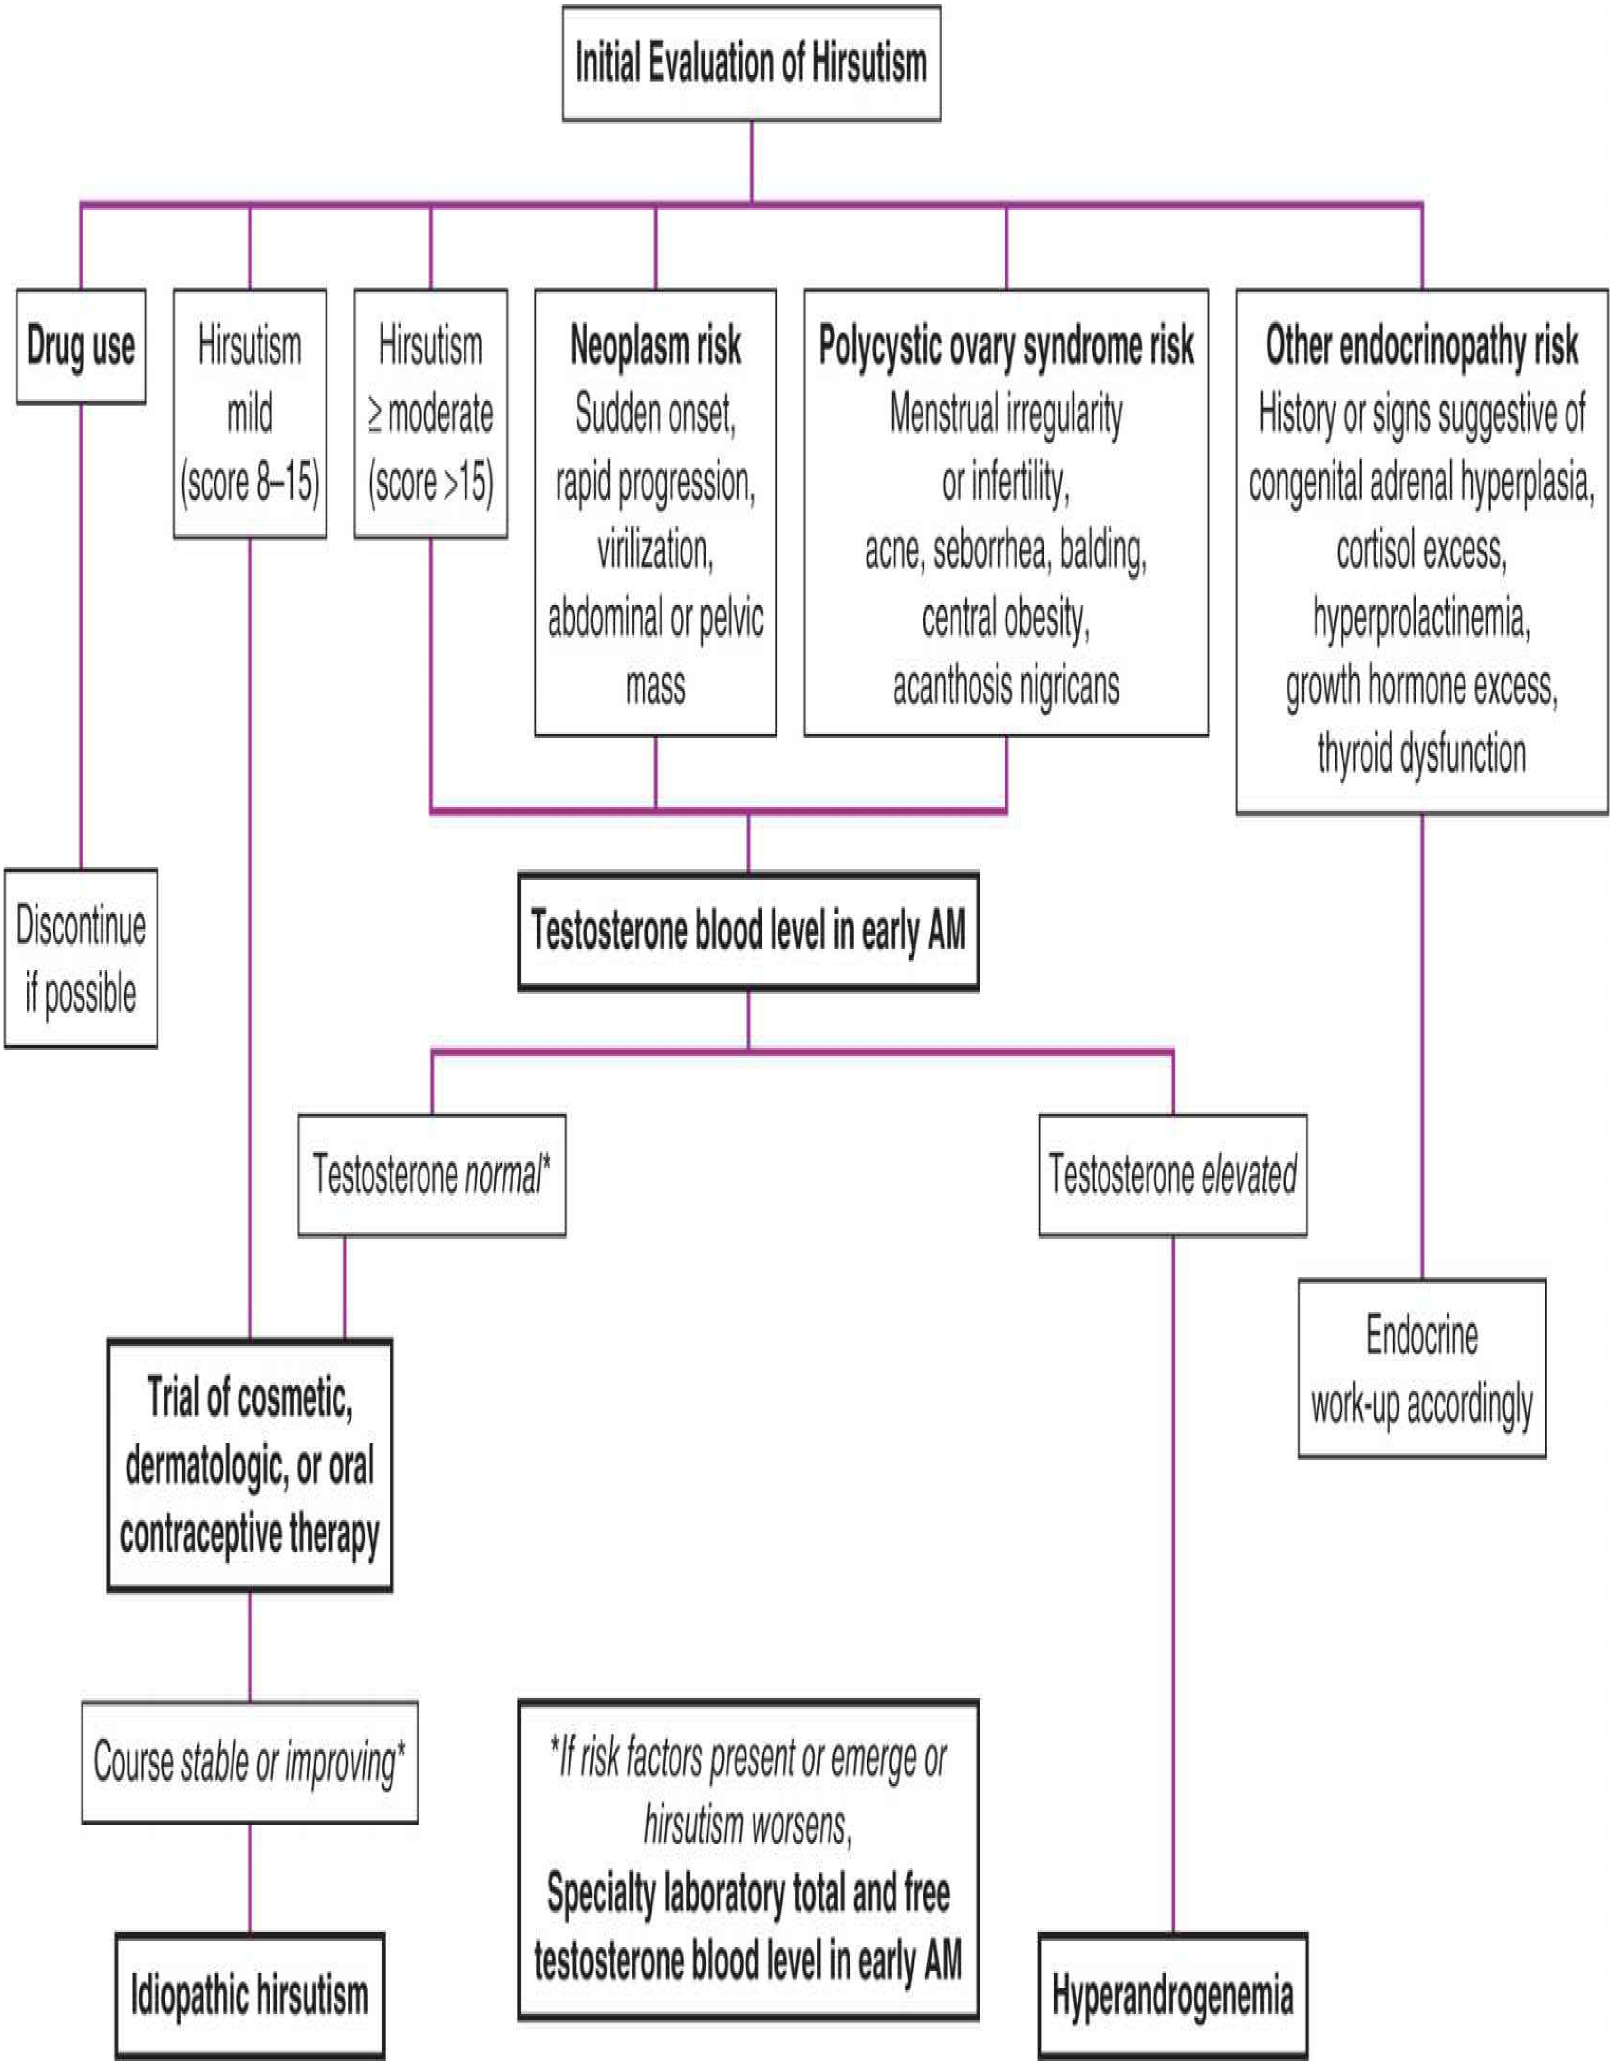
Sonographic scan of the ovaries is important in the evaluation of PCOS. Computerized tomography (CT) of the adrenal glands should be performed only when a high index of suspicion of tumor exists, especially when hair growth is sudden and heavy.

Differential Diagnosis of Excessive Hair Growth

Because some excess hair results from medical disorders, it is important to distinguish excess hair that is the result of an underlying medical problem from hair growth that is simply a cosmetic concern. Underlying medical problems of hirsutism and hypertrichosis are detailed in Tables 55–1 and 55–2, respectively.

Excessive growth of sexual hair may be due to excessive androgen production, increased sensitivity of the hair follicle to androgens, or increased conversion of weak androgens to potent androgens. Potential sources of increased androgens include the ovaries, the adrenal glands, exogenous hormones, and other medications.

Figure 55–2 provides an approach to the workup for hyperandrogenism that depends on both assessing the degree of hirsutism and elucidating risk factors for PCOS, virilizing disorders, androgenic medications, and other endocrinopathies.



Initial Evaluation of Hirsutism
Drug use
Hirsutism mild (score 8–15)
Hirsutism ≥ moderate (score >15)
Neoplasm risk
Sudden onset, rapid progression, virilization, abdominal or pelvic mass
Polycystic ovary syndrome risk
Menstrual irregularity or infertility, acne, seborrhea, balding, central obesity, acanthosis nigricans
Other endocrinopathy risk
History or signs suggestive of congenital adrenal hyperplasia, cortisol excess, hyperprolactinemia, growth hormone excess, thyroid dysfunction
Discontinue if possible
Testosterone blood level in early AM
Testosterone *normal**
Testosterone *elevated*
Endocrine work-up accordingly
Trial of cosmetic, dermatologic, or oral contraceptive therapy
Course *stable or improving**
**If risk factors present or emerge or hirsutism worsens,*
Specialty laboratory total and free testosterone blood level in early AM
Idiopathic hirsutism
Hyperandrogenemia

Figure 55–2. Suggested algorithm for the initial evaluation of hirsute women for hyperandrogenism. Risk assessment includes more than the degree of hirsutism. Medications that cause hirsutism include anabolic or androgenic steroids (consider in athletes and patients with endometriosis or sexual disfunction) and valproic acid (consider in neurologic disorders). If hirsutism is moderate or severe or if mild hirsutism is accompanied by features that suggest an underlying disorder, elevated androgen levels should be ruled out. Disorders to be considered, as shown, include neoplasm and various endocrinopathies, of which polycystic ovarian syndrome (PCOS) is the most common. Plasma testosterone should be rechecked in the early morning on day 4–10 of the menstrual cycle in regularly cycling women, the time for which norms are standardized. Plasma total testosterone should be rechecked along with free testosterone in a reliable laboratory if the plasma total testosterone is normal in the presence of risk factors or progression of hirsutism on therapy. Simultaneous assay of 17-hydroxyprogesterone may be indicated in subjects at high risk for congenital adrenal hyperplasia. A small minority of women initially diagnosed with idiopathic hirsutism by this algorithm will later be found to have otherwise asymptomatic idiopathic hyperandrogenism or previously unsuspected infertility as their only noncutaneous manifestation of PCOS. (Data from Rosenfeld RL. *N Engl J Med* 2005; 353:2578–2588.)

A. Ovarian Neoplastic Disorders Causing Hirsutism

Androgen-secreting ovarian neoplasms usually present with rapidly developing hirsutism, amenorrhea, and virilization and are rare causes of hirsutism. The most common androgen secreted by these tumors is testosterone, with serum testosterone levels usually in excess of 200 ng/dL. Most hormone-secreting neoplasms are palpable on pelvic examination and are unilateral.

1. Sertoli-leydig cell tumors and hilar (leydig) cell tumors—These are ovarian neoplasms typically associated with hirsutism and virilization. Sertoli-Leydig cell tumors constitute <0.5% of all ovarian tumors and occur mainly in young, menstruating females. Hilar cell tumors are rare neoplasms and are usually encountered in older women. Their presentation is often more indolent and less dramatic than that of Sertoli-Leydig cell tumors. Other ovarian neoplasms that may be associated with hirsutism are the gynandroblastomas, germ cell tumors, granulosa cell tumors, and gonadoblastomas. The latter occur mainly in male patients, with gonadal dysgenesis and resultant female phenotypes.

2. Ovarian tumors with functional stroma—Ovarian tumors with functional stroma are categorized as germ cell tumors containing syncytiotrophoblast cells and idiopathic and pregnancy-related tumors. In these tumors, the neoplastic cells do not secrete steroid hormones directly, but stimulate secretion by the ovarian stroma either within or immediately adjacent to the tumor. These tumors have been described in essentially all tumors that occur in the ovary, whether benign or malignant, metastatic or primary.

B. Ovarian Nonneoplastic Disorders Causing Hirsutism

PCOS, the most common cause of hirsutism, is typically associated with menstrual irregularities, infertility, and obesity. Histologic changes seen in PCOS include a thickened ovarian capsule and numerous follicular cysts surrounded by a hyperplastic, luteinized theca interna. The pathophysiology of this disease is not fully understood; proposed causes include ovarian dysregulation, a disturbance of the hypothalamic–pituitary axis, adrenal androgen excess, and increased insulin resistance. Regardless of the underlying defect, the degree of hyperandrogenism and the individual’s sensitivity to androgens may result in the complaint of hirsutism in 80% of these patients.

Other nonneoplastic ovarian disorders associated with hirsutism include stromal hyperplasia and stromal hyper-thecosis. Stromal hyperplasia results in the hypersecretion of androgens from hypertrophic ovaries. It has a peak incidence between 60 and 70 years of age and is usually associated with uniform enlargement of both ovaries. Stromal hyperthecosis is a proliferation of stroma with foci of luteinized thecal cells and also results in bilateral ovarian involvement. It frequently results in the clinical manifestations of virilism, obesity, hypertension, and disturbances of glucose metabolism, with most patients showing histologic evidence of concurrent stromal hyperplasia. A syndrome known as hyperandrogenism, insulin resistance, acanthosis nigricans (HAIR-AN) has also been described; however, this is thought to most likely represent a variation of one of the nonneoplastic disorders, rather than denoting a separate disease entity.

C. Pregnancy-Related Disorders

During pregnancy, elevated androgen levels that lead to severe hirsutism and virilization may be due to any of the previously mentioned conditions; however, pregnancy-specific disorders also exist.

1. Theca lutein cysts (Hyperreactio Luteinalis)—These are benign neoplasms that can cause bilateral ovarian enlargement, hirsutism, and, infrequently, virilization. These cysts occur almost exclusively in pregnancy and have an increased incidence in pregnancies complicated by gestational trophoblastic disease. Ovarian biopsy reveals cysts lined mostly with luteinized theca cells, but luteinized granulosa cells may also be present. Typically, resolution of the cysts occurs after pregnancy.

2. Luteoma of pregnancy—Is a benign human chorionic gonadotropin (hCG)–dependent ovarian tumor that may develop during pregnancy. High levels of testosterone and androstenedione are present, and virilization may occur in up to 25% of affected mothers and 65% of female fetuses. In most patients, spontaneous regression of the neoplasm and return of androgen levels to normal occur in the postpartum period.

D. Adrenal Disorders Causing Hirsutism

1. Enzyme deficiencies—Enzyme deficiencies affecting adrenal and ovarian steroidogenesis represent the second most common cause of hyperandrogenism in postmenarchal females, and congenital adrenal hyperplasia (CAH) represents the most common disorder in this group. CAH is inherited as an autosomal recessive trait, and is present in 1–5% of women who complain of hirsutism. It results from mutations in enzymes required for adrenal steroidogenesis. The most common form of CAH is characterized by a deficiency of 21-hydroxylase, with case reports of similar occurrences in patients with 3β-hydroxysteroid dehydrogenase and 11β-hydroxylase deficiencies. These defects prohibit cortisol synthesis from its precursor 17β-hydroxyprogesterone. The expectant decrease in serum cortisol stimulates pituitary secretion of ACTH in an effort to normalize cortisol levels. Higher levels of ACTH stimulate adrenal production of intermediates in the biosynthetic pathway of cortisol. Consequently, these intermediates cannot be used for cortisol production because of enzyme defects and are instead shunted into the biosynthetic pathways for androgens, with resultant increases in testosterone and androstenedione. Classical CAH is usually diagnosed in females during the neonatal period because of androgen-induced ambiguous genitalia (pseudohermaphroditism); however, a minor enzyme deficiency termed acquired, adult-onset CAH may go unrecognized until puberty, when hirsutism, amenorrhea, and virilization may occur. CAH causes severe hirsutism if adherence to glucocorticoids is poor. Late-onset CAH is important to exclude in hirsute women wishing to conceive. Glucocorticoids are the treatment of first choice during periconception.

2. Adrenal neoplastic disorders—Adrenal tumors are a rare cause of hirsutism, although when present, symptoms may be acute and quite severe. The main androgen produced by adrenal neoplasms is DHEAS, with serum levels usually >700–800 μg/dL. Rarely, adrenal neoplasms may secrete testosterone; when this occurs, testosterone values are usually higher than 200 ng/dL.

3. Cushing's syndrome—Cushing's syndrome and the associated overproduction of cortisol may increase androgen levels and cause hirsutism. The syndrome has 3 known etiologies: (1) adrenal tumor, (2) ectopic production of ACTH by a nonpituitary tumor, or (3) excess production of ACTH by the pituitary (Cushing's disease). Because androgens are formed from intermediates in the synthesis of cortisol, increased serum and tissue levels of cortisol and its intermediates may result in hyperandrogenism and clinically present as hirsutism, regardless of the underlying cause of this syndrome.

4. Other causes—Hyperprolactinemia has been shown to produce mild hirsutism. Several investigators have reported increased DHEAS levels with hyperprolactinemia. This likely results from adrenal stimulation after prolactin binds to its numerous receptors on the adrenal gland. Despite increased androgen secretion, clinical manifestations are mild or absent, due to the inhibitory effects of prolactin on the conversion of testosterone to dihydrotestosterone (DHT) and its metabolites.

The adrenal gland may be the source of excess androgen production in the absence of an identifiable cause. The cause of this adrenal hyperactivity is not clear, but mild enzyme deficiencies, stress, and hyper-functioning of the entire adrenal gland have been postulated as probable causes.

E. Iatrogenic Mechanisms Causing Hirsutism

Exogenous sources of androgens should also be considered as possible causes of hirsutism. Methyltestosterone, danazol, and anabolic steroids such as oxandrolone may lead to excessive hair growth. The 19-nortestosterones in low-dose oral contraceptives rarely cause hirsutism or acne.

1. Idiopathic hirsutism—Hirsutism that occurs without adrenal or ovarian dysfunction, in patients with normal menstrual cycles and in the absence of any exogenous source of steroid hormones is termed idiopathic hirsutism. The term idiopathic hirsutism is thought to be a misnomer, since a likely cause has been elucidated. When normal levels of testosterone, unbound testosterone, DHEAS, dihydrotestosterone, and androstenedione are present, increased 5α-reductase enzyme activity appears to be the major mechanism of action. This enzyme converts testosterone to the more potent dihydrotestosterone in the hair follicle. Many patients with idiopathic hirsutism have an elevated level of plasma 3α-androstanediol glucuronide, a metabolite of dihydrotestosterone, thought to reflect the increased peripheral androgen metabolism, which is responsible for the clinical manifestation of hirsutism.

In summary, hirsutism may result from an ovarian disorder, an adrenal disease, an iatrogenic cause, or an increase in peripheral androgen metabolism. Rarely, other endocrinologic disturbances such as hypothyroidism or acromegaly may be associated with excessive hair growth. An important clinical correlation is that hirsutism may be accompanied by infertility as a result of the underlying abnormality. Because infertility may be the inciting factor triggering a patient to seek medical care, questions regarding a history of hirsutism should be a part of any infertility workup.

Treatment

The overall quality of primary evidence of the relative efficacy of treatments for hirsutism is weak and is based on small studies of short duration that lack quality-of-life outcomes. Recently, however, systematic reviews have amalgamated this evidence, and new guidelines are now available (Table 55–4). It should be explained that hair grows in cycles. Thus it can take months for an individual hair follicle to proceed through catagen, anagen, and telogen phases.

Table 55–4. Treatment of hirsutism.

Cyproterone acetate
Spironolactone
Flutamide
Finasteride
Glucocorticoids
Dopamine
Insulin-lowering drugs
Cimetidine
Ketoconazole

A. Lifestyle Changes

Lifestyle changes that promote weight loss through diet and physical exercise are useful in obese patients. Obesity is present in 60% of patients with PCOS, the most common form of hirsutism and hyperandrogenism. Weight loss in patients with hyperandrogenism, with or without the clinical presence of PCOS, should be the first therapeutic option because it decreases androgen levels, increases SHBG, and may restore ovulation. As little as a 7% reduction in body weight can restore fertility, decrease hirsutism, and improve the response to induction of ovulation. Lifestyle measures that promote weight loss through diet and exercise are of paramount importance because obesity has an adverse effect on the outcome of all systemic treatments.

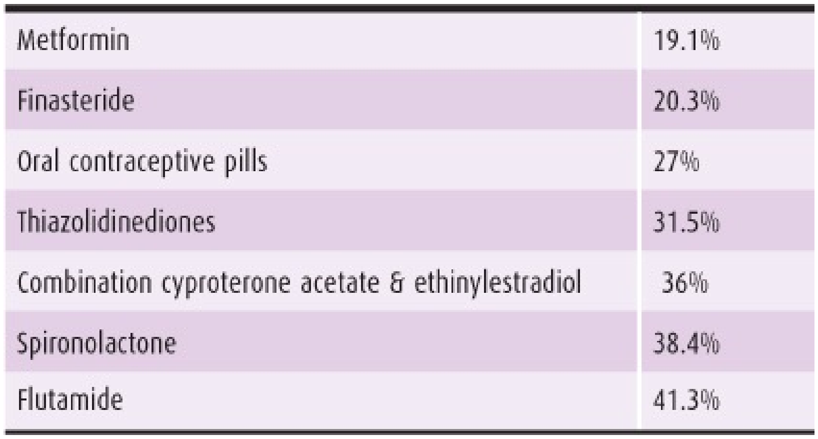
B. Medical

1. Local—Eflornithine, a topical agent, is an irreversible inhibitor of ornithine decarboxylase, an enzyme that catalyzes the rate-limiting step for follicular polyamine synthesis, which is necessary for hair growth. Eflornithine hydrochloride cream 13.9% (Vaniqa) is approved in many countries for the treatment of unwanted facial hair in women. Eflornithine does not remove hair but acts to reduce the rate of hair growth.

A large sponsored randomized trial showed a 26% reduction in facial hair after 24 weeks of treatment, with most of the benefit achieved in 8 weeks. Nevertheless, Endocrine Society Clinical Practice Guideline recommends against the use of topical antiandrogen therapy.

2. Systemic treatment—Systemic treatment reduces stimulation of the anagen growth phase by testosterone. Thus enough follicles have to pass through anagen before a clinical effect is observed. The goal of treatment is to find the lowest effective dose of treatment that maintains the benefit gained in the first phase of treatment. For all pharmacologic therapies for hirsutism a trial of at least 6 months should be conducted before making changes in dose, changing medication, or adding medication. Medical suppression of hirsutism is detailed in Table 55–5.

Table 55–5. Suppression of hirsutism over baseline over 6 months compared with placebo.



Metformin	19.1%
Finasteride	20.3%
Oral contraceptive pills	27%
Thiazolidinediones	31.5%
Combination cyproterone acetate & ethinylestradiol	36%
Spironolactone	38.4%
Flutamide	41.3%

3. Oral contraceptive pills—The primary driver of ovarian androgen secretion is LH, which can be suppressed using a combined oral contraceptive pill. The effectiveness of oral contraceptives in suppressing hirsutism will depend on the content of ethinylestradiol (20–35 μg) and on the nature of the progestogen. Pills containing progestogens with antiandrogenic properties, such as cyproterone acetate and drospirenone found in Diana and Yasmin, respectively, are effective in hirsutism. Pills containing levonorgestrel and norethisterone are more androgenic and could potentially exacerbate hirsutism. Third-generation progestogens such as desogestrel or gestodene have relatively neutral androgenic effects, and oral contraceptives containing these compounds can usefully be combined with an antiandrogen such as spironolactone. Only 1 small randomized controlled trial has compared different oral contraceptive pills, and current guidelines do not recommend one specific pill for treating hirsutism.

4. Gonadotropin-releasing hormone agonists—Severe hirsutism of ovarian origin can sometimes be treated by gonadotropin-releasing hormone (GnRH) analogues. GnRH analogs inhibit the secretion of gonadotropins from the pituitary gland, thereby inhibiting the secretion of androgens and estrogens from the ovary. Although GnRH agonists acutely stimulate ovarian production of androgens and estrogens, continued therapy causes a sustained decrease in ovarian steroid production compared with pretreatment levels. This suppression continues for the duration of GnRH agonist therapy. Significant decreases in serum levels of estradiol, testosterone, and androstenedione occur during treatment, although adrenal androgens are usually unaffected.

As a result of the hypoestrogenism associated with ongoing GnRH therapy, a potential risk of osteoporosis and menopausal symptoms exists with long-term therapy. However, concomitant use of estrogen and progesterone replacement therapy may counteract the adverse effects. Newer studies suggest that spironolactone may also simulate this effect.

Most studies have shown greater improvement of hirsutism with the use of GnRH agonists alone or in combination with oral contraceptives as compared with combination oral contraceptives alone; however, some studies show comparable efficacy. Endocrine society guidelines suggest against using GnRH agonists except in women with severe forms of hyperandrogenemia, such as ovarian hyperthecosis, who have a suboptimal response to oral contraceptive pills and antiandrogens.

5. Androgen receptor antagonists—In a proportion of women, ovarian suppression alone may not be sufficient, and antiandrogens will need to be added. Patient-important hirsutism that remains despite ≥6 months of monotherapy with an oral contraceptive justify combination therapy by adding an antiandrogen.

Antiandrogens are efficacious for treating hirsutism. There are 4 androgen receptor antagonists currently being used for the treatment of hirsutism. Despite proven efficacy in numerous clinical trials, none of these drugs has been approved by the US Food and Drug Administration for this indication. Additionally, similar reported efficacy has been reported with all of these medications. Hence the agent of choice should be dictated by the individual’s response, reported side effects, and known contraindications. All antiandrogens, and particularly finasteride, are potentially teratogenic, so some clinicians prescribe them only to women using reliable contraception.

A. CYPROTERONE ACETATE—This potent agent was the first androgen receptor antagonist used to treat hirsutism and is widely prescribed in Europe to treat hirsutism. Antiandrogenic effects result from competitive displacement of dihydrotestosterone from its receptor and reduction of 5α-reductase activity in the skin. Progestational activity results in gonadotropin suppression with subsequent suppression of ovarian testosterone secretion. Cyclical administration of 50–100 mg on days 1–10 of the menstrual cycle combined with oral estrogen on days 1–21 produces therapeutic levels. More prolonged use tends to induce amenorrhoea because of its progestogenic properties. This method counters hypoestrogenism and irregular bleeding and prevents pregnancy and the potential teratogenic complications that may result. Although effective in 50–75% of hirsute women, significant side effects include decreased libido, mental depression, and hepatotoxicity, which is rarely seen when cyclic administration is performed. Clinical studies have shown efficacy equivalent to that of spironolactone, with the latter showing fewer side effects (see next section). Currently, cyproterone acetate is not available in the United States.

B. SPIRONOLACTONE—Spironolactone, an aldosterone antagonist traditionally used as a diuretic in the treatment of hypertension, is also used to treat hirsutism. Cochrane review showed that spironolactone can effectively suppress hirsutism. It possesses antiandrogenic properties and exerts its peripheral antiandrogenic effects in the hair follicle by competing for androgenic receptors and displacing dihydrotestosterone at both nuclear and cytosol receptors. It also lowers testosterone levels by inhibiting the cytochrome P450 monooxygenases that are required for biosynthesis of androgens in gonadal and adrenal steroid-producing cells. Serum levels of SHBG, DHEAS, and DHEA are unaltered by treatment with spironolactone. The dosage used for treatment of hirsutism is between 50 and 200 mg/d. Serum androgen levels will drop within a few days of the start of treatment, and a clinical response can usually be seen within 2–5 months. Side effects include fatigue, transient diuresis, polydipsia, menorrhagia or unscheduled menstrual bleeding, gastro-intestinal bleeding and breast tenderness, but no long-term problems have been encountered. Its anti-mineralocorticoid and diuretic properties are rarely prominent in young women. Because spironolactone is a potent antiandrogen, all women using it should use effective contraception. Nevertheless, women taking spironolactone should be sent for periodic screening of potassium level to identify hyperkalemia.

C. FLUTAMIDE—Flutamide is a potent, highly specific, nonsteroidal antiandrogen with no intrinsic hormonal or antigonadotropin activity. Although the exact mechanism of action is unknown, it competitively inhibits target tissue androgen receptor sites. Recent studies suggest that 250 mg 1–3 times daily is a highly effective treatment for moderate to severe hirsutism. Side effects include decreased appetite, amenorrhea, decreased libido, or dry skin. A rare but serious reported side effect is hepatotoxicity. Consequently, flutamide is usually reserved for resistant cases of hirsutism, and liver enzymes should be checked regularly in patients who are taking the drug. Additionally, because of possible teratogenic effects, contraception must be used with this therapy. Endocrine Society Clinical Practice Guideline recommends against flutamide for the treatment of hirsutism.

D. FINASTERIDE—If additional treatment is needed, then finasteride would be a sensible option because it has a different mode of action. Finasteride is the newest antiandrogenic agent used for hirsutism. It is a selective type 2 5α-reductase inhibitor that blocks the conversion of testosterone to dihydrotestosterone. It has proven efficacy in up to 86% of patients with a subjective improvement rate of 21–45% when 5 mg is administered orally over 3 months to 1 year. Side effects at this dosage are usually mild or absent and include headaches, transient gastrointestinal upset, and an unexplained increase in total testosterone.

6. Glucocorticoids—Dexamethasone is used mainly to treat hirsutism in patients with hyperandrogenism of adrenal origin. Chronic low-dose dexamethasone, 0.5–1 mg orally taken at bedtime, will provide adequate adrenal androgen suppression. Diminution of hair growth is reported in 16–70% of patients. Glucocorticoid therapy has fallen out of favor due to frequent side effects, potential for adrenal suppression, and evidence that these agents are less effective than antiandrogens, even when there is a clear adrenal cause of hyperandrogenism. However, their use may be justified in some patients, as recent data suggest that concomitant use of glucocorticoids with GnRH agonists may prolong the disease-free interval when therapy is discontinued. Moreover, glucocorticoids are the treatment of choice to decrease ACTH levels and thereby decrease formation of androgenic precursors of cortisol for patients with CAH.

7. Dopamine—Dopamine is a centrally acting inhibitor of prolactin secretion and is frequently used in the treatment of hyperprolactinemia. Recently, hirsutism scores were shown to decrease significantly during dopamine treatment of hyperandrogenic women with hyperprolactinemia.

8. Insulin-Lowering Drugs—Insulin, which acts as a co-gonadotrophin and amplifies LH-induced testosterone production, is a secondary driver of ovarian androgen secretion. Troglitazone, an insulin-sensitizing agent of the thiazolidinedione class, results in a decrease in androgen level in patients with polycystic ovarian syndrome. Additionally, it has been shown that the administration of 600 mg/d results in improvement of hirsutism in this population. Endocrine Society Clinical Practice Guideline recommends against the use of insulin-lowering drugs for the treatment of hirsutism.

Conveniently, women for whom suppression of LH is not possible (eg, obese women who should not take the oral contraceptive pill because of the risk of thrombosis) are often the very women for whom suppression of insulin is most effective. Nevertheless, insulin sensitizers are of limited use as sole treatment for hirsutism.

9. Cimetidine—Cimetidine, an H2-receptor antagonist, has weak antiandrogenic properties. Recent studies show minimal or no beneficial effect in hirsutism.

10. Ketoconazole—Ketoconazole is a synthetic imidazole derivative that blocks adrenal and gonadal steroidogenesis; it has been advocated by some as a treatment for hirsutism. However, serious side effects result in poor compliance and preclude long-term use. Its use should be avoided because safer therapeutic regimens exist.

C. Mechanical Therapy

The goal of mechanical therapy is to limit new hair growth without affecting existing hair. For this reason, mechanical depilators such as lasers, electrolysis devices, creams, and waxes are often used as supplemental therapy (Table 55–4). Recent technology has made this procedure faster, easier, less painful, and generally free of any serious adverse effects. Many women will be familiar with routine methods of hair removal such as shaving, threading, waxing, and using depilatory creams and can be reassured that these methods do not exacerbate hair growth. Electrolysis and laser epilation or photoepilation are also widely available. A review of 11 trials of laser and light-assisted hair removal in 444 patients showed a 50% reduction in hair over 6 months but noted that the long-term efficacy of these treatments is not well established. Laser treatment is less effective in darker skin because a contrast is needed between skin and hair pigments, but some types of photoepilation can be of benefit patients with for darker skin.

D. Surgical Treatment

In the minority of hirsute patients in whom a specific cause can be identified, therapy should be directed toward the underlying disorder. For example, ovarian and adrenal tumors should be surgically excised. Additionally, women with Cushing’s disease are treated with transsphenoidal pituitary microsurgery. Alternatively, when Cushing’s syndrome is caused by an adrenal tumor, simple adrenalectomy is sufficient. Finally, acromegaly can be treated by transsphenoidal hypophysectomy. For persistent disease, bilateral adrenalectomy or pituitary irradiation is appropriate.

Similarly, a minority of older women may fail to respond to medical management for hyperthecosis despite good compliance. For these women, bilateral oophorectomy may be justified as definitive therapy.

Although wedge resection of the ovary has been successfully used to induce ovulation, it is not recommended for the treatment of hirsutism. This surgical procedure exposes patients to the risks of both anesthesia and possible formation of adhesions. More importantly, this procedure results in only a transient decrease in androgen levels and has successfully reduced the rate of hair growth in only 16% of patients. Wedge resection should not be used as a treatment for hirsutism.

Prognosis

Prognosis for women with hirsutism, hypertrichosis, and precocious sexual hair development depends on the underlying conditions leading to these physical findings, early appropriate evaluation, and appropriate treatment.

A. Follow-up

The success of treatment is usually based on subjective assessment, and clinicians should not contribute to unrealistic expectations of effectiveness. Patient expectations should be discussed, as even compliant patients should expect no more than 25% reduction in hair growth using systemic treatment. Some patients see no benefit, and some are resistant to any systemic treatment.

Women with mild hirsutism may not notice much benefit, and some women will prove resistant to all treatments. Psychologic interventions may be useful for women with unsatisfactory outcomes, but no trials have assessed the effectiveness of such interventions specifically for hirsutism. Testosterone measurements can be misleading because oral contraceptives cause a rise in SHBG, which results in an increase in the total blood testosterone concentration. No specific guidelines exist for monitoring long-term treatments, but it seems logical to measure liver function in users of cyproterone acetate; plasma potassium, liver function, and renal function in users of spironolactone; and vitamin B_{12} concentrations in users of metformin (which is associated with low concentrations of this vitamin).

In conclusion, hirsutism is a common problem, the effect of which is often underestimated. Various treatment options are available, which—when used in logical combinations and tailored to the individual’s clinical profile—can achieve good results in most cases.

Endometriosis

Susan Sarajari, MD, PhD
Kenneth N. Muse, Jr., MD
Michael D. Fox, MD

ESSENTIALS OF DIAGNOSIS

- Endometriosis is a disorder in which abnormal growths of tissue, histologically resembling the endometrium, are present in locations other than the uterine lining.
- Although endometriosis can occur very rarely in post-menopausal women, it is found almost exclusively in women of reproductive age.
- All other manifestations of endometriosis exhibit a wide spectrum of expression.
- The lesions are usually found on the peritoneal surfaces of the reproductive organs and adjacent structures of the pelvis, but they can occur anywhere in the body (Fig. 56–1).

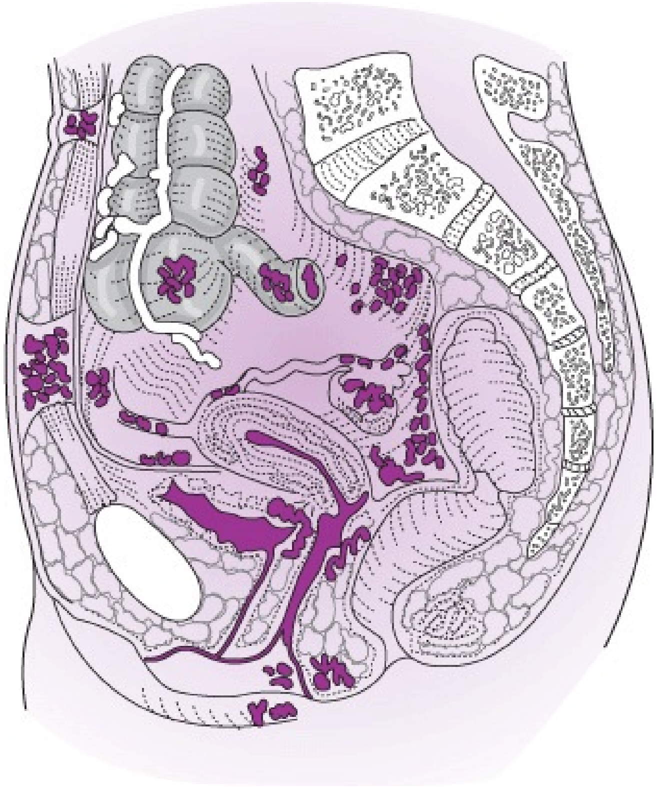

Figure 56–1. Common sites of endometrial implants (endometriosis). (Reproduced, with permission, from Way LW (ed). *Current Surgical Diagnosis & Treatment*. 7th ed. Los Altos, CA: Lange; 1985.)

- The size of the individual lesions varies from microscopic to large invasive masses that erode into underlying organs and cause extensive adhesion formation.
- Similarly, women with endometriosis can be completely asymptomatic or may be crippled by pelvic pain and infertility.

Epidemiology

Endometriosis is a common and important health problem of women. Its exact prevalence is unknown because surgery is required for its diagnosis, but it is estimated to be present in 6–10% of women in the reproductive age group and 25–35% of infertile women. It is seen in 1–2% of women undergoing sterilization or sterilization reversal, in 10% of hysterectomy surgeries, in 16–31% of laparoscopies, and in 53% of adolescents with pelvic pain severe enough to warrant surgical evaluation. Endometriosis is the commonest single gynecologic diagnosis responsible for hospitalization of women aged 15–44, being found in more than 6% of patients.

Pathogenesis

The cause of endometriosis is complex, and the leading theories include retrograde menstruation with transport of endometrial cells, metaplasia of coelomic epithelium, hematogenous or lymphatic spread, and direct transplantation of endometrial cells. A combination of these theories is likely to be responsible.

A theory of retrograde menstruation was proposed during the 1920s. It was postulated that endometriosis occurred because viable fragments of endometrium were shed at the time of menstruation and passed through the fallopian tubes. Once in the pelvic cavity, the tissue became implanted on peritoneal surfaces and grew into endometriotic lesions. Subsequent observations have confirmed that some degree of retrograde menstruation normally occurs in women with patent tubes, that outflow tract obstructions (cervical stenosis, transverse vaginal septa) increase the incidence of endometriosis, and that intentional deposition of endometrium onto peritoneum can initiate endometriosis. Also, the risk of developing the disease is higher in women with prolonged menstrual flow and in those with short menstrual cycle lengths (more menses per year). This theory is simple, attractive, and easily explains why endometriosis is most commonly found on the peritoneal surfaces of the ovaries, cul-de-sac, and bladder and why lesions may develop in episiotomies and other incisions. However, it does not explain why all women do not develop endometriosis, nor does it explain the rare cases of endometriosis in the lung, brain, or other soft tissues or in nonmenstruating subjects (women with Turner’s syndrome or with absent uteri).

There is evidence that altered humoral and cell-mediated immunity plays a role in the pathogenesis of endometriosis. The activity of natural killer cells may be reduced, and deficient cellular immunity may cause an inability to recognize endometrial tissue in abnormal locations. Endometriosis may occur when the deficiency in cellular immunity allows menstrual tissue to implant and grow on the peritoneum.

Genetic influences in the development of endometriosis have also been described. Studies have found that 7–9% of endometriosis patients' first-degree female relatives are diagnosed with the disease—significantly greater than the control rate of 1–2%. Further investigation has revealed a possible role for the HLA-B7 allele. The expression of HLA-B7 has been shown to inhibit the cytotoxic activity of natural killer-like T lymphocytes, suggesting that the growth of ectopic endometrial cells might be under genetic control.

Pathology

The gross appearance of endometriosis at operation is usually quite characteristic and, to an experienced surgeon, is sufficient for diagnosis. The smallest (and presumably earliest) implants are red, petechial lesions on the peritoneal surface. With further growth, menstrual-like detritus accumulates within the lesion, giving it a cystic, dark brown, dark blue, or black appearance. The surrounding peritoneal surface becomes thickened and scarred. These "powder burn" implants typically attain a size of 5–10 mm in diameter. With progression of disease, the number and size of lesions increase, and extensive adhesions may develop. When present on the ovary, cysts may enlarge to several centimeters in size and are called **endometriomas** or "chocolate cysts." Severe disease can erode into underlying tissues and distort the remaining organs with extensive adhesions. In addition to these traditional presentations, endometriosis lesions can have a variety of nonclassical appearances: clear vesicles, white or yellow spots or nodules, circular folds of peritoneum ("pockets"), and visually normal peritoneum (lesions so small they can only be detected microscopically).

The distribution of lesions also exhibits a characteristic pattern. Solitary lesions are possible, but multiple implantations are the rule. The most common site of disease is the ovary (approximately half of all cases), followed by the uterine cul-de-sac, posterior broad ligament, uterosacral ligaments, uterus, fallopian tubes, sigmoid colon, appendix, and round ligaments. Implants may occur over the bowel, bladder, and ureters; rarely, they may erode into underlying tissue and cause blood in the stool or urine, or their associated adhesions may result in stricture and obstruction of these organs. Implants can occur deep in tissue, especially on the cervix, posterior vaginal fornix, or within wounds contaminated by endometrial tissue. Very rarely, endometriosis is found distant from the pelvis, in such sites as the lung, brain, and kidney. Pleural implantations are associated with recurrent right pneumothoraces at the time of menses, termed **catamenial pneumothorax**. Similarly, lesions in the central nervous system can cause catamenial seizures.

The microscopic finding that these lesions are composed of tissue histologically resembling endometrial glands and stroma gives endometriosis its name (Fig. 56–2). The normal endometrial appearance is best seen in small, early lesions; with advanced disease, cyst formation, and fibrosis, the wall of the implant is lined by a monolayer of cells, if at all. Blood is present inside the cyst, and hemosiderin-laden macrophages are found in the cyst wall.

Pathologic Physiology

Overproduction of prostaglandins by an increase in cyclooxygenase-2 activity as well as overproduction of estrogen by increased aromatase activity are considered key factors in the development of endometriosis. Progesterone resistance is also seen, which weakens the antiestrogenic effect of progesterone. This can lead to a chronic inflammatory response, and the most commonly found inflammatory cytokines are interleukin 1,6, and 8, and tumor necrosis factor α.

It is generally agreed that pelvic pain occurs premenstrually in endometriosis patients. Because of this, pain from endometriosis is thought to be due to stimulation from estrogen and progesterone during the menstrual cycle; the tissue of the implant is stimulated to grow in much the same way as is the endometrium. The implants enlarge and may undergo secretory change and bleeding; however, the fibrotic tissues surrounding the implants prevent the expansion and escape of hemorrhagic fluid that occurs in the uterus. With subsequent cycles, this process repeats itself. Pain is produced by pressure and inflammation within and around the lesion, by traction on adhesions associated with the lesions, by the number of implants and their proximity to nerves and other sensitive structures, and by the mass effect of large lesions. Although this sequence of events explains why premenstrual pelvic pain can occur in endometriosis, it is incomplete, because many patients with extensive endometriosis have no pain. It is a common observation that the occurrence and severity of pain from endometriosis bear little relationship to the amount and distribution of the disease. Severe pain in patients with endometriosis is associated with deeply infiltrating lesions, and it is thought that the degree of pain is perhaps determined by the depth of invasion.

The relationship between endometriosis and infertility has been more extensively investigated. Moderate and severe endometriosis is associated with pelvic adhesions that distort pelvic anatomy, prevent normal tubo-ovarian apposition, and encase the ovary. Implants can destroy ovarian and tubal tissue, although occlusion of fallopian tubes is rare.

It is not difficult to understand how advanced disease can result in infertility, but minimal or mild endometriosis, in which pelvic anatomy is entirely normal except for a few peritoneal surface lesions, can also cause infertility. The mechanism by which this occurs is unknown. Various theories have been proposed to explain this phenomenon.

Several investigators have examined peritoneal fluid abnormalities. The peritoneal fluid is an ultrafiltrate of plasma, with <5 mL normally present in the pelvis. After ovulation, a transient rise to approximately 20 mL occurs. The volume of peritoneal fluid and the concentrations of various hormones and other substances in it affect the processes of ovulation, ovum pickup, tubal function, and sperm function.

A marker for ovarian reserve, antimüllerian hormone, has also been found to be decreased in early-stage endometriosis.

Risk Factors

Risk factors for endometriosis include family history, early menarche, long duration of menstrual flow, heavy bleeding during menses, and shorter cycles. Regular exercise of >4 hr/wk, higher parity, and longer duration of lactation were all associated with a decreased risk for endometriosis.

Prevention

Prevention of endometriosis is not currently possible. Traditionally, women with relatives affected by endometriosis—or in whom the diagnosis has recently been made—are advised not to postpone childbearing. The merits of this advice have not been proved. A more thorough understanding of the pathophysiology of endometriosis is required before preventive strategies can be devised.

Clinical Findings

Endometriosis is common among women of reproductive age, and its prevalence increases to 30–40% among infertile women. Clinical findings vary greatly depending on the number, size, and extent of the lesions and on the patient population being examined.

The diagnosis of endometriosis is often strongly suspected from a patient’s initial history. Infertility, dysmenorrhea, and dyspareunia are the main presenting complaints. Most patients complain of constant pelvic pain or a low sacral backache that occurs premenstrually and subsides after menses begins. Dyspareunia is often present, particularly with deep penetration. Lesions involving the urinary tract or bowel may result in bloody urine or stool in the perimenstrual interval. Implantations on or near the external surfaces of the cervix, vagina, vulva, rectum, or urethra may cause pain or bleeding with defecation, urination, or intercourse at any time in the menstrual cycle. Adhesions from endometriosis may cause discomfort at any time during the cycle, and a sensation of pelvic pressure may result if large masses are present. Premenstrual spotting may occur and is more likely to be associated with endometriosis than with luteal phase inadequacy. It must be emphasized, however, that many patients either have no symptoms or have infertility as their only symptom and that the extent of disease often has little correlation with the severity of symptoms.

The physical examination may also be helpful in discerning whether endometriosis is present. Classically, pelvic examination reveals tender nodules in the posterior vaginal fornix and pain upon uterine motion. The uterus may be fixed and retroverted due to cul-de-sac adhesions, and tender adnexal masses may be felt because of the presence of endometriomas. Careful inspection may reveal implants in healed wounds, especially episiotomy and caesarean section incisions, in the vaginal fornix, or on the cervix. Biopsy may be required to prove that the lesions are due to endometriosis. However, many patients have no abnormal findings on physical examination.

For the vast majority of patients, endometriosis is included in the differential diagnosis of infertility or pelvic pain. Endometriosis should be suspected in any patient of reproductive age complaining of pain or infertility. Medical treatment can be given for pelvic pain thought to be due to endometriosis, but the specific diagnosis of endometriosis should not be made unless documented by direct visualization. The final diagnosis of endometriosis can only be made at laparoscopy or laparotomy, by direct observation of the implants. Occasionally, an isolated endometrioma is removed, and the diagnosis must be made histologically by the demonstration of “endometrial” glands and stroma or of hemosiderin-laden macrophages in the cyst wall.

Except for special circumstances, such as urography or sigmoidoscopy for suspected bowel or urinary involvement, ancillary diagnostic studies (ultrasound, x-rays, computed tomography scans) are of little help in diagnosis. CA-125 is often elevated in women with endometriosis; however, it has been shown that this marker is elevated in many other pelvic diseases and therefore has little specificity in the diagnosis of endometriosis. However, an elevated CA-125 that returns to normal levels after medical or surgical treatment can be helpful in the evaluation for recurrences.

Vlahos N, Fortner KB. Emerging issues in endometriosis. *Postgrad Obstet Gynecol* 2005;25:1–9.

Differential Diagnosis

The varied presentations of endometriosis mandate that it be considered in the differential diagnosis of virtually all pelvic disease. In particular, the pain, infertility, and adhesions associated with endometriosis must be distinguished from similar symptoms accompanying pelvic inflammatory disease and pelvic tumors. Usually this will require operative evaluation. A patient with a persistent adnexal mass >5 cm should never be presumed to have an endometrioma even if endometriosis has been diagnosed previously. Such masses require surgical diagnosis.

Complications

True complications of endometriosis are few. Implants over the bowel or ureters may cause obstruction and silent impairment of renal function. The erosive nature of the lesions in advanced aggressive disease can cause a myriad of symptoms, depending on the tissue damaged. Endometriomas can cause ovarian torsion or can rupture and spill their irritating contents into the peritoneal cavity, resulting in a chemical peritonitis. Excision of endometriosis causing catamenial seizures or pneumothorax may be necessary.

Classification

Several classification schemes to assist in describing the anatomic location and severity of endometriosis at operation have been created. Although none is entirely satisfactory, the scoring systems are useful for reporting operative findings and for comparing the results of various treatment protocols. The revised American Fertility Society classification is the most commonly used system and is given in Table 56–1 and Figure 56–3. It should be noted that this system does not correlate well with the symptoms of pain, dyspareunia, or infertility, but is mainly designed for uniform recording of operative findings.

Table 56–1. American Society for Reproductive Medicine revised classification of endometriosis.

	Endometriosis	<1 cm	1-3 cm	>3 cm
Peritoneum	Superficial	1	2	4
	Deep	2	4	6
Ovary	R Superficial	1	2	4
	Deep	4	16	20
	L Superficial	1	2	4
	Deep	4	16	20
	Posterior Cul-de-sac Obliteration	Partial	Complete	
		4	40	
	Adhesions	<1/3 Enclosure	1/3-2/3 Enclosure	>2/3 Enclosure
Ovary	R Filmy	1	2	4
	Dense	4	8	16
	L Filmy	1	2	4
	Dense	4	8	16
Tube	R Filmy	1	2	4
	Dense	4[1]	8[1]	16
	L Filmy	1	2	4
	Dense	4[1]	8[1]	16

**Point assignment doubled

Figure 56–3. Staging of endometriosis. Determination of the stage or degree of endometrial involvement is based on a weighted point system (see Table 56–1 for point values). Distribution of points has been arbitrarily determined and may require further revision or refinement as knowledge of the disease increases. To ensure complete evaluation, inspection of the pelvis in a clockwise or counterclockwise fashion is encouraged. Number, size, and location of endometrial implants, plaques, endometriomas, and/or adhesions are noted. For example, 5 separate 0.5-cm superficial implants on the peritoneum (2.5 cm total) would be assigned 2 points. (The surface of the uterus should be considered peritoneum.) The severity of the endometriosis or adhesions should be assigned the highest score only for peritoneum, ovary, tube, or cul-de-sac. For example, a 4-cm superficial and a 2-cm deep implant of the peritoneum should be given a score of 6 (not 8). A 4-cm deep endometrioma of the ovary associated with more than 3 cm of superficial disease should be scored 20 (not 24). In patients with only 1 set of adnexa, points applied to disease of the remaining tube and ovary should be multiplied by 2. Points assigned may be circled and totaled. Aggregation of points indicates stage of disease (minimal, mild, moderate, or severe). The presence of endometriosis of the bowel, urinary tract, fallopian tube, vagina, cervix, skin, and so forth should be documented under “additional endometriosis.” Other pathology such as tubal occlusion, leiomyomata, uterine anomaly, and so forth should be documented under “additional pathology.” All pathology should be depicted as specifically as possible on the sketch of pelvic organs, and means of observation (laparoscopy or laparotomy) should be noted. (Reproduced, with permission, from American Society for Reproductive Medicine. Revised ASRM classification for endometriosis: 1996. *Fertil Steril* 1997;67:820.)

American College of Obstetricians and Gynecologists. Endometriosis. ACOG Technical Bulletin No. 114. Washington, DC: ACOG; July 2010.

Treatment

Treatment options are dictated by the patient’s desire for future fertility, her symptoms, the stage of her disease, and to some extent her age. It must be emphasized that therapy for endometriosis requires operative inspection of the lesions for correct diagnosis and staging and to be sure that the patient’s symptoms are attributable to endometriosis only.

A. Expectant Management

In asymptomatic patients, those with mild discomfort, or infertile women with minimal or mild endometriosis, expectant management may be appropriate. Although endometriosis is generally felt to be a progressive disease, there is no evidence that treating an asymptomatic patient will prevent or ameliorate the onset of symptoms later. Many reports have found expectant management of infertile women with minimal or mild endometriosis to be as successful as medical or surgical therapies.

B. Analgesic Therapy

Analgesic treatments include nonsteroidal anti-inflammatory agents and prostaglandin synthetase-inhibiting drugs. These drugs are appropriate sole therapy for endometriosis when the patient has mild premenstrual pain from minimal endometriosis, no abnormalities on pelvic examination, and no desire for immediate fertility.

C. Hormonal Therapy

The goal of treatment with hormonal therapy is to interrupt the cycles of stimulation and bleeding of endometriotic tissue. This can be achieved with various agents.

1. Oral contraceptive pills (OCPs)—OCPs are a good choice for patients with minimal or mild symptoms. Generally monophasic products are used, which are prescribed either cyclically or continuously for 6–12 months. The continuous exposure to combination oral contraceptive pills results in decidual changes in the endometrial glands. Continuous use of OCPs has been shown to be effective in decreasing dysmenorrhea and may also retard progression of endometriosis.

2. Progestins—These agents work via a mechanism similar to that of the OCPs, causing decidualization in the endometriotic tissue. Oral medroxyprogesterone acetate can be prescribed as a 10–30-mg dosage daily. An alternative regimen is norethindrone acetate 5 mg daily or megestrol acetate prescribed as a 40-mg daily dose. Depot medroxyprogesterone acetate 150 mg administered intramuscularly can also be given as a single injection every 3 months.

The levonorgestrel-releasing intrauterine device has also been shown to relief dysmenorrheal and pelvic pain. Eighty percent of women treated with progestins have a partial or complete relief of pain.

3. Danazol—Danazol is a 19-nortestosterone derivative with progestin-like effects. Danazol acts via several mechanisms to treat endometriosis. It acts at the hypothalamic level to inhibit gonadotropin release, inhibiting the mid-cycle surge of luteinizing hormone and follicle-stimulating hormone. Danazol also inhibits steroidogenic enzymes in the ovary that are responsible for estrogen production. As a result, a hypoestrogenic environment is created. This, in addition to the androgenic effects of danazol, prevents the growth of endometriotic tissue.

The dosage of danazol is 400 to 800 mg/d in divided doses for 6 months. Side effects of danazol include acne, oily skin, deepening of the voice, weight gain, edema, and adverse plasma lipoprotein changes. Most changes are reversible upon cessation of therapy, but some (such as deepening of the voice) may not be.

Pain relief is achieved in up to 90% of patients taking danazol.

4. GnRH agonists—Gonadotropin-releasing hormone (GnRH) agonists are analogues of the 10-amino-acid peptide hormone GnRH. With the continuous administration of GnRH analogues, suppression of gonadotropin secretion occurs, resulting in elimination of ovarian steroidogenesis and suppression of endometrial implants. Pain related to endometriosis is relieved in most cases by the second or third month of therapy. GnRH agonists can be administered intramuscularly as leuprolide acetate 3.75 mg once a month, intranasally as nafarelin 400 to 800 μg daily, or subcutaneously as goserelin 3.6 mg once a month.

The use of these agents is generally limited to 6 months because of the adverse effects associated with a hypoestrogenic state, particularly loss of bone mineral density. Other side effects include vasomotor symptoms, vaginal dryness, and mood changes.

Many side effects can be minimized by providing add-back therapy in addition to the GnRH agonists in the treatment of endometriosis. The addition of 2.5 mg of norethindrone or 0.625 mg of conjugated estrogens with 5 mg/d of medroxyprogesterone acetate seems to provide relief of vasomotor symptoms and decrease bone mineral density loss in a 6-month treatment period. The addition of 5 mg of norethindrone acetate alone or in conjunction with low-dose conjugated equine estrogen seems to eliminate the loss of bone mineral density effectively as well. Adding bisphosphonates, parathyroid hormone, or calcitonin can also minimize the bone loss.

5. Aromatase inhibitors—Anastrozole (1 mg daily) and letrozole (2.5 mg daily) are the most commonly used aromatase inhibitors. They act by inhibiting the enzyme aromatase, which functions in the conversion of androgens to estrogens. They can be used as an adjuvant treatment combined with other agents such as GnRH analogs.

6. Surgical treatment—In women who want to preserve fertility, who have severe disease, or who have adhesions, conservative surgical therapy is the treatment of choice. This surgery attempts to excise or destroy all endometriotic tissue, remove all adhesions, and restore pelvic anatomy to the best possible condition. Conservative surgery has traditionally been performed at laparotomy, but a laparoscopic approach is associated with a shorter hospital stay and less morbidity, and it is more cost effective. This is particularly true in contemporary practice, where this therapy is usually performed at the time of the initial diagnostic laparoscopy. Reported pregnancy rates after conservative surgery are inversely proportional to the severity of disease and vary greatly. In counseling patients, approximate pregnancy rates of 75% for mild disease, 50–60% for moderate disease, and 30–40% for severe disease should be quoted; however, individualization of therapy is stressed.

Presacral neurectomy to relieve pain should be performed only in selected cases, such as women with recurrent endometriosis, severe incapacitating dysmenorrhea, or disease that did not respond to initial treatment, as efficacy of this treatment is controversial.

If the patient does not desire future childbearing and has severe disease or symptoms, definitive surgery is appropriate and often curative. This entails total abdominal hysterectomy, bilateral salpingo-oophorectomy, and excision of remaining adhesions or implants. If endometriosis remains after excision, postoperative medical therapy may be indicated. After this or after complete excision, hormone replacement therapy is indicated. Estrogen-progestin therapy may be used without reactivating the endometriosis, but individualization of therapy is required.

7. Assisted Reproduction—Infertile women with endometriosis who are older, or who have failed other therapies for infertility, can undergo assisted reproduction, such as ovulation induction with intrauterine insemination or in vitro fertilization (IVF). However, it was found that women with endometriosis undergoing IVF have significantly lower pregnancy rates, fertilization rates, implantation rates, mean number of oocytes retrieved, and peak estradiol concentrations as compared with women with tubal factor infertility. The need to treat women surgically or medically before starting an IVF cycle remains unclear.

Prognosis

Proper counseling of patients with endometriosis requires attention to several aspects of the disorder. Of primary importance is the initial operative staging of the disease to obtain adequate information on which to base future decisions about therapy. The patient’s symptoms and desire for childbearing dictate appropriate therapy. Most patients can be told that they will be able to obtain significant relief from pelvic pain and that treatment will assist them in achieving pregnancy.

Long-term concerns must be more guarded in that all current therapies offer relief but not cure. Even after definitive surgery, endometriosis may recur, but the risk is very low (approximately 3%). The risk of recurrence is not significantly increased by estrogen replacement therapy. After conservative surgery, reported recurrence rates vary greatly but usually exceed 10% in 3 years and 35% in 5 years. Pregnancy delays but does not preclude recurrence. Recurrence rates after medical treatment also vary and are similar to or higher than those reported after surgical treatment.

Although many patients are concerned that endometriosis will progress inexorably, experience has been that conservative surgery avoids the necessity for hysterectomy in the great majority of cases. The course of endometriosis in any individual is impossible to predict at present, and future treatment options should greatly improve what can now be offered.

Assisted Reproductive Technologies: In Vitro Fertilization & Related Techniques

Konstantinos G. Michalakis, MD, PhD
Alan H. DeCherney, MD
Alan S. Penzias, MD

In vitro fertilization (IVF) is a process by which egg cells are fertilized in vitro, that is, by sperm outside of the womb. IVF is a major treatment in infertility when other methods of assisted reproductive technology have failed. Assisted reproductive technologies (ART) include multiple techniques that allow gamete manipulation outside the body and have evolved greatly over the past 2 decades.

IN VITRO FERTILIZATION

IVF involves egg retrieval from the ovary, fertilization in the laboratory (fluid medium), and replacement of the zygote in the patient’s uterus. The first live birth resulting from this technique occurred in June 1978. Since then, over 1 million children have been born throughout the world with the use of assisted reproduction.

Assisted reproductive techniques have been used for more than 20 years, reporting an increasing number of cycles treated, an increasing pregnancy rate, and an increase in live births per cycle (from 6.6% in 1985 to 27% in 2006) for IVF. In 2003 there were 122,872 ART cycles (99.4% were IVF cycles), whereas in 2006, 41,343 live-birth deliveries were reported; approximately <1.0% were gamete intrafallopian transfer for fertilization (GIFT) and <1.0 % accounted for zygote intrafallopian transfer (ZIFT) cycles. In approximately half of the ART cycles (53%), intracytoplasmic sperm injection (ICSI) is used.

One of the most important prognostic predictors for pregnancy is the age of the female partner. Whereas for women younger than 35 years, live birth rate/cycle varies from 30 to 35%, women older than 40 years face live birth rates <6%, down to 2.4%. Table 57–1 presents data according to the National Summary and fertility reports of the US Department of Health and Human Services.

Table 57–1. In vitro fertilization.

Cycles performed in relation to age groups

	<35 y	35-37 y	38-40 y	>40 y
Number of cycles performed	54,386	31,127	25,933	26,752

Outcomes according to age groups

	<35 y	35-37 y	38-40 y	41-42 y
% cycles resulting in pregnancy	45.2	37.7	23.5	19.0
% cycles resulting in live births	37.4	31.1	20.6	
Average number of embryos transferred	2.0	2.5	3.8	2.9
% of twin gestation	38.5	12.5		
% of cancellations	12.2	6.6	13.2	

Approximately 39% of patients who undergo egg retrieval will become pregnant with sonographic documentation of an intrauterine pregnancy (clinical pregnancy); 82% of these patients will carry to term. Many “biochemical pregnancies” occur, but these should not be included in pregnancy statistics. A biochemical pregnancy is one in which serum levels of human chorionic gonadotropin (hCG) rise and then fall before sonographic detection of pregnancy is possible. Eggs are almost always obtained by aspiration, and under ordinary circumstances, approximately 75% of eggs will fertilize and cleave. The clinical pregnancy rate of approximately 34% per embryo transfer per IVF cycle (women <35 years old) is > 20–25% pregnancy rate per cycle observed in spontaneous conceptions in the general population.

The success rate with ART has been augmented by replacing more than 1 embryo, but doing so results in one of the major complications of ART treatment: the development of multiple gestations. In 2002, the European Society of Human Reproduction and Embryology (ESHRE) reported a multiple gestation incidence between 26.3 and 29.1%, whereas in the United States, among pregnancies from fresh donor cycles, 57.3% were singletons, 37.1% were twins, and 5.6% were triplets or more. Although multiple gestations are often welcomed by the infertility couples, they are riskier pregnancies that may result in preterm births.

Indications

The basic concept of IVF–embryo transfer (IVF-ET) initially was to bypass the potential mechanical obstacles of the female reproductive tract. It was first developed for patients with severe tubal disease, for patients with bilateral salpingectomy, or for women whose tubes are so badly damaged that they cannot function. As expertise increased, the variations of IVF and ICSI applied to a wider spectrum of other infertility problems. Indications for ART now include the following:

1. Male factor infertility
2. Tubal disease (tubal and pelvic adhesions)
3. Absent or damaged fallopian tubes
4. Endometriosis
5. Preimplantation genetic diagnosis (PGD)
6. Need for third-party reproduction/donor eggs or gestational surrogate
7. Unexplained infertility
8. Age-related infertility
9. Decreased ovarian reserve
10. Recurrent intrauterine insemination failure

When the probability of conception by ART exceeds that of conception by conventional therapy, ART appears to be the procedure of choice. Because of an increased incidence of infertility in our modern society, the timing of reproduction tends to move to the right of the female reproductive curve, as career-women work earlier and conceive later. Thus there is an increased awareness and availability of ART, and the application of such alternatives has expanded.

Although IVF is successful in treating many infertility problems, its success hinges on entry of sperm into the egg. It was initially hoped that routine IVF could be used to compensate for severe oligospermia (<5 million sperm/mL). However, early results were often poor. Modern microsurgical techniques with ICSI are now used in several cases, attempting placement of sperm directly into the cytoplasm of the oocyte. This is discussed in detail later. In addition to male factor issues, another barrier to success with IVF is hydrosalpinx (fluid collection in the fallopian tube). This condition may interfere with implantation, and additional surgery may be needed so that implantation and pregnancy rates improve.

Technique

IVF consists of the following steps:

1. Ovarian stimulation
2. Oocyte retrieval
3. Fertilization with capacitated sperm and ICSI
4. Embryo culture
5. Embryo transfer

A. Ovarian Stimulation—Superovulation

Multiple eggs increase the possibilities of producing multiple embryos, which adds to the likelihood of successful conception. Apart from that, multiple eggs are desired because some eggs will not develop or fertilize after retrieval. By using fertility medication, the ovaries are stimulated to produce several high-quality eggs, and timing for aspiration is better controlled.

Almost all ART programs use superovulation. The type of ovulation-induction therapy varies from group to group. The following methods are used alone or in combination:

1. Combination of gonadotropins and gonadotropin-releasing hormone (GnRH) analogues
2. Combination of gonadotropins and GnRH antagonist
3. Follicle-stimulating hormone (FSH) products—urinary or recombinant
4. Human menopausal gonadotropins—urinary or recombinant
5. Luteinizing hormone (LH) agonists
6. Clomiphene citrate (rarely)

In order to monitor the number and growth of follicles, as well as the uterine lining, superovulation is carefully monitored with ultrasound. To assess the function of the follicles, serial serum estradiol levels are drawn. At least 2 or 3 follicles should be developing before proceeding with egg aspiration; otherwise, the cycle is usually abandoned, and an alternative stimulation regimen is selected for a subsequent cycle. Serum estradiol levels are complementary to ultrasonography in evaluating the maturation and growth of the developing follicles (200 pg/mL per mature follicle is expected). There is evidence that the pattern of serum estradiol may predict the cycles most likely to result in pregnancy. When the mature follicles have reached at least 17 mm in diameter and the amount of estradiol reaches approximately 500 pg/mL, 10,000 IU of hCG (either urinary or recombinant) are usually administered to induce ovulation. Ovulation and subsequent retrieval usually occurs 36 hours after hCG injection.

The introduction of GnRH agonists or antagonists to superovulation regimens has drastically reduced the likelihood of a premature LH surge; consequently, they are used in the majority of IVF patients in the United States. There are many ways to add an agonist in the whole procedure: commonly the GnRH agonists are administered on day 21 or the previous cycle (long protocol) or at the beginning of menses, along with the addition of gonadotropins (short protocol), and they are continued until the day of hCG. When GnRH antagonists are used, treatment with antagonists begins after 5–6 days of gonadotropins or when the lead follicle is 13 mm, whereas recent data allow the antagonist initiation even with a 16–17 mm leading follicle. The antagonists have the advantage of requiring fewer injections; however, there may not be a difference in pregnancy rates between the agonists or the antagonists.

B. Oocyte Retrieval

Aspiration of the preovulatory follicles is performed approximately 34–36 hours after the hCG injection. Egg aspiration is performed using either of 2 methods. Laparoscopy was the first method to be used and is rarely used today. The current method uses ultrasonography to direct transvaginal aspiration (occasionally, egg collection is performed through the abdominal wall under ultrasound guidance, in cases in which the ovaries are abnormally placed). In transvaginal aspiration, a needle is passed through the posterior vaginal fornix using a vaginal ultrasound probe and directed into the ovary. Fluid from the follicles is drawn into a test tube to retrieve the eggs. The advantage of ultrasound aspiration is that it can be performed on an outpatient basis (approximately 30-minute procedure), it is simpler, less invasive, and less expensive.

C. Fertilization With Capacitated Sperm and ICSI

Freshly ejaculated sperm cannot fertilize an egg; the sperm must be capacitated. Fortunately, capacitation is a very simple process in humans and involves only a short incubation period in a culture medium, soon after the collection procedure.

Because of the nature of the superovulatory process, eggs will be in different stages of maturation. Once the eggs have been identified, the embryologist classifies them as either mature (preovulatory) or immature. Mature eggs have an expanded cumulus oophorus, have undergone the first meiotic division (and so the first polar body is visible), and are usually fertilized 5 hours after aspiration, whereas immature eggs have a very compact cumulus, have not undergone the first meiotic division. and can be incubated in the laboratory for up to 36 hours before fertilization. If sperm and eggs are mixed too early, fertilization and cleavage will not take place. Between 50,000 and 150,000 motile sperm are placed with each egg.

Male infertility has been considered a major contributory factor to infertility. In order to face and eventually bypass male factor, microassisted fertilization techniques, principally ICSI, were developed. In the context of assisted conception, they seem to have revolutionized the management of couples with so-called male factor infertility. The causes of spermatogenetic failure found in most cases of male infertility remain largely idiopathic, however, and unfortunately, there is no effective treatment to improve spermatogenesis for idiopathic male infertility patients. For male factor infertility (<5 million total normal motile sperm/mL), ICSI has resulted in higher fertilization rates and expanded possibilities for cryopreservation. In this procedure, 1 normal motile sperm is selected per oocyte and injected through the intact zona pellucida directly into the cytoplasm away from the polar body. Other indications for ICSI include surgically retrieved sperm (for men with azoospermia who need testicular or epididymal biopsy), cryopreserved oocytes, or cases in which PGD is performed for single gene disorders. For couples with borderline quality semen, ICSI results in higher fertilization rates than IVF, and couples with very poor semen will have better fertilization outcomes with ICSI than with subzonal insemination or additional IVF. In 2005, approximately 60% of all ART cycles in the United States involved intracytoplasmic sperm injection, whereas in 2006, it was used in 1 in 2 cycles.

D. Embryo Culture

Embryos are incubated in an atmosphere of ≤5% carbon dioxide and 37°C temperature, close to the temperature of the fallopian tubes. Various culture media are used and are often supplemented with either the patient’s serum or synthetic albumin as well as essential and nonessential amino acids and sugars. At various intervals after the attempted fertilization, the embryos are examined in order to identify pronuclei, which confirm fertilization (genetic material from both partners), as well as the stage of cleavage.

After pronuclei identification, the embryos will develop for another 24 hours. At this point, embryos are usually monitored for cell division and should have evolved to 2- or 4-cell embryos.

Embryos can be cultured for various days, mostly relevant to the reproductive obstacles the parents were facing. Embryos can be cultured for:

- **2 Days**—This type of culture is used for couples who have a low number of embryos available for transfer or who have embryos that are slowly developing. Those embryos are transferred at the 2- or 4-cell stage.
- **3 Days**—Embryos cultured for 3 days are checked for gene activations and cleavage, thus increasing the potential of transferring a viable embryo. These embryos are usually transferred at the 6- to 8-cell stage.

- **5 Days**—These embryos reach the blastocyst stage. Blastocysts consist of 12 to 16 cells and are ready for implantation into the uterus.

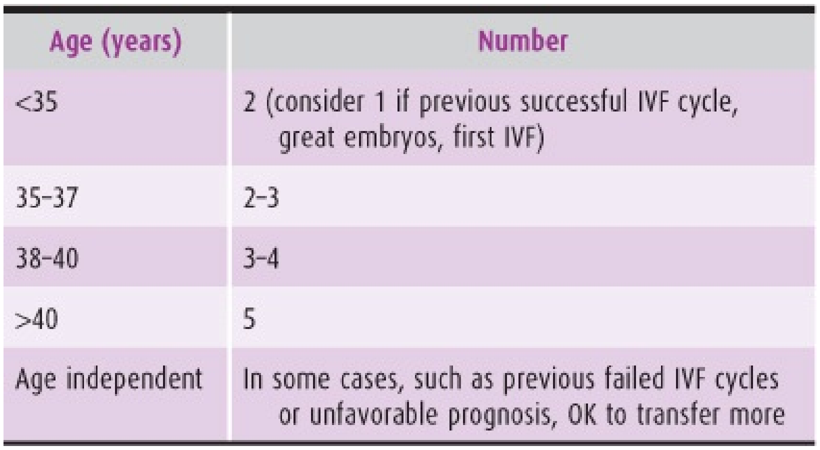
E. Embryo Transfer

After 3–5 days of laboratory culture, the embryos are replaced into the patient’s uterus, a procedure termed **embryo transfer**. Before transfer, the embryos are graded from A to D depending on their appearance and on the degree of fragmentation. Embryos that are not transferred at this time can be cryopreserved and stored in liquid nitrogen use in later IVF cycles, if necessary. If day 5 or 6 transfers are performed, the embryos are at the blastocyst stage, as mentioned earlier. There are 2 types of embryo transfers:

- Day 3 embryo transfer, which is performed 72 hours after egg retrieval
- Blastocyst transfer, which is the transfer of blastocysts and, as mentioned, raises the possibilities of transferring a healthy embryo

The decision of how many embryos to transfer is made by the patient in conjunction with the physician and the embryologist in accord with the American Society for Reproductive Medicine (ASRM) recommendations based on the patient’s age (Table 57–2). The exact number of embryos transferred depends on the number of embryos produced, the health of the embryos, the risk level for multiple pregnancy, and the woman’s age.

Table 57–2. Recommended number of embryos to transfer.



Age (years)	Number
<35	2 (consider 1 if previous successful IVF cycle, great embryos, first IVF)
35–37	2–3
38–40	3–4
>40	5
Age independent	In some cases, such as previous failed IVF cycles or unfavorable prognosis, OK to transfer more

Most embryo transfers are performed under direct visualization with 2-dimensional (2-D) or 3-dimensional (3-D) ultrasounds. Before the embryo transfer is performed, the patient is usually asked to drink water to fill the bladder. A full bladder helps straighten the uterus as well as improve visualization by ultrasound during the transfer. The embryologist prepares the best embryos by aspirating them into a small catheter with some media, and after the physician cleans the cervix with culture media and aspirates the extra cervical mucous, the catheter is passed transcervically into the uterus, and the embryos are injected into the uterine cavity under direct visualization, usually in the space at the top of the uterus. The probability of pregnancy after embryo transfer can be affected by the patient’s age, the cause of infertility, the endometrial thickness, and the average embryo grade.

In some patients, assisted hatching or an opening in the zona is performed in order to improve implantation. This is thought to be beneficial in older patients (age 38 years and older) who have harder zonae; however, it is not routinely performed in all IVF centers.

Retrospectively, the decision to establish such recommendations indeed helped the number of multiple births decrease substantially, although the absolute number did not ultimately increase because of the increase in total IVF births.

F. Luteal Phase Support

In order to avoid a short period of luteal phase, after embryo transfer is performed, progesterone supplementation is usually recommended by most physicians until approximately 7 weeks' gestation. Progesterone administration tends to correct the ratio of estradiol to progesterone and as a result provide a secretory endometrium, which is needed for the implantation. Progesterone is usually administered by an intramuscular injection or by a vaginal suppository or gel.

Complications

Few risks are associated with ART. The risks of ART can be considered in 5 major areas:

A. Risks Associated with Drugs Used to Stimulate Egg Production

1. Ovarian hyperstimulation syndrome—This syndrome is characterized by ovarian enlargement, ascites, and hemoconcentration, whereas the clinical manifestations are abdominal distention, abdominal discomfort, and nausea. Its incidence reaches 5%. Risk factors include polycystic ovary syndrome, multiple follicles, and high estradiol levels. The prognosis is usually worse in patients who get pregnant and have this syndrome. Patients with this syndrome may be at risk for blood clots. In 0.5–1.0% of all IVF cycles, admission is required, with fluid drainage and replacement of albumin. This situation resolves in 1–2 weeks.

2. Cancer—Two studies suggested that the use of the drug clomiphene increases the risk of ovarian cancer, although this has not been reported in other studies. Uterine, cervical, or breast cancer incidence does not increase with IVF.

B. Surgical Risks Associated with IVF

- General anesthetic and intravenous sedation: similar risk to any other surgery.
- Damage to other structures: 1 in 2500 retrievals.
- Pelvic infection: This could occur as a result of the needle insertion and manipulations and requires antibiotic treatment and, rarely, abscess drainage.

C. Risks Associated with Pregnancy

1. Multiple gestations—The likelihood of a twin pregnancy is 10% (0.5% for triplets) with the use of clomiphene, 20–30% after IVF with 2 embryos (increased incidence of triplets in 3 embryo replacement), and 10–20% after intrauterine implantation treatment (1–2%). The complications of multiple pregnancy are increased risk of miscarriage, increased risk of premature labor, increased risk for hemorrhage and high blood pressure, increased requirement for caesarian section, increased loss of an infant, and increased risk of an abnormal infant with a physical or learning disability. Transferring more embryos does not necessarily lead to a greater IVF success rate.

2. Ectopic and heterotopic pregnancies—Patients who undergo an ART procedure are at twice the risk for having an ectopic pregnancy as the general population (1–3% of all pregnancies from embryo transfer). Heterotopic pregnancies, which are rare but seen more commonly with ART, involve cases in which there is an intrauterine pregnancy and an ectopic pregnancy (usually in the fallopian tube) in the same patient.

3. Miscarriage—No difference has been reported in relation to naturally conceived pregnancies.

4. Preterm birth and low-birth-weight infants—These are higher in patients undergoing IVF.

D. Risk of an Abnormal Baby

The risk of congenital abnormalities may be slightly higher in patients who use ART; however, this concept is still controversial (2.6% risk of an abnormal baby with IVF, 2.0% with natural conception). In patients who use ICSI, the risk of imprinting disorders, such as Angelman's syndrome and Beckwith-Wiedemann syndrome, may be increased.

Intellectual impairment seems to occur more often in offsprings of fathers who had to go through ICSI or surgical extraction of sperm.

Babies born after replacement of thawed embryos do not show any increased incidence of abnormalities.

E. Cost

Currently only a few states allow health insurance to cover infertility treatment, which leaves many couples with tremendous expenses (the estimated cost per delivery is $66,667).

OTHER TECHNIQUES RELATED TO IVF-ET

Ovum Donation

Embryos have been donated from one woman to another with many resultant live births. Women who receive donated embryos include those with ovarian failure (premature, autoimmune) or absence (eg, gonadal dysgenesis), diminished ovarian reserve, or genetically transmitted disorders.

Ovum donation can occur under either of 2 circumstances. One circumstance is the infertile patient who produces a large number of oocytes during her own IVF or GIFT cycle and elects to donate some of them to another woman who is otherwise incapable of producing eggs. The other, more common circumstance involves the recruitment of a woman who undergoes superovulation and oocyte retrieval purely for the purpose of donating her oocytes. The donor may be known to the patient (a family member or friend) or, more commonly, may be anonymous. Although the genetics of the resulting pregnancy are derived from the husband and the donor, the infertile woman incapable of producing her own eggs goes through the pregnancy. In these cases, the endometrium of the recipient must be primed with estrogen and progesterone before transfer of the donated embryos, and progesterone and estrogen supplementation must be maintained for at least 10 weeks. The number of embryos transferred is decided based on the age of the donor, not the age of the recipient.

Gestational Surrogacy

A surrogate mother is a woman who is pregnant with a child but who does not intend to raise it after birth. The intended parent(s) is an individual or couple who intends to raise the child after its birth. In traditional surrogacy the surrogate is pregnant with her own biological child, but this child was conceived with the intention of relinquishing the child to be raised by others.

In gestational surrogacy the surrogate becomes pregnant via embryo transfer with a child of which she is not the biological mother. In altruistic surrogacy, the surrogate receives no financial reward for her pregnancy, whereas in commercial surrogacy, the gestational carrier is paid to carry out the pregnancy by the infertile couple. This procedure is legal in several countries.

Gamete Intrafallopian Tube Transfer (GIFT)

GIFT is an alternative to IVF but is used infrequently, typically for women with unexplained infertility or with normal tubal function plus endometriosis. Live birth rates per cycle are approximately 25–35% at most infertility centers. However, with the improved pregnancy rates in IVF, GIFT procedures are rarely done now. Usual indications for GIFT nowadays include patients who have moral or religious objections to IVF and want to have fertilization in vivo rather than in vitro. As with IVF, superovulation is induced, and the follicles are aspirated vaginally under ultrasound guidance. The eggs are then identified in the laboratory. Thereafter, sperm is collected and capacitated, and laparoscopy is performed. Sperm are then mixed with the eggs and drawn up into a catheter. The sperm and eggs can also be separated by an air bubble in the catheter, after which they are transferred into one of the fallopian tubes, permitting in vivo fertilization and cleavage.

Obviously, GIFT is useful only in patients who have normal tube function and are not of advanced age. It has been argued that the requirement of normal tubal function renders the direct comparison of IVF-ET and GIFT results impossible. Among proponents of each technique, there is vigorous ongoing debate regarding the advantages of GIFT over IVF-ET.

In unexplained infertility, IVF-ET will differentiate the etiology of fertilization problems between egg and sperm; GIFT will not. Additionally, GIFT exposes patients to the risks of general anesthesia and laparoscopy. GIFT is now rarely used.

Zygote Intrafallopian Transfer (ZIFT)

Zygote intrafallopian transfer (ZIFT) is used to treat infertility that is caused by a blockage in the fallopian tubes that prevents the normal binding of sperm to the egg. ZIFT is a procedure that combines IVF and GIFT. Ovulation is induced and the oocytes are removed and fertilized in vitro. Soon thereafter, the zygotes are placed into the fallopian tubes by laparoscopy, similar to GIFT, and the embryo travels to the uterine cavity. ZIFT has a success rate of 64.8% in all cases, but is now rarely used.

Preimplantation Genetic Diagnosis (PGD)

PGD is a technology that has been around since early 1990. It allows many genetically heritable diseases to be identified using a variety of molecular biologic techniques. These techniques include but are not limited to polymerase chain reaction and fluorescent in situ hybridization. Currently, there are mainly 2 groups of patients for which PGD is indicated.

1. Couples with a high risk of transmitting an inherited condition that is either a monogenic disorder (autosomal recessive, autosomal dominant, or X-linked disorders) or a chromosomal structural abnormality/translocation.
2. Couples whose embryos are screened for chromosome aneuploidies in the context of IVF procedures. The technique mostly used for screening is actually referred to as preimplantation genetic screening (PGS) and is used to increase the chances of an ongoing pregnancy. The main reasons for this procedure are advanced maternal age or history of recurrent miscarriages. Patients with nonobstructive azoospermia are also candidates for PGD.

Recent advances in embryo manipulation have made possible the removal of 1 or 2 cells, or blastomeres, from a developing 8-cell human embryo without harm to the embryo. Biopsy of the first and/or second polar bodies can also be done for several single-gene defects. In patients at risk of passing along a heritable genetic disease, PGD has made possible the identification of normal embryos (those with no risk of passing the heritable disease). PGD is available for a large number of monogenic disorders; the most frequently diagnosed autosomal recessive disorders are β-thalassemia, sickle cell disease, cystic fibrosis, and spinal muscular atrophy type 1. These normal embryos are then transferred back to the patient. More than 1000 live births have been reported after application of these techniques. PGD is also performed for patients with recurrent miscarriages, previous failed IVF cycles, aneuploidy diagnosis for patients with advanced maternal age, and for sex selection, but these indications are still controversial.

Cryopreservation

Cryopreservation is a process by which cells or whole tissues are preserved by cooling to low subzero temperatures, such as (typically) 77 K or −196° C (the boiling point of liquid nitrogen). At these low temperatures, all biologic activities, including cell death, are stopped.

As expected, the combination of cryopreservation and IVF means that embryos or eggs are frozen to be used at a later time after thawing (unfreezing). Cryopreservation of embryos is very successful and has greatly improved since the first case in 1983. Survival rates of frozen embryos have been reported to be between 50 and 90%. Before implanting thawed embryos, the patient’s cycle is usually synchronized so that embryo transfer occurs during the implantation window of the uterus. Consequently, pretreatment with estrogen and progesterone is recommended. In 2003, the live birth rate per transfer of frozen embryos was 27%.

Cryopreservation of oocytes has been gaining attention and has improved over the past few years. In the fall of 2004, the American Society for Reproductive Medicine (ASRM) issued an opinion on oocyte cryopreservation concluding that the science was “promising” because recent laboratory modifications have resulted in improved oocyte survival, fertilization, and pregnancy rates from frozen-thawed oocytes in IVF. The ASRM noted that from the limited research performed to date, there does not appear to be an increase in chromosomal abnormalities, birth defects, or developmental deficits in the children born from cryopreserved oocyes. Pending further research, oocyte cryopreservation should be introduced into clinical practice only on an investigational basis and under the guidance of an institutional review board.

Cryopreservation of ovarian tissue is of interest to women who want to preserve their reproductive function beyond the natural limit or whose reproductive potential is threatened by cancer therapy. Research on this issue is promising; autologous transplantation is the process by which the ovary is removed and transferred to a different location, such as the forearm or abdomen.

Contraception & Family Planning

Ronald T. Burkman, MD
Amnon Brzezinski, MD

CONTRACEPTION

Decision making concerning fertility control is, for many people, a deeply personal and sensitive issue, often involving religious or philosophical convictions. Thus it is important for the clinician to approach the subject with particular sensitivity, empathy, maturity, and nonjudgmental behavior.

Despite the introduction of modern contraceptives, unintended or unplanned pregnancies continue to be a major problem in the United States and worldwide. According to the 2009 National Survey of Family Growth, there were a total of 6,408,000 pregnancies in the United States, of which 49.2% were unintended. Among the unintended pregnancies, nearly half result in a pregnancy termination and more than 10% in spontaneous abortion, a substantial degree of pregnancy wastage. Unintended and unplanned pregnancies have social and economic ramifications; they also have a significant impact on public health. Approximately 40% of unintended pregnancies occur among women who do not desire pregnancy yet do not use a method of contraception. Approximately 60% of unintended pregnancies occur among women using some form of birth control. Such data suggest that many women and couples are inadequately motivated to use contraception, that side effects may be problematic for some, that access may be an issue for others, or that some methods may be difficult for women to use correctly. However, encouraging is the latest report of the National Survey of Family Growth (2009) that the teenage pregnancy rate dropped 40% from 1990 to 2005, reaching an historic low of 70.6 per 1000 women aged 15–19 years. Rates fell much more for younger than for older teenagers.

Individual Indications for Birth Control

Contraception is practiced by most couples for personal reasons. Many couples use contraception to space their children or to limit their family size. Others desire to avoid childbearing because of the effects of preexisting illness on the pregnancy, such as severe diabetes or heart disease. For all of these types of decisions, clinicians must provide accurate information about the benefits and risks of both pregnancy and contraception. However, medical conditions that may substantially increase the risk of using some form of contraception usually increase the risks associated with pregnancy to an even greater extent. As a matter of public policy, some countries, especially those that are less developed, promote contraception in an effort to curb undesired population growth.

Legal Aspects of Contraception

Contraceptives are prescribed, demonstrated, and sold throughout most of the United States without restriction.

Despite high rates of unprotected intercourse and unintended pregnancy, the pros and cons of providing contraceptive information and materials to teenagers have been vigorously debated. Most states either have legislation that permits access to contraception for persons under 18 years or have not addressed the issue legislatively. There is a general consensus among physicians that teenagers should be given contraceptive advice and prescriptions within the limits of the law. Physicians must be careful to avoid imposing their own religious or moral views on their patients.

Health care providers are obliged to provide all persons requesting contraception with detailed information about use of the method(s) and its benefits, risks, and side effects so that the patient can make an informed choice relative to a particular method. Not only is the provision of this information of ethical and legal importance, but such counseling is likely to increase the likelihood that the method will be used appropriately with overall improved compliance. Documentation of the discussion with the patient and her understanding of what has been said is important both clinically and legally. In particular, when using methods that require instrumentation or surgery and that also may require intervention by a health care professional for discontinuation (eg, intrauterine contraceptive device [IUD], injectable progestin, or sterilization), signed consent forms that outline the information discussed and the patient's understanding of it may reduce potential legal issues should a problem occur. If needed, the signed consent form serves as evidence that the patient was given counseling about use of a particular birth control method, that she appeared competent to understand what was said to her, and that she consented to receive contraceptive management in the manner specified.

METHODS OF CONTRACEPTION

The available methods of contraception can be classified in many ways. For this discussion, traditional or folk methods are coitus interruptus, postcoital douche, lactational amenorrhea, and periodic abstinence (rhythm or natural family planning). Barrier methods include condoms (male and female), diaphragm, cervical cap, vaginal sponge, and spermicides. Hormonal methods encompass oral contraceptives and injectable or implantable long-acting progestins. In addition, the IUD and sterilization (tubal ligation or vasectomy) are part of the contraceptive armamentarium. Sterilization is discussed in Chapter 46.

COITUS INTERRUPTUS

One of the oldest contraceptive methods is withdrawal of the penis before ejaculation. This process results in deposition of the semen outside the female genital tract. It has the disadvantage of demanding sufficient self-control by the man so that withdrawal precedes ejaculation. Although the failure rate probably is higher than that of most methods, reliable statistics are not available. Failure may result from escape of semen before orgasm or the deposition of semen on the external female genitalia near the vagina.

POSTCOITAL DOUCHE

Plain water, vinegar, and a number of "feminine hygiene" products are widely used as postcoital douches. Theoretically, the douche flushes the semen out of the vagina, and the additives to the water may possess some spermicidal properties. Nevertheless, sperm have been found within the cervical mucus within 90 seconds after ejaculation. Hence the method is ineffective and unreliable.

LACTATIONAL AMENORRHEA

The lactational amenorrhea method can be a highly efficient method for breastfeeding women to use physiology to space births. Suckling results in a reduction in the release of gonadotropin-releasing hormone, luteinizing hormone (LH), and follicle-stimulating hormone (FSH). β-Endorphins induced by suckling also induce a decline in the secretion of dopamine, which normally suppresses the release of prolactin. This results in a condition of amenorrhea and anovulation. During the first 6 months, if breastfeeding is exclusive, menses are mostly anovulatory and fertility remains low. A recent World Health Organization (WHO) study on lactational amenorrhea revealed that during the first 6 months of nursing, cumulative pregnancy rates ranged from 0.9 to 1.2%. However, at 12 months, pregnancy rates rose as high as 7.4%. When using lactation as a method of birth control, the mother must provide breastfeeding as the only form of infant nutrition. Supplemental feedings may alter both the pattern of lactation and the intensity of infant suckling, which secondarily may affect suppression of ovulation. Second, amenorrhea must be maintained. Finally, the method should be practiced as the only form of birth control for a maximum of 6 months after birth. If another pregnancy is undesired, most practitioners advise lactating women to use a reliable contraceptive method starting 3 months after delivery.

Van der Wijden C, Kleijnen J, Van den Berk T. Lactational amenorrhea for family planning. *Cochrane Database Syst Rev* 2003:CD001329. PMID: 14583931.

MALE CONDOM

The condom, or contraceptive sheath, serves as a cover for the penis during coitus and prevents the deposition of semen in the vagina. The most common material used for male condom manufacture is latex, although available condoms are also made from polyurethane material and lamb ceca. The advantages of the condom are that it provides highly effective and inexpensive contraception as well as protection against sexually transmitted infections (STIs). Some condoms now contain a spermicide, which may offer further protection against failure, particularly if the condom breaks. Given the concern about STIs, including HIV, condom use should be recommended for all couples except those in a mutually monogamous relationship.

The condom probably is the most widely used mechanical contraceptive in the world today. Condoms made of latex or polyurethane are impervious to both sperm and most bacterial and viral organisms that cause STIs or HIV infection. However, the less commonly used lamb’s cecum condom is not impermeable to such organisms. The failure of all condoms results from imperfections of manufacture (approximately 3 in 1000); errors of technique, such as applying the condom after some semen has escaped into the vagina; and escape of semen from the condom as a result of failure to withdraw before detumescence. In typical use, failure rates with condoms range from 10 to 30% in the first year of use.

When greater contraceptive effectiveness is desired, a second method such as contraceptive vaginal jelly or foam should be used in conjunction with the condom. This combination significantly reduces the chances for condom failure due to mechanical or technical deficiencies. No association has been established between the use of vaginal contraceptives (spermicides) and the occurrence of congenital malformations if a pregnancy occurs.

FEMALE CONDOM

The female condom (Fig. 58–1) is made of thin polyurethane material with 2 flexible rings at each end. One ring fits into the depth of the vagina, and the other ring sits outside the vagina near the introitus. Female condoms have the advantage of being under the control of the female partner and of offering some protection against STDs. Significant disadvantages may be their cost and overall bulkiness. Comparisons of the female condom with other female barrier methods such as the diaphragm and cervical cap indicate that typical use failure rates are comparable. The 6-month probability of failure during perfect use of the condom is 2.6%, which is much lower than the initial prediction of 15%. Perfect use of the female condom may reduce the annual risk of acquiring HIV by more than 90%.

VAGINAL DIAPHRAGM

The diaphragm (Fig. 58–2) is a mechanical barrier between the vagina and the cervical canal. Diaphragms are circular rings ranging from 50–105 mm in diameter. They are designed to fit in the vaginal cul-de-sac and cover the cervix. Although the designs vary, the arcing spring version probably is the easiest for most women to use. A contraceptive jelly or cream should be placed on the cervical side of the diaphragm before insertion because the device is ineffective without it. This medication also serves as a lubricant for insertion of the device. Additional jelly should be introduced into the vagina on and around the diaphragm after it is securely in place. The diaphragm can be inserted up to 6 hours before intercourse and should be left in place for at least 6–24 hours after intercourse. When the diaphragm is of proper size (as determined by pelvic examination and trial with fitting rings) and is used according to directions, its failure rate is as low as 6 pregnancies per 100 women per year of exposure. With typical use, however, the pregnancy rate is 15–20 pregnancies per 100 woman-years. The diaphragm has the disadvantages of requiring fitting by a physician or a trained paramedical person and the necessity for anticipating the need for contraception. Weight alterations and deliveries might change the vaginal diameter. Therefore, the fit of the diaphragm to the user must be assessed yearly during the routine pelvic examination. Failures may result from improper fitting or placement and dislodgment of the diaphragm during intercourse. It cannot be used effectively by women with significant pelvic relaxation, a sharply retroverted or anteverted uterus, or a shortened vagina. As with condoms, diaphragms offer some protection against STIs. The only side effects are vaginal wall irritation, usually with initial use or if the device fits too tightly, and an increased risk of urinary tract infections due to pressure of the rim against the urethra and alterations in the composition of the vaginal flora.

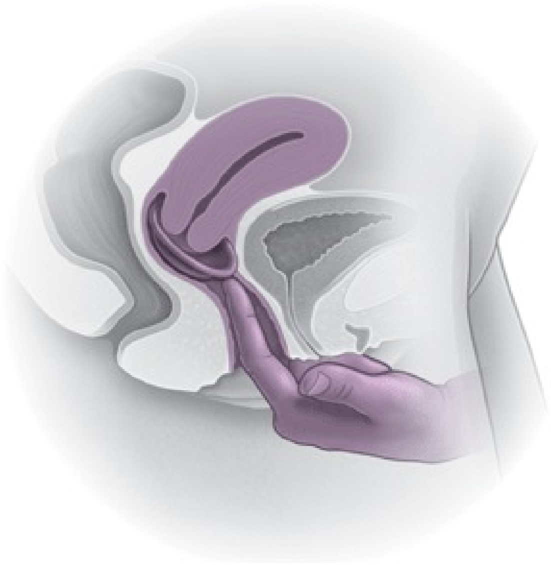

Figure 58–2. The diaphragm.

Allen RE. Diaphragm fitting. *Am Fam Physician* 2004;69:97–100. PMID: 14727824.

CERVICAL CAP

Cervical caps (Fig. 58–3) are small, cuplike diaphragms placed over the cervix that are held in place by suction. To provide a successful barrier against sperm, they must fit tightly over the cervix. Because of variability in cervical size, individualization is essential. Tailoring the cap to fit each cervix is difficult, greatly limiting the practical usefulness of the method. In addition, many women are unable to feel their own cervix and thus have great difficulty in placing the cap correctly over the cervix. Because of these problems, the cervical cap has few advantages over the traditional vaginal diaphragm. Although some advocates of the cervical cap recommend that it remain in place for 1 or 2 days at a time, a foul discharge often develops after approximately 1 day of use. With proper use, the efficacy of the cervical cap is similar to that of the diaphragm, with dislodgment being the most frequently cited cause of failure in most reports. The cap should be left in place for 8–48 hours after intercourse, and its proper placement over the cervix should be confirmed by digital self-examination after each sexual act.

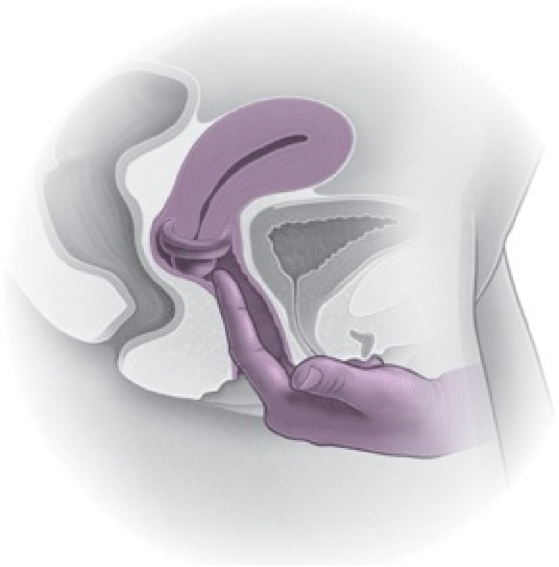

Figure 58–3. Cervical caps.

SPERMICIDAL PREPARATIONS

Spermicidal vaginal jellies, creams, gels, suppositories, vaginal sponge, and foams, in addition to their toxic effect on sperm, act as a mechanical barrier to entry of sperm into the cervical canal. The only spermicide available in the United States contains nonoxynol 9, which is a long-chain surfactant that is toxic to spermatozoa. Spermicides can be used alone or in conjunction with a diaphragm or condom. Some foam tablets and suppositories require a few minutes for adequate dispersion throughout the vagina, and failures may result if dispersion is not allowed to occur. In general, when used alone, spermicides have a failure rate of approximately 15% per year with perfect use but double that rate with typical use. These chemical agents may irritate the vaginal mucosa and external genitalia. Recent evidence indicates that spermicides containing nonoxynol 9 are not effective in preventing cervical gonorrhea, chlamydia, or HIV infection. In addition, frequent use of spermicides containing nonoxynol 9 without a barrier has been associated with genital lesions that may be linked to increased risk of HIV transmission.

PERIODIC ABSTINENCE

It has long been known that women are fertile for only a few days of the menstrual cycle. The periodic abstinence (rhythm or natural family planning) method of contraception requires that coitus be avoided during the time of the cycle when a fertilizable ovum and motile sperm could meet in the oviduct. Fertilization takes place within the tube, and the ovum remains in the tube for approximately 1–3 days after ovulation; hence the fertile period is from the time of ovulation to 2–3 days thereafter.

Accurate prediction or indication of ovulation is essential to the success of the periodic abstinence method. Data from surveys in developed and developing countries performed during the past decade indicate the use of natural family planning methods varies from 0 to 11%. Pregnancy rates vary, but most reliable studies report 1-year life-table pregnancy rates between 10 and 25 per 100 woman-years.

1. The **calendar method** predicts the day of ovulation by means of a formula based on the menstrual pattern recorded over a period of several months. Ovulation ordinarily occurs 14 days before the first day of the next menstrual period. The fertile interval should be assumed to extend from at least 2 days before ovulation to no less than 2 days after ovulation. An overlap of 1–2 days of abstinence either way increases the likelihood of success. Successful use of this approach is based on the knowledge that the luteal phase of a menstrual cycle is relatively constant at 14 days for normal women. Furthermore, for this approach to be successful as the only form of contraception requires regular menstrual cycles so that the various timing schedules retain validity. Although this is the most commonly used method of periodic abstinence, it is also the least reliable, with failure rates as high as 35% in 1 year's use.
2. A somewhat more efficacious approach to periodic abstinence is the **temperature method,** as more reliable evidence of ovulation can be obtained by recording the basal body temperature (BBT). The vaginal or rectal temperature must be recorded upon awakening in the morning before any physical activity is undertaken. Although it is often missed, a slight drop in temperature occurs 24–36 hours after ovulation. The temperature then rises abruptly approximately 0.3–0.4°C (0.5–0.7°F) and remains at this plateau for the remainder of the cycle. The third day after the onset of elevated temperature is considered the end of the fertile period. For reliability, care must be taken by the woman to ensure that true BBTs are recorded (ie, that temperature elevations due to other causes such as fever do not provide misleading information). A distinct limitation of this technique is that prediction of timing of ovulation in any given cycle is retrospective, making it difficult to predict the onset of the fertile period.
3. The **combined temperature and calendar method** uses features of the 2 methods to more accurately predict the time of ovulation. Failure rates of only 5 pregnancies per 100 couples per year have been reported in studies of well-motivated couples.
4. The **cervical mucus (Billings) method** uses changes in cervical mucus secretions as affected by menstrual cycle hormonal alterations to predict ovulation. Starting several days before and until just after ovulation, the mucus becomes thin and watery, whereas at other times the mucus is thick and opaque. Women using this approach are trained to evaluate their mucus on a daily basis. Success rates are similar to those described for the combined temperature and calendar method. Advantages of this approach include relative simplicity and lack of a requirement for charting. Disadvantages include difficulty in evaluating mucus in the presence of vaginal infection and the reluctance of some women to evaluate such secretions.
5. The **symptothermal method,** if used properly, probably is the most effective of all the periodic abstinence approaches. It combines features of both the cervical mucus and the temperature methods. In addition, symptoms that may occur just prior to ovulation, such as bloating and vulvar swelling, are used as adjuncts to ovulation.

   The most accurate method of determining ovulation time is to demonstrate the LH peak in serum specimens. Because of the cost and the time required for serial measurements of LH level that are essential to indicate the abrupt rise, this method is impractical as a method of birth control. It is valuable in the treatment of infertility, however, when the optimal time for coitus or artificial insemination is of great importance.

Figure 58–4 shows the relationships among ovulation, BBT, serum levels of LH and FSH, and menses. At least 20% of fertile women have enough variation in their cycles that reliable prediction of the fertile period is impossible.

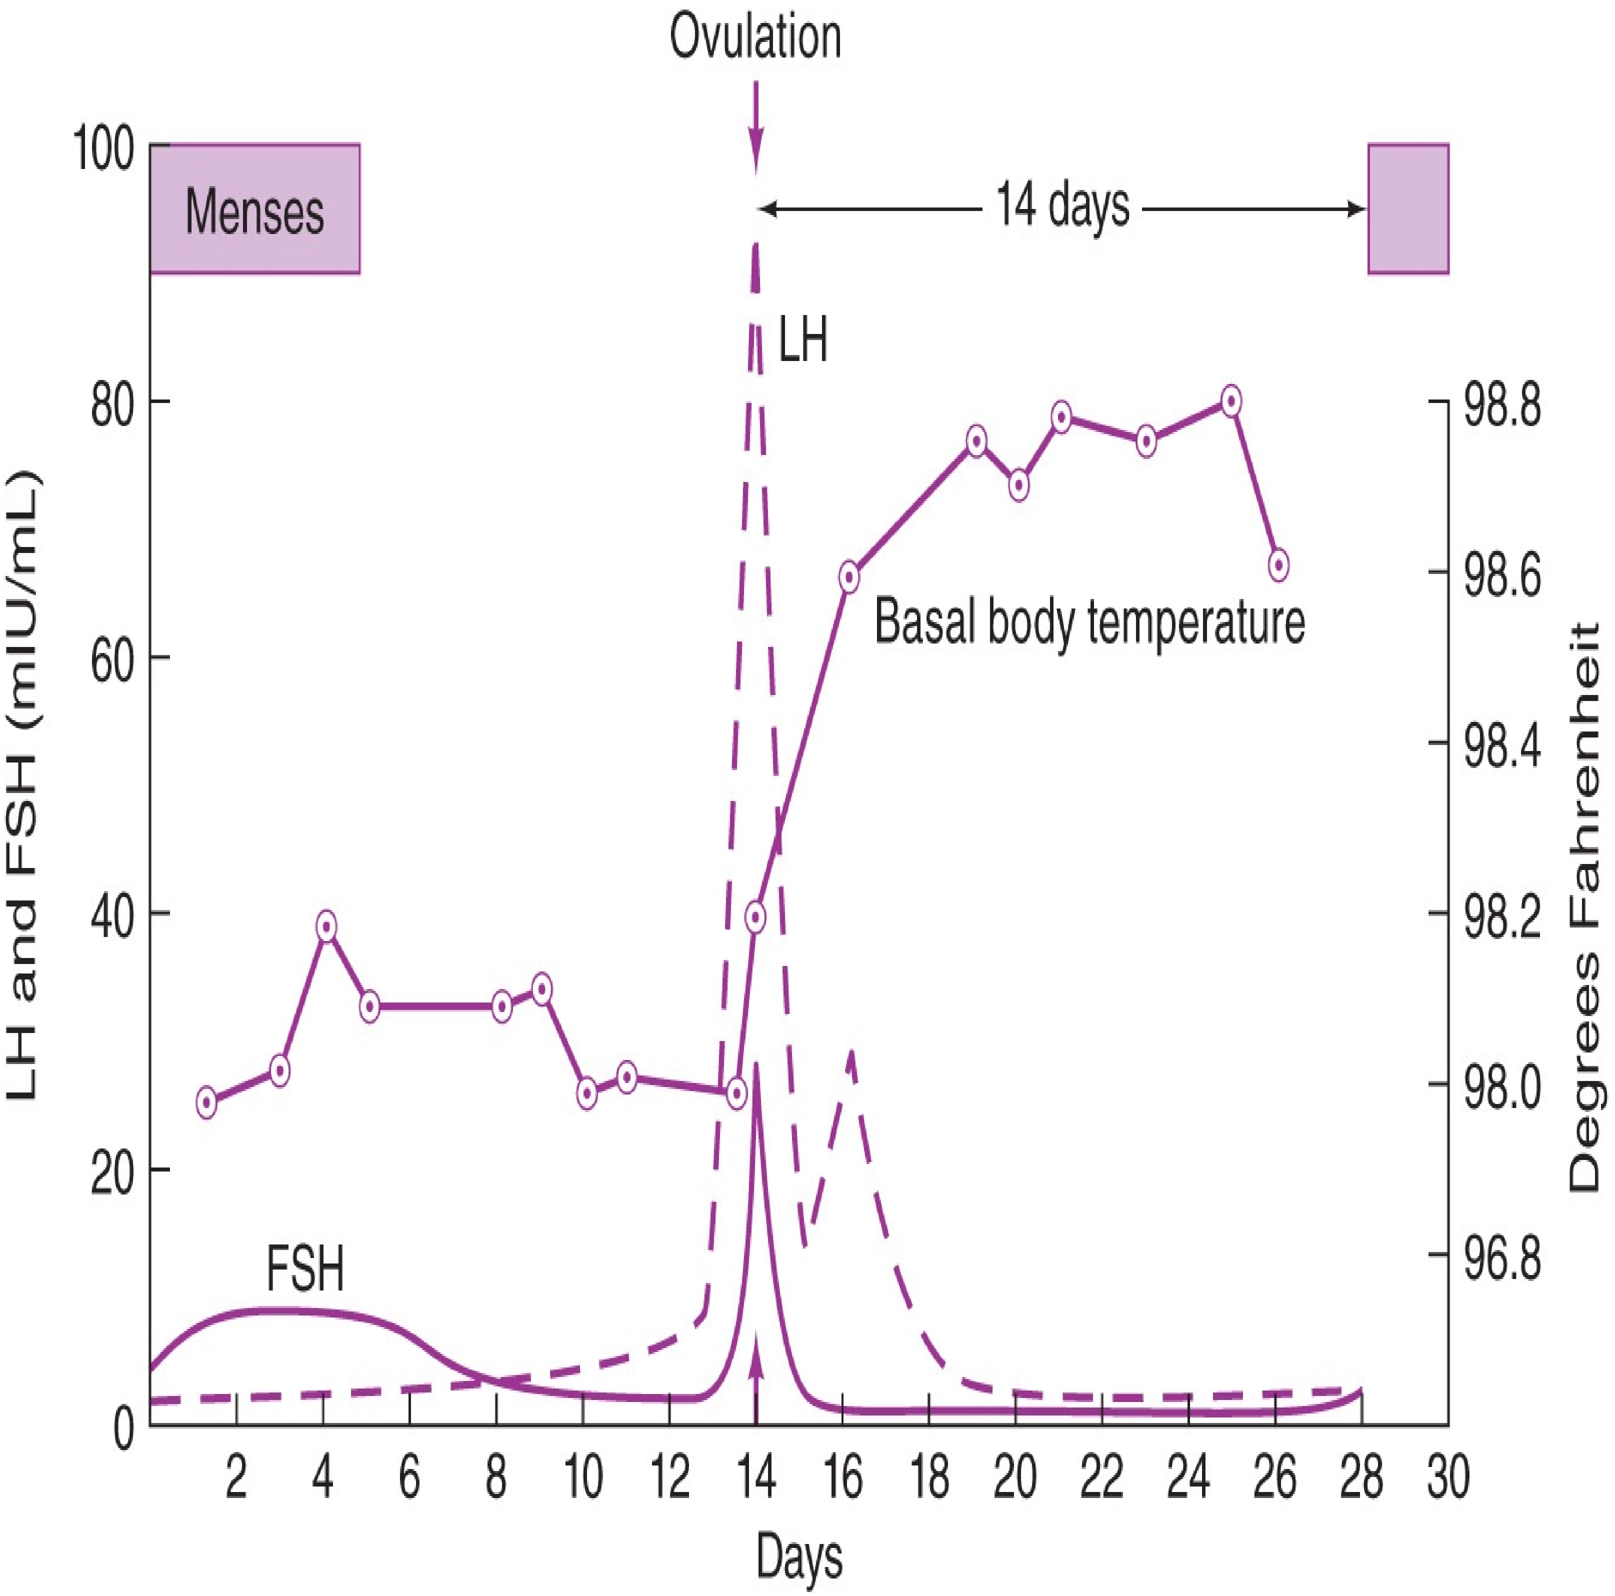

Figure 58–4. Relationships among ovulation, basal body temperature, and luteinizing hormone (LH) and follicle-stimulating hormone (FSH) surges in the normal menstrual cycle.

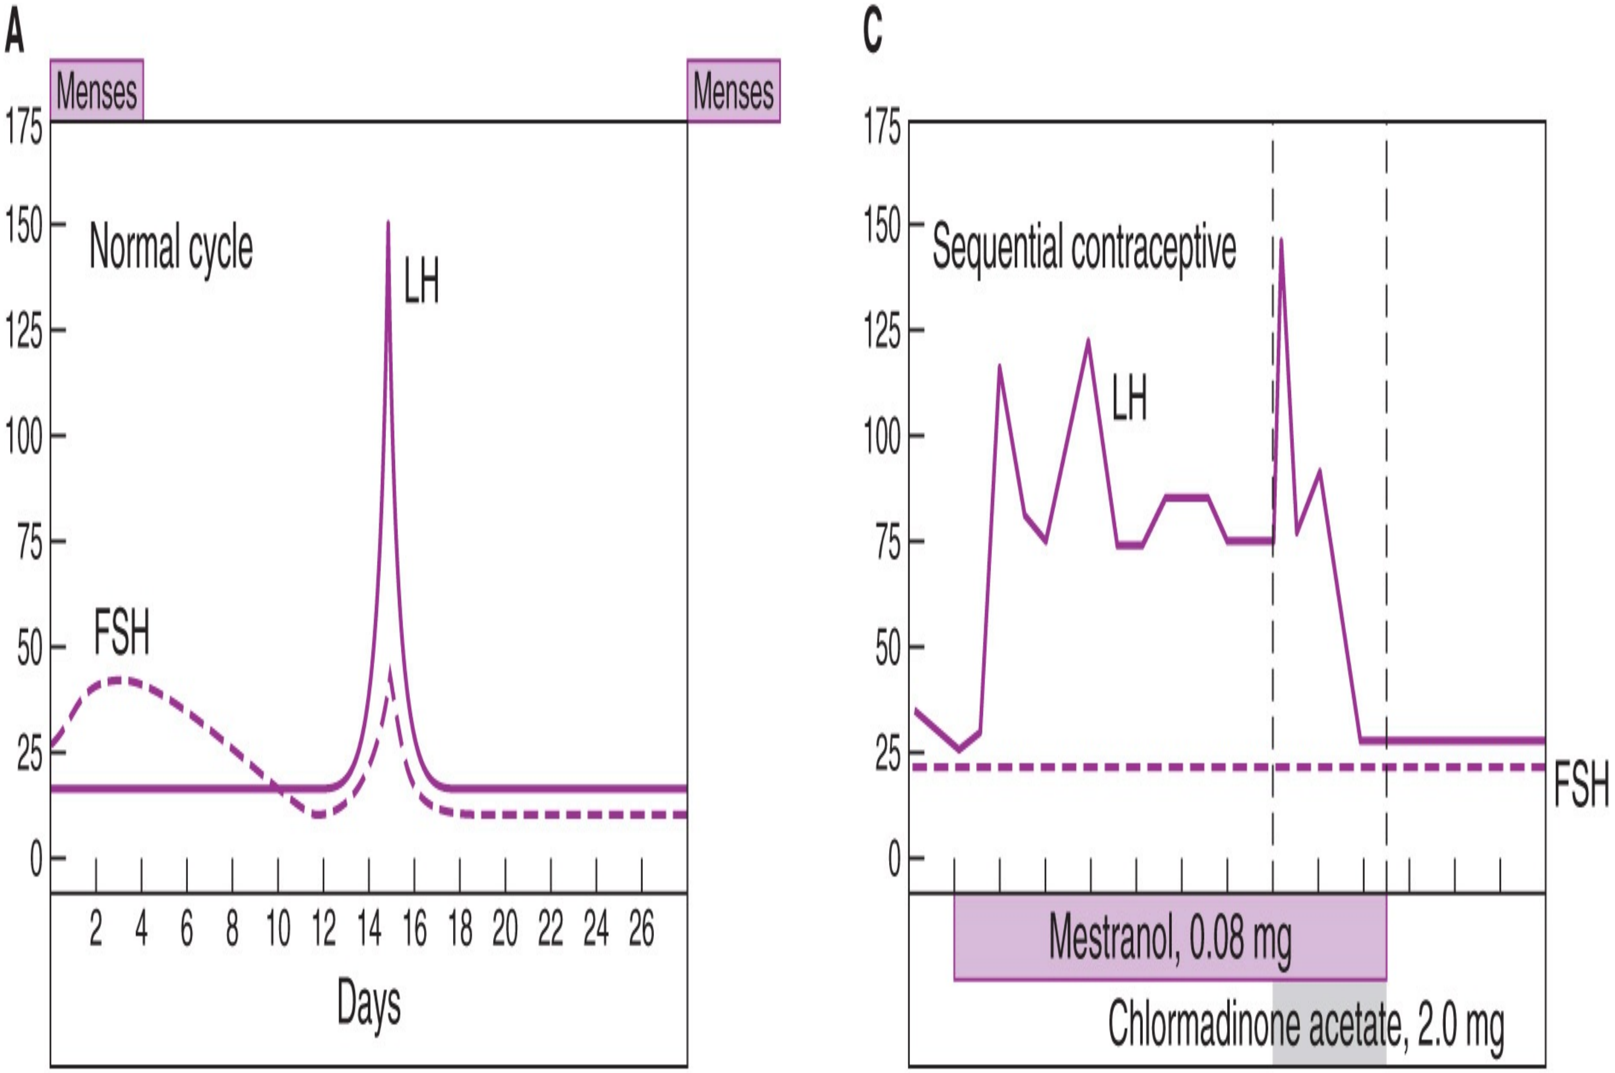
Epidemiologic studies of women using periodic abstinence have suggested an increased incidence of congenital anomalies, such as anencephaly and Down syndrome, among children resulting from unplanned pregnancies. Animal experiments have shown delayed fertilization results in an increased incidence of aneuploidy and polyploidy in off-spring, thus suggesting a possible explanation for similar human fetal anomalies. However, despite a theoretical explanation for the occurrence of such birth defects, it is important to recognize that much of the data are subject to bias, and concluding that such associations have been conclusively proved would be inappropriate.

ORAL HORMONAL CONTRACEPTIVES

Oral contraceptives, when placed in general use in 1960, heralded the modern era of contraception. Oral contraceptives provide an estrogen, ethinyl estradiol, and a progestin. The most commonly used progestins in the United States are the estranes: norethindrone and norethindrone acetate; the gonanes: levonorgestrel, desogestrel, and norgestimate; and the spironolactone analogue drospirenone. When first developed, the 2 principal regimens of oral contraception were combined and sequential. The sequential method has been abandoned in the United States because several studies showed a higher than normal incidence of endometrial cancer in women using this method of contraception. In the most commonly used combined method, pills containing both estrogen and progestin are taken each day for 21 days, followed by 7 days of placebo pills, during which time most women experience withdrawal bleeding. Over the past several decades the estrogen content has been reduced by a factor of 3-fold to 4-fold, such that the current dose of ethinyl estradiol ranges between 15 and 35 μg. Similarly, the progestin content has been substantially reduced. In general use, the combined regimen is started either with the onset of the menstrual cycle or on the Sunday closest to the start of menses. Because most oral contraceptive preparations are packaged in 28-day regimens, the Sunday start approach may be easier to follow for some women. However, a good practice is to recommend use of an additional form of contraception during the first week of the cycle to maximize efficacy. Recently, some practitioners have initiated an approach in which birth control pills are started on the day of the office visit if pregnancy is unlikely. It appears this approach may reduce unwanted pregnancies. However, backup contraception is required for at least 7 days after initiation of the method. With standard oral contraceptive preparations, withdrawal bleeding can be expected within 3–5 days after completion of the 21-day regimen of active pills.

The newest approach with combined oral contraceptives is to administer active pills for a prolonged period of time, causing extended periods of amenorrhea (extended-use regimen). A preparation of 84 days active pills followed by 7 days free of was approved by the US Food and Drug Administration (FDA) in 2003. The continuous use of a 30-μg ethinylestradiol and 3-mg drospirenone formulation over 126 days was reportedly safe, efficacious, and well accepted by the users. Although this approach is designed to reduce the number of withdrawal bleeding episodes to 3–4 per year, a significant number of women experience irregular bleeding, especially during the first few cycles of use. In 2007 the FDA approved for use an extended-use oral contraceptive (ethinylestradiol/levonorgestrel 20 μg/90 μg) that is designed for 365 days of continuous use. The pregnancy rate attributable to method failure in a large noncomparative trial of healthy, sexually active women during treatment for 12 months was 15 per 2134 women (adjusted Pearl Index 1.26 per 100 women-years of use). There were no differences in pregnancy rates over 12 months between of continuous-use and cyclical use in a small, randomized, unblinded trial. In small trials, hormonal and ultrasound changes indicative of reinstated ovulation occurred within a month of discontinuation of the drug, and menstruation began again in most women within 90 days. The incidence of adverse effects was similar in continuous-use and cyclical regimens.

The serum levels of FSH and LH throughout the normal menstrual cycle are shown in Figure 58–5A. During a typical cycle under the combined oral contraceptive regimen (Fig. 58–5B), there is no rise during the first half of the cycle; thus the growth of the dominant follicle and ovulation do not occur, and there are no midcycle alterations of FSH and LH levels. Oral contraceptives change the consistency of cervical mucus, resulting in less sperm penetration; make the endometrial lining less receptive to implantation; and alter tubal transport of both sperm and oocytes. During the sequential oral contraceptive regimen (Fig. 58–5C), the estrogen stimulates LH secretion in an irregular manner. There is no concomitant early rise in FSH level when progestin is added, and another LH surge usually is produced. When a progestin-only regimen (Fig. 58–5D) is followed (see Progestin-Only Pill), there are multiple LH surges but no significant changes in FSH levels.



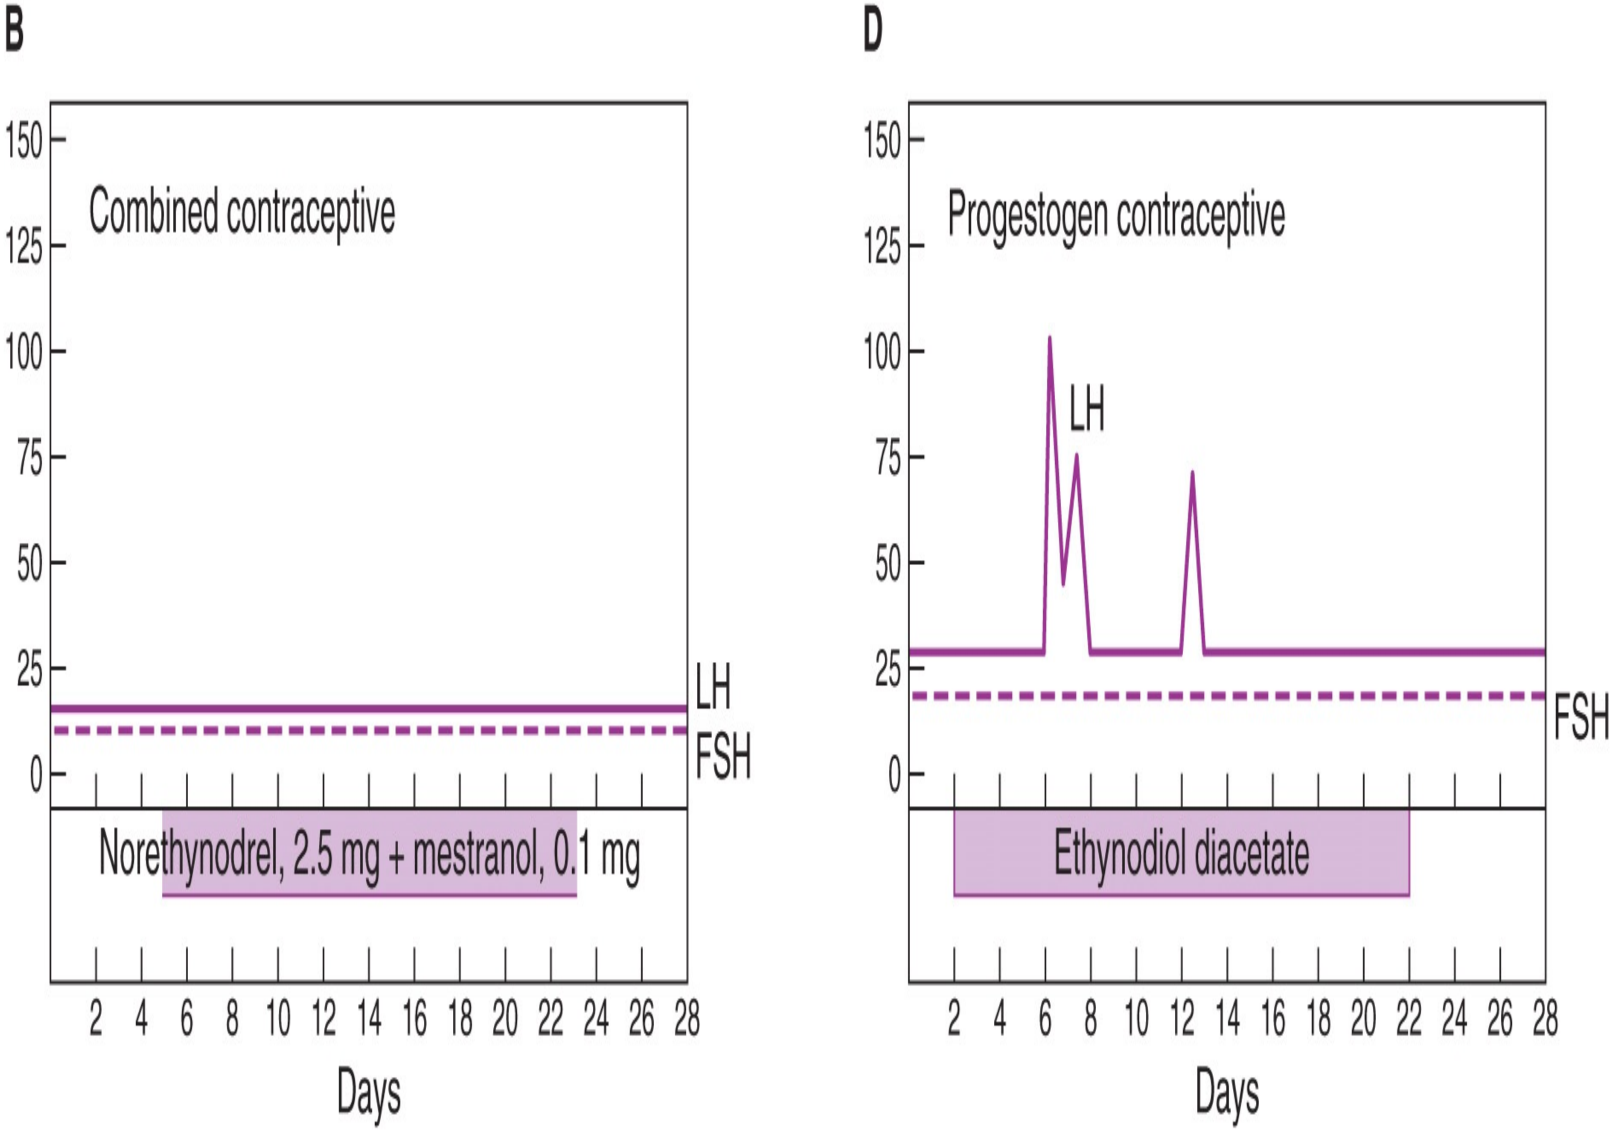


Figure 58–5. Serum levels (in mIU/mL) of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) during the menstrual cycle, with and without oral contraception. **A:** During a normal cycle without medication. **B:** During a typical cycle with combined medication (see text). **C:** During a typical cycle with sequential medication (see text). **D:** During progestin-only medication. (Reproduced, with permission, from Odell WD, Moyer DL. *Physiology of Reproduction*. St. Louis, MO: Mosby; 1971.)

A comprehensive survey of reported data indicates that the return of fertility in former oral contraceptive users (both cyclic and extended/continuous regimens) in women who stop use in order to conceive is comparable to that observed with other contraceptive methods.

Advantages

Benefits that are reasonably established include reduction in risk of ovarian and endometrial cancer, ectopic pregnancy, pelvic inflammatory disease (PID), menstrual disorders, benign breast disease, and acne. Emerging benefits include protection against bone mineral density loss, development of colorectal cancer, and progression of rheumatoid arthritis. Multiple observational studies have documented that combination oral contraceptives decrease the risk of ovarian cancer by 40–80% and endometrial cancer by approximately 50%. These effects take place after 1 year of use, and protection persists for a significant period after oral contraceptive use is discontinued. Oral contraceptives also reduce the risk of ectopic pregnancy by approximately 90% and the risk of acute salpingitis by as much as 50–80% in some studies, although other studies suggest the protection occurs to a lesser extent. However, birth control pills do not offer protection against lower tract infections such as gonorrhea or chlamydia. Oral contraceptives reduce menstrual blood loss as well as dysmenorrhea. There is a 30–50% overall decrease in benign fibrocystic conditions of the breast. Randomized placebo-controlled trials have demonstrated a reduction in acne lesions with some oral contraceptive preparations.

Disadvantages & Side Effects

Much attention has been paid to a possible relationship between the use of oral contraceptives and the incidence of thromboembolic disease, including pulmonary embolism. Use of most current combination oral contraceptives roughly triples a user's risk of venous thromboembolism (VTE) from approximately 3 to 9 events per 100,000 users annually, although some studies of formulations containing desogestrel suggest that the risk could climb as high as 7-fold. However, it is important to recognize that even with the worst-case scenarios, the attributable risk annually is approximately 18 additional events per 100,000 users compared with nonusers of combination oral contraceptives. VTE risk is enhanced by risk factors such as recent leg trauma, pelvic surgery, stasis (but not varicose veins), and the presence of the mutation known as factor V Leiden. Although the presence of this latter clotting abnormality markedly elevates a user's risk of VTE, the absolute risk is still low such that routine screening for the disorder among all potential oral contraceptive users would not be cost effective.

Myocardial infarction (MI) is a rare condition that occurs among combination oral contraceptive users only in the presence of risk factors such as hypertension, diabetes, severe dyslipidemia, and, in particular, cigarette smoking. Age above 35 years and smoking also act synergistically to increase risk; thus prescribing combination oral contraceptives to women over 35 years who smoke is not recommended. However, even with a 20- to 30-fold relative risk of MI among smoking combination oral contraceptive users, this risk equates to only a maximum of 500–600 events per million woman-years. However, unlike VTE, in which the case fatality rate in the reproductive age group is <1%, the case fatality rate for MI is approximately 50%.

Stroke is a rare condition among women in the reproductive age group, with hemorrhagic stroke somewhat more common than ischemic stroke. Among nonsmoking women, the rates range from 6–46 events per million woman-years; combination oral contraceptive use increases that risk only if risk factors such as age, cigarette smoking, migraine headaches (for ischemic but not hemorrhagic stroke), and especially hypertension are present. Overall, the relative risk of stroke varies between 2-fold and 10-fold, depending on the number of risk factors present.

Although cancer of the cervix among users of oral contraceptives has been a matter of concern, a major problem with many studies attempting to examine this relationship is confounding factors such as multiple sexual partners, age at first intercourse, and frequency of sexual activity and the concomitant use of barrier contraceptive methods. A recent meta-analysis determined that the risk of cervical cancer among oral contraceptive users compared with nonusers increased with duration of use, reaching a relative risk of approximately 4 after 10 years. For several decades, concern has been expressed regarding the possible association between oral contraceptive use and breast cancer. In 1996, a collaborative project representing a reanalysis of 54 studies demonstrated that for current users of oral contraceptives, the relative risk of breast cancer for users compared with women who had never used oral contraceptives was 1.24. This small increase in risk persisted for approximately 10 years after discontinuation of oral contraceptive use, with the risk essentially disappearing after that time. In addition, there was no overall effect of oral contraceptive use by dosage, specific formulation, duration of use, age at first use, age at time of cancer diagnosis, or family history of breast cancer. The pattern of disappearance of risk after 10 years coupled with a tendency toward localized disease suggests that the overall effect may represent detection bias or perhaps a promotional effect. Another recent, large population-based case-control study showed that neither current nor past use of any type of oral contraceptive increased the risk of breast cancer compared with population-based controls. Further, the results did not vary according to potential risk factors such as estrogen dose, duration of use, family history of breast cancer, or age at initiation of use. Other infrequent problems occasionally noted with oral contraceptive use include hypertension, cholelithiasis, and benign liver tumors. However, none of these problems occurs frequently enough to be of significant concern to most users.

Because the current formulations are associated with significant reductions in risk of serious sequelae, side-effect control will be of greater importance to most users in the future. Furthermore, studies have shown that compliance is affected by occurrence of side effects and that such “minor” problems, particularly spotting and breakthrough bleeding, account for approximately 40% of the discontinuations. Approximately 10–20% of women experience intermenstrual bleeding, including breakthrough bleeding and spotting, in the first few months of use. With today’s formulations, such problems stabilize after approximately 6 months and are seen in only approximately 5% of users. Missed menstrual periods or amenorrhea are relatively infrequent and of little clinical significance, except that these problems can raise concern as regarding contraceptive failure. Nausea may be seen in up to 10% of users; as with intermenstrual bleeding, this is a duration effect that declines rapidly after several months of use. Significant headaches and weight gain are far less frequent than reported with higher-dose preparations.

Contraindications for use of oral contraceptives include pregnancy; undiagnosed vaginal bleeding; prior history of VTE, MI, or stroke; women at increased risk for cardiovascular sequelae, such as active systemic lupus erythematosus, uncontrolled diabetes, or hypertension, and cigarette smokers over age 35 years; current or prior breast cancer; and active liver disease.

Because compliance and a clear understanding of how to take oral contraceptives are important to their successful use, health care providers should take the time at the initial visit to explain the packaging of the brand being prescribed, discuss the side effects, review how to start the first cycle, and discuss what to do when pills are missed. It should be emphasized that the patient package insert provides useful information on these topics. In addition, users should be encouraged to contact their provider or someone in the office or clinic who is familiar with oral contraceptive health care if problems occur. Finally, users should be advised to use alternate forms of contraception if oral contraceptive use is interrupted because of forgotten pills or the occurrence of side effects.

Table 58–1 lists the currently available oral contraceptives and their contents.

Table 58–1. Oral contraceptive agents in use.

	Estrogen (mg)	Progestin (mg)	
Combination tablets			
Loestrin 1/20	Ethinyl estradiol 0.02	Norethindrone acetate	1

*Active pills take 24 of 28 days.

Progestin-Only Pill (Minipill)

Several studies have demonstrated that a small daily quantity of a progestin alone, usually norethindrone or levonorgestrel, provides reasonably good protection against pregnancy without suppressing ovulation. The method has several advantages: the side effects attributable to the estrogen component of conventional oral contraceptives are eliminated because no estrogen is given, and no special sequence of pill-taking is necessary because the minipill is taken every day. Although the mechanism of action of progestin-only pills is not known, it has been postulated that the cervical mucus becomes less permeable to sperm and that endometrial activity goes out of phase so that nidation is thwarted even if fertilization does occur. In clinical trials, progestin-only oral contraceptives result in a pregnancy rate of approximately 2–7 pregnancies per 100 woman-years. Unlike combined oral contraceptives, which permit a certain margin of patient error and forgetfulness, minipill progestin agents must be taken each day promptly. Even a delay of 2–3 hours diminishes the contraceptive effectiveness for the coming 48 hours. Progestins given alone are associated with side effects, particularly irregular bleeding. Progestin-only contraceptives are ideal for women for whom estrogen is contraindicated. Ideal candidates include older women who smoke; women with sickle cell anemia, mental retardation, migraine headache, hypertension, or systemic lupus erythematosus; or women who are breastfeeding.

Emergency Contraception

Postcoital or emergency contraception is a therapy used to prevent unwanted pregnancy after unprotected intercourse or after a failure to use a contraceptive method appropriately. The major methods used for emergency contraception include combination oral contraceptives containing the progestin levonorgestrel (also known as the Yuzpe method), levonorgestrel tablets given alone, or the copper T 380A IUD. The hormonal methods prevent pregnancy by delaying or inhibiting ovulation or by disrupting the function of the corpus luteum. The usual combination hormonal formulation consists of 100 μg ethinyl estradiol and 500–600 μg levonorgestrel in several tablets administered twice, 12 hours apart. Under current recommendations, the first dose is administered within 72 hours of intercourse. The levonorgestrel-alone formulation requires administration of 750 μg of the progestin twice, also 12 hours apart. Many authorities currently recommend initial dosing within 72 hours, although data suggest this approach may be effective as long as 5 days after intercourse. Furthermore, data suggest that a single dose of 1500 μg levonorgestrel may be as effective as the 2-dose regimen. The IUD may inhibit implantation or possibly interfere with sperm function. The T 380A is inserted within 7 days from the time of unprotected intercourse.

Nausea occurs in approximately 50% and vomiting in 20% of the combination hormonal emergency contraception users. Administration of an antiemetic (eg, meclizine) 1 hour before may reduce this effect. The levonorgestrel-only approach is associated with rates of nausea and vomiting that are 50 and 70% lower than the rates experienced by combination emergency contraception users, respectively.

LONG-ACTING HORMONAL CONTRACEPTION

Depot medroxyprogesterone acetate (DMPA), an aqueous suspension of 17-acetoxy-6-methyl progesterone, has been used as a contraceptive in the United States for at least 4 decades. The usual dose is 150 mg administered intramuscularly into the gluteus maximus or deltoid every 3 months. The mechanisms of action include suppression of ovulation by suppressing the surge of gonadotropins, thickening cervical mucus to impede ascent of sperm, and thinning of the endometrium such that implantation of a blastocyst is less likely. Although labeled as effective for up to 13 weeks, the contraceptive activity actually persists for approximately 4 months after an injection, allowing some leeway for providers to schedule follow-up injections. During 1 year of use, the perfect use failure rate is 0.3 pregnancies per 100 woman-years, whereas the failure rate with typical use is 3 pregnancies per 100 woman-years.

Use of DMPA is associated with several health benefits. The risk of ectopic pregnancy is significantly lower among users compared to women who do not use contraception. The risk of endometrial cancer is reduced by as much as 80%, an effect that is long term and increases with duration of use. Studies have shown as much as a 70% reduction in the frequency of sickle cell crises; the mechanism for this effect is not known. Some women with endometriosis have improvement of symptoms with use of DMPA.

Use of DMPA does not increase the risk for arterial or venous disease. The most significant potential risk associated with DMPA use is a reduction in bone mineral density. Overall, prospective studies of at least 1 year’s duration have shown a maximum reduction of 1.5–2.3% in bone mineral density. No studies have shown any increase in fracture risk. Finally, retrospective studies have shown improvement in bone mineral density when DMPA was discontinued. Until further data become available, adequate calcium intake should be encouraged for DMPA users, particularly young patients and longer term users. Irregular bleeding and prolonged menstrual flow are not uncommon during the first 6 months of use. However, with continued use, many women become amenorrheic, and up to 70% of users experience no menses after 1 year. Mood change and depression have been reported in association with DMPA use. However, most studies are uncontrolled. Although earlier studies suggested DMPA users gained an average of 5 lb after 1 year of use, a recent randomized clinical trial demonstrated that DMPA was not associated with significant weight gain or changes in variables that might lead to weight gain. Finally, when DMPA users stop injections in an effort to achieve pregnancy, the return to baseline fertility may take an average of 10 months.

Implants

Although no implantable contraceptives currently are available in the United States, clinical trials of a single-rod implant 4 cm long and 2 mm in diameter have been completed. This system releases etonogestrel, the major metabolite of desogestrel, and maintains its efficacy for up to 3 years. The rod usually is inserted in the upper arm, using a trocar. Removal is easier than with other implants because it is a single-rod system. The likely mechanism of action is similar to that of DMPA. Overall efficacy is extremely high, with no reported pregnancies in more than 70,000 cycles of use. No major complications have been reported to date. Side effects include menstrual abnormalities and weight gain.

Vaginal Ring

The vaginal ring (Fig. 58–6) is approximately 5 cm in diameter and 4 mm thick. The ring is flexible. It releases ethinyl estradiol and etonogestrel at fairly constant rates. The ring is worn for 3 weeks per month, although the ring's reservoir contains enough contraceptive steroid for approximately 14 more days. The ring maintains its efficacy even if it is removed for up to 3 hours, although it is designed to be left in place even during intercourse. Users are instructed to insert the ring high into the vagina; fitting by a health professional is not required. The overall pregnancy rate over 1 year of use is 0.65 pregnancies per 100 woman-years.

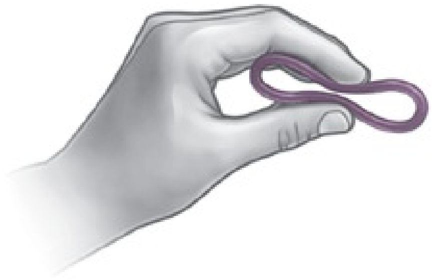

Figure 58–6. The vaginal ring.

No published data indicate the rates of major side effects or potential noncontraceptive benefits. However, because the vaginal ring contains steroids that are used in combination oral contraceptives, rates of serious side effects may be similar, and some of the noncontraceptive benefits may accrue to users of this method. Minor side effects are similar to those seen in users of combination oral contraceptives, although the frequency of breakthrough bleeding and spotting appears lower. Approximately 10–15% of users report vaginal-related symptoms, such as slight discomfort, a sensation of a foreign body, leukorrhea, vaginitis, or coital problems. There are reports that the ring might be used in an extended regimen, although this regimen was not yet approved by regulatory institutions.

Transdermal Patch

The transdermal contraceptive patch is 20 cm^2, roughly the size of a small adhesive-back (Post-It) pad consisting of 3 layers. The transdermal contraceptive patch is designed to deliver norelgestromin, the active metabolite of norgestimate, and ethinyl estradiol daily for a 7-day period. After 7 days, the patch is removed and a new patch is applied to another skin site. Three consecutive 7-day patches are applied in a typical cycle, followed by a 7-day patch-free period to allow withdrawal bleeding. Application sites include the buttocks, lower abdomen, upper outer arm, and upper torso, except for the breasts. Because this is a combination steroid preparation, the same contraindications noted for combination oral contraceptives use apply.

The transdermal contraceptive patch has a method use rate of 0.70 and a typical use rate of 0.88 pregnancies per 100 woman-years. These rates are comparable to pregnancy rates achieved with current oral contraceptives. However, a failure rate approaching the typical use failure rate seen with combination oral contraceptive users was noted for women weighing over 198 pounds who used the patch.

Although few reports have documented the rates of serious adverse events, one should assume that the events and risks will be similar to those noted for combination oral contraceptives. To date, 1 published study has indicated that the risk of venous thromboembolism is similar to that of an oral contraceptive. Similarly, no data on noncontraceptive benefits are available. The frequency of side effects such as headache and nausea are similar to that seen among users of combination oral contraceptives, although contraceptive patch users have application site reactions, more breast symptoms (only during the first 2 cycles), and more dysmenorrhea than combination oral contraceptive users. The pattern of breakthrough bleeding and spotting with the transdermal contraceptive patch is similar to that seen with oral contraceptive users. No evidence indicates that use of the patch influences body weight. Among users, 1.8% of women required replacement for complete detachment and 2.9% became partially detached. Detachment rates were similar for women living in warm, humid climates and for women who were subjected to vigorous exercise, swimming, and sauna use compared with other users. When patches do become detached, users should attempt to reattach them if possible, without using ancillary adhesives or tape. If detachment has occurred for 24 hours or less, the cycle continues as usual, with the patch changed on the previously determined change day. If detachment has occurred for more than 24 hours, a new patch should be applied, backup contraception should be used for 1 week, and the day that the new patch is applied now becomes the patch change day.

INTRAUTERINE CONTRACEPTIVE DEVICES

Two types of IUDs are available in the United States: the copper T 380A device and a levonorgestrel-releasing device (Fig. 58–7). The T 380A is a T-shaped device approximately 36 mm in length and 32 mm in diameter that contains 380 mm^2 of copper on its vertical and side arms. Two monofilament strings are attached to the vertical arm to ascertain placement in the uterus over the course of use. This IUD has a useful lifespan of at least 10 years. The exact mechanism of action is unknown, although current theories include spermicidal activity, interference with either normal development of ova or the fertilization of ova, and activity on the endometrium that may promote phagocytosis of sperm and that may impede sperm migration or capacitance. No data support this or other IUDs as abortifacients. The perfect use failure rate with the T 380A is 0.6 pregnancies per 100 woman-years and approximately 0.8 for typical use. In the past, IUDs were associated with an increased risk for PID around the time of insertion. However, by restricting use to mutually monogamous couples and couples currently at low risk of STIs, the absolute risk of PID in association with IUD use is almost negligible. PID appears to be associated primarily with the insertion of the device (Fig. 58–8) and not with its duration of use. Currently, with appropriately selected users, the rate of PID is approximately 1 case per 1000 insertions. Women at risk for HIV infection or who are already infected are not believed to be candidates for use of this device. Other ideal candidates are women in whom combination hormonal contraception is contraindicated. The other major risks reported in association with use of this IUD include ectopic pregnancy, spontaneous abortion, uterine perforation, and expulsion. Although 5–8% of pregnancies that occur with use of this IUD are ectopic, overall, because of the high effectiveness of this device, the absolute risk of ectopic pregnancy in users is substantially less than that experienced by nonusers of contraception. In addition, if a user becomes pregnant with the device in place, the risk of a spontaneous abortion is approximately 50%. Removing the device when the strings can be readily identified will reduce this risk by approximately 50%. If the pregnancy continues with the IUD in place, users should be apprised of an increased risk for premature rupture of the membranes and preterm delivery. Uterine perforation, which occurs at the time of insertion, has been reported at a rate of 1–2 events per 1000 insertions. This risk is minimized by performing a preinsertion pelvic examination to determine the position of the uterus and by using a tenaculum to straighten the uterine axis during insertion. Expulsions of the device are more common in the first few weeks of use, with rates of approximately 5%. Minor side effects include abnormal bleeding and cramping. Use of nonsteroidal anti-inflammatory drugs often will reduce the overall amount of flow as well as reduce cramping.

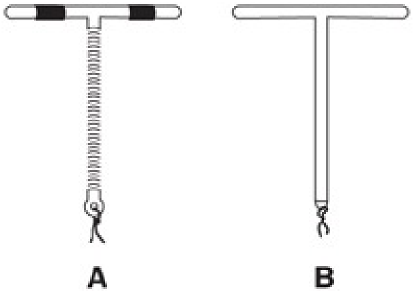

Figure 58–7. Intrauterine contraceptive devices currently available in the United States. **A**: The copper T 380A device; **B**: the levonorgestrel device.

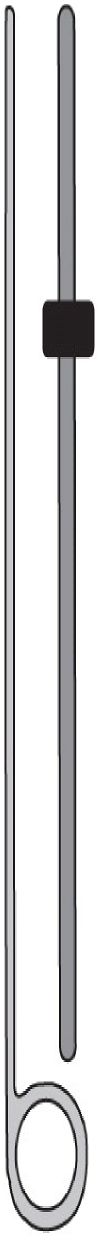

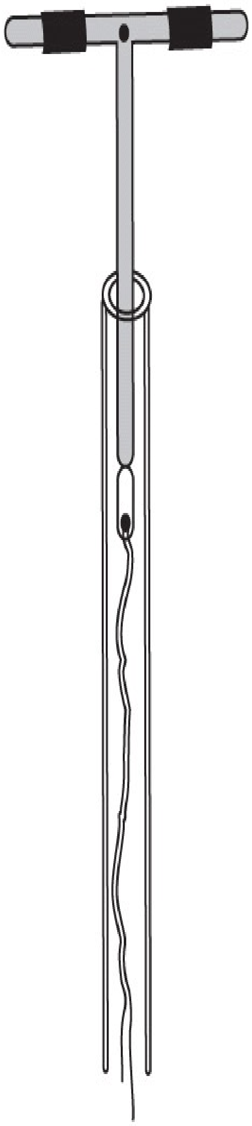

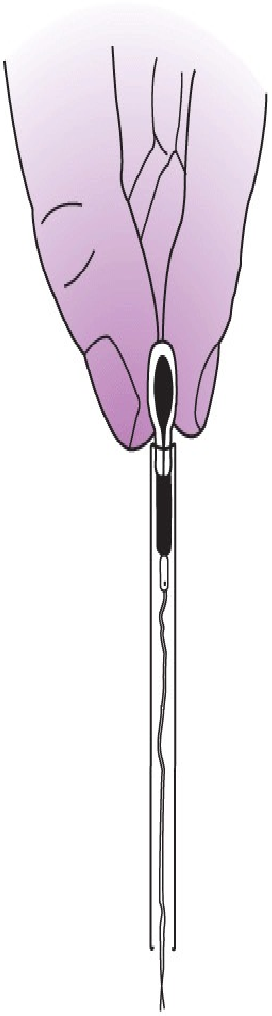

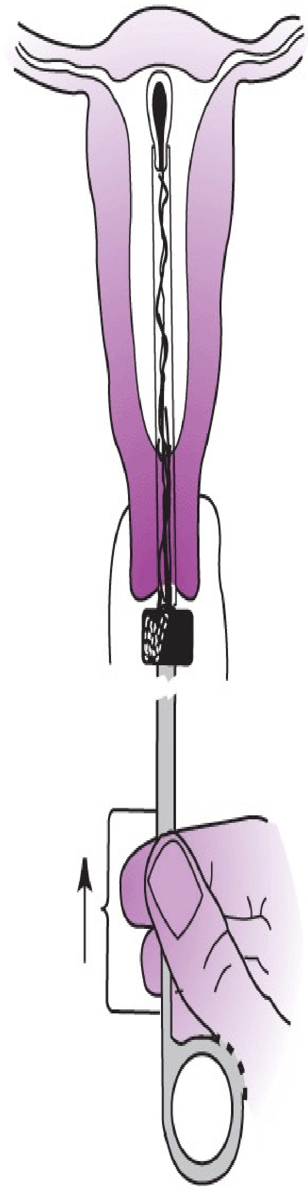

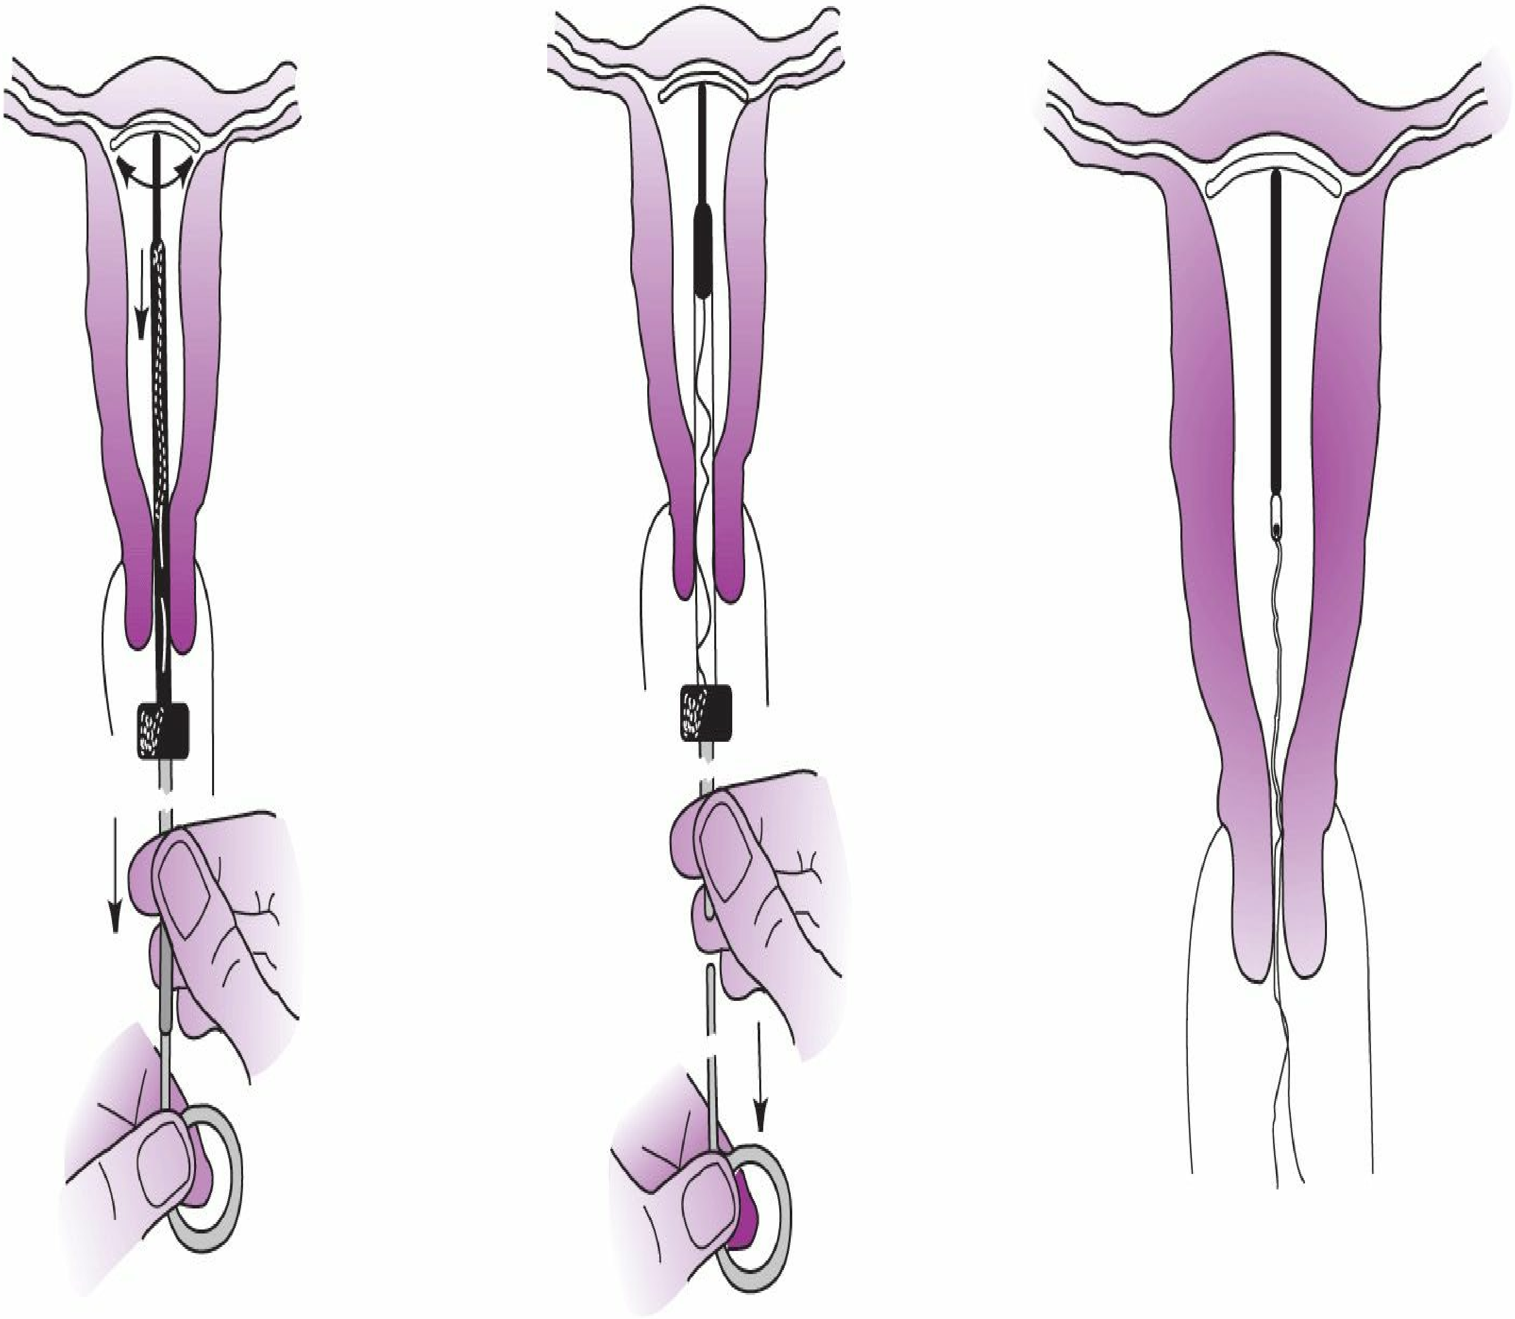

Figure 58–8. Insertion of the ParaGard T 380A intrauterine copper contraceptive device.

The levonorgestrel-releasing intrauterine device (LNG-20 IUD) has a T-shaped frame with a reservoir on the vertical arm that releases the progestin levonorgestrel daily. Two monofilament strings are attached to the vertical arm. Blood levels of levonorgestrel among users are approximately 25% the levels seen among users of oral contraceptives containing this progestin. In contrast to the copper T 380A device, the LNG-20 IUD has a life span of 5 years in clinical trials. The primary mechanisms of action of the LNG-20 IUD are thickening the cervical mucus to impede ascent of sperm and altering the uterotubal fluid to also interfere with sperm migration. This IUD causes anovulation in approximately 10–15% of cycles and changes the characteristics of the endometrium to reduce the likelihood of implantation. Candidates for use of this IUD fit the same profile as those who would consider use of the T 380A. The perfect and typical use pregnancy rates are 0.1 pregnancies per 100 woman-years after 1 year of use, and the cumulative pregnancy rate over 5 years is 0.7 pregnancies per 100 woman-years. Approximately 50% of the pregnancies that occur are ectopic. However, as with the T 380A device, the absolute risk of ectopic pregnancy still is substantially lower than that experienced by nonusers of contraception. Because the LNG-20 IUD releases a potent progestin at the endometrial level, the bleeding pattern is substantially different from that seen with the T 380A. During the initial 3–4 months of use, some women experience irregular bleeding that may be heavy at times. However, after a few months of use, most women experience a significant decrease in menstrual flow by as much as 70%. In some studies, 20–25% of users become amenorrheic in the second year of use. In addition, dysmenorrhea tends to improve with use of this device. Because of the effectiveness of the LNG-20 IUD in reducing menstrual blood flow, it has been used for treatment of menorrhagia, a significant noncontraceptive benefit. Major risks with this IUD are similar to those noted for the copper T 380A, except that PID has not been associated with use of this device. The minor side effects of bleeding and cramping are less frequent with this device, except for irregular bleeding patterns during the first few months of use. Some women have reported headache, acne, or mastalgia, which could be related to the systemic effects of the progestin.

A not infrequent issue with IUD use is the management of missing strings. First, the patient should be encouraged to use a backup contraceptive method until she is evaluated. If the IUD strings cannot be seen even with gentle probing of the endocervical canal, one should perform a pregnancy test if indicated and consider ordering a transvaginal ultrasound to determine whether the IUD is intrauterine, intraperitoneal, or likely has undergone expulsion. If the patient is pregnant, an ectopic pregnancy must be excluded. If the IUD is determined to be intraperitoneal in location, removal usually is indicated because of likely peritoneal irritation by the device.

MALE CONTRACEPTION

The development of contraceptive methods for men poses a different challenge because men are continuously producing sperm and therefore are continuously fertile, unlike women who have a limited number of fertile days each month. Recent surveys have shown that men want to be more involved in contraception decisions, and women trust their male partners to take an active role in this area. The current research is focused on developing contraceptive injections, implants, or vaccines that will reduce a male’s sperm count low enough to levels unlikely to cause pregnancy, but without damaging lifetime sperm production. Tests are currently being conducted overseas, and the information in this field will continue to be expanded. Nonsurgical steroidal methods comprising various derivatives of the androgens and their receptors are in various phases of clinical trials in men. The ideal male contraceptive should be coital-independent, nonsurgical, reversible, effective, and should not alter androgen levels or libido. Several nonsteroidal molecules and vaccines are being investigated in animal models for male contraception.

Naz RK, Rowan S. Update on male contraception. *Curr Opin Obstet Gynecol* 2009;21:265–269. PMID: 19469045.

CONTRACEPTION OVER 40

The majority of women 40–49 years of age need an effective method of contraception because the decline in fertility with age is an insufficient protection against unwanted pregnancy. Although pregnancy is less likely after the age of 40 years, the clinical and social consequences of an unexpected pregnancy are potentially detrimental. No contraceptive method is contraindicated by advanced reproductive age alone; thus there is a need to discuss the effectiveness, risks, and noncontraceptive benefits of all family planning methods for women in this age group. A review of the literature demonstrated that decline in fecundity in the fifth decade is insufficient for contraceptive purposes; thus a family planning method is needed. Sterilization is by far the most common method in several countries. Copper IUDs and hormone intrauterine systems have similar effectiveness, with fewer than 1% failures in the first year of typical use. Special considerations in this age group include the frequency of menstrual irregularity, sexual problems, and the possibility of menopausal symptoms, all of which may respond to hormonal methods of contraception.

The ESHRE Capri Workshop Group. Female contraception over 40. *Hum Reprod Update* 2009;15:599–612. PMID: 19458038.

INDUCED ABORTION

Induced abortion is the deliberate termination of pregnancy in a manner that ensures that the embryo or fetus will not survive. Societal attitudes toward elective abortion have changed markedly in the past few decades. In some situations the need for abortion is accepted by most people, but political and medical attitudes regarding induced abortion have continued to lag behind changing attitudes. Certain religious objections continue to prevail, resulting in personal, medical, and political conflicts.

Approximately one-third of the world's population lives in nations with nonrestrictive laws governing abortion. Another third live in countries with moderately restrictive abortion laws (ie, in countries where unwanted pregnancies may not be terminated as a matter of right or personal decision but only on broadly interpreted medical, psychologic, and sociologic indications). The remainder live in countries where abortion is illegal without qualification or is allowed only when the woman's life or health would be severely threatened if the pregnancy were allowed to continue.

An estimated 1 of every 4 pregnancies in the world is terminated by induced abortion, making it perhaps the most common method of reproduction limitation. In the United States, estimates of the number of criminal abortions performed before legalization of the procedure ranged from 0.25–1.25 million per year. The number of legal abortions now being performed in the United States approximates 1 abortion per 4 live births. In 1997, there were 1.33 million induced abortions compared with 3.88 million live births.

The procedures being used in the United States for legally induced abortions during the first trimester are relatively safe. Table 58–2 shows that first-trimester legal abortions are consistently safer for the woman than if she used no birth control method and gave birth. Table 58–2 also shows that although the number of maternal deaths related to births steadily increased from 5.6 to 22.6 per 100,000 women as age increased, the age-related increase in number of deaths per 100,000 women per year from legal abortions was insignificant.

Table 58–2. Pregnancy-related deaths per 100,000 women per year in developed countries compared with deaths resulting from legal abortion as a means of contraception.

	Age Groups (Years)					
Type of Birth Control	15–19	20–24	25–29	30–34	35–39	40–44
No birth control; birth related	5.6	6.1	7.4	13.9	20.8	22.6
First-trimester abortion only; method related	1.2	1.6	1.8	1.7	1.9	1.2

(Adapted from Tietze C. Induced abortion: 1977 supplement, Table 11. *Rep Popul Fam Plann* 1977; 14[2nd ed. Suppl]:16.)

In general, the risk of death from legal abortion is lowest when it is performed at 8 menstrual weeks or sooner. During 1988–1997, the overall death rate for women obtaining legally induced abortions was 0.7 per 100,000 legal induced abortions. The risk of death increased exponentially by 38% for each additional week of gestation. Compared with women whose abortions were performed at or before 8 weeks of gestation, women whose abortions were performed in the second trimester were significantly more likely to die of abortion-related causes. The relative risk (unadjusted) of abortion-related mortality was 14.7 at 13–15 weeks of gestation (95% confidence interval [CI] 6.2, 34.7), 29.5 at 16–20 weeks (95% CI 12.9, 67.4), and 76.6 at or after 21 weeks (95% CI 32.5, 180.8). Up to 87% of deaths in women who chose to terminate their pregnancies after 8 weeks of gestation may have been avoidable if these women had accessed abortion services before 8 weeks of gestation.

Legal Aspects of Induced Abortion in the United States

The United States Supreme Court ruled in 1973 that the restrictive abortion laws in the United States were invalid, largely because these laws invaded the individual’s right to privacy, and that an abortion could not be denied to a woman in the first 3 months of pregnancy. The Court indicated that after 3 months a state may “regulate the abortion procedure in ways that are reasonably related to maternal health” and that after the fetus reaches the stage of viability (approximately 24 weeks) the states may refuse the right to terminate the pregnancy except when necessary for the preservation of the life or health of the mother. Still, much opposition is raised by various “right-to-life” groups and religious groups. In spite of this opposition, more than 1 million procedures are still performed annually in the United States, with approximately one-third performed on teenaged women. The patient must be informed regarding the nature of the procedure and its risks, including possible infertility or even continuation of pregnancy. The rights of the spouse, parents, or guardian also must be considered and permission obtained when indicated (until the individual woman’s rights are clearly established). State laws must be obeyed with special reference to residence, duration of pregnancy, indications for abortion, consent, and consultations required.

Evaluation of Patients Requesting Induced Abortion

Patients give varied reasons for requesting abortion. Because in some cases the request is made at the urging of the woman’s parents, in-laws, husband, or peers, every effort should be made to ascertain that the patient herself desires abortion for her own reasons. In addition, one should be certain that the patient knows she is free to choose from among other methods of solving the problem of unplanned pregnancy, such as adoption or single-parent rearing.

Although the majority of abortions are performed as elective procedures (ie, because of social or economic reasons as opposed to medical reasons), some women still request such services for medical or surgical indications. For example, continuation of pregnancy may pose a threat to the life of women with certain medical conditions, such as Eisenmenger's syndrome and cystic fibrosis. Other indications are pregnancy resulting from a rape or pregnancy with a fetus affected with a major disorder, such as trisomy 13. In any event, the ultimate decision rests with the pregnant woman. Help from social agencies should be made available as necessary. A complete social history, medical history, and physical examination are required. Particular attention must be given to uterine size and position; the importance of accurate calculation of the duration of pregnancy (within 2 weeks but preferably within 1 week) cannot be overstated. With uncertainty, pelvic sonography should be used liberally. Routine laboratory tests should include pregnancy tests, urinalysis, hematocrit level, Rh typing, serologic tests for syphilis, culture for gonorrhea, and Pap smear.

Methods of Induced Abortion

Numerous methods are used to induce an abortion: suction or surgical curettage; medical abortion (performed with mifepristone alone, or with a combination of mifepristone and misoprostol or other prostaglandins), induction of labor by means of intraovular or extraovular injection of a hypertonic solution or other oxytocic agent; dilatation and evacuation; extraovular placement of devices such as catheters, bougies, or bags; hysterotomy—abdominal or vaginal; hysterectomy—abdominal or vaginal; and menstrual regulation.

The method of abortion used is determined primarily by the duration of pregnancy, with consideration for the patient's health, the experience of the physician, and the available physical facilities. The risk of repeat abortion is associated with various sociodemographic characteristics, but apparently the method of abortion used is not a risk factor for repeat termination of pregnancy.

Suction curettage on an outpatient basis performed under local or light general anesthesia can be accomplished with a high degree of safety. The safety of outpatient abortion and the shortage of hospital beds have led to the development of single-function, "freestanding" abortion clinics. In addition to providing more efficient counseling and social services, these clinics have effectively reduced the cost of abortion. Many hospitals have "short-stay units," which match the efficiency of outpatient clinics but also offer the backup facilities of the general hospital.

A. Suction Curettage

Suction curettage is the safest and most effective method for terminating pregnancies of 12 weeks' duration or less. This technique has gained rapid worldwide acceptance, and more than 90% of induced abortions in the United States are now performed by this method. The procedure involves dilatation of the cervix by instruments or by hydrophilic *Laminaria* tent (see Induction of Labor by Intra-Amniotic Instillation), followed by insertion of a suction cannula of the appropriate diameter into the uterine cavity (Fig. 58–9). Most procedures are performed using a paracervical block with local anesthesia with or without additional medication for sedation. Standard negative pressures used range from 30–50 mm Hg. Many physicians follow aspiration with light instrumental curettage of the uterine cavity.

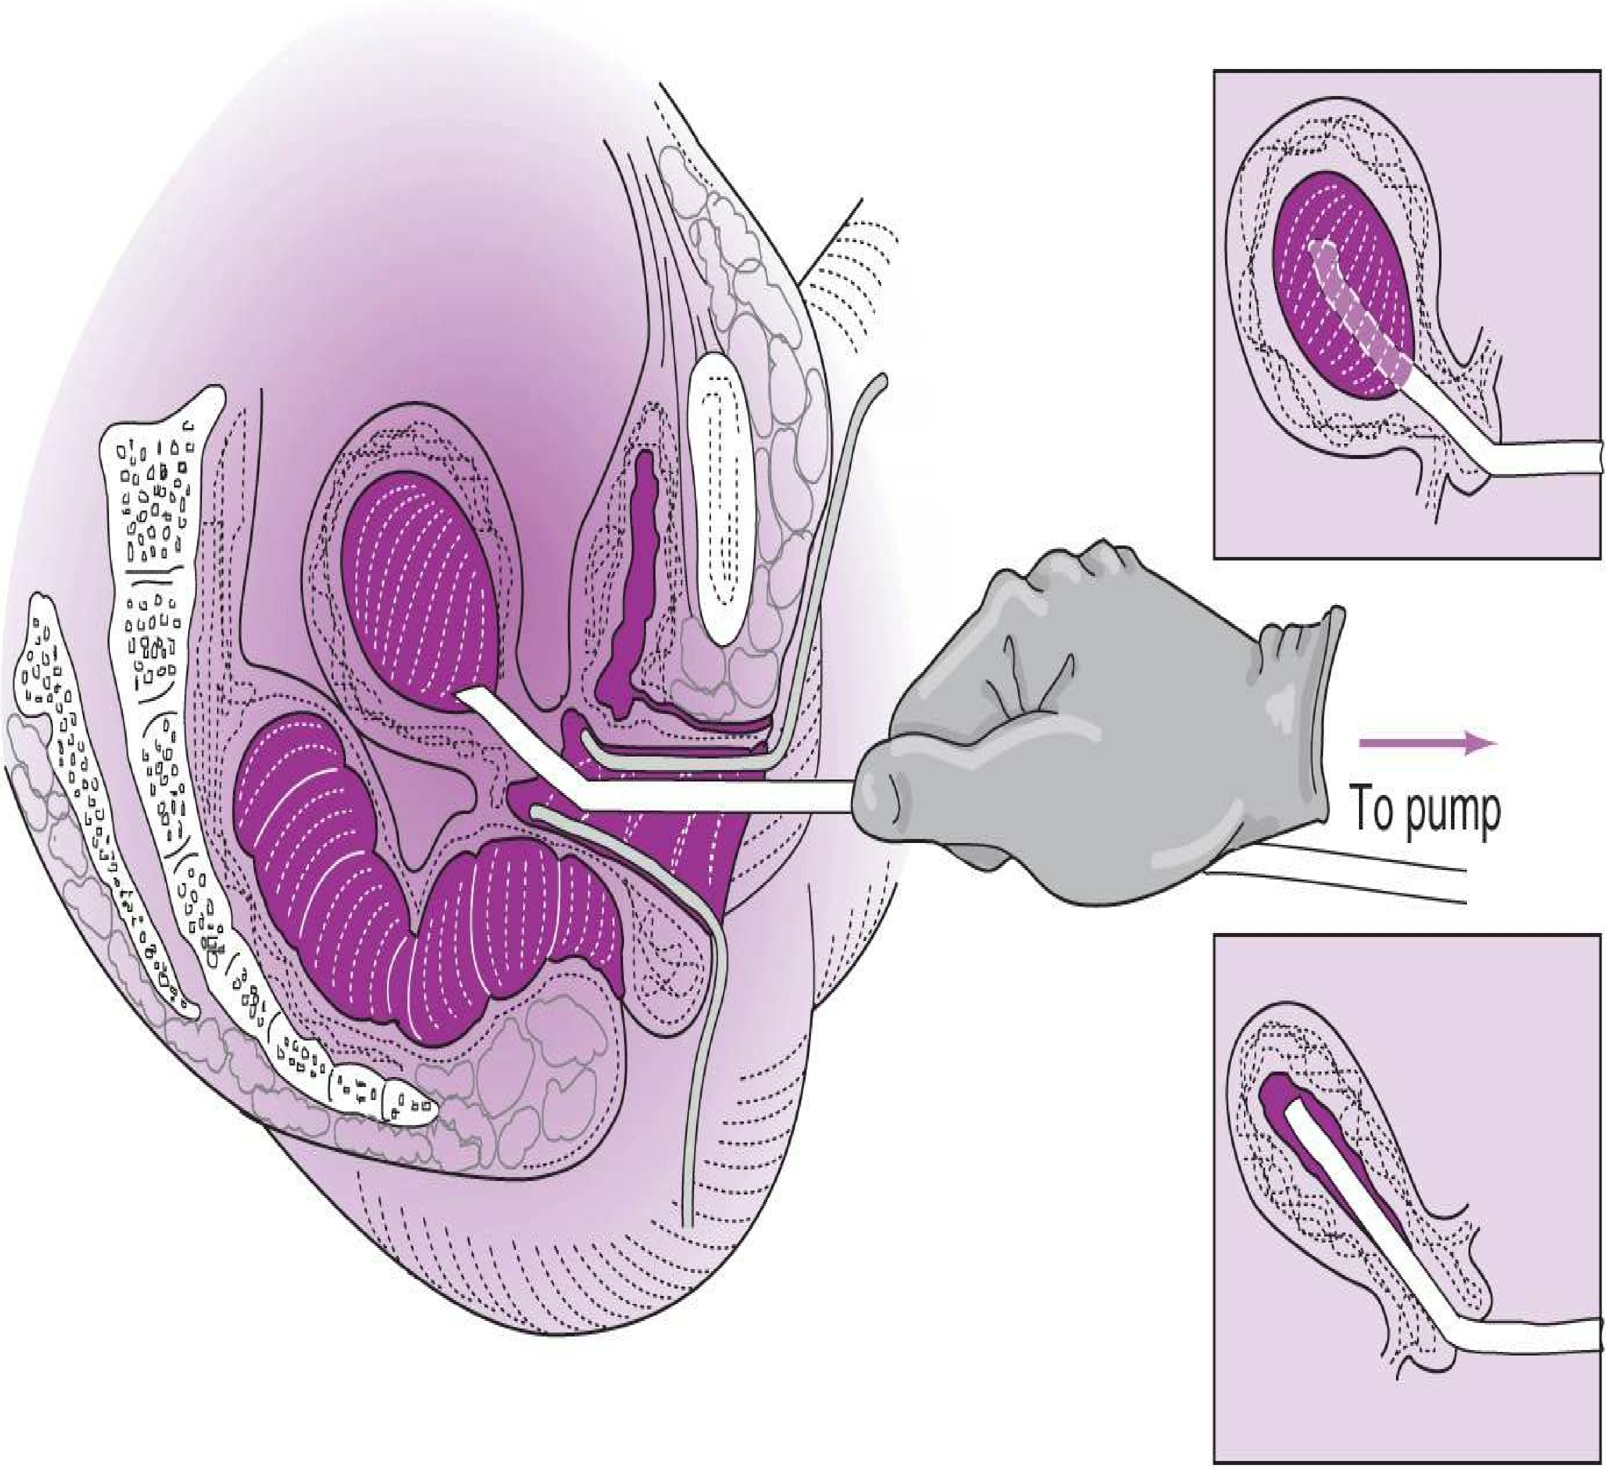

Figure 58–9. Suction method for induced abortion.

The advantages of suction over surgical curettage are that suction curettage empties the uterus more rapidly, minimizes blood loss, and reduces the likelihood of perforation of the uterus. However, failure to recognize perforation of the uterus with a cannula may result in serious damage to other organs. Knowledge of the size and position of the uterus and the volume of the contents is mandatory for safe suction curettage. Moreover, extreme care and slow minimal dilatation of the cervix, with special consideration for the integrity of the internal os, should prevent injury to the cervix or uterus. Attention to the decrease in uterine size that occurs with rapid evacuation helps to avoid uterine injury.

When performed in early pregnancy by properly trained physicians, suction curettage should be associated with a very low failure rate. The complication rate should be <1% for infection, approximately 2% for excessive bleeding, and <1% for uterine perforation. The risk of major complications, such as persistent fever, hemorrhage requiring transfusion, and unintended major surgery, ranges between 0.2 and 0.6% and is proportional to pregnancy duration. The incidence of mortality for suction curettage is approximately 1 in 100,000 patients.

B. Surgical Curettage

Surgical (“sharp”) curettage has been used for first-trimester abortion in the absence of suction curettage equipment. This procedure is performed as a standard dilatation and curettage, such as for the diagnosis of abnormal uterine bleeding or for the removal of endometrial polyps. The blood loss, duration of surgery, and likelihood of damage to the cervix or uterus are greatly increased when surgical curettage is used. In addition, the risk of uterine synechiae or Asherman’s syndrome is increased with this approach. Accordingly, suction curettage is generally preferred over sharp curettage for first-trimester termination procedures.

C. Medical Abortion

Medical methods for pregnancy termination in early gestation offer women an alternative to surgical evacuation and have the potential to improve access globally to safe abortion. Several drug regimens are used with varying efficacy, including mifepristone plus misoprostol, misoprostol alone, and methotrexate plus misoprostol. Where available, a mifepris-tone plus misoprostol regimen is most frequently used and is highly effective for early abortion. Overall, women who choose medical abortion report high levels of satisfaction.

Women with first-trimester pregnancies <49 days from their first day of the last menstrual period may be eligible for medical abortion. An alternative method of medical abortion consists of the administration of an oral antiprogestin (RU-486 [mifepristone]) followed by oral misoprostol 48 hours later. The reported success rate of this method is >90%, provided the protocol is started before 7 weeks from the last menstrual period. Complications include cramping, bleeding due to incomplete abortion, and failure to evacuate the uterus necessitating completion by suction curettage. With one of the more common protocols, 50 mg methotrexate is administered orally, followed by 800 mg misoprostol per vagina (by the patient at home) 3–7 days later using the same tablets as those used for oral dosing. The patient is seen at least 24 hours after the misoprostol administration; a vaginal ultrasound is performed to determine whether there has been passage of the gestational sac. If abortion has not occurred, the misoprostol dose is repeated. The patient is then followed up in 4 weeks; if abortion has not occurred by this time, a suction curettage is typically performed. If fetal cardiac activity is noted on ultrasound, office follow-up is more frequent. Efficacy with this method is up to 98% for pregnancies up to 49 days' gestation; complete abortion rates are inversely proportional to duration of gestation. Nausea is the most frequently reported side effect. Older age, previous spontaneous abortions, and multigravidity are apparently independent risk factors for unsuccessful medical abortion.

Contraindications include active liver disease, active renal disease, severe anemia, acute inflammatory bowel disease and coagulopathy, or anticoagulant therapy.

D. Induction of Labor by Intra-Amniotic Instillation

The Japanese developed this technique for induced abortion after the first trimester. Currently, the technique is used almost exclusively for initiating midtrimester abortion. The original procedure consisted of amniocentesis, aspiration of as much fluid as possible, and instillation into the amniotic sac of 200 mL hypertonic (20%) sodium chloride solution. In most (80–90%) cases, spontaneous labor and expulsion of the fetus and placenta occur within 48 hours. This technique has been modified, primarily to reduce the injection– abortion interval, and as a result of the development of other agents that initiate labor when instilled intra-amniotically.

Because of the problems associated with hypertonic sodium chloride, many clinicians have used intra-amniotic hyperosmolar (59.7%) urea, usually with oxytocin or prostaglandin or intra-amniotic prostaglandin alone. These approaches result in injection–abortion intervals of 16–17 hours for urea and 19–22 hours for prostaglandin. The urea is instilled in a fashion similar to that described for hypertonic sodium chloride. The prostaglandin, most frequently prostaglandin F_{2a} (PGF_{2a}), usually is instilled as a single dose of 40–50 mg or as 2 doses of 25 mg instilled 6 hours apart. When oxytocin is used to augment these agents, doses as high as 332 mU/min are required to produce uterine contractions because of the relative insensitivity of the myometrium to oxytocin at this stage of pregnancy. To avoid water intoxication, the oxytocin is made up in highly concentrated solutions and given at slow rates.

It is advantageous to soften the unripe cervix with *Laminaria* tents placed in the cervix a few hours before amniocentesis is performed. Such an approach markedly reduces the risk of cervical injury.

Midtrimester abortion induced by this method must be accomplished with scrupulous aseptic surgical technique, and the patient must be monitored until the fetus and placenta are delivered and postabortion bleeding is under control. The complication rate is high—up to 20% in some institutions—and the mortality rate is comparable to that of term parturition. Fortunately, because first-trimester abortion is now more readily available, more women are consulting their physicians early and thus availing themselves of the much safer suction curettage.

Several types of complications are associated with the use of instillation agents. Retained placenta is the most common problem; rates ranging from 13 to 46% have been reported. The placenta usually can be removed without difficulty using ring forceps and large curettes with the patient under local anesthesia. Hemorrhage may be caused by retained products or atony; coagulopathy is seen in up to 1% of patients in whom hypertonic sodium chloride is used. Infection can occur but is reduced significantly by use of prophylactic antibiotics in high-risk situations (eg, in patients with early ruptured membranes and during injection–abortion intervals >24 hours). Cervical laceration can occur but is reduced by the use of *Laminaria* tents. Hypernatremia can occur with the use of hypertonic sodium chloride if the drug is absorbed rapidly by the placental bed or if it is given intravascularly by mistake.

Failure of labor to expel the products of conception necessitates either a repetition of the procedure if the membranes are still intact or oxytocin stimulation, usually by intravenous injection or use of the dilatation and evacuation technique.

Emotional stress is an important factor for many women because they are awake at the time of the expulsion of the fetus and the fetus is well formed. (The emotional stress is also a factor for hospital personnel—a problem impossible to avoid.)

E. Induction of Labor with Vaginal Prostaglandins

Second-trimester abortions are most commonly performed in the United States via dilation and evacuation; however, there are instances in which the use of systemic abortifacients is necessary. Lack of trained staff to perform late abortion procedures, fetal anomalies, and patient preference are important considerations when selecting the method of termination. Second-trimester abortions with misoprostol-only protocols require higher doses, side effects are more common, and the time to complete the abortion is longer in comparison with mifepristone-misoprostol combinations. Feticidal agents are recommended to avoid transient fetal survival. Prostaglandin E_2 given intravaginally can be used to induce midtrimester abortion. Vaginal suppositories containing 20 mg are used every 3–4 hours until abortion occurs; the presence or absence of labor determines whether the prostaglandin E_2 should be stopped. Misoprostol, a synthetic prostaglandin E_1 analogue, is also used. Treatment–abortion intervals, rates of incomplete abortion, and complications are similar to those described for instillation agents. The major disadvantages are significant gastrointestinal side effects, a higher incidence of live abortion, and a more frequent occurrence of fever.

F. Dilatation & Evacuation

This technique for inducing midtrimester abortion is essentially a modification of suction curettage. Because fetal parts are larger at this stage of pregnancy, most operators use serial placement of *Laminaria* tents to effect cervical dilatation with less likelihood of injury. Larger suction cannulas and specially designed forceps are used to extract tissue. In most instances, the operation can be performed in the outpatient setting using paracervical block anesthesia and intravenous sedation on patients with pregnancies up to 18 weeks' gestation. Complications include hemorrhage (usually due to atony or laceration), perforation, and rarely infection. Retained tissue is uncommon, especially when tissue is carefully inspected for completion at the end of each procedure. Compared with instillation techniques or vaginal prostaglandin, the overall incidence of complications (in pregnancies up to 18 weeks' gestation) is less with dilatation and evacuation. In addition, most patients prefer the technique because it is an outpatient procedure and the woman does not undergo labor.

G. Hysterotomy & Hysterectomy

The use of hysterotomy and hysterectomy is currently reserved for special circumstances such as the failure to complete a midtrimester abortion due to cervical stenosis or the management of other complications. Both approaches, compared with other techniques discussed, have unacceptably high rates of morbidity and mortality, and neither should be used as a primary method.

H. Menstrual Regulation

Menstrual regulation consists of aspiration of the endometrium within 14 days after a missed menstrual cycle or within 42 days after the beginning of the last menstrual period by means of a small cannula attached to a source of low-pressure suction, such as a syringe or other suction machine. This is a simple and safe procedure that can be readily performed in the office or outpatient clinic, usually without any anesthetic, although paracervical block can be used if necessary. Menstrual regulation was used extensively in the 1970s and 1980s before reliable, inexpensive, and sensitive urine pregnancy tests became available. It offered a safe early approach to pregnancy termination; however, approximately 40% of women were not pregnant at the time of the procedure. With the advent of urine pregnancy tests that have the ability to document pregnancy even before a missed menstrual period, standard first-trimester suction curettage probably is more widely used. Complications are similar to those described for suction curettage except that persistent pregnancy is more common, particularly when very early menstrual regulation procedures are performed.

I. RU-486

RU-486 (mifepristone) is a synthetic drug, developed by French pharmacologists, that acts at least partially as an anti-progestational agent. When given orally in conjunction with a prostaglandin such as misoprostol, it effects first-trimester abortion. Complications include failure to terminate a pregnancy, incomplete abortion, and significant uterine cramping.

Follow-Up of Patients After Induced Abortion

Follow-up care after all procedures must be ensured. After abortion by all methods, human Rho (D) immune globulin (RhoGAM) should be administered promptly if the patient is Rh-negative, unless the male partner is known to be Rh-negative. The patient should take her temperature several times daily and report fever or unusual bleeding at once. She should avoid intercourse or the use of tampons or douches for at least 2 weeks. The physician should discuss with the patient the possibility that emotional depression, similar to that after term pregnancy and delivery, may occur after induced abortion. Follow-up care should include pelvic examination to rule out endometritis and parametritis, salpingitis, failure of involution, or continued uterine growth. Finally, effective contraception should be made available according to the patient’s needs and desires.

Long-Term Sequelae of Induced Abortion

Many studies during the past 2 decades have examined the possible long-term sequelae of elective induced abortion. Most of the attention has focused on subsequent reproductive function; unfortunately, many of the studies had inherent biases and serious methodologic flaws. Despite these problems, enough information is available to provide relative estimates of potential risks. Data from some studies suggest that midtrimester pregnancy loss is more common in women who have undergone 2 or more induced or spontaneous abortions. However, women who have undergone 1 procedure have essentially the same risk as women who have experienced a single term pregnancy. Regarding low birthweight, only women who have undergone a first-trimester procedure by sharp curettage under general anesthesia appear to have increased risks. The reason for this association might be related to the method of dilatation used. Finally, studies that have examined both ectopic pregnancy and infertility have failed to show any consistent association between these adverse events and prior induced abortion.

59
Menopause & Postmenopause

Lauren Nathan, MD

ESSENTIALS OF DIAGNOSIS

- Natural menopause diagnosed after 12 months of amenorrhea with no obvious pathologic cause
- Average age 51 years
- Estradiol <20 pg/mL and follicle-stimulation hormone level 21–100 mU/mL helpful in establishing the diagnosis
- Induced menopause is defined as permanent cessation of menstruation after bilateral oophorectomy or ablation of ovarian function (ie, by chemotherapy or radiation)
- Premature menopause defined as menopause reached at or before age 40 and can be natural or induced
- Perimenopause/menopause transition defined by menstrual cycle and hormonal changes that occur a few years before and 12 months after the final menstrual period resulting from natural menopause
- May be associated with vasomotor symptoms, sleep disturbance, and vaginal/urinary symptoms

---

General Considerations

According to the 2010 US census, of the 155 million women in this country, 41 million were 55 years of age or older. Most of these women had or shortly would have their last menstrual period, thus becoming postmenopausal. As a woman at age 55 years can expect to live another 28 years, a large portion of the female population is without ovarian function and lives about one-third of their lives after this function ceases. Consequently, physicians caring for women must understand the hormonal and metabolic changes associated with the menopause, or “change of life,” and the potential benefits and risks of hormone therapy (HT).

According to the Comite des Nomenclatures de la Federation Internationale de Gynecologie et d’Obstetrique, the **climacteric** is the phase of the aging process during which a woman passes from the reproductive to the nonreproductive stage. The signals that this period of life has been reached are referred to as “climacteric symptoms” or, if more serious, as “climacteric complaints.” **Perimenopause,** or **menopausal transition,** refers to the part of the climacteric before the menopause occurs when the menstrual cycle is likely to be irregular and when other climacteric symptoms or complaints may be experienced. The **menopause** is the final menstruation, which occurs during the climacteric. **Postmenopause** refers to the phase of life that comes after the menopause.

To develop a more functional staging system of reproductive aging, the Stages of Reproductive Aging Workshop (STRAW) was held in 2001 and again 10 years later in another workshop called “STRAW +10”. The specific goals of the workshop were to (a) develop a useful staging system for reproductive aging, (b) revise nomenclature, and (c) identify knowledge gaps that should be addressed by the research community. STRAW + 10 also added more supportive criteria using endocrinologic parameters (Follicle Stimulation Hormone [FSH], anti-mullerian hormone [AMH], Inhibin B) and

Antral Follicle count [AMC]). According to STRAW + 10, reproductive aging is divided into 7 stages (−5 to +2), with −5 beginning with menarche and +2 being defined as the late menopause. This staging system is not applicable to women who have undergone hysterectomy or endometrial ablation, who have chronic menstrual irregularity such as polycystic ovarian syndrome (PCO), or who have chronic illness and undergoing chemotherapy. STRAW +10 may also not be applicable to women with other chronic illnesses such as HIV-AIDs but further research into this population needs to be carried out in order to better characterize ovarian function across time in this group of patients.

The **menopausal transition,** or **perimenopause,** is divided into 2 stages—early (−2) and late (−1) and encompasses a wide age range. Both stages vary in length and both are characterized by an elevation in early follicular phase follicle-stimulating hormone (FSH). In stage −2, the menstrual cycles remain regular, but the cycle length changes by 7 days or more (ie, cycle length becomes 24 days instead of 31). FSH may be elevated but levels are variable. AMH, Inhibin B and AMC are all low. Duration is variable. Stage −1 (late menopausal transition) is characterized by an interval of amenorrhea of ≥60 days and is typically characterized by increased variability in cycle length. FSH is usually >25 IU/L during this stage. AMH, Inhibin B and AMC are low. Many women begin to experience symptoms during this time which may include vasomotor symptoms, and sleep disturbance. The duration is typically 1-3 years. The early postmenopausal period (stage +1) is divided into +1a, +1b and +1c and includes the first 6 years following the final menstrual period. +1a begins 12 months following the last menstrual period and marks the end of the menopausal transition or “perimenopause”. During stage +1, FSH remains elevated while AMH, Inhibin B and AMC drop further and become very low. The late postmenopausal period (stage +2) begins 6 years after the final menstrual period and continues until death.

Harlow SD, Gass M, Hall JE, et al. Executive Summary of the Stages of Reproductive Aging Workshop + 10: Addressing the Unfinished Agenda of Staging Reproductive Aging. *J Clin Endocrinol Metab*, 2012;97:1159–1168. PMID: 22344196.

U.S. Census Bureau. Age and Sex Composition: 2010. www.census.govprod/cen2010

Pathogenesis

A. Perimenopausal State

The decades of mature reproductive life are characterized by generally regular menses and a slow, steady decrease in cycle length. Mean cycle length at age 15 years is 35 days, at age 25 years it is 30 days, and at age 35 years it is 28 days. This decrease is a result of shortening of the follicular phase of the cycle, with the luteal phase length remaining constant. After age 45 years, altered function of the aging ovary is detectable in regularly menstruating women (Fig. 59–1). The mean cycle length is significantly shorter than in younger women and is attributable to a shortened follicular phase. The luteal phase is of similar length, and progesterone levels are no different from those observed in younger women. Estradiol levels are lower during portions of the cycle, including active follicular maturation, the midcycle peak, and the luteal phase. Concentrations of FSH are strikingly elevated during the early follicular phase and fall as estradiol increases during follicular maturation. FSH levels at the midcycle peak and late in the luteal phase are also consistently higher than those found in younger women and decrease during the midluteal phase. Luteinizing hormone (LH) concentrations are indistinguishable from those observed in younger women. The mechanism responsible for this early rise of FSH is probably related to inhibin. **Inhibin** is a polypeptide hormone that is synthesized and secreted by granulosa cells. It causes negative feedback on FSH release by the pituitary. As the oocyte number decreases, inhibin levels fall, resulting in a rise in FSH levels.

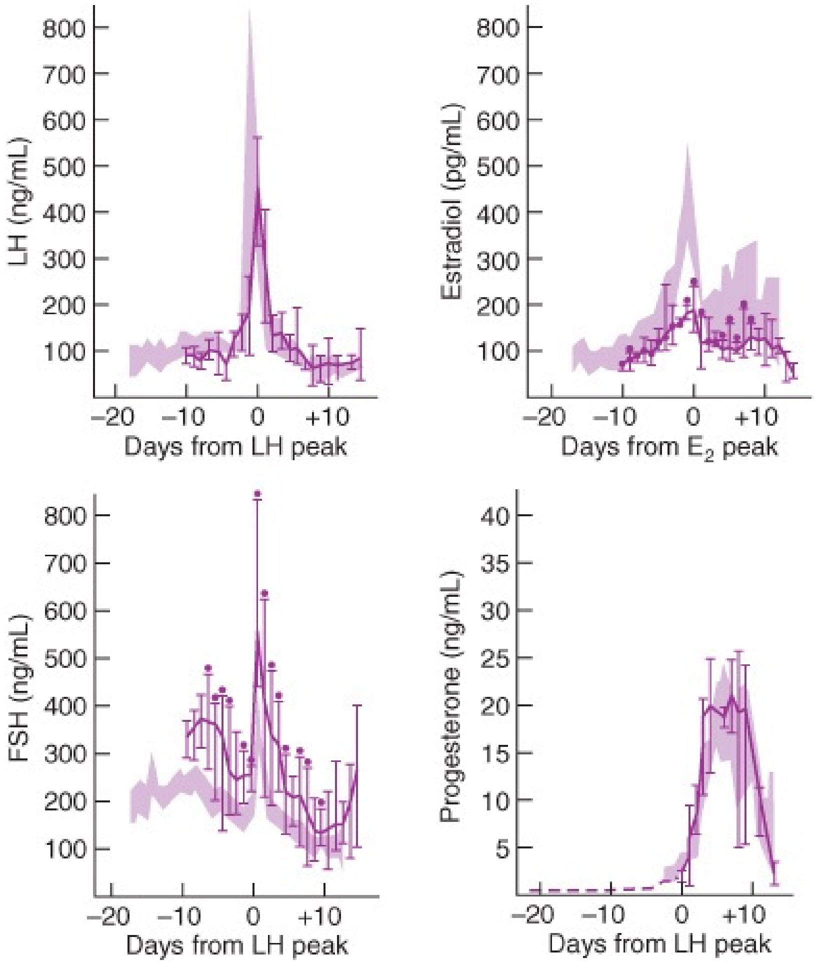

Figure 59–1. Mean and range of LH, FSH, estradiol (E_2), and progesterone levels in women over age 45 with regular menstrual cycles. Shaded area represents the mean (±2 SEM) in cycles found in young women. (Reproduced, with permission, from Sherman BM, Korenman SG. Hormonal characteristics of the human menstrual cycle throughout reproductive life. *J Clin Invest* 1975;55:699.)

The transition from regular cycle intervals to the permanent amenorrhea of menopause is characterized by a phase of marked menstrual irregularity. The duration of this transition varies greatly among women. Those experiencing the menopause at an early age have a relatively short duration of cycle variability before amenorrhea ensues. Those experiencing it at a later age usually have a phase of menstrual irregularity characterized by unusually long and short intermenstrual intervals and an overall increase of mean cycle length and variance.

The hormonal characteristics of this transitional phase are of special interest and importance. The irregular episodes of vaginal bleeding in premenopausal women represent the irregular maturation of ovarian follicles with or without hormonal evidence of ovulation. The potential for hormone secretion by these remaining follicles is diminished and variable. Menses are sometimes preceded by maturation of a follicle with limited secretion of both estradiol and progesterone. Vaginal bleeding also happens after a rise and fall of estradiol without a measurable increase in progesterone, such as is seen during anovulatory menses.

From these findings, it is clear that the transitional phase of menstrual irregularity is not one of marked estrogen deficiency. During the menopausal transition, high levels of FSH appear to stimulate residual follicles to secrete bursts of estradiol. Occasionally, estradiol levels will rise to concentrations 2 or 3 times higher than is normally seen, probably reflecting the recruitment of more than 1 follicle for ovulation. This may be followed by corpus luteum formation, often with limited secretion of progesterone. Because the episodes of follicular maturation and vaginal bleeding are widely spaced, premenopausal women may be exposed to persistent estrogen stimulation of the endometrium in the absence of regular cyclic progesterone secretion.

B. Menopausal State

The 2 types of menopause are classified according to cause.

1. Physiologic menopause—In the human embryo, oogenesis begins in the ovary around the third week of gestation. Primordial germ cells appear in the yolk sac, migrate to the germinal ridge, and undergo cellular divisions. It is estimated that the fetal ovaries contain approximately 7 million oogonia at 20 weeks' gestation. After 7 months' gestation, no new oocytes are formed. At birth, there are approximately 1–2 million oocytes, and by puberty this number is reduced to 300,000–500,000. Continued reduction of oocyte numbers occurs during the reproductive years through ovulation and atresia. Nearly all oocytes vanish by atresia, with only 400–500 actually being ovulated. Very little is known about oocyte atresia. Animal studies show that estrogens prevent the atretic process, whereas androgens enhance it.

Menopause apparently occurs in the human female because of 2 processes. First, oocytes responsive to gonadotropins disappear from the ovary, and second, the few remaining oocytes do not respond to gonadotropins. Isolated oocytes can be found in postmenopausal ovaries on very careful histologic inspection. Some of them show a limited degree of development, but most reveal no sign of development in the presence of excess endogenous gonadotropins.

The average age at menopause in the United States is 50–51 years. There does not appear to be any consistent relationship between age at menarche and age at menopause. Marriage, childbearing, height, weight, and prolonged use of oral contraceptives do not appear to influence the age of menopause. Smoking, however, is associated with early menopause.

Spontaneous cessation of menses before age 40 years is called **premature menopause,** or **premature ovarian failure**. It appears that approximately 0.9% of women in the United States may experience this early cessation of function. Cessation of menstruation and the development of climacteric symptoms and complaints can occur as early as a few years after menarche. The reasons for premature ovarian failure are unknown.

Disease processes, especially severe infections or tumors of the reproductive tract, can occasionally damage the ovarian follicular structures so severely as to precipitate the menopause. The menopause can also be hastened by excessive exposure to ionizing radiation; chemotherapeutic drugs, particularly alkylating agents; and surgical procedures that impair ovarian blood supply. The possibility of associated endocrine or chromosomal abnormalities should also be considered.

2. Artificial menopause—The permanent cessation of ovarian function brought about by surgical removal of the ovaries or by radiation therapy is called an artificial menopause. Irradiation to ablate ovarian function is rarely used today. Artificial menopause is used as a treatment for endometriosis and rarely may be used to treat estrogen-sensitive neoplasms of the breast and endometrium. More frequently, artificial menopause is a side effect of treatment of intraabdominal disease (eg, ovaries are removed in premenopausal women because the gonads have been damaged by infection or neoplasia). When laparotomy is being performed for intraabdominal or pelvic disease (ie, hysterectomy for leiomyomata), elective bilateral oophorectomy is sometimes used to prevent ovarian cancer. In some women who are genetically predisposed to ovarian cancer, elective laparoscopic oophorectomy is also performed.

C. Changes in Hormone Metabolism Associated with the Menopause

After the menopause, there are major changes in androgen, estrogen, progesterone, and gonadotropin secretion, much of which occurs because of cessation of ovarian follicular activity (Fig. 59–2).

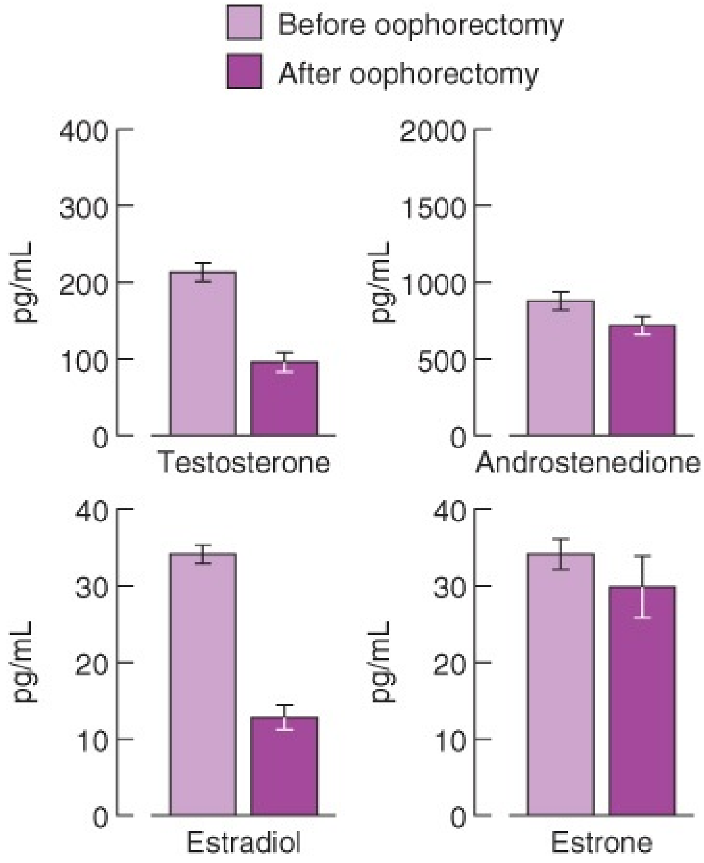

Figure 59–2. Serum androgen and estrogen levels in 16 postmenopausal women with endometrial cancer before and after oophorectomy. (Reproduced, with permission, from Judd HL. Hormonal dynamics associated with the menopause. *Clin Obstet Gynecol* 1976; 1:775.)

1. Androgens—During reproductive life, the primary ovarian androgen is androstenedione, the major secretory product of developing follicles. In postmenopausal women, there is a reduction of circulating androstenedione to approximately 50% of the concentration found in young women, reflecting the absence of follicular activity. In the year following the last menstrual period, the levels of this hormone are steady. In older women, there is a circadian variation of androstenedione, with peak concentration between 8:00 AM and 12 noon, and the nadir occurring between 3:00 PM and 4:00 AM. This rhythm reflects adrenal activity. The clearance rate of androstenedione is similar in pre- and postmenopausal women; therefore, the change in levels of circulating hormone reflects changes in production. Thus the average production rate of androstenedione is approximately 1.5 mg/24 h in older women, a rate that is 50% of the rate found in premenopausal women. The source of most of this circulating androstenedione appears to be the adrenal glands, but continued secretion by the postmenopausal ovary accounts for approximately 20%.

For testosterone, the level found in postmenopausal women is only minimally lower than that found in premenopausal women before oophorectomy and is distinctly higher than the level observed in ovariectomized young women. There is also a prominent circadian variation of this androgen, with the highest levels occurring at 8:00 AM and the nadir at 4:00 PM. There is no difference in the clearance rate of testosterone before and after the menopause. Thus the production rate in older women is approximately 150 μg/24 h, a rate that is only one-third lower than the rate seen in young women.

The source of circulating testosterone is more complex than that of androstenedione. Oophorectomy after menopause is associated with a nearly 60% decrease in testosterone. There is no change in the metabolic clearance rate of the androgen with oophorectomy; therefore, the fall in the circulating level reflects alterations of its production rate. Approximately 15% of circulating androstenedione is converted to testosterone. The small simultaneous fall of androstenedione after oophorectomy can only account for a small portion of the total decrease of testosterone. The remainder of the loss presumably represents loss from direct ovarian secretion of testosterone. Direct ovarian secretion in the postmenopausal ovary is larger than the amount secreted directly by the premenopausal ovary. Large increments in testosterone have been found in the ovarian compared with the peripheral veins of postmenopausal women. These increments are greater than those observed in premenopausal women, supporting the hypothesis that the postmenopausal ovary secretes more testosterone directly than the premenopausal ovary. Hilar cells and luteinized stromal cells (hyperthecosis) are present in most postmenopausal ovaries and have been shown to produce testosterone in premenopausal women. Presumably, these cells could do the same in post-menopausal subjects.

A proposed mechanism for increased ovarian testosterone production by postmenopausal ovaries is the stimulation of gonadal cells still capable of androgen production by excess endogenous gonadotropins, which, in turn, are increased because of reduced estrogen production by the ovaries. This increased ovarian testosterone secretion, coupled with a reduction of estrogen production, and decrease in sex hormone-binding globulin (SHBG) may partly explain the development of symptoms of defeminization, hirsutism, and even virilism occasionally seen in older women.

Levels of the adrenal androgens dehydroepiandrosterone (DHEA) and dehydroepiandrosterone sulfate (DHEAS) are reduced by 60% and 80%, respectively, with age. Whether these reductions are related to the menopause or to aging has not been determined. Again, a marked circadian variation of DHEA has been observed. Whether a similar rhythm is present for DHEAS is unknown. As with younger subjects, the primary source of these 2 androgens is thought to be the adrenal glands, with the ovary contributing <15%. Thus the marked decreases of DHEA and DHEAS reflect altered adrenal androgen secretion, and this phenomenon has been called the *adrenopause*. The mechanism responsible for it is unknown.

In premenopausal women, plasma androstenedione is approximately 1.5 ng/mL. Plasma testosterone is approximately 0.3 ng/mL. Mean DHEA and DHEAS levels are approximately 4 ng/mL and 1600 ng/mL, respectively, in samples drawn at 8:00 AM.

In postmenopausal women, the mean plasma androstenedione concentration is reduced by at least 50%, to approximately 0.6 ng/mL. Plasma testosterone levels are only slightly reduced (to approximately 0.25 ng/mL). Plasma DHEA and DHEAS levels are decreased to mean levels of 1.8 ng/mL and 300 ng/mL in women in their sixties and seventies.

2. Estrogens—After a woman has passed the menopause, there is good clinical evidence of reduced endogenous estrogen production in most subjects. When circulating levels have been assessed, the greatest decrease is in estradiol. Its concentration is distinctly lower than that found in young women during any phase of their menstrual cycle and is similar to the level seen in premenopausal women after oophorectomy. A decrease of this estrogen occurs up to 1 year after the last menstrual period. There does not appear to be a circadian variation of the circulating concentration of estradiol after the menopause. The metabolic clearance rate of estradiol is reduced by 30%. The average production rate is 12 μg/24 h.

The source of the small amount of estradiol found in older women has been established. Direct ovarian secretion contributes minimally, but the adrenal glands are the major source. Investigators who have examined the concentrations of estradiol in adrenal veins have reported minimal increments, arguing against direct adrenal secretion being a major contributor. Although both estrone and testosterone are converted in peripheral tissues to estradiol, it is conversion from estrone that accounts for most estradiol in older women.

After the menopause, the circulating level of estrone decreases—not as much as that of estradiol—and overlaps with values seen in premenopausal women during the early follicular phase in menstrual cycles. There is a circa-dian variation of circulating estrone, with the peak in the morning and the nadir in late afternoon or early evening. This variation is not as prominent as that observed for the androgens. In postmenopausal women, there is a 20% reduction of estrone clearance, and the average production rate is approximately 55 μg/24 h.

The adrenal gland is the major source of estrone. Direct adrenal or ovarian secretion is minimal. Most estrone results from the peripheral aromatization of androstenedione. The average percent conversion is double that found in ovulatory women and can account for the total daily production of this estrogen. Aromatization of androstenedione occurs in fat, muscle, liver, bone marrow, brain, fibroblasts, and hair roots. Other tissues may also contribute but have not been evaluated. To what extent each cell type contributes to total conversion has not been determined, but fat cells and muscle may be responsible for only 30–40%. This conversion correlates with body size, with heavy women having higher conversion rates and circulating estrogen levels than slender women.

During normal menstrual life, the mean plasma estradiol fluctuates from 50–350 pg/mL and estrone from 30–110 pg/mL. In postmenopausal women, the mean estradiol level is approximately 12 pg/mL, with a range of 5–25 pg/mL. The mean estrone level is approximately 30 pg/mL, with a range of 20–70 pg/mL. Estradiol levels in normal young women do not overlap with those observed in postmenopausal subjects. The finding of estradiol levels below 21 pg/mL can be helpful in establishing the diagnosis of menopause, as the fall of this estrogen is the last hormonal change associated with loss of ovarian function. There is substantial overlap of estrone levels in younger and older women. Measurement of this estrogen is not helpful in determining the ovarian status of a patient.

3. Progesterone—In young women, the major source of progesterone is the ovarian corpus luteum after ovulation. During the follicular phase of the cycle, progesterone levels are low. With ovulation the levels rise greatly, reflecting the secretory activity of the corpus luteum. In postmenopausal women, the levels of progesterone are only 30% of the concentrations seen in young women during the follicular phase. Because postmenopausal ovaries do not contain functional follicles, ovulation does not occur and progesterone levels remain low. The source of the small amount of progesterone present in older women is felt to be caused by adrenal secretion, as dexamethasone suppresses its level, adrenocorticotropic hormone (ACTH) increases its level, and human chorionic gonadotropin (hCG) administration has no effect.

In young menstruating women, the mean progesterone level is approximately 0.4 ng/mL during the follicular phase of the cycle, with a range of 0.2–0.7 ng/mL. During the luteal phase, progesterone levels rise and fall, reflecting corpus luteum function; the mean level is approximately 11 ng/mL, with a range of 3–21 ng/mL. In postmenopausal women, the mean progesterone level is 0.17 ng/mL. To date, no clinical use has been established for the measurement of progesterone in postmenopausal women.

4. Gonadotropins—With the menopause, both LH and FSH levels rise substantially, with FSH usually higher than LH. This is thought to reflect the slower clearance of FSH from the circulation. The reason for the marked increase in circulating gonadotropins is the absence of the negative feedback of ovarian steroids and inhibin on gonadotropin release. As in young women, the levels of both gonadotropins are not steady, but instead show random oscillations. These oscillations are thought to represent pulsatile secretion by the pituitary. In older women, these pulsatile bursts occur every 1–2 hours, a frequency similar to that seen during the follicular phase of premenopausal subjects. Although the frequency is similar, the amplitude is much greater. This increased amplitude is secondary to increased release by the hypothalamic hormone gonadotropin-releasing hormone (GnRH) and enhanced responsiveness of the pituitary to GnRH because of low estrogen levels. Studies with rhesus monkeys suggest that the site governing pulsatile GnRH release is in the arcuate nucleus of the hypothalamus. The large pulses of gonadotropin in the peripheral circulation are believed to maintain the high levels of the hormones found in postmenopausal women.

During reproductive life, the levels of both FSH and LH range from 4–30 mU/mL, except during the preovulatory surge, when they may exceed 50 mU/mL and 100 mU/mL, respectively. After the menopause, both rise to levels above 100 mU/mL, with FSH rising earlier and to higher levels than LH.

When contradictory or uncertain clinical findings make the diagnosis of the postmenopausal state questionable, measurement of plasma FSH, LH, and estradiol levels may be helpful. This situation occurs frequently in women after hysterectomy without oophorectomy. The findings of plasma estradiol below 20 pg/mL and elevated FSH and LH levels are consistent with cessation of ovarian function. In practical terms, it is not necessary to measure LH.

D. Physical Changes Associated with the Menopause

1. Reproductive tract—Because estrogen functions as the major growth factor of the female reproductive tract, there are substantial changes in the appearance of all the reproductive organs. Most postmenopausal women experience varying degrees of atrophic changes of the vaginal epithelium. The vaginal rugae progressively flatten and the epithelium thins. This may lead to symptomatic atrophic vaginitis (see Atrophic Vaginitis).

There are also atrophic changes of the cervix. It usually decreases in size, and the canal may become stenotic. There is a reduction of secretion of cervical mucous. This may contribute to excessive vaginal dryness, which may cause dyspareunia.

Atrophy of the uterus is also seen, with shrinkage of both the endometrium and myometrium. This shrinkage can be beneficial to women who enter the climacteric with uterine myomas. Reduction in size and elimination of symptoms frequently prevent the necessity for surgical treatment. The same applies to adenomyosis and endometriosis, both of which usually become asymptomatic after the menopause. Palpable and symptomatic areas of endometriosis generally become progressively smaller and less troublesome. With cessation of follicular activity, hormonal stimulation of the endometrium usually ceases. Endometrial biopsy may reveal anything from a very scanty, atrophic endometrium to one that is moderately proliferative. Spontaneous postmenopausal bleeding may occur in the presence of any of these patterns. Endometrial tissue revealing glandular hyperplasia (with or without uterine bleeding) is an indication of enhanced estrogenic stimulation from either endogenous estrogen production (eg, increased conversion of androgen) or from exogenous intake of estrogen.

The oviducts and ovaries also decrease in size postmenopausally. Although this produces no symptoms, the small size of the ovaries makes them difficult to palpate during pelvic examination. A palpable ovary in a postmenopausal woman must be viewed with suspicion, and the presence of an ovarian neoplasm must be considered.

The supporting structures of the reproductive organs suffer loss of tone as estrogen levels decline. Postmenopausal estrogen deficiency may be associated with symptomatic progressive pelvic relaxation.

2. Urinary tract—Estrogen plays an important role in maintaining the epithelium of the bladder and urethra. Marked estrogen deficiency may produce atrophic changes in these organs similar to those that occur in the vaginal epithelium. This may give rise to atrophic cystitis, characterized by urinary urgency, frequency, incontinence, and dysuria. Recurrent urinary tract infection may also develop in the setting of estrogen deficiency. Loss of urethral tone, with pouting of the meatus and thinning of the epithelium, favors the formation of a urethral caruncle with resultant dysuria, meatal tenderness, and occasionally hematuria. Treatment of symptomatic women involves topical vaginal estrogen (see Estrogen Therapy).

3. Mammary glands—Regression of breast size during and after menopause is psychologically distressing to some women. For those who have been bothered by cyclic symptoms of breast pain and cyst formation, the disappearance of these symptoms postmenopausally is a great relief.

Prevention of Menopause

Nothing can prevent the physiologic menopause (ie, ovarian function cannot be prolonged indefinitely), and nothing can be done to postpone its onset or slow its progress. However, artificial menopause can often be prevented. When ionizing radiation is used for the treatment of intraabdominal disease, incidental ablation of ovarian function often cannot be avoided. In such cases, if an operation will serve equally well to treat intraabdominal disease, it should be used in preference to radiation therapy in order to preserve the ovaries.

Elective removal of the ovaries to prevent ovarian cancer is frequently performed at laparotomy or laparoscopy in premenopausal women, with deliberate acceptance of artificial menopause. This form of therapy is increasingly used in women with genetic predisposition to breast and ovarian cancer. However, in low-risk women this remains controversial.

Clinical Conditions Associated with Menopause

A. Atrophic Vaginitis

1. Pathogenesis—As the epithelium thins after menopause, the capillary bed shines through as a diffuse or patchy reddening. Rupture of surface capillaries produces irregularly scattered petechiae, and a brownish discharge may be noted. Further atrophy of the vaginal epithelium renders its capillary bed increasingly sparse, so that the hyperemic appearance gives way to a smooth, shiny, pale epithelial surface. The epithelium lacks glycogen, which leads to a reduction in lactic acid production and an increase in the vaginal pH to 5.0–7.0. This is associated with disappearance of lactobacilli. Early in the process, local bacterial invasion may initiate vaginal pruritus and leukorrhea. Vaginal burning, soreness, dyspareunia, and a thin watery or serosanguineous discharge may also occur. Minimal trauma with examinations or coitus may result in slight vaginal bleeding. Urinary complaints, including urinary frequency, urgency, dysuria, and urge incontinence, have also been described in association with atrophic vaginitis.

2. Diagnosis—There is no specific test that reliably quantifies the degree of atrophy. Clinical decision making is therefore generally based on patient symptomatology and findings on physical examination. However, vaginal cytology has been used to assist in the diagnosis of atrophic vaginitis. The degree of maturation of exfoliated vaginal epithelial cells, as revealed by stained vaginal smears, is an index of estrogenic activity. Among the various methods of assessing the smears, the following are most commonly used: the **maturation index** consists of a differential count of 3 types of squamous cells—parabasal cells, intermediate cells, and superficial cells, in that order—expressed as percentages (eg, 10/85/5); a greater percentage of parabasal cells reflects a greater degree of atrophy. The **cornification count** is the percentage of precornified and cornified cells among total squamous cells counted. This is actually a simplified maturation index, because this percentage is essentially the same as that of the superficial cells.

The assessment of exfoliated vaginal epithelial cells is influenced not only by the level of estrogenic activity, but also by other hormones (particularly progesterone and testosterone), local vaginal inflammation, local medication, vaginal bleeding, the presence of genital cancer, the location of the vaginal area sampled, and variations in end-organ (epithelial) responses to estrogenic influence. Thus women with identical levels of circulating estrogens may have quite different cytograms.

The great variation in cytologic findings leads to the following conclusions regarding the use of smears in the clinical management of postmenopausal women: (1) the smear is only a rough measure of estrogenic status, and it may sometimes be grossly misleading. (2) The vaginal cytogram cannot predict whether or not an individual woman is experiencing menopausal signs and symptoms. (3) The smear cannot be used as the sole guide to steroid supplementation therapy; clinical signs and symptoms are more dependable for this purpose.

3. Treatment—Symptomatic atrophic vaginitis may be managed with water-soluble lubricants and/or topical vaginal estrogens, which are available in the form of creams, tablets, or estradiol-releasing rings (see Estrogen Therapy). Systemic estrogens are also effective in the treatment of atrophic vaginitis, but vaginal preparations are preferred when estrogen therapy is being used solely for the treatment of vulvovaginal atrophy.

B. Hot Flushes

1. General considerations—The most common and characteristic symptom of the climacteric is an episodic disturbance consisting of sudden flushing and perspiration, referred to as a **hot flash** or **flush**.

It is observed in approximately 75% of women who go through the physiologic menopause or have a bilateral ovariectomy. Of those having flushes, 82% experience the disturbance for more than 1 year, and 25–50% complain of the symptom for more than 5 years. Most women indicate that hot flushes begin with a sensation of pressure in the head, much like a headache. This increases in intensity until the physiologic flush occurs. Palpitations may also be experienced. The actual flush is characterized as a feeling of heat or burning in the face, neck, and chest, followed immediately by an outbreak of sweating that affects the entire body but is particularly prominent over the head, neck, upper chest, and back. Less common symptoms include weakness, fatigue, faintness, and vertigo. The duration of the whole episode varies from momentary to as long as 10 minutes; the average length is 4 minutes. The frequency varies from 1–2 per hour to 1–2 per week. In women with severe flushes, the mean frequency is 54 minutes.

Investigators have characterized the physiologic changes associated with hot flushes and have shown that the symptoms result from true alterations in cutaneous vasodilation, perspiration, reductions of core temperature, and elevations of pulse rate. Fluctuations in electrocardiographic data probably reflect changes in skin conductance. Changes in heart rhythm and blood pressure have not been observed.

The patient’s awareness of symptoms does not correspond exactly with physiologic changes. Women become conscious of symptoms approximately 1 minute after the onset of measurable cutaneous vasodilation, and discomfort persists for an average of 4 minutes, whereas physical changes persist for several minutes longer.

2. Pathogenesis—The exact mechanism responsible for hot flushes is unknown, but physiologic and behavioral data indicate that symptoms result from a defect in central thermoregulatory function. Several observations support this conclusion: (1) the 2 major physiologic changes associated with hot flushes—perspiration and cutaneous vasodilation—are the result of different peripheral sympathetic functions. Excitation of sweat glands results from sympathetic cholinergic fibers, and cutaneous vasodilation is under the control of tonic α-adrenergic fibers. It seems unlikely that any peripheral event could cause both cholinergic excitation of sweat glands and α-adrenergic blockade of cutaneous vessels, and it is well recognized that these are the 2 basic functions triggered by central thermoregulatory mechanisms that lower the central temperature. (2) During a hot flush, the central temperature decreases because of cutaneous vasodilation and perspiration. If hot flushes were the result of some peripheral event, the body’s regulatory mechanisms would be expected to prevent such a decrease. (3) There is also a change in behavior associated with hot flushes. Women feel warm and have a conscious desire to cool themselves by throwing off the bedcovers, standing by open windows or doors, fanning themselves, or by other means. This behavior is observed even in the presence of a steady or decreasing central temperature.

Most investigators believe the core temperature of the body is maintained near a central set point that is controlled by central thermoregulatory centers, particularly those in the rostral hypothalamus. This central set point temperature is analogous to a thermostat setting. Hot flushes appear to result from a narrowing of the thermoregulatory set point such that smaller than normal increases in core body temperature activate heat loss responses. As a consequence, heat loss mechanisms, both physiologic and behavioral, are activated so that the core temperature will be brought in line with the new set point; this results in a fall of central temperature.

Because hot flushes occur after the spontaneous cessation of ovarian function or following oophorectomy, it is presumed that the underlying mechanism is initiated through endocrinologic changes related primarily to ovarian estrogen withdrawal. Low estrogen levels alone do not appear to trigger hot flushes; prepubertal children and patients with gonadal dysgenesis have low estrogen levels but not flushing. Patients with gonadal dysgenesis do experience symptoms if they are given estrogens that are later withdrawn. Thus it appears that estrogen must be present and then withdrawn for hot flushes to be experienced.

Changes in central nervous system (CNS) concentrations of norepinephrine (NE) and serotonin likely play an important role in the development of hot flushes. Animal and human studies indicate that NE plays an important role in the etiology of hot flushes. Increased levels of NE have been correlated with a narrowing of the thermoneutral zone, and it has been demonstrated that plasma levels of metabolites of NE increase after a hot flush. In addition, use of pharmacologic agents that alter central noradrenergic activity (ie, clonidine, serotonin and norepinephrine reuptake inhibitors [SNRIs]) have been shown to lessen the severity and/or frequency of vasomotor symptoms.

Studies also suggest a role for serotonin in the development of vasomotor symptoms. Serotonin is thought to be important in thermoregulation, as studies have shown an increase in stimulation of serotonin receptors after a thermostimulus, which then results in sensation of a hot flush. In addition, an association between serotonin levels and severity of vasomotor symptoms in menopausal women has been demonstrated. Finally, the selective serotonin reuptake inhibitors (SSRI) class of drugs has been shown to be effective in the management of vasomotor symptoms in postmenopausal women.

A close temporal association between the occurrence of flushes and the pulsatile release of LH has been demonstrated. However, the observation that flushes occur after hypophysectomy suggests that they are not directly caused by LH release. The appearance of hot flushes in women with defects in GnRH release or synthesis (Kallmann’s syndrome) also suggests GnRH itself is not involved in the flushing mechanism. The absence of hot flushes in women with hypothalamic amenorrhea and hypoestrogenemia is intriguing. These women have defects in neurotransmitter or neurochemical input to their GnRH neurons. In particular, excessive endogenous opioid and dopamine input to GnRH neurons may account for chronic suppression of GnRH release, leading to hypothalamic amenorrhea. The absence of hot flushes in these women suggests that altered afferent input of neurotransmitters or neurochemicals to the GnRH neuron that is secondary to hypogonadism leads to hot flushes.

Hot flushes are a greater annoyance than most physicians recognize. Patients frequently complain of night sweats and insomnia. There is a close temporal relationship between the occurrence of hot flushes and nighttime awakening. Women with frequent flushes may experience flushes and awakening episodes hourly, which may cause a profound sleep disturbance that may, in turn, cause cognitive (memory) and affective (anxiety) disorders in some women.

3. Treatment—Estrogens are the principal medications used to relieve hot flushes. Estrogens block both the perceived symptoms and the physiologic changes. Their use also relieves some aspects of the sleeping disorder. Estrogen administration has been shown to enhance hypothalamic opioid activity in postmenopausal women. This increase of hypothalamic opiates may be involved in the relief of hot flushes with estrogen administration.

Progestins also block hot flushes and represent a reasonable form of substitutional therapy in women who cannot take estrogens. However, because addition of progestins to hormone therapy has been associated with an increased risk of breast cancer, a progestogen would not be the ideal alternative to estrogen for women who are seeking to avoid effects on breast disease. **Clonidine,** a centrally acting alpha agonist, is more effective than a placebo but is associated with side effects. More recently, certain **SSRIs and SNRIs** have been shown to be effective in the treatment of hot flashes. Their side effects may limit their overall benefit, but they are one of the first alternative choices in women who are not taking estrogen. Certain SSRIs may also affect the metabolism of tamoxifen to its active metabolite through the enzyme, CYP2D6, a member of the cytochrome P450 oxidase enzyme system. SSRIs such as paroxetine and fluoxetine have been associated with increased breast cancer recurrence and/or death amongst women using tamoxifen. Therefore, until further studies are available, caution must be used when using SSRIs, particularly paroxetine and fluoxetine, in women receiving tamoxifen. **Black cohosh** may have modest effects in decreasing hot flashes, but concerns remain regarding its potential to stimulate breast and uterine tissue. **Gabapentin** also decreases hot flashes by 50–80% and is therefore comparable to estrogen according to certain studies. However, sedation is a major side effect that limits its acceptability for many women. Small doses at night may be useful for women suffering from night-time awakening due to vasomotor symptoms. **Tibolone** is a synthetic steroid with estrogenic, progestogenic, and androgenic properties that alleviates menopausal symptoms and has been used in other countries for this purpose, as well as to preserve bone mineral density. However, its long-term safety profile with regard to breast and endometrial cancer remains controversial. Its mechanism of action would suggest that it is unlikely to increase the risk of breast cancer. However, the Million Women Study reported an increased risk of breast cancer among participants using tibolone as compared with controls. In addition, tibolone was associated with an increased risk of breast cancer recurrence in a randomized trial of breast cancer patient using tibolone for relief of vasomotor symptoms. Tibolone’s action on the endometrium also suggests that it is unlikely to cause endometrial proliferation. This is supported by findings from studies demonstrating a low incidence of vaginal bleeding and an absence of endometrial hyperplasia on histology. However, rates of endometrial cancer were also increased in the Million Women Study. Further study is required to ascertain whether tibolone can be used long term without increased risks for breast and endometrial cancer. Tibolone’s potential to modify risk for cardiovascular disease is also unknown. However, a study evaluating the effect of tibolone on myocardial blood flow demonstrated that tibolone improved myocardial blood flow in women with ischemic heart disease. Vitamins E and K, mineral supplements, and phytoestrogens have all been tried to alleviate menopausal symptoms, but have not been proven beneficial. Many women express a preference for **bioidentical hormones (BHT)**, with the expectation that they are safer, with comparable efficacy. The term may be used to describe varying formulations and therefore is not used consistently amongst patients or practitioners. For some, the term refers to hormones that are chemically identical to those produced by humans and includes formulations that are well-tested, US Food and Drug Administration (FDA)– approved brand names. For the majority of others, the term refers to custom-made hormone formulations that provide different doses and routes of administration of estrogens and progestogens. These compounded formulations are not subject to the same regulatory approval process as brand name formulations, and therefore safety, efficacy, and consistency are in no way assured. Cost to the patient can also be greater for these compounded formulations because they are often not covered by third-party payers. The FDA has declared that claims of compounding pharmacies stating that BHT drugs avoid the risks of FDA-approved treatments and these drugs reduce the risk of serious illness such as heart disease, stroke, or breast cancer are not supported by credible scientific evidence. They further state that safety and efficacy of estriol in these formulations has not been proven. Therefore, incorporation of estriol into these formulations may not occur without an investigational new drug authorization. According to the 2010 North American Menopause Society position statement: “Filled prescriptions for BHT should include a patient package insert identical to that required for products that have regulatory-agency approval. In the absence of efficacy and safety data for any specific prescription, the generalized benefit-risk ratio data of commercially available HT products should apply equally to BHT.”

C. Osteoporosis

1. General considerations—Osteoporosis is defined as a systemic skeletal disorder characterized by low bone mass and microarchitectural deterioration of bone tissue, with a consequent increase in fragility of bone and susceptibility to risk of fracture. Although gradual bone loss occurs in all humans with aging, this loss is accelerated in women after cessation of ovarian function. After attainment of peak bone mass by age 25–30 years, bone loss begins, accelerates in women at menopause, and then slows again but continues into advanced years at a rate of 1–2% per year (Fig. 59–3). Women can lose up to 20% of their bone mass in the 5–7 years after menopause.

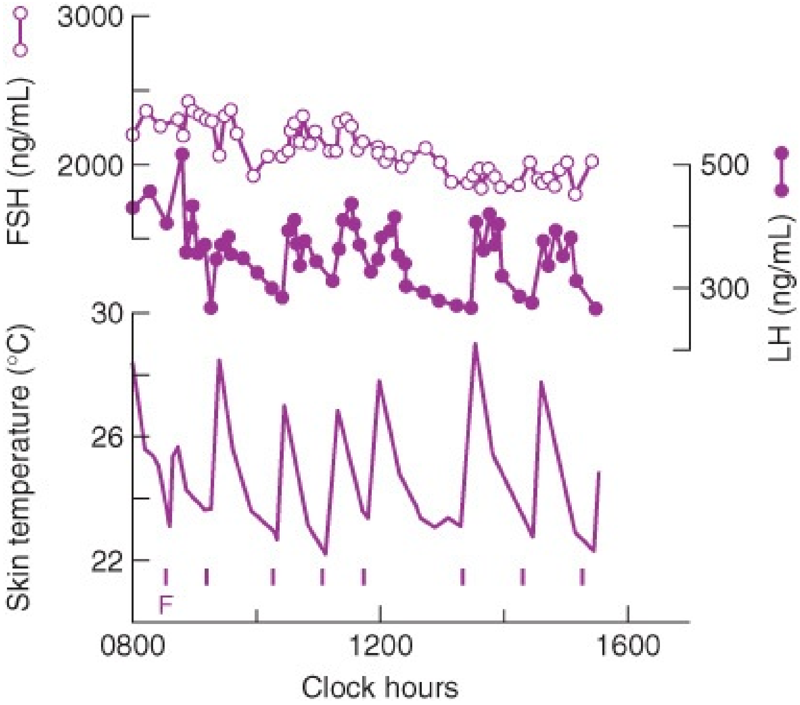

Figure 59–3. Changes in metacarpal cortical width, as determined by sequential measurements in pre- and postmenopausal women, age range 30–50 years. Note bone loss in postmenopausal women. (Reproduced, with permission, from Nordin BEC, et al. Postmenopausal osteopenia and osteoporosis. *Front Horm Res* 1975; 3:131.)

Osteoporosis affects an estimated 10 million Americans 50 years of age or older, 80% of whom are women. Of Americans 50 years of age or older, 34 million are estimated to have low bone mass at the hip, placing them at increased risk for osteoporosis. Osteoporosis is most severe in women who have had early oophorectomy or premature ovarian failure, and in those with gonadal dysgenesis. Osteoporosis occurs most often in whites, followed by Asians, Hispanics, and African Americans.

Bone loss produces minimal symptoms, but leads to reduced skeletal strength. Thus osteoporotic bones are more susceptible to fractures. The most common sites of fracture are in the vertebral body, proximal femur, and distal forearm/wrist. Recent figures from the National Osteoporosis Foundation show that osteoporosis is responsible for more than 1.5 million fractures per year. Due to the aging population, the prevalence of osteoporosis is expected to increase such that by 2020, 1 in 2 Americans is expected to have or be at risk for osteoporosis of the hip. Approximately 1 in 2 women older than the age of 50 years will have an osteoporosis-related fracture in her remaining lifetime. The incidence of hip fractures in women is 2–3 times that in men. The mortality rate associated with hip fractures is between 10 and 20% within 12 months after the injury. Of survivors, 15–25% are permanently disabled. The estimated cost for osteoporosis-related fractures in the United States totals more than $17 billion per year. According to the Surgeon General, these costs could double or triple by the year 2040.

Risk factors include certain lifestyle choices (ie, increased caffeine intake, smoking, excessive alcohol intake, lack of exercise, lifetime of low calcium intake), hormonal factors (ie, estrogen deficiency from menopause, eating disorders), genetic factors (ie, family history, cystic fibrosis, Ehlers Danlos), endocrinologic disorders (hyperparathyroidism, adrenal insufficiency, hyperthyroidism), medical disorders (ie, lupus, malabsorption syndromes, lymphoma), medication use (ie, corticosteroids, chemotherapy, excess thyroid supplementation), vitamin D deficiency, slender body size, and advanced age.

2. Pathogenesis—Bone loss occurs because bone resorption is excessive, bone formation is decreased, peak bone mass is low, or a combination of all 3 factors. Bone remodeling is regulated by many factors, including systemic hormones, local cytokines, prostaglandins, and local growth factors. Of the systemic hormones, sex steroids, parathyroid hormones, glucocorticoids, thyroid hormones, and growth hormone/insulinlike growth factors likely play a role.

Ovarian estrogen and estrogen administered postmenopausally are protective against osteoporosis. The exact mechanisms by which estrogen regulates bone remodeling are incompletely understood. Estrogens likely modulate osteoclast and osteoblast function possibly via effects on cytokines and growth factors such as transforming growth factor-β and tumor necrosis factor-α (TNF-α). Estrogens may decrease the depth of erosion of osteoclasts.

Interleukin-1 (IL-1) and TNF-α derived from bone marrow macrophages stimulate bone resorption and may inhibit bone formation. There is evidence to suggest they may be regulated by estrogen, as IL-1 activity in bone increases immediately after the menopause or oophorectomy. Furthermore, it has been shown in animal models that inhibition of IL-1 and TNF-α after ovariectomy attenuates bone loss. IL-6 and prostaglandins, especially prostaglandin E_2, are also involved in bone remodeling and are regulated by sex steroids. Other factors, such as insulin-like growth factor and fibroblast growth factor, also likely play a role in the pathogenesis of osteoporosis and may be regulated by sex steroids.

Androgens play a role in bone remodeling as androgen deficiency is associated with increased bone loss. The precise mechanism by which androgens alter bone remodeling is unknown but may involve conversion to estrogen. For example, men with aromatase deficiency have an elevated risk of developing osteoporosis, possibly due to decreased conversion of androgen to estrogen.

Progestogens may affect bone remodeling in a similar way to estrogens and androgens, but the mechanisms underlying these effects are not well understood. It is possible that they work through glucocorticoid receptors.

Parathyroid hormone (PTH) also plays a role in bone remodeling. PTH stimulates bone resorption, and absence of this hormone inhibits development of osteoporosis in animal and human studies. Thus far, it does not appear that PTH is elevated in most women with osteoporosis or that the sensitivity of bone to PTH is enhanced. It is interesting that the amino-terminus of PTH (1-34) inhibits bone resorption.

Thyroid hormones increase bone resorption. The exact mechanism is not fully understood, but possibly involves accelerated osteoclast function and altered calcium metabolism.

Growth hormone stimulates bone remodeling; however, studies evaluating the effect of exogenous growth hormone administration on established osteoporosis are inconclusive. Recently, new factors were discovered that are involved with the regulation of bone remodeling: osteoprotegerin, a naturally occurring protein, and RANKL (receptor activator of nuclear factor kappa beta ligand) both regulate osteoclastogenesis and bone resorption.

Genetic factors may also affect risk for osteoporosis. Variants in the estrogen receptors α and β expressed in bone are associated with altered risk for osteoporosis and fracture. Variants in the vitamin D receptor gene and bone morpho-genetic protein 2 may also play a role in the pathogenesis of osteoporosis.

3. Diagnosis & monitoring—Although much has been done to study urinary and serum factors as predictors of osteoporosis, the most predictive test remains bone densitometry with dual-energy x-ray absorptiometry (DXA). Results are given in grams or g/cm^2. In 1994, the World Health Organization created a clinically useful definition of osteoporosis. Bone mineral density (BMD) results are reported using T and Z scores. The T score is the number of standard deviations (SD) above or below the mean bone mineral density for sex-matched young normal controls. The Z score compares the patient with an age- and sex-matched population. Normal bone density is defined as a T score > –1.0 SD at the spine, hip or forearm. Osteopenic patients have T scores between –1.0 and –2.5, whereas osteoporotic patients have T scores below –2.5. In most studies, a decrease by 1 SD in mass increases the risk of fracture 2–3-fold. In postmenopausal women, the WHO T-score criteria should be applied. In premenopausal women, WHO BMD criteria should not be applied and other criteria should be used (ie, ethnic or race adjusted Z-scores, with –2.0 indicating low bone density for chronologic age).

Assessment of risk factors has not been nearly as predictive of fracture risk as density measurement. Similarly, assessment of biochemical markers of bone turnover have not been shown to be useful for diagnosing osteoporosis but may give some indication of future risk for fracture and/or be useful for monitoring response to antiresorptive therapy. Markers of bone formation include serum bone-specific alkaline phosphatase and osteocalcin. Markers of bone resorption include serum C-telopeptide (CTX) and urinary N-telopeptide (NTX).

National Osteoporosis Foundation has created a set of guidelines for the use and interpretation of measurement of bone mineral density. Measurements of bone mineral density are recommended for the following groups: (1) all post-menopausal patients younger than age 65 years who have ≥1 additional risk factors for osteoporosis (other than being white, postmenopausal, and female); (2) all women age 65 years and older regardless of additional risk factors; (3) postmenopausal women who present with fractures; (4) women considering therapy for osteoporosis if testing would facilitate the decision; (5) women who have been on hormone replacement therapy for prolonged periods; (6) women who have been on treatment to monitor the treatment effect; and (7) women considering discontinuation of treatment.

Another tool to assess risk and guide treatment is the Fracture Risk Algorithm (FRAX). This tool incorporates BMD, as well as other factors, to assess 10-year probability of hip fracture and 10-year probability of major osteoporotic fracture. It is most useful in patients with low hip BMD as opposed to low spine BMD. Special consideration needs to be taken into account for patients with normal hip BMD but low spine BMD, as FRAX incorporates hip BMD measurements. It is also intended for postmenopausal women, not for younger women. Therapy can be considered in patients with a 10-year probability of hip fracture of ≥3% and 10-year probability of major osteoporosis-related fracture of ≥20%. The FRAX calculator can be accessed at http://www.shef.ac.uk/FRAX/tool.jsp?locationValue=9.

4. Prevention and treatment—All individuals at risk for or who have been diagnosed with osteoporosis should be advised to consume adequate **calcium** (minimum of 1200 mg elemental calcium per day). The National Osteoporosis Foundation recommends **vitamin D** (800–1000 IU/d). Smoking cessation, avoidance of excessive alcohol intake, and participation in regular weight-bearing and muscle strengthening exercise should be encouraged. Pharmacologic therapy should be strongly considered in women with a hip or vertebral fracture, in women with BMD scores below –2.5 with no risk factors, and in women with BMD T-scores below –1.0 with a 10-year probability of hip fracture of ≥3% or a 10-year probability of major osteoporotic fracture of ≥20%. Current pharmacologic therapy for osteopenia/osteoporosis, listed in alphabetical order, includes (1) **bisphosphonates**, (2) **calcitonin**, (3) **estrogens** (with or without progestogens), (4) **parathyroid hormone**, (5) **raloxifene**, and (6) **denosumab**.

Bisphosphonates are excellent choices for prevention and treatment of osteoporosis. They are potent antiresorptive agents that bind to hydroxyapatite crystals on the surface of bones, enter osteoclasts, and decrease resorptive actions by reducing the production of hydrogen ions and lysosomal enzymes. In addition, they have indirect effects, causing osteoblasts to produce substances that inhibit osteoclasts. They increase bone mineral density at the spine, wrist, and hip in a dose-dependent manner and decrease the risk of vertebral fractures by 30–50%. In addition, they reduce the risk of subsequent nonvertebral fractures in women with osteoporosis. There are 4 bisphosphonates currently available for oral administration. **Alendronate** is approved by the FDA for the prevention of osteoporosis (5 mg daily and 35 mg weekly) and for the treatment of established osteoporosis (10 mg daily or 70 mg weekly). **Risedronate** is approved by the FDA for prevention and treatment of postmenopausal osteoporosis. The recommended daily dose is 5 mg daily or 35 mg weekly. **Ibandronate** is approved for both prevention and treatment of postmenopausal osteoporosis. It has the advantage of being available in an oral daily (2.5 mg) and oral monthly (150 mg) dosing regimen, as well as an intravenous regimen of 3 mg given every 3 months. The 2.5-mg daily and 150-mg monthly oral doses are approved for prevention and treatment of osteoporosis. The 3-mg intravenous dose is approved for treatment of osteoporosis. **Zoledronic acid** is approved for prevention and treatment of osteoporosis in postmenopausal women. It is given as 5-mg intravenous infusion over 15 minutes once yearly for treatment or once every 2 years for prevention. Intestinal absorption of bisphosphonates is poor, and therefore these medications should be taken in the morning with 8 ounces of water, before consumption of any food or beverage. Nothing else should be taken by mouth for at least 30–60 minutes after oral dosing. The patient should also remain upright for 30 minutes after administration. The most common side effects of bisphosphonates are gastrointestinal. Pain in the joints, bone, and muscle may also occur. Risks include gastric and esophageal ulceration and, rarely, osteonecrosis of the jaw. Most cases of osteonecrosis of the jaw have been described in cancer patients being treated with intravenous bisphosphonates, but some cases have occurred in patients being managed for postmenopausal osteoporosis. Some studies suggest an increased risk of esophageal cancer following bisphosphonate use, but others do not. Further study is needed to assess whether there is a direct link between use of bisphophonates and esophageal cancer. More recently, an increase in the risk of atypical fracture of the femur has been reported in women using bisphosphonates for >5 years. The risk is probably small, but should be discussed with patients who are considering use of this class of drug, or who have been using these drugs for prolonged periods of time. The FDA has required a labeling change of bisphosphonates to reflect this risk and will continue to monitor these outcomes closely. Clinicians and patients should be aware that diagnosis of these atypical fractures has been preceded by new onset thigh or groin pain.

Calcitonin is a peptide hormone that inhibits osteoclast activity and therefore inhibits bone resorption. It demonstrates positive effects on bone mineral density at the lumbar spine, although less effectively than estrogen or bisphosphonates. Salmon calcitonin is the most potent form and is available for intranasal administration or as a subcutaneous injection. Calcitonin 100 IU is given subcutaneously daily or every other day; the intranasal calcitonin dose is 200 IU daily. The most frequent side effect with the intranasal route is rhinitis. Other antiresorptive therapies, such as bisphosphonates, are preferred over calcitonin, as they produce greater increases in bone mineral density. However, because of calcitonin's analgesic properties, calcitonin is the preferred therapy in patients with pain from vertebral fracture.

Until recently, **estrogen** was the mainstay of therapy for prevention and treatment of postmenopausal osteoporosis. However, with the findings from the Women's Health Initiative (WHI) trial demonstrating overall greater health risks than benefits from hormone therapy, it is no longer first-line therapy for prevention of osteoporosis. Osteoporosis prevention does remain an FDA-approved indication for estrogen therapy, however. It is best used in women who would otherwise use estrogen/hormone therapy for management of menopausal symptoms, or in women who cannot tolerate alternate antiresorptive therapies.

In observational studies, estrogen decreases the risk of hip fractures by 25–50%, of vertebral fractures by approximately 50%, and reduces the risk of other fractures. Daily dosages of 0.3–0.625 mg of conjugated estrogens, 0.5–1 mg of micronized estradiol, 1.25 mg of piperazine estrone sulfate, 0.025–0.05 mg of transdermal estradiol, and a new low dose (0.014 mg) of transdermal estradiol all are appropriate for the prevention of osteoporosis. The lower doses (ie, 0.3 mg of conjugated equine estrogens) are not as effective as higher doses but do prevent bone loss. For best results, therapy should begin soon after the menopause.

Parathyroid hormone, teriparatide (**PTH [1-34]**) has been approved by the FDA for use in women and men who are at high risk for fracture, including those with previous fracture, multiple risk factors for fracture, and previous failed treatment. Despite its potential deleterious effect on bone, intermittent administration of recombinant PTH stimulates bone formation, and clinical trials support its use in the treatment of osteoporosis. It should only be used in high-risk patients because of its high cost, the need for daily injection, and a possible risk for osteosarcoma.

Selective estrogen receptor modulators (**SERMs**) are nonhormonal agents that bind to estrogen receptors and may exhibit either estrogen agonist or antagonist activity. Currently, there are 3 SERMs approved for use in humans (tamoxifen, toremifene, and raloxifene); however, raloxifene is the only SERM approved for the prevention and treatment of osteoporosis. It exhibits estrogen agonist properties in the bone (inhibits osteoclast function) and the liver (decreases low-density lipoprotein cholesterol) and acts as an antagonist in the breast and uterus. Raloxifene 60 mg daily for 24 months is associated with a 1–2% increase in lumbar spine and hip bone density.

Combination Therapy has been evaluated in the prevention and/or treatment of osteoporosis. This typically takes the form of a bisphosphonate (ie, alendronate) and systemic estrogen. Small increases in BMD have been seen with combination therapy, but the effect on fracture risk is unknown.

Other therapies have been proposed for osteoporosis treatment and prevention, some without proven benefit. **Progestins** decrease biochemical markers of bone resorption and preserve bone density. When used as monotherapy for osteoporosis, they may be more effective at preserving bone in the wrist than in the spine.

Fluoride has been used in Europe and the United States and is associated with a marked increase in trabecular bone, but did not improve fracture rates, and in some studies fracture rates were increased. This may be a result of a lack of increase in cortical bone. Sodium fluoride is generally not recommended for the treatment of osteoporosis.

Phytoestrogens are plant-derived compounds that have weak estrogen-like effects. Although some animal studies are promising, no effects on the incidence of fractures in humans have been shown.

Tibolone (see Hot Flushes) also increases lumbar spine and femoral neck bone density. Its effects on bone are comparable to those of estrogens. As discussed previously, however, issues regarding long-term safety are currently being evaluated.

D. Sexual Dysfunction

The determinants of sexual behavior are complex and interrelated. Sexual function is believed to be regulated by 3 general components: the individual's motivation (also called desire or libido), endocrine competence, and socio-cultural beliefs. Decreased libido is reported with increasing age. However, the relative contributions of the primary decrease in desire, anatomic limitations to sexual function, or beliefs that sexual behavior is inappropriate in older women to this decreased libido are unknown.

The hypoestrogenemic state leads to atrophy of the internal genitalia. Although dyspareunia is the most obvious symptom of vaginal atrophy, suboptimal sexual functioning can occur without frank dyspareunia. Diminished genital sensation (and therefore decreased sensory output in the arousal phase), lessened glandular secretions, less vasocongestion, and decreased vaginal expansion may not be perceived as discrete symptoms by the postmenopausal female, but may influence her perception that she is less responsive.

Genital atrophy, one cause of postmenopausal sexual dysfunction, responds to estrogen therapy. The specific impact of estrogen on libido has been difficult to determine. Improved anatomy may also have a positive psychologic impact and may indirectly encourage sexual motivation.

The role of androgen therapy in female sexual dysfunction is an active area of investigation. Despite the fact that the postmenopausal ovary continues to be a major source of androgens for several years after menopause, androgen levels overall are decreased, and this may contribute to the decrease in libido seen during menopause. Furthermore, the addition of testosterone to hormone therapy has been shown to improve sexual function in women in randomized, placebo controlled trials. However, improvements in sexual function have been modest at best. In addition, long-term safety has not been established. Some studies have suggested an increased risk of breast cancer amongst women using androgens. Therefore, its use remains controversial.

Differential Diagnosis of Common Signs and Symptoms During Menopause

Signs and symptoms similar to those of the climacteric can be caused by a variety of other diseases. In general, seeing the entire clinical picture is helpful in establishing the proper diagnosis. The absence of evidence of other disease points to cessation of ovarian function, whereas the presence of prominent features of other conditions, in the absence of other climacteric symptoms, suggests a nonclimacteric origin.

A. Amenorrhea

By definition, the primary symptom of the menopause is the absence of menstruation for 12 months. Amenorrhea can occur for many reasons, of which physiologic menopause is only one. Cessation of ovarian function is by far the most common reason for amenorrhea to occur in women in their forties or early fifties. Persistent amenorrhea in younger women may be a result of premature cessation of ovarian function, but must be differentiated from other causes. Obvious features of specific disease often suggest the proper diagnosis (ie, extreme weight loss in anorexia nervosa, galactorrhea in hyperprolactinemia, hirsutism and obesity in polycystic ovarian disease).

B. Hot Flashes

Several diseases can produce sensations of flushing that may be misinterpreted as menopausal vasomotor symptoms. Notable are hyperthyroidism, pheochromocytoma, carcinoid syndrome, diabetes mellitus, tuberculosis, and other chronic infections. None of these disorders produces the specific symptoms associated with the climacteric (ie, short duration and specific body distribution). Moreover, the absence of other signs or symptoms of the climacteric suggest some other cause of the flushes should be sought.

C. Abnormal Vaginal Bleeding

Before the menopause, irregular vaginal bleeding is expected and does not necessitate a diagnostic workup in many cases. However, organic disease can occur at this time, and some patients require evaluation. If a woman is in her forties or fifties and experiences an increase in cycle length and a decrease in the quantity of bleeding, menopausal involution can be presumed, and endometrial sampling is usually not necessary. However, if menses become more frequent and heavier, spotting between menses occurs, or any pattern of irregular bleeding persists, assessment of the endometrium should be performed. The usual procedure is an endometrial biopsy or dilatation and curettage (D&C) to rule out endometrial hyperplasia or cancer. The disadvantage of the former is that entry into the endometrial cavity may not be accomplished in the setting of a stenotic os, and the drawbacks of the latter are greater expense, risk and need for anesthesia.

It is most unusual for a woman to experience vaginal bleeding because of ovarian activity by 6 months after the menopause. Thus postmenopausal bleeding is much more ominous and necessitates evaluation each time it occurs. The only exception to this rule is the uterine bleeding associated with estrogen replacement therapy. Other guidelines are recommended for this type of bleeding (see Estrogen Therapy).

Organic disease is commonly associated with postmenopausal bleeding. Endometrial polyps may be found, which can be resected via the hysteroscope. Endometrial hyperplasia may be discovered, frequently in obese women. This can be treated by the periodic administration of progestin or by hysterectomy. If hyperplasia develops in a woman taking estrogens, the addition of progestins should be considered. If hyperplasia develops unrelated to hormone replacement, surgery should be considered if the patient is a good surgical risk or is not reliable in taking progestins. The finding of endometrial cancer necessitates appropriate therapy depending on the stage and grade of the tumor.

D. Vulvovaginitis

Many specific vulvar and vaginal diseases (ie, trichomoniasis and candidiasis) may mimic the atrophic vulvovaginitis of estrogen deficiency. Their special clinical characteristics usually suggest more specific diagnostic testing. When pruritus and thinning of the vaginal epithelium or the vulvar skin are the only manifestations, therapeutic testing with local applications of estrogen may help to establish the diagnosis of vulvovaginitis. When any whitening, thickening, or cracking of vulvar tissues is present, biopsy to rule out carcinoma is mandatory. Raised or erosive lesions should also be sampled. Biopsy to rule out carcinoma is also necessary for suspicious looking vaginal or cervical lesions.

E. Back Pain

Occasionally, the pain of vertebral compression from osteoporosis may mimic that of gastric ulcer, renal colic, pyelonephritis, pancreatitis, spondylolisthesis, acute back strain, or herniated intervertebral disk.

Common Clinical Conditions of the Aged, Postmenopausal Woman: Controversial Role of Estrogens

A. Coronary Heart Disease (CHD)

Heart disease affects approximately 8 million women in the United States. Deaths caused by CHD in women number more than 230,000 per year. The incidence of death from CHD increases with age in all populations and both sexes. Substantially more heart disease is seen in younger men, with the onset of cardiovascular problems occurring an average of 10 years later in women. Before the age of menopause, very few women die of a heart attack. After the menopause, a woman’s risk increases progressively such that CHD rates in women after menopause are 2–3 times those of women of the same age before menopause. Statistics such as these, indicating a role for both sex and menopause on the development of CHD, have led to the suggestion that estrogen deficiency that occurs after menopause is at least partially responsible for the increased risk of CHD in postmenopausal women.

The first attempts at ascertaining whether cessation of ovarian function is associated with an increased incidence of heart disease came from large epidemiologic studies. The Framingham study, in which nearly 3000 women were examined biennially, revealed that after the menopause, there is indeed an increased incidence of heart disease that is not just age-related. In the Nurses' Health Study cohort of 121,700 women, after controlling for age and cigarette smoking, women who had a natural menopause had no appreciable increase in risk compared with that of premenopausal women. However, women who underwent a bilateral oophorectomy and no estrogen replacement had an increased risk (relative risk = 2.2) compared with that seen in premenopausal women.

Case-control studies were also performed comparing the degree of CHD or the incidence of myocardial infarction in women who had undergone early oophorectomy with age-matched premenopausal controls. Most of these studies revealed an increased risk of cardiovascular disease after ovarian excision. All these reports have been criticized because of patient selection bias, particularly of the controls.

Numerous case-control and large-cohort studies have also since been carried out to assess the role of exogenous estrogens administered during menopause on morbidity and mortality from CHD. Most have shown a beneficial impact of exogenous estrogens on morbidity and mortality from CHD. Although the magnitude of change and the consistency of results appear compelling, it must be recognized that all these studies are observational and that the choice of controls has been questioned. In particular, women who take estrogens are more health conscious and must see a doctor regularly to receive their medication, whereas women who do not take estrogens may or may not receive regular medical checkups. Thus some or all of the apparent benefits of estrogens on heart disease may have been a consequence of these other considerations.

Based on these observational/case-controlled studies suggesting a beneficial effect of estrogens, numerous experimental studies were performed attempting to elucidate the mechanism(s) by which estrogens could prevent CHD. Evidence for both an indirect effect on circulating lipids and a direct action on the vascular system was found. Orally administered estrogens influence hepatic lipid metabolism and raise high-density lipoprotein (HDL) cholesterol and triglycerides and lower low-density lipoprotein (LDL) cholesterol. The impact of nonorally administered estrogens is of lesser magnitude and takes longer to become apparent.

Numerous studies have shown that estrogen and progesterone receptors are present in the heart and aorta. Thus the subcellular components necessary for direct hormonal action exist in these tissues. Endothelial cells of the arteries produce factors in response to estrogen. One of the most potent of these is believed to be nitric oxide (NO). NO exerts several effects on the arterial wall. It increases intracellular cyclic guanosine monophosphate in the arterial smooth muscle, which results in vasodilation. It also inhibits platelet adhesion and aggregation, as well as monocyte adherence to the arterial endothelium. Estrogen appears to increase NO production, and this may be important in preventing coronary vasospasm and thrombus formation. Estrogen has been shown in animals to prevent atherosclerosis. It has also been shown in a rabbit model to prevent 2 of the earliest steps in the atherogenic process—adhesion and migration of monocytes. This likely occurs through an NO-mediated mechanism. Estrogens also likely have adverse effects on the vessel wall. Estrogens lead to a hypercoagulable state which may increase the risk of coronary events. Although these mechanisms are only partially understood, they emphasize the importance of studying the direct effects of estrogen on the vascular system.

Interestingly, use of estrogen had been widespread for many years, yet it was not until recently that large-scale, prospective, randomized, placebo-controlled studies evaluating the effect of hormone therapy on relevant clinical end points in humans were performed. One of the first of these studies was the Heart and Estrogen/Progestin Replacement Study (HERS), which studied the use of estrogen and progestin in the secondary prevention of coronary events in women with known CHD. HERS showed that treatment with oral conjugated equine estrogen (CEE) plus medroxyprogesterone acetate (MPA) did not reduce the overall rate of CHD events in postmenopausal women with established heart disease. Furthermore, there was an early increased risk of CHD events within the first year of starting HT. In addition, the ERA (Estrogen Replacement and Atherosclerosis) Trial, which was the first randomized angiographic end point trial to test the effect of HT on the progression of atherosclerosis in postmenopausal women with documented coronary stenosis, showed no benefit of CEE either alone, or in combination with MPA, on angiographic progression of disease. Consequently, it is suggested that physicians not prescribe estrogen therapy (ET)/HT for the sole purpose of *secondary* prevention of coronary events.

The *primary* prevention of CHD by HT also had not been evaluated in a prospective, randomized fashion until recently. The WHI, a large, multicenter, prospective, randomized, placebo-controlled trial of primarily healthy post-menopausal women, was initiated to assess the effects of a specific regimen of CEE alone or in combination with MPA on several health-related outcomes, including CHD. The combined estrogen/progestin portion of the study was stopped after 5.2 years as overall health risks exceeded benefits. The increased risks included a greater number of cardiovascular events. The estrogen-only arm of the study was continued for approximately 7 years. This arm of the study was stopped early because of an increased risk of stroke. Overall, there was no reduction in the risk of coronary events. Interestingly, there appeared to be a trend toward a decreased risk of coronary events in the younger subset of postmenopausal women. This finding was confirmed in a subanalysis of the data for the 50–59-year-old age group where the investigators reported a lower relative risk for the combined end points of myocardial infarction, coronary death, coronary revascularization, and confirmed angina among women ages 50–59 years using estrogen alone. In addition, in the subset of women who were 50–59 years of age who were placed on the estrogen-alone arm, lower levels of coronary artery calcium were observed, suggesting that in this group of recently postmenopausal women that estrogen alone slows the development of calcified coronary atherosclerotic plaque.

There were several limitations of the WHI study. It did not assess different dosages, types of estrogens and progestogens, nor different routes of administration (ie, transdermal vs. oral). Finally, many of the subjects had become menopausal several years before entry into the study. Consequently, it was not possible to precisely ascertain whether starting HT with the onset of menopause, when initiation or more rapid acceleration of atherosclerosis may take place, is beneficial. Because estrogen has been shown in experimental models to prevent the very earliest steps in atherogenesis, but to raise cardiovascular risk in the setting of established atherosclerosis (possibly via increases in clotting factors), it is possible that the adverse cardiovascular effects seen in this study may have been because many women started HT following the onset of menopause when subclinical atherosclerotic changes and irreversible endothelial damage may have already set in. In order to evaluate the possible role of age and/or years since menopause in the development of CHD, WHI investigators performed additional analyses in various subgroups of women. These additional analyses suggested no effect of age (i.e. 50-50 vs. 70-79 year of age). However, there were was a suggestion that greater numbers of years since menopause was associated with greater risk. Women starting within 10 years of menopause had fewer CHD events than those starting >20 years since menopause. However, statistical analyses of the combined WHI trials did not demonstrate that time since menopause altered CHD risk overall. This emphasizes the importance of continuing to study the effects of estrogen, particularly in younger, recently postmenopausal women. Additional studies are currently underway to assess whether estrogen administration to younger, healthy, recently post-menopausal women is safe from a cardiovascular standpoint.

The decision to use HT should be based primarily on the proven benefits of ET/HT on other systems, the potential risks of therapy, and patient preference. It should not be prescribed for prevention of CHD. Short-term use of HT for relief of postmenopausal symptoms is still an option for women without contraindications.

B. Diabetes Mellitus

Hormone therapy may decrease the risk of developing diabetes in postmenopausal women. In the HERS trial, the incidence of diabetes was significantly lower in women receiving HT as compared to women receiving placebo. The WHI trial revealed similar results whereby the incidence of diabetes was less in the HT group as compared with the placebo group. The differences between groups in both studies persisted after adjusting for body mass index and waist circumference. These results provide some reassurance regarding the effects of HT on glucose tolerance in women. However, HT should not be prescribed to post-menopausal women for prevention of diabetes.

C. Mood Disorders

Studies assessing the effects of estrogen on depression and other mood disorders are conflicting. Although some studies suggest beneficial effects of estrogen, others, including the recent WHI, do not. Early cross-sectional surveys of community or large, general, medical practice–based populations attempted to measure the temporal association of depression and irritability to the cessation of menses. Some reports indicated an increased incidence of minor symptoms such as irritability, dysphoria, and nervousness early in the menopausal transition.

Reports from community-based cohort studies have refined knowledge in the area of mood, mentation, and menopause. The initial longitudinal report of the US cohort found an increase in overall nonspecific symptom reporting at the menopause. Depression for more than 2 interviews was noted in 26% of the cohort. Perceived health, rather than menopause or coincident life stresses, was most related to depression in this study. These findings are consistent with the concept of variability in a woman's response to the menopause; individual characteristics and self-perceptions appear to be important determinants of each woman's experience of the climacteric.

Hypotheses regarding the etiology of the affective complaints at the menopause also include a primary biologic cause (eg, an alteration in brain amines). Studies using the opioid antagonist naloxone have demonstrated that estrogen deficiency is associated with low levels of endogenous opioid activity and that estrogen supplementation increases opioid activity. These findings suggest that central neurotransmitters may contribute to the etiology of affective and cognitive complaints. Sociologic factors postulated to cause psychologic symptoms, such as negative cultural values attached to aging, may also promote a negative climacteric experience.

Double-blind studies have found improvements in self-reported irritability, mild anxiety, and dysphoria in women treated with estrogen alone or when combined with progestin. Improvement of the Beck depression score in women without hot flushes indicates that estrogens likely have direct effects on brain function.

Depression and other quality-of-life outcomes were studied in the WHI trial. Overall, CEE alone, or in combination with medroxyprogesterone acetate, did not improve depressive symptoms among postmenopausal women ages 50–79 years after 1 and 3 years. In a subgroup analysis of 50–54-year-old women experiencing hot flashes, estrogen plus progestin improved hot flashes and sleep disturbance, but no other quality-of-life outcomes. In the estrogen-alone group, there was a slight improvement in sleep disturbance and social functioning, but no other quality-of-life outcomes measured. Therefore, a role for HT/ET in improving depressive symptoms after the menopause remains unproven.

D. Cognitive Decline

As life expectancy in women has risen, there has been more research regarding the effects of estrogen on cognitive functioning in postmenopausal women. Research indicates that estrogen influences areas of the brain known to be important for memory. However, recent data from the WHI suggests that estrogen alone or in combination with progestin does not decrease, and in fact may increase, the risk of cognitive decline in women older than 65 years of age.

E. Skin & Hair Changes

With aging, noticeable changes occur in the skin. There is generalized thinning and an accompanying loss of elasticity, resulting in wrinkling. These changes are particularly prominent in the areas exposed to light (ie, the face, neck, and hands). “Purse-string” wrinkling around the mouth and “crow’s feet” around the eyes are characteristic. Skin changes on the dorsum of the hands are particularly noticeable. In this area, the skin may be so thin as to become almost transparent, with details of the underlying veins easily visible.

Histologically, the epidermis is thinned, and the basal layers become inactive with age. Dehydration is typical. Reduction in the number of blood vessels to the skin is also seen. Degeneration of elastic and collagenous fibers in the dermis also appears to be part of the aging process.

These skin changes are of cosmetic importance and are of great concern to many women. It is unclear whether these changes are primarily caused by the menopause, aging, or a combination of both factors. It is commonly stated that women undergoing estrogen replacement look younger, and the cosmetic industry has been putting estrogens in skin creams for years for precisely this reason.

The possibility that estrogens may have effects on skin was suggested by the demonstration of estrogen receptors in skin. The number of receptors is highest in facial skin, followed by skin of the breasts and thighs. This gives credence to the hypothesis that estrogens affect the skin.

Skin circulation is decreased in women after oophorectomy. Radiolabeled thymidine incorporation (an index of new DNA metabolism) is reported to decrease during the several months after oophorectomy. In some animal studies, estrogens increase the mitotic rate (a reflection of growth) of skin. Estrogens may alter the vascularization of skin. They also change the collagen content of the dermis, as reflected by mucopolysaccharide incorporation, hydroxyproline turnover, and alterations of the ground substance. In addition, dermal synthesis of hyaluronic acid and dermal water content are enhanced.

Skin collagen content and thickness have been studied in postmenopausal women. Decreases of both have been observed at a rate of 1–2% per year. The losses correlated with the number of years since the menopause, but not with chronologic age. Estrogen replacement prevents these losses or restores both parameters to premenopausal values. The greatest recovery is observed in women who began with low values. These data were interpreted to indicate that estrogen can prevent loss in women with high skin collagen levels, whereas it can restore content as well as prevent further loss in women with low collagen levels. Although these results are promising, it remains unclear whether they are clinically relevant. Estrogen should not be prescribed to improve the appearance of skin.

After the menopause, most women note some change in patterns of body hair. Usually there is a variable loss of pubic and axillary hair. Often there is loss of lanugo hair on the upper lip, chin, and cheeks, together with increased growth of coarse terminal hairs; a slight moustache may become noticeable. Hair on the body and extremities may either increase or decrease. Slight balding is seen occasionally. All of these changes may be partly a result of reduced levels of estrogen in the face of fairly well-maintained levels of testosterone.

F. Miscellaneous Symptoms

Many other symptoms are attributed to the endocrine changes of the postmenopausal state, but a direct cause-and-effect relationship has not been established for them. Some of these so-called climacteric symptoms are so common that they deserve brief mention.

Symptoms possibly related to specific autonomic nervous system instability—but equally attributable to anxiety or other emotional disturbances—are paresthesia (pricking, itching, formication), dizziness, tinnitus, fainting, scotomas, and dyspnea. Symptoms clearly not of endocrine origin are weakness, fatigue, nausea, vomiting, flatulence, anorexia, constipation, diarrhea, arthralgia, and myalgia.

Many women erroneously believe that the endocrine changes accompanying menopause will produce a steady weight gain. Women and men do tend to gain weight at this time of life, but the cause is usually a combination of decreased exercise and possibly increased caloric intake. There may be some redistribution of body weight occasioned by the deposition of fat over the hips and abdomen. Perhaps this is partly an endocrine effect, but more likely it is the result of decreased physical activity, reduced muscle tone, and other effects of aging.

Many of the previously mentioned symptoms occasionally respond promptly to administration of estrogen. This should not mislead physicians into assuming a specific endocrine action for what is actually a placebo effect.

Estrogen Therapy

Every woman with menopausal symptoms deserves an adequate explanation of the physiologic event she is experiencing to dispel her fears and address symptoms such as hot flashes and sleep disturbance. Reassurance should be emphasized. Specific reassurance about continued sexual activity is important.

As long as ovarian function is sufficient to maintain some uterine bleeding, no treatment is usually required. Occasionally, women complain of hot flushes while menstrual function is still present. Treatment with low-dose oral contraceptive pills, if no contraindications exist, will relieve these symptoms and help to regulate menstrual cycles during the menopausal transition.

A. Indications

Estrogen therapy has been used for many years for a variety of symptoms and conditions seen in the aged female population. However, despite suggestions from observational and experimental studies that estrogens prevent many common conditions of aging, such as Alzheimer's disease and CHD, estrogen therapy has only been proven to be effective in the prevention of osteoporosis, treatment of vasomotor symptoms, and treatment of vulvovaginal atrophy. Results from the WHI further call into question the degree to which estrogen can act as a "cure-all" for the common conditions of aging, particularly those affecting the brain and heart. Benefits beyond those already established are still possible, but await proof in large-scale studies in humans. Therefore, use of estrogens should be limited to the currently FDA-approved indications: prevention of osteoporosis, treatment of vasomotor symptoms, and treatment of vulvovaginal atrophy (see D. Management Guidelines for Estrogen Therapy).

B. Complications

Before discussing the management of estrogen replacement, it is necessary to review the complications of and contraindications to this type of therapy. These play an important role in the ultimate decision regarding treatment for all patients.

1. Endometrial cancer—The role of estrogen therapy in the development of endometrial cancer is one of the most highly charged issues related to the menopause. Current concerns are based on several lines of investigation. The scope of investigative efforts lead to the conclusion that estrogen stimulation of the endometrium, unopposed by progesterone, causes endometrial proliferation, hyperplasia, and, finally, neoplasia. In most studies, a strong association has been found, with 2- to 8-fold overall risk ratios. High dosage and prolonged treatment increase the risk. Disease is local in most cases, although more widespread invasive tumors have been reported. Consequently, it is recommended that a progestogen be added to ET to reduce the risk of endometrial hyperplasia or carcinoma. Some women may experience adverse side effects from progestogen therapy. In addition, increasing concerns about the role of progestogens in increasing risk of breast carcinoma amongst women using estrogen–progestogen therapy (EPT) have led to further efforts to find alternatives to progestogens to counteract the effects of estrogen on the endometrium. Agents with estrogen agonist/antagonist activity are currently being investigated as such possible alternatives.

2. Breast cancer—Early age at menarche and older age at menopause are known risk factors for breast cancer, and early oophorectomy is known to give protection against this disease. Ovarian activity is an important determinant of risk, thus estrogen may play a role in the development of breast cancer. Studies in rodents support that view. More than 30 epidemio-logic studies have been published since 1974 to determine the possible link between postmenopausal estrogen use and breast cancer. In general, the later studies have had better design, quality, and analytic strategies. The number of subjects in more recent studies has also been larger. These results have not always agreed. The recent prospective, randomized WHI trial also addressed this issue. In this study there was an increased risk of invasive breast cancer in the estrogen/progestin arm. However, in the estrogen-alone arm, the risk of breast cancer was not increased compared with controls.

Despite this inconsistency in studies, some trends have been observed: (1) Long-term use (ie, 4–10 years) has been associated with mild increased risk in some of the meta-analyses and the WHI. (2) The addition of a progestin does not appear to decrease risk and may increase risk. (3) Finally, risk does not vary in strata of family history of breast cancer or with benign breast disease.

It must be remembered that all women are at risk for breast cancer. Thus instructions for breast self-examination, a careful breast assessment, and routine screening mammography should be a part of the medical care of all older women.

3. Thromboembolic disease—Use of oral contraceptives increases the risk of overt venous thromboembolic disease and subclinical disease extensive enough to be detected by laboratory procedures such as ^{125}I fibrinogen uptake and plasma fibrinogen chromatography. The risk of venous thromboembolic disease was also increased among users of ET/EPT in the WHI, as well as among users of HT in the HERS trial.

The effects of estrogen on the clotting mechanism may contribute to or be responsible for a generalized hypercoagulable state. Oral estrogens affect synthesis of coagulation factors through a first-pass effect in the liver, an effect associated with an increased risk of thromboembolic disease. The risk for thromboembolic events with use of ET/EPT is also likely further increased amongst patients with inherited thrombophilias.

Use of transdermal estrogens is probably associated with a lowered risk for thromboembolic events as compared with use of oral estrogens. However, randomized trials are needed to better characterize the effects of transdermal estrogens on risk for clinical thromboembolic events.

4. Stroke—Several recent studies suggest that HT is associated with an increased risk of stroke. In the EPT arm of the WHI, there was an increased risk of ischemic stroke among those using EPT when compared with the placebo. In the estrogen-alone arm of the WHI, there was also a statistically significant increased risk of stroke after approximately 7 years of follow-up, and this outcome led to the trial being terminated.

5. Uterine bleeding—If patients are given sequential estrogen and progestins, the majority will experience some uterine bleeding, particularly soon after initiation of therapy. This bleeding can occur during the treatment-free interval (scheduled bleeding) or while the medications are being administered (unscheduled bleeding). Hyperplastic endometrium can develop with this type of therapy. If the bleeding is heavy or prolonged, a biopsy should be performed. In women using a combined continuous regimen of estrogen and progestin, bleeding is common in the first several months of therapy and usually doesn't indicate endometrial pathology. However, if bleeding persists in these patients, or is prolonged or heavy at any time, endometrial sampling should be performed. If endometrial hyperplasia is present, the medications can be discontinued, progestin dose can be increased, or a progestin can be given each day of estrogen administration. Whichever approach is adopted, a repeat biopsy should be performed to make certain that the hyperplastic endometrium has resolved. The cost-effectiveness ratio for periodic biopsy in women who do not bleed or bleed only during the medication-free interval is poor and indicates that such biopsy is probably unnecessary.

In women taking estrogen only, the incidence of endometrial hyperplasia can be as high as 25% after only 12 months of therapy. Hyperplasia occurs in women who do not experience vaginal bleeding, bleed only during the medication-free interval, or bleed during drug administration. Thus a pretreatment biopsy and yearly endometrial biopsies are necessary in all women receiving estrogens alone to assess for the presence of hyperplasia. Again, estrogen withdrawal or combined EPT may be used to treat the hyperplasia. The incidence of endometrial cancer will likely be reduced if the programs discussed previously are instituted.

6. Gallbladder disease—An increased incidence of gallbladder disease has been reported after estrogen replacement therapy. Estrogens cause increased amounts of cholesterol to collect in bile. Two primary bile salts, cholate and chenodeoxycholate, are produced by liver cells. In women taking estrogen, decreased levels of chenodeoxycholate and increased levels of cholate are found in bile. Chenodeoxycholate inhibits activity of the enzyme β-hydroxy-β-methylglutaryl-CoA reductase, which regulates cholesterol synthesis, and a decrease in chenodeoxycholate may therefore cause increased activity of β-hydroxy-β-methylglutaryl-CoA reductase, leading to increased synthesis of cholesterol. Bile normally has a 75–90% saturation in cholesterol, and even small increases of this substance can initiate cholesterol precipitation and stone formation. Three-fourths of gallstones are composed predominantly of cholesterol.

7. Lipid metabolism—Estrogen replacement also has an impact on circulating lipids. As discussed earlier, many of these effects are favorable. However, others may pose increased risk. Most lipids are bound to proteins in the blood, and the concentrations of the various types of lipo-proteins are associated with varying risks of heart disease. Lower levels of HDL cholesterol and higher concentrations of total cholesterol, LDL cholesterol, very-low-density lipoprotein cholesterol, and triglycerides are associated with increased risk of atherosclerosis and coronary artery disease. Estrogen replacement decreases LDL cholesterol and increases HDL cholesterol and triglycerides. Use of conjugated estrogens, 0.625 mg/d or less, causes approximately a 10% increase in HDL cholesterol. Much attention has been focused on the impact of estrogens on lipoproteins to explain what appeared to be a beneficial effect of HT on heart disease in earlier observational studies of younger postmenopausal women. The impact of estrogen-induced increases in triglycerides on cardiovascular risk is unclear. In patients with familial defects of lipoprotein metabolism, estrogen replacement therapy is associated with massive elevations of plasma triglycerides, leading to pancreatitis and other complications. However, this is a very unusual complication of estrogen replacement. Transdermal estrogens are probably less likely to raise triglyceride levels and thus are preferred in women with an elevation in triglyceride levels.

8. Miscellaneous—Other side effects of estrogen therapy include uterine bleeding, generalized edema, mastodynia and breast enlargement, abdominal bloating, signs and symptoms resembling those of premenstrual tension, headaches (particularly of a "menstrual migraine" type), and excessive cervical mucous. These side effects may be dose related or idiosyncratic, and are managed by lowering the dosage, by use of another agent, or by discontinuation of the medication.

C. Contraindications to Estrogen Replacement Therapy

Contraindications to ET are as follows: (1) Undiagnosed abnormal vaginal bleeding; (2) known, suspected, or history of cancer of the breast; (3) known or suspected estrogen-dependent neoplasia; (4) active deep vein thrombosis, pulmonary embolism, or a history of these conditions; (5) arterial thromboembolic disease (myocardial infarction, stroke); and (6) liver dysfunction or disease. In general, ET should be avoided in patients with a diagnosis of endometrial cancer. ET may stimulate growth of malignant cells remaining after treatment of breast or endometrial carcinoma and may thus hasten the recurrence of cancer. Therefore, it is prudent to avoid systemic ET in breast cancer patients and most endometrial cancer patients. Recently, it was suggested that women with early (stage 1) and well-differentiated (grade 1) endometrial cancer can be administered estrogens after primary treatment of the cancer. Care must be exercised in following this recommendation until it has been properly studied. Any decision to use ET/EPT after a diagnosis of endometrial cancer should be made in consultation with the patient's oncologist. Patients who have had estrogen receptor–positive malignant tumors of the breast probably should not receive systemic estrogen supplements. Topical vaginal estrogens to treat symptoms of urogenital atrophy in breast/endometrial cancer patients might be acceptable, but should first be discussed with the patient's oncologist. A history of treated carcinoma of the cervix or ovary is not a contraindication to ET. Estrogens may have undesirable effects on some patients with preexisting seizures, hypertension, fibrocystic disease of the breast, uterine leiomyoma, collagen disease, familial hyperlipidemia, migraine headaches, chronic thrombophlebitis, and gallbladder disease. At the low dosages recommended for replacement therapy, increased growth of uterine myomas, endometriosis, or chronic cystic mastitis is rarely a concern.

D. Management Guidelines for Estrogen Therapy

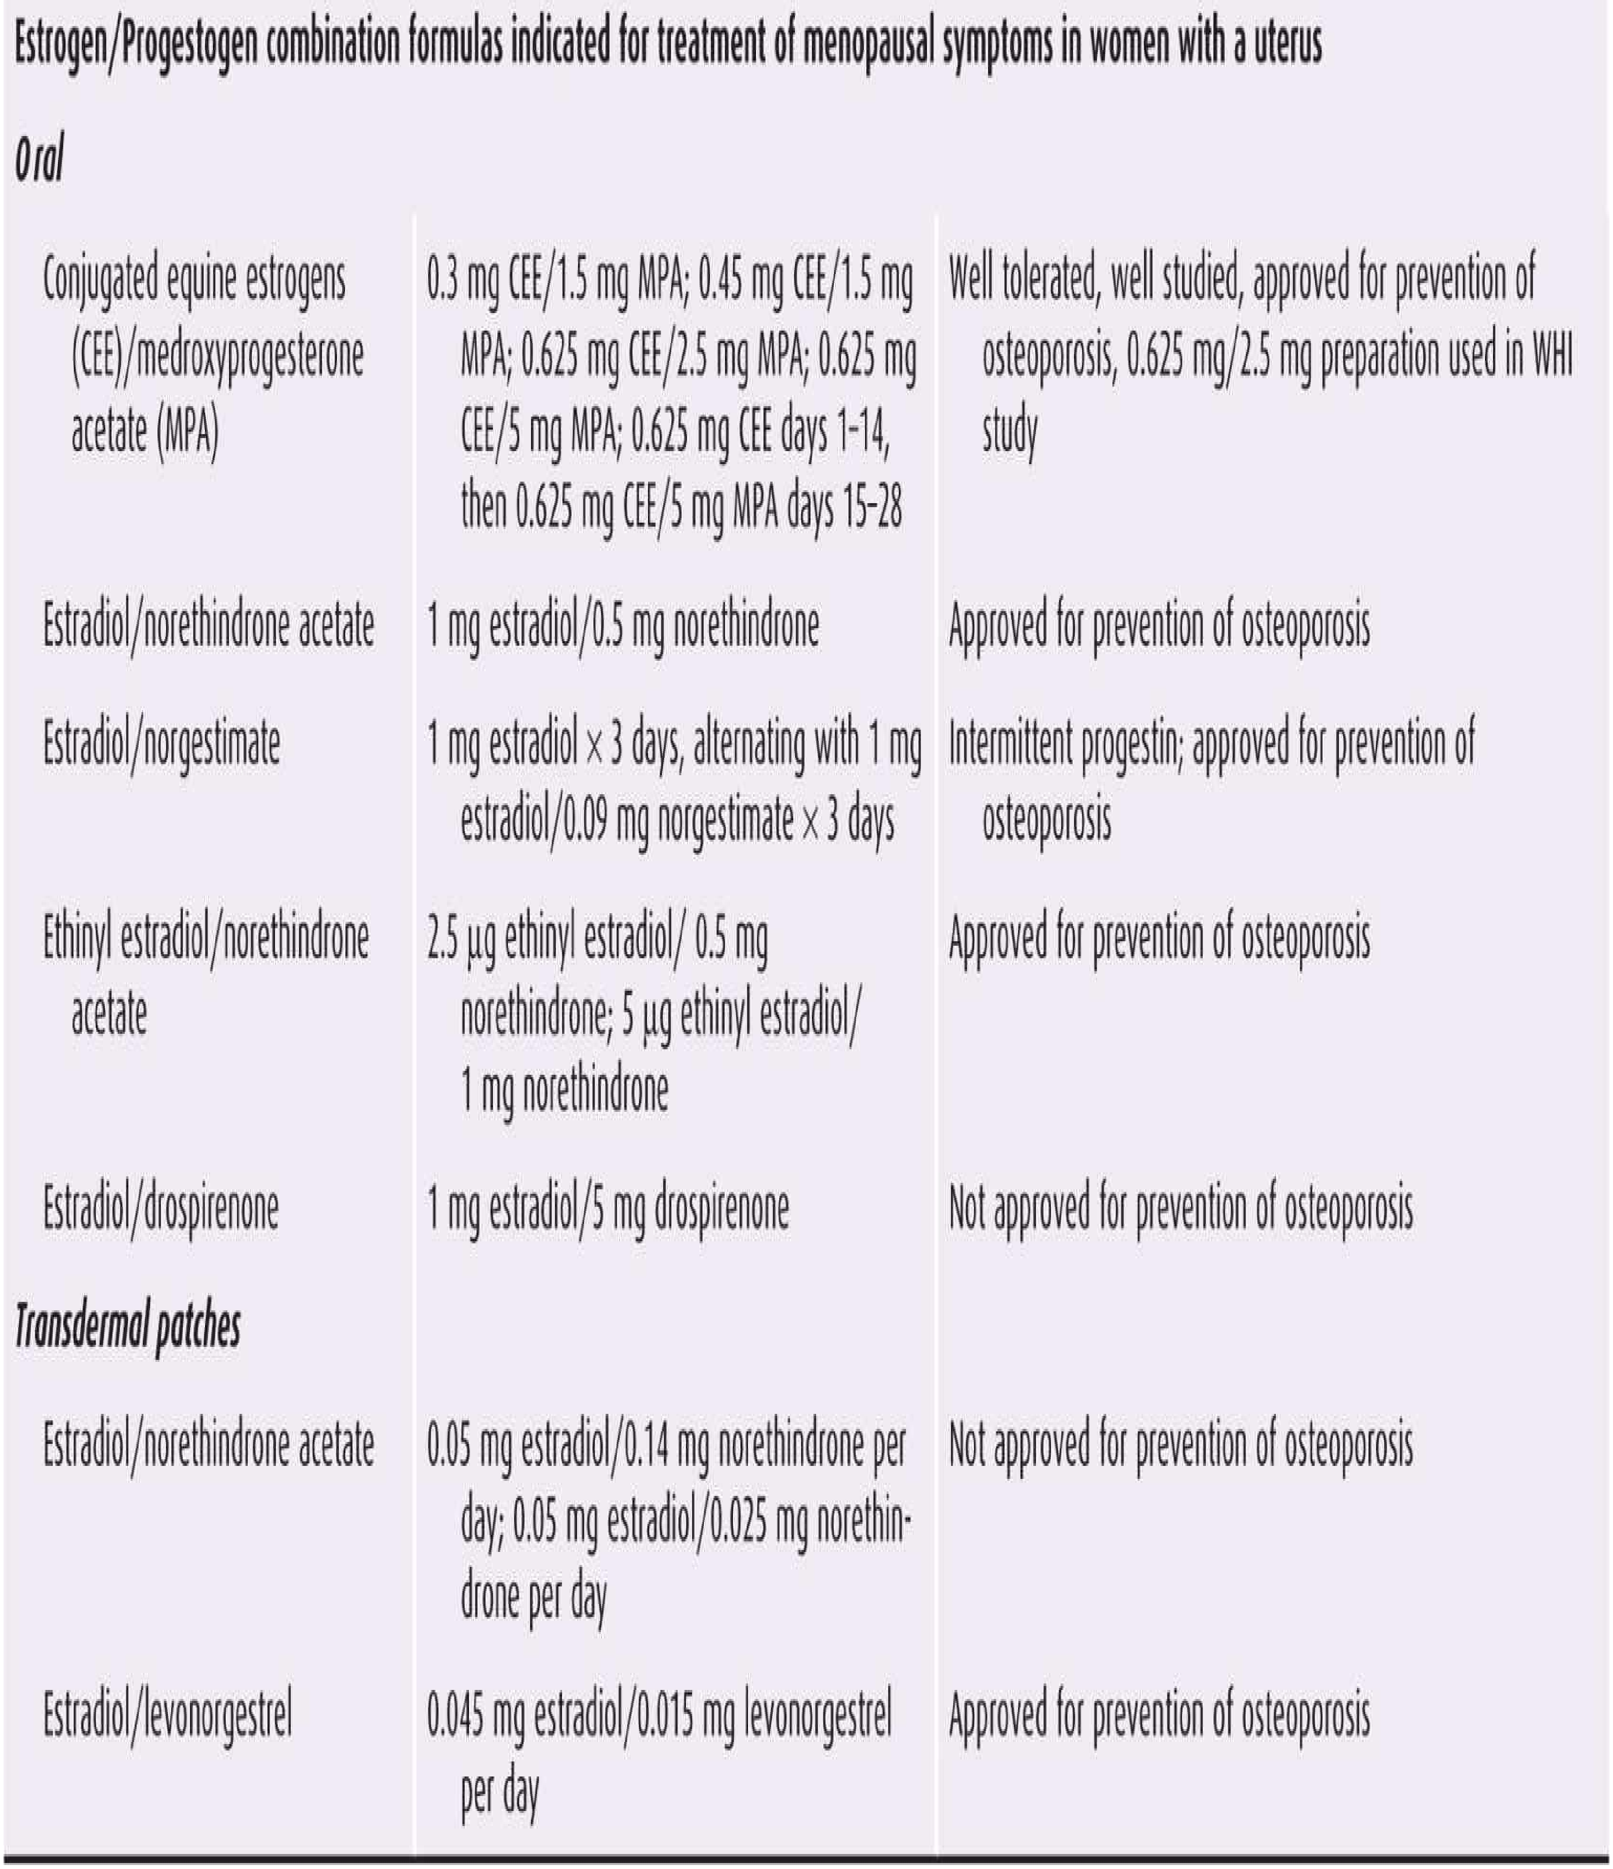
1. General—Only general guidelines can be offered, because risks and benefits must be evaluated for each patient. Numerous formulations of estrogen and estrogen plus progestin are available (Table 59–1). Current indications for ET are relief of menopausal symptoms (including hot flushes and vaginal atrophy) and prevention of osteoporosis. Caution should be exercised in providing therapy for other conditions until more definitive studies have been performed. If symptoms of hot flushes and vaginal atrophy are moderate to severe, therapy may be used for the shortest duration possible; minimal or no symptoms may not require hormones.

Table 59–1. Preparations of estrogens and progestogens available in the United States for hormone therapy.

Agent	How Supplied	Special Features
Oral estrogens for management of vasomotor and genitourinary symptoms; strongly consider progestogen for women with intact uterus		
Conjugated equine estrogens	0.3 mg, 0.45 mg, 0.625 mg, 0.9 mg, 1.25 mg tablets	Well studied, well tolerated; approved for prevention of osteoporosis, 0.625 mg dose used in WHI study
Estradiol	0.5 mg, 1 mg, 2 mg tablets	Well tolerated; approved for prevention of osteoporosis
Piperazine estrone (estropipate)	0.75 mg, 1.5 mg, 3 mg tablets	
Synthetic conjugated estrogens	0.3 mg, 0.45 mg, 0.625 mg, 0.9 mg, 1.25 mg tablets	Not approved for prevention of osteoporosis
Transdermal estrogens for management of vasomotor symptoms and genitourinary atrophy; strongly consider progestogen for women with intact uterus		
Estradiol patch (mg/day)	0.025 mg, 0.0375 mg, 0.05 mg, 0.06 mg, 0.075 mg, 0.1 mg patches	Well tolerated, 10% skin rash, available in weekly and biweekly formulations; approved for prevention of osteoporosis

Estradiol gel	0.06% gel; 0.75 mg estradiol per pump	Not approved for prevention of osteoporosis
Estradiol spray	1.5 mg/spray	Not approved for prevention of osteoporosis
Transdermal estrogen for prevention of osteoporosis		
Estradiol patch (low dose)	0.014 mg	Only approved for prevention of osteoporosis; not approved for prevention of vasomotor symptoms or genitourinary atrophy
Intravaginal ring for treatment of vasomotor symptoms and genitourinary atrophy; strongly consider progestogen for women with intact uterus		
Estradiol acetate	0.05 mg/day and 0.1 mg/day over 3 months	Remains in place for 3 months; not approved for prevention of osteoporosis

Vaginal estrogens for treatment of genitourinary atrophy (doses inadequate to treat vasomotor symptoms)		
Creams		
Conjugated equine estrogens	0.625 mg/g cream	Not approved for prevention of osteoporosis or vasomotor symptoms
Estradiol	0.1 mg/g cream	Not approved for prevention of osteoporosis or vasomotor symptoms
Tablets		
Estradiol	0.010 mg tablet	Not approved for prevention of osteoporosis or vasomotor symptoms
Rings		
Estradiol	0.0075 mg/day released over 3 months	Remains in place for 3 months; not approved for prevention of osteoporosis or vasomotor symptoms
Oral Progestogens		
Medroxyprogesterone acetate	2.5 mg, 5 mg, 10 mg tablets	Well tolerated, well studied
Micronized progesterone	100 mg, 200 mg capsules	Well tolerated, possible somnolence
Megestrol acetate	20 mg, 40 mg scored tablets	Not used routinely for postmenopausal hormone therapy
Norethindrone	0.35 mg tablets	Available as contraceptive “minipill”
Norethindrone acetate	5 mg scored tablets	Dosage probably too large for routine hormone therapy
Intrauterine Progestin		
Levonorgestrel releasing IUD	20 μg/day	Not routinely used for postmenopausal hormone therapy, approved for use as contraceptive and heavy menstrual bleeding; remains in place for 5 years; may prevent endometrial hyperplasia with fewer side effects but not approved for this use.



Estrogen/Progestogen combination formulas indicated for treatment of menopausal symptoms in women with a uterus

Oral		
Conjugated equine estrogens (CEE)/medroxyprogesterone acetate (MPA)	0.3 mg CEE/1.5 mg MPA; 0.45 mg CEE/1.5 mg MPA; 0.625 mg CEE/2.5 mg MPA; 0.625 mg CEE/5 mg MPA; 0.625 mg CEE days 1-14, then 0.625 mg CEE/5 mg MPA days 15-28	Well tolerated, well studied, approved for prevention of osteoporosis, 0.625 mg/2.5 mg preparation used in WHI study
Estradiol/norethindrone acetate	1 mg estradiol/0.5 mg norethindrone	Approved for prevention of osteoporosis
Estradiol/norgestimate	1 mg estradiol × 3 days, alternating with 1 mg estradiol/0.09 mg norgestimate × 3 days	Intermittent progestin; approved for prevention of osteoporosis
Ethinyl estradiol/norethindrone acetate	2.5 µg ethinyl estradiol/ 0.5 mg norethindrone; 5 µg ethinyl estradiol/ 1 mg norethindrone	Approved for prevention of osteoporosis
Estradiol/drospirenone	1 mg estradiol/5 mg drospirenone	Not approved for prevention of osteoporosis
Transdermal patches		
Estradiol/norethindrone acetate	0.05 mg estradiol/0.14 mg norethindrone per day; 0.05 mg estradiol/0.025 mg norethindrone per day	Not approved for prevention of osteoporosis
Estradiol/levonorgestrel	0.045 mg estradiol/0.015 mg levonorgestrel per day	Approved for prevention of osteoporosis

In women who require pharmacologic intervention for prevention of **osteoporosis,** estrogen may be used. However, ET for osteoporosis prevention is generally reserved for those women who are otherwise using estrogen for menopausal symptoms and/or who cannot tolerate other anti-resorptive therapies. Lower dosages of estrogen are being increasingly used for prevention of osteoporosis to minimize the risks of estrogen therapy. There are several options available for use of estrogen or estrogen plus progestin for prevention of osteoporosis (Table 59–1). In the past, standard doses included 0.625 mg of conjugated equine estrogens, 0.05 mg of transdermal estradiol, and 1 mg of micronized estradiol. However, 0.3 mg of conjugated equine estrogens, 0.5 mg of micronized estradiol, and 0.025-mg transdermal patches also prevent bone loss, although not as well as higher doses. A new **low-dose** (0.014 mg/d) transdermal formulation of estradiol was recently FDA approved for prevention of osteoporosis. Early commencement of prophylaxis after cessation of ovarian function will maintain the highest bone density. Initiation of HT well after the menopause will stop bone loss, but will not return bone density to that which was present at the time of the menopause.

For women with **hot flashes,** a standard dosage of estrogen, such as 0.3–0.625 mg of conjugated equine estrogens, 0.025 mg transdermal estradiol, or 0.5 mg oral estradiol should be given daily (Table 59–1). Higher doses may be necessary to relieve hot flashes. Progressive reduction of dosage should be attempted as soon as feasible. Additional formulations containing estradiol, synthetic estrogens, and estrogens plus progestins are also available (Table 59–1).

In women who are suffering from **atrophic vaginitis,** vaginal preparations can be used and are preferred over systemic estrogens. These preparations are available in the form of creams (ie, CEEs or estradiol 0.25–2 g given nightly for 2 weeks, followed by twice weekly), tablets (10 μg estradiol given nightly for 2 weeks, followed by twice weekly), and rings (estradiol releasing rings, which remain in place for 3 months at a time) (Table 59–1). With the tablets, rings, and lowest dose creams, endometrial proliferation is rare. However, higher doses, presence of vaginal bleeding, or other risk factors may necessitate periodic endometrial biopsy or ultrasound to assess the endometrial thickness. Progestogens may be necessary to prevent endometrial proliferation in some cases.

2. Progestogen–estrogen therapy—One of the most serious concerns about estrogen replacement is the occurrence of endometrial hyperplasia or cancer. Progestogens oppose the action of estrogen on the endometrium. Progestogens reduce the number of estrogen receptors in glandular and stromal cells of the endometrium. These agents also block estrogen-induced synthesis of DNA, and they induce the intracellular enzymes estradiol dehydrogenase and estrogen sulfotransferase. The former reduces estradiol to the much less potent estrone, whereas the latter converts estrogen to estrogen sulfates for rapid elimination from endometrial cells. In addition, full secretory transformation occurs if the progestogen is given at a large enough dosage for a sufficient length of time.

Progestogens reduce the occurrence of endometrial cancer. Epidemiologic studies show significant reduction of the occurrence of endometrial cancer with estrogen plus progestogen compared with estrogen alone. One study indicated use of the progestogen for more than 10 days a month reduced the occurrence more than use for a shorter interval. In treating women with hormones, a more practical concern is the prevention of endometrial hyperplasia. Initially, British investigators showed that high-dose estrogens (1.25 mg or greater of CEEs) resulted in 32% hyperplasia, whereas low doses (0.625 mg or less) stimulated 16% hyperplasias in women followed up for 15 months. In women given estrogen plus progestins, the occurrence of hyperplasia was 6% and 3%, respectively. In comparing length of therapy, 7 days of progestogen reduced the occurrence of hyperplasia to 4%, 10 days reduced it to 2%, and 12 days eliminated hyperplasia. Direct comparisons in drug trials have also shown reductions of hyperplasia in women given estrogens and progestogens compared with those given estrogen alone. It should be pointed out that the majority of endometrial lesions observed in women in these trials were either cystic or simple hyperplasias, which could be reversed by giving a progestogen or discontinuing the estrogen.

One option is to administer a progestogen such as medroxyprogesterone acetate at a dosage of 5–10 mg/d for 12–14 days each month (see Table 59–1). If this is accomplished, 80–90% of women will experience some vaginal bleeding monthly toward the end of or after the progestogen is administered. An alternative is to prescribe a lower dosage, 2.5 mg, continuously. Many newer formulations of hormone therapy contain both estrogen and progestin (Table 59–1). The combined, continuous administration of estrogen plus progestogen is the most common mode of administration today. This regimen promotes endometrial atrophy and results in amenorrhea in 70–90% of women who use continuous therapy for more than 1 year. The remainder will bleed occasionally, with the bleeding usually being less frequent, shorter, and lighter than with sequential therapy.

Administration of progestogens can be associated with other uncomfortable side effects including fatigue, depression, breast tenderness, bloating, menstrual cramps, and headaches. It is also important to keep in mind that it was a progestogen-containing regimen that was used in the WHI trial that was discontinued largely because of a trend toward an increased risk of **breast cancer**. In the estrogen-only arm, breast cancer rates were not increased over control levels. This raises concerns about the potential role of progestogens in increasing breast cancer risk. This concern combined with potential progestogen side effects may lead to elimination of or nonstandard progestogen administration. If lower dosages or shorter duration of progestogens are used, endometrial sampling to diagnose the development of hyperplasia or cancer should be performed. Use of locally administered progestogens through the use of the levonorgestrel intrauterine device is also being considered as an alternative strategy to minimize systemic side effects and risks while maintaining endometrial protection.

Rossouw JE, Anderson GL, Prentice RL, et al; Writing Group for the Women’s Health Initiative. Risks and benefits of estrogen plus progestin in healthy postmenopausal women: Principal results from the Women’s Health Initiative randomized controlled trial. *JAMA* 2002;288:321–333. PMID: 12117397.

Prognosis

The prognosis for the postmenopausal woman who does not develop clinically manifest estrogen deficiency includes only the ordinary hazards of disease and aging. For the woman who does develop signs of estrogen deficiency, hormone therapy can correct physical symptoms and signs and prevent the development of osteoporosis. Correction of minor distressing symptoms and signs can improve the general well-being of the postmenopausal woman and help her to pursue a vigorous life. However, HT for the postmenopausal woman who does not need it serves no purpose and can cause unpleasant side effects and impose unnecessary risks to her health.

Domestic Violence & Sexual Assault

Michael C. Lu, MD, MPH
Jessica S. Lu, MPH
Vivian P. Halfin, MD

For many victims of domestic violence and sexual assault, the first contact with the health care system is with the obstetrician-gynecologist or primary care doctor. Consequently, it is critical that these physicians be knowledgeable in the identification, evaluation, and treatment of such patients.

DOMESTIC VIOLENCE

ESSENTIALS OF DIAGNOSIS

- Chronic pelvic pain
- Sexual dysfunctions, such as decreased interest or arousal, dyspareunia, or anorgasmia
- Chronic or recurrent vaginitis
- Anxiety or tears before or during the pelvic examination
- Persistent multiple bodily complaints, such as chronic headaches, palpitations, abdominal complaints, or sleep and appetite disturbances
- Eating disorders
- Somatoform disorder
- Depressed or suicidal
- Anxiety or sleep disorders
- May self-medicate with alcohol or other substances
- Posttraumatic stress disorder
- Personality disorders characterized by maladaptive character traits
- Multiple personality disorder

Although the home is often thought of as a safe haven, it is the site of the most common manifestations of violence in our society today. Domestic or intimate partner violence typically refers to violence perpetrated against adolescent and adult females within the context of family or intimate relationships. Although victims of domestic violence may be male or female, 90–95% of the victims are women. Domestic violence is characterized by a behavior pattern manifested in physical and sexual attacks, as well as psychologic and economic coercion.

The abuser uses the behavior in order to establish and maintain domination and control over the victim. Because abuse is usually accompanied by shame and guilt, the victim often does not report the abuse. As a result of significant underreporting, it is difficult to compile exact data on the incidence of domestic violence. Every year, approximately 4–5 million women are believed to be battered by their intimate partners. Violence by an intimate partner accounts for approximately 21% of all the violent crime experienced by women. More than 40% of all female murder victims are murdered by their husbands, boyfriends, or ex-partners. It is estimated that at least one-fifth of all American women will be physically assaulted by a partner or ex-partner during their lifetime.

Violent acts may include threats, throwing objects, pushing, kicking, hitting, beating, sexual assault, and threatening with or using a weapon. Domestic violence frequently includes verbal abuse, intimidation, progressive social isolation, and deprivation of things such as food, money, transportation, or access to health care. The violence typically occurs in a predictable, progressive cycle. The tension-building phase is characterized by arguing and blaming as anger intensifies. This leads to the battering phase that may involve verbal threats, sexual abuse, physical battering, and use of weapons. The battering phase is followed by a honeymoon phase during which the abuser may deny the violence, make excuses for battering, apologize, buy gifts, and promise never to do it again, until the next cycle begins. Although unemployment, poverty, and alcohol and substance abuse increase the likelihood of abuse, domestic violence cuts across all racial, ethnic, religious, educational, and socioeconomic lines. Domestic violence often occurs within a framework of family violence that can include child abuse, elder abuse, or abuse of adults who are disabled. It is estimated that child abuse occurs in 33–77% of families where adults are abused.

Prevention

If the violence has escalated to the point where the patient is afraid for her safety or that of her children, she should be offered shelter. An important step in addressing ongoing violence is to help the victim establish a safety plan. The American College of Obstetricians and Gynecologists (www.acog.org) distributes pocket cards with suggested steps for making an exit plan. These cards can be handed to the patient or left in patient restrooms where a woman can pick it up without concern of being seen by an accompanying partner.

Providing educational materials about domestic violence and its consequences can sometimes help victims take action toward ending the violence. These materials demonstrate to women that their physicians' offices are both a resource and a safe place should they decide to take action. A list of referral resources should be readily available in medical offices. The list should include telephone numbers for police departments, emergency departments, shelters for battered women, rape crisis centers, counseling services, self-help programs, and advocacy agencies that can provide legal, financial, and emotional support.

Clinical Findings

Survivors of domestic violence or sexual abuse may present to health care professionals in a variety of clinical settings. The prevalence of domestic violence among patients in ambulatory care settings is estimated to be between 20 and 30%.

Such patients commonly report chronic pelvic pain to their gynecologists. A history of sexual abuse is found in significantly more women with chronic pelvic pain as compared with other gynecologic conditions. Others may complain of sexual dysfunctions such as decreased interest or arousal, dyspareunia, or anorgasmia. Incest victims have a very high rate of sexual dysfunction and may avoid sex or seek it out compulsively. Still others may present with chronic or recurrent vaginitis. Some women may present for a routine gynecologic appointment but become anxious and tearful before or during the pelvic examination.

Some women present to their primary care physicians with persistent multiple bodily complaints, such as chronic headaches, palpitations, abdominal complaints, or sleep and appetite disturbances.

Eating disorders may be more common among abuse victims. Others may have a somatoform disorder. This condition is characterized by physical symptoms suggesting a physical condition for which there are no demonstrable organic findings or physiologic mechanisms. In the face of a negative workup, there may be evidence of or a presumption that the symptoms are linked to psychologic factors or conflicts. Women who meet the criteria for somatoform disorder often have a history of abuse.

In a mental health setting, victims of domestic violence or sexual assault may note feeling depressed or suicidal. They may have anxiety or sleep disorders that they may self-medicate with alcohol or other substances. Most commonly, these women may have posttraumatic stress disorder (PTSD), which occurs in individuals who have experienced a psychologically distressing event that is outside the range of usual human experience. Symptoms of PTSD include re-experiencing the traumatic event through intrusive memories, dreams, flashbacks, or exposure to events symbolic of the trauma. Patients with PTSD also exhibit a “psychic numbing,” that is, they are detached from other people and have difficulty feeling emotions, especially those associated with intimacy or sexuality. Other clinical syndromes include personality disorders characterized by maladaptive character traits. In very extreme cases, patients may have multiple personality disorder, characterized by having ≥2 distinct personalities existing within them. This disorder is marked by a disturbance in the normally integrated functions of identity, memory, and consciousness as the result of dissociation from traumatic experiences.

The problem of domestic violence in pregnancy merits special mention because it is a threat to both the mother and her developing fetus. Estimates of prevalence of domestic violence in pregnancy are in the range of 1–20%, with most studies identifying rates between 4 and 8%. These estimates suggest that violence is a more common problem for pregnant women than preeclampsia, gestational diabetes, and placenta previa, conditions for which pregnant women are routinely screened and evaluated. Some evidence suggests that violence may escalate during pregnancy, especially in the postpartum period. Abuse is associated with increased physical and psychological stress, inadequate prenatal care utilization, poor nutrition and weight gain, and increased maternal behavioral risks (cigarette, alcohol, and substance abuse). These may lead to problems with fetal growth and development. Physical trauma can cause abruptio placentae, preterm labor, pre-term premature rupture of membranes, and maternal and fetal injuries and demise.

Differential Diagnosis

Although battered women seek medical care frequently, as few as 1 in 20 are correctly identified by the practitioner to whom they turn for help. Barriers to diagnosis include the practitioner’s lack of knowledge or training, lack of recognition of the widespread prevalence of the problem, time constraints, fear of offending the patient, and a feeling of powerlessness in the area of treatment. Research suggests that the use of abuse assessment questions on standard medical records may increase screening and documentation. In addition, because many women will not voluntarily disclose abuse, asking each patient directly about prior or ongoing victimization increases the likelihood of disclosure.

The screening assessment should be prefaced with a statement to establish that screening is universal, such as, “I would like to ask you a few questions about physical, sexual, and emotional trauma because we know that these are common and affect women’s health.” Direct questioning using behaviorally specific phrasing should follow:

- Has anyone close to you ever threatened to hurt you?

- Has anyone ever hit, kicked, choked, or hurt you physically?
- Has anyone, including your partner, ever forced you to have sex?
- Are you ever afraid of your partner?

Disclosure rates will be higher when the questions are asked face to face by the health care provider rather than through a questionnaire and when behaviorally specific descriptions rather than the terms “abuse,” “domestic violence,” or “rape” are used. Abuse victims are often accompanied to health care appointments by the perpetrator, who may appear overprotective or overbearing, and may answer questions directed toward the woman. It is important to ask the patient questions in private, apart from the male partner. It is also important to ask the patient questions apart from children, family, or friends and to avoid using them as interpreters when asking questions about violence.

In the office setting, the most effective and efficient strategy for providing assistance to a woman who has disclosed abuse involves acknowledging and documenting the trauma, assessing immediate safety and establishing a safety plan, and providing patient education and referrals to community support services. An essential first step is to acknowledge the trauma. It is important to reinforce to the victim that she is not to blame, as many victims have trouble believing that they are not responsible for the abuse.

Documenting domestic violence is no different from documenting other patient interactions, but such documentation may provide important supportive evidence in the courtroom to put an end to the violence. Direct quotations of the patient’s explanation of her injuries should be recorded. Photographs may be taken after consent is granted. Every effort should be made to maintain confidentiality to avoid retaliation by the perpetrators when they suspect disclosure of abuse. The physician or health care professional may be required by state law to report actual or suspected domestic violence.

Once domestic violence is acknowledged and documented, the next step is to assess immediate safety and to establish a safety plan. Lethality of the violence should be assessed by asking questions such as:

- Has your partner ever threatened to kill you or your children?
- Are there weapons in the house?
- Does your partner abuse alcohol or use drugs?
- Is it safe for you to go home?
- Are the children (or other dependents) safe?

Treatment

Given the high rate of psychiatric symptomatology in this population, referral for psychiatric screening and counseling can be useful. Patients who are experiencing posttraumatic stress disorder can benefit from psychotherapy and possibly medication as well. Those with depression, substance abuse, or anxiety, personality, or dissociative disorders will also require ongoing treatment. Psychiatrists or other mental health professionals can serve to coordinate a variety of treatment modalities for the victims: individual, couples, and family therapy; detoxification and substance abuse treatment; and advocacy groups.

Despite the best efforts of physicians and other health care professionals, some women may initially be unable to extirpate themselves from victimization. For such women, an encounter with a health care system that they experience as nonblaming, accessible, and supportive will help to maximize the chances of their making a positive life change at some future point.

SEXUAL ASSAULT

ESSENTIALS OF DIAGNOSIS

- ▶ Complaints of having been mugged
- ▶ Concerns about acquired immune deficiency syndrome (AIDS) or other sexually transmitted diseases
- ▶ Psychiatric symptoms include depression, anxiety, or a suicide attempt
- ▶ PTSD
- ▶ Somatic symptoms include disturbed sleeping and eating patterns, gastrointestinal irritability (with nausea predominating), musculoskeletal soreness, fatigue, tension headaches, and intense startle reactions
- ▶ Symptoms of vaginal irritation occur in more than 50% of victims
- ▶ Rectal pain and bleeding are frequent in patients subjected to anal penetration
- ▶ Gynecologic trauma
- ▶ Escape through the use of alcohol and drugs

Sexual assault is any sexual act performed by one person on another without the person's consent. Sexual assault includes genital, oral, or anal penetration by a part of the accused's body or by an object. It may result from force, the threat of force either on the victim or another person, or the victim's inability to give appropriate consent. Many states have now adopted the gender-neutral legal term *sexual assault* in favor of *rape*, which traditionally referred to forced vaginal penetration of a woman by a male assailant.

An estimated 700,000 to 1,000,000 American women are sexually assaulted every year. These estimates are higher than official crime reports because the majority of cases go unreported. According to one estimate, only 30% of rapes are reported to the police, and 50% of rape victims tell no one. At least 20% of adult women, 15% of college-age women, and 12% of adolescent girls have experienced sexual abuse and assault during their lifetime. Sexual assault occurs in all age, racialethnic, and socioeconomic groups, but its incidence may be higher for African American women and for adolescent females. In several studies, approximately one-fourth to one-half of the victims of sexual assault were younger than the age of 18 years. The very young, the elderly, and the physically or developmentally disabled may be particularly vulnerable to sexual assault.

Several variants of sexual assault deserve special mention. **Marital rape** is defined as forced coitus or related sexual acts within a marital relationship without the consent of a partner. **Acquaintance rape** refers to those sexual assaults committed by someone known to the victim. More than 75% of adolescent rapes are committed by an acquaintance of the victim. When the acquaintance is a family member, including step-relatives and parental figures living in the home, the sexual assault is referred to as **incest**. When the forced or unwanted sexual activity occurs in the context of a dating relationship, it is referred to as **date rape**. In this situation, the woman may voluntarily participate in sexual play but coitus occurs, often forcibly, without her consent. Alcohol use is frequently associated with date rape. “Date rape drugs” such as flunitrazepam (Rohypnol) and gamma-hydroxybutyrate (GHB) have also been used to diminish a woman’s ability to consent or to remember the assault.

Statutory rape refers to sexual intercourse with a female under an age specified by state law (ranging from 14–18 years of age); the consent of an adolescent younger than this age is legally irrelevant because she is defined as being incapable of consenting. **Child sexual abuse** is defined as contact or interaction between a child and an adult when the child is being used for the sexual stimulation of that adult or another person. All 50 states and the District of Columbia mandate reporting of child abuse, including child sexual abuse. Nearly half of the states also require physicians to report statutory rape. Physicians should be familiar with the laws in their states; failure to report sexual assault against children may subject the physicians to fines and incarceration for up to 1 year.

Our society has many misperceptions about sexual assault. The victims are often blamed for having encouraged the assault by their behavior or dress, for not sufficiently resisting the assault, for being promiscuous, or for having ulterior motives for pressing charges. This misplaced culpability is often internalized by the victims, which (in addition to fear of retribution) may explain their reluctance to report the violent crime to the authorities. Another common misperception is that rape is an impulsive or aggressive extension of normal sex drive on the part of the rapist. The motivation for most sexual assault, however, seems not to be sexual gratification but rather degradation, terrorization, and humiliation of the victim. The assault is often a demonstration of power (power rape), anger (anger rape), or sadism manifested in ritualized torture or mutilation of the victim (sadistic rape) on the part of the rapist.

Prevention

Much of this chapter addresses the role and responsibilities of the health care professional in caring for victims of domestic violence and sexual assault after they have occurred. One of the greatest challenges for health care and public health professionals working to improve women’s health continues to be the epidemic of violence against women in our society and around the world. A great deal remains to be learned and done about the primary prevention of violence.

Clinical Findings

The majority of rape victims who come to emergency rooms do not openly admit to having been sexually assaulted. Instead, they may complain of having been mugged or may voice concerns about acquired immune deficiency syndrome (AIDS) or other sexually transmitted diseases. Others may present with psychiatric symptoms including depression, anxiety, or a suicide attempt. Unless the primary care physician, obstetrician-gynecologist, or psychiatrist obtains a sexual history, assault victims will remain unidentified as such and will be inadequately treated.

A “rape-trauma” syndrome often occurs after a sexual assault. The initial response (acute phase) may last for hours or days and is characterized by a distortion or paralysis of the individual’s coping mechanisms. The initial outward responses vary from complete loss of emotional control (crying, uncontrolled anger) to an unnatural calm and detachment (although some physical signs such as shaking or lowered skin temperature are usually present). The latter behavior represents the victim’s need to reestablish control over herself and her environment while simultaneously abandoning the defense mechanism of denial and allowing the renewed invasion of privacy represented by the questioning and examination. The initial reactions of shock, numbness, withdrawal, and denial typically abate after the first 2 weeks. However, studies suggest there is a period, occurring from 2 weeks to several months postassault, in which symptomatology returns and may intensify. It is at this time that the victim may begin to seek help for her symptoms, often without telling the health care provider of the sexual assault that precipitated these symptoms.

The next phase (delayed phase) may occur months or years after the sexual assault and is characterized by chronic anxiety, feelings of vulnerability, loss of control, and self-blame. Long-term reactions include anxiety, nightmares, flashbacks, catastrophic fantasies, feelings of alienation and isolation, sexual dysfunction, psychologic distress, mistrust of others, phobias, depression, hostility, and somatic symptoms. More than half of rape victims experience substantial difficulty in reestablishing sexual and emotional relationships with spouses or boyfriends. Thirty-three percent to 50% of victims report suicidal ideation; suicide attempts have been reported in nearly 1 in 5 rape victims who do not seek treatment.

PTSD is a common long-term sequela of sexual assault, characterized by psychic numbing, intrusive re-experiencing of the trauma, avoidance of stimuli associated with the trauma, and intense psychologic distress. Women with prior victimization histories often have more severe sequela. Women assaulted sexually by family members or dates experience as severe levels of distress as women assaulted by acquaintances or strangers.

Up to 40% of victims who are sexually assaulted sustain injuries. Although most injuries are minor, approximately 1% of the injuries require hospitalization and major operative repair, and 0.1% are fatal. Somatic symptoms are common during the acute phase and include disturbed sleeping and eating patterns, gastrointestinal irritability (with nausea predominating), musculoskeletal soreness, fatigue, tension headaches, and intense startle reactions. Symptoms of vaginal irritation occur in more than 50% of victims, and rectal pain and bleeding are frequent in patients subjected to anal penetration. Ongoing health concerns include gynecologic trauma, risk of pregnancy, and the potential for contracting infections or sexually transmitted diseases, including HIV. Victims may also seek to escape the pain of rape’s effects through the use of alcohol and drugs.

Rape victims appear to be frequent users of medical services in the months and years after the assault. In one study, visits to physicians increased 18% in the year of the assault, 56% in the following year, and 31% in the year after, compared with previctimization levels. Reintegration of the self after sexual assault is a slow process that may take months to years as the victim works through the trauma and the loss of the event and replaces it with other life experiences. The prognosis for complete recovery is improved if health care professionals responsible for the victim’s care have a supportive, nonjudgmental approach and a well-developed understanding and competent treatment of the emotional, as well as physical, consequences of sexual assault.

Differential Diagnosis

The physician evaluating the victim has both medical and legal responsibilities and should be aware of state statutory requirements. Such requirements may involve the use of sexual assault assessment kits, which list the steps necessary and the items to be obtained for forensic purposes. If personnel trained in collecting samples and information are available, it is appropriate to request their assistance.

Informed consent must be obtained before examining a sexual assault victim. A careful history and physical examination should be performed in the presence of a chaperon or victim advocate. The patient should be asked to state in her own words what happened and to identify or describe her attacker, if possible. The history should include inquiry about last menstrual period, contraceptive use, preexisting pregnancy and infection, and last consensual intercourse before the assault. The patient's activities in the interval between the assault and the examination—whether the patient has eaten, drunk, bathed, douched, voided, or defecated—might affect findings on physical examination; such activities must be recorded.

A careful physical examination of the entire body should be performed. The physician should search for bruises, abrasions, or lacerations about the neck, back, buttocks, and extremities. Bite marks should be noted, particularly about the genitalia and breasts. Injuries to the mouth and pharynx may result from oral penetration. Injuries should be documented with photographs or drawings in the medical record. *Rape* and *physical assault* are legal terms that should not be used in medical records. Instead, the physician should report findings as "consistent with the use of force."

A pelvic examination should be performed. Injuries to the vulva, hymen, vagina, urethra, and rectum should be noted. Occasionally, foreign objects may be found in the orifices. The speculum must be moistened only with saline. Two milliliters of normal saline are injected into the vaginal vault. Nonabsorbent cotton swabs should be used to sample fluid from this vaginal pool and should then be placed in sterile glass tubes and refrigerated. Air-dried, nonfixed smears of this same fluid should be placed on glass slides. A Papanicolaou (Pap) test may also be obtained. Evidence of coitus will be present in the vagina for as long as 48 hours after the attack. Motile sperms may be noted in the vagina for up to 8 hours after intercourse, but may be present in the cervical mucous for as long as 2–3 days. Nonmotile sperm may be noted in the vagina for up to 24 hours and in the cervix for up to 17 days. Acid phosphatase is an enzyme found in high concentrations in the seminal fluid. Evidence of acid phosphatase should be sought by swabbing the vaginal secretions, even in the absence of sperm because the attacker may have had a vasectomy. DNA evaluation may also be performed from the vaginal swab. Nonmotile sperm may be found in the rectum for up to 24 hours after the assault, and acid phosphatase can also be detected in the rectum.

A wet mount or vaginal swab should be obtained to detect *Trichomonas vaginalis*. Testing for *Neisseria gonorrhoeae* and *Chlamydia trachomatis* should be performed from specimens from any sites of penetration or attempted penetration. A serum sample should be collected for subsequent serologic analysis if test results are positive. The risk of acquiring gonorrhea from sexual assault is estimated to be between 6 and 12%. Baseline serologic tests for hepatitis B virus, HIV, and syphilis should also be offered. The risk of acquiring syphilis from sexual assault is estimated to be 3%; the risk of acquiring HIV is undetermined.

An important part of the physician's legal responsibilities is to collect samples for forensic purposes. Pubic hair combings should be collected to look for pubic hair from the assailant. Fingernail scrapings should be obtained to look for skin or blood of the attacker. Skin washings and clothing should be investigated for the presence of blood or semen. A Wood light may be helpful because dried semen will fluoresce under its light. Saliva should be collected from the victim. Because seminal fluid is rapidly destroyed by salivary enzymes, identification of seminal fluid in the mouth after a few hours is difficult. Consequently, victims should be encouraged to come to a medical facility immediately after an assault, where they can be evaluated before they bathe, urinate, defecate, wash out their mouths, or clean their fingernails.

Proper processing and labeling of collected specimens is crucial. All collected specimens are placed in a larger sealed container and processed in a “chain of evidence” fashion. The person who collects the specimens verifies their completeness by signature on the sealed master container. The individual to whom they are transferred must verify by signature that all specimens were received in an untampered state. Thus each individual who has “custody” of the specimens during processing must verify that they were transmitted without alteration until they are turned over to the responsible law enforcement agency. The name of the law enforcement agent who receives the specimens should be noted in the medical record.

Treatment

Treatment of physical injuries sustained at the time of assault should be initiated immediately; prophylactic medical treatment may be indicated for prevention of sexually transmitted infections and pregnancy. For prophylaxis against sexually transmitted infections, empiric recommended antimicrobial therapy for chlamydial, gonococcal, and trichomonal infections may be given. One such regimen consists of the following:

- Ceftriaxone 125 mg intramuscularly in a single dose, plus
- Metronidazole 2 g orally in a single dose, plus
- Doxycycline 100 mg orally 2 times a day for 7 days

Alternative treatment may be given as recommended by the US Centers for Disease Control and Prevention. In addition, it is recommended that hepatitis B immunoglobulin be administered intramuscularly as soon as possible, but certainly within 14 days of exposure. It should be followed by the standard 3-dose active immunization series with hepatitis B vaccine at 0, 1, and 6 months, beginning at the time of passive immunization. Prophylaxis against HIV is controversial.

Emergency contraception can be offered as prophylaxis against pregnancy. The risk of pregnancy after sexual assault has been estimated to be 2–4% in victims who were not using some form of contraception at the time of the assault. A serum pregnancy test should be obtained before administration of emergency contraception to evaluate for preexisting pregnancy. Emergency contraception should be given within 72 hours of the assault, although it can still be effective up to 120 hours later. There are several different methods of emergency contraception. For many years, the most common method (Yuzpe method) involved the use of high-dose combined oral contraceptives within 72 hours of unprotected coitus, repeated 12 hours after the first dose. More recently, use of a progestin-only method has become popular. This method involves the use of levonorgestrel 0.75 mg, in 2 doses 12 hours apart, or a 1-time dose of 1.5 mg within 72 hours of unprotected coitus. A randomized study showed that this is more effective and better tolerated than the Yuzpe method. Levonorgestrel prevented 85% of pregnancies that would have occurred without treatment.

As most patients suffer significant psychologic trauma as a consequence of sexual assault, the physician must be prepared to provide access to counseling. It is preferable that follow-up psychologic counseling be provided by individuals who have extensive experience in the management of crisis response to rape. Even if the victim appears to be in control emotionally, she will probably experience aspects of rape-trauma syndrome at some time in the future. She should be made aware of the symptoms that she may experience and advised to seek help if and when these symptoms occur. No patient should be released from the facility until specific follow-up plans are made and agreed upon by the patient, physician, and counselor.

A follow-up visit should be scheduled approximately 2 weeks after the assault for repeat physical examination and collection of additional specimens. Testing for *N gonorrhoeae*, *C trachomatis*, and *T vaginalis* should be repeated unless prophylactic antimicrobials have been provided. Follow-up counseling should be discussed again at the second visit. Additional visits may be scheduled according to the victim’s needs; an additional follow-up visit approximately 12 weeks after the sexual assault is advisable to collect sera for detection of antibodies against *T pallidum*, hepatitis B virus (unless vaccine was given), and HIV (repeat test at 6 months). During each of these visits, assessment of the patient’s psychologic symptoms should be performed, and referrals for further counseling are made as indicated.

[*] The rectum is not described in this chapter.

*Embryonic or fetal ages given in this chapter are relative to the time of fertilization and should be considered estimates rather than absolutes.

*Trade names include Gamulin Rh, HypRho-D, and RhoGAM.

*Clitoral index (cm^2) = Length (cm) × width (cm). For example, a clitoris 1 cm long and 0.5 cm wide = 0.5 cm^2.
